Zinc treatment had no effect on lipid profiles in wild-type mice ($p > 0.1$) therefore the wild-type data represent values pooled over all three zinc treatments. Values are least square means ± sem; means carrying different superscripts within a row are significantly different ($p < 0.05$)

changed in mice receiving 15 mM $ZnSO_4$. In general, substrates of the Δ-5 and Δ-6 pathways were reduced in proportion to circulating GH ($p < 0.05$). Specifically, animals with the greatest circulating GH levels had reduced 18:2 and 20:3 (~10% reduction) with elevated 20:4n-6 (~2.4-fold increase); this pattern, though not the extent, was also true for the moderate level of GH (15 mM $ZnSO_4$). In contrast, animals exposed to the lowest level of chronic GH (transgenics receiving 0 mM $ZnSO_4$), while having significantly elevated 20:4n-6 (~1.2-fold increase), also had higher levels of 18:2 (~8%). The ratio of ARA to its 18:2 precursor was significantly elevated in animals exposed to high GH levels (~ 3- to 4-fold increase for the 15 and 25 mM $ZnSO_4$, respectively). Omega-3 lipids were not affected by the altered GH nor was the Δ-9 pathway ($p > 0.10$).

Hepatic Lipid Profiles

Similar to that found for adipose, dietary provision of zinc did not significantly alter any parameter evaluated for wild-type animals ($p > 0.2$), therefore values for wild-type animals were pooled across zinc treatments. The fatty acid composition of hepatic phosphatidyl choline esterified fatty acids, calculated as a mole percent for each lipid species, is presented in Table 2. For fatty acids associated with de novo lipogenesis, there was no affect of circulating GH levels on the proportion of the fatty acids within the hepatic tissue. In contrast, for all 18 carbon fatty acids other than 18:3n-6, elevated GH reduced their percentage in the membrane and did so in proportion to the level of transgene expression. A concomitant increase in 20:4n-6 (~1.8-fold increase) was seen also correlating with the level of GH

Table 2 Hepatic lipid profile as mole percent for wild-type (WT) mice and transgenic (TG) mice supplemented with either 0, 15, or 25 mM $ZnSO_4$ to induce variable levels of chronic circulating GH

Zinc treatment had no effect on lipid profiles in wild-type mice ($p < 0.1$) therefore the wild-type data represent values pooled over all three zinc treatments. Values are least square means ± sem; means carrying different superscripts within a row are significantly different ($p < 0.05$)

expressed from the transgene. Elevated GH reduced the 18:1/18:0 ratio by nearly 50% and the combined effects of GH raising ARA (20:4n-6) and decreasing alpha linoleic (18:2) resulted in a significantly elevated 20:4/18:2 (ARA: linoleic acid) ratio (~2.5-fold increase, $p < 0.001$). A similar result was detected for the 22:6/18:3n-3 (DHA: alpha linolenic acid) ratio ($p < 0.002$). The elevated ratios were proportional to the degree of elevated GH in circulation: the 25 mM $ZnSO_4$ treated transgenic animals had the greatest ratios followed by the 15 mM $ZnSO_4$ treated transgenics which were in turn greater than the 0 mM $ZnSO_4$; with the last group's ratios statistically equivalent to those of the wild-type controls.

Hepatic RNA

Wild-type control animals given 0, 15, and 25 mM $ZnSO_4$ supplementation did not exhibit significant differences in mRNA levels for any of the genes evaluated ($p > 0.1$) due to zinc treatment and were therefore pooled for analyses. Stearyl-CoA desaturase 1 hepatic mRNA levels were unaffected by alterations in circulating GH ($p > 0.5$) and SCD 2 levels were not significantly reduced in proportion to the level of circulating GH (Fig. 1; $p < 0.1$). Animals experiencing the highest levels of circulating GH had significantly reduced FAS mRNA compared to wild-type control animals ($p < 0.01$). The animals with low, but chronic GH had intermediate FAS mRNA values that were not significantly different than the wild-type animals that had the highest FAS mRNA levels. In contrast, SOD1 mRNA was elevated in animals expressing the highest levels of GH while animals with the low and moderately elevated GH levels had SOD1 levels equivalent to wild-type expression ($p < 0.001$). Levels of COX-1 mRNA were significantly elevated for the animals with moderate to highly elevated GH (transgenics supplemented with 15

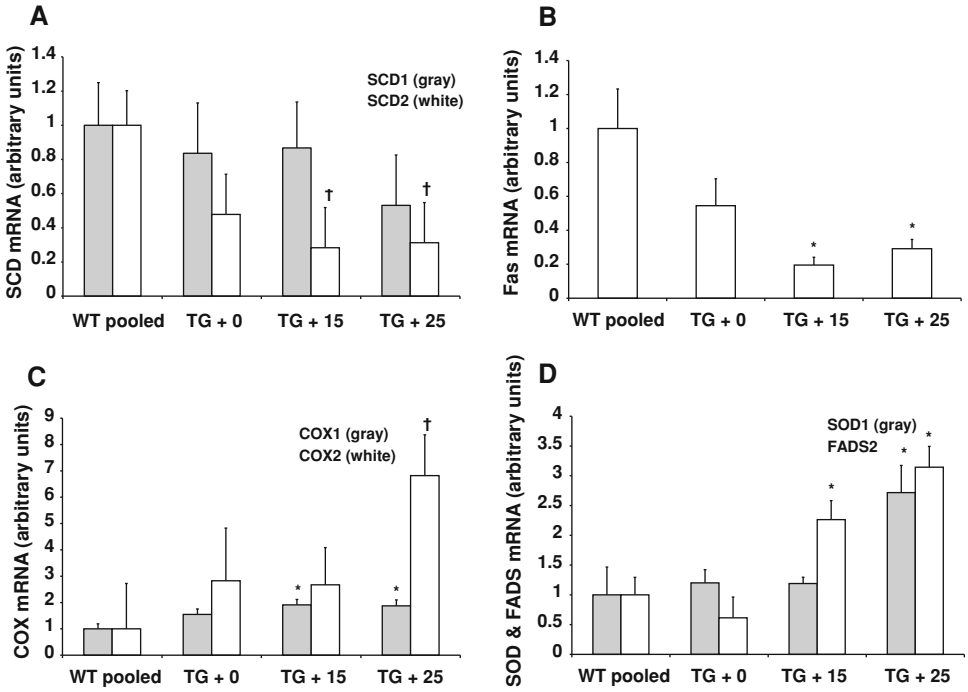

Fig. 1 Hepatic mRNA levels in oMT1a-oGH transgenic (TG) mice exposed to 0, 15, and 25 mM $ZnSO_4$ transgene stimulus used to vary the level of circulating GH as compared to wild-type control (WT) mice, pooled across all zinc treatment levels. Values are expressed as means + sem, $n = 5$–6 mice per group, and means with an *asterisk* differ from control mice $p < 0.05$; means denoted with a† differ from control mice $p < 0.1$. **a** Stearyl-CoA desaturase (SCD) 1 (*gray bars*) and 2 (*white bars*), **b** Fatty acid synthase (FAS), **c** Cyclooxygenase (COX) 1 (*gray bars*) and 2 (*white bars*), **d** Superoxide dismutase 1 (SOD1, *gray bars*) and FADS2 (*white bars*)

and 25 mM $ZnSO_4$, respectively) when compared to the wild-type animals ($p < 0.01$). Transgenic mice not given any zinc stimulus therefore having low chronic GH in circulation, had intermediate levels of COX-1 mRNA (Fig. 1). A similar trend was seen for the COX-2 mRNA levels ($p < 0.1$) with the highest mRNA levels showing a nearly a seven-fold increase, detected in the animals experiencing the greatest circulating GH. The mRNA levels of FADS2 paralleled the changes in hepatic lipid membranes: the highest GH exposure resulted in the greatest level of FADS2 mRNA ($p < 0.001$).

Experiment 2

Arachidonic Acid Metabolites

Because the transgene had not been stimulated during the growth phase of the adult males used in this experiment, body weights did not significantly differ: 42.5 ± 1.7 and 42.4 ± 0.9 g for the transgenic and wild-type mice, respectively. Upon activation of the transgene, circulating ovine GH levels in the adult transgenics were 332.0 ± 23.8 ng/ml. The arachidonic metabolite 12-HETE was significantly elevated in mice after 1 week of exposure to elevated GH ($p < 0.05$). Transgenic mice supplemented with 25 mM $ZnSO_4$ had over twice the quantity of 12-HETE in their lungs than wild-type mice also supplemented with 25 mM $ZnSO_4$ (Fig. 2). Similarly, plasma PGE2 was significantly elevated in response to high circulating GH. In contrast, the unstimulated transgenic mice

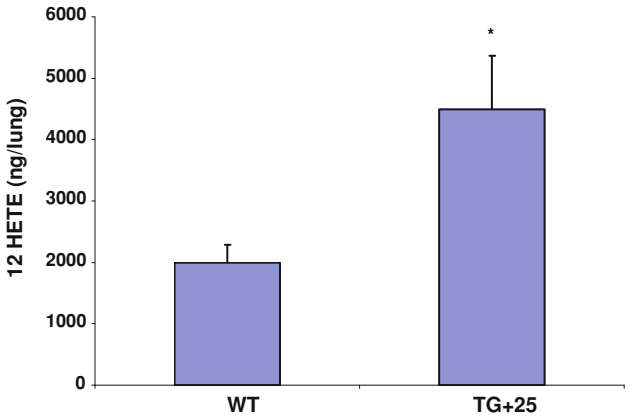

Fig. 2 Production of the 12 lipoxygenase product 12 HETE in lungs of wild-type control (WT) and oMT1a-oGH transgenic (TG) mice exposed to the transgene stimulus (25 mM zinc). Data are expressed as means + sem (ng/lung) and are significantly different ($n = 3$ per group)

with low chronic GH (0 mM $ZnSO_4$) did not exhibit any changes in PGE2 relative to the wild-type mice given 25 mM $ZnSO_4$ (Table 3). Circulating thromboxane was not significantly affected by elevated GH (Table 3).

Discussion

The effects of elevated circulating GH on the regulation of lipid profiles, specifically metabolites of the long chain saturated and polyunsaturated fatty acid desaturases, were

Table 3 Plasma arachidonic acid metabolites as a consequence of circulating growth hormone

Treatment	PGE2 (pg/ml)	Thromboxane (ng/ml)
WT + 25 mM $ZnSO_4$	13.54 ± 11.19[a] ($n = 8$)	224.8 ± 97.6 ($n = 8$)
TG + 0 mM $ZnSO_4$	13.23 ± 11.19[a] ($n = 8$)	385.3 ± 83.3 ($n = 11$)
TG + 25 mM $ZnSO_4$	49.84 ± 10.50[b] ($n = 9$)	237.1 ± 71.3 ($n = 15$)

Values are least square means ± sem; means carrying different superscripts within a column are significantly different ($p < 0.05$)

studied. In this GH transgenic model, mice exposed to moderate but chronically increased circulating GH become obese whereas highly elevated circulating GH reduces adipose stores [21] and alters hepatic membrane lipid profiles in a rapid and sustained manner [20, 23]. Although elevated GH is frequently associated with reduced adipose mass, in this model development of obesity in the presence of moderately elevated GH is thought to be mediated by greater expression of GH receptor binding protein [21] or through increased leptin and insulin secretion as seen in the moderately obese GHRH transgenic mouse that also has elevated GH levels [35].

In hepatic tissues, the activity of the Δ-9 desaturase as indicated by the lipid products was decreased in response to high circulating GH whereas the Δ-5 and Δ-6 enzymatic activities appeared to be increased in both adipose and hepatic tissues as evidenced by a greater percentage of ARA. Elevated DHA in response to GH was only detected in hepatic but not adipose tissue indicating that GH exerts tissue specificity in the processing of fatty acids. These findings corroborate previous studies evaluating hepatic lipid profiles [20, 23] although there were some discrepancies likely due to duration of GH exposure and downstream effects of the elevated GH. Specifically, short term elevated GH significantly depressed DHA and ARA in adipose, whereas the present study with long-term GH exposure did not significantly depress DHA and elevated ARA. Additionally, the data demonstrate that the GH induced change to lipid profiles occurs in both males and females. The latter is important in that women have lower Δ-6 enzymatic activities than men [36]; the finding that both male and female mice responded similarly with enhanced activity to GH suggests that GH may be a key endogenous regulator of the net flux through the desaturase pathway. The higher the circulating GH, the greater the Δ-5 and Δ-6 desaturase activity as evidenced by changes in the lipid profile and greater FADS expression. However, in this mouse model high GH is associated with elevated insulin; insulin levels decline following GH withdrawal [26] indicating that the transgenically derived GH impairs insulin signaling causing a mild diabetic state. Insulin is known to induce the expression of the Δ-5, Δ-6, and Δ-9 desaturases in rats [37] suggesting that long-term GH action observed in the present study may be mediated through elevated insulin.

An increased proportion of ARA in tissues would be expected to elevate ARA metabolites and that was the case for circulating PGE2 and lung produced 12-HETE. Similarly, the constitutively active COX1 mRNA as well as COX2 mRNA were increased in response to elevated circulating GH suggesting coordinated regulation of this pathway. In contrast, the most pro-thrombotic eicosanoid, thromboxane was unchanged despite the dramatic increase in the level of ARA, its precursor. Thromboxane has been shown to be associated directly with membrane arachidonate; specifically thromboxane is lower in animals fed alpha linolenic acid (18:3n-3) which correlates to higher levels of 18:3n-3 in the liver membranes [39] that replace 18:2 lowering overall arachidonate, a precursor of thromboxane [38]. Levels of circulating thromboxane in the current study did not significantly change with exposure to GH even though arachidonate was increased appreciably. The GH induced increase of ARA may not have been within the specific precursor pools for the thromboxane production.

Elevated highly unsaturated fatty acid species within membranes could serve as targets for reactive oxygen species and could increase the opportunities for oxidative modification and damage. As tissue membranes became more unsaturated in response to high GH, SOD1 mRNA was significantly elevated. Generally SOD1 is constitutively expressed although ARA can upregulate SOD1 gene transcription in vitro (39). High circulating GH with its shift toward unsaturated fatty acid species increased expression of SOD1 indicating that only supraphysiological arachidonic levels pose an oxidative risk and increase SOD1 expression in vivo.

Fatty acid synthetase, a key regulator of de novo long chain fatty acid biosynthesis, promotes adipose storage; inhibition of FAS in vivo results in weight loss [40]. FAS activity is regulated at the level of gene expression rather than enzymatic activation and FAS can be transcriptionally regulated by STAT5A, a GH signal transducer [41]. GH activation of STAT5 plays a defined role in adipogenesis [42] and by activating STAT5, GH can block the transcriptional activation of FAS in adipocytes [41] thereby reducing lipid accrual. GH also reduces glucose uptake thereby further reducing de novo long chain fatty acid biosynthesis and the substrates available for desaturation.

Hogan and Stephens [41] showed that GH inhibition of FAS is rapidly reversible, consistent with the observation that chronic exposure to GH produces a lean phenotype but withdrawal of GH results in the rapid accumulation of

adipose [25]. FAS mRNA was reduced in the presence of all levels of GH, even those known to promote adipogenesis and adipose accrual in these animals [21]. The increase in adipose deposition observed in these transgenic animals upon withdrawal of high GH or in response to moderate levels of GH occurs regardless of feed restriction [24] indicating that GH overrides the expected composition of gain observed for normal rodents [42] and the expectation of reduced adipose deposition associated with lowered FAS expression. Therefore, FAS expression alone is insufficient to account for adipose deposition in animals that become obese while experiencing moderately high GH levels. Although alterations in mRNA levels may not necessarily imply changes in protein activity, clearly this is an area that requires further exploration. Metabolic end-products of FAS, in particular 16:1n-7 have recently been identified as participating in tissue to tissue communication and the overall regulation of systemic energy [27]. In the present GH manipulated animals 16:1n-7 was elevated in the adipose of overweight animals and lowered in GH stimulated mice implying that an additional level of regulation by GH may be through this form of metabolic end product, i.e. lipokine signaling.

Exposure to GH did not significantly decrease hepatic SCD2 mRNA. In a study where only SCD1 mRNA was evaluated, lactating cows given recombinant bovine GH [43] had reduced SCD1 mRNA in adipose but not mammary tissue implying tissue specificity in GH modulation of SCD expression. SCD1 null mice have lowered body adiposity, depressed hepatic expression of fatty acid synthesis genes, and increased expression of fatty acid oxidation genes [44]. In response to elevated GH in the present study, SCD expression was reduced although not significantly so. FAS and fatty acid oxidation gene expression followed an expression pattern similar to that seen for the SCD1 null mouse indicating a potential mechanism of action for GH.

The interplay between circulating GH and adipose cannot be accounted for by changes in membrane lipids and their potential signaling metabolites. It is curious that GH stimulated the desaturase pathways in membrane lipids in a tissue specific manner between adipose and hepatic membranes with particular reference to the omega-3 lipids. Similarly, GH altered ARA metabolites differentially with PGE2 and 12-HETE elevated but with no effect on thromboxane. This mouse model, especially by targeting adipose tissue, may be useful in elucidating the mechanism behind the differential tissue and eicosanoid response. Particularly as the finding that the desaturase process responds to different GH levels is intriguing and suggests the possibility of modifying the pathway to minimize the negative aspects of inappropriately elevated eicosanoids.

Abstract Sphingolipids are constituents of cellular membranes and play important roles as second messengers mediating cell functions. As significant components in foods, sphingolipids have been proven to be critical for human health. Moreover, diverse metabolic intermediates of sphingolipids are known to play key roles both in proinflammatory and in anti-inflammatory effects. However, the effect of dietary sphingolipids on inflammation is a complicated field that needs to be further assessed. Our study evaluated the effects of orally administered maize glucosylceramide (GluCer), one of the most conventional dietary sphingolipids, on inflammation using the 2,4-dinitro-1-fluorobenzene-treated BALB/c murine model. Oral administration of GluCer inhibited ear swelling and leukocyte infiltration to the inflammatory site, suggesting that dietary GluCer has anti-inflammatory properties. ELISA analyses revealed that oral administration of GluCer for 6 days had not modified the Th1/Th2 balance, but significantly down-regulated the activation of TNF-α at the inflammatory site. Based on these results, the down-regulation of TNF-α by dietary GluCer may suppress vascular permeability and reduce the migration of inflammatory cells. Our findings increase understanding of the actions of dietary sphingolipids on the balance of the immune response.

Abbreviations

DNFB	2,4-Dinitro-1-fluorobenzene
GluCer	Glucosylceramide
IFN-γ	Interferon-gamma
IgE	Immunoglobulin E
IL-1β	Interleukin-1beta
IL-4	Interleukin-4
IL-6	Interleukin-6
NF-κB	Receptor activator of nuclear factor-kappa B
Th1	T-helper 1
Th2	T-helper 2
TNF-α	Tumor necrosis factor-alpha

Introduction

Sphingolipids are commonly believed to protect the cell surface against harmful environmental factors by forming the mechanically stable and chemically resistant outer leaflet of the plasma membrane lipid bilayer [1–4]. Sphingolipids generate diverse metabolic intermediates, notably ceramide, sphingosine, sphingosine-1-phosphate, and ceramide-1-phosphate, which serve as important mediators in the signaling cascades involved in apoptosis, proliferation, and stress responses [5–8]. Although we have already demonstrated that dietary sphingolipids are poorly absorbed by the intestine [9], sphingolipids that are significant components of foods have gained considerable attention for their potential and essential roles in human health

[10–14]. It has been reported that dietary supplementation with sphingolipids has diverse physiological effects, such as lowering plasma lipids [15], improving the skin barrier function [16], preventing melanin formation [17], contributing to central nervous system myelination [18] as well as protecting the colon against inflammation [19–25]. However, the functional, regulatory, and physiological significance of the immune regulating effects of dietary sphingolipids is an appreciably complicated field that is not well understood.

One hypothesis of immune regulation involves the balance between T-helper 1 (Th1) and T-helper 2 (Th2) cells, which direct different immune response pathways. Th1 cells drive the "cellular immunity" pathway to fight viruses and other intracellular pathogens, eliminate cancer cells, and stimulate delayed-type hypersensitivity skin reactions. Th2 cells are involved in "humoral immunity" and up-regulate antibody production to fight extracellular organisms. Either pathway can down-regulate the other. Disruption of the Th1/Th2 balance can cause immunological diseases [26, 27]. Via the actions of sphingolipid degrading enzymes, such as sphingomyelinase, glycoceramidases, and ceramidase, dietary sphingolipids are hydrolyzed to various kinds of metabolic intermediates which are critical for the activation and mediation of various types of immune cells. Metabolites of sphingolipids initiate and maintain diverse aspects of immune cell balance and functional responses by regulating cell migration and inflammatory pathways [8, 20, 28–31]. For instance, sphingolipid hydrolysis products regulate cyclooxygenase-2, interleukin 1β (IL-1β), interleukin 6 (IL-6), tumor necrosis factor α (TNF-α) and nuclear factor kappa B (NF-κB) via the sphingosine kinase 1/sphingosine-1-phosphate and ceramide kinase 1/ceramide-1-phosphate pathways, and thus cause the activation of mast cells, control thymocyte maturation and regulate the balance of lymphocyte subpopulations [32–37].

The goal of this study was to evaluate the effects of orally administered glucosylceramide (GluCer), one of the most important dietary sphingolipids, against DNFB-induced ear swelling in the BALB/c murine model, to provide further understanding of how dietary sphingolipids act on the balance between proinflammatory and anti-inflammatory responses.

Materials and Methods

Maize GluCer Preparation

GluCer from maize was kindly donated by Nippon Flour Mills Co. Ltd. (Atsugi, Japan). The purity of this GluCer was 96%, which was determined by HPLC equipped with an evaporative light-scattering detector, as described previously [12].

Animals

Female BALB/c mice (6 weeks old, 15–20 g body weight) were purchased from Japan SLC Inc. (Shizuoka, Japan). Animals were group-housed at six mice per cage, and were bred at the Institute's animal facilities at 25 °C with a 12-h light/dark cycle. Pure water and AIN-93G diet (Oriental Yeast Co., Ltd., Tokyo, Japan) were available ad libitum. All experiments were performed according to the guidelines of Kyoto University for the use and care of laboratory animals.

Contact Hypersensitivity Induced by DNFB

After a 2-week acclimatization period, allergic contact dermatitis was induced by DNFB in BALB/c mice according to a previously published method with minor modifications [38]. Briefly, mice were sensitized on day 0 by application of 100 µl 0.5% DNFB in acetone–soybean oil (4:1, v/v) on their shaved dorsal skin. The mice were divided into control, low dose (5 mg) and high dose (50 mg) groups ($n = 12$ in each group). An identifying mark was made on the tail of each mouse.

The maize GluCer was suspended in 0.5% carboxymethyl cellulose (CMC) (Nacalai Tesque Co. Ltd., Kyoto, Japan) solution and was orally administered at 5 or 50 mg to each mouse daily for 6 days. One hour after the final treatment, mice were challenged with 20 µL 0.5% DNFB in acetone–soybean oil (4:1) on both ears. The thickness of the right ear of each mouse was measured with a Dial Thickness Gauge (Mitutoyo Co., Kanagawa, Japan) at 0, 6 and 24 h after the DNFB challenge. Ear swelling was calculated as the difference in thickness before and after challenge [39].

Six hours ($n = 6$) and 24 h ($n = 6$) after DNFB treatment, blood was collected and mice were sacrificed under anesthesia. The right ear and spleen of each mouse was immediately excised and frozen in liquid nitrogen, then stored at −80 °C until use.

Morphological Analysis

The left ear of each mouse was fixed in 10% neutral buffered formalin solution and was then processed routinely into paraffin wax. Formalin fixed paraffin sections were stained with hematoxylin and eosin (H&E) to observe morphological changes using a microscope (Keyence Co., Osaka, Japan).

Measurement of Cytokine Production and Serum Immunoglobulin E

Amounts of IFN-γ, interleukin-4 (IL-4), TNF-α and interleukin-10 (IL-10) in homogenates of tissues were quantified using Murine IL-4 (Diaclone Research, Besancon, France), Murine IFN-γ (Diaclone Research), Mouse TNF-α (Pierce Biotechnology Inc., Rockford, IL, USA), and Murine IL-10 (Diaclone Research) ELISA kits, respectively, according to the manufacturer's instructions. Levels of those cytokines in each supernatant were normalized to total protein content, which was determined using a DC Protein assay kit (Bio-Rad Laboratories, Hercules, CA, USA). Total serum IgE levels of DNFB-challenged mice were quantified using a Mouse IgE ELISA kit (Immunology Consultants Laboratory, Newberg, ON, USA) according to the manufacturer's instructions.

Statistical Analysis

Data are reported as means ± SD. Statistical analyses were performed using one-way analysis of variance (ANOVA) with Fisher's PLSD method to identify levels of significance between the groups.

Results

GluCer Suppresses DNFB-Induced Ear Swelling of BALB/c Mice

After challenge with DNFB, typical allergic contact dermatitis was provoked in the ears of BALB/c mice, which was characterized by an initial increase in ear thickness and visible congestion of blood vessels. Oral treatment with maize GluCer suppressed DNFB-induced inflammatory symptom (redness and thickness) of ears. As shown in Fig. 1a significant depression of ear thickness was observed at 6 h in both low (5 mg/day) and high dose (50 mg/day) GluCer treated groups ($p < 0.05$). At 24 h, the average value of ear thickness was also reduced by GluCer, but there were no statistical differences among the three groups, which may due to large individual differences. The reduction of DNFB-induced ear swelling implies dietary GluCer has anti-inflammatory property.

GluCer Inhibits Inflammatory Infiltrates in the Ears of BALB/c Mice

Histological specimens of ears were prepared at 6 and 24 h after topical application of DNFB in BALB/c mice. In the control group, typical allergic contact dermatitis with congested blood vessels and apparent edema could be observed by H&E staining. As shown in Fig. 2a, b, microvascular dilations and dense leukocytes infiltrating the connective tissue, which are characteristics of inflammatory reactions, were clearly observed in the control group. At higher magnification, various kinds of migrated inflammatory cells could also be observed, including fibrocytes, mononuclear cells, degranulated mast cells and other leukocytes. These results confirm that DNFB induces severe inflammation in the ears of BALB/c mice and that a variety of lymphocytes migrated out from blood vessels during this contact sensitivity procedure. In both the low (5 mg/day) and the high (50 mg/day) dose GluCer-treated groups, microvascular dilation and leukocytes in inflammatory infiltrates were inhibited at 6 h (Fig. 2b, c) and 24 h groups (Fig. 2e, f). These results show that dietary GluCer inhibits microvascular dilation and inflammatory infiltration of DNFB-induced BALB/c mice.

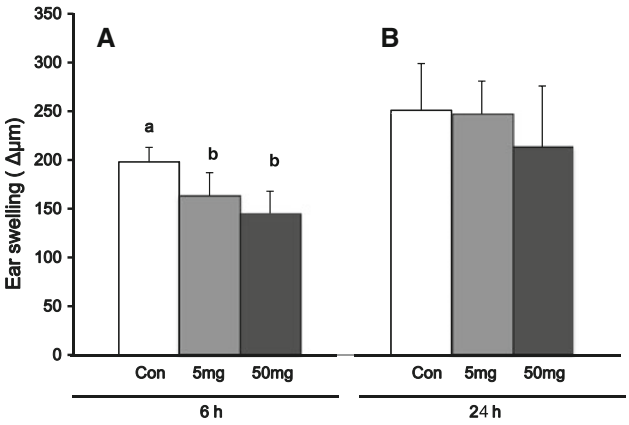

Fig. 1 Effect of orally administered GluCer on DNFB-induced ear swelling in BALB/c mice. The thickness of the left ear of each mouse was measured both before and after the DNFB challenge. Ear swelling values are presented as the *difference* in *thickness* at 6 h (**a**) and at 24 h (**b**). Ear swelling = ear thickness after challenge (6/24 h) − ear thickness before challenge (0 h). Con, 6 days 0.5% CMC (vehicle) orally administered; low, 6 days low dose (5 mg/day) maize GluCer orally administered; high, 6 days high dose (50 mg/day) maize GluCer orally administered. Values are means ± SD, $n = 6$. Values with different *superscript letters* are significantly different ($p < 0.05$)

GluCer Inhibits Inflammation by Reducing TNF-α Production in the Ear

To clarify the effect of GluCer on DNFB-induced inflammation, especially on Th1/Th2 balance, levels of IFN-γ as an indicator of Th1 cells and IL-4 as an indicator of Th2 cells were measured by ELISA assay. IFN-γ and IL-4 levels of GluCer-treated group were not significantly altered (Table 1). In other words, Th1/Th2 balance was not modified by oral administration of GluCer for 6 days.

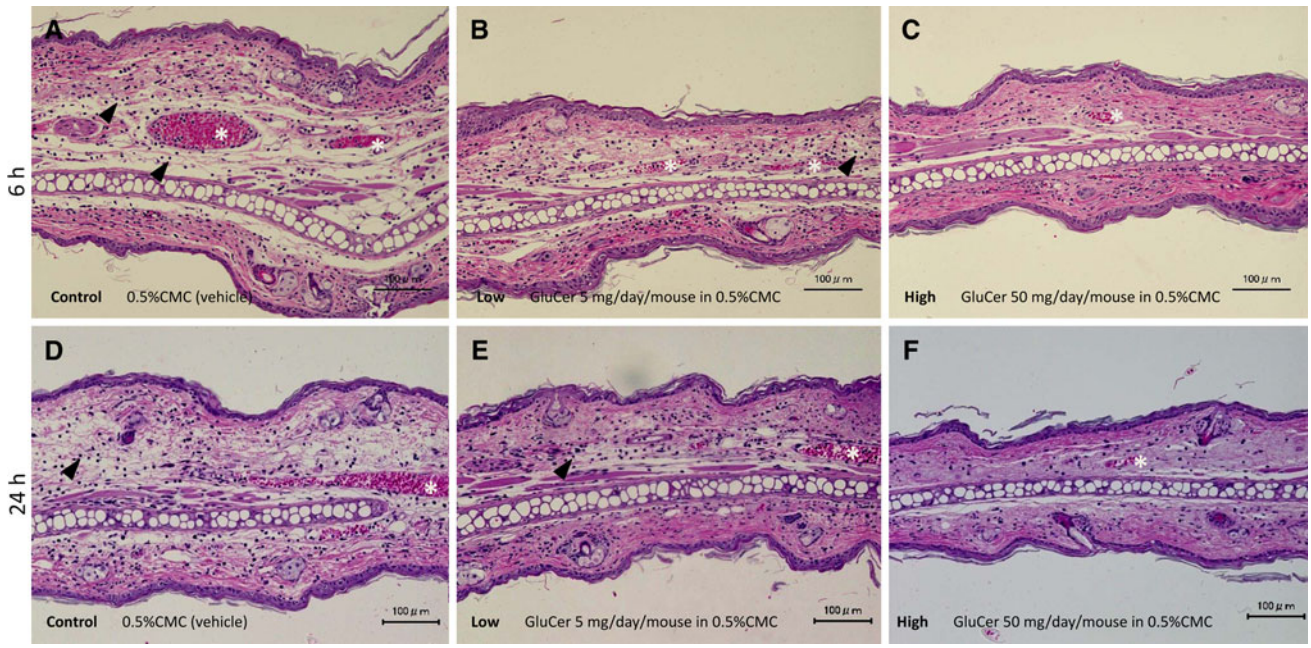

Fig. 2 Histopathological analysis of orally administered maize GluCer on DNFB-induced ear swelling in BALB/c mice. Morphological changes in the left ear of 6 and 24 h after DNFB-challenged BALB/c mice were observed. Ear sections from control mice (**a**), low dose (5 mg/day) maize GluCer administered mice (**b**) and high dose (50 mg/day) maize GluCer administered mice (**c**) were stained with hematoxylin and eosin (H&E). Microvascular (*asterisk* marks) and leukocyte (*arrowheads*) were pointed out in the histological sections. Sections are representatives of more than five observations

Table 1 IFN-γ, IL-4 and IL-10 levels in ears and spleens of DNFB-challenged BALB/c mice

GluCer Dose (mg/day)	Cytokines	Ear (pg/mg protein)		Spleen (pg/mg protein)	
		6 h	24 h	6 h	24 h
0	IFN-γ	482.4 ± 106.3	85.9 ± 16.7	7.6 ± 4.9	6.8 ± 1.7
5		362.0 ± 089.4	89.1 ± 18.3	7.5 ± 4.1	8.5 ± 2.7
50		373.2 ± 107.1	92.1 ± 13.1	5.9 ± 2.2	6.0 ± 2.9
0	IL-4	25.3 ± 4.4	10.3 ± 2.5	2.8 ± 0.9	1.9 ± 0.4
5		30.6 ± 6.5	10.7 ± 2.3	4.0 ± 1.0	1.8 ± 0.2
50		29.8 ± 8.4	09.0 ± 2.1	3.2 ± 0.7	1.5 ± 0.2
0	IL-10	3137.7 ± 881.3^{a}	698.7 ± 212.5	105.5 ± 23.5	56.3 ± 07.8^{a}
5		1326.7 ± 297.7^{a,b}	543.0 ± 158.9	131.0 ± 37.9	72.0 ± 33.1^{a,b}
50		1578.5 ± 352.3^{b}	618.0 ± 264.9	170.2 ± 47.6	110.4 ± 48.7^{b}

These data represent the means ± SD for groups of six mice. Values with different superscript letters in the same series differ significantly ($p < 0.05$)

For further evaluating the effect of GluCer on DNFB-induced inflammation, IL-10 was determined. In ear, IL-10 was significantly decreased at 6 h both low and high dose groups, whereas this effect did not prolong to 24 h (Table 1). However, in spleen, IL-10 was increased by GluCer treatment at 24 h, but not reached a statistical significance in 6 h because of the relatively large individual differences (Table 1).

TNF-α as the most important proinflammatory cytokine and IgE as the most important antibody in the serum were also measured. As shown in Fig. 3a, the TNF-α level in the ear was significantly suppressed both in the low and high dose GluCer groups ($p < 0.05$). Moreover, TNF-α level was also significantly down-regulated at 24 h by the effect of high dose GluCer (Fig. 3b). In contrast, IgE in the serum was almost at the same level among the control, low and high GluCer dose groups (Fig. 3c, d). The anti-inflammatory effect of dietary GluCer on contact dermatitis in DNFB-induced BALB/c mice is via regulation of the level of TNF-α secreted by inflammatory cells in the ear.

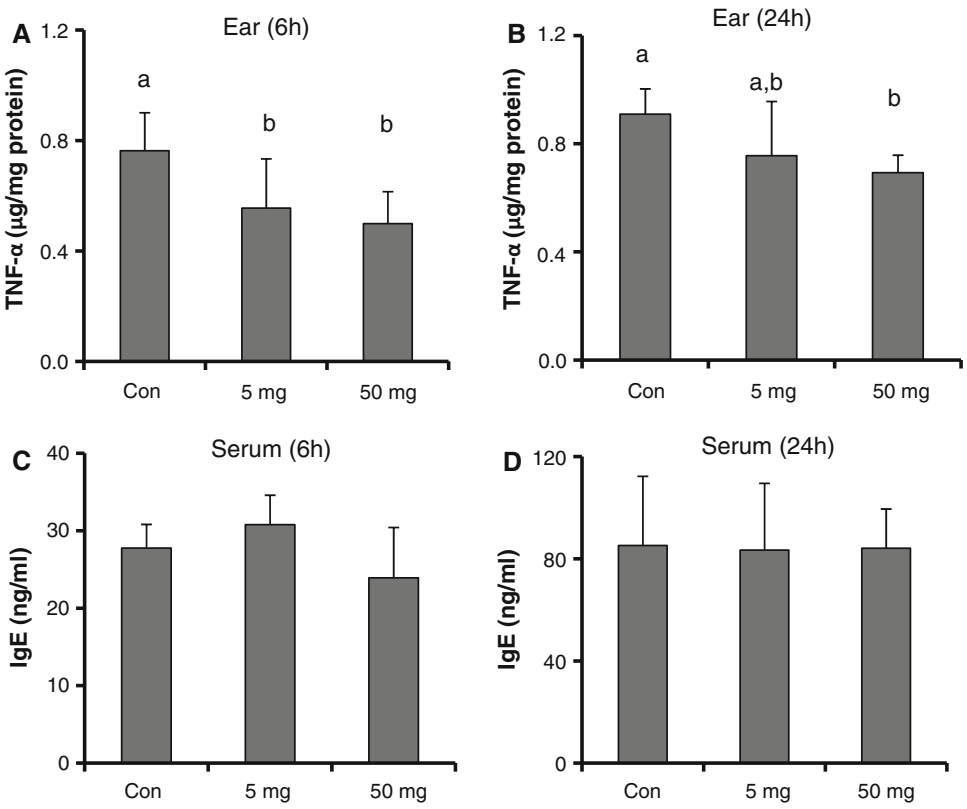

Fig. 3 TNF-α levels in the ears and IgE levels in the serum of DNFB-challenged BALB/c mice. TNF-α (**a**, **b**) levels in the right ear homogenates and IgE levels in the serum (**c**, **d**) of control, low dose (5 mg/day) and high dose (50 mg/day) maize GluCer administered mice were measured both 6 h (**a**, **b**) and 24 h (**b**, **d**) after the DNFB challenge. These data represent the means ± SD for groups of six mice. Values with *different letters* differ significantly ($p < 0.05$)

Discussion

The findings presented here indicate that dietary plant GluCer, one of the most important and abundant sphingolipids in food [12], suppresses the DNFB-induced ear swelling of BALB/c mice, and inhibits the microvascular dilation and inflammatory infiltration response via down-regulating levels of TNF-α, but not modifying the balance of Th1/Th2. Meanwhile, over-expressed IL-10 in inflammatory ear skin was suppressed by dietary GluCer. This anti-inflammatory effect of dietary GluCer increases our understanding of biofunctional sphingolipids.

Dietary GluCer is known to be hydrolyzed to ceramide, sphingosine and free fatty acids in the intestinal lumen. In mucosal cells, exogenous free sphingosine and dihydrosphingosine are rapidly absorbed and metabolized to palmitic acid [40]. A smaller portion of the sphingoid bases is reincorporated into ceramide and more complex sphingolipids. Our recent findings revealed that dietary GluCer originating from higher plants can be hydrolyzed in the intestine and that the intact plant form of sphingoid bases is barely absorbed by the tissues [9, 41]. Ono et al. [42] reported that dietary maize and yeast GluCer did not alter the sphingoid base composition in the skin of NC mice. We speculate that dietary maize GluCer accomplishes its anti-inflammatory effect, not only by producing bio-active metabolic intermediates through the sphingolipid metabolic pathways, but also via the activation of sphingolipid metabolic enzymes that affect endogenous sphingolipids at the inflammatory site, because diverse metabolic intermediates of sphingolipids, including ceramide, sphingosine, sphingosine-1-phosphate and ceramide-1-phosphate are well known important and highly bioactive endogenous regulators, which are involved in a complex metabolism network and play critical roles in inflammation [43–46].

In the case of our study, dietary maize GluCer accomplishes its inhibition of inflammation via the down-regulation of TNF-α level at the inflammatory site. TNF-α, produced by mononuclear phagocytes and other inflammatory cells (neutrophils, lymphocytes, natural killer cells, and mast cells) or non-inflammatory cells (endothelial cells), is known to be one of the most important inflammatory mediators [47, 48]. TNF-α facilitates the formation of adhesion molecules, vascular permeability and migration of leukocytes to sites of inflammation by affecting endothelial cells [49–51]. Our results reveal that dietary maize GluCer down-regulates levels of TNF-α in inflammatory ears. This down-regulation of TNF-α may affect endothelial cells and inflammatory cells, and also can inhibit vascular permeability at the site of inflammation. As a result, leukocyte migration is reduced. In the inflammatory cells, DNFB activates NF-κB by depredating the inhibitor of NF-κB (IκB) [52]. In addition, it has been reported that sphingolipids down regulated TNF-α via inactivating of NF-κB in

histamine-induced mouse skin tissues [53]. Thus, dietary GluCer seems to inhibit the DNFB activated NF-κB and down-modulate TNF-α expression in this study.

Moreover, IL-10 levels were increased in spleens but suppressed in ears by dietary GluCer. This well known anti-inflammatory cytokine, IL-10, has been reported over-expressed during the antigen-specific type of skin inflammation [54] and DNFB-challenged ear [55, 56]. IL-10 is released by CD4+ T helper 2 (Th2) cell clones and a variety of other cells, including keratinocytes, macrophages, B lymphocytes, and mast cells [56]. The suppressive effect of dietary GluCer on IL-10 expression in DNFB-challenged ears might be caused by the inhibition of leukocytes infiltrating to inflammatory site.

Ono et al. [42] demonstrated that supplementation of 0.1% GluCer diet for 7-week prevented atopic dermatitis-like symptoms in a mouse model by regulating the Th1/Th2 balance. However, IFN-γ, IL-4 and IgE levels, the markers of Th1/Th2 balance, were not notably affected by GluCer administration for 6 days in the present study. It appears that the period of treatment is important for immunological response of dietary GluCer.

Furthermore, allergic inflammatory skin disease is associated with a loss of ceramide in the extracellular lamellar membranes which causes an abnormal barrier function of the stratum corneum [57]. Application of ceramide on diseased skin could significantly reduce allergic inflammatory reactions by improving the severity score, stratum corneum cohesion and hydration [58–60]. Dietary GluCer might also improve the stratum corneum cohesion and hydration of ear skin to reduce the skin inflammation.

In summary, our data provide evidence that maize GluCer has anti-inflammatory effects on the DNFB-induced inflammation of BALB/c mice. We confirmed that dietary GluCer inhibits ear swelling and leukocyte infiltration. Furthermore, our results indicate that this effect is accomplished mainly by down-regulating TNF-α, but does not significantly affect Th1/Th2 balance or IgE levels in the serum. We hypothesize that dietary GluCer accomplishes its anti-inflammatory effect by down-regulating TNF-α to suppress vascular permeability. This reduces the migration of inflammatory cells, affects endogenous sphingolipids through metabolic pathways by activating sphingolipid-related enzymes, and moreover, by hydrolysis to ceramide to improve skin barrier function at the dermatitis site. Our findings increase the comprehensive understanding of the actions of dietary sphingolipids on the balance of immune responses.

Abstract Triglyceride (TAG) absorption involves its initial hydrolysis to fatty acids and monoacylglycerol (MAG), which are resynthesized back to diacylglycerol (DAG) and TAG within enterocytes. The resynthesis of DAG is facilitated by fatty acyl-CoA dependent monoacylglycerol acyltransferases (MGATs). Three MGAT enzymes have been isolated in humans and the expression of MGAT2 and MGAT3 in the intestines suggests their functional role in the TAG absorption. In this paper, we report that the Mogat3 gene appears to be a pseudogene in mice while it is a functional gene in rats. Examination of the mouse genomic Mogat3 sequence revealed multiple changes that would result in a translational stop codon or frameshifts. The rat Mogat3 gene, however, is predicted to encode a functional enzyme of 362 amino acids. Expression of rat MGAT3 in human embryonic kidney 293 (HEK293) cells led to the formation of a 36-kDa protein that displayed significant MGAT but not DGAT activity. Tissue expression analysis of rat MGAT3 by real-time PCR analysis indicated that rat MGAT3 has a high level of expression in intestines and pancreas. Our results thus provide the molecular basis to understand the relative functional role of MGAT2 and MGAT3 and also for future exploration of MGAT3 function in animal models.

Keywords Monoacylglycerol (MAG) · Diacylglycerol (DAG) · Triacylglycerol (TAG) · Acyl coenzymeA:monoacylglycerol acyltransferase (MGAT) · Acyl coenzymeA:diacylglycerol acyltransferase (DGAT)

Abbreviations

TAG	Triacylglycerol
DAG	Diacylglycerol
MAG	Monoacylglycerol
MGAT	Monoacylglycerol acyltransferase
DGAT	Diacylglycerol acyltransferase

Introduction

The pandemic of obesity is caused by the imbalance of energy absorption and energy expenditure. Nutrients are processed and absorbed primarily within the gastro-intestinal tract. The most energy-rich form of the nutrients, triacylglycerols (TAG), is first hydrolyzed primarily by pancreatic lipase into monoacylglycerols (MAG) and fatty acids. After absorption into the enterocytes within the intestinal tract, MAG and fatty acids are synthesized sequentially back to diacylglyceol (DAG) and TAG, which is subsequently assembled into chylomicrons and secreted into the lymph [1–4]. The critical role of TAG absorption

in energy homeostasis has triggered substantial interest in developing therapies against this pathway and this is highlighted by the success of Orlistat, which is a pancreatic lipase inhibitor that inhibits TAG absorption and accordingly reduces body weight [5, 6].

Fatty acyl-CoA dependent monoacylglycerol acyltransferases (MGAT) and diacylglycerol acyltransferases (DGAT) are responsible for the sequential re-esterification of MAG [7]. Breakthroughs were made in recent years when these enzymes were cloned and studied. DGAT1 was the first enzyme that was isolated in the family with a high level of expression in the intestines [8]. DGAT1 deficient mice were resistant to diet-induced obesity and developed significant improvement in insulin sensitivity and hepatic steatosis [9, 10]. While the mechanisms of metabolic benefits from DGAT1 deficiency were not entirely understood, it was found that DGAT1 deficiency did not alter the balance of intestinal lipid absorption while the rate of TG absorption was significantly reduced [11]. Interestingly, DGAT1 also displayed MGAT activity in vitro [12, 13].

The first MGAT gene cloned was MGAT1 with low expression in intestines [14]. This led to the discovery of MGAT2 and MGAT3, which have a high level of expression in the intestines. MGAT2 is largely expressed in the proximal intestines while MGAT3 appears to have a high level of expression in the distal intestines [15–18]. Both enzymes have demonstrated significant enzymatic activity in vitro in catalyzing the formation of DAG from MAG and fatty acyl-CoA substrates [16–18]. Interestingly, MGAT2/3 displayed DGAT activity as well [19, 20]. The physiological role of MGAT2 was studied recently by Farese and colleagues via Mogat2 deficient mice. Similar to DGAT1 mice, Mogat2 deficient mice were resistant to diet-induced obesity, and had significant improvement in insulin sensitivity, dislipidemia, and hepatic steatosis. These mice exhibited increased energy expenditure and reduced body weight that could potentially explain the metabolic benefits of these mice. Again, the total lipid absorption was not different in Mogat2 deficient mice compared to that of the wild type animals, but significant temperal and spatial delays in TG absorption were observed [21]. These studies convincingly established MGAT2 as a critical enzyme in the intestinal TAG absorption process and whole body energy homeostasis.

A relevant question is the physiological role of MGAT3 in the intestinal TAG absorption process because of its high expression in intestines. In this study, we report that the Mogat3 gene in mice appears to be a pseudogene while the gene in rats is functional. Our studies thus provide the molecular basis for future exploration of MGAT3 function in vivo.

Materials and Methods

cDNA Cloning and the Expression Construct

Rat Mogat3 cDNA was isolated by PCR from rat small intestine mRNA (BioChain Co.) based on sequence prediction of rat Mogat3 in rat genomic database using the following primers: 5′ primer, 5′-TTGCTAGTGTGTGACT CCCCTCTAAAG-3′; and 3′ primer, 5′-GTCTCTCAGGA AGGCCAGGACATG-3′. Multiple independent PCR clones were sequenced to eliminate PCR-induced mutations. The nucleotide sequences encoding full-length rat Mogat3 were inserted into a mammalian expression vector pcDNA3.1(+) (Invitrogen) with an N-terminal FLAG tag. The resulting construct was used in transfection and functional assays. Human MGAT2 and DGAT1 cDNA were cloned from human intestinal tissues and the proteins were expressed in insect sf9 cells via a baculoviral expression system.

Cell Culture

HEK293 cells were purchased from American Type Culture Collection (Manassas, VA) and cultured in Dulbecco's modified Eagle's/F-12 (3:1) medium supplemented with 5% fetal bovine serum in a humidified air atmosphere containing 5% CO_2. For transfections, 5×10^5 HEK293 cells were seeded into 6-well plates (Falcon, Corning, NY). One μg of DNA was transfected using FuGENE 6 (Roche Diagnostics, Indianapolis, IN) according to the manufacturer's instructions. Expression of FLAG-tagged rat MGAT3 was verified by Western blotting analysis with a mouse anti-FLAG monoclonal antibody (Sigma, St. Louis, MO).

Rat cDNA Panel, Reverse Transcription and Real Time PCR

The total RNA was isolated from Sprague Dawley rat tissues using TRIzol reagent (Invitrogen, Carlsbad, CA). The cDNA was synthesized from 1 μg of total RNA utilizing the SuperScript™ III First-strand Synthesis System (Invitrogen) with random hexamers for reverse transcriptase-PCR. The SYBR Green PCR Master Mix for the TaqMan gene expression assay was ordered from Applied Biosystems (Foster City, CA). The rat Mogat2 and Mogat3 primers were designed by Primer Express following the amplicon design guidelines defined by the software and the primers were tested and optimized for PCR. The sequences of the primers for rat Mogat2 and Mogat3 are as follows: rat Mogat2; 5′GGTGAGTGCTGATCACATTCTGA-3′ (forward) and 5′-AAGGGAGATGCCCATGATCT-3′ (reverse), rat Mogat3; 5′-AGCCTGGAACAGTGAGTTTGC-3′ (forward)

and 5′GGCTTCGCTGCACTGGAA-3′ (reverse). Real-Time PCR was performed on 7900HT Fast Real-time PCR System (Applied Biosystems) using TaqMan® SYBR Green PCR Master Mix. Cycle threshold (Ct) values were obtained using Applied Biosystems SDS2.3 software, with 18S rRNA used as a reference gene. The data were normalized by setting the average brain expression value to 1.

In Vitro MGAT Activity Assay

Cell pellets were homogenized with three short 10-s pulses from a Brinkmann Polytron homogenizer in 20 mM NaCl containing a protease inhibitor mixture (Roche Diagnostics). The resultant homogenates were used to assess the relative acyltransferase activity. Protein concentrations were determined using a commercially prepared protein assay kit (Pierce, Rockford, IL) with bovine serum albumin used as a standard. MGAT activity was determined at room temperature in a final volume of 100 µl. Briefly, MGAT or DGAT activity was determined by measuring the incorporation of [^{14}C]oleoyl-CoA (American Radiolabeled Chemical Inc., St. Louis, MO) into the acyl acceptor monooleoylglycerol or dioleoylglycerol. The acyl acceptors were introduced into the reaction mixture by liposomes. The acyl acceptor and dioleoylphosphatidylcholine (molar ratio 1:5) were dissolved in chloroform and dried by vacuum. Liposomes were formed by adding water and sonicating for 5 min. The reaction mixture contained 100 mM Tris/HCl, pH 7.4, 5 mM $MgCl_2$, 1 mg/ml fatty acid free bovine serum albumin (Sigma), 200 mM sucrose, 10 µM [^{14}C]oleoyl-CoA (50 mCi/mmol; American Radiolabeled Chemicals), 100 µM acyl acceptors in liposomes, and various amounts of cellular homogenates. The reaction was initiated by adding protein homogenate, incubated for 20 min at room temperature and was stopped by adding 1 ml of chloroform/methanol (2:1, v/v). Lipids were extracted with chloroform/methanol (2:1, v/v) by vortexing for 30 s. After centrifugation to remove debris, aliquots of the organic phase containing lipids were dried under a N_2 stream and separated by the Linear-K Preadsorbent TLC plate (Waterman Inc., Clifton, NJ) with hexane/ethyl ether/acetic acid (80:20:1, v/v/v). The TLC plates were exposed to a Phosphor-Imager screen to assess the incorporation of ^{14}C-labeled acyl moieties into dioleoylglycerol or trioleoylglycerol products. Phosphorimaging signals were visualized using a Storm 860 PhosphorImager (Amersham Biosciences).

Comparative Genomic DNA Sequence Analysis

The analysis was carried out using the Artemis comparison tool (ACT) [22]. Mouse, rat and human genomic sequences in the target gene cluster, corresponding to the human sequences between ZHHIT1 and VGF genes, were downloaded from NCBI using the Entrez Gene functions. Both FASTA and "GenBank_Full" files were downloaded for each sequence. The source genomic sequence (e.g., the human FASTA file) to be used as the source database was first formatted using the "formatdb" tool. The comparator files were then generated for ACT by running the blastall alignment program between target genomic (e.g., mouse) and database (e.g., human): blastall -m 8 -i mouse_genomic.fasta -d human_genomic.fasta -p blastn -o mouse.human.blastn. Another copy of FASTA file, without being formatted by the "formatdb" program, is needed for ACT. In the file, all features from GenBank file are copied to the top of the FASTA sequence. The ACT program was run according to its user manual.

Phylogenetic Analysis

The Clustal multiple sequence alignment of DGAT2 and MGAT2/3 protein sequences of mouse, rat and human was carried out, using default parameters, with the integrated tools in JalView [23]. The construction of the phylogenetic tree was based on the percent identity of the protein sequences.

Results

The DGAT2 and MGAT2 tandem gene pair is located within a gene cluster that is conserved among mouse, rat and human (Supplemental Figure 1A). We reasoned that a similar syntenic relationship may also exist between human MGAT3 and its rodent homologues. Indeed, there is extensive orthology between human and rodent gene clusters that contain Mogat3. All of the five human genes (RABL5, FIS1, CLDN15, ZNHIT1, and PLOD3, excluding pseudogenes) upsteam of Mogat3 were found in mouse and rat in the same order, except that Zhhit1 was absent in the rat. Downstream of Mogat3, the orthology between human and mouse further extends to at least three other genes (VGF, AP1S1, and Serpine1). This human-rodent orthology around Mogat3 (Fig. 1a) suggests the likely chromosomal location of rodent Mogat3. In support of this hypothesis, TBLASTN search of translated mouse and rat genomes using human MGAT3 protein sequence resulted in hits within this cluster. In the mouse genome, one of the hits was LOC639992 (Mm7284), a predicted gene immediately downstream of Plod3. The top hit in rat genome was LOC68550, a predicted gene known as "similar to monoacylglycerol O-acyltransferase 2", also located at the expected locus of Mogat3. Based on the orthology and the predicted coding sequence similarity, we reasoned that

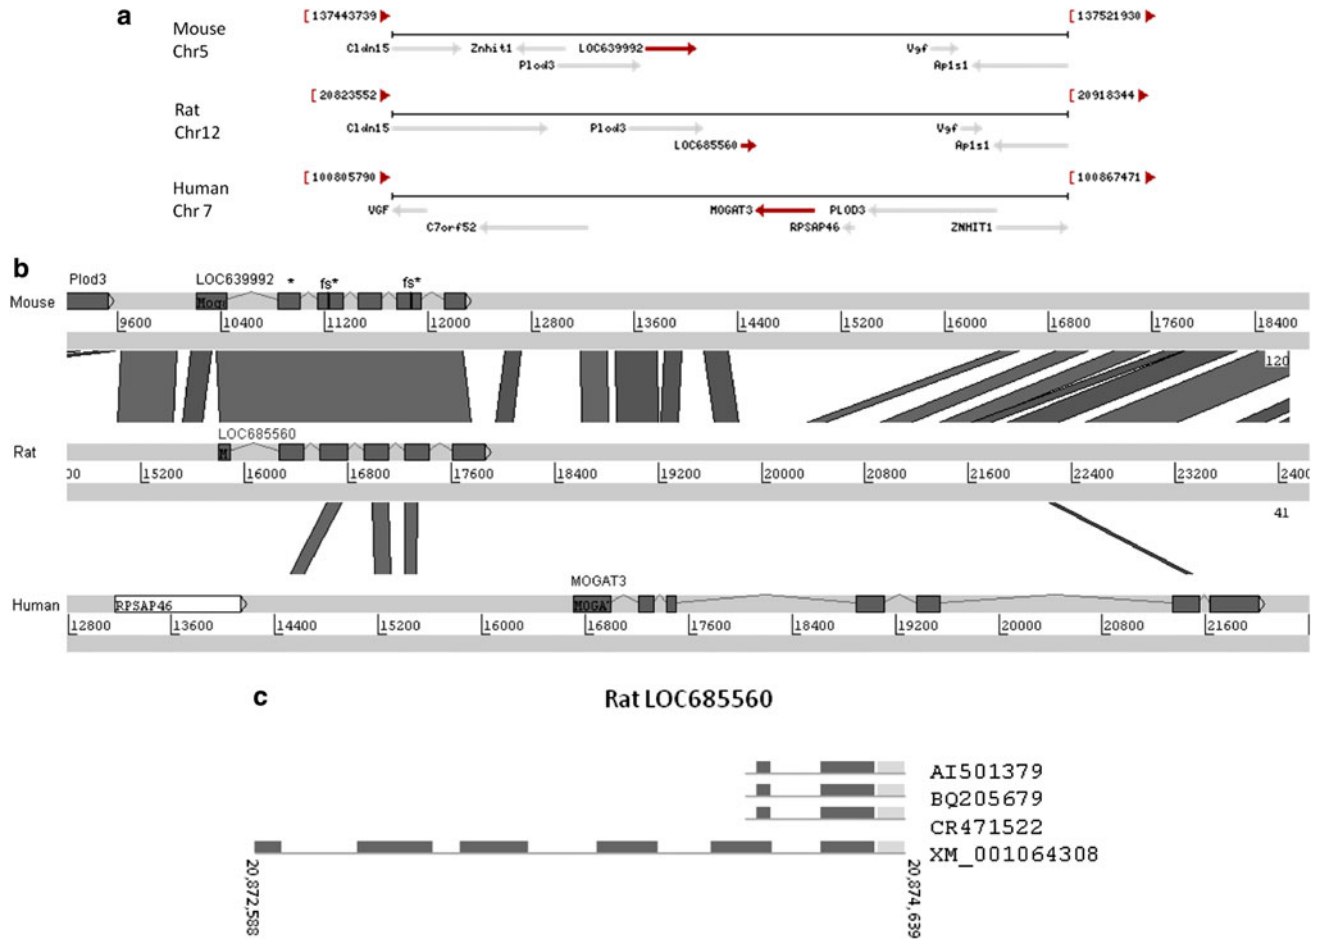

Fig. 1 **a** Conservation of the human chromosome 7 gene cluster surrounding Mogat3 in mouse chromosome 5 and rat chromosome 12. The human gene cluster is shown in opposite orientation to those of mouse and rat ones. Mogat3 and its suspected rodent homologues are marked with black *arrow*. Only the Cldn15-Zhhit1(mouse only)-Plod3 interval upstream of Mogat3, and Vgf-Ap1s1 interval downstream are shown. **b** Genomic sequence similarity between human MOGAT3 and suspected mouse and rat homologues. The predicted mouse and rat Mogat3 genomic sequences are highly homologous with each other throughout the entire gene, but only three exons (3, 4, and 5) showed similarity to human genomic sequences, and these are upstream of the Mogat3 locus. The predicted coding sequence of mouse Mogat3 is interrupted by one termination codon in exon 2 (marked with*) and two frameshifts in exon 3 (marked with Fs*). See supplemental Figure 2 for details. **c** Rat EST clone numbers and the relative locations within the rat Mogat3 gene

LOC639992 and LOC68550 could be MGAT3 candidate genes in mouse and rat, respectively.

Comparative genomic sequence analysis at the presumed Mogat3 locus showed a high degree of conservation between the mouse LOC639992 and the rat LOC68550 genomic DNA sequences (Fig. 1b). The putative rodent Mogat3 gene contains 6 exons and 5 introns (Fig. 1b). However, the mouse and rat genes exhibited low genomic sequence similarity to the human MGAT3 genomic sequence. Subsequent examination of the putative mouse Mogat3 gene revealed sequences that would result in an in-frame stop codon and frameshifts. Specifically, in the putative mouse Mogat3 gene, there is an in-frame stop codon in exon 2 and two deletions that would result in frameshifts within exon 3 (Supplemental Figure 2). Examination of the mouse Mogat3 genomic sequences of 12 different mouse strains from Perlegen revealed that the stop codons that interrupted exon 3 were present in all strains, thus precluding mutations or sequencing errors (data not shown). In addition, there was no Mogat3 EST discovered in the mouse expression sequence tag (EST) database. Our effort to amplify a potential Mogat3 cDNA did not yield any products either. Taken together, these data suggest that the mouse putative Mogat3 gene sequence does not appear to encode a functional gene and we conclude that the mouse Mogat3 is a pseudogene.

A similar analysis was performed in the rat genome, which revealed a potential functional gene product. Searches in the rat EST database revealed three EST clones at the 3′ end of the gene (Fig. 1c). Using sequences derived from the ESTs and the predicted rat cDNA sequence based on rat genomic sequences, a rat Mogat3 cDNA was cloned

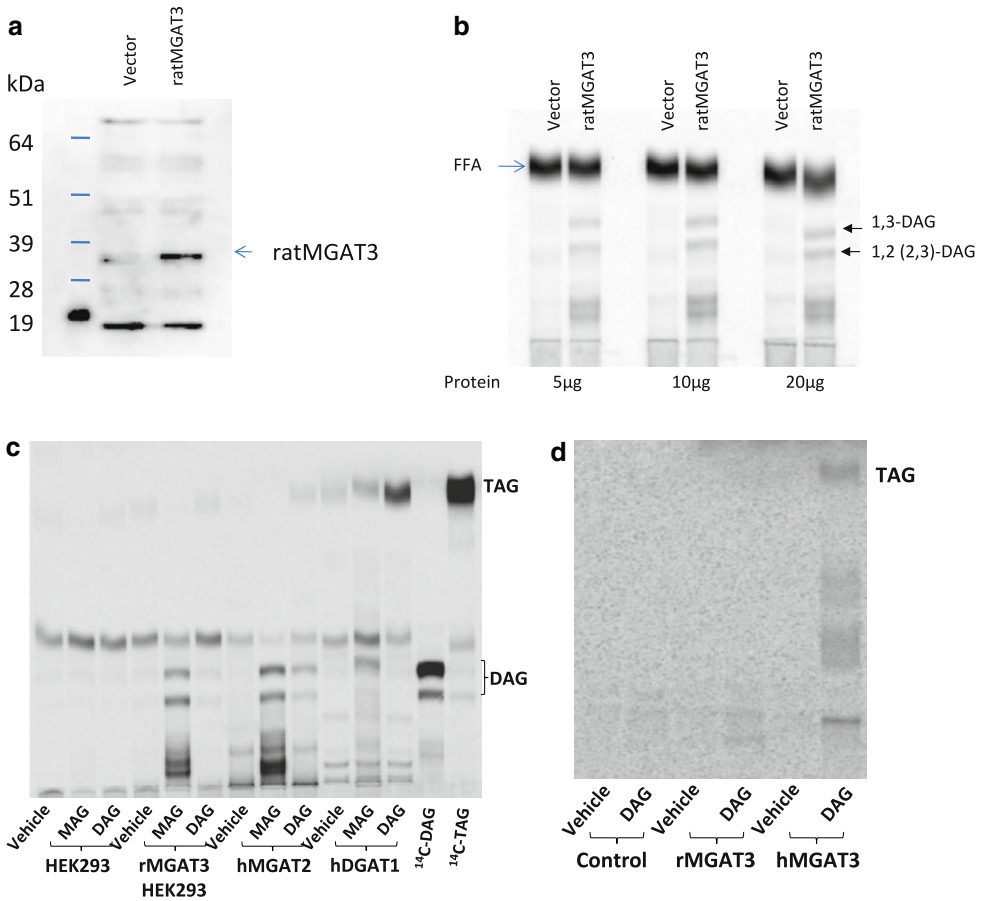

Fig. 2 **a** Rat MGAT3 protein expression in HEK 293 cells. Rat MGAT3 cDNA was cloned as described in the "Methods" section. The subcloning of rat MGAT3 cDNA into the expression vector and transfection to HEK293 cells were described in "Methods" section. Western blotting analysis was performed with a mouse anti-FLAG monoclonal antibody as described in the "Methods" section. **b** Rat MGAT3 protein displayed MGAT activity. The expression of rat MGAT3 in HEK293 cells, the preparation of cellular extracts for MGAT activity analysis and the details for MGAT activity assessment were described in the "Methods" section. Rat MGAT3 enzyme activity was compared to the vector control. **c** Rat MGAT3 protein has MGAT but not DGAT activity. Similar activity studies were carried out using either MAG or DAG as an acyl acceptor to assess potential MGAT or DGAT activity rat MGAT3 may have. Human MGAT2 and DGAT1 were used as controls. **d** Rat MGAT3 protein does not have DGAT activity. Rat MGAT3 and human MGAT3 were compared in the same experiment on their respective DGAT activity

from rat intestines and was subsequently subcloned into a mammalian expression vector. The predicted amino acid sequence and the alignment with human MGAT3; rat, mouse and human MGAT2 and DGAT2 are shown in Supplemental Figure 3. Rat MGAT3 protein contains 326 amino acids and shares 47% identity with human MGAT3 and is 56% identical compared to rat MGAT2 (Supplemental Table 1). To facilitate the expression analysis, a FLAG tag was inserted at the amino-terminus of the enzyme. When the expression vector was transfected into the human embryonic kidney (HEK) 293 cells and the cellular extracts were analyzed by Western blotting analysis against the FLAG tag, a protein of 36 kD was readily detectable compared to the vector control (Fig. 2a). To assess whether rat MGAT3 protein possesses MGAT activity, cellular extracts from HEK293 cells transfected with rat MGAT3 expression vector were incubated with substrates of MAG and radio-labeled oleoyl-CoA and the formation of DAG was analyzed by thin layer chromatography. Compared to the vector control, significant MGAT activity was detected using extracts from cells expressing rat MGAT3 (Fig. 2b). To further characterize the rat MGAT3 acyltransferease activity, we compared its relative MGAT and DGAT activities using either MAG or DAG as substrates. Human MGAT2 and DGAT1 proteins demonstrated significant MGAT or DGAT activities as controls (Fig. 2c). While rat MGAT3 displayed MGAT activity, no DGAT activity was detected. In the head-to-head experiment to compare human and rat MGAT3 activities, MGAT activity appeared comparable (data not shown) while only human MGAT3 displayed DGAT activities (Fig. 2d). Thus, the rat gene encodes a functional MGAT3 enzyme that displays only MGAT activity.

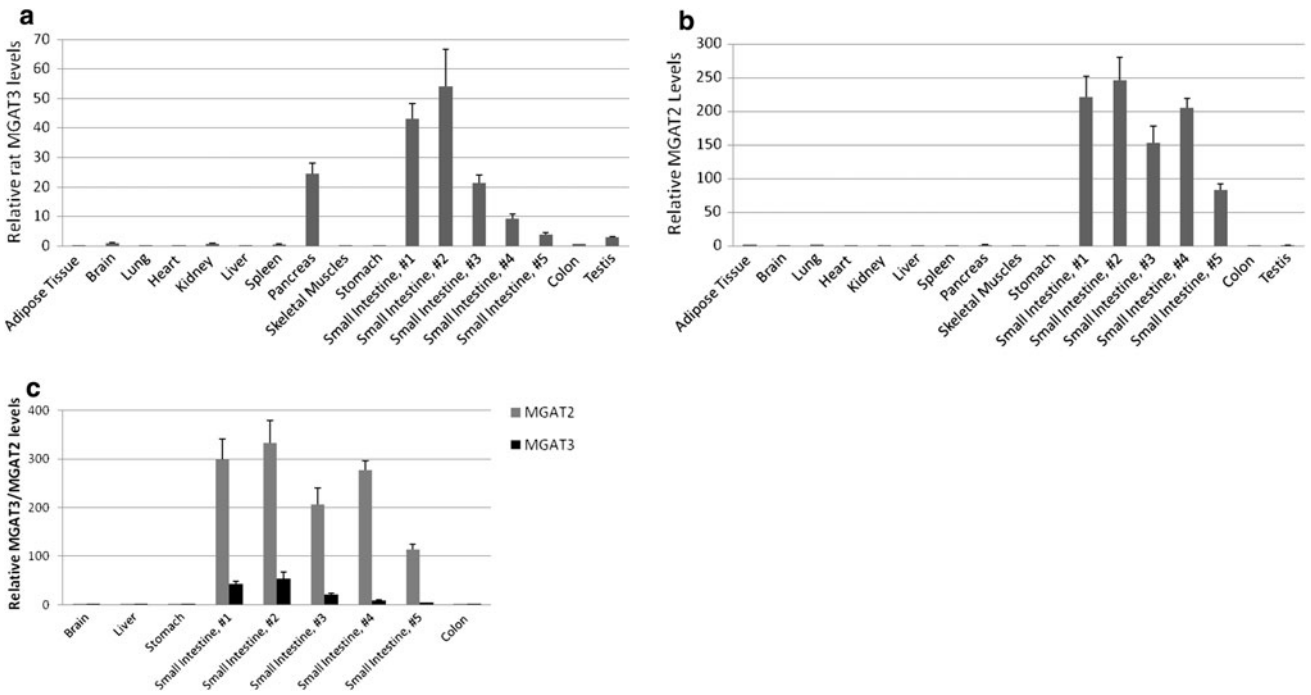

Fig. 3 **a** Tissue distribution of rat Mogat3. The Mogat3 mRNA level was quantified by real-time PCR and normalized by 18 s RNA. The small intestines were separated into 5 different parts from proximal to distal intestines. RNAs were prepared and analyzed as described in the "Methods" section. Data were normalized by setting the average brain expression value to 1. **b** Tissue distribution of rat Mogat2. The Mogat2 mRNA level was quantified by real-time PCR and normalized by 18 s RNA. The data were normalized by setting the average brain expression value to 1. **c** Relative expression levels of rat Mogat3 and Mogat2. The rat Mogat2 and Mogat3 mRNA levels were normalized by 18 s RNA level. Data were normalized by setting brain Mogat3 as 1

The rat Mogat3 mRNA expression pattern was examined in a rat tissue panel by real-time RT-PCR. As expected, rat Mogat3 was highly expressed within the intestines, and the expression was low in the majority of other tissues examined including the colon (Fig. 3a). Interestingly, rat Mogat3 had a fairly high level of mRNA expression in the pancreas as well (Fig. 3a). Rat Mogat2 expression was high in the intestines and low in all the other tissues examined as expected (Fig. 3b). On the relative scale as assessed by real-time PCR analysis, Mogat3 expression was much lower compared to rat Mogat3 although both genes had overlapping expression within the intestinal tract (Fig. 3c).

Because of its functional presence in rat but not in mouse, we searched for Mogat3 ESTs in other rodent species. There were two rodent EST hits, GH463792 and GH463793, belonging to oldfield mice (*Peromyscus polionotus subgrisieus*). A full-length oldfield mouse Mogat3 cDNA sequence was generated (Supplemental Figure 3), the function of which is yet to be tested.

A phylogenetic tree analysis (Fig. 4) was carried out on DGAT2/MGAT2/3 family proteins that suggested evolutionary branching of DGAT2 family genes including DGAT2 and MGAT2, while MGAT3 formed a distinct

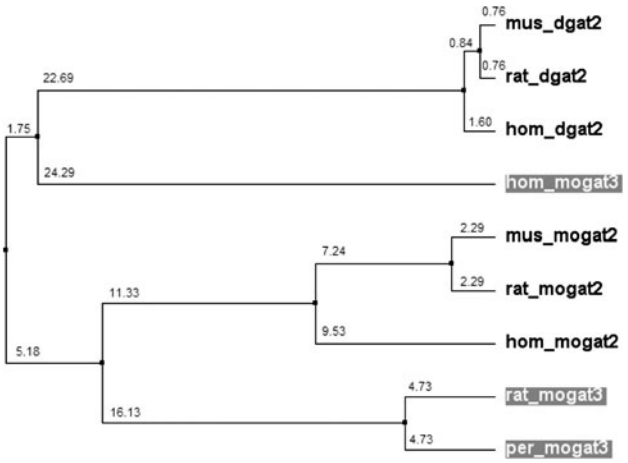

Fig. 4 Phylogenetic tree analysis of MGAT2/DGAT2/MGAT3 proteins based on sequence identity (See supplemental Figure 2 for sequence alignment). Evolutionary distances between different nodes are shown (as generated by JalView). mus_mogat2: NP_803231.1 (*Mus musculus*), hom_mogat2: NP_079374.2 (*Homo sapiens*), rat_mogat2: XP_001060766.1 (*Rattus norvegicus*), mus_dgat2: NP_080660.1 (*Mus musculus*), rat_dgat2: NP_001012345.1 (*Rattus norvegicus*), hom_mogat3: NP_835470.1 (*Homo sapiens*), rat_mogat3: Mogat3 sequence from this study (*Rattus norvegicus*), per_mogat3: Mogat3 sequence identified in this study (*Peromyscus polionotus*)

member of the family. Based on the percent identity assessment, rodent MGAT3 is closest evolutionarily to the MGAT2 gene, and human MGAT3 is most likely derived from gene duplication of DGAT2.

Discussion

The intestinal TAG absorption process is an important component of energy homeostasis. While it has been known for years that TAG is hydrolyzed to fatty acids and MAG, which are subsequently resynthesized back to TAG in enterocytes, it was only recently that the molecules responsible for sequential acylation of MAG to DAG and TAG were cloned and characterized. Specifically, the initial cloning of DGAT1, generation and characterization of DGAT1 deficient mice greatly improved the understanding in the field and also highlighted the importance of the pathway in the whole body energy balance. In addition, the metabolic benefits observed from the DGAT1 deficient mice triggered an industry-wide pursuit of DGAT1 inhibitors for metabolic disorders.

While MGAT1 does not have a high level of expression in intestines [14], successful cloning of both human and mouse MGAT2 revealed its tissue specific expression in intestines that implied a significant role of MGAT2 in the intestinal TAG absorption process [17, 18]. Not surprisingly, characterization of Mogat2 deficient mice indicated similar metabolic phenotypes to those of DGAT1 deficient mice [21]. A hypothesis was put forward suggesting that modulation of the dynamic intestinal TAG absorption process may trigger enteroendocrine and/or enteroneuronal signals that might control whole body energy homeostasis [21].

An interesting finding was made by Cheng and coworkers when the human MGAT3 gene was isolated and reported [16]. While the intestinal expression of MGAT3 also suggested its role in the intestinal TG absorption, its physiological role in this process is yet to be defined. In the case of Mogat2 deficient mice, a natural question arises as to whether MGAT3 and MGAT2 play complementary or overlapping roles in the intestinal TAG absorption process. We found that in mice, Mogat3 is likely a pseudogene and thus there is no other intestinal MGAT enzyme that would compensate for MGAT2 function in the Mogat2 deficient mice. In other words, Mogat2 deficient mice are actually Mogat2 and Mogat3 dual deficient mice. The finding of Mogat3 as a mouse pseudogene is supported by multiple changes in corresponding genomic regions that result in an in-frame stop codon and two frameshifts. The lack of mouse Mogat3 ESTs also supported this conclusion. More conclusively, we found that similar changes in nucleotide sequences within the Mogat3 gene exist in 12 different mouse strains.

We found in rats, however, the Mogat3 gene encodes a functional enzyme. First, the cDNA sequence predicted a functional MGAT3 orthologue in rats. Secondly, the presence of multiple ESTs in rat EST database and the successful cloning of a rat Mogat3 cDNA clearly indicated a possible functional MGAT3 enzyme. The expression of MGAT3 in mammalian cells resulted in the production of a protein of 36 kD, which is similar to the size of human MGAT3. In activity studies, expression of this enzyme in HEK293 cells produced robust MGAT activity. Taken together, we conclude that rat Mogat3 is a functional gene.

The expression pattern of Mogat3 in rats is similar to what was reported for human MGAT3. The quantitative assessment of rat MGAT2 against MGAT3 expression indicated that at the messenger RNA level, MGAT2 appears to be the predominant enzyme expressed in the intestinal tract. It is not known at the moment whether there is posttranslational regulation of MGAT2/3 expression, and thus our results do not necessarily prove that MGAT2 is the major enzyme responsible for intestinal TG absorption. While MGAT3 has overlapping expression with MGAT2, it is not clear whether MGAT3 can compensate for MGAT2 function when the MGAT2 gene is rendered deficient. The relative importance of MGAT2 versus MGAT3 in rats, humans or other species will need to be explored in future studies.

In summary, we report the functional cloning and biochemical characterization of a rat Mogat3 gene. In addition, we provide evidence that the mouse Mogat3 gene is a pseudogene. Our results provide an important molecular basis for understanding the relative roles of MGAT2 and MGAT3 in the intestinal TAG absorption and whole body energy homeostasis.

Acknowledgments The authors wish to thank Haihong Guo for technical assistance.

Received: 15 October 2010 / Accepted: 7 December 2010 / Published online: 15 February 2011

Abstract The aim of the study was to compare the efficacy of high-dose rosuvastatin, low-dose rosuvastatin plus fenofibrate and low-dose rosuvastatin plus omega-3 fatty acids with regard to the lipid profile in patients with mixed hyperlipidemia. The primary endpoint was changes in non-high density lipoprotein-cholesterol (non-HDL-C) levels. Study participants were randomly allocated to receive rosuvastatin 40 mg ($n = 30$, R group), rosuvastatin 10 mg plus fenofibrate 200 mg ($n = 30$, RF group) or rosuvastatin 10 mg plus n-3 fatty acids 2 g ($n = 30$, RN group). Non-HDL-C levels were reduced in all groups: in R group by 54%, in RF group by 42% and in RN group by 42%. Significant reductions in total cholesterol (TC), low density lipoprotein (LDL)-C and triglyceride levels were observed in all groups. The reductions in total and LDL-C were greatest in the R group while a more pronounced reduction of triglycerides in the RF group compared with that in the R and the RN group was observed. HDL-C levels were significantly increased only in the RF group. In conclusion, high doses of rosuvastatin and small doses of rosuvastatin plus either fenofibrate or n-3 fatty acids exhibit favorable effects on both LDL-C and non-HDL-C levels. However, rosuvastatin monotherapy more potently reduces these parameters. The combination of rosuvastatin plus fenofibrate leads to a greater decrease in triglyceride levels and a greater increase in HDL-C levels compared with the other two treatments. While awaiting the results of ongoing trials high doses of rosuvastatin may represent the treatment of choice in individuals with mixed dyslipidemia.

Keywords Mixed hyperlipidemia · Rosuvastatin · Fenofibrate · n-3 Fatty acids · Metabolic parameters · Non high-density lipoprotein · Triglycerides · High-density lipoprotein

Abbreviations

ApoA-1	Apolipoprotein A-1
apoB	Apolipoprotein B
ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
HDL	High density lipoprotein
HOMA	Homeostasis model assessment
IDL	Intermediate density lipoprotein
LDL	Low density lipoprotein
R group	Rosuvastatin group
RF group	Rosuvastatin-fenofibrate combination group
RN group	Rosuvastatin-n-3 fatty acids combination group
TC	Total cholesterol
TG	Triglycerides
TSH	Thyroid stimulating protein

Introduction

Mixed or combined hyperlipidemia is a common metabolic disorder characterized by elevated concentrations of both

cholesterol and triglycerides [1]. More specifically, patients with mixed hyperlipidemia have elevated low density lipoprotein-cholesterol (LDL-C) and triglyceride (TG) levels, a preponderance of small, dense LDL particles, and reduced concentrations of high density lipoprotein-cholesterol (HDL-C) [1]. Mixed hyperlipidemia usually results from the hepatic overproduction of apolipoprotein B that enters the circulation in the form of very low density lipoproteins (VLDLs) [1]. Although the term mixed dyslipidemia is used to describe a heterogeneous group of disorders with divergent metabolic causes that simply share a common clinical phenotype, it is widely accepted that this condition is associated with an increased cardiovascular risk [1]. Thus, this disorder should be promptly treated with lifestyle changes, dietary counseling, lipid-lowering drugs or combinations of these interventions. It is well known that monotherapy with conventional doses of statins or fibrates is usually sufficient to treat simple lipid disorders such as hypercholesterolemia or hypertriglyceridemia, respectively. On the other hand mixed hyperlipidemia represents an important therapeutic challenge since in this case monotherapies only partially correct the underlying metabolic defects.

Statins represent the cornerstone of hypolipidemic therapy. These compounds have shown enormous efficiency in reducing the incidence of cardiovascular disease, a phenomenon that is mainly related to the reductions in LDL-C concentrations. On the other hand, the use of older statins in individuals with mixed dyslipidemia usually results in residual hypertriglyceridemia and low HDL-C levels [2]. However, although the conventional doses of older statins do not markedly alter triglyceride or HDL-C levels, high doses of the newer statins such as rosuvastatin or atorvastatin may favorably affect these parameters. Thus, rosuvastatin (10 or 20 mg) and atorvastatin (20 or 40 mg) have been shown to reduce triglycerides by almost 30% in patients with primary hyperlipidemia [3]. In addition, rosuvastatin in high doses (40 mg) seems to be the most potent statin for HDL-C elevation demonstrating increases in HDL-C levels by 8–15% in large clinical trials [4–6]. Thus, the use of high doses of these potent statins represents a promising therapeutic option in patients with mixed dyslipidemia. An alternative approach to the treatment of mixed dyslipidemia is the combination of a statin with agents that reduce triglycerides and/or increase HDL-C values. Fibric acid derivatives (fibrates) and n-3 fatty acids represent ideal candidates for this kind of combination treatment. Fenofibrate belongs to a class of drugs that activate specific transcription factors known as peroxisome proliferator activated receptors α (PPAR-α) [7]. These drugs reduce the concentration of plasma TG by 30–50% and raise the level of HDL-C by 2–20%. Fenofibrate's effect on LDL-C is variable, ranging from a small decrease in hypercholesterolemic patients to no change or even a slight increase in individuals with combined dyslipidemia or hypertriglyceridemia [7]. Furthermore, the effects of fenofibrate on HDL-C are largely dependent on baseline HDL-C levels. In several clinical studies combined statin/fibrate therapy resulted in pronounced decreases in LDL-C, triglycerides and non-HDL-C as well as increases in HDL-C compared with either monotherapy [8]. However, the elevated risk for muscle side effects limits the widespread use of this combination [9]. The n-3 fatty acids mainly reduce TG concentration, but they exert many other anti-atherosclerotic properties [10]. Numerous prospective and retrospective trials from many countries have shown that moderate fish consumption lowers the risk of major cardiovascular events, such as myocardial infarction, sudden cardiac death, coronary heart disease, atrial fibrillation, and most recently, death in patients with heart failure [10, 11]. Adding n-3 fatty acids to statins reduces triglycerides and non-HDL-C to a greater extent than statin monotherapy [12]. It is currently unknown what would be the best treatment option for patients with mixed hyperlipidemia, i.e. high-dose statin therapy or low-dose statin plus fenofibrate (the only fibrate that can be coadministered with a statin) or low-dose statin plus n-3 fatty acids. The primary end-point of the present open-label randomized study was the lowering effect of high dose of rosuvastatin alone, low dose of rosuvastatin plus fenofibrate and low dose of rosuvastatin plus n-3 fatty acids treatment on non-HDL-C levels in patients with primary mixed hyperlipidemia. Secondary end-points were the treatment effects on LDL-C values, the percentage of patients that achieved their pre-specified LDL and non-HDL-C targets, the effects of these treatments on anthropometric variables (such as body weight and body mass index), lipid profile (triglycerides, HDL-C and apolipoprotein values), carbohydrate metabolism indices (fasting glucose and insulin concentrations, Homeostasis Model Assessment (HOMA)-index values) and serum uric acid (SUA) levels. To the best of our knowledge, this is the first time that these combinations have been compared directly.

Materials and Methods

Participants

Patients attending the Outpatient Obesity and Lipid Clinic of the University Hospital of Ioannina, Greece were recruited for the study. Patients were considered eligible if they had LDL-C >160 mg/dL and triglycerides >200 mg/dL at baseline. Exclusion criteria were known coronary heart disease or other atherosclerotic diseases, triglyceride values >500 mg/dL, renal disease (serum creatinine levels

>1.6 mg/dL or proteinuria of nephrotic range), diabetes mellitus (fasting blood glucose >126 mg/dL or ongoing treatment with oral hypoglycaemic agents), hypothyroidism [thyroid stimulating hormone (TSH) >5 IU/ml] and liver disease (ALT and/or AST levels > threefold upper limit of normal in more than two consecutive measurements). Patients with any medical conditions that might preclude successful completion of the study protocol were excluded. Patients with hypertension were included in the study but they were on stable medication for at least 3 months before study entry and their blood pressure was adequately controlled (no change in their treatment was be made during the study period). Patients currently taking lipid lowering drugs or having stopped them less than 4 weeks before study entry were excluded. After the initial screening all study participants gave a written informed consent. All subjects were given individualized dietary instructions by a clinical nutritionist, based on each one's basal energy requirements and on an estimation of the subject's typical activity level, according to NCEP-ATP III guidelines [13]. The treatment groups did not differ in their nutrient intake at baseline [regarding dietary cholesterol, total calories, percentage of calories from saturated, unsaturated, and monounsaturated fats, and percentage of calories from carbohydrates and alcohol (analyses not shown)]. There were no differences in diet composition between study groups. All patients were asked to attend the clinic monthly during the treatment in order to assess diet compliance. Patients who remained hyperlipidemic (LDL-C >160 mg/dL and triglycerides >200 mg/dL) on two consecutive measurements after a dietary intervention period of approximately 3 months were considered eligible for randomization. We followed a simple randomization method using a table of random numbers as previously described [14]. With this method patients were allocated to open-label rosuvastatin 40 mg ($n = 30$, group R), rosuvastatin 10 mg plus fenofibrate 200 mg ($n = 30$, group RF) or rosuvastatin 10 mg plus 2 gr of n-3 fatty acids [each gr of the preparation contained approximately 465 mg of eicosapentaenoic acid (EPA) and 375 mg of docosahexaenoic acid (DHA)] ($n = 30$, group RN) daily. Anthropometric variables and serum metabolic parameters were assessed at baseline and after 3 months of treatment. Non-HDL-C and LDL-C targets for each patient were determined according to NCEP-ATP III guidelines [13]. No external sponsor was involved in the study which was approved by the ethics committee of the University Hospital of Ioannina.

Biochemical Parameters

All laboratory determinations were carried out after an overnight fast. Non-HDL-C was calculated by the equation: non-HDL-C = TC − HDL-C. LDL-C was calculated using the Friedewald formula (provided that triglycerides were <400 mg/dL). Serum concentrations of fasting glucose, total cholesterol and triglycerides were determined enzymatically on an Olympus AU600 clinical chemistry analyzer (Olympus Diagnostica, Hamburg, Germany). HDL-C was determined in the supernatant, after precipitation of the apolipoprotein B-containing lipoproteins with dextran sulphate-Mg^{++} (Sigma Diagnostics, St. Louis, MO, USA). Serum apolipoproteins (Apo) A-I and B were measured by immunonephelometry on a BN ProSpec nephelometer (Dade-Behring, Lieberbach, Germany). Serum creatinine was measured using the Jaffé method. SUA was calculated with an enzymatic colorimetric test (uricase). Fasting serum insulin levels were measured by an AxSYM insulin assay microparticle enzyme immunoassay on an AzSYM analyzer (Abbott Diagnostics, Illinois, USA). Finally, HOMA index was calculated using the equation proposed by Matthews as follows: fasting insulin (mU/L) * fasting glucose (mg/dL)/405 [15].

Statistical Analyses

Values are given as means ± standard deviation (SD) and median (range) for parametric and non-parametric data, respectively. The chi-square test was used to access differences in proportions. Continuous variables were tested for lack of normality by the Kolmogorov–Smirnov test and logarithmic transformations were accordingly performed for triglycerides, insulin and HOMA index. The paired-samples t-test was used for assessing the effect of treatment in each group. Analysis of covariance (ANCOVA), adjusted for baseline values, was used for comparisons between treatment groups. Significance was defined as $p < 0.05$. Analyses were performed using the SPSS 15.0 statistical package for Windows (SPSS Inc., 1989–2004).

Results

We enrolled 90 patients (45 men and 45 women) with a mean age of 55 ± 10 years (Table 1). More than 75% of the study participants fulfilled the criteria for the diagnosis of metabolic syndrome [16]. On the other hand only exceptionally did study subjects have a positive family history of dyslipidemia and/or premature cardiovascular disease that could be consistent with the diagnosis of familial combined hyperlipidemia. There were no differences in age, sex distribution, body mass index values and proportion of smokers between study groups. The baseline values of TC, LDL-C, non-HDL-C and TG as well as the concentrations of apolipoproteins AI and B did not show any significant difference among the 3 treatment groups

Table 1 Baseline demographic characteristics of all study patients

Characteristic	Group R	Group RF	Group RN	*p*

R rosuvastatin, *RF* rosuvastatin + fenofibrate, *RN* rosuvastatin + n-3 fatty acids, *BMI* body mass index, *Apo* apolipoprotein, *NS* non significant

(Table 1). There were no significant changes in blood pressure, BMI, waist circumference, and body weight at 3 months (data not shown). At the end of the 3-month treatment period, there was a significant reduction of non-HDL-C in all treatment groups ($p < 0.001$ compared to baseline values) with a greater decrease in the R group ($p < 0.05$ compared to RF and RN groups). More specifically non-HDL-C was reduced by 54% in the R group, by 42% in the RF group and by 42% in the RN group (Table 2). Twenty-seven patients out of 30 achieved the non-HDL-C target in R group (90%). The percentage of patients that achieved the non-HDL-C target was 70% in RF group (21 patients out of 30) and 76.6% in the RN group (23 patients out of 30). The proportion of patients that reached the non-HDL-C target was significantly higher in the R group compared to RF group ($p < 0.05$) but not to RN group. There were significant reductions in plasma levels of TC, LDL-C, and triglycerides in all study groups (Table 2). The reductions of TC and LDL-C levels were significantly greater in the R group (−46 and −59%, respectively) compared with the RF (−34 and −44%, respectively) and RN (−35 and −44%, respectively) groups. A greater proportion of patients in the R group achieved their LDL-C targets (87%) compared to those in RF and RN groups (70 and 83%, respectively). On the contrary, the reduction of triglyceride levels was significantly higher in the RF group (−50%) compared with the R (−33%) and the RN (−31%) group ($p < 0.01$ for both comparisons). In order to compare the overall lipid-lowering efficacy of the regimens tested we used the dual goal of non-HDL-C below 160 mg/dL and triglycerides lower than 150 mg/dL. A greater proportion of patients in the RF group achieved this dual target compared to the R and RN groups (Fig. 1). However, these differences did not reach statistical significance. In all groups smokers had

R rosuvastatin, *RF* rosuvastatin + fenofibrate, *RN* rosuvastatin + n-3 fatty acids, *TC* total cholesterol, *LDL-C* low density lipoprotein cholesterol, *HDL-C* high density lipoprotein cholesterol

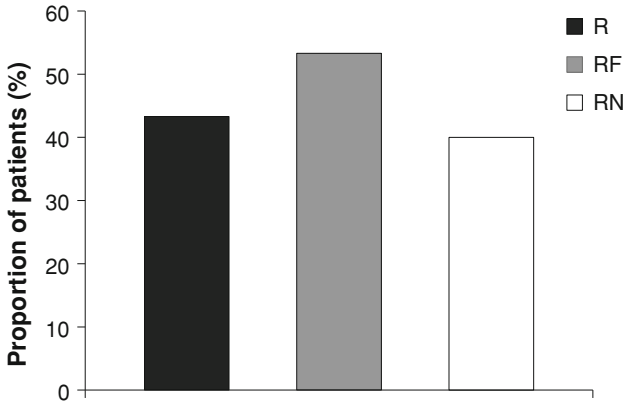

Fig. 1 Proportion of patients that reached the dual target of non-HDL-cholesterol <160 mg/dL and triglycerides <150 mg/dL. *R* rosuvastatin, *RF* rosuvastatin + fenofibrate, *RN* rosuvastatin + n-3 fatty acids

significantly lower HDL-C values compared to non-smokers (data not shown). HDL-C levels were significantly increased at 3 months in the RF group (+8%), while they were non-significantly increased in the R (+4%) and the RN (+4%) group (Table 2). Smoking status did not significantly affect the response of HDL-C levels to the therapeutic interventions (data not shown). After 3 months of treatment a more pronounced increase in ApoA-I levels was observed in the RF and RN groups (+4 and +5%, respectively) compared with changes in the R group (−5%). However this difference did not achieve statistical significance. ApoB levels were significantly reduced in all groups with a greater reduction in R compared with RN group. Serum uric acid levels decreased more in the RF group (−21%) compared with the R group (−9%) and with the RN group (−4%) (Table 2). Finally, serum creatinine significantly increased in the RF group (+12.8%) but it was not significantly altered in the R and RN groups (Table 2). Glucose in all groups was unaltered but insulin levels and HOMA index showed controversial results. HOMA index was significantly reduced in RF (−40%) group but it was increased in the R group (+55%, Table 3). The same results were observed as far as insulin levels were concerned. There were no significant changes in the HOMA index and insulin levels in the RN group.

Safety

Of the 90 patients enrolled 3 (3.3%) dropped out during the study: 1 man and 1 woman in the RF group due to adverse events (myalgia without elevated CK levels) and 1 woman in the RN group due to an asymptomatic abnormal liver function test (AST and ALT elevation >3 times the upper limit of normal). In the patients who completed the study rosuvastatin, fenofibrate and n-3 fatty acids were well tolerated.

Discussion

In this open-label randomized study, we directly compared for the first time high doses of rosuvastatin with low doses of this statin plus fenofibrate or n-3 fatty acids in the treatment of mixed hyperlipidemia. The primary endpoint of the study was the lowering effect of these three different regimens on non-HDL-C. According to NCEP-ATP III the goal for non-HDL in our patients was set to 30 mg/dL higher than the corresponding LDL-C goal [13]. Since no study participant had a history of coronary heart disease or equivalents the non-HDL-C target for virtually all patients was 160 mg/dL. In our study, 3 months of treatment with the above regimens led to a significant reduction in non-HDL-C levels in all study groups. However, this reduction was significantly greater in the rosuvastatin monotherapy group compared with the combination treatment groups. Similar differences were also observed in the LDL-C-decreasing potency of the regimens tested.

Epidemiological studies have shown that LDLs represent the most atherogenic lipoproteins of human plasma and thus the levels of LDL-C should be considered as the primary target of preventive or therapeutic strategies in all individuals [17]. However, the utilization of LDL-cholesterol as a target for therapy in patients with mixed hyperlipidemia has several important limitations. It is well known that LDL-C is commonly determined by the Friedewald equation in specimens from fasting subjects and with triglyceride concentrations lower than 400 mg/dL. However, the equation is considerably inaccurate even at triglyceride concentrations of 200–400 mg/dL [18]. Thus, since mixed dyslipidemia is by definition

characterized by increased concentrations of triglycerides the use of Friedewald equation for the determination of LDL-cholesterol values in this patient population may result in important measurement errors. On the other hand, it is well known that mixed dyslipidemia is characterized by elevated concentrations of potentially atherogenic lipoprotein particles (such as VLDL, IDL and small, dense LDL particles) whose levels are not captured by conventional LDL measurement. As a result, NCEP ATPIII guidelines introduced non-HDL-C values as secondary targets of therapy in all patients with triglyceride values greater than 200 mg/dL [13]. The calculation of this parameter (which represents the sum of the concentrations of all apolipoprotein B-containing particles) overcomes the methodological limitations of LDL-cholesterol determination, does not require fasting specimens and, most importantly, in addition to LDL particles takes into account the concentrations of all apolipoprotein B-containing particles. Numerous studies in populations with different characteristics have shown that non-HDL-C levels represent a precise estimator of future cardiovascular risk whose accuracy may be even greater than that of conventional lipid parameters (such as total or LDL-C) [19, 20]. According to our results monotherapy with high doses of rosuvastatin represents the most plausible option for the treatment of patients with mixed hyperlipidemia since this regimen is more effective in reducing the concentrations of both non-HDL-C and LDL-C compared to combination treatment with low dose of rosuvastatin and either fenofibrate or n-3 fatty acids. Although the number of patients that concomitantly reached the non-HDL-C and TRG targets was (non significantly) greater in the RF group, to our knowledge there is no data suggesting that the achievement of this "dual" goal is clinically more beneficial than the achievement of the non-HDL-C target. Indeed, this marginal difference in the number of patients that reached the dual goal was mainly driven by the greater triglyceride-lowering efficiency of the RF combination; however, it is currently controversial if this higher TG-reducing potency can be translated into clinical benefit [21].

Since the regimens used in our study have never been directly compared in studies with hard clinical endpoints it is not known if the differences observed in the lipid-lowering potency of these drugs are reflective of differences in their ability to reduce the incidence of cardiovascular disease in individuals with mixed hyperlipidemia. In an elegant review Rubenfire et al. [22] summarized the currently available treatment options for individuals with mixed dyslipidemia and proposed a therapeutic algorithm suggesting that the first priority in these patients should be the maximally tolerated effective dose of a potent statin. This approached is based on results from clinical trials showing that the reduction in the incidence of cardiovascular disease is closely related to the dose of statins [23] as well as to the magnitude of LDL-C and non-HDL-C reduction [20, 23]. In addition, although the combination of a statin with a fibrate is pathophysiologically attractive the recently published The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study showed that simvastatin-fenofibrate combination in patients with type 2 diabetes mellitus was not superior to simvastatin monotherapy in terms of cardiovascular risk reduction [24]. Although the study was not powered to assess efficacy on the basis of baseline lipids, there was a borderline significant reduction in major cardiovascular events in persons with a triglyceride level of 204 mg/dL or greater and an HDL cholesterol level of 34 mg/dL or less at baseline. We believe that our results are in line with the strategy proposed by Rubenfire et al. [22]; while awaiting the results of ongoing trials, monotherapy with high doses of potent statins seems to be the best therapeutic option in individuals with mixed dyslipidemia.

Although our study did not have sufficient power to assess differences in safety, our results indicate that the high doses of rosuvastatin as well as the combinations of low doses of this compound with fenofibrate or fish oils are extremely safe and very well tolerated. In agreement with previous studies we noticed a significant increase in serum creatinine levels after fenofibrate administration [25]. However, controversy exists as to whether this phenomenon represents a true deterioration in renal function or an increase in the rate of metabolic production of creatinine. On the other hand, the well-known uricosuric properties of fenofibrate possibly underlie the greater reduction in serum uric acid levels observed in the RF patient group [26]. In agreement with previous studies we found that the high doses of rosuvastatin (40 mg) may adversely affect glucose homeostasis leading to a worsening of insulin resistance indices [6, 27]. Indeed, in our patients rosuvastatin monotherapy resulted in a significant increase in HOMA index values by 55%, mirrored by a correspondent increase in serum insulin levels whereas fasting glucose values remained constant. These results seem to be in contrast with those reported in a recently published meta-analysis showing that statins, as a class, have no effect on insulin sensitivity [28]. However, when individual statins were analyzed separately a non significant trend towards insulin sensitivity deterioration was evident with rosuvastatin [28]. These changes were not of the same magnitude with those observed in our study; however, the differences in patients' selection criteria, in the duration of the study as well as in the dose of the drug may partially explain this discrepancy. The use of the inaccurate HOMA index as an indicator of insulin sensitivity in our study may also have played an important role. In the RN group the levels of HOMA index and insulin remained unaltered. This means either that the

lower doses of rosuvastatin and n-3 fatty acids do not exert any significant effect on carbohydrate metabolism or that the detrimental effect of the low doses of rosuvastatin on peripheral glucose uptake (that so far has been observed only in individuals with insulin resistance) [27] is milder and can be counterbalanced by the corresponding beneficial effect of fish oils [29, 30]. To make things more complicate other studies showed that n-3 fatty acids may exert an adverse effect on insulin sensitivity [31]. Finally, the significant reduction in the values of insulin resistance indices in the RF group can be attributed to the insulin sensitizing properties of the fibric acid derivatives [32]. It must be noted that the differential effects of the various treatments on insulin resistance indices (HOMA-IR and fasting insulin concentration) could have been influenced by the differences in the baseline values of these parameters. Although we tried to avoid this type of error by using ANCOVA and taking into account the baseline values of HOMA-IR and insulin as covariates we cannot fully exclude this possibility. Whether these differences are of potential clinical importance or not remains to be established.

In conclusion, in the present study mixed hyperlipidemic patients without diabetes responded generally well to rosuvastatin alone or in combination with fenofibrate or n-3 fatty acids. High doses of rosuvastatin, small doses of rosuvastatin plus fenofibrate and small doses of rosuvastatin plus n-3 fatty acids decreased significantly non-HDL-C with rosuvastatin monotherapy being more effective in reducing this parameter. On the contrary, the combination of rosuvastatin plus fenofibrate had a more potent effect in reducing triglyceride levels and increasing HDL-C values compared with the other two treatment groups. Larger, prospective clinical trials with a double blind design are needed to delineate whether these differences in biochemical efficiency can be translated into significant differences in clinical efficiency and more specifically in the ability of various regimens to reduce cardiovascular morbidity and mortality in patients with mixed dyslipidemia.

Received: 31 January 2011 / Accepted: 28 February 2011 / Published online: 17 March 2011

Abstract In this study, we investigated whether dietary glucosylceramide (GlcCer) and its metabolite sphingoid bases, sphingosine (SS), phytosphingosine (PS), sphingadienine (SD) and 4-hydroxysphingenine (4HS), influence cornified envelope (CE) formation. CE is formed during terminal differentiation of the epidermis through cross-linking of specific precursor proteins by transglutaminases (TGases), and is essential for the skin's barrier function. Oral administration of GlcCer (0.25 mg/day) for 14 consecutive days dramatically reduced transepidermal water loss, an indicator of the skin barrier condition, in hairless mice with barrier perturbation induced by single-dose ultraviolet B (UVB) irradiation. The GlcCer treatment also increased the level of TGase-1 mRNA in UVB-irradiated murine epidermis approximately 1.6-fold compared with the control. Further, all four sphingoid bases at 1 μM concentration enhanced CE formation of cultured normal human keratinocyte cells. Among them, SS, PS and SD, but not 4HS, stimulated production of involucrin, one of the CE major precursor proteins. SD increased the expression of TGase-1 mRNA, while SS increased the expression of TGase-3 mRNA. These results indicate that the skin barrier improvement induced by oral GlcCer treatment might be at least partly due to a reinforcement of CE formation in the epidermis mediated by sphingoid bases metabolically derived from GlcCer.

SC	Stratum corneum
SD	Sphingadienine
SS	Sphingosine
TEWL	Transepidermal water loss
TGase	Transglutaminase
UVB	Ultraviolet B

Introduction

The skin provides an effective barrier between the organism and the environment, preventing physical, chemical and microbial damage. The barrier function is mainly localized in the stratum corneum (SC), which is formed in the outmost layer of the epidermis, and consists of cornified envelope (CE) and intercellular multilamellar lipids.

The CE forms a highly durable and flexible barrier [1], consisting of a 15-nm thick structure composed of several insoluble proteins, such as involucrin, loricrin, small proline-rich proteins and other proteins, covalently cross-linked by transglutaminases (TGases) [2]. TGases are a family of calcium-dependent acyl-transfer enzymes. Some isozymes, TGase-1, -3 and -5, are expressed mainly in

human skin epidermis, and play roles in CE formation during keratinocyte differentiation [3]. TGase-1 and TGase-5 are present in the spinous and granular layers, and TGase-3 seems to be confined to the upper granular layer [4]. Several studies have shown that TGase-1 has an essential role in CE assembly for skin barrier formation. TGase-1 knockout mice show a phenotype with abnormal CE formation, and die within 4–5 h after birth due to dehydration [5]. TGase-1 function is also required for normal epidermal function in humans. Mutations of TGase-1 have been identified as a cause of lamellar ichthyosis (LI), and result in drastically reduced TGase-1 activity and deficiency of CE in the epidermis of patients with LI [6]. TGase-1 mutations are present in about 50% of autosomal recessive congenital ichthyosis patients [7]. In addition, cathepsin D, an aspartate protease, is involved in the activation of TGase-1 through cleaving the 150-kDa precursor of TGase-1 and producing its active 35-kDa form. Consequently, cathepsin D-deficient mice have a defective skin barrier, with reduced TGase-1 activity and impaired SC morphology [8]. These results suggest that CE formation by TGase-1 is crucial to maintain epidermal tissue homeostasis and a healthy skin surface.

Glucosylceramides (GlcCers), which are structurally constituted of sphingoid bases, long chain fatty acids, and sugar moieties, occur in plants, fungi and animals [9–11]. In animals, GlcCers are essential structural components of mammalian cell membranes and are mostly found at the cell surface; they participate in biological functions such as immunomodulation [12] and insulin resistance [13]. Likewise, GlcCers play vital roles in maintaining the skin barrier function, through their role as intracellular lipids [14]. Recently, it was reported that dietary GlcCer improves the skin barrier function, e.g., improving recovery of SC flexibility and reducing transepidermal water loss (TEWL) in acutely barrier-perturbed mice [15]. Furthermore, oral intake of GlcCer also improves TEWL in healthy human subjects [16]. However, the mechanism of improvement of the skin barrier function by oral GlcCer treatment remains unknown.

In this study, we initially examined the effect of dietary GlcCer, prepared from konjac tuber, on the improvement of skin barrier function and the level of TGase-1 gene expression in hairless mice following barrier perturbation by means of a single UVB exposure. Moreover, because sphingoid bases are generally known to be formed by digestion of GlcCer in the digestive tract [17–19] and are metabolites of ceramide in skin epidermis [20], we also investigated the effects of the four major sphingoid bases of konjac GlcCer on CE formation, TGase-1 and TGase-3 gene expression levels and involucrin production in normal human epidermal keratinocyte cells.

Materials and Methods

Materials

Normal human epidermal keratinocytes (NHEK) were obtained from Kurabo Co. Ltd. (Osaka, Japan). Serum-free keratinocyte growth medium (KGM) containing low calcium (0.06 mM), bovine pituitary extract (BPE) and epidermal growth factor (EGF), insulin, hydrocortisone and antibiotics (gentamycin/amphotericin) were purchased from GIBCO BRL (Montgomery County, USA). GlcCer, derived from konjac tubers, was kindly provided by Unitika Limited (Osaka, Japan). HPLC analysis indicated a purity of greater than 95%. Sphingadienine (SD) and 4-hydroxysphingenine (4HS) were isolated from konjac tubers by Unitika Limited, and the structures of these compounds were confirmed by spectroscopic analysis. Sphingosine (SS) and phytosphingosine (PS) were purchased from Avanti Polar Lipids, Inc. (Alabama, USA).

Animals

The present study was approved by the ethics committee of Shiseido Research Center in accordance with the guideline of the National Institute of Health. Hairless male mice (HR-1) were purchased from Hoshino Laboratory Animals, Inc. (Ibaraki, Japan). Five-week-old HR-1 mice were randomly allocated to two groups ($n = 6$ in each group), adjusted to be the same of weight average, and fed the AIN-93G (Oriental Yeast, Tokyo, Japan) rodent diet. GlcCer was prepared as an aqueous suspension in 1% tragacanth gum and was administered orally at 0.25 mg/day to each mouse in the dietary GlcCer group. The control group received an aqueous suspension in 1% tragacanth gum. After 2 weeks, each mouse was irradiated with a single dose of UVB (150 mJ/cm^2). TEWL was measured daily up to day 11 with a Tewameter (Courage + Khazaka, Cologne, Germany) to characterize the skin barrier function. In parallel, dorsal skin samples were obtained from each mouse at various time periods after UVB irradiation.

Cell Culture

NHEK were seeded at a density of 3–5 $\times$ 10^4 cells/cm^2 in 75-cm^2 cell culture flasks, and cultured in KGM with medium changes every other day at 37 °C under a 5% CO_2 atmosphere. Third passage cells were used for the experiments. Tested sphingoid bases were dissolved in ethanol and diluted with medium to obtain the appropriate concentrations, and the final volume of ethanol was adjusted to 0.05% (v/v). In some experiments, NHEK were cultured in KDM (KGM without BPE).

TGase-1 mRNA Expression Level in UVB-irradiated Mouse Skin

RNA was isolated from mouse skin epidermis as previously described [21]. Dorsal skin samples were obtained and the epidermis was separated from the dermis by heating. Epidermal sheets were placed in 1 ml of Isogen reagent (Nippon Gene, Toyama, Japan) and total RNA was isolated as recommended by the manufacturer. Total RNA was purified using a RNeasy® Mini Kit (Qiagen, California, USA) according to the instructions of the manufacturer. The total RNAs obtained (4 g) were used to produce cDNA and PCR using a LightCycler® TaqMan® Master kit (Roche Applied Science, Indianapolis, USA), following the manufacturer's protocols. The synthesized cDNAs were PCR-amplified with TGase-1 specific primer (Sigma-Aldrich Inc, Missouri, USA) and β-actin primer (Sigma-Aldrich Inc, Missouri, USA) as the internal control. Fluorograms are shown after 65 cycles of PCR for TGase-1 and β-actin. The sequences of the primer pairs, 5′ and 3′, were as follows. TGase-1: gtggtgccatcaccaaca and tccggtg acggtgttgta; β-actin: aaggccaaccgtgaaaagat and gtggtac gaccagaggcatac.

CE Formation Assay

CE content in NHEK cultures was determined as previously described [22]. NHEK suspended in KGM were seeded at 1.5×10^5 cells/well into 6-well plates and grown to confluence for 3 days. After confluence, NHEK were treated with test compounds for 8 days with medium changes every other day in KGM, then harvested with cell scrapers and homogenized in 2% sodium dodecylsulfate (SDS). After microcentrifugation at 12,000 rpm for 15 min, the obtained precipitates were boiled in 2% SDS and 20 mM dithiothreitol (DTT) for 1 h. Then, the amounts of soluble cross-linked envelopes were evaluated by measuring the absorbance (OD at 310 nm).

Involucrin Production Enhancement Assay

The amount of involucrin production in NHEK cultures was determined as previously described [22]. NHEK suspended in KGM were seeded at 7.5×10^4 cells/well into 12-well plates and grown to confluence for 3 days. The cultures were washed two times with KDM, grown in KDM for 1 day, and treated with test compounds for 4 days in KDM. After 4 days, cells were harvested and homogenized in 1 ml of TE buffer containing 10 mM Trs–HCl and 1 mM EDTA. After microcentrifugation at 12,000 rpm for 15 min, supernatants were collected and stored frozen at −80 °C until use. Supernatants were analyzed for protein production using an enzyme-linked immunosorbent assay (ELISA) kit (Biomedical Technologies Inc., Massachusetts, USA).

TGase-1 and -3 mRNA Expression Levels in Cultured NHEK Cells

NHEK suspended in KGM were seeded at 7.5×10^4 cells/well into 12-well plates and grown to confluence for 3 days. The cultures were washed two times with KDM, grown in KDM for 1 day, and treated with test compounds for 72 h in KDM. After treatment, cells were harvested and homogenized in lysis buffer. Total RNAs were extracted from harvested keratinocytes using a RNeasy® Mini Kit, according to the manufacturer's protocol. The total RNAs obtained (10 μg) were used for cDNA production with a LightCycler® TaqMan® Master Kit, following the manufacturer's protocols. The cDNAs were PCR-amplified with TGase-1 and -3 specific primers and β-actin primer as the internal control. Fluorograms are shown after 45 cycles of PCR for TGase-1 and -3 and β-actin. The sequences of the primer pairs, 5′ and 3′, were as follows. TGase-1: ccccaa gagactagcagtgg and agaccaggccattcttgatg; TGase-3: cagag gaagggcgaaacat and tctgtgtgatgcgcttgtc; β-actin: ccaacc gcgagaagatga and ccagaggcgtacagggatag.

Statistical Analysis

All data were expressed as the mean ± SD. Statistical significance of two-group comparisons was determined with Student's t test, while for multiple-group comparisons, we used Dunnett's multiple test or Steel's multiple test after Bartlett's multiple test, compared to a control group. Differences were considered significant at $P < 0.05$.

Results

Effect of Dietary GlcCer on Improvement of TEWL and TGase-1 mRNA Expression in HR-1 Mice with Barrier Perturbation Produced by a Single UVB Irradiation

A single dose of UVB irradiation perturbs the skin barrier in hairless mice, causing an increase in TEWL, which peaks at 2–4 days, and a simultaneous decrease in TGase-1 mRNA expression [23]. Here, we examined the effects of dietary GlcCer on the skin barrier improvement following damage caused by exposure to 150 mJ/cm^2 UVB irradiation. In control mice without oral GlcCer treatment, the TEWL dramatically increased within 3–4 days after irradiation, while the increase of TEWL of the oral GlcCer treatment mice group was significantly suppressed at 3–4 days, compared with the control group (Fig. 1).

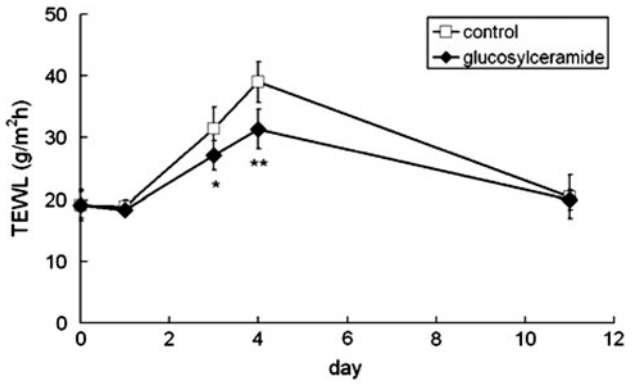

Fig. 1 Ameliorating effect of dietary GlcCer on the increase of TEWL in HR-1 mouse skin exposed to a single dose of UVB irradiation. HR-1 mice were fed either a control diet (without GlcCer) or a diet containing GlcCer for 2 weeks. Following a single UVB irradiation (150 mJ/cm^2), TEWL was measured up to day 11 in both groups. All data are expressed as means ± SD ($n = 6$). *$p < 0.05$ and **$p < 0.01$ compared with the control

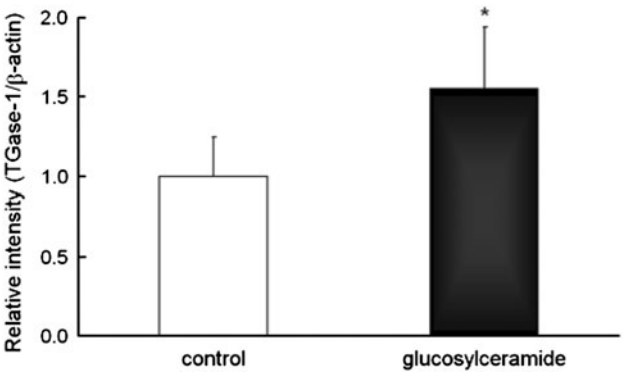

Fig. 2 Stimulatory effect of dietary GlcCer on TGase-1 mRNA expression in HR-1 mouse skin epidermis exposed to a single dose of UVB irradiation. HR-1 mice were fed either a control diet (without GlcCer) or a diet containing GlcCer for 2 weeks. Following a single UVB irradiation (150 mJ/cm^2), TGase-1 mRNA expression in the epidermis was analyzed by means of RT-PCR at day 3 in both groups. All data are expressed as means ± SD ($n = 5$). *$p < 0.05$ compared with the control

Finally, TEWL recovered completely in both the control group and oral GlcCer treatment group by day 11 (Fig. 1). Next, we determined the effect of dietary GlcCer on the decrease in expression of TGase-1 mRNA in epidermis of UVB-irradiated mice by means of RT-PCR. The oral GlcCer treatment group showed a significant increase in the level of TGase-1 mRNA expression in the epidermis on day 3, compared to the control group without GlcCer treatment (Fig. 2), and this coincided with the GlcCer-induced improvement of TEWL (Fig. 1).

Enhancement of CE Formation by Sphingoid Bases in Cultured NHEK Cells

It has been reported that ingested ceramide is metabolized to sphingoid bases, which are distributed into skin epidermis in mice [20]. Therefore, we investigated the effects of four sphingoid bases, which are metabolites of konjac GlcCer used in this study [24], on CE formation in cultured NHEK cells. NHEK cells were incubated in the presence or absence of each sphingoid base for 8 days, and CE formation was measured as described in Section Materials and Methods. As indicated in Fig. 3a, each sphingoid base enhanced CE formation at the concentration of 1 μM.

Increase of Involucrin Production by Sphingoid Bases in Cultured NHEK Cells

To determine whether the enhancement of CE formation by the four sphingoid bases is associated with increased production of CE precursors, the effects of the sphingoid bases on involucrin production were examined. Involucrin, a major early marker for terminal differentiation, is an important scaffold protein of CE, and is synthesized in the upper spinous layers of the epidermis [25]. Partly, involucrin forms ester-linkages with ω-hydroxyceramides at the outmost face of CE, catalyzed by TGase-1, and thus contributes to the barrier function of the epidermis [26]. As shown in Fig. 3b, in comparison with the control, involucrin production was increased by SS, PS or SD treatment of cultured NHEK cells at the concentration of 1 or 5 μM. In contrast, 4HS did not show any significant effect on involucrin production, even at 5 μM (data not shown).

Increase of TGase-1 and - 3 mRNA Expressions by Sphingoid Bases in Cultured NHEK Cells

Next, we examined whether the enhancement of CE formation by the four sphingoid bases was associated with an increase in gene expression of specific TGase isoforms, TGase-1 and -3, in cultured NHEK cells by means of RT-PCR. SD at 5 μM increased the TGase-1 mRNA level during 72 h incubation (Fig. 3c). In addition, SS increased the TGase-3 mRNA level at the same concentration (Fig. 3d).

Discussion

UVB irradiation causes a decline in the skin barrier function via down-regulation of TGase-1 gene [23], biophysical changes in the SC lipids [27], and perturbation of tight junction (TJ) function [28]. Further, TGase-1 is down-regulated in skin reconstructed in vitro after UVB exposure, and the expression levels of precursors of CE formation were also altered [29]. In UVB-exposed human skin, TGase-1 and involucrin expression levels were found

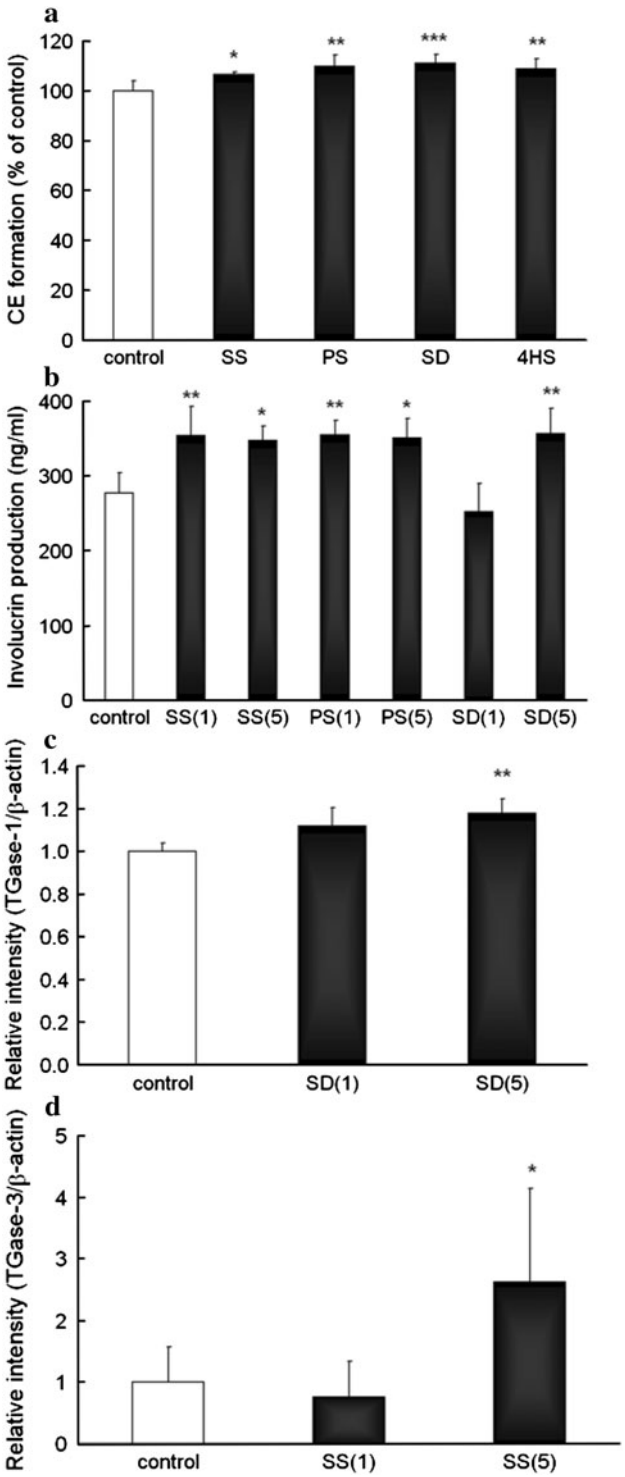

Fig. 3 Enhancing effects of sphingoid bases on CE formation via stimulation of TGase-1 and -3 gene expressions and involucrin production in cultured normal human epidermal keratinocyte cells. **a** Effects of sphingoid bases on CE formation. Normal human keratinocytes were treated with each sphingoid base (1 μM) in medium containing 0.06 mM Ca^{2+}. The cells were harvested 8 days thereafter and CE was assayed by means of spectrophotometry, measuring OD at 310 nm. **b** Effects of sphingoid bases on involucrin production. Normal human keratinocytes were treated with each sphingoid base (1 or 5 μM) in medium containing 0.06 mM Ca^{2+}. The cells were harvested after 96 h and involucrin levels were measured by means of ELISA. **c**, **d** Effects of sphingoid bases on the expression of TGase-1 and TGase-3 mRNAs. Normal human keratinocytes were treated with each sphingoid base (1 or 5 μM) in medium containing 0.06 mM Ca^{2+}. The cells were harvested after 72 h and TGase-1 (**c**) and TGase-3 (**d**) mRNA levels were measured by means of RT-PCR. All data are expressed as means ± SD ($n = 4$ or 6). $*p < 0.05$, $**p < 0.01$ and $***p < 0.001$ compared with the control

to decrease in histological and immunohistochemical studies [30]. Here, we used a single UVB-irradiated murine skin model to examine the effect of dietary GlcCer on skin barrier improvement and on the change of TGase-1 gene expression. We found that dietary GlcCer significantly suppressed the increase of TEWL and concomitantly stimulated the expression of TGase-1 mRNA in murine epidermis following UVB-induced barrier perturbation. These results suggested that one of the mechanisms of skin barrier improvement by dietary GlcCer is a reinforcement of CE formation mediated by increased TGase-1 gene expression in the epidermis. Further, the four sphingoid bases, SS, PS, SD and 4HS, which are metabolites of dietary konjac GlcCer [24], stimulated CE formation in cultured epidermal keratinocyte cells, and some of them significantly increased enhanced TGase-1 and TGase-3 mRNA expressions and involucrin production. Further, it is suggested that SD may participate in the enhancement effect of dietary GlcCer on TGase-1 gene expression, because SD stimulates TGase-1 mRNA expression in cultured epidermal keratinocyte cells, and accounts for about 40% of the total sphingoid bases constituting konjac GlcCer used this study [24]. However, further studies, such as investigation of the effect of oral SD treatment on TGase-1 gene expression in vivo, will be needed to confirm this. TGase-1 is known to catalyze the formation of ester bonds between specific glutaminyl residues of involucrin, localized the outmost face of CE and epidermal-specific ω-hydroxyceramides, forming the so-called corneocyte lipid envelope (CLE), and thus contributes to mature lamellar membrane formation in the SC and to skin barrier homeostasis [26, 31, 32]. Because UVB irradiation induces decreased levels of covalently bound ceramides in murine SC [23], and the tested sphingoid bases stimulated TGase-1 gene expression and involucrin production in cultured epidermal keratinocyte cells, it is possible that dietary GlcCer also contributes to changes in the levels of covalently bound ceramides in the SC.

Membrane-bound TGase-1 and cytosolic TGase-3 have proven themselves to play important roles in CE assembly during terminal differentiation of epidermal keratinocytes. TGase-1 is anchored on the inner surface of the plasma membrane, while TGase-3 is soluble and is localized in the

cytoplasm. Involucrin is cross-linked by TGase-1 in the presence of the plasma membrane as an early event [1, 2]. Some precursors, such as loricrin, are oligomerized by TGase-3 in cytosol, and then polymerized by TGase-1 to reinforce the insoluble structure of keratinocytes [33]. It is interesting that different sphingoid bases showed differential effects on TGase-1 and TGase-3 gene expressions. This suggests the existence of regulation at a specific transcriptional level, such as the activating protein 1 (AP-1) complex, which is involved in transcriptional regulation of epidermal genes, including TGase-1, TGase-3, involucrin and loricrin genes, during keratinocyte differentiation [34]. Although TGase-3 mRNA represents less than 2% of all TGase transcripts, the activated TGase-3 accounts for up to 75% of the total TGase activity in mammalian epidermis [35]. TGase activity in the SC also mediates the maturation of CE, and serves to maintain the water content in the SC, which has implications for the improvement of dry skin [36].

In conclusion, we have examined the mechanism of the skin barrier improvement induced by dietary GlcCer, and have shown that its metabolite sphingoid bases enhance CE formation via increased expression of TGase mRNAs and increased involucrin production in epidermis. These findings indicate that dietary GlcCer can play an important role in preserving a healthy skin barrier condition or in promoting recovery from skin barrier impairment, by enhancing CE formation. This information should help in the development of effective skin care through dietary supplements, i.e., internal skin care.

Abstract The purpose of this study was to determine the levels of *trans*-octadecenoic acid (C18:1-*trans*) and *trans*-isomers of linoleic acid (18:2-*trans*), as well as long-chain polyunsaturated fatty acids (LC-PUFA), in the plasma from infants of adolescent mothers at 3 months of age, exclusively breastfed, and the relationship with the levels of the same isomers in plasma and milk of the mothers. Samples of blood and mature milk were obtained from 49 healthy adolescent mothers and their exclusively breastfed infants treated at the Instituto Fernandes Figueira-Fundação Oswaldo Cruz (IFF-FIOCRUZ) in Rio de Janeiro, Brazil. *trans*-Fatty acids (TFA) were analyzed by gas chromatography. The results of this study showed low levels of TFA in milk (1.53%), maternal plasma (0.50%), and plasma of infants (0.74%). The results show that, although TFA have been found in the plasma of the studied infants, the LC-PUFA levels are kept within normal limits. No association between TFA presence and parameters of nutritional status of the infants was observed, probably due to the low levels of these fatty acids found in this study.

Introduction

The importance of essential fatty acids (EFA), linoleic acid (n-6, LNA) and alpha-linolenic acid (n-3, ALA), in infant development has led to several studies about FA in women during pregnancy and lactation [1–7] because the supply of EFA to the infant depends almost exclusively on breast milk, which is the main source of long chain

polyunsaturated fatty acids (LC-PUFA). LC-PUFA are essential for normal development of neuronal tissue. Of the total lipid content in the brain, 60–65% are polyunsaturated fatty acids (PUFA), of which >85% are docosahexaenoic acid (DHA; 35–40%) and arachidonic acid (ARA; 40–50%) [8]. These fatty acids (FA) act as regulators of various cellular functions and are constituents of membranes, in addition to playing the role of ligands and nuclear transcription factors as substrates in the synthesis of prostanoids (prostaglandins and thromboxane) [9–11], especially during the first 6 months of life [12].

In recent years, investigations on the nutritional and biological control of *trans*-fatty acids (TFA) have grown extensively due to the realization of the importance of lipids on growth and infant development [13]. TFA are unsaturated FA with at least one double bond in the *trans* configuration. The maternal TFA can be transferred to the child through breastfeeding. The content of TFA in human milk is variable, reflecting maternal dietary intake [14, 15].

These FA compete with the n-6 (LNA and ARA) and n-3 (ALA and DHA) series in the reactions of desaturation and elongation of the chain, resulting in the formation of eicosanoids without biological activity, and can inhibit the enzymes, delta-6 and delta-5 desaturase, the blocking the metabolism of EFA [16, 17].

The dietary lipids reflect their composition in the plasma. They have a prominent role in infant growth and development, and when consumed by the mother, may be transferred to the infant in breast milk. For these reasons and because of the scarcity of research with adolescent mothers, specifically assessing levels of infant plasma TFA, this study aimed to investigate the relationship between the proportions of these FA in maternal plasma and mature milk and between the levels of those FA in plasma from the infants.

Methods

Forty-nine healthy young mothers between 15 and 19 years of age who were breastfeeding their infants who were being treated at the Instituto Fernandes Figueira (IFF), an agency of the Oswaldo Cruz Foundation (FIOCRUZ) located in Rio de Janeiro (RJ), Brazil, were selected for this study. All the adolescents and their parents gave written informed consent prior to the beginning of the research. The study was approved by the Ethics in Research Committee of the Instituto Fernandes Figueira.

Data from maternal dietary intake were obtained by two methods: qualitative food frequency questionnaire, which evaluated the number of times in the frequency category in which food or food group was consumed [18]; and the 24-h recall. Data from the food records were tabulated in Software NutWin®-Nutrition Support Program, version 1.5 [19]. We included information on the nutritional composition of food sources of TFA, obtained from the Brazilian Table of Food Composition [20].

Information on maternal food consumption and the collection of maternal blood and blood from the infants and mature milk were obtained in the third month postpartum. Anthropometric measurements of weight, length, and head circumference were obtained in the third month postpartum according to the recommendations of the Brazilian Ministry of Health [21].

The weights of unclothed infants (in grams) were recorded on calibrated digital-type scales (Filizola) with a sensitivity of 10 g. The length (expressed in centimeters) was measured with the baby supine using a wooden stadiometer from the crown to the heel. The head circumference (expressed in cm) was obtained using a tape measure positioned in the region of the supra-orbital ridges and the largest frontooccipital diameter. The nutritional status of infants was performed by the index weight for age and height for age. The criteria for classification were those recommended by the World Health Organization [22] and Brazil [23].

The anthropometric characteristics of maternal weight and height were measured according to the recommendations of the Brazilian Ministry of Health [24]. Teenage girls were measured while barefoot without excess clothing. Weight was obtained with a platform-type scale (Filizola) with 100-g subdivisions and a maximum load of 150 kg. The scale for measuring the height was fixed to the balance on a vertical shaft, with 0.5-cm subdivisions and an extension range of 95–195 cm.

Nutritional status was assessed by maternal body mass index for age (BMI/A) and the cutoff points established in *z* scores for adolescents, according to the recommendations of the World Heath Organization [25, 26] and adapted for Brazil [23].

Collection and Storage of Samples of Mature Milk, Maternal Blood, and Infant Blood

The milk samples from nursing mothers (1 mL) in the third month postpartum, were obtained by manual expression of the breast that had not been sucked in the last feeding in the morning. The blood of mothers and infants (about 2 mL) was collected in the morning 2–3 h after a feeding (between 8 and 10 a.m.) by venipuncture in tubes containing 1 g Na_2-EDTA/L. The nursing mothers had fasted overnight for approximately 12 h. Plasma was immediately separated by centrifugation (3,000*g* for 15 min) in the Laboratory of Hematology of the IFF/FIOCRUZ, stored in Eppendorf tubes, and properly identified.

All samples were stored in a freezer at −20 °C, then transported on ice to the Laboratory of Nutritional

Biochemistry of the Institute of Nutrition Josué de Castro/Federal University of Rio de Janeiro–LBNINJC/UFRJ, where they remained stored at −70 °C until the separation of lipids and relative quantification of FA.

Analysis of FA

Lipids in the plasma and milk samples were extracted and purified in a chloroform:methanol (2:1) [27] solution. Total lipid extracts were saponified and the fatty acids methylated following the method of Lepage and Roy [28], which determines treatment with 2 ml methanol:toluene 4:1 (v/v) solution and 200 µl of acetyl chloride added in the cold. The mixtures were subjected to methanolysis at 80 °C over a period of 2.5 h. Fatty acid methyl esters were separated and quantified on a Perkin Elmer Autosystem XL chromatograph equipped with a hydrogen flame ionization detector and the software Turbochrom. The fatty acids were separated on a 100 × 0.25 mm × 0.20 µm capillary column SP 2560 (biscyanopropyl-polysiloxane, 100 m × 0.25 mm ID, 0.20 µm film thickness; Supelco, Bellefonte, PA, USA, Supelco, USA). Hydrogen was used as the carrier gas at a pressure of 28 psi. Fatty acid methyl esters were identified by comparison of their retention times with authentic standards (Nu-Chek-Prep, Inc., Elysian, MN, USA, and Supelco, Inc., Bellefonte, PA, USA) and the relative levels of individual fatty acids were calculated as a percentage of all detected fatty acids with a chain length of 04–24 carbon atoms. The final results were expressed as free fatty acids, whereas the analytical data were expressed as FAME. Therefore, according to Craske e Bannon [29], the quantification of the relative levels of the free fatty acids required the use of theoretical correction factors—based on weight percent content of "active" carbon—due to the differences in the hydrogen flame ionization detector response. The theoretical correction factors calculated in the present study were 1.00068 (C18:1 *trans*), 1.00000 (C18:2 *trans*), 1.00000 (C18:2n6 (LNA) (ALA), 0.99315 (C18:3n3 ALA) 0.97341 (AA), 0.96725 (EPA), e 0.95167 (DHA).

Statistical Analysis

Data analysis was carried out using the Statistical Package Program for Social Sciences (version 15.0 for Windows; SPSS Inc., Chicago, USA). To determine the correlation between the study variables, the Spearman correlation coefficient was used. The differences between the concentrations of FA in mature milk, and maternal and infant plasma lipids were then compared using the Kruskal–Wallis test. A P value <0.05 was considered statistically significant. Results are presented as means and the standard errors of the means.

Results

Most women (63.3%) had a BMI/A within the normal range. Regarding the nutritional status of infants, relative to the weight/age and length/age, 86 and 90% had weight and length appropriate to age, respectively (Table 1).

According to the qualitative food frequency questionnaires answered by all of the mothers interviewed, the majority of teens (80%) reported consumption of fish less than once a month. Soybean oil was consumed daily by all nursing mothers in food preparation. Processed foods, sources of TFA consumed regularly, i.e., at least once per week, included cream cracker biscuits (60%), bread (65%), sweet bread (30%), sandwich cookies (65%), sweet biscuits (49%), cakes (26%), snacks (42%), creamy ice cream (33%), ice cream (42%), creamy candy (46%), instant noodles (37%), chocolate (46%), and margarine (83%).

According to the 24-h recall questionnaires conducted with the mothers, the intake of fat contributed to approximately 25% of the total daily energy intake of lactating women. The average daily maternal intake of FA was 3.11 ± 0.55 g of C18:1 TFA, 0.19 ± 0.05 g of C18:2 TFA, 8.90 ± 0.51% saturated fatty acids (SFA), 8.82 ± 0.41% of monounsaturated fatty acids (MUFA), 4.13 ± 0.34% of PUFA, 0.46 ± 0.09% of ALA, 3.46 ± 0.32% of LNA, 0.08 ± 0.02% ARA, 0.03 ± 0.02% DHA, and the ratio of LNA: ALA was 9.58 ± 0.74% (data not shown).

Table 1 General characteristics of mothers and infants studied ($n = 49$) in Rio de Janeiro, 2005–2008

Variables	*n*	%
Maternal age (years)		
15	12	24.5
16	09	18.4
17	15	30.6
18	06	12.2
19	07	14.3
Maternal nutritional status (BMI/A)		
Surveillance for low BMI/A	05	10.2
Appropriate BMI/A	31	63.3
Surveillance for BMI/A high	07	14.3
Overweight	06	12.2
Nutritional status of infants (weight/age)		
Surveillance for low weight for age	04	8.2
Appropriate weight for age	42	86.0
Surveillance for high weight for age	03	6.0
Nutritional status of infants (length/age)		
Low length for age	05	10.0
Appropriate length for age	44	90.0

BMI/A Body mass index for age

There was no association between the level of TFA in maternal plasma to nutritional status ($P = 0.61$) or between the concentrations of TFA in the plasma of infants with their nutritional status (weight/age; $P = 0.90$) and (length/age; $P = 0.46$) (data not shown).

Chromatographic analysis showed that C18:1 TFA accounted for $1.53 \pm 0.22\%$, $0.50 \pm 0.04\%$, and $0.74 \pm 0.16\%$ of FA in mature milk, maternal plasma, and infant plasma, respectively (Table 2).

C18:1 TFA and ALA levels were higher in mature milk than in maternal and infant plasma. Furthermore, the level of C18:2 TFA, LNA, ARA, EPA, and DHA was lower in mature milk than in maternal and infant plasma. C18:2 TFA and DHA levels were lower and the LNA level was higher in the maternal plasma than in infant plasma (Table 2).

As shown in Table 3, there was a negative correlation between the proportion of C18:1 TFA and the proportion of LNA in mature milk ($r = -0.44$, $P = 0.001$) and a positive correlation between the proportion of C18:1 TFA in mature milk and the proportion of FA in maternal plasma lipids ($r = 0.34$, $P = 0.016$). There was negative correlation between the proportion of ARA in the mature milk and the proportion of LNA in infant plasma lipids ($r = -0.43$, $P = 0.002$) and between the proportion of EPA in mature milk and the proportion of ARA ($r = -0$, 45, $P < 0.001$) and LNA in infant plasma lipids ($r = -0.51$, $P < 0.001$). A negative correlation was demonstrated between the proportion of C18:1 TFA and the proportion of LNA in infant plasma lipids ($r = -0.33$, $P = 0.020$) and a positive correlation was demonstrated between the proportion of LNA and the proportion of ARA in infant plasma lipids ($r = 0.45$, $P = 0.001$) and between the proportion of EPA and the proportion of ALA ($r = 0.77$, $P < 0.001$) in infant plasma lipids ($r = 0.45$, $P < 0.001$). Finally, a negative correlation was observed between the proportion of C18:1 TFA and the proportion of LNA in maternal blood lipids ($r = -0.58$, $P < 0.001$) and a positive correlation between the proportion of EPA and DHA ratio in maternal plasma lipids ($r = 0.51$, $P < 0.001$).

Discussion

The first important observation derived from this study is that TFA was found in plasma of infants exclusively breastfed, confirming the transfer of this kind of fat through breast milk [14, 15], although in smaller proportion to those found in milk, and suggests that like the placenta [30], the mammary gland must provide some degree of discrimination against these FA.

The concern about children's exposure to TFA is based on the negative effects of these FA on child growth and development [31] and the potential negative effects on the metabolism of EFA through inhibition of desaturation of LNA ARA and ALA to DHA [32, 33].

As the TFA derived from partially hydrogenated fats are not synthesized in the mother, it is believed that the TFA of milk and maternal blood come from dietary intake [14, 15]. Experimental studies with rats confirm a direct dose–response relationship between the intake of TFA and the incorporation of these in breast milk, but transferred to the pups through lactation, appear in the plasma [15].

References have been found in literature suggesting that the quality, not the quantity, of the lipid source in the mother's diet impacts the quality of the fatty acids in human milk [34, 35]. The present study showed low levels of TFA in milk and plasma of nursing mothers and infants, probably due to a lower proportion of TFA in processed products due to the current standards of the National Agency for Sanitary Surveillance (ANVISA) [36], which contains the mandatory declaration of TFA content on food

Table 2 Composition of free fatty acids (FAA%) of total lipids in samples of mature milk and plasma of nursing mothers and infants

Fatty acids	Mature milk FAA (area %)[a]	Maternal plasma FAA (area %)[a]	Infants plasma FAA (area %)[a]
C18:1 TFA	1.51 (0.22)	0.50 (0.04)[b]	0.70 (0.01)[b]
C18:2 TFA	0.08 (0.01)	0.40 (0.07)[b]	0.80 (0.02)[b,c]
C18:2n-6 (LNA)	19.80 (0.70)	37.0 (0.81)[b]	27.0 (1.0)[b,c]
C18:3n-3 (ALA)	0.49 (0.04)	0.11 (0.02)[b]	0.19 (0.14)[b]
C20:4n-6 (ARA)	0.38 (0.03)	4.08 (0.26)[b]	4.47 (0.3)[b]
C20:5n-3 (EPA)	0.02 (0.01)	0.49 (0.05)[b]	0.34 (0.09)[b]
C22:6n-3 (DHA)	0.161 (0.03)	0.57 (0.05)[b]	1.42 (0.3)[b,c]

Rio de Janeiro, 2005–2008 ($n = 49$). All values are means and standard errors of the means in parentheses

LNA, linoleic acid, *ALA*, alpha-linolenic acid, *ARA*, arachidonic acid, *EPA*, eicosapentaenoic acid, *DHA*, docosahexaenoic acid

[a] Corrected by a theoretical correction factor from FAME to FFA (see "Methods" section)

[b] Significantly different from the respective value in mature milk, $P < 0.05$ (Kruskal–Wallis)

[c] Significantly different from the respective value in maternal plasma, $P < 0.05$ (Kruskal–Wallis)

Table 3 Correlation between the proportions of FA in mature milk lipids, maternal plasma lipids, and infant plasma lipids

Variables		*r*	*P*
Mature milk lipids	Mature milk lipids		
C18:1 TFA	LNA	−0.44	0.001
Mature milk lipids	Maternal plasma lipids		
C18:1 TFA	C18:1 TFA	0.34	0.016
Mature milk lipids	Infants plasma lipids		
ARA	LNA	−0.43	0.002
EPA	ARA	−0.45	<0.001
EPA	LNA	−0.51	<0.001

labels, allowing the consumer to know which foods contain this type of fat and in what quantities, which caused many companies to formulate their products with lower levels of TFA.

It is known that the content of TFA consumed by a population is directly related to feeding patterns [37, 38]. Recent studies in Spanish prepubertal obese children have shown low plasma percentages of *trans*-fatty acids, confirming that the TFA intake in southern Spain is actually very low [39]. In the present study, the average intake of total TFA to adolescent mothers investigated was equal to 3.19 g, corresponding to approximately 1.4% of the total daily energy, exceeding slightly the maximum recommended intake (1% of total daily energy) [40]. However, the relative percentage of the total daily energy of this FA to the adolescent mothers being investigated, is still lower than that among non-pregnant adolescents living in the US (2.8%) and Costa Rica (4.35%) [41]. Therefore, another factor that may have contributed to this result is a possible change in the dietary habits of the mothers in this physiological period. In fact, this study showed that the majority of mothers reported not consuming many of these manufactured products.

In this study we observed significant correlations among the levels of TFA. The content of C18:1 TFA in milk correlated with the values of the same FA found in lipids of maternal plasma, indicating therefore that the fat in the diet can be incorporated into human fluids such as plasma and milk [42]. There was also an inverse correlation between the content of C18:1 TFA and content of LNA in mature milk. A similar inverse correlation between TFA and LNA in milk had been previously reported [43, 44]. With regard to maternal plasma lipids, there was a negative correlation between the proportion of C18:1 TFA and the proportion of LNA. One explanation for this fact is that mothers with a higher intake of foods containing TFA tend to consume less food containing LNA [43] or that the increase of TFA may occur at the expense of EFA, as foods with large amounts of TFA usually contain less EFA [44]. Moreover, a negative correlation was observed between the proportion of C18:1 TFA and the proportion of LNA in plasma lipids of infants.

From what has been stated above, one can see that the maternal consumption of TFA is a factor that influences the state of EFA. However, we found no associations between TFA with parameters of maternal nutritional status or infants, probably due to low levels of this FA found in this study.

Finally, we observed several significant correlations between several different FA in biological fluids. We observed a negative correlation between the proportion of ARA in the mature milk and the proportion of LNA in infant plasma lipids. This finding suggests the action of specific enzymes acting on the active conversion of LNA to ARA in plasma from infants, a nutrient essential for development at the expense of decreased ARA in milk.

Another negative correlation was observed between the proportion of EPA in mature milk and the proportion of ARA and LNA in plasma lipids of infants. The negative association between the FA of series *n*-3 and *n*-6 series was expected since there is competition between them for the metabolic pathways of elongation and desaturation, since they share the same enzymatic systems [45, 46].

There were also positive correlations between the proportion of LNA and the proportion of ARA in plasma lipids of infants between the proportion of EPA and the proportion of ALA also in the infant plasma lipids and between the proportion of EPA and DHA proportions of lipids in maternal plasma. This finding may be explained by the sharing of the enzymes, delta-6 desaturase and delta-5 fatty acid desaturase, as mentioned above [46] favoring its conversion or retro-conversion.

An interesting fact is that this is the first study in Brazil with adolescent mothers showing levels of TFA and PUFA in infant plasma. Note that the plasma levels of these FA in infants are similar to those in maternal plasma and milk, suggesting differences in the selective transfer of FA in preference to those that are of vital importance for growth and development as is the case of ARA and DHA showed higher levels (ARA, 4.65%; DHA, 1.52%) in infant plasma when compared with maternal plasma (ARA, 4.23%; DHA, 0 59%) and milk (ARA, 0.42%; DHA, 0.17%).

In conclusion, the results show that, although TFA have been found in the plasma of the studied infants, the LC-PUFA levels remain within normal limits. No association between TFA presence and parameters of nutritional status of the infants was observed, probably due to the low levels of these fatty acids found in this study. On the other hand, such an association may occur with higher *trans* levels, and this may be extremely relevant, once the use of hydrogenated or non-hydrogenated fats in foods can vary according to the processing costs involved and depends on the current availability of these ingredients in the country.

Acknowledgments The authors thank all the adolescent mothers who participated in this study. The present work was in part supported by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq)–Brazil and Fundação de Amparo a Pesquisa do Rio de Janeiro (FAPERJ), Brasil.

METHODS

The Development of Flow-through Bio-Catalyst Microreactors from Silica Micro Structured Fibers for Lipid Transformations

Sabiqah Tuan Anuar · Carla Villegas · Samuel M. Mugo · Jonathan M. Curtis

Received: 10 August 2010 / Accepted: 22 December 2010 / Published online: 13 February 2011

Abstract This study demonstrates the utility of a flow-through enzyme immobilized silica microreactor for lipid transformations. A silica micro structured fiber (MSF) consisting of 168 channels of internal diameter 4–5 μm provided a large surface area for the covalent immobilization of *Candida antartica* lipase. The specific activity of the immobilized lipase was determined by hydrolysis of *p*-nitrophenyl butyrate and calculated to be 0.81 U/mg. The catalytic performance of the lipase microreactor was demonstrated by the efficient ethanolysis of canola oil. The parameters affecting the performance of the MSF microreactor, including temperature and reaction flow rate, were investigated. Characterization of the lipid products exiting the microreactor was performed by non-aqueous reversed-phased liquid chromatography (NARP-LC) with evaporative light scattering detector (ELSD) and by comprehensive two-dimensional gas chromatography (GC × GC). Under optimized conditions of 1 μL/min flow rate of 5 mg/mL trioleoylglycerol (TO) in ethanol and 50 °C reaction temperature, 2-monooleoylglycerol was the main product at >90% reaction yield. The regioselectivity of the *Candida antartica* lipase immobilized MSF microreactor in the presence of ethanol was found to be comparable to that obtained under conventional conditions. The ability of these reusable flow-through microreactors to regioselectively form monoacylglycerides in high yield from triacylglycerides demonstrate their potential use in small-scale lipid transformations or analytical lipids profiling.

Keywords Microreactor · Micro structured fiber · Lipid transformation · Immobilized enzyme

Abbreviations

APTES	3-(Aminopropyl)triethoxysilane
DAG	Diacylglycerol
DO	Dioleoylglycerol
EE	Ethyl oleate/C18:1 ethyl ester
ELSD	Evaporative light scattering detector
FID	Flame ionization detector
GC × GC	Comprehensive two-dimensional gas chromatography
HPLC	High performance liquid chromatography
MAG	Monoacylglycerol
MO	Monooleoylglycerol
MSF	Micro structured fiber
NARP-LC	Non-aqueous reversed-phased liquid chromatography
PCF	Photonic crystal fibers
PDMS	Poly-dimethylsiloxane
PMMA	Poly(methyl-methacrylate)
*p*NP	*p*-Nitrophenol
*p*NPB	*p*-Nitrophenyl butyrate
SEM	Scanning electron microscope

Introduction

Recently, microreactor technologies have gained attention for their application in clinical diagnostics, analytical and synthetic chemistry [1–3]. For example, Kawaguchi et al. [4] have successfully demonstrated the use of a flow-system microreactor for the Moffatt–Swern oxidation of alcohols into carbonyl compounds. A microreactor integrates various chemical or analytical processes into a single platform made up of reaction channels in the micrometer (50–1,000 μm) range. In such systems, the chemical reaction takes place under conditions of continuous flow [1]. Whether for analytical or synthetic applications, microreactor technology offers several advantages including: reduced reaction time [2, 3] due to the large surface area to volume ratio in the microchannel; enhanced control over the reaction process [3]; it is less wasteful since only low volumes of reagent are used [3] and rapid optimization of reaction conditions can be achieved [2–5]. The microreactors are also ideally suited for continuous flow processes, a highly desired paradigm in processing.

The fabrication of commercially available microreactors (mainly made from glass, quartz, silica or polymers) is however, generally achieved via expensive photolithographic and wet-etching processes which are complicated and require specialized clean-room facilities [6]. Therefore, there is much interest in developing cheaper and more easily accessible approaches to the fabrication of microreactors for laboratory applications [1–10]. Amongst the attractive platforms used, are microreactors obtained by means of imprinting on polymers including poly-dimethylsiloxane (PDMS), poly(methyl-methacrylate) (PMMA) [11] or polyurethanes. However, the use of silica capillaries is possibly the easiest platform to employ as a flow through microreactor with potential for numerous chemical modifications for use in enzyme-, organo-, or metal-catalysts immobilization [8–10].

There is considerable interest in the use of enzymes for lipid transformations such as in the preparation of structured lipids [12] as well as in biodiesel production [13]. The interest is due to the high yields, minimal side products and mild reaction conditions that can be achieved with enzyme-catalyzed processes. A major impediment to the potential commercialization of enzyme-mediated processes is the cost of enzymes and their unstable nature. However, enzyme immobilized over the high surface area of the capillary walls will result in an efficient flow-through microreactor which is reusable for many process cycles after which the microreactors can be regenerated with new enzyme.

Micro structured fibers (MSF), also commonly known as photonic crystal fibers (PCF), are silica capillaries that consist of a micro structured arrangement of air channels within a flexible acrylate polymer-coated silica tube. They are widely used as radiation optical guides and in sensor applications [14]. Basically, these optical fibers are made up of three layers: the core, cladding and the coating. Both the core diameter (an individual air channel, usually in the 8–40 μm range) and the number of channels in the photonic fiber can vary depending on the design of the fiber. In addition, the coating diameter—outer diameter of the fiber—could range from 200 to 500 μm depending on the requirements of the application [14], such as in networking or bio-sensing.

Here, we propose that the presence and chemistry of silanol groups within MSFs could be exploited as a platform for enzyme immobilization, as has been widely reported for other silica supports [8]. MSF contain an array of microchannels and hence an enormous surface is available for enzyme immobilization, and may offer an excellent platform for a flow-through microreactor. In order to demonstrate the performance of such a microreactor in mediating lipid transformations, the lipase from *Candida antarctica* was selected, since it is one of the most widely used enzymes for catalysis in lipid transesterification reactions [13, 15]. Overall, the objective of this study was to demonstrate the feasibility of immobilizing enzymes onto MSF capillaries and utilizing the microreactors in lipid transformations. This will combine the advantages of microreactor technology with the green chemistry achievable via enzyme immobilization.

Materials and Methods

Materials

MSF capillary (F-SM20, ID: 4–5 μm, outer diameter: 340 μm, 168 holes) was obtained from Newport Corp. (Irvine CA, USA). Canola oil was obtained from a local grocery store (with ~50% trioleoylglycerol). Sodium hydroxide powder (reagent grade, 97%), sodium phosphate monobasic monohydrate, 3-(aminopropyl)triethoxysilane (APTES, 99%), di-sodium hydrogen phosphate (bioUltra, Fluka, >99%), glutaraldehyde solution (BioChemika, ~50% in H_2O), sodium cyanoborohydride ($NaCNBH_3$, reagent grade, 95%), lipase from *Candida antarctica* (EC 3.1.1.3, BioChemika) potassium sodium tartrate, copper sulfate, and Folin phenol reagent all were obtained from

Sigma-Aldrich Ltd (ON, Canada). Acetic acid (glacial, HPLC) was purchased from Fisher Scientific (New Jersey, USA). C18:1 ethyl ester (EE)and TLC 18-1-A [contains by weight 25% of each of trioleoylglycerol (TO), dioleoylglycerol (DO), monooleoylglycerol (MO), methyl oleate (ME)] standards were purchased from Nu-Chek (Elysian, MN, USA), while 1-monooleoylglycerol standard (98%) was obtained from Sigma-Aldrich (ON, Canada). All organic solvents were HPLC analytical grade from Sigma-Aldrich (ON, Canada). Water was purified by a Milli-Q system (Millipore; Bedford MA, USA).

MSF Activation

The MSF capillary (15 cm) was activated by flushing with 1 M NaOH solution for 2 h at a flow rate of 10 μL/min. The sodium hydroxide activated the inner surface (silanol groups) of the capillary wall. The residual alkali was flushed by 0.1 M HCl for 2 h at a flow rate of 10 μL/min. The activated MSF was then dried under N_2 gas before the lipase enzyme immobilization step.

Lipase Immobilization onto MSF Capillary Support

Candida antarctica lipase was immobilized by introduction of amine functional groups onto the silica wall by a silanization reaction; this was followed by the formation of an imide using glutaraldehyde as a bifunctional reagent; finally immobilization was achieved via a condensation reaction with the lipase. This procedure was adapted with some minor modifications from the method reported by Ma et al. [8]. Briefly, the activated MSF was filled with 20% (v/v) APTES (5:2:3 water: acetic acid: APTES) and left overnight with both capillary ends submerged in the 20% APTES solution to complete the reaction. The MSF was then flushed with 0.1 M sodium phosphate buffer (pH 7), followed by reaction with glutaraldehyde solution (5% glutaraldehyde dissolved in 0.1 M sodium phosphate buffer) and left for 4 h in the solution. The capillary was then flushed with buffer again before continuously infusing it with 8 mg/mL lipase from *Candida antarctica* in sodium phosphate buffer (0.1 M, pH 7 with 0.1% $NaCNBH_3$) for 24 h at room temperature. The sodium borohydride is used to reduce the Schiff base formation and to stabilize the binding of the enzyme to the support. The enzyme-loaded microreactor was finally flushed with the 0.1 M sodium phosphate buffer at which point it was ready for use.

Immobilized Lipase Assay

The amount of lipase immobilized on the MSF was determined using the standard Lowry protein assay [16]. This was achieved by determining the difference in protein concentration before and after passing the *Candida antarctica* lipase solution through the MSF during the immobilization process. The Lowry solution was prepared freshly by mixing solution A (4 mg/mL NaOH and 20 mg/mL Na_2CO_3 in water) and solution B (10 mg/mL potassium sodium tartrate and 50 mg/mL $CuSO_4$ in water), prior to use. Solutions of known protein concentration (calibration solutions containing 0, 2.5, 5, 7.5, 10, 12.5, 15, 17.5, 20, 25, 30, and 35 μg protein) and lipase solutions (2 μL) were made up to a total volume of 200 μL with deionized water. 1 mL of Lowry solution was added to each protein solution then after waiting for 15 min, 100 μL Folin phenol reagent was added. After a further 30 min, an aliquot was sampled in a UV-Vis cuvette (10 mm square cuvette) and their absorbance was measured at 750 nm. The concentration of the enzyme solution before and after passing through the microreactor was determined from the protein calibration curve in order to estimate the amount of enzyme immobilized in the microreactor.

Lipase Activity Assay

To determine the lipase (esterase) activity, a 3.5 mM solution of *p*-nitrophenyl butyrate (*p*NPB) was prepared in a 1:1 mixture of acetonitrile (ACN) and 0.1 mM sodium phosphate buffer). The *p*NPB solution was passed through a 15 cm MSF lipase immobilized microreactor at 1 μL/min for 1 h. The hydrolysis products were then collected, their volume measured and then diluted to 2.0 mL in mixture of ACN: sodium phosphate buffer (1:1). The absorbance of the resulting solution of products (absorbing molecule, *p*-nitrophenol) was measured at a wavelength of 410 nm. A calibration curve was obtained by measuring the absorbance of *p*-nitrophenol (*p*NP) standard solutions prepared in the same solvent mixture ACN: 0.1 mM sodium phosphate buffer at concentrations of 0. 5, 1, 3, 5 and 7 mM. The concentration of *p*NP hydrolyzed was determined and lipase enzyme activity calculated. The enzyme activity was expressed as amount of *p*NP formed on the microreactor under the condition used per minute, i.e., μg *p*NP/min. One enzyme unit (U) was the amount of protein liberating 1 μg of *p*NP per minute.

Specific Activity of Immobilized Lipase

Based on the amount of protein loaded and lipase activity, a specific activity of lipase immobilized in the MSF was calculated according to Dizge et al. [17].

Lipid Sample Preparation and Transformation

The reactant solution of 5 mg/mL canola oil was prepared in ethanol. The mixture was mixed vigorously using a

vortex mixer to dissolve the lipid in ethanol. The parameters affecting the performance of the microreactor including reaction flow rate and temperature were investigated and optimized as follows:

Temperature

Lipid transformation using the immobilized MSF was carried out at room temperature (24 °C), 30, 40, 50, and 60 °C. A schematic illustrating the experimental conditions is shown in Fig. 1. A syringe pump system (Harvard '11' Plus) was used to infuse reactant through the MSF microreactor. The products from the reaction were collected in a small capped vials with the microreactor poked through the septum of the vial. The temperature that produced highest yield was then used to optimize the flow rate for the reaction.

Reaction Flow Rate

The reactant solution was then pumped through the lipase-immobilized MSF microreactor held at the optimized temperature (50 °C) and using various flow rates (0.5, 1, 5 and 10 μL/min), each held for 3 h. The products were collected into vials for analysis, as described below.

In both the temperature and reaction flow optimization experiments, the reaction products collected from MSF microreactor were diluted 10–25 times in HPLC solvent A (methanol with 0.1% glacial acetic acid) before being analyzed. Standard calibration curves were prepared using 0.05, 0.1, 0.5 and 1.0 mg/mL of total TLC 18-A-1 and 0.05, 0.1, 0.2, 0.5, and 1.0 mg/mL of EE standards. The amount of each compound in the reaction products was determined from the standard calibration curve prepared.

For GC × GC analysis, samples were diluted in dichloromethane and quantified against a calibration curve covering the range of 0.01–1 mg/mL of each lipid component.

Instrumentation

(a) A Harvard Model '11' Plus syringe pump (Harvard Apparatus, Holliston MA) was used to pass all solutions through the MSF both during preparation of the microreactor and for lipid transformations.
(b) High-performance liquid chromatography (HPLC) analysis was performed using an Agilent 1200 HPLC system equipped with an evaporative light scattering detector (ELSD) model 1260 Infinity (Agilent Technologies, Santa Clara CA, USA).
(c) Either an Agilent Zorbax HT C18 column (4.6 × 50 mm, 1.8 μm) (Agilent Technologies; Santa Clara CA, USA) or a Supelco Ascentis Silica column (4.6 × 150 mm, 3 μm) (Sigma-Aldrich; ON, Canada) were used as described below.
(d) UV/Visible measurements were made using a Jenway spectrophotometer 6320D series (Bibby Scientific, Staffordshire, UK).
(e) A LECO comprehensive 2-dimensional GC × GC/FID system (LECO; St. Joseph, MI, USA) was used (Fig. 2). It consists of a dual oven GC equipped with flame ionization detector and cryogenic modulator (quadjet) cooled with liquid nitrogen and split–splitless injector. All data was collected by Leco ChromaTOF-GC software v 3.34 optimized for GC × GC/FID. The columns used for GCxGC were a DB5HT gas chromatography column (30 m × 0.32 mm × 0.1 μm, bonded and cross-linked 5% phenyl methylpolysiloxane, Agilent technologies; Santa Clara CA, USA) and an RXT65 column (1 m × 0.25 mm × 0.1 μm, crossbond 65% diphenyl-dimethyl polysiloxane, Restek; Bellefonte PA, USA).

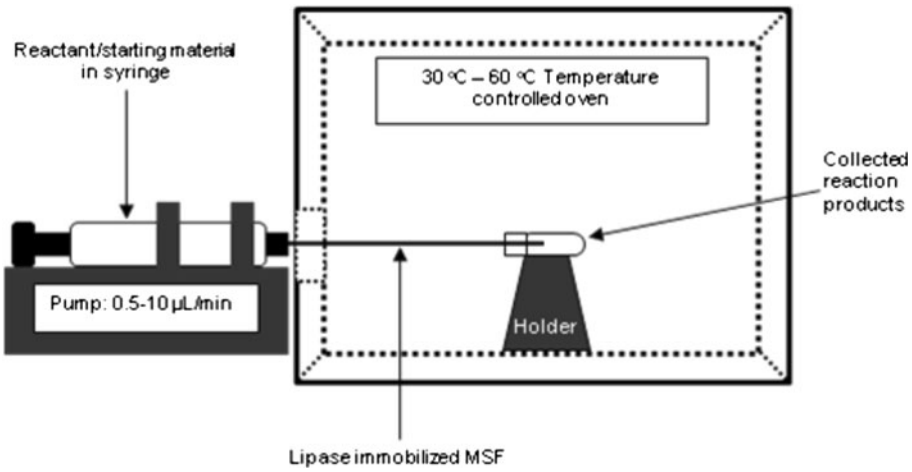

Fig. 1 Apparatus used with the fabricated MSF microreactor for small scale lipid reactions

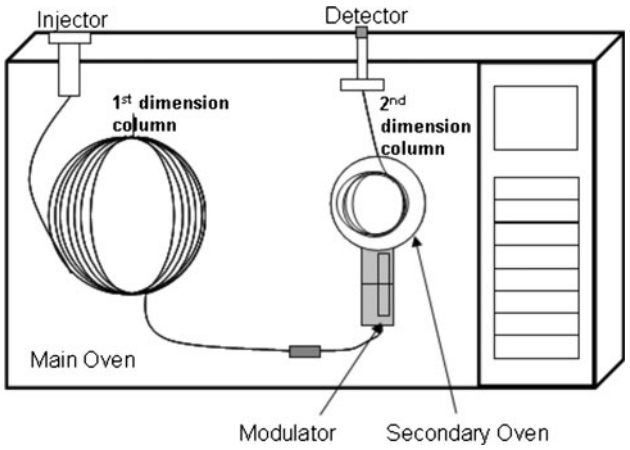

Fig. 2 Schematic diagram of GC × GC/FID used for analysis of lipid transformation products

NARP-LC/ELSD

Non-aqueous reversed phased (NARP) HPLC with a C18 column was used to speciate the lipid transformation products as well as the starting materials and lipid standards. The ELSD was set to 33 °C and the nitrogen gas flow rate was optimized. All samples were analysed using an injection volume of 10 μL and a mobile phase flow rate of 1 mL/min. A binary gradient of A, methanol with 0.1% glacial acetic acid; and B, isopropanol/hexane (5:4) was used. The starting condition was 0% B held for 5 min then increased to 66% B in 10 min, held at 66% B for 3.5 min before returning to 0% B (2.5 min) to equilibrate the column.

GC × GC

GC × GC was used as a second method to characterize the lipid classes produced by the MSF microreactor and to confirm the LC results. An aliquot of the product mixture was dissolved in dichloromethane prior to injection into the LECO GC × GC/FID system. The carrier gas was H_2 at a flow rate of 1.5 mL/min, injection volume 1 μL, split ratio of 15:1 and He FID make-up gas was used. The inlet and detector temperatures were set to 320 and 400 °C, respectively. The temperature program for the first oven was 45 °C (0.5 min) increased at 2 °C/min until 150 °C (0 min) then increased again at 3 °C/min until 375 °C (hold 10 min). The second oven tracked the first but at a temperature 25 °C higher at all times. The modulator offset was 15 °C.

Regiospecificity Determination Using Normal Phase-LC/ELSD

Normal phase HPLC with a silica column was used for the regiospecific separation of the MSF microreactor lipid products, following an AOCS standard method [18]. Aliquots of the products formed under the optimized conditions (50 °C, flow rate 1 μL/min) were analyzed by HPLC/ELSD along with a 1-monooleoylglycerol standard. The method used an injection volume of 10 μL, mobile phase flow rate of 0.5 mL/min, column temperature maintained at 40 °C and the ELSD operating at 90 °C. The mobile phase was a binary gradient of A hexane, and B hexane/isopropanol/ethyl acetate/10% formic acid (80:10:10:1, v/v) [18]. The gradient was 2% B, linear increase to 35% B in 15 min, then linearly increased to 98% in 1 min, and finally held for 10 min at 98% B. The column was allowed to equilibrate at the starting condition for 3 min. Note that all samples and standards were prepared in hexane/isopropanol (9:1, v/v) prior analysis.

Results and Discussion

Lipase-Immobilized Microreactor Fabrication

In this paper, we present the first demonstration of the use of a microreactor, fabricated by immobilizing lipase from *Candida antarctica* onto a silica MSF support, for the ethanolysis of canola oil triacylglycerols. The MSF morphology is shown in the scanning electron microscope image in Fig. 3.

Although the MSF have been mainly developed for use in light guiding optics, they contain numerous micrometer-sized pores (4–5 μm) and provide a very large surface area, which makes them ideally suited for immobilizing high amounts of catalysts. Furthermore, the fact that the MSF is made from silica makes it even more attractive for the enzyme immobilization by employing well-known

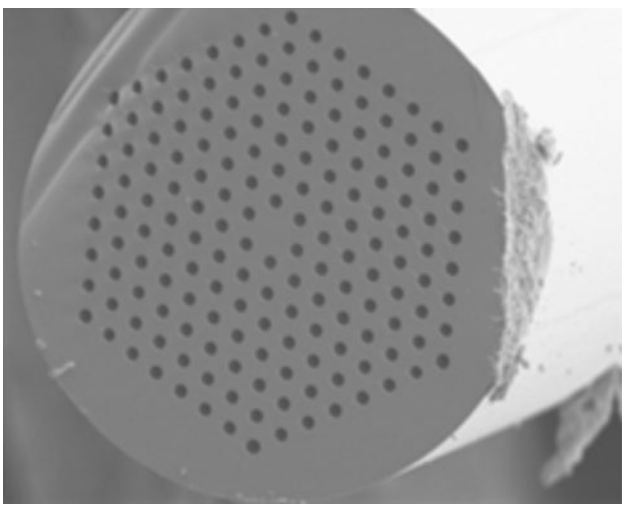

Fig. 3 Scanning electron microscope (SEM) image of a Lipase-Immobilized MSF (168 holes) at ×300 magnification

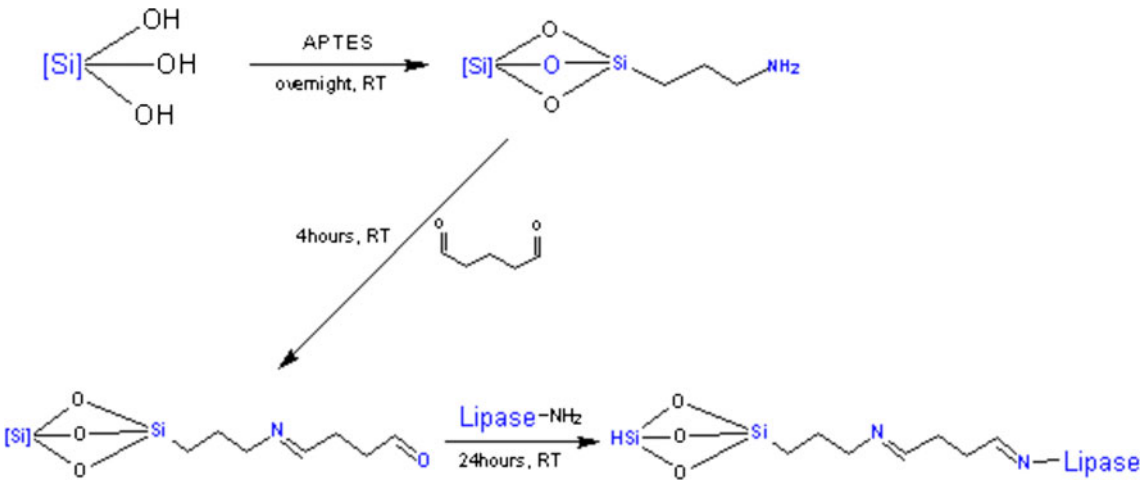

Fig. 4 The process of lipase-immobilization onto the silica support of a MSF

silanization chemistry. In order to ensure the maximum presence of silanol groups at the MSF surface, the use of alkali (NaOH) treatment has been shown to activate the silica wall by increasing hydrolysis of the silanol group [19]. The reaction sequence of the immobilization lipase from *Candida antarctica* onto the silica walls of the MSF is given in Fig. 4.

Immobilization onto the silica support was achieved by grafting aminopropyl triethoxysilane (APTES) onto the active silanol group (Si–OH) on the MSF wall [20]. The resultant pendant primary amine group provides a reactive functionality to form imines when reacted with the bifunctional reagent glutaraldehyde. This in turn results in a pendent carbonyl group from the grafted glutaraldehyde which further reacts with the amino groups of lipase forming a Schiff base, thus covalently attaching the enzyme to the MSF support [20, 21]. It is expected with such a strong covalent lipase attachment, the probability of enzyme leaching is low and hence the microreactor can potentially be reused multiple times. In contrast, using the simple, commonly used adsorption methods of immobilization, leaching is known to limit reusability [22, 23].

Enzyme Activity Assay

Before employing the lipase loaded MSF microreactor it was essential to determine the success of the immobilization method. The total free protein concentration was determined using the widely used Lowry protein assay [16]. The amount of protein bound to the MSF microreactor support was estimated by the difference between amount of protein in the lipase solution infused through the MSF and the effluent emerging from the MSF. Using this method, the amount of protein loaded on the MSF was determined to be 5.8 μg/μL (Table 1).

It is likely that not all lipase loaded in the MSF is active due to underlying physicochemical factors associated with the immobilization. As such, it was imperative to also determine the activity of the immobilized lipase. As described in detail in the Materials and Methods section, the lipase activity of immobilized MSF microreactor was determined by the enzymatic hydrolysis of p-nitrophenyl butyrate (*p*NBP) to *p*-nitrophenol which is quantified spectrophotometrically. Using this assay, a unit (U) of lipase activity is defined as the amount of enzyme that hydrolyses (liberates) 1 μg of *p*-nitrophenol (*p*NP) from *p*NPB as substrate. Table 1 summarizes of lipase activity assay yield. The enzymatic activity for the immobilized MSF microreactor was determined to be 4.7 μg *p*NP/min (U) for the 15 cm MSF microreactor. Hence, a specific activity of 0.81 U/mg was found for the immobilized lipase from *Candida antarctica* in the MSF microreactor. Data from the manufacturer indicates that the native lipase from *Candida antarctica* has specific activity of 1.06 U/mg

Table 1 Determination of the amount of lipase immobilized onto the MSF capillary

	Protein bound[a] from 1 mL lipase (mg/mL)	Protein bound yield (%)	Lipase activity[b] (μg *p*NP/min) (U)	Specific activity (U/mg) for 15 cm MSF microreactor	Specific activity for native enzyme (U/mg) before immobilization
Fabricated immobilized MSF	5.83	75.59	4.7	0.81	1.06

[a] 1 mL of 8 mg/mL lipase solution was immobilized onto the MSF capillary

[b] 1U = amount (mg) of enzyme to liberate 1 μg *p*NP/min under the assay condition

before immobilization (cf. Table 1). Therefore, only about 23.6% of the enzyme activity was found to have been lost using the proposed immobilization process. This result is comparable with that found in other studies, for example specific activities of 0.60–0.9 were found using similar methods for lipase immobilized onto styrene–divinylbenzene and styrene–divinylbenzene–polyglutaraldehyde copolymers for biodiesel production [17].

A goal in the development of the lipase immobilized MSF microreactor was to evaluate its performance in lipid transformations. This was done by transesterifying trioleoylglycerol (molecular weight 884, TO) in ethanol in the MSF microreactor. From this reaction, the major transesterified products which were obtained were monooleoylglycerol (MO) and ethyl oleate (EE). Since MO and EE results from the hydrolysis of two and three ester bonds/molecule, respectively, the theoretical conversion rates of trioleoylglycerol (TO) can be estimated from the measured lipase activity of 4.7 μg *p*NP/min (U) assuming that lipase catalysed hydrolysis of triacylglycerol (TAG) ester occurs at the same rate as the lipase catalysed hydrolysis of *p*NBP to give *p*NP. If this assumption is made, then the conversion rate of 5 mg/ml TO at 1 μL/min to MO and to EE would be predicted to be 10 and 6.7 μg/min (or 0.0115 and 0.0075 mol/min), respectively. It is apparent that notwithstanding the gross assumptions made, the observed conversion rate (TO–MO) is of the same order of magnitude as the rate predicted based on the measured enzyme activity. This implies that to a rough approximation, the enzyme activity assay is quite consistent with the measured results for TO conversion (described in the next section). It should also be pointed out that canola oil rather than TO was actually used in the experiments, but this does not change the general arguments used above.

Enzymatic-Catalyzed Ethanolysis Using the MSF Microreactor

The ethanolysis of canola oil was performed using the lipase-immobilized MSF microreactor at different temperatures and flow rates, in order to determine the optimal conditions. The selected temperature range was chosen based on the optimized lipase enzyme conditions of other researchers including Irimescu et al. [12] and Köse et al. [24] The former suggested optimal conditions at room temperature, while the latter indicated denaturation of enzyme at temperatures >50 °C, by decreasing the reaction yield. The products obtained were then analysed by NARP-LC/ELSD and Fig. 5a, b show the chromatograms obtained for both the starting material and pure standards. The conversion of TAG in canola oil was estimated by means of a calibration curve of a lipid standard consisting of TO, DO, MO and EE (Table 2).

The data in Table 2 show the relative concentrations of the reaction products obtained using a flow rate of 1 μL/min of canola oil triacylglycerols (TAG) in ethanol solution passing through the lipase immobilized MSF microreactor, conditioned at various temperatures. From the LC/ELSD analysis it was found that whilst EE and monoacylglycerols (MAG) products were formed under all conditions, diacylglycerols (DAG) were not observed above the limit of detection, possibly due to the microscale nature of our study. The predominant formation of MO relative to DO is consistent with results of others [12]. In Table 2 it is clear that at low temperatures, the conversion of TAG into other lipid forms was low, and a similar result was found at 60 °C. However, at around 50 °C virtually all of the TAG was consumed indicating a high efficiency of the immobilized lipase microreactor under these conditions.

The effect of the reaction flow rate on the lipid conversion was then investigated with the temperature fixed at 50 °C (cf. Fig. 5c–e). As indicated in Fig. 5c–e, the microreactor flow rates investigated included 1, 5 and 10 μL/min. The narrow flow rate range evaluated was due to the achievable linear force of the syringe pump utilized (Harvard '11' Plus). The results show that the optimal flow rate for the enzymatic MSF microreactor reaction is at 1 μL/min, where complete disappearance of the TAG starting material was evident along with the formation of MAG and EE. As the flow rate increased above 1 μL/min, a broad 'hump' is seen in the chromatogram, co-eluting with unreacted starting material (Fig. 5d, e). This is likely due to removal of oligomeric glutaraldehyde material from the walls of the microreactor attributable to the high pressures (~21 psi) that occur with higher flow rates through the small channels in the MSF reactor. However, since the flow rate of 1 μL/min (which corresponds to a residence time of 28.5 s in the 15 cm MSF) allows sufficient contact time between the starting material and the lipase immobilized in the microreactors, these destructive conditions can be avoided. As demonstrated in Fig. 5, the lipid transformation performance reduces as flow rate increases due to the lower contact time of the substrates with the immobilized lipase. At 10 μL/min the calculated MSF residence time was 3 s. Recently, there have been several reports describing how ethanolysis of TAG using immobilized lipase from *Candida antarctica* can, under certain conditions, become 1,3 regiospecific [12, 25]. Furthermore, the reaction in excess ethanol can also promote the formation of the 2-MAG, compared to other products [26]. For example, using an ethanol/TO molar ratio of 77:1 at 25 °C, Novozyme 435 beads and a reaction time of 4 h, Irimescu et al. [12] achieved an ~88% reaction yield of which >98% of the acylglycerol content was 2-monooleoylglycerol (2-MO). The actual molar ratio

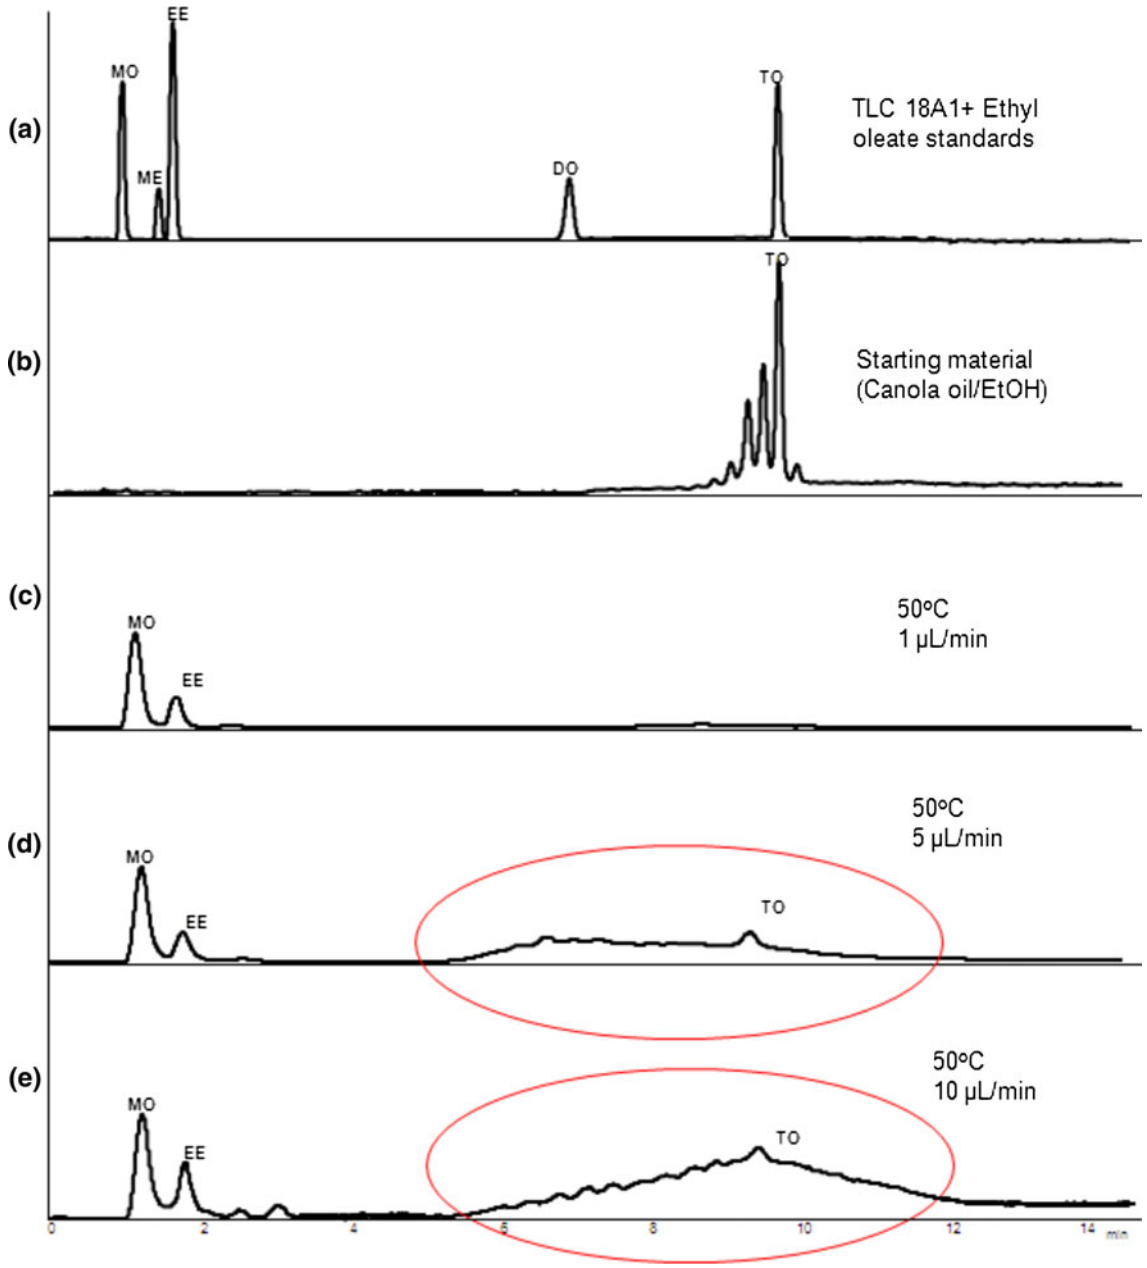

Fig. 5 NARP-LC/ELSD (nonaqueous reversed phase LC with evaporative light scattering detection (NARP-LC/ELSD) using a C18 column, ELSD temperature 33 °C, for gradient see "Materials and Methods") separation of **a** a lipid standard mixture containing *MO* monooleoylglycerol, *ME* methyl oleate, *EE* ethyl oleate, *DO* dioleoylglycerol, *TO* Trioleoylglycerol **b** canola oil/ethanol (the starting reactant mixture for the MSF microreactor), and **c**–**e** the effect of reaction flow rate for a canola oil solution in ethanol passing through the lipase immobilized MSF microreactor at: **c** 1 µL/min, **d** 5 µL/min; and, **e** 10 µL/min. All **c**–**e** reactions were carried out at 50 °C. The ellipse shows the MSF column carry-over around the TAG peak that could not be resolved

of ethanol:TAG has also been shown to be important in order to achieve regiospecificity and high reaction rates [27]. In systems where long reaction times are possible, it has been proposed [12, 25] that although 2-MAG is formed exclusively at low ethanolysis times, longer times (>7 h under the conditions used in that study) result in acyl migration forming some 1[3]-MAG. However, in the present experiment, reaction times range from seconds to a few minutes, so acyl migration is unlikely to occur.

To confirm the regiospecificity of the ethanolysis reaction in the microreactor, a sample of canola oil that passed through the reactor under the optimized conditions for maximum conversion of TAG to MAG (1 µL/min, 50 °C) was collected. The regiospecificity was then determined by

normal phase HPLC following AOCS official method Cd 11d-96 [18], as described in the Materials and Methods section. This confirmed that >96% of the MAG produced was indeed 2-MAG. Figure 6 illustrates that the addition of a 1-MO standard to the MAG product; before the addition there was no peak at the retention time of the 1-MO standard (data not presented) confirming that the product is the 2-MAG isomer.

It should be noted that Table 2 presents qualitative data which serves to illustrate the performance of the microreactor, rather than rigorous quantitative results. These shortcomings are in part due to the difficulties associated with collecting and manipulating small volumes of solution eluting from a prototype device. Also, there are several disadvantages of performing analysis using LC/ELSD, one which is that the ELSD response is not the same towards all compounds, being greatly affected by analyte volatility, and non-linearity. As a result, the measured EE concentration in particular, is less reliable. Another drawback of the LC/ELSD analysis is that it did not separate the microreactor column bleed from the DAG and TAG peaks, when operating at high reactant flow rates (Fig. 5d, e). Therefore, a second independent analytical method was carried out to support the findings of the LC/ELSD results. The method chosen uses comprehensive two-dimensional (GC × GC/FID) to separate neutral lipid microreactor products. GC × GC (cf. Fig. 2) is a multidimensional technique that consists of orthogonal hyphenation (via a cryogenic modulator) of two columns of different stationary phases, each housed in its own temperature programmable oven. On injection of the sample, chromatography

takes place conventionally on the first column but subsequently the modulator collects the effluent and periodically re-injects it into the second column for further separation [28, 29]. The sampling frequency is high enough that each peak eluting from first column is sampled at least multiple times, thus preserving the primary separation in addition to the separation on the second column phase[28–30]. Thus, GC × GC is essentially multiple sequential heart-cuts. The raw data has to be converted from the conventional linear form to a 2D representation using special software algorithms [29, 30]. The GC × GC results obtained for the MSF reaction products obtained at room temperature and 50 °C are presented in Fig. 7 and in Table 2. In both cases the optimal flow rate, 1 μL/min was used. Note that the tandem high temperature columns used in the GC × GC experiments preclude the need for the typical silylation derivatizations of lipids to increase their volatility in order to enable their GC analysis. Details of the development of this GC × GC method will be presented in a future report.

What is notable in Fig. 7 is the complete separation of EE, MAG, DAG and TAG along with the relatively higher response of EE compared to that seen by LC/ELSD. In addition, the presumably glutaraldehyde oligomeric material (carry-over) discharged from the microreactor especially at high flow rates does not interfere with the separation of lipid peaks (Fig. 7), further giving credence to the use of GC × GC. Using GC × GC method, the compounds with lower molecular weight (EE) elute first, followed by MAG, DAG and TAG. Also, the response for the volatile EE is higher than for the other lipid classes in contrast to the LC/ELSD method where the opposite is observed. This discrepancy in product yields (seen in Table 2) may be a consequence of the nonlinear nature of HPLC/ELSD, especially for compounds differing in volatility. In general, the GC × GC/FID results support the conclusions of the LC/ELSD data described above, but the estimated EE concentrations are considerably higher and likely much more realistic (Table 2).

In conclusion, these results clearly demonstrate the successful lipase immobilization on silica microstructure fibers and the use of the resulting microreactor for the ethanolysis of a vegetable oil under conditions of continuous flow. A high degree of regiospecificity was observed in the reaction under optimized conditions, with almost complete conversion to 2-MAG. This is consistent with earlier reports for ethanolysis using the same lipase [12, 25], although under quite different reaction conditions and at much lower reaction rates. Although not yet robust, the MSF microreactors have been reused several times, and future work will aim to produce microreactors with longer lifetimes. It is envisioned that on-line enzyme immobilized MSF microreactors will prove to be valuable in analytical lipid profiling applications.

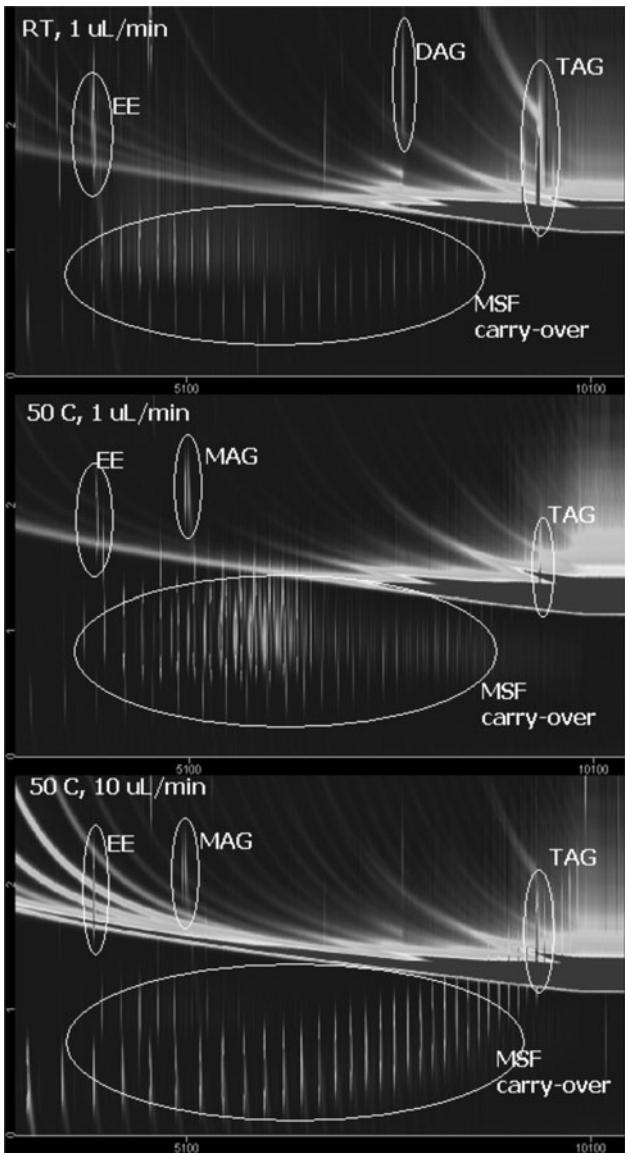

Fig. 7 GC × GC/FID chromatograms of products from ethanolysis of canola oil using the MSF microreactor. The microreactor bleed ("carry over") separates from the identified *circled* lipid products

ORIGINAL ARTICLE

Dietary n-3 Fatty Acids Significantly Suppress Lipogenesis in Bovine Muscle and Adipose Tissue: A Functional Genomics Approach

Beate Hiller · Andrea Herdmann · Karin Nuernberg

Received: 21 February 2011 / Accepted: 12 May 2011 / Published online: 26 May 2011

Abstract Changes in fatty acid composition of longissimus muscle and subcutaneous adipose tissue of German Holstein bulls induced by a grass-silage/n-3 fatty acid based intervention diet versus a maize-silage/n-6 fatty acid based control diet were analyzed and related to shifts in lipogenic gene expression, protein expression, and enzyme activity patterns. Significantly higher amounts of n-3 fatty acids and by mean factors of 2.2–2.5 decreased n-6/n-3 fatty acid ratios in both tissues were obtained upon n-3 fatty acid intervention. In longissimus muscle, these changes of fatty acid profiles were associated with reduced SREBP1c ($p = 0.02$), ACC ($p = 0.00$), FAS ($p = 0.10$) and SCD ($p = 0.03$) gene expression, Δ6D ($p = 0.03$) and SCD ($p = 0.03$) protein expression as well as SCD enzyme activity ($p = 0.03$). In subcutaneous adipose tissue, significantly reduced ACC ($p = 0.00$) and FAS ($p = 0.01$) gene expression, SCD protein expression ($p = 0.02$) and SCD enzyme activity ($p = 0.03$) were detected upon n-3 fatty acid intervention, although lower degrees of correlation between gene and corresponding gene products were obtained in relation to longissimus muscle. The study elucidates tissue-specific functional genomic responses to dietary fatty acid manipulation in regard to fatty acid profile tailoring of animal tissues.

Keywords Lipogenesis · Fatty acid profile · Functional genomic approach · SREBP1c · SCD · ACC · FAS · Δ5D · Δ6D

Abbreviations

ACC	Acetyl-CoA carboxylase α
ACTB	β-actin
B2M	B2-microglobulin
CG	Control group
Δ5D	Δ5 Desaturase
Δ6D	Δ6 Desaturase
EEF1A2	Eukaryotic translation elongation factor 1α2
FAME	Fatty acid methyl ester(s)
FAS	Fatty acid synthase
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
IG	Intervention group
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
RPS18	Ribosomal protein S18
SCD	Stearoyl-CoA desaturase
SFA	Saturated fatty acids
SF3A1	Splicing factor 3a, subunit 1
SREBP1c	Sterol regulatory element binding protein 1c

Introduction

In recent years, increasing interest has been directed towards altering the nutritional profile of food in regard to major public health concerns. Considering the continuously rising incidences of Western lifestyle diseases such as hyperlipidemia, hypertonus, obesity, type II diabetes and cardiovascular disorders, public health strategies primarily aim at

reducing the overall dietary intake of saturated as well as n-6 unsaturated fatty acids and at increasing the intake of health-promoting n-3 unsaturated fatty acids [1–4].

Studies indicated that up to half of the average adult intake of n-3 fatty acids in industrial countries originates from meat [5], and that the n-6/n-3 fatty acid ratio of meat can further be improved by dietary intervention of ruminant and non-ruminant farm animals with exogenous n-3 fatty acid sources, stimulating either direct fatty acid incorporation into animal tissues or affecting in vivo fatty acid biosynthesis [1, 6–9]. Levels of long-chain n-3 polyunsaturated fatty acids in lamb, beef and pork meat were reported to be effectively elevated upon dietary supplementation with linseed/linseed oil, rapeseed cake/oil, algae, linolenic acid rich forages [10] as well as novel alimentary fatty acid sources such as hemp, camelina, and lupin [6]. Beneficially reduced n-6/n-3 fatty acid ratios in meat were also demonstrated to result from, e.g., pasture versus concentrate [11], red clover-silage versus grass-silage [12] as well as grass-silage versus maize-silage [13] feeding regimes.

The underlying mechanisms facilitating fatty acid profile tailoring of animal tissues have not been completely understood and been ascribed to a complex regulation network of genetically [14–17] and physiologically [7, 17] affected lipogenic gene expression, protein expression and enzyme activity levels in animal tissues [17–21]. The results of different studies as yet showed minor degrees of consistency, ranging from negligible [22] to high degrees [18] of correlation between expression levels of lipogenic genes/proteins and fatty acid profiles.

In this context, the present study aimed at a more in-depth elucidation of the effect of dietary n-3 fatty acid intervention on fatty acid profiles via a functional genomic approach, relating shifts in fatty acid composition of bovine muscle and adipose tissue observed during preliminary investigations [13, 23] with effects on lipogenic transcriptome and proteome, focusing on key-lipogenic transcription factors (SREBP1c) and enzymes involved in fatty acid de novo synthesis (ACC, FAS), monodesaturation (SCD) and polyunsaturation (Δ5D, Δ6D).

Materials and Methods

Animals, Study Design and Tissue Sampling

From an animal experiment ($n = 29$) [13, 23] conducted within the framework of EU Project FOOD-CT-36241, tissue samples from German Holstein bulls ($n = 27$) were obtained.

Animals had been assigned to a maize-silage based control diet (control group (CG); $n = 14$) or a grass-silage based intervention diet (intervention group (IG); $n = 13$) during a fattening period of 245 ± 40 days until a live weight of 625 ± 26 kg (CG) or 631 ± 23 kg (IG) at an age of 477 ± 40 days (CG) or 510 ± 37 days (IG) was reached.

Experimental diets were isoenergetically formulated; actual energy intake ranged between mean values of 112.5 MJ (CG) and 108.5 MJ (IG) metabolizable energy per day. Control diet consisted of 0.153 g crude protein, 0.03 g crude fat (22.9% SFA, 26.0% MUFA, 51.1% PUFA; 46.3% n-6 FA, 4.8% n-3 FA; n-6/n-3 FA ratio = 9.6) and 0.07 g crude ash per g dry matter, intervention diet of 0.149 g crude protein, 0.04 g crude fat (23.6% SFA, 17.6% MUFA, 58.8% PUFA; 22.3% n-6 FA, 36.5% n-3 FA; n-6/n-3 FA ratio = 0.6) and 0.12 g crude ash.

Immediately after slaughter and exsanguination of the experimental animals, subcutaneous adipose tissue as well as longissimus muscle samples were taken from the right side of the carcass (between the thirteenth and fourteenth rib) under RNase-free conditions, snap-frozen in liquid nitrogen and stored at −80 °C until further analysis.

Gene Expression Analysis

RNA Extraction

Frozen tissue samples of an approximate weight of 100 mg were homogenized in 1 mL Qiazol lysis reagent (Cat. No. 79306) (Qiagen GmbH, Hilden, Germany) with a gentleMACS™ dissociator in gentleMACS™ M Tubes (Cat. No. 130-093-458) (Miltenyi Biotec GmbH, Bergisch-Gladbach, Germany). RNA was extracted from 1 mL homogenate with the RNeasy Lipid Tissue Mini Kit (Cat. No. 74804) according to the manufacturer's protocol; optional DNase digestion was performed with the RNase-free DNase Set (Cat. No. 79254) (Qiagen GmbH, Hilden, Germany), incubating samples with DNase (80 µL DNase working solution/sample) for 15 min at 20 °C.

RNA extracts were immediately analyzed for RNA quantity (OD_{260nm}) and purity (OD_{260nm}/OD_{280nm}) (NanoDrop ND-1000, Peqlab GmbH, Erlangen, Germany); RNA integrity was checked with a Bio-Rad Experion™ System and StdSens Analysis Kit (Bio-Rad GmbH, Munich, Germany). RNA quantity ranged between 498.2 ± 43.5 µg ($OD_{260nm}/OD_{280nm} = 1.95–2.12$) (longissimus muscle) and 158.6 ± 27.3 µg ($OD_{260nm}/OD_{280nm} = 1.93–2.17$) (adipose tissue) per g tissue sample, RNA quality between RQI-values of 9.5 ± 0.2 (longissimus muscle) and 9.3 ± 0.1 (adipose tissue).

RNA aliquots were stored at −80 °C and further processed within 2 weeks.

Reverse Transcription

RNA was reverse transcribed with the iScript™ cDNA Synthesis Kit (Cat. No. 170-8890) (Bio-Rad GmbH,

Munich, Germany), incubating a reaction mix of 4 μL 5× iScript mix, 1 μL iScript reverse transcriptase, 5 μL nuclease-free water and 10 μL RNA template (10 ng/μL) at temperatures of 25 °C for 5 min, 42 °C for 30 min and 85 °C for 5 min. cDNA aliquots were stored at −20 °C and subjected to further analysis within 4 w.

qRT-PCR

qRT-PCR analysis was performed with a Bio-Rad iCycler with 96 × 0.2 mL reaction module (Cat. No. 170-8720) and iCycler iQ real-time PCR detection system (Cat. No. 170-8740) (Bio-Rad Laboratories GmbH, Munich, Germany) using SYBR® Green I chemistry. Gene-specific oligonucleotides were designed with Primer3 (Version 0.4.0.); specificity of primers and identity of predicted PCR products was checked in silico (NCBI Primer Blast, NCBI Sequence Blast). Primers were custom-synthesized and RP1-purified by Sigma-Aldrich GmbH (Steinheim, Germany); oligonucleotide sequences and specifications are listed in Table 1.

Reaction mixes of 5 μL iQ SYBR® Green Supermix (Cat. No. 170-8860), 4 μL forward/reverse primer solution (0.2 μmol/L) and 1 μL cDNA template (10 ng/μL) were pipetted into 96-well 0.2 mL thin-wall PCR plates (Cat. No. 223-9441) and sealed with optical-quality Microseal adhesive tape (Cat. No. MSB-1001) (Bio-Rad Laboratories GmbH, Munich, Germany). After an initial denaturation at

ACC acetyl-CoA carboxylase α, *ACTB* β-actin, *B2M* β2-microglobulin, *Δ5D* Δ5 desaturase, *Δ6D* Δ6 desaturase, *EEF1A2* eukaryotic translation elongation factor 1α2, *FAS* fatty acid synthase, *GAPDH* glyceraldehyde-3-phosphate dehydrogenase, *RPS18* ribosomal protein S18, *SCD* stearoyl-CoA desaturase, *SF3A1* splicing factor 3a, subunit -1, *SREBP1c* sterol regulatory element binding protein 1c

[a] Determined by plotting the c_T-values of 10.0, 1.0, 0.5, 0.1 and 0.01 ng cDNA versus the logarithm of the corresponding cDNA amount

94 °C for 3 min, a thermocycling program of 10 s at 94 °C, 30 s at 60 °C and 45 s at 70 °C was applied (45 cycles); total fluorescence data and dynamic well factors were continuously collected to generate background subtracted amplification curves (iQ5 Software, Version 2.1.97.1001; Bio-Rad Laboratories GmbH, Munich, Germany). PCR analysis of cDNA samples was performed in triplicate; no-transcription and no-template samples were used as controls.

The specificity of the PCR amplification was confirmed by melt curve analysis (temperature range 60–94 °C), agarose gel electrophoresis of PCR products on 2% SYBR® Safe stained precast agarose gels (Cat. No. G5218-02) (Invitrogen GmbH, Darmstadt, Germany) as well as sequencing of PCR products. Accuracy, linearity and efficiency of the PCR reaction was checked by plotting the c_T-values of 10.0, 1.0, 0.5, 0.1 and 0.01 ng cDNA versus the logarithm of the corresponding cDNA amount. Accuracy was defined as the R^2 value of the standard curve, efficiency E was calculated as $E\,[\%] = (10^{-1/\text{slope of standard curve}} - 1) \times 100$.

Gene Expression Quantification and Statistical Evaluation

Relative gene expression of ACC [EC 6.4.1.2], FAS [EC 2.3.1.85], SCD [EC 1.14.19.1], Δ5D [EC 1.14.19.-], Δ6D [EC 1.14.19.3] and SREBP1c was calculated with the comparative, efficiency-corrected $\Delta\Delta C_T$ method. Based on preliminary investigations on tissue-specific reference genes, SF3A1, EEF1A2, RPS18 and B2M were selected for gene expression normalization of longissimus muscle and ACTB, GAPDH, RPS18 and B2M for gene expression normalization of subcutaneous adipose tissue. Differences in gene expression profiles between control and intervention group were tested for statistical significance using REST© algorithm (REST© 2009; Relative Expression Software Tool, Version V2.0.13) [24]; p values are given with the results.

Protein Expression and Enzyme Activity Analysis

Protein expression of ACC, SCD and Δ6D was determined by Western Blot analysis of cytosolic/microsomal tissue extracts as previously described [19].

Enzyme activity of SCD was assessed as time-dependent, enzyme-specific substrate-conversion rate (nmol substrate/mg microsomal protein/h) of ^{14}C-labeled palmitoyl-coenzyme A [23].

Data were analyzed for statistical significance by the least-squares method using the general linear model procedures of SAS® (2009) with the fixed factor feeding. $p \leq 0.05$ was considered as statistically significant.

Fatty Acid Analysis

Fatty acid analysis was performed by GC–FID analysis of fatty acid methyl esters (FAME), prepared by the isolation of fatty acids from homogenized tissue samples by chloroform/methanol extraction [25] and methylation as previously described [19, 26]. FAME were separated on a CP-Sil 88 fused-silica capillary column (100 m, 0.25 mm, 0.20 µm; Varian-Chrompack GmbH, Darmstadt, Germany) with a Perkin Elmer Autosystem XL gas chromatograph (Perkin Elmer, Watham, USA), applying a temperature gradient program [45 °C (4 min); to 150 °C (+13 °C/min); 150 °C (47 min); to 215 °C (+48 °C/min); 215 °C (35 min)] at a carrier gas flow rate of 1 mL hydrogen/min, and detected by flame ionization at 280 °C.

Analysis was performed in duplicate. FAME reference mixture (Cat. No. 18919-1; Sigma–Aldrich, Steinheim, Germany) plus *c*11-18:1, *c*9,*t*11-18:2, 18:4n-3, 22:5n-3 (Matreya, Biotrend, Cologne, Germany), *t*11-18:1 and 22:4n-6 FAME (Sigma-Aldrich, Deisenhofen, Germany) was used for calibration.

An unpaired, homoscedastic t test was applied to check fatty acid concentrations of both feeding groups for statistical significance, regarding p values of $p \leq 0.05$ as significant.

Results

Changes in fatty acid composition (Table 2) upon n-3 fatty acid supplementation of German Holstein bulls via a grass-silage based intervention diet versus a maize-silage based control diet were analyzed and related to corresponding shifts in lipogenesis-related gene expression (Fig. 1a, b, Table 3), protein expression (Table 3) and enzyme activity patterns (Table 3) of bovine muscle and adipose tissue.

Changes in Fatty Acid Composition

Table 2 summarizes the fatty acid composition of longissimus muscle and subcutaneous adipose tissue of control and intervention group. Significantly higher absolute concentrations (Table 2) as well as relative amounts (see Supplementary Table 1) of n-3 fatty acids were obtained in muscle (57.0 mg/100 g (IG) versus 27.5 mg/100 g (CG)) and adipose (472.9 mg/100 g (IG) versus 312.2 mg/100 g (CG)) tissue of intervention group animals. Furthermore, diminished amounts of n-6 fatty acids, saturated fatty acids and monounsaturated fatty acids as well as by factors of 2.5 (longissimus muscle) or 2.2 (adipose tissue) reduced n-6/n-3 fatty acid ratios were obtained upon n-3 fatty acid intervention (Table 2).

Functional Genomic Effect of n-3 Intervention on Lipogenesis in Longissimus Muscle

Expression profiles of lipid metabolism associated genes (SREBP1c, ACC, FAS, Δ5D, Δ6D, SCD) in the longissimus muscle of control and intervention groups as assessed in relation to tissue-specific reference genes (SF3A1, EEF1A2, RPS18, B2M) are given in Fig. 1a. Significantly higher c_T-values ($p < 0.05$) and by factors of 0.59–1.02 (ACC) and 0.63–1.05 (SCD) diminished expression levels of ACC and SCD gene were obtained in longissimus muscle of the intervention group compared to the control group animals. Expression levels of FAS, SREBP1c, Δ5D and Δ6D gene did not significantly differ between both feeding groups (Fig. 1a), although FAS expression tended to be lower ($p = 0.10$) in intervention group tissue samples.

Relating diet-induced changes of gene expression with corresponding gene products, strongest association was obtained for SCD, considering decreased SCD gene

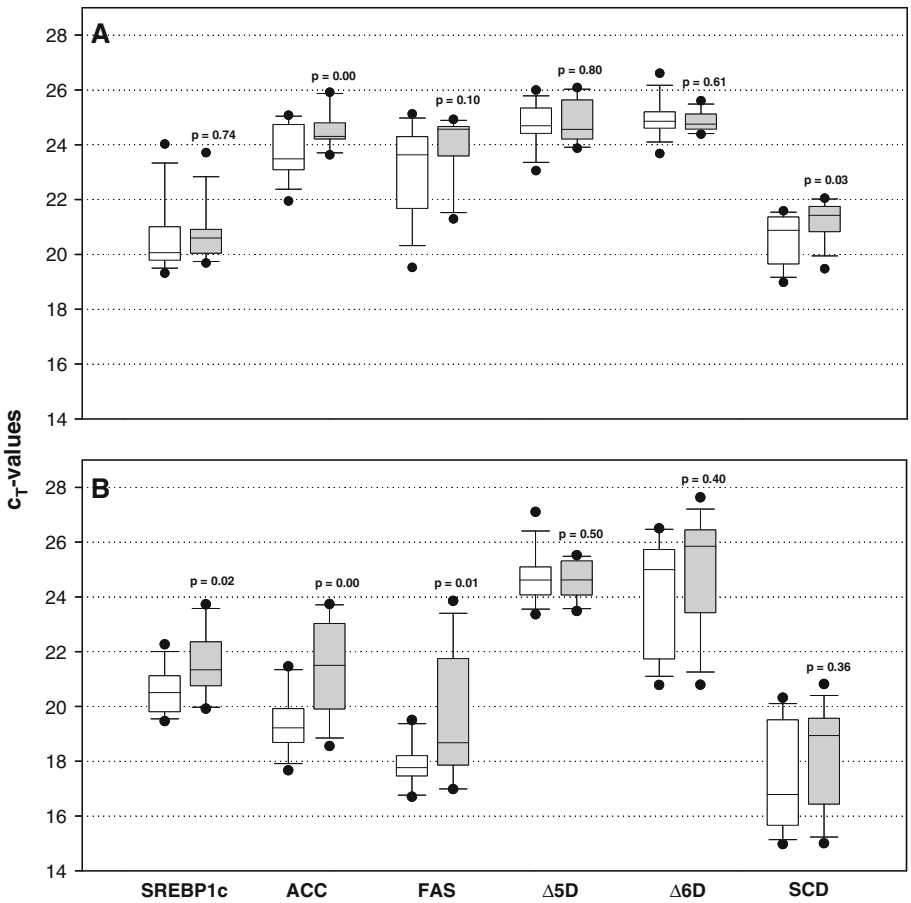

Fig. 1 Boxplots of c_T-values obtained by qRT-PCR gene expression analysis of longissimus muscle (**a**) and subcutaneous adipose tissue (**b**) of control (*squares*) ($n = 14$) and intervention (*filled squares*) ($n = 13$) group *SREBP1c* sterol regulatory element binding protein 1c, *ACC* acetyl-CoA carboxylase α, *FAS* fatty acid synthase, *Δ5D* Δ5 desaturase, *Δ6D* Δ6 desaturase, *SCD* stearoyl-CoA desaturase, *SF3A1* splicing factor 3a, subunit 1, *EEF1A2* eukaryotic translation elongation factor 1α2, *RPS18* ribosomal protein S18, *B2M* β2-microglobulin, *ACTB* β-actin, *GAPDH* glyceraldehyde 3-phosphate dehydrogenase *p* values represent significance levels of differences between control and intervention group, considering $p \leq 0.05$ as statistically significant; REST© hypothesis test; normalization via SF3A1, EEF1A2, RPS18 and B2M (longissimus muscle) or ACTB, GAPDH, RPS18 and B2M (subcutaneous adipose tissue)

expression ($p = 0.03$) (Fig. 1a), SCD protein expression ($p = 0.03$) (Table 3), SCD enzyme activity ($p = 0.03$) (Table 3) as well as amount of the SCD reaction products 14:1 ($p = 0.06$), 16:1 ($p = 0.01$) and 18:1n-9 ($p = 0.02$) (Tables 2 and 3) in intervention group than control group tissue samples. Similar interrelations were obtained for ACC and FAS, regarding their decreased levels of gene expression ($p = 0.00$, ACC; $p = 0.10$, FAS) (Fig. 1a) as well as minor amounts of their fatty acid reaction products 12:0 ($p = 0.03$), 14:0 ($p = 0.03$) and 16:0 ($p = 0.04$) (Tables 2 and 3) upon n-3 fatty acid intervention, although ACC protein expression ($p = 0.71$) (Table 3) was not found to be affected. Less consistent results were obtained for Δ5D and Δ6D: gene expression levels did not significantly differ between control and intervention group ($p = 0.80$, Δ5D; $p = 0.61$, Δ6D) (Fig. 1a), Δ6D protein expression was significantly lower ($p = 0.03$) (Table 2) in intervention group tissue samples, and the amounts of Δ5D and Δ6D reaction products were found to be significantly diminished in the intervention group in case of 20:4n-6 ($p = 0.03$) and 18:4n-3 ($p = 0.02$) and elevated in case of 20:5n-3 ($p = 0.00$) and 18:3n-6 ($p = 0.00$) (Tables 2 and 3).

Functional Genomic Effect of n-3 Intervention on Lipogenesis in Subcutaneous Adipose Tissue

Expression profiles of lipid metabolism associated genes (SREBP1c, ACC, FAS, Δ5D, Δ6D, SCD) as assessed in relation to tissue-specific reference genes (ACTB, GAPDH, RPS18, B2M) in subcutaneous adipose tissue samples are given in Fig. 1b. Comparing gene expression in adipose tissue of control and intervention group, significantly higher c_T-values ($p < 0.05$) and thus by factors of 0.36–1.01 (ACC), 0.35–1.13 (FAS) and 0.58–1.12 (SREBP1c) decreased expression levels of ACC, FAS and SREBP1c gene were obtained for intervention group tissue samples. Gene expression of Δ5D, Δ6D and SCD genes did not differ between the control and intervention group. Overall higher levels of ACC, FAS and SCD gene expression were detected in adipose (Fig. 1b) than in muscle tissue (Fig. 1a).

Relating genes and gene products, less consistent correlation was observed in adipose tissue than in muscle. Although ACC and FAS gene expression ($p = 0.00$, ACC; $p = 0.01$, FAS) (Fig. 1b) was significantly reduced upon n-3 fatty acid intervention, ACC protein expression

($p = 0.71$) (Table 3) as well as the amount of fatty acid reaction products 12:0 ($p = 0.67$) and 16:0 ($p = 0.19$) was not affected (Tables 2 and 3). SCD protein expression ($p = 0.02$) (Table 3), SCD enzyme activity ($p = 0.03$) (Table 3) and the amount of SCD product 18:1n-9 ($p = 0.03$) (Tables 2, 3) were significantly lower in intervention group than control group tissue samples, although SCD gene expression ($p = 0.36$) (Fig. 1b) as well as amount of SCD products 14:1 ($p = 0.38$), 16:1 ($p = 0.33$) and *c*9,*t*11-18:2 ($p = 0.94$) (Tables 2, 3) did not

substantially differ. Most consistent relationship was found for Δ6D which was neither affected in regard to gene expression ($p = 0.40$) (Fig. 1b), protein expression ($p = 0.50$) (Table 3) nor the amount of reaction products 18:3n-6 ($p = 0.61$) and 18:4n-3 ($p = 0.32$) (Tables 2, 3). Δ5D gene expression was found to be similar in both groups (Fig. 1b), but a significantly lower amount of Δ5D reaction product 20:4n-6 ($p = 0.04$) and a higher amount of 20:5n-3 ($p = 0.00$) was found in adipose tissue of the intervention group animals (Tables 2, 3).

Discussion

Strategies for improving the nutritional profile upon shifting the fatty acid composition of meat towards more beneficial ratios of n-6 to n-3 fatty acids have successfully exploited means of dietary intervention of farm animals with exogenous n-3 fatty acid sources [6, 10, 11, 27]. In this context, the present investigations revealed that n-3 fatty acid contents as well as n-6/n-3 fatty acid ratios in longissimus muscle and subcutaneous adipose tissue of German Holstein bulls were beneficially affected by a grass-silage based intervention diet versus a maize-silage based control diet, significantly reducing n-6/n-3 fatty acid ratios by mean factors of 2.5 in muscle and 2.2 in adipose tissue.

Considering an extensive biohydrogenation, isomerization and degradation of alimentary fatty acids by ruminal microbiota [7, 10], major mechanism underlying the obtained changes in fatty acid profiles seems to be an affected fatty acid biosynthesis in bovine tissues via shifted expression of lipogenic genes and gene products.

The present study applied a functional genomic approach to interrelate changes of fatty acid profiles with corresponding shifts in expression of lipogenic genes and gene products. Distinct functional genomic responses of muscle and adipose tissue to n-3 fatty acid intervention were obtained, indicating tissue-specific regulation networks between an initial induction of lipogenesis-related transcription factor SREBP1c, a subsequent expression of lipogenic ACC, FAS, Δ5D, Δ6D and SCD gene/protein, a regulation of lipogenic enzyme activities and an induction of feedback-mechanisms induced by fatty acid reaction products.

Lower total expression levels of the key-lipogenic genes ACC, FAS and SCD were found in longissimus muscle than in subcutaneous adipose tissue, probably due to the aspect that lipogenesis-related pathways play less fundamental metabolic roles in muscle than in adipose tissue, the primary site of energy storage via lipogenesis and lipid accumulation in ruminants [28]. In agreement with the present findings, higher expression in adipose tissue than in muscle was confirmed for the SCD gene [29] as well as the SCD protein [30] in cattle, and for SCD, ACC and FAS protein [31, 32] and enzyme activity [31] in pigs.

A comparatively more consistent relationship between the gene and associated gene products was obtained for muscle than for adipose tissue, supposedly due to the fact that the fatty acid profile of adipose tissue reflects rather long-term, cumulative anabolic developments, whereas more rapid lipid turnover [33] and thus a more real-time relation between gene, protein and metabolite can be found in muscle. Furthermore, the snap-shot approach of the present study addressed functional genomic relationships discontinuously, not dynamically during tissue development and maturation. Dynamic investigations performed in primary cell culture or animal experiments, for example, suggested that SCD gene expression and activity undergo marked dynamic fluctuations, considering peak among intermediate SCD gene expression levels at developmental stages of 24, 144 and 288 h of in vitro bovine preadipocyte differentiation [34] or of 7 and 20–28 months of in vivo bovine tissue development [35, 36]. In agreement with the present findings, more consistent effect of dietary manipulation via distinct feeding regimes was confirmed for SCD protein and activity levels in muscle than in adipose tissue [20, 31], an aspect which may also be explained by the occurrence of differentially regulated, tissue-specific isoenzyme forms [19, 30] as well as differences in cellular carbon precursor uptake [37].

Comparing distinct interrelations between genes and gene products, the most consistent correlation in both tissues was obtained for SCD. Reduced gene expression levels of transcription factor SREBP1c in adipose tissue, decreased SCD gene expression in muscle as well as significantly lower SCD protein expression, SCD enzyme activity and amount of major monounsaturated SCD fatty acid product 18:1n-9 in both tissues were detected upon n-3 fatty acid intervention

The results of the present study correspond to literature findings that SCD expression and activity in tissues positively relate to the levels of the SCD reaction products 14:1, 16:1, 18:1n-9 and *c*9,*t*11-18:2 [18, 21, 29, 30, 38–40]. For example, breed-specifically high levels of SCD expression were described as cause for increased intramuscular fat and monounsaturated fatty acid amounts in Japanese Black cattle muscle [29]. Effects of unsaturated fatty acid intervention on the SCD axis were discussed to relate to tissue- [41], gender- [41], breed- [30, 36, 42] and developmental stage- [35, 43] dependent decreases in SCD gene [36, 44–46] or protein expression [19], but also reduced expression of SCD transcription factor SREBP1c [18, 21, 38]. Reduced SCD gene expression was found to negatively correlate with the n-6/n-3 fatty acid ratio in bovine muscle tissue [18, 21], but no correlation between

SCD protein expression and its metabolites was observed in ovine muscle tissue [22]. Whereas no significant difference between intramuscular fat content of control (2.9 ± 1.3%) and intervention (2.2 ± 1.0%) group animals was found in the present investigations, some studies described SCD expression level as an indicator of intramuscular fat development [29, 32, 35, 39] and fat quality [47] in ruminants and non-ruminants, considering SCD as key-regulator of muscle metabolism by facilitating lipid biosynthesis and suppressing fatty acid degradation [48, 49]. The positive correlation between the amounts of SCD product 18:1n-9 and total fatty acids ($r = 0.984$) or saturated fatty acids ($r = 0.943$) in longissimus muscle obtained in this study strongly supports the lipogenic role of SCD in muscle metabolism.

Concerning enzymes involved in de novo fatty acid synthesis, the present study mainly suggested functional genomic correlations between gene and gene products in muscle tissue, relating decreased levels of ACC and FAS gene expression upon n-3 fatty acid intervention with significantly reduced amounts of their metabolites 12:0, 14:0 and 16:0. These results are in agreement with literature findings that supplementation with unsaturated fatty acids causes significantly down-regulated ACC and FAS gene expression in bovine muscle tissue [46] or reduced ACC and FAS enzyme activities and metabolite concentrations in bovine cell culture models [50].

Although intramuscular fat contents of both dietary groups did not differ in the present study, significantly minor total fatty acid amounts (1805.7 mg/100 g (IG) versus 2397.9 mg/100 g (CG)) in muscle tissue of intervention group animals correspond to postulations that FAS gene expression [35], FAS activity [51], ACC protein expression [37] or ACC activity [52] positively correlate with intramuscular fat deposition.

For enzymes involved in fatty acid polyunsaturation, inconsistent functional genomic effects were observed in the present study. Unaffected levels of Δ5D gene expression, but significantly higher amounts of Δ5D product 20:5n-3 and lower amounts of 20:4n-6 in muscle and adipose tissue were detected upon n-3 fatty acid intervention. Expression of Δ6D gene and its gene products was similar in adipose tissue samples of control and intervention group, whereas diminished Δ6D protein expression, increased amounts of Δ6D product 18:3n-6 and minor amounts of 18:4n-3 were obtained for muscle of intervention group animals.

Literature findings that Δ5D/Δ6D expression level positively correlates with tissue concentrations of n-6 unsaturated fatty acids [20] were only confirmed for Δ6D protein expression and n-6 fatty acid content in muscle. Anyhow, decreased levels of Δ5D product 20:4n-6 as well as Δ6D product 18:4n-3 in tissues of intervention group animals indicate that n-3 fatty acid supplementation indeed induced shifts in Δ5D/Δ6D expression and activity which probably occurred during tissue developmental stages preceding the chosen biological endpoints and finishing state.

Altogether, this study related shifts in fatty acid profiles upon n-3 fatty acid supplementation of farm animals with a broad spectrum of underlying functional genomic effects and thus expanded findings of previous cause-and-effect-studies. The aspect that an absolute functional genomic correlation between expression of genes and gene products was not obtained necessitates further investigations to address developmental stage dependencies [35], transcriptional, posttranscriptional, translational and posttranslational control mechanisms [17] as well as overlapping or conflicting effects of simultaneously proceeding, tissue-specific processes of substrate uptake, lipogenesis, lipolysis and lipid release [53].

The present study demonstrated that significantly higher amounts of n-3 fatty acids and by factors of 2.2–2.5 decreased n-6/n-3 fatty acid ratios were obtained in longissimus muscle and subcutaneous adipose tissue of German Holstein bulls upon n-3 fatty acid intervention by a grass-silage versus a maize-silage based diet.

Via a functional genomic approach, these beneficial changes in fatty acid profiles were related to reduced SREBP1c, ACC, FAS and SCD gene expression, Δ6D and SCD protein expression as well as SCD enzyme activity in longissimus muscle tissue, as well as to significantly reduced ACC and FAS gene expression, SCD protein expression and SCD enzyme activity in subcutaneous adipose tissue, although lower degrees of correlation between gene and corresponding gene products were observed for adipose tissue.

The study characterized a broad spectrum of functional genomic effects induced by dietary fatty acid manipulation, thus expanding findings of previous cause-and-effect-studies in regard to fatty acid profile tailoring of animal tissues.

Acknowledgments The study was conducted and financially supported within the framework of EU Project ProSafeBeef (Project No. FOOD-CT-2006-36241). The authors kindly thank B. Jentz and M. Dahm for their excellent technical assistance.

Abstract Branched chain fatty acids (BCFA) have recently been shown to be a major component of the normal human newborn gastrointestinal tract and have long been known to be a component of human milk. Ruminant food products are major sources of fat in the American diet, but there are no studies of milkfat BCFA content in retail milk. We report here the profile and concentrations of BCFA in a representative sampling of retail milk in the 48 contiguous United States (US), and their estimated intake in the American diet. Conventionally produced whole fluid milk samples were obtained from 56 processing plants across the contiguous 48 states. Retail milk samples contain exclusively *iso*- and *anteiso*-BCFA with 14–18 carbons. BCFA were 2.05 ± 0.14%, w/w of milkfat fatty acids (mean ± SD), and *anteiso*-BCFA comprised more than half this total. Based on these data and USDA food availability data, the average per capita BCFA intake of Americans is estimated to be about 220 mg/d from dairy; if current dietary recommendations were followed, BCFA intake would be about 400 mg/d. Adding intake from beef consumption, these estimates rise to approximately 400 and 575 mg/d, respectively. These results indicate that BCFA intake is a substantial fraction of daily fat intake, in amounts exceeding those of many bioactive fatty acids.

Keywords Branched chain fatty acids · Retail milk · Dietary intake · Milkfat

Abbreviations

BCFA	Branched chain fatty acids
CACI-MS	Covalent adduct chemical ionization mass spectrometry
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
FA	Fatty acids
FAME	Fatty acid methyl esters
FID	Flame ionization detector
GC	Gas chromatograph
MS	Mass spectrometry
NEC	Necrotizing enterocolitis
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids

Introduction

Milk and dairy products are major contributors to fat intake in the American diet. Cow's milkfat is characterized by high proportions of fatty acids (FA) with 16 carbons or less. Individual FA, such as conjugated linoleic acids (CLA), may have a beneficial effect on health maintenance and prevention of acute and chronic disease [1, 2]. The FA profile of milk in all species, including cow's milk, is sensitive to dietary fat intake, for instance, concentrate versus pasture versus fish oil supplementation [3–6], thus

milk composition may differ depending on production practices. O'Donnell-Megaro et al. [7] recently reported the composition of major FA retail milk in the United States (US). About 3.1% of FA were unidentified and listed as a group under "Other"; branched chain fatty acids (BCFA) are included in this group.

BCFA are primarily saturated FA (SFA) with one or more methyl branches. In human metabolism, they are best studied as components of skin lipids. Overall, several dozen specific BCFA, are found in milk and tissue of ruminants including sheep and goats, presumably synthesized by ruminal organisms that rely on them for membrane lipids [8, 9]. BCFA are conveniently categorized as mono- and di-/multi-methyl BCFA; in monomethyl BCFA, the predominant branching is at the terminal methyl (*iso*) or next to the terminal methyl (*anteiso*), as shown in Fig. 1. *iso*- and *anteiso*-BCFA are the main BCFA reported in cow's milk [3, 4, 6, 10, 11]. Terpenoid BCFA, exemplified by internal periodic poly-methyl branching such as phytanic acid (3,7,11,14 tetra-methyl hexadecanoic acid) and its alpha oxidation product pristanic acid (2,6,10,14 tetra-methyl pentadecanoic acid) are also reported in cow's milk [11, 12].

Information on human intake and metabolism of BCFA is scant, and there are no recommendations for or against dietary intake of BCFA. Ran-Ressler et al. [13] recently showed that BCFA are a major component of the late term fetal and newborn gut contents. They comprise almost one third of the FA in vernix [13], the white fatty film that covers the fetus in utero. Vernix suspended in amniotic fluid is normally swallowed by the fetus, increasingly so as parturition approaches [14], exposing the fetal gut to BCFA from an early age. Moreover, BCFA are also found in human milk [15, 16] where they reportedly comprise 1.5%, w/w. A 1981 report put the concentrations of *anteiso*-17:0 in colostrum at 0.45%, w/w, higher than the concentrations of docosahexaenoic acid (DHA; 22:6n-3; 0.32%, w/w) and arachidonic acid (20:4n-6; 0.4%, w/w) [16]. A study in rat pups shows that BCFA reduce the incidence of necrotizing enterocolitis (NEC), a devastating intestinal disease affecting premature infants (Ran-Ressler et al. unpublished data). Thus, BCFA are a major component in perinatal nutrition, and although they may have a beneficial role in human health, their presence in the US food chain has been almost completely neglected.

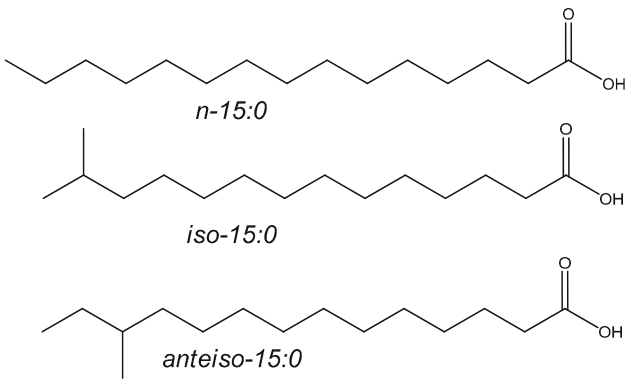

Fig. 1 Structures of *iso*- and *anteiso*-branched chain fatty acids (BCFA). *n*-(*normal*) hydrocarbon chains without branching. *iso*-BCFA have a bifurcated methyl branch (*iso*-15:0 is 13-methyl tetradecanoic acid). *anteiso*-BCFA have a methyl branch on the antepenultimate carbon. *anteiso*-15:0 is 12-methyl tetradecanoic acid

The objective of the present study is to analyze the levels and distribution of BCFA in US retail milk and to estimate the contribution of BCFA to the nutrition of Americans based on estimated intake of milk and other foods produced by ruminant animals such as cheese and beef. In a 1994 survey, dairy products contributed 7.5% of the protein, 4.2% of the total fat, and approximately 8% of the total saturated fat in the diet of adults [17]. Based on NHANES 1999–2004 [18] fluid milk, mostly whole milk, provided 7.5, and 6.4% of energy intake in children age 2–4 and 5–10, respectively. We hypothesized that BCFA are found in retail milk and dairy products in the US and thus are consumed in substantial amounts in the American diet. We report here the first data on the structure and quantitative analysis of BCFA in a representative samples of the US retail milk supply and we show that BCFA intake, per capita, is in excess than that of many bioactive FA.

Experimental Procedures

Sampling

Conventionally produced whole fluid milk samples were obtained from 56 US milk processing plants across the contiguous 48 states. All samples were whole milk obtained in December, 2008. They had been homogenized, pasteurized and packaged for transport to retail stores. Processing plants were selected based on the criteria that they represented at least 50% of the volume of milk produced in that area. Milk was shipped on ice overnight to Cornell University and immediately processed for the analysis of FA composition.

Fatty Acid Analysis

Milk fat extraction was based on the Mojonnier method (AOAC 995.19) as modified by Barbano [19]. Briefly, milkfat was obtained from 10 ml whole fluid milk by a sequence of 3 successive extractions. Ten milliliters of

95% alcohol and 25 ml ethyl ether plus milk was followed by vigorous mixing, then 25 ml petroleum ether was added and followed by vigorous mixing, and decanting of the ether layer. The second and third extractions were similar, except the volume of solvents was reduced to 5 ml of 95% alcohol and 15 ml each of ethyl and petroleum ethers, and the third extraction omitted the 95% alcohol. Ether solutions from the 3 extractions were combined, dried and resuspended in hexane. Methyl esters of the extracted fat were prepared using sodium methoxide as the methylation reagent, according to Christie [20] as modified by Chouinard [21].

Fatty acid methyl ester (FAME) analyses were performed using a Hewlett Packard 5890 Gas Chromatograph (GC) equipped with a split/splitless injector run in splitless mode at 250 °C, and with the flame ionization detector (FID) at 270 °C. A BPX-70 column (25 m × 0.22 mm × 0.25 μm, SGE, Austin, TX) was used for the analysis with H_2 as the carrier gas. The oven temperature program was initially 80 °C for one minute, increased by 30 °C per minute to 170 °C and held for 2 min, then increased by 10 °C per minute until a final temperature of 240 °C which was held for 1 min. An equal weight FAME mixture (68A; Nu-Chek Prep, Elysian, MN) was used to calculate response factors. Several pure BCFA were also used as reference standards: *iso*-14:0, *anteiso*-15:0; *iso*-16:0, *anteiso*-17:0, *iso*-18:0 and *iso*-20:0 (Larodan Fine Chemicals AB, Malmo, Sweden).

FAME identities were determined by electron impact ionization mass spectrometry (EI-MS), using a Varian Star 3400 GC coupled to a Varian Saturn 2000 ion trap MS, based on GC retention times and EI mass spectra. The GC–MS column was a BPX-70 (60 m × 0.32 mm × 0.25 μm, SGE, Austin, TX). The following primary characteristic ions were used for saturated and BCFA methyl ester identification: Molecular ion [M], 74 *m/z* (McLafferty rearrangement), and 87 *m/z* (formed by cleavage at the fourth carbon). Ions at 88 *m/z* and 101 *m/z* were used for the presence of a methyl branch in the second and third carbon, as in the multibranched FA pristanic and phytanic acid, respectively. In addition, the presence, in higher intensities compared to their normal homologues, of the fragments $[M\text{-}15]^+$ or $[M\text{-}43]^+$ or both indicated the presence of iso-BCFA; while the fragments $[M\text{-}29]^+$ or $[M\text{-}57]^+$ or both indicated the presence of *anteiso*-BCFA. The MS spectra of the BCFA were compared to the pure BCFA mixture described above and to an online spectra archive http://www.lipidlibrary.aocs.org/ms/arch_me/index.htm#branch.

Under the GC-FID conditions described above, two pairs of FAME coelute, *iso*-15:0/14:1 and *iso*-17:0/16:1. Coelutions of monoenic and BCFA are unavoidable even on long columns such as CP-Sil-88 [22]. The use of a semipolar column such as the CP-Sil 19 was reported recently to effectively separate BCFA from monounsaturated FA (MUFA) in cheese and fish samples [23]. In the present study, GC with covalent adduct chemical ionization mass spectrometry (CACI-MS) was used to resolve the two sets of overlapping peaks [24]. Solutions of pure 14:1, 15:0, 16:1, and 17:0 FAME (0.5 μg/μl, Nu-Chek Prep Inc., Elysian, MN) were used to determine response factors for ions characteristic of the respective FAME. Selected characteristic ions were plotted to resolve and quantify coeluting FAME. A plot for MH^+ was used for the *iso*-FAME in the milk sample, and a plot of $[MH\text{-}32]^+$, MH^+, and $[M + 54]^+$ intensities were used for the monounsaturated FAME. An example of GC-CACI-MS selected ion plots used for the resolution and quantification of *iso*-15:0 and 14:1 is shown in Fig. 2. An area to weight ratio [A/W, arbitrary units/(ug/ul)] was calculated for each of the pure FAME by dividing the area from the corresponding characteristic ions to the known concentrations of the pure FAME. The concentrations (ug/ul) of the sample *iso*- or the monounsaturated-FAME were then calculated using the ratio between the area under the characteristic ions of the sample FAME and the A/W of the pure corresponding FAME.

The relative percent contribution of the two interfering FAME was applied to the coeluting peaks to produce yield pure intensities. The percentages of the iso-15:0 and *iso*-17:0 that were obtained using this method fell within the range reported previously [10, 25].

Results and Discussion

BCFA in Retail Milk

Figure 3 presents in summary form the major classes of FA found in the present retail milk samples. The sum of palmitic acid (16:0) and all other SFA with shorter chain lengths comprised about 51%, w/w (mean). SFA with 17 or more carbons were 12%, MUFA were about 30%, and polyunsaturated FA (PUFA) were 4.7%. These values are similar to those previously found for our similar comprehensive retail milk sampling [7].

BCFA comprised a total of 2.05 ± 0.14% of FA, or most of the 3% of FA listed previously as "other" [7]. The mean BCFA levels reported in the present study fall within the range previously reported in studies that measured cow's milk FA in response to various diets in small scale experimental studies [3–5, 8, 10].

Table 1 presents the mean proportions of BCFA in retail milk as %, w/w of total FA and as a % of total BCFA (mean ± SD). BCFA with 14–18 carbons and *iso*- or *anteiso*-configuration were detected, and no BCFA with

anteiso-17:0	0.61 ± 0.06	29.9 ± 2.0
iso-18:0	0.04 ± 0.02	1.9 ± 0.9

[a] *BCFA* branched chain fatty acids

[b] *FA* fatty acids

multiple branching were found. Four *iso*-BCFA (*iso*-C14:0 to *iso*-C17:0) were detected in all samples; low levels of *iso*-18:0 were also detected in most but not all of the samples. *anteiso*-15:0 and *anteiso*-17:0 were the only *anteiso*-BCFA found. They were in comparable concentration and constituted more than half of the total BCFA detected.

BCFA with fewer than 14 carbons, such as *iso*- and *anteiso*-13:0, were not detected in any of the samples. Both *iso*- and *anteiso*-13:0 BCFA in cow's milk have been reported by some [3, 5, 8, 11] but not by others [4, 6, 26]. In the present study, retail milk samples were obtained from processing plants and represent pooled milk from many farms; use of specific feeds on some farms that may support small amounts of ruminal C13 BCFA could be diluted to below detection limits by the milk from other farms [10, 27].

Neither phytanic acid, a product of released phytol from chlorophyll by rumen bacteria [28], nor its peroxisomal oxidation product pristanic acid [29], were detected in the retail milk. As with C13 BCFA, these terpenoid BCFA were reported to be present in bovine milk by some [11, 12] but not by others [3–6]. When reported, the variance of these BCFA was high, and it was suggested [12] that differing feed compositions are responsible for variable terpenoid metabolizing ruminal bacteria. As with the case of *iso*- and *anteiso*-13:0, it is possible that minor amounts of phytanic and pristanic acid were present in milk from some farms, but diluted to below detection limits when pooled with milk from many farms in the processing plant.

For comparison with bioactive FA found primarily in dairy products, rumenic acid (*cis*-9, *trans*-11–18:2), the most concentrated conjugated linoleic acid (CLA) in cow's milk, was 0.55%, in conventionally produced retail milk. Vaccenic acid (*trans*-11–18:1), the most concentrated *trans* monoene in cow's milk, was 1.48% in US retail milk, and the sum of all *trans* FA was about 3.1% [7]. Thus, both *anteiso*- BCFA are at the same levels in milkfat as rumenic acid, and total BCFA are more than half the concentration of total *trans*-FA.

Estimated Human BCFA Intake from Retail Milk

Based on these data, we can estimate the contribution of BCFA to the nutrition of Americans, using measured and estimated milk intake. One cup (244 g = 8 oz) of whole milk (3.25% milkfat) contains 7.9 g fat [30]. Two percent of 7.9 g yields a total of 158 mg BCFA per cup whole milk. For comparison to intake of bioactive FA in the American diet, this value is greater than the 100 mg average *daily* consumption of the DHA and eicosapentaenoic acid (EPA) reported in a survey of 8604 Americans between 1999 and 2000 [31] and by women of child bearing age based on NHANES III data [32].

In some population groups, such as small children, milk consumption can be higher. Consumption by small children of 2.6 servings of milk was reported recently, mostly consumed as whole milk [33]. This consumption would thus represent 412 mg BCFA daily, which would provide almost 1% of the total fat intake of children age 2–5 [34]. It thus appears that the absolute daily intake of BCFA from milk—even more so, the amount of BCFA consumed per kilogram body weight—will be higher in some populations, such as in small children.

Apart from milk, other foods produced by ruminant animals, specifically cheese and beef, are expected to be other primary contributors of BCFA to the diet. US cheese BCFA can be estimated from the present measures of milkfat BCFA of about 2% of FA. BCFA averaged about 2%, w/w in Canadian retail beef [35], and similar to Malaysia beef tallow with C13-C20 BCFA with mean concentration 2.3% (mutton tallow had 4.0% BCFA) [36]. We assume American beef has the same BCFA levels as in Canada, and an average 28 and 18% fat content in cheese and in beef, respectively [30]. According to economic disappearance data adjusted for loss, American's average per capita consumption of cheese is 30 g (1.1 oz), at about 28% fat on average and at about 2% BCFA, cheese contributes 168 mg of BCFA. Similarly, Americans consume 50 g (1.8 oz) of cooked beef per day [37]; at about 18% fat and about 2% BCFA, beef contributes about 180 mg of BCFA per day. Table 2 presents these values summed to estimate total current per capita intake of BCFA of about 400 mg per day from the most common ruminant foods.

We also consider the implications of dietary guidelines on BCFA consumption [38]. Americans are advised to consume three servings from the milk group, where a serving, for example, is equal to 1 cup of milk or yogurt and 1.5 oz (42 g, 2 slices) of cheese. For simplicity we assume this to be represented by the present average dietary pattern of milk intake in the US, which is 31% whole milk, 39% low fat (2%) milk, 14% lower fat (1%) milk, with the balance nonfat milk [37]. Using these values we estimate a weighted sum of the total BCFA intake from three servings of milk and cheese to be about 400 mg.

Table 2 Estimated mean daily branched chain fatty acids (BCFA) consumption per capita in the US, based on actual and recommended[a] consumption of milk, cheese, and beef

Food	Actual[a]		Recommended[a]	
	Portion (g)	BCFA[b] (mg)	Portion (g)	BCFA[b] (mg)
Milk[c]	119	54	215	98
Cheese[d]	30	168	53	297
Beef[e]	50	180	50	180
Total	199	402	318	575

Intake data estimation based on reference [37]

[a] Actual consumption reflects the current consumption from milk, cheese and beef by Americans, which falls below recommended levels from the milk food group. Recommended consumption represents the levels of BCFA consumption that would obtain if Americans were to consume recommended amounts from the milk food group, keeping the same existing patterns as the actual consumption. For beef, the actual consumption was considered as the recommended one. Thus, the same value for beef was used for both

[b] *BCFA* branched chain fatty acids

[c] Mean, per capita, milk consumption, based on the proportions currently consumed by Americans of 3.25, 2, and 1% milk

[d] Cheese types included in the analysis are the main cheeses consumed by Americans. An average of 28% fat was used for estimation [30]. Amounts are based on patterns of current consumption of cheese

[e] For cooked beef, an average of 18% fat was used for estimation [30]. Americans consume enough from the meat food group, thus the actual and the recommended consumption were the same

Beef, cheese and milk together account for an average estimated recommended intake of about 575 mg BCFA per capita per day (Table 2).

Use of 2 cups of whole milk in place of reduced or no fat milks and consuming 1 serving of cheese (42 g, 1.5 oz) while consuming the same amount of beef would bring total BCFA to 731 mg/day (316 mg from milk + 235 mg from cheese + 180 mg from beef). These consumption levels, then, would be higher than the 500 mg/d intake for DHA and EPA for the general population recommended by the American Dietetic Association [39], and more than double the 300 mg/d of DHA and EPA recommended by the World Health Organization in pregnancy and lactation [32].

These estimates show that daily BCFA intake is substantial and that current recommendations promote an increase in present intake, considerably higher than other bioactive FA. Unlike DHA and EPA, for instance, BCFA sources include a greater variety of common food items, principally products of ruminants, regularly consumed by non-vegans. The low level of interest in BCFA nutrition is remarkable considering their long-standing intake.

The American dietary guidelines recommend consumption of low fat dairy products, however studies provide no convincing evidence that increased whole milk consumption is harmful with respect to ischemic heart disease and ischemic strokes [40], or vascular disease and diabetes [41]. Some studies provide evidence that higher consumption of whole fat compared to reduced fat milk was associated with lower body mass index in preschool- and elementary school-age children and less weight gain in adults [33, 42, 43] and with lower incidences of anovulatory infertility [44]. Thus, the emergence of potential benefits of whole milk consumption may have a significant effect on BCFA intake in the US population, increasing BCFA consumption even more.

BCFA are synthesized in large amounts by human skin [45], comprise 29%, w/w, of the FA in vernix and are normal constituents of the healthy newborn gut [13]. A systematic shift in BCFA profile was observed between vernix and meconium of the same infant, implying that the fetal alimentary canal selectively metabolizes BCFA. In very recent work, feeding anoxic rat pups rat milk substitute containing a mixture similar to most BCFA found in the retail milk samples (*iso*-14:0, *anteiso*-15:0, *iso*-16:0, *anteiso*-17:0, *iso*-18:0, and *iso*-20:0) reduced the incidence of NEC compared to a control group (Ran-Ressler et al. unpublished data) and elevated mRNA levels of the intestinal, anti-inflammatory cytokine IL-10. BCFA are selectively incorporated into phospholipids of rat pup ileum and into human Caco-2 cells [46]. The risk reduction in NEC development may be linked to these observations.

BCFA function in the membranes is similar to *cis* unsaturated double bonds; both interfere with the ability of saturated hydrocarbon chains to pack tightly forming rigid extended structures. Old data show that an *E. coli* strain that lost the ability to desaturate saturated FA was restored to wild-type growth rates by the addition of BCFA [47]. Apoptotic properties of BCFA on human breast cancer cells are structure-specific, with *iso*-16:0 having the highest activity among BCFA of C12-C20 [48]. *iso*-15:0 inhibited tumor growth in cultured cells and in an in vivo (mouse) models with no obvious deleterious effects [49]. Thus, BCFA of the type found in US retail milk may have a beneficial effect on proper tissue function and on gut development and function.

In conclusion, we document for the first time the profile and amounts of BCFA in retail whole milk in the US. Milk BCFA have chain lengths of 14–18 carbons and include both *iso*- and *anteiso*-BCFA. BCFA comprise 2.05%, w/w of the FA in retail whole milk. Estimated BCFA levels in beef and data on per capita milk, cheese, and beef intakes indicate that BCFA intake on average is in excess than that of many bioactive FA. Their importance in the US food supply and bioactivity suggest that they should be more carefully studied for their biological effects.

Abstract Feeding flaxseed to cattle may be a means of increasing omega-3 fatty acid levels in ruminant products, but possible interactions with conserved forages have not been investigated. Twelve Holstein cows were used in a replicated 4 × 4 Latin Square experiment. Cows were fed one of four 50:50 forage:concentrate diets (DM basis): hay (hay control, HC), hay plus 15% ground flaxseed (hay-flaxseed, HF), barley silage (silage control, SC), and barley silage plus 15% ground flaxseed (silage-flaxseed, SF). Plasma concentrations of alpha-linolenic acid (ALA) did not differ between SC and HC diets. Flaxseed increased ALA ($P < 0.05$), but levels were not influenced by forage type. Flaxseed slightly increased 18:2n-6 ($P < 0.05$) and some n-6 and n-3 elongation and desaturation products, particularly arachidonic acid (ARA) and eicosapentaenoic acid (EPA). Flaxseed also increased C18:0 ($P < 0.05$) with this increase being greater ($P < 0.01$) for cows fed SF than HF. Feeding flaxseed also increased plasma C18:1-*trans* isomers ($P < 0.01$), predominantly vaccenic acid (VAA, 18:1-*t*11), with this increase being greater ($P < 0.05$) in cows fed HF than SF. Although conjugated linoleic acid (CLA) was increased ($P < 0.001$) with flaxseed it was not influenced by forage type ($P = 0.06$). Overall, feeding flaxseed increased plasma ALA, EPA, ARA and CLA independently of forage type. Feeding flaxseed with silage, however, resulted in more 18:0, while feeding flaxseed with hay resulted in greater accumulations of plasma 18:1-*trans* isomers mainly in the form of VAA.

Keywords Cow · Flaxseed · Omega-3 fatty acids · Conjugated linoleic acid

Abbreviations

ARA	Arachidonic acid
ADF	Acid detergent fiber
ALA	Alpha-linolenic acid
BD	Becton–Dickinson
CLA	Conjugated linoleic acid
CP	Crude protein
DHA	Decosahexaenoic acid
DM	Dry matter
DPA	Docosapen
EPA	Eicosapentaenoic acid
FAME	Fatty acid methyl esters
HC	Hay control
HF	Hay-flaxseed
LNA	Linoleic acid
MUFA	Monounsaturated fatty acids
NDF	Neutral detergent fiber
NE	Net energy
RUA	Rumenic acid
SC	Silage control
SF	Silage-flaxseed
VAA	Vaccenic acid

Introduction

Previous studies in cattle suggest that including flaxseed in diets increases plasma alpha-linolenic acid (ALA, 18:3n-3) levels [1–3] and its levels in beef [4, 5]. Health-promoting omega-3 (or n-3) fatty acids [6, 7] and conjugated linoleic acids (CLA) including rumenic acid (RUA, 18:2-*c*9,*t*11) [8] have been shown to increase in the fat of ruminants supplemented with flaxseed. Levels of ALA and CLA have also been shown to be increased by providing grass forage to ruminants [9], but it is less clear if this same response is achieved if the forage is conserved as silage [10]. Only a few studies have investigated the effect of dietary forage type on the fatty acid composition of ruminant products [11, 12], and evidence of an interaction between forage type and supplemental oil source has arisen with regard to their impact on the fatty acid composition of goats milk [13, 14].

In western Canada, silage and hay are the two most common forage sources available for feeding. It is possible that the epiphytic microbial populations associated with these forages as well as alterations in endogenous ruminal microbes could alter ruminal biohydrogenation of fatty acids, but studies that directly compare the effects of method of forage conservation on plasma fatty acids profiles in ruminants have not been conducted. In a recent study, differences in rumen microbial communities were found between cull cows fed a hay-based diet and those fed a silage-based diet [15]. Additionally, as compared to hay, ensiling may degrade antioxidants and alter plant secondary compounds in the forage, a factor that could also alter the biohydrogenation activity of rumen bacteria [16].

Plasma levels of functional fatty acids could serve as predictors of their accumulation in body tissues [17–19], a tool that could prove useful in the production of fatty acid enriched ruminant products. In Canada, forage finishing of beef is not common and mature, breeding cattle typically receive the greatest proportion of forage in their diet. Among the Canadian beef grades, cull cows are known to have the highest levels of CLA and omega-3 fatty acids and may present an economically viable opportunity to produce beef with enhanced levels of beneficial fatty acids [20]. Including flaxseed in cattle diets has generally not been that successful at increasing ALA or its partial hydrogenation products in beef due to the high efficiency of bacterial hydrogenation in the rumen [21]. Therefore, in the present experiment we hypothesized that the levels of 18:1-*trans*, CLA and omega-3 fatty acids in blood plasma of cull cows fed flaxseed would be lower in cows fed barley silage as compared to grass hay.

Materials and Method

Animals

The study was approved by the Animal Care Committee at Lethbridge Research Centre of Agriculture and Agri-food Canada with ACC#0837. Twelve non-lactating, non-pregnant Holstein dairy cows 849 ± 156 kg were used in a replicated 4 × 4 Latin Square design with four experimental diets and four 21-day experimental periods. Cows were housed in individual tie stalls. Cows were fed once daily (13:00 h) their total daily feed intake (DM basis). During each 21-days feeding period, days 1–4 was a diet transition period when the cows were fed mixed diets that gradually substituted ingredients to obtain the final diet composition for the next period by day 5. Ad libitum intake was estimated in the first week (days 1–7) and confirmed in the following 3 days. The intake was subsequently restricted to 90% of this estimate for the remainder of the period (days 11–21) to ensure complete consumption of diets.

Diets

Four experimental diets were arranged as a 2 × 2 factorial using either chopped grass hay or barley silage as the forage source with or without ground flaxseed which was substituted for steam-rolled barley grain (Table 1). Experimental diets were designated as hay control (HC), hay + flaxseed (HF), silage control (SC) or silage + flaxseed (SF). The diets were formulated at a 50:50 forage to concentrate ratio and fed as a total mixed ration (TMR). Flaxseed was fed at 15% of ration DM, so that total oil content of the diet accounted for approximately 6.5% of ration DM. It has been recommended that total dietary fat should not exceed 6–7% of dietary DM as a higher concentration of fat may reduce intake [22].

Flaxseed was premixed with barley in a ratio of 7:3 and subsequently ground through a 4-mm screen in a hammer mill. The ground material was screened, and whole flaxseeds recovered were estimated to account for approximately 2% of the flaxseed that was originally added to the diet. The distribution of hay particles as fed were 200 g/kg fine (0-mm), 290 g/kg short (1.19-mm), 250 g/kg medium (8-mm), and 260 g/kg long (19-mm). The experimental diets were supplemented with minerals and vitamins to meet nutrient requirements as described in NRC [22, 23]. The ingredient and nutrient compositions of diets are shown on Table 1. Levels of net energy (NE), neutral detergent fiber (NDF) and acid detergent fiber (ADF) in DM were similar among diets. The crude protein (CP) % in DM met or exceeded requirements [22, 23].

Table 1 Composition and nutrient content of experimental diets

	Treatment			
	Hay	Hay-flax	Silage	Silage-flax
Ingredient (%)				
Barley	47.37	32.74	29.28	20.17
Barley silage	0.00	0.00	67.80	68.20
Grass hay	47.91	48.36	0.00	0.00
Flaxseed	0.00	14.13	0.00	8.71
Supplement[a]	4.72	4.76	2.92	2.93
Nutrient				
Dry Matter (%)	87.76	88.58	54.24	54.56
Protein (% of DM)	13.65	15.39	12.64	14.37
NEm (Mcal/kg DM)	1.69	1.73	1.77	1.81
NEg (Mcal/kg DM)	1.06	1.08	1.15	1.17
NDF (% of DM)	33.09	30.39	33.32	30.63
ADF (% of DM)	19.66	19.96	18.39	18.69
Lipids (% of DM)	1.63	6.68	1.95	6.34

[a] The supplement was composed of: 56.5% barley, 10% canola meal, 2% urea, 25% limestone, 3% salt, 0.066% VIT E 500, 1% premix, 0.05% flavor and 2.5% molasses, which provided to diets in 5% (in DM) and supply to 1 kg diet (in DM) with additional: 14.67 mg copper, 58.32 mg zinc, 26.73 mg manganese, 0.66 mg iodine, 0.23 mg cobalt, 0.29 mg selenium, 4,825 IU vitamin A, 478 IU vitamin D and 32 IU vitamin E

Blood Sampling

One set of blood samples was collected before the start of the experiment. Blood samples were collected on day 14 and day 21 during each period (i.e., days 0, 14, 21, 35, 42, 56, 63, 77 and 84 days of the experiment) at 15:00 h, i.e. 2 h after the feeding. Blood samples were collected from the jugular vein using Becton–Dickinson (BD) evacuated tubes (NJ, USA) containing Na_2-EDTA. The tubes containing blood samples were kept in a cooler and transferred to the laboratory within 30 min. The blood samples were centrifuged at 2,000×*g* at 5 °C for 15 min. The upper layer of plasma was then collected and 1 mL was taken for extraction of lipids with the remainder stored in the freezer at −40 °C until analyzed.

Lipid Extraction

Plasma lipids were extracted using the procedures described previously [4, 24] with minor modifications. On occasions where the suppliers are not designated, chemicals were purchased from Sigma–Aldrich Canada. Plasma (1 mL) was transferred into a test tube and mixed with 4 mL of isopropanol. Tubes were vortexed each time after the addition of 4 mL hexane and 4 mL aqueous sodium sulfate (66.8 g/L) and the final mixture was centrifuged at 2,000×*g* at 5 °C for 5 min. The upper hexane layer was aspirated into a new tube and the extraction was repeated through adding hexane (4 mL). The hexane extraction was evaporated under nitrogen at 38 °C in a water bath. The remaining residue was stored in a freezer at −80 °C until further analysis.

Methylation and Determination of Fatty Acids

Nonadecanoic acid (19:0) methyl ester (100 μL, 5.96 mg/mL hexane Nu-Chek Prep, Inc., MN, USA) was added to the residues to serve as an internal standard. Fatty acids were methylated using the combined base/acid methylation procedure [25]. Sodium methoxide (2 mL, 0.5 mmol/L in methanol) was added as each tube was flushed with nitrogen and mixed. Tubes were placed in a 50 °C water bath for 10 min. Subsequently, boron trifluoride (1 mL; 14% in methanol) was added and tubes were placed in a water bath at 50 °C for 10 min. After cooling, 5 mL of water and 5 mL of hexane were added and the solution was thoroughly mixed. Samples were allowed to stand for 10 min and the upper layer (hexane) was transferred to a gas chromatography ampoule that was flushed with nitrogen for fatty acid determination. Fatty acid methyl esters (FAME) were quantified using a gas chromatograph (Hewlett Packard GC System 6890; Mississauga, ON, Canada) equipped with a flame ionization detector and SP-2560 fused silica capillary column (100 m × 0.25 mm × 0.2 μm, Supelco Inc., Oakville, ON, Canada). Samples were loaded onto the column via 1-μL splitless injections. The initial oven temperature (55 °C) was held for 0.5 min and then the following program was used: increased at 32 °C/min to 120 °C and held for 15 min, increased at 6 °C/min to 160 °C and held for 10 min, increased at 3 °C/min to 170 °C and held for 45 min, and increased at 7 °C/min to 240 °C and held for 33 min. The helium carrier gas flow rate through the column was 1.7 mL/min. Hydrogen flow to the detector was 34 mL/min, air flow was 320 mL/min and helium make-up gas flow rate was 29 mL/min. Peaks in the chromatograms were identified and quantified using pure methyl ester standards (Sigma–Aldrich Inc., Oakville, ON, Canada). The identification of unknown FAME of some *trans* 18:1 and combined CLA peaks were based on the references reported previously [26–28]. The amount of fatty acids was calculated based on the fatty acid standards and expressed as μmol/L of plasma.

Statistical Analysis

The MIXED procedure of SAS [29] was applied for comparison of diet effects on FAME plasma concentration and the dietary intake. Fixed effects included diets (flaxseed supplementation and forage type), sampling time

(i.e., day 14 and 21 of each period) and all interactions. Random effects included square and cow × square. The plasma concentration of FAME was the average of two sampling days (day 14 and 21) during each sampling period. There were no significant differences ($P > 0.05$) in plasma fatty acids level between these designated sampling days (data not shown). The correlation analysis was done with CORR procedure of SAS [29] on concentration of FAME between diet (mmol/kg DM) and plasma (μmol/L), or between FAME intake (mmol/day) and plasma concentration (μmol/L).

Results

Dietary Lipids and Fatty Acid Concentration

Dietary lipid content of HF and SF were 6.68 and 6.34% (wt%/DM), respectively, which was considerably higher than that in HC and SC diets which averaged 1.63 and 1.95%, respectively (Table 1). In HC and SC, linoleic acid (LNA, 18:2n-6) was the most abundant fatty acid accounting for 39.44 and 42.84 mol% of total FAME followed by ALA, palmitic acid (16:0) and oleic acid (18:1-*c*9), respectively (Table 2). Supplementation with flaxseed in HF and SF diets resulted in ALA accounting for 53.53 and 50.00 mol%, respectively, of total FAME while mol% of ALA in HC and SC diets were 19.76 and 14.43%, respectively.

Intake of Feed and Dietary Fatty Acids

Comparison of the DM and fatty acid intake of cows among treatments are shown in Table 3. No difference in DM intake was found among treatments, however, fatty acid intake did differ with flaxseed supplementation and forage type. Flax supplementation of hay- or silage-based diets (HF and SF) increased ($P < 0.001$) the intake of total and individual fatty acids as compared to the control diets (HC and SC).

In treatments supplemented with flaxseed (HF and SF), ALA accounted for more than half of the total fatty acid intake with 1,221.7 mmol/day in HF and 1,062.7 mmol/day in SF. In comparison, ALA intake in HC and SC groups was far lower ($P < 0.05$) at only 80.0 and 72.6 mmol/day, respectively (Table 3). Few differences in fatty acid intake were observed between HC and SC, with only minor ($P < 0.05$) differences being observed for palmitoleic (16:1-*c*9) and ARA.

Plasma Fatty Acid Concentrations

The plasma concentration of total FAME was higher ($P < 0.001$) in cows consuming diets supplemented with flaxseed (Table 4), resulting in a 1.39- and 1.49-fold increase in the HF and SF treatments, respectively. This response was also more pronounced ($P = 0.03$) in silage- than hay-based diets.

LNA and stearic acid (18:0) accounted for the majority of plasma fatty acids. LNA increased ($P < 0.01$) when cows were fed flaxseed and this was accompanied by increases in its elongation and desaturation product (20:4n-6; $P < 0.001$). A flaxseed level by forage type interaction ($P < 0.01$) was observed for C18:0. Flaxseed increased C18:0 when fed with hay, but the magnitude of this increase was even greater when it was fed in combination with barley silage. Interactions of a similar nature were also found for total SFA ($P < 0.01$).

Plasma concentrations of total polyunsaturated fatty acids (PUFA) and n-3 fatty acids were also greatly increased ($P < 0.001$) as a result of flaxseed supplementation, a response that was not affected by forage type ($P = 0.67$). The majority of the increase in n-3 was due to higher plasma concentrations of ALA ($P < 0.001$). Dietary effects on elongation and desaturation products of ALA were mixed. Plasma concentrations of EPA were higher ($P < 0.001$) when feeding flaxseed irrespective of forage type. Overall, flaxseed and forage type had very little affect on levels of DPA and EPA, although minor interactions were found for DPA ($P < 0.06$) and DHA ($P < 0.04$) with

the addition of flaxseed to the hay diet resulting in minor increases in the plasma concentration of these fatty acids relative to silage.

Total plasma monounsaturated fatty acids (MUFA) were higher ($P < 0.001$) in cows fed flaxseed. Feeding silage resulted in lower MUFA in plasma as compared to the hay diet ($P = 0.05$). A flaxseed level by forage type interaction was found for total *trans* FA (CLA + 18:1-*trans*; $P < 0.03$), with flaxseed causing an increase in total *trans* FA, and this increase being even more magnified with hay as compared to the silage diet. Similar interactions were found for total 18:1-*trans* ($P = 0.03$) and all individual C18:1-*trans* isomers ($P < 0.05$ for *t*6-*t*8, *t*9, VAA and $P = 0.07$ for *t*10). Feeding flaxseed increased plasma concentrations of CLA (combined 18:2 *c*9,*t*11 and 18:2 *t*7,*c*9), but a flaxseed level by forage type interaction was not observed ($P > 0.05$).

Correlations Between Dietary and Plasma Fatty Acids

There was very strong correlation ($P < 0.001$) between dietary concentrations (Correlation 1) or the daily intake (Correlation 2) of SFA, USFA, MUFA and PUFA in the diet (mmol/kg DM) and the plasma concentrations (μmol/L) of these fatty acids with coefficients ranging from 0.51 to 0.75 (Table 5). Among individual fatty acids, these two correlations were the highest with plasma concentrations of ALA ($r = 0.93$ or 0.91, respectively; $P < 0.0001$). There were also strong correlations ($P < 0.01$) between diet or daily intake and plasma concentrations of palmitoleic (16:1 *c*-9), stearic (18:0), oleic (18:1 *c*-9), *cis*-vaccenic (18:1 *c*-11) and LNA. No correlations between plasma concentration and dietary intake of palmitic (16:0, $P = 0.28$), arachidic (20:0, $P = 0.52$) and behenic (22:0, $P = 0.32$) and arachidonic (20:4, $P = 0.37$) acids were observed.

Discussion

Consumption of high omega-3 fatty acid containing foods is recommended as result of their potential benefits for cardiovascular health [30]. Dietary strategies have been employed to enrich the omega-3 content of poultry, pork and dairy products, but attempts to significantly increase the omega-3 fatty acid of beef have been largely unsuccessful. Generally the transfer of dietary omega-3 fatty acids to animal tissues in non-ruminants is more efficient than ruminants due to hydrogenation of unsaturated fatty acids by rumen microorganisms. Even horse adipose tissues contain much higher concentrations of omega-3 fatty acids than beef cattle when these herbivores are fed similar diets [31].

In the present study, dietary flaxseed increased total plasma concentrations of omega-3 fatty acids. This result

reflects the ability of some dietary ALA in flaxseed to escape hydrogenation in the rumen and be absorbed into the blood with potential delivery to tissues. These findings are consistent with earlier studies [2, 32, 33] in which the composition of omega-3 fatty acids were doubled when flaxseed or flax oil was added to cattle diets. In a study by Farran et al. [3], supplementation of crossbred heifers with 13% dietary flaxseed resulted in a plasma ALA concentration of 262.7 μg/mL plasma, a concentration that is comparable to that observed in our study. However, Doreau et al. [34] examined the effect of supplementing 7.5% flaxseed or flaxseed oil on dry cow plasma fatty acid profiles and found no increase in plasma omega-3 fatty acids.

The hydrogenation of ALA by rumen bacteria can be affected by the forage to concentrate ratio in the diet. The study of Doreau et al. [34] found the extent of ruminal hydrogenation of dietary ALA was 95% in the rumen of dry cows fed a 70% forage (60% silage and 10% hay) diet and up to 97% if the diet was supplemented with 7.5% flaxseed. In an in vitro study, Kronberg et al. [35] found that the 43% of ALA in flaxseed was hydrogenated, but protection with tannins reduced this to 13%. However, no significant differences were found in plasma LNA in steers consuming forage or grain based diets containing flaxseed when tannins were either included or excluded from the diet [34]. In the present experiment, feeding flaxseed

increased plasma levels of ALA, but forage type did not influence ALA levels (mean value 1,142 μmol/L). Consequently, the forages in our study appear to have a similar impact on fatty acid biohydrogenation, even though ensiling may alter the activity of some plant secondary compounds that could alter this process [21].

Among the long chain omega-3-fatty acids, the plasma concentration of EPA was the only fatty acid that was increased as a result of the addition of flaxseed to diet. This result may reflect the high plasma concentrations of ALA as it is the precursor for the formation of EPA via elongation and desaturation. Others have previously found that feeding flaxseed to steers increased levels of EPA and DPA in bovine muscle without altering levels of DHA [6]. High levels of ALA may reduce formation of DHA as both ALA and the precursor for DHA synthesis compete for desaturation via Δ6 desaturase [36].

Feeding flaxseed to monogastric and ruminant animals has the potential benefit of increasing omega-3 fatty acids in meat, and for ruminants this is also accompanied by increased levels of ALA hydrogenation products, some of which have reported effects on human health. RUA is typically the most abundant CLA isomer in beef and it has many purported beneficial health effects [8]. RUA is a product of hydrogenation of PUFAs in the rumen and in the body arises mainly from endogenous synthesis via dehydrogenation of 18:1-*trans* fatty acids including VAA [37]. Overall, feeding flax increased plasma CLA, but levels were not influenced by forage type. Feeding flaxseed combined with silage, however, promoted more complete hydrogenation of ALA (i.e., 18:0) while feeding flaxseed combined with hay resulted in greater accumulations of plasma 18:1-*trans*, mainly in the form of VAA.

With the Latin square design used in the present study, it was possible to track the plasma ALA changes of the same animal during the overall experiment when the four different diets were fed. The plasma ALA concentration reached the highest level on day 14 and thereafter reached a plateau for the remaining time that flaxseed was supplemented. When changed to the control diet, without flaxseed, plasma ALA levels declined to pre-supplementation levels within 14 days (data not shown). These results suggest that the plasma ALA level was directly influenced by dietary flaxseed supplementation. Plasma fatty acid levels may be affected not only by absorption, but also by endogenous lipid metabolism including incorporation of fatty acids into tissues and lipolysis releasing fatty acids from adipose tissue. In a study using lactating dairy cows [1], it was found that inclusion of formaldehyde-treated (11%) or untreated flaxseed (13%) in silage diets resulted in a similar increase in plasma omega-3 fatty acid levels with ALA accounting for about 15% of the total fatty acids in plasma. Based on the current and previous studies [1–3, 33] it is suggested that including flaxseed in the diet at levels that result in 6% total lipid in the diet will result in significant levels of ALA escaping the rumen.

In fattening animals, plasma fatty acids may be directly used for incorporation into adipose tissue. A strong positive correlation has been reported for wt% of ALA between plasma and fat tissue with a coefficient (r) of 0.88 ($P < 0.0001$), while no correlation was observed for LNA ($r = 0.13$, $P = 0.33$) [38]. These results were based on 64 cull cows (16 per treatment) fed hay- or silage-based diet supplemented with or without ground flaxseed for 12 weeks. Plasma levels of ALA could have value as predictors for accretion of this fatty acid in adipose tissue, likely because this fatty acid is considered essential in mammals.

In conclusion, the results from this study indicated that flaxseed supplementation in cattle diets can be used to increase plasma levels of beneficial fatty acids including ALA, EPA, VAA and CLA (combined RUA and 18:2-*t*7,c9), but there is no difference in ALA, EPA or RA when flaxseed is included in a barley silage versus a hay-based diet. Feeding flaxseed combined with hay, however, can lead to preferential accumulations of plasma VAA which is a precursor for CLA synthesis [37]. Elevated plasma levels of this fatty acid could increase its availability for incorporation into tissues resulting in a more desirable fatty acid profile in beef.

ORIGINAL ARTICLE

Identification and Ruminal Outflow of Long-Chain Fatty Acid Biohydrogenation Intermediates in Cows Fed Diets Containing Fish Oil

Piia Kairenius · Vesa Toivonen · Kevin J. Shingfield

Received: 20 May 2010 / Accepted: 7 April 2011 / Published online: 12 May 2011

Abstract The abundance of 20- to 24-carbon fatty acids in omasal digesta of cows fed grass silage-based diets supplemented with 0 (Control) and 250 g/day of fish oil (FO) was examined to investigate the fate of long-chain unsaturated fatty acids in the rumen. Complimentary argentation thin-layer chromatography and gas-chromatography mass-spectrometry analysis of fatty acid methyl esters and corresponding 4,4-dimethyloxazoline derivatives prepared from fish oil and omasal digesta enabled the structure of novel 20- to 22-carbon fatty acids to be elucidated. Compared with the Control, the FO treatment resulted in the formation and accumulation of 27 novel 20- and 22-carbon biohydrogenation intermediates containing at least one *trans* double bond and the appearance of *cis*-14 20:1, 20:2n-3, 21:4n-3 and 22:3n-6 not contained in fish oil. No conjugated ≥20-carbon fatty acids were detected in Control or FO digesta. In conclusion, fish oil in the diet results in the formation of numerous long-chain biohydrogenation intermediates in the rumen of lactating cows. Comparison of the intake and flow of 20-, 21- and 22-carbon fatty acids at the omasum in cows fed the Control and FO treatments suggests that the first committed steps of 20:5n-3, 21:5n-3 and 22:6n-3 hydrogenation in the rumen involve the reduction and/or isomerisation of double bonds closest to the carboxyl group.

Introduction

Clinical studies in human subjects have established that eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) exert anti-thrombotic and anti-arrhythmic properties, with evidence that long-chain n-3 fatty acids decrease cardiovascular disease risk and the incidence of myocardial infarction [1–3]. Ruminant-derived foods are a major source of lipid in the human diet [4], and therefore a number of studies have examined the use of fish oil in the diet of growing and lactating cattle to enhance the concentrations of 20:5n-3 and 22:6n-3 in meat [5] and milk [4, 6] to improve long-term human health. However, the potential to enrich 20:5n-3 and 22:6n-3 in milk fat and tissue lipids is limited due to extensive metabolism of long-chain n-3 fatty acids in the rumen. It is well established that 20:5n-3 and 22:6n-3 are hydrogenated extensively in the rumen in vivo [7–9] and disappear during incubations with rumen fluid in vitro [10–12], but the metabolic pathways involved and the intermediates formed are not known. Characterizing the fatty acids formed during the metabolism of long-chain n-3 fatty acids in the rumen is important to providing a more fundamental understanding of the mechanisms involved in the hydrogenation of long-chain

unsaturated fatty acids in the rumen and also offering an explanation for the decreases in tissue adipogenesis and mammary lipogenesis in ruminants fed diets containing fish oil.

Several techniques have been developed for the determination of lipid composition in ruminal digesta [13, 14]. No single method in isolation can provide a comprehensive assessment of the occurrence of fatty acids in biological samples and therefore a combination of techniques are required [14–16]. Previous studies examining the effect of fish oil on ruminal biohydrogenation have been based on the determination of lipid composition in digesta using a combination of gas chromatography (GC), gas-chromatography mass-spectrometry (GC–MS) and silver-ion high-performance liquid-chromatography (Ag^+-HPLC) analysis of fatty acid methyl esters (FAME) [7–9]. However, these techniques provide only limited information on the structure of fatty acids formed during ruminal biohydrogenation of long-chain unsaturated fatty acids. In order to characterise the intermediates formed during ruminal biohydrogenation of long-chain fatty acids in fish oil, the structure and composition of 20- to 24-carbon fatty acids in fish oil and the omasal digesta of cows fed grass-silage-based diets supplemented with 0 or 250 g/day of fish oil was determined. Fatty acids were identified based on the fractionation of FAME by Ag^+-TLC and GC–MS analysis of FAME and corresponding 4,4-dimethyloxazoline (DMOX) derivatives. Detailed analysis of fish oil and omasal digesta fatty acid composition combined with measurements of nutrient flow at the omasum provided the first quantitative estimates of ruminal long-chain fatty acid biohydrogenation intermediate outflow in lactating cows.

Materials and Methods

Materials

Samples of freeze-dried omasal digesta reconstituted from individual liquid, small and large particulate fractions according to indigestible marker concentrations to represent true digesta at the omasal canal were obtained from following the completion of an experiment with five cows fed grass-silage-based diets supplemented with 0 (Control) or 250 g/day of refined fish oil (FO; EPAX 3000 TG, Pronova Biocare, Aalesund, Norway) fed over consecutive 14-day experimental periods [7]. Reconstituted omasal digesta of cows fed the Control and FO treatments were stored at −80 °C under nitrogen until analysed for non-esterified fatty acids [7] or subjected to more extensive analysis of total lipid composition as described in the present paper. All chemicals and solvents were of analytical grade. Authentic reference FAME standards were purchased from Nu-Chek Prep (GLC #463; 21:0, #N-21-M; 23:0, #N-23-M; 24:0, #N-24-M; *trans*-11 20:1, #U-64-M; *cis*-12-21:1, #U-85-M; *cis*-14 23:1, #U-87-M; Elysian, MN), Larodan Fine Chemicals (18:4n-3, #10-1840; *cis*-9 20:1, #20-2001-1-4; 20:4n-3, #20-2024-1; 21:3n-3, #20-2103-1-4; 21:5n-3, #20-2105-1-4; *trans*-13 22:1, #20-2210-9; 22:5n-6, #20-2265-7; 23:5n-3, #20-2305-1-4; 24:5n-3, #20-2405-4; 25:0, #20-2500-7; 29:0, #20-2900-7; 9-O-18:0, #14-1800-5-4; 12-O-18:0, #14-1800-6-4; 13-O-18:0, #14-1800-7-4; 16-O-18:0, #14-1800-8-39; Malmö, Sweden) and Sigma-Aldrich (26:0, #H-6389; 27:0, #H-6639; 28:0, #O-4129; 30:0 #T-1902; mixture of 18:2n-6 isomers, #L-8404; mixture of conjugated 18:2 isomers, #O-5632; mixture of 18:3n-3 isomers, #L-6031; St. Louis, MO).

Lipid Extraction and Preparation of Fatty Acid Methyl Esters

Samples (200 mg) of freeze-dried reconstituted omasal digesta were transferred into 10 mL glass tubes. Following the addition of 0.5 mL distilled water and 1 mL of internal standard (tridecanoic acid, #13-A, Nu-Check Prep) dissolved in ethanol (0.1%, w/v), the pH was adjusted to 2.0 with 2 M hydrochloric acid. After mixing for 5 min, lipid was extracted in duplicate with a mixture of hexane and isopropanol (3:2, v/v) [17]. After rinsing with 2 mL of deionized water, organic extracts were combined, dried over 1 g anhydrous sodium sulphate and dried at 45 °C under a steady stream of nitrogen. FAME were prepared using a two-step base-acid catalysed procedure. Extracted lipid was dissolved in 2 mL of hexane and transesterified using sodium methoxide in methanol [18]. After drying over 1 g calcium chloride for 30 min, the organic soluble phase was transferred to a clean test tube, evaporated to dryness under a stream of nitrogen at 30 °C and incubated at 50 °C for 30 min with 1.5 mL of 1% (v/v) sulphuric acid in methanol [7]. After rinsing according to standard procedures, [7] FAME were dissolved in hexane prior to GC analysis and Ag^+-TLC.

Argentation Silver Ion Thin Layer Chromatography

Argentation-TLC of FAME prepared from total lipid in digesta was performed using Silica gel G plates (200 × 200 mm and 0.50 mm thickness, No. 1.13894; Merck, Darmstadt, Germany) impregnated with 5% (w/v) silver nitrate in acetonitrile for 20 min and activated at 110 °C for 45 min just before sample application. Plates were developed with a solvent comprised of hexane and diethyl ether (90:10 v/v) and the separated bands were visualized under UV light after spraying with a 0.2% (w/v) solution of 2′,7′-dichlorofluorescein in methanol [14, 19, 20]. Five bands separated according to the degree of

unsaturation and corresponding to methyl esters of saturated, *cis*-, and *trans*-monoenoic, dienoic and polyenoic fatty acids containing three or more double bonds were removed individually from the plate and transferred to clean test tubes. Fractionated FAME were recovered from the silica after addition of 1 mL methanol, 2 mL of hexane and 1 mL of 6% (w/v) aqueous sodium chloride [21] and the hexane soluble phase was dried over anhydrous sodium sulphate. Each FAME fraction was submitted for GC and GC–MS analysis and converted to DMOX derivatives.

Preparation of 4,4-Dimethyloxazoline Derivatives

Samples of total and fractionated FAME were converted to DMOX derivatives by incubation overnight with 250 μL of 2-amino, 2-methyl, 1-propanol under a nitrogen atmosphere [22] at 170 °C. Once cooled, the reaction mixture was dissolved with 5 mL of a mixture of diethyl ether and hexane (1:1 v/v) and rinsed with 5 mL of distilled water. The organic phase was recovered, transferred to a clean tube and the extraction was repeated using 2 mL of the diethyl ether and hexane solvent mixture. Both organic extracts were combined, washed with 3 mL of distilled water, dried over anhydrous sodium sulphate, centrifuged and evaporated to dryness under nitrogen at 30 °C (http://lipidlibrary.aocs.org/ms/ms02/index.htm). Once prepared, DMOX derivatives were dissolved in hexane and analysed by GC–MS.

GC and GC–MS Analysis

Total FAME profile in a 2 μL sample at a split ratio of 1:50 was determined with a gas chromatograph (6890, Hewlett-Packard, Wilmington, DE) equipped with a flame ionization detector and a 100-m CP-Sil 88 fused silica capillary column (Chrompack, Middelburg, The Netherlands) using a temperature gradient program and hydrogen as the carrier gas operated at constant pressure (137.9 kPa) at a flow rate of 0.5 mL/min [7].

Mass spectra of FAME and DMOX derivatives were obtained using the same type of gas chromatograph and column used for analysis of FAME composition equipped with a selective quadrupole mass detector (model 5973 N, Agilent Technologies, Wilmington, DE) connected to a dedicated computer with ChemStation software installed. The mass spectrometer was operated at 230 °C in the electron impact ionization mode, and mass spectra were recorded under an ionization energy of 70 eV. The injector (split ratio of 1:50) and interface temperatures were maintained at 255 and 240 °C, respectively. Total DMOX profiles in a 4 μL sample volume were determined using helium as a carrier gas operated at constant pressure (142.6 kPa) at a flow rate of 0.6 mL/min and the same temperature gradient program applied for the analysis of FAME by GC.

Interpretation of mass spectra were performed according to established guidelines [23, 24]. Electron impact ionization spectra of DMOX derivatives were used to locate double bonds based on atomic mass unit distances (amu), with an interval of 12 amu between the most intense peaks of clusters of ions containing n and n − 1 carbon atoms being interpreted as cleavage of the double bond between carbon n and n + 1 in the fatty acid moiety. In addition, odd numbered fragments at *m*/*z* 139, 153 and 167 accompanied by even mass ions at *m*/*z* 138, 152 and 166 were used as diagnostic ions to locate double bonds at Δ4, Δ5 and Δ6, respectively [25–27]. When available, deduced fatty acid structure was verified by comparison with the mass spectrum of DMOX derivatives prepared from authentic FAME standards, reports in the literature [22, 25–27], and cross-referencing with an online reference spectra library (http://lipidlibrary.aocs.org/ms/masspec.html). Since GC–MS analysis of DMOX derivatives does not discriminate between geometric isomers, double bond geometry of monoenoic fatty acids was confirmed based on the appearance of FAME in bands separated by Ag^+-TLC. Fractionation of FAME by Ag^+-TLC did not resolve dienoic, trienoic, tetraenoic, pentaenoic and hexaenoic fatty acids, and therefore a *cis* or *trans* double bond configuration for fatty acids containing two or more double bonds was inferred based on comparisons of retention times of methyl esters in samples with authentic FAME standards and the known elution order of geometric isomers of 18:2n-6 and 18:3n-3 methyl esters (L-8404 and L-6031, Sigma-Aldrich) on a 100 m CP Sil 88 capillary column [28, 29].

Statistical Analysis

Differences in fatty acid flow at the omasum and ruminal fatty acid balance between the control and FO treatments were evaluated statistically by a paired *t* test (SAS® Systems, Release 9.2, SAS Institute, Cary, NC). A 95% confidence interval was used as the default for the hypothesis test and assumptions of data normality were validated using the univariate procedure (SAS® Systems). Differences at $P < 0.05$ were considered significant.

Results

Analysis of FAME by GC revealed the occurrence of a complex mixture of 20- to 22-carbon fatty acids in fish oil and omasal digesta of cows on the FO treatment eluting between 42.5 and 53.9 min (Figs. 1, 2, 3, 4). Relative abundance of long-chain methyl esters prepared from total

lipid in omasal digesta of cows on the FO diet was almost identical to the profile of FAME in the non-esterifed fatty acid fraction [7] (data not presented).

Development of TLC plates with hexane and diethyl ether allowed 18-, 20-, and 22-carbon *cis*-monoenoic isomers to be resolved from *trans*-monoenoic methyl esters, but did not result in the complete separation of methyl esters of long-chain dienoic and trienoic fatty acids. In total, five distinct bands comprised of saturated, *trans*- and *cis*-monoenoic, di- and trienoic species were recovered, while methyl esters of ≥18-carbon polyenoic fatty acids containing four or more double bonds remained at or near the origin (data not presented).

Initial identification of fatty acid carbon chain length and number of double bonds in fish oil and omasal digesta was based on GC–MS analysis of FAME. Appearance of 20:1, 20:2, 20:3, 20:4, 20:5, 21:3, 21:4, 21:5, 22:1, 22:2,

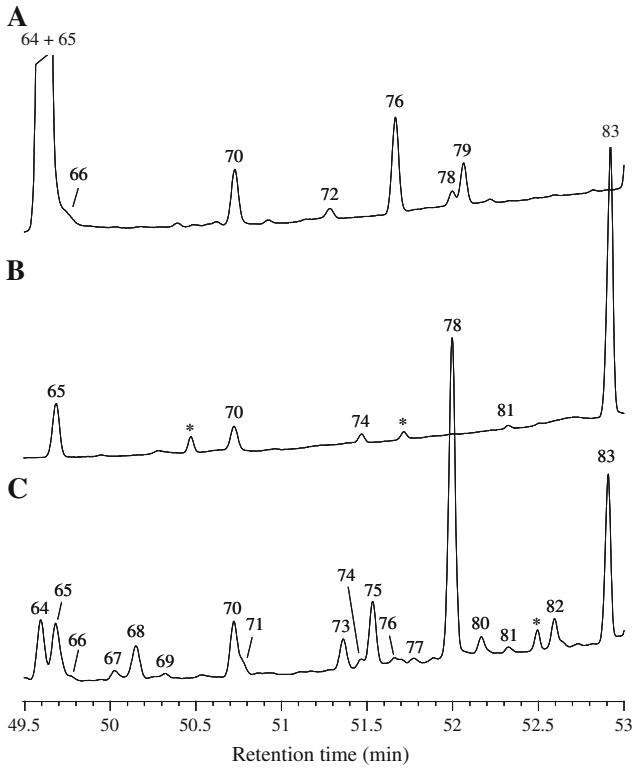

Fig. 3 Partial gas chromatogram indicating the separation of FAME prepared from total lipids in **a** refined fish oil and **b**,**c** omasal digesta of cows fed grass silage-based diets supplemented with 0 (**b**) or 250 g/day (**c**) of refined fish oil. Peaks were identified based on GC–MS analysis of 4,4-dimethyloxaline derivatives prepared from FAME fractionated by Ag^{+}-TLC. Molecular ions and key diagnostic ion fragments recorded during GC–MS analysis used to identify carbon chain length and locate the position of double bonds of unsaturated fatty acids are listed in Table 1. Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic methyl ester standards. Peak identification: *64*, *cis*-5, *cis*-8, *cis*-11, *cis*-14, *cis*-17 20:5; *65*, 24:0; *66*, (*cis*)-10, (*trans*)-14, (*cis*)-19 22:3; *67*, *cis*-10, *cis*-13, *cis*-16 22:3; *68*, (*trans*)-12, (*cis*)-16, (*cis*)-19 22:3; *69*, unresolved *cis*-9, *cis*-12, *cis*-15, *cis*-18 21:4 and *cis*-11 24:1; *70*, *cis*-15 24:1; *71*, *cis*-13, *cis*-16, *cis*-19 22:3; *72*, *cis*-7, *cis*-10, *cis*-13, *cis*-16 22:4; *73*, (*trans*)-10, (*trans*)-13, (*cis*)-16, (*cis*)-19 22:4; *74*, 25:0; *75*, (*trans*)-8, (*cis*)-13, (*cis*)-16, (*cis*)-19 22:4; *76*, *cis*-6, *cis*-9, *cis*-12, *cis*-15, *cis*-18 21:5; *77*, (*cis*)-7, (*trans*)-13, (*cis*)-16, (*cis*)-19 22:4; *78*, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:4; *79*, *cis*-4, *cis*-7, *cis*-10, *cis*-13, *cis*-16 22:5; *80*, 10-O-16:0; *81*, *cis*-16 25:1; *82*, (*trans*)-5, (*cis*)-10, (*cis*)-13, (*cis*)-16, (*cis*)-19 22:5; *83*, 26:0; *asteriks*, unidentified peaks

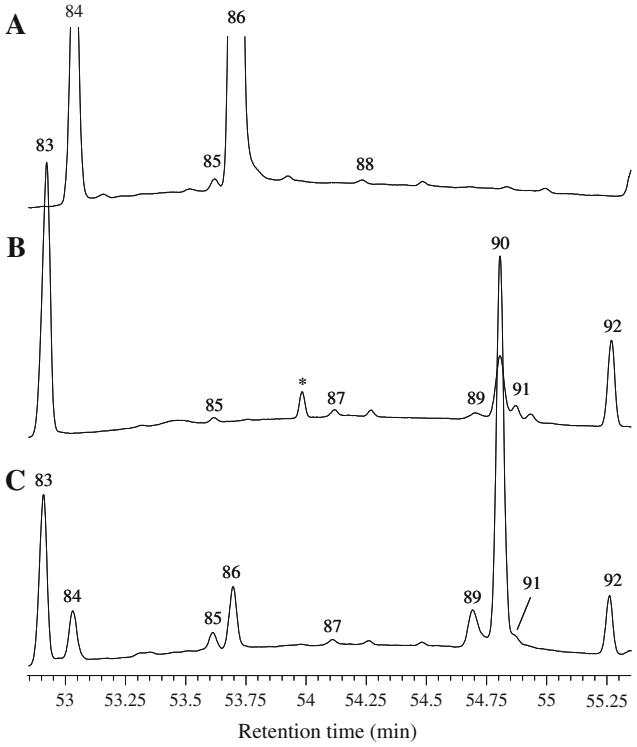

Fig. 4 Partial gas chromatogram indicating the separation of FAME prepared from total lipids in **a** refined fish oil and **b**,**c** omasal digesta of cows fed grass silage-based diets supplemented with 0 (**b**) or 250 g/day (**c**) of refined fish oil. Peaks were identified based on GC–MS analysis of 4,4-dimethyloxaline derivatives prepared from FAME fractionated by Ag^{+}-TLC. Molecular ions and key diagnostic ion fragments recorded during GC–MS analysis used to identify carbon chain length and locate the position of double bonds of unsaturated fatty acids are listed in Table 1. Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic methyl ester standards. Peak identification: *83*, 26:0; *84*, *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5; *85*, *cis*-17 26:1; *86*, *cis*-4, *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:6; *87*, 27:0; *88*, *cis*-8, *cis*-11, *cis*-14, *cis*-17, *cis*-20 23:5; *89*, unresolved 10-OH-18:0 and 9-O-18:0; *90*, 10-O-18:0; *91*, 13-O-18:0; *92*, 28:0; *asterisks*, unidentified peaks

22:3, 22:4, 22:5, 22:6, 23:5, 24:5 and 24:6 methyl esters was confirmed based on molecular ions at *m*/*z* 324, 322, 320, 318, 316, 334, 332, 330, 352, 350, 348, 346, 344, 342, 358, 372 and 370, respectively. However, the mass spectra of FAME did not contain sufficient characteristic ion fragments to allow the position of double bonds to be located. Therefore, the structure of long-chain fatty acids contained in fish oil and omasal digesta were formally identified based on GC–MS analysis of DMOX derivatives. Selected regions of the total ion chromatogram for DMOX derivatives prepared from total lipid in omasal digesta of cows fed the FO treatment are shown in Figs. 5 and 6. Separation and relative retention of DMOX derivatives during GC–MS analysis was comparable to that obtained for FAME by GC analysis, but the elution order of certain peaks differed. For example, during the analysis of DMOX derivatives 18:3n-3 eluted after *cis*-13 20:1 and 22:0 eluted before *cis*-9, *trans*-11, *cis*-15 18:3, *cis*-14, *cis*-17 20:2 and *trans*-9, *trans*-14, *trans*-17 20:3 (Fig. 5), whereas the reverse was true during the analysis of methyl esters (Fig. 1). Relative retention times of *trans*-11, *cis*-14, *cis*-17 20:3, 20:3n-3, 20:5n-3, *cis*-11 22:1, *cis*-13 22:1, *cis*-15 22:1, *trans*-12, *trans*-17 22:2, Δ10,13,17 22:3, *trans*-10, *trans*-13, *cis*-16, *cis*-19 22:4, 22:4n-3, *trans*-5, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5, 23:0, 24:0, *cis*-16 25:1 and 26:0

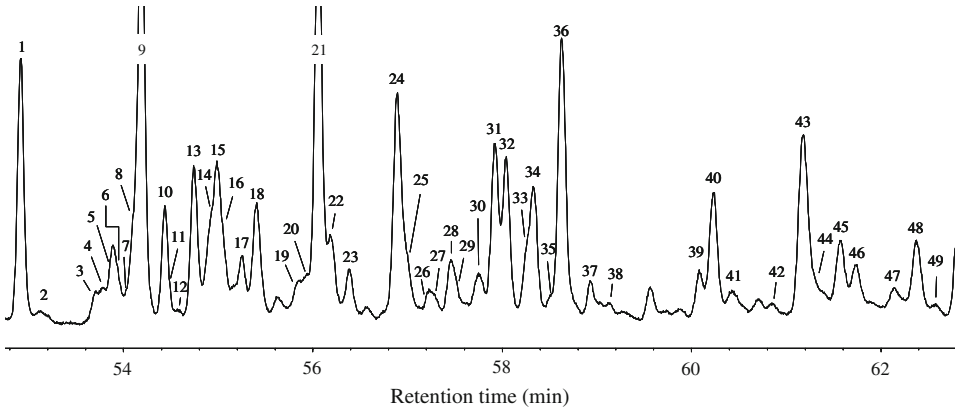

Fig. 5 Partial total ion mass chromatogram of 4,4-dimethyloxaline derivatives prepared from total lipids in omasal digesta of cows fed grass silage-based diets supplemented with 250 g/day of refined fish oil. Molecular ions and key diagnostic ion fragments recorded during GC–MS analysis used to identify unknown peaks are listed in Table 1. Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic methyl ester standards. Corresponding peaks in the partial gas chromatograms for FAME (Figs. 1–3) are indicated in parenthesis. Peak identification: *1*, 20:0 (#1); *2*, Δ7,9-17:2 (#2); 3, unresolved *trans*-9 20:1 and *trans*-10 20:1 (#4); *4*, *trans*-11 20:1 (#6); *5*, *trans*-12 20:1 (#7); *6*, *trans*-13 20:1 (#8); *7*, *trans*-14 20:1 (#10); *8*, *trans*-15 20:1 (#12); *9*, *cis*-11 20:1 (#13); *10*, *cis*-13 20:1 (#15); *11*, *cis*-9, *cis*-12, *cis*-15 18:3 (#14); *12*, *cis*-14 20:1 (#16); *13*, *cis*-9, *trans*-11 18:2 (#17); *14*, unresolved *cis*-11, *trans*-13 18:2 and *trans*-11, *trans*-15 20:2 (#20); *15*, unresolved *trans*-10, *cis*-12 18:2, *cis*-16 20:1 and *trans*-9, *trans*-15 20:2 (#21 and #22); *16*, *trans*-10, *trans*-16 20:2 (#24); *17*, *trans*-13, *trans*-17 20:2 (#26); *18*, *trans*-11, *cis*-15 20:2 (#27); *19*, unresolved conjugated 18:2 isomers and *trans*-11, *cis*-17 20:2 (#31 and #33); *20*, *cis*-10, *trans*-15 20:2 (#32); *21*, *trans*-13, *cis*-17 20:2 (#35); *22*, *cis*-11, *cis*-14 20:2 (#37); *23*, *trans*-14, *cis*-17 20:2 (#38); *24*, 22:0 (#42); *25*, unresolved *cis*-9, *trans*-11, *cis*-15 18:3 and *cis*-14, *cis*-17 20:2 (#39 and #40); *26*, (*trans*)-9, (*trans*)-14, (*trans*)-17 20:3 (#41); *27*, (*trans*)-10, (*trans*)-14, (*trans*)-17 20:3 (#43); *28*, (*cis*)-10, (*trans*)-14, (*trans*)-17 20:3 or (*trans*)-10, (*cis*)-14, (*trans*)-17 20:3 (#44); *29*, (*cis*)-11, (*trans*)-14, (*trans*)-17 20:3 or (*trans*)-11, (*cis*)-14, (*trans*)-17 20:3 (#45); *30*, (*cis*)-11, (*cis*)-14, (*trans*)-17 20:3 (#47); *31*, unresolved (*trans*)-10, (*trans*)-14, (*cis*)-17 20:3 and Δ11,14,18-20:3 (#48 and #49); *32*, *cis*-11 22:1 (#51); *33*, *cis*-13 22:1 (#52); *34*, (*trans*)-11, (*cis*)-14, (*cis*)-17 20:3 (#50); *35*, *cis*-15 22:1 (#54); *36*, *cis*-11, *cis*-14, *cis*-17 20:3 (#53); *37*, 23:0 (#57); *38*, *trans*-12, *trans*-17 22:2 (#56); *39*, (*trans*)-7, (*cis*)-11, (*cis*)-14, (*cis*)-17 20:4 (#58); *40*, *cis*-8, *cis*-11, *cis*-14, *cis*-17 20:4 (#59); *41*, unresolved *cis*-13, *cis*-16 22:2 and *cis*-14 23:1 (#60 and #61); *42*, *cis*-12, *cis*-15, *cis*-18 21:3 (#62); *43*, 24:0 (#65); *44*, Δ10,13,17-22:3 (#63); *45*, *cis*-5, *cis*-8, *cis*-11, *cis*-14, *cis*-17 20:5 (#64); *46*, (*cis*)-10, (*trans*)-14, (*cis*)-19 22:3 (#66); *47*, *cis*-10, *cis*-13, *cis*-16 22:3 (#67); *48*, (*trans*)-12, (*cis*)-16, (*cis*)-19 22:3 (#68); *49*, unresolved *cis*-9, *cis*-12, *cis*-15, *cis*-18 21:4 and *cis*-11 24:1 (#69)

were also found to differ when analysed as a methyl ester or DMOX derivative.

Characteristic ion fragments in the mass spectrum of DMOX derivatives used to locate the position of double bonds of 20-, 21- and 22-carbon unsaturated fatty acids in Control and FO omasal digesta are listed in Table 1. Spectra of all DMOX derivatives contained prominent ions at *m*/*z* at 113 and 126 (Table 1). A prominent fragment at *m*/*z* at 113 arises from a McLafferty rearrangement ion formed by the migration of the γ-hydrogen followed by cleavage between carbon atoms 2 and 3, while the abundant ion at *m*/*z* at 126 is thought to be formed due to cyclization-displacement reaction and cleavage between carbon atoms 4 and 5 [25]. Molecular ions of DMOX derivatives at *m*/*z* 363, 361, 359, 357, 355, 373, 371, 369, 391, 389, 387, 385, 383 and 381 confirmed a 20:1, 20:2, 20:3, 20:4, 20:5, 21:3, 21:4, 21:5, 22:1, 22:2, 22:3, 22:4, 22:5 and 22:6 structure, respectively. GC–MS analysis of DMOX derivatives revealed the appearance of several 20-carbon unsaturated fatty acids in FO omasal digesta not contained in fish oil or Control digesta (Table 2). Comparisons of 20-carbon unsaturated fatty acids in fish oil with Control and FO omasal digesta indicated that fish oil in the diet of lactating cows was associated with the formation of *cis*-14 20:1, several position and geometric 20:2 ($n = 10$) and 20:3 ($n = 8$) isomers and an unusual 20:4 isomer (Table 2).

The mass spectrum of the DMOX derivative of the unusual 20:4 intermediate in FO digesta contained four ions separated by 12 amu gaps at *m*/*z* 168 and 180; 222 and 234; 262 and 274; 302 and 314 (Fig. 7a) locating double bonds at positions Δ7, Δ11, Δ14 and Δ17, respectively. A prominent ion at *m*/*z* 208 that represents cleavage between carbon atoms at the 8 and 9 position corroborated a di-methylene-interupted ethylenic bond system [30], and confirmed the position of the first double bond between carbon atom 6 and 7 and the Δ7,11,14,17 20:4 structure. During GC analysis Δ7,11,14,17 20:4 eluted before 20:4n-3 (Fig. 2) indicating that this intermediate contains at least one *trans* double bond. Furthermore, the occurrence of a double bond between carbon atom 7 and 8 rather between carbon 8 and 9 as for 20:4n-3 and 20:5n-3, which share an all *cis* methylene-interrupted (homo-allylic) molecular structure provided further evidence to support the identification of *trans*-7, *cis*-11, *cis*-14, *cis*-17 20:4.

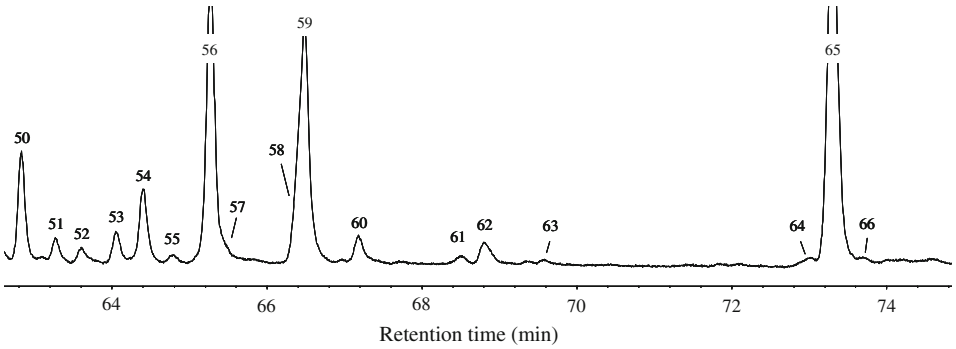

Fig. 6 Partial total ion mass chromatogram of 4,4-dimethyloxaline derivatives prepared from total lipids in omasal digesta of cows fed grass silage-based diets supplemented with 250 g/day of refined fish oil. Molecular ions and key diagnostic ion fragments recorded during GC–MS analysis used to identify unknown peaks are listed in Table 1. Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic methyl ester standards. Corresponding peaks in the partial gas chromatograms for FAME (Figs. 3, 4) are indicated in parenthesis. Peak identification: *50*, *cis*-15 24:1 (#70); *51*, *cis*-13, *cis*-16, *cis*-19 22:3 (#71); *52*, 25:0 (#74); *53*, (*trans*)-10, (*trans*)-13, (*cis*)-16, (*cis*)-19 22:4 (#73); *54*, unresolved (*trans*)-8, (*cis*)-13, (*cis*)-16, (*cis*)-19 22:4 and *cis*-6, *cis*-9, *cis*-12, *cis*-15, *cis*-18 21:5 (#75 and #76); *55*, (*cis*)-7, (*trans*)-13, (*cis*)-16, (*cis*)-19 22:4 (#77); *56*, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:4 (#78); *57*, *cis*-16 25:1 (#81); *58*, unresolved 10-O-16:0 and (*trans*)-5, (*cis*)-10, (*cis*)-13, (*cis*)-16, (*cis*)-19 22:5 (#80 and #82); *59*, 26:0 (#83), *60*, *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5 (#84); *61*, *cis*-17 26:1 (#85); *62*, *cis*-4, *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:6 (#86); *63*, 27:0 (#87); *64*, unresolved 10-OH-18:0 and 9-O-18:0 (#89); *65*, 10-O-18:0 (#90) and *66*, 13-O-18:0 (#91)

Eight 20:3 isomers were detected in FO omasal digesta (Table 2). Recorded mass spectra of DMOX derivatives of all detected 20:3 isomers enabled the basic structure of these intermediates to be characterized. The mass spectrum of the DMOX derivative of Δ9, 14, 17, 20:3 (Fig. 7b) contained ions at *m*/*z* 196, 208, 264, 276, 304 and 316, separated by a series of ions 14 amu apart (Table 1) defining the position of double bonds in the fatty acid moiety at Δ9, Δ14 and Δ17. For isomers of Δ10,14,17 20:3, double bonds were located based on 12 amu intervals between ion fragments at *m*/*z* 210, 222, 264, 276, 304 and 316 (Table 1). The position of the first double bond at Δ10 was corroborated by an abundant ion at *m*/*z* 250 formed by cleavage between carbon 12 and 13 (Fig. 7c). Double bonds in geometric isomers of Δ11,14,17 20:3 were located based on 12 amu gaps at *m*/*z* 224, 236, 264, 276, 304 and 316 (Table 1) and a molecular ion at *m*/*z* 359 (Fig. 7d). A Δ11,14,17 20:3 structure was verified by comparison with published spectra [22]. Omasal digesta of cows fed fish oil also contained Δ11,14,18 20:3 (Table 2). Double bonds at Δ11, Δ14 and Δ18 were located based on ion fragments at *m*/*z* 224, 236, 264, 276, 318 and 330 (Table 1), while an abundant ion at *m*/*z* 304 attributable to cleavage between carbon atom 15 and 16 confirmed the occurrence of a bis-methylene-interrupted double bond system. During GC analysis of FAME two Δ10,14,17 20:3 and a Δ11,14,17 20:3 intermediate were found to elute before 20:3n-6, while other geometric Δ11,14,17 20:3 isomers, and a Δ10,14,17 20:3 and Δ11,14,18 20:3 intermediate eluted after 20:3n-6 but before 20:3n-3 (Fig. 2), indicating that all unique 20:3 isomers in FO omasal digesta contained at least one *trans* double bond. Relative retention and elution order of geometric 18:3n-3 methyl esters (*trans*-9, *trans*-12, *trans*-15 18:3 unresolved *trans*-9, *cis*-12, *trans*-15 and *cis*-9, *trans*-12, *trans*-15 18:3, unresolved *trans*-9, *trans*-12, *cis*-15 and *cis*-9, *cis*-12, *trans*-15 18:3, *cis*-9, *trans*-12, *cis*-15 18:3 and *trans*-9, *cis*-12, *cis*-15 18:3) [28, 29] enabled the tentative identification of *trans*-9, *trans*-14, *trans*-17 20:3, *trans*-10, *trans*-14, *trans*-17 20:3, *cis*-11, *cis*-14, *trans*-17 20:3, *trans*-10, *trans*-14, *cis*-17 20:3 and *trans*-11, *cis*-14, *cis*-17 20:3 in FO omasal digesta.

Inclusion of fish oil in the diet was also associated with the appearance of several 20:2 biohydrogenation intermediates in omasal digesta (Table 2). Mass spectrum of DMOX derivatives enabled the structure of Δ9,15 20:2, Δ10,15 20:2, Δ10,16 20:2, Δ11,15 20:2, Δ13,17 20:2 (Fig. 7e) and Δ14,17 20:2 to be identified. Double bonds were located based on 12 amu intervals between ions at *m*/*z* 196, 208, 278 and 290; 210, 222, 278 and 290; 210, 222, 292 and 304; 224, 236, 278 and 290; 252, 264, 306 and 318; 266, 278, 306 and 318, respectively (Table 1). Abundant ions at *m*/*z* 264 and 292 that represent the cleavage between carbon atom 12 and 13 and between carbon atom 14 and 15, respectively, confirmed the Δ11,15 20:2 (Table 1) and Δ13,17 20:2 structure (Fig. 7e). Elution order of 20:2 intermediates relative to 20:2n-6 and 20:2n-3 during GC analysis in combination with the relative retention of geometric 18:2n-6 methyl esters (*trans*-9, *trans*-12 18:2, *cis*-9, *trans*-12 18:2, *trans*-9, *cis*-12 18:2 and *cis*-9, *cis*-12 18:2 [28, 29]) enabled *trans*-9, *trans*-15 20:2, *trans*-10, *trans*-16 20:2, *trans*-13, *trans*-17 20:2, *trans*-11, *cis*-15 20:2, *cis*-10, *trans*-15 20:2, *trans*-11, *cis*-17 20:2, *trans*-13, *cis*-17 20:2 and *trans*-14, *cis*-17 20:2 to be identified.

Table 1 Characteristic ion fragments recorded during gas-chromatography mass-spectrometry (GC–MS) analysis of 4,4-dimethyloxazoline derivatives of selected 20- and 22-carbon unsaturated fatty acids in omasal digesta of cows fed grass silage-based diets supplemented with 250 g/day of refined fish oil

Fatty acid	RT[a] (min)	RT[b] (min)	Characteristic ion fragments (*m/z*, relative intensity)

Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of fatty acid methyl esters (FAME) during GC analysis relative to authentic methyl ester standards

[a] Retention time of FAME on a 100 m CP-Sil 88 fused silica capillary column using a temperature gradient program [7] and hydrogen as the carrier gas operated at constant pressure (137.9 kPa) at a flow rate of 0.5 mL/min

[b] Retention time of 4,4-dimethyloxazoline derivatives of fatty acids on a 100 m CP-Sil 88 fused silica capillary column using a temperature gradient program [7] and helium as the carrier gas operated at constant pressure (142.6 kPa) at a flow rate of 0.6 mL/min

Omasal digesta from cows fed both the Control and FO treatments contained several positional isomers of 20:1 (Table 2). Mass spectra of DMOX derivatives of 20:1 isomers allowed the position of double bonds at Δ9, Δ10, Δ11, Δ12, Δ13, Δ14 and Δ15 to be localized readily by ions at *m/z* 196, 208; 210, 222; 224, 236; 238, 250; 252, 264; 266, 278; 280 and 292, respectively (Table 1). Separation of FAME by Ag^+-TLC along with retention times during GC analysis (Fig. 1) confirmed that all 20:1 isomers unique to omasal digesta contained a *trans* double bond. Inclusion of fish oil in the diet also resulted in the appearance of *cis*-11, -13, -14 and -15 20:1 in FO omasal digesta (Table 2).

Characterization of 22-carbon unsaturated fatty acids in fish oil and omasal digesta of cows fed the control and FO treatment revealed that the inclusion of 22-carbon unsaturated fatty acids from fish oil was associated with the formation of several novel 22:2 ($n = 1$), 22:3 ($n = 3$), 22:4 ($n = 3$) and 22:5 ($n = 1$) intermediates in the rumen (Table 3).

The spectrum of the DMOX derivative of the 22:5 intermediate contained ion fragments with a mass interval of 12 amu at *m/z* 208, 220, 234, 248, 260, 274, 288, 300, 314, 328 and 340 that were separated by gaps of 14 amu (Fig. 8a), which enabled four of the five double bonds to be located at Δ10, Δ13, Δ16, and Δ19, respectively [25, 26]. The position of the final double bond between carbon atoms 4 and 5 was discerned based on the presence of ions at *m/z* 153, 166 and 180 (Table 1), and an even ion at *m/z* 152 (Fig. 8a) in the mass spectrum that served as characteristic fragments of a double bond in the Δ5 position [22, 26, 27] allowing the Δ5,10,13,16,19 22:5 structure to be elucidated. During GC analysis of FAME Δ5,10,13,16,19 22:5 eluted after 22:5n-6 but before 22:5n-3, which combined with considerations on the methylene-interrupted

Table 2 Mean concentration of 20- and 21-carbon fatty acids in refined fish oil and omasal digesta of lactating cows fed grass silage-based diets supplemented with 0 (Control) or 250 g/day of refined fish oil (FO)

Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic methyl ester standards

[a] Values are expressed as mean ± SE ($n = 3$)

[b] Values are expressed as mean ± SE ($n = 5$)

[c] Retention time comparisons inferred a *cis*, *trans*, *trans* or *trans*, *cis*, *trans* double bond configuration

[d] Not detected

(homo-allylic) molecular structure of 22:5n-3 and 22:6n-3 were used to infer a *trans*-5, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5 structure.

Mass spectra of the DMOX derivatives of 22:4 isomers enabled the position of double bonds to be identified (Table 1). Ion fragments separated by 12 amu intervals at

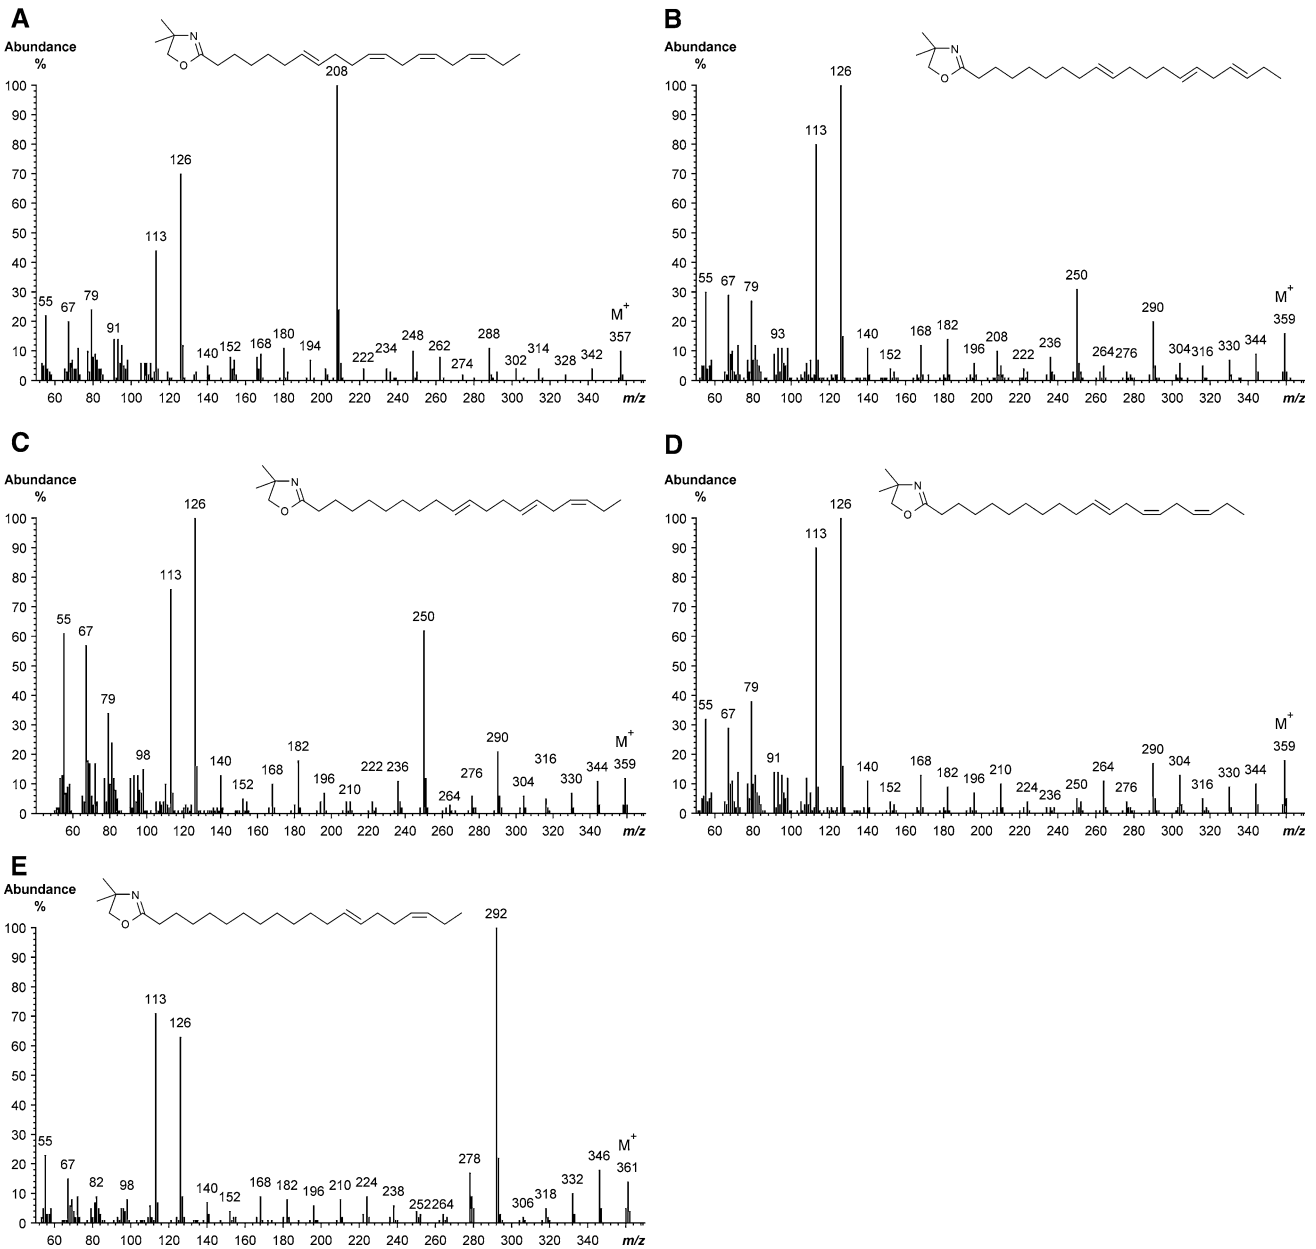

Fig. 7 Gas chromatography-electron-impact mass spectrum of the 4,4-dimethyloxaline (DMOX) derivative of (**a**) *trans*-7, *cis*-11, *cis*-14, *cis*-17 20:4, (**b**) *trans*-9, *trans*-14, *trans*-17 20:3, (**c**) *trans*-10, *trans*-14, *cis*-17 20:3, (**d**) *trans*-11, *cis*-14, *cis*-17 20:3 and (**e**) *trans*-13, *cis*-17 20:2 detected in omasal digesta of cows fed grass silage-based diets containing fish oil. The mass spectrum of DMOX derivatives in Fig. 7a–e corresponds to peaks #58, #41, #48, #50 and #35, respectively, in the GC chromatogram of methyl esters

m/*z* 182, 194, 250, 262, 290, 302, 330 and 342 (Fig. 8b) confirmed a Δ8,13,16,19 22:4 structure [22, 26, 27]. Similarly, readily discernible 12 amu gaps in the mass spectrum of DMOX derivatives also enabled Δ7,13,16,19 22:4 and Δ10,13,16,19 22:4 in FO omasal digesta to be identified (Table 1). Retention time comparisons with authentic FAME standards and the elution order of geometric isomers of 18:3 methyl esters during GC analysis was used in combination with the recorded mass spectra of DMOX derivatives to identify *trans*-8, *cis*-13, *cis*-16, *cis*-19 22:4, *cis*-7, *trans*-13, *cis*-16, *cis*-19 22:4 and *trans*-10, *trans*-13, *cis*-16, *cis*-19 22:4.

Four 22:3 intermediates were detected in variable concentrations in FO omasal digesta (Table 3). The DMOX derivative of Δ12,16,19 22:3 included ion fragments separated by 12 amu gaps at *m*/*z* 238, 250, 292, 304, 332 and 344 (Fig. 8c) that located double bonds at Δ12, Δ16 and Δ19, respectively [22, 25, 26]. A prominent ion at *m*/*z* 278 (Fig. 8c) confirmed the presence of allylic bonds at Δ12 and Δ16. A putative *trans*-12, *cis*-16, *cis*-19 22:3 structure

was deduced based on retention time during GC analysis of FAME. Trace amounts of Δ10,13,17 22:3 in fish oil and FO omasal digesta (Table 3) were able to be identified based on ions at *m/z* 210, 222, 250, 262, 292, 304 and 316 in the DMOX mass spectrum (Table 1), but it was not possible to establish or speculate on double bond geometry.

Inclusion of fish oil in the diet resulted in the appearance of 22:2n-6 and Δ12,17 22:2 in omasal digesta (Table 3). GC–MS analysis of DMOX derivatives confirmed the 22:2 structure based on a molecular ion at *m/z* 389, while ion fragments at *m/z* 252, 264, 292 and 304 located the position of double bonds at Δ13 and Δ16 (Table 1) and ions separated by 12 amu intervals at *m/z* 238, 250, 306 and 318 indicated double bonds at Δ12 and Δ17 (Fig. 8d). Differences in the retention time during GC analysis between an authentic 22:2n-6 methyl ester standard and the Δ12,17 22:2 biohydrogenation intermediate corroborated the identification of *trans*-12, *trans*-17 22:2.

Both fish oil and FO omasal digesta contained *cis*-11, -13 and -15 22:1 while trace amounts of *cis*-13 22:1 were also detected in the digesta of cows fed the Control diet (Table 3).

Detailed analysis of DMOX prepared from total lipid of omasal digesta provided no evidence of 20-, 21- or 22-carbon conjugated intermediates (Fig. 5). During GC analysis of FAME, several peaks in omasal digesta but absent in fish oil were found to elute towards the end of chromatogram between 54.6 and 54.9 min (Fig. 4). Retention time comparisons with authentic standards were consistent with the occurrence of one or more oxygenated 18-carbon fatty acids. GC–MS analysis of FAME and DMOX derivatives prepared from experimental samples

Table 3 Mean concentration of 22-, 23- and 24-carbon fatty acids in refined fish oil and omasal digesta of lactating cows fed grass silage-based diets supplemented with 0 (Control) or 250 g/day of refined fish oil (FO)

Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of fatty acid methyl esters during GC analysis relative to authentic methyl ester standards

[a] Values are expressed as mean ± SE ($n = 3$)

[b] Values are expressed as mean ± SE ($n = 5$)

[c] Not detected

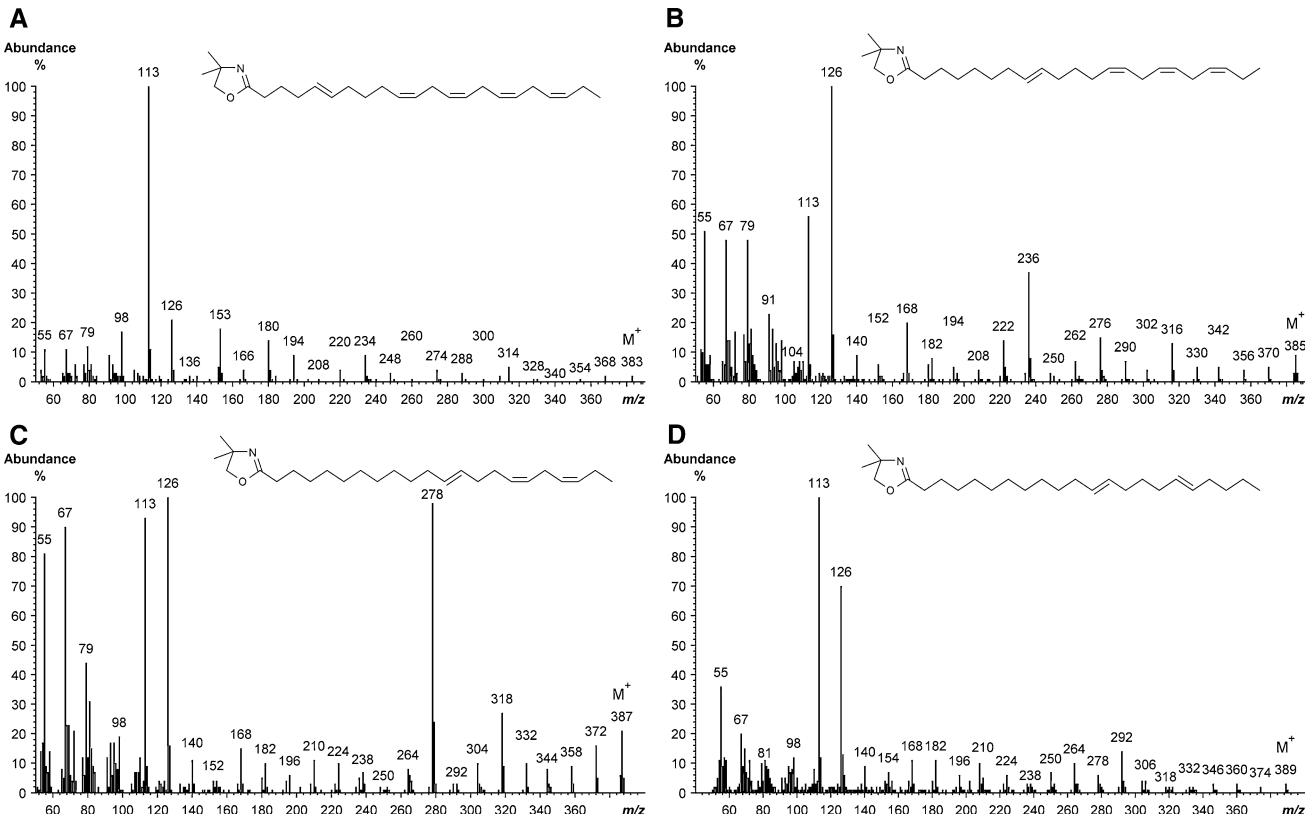

Fig. 8 Gas chromatography-electron-impact mass spectrum of the DMOX derivative of *trans*-5, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5 (**a**), *trans*-8, *cis*-13, *cis*-16, *cis*-19 22:4 (**b**), *trans*-12, *cis*-16, *cis*-19 22:3 (**c**) and *trans*-12, *cis*-17 22:2 (**d**) detected in omasal digesta in cows fed grass silage-based diets containing refined fish oil. The mass spectrum of DMOX derivatives in Fig. 8a–d corresponds to peaks #82, #75, #68 and #56, respectively in the GC chromatogram of methyl esters

and available authentic standards, combined with reference to published mass spectra [31–34], enabled the appearance of 9-O-18:0, 10-O-18:0 and 13-O-18:0 in omasal digesta to be determined. Fish oil in the diet also resulted in the appearance of 10-O-16:0 in omasal digesta (Fig. 3).

The mass spectrum of the methyl ester of 10-O-18:0 indicated a molecular ion at *m/z* 312 and a characteristic fragmentation pattern with abundant ions at *m/z* 141, 171 and 199 arising from alpha cleavage with respect to the oxo group and ions at *m/z* 156 (155 + H) and 214 (213 + H) corresponding to beta cleavage (Fig. 9a) enabling the position of the oxo group to be located at the Δ10 position [31, 34]. GC–MS analysis of the corresponding DMOX derivative confirmed the appearance of 10-O-18:0 in omasal digesta based on a molecular ion at *m/z* 351, fragments at *m/z* 196 and 210 due to cleavages alpha and beta to the oxo group on the side of the oxiran ring and less abundant ions at *m/z* 238, 253 and 266 arising from cleavages on the other side of the oxo group (Fig. 9b) [33]. The mass spectrum of the methyl ester of 13-O-18:0 contained several diagnostic ions at *m/z* 99, 114, 167, 199, 241 and 256 (Fig. 9c) locating the position of the oxo group at the Δ13 position [31]. An expected molecular ion at *m/z* 312 was not detected (Fig. 9c) but could be deduced from the ion at *m/z* 281 (M-31). An inferred 13-O-18:0 structure was confirmed based on characteristic ion fragments in the mass spectrum of the corresponding DMOX derivative at *m/z* 238, 252, 280, 295 and 308 and a molecular ion at *m/z* 351 (Fig. 9d) [33].

Analysis of lipid in omasal digesta of cows fed grass-silage-based diets supplemented with 0 or 250 g/day of refined fish oil along with measurements of nutrient flow at the omasum [7] provided the first quantitative estimates of the ruminal outflow of long-chain fatty acid biohydrogenation intermediates in cattle (Table 4). Fish oil in the diet enhanced ($P < 0.05$) the flow of 20:5n-3, 22:5n-3, 22:6n-3 and 24:5n-3, but the increases were marginal relative to intake (Table 4). Ruminal long-chain fatty acid balance determined as the difference between flow at the omasum and intake confirmed that 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-3, 22:6n-3, 23:5n-3, 24:5n-3 and 24:6n-3 were extensively hydrogenated in the rumen (95.6, 97.6, 100.0, 88.1, 98.2, 100.0, 87.4 and 100%, respectively), but also indicated a lower apparent disappearance of 20:2n-6 and 20:4n-3 in the rumen (3.0 and 66.9%, respectively). Inclusion of fish oil in the diet increased ($P < 0.05$) the flow of 20- and 22-carbon

intermediates containing at least one *trans* double bond from between 0.08–2.00 and 0.14-1.09 g/day, respectively (Table 4). Furthermore, measurements of ruminal fatty acid balance also indicated that fish oil in the diet was associated with the net synthesis of several all *cis* 20- (20:2n-3, 20:3n-3 and 20:3n-6), 21- (21:3n-3, 21:4n-3) and 22- (22:2n-6, 22:3n-6 and 22:4n-3) carbon fatty acids (Table 4). Even though fish oil in the diet increased the intake of 20- and 22-carbon unsaturated fatty acids, ruminal 20:0 and 22:0 balance was lower ($P < 0.05$) in cows fed the control than the FO treatment (Table 4). Fish oil in the diet also enhanced ($P < 0.05$) the flow of 10-O-16:0, 9-O-18:0 + 10-OH-18:0 and 10-O-18:0 at the omasum from 0.0, 0.12 and 2.00 to 1.91, 1.20 and 19.4 g/day, but had no effect ($P > 0.05$) on ruminal outflow of 13-O-18:0 (0.61 and 0.46 g/day for the Control and FO, respectively).

Discussion

The present report documents the re-analysis of omasal digesta collected from cows fed 0 or 250 g/day of refined fish oil. A more detailed analysis was initiated due to the relatively high number of unknown peaks in the GC chromatogram of methyl esters prepared from the non-esterified fatty acid fraction that could not be identified due to the lack of authentic standards. However, elucidating the structure of unknown intermediates in order to understand the fate of long-chain unsaturated fatty acids in the rumen relies on the assumption that no substantial changes in lipid composition occurred during the storage of digesta. Comparable flows of 20:4n-3, 20:5n-3, 22:4n-3, 22:5n-3 and 22:6n-3 at the omasum of cows on the Control and FO treatments based on the analysis of non-esterified fatty acids [7] or total lipid confirm that there were no substantial changes in the abundance of 20- and 22- carbon polyenoic fatty acids in samples used in this and earlier analysis. Furthermore, analysis of total lipid in omasal digesta also revealed that 10-O-16:0 in the non-esterified fatty acid fraction of FO omasal digesta was erroneously identified as 22:5n-6 [7].

Comparisons of the profile of FAME in fish oil and omasal digesta revealed the occurrence of numerous novel 20-, 21- and 22-carbon fatty acids in fish oil digesta, indicating that these isomers must originate from the incomplete hydrogenation of fish oil fatty acids in the

Parenthesis indicate tentative geometry of double bonds as inferred based on retention times and elution order of FAME during GC analysis relative to authentic FAME standards

[a] Calculated as [mean flow at the omasum (g/day) − intake (g/day)] for cows fed grass-silage-based diets supplemented with 0 (Control) or 250 g/day of refined fish oil (FO)

[b] Retention time comparisons inferred a *cis*, *trans*, *trans* or *trans*, *cis*, *trans* double bond configuration

rumen. In total, 27 novel 20-, 21- and 22-carbon fatty acids containing at least one *trans* double bond and several unique all *cis* long-chain polyunsaturated fatty acids were detected in variable concentrations in omasal digesta of cows fed fish oil, with the implication that the hydrogenation of long-chain unsaturated fatty acids in the rumen involves a complicated series of metabolic reactions and the formation of numerous intermediates. GC–MS analysis of FAME confirmed chain length and degree of unsaturation of 20- to 24-carbon fatty acids in fish oil and omasal digesta but did not yield sufficient information enabling the position of double bonds to be located, which can be attributed to the high sensitivity of the carboxyl group to fragmentation and the propensity of double bonds in unsaturated methyl esters to migrate along the carbon chain [24].

During analysis of FAME by GC and GC–MS, the relative retention times of FAME, especially those of saturated compared with unsaturated methyl esters, were found to differ between CP-Sil 88 columns obtained from the same supplier, causing, for instance, the elution order of 20:5n-3 and 24:0 to vary, which is consistent with previous reports [35]. Furthermore, the use of helium as a carrier gas during GC–MS analysis was found to alter the relative retention times of certain FAME compared with hydrogen used for GC analysis. Differences in chromatography between columns, carrier gases and also the molecular weight of analysed fatty acid derivatives served to complicate the cross-referencing of peaks between GC and GC–MS analysis and the identification of minor fatty acids in analysed samples. Pinpointing unknown peaks resolved during GC analysis of FAME in the total ion chromatogram during GC–MS analysis of FAME and DMOX derivatives was achieved based on the relative abundance of specific isomers in omasal digesta and repeated injection and analysis of fatty acid derivatives over an extended period enabling variations in relative retention time and elution order of FAME and DMOX to be taken into account. While it is generally accepted that DMOX derivatives exhibit chromatographic properties comparable to those of FAME [23, 24], the current investigation highlighted that even subtle variations in the relative

retention and elution order of FAME and DMOX derivatives can introduce major challenges in attempts to identify the structure of minor components in samples containing a highly complex mixture of fatty acids.

Identification of the structure of unknown fatty acids was based on GC–MS analysis of DMOX derivatives since these can be prepared from FAME and purified without substantial losses of polyenoic fatty acids and are highly volatile, allowing the recording of mass spectra even for isomers at very low concentrations in complex samples under the same chromatographic conditions applied to FAME [23]. However, some reports have indicated that, in certain circumstances, fatty acid derivatization may cause the isomerization of double bonds and formation of artefacts [36–38]. Prior to the preparation of DMOX from FAME of fish oil and omasal digesta, a wide range of authentic FAME standards containing between one and six double bonds were converted to DMOX derivatives and analysed by GC–MS. There was no evidence based on the chromatography, order of elution of DMOX derivatives relative to parent FAME, or from the recorded mass spectrum to indicate that heating at 170 °C overnight altered the composition of fatty acids in the analysed samples.

Fractionation of FAME according to the degree of unsaturation and double bond geometry by Ag^+-TLC allowed *cis* and *trans* monoenoic fatty acids to be completely resolved, confirming the configuration of double bonds for 20:1 and 22:1 isomers. Despite the fractionation of FAME prior to the conversion of DMOX derivatives, it was not possible to elucidate the structure of all 20- and 22- carbon fatty acids due to a very low abundance and/or co-elution with other components. A mixture of hexane and diethyl ether was used to develop TLC plates based on reports that this solvent system resolves *trans* and *cis* 18:1 isomers in bovine milk fat [14, 19, 20], and therefore applied in the analysis of omasal digesta due to the occurrence of *cis* and *trans* 20:1 and *cis* 22:1 isomers. Previous investigations have reported the separation of methyl esters of *cis* 20:1, *cis* 22:1, *trans* 20:1, *trans* 22:1 and geometric isomers of 20:5n-3 and 22:6n-3 by Ag^+-TLC using plates developed with a mixture (50:50, v/v) of toluene and hexane [39] or a mixture (85:15, v/v) of toluene and methanol [40, 41], but the use of alternative solvents was not explored further in the current analysis. Methyl esters of 22-carbon fatty acids containing four or more double bonds were not resolved by Ag^+-TLC, which, combined with the inability of GC–MS analysis of DMOX derivatives to distinguish between geometric isomers, meant that inferences on double geometry of specific biohydrogenation intermediates in omasal digesta of cows fed fish oil had to be drawn on the basis of retention times and order of elution relative to authentic standards during GC analysis.

Fish oil in the diet is known to alter the hydrogenation of unsaturated fatty acids in the rumen, causing an increase in the flow of 16:1, 18:1, and 18:2 intermediates at the omasum or duodenum in cattle [7–9]. Studies in sheep have demonstrated that the inhibitory effects of fish oil fatty acids on the reduction of *trans* 18:1–18:0 is also associated with the accumulation of 10-OH-18:0 [42] and 10-O-18:0 [43] in the rumen. Identification of oxygenated 18-carbon fatty acids in Control and FO digesta confirmed that fish oil in the diet causes an increase in ruminal outflow of 10-O-16:0, 9-0-18:0, 10-OH-18:0 and 10-O-18:0 in cattle but has no effect on 13-O-18:0 at the omasum. Incubations of fatty acid substrates with rumen fluid or pure cultures of rumen bacteria have established that *cis*-9 18:1 [44–46] and *trans*-10 18:1 [46] can be hydrated to yield 10-OH-18:0, which is further oxidized to 10-O-18:0. Rumen bacteria are also known to be capable of converting 18:2n-6 to *cis*-9, 13-OH 18:1 [47]. It remains uncertain if one or more fatty acids in fish oil promote the hydration of unsaturated fatty acids or alternatively inhibit further transformations of 18-carbon oxo fatty acids in the rumen.

The inhibitory effects of fish oil in the diet on the complete reduction of 18-carbon unsaturated fatty acids to 18:0 in the rumen are thought to be related to the toxic effects of 20:5n-3 and 22:6n-3 on the growth and metabolic activity of ruminal bacteria capable of biohydrogenation [12, 48, 49]. Even though it is well established that 20:5n-3 and 22:6n-3 are extensively hydrogenated in the rumen [7–9], the intermediates formed and metabolic pathways responsible are not known.

Fish oil in the diet enhanced the flow of 20:5n-3, 22:5n-3 and 22:6n-3 at the omasum, with the increases determined from the analysis of total lipid in omasal digesta being almost identical to those based on the flow of non-esterified fatty acids at the omasum [7], indicating that the small amounts of long-chain fatty acids that escape the rumen are in free fatty acid form. Measurements of ruminal fatty acid balance indicated that fish oil in the diet resulted in the net synthesis of *cis*-14 20:1, 20:2n-3, 20:3n-3, 21:3n-3, 21:4n-3, 22:2n-6, 22:3n-6 and 22:4n-3. Extensive investigations have not yielded any substantive evidence that the carbon chain of unsaturated fatty acids is elongated or shortened during biohydrogenation in the rumen [50, 51]. Therefore, the occurrence of 21:3n-3 and 21:4n-3 in FO digesta must arise from the hydrogenation of 21:5n-3 in fish oil by a series of reactions that result in the sequential reduction of *cis* double bonds at Δ6 and Δ9. A serial reduction of double bonds closest to the carboxyl group also appears to represent one of the main pathways explaining the disappearance of 20:5n-3 and 22:6n-3 in the rumen. Hydrogenation of 20:5n-3 involving the reduction of *cis* double bonds at Δ5, Δ8 and Δ11 offers an explanation for the formation and accumulation of 20:2n-3 and 20:3n-3 and the lower extent

of hydrogenation of 20:4n-3 than 20:5n-3 in the rumen. Similarly, the lower ruminal hydrogenation of 22:5n-3 compared with 22:6n-3, along with the net synthesis of 22:4n-3 provides further evidence that one of the main transformations of 22:6n-3 in the rumen involves the initial removal of the double bond between carbon atoms 4 and 5 followed by the reduction of the double bond at Δ7. Measurements of ruminal fatty acid balance in cows fed fish oil also suggest that hydrogenation of 20:4n-6 may proceed via the reduction of double bonds at Δ5 and Δ8 to yield 20:2n-6, and that hydrogenation of 22:5n-6 involves the formation of 22:4n-6, 22:3n-6 and 22:2n-6 via sequential reduction of double bonds at Δ4, Δ7 and Δ10.

Inclusion of fish oil in the diet also resulted in the accumulation of numerous polyenoic 20- and 22-carbon intermediates containing at least one *trans* double bond, indicating that hydrogenation of long-chain unsaturated fatty acids also involves the isomerisation of *cis* double bonds. Owing to the complex composition of fish oil it is not possible to establish the metabolic origins of many of these biohydrogenation intermediates. However, the position of double bonds in *trans*-5, *cis*-10, *cis*-13, *cis*-16, *cis*-19 22:5 identified in FO omasal digesta indicate that this intermediate must originate from metabolism of 22:6n-3 in the rumen by a series of reactions involving isomerization of the *cis*-4 double bond and reduction of the *cis*-7 double bond. Furthermore, isomerisation of the *cis* bond between carbon atoms 8 and 9 in 20:4n-3 would also account for the formation of *trans*-7, *cis*-11, *cis*-14, *cis*-17 20:4 in the rumen but it remains unclear if this intermediate arises from 20:4n-3 in fish oil or from 20:4n-3 liberated from 20:5n-3 following the reduction of the *cis*-5 double bond. Since fish oil contained 18-fold more 20:5n-3 than 20:4n-3, it seems more likely that *trans*-7, *cis*-11, *cis*-14, *cis*-17 20:4 originates from 20:5n-3 in the diet.

By analogy with the known pathways of 18-carbon unsaturated fatty acid metabolism in the rumen it has been speculated that ruminal hydrogenation of 20:5n-3 and 22:6n-3 yields intermediates with 5 or 6 double bonds, containing at least one *trans* double bond [51]. Omasal digesta of cows on the FO treatment was devoid of 20:5 or 22:6 biohydrogenation intermediates, and no 20- and 22-carbon fatty acids containing a conjugated double bond were detected. Several studies have reported the occurrence of geometric and position isomers of conjugated 18:2 in omasal or duodenal digesta of cattle [7–9], and the appearance of *cis*-9, *trans*-11, *cis*-15 18:3 in omasal digesta of cows fed grass-silage-based diets [52]. Even though intermediates produced during the initial stages of biohydrogenation are known to be transient and rapidly hydrogenated [50, 51], it has been possible to isolate and identify conjugated intermediates formed during incubations of 18:2n-6 and 18:3n-3 with ruminal fluid [12, 53, 54]. An absence of conjugated 20- or 22- fatty acids in digesta of cows fed fish oil requires further corroboration based on reverse-phase HPLC analysis of FAME [55], but evidence from this investigation suggests that the first committed steps of 20:5n-3, 21:5n-3, 22:5n-3 and 22:6n-3 hydrogenation in the rumen do not appear to involve the formation of a conjugated bond system.

Fish oil in the diet enhanced the flow of *trans* 20:1 and *trans* 22:1 isomers at the omasum consistent with recent reports on temporal changes in fatty acid composition of ruminal digesta of sheep fed high concentrate diets containing fish oil and sunflower oil [43]. Increases in ruminal outflow of *trans* 20:1 and *trans* 22:1 were not accompanied by higher amounts of 20:0 and 22:0 leaving the rumen, indicating that one or more fatty acids in fish oil inhibit the complete hydrogenation of 20- and 22-carbon unsaturated fatty acids in the rumen. Studies in growing cattle have also shown that incremental amounts of fish oil in the diet do not increase 20:0 and 22:0 at the duodenum [8, 9].

Incubations with rumen fluid have established that 20:5n-3 and 22:6n-3 inhibit the complete hydrogenation of 18-carbon unsaturated fatty acids causing *trans* 18:1 isomers to accumulate [11]. Changes in the flow of *trans* 20:1 biohydrogenation intermediates were also accompanied by an increase in the amount of *cis*-11, -13, -14 and *cis*-15 20:1 at the omasum that may reflect ruminal escape of these fatty acids contained in fish oil, or formation of these isomers during the hydrogenation of 20-carbon polyunsaturated fatty acids in the rumen. Ruminal escape of fish oil fatty acids may also account for the increase in *cis*-11, -13 and -15 22:1 in FO omasal digesta, but the possibility that one or more of these isomers is formed during the penultimate step of 22-carbon polyunsaturated fatty acid hydrogenation in the rumen cannot be excluded.

Detailed analysis of lipid in omasal digesta of cows fed FO suggests that hydrogenation of long-chain polyenoic fatty acids in the rumen may proceed via two distinct mechanisms that involve sequential reduction and/or isomerization of *cis* double bonds closest to the carboxyl group. Further studies examining the fate of C^{13} labeled 20:5n-3 and 22:6n-3 administered in the rumen in vivo or incubations of pure fatty acid substrates with mixed rumen bacteria in the presence of deuterium oxide [46, 54] are required to verify these considerations. Techniques applied to the analysis of fatty acid composition allowed carbon chain length and double bond position for most of the 20- and 22-carbon biohydrogenation intermediates in omasal digesta to be identified, but the structure of several minor fatty acids remains unknown. Furthermore, double bond geometry of most polyenoic biohydrogenation intermediates had to be inferred rather than determined. Additional investigations based on GC–MS analysis of other FA derivatives including picolinyl esters [24], or analysis of

FAME by covalent adduct chemical ionization tandem MS [56, 57], two-dimensional GC analysis [58], GC-Fourier infrared spectroscopy-MS [59], reverse-phase HPLC [55] and Ag + HPLC [41] are required to verify the double bond geometry of polyenoic biohydrogenation intermediates and characterize other minor fatty acids formed during the hydrogenation of long-chain unsaturated fatty acids in the rumen.

The biological significance of the formation and accumulation of numerous 20- and 22-carbon fatty acids containing one or more *trans* double bonds in the rumen of cows fed fish oil remains uncertain. Ruminal outflow of specific 20- and 22-carbon biohydrogenation intermediates was of the same magnitude as the amount of 20:5n-3, 22:5n-3 and 22:6n-3 and it is probable that most of these intermediates are also incorporated into milk fat triacylglycerides and tissue lipids, albeit at low concentrations. A higher consumption of *trans* fatty acids in the human diet is known to be associated with an increase in cardiovascular disease risk, with recent evidence from clinical trials implicating 18-carbon fatty acids containing more than one double bond as being particularly harmful [60]. It is possible that increases in polyenoic *trans* fatty acids may offset some of the expected benefits to human health from the enrichment of 20:5n-3 and 22:6n-3 in ruminant derived foods.

ORIGINAL ARTICLE

Structure and Function of Cholesteryl Ester Transfer Protein in the Tree Shrew

Huirong Liu · Gang Wu · Bing Zhou · Baosheng Chen

Received: 13 October 2010 / Accepted: 15 March 2011 / Published online: 1 April 2011

Abstract Cholesteryl ester transfer protein (CETP) plays an important role in reverse cholesterol transport (RCT). To study on the structure and function of CETP in the tree shrew, a kind of animal resistant to atherosclerosis, we completed the cloning of the full-length tree-shrew CETP cDNA sequence based on the reported partial sequence. The full-length cDNA of tree shrew CETP was 1,704 bp and the deduced protein of the cDNA showed a sequence identity of 81, 80 and 74%, respectively, with the human, monkey and rabbit CETP. The level of CETP mRNA in the liver was much more abundant than that in the other tissues. A mutant protein with a substitution of Asn at position 110 by Gln was found to possess an impaired secretion property compared with the wild-type tree shrew CETP. The mutant proteins, respectively, with a substitution of Pro at position 344 by Ser and a substitution of Gln at position 452 by Arg displayed similar secretion ability, but a decreased cholesteryl ester transfer capability compared with the wild type (48 and 26% lower, respectively). These findings demonstrate that liver is the main tissue synthesizing CETP in the tree shrew. Asn at position 110 plays an important role in the secretion of tree shrew CETP. The residues at position 344 and 452 play essential roles in cholesteryl ester transferring process.

Keywords Tree shrew · Cholesteryl ester transfer protein · Structure · Function

Abbreviations

apoB	Apolipoprotein B
AS	Atherosclerosis
CE	Cholesteryl ester
CETP	Cholesteryl ester transfer protein
CHD	Coronary heart disease
HDL	High density lipoprotein
HDL-C	High density lipoprotein cholesterol
LDL	Low density lipoprotein
LDL-C	Low density lipoprotein cholesterol
RCT	Reverse cholesterol transport
VLDL	Very low density lipoprotein

Introduction

Tree shrews are animals belonging to the Class Mammalia, Order Scandentia, Family Tupaiidae, Genus *Tupaia* and supposed to be more closely related to humans than the rodents [1, 2]. It is documented that there is a very high plasma level of high density lipoprotein (HDL) in the tree shrew which accounts for about 70% of the total plasma lipoprotein levels [3]. Moreover, when the tree shrews are put on a high cholesterol diet, the plasma HDL still remains a similar high level to that prior to the diet and no typical atherosclerotic plaques are found in the artery wall though the gallstones are observed in 70% of the tested tree shrews. All of these data point out a high resistance of the tree shrew to atherosclerosis (AS).

Cholesteryl ester transfer protein (CETP) is a hydrophobic plasma glycoprotein, possessing the ability to promote the transfer of cholesteryl ester (CE) from HDL to apolipoprotein B (apoB)-containing particles [i.e., very low density lipoprotein (VLDL) and LDL] in exchange for triacylglycerols in reverse cholesterol transport (RCT) [4–6]. Thus, CETP is a key protein in RCT because of its involvement in the regulation of plasma lipoprotein cholesterol levels and the remodeling of lipoprotein particles. Although the overall role of CETP in atherosclerosis is still unclear, numerous studies show that deficiency and decrease of CETP activity can lead to an increase in high density lipoprotein cholesterol (HDL-C) as well as a decrease in low density lipoprotein cholesterol (LDL-C) and finally a lower incidence of stroke and coronary heart disease (CHD) [7–9]. However, an increase in CETP activity decreases HDL-C, increases LDL-C, and finally increases atherosclerosis [10–12]. Recent comparative studies show that plasma CETP activity is significantly lower but the HDL-C/LDL-C ratio is higher in the tree shrew than in human and in the two species the CETP activities are negatively related with the HDL-C/LDL-C ratios, suggesting that the low CETP activity could lead to the high HDL-C level and resistance to AS in the tree shrew [13].

In 2001, Zeng et al. [14, 15] cloned the partial sequence of tree shrew CETP cDNA (AF334033). However, up until now, the full-length cDNA of tree shrew CETP had still not been discovered. In this study, we completed the molecular cloning of the full-length CETP cDNA in the tree shrew based on the reported partial sequence and revealed the distribution of CETP mRNA in 12 tissues. We also expressed tree shrew CETP in COS-7 cells and studied on the structure and function of tree shrew CETP by site-directed mutations.

Experimental Procedures

Materials and Reagents

TRIZOL reagent, SuperScript™ First-Strand Synthesis System for RT-PCR, culture media and reagents, and pcDNA3.1/myc-His(−)A were purchased from Invitrogen (Carlsbad, CA, USA). The SMART™ RACE cDNA Amplification Kit and Advantage® 2 PCR Kit were purchased from BD Clontech (Palo Alto, CA, USA). The fluorescein isothiocyanate (FITC) conjugated goat anti-rabbit secondary antibody, horseradish peroxidase-conjugated mouse anti-rabbit IgG, and the Enhanced Chemiluminescence (ECL) Western Blotting System were purchased from SantaCruz Biotechnology, Inc. (Santa Cruz, CA, USA). The CETP activity assay kit was purchased from BioVision, Inc. (Mountain View, CA, USA). The high performed transfection kit was purchased from Vigorous Instruments (Beijing) Co., Ltd. (Beijing, China). The QuikChange™ site-directed mutagenesis kit was purchased from Stratagene (La Jolla, CA, USA). Pyrobest DNA polymerase, *Taq* DNA polymerase, *Eco*RI, and *Xba*I, were purchased from TaKaRa Biotechnology (Dalian) Co., Ltd. (Dalian, China). The SYBR Green I was purchased from Molecular Probes (Eugene, OR, USA). The pGEM-T Easy Vector was purchased from Promega Corporation (Madison, WI, USA). The COS-7 cell line was purchased from the American Type Culture Collection (Manassas, VA, USA). All other reagents were from Sigma-Aldrich Chemical Co (St. Louis, MO, USA) unless stated otherwise.

Samples

All tissue samples were taken from 6-month-old male tree shrews (provided by Kunming Institute of Zoology, Chinese Academy of Science) and frozen in liquid nitrogen until use. The study protocol was approved by the Animal Research Ethical Committees at the Inner Mongolia Agricultural University and Peking Union Medical College.

Cloning of the 5′ Terminal Sequence of Tree Shrew CETP cDNA

Total RNA from tree shrew liver was prepared using TRIZOL reagent and checked by agarose gel electrophoresis. The liver RNA was reverse transcribed to the first strand cDNA using SMART™ RACE cDNA Amplification Kit. Based on the reported partial sequence of tree shrew CETP cDNA [14], a specific primer (5′-GGTAG-CAGTTGGGGGCGTTGGTCCG-3′) was synthesized for 5′ RACE. The RACE procedure was carried out using Advantage® 2 PCR Kit according to the manufacturer's instructions. The PCR products were cloned into pGEM-T Easy Vector for sequencing.

mRNA Quantitation

The relative expression of CETP mRNA in 12 tissues from tree shrews was measured by real-time RT PCR using β-actin as an internal control. Total RNA samples from the different tree shrew tissues were extracted by TRIZOL reagent. The RNA was reverse transcribed to the first strand cDNA using SuperScript™ First-Strand Synthesis System for RT-PCR. 1 μg of total RNA, 1 μl of 10 mM dNTP mix, 1 μl of oligo(dT)$_{12–18}$ (0.5 μg/μl), and some diethylpyrocarbonate (DEPC)-treated water were added into a tube to a final volume of 10 μl, mixed, and incubated at 65 °C for 5 min, then cooled on ice for at least 1 min. In a separate tube, 2 μl of 10× RT buffer, 4 μl of 25 mM

Table 1 The mutant tree shrew CETP

Mutants	Amino acid change	Mutagenic primers
N110Q	Asn110 to Gln110	5′-GGGGATTGAGCATTCAGCAGTCTGTCGACTTCG-3′
		5′-CGAAGTCGACAGACTGCTGAATGCTCAATCCCC-3′
P344S	Pro344 to Ser344	5′-GTGTCGTGGTCAACTCTTCTGTGGTCGTGAAATTCC-3′
		5′-GGAATTTCACGACCACAGAAGAGTTGACCACGACAC-3′
Q452R	Gln452 to Arg452	5′-CCTGAGATTATCACTCGGGATGGCTTCCTGCTGC-3′
		5′-GCAGCAGGAAGCCATCCCGAGTGATAATCTCAGG-3′

$MgCl_2$, 2 μl of 0.1 M DTT, and 1 μl of RNaseOUT™ (40 U/μl) were added and mixed with the first mixture. The mixture was incubated at 42 °C for 2 min. 1 μl of Super-Script™ II RT was added, mixed, and incubated at 42 °C for 50 min. The reaction was terminated at 70 °C for 15 min and chilled on ice. 1 μl of RNase H was added and incubated for 20 min at 37 °C. The sample was stored at −20 °C until use.

The primers for the amplification of tree shrew CETP cDNA were TC1 (5′-CAGTGGACGGTTACTTGGGC-3′) and TC2 (5′-GCAGTGTGCGGACCAACG-3′). The primers for the amplification of tree shrew *β*-actin cDNA were TA1 (5′-TCAGAAGGACTCCTATAGTGG-3′) and TA2 (5′-TCTCTTTGATGTCACGCACG-3′), which were designed according to the conserved sequences of the reported mouse, human, and other animal's *β*-actin cDNA. All Real-Time PCR reactions were performed in a 20 μl mixture containing 25 ng of the cDNA template, 0.6 μl of 1× SYBR Green buffer, 2 μl of 10× PCR buffer, 0.25 μM of each primers, 0.5 mM dNTPs mix and 1 Unit of *Taq* DNA polymerase. The cycling conditions comprised one cycle at 95 °C for 5 min, 35 cycles at 94 °C for 30 s, 56 °C for 30 s and 72 °C for 1 min and 30 s, and one cycle at 72 °C for 10 min. The real-time PCR was performed on the Opticon Continuous Fluorescence Detection System (MJ Research Inc., Boston, USA) and the fluorescence threshold value was calculated using the Opticon Continuous Fluorescence Detection System software. The data was analyzed by the comparative Ct method ($2^{-\Delta Ct}$ method) [16]. Assay was triplicate.

Construction of the Eukaryotic Expression Vector of the Wild-Type Tree Shrew CETP Gene

The coding region of the tree shrew CETP cDNA was amplified by PCR using 5′-Forward and 3′-Reverse oligonucleotides with desired restriction sites (5′ *Xba*I, 3′ *EcoR*I) as primers and tree shrew liver cDNA as template. The primers were TC5 (5′-GCTCTAGAGCCATGCTTGCCAC CACAC-3′) and TC3 (5′-CGGAATTCCTAACTCAAGCT CTGGAGG-3′). The PCR system was constructed as shown below: 25 ng of the cDNA template, 2 μl of 10× PCR buffer, 0.25 μM of each primer, 0.5 mM dNTPs mix and 1 Unit of Pyrobest DNA polymerase (TaKaRa).Thermal cycling was done using the following program: 1 cycle at 94 °C for 3 min, 30 cycles at 94 °C for 1 min, 63 °C for 1 min, 72 °C f or 3 min and 1 cycle at 72 °C for 10 min. The PCR product was restriction-cleaved and ligated into the mammalian expression vector pcDNA3.1/myc-His(−)A and was checked for mutations by DNA sequencing.

Site-Directed Mutagenesis and Transfection

Starting with the wild-type tree shrew CETP cDNA cloned into pcDNA3.1/myc-His(−)A, we conducted site-directed mutagenesis using a QuikChange™ site-directed mutagenesis kit according to the manufacturer's instructions. The mutagenic primers were designed according to the desired mutations (Table 1). 2.5 μl of 10× reaction buffer, 50 ng of dsDNA template, 2 μl of dNTP Mix (2.5 mM), 0.5 μl of each primer (10 μM), 0.5 U Pfu DNA polymerase, some PCR-Grade Water were added to a final volume of 25 μl and mixed. The cycling conditions were as follows: 1 cycle at 95 °C for 30 s, 14 cycles at 95 °C for 30 s, 55 °C for 1 min, and 68 °C for 14 min, 1 cycle at 68 °C for 14 min. The reaction was placed on ice for 2 min. Then, 1 μl of the *Dpn* I restriction enzyme (10 U/μl) was added directly to each amplification reaction, mixed, and incubated at 37 °C for 1 h. 1 μl of the *Dpn* I-treated DNA from each sample reaction was transformed to the supercompetent cells of *E. coli* DH5α. The mutants were verified by DNA sequencing.

COS-7 cells seeded on the culture dishes 1 day before transfection were transfected with the constructs using the high performed transfection kit according to the manufacturer's instructions. The cells were thereafter incubated in serum-free Dulbecco's modified Eagle's medium (DMEM) for expression.

Western Blot Analysis

After incubating for 72 h, the transfected cells and their culture medium were harvested, respectively. The medium was concentrated to 200× by ultrafilter centrifugation. The

transfected cells were washed with 1× PBS buffer and then were treated with 500 µl of 1× sample buffer (1% SDS, 10% glycerol, 25 mM Tris-HCl pH 6.8, 1 mM EDTA, 0.7 M mercaptoethanol). Aliquots of cell medium and lysates were submitted to SDS-PAGE using 12% gels. The resulting protein bands were transferred to a PVDF membrane and incubated in rabbit anti-CETP serum (1:1,000) raised in rabbit against the recombinant human CETP produced in *E. coli* [17]. Finally, the membrane was incubated with horseradish peroxidase-conjugated mouse anti-rabbit IgG (1:5,000) and the immunoreactive bands were visualized using the Enhanced Chemiluminescence (ECL) Western Blotting System according to the manufacturer's instructions. The cells transfected with the plain vector pcDNA3.1/myc-His(−)A were used as controls.

Immunofluorescence Microscopy

After incubating, respectively, for 24, 48, and 72 h, the transfected COS-7 cells were fixed for 10 min in 4% paraformaldehyde, 1× PBS, pH 7.4 and permeabilized with 0.1% Triton X-100 for 30 min at 4 °C. After blocking nonspecific binding of antibodies with 2% BSA/PBS, incubation was continued for about 12 h at 4 °C in the presence of the polyclonal rabbit anti-CETP serum diluted in 2% BSA/PBS (1:500). The bound antibody was detected with fluorescein isothiocyanate (FITC) conjugated goat anti-rabbit secondary antibody (1:5,000), and the cells were viewed with a Nikon fluorescence microscope (magnification, ×400) (Nikon, Tokyo, Japan). The cells transfected with the plain vector pcDNA3.1/myc-His(−)A were used as controls.

Cholesteryl Ester Transfer Activity

The medium was concentrated 200× by ultrafilter centrifugation. The cholesteryl ester transfer activity in the culture supernatants was determined by incubating aliquots of the concentrated medium together with the reagents from a CETP activity assay kit according to the manufacturer's instructions. Briefly, 3 µl of the supernatant sample (as the source of CETP) was added to the reaction mixture containing a fluorescent self-quenched neutral lipid as the donor molecule and an acceptor molecule. A CETP-mediated transfer of the fluorescent neutral lipid to the acceptor molecule resulted in an increase in fluorescence, which was read in a fluorescence plate reader at excitation 465 nm and emission 535 nm. CETP activity was expressed as picamole of neutral lipid transferred per microlitre plasma per hour. The cells transfected with the plain vector pcDNA3.1/myc-His(−)A were used as controls. Assay was triplicate. All CETP analyses were conducted in the same day to decrease variability. The relative mass of CETP mutants secreted in the culture supernatants was determined by Western blotting and quantitated with the UVIpro system (UVItec Ltd., Cambridge, UK). The specific activity of the mutants was expressed relative to that of the wild-type tree shrew CETP.

Statistical Analysis

Data were analyzed using SPSS for Windows XP. All descriptive data collected were expressed as mean values (±SEM) and the Student '*t*' test was used for analysis. Values of $P < 0.05$ were regarded as statistically significant.

Results

Sequence Analysis of the Full-Length Tree Shrew CETP cDNA

In 2001, Zeng et al. [14, 15] cloned the partial sequence of tree shrew CETP cDNA (AF334033). The sequence was 1,636 bp, including 178 bp at the 3′ end of the untranslated region and a 1,458 bp fragment in a coding region, which comprises the complete coding sequence of mature tree shrew CETP and partial coding sequence of signal peptide. According to the partial cDNA sequence [14], we cloned the 5′ terminal sequence of the tree shrew CETP cDNA. The 5′ terminal sequence was 68 bp long, including the putative initiation codon ATG (GenBank accession number: HQ589337). Combining the 5′ terminal sequence with the reported partial sequence, we obtained the full-length cDNA sequence of tree shrew CETP. The full-length cDNA was 1,704 bp, comprising of a 41 bp 5′-noncoding region, a 1,485 bp coding region, and a 178 bp 3′-noncoding region (excluding poly(A)-tail) (Fig. 1). The predicted protein comprised of 494 amino acids (including a predicted 17 amino acid signal peptide) and the calculated molecular mass of the protein was 54,888 Da (pI5.86). The predicted protein showed a sequence identity of 81, 80 and 74%, respectively, with the human, monkey and rabbit CETP (data not shown). The cysteine residues important for synthesis, secretion, and specific activity of CETP [18, 19] were all conserved in human, monkey, rabbit and tree shrew CETP. Moreover, more than half of the predicted glycosylation sites in these proteins were also conservative (PROSITE motif search, http://cubic.bioc.columbia.edu/predictprotein/). Interestingly, tree shrew CETP showed a characteristic proline insertion (amino acid 317 in the mature protein) which was absent in human and monkey CETP but corresponded to a threonine insertion in rabbit CETP. Same as human and monkey CETP, tree shrew

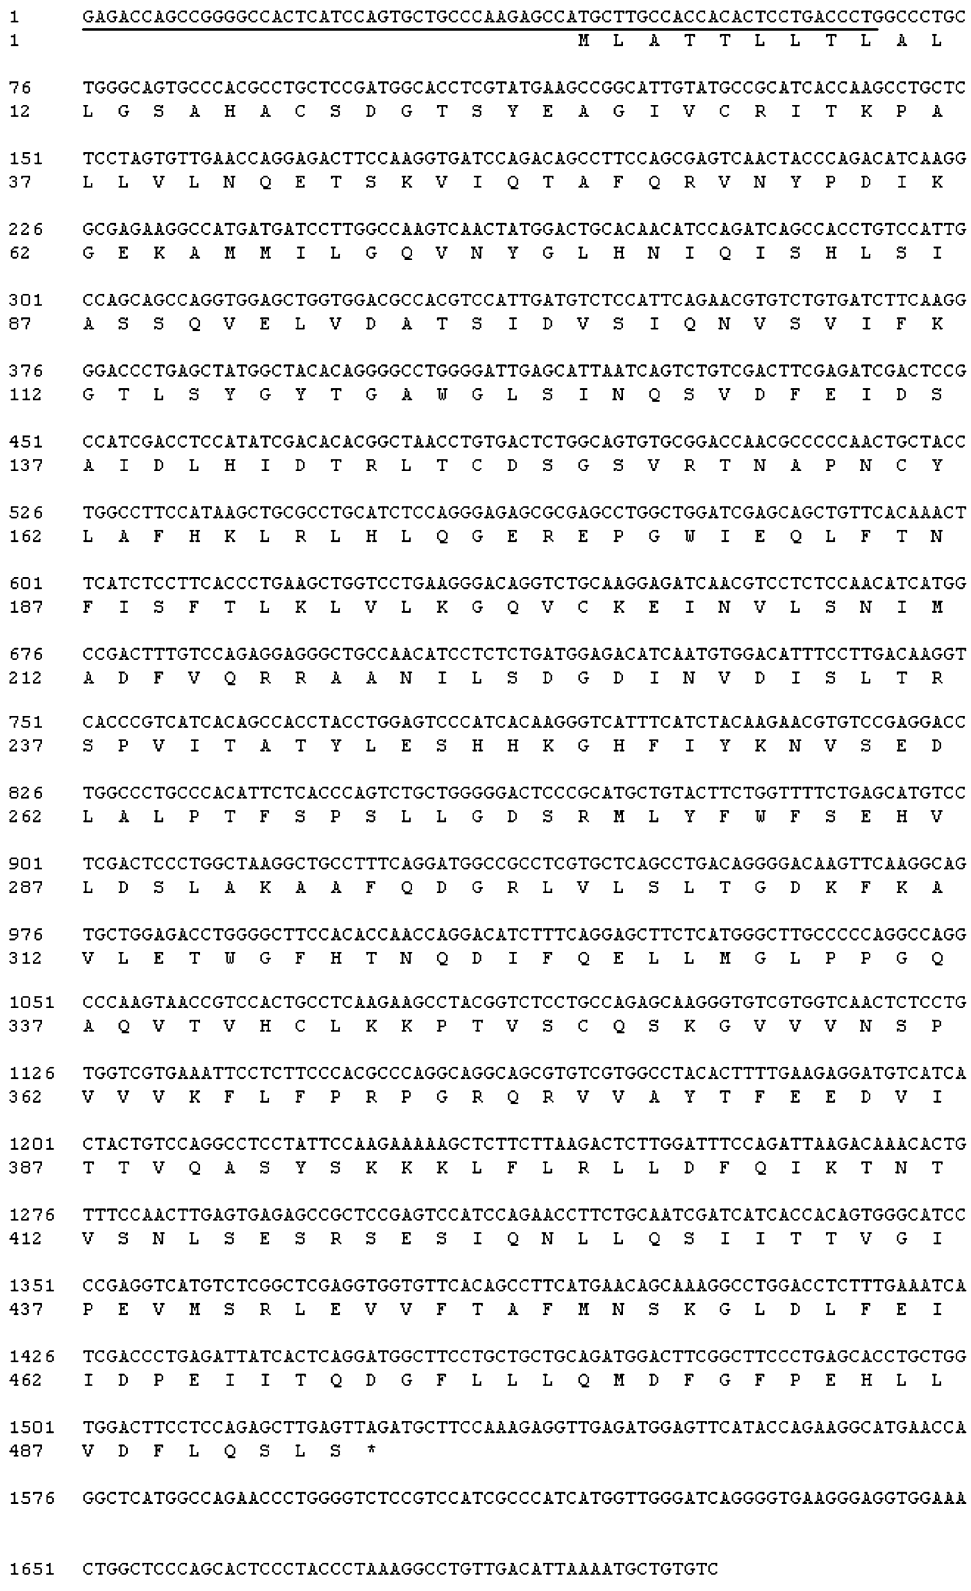

Fig. 1 Nucleotide and amino acid sequences of tree shrew CETP. The 5′ terminal sequence cloned in this study is *underlined*

CETP also did not have 19 amino acids insertion compared with rabbit CETP. However, due to the conservative character of most amino acids, prediction of the secondary structures (PROF predictions, http://cubic.bioc.columbia.edu/predictprotein/) revealed no significant differences between tree shrew CETP and the CETPs of other species.

Tissue Distribution of Tree Shrew CETP mRNA

To gain some information regarding which tissues synthesized CETP mRNA in tree shrews, total RNA was isolated from 12 tissues of tree shrews, and the levels of CETP mRNA were assessed by real-time RT PCR analysis. In 12 tissues investigated (Fig. 2), the relative quantitation of tree shrew CETP mRNA in the liver was much more abundant than that in the other tissues. Adipose and thoracic aorta also synthesized some CETP mRNA. Spleen, lung, and gallbladder had low levels of CETP mRNA, whereas brain, testicle, intestine, heart, kidney and muscle had almost undetectable levels. The tissue distribution profile that tree shrew CETP exhibited here was different from that of monkey [20], human [21], and rabbit CETP [22]. In monkeys, the levels of CETP mRNA in the liver and thoracic aorta were much higher than that in the other tissues, while the mesenteric fat, adrenal gland, spleen, and abdominal aorta had low but detectable levels of the mRNA. In humans, CETP mRNA was synthesized predominantly in adipose tissue, liver, and spleen, with lower levels of expression in the small intestine, adrenal gland, kidney, skeletal muscle, and heart. In rabbits, CETP mRNA was mainly synthesized in liver, adrenal gland and kidney. These data indicate a species-specific transcription control of CETP gene in tree shrews.

Expression and Secretion of Wild-Type and Mutant Tree Shrew CETP in COS-7 Cells

The sequence identity between human [21] and tree shrew CETP was analyzed in detail (data not shown). Three sites

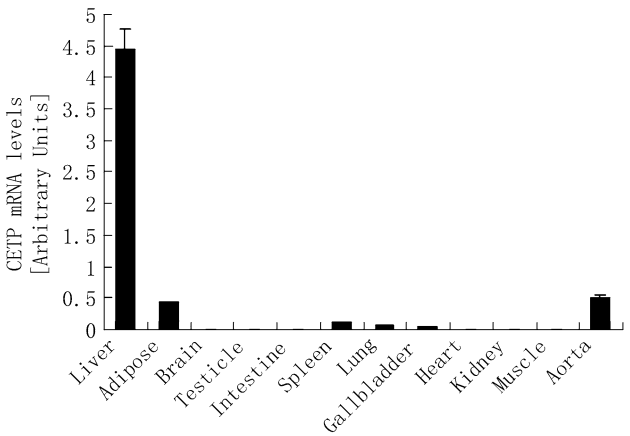

Fig. 2 Relative quantity of CETP mRNA in 12 tissues from tree shrews. The relative expression of CETP mRNA in 12 tissues from tree shrews was measured by the real-time RT PCR using β-actin as an internal control. Total RNA samples from the different tree shrew tissues were extracted and reverse transcribed to the first strand cDNA. The Real-Time PCR reactions were performed and the data was analyzed by the comparative Ct method ($2^{-\Delta Ct}$ method). Assay was triplicate

of tree shrew CETP, N110, N342 and Q452, were remarkable. N110 was a potential N-glycosylation sites in tree shrew CETP (PROSITE motif search, http://cubic.bioc.columbia.edu/predictprotein/), whereas the corresponding amino acid in human CETP was glutamine, a non-N-glycosylation site. It was reported that glycosylation was the crucial step for the secretion of human CETP [23]. So, N110 could be very important to the secretion of tree shrew CETP. In order to study the function of N110, we mutated it into Gln, a non-glycosylation site. N-glycosylation generally occurs at the β-amide of the asparagine of the Asn-Xaa-Ser/Thr sequon [24–26]. N342 in tree shrew CETP was a non-N-glycosylation site, corresponding to a variable glycosylation site at position 341 in human CETP [23]. It was suggested that the non-glycosylated form of human CETP at Asn_{341}-X-Ser was well secreted and displayed moderately increased cholesteryl ester transfer activity [23]. In order to study the function of N342 in tree shrew CETP (Asn_{342}-X-Pro, a non-glycosylation site), Pro344 was mutated into Ser, which made Asn342 become a potential N-glycosylation site. In tree shrew CETP, the amino acid Q452 corresponded to the R451Q polymorphism in human CETP. It was reported that the Q451 allele was associated with higher CETP activity [27–29]. Therefore, Q452 could be crucial to the activity of tree shrew CETP. To analyze the function of this site, we mutated it into R452. The above mutants were, respectively, named as N110Q, P344S and Q452R (Table 1).

The wild-type tree shrew CETP and the mutants were transiently expressed in COS-7 cells for 72 h. The culture medium and the cells were collected, respectively, for Western blot analysis. The results showed that the wild type protein was detectable in the culture medium and the cell lysates and had a molecular mass of approximately 68 kDa. The molecular mass of N110Q ($\sim$66 kDa) was about 2,000 lower than that of the wild type. Moreover, N110Q was only detectable in the cell lysates, but undetectable in the culture medium. These results indicated that the mutation at the amino acid N110 could affect the modification and secretion of the mutant protein. However, except N110Q, the other two mutant proteins (P344S and Q452R) were all detected in the culture medium and the cell lysates, and the mutant protein bands had similar molecular mass ($\sim$68 kDa) and strength compared with the wild type protein band either in the culture medium or in the cell lysates, suggesting that the mutation at the amino acid Q452 or P344 could not affected the modification and secretion property of the mutant protein (Fig. 3).

The secretion properties of the mutants were also showed in the immunofluorescence microscopic analysis (Fig. 4). At 24 h, all of the expressed proteins were localized around the cell nucleus. At 72 h, with the exception of N110Q, which was still localized around the cell nucleus, the other expressed proteins including the wild

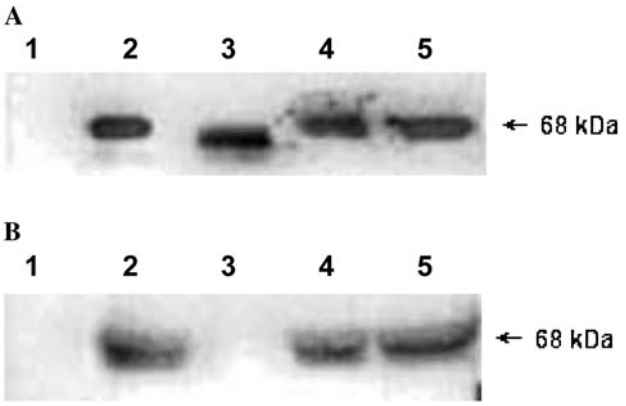

Fig. 3 Western blot analysis of the wild-type and mutant tree shrew CETP expressed in the COS-7 cells. COS-7 cells were transfected with the wild-type and mutant tree shrew CETP expressing vectors. After incubating for 72 h, the transfected cells and their culture medium concentrated to 200× were used to do the western blot analysis. **a** Western blot analysis of the cell lysates. **b** Western blot analysis of the cell culture medium. *Lane 1*, control (samples from the COS-7 cells transfected with plain vector plasmid); *lane 2*, samples from the COS-7 cells transfected with the expression vector of the wild-type tree shrew CETP gene; *lane 3*, samples from the COS-7 cells transfected with the expression vector of the N110Q mutant tree shrew CETP gene; *lane 4*, samples from the COS-7 cells transfected with the expression vector of the P344S mutant tree shrew CETP gene; *lane 5*, samples from the COS-7 cells transfected with the expression vector of the Q452R mutant tree shrew CETP gene

type were situated on one side near the cell nucleus. It appeared that the wild type, P344S, and Q452R were transferred gradually to one side near the cell nucleus from 24 to 72 h after expressed. The data suggested that the secretion property of N110Q was different from that of the others.

Cholesteryl Ester Transfer Activity of Tree Shrew CETP Mutants

The culture medium of the transfected cells was collected, concentrated, and then used to measure the cholesteryl ester transfer activity (Fig. 5). The results showed that the mutations at P344 and Q452 in tree shrew CETP impaired the activities of the mutant proteins, respectively, resulting in 48 and 26% reduction of cholesteryl ester transfer compared with the wild type protein, indicating that P344 and Q452 played an important role in tree shrew CETP-mediated cholesteryl ester transfer. However, the culture medium from the cells expressing N110Q did not show the cholesteryl ester transfer activity, providing further evidence that this mutant protein could not be secreted into the medium.

Discussion

In our study, tree shrew CETP showed a high sequence identity to human (81% identical), monkey (80% identical) and rabbit (74% identical) CETP, suggesting that tree shrew CETP might have similar structure and function with these proteins. However, there were also some significant differences on the amino acid sequences between tree shrew CETP and the other species' CETPs, which might cause some differences on the structure and function of the proteins.

In 12 tissues investigated (Fig. 2), the relative quantitation of tree shrew CETP mRNA in the liver was much more abundant than that in the other tissues, suggesting that the liver could be the main tissue synthesized CETP. The liver is a key organ in controlling systemic lipid metabolism. Its functions include lipoprotein clearance, intracellular lipid metabolism, synthesis and secretion of lipoproteins, and remodeling of circulating lipoproteins [30]. Therefore, high level of CETP in the liver could not only be the main source of the circulating CETP mass but also play an important role in the local uptake or removal of lipid in the liver [31]. In tree shrews, adipose tissue also synthesized some CETP mRNA. Radeau et al. [32] reported that adipocyte size was inversely correlated with CETP mRNA abundance in fresh human adipose tissue. In mice, adipose tissue-specific CETP expression led to decreased cholesterol and triglyceride contents and reduced adipocyte size [33]. CETP expressed in adipose could be involved in the local lipid metabolism by promoting HDL remodeling and then cholesterol efflux. The aorta also synthesized some CETP mRNA in the tree shrew. CETP synthesized in the aorta could participate in the removal of excessive cholesteryl ester from the arterial wall.

Glycosylation was crucial for the secretion of human CETP [23]. When the N-linked glycosylation was absent, the mutant proteins were poorly secreted, and the Mr of the mutants showed about 2,000 lower than that of the wild type protein. In our study, after analyzed, four potential glycosylation sits were found in the tree shrew CETP, of which three sites were the same as that in human CETP, but only one site, N110, corresponding to a non-N-glycosylation site Q110 in human CETP. Therefore, we mutated it into Gln, a non-glycosylation site, for studying its function. The results showed that the mutant protein in the cell lysates had about 2,000 lower molecular mass than the wild-type tree shrew CETP and was not able to be detected in the culture medium by the western blot analysis and the activity test (Figs. 3, 5), indicating that the mutant protein could not be secreted out of the cells because of the deficiency of the glycosylation at the amino acid 110. The immunofluorescence microscopic analysis also supported this conclusion (Fig. 4). It's well known that most of the secreted proteins are synthesized and glycosylated in the endoplasmic reticulum (ER) [34, 35]. The proteins are then delivered into the Golgi apparatus for further modification and finally secreted out of the cell. In our study, N110Q

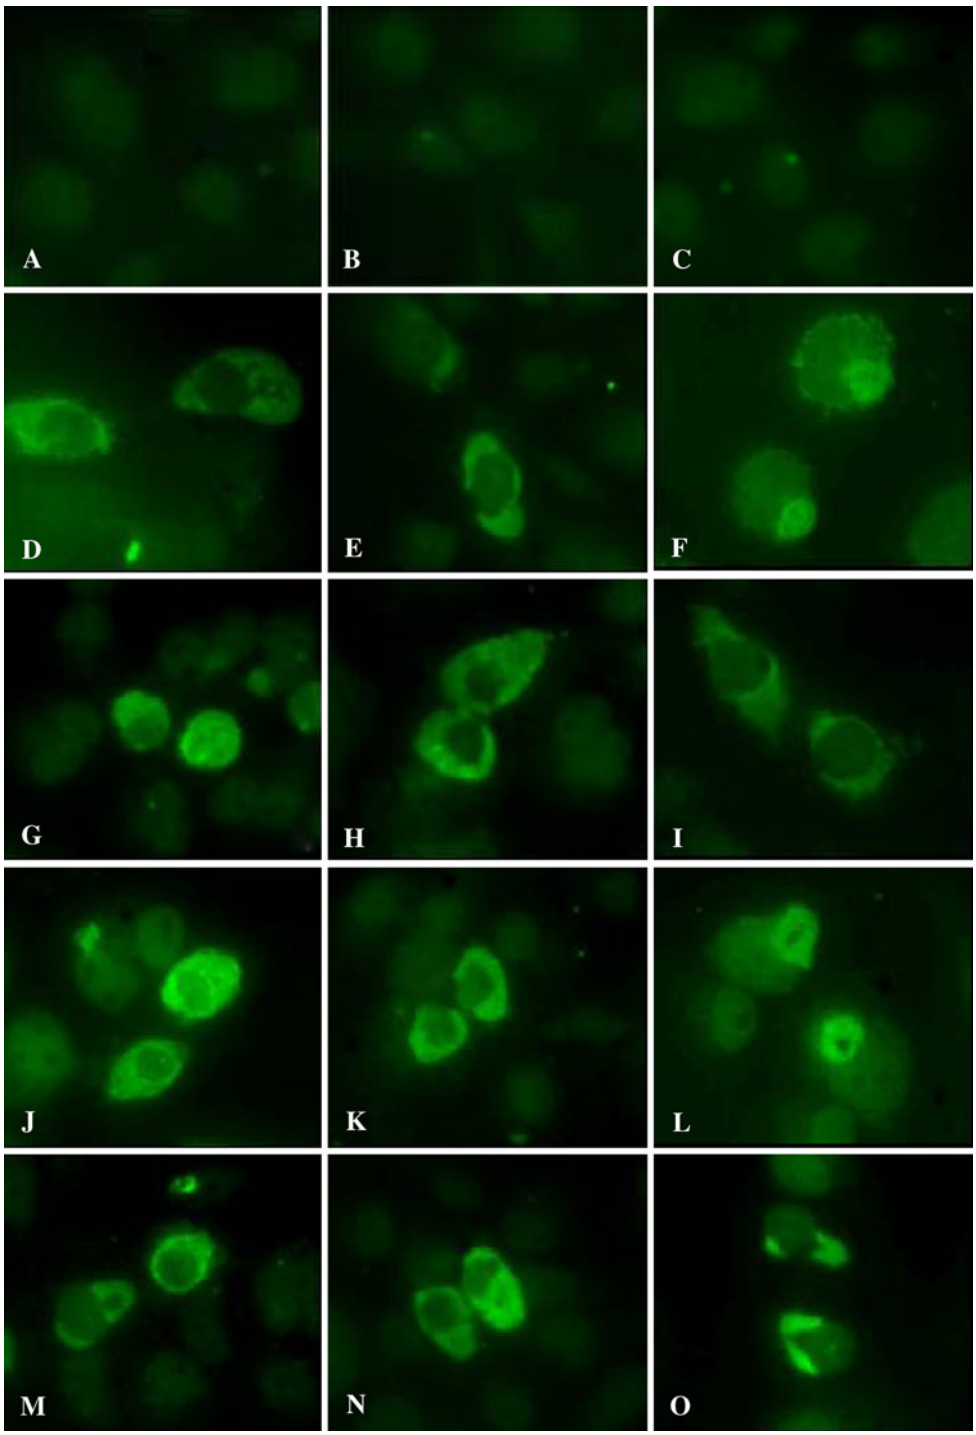

Fig. 4 Immunofluorescence microscopy analysis of the transfected COS-7 cells. COS-7 cells were transfected with the wild-type and mutant tree shrew CETP expressing vectors. After incubating, respectively, for 24, 48, and 72 h, the transfected COS-7 cells were used for immunofluorescence microscopy analysis. **a–c** the cells transfected with the plain vector plasmid; **d–f** the cells transfected with the expression vector of the wild-type tree shrew CETP gene; **g–i** the cells transfected with the expression vector of the N110Q mutant tree shrew CETP gene; **j–l** the cells transfected with the expression vector of the P344S mutant tree shrew CETP gene; **m–o** the cells transfected with the expression vector of the Q452R mutant tree shrew CETP gene. Expression time: **a–m**, 24 h; **b–n**, 48 h; **c–o**, 72 h

appeared to be always localized around the nucleus (possibly in the ER) from 24 to 72 h after expressed, whereas the other proteins including the wild type were localized around the cell nucleus (possibly in the ER) at 24 h and situated on one side near the cell nucleus (possibly associated with the Golgi apparatus) at 72 h, suggesting that N110Q could be remained in the ER instead of being delivered into the Golgi apparatus for the secretion because of deficiency of the glycosylation at the amino acid 110. Of cause, this hypothesis need to be proved further. In brief, these results suggested that the Glutamine at position 110 in tree shrew CETP could be a N-glycosylation site and the glycosylation of this site could be crucial for the secretion of the protein.

N342 in tree shrew CETP, a non-N-glycosylation site (Asn_{342}-X-Pro), correspond to a variable glycosylation site at position 341 in human CETP [23]. The non-glycosylated form of human CETP at Asn_{341}-X-Ser was well secreted

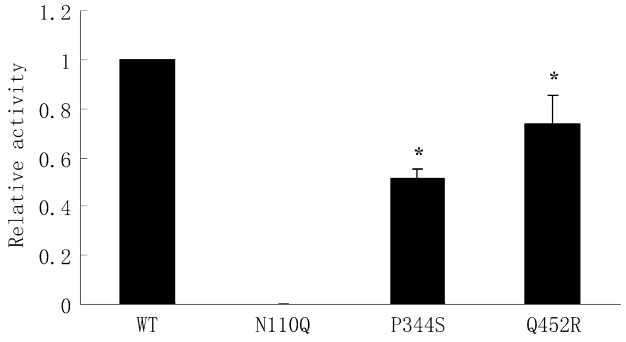

Fig. 5 Cholesteryl ester transfer activity of the wild-type and mutant tree shrew CETP. COS-7 cells were transfected with the wild-type and mutant tree shrew CETP expressing vectors. After incubating for 72 h, the culture medium was harvested and concentrated to 200×. The cholesteryl ester transfer activity in the culture supernatants was determined using a CETP activity assay kit according to the manufacturer's instructions. The results are mean values (±SEM) of three independent experiments, and are expressed relative to the activity of the wild-type tree shrew CETP (set at 1.0). The *asterisks* indicate a statistically significant difference (*t* test; $*P < 0.05$) from the wild-type tree shrew CETP

and displayed moderately increased cholesteryl ester transfer activity. To analyze the function of N342 in tree shrew CETP, we carried out mutagenesis study on the site. A Ser substitution for Pro at position 344 made N324 become a potential N-glycosylation site. From the western blot and immunoflouresence analysis (Figs. 3, 4), the secretion property of P344S was similar to that of the wild-type tree shrew CETP. Furthermore, the molecular mass of the mutant was also the same as that of the wild type, implying that the mutant could not be glycosylated at N342. In the case of NXS sequon, it was reported that the hydrophobic residues at positions 9th to 17th upstream of the sequons as well as the positively charged residues at positions 5th and 7th downstream of the sequons are crucial to the domains flanking glycosylated sequons [36]. The amino acid Lysine at position 13th upstream of the N-glycosylation site (Asn_{342}) in P344S was positively charged and significantly different from the amino acid Methionine at the corresponding position in human CETP. This could lead to the deficiency of N-glycosylation at N342 in the mutant. However, the activity of P344S was about 48% lower than that of the wild-type tree shrew CETP (Fig. 5), indicating that P344 plays an important role in the activity of tree shrew CETP. It has been observed [37–39] that Pro restricts the conformation of the residue preceding it in a protein sequence and can potentially increase protein stability. Therefore, Pro is usually conserved in proteins and often plays an important role in protein structure and function [38, 40, 41]. In our study, a Ser substitution for Pro could cause changes in the structure conformation of the mutant and lead to the decreased activity eventually.

Q452 in tree shrew CETP corresponded to the R451Q polymorphism in human CETP. The Q451 allele in human CETP was associated with higher CETP activity [27–29]. To analyze the function of this site in the tree shrew CETP, we mutated Q452 into R452. The results showed that the molecular mass and secretion of Q452R was similar to that of the wild-type tree shrew CETP (Figs. 3, 4). However, the activity of the mutant decreased by 26% (Fig. 5), indicating that Q452 was very important to the activity of tree shrew CETP. It is reported that human CETP has an elongated 'boomerang' shape with two similar domains connected by a linker, residues 240–259 in CETP [42]. The structure of CETP reveals four bound lipid molecules, which can be two neutral lipids and two phospholipids. The four lipids occupy a continuous tunnel that traverses the core of the protein and has two distinct openings. The two cholesteryl esters are buried in the middle of the tunnel called 'neck' and two phospholipids plug the tunnel, one at each end. Tunnel mutation experiments suggested that in CETP, I443, L457, and M459 are located at the neck. The neck of the tunnel makes marginal contacts with the flexible parts of bound cholesteryl ester and lipid passage through the neck is required for transfer activity. R451 is between I443 and L457 and could be involved in the formation of the neck of the tunnel. The Q451 allele in human CETP has higher CETP activity because Q451 could be more suitable to the formation of the neck of the tunnel and the binding of neutral lipid to CETP. Tree shrew CETP shared a high sequence identity with human CETP, about 81%, suggesting that the proteins might also have similar structure. So, a Arg substitution for Gln at position 452 in tree shrew CETP could affect the formation of the neck of the tunnel and the binding of neutral lipid to CETP and so the cholesteryl ester transfer activity at last. Of course, this hypothesis need to be confirmed in the future.

Taken together, our data demonstrate that tree threw CETP shares a high sequence identity with human, monkey and rabbit CETP. The liver is the major tissue synthesizing CETP mRNA. In tree shrew CETP, residues 344 (Pro) and 452 (Gln) play an important role in maintenance of high cholesteryl ester transfer activity and residue 110 (Asn) is crucial to the secretion of the protein.

Abstract We analyzed the effect of a 6-week aerobic exercise training program on the in vivo macrophage reverse cholesterol transport (RCT) in human cholesteryl ester transfer protein (CETP) transgenic (CETP-tg) mice. Male CETP-tg mice were randomly assigned to a sedentary group or a carefully supervised exercise training group (treadmill 15 m/min, 30 min sessions, five sessions per week). The levels of plasma lipids were determined by enzymatic methods, and the lipoprotein profile was determined by fast protein liquid chromatography (FPLC). CETP activity was determined by measuring the transfer rate of ^{14}C-cholesterol from HDL to apo-B containing lipoproteins, using plasma from CETP-tg mice as a source of CETP. The reverse cholesterol transport was determined in vivo by measuring the [^{3}H]-cholesterol recovery in plasma and feces (24 and 48 h) and in the liver (48 h) following a peritoneal injection of [^{3}H]-cholesterol labeled J774-macrophages into both sedentary and exercise trained mice. The protein levels of liver receptors were determined by immunoblot, and the mRNA levels for liver enzymes were measured using RT-PCR. Exercise training did not significantly affect the levels of plasma lipids or CETP activity. The HDL fraction assessed by FPLC was higher in exercise-trained compared to sedentary mice. In comparison to the sedentary group, a greater recovery of [^{3}H]-cholesterol from the injected macrophages was found in the plasma, liver and feces of exercise-trained animals. The latter occurred even with a reduction in the liver CYP7A1 mRNA level in exercised trained animals. Exercise training increased the liver LDL receptor and ABCA-1 protein levels, although the SR-BI protein content was unchanged. The RCT benefit in CETP-tg mice elicited by exercise training helps to elucidate the role of exercise in the prevention of atherosclerosis in humans.

Keywords Atherosclerosis · CETP · HDL · Physical exercise · Cholesterol

Abbreviations

ABC	Transporters ABCA-1 and ABCG-1
AcLDL	Acetylated LDL
Apo AI	Apolipoprotein AI
Apo E	Apolipoprotein E
B-E	Low density lipoprotein receptor
CETP	Cholesteryl ester transfer protein
CYP7A1	7 alpha hydroxylase
CYP27A	27 alpha hydroxylase
EC	Esterified cholesterol
EDTA-PBS	Ethylene diamine tetra acetic phosphate-buffered saline
FPLC	Fast protein liquid chromatography
HDL	High density lipoprotein
LCAT	Lecithin cholesterol acyltransferase
LDL	Low density lipoprotein
LRP	LDL-receptor related protein
LXR	Liver X receptor
LP	Lipoprotein
RCT	Reverse cholesterol transport

SR-BI Scavenger receptor class B type I
VLDL Very low density lipoprotein

Introduction

Regular exercise is independently associated with a reduced incidence of coronary heart disease and mortality by improving the cardiovascular risk profile [1]. In fact, a negative correlation between physical activity level and the carotid intima media thickness has been shown in aerobically exercised individuals [2].

Ramachandran et al. [3] demonstrated that regular, aerobic exercise reduces pre-existing atherosclerotic lesions in low density lipoprotein (LDL) receptor knockout mice, and more recently, Matsumoto et al. [4] showed that in low-density lipoprotein-receptor-deficient mice, regular exercise training prevents aortic valve sclerosis by numerous mechanisms, including preservation of endothelial integrity, reduced inflammation and oxidative stress, and inhibition of the osteogenic pathway. It has also been reported that a progressive aerobic exercise training protocol improves the apo E knockout mouse survival rate, an effect that was ascribed to the stabilization of atherosclerotic lesions and prevention of plaque rupture [5]. These events are most likely related to the role of aerobic exercise in improving high density lipoprotein (HDL) plasma levels, as well as antioxidant and anti-inflammatory defenses in the arterial wall [6].

Through the reverse cholesterol transport (RCT) process, HDL mediates the cholesterol removal from macrophages and peripheral cells and its delivery to the liver, where it is secreted into the bile and feces. The cholesteryl ester transfer protein (CETP) transfers esterified cholesterol from HDL to apo B-containing lipoproteins (LP) that are ultimately removed by the hepatic LDL receptor (B-E), LRP and E receptors. There are no consistent data in the literature regarding the effect of aerobic exercise training on the RCT, and most of the results were drawn from in vitro analyses that may not reflect the whole animal system in vivo. In this regard, an interplay of actions involving CETP, lecithin cholesterol acyltransferase (LCAT), ABC transporters (ABCA-1 and ABCG-1) and scavenger receptor class B, type I (SR-BI) could dictate the flow of cholesterol to the liver [7].

In the present study, we tested the hypothesis that aerobic exercise training can improve the in vivo RCT by modulating proteins and enzymes involved in the cholesterol flow to the liver. For this purpose, we used CETP transgenic C57BL/6 mice (CETP-tg), an animal model that simulates the RCT in humans. We assessed the effect of a 6 week aerobic training program on the redistribution of radiolabeled cholesterol into the plasma, liver and feces following the intraperitoneal injection of macrophages enriched with [^{3}H] cholesterol. We also investigated the hepatic protein levels of receptors involved in lipid metabolism, such as SR-BI, ATP-binding cassette transporter A-1 (ABCA-1), liver X receptor (LXR) and LDL receptor, and the mRNA of enzymes that convert cholesterol in bile acids (CYP7A1 and CYP27A). We found that aerobic exercise training improves the macrophage RCT. Exercise-trained mice had higher levels of macrophage-derived ^{3}H-cholesterol in their plasma, liver and feces. The enhanced protein levels of hepatic ABCA-1 and LDL receptor contributed to greater HDL plasma concentration and cholesterol flow into the liver, respectively. The RCT benefit seen in exercise-trained CETP-tg mice helps to elucidate the role of exercise in the prevention of atherosclerosis in humans.

Materials and Methods

Animals and Aerobic Exercise Protocol

Two-month-old male transgenic mice homozygous for human CETP (human natural promoter-driven CETP transgenic mice, CETP-tg; line 5203; back-crossed on a C57BL/6 background for 10 generations) that originated in Dr. AR Tall′s laboratory and were kindly provided by Dr. HCF Oliveira (University of Campinas, São Paulo, Brazil) were fed a pelleted commercial chow ad libitum (Nuvilab-Nuvital, São Paulo, Brazil) with free access to water. Animals were housed in conventional housing at 22 ± 2 °C with a 12 h light/dark cycle. Protocols were approved by the Institutional Animal Care and Research Advisory Committee (Hospital das Clinicas of the Faculty of Medical Sciences, University of São Paulo-CAPPesq # 773/06) according to the US National Institutes of Health Guidelines. Animal care was provided in accordance with the procedures outlined in the Guide for the Care and Use of Laboratory Animals [8], and experiments were performed under adherence to the American College of Sports Medicine (ACSM) animal care standards. CETP-tg animals were subjected to a 6 week monitored aerobic exercise training protocol performed on a treadmill (WEG CFW-08, São Carlos, Brazil) at 15 m/min during 30 min sessions five times a week. A control group was kept sedentary for the same amount of time. Exercise sessions were carried out in the late afternoon and were supervised by the same investigator (DDFM Rocco).

LDL Isolation and Acetylation

Procedures with humans conformed to the Declaration of Helsinki and all participants signed an informed written

consent form previously approved by The Ethical Committee for Human Research Protocols of the Hospital of the Faculty of Medical Sciences, University of São Paulo (CAPPesq # 773/06). Low density lipoprotein (LDL) was isolated from healthy plasma donors by sequential ultracentrifugation ($d = 1.019-1.063$ g/mL) and was further purified by discontinuous gradient ultracentrifugation. After dialysis against PBS, the protein content was determined using the Lowry procedure [9], and acetylation was performed with acetic anhydride according to Basu et al. [10]. After extensive dialysis against ethylene diamine tetra acetic phosphate-buffered saline (EDTA–PBS), acetylated LDL (AcLDL) was kept sterile at 4 °C under nitrogen atmosphere and was used within a month.

Measurement of the In Vivo RCT

J-774 macrophages were grown in an RPMI 1640 culture medium supplemented with 10% fetal bovine serum (FBS), labeled with 5 μ Ci/mL [^{3}H]-cholesterol and enriched with 50 μg/mL of AcLDL for 48 h, as previously described [11]. Cells were then removed from plaques by trypsin treatment followed by inactivation of the enzyme by adding RPMI plus FBS. The cells were then spun down by centrifugation at 4 °C at 1,500 rpm and rediluted in a small volume of PBS. Cell viability, assessed by exclusion with Trypan blue, was greater than 98%, and an aliquot was placed in a beta counter (Beckman model; Palo Alto, USA) to determine the radioactivity. The intracellular distribution of cholesterol fractions was determined by thin-layer chromatography and consisted of 96 and 4% in the free and esterified forms, respectively.

Forty-eight hours after the last bout of exercise, [^{3}H]-cholesterol-labeled J-774 foam cells (3.5×10^6 cells; ~80,000 dpm in 100 μL of PBS) were intraperitoneally injected into the exercise-trained and sedentary mice, which were individually housed in metabolic cages with free access to food and water. Samples of blood from the tail vein and feces were taken after 24 and 48 h. Plasma radioactivity was immediately determined after spinning the blood at 1,500 rpm for 20 min at 4 °C. The mice were euthanized 48 h after the injection. Their organs (liver, spleen, lung, heart, kidneys and adrenal glands) were subsequently removed, carefully washed with cold 0.9% NaCl solution, gently dried with filter paper and weighed.

The feces and organs were stored at −70 °C until further analyses. Total feces and organs or liver aliquots were homogenized with a 2:1 (v/v) mixture of chloroform/methanol [12] and stored at 4 °C overnight for lipid extraction. The lipid layer was drawn and evaporated under nitrogen flow, and the radioactivity was determined. Results are expressed as percentages of total dose (dpm) injected per gram of sample (liver or feces) or plasma volume (mL). The radioactivity recovery in heart, lung, spleen, kidney and adrenal glands was too low and represented less than 1% of the total radioactivity injected (data not shown).

Measurement of Hepatic Cholesterol Content

Lipids were extracted from the liver, and total cholesterol was determined from a supernatant aliquot using the enzymatic method (Roche Diagnóstica, SP, Brazil), and the protein concentration by using the Lowry technique [9].

Plasma Lipid Analysis

Plasma (100 μL) from each mouse was analyzed by fast protein liquid chromatography (FPLC) gel filtration on two Superose-6 columns. The cholesterol concentration in all LP fractions was measured with a Cobas Mira using an enzymatic colorimetric kit (Roche Diagnostic, Brazil).

CETP Activity Determination

CETP activity was measured as the transfer of [^{14}C]-cholesteryl oleate from HDL to VLDL and LDL using LP isolated from pools of human normolipidemic individuals and plasma from CETP-tg mice as a source of CETP as previously described [13].

Western Blotting Analysis

Protein lysates were obtained from frozen hepatic tissue from exercise-trained and sedentary CETP-tg mice. Tissue was homogenized in a Polytron (MA099 Potter Unit, Marcone Equip., Sao Paulo, Brazil) with a buffer containing 20 mM Hepes, 150 mM NaCl, 10% glycerol, 1% triton, 1 mM EDTA, 1.5 mM $MgCl_2$ and protease inhibitors. The supernatant was obtained after centrifugation, and an aliquot was dissolved in SDS-glycerol. Equal amounts of sample protein were applied to a polyacrylamide gel. SR-BI, ABCA-1, LXR and the LDL receptor protein levels were determined using anti-SR-BI (1:1,000), anti-ABCA-1 (1:1,000), anti-LXRα/β (1:1,000) (Novus Biologicals, Inc., Littleton, CO, USA), and anti-LDL receptor (M-20):sc-11826, (1:1,000) (Santa Cruz Biotechnology Inc, USA) followed by incubation with HRP-conjugated antibody and ECL reaction (Super Signal West Pico Chemiluminescent substrate, Pierce, Rockford, IL, EUA). Protein membrane stripping was performed by rinsing with 0.8 mM NaOH. The difference between the bands was analyzed in pixels using the JX-330 Color Image Scanner (Sharp®) and ImageMaster software (Pharmacia Biotech). The results are

expressed as arbitrary units. β-actin protein levels (anti β-actin 1:1,000, Fitzgerald Industries International, Inc., Concord, MA) were used as a control, and Ponceau staining of nitrocellulose membranes was implemented to assure equal protein loading.

CYP7A1 and CYP27A mRNA Expression in the Liver

At the final period of the study, the liver was removed and immediately frozen in liquid nitrogen. mRNA from liver samples (~50 mg) was extracted with 1 mL of Trizol (Invitrogen Life Technologies, Carlsbad, CA, USA). Reverse transcription reactions were performed with 2 μg of RNA using TaqMan Reverse Transcription Reagents (Applied Biosystems, Foster City, CA). Real time-PCR was performed on an Mx3000P QPCR System (Stratagene, La Jolla, CA) using the Brilliant SYBR Green QPCR Master Mix (Stratagene, catalogue no. 600548). The following primers were used: β actin sense 5′-TGG AGAGCACCAAGACAGACA-3′ and antisense 5′-TGC CGGAGTCGACAATGAT-3′; CYP7A1 sense 5′-AGCA ACTAAACAACCTGCCAGTACTA-3′ and antisense 5′-GTCCGGATATTCAAGGATGCA-3′; CYP27A sense 5′-GGAGGGCAAGTACCCAATAAGA-3′ and antisense 5′-TGCGATGAAGATCCCATAGGT-3′.

Determination of Apo A-I in the Peritoneal Fluid

Mouse peritoneal cavities were rinsed with PBS, and the fluid was collected in order to measure the apo A-I content. The sample volume was reduced using Amicon filters (Millipore, USA), and the same amount of protein was submitted to immunoblot analysis as described above using anti apo A-I Ab 1:1,000 (Santa Cruz Diag, USA).

Statistical Analysis

Statistical analyses were performed using GraphPad Prism 4.0 software (GraphPad Prism, Inc., San Diego, CA). A non-paired Student's *t* test was used to compare differences between groups. Summary data are reported as mean values ± standard error or mean values ± standard deviation as indicated. A p value <0.05 was considered statistically significant.

Results

CETP-tg C57BL/6 male mice were submitted to a 6 week period of supervised aerobic exercise training. Body weight, total plasma cholesterol and triacylglycerols were not modified by exercise training (Table 1). As shown in Fig. 1, the VLDL-cholesterol and LDL-cholesterol plasma profile was not modified by the aerobic exercise training, although the HDL-cholesterol fraction área was higher in the trained animals compared to the sedentary animals in the final period of the protocol. Plasma CETP activity was similar in sedentary and trained mice at the beginning of the protocol and did not change after the exercise training period. Moreover, CETP plasma activity was not different between the sedentary and trained groups when the initial and final periods were compared (Table 1).

Table 1 Body weight, plasma lipid profile and CETP activity in exercise trained and sedentary CETP-tg mice

	Trained ($n = 10$)		Sedentary ($n = 11$)	
	Basal	Final	Basal	Final
Weight (g)	19.4 ± 1.2	20.3 ± 1.3	20.0 ± 1.0	19.2 ± 1.0
TC (mg/dL)	52 ± 6	48 ± 5	64 ± 15	58 ± 11
TAG (mg/dL)	56 ± 19	55 ± 19	41 ± 13	46 ± 14
CETP activity (%)	29 ± 5	32 ± 8	28 ± 5	34 ± 11

TC total cholesterol, *TAG* triacylglycerols

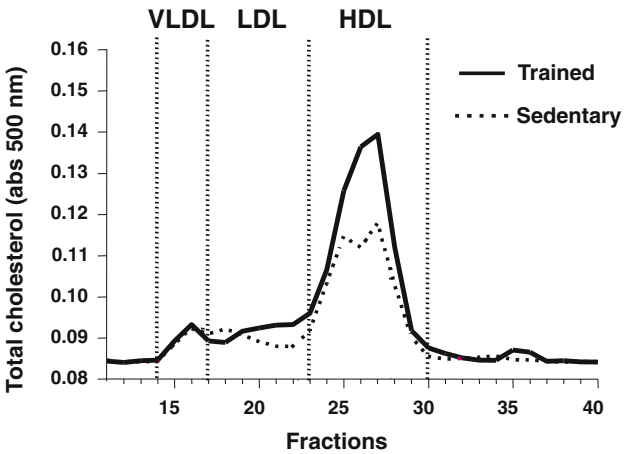

Fig. 1 Plasma lipoprotein profile of aerobically trained and sedentary CETP-tg mice. Plasma lipoproteins were isolated by fast protein liquid chromatography (FPLC), and total cholesterol was determined in all fractions using an enzymatic colorimetric kit. Sedentary (*dashed line*) and trained (*filled line*) CETP-tg mice

The [^{3}H]-cholesterol content was analyzed in plasma and feces at 24 and 48 h and in the liver at 48 h following the intraperitoneal injection of J774 macrophages enriched with AcLDL and radiolabeled cholesterol. A higher percentage of [^{3}H]-cholesterol was recovered from the plasma (Fig. 2a), liver (Fig. 2b) and feces (Fig. 2c) of the trained mice when compared to the sedentary animals.

As compared to the sedentary group, the increase in radiolabeled cholesterol in the liver of exercise-trained mice was accompanied by a 50% increase in protein levels of the hepatic LDL receptor (Fig. 3). In contrast, exercise

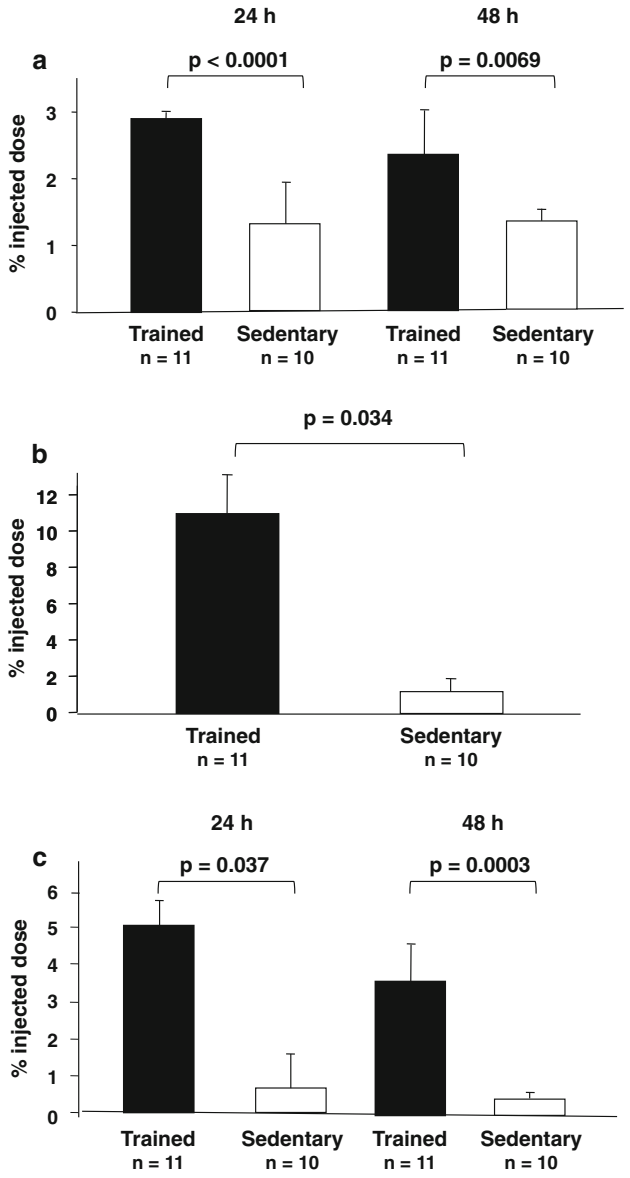

Fig. 2 Macrophage-derived [^{3}H]-cholesterol recovery in **a** plasma, **b** liver and **c** feces from aerobically trained and sedentary CETP-tg mice. J774 macrophages enriched with acetylated LDL and [^{3}H]-cholesterol were injected into the peritoneal cavities of sedentary and trained CETP-tg mice. **a** Plasma and **c** feces were collected after 24 and 48 h of the injection, and **b** the liver was removed after 48 h. After lipid extraction, the radioactivity was determined, and the recovery of [^{3}H]-cholesterol is expressed as the percentage of injected dose/mL of plasma or percentage of injected dose/mg of tissue or feces. Data are expressed as mean values ± standard error

training did not raise the SR-BI hepatic level (Fig. 3a). No changes were observed in the protein levels of LXR in the liver of exercise-trained animals (Fig. 3a). The hepatic ABCA-1 protein level was increased 100% in exercise-trained animals (Fig. 3a). CYP7A1 mRNA levels were reduced in exercise-trained CETP-tg mice, whereas their CYP27A mRNA levels were not influenced by exercise training (Fig. 3b). Total cholesterol content in the liver (mg of cholesterol/g of organ; mean ± SE) was not different between trained (43.3 ± 9.9; $n = 6$) and sedentary (40.4 ± 1.38; $n = 6$) animals.

The apo A-I content in peritoneal fluid as assessed by immunoblot was similar before and after exercise training (Fig. 4). Thus, the increase in the RCT after exercise training could not be ascribed to changes in apo A-I content.

Discussion

The importance of regular exercise for the prevention and treatment of chronic diseases is widely acknowledged [1]. Aerobic exercise improves LP metabolism and prevents the development of cardiovascular disease. Apart from the well-documented favorable effects of regular exercise on cardiovascular risk factors, it has been suggested that physical training may involve additional mechanisms that ameliorate atherosclerosis.

HDL is known for its anti-atherogenic properties that rely on its ability to support the cholesterol efflux from cholesterol-loaded arterial macrophages. Previous investigations focused on the benefits of exercise on lipoprotein lipase activity, including the mediation of triacylglycerol-rich LP metabolism and the increased levels of plasma HDL cholesterol [14, 15]. Nonetheless, it is unclear whether exercise plays a role in the RCT system in vivo. In this study, we used an experimental model designed to evaluate in vivo RCT and found that a 6 week carefully controlled aerobic exercise training program accelerates the RCT in CETP-tg mice.

CETP-tg mice are a useful tool for investigating the contribution of CETP to RCT. CETP is known to play a major role in RCT in humans. In huCETP-tg mice, the uptake of apo B-containing LP by the LDL receptor offers an additional route for the delivery of plasma esterified cholesterol to the liver. Accordingly, the increased RCT observed in the exercise-trained mice in this study may be ascribed to the enhanced protein levels of the LDL receptor in the liver. Elevated levels of hepatic LDL receptor mRNA have previously been shown in aerobic trained mice [16, 17], although the protein content has never been reported. In our investigation, exercise in the presence of CETP increased the uptake of LDL cholesterol by the liver and ABCA-1 protein levels, which may have prevented to liver cholesterol content from increasing by enhancing the export of cholesterol. In addition, by increasing the HDLc fraction as assessed by FPLC, exercise training may have contributed to a greater removal of cell cholesterol, despite a slight reduction in CYP7A1 mRNA levels.

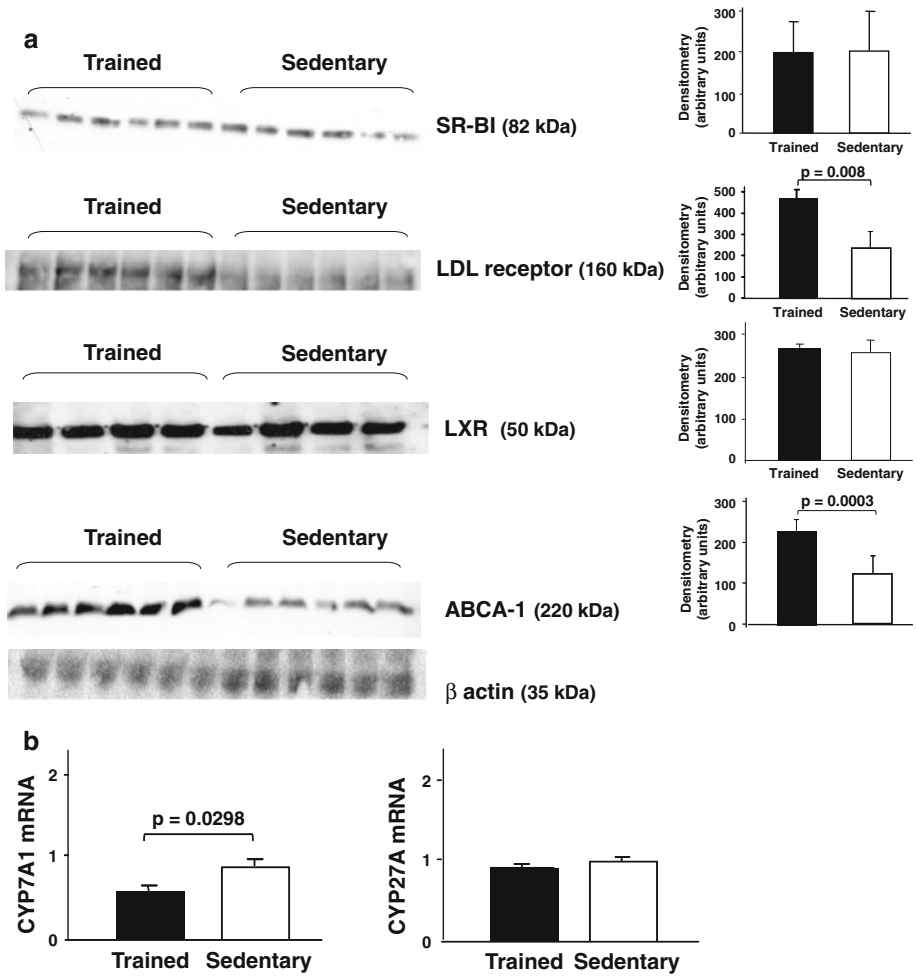

Fig. 3 LDL receptor, scavenger receptor class B type 1 (SR-BI), liver X receptor (LXR) and ATP binding cassette transporter (ABCA-1) protein levels and CYP7A1 and CYP27A mRNA in the livers of aerobically trained and sedentary CETP-tg mice. **a** liver samples from aerobically trained and sedentary CETP-tg mice were homogenized and dissolved in SDS-buffer. Equal amounts of protein lysates were applied to a 10% polyacrylamide gel and submitted to electrophoresis and immunoblotting with anti-LDL receptor Ab (1:1,000), anti-SR-BI Ab (1:1,000), anti-LXR Ab (1:1,000) and anti-ABCA-1 Ab (1:1,000). Following incubation with secondary Ab conjugated with HRP, bands were visualized after ECL reaction. Each *lane* represents one animal sample. Data are expressed as mean values ± standard deviation. **b** CYP7A1 and CYP27A mRNA was determined by RT-PCR as described in Material and Methods

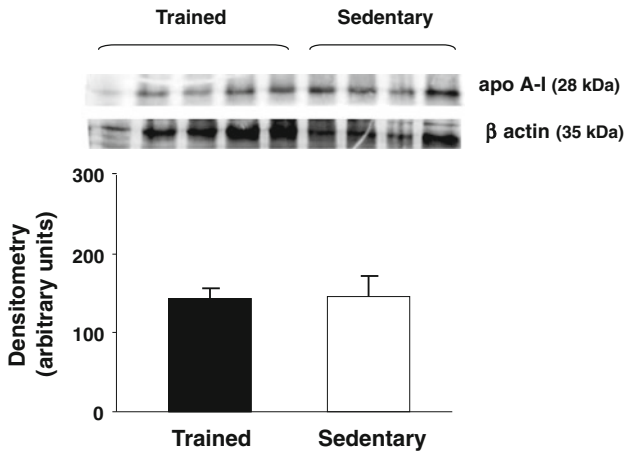

Fig. 4 Content of apo A-I in peritoneal fluid from aerobically trained and sedentary CETP-tg mice. Mouse peritoneal cavities were rinsed with PBS, and the fluid was collected. Protein was submitted to immunoblot analysis with anti apo A-I Ab 1:1,000

SR-BI plays a major role in the final step of the RCT system. Although macrophage SR-BI could not be related to an improvement in RCT efficiency [18], SR-BI protein levels in the liver are a positive regulator of macrophage RCT [19]. In fact, hepatic SR-BI is directly related to the secretion of cholesterol into the bile and to the reduction of atherosclerosis in animal models with low levels of HDL in plasma [20, 21]. Wei et al. [16] have described an enhancement of the hepatic SR-BI mRNA levels in wild-type C57BL/6 mice submitted to a 2 week aerobic training program. Surprisingly, the liver SR-BI protein levels did not change after aerobic exercise training in our study. This is likely due to a greater cholesterol influx mediated by the LDL receptor.

In huCETP-tg mice, a direct role of CETP in accelerating the tissue uptake of esterified cholesterol (EC) was demonstrated [22, 23]. Although improved HDL-EC removal and increased cholesterol content in the liver have been seen in CETP-tg mice, the excretion of biliary lipids and fecal bile acid have not been consistently found in these animals when compared to wild-type mice [24]. In CETP-tg mice, the in vivo RCT from macrophage to feces was not modified [25]. Nonetheless, the hypothesis that CETP facilitates RCT is strengthened by evidences related to mice expressing CETP alone [26] or combined with

knock-outs of LDL or SR-BI receptors. In these animals, CETP elicited macrophage RCT despite a reduction in HDL [27], and SR-BI-deficient mice were protected against diet-induced atherosclerosis [28]. On the other hand, the treatment of hamsters with torcetrapib, a drug that suppresses the CETP activity, increased the appearance of cholesterol originating from peritoneally injected macrophages in plasma and feces [26].

Increased levels of CYP27A mRNA have been described by Wilund et al. [17] in mice submitted to a 12 week aerobic exercise training program. In addition, voluntary wheel running increased fecal bile acid and cholesterol output and reduced intestinal cholesterol absorption in mice [29]. In our study, the CYP7A1 mRNA levels were reduced but CYP27A mRNA was not modified by exercise training, suggesting that the greater amount of radiolabeled cholesterol found in feces could be attributed to the increased excretion of cholesterol instead of bile acids. A recent paper from Yasuda et al. [30] showed that the activation of RCT resulted in a higher excretion of cholesterol, but not bile acids, in the feces of LXR agonist-treated mice. A limitation of our study was the fact that we did not measure the intestinal cholesterol absorption that could affect RCT in vivo as occurred in mice treated with ezetimibe [31]. Also, Temel et al. [32] used genetic and surgical models of biliary cholesterol insufficiency to demonstrate that a non-classical hepatobiliary pathway can contribute to RCT independently of biliary sterol secretion.

While this manuscript was under preparation, Meissner et al. [33] published a paper showing that the in vivo RCT, assessed by the same methodology used here, was not modified by voluntary wheel running in wild-type C57BL-6 mice compared to sedentary animals. Differences between their report and our results are likely ascribed to: (1) the presence of CETP in our model and its role in the alternative pathway of cholesterol disposal via the LDL receptor; (2) their results were obtained in free running wheel mice, which cannot assure equal training intensities along the protocol period, as opposed to the regular and carefully supervised exercise training protocol that was utilized in our study.

Although CETP activity was not changed after exercise training in our study, we should bear in mind that the CETP-mediated HDL-EC uptake by the liver is independent of the plasma activity responsible for the exchange of EC and TAG between LP [22]. Nonetheless, divergent data have been published regarding the role of CETP inhibitors like torcetrapib on this process [26]. Zhou et al. [34] suggested that the hepatic acquisition of EC from HDL mediated by CETP occurs independently of SR-BI, LDL-receptor related protein (LRP) and possibly the LDL receptor.

Controversial results have been published regarding the effect of exercise on the CETP mass and activity, which could be ascribed to the different methodologies used to measure CETP, as well as to variations in exercise intensity and frequency and the measurement of acute or chronic effects of exercise [14, 15]. Moreover, the efficiency of aerobic exercise in modulating the lipid profile is related to gender, age, insulin resistance, weight loss and genetic polymorphisms of CETP, apo E and apo A-I [36–38].

Exercise training did not modify the protein levels of LXR in CETP-tg mice. On the other hand, ABCA-1 was greatly enhanced following training, and this could have contributed to the higher levels of HDLc observed in exercise-trained CETP-tg mice in the final period of the study. ABCA-1 in the liver is known to contribute to HDL formation and plasma HDL cholesterol levels. Adenovirus-targeted protein levels of ABCA-1 in the liver increased HDL plasma levels in mice [39, 40]. On the other hand, an 80% reduction in plasma HDL cholesterol levels was observed in mice with a targeted inactivation of hepatic ABCA-1 [41], and ABCA-1 has been shown to play a critical role in HDL catabolism by the liver [42].

Systemic and macrophage ABCA-1 are positive regulators of macrophage RCT in vivo [18, 35]. This is consistent with our findings. An enhancement in ABCA-1 mRNA levels in the livers isolated from exercise-trained rats has also been described [43]. Furthermore, Butcher et al. [44] reported an increased expression of ABCA-1 and ABCG-1 mRNA in leukocytes isolated from trained subjects compared to sedentary ones.

In conclusion, aerobic exercise training improves RCT from macrophages in CETP-tg mice by increasing the concentration of HDL in plasma and by distinctly modulating the protein levels of liver receptors involved in the uptake of EC, which may contribute to the prevention and regression of atherosclerosis as previously reported by others [3, 5, 45]. With regards to the role of CETP in lipid metabolism in humans, the findings of our study shed light on an important effect of exercise on the RCT system. Taking into account that exercise has many effects on lipid and LP metabolism, the exact mechanisms by which exercise favorably modulates the lipid transport should be further investigated.

Abstract It is well recognized that a high dietary intake of long-chain polyunsaturated fatty acids (LC-PUFA) has profound benefits on health and prevention of chronic diseases. In particular, in recent years there has been a dramatic surge of interest in the health effects of n-3 LC-PUFA derived from fish, eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids. Notwithstanding, the metabolic fate and the effects of these fatty acids once inside the cell has seldom been comprehensively investigated. Using cultured neonatal rat cardiomyocytes as model system we have investigated for the first time, by means of high-resolution magic-angle spinning nuclear magnetic resonance (HR-MAS NMR) spectroscopy in combination with gas chromatography (GC), the modification occurring in the cell lipid environment after EPA and DHA supplementation. The most important difference between control and n-3 LC-PUFA-supplemented cardiomyocytes highlighted by HR-MAS NMR spectroscopy is the increase of signals from mobile lipids, identified as triacylglycerols (TAG). The observed increase of mobile TAG is a metabolic response to n-3 LC-PUFA supplementation, which leads to an increased lipid storage. The sequestration of mobile lipids in lipid bodies provides a deposit of stored energy that can be accessed in a regulated fashion according to metabolic need. Interestingly, while n-3 LC-PUFA supplementation to neonatal rat cardiomyocytes causes a huge variation in the cell lipid environment, it does not induce detectable modifications in water-soluble metabolites, suggesting negligible interference with normal metabolic processes.

Introduction

Cardiovascular diseases are responsible for significant morbidity and mortality throughout the world. It is well recognized that a significant dietary intake of polyunsaturated fatty acids (PUFA) has profound benefits on health and on prevention of chronic disease states, although the overall responsible mechanism remains partially unclear [1, 2].

Supplementation with the main n-3 long-chain polyunsaturated fatty acids (LC-PUFA), eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA), has been widely reported as protective for cardiovascular health, and fish oil feeding has been associated with reduced mortality in several studies [3–5]. Notwithstanding, the effects of these fatty acids (FA) on the cardiac cell lipid environment are almost unknown.

In this study we have coupled gas chromatographic (GC) analysis and high-resolution magic-angle spinning (HR-MAS) nuclear magnetic resonance (NMR) spectroscopy to obtain evidence of modifications occurring in the lipid environment and in the metabolic profile of cultured cardiomyocytes supplemented with n-3 PUFA. Chromatographic methods have become the standard for analyzing FA composition [6]. In particular, GC is sensitive and specific for FA analysis, and HR-MAS NMR spectroscopy takes a picture of the whole metabolic profile detecting lipids, macromolecules, and small metabolites. Using MAS NMR the sample can be analyzed directly with minimal manipulation, and many different compounds, for example macromolecules, lipids, and small metabolites, can be detected simultaneously [7–10]. Study of cellular metabolism in cell extracts solution, either hydrophilic or lipophilic, has been successfully carried out for years by use of NMR spectroscopy. More recently, the development of HR-MAS techniques has made the direct analysis of cells increasingly preferred for metabolomic studies [11]. HR-MAS NMR spectroscopy is currently used for analysis of the biochemical profile of complex systems such as biofluids, biological tissues, or cells. In fact, it can detect many different metabolites, and furnish information about the metabolic changes occurring in response to external stimuli, e.g. drug exposure, or disease [10]. As far as we are aware, HR-MAS NMR investigations, alone or combined with GC analysis, involving cardiomyocytes are still virtually non-existent. In our opinion, they could furnish baseline data for future investigation of the effects on mammalian cells of FA supplementation.

Materials and Methods

Materials

FA, Ham F10 media, fetal calf serum (FCS), horse serum (HS), gentamicin, amphotericin B, and 2′,7′-dichlorofluorescein were from Sigma (St Louis, MO, USA). Hexane, diethyl ether, and formic acid were purchased from Carlo Erba (Milan, Italy). All other chemicals and solvents were of the highest analytical grade.

Cardiomyocytes Cell Cultures

Primary cultures of neonatal rat cardiomyocytes were obtained from the ventricles of two to four-day old Wistar rats according to Yagev et al. [12]. Cells were seeded at a density of 1.5×10^6 cells/ml in 100-mm i.d. Petri dishes in Ham F10 nutrient mixture supplemented with 10% (*v*/*v*) FCS, 10% (*v*/*v*) HS, gentamicin (1%), amphotericin B (1%), and grown at 37 °C, 5% CO_2, and 95% humidity. The study protocol was approved by the Animal Care Committee of the University of Bologna (Italy) (prot. n. 58897-X/10). Forty-eight hours after seeding, cardiomyocytes were randomly divided into control and FA supplemented groups. EPA and DHA were dissolved in ethanol,

added to FCS to enable binding to albumin, and supplemented at 60 μM concentration. Control medium was added with the same volume of ethanol (≤0.1% *v*/*v*) to avoid interference from vehicle. Media were changed every 48 h, and cardiomyocytes were grown till complete confluence in a monolayer (day 8 from seeding).

Cardiomyocytes FA Composition

At confluence cardiomyocytes were washed three times with ice-cold phosphate-buffered saline, scraped off, and cell total lipids were extracted according to Folch et al. [13]. Washings were analyzed by GC to ensure that supplemented FA had been completely removed and did not interfere with subsequent analyses. Total cell lipids were separated by thin-layer chromatography (TLC) using plates coated with silica gel G. Plates were developed in hexane–diethyl ether–formic acid (8:2:0.1 *v*/*v*). Spots were made visible under ultraviolet light by spraying with 2′,7′-dichlorofluorescein (0.2% *w*/*v* in ethanol), and identified by comparison with authentic co-chromatographed standards. Spots corresponding to the phospholipid (PL) and triacylglycerol (TAG) fractions were scraped off, extracted with methanol or diethyl ether, respectively, and methylated according to Stoffel et al. [14]. Before methylation, pentadecanoic acid was added as internal standard. FA composition (as methyl esters) was determined by GC (GC 8000; Fisons, Milan, Italy) using a capillary column (SP 2340, 0.2 μm film thickness) with a programmed temperature gradient (160–210 °C, 8 °C/min), as previously reported [15]. The gas chromatographic peaks were identified on the basis of their retention time ratios relative to methyl stearate and predetermined by use of authentic samples. Gas chromatographic traces and quantitative evaluations were obtained using a Chrom Card Software computing integrator (Thermo Electron Scientific, Milan, Italy).

Nuclear Magnetic Resonance Spectroscopy

At confluence, after washing with ice-cold phosphate-buffered saline, cells were scraped off in deuterated water. Cell suspension (50 μl) was placed in a 50-μl MAS zirconia rotor (4 mm OD), closed with a cylindrical insert to increase sample homogeneity, then transferred to the probe cooled to 4 °C. ^{1}H and ^{13}C HR-MAS NMR spectra were recorded with a BrukerAvance 400 spectrometer operating at 400.13 and 100.61 MHz, respectively. The instrument was equipped with a ^{1}H,^{13}C HR-MAS probe, the temperature of which was controlled by a Bruker Cooling Unit. All experiments were performed at 4 °C to prevent cell degradation processes [16]. Samples were spun at 4,000 Hz. After set up for approximately 20 min, three different types of monodimensional (1D) proton spectra were acquired by using:

1. a composite pulse sequence (zgcppr) [17], with 1.5 s water-presaturation during relaxation delay, 8 kHz spectral width, 32 k data points, 32-64 scans;
2. a water-suppressed spin–echo Carr–Purcell–Meiboom–Gill (CPMG) sequence (cpmgpr) [18], with 1.5 s water presaturation during relaxation delay, 1 ms echo time (τ), and 360 ms total spin–spin relaxation delay ($2n\tau$), 8 kHz spectral width, 32 k data points, 128 scans; and
3. a sequence for diffusion measurements based on stimulated echo and bipolar-gradient pulses (ledbpgp2s1d) [19] with big delta 200 ms, eddy current delay T_e 5 ms, little delta 2 × 2 ms, sine-shaped gradient with 32 G/cm followed by a 200 μs delay for gradient recovery, 8 kHz spectral width, 8 k data points, 256 scans.

Two-dimensional (2D) ^{1}H,^{1}H-correlation spectroscopy (COSY) spectra [20, 21] were acquired using a standard pulse sequence (cosygpprqf) and 0.5 s water presaturation during relaxation delay, 8 kHz spectral width, 4 k data points, 32 scans per increment, 256 increments. 2D ^{1}H,^{1}H-total correlation spectroscopy (TOCSY) spectra [22, 23] were acquired using a standard pulse sequence (mlevphpr) and 0.5 s water-presaturation during relaxation delay, 100 ms mixing (spin-lock) time, 4 kHz spectral width, 4 k data points, 32 scans per increment, 128 increments. NMR spectra of specimens were analyzed using MestReC software (Mestrelab Research, Santiago de Compostela, Spain). A line-broadening apodization function of 5 Hz was applied to lead diffusion-edited HR-MAS ^{1}H FIDs before Fourier transformation. NMR spectra were referenced to the FA terminal $-CH_3$ signal at δ 0.89 ppm, manually phased, and a Whittaker baseline estimator was applied to subtract the broad components of the baseline.

Statistical Analysis

Three batches for each type of sample (control, EPA-supplemented, and DHA-supplemented cardiomyocytes) derived from three independent cell cultures were analyzed. Statistical analysis was performed by one-way ANOVA with Tukey as post test.

Results

HR-MAS NMR

The metabolic pattern of unsupplemented, control cardiomyocytes can be derived by analysis of the spectra shown in Fig. 1. The first spectrum (Fig. 1a) is a conventional

presaturated 1D spectrum detecting lipids, macromolecules, and small metabolite contribution. Figure 1b shows the spectrum obtained using a CPMG spin–echo sequence. This enables separation of signals according to their different T_2, and enhancement of the resonance of small metabolites relative to that of macromolecules. The small metabolites are labeled in Fig. 1b: alanine (Ala), choline-containing compounds (ChoCC), creatine (Cr), glutamate (Glu), glycine (Gly), *myo*-inositol (Myo), phosphoethanolamine (PEtn), *scyllo*-inositol (Scy), taurine (Tau), α-CH of aminoacids (α-CH). The diffusion-edited spectrum (Fig. 1c) displays broad resonances arising from macromolecules. In particular, mobile FA chains (signals at 0.89 ppm (–C**H**$_3$), 1.33 ppm (C**H**$_2$)$_n$, and 2.03 ppm C**H**$_2$C=C) and phosphatidylcholine (PtdCho) (signal at 3.26 ppm N(C**H**$_3$)$_3^+$) are clearly detectable. Membrane PL do not contribute significantly to the NMR signals because of their low mobility and short relaxation times. Control cardiomyocytes ^{1}H HR-MAS NMR spectra were used for the comparison with spectra obtained from cells supplemented with EPA and DHA.

In Fig. 2 the conventional water-presaturated ^{1}H spectra obtained from control (Fig. 2a), EPA-supplemented (Fig. 2b), and DHA-supplemented (Fig. 2c) cardiomyocytes are reported. In the spectra of n-3 LC-PUFA-supplemented cardiomyocytes it is possible to recognize the characteristic signals from unsaturated FA. The resonances of FA chains are identified as: 1, methyls (–C**H**$_3$) at 0.89 ppm (saturated FA chains), and 2, –C**H**$_3$ at 0.96 ppm (n-3 EPA, and DHA); 3, acyl chain methylenes (C**H**$_2$)$_n$ (1.33 ppm); 4, C**H**$_2$–C–CO (1.58 ppm); 5, C**H**$_2$C=C (2.02 ppm); 6, C**H**$_2$CO other than DHA (2.25 ppm) and 7, C**H**$_2$CO of DHA, (2.33 ppm); 8, =C–C**H**$_2$-C= (2.78 ppm); 9, –C**H**=C**H**-(5.33 ppm) [24–26]. Signals at 2.02 ppm are assigned to methylene protons of the C**H**$_2$–CH=CH moiety of both monounsaturated FA (MUFA) and PUFA, and the signal at 2.78 ppm is characteristic of PUFA [24, 25]. Both MUFA and PUFA are also identified by the signals at 5.33 ppm, because of the protons of the –C**H**=C**H**– moiety.

Comparison of ^{1}H NMR spectra of supplemented and control samples shows that the PUFA signals are dominant in EPA and DHA-supplemented cardiomyocyte spectra, whereas they are almost absent in those of control cells. Moreover, the signal at 2.33 ppm, characteristic of DHA

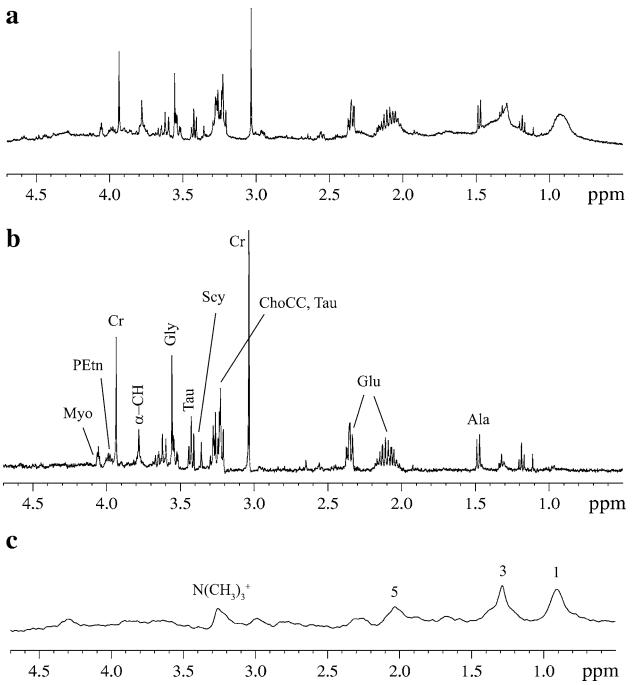

Fig. 1 Representative ex-vivo HR-MAS ^{1}H NMR spectra of neonatal rat cardiomyocytes: water-presaturated pulse sequence with composite pulse (**a**), CPMG spectrum (**b**), and diffusion-edited spectrum (**c**). The major metabolites are labeled: *Ala* alanine, *ChoCC* choline-containing compounds, *Cr* creatine, *Glu* glutamate, *Gly* glycine, *PEtn* phosphoethanolamine, *Scy scyllo*-inositol, *Myo myo*-inositol, *Tau* taurine, *α-CH* α-CH of aminoacids. Lipid components are labeled: *1*, –CH$_3$; *3*, acyl chain methylene (CH$_2$)$_n$; *5*, CH$_2$C=C; *N(CH$_3$)$_3^+$*, signal for PL components

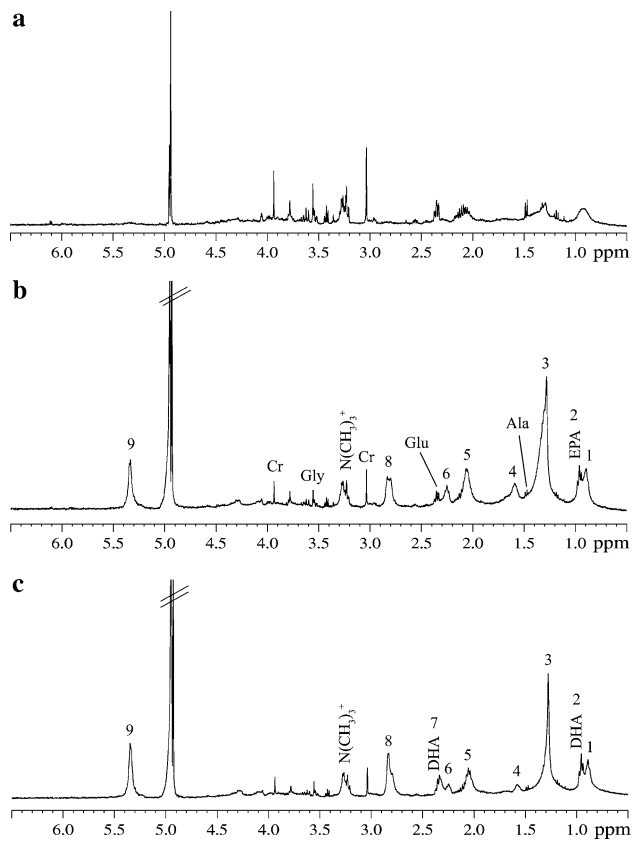

Fig. 2 Water-presaturated ex-vivo HR-MAS ^{1}H NMR spectra of control (**a**), EPA-supplemented (**b**), and DHA-supplemented (**c**) cardiomyocytes. Lipid components are labeled as in the previous figure and: *2*, DHA and EPA –CH$_3$; *4*, CH$_2$–C–CO; *6*, CH$_2$CO other than DHA; *7*, CH$_2$CO and CH$_2$–C–CO of DHA; *8*, =C–CH$_2$–C=; *9*, CH=CH

$C\underline{H_2}$–CO and $C\underline{H_2}$–C–CO protons, enables distinction between DHA and EPA-supplemented samples.

In Fig. 3 the ^{1}H HR-MAS NMR diffusion-edited spectra of control (Fig. 3a), EPA-supplemented (Fig. 3b), and DHA-supplemented (Fig. 3c) cardiomyocytes are reported. In accordance with the literature, lipid components are identified as above. Signals 10 and 11, from bonded glycerol (4.10 and 4.30 ppm) are clearly detected, especially for the DHA-supplemented cells.

These spectra show an increase of signals from mobile lipids in PUFA-supplemented cells compared with the unsupplemented cells. Low PL signals (in particular that of $N(CH_3)_3^+$ at 3.26 ppm) are present, together with broad peaks from the macromolecules, in the control cell spectrum (Fig. 3a). In supplemented cells, these signals are obscured by the high intensity of signals from PUFA, mainly bonded to glycerol in TAG. Signals from CH_2 of bonded glycerol in TAG are clearly seen at 4.30 and 4.10 ppm (Fig. 3, signals 10, 11), whereas the CH resonance at 5.26 ppm is overlapped by the CH=CH protons of FA chains. Signals attributable to cholesterol (C) or cholesteryl esters (CE), the most characteristic of which is that of 18-CH_3, at approximately 0.7 ppm, are not detected.

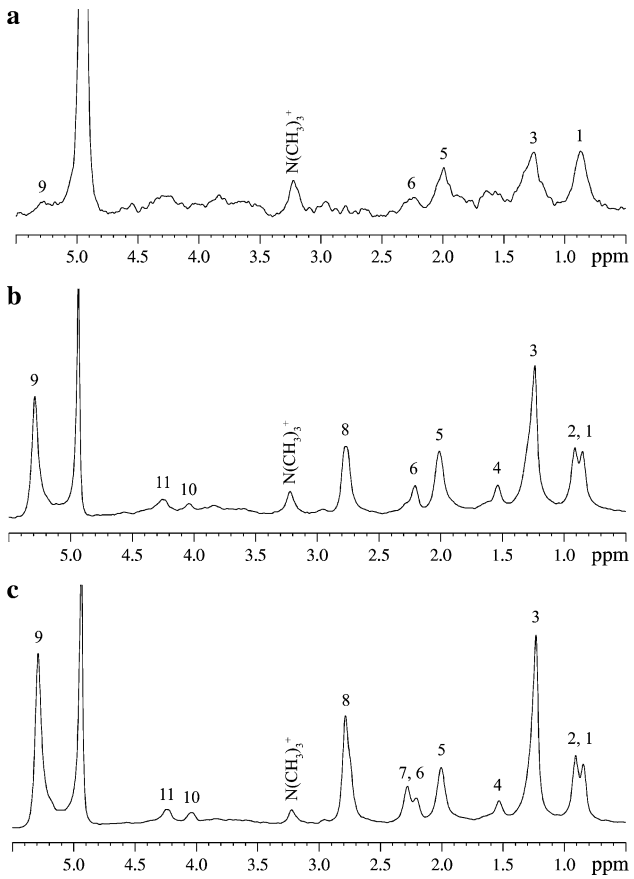

Fig. 3 ^{1}H HR-MAS NMR diffusion-edited spectra from control (**a**), EPA-supplemented (**b**), and DHA-supplemented (**c**) cardiomyocytes. Lipid components are labeled as in previous figures and: 10 and 11, bonded glycerol

Variation of the mobile lipid components can be evaluated by integration of the resonances present in HR-MAS led diffusion-edited spectra (Fig. 4). Supplemented cardiomyocytes furnish a general increase of lipid signals, particularly unsaturated FA, which are almost absent in control cells (lack of signals at 2.78 ppm and 5.33 ppm). Instead, the PL fraction ($N(CH_3)_3^+$ signal at 3.26 ppm) does not seem significantly affected by supplementation (Fig. 3). In EPA and DHA-supplemented cardiomyocytes glycerol bonded signals (at 4.10 and 4.30 ppm), absent in control cells, are detected, indicating that NMR-visible FA are involved in TAG. Comparison of the theoretical (6:4) and experimental (7.4:4) TAG integral ratio between the CH_2CO (2.25 ppm) and glycerol (4.30 and 4.10 ppm) signals in EPA-supplemented cell spectra points to the presence of almost completely glycerol-esterified FA chains, and a slight excess of unesterified FA (FFA). The same approach, if applied to DHA samples, is less straightforward. In this case two signals, at 2.33 and 2.25 ppm, are derived from CH_2CO protons (DHA and other FA, respectively), and the former also receives a contribution from CH_2–C–CO protons of DHA. Moreover, the signal at 2.25 ppm accounts for approximately 25–30% of the total integral (2.25 + 2.33). The theoretical ratio between the integrals of the signals at 2.25 + 2.33 ppm and that of glycerol (4.30 and 4.10 ppm) is 12:4 for glycerol-triesterified with DHA (signal at 2.25 ppm absent) and 6:4 for glycerol-triesterified with FA other than DHA (signal at 2.33 ppm absent). On this basis, for DHA-supplemented cells we calculate a [DHA/(FA other than DHA)] ratio of approximately 3:2 and a theoretical ratio of $(12 \times 0.6 + 6 \times 0.4) = 9.6{:}4$ for FA involved in TAG. This compares well with the experimental value of 10.1:4, and indicates that the NMR-visible lipid signals arise from almost completely glycerol-esterified FA chains in DHA-supplemented cells also.

Figure 5 reports the CPMG HR-MAS ^{1}H NMR spectra of control (Fig. 5a), EPA-supplemented (Fig. 5b), and DHA-supplemented (Fig. 5c) cardiomyocytes. In the spectra some residual signals from EPA and DHA are present, indicating that some protons in PUFA chains are characterized by long transverse relaxation times T_2. Hence the chains are not only slowly diffusing (as is apparent from diffusion edited spectra) but also free to rotate. This situation is usually indicative of the presence of lipid bodies (LB) in the cell [24, 25, 27]. As reported above, the NMR data show that these lipids are essentially constituted by mobile TAG.

Analysis of the CPMG spectra shows that supplementation has no relevant effects on the profile of the small

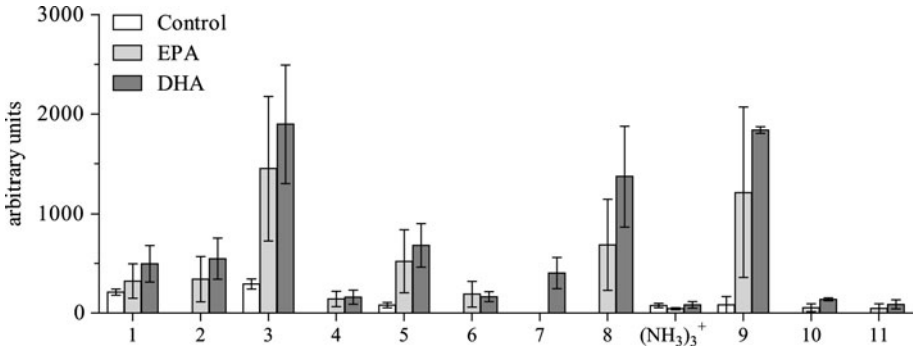

Fig. 4 Relative amount of lipid components from control, EPA and DHA-supplemented cardiomyocytes, as derived from integration of HR-MAS diffusion-edited spectra. The data are scaled relative to $-CH_3$, and reported as means ± SEM. Lipid components are labeled: *1*, $-CH_3$ (0.89 + 0.96 ppm); *2*, $-CH_3$ from EPA and DHA (0.96 ppm); *3*, acyl chain methylene- $(CH_2)_n$; *4*, CH_2–C–CO; *5*, CH_2C=C; *6*, CH_2CO (2.25 ppm); *7*, CH_2CO and CH_2–C–CO from DHA (2.33 ppm); *8*, =C–CH_2–C=; *9*, CH=CH; *10* and *11*, bonded glycerol (4.10 and 4.30 ppm)

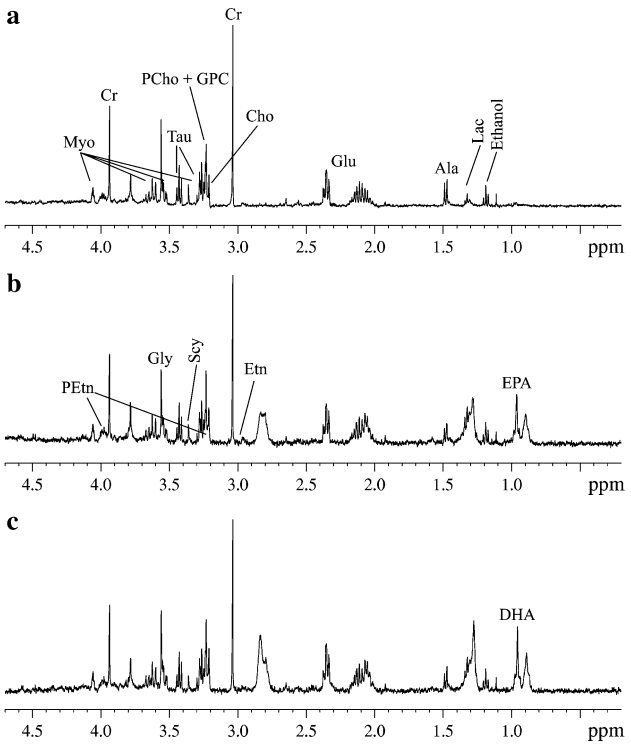

Fig. 5 CPMG ex-vivo HR-MAS ^{1}H NMR spectra of control (**a**), EPA-supplemented (**b**), and DHA-supplemented (**c**) cardiomyocytes. The major metabolites are labeled as in previous figures and: *Cho* choline, *Etn* ethanolamine, *GPC* glycerophosphocholine, *Lac* lactate, *PCho* phosphocholine

metabolites (polyols, osmolytes, and aminoacids). They were assigned by direct inspection of 1D and 2D spectra (COSY and TOCSY spectra, here not reported), and by comparison with literature data [28, 29]. The main metabolites detected by HR-MAS NMR in cardiomyocytes are ethanol, lactate (Lac), Ala, acetate (Ac), Glu, Cr, Tau, Gly, choline (Cho), ethanolamine (Etn), phosphocholine (PCho), glycerophosphocholine (GPC), Scy and Myo, PEtn, uridine-diphosphate (UDP), adenine, a trace of glutamine (Gln), and lysine (Lys).

GC

In the PL fraction (Fig. 6a), EPA supplementation of cardiomyocytes leads to enhancement of the relative molar content of both EPA itself and its metabolic elongation derivative docosapentaenoic acid (22:5n-3, DPA) [30]. No further conversion of n-3 DPA to DHA is detected. After DHA supplementation, the relative molar content of this FA increases, without any appreciable retroconversion to DPA or EPA. The increased incorporation of n-3 PUFA is accompanied by a decrease in the relative molar contents of palmitoleic (16:1n-7), oleic (18:1n-9), and arachidonic (20:4n-6, ARA) acids.

In the TAG fraction (Fig. 6b), EPA is not incorporated as itself but after conversion to its derivative DPA [30], whereas DHA is incorporated without any further metabolism. In both cases, a concomitant decrease in the relative molar content of saturated FA and ARA is detected.

The total amount of FA esterified in the PL fraction is lower in DHA-supplemented cells than in controls (Fig. 7a). In contrast, the small amount of FA esterified in the TAG fraction of control cells increases substantially after EPA and DHA supplementation, as shown in Fig. 7b.

Discussion

Cells contain a substantial amount of polar lipids, PL and C, and neutral lipids, for example TAG and CE. Taken together, these account for approximately 4–16% of total cell mass and approximately 20–50% of dry cell mass [31]. Although NMR is regarded as a universal detector, lipid ^{1}H NMR resonances are not always observed in tissues that

Data are expressed as µg/plate and are means ± SD from at least three independent cell cultures. Statistical analysis was performed by one way ANOVA (p values are shown above bars) with Tukey as post test comparing control and n-3 LC-PUFA-supplemented cells ($^{\#}p < 0.05$; $^{\circ}p < 0.01$; $^{*}p < 0.001$)

are rich in C and PL. This directly implies that ^{1}H NMR-visible lipids must have unique structural and biochemical properties that set them apart from the bulk of tissue lipids. This apparent paradox is resolved by considering the physical basis of NMR, which emphasizes the importance of sufficient molecular mobility in the immediate chemical environment for a given molecule to become detectable by NMR [27]. The first explanation of the contributions of mobile and non-mobile components to the NMR spectra of biological samples was reported in the key work on C-13 NMR by William et al. [32]. Much later, the important applications of MAS NMR to biological systems by the Oldfield [33] and Hamilton groups [34, 35] meticulously discriminated phase and molecules with different mobilities. Lipid resonances must arise from molecules with high molecular mobility. Because it is known that LC-PUFA is mainly incorporated into membrane PL, which do not significantly contribute to the NMR signal because of their rigid environment, we coupled GC analysis to NMR. As expected, the signal from PL is very weak in NMR analysis, irrespective of the experimental conditions, whereas GC analysis, besides detecting PL, shows that EPA and DHA supplementation causes substantial modification of PL FA composition. In several studies, the biological effects of n-3 LC-PUFA have been ascribed to the incorporation of these FA into PL into cellular membranes, where they may alter membrane fluidity and functionality,

and may affect cellular eicosanoid synthesis [36–39]. According to GC data, EPA and DHA are actively incorporated in the PL fraction, displacing ARA, the relative molar content of which is reduced by more than 50%. It is conceivable that the modifications occurring in PL after EPA and DHA supplementation could cause important changes not only in membrane structure, but also in membrane and cell functionality. The total amount of FA esterified in PL is reduced in DHA-supplemented cardiomyocytes (Fig. 7a). The larger packing free volume associated with LC-PUFA-rich membranes could explain in part the reduction of the acyl content in the PL fraction. In fact, in saturated or monounsaturated membranes the acyl chains pack quite uniformly whereas in membranes containing DHA the packing is distorted by the steric restrictions associated with a higher surface area of the FA [40]. As an alternative, DHA could have triggered a remodeling mechanism causing an increase in lyso-PL. Actually, DHA has been shown to alter cell membranes increasing the activation of phospholipase A2 [41].

The most important difference between control and n-3 LC-PUFA-supplemented cardiomyocytes highlighted by HR-MAS NMR spectroscopy is the increase of signals from mobile lipids, identified as TAG. Regarding TAG, two alternative sources of ^{1}H NMR-visible mobile lipid resonances have been proposed, i.e. membrane-associated globular microdomains [42, 43] and intracellular LB [44, 45]. Many in-vitro cell studies and in-vivo diffusion measurements have suggested the importance of LB as contributors to ^{1}H NMR-detectable lipid resonances [27, 44–46]. It is therefore conceivable that the observed increase of NMR-visible TAG in supplemented cells is associated with an enhanced presence of LB, as already reported for human cardiomyocytes [47]. The observed increase of mobile TAG could be a metabolic response to n-3 LC-PUFA supplementation, which leads to increased lipid storage. The increase in the total amount of FA incorporated in TAG, and the higher relative molar content of n-3 LC-PUFA in this fraction after supplementation, is confirmed by GC. Our results are in agreement with those of Finstad et al. [48], who observed an increase in the TAG content of monocytic U937-1 cells after treatment with 60 μM EPA. This TAG increase was accompanied by accumulation of LB.

The second hypothesis has been considered the more probable in recent years [49, 50]. The sequestration of mobile lipids in LB provides a deposit of stored energy that can be accessed in a regulated fashion according to metabolic need [51]. In particular, the myocardium stores FA, the major energy substrate for normal heart function, as TAG in LB [52].

Incorporation of n-3 LC-PUFA into TAG-rich LB could also be the basis for a yet unknown mechanism important for cell regulation. First, storage of FA in LB may function to protect the cells from exposure to high concentrations of FFA. Second, a TAG pool rich in LC-PUFA may be an important reservoir for signal molecules. Finstad et al. [48] suggested that EPA, DPA, and DHA, when liberated from an intracellular storage pool, affect intracellular signal transduction systems differently from when released from cellular PL. Furthermore, LC-PUFA stored as TAG in LB could be used for membrane PL synthesis. In the heart, the synthesis of PL to ensure membrane homeostasis is a priority that warrants the membrane depolarization that triggers cardiac contraction [52]. It is also possible that n-3 LC-PUFA stored in TAG may affect cardiomyocytes gene expression via PPAR-dependent signal pathways. We have already demonstrated that incubation of with 60 μM EPA and DHA alters the expression of different genes [53].

The accumulation of LB has been correlated with the reduction in cell number, inhibition of proliferation, and induction of apoptosis in monocytic U937-1 cells [48]. In a previous study in which neonatal rat cardiomyocytes were supplemented with the same EPA and DHA concentrations, we observed a modest increase in cell growth and no significant alteration in cell cycle distribution. Furthermore, n-3 LC-PUFA supplementation significantly protected cardiomyocytes from apoptosis [53]. The different cell type used in these studies might explain the different results, emphasizing that cell response to LC-PUFA supplementation can be very different.

The signals from C and, even more so, from CE are not detected in cardiomyocyte NMR spectra, probably because of their low mobility [54, 55]. Similarly, the TLC spot corresponding to CE was hardly detectable, irrespective of the supplementation. This is in agreement with Finstad et al. [56] who, supplementing different cell lines with labeled EPA, found only 1% of the FA was recovered in the CE fraction.

Regarding the small molecules, HR-MAS NMR metabolic characterization of cardiomyocytes reveals only negligible variations of the metabolic profile among differently treated cells. Indeed, the metabolome of unsupplemented and supplemented cells is characterized by the same small metabolites (mainly Ala, Lac, Ac, Glu, Cr, Tau, Gly, Cho, PCho, GPC, Scy, Myo, PEtn, Gln, UDP, adenine, and Lys) in almost the same relative ratios. N-3 LC-PUFA supplementation of neonatal rat cardiomyocytes causes a huge variation in the cell lipid environment, but negligible variation of the metabolome.

In conclusion, simultaneous use of ^{1}H HR-MAS NMR spectroscopy and GC furnishes information on the cell lipidome and metabolome. This work shows the complementary potential of these techniques. Furthermore, as far as we are aware this is the first report on changes in the lipid components of cardiomyocytes after n-3 LC-PUFA

supplementation. Understanding of the modification of the lipid environment is a further step toward clarification of the involvement of n-3 LC-PUFA in the prevention of cardiovascular disease.

Abstract Early accumulation of n-3 long-chain PUFA (LCPUFA) in the brain may contribute to differences in later cognitive abilities. In this study, our objective was to examine whether fish oil (FO) supplementation during lactation affects processing speed, working memory, inhibitory control, and socioemotional development at 7 years. Danish mothers ($n = 122$) were randomized to FO [1.5 g/d n-3 LCPUFA] or olive oil (OO) supplementation during the first 4 months of lactation. The trial also included a high-fish intake (HFI) reference group ($n = 53$). Ninety-eight children were followed-up with an assessment of processing speed, an age-appropriate Stroop task, and the Strength and Difficulties Questionnaire at 7 year. A group effect of the intervention (FO vs. OO) was found in prosocial behavior scores; this negative effect was carried by the boys. Exploratory analyses including all participants revealed the speed of processing scores were predicted by maternal n-3 LCPUFA intake during the intervention period (negative relation) and maternal education (positive relation). Stroop scores indicative of working memory and inhibitory control were predicted by infant erythrocyte DHA status at 4 months of age (negative relation). Early fish oil supplementation may have a negative effect on later cognitive abilities. Speed of processing and inhibitory control/working memory are differentially affected, with speed of processing showing effects of fish oil intake as a whole, whereas inhibitory control/working memory was related more specifically to DHA status.

SDQ	Strength and Difficulties Questionnaire

Introduction

Long-chain n-3 polyunsaturated fatty acids (n-3 LCPUFA) are accumulated in the central nervous system during early life and are thought to play an important role in the proper function and development of the brain and retina [1, 2]. Early intake of n-3 LCPUFA has been shown to affect the development of visual acuity in both preterm and term infants [3, 4], but its effect on mental function is less well established [5]. Recent reviews of randomized controlled trials (RCT) conclude that further studies are needed to determine if early intake of n-3 LCPUFA is associated with changes in cognitive or behavioral performance [6, 7]. Moreover, the optimal intake of n-3 LCPUFA during early life is not yet known [2].

Breastfeeding has been shown to confer a long-term advantage in cognitive performance in meta-analyses [8],

and studies has shown that the advantage is dependent on both maternal and infant genotypes at certain single nucleotide polymorphisms on the fatty acid desaturase gene complex (FADS1/FADS2) indicating that this is at least partly due to LCPUFA [9, 10]. Maternal supplementation studies have been performed to examine if variations in maternal n-3 LCPUFA intake can affect functional outcomes in the infants. Researchers observed improved mental processing scores at 4 years of age in children of mothers who were supplemented with fish oil during pregnancy and lactation [11]. Sequential processing at 7 years of age was related to alpha-linolenic acid (18:3n-3) and docosahexaenoic acid (DHA, 22:6n-3) levels in maternal plasma during pregnancy [12]. Perinatal plasma DHA status as measured in cord blood has also been found to be significantly negatively correlated with internalizing problem behavior at 7 years of age [13]. Moreover, scientists who conducted a large cohort study found positive associations between maternal intake of marine foods and verbal IQ measured at 8 years of age [14]. Thus, maternal fatty acid status may have long-lasting effects on the cognitive abilities of the offspring.

Conceptually, fish oil supplementation during pregnancy and lactation, which are critical periods for brain development, should affect subsequent cognitive development as DHA is implicated in many neural processes. DHA is involved in synaptogenesis and maturation of the synapses [15] and neuronal membrane structure and function [16]. Importantly, there is direct evidence that the presence of DHA increases processing speed at the membrane [17]. Speed of processing, a basic cognitive process which underlies all cognitive functioning, can be defined as the time required to move information from one neuron to the next, and it is reasonable to hypothesize that DHA will have an effect on speed of processing.

Higher, more complex, cognitive processes are subserved by the frontal lobes, which have a high concentration of DHA [18]. The frontal lobes and the cognitive functions that they support show a protracted development reaching functional maturity at 12–15 months of age and continuing to develop into adolescence [19]. Moreover, dopamine, an important modulator of higher-order cognitive functions [20], has been shown to be low in the frontal lobes when DHA is low [21]. Thus, it is reasonable to posit that DHA status will be related to the higher-order functions subserved by the frontal lobes. Cognitive abilities thought to be early precursors of the higher-order functions, such as means-end problem solving, begin to emerge at the end of the first year of life and have been shown to be related to DHA levels [22]. However, higher-order cognitive functions such as working memory and inhibitory control cannot be reliably tested until children reach 3–5 years of age.

Socioemotional behaviors related to higher-order cognition such as hyperactivity and inattention have been studied in relation to differences in LCPUFA status [23]. Treatment with n-3 LCPUFA has been found to ameliorate the symptoms of attention deficit hyperactivity disorder [24]. It is not known whether improved LCPUFA status early on is related to the differences in socioemotional behavior in typically developing children. In one study, scientists reported that higher n-3 LCPUFA status in children was related positively to prosocial behavior and negatively to inattention, emotional difficulties, and hyperactivity [25]. However, it is not known whether maternal n-3 LCPUFA status is similarly related.

Here we report the results of a follow-up of an RCT in which lactating mothers were supplemented with either fish oil or olive oil for the first 4 months of their infants' lives [26, 27]. The aim was to investigate whether maternal n-3 LCPUFA intake during lactation had an effect on socioemotional functioning, as assessed by the Strength and Difficulties Questionnaire (SDQ), and cognition, specifically speed of processing, working memory, and inhibitory control, when the children were 7 years of age. The results indicated no group effects of the early intervention on cognitive scores at 7 years of age, but exploratory model building using continuous biochemical markers revealed that maternal n-3 LCPUFA intake was negatively related to speed of processing, and the DHA content of infant erythrocytes was negatively related to working memory/inhibitory control scores. Regarding the socioemotional scores, there was a group effect of the intervention on the prosocial score. Post hoc analyses revealed this negative relation was carried by the boys.

Methods

Participants and Intervention

The trial and its follow-up studies at 2.5 and 7 years were approved by the Scientific-Ethical Committees for Copenhagen and Frederiksberg (KF 01-300/98, KF 01-183/01 and KF 11321572, respectively). The RCT was by design double-blinded throughout the intervention period and the researches were blinded at both the 2.5 and 7 year follow-ups, but the participants and their parents were not. Both parents of the child gave written consent to participate in the 7 year follow-up after the study had been explained to at least one of them orally, as well as in writing.

The participating mothers were recruited during pregnancy from the Danish National Birth Cohort during December 1998–November 1999. The dietary intake of the mothers in the Danish National Birth Cohort was determined in the 25th week of pregnancy using a food

frequency questionnaire as described by Olsen and colleagues [28]. Women in the 36th week of pregnancy living in the greater Copenhagen area and having a fish intake below population median (fish intake of 12.3 ± 8.2 g/d and less than 0.40 g/d of n-3 LCPUFA) were asked to participate in the trial as a low fish group. Women with a fish intake in the highest quartile of the population (fish intake of 55.2 ± 26.7 g/d or 0.82 g/d of n-3 LCPUFA) were also asked to participate in the trial as a high fish intake reference group (HFI group). One hundred and twenty-two women with a low fish intake and 53 with a high fish intake were accepted to participate in the trial. The trial is described in detail elsewhere [26].

After the birth of their children, the women in the low fish intake group were randomly assigned to one of two supplementation groups with stratification according to mean parental education: an experimental group receiving fish oil (FO) supplement and a control group receiving an equal amount of olive oil (OO) supplement as described previously [26]. Both supplements were given as microencapsulated oils (from BASF Health and Nutrition A/S, Ballerup, Denmark) incorporated and concealed in müsli bars (produced by Halo Foods Ltd., Tywyn Gwynedd, Wales, United Kingdom) or home baked cakes (ordinary capsules were given as an alternative if the women disliked the dishes). The supplement levels in the FO group were intended to match the intake of the HFI reference group. The FO supplement supplied the women with 4.5 g/d fish oil containing 1.5 g/d of *n*-3 LCPUFA, of which 0.62 g was eicosapentaenoic acid (EPA, 20:5n-3) and 0.79 g was DHA. Throughout the 4 month intervention, the mean self-reported compliance, expressed as the percentage of oil consumed relative to the intended dose was in both groups 88% (SD = 9%, $n = 99$). Of the 150 women who completed the supplementation period, 107 mothers fulfilled the criterion of exclusive breastfeeding during the 4 months. The children who were partially breastfed were not excluded from the study, but the degree of breastfeeding was taken into account in the analysis of the results [26].

The n-3 LCPUFA intakes of the mothers were determined at recruitment and at the 2, 4, and 9 month visit by food frequency questionnaires of fish intake [26] and the diet of the children was determined at 2.5 [29] and 7 years of age [30]. Breastmilk was collected at 9 days and 2, 4, and 9 months of age. Additionally, a blood sample was collected from the mother at recruitment and at the end of the intervention and from the infant at 4 months of age in order to measure the biochemical effect of the intervention by analyzing the fatty acid composition of the red blood cells [26].

All the children who participated in the 9 month follow-up visit ($n = 149$) were invited to participate in the 7 year follow-up study. Nine of the children were lost to follow-up due to lack of contact. Ten participants were excluded because they were living outside Zealand, one child was excluded due to a broken leg, and 31 did not wish to participate. Thus, 98 children participated in the 7 year follow-up study. The characteristics of these children are given in Table 1.

Cognitive and Socioemotional Assessments

Means-End Problem Solving at 9 Months

The effects of the intervention on the mental development of the infants were tested with a means-end problem solving task at 9 months of age (36.6–40.6 weeks) as previously reported [27]. In short, the means-end problem solving ability was assessed with The Infant Planning Test

Table 1 Characteristics of the participants

	High fish	Olive oil	Fish oil
Children included *(n)*	34	28	36
Sex ratio in group (M:F)[b]	18:16	12:16	24:12
Age at follow-up (years)[c]	7.3, 6.9–7.6 (34)	7.3, 6.8–7.7 (28)	7.4, 6.9–7.8 (36)
Birth weight (kg)[a]	3.7 ± 0.5 (34)	3.6 ± 0.4 (28)	3.7 ± 0.4 (36)
Birth length (cm)[c]	52.5, 50.0–55.5 (34)	52.0, 49.9–55.1 (28)	52.0, 50.0–55.3 (36)
Head circumference at birth (cm)[a]	36.1 ± 1.6 (33)	35.7 ± 1.3 (25)	36.0 ± 1.2 (33)
Degree of breastfeeding during the 4-month intervention *(%)*[c]	100, 86–100 (34)	100, 97–100 (28)	100, 35–100 (26)

[a] Values are given as means ± SD (*n*). Differences between groups are tested with a Student *t* test when comparing the two randomized groups and with an ANOVA when comparing all three groups

[b] Values are given as a ratio. Differences between groups are tested with a χ^2 test

[c] Data are not normally distributed. Values are given as median, 10th–90th percentile (*n*). Differences between the two randomized groups were tested with the Mann–Whitney *U* test and differences between all three groups were tested with a Kruskall–Wallis test

designed by Willatts [31] by one trained tester (72.5%) or in her absence, by one of two trained tester stand-ins (17.2 and 10.3%). The infant was presented with the same two-step problem multiple times (3.7 ± 1.8 presentations; equal in the three groups). All trials were recorded on videotape, and two trained observers scored the behavior independently. Two outcome measures were coded: scores on individual problems (0–6 points) and percent of intentional solutions (defined as problems solved with a score of at least one in all single score parameters or a minimum score of 6). Successful results on the problem-solving test were obtained for 89% of the tested children ($n = 122$ of 138; 14 refused, 2 video malfunctions).

Speed of Information Processing Test at 7 Years

Speed of processing was assessed using a subtest of the Woodcock Johnson Tests of Cognitive Abilities III® [32]. Participants were presented with a page of pictures of puppies, balls, and cups in random order. They were instructed to work as quickly as possible and to circle all instances where the picture of the ball was followed immediately by a picture of a puppy. They were given 3 min to complete the task: there were 69 possible pairs. Scoring was a simple count of correct pairs divided by the expected number of correct pairs for the specific age of the participant.

Higher-Order Cognitive Functioning Test at 7 Years of Age

Working memory and inhibitory control were tested using an age-appropriate day/night Stroop task as described in Archibald and Kerns [33]. The Stroop task requires the participant to inhibit a prepotent response and respond according to a rule held in working memory. Participants were presented with a booklet of pages populated with pictures of suns and moons. For the first phase, they were instructed to quickly say "sun" when they saw a picture of a sun and "moon" when they saw a picture of a moon. After 45 s, the administrator said to stop. For the second phase, they were instructed to say "moon" when they saw a picture of a sun and "sun" when they saw a picture of a moon. The Stroop score was computed as an interference score (difference between # correct in Phase 2 and # correct in Phase 1 divided by the # correct in Phase 1).

Strengths and Difficulties Questionnaire (SDQ) at 7 Years of Age

Caregivers completed the SDQ revised for Danish speakers [34]. The SDQ elicits ratings of 25 behaviors on a 3-point scale (not true, somewhat true, or certainly true). Behaviors include things such as "Considerate of other people's feelings" and "Often loses temper". Items were combined to yield sub-scale scores for Emotional Symptoms, Conduct Problems, Hyperactivity, Peer Problems, and Prosocial Behavior. All sub-scale scores except Prosocial Behavior were added together to yield the Total Difficulties Score.

Statistics

All cognitive data were normally distributed and met all assumptions for analyses. To assess the validity of the measures (i.e. continuity in cognitive abilities), 7 year speed of processing scores, 7 year Stroop scores, 9 month means-end problem solving, and 9 month means-end intentional solutions were entered into a bivariate correlation analysis. In addition, correlations between cognitive measures and socioemotional behavior (SDQ scores) were evaluated.

To test the efficacy of the intervention on cognitive abilities at 7 years of age, speed of processing scores and Stroop scores were entered in a multivariate analysis of variance (MANOVA) by RCT groups (FO and OO). The SDQ data were analyzed by non-parametric tests (Mann–Whitney U test) as these variables tended to be limited to a few distinct values. The HFI group was not included in these analyses in accordance with the trial design.

To explore individual differences in the cognitive outcomes as they related to the continuous biochemical data, we undertook model-building analyses subsequent to the trial analyses that included all the participants (HFI, FO, and OO). First, each independent variable was regressed onto the set of remaining independent variables to test for multicollinearity issues as described by Lewis-Beck [35]. Using the criterion of $r^2 < 0.80$, it was determined that maternal RBC–DHA and breastmilk DHA accounted for significant variance in the other independent variables. Thus, maternal RBC–DHA and breastmilk DHA were not considered in further analyses. Variables determined to be independent variables and thus, utilized in the model-building analyses were infant RBC–DHA (FA%) at 4 months, weighted infant DHA intake (breastmilk DHA content x% of total nutrition that was from breastmilk), and mean maternal intake of DHA during intervention period (g/d; includes intake from intervention supplement plus daily intake related to lifestyle). Maternal education was used as a proxy for socio-economic factors. Data were entered into regression analyses using backward elimination. Using the same independent variables (infant RBC–DHA at 4 months, weighted infant DHA intake, and mean maternal intake of n-3 LCPUFA), backward elimination was used to predict the individual sub-scale and total scores from the SDQ.

Results

Randomized Controlled Trial Analyses (Only FO and OO Groups)

The cognitive scores at 7 years of age in the two randomized groups (OO and FO) and the HFI-reference group are shown in Table 2. There were no group differences between the randomized groups with respect to the speed of processing score [$F(1, 62) = 0.777$, ns] or the Stroop score [$F(1, 61) = 0.302$, ns]. Given that degree of breastfeeding was not controlled, we repeated the analyses controlling for the weighted infant intake. The results did not change. There were also no significant group differences (between FO and OO) in the socioemotional behavior data from the SDQ (see Table 3) although the Prosocial score tended to be higher in the control group [$Z(62) = -1.796$, $p < 0.10$]. Post hoc analyses revealed this effect was carried by the boys and in fact, was significant when analyses included only the boys [$Z(35) = -2.264$, $p < 0.05$].

Correlations Between Cognitive and Behavioral Scores Across and Within Ages (FO and OO Groups)

Across ages, the 9 month means-end intentional solution scores were correlated with the 7 year speed of processing scores [$r(56) = 0.281$, $p = 0.03$]. No relation was found between means-end intentional solutions at 9 months and working memory/inhibitory control, as measured by the Stroop score at 7 years of age [$r(55) = -0.02$, ns]. However, intentional solution scores were related to the aspect of the Stroop task that relies directly on speed of processing (number of correct responses when asked to say sun when the picture was a sun) [$r(56) = 0.335$, $p = 0.01$]. Because degree and length of breastfeeding were not controlled in the intervention, analyses were repeated partialling out the weighted infant intake variable. The same pattern of significance was found. Means-end scores were also positively related to the Prosocial score [$r(54) = 0.261$, $p < 0.05$], but not to any other SDQ scores.

Within ages, speed of processing scores were not related to the Stroop interference score, but as one would expect, were related to the individual aspects of the Stroop task (i.e. sun = sun and sun = moon) [$r(63) = 0.285$, $p = 0.02$ and $r(62) = 0.309$, $p = 0.01$, respectively]. Also as expected, processing speed was negatively related to the Emotional score [$r(61) = -0.247$, $p = 0.05$] and Total Difficulties score [$r(61) = -0.272$, $p = 0.03$], whereas the Stroop scores were negatively related to the Hyperactivity score [$r(61) = -0.343$, $p = 0.007$], Conduct score [$r(61) = -0.392$, $p = 0.002$], and Total Difficulties score [$r(61) = -0.357$, $p = 0.005$]. When analyses were repeated partialling out weighted infant DHA intake, the relations remained.

Exploratory Analyses of Prediction by the Continuous Biomarkers (FO, OO, and HFI groups)

Bivariate correlations between the variables used in the exploratory analyses are provided in Table 4. When predicting the speed of processing scores, one multiple regression model was significant: predictors were total maternal n-3 LCPUFA intake [$t(72) = -1.98$, $p = 0.05$], and maternal education [$t(72) = 2.13$, $p = 0.04$]. This model accounted for 9% of the variance in the speed of processing scores. For the Stroop interference scores, the best model included only infant RBC–DHA [$t(72) = -2.23$, $p = 0.05$]. This model accounted for 7% of the variance in the Stroop interference scores. In the model-building undertaken to explore the effects of the biological markers on socioemotional behavior as measured by the SDQ, no variable predicted the Prosocial, Emotional, Hyperactivity, or Conduct sub-scores. However, maternal education predicted the Peer Problems sub-score [$t(72) = -2.04$, $p = 0.04$], and Total Difficulties [$t(72) = -2.32$, $p = 0.02$], accounting for 6% and 7% of the variance, respectively.

Table 2 Description of the cognitive test scores at 7½ years and biological markers in the two randomized groups (OO and FO) and the reference group (HFI)

Mean ± SD (*n*)	High fish	Olive oil	Fish oil
Standardized speed of processing	1.08 ± 0.27 (32)	1.02 ± 0.26 (27)	0.96 ± 0.26 (36)
Stroop scores	−0.19 ± 0.13 (32)	−0.21 ± 0.10 (28)	−0.23 ± 0.14 (35)
Maternal education[a]	5.34 ± 1.26 (32)	5.43 ± 1.17 (28)	5.39 ± 1.10 (36)
Maternal n-3 LCPUFA intake (g/dg)	0.93 ± 0.48 (32)	0.26 ± 0.19 (28)	1.59 ± 0.32 (35)
Infant DHA intake (FA%)	0.74 ± 0.34 (32)	0.42 ± 0.23 (28)	1.22 ± 0.52 (33)
Infant RBC–DHA at 4 months (FA%)	7.30 ± 1.60 (29)	6.49 ± 1.52 (25)	9.04 ± 1.79 (23)

[a] Official Danish Classification of Educations from 1994 (1 = primary school and 8 = Ph.D. from university). The rank of 5 is equivalent to a category of parental education ≥14 years, the rank of 4 to 12–13 years, the rank of 3 to 11 years, the rank of 2 to 9–10 years and the rank of 1 to ≤8 years of education

Table 3 Description of the SDQ scores at 7½ years in the two randomized groups (OO and FO) and the reference group (HFI) (Panel A) and scores by gender (Panel B)

Panel A mean ± SD (min–max)	High fish $n = 30$	Olive oil $n = 28$	Fish oil $n = 34$	Fish oil versus olive oil[a] p
Prosocial score	8.7 ± 1.2 (6.0–10.0)	8.3 ± 1.7 (4.0–10.0)	7.6 ± 1.7 (3.0–10.0)	0.072

Discussion

To our knowledge, this is the first report of a direct assessment of executive functions in 7-year-olds from an early intervention RCT. No group effect of the intervention was evident in the speed of processing, inhibitory control, and working memory abilities of 7-year-olds whose mothers were supplemented with DHA during the first 4 months of breastfeeding. However, there was a trend in the behavioral data for the group whose mothers consumed fish oil to have lower prosocial scores relative to the OO group; this effect was carried by the boys. These results are consistent with the reported results at 9 months and at 1–2 years in this sample. No differences were found between groups on the means-end task at 9 months of age [27]. Importantly, lower language comprehension scores found in the FO group relative to the OO group at one year of age were also found to be specific to the boys. This decrement in language comprehension at 1 year by the boys in the FO group may account for the lower Prosocial scores in the same boys: perceived pro-sociality is related to language abilities [36]. It is not clear from these data why early maternal fish oil intake would have a negative effect on prosocial development in boys.

Exploratory analyses revealed a negative relation between total maternal n-3 LCPUFA intake (intervention supplement plus background diet) during the intervention period and speed of processing scores: the higher the early intake, the lower the speed of processing scores. Level of maternal education was a positive predictor of speed of processing scores. Stroop scores, which are indicative of working memory and inhibitory control, were negatively related to infant RBC–DHA levels. The differential prediction of cognitive abilities by maternal and infant biomarkers may be attributed to the differences between the predictors themselves: maternal intake is a measure of whole food fatty acid intake (fish and fish oil), whereas the infant status reflects only DHA. Therefore, it is possible that speed of processing relies on more than just DHA for optimal functioning. Conceptually, it is feasible as speed of processing is a ubiquitous function occurring in whole brain; working memory and inhibitory control may be more specific to frontal lobe function where DHA levels are reported the highest in the brain. Moreover, a study of the effect of fish consumption on breastmilk revealed that maternal intake results in significant differences in EPA and docosapentaenoic acid (22:5n-3) as well as DHA [37]. Further research is needed to explore the potential effects of these n-3 LCPUFA on speed of processing.

Our data indicate continuity in some of the tested cognitive abilities, as the scores of the means-end task administered at 9 months of age in this sample were correlated with the speed of processing scores obtained at

7 years of age. The means-end task is a problem-solving assessment that has been considered by some to be an early indication of executive function abilities [38]. However, we found that the 9 month scores were not related to the 7 year executive functions working memory and inhibitory control, but rather were related only to 7 year speed of processing. Working memory and inhibitory control are late-emerging abilities. It is possible that the precursor abilities related to working memory and inhibitory control that are present at 9 months of age are not necessary in the successful completion of a means-end problem. Nonetheless, the relation between means-end problem solving at 9 months of age and speed of processing at 7 years of age is evidence that the children's general underlying cognitive abilities were continuous throughout the follow-up years. Thus, our outcome measures are valid.

Importantly, the 9 month cognitive scores were not significantly related to the continuous n-3 LCPUFA intervention variables. Thus, the negative relation between the early RBC–DHA levels and cognitive abilities was not evident in this sample previous to the 7 year assessment. One could speculate that early intervention with DHA presents an environmental "mismatch" between prenatal and postnatal life that may be detrimental to the organism [39, 40] over time. However, given the small effect size (0.06–0.09), it is premature to speculate from these data. Conclusions regarding these negative relations between early intake/status and later cognitive functions (specifically speed of processing, working memory, and inhibitory control) cannot be confidently drawn from these data alone and certainly, replication will be necessary.

The intervention in the first 4 months of life did not have an effect on cognitive abilities at 7 years of age. There is much discussion in the literature as to the optimal timing of n-3 LCPUFA supplementation. Importantly, DHA should be present during critical periods of brain development to exact a measurable effect [41]. Thus, it is possible that an intervention during the first 4 months of life was not appropriate timing given the outcomes assessed. Indeed, the period of most rapid frontal lobe development is toward the end of the first year of life [42]. An n-3 LCPUFA intervention during this period might have a more measurable effect on executive functions.

The reported study has many strengths including randomization and the inclusion of a high fish intake reference group. However, there are a few potential weaknesses. First, the sample size may not have been sufficient. When all three groups were included in a MANOVA controlling for infant intake, a group difference began to emerge [$F(2, 82) = 2.74$, $p = 0.07$]. This could be taken as evidence that the sample size was too small to detect the small effect size. Second, the generalizability of these results may be limited. The Danish people have a high intake of n-3 LCPUFA compared to samples from other studies exploring the relationship between n-3 LCPUFA intake/status and cognitive functions. Third, the study was not designed to evaluate whether the results suggest an inverted-U effect of fish oil supplementation. The negative relations detected

may indicate that DHA has an optimum level below and above which may be detrimental to the developing brain.

In summary, the results of this intervention were not as hypothesized. Boys whose mothers consumed fish oil had lower prosocial scores relative to the OO group. Moreover, speed of processing scores and inhibitory control/working memory scores were differentially negatively predicted by maternal n-3 LCPUFA intake and infant RBC–DHA status. Continuity in outcome measures lends confidence, but the study was not without limitations. However, this study is the first of its kind. The results presented here provide important information for the design of future studies to elucidate these long-term effects from which we will be able to draw more firm conclusions.

Acknowledgments LL planned and designed the RCT in collaboration with KFM. CLC designed the 7 year cognitive follow-up and trained SN and MA who completed all the data collection. LL and CLC were responsible for data management, statistical analysis, interpretation, and writing of the manuscript. All authors approved the paper in its final version. None of the authors has any financial or personal relationships with the company or organization sponsoring the research. This trial was funded by the Food Technology Research and Development Programme, Denmark (FØTEK).

Vaccenic and Elaidic Acid Equally Esterify into Triacylglycerols, but Differently into Phospholipids of Fed Rat Liver Cells

Zhen-Yu Du · Pascal Degrace · Joseph Gresti · Olivier Loreau · Pierre Clouet

Received: 20 December 2010 / Accepted: 2 May 2011 / Published online: 26 May 2011

Abstract Elaidic acid (*trans*-9-$C_{18:1}$ or *trans*-9) is assumed to exert atherogenic effects due to its double bond configuration. The possibility that *trans*-9 and vaccenic acid (*trans*-11-$C_{18:1}$ or *trans*-11), its positional isomer, were biochemically equivalent and interchangeable compounds, was investigated by reference to their *cis*-isomers through esterification-related activities using rat liver cells and subcellular fractions. In hepatocytes, both *trans*-$C_{18:1}$ were incorporated to the same extent in triacylglycerols, but *trans*-9 was more esterified than *trans*-11 into phospholipids ($P < 0.05$). Glycerol-3-phosphate acyltransferase activity in microsomes was lower with *trans*-11 than with *trans*-9, while this activity in mitochondria was ~40% greater with *trans*-11 than with *trans*-9 ($P < 0.05$). Activity of 2-lysophosphatidic acid acyltransferase in microsomes was of comparable extent with both *trans* isomers, but activity of 2-lysophosphatidylcholine acyltransferase was significantly greater with *trans*-9 than with *trans*-11 at $P < 0.01$. Lipoproteins secreted by hepatocytes reached equivalent levels in the presence of any isomers, but triacylglycerol production was more elevated with *trans*-11 than with *trans*-9 at $P < 0.05$. Cholesterol efflux from previously labelled hepatocytes was lower with *trans*-11 than with *trans*-9. When these cells were exposed to either *trans*-$C_{18:1}$, the gene expression of proteins involved in fatty acid esterification and lipoprotein synthesis was unaffected, which indicates that the biochemical differences essentially depended on enzyme/substrate affinities. On the whole, vaccenic and elaidic acid were shown to incorporate cell phospholipids unequally, at least in vitro, which suggests they can differently affect lipid metabolic pathways in normal cells.

Keywords Vaccenic and elaidic acid · Esterification · Phospholipid · Cholesterol efflux · Gene expression

Abbreviations

ACC	Acetyl-CoA carboxylase
cis-9	*cis*-9-$C_{18:1}$, oleic acid
cis-11	*cis*-11-$C_{18:1}$
CLA	Conjugated linoleic acid
DGAT	Diacylglycerol acyltransferase
FA	Fatty acid
GPAT	Glycerol-3-phosphate acyltransferase
HMG-Red	Hydroxymethylglutaryl-CoA reductase
LDL-R	Low-density lipoprotein-receptor
mtGPAT	Mitochondrial GPAT
trans-9	*trans*-9-$C_{18:1}$, elaidic acid
trans-11	*trans*-11-$C_{18:1}$, vaccenic acid

Introduction

The consumption of fats containing *trans*-fatty acids (FA) has been correlated with an increased risk of coronary

heart disease, principally through elevated levels of plasma total cholesterol, LDL cholesterol, apolipoprotein B and increased LDL/HDL ratios [1, 2]. The partial hydrogenation of vegetable oils for margarine production [3, 4] gave rise to by-products as *trans*-FA whose levels may reach 60% of total FA [5]. Among these, elaidic acid (*trans*-9) could represent 30–40% and vaccenic acid (*trans*-11) 10% [6, 7]. *trans*-9 was assumed to exert atherogenic effects because its concentration in margarines was associated with abnormal plasma lipid concentrations [2, 8]. Some *trans*-$C_{18:1}$ are also produced in the digestive system of ruminants through the microbial hydrogenation of vegetable oils and are consequently recovered in related products as milk and meat. In dairy fats, *trans*-11 was found to represent more than 80% of all the identified *trans*-$C_{18:1}$ isomers [9, 10]. Epidemiological surveys suggested that *trans*-9 increases more the cardiovascular risk than *trans*-11 [11–13]. However with hamsters, plasma LDL/HDL-cholesterol ratios were more elevated with diets enriched in *trans*-11 than in *trans*-9 [14]. Yet with the same animal model, the hypercholesterolemic effects of partially hydrogenated vegetable oils was demonstrated not to directly depend on the presence of *trans*-9 or *trans*-11 [15]. In the whole, the use of versatile experimental models, atherosclerosis markers and dietary fat blends provide inconsistent results, which suggests that *trans*-9 and *trans*-11 exert similar effects, but whose amplitude would depend in humans on particular parameters as specific dietary lipid levels [16] or hormonal status [6].

Geometrical isomers exhibit comparable fates as regards their hydrolysis from triacylglycerols and their absorption in the intestinal tract [17], as well as their distribution among lymph lipids [18]. Thus the specific effects of *trans* isomers would occur beyond the intestinal step and then affect most organs with possible interrelations. This prompted us to limit the whole issue to the comparison of actions of pure *trans*-$C_{18:1}$ isomers by using only one tissue model. Liver was chosen because of its pivotal role in the re-distribution of ingested lipids to other organs via lipoprotein secretion. *trans*-9 and *trans*-11 were all the more recovered in lipoproteins because they were shown to be weakly oxidised in liver mitochondria [19, 20] and were then available for the esterification reactions. Besides, the incorporation of FA into membrane lipids is associated with cholesterol efflux, which should increase plasma cholesterol levels [1, 2]. The present study was designed to compare first the esterification capacities of *trans*-9 and *trans*-11, relative to their respective *cis*-isomers, in rat liver extracts, second the effects of the four $C_{18:1}$ isomers on membrane cholesterol efflux and esterification-related gene expression in isolated hepatocytes. Rats were fed a standard diet, instead of diets enriched in the tested isomers, to prevent alterations of enzyme activities induced by these isomers within membranes [21].

Experimental Procedure

Chemicals

Oleic (*cis*-9-$C_{18:1}$), elaidic (*trans*-9-$C_{18:1}$), *cis*-11-octadecenoic (*cis*-11-$C_{18:1}$) and vaccenic (*trans*-11-$C_{18:1}$) acids, abbreviated *cis*-9, *trans*-9, *cis*-11 and *trans*-11, respectively, were purchased from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C] oleic acid and [4-^{14}C] cholesterol were obtained from Amersham Biosciences Europe (Saclay, France). The other [1-^{14}C] isomers were specifically prepared by CEA (Gif sur Yvette, France) from commercial unlabelled FA and $^{14}CO_2$ using procedures described in [22]. Radiochemical purity (>98%) of [1-^{14}C] labelled compounds was determined by RP-HPLC (Zorbax SB C18; acetone/(methanol/water/acetic acid, 50:50:1, by vol), 60:40, by vol) and TLC (Silicagel Merck 60F254, pentane/diethylether/acetic acid, 80:20:0.1, by vol). They were all stored in chloroform/ethyl alcohol (50:50, by vol) at −30 °C. Evaporation of solvents under nitrogen was followed by the saponification of FA with NaOH or KOH for assays with whole cells or intracellular organelles, respectively, and their binding to essentially FA-free bovine serum albumin (BSA). These preparations were added to the other components of media immediately prior to incubations. [U-^{14}C]Glycerol-3-phosphate was obtained from NEN Life Science Products (NEN, Paris, France). BSA, cholesterol, collagenase (type I) and other biochemicals were from Sigma. Methylene chloride, 2,4,6-collidine, ethyl chloroformate and tetrahydrofuran, supplied by Aldrich Chemical Co. (Milwaukee, WI), were used for acyl-CoA synthesis [23]. Concentrations of synthesised acyl-CoAs were determined through their respective molar extinction coefficients at 260 nm and corrections based on their 232/260 nm ratios, relative to those with pure products [24–26].

Animals

Official French regulations (No. 87848) for the use and care of laboratory animals were followed throughout and the experimental protocol was approved by the local ethics committee for animal experimentation (No. BL0612). Male Wistar rats were purchased from Janvier (Le Genest St Isle, France). They were kept at 23 °C in a light-controlled room (light period fixed between 08:00 a.m. and 08:00 p.m.). They had free access to tap water and were fed a standard laboratory chow (ref AO4 from UAR, Epinay-sur-Orge, France) containing 58.7% carbohydrate, 17% protein, and 3% fat (palmitic, stearic, oleic and linoleic acids

representing 8.7, 1.7, 26.7 and 48.3%, respectively, of the total FA mass). When rats were 7–8 weeks old (250–300 g), they were anaesthetised with isoflurane and killed by exsanguination at 08:00 a.m.

Activity Rate Measurements

All the biochemical activity measurements were performed with increasing substrate concentrations, but the concentration retained for each experimental presentation was selected among those giving rise to the increasing part of activity curves.

FA Esterification by Isolated Hepatocytes and Liver Slices (Intact Cells)

Hepatocytes were isolated through a two-step collagenase perfusion as in [27]. Cell viability was assessed by trypan blue exclusion and suspensions with viability lower than 85% were discarded. Immediately after isolation, cells were preincubated in William's Medium E (WME) from PAN-Biotech GmbH (Aidenbach, Germany) containing 10% (v/v) fetal bovine serum and 1% (v/v) antibiotic antimycotic solution (Sigma Chemical, Co.) in water-saturated atmosphere (5% CO_2, 95% air) for ~3 h at 37 °C, in dishes of 60-mm diameter (~3×10^6 cells per dish). The attached cell monolayer was gently washed with 3 mL of fresh WME that was replaced by 2.5 mL of Krebs-Henseleit buffer (KHB) containing 118 mM NaCl, 4.7 mM KCl, 1 mM KH_2PO_4, 1.2 mM $MgSO_4$, 0.5 mM $CaCl_2$, and 25 mM $NaHCO_3$, pH 7.4. The reaction was started by addition of 1 mL of [1-^{14}C] FA (2.25 Ci/mol) with BSA (0.4 and 0.1 mM of final concentration, respectively) under 95% O_2 and 5% CO_2 atmosphere. Liver slices were also prepared using the procedure detailed in [19] and were incubated (0.2 g per assay) in 2.5 mL of KHB. The reaction was initiated by addition of 1 mL of labelled FA with BSA, as above for the cell monolayers. After 2 h of incubation at 37 °C, the supernatants were decanted, and the cell monolayers or tissue stripes were washed two times with KHB containing 2% FA-free BSA at 37 °C. Total lipids of both liver extracts were obtained using the Folch procedure [28] and were separated by TLC in hexane/ethyl ether/acetic acid/methanol (90:20:2:3, by vol). The radioactivity of triacylglycerol (TAG) and phospholipid (PL) spots was measured by AR-2000 TLC Imaging Scanner (Bioscan, Inc., Washington DC).

FA Esterification by Liver Homogenates (Disrupted or Disorganised Cells)

Liver pieces were homogenised by manual rotation of a Teflon pestle in an ice-cooled Potter–Elvehjem apparatus and diluted (1:40, w/v) in a chilled mixture of 0.25 M sucrose, 2 mM EGTA and 10 mM Tris/HCl, pH 7.4 [29]. The reaction was initiated by the injection of 0.1 mL homogenate into 1.5 mL of a mixture containing 2 mM ATP, 50 μM CoA, 4 mM $MgCl_2$, 1% glucose and 120 μM [1-^{14}C] FA (3.7 Ci/mol). Incubations were performed at 37 °C for 30 min and total lipids were extracted and separated as above for whole cells.

Microsomal and Mitochondrial Esterification onto the *sn*-1 Position of Glycerol-3-phosphate

The isolation of mitochondrial fractions was performed as in [29], using a medium containing 1% FA-free BSA to bind free FA released during and after the cell disruption. Microsomal fractions were isolated after mitochondria pelleting as in [30]. The protein content of these fractions cleared from BSA was measured using the bicinchoninic acid procedure [31] and their purity was checked through activity of enzymes specific to mitochondria, peroxisomes and microsomes, as detailed in [30]. Glycerol-3-phosphate acyltransferase (GPAT) activity was measured in 1 mL of medium buffered at pH 7.4 and containing 75 mM KCl, 0.2 mM EGTA, 4 mM $MgCl_2$, 80 mM mannitol, 25 mM HEPES, 2 mM KCN, 2 mM ATP, 50 μM CoA, 0.5 mM L-[H^3] glycerol-3-phosphate (0.72 mCi/mol), 0.1 mM of each $C_{18:1}$ isomer and 50 μM BSA, at 37 °C. The reaction was initiated by addition of 0.3 mg of microsomal or mitochondrial protein, or of 0.1 mL of liver homogenate (2.5 mg liver). After 7 min, 3 mL of 0.1 M HCl containing 10 mM DL-glycerol-3-phosphate (Prolabo, Paris, France) was added and the radioactivity of 1-monoacyl-[H^3] glycerol phosphate extracted with butan-1-ol [32] was determined after mixing with Ultima Gold XR (Packard, Meriden, CT).

Microsomal Esterification onto the *sn*-2 Position of Monoacylglycerolipids

2-lysophosphatidic acid acyltransferase and 2-lysophosphatidylcholine acyltransferase activities were measured according to the method described in [33]. Briefly, a preincubation time of 2 min was performed at 25 °C by addition of 0.2 mg of microsomal protein to 2 mL of a medium containing 10 mM 5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB), 5 mM Tris–boric acid and 5 μM of $C_{18:1}$-CoA, at pH 7.4. The specific reactions of esterification were recorded over 4 min after addition of 50 mM 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphate or 150 mM 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (Avanti Polar Lipids, Alabaster, AL). The change in absorption at 413 nm results from the binding to DTNB of thiol groups released by acyl-CoA hydrolysis during the esterification reactions.

Results were corrected from control values obtained in the absence of $C_{18:1}$-CoA.

Components of Lipoprotein Secreted by Hepatocytes Exposed to $C_{18:1}$ Isomers

Hepatocytes prepared as already described were incubated in 4 mL of WME containing 100 μM of each $C_{18:1}$ isomer bound to 50 μM BSA, 100 nM insulin and 1% antibiotic antimycotic solution, under a water-saturated atmosphere (5% CO_2, 95% air) at 37 °C. Control assays were performed in the same way, but in the absence of exogenous $C_{18:1}$ isomer. After 24 h, the media were centrifuged at 2,000×*g* for 5 min and the supernatants containing the cell lipid secretions were assayed with commercial kits from Orion Diagnostica (Espoo, Finland) for apolipoproteins A1 and B100, and from BioMérieux (Marcy l'Etoile, France) for triacylglycerols (TG PAP 150) and cholesterol (Cholesterol RTU). The efflux of cholesterol originating from all the cell structures was measured as follows: Hepatocytes prepared as above were cultured until the attachment step (∼4 h), then were added with 4 mL of WME containing 10% BSA, 4 μCi [4-^{14}C] cholesterol and 75 μL of fresh rat plasma. In this medium, the final amounts of cholesterol and LDL, expressed per mL, were 65 nmol and 50 μg, respectively. After 24 h of incubation at 37 °C in water-saturated atmosphere (5% CO_2, 95% air), radioactive and unlabelled forms of cholesterol in cells were assumed to balance each other. The supernatants were decanted and cells were washed once with KHB containing 1% BSA. Hepatocytes were then incubated in 4 mL of WME in the presence of 0.2 mM $C_{18:1}$ isomer and 70 μM BSA, with control assays performed in the absence of isomer. After 5 h, the supernatants were centrifuged to discard cells detached from the ground monolayer and the radioactivity of clarified samples, mixed with Ultima Gold XR, was measured in a scintillation spectrometer.

Gene Expression in Hepatocytes Exposed to $C_{18:1}$ Isomers

Hepatocytes prepared as above were incubated in 4 mL of WME containing 100 μM of $C_{18:1}$ isomer, 50 μM BSA, 100 nM insulin and 1% antibiotic antimycotic solution, in water-saturated atmosphere (5% CO_2, 95% air) at 37 °C. After 24 h, total mRNA of hepatocyte monolayers was extracted using Tri-Reagent (Euromedex, Souffelweyersheim, France) as described in [34]. Total mRNA was reverse-transcripted using Iscript cDNA kit (Bio-Rad, Marnes-La-Coquette, France). Real-time quantitative PCR was performed in 96-well plate using an iCycler iQ (Bio-Rad). Each well contains: 12.5 μL of iQ Sybr Green Supermix (Bio-Rad), 2.5 μL of forward primer (0.3 μM), 2.5 μL of reverse primer (0.3 μM), 5 μL of cDNA (25, 2.5, 0.25 and 0.025 ng for standards and 2.5 ng for samples) and 2.5 μL of water. Primer pairs were designed using 'Primers!' software and were synthesised by MWG-Biotech AG (Ebersberg, Germany). The sequences of the forward and reverse primers used were, respectively, as follows: 5′-caccggctgaaggacatac-3′ and 5′-gctcaaaggggtct caaaaga-3′ for acetyl-CoA carboxylase 2 (ACC 2); 5′-tt caaccccagtatcccatct-3′ and 5′-ggtgccttgtgtgagtttca-3′ for mitochondrial glycerol-3-phosphate acyltransferase (mtG-PAT); 5′-tcctaccgggatgtcaatct-3′ and 5′-ctcggtaggtcagg ttgtcc-3′ for diacylglycerol acyltransferase (DGAT); 5′-tgagcttagcgttgcttttg-3′ and 5′-agctttctttggggtcacg-3′ for HMG-CoA reductase; 5′-tgggttccatagggtttctg-3′ and 5′-ttg gggatcaggctggtat-3′ for LDL-receptor (LDL-R); and 5′-aat cgtgcgtgacatcaaag-3′ and 5′-gaaaagagcctcagggcat-3′ for *β*-actin. The relative expression of each gene was calculated with cDNA standard curves and normalised with actin cDNA.

Statistics

Differences between groups were determined performing repeated measures of ANOVA followed by the Tukey–Kramer multiple comparison post-hoc test using GraphPad Instat 3.1 software. Difference were considered significant at $P < 0.05$.

Results

Esterification of $C_{18:1}$ Isomers in Intact Cells

In hepatocytes (Fig. 1a) and liver slices (data not presented), the results were qualitatively comparable and showed that all the isomers were ∼2 times as much esterified into TAG as into PL. In TAG, *trans*-$C_{18:1}$ were ∼2-fold less incorporated than the *cis*-ones, while in PL, the amount of *trans*-9 was 25% greater than that of *trans*-11, and 3 times as elevated as that of *cis*-9 at $P < 0.05$. In liver homogenates, i.e. in disrupted cells, all the isomers were ∼2 times more incorporated into PL than into TAG (Fig. 1b). In TAG, the *trans*-$C_{18:1}$ were 40% less abundant than the *cis*-forms, while in PL, both *trans*-$C_{18:1}$ and *cis*-11 amounted to ∼50% more than *cis*-9 at $P < 0.05$.

Esterification onto the *sn*-1 Position of Glycerophosphate in Microsomes and Mitochondria

GPAT, through the esterification of acyl groups in *sn*-1 position of glycero-3-phosphate, initiates the synthesis of glycerolipids. In liver homogenates (Fig. 2a), GPAT activity was maximum with *cis*-9 and minimum with *trans*-11,

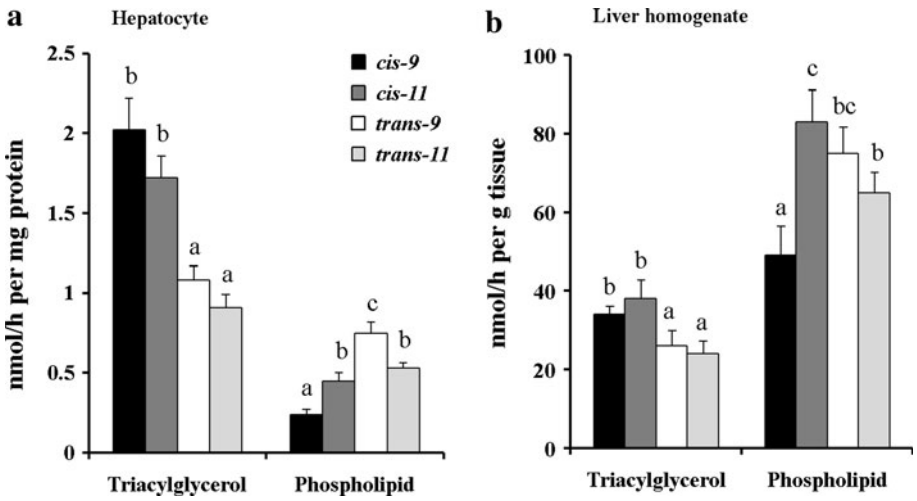

Fig. 1 Incorporation of $C_{18:1}$ isomers into TAG and PL of intact (**a**) and disrupted (**b**) liver cells. Concentrations of [1-^{14}C] isomer substrates in the final media were 0.4 and 0.12 mM with hepatocytes and liver homogenates, respectively. All results are expressed as nmol of $C_{18:1}$ isomers esterified per hour per mg hepatocyte protein or g wet liver. *T-bars* show SEM ($n = 3$). For each series and lipid class, values with different *letters* on columns statistically differ at $P < 0.05$

this latter exhibiting activity values lower than those of *trans*-9 at $P < 0.05$. The same pattern was observed in microsomes (Fig. 2b) except that the enzyme activity was comparable with *cis*-9 and *cis*-11. In mitochondria (Fig. 2c), GPAT (mtGPAT) was shown to exert activities of different extents as the considered $C_{18:1}$ isomer, in the following order: *cis*-11 > *cis*-9 > *trans*-11 > *trans*-9 ($P < 0.05$).

Esterification onto the *sn*-2 Position of Monoacylglycerolipids in Microsomes

The acylation in *sn*-2 position of 1-palmitoyl-2-hydroxyl-*sn*-glycero-3-phosphate is catalysed by 2-lysophosphatidic acid acyltransferase and regards as a step of the synthesis of glycerolipids as TAG and PL. Fig. 3a indicates that both *trans*-isomers were 40% less esterified in the *sn*-2 position than their *cis*-isomers ($P < 0.05$). The acylation at the same position of 1-palmitoyl-2-hydroxy-*sn*-3-phosphocholine is carried out by 2-lysophosphatidylcholine acyltransferase and reflects the renewing of cellular PL. This reaction was shown to be highly sensitive to the position of the double bond in the acyl chain, both Δ-11 isomers being ~4.5 times less esterified than both Δ-9-$C_{18:1}$ (Fig. 3b).

Lipid Secretion by Hepatocytes Exposed to $C_{18:1}$ Isomers

Total apolipoprotein A1 secretion was, compared to the control assay performed in the absence of FA, unaffected after 24 h-exposure of hepatocytes to any $C_{18:1}$ isomers, except that this production was decreased with *cis*-11 by reference to the control and *trans*-9 assays (Fig. 4a). Secretion of apolipoprotein B100 and total cholesterol was also unchanged after the same time of exposure to $C_{18:1}$ isomers (Fig. 4b, d). The TAG secretion was greater with *cis*-9 and *trans*-11 than with the control and *trans*-9 assays (Fig. 4c). When the efflux of cholesterol was studied with hepatocytes in which labelled cholesterol was previously balanced with the unlabelled cholesterol of cell structures (Fig. 5), values obtained after 5 h of incubation with the

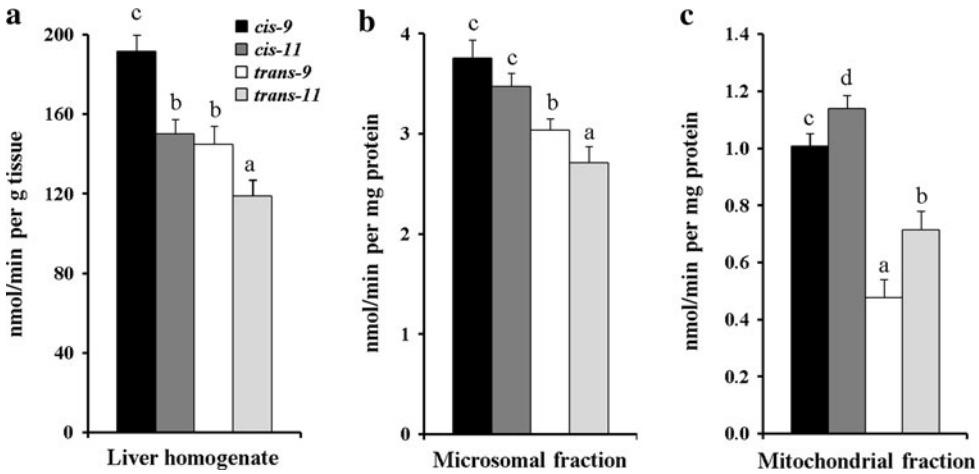

Fig. 2 Activity of glycerol-3-phosphate acyltransferase in the presence of 0.1 mM $C_{18:1}$ isomers with liver homogenates (2.5 mg wet liver) and 0.3 mg of microsomal or mitochondrial protein. All results are expressed as nmol of $C_{18:1}$ bound to glycerol-3-phosphate per min per g wet liver or mg microsomal protein. *T-bars* show SEM ($n = 3$). For each series, values with different *letters* on columns statistically differ at $P < 0.05$

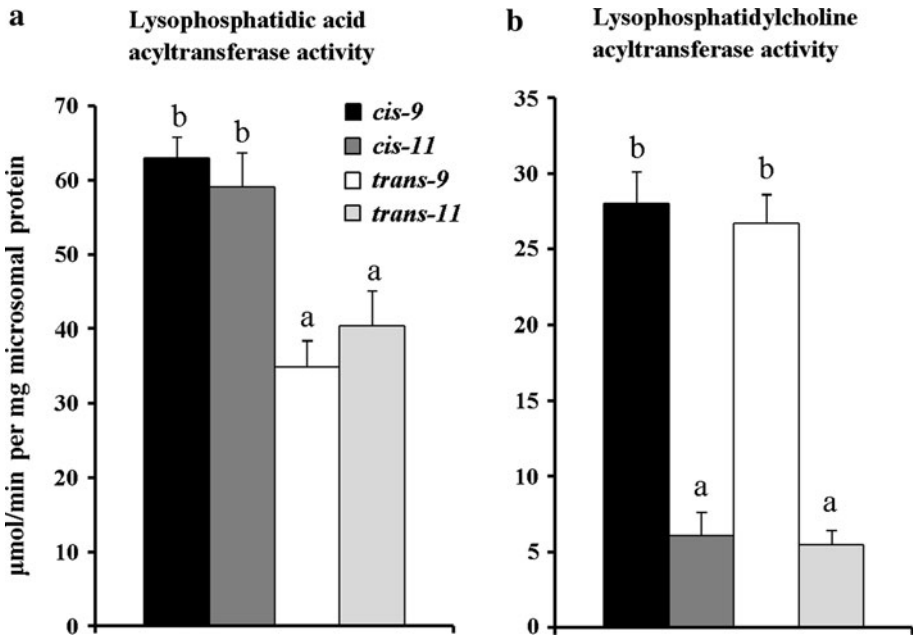

Fig. 3 Activity of 2-lysophosphatidic acid or 2-lysophosphatidylcholine acyltransferase in the presence of 5 µM $C_{18:1}$ isomers as CoA-esters with 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphate (**a**) or 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (**b**), respectively, in liver microsomes. Enzyme activities were measured by following the absorbance at 413 nm of the binding of CoA (released from CoA-esters) to DTNB. Results are expressed as µmol of $C_{18:1}$ esterified per min per mg microsomal protein. *T-bars* show SEM ($n = 3$). For each activity, values with different *letters* on columns statistically differ at $P < 0.05$

isomers were all greater than in their absence, but were ~30% lower with *cis*-11 and *trans*-11 than with *cis*-9 and *trans*-9 at $P < 0.05$.

Esterification-Related Gene Expression

In hepatocytes cultured over 24 h with each $C_{18:1}$ isomer, the levels of gene expression for mtGPAT, DGAT and LDL-R were comparable to those obtained in the absence of FA (Fig. 6). A decrease in expression levels was observed only for ACC-2 with the *cis*-11 isomer and for HMG-CoA reductase with *trans*-11 at $P < 0.05$.

Discussion

The aim of the study was to determine whether the small difference in the double bond position of *trans*-11 versus *trans*-9 gave rise to comparable effects on FA esterification-related parameters. In this goal, rats were used in the fed state because this nutritional condition was shown to depress FA oxidation in liver and most other organs [35], which made all unbound FA available for TAG and PL synthesis. This ex vivo study shows that *trans*-11 and *trans*-9 were not interchangeable substrates for the esterification reactions in intact or disrupted liver cells, as well

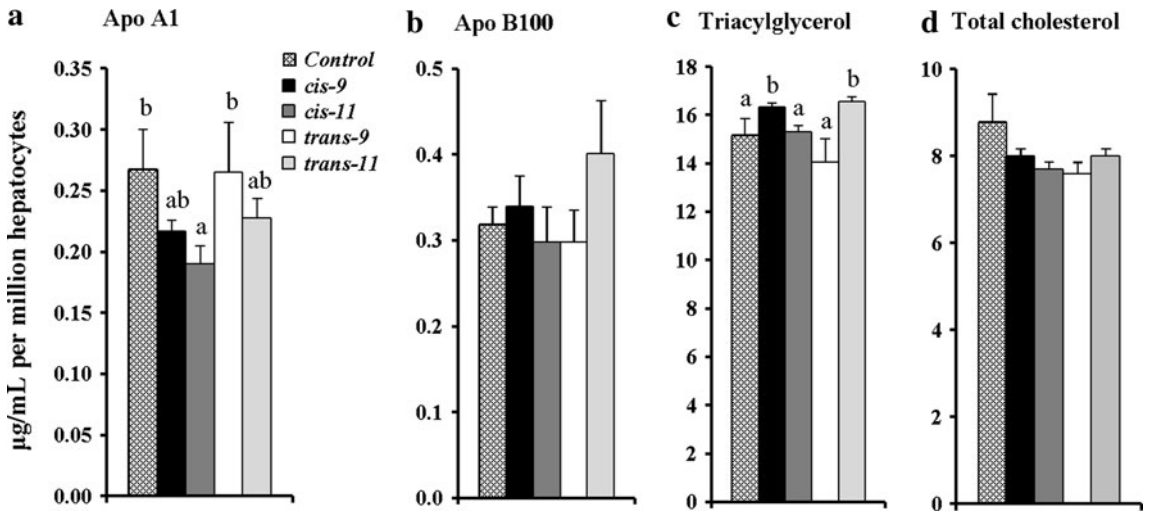

Fig. 4 Components of lipoproteins secreted by hepatocytes cultured for 24 h in the absence (*control assay*) or presence of 0.1 mM $C_{18:1}$ isomers. Results are expressed as µg of each component per mL of incubation medium per million hepatocytes. *T-bars* show SEM ($n = 3$). For each measurement, values with different *letters* on columns statistically differ at $P < 0.05$

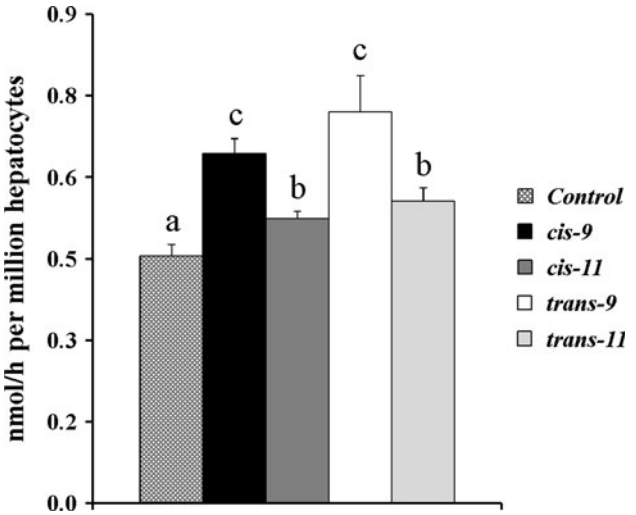

Fig. 5 Efflux of cholesterol from cholesterol-prelabelled hepatocytes in the presence of 0.2 mM $C_{18:1}$ isomers. After 5 h of incubation, the media were centrifuged and the radioactivity of their supernatants was determined as indicated in the "Experimental procedure" section. Results are expressed as nmol labelled cholesterol released per hour per million hepatocytes. *T-bars* show SEM ($n = 3$). Efflux values with different *letters* on columns statistically differ at $P < 0.05$

as in isolated microsomes and mitochondria. Yet the *trans* configuration of the single double bond gives both *trans*-11 and *trans*-9 a common linear aspect as for saturated FA [36–38]. Enzyme activities mainly depend on specific protein synthesis regulated by genes and on affinity of enzymes for their substrates. The genic expression of enzymes related to lipogenesis (FA and cholesterol synthesis) and FA esterification was about of the same range in the assays performed in the presence or not of isomers. These data may indicate that the expression levels of genes were increased with insulin, but without additional effects of isomers. Indeed, after various treatments, weakly higher or lower expression levels of the involved genes were found in fed animals [39–42]. Consequently, under this nutritional condition, the study of biochemical reactions related to TAG and PL synthesis appeared to be convenient to test the possible similarity of both *trans*-isomers through activity levels only depending on enzyme/substrate affinities.

Esterification of Isomers into TAG and PL of Liver Cells

In liver slices and isolated hepatocytes, i.e. in intact cells, the esterification of isomers into TAG and PL implied that some of their OH groups were available from pre-existent TAG and PL after specific hydrolysis [43–45]. In each of our assays, the labelled isomers, once within cells, were expected to compete for the esterification reactions with the endogenous FA present in the surroundings of partially hydrolysed TAG and PL. This competition also depended on the position of available OH groups in these lipids and the amounts of compatible FA. For instance, as regards a convenient position of esterification, the labelled isomers were recovered on TAG and PL to a greater extent when these lipids were previously weakly hydrolysed.

In perfused liver, *trans*-9 and *trans*-11, as well as stearic acid ($C_{18:0}$), were principally recovered on the 1- and 3-positions of TAG, while *cis*-9 and -11 isomers were mainly present on the 2-position [36]. With this specific information, our results show that, in intact and disrupted cells, the affinities of either *trans*-$C_{18:1}$ for the external 2 positions of TAG were equivalent and always at a

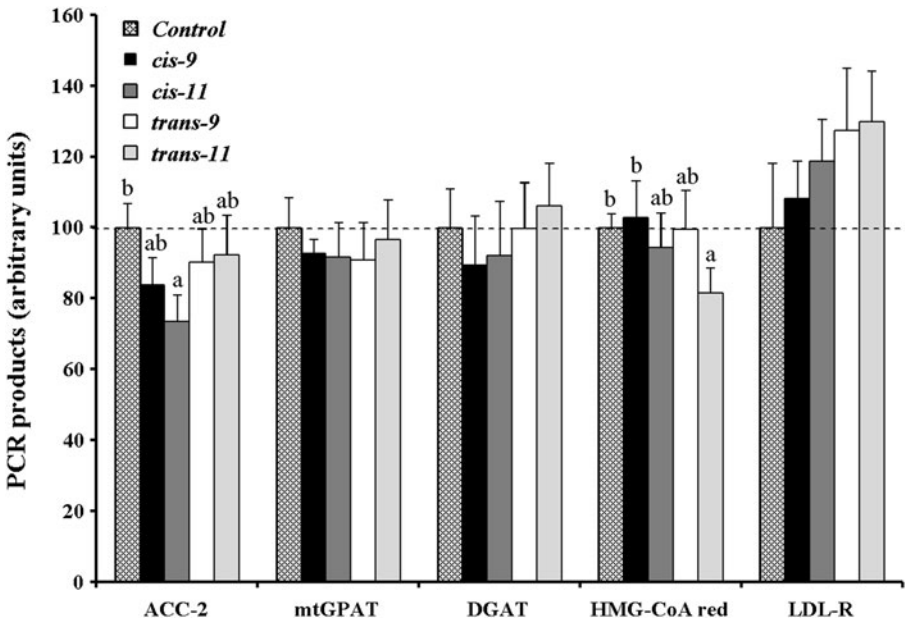

Fig. 6 mRNA levels of FA synthesis- and esterification-related proteins after incubation of fed rat hepatocytes with 0.1 mM of each $C_{18:1}$ isomer for 24 h. Arbitrary units ± SEM with $n = 3$ (different hepatocyte culture dishes) are percentages expressed by reference to control assays (*dotted line*) performed in the absence of any $C_{18:1}$ isomer (=100 for each gene). Different *letters* on columns denote statistically different results at $P < 0.05$

significantly less extent than those of either *cis*-$C_{18:1}$ for the internal position alone. The inversion of the rough distribution of the labelling between TAG and PL in intact and disrupted cells (Fig. 1a vs. b) could originate, as mentioned above, from a weak rate of TAG hydrolysis in intact cells and, after cell disruption, from increased hydrolysis of both TAG [44, 46] and PL through phospholipase activation [46, 47].

In PL, as the *sn*-2 position was preferentially occupied by *cis*-unsaturated FA [36–38], the low level of esterification of labelled *cis*-9 (see Fig. 1a) could result from the dilution of this exogenous isomer with endogenous *cis*-9 and other unsaturated FA, as linoleic acid representing ~50% of total FA of dietary lipids (see "Experimental procedure" section). The incorporation of *cis*-11 also occurred onto the *sn*-2 position, but was significantly greater than that of *cis*-9 both in intact and disrupted cells. This may be due to the fact that, contrary to oleic acid, *cis*-11 is not present in the natural lipids and its labelled form, once within cells, had not to compete with any endogenous equivalent, allowing it to be better incorporated than *cis*-9 into PL. In spite of the presence of endogenous *cis*-unsaturated FA, the notable incorporation of both *trans*-$C_{18:1}$ into PL suggests that these isomers, like saturated FA, were more convenient substrates for the *sn*-1 position, as has already been shown [36–38]. In this context, *trans*-9 was esterified significantly more than *trans*-11 in hepatocytes and marginally more in disrupted cells, which could result from greater or lower cell concentrations of unesterified *trans*-9 or *trans*-11, respectively. In this line, *trans*-9 that is less oxidised than *trans*-11 in liver mitochondria from fasted rats [19], should be present in concentration greater than that of *trans*-11 within cells. However in fed rat livers, the FA-oxidation pathway is strongly inhibited [48], which should normally maintain labelled *trans*-9 and *trans*-11 concentrations to equivalent levels in cells. A possibility was that either *trans*-isomer was transformed into another compound exhibiting distinct affinities for the available OH groups of PL. Indeed, *trans*-11 was found to give rise to *cis*-9, *trans*-11-$C_{18:2}$ (as a conjugated linoleic acid, CLA) through Δ-9 desaturation in liver microsomes, while under the same experimental conditions *trans*-9 stayed unchanged [49]. In whole rats, dietary *trans*-11 was also transformed into *cis*-9, *trans*-11-$C_{18:2}$ in most organs [50]. This CLA added to the diet of pigs was abundantly recovered in liver PL [51]. The gain of a *cis*-9 double bond could be thought to confer to the resulting CLA a high affinity for the *sn*-2 position of PL, but being then in competition, as labelled *cis*-9, with endogenous FA for this position, which would decrease its incorporation into PL via the initial labelling of its precursor. This hypothesis however was not relevant under our experimental conditions because the Δ-9 desaturation of *trans*-11 into CLA has been shown to be very weak in liver and to take place exclusively in peripheral tissues [52]. Further, contrary to what could be expected, *cis*-9, *trans*-11-CLA preferentially esterified as *trans*-11 onto the *sn*-1 position of PL [53].

Esterification-Related Enzyme Activities

As previously mentioned, the esterification of isomers in intact and disrupted cells could be distorted because of the competition with endogenous FA and the fact that this reaction was connected or not to lipoprotein formation and membrane remodeling. By contrast, the measurement of biochemical activities with isolated subcellular particles in appropriate medium strongly limited the mentioned interferences and allowed exogenous *trans*-11 and *trans*-9 to be strictly compared as substrates in the chosen activities. GPAT activity represents an early step common to TAG and PL synthesis with the esterification of acyl groups onto the *sn*-1 position of glycerol-3-phosphate. The about same decreasing order of activities with all the isomers in liver homogenates and microsomal fractions suggests that the whole cell GPAT activity was mainly supported by endoplasmic reticulum. The differences of activities found between both *trans*-$C_{18:1}$ could result from a preferential channeling of *trans*-9 towards the PL synthesis pathway in hepatocytes (Fig. 1a). Unexpectedly, these differences did not concomitantly give rise to comparable effects on the incorporation of both *trans*-$C_{18:1}$ into TAG. GPAT activities in mitochondria (mtGPAT) were qualitatively inversed with these isomers, compared to those in microsomes, but were likely of too low amplitude to affect the distribution of these labelled isomers in TAG and PL of intact or disrupted cells (Fig. 1a, b). This effect could however influence the FA esterification/oxidation balance in mitochondria, since mtGPAT and carnitine palmitoyltransferase I activities have been shown to interfere negatively each other in fasted rats [54].

With glycerol-derived compounds whose *sn*-1 and *sn*-3 positions are already occupied, the esterification activity in microsomes was comparable with both *trans*-isomers when the *sn*-3 position was bound to phosphate, but totally different when this position was bound to phosphocholine. The latter activity was much more greater with *cis*-9 and *trans*-9 isomers than with their *cis*-11 and *trans*-11 counterparts, which indicates that the position of the double bond in the acyl chain was then more important than its geometric configuration. This reaction, catalysed by 2-lysophosphatidylcholine acyltransferase, was shown to possess lysophospholipase and transacylase activities [55], and was believed to take part in the permanent remodeling of membrane PL [56]. Further the purified enzyme exhibited much affinity for arachidonoyl-CoA and to a lesser extent for linoleoyl- and oleoyl-CoA [57, 58]. The comparable

enzyme activity in our assays with oleoyl- and elaidoyl-CoA suggests that *trans*-9 could participate much more actively than *trans*-11 in the PL remodeling. The higher GPAT and 2-lysophosphatidylcholine acyltransferase activities exhibited by isolated microsomes could explain, at least partly, that *trans*-9 was incorporated to a greater extent than *trans*-11 into PL of hepatocytes (Fig. 1a). This point was supported by other studies carried out in hamsters fed diets containing both *trans*-isomers and showing that *trans*-9 was recovered more abundantly than *trans*-11 in *sn*-2 position of platelet PL [14].

Lipoprotein Secretion by Hepatocytes

Measurements of apolipoproteins, TAG and total cholesterol did not reveal any manifest effect of the exposure of hepatocytes to isomers, relative to control assays. Indeed similar experiments performed in the presence of insulin demonstrated that TAG synthesis and secretion were stimulated [59, 60], but that apolipoprotein secretions were equivalent [59] or decreased [60, 61], depending on the time of incubation. When oleic acid was added to incubation medium [59], TAG synthesis and secretion were increased, which meets our results (Fig. 4c). The same effect was observed with *trans*-11, but not with *trans*-9 that could be used preferentially for PL synthesis/remodeling as already suggested. The same amounts of cholesterol secreted by hepatocytes exposed to *trans*-11 versus *trans*-9 (Fig. 4d) appeared to disagree with the different levels of labelled cholesterol released from cells previously incubated with [^{14}C] cholesterol after exposure to both *trans*-$C_{18:1}$ (Fig. 5). In fact during the preincubation time of this latter experiment, exogenous cholesterol was expected to settle down between membrane PL. The collected data suggest that the greater incorporation of *trans*-9 versus *trans*-11 into whole PL of hepatocytes (Fig. 1a) allowed more cholesterol molecules to be shifted from their unsteady positions into the surrounding medium for lipoprotein formation. This would not be the case for *trans*-11 that, contrary to *trans*-9, was associated with lower blood total and LDL-cholesterol in rats [62].

This study carried out with intact cells and cell subfractions demonstrates that vaccenic and elaidic acids, in spite of their chemical resemblance, differ as substrates in esterification-related activities, particularly for PL synthesis and remodeling. It could be assumed that the differences observed would be modified by the fasting period, known to be associated with increased FA oxidation [48], reduced mitochondrial GPAT activity [54] and greater oxidability of vaccenic versus elaidic acid [19]. All these differences found in ex vivo and in vitro assays with liver extracts could be modulated in whole animals, for instance because *cis*-9, *trans*-11-CLA mainly synthesised from *trans*-11 in extrahepatic organs might interfere in the liver lipid metabolism. In the same way, hormonal specificities could differently affect FA oxidation and esterification pathways in humans ingesting both *trans*-$C_{18:1}$ [6]. These data support the fact that vaccenic and elaidic acids are dissimilar substrates for crucial steps of the PL synthesis pathway in liver.

Acknowledgments We thank Mr Jean-Michel Chardigny DR INRA, Mr Koenraad Duhem, Mrs Corinne Marmonier for helpful discussions, and Mrs Monique Baudoin for figure construction and typing of the manuscript. This work was supported by Grants from the CNIEL (Paris) and the Région Bourgogne (Dijon), France.

METHODS

Fast and Minimally Invasive Determination of the Unsaturation Index of White Fat Depots by Micro-Raman Spectroscopy

Abstract In the last 20 years increasing interest has been devoted to the investigation of white adipose tissue (WAT) because hypo- or hyperfunction of WAT is involved in the pathogenesis of obesity and other pathologies. The investigation and discrimination of different characteristics in adipose tissues by means of spectroscopic techniques appears as a topic of current interest, also in view of possible medical–technological applications. The aim of this work was to establish micro-Raman spectroscopy as a tool for the characterization of mammals fat tissue. After preliminary tests aimed at defining a suitable sample preparation protocol, Raman spectra of WAT specimens excised from mice of different ages were recorded in the energy range 750–3,350 cm^{-1}. Quantitative values of the unsaturation index were obtained through the calibration with HR-NMR spectra of lipid extracts. Raman spectroscopy detected a sharp increase in the unsaturation index between 22 and 30 days of age in close correspondence with the weaning of mice (21 days). The present results show that Raman spectroscopy is an inexpensive, fast and robust technique to analyze the unsaturation index of mammals fat tissues that could be routinely used in bioptic samples.

Introduction

The adipose tissue exists in two morphologically and functionally distinct forms, i.e. white adipose tissue

(WAT) and brown adipose tissue (BAT). These two forms of adipose tissue have, in fact, different cell structure, location, vascularization, morphology and biological functions [1, 2]. The characterization of WAT is very important due to its role in well defined metabolic dysfunctions leading to several diseases, like obesity [3], heart disease, diabetes, hypertension and atherosclerosis [4]. Three main functions of this adipose tissue in mammals are nowadays well recognized. The first one is the storage of triglycerides, i.e. the uppermost energy reserve. The second one is the catabolization of triglycerides which results in the release of glycerol and fatty acids participating in glucose metabolism in liver and in other organs and tissues. Finally, its adipocytes secrete the adipokines, which include hormones and other proteins with specific biological functions [5]. In addition, recent studies have shown a strong correlation between age of the living organisms and specific changes of the fat characteristics in obese individuals [6, 7]. Some results indicate that during the first three months of rat life there are distinct phases of the metabolic evolution in WAT related to leptin mRNA and serum leptin concentration changes regulating the amount of body fat [6, 7].

In the past years, several studies, mainly based on invasive approaches, have investigated the release process of fatty acids [8–15] but only few of them have considered their mobilization [8, 9, 14, 15]. On the other hand, this last property is related to their degree of unsaturation [9, 14, 15], a very important feature because differential mobilization could greatly influence the storage and the subsequent utilization of the individual fatty acids. The mobilization also determines the type of fatty acids supplied by adipose tissue to other tissues and organs, notably in conditions of negative energy balance.

In more recent years there has been an increasing interest in spectroscopic techniques for fast, non destructive and minimally invasive characterization of adipose tissue [16, 17]. To this aim vibrational spectroscopy, dealing with Raman scattering, has been extensively used for the analysis of fats with specific concern for its classification, in terms of its composition and constituents [18–26]. Part of these Raman investigations were focused on fatty acids [18, 20, 22–24, 26] while some of them were specifically addressed to the assessment of their molar unsaturation [20, 23, 24, 26].

Fat composition assessment by high resolution proton NMR spectra (HR-NMR) of tissue extracts is a relatively simple matter since signals from protons adjacent to double bonds are easily resolved [27]. Nevertheless, NMR analysis of fat requires an extraction procedure that is time consuming and destructive for the sample. Recently, we have demonstrated that micro Raman spectroscopy performed in freshly excised and unprocessed fat tissues allows the determination of the unsaturation index (UI), with results in good agreement with the literature [28].

In the present work we further validate the usefulness of Raman spectroscopy by a quantitative comparison with proton HR-NMR and demonstrate that both techniques are able to detect the substantial increase in the unsaturation index occurring in mice WAT after weaning. Since HR-NMR spectra are acquired in lipid extracts while Raman spectra are recorded in unprocessed tissue, localized Magnetic Resonance Spectroscopy (MRS) of in vivo WAT tissue was also exploited in order to detect the possible effect of the extraction procedure. Hereafter, the experimental results will be presented and discussed in terms of lipid mobilization and of the related physiological aspects.

Materials and Methods

Animals and Tissue Extraction

Male young (10, 15, 22 days), adult (1, 3, 6 months) and old (12 months) mice of FVB/NHsd strain (Harlan, Italy) were used for the study. They were maintained in a colony at 25 °C with an alternating 12 h dark and light schedule and had free access to standard mice feed and drinking water. Experimental protocols were approved by the animal ethical committee of the University of Verona and followed the NIH Guide for the Use Care of Laboratory Animals and the European Community Council (86/609/EEC) directive. For each age, $n = 4$ mice were used, except for the 12 months group ($n = 3$). After in vivo MRS experiments, animals were killed by cervical dislocation and inguinal adipose tissue was removed for ex vivo Raman and HR-NMR measurement.

Raman measurements were run on the tissue immediately after its removal. For HR-NMR, the lipidic fraction of adipose WAT was extracted in a chloroform–ethanol mixtures (2:1 v/v) according to Folch et al. [29]. The procedure yielded an aqueous fraction containing water-soluble molecules and an organic fraction containing lipids. The latter phase was dried under a stream of anhydrous nitrogen gas, lyophilized in a freeze-drying apparatus (Freeze-Dryer Modulyo) and dissolved in 600 µl deuterated chloroform for HR-NMR measurements. A similar extraction procedure was applied to standard mice feed. After a short period of suckling, two pups were killed by cervical dislocation and a few drops of milk samples obtained by manual squeezing of the stomach. Raman spectra were recorded on mother milk without any treatment.

Raman Measurements

Micro-Raman spectra were carried out in backscattering geometry at room temperature using a triple-monochromator (Horiba-Jobin Yvon, model T64000), set in double-subtractive/single configuration, and equipped with holographic gratings having 1,800 lines mm^{-1}. The scattered radiation was detected at the spectrograph output by a charge coupled device (CCD) detector, with 1,024 × 256 pixels, cooled by liquid nitrogen. The spectra were excited by the 514.5 nm line of a mixed Ar–Kr ion gas laser and laser power on the sample surface was kept below 5 ± 0.1 mW, and was focused with a spot of 2 μm in diameter through the lens of an objective 80× (numerical aperture 0.75). The spectral resolution was better than 0.6 cm^{-1} pixel while the spectral linearity of the system was calibrated using a 50:50 (v/v) acetonitrile/toluene mixture and comparing to frequency standards from the American Standard Testing Method ASTM E 1840 (1996). Repeated micro-Raman measurements were carried out under the same experimental conditions from several regions of the same sample, obtaining very reproducible spectra for WAT tissue. The spectra collected from morphologically similar regions showed good reproducibility (the mean error of peak intensity was of the order of 3%). The recorded spectra were processed to remove artifacts due to cosmic rays, while the luminescence background, consisting of a flat and structureless background of very weak intensity spread over the whole Raman spectrum, was removed by comparing replicate spectra of each sample over the whole sampled spectral range.

MRS and HR-NMR Measurements

In vivo MRS experiments were carried out using a Biospec System (Bruker Biospin, Germany) equipped with a 4.7 T horizontal Oxford Magnet, 33-cm bore size. A 72-mm internal diameter bird-cage coil and a flat surface receiver coil were used. Animals were pre-anesthetized with 5% of isofluorane, and maintained during acquisitions with 1–1.5% of isofluorane in a mixture of O_2 and air. The surface coil was carefully positioned in the inguinal part of the mice. After acquisition of reference images for localization of inguinal fat deposits, localized proton spectra were acquired from a volume-of-interest (VOI) of 1 mm^3. The dimensions of the inguinal fat deposits in young animals were too small to reliably position the 1 mm^3 Voxel. In vivo spectra were consequently acquired only in adult and old mice. Spectra were acquired using a Point Resolved Spectroscopy (PRESS) sequence with TR = 4,000 ms, TE = 22 ms, 256 number of excitations (NEX), 1,024 points, without water suppression. PRESS sequence uses a combination of magnetic fields gradients and r.f. pulses (90°–180°–180°) to select a three dimensional voxels of a well defined size. In vivo spectra were then analyzed with LCModel [30].

HR-NMR was performed using a Bruker DRX-500 spectrometer operating at 500.13 MHz proton Larmor frequency, and equipped with a 5 mm TXI probe head. The sample temperature in the probe was 25 °C. Pulse programs from the standard Bruker library (Topspin 1.3) were used. Proton NMR spectra were acquired with an acquisition time of 1.6 s, flip angle of 45°, 2 s of relaxation delays, spectral width of 5 kHz, 16 K acquired points, and total number of scans equal to 128. Data were processed with 32 K points, baseline corrections and phase adjustments. No line broadening was applied in data processing. The chloroform proton signal at 7.27 ppm was used as chemical shift reference. Resonances were identified based on available chemical shift data. Mean lipid acyl chain unsaturation and polyunsaturation indexes were calculated from proton spectra according to the methods reported in literature [31], exploiting the areas of the peaks of the different chemical groups in the lipid chains.

Peak assignment and the procedures followed for extraction of triglyceride (TG) parameters, both for HR-NMR and MRS spectra, are reported hereafter.

Peak Assignment and Calculation of TG Parameters

White adipose tissue is mainly constituted by TG molecules and NMR spectra reflect its composition. Figure 1a, b shows representative ex vivo and in vivo spectra of inguinal adipose tissue, respectively. The proton resonance peaks are labelled according to the different chemical groups constituting TG molecules (see Fig. 1c). The two spectra show the same number of peaks at the same chemical shifts, with the exception of a small water (W) signal that is present in the in vivo experiments (Fig. 1b).

The chemical properties of TG molecules namely unsaturation (UI) and polyunsaturation (PI) indexes and mean chain length (MCL) were determined by applying the following formulas according to Zancanaro et al. [31].

$$\mathrm{UI} = (L + M)/(2/3A)$$

$$\mathrm{PI} = G/(2/3A)$$

$$\mathrm{MCL} = (2/3A + B + C + D + E + F + G + 2(L + M))/(2/3A)$$

where, each letter represents the area under the corresponding peak. The index UI is equivalent to the number of vinilyc protons ratioed to the terminal methyl group and is a molar measurement of unsaturation. The index PI is equivalent to the number of protons attached to the diallylic methylene of conjugated double bonds ratioed

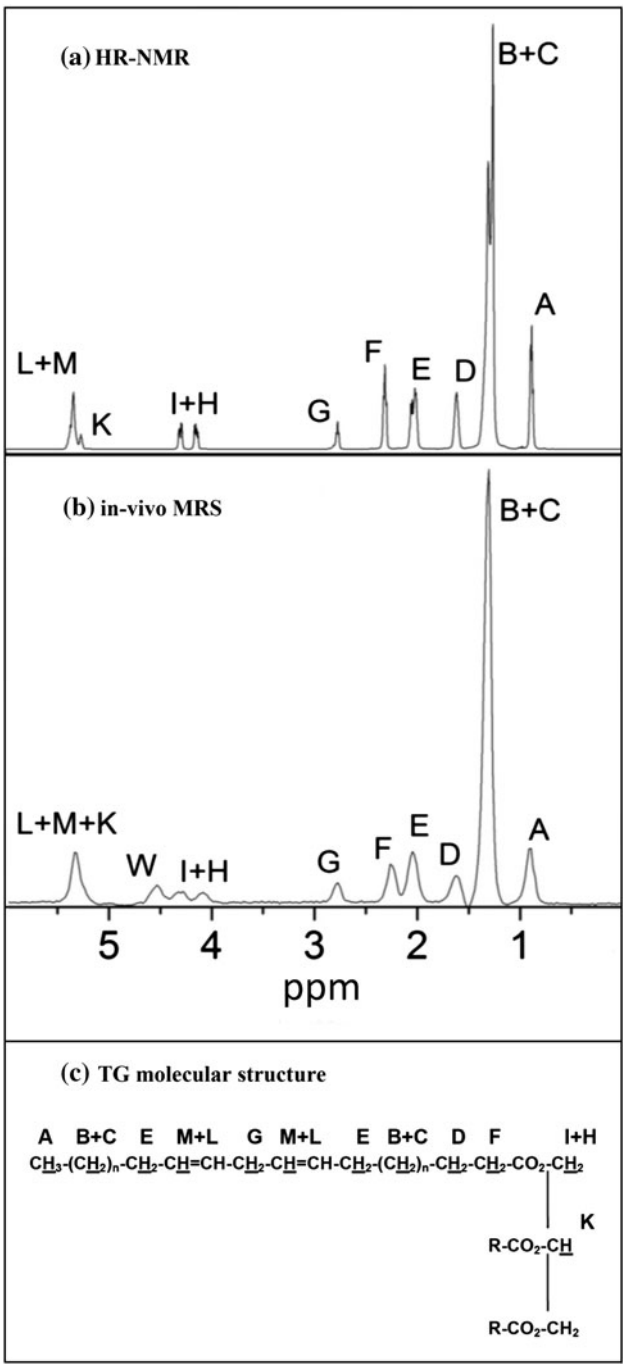

Fig. 1 The representative ex vivo (**a**) and in vivo (**b**) spectra of inguinal adipose tissue. The areas under a peaks (*A*, *B*, *C*…) are proportional to the number of protons in a given chemical environment within a TG molecular structure (**c**)

to the methyl group and provides a measurement of molar poly-unsaturation. In agreement with Zancanaro et al. [31], relevant presence of mono- and diglycerides in WAT samples was excluded by verifying that the two following relationships were in good agreement with experimental data:

$$A/(I+H) = 9/4$$

$$F/(I+H) = 6/4$$

The two relationships represent, respectively, the ratio between the number of protons bound to the methyl (*A*) or acetalyc (*F*) groups and the glyceril esterified methylene ones ($I + H$).

Thanks to high resolution and good separation of the signals, the areas under the peaks could be calculated by simple integration in HR-NMR spectra. This procedure could not be applied to in vivo MRS experiments, because of the low resolution and partial overlapping of the peaks [27] as clearly apparent in Fig. 1b. MRS spectra were consequently analyzed by using the LCModel software [30]. Since LCModel does not distinguish peak *K* from ($L + M$), the integral of the peak *K* was obtained from the peak *A* according to the theoretical value $K = A/9$ which holds for TG molecules, i.e. the number of methynic esterified glycerol protons (*K*) is assumed to be 1/9 of that of methyl group (*A*). In agreement with the fact that WAT consists mainly of TG molecules, ex vivo HR-NMR spectra confirmed that the ratio between *A* and *K* is in agreement with the above mentioned theoretical value. Then the ($L + M$) peak was obtained using the following formula:

$$(L+M) = (L+M+K) - A/9$$

Results and Discussion

A typical micro-Raman spectrum of WAT, after subtraction of the luminescence background, in the extended wave number range 750–3,350 cm^{-1} is reported in Fig. 2 (full panel). It consists of several bands and some sharp peaks of different intensity occurring in the spectral region between 800 and 1,800 cm^{-1}, but is dominated by some very strong bands in the region 2,800–3,100 cm^{-1}.

In order to identify the origin of the different spectral features of adipose tissue we can refer to some reference database of Raman spectra of bio-molecules, either in form of text-book [32] or full-length paper [17]. Table 1 lists both the position, in terms of wave numbers, and the assignment of main bands observed in the 800–3,050 cm^{-1} spectral region of Raman spectrum of WAT, according the some available literature reports [17, 25, 33–43].

According to the assignments of this Table we can claims that the overall structure of the observed spectrum is that of TG molecules, which indeed constitute the main component of WAT [30]. Therefore, a finer spectral analysis of the Raman features of TG component of WAT will allow us to gain further insights into the white adipose tissue, especially into its unsaturation index, which is related to the number of double C=C bonds present in each

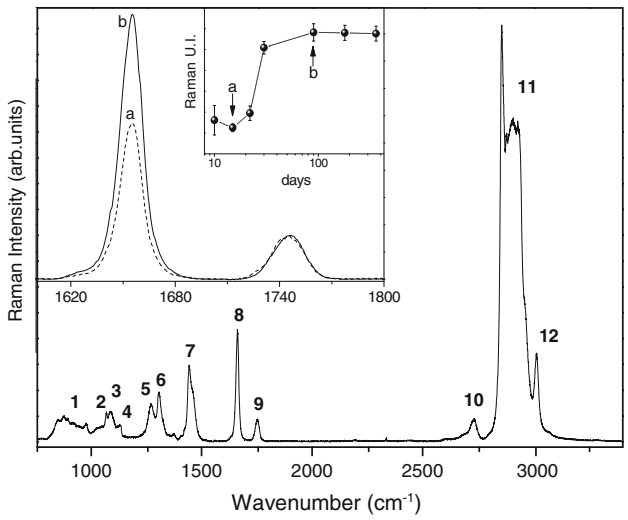

Fig. 2 Typical Raman spectrum of WAT recorded at room temperature in the wave number range 750–3,350 cm^{-1} (*full panel*); partial Raman spectra of WAT in the region of C=C and C=O symmetric stretching modes (*internal panel*). Representative spectra acquired at 15 (**a**) and 90 days (**b**) are compared. The *inset* of the *internal panel* shows the dependence of the normalized intensity of the 1,655 cm^{-1} peak as a function of the mice age is reported. *Points* labelled by "*a*" and "*b*" refer to the UI obtained from spectra plotted in the figure

TG chain. To this aim, the key spectral feature is the peak at 1,655 cm^{-1}, which is attributed to the symmetric stretching mode of the double C=C bonds of the TG component [17, 39]. Obviously, the spectral intensity of this peak is expected to depend on the number of C=C bands in TG, and therefore, the intensity of Raman peak at 1,655 cm^{-1} can be straightforwardly related to unsaturation index of lipid component in WAT. Therefore, white adipose tissues characterized by different unsaturation index will show different spectral intensity of the 1,655 cm^{-1} peak.

Representative, partial Raman spectra, acquired in the spectral region between 1,600 and 1,800 cm^{-1}, from two WAT specimens, excised from 15-day (spectrum a) old and 90-day (spectrum b) old mice, respectively, are also shown in Fig. 2 (internal panel). Before the plot, the spectra were normalized to the area of the peak centred at about 1,745 cm^{-1}, which is attributed to the stretching vibration of the C=O group [17, 38]. The Raman peak due to the vibrational of C=O groups is assumed to be an internal reference because the number of carbonyl groups for each TG is constant independent of the unsaturation index of their hydrocarbon chains. This assumption is justified because the presence of mono- and diglycerides in WAT is negligible [31].

We have taken the intensity of the peak at 1,745 cm^{-1} as the reference, instead of that of the band at 1,440 cm^{-1}, because this one constitutes, in our opinion, a much less reliable standard, since it clearly consists of some overlapping spectral components (see, for instance, the spectrum of Fig. 2, full panel, or ref. [17]), the position of which turns out to depend on the length of the fatty acid (FA) chains. In fact, it has been proved that the intensity of this 1,440 cm^{-1} band turns out to depend on the number of carbons within the FA chain [20, 44], which, on the other hand, is not constant in TGs chains forming WAT. In alternative, in the case of adipose tissue, the peak at 1,745 cm^{-1} seem to provides a much more reliable standard for evaluating the UI of WAT, being specifically related to number of carbonyl groups in TGs, i.e. the paramount component of WAT, as revealed by the NMR measurements, which also were not able to detect any

Table 1 Assignment of bands observed in the Raman spectra of white adipose tissue

Band regions	Band position (cm^{-1})	Band assignment [refs.]
1	800–920	ν (C–C), $CH_{3\ rk}$ mixture of stretch and rock modes at acyl and methyl terminals in solid state [33]
2	1,060–1,065	ν_{op} (C–C) out-of-phase aliphatic C–C stretch all *trans* [34]
3	1,080–1,090	ν_g (C–C) liquid: aliphatic C–C stretch in *gauche* [35]
4	1,100–1,135	ν_{ip} (C–C) in-phase aliphatic C–C stretch all *trans* [36]
5	1,250–1,280	δ_{ip} (=CH) in-plane *cis* olefinic hydrogen bend [37]
6	1,295–1,305	δ_{tw} (CH_2) methylene twist deformation [37]
7	1,400–1,500	δ_{sc} (CH_2) methylene scissor deformation [17] and asymmetric bending CH_3 [32]
8	1,650–1,680	ν (C=C) *cis* and *trans* olefinic stretch [17, 39]
9	1,730–1,750	ν (C=O) carbonyl stretch [17, 38]
10	2,720–2,730	ν (CH) olefinic stretching mode [40] or combination of δ_{sc} ($-CH_2$) + ρ_w ($-CH_2$) methylene modes [41, 42]
11	2,800–2,950	ν_s (CH_2), ν_{as} (CH_2) symmetric and anti-symmetric methylene stretch and ν_s (CH_3), ν_{as} (CH_3) symmetric and anti-symmetric methyl stretch [42, 43]
12	3,010–3,040	ν_{as} (=C–H) anti-symmetric =C–H stretch [25]

The band regions are defined in Fig. 2 (full panel)

ν stretching modes, δ deformation modes, ρ_w wagging mode

appreciable component of free fatty acids in it [31]. By the way, it is worth to mention that the intensity of the peak at 1,745 cm^{-1} is is taken as the reference to evaluate the molar parameters of fatty acids methyl esthers (FAME) by some authors [20, 43–45]. On the other hand, the intensity of this peaks cannot be properly adopted as the reference for the assessment of the UI of free fatty acids, for which the situation is much more complex due to the spectral intermixing of C=C and C=O stretching modes. In fact, in the case of oleic acid, a well-known free FA, Muik et al. [24] did not observe any peak at about 1,740 cm^{-1} associated with C=O stretching mode since the wave number of the C=O stretching vibration in the free FA chains at room temperature occurs near the C=C stretching vibration peak at 1,650 cm^{-1} as it can be clearly inferred from Ref. [25]. On the other hand, Tandon et al. [25] show that the peak wave number of C=O stretching in free FA shifts from about 1,638 to 1,643 cm^{-1} when the temperature varies from −20 to +12 °C. Therefore, this finding clearly shows that, in the case of free FA, it is improper to refer to the intensity of the band peaked at 1,650 cm^{-1} at room temperature in order to evaluate the molar unsaturation parameter of free FA, since this peak intensity could be affected by the contribution of the C=O stretching mode, which is nearly degenerate with the C=C mode. Therefore, on the basis of the above considerations it should be inferred that the unsaturation parameter of FA, assessed according to this procedure, is affected by a systematic error, e.g., overestimated, due to the spurious contribution of the C=O stretching.

In conclusion, taking the above discussed considerations into account, in the case of WAT a quantitative evaluation of the unsaturation index of TG chains can be obtained simply by measuring the area of the 1,655 cm^{-1} peak normalized to the intensity of the 1,745 cm^{-1} peak, in the following referred to as the normalized area (NA). The NA of the peak at 1,655 cm^{-1} versus animals age (in days) is reported in the internal panel inset of Fig. 2. This plot suggests a remarkable change of the unsaturation index of lipid component of WAT between 21 and 30 days of age.

The chemical properties extracted from HR-NMR and MRS spectra at different mice age are summarized in Table 2. Mice younger than 1 month were not examined by MRS due to small size (<1 mm^3) of inguinal deposits. Mean values of UI obtained by the two techniques are very close. PI values could not be calculated by MRS spectra due to the low signal/noise of peak *G*. MCL values evaluated by HR-NMR differ substantially from those evaluated by MRS. The reasons for this discrepancy are currently under evaluation. However, the results of HR-NMR, obtained on mice older than 21 days, correlate with the literature data [18, 19]. In fact, UI and MCL values obtained by us on WAT samples of mice older that 21 days are quite close to those observed by Beattie et al. [19] on pork and kitchen fat. This fact seems to confirm that a strong correlation exists between the adipose tissue composition and the presence of mono and poly-unsaturated fatty acids in the diet of different species of mono-gastric animals [46, 47].

Table 2 Chemical properties of TGs (UI, PI and MCL) calculated from HR-NMR spectra

Mice age (days)	UI	PI	MCL
HR-NMR			
10	0.64 ± 0.06	0.19 ± 0.01	16.23 ± 0.25
15	0.61 ± 0.01	0.18 ± 0.00	16.13 ± 0.24
22	0.65 ± 0.01	0.18 ± 0.00	16.30 ± 0.22
30	0.99 ± 0.01	0.34 ± 0.01	17.26 ± 0.21
90	1.02 ± 0.03	0.32 ± 0.01	17.08 ± 0.09
180	1.08 ± 0.01	0.33 ± 0.01	17.25 ± 0.12
360	1.03 ± 0.05	0.30 ± 0.02	16.96 ± 0.16
MRS			
30	0.98 ± 0.06	–	15.19 ± 0.21
90	1.06 ± 0.12	–	13.45 ± 0.28
180	1.05 ± 0.10	–	14.19 ± 0.46
360	1.07 ± 0.24	–	12.45 ± 0.20

Figure 3 shows the behaviour of the value of NA versus the unsaturation index obtained by HR-NMR in the WAT samples of the animals investigated. The plot shows a good linear correlation between the Raman normalized intensity and the unsaturation index, as determined by HR-NMR. By using the extrapolated linear relationship, quantitative values of the unsaturation index can be straightforwardly obtained from Raman spectra of WAT.

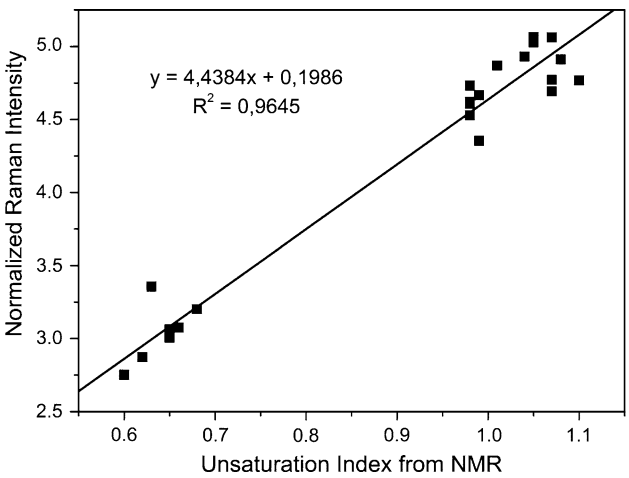

Fig. 3 Correlation between UI, as determined by HR-NMR, and the intensity of the Raman 1,650 cm^{-1} peak (normalized to that of the peak at 1,745 cm^{-1}, see text)

Figure 4 shows the dependence of the UI, determined either by Raman or HR-NMR versus mice age in days. Here the data are plotted in the form of mean values with related standard deviations. Values obtained by MRS are additionally reported in the inset, but only for animals older than 22 days. Both in Raman and HR-NMR data, a sudden increase in the unsaturation index between 22 and 30 days is clearly evident in close correspondence with the weaning of mice (21 days). A similar trend was observed also for the PI. Moreover, MRS and HR-NMR provide results in good agreement, indicating that the extraction procedure does not affect the determination of the UI. The substantially higher standard deviation in MRS determinations compared to either HR-NMR or Raman data is due to errors introduced in the in vivo measurement by imperfect shimming, mouse movements and relatively low signal-to-noise ratio.

The physiological aspects of the observed experimental results need to be discussed. In principle, the dietary FA could have a profound influence on both the quantity and quality of the FA of adipose tissue, which in turn determines the kinds and amounts of FA available to meet metabolic requirements. In fact, a direct correlation between the amount of FA present in the diet and their deposition into the adipose tissue was observed, although the degree of FA deposition varied with the unsaturation, saturation and structure of the FA of the diet [48]. In our case, the sudden increase of the UI up to about 160% of its starting value, observed soon after weaning of animals, correlates, at least qualitatively, with the dietary change. In fact, the ratio between the Raman Index for the unsaturation index, namely the NA of the peak at 1,655 cm^{-1}, was estimated to increase by a factor of about 1.5 when the spectra of the mother milk and of the standard mice feed are considered. It is noteworthy that UI starts increasing immediately after weaning and its increase seems to be almost complete within approximately 1 week after the diet change. To the best of our knowledge, such a sudden increase in the UI in correspondence to mice weaning has not been reported previously. It is reasonable to expect that similar changes, although slower than in mice because of the different metabolism, may occur in other mammals, including humans. Our data show that, soon after the weaning, the mice body builds up a reservoir of TG composed of unsaturated fatty acids, which are easily mobilized from fat tissue toward organs and tissues for the energetic needs. In fact, mobilization of fatty acids from cells and tissues has been investigated in mammals, including humans, and more recently, in migratory birds [9, 12, 14].

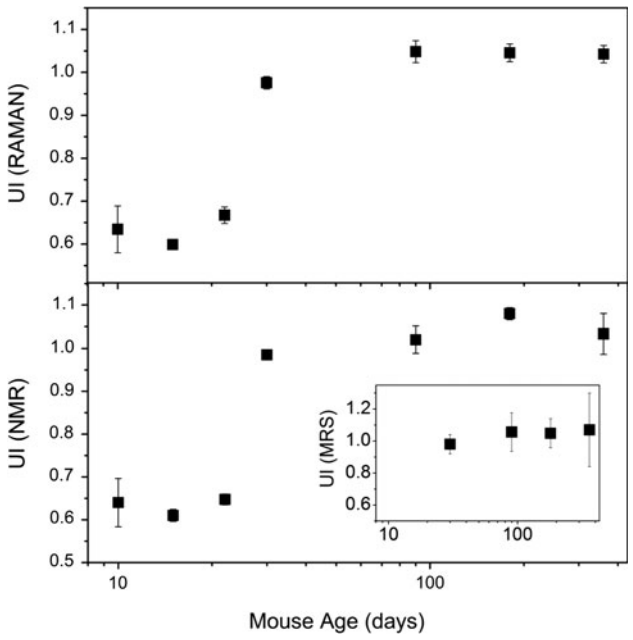

Fig. 4 Dependence of UI on the mouse age (days) as determined by Raman (*top panel*) and HR-NMR (*bottom panel*). The values of UI determined in vivo by MRS are shown in the *inset* of the *bottom panel*

It appears that fatty acids are not mobilized in direct proportion to TG contents of cells but differentially depending on their unsaturation. Specifically, polyunsaturated rather than saturated fatty acids are preferentially mobilized from adipose tissue [12]. Our results thus show that after weaning mice body possesses a reservoir of TGs more easily mobilized than before weaning. This is probably related to changes in energy metabolism. During the first days of ectopic life, shivering thermogenesis is not active. Heat production occurs mainly through not-shivering thermogenesis in brown adipose tissue (BAT) the last tissue being strongly developed and active in pups. At weaning, a substantial change in energetic metabolism does occur: BAT, which posses its own lipid depots, decreases its activity while muscle increases its motor activity and shivering thermogenesis. Differently from BAT, muscle does not have its own lipid reserve. This fact determines the organism request of the need of a lipid reservoir of easy mobilization. On the bases of the above considerations, our results shows that, after weaning, fat depots are composed by unsaturated (i.e. easily mobilized) fatty acids which, likely, can meet the growing energy demands of mature muscle tissue.

Conclusions

In the present paper Raman spectroscopy has been used to quantitatively determine the unsaturation index of mammal fat tissues. The UI value have been quantitatively assessed through calibration with HR-NMR data. Both Raman and HR-NMR require animal sacrifice and tissue resection. Differently from HR-NMR, Raman spectroscopy does not

need chemical extraction of the lipid component that is time consuming and destructive for the sample. Raman spectra can be acquired from a few milligrams of fat tissue in a few seconds with a good signal-to-noise ratio. In fact, they were carried out in a systematic way from WAT specimens of mice of different ages, ranging between a few days and 12 months. Our Raman results turns out to be very reliable in monitoring, in a very simple way, the sudden changes occurring in the fat composition after the mice were weaned, through the evaluation of the intensity changes of the C=C stretch mode peaked at 1,655 cm^{-1}, normalized to the C=O group stretching mode intensity.

In conclusion, Raman spectroscopy could provide an inexpensive, fast and robust approach to analyze important characteristics of the fat tissues of mammals for routine use in bioptic samples. The present results demonstrate that the method is useful for monitoring diet-induced changes of the unsaturation index of fat deposits. Moreover, they show that, soon after weaning, the organisms build up adipose tissue depots rich in unsaturated TG, easily mobilized from the tissue itself. On one side this process is correlated to dietary changes, but, on the other side, it is probably also related to the switch from non-shivering to shivering thermogenesis.

Acknowledgments The authors are grateful to G. Guella for the useful discussions and the critical reading of the manuscript. One of the authors (E. M.) is a Ph.D. student supported by Veneto Nanotech S.C.p.A., Italy. This research was partially funded by the Fondazione Cariverona, Italy, under contract with the University of Verona.

Abstract Patients with cystic fibrosis, caused by mutations in CFTR, exhibit specific and consistent alterations in the levels of particular unsaturated fatty acids compared with healthy controls. Evidence suggests that these changes may play a role in the pathogenesis of this disease. Among these abnormalities are increases in the levels of n-7 and n-9 fatty acids, particularly palmitoleate (16:1n-7), oleate (18:1n-9), and eicosatrienoate or mead acid (20:3n-9). The underlying mechanisms of these particular changes are unknown, but similar changes in the n-3 and n-6 fatty acid families have been correlated with increased expression of fatty acid metabolic enzymes. This study demonstrated that cystic fibrosis cells in culture exhibit increased metabolism along the metabolic pathways leading to 16:1n-7, 18:1n-9, and 20:3n-9 compared with wild-type cells. Furthermore, these changes are accompanied by increased expression of the enzymes that produce these fatty acids, namely Δ5, Δ6, and Δ9 desaturases and elongases 5 and 6. Taken together, these findings suggest that fatty acid abnormalities of the n-7 and n-9 series in cystic fibrosis are as a result, at least in part, of increased expression and activity of these metabolic enzymes in CFTR-mutated cells.

Introduction

Cystic fibrosis (CF) is the most common life-threatening genetic disease in the Caucasian population, affecting 1 in every 3,000 newborns [1]. CF is caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene [2]. The protein product of this gene is a cAMP-regulated chloride channel that belongs to the ATP binding cassette family. This protein also transports bicarbonate and indirectly regulates sodium flux. The mutations in CFTR cause accumulation of viscous secretions in the body, ultimately leading to pancreatic insufficiency, intestinal malabsorption, chronic airway infection, inflammation, and progressive lung disease [1].

In addition to the classic clinical findings in CF, specific fatty acid abnormalities have been consistently identified in the plasma and tissues of CF animal models, human patients, and cultured cell models compared with wild-type controls (reviewed in Refs. [3, 4]). The most noted of these are decreases in linoleate (18:2n-6) and docosahexaenoate (22:6n-3), and, in most cases, elevation of arachidonate

(20:4n-6). Studies in mice suggest that these abnormalities are involved in the pathophysiology of CF [5].

Less attention has been paid to important fatty acid changes outside of the n-6 and n-3 pathway. These include increased concentrations of palmitoleate (16:1n-7), oleate (18:1n-9), and eicosatrienoate or mead acid (20:3n-9) in the cells and plasma of CF patients. In some studies, these changes were present along with pancreatic insufficiency and intestinal malabsorption [6, 7], and elevations of these fatty acids are a known marker of essential fatty acid deficiency [8, 9]. However, similar observations have been made in well-nourished CF patients [10–12] and some cultured CF cells [13], suggesting additional underlying causes exist to explain these alterations. Importantly, DHA therapy, which is known to reverse the n-3 and n-6 fatty acid abnormalities in CF patients and correct CF pathology in mice, also reduces 20:3n-9 levels [14].

These fatty acids are of particular interest in CF pathophysiology because of their functional properties outside cell membranes. A recent study revealed that 16:1n-7 acts as a lipid hormone, a so-called lipokine, providing communication between adipose tissue and distant organs to regulate systemic metabolic homeostasis [15]. Furthermore, there is evidence suggesting that products of Δ9-desaturase, which include 16:1n-7 and 18:1n-9, are involved in modulating inflammation [16–18], as are oxygenated products of 20:3n-9 [19].

Unlike the n-3 and n-6 series fatty acids, 16:1n-7, 18:1n-9, and 20:3n-9 can be synthesized de novo. Palmitate (16:0; PAM), synthesized from acetyl CoA, can be converted to these fatty acids via the pathways indicated in Fig. 1. Our group has shown that alterations in n-3 and n-6 fatty acids in CF cells are associated with increased expression and activity of Δ6 and Δ5 desaturases compared with wild-type cells [20]. The objective if this study was to test whether the above-described changes in n-7 and n-9 fatty acids are also a result of altered activity of fatty acid metabolizing enzymes.

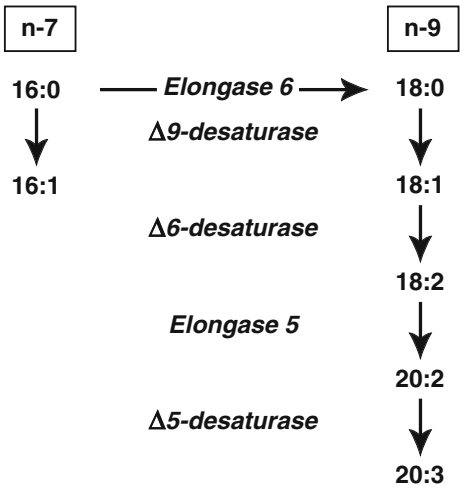

Fig. 1 Fatty acid metabolism through the n-7 (*left*) and n-9 (*right*) pathways

This hypothesis was tested in two cell culture models of CF with similar fatty acid abnormalities to those present in humans [13, 21]. To investigate the relative activities of fatty acid-metabolizing enzymes, the conversion of radiolabeled palmitate (16:0), stearate (18:0), and 18:1n-9 to downstream fatty acid products was measured and correlated with the expression of desaturase and elongase enzymes in CF cells. The results show increased metabolism of these fatty acids to 16:1n-7, 18:1n-9, and 20:3n-9 in CF compared with wild-type cells. There was also increased expression of Δ9, Δ6, and Δ5 desaturases and elongase 6. These findings suggest that increases in the expression and activity of these fatty acid metabolic enzymes are at least in part responsible for changes in the levels of these fatty acids observed in CF.

Materials and Methods

Materials

Radiolabeled fatty acids, [1-^{14}C]16:0 (55 mCi/mmol), [1-^{14}C]18:0 (55 mCi/mmol), and [1-^{14}C]18:1n-9 (55 mCi/mmol) were obtained from American Radiolabeled Chemicals (St Louis, MO, USA). Fatty acid methyl ester (FAME) standards were purchased from NuChek Prep (Elysian, MN, USA). HPLC-grade solvents were purchased from Fisher Scientific (Pittsburgh, PA, USA) and liquid scintillation cocktail (IN-flow 2:1) was purchased from IN/US Systems (Tampa, FL, USA).

Cell Culture

16HBEo^{-} sense and antisense cells were a gift from Dr Pamela Davis (Case Western Reserve University School of Medicine, Cleveland, OH, USA). These are human bronchial epithelial cells stably transfected with plasmids expressing the first 131 nucleotides of human CFTR in the sense or antisense orientation such that sense cells express wild-type CFTR and antisense cells lack CFTR expression [22]. IB3 and C38 cells were obtained from ATCC (Manassas, VA, USA). IB3 cells are compound heterozygotes which contain one ΔF508 allele and one nonsense mutation, W1282X, with a premature termination signal [23]. The CF phenotype present in the IB3-1 cells has been corrected in the C38 cell line by transfection with wild-type CFTR [24]. Cell culture techniques were performed as previously described [13, 21]. Cells were grown in

tissue-culture flasks coated with LHC basal media (Invitrogen, Carlsbad, CA, USA) containing 0.1 mg/mL BSA (Sigma–Aldrich, St Louis, MO, USA), 10 μg/mL human fibronectin (Sigma–Aldrich), and 3 μg/mL vitrogen (Angiotech Biomaterials, Palo Alto, CA, USA). Complete culture medium comprised minimum essential medium + glutamax (Invitrogen) supplemented with 100 μg/mL streptomycin, 100 U/mL penicillin, and 10% horse serum (Atlanta Biologicals, Lawrenceville, GA, USA). Cells were grown at 37 °C in a 5% CO_2 humidified incubator. Medium was changed three times weekly.

For experiments, cells were seeded in six-well experimental plates. Sense cells were seeded at 3×10^5 cells/well and antisense cells were seeded at 1×10^5 cells/well. This enables the sense cells, which are smaller in size, to reach confluence at approximately the same time as antisense cells. C38 and IB3 cells were seeded at 1×10^5 cells/well. All cells were allowed to grow until two days post-confluence (7–8 days) before being used for experiments. This time point was chosen because it is the point at which the fatty acid abnormalities are most distinct [13].

Fatty Acid Composition Analysis

Sense and antisense cells were cultured as above until two days post-confluence, after which they were washed twice in ice-cold PBS, scraped, and transferred to a glass tube. The saturated fatty acid 17:0 (10 μg) was added as an internal standard. Lipids were extracted using a modification of the method of Folch et al. [25]. Cells were harvested by rinsing twice with ice-cold phosphate-buffered saline (Invitrogen), then scraping on ice with a rubber policeman. The cells were pelleted by centrifugation (100×*g* for 8 min). The cell pellet was resuspended in 0.5 mL cold phosphate-buffered saline, and lipids were extracted by adding six volumes of chloroform–methanol (2:1, *v*/*v*). These samples were incubated on ice for 10 min, vortex mixed, and centrifuged (1,100×*g* for 10 min). The lower, organic, phase was transferred to a new glass tube and dried down completely under a stream of nitrogen. Fatty acids were methylated using boron trifluoride (BF_3; 14% in methanol; Sigma–Aldrich) and a methanolic-base reagent [26] as follows: 0.5 mL 0.5 M methanolic NaOH (Acros Organics, Geel, Belgium) was added to the sample, vortex mixed, and heated at 100 °C for 3 min, followed by addition of 0.5 mL BF_3 at 100 °C for 1 min. To extract the fatty-acid methyl esters (FAMEs), 1 mL hexane was added to the mixture which was then incubated at 100 °C for 1 min, followed by addition of 6.5 mL saturated NaCl solution. The sample was then vortex mixed and centrifuged (500×*g* for 4 min) to separate the liquid phases. The upper, hexane, layer was used for quantification of FAMEs by gas chromatography (GC) using an Agilent 7980A GC system (Agilent Technologies, Santa Clara, CA, USA) equipped with a Supelcowax SP-10 capillary column (Supelco, Bellefonte, PA, USA) coupled to a mass spectrometer (model 5975c, Agilent Technologies). FAME mass was determined by comparing areas of unknown FAMEs with that of a fixed concentration of the 17:0 internal standard. Results were expressed as the molar percentage (mol%) of each FAME relative to the total FAME mass of the sample.

Fatty Acid Metabolism Experiments

For fatty acid metabolism experiments, medium containing radiolabeled fatty acids was prepared by drying the fatty acids dissolved in ethanol under a continuous stream of nitrogen gas. Reduced-lipid medium was added to the tube and sonicated three times for 5 s each. At two days post-confluence, each well was incubated for 4 h with media supplemented with reduced-lipid fetal bovine serum (Hyclone, Logan, UT, USA) and containing 0.5 μCi/well radiolabeled 16:0, 18:0, or 18:1n-9 and either harvested (4 h samples) or washed with PBS and incubated in complete medium for an additional 20 h before harvest (24 h samples). Lipids were then extracted and methylated as above. After methylation, the samples were dried under nitrogen, reconstituted in 200 μL methanol, then dried to a volume of approximately 50 μL. The mixture was vortex mixed, and 20 μL was injected for HPLC analysis (Agilent Technologies 1200 series instrument) on a 4.6 × 250 mm, 5 μm, Agilent Zorbax Eclipse XDB-C18 column. A 4.6 × 12.5 mm, 5 μm, guard column was used in conjunction with the analytical column. The fatty acids were separated using a binary mobile phase with a constant flow rate of 1 mL per minute. The solvent program began with 90% solvent A (100% HPLC-grade methanol) and 10% solvent B (HPLC-grade H_2O) for 40 min, followed by 100% solvent A for 20 min. Peaks were detected using ultraviolet detection at 205 nm and identified by comparing retention times with those of unlabeled FAME standards. Quantification of the radiolabeled peaks was performed by use of a scintillation detector (β-RAM Model 4, IN/US Systems) coupled to the HPLC. Data are reported as percentage of total counts.

Quantitative Real-Time PCR

Specific primers for each gene of interest were designed using Beacon Designer software (Premier Biosoft International, Palo Alto, CA, USA), the sequences of which are listed in Table 1. To prevent amplification of genomic DNA, forward and reverse primers were designed from adjacent exons. Primer fidelity and efficiency were tested using an iCycler iQ system (Bio-Rad Laboratories,

Table 1 Primer sequences used for quantitative real-time PCR

Gene name	Product	Sequence of forward and reverse primers (5′–3′)	Genbank accession no.
RPLP0	Ribosomal protein, large, P0	ATGGCAGCATCTACAACCC GACAGACACTGGCAACATTG	NM_001002
SCD	Δ9- (stearoyl-CoA) desaturase	CCCAAGCCCCAAGGTTGAATATG CCCCAAAGCCAGGTGTAGAAC	NM_005063
ELOVL6	Fatty acid elongase 6	CAACGAGAATGAAGCCATC GCAGCATACAGAGCAGAA	NM_024090

Hercules, CA, USA) using iQ5 software (Bio-Rad). Each primer pair produced a single product on melt curve analysis and had amplification efficiencies >94%.

At two days post-confluence, total RNA was prepared from cells using TRIzol reagent (Invitrogen) according to the manufacturer's instructions. Residual DNA was removed by treatment with DNase I (DNA-free kit; Ambion, Austin, TX, USA). First-strand cDNA was synthesized from 2 μg total RNA using TaqMan reverse transcription reagents with random hexamer primers (Applied Biosystems, Foster City, CA, USA).

Quantitative real-time PCR was performed in a 20 μL reaction containing 50 ng reverse-transcribed total RNA, 156 nM forward and reverse primers, and 10 μL 2× SYBR green PCR Master Mix (Applied Biosystems). PCR reactions were performed in triplicate in 96-well plates using the iCycler iQ or CFX96 system (Bio-Rad). Results were analyzed using iQ5 or CFX Manager software (Bio-Rad). The relative amount of mRNAs was calculated using the comparative C_T method [27]. RPLP0 mRNA was used as an invariant control.

Statistical Analysis

Data are presented as mean ± standard error of the mean (SEM). Statistically significant differences between groups were evaluated by use of Student's *t* test to compare means in the sense and antisense groups using Excel (Microsoft, Redmond, WA, USA). $P < 0.05$ was interpreted as statistically significant.

Results

The metabolic pathways leading to the formation of 16:1n-7, 18:1n-9, and 20:3n-9 are shown in Fig. 1. These pathways were evaluated first in 16HBEo$^-$ human bronchial epithelial cells stably transfected with plasmids expressing the first 131 nucleotides of the *cftr* gene in either the sense or antisense orientation [22]. Consequently, the sense cells express CFTR protein whereas the antisense cells show nearly complete loss of both CFTR expression and activity [13, 22].

The relative fatty acid composition of sense and antisense cells is shown in Table 2. A small, but statistically significant increase in the saturated fatty acids 16:0 and 18:0 was observed for antisense cells (3.2 and 4.1% increase, respectively, compared with sense cells). Larger increases are seen in the monounsaturated derivatives of these fatty acids, 16:1n-7 and 18:1n-9 (13 and 15% increase, respectively). The largest relative increase in antisense cells was for 20:3n-9, which was 80% higher in antisense than sense cells. Of note, the 20:3n-9/20:4n-6 ratio, a marker of EFA deficiency [28], is significantly increased in antisense versus sense cells (0.09 vs. 0.05; $P < 0.001$).

To determine if these fatty acid changes in antisense cells were a result of alterations in enzymatic metabolism, sense and antisense cells were incubated with radiolabeled 16:0, 18:0, and 18:1n-9, and conversion to downstream metabolites was measured. The results of labeling experiments with [1-^{14}C]16:0 are shown in Fig. 2. After 4 h incubation, there was significant diminution of 16:0 with increased conversion to 16:1n-7, 18:0, and 18:1n-9 in antisense cells compared with sense cells (Fig. 2a). This effect persisted for all but 18:0 at 24 h (Fig. 2b), perhaps because of subsequent conversion to 18:1n-9.

Similar results were observed when cells were incubated with [1-^{14}C]18:0. Metabolism of 18:0 to 18:1n-9 was increased in antisense versus sense cells at both time points (Fig. 3a, b), although these differences were statistically significant at 24 h only. Further metabolism to 20:3n-9 was significantly increased in antisense cells at both time points.

Increased production of 20:3n-9 is, in part, because of increased metabolism of 18:1n-9. When incubated with [1-^{14}C]18:1n-9, antisense cells showed increased conversion of this substrate to 20:3n-9 at both time points, with difference reaching statistical significance at 24 h (Fig. 4a, b).

Taken together, these fatty acid metabolism results indicate that antisense cells exhibit increased enzymatic activity catalyzing the conversion of 16:0 to 16:1n-7 and from 16:0 through 18:0 to 18:1n-9. The enzymes responsible for these metabolic conversions are Δ9-desaturase

and elongase 6, which are regulated almost entirely at the transcriptional level [29, 30]. To test potential changes in the expression of these enzymes, quantitative RT-PCR was performed on total RNA extracted from sense and antisense cells using primers specific to these two enzymes. As predicted, there was a significant increase in the relative mRNA levels corresponding to both elongase 6 and Δ9-desaturase (Fig. 5a).

To confirm these findings, expression of these enzymes was measured in a second cell-culture system. The IB3 cell line consists of immortalized bronchial epithelial cells from an actual CF patient that carried a compound heterozygous genotype (ΔF508/W1282X) [23]. C38 cells are IB3 cells stably transfected with a wild-type *cftr* gene, restoring normal CFTR function [24]. They were used as controls. Similar to the sense and antisense cells, the IB3 cells exhibit increased expression of both elongase 6 and Δ9-desaturase compared with C38 cells (Fig. 5b).

Further metabolism of 18:1n-9 is catalyzed by Δ6-desaturase, elongase 5, and Δ5-desaturase (Fig. 1). Previous studies [20] in these cell culture systems demonstrated that expression of the two desaturase enzymes is significantly increased in antisense versus sense cells. All three enzymes show increased expression in IB3 versus C38 cells.

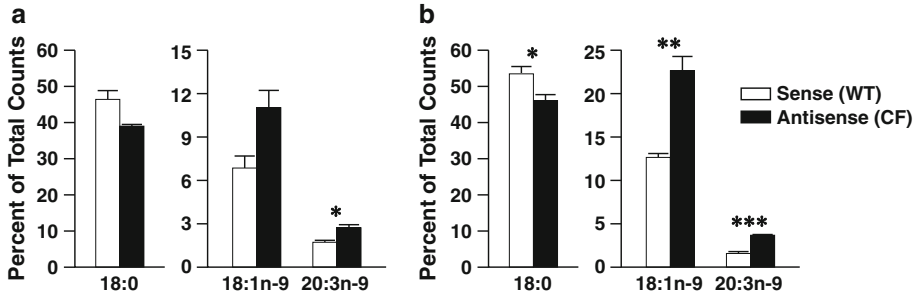

Fig. 3 Stearate (18:0) metabolism through the n-9 pathway in 16HBE cells. Sense (WT) and antisense (CF) cells were cultured in complete medium for seven days and then incubated with 4.1 μM [1-^{14}C]18:0 in reduced-lipid cell culture medium for 4 h and harvested (**a**) or washed twice in PBS and incubated for an additional 20 h in serum-containing medium (**b**). Levels of labeled 18:0, 18:1n-9, and 20:3n-9 were determined by HPLC as described in "Materials and Methods". Discussion

Changes in fatty acid levels are a consistent feature of CF and there is increasing evidence that they are involved in the pathogenesis of the disease. For example, studies have shown that fatty acid alterations are more pronounced in patients carrying genotypes associated with more severe disease [12, 31]. Accordingly, the degree of fatty acid alteration correlates with the severity of CF-associated clinical data [32–34]. Furthermore, correction of fatty acid alterations by docosahexaenoate (22:6n-3) in a mouse model of CF also corrects CF-associated respiratory and gastrointestinal tract pathology [5].

If fatty acid imbalances play a role in CF pathogenesis, it is important to understand their underlying molecular mechanisms. A recent study demonstrated that changes in n-3 and n-6 polyunsaturated fatty acids in CF cells are a result of increased expression of fatty acid metabolic enzymes, specifically the Δ5 and Δ6 desaturases [20]. Our study extends this analysis to alterations observed in n-7 and n-9 fatty acids. It demonstrates increased metabolism of 16:0 to 16:1n-7 and of 16:0 through 18:0 to 18:1n-9 and 20:3n-9 in antisense cells. These changes are associated with increased expression of fatty acid metabolic enzymes, including Δ5, Δ6, and Δ9 desaturases and elongase 6 both in antisense cells and in IB3 cells. Combined, the findings of these two studies strongly support the notion that induction of metabolic enzymes underlies alterations of fatty acid composition in CF. Furthermore, the detection of these changes in an isolated, homogenous cell culture system confirms that the alterations are a result of intrinsic alterations in the CFTR-mutated cells, and not caused by malabsorption or other physiologic abnormalities of CF patients.

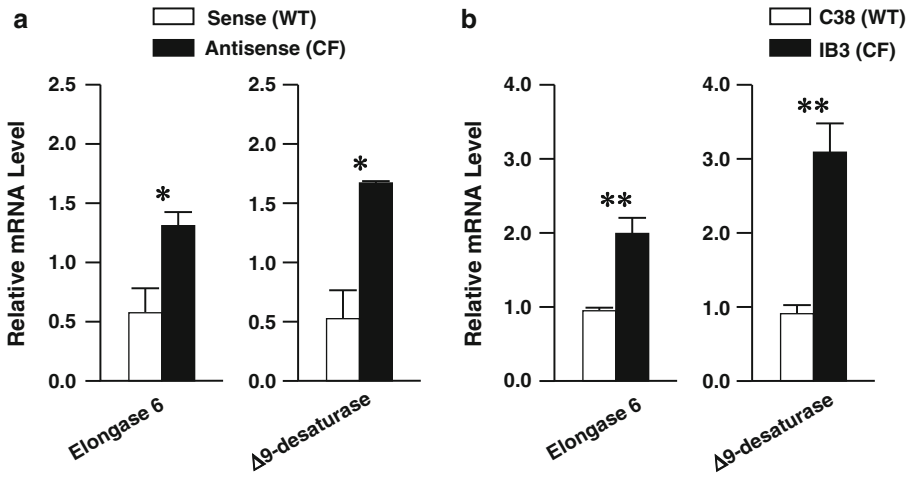

Fig. 5 Relative mRNA expression of metabolic enzymes in the n-7 and n-9 pathways. Sense (WT) and antisense (CF) cells (**a**) or C38 (WT) and IB3 (CF) cells (**b**) were incubated in complete medium for seven days, after which RNA was extracted and cDNA synthesized as described in "Materials and Methods". qRT-PCR was performed using primers for the mRNA sequences of elongase 6 (*ELOVL6*) and Δ9-desaturase (*SCD*). Relative expression was determined by the $\Delta\Delta C_T$ method using ribosomal protein *RPLP0* as a control. *Bars* represent mean ± SEM ($n = 3$). The findings are representative of at least two independent experiments. $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ for sense versus antisense or IB3 versus C38 cells

Although this study begins to unravel the mechanisms of fatty acid changes in CF, the relationship between CFTR mutations and these alterations remains unclear. While CFTR, functions primarily as a chloride channel, it interacts with other proteins and is involved in several other physiologic processes [35]. Thus, changes in fatty acid metabolism could result from a number of different molecular and physiologic alterations caused by CFTR mutation. Consequently, it may be most sensible to begin with the fatty acid metabolic changes and work backwards, establishing this connection step by step. Our work contributes to early first steps in that process.

Others have described similar changes in fatty acid metabolism. Mailhot et al. [36], using a different cell type, a model of Caco-2/15 cells deficient in CFTR, showed altered regulation of lipid metabolism in the CFTR deficient cells. These cells had higher cellular fatty acid content and an elevated proportion of saturated and n-7 fatty acids. These changes were felt to be a result of increased de-novo lipogenesis, enhanced fatty acid uptake, and suppression of transcription factors PPAR-α, RXR-α, LXR-α, and LXR-β mRNA, which are involved in the regulation of lipid metabolism. Altered Δ9-desaturase expression in CF is also supported by the findings of Xu et al. [37], who examined the expression of selected lipid metabolizing enzymes in bone marrow-derived dendritic cells from wild-type and *cftr*$^{-/-}$ knockout mice. They did not detect a difference in Δ9-desaturase mRNA levels between wild-type and CF cells at baseline. However, when exposed to *Pseudomonas* infection, Δ9-desaturase expression was down-regulated in wild-type, but not CF cells. The net result was significantly increased expression of this enzyme in infected CF versus wild-type cells.

Some have speculated that abnormalities in n-3 and n-6 fatty acid levels contribute to CF pathogenesis by increasing production of oxygenated fatty acid species, notably the eicosanoids. The specific role that increased n-7 and n-9 fatty acids, for example 16:1n-7, 18:1n-9, and 20:3n-9, might play in the pathophysiology of CF is less obvious. However, there is a growing recognition that these lipids are important in mammalian physiology and disease. For example, several recent studies have demonstrated that 16:1n-7 increases the insulin sensitivity of peripheral tissues, particularly muscle and liver [15, 38]. In this "lipokine" role, it may also partially mediate the effect of insulin-sensitizing drugs, for example thiazolidinediones [39]. These findings may partially explain the described role of Δ9-desaturase in obesity and insulin resistance [40] and emphasize the role of 16:1n-7 as a signaling molecule.

The other major product of Δ9-desaturase metabolism, 18:1n-9, has been shown to be involved in inflammation, a process particularly germane to CF pathophysiology. Liu et al. [17] showed that decreased 18:1n-9 in Δ9-desaturase-deficient mice attenuated inflammation in adipocytes, macrophages, and endothelial cells. In contrast, Harvey et al. [41] showed that 18:1n-9 blocks 18:0-induced cell growth inhibition and inflammatory signaling. Other studies [16, 18] have found that decreased 18:1n-9 levels because of Δ9-desaturase inhibition or deletion exacerbate inflammation in mouse models of acute colitis and atherosclerosis. Thus, 18:1n-9 may have cell-specific effects in inflammation. In addition, Patel et al. [19] demonstrated that 20:3n-9 may mediate inflammation via oxygenated

derivatives. This study found that the major product of 20:3n-9 metabolism was 5-hydroxy-20:3, a potent pro-inflammatory mediator and activator of neutrophils and eosinophils.

It should be noted that a high-fat diet is recommended for patients with CF, with no suggestion that the fat be of a specific type and therefore provide the patient with higher concentrations of specific fatty acids. Understanding the metabolic mechanisms responsible for the specific fatty acid alterations observed in CF may lead to better informed and more specific dietary and therapeutic recommendations that may be beneficial for patients.

Abstract The administration of tetradecylthioacetic acid (TTA), a hypolipidemic and anti-inflammatory modified bioactive fatty acid, has in several experiments based on high fat diets been shown to improve lipid transport and utilization. It was suggested that increased mitochondrial and peroxisomal fatty acid oxidation in the liver of Wistar rats results in reduced plasma triacylglycerol (TAG) levels. Here we assessed the potential of TTA to prevent tumor necrosis factor (TNF) α-induced lipid modifications in human TNFα (hTNFα) transgenic mice. These mice are characterized by reduced β-oxidation and changed fatty acid composition in the liver. The effect of dietary treatment with TTA on persistent, low-grade hTNFα overexpression in mice showed a beneficial effect through decreasing TAG plasma concentrations and positively affecting saturated and monounsaturated fatty acid proportions in the liver, leading to an increased anti-inflammatory fatty acid index in this group. We also observed an increase of mitochondrial β-oxidation in the livers of TTA treated mice. Concomitantly, there were enhanced plasma levels of carnitine, acetyl carnitine, propionyl carnitine, and octanoyl carnitine, no changed levels in trimethyllysine and palmitoyl carnitine, and a decreased level of the precursor for carnitine, called γ-butyrobetaine. Nevertheless, TTA administration led to increased hepatic TAG levels that warrant further investigations to ascertain that TTA may be a promising candidate for use in the amelioration of inflammatory disorders characterized by changed lipid metabolism due to raised TNFα levels.

Keywords Tetradecylthioacetic acid · hTNFα transgenic mice · Low-grade inflammation · Dietary treatment · Plasma · Liver

Abbreviations

ACC	Acetyl-CoA carboxylase
ACS	Acyl-CoA synthetase
CPT-I and -II	Carnitine palmitoyltransferase-I and -II
FAO	Fatty acyl-CoA oxidase
FAS	Fatty acid synthase
HDL	High-density lipoprotein
HMG-CoA synthase	3-Hydroxy-3-methylglutaryl-coenzyme A synthase
HPLC	High-performance liquid chromatography
MUFA	Monounsaturated fatty acid(s)
PPAR	Peroxisome proliferator-activated receptor(s)
PUFA	Polyunsaturated fatty acid(s)
SFA	Saturated fatty acid(s)
TAG	Triacylglycerol
TCA	Tricarboxylic acid cycle (Krebs cycle)
hTNFα	Human tumor necrosis factor α
TTA	Tetradecylthioacetic acid
VLDL	Very low density lipoprotein

Introduction

Chronic low-grade inflammation accompanies the development of metabolic syndrome features, like abdominal obesity, dyslipidemia, hypertension, and insulin resistance, known risk factors for cardiovascular disease affecting millions of people worldwide. The first indication that there is a connection between obesity, diabetes and chronic inflammation came from the observation that the pro-inflammatory cytokine tumor necrosis factor (TNF) α is overexpressed in adipose tissues of obese mice and humans [1, 2]. Moreover, its inactivation with anti-TNFα antibodies improved insulin resistance in obese mice [2], whereas TNFα null mice would not develop insulin resistance after diet-induced obesity [3]. The multifunctional cytokine TNFα was shown thereafter to perturb lipid metabolism by increasing free fatty acid production [4, 5], promoting lipolysis [6–9], affecting lipid-metabolism-related gene expression [10, 11], controlling cholesterol metabolism [12, 13], and influencing expression and secretion of other adipokines [14–17].

Used as a model for persistent low-grade TNFα exposure, we have found previously that hTNFα transgenic mice show a down-regulation of peroxisome proliferator-activated receptor (PPAR) α target genes [18]. The mitochondrial enzymes involved in hepatic lipid metabolism were influenced, leading to changes in fatty acid synthesis and oxidation [18]. In particular, not only carnitine palmitoyltransferase-I and -II (CPT-I and -II), proteins important for the β-oxidation of long-chain fatty acids in mitochondria, but also fatty acyl-CoA oxidase (FAO), which is important for peroxisomal β-oxidation, proved to have decreased hepatic activity in the hTNFα transgenic mice [18]. In addition, TNFα overexpression was associated with a significant reduction of hepatic mRNA levels of mitochondrial HMG-CoA synthase, the rate-limiting enzyme in ketogenesis [18]. Moreover, lipogenesis is affected by TNFα. Namely, the two important enzymes in lipogenesis, acetyl-CoA carboxylase (ACC), which produces malonyl-CoA for fatty acid synthesis, showed a tendency for lowered activity, whereas fatty acid synthase (FAS), an enzyme involved in long-term regulation of fatty acid synthesis, displayed a significantly decreased activity [18].

As lipids have the ability to modulate metabolic, inflammatory and innate immune processes [19], we investigated in the present study, whether the fatty acid analogue tetradecylthioacetic acid (TTA) could counteract the health risks as a consequence of TNFα-overexpression. To be able to investigate inflammation in relation to lipid accumulation as seen in the nutritional disorder of obesity, we chose to administer a high-fat diet. TTA is a saturated fatty acid containing 16 carbons and one sulfur atom at position three of the carbon chain from the alpha end, a characteristic that results in its increased metabolic stability [20]. TTA is known to act, at least partly, through the activation of PPAR [21–23], and influence plasma lipids by increasing hepatic β-oxidation [24, 25]. Moreover, we have reported that TTA has antioxidant and antiinflammatory properties [26].

In the present work, we show that the administration of TTA to hTNFα transgenic mice fed a high-fat diet showed beneficial effects on serum cholesterol and triacylglycerol (TAG) levels, hepatic fatty acid composition and cholesterol levels, with a concurrent increase in hepatic β-oxidation and fatty inflammatory index.

Experimental Procedure

Transgenic Mice

The study was performed on female transgenic mice expressing low levels of human TNFα (hTNFα) mice from Taconic (Germantown, USA). The transgenic mouse line was generated in strain C57Bl/6 [27]. The experiments were performed in accordance with, and under the approval of, the Norwegian State Board for Biological Experiments, the Guide for the Care and Use of Laboratory Animals, and the Guidelines of the Animal Welfare Act. The mice were between 6 and 8 weeks of age at the start of the experimental feeding and were divided into two experimental groups of five animals each with comparable mean body weight. They were housed in cages with constant temperature (22 ± 2 °C) and humidity (55 ± 5%), where they were exposed to a 12 h light-dark cycle (light from 07.00 to 19.00) and had unrestricted access to tap water and food. The mice were acclimatized to these conditions before the start of the experiment.

Protein and fat of the feeding diets were from casein sodium salt from bovine milk, 20% (Sigma-Aldrich Norway AS, Oslo, Norway) and lard, 23% (Ten Kate Vetten BV, Musselkanaal, Netherlands) plus soy oil, 2% (Dyets Inc., Bethlehem, PA, USA). In addition, in the TTA group 0.6% of the lard was substituted by TTA. The TTA was synthesized as described earlier [28]. There were no significant differences in fatty acid composition between control and TTA diets, except the TTA content (SFA 43.9 vs. 42.8 wt%, MUFA 38.8 vs. 37.8 wt%, PUFAn-3 1.51 vs. 1.48 wt%, PUFAn-6 15.6 vs. 15.3 wt%, TTA 0.0 vs 2.5 wt%).

The mice were anaesthetized under fasting conditions by inhalation of 2% isoflurane (Schering-Plough, Kent, UK) after two weeks of feeding. Blood was collected by aortic

puncture with 7.5% EDTA and immediately chilled on ice. Plasma was prepared and stored at −80 °C prior to analysis. Parts of the liver were used for β-oxidation analysis and chilled on ice, and the rest was freeze-clamped and stored at −80 °C until the analysis of fatty acids, triacylglycerols, cholesterol, and enzyme activities.

Plasma and Hepatic Lipids

Liver lipids were extracted according to Bligh and Dyer [29], evaporated under nitrogen, and redissolved in isopropanol before analysis. Lipids were subsequently measured enzymatically on a Hitachi 917 system (Roche Diagnostics GmbH, Mannheim, Germany) using the triacylglycerol (GPO-PAP) and cholesterol kit (CHOD-PAP) from Roche Diagnostics (Mannheim, Germany) and the phospholipid kit from bioMérieux SA (Marcy l'Etoile, France).

Hepatic Fatty Acid and Plasma Carnitine Compositions

Total hepatic fatty acid composition was analyzed as described previously [18]. The anti-inflammatory fatty acid index was calculated as (docosapentaenoic acid + docosahexaenoic acid + dihomo-γ-linolenic acid + eicosapentaenoic acid)x100/arachidonic acid. Slightly different indexes have been used by [30, 31]. Free carnitine, short-, medium-, and long-chain acylcarnitines, and the precursors for carnitine, trimethyllysine and γ-butyrobetaine, respectively, were analysed in plasma using HPLC/MS/MS as described previously [32] with some modifications (Svardal et al., in preparation).

Hepatic Enzyme Activities

The livers were homogenized and fractionated as described earlier [33]. Palmitoyl-CoA oxidation was measured in a mitochondria-enriched extract from liver as acid-soluble products [34]. The activities of carnitine palmitoyltransferase (CPT)-I [35] and acyl-CoA synthetase (ACS) [35] were measured in the mitochondrial fraction. Fatty acid synthase (FAS) was measured in the post-nuclear fraction as described by Skorve et al. [36].

Statistical Analysis

Data sets were analyzed using Prism Software (Graph-Pad Software, San Diego, CA) to generate the figures and determine statistical significance. The results are shown as means with their standard deviations (S.D.). A *t*-test was used to determine significant differences between the control and the TTA treatment group. *P*-values < 0.05 were considered significant.

Results

Body/Liver Weights and Feed Intake

We found that TTA supplementation for two weeks to hTNFα-overexpressing mice promoted a significant decrease in body weights (−0.8 ± 0.8 g) as compared to high-fat-fed control animals (1.4 ± 0.6 g) (Table 1). Whereas liver weights and liver index were significantly increased in the TTA supplemented group (1.4 ± 0.09 and 7.2 ± 0.43) in comparison to the control group (0.9 ± 0.08 and 4.3 ± 0.3). The TTA group displayed a reduced total feed intake, 30 g versus 34 g of diet per TTA- or control-fed mouse, respectively. Thus, the TTA group seems more efficient in converting feed into increased body mass, as shown by a lower total feed efficiency (−0.03) in comparison to the control group (0.04).

Serum and Hepatic Lipids

In previous studies, comparing transgenic hTNFα-overexpressing with wildtype mice, TNFα interfered with lipid metabolism, leading to increased hepatic TAG and total cholesterol levels. Serum cholesterol concentrations were decreased, whereas serum TAG levels were unchanged [18].

In this study, two weeks of 0.6% TTA administration promoted positive effects on plasma parameters in hTNFα-overexpressing mice fed a high fat diet. The transgenic mice showed increased levels of total cholesterol due to a 39% increase in HDL-cholesterol in the TTA treated group (Fig. 1a) as compared to the high fat-fed controls. With regard to plasma TAG, a drastic reduction of 54% was observed after TTA treatment (Fig. 1b) as compared to the control. Plasma phospholipids (Fig. 1c) and free fatty acids (data not shown) were not significantly changed. The hepatic levels of total cholesterol showed a non-significant tendency to decrease in the TTA-treated group (Fig. 1d), and the already high TAG amounts in transgenic mice

Table 1 Body and liver weights, liver index [100 × (liver weight in g/body weight in g)], total feed intake, and feed efficiency (weight gain in g/food intake in g)

	Control	TTA
Initial body weight (g)	19.2 ± 1.1	20.2 ± 1.3
Final body weight (g)	20.6 ± 1.5	19.4 ± 1.3
Body weight gain (g)	1.4 ± 0.6	−0.8 ± 0.8
Liver weight (g)	0.9 ± 0.08	1.4 ± 0.09
Liver index	4.3 ± 0.3	7.2 ± 0.43
Total feed intake (g)	34.2	30
Total feed efficiency	0.04	−0.03

Values are mean ± S.D. ($n = 5$)

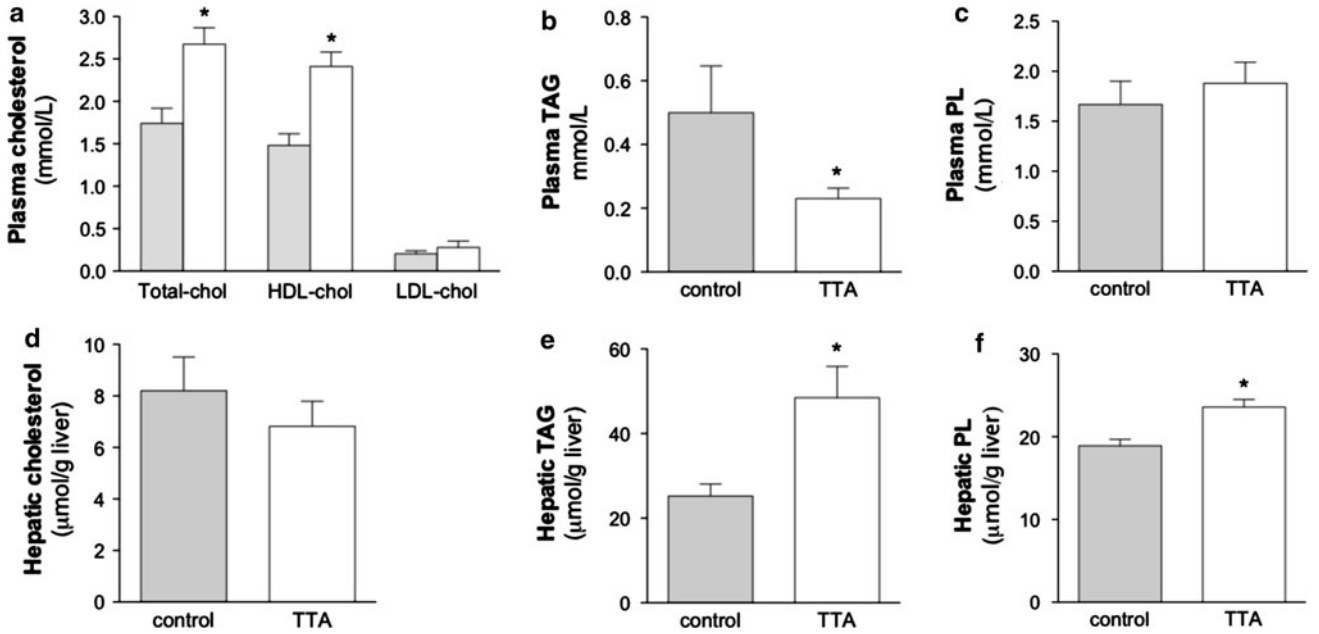

Fig. 1 TTA treatment induces a significant increase in plasma HDL-cholesterol levels in hTNFα transgenic mice (**a**) and a decrease in plasma TAG levels (**b**), whereas phospholipids showed no change (**c**). Hepatic cholesterol showed no significant change (**d**), but a TAG and phospholipid-increasing effect in the liver was found after treatment with TTA (**e**, **f**). Data are means ± S.D. ($n = 5$). * denotes statistical significant differences by Student's *t*-test between control (*grey bars*) and TTA (*white bars*) ($P < 0.05$). *chol*, cholesterol; *HDL*, high-density lipoprotein; *LDL*, low density lipoprotein; *PL*, phospholipid; *AG*, triacylglycerol; *TTA*, tetradecylthioacetic acid

further increased after TTA treatment (Fig. 1e). The hepatic phospholipid level was also elevated after TTA administration in comparison to control mice (Fig. 1f).

Fatty Acid Composition in Liver

In order to investigate if the results obtained for hepatic lipids were specific for cholesterol and TAG or if fatty acids were also affected significantly, we performed an analysis of the total hepatic fatty acid composition. We have previously demonstrated an increased weight % of saturated fatty acids (SFAs) in TNFα-overexpressing mice on a chow diet [18].

Here we observed a comparable level of SFAs in TNFα-overexpressing mice (in spite of higher dietary SFA content in the high-fat diet used- see Discussion). TTA treatment lead to decreased weight % in saturated fatty acid levels (Fig. 2a). The most significant individual decreases could be found in the fatty acids C15:0, C17:0, C18:0, C22:0, C23:0, and C24:0 (Table 2). The most impact on decreasing total SFAs had C18:0.

The relative amounts of monounsaturated fatty acids (MUFA) that were shown to be decreased in hTNFα transgenic in comparison to wildtype mice [18], were significantly increased by TTA in the diet (Fig. 2b). This was mainly due to the increased amount of oleic acid (C18:1n-9) that was to some extent induced by increased Δ9 desaturase activity as the index Δ9 desaturase activity suggests (Table 2).

A significant decrease in weight % of n-3 and n-6 polyunsaturated fatty acids (PUFA) was observed in the transgenic mice treated with TTA (Fig. 2c and d) when compared to control animals. This was reflected in decreased amounts of the n-3 PUFA alpha-linolenic acid (18:3n-3), stearidonic acid (C18:4n-3) and docosahexaenoic acid (C22:6n-3), along with linoleic acid (C18:2n-6) and arachidonic acid (C20:4n-6) that can mainly be attributed to lowered levels of n-6 PUFA (Table 1). The sums result in a decreased ratio of n-3 to n-6 PUFA (Table 1). TTA seems to counteract the increased PUFA levels seen in transgenic mice in contrast to wildtype mice that were due to increased weight % of n-3, with unchanged n-6 levels, giving an increased n-3 to n-6 ratio [18].

In addition, after TTA administration, there was a strong decrease in the C20:4n-6/C20:3n-6 ratio as an indirect measure of the n-6 Δ5 desaturase activity, an enzyme important for the production of arachidonic acid (Table 2). This indicates that TTA might decrease the hepatic desaturation of dihomo-γ-linolenic acid (20:3n-6) to arachidonic acid (20:4n-6) in hTNFα transgenic mice. Whereas beforehand, we observed increased ratios pointing towards increased activities of Δ6 and Δ5 desaturases in transgenic mice in comparison to control animals [18].

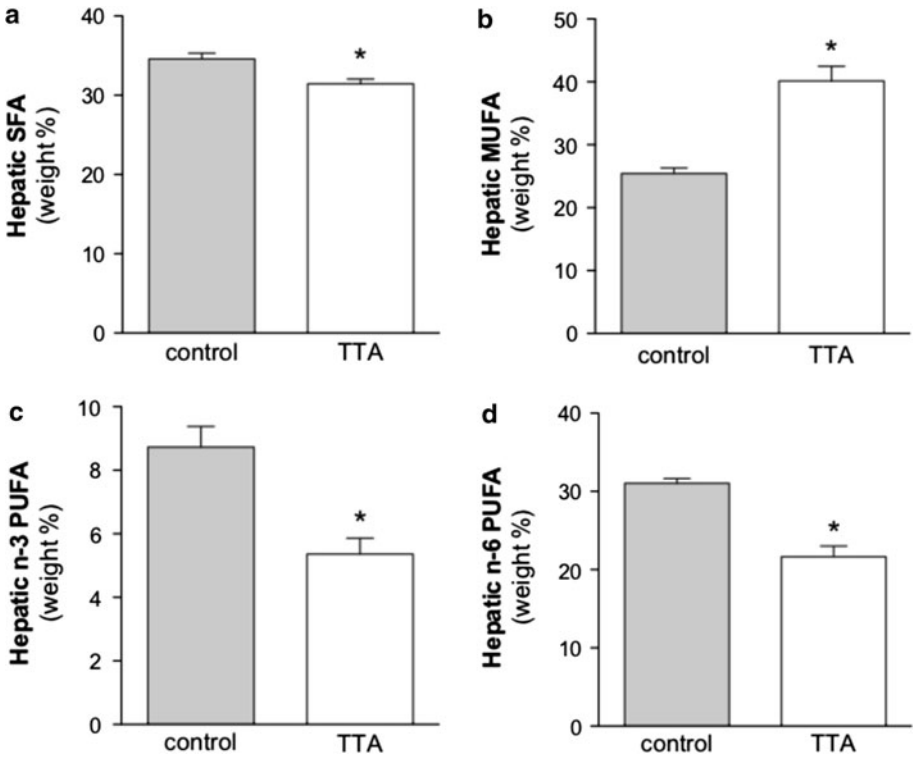

Fig. 2 Dietary treatment for 2 weeks with TTA affects hepatic fatty acid composition and changes saturated fatty acids (**a**), monounsaturated fatty acids (**b**), n-3 polyunsaturated fatty acids (**c**), and n-6 polyunsaturated fatty acids (**d**) levels significantly. The data is given as weight % of total fatty acid ± S.D. ($n = 5$). * denotes statistical significant differences to the control by Student's t test ($P < 0.05$). *SFA* saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids, *TTA* tetradecylthioacetic acid

The anti-inflammatory fatty acid index, calculated as (docosapentaenoic acid + docosahexaenoic acid + dihomo-γ-linolenic acid + eicosapentaenoic acid) × 100/arachidonic acid [30], increased after TTA treatment.

Hepatic β-Oxidation of Fatty Acids

The TAG-lowering effect observed in plasma of hTNAα transgenic mice after TTA treatment, could be due to an enhanced mitochondrial and peroxisomal β-oxidation that is responsible for the shortening of long-chain fatty acyl-CoAs. Indeed, β-oxidation increased by 48% in the TTA treated mice, when using ^{14}C-palmitoyl-CoA as substrate (Fig. 3a), counterbalancing the decreased β-oxidation values from transgenic mice [18]. In the previous study, the sensitivity towards malonyl-CoA, an inhibitor of CPT-I, was unaffected by TNFα [18]. However, in the TTA treated group we detected a lowering of the inhibition capacity of malonyl-CoA from 35% to 14% inhibition (Fig. 3b) and the transport of fatty acids across the mitochondrial outer membrane is facilitated even in the presence of malonyl-CoA.

Activities of Enzymes Involved in Degradation and Biosynthesis of Fatty Acids

In order to explain the mechanisms of TTA in more detail, enzyme activities were measured in the post-nuclear fraction of the liver. The enzymatic activity of CPT-I, the rate-limiting enzyme of mitochondrial β-oxidation, involved in acyl group transport into the matrix, was increased after TTA treatment (Fig. 4a). Likewise, the mitochondrial enzyme acyl-CoA synthetase (ACS) that activates fatty acids prior to oxidation, showed increased activity (Fig. 4b). On the other hand, a major cytosolic, multifunctional enzyme involved in the biosynthesis of fatty acids, called fatty acid synthase (FAS), showed reduced activity (Fig. 4c).

Oxidation of fatty acids can be facilitated not only by the up-regulation of CPT-I, but also by an increased concentration of its substrate carnitine, to ensure efficient transport of fatty acids into mitochondria. Carnitine can be taken up from dietary sources or is endogenously synthesized primarily in the liver and kidney [37, 38]. All other tissues have to take carnitine actively up from the blood. We found that in plasma, free carnitine concentrations have increased during TTA treatment by 36% in comparison to control animals (Fig. 5a). The precursors for carnitine, were either unchanged (trimethyllysine, Fig. 5b) or reduced (γ-butyrobetaine, Fig. 5c). The two quantitatively most important acyl-esters, acetyl carnitine (Fig. 5d) and propionyl carnitine (Fig. 5e) were significantly increased by TTA compared to high fat-fed controls. The plasma medium-chain acylcarnitine, octanoyl carnitine, was significantly increased (Fig. 5f) and the long-chain acylcarnitine, palmitoyl carnitine, remained unchanged by TTA treatment (Fig. 5g).

The anti-inflammatory index is calculated as described in Experimental Procedure. The ratio of C20:4n-6 to C20:3n-6 gives an indirect index of the n-6 Δ5 desaturase activity. The data are given as weight % ± S.D. ($n = 5$). A two sample, two-tailed *t*-test assuming equal variance was calculated. NS means not significant

Discussion

Obesity-related metabolic disorders are associated with a state of chronic low-intensity inflammation. Inflammation induces a wide array of metabolic changes in the body and affects expression of many proteins involved in lipid metabolism. The different subtypes of the nuclear ligand-dependent transcription factors, PPAR, play key roles in lipid homeostasis. They are involved in the regulation of lipoprotein metabolism, fatty acid oxidation, glucose and carnitine homeostasis and also seem to be involved in inflammatory processes [39]. TNFα is one of the factors that mediate alterations in lipid metabolism, including decreased PPARα mRNA and protein levels [40]. With the knowledge in mind that previous studies have shown that the biological response to TTA treatment is at least partly a result of PPAR activation, and that this bioactive fatty acid analogue has the ability to activate all three isoforms of PPAR [21, 23, 41], as well as increase the mRNA level of PPARα [42], we wanted to test if TTA was able to counteract TNFα-induced metabolic aberrations.

In the present study we demonstrated that TTA, in addition to its health-promoting effects in previous in vivo [43] and in vitro experiments [26, 44], could also ameliorate several parameters in a mouse model of chronic inflammation. TNFα might induce hypertriglyceridemia, characterized by the accumulation of very low density lipoprotein (VLDL) in the plasma, due to impaired removal of VLDL [45] and increased hepatic lipogenesis [46]. TAG-rich lipoproteins were shown to be important for the acute phase response by binding to endotoxins to reduce their harmful action [47]. However, systemic low-grade inflammation with elevated circulating levels of TNFα seen in obese subjects is typically associated with high plasma TAG levels that will increase the risk for metabolic and cardiovascular complications [48]. It is therefore of importance to note that TTA has the capability to strongly reduce plasma TAG levels in a chronic inflammatory state with persistently high TNFα levels.

The observation of decreased TAG in the plasma is compatible with the hypothesis that there is a higher flux of fatty acids from the plasma to the liver, with a

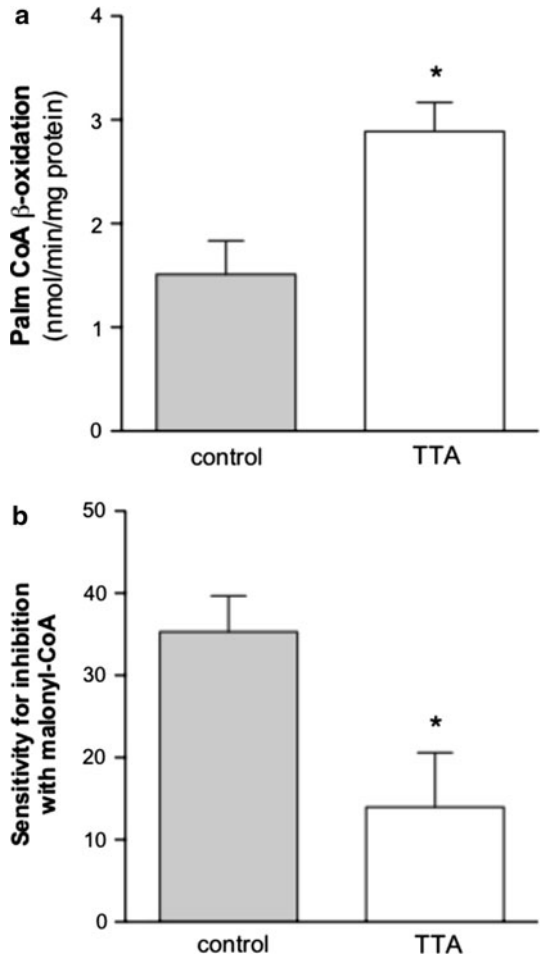

Fig. 3 Palmitoyl-CoA β-oxidation is increased in liver mitochondria of TTA-treated mice (**a**) and the sensitivity for inhibition of oxidation of palmitoyl-CoA with malonyl-CoA (given in % inhibition) is lower in the TTA group compared to high fat-fed controls (**b**). Oxidation of palmitoyl-CoA was measured in purified mitochondria as acid-soluble products. *Bars* indicate $\pm$ S.D. ($n = 5$). * $P < 0.05$ different from the control. *Palm-CoA*, palmitoyl-CoA; *TTA*, tetradecylthioacetic acid

simultaneous reduction in fatty acid biosynthesis. But even though TTA up-regulates hepatic mitochondrial CPT-I and ACS activities, accompanied by an increase in hepatic β-oxidation and plasma carnitine levels, it is not sufficient to deal with the already existing high TAG levels in the transgenic mice. It is noteworthy that TTA has the capability to downregulate the hepatic biosynthesis of fatty acids, since the FAS activity is reduced by 27% in the TTA treated animals. Reduced lipogenesis and increased fatty acid oxidation after TTA treatment seem to be the reason for decreased plasma TAG levels by 54% after TTA treatment. Yet, the exact reasons why hepatic TAG were not affected similarly by TTA are not yet elucidated at the molecular level and will require further detailed studies. It might be that a higher dose of TTA is required to get a more pronounced effect on lipogenesis, thereby influencing hepatic TAG levels. Previously, we have found indications that the effect on hepatic TAG metabolism may be dose dependent and that the amount of hepatic TAG is decreased with increasing doses of TTA [49]. It could also be that a longer feeding period than the two weeks applied is needed to overcome hepatic TAG accumulation. Noteworthy is that we have never detected a TTA-induced liver steatosis in any of the mouse or rat models used previously. It is however of importance to verify in future studies if increasing amounts of TTA could counteract this effect in the mouse model used and if this finding is of significance for humans.

The increased hepatic phospholipid level that we measure in the TTA treated group, is probably a consequence of increased membrane production due to mitochondrial and peroxisomal proliferation as seen after TTA treatment previously [50–52]. Moreover, administration of PPARα ligands has been described to lead to hepatic hypertrophy and hyperplasia leading to increased liver weights as seen in our study. The liver enlargement is however restricted to rodents and has never been described in humans [53–58].

By measuring plasma free carnitine and its acyl-esters, in particular the two most abundant species, acetyl carnitine and propionyl carnitine, we looked at overall changes in the β-oxidation process. We found that plasma free carnitine levels were increased due to TTA administration, as well as the short- and medium-chain carnitine esters, but not long-chain fatty acyl carnitines. It is important to note that in addition to being essential for transport of fatty acids into mitochondria, carnitine is crucial to increase acyl and acetyl group export out of mitochondria into the blood [59]. By increasing carnitine levels through TTA administration, lipotoxicity of β-oxidation metabolites is reduced and mitochondrial capacity is improved. The excess short-chain acyl-esters, that cannot be used by the TCA cycle, will be secreted in urine. The formation of trimethyllysine and its conversion to γ-butyrobetaine is reported to occur in most tissues, but the last step in carnitine biosynthesis, the hydroxylation of γ-butyrobetaine to carnitine, occurs only in liver and kidney in mice. Therefore interorgan transport of γ-butyrobetaine and carnitine are of importance. It was of interest that plasma γ-butyrobetaine levels were decreased, whereas carnitine levels were increased. This may be due to increased consumption of γ-butyrobetaine for carnitine biosynthesis and increased mitochondrial oxidation of long-chain fatty acids.

TTA affects the capacity for insertion of double bonds and counteracts the abnormal hepatic fatty acid composition levels under the influence of TNFα. Correct proportions of fatty acids are crucial to maintain cellular

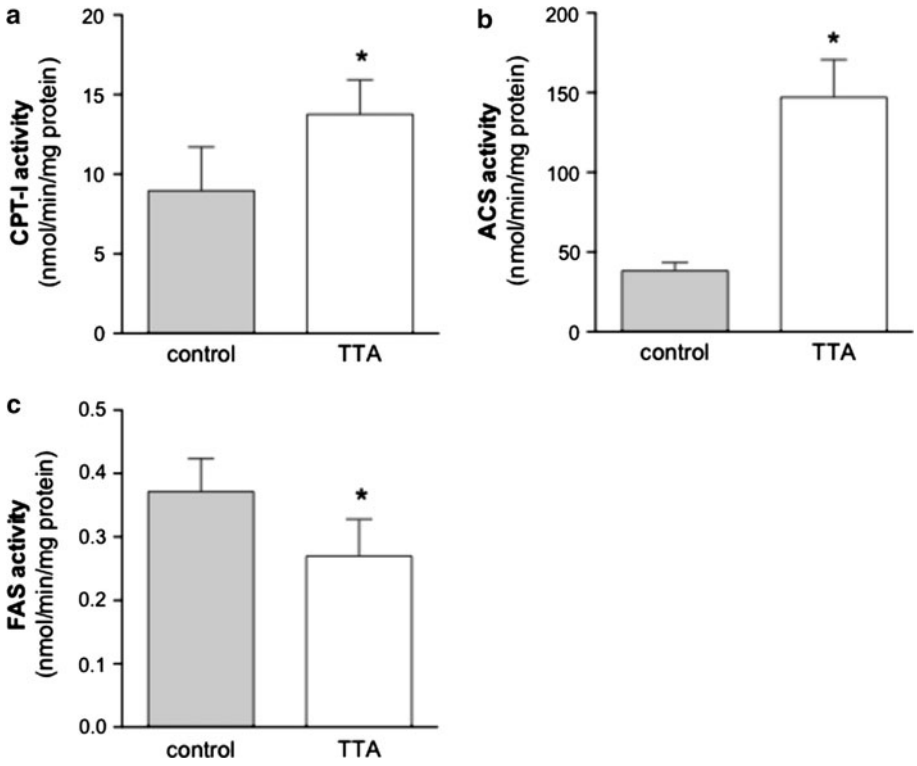

Fig. 4 Enzyme activities of the mitochondrial enzymes CPT-I (**a**) and ACS (**b**) involved in β-oxidation are increased in the liver of hTNFα transgenic mice treated with TTA, whereas the cytosolic FAS activity involved in biosynthesis of fatty acids shows reduced activity after two weeks of treatment (**c**). Values are means ± S.D. ($n = 5$) and * shows a $P < 0.05$ difference from the control. *CPT-I*, carnitine palmitoyl transferase I; *ACS*, acyl-CoA synthetase; *FAS*, fatty acid synthase; *TTA*, tetradecylthioacetic acid

functions, a balance that was disturbed in the TNFα transgenic mice. hTNFα overexpression was accompanied by increased saturated and polyunsaturated fatty acids, but decreased levels of monounsaturated fatty acids in liver [18]. The basic values of these fatty acid families in hTNFα control group in our high fat diet experiment compared to the previous study were less pronounced, which could be partially attributed to a different diet in [18] (low fat standard mouse chow with 26 % SFA, 25 % MUFA, 4 % PUFAn-3 and 45 % PUFAn-6). Nevertheless, it did not affect the trends of fatty acid changes inside the dietary groups (high fat diet and standard chow diet, respectively). Moreover, TTA reduced the n-6 Δ5 desaturase activity index in transgenic mice as fatty acid saturation was increased. This was accompanied by decreases of n-3 and n-6 polyunsaturated fatty acids including stearidonic acid (C18:4n-3) and docosahexaenoic acid (C22:6n-3), as well as linoleic acid (C18:2n-6) and arachidonic acid (C20:4n-6). The amount of arachidonic acid is of importance for the calculation of the anti-inflammatory fatty acid index, and decreased amounts after TTA treatment increased the fatty anti-inflammatory index in this group. Saturated fatty acids, that have pro-inflammatory and insulin-antagonizing properties [60], were decreased by TTA, thereby lowering the risk for the development of metabolic syndrome. On the other hand, monounsaturated fatty acids were increased after TTA treatment. This is potentially beneficial, as high levels were associated with low rates of cardiovascular disease [61]. Another risk factor for cardiovascular disease in humans is low HDL-cholesterol due to its important function in reverse cholesterol transport to the liver [62]. We found elevated plasma HDL-cholesterol levels with an increase of 63% in TTA treated TNFα transgenic mice. However, in a study including a small group of HIV-infected patients, we found that TTA in combination with dietary intervention can reduce total cholesterol, LDL-cholesterol, and LDL/HDL cholesterol, but no increase in HDL-cholesterol could be observed [63]. It has been shown previously that apolipoprotein compositions and responses to PPARα activation are different between humans and rodents [64, 65]. The result of increased HDL-cholesterol in hTNFα overexpressed mice in our study might therefore be rodent-specific. However, effects of PPARα activation on other pathways of lipid metabolism including FA uptake and activation, β-oxidation, and lipogenesis support similarities between mice and humans [39]. This suggests similar responses upon TTA treatment in humans as seen in our mice study.

In summary, given the ability of TTA to increase β-oxidation, reduce plasma TAG, and positively affect hepatic saturated and monounsaturated fatty acid compositions

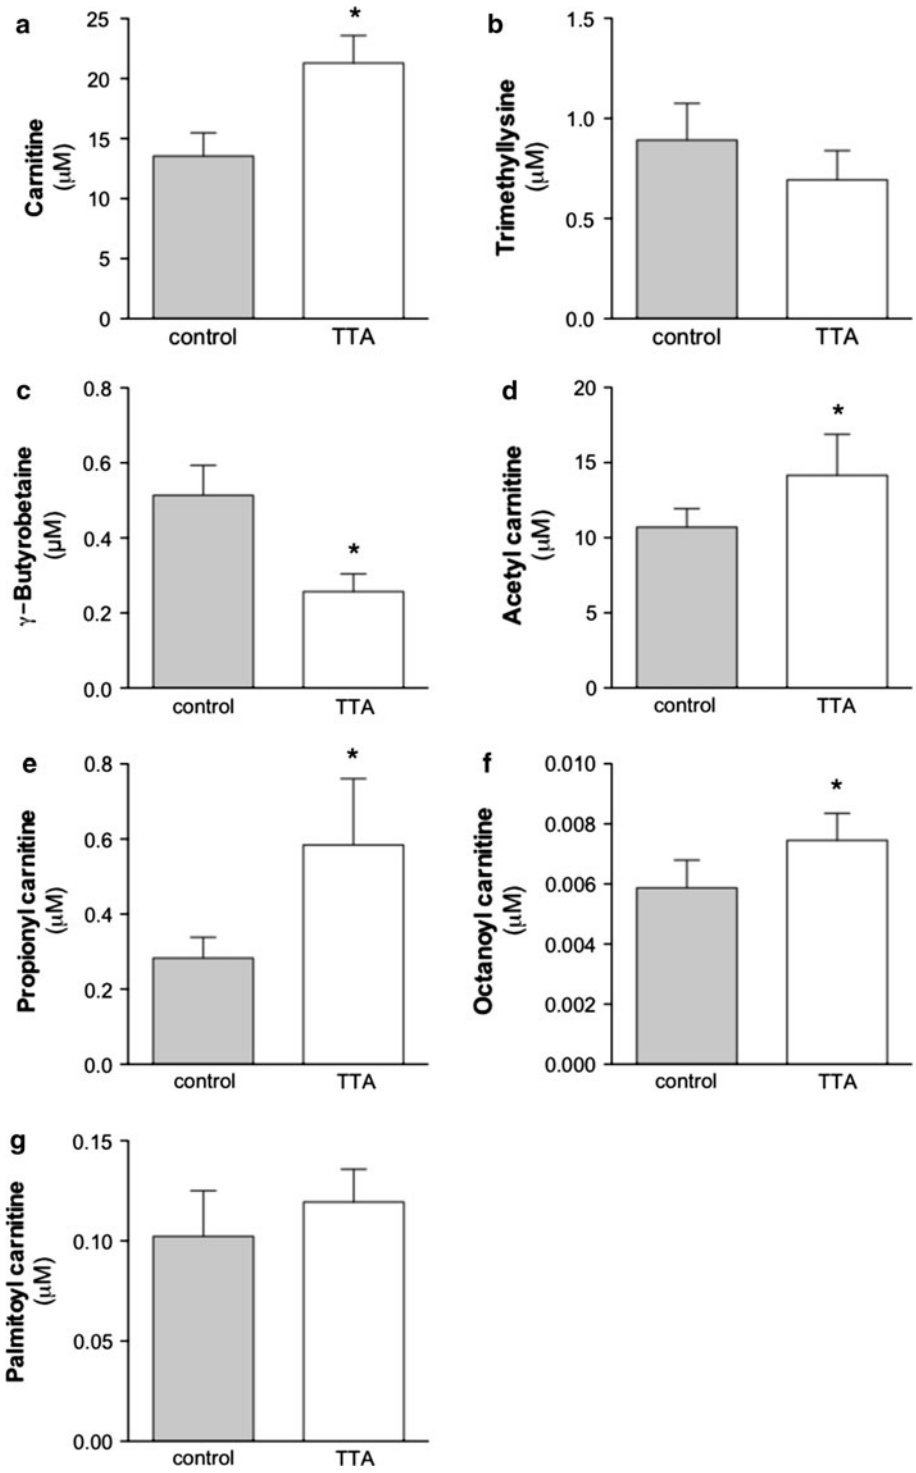

Fig. 5 A change in plasma levels of free carnitine (**a**), trimethyllysine (**b**), γ-butyrobetaine (**c**), acetyl carnitine (**d**), propionyl carnitine (**e**), octanoyl carnitine (**f**), and palmitoyl carnitine (**g**) could be detected after TTA treatment. * denotes statistical significant differences by Student's *t*-test between control (*grey bars*) and TTA (*white bars*) ($P < 0.05$) and *bars* indicate ± S.D. ($n = 5$)

leading to an increase in the anti-inflammatory fatty acid index, indicates that TTA has a high potential to ameliorate chronic inflammation such as with obesity, arthritis or atherosclerosis.

Identification of Diacylglycerol Acyltransferase Inhibitors from *Rosa centifolia* Petals

Hidehiko Kondo · Kohjiro Hashizume · Yusuke Shibuya · Tadashi Hase · Takatoshi Murase

Received: 2 September 2010 / Accepted: 14 March 2011 / Published online: 3 May 2011

Abstract Diacylglycerol acyltransferase (DGAT) catalyzes the final step of triacylglycerol (TAG) synthesis, and is considered as a potential target to control hypertriglyceridemia or other metabolic disorders. In this study, we found that the extract of rose petals suppressed TAG synthesis in cultured cells, and that the extract showed DGAT inhibitory action in a dose-dependent manner. Fractionation of the rose extract revealed that the DGAT inhibitory substances in the extract were ellagitannins; among them rugosin B, and D, and eusupinin A inhibited DGAT activity by 96, 82, and 84% respectively, at 10 μM. These substances did not inhibit the activities of other hepatic microsomal enzymes, glucose-6-phosphatase and HMG-CoA reductase, or pancreatic lipase, suggesting that ellagitannins inhibit DGAT preferentially. In an oral fat load test using mice, postprandial plasma TAG increase was suppressed by rose extract; TAG levels 2 h after the fat load were significantly lower in mice administered a fat emulsion containing rose extract than in control mice (446.3 ± 33.1 vs 345.3 ± 25.0 mg/dL, control vs rose extract group; $P < 0.05$). These results suggest that rose ellagitannins or rose extract could be beneficial in controlling lipid metabolism and used to improve metabolic disorders.

Abbreviations

AUC	Area under the curve
ACAT	Acyl coenzyme A:cholesterol acyltransferase
BALB	Dimercaptopropanol tributyrate
DGAT	Diacylglycerol acyltransferase
DMEM	Dulbecco's modified Eagle's medium
DTNB	5,5′-dithiobis(2-nitrobenzoic acid)
EGCG	Epigallocatechin gallate
G6Pase	Glucose-6-phosphatase
MFI	Mean fluorescent intensity
TAG	Triacylglycerol

Introduction

Epidemiologic studies have indicated that hypertriglyceridemia is associated with obesity, diabetes, and coronary heart disease [1–4]. Carlson et al. [2] have reported that fasting levels of plasma triacylglycerol (TAG) act as an independent risk factor for death by myocardial infarction. Additionally, a postprandial increase in serum TAG levels is also reported to be a risk marker for ischemic heart diseases [5–8]. TAG-rich lipoproteins are thought to decrease endothelial dysfunction and increase oxidative stress, contributing to the development of metabolic disorders [9, 10].

Diayclglycerol acyltransferase (DGAT) catalyzes the final step of TAG synthesis [11, 12], and thereby plays an important role as one of the key enzymes responsible for the incorporation of TAG into the body. DGAT also plays essential roles in the synthesis and secretion of very-low-density lipoprotein (VLDL) in the liver, and TAG accumulation in adipose tissue. Several studies have shown that

DGAT is a potential target to control hypertriglyceridemia or other metabolic disorders [13–16]. It has been reported that mice genetically lacking DGAT1—one of two known DGAT isozymes—showed substantially decreased levels of chylomicron-derived plasma TAG following oral fat load [13, 14]. The DGAT1-deficient mice showed resistance to obesity, and increased insulin and leptin sensitivity [15]. In addition, Liu et al. [16] have demonstrated that knockdown of DGAT2—another DGAT isozyme—using antisense oligonucleotide resulted in the reduction of VLDL-TAG and apoB secretion in mice.

So far, several natural DGAT inhibitors have been reported [17–20]. Tabata et al. [18] found that xanthohumols from *Humulus lupulus* showed DGAT inhibitory action, and TAG formation in cultured cells. Recently, Casaschi et al. [19] reported that taxifolin, a plant flavonoid, reduced DGAT activity as well as microsomal triglyceride transfer protein in HepG2 cells; however, few reports have demonstrated that DGAT inhibitors showed a beneficial effect in vivo.

On the other hand, by screening hundreds of plant extracts, we found that an extract of petals of *Rosa centifolia* showed inhibitory action against TAG synthesis in IEC-6 cells. Rose petals are rich in polyphenols and free gallic acid, and have been demonstrated to have antioxidant [21] and antibacterial activities [22], but there are no reports on the inhibition of TAG synthesis. In this study, we investigated the biological activity of rose extract, and the causative substances inhibiting TAG synthesis contained in rose petals.

Experimental Procedure

Materials

Pink rose petals (*Rosa centifolia*) were purchased from Tochimoto Tenkaido (Osaka, Japan). Epigallocatechin gallate (EGCG) was obtained from Tokyo Chemical Industry (Tokyo, Japan).

Flow Cytometry Analysis of Lipid Accumulation

The rat small intestinal epithelial cell line IEC-6 (American Type Culture Collection, Rockville, MD) was cultured in Dulbecco's modified Eagle's medium (DMEM) (Invitrogen, Paisley, UK) supplemented with 5% FBS and 100 units/mL penicillin and 100 μg/mL streptomycin (complete medium) at 37 °C in air and 5% CO_2. Cells were seeded with 1×10^5 cells/well in 6-well plates. After overnight incubation, the culture medium was changed to complete medium containing 500 μM oleic acid (Cayman Chemical, Ann Arbor, MI) complexed with 250 μM fatty acid-free BSA (Wako Chemical, Osaka, Japan) and 0.01% rose extract. After incubation for 6 h, the culture medium was removed and the remaining cells were rinsed twice with PBS and detached from plates with 0.25% trypsin and 1 mM EDTA in PBS. Cells were collected with 1 mL complete medium, precipitated by centrifugation, and suspended in PBS containing 100 ng/mL Nile Red (Acros Organics, Geel, Belgium). The suspension was then incubated at room temperature for 5 min, and analyzed by FACSCalibur (Becton-Dickinson Bioscience, San Jose, CA). Fluorescence-activated cell scan excitation was 488 nm, and emission was monitored through band-pass filters at 530 ± 15 nm (FL1) to detect the yellow-gold fluorescence of neutral lipids [23]. Effects of samples on lipid accumulation were judged by suppression of the increase of mean fluorescent intensity by incubation with 500 μM oleic acid.

Analysis of TAG Synthesis and Secretion in Cultured Cells

The hepatoma cell line HepG2 (American Type Culture Collection) was seeded with 1×10^5 cells/well in 6-well plates and cultured at 37 °C in air and 5% CO_2 in complete medium. After 3 days, the medium was changed and incubated with or without 0.01% rose extract. After 24 h, the medium was changed to serum-free medium containing 250 μM [1-^{14}C] oleic acid (3.7 MBq/mmol; PerkinElmer Life Science, Boston, MA) complexed with 125 μM fatty acid-free BSA, supplemented or not with 0.01% rose extract. After incubation for 6 h, the medium was removed and the remaining cells were rinsed twice with PBS, and lysed with 0.1M NaOH. The cell lysate was collected after neutralization by addition of 1/30 volume 3M HCl. Lipids in the cell lysate and the medium were extracted following the method of Bligh-Dyer [24]. The organic phase was dried under a stream of nitrogen at 30 °C. Radioactivity was measured using a liquid scintillation counter TriCarb 1500 (Packard Instrument, Meriden, CT). The extracted lipids were separated by TLC using a Silica gel 60 F 254 plate (Merck, Darmstadt, Germany) and hexane/diethyl ether/acetic acid (80/20/1, by vol) as the development solvent. The TLC plates were exposed to a Fuji Imaging Plate (Fuji Photo Film, Tokyo, Japan) for 2 days, and the obtained fluorograms were analyzed with a BAS2500 system (Fuji Photo Film) to quantitate the amount of radiolabeled TAG.

Fractionation of Rose Extract

Pink rose petals were extracted by soaking in 10 volumes of 50% ethanol at room temperature for 1 week. The insoluble substances were filtrated, and the obtained 50% ethanol extract was concentrated in vacuum and

resuspended in water. After liquid–liquid separation with an equal volume of hexane, the water phase was extracted by an equal volume of *n*-butanol. The resultant *n*-butanol extract was concentrated in vacuum, resuspended in 20% ethanol, and then fractionated by column chromatography using a Diaion HP-20 column (Mitsubishi Chemical, Tokyo, Japan). The column was washed and eluted with 20, 40, 60, and 99.5% ethanol. The fractions containing DGAT inhibitory substances were separated by column chromatography using a Sephadex LH-20 column (GE Healthcare, Tokyo, Japan). The column was washed and eluted with 50% methanol, 99.5% ethanol, and ethanol/acetone (1:1, by vol), and then the fractions containing DGAT inhibitory substances were separated by HPLC using an Intersil ODS-3 column (20 × 250 mm; Metachem Technologies, Torrance, CA). The column was eluted with 0.5% trifluoroacetic acid/acetonitrile (87:13, by vol) for 30 min, and then 0.5% trifluoroacetic acid/acetonitrile (1:1, by vol) for 20 min. Separated fractions were analyzed by HPLC using an Inertsil ODS-3 column (4.6 × 250 mm) under the following conditions: a 30-min gradient from 0.1% acetic acid to 100% methanol; 1.0 ml/min; 40 °C. UV spectra were obtained using a UV–VIS Detector L-7420 (Hitachi, Tokyo, Japan).

Oral Fat Load Test

C57BL/6J mice were obtained from Charles River Japan (Yokohama, Japan) at 7 weeks of age, and maintained at 23 ± 2 °C under a 12-h light–dark cycle (lights on from 7:00 a.m. to 7:00 p.m.). The mice were fed laboratory chow for 1 week to stabilize their metabolic conditions, and divided into two groups so that the average plasma TAG level and body weight could be equalized between the groups. Following an overnight fast, 40 μL/g body weight of fat emulsion with or without 1% rose extract was administered orally. The fat emulsion contained 10% (w/v) edible oil, 1% (w/v) egg yolk lecithin (Wako), and 4% (w/v) BSA. The edible oil was composed of 98.1% TAG and 1.9% diacylglycerol with the fatty acid composition of 5.5% C16:0; 2.2% C18:0; 37.2% C18:1; 46.1% C18:2; 8.0% C18:3; 0.5% C20:0; 0.3% C20:1; 0.1% C22:0; 0.1% C22:1. Blood samples were collected from mice via the tail vein at the times indicated, and the plasma was isolated. Plasma TAG and FFA concentrations were determined using enzyme assay kits: L-type Wako TG-H, NEFA-HA test Wako, (Wako), respectively. This study was approved by the Animal Care Committee of Kao Tochigi Institute.

Measurement of Enzyme Activities

The liver was homogenized on ice with 8 volumes (w/v) of 250 mM sucrose buffer containing 0.1 mM EDTA and 2 mM HEPES (pH 7.3). Subcellular fractionation was performed according to the methods described by de Duve et al. [25]. After centrifugation of the homogenate of the intestinal mucosa at 12,500 *g* for 20 min, the supernatant was centrifuged at 100,000 *g* for 60 min. The resultant precipitate was resuspended and used as a microsomal protein. Protein concentrations were determined using a Micro BCA protein assay kit (Pierce, Rockford, IL).

DGAT activity was determined according to the method described by Luan et al. [26]. Microsomal protein (50 μg) was incubated at 37 °C for 20 min in 200 μL of a reaction mixture in the presence or absence of test samples. EGCG, a major polyphenol present in green tea, which has an anti-obesity effect [27, 28], was used as a control.

The reaction mixture contained 250 mM sucrose, 10 mM Tris–HCl (pH 7.5), 10 mM $MgCl_2$, 0.8 mM EDTA, 0.1% BSA, 100 μM oleoyl-CoA (55 mCi/mmol), and 1.2 mM 1,2-diolein. Incubation was terminated by the addition of 1.5 mL chloroform/methanol (1:1, by vol). Lipids were extracted by the Folch method [29]. Radioactivity was measured using a liquid scintillation counter, TriCarb 1500. The extracted lipids were separated by TLC using a Silica gel 60 F 254 plate (Merck) and hexane/diethyl ether/acetic acid (80:20:1, by vol) as the development solvent. The TLC plates were exposed to a Fuji Imaging Plate (Fuji) for 1 or 2 days, and the obtained fluorograms were analyzed with a BAS2500 system (Fuji Photo Film). DGAT activity was calculated based on the radioactivity of the extracted lipid and the ratio of labeled TAG to labeled lipid.

In addition, acyl coenzyme A:cholesterol acyltransferase (ACAT) activity, cholesteryl ester formation from endogenous cholesterol was also calculated based on the radioactivity of the extracted lipid and the ratio of labeled cholesteryl ester.

Glucose-6-phosphatase (G6Pase) activity was measured according to the method described by Tang et al. [30]. Microsomal protein (50 μg) was incubated in reaction mixture [50 mM HEPES (pH 7.2), 100 mM KCl, 2.5 mM EDTA, 2.5 mM $MgCl_2$, 1 mM DTT, 10 mM glucose-6-phosphate, 2 mM EDTA] at 37 °C for 30 min. The reaction was stopped by the addition of 4 volumes of stop solution (6:2:1, by vol, mixture of 0.42% ammonium molybdate tetrahydrate in 1 *N* H_2SO_4, 10% SDS, and 10% ascorbic acid), and then incubated at 50 °C for 30 min. Absorbance (OD_{820}) was measured using a microplate absorbance plate reader Viento XS (DS Pharma Biomedical, Osaka, Japan). A standard curve was obtained using inorganic phosphorus solution (Wako).

3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase activity was measured according to the method described by Sumiyoshi et al. [31]. Microsomal protein (50 μg) was incubated in reaction mixture [0.128 mM

^{14}C-HMG-CoA (72 MBq/mmol), 1 mM NADPH, 10 mM DTT, 10 mM EDTA, 0.12 mM phosphate buffer (pH 7.2)] at 37 °C for 20 min. The reaction was stopped by the addition of 1/10 volume of 5 *N* HCl, and further incubated for 30 min. After the addition of 4-^{14}C-testosterone (0.08 nCi) as an internal standard, mevalonolactone generated from mevalonic acid by HMG-CoA reductase was extracted by ethyl acetate. Part of the extract was separated by TLC using benzene/acetone (1:1, by vol) as a developing solvent.

Lipase activity was measured using lipase kit S (DS Pharma Biomedical) according to the improved dimercaptopropanol tributyrate (BALB) method [32]. Two units/reaction of porcine pancreas lipase (Sigma, St. Louis, MO) were used as the enzyme source. Absorbance (OD_{412}) of the products formed by reaction of the SH groups formed from lipase cleavage of BALB with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) was measured at 412 nm using the microplate absorbance plate reader Viento XS.

NMR

^{1}H- and ^{13}C-NMR spectra were recorded on a JNM-α500 spectrometer (JEOL Ltd., Tokyo, Japan; 500 MHz for ^{1}H-NMR and 125.7 MHz for ^{13}C-NMR). Chemical shifts are given in δ (ppm), based on those of the ^{1}H and ^{13}C signals of acetone-d_6 (δ_H 2.04; δ_C 29.8).

Statistical Analysis

All values are presented as the means ± SEM. Statistical analyses between two groups were performed with an unpaired *t* test. In the analysis of enzyme inhibition by serial concentration of rose extract, ellagitannins, or EGCG, one-way analysis of variance (ANOVA) followed by Dunnett's test was performed. $P < 0.05$ was considered statistically significant.

Results

Effect of Rose Extract on TAG Accumulation in IEC-6 Cells

Firstly, screening of plant extracts that inhibit TAG accumulation was conducted against hundreds of plant extracts, using fluorescent flow cytometry analysis on IEC-6 cells cultured with oleic acid in the presence or absence of the plant extracts. As a result, we found that 50% ethanol extract of rose petals exhibited an inhibitory action against TAG accumulation as shown in Fig. 1. Incubation of IEC-6 cells with 500 μM oleic acid increased the fluorescent intensity of TAG stained by Nile Red compared with incubation without oleic acid (Fig. 1a). Mean fluorescent intensity (MFI) was significantly different between groups ($P < 0.01$); MFI was 75.8 ± 0.8 in the absence of oleic acid, whereas MFI in the presence of oleic acid was 119.3 ± 3.4. When IEC-6 cells were pre-incubated in the presence of the rose extract at final 0.01%, the FFA-induced increase of MFI was significantly suppressed ($P < 0.05$) (Fig. 1a). MFI (106.1 ± 2.9) was decreased by 30.4 ± 6.6%.

Furthermore, in the analysis of TAG synthesis and secretion using HepG2 cells, incubation in the presence of

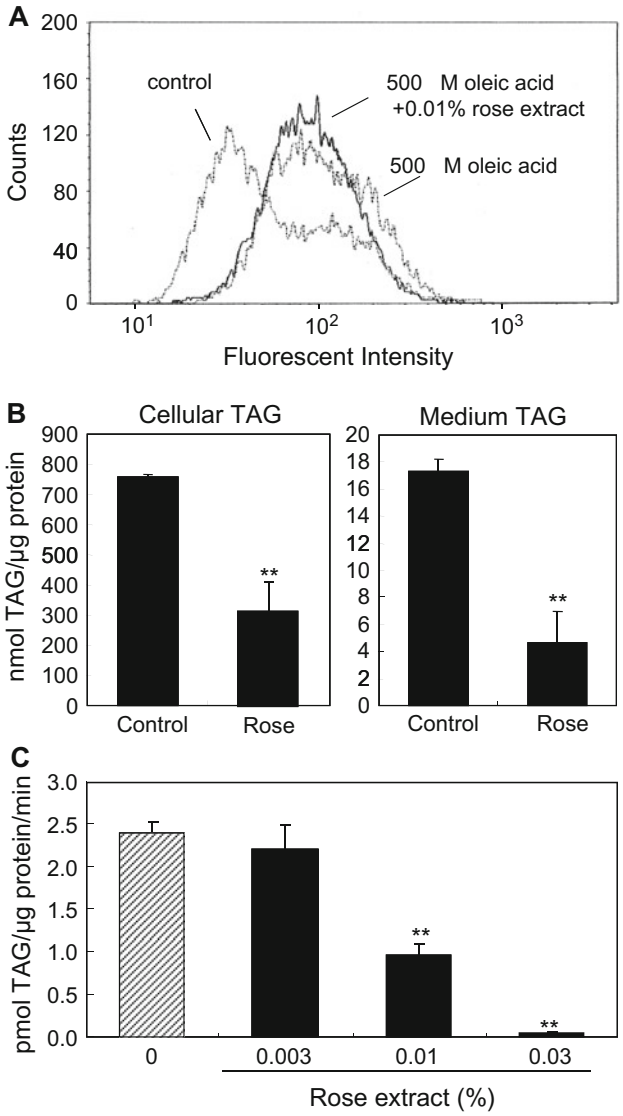

Fig. 1a–c Effect of rose extract on triacylglyceraol (TAG) synthesis and diayclglycerol acyltransferase (DGAT) activities. **a** Flow cytometric analysis of IEC-6 cells stained with Nile Red. Flow cytometric histograms show the relative fluorescence intensities of 10^4 cells. **b** Analysis of TAG synthesis and secretion in HepG2 cells. Cells were treated and analyzed as described in Materials and Methods. **c** Effect of rose extract on microsomal DGAT activities. Values are shown as the mean ± SEM ($n = 3$). $^{**}P < 0.01$

0.01% rose extract reduced cellular TAG synthesis from radio-labeled oleic acid, and TAG secretion into the medium by 58.5 ± 6.7%, and 73.4 ± 15.0%, respectively ($P < 0.01$) (Fig. 1b). These results indicate that the rose extract inhibits TAG synthesis from FFA.

In the measurement of DGAT activity using microsomal protein, the addition of rose extract to the reaction mixture reduced DGAT activity in a dose-dependent manner; microsomal DGAT activity was reduced by 60.0 ± 5.8% at a concentration of 0.01%. This result suggests that rose extract suppresses TAG synthesis via the inhibition of DGAT activity (Fig. 1c).

Fractionation of Rose Extract

First, 50% ethanol extract (solid content: 260 g) obtained from 600 g pink rose petals was extracted by hexane/water partition, and then the water phase was extracted by *n*-butanol (liquid–liquid partition; Fig. 2a). Next, the *n*-butanol extract was fractionated using a Diaion HP-20 column. Fractions containing DGAT inhibitory substances were determined by measurement of DGAT activity using microsomal protein in the presence of one of the fractions supplemented at the original weight ratio in the rose extract. Measurement of DGAT activity revealed that most of the DGAT inhibitory substances were eluted by 20% ethanol. In subsequent fractionation using a Sephadex LH-20 column of the 20% ethanol fraction, DGAT inhibition was found in the ethanol elution fraction (fraction RO-Bu-a5) and acetone/ethanol elution fraction (fraction RO-Bu-a6).

In further separation of part of the fraction RO-Bu-a5 by reversed phase HPLC, two fractions (RO-Bu-a5A and -a5B) showed DGAT inhibition (Fig. 2b). NMR analysis of fraction RO-Bu-a5A, which was composed of a single component (>99% pure), revealed that the chemical shift was coincident with the actual measurement value and the reported value of an ellagitannin, tellimagrandin I [33]. In addition, further separation by HPLC and NMR analysis of fraction RO-Bu-a5B revealed that the fractions contained tellimagrandin I (RO-Bu-a5B1) and another ellagitannin (RO-Bu-a5B2); the chemical shift of the latter (>99% pure) was coincident with the reported value of rugosin B [34, 35]. Fraction RO-Bu-a5B3 was a mixture of tellimagrandin I and rugosin B, which were likely separated as anomers of the ellagitannins.

On the other hand, further separation of part of fraction RO-Bu-a6 by HPLC revealed that the fraction was composed of at least three >99% pure components (Fig. 2c). Structure determination by NMR of the components isolated in fractions RO-Bu-a6D, -a6E, and -a6F revealed that their chemical shifts were coincident with the values of rugosin A [34, 35], rugosin D [36, 37], and eusupinin A

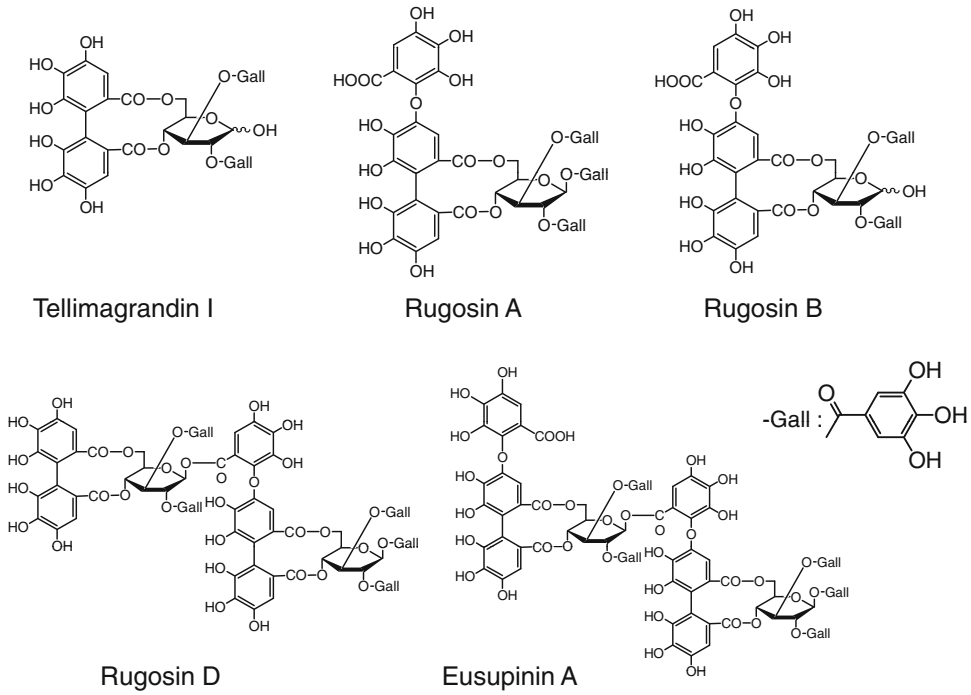

Fig. 3 Chemical structure of DGAT inhibitory ellagitannins identified from rose petals

[38], respectively. The chemical structures of these ellagitannins isolated from rose petals are shown in Fig. 3.

Effects of Rose Ellagitannins on Enzyme Activities

The ellagitannins isolated from rose petals inhibited DGAT activity in a dose-dependent manner (Fig. 4a). In particular, rugosin B, rugosin D, and eusupinin A strongly inhibited activity; these ellagitannins inhibited activity by 96, 82, and 84%, respectively, at 10 μM. Ellagic acid, a constituent of ellagitanin, did not affect activity even when used at 20 and 60 μM (data not shown). EGCG, a major polyphenol present in green tea, also did not affect DGAT activity (Fig. 4a).

In order to examine the selectivity of the enzyme-inhibitory action of ellagitannins, their effects on other hepatic microsomal enzymes were investigated. Since, in measurement of DGAT activity, substantial amount of label added as ^{14}C oleoyl-CoA was incorporated into cholesteryl ester (10.4 ± 1.0% of labeled lipid) as well as TAG (27.1 ± 0.9% of labeled lipid), the effect of rose ellagitannins on formation of cholesteryl ester (i.e., ACAT activity) was also evaluated. While the ellagitannins showed substantial inhibition of ACAT activity, the degree of inhibition of ACAT activity by ellagitannins was less than that of DGAT activity.

On the other hand, none of the five ellagitannins isolated from rose petals inhibited G6Pase activity (Fig. 4c). These ellagitannins had little effect on HMG-CoA reductase activity at 5 and 10 μM, although rugosin B, rugosin D, and eusupinin A significantly suppressed activity at 20 μM (Fig. 4d); however, the degree of inhibition of HMG-CoA reductase activity by ellagitannins was also less than that of DGAT activity.

In addition, the inhibitory action of ellagitannins against a pancreatic lipase, a major lipid degradation enzyme, was examined. As a result, the five rose ellagitannins had little effect on lipase activity at 5–20 μM, whereas EGCG inhibited lipase activity by more than 20% at 20 μM (Fig. 4e). Thus, the rose ellagitannins showed preferable DGAT inhibitory action.

Reduction by Rose Extract of Postprandial Increase in Plasma TAG

An oral fat load causes an increase in plasma TAG levels with a peak at 2 h. Administration of a fat emulsion containing 1% rose extract resulted in suppression of the postprandial plasma TAG increase (Fig. 5a); TAG levels 2 h after loading were significantly lower than in mice administered the fat emulsion without rose extract (446.3 ± 33.1 vs 345.3 ± 25.0 mg/dL, control vs rose extract group; $P < 0.05$). The total area under the curve (AUC) for the plasma TAG increase was also significantly reduced in mice administered rose extract (Fig. 5b; $P < 0.05$). In addition, plasma FFA levels of mice administered the fat emulsion containing rose extract showed a reducing trend compared with those given emulsion without the extract (Fig. 5c,d).

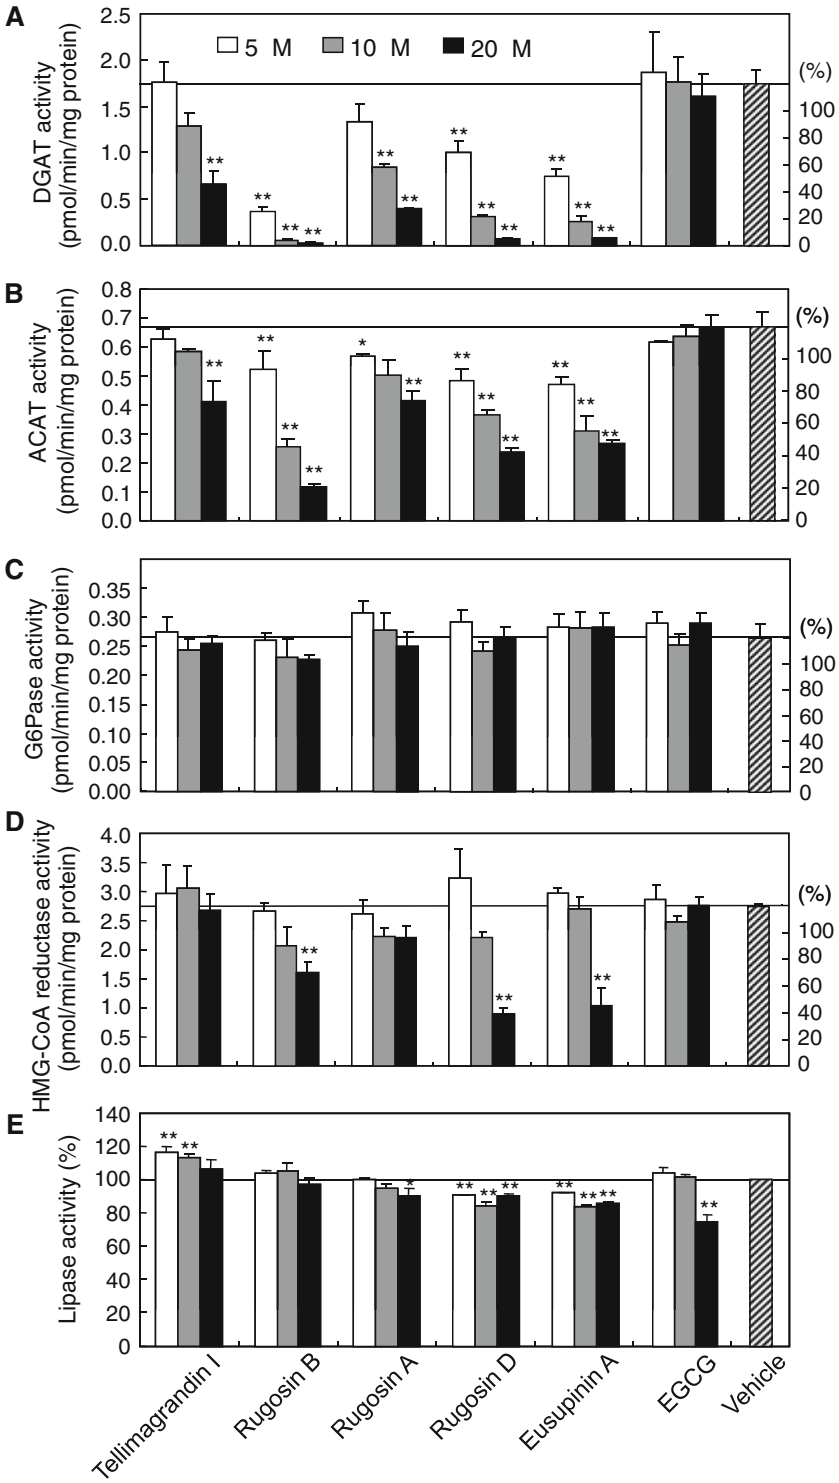

Fig. 4a–e Effect of rose ellagitannins on hepatic microsomal enzyme and lipase activities. **a** DGAT, **b** acyl coenzyme A:cholesterol acyltransferase (ACAT), **c** glucose-6-phosphatase (G6Pase), and **d** 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase activities in the hepatic microsomal fraction, and **e** pancreatic lipase activity were measured in the presence of rose ellagitannins or rose extract, as described in Materials and Methods. Discussion

In this study, we found that ellagitannins present in rose petals, i.e., tellimagrandin I, rugosins A, B, and D, and eusupinin A, showed DGAT inhibitory action. Several studies have demonstrated that ellagitannins have diverse biological activities [39–43]; rugosin D and tellimagrandin II show antibacterial activities against intestinal bacteria [39]; several ellagitannins, including rugosin A, have anti-tumor activity and induce interleukin-1 [40]; however, no report has demonstrated that ellagitannins have DGAT inhibitory actions. This study therefore revealed a novel

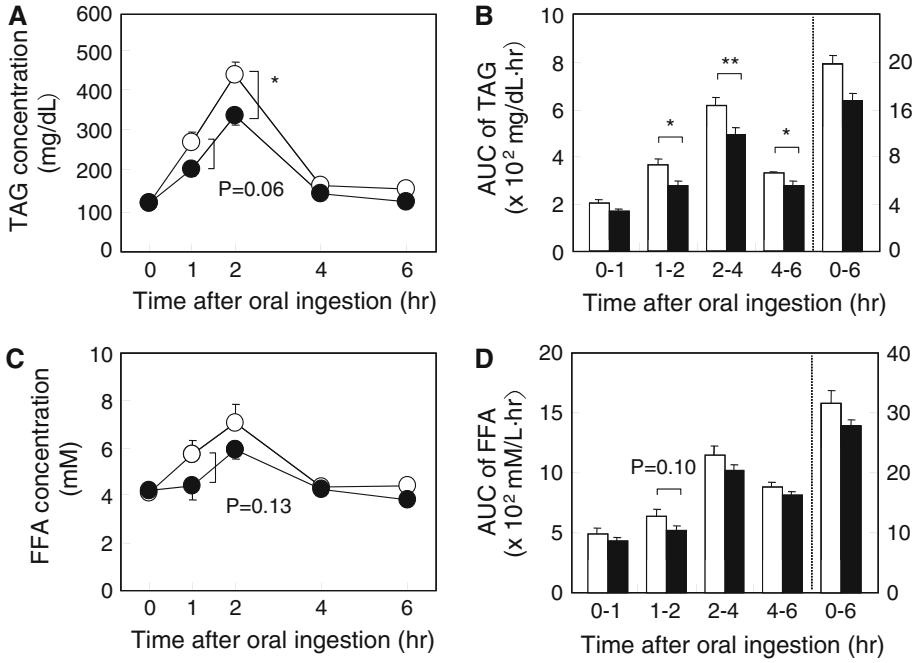

Fig. 5a–d Effect of rose extract on plasma TAG and free fatty acid (FFA) increase in mice after oral fat loading. **a** At 8 weeks of age, C57BL/6J mice were administered orally fat emulsions with or without 1% rose extract. feature of rose ellagitannins; DGAT inhibitory action was not observed in EGCG, a major polyphenol present in green tea, which has an anti-obesity effect [28, 44].

So far, several DGAT inhibitory substances derived from plants and fungi have been reported [17–20]. Quinolone alkaloids isolated from the fruits of *Evodia rutaecarpa* have been demonstrated to inhibit DGAT activity with IC_{50} values of 13–70 μM [45]. Prenylflavonoids isolated from the roots of *Sophora flavescens* have been reported to inhibit DGAT activity with IC_{50} values of 9–250 μM [46]. Ganji et al. have shown that niacin, widely distributed among plants and animals and used as a lipid-regulating agent in dyslipidemic patients, inhibited DGAT activity with IC_{50} values of 0.1 mM [47]. In this study, ellagitannins inhibited DGAT activity with comparable or somewhat higher efficiency than these naturally occurring DGAT inhibitory compounds; IC_{50} of rugosin B and eusupinin A was less than 5 μM.

Rugosin D and eusupinin A, which inhibit DGAT more than rugosin A, are dimeric hydrolyzable tannins, including the rugosin A moiety. Rugosin B, which showed the highest DGAT inhibitory activity among the examined ellagitannin, differ from rugosin A by the presence of the galloyl group at the anomeric position in the former. Further detailed analysis using ellagitannin derivatives, however, are needed to clarify the relation between the DGAT inhibitory action and the structures of ellagitannins.

In this study, we demonstrated that rose ellagitannins inhibit DGAT activity preferentially. The ellagitannins had little effect on hepatic enzymes (i.e., G6Pase and HMG-CoA reductase) or pancreatic lipase. So far, it has been reported that tea catechins with a galloyl moiety, which showed lipase inhibitory action at much higher concentration (1–2 mM), suppressed postprandial hypertriglyceridemia, suggesting the hypolipidemica action of tea catechins through lipase inhibition [48]; however, since the ellagitannis intensely inhibited DGAT activity at concentrations that had little effect on lipase activity, it is plausible that the hypolipidemic action of rose extract could be attributed to the DGAT inhibitory action of ellagitannins.

The structures of these ellagitannins possess at least a superficial similarity to the structures of the phorbol esters, which have been demonstrated to activate protein kinase C via interaction with the binding domain common to diacylglycerol, an obligatory substrate of DGAT [49]. This suggests that ellagitannins inhibit DGAT activity through the competitive interaction with a binding domain common to diacylglycerol. In addition, it is also possible that rose extract and rose ellagitannins affect the expression of DGAT. So far, it has been demonstrated that expression of DGAT is regulated not only transcriptionally but also post-transcriptionally; the expression of DGAT1 is reportedly regulated mainly at the translational level [50]. In all cases, the detailed mechanisms of the inhibitory action of rose extract and rose ellagitannins should be clarified by future intensive studies.

It is well known that DGAT plays an important role in the synthesis of TAG in the small intestine [51]. Dietary TAG is hydrolyzed to 2-monoacylglycerol and FFA in the intestinal lumen. Most of the digestive products are absorbed by the intestinal mucosa and re-synthesized into TAG by monoacylglycerol acyltransferase (MGAT) and

DGAT. Subsequently, the re-synthesized TAG is assembled into chylomicron and released into the bloodstream; therefore, it is assumed that inhibition of DGAT activities in the small intestine results in a reduction of the rate of TAG synthesis and secretion in the intestine. Consistent with this assumption, in this study, we found that the extract of rose petals suppressed the postprandial increase of plasma TAG levels.

It has been demonstrated that elevations of serum FFA cause insulin resistance [52, 53]. Since most of the FFA generated from chylomicron TAG has been shown to mix in the same metabolic compartments as does plasma FFA [54], it is likely that the reduction in plasma TAG mass after fat loading results in FFA reduction. In this study, however, the administration of rose extract did not significantly affect the plasma FFA increase after fat loading, regardless of the suppression of plasma TAG increase by the administration of rose extract. It is likely that the efficient utilization of FFA by peripheral tissues, such as skeletal muscles after fat loading [55], reduced the difference in FFA levels in normal mice.

In conclusion, we demonstrated that ellagitannins isolated from rose petals have DGAT inhibitory action, and that rose extract rich in ellagitannins reduced postprandial increase of the plasma TAG level. These results suggest that rose ellagitannins or rose extract can be beneficial in controlling lipid metabolism and could be used to improve metabolic disorders.

ORIGINAL ARTICLE

Glycosidic Bond Cleavage is Not Required for Phytosteryl Glycoside-Induced Reduction of Cholesterol Absorption in Mice

Xiaobo Lin · Lina Ma · Robert A. Moreau · Richard E. Ostlund Jr.

Received: 11 February 2011 / Accepted: 15 April 2011 / Published online: 3 May 2011

Abstract Phytosteryl glycosides occur in natural foods but little is known about their metabolism and bioactivity. Purified acylated steryl glycosides (ASG) were compared with phytosteryl esters (PSE) in mice. Animals on a phytosterol-free diet received ASG or PSE by gavage in purified soybean oil along with tracers cholesterol-d_7 and sitostanol-d_4. In a three-day fecal recovery study, ASG reduced cholesterol absorption efficiency by $45 \pm 6\%$ compared with $40 \pm 6\%$ observed with PSE. Four hours after gavage, plasma and liver cholesterol-d_7 levels were reduced 86% or more when ASG was present. Liver total phytosterols were unchanged after ASG administration but were significantly increased after PSE. After ASG treatment both ASG and deacylated steryl glycosides (SG) were found in the gut mucosa and lumen. ASG was quantitatively recovered from stool samples as SG. These results demonstrate that ASG reduces cholesterol absorption in mice as efficiently as PSE while having little systemic absorption itself. Cleavage of the glycosidic linkage is not required for biological activity of ASG. Phytosteryl glycosides should be included in measurements of bioactive phytosterols.

Introduction

Phytosterols are structurally similar to cholesterol, occur naturally in plant-derived foods, and reduce cholesterol absorption [1–4] and plasma LDL-cholesterol [5, 6]. Because of these potentially beneficial health effects, the US National Cholesterol Education Program Adult Treatment Panel III has recommended adding 2.0 g/day phytosterols to the diet of adults to reduce LDL-cholesterol and coronary heart disease risk [7, 8].

To reach the 2.0 g/day of phytosterols, pure phytosterols (free or esters) have been routinely added to various functional foods. The chemical or physical form of the phytosterol is potentially important for bioactivity because crystalline phytosterols are not readily soluble in bile and do not reduce cholesterol absorption [9]. When properly formulated with lecithin or other emulsifiers, free phytosterols do reduce cholesterol absorption and plasma LDL cholesterol [10]. Phytosteryl esters solubilized in the triglyceride phase of margarines are also bioactive [11, 12].

Phytosterols are conjugated to various components in food matrices and not all have been tested for bioactivity [13]. Recently, we have demonstrated that pure phytosteryl esters supplemented at an amount achievable from a diet (459 mg phytosterols/day) reduce cholesterol absorption and increase fecal cholesterol excretion in humans [14].

Furthermore, phytosterols present in natural food matrices (449 mg/day) are also bioactive in reducing cholesterol absorption and enhancing fecal cholesterol excretion [15]. Because phytosteryl glycosides comprise a significant proportion of naturally occurring phytosterols in some foods [16–18], we have studied them and demonstrated that phytosteryl glycosides (mostly acylated steryl glycosides, ASG) purified from soybean-derived lecithin reduce cholesterol absorption efficiency in humans [19]. However, several questions remain unanswered regarding their mechanisms of action. Phytosteryl glycosides could act intact, as glycosides (with the fatty acid cleaved), or as free phytosterols (with both fatty acid and glucose cleaved).

ASG consist of a fatty acid and a glucose moiety in addition to the phytosterol [19]. Previous work has shown that fatty acids are cleaved from glycosylated phytosterols in vitro by pancreatin and cholesterol esterase but the sugar moiety itself is not removed [20]. Acetylated ^{14}C-sitosteryl glucoside was not absorbed in the stomach or small bowel of rats after intragastric administration [21]. However, the ^{14}C label was located in the phytosterol moiety, which did not enable the authors to answer whether or not any cleavage had occurred in vivo.

In this study we prepared purified ASG and tested the hypotheses that ASG is active in reducing cholesterol absorption efficiency in mice and that it is cleaved to SG or free phytosterols in mice consuming a cholesterol and phytosterol-free diet.

Materials and Methods

Materials

[25,26,26,26,27,27,27-$^{2}H_7$]Cholesterol (cholesterol-d_7) was purchased from CDN Isotopes (Pointe-Claire, QC, Canada). Soybean oil (Bakers & Chefs, Sam's Club) was purified as described elsewhere [3] to reduce the content of phytosterols. [5,6,22,23-$^{2}H_4$]sitostanol (sitostanol-d_4) was obtained from Medical Isotopes (Pelham, NH, USA). The phytosteryl glycosides were partially purified from lecithin granules (Vitamin Shoppe, North Bergen, NJ, USA) as previously described [19]. Crude phytosteryl glycosides were then dissolved in hexane and applied to a Supelclean LC-Si SPE column (Sigma, St Louis, MO, USA) that had been conditioned with hexane. The column was eluted with 30% ethyl acetate in hexane, followed by 50% ethyl acetate in hexane. The material in the second elution was ASG without free phytosterols, phytosteryl esters, or phospholipids. ASG contained 48.5% phytosterols by weight. Phytosteryl esters (PSE) were derived from soy and 60.6% of the mass was the phytosteryl moiety. ASG and SG for HPLC standards were obtained from Matreya (Pleasant Gap, PA, USA).

Mice

Male C57BL/6J mice (5 weeks old) were purchased from Jackson Laboratory (Bar Harbor, ME, USA). Mice were housed in a room maintained at 24°C with a 12:12 h light–dark cycle (6:00 a.m.–6:00 p.m.). All mice were fed first on Purina mouse chow 5053 containing 4.5% fat, 20.0% protein, and 54.8% carbohydrate (LabDiet) for one week before switching to the sterol-free diet. All animal procedures were performed in accordance with guidelines of Washington University's Animal Studies Committee and approved by the Institutional Animal Care and Use Committee of Washington University (study protocol: 20070024).

Effect of a Single-Dose ASG/PSE on Cholesterol Absorption Over a Three-Day Period

Mice (5 each for control, PSE, or ASG) were fed a special cholesterol and phytosterol-free diet [22] for two weeks to minimize the effects of dietary sterols. Each mouse was gavaged with 0.5 mL purified soybean oil containing 40 μg cholesterol-d_7 and 10 μg sitostanol-d_4. The oil also contained 1.0 mg phytosterols delivered as either phytosteryl esters or glycosides or no addition (control). Stool samples from each mouse was collected individually in a cage with wire floor for three days. Mice were approximately eight weeks old at the time of experimentation.

Single-Time-Point Oral Study

Male C57BL/6J mice were equilibrated on the sterol-free diet and then fasted for 2 h before gavage of 0.5 mL purified soybean oil with 40 μg cholesterol-d_7 containing 6.1 mg phytosterols given as either phytosteryl esters (PSE, $n = 5$) or phytosteryl glycosides (ASG, $n = 5$), or oil only (control, $n = 5$). Mice were sacrificed 4 h after gavage. Blood was obtained by heart puncture and centrifuged at 8,000 rpm for 5 min to obtain serum. The liver and small intestine were removed and the small intestine was divided into four equal segments, lumenal contents were washed out and collected with ice-cold PBS. After the small bowel was opened longitudinally, the mucosa was extruded from the bowel wall by exerting pressure using a microscopic slide.

Gas Chromatography–Mass Spectrometry (GC–MS)

For the cholesterol absorption study, lipids were extracted from stool samples by the Bligh and Dyer method [23], hydrolyzed in alkali, and the neutral sterols were extracted

into petroleum ether, dried, and converted to pentafluorobenzoyl esters [24]. The derivatized material was analyzed for cholesterol-d_7, coprostanol-d_7, and sitostanol-d_4 by negative-ion chemical ionization gas chromatography–mass spectrometry (GC–MS) [14]. For the single-time-point oral study, 40 μg sitostanol-d_4 was added as an internal recovery standard and lipids were extracted [23] from liver, lumen washings, and mucosa; aliquots of extracted lipids were processed by both acid and alkaline hydrolysis as described elsewhere [25] and analyzed by GC–MS [26]. Plasma was analyzed as described for liver, lumen washings, and mucosa without undergoing lipid extraction. Acid hydrolysis liberates free phytosterols from ASG and SG whereas alkaline hydrolysis does not.

ASG/SG Analysis

The ASG/SG contents of lumenal and mucosal samples and stool samples were analyzed by HPLC with an evaporative light scattering detector, exactly as described elsewhere [27]. A standard curve using ASG and SG standards was constructed and used to calculate the amount of ASG and SG in the samples.

Statistical Analysis

Data are reported as means ± SEM. All statistical analyses were performed with SAS (version 9.2; Cary, NC, USA). The Proc Mixed procedure was used to analyze treatment effects on cholesterol absorption and cholesterol-d_7 levels in liver and plasma with Tukey adjustment for multiple comparisons. Proc Mixed was also used to analyze the independent effect of treatments and quarters and their interactions. Statistical significance was accepted if $P < 0.05$, or otherwise as indicated.

Results

Purity of Phytosteryl Glycosides

Phytosteryl glycosides were obtained from lecithin granules by removing most of the phospholipids and neutral sterols [19]. To further increase purity the material was passed through a Supelclean LC-Si SPE column. Thin layer chromatographic analysis showed no detectable sterols or phospholipids (data not shown). The purified phytosteryl glycosides contained mostly ASG (92.5%) and a smaller fraction of SG (7.5%) by HPLC. Campesterol, stigmasterol, and sitosterol accounted for 27.3 ± 0.5, 21.4 ± 0.2, and 51.6 ± 0.8% of total phytosterols, respectively, for the phytosteryl esters; corresponding values for the phytosteryl glycosides were 21.3 ± 0.8, 17.5 ± 0.5, and 53.9 ± 1.2%.

Effect of ASG on Percent Cholesterol Absorption in Mice

To determine whether phytosteryl glycosides were bioactive in reducing cholesterol absorption efficiency [19], we gavaged mice with ASG (1.0 mg phytosterols) solubilized in purified soybean oil. PSE (1.0 mg phytosterols) was administered in the same way as an experimental positive control and purified soybean oil alone was given to another group as a negative control. As expected, relative to control, PSE reduced cholesterol absorption by 40 ± 6% in a three-day fecal recovery experiment (Fig. 1). ASG reduced cholesterol absorption by 45 ± 6% when compared with control. The difference between ASG and PSE treatment groups was not statistically significant.

Single-Time-Point Oral Study

To explore the site where ASG reduced cholesterol absorption efficiency, groups of mice were gavaged with soybean oil containing ASG (6.1 mg phytosterols), PSE (6.1 mg phytosterols), or no addition and sacrificed 4 h later. Figures 2 and 3 report the levels of phytosterols, ASG, and SG found in the gut, lumen, and mucosa by quarter of small intestine. When no phytosterols were included in the gavage the measured phytosterol levels were very low, demonstrating the effectiveness of the prior two-week low-phytosterol baseline diet in reducing background. When either ASG or PSE was given, the total phytosterols found in the lumen (which included those

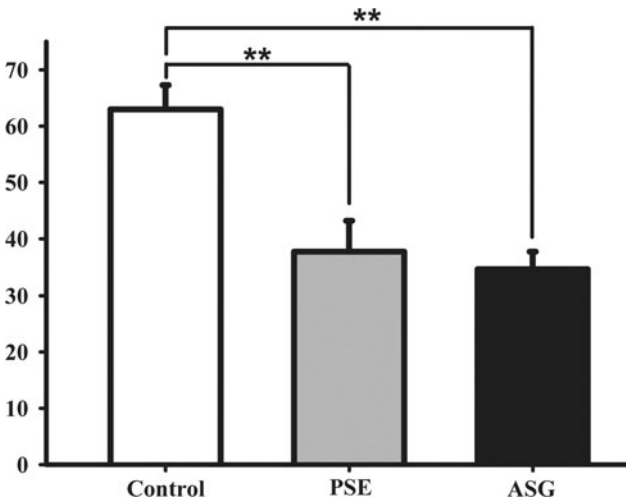

Fig. 1 Three-day study: effect of ASG on percent cholesterol absorption in mice. Mice were gavaged with purified soybean oil containing ASG (1.0 mg phytosterols), PSE (1.0 mg phytosterols), or no addition ($n = 5$ for each group). Percent cholesterol absorption was determined as described in "Materials and Methods". *Bars* represent means ± SE. Significance of differences between treatments is indicated by **($P < 0.01$)

present in the form of ASG and SG) were elevated and there was a significant treatment effect on total lumenal phytosterols ($P = 0.0088$, Fig. 2a). There was no significant relation of intestinal quarter to lumenal phytosterols ($P = 0.54$). Figure 2b shows that phytosterols accumulated in the mucosa after both ASG and PSE gavage. Total phytosterol content was largest in quarters 3 and 4 and was similar for the two phytosterol forms. There were statistically significant and independent effects of quarter ($P = 0.012$) and treatment ($P = 0.0039$) on total mucosal phytosterols.

Further studies were performed to determine the chemical form of phytosterols present in lumen and mucosa after ASG treatment. Differential hydrolysis strongly suggested that they were present as glycosides. While combined acid + alkaline hydrolysis enables total phytosterols to be measured, alkaline hydrolysis alone does not liberate free phytosterols from glycosides to be measured by GC–MS. Phytosterols from lumen and mucosa after ASG treatment determined after alkaline-only hydrolysis were very low and similar to those in the control group (data not shown), suggesting that the total phytosterols reported in Fig. 2 after ASG treatment were derived from glycosylated phytosterols. This was confirmed by direct HPLC measurement of ASG and SG in intestinal fractions (Fig. 3; Table 1). As expected, after PSE or control gavage there was no detectable ASG or SG in the lumen or mucosa. However, after ASG gavage both ASG and SG were present in lumen and mucosa. The amount of SG exceeded that of ASG in all quarters, showing active but incomplete hydrolysis of the fatty acid of ASG to yield the deacylated product SG. In other experiments in which stools were collected for three days and analyzed by HPLC, the biological hydrolysis of ASG to SG was complete (Table 1). Recovery of SG in stool samples was 95.3 ± 1.9% of the ASG given. No detectable SG was found in stool samples from control or PSE groups.

ASG administration was associated with less systemic absorption of total phytosterols than PSE (Fig. 4). Four hours after gavage, total liver phytosterols were increased 34.0 ± 8.5% (SEM) over control with PSE but only 2.7 ± 4.7% with ASG. Plasma phytosterol levels did not change significantly with either treatment.

ASG had a large inhibitory effect on absorption of cholesterol-d_7 into plasma and liver at 4 h (Fig. 5). Compared with control, ASG reduced plasma cholesterol-d_7 by 90 ± 3.7% (SEM) and liver cholesterol-d_7 by 86.2 ± 3.8%. Reductions by PSE of 51.4 ± 19.4% in plasma and 45.9 ± 25.7% in liver were more variable and not statistically significant.

Discussion

Extensive research has demonstrated that pure phytosterols, when properly formulated, reduce cholesterol absorption efficiency and plasma LDL cholesterol in animals and in humans. On the other hand, there is little published research on the physiological effects of phytosteryl glycosides. Recently we have demonstrated that ASG reduced cholesterol absorption efficiency in humans [19]. In the current study, ASG obtained from soybean-derived lecithin, was further purified and used to determine effects on cholesterol absorption and on uptake and cleavage of ASG

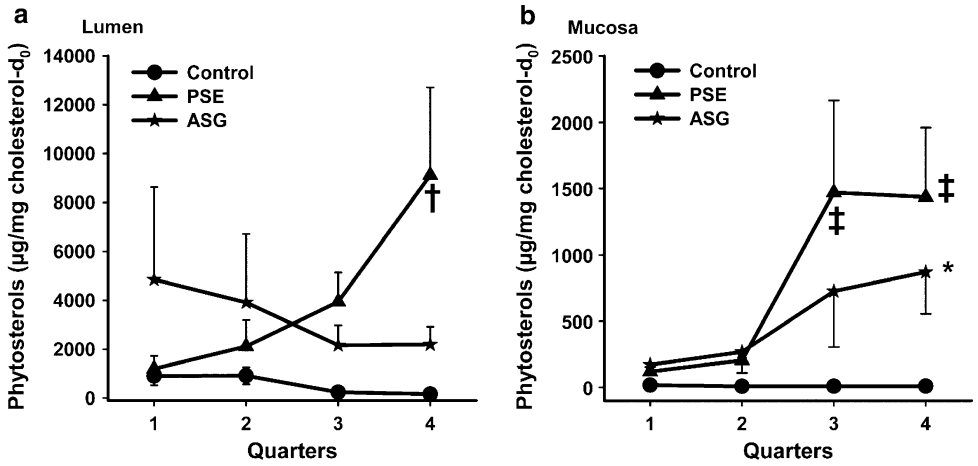

Fig. 2 Single-time-point study: total phytosterols in lumen (panel **a**) and mucosa (**b**). Mice ($n = 5$ for each group) were fasted for 2 h before gavage of purified soybean oil with cholesterol-d_7 containing ASG (6.1 mg phytosterols), PSE (6.1 mg phytosterols), or no addition. Mice were sacrificed 4 h later, the small intestine was cut into four equal quarters (quarter 1: proximal, quarter 4: distal), and mucosa was scraped after removal of lumenal contents. Levels of total phytosterols relative to natural cholesterol in the lumen and mucosa were determined by GC–MS as described in "Materials and Methods". Values are means ± SE. Statistical significance is indicated by $^{\dagger}(P < 0.05)$ or $^{\ddagger}(P < 0.01)$ (between control and PSE) and by $^{*}(P < 0.05)$ (between control and ASG)

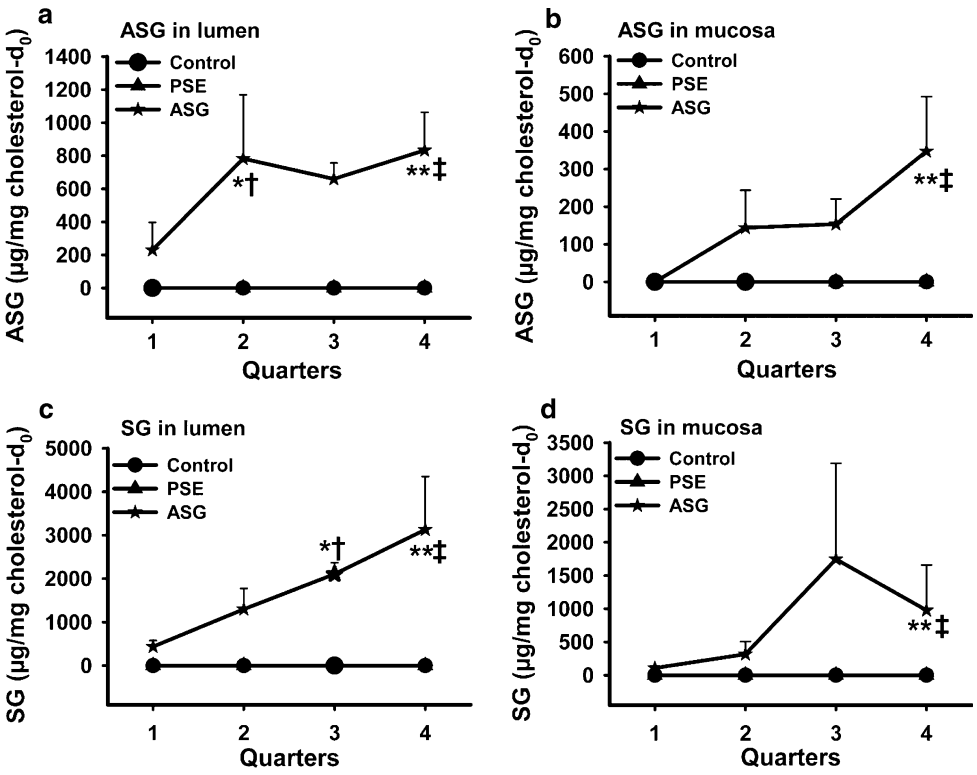

Fig. 3 Single-time-point study: ASG and SG in lumen and mucosa. Mice ($n = 5$ for each group) were fasted for 2 h before gavage of purified soybean oil with cholesterol-d_7 containing ASG (6.1 mg phytosterols), PSE (6.1 mg phytosterols), or no addition. Mice were sacrificed 4 h later, the small intestine was cut into four equal quarters (quarter 1: proximal, quarter 4: distal), and mucosa was scraped after removal of lumenal contents. The levels of directly measured ASG and SG relative to natural cholesterol in lumen and mucosa were determined as described in "Materials and Methods". Values are means ± SE. Significance is indicated by *($P < 0.05$) or **($P < 0.01$) (between control and ASG) and by †($P < 0.05$) or ‡($P < 0.01$) (between PSE and ASG). Symbols for control and PSE overlap near zero

Table 1 Phytosterol recovery in the form of steryl glycosides from stool samples three days after gavage

	Control ($n = 5$)	PSE ($n = 5$)	ASG ($n = 5$)

Phytosterols contained in SG (μg)	ND	ND	810.8 ± 11.7
Recovery rate in the form of SG (%)	NA	NA	95.3 ± 1.9

C57BL/6J male mice (nine weeks old) were gavaged with 0.5 mL soybean oil alone (control, $n = 5$), 0.5 mL soybean oil with phytosteryl esters (PSE, $n = 5$) containing 1.0 mg phytosterols, and 0.5 mL soybean oil with phytosteryl glycosides (ASG, $n = 5$) with 1.0 mg phytosterol equivalents. SG was determined as described in "Materials and Methods"

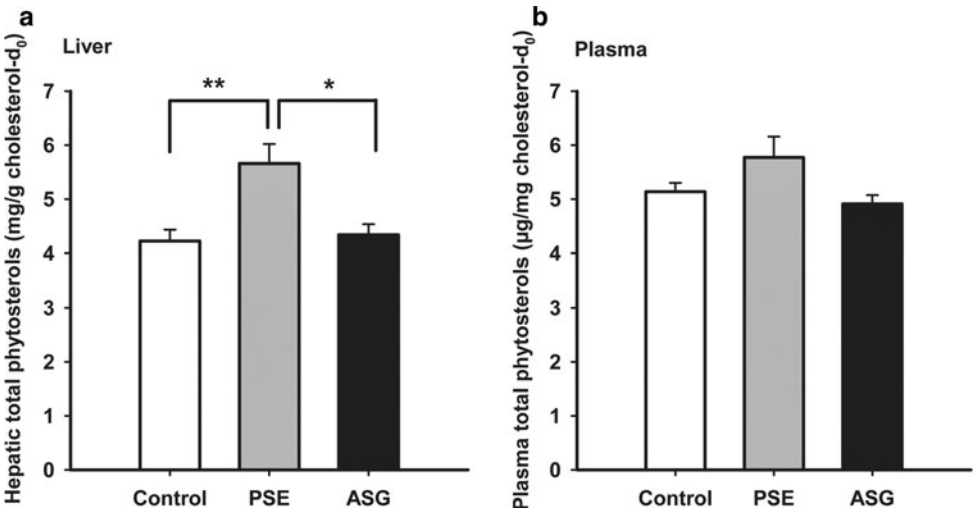

Fig. 4 Single-time-point study: total phytosterols in liver (**a**) and plasma (**b**). Mice ($n = 5$ for each group) were fasted for 2 h before gavage of purified soybean oil with cholesterol-d_7 containing ASG (6.1 mg phytosterols), PSE (6.1 mg phytosterols), or no addition and were sacrificed 4 h later. Levels of total phytosterols in liver and plasma expressed relative to natural cholesterol were determined as described in the "Materials and Methods". Values are means ± SE. Significance is indicated by *($P < 0.05$) or **($P < 0.01$)

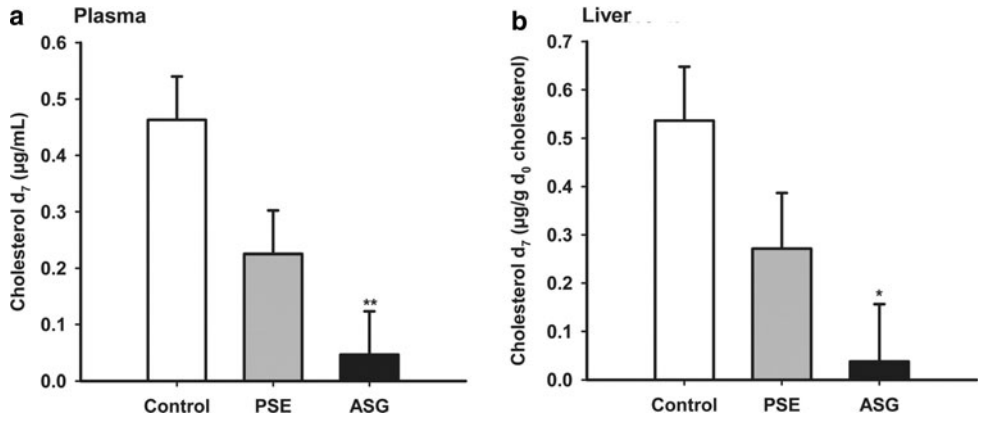

Fig. 5 Single-time-point study: cholesterol-d_7 in plasma (**a**) and liver (**b**). Mice ($n = 5$ for each group) were fasted for 2 h before gavage of purified soybean oil with cholesterol-d_7 containing ASG (6.1 mg phytosterols), PSE (6.1 mg phytosterols), or no addition. Mice were sacrificed 4 h later and levels of cholesterol d_7 in plasma and liver were determined as described in "Materials and Methods". Values are means ± SEM. Significance is indicated by **($P < 0.01$)

in mouse intestine. Consistently, ASG reduced cholesterol absorption in vivo in mice, as observed in humans. ASG seemed to act locally in the gut lumen and mucosa with very little absorption into the systemic circulation. Furthermore, cleavage of glycosidic bonds was not required for biological activity of ASG. Most of the fatty acid moieties of ASG were removed, converting them to SG whereas the glycosidic bond remained intact.

Consistent with the known reduction in cholesterol absorption in humans, ASG reduced cholesterol absorption by 45% as determined by a three-day procedure when compared with the negative control (Fig. 1), indicating that ASG was bioactive in mice. PSE, the experimental positive control, reduced cholesterol absorption by 40% (Fig. 1). In a shorter time frame of 4 h, cholesterol d_7, gavaged together with ASG in purified soybean oil, was subsequently found to be significantly reduced in liver and plasma compared with control (Fig. 5). These results show that ASG acts rapidly to reduce both the rate of cholesterol transport and the overall extent of cholesterol absorption.

Because standard rodent chow diets are rich in phytosterols, we used a novel cholesterol and phytosterol-free diet to enable better assessment of phytosterol absorption. Total phytosterols in the liver of mice given PSE were significantly higher than in those of control or ASG mice (Fig. 4a). In contrast, total phytosterols in the liver or plasma of mice gavaged with ASG were similar to those of the control (Fig. 4a, b), indicating that ASG was not absorbed into the systemic circulation. Our finding agrees with results from a study in which [4-^{14}C]sitosteryl β-D-glucoside administered intragastrically to rats was not found after 3 h in liver, kidney, heart, lungs, spleen, muscle, brain, adipose tissue, or blood [21]. The same study fed unlabeled sitosteryl β-D-glucoside at 0.5 g/kg body weight to rats for four weeks and neither sitosteryl β-D-glucoside nor sitosterol or sitosteryl esters were found in significant amounts in tissues outside the alimentary canal during the entire feeding period. It is therefore unlikely that ASG enters the systemic circulation.

ASG seemed to act locally in the lumen or in the mucosa or both. After PSE treatment total phytosterols seemed to accumulate in the lumen across the quarters (Fig. 2a), consistent with the established mechanism of action of interfering with micellar cholesterol formation in the lumen. Total phytosterols in the mucosa from the PSE group increased rapidly from the second quarter onward, indicating uptake of phytosterols into mucosa and possible action of phytosterols inside the mucosa (Fig. 2b), albeit present at a much lower level compared with lumenal total phytosterols. After ASG treatment, total phytosterols in the mucosa increased from the second quarter onward (Fig. 2), similar to the pattern with PSE. Direct HPLC measurement confirmed that the accumulated phytosterols were in the form of ASG and SG (Fig. 3).

Our results strongly suggest that the bioactive components reducing cholesterol absorption are ASG or SG, but not the free phytosterols. Most of the phytosterol glycosides (92.5%) administered were in the form of ASG. Yet both ASG and SG were abundant in the lumen and mucosa in 4 h, indicating that ASG was hydrolyzed to SG in these locations. Consistent with the previous report that ASG was cleaved to SG in vitro by pancreatin and cholesterol esterase [20], most of the ASG was recovered as SG in stool samples three days after gavage, indicating that cleavage of ASG to SG was complete in three days. The complete recovery of ASG as fecal SG also indicates that SG were not hydrolyzed to free phytosterols. Furthermore, total phytosterol levels in the liver or plasma were similar to the respective levels in the control. This also is in agreement with the finding that only a small fraction of

[4-^{14}C]sitosteryl β-D-glucoside (<0.5%) was detected in the form of sitosterol and sitosteryl esters in the duodenum, jejunum, ileum, and stomach [21]. Therefore, cleavage of the glycosidic bond seems to not be required for the biological activity of ASG in mice.

In summary, the results of this study have demonstrated that ASG is bioactive in mice. ASG was taken up rapidly into the mucosa 4 h after oral gavage. ASG was cleaved to SG so that most of the ASG given was present in the form of SG in the lumen and mucosa. ASG administered was recovered quantitatively from stool samples as SG. There was little systemic absorption of ASG into the plasma or liver and ASG/SG seemed to act locally in both the lumen and mucosa without being significantly absorbed into the systemic circulation. Bioactive in reducing cholesterol absorption in mice and humans, phytosteryl glycosides from either natural or synthetic sources could potentially be used for the treatment of hypercholesterolemia. Phytosteryl glycosides must be measured and taken into account when assessing the effects of phytosterols in the diet and for treatment of hypercholesterolemia.

Acknowledgments This work was supported by National Institutes of Health Grant R01 50420 and the Washington University Mass Spectrometry Resource (P41 RR00954). We appreciate Mrs. Robin Fitzgerald for her excellent technical assistance.

Conflict of interest Dr. Ostlund and Washington University have a financial interest in Lifeline Technologies, a biotechnology company developing bioactive phytosterols. Lifeline products were not used in this study, and Lifeline and the authors have no financial interest in phytosteryl glycosides.

Received: 25 May 2010 / Accepted: 1 April 2011 / Published online: 13 May 2011

Abstract We studied the fatty acid (FA) content and composition of ten zoobenthic species of several taxonomic groups from different freshwater bodies. Special attention was paid to essential polyunsaturated fatty acids, eicosapentaenoic acid (EPA, 20:5n-3), docosahexaenoic acid (DHA, 22:6n-3), and arachidonic acid (ARA, 20:4n-6); and the n-3/n-6 and DHA/ARA ratios, which are important for consumers of higher trophic levels, i.e., fish. The content and ratios of these FA varied significantly in the studied zoobenthic species, consequently, the invertebrates were of different nutritional quality for fish. *Eulimnogammarus viridis* (Crustacea) and *Dendrocoelopsis* sp. (Turbellaria) had the highest nutrition value for fish concerning the content of EPA and DHA and n-3/n-6 and DHA/ARA ratios. Using canonical correspondence analysis we compared the FA profiles of species of the studied taxa taking into account their feeding strategies and habitats. We gained evidence that feeding strategy is of importance to determine fatty acid profiles of zoobenthic species. However, the phylogenetic position of the zoobenthic species is also responsible and may result in a similar fatty acid composition even if species or populations inhabit different water bodies or have different feeding strategies.

Keywords Benthic invertebrates · Fish · Feeding strategy · Phylogeny · Polyunsaturated fatty acids

Abbreviation

ALA	α-Linolenic acid, 18:3n-3
ARA	Arachidonic acid, 20:4n-6
BFA	Branched fatty acids
DHA	Docosahexaenoic acid, 22:6n-3
DPA	Docosapentaenoic acid, 22:5n-3
EPA	Eicosapentaenoic acid, 20:5n-3
FA	Fatty acid(s)
FAME	Fatty acid methyl ester(s)
LNA	Linoleic acid, 18:2n-6
MUFA	Monounsaturated fatty acid(s)
NMI	Nonmethylene interrupted
PUFA	Polyunsaturated fatty acid(s)
SFA	Saturated fatty acid(s)

Introduction

The fatty acid composition and FA ratios of different taxonomic groups are widely used as biochemical markers of trophic interactions in aquatic ecosystems [1, 2]. FA markers have been used to trace the transfer of the organic matter through aquatic food webs and to evaluate diet patterns of the aquatic animals [3–5]. Some polyunsaturated fatty acids (PUFA), namely eicosapentaenoic and docosahexaenoic acids are essential components in the nutrition of aquatic invertebrates and fish [6, 7]. It should

be noted that the essential PUFA are of large physiological importance for animals of different taxonomic levels, including humans [8–10]. Besides the PUFA content, the n-3/n-6 and DHA/ARA ratios are very important. These ratios are quite species-specific and their dietary levels must be optimal to sustain normal growth and development of organisms [11].

Benthic invertebrates (zoobenthos) are one of the most important components of riverine ecosystems and a major food source for fish. The most data on fatty acid content and the composition of benthic invertebrates come primarily from the aquaculture of marine economically important food species [12–16]. In contrast, data on the fatty acid composition of freshwater zoobenthos in rivers are scarce.

As it is known, the FA profiles of aquatic animals can be affected both by their food sources and by genetically predetermined metabolism [17]. The relative importance of these factors is continuously discussed, especially for zooplankton species. On the one hand, there is experimental evidence that some zooplankton species, e.g. *Daphnia*, have quite variable FA profiles that are strongly influenced by diet [18–21]. Variations in FA composition of natural zooplankton were also determined primarily by seasonal changes in the FA composition of their food, seston [22]. On the other hand, some zooplankton species are believed to selectively accumulate and metabolically alter dietary essential fatty acids [23–26].

In contrast to the comparatively well-studied zooplankton, there are sparse data on factors determining FA profiles of freshwater benthic invertebrates. Though there are several studies that demonstrate a capacity of zoobenthic species to synthesize long-chain PUFA from short-chain precursors. For instance, the free-living nematode *Caenorhabditis elegans* evidently has a unique pathway of PUFA synthesis from oleic acid to linoleic (LNA, 18:2n-6) and α-linolenic (ALA, 18:3n-3) acids and then to ARA and EPA, and, as a result, FA composition of *C. elegans* does not reflect the FA composition of its food [27]. Larvae of chironomids, *Chironomus riparius* are able to synthesize a large enough quantity of ARA and EPA from dietary LNA and ALA to support normal larval growth and development [28]. However, the above-mentioned zoobenthic species neither synthesized DHA nor accumulated this acid from their food [28]. We have previously demonstrated using fatty acids as trophic markers that benthic *Chironomus plumosus* selectively consumed food particles originating from green algae and cyanobacteria and contained little EPA and no DHA [4]. Riverine larvae of chironomids were shown to contain only traces of DHA [29, 30]. In contrast to the nematode and chironomids mentioned, larvae of caddisfly, *Hydropsyche* sp., have been shown to have a very limited ability to elongate and desaturate C18 PUFA to C20 PUFA [31]. There is evidence that the PUFA composition in gammarids depends on both diet and the inherent capacity of the animals to desaturate and elongate linoleic and linolenic acids to long-chain PUFA [32].

Kraffe and coauthors [33] have revealed a striking relationship between cardiolipin FA composition and phylogenetic groups of bivalve mollusks. They have suggested that cardiolipin FA profiles in bivalves are likely similar in species of the same phylogenetic group.

The majority of the above cited studies were focused on rather narrow phylogenetic groups of zoobenthos or did not consider the effect of phylogenetic factors. Therefore, a notion still occurs that trophic factors are key determinants of FA composition including essential PUFA in most aquatic invertebrates. We considered that studies covering a wider range of taxa and habitats were necessary to elucidate the true role of trophic and phylogenetic factors as determinants of FA profiles in zoobenthic invertebrates.

The aim of the present work was to compare the FA composition of freshwater benthic invertebrates of diverse taxonomic groups, potentially important for fish feeding, from different aquatic ecosystems. We addressed the following questions: (1) Whether phylogenetically close species inhabiting the same water body have different fatty acid spectra? (2) Can the populations of the same species inhabiting different water bodies with variable food sources, have a similar fatty acid composition? (3) Do phylogenetic factors are important determinants of essential EPA and DHA contents in benthic invertebrates?

Materials and Methods

Sampling and Fatty Acid Analysis

We included ten zoobenthic species in the study; most of them were taken from one water body, and only one species, *C. plumosus*, was sampled from two water bodies. Invertebrates were collected from the Yenisei River, Rybinskoe reservoir, Bugach reservoir and Chistoe lake (Table 1). The total number of samples was 100. Samples were collected in different periods of the year due to the seasonal occurrence and dominance of the species. The list of species, number of samples, and sampling periods are shown in Table 1. Each sample consisted of 2–20 individuals of various sizes, most of them were adults or premature larval stages. Whole bodies of the animals were taken for the analyses, except dreissenids, from which the closing muscle was removed and used for the following analysis.

Organisms from the river littoral were sampled using a Surber-type kick-bottom sampler by disturbing an area in a frame 40 × 35 cm upstream of an attached net (mouth

Table 1 Sampling protocol of studied invertebrates

Species	Number of samples	Sampling period	Water body
Dendrocoelopsis sp.	7	2005 April, October 2006 January, October, December 2007 January, September	The Yenisei River (Siberia, Russia, 55°58′ N and 92°43′ E)
Lumbriculus variegatus O.F. Muller	4	2004 June, August, November, December	The Yenisei River
Tubifex tubifex O.F. Muller	3	2005 February, April 2006 December	The Yenisei River
Eulimnogammarus viridis Dybowsky	6	2004 March, June, July 2005 March 2006 July 2008 March	The Yenisei River
Apatania crymophila MacLachlan	18	2004 September, November 2005 February, April, July–November 2006 January, February, September–December, 2007 January, February, September	The Yenisei River
Ephemerella setigera Bajkova	3	2006 September, December 2007 January	The Yenisei River
Prodiamesa olivacea Meigen	3	2006 October–December	The Yenisei River
Chironomus plumosus Linnaeus 'B'*	19	2007 May–September 2008 May–September	Bugach reservoir (Siberia, Russia, 56°03′ N and 92°43′ E)
Chironomus plumosus Linnaeus 'C'*	6	2008 June–August	Chistoe lake (Volga River basin, Russia, 57°43′ N and 40°33′ E)
Dreissena polymorpha Pallas	15	2007 June–September 2008 June–September	Rybinskoe reservoir (Volga River basin, 58°03′ N and 38°17′ E)
Dreissena bugensis Andrusov	16	2007 June–September 2008 June–September	Rybinskoe reservoir

* The designations of two populations of *Chironomus plumosus* are the same in the text

40 × 40 cm, mesh size 0.25 mm). Organisms from the reservoirs and the lake were sampled using Petersen-type bottom samplers. Immediately after sorting, the live animals were placed in beakers with tap water for 24 h to empty their guts. Then the animal's body surfaces were gently wiped with filter paper and the animals were weighed and placed in chloroform:methanol mixture (2:1, v/v) and kept until further analysis at −20 °C.

Laboratory FA analyses and the comprehensive identification of fatty acids are described in detail elsewhere [29, 34]. Briefly, lipids from the samples were extracted with chloroform:methanol (2:1, v/v) 3 times simultaneously with mechanical homogenization of the tissues with glass beads. Before the extraction, a fixed volume of an internal standard solution (19:0) was added to the samples. The combined lipid extracts were filtered, dried by passing through anhydrous Na_2SO_4 layer and evaporated at 35 °C. The lipid extract was subjected to acidic methanolysis as described previously [5]. Fatty acid methyl esters (FAME) were analyzed on a gas chromatograph equipped with a mass spectrometer detector (GCD Plus, Hewlett-Packard, USA) and a 30-m long × 0.32-mm internal diameter capillary column HP-FFAP. The column temperature programming was as follows: from 100 to 190 °C at 3 °C/min, 5 min isothermally, to 230 °C at 10 °C/min, and 20 min isothermally. Other instrumental conditions were as described elsewhere [5]. Peaks of FAME were identified by their mass spectra compared to those in the database (Hewlett-Packard, USA) and to those of available authentic standards (Sigma, USA). Positions of double bonds in monoenoic acids were determined by GC–MS of FAME dimethyl disulfide adducts prepared as described elsewhere [35]. To determine double bond positions in polyenoic acids, GC–MS of dimethyloxazoline derivatives of FA was used [29].

Statistical Analysis

Means, standard errors (SE) and Fisher LSD tests were calculated conventionally [36]. To check differences among taxa and the seasonal effect, the data matrix was formed which included all samples of the animals. Mollusk

samples were averaged for each date and used in the analysis. The data matrix included percentages of total FA of the most prominent FA and those of high marker significance, in the total eighteen FA. Canonical correspondence analysis of the data matrix was carried out using STATISTICA software (version 9; StatSoft Inc., Tulsa, OK, USA). To test differences among phylogenetic groups, such as classes Insecta, Oligochaeta, Crustacea, Turbellaria, Bivalvia, the data matrix was formed in similar manner as for the canonical correspondence analysis. Taxa groups comprised: Insecta—*A. crymophila*, *E. setigera*, *P. olivacea*, *C. plumosus*; Oligochaeta—*L. variegates* and *T. tubifex*; Crustacea—*E. viridis*; Turbellaria—*Dendrocoelopsis sp.*; Bivalvia—*D. polymorpha* and *D. bugensis*. The data matrix included percentages (mol% of the total) of essential FA, such as LNA, ALA, EPA, DPA, and DHA, and 16:0 and 18:1n-9 which is the most significant as energy sources. Tukey HSD test of the data matrix was carried out using STATISTICA software (version 9; StatSoft Inc., Tulsa, OK, USA).

Results

Fatty acid content and composition of zoobenthos from four phyla were studied. Taxonomy position and phylogenetic relationships between the studied species are shown in Fig. 1 [37].

More than fifty FA species were identified in samples (Tables 2, 3).

The levels of saturated fatty acids (SFA) in the studied species varied from 26.3 to 41.4% (mol% of the total) (Tables 2, 3). Levels of SFA were low in *E. viridis* and *Dendrocoelopsis* sp. and high in mollusks. Among SFA, 16:0, 18:0 and 14:0 dominated in most of the invertebrates, although their ratios significantly differed among the species (Tables 2, 3).

Branched fatty acids (BFA) comprised mostly i15:0, ai15:0, i17:0 and ai17:0 and their levels varied from 1.0 to 9.2% of the total (Tables 2, 3). The distribution of 15:0 BFA differed from that of 17:0 BFA. The levels of i15:0 and ai15:0 were significantly higher in *C. plumosus* 'C' in comparison with other species (Tables 2, 3). The levels of i17:0 and ai17:0 were high in mollusks and oligochaetes, especially in *L. variegatus*.

Monoenoic acids (MUFA) varied from 17.8 to 36.5% of the total and were primarily represented by 16:1n-7, 18:1n-7, 18:1n-9, 20:1n-7, 20:1n-9 and 20:1n-11 (Tables 2, 3). However, MUFA profiles differed among the species studied. *Dendrocoelopsis* sp. and *E. viridis* showed significant levels of 18:1n-9, while mollusks had the highest level of 20:1n-9. It should be noted that 20:1n-11 was found in all studied species in traces, except mollusks and oligochaetes, which had this acid dominant among MUFA. Monoenoic C22 acids were found mainly in worms and mollusks (Table 2).

The levels of polyunsaturated fatty acids varied from 25.1 to 39.3% of the total. The lowest value of PUFA was found in larvae of Chironomidae and the highest value was in *E. viridis* and *D. bugensis.* Dominant PUFA patterns in the studied invertebrates were evidently species-specific (Tables 2, 3).

In samples of *Dendrocoelopsis* sp. 20:5n-3, 22:5n-3, ALA, LNA and 22:6n-3 dominated. Note that the studied planarian was characterized by a very high content of 22:5n-3 (Tables 2, 4).

In both mollusk species, 22:6n-3, 20:5n-3, 22:5n-3, 22:5n-6, 20:4n-6 dominated, while their levels of C16 and C18 PUFA were negligible. The levels of 22:6n-3 in mollusks were significantly higher in comparison with other species (Tables 2, 3).

In oligochaetes the following acids dominated: 20:5n-3, LNA, ALA, 20:4n-6, and 22:6n-3. The per cent levels of 20:5n-3 in both Oligochaeta species were high and

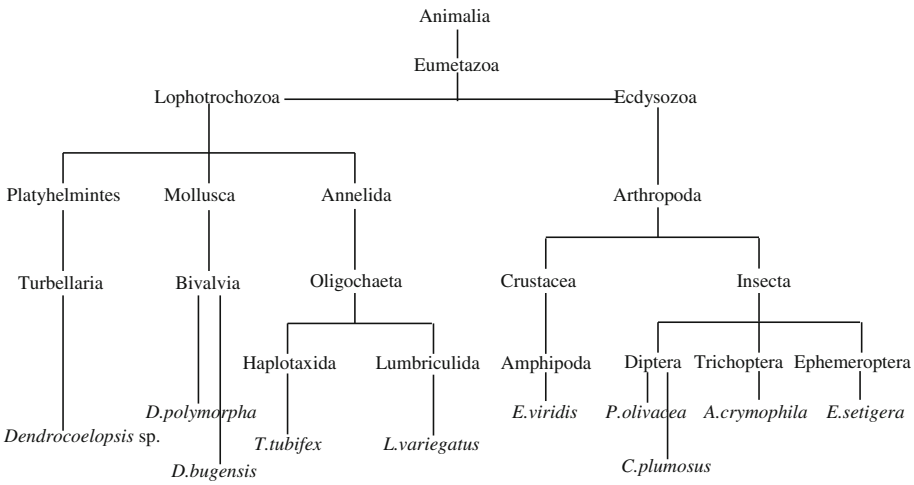

Fig. 1 The scheme of phylogenetic tree of benthic invertebrates, *Dendrocoelopsis sp.*, *D. polymorpha*, *D. bugensis*, *T. tubifex*, *L. variegatus*, *E. viridis*, *C. plumosus*, *P. olivacea*, *A. crymophila*, and *E. setigera* [by 37]

Designations are the same as in Table 2

comparable with those in some arthropod species, *E. setigera*, *E. viridis*, and *P. olivacea* (Tables 2, 3).

All chironomids had similar dominant PUFA: 20:5n-3, LNA, ALA, with their levels being markedly different. Both populations of *C. plumosus*, 'B' and 'C', contained significant levels of LNA (Table 3). In contrast, *P. olivacea* was rich in 20:5n-3. In addition, *P. olivacea* had the highest level of 16:2n-4; and *C. plumosus* 'B' had the highest level of 18:4n-3. Studied chironomids were lacking in DHA, moreover in *C. plumosus* 'C' DHA was not detected at all (Table 3).

Like in Chironomidae, the dominant PUFA of *A. crymophila*, *E. setigera* and *E. viridis* also comprised 20:5n-3, ALA and LNA. In addition, these invertebrates had significant percentage levels of 18:4n-3 and C16 PUFA, especially 16:2n-4, 16:3n-4, 16:4n-1. In contrast to most of the invertebrates, *A. crymophila* had the highest values of 16:4n-3 and 16:3n-3 (Table 3).

In the invertebrates studied the highest values of n-3/n-6 and DHA/ARA ratios were found in *E. viridis* and *Dendrocoelopsis* sp. (Table 4). *A. crymophila* and *T. tubifex* had comparatively high values of n-3/n-6 ratio and low values of DHA/ARA. High n-3/n-6 ratios were found in *E. setigera* and *P. olivacea* however, DHA/ARA ratios were very low in these species (Table 4). In both mollusks, n-3/n-6 ratios were similar to DHA/ARA ratios. In samples of *C. plumosus* 'B' and 'C' both ratios were very low (Table 4).

Using correspondence analysis, the zoobenthic invertebrates studied were represented in a two-dimensional space according to their levels (mol% of the total) of prominent fatty acids (Fig. 2). The first dimension explained 51.65% of inertia (of total Chi-square value) of the data set, and the second dimension reproduced 13.34%. Chi-square values for both dimensions and the total Chi-square were significant ($p < 0.0001$). The first dimension (Fig. 2) demonstrated large differences between mollusks on the one hand and larvae of insects on the other. *E. viridis* and worms had an intermediate position. These positions of invertebrates in the first dimension were provided mostly by difference in their levels of 22:5n-6 and 20:1n-11 on the one hand and 16:4n-3, 16:2n-4, LNA and ALA on the other. The second dimension, although comparatively less substantial was also significant, indicating that the largest differences between *C. plumosus* and *A. crymophila* with *E. setigera* is primary due to LNA and 16:4n-3. *P. olivacea* had an intermediate position. Besides, the second dimension demonstrated differences between *T. tubifex*, *L. variegatus* and *E. viridis*, *Dendrocoelopsis* sp. provided mostly by the difference in their levels of 15:0 and 18:1n-9 (Fig. 2). Note, none of each studied species showed evident seasonal tendencies in the two-dimensional space. For example,

Total total content of fatty acids, *n.c.* not calculated

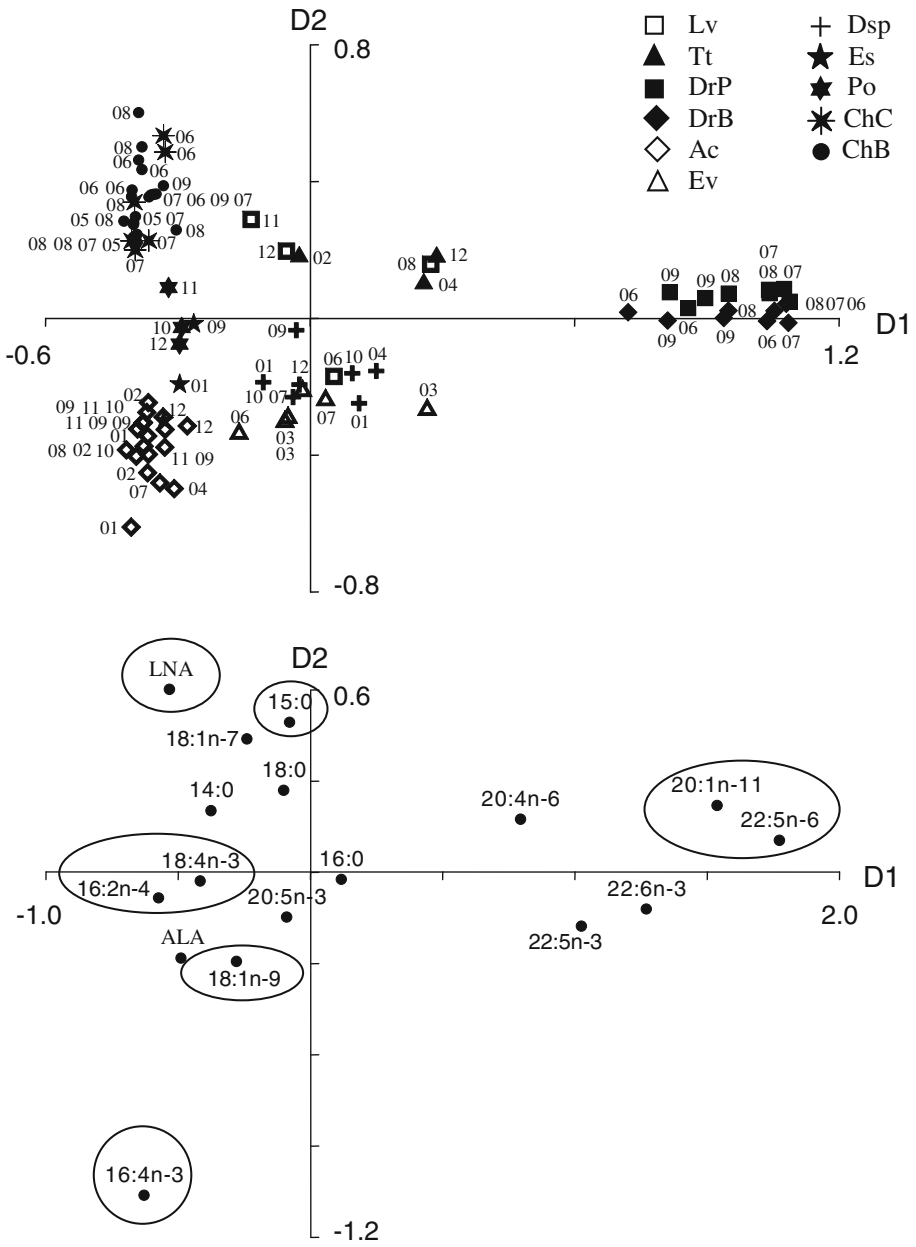

Fig. 2 Results of correspondence analysis of zoobenthic invertebrates and fatty acids (mol% of the total) represented in a two-dimensional space reproduced 65% of total inertia. *Lv*: *L. variegatus*, *Tt*: *T. tubifex*, *DrP*: *D. polymorpha*, *DrB*: *D. bugensis*, *Ac*: *A. crymophila*, *Ev*: *E. viridis*, *Dsp*: *Dendrocoelopsis sp*., *Es*: *E. setigera*, *Po*: *P. olivacea*, *ChC*: *C. plumosus* from Chistoe lake, *ChB*: *C. plumosus* from Bugach reservoir. The *numbers* indicate the months of sampling dates, e.g. 05 May, 08 August, 11 November. The FA which provided the major part of total inertia for axes D1 and D2 are *circled*

samples of *C. plumosus* collected in May, July and August were close to each other, while all samples of *C. plumosus* collected in August, were distant. The samples of *A. crymophila* collected in different seasons, such as February, August and November, were closer than the samples of winter months (Fig. 2).

To find differences in percentages of the essential and quantitatively valuable FA between large phylogenetic groups, such as Classes, we performed Tukey HSD test (Table 5). The mean levels of all eight tested FA were different among the groups. Bivalvia were markedly high in 16:0, while Crustacea and Turbellaria showed the significantly high levels of 18:1n-9. The highest level of LNA and ALA was found in Insecta. Oligochaeta and Bivalvia were rich in ARA, while the former group and Crustacea were rich in EPA. C22 n-3 PUFA were highly variable, being the most prominent in Bivalvia, Turbellaria and Crustacea (Table 5).

Discussion

We found that the FA content and composition of the studied benthic invertebrates differed significantly. Levels of essential PUFA, EPA and DHA, in the species varied by more than an order of magnitude (Tables 2, 3). Some

Table 5 Tukey HSD test on mean FA levels (mol% of the total) in groups of zoobenthic invertebrates combined as described in the text ("Materials and Methods", "Statistical Analysis")

Cells in a row labeled with the same letter are not significantly different at $p < 0.05$

authors emphasized the importance of n-3/n-6 and DHA/ARA ratios in zoobenthos because higher aquatic consumers, fish, need food with optimal FA ratios to achieve high rates of growth and reproduction and to optimize immune functioning [11, 38]. Some data collected from the literature showed that n-3/n-6 and DHA/ARA ratios in the fish food should be at least 2–3 and >0, respectively, i.e. some ARA are also needed to give good growth and reproduction [11]. In addition, the ratio values depend on trophic positions of fish, e.g., n-3/n-6 and DHA/ARA ratios in the carnivorous-benthivorous freshwater fish were 3.8 and 4.8, respectively, while for carnivorous-piscivorous fish the ratios were 2.6 and 2.7, respectively [11]. In the Yenisei River, the habitat for seven of the studied invertebrates, one of the most abundant fish species is Siberian grayling *Thymallus arcticus* (Pallas) which is benthivorous during most of its life stages. The ratios of n-3/n-6 and DHA/ARA in *Thymallus arcticus* are 9.4 and 5.5, respectively [39]. These ratios in *Thymallus arcticus* are markedly higher in comparison with those in other carnivorous-benthivorous freshwater fish species described by Ahlgren and colleagues [11].

Considering the food quality for the dominant fish *Thymallus arcticus*, the ratios in *E. viridis* and *Dendrocoelopsis* sp. are the most optimal. The larvae of *A. crymophila*, *E. setigera*, *P. olivacea* and oligochaete *T. tubifex* are of good nutritional quality in respect to the n-3/n-6 ratio, but their DHA/ARA ratios are lower than required (Table 4). Thus, the zoobenthic species from the Yenisei River are of variable food quality in respect to the fatty acid ratios.

In the Bugach reservoir, the habitat for *C. plumosus*, the most abundant benthivorous fish is *Carassius auratus gibelio* (Bloch). The mean ratios in *C. auratus* are 3.3 and 3.9, respectively (Sushchik and Makhutova, unpublished data). In contrast to the fish, *C. plumosus* had very low ratios, as a result, it was of low food quality for the population of crucian carp. Note that crucian carp of the Bugach reservoir had comparatively lower FA ratios than found in other benthivorous species [11] probably due to the food being of low biochemical quality.

We compared n-3/n-6 and DHA/ARA ratios of the studied invertebrates with available data. On average, n-3/n-6 ratios of chironomids were reported to vary from 1 to 3 [29, 30, 40]. Three chironomids studied in the present work were from different water bodies and showed differences in n-3/n-6 ratio. Both populations of *C. plumosus* inhabited black silts and had a relatively low n-3/n-6 ratio, within 1–2, while the population of *P. olivacea*, inhabited a river site rich in epilithic biofilms, had significantly higher value, >3. Hence, *C. plumosus* showed an n-3/n-6 ratio close to the range reported in the literature, while riverine *P. olivacea* was enriched in n-3 PUFA.

The studied oligochaetes and larvae of Trichoptera and Ephemeroptera had ratios very similar to the literature data [29, 30, 40–42].

Many researchers reported n-3/n-6 and DHA/ARA ratios in Gammaridae as 1–3 and ≤1, respectively [29, 32, 34, 41, 43, 44]. These values were significantly lower than those for the gammarids in the present study (Table 4). It is noteworthy that the studied *E. viridis* had n-3/n-6 and DHA/ARA ratios similar to those of predatory *Mysis relicta* [45].

There are many data on the FA composition of various taxa of mollusks, except for the dreissenids. The FA composition of mollusks is highly variable. Some representatives of mollusks, especially bivalves, have high levels of EPA and DHA [46–49], while others, especially gastropods, have high values of n-6 PUFA, 22:4n-6, 20:4n-6 and LNA [50, 51]. The mussels of *D. polymorpha* and *D. bugensis* in the present study were rich both in n-3 and n-6 C20-22 PUFA (Table 2). The bivalve mollusk *Potamocorbula amurensis* had the ratios similar to those in the studied dreissenids, n-3/n-6 ca. 2.5 and DHA/ARA ca. 2 [46].

The data on the FA composition of planarians are scarce. The only paper that describes the FA composition of phospholipids in the planarian *Dugesia anceps* is Ref.[52]. Both planarians, *D. anceps* studied by Politi and colleagues [52], and *Dendrocoelopsis* sp., studied in the present work, were characterized by unusually high levels of 22:5n-3. The level of this acid in the studied

Dendrocoelopsis sp. was close to 20:5n-3, and it was 2–10 times higher than that of 22:6n-3 (Table 2). In contrast to the species studied in the present work, *D. anceps* had significant levels of n-6 PUFA, 20:4n-6, LNA and 22:5n-6 [52]. Ratios of n-3/n-6 and DHA/ARA in phospholipids of *D. anceps* were much lower than those in *Dendrocoelopsis* sp.

We used FA trophic markers to elucidate nutritional preferences of the studied invertebrates. We considered increased levels of C16 PUFA of n-1, n-4, n-7 family and 20:5n-3 in biomass of the animals as markers of consumption of diatoms. *P. olivacea*, *A. crymophila*, *E. setigera*, *C. plumosus* 'B' and *E. viridis* accumulated C16 PUFA of n-1, n-4, n-7 family and 20:5n-3, therefore, a significant part of their diet probably comprises diatoms. Diatoms were also present in diets of *Dendrocoelopsis* sp. and *L. variegatus*, but in comparatively lower proportions. High levels of C16 and C18 PUFA of n-3 and n-6 family in *A. crymophila*, both *C. plumosus* populations and *E. setigera* indicated that green algae and cyanobacteria were probably abundant in their diets. Hence, *A. crymophila*, *E. setigera* and *C. plumosus* 'B' probably had a mixed diet. High levels of bacterial FA and C18–22 SFA was found in deposit-feeding *C. plumosus* 'C', *T. tubifex* and *L. variegatus*, indicating that detritus composed a significant part of their diets. Content of DHA and ratios of 18:1n-9/18:1n-7 and PUFA/SFA were reported to be high in carnivorous species [53–55]. Thus, *E. viridis*, which contained the highest value of DHA and the highest 18:1n-9/18:1n-7 and PUFA/SFA ratios among the studied benthic invertebrates, seemed to be partly a carnivore. In spite of the above-mentioned ratios in *Dendrocoelopsis* sp. being moderate, planarians are known to be carnivores [56, 57].

We suppose that benthic organisms have variable requirements in dietary FA, essentially determined by genetic and metabolic factors. To meet such requirements, most zoobenthic species need to feed selectively and to have the capacity to selectively retain and (or) convert dietary FA, which is reflected in the FA composition of their bodies.

Some authors have discussed different feeding strategies of zoobenthic species, as detritivorous, omnivorous, carnivorous [e.g. 33, 54]. Using the canonical correspondence analysis we obtained evidence that feeding strategy can be of importance to predetermine the fatty acid profile of a zoobenthic species, however, the phylogenetic position of a species is a more powerful factor which results in close FA composition even if taxonomically close species or populations inhabit different places. We initially suggested that a seasonal variation within each invertebrate's species composition is a very important factor. However, most species formed distinct groups in the two-dimensional space of the multivariate analysis. Note that these groups comprised samples of the same species taken in various seasonal periods (Table 1). One can easily see that phylogenetic differences were much larger than seasonal ones (Fig. 2). Thus, the seasonal variations in the FA composition of the zoobenthos were obviously a factor of secondary importance.

In correspondence analysis of the FA composition, we found large differences among mollusks, larvae of insects, and worms. However, samples of the crustacean *E. viridis* and the planarian *Dendrocoelopsis* sp. are very close to each other (Fig. 2). Although these species are very phylogenetically distant (Fig. 1), they both feed like carnivores, at least partly.

D. polymorpha and *D. bugensis* differ from other species by feeding strategy (filter feeders) and taxonomic position (particular phylum), and they were sampled from another water body. As a result, all samples of dreissenids formed the group that was the most distant from others (Fig. 2). *A. crymophila* and *E. setigera*, which formed a joint group, belonged to the same class Insecta (Figs. 1, 2). In addition, they inhabited the same site (Table 1). Note that samples of the two populations of the chironomid *C. plumosus*, although taken in waters from geographically very distant regions, formed a joint group, too. Obviously, populations of the same species have the close metabolic processes including FA biosynthesis and conversion capacity of dietary FA. Alternatively, *C. plumosus* has selective feeding [4] and thereby might have the same feeding spectrum even in different water bodies. Nevertheless, we consider the phylogenetic proximity as a factor that mostly determines similarity in FA profiles of the two different populations of *C. plumosus*. Another species of chironomids, *P. olivacea*, inhabitant of the river, formed a small separate group (Fig. 2).

Oligochaetes, *L. variegatus* and *T. tubifex,* showed variable levels of most FA, therefore, they were the only phylogenetic group that did not show a clear trend in the multidimensional analysis (Fig. 2). This finding is probably explained by the feeding strategy of the Oligochaetes. Due to detritivorous feeding, their diet might change strongly during the studied period, and FA profiles of their bodies reflected this variation in the diet.

It is important to note that positions of *C. plumosus*, *P. olivacea*, and *A. crymophila* with *E. setigera* were rather close to each other in the first dimension, which explained the major part of the total inertia (Fig. 2). All of these species are of the same class, Insecta, but were sampled from different water bodies (the Yenisei River, the Chistoe lake and the Bugach reservoir). Moreover, their feeding strategies are variable. Therefore, the FA profiles of the studied species of Insecta were likely primarily dependent on the genetically predetermined FA metabolism rather than on the biochemical composition of their diet.

Besides the differences in FA profiles between the particular species studied, we revealed significant variation in the mean levels of essential PUFA for large taxa which joined several species (Table 5). It is interesting to remark that C22 n-3 PUFA are depleted in the phylogenetically advanced group, Insecta, compared to that in worms, mollusks and crustaceans. It is well known that DHA is crucial for nervous system functioning [9] and enriched in neural tissues of highly organized animals. It is surprising that the larvae of Insecta which have a rather well-developed nervous system and complicated behavior do not evidently possess a mechanism for accumulating C22 n-3 PUFA.

In general, the fatty acid content and composition of the studied zoobenthic species significantly differed, including the essential PUFA and the FA ratios which are important factors of biochemical food quality for fish. *E. viridis* (Crustacea, Gammaridae) and *Dendrocoelopsis* sp. (Turbellaria) were of the highest nutritional value for carnivorous-benthivorous fish. Answering the initially formulated questions we can conclude that: (1) most phylogenetically close species inhabiting the same water body have similar fatty acid spectra; (2) the populations of the same species inhabiting different water bodies, e.g., the populations of *C. plumosus*, may have similar fatty acid composition; (3) just as trophic strategies, phylogenetic factors seem to be the important determinants of fatty acid profiles in benthic invertebrates.

ORIGINAL ARTICLE

Characteristics of Fatty Acid Composition of the Deep-Sea Vent Crab, *Shinkaia crosnieri* Baba and Williams

Hiroaki Saito

Received: 1 November 2010 / Accepted: 19 January 2011 / Published online: 12 April 2011

Abstract The neutral and polar lipids of the Galatheidae vent crab, *Shinkaia crosnieri*, with its eggs were studied to assess its lipid physiology and trophic relationship at hydrothermal vents. The vent crab obtained many of its lipids from *Bathymodiolus* mussels and chemosynthetic microorganisms which live on a mat of long, silky setae on the crab body as exosymbionts. In all lipid classes, the major monounsaturated fatty acids were 16:1n-7 and 18:1n-7, which originate from bacteria. The major polyunsaturated fatty acids (PUFA) in the triacylglycerols were 16:2n-4, 18:2n-4, 18:2n-7, 18:3n-4,7,10, and 16:2n-3, while those of the crab polar lipids were 16:2n-4, 18:2n-4, 18:3n-4,7,10, 20:4n-6 (arachidonic acid), 20:5n-3 (icosapentaenoic acid), and 22:6n-3 (docosahexaenoic acid) in the phosphatidylethanolamine, and 16:2n-4, 18:2n-4, and 18:3n-4,7,10, with noticeable levels of 20:4n-6, 20:5n-3, and 22:6n-3 in the phosphatidylcholine. In the crab and its eggs, TAG and phospholipid PUFA consisted primarily of n-4 family (n-4 and n-7) methylene-interrupted PUFA with n-3 and n-6 PUFA. The unique fatty acid composition mix of n-3, n-4, and n-6 PUFA in *S. crosnieri* lipids suggests the vent crab utilizing chemosynthetic bacteria, which produce both unusual n-4 and normal n-3 and n-6 PUFA. Such unique fatty acid composition differs from that reported for other common marine animals, which depend on organic matter derived from phytoplankton lipids.

PE	Phosphatidylethanolamine
PUFA	Polyunsaturated fatty acids
TAG	Triacylglycerols
TFA	Total fatty acids

Introduction

All marine animals contain n-3 polyunsaturated fatty acids (PUFA), which originate from both phytoplankton and symbiotic microorganisms, depending on solar energy [1], and from unique deep-sea barophilic bacteria [2, 3]. In particular, marine animals contain high levels of long-chain n-3 PUFA, such as docosahexaenoic acid (DHA, 22:6n-3) and icosapentaenoic acid (EPA, 20:5n-3), in both their depot and tissue lipids [1, 4]. Similarly, n-6 PUFA, such as linoleic acid (LA, 18:2n-6) and arachidonic acid (ARA, 20:4n-6), are generally vital for terrestrial animals [5, 6]. Either n-3 or n-6 PUFA usually dominate in marine or terrestrial animals, especially in their cell membrane phospholipids.

In the deep sea, many nutritional constituents are provided by the fall of organic matter from the surface (the detrital food chain) and vertical migrations of both

zooplankton and micronekton (the grazing food chain) [7]. Not only do all marine animals in the upper water layers gain nutrition through the marine grazing food chain, but also benthic animals involved in the detrital food chain on or near the ocean bottom in some communities are indirectly supported by surface phytoplankton [1, 8].

However, in previous papers [9, 10], several novel unusual n-4 family PUFA (n-1, n-4, and n-7 non-methylene-interrupted PUFA and n-4 and n-7 methylene-interrupted PUFA) were observed in the lipids of vent bivalves (*Calyptogena* clams and *Bathymodiolus* mussels). Both vent Vesicomyidae clams (Bivalvia, Veneroida, genera *Vesicomya* and *Calyptogena*) and *Bathymodiolus* mussels (Bivalvia, Mytiloida, Mytilidae) are important members of the community that are supported by chemosynthetic bacteria [11–13]. Their major PUFA consist of only the n-4 family PUFA and were completely lacking in n-3 and n-6 PUFA [9, 10]. They assimilate the products and energy from chemosynthetic symbionts [14–16], which use only geothermal energy and minerals from the vents. The chemosynthetic bacteria essential for these communities must use geothermal energy and nutrients originating from the vents, and be independent of food sources originating from photosynthesis [9, 11, 17].

In deep-sea hydrothermal vents, crustaceans were also found as other important members of the community (Figs. 1, 2, 3). Vent Galatheidae crab, *Shinkaia crosnieri* Baba and Williams [18], is a typical member and feeds on polychaetes and "culture" filamentous bacteria on their abdominal surface [19, 20]. Its phylogeny has begun to be studied [21], but there is no information on the chemical components and trophic relationship between the crab and its symbionts. Although isolation and cultivation of symbiotic marine microorganisms from their hosts is very difficult, particularly in vent organisms, we are able to know their lipid physiology by studying the host lipids, which reflect those of the symbionts. In the present paper, the fatty acids of the lipids in the crab, which were sampled near hydrothermal vents on the Iheya Ridge, Mid-Okinawa Trough (at a depth of 1,005 m), were analyzed to determine trophic relationships at hydrothermal vents.

Fig. 1 *Shinkaia crosnieri* Baba and Williams, 1998, sampled by the submersible *Shinkai 2000*, 115 mm, dorsal view. It bears *Beggiatoa*-type filamentous bacteria on abdominal surface. After measurements of body length and weight of *S. crosnieri*, the body (whole body with filamentous epibiotic bacteria) and eggs were separated

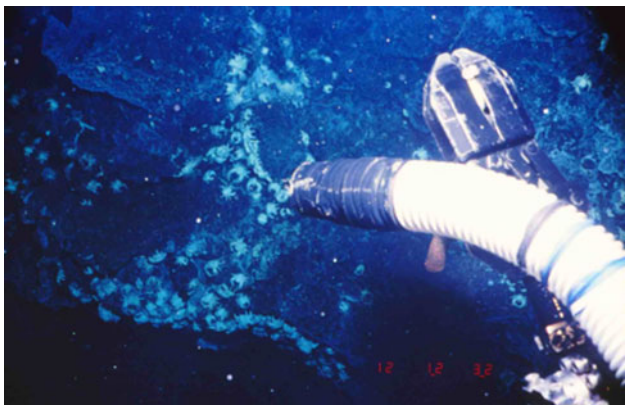

Fig. 2 The sampling site of *S. crosnieri*. The deep-sea crab was caught at the hydrothermal vents at the depth of 1,047 m at 27°47′N and 126°54′E on the Iheya Ridge, Mid Okinawa Trough in the East China Sea on May 12, 1999 (No. 1097 dive for the submersible "*Shinkai 2000*" belonging to the Japan Marine Science and Technology Center)

Results are expressed as mean ± standard error ($n = 2$–15). *S. crosnieri* were collected by #1097 dive of *Shinkai 2000*

Two females holded eggs, and the body (whole body with filamentous epibiotic bacteria) and eggs were separated

the Iheya Ridge of the East China Sea. The specimens are described in detail in Table 1 (Figs. 1, 2, 3). The morphological data of the specimens are presented in Fig. 1. A total of 32 specimens (mean weight: 23.4 ± 1.4 g) was collected, out of which 15 randomly selected specimens (sample No. 1; mean length: 35.8 ± 1.6 cm, mean width: 49.6 ± 2.3 cm, mean weight: 37.3 ± 4.9 g in Table 1) were considered for lipid analysis. Two female specimens (sample No. 2; mean length: 29.5 ± 1.5 cm, mean width: 42.5 ± 0.5 cm, mean weight: 19.7 ± 0.1 g in Table 1) laden with eggs were also analyzed. After measurements of body length and weight of *S. crosnieri*, the eggs were separated from the bodies.

Lipid Extraction and Analysis of Lipid Classes

Each specimen (whole body with filamentous epibiotic bacteria) was immersed in a reagent mixture containing chloroform and methanol (2:1, v/v) after the biological data were measured. The lipids of the specimens were individually analyzed. Briefly, each sample (samples No. 1 and 2 in Tables 1, 2) was homogenized in the same reagent mixture as described above, and the crude lipid of each homogenized sample was extracted according to the Folch extraction procedure [22]. The eggs (sample No. 3 in Table 2), which were carried outside by the two female crabs, were also individually extracted by the same kinds of solvents.

The extracted crude lipids were individually separated into classes on silicic acid columns (Merck and Co. Ltd., Kieselgel 60, 70–230 mesh) and a quantitative analysis of the lipid constituents was performed using gravimetric analysis of the fractions collected from column chromatography [23]. The first eluate (dichloromethane/*n*-hexane, 2:3, v/v: first fraction) was collected as steryl ester, wax ester, and diacylglyceryl ether fractions. This was followed by dichloromethane (second fraction) which eluted the triacylglycerols (TAG) and dichloromethane/ether (35:1, v/v: third fraction) which eluted the sterols. Dichloromethane/ether (9:1, v/v: fourth fraction) eluted the diacylglycerols; dichloromethane/methanol (9:1, v/v: fifth fraction) eluted the free fatty acids; dichloromethane/methanol (1:5, v/v: sixth fraction) eluted the phosphatidylethanolamine (PE); dichloromethane/methanol (1:20,v/v: seventh fraction) eluted the ceramide aminoethyl phosphonate with other minor phospholipids; and dichloromethane/methanol (1:50, v/v: eighth fraction) eluted phosphatidylcholine (PC).

The lipid classes from each lipid fraction were identified by comparison of the retention (R_f) values of standards using plate thin-layer chromatography (Merck & Co. Ltd., Kieselgel 60, thickness of silica gel: 0.25 mm) for analysis. All lipids were dried under argon at room temperature and stored at −40 °C.

Data are mean ± standard errors (n = 2–20)

[a] Results are expressed as weight percent of wet tissues

[b] Results are expressed as weight percent of total lipids

[c] WE, SE, DAGE, TAG, ST, DG, and FFA means wax esters, steryl esters, diacylglyceryl ethers, triacylglycerols, sterols, diacylglycerols, and free fatty acids, respectively. PE, PL, and PC means phosphatidylethanolamine, other phospholipids, and phosphatidylcholine, respectively

Nuclear Magnetic Resonance Spectrometry and Determination of Lipid Classes

Spectra were recorded on a GSX-270 nuclear magnetic resonance (NMR) spectrometer (JEOL Co. Ltd., Tokyo, Japan) in pulsed Fourier transform mode at 270 MHz in a deuterochloroform solution using tetramethylsilane as the internal standard. Some fractions often contained several classes. For example, the first fraction contained wax esters, diacylglyceryl ethers, and steryl esters. The molar ratios of these classes were determined by quantitative analysis of the NMR results using characteristic peaks [9]. In NMR, the amount of wax esters was obtained by the total amount of combined integrations of the triplet peaks (from 3.90 to 4.20 ppm) as the two protons at the ester alcohol, that of diacylglyceryl ethers was obtained by that of the singlet peak (3.50–3.80 ppm) as the two ether protons linked with glycerol carbons, and that of steryl esters was obtained by that of multiplet peaks (4.30–4.80 ppm) as one proton at the carbon linked esterified C-3 alcohol of the sterols. The actual ratios of the wax esters, diacylglyceryl ethers, and steryl esters in the first fraction were determined as the respective integration divided by the sum of total integrations of the three combined peaks from 3.50 to 4.80 ppm. The actual weight of each class was obtained by calculating the ratio and multiplying by the total weight of the first fraction. Similarly, the third fraction sometimes contained TAG and sterols, which have two characteristic peaks: for TAG (3.90–4.40 ppm), an octet-like peak for four protons, and for sterols (3.40–3.60 ppm), a multiplet peak for one proton. The actual weight of the TAG and sterols in the third fraction was obtained by calculating the integration of the divided respective peak and multiplying it by the total weight of the third fraction [9].

Preparation of Methyl Esters and Gas–Liquid Chromatography Analysis

Individual components of TAG, PE, and PC fractions were converted into fatty acid methyl esters by direct transesterification with methanol containing 1% concentrated hydrochloric acid under reflux for 1.5 h. The methyl esters were purified using silica gel column chromatography by elution with dichloromethane/*n*-hexane (2/1, v/v) [23].

The compositions of the fatty acid methyl esters were determined by gas–liquid chromatography. Analysis was performed on a Shimadzu GC-8A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and HP-5890 series II (Hewlett Packard Co. Ltd., Yokogawa Electric Corporation, Tokyo, Japan) using gas chromatographs equipped with an Omegawax 250 fused silica capillary column (30 m × 0.25 mm i.d.; 0.25-μm film, Supelco Japan Co. Ltd., Tokyo, Japan). The temperatures of the injector and the column were held at 230 and 215 °C, respectively, and the split ratio was 1:76. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min. PE contained noticeable levels of plasmalogen-type PE [23, 24] and significant levels of dimethylacetals (DMA), such as DMA 18:0, were included in the fatty acid composition of PE (Fig. 4). The theoretical values of the fatty acid composition were obtained by deleting the DMA from the total fatty acids (TFA) of PE. After this treatment, we expressed the PE so as to provide a more correctable form in Table 3.

Quantitation of the components was performed by Shimadzu Model C-R3A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and HP ChemStation System (A. 06 revision, Hewlett Packard Co. Ltd., Yokogawa Electric Corporation, Tokyo, Japan) electronic integrators.

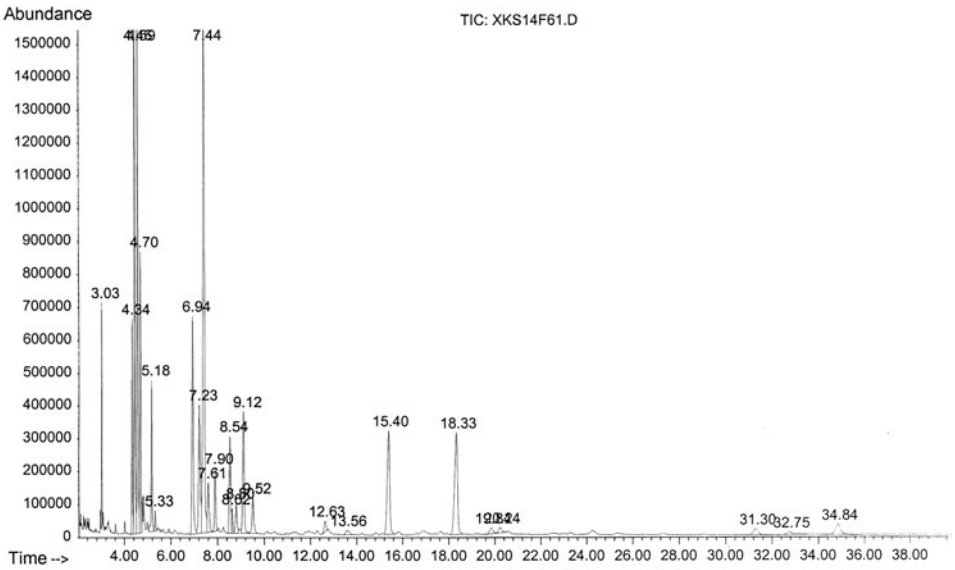
Preparation of 4,4-Dimethyloxazoline Derivatives (DMOX) and Analysis of DMOX by Gas Chromatography–Mass Spectrometry

DMOX derivatives were prepared by adding an excess amount of 2-amino-2-methyl propanol (1 mL) to a small amount of fatty acid methyl esters (10.0 mg) in a test tube under an argon atmosphere. The mixture was heated at 180 °C for 18 h. The reaction mixture was cooled and poured into saturated brine and extracted with *n*-hexane (3 times). The pooled *n*-hexane extract was washed with saturated brine and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure and the samples were again dissolved in *n*-hexane for analysis by gas chromatography–mass spectrometry (GC–MS) [23, 25].

Analysis of the DMOX derivatives was performed on a HP G1800C GCD Series II (Hewlett Packard Co. Ltd., Yokogawa Electric Corporation, Tokyo, Japan) GC–MS equipped with the same capillary column for determining the respective fatty acids with the HP WS (HP Kayak XA, G1701BA version, PC workstation). The temperatures of the injector and the column were held at 230 and 215 °C, respectively. The split ratio was 1:75, and the ionization voltage was 70 eV. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min. Fatty acid methyl esters were simultaneously analyzed by GC–MS and identified by comparison to the mass spectral data obtained by GC–MS. The author did not check the quantification of the fatty acid methyl esters by the internal standards.

Structural Elucidation of the DMOX Derivatives of the Fatty Acids in *S. crosnieri* Lipids

Representative chromatograms of the DMOX derivatives of the *S. crosnieri* lipids and the MS charts of the major fatty acids are displayed in Figs. 4, 5, 6, 7, 8, 9. Each MS



Retention time (min)	Fatty acids	Area % (total ion chromatogram)
3.03	16:0 DMA	2.46
4.34	16:0	4.00
4.46	18:0 DMA	12.01
4.59	16:1n-7	10.40
4.70	18:1 DMA	5.10
5.18	16:2n-4,7	3.10
5.33	16:2n-3,6	0.40

		100.00

a DBPh and DOPh means dibutyl phthalate and dioctyl phthalate as an impurity, respectively.

Fig. 4 The chromatogram of the DMOX derivatives of the fatty acids in *S. crosnieri* lipids. Analysis of the DMOX derivatives was performed on a HP G1800C GCD Series II gas chromatograph mass spectrometer equipped with an Omegawax-250 fused silica capillary column with the HP WS (HP Kayak XA, G1701BA version, personal computer workstations). The temperatures of the injector and the column were held at 230 and 215 °C, respectively. The split ratio was 1:75, and the ionization voltage was 70 eV, respectively. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min. Each MS spectrum was obtained by every 0.009 min

spectrum was obtained every 0.009 min (Figs. 4, 5, 6, 7, 8, 9). For example, a spectrum at 18.283 min (Scan No. 1814 in Fig. 10) is one of the representative spectra of 20:5n-3 (Δ5,8,11,14,17–20:5) because 20:5n-3 was detected near 18.33 min as one peak in the chromatogram (Fig. 4) of DMOX derivatives of the crab lipids; more than 35 spectra (M^+-355) were obtained by scanning the peak (18.15–18.50 min).

In Fig. 5 (5.185 min, Scan No. 352), MS peaks of a DMOX derivative of 16:2n-4,7 are M^+-305, 290, 276, 262, 248, 236, 222, 208, 196, 182, 168, 154, 140, 126, 113 (base peak) and two pairs of the peaks (M-248/M-236 and M-208/M-196) are, respectively, reflected by two double bonds: Δ-12 (n-4) and Δ-9 (n-7). In Fig. 6 (8.509 min, Scan No. 723), MS peaks of a DMOX derivative of 18:2n-4,7 are M^+-333, 318, 304, 290, 276, 264, 250, 236, 224, 210, 196, 182, 168, 154, 140, 126, 113 (base peak) and two pairs of the peaks (M-276/M-264 and M-236/M-224) are, respectively, reflected by two double bonds: Δ-14 (n-4) and Δ-11 (n-7). In Fig. 7 (9.055 min, Scan No. 784), MS peaks of a DMOX derivative of 18:3n-4,7,10 are M^+-331, 316, 302, 288, 274, 262, 248, 234, 222, 208, 194, 182, 168, 154, 140, 126, 113 (base peak) and three pairs of the peaks (M-274/M-262, M-234/M-222, and M-194/M-182) are, respectively, reflected by three double bonds: Δ-14 (n-4), Δ-11 (n-7) and Δ-8 (n-10). In Fig. 8 (5.355 min, Scan No. 371), MS peaks of a DMOX derivative of 16:2n-3,6 are M^+-305, 290, 276, 262, 250, 236, 222, 210, 196, 182, 168,

Results are expressed as weight per cent of total fatty acids. The average data are mean ± standard errors of 3–28 replications. In Table 3, the major fatty acids are selected if at least one mean datum was detected at a level of about 0.3% or more of total fatty acids

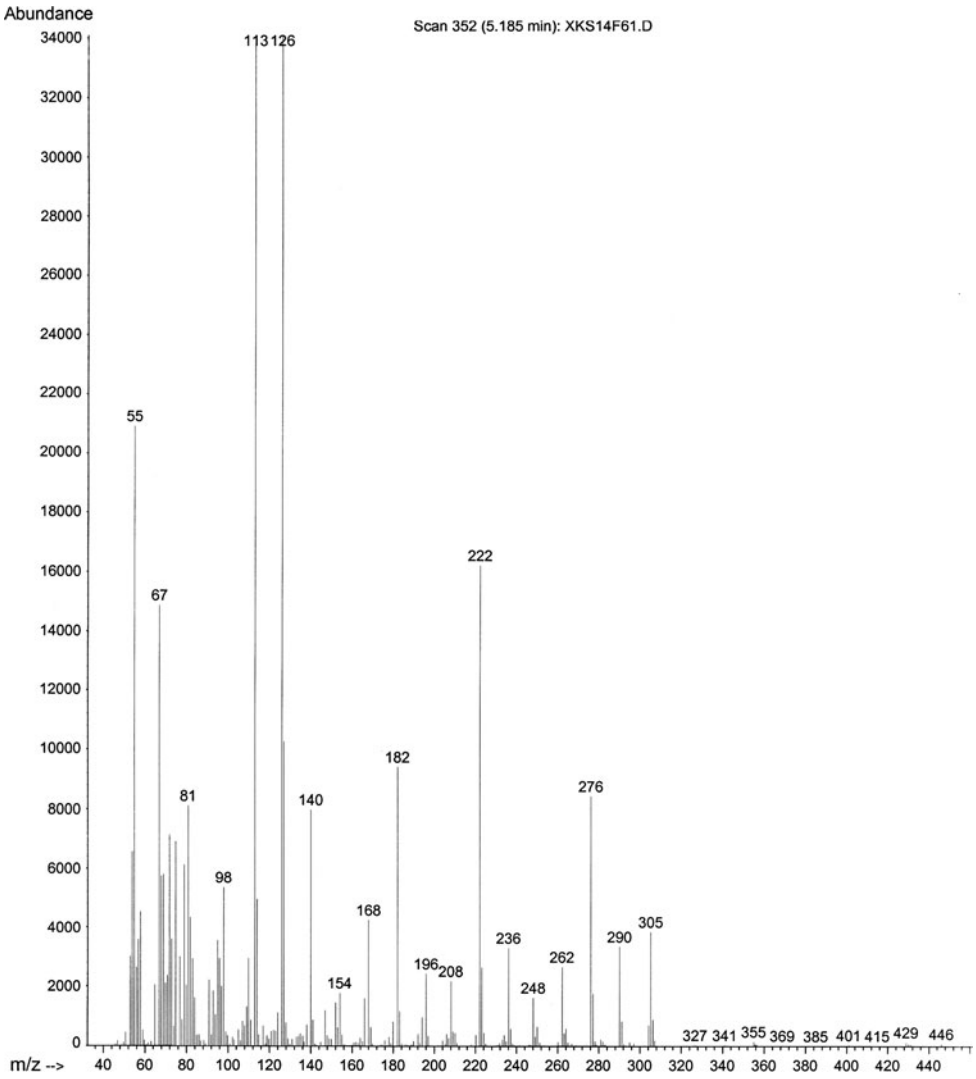

Fig. 5 The MS peaks (5.185 min, Scan No. 352) of the DMOX derivative of 16:2n-4,7 are M^+-305, 290, 276, 262, 248, 236, 222, 208, 196, 182, 168, 154, 140, 126, 113 (*base peak*), and two pairs of peaks (M-248/M-236 and M-208/M-196) are, respectively, reflected by two double bonds; Δ-12 (n-4) and Δ-9 (n-7)

154, 140, 126, 113 (base peak) and two pairs of peaks (M-262/M-250 and M-222/M-210) are, respectively, reflected by two double bonds: Δ-13 (n-3) and Δ-10 (n-6). In Fig. 9 (9.494 min, Scan No. 833), the MS peaks of a DMOX derivative of 18:4n-4,7,10,13 are M^+-329, 314, 300, 286, 272, 260, 246, 232, 220, 206, 192, 180, 166, 153, 136, 126, 113 (base peak) and three pairs of the peaks (M-272/M-260, M-232/M-220, and M-192/M-180) are, respectively, reflected by three double bonds: Δ-14 (n-4), Δ-11 (n-7) and Δ-8 (n-10): a pair of the peak (M-153/M-136) shows a Δ-5 (n-13) double bond. This is the same as the authentic n-3 PUFA in Christie's home page [26] and n-4 PUFA [10].

Statistical Analyses

Two to 15 experimental replications were completed for each lipid class. For all samples of fatty acids analyzed by GLC, four to 39 replications were completed. Significant mean differences were determined using Student's *t* test at a significance level of $p < 0.05$.

Results

Lipid Content and Classes of *S. crosnieri*

The lipid content of female *S. crosnieri*, which was laden with eggs, was relatively high (sample No. 2, 1.3 ± 0.7%, Table 2) in comparison to those of both sexes (sample No. 1, 0.8 ± 0.1%, Table 2). Furthermore, the lipid content of *S. crosnieri* eggs was very high (sample No. 3, 53.4 ± 0.2%, Table 2). The lipids of the bodies and eggs (samples No. 1–3) contained a high level of neutral lipids (mainly TAG, 46.1–58.9%) with noticeable levels of polar lipids (PE and PC). All PE

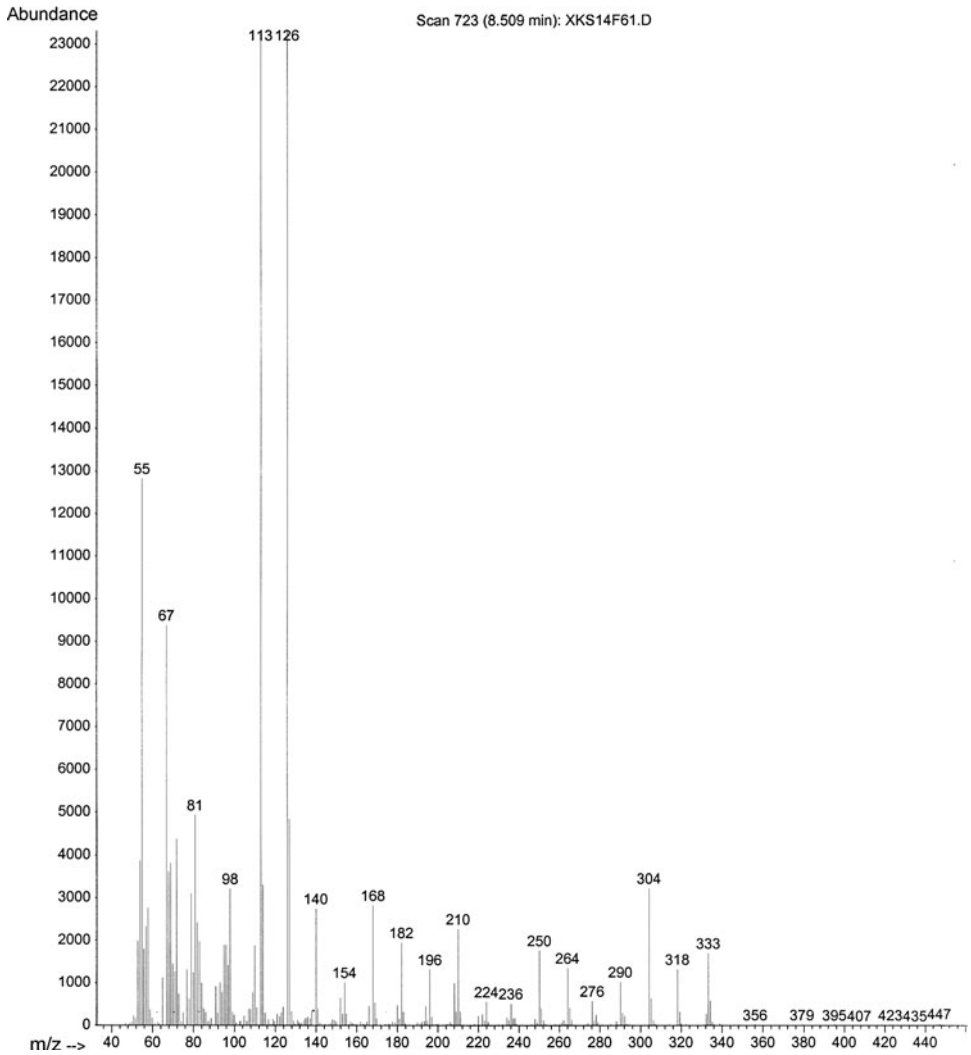

Fig. 6 The MS peaks (8.509 min, Scan No. 723) of the DMOX derivative of 18:2n-4,7 are M^+-333, 318, 304, 290, 276, 264, 250, 236, 224, 210, 196, 182, 168, 154, 140, 126, 113 (*base peak*), and two pairs of the peaks (M-276/M-264 and M-236/M-224) are, respectively, reflected by two double bonds; Δ-14 (n-4) and Δ-11 (n-7)

contained noticeable levels of plasmalogen-type PE (Fig. 4) and the fatty acid composition of PE contained significant levels of DMA [23, 24].

Fatty Acid Composition in Depot TAG of *S. crosnieri* Lipids

More than 50 kinds of fatty acids from C_{12} to C_{22} were determined in *S. crosnieri* lipids. The fatty acids in the body TAG (more than 0.3% of TFA) are listed in Table 3. In its body TAG (samples No. 1–2), 11 dominant fatty acids (each accounted for more than about 3% of TFA) were detected: 14:0 and 16:0 as saturated fatty acids; 14:1n-9, 16:1n-7, 18:1n-7, and 18:1n-9 as monounsaturated fatty acids (MUFA); 16:2n-4 (Fig. 5), 18:2n-4 (Fig. 6), 18:2n-7, and 18:3n-4 (Fig. 7) as n-4 family PUFA; and 16:2n-3 (Fig. 8) as n-3 dienoic acid with noticeable levels (more than about 1% of TFA) of 5 other minor fatty acids: 12:0, 12:1n-8, 13:0, 18:0, and 20:1n-7. Similarly, the same major fatty acids were observed in its egg TAG (sample No. 3). Nine dominant fatty acids were detected: 16:0, 16:1n-7, 18:1n-7, 18:1n-9, 16:2n-4, 18:2n-4, 18:2n-7, 18:3n-4, and 16:2n-3 as n-3 with noticeable levels of the same four minor fatty acids: 14:0, 14:1n-5, 18:0, and 20:1n-7.

High levels of total MUFA (sample No. 1, 50.1 ± 0.7% for 15 specimens; sample No. 2, 55.2 ± 2.1% for 2 female specimens; sample No. 3, 60.4 ± 2.3% for 2 eggs) were observed in *S. crosnieri* TAG, while it had comparatively low levels of saturated fatty acids (sample No. 1, total saturated fatty acids: 17.2 ± 0.9% for 15 specimens; sample No. 2, 13.0 ± 1.7% for 2 female specimens; sample No. 3, 10.7 ± 0.6% for 2 eggs). For example, palmitoleic acid 16:1n-7 (22.5–28.8% for the whole body of samples No. 1–2; 28.9% for the eggs of sample No. 3) and vaccenic acid 18:1n-7 (11.8–12.0% for the whole body of samples No. 1–2; 12.2% for the eggs of sample No. 3) were determined as major MUFA in *S. crosnieri* body TAG.

In all *S. crosnieri* TAG (samples No. 1–3), the four n-4 methylene-interrupted PUFA (16:2n-4, 18:2n-4, 18:2n-7, and 18:3n-4) were observed as major PUFA (Table 3).

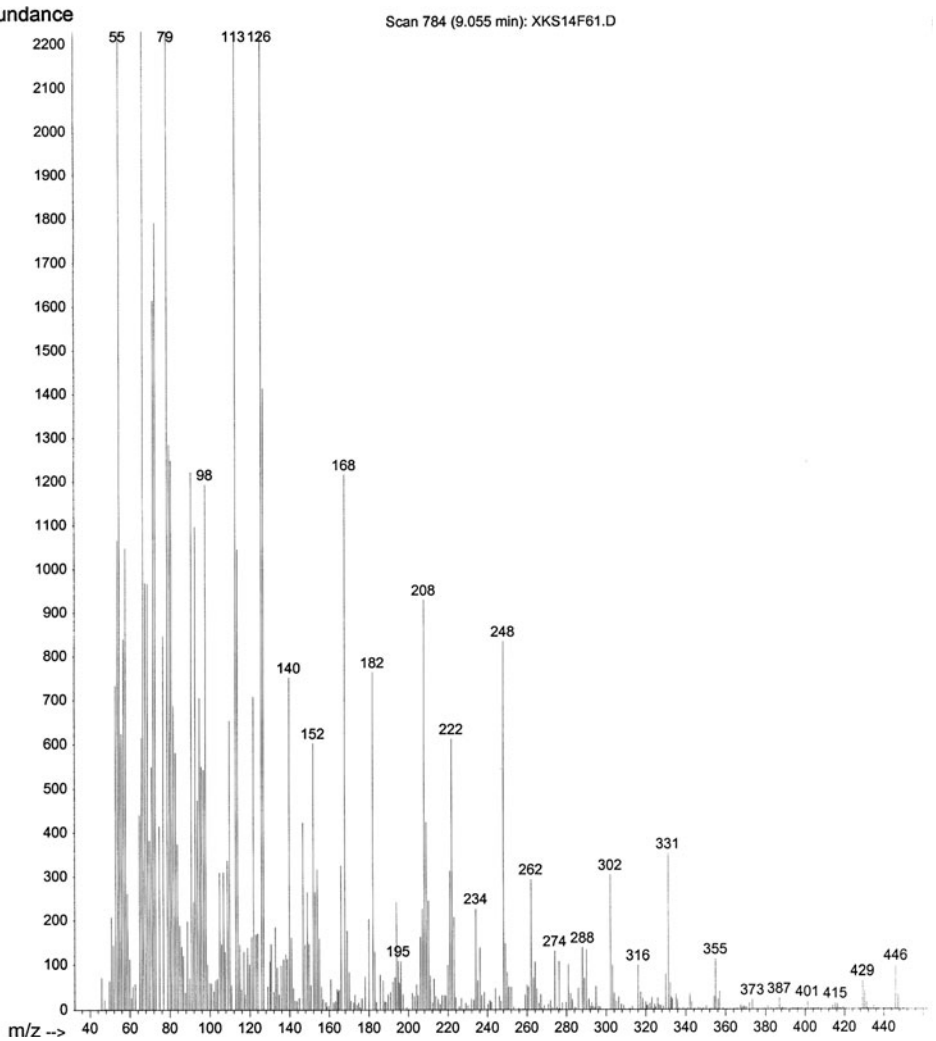

Fig. 7 The MS peaks (9.055 min, Scan No. 784) of the DMOX derivative of 18:3n-4,7,10 are M^{+}-331, 316, 302, 288, 274, 262, 248, 234, 222, 208, 194, 182, 168, 154, 140, 126, 113 (*base peak*), and three pairs of the peaks (M-274/M-262, M-234/M-222, and M-194/M-182) are, respectively, reflected by three double bonds; Δ-14 (n-4), Δ-11 (n-7) and Δ-8 (n-10)

With the four major n-4 PUFA, various other n-4 methylene-interrupted PUFA and n-7 MUFA were found in all crab TAG. Furthermore, significant levels of unusual n-3 PUFA 16:2n-3, with trace levels of normal n-3 and n-6 PUFA were found in the *S. crosnieri* body TAG (samples No. 1–2). In the egg TAG (sample No. 3), the same n-3, n-4, and n-6 PUFA were also observed at a similar level and the high levels of n-7 MUFA were observed in both body and egg lipids (Table 3).

Fatty Acid Composition in Tissue Phospholipids of *S. crosnieri* Lipids

Compared with the fatty acid composition in the TAG (Table 3), similar saturated fatty acids and MUFA were determined as dominant in the two major *S. crosnieri* body phospholipids (PE and PC): 16:0, 18:0, 16:1n-7, 18:1n-7, and 18:1n-9. In both PE and PC, 16:0 and 18:0 were major saturated fatty acids while 14:0, which was a major acid in the *S. crosnieri* body TAG, was a minor acid. As for MUFA in the phospholipids, the same trends between PE and PC were found. For example, low levels of 14:1n-9 with slightly higher levels of 18:1n-7 and 18:1n-9 with noticeable levels of 20-carbon n-7 and n-9 MUFA were found in the phospholipids.

Similar to the major PUFA in the *S. crosnieri* body TAG, the same four n-4 methylene-interrupted PUFA (16:2n-4, 18:2n-4, 18:2n-7, and 18:3n-4) were also observed as major PUFA in the phospholipids (Table 3). Furthermore, a tetraenoic fatty acid, 18:4n-4 (Fig. 9) was found at noticeable levels in the body PE, with small levels of other various n-4 family PUFA.

In contrast, the levels of n-3 and n-6 PUFA in the *S. crosnieri* polar lipids markedly differed from those in its TAG. In particular, significantly high levels of n-3 and n-6 long-chain PUFA were contained in PE: 20:4n-6 (ARA, 8.7–9.1% in the body PE), 20:5n-3 (EPA, 12.2–14.4% in the body PE), and 22:6n-3 (DHA, 3.4–4.8% in the body PE). Furthermore, different from the medium levels of 16:2n-3 in the TAG (4.7–5.3%) without DHA, significant

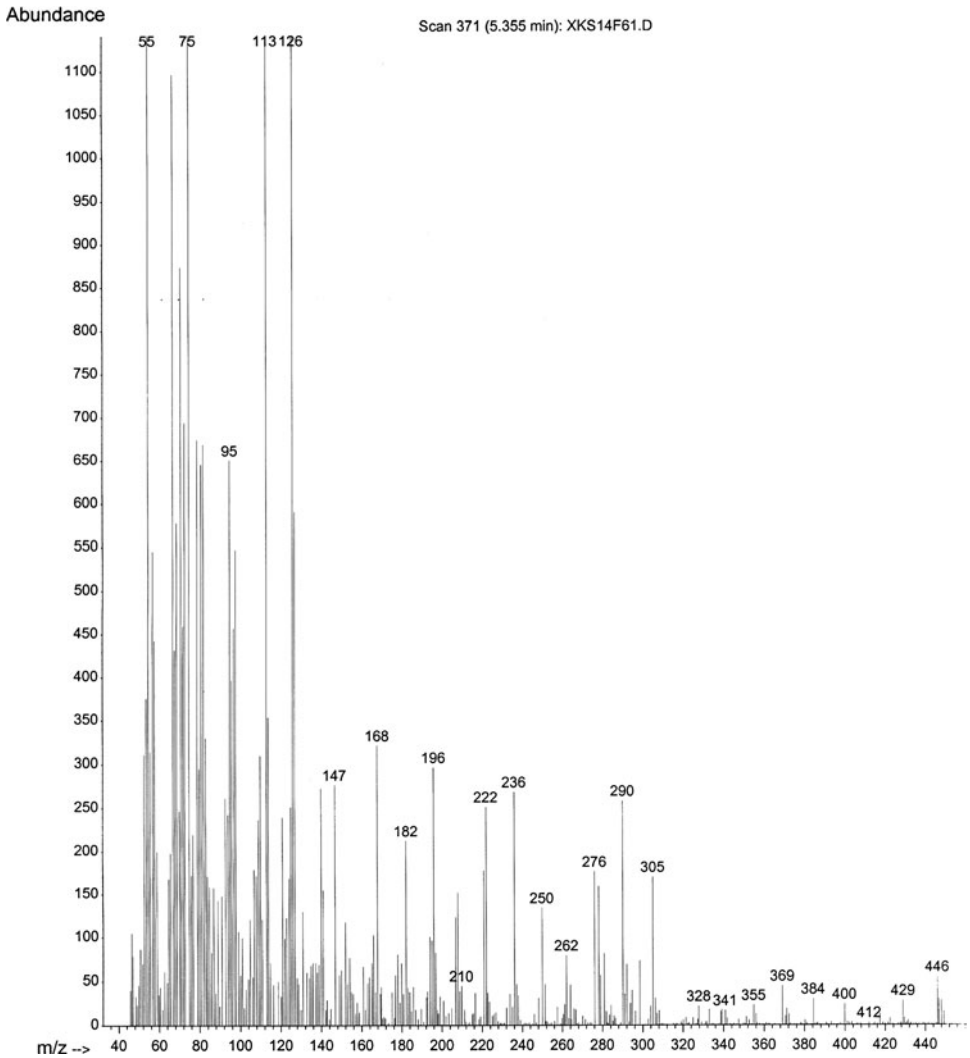

Fig. 8 The MS peaks (5.355 min, Scan No. 371) of the DMOX derivative of 16:2n-3,6 are M^{+}-305, 290, 276, 262, 250, 236, 222, 210, 196, 182, 168, 154, 140, 126, 113 (*base peak*), and two pairs of peaks (M-262/M-250 and M-222/M-210) are, respectively, reflected by two double bonds; Δ-13 (n-3) and Δ-10 (n-6)

levels of ARA, EPA, and DHA were characteristically detected in both phospholipids (Table 3).

In egg PE, the same n-4, n-3, and n-6 PUFA (2.6% for ARA, 5.4% for EPA, and 4.0% for DHA) were observed. However, the total n-4 and n-7 PUFA levels in the egg phospholipids were higher than those in body phospholipids, while the levels of n-3 and n-6 PUFA in the egg polar lipids were lower than those in the body polar lipids.

Discussion

Lipid Content and Classes of *S. crosnieri*

The slightly high lipid content of female *S. crosnieri* suggests that females at spawning season need good nutritional conditions, and transfer lipids to their eggs (sample No. 3, 53.4 ± 0.2%, Table 2) in a manner similar to marine common crustaceans [27–29]. The lipid classes of *S. crosnieri*, whose body lipids contain a high level of neutral TAG lipids (sample No. 1–2, Table 2), differed from those of other vent crustaceans, such as shrimps *Microcaris fortunata* and *Rimicaris exoculata*, which have high levels of wax esters as depot lipids [30, 31]. In spite of the difference between crab TAG and shrimp wax esters, the consistently high levels of both their depot neutral lipids is a common feature of vent crustaceans, and this finding suggests similar high nutritional levels, which imply abundant food resources in the vent habitat. Similar to other reports about invertebrate PE [32, 33], the *S. crosnieri* PE also contained noticeable levels of plasmalogen-type PE. This trend was similar to those in crustacean lipids whose PE contained comparatively high levels of plasmalogens (37.5–69.4%) [32].

High Levels of n-7 MUFA in Depot TAG of *S. crosnieri* Lipids

Similar to some bacterial fatty acids [34, 35], high levels of n-7 MUFA were observed in all *S. crosnieri* TAG. In

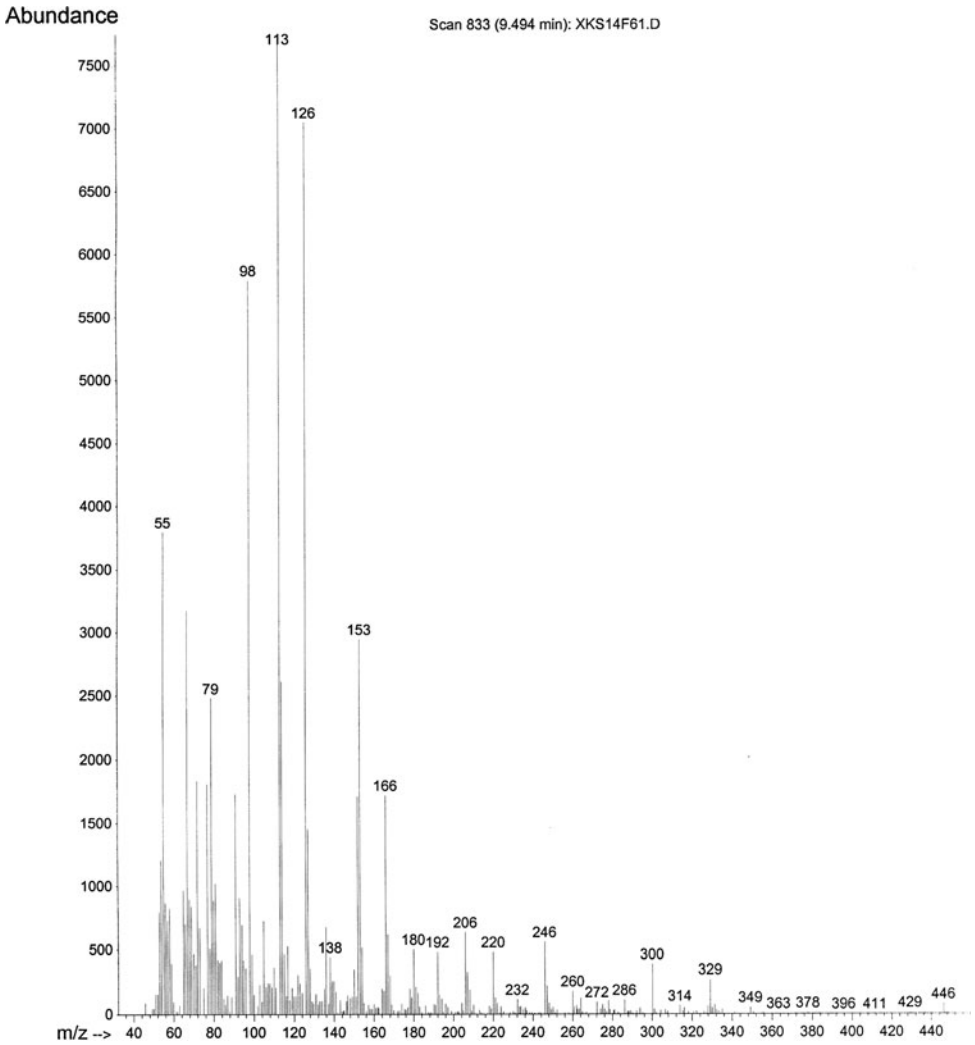

Fig. 9 The MS peaks (9.494 min, Scan No. 833) of the DMOX derivative of 18:4n-4,7,10,13 are M^+-329, 314, 300, 286, 272, 260, 246, 232, 220, 206, 192, 180, 166, 153, 136, 126, 113 (*base peak*), and three pairs of the peaks (M-272/M-260, M-232/M-220, and M-192/M-180) are, respectively, reflected by three double bonds; Δ-14 (n-4), Δ-11 (n-7) and Δ-8 (n-10), and a pair of the peak (M-153/M-136) shows a Δ-5 (n-13) double bond

particular, two short-chain n-7 MUFA (16:1n-7 and 18:1n-7: both more than 10% of TFA) were determined as major MUFA in *S. crosnieri* body TAG, similar to those in various vent animal lipids (neutral lipids for shrimp, *R. exoculata* [31]; for a clams, *Calyptogena* spp. [9, 36]; for mussels, *Bathymodiolus* spp. [10, 36, 37]; and for gastropods, *Ifremeria nautilei* [23] and *Alviniconcha hessleri* [38]). Similar trends are also found in total lipids of vent animals (total lipids for crabs, *Munidopsis subsquamosa* [39] and *Bythograea thermydron* [39]; for shrimp, *M. fortunata* [30]; for worms, *Ridgea piscesae*, *Protis hydrothermica* [40], and *Riftia pachyptila* [39]; for clam, *Calyptogena pacifica* [41]; and for mussels, *Bathymodiolus* spp. [42]). For adaptation to deep-sea low temperatures (4.6 °C, Table 1), high levels of MUFA are more advantageous than are those of saturated fatty acids [43]. 18:1n-7, which might be directly derived from C_2 elongations of 16:1n-7 as a parent acid [1] or by an exceptional anaerobic pathway of bacteria [34], was determined as a major MUFA in *S. crosnieri*, while stearic acid (18:0) was detected at a low level (0.9–1.4%). In general, two n-9 MUFA (18:1n-9 and 20:1n-9) are observed as major MUFA in marine deep-sea animal lipids [8, 44–46] because almost all animals biosynthesize long-chain MUFA mainly by derivation from 18:0 with a reaction of the same Δ-9 desaturase through a normal oxygen-dependent pathway [34, 35]. In contrast, some species of bacteria, such as *Thiobacillus* A2 [47] and *Paracoccus versutus* [48], mainly produce 18:1n-7 in their lipids. The similarity to the n-7 MUFA in the bacteria, as well as the significant presence of 18:1n-7 in *S. crosnieri* TAG (Table 3), indicate that this crab depends on the above types of bacterial lipids. It is known that the crab assimilates several species of sulfur-oxidizing bacteria [19–21] that inhabit the mat of long, silky setae on the crab body as exosymbionts. Both ecological and chemical aspects suggest that one main food source of the crab is these vent bacteria [19–21].

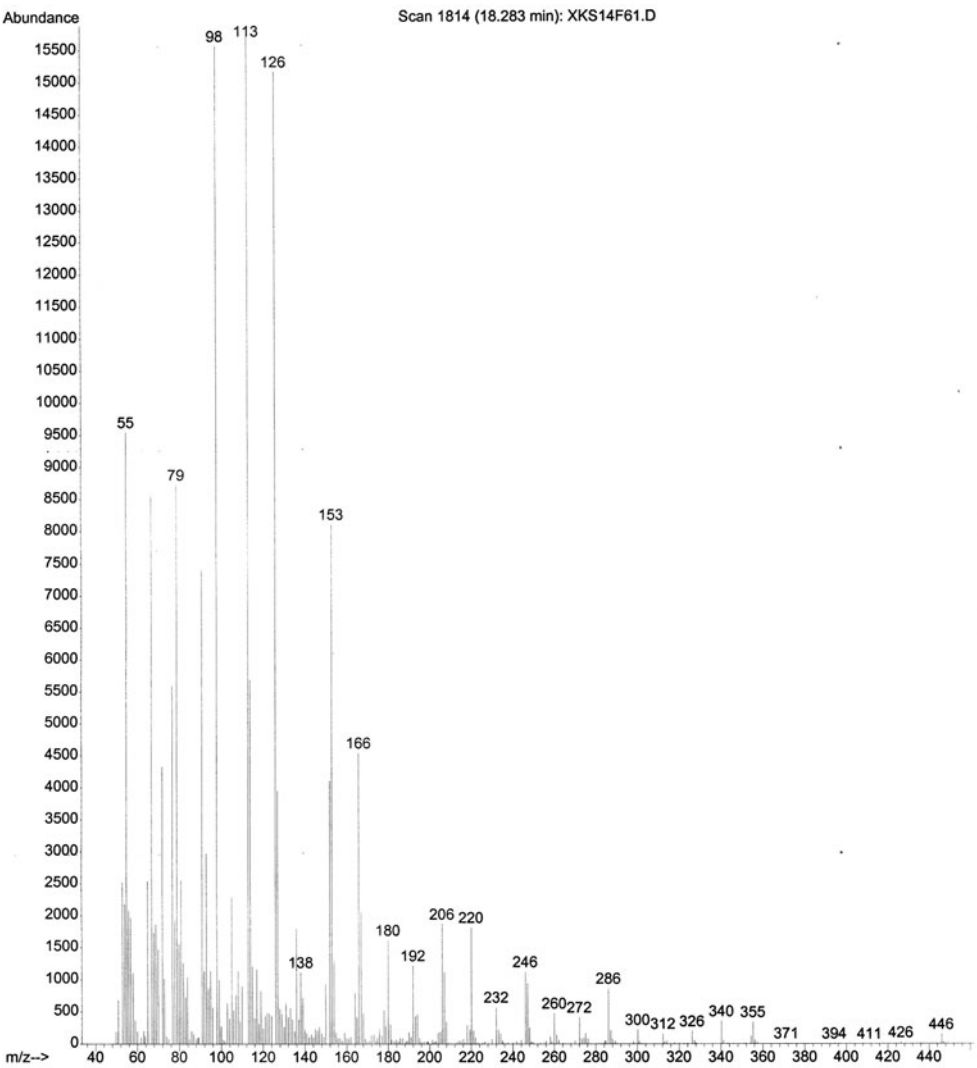

Fig. 10 The MS peaks (18.283 min, Scan No. 1814) of the DMOX derivative of 20:5n-6, 9,12,15,18 are M^+-355, 340, 326, 312, 300, 286, 272, 260, 246, 232, 220, 206, 192, 180, 166, 153, 136, 126, 113 (*base peak*), and four pairs of the peaks (M-312/M-300, M-272/M-260, M-232/M-220, and M-192/M-180) are, respectively, reflected by four double bonds; Δ-17 (n-3), Δ-14 (n-6), Δ-11 (n-9) and Δ-8 (n-12), and a pair of the peak (M-153/M-136) shows a Δ-5 (n-15) double bond

High Levels of Various n-4 PUFA in *S. crosnieri* Depot TAG

Marine animals at the higher trophic levels in the marine food chain generally contain significant levels of DHA and EPA even in their TAG [1, 4] because they have a chance to take these long-chain n-3 PUFA and accumulate them as needed. Different from the high levels of the n-3 PUFA in common marine animal TAG, the main PUFA in the *S. crosnieri* TAG only consist of short-chain (C_{14}–C_{18}) low unsaturated (mono, di, and tri) n-4 family methylene-interrupted PUFA, with trace levels of EPA, 22:5n-3 (docosapentaenoic acid), and DHA. This indicates that the food source of the crab is primarily bacterial and that the symbionts supplying nutrition to the crab are able to make simple MUFA, dienoic acids, and short-chain PUFA.

Four major PUFA in the crab TAG (Table 3) were 16:2n-4 (Fig. 5), 18:2n-4 (Fig. 6), 18:2n-7, and 18:3n-4 (Fig. 7) and these unusual n-4 family PUFA have already been found in vent shrimps and mussels [10, 30, 31]. For example, *Bathymodiolus* mussels, bresilioid shrimp, and vent worms have the same n-4 and n-7 methylene-interrupted PUFA (16:2n-4, 18:2n-4, 18:2n-7, 18:3n-4, 18:3n-7, and 20:3n-7) at small levels [10, 31, 40, 42]. As for the unique n-4 family PUFA in vent crustacean lipids, Pond et al. [31] found small levels of 18:2n-4 and 18:3n-7 in bresilioid shrimp and 18:2n-4 in another vent shrimp [30]. All four major n-4 family PUFA with various other n-4 family PUFA and n-7 MUFA were common in some *Bathymodiolus* mussels previously reported [10, 42]. Similarly, some vent bivalves have many unknown PUFA [36–38, 41] whose double bond positions were undetermined. These might correspond to n-4 family PUFA [9, 10].

In particular, two *Bathymodiolus* mussels (*Bathymodiolus japonicus* and *Bathymodiolus platifrons*) have the same n-4 and n-7 methylene-interrupted PUFA as *S. crosnieri* TAG [10]. The similarity of all major fatty

acids in TAG between the crab and these mussels suggests the similarity of their symbionts or a strong trophic relationship between them. High levels of n-4 PUFA in crab TAG also suggest that methanotrophic bacterial lipids, which pass through vent *Bathymodiolus* mussels, are a primary source of key nutrition for the crab. If the crab can prey on polychaetes [20], it can also take parasitic polychaetes from the mussels. Otherwise, *S. crosnieri* may directly prey on mussel carcasses or indirectly use nutrition originating from mussels and their symbionts because many crabs are regularly observed on *B. platifrons* beds (Fig. 3). If not, the lipid characteristics of the chemosynthetic exosymbionts (*Beggiatoa*-type filamentous bacteria of the crab) may be implausibly close to those of the *Bathymodiolus* endosymbionts [16].

Significant Levels of Unusual n-3 Short-Chain PUFA, 16:2n-3 in *S. crosnieri* Depot TAG

Different from that of all other marine animals, the fatty acid composition of *S. crosnieri* TAG contained significant levels of unusual short-chain n-3 PUFA (16:2n-3, Fig. 8) with trace levels of normal n-3 and n-6 PUFA. The exosymbiotic bacteria probably biosynthesize the 16 carbon n-3 fatty acid because in all other organisms have it is at non-detectable levels and no sufficient sources for the acid have been reported in the literature. Some vent chemosynthetic bacteria produce noticeable levels of various short-chain n-4 and n-6 fatty acids, such as 16:1n-6, 16:2n-4, 16:3n-3, 18:1n-6, 18:2n-4, and 18:2n-6 [30, 31, 38]. Therefore, it is thought that the symbionts of *S. crosnieri* might be able to make 16:2n-3.

The same n-3 and n-4 PUFA in *S. crosnieri* egg TAG observed at a level similar to its body TAG suggests that the crab transfers various PUFA of the body depot lipids to its ovary TAG as is (Table 3). However, higher levels of MUFA (16:1n-7, 18:1n-7, and 18:1n-9) in egg TAG were found compared with those lower levels of short-chain fatty acids (12:0, 13:0, 14:0, 12:1n-8, and 14:1n-9) in the body TAG. This suggests that MUFA are the most important energy source for the larvae, and that *S. crosnieri* selectively accumulates the MUFA, similar to those in other ordinary deep-sea organisms [27, 28, 44–46].

High Levels of n-4 PUFA in Tissue Phospholipids of *S. crosnieri*

Compared with noticeable levels of short-chain fatty acids (12:0, 13:0, and 14:0) in the TAG, 16:0 and 18:0 were the major saturated fatty acids in both body PE and PC. This fact indicates that the crab is able to elongate fatty chains in its tissues by using C_2 elongase.

Similar to *S. crosnieri* depot TAG, the same four n-4 family PUFA (16:2n-4, 18:2n-4, 18:2n-7, and 18:3n-4) were observed as major acids in its phospholipids (Table 3). Furthermore, n-4 tetraenoic PUFA,18:4n-4 (Fig. 9), which had already been found in the *B. platifrons* lipids [10], were observed at noticeable levels in the *S. crosnieri* body PE (Table 3). Similar to the high levels of various n-4 family PUFA in the *Bathymodiolus* mussel lipids, the crab has high levels of the same n-4 PUFA both in its depot and tissue lipids. The crabs inhabit mussel beds, and both the crabs and mussels accumulate n-4 PUFA in their phospholipids.

High Levels of n-3 and n-6 PUFA in *S. crosnieri* Tissue Phospholipids

The n-4 family PUFA, which were found in *S. crosnieri* lipids, have been characteristically found in some vent bivalve lipids [9, 10, 42], entirely different from various n-3 and n-6 PUFA found in the lipids of common crustaceans in normal marine food webs [27–29]. Contrary to the lipid profiles of these specific vent bivalves [9, 10, 42], significant levels of long-chain PUFA (ARA, EPA, and DHA) were simultaneously found as major PUFA in *S. crosnieri* PE (Table 3), which is similar to that in vent crustaceans [30, 31, 39]. Although high levels of n-3 and n-6 PUFA were found in *S. crosnieri* polar lipids, its fatty acid composition differed from those in pelagic marine animals, which have the same n-3 and n-6 PUFA without n-4 PUFA. Deep-sea animals require sufficient levels of PUFA in their plasma membrane lipids to maintain fluidity [40], either because of the low seawater temperature of the habitat [49, 50] or due to close packing in membranes under high pressure [2, 51]. *S. crosnieri* uses both n-4 family PUFA and n-3 and n-6 PUFA in its cellular membrane phospholipids for its plasma membrane fluidity. It is different from vent bivalves [9, 10, 36, 37, 41, 42], which have small or non-detectable levels of these n-3 and n-6 PUFA. High levels of total PUFA in crab phospholipids (44.3–47.7% for PE and 25.0–28.6% for PC) suggest its adaptation to extremely high pressure and low seawater temperature (Table 1) because measured seawater temperatures and depths around the colonies were about 4.5–4.7 °C and more than 950 m, respectively [43, 51]. Furthermore, significantly high levels of ARA, EPA, and DHA contained in *S. crosnieri* PE were markedly different from those in its TAG, which contained only 16:2n-3 without DHA. Some other vent crustaceans also have significant levels of these n-3 and n-6 PUFA in their polar lipids (for vent crabs [39] and for vent shrimps [30, 31]) and these findings suggest that both high n-3 and n-6 PUFA levels in their polar lipids is common for vent crustaceans. Although tubeworms and vent gastropods also contain high levels of n-3 and n-6 PUFA in their lipids similar to those in the lipids of vent crustaceans, their n-3 PUFA generally consist of only

ARA and EPA without DHA [23, 38–40]. These phenomena imply that crustaceans with their symbionts are able to produce various n-3 PUFA, while vent mollusks and tubeworms with their symbionts are unable to biosynthesize DHA, which is not essential for them.

Biosynthesis of DHA in *S. crosnieri* tissue Levels

Long-chain n-3 PUFA are often found in the cells of deep-sea barophilic prokaryotes with high levels of n-7 MUFA [2, 51]. These barophilic bacteria heterotrophically biosynthesize DHA and EPA by using organic matter from surface or intestinal matter of deep-sea animals. Compared with the negligible levels of long-chain n-3 and n-6 PUFA in *S. crosnieri* depot TAG, high ARA, EPA, and DHA levels were found in its polar lipids. This suggests that enzymatic biosynthesis and chemical modification of these PUFA occurs at the crab tissue level. Actually, high levels of EPA and DHA with low levels of 16:2n-3 in PE (12.2-14.4% for EPA and 3.4-4.8% for DHA) and PC (1.6–2.7% for EPA and 0.5–0.8% for DHA, Table 3) differed markedly from non-detectable levels of these PUFA (for EPA 0.2–0.2% and for DHA 0.0–0.2%) with significant levels of 16:2n-3 (4.7–5.3%) in the crab body TAG. This points to active accumulation or biosynthesis of ARA, EPA, and DHA in crab polar lipids after intake of short-chain n-3 PUFA, such as 16:2n-3. Otherwise, similar to deep-sea barophilic bacteria, some of the exosymbiotic bacteria might biosynthesize n-3 and n-6 PUFA in polar lipids for their plasma membrane fluidity [2, 3, 43, 51, 52]. Similar to pelagic crustaceans [53], *S. crosnieri* may biosynthesize DHA, in contrast with low n-3 PUFA essentiality for vent bivalves, which exclusively depend on symbiotic organisms making only n-4 family PUFA [9, 10]. Similarly, this trend is found in significant DHA levels in other vent crabs [39] and mixotrophic polychaeta [40, 54]. Different from strong trophic linkages between some vent bivalves and their symbionts through n-4 family PUFA, *S. crosnieri* utilize nutrition from both symbiotic n-3 and n-6 PUFA and n-4 family PUFA of the prey mussels. This finding suggests similarity of the filamentous symbionts and chemosynthetic bacteria in vent gastropods (*I. nautilei* and *A. hessleri*) [23, 38] or vent crabs (*M. subsquamosa* and *B. thermydron*) [39], whose lipids contained high levels of both n-3 and n-6 PUFA. The unique fatty acid composition of mixed n-3, n-4, and n-6 PUFA in *S. crosnieri* lipids indicates the existence of a specific vent crustacean utilizing both filamentous symbionts and outside mussel beds. Compared with high levels of n-3, n-4, and n-6 PUFA in *S. crosnieri* body phospholipids, slightly higher levels of n-4 family PUFA with lower levels of n-3 and n-6 PUFA in egg PE were found. These findings suggest that the n-3 and n-6 PUFA were biosynthesized or concentrated in the crab tissues concerned with PE and the body polar lipids were transferred to the ovary, similar to its depot lipids. It is thought that both these normal n-3 and n-6 PUFA with unusual n-4 family PUFA are important cell membrane lipids for the crab and its larvae (Table 3).

Acknowledgments The author thanks Mikiko Tanaka and Akihito Takashima for their skilled technical assistance. The author also thanks the captains and crews of the Research Vessel "*Natsushima*" and the submersible "*Shinkai 2000*" operation teams for their cooperation and enthusiasm throughout the work. He also recognizes the Japan Marine Science and Technology Center for providing us with the opportunity to use their submersible.

Received: 20 January 2011 / Accepted: 20 April 2011 / Published online: 7 May 2011

Abstract This study was conducted to investigate the effects of fish oil (FO) supplements on fatty acid composition and the expression of Δ6 desaturase and elongase 2 genes in Jade Tiger abalone. Five test diets were formulated to contain 0.5, 1.0, 1.5, 2.0 and 2.5% of FO respectively, and the control diet was the normal commercial abalone diet with no additional FO supplement. The muscle, gonad and digestive glands (DG) of abalone fed with all of the five test diets showed significantly high levels of total n-3 polyunsaturated fatty acid (PUFA), eicosapentaenoic acid (EPA), docosapentaenoic acid n-3 (DPAn-3), and docosahexaenoic acid (DHA) than the control group. In all three types of tissue, abalone fed diet supplemented with 1.5% FO showed the highest level of these fatty acids ($P < 0.05$). For DPAn-3 the higher level was also found in muscle and gonad of abalone fed diet supplemented with 2% FO ($P < 0.05$). Elongase 2 expression was markedly higher in the muscle of abalone fed diet supplemented with 1.5% FO ($P < 0.05$), followed by the diet containing 2% FO supplement. For Δ6 desaturase, significantly higher expression was observed in muscle of abalone fed with diet containing 0.5% FO supplement ($P < 0.05$). Supplementation with FO in the normal commercial diet can significantly improve long chain n-3 PUFA level in cultured abalone, with 1.5% being the most effective supplementation level.

Introduction

The long chain n-3 polyunsaturated fatty acids (PUFA) particularly, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are associated with a broad range of health benefits including reducing the risk of coronary

heart disease [1], lowering blood pressure [2] and plasma triacylglycerol level [3], reducing the risk of colorectal cancer [4] and breast cancer [5]. In addition, they have also been found to play a role in reducing the risk of Alzheimer's disease [6], depression and schizophrenia [7]. A more recent study also suggested that long chain n-3 PUFA have the potential to improve calcium absorption in the intestine, reduce bone demineralization and inflammatory factors [8].

Blacklip abalone (*Haliotis rubra*), greenlip abalone (*H. laevigata*) and hybrid abalone (*H. laevigata x H. rubra*) are the three main types of abalone farmed in Australia [9], and like other seafood, they are a good source of long chain n-3 PUFA [10–12]. However, a previous study reported that cultured Australian blacklip abalone fed an artificial diet showed lower concentrations and compositions of total n-3 PUFA, EPA, docosapentaenoic acid (DPAn-3) and alpha linolenic acid (ALA) than wild abalone [12]. Dunstan et al. [9, 10] found that the muscle of wild adult greenlip abalone fed a natural diet of macroalgae contained higher EPA, DPAn-3 and total n-3 PUFA proportion compared to juvenile cultured hybrid abalone fed artificial diets. Similarly wild adult blacklip abalone fed a natural diet of macroalgae contained a higher proportion of DPAn-3 compared to hybrid abalone fed artificial diets. In addition Dunstan et al. [10] reported that muscle of juvenile cultured greenlip and hybrid abalone fed an artificial diet showed lower levels of EPA, DPAn-3 and total n-3 PUFA than those fed green algae. Lower level of ALA was also recorded in juvenile hybrid abalone fed an artificial diet compared to the juvenile cultured greenlip abalone fed green algae.

Fatty acid biosynthesis in fish has been well studied and it has been found that the overall conversion of ALA to highly unsaturated fatty acids (HUFA) occurs poorly in the marine species [13, 14]. For abalone, however, there is no direct evidence on the pathways of fatty acid biosynthesis. Available information suggested that *H. discus hannai* may have the capacity to synthesize EPA and DHA from ALA through elongation and desaturation [15]. Another study also suggested that *H. fulgens* is capable of desaturation and elongation of ALA to EPA [16]. Fatty acid desaturases and fatty acid elongases were found to be critical in the biosynthetic pathways of highly unsaturated fatty acids from shorter chain PUFA [17]. Desaturases genes have been cloned and characterized from a number of fish, including Δ6 desaturase from rainbow trout [18], and Δ5 and Δ6 desaturase from Atlantic salmon [19]. Genes coding for proteins specifically involved in the elongation of HUFA biosynthesis have been cloned from a number of fish including fresh water zebra fish, carp and tilapia, the salmonoids, rainbow trout and Atlantic salmon, and marine fish, including cod, turbot and sea bream [20–22].

This study investigated the effects of feed supplemented with fish oil on fatty acid composition in muscle, gonad and digestive gland (DG) of cultured adult female jade tiger hybrid abalone. In addition the effects of FO supplementation on fatty acid Δ6 desaturase and elongase 2 gene expressions in muscle tissue of this animal were also studied. These data will provide useful information for seafood and abalone aquaculture industries. To the best of our knowledge, there is no information available on desaturase and elongase gene expression in abalone.

Materials and Methods

Experimental Diets

A commercial diet (Adam and Amos Pty Ltd) of Australian abalone was used in the formulation of experimental diets. Diet 1 (control diet) was the normal commercial abalone diet with no additional fish oil (FO) supplement. Diets 2–6 were supplemented with 0.5, 1, 1.5, 2, and 2.5% FO respectively. Fatty acid composition and total lipid content of the experimental diets are shown in Table 1. The control diet contained 57.6% total saturated fatty acid (SFA), 5.6% monounsaturated fatty acid (MUFA) and 36.8% polyunsaturated fatty acid (PUFA). The diets with FO supplements (diets 2–6) contained 21–24.7% total SFA, 18.6–22.9% total MUFA, and 52.3–60.3% total PUFA. The composition of EPA, DPAn-3, DHA and total n-3 PUFA of the diets with FO supplement were gradually increased in the experimental diets. The control diet contained 0.42 g/100 g total lipids while other diets contained lipids ranging from 1.10 to 2.72 g/100 g. All of these experimental diets were stored at 4 °C until use.

Abalone and Experimental Conditions

Ninety cultured adult Jade Tiger abalone with an average body weight of 44.0 ± 0.3 g were obtained from Great Southern Waters abalone farm, Victoria, Australia. Abalone were acclimatized to laboratory conditions and fed a normal commercial diet for a week before initiation of the feeding experiments. Each individual abalone was gently blotted dry on a paper towel, tagged, measured and weighed, and then five abalone were placed into a 30 L plastic aquarium supplied with filtered seawater via a flow through system, and assigned one of the six experimental diets. There were three replicates for each of the six dietary treatments. All animals were maintained under a 24 h dark photoperiod. Temperature was maintained at 16 °C throughout the feeding trial. Salinity (31–35 ppt), dissolved oxygen (no less than 6 mg/L), nitrite, ammonia and pH (7–8) were monitored daily. Aquaria were cleaned three

times a week. The experimental diets were hand-fed every day in the evening at a rate of 2% of body weight. At the end of the experiment, abalone were fasted for 1 day and collected from their aquaria. They were then measured and weighed. Fourteen abalone per treatment were sampled to obtain muscle, gonad and DG tissues for lipid and fatty acid analyses. Four samples from each treatment group were used for investigation of gene expression. This feeding trial was conducted for 90 days.

Analyses of Lipid and Fatty Acids

Five grams of fresh muscle, gonad and digestive gland (DG) were cut finely and left in chloroform to extract the lipids overnight in the dark: methanol (2:1, v/v) which contained 10 mg/L butylated hydroxytoluene was an antioxidant. The lipid extracts were washed according to the Folch procedure [23]. The solvent containing lipids were evaporated under vacuum in a rotary evaporator (Heidolph Standard evaporator, VV2000). The lipid content was determined gravimetrically [24].

Fatty acid methyl esters (FAME) were prepared by saponification of approximately 10 mg of lipid, using KOH (0.68 mol/L in methanol), followed by esterification with 14% boron trifluoride in methanol, with 0.25 mg of tricosanoic acid (23:0) added as an internal standard. FAME were separated by a capillary gas liquid chromatograph (Varian 3400) equipped with an auto sampler and a flame ionization detector (FID) using a 50 m × 0.32 mm (I.D) fused silica bonded phase capillary column (BPX70, SGE, Melbourne, Australia). The column oven was programmed from 140 to 220 °C at 5 °C/min and held for 3 min. The oven temperature was then increased to 260 °C at a rate of 8 °C/min and held for 8 min. Helium was used as the carrier gas at a flow rate of 1.6 mL/min and a linear velocity 43 cm/s. The injector and detector were maintained at 250 and 300 °C respectively. Fatty acids were identified by comparison of retention times with those of standard mixtures of fatty acid methyl esters (GLC reference standard 403) and the results were calculated using response factors derived from chromatograph standards of known composition (Nu-Chek-Prep, Elysian, MN, USA).

RNA Extraction and Quantitative Polymerase Reaction

After the completion of the feeding trial, muscle samples of four abalone were randomly selected from each treatment group. They were then frozen immediately in liquid nitrogen and stored at −80 °C prior to RNA extraction. Total RNA was extracted from 50 mg of muscle tissue using TRI reagent (Molecular Research Center, USA) according to the manufacturer's specification. The total RNA concentration was determined by A260/A280 measurement. One microgram of total RNA was reverse transcribed into cDNA using AMV reverse transcriptase first strand cDNA synthesis kit (Marligen Biosciences, USA). The expression of Δ-6 desaturase and elongase 2 genes in muscle tissue from abalone fed with the different experimental diets were studied by real-time polymerase chain reaction (RT-PCR). PCR primers known to be specific for, Δ6 desaturase (F 5′-ACCTAGTGGCTCCTCTGGTC-3′ and R 5′-CAGATCCCCTGACTTCTTCA-3′, AF301910) and elongase 2 (F 5′-GAACAGCTTCATCCATGTCC-3′ and R 5′-TGACTGCACATATCGTCTGG-3′, AY605100) were used for PCR amplification of cDNA. ß-actin (F 5′-CAAGCAGGAGTACGACGAGT-3′ and R 5′-CTGAAG TGGTAGTCGGGTGT-3′, AJ438158) was used as a housekeeping gene for normalizing mRNA levels of the

target genes. The amplification of cDNA samples was carried out using the SYBR green PCR kit. Fluorescent emission data were captured and mRNA levels were analyzed using the critical threshold (CT) value [25]. Thermal cycling and fluorescence detection were conducted using the Biorad IQ50 sequence detection system (Biorad USA).

Statistical Analyses

Results are presented as means ± SD. The data were tested for homogeneity of variances using a Levene test. All data were analysed by one-way analysis of variance (ANOVA) to determine significance of differences among total lipid content, fatty acid composition and gene expression of abalone fed the different experimental diets. Tukey HSD tests were used for post hoc comparison. P values of less than 0.05 were considered statistically different. Statistical analysis was performed using the SPSS package (version 17.0).

Results

The fatty acid composition of muscle, gonad and DG of Jade Tiger hybrid abalone fed different experimental diets are given in Tables 2, 3 and 4. In general, fatty acid profiles

Table 2 Fatty acid composition (mol %) and total lipid content (g/100 g wet tissue) of muscle in Jade Tiger abalone fed different experimental diets for 12 weeks ($n = 10$)

of abalone tissue reflected the fatty acid profiles of experimental diets (Table 1). Feed supplemented with FO at levels between 0.5 and 2.5% (diets 2–6) showed significant effects on n-3 PUFA composition in all three types of tissues (Tables 2–4). Higher levels of total PUFA, n-3 PUFA, EPA, DPAn-3, and DHA ($P < 0.05$) were observed in all the groups fed with diets supplemented with FO, with the most significant improvement being recorded from the group fed the diet containing 1.5% FO supplement (diet 4). For DPAn-3 the higher level was also found in muscle and gonad of abalone fed diet supplemented with 2% FO (diet 5) ($P < 0.05$). The higher ALA level was found in the muscle of abalone fed diets containing 1–2% FO (diets 3, 4 & 5). In gonad and DG, higher ALA was recorded in abalone fed diet containing 1.5% FO (diet 4).

FO supplementation also improved the n-3/n-6 PUFA ratio in all three types of tissue. In muscle tissue all of the five treatment groups fed the diets with FO supplement showed a significantly higher ratio ($P < 0.05$) than the control group (Table 2). For gonad, no marked differences were recorded between the control group and the five treatment groups fed FO supplement (Table 3). The significantly higher ratio of n-3/n-6 PUFA in DG (Table 4) was found in abalone fed diets containing 1.0–2.5% FO supplements (diets 3–6).

There were no significant differences in the total MUFA composition between the six treatment groups in the

SFA saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids, *NMI* non-methylene-interrupted fatty acids

muscle. However, for gonad and DG higher MUFA level was recorded in abalone fed diet with 2.5% FO supplement (diet 6) ($P < 0.01$). In all three types of tissue, abalone fed the diets with FO supplements (diets 2–6) showed significantly lower SFA than the control group (diet 1) ($P < 0.05$) with diet containing 1.5% FO supplement (diet 4) being the most effective.

The total lipid content in muscle, gonad and DG are also shown in Tables 2–4. Muscle of abalone fed the five diets supplemented with FO contained significantly higher contents of total lipid than the control group ($P < 0.05$). The highest total lipid content was recorded in abalone fed diet containing 1.5% FO supplement (diet 4) with 1.40 g/100 g, 5.64 g/100 g and 6.05/100 g being recorded in muscle, gonad and DG respectively while the control group (diet 1) showed 1.24 g/100 g total lipid in muscle, 3.88 g/100 g in gonad and 3.44 g/100 g in DG ($P < 0.01$).

The expression of fatty acid elongase 2 and Δ6 desaturase genes in muscle tissue from abalone fed diets 1–6 are shown in Figs. 1 and 2. Values are expressed as arbitrary units of elongase and desaturase normalized against the expression levels of β-actin. For Δ6 desaturase, significantly higher expression was observed in the muscle of abalone fed diet 2 (with 0.5% FO supplement, $P < 0.05$). There were no significant differences between other treatment groups (Fig. 2). Elongase 2 expression was

significantly higher in muscle of abalone fed 1.5% FO (diet 4), followed by 2.0% FO (diet 5). No marked differences were recorded between the treatment groups fed diets containing 0.5, 1.0 and 2.5% FO (diets 2, 3 & 6) ($P > 0.05$) (Fig. 1).

Discussion

Abalone fed diets with fish oil supplement significantly improved the levels of total n-3 PUFA, EPA, DPAn-3 and DHA in Jade Tiger hybrid abalone. These results are consistent with previous reports on other abalone species, such as greenlip abalone (*Haliotis laevigata*) [9], green abalone (*Haliotis fulgens*) [16], Donkey ear abalone (*Haliotis asinine* Linne) [26] and *Haliotis discus hannai* Ino [15]. The present study showed that muscle, gonad and digestive gland (DG) of Jade Tiger abalone fed diet supplemented with 1.5% FO (diet 4) contained the highest levels of total n-3 PUFA, EPA, DPAn-3 and DHA. This might be attributed to the efficiency in utilization of dietary lipids by abalone. Abalone are herbivores and previous study showed that their lipid requirement is very low as they are highly efficient in utilizing lipids [31]. An optimal increase of FO in the diet has resulted in a higher n-3 PUFA profiles and growth rate. It has been reported that greenlip abalone showed an improved composition of long chain n-3 PUFA and optimal growth when fish oil levels are at 1.0–2.5% in the diets. Juvenile abalone, *Haliotis discus hannai* Ino also showed higher levels of EPA and DHA when diet supplemented with 2% FO [15].

In general the lipid level of balanced diets developed for abalone ranges from 1.5 to 5.0% [30]. Abalone showed a poor response to elevated lipid levels due to the lower capacity of dealing with high dietary oil and this might be attributed to the low digestibility of lipids in this animal [9, 16, 27–31]. This probably explains why at higher FO levels (2 & 2.5% as in diets 5 & 6) in the present study, the long chain n-3 PUFA, EPA and DHA tended to decrease in comparison with the effect of diet containing 1.5% FO. The similar results have also been reported from other herbivorous marine species [33, 34]. In addition a decreased utilization of dietary fat in juvenile cod (*Hexagrammos otakii* Jordan et Starks) with excessive dietary level of long chain n-3 PUFA has been reported [32]. In green abalone (*Haliotis fulgens*), maximum growth rates were obtained when they were fed a formulated feed containing 1.5% lipids [16]. The Japanese feed Nihon Kogyo contained only 1.5% lipid but produced significantly increased growth rates in abalone relative to those with 3% lipid [9]. In contrast, some species showed an improved growth rate at the higher lipid levels. In greenlip abalone, growth rates were improved when abalone fed diets containing 2.6 and 4.2% total lipids. Other diet with total lipid content of 3.8% also increased growth rates [9]. The dietary lipid level of 3.5% has been considered to be optimum level for Juvenile *Haliotis discus hannai* Ino [29]. It appears that the lipid requirements of abalone might be species specific although the overall range is lower in comparison with other animals. In our study the total dietary lipid contents ranged from 0.42 to 2.92% dry wt. The diet supplemented with 1.5% FO had 1.92% of total lipid and this probably is the optimal lipid level for Jade Tiger hybrid abalone and thus achieved the best outcome.

Study also showed that, addition of marine or vegetable oils to commercial abalone diets should be limited to 3% in order to maintain the optimal digestibility of nitrogen and

amino acids, and gross energy [34]. Formulated abalone diets from around the world contain a wide range of total lipid content (1–11% wet wt) [9]. In these diets, a large variation in fatty acid composition was evident. The diets containing high lipid level and no fish products are not recommended [9].

Abalone require n-3 and n-6 PUFA as essential fatty acids [46] with the n-3/n-6 ratio providing a broad indication of fatty acid utilization within the tissues. The foot muscle contained a high proportion of n-3 PUFA; whereas n-6 PUFA were more prominent in the gonad and DG. One of the abundant fatty acids in the diet, LA only formed a moderate component of the fatty acid fraction in the muscle but was more common in the gonad and DG. In the muscle, arachidonic acid (ARA, 20:4n-6) composition was higher but a lower level was found in the gonad and DG. In all three tissues the proportion of EPA was present in similar abundance, resulting in a relatively high EPA: ARA ratios in the gonad and DG. Dunstan et al. [9] reported that most of the tissue ARA originated from dietary linoleic acid (LA). Our results showed a similar trend. Although a high level of ARA may not be required for muscle growth, it may be required for oogenesis and embryogenesis. In agreement with our present results, Nelson et al. [45] also observed a higher ARA level in the muscle of *Haliotis fulgens* than in the gonad and DG. One of the less abundant n-3 PUFA in the diet, DPAn-3 formed a major component of n-3 PUFA fraction in the muscle but was less prominent in the gonad and DG. These results suggest that abalone may require less DPAn-3 in the gonad and DG to meet their physiological needs in comparison with muscle. Other possible explanation is that DPAn-3 in the gonad and DG may be converted to DHA through desaturase and elongase at a higher rate than in the muscle tissue. However further study is required to compare the level of gene expression in different tissues. Lower composition of DPAn-3 in the gonad and DG has also been reported for female green abalone [45], greenlip and blacklip abalone [47]. In general, the variation in LA, ARA, and DPAn-3 were largely responsible for the differences in n-3/n-6 ratio in tissues of Jade Tiger abalone. This may explain the differential proportion of n-3/n-6 ratio between the tissues in the present study. In our study all the five diets supplemented with FO have improved the n-3/n-6 PUFA ratio in the muscle. This is in agreement with the reports that muscle n-3/n-6 ratio is affected by dietary n-3 levels [9, 16, 35–44]. As muscle is widely used for human consumption, the higher n-3/n-6 PUFA ratio will improve the nutritional value of cultured abalone.

Previous studies showed that cultured abalone contained less long chain n-3 PUFA than wild abalone. The results of our study demonstrated that the muscle of abalone fed with diet containing 1.5% FO supplement can reach similar amounts of EPA, DPAn-3 and total n-3 PUFA as those in wild abalone [10, 12]. Dunstan et al. [10] reported that the muscle of wild greenlip abalone contained 0.2% DHA, 14.1% DPAn-3, 9.9% EPA, and 25.1% total n-3 PUFA, while wild blacklip abalone contained 0.3% DHA, 13.5% DPAn-3, 6.8% EPA, and 22.2% total n-3 PUFA. The study by Su et al. [12] also showed the similar composition of fatty acids in the muscle of wild blacklip abalone with DHA, DPAn-3, EPA, and total n-3 PUFA at 0.4, 10.1, 8.8 and 20.5% of total fatty acids, respectively. As shown in Table 2, we found that DHA, DPAn-3, EPA and total n-3 PUFA levels were at 4.9, 14.3, 10.4 and 30.8% of total fatty acids respectively in the muscle of abalone fed a diet with a 1.5% FO supplement. These results are comparable with the published data on wild abalone. In addition a higher DHA level was observed in all three types of tissue from our study. Thongrod et al. [26] showed that cultured abalone (*H. asinina,* Linne) fed a diet supplemented with FO contained similar long chain n-3 PUFA to wild-caught abalone. The higher DHA level recorded in the present study might be attributed to the higher DHA levels in the experimental diets than in the natural macroalgae diets reported in the previous studies [10, 12, 45]. The macroalgae diet of the adult wild greenlip and blacklip abalone contained 0.7% DHA and produced only 0.2% to 0.4% DHA in the muscle tissue [9, 10, 12]. Uki et al. [27] found that the level of DHA in abalone tissue increased when abalone were fed a diet containing more DHA although DPAn-3 remained the most abundant long chain n-3 PUFA [46]. The higher DHA level in our study also implicates that Jade Tiger abalone can accumulate DHA directly from dietary sources and may also have the ability to bio-convert 18-carbon n-3 PUFA, such as ALA, to EPA and DHA to a certain extent. The low level of ALA in abalone tissue at the present study supports this possibility. Wei et al. [15] suggested that *H. discus hannai* has the capability to synthesize EPA and DHA from ALA through elongation and desaturation. A similar study by Durazo-Beltran et al. [16] with *H. fulgens* also suggested that abalone is capable of desaturation and elongation of ALA to EPA.

Data presented here represent new information on the Δ6 desaturase and elongase 2 gene expression in abalone. The expression of Δ6 desaturase and elongase 2 involved in the highly unsaturated fatty acid biosynthetic pathway varied in muscle of abalone fed with the different experimental diets (Figs. 1, 2). Elongase 2 gene expression was significantly increased in abalone fed 1.5% FO. The increase in elongase 2 gene expression positively coincides with the highest EPA, DPAn-3 and DHA levels in muscle of abalone fed with this diet. This may indicate the metabolism of ALA and further suggests that abalone have the ability to convert ALA to EPA, DPAn-3 and DHA to a certain extent. The highest level of elongase gene

expression in the abalone fed with 1.5% FO diet may also relate to the direct conversion of EPA to DPAn-3 and then DHA. Dietary EPA bypass the initial rate limiting Δ6 desaturase step in the n-3 long chain PUFA biosynthetic pathway and this may lead to DPAn-3 and DHA being synthesized. Abalone fed the diet with the highest level of FO supplement (2.5%) did not produce the highest level of elongase 2 expression. This may suggest that abalone have a limited capacity to utilize and/or a limited requirement for long chain n-3 PUFA [9] and an elevated level of these fatty acids in the diet may decrease elongase 2 expression. Conflicting results have been reported on fatty acid elongase gene expression in salmon liver with the replacement of dietary FO with vegetable oil [17, 52]. Fatty acid elongase gene expression increased in liver with graded replacement of linseed oil [17]. However, in a more recent trial, a high level of elongase gene expression in salmon fed FO compared to salmon fed with vegetable oil has been reported [52]. This is in agreement with our findings that, FO inclusion in abalone increased elongase 2 expression.

Gene expression of Δ6 desaturase showed a significant increase in muscle of abalone fed the diet containing the 0.5% FO supplement. This result does not coincide with the highest EPA, DPAn-3 and DHA levels in abalone muscle. Previous studies demonstrated that dietary concentrations of substrates such as ALA had a positive correlation with the expression of the fatty acid desaturase gene [17, 48]. The reason that the diet containing 0.5% FO (diet 2) increased expression of desaturase compared to the control diet in the present study may also relate to the high level of ALA in the diet. The high level of dietary n-6 PUFA relative to n-3 PUFA in the diet containing 0.5% FO, contributed to a high n-6/n-3 ratio, particularly LA to ALA ratio in the diet. This may have resulted in a smaller rise in EPA, DPAn-3 and DHA levels in tissue due to the competitive inhibitory effect of n-6 and n-3 at the level of initial desaturation reaction. Miller et al. [48] also suggested that increased n-6 PUFA in fish fed a diet containing a high level of n-6 PUFA is probably associated with the markedly higher n-6/n-3 fatty acid ratio in the white muscle and liver of fish and increased competition between n-6 and n-3 PUFA for desaturase enzymes. It is also known that the conversion rate of ALA to long chain n-3 PUFA is affected by the fatty acid composition of the diet. In particular the presence of LA has been demonstrated to compete with the ALA for the desaturase and elongase enzymes [14, 49]. Our results suggest that essential fatty acids such as ALA can be metabolized into EPA, DPAn-3 and DHA. Also, EPA may be converted to DPAn-3 and DPAn-3 to DHA to certain extent. This process involves sequential desaturase (adding double bonds) and chain elongase (adding carbon atoms to the hydrocarbon backbone [50]. The enzymatic competition between n-6 and n-3 PUFA require dietary balance in the precursor fatty acids, as an overabundance in one will lead to a relative deficiency in the metabolites of the other and vice versa [14, 49].

Studies also showed that dietary fatty acids, environmental factors, and the life cycle can affect elongase and desaturase activity [17, 51, 52]. Each step along the long chain n-3 PUFA pathway depends on the amount of substrate. Therefore, increased elongase 2 and Δ6 desaturase gene expression could be influenced by increased dietary concentrations of substrate ALA. The elongase and desaturase genes also act upon the n-6 pathway. However, fatty acid profiles and the Δ6 desaturase and elongase 2 gene expression of this study indicate that there is a preference for the n-3 pathway. Available information suggested that abalone have the capacity to synthesize EPA and DHA from ALA through elongation and desaturation [15, 16]. These few studies were all based on the feeding trial which involved only dietary lipid sources. Our results on the Δ6 desaturase and elongase 2 gene expression in abalone provide further evidence on biosynthesis pathway of long chain n-3 PUFA. Although actual enzymatic activities of both genes were not measured, studies on several fish species have shown that expression of Δ6 desaturase and elongase mRNA correlated with their enzymatic activities [53–55]. To the best of our knowledge, this is the first study on abalone gene expression. Future studies on the gene expression in other tissues/organs such as the DG as well as the analysis of actual enzymatic activities of both Δ6 desaturase and elongase 2 are required to further support the suggestion of HUFA biosynthesis activities within the muscle.

In conclusion, the present study demonstrated that supplementation with FO in the normal commercial diet of abalone can increase the level of long chain n-3 PUFA in cultured abalone. FO supplementation at a concentration of 1.5% appears to achieve the best outcome. The study also found that Jade Tiger abalone fed a diet containing 1.5% FO supplement contained similar amounts of EPA, DPAn-3 and total n-3 PUFA, and even higher DHA than in wild-caught abalone. In addition, the expression of Δ6 desaturase and elongase 2 genes in muscle of Jade Tiger abalone could be enhanced with FO supplementation. Elongase 2 expression in the muscle of abalone fed with the diet containing 1.5% FO supplement coincided with the level of long chain n-3 PUFA in the tissue. Overall, these findings suggest that abalone have the ability to synthesize the highly unsaturated fatty acids in their tissues and further studies to detail the activity of elongation/desaturation pathway is warranted.

Acknowledgments This project was funded by a postgraduate scholarship at Victoria University, Australia. We thank the Great Southern Waters abalone farm, Victoria, Australia for suppling

abalone samples and ADAM and AMOS Pty Ltd, SA, Australia for their assistance in formulating the experimental diets. The authors also thank Melrose Laboratories Pty Ltd, Victoria, Australia for the supply of fish oil, and Assoc. Prof. David Cameron-Smith, Deakin University, Victoria, Australia for providing the PCR primers.

Abstract Fish oils are rich in omega-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFA), predominantly 20:5n-3 and 22:6n-3, whereas vegetable oils contain abundant C_{18}-PUFA, predominantly 18:3n-3 or 18:2n-6. We hypothesized that replacement of fish oils with vegetable oils would increase the oxidative stability of fish lipids. Here we have used the long established and easily cultivated FHM cell line derived from the freshwater fish species fathead minnow (*Pimephales promelas*) to test this hypothesis. The FHM cells were readily able to synthesize 20:5n-3 and 24:6n-3 from 18:3n-3 but 22:6n-3 synthesis was negligible. Also, they were readily able to synthesize 20:3n-6 from 18:2n-6 but 20:4n-6 synthesis was negligible. Mitochondrial β-oxidation was greatest for 18:3n-3 and 20:5n-3 and the rates for 16:0, 18:2n-6, 22:6n-3 and 18:1n-9 were significantly lower. Fatty acid incorporation was predominantly into phospholipids (79–97%) with very little incorporation into neutral lipids. Increasing the fatty acid concentration in the growth medium substantially increased the concentrations of 18:3n-3 and 18:2n-6 in the cell phospholipids but this was not the case for 20:5n-3 or 22:6n-3. When they were subjected to oxidative stress, the FHM cells supplemented with either 20:5n-3 or 22:6n-3 (as compared with 18:3n-3 or saturated fatty acids) exhibited significantly higher levels of thiobarbituric reactive substances (TBARS) indicating higher levels of lipid peroxidation. The results are discussed in relation to the effects of fatty acid unsaturation on the oxidative stability of cellular lipids and the implications for sustainable aquaculture.

Keywords Aquaculture · β-oxidation · Cell culture · Fish oil replacement · Lipid peroxidation · Phospholipids · Polyunsaturated fatty acids

Abbreviations

ALA	α-Linolenic acid
ARA	Arachidonic acid
BHT	Butylated hydroxytoluene
CerPCho	Sphingomyelin
DHA	Docosahexaenoic acid
EDTA	Ethylenediamine tetraacetic acid
EPA	Eicosapentaenoic acid
FAF-BSA	Fatty acid free-bovine serum albumin
FAME	Fatty acid methyl esters
FBS	Foetal bovine serum
FHM	Fathead minnow
HP-TLC	High performance-thin layer chromatography
LC-PUFA	Long-chain polyunsaturated fatty acids (carbon chain length $\geq C_{20}$ with ≥ 3 double bonds)
LNA	Linoleic acid
NR	Neutral red
OLA	Oleic acid
PAM	Palmitic acid
PBS	Phosphate buffered saline
PBSA	Phosphate buffered saline without Ca^{2+} or Mg^{2+}
PCR	Polymerase chain reaction
PtdCho	Phosphatidylcholine

Introduction

Fisheries and aquaculture are major contributors to world food security with ≥15% of animal protein for human consumption being derived from these sources in recent years [1]. Traditionally, feeds for farmed fish have contained high proportions of fish oil derived from wild-catch fisheries. However, in the 10 years prior to 2007, wild-catch fisheries production has remained static whereas aquaculture production has almost doubled [1]. Thus, there has been considerable interest in the replacement of fish oils with more sustainable oils [2, 3]. The preferred candidates have been vegetable oils from oilseed plants. However, while these are rich in C_{18} polyunsaturated fatty acids (PUFA), they are completely lacking in the omega-3 long-chain PUFA (n-3 LC-PUFA) that are abundant in fish oils. These n-3 LC-PUFA give seafood its reputation as a health food. In particular, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) have been shown to be beneficial in the prevention of cardiovascular disease, rheumatoid arthritis, inflammatory bowel disease, childhood learning and behavior disorders and adult psychiatric and neurodegenerative illnesses [4].

The fatty acid profile of fish flesh generally reflects the fatty acid profile of their diet [5]. Therefore, the dietary substitution of fish oils with vegetable oils reduces the n-3 LC-PUFA content of fish flesh thereby reducing its human health value [6–10]. In freshwater fish and salmonids (e.g. trout and salmon), this may be partially offset by their varying ability to synthesize LC-PUFA from C_{18} PUFA but in marine fish this is not the case [11–14]. Marine fish appear to be poorly able to synthesize LC-PUFA from C_{18} PUFA and this may reflect the relative abundance of preformed LC-PUFA, particularly 22:6n-3, in the marine food web [5]. Although freshwater fish and salmonids have some capacity to synthesize LC-PUFA from C_{18} PUFA, this is insufficient to compensate for a decreased dietary intake of LC-PUFA.

The generally accepted pathway for the synthesis of LC-PUFA from C_{18} PUFA in fish, as in mammals, is a series of desaturation and elongation steps in the endoplasmic reticulum followed by chain shortening in the peroxisomes (Fig. 1). In particular, the synthesis of 22:6n-3 from 18:3n-3 involves a Δ6 desaturation step followed by a chain elongation step, a Δ5 desaturation step and two consecutive chain elongation steps before a second Δ6 desaturation step and the final chain shortening step. Recent studies indicate that the C_{18} and C_{20} elongation steps are catalysed by an ELOVL5-like elongase whereas the C_{22} elongation step is catalysed by an ELOVL2-like elongase [15, 16]. Studies with fish cell lines indicate that freshwater fish and salmonids have substantial activities of the desaturase and elongase enzymes required to synthesize 20:5n-3 from 18:3n-3 whereas for marine fish there is an apparent limitation at either the C_{18} elongation or the Δ5 desaturation step [11–14]. In contrast, synthesis of 22:6n-3 appears to be limited in all fish species.

Fish lipids are highly susceptible to peroxidative deterioration because of the high proportions of LC-PUFA they contain and this explains the shorter shelf life of fish flesh products as compared with terrestrial animal meat products [17]. The C_{18} PUFA abundant in vegetable oils, 18:2n-6 and 18:3n-3, contain 2 and 3 double bonds, respectively, whereas the LC-PUFA abundant in fish oils, 20:5n-3 and 22:6n-3, contain 5 and 6 double bonds, respectively. Lipid peroxidation occurs when reactive oxygen species (ROS) attack PUFA at their double bonds setting off a chain reaction of hydrogen abstraction and lipid radical formation. This is particularly damaging to cell membranes because of the close proximity of fatty acids in the phospholipid bilayer [17]. Thus, a cell culture model would be useful to precisely define the effects of fish oil replacement at the cellular level.

The abundance of individual fatty acids in cellular lipids, particularly phospholipids, is affected by their uptake and esterification into the different lipid classes as well as by their mitochondrial β-oxidation for energy generation and their possible desaturation and/or elongation to form LC-PUFA [5]. Thus, all of these factors need to be considered when developing a cell culture model. Here we have used the long established and easily cultivated FHM cell line derived from the freshwater fish species fathead minnow (*Pimephales promelas*). In particular we have investigated the capacity of the cell line to synthesize LC-PUFA from C_{18} PUFA, to metabolize various fatty acids by β-oxidation and to incorporate various fatty acids into cellular lipids. Finally, we have investigated the impact of fatty acid unsaturation on the susceptibility of the cells to lipid peroxidation.

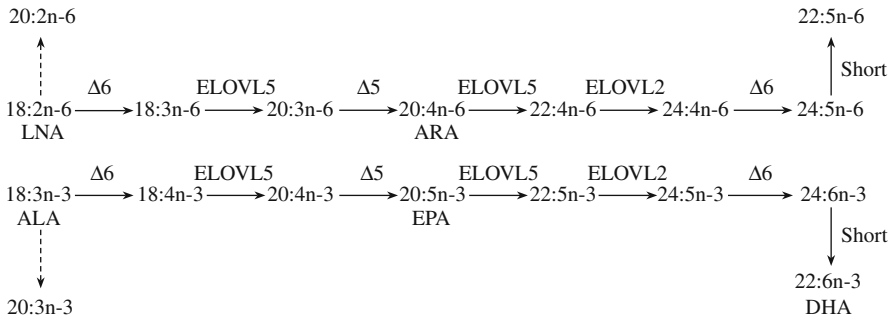

Fig. 1 The generally accepted pathway for the synthesis n-3 and n-6 LC-PUFA from their C_{18} fatty acid precursors in fish (adapted from Miller et al. [2]) showing the alternative reactions when Δ6 fatty acyl desaturase activity is limiting (*broken lines*). *Δ5* Δ5 fatty acyl desaturase, *Δ6* Δ6 fatty acyl desaturase, *ARA* arachidonic acid, *ALA* α-linolenic acid, *DHA* docosahexaenoic acid, *ELOVL2* fatty acyl elongase 2, *ELOVL5* fatty acyl elongase 5, *EPA* eicosapentaenoic acid, *LNA* linoleic acid, *short* peroxisomal shortening of LC-PUFA

Materials and Methods

Cells, Media and Standard Culture Conditions

A stock culture of the FHM cell line derived from fathead minnow (*Pimephales promelas*) was obtained from the Australian Animal Health Laboratory (CSIRO Livestock Industries, Geelong, Victoria, Australia) and the species of origin was confirmed by polymerase chain reaction (PCR) using the mitochondrial cytochrome oxidase subunit I (*cox1*) primers of Ward et al. [18]. For routine culture, the FHM cells were maintained in 75 cm^2 flasks containing 20 ml Leibovitz's L-15 medium supplemented with antibiotics (100 IU ml^{-1} penicillin, 100 μg ml^{-1} streptomycin) and 10% (v/v) foetal bovine serum (FBS). To subculture or harvest the cells, the medium was decanted, the cell monolayer was rinsed with phosphate buffered saline without Ca^{2+} or Mg^{2+} (PBSA) and the cells were detached with T/V solution containing 0.05% (w/v) trypsin and 0.02% (w/v) ethylenediamine tetraacetic acid (EDTA) in PBSA. For the experiments with [1-^{14}C]-labelled fatty acids, the cells were cultured to 80% confluence in 75 cm^2 flasks containing 20 ml L-15 medium supplemented with 5% (v/v) FBS. The medium was then replaced with 10 ml of fresh medium containing no FBS and the [1-^{14}C]-labelled fatty acids as complexes with fatty acid free-bovine serum albumin (FAF-BSA). The complexes were prepared as described by Ghioni et al. [19]. For the experiments with unlabelled fatty acids, the cells were cultured to 80% confluence in 75 cm^2 flasks containing 20 ml L-15 medium supplemented with 10% (v/v) FBS and then they were subcultured (at a split ratio of 1 to 12) into 25 cm^2 flasks containing 10 ml L-15 medium supplemented with 2% (v/v) FBS and the unlabelled fatty acids as complexes with FAF-BSA. The complexes were prepared as described by Best et al. [20] with a molar ratio of fatty acid to BSA of 4:1. For all experiments, the culture temperature was 25 °C and the incubation period with either the [1-^{14}C]-labelled or the unlabelled fatty acids was 24 h.

LC-PUFA Synthesis Assay Using [1-^{14}C]-labelled Fatty Acids

The FHM cells were incubated for 24 h in 75 cm^2 flasks containing 1 μCi (2 μM) [1-^{14}C]-labelled 18:2n-6, 18:3n-3 or 20:5n-3 in 10 ml L-15 medium containing no FBS. At the end of the 24-h incubation, the cells were detached with T/V solution and washed with FAF-BSA to remove any residual labelled fatty acid. Total lipids were extracted from the cell pellets by the addition of 5 ml ice-cold chloroform/methanol (2:1, v/v) containing 0.01% (v/v) butylated hydroxytoluene (BHT) followed by 1 ml 0.88% (w/v) KCl. The method was essentially that of Folch et al. [21] with the modifications described by Tocher et al. [22]. Fatty acid methyl esters (FAME) were prepared by incubating the lipid extract overnight at 50 °C with 1 ml of toluene and 2.5 ml of 1% (v/v) H_2SO_4 in methanol. The method was essentially that of Christie [23]. At the end of the incubation, the FAME were extracted by the addition of 2 ml of 2% (w/v) $KHCO_3$ followed by 5 ml isohexane/diethyl ether (1:1, v/v) containing 0.01% (v/v) BHT. The mixture was centrifuged at 500*g* and the upper layer was re-extracted with 5 ml isohexane/diethyl ether (1:1, v/v) containing no BHT. The upper layers were combined and the solvent was evaporated under a stream of N_2. The dried FAME were dissolved in 100 μl isohexane containing 0.01% (w/v) BHT and separated by thin-layer chromatography (TLC) on 20 × 20 cm TLC plates which had been impregnated with 2 g $AgNO_3$ in 20 ml acetonitrile before being dried/activated at 110 °C for 30 min. The TLC plates were developed in toluene/acetonitrile (95:5, v/v). The method was essentially as described by Wilson and Sargent [24]. Autoradiography was performed and the areas of silica containing the individual PUFA were scraped into

scintillation vials and radioactivity determined using a scintillation counter as previously described [25].

β-Oxidation Assay Using [1-^{14}C]-labelled Fatty Acids

The FHM cells were incubated for 24 h in 75-cm^2 flasks containing 0.5 μCi (1 μM) [1-^{14}C]-labelled 16:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 or 22:6n-3 in 10 ml L-15 medium containing no FBS. At the end of the incubation, 0.5 ml of the medium was removed for scintillation counting and the cells were detached with T/V solution and washed as described above. The washed cell pellets were resuspended in 1 ml PBS and homogenized to disrupt the cells. Acid soluble products were obtained by adding 100 μl of 6% (w/v) FAF-BSA and 1.0 ml ice-cold 4 M $HClO_4$ to 500 μl each of the growth medium and the cell homogenate and then centrifuging to remove the precipitated material. An aliquot of the supernatant (500 μl) was mixed with 4 ml scintillation fluid and radioactivity determined using a scintillation counter as previously described [25].

Incorporation of [1-^{14}C]-labelled Fatty Acids into Various Lipid Classes

The FHM cells were incubated for 24 h in 75 cm^2 flask containing 1.0 μCi (2 μM) [1-^{14}C]-labelled 16:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 or 22:6n-3 in 10 ml L-15 medium containing no FBS. At the end of the 24-h incubation, the cells were harvested and total lipid was extracted as described above. To separate the various lipid classes, the total lipid was dissolved in 100 μl chloroform/methanol (2:1, v/v) and applied to a high performance-thin layer chromatography (HPTLC) plate. The plate was developed in methyl acetate/isopropanol/chloroform/methanol/0.25% (w/v) aqueous KCl (25/25/25/10/9, by volume) as described by Vitiello and Zanetta [26]. The separated lipids were stained with iodine and the corresponding bands of silica were scraped into scintillation vials. Scintillation fluid (2.5 ml) was added and radioactivity determined using a scintillation counter as above.

Incorporation of Unlabelled Fatty Acids into the FHM Cell Phospholipids

The FHM cells were incubated for 24 h in 25-cm^2 flasks containing 10 ml L-15 medium supplemented with 2% (v/v) FBS and various concentrations of unlabelled 18:3n-3, 18:2n-6, 20:5n-3, 20:4n-6 or 22:6n-3. At the end of the incubation, the cells were harvested and total lipid was extracted from approximately 10^6 cells according to the method of Folch et al. [21]. The phospholipids were separated from the neutral lipids by TLC with petroleum ether/glacial acetic acid (3:1, v/v) and then they were transmethylated by incubation with 1% (v/v) H_2SO_4 in methanol for 3 h at 70 °C. The resulting FAME were extracted in heptane and analyzed by gas chromatography using a Hewlett-Packard 6890 gas chromatograph (Hewlett Packard, Palo Alto, CA, USA) fitted with a flame ionisation detector and a BPX-70 50 m capillary column coated with 70% (v/v) cyanopropyl polysilphenylene-siloxane (0.25 mm film thickness and 0.32 mm internal diameter, SGE, Australia). The carrier gas was helium at a flow rate of 2.0 ml min^{-1} and the split-ratio was 20:1. The injection port temperature was 250 °C and the detector temperature was 300 °C. The column temperature was increased from 140 to 220 °C at a rate of 4 °C min^{-1} and then held at 220 °C for up to 3 min. The identity of each fatty acid peak in the chromatogram was ascertained by comparison with an authentic lipid standard (Nu-Chek Prep, Inc., MN, USA). The amount of each fatty acid was quantified by comparing its peak area with the peak area of a heptadecaenoic acid (17:0) internal standard added prior to lipid extraction.

Effect of Fatty Acid Unsaturation on Cell Viability and Lipid Peroxidation

The FHM cells were seeded into 6-well plates at a density of 5×10^5 cells per well in L-15 medium containing 2% (v/v) FBS. The cells were allowed to attach overnight and then they were incubated for 24 h with fresh medium containing 2% (v/v) FBS and 20 μM 16:0, 18:0, 18:3n-3, 20:5n-3 or 22:6n-3 coupled with FAF-BSA in a 4:1 fatty acid to BSA ratio. At the end of the incubation period, the cell monolayer was rinsed twice with PBSA and then lipid peroxidation was induced by treating the cells for 1 h with 500 μM cumene hydroperoxide plus 100 nM hemin in PBSA. Following this treatment, the cell monolayer was rinsed twice with PBSA and the cells were subjected to either the Neutral Red (NR) cell viability assay [27] or the thiobarbituric acid reactive substances (TBARS) assay for lipid peroxidation [28]. Briefly, the NR cell viability assay involved incubating the cells for 3 h in NR dye diluted in L-15 containing 10% (v/v) FBS and then fixing them in 10% (w/v) $CaCl_2$:4% (v/v) formaldehyde before solubilizing the incorporated dye with 50% (v/v) ethanol:1% (v/v) acetic acid and reading the absorbance at 550 nm. Viable cells take up the dye whereas non-viable cells do not. For the TBARS assay, the cells were lysed with 1% (w/v) sodium dodecyl sulphate (SDS), the cell lysates were mixed 1:1 with the TBARS reagent and the mixture was incubated for 2 h at 75 °C before removing any insoluble material by centrifugation and reading the fluorescence

using excitation/emission wavelengths of 540/590 nm. The TBARS reagent contained 25 mM thiobarbituric acid (TBA), 15% (w/v) trichloroacetic acid and 0.005% (w/v) BHT dissolved in 1 M HCl.

Statistical Analyses

Statistical analyses were performed using SPSS software. The Levene statistic was calculated to test for homogeneity of variances and means were compared using one-way ANOVA followed by Tukey's post-hoc test. Differences where the P value was >0.05 were considered to be significant.

Results

Effect of the FBS Concentration in the Growth Medium on the Fatty Acid Composition of the FHM Cell Phospholipids

The fatty acid composition of the FHM cell phospholipids closely resembled that of the FBS in the growth medium, with the exceptions that 16:0 and 18:0 were less abundant and 18:1n-9 was more abundant (Table 1). Increasing the concentration of FBS in the growth medium from 2 to 20% (v/v) significantly increased the concentrations of 22:5n-3, 22:6n-3 and 20:4n-6 in the cell phospholipids (Fig. 2).

Metabolism of [1-^{14}C]-labelled Fatty Acids by the FHM Cells

Radioactivity from [1-^{14}C]18:3n-3 was readily recovered in 20:4n-3, 20:5n-3, 22:5n-3 and 24:6n-3 but there was relatively little recovery in 22:6n-3 (Table 2). Thus, the cells expressed considerable desaturase and elongase activity but only limited peroxisomal chain shortening activity. This was confirmed by supplying the cells with [1-^{14}C]20:5n-3. A somewhat different pattern was observed when the cells were supplied with [1-^{14}C]18:2n-6. In this case, the label was incorporated predominantly into 20:3n-6. This indicated considerable Δ6 desaturase activity to yield 18:3n-6 followed by elongase activity to yield 20:3n-6 but limited Δ5 desaturase activity to yield 20:4n-6. Thus, the FHM Δ5 desaturase apparently preferred the n-3 over the n-6 substrate.

The capacity of the FHM cells to metabolise fatty acids by mitochondrial β-oxidation was also investigated (Fig. 3). This showed that 18:3n-3 and 20:5n-3 were more readily oxidized than 16:0, 18:2n-6 or 22:6n-3 which in turn were more readily oxidized than 18:1n-9. This result was consistent with the high retention levels for 18:1n-9 in the cell phospholipids (Table 1).

Table 1 Fatty acid composition of foetal bovine serum (FBS) and the phospholipids of FHM cells maintained in L-15 medium containing 10% (v/v) FBS

Fatty acid	Fatty acid composition (% of total fatty acids)	
	FBS	FHM cells in L-15 + 10% FBS
14:0	0.8	1.3
16:0 (PAM)	23.0	17.8
18:0 (STA)	18.8	9.0
Total saturates[a]	45.3	32.0
16:1n-9	0.9	2.0
16:1n-7	1.3	2.2
18:1n-9 (OLA)	15.3	24.1
18:1n-7	2.0	7.9
Total monounsaturates[b]	23.5	42.4
18:2n-6 (LNA)	7.6	1.8
18:3n-6	0.3	0.4
20:2n-6	0.2	0.4
20:3n-6	3.4	3.0
20:4n-6 (ARA)	9.9	8.4
Total n-6 PUFA[c]	23.3	15.3
18:3n-3 (ALA)	0	0.2
20:5n-3 (EPA)	0.3	0.2
22:5n-3 (DPA)	3.7	1.5
22:6n-3 (DHA)	4.0	2.9
Total n-3 PUFA[d]	8.1	4.9
Total PUFA	31.4	20.2
n-3/n-6	0.35	0.32

For the FHM cells, the data are the mean of 3 replicate flasks; [a] also includes 15:0, 17:0, 20:0, 22:0 and 24:0; [b] also includes 20:1, 22:1 and 24:1; [c] also includes 22:4n-6; [d] also includes 18:4n-3 and 20:4n-3

PAM palmitic acid, *STA* stearic acid, *OLA* oleic acid, *LNA* linoleic acid, *ARA* arachidonic acid, *ALA* α-linolenic acid, *EPA* eicosapentaenoic acid, *DHA* docosahexaenoic acid,

Incorporation of [1-^{14}C]-labelled Fatty Acids into Lipid Classes in the FHM Cells

Total incorporation into all lipid classes was similar for 18:1n-9, 18:2n-6 and 20:5n-3 but significantly greater for 18:3n-3 and significantly less for 16:0 and 22:6n-3 (Table 3). The lower incorporation rate for 16:0 was consistent with its lower steady state level in the FHM cell phospholipids as compared with FBS (Table 1). This contrasts with the higher steady state level for 18:1n-9 which was apparently due to a lower rate of β-oxidation. For all of the fatty acids tested, the majority of the label (79–97%) was incorporated into phospholipids with very little incorporation into neutral lipids. For 16:0, 18:1n-9

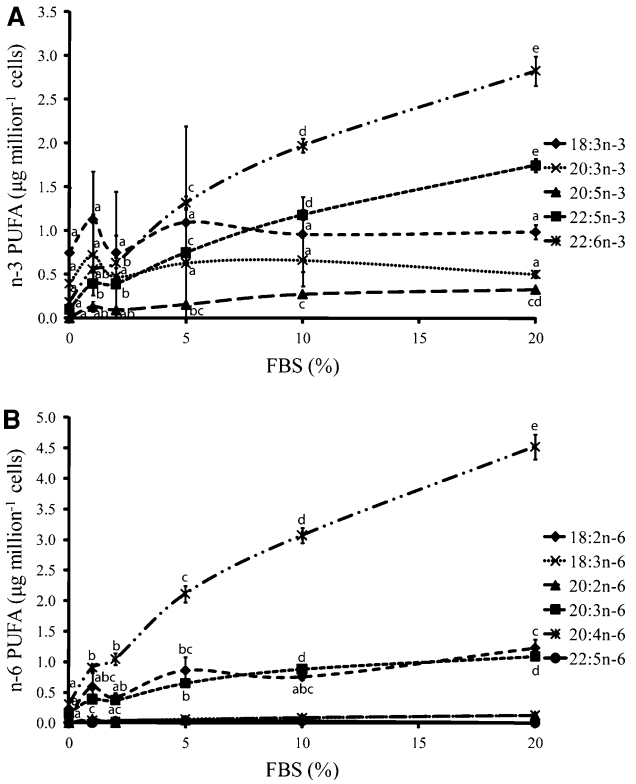

Fig. 2 The effect of increasing FBS concentration in the growth medium on the PUFA content of the FHM cell phospholipids. The growth medium contained 2% (v/v) BSA, 2 μM 18:3n-3 and increasing concentrations of FBS and the cells were cultured for 24 h at 25 °C. Each data point represents the mean of 3 flasks and the *vertical bars* represent the standard error of the mean. For each fatty acid, data points with *different letters* represent values that are significantly different from one another at the $P = 0.05$ level

and 18:2n-6, most of the label (44–50%) was incorporated into phosphatidylcholine (PtdCho) with phosphatidylethanolamine (PtdEtn) ranked second. For 18:3n-3 and 20:5n-3, the ranking was reversed with the greatest incorporation into PtdEtn followed by PtdCho. For 22:6n-3, the pattern was different again with the greatest incorporation into PtdEtn followed by phosphatidylserine (PtdSer) and then PtdCho. Thus, the lower overall incorporation of 22:6n-3 into total lipids was associated with lower incorporation into PtdCho and higher incorporation into PtdSer. In addition, as the unsaturation of the fatty acids increased, there was a trend away from incorporation into PtdCho.

Effect of Concentration on the Accumulation of Unlabelled Fatty Acids in the FHM Cell Phospholipids

Figure 4 shows the effects of increasing concentrations of 18:3n-3 or 18:2n-6 in the growth medium on their accumulation in the cell phospholipids. In both cases, accumulation in the cell phospholipids paralleled the increase in concentration in the growth medium up to a concentration of 5 μM but above this concentration an incorporation threshold was reached. The accumulation of 18:3n-3 was roughly paralleled by an accumulation of 20:3n-3, the direct elongation product of 18:3n-3. Thus, Δ6 desaturase activity, which would have produced 18:4n-3, appeared to be limiting. In contrast, 18:2n-6 was a poor substrate for direct elongation as evidenced by limited accumulation of 20:2n-6. However, 20:3n-6 accumulation was significant and this is consistent with the earlier observation of limited Δ5 desaturase activity towards 20:3n-6 in the [1-^{14}C]-labelling experiment (Table 2).

Further metabolism of 18:3n-3 to produce 20:5n-3 and 22:6n-3 or of 18:2n-6 to produce 20:4n-6 was negligible. This was surprising given the results of the [1-^{14}C]-labelling experiment which showed significant synthesis of 20:5n-3 from 18:3n-3 (Table 2). To determine whether this apparent anomaly was due to limited incorporation of higher concentrations of LC-PUFA into the cellular phospholipids, the FHM cells were supplied with various concentrations of either 20:5n-3, 20:4n-6 or 22:6n-3 (Figs. 5, 6). Incorporation of 20:5n-3 into the cell phospholipids increased approximately linearly with the increase in the concentration in the growth medium up to a concentration of 5 μM whereas at higher concentrations it reached a plateau. The accumulation of 20:5n-3 was paralleled by an accumulation of 22:5n-3, the direct elongation product of 20:5n-3. Further metabolism of

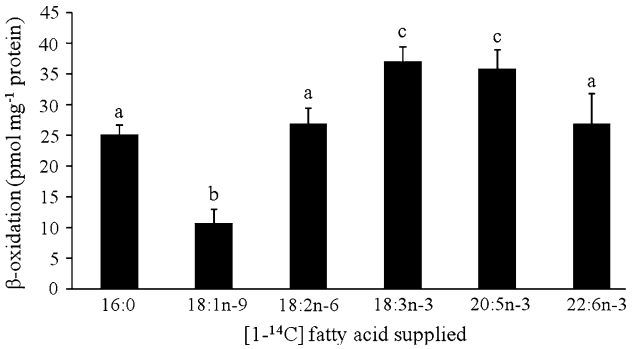

Fig. 3 *β*-oxidation activity of the FHM cell line with various fatty acids. The cells were incubated for 24 h at 25 °C with 1 μCi (2 μM) of the [1-^{14}C]-labelled fatty acids in L-15 medium containing no FBS. Data points with *different letters* represent values that are significantly different from one another at the $P = 0.05$ level

20:5n-3 to produce 22:6n-3 by chain shortening was negligible.

Incorporation of 20:4n-6 was less straightforward (Fig. 5). At lower concentrations up to 5 μM, there was some evidence of increasing incorporation with increasing concentration in the medium. However, at higher concentrations in the medium (5–20 μM) there was no increase in incorporation of 20:4n-6 into the cells. This was not unexpected given that the cells were cultured in the presence of 2% (v/v) FBS which is relatively rich in 20:4n-6 and therefore the capacity of the cell phospholipids to incorporate 20:4n-6 may already have reached its maximum level.

Incorporation of 22:6n-3 into the cell phospholipids reached its maximum level at a very low concentration of only 2 μM in the growth medium (Fig. 6). This was lower than the concentration of approximately 5 μM observed for 20:5n-3. This was consistent with the ^{14}C-labelling data which showed significantly lower incorporation of 22:6n-3 into total lipid (Table 3). Interestingly, there was also some evidence for retro-conversion of 22:6n-3 to 20:5n-3 (Fig. 6).

Effect of Fatty Acid Unsaturation on Cell Viability and Lipid Peroxidation

There was no significant difference in cell viability between any of the fatty acid treatments except for the treatment with 18:0 which showed significantly higher cell viability (Fig. 7). For TBARS, the concentration was significantly greater in the cells supplemented with either 20:5n-3 or 22:6n-3 as compared with the cells supplemented with either 16:0, 18:0 or 18:3n-3. Thus, increasing fatty acid unsaturation increased the susceptibility of the cells to lipid peroxidation but did not decrease cell viability.

Discussion

The aim of this study was to develop a cell culture model for the impact of fish oil replacement with vegetable oils on the oxidative stability of fish lipids. Fish oils are rich in LC-PUFA with 5 or 6 double bonds whereas vegetable oils are rich in C_{18} PUFA with only 2 or 3 double bonds [3] and since the fatty acid composition of fish lipids reflects the fatty acid composition of their diet and fatty acid susceptibility to peroxidation increases with increasing unsaturation, we hypothesized that replacing LC-PUFA with C_{18} PUFA would increase the oxidative stability of fish lipids. Previous studies had shown that fish cells in culture have decreased proportions of n-3 LC-PUFA in their lipids as compared with whole fish or fish fillets and this was

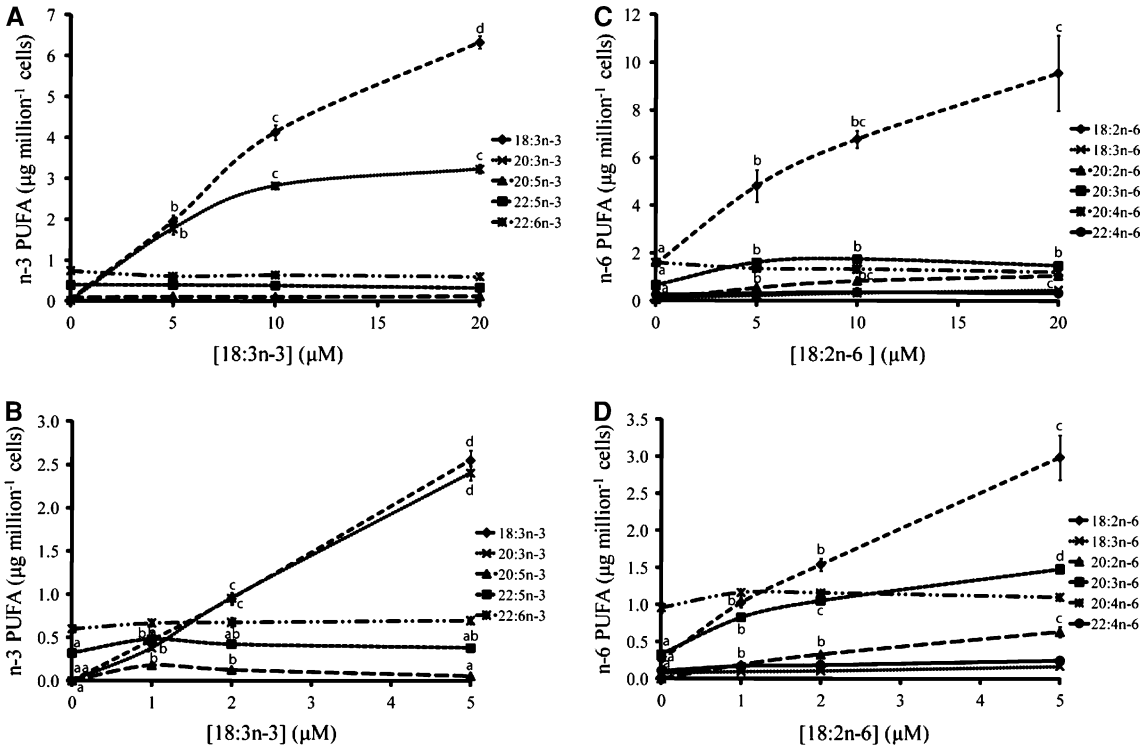

Fig. 4 The effect of increasing 18:3n-3 or 18:2n-6 concentration in the growth medium on the PUFA content of the FHM cell phospholipids. The growth medium contained 2% (v/v) BSA and increasing concentrations of either 18:3n-3 or 18:2n-6 and the cells were cultured for 24 h at 25 °C. Each data point represents the mean of 3 flasks and the *vertical bars* represent the standard error of the mean. For each fatty acid, data points with *different letters* represent values that are significantly different from one another at the $P = 0.05$ level

attributed to the low concentrations of n-3 LC-PUFA in the mammalian serum which is the usual source of fatty acids for cells in culture [13, 22, 29]. The present study confirmed this and in particular we found that the proportions of the beneficial n-3 LC-PUFA, 20:5n-3 and 22:6n-3, were much lower in the FHM cells in culture than in fish tissues in general.

The effects of fish oil replacement on the fatty acid profile of fish flesh are determined by fatty acid metabolism and incorporation into cellular lipids. Previous studies had shown that cell lines derived from fresh water or anadromous fish species (Atlantic salmon, rainbow trout and common carp) were readily able to synthesize 20:5n-3 from 18:3n-3 whereas cell lines derived from carnivorous marine fish species (turbot and gilthead sea bream) were not [11–14]. In turbot this was attributed to low C_{18} to C_{20} elongase activity whereas in gilthead sea bream it was attributed to low Δ5 desaturase activity. Importantly, none of these cell lines could synthesize significant quantities of 22:6n-3. In the present study, the FHM cell line was readily able to synthesize 20:5n-3, 22:5n-3 and 24:6n-3 from 18:3n-3 and/or 20:5n-3 but 22:6n-3 synthesis was negligible. Thus, the FHM cell line expressed substantial Δ5 and Δ6 desaturase activities as well as $C_{18\text{-}20}$, $C_{20\text{-}22}$ and $C_{22\text{-}24}$ elongase activities but negligible peroxisomal chain shortening activity. This was similar to cell lines from other freshwater fish species.

The FHM cells were also readily able to desaturate 18:2n-6 to 18:3n-6 and further elongate this to 20:3n-6 but they synthesized little 20:4n-6. This suggested limited Δ5 desaturase activity towards n-6 fatty acids, which was in contrast to the results obtained with the n-3 substrates. Thus, the Δ5 desaturase of the FHM cell line appeared to prefer n-3 over n-6 fatty acids. Previous studies with cell lines from Atlantic salmon, rainbow trout, turbot and gilthead sea bream also showed limited Δ5 desaturase activity towards 20:3n-6 [11–13]. Thus, this appears to be a general phenomenon for fish cell lines regardless of whether they originate from freshwater, anadromous or marine fish species.

Fatty acid utilization via *β*-oxidation in the FHM cells was investigated by supplying them with [1-^{14}C]-labelled 16:0, 18:1n-9 18:2n-6, 18:3n-3, 20:5n-3 or 22:6n-3. The *β*-oxidation rates were similar for 16:0, 18:2n-6 and 22:6n-3 but significantly lower for 18:1n-9 and significantly higher for 18:3n-3 and 20:5n-3. In a previous study with Atlantic salmon hepatocytes isolated from fish fed a fish oil-based diet, *β*-oxidation rates were similar for 16:0 and 18:2n-6,

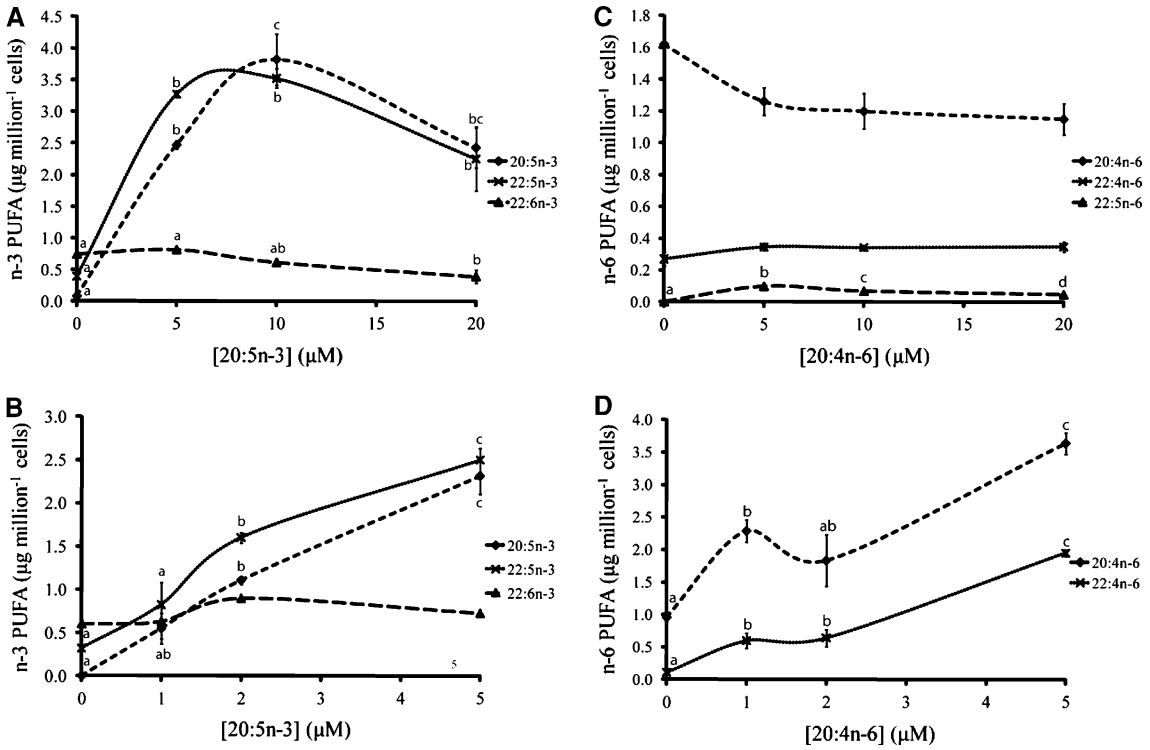

Fig. 5 The effect of increasing 20:5n-3 or 20:4n-6 concentration in the growth medium on the PUFA content of the FHM cell phospholipids. The growth medium contained 2% (v/v) BSA and increasing concentrations of either 20:5n-3 or 20:4n-6 and the cells were cultured for 24 h at 25 °C. Each data point represents the mean of 3 flasks and the *vertical bars* represent the standard error of the mean. Fig. 6 The effect of increasing 22:6n-3 concentration in the growth medium on the PUFA content of the FHM cell phospholipids. The growth medium contained 2% (v/v) BSA and increasing concentrations of 22:6n-3 and the cells were cultured for 24 h at 25 °C. Each data point represents the mean of 3 flasks and the *vertical bars* represent the standard error of the mean. For each fatty acid, data points with *different letters* represent values that are significantly different from one another at the $P = 0.05$ level

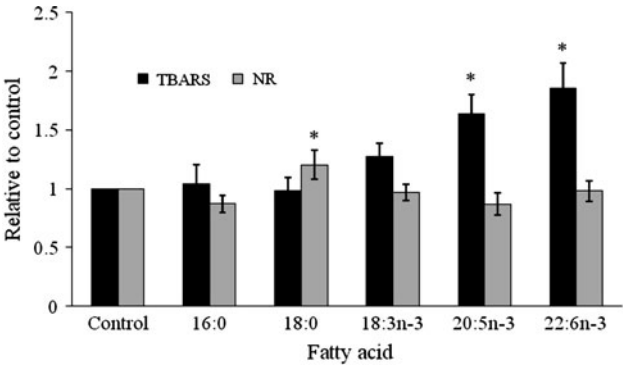

Fig. 7 The effect of increasing fatty acid unsaturation on cell viability and lipid peroxidation in the FHM cells. The cells were supplied with the various fatty acids at a concentration of 20 μM in L-15 medium containing 2% (v/v) FBS. The control contained ethanol at the concentration present in the fatty acid supplements. Three separate flasks of cells were analyzed for each data point and the columns represent the mean while the *vertical bars* represent the standard deviation. For the TBARS assay, * indicates a significant difference (at the $P = 0.05$ level) between the results for 20:5n-3 and 22:6n-3 and the results for the other fatty acids. For the NR assay * indicates a significant difference (at the $P = 0.05$ level) between the results for 18:0 and the results for the other fatty acids

slightly lower for 18:1n-9 and much lower for 18:3n-3, 20:5n-3 and 22:6n-3 [30]. Feeding the fish a predominantly vegetable oil-based diet significantly increased the β-oxidation of 18:1n-9, 18:2n-6, 18:3n-3 and 20:5n-3 but the rank order was still similar. Clearly the metabolism of primary hepatocytes is likely to be different to that of cells maintained in culture for long periods of time and therefore more work needs to be done to understand β-oxidation in fish cell lines. In particular, the rates measured using

radiolabelled substrates may be affected by the pool sizes of unlabelled substrates in the cells due to dilution of the label. The FHM cell phospholipids were particularly rich in 16:0 and 18:1n-9, with moderate levels of 18:2n-6 and 22:6n-3 and low levels of 18:3n-3 and 20:5n-3. Thus, the β-oxidation rates for 16:0 and 18:1n-9, in particular, may have been underestimated. In addition, the incorporation of 22:6n-3 into total cellular lipids was significantly lower compared with the other fatty acids and this may have resulted in an underestimation of the β-oxidation rate for this fatty acid as well. Overall, therefore, the FHM cells were readily able to oxidize all six of the different fatty acids supplied to them.

The incorporation of fatty acids into cellular lipids in the FHM cells was studied in two different ways, firstly using a trace (2 μM) concentration of [1-^{14}C]-labelled fatty acids and secondly using increasing concentrations of unlabelled fatty acids in the range 1–20 μM. Previous studies with fish cell lines and trace concentrations of [1-^{14}C]-labelled 18:2n-6, 18:3n-3 and 20:5n-3 had shown that the label was incorporated predominantly (mostly >90%) into phospholipids, especially PtdCho and PtdEtn, with very little incorporation into neutral lipids [11, 13, 14]. The FHM cell line behaved the same way. In addition, we found that [1-^{14}C]-labelled 16:0, 18:1n-9 and 22:6n-3 were also incorporated predominantly into phospholipids. Interestingly, there was substantial incorporation of [1-^{14}C]-labelled 22:6n-3 into PtdSer and less incorporation into PtdCho than for the other fatty acids. This has also been observed for cell lines from rainbow trout, Atlantic salmon and turbot [31–33]. PtdSer is less abundant than PtdCho in fish cell lines in general [13, 14] and this may explain the lower level of incorporation of [1-^{14}C]-labelled 22:6n-3 into total lipid observed in the present study.

Increasing the concentration of unlabelled 18:3n-3 in the culture medium from 1 to 20 μM resulted in a roughly corresponding increase in the concentration of this fatty acid in the FHM cell phospholipids but there was no corresponding increase in the conventional desaturation/elongation products 20:5n-3, 22:5n-3 or 24:6n-3. Instead, there was an accumulation of 20:3n-3. This fatty acid is produced by the direct elongation of 18:3n-3. Thus, Δ6 desaturase activity apparently limited the flux through the conventional pathway as the 18:3n-3 concentration was increased above the trace concentration used in the [1-^{14}C]-labelling experiments. This was in contrast to the results of previous studies with rainbow trout and Atlantic salmon cell lines supplied increasing concentrations of unlabelled fatty acids [34, 35]. In those studies, increasing the concentration of unlabelled 18:3n-3 from 5 to 50 μM resulted in a greater increase in 20:5n-3 than 20:3n-3. The main difference between the present and the previous studies is that the previous studies analyzed total lipid whereas in the present study we analyzed phospholipids. Thus, there may have been incorporation into neutral lipids which was not detected in the present study. Tocher et al. [34] noted that there were no large increases in neutral lipids in either rainbow trout or turbot cell lines supplied fatty acids at concentrations up to 20 μM however lipid droplets did appear when the concentration was increased above 50 μM. Thus, in the future, it will be interesting to investigate the incorporation of fatty acids into neutral lipids in the FHM cells and compare this with their incorporation into phospholipids to determine the relative distributions as fatty acid concentrations are increased.

Incorporation of 18:2n-6 into the FHM cell phospholipids with increasing concentrations of this fatty acid in the growth medium showed a similar pattern to that observed with 18:3n-3 except that 20:3n-6 was the major desaturation/elongation product incorporated. This is produced by the conventional Δ6 desaturation of 18:2n-6 to yield 18:3n-6 followed by the conventional elongation of 18:3n-6 to yield 20:3n-6. Thus, the result obtained with unlabelled 18:2n-6 was similar to that obtained with labelled 18:2n-6 and this confirmed that Δ5 desaturase was the limiting step in n-6 LC-PUFA synthesis in the FHM cell line. This was consistent with the results of previous work with other freshwater and anadromous fish cell lines [34, 35]. Taking the results with 18:3n-3 and 18:2n-6 together, it suggests that fish cells in culture are suitable for the study of the effects of increasing concentrations of C_{18} PUFA derived from vegetable oils. However, in order to have a control representative of a fish oil-based diet, it will be necessary to supply the cultured cells with either 20:5n-3 or 22:6n-3 to significantly raise the levels of these fatty acids in the cellular lipids. Thus, this was also investigated.

When the FHM cells were supplied with increasing concentrations of 20:5n-3, there was a corresponding increase in the concentration of this fatty acid in their phospholipids but only up to a culture medium concentration of 10 μM. Above this concentration, the incorporation of 20:5n-3 into the cell phospholipids did not change significantly. Thus, incorporation of 20:5n-3 reached a plateau at a lower concentration than incorporation of either of the C_{18} fatty acids. This was in contrast to the results obtained with a cell line from turbot, a marine fish species [34]. In that case 20:5n-3 incorporation continued increasing up to a culture medium concentration of at least 50 μM. Perhaps this reflects a greater capacity for incorporation of 20:5n-3 in marine fish than in freshwater fish but it should also be noted that total lipid was analyzed in the previous study whereas only phospholipids were analyzed in the present study. The direct incorporation of 22:6n-3 into the FHM cell phospholipids was also investigated. This reached a plateau at a very low concentration

of only 2 μM in the culture medium. This has not been studied before and it clearly warrants further investigation.

In general fish flesh products (i.e. seafood) have a shorter shelf life than terrestrial animal meat products and this is due to the greater susceptibility of fish flesh to lipid peroxidation as a result of the higher proportions of LC-PUFA in fish lipids [17]. Thus, it can be hypothesized that feeding farmed fish vegetable oils with their abundance of either 18:3n-3 or 18:2n-6 as opposed to fish oils with their abundance of 20:5n-3 and 22:6n-3 will result in extended shelf life. To test this hypothesis in our in vitro system, we enriched the FHM cells with either saturated fatty acids (16:0 or 18:0), PUFA (18:3n-3) or LC-PUFA (20:5n-3 or 22:6n-3) and then subjected them to oxidative stress to stimulate lipid peroxidation. The cells enriched with 20:5n-3 or 22:6n-3 had significantly higher concentrations of TBARS than the cells enriched with 16:0, 18:0 or 18:3n-3. TBARS is a commonly used indicator of lipid peroxidation in fish [17]. Thus, increasing the unsaturation of the FHM lipids increased the susceptibility of the cells to lipid peroxidation. Therefore in this respect, the cells are a good model for the effects of dietary fish oil replacement on the flesh quality of farmed fish. Previous studies with Atlantic salmon fed diets containing either fish oil, vegetable oil or oils enriched with either 20:5n-3 or 22:6n-3 showed that increasing dietary unsaturation increased indicators of oxidative stress and apoptosis in liver and white adipose tissue [36, 37]. In particular, fish fed diets enriched with either 20:5n-3 or 22:6n-3 had greater activities of the antioxidant enzyme superoxide dismutase and the apoptosis marker caspase 3 as well as reduced integrity of their mitochondria as evidenced by almost undetectable levels of β-oxidation of ^{14}C-palmitoyl CoA. More direct evidence for the effect of dietary fatty acid unsaturation on the oxidative stability of fish lipids comes from a study with grass carp fed diets containing either lard, plant oil or fish oil [38]. In that study, TBARS concentration in the plasma of the fish increased with increasing dietary lipid content and also with increasing unsaturation of the dietary oil. It has also been shown that supplementing the growth medium with the antioxidant α-tocopherol (vitamin E) decreased the longer term inhibitory effect of 20:5n-3 supplementation on the growth of a turbot cell line [39].

In conclusion, the FHM cells had substantial capacity to synthesize 20:5n-3 from 18:3n-3 but only limited capacity to synthesize 22:6n-3. In addition they had substantial capacity to synthesize 20:3n-6 from 18:2n-6 but only limited capacity to synthesize 20:4n-6. Together the data indicated limited chain shortening activity in the peroxisomes and limited Δ5 desaturase activity especially towards 20:3n-6 but also towards 20:4n-3. At a trace (2 μM) concentration, fatty acid incorporation into total lipid was greatest for 18:3n-3 followed closely by 18:2n-6 and 20:5n-3 with incorporation of 22:6n-3 being substantially less. Fatty acid incorporation into phospholipids reached a plateau at much lower concentrations for 20:5n-3 and 22:6n-3 than for 18:3n-3 and 18:2n-6 indicating that the cell membranes had limited capacity for incorporation of 20:5n-3 and 22:6n-3 presumably because of the need to maintain appropriate levels of fluidity. Thus, dietary fish oil replacement with vegetable oils may result in substantial displacement of LC-PUFA by C_{18} PUFA in fish cell membranes. Despite the limited capacity of the cell membranes to incorporate either 20:5n-3 or 22:6n-3, the FHM cells still showed greater susceptibility to lipid peroxidation when the culture medium was supplemented with LC-PUFA as compared with either 18:3n-3 or saturated fatty acids. Thus, the FHM cell line can be a useful model for the effects of dietary fish oil replacement on lipid stability and shelf life in farmed fish.

Hydrophilic Interaction Liquid Chromatography: ESI–MS/MS of Plasmalogen Phospholipids from *Pectinatus* Bacterium

Tomáš Řezanka · Lucie Siristova · Dagmar Matoulková · Karel Sigler

Received: 3 February 2011 / Accepted: 3 March 2011 / Published online: 11 April 2011

Abstract Liquid chromatography–electrospray tandem mass spectrometry (LC/ESI–MS/MS) was used to analyze phospholipids from three species of the anaerobic beer-spoilage bacterial genus *Pectinatus*. Analysis of total lipids by HILIC (Hydrophilic Interaction Liquid Chromatography) column succeeded in separating diacyl- and plasmalogen phospholipids. Plasmalogens were then analyzed by means of the ESI–MS/MS and more than 220 molecular species of four classes of plasmalogens (PlsCho (choline plasmalogen), PlsEtn (ethanolamine plasmalogen), PlsGro (glycerol plasmalogen), and PlsSer (serine plasmalogen)) were identified. Major molecular species were c-p19:0/15:0 PlsEtn and PlsSer, which accounted for more than 4% of the total lipids.

Introduction

Microbial contamination that can occur during the brewing process can negatively affect the process of beer production and the quality of the final product. The contaminants can include, besides the so-called wild yeasts and molds, a

number of bacterial genera [1–3]. Improvements in beer handling and bottling technology have resulted in a significant reduction in the oxygen content during the process and in packaged beer, which has permitted the growth of anaerobic beer-spoilage bacteria such as *Pectinatus*, *Megasphaera*, *Selenomonas* and *Zymophilus* [1–5].

These anaerobic beer-spoilage bacteria belong to the class *Clostridia* and the family Veillonellacea; despite their phylogenetic affiliation to Gram-positive bacteria the cells stain Gram-negative or Gram-variable [6, 7]. The bacteria *Pectinatus* and *Zymophilus* have been isolated only from breweries, and their natural environment is still unknown [5, 6, 8].

The anaerobic beer-spoilage bacterium *Pectinatus* has become a serious problem in the brewing industry because it can cause strong turbidity and sediment in beer and produces unpleasant volatile compounds, mostly acids, e.g. acetic, propionic, succinic, butyric, valeric and caproic acid and also acetoin and hydrogen sulfide [1–3]. As a result, bacterial spoilage activity can completely damage the beer taste and quality and thus cause serious financial problems to the brewery.

Detection of these spoilage bacteria in breweries is still based on traditional incubation on special diagnostic/selective media [2, 3], which is very time-consuming. For example, development of turbidity in beer forcing tests takes 4–6 weeks [5, 6]. Using the SMMP-medium (a selective medium for *Megasphaera* and *Pectinatus*) the incubation takes up to 14 days [5]. Further alternatives are fatty acids or *O*-alk-1′-enyl chains analysis [3], epifluorescence microscopy, immunofluorescence [6] or modern genetic methods such as PCR [5], fluorescence in situ hybridization [6] or oligonucleotide microarrays [9].

Plasmalogen is any derivative of *sn*-glycero-3-phosphoric acid that contains an *O*-alk-1′-enyl residue (sometimes named vinyl ether moiety or enol ether moiety, see Fig. 1) attached to the glycerol moiety at *sn*-1 position and a polar head made of a nitrogenous base, a glycerol, inositol, etc. moiety.

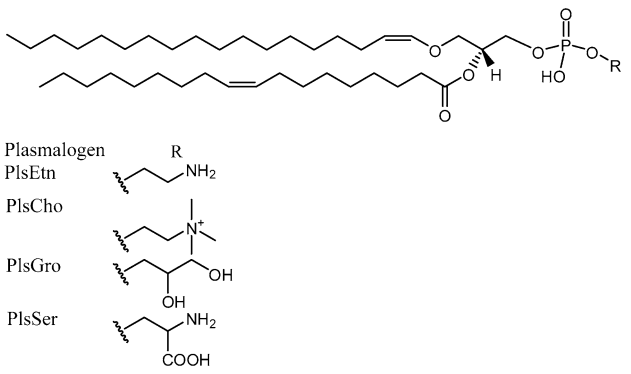

Fig. 1 The structures of plasmalogens. The explanation is in the abbreviations, the structures of the major ions is in Tables 2, 3, 4 and 5

Plasmalogens are among the most specific lipids since their occurrence is limited to strictly anaerobic bacteria [10] and they are not present in aerobic or facultatively anaerobic bacteria. They have been exceptionally found also in fungi [11] while their presence in higher plants is a matter of contention [12, 13]. By contrast, they are common constituents of animal lipids from invertebrates to humans [14]. They are found mostly as PlsCho (choline plasmalogen), PlsEtn (ethanolamine plasmalogen), PlsGro (glycerol plasmalogen), and PlsSer (serine plasmalogen), etc. (Fig. 1).

Analysis of plasmalogens makes use of their vinyl ether bond at the *sn*-1 position, which is liable to acid-catalyzed hydrolysis. The presence of mere traces of an acid causes hydrolysis resulting in a lysophospholipid and a fatty aldehyde. Following their separation by, e.g., TLC, fatty aldehydes can be determined by GC–MS. Another possibility is the removal of the polar moiety of the molecule by phospholipase C and identification of alkyl-acyl, alkenyl-acyl and diacyl-glycerols by HPLC or, after derivatization of the free hydroxyl group, by GC [15]. All these methods are time- and labor-demanding. Another possibility, which has rather rarely been mentioned in the literature, is the separation of intact plasmalogens from diacylphospholipids by HPLC on diol columns [15]. The authors [16–18] have always used an HPLC column with a diol bonded stationary phase and a highly complex organic phase consisting of up to six solvents [17] and, in addition, elution with a nonlinear gradient. The mobile phase also contained a buffer composed of an organic acid (acetic or formic) and base (ammonia, ammonium acetate or triethylamine). The elution order of individual phospholipids was different but, fortunately, plasmalogen was always eluted ahead of the corresponding diacyl-derivative.

Amphiphilic molecules such as phospholipids can be separated on a HILIC (Hydrophilic Interaction Liquid Chromatography) column, although it has more often been used for separating water-soluble analytes [19]. Separation of phospholipids on a HILIC column is described in only a few papers, with relatively controversial results concerning especially the elution of individual phospholipid classes. Thus Schwalbe-Herrmann has described an elution order of PtdGro, PtdEtn and PtdCho [20], whereas Kamleh reported on the order PtdCh, PtdSer and PtdGro [21] and Scherer obtained the sequence PtdGro and PtdOH [22]. To our knowledge, our paper is the first to describe gradient HILIC separation of at least five phospholipid classes including plasmalogens.

Identification of intact plasmalogens has already been described by, e.g., Hsu et al. [23–26] who reported on ESI–MS or ESI–MS/MS identification as lithiated adducts, e.g.

$[M + Li]^+$ molecular ions and their cleavage to give characteristic fragments that allow identification of individual molecular species. The CID spectra of $[M + H]^+$ and $[M + Na]^+$ ions of PtdCho and PtdEtn are rather uninformative regarding the nature and position of the fatty acyl substituents in lipids [27]. In the presence of lithium salts, PtdCho and PtdEtn form $[M + Li]^+$ ions which, upon CID, produce product ion spectra that contain diagnostic fragment ions for both the polar head group and the fatty acyl groups.

This report is part of our investigation of analysis bacterial lipids within the framework of a comprehensive program on the analysis and biosynthesis of lipids [28, 29].

In this article, we present for the first time separation of intact plasmalogen phospholipids from diacyl phospholipids of anaerobic bacteria, and identification and quantitation of individual molecular species of four plasmalogens, i.e. PtdEtn, PtdGro, PtdSer, and PtdCho by LC-ESI/MS^2 from the three strains of bacterium *Pectinatus*.

Experimental

Bacterial Strains

Pectinatus frisingensis DSM 20465 and *P. cerevisiiphilus* DSM 20467 were purchased from the DSMZ Collection (Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany). *P. frisingensis* RIBM 2-86 was obtained from the RIBM Collection (Research Institute of Brewing and Malting, Prague, Czech Republic). All strains originated from brewery environment.

Cultivation and Extraction of Bacterium Strains

Pectinatus strains were grown in a modified MRS broth (medium according to de Man, Rogosa, and Sharpe, Merck, Darmstadt, Germany) supplemented with cysteine hydrochloride (0.5 g/L) and sodium thioglycollate (0.5 g/L), pH 5.6–5.7, for 48 h at 28 °C. Cultivation was performed under aerobic conditions (300 mL of modified MRS broth in 500-mL Erlenmeyer flasks, the surface of the medium was covered with sterile mineral oil to ensure anaerobiosis). No anaerobic atmosphere is needed if the medium is freshly prepared, is not stirred, the transfer of culture by pipette is quick and the inoculum is placed in the bottom of the test tube. After cultivation, the biomass was transferred to new tubes, chilled on ice and harvested immediately by centrifugation (10 min/6,000 rpm/0 °C). The tubes with pellets were placed on dry ice and stored frozen until freeze-dried. The yields of biomass and their lipid components are given in Table 1.

The extraction procedure was based on the method of Bligh and Dyer [30], except that 2-propanol was substituted for methanol, since 2-propanol does not serve as a substrate for phospholipases [31]. The alcohol–water mixture was cooled and one part chloroform was added and the lipids were extracted for 30 min. Insoluble material was sedimented by centrifugation and the supernatant was separated into two phases. The aqueous phase was aspirated off and the chloroform phase was washed three times with two parts 1 M KCl each. The resulting chloroform phase was evaporated to dryness under reduced pressure.

Table 1 Yields of biomass, total lipids and phospholipids of *Pectinatus frisingensis* DSM 20465, *P. cerevisiiphilus* DSM 20467, and *P. frisingensis* RIBM 2-86

	RIBM 2-86	DSM 20465	DSM 20467
Biomass in mg	306.0	407.0	469.0
Total lipids in mg	12.3	13.7	14.1
Total lipids in %	4.0	3.4	3.0
Phospholipids in mg	5.9	7.1	7.5
Phospholipids in % of total lipids	48.0	52.0	23.0

Data were obtained by weighing and by means of a Sep-Pak Cartridge with an aminopropylsilica-based polar bonded phase

First, total lipid extracts were applied to the Sep-Pak Cartridge Vac 35 cc (Waters; with 10 g of aminopropylsilica-based polar bonded phase), and from the cartridge were subsequently eluted nonacidic lipids with 40 mL of chloroform–methanol (7:3), and acidic lipids with 30 mL of chloroform–methanol-concentrated aqueous ammonia (70:30:2) containing 0.4% (w/v) ammonium acetate. The eluate was reduced in volume and subjected to semipreparative HILIC or LC–MS. No alkyl acyl species were present.

LC–MS Analysis and Semipreparative HILIC

The HPLC equipment consisted of a 1090 Win system, a PV5 ternary pump and an automatic injector (HP 1090 series, Hewlett Packard, USA). Gradient chromatographic separation was performed on a Merck ZIC®-HILIC HPLC column, with 3.5 µm 100 Å and 2.1 × 250 mm. The injection volume was 5 µL, and the column was maintained at 50 °C. The mobile phase consisted of (a) acetonitrile/water (8:2) with buffer (10 mM ammonium formate, 0.5 mM LiOH and 0.5 mM AcOLi) and (b) acetonitrile/water (5:5) with buffer (20 mM ammonium formate, 0.5 mM LiOH and 0.5 mM AcOLi). A gradient elution was performed with 100% A for 1 min, a step to 75% A until 5 min, a linear decrease to 50% A until 25 min, 50% A up to 10 min, and re-equilibration to 100% A for less than 5 min. The flow rate was set to 180 µL/min. The efficiency of the column was approximately 25,000 plates/250 mm.

The detector was an Applied Biosystems Sciex API 4000 mass spectrometer (Applied Biosystems Sciex, Ontario, Canada) using electrospray mass spectra. The ionization mode was positive, the nebulizing gas (N_2) pressure was 345 kPa and the drying gas (N_2) flow and temperature were 9 L/min and 300 °C, respectively. The electrospray needle was at ground potential, whereas the capillary tension was held at 3,900 V. The cone voltage was kept at 240 V. The mass resolution was 0.1 Da and the peak width was set to 6 s. For an analysis, total ion currents (full scan) were acquired from 200 to 1,100 Da.

CID ions mass spectra were acquired by colliding the Q1 selected precursor ions with Ar gas as a collision target gas and applying a collision energy of 50 eV in Q2. The scanning range of Q3 was *m*/*z* 150–1,100 with a step size of *m*/*z* 0.3 and a dwell time of 1 ms. A peak threshold of 0.3% intensity was applied to the mass spectra. The instrument was interfaced to a computer running Applied Biosystems Analyst version 1.4.1 software.

The liquid chromatograph was the semipreparative Gradient LC System G-1 (Shimadzu, Kyoto, Japan) with two LC-6A pumps (0.5 mL/min), an SCL-6A system controller, an SPD ultraviolet detector, an SIL-1A sample injector and a C-R3A data processor, with semipreparative normal phase HPLC ZIC®-HILIC 250 × 10 mm, 5 μm, 200 Å column. The gradient was as described above, with a flow rate of 4.5 mL/min, and was monitored by a variable wavelength detector at 210 nm (HP 1040 M Diode Array Detector).

Isolation of Aldehydes and Fatty Acids from Plasmalogens

In order to hydrolyze plasmalogens, the eluted compounds from semipreparative HILIC (∼ 10–100 μg) were treated with 90% acetic acid at 37 °C for 18 h and dried under reduced pressure. The products were dissolved in a small volume of chloroform and subjected to thin-layer chromatography on silica gel G, eluted by chloroform–methanol–7 M ammonia 60:35:5 (v/v/v) mixture and spots were located by spraying with water. The aldehydes, derived from the alk-l-enyl groups, and lysophospholipids were extracted from the plates with chloroform–methanol 1:2 (v/v). The fatty aldehydes were stored in hexane at −20 °C until analyzed. The lysophospholipid was heated at 75 °C in the presence of 10% NaOH and 50% methanol (1 mL) for 3 h. The hydrolysate was cooled, extracted twice with petroleum ether, and then adjusted to pH 3 with concentrated HCl. The acidified solution was extracted three times with diethyl ether (1 mL) and the combined extracts were then washed with water, and the sample was concentrated under nitrogen. The fatty acids were then methylated with diazomethane [32].

GC–MS

Gas chromatography–mass spectrometry of FAME and free aldehydes was done on a GC–MS system consisting of a Varian 450-GC, a Varian 240-MS ion trap detector with electron impact ionization, and a CombiPal autosampler (CTC, USA). The sample was injected onto a 25 m × 0.25 mm × 0.1 μm Ultra-1 capillary column (Supelco, Czech Republic) under a temperature program: 5 min at 50 °C, increasing at 10 °C/min to 280 °C and 15 min at 280 °C. Helium was the carrier gas at a flow of 0.52 °C/min. All spectra were scanned within the range *m*/*z* 50–500.

Results

Cells of three strains of genus *Pectinatus* were cultivated as described in Experimental and were harvested in log phase when the optical density of the culture was maximal. The time of cultivation was 48 h. The yield of lyophilized cells is shown in Table 1, which also gives the yield of lipids obtained by the Bligh–Dyer [30] extraction of lyophilized cells. Part of total lipids was fractionated by means of cartridges with aminopropyl silica-based polar bonded phase, which were rinsed in a chloroform–methanol mixture and phospholipids were further eluted by a mixture of chloroform–methanol–concentrated aqueous ammonia.

The HILIC employing a column with sulfobetaine group (3-(trimethylammonio)propane-1-sulfonate) with a zwitterionic character phase is suitable for separating phospholipids as well as their plasmalogen forms thanks to the use of an appropriate mobile phase, i.e. a buffer containing ammonium formate. This prevents acid hydrolysis of the enol bonds. Baseline resolution was achieved between all identified lipid classes, with partial resolution between alkenylacyl and diacyl phospholipids (Fig. 2) and Fig. 1 in Supplemental, describing the separation of five standards (16:0–18:1 PtdCho, 16:0–18:1 PtdEtn, 16:0–18:1 PtdSer, 16:0–18:1 PtdOH, and 16:0–18:1 PtdGro). The identities of alkenylacyl- and diacyl-phospholipid peaks were confirmed after HILIC separation followed by ESI–MS/MS, see below.

Baseline was stable and retention times of all identified classes of phospholipids were well reproducible, with standard deviations ± 0.05 min for the commercially obtained standards 1-*O*-1′-(*Z*)-octadecenyl-2-(9*Z*-octadecenoyl)-*sn*-glycero-3-phosphoethanolamine (p18:0/9*Z*-18:1-PtdEtn) and ± 0.07 min for 1-*O*-1′-(*Z*)-octadecenyl-2-(9*Z*-octadecenoyl)-*sn*-glycero-3-phosphocholine (p18:0/9*Z*-18:1-PtdCho).

Under these conditions, the main phospholipid classes were separated well. PtdGro was eluted first, followed by

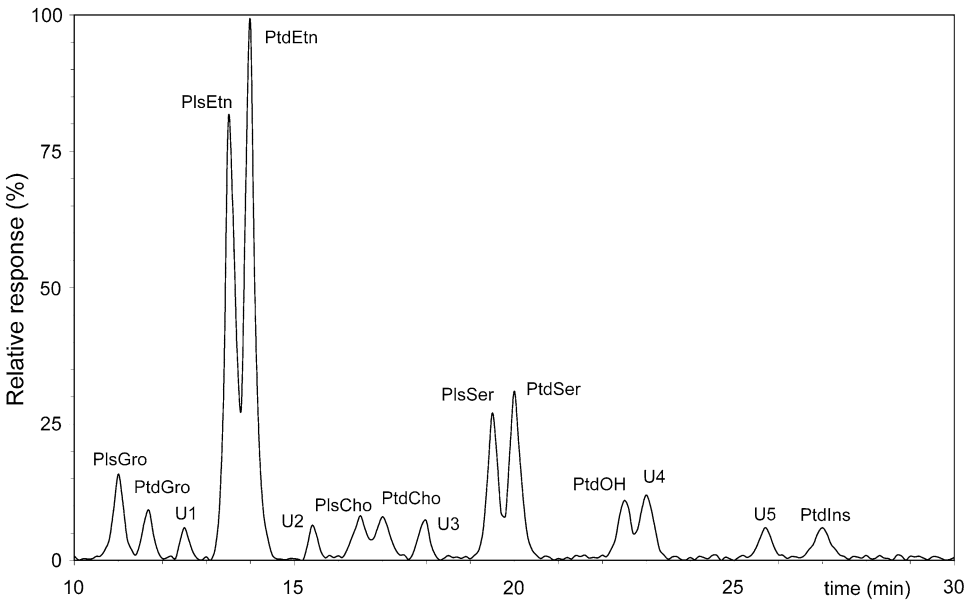

Fig. 2 HILIC/APCI-MS chromatogram of the phospholipids from *Pectinatus frisingensis* DSM 20465, analyzed by a linear gradient semipreparative normal phase HPLC ZIC®-HILIC 250 × 10 mm, 5 µm, 200-Å column, with a flow rate of 4.5 mL/min, and monitored by a variable wavelength detector at 210 nm

PtdEtn, PtdCho, PtdSer, PtdOH, and PtdIns (Fig. 2). Because different molecular species within a class have the same polar head, their retention times in HILIC are very similar. The differences in retention times for compounds within one class are less than that between two different classes. The different molecular species can be determined by MS/MS.

As mentioned in the Introduction, mass spectrometry fragmentation of diacylphospholipids has already been described but the situation with plasmalogen phospholipids is different. ESI tandem mass spectra of phospholipids as monolithiated $[M + Li]^+$ adduct molecular ions, arising at about 1 mM lithium salt concentrations in the mobile phase, show rich fragmentation, i.e. loss of some different neutral moieties, chiefly substituents at *sn*-3 or *sn*-2 position, exceptionally *sn*-1 (1-*O*-alk-1′-enyl) of plasmalogen. The corresponding ions are given in Tables 2, 3, 4 and 5. Apart from these ions that occur regularly in all four plasmalogens, some plasmalogens give rise to specific ions that can serve for direct identification of the given plasmalogen. Fast and exact identification was based on the separation by HILIC column and identification of phospholipids as monolithiated adducts, which allows for a ready identification of plasmalogens even in very low concentrations of about ~0.7 ng/µl.

The most abundant phospholipid was PtdEtn (29.7% total lipids) including its plasmalogen form (PlsEtn; 24.2%). Structural characterization of PlsEtn is complicated by numerous homologues that consist of various isomers (Fig. 3). Identification of individual molecular species was based on tandem MS. For example, the MS/MS spectrum of ion at *m/z* 678 of lithiated molecular species c-p17:0/15:1 PlsEtn showed the most abundant ion at *m/z* 635 ($[M + Li\text{-}43]^+$), i.e. ion with the structure shown in Fig. 4 and Table 2. Other ions present in the spectrum are formed by cleavage of neutral molecules, see e.g. ions at *m/z* 555 $[M + Li\text{-}123]^+$, *m/z* 549 $[M + Li\text{-}129]^+$, *m/z* 532 $[M + Li\text{-}141]^+$ and *m/z* 531 $[M + Li\text{-}147]^+$, arising from neutral losses; for structures see Table 2.

Two ions with moderate abundance at *m/z* 383, representing combined losses of aziridine and the *sn-1* alk-1′-enyl as an alcohol, i.e. $C_{15}H_{29}CH = CHOH$ and ion at *m/z* 291, representing the combined losses of lithium 2-aminoethyl hydrogenphosphate (for the structure see Table 2) and the *sn-2* fatty acid, i.e. pentadecenoic acid, were identified. The nature of the fatty acid at *sn*-2 was further verified by the presence of the acylium ion at *m/z* 240. Based on the above ions it is thus possible to determine in this plasmalogen the bond of the alkenyl ether at *sn-1* as well as the fatty acid at *sn-2*. The mass spectrum displays, below *m/z* 200, a dominant ion at *m/z* 148, which, though it does not provide information about the pPE structure, is nevertheless characteristic for PlsEtn and naturally also PtdEtn. This ion is not shown in the spectrum.

Identification of molecular species with the same molecular mass, i.e. isobaric species, was more complicated but not unfeasible, see Fig. 5. This can be best illustrated on two cases. First the mixture of two molecular species, i.e. c-p17:0/c-19:0 (5.5% of total PlsEtn) and c-p19:0/c-17:0 (4.8% of total PlsEtn), exhibits ions $[M + Li\text{-neutral molecules}]^+$, i.e. ions at *m/z* 691, 673, 611, 605, 593, and 587, which only confirm the structure of both molecular species and do not permit an even semi-quantitative estimate of their abundances. This estimate was only possible based on the cluster of cluster of four ions, i.e. two pairs (losses of aziridine with the *sn-1*

Table 2 Some important ions observed in the product ion spectrum of the $[M + Li]^+$ of molecular species c-p17:0/15:1-PlsEtn at *m/z* 678

PlsEtn	*m/z* for c-p17:0/15:1-PlsEtn
$[M+Li]^+$- 	678 − 43 = 635
$[M+Li]^+$-  -H_2O	678 − 43 − 18 = 617
*$[M+Li]^+$- 	678 − 123 = 555
*$[M+Li]^+$- 	678 − 129 = 549
$[M+Li]^+$- 	678 − 141 = 537
$[M+Li]^+$- 	678 − 147 = 531
$[M+Li]^+$-  -$R_1CH{=}CHOH$	678 − 43 − 252 = 383
$[M+Li]^+$-  -R_2COOH	678 − 147 − 240 = 291
R_2CO^+	223

Though Hsu and Turk [24] describe a linear structure of neutral fragments, i.e. $(HO)P(O)(OCH_2CH_2NH_2)$, a cyclic structure gives a better fit (see the neutral loss products in the paper by Zemski Berry and Murphy [50])

Data were obtained by RP-HPLC/ESI-tandem MS/MS operated in positive ionization mode

alk-1′-enyl and combined losses of lithium 2-aminoethyl hydrogen phosphate with the *sn-2* fatty acid. The abundance of ions at *m/z* 439 and 409, or those at *m/z* 319 and 291, enabled us to determine the semiquantitative abundances of individual molecular species.

The same holds for four molecular species, i.e. a most complex mixture of positional isomers containing these four molecular species, i.e. p15:0/c-17:0, p17:0/15:1, c-p17:0/15:0, and c-p19:0/13:0. Based on losses of aziridine with the *sn-1* alk-1′-enyl and combined losses of lithium 2-aminoethyl hydrogen phosphate with the *sn-2* fatty acid we could again determine the percent abundances. Further molecular species of next plasmalogens were identified similarly.

Like with the PlsEtn, also the tandem MS/MS spectrum of p17:0/15:0-PlsSer having $[M + Li]^+$ ion at *m/z* 726 contains prominent ions at *m/z* 541 and at *m/z* 535 arising from loss of phosphoserine as free acid and as a lithium salt, respectively (see Table 3). ESI spectrum of PlsGro is shown in Fig. 2 in Supplemental. The ion at *m/z* 639 (726-aziridine carboxylic acid) having medium abundance, and ions at *m/z* 397 (639-R_2COOH) and at *m/z* 415 (639-$R_2'CH = CO$) resulting from loss of the 15:0-fatty acid moiety and the corresponding loss of fatty acyl ketene, respectively, provide information needed for assignment of the *sn*-2 position of the fatty acyl substituents on the glycerol backbone. The ion at *m/z* 628 corresponding to loss of the phosphoric acid originated by rearrangement in which the anionic site of the serine head group makes a nucleophilic attack on C-3 of the glycerol backbone, followed by expulsion of the phosphoric acid. The mass spectrum also features an ion at *m/z* 484 arising from $[M + Li]^+$ loss of the fatty acid group. The presence of ion at *m/z* 281 confirms the position of the alkenyl ether at *sn*-1. The structure of fatty acid bonded to glycerol backbone was again confirmed by the presence of ion $[R_2CO]^+$

Table 3 Some important ions observed in the product ion spectrum of the $[M + Li]^+$ of molecular species p17:0/15:0 PlsSer at *m/z* 726

PlsSer	*m/z* for p17:0/15:0 PlsSer
 $[M+Li]^+$-	726 − 87 = 639
$[M + Li]^+$-H_3PO_4	726 − 98 = 628
 $[M+Li]^+$-	726 − 185 = 541
 $[M+Li]^+$-	726 − 191 = 535
$[M + Li]^+$-R_2COOH	726 − 242 = 484
 $[M+Li]^+$- -R´$_2$CH=C=O	726 − 87 − 224 = 415
 $[M+Li]^+$- -R_2COOH	726 − 87 − 242 = 397
 $[M+Li]^+$- -R´$_1$CH=CHOH	726 − 191 − 214 = 321
R_2CO^+	225

Data were obtained by RP-HPLC/ESI-tandem MS/MS operated in positive ionization mode

at *m/z* 225. Further, the spectrum displayed an ion at *m/z* 192 corresponding to a lithiated phosphoserine ion via cleavage of the C_3-OP bond. This ion (not shown in our spectrum) is characteristic only for PtdSer and therefore also for PlsSer.

The qualitative and quantitative abundance of molecular species having the same summary formula and thus the same molecular weight, i.e. c-p19:0/18:1 and p18:1/c-19:0, was analyzed as described with PlsEtn. Hence we can determine the abundance of two ions at *m/z* 423 and at *m/z* 409, i.e. ion with structure [M-aziridine carboxylic acid-fatty acid]$^+$ and two appropriate ions at *m/z* 335 and at *m/z* 321 with structure [M-phosphoserine as lithium salt-$R_1'CH = CHOH]^+$. Semiquantitative abundance of three or four molecular species with the same summary formula, e.g. c-p19:0/15:0, p18:1/16:1, c-p17:0/17:0, and p17:0/c-17:0, was estimated as described above with PlsEtn.

The c-p17:0/15:1 PlsCho molecular species having $[M + Li]^+$ ion at *m/z* 720 yields a prominent product ion at *m/z* 661 caused by loss of $N(CH_3)_3$ (Table 4). For the ESI spectrum of PlsCho from *Pectinatus frisingensis* see Fig. 3 in the Supplemental Material. This *m/z* 661 $[M + Li-59]^+$ ion yields ions of *m/z* 537 $[M + Li-183]^+$ and *m/z* 531 $[M + Li-189]^+$ resulting from losses of ethylene phosphate and lithium ethylene phosphate, respectively. Identification of the fatty acid substituent at *sn*-2 is based on the occurrence of the *m/z* 472 ion $[M + Li-R_2COOLi]^+$ that is produced by loss of lithium pentadecanoate from *m/z* 720, and a prominent ion of *m/z* 291 $[531-C_{16}H_{31}COOH]^+$ caused by loss of pentadecenoic acid from *m/z* 531. The pentadecanoate moiety is clearly identified by the presence of the acylium ion at *m/z* 223 $[C_{16}H_{31}CO]^+$. Weak ions at *m/z* 468 and 409, which identify the 1-*O*-heptadecenyl moiety, arise by loss of the 1-alkenyl moiety as an alcohol ($C_{13}H_{27}CH = CHOH$) from *m/z* 720 and 661, respectively, and further dissociation of the latter ion yields a weak ion at *m/z* 395.

The last plasmalogen was identified as PlsGro; its ESI spectrum is shown in Fig. 4 in Supplemental. The tandem MS/MS spectrum of an ion $[M + Li]^+$ at *m/z* 793 indicates

the structure of p19:0/c-19:0 PlsGro. Loss of dihydroxycyclopropane from this $[M + Li]^+$ ion gives rise to a prominent ion at *m/z* 719, see Table 4. Loss of fatty acid from this ion yields in turn an ion at *m/z* 423, which is important for the diagnostics of the structure of fatty acid at *sn*-2. Also the ion at *m/z* 497, arising by a mere loss of fatty acid from the $[M + Li]^+$, determines the structure of fatty acid at *sn*-2. Like PtdSer, also PtdGro molecule undergoes a rearrangement with a concomitant expulsion of phosphoric acid, giving rise to the ion $[M + Li\text{-}H_3PO_4]^+$ at *m/z* 695. As mentioned in the Introduction, many ions are common for all phospholipids; in the case of PtdGro these are the ions arising by splitting of the polar part of molecule form *sn*-3 of glycerol backbone, i.e. ions at *m/z* 621 and at *m/z* 615. These ions arise by the splitting of glycerophosphoric acid (systematic name is 2,3-dihydroxypropyl dihydrogen phosphate) or its lithium salt $[M + Li\text{-}172]^+$ and $[M + Li\text{-}178]^+$, respectively. For structure of both ions see Table 5.

The remaining two phospholipids, i.e. PtdOH and PtdIns, in which no plasmalogens have been found, were identified based on literature data, see below. After identifying all four plasmalogens we performed quantitation of fatty acids and phospholipids in the three strains of genus *Pectinatus*.

Phospholipids were further separated by semipreparative HILIC, see Experimental. The major phospholipids were PtdGro, PtdEtn, PtdCho, and PtdSer, including their plasmalogens; PtdIns was present in minor amounts. Five peaks were not identified, see Fig. 3.

The content of fatty acids determined by GC–MS in the three species of *Pectinatus* is given in Table 6. The fatty acids included saturated ones from C11 to C18, as well as monoenoic ones and also two acids having a cyclopropane ring in the midchain position. The quantitative proportion of FA in different phospholipids of one species, as well as in individual strains did not substantially differ.

A similar situation was found in the case of aldehydes arising by mild acidic hydrolysis; an interesting feature was the minor proportion of octadecenal in all three PlsEtn.

Discussion

The comparison of our results with the literature data is difficult or nearly impossible. As was found already in the

Table 5 Some important ions observed in the product ion spectrum of the $[M + Li]^+$ of molecular species p19:0/c-19:0-PlsGro at *m/z* 793

PlsGro	*m/z* for p19:0/c-19:0-PlsGro
 $[M+Li]^+$-	793 − 74 = 719
$[M + Li]^+$-H_3PO_4	793 − 98 = 695
 $[M+Li]^+$-	793 − 172 = 621
 $[M+Li]^+$-	793 − 178 = 615
$[M + Li]^+$-R_2COOH	793 − 296 = 497
 $[M+Li]^+$- -R_2COOH	793 − 74 − 296 = 423
R_2CO^+	279

Data were obtained by RP-HPLC/ESI-tandem MS/MS operated in positive ionization mode

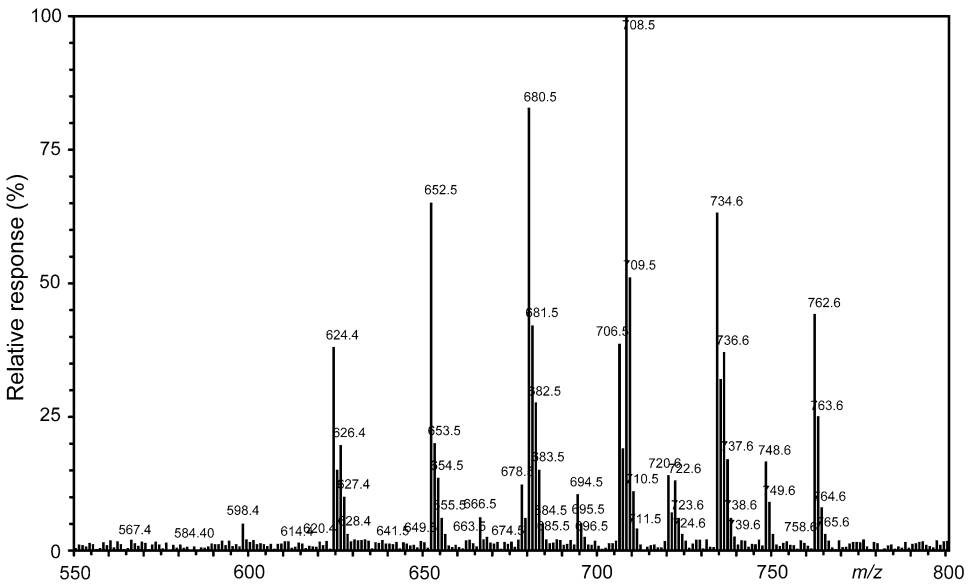

Fig. 3 ESI spectrum of PlsEtn from *Pectinatus frisingensis* DSM 20465. MS was run by using the electrospray mode and set to scan from 200 to 1,100 kDa. Only the most relevant part of the mass spectrum is shown (550–800 kDa). Adduct ions in the form of $[M + Li]^+$ are seen throughout the spectrum

1960s, fatty acids with a cyclopropane ring are very susceptible to acidic conditions that cause cleavage of the ring. This was documented in 1965 by Nesbitt and Lennarz [33] who therefore saponified cells of the genus *Proteus* by 10% NaOH and methylated free FA by diazomethane. This approach, which was used also by other authors [34], avoided the cleavage of the cyclopropane ring. As noted in 1989 by Christie in his book, "Cyclopropane fatty acids of bacterial origin are more susceptible to chemical attack, e.g. cyclopropane ring is disrupted by acidic conditions, and lipid samples containing such acids are best transesterified with basic reagents; the free fatty acids can be methylated safely with diazomethane" [35]. The dramatic drop in the content of cyclopropane FA under acidic conditions when preparing FAME was recently amply documented by Basconcillo and McCarry [36]. The table published in their paper shows that basic hydrolysis and acid esterification of FA from the bacterium *Sinorhizobium meliloti* brings about a drop of cis-11,12-C19:0_{cyclo} from 31 to 2.5% total FA, i.e. by more than one order of magnitude.

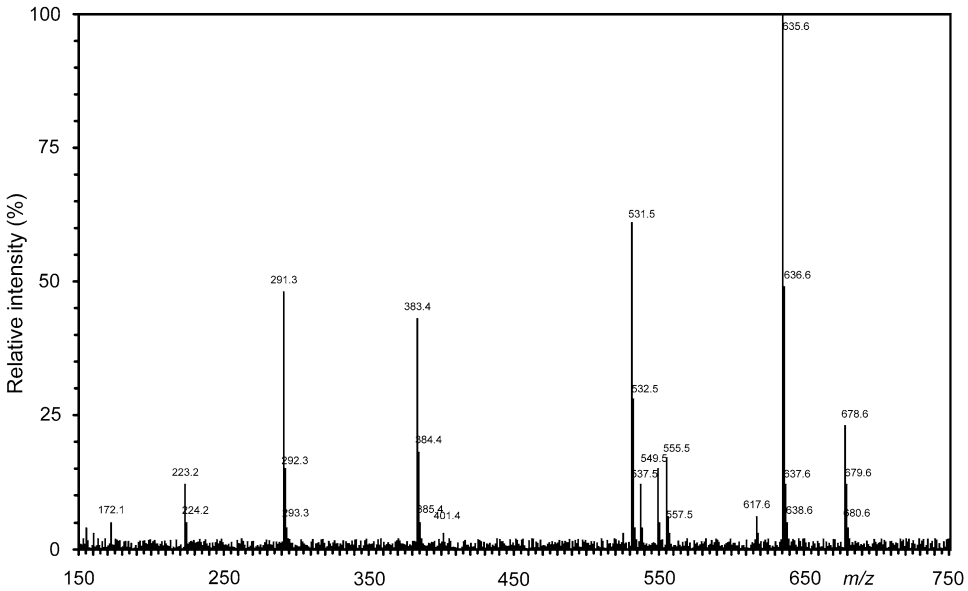

Fig. 4 The MS/MS spectrum of lithiated molecular species c-p17:0/15:1 PlsEtn obtained in ESI. The ion at *m/z* 678.6 was selected for fragmentation. This ion was further fragmented with CID resulting in the presented spectrum. Fragment identities and their structures are explained in Table 2

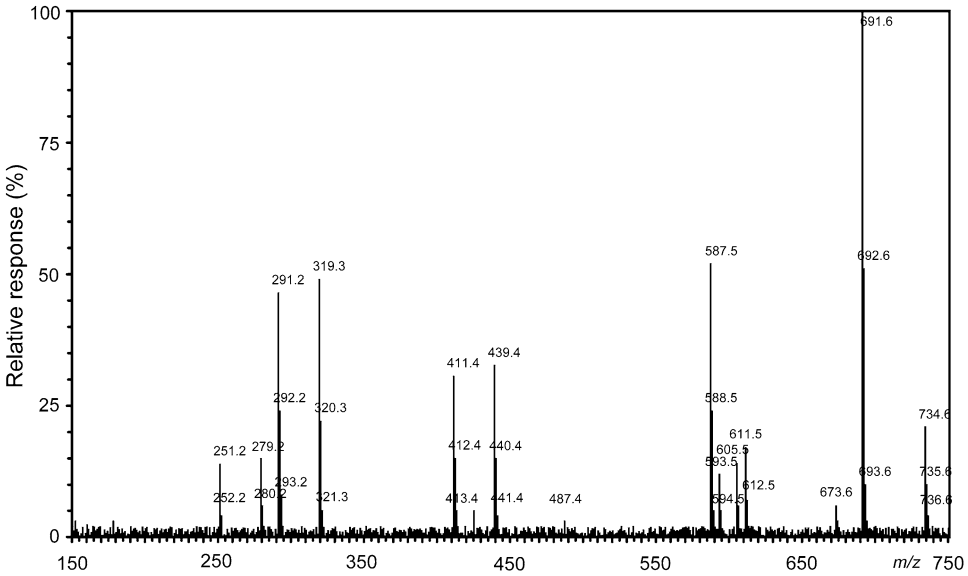

Fig. 5 Tandem MS/MS of the mixture of two molecular species—c-p17:0/c-19:0 and c-p19:0/c-17:0 PlsEtn. Quantification of isobaric species of plasmalogens was based on six ions, i.e. ions at *m/z* 251 and 279 $[RCO]^+$, *m/z* 291.3 and 319.3 $[M + Li\text{-}147\text{-}R'2COOH]^+$, and *m/z* 411.4 and 439.4 $[M + Li\text{-}43\text{-}R'1CH = CHOH]^+$

Accordingly, Moore et al. [37], who used basic hydrolysis and acid-catalyzed esterification, found no cyclopropane FA in *Pectinatus*. Gonzalez et al. [38], who erroneously identified the species *P. portalensis*, also failed to find any cyclo-FA, not even in the previously described *P. frisingensis* or *P. cerevisiiphilus*. Moreover, their data showed completely baffling differences between the contents of FA in individual species. Johnston and Goldfine [39], who analyzed the related genus *Megasphaera*, realized that the chromatographic peak of monoenoic FAME could contain cyclopropane FAME and found that, following catalytic reduction that disrupts the cyclopropane ring, major c-17:0 acyl chain peak decreased from 60.5 to 2.9% of total FA. This means that it was in fact a mixture of two FA, i.e. cyclo-17:0 and 17:1 in a ratio of about 20:1, not a pure 17:1.

Unusual ions arising from 9-methoxy acids and found in the MS spectrum by Helander and Haikara [3] led to the conclusion that these acids were artificially created during methanolysis from cyclopropane acids. The substantial differences between FAME prepared by methanolysis and those prepared by saponification can thus be explained by the degradation of cyclopropanoic acids.

Even when using reaction conditions preventing degradation of cyclopropane FA, the experimenter is faced with two other problems. As has been known for several decades [35], the ECL values of C18 cyclopropane FAME and corresponding C18 monoenoic methyl esters are approximately equal, see, e.g., Fig. 2 in the paper by Helander and Haikara [3]. Moreover, cyclopropanoid FAME are not readily distinguished by MS from monoenoic FAME with a

Data were obtained by GC–MS of fatty acid methyl esters, the structure of unsaturated fatty acids was determined by the mass spectra of picolinyl esters

similar total number of carbon atoms, apparently because on ionisation the cyclopropane ring opens up to form some degradation products [40, 41]. Much better results are obtained with picolinyl ester derivatives (see Harvey [42] and also our two mass spectra given in Figs. 5 and 6 of Supplemental).

Most authors analyzing the *Pectinatus* FA failed to employ optimum conditions and the reliability of their data is therefore questionable. The same holds for monoenoic and cyclopropanoic aldehydes.

Quantification of individual classes of phospholipids including plasmalogens is based on the total ion current of commercially available standards. The calibration curves of four standards, i.e. PtdCho, PlsCho, PtdEt and PlsEtn (9*Z*-18:1/9*Z*-18:1-PtdCho, p18:0/9*Z*-18:1-PlsCho, 9*Z*-18:1/9*Z*-18:1-PtdEtn, and p18:0/9*Z*-18:1-PlsEtn) showed that these molecular species have a linear response in the range of nearly four orders of magnitude, i.e. from 1 μmol/mL to 10 mmol/mL (i.e. ~0.7 μg/mL to ~7 mg/mL). The worst values of % RSD (relative standard deviation) were obtained for the lowest and the highest chromatographic peaks. This could be due to the signal being too weak (a low signal to noise ratio) or to a charge space phenomenon caused by the accumulation of too many ions in the mass spectrometer (in the case of the highest chromatographic peak, i.e. at a high concentration of the compound). The samples were therefore appropriately diluted to an optimal concentration (100 μmol/mL) to avoid the loss of signal from the lowest chromatographic peak and limit the charge space phenomenon for the highest chromatographic peak. This compromise maximizes reproducibility. Unfortunately, PlsGro and PlsSer are not commercially available but both these plasmalogens can be assumed to have a very similar mechanism of ionization (see above) allowing thus also the same quantification by means of the total ion current. Comparison of relative concentrations of individual FAME calculated from GC/MS and from HPLC/MS-APCI of TAGs is given in Table 1 in Supplemental.

The quantification of single ion molecular species was much more complicated. Based on the measurements of commercially available standards PlsCho and PlsEtn and the corresponding homologs PtdCho and PtdEtn (i.e. 9*Z*-18:1/9*Z*-18:1-PtdCho and 9*Z*-18:1/9*Z*-18:1-PtdEtn, respectively) we found that the abundant ions at *m/z* 425 $[M + Li\text{-}43\text{-}R'_1CH = CHOH]^+$ and at *m/z* 305 $[M + Li\text{-}147\text{-}R'_2COOH]^+$ in PlsEtn and ions at *m/z* $[M + Li\text{-}43\text{-}R_1COOH]^+$ and $[M + Li\text{-}43\text{-}R_2COOH]^+$ in PtdEtn, and also ions $[M + Li\text{-}59\text{-}R_1COOH]^+$ and $[M + Li\text{-}59\text{-}R_2COOH]^+$ in PtdCho and ions at *m/z* 465 ($[M + Li\text{-}59\text{-}R'_1CH = CHOH]^+$) and at *m/z* 395 ($[M + Li\text{-}103\text{-}R'_2$

$CH = C{=}O]^+$) in PlsCho show a linear response in an interval of more than three orders of magnitude, i.e. from 5 to 10 mmol/mL. Individual molecular species of plasmalogens were therefore quantified based on the above ion. Because of the lack of commercial standards of PlsGro and PlsSer we again used the assumption of a very similar mechanism of ionization. More exact quantification would require either the use of two-dimensional HPLC (normal and reversed phase HPLC) or acquisition (synthesis) of appropriate standards, i.e. different molecular species of PlsSer and PlsGro.

As already mentioned in the Introduction and in the paragraph describing the occurrence of fatty acids in *Pectinatus* and related bacteria, the determination of both qualitative and quantitative proportions of FA is highly questionable. To our knowledge, no paper devoted to identification and quantitation of molecular species of plasmalogens in *Pectinatus* has as yet been published. The results of our analyses of these molecular species are shown in Table 7. Although the molecular species of individual classes of phospholipids have been described in bacteria such as *Escherichia coli* [43] or *Corynebacterium* [44], these bacteria are taxonomically relatively distant from *Pectinatus*. The taxonomically nearest bacterial genus that has been described in the literature is *Clostridium*, which also belongs to anaerobes and is taxonomically classed to the same order (Clostridiales), although to a different family (Clostridiaceae) [45].

Both our literature survey and a recent review [15] point to the scarcity of data on the analysis of molecular species of phospholipids, especially of plasmalogens in bacteria. Only a single study by Hsu and Turk [43] reported on the analysis of cardiolipin from *E. coli* using modern techniques, identified cardiolipin and described the quantitative analysis of isobaric molecular species.

Only six molecular species of *O*-alanylphosphatidylglycerol and six molecular species of phosphatidylethanolamine were identified in the genus *Clostridium*, which

Data were obtained from ESI spectra

belongs to the same order as the genus *Pectinatus*, although the polar lipids of *C. perfringens* were analyzed by LC/MS with electrospray ionization. The assumed presence of plasmalogens was based only on a TLC plate treated with HCl vapors, lyso-phosphatidylethanolamine being derived by acid hydrolysis of the plasmalogens of PtdEtn [46].

A later work on *C. tetani* identified phospholipids such as PtdEtn, PtdGro, cardiolipin and EtnPGlcNAcdiradylglycerol. FA on *sn*-1/*sn*-2 were determined only in

seven out of 35 molecular species of PE and PG, no data on their quantitative proportions being given [47].

The high variability of bacteria can be illustrated in the paper [48] in which plasmalogens were identified in *C. tetani* ATCC 454 but not in strain ATCC 10779. The authors again identified plasmalogen forms of PtdEtn, PtdGro, cardiolipin, etc., but acyls at the *sn*-1 and *sn*-2 positions were determined in only 7 of them, again with no quantification.

An excellent paper on phospholipids and also plasmalogens of lower organisms was published in Parasitology [49]. Many hundreds of molecular species of phospholipids were identified in parasitic protist species *Trypanosoma brucei*, which included, e.g., 128 molecular species of PtdEtn, out of which 15 were plasmalogens.

Conclusion

The HILIC/ESI-MS^n method used here efficiently separated plasmalogens and all other phospholipids usually found in anaerobic bacteria by a single chromatographic run. We determined more than 200 lipid molecular species from four lipid classes with one injection on an HILIC column, which is nearly ideal for separating amphiphilic compounds such as phospholipids with excellent reproducibility, high sensitivity (from 1 μmol/mL) and dynamic range (4 orders of magnitude). This column was used for both analytical determination and semipreparative isolation of alkenyl-acyl- and diacyl-phospholipids. Irrespective of the class of phospholipids, plasmalogen is eluted first and this is followed by a nearly baseline-separated corresponding diacyl-phospholipid. The elution can be performed conveniently by an aqueous phase with a buffer compatible with ESI.

Simultaneous detection of intact plasmalogens together with other phospholipid classes (odd-chains fatty acids, aldehydes) offers a valuable tool for the study of phospholipids. The fragmentation processes observed by tandem MS of plasmalogens generate unique determinants of the identities of the 1-*O*-alk-1-enyl chains at the *sn*-1 position and the fatty acid esterified at the *sn*-2 position of the glycerol backbone.

Tandem MS of plasmalogen molecules as lithiated adduct ions offers an optimum means for structural characterization. The structure of plasmalogen molecules can be easily determined from the positive ESI showing abundant fragment ions with different polar head groups, fatty acid constituents and regiospecificity. The $[M + Li]^+$ ions of plasmalogens that have undergone consecutive losses of the fatty acid substituent at *sn*-2 and the polar head group, i.e. the $[M + Li–R_2COOH–polar\ head\ group]^+$ ions greatly aid in the differentiation of the plasmenyl- and diacyl-phospholipid subclasses, including PtdEtn, PtdCho, PtdGro and PtdSer. Thus, structures of plasmalogens with isobaric isomers in mixtures can be unambiguously unveiled.

We believe that the method will be valuable for studying phospholipid profiles in different biological samples.

ORIGINAL ARTICLE

Non-Polar Lipid Components of Human Cerumen

Karel Stránský · Irena Valterová · Edita Kofroňová · Klára Urbanová · Marie Zarevúcka · Zdeněk Wimmer

Received: 21 January 2011 / Accepted: 19 April 2011 / Published online: 6 May 2011

Abstract Human cerumen was separated by column chromatography into the following groups of compounds: hydrocarbons, squalene, wax esters and cholesterol esters, triacylglycerols, free fatty acids, free fatty alcohols, monoacylglycerols, free cholesterol, free sterols, and free hydroxy acids. The groups of compounds obtained were examined in detail by gas chromatography and gas chromatography–mass spectrometry. In total, about one thousand compounds have been identified.

Keywords Cerumen · Ear wax · Lipids · ECL values · ACL values

Abbreviations

ACL	Alcohol chain length
APCI	Atmospheric pressure chemical ionization
CC	Column chromatography
DMDS	Dimethyl disulfide
ECL	Equivalent chain length
FAME	Fatty acid methyl ester
GC–MS	Gas chromatography/mass spectrometry
HPLC	High performance liquid chromatography
I	Kováts index
PTLC	Preparative thin layer chromatography
R_F	Retention factor
TAG	Triacylglycerol(s)
TLC	Thin layer chromatography
UV	Ultra violet

Introduction

Cerumen is the secretory product of the sebaceous and ceruminal glands in the outer third of external auditory canal and it is the main component of earwax. Other components of earwax are sheets of desquamated keratin squames, sweat, sebum, and various foreign substances (hair spray, shampoo, shaving cream, bath oil, cosmetics, dirt, etc. [1, 2]. A number of scientists have dealt with its chemical composition. Several papers have been focused on investigation of proteins [3–6], amino acids [3, 7–9], and other nitrogen-containing compounds [3, 10], sugars [9, 11], and glycopeptides [12–14]. Several elements (Na, K, Ca, Mg, P and Cu) were identified and the presence of volatile products was mentioned as well [15]. A majority of papers have been focused on the investigation of lipids, which represent major components of ear wax (up to 64%) [4, 16]. Nakamichi [17] described the presence of a large quantity of glycerol esters and cholesterol esters, and Nakashima [3] identified several fatty acids, triacylglycerols, and cholesterol. Nitta and Ikai [18] found short chain fatty acids (C_4–C_6). Wheatley [19] was the first one who identified squalene in human cerumen, but he also

described [20] the presence of hydrocarbons, wax alcohols, cholesterol, and sterol-like substances. Akobjanoff et al. [21] found cholesterol and fatty acids. For the first time, gas chromatography was used by Haahti et al. [22, 23] for identification of fatty acids, squalene, cholesterol, alcohols, and esters. Sumiko and Akikatsu [8] used fractionation into different solvent systems for separation the cerumen components, and described the presence of free cholesterol and its esters, triacylglycerols and phospholipids. Kataura [24] used column chromatography on silica gel for isolation of several groups of compounds (cholesterol, triacylglycerols, fatty acids and unidentified lipids). Kataura and Kataura [25] isolated cholesterol esters, triacylglycerols, diacylglycerols, monoacylglycerols, free fatty acids, and unidentified polar lipids by column chromatography on silica gel. Aitzetmüller and Koch [26] found by HPLC of methylated and non-methylated chloroform extracts that cerumen contains lipid classes similar to sebum. Gershbein et al. [27] used alumina for fractionation of the groups of compounds. Saponified part of human cerumen was separated into hydrocarbons (with squalene as the main component), cholesterol, alcohols, and fatty acids. Lipid composition of earwax in connection to hircismus (strong odor) was studied by Inaba et al. [28]. Bortz et al. [29] also studied the hydrocarbon content in cerumen. However, Harvey [30] published so far the most detailed analysis of cerumen by application of a GC–MS analysis. Human cerumen was saponified, and the compounds were analyzed by GC-MS after derivatization. Nearly 200 compounds were found in a chromatogram, and nearly one half of them were identified. In view of the fact that a majority compounds were present both free and bonded, it has not been possible to characterize their "origin". Bortz et al. [1] solved this handicap: They separated the human cerumen into the individual groups of compounds (squalene, cholesterol esters, wax esters, triacylglycerols, fatty acids, cholesterol, ceramides, and cholesterol sulfate) using preparative chromatography, however, they did not perform a more detailed analysis of these product groups.

For quantitative evaluation of sebum lipid components, nuclear magnetic resonance was also used [31]. The composition of cerumen was also investigated by using flash pyrolysis–gas chromatography–mass spectrometry analysis [32]. Simple aromatic hydrocarbons were found together with non-branched chain aliphatic hydrocarbons, several diterpenoids and steroid compounds including cholesterol. Due to the destructive character, this method may be only used for fingerprinting of cerumens from different origin.

Besides the human cerumen, lipids in cow's cerumen [33], in dog's cerumen [34–36], and complex carbohydrates in the ceruminous glands of the goats [37] were studied. Cerumen was also studied from a microbiology point of view [38–40]). Its bacteriostatic and fungistatic properties were described in the 1960s [22, 35, 36, 41–48]. A considerable number of people suffer from cerumen secretion, which may result in serious health problems. Absence of cerumen may lead to infection, in that, cerumen plays an antibacterial role through physically protecting the external auditory canal skin, establishing a low pH and an inhospitable environment for pathogens and producing antimicrobial compounds such as lysozyme, so that its absence leaves the canal vulnerable to infection [48].

Cerumen represents a complex mixture of at least one thousand compounds the systematic analysis of which has not been done yet. In this paper, we present a detail analysis of non-polar lipids of human cerumen achieved by current analytical methodology.

Experimental

Collection of Materials

Ear wax (1.323 g) was collected twice a week from both ears of a healthy individual (a male, 65 years old) by means of a small wooden spatula (approx. 200 doses collected throughout 1 year, each approx. 6.6 mg), and it was kept at −18 °C up to the work-up. One of the authors of this work was the volunteer to have ear wax collected and, therefore, no special regulations for including humans in this research were needed.

Column Chromatography (CC)

Ear wax (1.323 g) was adsorbed on silica gel (6.5 g, 60–120 μm) and chromatographed on a column (2.5 × 31 cm) containing silica gel Pitra (Technical support laboratories of IOCB, Czech Republic; 80 g, 60–120 μm, water content 12%). Preparation of silica gel for chromatography was made by its 48-h extraction of silica gel with methanol/chloroform (1:1, v/v) in a Soxhlet apparatus, followed by drying, activating at 120 °C for 24 h, and finally by controlled deactivating the purified silica gel by adding water (12%, w/w). The components were eluted with a mixture of light petroleum-diethyl ether (concentration of diethyl ether increased continuously from 0 to 100%, v/v), and then with a mixture of chloroform–methanol (1:1 v/v). All solvents were distilled before using. The mixture was separated into 35 fraction [(25–100 ml, total solvent volume 1,750 ml (light petroleum-diethyl ether), and 1,000 ml (chloroform–methanol)]. Eluted compounds were monitored using thin-layer chromatography (TLC) and fractions containing compounds with the same R_F were combined.

Thin-layer Chromatography (TLC)

Analytical TLC was carried out on glass plates (36 × 76 mm) coated with Adsorbosil-Plus, layer thickness 0.2 mm (Applied Science Laboratories, USA) with gypsum (12%, w/w). Visualization of the spots was achieved by heating the plates sprayed with conc. sulfuric acid.

Preparative TLC (PTLC) was carried out on glass plates (20 × 20 cm) coated with the same silica gel as in analytical TLC. Visualization of the bands were achieved by spraying with Rhodamine 6G (Merck, Germany, 0.05% in ethanol), UV 235 nm. The chromatographic bands consisting of group of compounds were scraped off and transferred into small columns (8 mm i.d.) filled with silica gel (0.3 g, 25–50 μm), eluted with freshly distilled dry diethyl ether (15 ml), and evaporated to dryness.

Gas Chromatography (GC)

GC was performed on a 5890A gas chromatograph (Hewlett-Packard, USA) equipped with a flame ionization detector and split/splitless injector, the carrier gas was hydrogen. The following programs (a)–(f) were used for the columns DB-1 and DB-WAX (J&W Scientific, USA, length 30 m, I.D. 0.25 mm, film thickness 0.25 μm):

DB-1: (a) injector and detector temperatures 250 °C, oven temperature 140 °C (0 min), then increased at a rate of 5 °C min^{-1} to 320 °C (20 min or more), 90 kPa, $\bar{u}$ 45 cm s^{-1} (at 150 °C), split ratio 39:1; (b) injector and detector temperatures 250 °C, oven temperature 200 °C, 86 kPa, $\bar{u}$ 40 cm s^{-1}, split ratio 35:1; (c) injector temperature 280 °C, detector and oven temperatures 270 °C, 83 kPa, $\bar{u}$ 35.6 cm s^{-1}, split ratio 25:1.

DB-1 ms: (d) injector and detector temperatures 260 °C, oven temperature 240 °C (0 min), then increased at a rate of 1 °C min^{-1} to 340 °C (15 min), $\bar{u}$ 61 cm s^{-1} at 260 °C, split ratio 29:1.

DB-WAX: (e) injector temperature 220 °C, detector temperature 250 °C, oven temperature 140 °C (0 min), then increased at a rate of 5 °C min^{-1} to 230 °C (20 min or more), 90 kPa, $\bar{u}$ 46.2 cm s^{-1} (at 150 °C), split ratio 36:1; (f) injector and detector temperatures 250 °C, oven temperatures 200 °C, $\bar{u}$ 40 cm s^{-1}, split ratio 35:1.

Gas Chromatography–Mass Spectrometry

Gas Chromatography–Mass Spectrometry (GC–MS) was performed on a gas chromatograph (CE 8000 series, Fisons, Milan, Italy) coupled with a mass detector (Fisons MD 800 VG Masslab, Manchester, UK) working in electron ionization mode. DB-5 ms and DB-WAX columns (30 m × 0.25 mm × 0.25 μm, J & W Scientific) with helium flow 0.95 ml min^{-1} (at 140 °C) were used. Chromatographic conditions: injector temperature 250 °C, interface temperature 200 °C, oven temperature 140 °C (0 min), then increased at a rate of 5 °C min^{-1} to 320 °C (30 min or more for DB-5 ms) and to 230 °C (50 min for DB-WAX), split ratio 50:1. The National Institute of Standards and Technology (NIST) Library was used for identification of some compounds.

High Performance Liquid Chromatography

High Performance Liquid Chromatography (HPLC) was performed on a liquid chromatograph (Thermo Separation Products, San Jose, USA), which consisted of a SCM 1000 vacuum membrane degasser, a P 4000 quaternary gradient pump, an AS 3000 autosampler) and an LCQ classic ion trap mass spectrometer (Thermo Finnigan, San Jose, USA). The system was controlled by an SN 4000 control unit (Thermo Separation Products, San Jose, USA) and a PC using Xcalibur Software (Thermo Finnigan). TAG were separated on two Nova-Pack C18 stainless steel columns (length 300 mm, i.d. 3.9 mm, film thickness 4 μm (Waters, USA) connected in series. The mobile phase was a mixture of acetonitrile (A) and 2-propanol (B). The linear gradient from 0 to 70% of B in 108 min (1 mL min^{-1}) was followed by a linear gradient to 80% of B (130 min, 0.7 mL min^{-1}). The columns were kept at 30 °C during analysis. The mobile phase was mixed post-column in a low dead-volume T-piece with 100 mM ammonium acetate prepared in 2-propanol/water (1:1, v/v), flow rate 10 μL min^{-1}. The full scan mass spectra were recorded in the range of *m/z* 75–1,300. The temperatures of the vaporizer and heated capillary were set to 400 and 200 °C, respectively. The corona discharged current was 4.5 μA, capillary voltage and tube lens offset were 3 and 10 V, respectively. TAG were quantified from reconstructed chromatograms calculated for $[M + H]^+$ and $[M + NH_4]^+$ ions [49].The mass spectra (MS) were interpreted by software program TriglyAPCI developed specially for interpretation of APCI mass spectra of TAG isolated from various natural sources [50].

Transesterification

A mixture of TAG (1.5 mg) was dissolved in a mixture of chloroform/methanol (2:3 (v/v), 250 μl) in a sealed glass vial. Acetyl chloride (29.4 μl) was added and the vial was sealed and heated in a water bath at 70 °C for 90 min. The reaction mixture was neutralized with silver carbonate (57.1 mg). This procedure prevents the loss of volatile fatty acid methyl esters (FAME). After centrifugation, the supernatant was directly analyzed by GC or GC–MS. Using this method, fatty acid methyl esters were more easily prepared also from the free fatty acids and from free hydroxy acids [51, 52].

Calculation of Kováts Retention Indexes (I), Equivalent Chain Length Values and Alcohol Chain Length Values

Calculation of the I, equivalent chain lengths (ECL) and alcohol chain lengths (ACL) values was made by using the method described earlier [53, 54], using the reference compounds (*n*-alkanes, fatty acids methyl esters, 1-alkanols) co-injected with a sample. The number of experimental points (n) was a minimum of 5, remote experimental points were automatically excluded using the Dixon test (significance level $p = 0.01$).

Results

By means of gradient CC on silica gel, cerumen was separated into the following well-defined groups of compounds: aliphatic hydrocarbons, squalene, wax esters and cholesterol esters, triacylglycerols, free fatty acids, free fatty alcohols, monoacylglycerols, free cholesterol, free sterols, and free hydroxy acids (Table S1). These groups of compounds were then analyzed separately, and identified by GC and GC–MS techniques. The composition of these fractions is described below in the Discussion section, and the quantitative data are summarized in Tables S1–S8, located in the supplements.

Discussion

Hydrocarbons

The fractions 1–4 appeared as one spot at TLC (hexane, $R_F = 0.98$). The main part is formed by a homologous series of *n*-alkanes (C_{14}–C_{47}) with almost identical quantity of odd and even homologs (1.18:1). The branched and unsaturated hydrocarbons were present in small quantities (Fig. S1) and were not analyzed in details. Wheatley [20] mentioned hydrocarbons in cerumen for the first time in 1954. Due to the fact that the content of the minor quantity of alkanes could not be analyzed at that time, it has been supposed that he detected squalene [19], the content of which is much higher. Later, Bortz et al. [29] investigated the content of alkanes in a human skin surface lipid layer and in the ear wax. Although the composition of these alkanes strongly resembles petroleum waxes, it has been proposed that they are biosynthetic products of human skin. Hydrocarbons found in human cerumen are not environmental contaminants [29]. The presence of hydrocarbons had been reported by Harvey [30], however, without analytical details.

Squalene

The fractions 5–11 appeared as one spot at TLC (hexane, $R_F = 0.28$). The R_F value of this fraction was identical with that of squalene (2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene). Gas chromatography analysis resulted in finding one main peak (98.3%), the Kováts retention index ($I = 2819.03$) of which was found identical with that of the reference compound ($I = 2819.09$) [DB-1, program (**c**)]. The mass spectra were also found to be identical. Squalene forms almost 1% of the cerumen (Table S1).

Wax Esters and Cholesterol Esters

The fractions 14 and 15 appeared as one spot at TLC (hexane/diethyl ether 93:7, $R_F = 0.78$). Their R_F value was identical with that of stearyl palmitate. The chromatogram (DB-1, program (a) and DB-1 ms column, program (d) showed approximately 135 peaks, of which about 100 peaks (84 area %) represented the wax esters, 36 peaks (16 area %) represented cholesterol esters. Wax esters were analyzed by GC–MS. They formed a homologous series of the saturated and unsaturated, even and odd higher esters in the range from C_{23} to C_{41} with a maximum $C_{36:1}$. Based on a detailed analysis of the mass spectra [55, 56], one single GC peak of aliphatic esters always represents at least three isomers. The position of the ester functionality in the molecule has a low influence on the retention behavior at the GC, and a majority of the isomers could not be separated [57]. In total, about 550 esters (Table S2) were identified; their relative content has not been given because it rarely exceeded an area of 1%.

After transesterification of an aliquot part of the esters, three groups of compounds were found: methyl esters of acids ($R_F = 0.62$), aliphatic alcohols ($R_F = 0.15$) and cholesterol ($R_F = 0.09$) (TLC in hexane/diethyl ether 93:7). Each of the identified groups of compounds was isolated by PTLC and subsequently analyzed by GC and GC–MS.

The acid fraction (as methyl esters) consisted of a homologous series of saturated and unsaturated fatty acids (Table S3). Their identification was performed both by measurement of ECL values [53, 54] and by mass spectrometry of dimethyl disulfide (DMDS) adducts [58, 59]. Saturated acids formed a homologous series (C_{12}–C_{34}; 33.2%) with prevalent hexadecanoid acid (16:0, 9.0%). To a lesser extent, *n*-acids with odd C-atoms are present (4.2%), predominant 15:0 (3.0%) and branched *iso*-acids (7.9%) and *anteiso*-acids (5.2%). Monoenic fatty acids (C_{13}–C_{32}, 64.1%) form more than one half of all the acids. Based on retention times and mass spectra, one can deduce

that some unsaturated homologs are branched (9.4%, shown in the Tables with the prefix *br*-). A small quantity of dienoic acid 18:2 n-6 acid (2.4%) was also identified. Several unidentified minor peaks (0.3%) were also present in the chromatogram.

The alcohol fraction consisted of a homologous series of saturated and unsaturated 1-alkanols and 1-alkenols (Table S4). Their identification was performed both by measurement of the ACL values, and by mass spectrometry of underived alcohols and their DMDS adducts [60]. The ACL values were introduced for easier identification of unknown alcohols. The ACL value is analogous to the equivalent chain length value (ECL). Saturated non-branched chains of 1-alkanols were used in the measurement and calculation of the ACL values instead of methyl esters of saturated fatty acids used in the measurement and calculation of the ECL values. It was found that the ACL values for *iso*- and *anteiso*- alcohols are identical with the ECL values of the corresponding fatty acids methyl esters. As an example, several pairs of ECL values for methyl esters and ACL values for the corresponding alcohols are given: *i*-14:0 (13.6470; 13.6508), *i*-15:0 (14.6447; 14.6475), *a*-15:0 (14.7296; 14.7310), *i*-16:0 (15.6437, 15.6450); *i*-18:0 (17.6411; 17.6412), *i*-20:0 (19.6397; 19.6417), *i*-22 (21.6376; 21.6404), and *a*-22 (21.7238; 21.7197). It should be noted that the ECL values were measured in 1996 [54] while the ACL values were calculated only recently (2009) from another column [DB-1, program (**b**)].

Saturated alkanols form a homologous series (C_{12}–C_{30}, 73.2%) with prevailing 1-octadecanol (18:0, 8.8%). It is worth mentioning that there are high proportions of alkanols with odd C-atoms (8.4%) and branched *iso*-alkanols (17.3%) and *anteiso*- alkanols (17.2%). Unsaturated alcohols form a homologous series (C_{18}–C_{31}, 24.3%) with prevalent 1-icosenols (20:1, 8.9%). Some of them are branched (5.6%). Several minor peaks were not identified (2.6%).

In the case of alcohols, the DMDS derivatization under conditions described in the literature [58] was not quantitative and the unreacted alcohols made the identification of products difficult. Therefore, the procedure was modified (70 °C, 5 h in a sealed vial), and under those conditions the yield was almost 100%.

Cholesterol was represented by one peak by GC and its Kováts retention index ($I = 3093.45$) was identical with that of standard cholesterol [$I = 3093.43$; DB-1, program (**c**)]. Both the R_F value at TLC ($R_F = 0.30$, hexane/diethyl ether 7:3) and the mass spectrum were identical with those of the reference.

Triacylglycerols

The fractions 19 and 20 gave one spot at TLC, its R_F value was identical with that of tripalmitin (TLC in hexane/diethyl ether, 93:7, $R_F = 0.34$). A more detailed analysis was done by HPLC. 95 peaks were found in the chromatogram, but only 19 peaks represented individual triacylglycerols. The remaining 76 peaks were mixtures of two or more compounds. The applied method enabled assigning positions of fatty acids in TAG [49, 50] (Table S5). More than 200 TAG were identified in total with over 120 present in significant amounts (printed in bold).

The *acids* were determined by means of the ECL values of their methyl esters and by GC–MS after transesterification of the original TAG. Acids formed a homologous series of saturated and unsaturated fatty acids (Table S6). Saturated acids (C_{12}–C_{30}, 62.1%) with prevalent 16:0 (26.9%) contain considerable part of *n*-acid with odd C-atoms (12.1%), and branched *iso*-acids (5.2%) and *anteiso*-acids (3.5%). Monounsaturated acids (C_{12}–C_{22}) were found at a level of 28.5% and the 18:2n-6 and 2-hydroxyhexadecanoic acids were found in quantities of 0.33 and 1.29%, respectively. Several minor peaks remained unidentified (4.8%).

Free Fatty Acids, Free Alcohols and Monoacylglycerols

Fractions 23–26 contained a mixture of free fatty acids and free alcohols together with a small quantity of *monoacylglycerols*. PTLC enabled separation of monoacylglycerols (hexane/diethyl ether mixture, 80:20, $R_F = 0.05$). A GC chromatogram [DB-1 program (**a**)] showed 2 peaks in a 1:1 ratio, which were determined as 2-monopalmitin (2-hexadecanoylglycerol) and 2-monostearin (2-octadecanoylglycerol).

To enable separation of free fatty acids from free alcohols, the mixture was esterified, and the fatty acid methyl esters were separated from the free alcohols subsequently by means of PTLC. Each fraction was then analyzed by GC, GC–MS and GC–MS of DMDS derivatives.

Free fatty acids form a series of odd and even homologs ($C_{12:0}$ to $C_{34:0}$, 58.6%) (Table S7) with two maxima at $C_{16:0}$ (19.0%) and at $C_{24:0}$ (5.3%), but *iso*- and *anteiso*-fatty acid content was 4.1 and 3.0%, respectively. A smaller content was formed by the monounsaturated acids, namely 37.8%, with some of them being branched. The 18:2n-6 fatty acid formed only 1.2%. Several minor peaks were not identified (2.5%).

Free alcohols form a homologous series of saturated (75.4%) and unsaturated (14.9%) alcohols in the range of C_{12}–C_{31} (Table S8). A high content of *iso*- and *anteiso*-fatty acids (19.4 and 16.0%, respectively) was found analogously as already mentioned in the fraction of alcohols originating from the wax esters. The content of unsaturated alcohols (15.0%) is lower than the content of alcohols from wax esters. Identification of the peaks was made by GC–MS analysis of free and derived alcohols in combination with the ACL values.

Free cholesterol

Fractions 27 and 28 were characterized as a single spot in the TLC (hexane/diethyl ether 7:3). The R_F value = 0.30 was identical with that of cholesterol used as a reference. The main peak (97.4%, Kováts retention index $I = 3093.59$) was identical with that of the standard [$I = 3093.43$; DB-1, program (**c**)] and it was confirmed by its mass spectrum. A minor peak (2.6%) was identified as 3β-cholest-7-en-3-ol, which was the main peak in fractions 29 and 30.

Free Sterols

Fractions 29 and 30 were characterized by the R_F value identical with the R_F value of β-sitosterol (3β-stigmast-5-en-3ol; TLC in hexane/diethyl ether 7:3). The GC analysis showed two peaks: the first (minor) peak was identified as cholesterol (3β-cholest-5-en-3-ol; $I = 3094.14$), the second one (main peak) was identified as 3β-cholest-7-en-3-ol ($I = 3138.78$).

Free Hydroxy Acids

Based on a GC analysis (Fig. S2), fraction 31 contained mainly two peaks in a 8.4 : 1 ratio, which were characterized by their Kováts indexes ($I_1 = 2080.79$ and $I_2 = 2091.24$, [DB-1, program (**b**)]. Their mass spectra indicated two isomeric C_{17} hydroxy acids bearing a single double bond. The structures of both hydroxy acids were suggested on the basis of molecular peaks of free acids ($m/z = 284$) and their methyl esters ($m/z = 298$). The hydroxy acids were eluted from the silica gel column after the free fatty acid fraction, which indicates higher polarity of these products in comparison with free fatty acids. Their longer retention time in comparison with that of free fatty acid fraction supports the suggested structures of unsaturated hydroxy acids over saturated epoxy acids with identical molecular peaks. The yield of hydroxy acids was low, which fact prevented their derivatization for assigning the double bond location, and hydroxyl group location in the acid chains.

Conclusion

The data presented show that cerumen is a very complex mixture of compounds. Non-polar lipids (11%) were separated into ten groups of compounds by column chromatography and by PTLC on silica gel. Polar lipids form about 30% of the cerumen. The remaining compounds (60%) represent a highly polar fraction that could not be eluted from the column even by a mixture of chloroform–methanol.

Among the cited papers, only Harvey [30] analyzed a broad spectrum of compounds in cerumen systematically. However, that analysis was performed after saponification of the cerumen extract. Therefore, wax esters, cholesterol esters, and mono- and triacylglycerols could not be identified in the mixture. Our results are in agreement with those of Harvey [30], but we added new information on the content of wax esters and mono- and triacylglycerols. We found that the main part of the long-chain unsaturated fatty acids is formed by those bearing a Δ6 double bond. In turn, most of the unsaturated fatty alcohols bear Δ10 unsaturation.

In the analyses of some groups of compounds (wax esters, fatty acids, fatty alcohols), we were faced with the following problems: (a) in many peaks of the chromatogram several isomers were overlapping, causing shifts of the retention values; (b) the retention values (ECL, ACL) of many compounds could not be compared with those of unavailable reference compounds; (c) coelution of peaks of non-derived compounds with the formed adducts (retention times of DMDS adducts are shifted by 6 carbon atoms approx.); (d) mass spectra of methyl-branched compounds (*iso-, anteiso-*) are very similar to those of straight-chain compounds. To avoid misinterpretation of the mass spectra, it is always necessary to consider the retention data (RT, ECL values, ACL values).

Supplements

We have very large amounts of experimental data, and all of them cannot be placed in the text of the paper. We therefore decided to make the supplements available on the web page of the journal, where they can be found. The data summarize the composition of cerumen, and the lists of fatty acid derivatives found in the cerumen (Tables S1–S8), and the chromatograms of the selected compounds (Figs. S1–S2).

Acknowledgments The authors thank the Czech Science Foundation (grant No. 502/10/1734), and the Ministry of Education, Youth and Sports of the Czech Republic (grants Nos. 2B06024, 2B06007, and OC10001 and research program MSM6046137305) for the financial support. The authors also thank Ms. Helena Ernyeiová and Ms. Anna Nekolová for their skillful technical assistance.

Received: 18 January 2011 / Accepted: 9 May 2011 / Published online: 25 May 2011

Abstract Guar gum has a well-recognized hypolipidemic effect. This effect is thought to be due to the physicochemical properties of guar gum, which may cause changes in adsorption of lipids or the viscosity of the intestinal contents. Guar gum is a non-specific absorption inhibitor of any type of lipid-soluble compound. Permanent lymph duct cannulation was performed on rats to investigate the effects of dietary guar gum on lymph flow and lipid transport. Rats fed a 5% guar gum diet were compared with those fed a 5% cellulose diet, and lymph was collected after feeding. The water-holding capacity (WHC), settling volume in water (SV), and viscosity of guar gum were compared with those of cellulose. Rats fed with the guar gum diet had significantly lower lymph flow and lymphatic lipid transport than did rats fed with the cellulose diet. The WHC, SV, and viscosity of guar gum were significantly higher than those of cellulose. We propose that dietary guar gum reduces lymph flow and thereby diminishes lipid transport by means of its physicochemical properties related to water behavior in the intestine.

SV	Settling volume in water

Introduction

Many previous studies have shown that water-soluble fibers, such as β-glucan, psyllium, pectin, and guar gum, are more effective in preventing cardiovascular disease than are water-insoluble fibers [1]. Several studies on men have demonstrated that consumption of water-soluble dietary fibers may produce a hypocholesterolemic effect [1, 2]. This effect is exerted in the intestine. The hypocholesterolemic effect may be attributed to the adsorption of cholesterol and bile acids by the dietary fibers in the intestine [1], the fermentability of these fibers in the colon, and the physicochemical properties of the dietary fibers, such as viscosity [3].

Guar gum consists of a (1 → 4)-linked-β-D-mannopyranose backbone with (1 → 6)-linked-α-D-galactose side chains, with the overall ratio of mannose to galactose being around 2:1 (Fig. 1). Numerous studies suggest that dietary guar gum inhibits absorption of lipid-soluble compounds such as cholesterol [1–3], lutein [4], canthaxanthin [4], α-tocopherol [4], 1,1,2-trichloroethylene [5], and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [6]. One of the characteristics of guar gum is that it is a non-specific absorption inhibitor of any type of lipid-soluble compound.

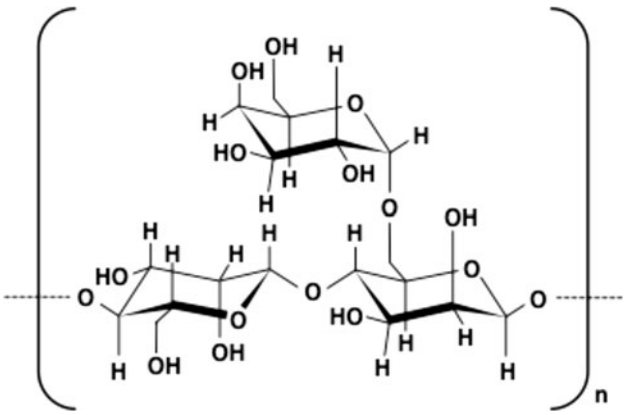

Fig. 1 The chemical structure of guar gum

The lymphatic transport of dietary lipids in rats has often been measured by infusing a lipid emulsion into the stomach or duodenum for quantitative measurement [7, 8]. However, the methods used have failed to take into account the interaction of the lipid emulsion with other dietary components, particularly proteins and carbohydrates, which is necessary to investigate the interaction between the respective dietary fibers and food components [9]. In this study, we used permanent cannulation of the thoracic duct to measure the lymphatic transport of dietary lipids in rats under near-physiological conditions. This method has the advantage of evaluating the lymphatic transport of dietary lipids during actual dietary fat absorption, using "actual" diets without restraint stress [10–12].

In this study, rats were fed a diet containing guar gum or cellulose (a water-insoluble dietary fiber). The lymphatic transport of cholesterol, triacylglycerols, and phospholipids in the rats was measured using permanent cannulation of the thoracic duct. Additionally, we compared the water-holding capacity (WHC), settling volume in water (SV), and viscosity of guar gum with those of cellulose.

Materials and Methods

Materials

Crystalline guar gum powder (MW, approximately 20,000) containing 80% fiber, 5% protein, and 1% ash was purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Crystalline cellulose powder containing 96.4% fiber, 4.6% moisture, and 0.1% protein was purchased from Oriental Yeast Co. Ltd. (Tokyo, Japan).

Animals, Diets, and Permanent Thoracic Lymph Duct Cannulation

Male Sprague–Dawley rats (Kud:SD), 7 weeks old, were obtained from Kyudo (Kumamoto, Japan) and maintained in a temperature-controlled room (23 °C). Experimental diets were prepared according to recommendations of the AIN-93G [13] and contained the following ingredients (in weight %): cellulose or guar gum, 5; casein, 20; α-cornstarch, 13.2; sucrose, 10; mineral mixture, 3.5; vitamin mixture, 1; choline bitartrate, 0.25; soybean oil, 7; cholesterol, 0.5; cholic acid, 0.125; *tert*-butylhydroquinone, 0.0014; and *β*-cornstarch, 39.4236. The rats were trained to consume the cellulose diet as a basal diet twice a day from 10:00–11:00 to 16:00–17:00, respectively, for 5 days. On day 6, all the rats were anesthetized using Nembutal prior to permanent cannulation of the thoracic duct lymph, as described previously [12]. In brief, a cannula (SH silicon tube, 0.5 mm i.d. and 1.0 mm o.d.; Kaneka Medics, Osaka, Japan) filled with heparinized saline was inserted into the thoracic duct and secured within the abdominal cavity. The rats were returned to their cages and provided glucose isocratic liquid (139 mM glucose and 85 mM NaCl in distilled water) alone. On days 7 and 8, the rats were provided with the cellulose diet twice a day, as described. On day 9, the rats were attached to a long polyethylene cannula (0.58 mm i.d. and 0.97 mm o.d.; Becton–Dickinson and Company, MD, USA) to collect the lymph. The end of the cannula was located 5–10 cm below the bottom of the cage to allow the lymph to drain into the cannula. The lymph was collected for 20 min, and the rats were then given free access to the cellulose diet or the guar gum diet for 30 min from 10:00 to 10:30 hours. Therefore, the fasting period from 17:00 to 10:00 hours was between meals. At this time, the lymph was collected every hour for 7 h. The collected lymph was kept at 4 °C overnight, after which the fibrin was removed. The lymph was stored at −30 °C until lipid analysis.

The rats had free access to deionized water throughout the feeding periods and during lymph collection. This experiment was carried out following the Guidelines for Animal Experiments of Kyushu University (Fukuoka, Japan) and the Law (No. 105) and Notification (No. 6) of the Government of Japan. The authorization number was A19-195-0.

Measurement of Lymphatic Lipids

Lymphatic cholesterol levels were measured using a commercial enzyme assay kit (T-CHO Kainos kit; Kainos Laboratories Inc., Tokyo, Japan). Lymphatic triacylglycerol and phospholipid levels were measured using commercial enzyme assay kits (Triglyceride *E* test Wako and Phospholipid *C* test Wako, respectively; Wako Pure Chemicals, Tokyo, Japan,).

Water-Holding Capacities of Guar Gum and Cellulose

The WHC of guar gum and cellulose were measured according to the method reported by Takeda and Kiriyama

[14]. Samples (0.1 g) were placed on 2 filter papers fitted in a stainless steel container (hole diameter, 2.5 cm; diameter, 5 cm; and height, 1.5 cm) with a polypropylene net. This weight was measured as dry weight. After being placed in a case with distilled water for 24 h at room temperature, the container was removed and weighed. The WHC of guar gum and cellulose were evaluated by measuring the difference between the wet and dry weights.

Settling Volumes in Water of Guar Gum and Cellulose

The SV of guar gum and cellulose were measured according to the method described by Takeda and Kiriyama [14]. Samples (17.5 mg) were blended with 7 ml of distilled water in 10-ml graduated cylinders. The cylinders were left to stand for 24 h at room temperature. The SV of guar gum and cellulose were evaluated on the basis of precipitation volume.

Viscosities of Guar Gum and Cellulose

The viscosities of guar gum and cellulose were measured using an Ostwald viscometer with a 0.75-mm capillary diameter. Samples (0.1 g) were blended with distilled water. After being stored for 24 h at room temperature, 0.1% (w/v) suspending solutions were prepared in 100-ml volumetric flasks. The solutions were preheated at 37 °C for 15 min, and then the flow times were determined. Each measurement was repeated three times. The viscosities of guar gum and cellulose were calculated relative to the viscosity of distilled water, and therefore, they had no units.

Statistical Analysis

All values are expressed as means ± SEM. The significance of differences between means for two groups was determined by Student's *t* test. Differences were considered significant at $P < 0.05$.

Results and Discussion

There was no significant difference between the consumption of the cellulose and guar gum diets for 30 min (4.64 ± 0.15 and 3.94 ± 0.55 g, respectively, $n = 5$). Therefore, the input levels of cellulose and guar gum were identical. However, as shown in Fig. 2a, rats fed the guar gum diet had significantly lower lymph flow than did rats fed the cellulose diet (3.88 ± 1.31 and 11.9 ± 1.1 ml, respectively, for 7 h; $P < 0.005$). In comparison with the cellulose diet, the guar gum diet also significantly reduced

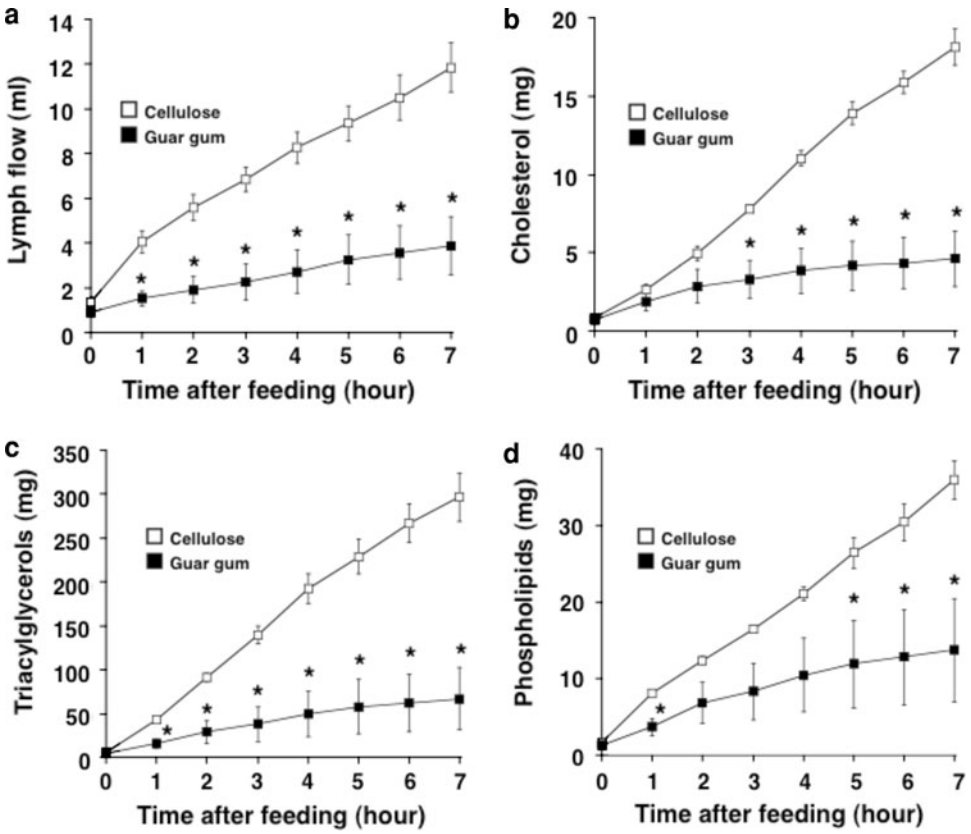

Fig. 2 Cumulative lymph flow (**a**), lymphatic transport of cholesterol (**b**), triacylglycerols (**c**), and phospholipids (**d**) in rats fed a cellulose or guar gum diet. Values are expressed as mean ± SEM ($n = 5$). *Asterisk* shows a significant difference at $P < 0.05$

Table 1 Water-holding capacities, settling volumes in water, and viscosities of the cellulose and the guar gum

	Cellulose	Guar gum
Water-holding capacity (g wet fiber per g dry fiber)	3.33 ± 0.13	44.5 ± 1.9*
Settling volume in water (ml per g fiber)	3.37 ± 0.03	72.3 ± 4.3*
Viscosity	1.00 ± 0.00	3.33 ± 0.00*

Values are expressed as mean ± SEM ($n = 3$)

* Significant difference at $P < 0.05$

the transport of cholesterol (4.60 ± 1.77 and 18.1 ± 1.1 mg, respectively, for 7 h; $P < 0.0005$) (Fig. 2b), triacylglycerols (66.8 ± 35.3 and 297 ± 27 mg, respectively, for 7 h; $P < 0.001$) (Fig. 2c), and phospholipids (13.7 ± 6.7 and 36.0 ± 2.5 mg, respectively, for 7 h; $P < 0.05$) (Fig. 2d). The apparent lymphatic recovery rates of cholesterol and triacylglycerols were calculated on the basis of their consumption. The guar gum diet as compared to the cellulose diet significantly reduced the apparent lymphatic recovery rates of cholesterol (78.3 ± 4.4 and 24.8 ± 10.1%, respectively; $P < 0.005$) and triacylglycerols (91.0 ± 7.0 and 27.9 ± 15.4%, respectively; $P < 0.01$) for a 7-h period. We did not calculate the apparent lymphatic recovery rate of phospholipids. The lymphatic phospholipids may be derived from bile, intestinal mucosa exfoliation, bacterial flora, etc., but not from the diet. The reduction pattern of phospholipid absorption by the guar gum diet was similar to that of lymph flow at around 35% lower than the cellulose diet. However, the reduction in the absorption of cholesterol and triacylglycerols were accelerated by the guar gum diet. This accelerated suppression of the absorption of cholesterol and triacylglycerols by the guar gum diet may be due to the reduction of lymph flow as well as other mechanisms. For example, guar gum might form a stable thick unstirred water layer that acts as a physical barrier in the intestinal lumen [1]. In contrast to our results, Ikeda et al. [15] showed that the thoracic duct lymph flow of rats administered cellulose or guar gum were identical. This discrepancy may be due to differences between the administration protocols and the quantities of dietary fiber infused. Ikeda et al. [15] employed forced administration with an indwelling stomach catheter to feed emulsions containing 25 mg of [^{14}C] cholesterol, 50 mg of either cellulose or guar gum, and 200 mg of either safflower, high-oleic safflower, or palm oil prior to continuous infusion of physiological saline—5% glucose solution for 24 h. The forced administration of saline–glucose solution resulted in a higher lymph flow rate (approximately 100 ml/24 h) compared with that in our experiment. The main purpose of Ikeda's study was to acquire knowledge about the interaction of dietary fibers and fats. Therefore, our results may provide a novel understanding about the inhibition of lipid absorption by dietary fiber via a change in lymph flow.

Although there was a previous study about WHC of guar gum and cellulose [16], our study also indicated clear differences between the WHC of guar gum and cellulose (Table 1). The WHC of guar gum was approximately 13 times higher than that of cellulose. The SV of guar gum was approximately 22-fold higher than that of cellulose (Table 1). Moreover, the viscosity of guar gum was approximately 3 times higher than that of cellulose (Table 1). Rainbird et al. [17] showed that guar gum decreases water absorption in isolated loops of the jejunum obtained from conscious growing pigs. The addition of guar gum to the intestine reduced the percentage of water absorption to approximately 25%. They suggested that this effect is related to the WHC of guar gum. Furthermore, Phillips reported a reduction in the rate of diffusion of cholesterol mixed micelles with an increase in guar gum concentration [18]. He also demonstrated that this reduction in rate was related to the viscosity of guar gum. These physicochemical properties of the water-soluble fiber are thought to exert their effects in the gut, thereby reducing the lymph flow. The WHC and viscosity of dietary fibers have been shown to affect intestinal transit time [19]. A fiber with a higher WHC and viscosity, such as guar gum, can delay gastric emptying and slow transit through the gut, thereby reducing the rate of dietary lipid absorption [20]. Moreover, the inhibition of absorption of various lipid-soluble compounds may rely almost entirely on these physicochemical properties. The hypolipidemic mechanism of guar gum has been shown to occur because of the adsorption of bile acids and cholesterol by this fiber in the intestine [1]. Therefore, further studies are necessary to evaluate the effects of dietary guar gum on time courses of the change of bile acid levels in feces and portal blood.

In conclusion, dietary guar gum (a water-soluble fiber) decreased the absorption of dietary cholesterol, triacylglycerols, and endogenous phospholipids through a reduction in the lymph flow. These effects may be due to the physicochemical properties of guar gum.

Mifepristone Treatment Results in Differential Regulation of Glycerolipid Biosynthesis in Baby Hamster Kidney Cells Expressing a Mifepristone-Inducible ABCA1

Received: 2 March 2011 / Accepted: 9 June 2011 / Published online: 28 June 2011

Abstract ATP binding cassette A1 (ABCA1) transports cholesterol, phospholipids and lipophilic molecules to and across cellular membranes. We examined if ABCA1 expression altered cellular de novo glycerolipid biosynthesis in growing Baby hamster kidney (BHK) cells. Mock BHK cells or cells expressing a mifepristone-inducible ABCA1 (ABCA1) were incubated plus or minus mifepristone and then with [^{3}H]serine or [^{3}H]inositol or [^{3}H]ethanolamine or [*methyl*-^{3}H]choline or [^{3}H]glycerol or [^{14}C]oleate and radioactivity incorporated into glycerolipids determined. Mifepristone did not affect [1,3-^{3}H]glycerol or [^{14}C]oleate or [^{3}H]ethanolamine or [*methyl*-^{3}H]choline uptake in BHK cells. In contrast, [^{3}H]glycerol and [^{14}C]oleate incorporated into phosphatidylserine (PtdSer) were elevated 2.4-fold ($p < 0.05$) and 54% ($p < 0.05$), respectively, upon ABCA1 induction confirming increased PtdSer biosynthesis from these precursors. However, mifepristone inhibited [^{3}H]serine uptake and incorporation into PtdSer indicating that PtdSer synthesis from serine in BHK cells is dependent on serine uptake. Mifepristone stimulated [^{3}H]inositol uptake in mock and ABCA1 cells but not its incorporation into phosphatidylinositol indicating that its synthesis from inositol is independent of inositol uptake in BHK cells. [^{3}H]glycerol and [^{14}C]oleate incorporated into triacylglycerol were reduced and into diacylglycerol elevated only in mifepristone-induced ABCA1 expressing cells due to a decrease in diacylglycerol acyltransferase-1 (DGAT-1) activity. The presence of trichostatin A, a class I and II histone deacetylase inhibitor, reversed the ABCA1-mediated reduction in DGAT-1 activity but did not affect DGAT-1 mRNA expression. Thus, mifepristone has diverse effects on de novo glycerolipid synthesis. We suggest that caution should be exercised when using mifepristone-inducible systems for studies of glycerolipid metabolism in cells expressing glucocorticoid responsive receptors.

Introduction

Phospholipids and cholesterol are the principal lipid components in mammalian cellular membranes [1]. Phospholipids provide a protective barrier for selective permeability, define organelles and are key components of various metabolic and cellular reactions. For example, phosphatidylserine (PtdSer) is present in significant quantities in mammalian tissues and is required for surface recognition of apoptotic cells by phagocytes [2]. Cholesterol regulates the fluidity of cell membranes and is found in plasma membrane lipid rafts where it anchors cell signaling proteins [3]. Alteration of intracellular lipid transport within and between membranes may affect eukaryotic glycerolipid biosynthesis. For example, mitochondrial phosphatidylethanolamine (PtdEtn) de novo biosynthesis in yeast was regulated by control of PtdSer import into the mitochondria [4]. Sphingomyelin (CerPCho) de novo biosynthesis in hepatocytes was regulated by control of phosphatidylcholine (PtdCho) transport from the endoplasmic reticulum to the Golgi [5]. Expression of phospholipid scramblase-3 in Hela cells which altered movement of cardiolipin (Ptd_2Gro) between inner and outer mitochondrial membranes stimulated de novo Ptd_2Gro biosynthesis [6]. In contrast, there is little information on the role that altered plasma membrane lipid transport plays in regulating glycerolipid de novo biosynthesis.

ATP binding cassette A1 (ABCA1) is a 2261 amino acid integral membrane protein and member of the ATP binding cassette transporter family of transporters [reviewed in 7]. ABCA1 functions to transport cholesterol, phospholipids and other lipophilic molecules to and across the cellular membranes where they can be removed by lipid-poor high density lipoprotein apolipoproteins. Induction of ABCA1 in baby hamster kidney (BHK) cells was shown to increase PtdSer levels in the plasma membrane exofacial leaflet [8]. However, it was unknown if this increase in PtdSer level in the plasma membrane exofacial leaflet was associated with altered PtdSer de novo biosynthesis.

Mifepristone or 17β-hydroxy-11β-(4-dimethyl-aminophenyl 1)-17α-(prop-1-ynyl)-estra-4,9-dien-3-one (RU 486) is a potent abortifactant in clinical use [9]. It acts during the luteal phase in the endometrium, provoking bleeding, and also decreases luteinizing hormone secretion which results in luteolysis. In addition to its role as an abortifactant, mifepristone is used for expression of proteins in the mifepristone-inducible gene regulatory system. The mifepristone-inducible gene regulatory system allows for the control of spatiotemporal expression of transgenes in vivo in a ligand-dependent manner [reviewed in 10]. The regulatory system is composed of two components: (1) a chimeric transactivator protein that activates transgene transcription only in the presence of mifepristone, and (2) a target transgene placed in the context of a promoter which is responsive only to the mifepristone-bound chimeric transactivator.

In this study, we examined if increased expression of ABCA1, mediated by the mifepristone-inducible gene regulatory system altered cellular glycerolipid de novo biosynthesis. We show that expression of ABCA1 using the mifepristone-inducible gene system stimulates PtdSer de novo biosynthesis from glycerol and oleic acid (OLA) precursors in growing BHK cells. In addition, expression of ABCA1 decreases triacylglycerol (TAG) de novo biosynthesis by reducing the activity of diacylglycerol acyltransferase-1 (DGAT-1). Moreover, we show that the glucocorticoid antagonist mifepristone, at concentrations (10 nM) widely used for the mifepristone-inducible gene system, inhibits serine uptake and stimulates *myo*-inositol uptake in BHK cells. Our findings indicate that mifepristone has diverse effects on de novo glycerolipid synthesis and thus caution should be exercised when using mifepristone-inducible systems for the study of cellular glycerolipid metabolism.

Materials and Methods

Materials

[1,3-^{3}H]Glycerol, [1-^{14}C]OLA, *myo*-[^{3}H]inositol, [1-^{14}C] palmitate (PAM), [*methyl*-^{3}H]choline, [^{3}H]ethanolamine, [^{3}H]serine and Ptd[^{14}C]Cho were obtained from either Dupont, Mississauga, Ontario, or Amersham, Oakville, Ontario, Canada. DMEM and fetal bovine serum were products of Canadian Life Technologies (GIBCO), Burlington, Ontario, Canada. Lipid standards were obtained from Serdary Research Laboratories, Englewood Cliffs, New Jersey, USA. Thin layer chromatographic plates (silica gel G, 0.25 mm thickness) were obtained from Fisher Scientific, Winnipeg, Canada. Ecolite scintillant was obtained from ICN Biochemicals, Montreal, Quebec, Canada. BHK cells expressing mifepristone-inducible ABCA1 were a generous gift from Dr. John F. Oram, University of Washington, Seattle, WA, USA [11]. The rate of growth of mock and ABCA1 cells were similar. Primary ABCA1 and heat shock protein-70 (HSP-70) antibodies and secondary antibodies were obtained from Novus Biological Inc. Littleton, CO, USA. All other chemicals were certified ACS grade or better and obtained from Sigma Chemical Company, St. Louis, USA or Fisher Scientific, Winnipeg, Manitoba, Canada.

Cell Culture and Radiolabeling Experiments

Cells (mock, BHK control; ABCA1, BHK cells containing mifepristone-inducible ABCA1) were grown in DMEM

containing 10% fetal bovine serum until 70% confluence. Cells were then incubated for 24 h in the absence or presence of 10 nM mifepristone and then for 4 h with DMEM medium in the presence of 0.1 μM [^{3}H]serine (5 μCi/dish) or *myo*-[^{3}H]inositol (2 μCi/dish). Phospholipids were separated by two-dimensional thin-layer chromatography and radioactivity incorporated into phospholipids determined as described [12]. Essentially, the medium was removed and the cells washed twice with ice cold saline and then harvested from the dish with 2 mL methanol:water (1:1, v/v). The mixture was vortexed, and a 25 μL aliquot was taken for protein analysis and a 25 μL aliquot taken for determination of total radioactivity. Appropriate volumes of chloroform, 0.9% NaCl and methanol were added to the tubes in a 4:3:2 ratio to initiate phase separation. The tubes were vortexed and then centrifuged at 2,000 rpm for 10 min in a bench top centrifuge) and the aqueous phase was removed and 2 mL of chloroform/methanol/NaCl (3:48:47, by vol) was added to wash the organic phase. The tubes were vortexed and centrifuged as described above and the aqueous phase removed. The organic phase was dried under a stream of N_2 gas and resuspended in 100 μL chloroform. A 50-μL aliquot of organic phase was placed onto a thin-layer plate along with phospholipid standards and phospholipids were separated by two-dimensional thin-layer chromatography. In the first dimension, the plate was developed in a solvent system containing chloroform/methanol/NH_4OH/water (70:30:2:3, by vol). The second dimension, at 90° to the first separation, was performed in a solvent system containing chloroform/methanol/water (65:55:5, by vol). Plates were allowed to dry overnight and the separated phospholipids were visualized by exposing the plate to iodine vapor. Corresponding radioactive phospholipids of interest were removed and placed in 6-mL scintillation vials containing 5 mL Ecolite scintillation cocktail. The radioactivity was determined in a Beckman Model LS3801 liquid scintillation counter. For phospholipid pool size analysis, the organic phase was separated on thin-layer chromatographic plates as above in the absence phospholipid standards.

In other experiments, cells were incubated for 24 h in the absence or presence of 10 nM mifepristone and then for 4 h with 0.1 mM [1,3-^{3}H]glycerol (10 μCi/dish) or 0.1 mM [1-^{14}C]OLA (bound to albumin 1:1 molar ratio) (1 μCi/dish) or 0.1 mM [1-^{14}C]PAM (bound to albumin 1:1 molar ratio) (1 μCi/dish) and radioactivity incorporated into phospholipids determined as described above. For neutral lipid analysis, the organic phase was isolated as described above and dried under a stream of N_2 gas and resuspended in 100 μL chloroform [13]. A 50-μL aliquot of organic phase was placed onto a thin-layer plate along with neutral lipid standards and DAG and TAG were separated by one-dimensional thin-layer chromatography in a solvent system containing benzene/diethylether/absolute ethanol/acetic acid (50:45:2:0.2, by vol). Plates were allowed to dry overnight and the separated DAG and TAG were visualized by exposing the plate to iodine vapor. Corresponding radioactive DAG and TAG were removed and placed in 6-mL scintillation vials containing 5 mL Ecolite scintillation cocktail and radioactivity incorporated determined as described above.

Subcellular Fractionation and Assay of Enzyme Activities

Cells were incubated for 24 h in the absence or presence of 10–100 nM mifepristone washed twice with ice cold saline and harvested with 2 mL lysis buffer (10 mM Tris–HCL, pH 7.4, 0.25 M sucrose). Cells were homogenized with 30 strokes of a Dounce A homogenizer. The homogenate was centrifuged at 1,000×*g* for 5 min to remove debris. The pellet was resuspended in 0.5 mL homogenization buffer and used for assay of enzyme activities. 1,2-Diacylglycerol acyltransferase (DGAT) was determined in membrane fractions prepared from BHK cells in the absence or presence of 100 mM $MgCl_2$ to distinguish between DGAT-1 and DGAT-2 isoforms as previously described [14]. Essentially, the assay measured the incorporation of [^{14}C]oleoyl-CoA (specific activity: 20,000 dpm/nmol) into TAG in a 5 min assay using 50 μg protein, 0.4 mM DAG and 25 μM oleoyl-CoA plus or minus 100 mM $MgCl_2$ in 0.25 M sucrose, 1 mM EDTA, 100 mM Tris–HCl buffer pH 7.5. The reaction was terminated by the addition of chloroform:methanol (2:1 v:v). Tubes were vortexed and the organic phase removed and separated by thin-layer chromatorgraphy as described above for neutral lipid synthesis. Prior to chromatography TAG standard was added to the plate. The TAG band was identified by iodine vapor and radioactivity in TAG measured by liquid scintillation counting as described above. PS synthase activity was determined as described [15]. Essentially, the assay measured the incorporation of 0.5 mM L-[^{3}H]serine (10,000 dpm/nmol) into PtdSer in 50 mM Tris–HCl buffer (pH 8.0) with 0.6 mM $MnCl_2$, 0.2 mM CDP-diacylglycerol. 4 mM Triton X-100 and 25 μg enzyme protein in a total volume of 0.1 mL assayed a 30 °C for 10 min. The reaction was terminated by addition of 0.1 N HCl followed by phase separation with 1 mL chloroform and 1.5 mL 1 M $MgCl_2$. A 0.5-mL aliquot of the organic phase was removed, dried and radioactivity determined. Phospholipase A_2 (PLA_2) activity was determined as described [16]. Essentially, the assay measured the hydrolysis of 0.2 mM Ptd[^{14}C]Cho (1,000 dpm/nmol) to lysoPtD[^{14}C]Cho in 0.25 M Tris–HCl, pH 8.5, 25 mM $CaCl_2$ and 0.1 mg protein in a total volume of 0.5 mL at 37 °C for 30 min. The reaction was terminated by addition of 2 mL of chloroform

followed by 1 mL of 0.1 M HCl in methanol and 1 mL of 0.73% NaCl. The mixture was vortexed and the organic phase removed, dried and separated on a thin layer plate as described above for phospholipids with lysoPtdCho standard. The lysoPtdCho spot was visualized by iodine vapor, removed and radioactivity determined by liquid scintillation counting as described above. In other experiments, ABCA1 cells were incubated for 24 h in the absence or presence of 10 nM mifepristone or 100 μM trichostatin A or both and DGAT-1 activity determined as above.

Real Time-PCR Analysis of DGAT-1

ABCA1 cells were incubated for 24 h in the absence or presence of 10 nM mifepristone or 100 μM trichostatin A or both. Total RNAs from cells were isolated using the TRIZOL Reagent according to the manufactures instructions. The RNA pellets were suspended in autoclaved, double-distilled water and quantitated by absorbance at 260 nm using the 260:280 nm ratio as an index of purity. The integrity of the RNA was confirmed by denaturing agarose gel electrophoresis of the isolated RNA. Primers were synthesized by Invitrogen™ Life Technologies. The primers for DGAT-1 were Forward 5′-GTA GAA GAG GAC GAG GTG CGA GAC -3′; Reverse 5′-GGG CTT CAT GGA GTT CTG GAT AGT -3′. The primers for β-actin were Forward 5′-GTG GGG CGC CCC AGG CAC CA-3′; Reverse 5′-CTC CTT AAT GTC ACG CAC GAT TTG-3′. DGAT-1 mRNA expression relative to the constitutive expression of β-actin was determined under the conditions described [17].

Western Blot Analysis of ABCA1

Mock and ABCA1 cells were incubated with 10 nM mifepristone for 24 h. Cells were placed on ice, media was aspirated, and cells washed twice with cold 1X PBS. Cells were lysed with 1× SDS buffer (50 mM Tris–Cl pH 6.8, 100 mM dithiothreitol, 2% SDS, 10% glycerol, and 1 tablet PhosSTOP per 10 mL buffer). Cells were immediately scraped off plates and transferred to microcentrifuge tubes on ice. Lysates were sonicated for 10–15 s (to shear DNA) and then heated to 72 °C for 5 min. Lysates were centrifuged for 2 min at 9000×*g* and protein levels determined as described below. 4× SDS loading buffer (200 mM Tris HCl pH 6.8, 400 mM dithiothreitol, 8% SDS, 40% glycerol, 0.4% bromophenol blue) was added to 30–45 μg of cell lysates. Samples were loaded onto 10% acrylamide resolving gels (10% acrylamide mix (9.67% acrylamide, 0.33% bis), 375 mM Tris–HCl, pH 8.8, 1% SDS, 1% ammonium persulfate, 0.04% TEMED) and subjected to SDS-PAGE at 180 V for 90 min. Separated proteins were electro-transferred to PVDF membranes at 70 V for 150 min. PVDF membranes were blocked with TBS-T (50 mM Tris HCl, (pH 7.4) 150 mM NaCl, 0.1% Tween-20) containing 2.5% BSA for 30 min. Membranes were incubated with primary ABCA1 antibody (1:1,000), or primary HSP-70 antibody as protein loading control, with gentle agitation overnight at 4 °C. Membranes were then washed with TBS-T three times for 5 min. Membranes were then incubated and gently agitated for 2 h in secondary antibody (1:2,000) diluted in TBS-T with 5% BSA. Once again, membranes were washed three times for 5 min each with TBS-T. PVDF membranes were incubated for 1 min with 1–2 mL chemiluminescent substrate, excess substrate was drained, and membranes were covered in plastic wrap. In a dark room, membranes were exposed to X-ray film for appropriate exposure time and then processed using Raytech Medical Film Processor SRX-101A.

Other Determinations

The pool size of the major phospholipids were determined as described [18]. Protein was determined as described [19]. Dunnet's *t* test for multiple comparisons with a single mean was used for determination of statistical significance. The level of significance was defined as $p < 0.05$.

Results

Expression of ABCA1 Does not Alter Glycerophospholipid Pool Size

Expression of the ABCA1 cholesterol transporter was shown to increase PtdSer levels in the plasma membrane exofacial leaflet [8]. However, it was unknown if this was associated with elevated biosynthesis. BHK cells expressing a mifepristone-inducible ABCA1 (ABCA1 cells) were incubated in the absence or presence of 10 nM mifepristone for 24 h and western blot analysis performed. Mifepristone-treatment of ABCA1 cells resulted in a marked increase in the expression of ABCA1 (Fig. 1). To examine if expression of ABCA1 would alter the glycerophospholipid pool size BHK cells (mock) and ABCA1 cells were incubated in the absence or presence of 10 nM mifepristone for 24 h and the pool size of glycerophospholipids determined. Mifepristone-treatment did not alter the pool size of the major glycerophospholipids in mock or ABCA1 cells (Table 1). Thus, total PtdSer levels in ABCA1 expressing cells were unaltered.

Mifepristone Alters Serine and *myo*-Inositol Uptake

To examine if expression of ABCA1 would alter glycerophospholipid de novo biosynthesis, mock and ABCA1 cells

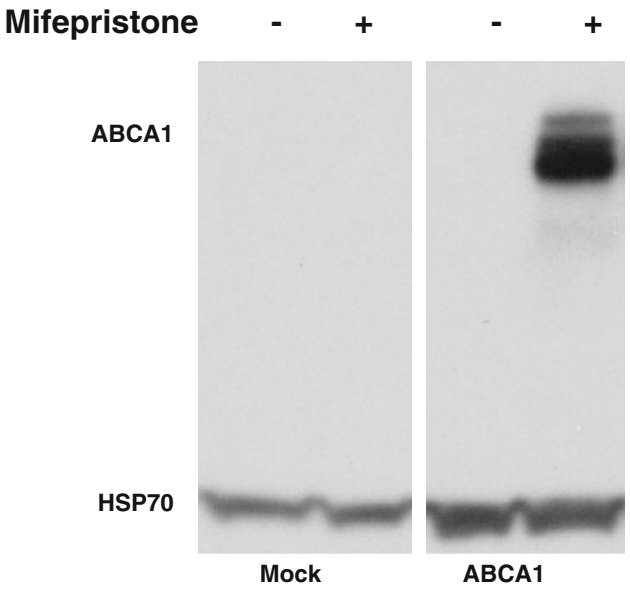

Fig. 1 Western blot analysis of Mock and ABCA1 cells treated with mifepristone. Mock and ABCA1 cells were incubated for 24 h in the absence (−) or presence (+) of 10 nM mifepristone and western blot analysis performed as described in "Materials and Methods". A representative blot is depicted

were incubated for 24 h in the absence or presence of 10 nM mifepristone and then for 4 h with [^{3}H]serine or *myo*-[^{3}H]inositol or [*methyl*-^{3}H]choline or [^{3}H]ethanolamine and radioactivity incorporated into glycerophospholipids was determined. [^{3}H]Serine incorporated into PtdSer was reduced 41 and 38% in mock and ABCA1 cells treated with mifepristone, respectively, compared to untreated cells (Table 2). However, this reduction of [^{3}H]serine incorporated into PtdSer was likely due to a mifepristone-mediated inhibition of serine uptake since mifepristone inhibited [^{3}H]serine uptake 38 and 25% in mock and ABCA1 cells, respectively, compared to untreated cells. These data indicate that de novo PtdSer synthesis from serine is dependent upon serine uptake in BHK cells and that mifepristone attenuates serine uptake in these cells. Mifepristone-treatment of mock and ABCA1 cells resulted in a 3.5- to 4.8-fold increase in *myo*-[^{3}H]inositol uptake, respectively, but this had no effect on *myo*-[^{3}H]inositol incorporation into phosphatidylinositol (PtdIns) (Table 2). These data indicate that mifepristone increased *myo*-inositol uptake but that de novo synthesis of PtdIns in BHK cells is independent of *myo*-inositol uptake. Mifepristone-treatment did not affect [*methyl*-^{3}H]choline into phosphatidylcholine (PtdCho) or [^{3}H]ethanolamine incorporation into phosphatidylethanolamine (PtdEth) in mock or ABCA1 cells (data not shown), indicating that the de novo biosynthesis of these phospholipids were not altered by mifepristone or the expression of ABCA1 in BHK cells.

Expression of ABCA1 Stimulates PS Synthesis from Glycerol and OLA Precursors and Inhibits TAG Synthesis

Since glycerol and fatty acids form the diacylglycerol (DAG) backbone for all glycerophospholipids we examined glycerophospholipid and neutral lipid synthesis from glycerol and OLA precursors in mock and ABCA1 expressing cells treated with mifepristone. Cells were incubated for 24 h in the absence or presence of 10 nM mifepristone and then for 4 h with [1,3-^{3}H]glycerol or [^{14}C]OLA and radioactivity incorporated into the major glycerophospholipids and neutral lipids determined. [1,3-^{3}H]Glycerol incorporated into PtdSer was elevated 75% in ABCA1 cells treated with mifepristone compared to untreated ABCA1 cells (Table 3). In contrast, mifepristone-treatment did not affect [1,3-^{3}H]glycerol incorporated into PtdSer in mock cells compared to untreated cells. In addition, mifepristone did not alter the uptake of [1,3-^{3}H]glycerol into mock or ABCA1 BHK cells. These data indicated that PtdSer de novo biosynthesis from [1,3-^{3}H]glycerol was elevated by ABCA1 induction. Interestingly, mifepristone-treatment resulted in a 42% reduction in [1,3-^{3}H]glycerol incorporated into TAG and a 55% increase in [1,3-^{3}H]glycerol incorporated into DAG in ABCA1 cells but did not affect [1,3-^{3}H]glycerol

Table 1 Pool size of major glycerophospholipids in Mock and ABCA1 cells treated with mifepristone

Phospholipid (nmol/mg protein)	Mock (−)	Mock (+)	ABCA1 (−)	ABCA1 (+)
PtdCho	38.8 ± 3.0	39.1 ± 3.1	39.8 ± 3.5	37.0 ± 3.7
PtdEtn	13.8 ± 2.0	14.3 ± 2.0	14.4 ± 2.0	13.3 ± 2.1
PtdSer	2.9 ± 0.3	2.7 ± 0.2	2.9 ± 0.2	3.1 ± 0.3
PtdIns	6.5 ± 0.5	6.6 ± 0.5	6.8 ± 0.6	6.6 ± 1.2
Ptd_2Gro	4.9 ± 0.6	5.0 ± 0.6	6.1 ± 0.5	6.1 ± 1.2

Mock or ABCA1 cells were incubated for 24 h in the absence (−) or presence (+) of 10 nM mifepristone and the pool size of the major phospholipids determined as described in "Materials and Methods". Data represent the mean ± standard deviation of three dishes assayed in duplicate. The pool size of PtdGro and PtdOH were too low to be accurately determined

Table 2 PtdSer synthesis from [^{3}H]serine and PtdIns synthesis from *myo*[^{3}H]inositol in Mock and ABCA1 cells

	Mock (−)	Mock (+)	ABCA1 (−)	ABCA1 (+)
PtdSer (dpm/mg protein $\times 10^3$)	2.7 ± 0.5	1.5 ± 0.4*	2.1 ± 0.4	1.3 ± 0.1*

* $p < 0.05$

incorporated into TAG or DAG in mifepristone-treated mock cells compared to untreated cells. These data indicated that TAG de novo biosynthesis from glycerol was reduced by expression of ABCA1 in BHK cells.

[1-^{14}C]OLA incorporated into PtdSer was elevated 32% in ABCA1 cells treated with mifepristone compared to untreated cells (Table 4). Mifepristone-treatment did not affect [1-^{14}C]OLA incorporated into PtdSer in mock cells compared to untreated cells. In addition, mifepristone did not alter the uptake of [^{14}C]OLA into mock or ABCA1 BHK cells. These data indicate that PtdSer synthesis from [1-^{14}C]OLA was stimulated by ABCA1 expression in BHK cells. Mifepristone-treatment of ABCA1 cells resulted in a 21% reduction in [1-^{14}C]oleate incorporated into TAG and a 21% increase in [1-^{14}C]OLA incorporated into DAG. In contrast, mifepristone-treatment did not affect [1-^{14}C]OLA incorporation into DAG or TAG in mock cells. These data confirmed that TAG de novo biosynthesis from OLA was reduced by expression of ABCA1 in BHK cells. A previous study had shown that 10 nM mifepristone did not alter PtdEth, PtdCho and PtdSer synthesis from [1-^{14}C]PAM in a murine fibroblast cell line [20]. We confirmed this observation in BHK cells using [1-^{14}C]PAM (Table 5). This indicates that the mifepristone-mediated effects on phospholipid metabolism involved unsaturated fatty acids.

The reason for the increase in PtdSer synthesis from glycerol and OLA precursors was examined in mifepristone-treated ABCA1 cells. Cells were incubated for 24 h in the absence or presence of 10 nM mifepristone then harvested and cell lysates prepared and PtdSer synthase activity determined. PtdSer synthase activity was 39 ± 2 pmol/min/mg protein in ABCA1 cells and was unaltered (38 ± 2 pmol/min/mg protein) in mifepristone-treated ABCA1 cells. These data indicate that de novo PtdSer biosynthesis from glycerol and OLA precursors was increased but not via an increase in PtdSer synthase activity. Interestingly, the increase in de novo PtdSer synthesis from [1,3-^{3}H]glycerol or [1-^{14}C]OLA precursors seen with induction of ABCA1 did not correlate with an accumulation of PtdSer mass nor changes in PtdSer synthase activity. This may have been due to an increase in PLA_2 activity towards newly synthesized PtdSer in ABCA1 cells treated with mifepristone (Fig. 2).

Table 4 Glycerolipid synthesis from [1-^{14}C]OLA in Mock and ABCA1 cells

Phospholipid (dpm/mg protein $\times 10^3$)	Mock (−)	Mock (+)	ABCA1 (−)	ABCA1 (+)

Mock or ABCA1 cells were incubated for 24 h in the absence (−) or presence (+) of 10 nM mifepristone and then incubated for 4 h with [1-^{14}C] and radioactivity incorporated into PtdCho, PtdEtn and PtdSer determined. Data represent the mean ± standard deviation of three dishes assayed in duplicate

Expression of ABCA1 Reduces DGAT-1 Activity

The reason for the reduction in [1,3-^{3}H]glycerol and [1-^{14}C]oleate incorporation into TAG in ABCA1 cells was examined. Mock and ABCA1 cells were incubated for 24 h in the absence or presence of various concentrations of mifepristone and then membrane fractions prepared and DGAT activity determined in the absence or presence of 100 mM $MgCl_2$ in the assay incubation mixture. The presence of 100 mM $MgCl_2$ in the incubations will inhibit DGAT-2 enzyme activity [14]. Mifepristone-treatment (10–100 nM) resulted in a 34–39% ($p < 0.05$) reduction in DGAT-1 activity in ABCA1 cells but not in mock cells (Fig. 3a). In contrast, mifepristone-treatment did not affect DGAT-2 activity in either ABCA1 cells or mock BHK cells (Fig. 3b). The decrease in DGAT-1 enzyme activity was maximum with ABCA1 expression using 10 nM mifepristone.

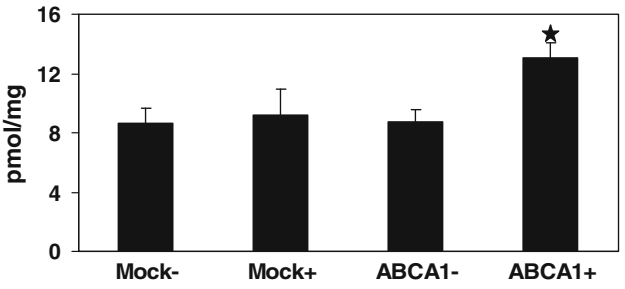

Fig. 2 PLA_2 activities in Mock and ABCA1 cells. Mock or ABCA1 cells were incubated for 24 h in the absence (Mock − or ABCA1 −) or presence (Mock + or ABCA1 +) of 10 nM mifepristone and PLA_2 activities determined as described in "Materials and Methods". Data represent the means ± standard deviation of three dishes assayed in duplicate *$p < 0.05$

Membrane fractions from ABCA1 cells were then prepared and DGAT-1 activity determined in the absence or presence of 10–100 nM exogenous mifepristone in the assay. The presence of exogenous mifepristone added to the assay incubation mixture did not affect DGAT-1 in vitro enzyme activity in membrane fractions prepared from ABCA1 cells indicating that mifepristone did not directly affect in vitro DGAT-1 activity (data not shown). We next examined if DGAT-1 activity and its mRNA expression were regulated by ABCA1 expression in ABCA1 cells. ABCA1 cells were incubated for 24 h in the absence or presence of 10 nM mifepristone and DGAT-1 enzyme activity determined. In addition, total mRNA was isolated and DGAT-1 mRNA expression examined by real

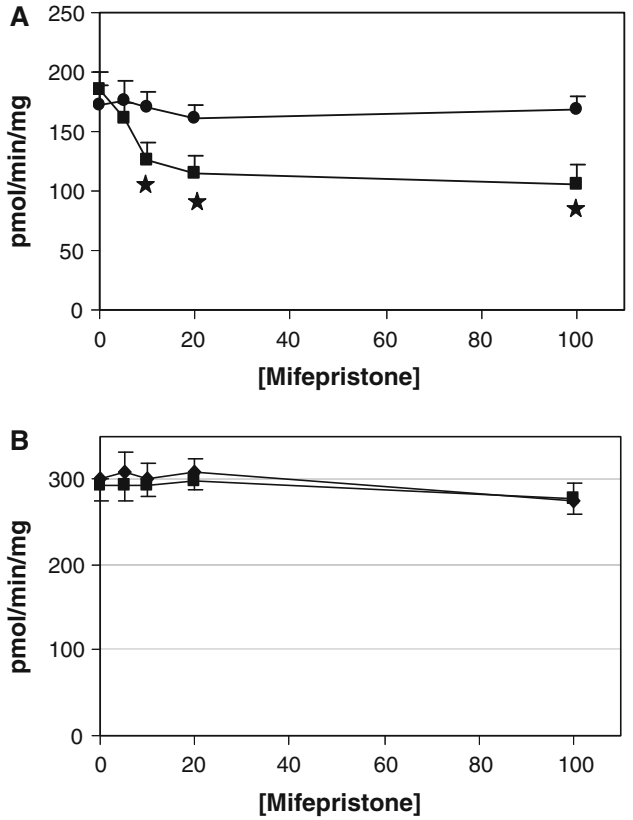

Fig. 3 Concentration-dependent effect of mifepristone on DGAT activities in mock BHK and ABCA1 cells. Mock cells (*circles*) or ABCA1 cells (*squares*) were incubated for 24 h in the absence or presence of 5–100 nM mifepristone and DGAT-1 (**a**) and DGAT-2 (**b**) activities determined as described in "Materials and Methods". Fig. 4 DGAT-1 activity and mRNA expression in ABCA1 cells treated with mifepristone or trichostatin A or both. **a** ABCA1 cells were incubated for 24 h in the absence (−) or presence (+) of 10 nM mifepristone or 100 μM trichostatin A or both and DGAT-1 enzyme activity determined as in Fig. 2. **b** ABCA1 cells were incubated for 24 h in the absence (−) or presence (+) of 10 nM mifepristone or 100 μM trichostatin A or both and DGAT-1 mRNA expression determined by real time-PCR as described in "Materials and Methods". Data represent the means ± standard deviation of three dishes assayed in duplicate $*p < 0.05$

time-PCR. As expected DGAT-1 activity was reduced by mifepristone treatment (Fig. 4a). In contrast, DGAT-1 mRNA expression relative to the constitutive expression of β-actin was unaltered (Fig. 4b). Histone deacetylation increases the charge density on the N-termini of the core histones and thus strengthens histone tail-DNA interactions and blocks access of transcriptional machinery to the DNA template [21]. ABCA1 cells were then incubated for 24 h with 10 nM mifepristone in the absence or presence of 100 μM trichostatin A, a class I and II histone deacetylase inhibitor, and DGAT-1 activity and mRNA expression determined. Trichostatin A-treatment reversed the ABCA1-mediated reduction in DGAT-1 activity (Fig. 4a). In addition, trichostatin A-treatment increased the mRNA expression of DGAT-1 in both mock and ABCA1 cells but did not alter DGAT-1 mRNA expression in cells incubated in the absence or presence of mifepristone (Fig. 4b). These data indicate that the expression of ABCA1 reduces DGAT-1 enzyme activity but not DGAT-1 mRNA expression.

Discussion

The objective of this study was to examine if expression of ABCA1 altered cellular glycerolipid de novo biosynthesis in BHK cells. The main findings of this study are; (1) mifepristone inhibits serine uptake and its incorporation into PtdSer and stimulates *myo*-inositol uptake but does not affect PtdIns de novo biosynthesis, (2) expression of ABCA1 stimulates PtdSer de novo biosynthesis from glycerol and OLA precursors, (3) expression of ABCA1 inhibits TAG de novo biosynthesis and this is due to a decrease in DGAT-1 activity and, (4) caution should be exercised when using the mifepristone-inducible gene system for the study of cellular glycerolipid de novo biosynthesis.

Treatment of both mock and ABCA1 cells for 24 h with 10 nM mifepristone resulted in a dramatic increase in *myo*-[^{3}H]inositol uptake but had no effect on *myo*-[^{3}H]inositol incorporation into PtdIns compared to untreated cells

indicating that de novo synthesis of PtdIns from *myo*-[^{3}H]inositol in BHK cells is independent of *myo*-[^{3}H]inositol uptake. This was confirmed in mock and ABCA1 cells incubated with [1-^{14}C]OLA and [1,3-^{3}H]glycerol in which PtdIns synthesis from these precursors was unaltered. On the other hand, 10 nM mifepristone inhibited [^{3}H]serine uptake and its incorporation into PtdSer in both mock and ABCA1 cells indicating that de novo PtdSer synthesis from serine is dependent upon serine uptake in BHK cells. In contrast, PtdSer synthesis from OLA and glycerol precursors was increased possibly as a compensatory mechanism to maintain PtdSer levels. It is possible that the increase in [^{3}H]serine incorporation into PtdSer upon ABCA1 expression in [1-^{14}C]OLA and [1,3-^{3}H]glycerol incubated cells was due to altered movement of newly synthesized PtdSer to the plasma membrane and/or efflux from the cells. However, in the [1,3-^{3}H]glycerol radiolabeling experiments, no protein acceptor (albumin) was present in the medium to bind phospholipid. The fact that the PtdSer content did not change might have been due to an increase in PLA_2 activity towards newly synthesized PtdSer in ABCA1 cells treated with mifepristone. Alternatively, it is possible that the change in PtdSer localization due to ABCA1 expression makes the phospholipid more accessible to PLA_2. To our knowledge this is the first demonstration that *myo*-inositol and serine uptake may be regulated by inhibition of glucocorticoid responsive receptors. In addition, the above findings indicate that caution with the use of the mifepristone-inducible gene system should be exercised when studying cellular processes which may be influenced by uptake of glycerolipid precursor molecules. The level of mifepristone used for ABCA1 induction in our study (10 nM) and incubation time (24 h) are typical of that used for the mifepristone-inducible gene system [22].

Mifepristone (RU486) is a Type I high affinity glucocorticoid antagonist that is known to induce a glucocorticoid receptor conformation capable of binding to DNA [23]. In addition, mifepristone (at 1–1,000 nM) treatment of COS cells transfected with human glucocorticoid receptor α exhibited an increased receptor translocation rate to the nucleus compared to the potent glucocorticoid receptor agonist dexamethasone [24]. These authors hypothesized that upon ligand binding the glucocorticoid receptor undergoes a conformational change, of which the degree correlates with the affinity of the ligand. This conformational change enables the receptor to transiently bind nuclear structures or domains that are immobile or moving slowly, which is reflected in a decrease in the average mobility of the receptors in the nucleus. Previous studies had shown that injection of the glucocorticoid agonist dexamethasone into rats stimulated hepatic TAG synthesis [25] and stimulated hepatic microsomal DGAT activity 22% and the mRNA expression of both DGAT-1 and DGAT-2 [26]. Since BHK cells contain glucocorticoid responsive receptors [27], it is logical to surmise that mifepristone might have had an opposing effect on DGAT activity. A previous study had shown that mifepristone treatment of human amnion cells inhibited [^{14}C]ARA release in either untreated or dexamethasone-treated cells indicating an independent effect of mifepristone from that of dexamethasone [28]. However, in our study in BHK cells mifepristone did not alter DGAT-1 activity in the absence of ABCA1 expression.

DGAT-1 was previously shown to be regulated mainly at the posttranscriptional level in differentiated 3T3-L1 preadipocytes [29]. In addition, protein stability is not a significant factor in the control of DGAT-1 expression. In the current study, expression of ABCA1 in BHK cells resulted in a reduction in de novo biosynthesis of TAG from OLA and glycerol precursors. This reduction in TAG de novo biosynthesis was mediated by a reduction in the enzyme activity of DGAT-1. The histone deacetylase inhibitor trichostatin A blocked the ABCA1-mediated reduction in DGAT-1 enzyme activity but did not affect DGAT-1 mRNA expression indicating that DGAT-1 mRNA expression was not regulated by ABCA1 expression.

Previous studies in murine macrophages and ABCA1-transfected BHK cells indicated that unsaturated fatty acid, but not saturated fatty acid, increased the rate of ABCA1 degradation via destabilization of ABCA1 by increasing the phosphorylation of serine residues of ABCA1 and this was mediated via activation of PKCδ [30, 31]. In the current study, the destabilizing effect of OLA on ABCA1 did not appear to alter PtdSer, DAG or TAG biosynthesis since the changes in biosynthesis of these lipids were similar in ABCA1 cells incubated with [1,3-^{3}H]glycerol in the absence of OLA. A previous study had shown that although the cellular contents of most phospholipids were not significantly altered in cells from Tangier Disease patients, in which ABCA1 is defective, Ptd_2Gro levels were elevated three- to five-fold [32]. In the present corollary study, expression of ABCA1 did not alter Ptd_2Gro levels or the mass of any other major glycerophospholipid.

We observed a markedly elevated expression of ABCA1 protein in BHK ABCA1 cells incubated with mifepritone for 24 h. A previous study had demonstrated over a 60-fold increase in ABCA1 protein expression in BHK ABCA1 cells after an 18 h treatment with mifepritone [11]. This large elevation in ABCA1 protein was associated with a dramatic efflux of cholesterol in the ABCA1 overexpressing cells. It is difficult to interpret the direct physiological effects of ABCA1 overexpression versus the effects of ABCA1 alone on lipid metabolism when the model may vastly and rapidly change various lipid pathways as a compensatory effect resulting in changes in cholesterol and

other biosynthetic pathways. The mechanism of how ABCA1 expression alters DGAT-1 activity is intriguing. Is it due to a particular lipid transport activity of ABCA1 or changes in plasma membrane lipid composition or a direct signaling event that leads to repression of DGAT-1 activity? These questions will form the basis for future studies on how ABCA1 expression regulates DGAT-1 activity. In summary, mifepristone has diverse effects on cellular de novo glycerolipid synthesis in BHK cells. Thus, caution should be exercised when using mifepristone-inducible systems for studies of cellular glycerolipid metabolism in cells which express glucocorticoid responsive receptors.

Ethanolic Extract of Propolis Promotes Reverse Cholesterol Transport and the Expression of ATP-Binding Cassette Transporter A1 and G1 in Mice

Yang Yu · Yanhong Si · Guohua Song · Tian Luo · Jiafu Wang · Shucun Qin

Received: 10 September 2010 / Accepted: 27 April 2011 / Published online: 3 June 2011

Abstract The ethanolic extract of propolis (EEP) is beneficial in increasing high density lipoprotein (HDL) cholesterol (HDL-C) and diminishing risks of atherosclerosis. In this study, we examined the effects of EEP on reverse cholesterol transport in mice. ^{3}H -cholesterol laden macrophage was injected intraperitoneally into mice fed by gastric gavage with EEP. Plasma lipid level was determined and ^{3}H-cholesterol was traced in plasma, liver and feces. The effects of EEP on ATP-binding cassette transporter A1 and G1 (ABCA1 and ABCG1) and scavenger receptor BI (SR-BI) in mice liver and in cultured cells were also investigated. EEP administration led to a significant increase in HDL-C and peritoneal macrophage-original ^{3}H-cholesterol in plasma, liver and feces. Liver protein expressions of ABCA1 and ABCG1 were increased but SR-B1 was not. In vitro experiments with HepG2 and Raw264.7 cell lines confirmed the above results. The finding of these studies shows that EEP-enhanced reverse cholesterol transport may have resulted from EEP stimulated plasma HDL level and hepatic ABCA1 and ABCG1 expression.

Keywords Ethanolic extract of propolis · Reverse cholesterol transport · High density lipoprotein · ATP-binding cassette transporters A1 · ATP-binding cassette transporters G1 · Scavenger receptor BI

Abbreviations

ABCA1	ATP-binding cassette transporter A1
ABCG1	ATP-binding cassette transporter G1
Ac-LDL	Acetylated low density lipoprotein

Introduction

Atherosclerosis is the principle cause of coronary artery disease and stroke. There is a strong inverse relation between plasma high density lipoprotein cholesterol (HDL-C) levels and the incidence of atherosclerotic cardiovascular diseases. The primary function of high density lipoprotein (HDL) is to mediate reverse cholesterol transport

(RCT), a vital transport fashion of cholesterol metabolism [1]. Excess cholesterol from peripheral tissue is transferred to the liver by HDL for bile acid synthesis and excretion to the feces. Cholesterol efflux from peripheral tissues to HDL is mediated by ATP-binding cassette transporter A1 and G1 (ABCA1 and ABCG1) [1, 2]. Afterward, cholesterol in HDL is transported into hepatocytes through the scavenger receptor BI (SR-BI) [3]. Cholesterol efflux is the initial step of RCT and has become one of the therapeutic targets for atherosclerotic disease [4].

Propolis is a sticky, resinous substance collected by honey bees (*Apis mellifera*) and has been used as a folk medicine from ancient times in South America, Asia and Eastern Europe. The chemical composition of the ethanolic extract of propolis (EEP) is extremely complex and its flavonoid derivatives have been widely cited as its biologically active compounds [5].

Recent studies have indicated that EEP and its subfractions are beneficial in increasing plasma HDL-C level as well as diminishing the risk of atherosclerosis in the rabbit [6–9]. It is therefore conceivable that propolis might play a positive role in RCT. In this study, we examined the effects of EEP on RCT in mice and investigated the change of certain transporters involved in RCT. The results showed that EEP enhances cholesterol transport to the feces, which might be related to an increased plasma HDL-C level and ABCA1 and ABCG1 expression stimulated by EEP.

Materials and Methods

Materials

EEP was obtained from the Taishan bee yard in China. Beeswax was removed and refined. EEP was extracted as described previously [10]. EEP used in this study contained 6.8 mg/mL of flavonoids. Acetylated low density lipoprotein (Ac-LDL) was prepared following a previous study with partial modification [11]. Raw264.7 and HepG2 cell lines were obtained from the American Type Culture Collection (USA). [1,2-^{3}H]-cholesterol was obtained from Perkin-Elmer (USA). Assay kits for triglycerides (TG), high density lipoprotein (HDL)-cholesterol (HDL-C) and low density lipoprotein (LDL)-cholesterol (LDL-C) were from Biosino Bio-technology and Science Inc. Antibodies of ABCA1 and ABCG1 were obtained from Abcam (Cambridge, UK). Antibodies of SR-BI and β-actin were obtained from Novus (USA) and Cell Signaling Technology (USA), respectively.

Animals

Twenty-week old C57BL/6 mice were obtained from the experimental animal center of Peking University, and fed a chow diet and water ad libitum. The mice were kept in a temperature- and humidity-controlled room with a 12/12 h light–dark cycle. This study was approved by the Laboratory Animal Care Committee of Taishan Medical University, and all animal experiments were conducted in accordance with the Guidelines of Care and Use of Laboratory Animals at the Taishan Medical University.

Preparation of ^{3}H-Cholesterol-Laden Cells

Raw264.7 cells were grown in RPMI/HEPES supplemented with 10% FBS. Cells were cultured in Teflon flasks and radiolabeled with 5 μCi/mL ^{3}H-cholesterol and cholesterol loaded with 50 μg/mL acetylated LDL (acLDL). Forty-eight hours later, cells were washed with RPMI/HEPES and equilibrated for 4 h in fresh RPMI/HEPES supplemented with 0.2% BSA, then harvested for mice intraperitoneal injection. Ratio of intracellular ^{3}H-cholesterol and total ^{3}H-cholesterol in cell suspension were determined by liquid scintillation counter (LSC).

In Vivo Experiments

Twelve mice were divided into two groups. The EEP group was dosed with 150 mg/kg EEP once a day for 4 weeks using oral gavage. The control group received only the vehicle (20% pure honey in distilled water) of 10 mL/kg mouse weight. Before injection of Raw264.7 cells, all animals were bled to measure plasma lipid levels (total cholesterol, TC; triglyceride, TG; HDL-C; LDL-cholesterol; LDL-C). On the day of injection, animals were caged individually with access to food and water ad libitum. ^{3}H-Cholesterol-labeled and acLDL-loaded Raw264.7 cells (typically 6.6×10^6 cells containing 1.86×10^6 counts/min [cpm] in 6.2 mL RPMI1640 medium, 0.5 mL/mouse) were injected intraperitoneally as described previously [12]. Both vehicle-treated and EEP-treated mice were injected. Blood was collected at 6, 24, and 48 h after injection, and plasma were used for LSC. Feces were collected continuously at 24 and 48 h and stored at 4 °C before extraction of cholesterol and bile acid. Animals continued to receive vehicle or drug during the 48-h RCT study. At study termination (48 h after injection), mice were exsanguinated and perfused with cold PBS, and portions of the liver were removed and flash-frozen for lipid extraction and protein expression analysis.

Liver ^{3}H-Cholesterol Extraction

Tissue lipids were extracted according to the procedure described previously [13] Results for liver were expressed as percentages of CPM injected (whole organ). Briefly, a 10-mg piece of tissue was homogenized in water, and then lipids were extracted with a mixture of hexane/isopropanol

3:2 (v/v). The lipid layer was collected, evaporated, resuspended in toluene, and counted in a LSC.

Fecal ^{3}H-Tracer Extraction

Feces were weighed and soaked in Millipore water (1 mL water/100 mg feces) overnight at 4 °C. The next day, an equal volume of ethanol was added, and the samples were homogenized. A 200-μL aliquot of each homogenized fecal sample was counted in a LSC to calculate the ^{3}H-total sterols [13].

In Vitro Experiments

Raw264.7 or HepG2 cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS). Cultured media was refreshed by DMEM with 1% FBS, 0.1% dimethyl sulfoxide (DMSO) containing various concentrations of EEP (0, 0.2, 1.0, 5.0 μg/mL) for another 48 h incubation. Cells were harvested and stored at −70 °C for Western blot analysis.

Western Blot

Total protein extracted from liver tissue or cultured cell was separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The proteins were transferred on polyvinylidene fluoride (PVDF) membranes. Protein levels of ABCA1, ABCG1 and SR-BI were evaluated and referenced with β-actin by Western blot. The target bands were quantified using Image-Pro Plus software ver. 6.0 (Media Cybernetics Corp., USA).

Statistics

Data were reported as means ± standard deviations (SD) and subjected to ANOVA analysis. F test and the Student–Neuman–Keuls post test analyses were performed on these data to analyze the variances and significances between groups. Probability values <0.05 were considered significant.

Results

Effects of EEP on Plasma Cholesterol

Figure 1 shows the effects of EEP on plasma lipid. HDL-C increased significantly by 10% in EEP group compared with the control (74.24 vs. 81.76 mg/dL). Plasma TC also increased significantly in the EEP group by 17% compared with the control (90.28 vs. 106.56 mg/dL). Yet no significant change was observed in either LDL-C or TG levels between the control and EEP group.

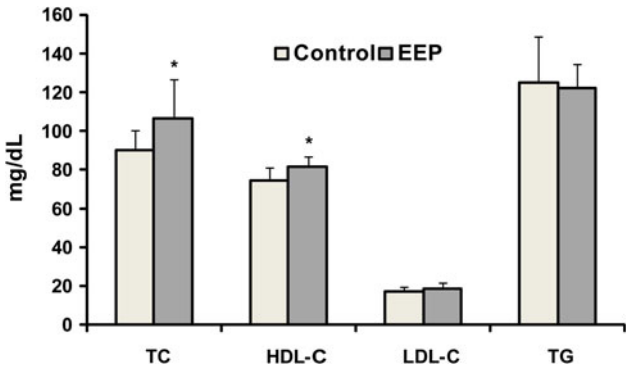

Fig. 1 Plasma HDL-C increased in the EEP Group. Plasma total cholesterol (TC), triglycerides (TG), high density lipoprotein cholesterol (HDL-C) and low density lipoprotein cholesterol (LDL-C) were determined by enzyme methods, respectively. Data (means ± SD, $n = 6$) are expressed as microgram per deciliter. *$P < 0.05$ versus control

Effects of EEP on Reverse Cholesterol Transport

To evaluate the role of EEP in cholesterol transport from peripheral tissue to feces, a classic isotope-labeled cholesterol tracing assay was employed. As shown in Fig. 2a, plasma ^{3}H-labelled cholesterol had increased significantly by 118 and 99% in EEP group at 6 and 24 h, respectively, after injection compared with the control, but there was no significant difference in the ^{3}H-tracer at 48 h. This time course of ^{3}H-cholesterol distribution in plasma suggests that in the first 24 h, EEP enhances cholesterol transport from the macrophages to plasma at the first 24 h. Tritium-labeled cholesterol also increased significantly by 130% in liver from the EEP group compared with the control group (Fig. 2b). The fecal ^{3}H-tracer level was augmented significantly by 49 and 20% in the EEP group at 0–24 h and at 24–48 h, respectively (Fig. 2c).

Effects of EEP on ABCA1, ABCG1 and SR-BI Expression in Mice Liver

Liver protein levels of ABCA1, ABCG1, and SR-BI may involve both HDL formation and RCT. As shown in Fig. 3, ABCA1 and ABCG1 in liver increased significantly (by 28.9 and 140.5%, respectively) in the EEP group compared with the control. No significant change in SR-BI was observed between the EEP and control group.

Effects of EEP on ABCA1, ABCG1 and SR-BI Expression in Cultured Cells

To further elucidate the effect of EEP on ABCA1, ABCG1 and SR-BI, we treated cultured HepG2 and Raw264.7 with EEP in different dosage. When treated with 0.2–5 μg/mL EEP, HepG2 cell showed that both ABCA1 and ABCG1 protein levels increased significantly compared with the

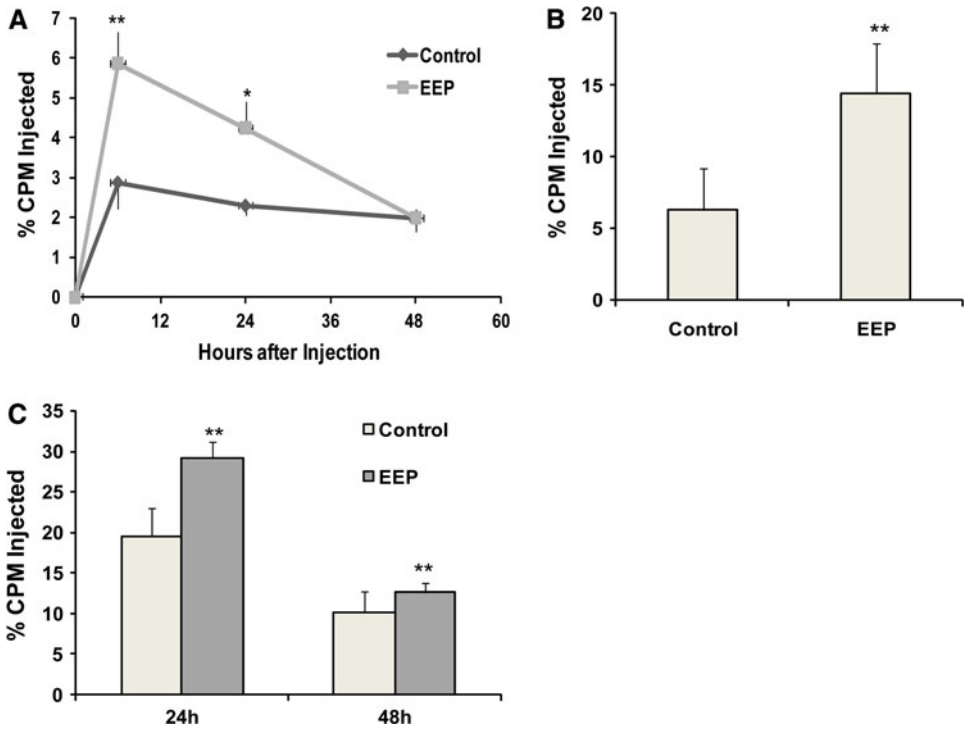

Fig. 2 EEP promoted reverse cholesterol transport in mice. **a** Time course of ^{3}H-cholesterol distribution in plasma. C57BL/6 mice were treated with either vehicle alone or with EEP for 4 weeks. ^{3}H-Cholesterol-labeled and acLDL-loaded Raw264.7 cells (typically 6.6×10^{6} cells containing 1.86×10^{6} counts/min [cpm] in 6.2 mL RPMI1640 medium, 0.5 mL per mouse) were injected intraperitoneally. Plasma was collected at 0, 6, 24, and 48 h after injection for liquid scintillation counting and the levels were expressed as the percentage of total counts per minute (means ± SD, $n = 6$). $^{*}P < 0.05$; $^{**}P < 0.01$ versus control. **b** Liver ^{3}H-cholesterol distribution in mice. C57BL/6 mice were treated with either vehicle alone or with EEP for 4 weeks. ^{3}H-cholesterol-labeled and acLDL-loaded Raw264.7 cells (typically 6.6×10^{6} cells containing 1.86×10^{6} counts/min [cpm] in 6.2 mL RPMI1640 medium, 0.5 mL per mouse) were injected intraperitoneally. At the end of the study (48 h after injection), mice were exsanguinated and perfused with cold PBS, and portions of the liver were removed and flash-frozen for ^{3}H-tracer analysis. The levels were expressed as the percentages of the total counts per minute (means ± SD, $n = 6$). $^{*}P < 0.05$; $^{**}P < 0.01$ versus control. **c** Fecal ^{3}H-tracer distribution in mice. C57BL/6 mice were treated with either vehicle alone or with EEP for 4 weeks. ^{3}H-cholesterol-labeled and acLDL-loaded Raw264.7 cells (typically 6.6×10^{6} cells containing 1.86×10^{6} counts/min [cpm] in 6.2 mL RPMI1640 medium, 0.5 mL per mouse) were injected intraperitoneally. Feces were collected continuously at 24 and 48 h and stored at 4 °C before analysis of ^{3}H-tracer. The levels were expressed as the percentages of the total counts per minute (means ± SD, $n = 6$). $^{*}P < 0.05$; $^{**}P < 0.01$ versus control

control regardless of dosage amount (Fig. 4a). In addition, no significant change of SR-BI expression was observed between EEP and control groups.

In the Raw264.7 cell experiment (Fig. 4b), partially similar to the HepG2 setting, ABCG1 protein levels increased significantly in each EEP group compared with the control, whereas no dose-dependent manner of ABCG1 expression was observed in the groups of higher EEP concentrations (1–5 μg/mL). The ABCA1 expression level was improved significantly in 1 and 5 μg/mL EEP groups only. Additionally, no significant change of SR-BI expression was observed between the EEP and control groups.

Discussion

In this study, we found that EEP promoted the reverse cholesterol transport from intraperitoneal macrophages to feces. This result suggests that EEP plays a positive role in cholesterol transport from peripheral tissue to the liver and secreted into the feces. It is well known that the RCT pathway includes a series of steps beginning in peripheral tissues with the efflux of cholesterol to lipid-poor HDL and ending in the liver and gastrointestinal tract with the secretion of cholesterol into the bile and their removal through the feces. Among this series of steps, HDL and its related cholesterol transporters play a crucial role. In this study our novel findings also indicate that EEP increases plasma HDL-C level and enhances liver ABCA1 and ABCG1 protein expression. The results suggest that EEP may involve increased nascent HDL particle formation, thus leading to an increased plasma HDL concentration and promoting RCT.

Our previous studies in the rabbit [6, 9] reported that EEP could diminish atherogenesis by improving the plasma lipid profile and endothelial function. However,

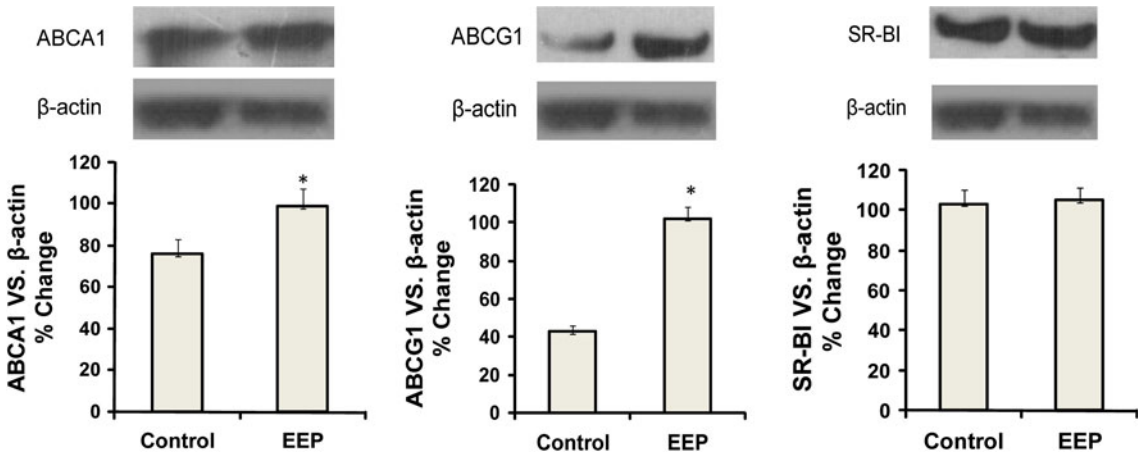

Fig. 3 EEP increased the liver expression of ABCA1 and ABCG1 in mice. Liver protein levels of ABCA1, ABCG1, and SR-BI in mice fed with EEP (EEP) and vehicle (control) group. 20 μg protein of liver tissue from EEP or control were conducted to SDS-PAGE and the proteins were transferred on PVDF membranes for Western blot analysis and quantified by densitometry (see details in "Materials and Methods"). A representative Western blot result from four independent experiments is shown in the (*upper panel*) and the quantification of these proteins is shown in the *down panel*. All values are presented as means ± SD of four independent experiments. $^{*}P < 0.01$ versus control

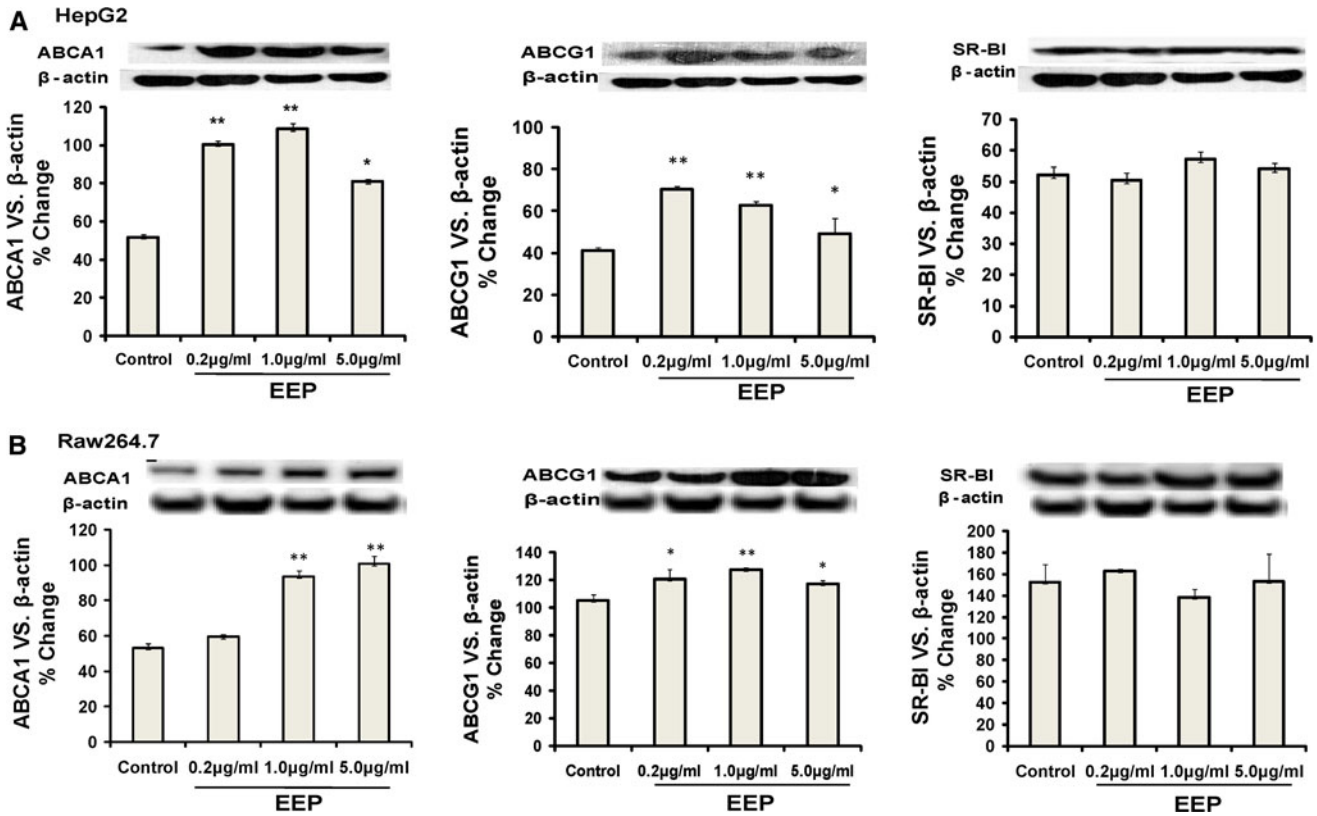

Fig. 4 EEP stimulated the expression of ABCA1, ABCG1 in HepG2 and Raw264.7. Protein levels of ABCA1 and ABCG1 and SR-BI in HepG2 and Raw264.7 were determined with the treatment of EEP in various concentrations (control, 0.2, 1.0, 5.0 μg/mL). Then 20 μg protein of the cells from each group was conducted to SDS-PAGE and the proteins were transferred on PVDF membranes for Western blot analysis and quantified by densitometry (see details in "Materials and Methods"). **a** ABCA1 and ABCG1 and SR-BI expression in HepG2 cell line. **b** ABCA1 and ABCG1 and SR-BI expression in Raw264.7 cell line. A representative Western blot result from four independent experiments is shown in the (*upper panel*) and the quantification of these proteins is shown in the *down panel*. whether propolis or EEP is beneficial to RCT in the animal model remains unsolved. In this study, our result provides evidence for the first time that EEP can promote reverse cholesterol transport in the murine model for the first time.

ABCA1 and ABCG1 are members of the ABC family of transporters. Many studies have shown that macrophage ABCA1 and ABCG1 play important roles in cholesterol efflux from peripheral tissues to plasma [14]. The main bioactive component of EEP in this study is the phenolic compounds named flavonoids. One in vitro study indicated that a flavonoids pigment, anthocyanins induced cholesterol efflux from mouse peritoneal macrophages and macrophage-derived foam cells by activating liver X receptor α—ABCA1 signaling pathway [15]. Another flavonoids derivates study also demonstrated that procyanidins could attenuate the development of foam cell formation via reducing CD36 expression and enhancing ABCA1 expression [16]. All the studies showed us a phenomenon that flavonoids could stimulate the expression of ABCA1 in macrophages. In the present study, we found EEP not only increased the expression of macrophage ABCA1, but also ABCG1, which might play a role, at least in part, in promoting the first step of RCT by EEP. In addition, the plasma LDL-C level was not affected by EEP treatment, but the HDL-C level was increased by EEP which might also contribute to the enhancement of reverse cholesterol transport by EEP. The elevated TC level by EEP might be attributable to the increased HDL-C level, not LDL-C.

Besides macrophage ABC transporters, previous studies support hepatic ABCA1 exerted anti-atherogenic effect via its contribution to HDL formation [12] and hepatic ABCG1 might mediate hepatocyte cholesterol efflux towards plasma from a pool accessible for biliary secretion [17]. Our results showed that the expression of hepatic ABCA1 and ABCG1 was increased by EEP treatment in vitro and in vivo, these data gave us a clue that the elevated plasma HDL-C level by EEP in this study might be closely associated with the enhanced hepatic ABCA1 and ABCG1 expression stimulated by EEP. Additionally, our unpublished data showed ABCA1 and ABCG1 expressions in endothelial cell were not affected by EEP, which indicated that no other cell types but hepatocyte might be the target contributing to the enhancement of hepatic ABCA1 and ABCG1 expression treated by EEP.

Distribution and regulation of SR-BI are more complex than those of ABCA1 or ABCG1. For instance, hepatic expression of SR-BI is modulated by many factors including farnesoid X receptor, liver X receptors, the liver receptor homolog 1, peroxisome proliferator-activated receptor γ and hepatocyte nuclear factor 4 α. As a result, strong activators or specific stimulatory factors might be effective in promoting SR-BI expression. A recent report has shown that two flavonoids acids in coffee could increase SR-BI and ABCG1 expression and enhance HDL-mediated cholesterol efflux from the macrophages [18]. However, in the present study, no SR-BI change was observed, which probably indicates that EEP employed in this study might be deficient in a component that stimulates SR-BI expression.

Additionally, in the present in vitro experiment we did not observe a dose-dependent manner of enhancement of ABCG1 expression stimulated by EEP. The multi-step regulatory mechanism of ABCA1 and ABCG1 might be the possible reason and the stimulation of EEP (0.2–5 μg/mL) in this study could be attenuated through liver X receptor—ABCA1/ABCG1 signalling pathways. As mentioned above, Uto-Kondo found that dose-dependent manner of ABCG1 and SR-BI expression was observed neither when macrophage was treated with 0.25–0.5 μM caffeic acid nor in ferulic acid [18]. Therefore, the results from this study and from other team's suggest that the effective range of the effect of EEP and flavonoids on the expression of ABCA1 and ABCG1 still needs further investigation.

To summarize, our study showed that EEP promoted cholesterol transport to the plasma and increased expression of ABCA1 and ABCG1 in both in vitro and in vivo experiments. These findings suggest that EEP is an effective substance in improving RCT, one of the contributors to the inhibition of atherosclerosis. The present study adds to the accumulating evidence for bioactive components in cholesterol metabolism. To further understand the promotion of EEP on cholesterol efflux in mice, investigations are required to focus on its isolated bioactive components and signalling pathways involved in RCT. In this study, EEP showed a significant increasing HDL-C effect without affecting LDL-C in plasma, which suggests that EEP and its flavonoids contents may be beneficial in developing medications on atherosclerotic diseases.

Acknowledgments This study was supported by a grant from the "Tai Shan Scholars" foundation of Shandong province (ZD056, ZD057), and by a special foundation of Tai Shan Medical College (1065). We would like to thank Guanghai Zhou and Xinnong Wang for expert technical assistance.

Abstract The mechanism of adipose tissue lipolysis has not been fully elucidated. Greater understanding of this process could allow for increased feed efficiency and reduced fat in poultry. Studies in avian species may provide important insight in developing therapies for human obesity, as lipolytic pathways are highly conserved. Adipose triglyceride lipase (ATGL) cleaves triacylglycols, releasing non-esterified fatty acids (NEFA) into the bloodstream. Glucocorticoids have been shown to elevate circulating NEFA. To determine the regulation of ATGL and regulator proteins comparative gene identification-58 (CGI-58) and G(0)/G(1) switch gene 2 (G0S2) by glucocorticoid, 36 chickens received an injection of dexamethasone (4 mg/kg). Saline was administered to an additional 12 birds to determine any effect of stress during handling. Dexamethasone-injected birds were harvested at 0, 0.5, 1, 2, 4, and 6 h after treatment; saline-treated birds were collected at 4 and 6 h. Abdominal and subcutaneous adipose tissue and blood were collected. Gene and protein expression were analyzed via quantitative real-time PCR and western blot. Compared with the saline group, ATGL expression increased in birds injected with dexamethasone. When dexamethasone response was compared to the untreated group up to 6 h following injection, an increase in ATGL protein was observed as quickly as 0.5 h and increased further from 1 to 6 h. Plasma NEFA and glucose increased gradually from 0 to 6 h, reaching statistical significance at 4 h. These data show that ATGL expression is stimulated by glucocorticoid in a time-dependent manner.

Introduction

Lipolysis is an important process in animal adipose tissue. Adipose depots are highly adapted to provide energy as glycerol and fatty acids in times of stress, nutrient deprivation, or high activity or to store excess energy as triacylglycerides in a postprandial state. The ability to switch quickly and efficiently between catabolic and anabolic states in adipose is important for survival; therefore, proteins involved in lipolytic and lipogenic processes are highly regulated at multiple levels.

Understanding the mechanisms of adipose tissue lipolysis is of great importance in animal agriculture. The maximization of feed efficiency is a chief concern to producers, decreasing the energy stored in fat and increasing the energy directed toward lean muscle growth is a key concept in providing lean meat at a low cost. Additionally, as the lipolytic pathways are highly conserved across species, enhancing our knowledge of the regulation of lipolysis may be beneficial in developing new therapies for

human obesity. Adipose triglyceride lipase (ATGL) is the rate-limiting enzyme in triacylglycerol hydrolysis [1, 2]. The regulation of ATGL is not yet fully understood.

Recently, studies in mice have shown that ATGL is stimulated by the synthetic glucocorticoid, dexamethasone [3]. Glucocorticoids (GC) are an end product of the hypothalamic-pituitary-adrenal axis and have a variety of metabolic effects to maintain energy homeostasis during stress [4]. Glucocorticoids regulate adipose differentiation, function, and distribution and in excess, promote hyperlipidemia [5]. Daily GC exposure has been shown to decrease body weight and feed intake in broiler chickens after 2 weeks, however, no significant long-term changes in ATGL expression were observed at the conclusion of the study [6]. It is the hypothesis of this study that injection of dexamethasone may acutely increase ATGL expression and increase plasma fatty acids in broiler chickens.

Materials and Methods

Experimental Animals

Animal care and experimental procedures were approved by the OSU Institutional Animal Care and Use Committee. Experimental animals were allowed ad libitum access to food and water throughout the experiment. To investigate the effect of glucocorticoid administration in vivo, 30 Ross 308 broiler chickens, 25 days old, were injected with a synthetic glucocorticoid, dexamethasone (DEX; 4 mg/kg). At 0.5, 1, 2, 4, and 6 h following injection, six birds were euthanized via CO_2 inhalation. Six additional chickens were euthanized without receiving a DEX injection to be used as a negative control; an additional 12 chickens received saline injections as a placebo and were harvested 4 and 6 h after injection. Tissue samples were collected from abdominal and subcutaneous adipose depots and snap frozen in liquid nitrogen. Prior to euthanasia, blood samples were collected via cardiac puncture and cooled on ice. Tissues were kept at −80 °C for analysis by western blot, RNA isolation, and quantitative real-time PCR (qRT-PCR). Blood samples were centrifuged at 1,700×*g* at 4 °C for 10 min to obtain plasma for glucose, insulin, and non-esterified fatty acid (NEFA) assays.

Primary Cell Culture and In Vitro Treatments

Abdominal adipose tissue was obtained from an adult broiler chicken. Primary cells were cultured by a procedure which has been previously described [7]. Adipose tissue was washed in PBS, finely minced and incubated, shaking, at 37 °C in a digestion buffer containing 2 mg/mL collagenase I (5 mL per gram of tissue). After 45 min, the tissue was passed through nylon strainers with 100 μm openings. The filtered cells were centrifuged to separate floating adipocytes from pelleted stromal-vascular cells. The pellet was washed in fresh DMEM, centrifuged, and re-suspended in DMEM medium containing 5% chicken serum to a concentration of 6×10^6 cells/mL. Cells were seeded in 12-well plates at a density 3×10^6 cells/mL and maintained in a humidified incubator at 37 °C, 5% CO_2. When the cells reached 50% confluence, the cell media was altered to contain 5% chicken serum and 50 mm linoleic and oleic acids in DMEM to induce adipocyte differentiation. Cells were maintained in this media for 2 days, at which point there was visible lipid accumulation in the cells. All cells were serum-starved for 3 h prior to treatment by incubation in DMEM alone. The cells were then treated at the indicated time-points by removing the media and replacing it with fresh DMEM for control cells, or 1,000 nM DEX in DMEM. Cells were treated at −12, −6, −3 and 0 h prior to collection of cells in Trizol reagent for RNA isolation.

RNA Isolation and Quantitative Real-Time PCR

Tissue samples were homogenized in Trizol reagent (Invitrogen, Carlsbad, CA) using a Tissuemiser homogenizer (Fischer Scientific, Pittsburgh, PA). Total RNA was isolated according to the manufacturer's protocol. The quality and relative quantity of RNA was assessed via gel electrophoresis. To investigate mRNA expression of ATGL, comparative gene identification-58 (CGI-58) and G(0)/G(1) switch gene 2 (G0S2), cDNA was generated by reverse transcription using 1 μg total RNA and M-MLV RT (Moloney murine leukemia virus reverse transcriptase, Invitrogen) according to the manufacturer's protocol using OligoDT as the primer. Reverse transcription conditions for cDNA amplification were as follows: 65 °C for 5 min, 37 °C for 52 min, and 70 °C for 15 min. Relative gene expression was quantified by SYBR green real-time PCR on an ABI 7300 real-time PCR Instrument (Applied Biosystems, Foster City, CA). Primer sequences for the ATGL, G0S2, and β-actin genes have been described in our previous reports [7, 8]. Primer sequences for the chicken CGI-58 gene are forward primer 5′-ACC GTG GTT TAT GGA GCA CG-3′ and reverse primer 5′- GAA ACA GTG TGC AAA CAG AGC C-3′. Forward and reverse primers were designed to span genomic introns (> 1 Kb) to avoid the amplification of genomic DNA that may have been present. PCR was performed using AmpliTaq Gold polymerase (Applied Biosystems) with SYBR green as a detection dye. Reactions were performed in duplicate 25 μL reactions. Conditions for qRT-PCR were 95 °C for 10 min, 40 cycles of 94 °C 15 s, 60 °C 40 s, 72 °C 30 s, and 82 °C 33 s. The comparative $2^{-\Delta\Delta Ct}$ method for relative quantification [9]

was used to calculate the relative gene expression (as determined by ABI software). Beta-actin was used as the housekeeping gene to normalize the qRT-PCR calculation.

Protein Isolation and Western Blot Analysis

For protein analysis, adipose samples were homogenized in ice-cold 1X lysis buffer (62.5 mM Tris, 5% SDS) with a tissuemiser and combined with 2× Laemmli buffer (Bio-Rad Laboratories, Hercules, CA) containing 62.5 m*M* Tris, 1% SDS, 5% 2-mercaptoethanol, 12.5% glycerol, 0.05% bromophenol blue. Proteins were separated by SDS-PAGE and wet-transferred to a 0.45 μm pore polyvinylidine fluoride membrane (GE Biosciences, Piscataway, NJ). Membranes were blocked in 5% nonfat dry milk in Tris-buffered saline-Tween (TBST; 20 mM Tris, 150 mM NaCl, pH 7.4, plus 0.15% Tween 20) for 1 h at room temperature. Membranes were incubated overnight at 4 °C in primary antibodies ATGL (1:1,000 dilution; Cell Signaling Technology, Inc., Danvers, MA) or α-tubulin (1:7,000 dilution; Developmental Studies Hybridoma Bank, The University of Iowa, Iowa City, Iowa). The specificity of the ATGL antibody to avian ATGL has been demonstrated previously [8]. Membranes were then washed in TBST for 1 h and incubated with horseradish peroxidase-conjugated secondary antibodies (Santa Cruz Biotechnology Inc., Santa Cruz, CA) for 2 h at room temperature. Membranes were washed again for 1 h in TBST followed by detection with ECL Plus (GE Biosciences). The membranes were exposed to Bio-Max X-ray film (GE Biosciences) for visualization of the ATGL and α-tubulin proteins.

Plasma Parameter Analysis

Blood samples were collected in tubes containing sodium heparin (BD Medical, Franklin Lakes, New Jersey), cooled on ice, and centrifuged at 1,700×*g* for 10 min at 4 °C to separate plasma. Glucose was measured by glucose oxidase method using Autokit Glucose Enzymatic Method (Mutarotase-GOD) (Wako Pure Chemical Industries Ltd., Osaka, Japan). Non-esterified fatty acid (NEFA) concentration was measured with the HR Series NEFA-HR (2) ACS-ACOD kit (Wako Pure Chemical Industries Ltd.) at the Laboratory of Veterinary Diagnostic Medicine at the University of Illinois. Plasma insulin determination was performed using an Insulin RIA kit (Diagnostic Systems Laboratories, Inc, Webster, TX) at the Michigan State University Diagnostic Center for Population and Animal Health.

Gene Promoter Analysis

Transcription factor binding sites on the promoter region of the ATGL gene were identified by entering the nucleic acid sequence into the MatInspector program version 8.0 (Genomatrix software).

Statistical Analysis

Comparison of gene expression and plasma metabolites between saline- and DEX-treated chickens was done by a Student's *t* test. Time-dependent plasma parameters and qRT-PCR data were analyzed by the PROC GLM procedure of the SAS software system (version 9.1, SAS Institute Inc., Cary, NC). Individual comparisons between groups are by one-way ANOVA followed by Tukey's test.

Results

To ensure any changes in gene expression were not due to the stress of handling, DEX treated birds were compared with birds injected with saline as a placebo. When compared with saline-injected birds, qRT-PCR data reveal a significant increase of ATGL mRNA expression in DEX-injected birds in both the abdominal and subcutaneous adipose depots (Fig. 1a, b). Western blot analysis shows that ATGL protein responds similarly, with greater expression in the DEX treatment group over the placebo group (Fig. 1c, d). Plasma measurements of NEFA and glucose were compared between saline- and DEX- injected birds. In the DEX group, NEFA was greater 4 and 6 h after treatment ($P < 0.05$) than that of the saline group; plasma glucose was clearly elevated at in the DEX-treated birds (Fig. 2).

Quantitative RT-PCR was performed to investigate the mRNA expression of ATGL and regulatory proteins, comparative gene identification-58 (CGI-58) and G(0)/G(1) switch gene 2 (G0S2) following DEX treatment. In subcutaneous fat, ATGL expression begins increasing incrementally at 1 h post-injection, and is significantly elevated from basal expression at 4 and 6 h ($P < 0.05$; Fig. 3a). The mRNA expression of CGI-58 is not significantly altered with treatment, though G0S2 is decreased slightly from control levels at 1 h, and it increases significantly thereafter, reaching peak expression at 6 h (Fig. 3b, c). In abdominal fat, ATGL expression increased starting 2 h following DEX injection, reaching its highest expression at 6 h, a 12-fold increase ($P < 0.05$; Fig. 4a). Similar to the pattern seen in subcutaneous fat, changes in CGI-58 expression were negligible and G0S2 decreased slightly following injection (0.5–1 h) and increased about 5-fold at 4 h ($P < 0.05$; Fig. 4b, c).

To evaluate acute changes in ATGL protein following glucocorticoid exposure, Western blot analysis was performed for 0, 0.5, 1, and 2 h after treatment. Subcutaneous and abdominal fat both showed increases in ATGL protein following DEX injections (Fig. 5). The subcutaneous fat

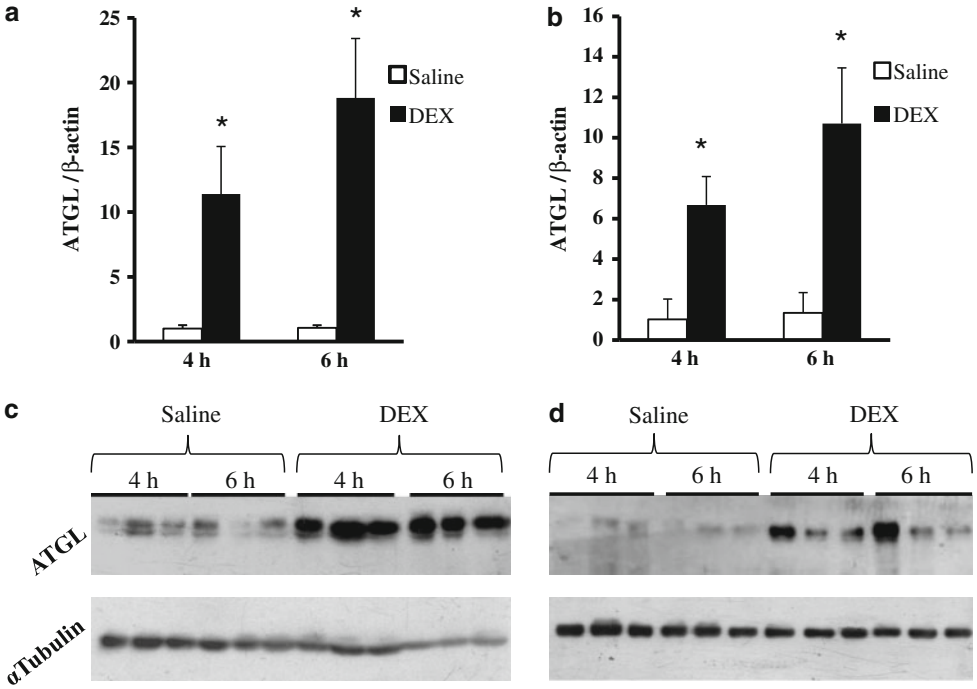

Fig. 1 Expression of adipose triglyceride lipase (ATGL) in chickens following saline or dexamethasone (DEX) injection. The mRNA expression of ATGL was measured by quantitative Real-Time PCR in **a** abdominal and **b** subcutaneous adipose tissue of chickens injected with saline or DEX (4 mg/kg). *β*-actin was used as a housekeeping gene. Unfilled and filled bars represent samples collected 4 h and 6 h post-injection, respectively. *Bars* represent mean ± SEM, with * indicating ($P < 0.05$) between treatments. Expression of ATGL protein was visualized by Western blot analysis of cell lysates from **c** abdominal **d** abdominal fat of chickens injected with saline or DEX. α-Tubulin was used to normalize loading

exhibits increased ATGL at 0.5 h; abdominal expression is apparently greater at 1 h. The slightly delayed ATGL protein expression in abdominal fat compared to subcutaneous fat is concordant with mRNA expression in these depots.

To evaluate the effect of DEX on fatty acid release, plasma NEFA was measured (Fig. 6a). Plasma NEFA increased gradually following DEX-injection reaching its greatest levels at 4 and 6 h ($P < 0.05$), concurrent with peak ATGL mRNA expression. Daily treatment with dietary glucocorticoid has been associated with hyperinsulemia and hyperglycemia in chickens [10]. We measured plasma insulin and glucose to determine if there is an acute response to dexamethasone. Glucose increases steadily from 0.5 to 6 h following treatment, whereas insulin increases up to 2 h (Fig. 6b, c). At 4 h post-injection, insulin levels return to those seen in control birds.

In a whole-body system, there are numerous factors that may alter gene expression in response to exogenous chemicals. To test whether ATGL expression is altered directly by dexamethasone or through indirect mechanisms, we treated cultured chicken adipocytes with DEX for 0, 3, 6, and 12 h. In DEX-treated adult chicken adipocytes, mRNA expression of ATGL is increased by 13-fold at 3 h ($P < 0.05$; Fig. 7). We also measured the expression of CGI-58 and G0S2, which were largely unchanged.

Discussion

Glucocorticoids, primarily corticosterone in chickens, are the final effectors of the hypothalamic–pituitary–adrenal axis [6]. Synthesis of GC occurs in the adrenal cortex and has a wide array of metabolic effects to maintain homeostasis during times of stress [4], including the elevation of circulating free fatty acids and hepatic glucose [3, 10]. Multiple mechanisms for GC-enhanced lipolysis have been suggested, including through the activation of cAMP-dependent hormone sensitive lipase [11], "permissive" effects through disrupted insulin signaling, and direct action on ATGL [3]. The primary objective in this study is to determine the acute regulation of ATGL by glucocorticoid in broiler chickens.

Handling is a known stressor to broiler chickens. To ensure any responses observed were not due to handling during injection, a saline injection was administered to two groups of chickens as a placebo and compared with the DEX groups. The marked increase in ATGL expression and plasma NEFA in the DEX groups over saline groups support that there is a physiological response specifically to the dose of DEX administered. Over the course of 6 h, ATGL mRNA and protein expression increases in abdominal and subcutaneous fat, concurrent with a gradual increase in plasma NEFA. These changes occur quickly after injection (about 1 h); we suspect such an early onset of this response is unlikely to be through an indirect mechanism involving other hormones, but may occur at the cellular level within adipose tissue.

To provide further support for CG regulation of ATGL at the cellular level, we treated cultured chicken adipocytes with DEX over a period of 12 h. After 3 h incubation with DEX, ATGL expression increased dramatically (13-fold). Interestingly, at 6 h, when in vivo ATGL expression is

greatest, the in vitro expression has decreased by more than half of its peak expression. This observation has led us to postulate that the regulation of ATGL by dexamethasone may occur in two waves: (1) transcriptional regulation in the very short-term, and (2) through reduced insulin signaling within several hours. Immediate transcriptional regulation by steroid hormones can occur through hormone response elements present on the 5' flanking region of the target gene [12]. Using the MatInspector program version 8.0 (Genomatrix software), transcription factor binding sites were analyzed in the nucleic acid sequence of the ATGL. Five glucocorticoid response elements were identified at −4602 {ctgGGACagagcgtcctaa (−)}, −3787 (aaaGAACagttaattcttt (−)), −3334 {agaGAACatccagttacca (−)}, −2044 {aggGAACaaaaggtcccat (+)}, and −907 {gtaGCACatgtggtgatgt (+)} bp upstream of the transcription start site. The presence of these response elements, combined with the observed increase in ATGL expression in an insulin-free in vitro system, suggests direct transcriptional regulation by GC. Insulin promotes triacylglycerol storage in adipose tissue, and is reported to downregulate ATGL expression [13]. In addition, insulin introduced in cultured rat adipose cells is capable of blocking DEX-stimulated fatty acids release [14]. Our plasma analysis revealed that insulin concentration increases 0.5–2 h after DEX injection, and begins to taper to basal levels at 4 h. Interestingly, glucose and NEFA continue to elevate concurrent with increased insulin following injection, demonstrating some insensitivity. We believe that decreased insulin sensitivity and secretion may permit increased ATGL expression and fatty acid release through the absence of insulin-mediated suppression, though future research should be conducted to confirm this hypothesis.

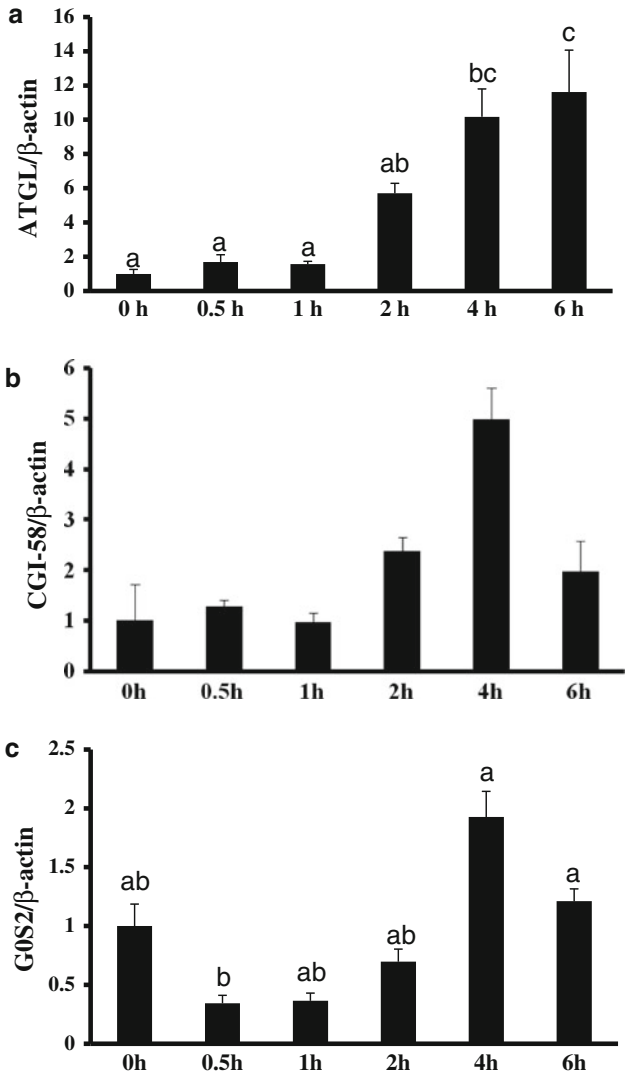

Fig. 4 Relative mRNA expression in abdominal adipose tissue of dexamethasone-injected broiler chickens. Total RNA was isolated from abdominal fat of treated birds collected 0.5–6 h following injection ($n = 6$). Untreated control birds are indicated as 0 h. Quantitative Real-Time PCR was done to determine relative expression of **a** adipose triglyceride lipase (ATGL), **b** comparative gene identification-58 (CGI-58), **c** G(0)/G(1) switch gene 2 (G0S2). *Bars* are means ± SEM. Letters represent a significant difference ($P < 0.05$) among groups at various time points

Recent studies have reported that ATGL activity may be regulated through interactions with activator protein CGI-58 and inhibitor protein G0S2. Upon stimulated lipolysis, mammalian CGI-58 co-localizes with ATGL on the lipid droplet surface. Disruption of this interaction results in complete inability of CGI-58 to activate ATGL-mediated triacylglyceride hydrolysis [15]. Conversely, G0S2 interaction with ATGL inhibits its activity as a lipase [16]. We have recently observed that upregulation of ATGL during fasting in chickens occurs simultaneously with increased CGI-58 expression [17, 18] and decreased expression of

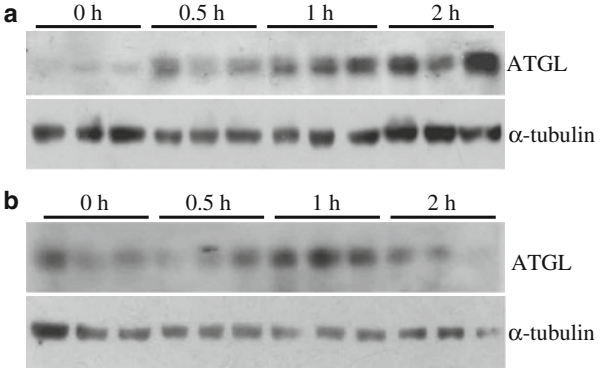

Fig. 5 Western blot analysis of adipose triglyceride lipase (ATGL) protein following dexamethasone injection. Protein lysates of **a** subcutaneous and **b** abdominal adipose tissue were separated by SDS-PAGE. α-Tubulin was used as a loading control. ATGL protein was determined at 0.5, 1, and 2 h following treatment, 0 h indicates control birds receiving no treatment

G0S2 [7], suspecting that changes in regulator protein expression contributes to NEFA release during nutrient deprivation. To evaluate whether regulatory proteins are involved in GC-stimulated lipolysis, we measured the expression of CGI-58 and G0S2 during our in vivo and in vitro DEX treatments. Only negligible changes in CGI-58 expression were observed in both experiments. Interestingly, G0S2 expression decreased slightly immediately following DEX injections in vivo. It has been reported by Lu and colleagues that overexpression of ATGL in G0S2-expressing HeLa cells failed to enhance lipolytic activity as it did in non-G0S2 control cells [19]. We therefore suspect that downregulation of G0S2 may be necessary at some point in stimulated lipolysis. It is possible that GC may directly regulate G0S2 within 1 h of exposure; however, additional research is needed to support this hypothesis. Further study is needed, also, to determine if GC may regulate ATGL-mediated lipolysis through changes in physical interaction between ATGL, CGI-58, and G0S2.

In summary, we investigated the effect of exogenous glucocorticoids on the expression of ATGL in chickens. Our analyses show that ATGL mRNA and protein are stimulated by DEX in vitro and in vivo, contributing to increased plasma NEFA. The increased ATGL expression following DEX treatment may result from a combination of direct transcriptional regulation at hormone response elements and disrupted insulin signaling. A known activator of ATGL, CGI-58, does not appear to respond to DEX stimulation. The ATGL-inhibitor G0S2 may have some immediate transcriptional response, though further research is needed to confirm this.

Abstract Mice fed diets containing conjugated linoleic acid (CLA) are leaner than mice not fed CLA. This anti-obesity effect is amplified in mice fed coconut oil-containing or fat free diets, compared to soy oil diets. The present objective was to determine if CLA alters lipolysis in mice fed different base oils. Mice were fed diets containing soy oil (SO), coconut oil (CO), or fat free (FF) for 6 weeks, followed by 10 or 12 days of CLA or no CLA supplementation. Body fat, tissue weights, and ex vivo lipolysis were determined. Relative protein abundance and activation of perilipin, hormone sensitive lipase (HSL), adipose triglyceride lipase (ATGL), and adipose differentiation related protein (ADRP) were determined by western blotting. CLA feeding caused mice to have less ($P < 0.05$) body fat than non-CLA fed mice. This was enhanced in CO and FF-fed mice (CLA × oil source, $P < 0.05$). There was also a CLA × oil source interaction on lipolysis as CO + CLA and FF + CLA-fed mice had increased ($P < 0.05$) rates of lipolysis but SO + CLA-fed mice did not. However, after 12 days of CLA consumption, activated perilipin was increased ($P < 0.05$) only in SO + CLA-fed mice and total HSL and ATGL were decreased ($P < 0.05$) in CO + CLA-fed mice. Therefore, the enhanced CLA-induced body fat loss in CO and FF-fed mice appears to involve increased lipolysis but this effect may be decreasing by 12 days of CLA consumption.

Introduction

Conjugated linoleic acid (CLA) refers to a group of positional and geometric isomers of linoleic acid. A biological function of CLA was first discovered in ground beef as it

was found to have anti-carcinogenic properties [1]. Since then, dietary CLA has been found to have anti-inflammatory [2], anti-atherogenic [3–5], anti-carcinogenic [1, 6, 7], and anti-obesity effects [8, 9]. The 18:2 c9, t11 and t10, c12 isomers are the two biologically active isomers known to date. The t10, c12 isomer is solely responsible for the induction of body fat loss [6, 10].

The loss of body fat induced by dietary CLA can be enhanced when mice are fed a coconut oil (CO)-containing diet compared to mice fed a soybean oil (SO)-containing diet [11]. CO is composed of a higher concentration of short (8–10 carbons) and medium chain saturated fatty acids (12–16 carbons) and is deficient in the essential fatty acids linoleic acid and α-linolenic acid, compared to SO which has mostly saturated and unsaturated 18 carbon fatty acids and an abundant supply of linoleic acid. We have also reported increased sensitivity to CLA-induced body fat loss in mice consuming fat free diets [12], indicating that something in SO, and not in CO, interferes with the full effect of CLA. The mechanism behind the enhanced response with CO feeding is not yet known. However, several cell culture studies have reported that CLA supplementation causes an increase in lipolysis [13, 14]. Coconut oil is composed mainly of medium chain saturated fatty acids hence it is likely that they would undergo oxidation more rapidly as compared to the longer chain and unsaturated fatty acids present in soy oil diets [15, 16]. Hence when CLA is supplemented to these diets we hypothesize that there will be an enhanced turnover of fatty acids, leading to an increased lipolysis.

Mature adipocytes have unilocular lipid droplets (LD) surrounded by the protein perilipin. In the basal state of lipolysis, perilipin and comparative gene identification-58 (CGI-58) form a complex on the LD, adipose triglyceride lipase (ATGL) is localized partially to the LD, and hormone sensitive lipase (HSL) is localized to the cytoplasm [17]. When lipolysis is stimulated, cAMP-dependent protein kinase (PKA) activation results in phosphorylation of HSL and perilipin. Phosphorylated perilipin (p-perilipin) releases CGI-58, which binds and activates ATGL and initiates lipolysis. Phosphorylated HSL (p-HSL) translocates to the LD, interacts with p-perilipin, and degrades diacylglycerol (DAG) [18]. CLA has caused an increase in cytosolic perilipin (activated form of perilipin) followed by a decrease in HSL and total perilipin expression in human adipocyte cultures [13]. It was observed that the expression of cytosolic perilipin increases with CLA exposure for 12 h, while treatment with CLA for 24 h caused a decrease in perilipin expression. Thus the effects of CLA on lipolysis appear to vary with the duration of exposure to CLA.

In addition to perilipin, adipocyte differentiation related protein (ADRP), is known to surround the multilocular lipid droplets of immature adipocytes [19]. CLA has been reported to suppress perilipin expression while enhancing ADRP expression in human adipocyte cultures [13], this could indicate reduced lipolytic potential in these cells and possible de-differentiation of the mature adipocytes. In the current study, we determined the effect of base oil and CLA on lipolysis and the expression and activation of perilipin, associated lipases, and ADRP in vivo.

Methods and Procedures

Animal Protocol

Study 1: All animal procedures were approved by the University of Nebraska Institutional Animal Care and Use Committee. Male mice ($n = 48$) used were from a control line four-way composite developed at the University of Nebraska [20, 21] which was maintained without genetic selection and were housed in a temperature-controlled room (22 °C) with a 12 h light:dark cycle. Mice were fed a purified base diet (Dyets Inc., Bethlehem, PA), identical to those fed previously ([11, 12]; Table 1). A modification of the purified AIN-93G diet with soy protein instead of casein was used so as to avoid possible intake of CLA from the casein. For the coconut oil (CO) diet, soybean oil was replaced by fully hydrogenated coconut oil (wt/wt); Dyets Inc. For the fat free (FF) diet, oil was replaced completely by cornstarch (wt/wt). CLA replaced the base oil or cornstarch (wt/wt) and was added in the diets to provide 0.5% CLA isomers in the diet. The CLA mixture contained an equal amount of c9, t11 and t10, c12 (60% pure, LUTA-CLA, Catalog #56746397, BASF, Offenbach/Quiech, Germany). It has been previously shown that the mixture of CLA isomers (50:50) cause a lowering of the fat pad weight or triacylglycerol content to the same extent as that caused by t10, c12 isomer alone in mouse adipose tissue and in 3T3-L1 cells [10, 22]. All diets were stored at 4 °C. Mice were fed ad libitum throughout the study and fresh feed was added every 2 days.

Weanling male mice were housed individually. Animals were blocked by body weight and litter and assigned to base diets: SO (soy oil) or CO (coconut oil) or FF (fat free). After 6 weeks, half of each group were fed a 0.5% CLA diet for 10 days. Body weight and feed intake were measured weekly. At the end of the study, the mice were killed by carbon dioxide asphyxiation. Epididymal and retroperitoneal fat pads were collected and tissues were weighed. Epididymal fat pads were utilized for lipolysis analysis. A body fat index was calculated as: [(epididymal + retroperitoneal fat pad weights)/total body weight]*100.

Study 2: A second study to allow for the analysis of lipolysis-associated protein in adipose tissue was conducted with all animal procedures approved by the West Virginia

[a] Study 1, all ingredients obtained from Dyets, Inc. Study 2, diets were prepared by Harlan

[b] The purity of CLA used in study 1 and study 2 was different. Hence the actual amount of CLA added was different to include 0.5% CLA in the diet. Values shown are for study 1; study 2 included 5.3 g/kg CLA and 64.7 g/kg soybean or coconut oil

[c] TBHQ (*tert*-butylhydroquinone)

University Animal Care and Use Committee. Weanling male mice [$n = 80$; 3 weeks old; ICR (Imprinting Control Region)] were obtained from Harlan Inc. (Madison, WI) and housed in a temperature-controlled animal room (25 °C) with a 12:12 h light:dark cycle. The composite strain was not available at West Virginia University; therefore the ICR strain was selected as it was one of the strains in the four-way composite used in study 1, and has been previously reported to respond to dietary CLA with reduced body fat [6, 8]. Diets were formulated to match study 1 (Table 1) except only SO and CO were used and were obtained from Harlan Teklad (Madison, WI). The FF diet was not used as based on previous results [12] it was expected to yield similar results to CO. The CLA mixture (95% purity, methyl esters of CLA, catalog # UC-59-MX) was obtained from Nu-Check-Prep (Elysian, MN). All diets were stored at 4 °C. Mice were fed ad libitum throughout the study and fresh feed was added every 2 days.

Mice were housed four per cage for weeks 1–5 and then were individually caged during weeks 6–8. Animals were randomly assigned to base diets: SO or CO. After 6 weeks, half of each group were fed 0.5% CLA, replacing base oil w/w, for 12 days. Previous reports studying CO–CLA interaction consisted of 14 days of CLA consumption, by the end of which the CO + CLA mice have extremely small fat pads [12], thus in order to have adequate lipid stores to study lipolysis we chose a 10 day feeding period for study 1. However, we were unable to detect the oil × CLA interaction on body fat index. So we subsequently chose a 12 day feeding period for study 2, with the goal of being able to detect both lipolysis and the oil × CLA interaction on body fat.

At the end of the 54 days, the mice were killed by carbon dioxide asphyxiation. One fat pad pool, consisting of one epididymal and one retroperitoneal fat pad (~3:1 based on weight), for each of eight mice per diet was utilized for lipolysis analysis and the remaining tissues were flash frozen in liquid nitrogen and stored at −80 °C until further analysis was performed. The pooling of two abdominal fat pads per mouse was used to allow for lipolysis and protein expression to be analyzed in the same depots. No differences in the response to CLA by the two depots were expected, based on a recent report [23] of no differences in epinephrine-induced lipolysis between epididymal and retroperitoneal adipocytes. All measurements of body weight, feed intake, and body fat index were done as in study 1.

Lipolysis

The lipolysis assay was performed as described previously [24, 25] with slight modifications. Briefly, tissue pieces (~50 to 100 mg) were incubated in 0.8 ml of DMEM (containing 250 mU/ml adenosine deaminase (Sigma-Aldrich Inc., St Louis, MO) without serum) for 3 h at 37 °C in a shaking water bath. This was done in triplicate for both baseline and stimulated lipolysis (10 μM isoproterenol (Sigma-Aldrich Inc.). Media samples were collected and analyzed for non-esterified fatty acids (NEFA- HR kit, Wako Chemicals, Richmond, VA) and glycerol (free glycerol reagent, Sigma-Aldrich Inc., St Louis, MO) by colorimetry, following the manufacturer's instructions. NEFA and glycerol concentrations were corrected for tissue weight and reported as μmol released per gram tissue.

Blood was collected at the time of euthanasia approximately 2 h after the start of the light cycle and maintained on ice until centrifugation at 2,000×*g* for 20 min at 4 °C was performed. The serum was collected and stored at −20 °C until analysis. Mice had free access to feed up until euthanasia. The concentration of serum NEFA was

analyzed similar to the method above ($n = 20$/diet). Samples were run in triplicate for the assay.

Western Blotting

The additional fat pad pool per mouse from study 2 ($n = 12$/diet) which was flash frozen at the time of sample collection and stored at −80 °C until next day, was homogenized in 1 ml of lysis buffer [25 mM HEPES, 5 mM EDTA, 5 mM $MgCl_2$, 10 µl/ml of protease and phosphatase inhibitor mix (Thermo Scientific, Rockford, IL)] and centrifuged at 14,000×*g* for 20 min at 4 °C within 24 h of freezing. These samples represent the in vivo basal state. Protein content of the supernatant was analyzed by the BCA method (BCA kit, Thermo Scientific, Rockford, IL). Polyacrylamide gels (12.5%) were prepared and equal amounts of protein (2 µg for ADRP, ATGL or 5 µg for perilipin, HSL) were resolved at 75 V and transferred to a nitrocellulose membrane (Bio-Rad, Hercules, CA) at 100 V for 45 min on ice. The membranes were blocked with tris-buffered saline containing 0.05% Tween and 5% skimmed milk powder overnight at 4 °C, then probed with antibodies for perilipin (1:500, Santa Cruz Biotechnology, Santa Cruz, CA), ATGL (1:1,000, Santa Cruz Biotechnology), ADRP (1:500, Santa Cruz Biotechnology), phosphorylated-PKA (p-PKA) substrate (1:1,000 for p-perilipin, Cell Signaling Technology, Danvers, MA), HSL (1:1,000, Cell Signaling Technology), and p-HSL (1:500, Cell Signaling Technology) for 2 h at room temperature. The membranes were then probed with a HRP-conjugated secondary antibody (1:10,000, Santa Cruz Biotechnology) for 1 h at room temperature. Membranes were stripped and re-probed for β-actin (1:1,000, Santa Cruz Biotechnology). All antibodies were diluted in 1× PBS with 5% non fat dry milk. Chemiluminescence was produced using Super Signal West Pico chemiluminescent substrate (Thermo Scientific). Band density was analyzed by densitometry (Fluor Chem 8000 imaging system). Blot to blot variability was corrected for by running a pooled sample on each blot and adjusting the blots based on the relative expression of the pooled sample. The results are presented as the protein of interest/β-actin or in case of the phosphorylated proteins the results are presented as phospho-protein/total protein. The specificity of the p-PKA antibody was determined by performing an immunoprecipitation with the perilipin antibody and then probing the membrane with the p-PKA antibody. The immunoprecipitation determined that the band at 57 KDa was specific to p-perilipin (Fig. 1).

Statistical Analysis

All data were analyzed by two-way analysis of variance (ANOVA) using a fixed model testing the main effects of oil source (SO, CO, FF) and CLA, and the interaction of oil source × CLA. Body weight and feed intake measurements were analyzed by day. *F* tests, least-squares means, and standard errors of means (SEMs) were calculated using the mixed procedure of SAS (SAS Institute Inc., Cary, NC). For all tests $P < 0.05$ was considered significant, $0.05 > P < 0.1$ was considered a trend.

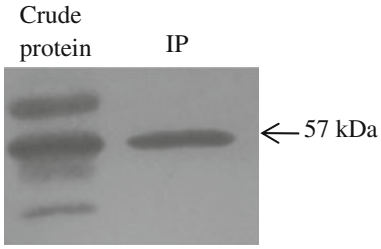

Fig. 1 Immunoprecipitation with anti-perilipin antibody and then probing with p-PKA antibody. Perilipin was identified at 57 kDa, indicated by the *arrow*

Results

Body Weight, Feed Intake, and Body Composition

Body weight was not affected by diet in study 1 (Table 2). In study 1, CLA inhibited feed intake ($P < 0.01$). Also, CLA caused a decrease in body fat index which was more pronounced in the CO and FF-fed mice (Fig. 2a).

In study 2, body weight was also not affected except in the last week when an oil source × CLA interaction was detected ($P < 0.05$). CLA caused a 6% increase in weight in SO-fed mice while causing a 5% decrease in CO-fed mice (Table 2). In study 2, feed intake was not affected by oil source until week 6, but during the last 2 weeks there was a main effect of oil source ($P < 0.05$) when CO-fed mice consumed 5% more feed than SO-fed mice. An oil source × CLA interaction ($P < 0.05$) indicated that CLA caused a decrease in feed intake, but only in CO-fed mice. When total feed intake for the 12 day period of CLA consumption was analyzed there was a main effect of oil source ($P < 0.05$) where SO-fed mice consumed less than CO-fed mice, but we did not observe a main effect of CLA (data not shown). Both CO ($P < 0.001$) and CLA ($P < 0.05$) caused decreases in the body fat index (Fig. 2b). CO caused a 32% decrease in the body fat index while CLA caused a 20% decrease in body fat index.

Lipolysis

In study 1, there was an interaction of oil source × CLA ($P < 0.05$) on the amount of NEFA released under basal conditions (Fig. 3a); CLA caused an increase in NEFA

release in CO and FF-fed mice, but not in SO-fed mice. There was also an interaction of oil source × CLA ($P < 0.05$) on the amount of glycerol released (Fig. 3b) where CLA caused an increase in CO and FF-fed mice but not SO-fed mice. There were no differences in either NEFA or glycerol release under stimulated conditions.

The effect on NEFA release was confirmed in study 2 where there was an interaction of oil source × CLA ($P < 0.05$), where CLA caused an increase in NEFA release in CO-fed mice but not in SO-fed mice (Fig. 3c). In study 2, there was no significant effect on the amount of glycerol released (Fig. 3d), although it followed the same numeric trend as NEFA release. Similar to study 1 there were no differences under stimulated conditions. Furthermore, the serum NEFA concentration did not differ between mice fed any of the dietary treatments, although CO-fed mice tended ($P < 0.1$) to have higher serum NEFA levels compared to the SO-fed mice (Fig. 3e).

Protein Expression

The lipolysis data indicated an effect of diet on NEFA release, so we also determined the effect of diets on the expression of proteins involved in lipolysis. The western blots indicated that the total protein concentration of perilipin was reduced ($P < 0.05$) in CO-fed mice compared to SO-fed mice (Fig. 4a). The activation of perilipin (concentration of p-perilipin) had a tendency toward an interaction of oil source × CLA ($P < 0.1$), as CLA tended to increase the amount of p-perilipin but only in SO-fed mice (Fig. 4b). SO + CLA-fed mice had 255% of the p-perilipin expression found in SO-fed mice, while CO + CLA-fed mice had only 76% of the p-perilipin expression found in CO-fed mice. HSL expression and activation weren't altered by CLA (Fig. 4c, d), but there was a decrease in total HSL expression in CO-fed mice ($P < 0.05$; Fig. 4c). ATGL expression was also decreased in CO-fed mice ($P < 0.01$) but there was no effect of CLA (Fig. 4e). ADRP expression was not altered (Fig. 4f).

Discussion

We have previously reported that feeding coconut oil enhances the CLA-induced body fat loss in mice [11, 12]. This effect was again observed in the present study. Based on the results presented here, it appears to involve CLA-induced lipolysis in CO-fed mice. Previously, some studies have reported that CLA enhances lipolysis in adipocyte cultures [13]. In our study we observed an enhanced lipolysis in response to dietary CLA but only in CO-or FF-fed mice.

We did not detect a significant interaction of oil source × CLA on body fat. This is likely due to the fact that in the current study a body fat index was calculated, which may not be as sensitive to changes in body fat as direct measurements using DEXA (Dual-emission X-ray absorptiometry) or whole carcass ether extractions as have been

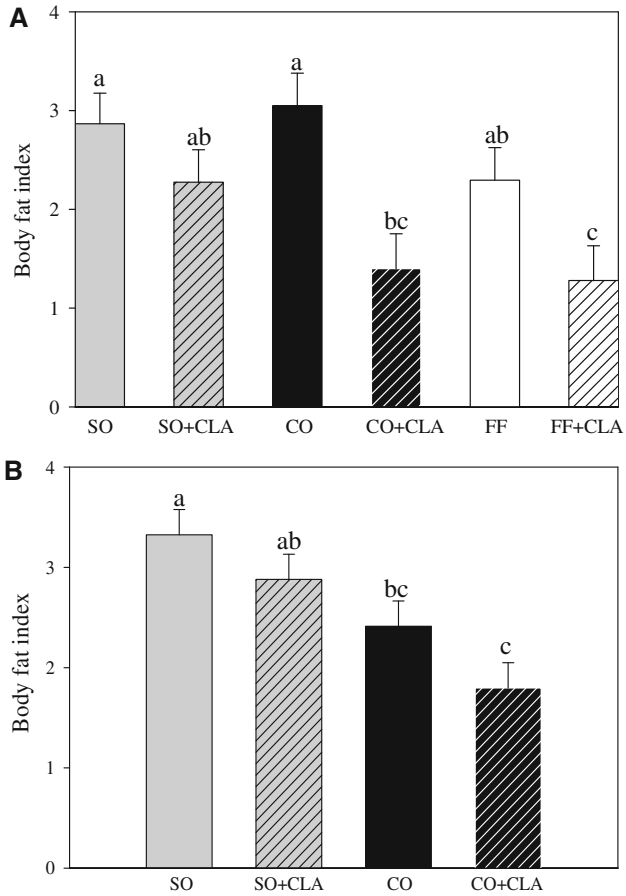

Fig. 2 Effect of dietary CLA and oil source on body composition. *Body fat index* [(Retroperitoneal + Epididymal fat pad weights)/body weight] × 100; study 1, $n = 7$/diet; study 2, $n = 20$/diet. *Diets* SO (7% soy oil), SO + CLA (6.5% soy oil + 0.5% CLA), CO (7% coconut oil), CO + CLA (6.5% coconut oil + 0.5% CLA), FF (0% oil), FF + CLA (0.5% CLA). **a** Study 1, CLA, $P < 0.001$. **b** Study 2, oil source, $P < 0.001$; CLA, $P < 0.05$. used previously [11, 12]. Additionally in study 1, the mice fed the FF diet had less body fat and hence the reduction due to CLA supplementation in these mice was not as pronounced. In study 2, we observed that CO diets caused a decrease in body fat even without CLA supplementation, which is in contrast to the previous reports [11, 12] and to study 1 results. These mice didn't consume as much feed or gain as much as weight as in previous experiments [12], which could have led to the differing results. Although, a previous study has shown that reduction in feed intake alone is not sufficient to explain the CLA-induced body fat loss as mice pair-fed a control diet to the intake level of CLA-fed mice didn't differ in body fat compared to ad libitum fed controls, while the CLA-fed mice were leaner [10].

Similar to the body fat index, there was an effect of CO itself on the expression of perilipin, HSL, and ATGL. The reason for this effect of CO is not known but perhaps may be related to mouse strain (ICR vs. a four strain composite of ICR, C57BL/6, NIH Swiss, and CF-1). Although, others have reported anti-obesity actions of coconut oil; Dulloo et al. [26] fed mice different fat sources after a period of energy restriction and reported that the coconut oil-fed group had a lower body fat compared to groups fed other high fat diets. In fact, the level of body fat and serum cholesterol were similar to mice fed low fat diets. Others have found that coconut oil feeding causes an increase in uncoupling protein-1 (UCP1) expression in energy restricted mice [27]. Therefore, the lower body fat in coconut oil-fed mice may be due to diet-induced thermogenesis. The mice on study 1 and study 2 were housed under different temperatures (22 vs 25 °C), this small difference potentially could cause a difference in UCP expression, but a previous study has shown that UCP expression was not significantly different between mice housed at 20 versus 25 °C [28]. Hence we concluded that the different effects seen in the two studies was not likely to be attributed to differences in housing temperature. More likely, coconut oil has a higher content of medium chain saturated fatty acids that would undergo oxidation at a greater rate as compared to the fatty acids present in SO diets [16].

We observed a CLA-induced increase in basal lipolysis in CO-fed mice, but not SO-fed mice. This differential effect of CLA likely contributes to the overall enhanced body fat loss, although we cannot rule out an effect on lipogenesis or fatty acid oxidation at this time. Although, we have not observed any difference in total CPT activity between CLA supplemented SO and CO-fed mice in the muscle (unpublished data). Hence we hypothesize that there is no difference in transport of fatty acids into the mitochondria. There is difference in nutrient partitioning as we have previously observed an increase in muscle mass in CLA-fed animals [12]. The CLA-supplemented CO diets caused an increase in NEFA release but a significant effect on the amount of glycerol released was only detected in study 1. This is not unexpected given that 2–5 times more NEFA were released in study 1 and glycerol:NEFA exists in a 1:3 ratio, so the amount of glycerol released was small in study 2. This is likely an effect of feeding CLA for 12 versus 10 days, but could also be impacted by mouse strain. Additionally, we used only epididymal fat pads in study 1 and combined the two depots in study 2, but no differences in the response to CLA by the two depots were expected, based on a recent report [23] of no differences in epinephrine-induced lipolysis between epididymal and retroperitoneal adipocytes. Also it has been shown in previous studies that dietary CLA causes a reduction in both epididymal and retroperitoneal fat pad weights [10].

Several studies have shown that CLA causes an increase in lipolysis [13, 14], while others have reported no effect of CLA on lipolysis [29–31]. The responses to CLA tended to be observed in cells that had been cultured in serum-free media [13, 14]. Serum starving makes the cultures devoid of fatty acids that could potentially interfere with CLA. Explant cultures of WAT from CLA-fed pigs didn't exhibit enhanced lipolysis in response to CLA [29]; similar to our SO + CLA-fed mice, as both the pig and mouse diets were rich in linoleic acid. Coconut oil is deficient in essential fatty acids. Although this may be the reason for the increased CLA interaction, we found no change in the CLA interaction after supplementing essential fatty acids to CO diets [12]. The CO × CLA interaction thus does not appear to depend on a nutritional deficiency of essential fatty acids. SO, however, contains large amounts of linoleic acid (LNA), well in excess of the dietary requirement, that perhaps interferes with the actions of CLA. LNA is converted to arachidonic acid (AA) via desaturation and elongation; AA can then be converted to PGE_2 (prostaglandin E2) via cyclooxygenase. PGE_2 has 4 cognate receptors (EP (E-prostanoid) 1, EP2, EP3, and EP4), G_i-coupled EP3 is expressed at >10-fold higher levels than the other EP receptors in adipose tissue. The binding of PGE_2 to this receptor causes an inhibition of lipolysis [32]. CLA can undergo the same desaturation and elongation forming a conjugated AA [33, 34]. The formation of conjugated isomers of AA from CLA could reduce the EP3 signaling, as PGE_2 synthesis has been shown to be reduced [35] and cause an increase in cAMP levels which could stimulate lipolysis. The lack of LNA in the CO diet could result in a greater amount of CLA being converted to conjugated AA, which could lead to the enhancement in CLA-induced lipolysis in CO-fed mice. This hypothesis can be supported by our study, which showed that the inhibition of delta 6-desaturase prevented CLA from inducing a body fat loss [36]. Further research is needed to identify and quantify the conjugated AA isomers formed in

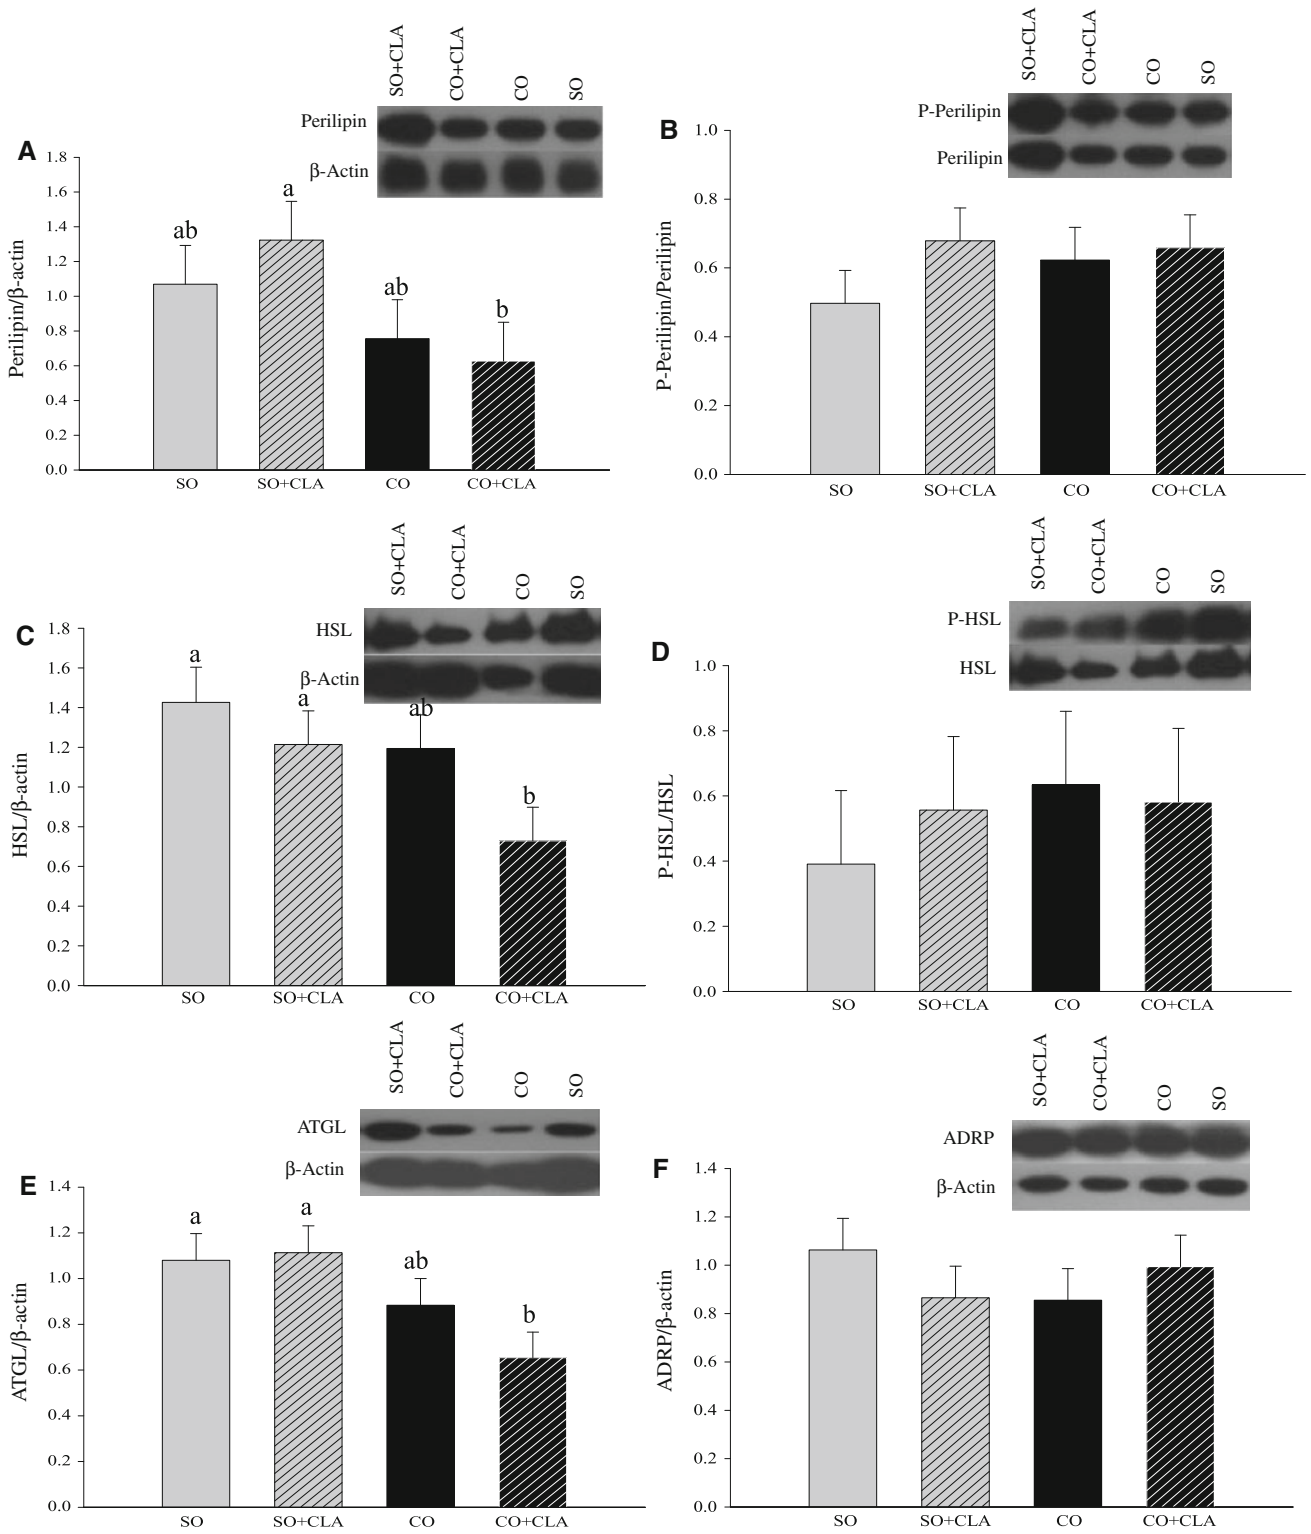

Fig. 4 Effect of dietary CLA and oil source on adipose tissue protein expression, study 2. Densitometry analysis of each protein, relative to β-actin or total protein was performed; A representative blot and the quantification of $n = 12$/diet are shown. *Diets* SO (7% soy oil); SO + CLA (6.5% soy oil + 0.5% CLA); CO (7% coconut oil); CO + CLA (6.5% coconut oil + 0.5% CLA). **a** Total perilipin expression, oil source, $P < 0.05$. **b** P-Perilipin expression, oil source × CLA, $P = 0.08$. **c** Total HSL expression, oil source, $P < 0.05$; CLA $P = 0.05$. **d** P-HSL expression. **e** ATGL expression, oil source, $P < 0.01$. **f** ADRP expression. SO versus CO-fed mice supplemented with CLA, and to determine their potential role in CLA-induced lipolysis.

We detected no differences in stimulated lipolysis, indicating that there were no differences in the total amount of lipases present in the cell. When lipolysis is stimulated perilipin is phosphorylated by PKA. Phosphorylated perilipin releases CGI-58, which then binds to ATGL, activating it [17]. ATGL is a major lipase which is known to catalyze the first step of triacylglycerol (TAG) hydrolysis [37]. Also, when lipolysis is stimulated HSL is phosphorylated by PKA, and activated. The p-HSL then rapidly and specifically translocates from the cytosol to the surface of the lipid droplets. This translocation is dependent on presence of p-perilipin [17]. Based on the lipolysis data we expected an increase in the relative expression of p-perilipin and p-HSL. However, we found that CLA did not increase lipolysis-associated protein expression in CO-fed mice. Rather, CLA caused an increase in expression of p-perilipin but only in SO-fed mice. There was no effect of CLA on any of the other proteins. We hypothesize that the effect of CLA is time-dependent and feeding CLA first causes an increase in lipase activation, followed by a decrease in the expression or activation, as this has been reported in a cell culture study [13]. CLA supplemented to human adipocytes caused an increase in lipolysis and in cytosolic perilipin, indicating activation, after 12 h of CLA supplementation. This was followed by a decrease in the expression of perilipin and HSL at 24 h of supplementation. It is possible that after 12 days of CLA consumption our mice were experiencing a decline in perilipin and lipase expression. This might have also contributed to the lowered degree of lipolysis in study 2, compared to study 1, when the mice were fed CLA for only 10 days. In this study we didn't observe any effect of CLA on ADRP expression.

The body fat lowering effect of CLA in mice has not been fully reciprocated in humans. The exact reasons for this are not known. One possibility maybe that the large quantity of various PUFA in a typical human diet could have an antagonist effect on the body-fat lowering effect of CLA. The adequate intake levels of PUFA as determined by the Institute of Medicine's Food and Nutrition Board (DRI report for energy and macronutrients (2002/2005)) is 17 g/day for males and 12 g/day for females. In support of this, we have reported previously [11, 12] and in the current study that the CLA-induced body fat reduction is enhanced in CO and fat-free fed mice as compared to SO-fed mice which have a much higher content of PUFA.

In conclusion, coconut oil enhances the anti-obesity effect of CLA and this effect, at least in part, appears to be due to enhanced lipolysis. The effect of CLA on the expression and activation of lipases and other lipolysis-related proteins may be time-dependent and therefore, were not clear in the current experiment. Further studies evaluating the effect of different feeding durations of CLA will be helpful in determining the mechanism of CLA action on lipolysis.

Trans-18:1 and CLA Isomers in Rumen and Duodenal Digesta of Bulls Fed n-3 and n-6 PUFA-Based Diets

Xiangzhen Shen · Dirk Dannenberger · Karin Nuernberg · Gerd Nuernberg · Ruqian Zhao

Received: 6 December 2010 / Accepted: 20 June 2011 / Published online: 8 July 2011

Abstract The aim of the study was to investigate the effect of n-6 PUFA (maize silage/grass silage, soybean meal and soybean oil, control) and n-3 PUFA (grass silage, rapeseed cake and rapeseed oil, experiment) based diets on the occurrence of rumen- and duodenal digesta *trans*-C18:1 and CLA isomers of German Simmental bulls. The results based on rumen and duodenal digesta samples immediately taken from the bulls just after slaughter. The diet affected the occurrence of individual *trans*-C18:1 and CLA isomers in the rumen and duodenal digesta in different ways. The isomer *trans*-11,*cis*-13 CLA was detected as the most abundant isomer in the rumen of n-3 PUFA based diet fed bulls compared to n-6 PUFA based diet fed bulls. The *trans*-7,*cis*-9 CLA isomer was not detected in the rumen samples of bulls fed both diets, however abundant *trans*-7,*cis*-9 CLA was identified and quantified in the duodenum digesta. Both the concentration of the sum of *trans*-18:1 fatty acids and individual isomers in the rumen were not affected by the diet, except *trans*-16-18:1. The concentration of *trans*-16-18:1 was significantly decreased in the rumen of n-3 PUFA supplemented-fed bulls compared to n-6 PUFA supplemented-fed bulls.

Keywords Rumen · Digesta · CLA isomers · *Trans*-18:1 isomers · Bulls

Abbreviations

CLA	Conjugated linoleic acids
DM	Dry matter
PUFA	Polyunsaturated fatty acid(s)
SCD	Stearoyl-CoA desaturase
MFD	Milk fat depression
FAME	Fatty acid methyl ester(s)
HRGC	High resolution gas chromatography
FID	Flame ionization detector
Ag^{+}-ion HPLC	Silver ion high performance liquid chromatography
SEM	Standard error of mean
LSM	Least square mean
TMR	Total mixed ratio
VA	Vaccenic acid
GC	Gas chromatography
PDA	Photodiode array

Introduction

During the biohydrogenation in the rumen microbial ecosystem, a broad range of intermediates are formed, such as monounsaturated *cis*- and *trans*-fatty acids and conjugated linoleic acid (CLA) isomers. It is widely recognized that diet plays a major role in modulating fatty acid composition in ruminant meat and milk. Understanding the mechanisms underlying the biosynthesis of individual *trans*-18:1 and CLA isomers in the rumen are important because the ruminal outflow affects the availability of these bioactive

fatty acid isomers for incorporation into muscle and milk [1–3]. CLA is a term used to describe a mixture including a range of positional and geometric isomers of conjugated octadecadienoic acids. The predominant isomer in ruminant muscle is *cis*-9,*trans*-11 CLA accounting for more than 80% of the total CLA, yet *trans*-10,*cis*-12 CLA comprises 3–5% of the total CLA, however the occurrence of these bioactive fatty acid isomers is also diet dependent [4, 5]. Until now, predominantly two CLA isomers, *cis*-9,*trans*-11 CLA and *trans*-10,*cis*-12 CLA, have been shown to have biological activity including prevention of different types of cancer, cardiovascular health and improved immune response predominantly in animal models; however, in recent human studies inconsistent effects have been reported [6, 7]. Very recently, it has also been shown that *trans,trans* CLA isomers (*trans*-9,*trans*-11 CLA, *trans*-10,*trans*-12 CLA) inhibit rat mammary tumorigenesis through the induction of apoptosis in conjunction with the reduction of arachidonic acid metabolites [8]. There is much evidence that the physiological properties of CLA are isomer specific with partly opposing effects [6–8]. Ruminant meat, milk and their products are the major source of CLA in human diet [9, 10]. The monounsaturated *cis*- and *trans*-fatty acids and CLA isomers are formed either directly in the rumen or from precursors formed in the rumen during the biohydrogenation of dietary PUFA. Over 10 years ago, ruminal fatty acid metabolism was described in a classic review [11] and the intensive research was more recently summarized [12]. Most dietary fatty acids are esterified, and they are almost completely metabolized to free fatty acids in the rumen. Until now not all biohydrogenation processes and pathways are fully understood [1–3]. It is well known that the main CLA isomer, *cis*-9, *trans*-11 CLA, is formed from different sources. This bioactive compound can be produced in the rumen via biohydrogenation by *Butyrivibrio fibrisolvens* and other microbes, with consequent transport into tissues and endogenous synthesized in the mammary gland of dairy cows and ruminant adipose tissues by the conversion of *trans*-11-18:1 (VA) catalysed by stearoyl-CoA desaturase (SCD, EC 1.14.19.1) [13, 14]. So, VA is a major precursor in the formation of *cis*-9,*trans*-11 CLA in tissues. The diet is the most important factor affecting the *cis*- and *trans*-18:1 and CLA isomers profiles in different tissues and milk of cattle. Dietary fatty acid biohydrogenation in the rumen has a major influence on fatty acid composition of ruminant meat and milk. The phenomenon of diet-induced milk fat depression (MFD) has been of extensive research interest over many years and is also actually under investigation [1, 2, 15, 16]. MFD is associated with an increase in the content of *trans*-10-18:1, and the *trans*-10,*cis*-12 CLA is also responsible for reduced milk fat synthesis, whereas *cis*-9,*trans*-11 CLA has no effect [1, 2, 14]. Recently, the role of protozoa in the biosynthesis of *trans*-18:1 fatty acids and CLA isomers in the rumen contents of fistulated cows was investigated [2, 17]. The rumen protozoa are capable for synthesizing CLA isomers from 18*:*2n-6, however they are incapable of metabolizing CLA isomers further. In vitro batch incubations showed the dynamic feature of rumen metabolism of pure 18:3n-3 and 18*:*2n-6 in comparison to linseed oil [18]. Investigations of ruminal bacteria cultures revealed that the reduction of 9,11 geometric CLA isomers occurs via different mechanisms compared to other unsaturated fatty acids [19].

However, until now there has been a lack of results from in vivo studies of animals fed n-3 and n-6 PUFA-based diets on *trans*-18:1 and CLA isomers occurrence in the rumen and duodenum digesta in cattle using different GC and additional Silver ion-HPLC (Ag^{+}-ion HPLC) methods [20]. A study with 25 German Simmental bulls fed n-3 and n-6 PUFA-based diets was carried out to investigate dietary effects on the lipid metabolism in different tissues [21, 22]. The objective of the present paper is focused on the occurrence of *trans*-18:1 and CLA isomers in the rumen and duodenal digesta by feeding diets based on n-3 PUFA (grass silage and a concentrate containing rapeseed cake and rapeseed oil) and n-6 PUFA (maize silage/grass silage and a concentrate containing soybean meal and soybean oil) of German Simmental bulls after slaughter.

Experimental Materials and Methods

Animals, Diet Treatments and Experimental Design

Twenty-five German Simmental bulls (9–10 months old, approximately 290 kg initial weight) were assigned to three groups in the experiment with different feeding regimes, the control group and two experimental groups. All the animals were housed in individual tie stalls and offered three different dietary treatments. The details of the experiment were recently reported [21, 22]. One experimental group was fed a diet restricted to 1 kg of concentrate (50%) per day during the first 112 days of the fattening period [21]. However, the main objective of the present paper is the effect of n-3 and n-6 PUFA based diets on rumen digesta and duodenal digesta lipids. A diet restriction in the fattening period approximately 250 days before slaughter not affects the rumen digesta and duodenal digesta lipids after slaughter. Because of that the animals of restricted experimental group were excluded. In this paper the results of the control group ($n = 9$) and the experimental group ($n = 7$) are presented (Table 1). The control group ($n = 9$) were daily fed maize silage/

Table 1 Experimental design and fatty acid composition of the diets, part of the experiment [21, 22]

[b] Percentage of total fatty acids

grass silage (70/30, ad libitum), 1 kg of molasses, 1 kg of hay and concentrate including soybean meal (2 kg the first 112 days, 2.5 kg the next 110 days and 3 kg until slaughter). The experimental group I ($n = 7$) were fed grass silage (ad libitum), 1 kg of molasses, 1 kg of hay and concentrate (39% triticale, 22% barley, 32% rape cake, 5% minerals, 2% rapeseed oil). Both groups have got the same amount of hay and straw. In Table 1 fatty acid composition of the main diet components (maize silage/grass silage (70%/30%) and grass silage) is presented. The main fatty acids in the fat of the total mixed ratio (TMR, control group) were 18:2n-6 (46.6%), 18:1*cis*-9 (23.1%), 16:0 (12.1%), 18:3n-3 (7.2%) and 18:0 (3.0%). The main fatty acids in the fat of the TMR (experimental group) were 18:1*cis*-9 (35.6%), 18:2n-6 (27.0%), 18:3n-3 (8.1%), 16:0 (7.9%), and 18:0 (1.5%). All animals were fasted with fixed time before slaughter. The morning meal at the day before slaughter was the last meal. The animals were slaughtered next midmorning at approximately 620 kg live weight in the abattoir of the Leibniz Institute for Farm Animal Biology in Dummerstorf, Germany. The slaughter and dressing procedures were in accordance with European Union (EU) specifications. Approximately 50 g rumen content (representative mix of whole rumen content) and 50 g duodenal digesta (1 m after pylorus, representative mix of duodenal digesta content) samples were taken immediately after slaughter, and were stored frozen at –20 °C and freeze-dried until lipid extraction.

Extraction and Methylation of Lipids

Approximately 1.5 g freeze-dried rumen and 2.0 g freeze-dried duodenal digesta samples were taken for total lipid extraction (triplicates). A modified direct fatty acid methylation method was used [23]. The samples were treated with 3.5 mL toluene (containing 19:0 fatty acid methyl ester as internal standard) and 5.25 mL of 5% methanolic hydrochloric acid. The mixture was shaken in water bath at 70 °C for 2 h. After cooling down to room temperature, methyl esters of total fatty acids (FAME) were extracted with 3.5 mL *n*-hexane in the presence of 8.75 mL 6% K_2CO_3 solution and mixed with a vortex mixer. After centrifugation (1230*g* for 5 min at 4 °C), toluene phase was separated and transferred to a new tube. Then, 1 g Na_2SO_4 and activated charcoal were added and stored at 4 °C overnight until disappearance of the yellow color in the extracts. Samples were centrifuged at 800*g* for 2 min at 4 °C, filtered and evaporated with a gentle N_2 stream to dryness. For high resolution gas chromatography (HRGC) analysis, rumen samples were resolved with 500 µL *n*-heptane and duodenal digesta samples with 200 µL *n*-heptane.

For Ag^+-HPLC analysis, both rumen and digesta samples were resolved with 200 μL *n*-heptane.

Separation of Total Fatty Acid and Trans-18:1 Isomers by HRGC

A Perkin Elmer gas chromatograph Autosys XL was used and equipped with a flame ionization detector (FID), split injection and TotalChrom software (Perkin Elmer Instruments, Shelton, USA). The fatty acid composition of the FAME extract samples was determined on a CP SIL 88 100 m × 0.25 mm × 0.25 μm capillary column (Chrompack-Varian, USA). The initial oven temperature was 150 °C, held for 5 min, subsequently increased to 175 °C at a rate of 2 °C min^{-1} to 200 °C, held for 10 min, then at 1.5 °C min^{-1} to 225 °C and held for 25 min. Hydrogen was used as the carrier gas at a flow rate of 1 ml min^{-1}. The split ratio was 1:20; the injector was set at 260 °C and the detector at 280 °C [24]. A combination of two HRGC temperature programs with the above-mentioned capillary column was used for the separation and identification of *trans*-18:1 isomers in rumen and digesta extracts as recently described for milk fat [25]. By the use of only one GC time program the problem of overlapping of some *trans*- and *cis*-18:1 isomers remains and the correct identification and quantification of individual isomers cannot be achieved [25]. The details of first temperature program: initial oven temperature was 45 °C, held for 4 min, then increased to 150 °C at a rate of 13 °C min^{-1}, held for 47 min, then to 215 °C at a rate of 4 °C min^{-1}, held for 35 min. The use of the time program with the plateau at 150 °C permits the correct identification of *trans*-4-18:1, *trans*-5-18:1, *trans*-6/7/8-18:1, *trans*-10-18:1 and *trans*-11-18:1 isomers. The second temperature program: initial oven temperature was 45 °C, held for 4 min, then increased to 175 °C at a rate of 13 °C min^{-1}, held for 27 min, then to 215 °C at a rate of 4 °C min^{-1}, held for 35 min. The use of the time program with the plateau at 175 °C permits the correct identification of *trans*-12-18:1, *trans*-13/14-18:1, *trans*-15-18:1 and *trans*-16-18:1 isomers. Injector temperature was kept at 260 °C, and detector at 280 °C. Hydrogen was used as carrier gas at a flow rate of 1 mL min^{-1}. The injection volume was 1 μL for rumen samples and 2 μL for digesta samples. The split ratio was 1:19.2. The concentrations were calculated by internal standard method and 19:0 was used as internal standard.

Separation and Identification of CLA Isomers by Ag^+-HPLC

Identification and quantification analysis of the CLA isomers in rumen and digesta extracts was performed by Ag^+-ion HPLC involved an HPLC system (LC 10A, Shimadzu, Japan) equipped with a pump (LC-10AD VP), auto sampler (SIL-10AF), 50 μL injection loop, a photodiode array detector (SPD-M 10Avp, Shimadzu, Japan), and a Shimadzu CLASS-VP software system (Version 6.12 SP4). Four ChromSpher 5 Lipids analytical silver ion-impregnated columns (4.6 mm i.d. × 250 mm stainless steel; 5 μm particle size; Chrompack-Varian, USA) were used in series. The mobile phase (0.1% acetonitrile in *n*-hexane) was prepared fresh daily and pumped at a flow rate of 1.0 mL/min as described in detail before [4, 20]. The injection volume was 50 μL, since the content of minor CLA isomers in rumen and duodenal digesta was low. The detector was operated at 233 nm to identify CLA isomers based the measurement of integrated area under the 233 nm peaks attributed to conjugated dienes. The identification of CLA isomers was made by the retention time of individual CLA methyl esters (*cis*-9,*trans*-11 CLA, *trans*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, *cis*-9,*trans*-11 CLA, *cis*-9,*cis*-11 CLA and *cis*-11,*trans*-13 CLA). The external calibration plots of the standard solutions were adapted to different concentration levels of individual CLA isomers in the lipid extracts, recently in detail described [4].

Reagents

A reference standard 'Sigma-FAME mixture' was obtained from Sigma-Aldrich (Deisenhofen, Germany). Additionally, individual methyl esters of 18:4n-3, 22:4n-6, 22:5n-3 and the individual isomers of CLA methyl esters (CLA-ME), *cis*-9,*trans*-11 CLA, *trans*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, *cis*-9,*cis*-11 CLA and *cis*-11,*trans*-13 CLA (as a free fatty acid) were purchased from Matreya (Pleasnet Gap, United States). Methyl esters of *trans*-11-18:1 and *cis*-11-18:1 were purchased from Larodan Fine Chemicals (Malmö, Sweden). Additional, *trans*-6 and *trans*-13-18:1 FAME was purchased from Nu-Check Prep (MN, USA). All solvents used for GC and Ag^+-HPLC were HPLC grade from Lab-Scan (Dublin, Ireland). The derivatization reagents, sodium methylate and boron trifluoride/methanol (14% w:v), were respectively obtained from Fluka (Buchs, Switzerland) and from Sigma-Aldrich (Deisenhofen, Germany).

Statistical Analysis

Statistical data analysis was conducted by one-way analysis of variance with fixed factor feed (three feeding groups) using the GLM procedure of SAS®/STAT software (Version 9.2, SAS Inst. Inc.,Cary, NC, 2008). All data were expressed as least squares means (LSM) and the standard error (SEM) of the LSM. Statistical significance was considered at $P < 0.05$.

Results

Trans-18:1 and CLA Isomer Concentrations in the Rumen and Duodenal Digesta of Bulls Fed n-3 and n-6 PUFA-Based Diets

Generally, the sum of *trans*-18:1 isomer concentrations were up to approximately 60 times higher compared to sum CLA isomer concentrations in the rumen and duodenal digesta of differently fed German Simmental bulls. The *trans*-18:1 isomer concentration in Tables 2 and 3 based on mg/100 g dry matter (DM) and CLA isomers concentration based on μg/100 g DM. The most abundant isomer was *trans*-11-18:1 (VA), however, no dietary effect was detected. The concentration of the sum and individual *trans*-18:1 isomers in the rumen was not affected by the diet, except only one individual *trans* isomer, *trans*-16-18:1. The concentration of *trans*-16-18:1 was significantly decreased in the rumen of the experimental group compared to control group. There was a tendency for increasing concentrations of *trans*-6/7/8-18:1, *trans*-10-18:1, *trans*-11-18:1 from control group to experimental group, however without statistical significance. There was a large variation of *trans*-18:1 data in the duodenal digesta and the sum of *trans*-18:1 fatty acids was significantly lower, compared to the rumen (Tables 2, 3). The individual and sum of *trans*-18:1 isomers showed no dietary effects. *Trans*-4,-5- and *trans*-13/14-18:1 was not detected in duodenal digesta samples according to the used sample preparation method.

Up to eleven individual CLA isomers were detected and quantified in rumen and duodenal digesta samples of the different diet groups (Table 2, 3). The isomers, *trans*-8,*cis*-10 CLA and *trans*-7,*cis*-9 CLA were not detected in the rumen whether in animal of the control or the experimental group (Table 2). The minor isomer *trans*-7,*trans*-9 CLA was below the detection limit (<1 μg/100 g DM) in the rumen of control animals (Table 2). The CLA isomer distribution pattern in the rumen of German Simmental bulls fed n-3 and n-6 PUFA-based diets was significantly affected. The main isomer in the rumen content was *trans*-11,*cis*-13 CLA, and it was significantly increased in the experimental group compared with control group. The second abundant CLA isomer was *cis*-9,*trans*-11 CLA showing no dietary effect, however in tendency higher concentrations in the experimental group. The third abundant CLA isomer was *trans*-11,*trans*-13 CLA, and compared to the control group, the concentration of this isomer increased significantly in the experiment diet group. *Trans*-10,*cis*-12 CLA was decreased by experimental feeding, however not reached statistical significance because of a high data variation (Table 2). The sum of CLA concentrations in the duodenal digesta of all animals was significantly lower compared to the rumen sum CLA concentrations. However, also the CLA isomer distribution pattern in duodenal digesta was affected by different diet systems. Contrary to that in the rumen, the main isomer in duodenal digesta samples was *cis*-9, *trans*-11 CLA, and the experiment diet resulted in a significant increase in this isomer compared to the control group (Table 3). The second most abundant CLA isomers in duodenal digesta samples were *trans*-11,*trans*-13 CLA, *trans*-9,*trans*-11 CLA and *trans*-11,*cis*-13 CLA. The concentration of *trans*-11,*cis*-13 CLA was significantly higher in the duodenal digesta of the experimental group. The isomers *cis*-11,*trans*-13 CLA and *trans*-7,*cis*-9 CLA were in tendency decreased in experimental group compared to control group, however the values did not reach statistical significance. No dietary effects were detected for all identified *trans*,*trans* CLA isomers. *Trans*-7,*trans*-9 CLA and *cis*-12,*trans*-14 CLA were below the detection limit (<1 μg/100 g DM) in digesta samples of both feeding groups (Table 3).

Total Fatty Acid Concentration in the Rumen and Digesta of Bulls Fed n-3 and n-6 PUFA-Based Diets

The total fatty acid composition (mg/100 g DM) in the rumen and duodenal digesta contents of differently fed German Simmental bulls after slaughter is given in Tables 4 and 5. The concentration of the saturated fatty acids (12:0, 14:0, 16:0 and 16:0) in the rumen of the bulls of the experimental group had a tendency to decrease compared to the corresponding concentration of SFA in the control group, however, without statistical significance. Only, the content of 20:5n-3 in the rumen of the experimental group increased significantly compared to control group (Table 4). There was no significant dietary effect on concentration of other fatty acids in the rumen digesta. There was a large individual data variation, and the total concentration of fatty acids in the duodenal digesta was much lower compared to the rumen (Table 5). The content of 22:5n-3 in duodenal digesta of the animals of the experimental group increased significantly, compared to the control group. There was a declining tendency of n-6/n-3 fatty acid ratio from control group to the experimental group without significant relevance.

Discussion

Bioactive fatty acids that escape the rumen via the duodenal digesta, either in unmodified forms or intermediates

[A] *trans*-11-18:1

of incomplete ruminal biohydrogenation of dietary lipids, have a significant potential to improve the nutritional value of ruminant foods. Investigation of metabolic pathways for the formation of *trans*-18:1 and CLA isomers in the rumen and duodenal digesta could help to explain the endogenous synthesis and post ruminal deposition of these bioactive fatty acids in muscle tissues and milk. Research on mechanisms of ruminal biohydrogenation of 18:2n-6 or 18:3n-3 has been most focused with regard to milk fat synthesis in dairy cows [1, 15, 26, 27]. However, investigations into the occurrence of *trans*-18:1 and CLA isomers in the rumen and duodenum digesta of bulls fed 18:2n-6 or 18:3n-3 PUFA-based diets were only sparsely described. The occurrence of CLA isomers in the rumen and digesta of German Holstein bulls compared pasture with indoor feeding has been recently described by Dannenberger et al. [20], however, not with regard to *trans*-18:1 isomers. It has to take into account in the following discussion that the rumen and duodenal digesta samples of the present study with German Simmental bulls were taken at slaughter only. The *trans*-18:1 and CLA isomer contribution in the rumen and duodenal digesta is a reflection of the diet of the last few days prior to slaughter.

The major pathway of 18:2n-6 metabolism in the rumen involves the formation of *cis*-9,*trans*-11 CLA as the initial intermediate by isomerization, then this isomer is subsequently reduced via VA to 18:0 [11]. The dynamic feature of rumen metabolism of pure 18:2n-6 and in in vitro batch incubations showed the predominantly formation of *trans*-10-18:1, *cis*-12-18:1, *cis*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, *cis*-10,*trans*-12 CLA, *trans*-9,*trans*-11 CLA [18]. The sum of the two main *trans*-18:1 isomers (*trans*-10 and VA) accounted for approximately 50% of the total 18:1 isomers. The sum of the two main CLA isomers in the in vitro investigations (*cis*-9,*trans*-11 CLA and *trans*-10,*cis*-12 CLA) accounted for about 50% of the total 18:2

[A] *trans*-11-18:1

intermediates [18]. Also, investigations of in vitro studies of ovine rumen samples and pure bacteria incubated with 18:2n-6 yield the main CLA isomers *cis*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, *trans*-9,*trans*-11 CLA with traces of *trans*-9,*cis*-11 CLA and *cis*-10,*cis*-12 CLA [28]. Further investigations of ruminal bacteria cultures revealed that the reduction of 9,11 geometric CLA isomers occurs via different mechanisms compared to other unsaturated fatty acids [19]. Recently, beside the bacterial metabolism the contribution of protozoa in the biosynthesis of *trans*-18:1 fatty acids and CLA isomers in the rumen was investigated [2, 17]. Protozoa only isomerizes 18:2n-6 to *cis*-9,*trans*-11 CLA, *trans*-9,*cis*-11 CLA, *trans*-10,*cis*-12 CLA, *trans*-9,*trans*-11 CLA, and *trans*-10,*trans*-12 CLA, however, these isomers were not further metabolized. Additionally, bacteria in the rumen produce two *cis,cis* CLA isomers (*cis*-10,*cis*-12 CLA, *cis*-9,*cis*-11 CLA) and these isomers are biohydrogenated to *trans*-18:1 isomers and 18:0 [2, 17].

The results of the present in vivo study with German Simmental bulls fed 18:2n-6 or 18:3n-3 PUFA-based diets confirmed the results of the occurrence of the predominantly formed *trans*-18:1 and CLA isomers from the in vitro studies mentioned above, except *cis,cis* CLA isomers. In contrast to the previous in vitro studies based only on GC investigations, the present study involved two different GC methods and an Ag^+-HPLC method for correct isomer identification of *trans*-18:1 and CLA isomers. By the use of the latter HPLC method the correct CLA isomer identification was achieved in rumen and duodenal digesta samples (Fig. 1).

Contrary to the in vitro studies based on GC measurements, the Ag^+-HPLC measurements in this study did not show the occurrence of *cis,cis* CLA isomers in the rumen samples. The peaks detected in the retention time region of the *cis,cis* CLA isomers in standard solution of the chromatograms did not show UV-spectra typical of *cis,cis* CLA

isomers using PDA detector and were not identified as *cis,cis* CLA isomers, also described in our earlier study with German Holstein bulls [20]. The rumen biohydrogenation of the CLA isomers to *trans*-10-18:1 and *trans*-11-18:1 yields between 47 and 53% of the total *trans*-18:1 isomers without significant differences between the different groups.

Ruminal biohydrogenation of 18:3n-3 is not fully understood compared to that of 18:2n-6 [2, 28]. In vitro incubations with 18:3n-3 resulted predominantly in VA, *trans*-13/14-18:1, *trans*-11,*cis*-13 CLA, *trans*-11,*trans*-13 CLA, *cis*-11,*trans*-13 CLA and conjugated linolenic isomers compared to 18:2n-6 incubations [2, 18]. After 24 h incubation of 18:3n-3 the biohydrogenation yielded mainly in *trans*-18:1 isomers and lower in the final product (18:0) of this process [18]. Also, these findings based on GC measurements correspond to the results of our feeding experiment with German Simmental bulls. *N*-3 PUFA based diet (experimental group) resulted in significant higher concentration of predominantly *trans*-11,*cis*-13 CLA and *trans*-11,*trans*-13 CLA determined by the use of Ag^{+}-HPLC in the rumen of bulls compared to bulls of the control group. It was shown that *cis*-9,*trans*-11 CLA is rapidly metabolized, while VA accumulates during biohydrogenation of PUFA in the rumen as shown by Piperova et al. [29]. The ratio of VA to *cis*-9,*trans*-11 CLA in the rumen of the present study was high and ranged between 82-105:1, however, not diet dependent (Table 2). This high ratio of VA to *cis*-9,*trans*-11 CLA in the rumen is supported by other studies [20, 29]. The complete biohydrogenation in the rumen of the diet groups seems not affected by the diet,

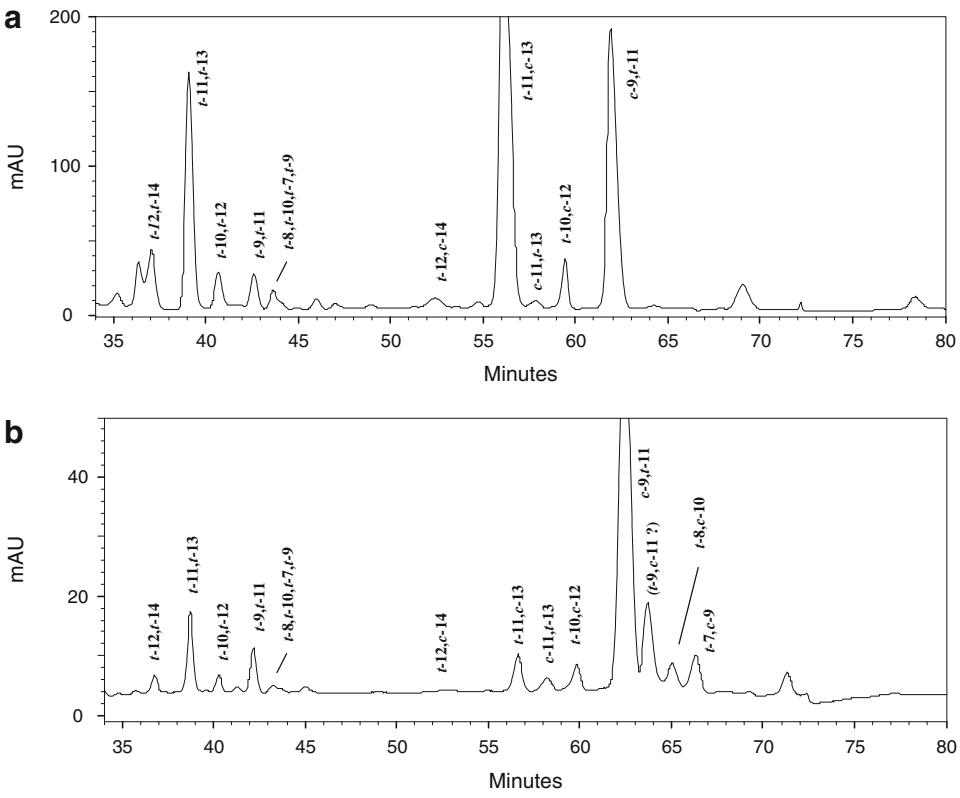

Fig. 1 CLA isomers in rumen content (**a**) and duodenal digesta (**b**) of German Simmental bulls of an experimental group (partial Ag^{+}-HPLC/DAD chromatograms, detected at 233 nm)

because the concentrations of the final product of rumen biohydrogenation 18:0 showed no significant differences between both groups (Table 4). The total *trans*-18:1 and CLA isomers concentrations in the duodenal digesta of slaughtered bulls were approximately 22 and 19 times lower, respectively, compared to the corresponding concentrations in the rumen. This is not in agreement with another bull experiment where approximately 1.4-fold higher CLA isomer concentration was measured in the duodenal digesta compared to the rumen [20]. In contrast, the total *trans*-18:1 concentration was up to 3.9 times higher in the rumen compared to duodenal digesta [20]. A more detailed discussion was complicated by a lack of available data in the literature using complimentary GC techniques and an additional Ag^{+}-HPLC method. Furthermore, the CLA isomer distribution pattern in duodenal digesta was totally different compared to the rumen. In the duodenal digesta, *cis*-9,*trans*-11 CLA, the second most abundant isomer in the rumen, occurred as the main CLA isomer in the duodenal digesta with significant higher concentrations in the experimental group. The comparison of VA/*cis*-9,*trans*-11 CLA ratio in the rumen and duodenal digesta pointed to a predominantly production of VA in the rumen (82-105:1, Table 2). In contrast, the VA/*cis*-9,*trans*-11 CLA ratio in the duodenum digesta revealed higher amounts of *cis*-9,*trans*-11 CLA resulting in lower ratio compared to the rumen (27-33:1, Table 3). The study of Piperova et al. [29] investigated the duodenal *trans*-18:1 and CLA isomers in lactating dairy cows found similar VA/*cis*-9,*trans*-11 CLA ratio. However, no comparable investigation has been conducted in the rumen of lactating dairy cows. One probably explanation for the higher *cis*-9,*trans*-11 CLA concentration in the duodenal digesta could be that the collected samples include bile and pancreatic juice because the sample-taking was 1 m after the pylorus and both the bile and the pancreatic duct open less than 1 m after the pylorus. Another explanation could be the conversion of VA to *cis*-9,*trans*-11 CLA catalyzed by the SCD enzyme in the duodenal digesta. Archibeque et al. [30] found a high SCD enzyme activity in duodenal mucosal tissue of beef steers fed with different grains [30]. However, until now it remains unclear if the SCD enzyme in the duodenal mucosal tissue is involved in the conversion of VA to *cis*-9,*trans*-11 CLA. Generally, *cis*-9,*trans*-11 CLA, known as the main isomer in beef muscle, resulting most likely from the endogenous biosynthesis via SCD enzyme activity of ruminally formed VA [13, 15]. Furthermore, the isomers *trans*-7,*cis*-9 CLA and *trans*-8,*cis*-10 CLA including their geometrical isomers occurred in the duodenal digesta samples, but were not detected in the rumen (Fig 1). Consistent with this result, the *trans*-7,*cis*-9 CLA and *trans*-8,*cis*-10 CLA isomers were not present in the fatty acids isolated from the rumen fluid of lactating dairy cows [29]. To our knowledge, it seems unclear if the formation of these CLA isomers from the corresponding *trans*-18:1 isomers is based on the activity of SCD enzyme in the duodenal mucosal tissue [30] or other mechanisms in the duodenal digesta. The present results were supported by other studies investigating the reduction of *trans*-7,*cis*-9 CLA concentrations in milk by the use of SCD inhibitors [29, 31]. Taking into account that the inhibition of SCD is not complete, the authors measured endogenous synthesis rates of *trans*-7,*cis*-9 CLA between 85 and 100% in milk fat and concluded that this CLA isomer is biosynthesized almost exclusively from endogenous synthesis via SCD [31].

The results indicated that the diet-dependent occurrence of predominantly CLA isomers in rumen and duodenal digesta gives us the opportunity to regulate the post ruminal deposition of bioactive fatty acids in tissue lipids.

Acknowledgments This study was supported by the Federal Ministry of Food, Agriculture and Consumer Protection of Germany and the Ministry of Agriculture of China (Grant No. 30/2008-2009 "Biosynthesis of CLA in beef"), and the National Natural Science Foundation of China (No. 30371040) funding to Xiangzhen Shen. The authors gratefully appreciate B. Jentz and H. Rooch of the Research Unit Muscle Biology and Growth for excellent technical assistance in sample preparation and fatty acid isomer analysis. All the authors have contributed to the preparation of the paper and agree with the submitted manuscript content. There are no conflicts of interest.

Isomerization of Vaccenic Acid to *cis* and *trans* C18:1 Isomers During Biohydrogenation by Rumen Microbes

S. Laverroux · F. Glasser · M. Gillet · C. Joly · M. Doreau

Received: 10 September 2010 / Accepted: 7 June 2011 / Published online: 26 June 2011

Abstract In ruminants, *cis* and *trans* C18:1 isomers are intermediates of fatty acid transformations in the rumen and their relative amounts shape the nutritional quality of ruminant products. However, their exact synthetic pathways are unclear and their proportions change with the forage:concentrate ratio in ruminant diets. This study traced the metabolism of vaccenic acid, the main *trans* C18:1 isomer found in the rumen, through the incubation of labeled vaccenic acid with mixed ruminal microbes adapted to different diets. [1-^{13}C]*trans*-11 C18:1 was added to in vitro cultures with ruminal fluids of sheep fed either a forage or a concentrate diet. ^{13}C enrichment in fatty acids was analyzed by gas-chromatography-mass spectrometry after 0, 5 and 24 h of incubation. ^{13}C enrichment was found in stearic acid and in all *cis* and *trans* C18:1 isomers. Amounts of ^{13}C found in fatty acids showed that 95% of vaccenic acid was saturated to stearic acid after 5 h of incubation with the concentrate diet, against 78% with the forage diet. We conclude that most vaccenic acid is saturated to stearic acid, but some is isomerized to all *cis* and *trans* C18:1 isomers, with probably more isomerization in sheep fed a forage diet.

Introduction

In ruminants, dietary fatty acids (FA) are extensively hydrogenated and isomerized by rumen microbes. These transformations directly determine milk and meat FA composition, which is a criterion of the nutritional quality of the products [1]. Ruminal contents contain numerous C18:1 isomers (from *cis*-6 to *cis*-15 and from *trans*-6 to *trans*-16), which relative proportions depend on diet composition [2]. However, the detailed production pathways of all the C18:1 isomers found in the rumen are unclear. Recently Shingfield [3] reviewed studies on ruminal biohydrogenation and advanced some hypotheses on the production of many C18:1 isomers from the biohydrogenation of oleic, linoleic and linolenic acids. More specifically, Mosley et al. [4] and Proell et al. [5] found that *cis*-9 and *trans*-9 C18:1 were not only hydrogenated to stearic acid, but were also isomerized to several positional and geometric isomers. However, little is known about the metabolization of other C18:1 isomers in ruminants or about the share of these metabolized FA between stearic acid and C18:1 isomers. As vaccenic acid

(*trans*-11 C18:1) is the main *trans* C18:1 isomer present in the rumen [6], we undertook to study its isomerization and biohydrogenation pathways. As the forage:concentrate ratio of the diet modifies the ruminal FA profile and biohydrogenation [7, 8], as well as the rumen microbial community [9], we also examined whether this ratio modified the isomerization and biohydrogenation pathways of vaccenic acid. For this purpose, rumen fluid from sheep fed two contrasting diets was incubated with [1-^{13}C]*trans*-11 C18:1 during 24 h and the appearance of ^{13}C was traced in stearic acid and in the C18:1 isomers.

Materials and Methods

Experimental Design

Four adult sheep at maintenance, weighing on average 62 kg and fitted with ruminal cannulas were used as donors of ruminal contents. Animal surgery and care complied with the Guide for the Care and Use of Laboratory Animals [10]. Two sheep received a forage diet (F) composed of 100% meadow hay. The other two sheep were progressively switched to a concentrate diet (C) composed of 40% meadow hay and 60% barley pellets. The sheep were fed 1,200 g dry matter per day in two equal meals. The ruminal contents were collected after 2 weeks of adaptation to the diets. On 3 days (three replicates), 250 mL of ruminal contents were collected before the morning meal, pooled by diet and immediately transferred to the laboratory for in vitro incubation.

In Vitro Incubations

For each of the three replicates, two series of incubators (F and C) were prepared for the ruminal contents of sheep fed the F and C diets. Each series contained three control incubators (without labeled vaccenic acid) and three experimental incubators (with labeled vaccenic acid), corresponding to the three incubation times (0, 5 and 24 h). Each incubator was a 120-mL bottle containing 500 mg of substrate (50% meadow hay, 50% barley pellets) and 25 mL of Simplex buffer [11] prewarmed to 39 °C. The control incubators received 250 µL of pure ethanol. The experimental incubators received 5 mg of [1-^{13}C]*trans*-11 C18:1 in 250 µL of pure ethanol [4]. [1-^{13}C]*trans*-11 C18:1 (chemical purity >95%, isotopic enrichment >99%) was synthesized by the Commissariat à l'Énergie Atomique (CEA, Gif-sur-Yvette, France) according to well-established procedures [12, 13]. The ruminal contents were strained through a 250-µm nylon cloth and 15 mL of ruminal fluid were added to the corresponding incubators previously gassed with CO_2 for 10 min. The incubators were sealed to ensure anaerobic conditions and placed in a shaking water bath at 39 °C and 100 shakes/min. One control incubator and one experimental incubator from each series (F and C) were taken just before incubation (t_0) or removed after 5 or 24 h of incubation. The pressure was measured with a pressure sensor to calculate gas production, gases were sampled with a syringe to analyze the gas composition as described by Broudiscou et al. [14], pH was measured and the whole content of each incubator was immediately frozen. The contents were then freeze-dried and weighed to determine the total dry matter content. The contents were ground in a micro hammer mill through a 1-mm sieve before FA analysis.

Fatty Acid Analysis

Fatty acids were directly transmethylated, essentially as described by Sukhija and Palmquist [15] with modifications according to Loor et al. [16]. In addition, recovered methyl esters were purified through a florisil column (Florisil®, Sigma-Aldrich, St Louis, USA). Methyl tricosanoate (0.2 mg, Sigma-Aldrich, St Louis, USA) was used as internal standard. Fatty acid methyl esters (FAME) were divided into three fractions. A first fraction was used for FA quantification. For this purpose, 1 µl of FAME at a 30:1 split ratio was injected by auto-sampler into a Varian CP-3800 gas chromatograph (GC) equipped with a flame ionization detector (FID) and a 100 m × 0.25 mm i.d. CP-Sil 88 fused silica capillary column (ChromPack—Varian Inc., Lake Forest, USA). Chromatographic conditions followed the procedure of Loor et al. [16] except that the detector temperature was 300 °C. Pure methyl ester standards purchased from Supelco (Bellefonte, USA), Sigma (St Louis, USA), Nu-chek Prep (Elysian, USA), and Biovalley (Conches, France) were used to identify FA peaks, except for some *trans* and *cis* C18:1 isomers that were identified by order of elution according to Kramer et al. [17]. Some C18:1 isomers were coeluted (as stated in Tables 1, 2).

^{13}C Enrichment of Palmitic, Stearic, Linoleic and Linolenic Acids

A second fraction of the FAME was used to measure ^{13}C enrichment in C16:0, C18:0, C18:2 n-6 and C18:3 n-3. Analysis was performed by GC (Agilent model 7890A) equipped with a mass spectrometer (MS) (Agilent model 5975C inert XL EI/CI) and a 100 m × 0.25 mm i.d. CP-Sil 88 fused silica capillary column (ChromPack—Varian Inc., Lake Forest, USA). GC–MS conditions were as follows: 1 µL was injected in splitless mode; the injector temperature was maintained at 250 °C; the carrier gas was helium at

a constant injector pressure of 30 psi; the oven temperature was started at 60 °C, ramped to 165 °C at 15 °C/min (held for 1 min) and then to 225 °C at 2 °C/min (held for 5 min); the mass spectrometer was operated under positive chemical ionization with ammonia reagent gas at 20 mL/min.

^{13}C Enrichment of C18:1 Isomers

To analyze ^{13}C enrichment of each *cis* and *trans* C18:1 isomers, a third fraction of the FAME was separated into *cis* and *trans* C18:1 fractions, which were converted into DMDS adducts and analyzed by GC–MS. More precisely, this third fraction of the FAME was evaporated under N_2 and dissolved in acetone for HPLC separation of *cis* and *trans* C18:1. The HPLC analysis was performed as described by Juaneda [18], except that the detector was a photodiode spectrophotometer at 194 nm (Beckman 168 Detector, Brea, CA). The fractions containing the *cis* and *trans* C18:1 isomers were collected and converted into DMDS adducts using the procedure of Bernard et al. [19]. The DMDS adducts were analyzed by GC (Agilent model 7890A) with mass spectrometry detection (Agilent model 5975C inert XL EI/CI mass detector) using a 30 m × 0.25 mm i.d. with 0.25 μm film HP5MS (Agilent Technologies, Santa Clara, USA). Injection volume was 1 μL in splitless mode. Injector temperature was maintained at 250 °C. The carrier gas was helium at a constant flow rate of 1 mL/min. The oven temperature was started at 70 °C, ramped to 195 °C at 20 °C/min, then to 225 °C at 1 °C/min (held for 5 min), and finally to 290 °C at 10 °C/min (held for 5 min). The transfer line heater was set at 300 °C. The mass spectrometer was operated under electron impact ionization conditions (electron energy 70 eV, source temperature 200 °C). Data were collected in single reaction monitoring mode.

Calculations and Statistics

Biohydrogenation rates were calculated for oleic, linoleic and linolenic acids as follows: $(\%FA_{t0} - \%FA_{5\ or\ 24h})/\%FA_{t0} \times 100$. A statistical analysis of biohydrogenation rates and fermentation data (pH, gas production and composition) was performed using the Mixed procedure of SAS with diet and vaccenic acid addition as fixed effects, replicate as random effect and incubation time as repeated measure.

For C16:0, C18:0, C18:2 n-6 and C18:3 n-3 methyl esters, the atom percent excess (APE) was calculated from the mass abundance of the labeled and unlabeled molecular ions using the equation $APE = (^{13}C)/(^{12}C + {}^{13}C)$. The DMDS adducts produce two distinct spectral fragments

that are indicative of the double bond position when analyzed by mass spectrometry. The F fragment is the methyl thio adduct of the methyl end of the FAME, and the G fragment is the methyl thio adduct of the carboxyl end. Thus for DMDS adducts of C18:1 isomers, APE was calculated from the mass abundance of G and G + 1 fragments using the equation APE = (G + 1)/[G + (G + 1)]. To eliminate the natural levels of ^{13}C, ^{13}C enrichment (%E) of each FA was calculated as $(APE_{experimental} - APE_{control}) \times 100$ for each incubation time. Data of total FA content, FA percentages, and ^{13}C enrichments (all on experimental incubators) were analyzed using the Mixed procedure of SAS with diet as fixed effect, replicate as random effect and incubation time as repeated measure.

We estimated the fraction of vaccenic acid that was saturated to C18:0 or isomerized to the other C18:1 isomers. To this end, we calculated the amounts of ^{13}C-labeled FA that appeared between 0 and 5 h in C18:0 and in all C18:1 isomers. For the isomers that were strongly metabolized (*cis*-6, *cis*-7 and *cis*-9), these amounts were corrected for their metabolization rates. The amounts of ^{13}C that appeared in C18:0 and in each C18:1 isomer were expressed as a percentage of the ^{13}C-labeled vaccenic acid that disappeared. This calculation was made after 5 h of incubation, which corresponds to the beginning of biohydrogenation, whereas after 24 h of incubation most FA were saturated and isomerization could not be accurately assessed. These data were analyzed using the Mixed procedure of SAS with diet as fixed effect and replicate as random effect.

Results

Fermentation Parameters

Addition of 5 mg of vaccenic acid to the incubators did not modify the fermentations, as no modification of the fermentation parameters (pH, gas production and composition) was observed between the control and experimental incubators (data not shown).

The pH of the ruminal fluid did not vary between diets (7.00 vs. 6.81 for F donors and C donors, respectively). However, the diet of the ruminal fluid donors induced some modifications of in vitro fermentations: pH at 24 h was not significantly different for C control incubators and for F control incubators (6.05 vs. 6.12) but gas production was higher in C control incubators (3.2 vs. 2.6 mmol after 24 h; $P < 0.001$) with a higher percentage of CH_4 (20.6 vs. 17.1% at 24 h; $P < 0.001$).

Fatty Acid Composition and Kinetics

The amounts and composition of the FA in the whole contents of the control incubators at t_0 are in Table 1. The diet of the ruminal fluid donor modified the amounts and composition of the FA in the incubators: at t_0 the C incubators contained more FA and had higher percentages of C18:0 and *trans* C18:1, and lower percentages of *cis* C18:1, C18:2 and C18:3 n-3 than the F incubators.

The amounts and composition of the FA in the experimental incubators during the incubations are presented in Table 2. Linolenic, linoleic and oleic acid percentages declined with time, stearic acid percentage increased and percentages of the intermediates of biohydrogenation increased for the first 5 h of incubation, and decreased thereafter. The amounts of vaccenic acid decreased over time in the experimental incubators.

Across control and experimental incubators, the biohydrogenation of linolenic acid was not modified by the diet (82.2% for C incubators, and 83.7% for F incubators after 24 h of incubation). The biohydrogenation of oleic and linoleic acids were lower in C incubators than in F incubators (54.2 vs. 65.8% for oleic acid and 79.0 vs. 89.2% for linoleic acid after 24 h of incubation).

Vaccenic Acid Metabolism

No ^{13}C enrichment was found in palmitic, linoleic or linolenic acids (data not shown).

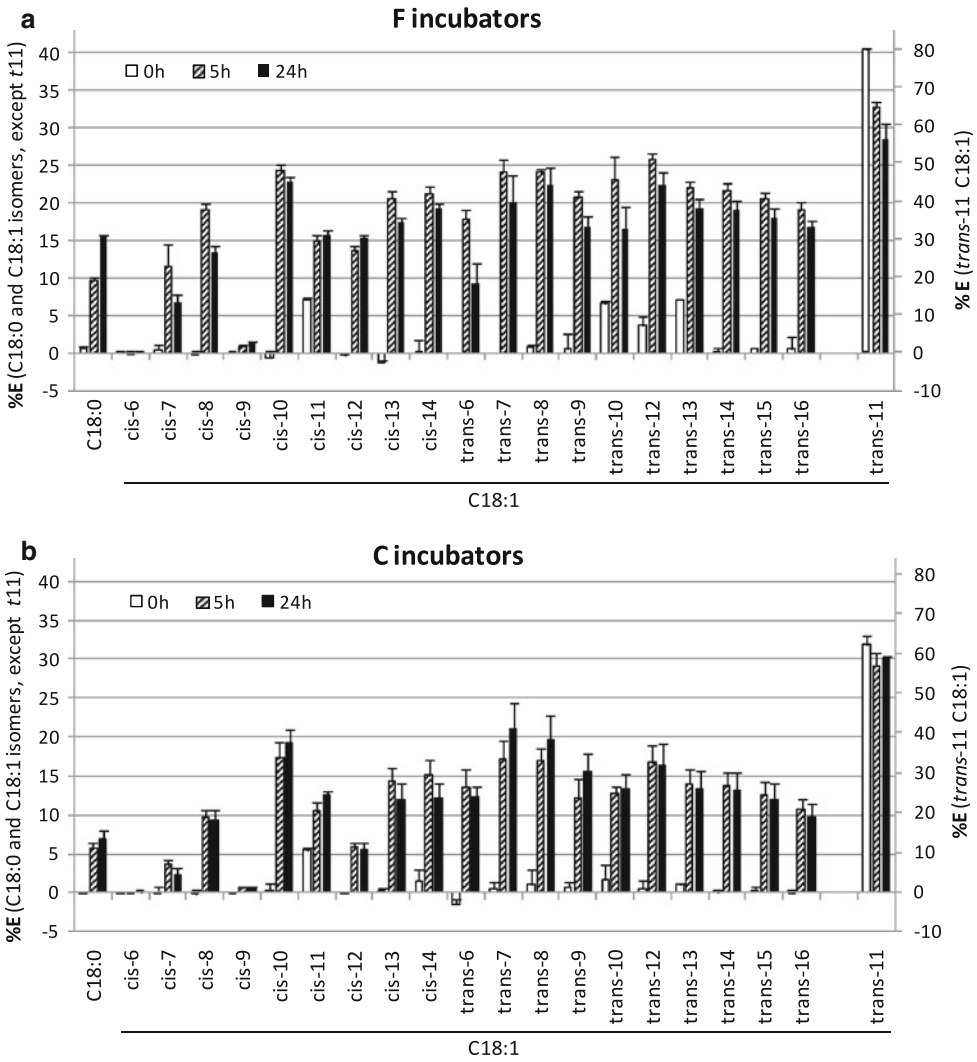

Fig. 1 ^{13}C enrichment of C18:0 and C18:1 isomers after 0 (*white bars*), 5 (*hatched bars*) and 24 h (*black bars*) of incubation of [1-^{13}C]*trans*-11 C18:1 with ruminal fluid of sheep fed a forage diet (**a**) or a concentrate diet (**b**). Each bar is the mean of three replicates. *Error bars* are SE

Following the introduction of labeled vaccenic acid into the experimental incubators, ^{13}C enrichment was significant in C18:0 and in all the *cis* and *trans* C18:1 isomers after 5 and 24 h of incubation, except in *cis*-6 C18:1 at 5 h (Fig. 1). *cis*-6 and *cis*-9 C18:1 were strongly metabolized compared with the other isomers, as shown by the decrease in their amounts between t_0 and 5 h or 24 h (data not shown), which could explain their lower ^{13}C enrichment.

We observed some ^{13}C enrichment of *cis*-11 C18:1 at t_0. This might be due to an analytical bias with some contamination between *cis* and *trans* C18:1 isomers, or possibly to a very rapid isomerization of vaccenic acid to its geometric isomer. We also observed ^{13}C enrichment of *trans*-10, *trans*-12 and *trans*-13 C18:1 at t_0 in F incubators. This might also be due to an analytical bias (the large amount of vaccenic acid did not allow complete separation of isomers by GC–MS), or to a rapid isomerization to neighboring positional isomers (during the freezing time just after vaccenic acid addition) that was more marked in the F incubators. Indeed, isomerization of vaccenic acid to these isomers is confirmed by the fact that the ^{13}C enrichment of these isomers increased between t_0 and 5 h.

In general, ^{13}C enrichment of all FA was higher in the F incubators (diet effect was significant ($P < 0.05$) for C18:0, *cis*-7 to *cis*-14 C18:1 and *trans*-11 to *trans*-16 C18:1). The ^{13}C enrichment of vaccenic acid in the F incubators decreased as early as 5 h of incubation, but the total amount of vaccenic acid was stable. In the C incubators, ^{13}C enrichment of C18:0 and the C18:1 isomers markedly increased between t_0 and 5 h and then remained stable between 5 and 24 h. In contrast, in the F incubators, ^{13}C enrichment of C18:0 and the C18:1 isomers increased between t_0 and 5 h, and then ^{13}C enrichment of the C18:1 isomers decreased while ^{13}C enrichment of C18:0 markedly increased between 5 and 24 h.

The ^{13}C enrichments were different between the C18:1 isomers but the amounts of these isomers also differed. ^{13}C enrichment data could thus not be used directly to estimate the fraction of labeled vaccenic acid converted to C18:0 or C18:1 isomers. For this reason, we calculated the percentage of disappeared ^{13}C-labeled vaccenic acid that appeared in C18:0 and in each of the C18:1 isomers (Fig. 2). Most vaccenic acid was saturated to stearic acid. Saturation tended to be higher in the C incubators than in the F incubators (95 vs. 78%, $P = 0.06$), and conversely the isomerization into other C18:1 isomers was (or tended to be) higher in the F incubators. Figure 2 shows a preferential isomerization of vaccenic acid to *trans*-12, *trans*-13, *trans*-14, *trans*-15 and *cis*-11 C18:1, and then to *cis*-9, *cis*-10 ans *cis*-12 C18:1. The isomerization to the other isomers was markedly lower. These isomerization preferences were the same for F and C incubators.

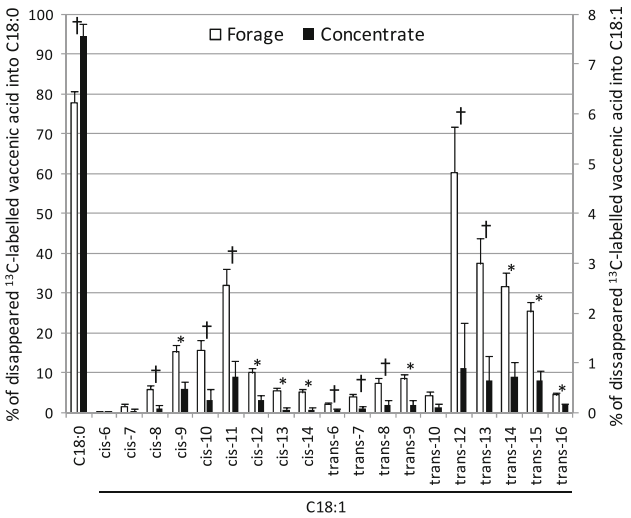

Fig. 2 Distribution of disappeared ^{13}C-labeled vaccenic acid into C18:0 (*left scale*) and C18:1 isomers (*right scale*) after 5 h of incubation with ruminal fluid of sheep fed a forage diet (*white bars*) or a concentrate diet (*black bars*). Each bar is the mean of three replicates. *Error bars* are SEM. † diet effect, $P < 0.10$; * diet effect, $P < 0.05$

Discussion

As the substrate was the same between incubators, the differences between diets in the fermentation parameters were probably due to a difference between the ruminal fluids. As the pH of the ruminal fluids was the same between diets and as the pH of C incubators was not significantly different from that of the F incubators, we can infer that the differences were mainly due to differences in metabolic activity of the microbial communities [20, 21] rather than pH.

Differences in the amounts of FA at t_0 in control incubators show that the ruminal fluid of sheep fed the F diet contained less FA than the ruminal fluid of sheep fed the C diet, probably because of a low quality hay that was very poor in lipids. As the ruminal fluid of sheep fed the F diet contained small amounts of FA, the proportion of FA provided by the substrate was higher in the F incubators than in the C incubators. This explains the differences in FA percentages between incubators at t_0: the FA profile of the F incubators was closer to the FA profile of a feedstuff (lower in C18:0 and higher in polyunsaturated FA).

The kinetics of the FA were consistent with the literature [6], with a decrease in C18 unsaturated FA and an increase in C18:0 over time. In the control incubators, vaccenic acid concentration increased during the first 5 h and decreased thereafter, like all intermediates of biohydrogenation. In the experimental incubators, vaccenic acid decreased over time, which can be explained by the biohydrogenation of the exogenous vaccenic acid that was

higher than the synthesis of vaccenic acid from the polyunsaturated FA.

A lower biohydrogenation is generally observed with high concentrate diets compared with forage diets [7, 16]. Our data are consistent with the literature and show that our in vitro study was representative of FA metabolism in the rumen.

The ^{13}C enrichment of C18:0 reflects the saturation of vaccenic acid and the ^{13}C enrichment of the *cis* and *trans* C18:1 isomers reflects its isomerization. Some authors have shown isomerization of *cis* C18:1 isomers [4, 22] but few have studied the isomerization of *trans* isomers. Kemp et al. [23] reported the isomerization of some *trans* C18:1 isomers but only to the adjacent positional isomers and to the isomer with the opposite geometric configuration. Proell et al. [5] showed isomerization of *trans*-9 C18:1 but only to other *trans* C18:1 and to *cis*-9 and *cis*-11 C18:1.

The larger ^{13}C enrichment of FA in the F incubators was probably due to a higher initial ^{13}C enrichment of vaccenic acid in these incubators as less vaccenic acid was naturally present in the incubators. The decrease in ^{13}C enrichment of vaccenic acid while its amount did not vary shows a synthesis of unlabeled vaccenic acid, most probably from the partial biohydrogenation of the linoleic and linolenic acids present in the incubators. The initial percentages of linoleic and linolenic acids and their biohydrogenation were higher in the F incubators and so induced a higher synthesis of unlabeled vaccenic acid.

The kinetics of ^{13}C enrichment of C18:0 and the C18:1 isomers show that the microbial community of sheep fed the C diet metabolized vaccenic acid rapidly (saturation and isomerization) during the first 5 h and was less active thereafter. By contrast, in F incubators there seemed to be either a promotion of saturation after 5 h or an increased synthesis of the intermediates (C18:1) from biohydrogenation of polyunsaturated FA present in the F incubators.

Figure 2 shows a slightly lower isomerization of vaccenic acid in the C incubators than in the F incubators. Abughazaleh et al. [24] studied labeled *cis*-9 C18:1 in continuous cultures of ruminal content and showed that a low pH decreased the conversion of *cis*-9 C18:1 to *trans* C18:1. He advanced the hypotheses of a diminution of bacterial growth, a diminution of microbial attachment to feed particles, a change in microbial community, or an altered enzyme activity. Several authors have shown that isomerization and saturation can be altered by the composition of the diet, especially fish oil supplementation [25] or by pH and polyunsaturated FA present in the rumen [26]. In our study, the pH were similar between conditions; the differences between C and F incubators could thus arise from differences in initial polyunsaturated FA contents or differences in microbial community or activity [25]. Our study show that a diet rich in forage tends to stimulate isomerization at the expense of saturation of vaccenic acid; however our study cannot show whether the difference between diets was due to an increase in isomerization or to a decrease in saturation, because the amounts of FA at t_0 were very different.

Conclusion

In conclusion, vaccenic acid was preferentially saturated to stearic acid by rumen microbes in vitro but was also isomerized to all C18:1 isomers, though in variable proportion. A higher forage:concentrate ratio tended to increase isomerization of vaccenic acid at the expense of saturation but did not modify the profile of the isomers synthesized.

Received: 23 December 2010 / Accepted: 1 June 2011 / Published online: 6 July 2011

Abstract Cytoplasmic oil globules of *Haematococcus pluvialis* (Chlorophyceae) were isolated and analyzed for pigments, lipids and proteins. Astaxanthin appeared to be the only pigment deposited in the globules. Triacyglycerols were the main lipids (more than 90% of total fatty acids) in both the cell-free extract and in the oil globules. Lipid profile analysis of the oil globules showed that relative to the cell-free extract, they were enriched with extraplastidial lipids. A fatty acids profile revealed that the major fatty acids in the isolated globules were oleic acid (18:1) and linoleic acid (18:2). Protein extracts from the globules revealed seven enriched protein bands, all of which were possible globule-associated proteins. A major 33-kDa globule protein was partially sequenced by MS/MS analysis, and degenerate DNA primers were prepared and utilized to clone its encoding gene from cDNA extracted from cells grown in a nitrogen depleted medium under high light. The sequence of this 275-amino acid protein, termed the *Haematococcus* Oil Globule Protein (HOGP), revealed partial homology with a *Chlamydomonas reinhardtii* oil globule protein and with undefined proteins from other green algae. The HOGP transcript was barely detectable in vegetative cells, but its level increased by more than 100 fold within 12 h of exposure to nitrogen depletion/high light conditions, which induced oil accumulation. HOGP is the first oil-globule-associated protein to be identified in *H. pluvialis*, and it is a member of a novel gene family that may be unique to green microalgae.

Keywords Astaxanthin · *Haematococcus* · Oil globules · Oil globule protein · Triacylglycerols

Abbreviations

CFE	Cell-free extract
CGP	Carotene globule protein
DGDG	Digalactosyldiacylgycerol
DGTS	Diacylglyceroltrimethylhomoserine
EDA	Eicosadienoic acid
HOGP	*Haematococcus* oil globule protein
IEF	Isoelectric focusing
LHCP	Light-harvesting complex proteins
MGDG	Monogalactosyldiacylglycerol
ORF	Open reading frame
SQDG	Sulfoquinovosyldiacylglycerol
TFA	Total fatty acids

Introduction

Oil globules are discrete, sub-cellular organelles surrounded by a monolayer of polar phospholipids, glycolipids or sterols that encircle a hydrophobic core of neutral lipids [1]. These oil globules are ubiquitous in animals, plants, and microorganisms. In many microorganisms, such as yeasts, microalgae and bacteria, the accumulation of oil globules appears to be induced specifically in response to environmental stresses, such as nutrient limitation, high

irradiance or osmotic stress [1, 2]. Although a variety of oil globule biogenesis models have been postulated, the actual process remains to be elucidated. Nonetheless, it is commonly accepted that globules are formed by vesiculation from the endoplasmic reticulum (ER) [3].

Two major groups of surface-associated proteins, oleosins and caleosins, are contained in the oil globules of plants. Oleosins comprise the most abundant family of oil–body-associated proteins identified in plants, but to date they have not been found in algae [4]. Caleosin, a calcium binding lipid-body protein that has also been found to be associated with ER membranes [5–7], is ubiquitous among higher plants, and a database search by the authors has revealed putative caleosin super-family proteins in green microalgae (unpublished data). A number of studies have attributed different roles to globule proteins, including globule formation, degradation, stabilization, and involvement in globule–globule or globule-other organelle interactions [1, 4, 7, 8]. Drosophila, yeast, and mammalian globules have also been shown to house refugee proteins that are not directly linked to lipid metabolism [9, 10].

It is known that some unicellular algae contain very large amounts of oil sequestered in oil globules. In some species, oil can amount to as much as 60% of the cell dry mass, with oil accumulation usually being accompanied by the cessation of cell growth [11–13]. However, little is known about the protein composition and functional roles of algal oil globules.

Of particular interest is the high-oil-producing unicellular green alga *Haematococcus pluvialis*. This alga is regarded as the best natural source of the high-value red pigment astaxanthin, a carotenoid that accumulates in algal cytoplasmic oil globules under various stress conditions [14]. The accumulation of astaxanthin in *H. pluvialis* is positively correlated with lipid accumulation, with the former depending on the latter but not vice versa [15]. Lipid accumulation, in turn, depends on de novo fatty acid synthesis [2, 15, 16]. Under nitrate deprivation, astaxanthin and fatty acids may comprise up to 4 and 40%, respectively, of cell dry mass [16]. As is the case for other organisms, oil globule formation in *Haematococcus* was suggested to be structurally related to ER membranes [17].

H. pluvialis is a unique organism for studying oil globule formation, since it accumulates both lipids and carotenoids in the same compartment. Analyses of lipid class distribution in isolated globules have previously been reported by Grunewald et al. [18], whose studies indicated the cytoplasmic origin of globule polar lipids. Zhekisheva et al. [2] found 16:0, 18:1 and 18:2 fatty acids to be the major fatty acids in TAG and astaxanthin esters. To deepen the current understanding of oil globule biogenesis and function, we isolated astaxanthin-rich oil globules from *H. pluvialis* to characterize and identify oil globule proteins.

Seven distinct protein bands associated with globules were identified. The mRNA for one 33-kDa protein was isolated and sequenced. The resulting sequence was found to encode a novel, hydrophobic protein that may have a specific function in green algae, since homologous sequences were found only in other species of green algae.

Materials and Methods

Haematococcus pluvialis Strain

H. pluvialis Flotow 1,844 em. Wille K-0084 (Chlorophyceae, order Volvocales) was obtained from the Scandinavia Culture Center for Algae and Protozoa (SCCAP) at the University of Copenhagen, Denmark.

Growth Conditions for Algal Cultures

H. pluvialis algal cultures were cultivated as previously described [2]. To induce the accumulation of astaxanthin-rich oil globules, cultures were inoculated into nitrate-free mBG-11 medium to a final cell concentration of 2×10^5 cell mL^{-1} and subjected to 350 µmol photon m^{-2} s^{-1} (designated high light). After 7 days, red cells were harvested for globule isolation.

For RNA isolation, axenic cultures were grown up to a cell concentration of 2×10^5 cell mL^{-1} in 250-mL flasks, each containing 100 mL of mBG-11; the flasks were held in a shaker (150 rpm) and exposed to light of 90 µmol photon m^{-2} s^{-1}. Cells were then transferred to 250-mL flasks, each containing 50 mL of nitrogen-depleted mBG-11 medium and exposed to a light intensity of 200 µmol photon $m^{-2}s^{-1}$ to induce astaxanthin accumulation. For each sample, a separate flask was harvested at 0, 12, 24, 48, and 72 h.

Growth Parameter Measurements and Pigment Extraction and Quantification

Culture cell concentration, chlorophyll quantification and total carotenoid quantification were evaluated as previously described [16].

Isolation of Globules

An *H. pluvialis* culture was harvested by centrifugation (1,500×*g*, 10 min), suspended in breakage buffer comprising 0.2 M sucrose (10 mM MOPS, pH 7.0; 10 mM KCl; 5 mM Na EDTA; 1 mM DTT; 1 mM PMSF; 1 mM benzamidine; and 0.5 mg/mL leupeptin), and ruptured with a Mini Beadbeater (BioSpec Products Inc., OK, USA) using 2.5-mm glass beads for 4 min. The resulting

homogenate was centrifuged (1,500×g, 10 min), and the cell-free extract obtained was fractionated by centrifugation (25,000×g, 60 min, Sorvall RC 5C plus) on a discontinuous sucrose flotation gradient (0.6, 0.4, 0.2, 0 M sucrose in breakage buffer). The upper layer of the sucrose gradient containing the oil globules was collected and centrifuged in an ultracentrifuge (100,000×g, 120 min, Sorvall Combi plus). The floating oily layer was collected in 0.3-mL aliquots and kept frozen (−20 °C) until analyzed. The microsomal fraction comprised the ultracentrifuge (100,000×g, 120 min) pellet of the sucrose gradient supernatant minus the oil globules.

High-Performance Liquid Chromatography Pigment Analysis

The pigment profile was determined by high-performance liquid chromatography (HPLC) as described in Zhekisheva et al. [2]. The chromatogram was recorded at 450 nm, but the quantification of pigments (in % based on pigment weights) was performed at 478 nm for xanthophylls, 655 nm for chlorophyll a and 645 nm for chlorophyll b. Astaxanthin and chlorophylls were identified by comparison to their standards, and astaxanthin isomers were identified from their UV–VIS absorbance spectra, according to Yuan and Chen [19]. Xanthophylls other than astaxanthin were identified by their absorbance spectra and calculated peak III/II ratios, according to Briton et al. [20].

Lipid Analysis

Lipids were extracted from the cell-free extract and oil globules by the method of Bligh and Dyer [21]. Total lipid extract was separated into neutral and polar lipids by silica Bond-Elute cartridges (Varian, CA) using 1.5% methanol in chloroform (v/v) and methanol to elute neutral and polar lipids, respectively.

Polar lipids were separated into individual lipids by two dimensional TLC on Silica Gel 60 glass plates (10 × 10 cm, 0.25 mm thickness [Merck, Darmstadt, Germany]) according to Khozin et al. [22]. Neutral lipids were resolved with petroleum ether:diethyl ether:acetic acid (70:30:1, v/v/v). Lipid spots on TLC plates were visualized with 0.05% 8-anilino-4-naphthosulphonic acid in methanol (w/v) and UV light exposure and then scraped from the plates and transmethylated for fatty acid analysis.

Fatty Acid Analysis

Fatty acid methyl esters (FAME) were obtained by transmethylation of the lipid extracts or individual lipids with dry methanol containing 2% H_2SO_4 (v/v) and heating at 80 °C for 1.5 h while stirring under an argon atmosphere. Gas chromatographic analysis of FAME was performed on a Thermo Ultra Gas chromatograph (Thermo Scientific, Italy) equipped with PTV injector, FID detector, and a fused silica capillary column (30 m × 0.32 mm; ZB WAXplus, Phenomenex). FAME were identified by co-chromatography with authentic standards (Sigma Chemical Co., St. Louis, MO; Larodan Fine Chemicals, Malmö, Sweden) and FAME of fish oil (Larodan Fine Chemicals). Each sample was analyzed in duplicates of three independent experiments.

Protein Analysis

Protein samples were prepared as described in Wang et al. [23], and the BCA method was used for protein determination [24]. Separation of isolated protein fractions was performed by SDS PAGE (12%) according to Laemmli [25] with minor changes. Sample preparation entailed 1 h of incubation at room temperature in sample buffer containing 80 mM DTT. Bio Rad Precision Plus protein unstained standards were used as molecular weight markers.

Two-dimensional gels were prepared as described [26] with minor changes. Samples of 130 µl, each containing 50 µg of protein, were loaded on 7-cm isoelectric focusing (IEF) dry strips, pH 3–10 nonlinear (Amersham Biosciences AB, Uppsala). Protein spots of about 33 kDa were selected for analysis by mass spectrometry (MS).

Partial Amino Acid Sequencing

Protein spots were manually excised from 2D gels and digested in-gel with trypsin.

The peptide mixtures were subjected to solid phase extraction with a C18 resin filled tip (ZipTip Milipore, Billerica, MA USA) and nanosprayed into the Orbi-trap MS system in a 50% CH_3CN/1% CHOOH solution. MS was carried out with an Orbi-trap (Thermo Finnigen) using a nanospray attachment [27]. Data analysis was done using the Bioworks 3.3 package, and database searches were performed against the NCBInr database with the Sequest and Mascot software packages (Matrix Science, England). De novo sequencing was performed using the Biolynx package (Micromass, England).

Isolation of Total RNA

Total RNA was isolated with an SV Total RNA Isolation Kit (Promega USA). From 40 ml of medium containing 2 × 10^5 cells mL^{-1}, cells were harvested, resuspended in the kit lysis buffer and broken in Mini Beadbeater (Bio-Spec Products Inc., OK, USA) using 2.5-mm glass beads for 4 min. RNA samples were quantified with a Nano Drop

(ND-1000, Thermo Scientific, USA) spectrophotometer and stored at −80 °C.

cDNA Preparation, PCR and Sequencing

The Reverse iT 1st Strand Synthesis Kit (ABgene, UK) was used according to the manufacturer's instructions to synthesize cDNA from total RNA. The synthesized cDNA was used as the template in PCR amplification (with the degenerate primers listed in Table 3) using touch down PCR at 56 to 46 °C. The PCR product was extracted and subcloned, and specific primers for 3′ and 5′ RACE were designed. Full-length cDNA was synthesized according to the protocol described in the manufacturer's instructions (BD SMART RACE, Clontech). Searches for homologues sequences were performed in the NCBI database using the BLAST program [28].

Results

Globule Isolation

Oil globule accumulation was induced by exposing exponentially growing cells (chlorophyll and astaxanthin were 5 and 1 μg mL^{-1}, respectively) to high light and to nitrogen deprivation. Chlorophyll and astaxanthin contents in red cells harvested after seven days were 5 and 168 μg mL^{-1}, respectively.

The isolation of pure oil globules from *H. pluvialis* was hampered by the need to first rupture the robust algal cell wall. In light of this problem, earlier studies have explored the rupture process, examining the methods available for cell breakage (including grinding, French press or freeze thaw cycles), algal strains with different cell wall morphologies, and the treatments for purifying the isolated globules, including high ionic strength washes, chaotropic agents and detergents [29]. Although it was found that the different procedures produced similar results in terms of the pigment, fatty acid, and protein compositions of the isolated globules, all preparations also contained some contaminating membranes and proteins that were probably introduced into the globules during cell breakage. We found that breaking the cells with a Mini Beadbeater was an efficient and reproducible method for producing a high oil globule yield. Light microscopy of our preparations showed a mixed-sized population of yellow–red globules ranging in diameter from about 200 nm to 4 μm (Fig. 1).

Pigment Analyses

Eight different astaxanthin esters, amounting to about 70% of the total pigments, were found in the cell-free extract (CFE), while in the oil globules astaxanthin esters amounted to about 86% of the total pigments. The three major peaks on the HPLC chromatogram were attributed to astaxanthin esters 3, 5 and 6 (peaks 7, 8 and 9, respectively, in Fig. 2). UV–VIS absorbance spectra (not shown) indicated that peaks 8 and 9 were those of the *trans* isomer. In addition to the astaxanthin esters, minor amounts of chlorophyll and the chloroplast-derived xanthophylls—antheraxanthin, lutein and zeaxanthin—were also detected (Fig. 2). The retention time of zeaxanthin differed from the typical retention time previously reported by our group [2], and zeaxanthin may thus have been present in ester form. The relative chlorophyll content was higher in the CFE than in the oil globules—12.7% versus 4.5% (Table 1). The relative amounts of the other three xanthophylls were also higher in the CFE than in the oil globule fraction.

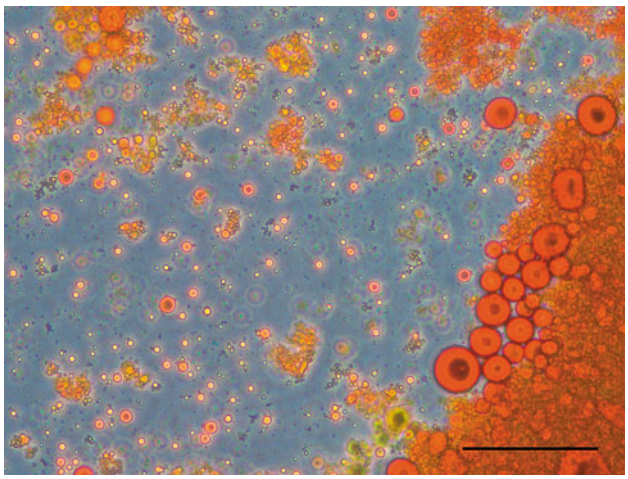

Fig. 1 Oil globules isolated from *H. pluvialis*. The oil globules were fractionated on a sucrose flotation gradient. *Bar* 20 μm

Fatty Acid and Lipid Analyses

Fatty acid composition of the total homogenate was similar to that of the oil globules and was characterized by the four major fatty acids: 16:0, 18:1, 18:2 and 18:3n-3 (not shown). To further analyze fatty acid composition and estimate the distributions of polar and neutral lipids in the oil globule enriched fraction, we performed a detailed lipid analysis of the representative sample of oil globules fractionation by two-dimensional TLC followed by GC analysis of fatty acid composition and content. About 70% of the total fatty acids (TFA) in CFE were recovered in the oil globule fraction, but polar membrane glycerolipids (PL), which constituted only 3.5% of the TFA in CFE, were reduced to 1.5% in the oil globules. Accordingly, neutral lipid TAG was a major component of both fractions (Table 2), accounting for more than 70% of the TFA in neutral lipids (NL). Diacylglycerol (DAG) and free fatty acids (FFA)

constituted 7% each of the TFA in NL. FFA were also included in the calculation due both to their relatively high proportion and to their potential involvement in NL turnover. A relatively large percentage of the fatty acids in the NL fraction were esterified to astaxanthin in its mono- and diester forms, with the majority existing as monoesters.

The most salient difference between the oil globules and the CFE was the decreased proportion of the major thylakoid and inner chloroplast membrane lipid [30] monogalactosyldiacylglycerol (MGDG) in the oil globules. The ratio of two galactolipids, MGDG to digalactosyldiacylglycerol (DGDG), decreased from 1.3 to 0.4 during oil globule purification. Consequently, the relative proportions of the polar lipids—DGDG, sulfoquinovosyldiacylglycerol (SQDG) and diacylglyceroltrimethylhomoserine (DGTS)—increased, while that of phosphatidylcholine (PtdCho) remained unchanged.

There were no substantial differences between the fatty acid compositions of individual lipids in the CFE (not shown) and in the oil globule fraction. Despite tiny amounts of PL, a characteristic fatty acid signature was evident for each lipid class (Table 2). The galactolipids MGDG and DGDG were typically enriched with chloroplast PUFA, specifically linoleic acid (LNA, 18:2n-6) and α-linolenic acid (ALA, 18:3n-3), and with C16 PUFA 16:3n-3 and 16:4n-3. Another chloroplast-associated lipid, SQDG, contained less PUFA but was rich in saturated palmitic acid, 16:0. Phosphatidylglycerol (PtdGro) contained about 3% 16:1Δ3-*trans*—a distinctive feature of this class of chloroplast lipids (not shown). It appeared that *H. pluvialis* oil globules contained the phospholipid PtdCho and the betaine lipid DGTS as major extraplastidial polar lipids. PtdCho and DGTS featured similar fatty acid compositions, namely, the highest percentages of γ-linolenic acid (GLA; $18{:}3^{\Delta6,9,12}$, n-6) and stearidonic acid (SDA; $18{:}4^{\Delta6,9,12,15}$, n-3), indicating their possible involvement in the Δ6 lipid-linked desaturation of LNA ($18{:}2^{\Delta9,12}$, n-6) and of ALA ($18{:}3^{\Delta9,12,15}$, n-3), respectively. Phosphatidylethanolamine (PtdEth), the minor component of the PL fraction, contained the highest proportions of C20 long-chain PUFA, particularly, of arachidonic acid (AA; $20{:}4^{\Delta5,8,11,14}$, n-6) at 16%. In addition eicosadienoic acid (EDA; $20{:}2^{11,14}$, n-6) and eicosapentaenoic acid (EPA; $20{:}5^{\Delta5,8,11,14,17}$, n-3) comprised for about 4% each of TFA in this lipid class. This characteristic fatty acid composition allows speculation on the involvement of PtdEth in the Δ8 desaturation of 20:2n-6 and Δ17 (n-3) desaturation of AA. In this context, although it is worth

noting the abundance of EDA in the FFA pool, we realize that more thorough studies of PUFA biosynthesis in *H. pluvialis* are obviously needed to confirm the predictions made in the present work.

The neutral acyl lipids TAG and DAG and astaxanthin esters were enriched with oleic acid (OA, 18:1n-9) and LNA. The astaxanthin monoesters contained the highest relative proportions of ALA, and the percentage of palmitic acid was lowest in DAG and FFA.

Protein Analysis

Four major protein bands with estimated molecular weights of 20–30 kDa (Fig. 3 lane 8) that appeared in the isolated globule preparation were also evident in the total homogenate fraction of both green (astaxanthin and oil free) and red (astaxanthin and oil rich) cells (Fig. 3, lanes 1 and 7). These proteins were identified as chloroplast light-harvesting proteins on the basis of their positive cross-reactivity with anti light-harvesting complex protein (LHCP) antibodies (not shown). To reveal the native proteins of the globules, we followed the changes in protein profile during 14 days of exposure to nitrate depletion and high light. During this period, astaxanthin accumulated and chlorophyll levels decreased (Fig. 4).

As the globules accumulated, the relative abundances of only a few protein bands seemed to increase while the total protein content decreased. Of the proteins that did increase, we could distinguish seven different protein bands that appeared in the globule fraction but not in the microsomal fraction. These proteins were thus all considered to be globule-associated proteins (Fig. 3).

Globule proteins were also analyzed by 2D gel electrophoresis. Two major protein spots, both of about 33 kDa but with different PI values (Fig. 5), were cleaved with trypsin and analyzed by MS/MS. Identical partial sequences comprising 12 peptides were obtained for the two 2D protein spots, and these were designated *Haematococcus* oil globule protein (HOGP). Based on the sequences of five peptides, forward and reverse degenerate nucleotide primers were designed and used in different combinations for PCR amplification on cDNA from induced cells. The three peptides whose primers produced PCR amplification products are shown in Table 3, and the five peptides identified in the final amino acid sequence are indicated in bold letters in Fig. 6. A PCR product was initially cloned, and the sequencing was completed by 3′-RACE and 5′-RACE extensions (see Table 3 for the primers). A DNA product of 910 bp was obtained with an open reading frame (ORF) of 825 bp (accession number HQ213938) that encoded for a protein of 275 amino acids. An NCBI search with the protein query produced significant hits only from green microalgae. Multiple sequence alignment of HOGP with putative green algal orthologs revealed identities of 40, 38, and 36% with

Volvox carteri f. nagariensis, *Polytomella parva*, and *Chlamydomonas reinhardtii*, respectively (Fig. 6). A significant but smaller homology of 27% identity was also found with *Coccomyxa* sp., accession number GW230985 (not shown).

A comparison of the secondary structure of HOGP with its *C. reinhardtii* ortholog, which is the only full-length published sequence, was performed by hydrophobicity plot analyses [31]. The two proteins showed very similar patterns, with the majority of their hydrophobic regions situated between amino acids 55–65 and 170–190 of HOGP (Fig. 7). A short hydrophilic region that is evident in HOGP at amino acids 105–113 also appeared in the *P. parva* sequence but is absent in the *C. reinhardtii* and *V. carteri f. nagariensis* sequences (Figs. 6, 7).

To characterize the induction of the *Hogp* gene, cultures were induced to accumulate astaxanthin (see above) for a period of 72 h, during which RNA was isolated at different time intervals. Specific primers were designed from our cDNA sequence, while actin control primers were adopted from Huang et al. [32]. Astaxanthin accumulation could be detected spectrophotometrically in a total pigment extract after as short a time as 12 h, and after three days astaxanthin increased by more than tenfold (Fig. 8). Transcript levels of the *Hogp* gene, which were almost undetected in green non-stressed cells, increased by >100-fold after 12 h of induction. They remained almost constant for 48 h and started to decrease after 72 h (Fig. 9).

Discussion

The ability of plant or algal cells to accumulate secondary carotenoids depends on the availability of a sink for carotenoid deposition [33, 34]. It is likely that deposition of carotenoids in a lipid sink will prevent end product inhibition of the biosynthetic pathway [35]. In yeasts, for example, the expression of carotenogenic genes leads only to minor astaxanthin accumulation [36–38], supposedly as a consequence of the lack of sinks for the carotenoid end product. This "sink hypothesis" is supported by our earlier studies with the carotene globule protein (Cgp), a protein that is associated with plastidic β-carotene oil globules in *Dunaliella bardawil* and that functions in globule stabilization [8]. The "sink hypothesis" may also be applicable to TAG biosynthesis, where the availability of oil globules or the enhanced ability to produce them should facilitate the parallel synthesis and accumulation of storage lipids. Identifying the main globule-associated enzymes and

proteins taking part in the assembly of oil globules can therefore be a key to future biotechnological manipulation of microalgae for the high yield production of oil and carotenoids. Indeed, carotenoid biosynthetic enzymes have already been shown to be localized in oil globules [18, 39].

The lack of sufficient molecular information and sequence data for *H. pluvialis* limits the use of bioinformatics to identify specific protein genes. We therefore applied proteomics approaches to identify possible globule-associated proteins, an approach requiring enriched and contaminant-free oil globule preparations. This approach poses a major challenge when organelles have to be isolated from cells with a rigid cell wall, as is the case for *Haematococcus*, which necessitates aggressive cell breakage. This is particularly true for the isolation of hydrophobic organelles such as oil globules, which can easily adsorb hydrophobic proteins or pigments released from the chloroplast during aggressive lysis in apparatuses such as a French press or a bead beater [40]. Indeed, the chlorophylls, xanthophylls and some of the plastid lipids in our preparations undoubtedly originated in chloroplast membranes, and the consistent detection of LHCPs as the major proteins in isolated globules (also verified by MS analysis), even after purification, may be an artifact of isolation. A possible solution may lie in the production of spheroplasts by enzymatic treatment, followed by gentle lysis via osmotic shock. Although previous studies have reported the successful application of this approach in *H. pluvialis* [41, 42], our group has never succeeded in reproducing their results, even after successful removal of the cellulose layer from the cell wall [43]. As an alternative, we tried to use flagellated (motile) cells with reduced cell walls. Our attempts to isolate oil globules using different breakage methods and/or motile cells, however, resulted in almost the same globule composition as that presented in Fig. 1 and Tables 1 and 2.

The globule preparations obtained were rich in astaxanthin and in the fatty acids that are characteristic of TAG in microalgae as compared to the CFE. Moreover, some chloroplast lipids (MGDG) were substantially reduced in globule fraction (Table 2). We are therefore confident that our preparations are largely representative of oil globules composition in vivo, with the exception of some contaminating pigments, lipids and proteins, as mentioned above.

Based on the pigment content of the globules, we concluded that astaxanthin is the only carotenoid accumulating in the globule fraction. This conclusion is supported by earlier findings of Grunewald and Hagen [44]. Three astaxanthin esters comprise the majority of astaxanthin contributing to the absorbance maximum at 476.6–480 nm. None of the intermediates of the astaxanthin biosynthesis pathway or free astaxanthin or β-carotene was detected in globules, although minor amounts of these pigments were reported in the total homogenate of red *H. lacustris* cells [19]. The fatty acids content of oil globule resembled that of the CFE, which is to be expected, since oil globule TAG comprise the vast majority of lipids [16] (Table 2). These results are in agreement with the findings of Zhekisheva et al. [2], who induced astaxanthin accumulation in *H. pluvialis* only by high light exposure, and those of Wang et al. [45] for *C. reinhardtii* cytosolic isolated oil globules.

The results of oil globule individual lipid analysis are largely in agreement with the data of Grunewald et al. [18], who estimated the proportions of different lipid classes in oil globules of vegetative cells of *H. pluvialis* by densitometry of charred lipid spots on TLC plates. In the course of their preparations, the authors also detected lipids of plastid origin—DGDG, SQDG, and PG—but they reported the complete absence of MGDG. We were able to detect a relatively low proportion of MGDG in our oil globule preparations; however, this lipid class was substantially reduced in oil globules compared to in CFE, indicating enrichment of oil globules with other oil globule-specific lipid classes. The betaine lipid DGTS and the phospholipid PtdCho constituted the major portion of extraplastidial lipids in oil globules (about 40% of PL). It appears that DGTS contributed significantly to the formation of an oil globule polar lipid monolayer in green algae [18, 46] in contrast to higher plants whose oil globule phospholipid monolayer is enriched in PtdCho and PtdEtn. DGTS shares some properties with PtdCho, and is abundant in some algal groups and low plants,

but it is absent in higher plants. In *C. reinhardtii,* PtdCho is missing, and DGTS is present as a major polar lipid in the oil globule-enriched fraction [46].

Protein analysis of the isolated globule fraction by SDS PAGE identified at least seven protein bands that were not present in the microsomal fraction. The same proteins accumulated during astaxanthin accumulation, as can be seen in the protein pattern of total cell homogenates (Fig. 3). These findings support the notion that the bands are indeed authentic oil-globule-associated proteins (Fig. 3). One of the protein bands showed two major 33 kDa spots on 2D gel electrophoresis and was termed HOGP. The different PIs of the two HOGP spots could be due to protein phosphorylation. HOGP was analyzed by MS/MS, and the partial amino acid sequences were utilized to prepare degenerate DNA primers that were used to clone the gene encoding HOGP. A database search revealed that HOGP has orthologs only among green algae. One such ortholog was recently identified in *C. reinhardtii* oil globules and has been shown to affect globule size [46].

The novel family of globule-associated proteins differs completely in sequence and in secondary structure from plant oleosins and caleosins, suggesting that green algae evolved these unique globule-associated proteins, which may or may not share similar functions with plant oleosins. A comparison of the orthologous amino acid sequences from four microalgal species showed that the *H. pluvialis* and *P. parva* sequences each have an insert of 11 amino acids (Fig. 6) that is not found in *C. reinhardtii* or *V. carteri f. nagariensis*. The hydropathy plot comparison between the *H. pluvialis* and *C. reinhardtii* proteins revealed another significant difference between the two proteins, i.e., a highly hydrophilic 9-amino-acid domain following the 11-amino-acid insertion in *H. pluvialis* (and *Polytomella*) that is hydrophobic in *C. reinhardtii* and *Volvox*. Both differences may account for the divergent functions of the two proteins. The induction pattern of HOGP is consistent with its predicted localization in oil globules: the appearance of the 33-kDa protein in nitrate depletion/high light inductive conditions is roughly correlated with astaxanthin induction (Figs. 3, 4). The transcript of the *Hogp* gene is hardly detectable in green cells but is highly induced upon exposure of the cells to astaxanthin-inducing conditions, preceding the appearance of the protein as expected. The findings presented in this paper thus indicate that the HOGP protein is a promising candidate for involvement in globule biogenesis and the stress response in *Haematococcus* and related species of green algae.

Acknowledgments The authors would like to thank Mrs. Shoshana Didi-Cohen for the help in lipid and fatty acid analysis. This work was supported in part by the FP 7 project GIAVAP.

Changes in the Composition of Triacylglycerols in the Fat Bodies of Bumblebee Males During Their Lifetime

Pavel Jiroš · Josef Cvačka · Robert Hanus · Jiří Kindl · Edita Kofroňová · Irena Valterová

Received: 8 November 2010 / Accepted: 8 June 2011 / Published online: 1 July 2011

Abstract The age-dependent changes in the composition of triacylglycerols (TAG) in the fat bodies of bumblebee males were studied using HPLC/MS. Two related species (*Bombus terrestris* and *B. lucorum*) were compared, with the age of the males being 0–30 days. The total amount of TAG in *B. lucorum* was about 2.7 times higher than that in *B. terrestris* for all of the ages studied. One to three-day-old males had the highest content of TAG in their fat bodies (1.6–2.3 mg/individual in *B. terrestris* and 3.8–4.2 mg/individual in *B. lucorum*). The analytical data show different patterns in both species. The qualitative composition of fatty acids in TAG was similar, but the mean relative abundance between *B. terrestris* and *B. lucorum* differed: 14:0, 7 and 14%; 16:0, 20 and 44%; 18:3, 62 and 23%; 18:1, 3 and 8%, respectively (the data is based on a GC/MS integration). A statistical evaluation of the dynamic changes in the TAG composition revealed that in *B. terrestris* different age classes were well separated according to their TAG composition while in *B. lucorum* the TAG did not change substantially during the male's life. The TAG analyses provide more precise information on the differences between the classes studied than the FA composition alone.

DA	Discriminant analysis

Introduction

The metabolism and management of the nutrients in insects take place in the fat body [1]. It is a relatively large organ unique to insects, which is distributed throughout the insect body, preferentially underneath the integument, and

surrounding the gut as well as the reproductive organs [2, 3]. The fat body is composed of adipocytes containing lipid droplets. Most of the energy stores are triacylglycerols (TAG) and carbohydrates (mainly glycogen); the latter serves as a fast energy source. Long-term storage is covered by TAG because of a higher caloric content per weight unit than that of glycogen. TAG provide a useful source of water upon oxidation, yielding almost twice as much metabolic water as glycogen does. These considerations have direct implications on the energy metabolism of insects [4]. TAG originate either from dietary fats or de novo biosynthesis. Newly-formed fatty acids (FA) are bound to the glycerol backbone by acyl transferases. The composition of the TAG depends both on the acyl transferase specificity and on the pool of available FA [5].

Lipids supply energy for flight and reproduction; they are crucial during starvation and stress. When needed, lipases in the fat body hydrolyze TAG to 1,2-diacylglycerols, which are bound to lipophorins in the hemolymph and transported to target tissues. The target cells unload diacylglycerols, hydrolyze them, and liberate FA. The FA act as a source of metabolic energy to meet the energy requirements of the insect. They are also essential precursors in the biosynthesis of many important compounds, including eicosanoids acting in reproduction or hormone signal transduction, cuticular hydrocarbons that protect insects from desiccating, or pheromones and other semiochemicals [6, 7].

Recently, we have studied the TAG composition in male fat bodies of several bumblebee species [8, 9] and found that TAG are species-specific. Our results on lipids and male-marking pheromones in particular bumblebee species have led us to a hypothesis on pheromone formation from lipidic precursors [10, 11]. In several species, the chain length and double-bond positions in FA seem to correlate with those in the pheromonal components (*B. lapidarius, B. pratorum, B. ruderatus, B. confusus, B. campestris* and *B. bohemicus*). Statistical evaluation of our previous analytical results has revealed a great similarity in TAG composition between closely related species, *B. terrestris* and *B. lucorum* [8, 9]. On the other hand, the male-marking pheromone of these species differs in its main components and only medium or minor components are shared [12, 13]. Furthermore, the dynamics in the pheromone production differ greatly; in *B. terrestris*, the pheromone is formed only during the first 5 days and stored for the rest of the male's life, whereas in *B. lucorum* the biosynthesis goes on for the male's entire life [14, 15]. In connection with our hypothesis on pheromone formation from lipidic precursors, the different ontogeny of the pheromonal gland in these closely related species raised the question of whether the fat bodies will follow a similar pattern. The present study therefore focuses on the temporal dynamics in TAG compositions in the fat bodies of *B. terrestris* and *B. lucorum* males.

Materials and Methods

Insect Material

Colonies of *Bombus lucorum* (L.) and *Bombus terrestris* (L.) were established by the two-queen cascade method [16]. All of the mother queens were taken from their natural habitats during the nest-searching period in order to minimize the possible negative influence of artificial conditions on the progeny. Bumblebee colonies were kept in plastic boxes with a volume of 0.6–1 L and fed with honeybee pollen pellets and concentrated sugar solution (sucrose: fructose 1:1). When the colonies started to produce males, male cocoons were removed from the parental hives and left to mature separately under the care of several workers supplied with food [16]. The freshly emerged males were removed and kept according to age. Animals of the following age were studied: *Bombus terrestris*: shortly after eclosion, 1, 2, 3, 4, 5, 7, 10, 12, and 24 days after eclosion (5 individuals of each age); *B. lucorum*: shortly after eclosion, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 25, and 30 days after eclosion (5 individuals of each age). The males were killed by freezing (−18 °C) and kept frozen prior to dissection. The abdomens were opened with fine scissors. The incision was made from the tip of the abdomen along the right side of the tergites and transversely back to the left side of the tergites at the upper end of the abdomen, so the cavity of the abdomen could be opened like a tin can. The digestive tract and genital organs including the accessory glands were removed. All of the other tissues (muscles, dorsal vessel, central nervous system) covered by peripheral fat body were removed with microsurgery forceps. The remaining fat was used for further analysis to minimize the loss of mass.

Chemicals

The TAG standards (99% purity) were purchased from Larodan Fine Chemicals (Malmö, Sweden) or Nu-Chek Prep (Elysian, MN, USA). Gradient grade methanol and hexane (Merck) were used as received; the other solvents (chloroform, diethyl ether, and 2-propanol) were distilled in glass from analytical-grade products. The 2,6-di-*tert*-butyl-4-methylphenol (butylated hydroxytoluene, BHT) and ammonium acetate were purchased from Fluka (Buchs, Switzerland).

Sample Preparation

The dissected fat bodies were transferred one by one into glass vials with 100 μL of a $CHCl_3/CH_3OH$ mixture (1:1, v/v) containing BHT (25 mg/mL). The samples were sonicated for 15 minutes and stored at −28 °C prior to TLC.

The isolation of the TAG from the fat body tissues using semipreparative TLC has been described previously [8]. Briefly, the tissue in the vial was crushed using a small glass stick, extracted several times with $CHCl_3$, and the combined total extracts were separated on TLC plates with hexane/diethyl ether/formic acid (80:20:1) as the mobile phase. The TAG zone was scraped off the plate and extracted with freshly distilled diethyl ether. The solvent was evaporated under an argon stream to dryness and the residues were weighed and reconstituted in chloroform to a concentration of 1%. The TAG samples were stored in sealed amber glass ampoules at −28 °C. For measuring the TAG age profile of the bumblebee males, we used five repetitions for each age class.

High Performance Liquid Chromatography/Mass Spectrometry

HPLC/MS analyses were performed on a system that consisted of a SMC 1000 vacuum membrane degasser, P 4000 gradient pump, SN 4000 control unit, LCQ classic ion-trap mass spectrometer (Thermo Finnigan, San Jose, CA, USA) (all of the instruments come from Thermo Separation Products, San Jose, CA, USA), and a personal computer with Xcalibur software (Thermo Finnigan). Manual injection was accomplished with a Rheodyne-type Model D injection valve (Ecom, Prague, Czech Republic) equipped with a 5 μL internal injection loop. A Labio RT 04 column thermostat (Labio, Prague, Czech Republic) served to maintain the column temperature at 30 °C. Two stainless-steel columns Nova-Pak C18 (300 × 3.9 mm, 150 × 3.9 mm, with a particle size of 4 μm; Waters, Milford, MA, USA) connected in a series were used. Non-aqueous reversed phase HPLC gradient separations were performed using acetonitrile (A) and 2-propanol (B) as the mobile phases. The gradient program was 0 min—100% A, with a flow rate of 1 mL/min; 108 min—30% A, 70% B, 1 mL/min; 122 min—20% A, 80% B, 0.7 mL/min; 127 min—100% A, 0.7 mL/min; 130 min—100% A, 1 mL/min. Ammonium acetate dissolved in 2-propanol/water (1:1) at a 100 mmol/L concentration was added post-column via a tee at a flow rate of 10 μL/min. These conditions are based on our previous work [17]. The atmospheric pressure chemical ionization (APCI) source was operated at 400 °C, where the heated capillary temperature was 200 °C and the corona discharge current was set to 4.5 μA. The full-scan mass spectra were recorded in the *m/z* range of 75–1,300. The mass spectra were interpreted with the aid of *TriglyAPCI* software [18]. Because of the different probabilities of FA loss during fragmentation, the relative intensities of the diacylglycerol ions provide regiospecific distribution information of the FA on the glycerol backbone. APCI-MS has not been demonstrated to be able to differentiate between diacylglycerol ions formed by the loss of *sn*-1 versus *sn*-3 FA. Therefore, one can distinguish FA bonded to the *sn*-2 position from those attached to the *sn*-1/*sn*-3 positions [19]. In this work, the FA in *sn*-2 positions are deduced from the diacylglycerol fragment with the least abundance. However, the intensity ratio depends also on the number and position of the double bonds in a particular FA. Therefore, if the TAG standards are not available, the positions of the FA on the glycerol backbone may be interpreted incorrectly [20]. The peak areas were calculated from reconstructed chromatograms for the $[M + H]^+$ and $[M + NH_4]^+$ ions (with the two added together).

Transesterification

The TAG fractions were transesterified using a method described earlier [21]. Briefly, the TAG were dissolved in $CHCl_3/CH_3OH$ (2:3, v/v) in a small glass ampoule. After adding acetyl chloride, the ampoule was sealed and placed in a water bath at 70 °C. This procedure prevents the loss of volatile FAME during transesterification. After 90 min, the ampoule was opened and the reaction mixture was neutralized with silver carbonate. After a brief centrifugation, the supernatant was directly analyzed by GC/MS.

Gas Chromatography/Mass Spectrometry

The FAME were analyzed to confirm the results of the TAG composition. The GC/MS analyses were performed using a Focus GC (Thermo) coupled with a MD800 quadrupole mass detector (Fisons). A non-polar DB-5 ms column (30 m × 0.25 mm i.d., with a film thickness of 0.25 μm; J&W Scientific, Folsom, CA, USA) was used. The injector was operated in the splitless mode at 220 °C. The detector temperature was set to 200 °C; the standard 70 eV spectra were recorded at 1 scan/s. The temperature of the GC oven was programmed as follows: 50 °C held for 1 min, 7 °C/min to 320 °C, held at 320 °C for 10 min. Helium was used as a carrier gas at 1 ml/min. The data were analyzed using the Xcalibur (ver. 2.0.7) program. The relative proportions of the FAME were estimated from the total ion current (TIC) integration.

Data Analysis

The data for both species were processed with multivariate exploratory tools to visualize and evaluate the chemical variability among the particular age classes. All of the analyses were performed in the Statistica 8 Package by Statsoft. The relative peak areas representing more than 1 relative percent (0.5% in the FAME analyses) in at least two individuals of at least one age group were selected and

standardized again to 100%. Then the relative percentages were subjected to an analysis of the principle components (PCA) to reduce the number of descriptive variables. The PCA allowed us to extract 7 factors explaining more than 92% of the variability in *B. terrestris* and 8 factors explaining more than 90% of the variability in *B. lucorum*. The factor scores for each individual and the selected factors were subsequently used to separate the age classes by means of discriminant analysis (DA) with the age class as a grouping variable. The dissimilarities between the age classes were evaluated using the matrix of the Mahalanobis distances, visualized using cluster analysis with the unweighted pair-group method with arithmetic mean (UPGMA).

Results

TAG Quantity

In both species, the amounts of TAG changed during the life with a high content in the first 5 days in *B. terrestris* and 7 days in *B. lucorum*, respectively (Fig. 1, Tables S1 and S2 in the Supplementary Material). The amount reached a maximum at 1–2 days in *B. terrestris* (2.3 mg/individual) and 2–3 days in *B. lucorum* (5.1 mg/individual). After that, a slowly decreasing trend was observed. In *B. terrestris*, the seven-day-old males contained around 50% of the highest amount. In very old males, approximately 10% of the highest values were left (Table S1). In *B. lucorum*, the observed trend was similar but with the amounts shifted to higher values and with higher age (Table S2). The amount of TAG in *B. lucorum* was about 2.2 times higher than that in *B. terrestris* for all of the ages studied. If we take into account the body weight, the *B. lucorum* males (an average weight of 222 mg) contained 2.7 times more TAG in the fat body than *B. terrestris* (with an average weight of 280 mg).

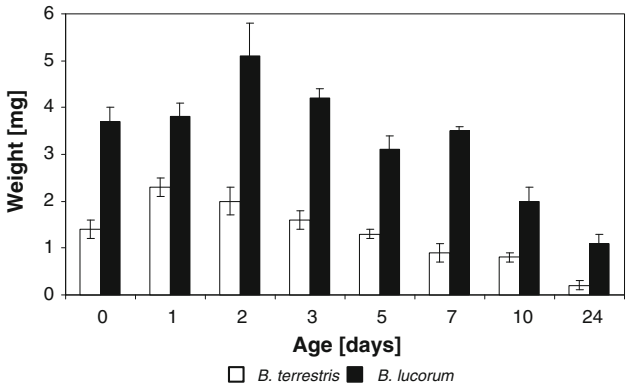

Fig. 1 The weight of the TAG (in milligrams) extracted from the fat bodies of males of different ages. The data represent the mean values of five specimens ± standard error

LC/MS Analysis of TAG

The main TAG in both species was POLn (10–20% in *B. terrestris* and 11–26% in *B. lucorum*; Tables S3 and S4 in the Supplementary Material). Other relatively abundant components differed. In *B. terrestris* these were OLnLn (3–14%) and LLL + OLLn (5–13%), whereas in *B. lucorum* POO (7–13%) and OOO (3–13%) were of relatively high abundance. A seemingly identical medium-abundant component turned out to be the isomeric TAG OLnO (12–19% in *B. terrestris*) and OOLn (9–18% in *B. lucorum*), based on the fragment intensities in mass spectra. A difference between the species was observed in the composition of the TAG with respect to the male's age. In *B. terrestris*, differences in TAG profiles were observed among young, mature, and old males (Fig. 2, left). The profiles of the old males were more complex than those of the younger ones. Interestingly, this was not the case in *B. lucorum*, where the TAG profiles were more or less stable during the male's entire life (Fig. 2, right). The variations within particular age classes were small in both species.

Regarding the particular compounds in the lipids of the specimens of different age (Tables S3 and S4 in Supplementary Material), all *B. lucorum* males as well as younger *B. terrestris* males differed only on a quantitative level. A statistical evaluation (PCA) led to the formation of data clusters separating several age classes in *B. terrestris* (Fig. 3). 1-, 2-, and 3-day-old males have very similar TAG profiles, 0-, 5-, and 10-day-old males are mixed together, and 7- and 12-day-old males are distinguished from other classes as well as from one another. The compounds responsible for the separation of the class of seven-day-old males were LLnLn, MoLnO, PLnLn, OLnLn, and LLL + OLLn. These components were significantly more abundant in TAG of seven-day-old males as compared to the other age classes. A clearly distinct class of old *B. terrestris* males (24 days) was characterized by the presence of several unique TAG: MoLL, LL20:4, XLLn, XLP, XOL, XOP, XOO, and XLnLn. The X moiety appears at a nominal mass of 15:2 FA, but its presence was not confirmed after transesterification and the FAME analysis. It is more likely that X belongs to an oxidation product. The fat body of old specimens is different from the younger ones. Its color is darker and the structure looks corrupted. Thus, some less stable FA may undergo oxidative processes in lipids of the old males [22].

No trend for grouping according to age classes was observed in *B. lucorum*. The TAG composition changes very little with age. The newborn class (0 days) is separated to some extent because of higher quantities of

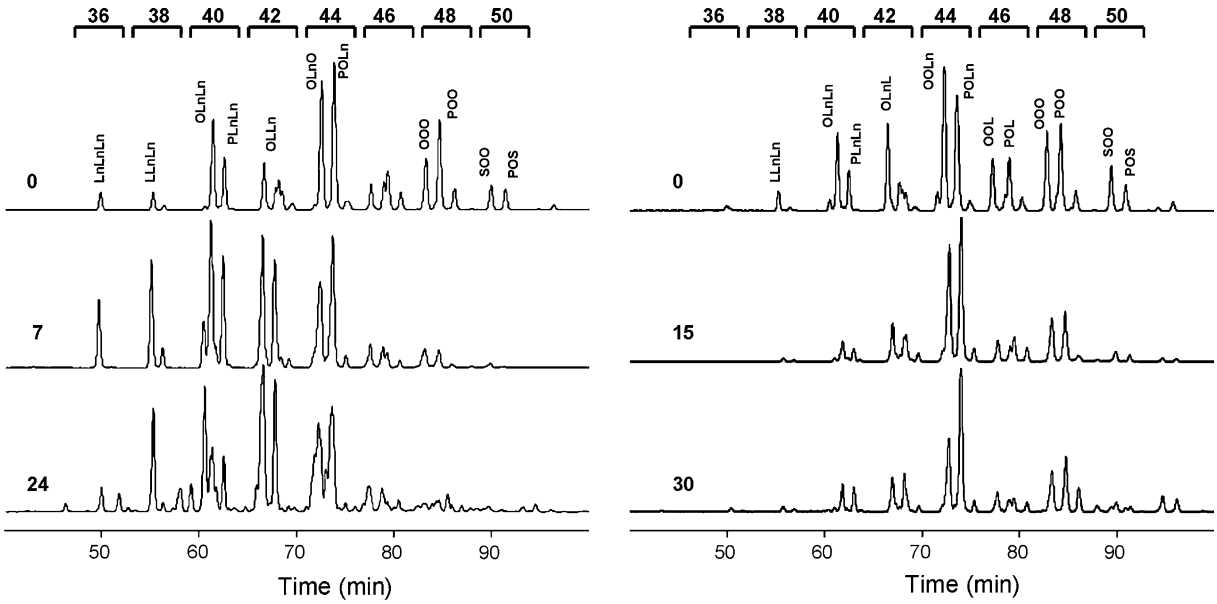

Fig. 2 The TIC chromatograms of the TAG of three age classes of *B. terrestris* males (0, 7 and 24 days, *left*) and *B. lucorum* males (0, 10 and 30 days, *right*). The numbers above chromatograms represent equivalent carbon numbers (ECN)

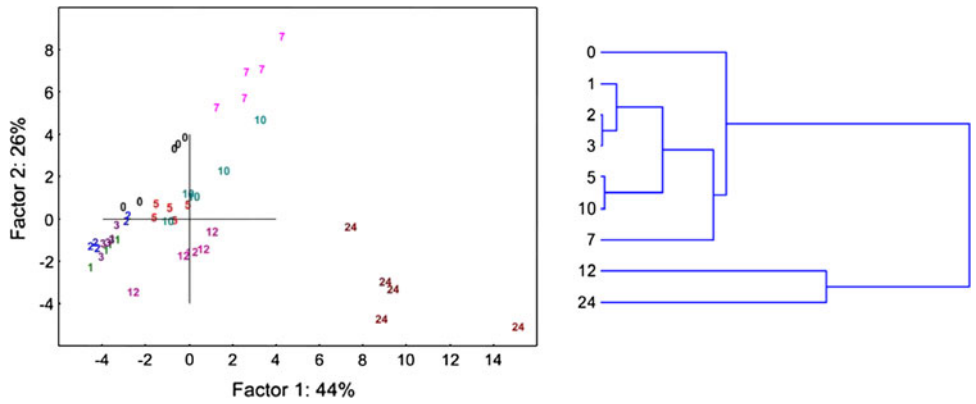

Fig. 3 A multivariate exploratory analysis of the data from the LC–MS analyses in *B. terrestris*. *Left* A graphic representation of the factor scores based on the first 2 principal components extracted from the PCA performed with the relative areas of the 43 most represented peaks. *Right* The patterns of the dissimilarities among the particular age classes inferred from the LC–MS analysis, visualized as a cluster tree based on the matrix of the Mahalanobis distances (UPGMA clustering)

LLnLn, PLnLn, SLnO, and POS in the TAG. At its developmental stage, the metabolism undergoes a lot of complex processes that may be responsible for a clear separation of this age class. A continuous shift from younger to older males (from right to left) can be seen in Fig. 4. However, in the cluster tree (Fig. 4, right), the age classes are distributed more or less randomly.

Our TAG quantifications are based on the integration of signal $[M + H]^+$ and $[M + NH_4]^+$ ions (summed together) from the MS detector. The post-column addition of ammonium acetate enabled us to visualize the TAG-bearing saturated FA (the $[M + H]^+$ fragment in these is very low or almost absent). The response factors (within a range of 0.4–2.8 according to the data published by Holčapek et al. [23]) were not taken into account. The aim of our study was a comparison of the TAG composition between insect species and age classes, not an absolute quantification that would have to be based on many standards and calibration curves. Even without an absolute quantification, we were able to compare the analyzed samples and see the differences.

GC/MS Analysis of Methyl Esters After Transesterification

At least three samples of each age class for both studied species were transesterified and the resulting FAME were

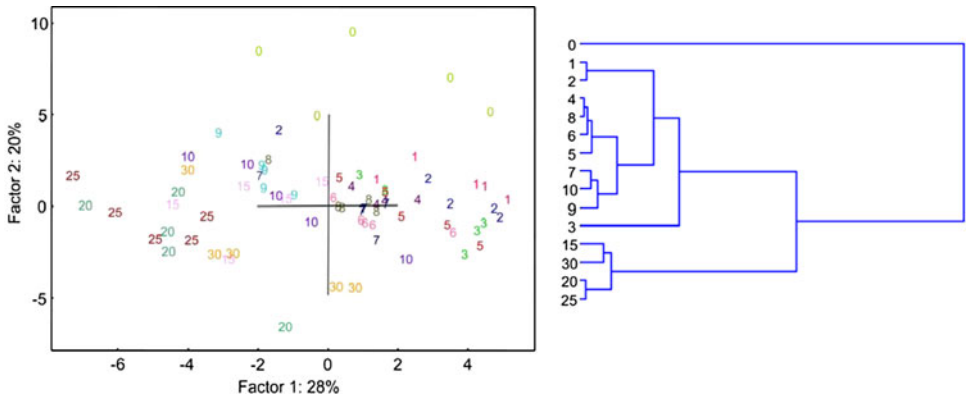

Fig. 4 A multivariate exploratory analysis of the data from the LC–MS analyses in *B. lucorum*. *Left* A graphic representation of the factor scores based on the first 2 principal components extracted from the PCA performed with the relative areas of the 34 most represented peaks. *Right* The patterns of the dissimilarities among the particular age classes inferred from the LC–MS analysis, visualized as a cluster tree based on the matrix of the Mahalanobis distances (UPGMA clustering)

analyzed using GC/MS. In both species, the FA with chain length of 16 and 18 carbon atoms dominate (Tables S5 and S6 in the Supplementary Material). The composition does not change much during the life of the males. For *B. lucorum,* lower amounts of unsaturated FA are characteristic; the *B. terrestris* samples contained up to twice as high amounts of unsaturated C18 FA than the *B. lucorum* ones.

The distribution of the FAME in the PCA plot (Fig. 5) in *B. terrestris* lipids shows only a slight tendency of grouping, much less pronounced than that with TAG (Fig. 3). The 24-day-old males are again far from the other samples. We can see from a comparison of Figs. 5 and 3 that an analysis of the TAG yields more information on species-specific lipids than an analysis of the FAME after transesterification. For *B. lucorum*, the PCA plot of FAME shows a similar distribution as the above-discussed TAG plot (Fig. 4). We can see small changes with increasing age. The FAME responsible for this trend are C16Me, C20:1Me, C20Me and C22Me. It corresponds to the LC/MS analyses, where the TAG containing these acids were present only in the old specimens. The species-specificity of the lipid composition can be seen in Fig. 5 as two well-separated groups, one for each species. The fine structure of the age classes is not so obvious in this plot.

Discussion

When we compare the results on TAG with our previous studies [8, 9] regardless of the *sn*-positions, we can see a high similarity. The small differences between the results may be caused by the use of another LC separation method [17]. The resolution of the peaks in this study is better than in the previous paper [8]. The overlapping peaks are thus resolved here and their integration differs. Furthermore, the insect specimens were different, and one has to take into account a natural variability of samples from living organisms. In addition, our threshold (1% for at least 2 samples per age group) can contribute to the difference. What differs more is the comparison of the *sn*-positions for each TAG. The abilities of reversed-phase chromatographic systems to separate regioisomers are limited. Although the general principles of the determination of *sn*-positions from mass spectra are known [19], the complexity of our biological samples prevents us from drawing unambiguous conclusions about the regioisomery of a particular molecular species. The use of silver-ion HPLC [24], particularly in the 2D arrangement [25], would certainly help, but such a detailed analysis of TAG is not required in this work. The TAG proportions in such a mixed peak can vary during the life of males. Therefore, significant conclusions should not be drawn from the *sn*-positions determined by this method.

During the life of the male, the TAG in the fat body undergo structural changes with some TAG dominating in young males and others in the older males despite the amounts of a particular FA remaining the same. According to the earlier literature, all insect lipids share the same FA composition based on 8 fatty acids, saturated, monounsaturated, and 2 polyunsaturated ones, 18:2 and 18:3 [26]. However, many exceptions from this rule have since been reported [27]. These exceptions may be the result of selective adaptations of different insect species. The two bumblebee species studied in this paper fall more or less into the pattern of the most common insect FA.

The polyunsaturated FA, 18:2 and 18:3, are highly abundant in both species; they dominate the FA of the *B. terrestris* fat body. It was generally accepted earlier that polyunsaturated FA (PUFA) are essential to animals and cannot be biosynthesized. Later, many authors demonstrated the ability of some insect orders to synthesize linoleic acid [27]. The literature data about the TAG

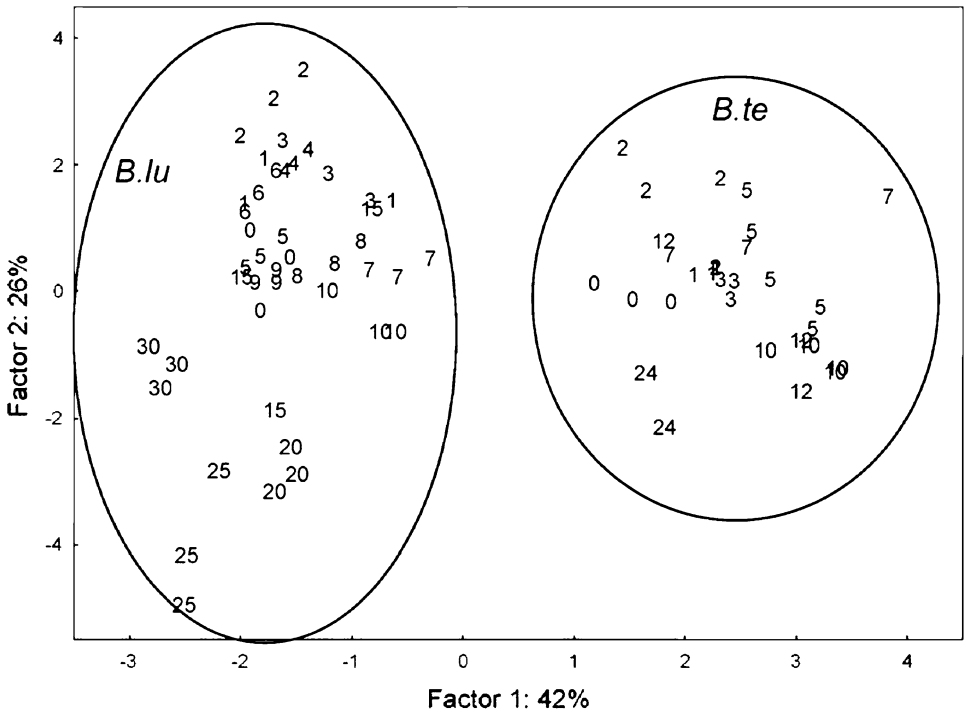

Fig. 5 A graphic representation of the factor scores based on the first two principal components extracted from the PCA performed with the relative areas of the FAME in *B. terrestris* and *B. lucorum* added together

composition in Hymenoptera are scarce. The TAG were studied on the prepupae of the leafcutting bee *Megachile rotundata* [28]. Their results show that about 76% of all of the FA are unsaturated, mainly 16:1 and 18:3. Such a high amount of unsaturated FA is probably connected to their adaptation for overwintering and a cold climate.

The composition of the TAG correlates with the FAME analysis except for the lauric acid. After transesterification, the proportion of this acid is not insignificant (0.7–3.5% in *B. terrestris* and 1.5–5.3% in *B. lucorum*). However, the amounts of those TAG containing La seem to be too low (LaOLn 1%; LaOP 1.2%, Table S3). These discrepancies arise from the fact that La is distributed in many small peaks that were cut off by the set threshold.

The fatty acids bound in the TAG are not only a pool of energy [2], but there is a great deal of evidence that they participate in the biosynthesis of the FA-derived sex pheromones in Lepidoptera and Diptera [29–31]. Lipophorin, the protein transporting diacylglycerols (DAG) in the hemolymph, is able to transport other molecules, too, such as TAG, free FA, sterols, carotenoids, and hydrocarbons [32]. Thus, the role of lipids as pheromone precursors has been demonstrated. In bumblebees, our recent results indicate that the male-marking pheromones, typically consisting of ethyl esters of fatty acids, may be formed from precursors bound in TAG in the fat body [10]. The original idea on the connection between a primary lipid metabolism and the patrolling male sex pheromone was based on an observation of the structural similarity of the lipids in the fat tissue and the labial gland extracts. The chain length, double-bond position, and geometry are the same, the putative lipid precursors only need to be transesterified or further modified to a labial-gland major component. Indeed, we have found lipase activity in the labial gland tissue in vitro trans-esterification (Jiroš et al., unpublished results). Assuming energy efficiency in nature, it seems to be unnecessary for bumblebees to invest in an enzymatic system producing the sex-pheromone component in the gland if a large pool of precursors has been produced already. The amounts of the pheromone stored in the gland are huge when compared to Lepidoptera (several milligrams per gland as reported by Žáček et al. [15]). Lepidopteran sex pheromones have double-bond positions, and their configuration is different from the fat lipids [33, 34]. The "trick" used by bumblebees is that the common fatty acid is esterified to uncommon ethyl esters, thus becoming a distinct pheromone signal.

In some species such as *B. pratorum, B. lapidarius, B. ruderatus, B. confusus, B. campestris,* or *B. bohemicus*, striking similarities were found in the chain length and double-bond positions of some FA in the TAG and the pheromonal components [10, 11]. We have shown in our previous study that the TAG compositions in fat bodies of bumblebee males are species-specific [9]. However, no attention has been paid to the influence of the age of the specimens studied on the TAG composition. Reports exist in unrelated insects (moths, beetles or fruit flies) on the changes of the FA pattern at various stages of development [35–37]. We have shown here that such changes exist in bumblebees even within one developmental stage (adult

males) depending on the age of the specimens. These changes must be based on the males' physiology, as their diet was a standard one, identical in both species and in all age classes.

B. terrestris and *B. lucorum* males differ in the temporal dynamics of the physiological activity of the pheromone gland and consequently in the time-related production of the marking pheromone [14, 15]. While in *B. terrestris* the pheromone is produced up to the fifth day of a male's life and then stored in the gland, in *B. lucorum* the pheromone biosynthesis goes on for the male's entire life. Our finding on the lipid composition as a result of the fat-body development correlates with the earlier published ontogeny of the pheromonal gland: it confirmed significant changes of the TAG composition with age in *B. terrestris* as opposed to *B. lucorum*, where the TAG did not significantly differ with the males' age.

It could still be possible that de novo synthesis is additionally involved, perhaps for a tighter regulation of its production. It has been shown in leaf beetles that different strategies for producing allomonal compounds are related to its evolution. The older species are sequestering the host plant-related compounds while the more evolved species produce those or similar compounds de novo. The insects can even switch between the two pathways according to the conditions and availability of precursors [38]. In bumblebees, we still do not have clear evidence disproving our original schemes of how the male-marking pheromones are produced. The analytical results on fat-body TAG do not support our above-mentioned hypothesis showing anticipated higher levels of particular TAG as possible precursors. Thus, the biosynthesis of the male-marking pheromone will be a more complex process than so far believed.

Acknowledgments The financial support of the Czech Science Foundation (Project 502/10/1734) is herewith acknowledged with appreciation. The research was also carried out as a part of Project No. Z4 055 0506 (Academy of Sciences of the Czech Republic). The authors are deeply indebted to Prof. Vladimír Ptáček for the insect material, Dr. Ales Svatoš for his valuable advice and Mr. Sean Mark Miller for language correction.

COMMUNICATION

Efficient and Specific Conversion of 9-Lipoxygenase Hydroperoxides in the Beetroot. Formation of Pinellic Acid

Mats Hamberg · Ulrika Olsson

Received: 31 May 2011 / Accepted: 24 June 2011 / Published online: 10 July 2011

Abstract The linoleate 9-lipoxygenase product 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid was stirred with a crude enzyme preparation from the beetroot (*Beta vulgaris* ssp. *vulgaris* var. *vulgaris*) to afford a product consisting of 95% of 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid (pinellic acid). The linolenic acid-derived hydroperoxide 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid was converted in an analogous way into 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*),15(*Z*)-octadecadienoic acid (fulgidic acid). On the other hand, the 13-lipoxygenase-generated hydroperoxides of linoleic or linolenic acids failed to produce significant amounts of trihydroxy acids. Short-time incubation of 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid afforded the epoxy alcohol 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid as the main product indicating the sequence 9-hydroperoxide → epoxy alcohol → trihydroxy acid catalyzed by epoxy alcohol synthase and epoxide hydrolase activities, respectively. The high capacity of the enzyme system detected in beetroot combined with a simple isolation protocol made possible by the low amounts of endogenous lipids in the enzyme preparation offered an easy access to pinellic and fulgidic acids for use in biological and medical studies.

Introduction

The first characterization of unsaturated trihydroxy oxylipins was published by Graveland in 1970 [1]. In this study, lipoxygenase-catalyzed oxygenation of linoleic acid in doughs and flour–water suspensions afforded hydroperoxides, hydroxides and epoxy alcohols as well as a fraction consisting of a mixture of 9,12,13-trihydroxy-10-octadecenoic and 9,10,13-trihydroxy-11-octadecenoic acids. Although separation of the regio- and stereoisomeric trihydroxyoctadecenoates was not achieved, it could be concluded that the 9,12,13-trihydroxy isomer was the dominating one and further be deduced that this compound originated in linoleic acid 9-hydroperoxide (9-HPODE). Eight stereoisomers (four pairs of enantiomers) of 9,12,13-trihydroxy-10-octadecenoic acid are possible because of the three chiral carbons at C-9, C-12 and C-13. In 1991, two studies demonstrated that naturally occurring 9,12,13-trihydroxy-10-octadecenoic acid has the

9(*S*),12(*S*),13(*S*) configuration [2, 3]. More recently, 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid was isolated from tubers of *Pinellia ternata* (crow-dipper), and the trivial name *pinellic acid* was given to the compound [4]. The $\Delta^{15(Z)}$-unsaturated analog of pinellic acid, *i.e.* fulgidic acid, has also been described [5].

Biosynthesis of pinellic acid in plants can take place by lipoxygenase-catalyzed oxygenation of linoleic acid into 9(*S*)-HPODE, which can be further converted into the epoxy alcohol 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid in the presence of epoxy alcohol synthase (EAS) [6, 7] or peroxygenase [8]. Pinellic acid is formed from the epoxy alcohol by action of epoxide hydrolase activity, which catalyzes regio- and stereospecific opening at C-12 of the C-12/C-13 epoxide [7, 8]. Also linoleic acid 13-hydroperoxide (13-HPODE) can be converted to 9,12,13-trihydroxyoctadecenoates as shown in chemical model systems [9, 10].

Pinellic acid and other trihydroxyoctadecenoates are produced in plants during wounding and infection by fungal pathogens [11–13]. Interestingly, such trihydroxy oxylipins inhibit growth of fungi and germination of spores [12, 13] and may play a role in plants' defense against pathogenic fungi. Further interest in trihydroxyoctadecenoates stems from their presence in beer [3, 14, 15], in which beverage they may contribute a bitter taste [16]. More recent studies on pinellic acid are focussed on the use of this trihydroxy oxylipin as an oral adjuvant for nasal influenza vaccines [4, 17–19].

The present paper describes a new EAS-epoxide hydrolase pathway in the beetroot by which 9-lipoxygenase-generated fatty acid hydroperoxides are converted into specific trihydroxy acids. Based on the results, a procedure for easy preparation of pinellic acid of >99.5% stereochemical purity was elaborated. This enzymatic approach offers an alternative to earlier described preparations of pinellic acid by organic chemical synthesis [17, 20–23].

Experimental Procedures

Fatty Acid Hydroperoxides

9(*S*)-HPODE, 13(*S*)-HPODE, 9(*S*)-HPOTrE and 13(*S*)-HPOTrE were prepared by lipoxygenase-catalyzed oxygenation of linoleic or linolenic acids [7] followed by purification by straight-phase high-performance liquid chromatography (SP-HPLC). [1-^{14}C]9(*S*)-HPODE (specific radioactivity 15.1 kBq/μmol) was prepared in the same way starting with [1-^{14}C]linoleic acid (Perkin-Elmer, Boston, MA).

Reference Oxylipins

Regio- and stereoisomeric epoxy alcohols including methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate were prepared by incubating fatty acid hydroperoxides with peroxygenase from broad bean or oat seeds followed by isolation by SP-HPLC [7]. 9(*S*),12(*S*),13(*S*)-Trihydroxy-10(*E*)-octadecenoic acid (pinellic acid), 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*),15(*Z*)-octadecadienoic acid (fulgidic acid) and other isomeric trihydroxy oxylipins were prepared from linoleic and linolenic acids as described in detail [7].

Enzyme Preparation

Beetroots (red beets) obtained from a local market were peeled and the flesh portion finely diced in 6 volumes/weight of ice-cold 0.1 M phosphate buffer pH 6.7. The mixture was homogenized at 0 °C for 3 × 30 s using a Polytron and then filtered through gauze. The filtrate was used for all preparative incubations with fatty acid hydroperoxides. For ultraviolet (UV) spectrophotometric assay, the filtrate was diluted 1:7.7 (v/v) with 0.1 M phosphate buffer pH 6.7.

Incubations and Treatments

For generation of oxidation products for structural work, fatty acid hydroperoxides (300 μM) were stirred with enzyme preparation (5 mL) at 23 °C for 5 or 30 min. The mixtures were acidified to pH 5 and rapidly extracted with 75 mL of diethyl ether. Material obtained after evaporation of the solvent was methyl-esterified by treatment with diazomethane and either analyzed by SP-HPLC or trimethylsilylated and analyzed by gas–liquid chromatography-mass spectrometry (GC–MS) or gas–liquid chromatography with flame-ionization detection (GLC-FID).

Preparation of Pinellic Acid (free acid form of compound **II**)

A typical preparation of pinellic acid (batches of 15–20 mg) was carried out as follows. Beetroots were peeled and the flesh portion finely diced (40 g). Potassium phosphate buffer (240 mL) was added, and homogenization was performed at 0 °C using a Polytron. Following filtration through gauze, 179 mL of the filtrate was stirred with 500 μM 9(*S*)-HPODE (27.9 mg) at 23 °C for 1 h. The incubation mixture was acidified to pH 3 and extracted with ethyl acetate. The extracted product (53 mg) was dissolved in 3 mL of 2-propanol/chloroform 1:2 (v/v); this solution was divided and loaded on two 0.5-g aminopropyl cartridges (Supelco, Bellefonte, PA). Neutral lipids were eluted with 6 mL of the

same solvent mixture, whereas pinellic acid was obtained by elution with 15 mL of ethyl acetate/acetic acid 98:2 (v/v). The latter eluates from the two columns were combined and taken to dryness affording a white solid (23.6 mg; yield, 80%). Analysis of this material by GC–MS and GLC-FID revealed 97% trihydroxyoctadecenoate and 3% other materials (mainly 9-HODE). Regio- and stereochemical analysis of the trihydroxyoctadecenoate [24] showed 98% 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid (pinellic acid) and 2% of other isomeric trihydroxyoctadecenoates. An aliquot of this material was crystallized from methanol/diethyl ether to provide pinellic acid, >99.5% pure according to GC–MS and GLC-FID, m.p. 105.5–106.5 °C (earlier reported, 104–106 °C [17, 21]).

Instrumental Methods

For SP-HPLC, a column of Nucleosil 50-5 (200 × 4.6 mm) purchased from Macherey–Nagel (Düren, Germany) was used. The column effluent was passed through serially connected detectors for measurement of UV absorbance (210 or 234 nm) and radioactivity. For isolation of methyl esters of epoxy alcohols and trihydroxy acids, solvent systems of 2-propanol/hexane (1.5:98.5, vol/vol) and 2-propanol/hexane (7:93, vol/vol), respectively, were used. The flow rate was 2 mL/min.

For GC–MS, a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph equipped with a 12-m phenylmethylsilicone capillary column was used.

GLC-FID was carried out with a Hewlett-Packard model 5890 gas chromatograph equipped with a flame-ionization detector and a 25-m methyl silicone capillary column. Helium at a flow rate of 25 cm/s was used as the carrier gas. Retention times were converted into C-values as described [25].

UV spectra were recorded on a Hitachi (Tokyo, Japan) model U-2000 UV/VIS instrument. Assay of EAS activity was performed by continuous measurement of the absorbency at 235 nm.

^{1}H-NMR spectra were recorded on deuteriochloroform solutions using a Bruker 400 MHz instrument. Tetramethylsilane was used as internal chemical shift reference.

Chemical Methods for Structure Determination

Catalytic hydrogenation of epoxy alcohols and trihydroxyesters [26], oxidative ozonolysis [27], and acid-promoted hydrolysis of allylic epoxy alcohols [24] were performed as indicated. Steric analysis of epoxy alcohols and trihydroxyesters was carried out as described in detail [24].

Results and Discussion

Isolation of oxidation products

[1-^{14}C]9(*S*)-HPODE (300 μM) was stirred at 23 °C for 30 min with the enzyme preparation from beetroot, and the methyl-esterified product was subjected to SP-radio-HPLC. A major peak of radioactivity due to compound **II** appeared (95% of the chromatographed radioactivity) (Fig. 1b). Reducing the time of incubation to 5 min resulted in lower formation of compound **II**, and instead the less polar compound **I** was the main product (Fig. 1a).

Incubation of 9(*S*)-HPOTrE (300 μM) with enzyme preparation for 30 min followed by extraction, methyl-esterification and isolation by SP-HPLC afforded the trihydroxyester compound **III** (>90%). As described for 9(*S*)-HPODE, when the incubation time was reduced to 5 min, the yield of compound **III** was lowered, and instead an epoxy alcohol methyl ester was the main product; this however, was not further characterized.

Structure of Compound I

No absorption band in the range 210–300 nm was observed in the UV spectrum of compound **I** demonstrating the disappearance of the conjugated diene of the incubated 9(*S*)-HPODE. On SP-HPLC, compound **I** comigrated with methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate, suggesting the identity of compound **I** with this epoxy alcohol or an isomer thereof. The mass spectrum of the Me_3Si derivative of compound **I** showed a molecular ion at *m/z* 398 (relative intensity, 2%) and further ions at *m/z* 383 (3; M^+—15; loss of $\cdot CH_3$), 259 [18; Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$], 241 [87; M^+ - 157; loss of $\cdot(CH_2)_7$-$COOCH_3$], 225 (21), 99

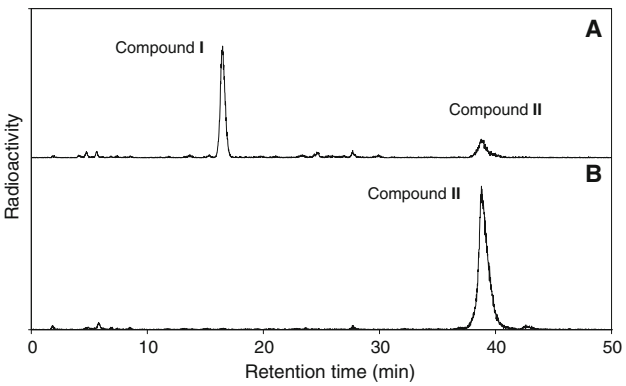

Fig. 1 SP-radio-HPLC analysis of methyl-esterified incubation products obtained after incubation of [1-^{14}C]9(*S*)-HPODE (300 μM) with enzyme preparation (5 mL) from beetroot. **a** Incubation at 23 °C for 5 min. **b** Incubation at 23 °C for 30 min. The column was eluted with 2-propanol/hexane (1.5:98.5, vol/vol) (0–20 min) followed by 2-propanol/hexane (7:93, vol/vol) (20–50 min) at a flow rate of 2 mL/min

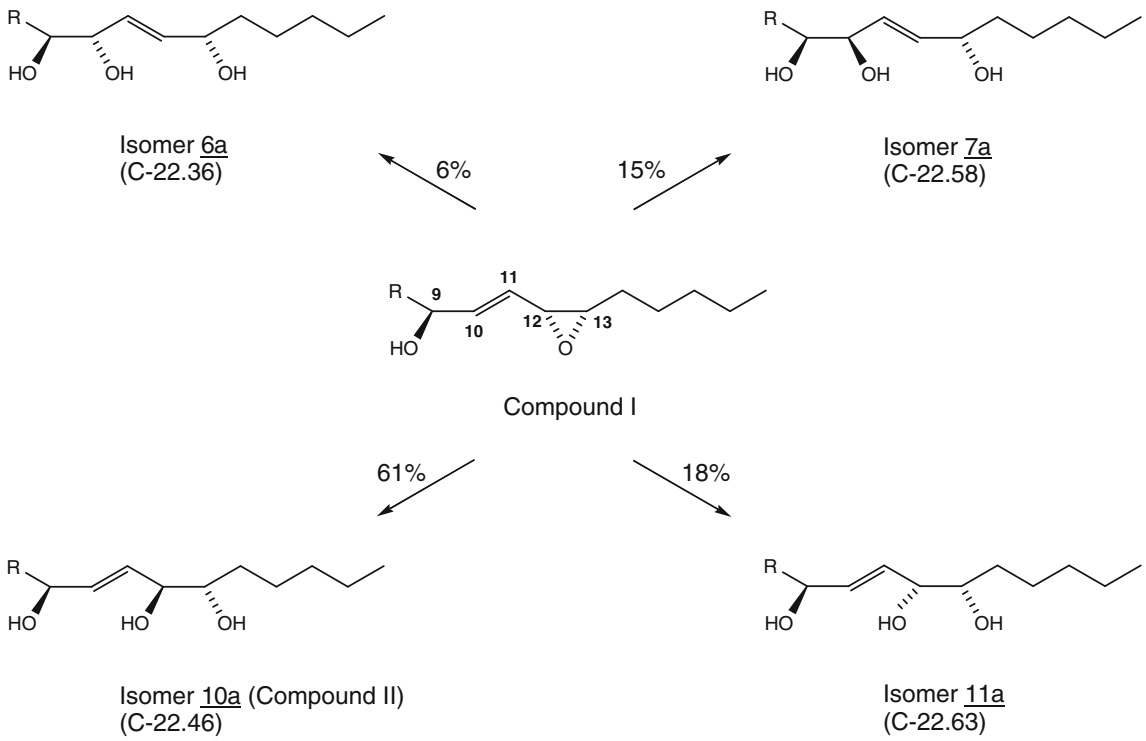

Scheme 1 Structures, percentages and C-values of isomeric trihydroxyesters produced upon acid-catalyzed hydrolysis of compound **I**. Numbering of trihydroxyesters corresponds to numbers used in Ref. [24]. R = $(CH_2)_7$-$COOCH_3$

[100; $^+O{\equiv}C$-$(CH_2)_4$-CH_3], and 73 (80; Me_3Si^+), thus indicating the presence of an epoxide group at C-12/C-13 and a hydroxyl group at C-9. The mass spectrum and C-value were identical to those of the Me_3Si derivative of authentic methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate [7]. Oxidative ozonolysis performed on the (-)-menthoxycarbonyl (MC) derivative of compound **I** followed by methyl-esterification afforded the MC derivative of dimethyl 2(*S*)-hydroxy-1,10-decanedioate, in this way demonstrating the presence of a double bond in the Δ^{10} position and showing that the C-9 alcohol had the "*S*" configuration. Oxylipins possessing an allylic epoxy alcohol structure undergo facile hydrolysis into predictable patterns of trihydroxyesters under mildly acidic conditions [10, 24], and accordingly a sample of 1 mg of compound **I** was treated with methanol/1 mM hydrochloric acid (1:50, v/v) at 23 °C for 10 min. Regio- and stereochemical analysis [24] of the resulting trihydroxyesters (Me_3Si derivatives) by GC–MS and GLC-FID revealed the presence of the following compounds (abundance, C-value, numbering according to Ref. [24]): methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (61%, C-22.46, isomer 10a), methyl 9(*S*),12(*R*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (18%, C-22.63, isomer 11a), methyl 9(*S*),10(*R*),13(*S*)-trihydroxy-11(*E*)-octadecenoate (15%, C-22.58, isomer 7a), and methyl 9(*S*),10(*S*),13(*S*)-trihydroxy-11(*E*)-octadecenoate (6%, C-22.36, isomer 6a) (Scheme 1). Acid treatment of authentic methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate produced an identical result, thus conclusively demonstrating the identity of compound **I** with this epoxy alcohol.

Structure of compound **II**

The mass spectrum of the Me_3Si derivative of compound **II** showed ions at *m/z* 545 (0.4%; M^+-15; loss of $\cdot CH_3$), 460 [15; M^+-100; rearrangement with loss of OHC-$(CH_2)_4$-CH_3], 439 [2; $M^+-(31+90)$; loss of $\cdot OCH_3$ plus Me_3SiOH], 387 (4; M^+ - 173; loss of $\cdot CH(OSiMe_3)$-$(CH_2)_4$-CH_3), 259 [16; Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$], 230 [5; rearrangement with loss of OHC-CH = CH–$CH(OSiMe_3)$-$CH(OSiMe_3)$-$(CH_2)_4$-CH_3], 173 [100; Me_3SiO^+=CH-$(CH_2)_4$-CH_3], 147 (11; Me_3Si-O^+=$SiMe_2$), 103 (11; Me_3SiO^+=CH_2), and 73 (69; Me_3Si^+), thus indicating a 9,12,13-trihydroxyoctadecenoate. The C-value (22.46) was identical to that of the corresponding derivative of authentic methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate but differed from those of other possible trihydroxyoctadecenoate isomers (*cf.* Ref. [24]). Oxidative ozonolysis performed on the tris-MC derivative of compound **II** followed by methyl-esterification afforded the MC derivative of dimethyl 2(*S*)-hydroxy-1,10-decanedioate, thus locating the double bond to the Δ^{10} position and assigning the "*S*" configuration to C-9. ^{1}H-NMR spectral data of compound **II** are given in Table 1. The coupling constant observed for the

Table 1 ^{1}H-NMR data for compound **II**

Proton	δ (ppm)	Multiplicity	J (Hz)
2	2.31	t	7.4
3	1.62	m

Recorded at 400 MHz in $CDCl_3$ with tetramethylsilane as internal chemical shift reference

olefinic protons at C-10 and C-11 (J = 15.5 Hz) confirmed that the Δ^{10} double bond had the "*E*" configuration. Final identification of compound **II** as methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (methyl ester of pinellic acid) was provided by melting point data, *i.e.* 92.0–92.5 °C; earlier reported 92.5–93.0 °C [21].

Structure of Compound **III**

The trihydroxyester formed following incubation of 9(*S*)-HPOTrE gave analytical results identical to those previously recorded for methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*),15(*Z*)-octadecadienoate (methyl ester of fulgidic acid) with regard to C-value and mass spectrum [7]. Proof for the identity of compound **III** with this oxylipin, i.e., the $\Delta^{15(Z)}$-unsaturated analog of compound **II**, was provided by results of catalytic hydrogenation, which produced methyl 9(*S*),12(*S*),13(*S*)-trihydroxyoctadecanoate, and oxidative ozonolysis, which produced methyl hydrogen 2(*S*)-hydroxy-1,10-decanedioate (cf. Ref. [7]).

Substrate Specificity of the Beetroot EAS Activity

As described above, 9(*S*)-HPODE and 9(*S*)-HPOTrE were both rapidly converted when added to the enzyme preparation from beetroot. However, neither 13(*S*)-HPODE nor 13(*S*)-HPOTrE were similarly converted as judged by analysis of the incubation products by SP-HPLC or GC–MS. In order to further study this point, UV spectrophotometric assays of the rate of hydroperoxide consumption by the beetroot enzyme preparation were performed. As seen in Fig. 2, a rapid disappearance of the conjugated diene chromophore absorbing at 235 nm was noted for the two 9-hydroperoxides, whereas the two 13-hydroperoxides were essentially stable during the incubation period.

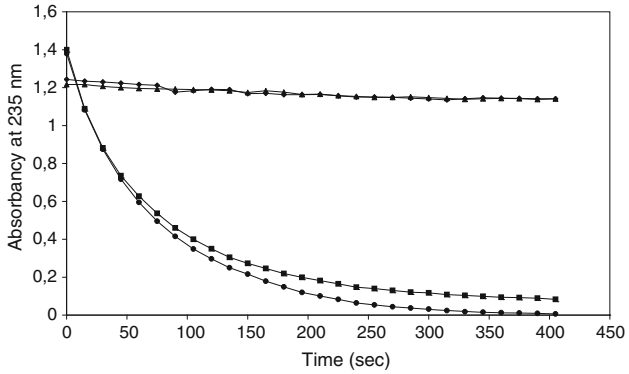

Fig. 2 UV-spectrophotometric assay of hydroperoxidase activity in the beetroot. Enzyme preparation diluted 1:7.7 (v/v) with potassium phosphate buffer pH 6.7 (2 mL) was treated at 23 °C with the following fatty acid hydroperoxides: 9(*S*)-HPODE (51 μM; *filled circles*), 9(*S*)-HPOTrE (52 μM; *filled squares*), 13(*S*)-HPODE (46 μM; *filled diamonds*), and 13(*S*)-HPOTrE (45 μM; *filled triangles*). The absorbance at 235 nm was monitored versus time

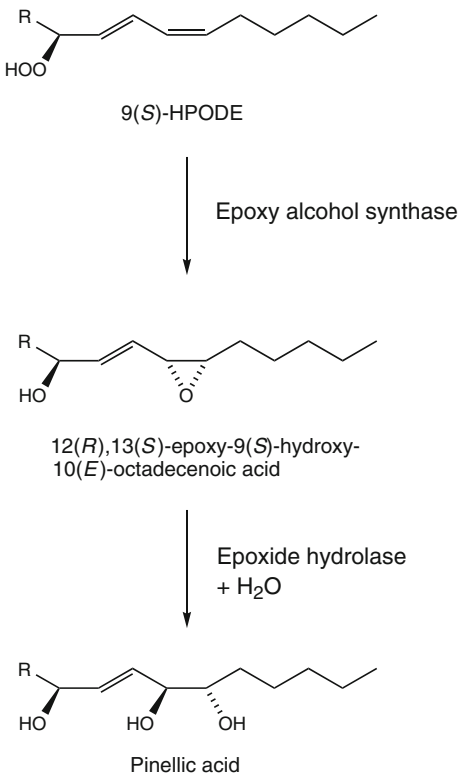

Scheme 2 Sequence of reactions in the conversion of 9(*S*)-HPODE into pinellic acid (free acid form of compound **II**). R = $(CH_2)_7$-COOH

Conclusion

Beetroot contains a strong EAS activity, which is active on linoleic and linolenic acid 9-hydroperoxides, as well as an epoxide hydrolase activity, which stereospecifically converts the epoxy alcohol produced into a trihydroxy acid

(Scheme 2). The former activity is reminiscent of the EAS enzymes earlier studied in the fungus *Saprolegnia parasitica* [6] and in potato leaves [7], however, whereas these enzymes produce two isomeric epoxy alcohols from each hydroperoxide, the beetroot EAS forms a single one. A related conversion has been studied using an enzyme preparation from oat seeds, in which case the EAS activity was due to a peroxygenase [8]. The epoxide hydrolase activity found in beetroot appears to be related to similar activities earlier found in potato leaves [7] and oat seeds [8].

The nature of the beetroot EAS and epoxide hydrolase is currently under investigation and the results will be reported shortly. Meanwhile, the high catalytic activities of the two enzymes, combined with an uncomplicated protocol for product isolation, offer a practical way to prepare considerable amounts of pinellic and fulgidic acids.

Acknowledgments The expert technical assistance of Mrs. G. Hamberg is gratefully acknowledged. This work was supported by a grant from the Swedish Research Council (project 2009-5078).

Abstract LipidomeDB Data Calculation Environment (DCE) is a web application to quantify complex lipids by processing data acquired after direct infusion of a lipid-containing biological extract, to which a cocktail of internal standards has been added, into an electrospray source of a triple quadrupole mass spectrometer. LipidomeDB DCE is located on the public Internet at http://lipidome.bcf.ku.edu:9000/Lipidomics. LipidomeDB DCE supports targeted analyses; analyte information can be entered, or preformulated lists of typical plant or animal polar lipid analytes can be selected. LipidomeDB DCE performs isotopic deconvolution and quantification in comparison to internal standard spectral peaks. Multiple precursor or neutral loss spectra from up to 35 samples may be processed simultaneously with data input as Excel files and output as tables viewable on the web and exportable in Excel. The preformulated compound lists and web access, used with direct-infusion mass spectrometry, provide a simple approach to lipidomic analysis, particularly for new users.

Introduction

Lipidomics is a developing strategy for functional genomics. Characterizing large numbers of mutants or the results of experimental manipulations applied to large numbers of samples is becoming increasingly feasible. Triple quadrupole (QqQ) mass spectrometers are robust and widely available instruments, and their ability to isolate a signal stemming from the subset of a sample's molecules that produce a specific pair of mass/charge (*m/z*) values provides detection specificity for lipidomic analysis. Direct-infusion QqQ mass spectrometry (MS), using precursor and neutral loss scans, as originally proposed by Brügger et al. [1], offers many advantages as a lipidomics platform. Direct infusion, in comparison to introducing samples through a liquid chromatography interface, is more easily implemented and allows for the rapid analysis of many samples. Another, less recognized advantage of

direct-infusion is that the continuous influx of sample allows the user to adjust the scanning time to improve signal detection, without concern for elution time. However, a potential bottleneck in the implementation of any lipidomic strategy is the ability to process the data into quantitative lipid profiles. In particular, new users need a simple approach, and many users need to be able to process large data sets.

A number of tools for analysis of mass spectral data from lipids have been developed. Tools designed for direct-infusion QqQ MS analysis include the algorithm developed by Kurvinen et al. [2], LIMSA [3, 4], and the method developed by Ejsing et al. [5], LipidQA [6] and AMDMS-SL [7]. Each tool is capable of lipid quantification from direct infusion QqQ mass spectral data, and each has special features. Some have the ability to combine data from multiple spectra for identification and analysis of lipids at the true molecular species level [5–7]. Some provide for visualization and statistical analysis of the output data [2–5].

Here we describe a new tool for mass spectral data analysis for lipidomics. The strength of LipidomeDB Data Calculation Environment (DCE) is its ability to rapidly and simultaneously analyze multiple spectra from up to 35-sample input in one step. It differs from currently available tools in being on the web. It provides pre-formulated lists of target lipid analytes, including lists for plant lipids, and can accept user-defined target analyte lists.

Materials and Methods

Programming

LipidomeDB DCE has a web interface and a database backend (called LipidomeDB), and scripts to read and perform calculations on input data provided in Excel format. LipidomeDB is a MySQL database that stores the defined lipid species and formulas, and the users' experimental data. Much of the LipidomeDB DCE is coded in JSP. The user interface is implemented primarily in JSP with Javascript used to perform client-side computations, such as those related to isotopic abundances, and with Java used for server-side data analysis, such as searching the database for target lipid species matching uploaded data with the target species lists, and isotopic deconvolution.

Input Spectral Data

The input data are spectral peak lists acquired by precursor or neutral loss scanning, typically using a triple quadrupole mass spectrometer in the multiple channel analyzer (MCA) mode (a mode that averages or sums the signal from multiple scans to produce a spectrum). Data processing, i.e., baseline subtraction, smoothing and centroiding (or integration), are performed with the mass spectrometer's acquisition software. Spectra, each as a list of *m/z* versus signal, are exported from the acquisition program to Excel files for upload to LipidomeDB DCE. AB Sciex programmers have written a script, called "Multiple Period Processing," that exports data in the proper format; however, the format may be replicated manually or through other scripts. The format of the Excel spreadsheets for upload is specified in the documentation accompanying LipidomeDB DCE, and example files are provided.

Algorithms and Functions

Algorithms and functions are described briefly below. Full details are provided in the documentation (tutorial) for LipidomeDB DCE accessed from its home page: http://lipidome.bcf.ku.edu:9000/Lipidomics.

Target Lipid Information

The mass of target lipids and abundances of their isotopic variants are calculated from the chemical formula by adding the masses of the component atoms. The adduct formed by the target lipids is specified by the user. Possible adduct choices, in the negative mode, are $[M - H]^-$, $[M-CH_3]^-$, $[M + Cl]^-$ and $[M + C_2H_3O_2]^-$ (i.e., $[M +$ acetate$]^-$), and in the positive mode, $[M + H]^+$, $[M + NH_4]^+$, $[M + Li]^+$, $[M + Na]^+$ and $[M + K]^+$.

Lipid Search

The peaks corresponding to specified adduct ions of the internal standards and target lipids are located in the input data by *m/z*, and the value of each corresponding signal is collected. Any mass that is within the specified mass tolerance window (specified compound mass ± the mass tolerance) is considered a candidate mass for the specified target lipid or internal standard. The search algorithm provides three options, in case multiple masses are found within the mass tolerance window. The three options are: "Nearest Mass," which selects the *m/z* closest to the lipid ion's *m/z*, "Highest Signal," which selects the *m/z* having the highest corresponding signal value, and "Sum of Signals," which sums signals within the specified mass tolerance target window.

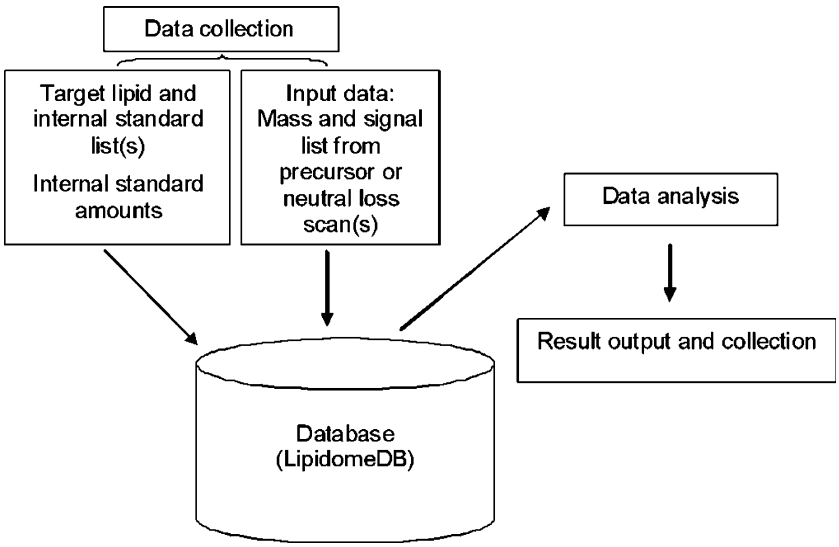

Fig. 1 Scheme indicating the workflow of the system and relationships of the three phases of LipidomeDB DCE: data collection, data analysis, and result output and collection

Isotopic Deconvolution (Correction) of Signal and Lipid Analyte Quantification

Quantification is essentially the method described by Brügger et al. [1] and used in the LIMSA analytical tool [3, 4]. Isotopic deconvolution to remove signals because of "A + 1" and "A + 2" isotopic variants (in LipidomeDB DCE, called a_1 and a_2), in order to detect the "A" peaks of other compounds at the same nominal mass, is performed in a manner similar to the "subtraction" method in the LIMSA analytical tool [3].

After the corrected signals are established by deconvolution, the amount of each target lipid is calculated. The amount is calculated from the corrected signals for the target lipids, the signals for 1–3 internal standards and the corresponding internal standard amounts specified by the user. A linear calibration curve (signal vs. *m/z*) fits the signals of the internal standards [3] and is used to correct for mass-dependent variation in instrument response. If any internal standard is not detected, an error message appears on an output page for the individual spectrum (i.e., the spectrum for one target list and one sample); if this error is present, the target analytes are not quantified in the sample with the missing standards. If the internal standards are detected, data calculations are shown on the output page for the individual spectrum.

Results and Discussion

The primary function of LipidomeDB DCE is to search for *m/z* and signal for entered target lipid species in integrated (centroided) mass spectra uploaded by the user, to isotopically deconvolute the signals, and to quantify the signals in comparison to internal standard signals and amounts, in order to calculate the amount of each target lipid species in the samples. LipidomeDB DCE has three phases, shown in Fig. 1, data collection, data analysis, and result output and collection.

Getting Started

To use LipidomeDB DCE, a login ID can be acquired by following instructions on the home page. A "tutorial" (i.e., documentation) accessible from the home page includes complete instructions for the use of LipidomeDB DCE. The instructions include brief directions for performing the lipidomic experiments, including suggestions for sample preparation, internal standards and their addition, acquisition of the mass spectral data and formatting of the mass spectral data for input into LipidomeDB DCE. The intent of this part of the tutorial is to simplify and describe the process of performing lipidomic analyses. Also available, on the home page and by following links in the tutorial, are example input data files, acquired on mouse intestinal lipid

Table 1 Categories of step-by-step directions in the LipidomeDB DCE tutorial

Step 1. Assemble the data to be entered
Step 2. User log-in
Step 3. Enter data about the samples
Step 4. Enter the first target compound set
a. Enter a target compound set from an existing (pre-formulated) list
b. Enter your own target compound set
Step 5. Enter any additional target compound sets
Step 6. Provide data about internal standard amounts
Step 7. Upload the input data generated from the experiments in Excel format
Step 8. Collect the results

new sheet

Fig. 4 Screenshot of summary. A summary of data for all targeted compound sets from all samples can be exported as an Excel file

extracts, and the output file that should be obtained when the data are processed according to the instructions, allowing users to test the interface function and verify correct usage. Step-by-step directions for using LipidomeDB DCE (as shown in Table 1) with screenshots are provided in the tutorial. Also in the tutorial are sections discussing normalization to tissue metrics and practical considerations about the limitations of the quantitative capabilities of direct-infusion electrospray ionization QqQ MS-based analysis.

Input Data

The input to LipidomeDB consists of lists of target lipids, i.e., lipid species being analyzed, lists of internal standards utilized, internal standard amounts, and the mass and signal lists from precursor or neutral loss scan(s) (Fig. 1). Either pre-formulated lipid species target lists, user-specified lipid target lists or a combination of the two types of lists can be used. If the user composes his own sheets, they can be saved for his later use. The pre-formulated target lists for "plants"

and "animals" are based on lipid species detected by the Kansas Lipidomics Research Center's analytical laboratory by electrospray ionization QqQ MS in a number of higher plant and mammalian species. Figure 2 is a screenshot of the interface for indicating the target lipids and the corresponding internal standards. Similar pages are used for each group of lipids to be analyzed (i.e., for each precursor or neutral loss scan). The pre-formulated lists provide a suitable and quick starting point for many users. Amounts of internal standards are entered, and mass spectral data are uploaded in Excel files. The interface for uploading the mass spectral data is shown in Fig. 3. LipidomeDB DCE searches the *m/z* of mass spectral data for the *m/z* values of lipids and internal standards in the target lists.

Data Calculation and Output

Data calculation is described briefly in the "Materials and Methods" section, and in more detail in the tutorial. The output of LipidomeDB DCE can be viewed on (1) a sheet showing calculations for one target list for one sample, (2) as a summary showing calculated data for one target compound set from all samples or (3) as a summary of data for all targeted compound sets from all samples (Fig. 4). The sheet showing calculations for one target list for one sample (i.e., data from one spectrum) allows the user to confirm detection of the internal standards, to view the corrections for isotopic variants (isotopic deconvolution results) and to view the results of the quantification. The summary sheets provide the data in several convenient forms. All sheets can be viewed on the web or exported in Excel format.

Summary

LipidomeDB DCE is a well-documented web application for analysis of direct infusion electrospray ionization QqQ mass spectral data, with the capability to analyze multiple scans from up to 35 samples simultaneously. The pre-formulated lists of plant and animal polar lipids provide a quick start for lipidomic data analysis that should provide for ease in performing lipidomics analyses. In the long term, the web-accessible lipidomics data calculation system and database can be developed for storage and retrieval of lipidomics data in the context of experimental metadata.

Acknowledgments The authors would like to thank Dr. Susan Brown for helping us start the LipidomeDB project and obtain financial support for it. We are also grateful to Dr. Youping Deng for his efforts to initiate a lipidomics database and to Drs. Todd Williams and Xuemin Wang for helping us initiate lipidomics work. We appreciate Emily Archer Slone, Byron Sparkes and Dr. Sherry Fleming for allowing us to use their data as example data. We also wish to thank members of the Welti and Visvanathan groups, who provided helpful suggestions. Funding for development of LipidomeDB Data Calculation Environment was from Kansas IDeA Networks of Biomedical Research Excellence (National Institutes of Health grant P20 RR16475 from the National Center for Research Resources). Mass spectrometer acquisition and mass spectrometry method development were supported by National Science Foundation grants MCB 0455318, MCB 0920663 and DBI 0521587, Kansas National Science Foundation EPSCoR grant EPS-0236913, Kansas Technology Enterprise Corp. and Kansas State University. Contribution no. 11-295-J from the Kansas Agricultural Experiment Station.

JNK Inhibition by SP600125 Attenuates *trans*-10, *cis*-12 Conjugated Linoleic Acid-Mediated Regulation of Inflammatory and Lipogenic Gene Expression

Kristina Martinez · Arion Kennedy · Michael K. McIntosh

Received: 1 April 2011 / Accepted: 20 June 2011 / Published online: 10 July 2011

Abstract Supplementation with a mixture of *trans*-10, *cis*-12 (t10,c12) and *cis*-9, *trans*-11 (c9,t11) isomers of conjugated linoleic acid (CLA), or t10,c12 CLA alone, reduces body weight and fat deposition in animals and some humans. However, these anti-obesity actions of t10,c12 CLA are routinely accompanied by increased markers of inflammation and insulin resistance. Thus, we examined the extent to which blocking c-Jun NH2-terminal kinase (JNK) signaling using the JNK inhibitor SP600125 attenuated markers of inflammation and insulin resistance in primary human adipocytes treated with t10,c12 CLA. SP600125 attenuated t10,c12 CLA-mediated phosphorylation of cJun and increased protein levels of activating transcription factor (ATF) 3, two downstream targets of JNK. SP600125 attenuated t10,c12 CLA-mediated induction of inflammatory genes, including interleukin (IL)-6, IL-8, IL-1β, ATF3, monocyte chemoattractant protein (MCP)-1, and cyclooxygenase-2. Consistent with these data, SP600125 prevented t10,c12 CLA-mediated secretion of IL-8, IL-6, and MCP-1. SP600125 prevented t10,c12 CLA suppression of lipogenic genes including peroxisome proliferator activated receptor gamma, liver X receptor, sterol regulatory element binding protein, acetyl-CoA carboxylase, and stearoyl-CoA desaturase. Additionally, SP600125 blocked t10,c12 CLA-mediated induction of suppressor of cytokine synthesis-3 and suppression of adiponectin and insulin-dependent glucose transporter 4 mRNA levels. Collectively, these data suggest that JNK signaling plays an important role in t10,c12 CLA-mediated regulation of inflammatory and lipogenic gene expression in primary cultures of human adipocytes.

Keywords Conjugated linoleic acid · Adipocytes · JNK · cJun · Inflammation · Lipogenic genes

Abbreviations

ACC	Acetyl-CoA carboxylase
AP-1	Activator protein
apm-1	Adiponectin
ATF	Activating transcription factor 3
BMI	Body mass index
BSA	Bovine serum albumin
c9,t11 CLA	*Cis*-9, *trans*-11 conjugated linoleic acid
t10,c12 CLA	*Trans*-10, *cis*-12 conjugated linoleic acid
COX	Cyclooxygenase
DEX	Dexamethasone
ER	Endoplasmic reticulum
ERK	Extracellular signal-regulated kinase
FA	Fatty acid
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GLUT4	Insulin-dependent glucose transporter 4
HBSS	Hanks balanced salt solution
IBMX	1-methyl-3-isobutylxanthine
IL	Interleukin
IRS	Insulin receptor substrate
ISR	Integrated stress response
JNK	c-Jun-NH2-terminal kinase
LXR	Liver X receptor

Introduction

Obesity is a global health issue with ~500 million people classified as obese and 1.5 billion overweight in 2008, including 43 million children under the age of five reported in 2010 [1]. One potential strategy for reducing adiposity is consumption of conjugated linoleic acid (CLA), unsaturated fatty acids found in ruminant meats and dairy products, or in dietary supplements and fortified foods. Conjugated linoleic acid refers to a group of conjugated octadecadienoic acid isomers derived from linoleic acid, a fatty acid that contains 18 carbons and 2 double bonds in *cis* configuration at the 9th and 12th carbons [i.e., *cis*-9, *cis*-12 octadecadienoic acid]. Microbes in the gastrointestinal tract of ruminant animals convert linoleic acid into different isoforms of CLA through biohydrogenation. This process changes the position and configuration of the double bonds, resulting in a single bond between one or both of the two double bonds (i.e., *cis*-9, *trans*-11 (c9,t11) or *trans*-10, *cis*-12 (t10,c12) octadecadienoic acid). Consuming a mixture of c9,t11 and t10,c12 CLA isomers, or t10,c12 CLA alone, reduces body fat mass in rodents, particularly mice, and some humans [reviewed in 2]. However, the isomer-specific mechanism by which CLA reduces adiposity is unclear. Furthermore, a number of clinical studies report potential side effects of CLA supplementation including increased levels of markers of inflammation (e.g., inflammatory cytokines, chemokines, or prostaglandins), insulin resistance, hyperlipidemia, and lipodystrophy [3–7]. These anti-obesity and adverse side effects of CLA appear to be due primarily to the t10,c12 isomer. In contrast, the c9,t11 isomer appears to have anti-inflammatory and anti-diabetic properties without reducing body weight [8].

We have demonstrated that t10,c12 CLA reduces glucose and fatty acid uptake and triglyceride content in cultures of human adipocytes, in part, by activating extracellular signal-related kinase (ERK) [9] and nuclear factor kappa B (NFκB) [10]. These in vitro data have been confirmed in vivo [11]. Activated NFκB [12–14] and ERK [15–17] induce markers of inflammation and antagonize peroxisome proliferator activated receptor (PPAR)γ activity, thereby causing insulin resistance. However, the extent to which t10,c12 CLA activates other kinases or transcription factors that impact inflammatory signaling, insulin sensitivity, and triglyceride content in human adipocytes, and their mechanism of action, are unclear.

We recently demonstrated that t10,c12 CLA increased the phosphorylation levels of c-Jun NH2-terminal kinase (JNK) and downstream targets cJun and activating transcription factor (ATF3), members of the redox-sensitive transcription factor activator protein-1 (AP-1), that induce inflammatory gene transcription [18, 19]. c-Jun NH2-terminal kinase activation is known to enhance inflammation and insulin resistance associated with obesity, and lack of JNK1 or JNK2 reduces body fat and improves insulin sensitivity in vivo [20, 21] and in vitro [22]. However, the role of JNK in activating cJun or ATF3 in CLA-treated cultures and the extent to which this activation regulates inflammatory and lipogenic gene expression has not been investigated.

Based on these data, we hypothesized that JNK plays an important role in t10,c12 CLA-mediated activation of AP-1 and induction of inflammatory genes and suppression of lipogenic genes. To test this hypothesis, we employed the chemical JNK1-3 inhibitor, SP600125. By using this inhibitor, we demonstrate that JNK is involved in the regulation of t10,c12 CLA-induced inflammatory signaling, and suppression of gene markers for adipogenesis, lipogenesis, and insulin signaling in cultures of newly-differentiated human adipocytes. Therefore, JNK may be an important target for preventing 10,12 CLA-mediated inflammation.

Materials and Methods

Materials

All cell culture ware were purchased from Fisher Scientific (Norcross, GA). Lightning Chemiluminescence Substrate was purchased from Perkin Elmer Life Science (Boston, MA). Immunoblotting buffers and precast gels were purchased from Invitrogen (Carlsbad, CA). Adipocyte media was purchased from Zen Bio (Research Triangle Park, NC). The Nuclear Extract Kit was purchased from Active Motif (Carlsbad, CA). Polyclonal antibodies for anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and ATF3 and monoclonal antibody for anti-PPARγ were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Anti-total and anti-phospho (P) JNK (Thr183/Try185) and P-cJun (Ser63) antibodies were purchased from Cell

Signaling Technologies (Beverly, MA). Anti-nucleoporin was purchased from BD transduction laboratories (San Jose, CA). HyClone fetal bovine serum was purchased from Fisher Scientific. Isomers of CLA (+98% pure) were purchased from Matreya (Pleasant Gap, PA). The cell permeable selective JNK1-3 inhibitor SP600125 (#420119; Anthra [1,9-*cd*]pyrazol-6(2*H*)-one, 1,9-pyrazoloanthrone; JNKII) was purchased from EMD Chemicals (Gibbstown, NJ). This inhibitor of JNK1-3 is competitive with respect to ATP, and has over a 300-fold greater selectivity for JNK compared to other mitogen-activated protein kinase (MAPK) including ERK and p38 [23], and specifically inhibits the phosphorylation of cJun serine residues 63 and 67 [24, 25]. All other reagents and chemicals were purchased from Sigma Chemical Co. (St. Louis, MO) unless otherwise stated.

Culturing of Human Primary Adipocytes

Abdominal white adipose tissue was obtained with consent from the Institutional Review Boards at the University of North Carolina at Greensboro and the Moses Cone Memorial Hospital, during elective abdominoplasty of non-diabetic Caucasian and African American females between the ages of 20–50 years old with a body mass index $\leq$32.0. These selection criteria allow for reduced variation in gender, age, and obesity status. Tissue was digested using collagenase; stromal vascular cells were isolated as previously described [9]. Stromal vascular cells were differentiated with adipocyte media (AM-1) containing 1 μM rosiglitazone and 250 μM 1-methyl-3-isobutylxanthine for 3 days, which yielded cultures containing $\sim$30–50% adipocytes. On days 6–12, cells were pretreated with 5, 20, or 80 μM SP600125 JNK inhibitor dissolved in DMSO for 30 min, and subsequently treated with 50 μM t10,c12 CLA or bovine serum albumin (BSA) vehicle control for 12–24 h depending on the experimental outcome measured. All cultures were normalized to contain the same amount of BSA and DMSO vehicles. Each independent experiment was repeated at least twice using a mixture of cells from three subjects, unless otherwise indicated.

Fatty Acid Preparation

t10,c12 CLA was delivered as a free acid complexed to 7.5% fatty acid-free BSA at a 4:1 molar ratio as previously described [9].

RNA Isolation and PCR

Total RNA was isolated from the cultures using Tri Reagent purchased from Molecular Research Center (Cincinnati, OH), according to manufacturer's protocol. For quantitative real time PCR, 2.0 μg total RNA was converted into first strand cDNA using Applied Biosystems High-Capacity cDNA Archive Kit (Foster City, CA). Real time PCR was performed in an Applied Biosystems 7500 FAST Real Time PCR System using Taqman Gene Expression Assays. To account for possible variation in cDNA input or the presence of PCR inhibitors, the endogenous reference gene GAPDH was simultaneously quantified for each sample, and these data normalized accordingly. The Relative Standard Curve Method using seven, two-fold dilutions ranging from 100–1.56 ng RNA was used to check primer efficiency and linearity of each transcript according to Applied Biosystem's Guide to Performing Relative Quantification of Gene Expression Using Real-Time Quantitative PCR.

Nuclear and Cytosolic Separation

Nuclear and cytosolic cellular fractions were prepared using a commercially available kit from Active Motif as previously described [10].

Immunoblotting

Immunoblotting using 20 μg of protein per lane was conducted using 4-12% NuPage precast gels (Invitrogen) as previously described [10]. Briefly, PVDF membranes were blocked with 5% milk in TBST for 1 h and washed 3 × in TBST for 5 min. Blots were incubated overnight at 4°C with primary antibodies targeting P-JNK, P-cJun, total cJun, and ATF3 at a dilution of 1:1,000, and subsequently incubated in the respective horseradish peroxidase-conjugated secondary antibody at a dilution of 1:5,000 at room temperature for 1 h. Primary and secondary antibodies targeting GAPDH were used at a 1:5,000 dilution. Primary and secondary antibodies targeting PPARγ were used at dilutions 1:200 and 1:2,000, respectively. After washing, blots were treated with chemiluminescence reagent for 1 min and film was exposed using a SRX-101A Konica Minolta flim developer. Densitometry was performed using a Kodak Image Station 440 CF by Perkin Elmer and Kodak Molecular Imaging Software Version 4.0.

Secretion of IL-6, IL-8, and Monocyte Chemoattractant Protein (MCP)-1

The concentrations of IL-6, IL-8, and MCP-1 were determined using the BioPlex® Suspension Array System from Bio-Rad (Hercules, CA) following the manufacturer's protocol. Briefly, media was collected from cultures that were pretreated with 5, 20, or 80 μM SP600125 for 30 min, and subsequently treated with 50 μM t10,c12 CLA or BSA for 24 h. The media was centrifuged at 13,200×*g* for

10 min at 4°C to clear the samples of any cell debris. Samples and standards were run in duplicate. Based on the manufacturer's report 'Bio-Plex Pro Human Cytokine, Chemokine, and Growth Factor Assays-Bulletin 5828,' the intra-assay % CVs for IL-6, IL-8, and MCP-1 are 7, 9, and 9%, respectively. The inter-assay % CVs are 11, 4, and 7%, respectively.

Statistical Analyses

Data are expressed as the means ± S.E. Data were analyzed using one-way analysis of variance followed by Tukey's-HSD tests for each pair for multiple comparisons. Differences were considered significant if $p < 0.05$. All analyses were performed using JMP IN, Version 9 Software (SAS Institute, Cary, NC).

Results

The JNK Inhibitor SP600125 Attenuates t10,c12 CLA-Mediated Activation of cJun and ATF3

We previously demonstrated that treatment of newly-differentiated human adipocytes with 50 μM t10,c12 CLA, but not c9,t11 CLA, for 6 h increased phosphorylation levels of JNK and cJun, which was sustained for 24 h when compared to vehicle (BSA)-treated cultures in total cell extract [18, 19]. However, a direct role for JNK in the activation of cJun and upregulation of inflammatory genes in response to t10,c12 CLA treatment has not been determined. In order to implicate a role for JNK in the activation of cJun, we examined JNK and cJun phosphorylation in cytosol and nuclear fractions after 6, 12, and 24 h of treatment with t10,c12 CLA. Phosphorylation of JNK was increased at 6 h and was sustained at 24 h in the cytosolic fraction, and increased in the nuclear fraction at 24 h with t10,c12 CLA. Consistently, cJun phosphorylation by t10,c12 CLA was detected almost exclusively in the nuclear fraction at all time points (Fig. 1a). Interestingly, t10,c12 CLA increased total cJun levels compared to the BSA control in the nuclear fraction at all time points. Based on the robust t10,c12 CLA-mediated activation of JNK and cJun, we investigated the extent to which pretreatment with the JNK inhibitor SP600125 blocked t10,c12 CLA-mediated phosphorylation of cJun after 12 h of treatment. Concentrations of SP600125 ranging between 5–80 μM were chosen based on studies using Jurkat T cells in which the IC_{50} for blocking cJun phosphorylation was 10 μM and using CD4 + cells isolated from human peripheral blood mononuclear cells in which the IC_{50} for blocking cyclooxygenase (COX)-2 and tumor necrosis factor alpha expression was 5 and 10 μM, respectively [23]. SP600125 suppressed t10,c12 CLA-mediated phosphorylation of cJun and increase in the protein levels of ATF3, an AP-1 family member, in total cell lysates (Fig. 1b). These data suggest that JNK is involved in t10,c12 CLA-mediated cJun activation.

SP600125 Attenuates t10,c12 CLA Induction of Inflammatory Genes

Next, we determined the extent to which SP600125 blocked t10,c12 CLA-induced inflammatory gene expression. Pretreatment of cultures with SP600125 attenuated t10,c12 CLA-induction of IL-8, IL-6, IL-1β, MCP-1, COX2, and ATF3 (Fig. 2a). Consistent with these data, SP600125 attenuated t10,c12 CLA-mediated secretion of IL-8, IL-6, and MCP-1 (Fig. 2b). Collectively, these data demonstrate that SP600125 suppresses t10,c12 CLA-mediated induction of inflammatory gene expression and protein secretion.

SP600125 Blocks t10,c12 CLA Suppression of Lipogenic Genes

Inflammatory transcription factors such as NFκB and AP-1 in concert with MAPKs like ERK have been shown to inhibit lipogenic gene expression, in part, by suppressing

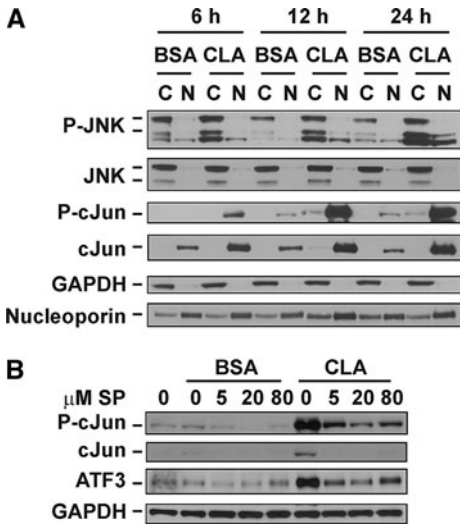

Fig. 1 **a** Cultures of newly-differentiated human adipocytes were treated with BSA vehicle or 50 μM t10,c12 CLA for 6, 12, or 24 h. Nuclear and cytosolic fractions were prepared using the Nuclear Extract Kit from Active Motif and analyzed for the determination of the protein levels of P-JNK, JNK, P-cJun, cJun, GAPDH, and nucleoporin. **b** Cultures were pretreated for 30 min with 5, 20, or 80 μM SP600125 (SP) followed by a 12 h treatment with BSA vehicle or 50 μM t10,c12 CLA. Subsequently, total cell lysates were harvested for the determination of the protein levels of P-cJun, cJun, ATF3, and GAPDH. Data are representative of two **a** or three **b** independent experiments

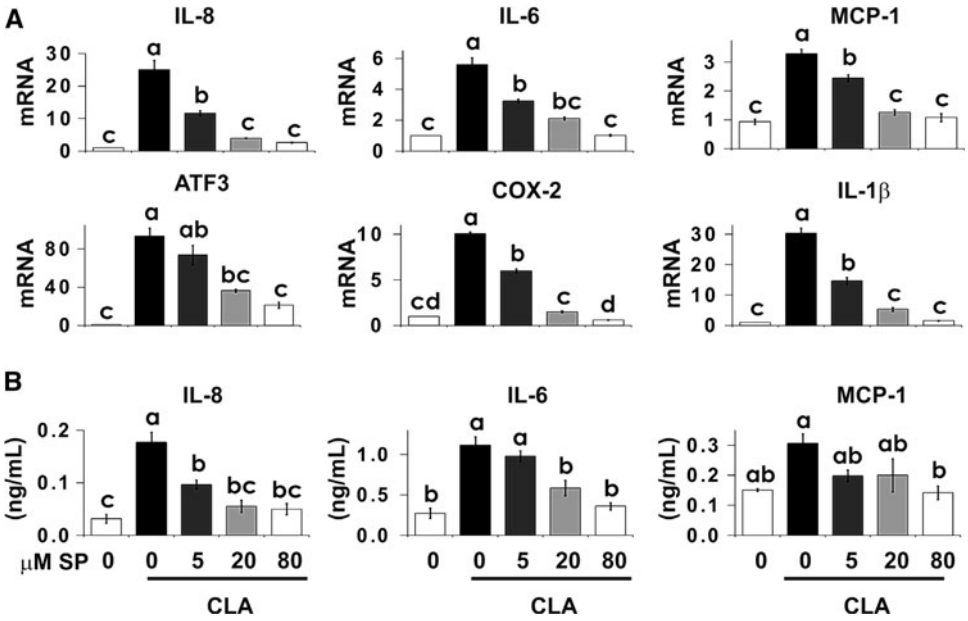

Fig. 2 **a** Cultures of newly-differentiated human adipocytes were pretreated with 5, 20, or 80 μM SP600125 (SP) for 30 min, followed by treatment with BSA vehicle or 50 μM t10,c12 CLA for 18 h **a** or 24 h **b**. Subsequently, RNA was harvested and the mRNA levels of IL-8, IL-6, IL-1β, MCP-1, ATF3, and COX-2 were measured by real time qPCR and normalized to GAPDH endogenous control. PPARγ activity [12–17]. Due to the hypothesized role of JNK in regulating t10,c12 CLA-induced inflammation, we investigated the impact of SP600125 on t10,c12 CLA-mediated suppression of lipogenic gene expression and PPARγ protein levels. Consistent with our hypothesis, SP600125 blocked t10,c12 CLA-mediated suppression of the expression of transcription factors that regulate lipid metabolism (i.e., PPARγ/α, sterol regulatory element binding protein (SREBP)-1c, liver X receptor (LXR)α) and several of their downstream targets (i.e., acetyl-CoA carboxylase (ACC)-1, stearoyl-CoA desaturase (SCD)-1) in a concentration-dependent manner (Fig. 3a). Additionally, 20 μM SP600125 modestly prevented a CLA-mediated decrease in PPARγ protein levels (Fig. 3b). Taken together, these data suggest that JNK activity regulates t10,c12 CLA-mediated suppression of lipogenic genes, which may contribute to the ability of t10,c12 CLA to decrease the triglyceride levels in adipocytes.

SP600125 Prevents t10,c12 CLA-Mediated Regulation of Genes Involved in Insulin Signaling

We previously demonstrated that t10,c12 CLA-induced inflammation leads to a suppression of insulin signaling and sensitivity [9, 10, 18, 19]. Therefore, we determined the extent to which JNK impacted the expression of genes associated with insulin signaling. SP600125 attenuated t10,c12 CLA-mediated induction of suppressor of cytokine synthesis (SOCS)-3, a protein reported to cause insulin resistance (Fig. 4). Consistent with these data, t10,c12 CLA-mediated suppression of insulin-dependent glucose transporter (GLUT) 4 and adiponectin mRNA levels, which are positively associated with insulin sensitivity, was attenuated by SP600125 in a concentration-dependent manner (Fig. 4). Further studies are needed to confirm a role for JNK in CLA-mediated suppression of insulin-stimulated glucose uptake.

Discussion

Consistent with our hypothesis, t10,c12 CLA-mediated activation of cJun and ATF3 was attenuated by the chemical JNK inhibitor, SP600125. SP600125 also blocked t10,c12 CLA-induced inflammatory gene expression and cytokine secretion, and suppression of lipogenic genes and markers of insulin signaling. Taken together, these data suggest that JNK plays a role in t10,c12 CLA-mediated induction of markers of inflammation and insulin resistance in cultures of human adipocytes. However, due to the potential lack of specificity of chemical inhibitors (i.e., they can inhibit other kinases including ERK and p38, albeit at much lower selectivities [23]), JNK gene silencing experiments are needed to confirm these results. Knockdown experiments are also need to determine the extent to which JNK signaling impairs insulin-stimulated glucose uptake in t10,c12 CLA-treated cultures, because such longer-term studies were not possible with SP600125 (data not shown).

Treatment times differed based on the experimental outcome measured. Historically, we have shown in our primary cultures of newly-differentiated human adipocytes that t10,c12 CLA increases phosphorylation of MAPKs between 6–24 h, induces inflammatory gene expression and protein secretion between 12–48 h, decreases adipogenic gene expression from 18 to 72 h, and PPARγ protein

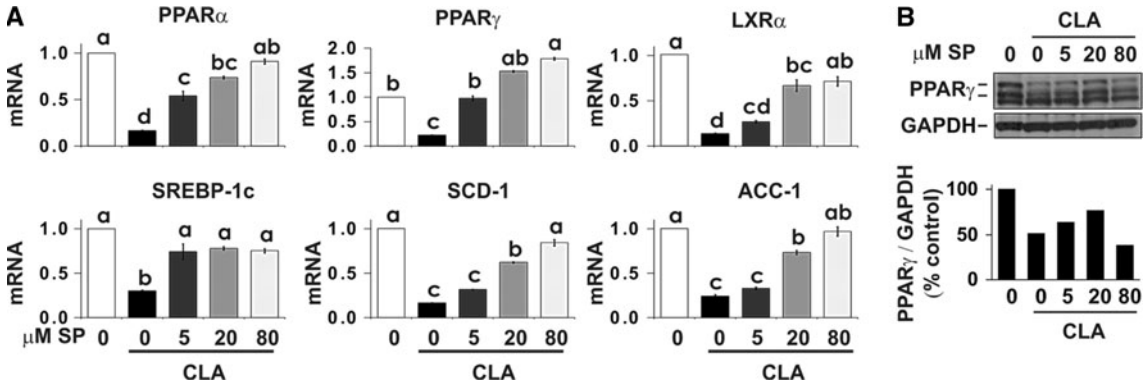

Fig. 3 Cultures of newly-differentiated human adipocytes were pretreated with 5, 20, or 80 μM SP600125 (SP) for 30 min, followed by treatment with BSA vehicle or 50 μM t10,c12 CLA for 24 h. **a** RNA was harvested and the mRNA levels of PPARγ, PPARα, LXRα, SREBP-1c, ACC-1, and SCD-1 were measured using real time qPCR and normalized to GAPDH endogenous control. Means (+SE; n = 2–3) not sharing a lower case letter differ significantly ($p < 0.05$). **b** Cultures were harvested for the determination of the protein levels of PPARγ and GAPDH. PPARγ levels were quantified by densitometry and normalized to the loading control, GAPDH. Densitometry values are expressed as % of BSA vehicle control. Data are representative of two **b** or three **a** independent experiments

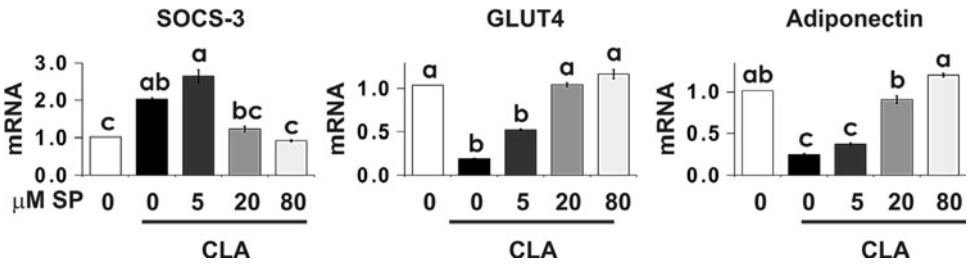

Fig. 4 Cultures of newly-differentiated human adipocytes were pretreated with 5, 20, or 80 μM SP600125 (SP) for 30 min, followed by treatment with BSA vehicle or 50 μM t10,c12 CLA for 24 h. Subsequently, RNA was harvested and the mRNA levels of SOCS-3, GLUT4, and apm1 were measured by real time qPCR and normalized to GAPDH endogenous control. Means (+SE; n = 2–3) not sharing a lower case letter differ significantly ($p < 0.05$)

from 24 to 48 h [9, 10, 18, 19, 32, 33]. Therefore, we chose a 12 h time point to examine JNK phosphorylation, 18 h for inflammatory gene expression, 24 h for cytokine/chemokine secretion, and 24 h for adipogenic, lipogenic, and insulin-sensitizing gene expression. The timing of these events fits our hypothesis that JNK phosphorylation occurs prior to t10,c12 CLA-mediated induction and secretion of inflammatory proteins, leading to the suppression of adipogenic/lipogenic gene and protein levels.

c-Jun NH2-terminal kinase-mediated activation of cJun results in induction of several inflammatory genes including IL-8, IL-6, and COX2, and also genes involved in cell death or apoptosis. For example, SP600125 or RNA interference of JNK in 3T3-L1 adipocytes prevented free fatty acid-induced MCP-1 expression [26]. Consistent with these data, we showed that inhibiting JNK with the chemical inhibitor SP600125 prevented t10,c12 CLA-mediated inflammatory gene expression and protein secretion (Fig. 2). This prevention was accompanied by an increase in the expression lipogenic and insulin sensitizing genes and PPARγ protein levels that promote lipogenesis or insulin signaling (Fig. 3).

One possible explanation for these data is that by inhibiting JNK activity, t10,c12 CLA was unable to decrease PPARγ activity, which drives the expression of genes that promote glucose and fatty acid uptake and triglyceride synthesis and deposition in adipocytes. Indeed, PPARγ2 activity is regulated by phosphorylation [27]. Notably, phosphorylation at serine residue 112 by ERK or JNK has been reported to decrease PPARγ activity by ubiquination and proteosome degradation [28], and by decreasing its ligand-dependent and ligand-independent transactivating functions [15, 29–31]. Consistent with this hypothesis, we have shown that t10,c12 CLA increases PPARγ phosphorylation prior to reducing PPARγ protein levels. Furthermore, supplementation with Rosiglitazone, a PPARγ agonist [32], or resveratrol, an anti-inflammatory polyphenol [33], attenuates delipidation by t10,c12 CLA. Thus, inhibiting t10,c12 CLA-mediated JNK signaling may increase PPARγ activity, thereby increasing the expression of lipogenic and insulin-signaling genes. Consistent with this hypothesis, SP600125 supplementation of t10,c12 CLA-treated cultures increased the expression of lipogenic and insulin-

signaling genes compared to cultures treated with t10,c12 CLA alone (Fig. 3).

We previously showed using the ERK inhibitor U0126 that ERK activation by t10,c12 CLA is one mechanism by which t10,c12 CLA suppresses lipogenic gene expression and insulin-stimulated glucose uptake [9]. Therefore, it is tempting to speculate that t10,c12 CLA antagonizes PPARγ activity via activation of MAPKs like ERK and JNK, thereby inhibiting PPARγ target genes. In support of this hypothesis, knockdown of JNK1, but not JNK2, increased basal and troglitazone-stimulated PPARγ reporter activity [34].

c-Jun NH2-terminal kinase deficiency in animals on a high-fat diet protects them from developing insulin resistance [20]. Similarly, mitochondrial dysfunction-induced insulin resistance in 3T3-L1 adipocytes is prevented by knockdown of JNK1 [35]. Several reports show that JNK directly phosphorylates insulin receptor substrate (IRS)-1 at serine 307, thus inactivating insulin receptor signaling. However, we did not observe any effects of t10,c12 CLA or SP600125 on IRS-1 ser 307 phosphorylation (data not shown), in spite of SP600125 blocking t10,c12 CLA induction of SOCS-3, a protein reported to phosphorylate ser 307 on IRS-1. Nevertheless, t10,c12 CLA-mediated suppression of the mRNA levels adiponectin and GLUT4, proteins associated with insulin sensitivity, was completely prevented by SP600125 (Fig. 4).

Taken together, these data suggest that JNK may be an important target for preventing t10,c12-CLA mediated inflammation. Further studies are needed to confirm a role for JNK in t10,c12 CLA-mediated insulin resistance. RNA interference studies targeting JNK are also needed to confirm these data. Future research will also focus on identifying upstream activators of JNK and ERK and potential mechanisms by which these MAPK pathways are linked to insulin resistance and suppression of lipogenesis in adipocytes.

2-Polyunsaturated Acyl Lysophosphatidylethanolamine Attenuates Inflammatory Response in Zymosan A-Induced Peritonitis in Mice

Nguyen Dang Hung · Mee Ree Kim · Dai-Eun Sok

Received: 18 April 2011 / Accepted: 16 June 2011 / Published online: 10 July 2011

Abstract In the present study, the anti-inflammatory action of lysophosphatidylethanolamine (lysoPtdEtn), orally administered, in zymosan A-induced peritonitis was examined. Oral administration of 2-DHA-lysoPtdEtn (ED_{50}, ~111 μg/kg) or 2-ARA-lysoPtdEtn (ED_{50}, 221 μg/kg) was found to inhibit the plasma leakage in mice treated with zymosan A. In support of this, 2-polyunsaturated acyl-lysoPtdEtn diminished the formation of LTC_4, a lipid mediator responsible for vascular permeability. Next, 2-DHA-lysoPtdEtn (ED_{50}, 110 μg/kg) or 2-ARA-lysoPtdEtn (ED_{50}, 123 μg/kg) effectively inhibited the leukocyte extravasation into the peritoneum. Consistent with this, each polyunsaturated-lysoPtdEtn diminished the formation of LTB_4 and 12-HETE, potent chemotactic factors. Additionally, the level of pro-inflammatory mediator (IL-1 β, IL-6, TNF-α or NO) was lowered remarkably in contrast to the augmentation of anti-inflammatory interleukin IL-10. Furthermore, 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn, 15-lipoxygenation product of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, respectively, were more potent than corresponding lysoPtdEtn, suggesting the action of 2-acyl-lysoPtdEtn might be expressed through 15-lipoxygenation. In support of this, the formation of 15-HETE and LXA_4 was upgraded in accordance with an increasing dose of 2-ARA-lysoPtdEtn. Separately, anti-inflammatory actions, 2-polyunsaturated acyl-lysoPtdEtns also drastically diminished leukocyte infiltration in a later phase of zymosan A-induced peritonitis, indicating that these lipids also possess pro-resolving activity. Taken together, it is suggested that polyunsaturated lysoPtdEtns and their lipoxygenation derivatives, could be classified as potent anti-inflammatory lipids.

Introduction

Inflammation is defined as a part of complex biological responses of vascular tissue toward exogenous harmful stimuli [1]. It becomes apparent that inflammation, normally results from an excessive inflammatory response or failure of resolution [2], is recognized as a causative in various diseases such as atherosclerosis, cancer, or asthma, and some neuropathological disorders such as Alzheimer's disease or Parkinson's disease. Additionally, lipid-derived mediators have proved to actively participate in the inflammation process and cooperate with others components in regulating the biological response to inflammation [3]. During the time course of inflammation, the lipid mediator could switch from a pro-inflammatory class such as prostaglandins and leukotrienes in the initial phase to biosynthesis of an anti-inflammatory and pro-resolving class including resolvin D series, resolvin E series, protectin D [4], maresin [5] in the resolution phase.

Lysophospholipid is a bioactive lipid class that plays important roles in the physical function and pathological conditions in the human body [6, 7]. Whereas the biological function of lysophosphatidylcholine (lysoPtCho), an abundant lysophospholipid in vivo, in inflammation it has been extensively studied and proved to be dependent upon the length and unsaturation degree of fatty acyl group [8, 9], the biological action of lysoPtdEtn, presents in human serum at a level of about several hundred ng mL^{-1}, has been still unknown [10] except that the report that lysoPtdEtn expressed a potent anti-inflammatory activity in colitis induced by rectal administration of ethanol and trinitrobenzene sulfonic acid in rats [11]. Our recent works have proved that polyunsaturated-lysoPtCho, containing omega-3 or omega-6 fatty acid and its hydroxyl derivatives possess potent anti-inflammatory properties in vivo as well as in the in vitro model [8, 9, 12]. Anti-inflammatory activity of polyunsaturated lysoPtCho was suggested to be due to the combination effect of lysoPtCho itself and its metabolites. Moreover, 15-hydroxy derivative or 17-hydroxy derivative, derived from the sequential action of 15-LOX [13, 14] and GSH-peroxidase [15] on 1-ARA-lysoPtCho and 1-eicosapentaenoyl-lysoPtCho or 1-DHA-lysoPtCho, respectively, proved to possess more potent anti-inflammatory activity than their corresponding lysoPtCho suggesting that 15-lipoxygenase might be crucial for the anti-inflammatory effect of polyunsaturated lysoPtChos. However, the lysoPtCho form had been reported to be cytotoxic at relative small concentrations, in contrast to lysoPtdEtn which was less cytotoxic [16, 17]. Separately, it was reported that 18:0a/15S-HETE-PE potently inhibited cytokine generation in human monocytes, providing more evidence for anti-inflammatory activity of phosphatidylethanolamine (PtdEtn) in vitro [18]. However, it is still questionable whether polyunsaturated-lysoPtdEtn could express anti-inflammatory activity as observed with polyunsaturated acyl lysoPtCho. In this study we examined the anti-inflammatory actions of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, their corresponding oxygenation products, 2-(15-HETE)-lysoPtdEtn and 2-(17-HpDHE)-lysoPtdEtn, respectively, to elucidate the mechanism responsible for their anti-inflammatory actions.

Materials and Methods

C18 (plasm)-22:6 PtEtn and C18 (plasm)-20:4 PtEtn, arachidonic acid (ARA), docosahexaenoic acid (DHA) (purity, 99%) were procured from Avanti Polar Lipids Inc. (Alabaster, Alabama, USA). All the enzyme were from the Sigma Company, unless otherwise indicated. Soybean lipoxygenase-1 (Type I-B), zymosan A (Z4250-1G) (*Saccharomyces cerevisiae*) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). 12/15-lipoxygenase (porcine leukocyte, 135.6 units/ml), 15-lipoxygenase-2 (human recombinant, 250 units/ml), 15-LOX inhibitor (PD 146176), EIA assay kits for prostaglandin E_2 (PGE_2), 15-HETE, leukotriene B_4 (LTB_4), leukotriene C_4 (LTC_4), and the nitrate/nitrite colorimetric assay kit were from Cayman Chemical (Ann Arbor, MI, USA). Lipoxin A_4 (LXA_4) and 12-HETE were from Oxford Biochemical Research Corp. (Box 522, Oxford, MI, USA) and Assay Designs Corp., respectively. The EIA assay kit for

12-HETE was supplied by Assay Design Inc. (Ann Arbor MI, USA). ELISA assay kits for cytokines (TNF-α, IL-1β, IL-4, IL-6 and IL-10) were obtained from eBioscience, Inc. (Science Center Drive, San Diego, USA).

Preparation of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn

2-DHA-lysoPtdEtn and 2-ARA-lysoPtdEtn were from the acidic hydrolysis of C18 (plasm)-22:6 PE and C18 (plasm)-20:4 PE, respectively according to a previous report with slight modification [19]. Briefly, PE was suspended in a mixture of 2.5 M HCl (0.8 ml), methanol (2 ml) and chloroform (1 ml) for 20 min at room temperature with vigorous stirring. Hydrolysis products were extracted from the reaction mixtures by the method of Bligh and Dyer and further purified by TLC on silica gel 60 plate, which was developed with a mobile solvent system (chloroform: methanol: H_2O; 65:25:4). Eventually, the band containing lysoPtdEtn was scraped off, extracted with methanol and kept at −80 °C until used.

Preparation of 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn

2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn (200 μM) was oxidized by soybean LOX-1B (4 KU/ml) in 5 ml of borax buffer (50 mM, pH 9.0) for 1 h. Then, hydroperoxide was subsequently reduced to the corresponding hydroxide by addition of $SnCl_2$ (1 mM) with vigorous stirring for 10 min at room temperature. The hydroxide derivative product was extracted using the Bligh and Dyer method [9, 20] and further purified by RP-HPLC using Zorbrax eclipse XDB C18 column (5 μm, 50 × 4.6 mm, Agilent Technologies, USA) with an isocratic solvent system (ACN: water: formic acid; 60:40:0.1) [21]. The amount of 1-(15-HEPE)-lysoPtdEtn or 2-(17-HDHE)-lysoPtdEtn was determined by measuring absorbance of purified lipid at 234 nm using $E_{1m,1cm} = 28{,}000$, and the lipids were stored at −80 °C until used [18]

Determination of Kinetic Values in LOXs-Catalyzed Oxygenation of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn

Oxygenation of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn by LOXs was monitored via the increase in absorbance at 234 nm according to the formation of conjugated diene. In the kinetic study, lysoPtdEtns (0–20 μM) were incubated with soybean LOX-1B (2.5 units/ml), porcine leukocyte 12/15 LOX (1 unit/ml), or human 15-LOX-2 (1 unit/ml) in 50 mM borax buffer (pH 9.0), 50 mM phosphate buffer (pH 7.4) containing 5 mM EDTA and 0.03% Tween 20, or 50 mM Tris–HCl buffer (pH 7.2) containing 0.003% Tween 20, respectively. The kinetic parameters, Km and Vm, were determined by Linwear–Burk plot analysis as previously reported [9]. One unit of LOX activity was defined as the amount of LOX that can produce one nanomole of conjugated diene per min.

Identification of Oxygenation of 2-docosahexaenoyl-lysoPtdEtn or 2-ARA-lysoPtdEtn by Soybean 15-LOX Using LC/ESI-MS

Soybean 15-LOX-1B (10 units/ml) was incubated with either 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn (100 μM) in 500 μl of 5 mM borax buffer (pH 9.0). After 30 min incubation at room temperature, the reaction products (30 μl) were directly analyzed by LC/ESI-MS which was performed using a MSDI spectrometer (HP 1100 series LC/MSA, Hewlett Packard, USA), equipped with a Zorbrax eclipse XDB C18 column (5 μm, 50 × 4.6 mm, Agilent Technologies, Washington, USA). The LC–MS solution was utilized for data collection and manipulation. The oxidized product was eluted (0.5 ml/min) with an isocratic solvent system of 60% solvent B [0.1% formic acid/acetonitrile in solvent A (0.1% formic acid/methanol], and the eluent was monitored at 234 nm, full-scan mass spectra were obtained within the range of m/z 400–700, and the data acquisition was conducted in both negative and positive modes. The condition for EIS–MS analysis of HPLC peak included a capillary voltage of 200 V, a drying gas flow of 1.5 mL/min, and a temperature of 200 °C.

Animal Experiment

ICR mice (4–6 weeks of age, 29–30 g body weight) were procured from Koatech Co., Korea, and housed in cages (10 mice per cage) under viral antibody-free conditions. Mice were fed with standard food (Sangyang Co., Korea) that containing no less than 4.5% total fat with 0.26% omega-3 fatty acid and <0.01% ARA acid. All animal experiments were conducted according to the Guide for Care and Use of Laboratory Animals of the National Research Council (NRC, 1996), which was approved by the Committee of Animal Care and Experiment of Chungnam National University, Korea.

Zymosan A-Induced Peritonitis in ICR Mice

Peritonitis was stimulated by i.p. administration of zymosan A (1 mg/mouse) as described previously [22–24]. For the measurement of plasma leakage, mice were treated orally with 200 μl of each lysoPtdEtn taken from

ethanol stock solution and diluted in PBS buffer (final ethanol concentration <0.5%), 60 min prior to i.p. administration (1 mg/mouse) of zymosan A, and 100 μl of 0.5% Evans Blue dye, dissolved in PBS, was intravenously injected just prior to zymosan A injection [25, 26]. Sixty minutes later, unless otherwise indicated, mice were killed using isoflurane inhalation, and peritoneal lavage was performed with 3 ml of ice cold PBS. Then, cells were centrifuged out of the lavage fluid. Finally, Evans blue dye extravasation amount was determined by measuring the absorbance of supernatants at 610 nm, and normalized with a standard curve [22, 23, 27]. Separately, in order to measure leukocyte infiltration, lipids were administered 60 min prior to i.p administration of zymosan A. Four hours after zymosan A injection, peritoneal lavage was taken, and total cells in the lavage fluid was enumerated using light microscopy with trypan blue staining [22, 28]. In an attempt to evaluate the effect of 15-LOX inhibitor (PD146176) [29] on the pharmacological activity of polyunsaturated lysoPtdEtns, mice were treated orally with 2-ARA-lysoPtdEtn or 2-docosahexaenoyl-lysoPtdEtn (50–150 μg/kg), followed by i.p. administration of PD146176, a specific 15-LOX inhibitor, 60 min prior to intra-peritoneal administration of zymosan A (1 mg/mice) and eventually, leukocyte infiltration was assessed as described above.

Determination of Inflammatory Lipid Mediators or Cytokine Level in Peritoneal Lavage Fluid

To determine the level of pro-inflammatory lipid mediators in exudates, 1 ml of peritoneal lavage fluid was transferred to micro-centrifuge tubes and centrifuged (15,000 rpm, 3 min). Supernatants were used directly for enzyme immunoassay (EIA) analysis of PGE_2, LTB_4, LTC_4, 12-HETE, 15-HETE, or LXA_4 level as described before [24, 30]. Whereas levels of pro-inflammatory (IL-1β, IL-6, TNF-α) or anti-inflammatory cytokines (IL-4, IL-10) were determined by ELISA assay according to the manufacturer's instructions. Additionally, the content of nitric oxide (NO) in the lavage fluid was quantitated by a nitrate/nitrite colorimetric assay kit supplied by Cayman Chemical Company (Ann Arbor, MI, USA).

Statistical Analysis

Data were calculated and displayed as means ± SEM. Group comparisons were performed using one-way analysis of variance (ANOVA) followed by Neuman Keuls multiple comparison test or Student's t test where appropriate; with P value ≤ 0.05 was considered as statistically significant (sufficient to reject the null hypothesis).

Results

Identification of Product from 15-LOX-catalyzed Oxygenation of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn

The formation of 2-(15-HpETE)-lysoPtdEtn and 2-(17-HpDHE)-lysoPtdEtn, 15-LOX-catalyzed oxidation products of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, respectively, was analyzed by LC–ESI–MS using both the positive and negative mode. Figure 1 shows that a peak with a retention time of 1.6 min (Inset, Fig. 1a) appeared as a predominant product possessing the mass spectrum of a compound corresponding to hydroperoxy derivative of 2-ARA-lysoPtdEtn (Fig. 1a); mass-to-charge ratio (m/z) at 532 $(M–H)^-$ in negative scan mode, and 500 $(M + H–H_2O–O)^+$, 516 $(M + H–H_2O)^+$, 534 $(M + H)^+$, 556 $(M + Na)^+$, and 572 $(M + K)^+$ in positive scan mode (Fig. 1b). Likewise, as shown in Fig. 1c, d, the mass spectrum of the major peak (RT, 1.7 min) (Inset, Fig. 1c) including molecular ions indicative of hydroperoxy derivative of 2-DHA-lysoPtdEtn had been obtained; m/z at 556 $(M–H)^-$ in negative scan mode, and 524 $(M + H–H_2O–O)^+$, 540 $(M + H–H_2O)^+$, 558 $(M + H)^+$, 580 $(M + Na)^+$, and 596 $(M + K)^+$ in positive scan mode [31]. Therefore, it was suggested that soybean LOX effectively converted 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn into their corresponding 15-hydroperoxy derivative products.

Determination of Kinetic Values in Oxygenation of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn by Various LOXs

As 15-lipoxygenation had been known to be required for anti-inflammatory action of polyunsaturated lysoPtCho [12], the oxygenation of 2-polyunsaturated acyl-lysoPtdEtn by different LOXs was examined. When 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn was incubated with 15-LOXs (soybean LOX-1, leukocyte 12/15-LOX or human recombinant 15-LOX-2), a time-dependent increase in absorbance at 234 nm was observed, indicating the formation of a conjugated diene (data not shown). Subsequently, the kinetic values for oxygenation of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn by 15-LOX were determined from Lineweaver–Burk plot analysis, and compared to those for ARA or DHA. As displayed in Table 1, the most favorable substrate in case of soybean LOX-catalyzed oxygenation was found to be 2-DHA-lysoPtdEtn, showing catalytic efficacy (Vm/Km) value of 30.4 units/μg/μM, which was approximately ninefold higher than that of DHA (Vm/Km, 3.5 units/μg/μM). Meanwhile, 2-ARA-lysoPtdEtn demonstrated a Vm/Km value of 10.9 units/μg/μM, which was

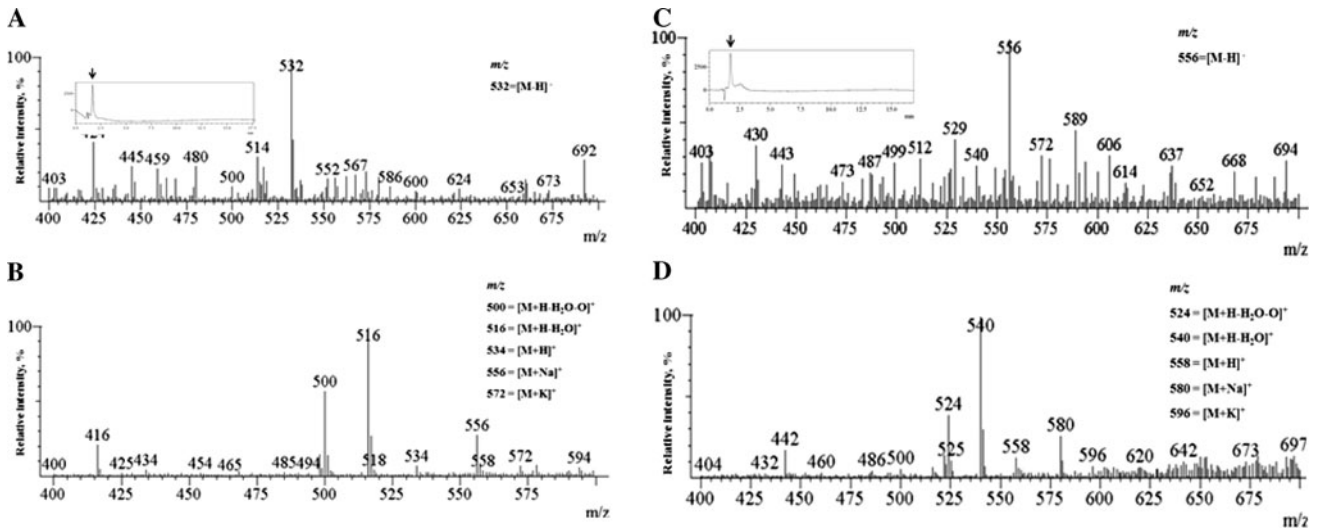

Fig. 1 LC/ESI–MS analysis of products from soybean 15-LOX catalyzed oxidation of 2-ARA-lysoPtdEtn (**a**, **b**) or 2-DHA-lysoPtdEtn (**c**, **d**). The hydroperoxide derivative obtained from 30 min-incubation of soybean 15-LOX with 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn (100 μM) in 500 μl of 5 mM borax buffer (pH 9.0) was directly analyzed by LC/ESI-MS as described in "Materials and Methods". The representative mass spectra of a major peak with retention time of 1.6 and 1.7 min (*inset* of **a** and **b**), respectively were obtained by the ESI–MS system using negative scan mode (**a**, **b**) and positive scan mode (**c**, **d**)

larger than that of ARA (Vm/Km, 7.4 units/μg/μM). Similarly, when the oxygenation of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn by human 15-LOX-2 was analyzed, the Vm/Km values for 2-DHA-lysoPtdEtn and 2-ARA-lysoPtdEtn were estimated to be 48.2 and 14.8 units/μg/μM, respectively, which were about 8- and 1.5-fold higher than that of DHA and ARA, respectively. Thus, it was demonstrated that 2-DHA-lysoPtdEtn and 2-ARA-lysoPtdEtn were more effective substrates than DHA and ARA, respectively, for human recombinant 15-LOX-2. Finally, in the oxygenation by leukocyte 12-LOX, the Vm/Km value for 2-ARA-lysoPtdEtn was estimated to be 10.3 units/μg/μM, which was found to be two times larger than that of ARA (Vm/Km, 4.5 units/μg/μM). Taken all together, it was suggested that 2-polyunsaturated acyl-lysoPtdEtn is a more effective substrate than the acid form in 12-LOX or 15-LOX-catalyzed oxygenation. Nonetheless, 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn were not oxygenated significantly by murine recombinant 12-lipoxygenase from platelets (data not shown).

Table 1 Kinetic values in oxygenation of each lipid by soybean LOX-1, leukocyte 12/15-LOX, or human recombinant 15-LOX-2

Enzyme	Substrate	Km (μM)	Vmax (units/mg)	Vm/Km (units/mg/μM)
Soybean LOX-1	2-ARA-lysoPtdEtn	5.4 ± 0.9[a]	59.0 ± 8.6[a]	10.9 ± 0.2[a]
	2-DHA-lysoPtdEtn	2.7 ± 0.7[b]	80.6 ± 8.3[a]	30.4 ± 5.1[b]
	ARA	12.7 ± 0.4[c]	93.5 ± 6.5[a]	7.4 ± 1.5[a]
	DHA	24.2 ± 2.1[d]	84.4 ± 5.2[a]	3.5 ± 0.2[c]
Leukocyte 12-LOX	2-ARA-lysoPtdEtn	8.4 ± 0.5[a]	87.1 ± 3.9[a]	10.3 ± 1.0[a]
	2-DHA-lysoPtdEtn	6.1 ± 0.0[a]	60.2 ± 4.5[a]	9.9 ± 2.2[a]
	ARA	8.5 ± 0.6	30.9 ± 6.5	4.5 ± 1.0[b]
	DHA	11.6 ± 1.6[c]	95.8 ± 8.2[c]	8.2 ± 0.8[a]
Human 15-LOX-2	2-ARA-lysoPtdEtn	2.1 ± 0.4[a]	31.9 ± 3.7[a]	14.8 ± 0.9[a]
	2-DHA-lysoPtdEtn	1.4 ± 0.3[a]	68.8 ± 10.1[b]	48.2 ± 4.5[b]
	ARA	5.1 ± 1.2[b]	59.7 ± 7.6[b]	11.7 ± 0.4[a]
	DHA	8.1 ± 1.5[c]	50.2 ± 4.6[b]	6.2 ± 0.1[c]

Each lipid (0–20 μM) was incubated with soybean LOX-1B (2.5 units/ml), porcine leukocyte 12/15 LOX (1 unit/ml), and human 15-LOX-2 (1 unit/ml) in 50 mM borax buffer (500 μl, pH 9.0), 50 mM phosphate buffer (500 μl, pH 7.4) containing 5 mM EDTA and 0.03% Tween 20, and 50 mM Tris–HCl buffer (500 μl, pH 7.2) containing 0.003% Tween 20, respectively. Data were expressed as means ± SEM values of triplicates experiments. Means displayed with same letter are not significantly different

Prevention by 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn Against Zymosan A-Induced Plasma Leakage

Increased vascular permeability caused by reversible opening of endothelial cells tight junction, followed by the leak of protein and fluids from the vascular compartment into the extravascular compartment, is one predominant event in acute inflammation. In order to see anti-inflammatory actions of 2-ARA-lysoPtdEtn or 2-docosahexaneoyl-lysoPtdEtn in acute inflammation, we investigated the effect of lysoPtdEtn, orally administered, on zymosan A-induced vascular permeability based on the extravasation of Evans Blue dye as marker. As shown in Fig. 2, both 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, orally administered, 60 min prior to zymosan A treatment (i.p., 1 mg/mouse) dose-dependently decreased zymosan A-induced plasma leakage in ICR mice. Oral intake of 2-ARA-lysoPtdEtn at doses of 50 and 150 μg/kg suppressed the plasma leakage by 17 and 36%, respectively, while that of 2-DHA-lysoPtdEtn at doses of 50 and 150 μg/kg caused ~42 and ~58% reduction of plasma leakage, respectively. The 50% effective dose (EC_{50}) for 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn was estimated to be about 221 and 111 μg/kg, respectively. By contrast, no remarkable inhibition of plasma was expressed by oral intake of DHA up to 150 μg/kg (data not shown), suggesting the structural importance of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn.

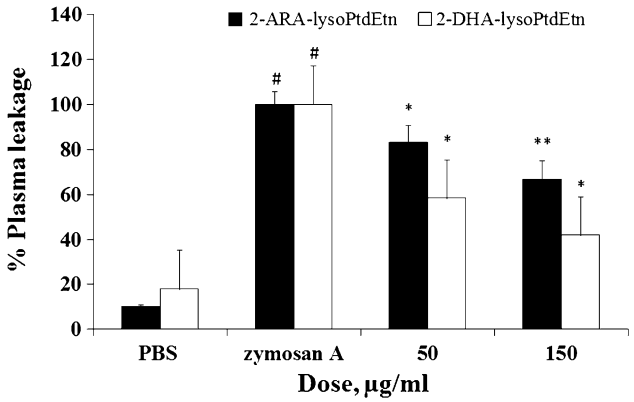

Fig. 2 Prevention by 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn against zymosan A-induced plasma leakage. 2-ARA-lysoPtdEtn (*filled*) or 2-DHA-lysoPtdEtn (*blank*) (50 or 150 μg/kg), diluted in ice cold PBS, was administered orally to mice, 1 h prior i.p. administration of zymosan A (1 mg/mouse), followed by intravenous injection of Evans blue (5% in PBS, 100 μl/mouse). Two hours later, plasma leakage was determined by measuring the absorbance of cell free-supernatant of lavages at 610 nm, and calculating the amount of Evans blue using a standard curve of known concentrations of the dye. The value was expressed as the percentage of the sample value of the value of the zymosan A-treated group. Result are presented as means ± SEM ($n = 5$). #, $P < 0.001$ when compared to PBS-treated group; *, $P < 0.05$ and; **, $P < 0.01$ when compared to zymosan A-treated group

Effect of the 15-LOX Inhibitor, administrated i.p., on Anti-inflammatory Action of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn in Zymosan A-Induced Leukocyte Infiltration

Leukocyte extravasation is a subsequent event after the reversible opening of the endothelial cell tight junction at the onset of acute inflammation [32]. Therefore, in order to examine the ability of polyunsaturated lysoPtdEtn to regulate zymosan A-induced inflammation, the effect of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn on zymosan A-induced leukocyte infiltration was investigated. As displayed in Fig. 3, 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, orally administered, significantly ($P < 0.05$) prohibited the zymosan A-induced migration of leukocytes into the peritoneum in dose-dependent fashion; 2-ARA-lysoPtdEtn and 2-DHA at 150 μg/kg decreased total leukocyte infiltration by 56 and 60%, respectively, compared with the group challenged with zymosan A alone, suggesting that two lysoPtdEtn derivatives were potent inhibitors of leukocyte trafficking. The EC_{50} values for 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn were estimated to be about 123 and 110 μg/kg, respectively. However, such anti-inflammatory actions of 2-DHA-lysoPtdEtn or 2-ARA-lysoPtdEtn were completely reversed by concomitant treatment with PD146176, a specific 15-LOX inhibitor (Fig. 3), indicating that the action of 2-DHA-lysoPtdEtn or 2-ARA-lysoPtdEtn might be expressed mainly through the 15-LOX-induced oxygenation pathway.

Suppressive Effect of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn on Zymosan A-Induced Formation of Pro-inflammatory Lipid Mediator in Peritoneum

In separate experiments, to investigate the mechanism responsible for the inhibitory effect of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn on plasma leakage as well as leukocyte infiltration, the effect of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn on zymosan A-induced formation of pro-inflammatory or anti-inflammatory lipid mediators was assessed. As displayed in Fig. 4a, oral administration of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn significantly reduced zymosan A-induced formation of LTC_4 with EC_{50} values of about 132 and 84 μg/kg, respectively. Thus, 2-DHA-lysoPtdEtn was more potent than 2-ARA-lysoPtdEtn in suppressing the formation of LTC_4, an important vascular permeability inducer. Furthermore, Fig. 4b indicated that the formation of LTB_4, a potent chemoattractant lipid, was also diminished by 2-ARA-lysoPtdEtn

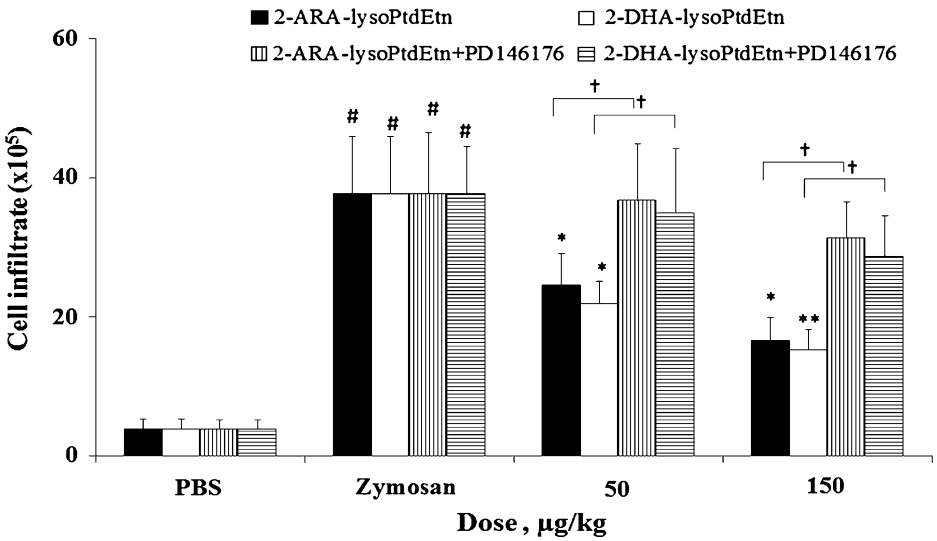

Fig. 3 Effect of 15-LOX inhibitor on anti-inflammatory action of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn in zymosan A-induced leukocyte extravasation. Mice were orally given 2-ARA-lysoPtdEtn (*filled*) or 2-DHA-lysoPtdEtn (*blank*) (50 or 150 μg/kg) concurrently with or without PD146176 (i.p., 100 μg/mouse), 60 min prior i.p. administration of zymosan A (1 mg/mouse). Peritoneal lavages were collected after 4 h, and the total number of leukocyte was enumerated utilizing light microscopy after staining with trypan blue dye. Results are mean ± SEM. ($n = 5$). $^{\#}$, $P < 0.001$ when compared to PBS-treated group; *, $P < 0.05$; **, $P < 0.01$ when compared to zymosan A-treated group; †, $P < 0.05$, significant difference between treated groups

(EC_{50}, 139 μg/kg) and 2-DHA-lysoPtdEtn (EC_{50}, 211 μg/kg) in a dose-dependent manner, supporting the notion that the reduction of LTB_4 formation might be related to the suppressive effect of 2-polyunsaturated acyl-lysoPtdEtn on zymosan A-induced leukocyte extravasation. Additionally, the amount of 12-HETE, another chemo-attractant lipid mediator was also dose-dependently reduced by 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn (Fig. 4c), supporting the idea that the decrease of 12-HETE level might at least partially account for the suppressive effect of 2-polyunsaturated acyl-lysoPtdEtn on vascular permeability. Especially, 2-DHA-lysoPtdEtn almost completely inhibited 12-HETE formation at dose of 150 μg/kg. However, no significant alternation of PGE_2 level was observed after the treatment with 2-polyunsaturated acyl-lysoPtdEtn (not shown), suggesting that suppression of PGE_2 might not be responsible for the anti-inflammatory action of 2-polyunsaturated acyl-lysoPtdEtn.

Effect of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn on Zymosan A-Induced Formation of Pro-inflammatory or Anti-inflammatory Cytokine

Production of both pro-inflammatory cytokines (e.g. IL-1, IL-6, TNF-α) and anti-inflammatory cytokines such as IL-10 is essential in the control of inflammation [1]. Here, we monitored a panel of cytokines in the exudate to assess whether 2-polyusaturated acyl-lysoPtdEtn could regulate their levels. Four hours after zymosan A treatment, most cytokine was dramatically up-regulated, compared to the control (Fig. 5). Of interest, 2-ARA-lysoPtdEtn and 2-docosahexaenoyl-lysoPtdEtn dose-dependently reduced the levels of pro-inflammatory cytokine including TNF-α, IL-1β or IL-6, while showing no significant effect on other pro-inflammatory cytokines such as IL-2 or IFN-γ (not shown). In the meantime, oral administration of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn caused a dose-dependent elevation of anti-inflammatory cytokine, IL-10. Noticeably, 2-DHA-lysoPtdEtn and 2-ARA-lysoPtdEtn (150 μg/kg) increased the IL-10 level by approximately four- and five-fold, respectively, compared to the zymosan A-challenged group ($P < 0.05$).

Suppressive Effect of 2-polyunsaturated Acyl-lysoPtdEtn on Zymosan A-Induced NO Production in Plasma Leakage

Nitric oxide (NO) plays a key role in the inflammation process especially including regulation of inflammatory cell transmigration into the inflamed site and up-regulation of vascular permeability In zymosan A-induced peritonitis, NO is produced by activated macrophages and eventually be oxidized within few second to nitrite or nitrate [33]. Therefore, to examine whether 2-polyusaturated acyl-lysoPtdEtn could attenuate the level of NO, we determined the amount of NO formation in exudate. As expected, 2-DHA-lysoPtdEtn as well as 2-ARA-lysoPtdEtn, orally administered, drastically suppressed zymosan A-induced NO production in ICR mice (Fig. 6). Interestingly, 2-DHA-lysoPtdEtn (50 μg/kg) almost completely suppressed the

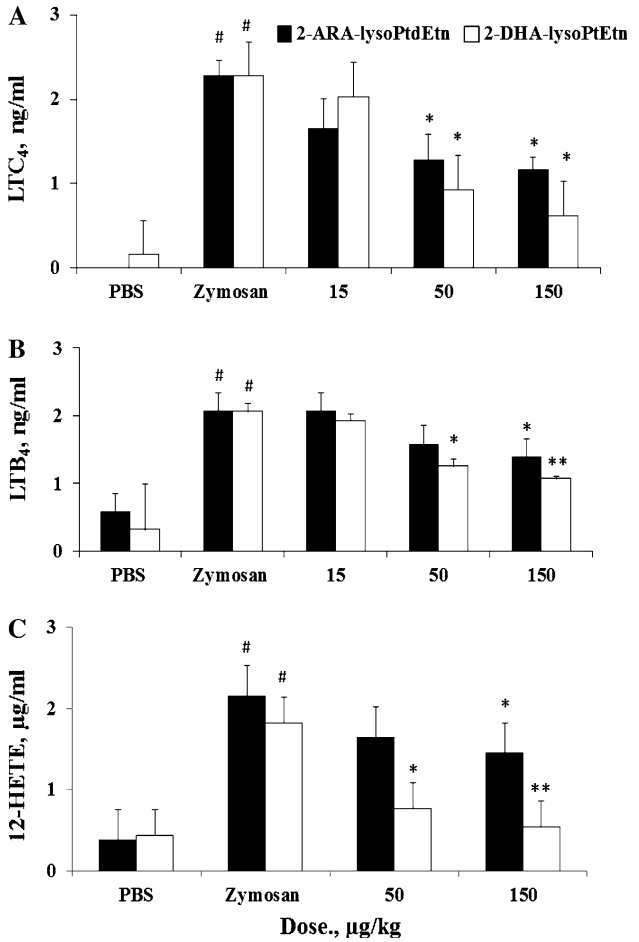

Fig. 4 Suppressive effect of 2-ARA-lysoPtdEtn or 2-docosahexaenoyl-lysoPtdEtn on zymosan A-induced pro-inflammatory lipid mediator formation in mice. Mice were orally given 2-ARA-lysoPtdEtn (*filled*) or 2-DHA-lysoPtdEtn (*blank*) (15–150 μg/kg) 60 min prior to administration of zymosan A (i.p., 1 mg/mouse). Peritoneal lavages were collected at 4 h and the level of pro-inflammatory lipid mediator in cell-free supernatant was assessed by an EIA kit according to the manual. Each sample was determined in duplicate. Results are means ± SEM ($n = 5$). #, $P < 0.001$ when compared to the PBS-treated group; *, $P < 0.05$; **, $P < 0.01$ when compared to zymosan A-treated group

NO formation caused by zymosan A stimulation; 2-ARA-lysoPtdEtn at 50 and 150 μg/kg diminished the NO level by 60 and 70%, respectively. Taken all together, it was suggested that at least some part of inflammatory action of 2-polyunsaturated lysoPtdEtn was ascribed to the inhibition of NO production.

Suppressive Effect of 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn on Zymosan A-Induced Plasma Leakage and Leukocyte Infiltration

In a subsequent experiment, we elucidated which metabolic pathway is crucial for the anti-inflammatory action of 2-polyunsaturated acyl-lysoPtdEtn. Since 15-LOX activity, but not COX activity, was crucial for the anti-inflammatory action of 2-polyunsaturated lysoPtdEtn (Figs. 3, 4), we investigated the anti-inflammatory effect of 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn, derived from 15-LOX-oxygenation of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, respectively, on zymosan A-induced peritonitis. As demonstrated in Fig. 7a, plasma leakage induced by zymosan A was suppressed by 2-(15-HETE)-lysoPtdEtn (EC_{50}, ~48 μg/kg) and 2-(17-HDHE)-lysoPtdEtn (EC_{50}, 42 μg/kg) in a dose-dependent manner. Of notice, Fig. 7b indicated that EC_{50} of 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn was estimated to be about ~42 and 28 μg/kg, respectively. Especially, 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn, orally administered at a dose as low as 50 μg/kg could almost completely suppress leukocyte infiltration. In comparison, it was found that the suppression effect of 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn on leukocyte infiltration was more potent than that of 2-ARA-lysoPtdEtn (EC_{50}, ~123 μg/kg) and 2-DHA-lysoPtdEtn (EC_{50}, ~110 μg/kg), respectively ($P < 0.01$), indicating that oxidized derivatives were more potent than the corresponding polyunsaturated acyl lysoPtdEtn in expressing anti-inflammatory action in vivo. Taken together, these data indicate that 15-LOX oxygenation products of 2-polyunsaturated acyl-lysoPtdEtn could be active metabolites directly responsible for the anti-inflammatory action in vivo.

Effect of 2-ARA-lysoPtdEtn on the Formation of 15-HETE and LXA_4 in the Peritoneum of Mice

Previously, lysophospholipids administered to mice, were reported to be hydrolyzed by lipase activity [9] to release the hydrolysis product which in turn was converted to an active anti-inflammatory metabolite [12]. With this in mind, we examined the possible formation of 15-HETE and LXA_4 from 2-ARA-lysoPtdEtn in peritoneal exudate after oral administration of 2-ARA-lysoPtdEtn. Figure 8 indicates that oral administration of 2-ARA-lysoPtdEtn causes an increase in the level of 15-HETE (Fig. 8a) and LXA_4 (Fig. 8b) in the exudate; 2-ARA-lysoPtdEtn at 15, 50 and 150 μg/kg enhances 15-HETE level by approximately 3.5-, 5- and 9-fold, respectively, and the LXA_4 level by about 2-, 4- and 5.5-fold, respectively. However, the formation of 15-HETE was not significant in the exudate from mice administered with 2-ARA-lysoPtd in combination with PD146176 (100 μg/mouse) (data not shown). Separately, the 4 h hydrolysis of the exudate sample in 1 N NaOH was carried out to see the possible reincorporation of the 15-HETE product into the phospholipids. As illustrated in Fig. 8a, the amount of 15-HETE in hydrolyzed samples, obtained from alkaline hydrolysis of peritoneal exudates was apparently greater than that in the

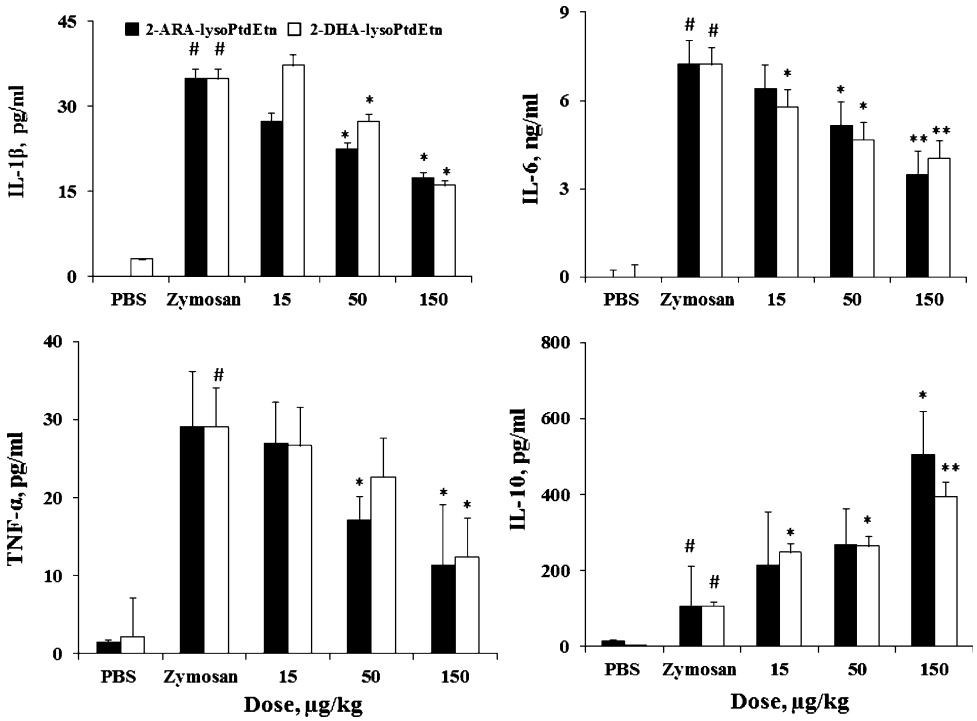

Fig. 5 Effect of 2-ARA-lysoPtdEtn or 2-docosahexaenoyl-lysoPtdEtn on zymosan A-induced pro-inflammatory and anti-inflammatory cytokine formation. Mice were orally given 2-ARA-lysoPtdEtn (*filled*) or 2-DHA-lysoPtdEtn (*blank*) (15–150 μg/kg) 60 min prior administration of zymosan A (i.p., 1 mg/mouse). Peritoneal lavages were collected at 4 h, and the cytokine level in cell-free supernatant was assessed by ELISA assay kit according to manufactures' protocol. Results are means ± SEM ($n = 5$). #, $P < 0.001$ when compared to PBS-treated group; *, $P < 0.05$; **, $P < 0.01$ when compared to the zymosan A-treated group

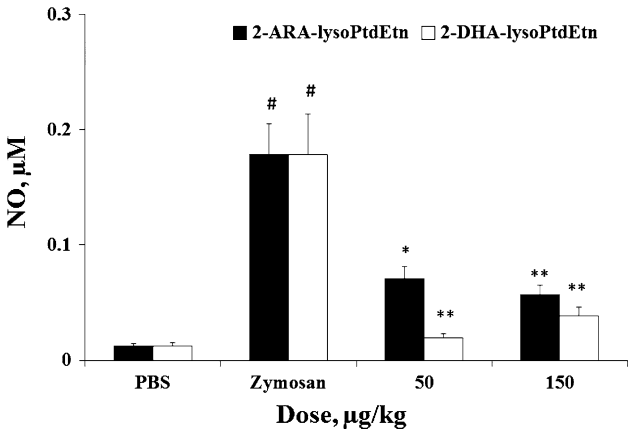

Fig. 6 Suppressive effects of 2-ARA-lysoPtdEtn and 2-docosahexaenoyl-lysoPtdEtn on zymosan A-induced formation of NO in mice. Mice were orally given 2-ARA-lysoPtdEtn (*filled*) or 2-DHA-lysoPtdEtn (*blank*) (15–150 μg/kg), 60 min prior to administration of zymosan A (i.p., 1 mg/mouse). Peritoneal lavages were collected at 4 h and the NO level in cell-free supernatant was measured by colorimetric assay according to the manufacturer's protocol. Results are means ± SEM ($n = 5$). #, $P < 0.001$ when compared to PBS-treated group; *, $P < 0.05$; **, $P < 0.01$ when compared to the zymosan A-treated group

corresponding non-hydrolyzed samples, suggesting that some part of 15-lipoxygenation products of 2-ARA-lysoPtdEtn, could exist as the lysophospholipid or phospholipid form. In contrast, there was no alteration of the 15-HETE level irrespective of alkaline hydrolysis in peritoneal samples from mice treated orally with 2-DHA-lysoPtdEtn up to 150 μg/kg (data not shown). From this, it was supposed that some part (<40%) of 15-HETE might be deposited in the lysophospholipid or phospholipid. The presence of lysophospholipid- and phospholipid-bound 15-HETE could provide a support for the 15-lipoxygenation of polyunsaturated acyl-lysoPtdEtn in vivo. Nonetheless, it is not excluded that free 15-HETE was reincorporated into the phospholipid.

Oral Administration of 2-Polyunsaturated Acyl-lysoPtdEtn Induced Resolution of Zymosan A Induced Peritonitis

In order to see whether 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn could attenuate the resolution of zymosan A-induced peritonitis, we examined the effect of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn on zymosan A-induced leukocyte infiltration in ICR mice. In our previous data [9], it was observed that the total number of leukocytes infiltrated reached a maximum approximately 12 h after zymosan A treatment. Therefore, 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn was administered 12 h after zymosan A treatment to see their effect on the resolution phase in zymosan A-induced peritonitis. As shown in Fig. 9, 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn, orally administered at the peak of inflammation (12 h post-zymosan A treatment), effectively decreased the total leukocyte infiltration at the time points of 15, 20 and 24 h, whereas 2-ARA-lysoPtdEtn produced ~23, 21 and 33% reduction of total leukocyte number, respectively, 2-DHA-lysoPtdEtn gave approximate 29, 33 and 44% reduction. In summary,

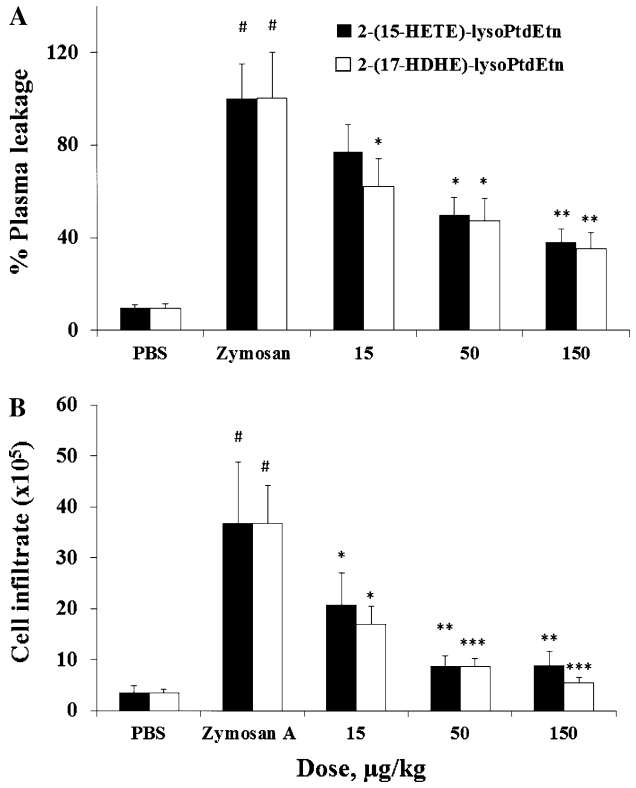

Fig. 7 Suppressive effect of hydroxyl derivatives of polyunsaturated acyl-lysoPtdEtn on zymosan A-induced plasma leakage or leukocyte infiltration. 2-(15-HETE)-lysoPtdEtn (*filled*) or 2-(17-HDHE)-lysoPtdEtn (*blank*) was orally administered to mice 60 min prior to the zymosan A challenge (1 mg/mouse; i.p.). Plasma leakage (**a**) and total leukocyte migration (**b**) was determined according to the methods described in Figs. 2 and 3, respectively. Results are means ± SEM ($n = 5$). #, $P < 0.001$ when compared to PBS-treated group; *, $P < 0.05$; **, $P < 0.01$, ***, $P < 0.001$ when compared to the zymosan A-treated group

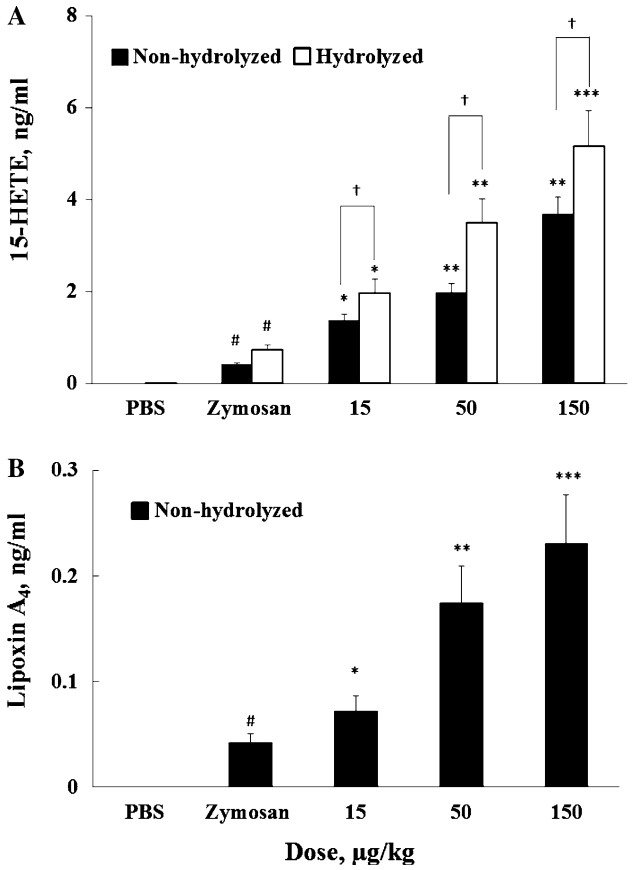

Fig. 8 Dose-dependent effect of 2-ARA-lysoPtdEtn on the level of 15-HETE or LXA_4 before or after alkaline hydrolysis of the exudate from mice. Mice were orally treated with 2-ARA-lysoPtdEtn, 60 min prior to administration of zymosan A (i.p., 1 mg/mouse). The exudate samples were collected at 120 min after zymosan A treatment, and then 15-HETE (**a**) or LXA_4 (**b**) in non-hydrolyzed (*filled*) or 1 N NaOH-hydrolyzed sample (*blank*) was extracted and determined by EIA kit according to manual. Results are means ± SEM ($n = 5$). #, $P < 0.01$ when compared to the PBS-treated group; *, $P < 0.05$; **, $P < 0.01$, ***, $P < 0.001$ when compared to the zymosan A-treated group; +, $P < 0.05$ was the significant difference between groups

it is suggested that 2-polyunsaturated acyl-lysoPtdEtn accelerates the resolution of zymosan A-induced peritonitis.

Discussion

Nowadays, inflammation has been recognized as the central component of many prevalent diseases such as atherosclerosis, cancer, asthma, autoimmune disease, stroke, Alzheimer's disease and Parkinson's disease [1]. Interestingly, it now become apparent that inflammation is a dynamic process with the participation of new family of endogenous anti-inflammatory and pro-resolving lipid mediators such as resolvins, maresin and protectin derived from omega 3-polyunsaturated fatty acids [4, 5, 34]. These lipid mediators, actively biosynthesized in the resolution phase of acute inflammation, control the duration and magnitude of inflammation [4]. Whereas anti-inflammatory actions of lipid mediators, derived from polyunsaturated fatty acids and polyunsaturated lysoPtCho, have been well-established [3, 4, 8, 9, 12, 35], the biological function of polyunsaturated lysoPtdEtn derivatives in inflammation has not been clarified yet. Very recently, we found that oral administration of 1-DHA-lysoPtCho prevented zymosan A-induced peritonitis [13]. In our present study, it is proposed that 2-polyunsaturated acyl lysoPtdEtns also effectively suppresses acute inflammation induced by zymosan A.

It has been known that induction of vascular permeability and leukocyte infiltration are important events of biological response at the onset of acute inflammation [36]. In the present work, the anti-inflammatory action of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn was first substantiated by their effective prevention against zymosan A-induced plasma leakage with a potency similar to that of

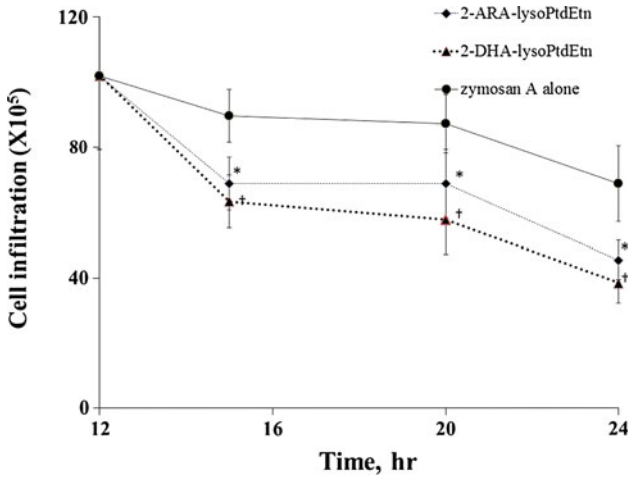

Fig. 9 Induction of resolving zymosan A-induced peritonitis by 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn. Mice were i.p. administered with zymosan A (1 mg/mouse) alone (*triangles*) or with either 2-ARA-lysoPtdEtn (*open circles*) or 2-DHA-lysoPtdEtn (*closed circles*) (12 h after zymosan A treatment). At the indicated periods, peritoneal lavage samples were collected and the total number of leukocyte infiltrated was enumerated according to the method described in Fig. 3. Results are means ± SEM ($n = 5$). *, $P < 0.05$; the 2-ARA-lysoPtdEtn-treated group vs. the zymosan A-treated group; †, $P < 0.05$, ††, $P < 0.01$, 2-DHA-lysoPtdEtn-treated group vs. zymosan A-treated group

polyunsaturated lysoPtCho [12]. Such a potent effect is possibly associated with the suppressive effect of 2-acyl-lysoPtdEtn on the formation of LTC_4 since early vascular permeability depends largely on cysteinyl-leukotriene (cysLT) released by resident peritoneal macrophages. Although vascular permeability is known to depend on PGE_2 from multiple cellular origins in zymosan A-induced peritonitis [26, 37], the level of PGE_2 was not altered by 2-polyunsaturated-lysoPtdEtn. Another mechanism possibly responsible for the anti-inflammatory action of polyunsaturated acyl lysoPtdEtns could be due to the decreased formation of NO, released from macrophages, which reversibly opens the endothelial cells tight junction leading to an enhancement of vascular permeability [33]. This might be partly supported by our present finding that the formation of NO in the peritoneum was reduced by 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn at relatively small doses.

In addition, the anti-inflammatory action of 2-polyunsaturated-lysoPtdEtn, represented by inhibition of leukocyte migration, could be related to the suppression of the formation of pro-inflammatory chemotactic lipid mediators. Support for this may come from the suppressive effect of 2-polyunsaturated-lysoPtdEtns on the formation of LTB_4 [4] and 12-HETE [38, 39], two potent arachidonate-derived chemo-attractants responsible for leukocyte infiltration in the initial process of the inflammatory phase. Moreover, the levels of representative pro-inflammatory cytokines (TNF-α, IL-1β, IL-6), possessing chemo-attractant properties [1, 40] were significantly diminished by 2-polyunsaturated-lysoPtdEtns. Noteworthy is that 2-polyunsaturated acyl-lysoPtdEtn up-regulated IL-10, a potent anti-inflammatory cytokine, secreted by macrophage in acute inflammation, which showed a tonic inhibitory effect on the leukocyte migration and the formation of pro-inflammatory cytokine (TNF-α, IL-1β, IL-6) as well as chemokines (MCP-1, MIP-1α and MIP-2) in zymosan A peritonitis [41]. Additionally, IL-10 could block NF-kB activation by stabilization of IkBα [42, 43], and in turn, inhibit the induction of inducible nitric oxide synthetase (iNOS), resulting in decreased formation of nitric oxide (NO). Furthermore, activation of human monocyte and monocyte-derived dendritic cells by cysteinylated leukotrienes was down-regulated by IL-10 [44]. Collectively, IL-10 could extensively regulate zymosan A-induced peritonitis through both direct and indirect manners.

In previous studies we proved that 15-lipoxygenase activity was necessary for the anti-inflammatory function of 2-polyunsaturated acyl-lysoPtCho in zymosan A-induced peritonitis [8, 9]. Our present study also indicated that 15-lipoxygenase activity was crucial for the anti-inflammatory function of 2-polyunsaturated acyl-lysoPtdEtn, since PD146176, a specific inhibitor of 15-LOX, suppressed the effect of 2-polyunsaturated acyl-lysoPtdEtn on leukocyte infiltration. In support of this, 2-(15-HETE)-lysoPtdEtn and 2-(17-HDHE)-lysoPtdEtn were more potent as anti-inflammatory lipids than 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, respectively, supporting the assumption that the hydroxyl derivatives might be more direct precursors for active metabolites accounting for the anti-inflammatory action of 2-polyunsaturated acyl-lysoPtdEtn in vivo.

A pathway for further metabolism for 2-polyunsaturated acyl-lysoPtdEtn might be a hydrolytic process since a lipase activity capable of hydrolyzing polyunsaturated lysophospholipids had been reported to be available in an in vivo system [9]. In support of this notion, the formation of 15-HETE in the peritoneum was augmented in accordance with an increasing dose of 2-ARA-lysoPtdEtn, and diminished by PD146176, a specific inhibitor for 15-LOX. Therefore, 15-HETE-lysoPtdEtn metabolite, generated from the oxygenation of 2-ARA-lysoPtdEtn, orally administered, by 15-LOX, could serve as a source for the 15-HETE supplement in vivo. Noteworthy, the 15-HETE level of 1 N NaOH-hydrolyzed sample was significantly higher than that of non-hydrolyzed sample, suggesting two possibilities; some part of 2-(15-HETE)-lysoPtdEtn was still not hydrolyzed by lipase activity or 15-HETE, released from 2-(15-HETE)-lysoPtdEtn, could be re-incorporated into the lipid or lysophospholipid by the lysophospholipid acyltransferase activity [45] in the in vivo condition. It had

been previously reported that 15-HETE could be stored in the phospholipid, and the lipid after hydrolysis might be used as precursory substrate for LXA_4 formation [46]. In this regard, the dose-dependent increase of LXA_4 formation in the peritoneum after oral administration of 2-ARA-lysoPtdEtn may indicate that 15-HETE generated from 15-lipoxygenation of 2-ARA-lysoPtdEtn and subsequent enzymatic hydrolysis, was oxygenated by 5-LOX activity to produce 5-hydroperoxy, 15-hydroxyeicosatetraenoic acid, a direct precursor for LXA_4 and LXB_4 formation [47]. Likewise, it is quite possible that 2-DHA-lysoPtdEtn may be oxygenated to form 2-(17-hydroxyDHA)-lysoPtdEtn, which subsequently is hydrolyzed by a lipase activity to release 17-hydroxydocosahexaenoic acid (17-HDHE), a precursor for the formation of anti-inflammatory and proresolving lipid mediators such as protectin D [34] or resolvin D [32, 48]. Taken together, it is quite possible that the anti-inflammatory activity of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn in zymosan A-induced peritonitis is the consequence of bioactive oxygenated lipid mediators. Besides, an additional mechanism for anti-inflammatory activity of 2-polyunsaturated acyl-lysoPtdEtn was reported to be related to the inhibition of 5-LOX activity by 15-HETE [49], resulting in the reduction of LTB_4 and LTC_4 level, as well as the suppression of LTB_4-evoked chemotaxis for leukocyte in acute inflammation [50]. Likewise, DHA [51] and 17-HDHE [52], generated from the metabolite of 2-DHA-lysoPtdEtn can indirectly or directly participate in the inhibition of 5-LOX activity, leading to the reduction of the leukotrienes level. As suggested from the present results, the anti-inflammatory action of 2-ARA-lysoPtdEtn in vivo might be at least partially ascribed to the effect of its oxygenated metabolites such as lipoxins (LXs). Previously, the anti-inflammatory activity of LXA_4 through various mechanistic routes has been well-established. For instance, LXs inhibit leukocytes activation, chemotaxis, adhesion, transmigration, and pro-inflammatory mediator generation [53, 54]. Additionally, it also inhibits the increase in vascular permeability triggered by activated leukocytes [55, 56]. Additionally, LXA_4 could diminish LTC_4-induced vascular permeability [56]. Noteworthy, LXA_4 formation could give an elevation of IL-10 level [57]. Meanwhile, the anti-inflammatory action of 2-DHA-lysoPtdEtn in vivo may be derived from the effect of its bioactive metabolites such as 17-HDHE or protectin D in vivo [27, 32]. 17-HDHE has been known to express the anti-inflammatory action through inhibition of the NF-κB pathway and down-regulation of 5-LOX expression in macrophages [52]. Besides, anti-inflammatory lipids such as protectin D1 or resolvin D [32, 48], presumably derived from the in vivo metabolism of 2-DHA-lysoPtdEtn, might be involved in its anti-inflammatory activity through suppression of leukocyte migration, down-regulation of pro-inflammatory cytokines, and inhibition of the NF-κB pathway. Since the anti-inflammatory effect of 2-DHA-lysoPtdEtn was almost completely reversed by a specific inhibitor of 15-LOX, it was suggested that maresin [5], formed via 12-LOX oxygenation pathway, might not be important for the anti-inflammatory action of 2-DHA-lysoPtdEtn [5]. Moreover, 2-DHA-lysoPtdEtn was not oxygenated by platelet 12-LOX (data not shown). Separately, the suppressive effects of 2-arachidonoyl-lysoPtdEtn and 2-DHA-lysoPtdEtn on leukocyte infiltration in the exudate in a later phase (12 h) of zymosan A-induced peritonitis may reflect their effects on pro-resolution through the removal of phagocytized cells [58]. Such a pro-resolving action of 2-polyunsaturated acyl-lysoPtdEtn may be related to the generation of bioactive metabolites such as LXA_4, resolving or protectin, responsible for resolution of acute inflammation [59].

An alternative mechanism accountable for the anti-inflammatory action of 2-ARA-lysoPtdEtn or 2-DHA-lysoPtdEtn could be re-acylation of the corresponding oxygenation product; 15-HETE or 17-HDHE into phospholipids [18, 60]. In an earlier study, 18:0/15-HETE-phosphatidylethanolamine derivatives, generated from the re-acylation of 15-HETE into lysophospholipid, was reported to inhibit the release of pro-inflammatory cytokine from lipopolysaccharide-stimulated monocytes [18]. Another plausible mechanism for the anti-inflammatory actions of 2-polyunsaturated acyl-lysoPtdEtn in vivo may be from the inhibitory effect 15-HETE and 17-HDHE on 12-LOX activity, responsible for 12-HETE formation, as suggested from a strong inhibition of 12/15 LOX by 15-HETE and 17-HDHE [61]. In agreement with this, the present study has shown that oral administration of 2-ARA-lysoPtdEtn and 2-DHA-lysoPtdEtn, precursors for formation of 15-HETE and 17-HDHE, respectively, diminished the level of 12-HETE in the peritoneum dose-dependently. In turn, the reduction of 12-HETE could result in abrogation of pro-inflammatory cytokine levels and monocyte chemoattractant protein (MCP-1) as had been reported previously [62–64]. Of note, the suppressive effect of 2-polyunsaturated acyl-lysoPtdEtns on zymosan A-induced 12-HETE formation in the present study was greater than that of 1-polyunsaturated acyl-lysoPtChos [9]. Taken together, the anti-inflammatory actions of 2-polyunsaturated acyl-lysoPtdEtn could be exerted through multiple mechanisms.

In conclusion, our present observations concerning the anti-inflammatory and pro-resolving activity of 2-polyunsaturated acyl-lysoPtdEtn may suggest that it can be a new anti-inflammatory lipid useful for the prevention as well as treatment of the zymosan A-induced peritonitis model. In future studies to expand its application, anti-inflammatory and pro-resolving activity of 2-polyunsaturated

acyl-lysoPtdEtn is to be studied using other inflammation models. Furthermore, the structural design to obtain more stable derivatives of 2-polyunsaturated acyl-lysoPtdEtn should be also considered to broaden the practical use of 2-polyunsaturated acyl-lysoPtdEtn as an anti-inflammatory lipid agent.

Abstract The schweinfurthins, a family of natural products derived from the isoprenoid biosynthetic pathway (IBP), have marked growth inhibitory activity. However, the biochemical basis for the schweinfurthins cellular effects has remained ill-defined. Here, the effects of the synthetic schweinfurthin, 3-deoxyschweinfurthin (3dSB) on multiple aspects of isoprenoid homeostasis are explored. Cytotoxicity assays demonstrate a synergistic interaction between 3dSB and the HMG-CoA reductase inhibitor lovastatin but not with other IBP inhibitors in a variety of human cancer cell lines. The cytotoxic effects of 3dSB were enhanced in cells incubated in lipid-depleted serum. 3dSB was found to enhance the lovastatin-induced decrease in protein prenylation. In addition, 3dSB decreases intracellular farnesyl pyrophosphate and geranylgeranyl pyrophosphate levels in both established cell lines and primary cells. To determine whether 3dSB alters the regulation of expression of genes involved in isoprenoid homeostasis, real-time PCR studies were performed in human cell lines cultured in either lipid-replete or -deplete conditions. These studies demonstrate that 3dSB abrogates lovastatin-induced upregulation of sterol regulatory element-containing genes and lovastatin-induced downregulation of ABCA1. In aggregate, these studies are the first to demonstrate that a schweinfurthin exerts pleiotropic effects on isoprenoid homeostasis.

Keywords Isoprenoid · Schweinfurthin · Lovastatin · Farnesyl pyrophosphate · Geranylgeranyl pyrophosphate · Sterol · ABCA1 · Prenylation

Abbreviations

3dSB	3-Deoxyschweinfurthin B
ABCA1	ATP-binding cassette transporter 1
DGBP	Digeranyl bisphosphonate
ER	Endoplasmic reticulum
FCS	Fetal calf serum
FDPS	Farnesyl diphosphate synthase
FPP	Farnesyl pyrophosphate
FTase	Farnesyl transferase
GGDPS	Geranylgeranyl diphosphate synthase
GGPP	Geranylgeranyl pyrophosphate
GGTase	Geranylgeranyl transferase
GI_{50}	50% growth inhibition
HMGR	3-Hydroxy-3-methyl-glutaryl-CoA reductase
IBP	Isoprenoid biosynthetic pathway
LPDS	Lipoprotein deficient serum
LXR	Liver X receptor
MTT	3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide
SRE	Sterol regulatory element
SREBP	Sterol regulatory element-binding protein
SS	Squalene synthase
ZA	Zoledronic acid
Zara	Zaragozic acid

Introduction

Schweinfurthins are a family of natural compounds that were originally isolated from the leaves of the flowering tree *Macaranga schweinfurthii* in Western Cameroon [1]. The extracts from these leaves were noted to have potent growth inhibitory activity in the NCI 60-cell line cancer screen and subsequent isolation of the active components identified schweinfurthins A and B with mean GI_{50}'s of 0.36 and 0.81 μM, respectively [1]. Extensive structure–function analysis has provided insight into the key structural features which are necessary to retain schweinfurthin-like activity [2–7], but the mechanism of action has yet to be determined. Given the difficulty in isolating sufficient quantities of these compounds to allow for further biological exploration, a number of analogues have been prepared, including 3-deoxyschweinfurthin B (3dSB) (Fig. 1), which has a mean GI_{50} of 0.74 μM and has been shown to retain schweinfurthin-like activity [8].

The schweinfurthin family shares the common structural feature of having one or more prenyl side chains. The prenyl groups are derived from the isoprenoid biosynthetic pathway (IBP) which is responsible for the synthesis of all sterol and non-sterol isoprenoids (Fig. 1). In addition to the products displayed in Fig. 1, this pathway also leads to the synthesis of other biologically important molecules such as the ubiquinones, dolichols, and retinoids [9]. There is an extraordinary degree of complexity with regards to regulation of the IBP and sterol homeostasis [10]. The expression of the majority of the enzymes in the IBP are regulated through sterol regulatory element-binding protein (SREBP) transcription factors [11, 12]. In conditions of sterol depletion, SREBPs upregulate the expression of genes with SRE-containing promoters, leading to increased de novo synthesis of sterols and nonsterols as well as increased cellular uptake of sterols via the LDL receptor. Conversely, in conditions of sterol excess, SREBPs are sequestered in the endoplasmic reticulum (ER) via Insigs and there is upregulation of sterol efflux proteins such as ATP-binding cassette transporter 1 (ABCA1) via liver X receptor (LXR)-mediated regulation [13–15].

Sterols (including oxysterols, cholesterol, and lanosterol), nonsterols [e.g., farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate (GGPP)], and miRNA (MiR-33) have all been shown to be important regulators of isoprenoid homeostasis [16–21]. Furthermore, a multitude of natural products derived from the IBP have been demonstrated to affect IBP regulation and sterol homeostasis through a variety of mechanisms, including the diterpenes cafestol, Daphnetoxin and Gniditrin [22, 23], monoterpenes [24, 25], tocotrienols [26], and triterpenoids [27–29], further highlighting the extraordinarily complex relationship between the IBP and its products. Finally, select inhibitors of the IBP also alter regulation of the IBP and affect the expression of derivatives of the IBP [30–35]. Thus, given the extent to which IBP products and inhibitors can influence IBP regulation, we were interested in exploring the potential interaction between schweinfurthins

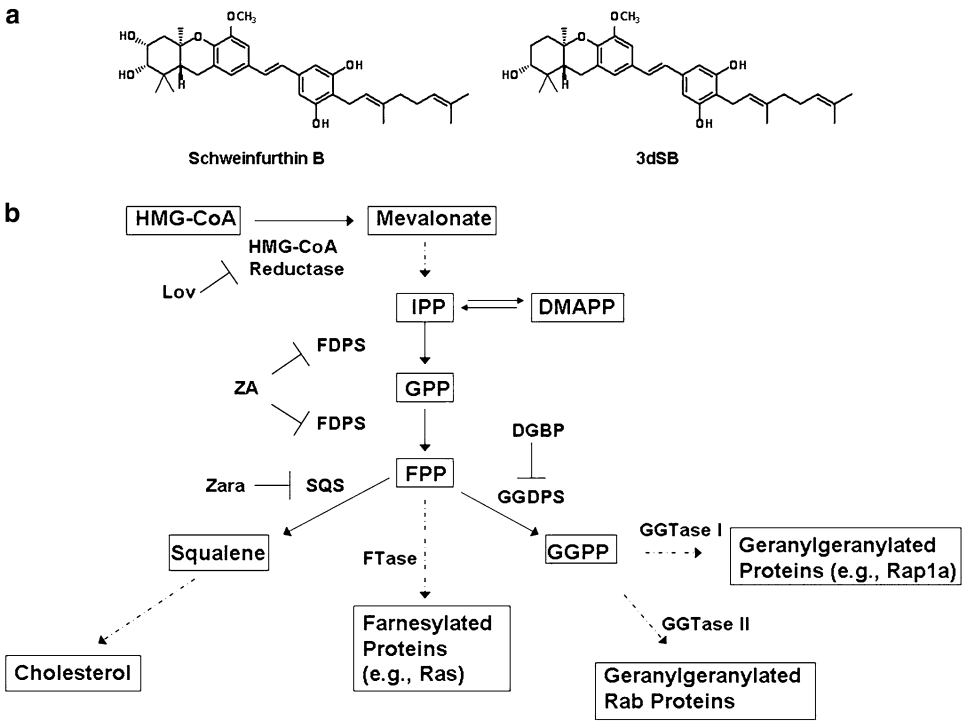

Fig. 1 **a** Structures of schweinfurthin B and 3-deoxyschweinfurthin B (3dSB). **b** The isoprenoid biosynthetic pathway (IBP) and pharmacological inhibitors. Abbreviations: *Lov* lovastatin, *ZA* zoledronic acid, *Zara* zaragozic acid, *DGBP* digeranyl bisphosphonate

and IBP inhibitors, determining the effects of schweinfurthins on isoprenoid homeostasis, and providing insight into the basis for schweinfurthins' biological activity. Here we demonstrate that the synthetic schweinfurthin 3dSB enhances inhibition of protein prenylation and induction of cytotoxicity in the setting of mevalonate depletion and reveal that 3dSB disrupts regulation of isoprenoid homeostasis.

Materials and Methods

Reagents

Lovastatin (converted to the dihydroxy-open acid form prior to use), DL-mevalonic acid lactone (converted to mevalonate prior to use), FPP, GGPP, and zaragozic acid were obtained from Sigma (St. Louis, MO). Zoledronic acid was purchased from Novartis (East Hanover, NJ). Digeranyl bisphosphonate (DGBP) [36] and 3-deoxy-schweinfurthin [5] were kindly supplied by Professor David Wiemer, Department of Chemistry, University of Iowa. 3dSB was dissolved in DMSO. Anti-pan-Ras was obtained from InterBiotechnology (Tokyo, Japan). Anti-β-tubulin, anti-Rap1a, anti-Rab6, and anti-goat IgG HRP antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Anti-mouse and anti-rabbit HRP-linked antibodies were obtained from Amersham (GE Healthcare, Piscataway, NJ). D*-GCVLS and D*-GCVLL (dansyl-labeled peptides) were obtained from Bio-Synthesis (Lewisville, TX). Rat recombinant FTase and GGTase I were purchased from Jena Biosciences (Jena, Germany). HPLC-grade water was prepared with a Milli-Q system (Millipore, Bedford, MA). All solvents were optima or HPLC grade. Lipoprotein deficient serum was obtained from Hyclone (Thermo Scientific, Logan, UT).

Cell Cultures

Human multiple myeloma (RPMI-8226 and U266) and human glioblastoma multiforme (SF-295) cell lines were purchased from American Type Culture Collection (Manassas, VA). A549 cells, a human non-small cell lung cancer cell line, were obtained from the NCI (Frederick, MD). Cells were grown in RPMI-1640 media with 10% (RPMI-8226, SF-295) or 15% (U266) heat-inactivated fetal calf serum supplemented with glutamine and penicillin–streptomycin at 37 °C and 5% CO_2. A549 cells were maintained in F-12 media supplemented with 10% fetal calf serum, glutamine, and penicillin–streptomycin. For the studies involving primary cells, after informed consent, peripheral blood samples were obtained from patients with acute leukemia. The protocol (IRB ID # 200610770) was approved by our Institutional Review Board for human subjects. Mononuclear cells were isolated from peripheral blood of patients with newly diagnosed acute leukemia and incubated ex vivo with 3dSB or lovastatin for 24 h. Formal pathological review of the bone marrow samples as well as cytogenetic analysis was performed by UIHC Hemato-pathology.

MTT Assay

For the suspension cell lines (RPMI-8226 and U266), cells were seeded (5×10^4/150 μL per well) in 96-well flat-bottom plates and incubated for 48 h at 37 °C and 5% CO_2 in the presence or absence of compounds. For the adherent cell lines (SF-295 and A549), cells were plated in 24-well plates, allowed to reach 65% confluency, and then incubated in the presence or absence of compounds for 48 h. MTT assays were performed as previously described [3, 43]. The absorbance for control untreated cells was defined as an MTT activity of 100%. DMSO treatment did not alter MTT activity by more than 5%.

Western Blot Analysis

Cells (5×10^6/5 mL) were incubated in the presence or absence of drugs. At the conclusion of the incubations, cells were collected, washed with PBS, and lysed in RIPA buffer (0.15 M NaCl, 1% sodium deoxycholate, 0.1% SDS, 1% Triton (v/v) X-100, 0.05 M Tris–HCl) containing protease and phosphatase inhibitors. Protein content was determined using the bicinchoninic acid method (Pierce Chemical, Rockford, IL). Equivalent amounts of cell lysate were resolved by SDS-PAGE, transferred to polyvinylidene difluoride membrane, probed with the appropriate primary antibodies, and detected using HRP-linked secondary antibodies and Amersham Pharmacia Biotech ECL Western blotting reagents per manufacturer's protocols.

Intracellular FPP and GGPP Measurements

Intracellular FPP and GGPP levels were measured using the previously reported reversed phase HPLC methodology [38]. Briefly, following incubation with drugs, cells were collected and counted using a hemocytometer. Isoprenoid pyrophosphates were extracted from cell pellets with extraction solvent (butanol/75 mM ammonium hydroxide/ethanol 1:1.25:2.75). Following drying down by nitrogen gas, the FPP and GGPP in the residue were incorporated into fluorescent GCVLS or GCVLL peptides by farnesyltransferase or geranylgeranyl transferase I, respectively. The prenylated fluorescent peptides were separated and quantified by reversed phase HPLC with fluorescence detection.

HMGR Activity Assay

The HMG-CoA reductase assay kit was purchased from Sigma (St. Louis, MO) and the assay was performed according to manufacturer's specifications. This assay detects the oxidation of NADPH by HMGR in the presence of HMG-CoA. The decrease in absorbance at 340 nm over time was measured using a Molecular Devices SpectraMax M2e microplate reader. Measurements were taken every 25 s. Pravastatin, which was included in the kit, was used as the positive control. The reaction mixture was incubated in the presence or absence of varying concentrations of 3dSB.

Real-Time PCR

RPMI-8226 or U266 cells were grown in the presence or absence of drugs in media containing either standard FCS or 10% LPDS for 24 h. Each condition was performed in triplicate. RNA was isolated using an RNeasy kit (Qiagen, Valencia, CA) and a BioRad (Hercules, CA) cDNA synthesis kit was used to prepare cDNA. Primers for HMGR, FDPS, SS, GGDPS, SREBP-2, Insig-1, LXRα, ABCA1 and β-actin (Supplementary Table 1) were designed using PrimerQuest. Real-time PCR was performed on an Applied Biosystems Model 7900HT using an Applied Biosystems (Carlsbad, CA) reaction kit with SYBR green. Data were analyzed using ABI SDS 2.3 software and normalized to β-actin RNA. Quantities were determined using the relative standard curve method. Each sample was run in triplicate.

Statistical Analysis

Two-tailed t testing was used to calculate statistical significance for the studies involving measurement of FPP and GGPP levels. An α of 0.05 was set as the level of significance. Isobologram analysis was used to evaluate the data from the MTT assays via CalcuSyn software (Biosoft). The software analyzes drug interactions based on the method of Chou and Talalay [26]. Combination indices (CI) <0.8 were deemed synergistic, CI >1.2 antagonistic, and CI >0.8 but less than 1.2 were deemed additive. ANOVA was used to compare changes in gene expression level following treatment with two drugs (lovastatin alone, 3dSB alone, and the two in combination) under four sets of conditions (two cell lines, two media conditions). The gene expression levels were compared separately for each of the four conditions. Expression levels were log-transformed to satisfy the ANOVA assumptions of normality and equal variances. Differences in expression levels were evaluated with the two-sided pair-wise comparisons of the treatment groups. The False Discovery Rate approach using q values was applied to adjust for multiple comparisons [39, 40] (Supplementary Table 2). Pair-wise comparisons for which the q values were less than 0.05 were declared to be statistically significant. This criterion ensures that the expected proportion of incorrectly rejected pair-wise comparisons is no greater than 5%. SAS version 9.2 and R 2.11.1 were used for the analysis.

Results

The Combination of 3dSB and Lovastatin Induces Synergistic Cytotoxic Effects in Human Malignant Cell Lines

The cytotoxic effects of 3dSB, both alone and in combination with the HMGR inhibitor lovastatin, in MTT assays were assessed in two human multiple myeloma cell lines (RPMI-8226 and U266), a human glioblastoma multiforme cell line (SF-295) and a human non-small cell lung cancer cell line (A549) (Fig. 2a). The RPMI-8226 and SF-295 cells have been previously noted to be particularly sensitive to schweinfurthins with mean GI_{50}'s for schweinfurthin B of 15 and 24 nM, respectively [1]. The A549 cells, on the other hand, represent a relatively more resistant cell line, with a mean GI_{50} of 0.34 μM [1]. The U266 cell line was not part of the NCI 60-cell line panel, but was chosen for these studies based on our prior work which demonstrated resistance to select IBP inhibitors as a consequence of markedly elevated basal isoprenoid levels [41]. Consistent with the NCI findings for schweinfurthin B, the RPMI-8226 cells were noted to be the most sensitive to 3dSB with an IC_{50} of $\sim$150 nM and the A549 cells the least sensitive with an IC_{50} of 5 μM at 48 h. The SF-295 and U266 cells displayed intermediate sensitivity to 3dSB alone with IC_{50} values of 0.5 and 1 μM, respectively. Interestingly, the addition of lovastatin to 3dSB resulted in enhanced cytotoxicity in all four cells. The nature of this interaction was evaluated by isobologram analysis and determined to be synergistic (Table 1). Furthermore, when RPMI-8226 or U266 cells were incubated in media containing lipoprotein deficient serum (LPDS), the cytotoxicity of 3dSB, both alone (3dSB IC_{50} of 80 nM for RPMI-8226 and 0.3 μM for U266) and in combination with lovastatin, was increased (Fig. 2b). This suggested a dependence on sterol availability for 3dSB cytotoxicity.

To determine whether the synergistic interaction was unique to lovastatin, or was observed with other IBP inhibitors, additional MTT assays were performed in which cells were treated with 3dSB in the presence or absence of the FDPS inhibitor zoledronic acid (ZA), the GGDPS inhibitor digeranyl bisphosphonate (DGBP), or the squalene synthase inhibitor zaragozic acid (Zara). As shown in Table 1, none of these agents displayed a synergistic

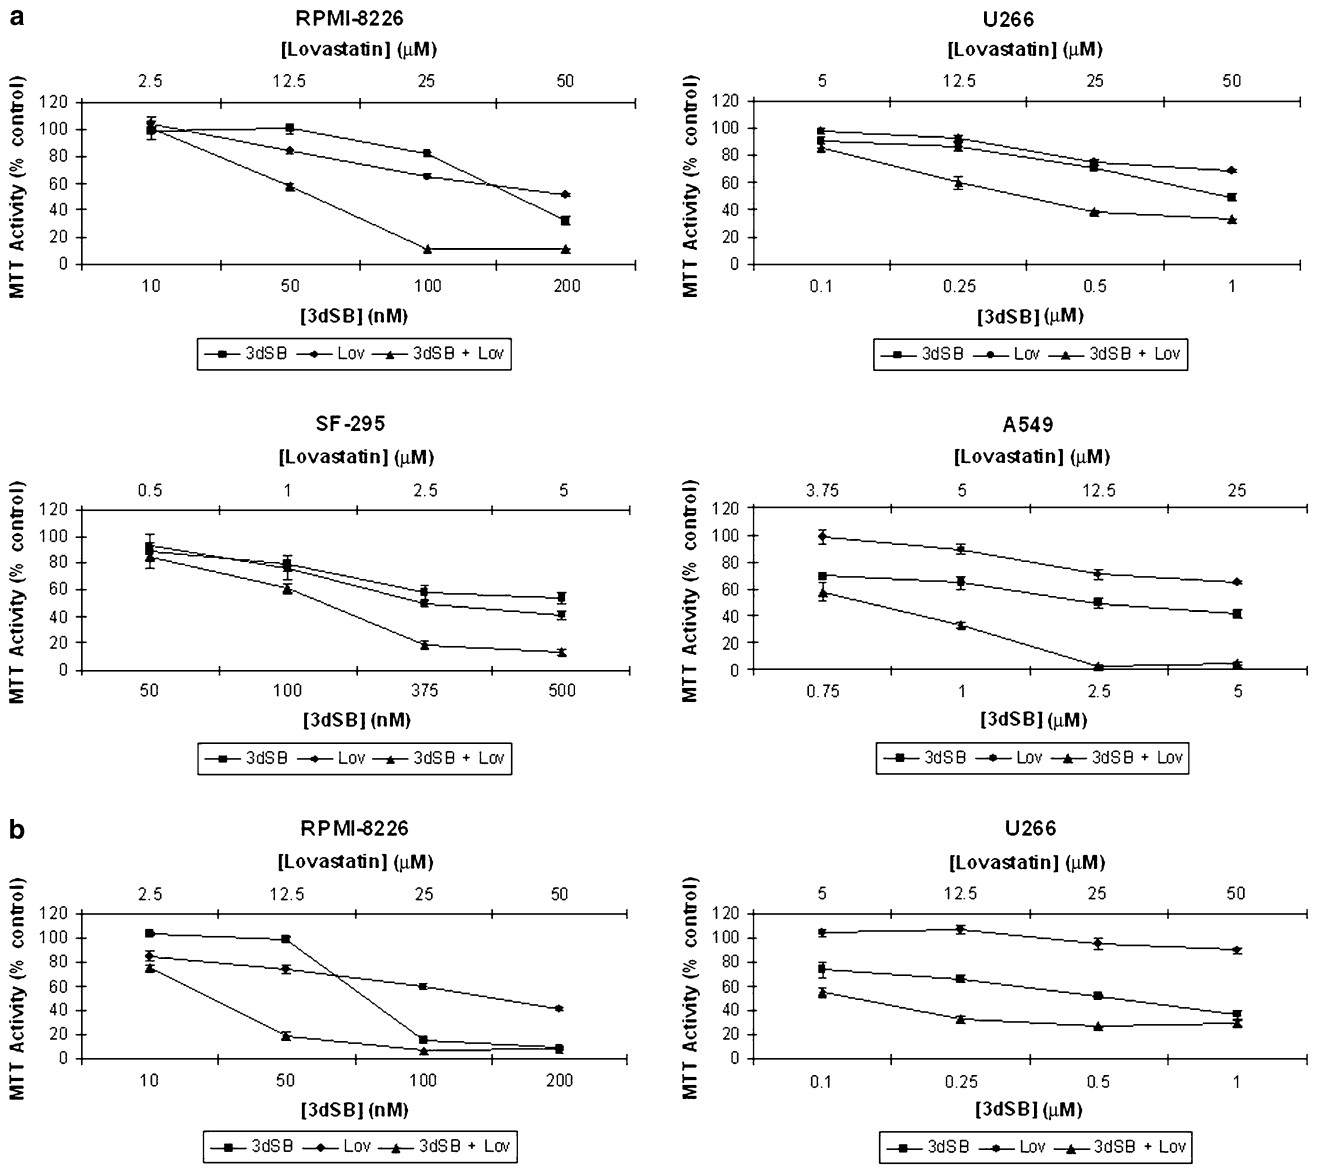

Fig. 2 The combination of lovastatin and 3dSB induces a synergistic cytotoxic effect in malignant cell lines. Cells were incubated for 48 h in the presence or absence of drugs and the MTT assay was performed as described in the "Materials and methods". **a** RPMI-8226, U266, SF-295, and A549 cells were incubated in standard FCS. **b** RPMI-8226 and U266 cells were incubated in LPDS. interaction with 3dSB. In particular, for the RPMI-8226 cells, both DGBP and ZA displayed an antagonistic interaction with 3dSB.

3dSB Enhances Lovastatin-Induced Decrease in Protein Prenylation

The pleiotropic effects of statins in malignant cells have generally been attributed to their ability to inhibit protein prenylation. To determine whether 3dSB, either alone or in combination with lovastatin, altered protein prenylation, immunoblot analysis was performed. Antibodies directed against Ras (substrate of FTase), Rap1a (substrate of GGTase I) and Rab6 (substrate of GGTase II) were utilized. For Ras and Rab6, the appearance of a more slowly migrating band represents unmodified protein, while for Rap1a, the antibody detects only unmodified protein. As shown in Fig. 3a, 3dSB alone has no effect on the prenylation status of the three proteins. As expected, lovastatin decreases both farnesylation and geranylgeranylation. Interestingly, 3dSB was noted to potentiate the effects of lovastatin in the RPMI-8226 cells as evidenced by the increase in the ratio of unmodified to modified protein for Ras and Rab6 and the increase in total unmodified protein

Table 1 Summary of 3dSB-IBP inhibitor interactions in MTT cytotoxicity assays

Combination	Cell line			
	RPMI-8226	U266	SF-295	A549
3dSB + Lov	Synergistic[a]	Synergistic[a]	Synergistic[a]	Synergistic[a]
3dSB + ZA	Additive[b]	Antagonistic[d]	Antagonistic/Additive[f]	ND
3dSB + DGBP	Antagonistic[c]	Antagonistic[d]	Additive[b]	ND
3dSB + Zara	Antagonistic[e]	Antagonistic[e]	ND	ND

Cells were incubated in standard FCS for 48 h in the presence of 3dSB and/or IBP inhibitors (*Lov* lovastatin, *ZA* zoledronic acid, *DGBP* digeranyl bisphosphonate, *Zara* zaragozic acid) prior to the addition of MTT salt. Combination indices (CI) for ED_{30} and ED_{50} (unless otherwise specified) were determined via isobologram analysis

ND Not determined

[f] CI antagonistic for ED_{30} and additive for ED_{50}

for Rap1a. This potentiation occurred in a concentration-dependent manner and was observed for all three prenylated proteins. This effect was particularly evident in cells incubated with LPDS; disruption of protein prenylation was not detected in cells treated with 2.5 μM lovastatin alone, but was detected when cells were co-incubated with ≥50 nM 3dSB. Minimal potentiation was noted when cells were incubated with 3dSB and either zoledronic acid or DGBP (Fig. 3a). 3dSB was also found to potentiate lovastatin's effects in U266 cells, particularly in cells treated with 2.5 μM lovastatin in either FCS or LPDS conditions (Fig. 3b). The effect of 10 μM lovastatin on disruption of protein prenylation in cells incubated with standard FCS was near maximal and the addition of 3dSB did not significantly alter the prenylation pattern.

To determine whether the induced changes in protein prenylation could be prevented by exogenous isoprenoid species, studies were performed in which RPMI-8226 or U266 cells incubated in media containing standard FCS were treated with 3dSB and/or lovastatin in the presence or absence of mevalonate or GGPP. As shown in Fig. 3c, addition of mevalonate or GGPP completely prevented the lovastatin- or lovastatin + 3dSB-induced decrease in Rap1a geranylgeranylation. Mevalonate completely prevented the disruption of Ras prenylation while GGPP only partially restored Ras prenylation, consistent with the ability of normally farnesylated N- and K-Ras isoforms to undergo geranylgeranylation when farnesylation is disrupted [42].

Effects of 3dSB on Intracellular FPP and GGPP Levels

As 3dSB alone did not appear to inhibit protein prenylation, but did potentiate lovastatin's effects, it was hypothesized that 3dSB could be altering isoprenoid availability. Therefore, the effects of 3dSB on intracellular FPP and GGPP levels were determined. Lovastatin, which depletes cells of both FPP and GGPP, was used as a positive control. As shown in Fig. 4a, 3dSB decreased both FPP and GGPP levels in a concentration-dependent manner in all tested cell lines, with the exception of the RPMI-8226 cells. In addition, 3dSB also variably decreased FPP and GGPP levels in primary human acute myeloid leukemia cells which were incubated with the drug in an ex vivo manner (Fig. 5).

The effects of 3dSB on FPP and GGPP levels were also evaluated in RPMI-8226 and U266 cells incubated with media containing LPDS. As shown in Fig. 4b, little effect was seen in the RPMI-8226 cells, but an enhanced depletion of FPP and GGPP levels was observed in the U266 cell line. As described previously [41], basal FPP levels are significantly higher in the U266 cell line compared with the RPMI-8226 line. Of note, incubation in LPDS-containing media significantly increased basal FPP (8.3-fold), but not GGPP levels in the U266 cells (Table 2), while basal levels of FPP and GGPP did not significantly change in RPMI-8226 cells. The LPDS-induced increase in FPP observed in the U266 cells could be overcome by either lovastatin or 3dSB (Fig. 4b). Incubation of SF-295 and A549 cells in LPDS resulted in an approximately 1.5-fold increase in FPP and GGPP levels compared with cells incubated in standard FCS (Table 2).

To investigate the effect of combining 3dSB on IBP inhibitor-induced changes in FPP and GGPP levels, studies were performed in which U266 cells were treated with 3dSB and/or lovastatin, ZA, or DGBP. Consistent with our prior studies, treatment with ZA or DGBP only partially

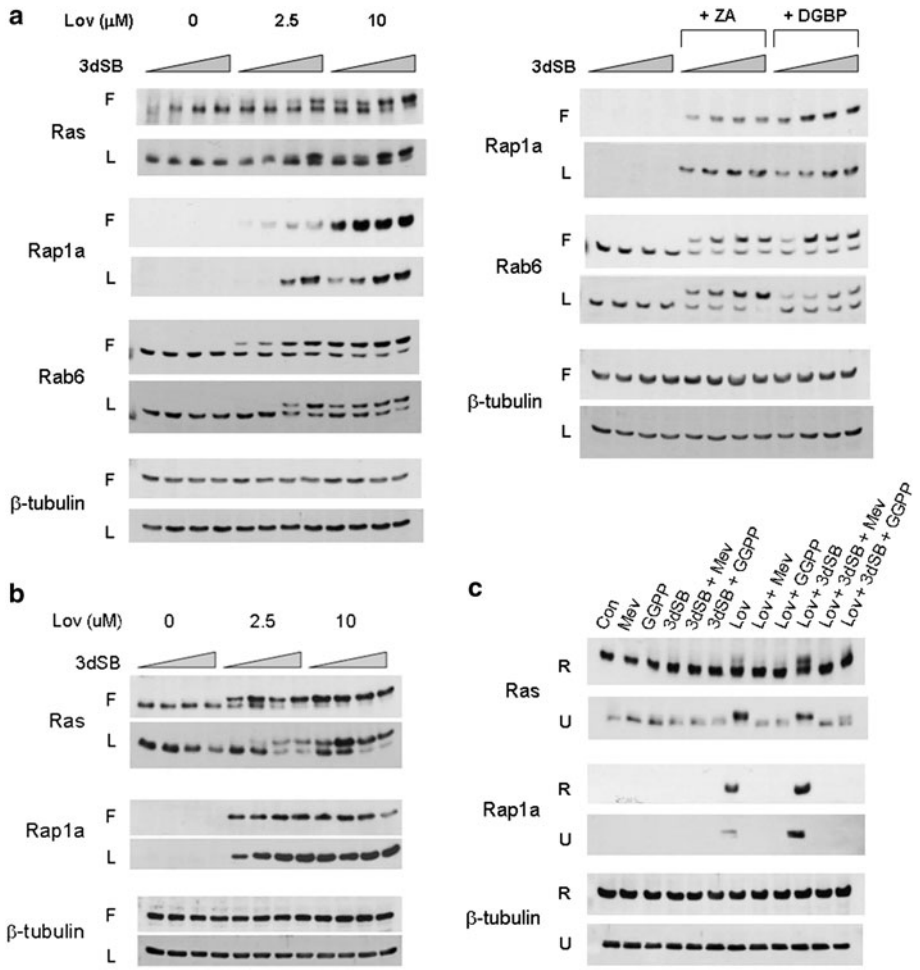

Fig. 3 3dSB potentiates lovastatin-induced decrease in protein prenylation. **a** RPMI-8226 or **b** U266 cells were incubated in the presence or absence of 3dSB ± IBP inhibitor (*Lov* lovastatin, *ZA* zoledronic acid (50 μM) or *DGBP* digeranyl bisphosphonate (2.5 μM)) in either standard FCS (F) or LPDS (L) for 24 h. The wedge indicates increasing concentrations of 3dSB (0, 10, 50, 100 nM for RPMI-8226 cells and 0, 0.1, 0.5, 1 μM for U266 cells). **c** Lovastatin- or lovastatin + 3dSB-induced decrease in protein prenylation is prevented by co-incubation with select isoprenoid intermediates. RPMI-8226 (*R*) and U266 (U) cells were incubated for 24 h in media containing standard FCS in the presence or absence of lovastatin (10 μM), 3dSB (50 nM for RPMI-8226 and 1 μM for U266), mevalonate (1 mM), or GGPP (10 μM). Western blot analysis of Ras (more slowly migrating band represents unmodified Ras), Rap1a (antibody detects only unmodified Rap1a), Rab6 (more slowly migrating band represents unmodified Rab6) and *β*-tubulin (as a loading control) was performed. Data are representative of at least two independent experiments

depletes FPP or GGPP levels, respectively, in U266 cells incubated in standard FCS [43]. Interestingly, however, the addition of 3dSB to either ZA or DGBP results in a significant decrease in both FPP and GGPP levels. Similar results were observed when cells were incubated in media containing LPDS (Fig. 6). The lovastatin-induced depletion of FPP and GGPP was near maximal in U266 cells incubated with standard FCS and the addition of 3dSB did not significantly alter FPP or GGPP levels. In contrast, when cells were incubated with LPDS, the addition of 3dSB to lovastatin resulted in a further decrease in GGPP levels. In aggregate these studies demonstrate the ability of 3dSB to lower intracellular FPP and GGPP levels irrespective of the presence of agents which disrupt the IBP. Finally, the ability of 3dSB to directly inhibit HMGR was evaluated in an in vitro enzyme assay and inhibitory activity was not observed (Fig. 7).

The Effects of Exogenous Isoprenoids on 3dSB-Induced Cytotoxicity and FPP and GGPP Levels

Lovastatin-induced cytotoxicity has previously been shown to be prevented by co-incubation with select isoprenoid species [43]. To determine whether 3dSB-induced cytotoxicity could be similarly prevented, MTT experiments were performed in which RPMI-8226 and U266 cells were treated with 3dSB and/or lovastatin in the presence or

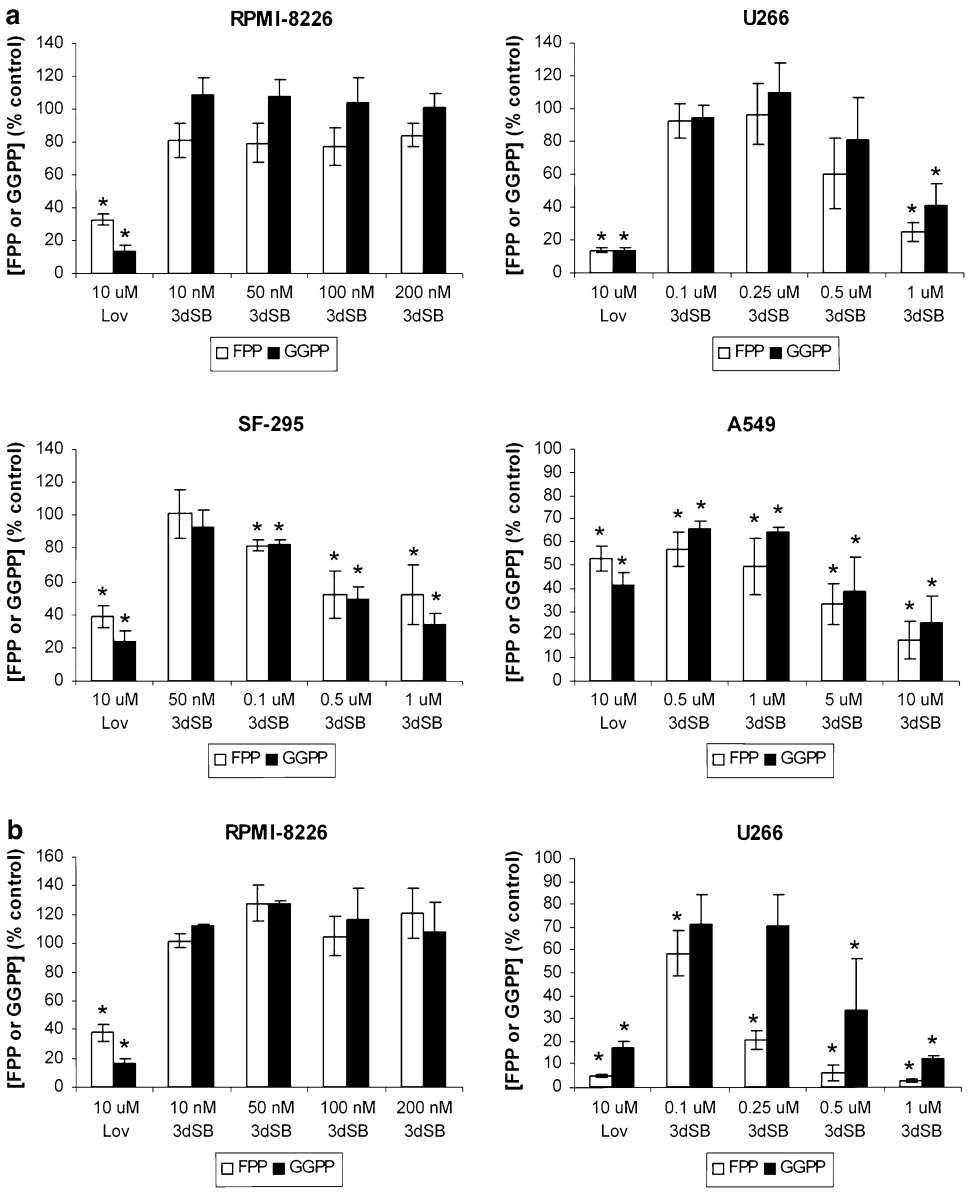

Fig. 4 Effects of 3dSB on intracellular FPP and GGPP levels. Cells were incubated in the presence of 3dSB or lovastatin (Lov) for 24 h in media containing either standard FCS (**a**) or LPDS (**b**). Intracellular FPP and GGPP levels were determined as described in the "Materials and methods" and are expressed as a percent of control (mean ± SD of three independent experiments). * Denotes $p < 0.05$ per unpaired two-tailed t test and compares the treated cells to the control untreated cells

absence of select isoprenoids (mevalonate, FPP, or GGPP). As shown in Fig. 8a, mevalonate or GGPP, and to a lesser extent FPP, could prevent lovastatin-induced cytotoxicity. However, none of the isoprenoid species prevented 3dSB-induced cytotoxicity. The enhanced cytotoxicity observed with the combination of 3dSB and lovastatin was only partially reversed by co-incubation with the isoprenoids. Co-incubation with either mevalonate or GGPP induced a level of cytotoxicity equivalent to 3dSB alone in the drug-combination treatment. To determine whether the add-back of isoprenoid species was effective in repleting FPP and GGPP levels in 3dSB and/or lovastatin-treated cells, levels of FPP and GGPP were measured in U266 cells. As shown in Fig. 8b, mevalonate most efficiently restored both FPP and GGPP levels in drug-treated cells. Incubation with exogenous FPP only partially restored FPP levels in drug-treated cells and had no effect on GGPP levels. Incubation with GGPP completely restored GGPP levels in either 3dSB- or lovastatin-treated cells and partially restored levels in 3dSB + lovastatin-treated cells. Thus, although incubation with exogenous isoprenoids (mevalonate/GGPP > FPP) restores isoprenoid levels in 3dSB-treated cells, this agent's cytotoxic effects are not significantly altered. In aggregate these data suggest that the mechanism underlying 3dSB's cytotoxic effects extends beyond this agent's ability to alter FPP and GGPP levels.

3dSB Disrupts Regulation of Isoprenoid Homeostasis

While lovastatin disrupts sterol homeostasis by targeting HMGR and inhibiting isoprenoid biosynthesis, it appeared that 3dSB might be more indirectly disrupting the IBP. To

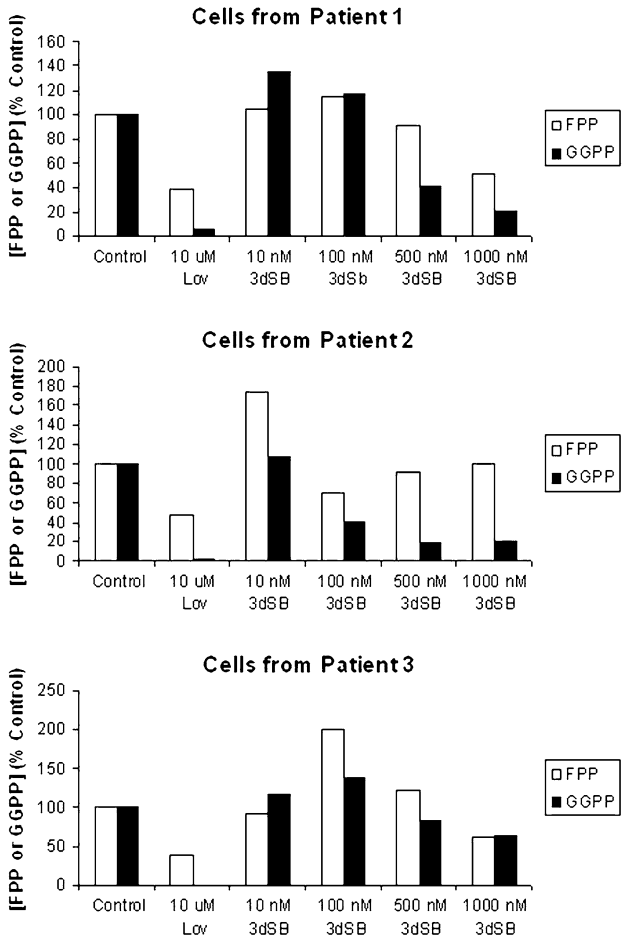

Fig. 5 Effect of 3dSB on FPP and GGPP levels in primary acute leukemia cells. Mononuclear cells were isolated from the peripheral blood of patients with newly diagnosed acute leukemia and incubated ex vivo with 3dSB or lovastatin for 24 h. All patients had greater than 40,000 K/mm^3 circulating blasts. Formal pathological review of the patient bone marrow samples revealed acute myelomonocytic leukemia for patient 1, acute myeloid leukemia with t(11;17) translocation for patient 2, and acute myeloid leukemia with aberrant CD7 expression for patient 3

address this hypothesis, real-time PCR was used to assess the effects of 3dSB, either alone or in combination with lovastatin, on the expression of key components of the IBP (HMGR, FDPS, SS, GGDPS) and regulators of sterol homeostasis (SREBP-2, Insig-1, LXRα, ABCA1). Treatment with lovastatin resulted in an increase in expression (1.5- to 4-fold) of the SRE-containing genes HMGR, FDPS, SS, SREBP-2, and Insig-1 in the RPMI-8226 and U266 cells under standard serum conditions while decreasing ABCA1 expression (Fig. 9). With the exception of HMGR (increase) and ABCA1 (decrease), 3dSB had little effect on any of the tested genes in the RPMI-8226 cell line, while in the U266 cells, statistically significant increases in HMGR, SS, SREBP-2, and Insig-1 levels were observed. Interestingly, 3dSB abrogated lovastatin-induced upregulation of HMGR,

Table 2 Effects of serum composition on basal FPP and GGPP levels

	FPP (pmol/10^6 cells) (Mean ± SD)	GGPP (pmol/10^6 cells) (Mean ± SD)
RPMI-8226, FCS	0.168 ± 0.030	0.273 ± 0.022
RPMI-8226, LPDS	0.122 ± 0.033	0.235 ± 0.096
U266, FCS	1.87 ± 0.271	0.682 ± 0.193
U266, LPDS	15.5 ± 1.25[a]	1.115 ± 0.223
SF-295, FCS	0.088 ± 0.002	0.367 ± 0.023
SF-295, LPDS	0.155 ± 0.005[a]	0.534 ± 0.032[a]
A549, FCS	0.146 ± 0.003	0.291 ± 0.031
A549, LPDS	0.242 ± 0.026[a]	0.460 ± 0.048[a]

Cells were incubated for 24 h in media containing either standard FCS or LPDS. FPP and GGPP levels were measured as described in the section "Materials and Methods". The means and standard deviations of the results of three independent experiments are shown

[a] $p < 0.05$ by two-tailed t testing comparing FCS to LPDS levels

FDPS, SS, and Insig-1 in the RPMI-8226 cell line while potentiating the upregulation of GGDPS. In contrast, in the U266 cell line, 3dSB minimally altered lovastatin-induced upregulation of HMGR, FDPS, SS, or SREBP-2 but enhanced the upregulation of GGDPS, LXR, and ABCA1 compared with either drug alone.

These studies were also performed with cells that had been incubated with LPDS (Fig. 9). Overall, there was little difference in effect on gene expression between the FCS- and LPDS-treated RPMI-8226 cells: lovastatin induced an increase in HMGR, FDPS, SS, SREBP-2, and Insig-1, had little effect on LXRα, and decreased ABCA1 expression. 3dSB induced minimal effects on HMGR and Insig-1levels. Likewise, as seen in the FCS-treated cells, the combination of lovastatin and 3dSB resulted in suppression of the lovastatin-induced increase in the SRE-dependent genes and an increase in GGDPS expression. While the effects of the drugs on the expression profile were concordant between FCS and LPDS conditions in the RPMI-8226 cells, there were profound differences noted between FCS and LPDS conditions in the U266 cell line. Notably, lovastatin failed to induce an increase in any of the tested SRE-containing genes. In addition, with the exception of SREBP-2, 3dSB markedly decreased the expression of the SRE-containing genes. Most striking was the greater than 60-fold increase in ABCA1 expression induced by 3dSB in the LPDS-treated U266 cells; an effect which was further enhanced by co-incubation with lovastatin.

Discussion

The basis for the schweinfurthins' potent cellular activities has thus far not been determined. In the studies presented

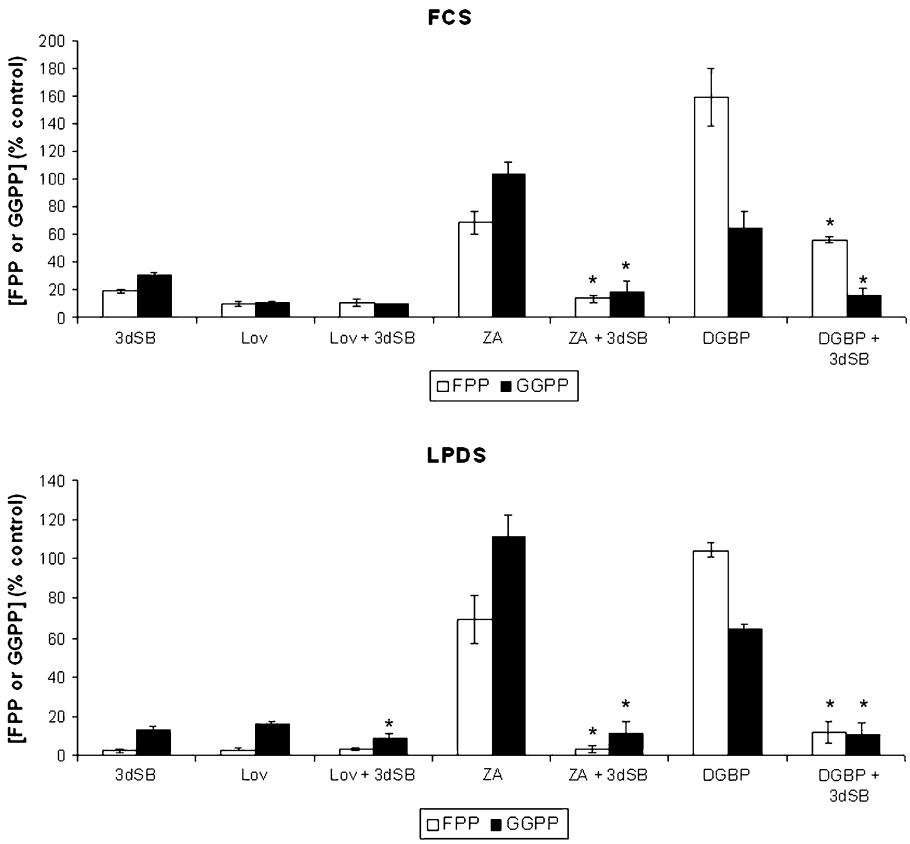

Fig. 6 Effects of 3dSB on IBP inhibitor-induced changes in FPP and GGPP levels in U266 cells. Cells were incubated in the presence or absence of 1 μM 3dSB and/or 10 μM lovastatin, 50 μM ZA, or 10 μM DGBP for 24 h in media containing either standard FCS or LPDS. Intracellular FPP and GGPP levels were determined as described in the section "Materials and Methods" and are expressed as a percentage of the control (mean ± SD of three independent experiments). The * denotes $p < 0.05$ per unpaired two-tailed t test and compares the IBP inhibitor + 3dSB combination to the IBP inhibitor alone

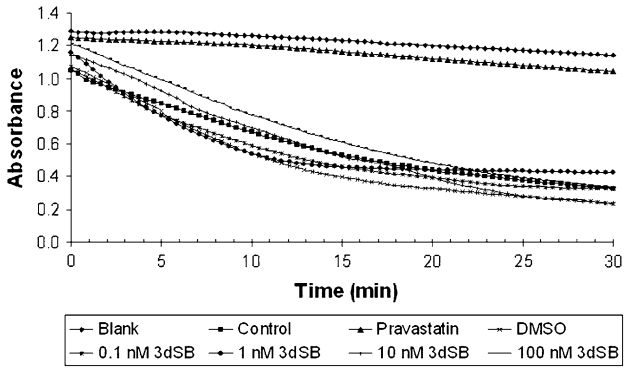

Fig. 7 3dSB does not inhibit HMGR in an in vitro enzyme assay. The enzyme assay was performed as described in the "Materials and methods" section. *Blank* represents reaction mixture lacking HMGR while *Control* represents the complete reaction mixture. Pravastatin was used as a positive control

herein we demonstrate that the synthetic schweinfurthin 3dSB has a very complex relationship with the IBP. In particular, 3dSB: (1) exerts a synergistic cytotoxic effect with the HMGR inhibitor lovastatin but additive or antagonistic effects with other IBP inhibitors, (2) enhances lovastatin-induced disruption of prenylation, (3) induces changes in intracellular FPP and GGPP levels, and (4) disrupts both SRE- and LXR-mediated regulation of genes involved in the IBP and sterol homeostasis. That these effects are enhanced under conditions of limited sterol availability, provides further evidence for the link between 3dSB and isoprenoid homeostasis.

The synergistic interaction between 3dSB and lovastatin is a consequence of lovastatin's ability to deplete cells of one or more down-stream isoprenoids such as FPP, GGPP, or sterols. Notably, an antagonistic interaction was observed between 3dSB and agents that increase FPP levels but have disparate effects on GGPP and sterol synthesis (the GGDPS inhibitor DGBP and the squalene synthase inhibitor Zara), suggesting that the lovastatin/3dSB interaction is dependent on depletion of both nonsterols and sterols down-stream of FPP. Furthermore, 3dSB-induced cytotoxicity is enhanced under conditions of sterol depletion, providing further evidence for a connection between 3dSB activity and isoprenoid levels. In fact, 3dSB was found to decrease cellular FPP/GGPP levels in a variety of cultured and primary cells (Figs. 4, 5, 6). It is interesting to note that although 3dSB decreased FPP and GGPP to levels equivalent to lovastatin in the U266 cell line (Fig. 4), 3dSB alone did not decrease protein prenylation (Fig. 3). In addition, while 3dSB did not significantly alter FPP and GGPP levels in the RPMI-8226 cells, this agent did enhance lovastatin-induced decrease of protein prenylation

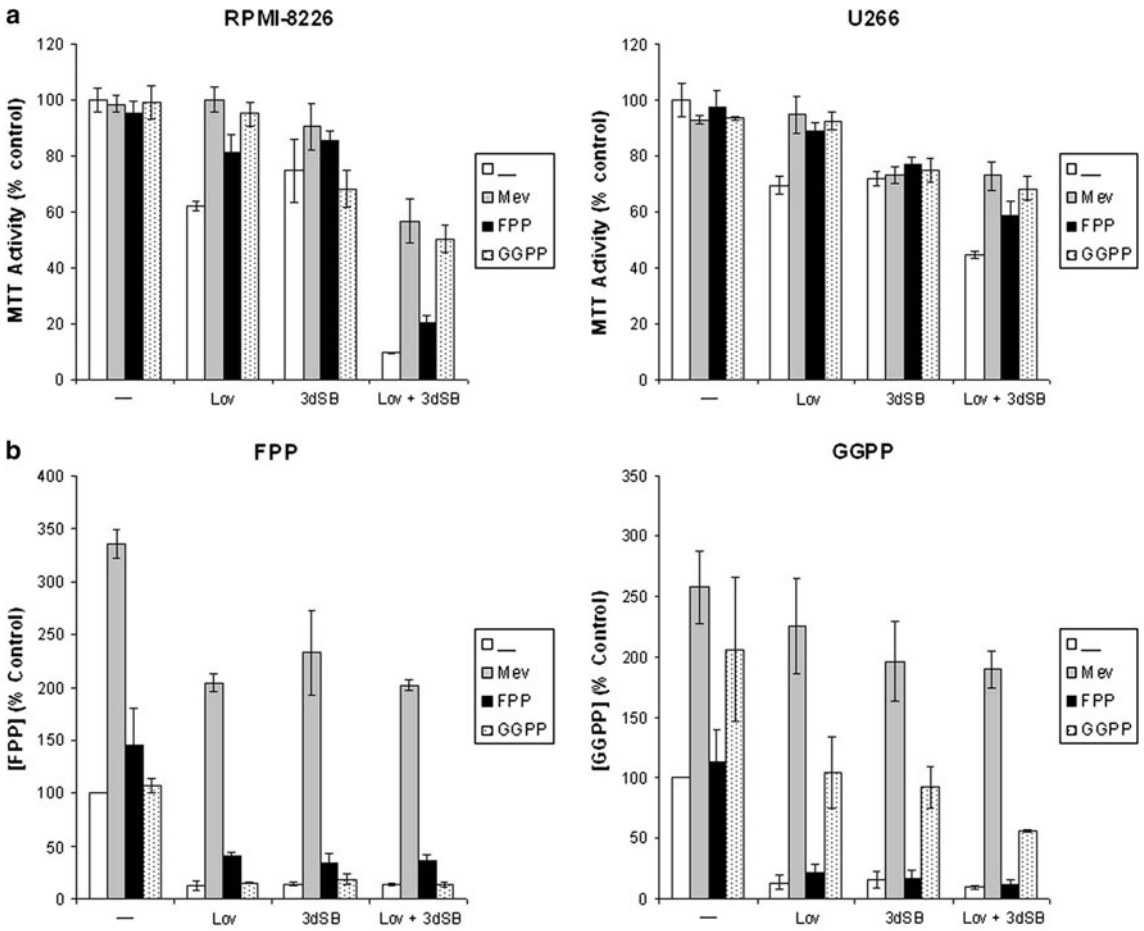

Fig. 8 **a** Add-back of select IBP intermediates prevents lovastatin-, but not 3dSB-induced cytotoxicity in RPMI-8226 and U266 cells. Cells were incubated for 48 h in the presence or absence of 25 μM lovastatin (Lov), 3dSB (0.1 μM for RPMI-8226 and 0.5 μM for U266), 1 mM mevalonate (Mev), 10 μM FPP or 10 μM GGPP. MTT assays were performed as described in the "Materials and methods". Data are expressed as a percent of control (mean ± SD, $n = 4$) and are representative of two independent experiments. **b** Effects of exogenous IBP intermediates on intracellular FPP and GGPP levels in U266 cells treated with 1 μM 3dSB and/or lovastatin for 24 h. Data are expressed as a percent of control (mean ± SD, $n = 3$ independent experiments)

(Fig. 3). These results, in conjunction with the finding that 3dSB-mediated enhancement of lovastatin-induced decrease of protein prenylation is further augmented in the presence of LPDS, suggests that these effects are not only due to changes in steady state levels of isoprenoids, but may also reflect alterations in flux through the pathway. The FPP/GGPP assay that was employed measures steady state total cellular FPP/GGPP levels. It remains to be determined whether shunting of isoprenoids to various branches of the IBP is altered in the presence of 3dSB. In addition, it is unknown whether there are discrete pools of these isoprenoid intermediates within the cell, and if so, whether 3dSB alters specific pools, thereby affecting substrate availability for disparate processes.

Further understanding of the mechanism(s) for 3dSB activity may be gained from the marked increase in FPP levels in U266 cells, but not in RPMI-8226 cells in response to incubation with LPDS. We have previously demonstrated that the U266 cell line is less sensitive than the RPMI-8226 cells to lovastatin and is resistant to downstream IBP inhibitors such as ZA and DGBP, likely a consequence of the markedly elevated basal FPP levels [43]. It has been noted that statin sensitivity in myeloma cell lines may be a consequence of altered HMGR regulation [44]. However, our work, which demonstrates a loss of lovastatin-induced upregulation of SRE-regulated genes in U266 cells incubated in LPDS-containing media suggests that statin-sensitivity is dependent on factors that extend beyond the level of HMGR regulation. In a similar manner, 3dSB-sensitivity may be a consequence of variation in isoprenoid pathway regulation.

In addition to revealing novel activities of 3dSB, these studies also provide insight into the regulation of isoprenoid levels. In our studies, GGDPS expression was minimally induced by either lovastatin or 3dSB alone, but was upregulated to a greater extent when the two agents were

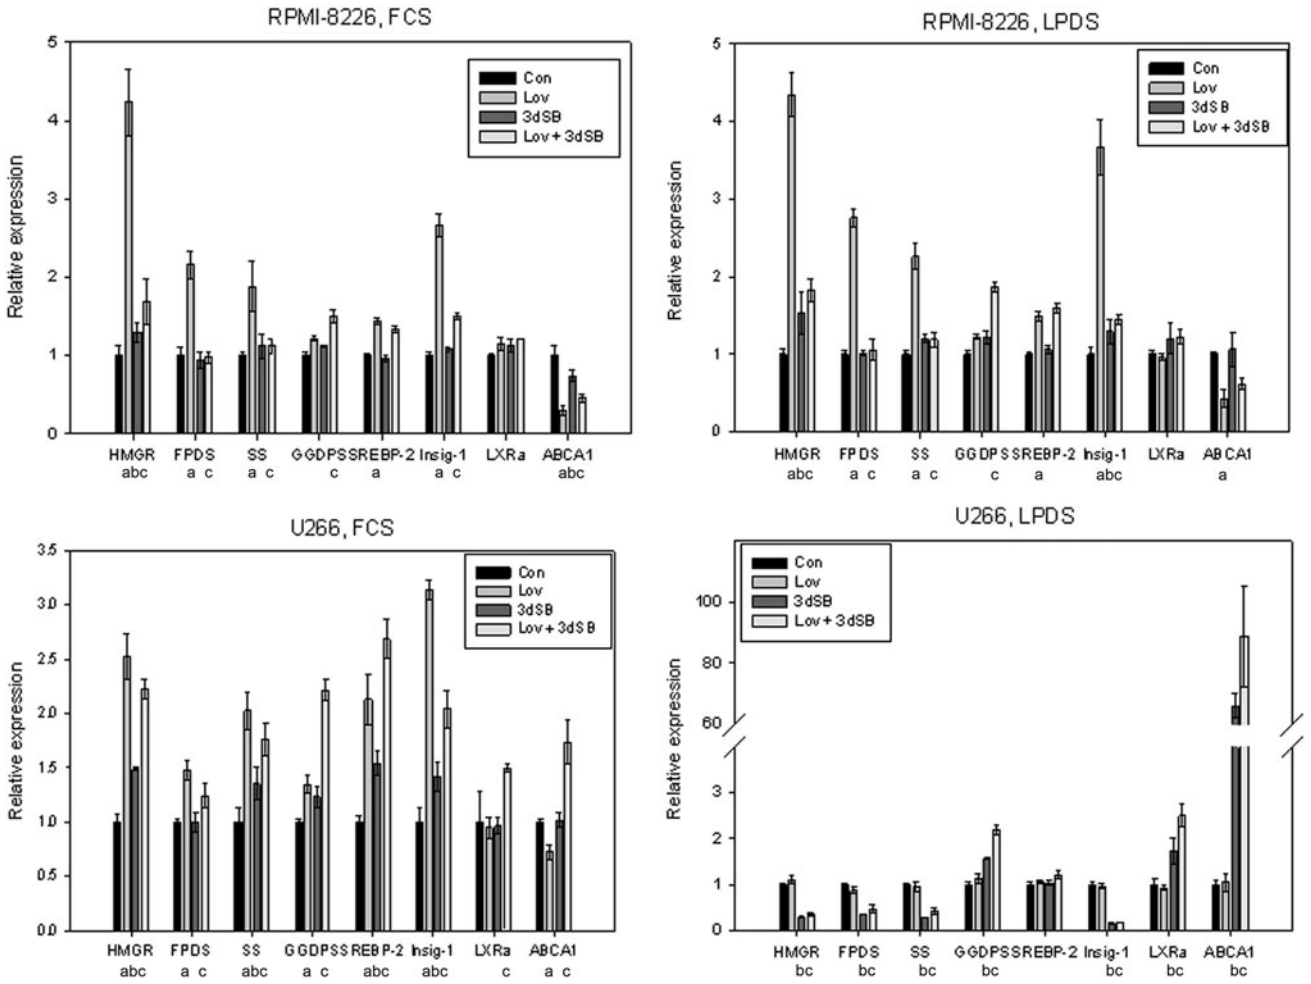

Fig. 9 3dSB induces alteration in expression of genes involved with isoprenoid homeostasis. RPMI-8226 or U266 cells were incubated for 24 h in the presence or absence of lovastatin (Lov, 10 μM) and/or 3dSB (0.1 μM for RPMI-8226 and 0.5 μM for U266) in either standard FCS or LPDS. Real-time PCR was performed using primers for HMG-CoA reductase (HMGR), farnesyl diphosphate synthase (FDPS), squalene synthase (SS), geranylgeranyl diphosphate synthase (GGDPS), SREBP-2, Insig-1, ABCA1 and LXRα. Data were normalized to β-actin levels and are expressed as relative to control untreated cells (mean ± SE, $n = 3$). Data are representative of two independent experiments. Statistical significance, as described in the "Materials and methods" (q value <0.05), is represented by "*a*" (lovastatin compared to control), "*b*" (3dSB compared to control), and "*c*" (3dSB + lovastatin compared to lovastatin)

used in combination (Fig. 9). This effect was particularly evident in the LPDS-treated cells. Analysis of FDPS has demonstrated that it is transcriptionally regulated by both SREBP and LXR [37, 45–47]. Less is known about the regulation of GGDPS. While one report in a transgenic system suggested that GGDPS is a target of SREBP, another demonstrated that GGDPS mRNA levels did not significantly change in HeLa cells incubated with either an HMGR inhibitor or with LPDS in the presence or absence of sterols [48, 49]. The product of this enzyme, GGPP, has been shown to serve as a negative regulator for LXR [21, 50]. Our results suggest that GGPP levels may in part regulate expression of GGDPS. Whether this is due to an effect on LXR activity or is via another mechanism remains to be determined.

The add-back experiments, which demonstrated that exogenous FPP/GGPP can restore isoprenoid levels in 3dSB-treated cells, but does not reverse the cytotoxic effects (Fig. 8), further suggest that 3dSB's effects extend beyond altering FPP and GGPP levels. In fact, we found that in RPMI-8226 cells, 3dSB abrogates statin-induced upregulation of SREBP-2-dependent genes as well as statin-induced downregulation of ABCA1 in both sterol replete (FCS) and deplete (LPDS) conditions (Fig. 9). In aggregate these data suggest that 3dSB shifts the cell's sterol regulatory pathways from a sterol-deficient state to a sterol-replete state. This hypothesis is further supported by the findings from the U266-LPDS studies. As noted in Table 2, U266 cells, in response to incubation with LPDS, markedly increase intracellular FPP levels, presumably in

an effort to compensate for the exogenous depletion of sterols. In this setting, 3dSB alone significantly downregulates SREBP-2-dependent genes while markedly upregulating ABCA1 (a LXRα-dependent gene). This pattern implies sterol excess. Possible mechanisms by which 3dSB could induce these changes include interference by 3dSB of the SRE-SREBP-2 interaction, disruption of SREBP-2 trafficking, direct activation of LXR, RXR or PPAR, or interference with the function of oxysterol binding proteins (OSBPs). A variety of oxysterols have been shown to be ligands for LXR and to induce LXR-target gene expression [51]. For example, the dietary plant sterol, stigmasterol, has been shown to induce ABCA1 expression and to suppress the SREBP pathway by promoting the formation of a Scap-SREBP-Insig-1 complex in the ER, thereby decreasing expression of SREBP target genes [16]. Whether 3dSB shares a similar mechanism of action, changes sterol levels, or alters the sterol-sensing machinery is of considerable interest and studies addressing these hypotheses are underway.

Schweinfurthin A has recently been shown to induce reorganization of the actin cytoskeleton and to inhibit EGF-induced Rho activation in serum-starved astrocytoma cells [52]. It is interesting to note that a variety of interactions have been described between OSBPs and elements of the cytoskeleton. For example, overexpression of ORP4S induced collapse of the vimentin network and inhibited LDL-cholesterol esterification while silencing of ORP3 resulted in reorganization of the actin cytoskeleton [53, 54]. It remains to be determined whether schweinfurthins, either directly or indirectly, interact with OSBPs, thereby impairing sterol sensing/trafficking and disrupting the cytoskeleton.

In conclusion, these studies are the first to demonstrate that the synthetic schweinfurthin 3dSB exerts pleiotropic effects on isoprenoid homeostasis. Specifically, 3dSB has a synergistic interaction with lovastatin, can alter steady state isoprenoid levels, and can disrupt multiple aspects of the regulatory elements controlling the IBP and sterol homeostasis. These studies, which advance understanding the basis for schweinfurthin activities, also indicate that there is a complexity to regulation of the isoprenoid pathway that is as yet unknown but may depend upon isoprenoid flux as compared to absolute isoprenoid levels.

Abstract Policosanol is a poorly absorbed nutritional supplement used primarily for cholesterol management. Findings from previous trials evaluating the effects of policosanol are mixed with early data reporting positive lipid effects while more recent studies indicate negligible efficacy. We hypothesized that re-formulating policosanol would result in an improvement in major lipoproteins and possibly provide some explanation for previously conflicting trial data. Our primary objectives were to assess the efficacy and safety of modified-policosanol (MP) on the major lipoproteins among hyperlipidemic subjects receiving background statin therapy or as monotherapy. This 8-week clinical trial consisted of 3 arms. Subjects receiving chronic statin therapy ($N = 36$) were randomized in a double-blind design to MP 20 mg daily or placebo. In the third arm, subjects not receiving statin therapy ($N = 18$) were assigned open-label MP 20 mg daily. The utilization of MP when added to background statin therapy or as monotherapy resulted in no significant changes in major lipoproteins (all $p > 0.05$). The MP therapy was well tolerated with no major adverse events reported. Consistent with recent clinical trial data, MP demonstrated an excellent safety profile but produced no significant effects on major lipoproteins when used as monotherapy or when given with concomitant statin therapy.

Introduction

Elevated low-density lipoprotein cholesterol (LDL-C) is a major modifiable risk factor for coronary heart disease (CHD) [1]. The National Cholesterol Education Program (NCEP) Adult Treatment Panel's third report (ATP-III) and 2004 Update focus on LDL-C treatment to reduce CHD events [1, 2]. For most patients statins are the cornerstone for LDL-C reduction. However, because of aggressive LDL-C goals and dose-dependent side effects associated

with statin therapy, additional agents are often required to achieve optimal LDL-C levels [3]. Other lipoproteins also play key roles in the development of atherosclerosis. Lipoprotein (a) [Lp (a)] is an emerging risk factor that has recently demonstrated an independent association with CHD [4]. Effective therapies for treating Lp (a) are limited, therefore new treatment options are greatly needed.

Policosanol is a nutritional supplement used for the treatment of hypercholesterolemia. The agent consists of a natural mix of aliphatic alcohols that are derived primarily from sugar cane (*Saccharum officinarum* L) and/or rice wax. The formulation of policosanol can vary between products but the major components are octacosanol, triacontanol and hexacosanol [5]. The clinical pharmacology of policosanol is not fully understood but findings suggest suppression of hydroxymethylglutaryl Coenzyme A (HMG-CoA) reductase and increased LDL-C degradation via enhanced hepatic binding and internalization [6, 7]. The agent has been associated with a low rate of generally mild and transient adverse effects with no reports of increased hepatic transaminases [5, 8].

Early studies indicated policosanol, when used as monotherapy, significantly reduced LDL-C and raised high-density lipoprotein cholesterol (HDL-C) [9–16]. Another study indicated the agent produced significant reductions in Lp (a) [17]. However, more recent studies, including one evaluating policosanol in combination with statin therapy, have not replicated the beneficial findings seen from the early trials [18–27]. Despite the lack of proven benefit, policosanol use remains widespread. A recent internet search indicated many common retailers continue stocking the product.

The discrepant results from clinical trials are not well understood, however, limited absorption and subtle composition differences between products may be key variables. The mixture of very long chain aliphatic alcohols and very long chain fatty acids composing policosanol have limited bioavailability and varying composition, are highly hydrophobic, with very poor overall absorption [28]. Although data are limited, the plasma concentrations of very long chain fatty alcohols present in policosanol are increased in high fat dietary states (i.e. ketogenic diets) [29]. Other trials evaluating lipid-based delivery systems further support this data. Porter et al. [30] describe how exogenous lipids in the small intestine stimulate the secretion of factors (e.g. bile salt) aiding in the solubilization for both lipid products and drugs. Because of these findings and known properties of policosanol we formulated the product with a lipid-base to potentially enhance absorption and ultimately clinical efficacy. Lastly, most clinical trials utilized a similar policosanol mixture consistent with octacosanol (66%), triacontanol (12%) and hexacosanol (7%), despite each apparently possessing lipid-altering properties [18].

The inconsistent findings from previous trials with similarly composed alcohol mixtures, and data indicating improved absorption with increased fat intake, led us to perform a prospective clinical study designed to answer some of the lingering questions regarding policosanol. We hypothesized adjusting the aliphatic alcohol content and formulating the agent with a vehicle composed of a long chain fatty acid would enhance the lipid-altering effects, including Lp (a). Our findings add to the negligible results of recent studies but also demonstrate markedly altering the aliphatic alcohol content to the formulation utilized in the present study and adding long chain fatty acids do not provide lipid-altering effects.

Materials and Methods

Study Design and Protocol

This was an 8-week, single-site, three arm clinical trial. Subjects receiving chronic statin therapy ($N = 36$) were randomized, in a double-blind parallel design, to modified-policosanol (MP) 20 mg daily or matching placebo (arms 1 and 2). Subjects not receiving statin therapy ($N = 18$) were assigned to receive open-label MP 20 mg daily (arm 3). Prior to commencement, the study was approved by the institutional review board at the Kansas University Medical Center.

The policosanol doses and matching placebo capsules were compounded with long chain fatty acids by the University of Kansas Inpatient Pharmacy. The mixture consisted of 0.48 ml United States Pharmacopeia (USP) soybean oil, 0.05 ml beeswax, and 20 mg policosanol. Matching placebo capsules were formulated with 0.495 ml USP soybean oil and 0.05 ml beeswax. All doses for arms 1 and 2 were packaged in identical bottles and labeled by a non-investigator pharmacist according to the randomization table. The policosanol (Marcosanol)®, derived from rice bran wax, was provided by Marcor Development Corporation (Carlstadt, NJ) and the certificate of analysis indicated the composition consisted of 98.8% C22–C36 alcohols including 1-octacosanol 33.5%, 1-triacontanol 44.1%, 1-hexacosanol 13.3% and 1-dotriacontanol 7.9%.

Fasting blood samples were drawn for lipoprotein analysis and safety measures at visit 1 (baseline) and visit 2 (8-weeks). All subjects received counseling at visit 1 on the Adult Treatment Panel III Therapeutic Lifestyle Changes including dietary changes, weight reduction and increased physical activity. Demographic information was also collected and vitals were measured at each visit. Adherence was determined at the 8-week visit by pill count, subjects who had a >20% non-adherence rate were excluded from the final data analysis.

The primary outcome measures of the study were to determine the changes in lipoproteins [LDL-C, HDL-C,

triglycerides, total cholesterol, non-HDL, and Lp(a)] from baseline to 8-weeks, when MP was added to statin therapy (compared to placebo) or when administered as monotherapy. The evaluation of safety measures (i.e. hepatic transaminases) and reported adverse events among groups were also assessed.

Subjects

Adult hyperlipidemic subjects between the ages of 18 and 75 years with serum LDL-C levels >80 mg/dl were eligible for enrollment. For arms 1 and 2 participants were required to be on background statin therapy with intentions to continue the same dose throughout the course of the trial. Key exclusion criteria included patients with chronic renal or hepatic disease, dependence on alcohol or illicit drugs, previous sensitivity to policosanol, or currently receiving agents with potential to interact with policosanol (i.e. warfarin, high-dose aspirin). Female subjects were allowed to enroll if they were using a reliable form of contraception or surgically sterile, not pregnant or lactating, or postmenopausal and not on hormone replacement therapy (HRT) or using HRT with the intention of continuing the same agent and dose throughout the study.

Laboratory Analysis

The Vertical Auto Profile II method was used to assess the concentration of cholesterol carried in large, buoyant (LDL_1 and LDL_2) and small, dense (LDL_3 and LDL_4) LDL particles. The Vertical Auto Profile II method utilizes single vertical spin density gradient ultracentrifugation to separate the various plasma lipoprotein fractions. After centrifugation, the cholesterol content of the tube is continuously analyzed and digitized. A cholesterol absorbance curve profile is generated by plotting digitized absorbance units on the *Y* axis and the relative gradient position on the *X* axis. A deconvolution program is used to separate the different lipoprotein classes and subclasses [31].

Statistical Analysis

Sample size estimation was based on the percentage change in LDL-C levels from baseline to visit two (8-weeks). It was expected that the active treatment would result in a 24% reduction in LDL-C with a SD of 20 compared to placebo. To achieve a power of 80% and Type 1 error of 0.05, at least 12 subjects had to be enrolled in each treatment group.

Data analyses were performed using SPSS for Windows (Statistical Package for the Social Sciences) software (SPSS version 11.5, Chicago, IL). One way ANOVA was used to assess the change in lipid parameters from baseline to 8 weeks of supplementation among groups, followed by a post hoc analysis with a Bonferroni correction. Data are expressed as means ± SD, unless indicated otherwise. The level of significance was set at $p < 0.05$ for the primary analyses.

Results

A total of 54 subjects were enrolled, of whom all completed the study. Baseline characteristics were similar between groups with the exception of total cholesterol, LDL-C and non-HDL concentrations (Table 1). Subjects not receiving background statin therapy had significantly higher baseline total cholesterol and LDL-C levels compared to those receiving statins. Among the statin groups, participants receiving statin/MP also had higher baseline total cholesterol and LDL-C levels compared to those receiving statin/placebo.

The addition of MP 20 mg daily for 8-weeks to background statin therapy or when given as monotherapy did not significantly alter any major lipoproteins including total cholesterol, LDL-C, HDL-C or Lp (a) (Table 2). No differences were observed when comparing between background statin groups (arms 1 and 2) or when evaluating changes in lipoprotein levels from baseline to follow-up across all arms. Additionally, we examined LDL-C changes among those patients with higher and lower baseline LDL-C levels based on median value split. Only patients in Arm 2 (statin/placebo) with higher baseline levels demonstrated a modest reduction in LDL-C values (see Table 3) at 8 weeks.

Adverse events were collected throughout the study from subject reports and by a questionnaire at visit two. Overall, adverse events associated with the use of MP were minimal and considered mild to moderate with rates similar to placebo. Of those receiving MP, one subject reported an intermittent headache while another reported constipation. No patients withdrew from the study due to adverse events in any arm. The use of MP did not affect hepatic transaminases including aspartate aminotransferase or alanine aminotransferase levels. Adherence to therapy in all arms was excellent (>80%); no subject data was excluded from final analysis secondary to non-adherence.

Discussion

The results of the present study are consistent with findings from recent clinical trials performed in the United States and Germany. Earlier studies, performed primarily in Latin America, indicated policosanol was highly effective at lowering LDL-C and raising HDL-C. We theorized that

these inconsistent results may have been due to the poor absorption and bioavailability of policosanol.

It was our goal to develop an MP agent which would significantly improve major lipoproteins when used as monotherapy or when given with a background statin, and provide some possible explanation for previously mixed clinical trial data. We evaluated this by designing a rigorous, randomized, placebo-controlled, parallel, and double-blind trial with an additional open-label arm. However our findings indicate that the addition of long chain fatty acids to a mixture of aliphatic alcohols (policosanol) does not offer any additional lipoprotein benefit when added to background statin therapy or produce significant changes in lipids when used as monotherapy. When evaluating safety measures and adverse events, our results are consistent with previous data demonstrating that policosanol is well tolerated with a safety profile similar to placebo.

The MP failed to provide any significant changes to the major lipoproteins including LDL-C, HDL-C, very low-density lipoprotein cholesterol (VLDL-C), triglycerides or Lp (a). It is plausible that the effects of policosanol may be dependent upon baseline LDL-C levels. We therefore grouped subjects into high or low baseline LDL-C values based on median value splits. However, similar to the overall findings MP was ineffective at reducing LDL-C regardless of baseline levels. Arm 2 (statin/placebo) did experience a modest reduction in LDL-C from baseline to end of study. However, with the Bonferroni adjustment, the LDL-C reduction was not considered statistically significant.

The vast majority of the positive trials evaluating policosanol were conducted in Cuba prior to 2004 [10, 11, 13–16]. In fact, a meta-analysis of these early trials published in 2005, indicating overall mean LDL-C reductions of 24% and HDL-C increases of 11% drew the attention of many practitioners [14]. However, subsequent studies performed outside of Cuba have failed to reproduce the same positive results. A randomized, placebo-controlled trial using policosanol derived from wheat germ conducted in the Netherlands found no lipid-alterations among its 58 participants [20]. A well-designed, placebo-controlled, multicenter trial evaluating the dose-dependent effects of policosanol (10–80 mg/day) further questioned the efficacy of the agent [19]. The German investigators utilized the same sugarcane policosanol product (Dalmer Laboratories; La Habana, Cuba) as the early Cuban studies, yet failed to produce any significant changes on the lipid profile among 143 subjects. A US study evaluating the effects of policosanol as monotherapy or when added to statin therapy yielded similar results; policosanol produced no significant

changes to major lipoproteins when used alone or in addition to statin therapy [18]. Since the publication of these trials additional studies have continued to corroborate their negative findings [21–27]. Conversely, the last positive trials demonstrating lipid alterations with policosanol were performed in Cuba and published in 2005 [9, 12].

An explanation for the inconsistent results among the clinical studies evaluating policosanol remains unclear. One potential factor is the variability in aliphatic alcohol content of the different policosanol mixtures used in studies. The formulation in the present study differed from Cuban-manufactured policosanol by having lower octacosanol and higher triacontanol and hexacosanol composition. However, each of these three major alcohols is proposed to be responsible for the apparent lipid-altering effects of policosanol [18]. Additionally, the recent clinical trials demonstrating a lack of response with policosanol utilized formulations comparable in composition to previous studies indicating lipid-altering benefits [18]. Therefore, we find it unlikely that the variable alcohol compositions played a major role in our findings or previous studies.

Additional factors that may account for the discrepancy in results include dosage and duration of study. Prior positive studies evaluated dosages ranging from 2 to 40 mg daily [14]. Dose-dependent improvements in most lipoproteins were observed with doses up to 20 mg/day. Trial duration for most studies ranged from 4 to 104 weeks with a mean of 30 weeks. The trials with shorter duration (4–8 weeks) still produced significant reductions in LDL-C ($\sim$17–40%). Because of these data, we find it doubtful that the dosage of policosanol utilized or duration of the present trial was sub-optimal.

There are perceivable limitations to our study. While two arms of the trial were randomized, double-blind and placebo controlled the third arm evaluating the efficacy of MP as monotherapy was open-label and without a control group. Additionally, significant differences in baseline total cholesterol, LDL-C and non-HDL values were present between the statin/placebo and the statin/MP arms. However, given the overall lack of response with MP, we do not feel that the absence of a placebo comparator group for the monotherapy arm or differences between groups at baseline impact our overall findings. Lastly, although we encouraged subjects to follow the guidelines set forth by ATPIII Therapeutic Lifestyle Changes we have no information on dietary patterns and we did not assess physical activity levels during the study. However, weight did not significantly change across the 3 groups at 8 weeks.

In summary, our study findings support the growing body of evidence published in the last 5 years indicating policosanol does not significantly improve any major lipoproteins including LDL-C, HDL-C and Lp (a). Our policosanol formulation was unique because of the added long chain fatty acids and differing composition of aliphatic alcohols compared to most products used in clinical trials. However, despite these factors, the MP formulation produced no lipid-altering benefits when added to background statin therapy or when used as a monotherapy. Lastly, the history of policosanol perfectly illustrates the dire need for more independent research in evaluating the safety and efficacy of nutritional supplements prior to mass utilization by consumers worldwide. Fortunately with policosanol we found a supplement that was safe but simply not effective.

Acknowledgments This study was supported by the University of Kansas General Research Fund allocation #23011083 and by Marcor Development Corporation (Carlstadt, NJ). We would also like to express our sincere gratitude to David Mueller, R.Ph., for his diligence and expertise in pharmaceutical compounding and Roger Rajewski Ph.D. for his expertise and assistance in product formulation.

Abstract Type 2 diabetes and dyslipidemia are risk factors for cardiovascular disease. However, mechanisms by which hypertriglyceridemia influences atherogenesis remain unclear. We examined effects of dyslipidemic diabetic serum on macrophage lipid accumulation as a model of foam cell formation. Normal human macrophages were cultured in media supplemented with 10% serum from non-diabetic normolipidemic or non-diabetic hypercholesterolemic adults versus adults with Type 2 diabetes; diabetes and hypertriglyceridemia; or diabetes and hypercholesterolemia. Exposure to diabetic sera resulted in increased macrophage fatty acids (2–3 fold higher, both saturated and unsaturated). Macrophage expression of CD36, scavenger receptor A (SR-A) and stearoyl-CoA desaturase (SCD) was increased, most prominently in macrophages exposed to hypertriglyceridemic diabetic serum (twofold increase in CD36 and fourfold increase in SCD, $p < 0.05$). In these conditions, RNA inhibition of CD36 reduced macrophage free cholesterol (163.9 ± 10.5 vs. 221.9 ± 26.2 mmol free cholesterol/g protein, $p = 0.04$). RNA inhibition of SCD decreased macrophage fatty acid content, increased ABCA1 level and enhanced cholesterol efflux (18.0 ± 3.9 vs. $8.0 \pm 0.8\%$ at 48 h, $p = 0.03$). Diabetic dyslipidemia may contribute to accelerated atherosclerosis via alterations in macrophage lipid metabolism favoring foam cell formation. Increased expression of CD36 and SR-A would facilitate macrophage lipid uptake, while increased expression of SCD could block compensatory upregulation of ABCA1 and cholesterol efflux. Further studies are needed to clarify whether modulation of macrophage lipid metabolism might reduce progression of diabetic atherosclerosis.

Keywords Type 2 diabetes · Dyslipidemia · Macrophage · Fatty acid · Cholesterol · CD36 · Stearoyl-CoA desaturase

Abbreviations

ABCA1	ATP-binding cassette transporter A1
ABCG1	ATP-binding cassette transporter G1
CD36	Cluster of differentiation 36
CE	Cholesterol ester
CVD	Cardiovascular disease
FA	Fatty acid(s)
FC	Free cholesterol
GC	Gas chromatography
GC–MS	Gas chromatography–mass spectrometry
HDL	High density lipoprotein
hMDM	Human monocyte-derived macrophage(s)
LDL	Low density lipoprotein
LXR	Liver X receptor
PPARγ	Peroxisome proliferator-activated receptor gamma
RNAi	RNA inhibition
SCD	Stearoyl-CoA desaturase

Introduction

Atherosclerosis is the underlying pathology behind cardiovascular disease (CVD) which is increased in patients with Type 2 diabetes mellitus [1]. Patients with Type 2 diabetes exhibit a characteristic dyslipidemia with increased TG and reduced HDL [2]. Concentrations of LDL cholesterol are typically not raised, with a predominance of small dense forms. However, specific pathways by which dyslipidemia accelerates development of atherosclerosis in patients with diabetes have not been fully elucidated.

In the process of atherogenesis macrophages within arterial walls express scavenger receptors such as CD36 which mediate uptake of excess oxidized LDL leading to foam cell development, fatty streaks and atheromatous plaque [3, 4]. Macrophage lipid accumulation is balanced by the function of ATP-binding cassette transporter family members ABCA1 and ABCG1 which mediate cholesterol efflux, thus facilitating reverse cholesterol transport to inhibit progression of atherosclerosis [5–7]. Macrophages from patients with Type 2 diabetes cultured in autologous serum exhibited altered fatty acid (FA) profiles with increased ratios of unsaturated to saturated FA [8], and reduced ABCG1 expression and cholesterol efflux [9]. Similar differences in fatty acid content and composition are found in macrophages exposed to serum containing moderately increased TG levels [10]. However, the wider applicability of these findings and other mechanisms by which diabetes might contribute to altered macrophage phenotypes remain unclear.

The enzyme stearoyl-CoA desaturase (SCD) represents a potential link between macrophage FA content and cholesterol efflux. Increased activity of SCD results in conversion of saturated FA to their monounsaturated equivalents and inhibits ABCA1-mediated cholesterol efflux [11, 12]. Recently there has been high interest in the putative role of SCD as a modulator of atherogenesis, based on experimental work in knockout mice [13–15]. However, these data are contradictory, with *SCD*−/− mice exhibiting increased inflammation and atherosclerosis in one study [13], but reduced inflammation and inhibition of atherosclerosis in others [14, 15]. Data which examine the role of SCD in human macrophages cultured in an environment representative of diabetic dyslipidemia could clarify the relevance of these experimental findings to human disease.

We examined the effects of the dyslipidemia encountered in patients with Type 2 diabetes on macrophage lipid accumulation, using macrophages from a common source to isolate the effects of diabetic serum on macrophage phenotype. By replicating in vitro the dyslipidemia seen in patients with diabetes in vivo we tested the hypothesis that diabetic serum with or without dyslipidemia modulates macrophage lipid content and composition reflecting differential expression of proteins involved in lipid uptake. We found that expression of macrophage CD36 and SCD was increased in the presence of diabetic sera and tested the effect of RNA inhibition (RNAi) of these genes on macrophage cholesterol efflux.

Materials and Methods

Study Protocol

Inclusion criteria were: age 35–60 years, non-smoker or ex-smoker, no history of CVD, not on lipid lowering therapy, consumption of <3 standard drinks alcohol/day (<30 g ethanol/day), body mass index <35, blood pressure <160/90. Additional criteria for participants with Type 2 diabetes were: known history of Type 2 diabetes (duration >6 months) and HbA1c <8.5%. Exclusion criteria were: major medical comorbidity or treatment with insulin or glitazones within the previous 6 months. A fasting blood sample (80 mL) was obtained from each study participant. The study was approved by the South Metropolitan Area Health Service Human Research Ethics Committee and participants provided written informed consent.

Serum Preparation

Blood from study participants was stood for 30 min and centrifuged at 16,000×*g* for 10 min before collection of the serum supernatant. Sera were pooled into 5 groups (A–E) and stored at −40 °C until use.

Biochemical Analysis

Fasting glucose, serum total cholesterol (TC), HDL-cholesterol and triglyceride (TG) were measured using the Cobas Integra 800 analyser (Roche Diagnostics) as previously described [8]. LDL-cholesterol levels were calculated using the formula LDL = TC − HDL − (TG/2.22) [16].

Cell Culture and Experimental Strategy

Buffy coats from healthy blood donors were obtained from the Australian Red Cross Blood Service and human monocyte-derived macrophages (hMDM) prepared from white

cell concentrates as previously described [8]. Briefly, monocytes were differentiated by plating at 1.5 × 10^6 cells/ml in RPMI-1640 containing 10% heat-inactivated normal human serum and re-fed at Day 2. For experiments, hMDM were washed at Day 5 and incubated for a further 8 days (to Day 13) in RPMI 1640 containing 10% heat-inactivated pooled human serum (A–E). Macrophages were re-fed every 3 days (Days 8 and 11) with the respective pooled human sera (A–E), and harvested on Day 13 for analyses.

RNA Inhibition of Macrophage CD36 and SCD

At Day 7, transfection of small interfering RNA (siRNA) targeting either CD36 or SCD, or a negative control siRNA was performed using Lipofectamine™ RNAiMAX according to the manufacturer's forward transfection procedure (Invitrogen). The cells were incubated for 24 h at 37 °C in a 5% CO_2 atmosphere. On Day 8, the transfected hMDM were washed with warm PBS and re-fed with experimental media containing 10% sera (A–E). Macrophages were re-fed on Day 10 and harvested on Day 12 for analyses.

Visualization of Lipids with Nile Red Stain

Nile Red (Invitrogen) stains neutral lipids and can be visualized with fluorescence microscopy. At Day 13, human monocyte-derived macrophages (hMDM) were washed with PBS, 1.5% glutaraldehyde added and cells fixed by incubation at 4 °C for 5 min. Cells were washed several times with PBS, Nile Red in PBS (100 ng/mL) was added and left to incubate at room temperature for 5 min. Cells were washed with PBS before visualization under fluorescence microscopy at yellow gold fluorescence (excitation 450–500 nm, emission >528 nm).

Lipid Extraction and Fatty Acid Analysis Through Gas Chromatography

Fatty acid (FA) content and composition for both media and hMDM was analysed using gas chromatography (GC) as previously described [8]. The ratios of C16:1/C16:0 and C18:1/C18:0 was calculated with higher ratios being consistent with increased SCD activity [17].

Cholesterol Analysis Using Gas Chromatography Mass Spectrometry

Cholesterol was extracted using $CHCl_3$/MeOH in the same way FA extraction was conducted as previously described [8]. For total cholesterol analysis, deuterated cholesterol ($^{13}C_2$)(Sigma) was added as an internal standard (10 nmol) to extracted samples and dried under N_2 before addition of 1 mL of KOH/MeOH (1 M) and overnight saponification. Samples were dried under N_2, derivatised by addition of pyridine (30 μL) (Sigma) and *N*,*O*-bis(trimethylsilyl) trifluoro acetamide (BSTFA) (30 μL) (Sigma) followed by heating at 60 °C for 20 min. Lastly, samples were dried under N_2 and reconstituted in iso-octane (200 μL) followed by analysis in a gas chromatograph (Hewlett Packard 6890) mass spectrometer (GC–MS) using a HP-1MS column (Agilent) (30 m × 0.25 mm internal diameter). Ions that were monitored were cholesterol (458.8) and $13C_2$ (460.8). For free cholesterol (FC) analysis, internal standard was added to samples and derivatisation was carried out in the same way. Samples were reconstituted in iso-octane (200 μL) followed by analysis via GCMS. Cholesterol ester (CE) was calculated by subtracting FC content in samples from total cholesterol content.

Western Analysis

hMDM were lysed in RIPA lysis buffer (Sigma) and lysates stored at −80 °C. Protein was quantified using BCA protein assay kit (Pierce) and absorbance measured at 580 nm. SDS-PAGE was performed using 20–50 μg of protein lysate per lane followed by semi-dry blot transfer. Membranes were blocked with 5% skim milk powder in TBS-T (20 mM Tris pH 7.4, 150 mM NaCl, 0.1% Tween-20) before sequential incubations with antibodies to detect CD36 (Novus), SRA (Santa Cruz), ABCA1 (Novus), ABCG1 (Novus), SCD (Sigma), PPARγ (Sigma) and LXRα. (Invitrogen). Actin (Sigma) was used as a loading control. ECL was performed with GE Healthcare ECL Western blotting detection reagents according to the manufacturer's protocol.

Cholesterol Efflux

hMDM were loaded by adding 2 μCi/mL [^{3}H]-cholesterol (PerkinElmer) in ethanol to the media for 24 h. Cells were subsequently washed and equilibrated overnight in RPMI 1640 containing 0.1% (v/v) fatty acid free BSA. [^{3}H]-cholesterol-enriched cells were washed with PBS and incubated in 1.0 mL of efflux medium comprising media with 0.1% (v/v) fatty acid free BSA and 25 μg/mL apoA-1. At 24 and 48 h, an aliquot of media (100 μL) were removed and spun for 5 min at 16,000×*g* to remove any detached cells. The cultures were washed twice with ice cold PBS and then scraped into cold PBS (500 μL). 60-μL media aliquots and 10-μL cell aliquots were analysed by scintillation counting to quantify efflux of [^{3}H]-cholesterol.

Statistical Analysis

Data are presented either as mean ± standard deviation (SD) or mean ± standard error of the means (SE) of means

from multiple independent experiments. Mean comparisons were made using one-way analysis of variance (ANOVA). A p value of <0.05 was considered significant.

Results

Lipid Content of Sera

Sera from participants were pooled into 5 conditions termed A–E. Sera A was from non-diabetic normolipidemic adults; B was from non-diabetic hypercholesterolemic adults; C was from adults with Type 2 diabetes; D was from adults with Type 2 diabetes and hypertriglyceridemia; and E was from adults with Type 2 diabetes and hypercholesterolemia (Table 1). Glucose concentrations in media were fixed at 10.4–11.2 mmol/L. Due to high TG levels in two of the participants from group D, calculated LDL values were not available for this condition.

Effect of Diabetic and Hyperlipidemic Sera on Macrophage Lipid and Fatty Acid Content

On Day 13, there was increased fluorescent staining of hMDM cultured in C, D and E versus A and B (Fig. 1). We performed quantitative analysis using GC which demonstrated increased total FA in hMDM cultured in diabetic, dyslipidemic and hypercholesterolemic conditions (C, D and E) compared with non-diabetic controls (A and B) (Fig. 2a). The increase in FA content in hMDM exposed to diabetic sera (two- threefold increase for C, D and E vs. A, B) was substantially larger than the difference in FA content in the respective media ($\sim$50% higher in D, E vs. A, B) (Fig. 2c). Of note, FA content of media containing A, B and C was similar (Fig. 2c), but hMDM cultured in C had increased macrophage FA content compared to B (Fig. 2a).

Effect of Diabetic and Hyperlipidemic Sera on Macrophage Fatty Acid Composition

hMDM cultured in diabetic conditions C, D and E exhibited increased levels of the individual FA, namely, palmitic (C16:0), palmitoleic (C16:1), stearic (C18:0), oleic (C18:1), linoleic (C18:2) and arachidonic (C20:4) acids compared to A and B (Fig. 2b). These differences in hMDM were greater than differences in FA levels in the respective media (Fig. 2d). hMDM cultured in C accumulated more C16:0, C16:1, C18:0, C18:1 and C18:2 than hMDM in control A or B (Fig. 2b) although FA composition in media C was similar to media A or B (Fig. 2d). hMDM cultured in D had higher levels of C16:0, C16:1, C18:1 and C18:2 compared with A (Fig. 2b). hMDM cultured in E had higher levels of C16:0, C18:0, C18:1, C18:2 and C20:4 compared to A (Fig. 2b).

Ratios of Unsaturated to Saturated Fatty Acid in Macrophages

The ratio of both C16:1/C16:0 and C18:1/C18:0 were significantly higher in hMDM cultured in condition D compared to A (D vs. A, C16:1/C16:0: 2.5 ± 0.4 vs. 1.0 ± 0.2, $p = 0.005$ and C18:1/C18:0: 2.2 ± 0.1 vs. 1.0 ± 0.2, $p < 0.001$).

Effect of Diabetic and Hyperlipidemic Sera on Macrophage Cholesterol Content and Composition

The amounts of free cholesterol (FC) and cholesterol ester (CE) in hMDM cultured under conditions A to E was measured via GC–MS. FC and CE in hMDM was normalized according to the quantity per number of cells, and compared with their concentrations in the respective media. hMDM contained a greater quantity of FC compared to CE (Fig. 3a, b), despite the concentration of CE in the media being higher than that of FC (Fig. 3c, d). There

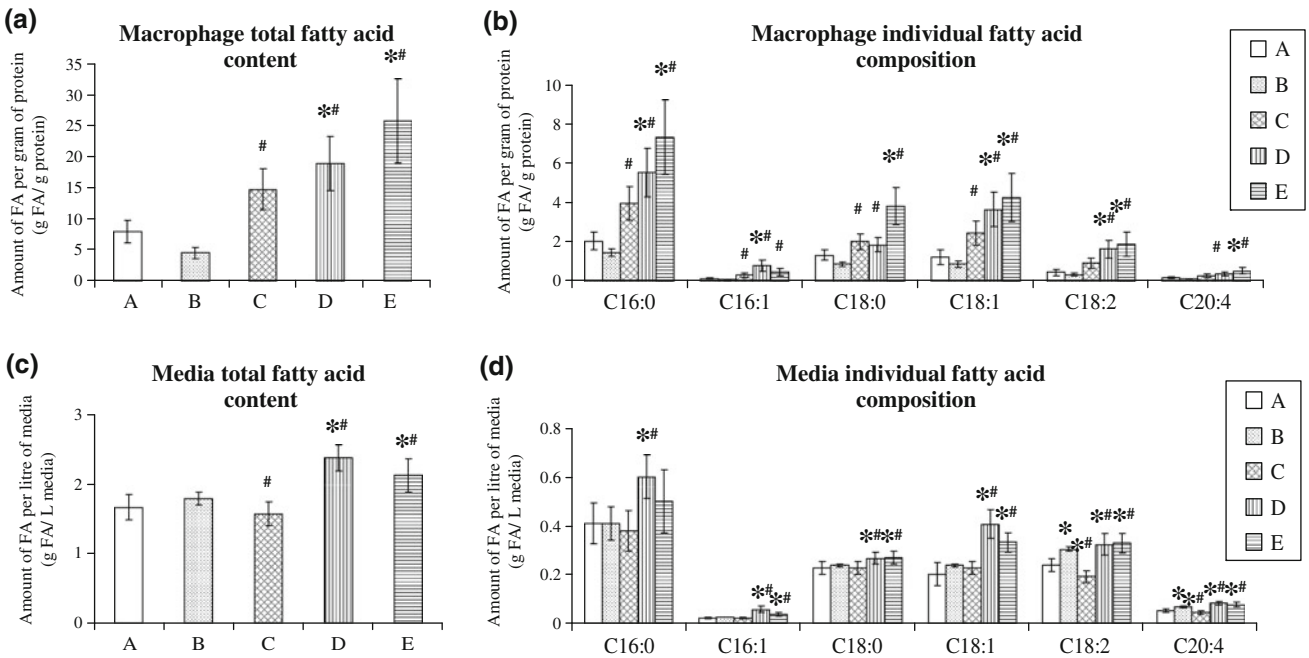

Fig. 2 Macrophage fatty acid (FA) content (**a**) and composition (**b**), and media FA content (**c**) and composition (**d**) following exposure to sera A–E. C16:0, palmitic acid; C18:0, stearic acid; C18:1, oleic acid; C18:2, linoleic acid; C20:4, arachidonic acid. Data are shown as mean ± SE of 3 independent experiments in triplicates. One-way ANOVA; $^{*}p < 0.05$ versus A; $^{\#}p < 0.05$ versus B

was a higher level of FC in media E (Fig. 3c). There was a trend for increased CE content in hMDM cultured across conditions A–E, but CE was increased significantly only in hMDM cultured in E (E vs. A: 2.3 ± 0.4 vs. 1.0 ± 0.2 nmol Chol/5 × 10^5 cells, $p = 0.01$) (Fig. 3b).

Western Analysis in Macrophages Cultured in Conditions A, B, C, D and E

CD36 protein was increased significantly in D compared to controls A or B (Fig. 4). SR-A protein were increased in hMDM cultured in C and D compared to A. ABCA1 protein levels did not vary appreciably between hMDM cultured in A–E. ABCG1 protein was not detected (data not shown). SCD protein level was increased in hMDM cultured in C, D and E compared to A (Fig. 4). PPARγ protein was decreased in hMDM cultured in C, D and E compared to A. LXRα protein levels were similar across conditions A–E.

RNA Inhibition of Macrophage CD36 and SCD

As upregulation of CD36 and SCD protein levels was greatest in hMDM in D, this condition was selected for functional studies using RNAi. hMDM were treated with

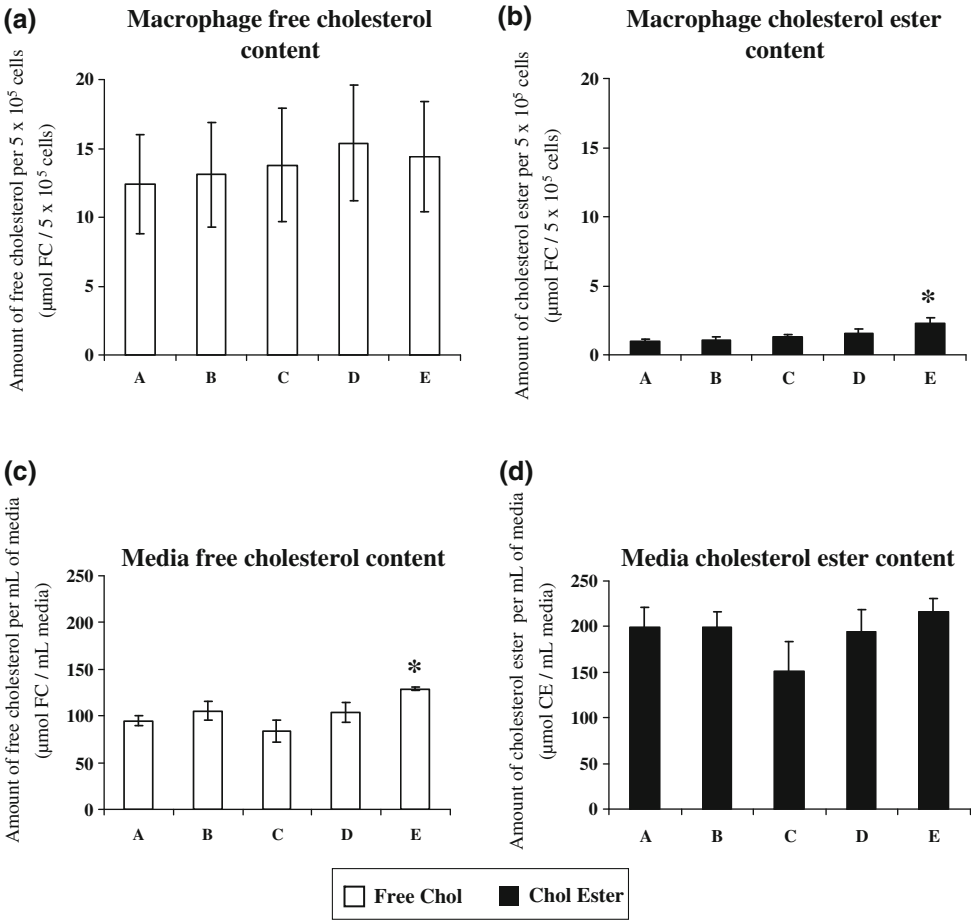

Fig. 3 Free cholesterol (FC, *white bars*) and cholesterol ester (CE, *black bars*) mass in macrophages (**a**), (**b**), and in media (**c**), (**d**). Data are shown as mean ± SE of three experiments in triplicates. One-way ANOVA; $*p < 0.05$ versus A

siRNA targeting CD36 or SCD followed by incubation in A or D. A random siRNA was used as a negative control. Treatment with the respective siRNA successfully reduced CD36 and SCD protein levels (Fig. 5a, e).

Results of siRNA Inhibition of Macrophage CD36 and SCD in Conditions A and D

As expected baseline FA content was higher in D than A (controls in Fig. 5b, d). CD36 siRNA treatment of hMDM cultured in D reduced the amount of macrophage C16:0 and C16:1 (Fig. 5c), and reduced macrophage FC content (D: CD36 siRNA vs. control: 163.9 ± 10.5 vs. 221.9 ± 26.2 mmol free cholesterol/g protein, $p = 0.04$) (Fig. 5d). Treatment with SCD siRNA significantly reduced FA content in hMDM cultured in either A or D (SCD siRNA vs. control: A, 2.1 ± 0.2 vs. 3.4 ± 0.4 g FA/g protein, $p = 0.01$; and D, 3.5 ± 0.3 vs. 4.8 ± 0.5 g FA/g protein, $p = 0.03$) (Fig. 5d). SCD siRNA reduced the amount of C16:0, C16:1, C18:1, C18:2 and C20:4 in A, and the amount of C16:0, C16:1 and C18:1 in D (Fig. 5g). SCD siRNA appeared to reduce macrophage FC content, with the difference in condition A being statistically significant (SCD siRNA vs. control: A, 168.6 ± 9.3 vs. 212.1 ± 23.2 mmol free cholesterol/g protein, $p = 0.04$) (Fig. 5h).

Effects of SCD Inhibition on Macrophage Cholesterol Efflux

Treatment of macrophages with CD36 siRNA did not alter ratios of C16:1/C16:0 or C18:1/C18:0 (Fig. 6a). By contrast, RNA inhibition of SCD decreased the ratios of C16:1/C16:0 and C18:1/C18:0 in macrophages cultured in media A and D (Fig. 6a). The amount of ABCA1 protein was increased consistently after SCD siRNA treatment compared to control siRNA in macrophages cultured in medium D (Fig. 6b). Cholesterol efflux was increased after SCD siRNA treatment in macrophages cultured in condition D (SCD siRNA vs. control siRNA: 18.0 ± 3.9% vs. 8.0 ± 0.8, $p = 0.03$) (Fig. 6c).

Discussion

We found that normal human macrophages exposed to diabetic sera had greater FA accumulation compared to

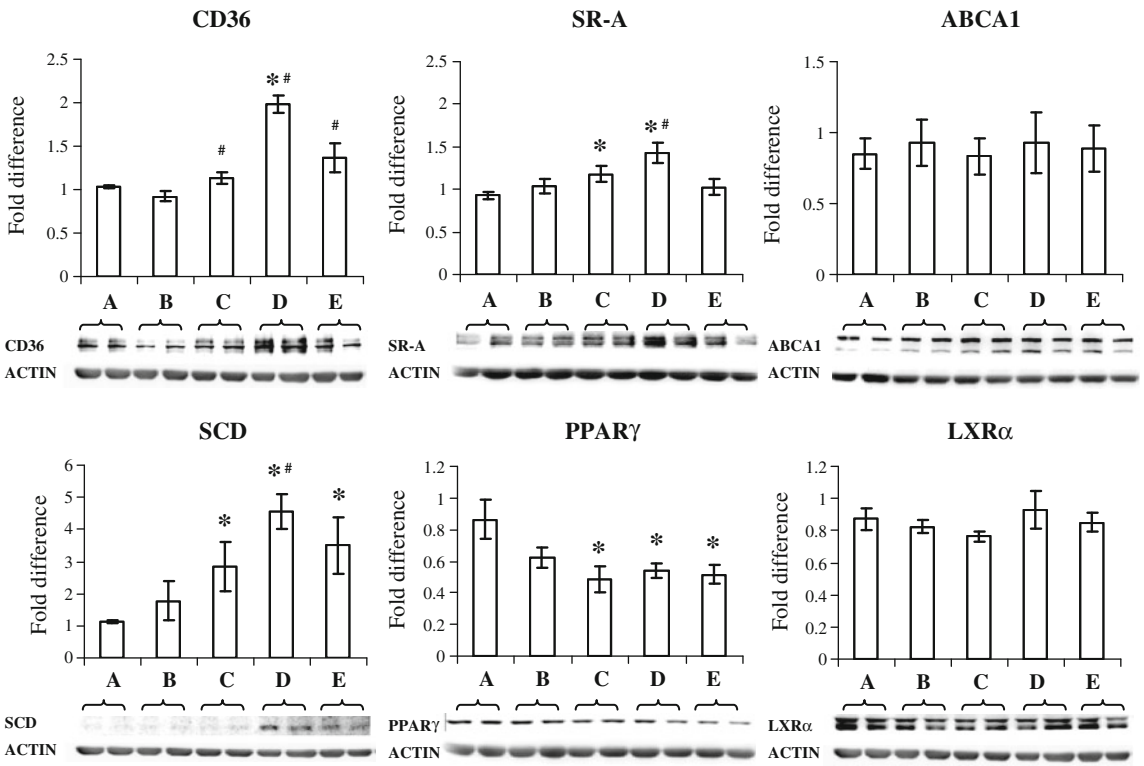

Fig. 4 Western analysis of protein lysates from macrophages cultured in conditions A–E. Data are shown as a representative blot from one experiment in duplicates. β-actin was used as a loading control. Quantitative data are mean ± SE of three independent experiments in duplicates, normalized to A = 1.0. One-way ANOVA; $^{*}p < 0.05$ versus A; $^{\#}p < 0.05$ versus B

non-diabetic sera. Exposure to hypertriglyceridemic diabetic serum resulted in even greater FA accumulation, while exposure to hypercholesterolemic diabetic serum resulted in the highest FA content and increased macrophage CE. Of note, both saturated and unsaturated FA was increased. Alterations in macrophage phenotype were accompanied by increased CD36, SR-A and SCD but reduced PPARγ protein level. A key finding was that in the dyslipidemic environment, RNA inhibition of macrophage SCD not only altered FA composition, but also increased ABCA1 protein level and enhanced cholesterol efflux.

We employed a common source of human monocytes from healthy blood donors thus allowing the specific effect of different diabetic sera to be evaluated. The media content of FC and CE approximately corresponded to total cholesterol levels in the original sera. There was a "dose–response" gradient with the lowest FA content present in macrophages exposed to A and B, intermediate FA content with C and the highest FA content with D and E, with macrophages exposed to E also having increased CE. Increases in saturated and unsaturated FA are potentially relevant to a range of cellular and metabolic functions (for review, see [18]). By contrast, previous studies have used murine macrophages, or loaded macrophages with supra-physiological levels of chemically oxidized lipoproteins [19–21]. Our findings are in keeping with a previous report in which lipoprotein constituents of hypertriglyceridemic sera including chylomicron remnant-like particles induced macrophages to form foam cells and were present in atherosclerotic lesions [22]. By using sera collected from study participants with diabetes, hypertriglyceridemia and hypercholesterolemia, we provided a series of culture environments which more closely replicated the pathophysiology of Type 2 diabetes.

Mauldin et al. [9] found that hMDM from patients with Type 2 diabetes cultured over a 4 day period in autologous serum had reduced cholesterol efflux. Loading macrophages with cholesterol would be expected to result in up-regulation of ABCA1 expression [23]. The degree of macrophage cholesterol loading induced under conditions D and E may be less than seen in experiments using pharmacological concentrations of lipoproteins, and thus could have been insufficient to up-regulate ABCA1. However, conditions B and more so E contained substantial concentrations of LDL thus providing adequate substrate for uptake and there was a trend for increasing macrophage CE content across A–E. It is possible that a particular diabetic milieu suffices to stimulate macrophage lipid accumulation without crossing a threshold needed to induce compensatory increases in cholesterol efflux. An

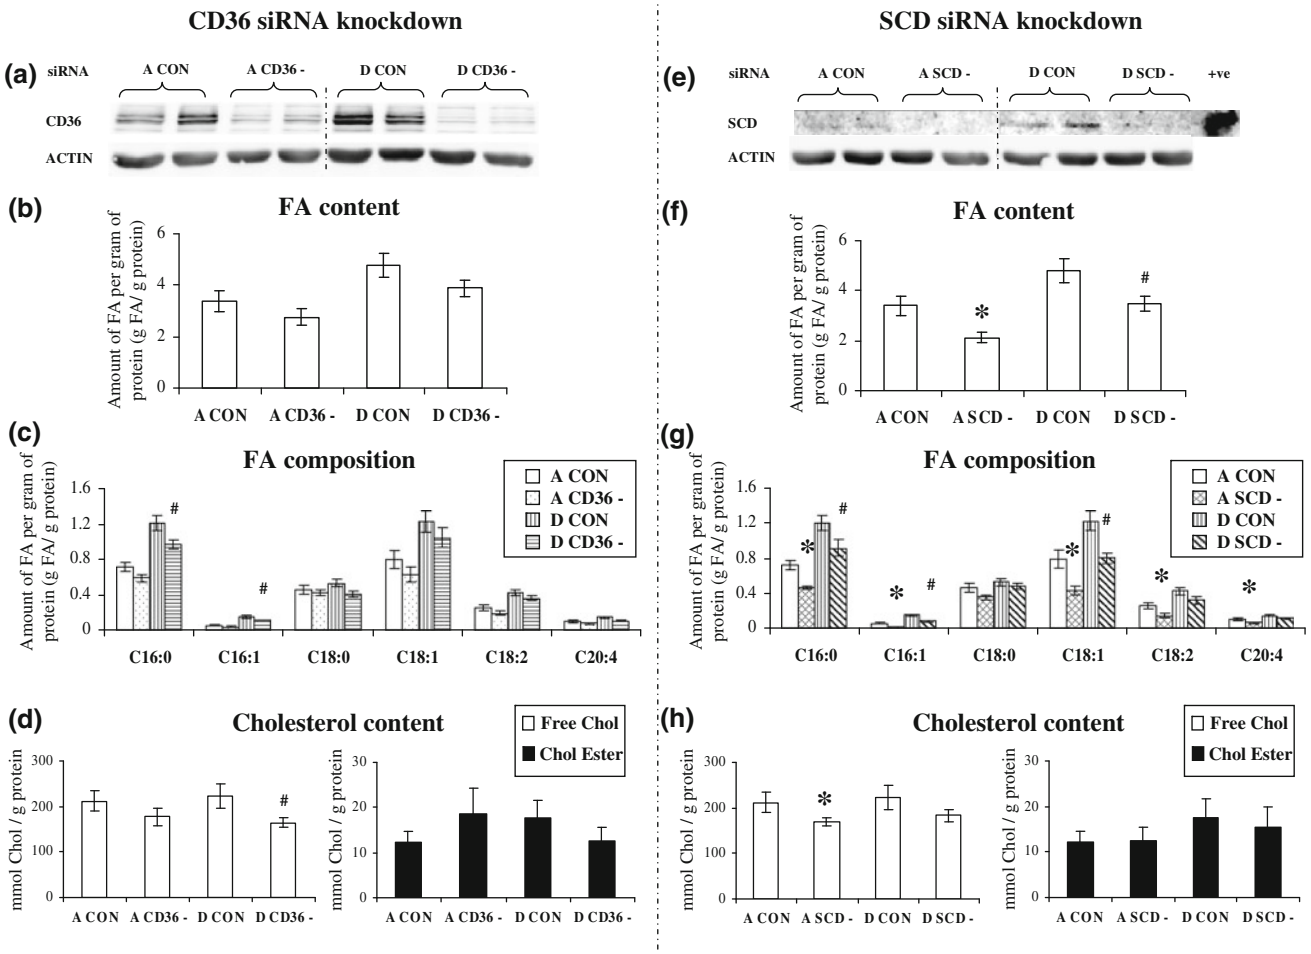

Fig. 5 Macrophages were treated with random siRNA as a negative control (CON) or with siRNA to inhibit CD36 (CD36−) or SCD expression (SCD−). This was followed by culture in conditions A or D. **a** Western blot of CD36 protein level in macrophages ± CD36 siRNA. **b** FA content, **c** FA composition and **d** cholesterol content of macrophages cultured in A or D following siRNA inhibition of CD36. **e** SCD protein level in macrophages ± SCD siRNA. **f** FA content, **g** FA composition and **h** cholesterol content of macrophages cultured in A or D following siRNA inhibition of SCD. Two experiments were done in duplicates for protein analysis and a representative blot is shown. Data are FA or cholesterol content/g protein and shown as mean ± SE of four independent experiments done in triplicates. One-way ANOVA; $^{*}p < 0.05$ versus A control; $^{\#}p < 0.05$ versus D control

alternative explanation is that increased macrophage SCD and unsaturated FA levels seen on exposure to dyslipidemic diabetic sera could blunt the expected upregulation of ABCA1 and cholesterol efflux. Greater SCD expression and activity would increase cellular content of monounsaturated FA such as oleic acid resulting in destabilization of ABCA1 [11, 12], thus inhibiting increases in ABCA1 protein level and cholesterol efflux on exposure to lipid-rich diabetic sera.

Since levels of CD36 and SCD protein were increased in macrophages exposed to dyslipidemic diabetic sera, we selected this condition for extended investigation using RNA inhibition. The experimental protocol was successful in reducing CD36 and SCD protein levels in macrophages cultured under control (A) and diabetic dyslipidemic (D) conditions. CD36 inhibition reduced C16:0 and C16:1 and FC levels in macrophages exposed to diabetic dyslipidemic sera. Therefore, this observation supports a role for elevated CD36 protein levels in macrophages exposed to diabetic and dyslipidemic diabetic sera to enhance FA and cholesterol accumulation.

A key finding was that SCD siRNA reduced unsaturated FA in hMDM exposed to both non-diabetic (A) and dyslipidemic diabetic serum (D). SCD inhibition in macrophages exposed to dyslipidemic diabetic serum consistently reduced macrophage FA levels and reduced the C16:1/C16:0 and C18:1/C18:0 ratios to levels comparable to non-diabetic normolipidemic controls. Furthermore, SCD inhibition in macrophages exposed to dyslipidemic diabetic serum resulted in increased ABCA1 protein levels

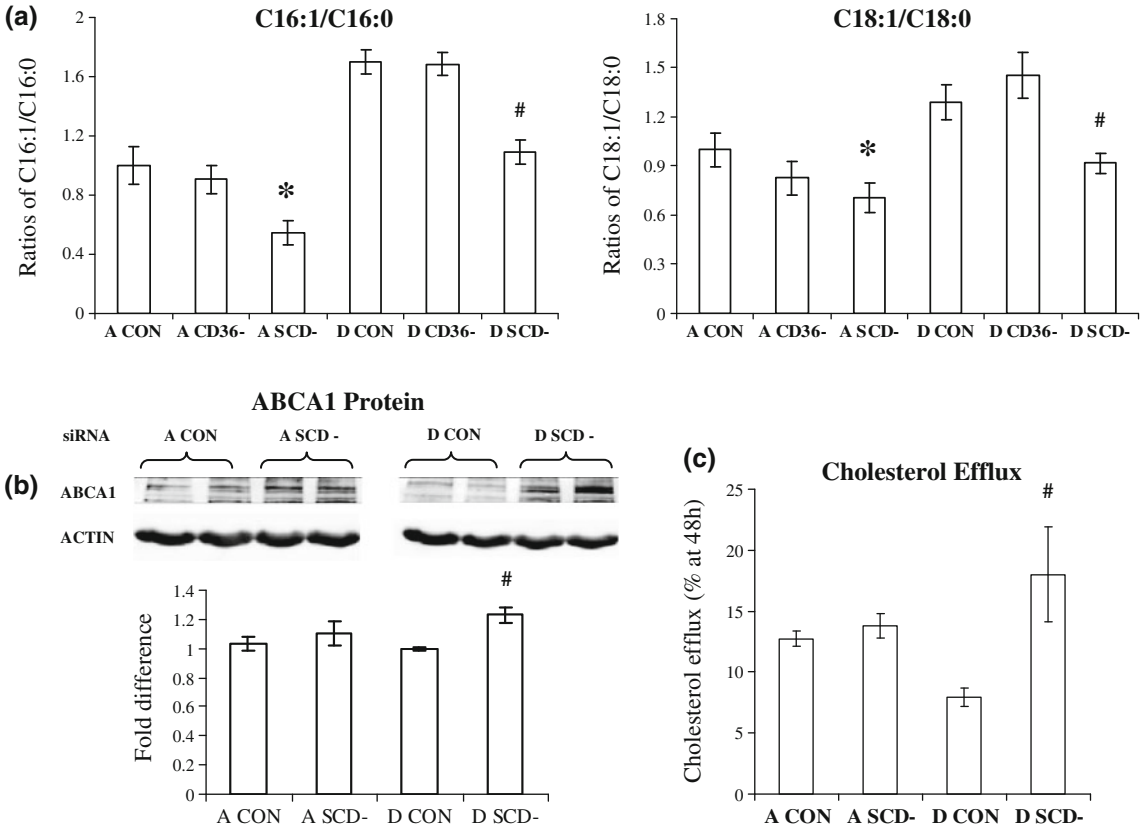

Fig. 6 Macrophages were treated with random siRNA as a negative control (CON) or with siRNA to inhibit CD36 (CD36−) or SCD expression (SCD−) followed by culture in conditions A or D. **a** Effect of CD36 or SCD siRNA on ratios of C16:1/C16:0 and C18:1/C18:0 in macrophages. Data for FA ratios are shown as mean ± SE of four independent experiments, each performed in triplicate. **b** Effect of SCD siRNA on ABCA1 protein level in macrophages. Data are from two independent experiments, each performed in duplicate. **c** Cholesterol efflux from macrophages treated with anti-SCD siRNA and cultured in conditions A and D for 48 h. and enhanced cholesterol efflux. These findings support the concept that increased SCD protein levels seen in macrophages exposed to dyslipidemic diabetic serum might prevent the anticipated compensatory increase in ABCA1 expression and cholesterol efflux, thus predisposing to foam cell formation. Further investigation is required to evaluate whether modulation of macrophage SCD might inhibit the development or progression of atherosclerosis in the context of Type 2 diabetes.

We observed reduced macrophage PPARγ protein levels on exposure to diabetic sera, while LXRα protein levels were stable. Previously activation of macrophage PPARγ has been reported to increase expression of CD36, reduce SR-A, and enhance expression of ABCA1 in part via activation of LXRα [5, 24]. Therefore, downregulation of PPARγ may contribute to a pro-atherogenic macrophage phenotype in the presence of diabetic dyslipidemia. Examining the effects of PPARγ and LXR ligands was beyond the scope of this project, and further investigation would be needed to assess whether LXR agonists might inhibit foam cell formation in the context of Type 2 diabetes [25].

Of note, a 10% serum supplement was used in each condition. The differences observed in the experiments might reflect variation in the amount of lipid added to macrophages, in addition to intrinsic differences in diabetic sera. Nevertheless, these conditions still provide a model for diabetes-related differences in circulating lipids. Sera were frozen promptly following collection which should have minimized in vitro oxidation of lipids. However we can not exclude the possibility that some differences in susceptibility of lipids within diabetic serum to oxidation may have contributed to increased uptake by the scavenger receptor pathway. It is possible that larger differences in the experimental results might have been seen had higher concentrations of serum been used, however 10% is the usual serum supplement for cell culture.

We acknowledge several limitations of this study. We were unable to recruit non-diabetic hypertriglyceridemic persons to provide an additional comparison which would

have been useful. HDL concentrations were highest in condition A, and we did not extend the analysis to differences in lipoprotein subclasses [26]. Therefore, additional investigation would be needed to clarify the role of HDL in this context. As a fixed volume of blood was sampled from each study participant, there was a finite supply of pooled sera for experiments. Consequently the analysis of proteins was not exhaustive, for example cellular lipid loss also involves mobilization of FC from macrophages to HDL via scavenger receptor class B Type 1 (SR-B1) [27]. Within a fixed number of experiments we could not extend the Western analyses to encompass SR-B1 or other proteins. Finally, availability of sera and the protocol for maintaining optimal macrophage growth placed constraints on the functional studies involving RNAi. These experiments were limited to conditions A and D representing a non-diabetic normolipidemic control and a diabetic dyslipidemic condition. Nevertheless, the significant alterations in macrophage phenotypes observed following RNAi of CD36 and particularly SCD were sufficient to demonstrate functional effects attributable to these proteins in human macrophages in the setting of diabetic dyslipidemia.

Our findings also provide an additional helpful context for considering the metabolic role of SCD. Mice with a targeted disruption in the SCD gene are resistant to diet-induced weight gain and have increased insulin sensitivity relative to the WT controls [28]. In another study, inhibition of *Scd* in severely hyperlipidemic LDL receptor-deficient mice challenged with a Western diet reduced plasma triglycerides and weight gain, and increased insulin sensitivity [29]. Despite favorable metabolic characteristics, SCD-deficient mice had increased skin inflammation and atherosclerosis [13], but reduced inflammation in adipocytes [14]. If SCD is inhibited rather than completely abrogated, and combined with dietary fish oil supplements this prevents atherosclerosis in mice [15]. Our results extend these previous reports and support a pro-atherogenic role for SCD in human macrophages in response to dyslipidemic diabetic serum. Further investigation is necessary to extend these findings and to evaluate whether inhibition of macrophage SCD might modulate development or progression of diabetic atherogenesis.

In summary, replicating in vitro diabetic dyslipidemia encountered in vivo provides an informative model to study macrophage phenotypes relevant to diabetic atherogenesis. Macrophages exposed to dyslipidemic diabetic sera exhibited a lipid-rich phenotype, increased expression of CD36 and SR-A, and higher levels of SCD. Inhibition of CD36 reduced macrophage free cholesterol, while inhibition of SCD decreased macrophage FA content, increased ABCA1 protein and enhanced cholesterol efflux. Additional research is needed to clarify whether abrogating the increased macrophage expression of CD36 and SCD that occurs on exposure to dyslipidemic diabetic sera might inhibit diabetic atherogenesis, thus reducing the burden of cardiovascular disease in persons with Type 2 diabetes.

Acknowledgments We thank staff from Biochemistry, Specimen Reception and Transfusion Medicine, Fremantle Hospital for their assistance with this project, and the Australian Red Cross Blood Service for providing buffy coats. Received: 14 April 2011 / Accepted: 14 June 2011 / Published online: 6 July 2011

Abstract It has been demonstrated in vivo that lipid glycation products such as Amadori-glycated phosphatidylethanolamine (Amadori-PE) accumulate in the plasma of diabetic humans and animals, but how lipid glycation products are formed under hyperglycemic conditions are not clear. We sought to clarify the occurrence of lipid glycation and its relationships with lipid peroxidation and protein glycation during the development of hyperglycemia using the streptozotocin (STZ)-induced diabetic rat model. A significant increase in Amadori-PE was observed in STZ rats 7 days after STZ treatment, and Amadori-PE (especially 18:0–20:4 Amadori-PE) was found at high levels in the blood and in organs that are strongly affected by diabetes, such as the kidney. Significant changes in Amadori-PE appeared to occur prior to changes in levels of oxidized lipids, which increased after 21–28 days. In addition, accumulation of *N*ε-(carboxymethyl)lysine (CML), a protein glycation product, proceeded somewhat more slowly and moderately than that of Amadori-PE, suggesting that Amadori-PE and CML are early and advanced glycation products, respectively. Our results suggest that Amadori-PE may be a useful predictive marker for hyperglycemia, particularly in the early stages of diabetes. Similar speculations have been made from previous human studies, but this study provides a direct evidence to support the speculations in rat study.

Keywords Diabetes · Hyperglycemia · Lipid glycation · Oxidized lipids

Abbreviations

1,5-AG	1,5-Anhydroglucitol
ALT	Alanine aminotransferase
Amadori-PE	Amadori-glycated phosphatidylethanolamine
AST	Aspartate aminotransferase
CL	Chemiluminescence
CML	*N*ε-(carboxymethyl)lysine
Hb_{A1c}	Hemoglobin A1c
LC	Liquid chromatography
MRM	Multiple reaction monitoring
MS/MS	Tandem mass spectrometry
NFPA	Nonafluoropentanoic acid
NLS	Neutral loss scanning
PCOOH	Phosphatidylcholine hydroperoxide
PE	Phosphatidylethanolamine
PL	Phospholipid
RBC	Red blood cells
STZ	Streptozotocin
TBARS	Thiobarbituric acid reactive substances
T-cho	Total cholesterol
TAG	Triacylglycerol

Introduction

The clinical significance of non-enzymatic protein glycation in complications of diabetes has been studied

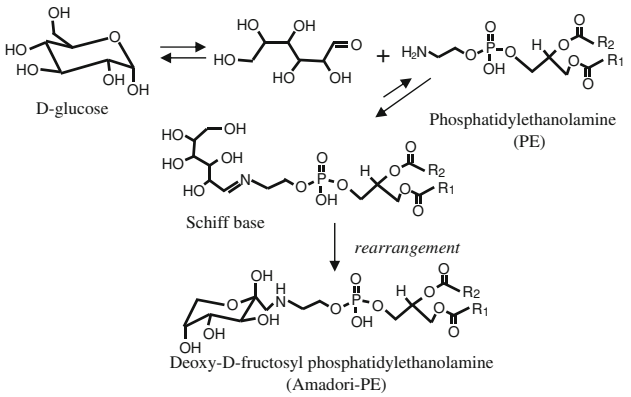

Fig. 1 Scheme for the glycation of phosphatidylethanolamine (PE). Glucose reacts with the amino group of PE to form a Schiff base, which undergoes an Amadori rearrangement to yield deoxy-D-fructosyl PE (Amadori-PE)

extensively [1]. In addition to protein glycation, our group and other researchers have found that glycation of lipids and glucose also occurs in vivo [2–4]. A previous study by our group demonstrated that Amadori-glycated phosphatidylethanolamine (Amadori-PE, Fig. 1) can accumulate in the plasma of diabetic rats [5]. Accumulation of Amadori-PE was also detected in the plasma of diabetic patients [6], and a positive correlation was found between Amadori-PE and lipid peroxides such as phosphatidylcholine hydroperoxide (PCOOH). This relationship between Amadori-PE and lipid peroxides suggests that lipid glycation may play an important role in diabetogenesis and the development of diabetic complications such as retinopathy, nephropathy, neuropathy, and atherosclerotic macrovascular disease [7, 8].

Although there is increasing evidence of the involvement of lipid glycation in diabetic complications, it is still unclear how lipid glycation products are formed during the development of hyperglycemia. Furthermore, since Amadori-PE is able to induce lipid peroxidation [9], it is of interest to determine whether levels of Amadori-PE and lipid peroxides change during the development of hyperglycemia. In addition, lipid and protein glycation are understood to be related to the pathogenesis of diabetes, but there have been no comparative studies of the prevalence of the two glycation products (glycated lipids and glycated proteins) during diabetes development. Such a comparative study would provide greater insight into the relationship between glycation and diabetogenesis, and could reveal whether glycation products can be used as indicators of diabetes.

Therefore, in the present study, we sought to confirm the occurrence of lipid glycation (Amadori-PE) during the development of hyperglycemia and to investigate the relationship between lipid glycation, lipid peroxidation, and protein glycation in streptozotocin (STZ)-induced diabetic rats. Since Amadori-PE is comprised of two fatty acids, several molecular species are possible due to the presence of different fatty acid structures. Accordingly, in this study, a recently developed liquid chromatography–tandem mass spectrometry (LC–MS/MS) technique was used to quantify eight molecular species of Amadori-PE [6, 10]. STZ rats were evaluated for biological and pathological changes (including formation of lipid glycation and protein glycation products) during the period of diabetes development. Based on the results of this study, we discuss the presence and significance of lipid and protein glycation products during diabetes development and the potential use of lipid glycation products as biomarkers for hyperglycemia.

Materials and Methods

Materials

All PE molecular species were purchased from Avanti Polar Lipids (Alabaster, AL). PE molecular species were identified by carbon chain length and degree of unsaturation of the *sn*-1,2 acyl chains; e.g., "18:0–18:1 PE" for 1-octadecanoyl-2-octadecenoyl-*sn*-glycero-3-phosphoethanolamine. Amadori-PE standards were synthesized using PE species as starting materials, as previously described [9] with minor modifications. In brief, PE (e.g., 18:0–18:1 PE; 15 μmol) and glucose (5 mmol) were dissolved in 50 ml of methanol, and incubated at 60 °C for 24 h. After incubation, lipid-soluble products were extracted using Folch's partition [11]. The extract was evaporated to dryness, and the residue was dissolved in 10 ml of chloroform–methanol (2:1, v/v). Amadori-PE was then isolated using a preparative reversed-phase column (5C-18-MS-II, 250 × 10 mm; Nacalai Tesque, Japan) with methanol-5 mM aqueous ammonium acetate (99:1, v/v) as the eluent. The structure and purity of each synthesized Amadori-PE was evaluated by LC–MS (Mariner, Applied Biosystems, Foster City, CA), high resolution fast atom bombardment MS (JEOL-JMS-700 mass station, JEOL, Tokyo, Japan), and NMR (Varian Unity 600 spectrometer, Varian, Palo Alto, CA). All other reagents were purchased from Wako (Osaka, Japan) using the highest grade available.

Animal Experiments

Male Sprague–Dawley rats (4 weeks of age) were purchased from Japan SLC (Hamamatsu, Japan). Rats were given free access to standard laboratory chow (MF pellet; Oriental Yeast, Tokyo, Japan) and water for 1 week before the experiment began. Rats were housed in a temperature- and humidity-controlled room with a 12 h light cycle. All animal experiments were conducted in accordance with the Animal Experimentation Guidelines of Tohoku University.

On day 0 (the first experimental day after acclimatization for 1 week), diabetes was induced in rats by a single intraperitoneal injection of 70 mg/kg streptozotocin (STZ; Sigma, St. Louis, MO) dissolved in citric acid buffer (50 mM, pH 4.5), whereas control rats received an injection of buffer only. Blood glucose was measured 3 days after STZ injection, and rats with blood glucose levels >250 mg/dl were considered diabetic.

On days 0, 7, 14, 21 and 28, diabetic and control rats ($n = 6$ for each time point) were anesthetized with Avertin and slaughtered. Blood (10 ml) was collected into a tube containing heparin as an anticoagulant, and was centrifuged at 1,000*g* for 10 min at 4 °C. After the plasma and buffy coat were removed, red blood cells (RBC) were washed three times with phosphate-buffered saline (pH 7.4) to prepare packed cells. Total lipids were extracted from 1 ml of the packed cells using 2-propanol and chloroform [12]. Plasma (0.5 ml) was subjected to total lipid extraction using Folch's partition [11]. For tissue analysis, liver, kidney, pancreas, cerebrum, and cerebellum were collected, and these samples (100 mg) were also subjected to Folch lipid extraction. Each lipid extract was evaporated to dryness, and the residue was dissolved in 0.5 ml of chloroform–methanol (2:1, v/v).

MS/MS Analysis of Amadori-PE

A 4000 QTRAP quadrupole/linear ion-trap tandem mass spectrometer (Applied Biosystems) was used for MS/MS analysis. MS/MS parameters (e.g., collision energy) were optimized using synthesized 18:0–18:1 Amadori-PE as a reference compound. After optimization, neutral loss scanning (NLS) was performed to profile Amadori-PE molecular species in blood samples. The MS/MS instrument was programmed to scan parent ions that yielded a neutral loss of 303 Da after fragmentation in the collision cell. Sample (lipid extract, 5 μl) was injected directly into MS/MS using methanol as a carrier solvent (0.2 ml/min). Electrospray ionization was used as an ion source with collision energy of 45 eV, transition dwell time of 100 ms, turbo gas temperature of 500 °C, and spray voltage of 5,500 V. Nitrogen pressure values for turbo, nebulizer, and curtain gases were set at 40, 60, and 20 pounds per square inch, respectively.

LC–MS/MS Analysis of Amadori-PE

For LC–MS/MS analysis, a Shimadzu liquid chromatography system (Shimadzu, Kyoto, Japan) was equipped with the 4000 QTRAP. Amadori-PE was analyzed using a silica column (Inertsil, 2.1 × 100 mm; GL Sciences, Tokyo, Japan) with a binary gradient consisting of solvent A [acetonitrile–methanol–1 M aqueous ammonium formate (pH 6.0) (78:20:2, v/v/v)] and solvent B [acetonitrile–methanol–1 M aqueous ammonium formate (pH 6.0) (49:49:2, v/v/v)]; [10]. The gradient profile was as follows: 0–1.25 min, 10% B; 1.25–2 min, 10–100% B linear gradient; 2–6 min, 100% B; 6–6.5 min, 100–10% B linear gradient; 6.5–8 min, 10% B. The flow rate was 0.4 ml/min, and the column temperature was 40 °C. Amadori-PE was detected in the postcolumn by MS/MS with multiple reaction monitoring (MRM) for the transition of parent ion to product ion.

For quantitation of Amadori-PE in blood and tissue samples, we focused on eight molecular species (16:0–18:1, 16:0–18:2, 16:0–20:4, 16:0–22:6, 18:0–18:1, 18:0–18:2, 18:0–20:4, and 18:0–22:6 Amadori-PE), because their presence in RBC was revealed by NLS by MS/MS analysis. Using synthesized Amadori-PE species, we prepared standard solutions at concentrations of 5–1,000 pmol/ml (a range expected to encompass concentrations encountered in vivo). Plasma extract, RBC extract, tissue extract, or standard solution (2 μl each) was then subjected to LC–MS/MS, and the Amadori-PE molecular species were individually detected using MRM. The concentrations of Amadori-PE in plasma, RBC, and tissues were calculated using calibration curves for the synthesized Amadori-PE molecules. The concentrations of PE in plasma, RBC, and tissues were similarly determined by LC–MS/MS with MRM [10].

Detection of Lipid Peroxides

To examine oxidative stress, PCOOH in total lipid extracts from plasma and liver was measured by HPLC with chemiluminescence (CL) detection [13, 14]. The column was a Finepak SIL NH2-5 (4.6 × 250 mm; Japan Spectroscopic Co., Tokyo, Japan), the eluent was 2-propanol–methanol–water (135:45:20, v/v/v), and the flow rate was 1 ml/min. Post-column CL detection was carried out using a CLD-100 detector (Tohoku Electronic Industries Co., Sendai, Japan). A mixture of luminol and cytochrome c in 50 mM borate buffer (pH 10.0) was used as a hydroperoxide-specific post-column CL reagent. Calibration was carried out using standard PCOOH. In addition to PCOOH, thiobarbituric acid reactive substances (TBARS) were measured as described previously [15].

*N*ε-(Carboxymethyl)lysine Analysis

*N*ε-(Carboxymethyl)lysine (CML) was measured by LC–MS/MS [16]. Blood and tissue samples were analyzed by reversed-phase HPLC on an Atlantis T3 column (2.1 × 100 mm, Waters, Milford, MA). Mobile phase A was 5 mM aqueous nonafluoropentanoic acid (NFPA) and mobile phase B was acetonitrile containing NFPA (5 mM).

The gradient profile was as follows: 0–8 min, 15–50% B linear gradient; 8–8.5 min, 50–90% B linear gradient; 8.5–9.5 min, 90% B; 9.5–11 min, 90–15% B linear gradient; 11–15 min, 15% B. Analyses were performed in positive-ion mode with the ion-spray voltage at 5,500 V. MRM pairs (parent ion/product ion) for CML and lysine were 205/84 and 147/84, respectively.

Other Biochemical Measurements

Blood glucose and insulin levels were measured using a Glucose C II test kit (Wako) and a Rat/Mouse Insulin ELISA Kit (EZRMI-13K, Linco Research, St. Charles, MO) according to the manufacturers' protocols. Blood parameters, including 1,5-anhydroglucitol (1,5-AG), hemoglobin A1c (Hb_{A1c}), aspartate aminotransferase (AST), alanine aminotransferase (ALT), triacylglycerol (TG), and total cholesterol (T-cho), were analyzed by Mitsubishi Chemical Medicine Corporation (Japan). Phospholipid (PL) content in plasma was measured using methods described by Bartlett [17]. Hepatic lipid parameters were analyzed using standard methods.

Statistical Analysis

Data are expressed as mean values ± SD. Statistical analyses in this study included the Student's t test and Mann–Whitney U test. Differences were considered significant at $P < 0.05$ and $P < 0.01$.

Results

General Characteristics of STZ Rats

During the 28-day experimental period, weight gain, plasma insulin, and 1,5-AG were suppressed in STZ rats, and blood glucose and Hb_{A1c} levels were consistently elevated in these animals (Fig. 2). Plasma levels of AST, ALT, TG, T-cho, and

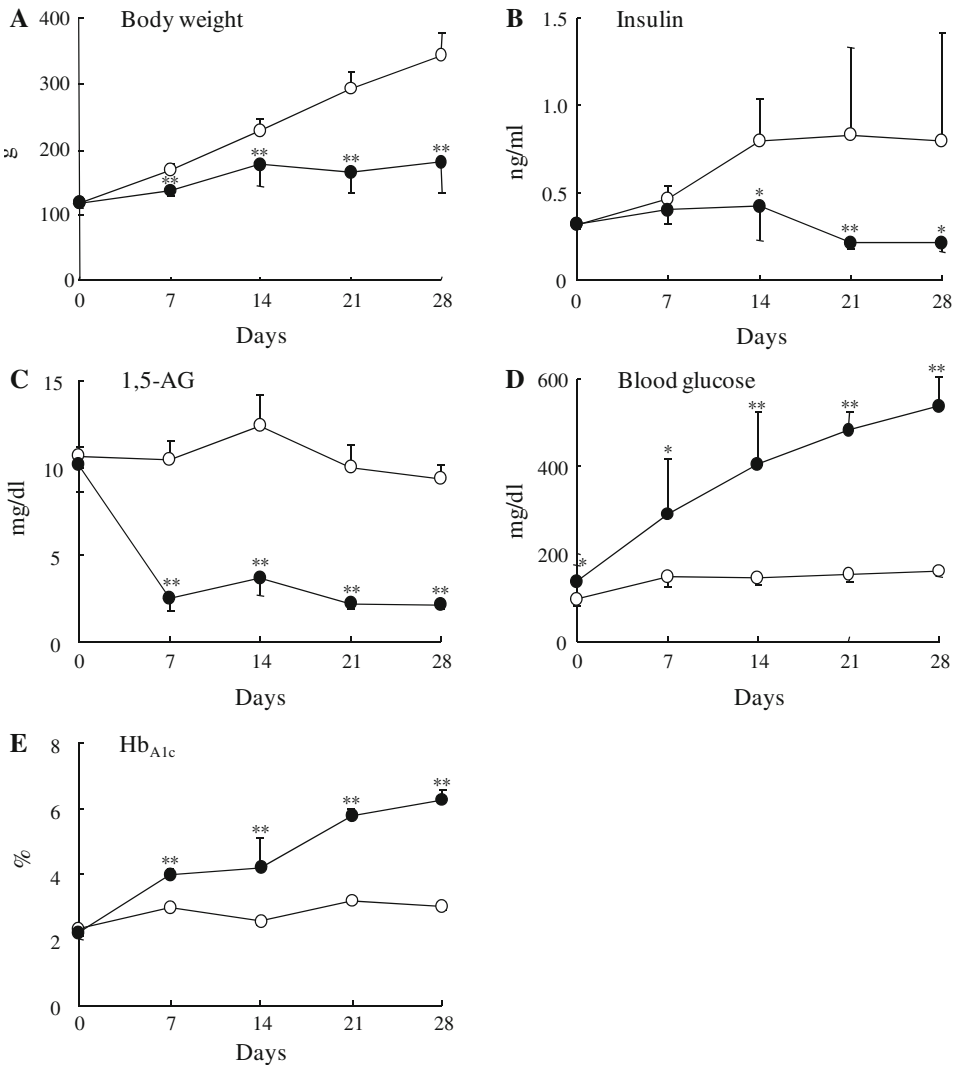

Fig. 2 Characteristic changes in **a** body weight, **b** insulin, **c** 1,5-AG, **d** blood glucose, and **e** Hb_{A1c}. Values are means ± SD ($n = 6$; $*P < 0.05$ and $**P < 0.01$). *White circles* represent control rats, and *black circles* represent STZ rats

AST aspartate aminotransferase, *ALT* alanine aminotransferase, *TG* triacylglycerol, *T-Cho* total cholesterol, *PL* phospholipids

PL were higher in the STZ group (Table 1). Among hepatic lipid parameters, TG and T-cho were increased in the STZ group (Table 1). These data indicate that low insulin secretion in these STZ rats led to hyperglycemia and hyperlipidemia, and resulted in severe diabetes.

(LC)-MS/MS Profiling and Determination of Amadori-PE Molecular Species

MS/MS NLS is useful for analyzing PE glycation [6, 10], and Amadori-PE can be detected by searching for the loss of glycated group ($H_2PO_4CH_2CH_2NHC_6H_{11}O_5$, 303 Da) (refer to Fig. 3a). Using NLS, we profiled the molecular Amadori-PE species in STZ rats. For example, in neutral loss spectra of 303 Da of STZ rat RBC, a series of ion peaks was observed to correspond to Amadori-PE molecular species (16:0–18:1, 16:0–18:2, 16:0–20:4, 16:0–22:6, 18:0–18:1, 18:0–18:2, 18:0–20:4, and 18:0–22:6) (Fig. 3b). Based on the NLS data, the eight Amadori-PE species were individually quantified using LC–MS/MS with MRM (Fig. 3c).

PE Glycation During the Development of Hyperglycemia

Changes in accumulation of total Amadori-PE (as determined by LC–MS/MS with MRM) in plasma, RBC, liver, kidney, pancreas, cerebrum, and cerebellum over the study period are shown in Fig. 4. Amadori-PE content was significantly increased in blood and in most tissues of STZ rats compared with the control group after experimental day 7, and the difference between the two groups increased over time. The accumulation of Amadori-PE was greatest in liver, followed by kidney, cerebrum, cerebellum, and pancreas. Among Amadori-PE molecular species, 18:0–20:4 Amadori-PE and 18:0–18:2 Amadori-PE were predominant in the blood and tissues of STZ rats (Fig. 5). After 28 experimental days, STZ rats showed marked accumulation of 18:0–20:4 Amadori-PE, and the ratios of those species in the STZ and control groups were 20, 8, 3, 4, 35, 7, and 5 in plasma, RBC, liver, kidney, pancreas, cerebrum, and cerebellum, respectively. These results suggest that PE glycation actually proceeded and Amadori-PE concentration markedly increased under hyperglycemic conditions. Consistent with this hypothesis, glycation rates (mol % Amadori-PE vs. native PE), especially to 18:0–20:4 PE, were higher in STZ rats (Supplementary Figs. 1 and 2).

Lipid Peroxidation and Protein Glycation

Given our previous finding that Amadori-PE can cause lipid peroxidation [9], we also monitored changes in lipid peroxides during the experimental period. On day 28, PCOOH and TBARS were observed at high levels in the plasma and livers of STZ rats (Fig. 6). With respect to protein glycation, all blood and tissues analyzed showed higher CML accumulation

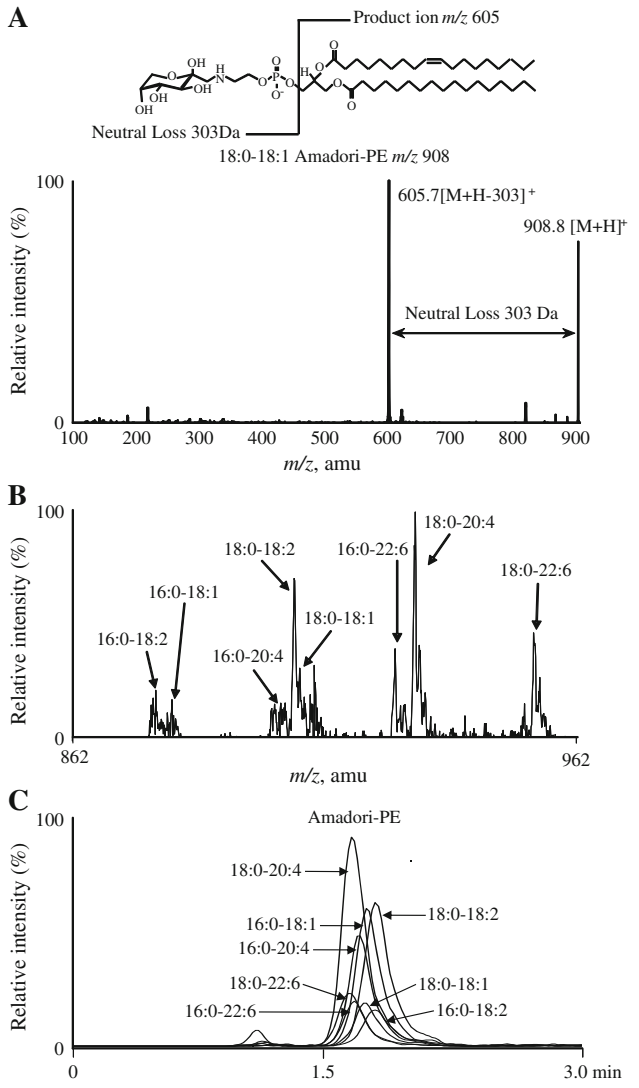

Fig. 3 MS/MS and LC–MS/MS analysis of Amadori-PE. **a** Product ion scan of synthesized 18:0–18:1 Amadori-PE. **b** Neutral loss scan spectrum of 303 Da allowing detection of predominant Amadori-PE species (16:0–18:1, 16:0–18:2, 16:0–20:4, 16:0–22:6, 18:0–18:1, 18:0–18:2, 18:0–20:4, and 18:0–22:6) in RBC of STZ rats. **c** MRM chromatograms of the eight Amadori-PE species in RBC of STZ rats

in STZ rats (Fig. 7). However, the accumulation of CML was somewhat slower and more moderate than that of Amadori-PE. These results suggest the importance of lipid glycation, and imply the potential involvement of lipid glycation and peroxidation in diabetogenesis.

Discussion

Like proteins, lipids (PE) can be modified by glycation during the development of hyperglycemia. PE glycation is likely to induce changes in the biosynthesis and turnover of membrane phospholipids, the physical properties of membranes, the activity of membrane-bound enzymes, and the susceptibility to oxidative stress [9, 18–20]. These changes may contribute to diabetogenesis and the development of diabetic complications. In the present study, we sought to characterize the occurrence of Amadori-PE and its relationship with lipid peroxidation and protein glycation during the development of hyperglycemia in STZ-induced diabetic rats.

In the present study, STZ rats showed significant decreases in weight, plasma insulin, and 1,5-AG (Fig. 2). High levels of blood glucose and Hb_{A1c} were also observed in these rats. Based on these characteristic features, it was presumed that these rats had undergone the irreversible necrosis of pancreatic β-cells that is characteristic of STZ treatment [21], resulting in lowered insulin secretion, and thereby inducing severe type-1 diabetes. Blood lipid levels were also increased in STZ rats (Table 1), probably due to increased free fatty acid release from adipose tissue [22] in response to low insulin levels. Low insulin secretion also decreases hepatic lipase activity [23], thereby increasing hepatic TG content (Table 1).

We used a recently developed (LC)-MS/MS method [6, 10] to analyze Amadori-PE in STZ rats in this study. With the advent of MS/MS, the product ion scan, NLS, and MRM can provide useful structural information about the analyte, even in the presence of major background contaminants from complex biological matrices [24]. Indeed, as shown in this study (LC)-MS/MS is particularly suitable for analysis of Amadori-PE. MS/MS NLS is highly effective at "fishing out" major Amadori-PE species in blood and tissue samples (Fig. 3a, b). LC–MS/MS with MRM also enables quantitative determination of individual Amadori-PE species (Fig. 3c). These techniques constitute a powerful tool to understand the pathophysiological consequences of in vivo lipid glycation.

As mentioned in the introduction, although there is increasing evidence for the involvement of lipid glycation in diabetic complications [2–10], it is still unclear how lipid glycation products are formed during the development of hyperglycemia. In this study, we used STZ rats to demonstrate that PE glycation occurs during the development of hyperglycemia and that Amadori-PE concentrations are markedly increased under hyperglycemic conditions (Fig. 4). To our knowledge, this is the first report documenting the occurrence of Amadori-PE species in various organs. Amadori-PE content in the kidneys of STZ rats appeared to be equivalent to that in liver. Furthermore, pancreatic Amadori-PE levels were 35 times higher in STZ rats than in control rats. These findings suggest that Amadori-PE is more likely to be generated in organs that are involved in the pathogenesis of diabetes. We measured eight Amadori-PE molecular species and

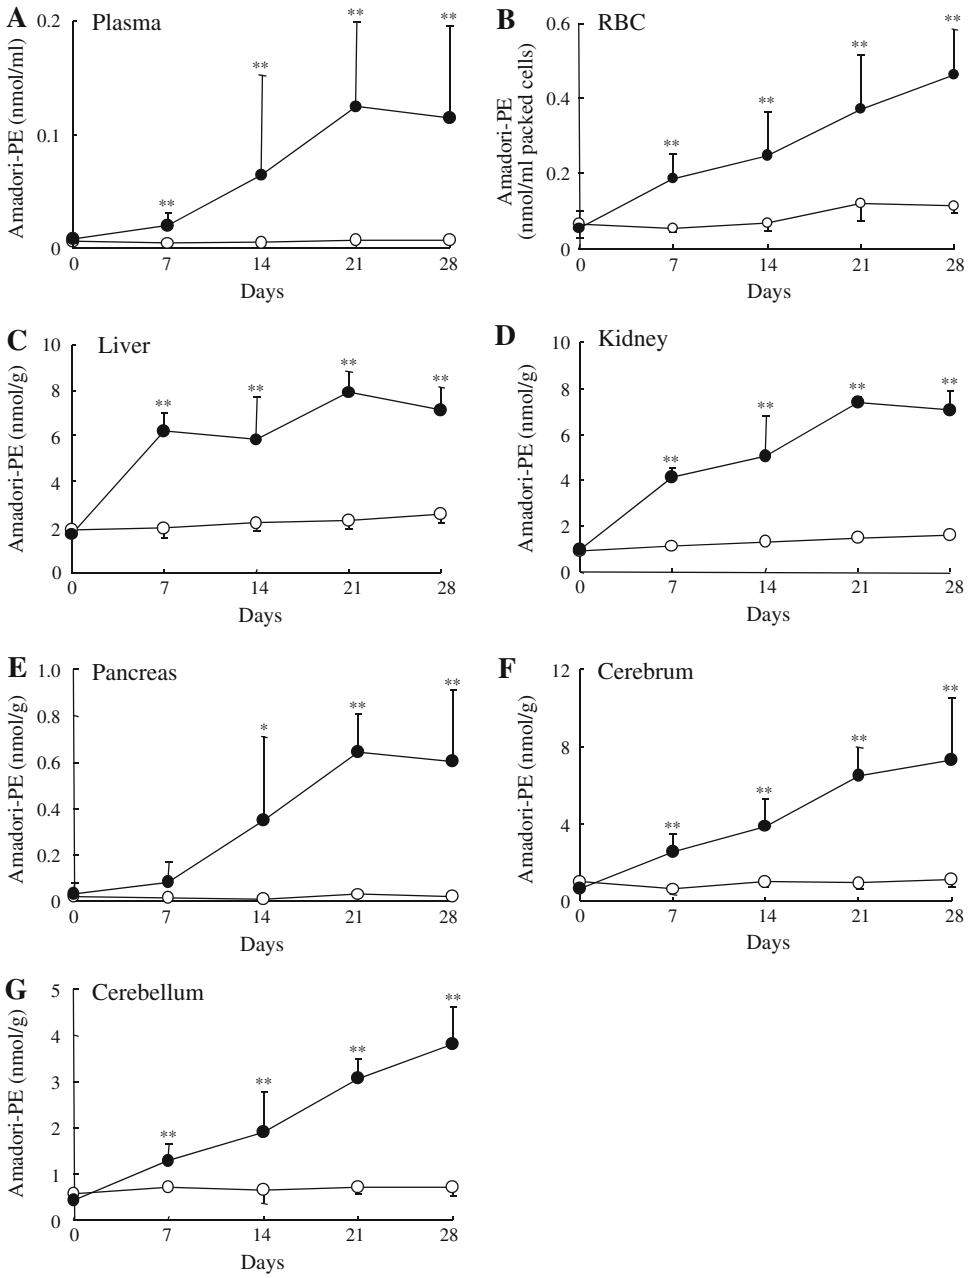

Fig. 4 Time course of changes in total Amadori-PE (sum of 8 species) in **a** plasma, **b** RBC, **c** liver, **d** kidney, **e** pancreas, **f** cerebrum, and **g** cerebellum. found that PE glycation did not simply occur in proportion to PE content in blood or tissues, but was influenced by differences in fatty acid structure in the PE bodies. In the first 7 days after STZ treatment, 18:0–20:4 PE was the first PE species to be glycated, and other PE species (e.g., 18:0–18:2 PE) were glycated subsequently (data not shown). Consequently, by day 28, 18:0–20:4 Amadori-PE and 18:0–18:2 Amadori-PE were the predominant species in blood and many tissues (Fig. 5). This finding suggests that these two Amadori-PE species are highly susceptible to glycation, probably due to relatively higher amount of 18:0–20:4 PE and 18:0–18:2 PE in blood and tissues. Another possibility is that these 18:0–20:4 Amadori-PE and 18:0–18:2 Amadori-PE might be more stable in the glycated state than other Amadori-PE species. Thus, these Amadori-PE species (18:0–20:4 Amadori-PE and 18:0–18:2 Amadori-PE) could potentially be utilized as a sensitive marker of the early stages of diabetes. However, further study is needed to clarify the relationship between PE fatty acid structure and glycation rate, since other factors may also influence PE glycation.

In the present study, significant increase in Amadori-PE was observed in STZ rats 7 days after STZ treatment, but meaningful changes in oxidized lipid levels (PCOOH and TBARS) were observed only after 21 or 28 days (Fig. 6). This suggests that Amadori-PE is pathologically formed

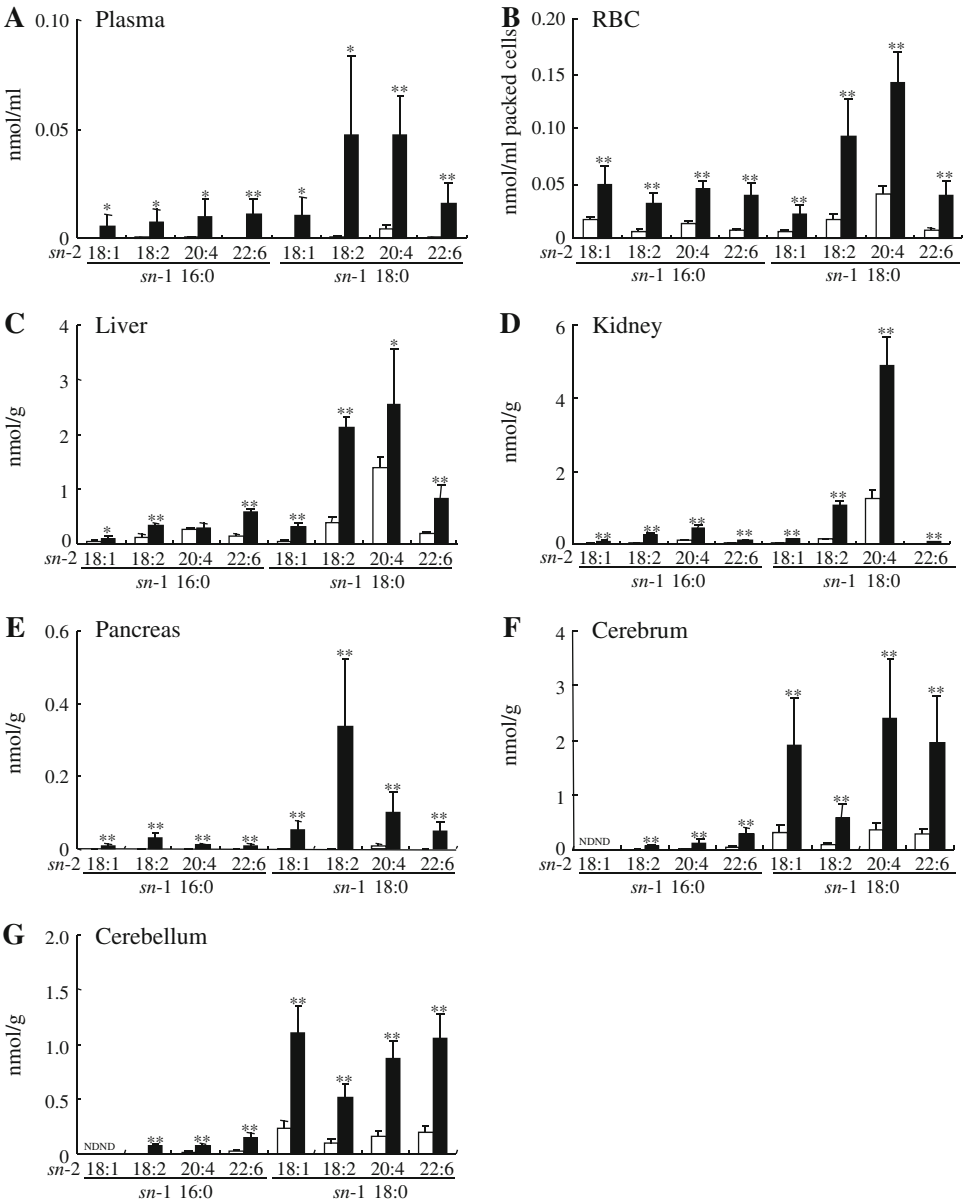

Fig. 5 Concentration of each Amadori-PE species 28 days after STZ injection. **a** Concentration in plasma, **b** RBC, **c** liver, **d** kidney, **e** pancreas, **f** cerebrum, and **g** cerebellum. prior to the induction of lipid peroxidation. Accordingly, the increased accumulation of oxidized lipids during diabetes pathogenesis may be partly due to the ability of Amadori-PE to induce oxidation of lipids [9, 20], which can worsen diabetes. On the other hand, accumulation of advanced protein glycation end products such as CML is also well-known to be related to diabetic complications [25, 26]. It has been reported that STZ treatment can increase levels of CML by up to 200% in plasma and up to 150–200% in the kidneys of diabetic animals [27, 28]. Our study showed similar effects of STZ treatment on CML levels (Fig. 7). However, CML accumulation was somewhat slower and more moderate than Amadori-PE accumulation. This may be due to the fact that Amadori-PE and CML are early and advanced glycation products, respectively. In addition, concentrations of Hb_{A1c} in STZ rats on days 7 and 28 were 180% and 300% of the initial values, respectively, whereas Amadori-PE levels in erythrocytes on days 7 and 28 were 330% and 800% of initial values, respectively (Figs. 2, 4). These findings support the idea that Amadori-PE can be used as a sensitive predictive marker for hyperglycemia development in the early stages of diabetes.

As for the involvement of Amadori-PE on the development of STZ-induced diabetes, Amadori-PE showed higher concentrations in blood and tissues immediately (7 days) after injection of STZ. It is therefore likely that formation and accumulation of Amadori-PE might be closely related with the progression and worsening of the STZ-induced diabetes. Now, we are preparing Amadori-PE

antibody and clarify these points by using histological techniques.

In conclusion, we monitored the periodical change of Amadori-PE species during hyperglycemia development in STZ-induced diabetic rats and found that Amadori-PE tends to accumulate in blood and in organs that are involved in the pathogenesis of diabetes, such as the kidney. Certain molecular species of Amadori-PE, such as 18:0–20:4 Amadori-PE may be more sensitive indicators of early hyperglycemia than markers such as CML and Hb_{A1c}. Therefore, Amadori-PE should be considered for use as a predictive marker for hyperglycemia.

Abstract The objective of the present study was to evaluate the effects of acute infection with *Leptospira interrogans* on lipids, lipoproteins and associated enzymes. Fasting serum levels of total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), triglycerides (TG), apolipoproteins (apo) A-I, B, E, C-II, C-III and lipoprotein (a) [Lp(a)] were determined in patients with Leptospirosis on diagnosis and 4 months after recovery as well as in age- and sex-matched controls. Activities of cholesteryl-ester transfer protein (CETP) and lipoprotein-associated phospholipase A_2 (Lp-PLA_2) as well as paraoxonase 1 (PON1) hydrolysing activity and levels of cytokines were determined. LDL subclass analysis was performed with Lipoprint LDL System. Eleven patients (10 men, mean age 49.5 ± 8.4 years) and 11 controls were included. TC, HDL-C, LDL-C, apoA-I, apoB and Lp(a) levels were lower at baseline, whereas TG and apoE levels were elevated compared with 4 months later. At baseline, higher levels of cytokines and cholesterol concentration of small dense LDL particles (sdLDL-C) were noticed, whereas LDL particle size was lower compared with follow-up. Activities of plasma Lp-PLA_2 and HDL-associated Lp-PLA_2 were lower at baseline compared with post treatment values, whereas PON1 activity was similar at baseline and 4 months later. 4 months after recovery, the levels of all lipid parameters evaluated did not differ compared with controls, except for HDL-C which remained lower. PON1 activity both at baseline and 4 months later was lower in patients compared with controls. Leptospirosis is associated with atherogenic changes of lipids, lipoproteins and associated enzymes.

Keywords Leptospira · Lipids · Lipoproteins · Cytokines · sdLDL · LDL Particle size

Abbreviations

CMV	Cytomegalovirus
HSV	Herpes simplex virus
HIV	Human immunodeficiency virus
sdLDL	Small dense LDL
EBV	Epstein-Barr virus
sdLDL-C	sdLDL cholesterol
Lp-PLA_2	Lipoprotein-associated phospholipase A_2
PON1	Paraoxonase 1
CETP	Cholesteryl-ester transfer protein
HDL-C	HDL cholesterol
TSH	Thyroid-stimulating hormone
TC	Total cholesterol
TG	Triglycerides
LDL-C	LDL cholesterol
Apo	Apolipoprotein
Lp(a)	Lipoprotein (a)
IL	Interleukin

Introduction

Leptospirosis is a zoonotic acute bacterial infection, caused by spirochetes of the genus *Leptospira*, with a worldwide distribution [1]. Human infection results from exposure to infected urine of carrier mammals, either directly or via contamination of soil or water [1]. Host infection produces a diverse array of clinical manifestations ranging from subclinical infection to undifferentiated febrile illness to jaundice, renal failure, and potentially lethal pulmonary haemorrhage [1]. Weil's disease represents the most severe form and can develop after the acute phase as the second phase of a biphasic illness or as a progressive illness. It is characterised by jaundice, renal failure, bleeding disorders and altered mental status [1].

Various infectious agents have been previously linked to an increased atherogenic potential and these include *Chlamydia pneumoniae*, CMV, HSV and *Helicobacter pylori* [2]. Moreover, regardless of the cause, infection is associated with alterations in lipid and lipoprotein concentrations [2]. Several studies have shown that sdLDL particles are more atherogenic compared with large buoyant ones [3]. Periodontitis, HIV infection as well as *Brucella melitensis* and EBV infections have been associated with increased levels of sdLDL-C [4–7].

Lp-PLA_2, a risk factor for vascular disease [8], is mainly distributed on LDL subclasses while the remaining is found on HDL (HDL-Lp-PLA_2) [9, 10]. Various changes in Lp-PLA_2 activity in response to infection have been reported among different animal species [11] and in human studies [4, 7, 12, 13]. PON1 is an esterase exclusively associated with HDL in plasma which plays an important role in HDL-mediated anti-atherogenic action [14]. During infection and inflammation serum PON1 activity may decrease and acute-phase HDL is unable to protect LDL against oxidation [15]. CETP, which plays a central role in the regulation of serum HDL-C levels, may exert higher activity during infection leading to decreased HDL-C levels [7].

We have previously shown that severe Leptospirosis was associated with altered lipid profile in a small number of patients ($n = 5$) [16]. However, there are no detailed data on the possible alterations in lipid and lipoprotein profile and associated enzymes in patients with Leptospirosis. We undertook the present study to evaluate the possible quantitative and qualitative effects of Leptospirosis on serum lipid parameters and associated enzymes.

Materials and Methods

Study Population

Eleven consecutive patients who were diagnosed with Leptospirosis at the 2nd Department of Internal Medicine, University Hospital of Ioannina, Greece, between January 2006 and September 2008 were included in the present study. The diagnosis of Leptospirosis was established by the presence of specific IgM antibodies against *L. interrogans* as determined by ELISA. No patient was receiving any hypolipidaemic agents or had any evidence of any disease known to affect lipid metabolism, such as neoplasia and hypo- (TSH $>$ 5 μU/mL) or hyperthyroidism (TSH $<$ 0.01 μU/mL). Moreover, patients with a known history of renal dysfunction (serum creatinine levels $>$1.5 mg/dL) were not included. All patients were examined on diagnosis and 4 months after recovery. No change in patients' dietary habits and body weight was recorded during follow-up. Eleven age- and sex-matched healthy volunteers (control population) were also included. These individuals visited the outpatient clinic of the 2nd Department of Internal Medicine for a regular check-up and were selected for the participation in the present study based on their age. All individuals signed a form giving their informed consent for the participation in the present study. This study was approved by the Ethics Committee of the University Hospital of Ioannina.

Laboratory Measurements

All laboratory parameters were blindly assessed with regard to each subject's group and sampling time.

Fasting serum levels of TC, HDL-C and TG were determined enzymatically on an Olympus AU600 Clinical Chemistry analyser (Olympus Diagnostica, Hamburg, Germany). LDL-C was calculated using the Friedewald formula (except for one patient whose TG levels exceeded the cut-off point of 400 mg/dL, for whom LDL-C concentration was not calculated). Apo A-I, B, E as well as Lp(a) levels were measured with a Behring Nephelometer BN100 using reagents from Date Behring Holding Gmbh (Liederbach, Germany). ApoC-II and apoC-III were determined by an immunoturbidimetric assay provided by Kamiya Biomedical Company (Seattle, WA).

LDL subclass analysis was performed electrophoretically using high-resolution 3% polyacrylamide gel tubes and the Lipoprint LDL System (Quantimetrix) according to the manufacturer's instructions [9].

Lp-PLA_2 and CETP activities as well as PON1 hydrolysing activities against paraoxon [PON1 (paraoxonase)] and phenyl acetate [PON1 (arylesterase)] were determined as previously described [7, 17].

Cytokines (IL-1b, IL-6 and TNFα) were determined by ELISA using a commercially available immunoassay kit (Quantikine; R&D Systems, Inc., Minneapolis, MN, USA). Each sample was measured in duplicate with appropriate sensitivities for IL-1b (<0.1 pg/mL), IL-6 (<0.7 pg/mL) and TNFα (<4.4 pg/mL). The median and mean intra-assay and inter-assay CVs were <10% for all the above measurements.

CRP levels were measured by an immunoturbidimetric assay (Roche Diagnostics).

Statistical Analysis

Preliminary analysis was performed to ensure no violation of the assumptions of normality and linearity. The Shapiro–Wilk test was used to evaluate whether each variable followed a Gaussian distribution. Data are expressed as means ± SD, except for parameters not following a Gaussian distribution which are expressed as median (range). Paired samples *t* test (or Wilcoxon's rank test, as appropriate) was used for the comparison of study parameters between baseline and 4 months later. Independent samples *t* test (or the Mann–Whitney *U* test, as appropriate) was used for the comparison of the study parameters between patients and controls. Analysis of covariance (ANCOVA) was used to assess whether the lipid profile of patients was impaired compared with the lipid profile of controls after adjusting for differences between the two groups regarding renal function as assessed by serum creatinine levels. The relationships between study parameters were investigated using Spearman correlation coefficient (ρ). In order to minimise the possibility of differences observed been a random effect due to multiple comparisons, a p value of <0.03 was considered as significant [18]. All analyses were carried out with SPSS 16.0 softpack (SPSS Inc., 2008, Chicago, IL, USA).

Results

Clinical Characteristics and Lipid Profile

The patients (10 male and 1 female, mean age 49.5 ± 8.4 years) presented with fever and myalgias, while 4 of them (36%) also presented with jaundice and acute renal failure. The clinical and biochemical characteristics of study participants are shown in Table 1. After confirmation of the diagnosis, patients were treated with ceftriaxone 1 g IV o.d. for 7 days.

Patients with Leptospirosis had decreased levels of TC, HDL-C, LDL-C, Lp(a) and apoA-I, whereas TG, apoE and VLDL-C levels as well as apoB/apoA-I ratio were elevated compared with 4 months after recovery (Table 1). On the other hand, apoC-II and apoC-III levels were not significantly different at baseline compared with 4 months later. Mean LDL particle size was decreased and sdLDL-C levels were increased at baseline compared with 4 months after recovery. Also, sdLDL-C% was markedly elevated at baseline compared with the values after recovery (Table 1).

We adjusted the baseline lipid and lipoprotein levels for serum creatinine concentration (data not shown). According to these results, the only parameters significantly affected by creatinine levels were LDL-C and large LDL-C levels ($p < 0.05$ for both). Moreover, we divided patients into two subgroups according to serum creatinine levels (<1.5 mg/dL, $n = 7$ vs. ≥1.5 mg/dL, $n = 4$). We found that the two subgroups differed in HDL-C (23 ± 5 mg/dL vs. 11 ± 2 mg/dL, $p < 0.01$), LDL-C (100 ± 25 mg/dL vs. 52 ± 21 mg/dL, $p < 0.05$) and large LDL-C (88 ± 18 mg/dL vs. 61 ± 21 mg/dL, $p < 0.05$) levels. However, all three parameters in the subgroup of patients with serum creatinine levels <1.5 mg/dL were still significantly lower compared with the corresponding values of the control population ($p < 0.03$ for all). We also found that the subgroup of Leptospirosis patients with impaired renal function had more severe infection defined as higher cytokine levels [IL-1b: 14.9 (4.6–16.9) pg/mL vs. 4.2 (3.7–5.5) pg/mL, $p < 0.03$, IL-6: 11.4 (2.5–58.2) pg/mL vs. 3.6 (3.4–58.4) pg/mL, $p < 0.03$ and TNFα: 24.4 (17.2–39.0) pg/mL vs. 12.0 (10.7–31.2) pg/mL, $p < 0.03$] as well as higher CRP levels [150 (38–224) mg/L vs. 31 (29–325) mg/L, $p < 0.01$].

With the exception of HDL-C and apoA-I levels, which remained low (Table 1), all other parameters had returned to levels similar to controls 4 months after recovery (Table 1).

CETP activity was similar in patients with acute Leptospirosis and 4 months after recovery, while no significant difference was observed in its activity between post-recovery and controls (Table 1).

Lp-PLA_2 and PON1 Activities

At baseline, total plasma Lp-PLA_2 and HDL-Lp-PLA_2 activity were decreased compared with 4 months after recovery from Leptospirosis (Table 2). No difference was observed in the activities of PON1 (paraoxonase) and PON1 (arylesterase) between baseline and 4 months after recovery.

Total plasma Lp-PLA_2 and HDL-Lp-PLA_2 activities were similar in patients 4 months after recovery and controls. However, both PON1 (paraoxonase) and PON1 (arylesterase) activities were lower in patients 4 months after recovery as compared with the control population.

Markers of Inflammation

Levels of inflammatory markers (CRP, IL-1β, IL-6, and TNFα) were increased at baseline compared with 4 months

Correlations Between Lipid and Lipoprotein Levels and Cytokine Concentrations

At baseline, HDL-C levels were inversely associated with IL-1b concentration (Table 4), while the increase in HDL-C levels 4 months after recovery was associated with the decrease in TNFα (ρ 0.47, $p < 0.05$) and CRP levels (ρ 0.65, $p < 0.05$) (data not shown). TG levels at baseline were positively associated with IL-6 and CRP levels (Table 4), and also the decrease in TGs after treatment was associated with the decrease in these inflammatory markers (ΔIL-6 ρ 0.75, $p < 0.01$ and ΔCRP ρ 0.66, $p < 0.05$). Baseline LDL-C levels were negatively associated with IL-6, TNFα and CRP concentration, while apoB levels were associated only with IL-6 and CRP levels (Table 4). While apoE concentration was not correlated with any inflammatory markers, its decrease post-recovery was associated with the fall in TNFα levels (ρ 0.75, $p < 0.05$). No correlation was established between Lp(a) levels or its increase following recovery and any inflammatory marker. At baseline, sdLDL-C levels were inversely associated with all inflammatory markers evaluated (Table 4), while LDL particle size was positively associated only with CRP levels (Table 4).

It should be noted that the increase in the activity of Lp-PLA$_2$ observed after recovery from Leptospirosis was marginally associated with the increase in LDL-C levels (ρ 0.45, p 0.04) while the elevation of HDL-Lp-PLA$_2$ activity was strongly associated with the increase in HDL-C concentration (ρ 0.65, p 0.03).

Discussion

In the present study, we showed for the first time that Leptospirosis is associated with an atherogenic lipid profile (i.e. increased TGs, apoB/apoA-I ratio, and sdLDL-C levels and decreased HDL-C concentration, LDL particle size and HDL-Lp-PLA$_2$ activity). This profile is restored 4 months after the recovery from Leptospirosis, with the exception of HDL-C levels and PON1 activities which remain lower compared with the control population.

Infection-induced alteration in lipid profile include increases in TG and apoE levels and decreases in the concentration of LDL-C, HDL-C, apoA-I, apoB and Lp(a) [2]. These changes are largely due to the actions of cytokines (IL-1b, IL-6 and TNFα) [19].

We have shown that acute brucellosis and EBV infection are associated with a reduction in LDL-C levels compared with values after recovery and controls [7] and these reductions were associated with IL-6 levels. IL-6 stimulates LDL receptor expression in hepatic cells and subsequently leads to increased uptake of LDL particles and decreased LDL-C levels [20]. In the present study, we found that baseline LDL-C levels were associated not only with IL-6 concentration, but also with TNFα and CRP levels. TNFα may increase LDL receptor activity [2]. Moreover, experimental data show that hepatic cells exposed to TNFα, IL-1b and IL-6 exhibit decreased synthesis of apos (such as apoB), leading to decreased LDL-C levels [21].

The markedly increased TG levels at the time of the diagnosis of Leptospirosis were associated with CRP and IL-6 levels, while the decrease in their concentration followed the fall in cytokine levels. TNFα, ILs and interferons can increase serum TG levels [2] by stimulating hepatic fatty acid synthesis, resulting in elevated VLDL production [19], consistent with our finding of increased VLDL-C levels at baseline. To further elucidate this hypothesis, we measured apoC-II and apoC-III which are critical determinants of the metabolism of TG-containing lipoproteins [22]. However, no change in the concentration or either apoC-II or apoC-III was established in the present study. ApoE has been shown to accelerate the secretion rate and decrease the efficiency of lipolysis of the TG-rich lipoproteins [23]. The elevated apoE levels at baseline, possibly due to increased apoE synthesis by the activated macrophages and/or the liver, might contribute to the observed hypertriglyceridaemia [16]. This finding is in agreement with our previous observations that apoE behaves as a positive acute-phase protein in patients with infection [16].

During infection, serum levels of HDL-C and apoA-I decrease [2]. Patients with Leptospirosis at baseline had markedly lower HDL-C and apoA-I levels compared with 4 months later. The exact mechanisms for the reduction in HDL-C levels during acute infection have not been firmly established. EL overexpression leads to reduced HDL-C levels, and this effect may be mediated by TNFα and IL-1b [24]. Accordingly, we have shown that HDL-C levels at baseline were negatively associated with IL-1b concentration, while 4 months after recovery the increase in HDL-C levels was associated with the decrease in TNFα levels. It is worth mentioning that TNFα attenuates the activity of LCAT [25], and a decrease in LCAT activity could decrease HDL-C concentration. Cytokines also stimulate the displacement of apoA-I by SAA, thus resulting in decreased HDL-C levels [26]. The altered HDL metabolism during infection may be mediated by the cytokine-induced changes in CETP activity. However, no change in CETP activity was established in patients with Leptospirosis at baseline compared with 4 months later or with controls. Of note, no measurements of EL and LCAT activity or SAA levels were performed in the present study.

Lp(a) behaves as a negative acute-phase reactant during major inflammatory response in humans [27]. Transforming growth factor-β1 and TNFα, which predominate in severe inflammation, inhibit the expression of the apo(a) gene in primary cultures of monkey hepatocytes [28], leading to decreased Lp(a) levels. However, no association between the low Lp(a) levels at baseline and TNFα concentration was established, possibly due to the small sample size.

Serum PON1 activity has been shown to be low in several infections such as hepatitis C [29], HIV [30] and helicobacter pylori [31, 32], primarily because of changes in synthesis and/or secretion of HDL and apoA-I particles. The activities of both PON1 (paraoxonase) and PON1 (arylesterase) were lower in patients 4 months after recovery compared with controls. This finding implies that the activities of PON1 may have not yet returned to normal 4 months later, as is the case for HDL-C. TNFα and IL-1 treatment of HEPG2 cells results in a decrease in PON1 mRNA levels [33]. No association between PON1 activity and cytokine levels was established at baseline. Therefore, the mechanisms for the decrease of PON1, other than the decrease in HDL-C, remain unknown.

An increase in plasma Lp-PLA_2 activity in patients with sepsis [34, 35] or HIV [13] has been reported, while other studies showed that total plasma Lp-PLA_2 activity is decreased in sepsis [12, 36–38]. Moreover, HDL-Lp-PLA_2 activity is acutely increased during acute infection and later decreased [11, 39, 40]. Serum Lp-PLA_2 activity may be a potential marker for *Leptospira*-induced pulmonary haemorrhage [41]. In our study, total plasma Lp-PLA_2 and HDL-Lp-PLA_2 activities were lower in patients on admission compared with 4 months after recovery. The changes in Lp-PLA_2 and HDL-Lp-PLA_2 activities can be explained by the parallel changes in the levels of LDL-C and HDL-C. Moreover, there was a slight -although not significant-association between low Lp-PLA_2 activity and elevated TNFα levels at baseline (ρ 0.44, $p = 0.07$). Indeed, TNFα is considered as one potent inhibitor of Lp-PLA_2 secretion [42]. Of note, the increase in HDL-Lp-PLA_2 activity was associated with the decrease in TNFα levels.

There was a shift in LDL subclass distribution toward smaller particles in patients with Leptospirosis compared with 4 months later. Studies have shown that advanced HIV infection and severe periodontitis are associated with a high prevalence of sdLDL particles [5, 6]. We have previously shown that patients with acute brucellosis and EBV infection have decreased mean LDL particle size

[4, 7]. Very recently it was shown that oligouric patients with *Hantaan virus* infection also exhibit a shift towards smaller LDL particles [43]. In the present study, the increased sdLDL particles and the decreased LDL particle size can be explained by the elevated TG concentration at baseline. The association between increased TG levels and the preponderance of sdLDL particles is well established [3]. Moreover, possibly through their actions on VLDL metabolism during infection, cytokines may affect the metabolic rate of LDL towards a more atherogenic profile, as implied by the association between the sdLDL-C at baseline and elevated levels of cytokines.

ARF is associated with increased TG and decreased LDL-C and HDL-C levels [44] due to impaired lipolysis, increased mobilisation of fat from adipose tissue and altered lipid clearance. In our study, Leptospirosis patients with ARF had lower HDL-C and LDL-C levels compared with the subgroup with normal kidney function, while no difference was observed in TG levels. However, this finding may be attributed to the more severe infection seen in the ARF subgroup as evidenced by the higher levels of cytokines compared with those with normal kidney function.

It must be noted that the lipid alterations found in patients with Leptospirosis seem more prominent than those observed in patients with brucellosis or EBV infection, especially in the case of TG and HDL-C levels and sdLDL-C concentration. However, the lipid profile of patients with Leptospirosis after recovery is almost fully restored while patients with brucellosis and EBV infection after recovery still exert alterations in the lipid profile compared with the control population.

Study Limitations

The number of study participants is small, since the prevalence of Leptospirosis is relatively low. We used a cross-over design to compare subjects with matched healthy controls. Despite the limitations of this design, a prospective study of lipid alterations in this setting is not possible. Although this study was open-label, laboratory data was blindly assessed with regard to the investigator who performed the measurements and the experiments.

Conclusion

Leptospirosis causes impressive alterations in the lipid profile that include markedly elevated TG and sdLDL-C concentration and low HDL-C and LDL-C levels. Most of these disturbances return to normal after recovery. However, HDL-C levels and the activities of PON1 remain lower than the control population 4 months after recovery.

Conflict of interest None declared.

Received: 2 February 2010 / Accepted: 13 June 2011 / Published online: 9 July 2011

Abstract Conjugated linoleic acid (CLA) is a collection of octadecadienoic fatty acids that have been shown to possess numerous health benefits. The CLA used in our study was produced by the photoisomerization of soybean oil and consists of about 20% CLA; this CLA consists of 75% *trans–trans* (a mixture of t8,t10; t9,t11; t10,t12) isomers. This method could be readily used to increase the CLA content of all soybean oil used as a food ingredient. The objective of this study was to determine the effects of *trans–trans* CLA-rich soy oil, fed as a dietary supplement, on body composition, dyslipidemia, hepatic steatosis, and markers of glucose control and liver function of obese *fa/fa* Zucker rats. The *trans–trans* CLA-rich soy oil lowered the serum cholesterol and low density lipoprotein–cholesterol levels by 41 and 50%, respectively, when compared to obese controls. *Trans–trans* CLA-rich soy oil supplementation also lowered the liver lipid content significantly ($P < 0.05$) with a concomitant decrease in the liver weight in the obese rats. In addition, glycated hemoglobin values were improved in the group receiving CLA-enriched soybean oil in comparison to the obese control. PPAR-γ expression in white adipose tissue was unchanged. In conclusion, *trans–trans* CLA-rich soy oil was effective in lowering total liver lipids and serum cholesterol.

VLDL	Very low density lipoprotein

Introduction

Obesity, cardiovascular disease, and type 2 diabetes are international health problems with their rates predicted to rise [1]. Research has shown that when human weight increases to the point of being classified as "obese," the risk of health problems such as hypertension, type 2 diabetes, coronary heart disease, stroke, cancer, gallbladder disease, osteoarthritis, sleep apnea, and respiratory problems increase [2–7].

Conjugated linoleic acid (CLA) is a collection of octadecadienoic fatty acid isomers that have been shown to positively affect health in human and animal models [8]. Some of the health benefits of CLA include reduced adiposity, antidiabetogenic, antiatherogenic, and anticarcinogenic effects [9–12]. The benefits have been seen primarily with the *cis*-9,*trans*-11 (c9,t11) and *trans*-10,*cis*-12 (t10,c12) isomers. At present, it is known that the effects of

CLA are dose-, time-, and species-dependent [13]. In addition, the activity of CLA is highly isomer specific; t10,c12 CLA isomer is antiadipogenic in differentiating human preadipocytes and the c9,t11 CLA isomer promotes adipogenesis [14]; therefore, it is important to identify isomer-specific responses.

Determination of the isomer-specific effects of CLA is necessary before CLA can be used in fortified foods or supplements. The major sources of CLA in the human diet are meat and dairy products derived from ruminants, and in these products the predominant CLA isomer (>90%) is c9,t11 [15]. However, to obtain the estimated optimum dietary CLA levels of about 3 g/d, from natural sources it would be necessary to increase the animal or dairy products which would increase saturated fat intake [16, 17]. Therefore, a concentrated source of dietary CLA that is low in saturated fat is desirable [18]. Jain and Proctor [18] showed that CLA isomers can be rapidly produced in large quantities in a pilot scale by efficient photoisomerization of soy oil. This reaction produces mainly *trans–trans* CLA isomers, the nutritional effects of which have not been studied. This CLA-rich soy oil produced by the pilot-scale system contained 180 times the total CLA isomers obtained from beef or dairy products [18]. Hence, the objectives of this study were to determine the effects of dietary supplementation of *trans–trans* CLA-rich soy oil on body composition, dyslipidemia, hepatic steatosis, and markers of glucose control and liver function of obese *fa/fa* Zucker rats.

Experimental Procedures

Study Design

This study was conducted using 3-month old female obese *fa/fa* Zucker rats (Harlan Laboratories, Indianapolis, IN), a commonly used model for studying obesity. Thirty-six rats were divided into the following treatment groups ($n = 12$): lean control (L-Ctrl), obese control (O-Ctrl), and obese CLA (O-CLA). The L-Ctrl and O-Ctrl groups were fed AIN-93M purified rodent diet. The O-CLA group was fed AIN-93M modified to contain ~0.5% *trans–trans* CLA isomers by diet mass. All animals were pair-fed to the mean intake of the L-Ctrl group and the food intake was measured three times a week. Although pair-feeding may cause stress in hyperphagic obese Zucker rats, in this study we did not observe any visual signs of stress. Pair-feeding was necessary to match the macronutrient intake of all the groups. The body weight of the animals was recorded once per week. The rats had free access to deionized water. After 100 days of treatment, the rats were fasted for 12 h before being sacrificed by exsanguination via cardiac puncture. University of Arkansas Institutional Animal Care and Use Committee guidelines for the treatment and care of the animals were followed throughout the study duration.

Diets

Animals in the control group were fed AIN-93M purified rodent diet formulated in accordance to the American Institute of Nutrition committee report [19]. Animals in the O-CLA group received AIN-93M containing 40 g/kg of *trans–trans* CLA-rich soybean oil substituted for regular soybean oil. The rat diet composition is given in Table 1. Refined, bleached deodorized soy oil was photo-irradiated in a pilot-plant regime using the optimal conditions discussed by Jain and Proctor [18]. The total CLA and isomer content of the oil was measured as fatty acid methyl esters (FAMES) by base-catalyzed conversion [20]. The CLA isomer composition of the CLA-rich soybean oil is presented in Table 2.

Body Composition

Dual-energy X-ray Absorptiometry (DXA; GE Lunar DXA, Waukesha, WI) was used to analyze the body composition of the rats at baseline and immediately prior to sacrifice. The animals were anesthetized and placed stomach down on the scan bed of the DXA. The absorbance of two X-ray beams was measured and percent lean tissue and percent fat tissue were calculated by software (enCORE, GE Lunar, Waukesha, WI) appropriate for the body composition assessment of small animals.

Necropsy and Tissue Collection

Organs and tissues of interest were removed from the animal immediately after sacrifice. The liver and white adipose tissue were placed in cryogenic storage containers and flash-frozen in liquid nitrogen before being stored at −80 °C. Approximately 7 mL of blood collected from the animal via cardiac puncture during sacrifice was stored on ice before being centrifuged to separate serum from whole blood. Aliquots of serum were transferred to microcentrifuge tubes and stored at −80 °C until analysis. A small amount of blood collected from the heart during sacrifice was placed in a microtube containing K_2 EDTA (an anticoagulant) and stored at −80 °C.

Biochemical Analysis

Serum triglycerides (TG), total cholesterol (TC), high density lipoprotein–cholesterol (HDL–C), low density lipoprotein–cholesterol (LDL–C), aspartate transaminase (AST), blood urea nitrogen (BUN), glycated hemoglobin (HbA1c), and glucose concentrations were determined using commercially available kits from Alfa Wassermann Diagnostic Technologies (West Caldwell, NJ). An ACE Alera clinical chemistry system (Alfa Wassermann Diagnostic Technologies, West Caldwell, NJ) was used according to the manufacturer's instructions to perform these tests.

Insulin

Serum insulin was quantified using a commercially available ELISA kit (Alpco Immunoassays, Salem, NH). An aliquot of serum was thawed at 2–8 °C before use. A 96-well plate in the kit was prepared per manufacturer instructions to include duplicate standards, appropriate controls, and sample duplicates. Absorbance was measured using a BioTek ELx808 microplate reader (Winooski, VT) attached to a PC running BioTek Gen5 data analysis software (Winooski, VT).

Liver Lipids

One gram of liver was homogenized in a 20-fold volume of 2:1 chloroform–methanol (v/v) mixture. Following homogenization, 0.58% NaCl solution was added to achieve separation of the phases and centrifuged for 20 min at $500\times g$. Supernatant was discarded and the organic phase was filtered and washed with chloroform through fat free filter paper (3.2 cm Whatman, Whatman International Ltd, Maidstone, England). The filtered organic phase containing the tissue lipids was then transferred to a pre-weighed scintillation vial. Liver lipids were determined using the Folch gravimetric method [21]. Liver total cholesterol was determined using the method described by Searcy and Bergquist [22].

Gene Expression in White Adipose Tissue

RNA Extraction and cDNA Synthesis

RNA was extracted from approximately 100 mg of white adipose tissue by TRIzol Reagent method using RNeasy Lipid Tissue Mini Kit (Qiagen, USA) by following the supplier's instructions. The total amount of RNA present in each sample was quantitated using Nanodrop (Thermo Scientific, Wilmington, DE) and 1 μg/sample of total RNA was used for cDNA synthesis using a QuantiTect Rev. Transcription Kit (Qiagen, USA).

Quantitative Real-Time PCR

Following cDNA synthesis, qRT-PCR was performed using the Mastercycler ep realplex with SYBR Green system (Eppendorf, Hamburg, Germany). Concentrations of reagents were used per the manufacturer's instructions. Real-time PCR primers were designed using Primer3 primer design software and all primer sets were synthesized by Invitrogen (Invitrogen, Carlsbad, CA). Primer sequences used for this study are summarized in Table 3. The following experimental conditions were used for all target gene expression including generation of standard curves. The initial denaturation cycle was performed at 95 °C for 5 min. All subsequent denaturation and annealing cycles were repeated 45 times at 95 °C for 15 s and 60 °C (55 °C annealing for reference gene β-actin) for 45 s, respectively. The relative gene expression ratio by qRT-PCR was calculated using "REST" software.

Statistical Methods

The data analysis involved estimation of means and standard error (SE) using JMP 8 (2009 SAS Institute Inc. Cary, NC). The effects of treatment were analyzed by one-way

Table 3 Primers used in real time qPCR

Gene name	Gene bank accession no.	Primer sequence		BP size

PPAR-γ Peroxisome proliferator-activated receptor-γ, *NF-κB* nuclear factor-κB

ANOVA model followed by post hoc analysis using the Fisher's least squares means separation test when F values were significant. For all analyses, a P-value less than 0.05 was considered significant.

Results

Food Intake, Body Weight, Body Composition, and Organ Weights

There were no significant differences ($P > 0.05$) in the mean food intake between the three experimental groups, as the rats were pair-fed to the mean intake of the L-Ctrl group. The effects of treatment on body weights, body composition, and organ weights are shown in Table 4. There were no significant differences in the final body weights or body composition of O-Ctrl and O-CLA groups. A significant difference was found between the body weights and body composition of the L-Ctrl group when compared to the O-Ctrl and O-CLA group. The liver weights of the O-CLA group were significantly lower than those of the O-Ctrl, but were significantly higher than the liver weights for the L-Ctrl group ($P < 0.05$). These results provide evidence that *trans–trans* CLA enriched soybean oil reduces hepatomegaly in *fa/fa* obese Zucker rats.

Serum Lipid Profiles

The serum lipid profiles are presented in Table 5. The serum TC and LDL-C concentrations of the rats in the O-CLA group were significantly lower compared to the obese control, 41 and 50%, respectively. There was no difference in the TG and HDL-C levels in rats in the O-CLA and O-Ctrl group. This indicates that CLA was able to reduce the total cholesterol concentration without lowering the HDL-C. All serum lipid parameters measured (TC, LDL-C, HDL-C, and TG) were significantly lower in the L-Ctrl group when compared to the O-CLA and O-Ctrl groups ($P < 0.05$).

Liver Lipids

The liver lipid data is presented in Table 5. Percent total liver lipids were significantly different among the experimental groups. Percent liver lipids in the O-CLA group were significantly lower than the percent liver lipids in the O-Ctrl group. The reduced liver lipid content of the O-CLA group could explain the lower liver weights in the O-CLA group compared to the O-Ctrl group, and also support a claim that *trans–trans* CLA-rich soy oil supplementation lowers the accumulation of fat in the liver. The percentage of liver cholesterol was reported as the ratio of cholesterol to total liver lipids. No significant differences were found between the percent liver cholesterol in rats in the O-CLA and O-Ctrl group, and rats in the L-Ctrl group showed

Table 4 Effects of CLA enriched soybean oil on food consumption, body weight, body composition, and organ weights in obese zucker rats

	L-Ctrl		O-Ctrl		O-CLA	
	Mean	SE	Mean	SE	Mean	SE

Liver lipid (%)	9.7[c]	0.4	32.9[a]	1.3	20.1[b]	1.8
Liver cholesterol (%)	21.9[b]	0.4	23.7[a]	0.3	23.4[a]	0.6

Data represents the mean values and standard error (SE; $n = 12$/group)

Values in a row without common superscripts are significantly different ($P < 0.05$)

Cholesterol, HDL-C, LDL-C, and triglycerides were measured in serum. Liver lipid percentage and liver cholesterol percentage were measured in the liver. Liver lipid percentage refers to the percentage of total liver weight found to be lipid. Liver cholesterol percentage refers to the percentage of liver lipids found to be cholesterol

L-Ctrl Lean + control diet, *O-Ctrl* obese + control diet, *O-CLA* obese + conjugated linoleic acid diet (0.5%)

significantly ($P < 0.05$) lower liver cholesterol values than the O-Ctrl and O-CLA groups.

Serum Glucose, HbA1c, AST and Insulin

The serum and whole blood metabolite results are presented in Table 6. Glucose and AST levels in the L-Ctrl group were significantly lower than in the O-Ctrl and O-CLA groups. There was no significant difference in the AST level between the O-CLA and O-Ctrl group. Rats in the L-Ctrl group also had serum insulin values significantly lower than the O-Ctrl group. CLA supplementation had an intermediary effect in lowering the serum insulin levels as the values were not different from either L-Ctrl or O-Ctrl groups. The HbA1c levels of the rats in the O-CLA treatment were found to be significantly lower than the O-Ctrl group, indicating that CLA supplementation effectively regulates the blood sugar levels.

Expression of PPAR-γ in White Adipose Tissue in Zucker Rats

We measured the expression of PPAR-γ in white adipose tissue (WAT). We found no significant difference in the expression of PPAR-γ in the O-CLA group when compared to the O-Ctrl group (Figure 1). The expression of PPAR-γ mRNA in both O-Ctrl and O-CLA groups were significantly lower than the L-Ctrl group.

Discussion

Natural CLA sources, such as dairy fats, reportedly contain over twenty-five CLA isomers; chemical synthesis and modification of existing isomers are adding to this list [23]. Most studies examining the biological activities of CLA have used c9,t11 CLA and t10,c12 CLA which are primarily derived from an alkaline catalyzed reaction of

Table 6 Effects of CLA enriched soybean oil on serum and whole blood parameters in obese Zucker Rats

linoleate [10]. To the authors' knowledge, no studies have been done to examine the effects of *trans–trans* CLA-enriched soybean oil on the body composition, cardiovascular risk factors, and diabetes risk factors in animal models or humans. Lack of knowledge on the health effects of dietary supplementation of *trans–trans* CLA isomers is due to fiscal impracticalities in obtaining enough *trans–trans* CLA isomers to conduct a feeding trial. The development of a new method of CLA production by the photoisomerization of soy oil that creates primarily *trans–trans* CLA isomers by Jain and Proctor [18, 24] allowed us to examine the possible in vivo health benefits of *trans–trans* CLA isomers. Unfortunately, at the time of study it was not possible to produce CLA-rich soybean oil containing only *trans–trans* CLA isomers. However, *trans–trans* CLA isomers make up 75% of the CLA isomers in the oil, and we think it unlikely that the small portion of the remaining *cis–trans* and *trans–cis* could have confounded our results. This study was designed to determine whether dietary supplementation of soybean oil rich with *trans–trans* CLA isomers is effective in improving body composition, dyslipidemia, hepatic steatosis, and markers of glucose control and liver function in obese *fa/fa* Zucker rats that are associated with an increased risk for type 2 diabetes and cardiovascular disease.

The present study demonstrated that *trans–trans* CLA rich soybean oil had no effect on the body composition, which is in agreement with the findings of Sanders and colleagues [25], who also reported that the body fat percentage of female obese Zucker rats treated with CLA (50:50 t9,c11:c10,t12 or t9,c11 or c10,t12) via intragastric gavage at 1.5 g CLA/kg bwt did not differ from those receiving the control corn oil vehicle. In contrast, Sisk and others [26] reported that supplementing with 0.5% CLA consisting of primarily c9,t11 and c10,t12 isomers caused an increase in adiposity in obese Zucker rats. Others have shown that dietary supplementation of CLA is effective in reducing the percentage of body fat and increasing the percentage of body protein [27, 28]. These contradictory results can be explained due to the sex of the rats and the type of CLA isomers used in the study. Poulos and others [29] demonstrated that dietary CLA can have sex-dependent effects on the body composition of rats. With dietary CLA supplementation of c9,t11 and c10,t12 isomers at 0.5% concentration, the CLA was found to have positive effects on male rats by increasing muscle mass and bone growth, but similar changes were not observed in the females [29]. Nonetheless, we observed that the *trans–trans* CLA isomers are effective in reducing hepatic steatosis which was in contrast to the results reported by Sanders and colleagues [25] who indicated that supplementation of c9,t11 CLA, t10,c12 CLA or a mixture of the two isomers did not lower hepatic steatosis. Our study shows that dietary supplementation of CLA rich soybean oil significantly ($P < 0.05$) reduced the total liver lipid content. This is in agreement with similar findings by Noto et al. [30] who reported a similar decrease ($\sim$60% Noto, $\sim$40% current study) in the liver lipid content of Zucker rats supplemented with a 1.5% (w/w) CLA. Although we saw no improvement in liver function like was reported by Noto et al., the lack of significant difference in the AST, BUN, or total protein, supports a claim that liver function was not adversely affected by CLA supplementation. The discrepancy in improved liver function and reduction in liver lipid percentage could be attributed to the higher CLA level used by Noto et al. and the fact that CLA intake in the present study was controlled by pair-feeding.

Excess accumulation of lipid in the liver is associated with insulin resistance [30]. Interestingly, our study showed that dietary supplementation of *trans–trans* CLA lowered the HbA1c, a long-term measure of glucose control and reduced the circulating insulin levels, moderately but not significantly, in the obese rats. However, we did not see any improvements in fasting blood glucose. We feel that the elevated glucose values were caused by both the anesthetic mixture, which is known to elevate fasting glucose values and the stress response of the animal model [31–33]. Similar insulin-sensitizing effects of CLA were reported by Houseknecht and coworkers in the ZDF rat [34]. The insulin-sensitizing effect of CLA is believed to be by activation of peroxisome proliferator-activated receptor-γ (PPAR-γ) [35]. Polyunsaturated fatty acids and their metabolites have been identified as PPAR-γ ligands [36]; hence, based on the data discussed above, insulin sensitizing effects of *trans–trans* CLA rich soy oil may be

due to prevention of hepatic steatosis and moderate upregulation of PPAR-γ. However, upregulation of PPAR-γ in white adipose tissue was not found to be significant (Fig. 1).

CLA rich soybean oil supplementation in obese rats also reduced the serum cholesterol and LDL-C levels. Our results are in agreement with other studies that have shown that dietary CLA can lower the serum cholesterol levels [30, 37]. This decreased serum cholesterol and LDL levels by CLA rich soybean oil can be due to a possible transcriptional activation of the LDL receptor gene which in turn enhances the uptake of VLDL and LDL cholesterol via hepatic LDL receptors [38]. Other possible cholesterol lowering effects of CLA could be due to inhibition of secretion of apolipoprotein B or by inhibiting cholesterol absorption by down-regulating the intestinal sterol O-acyltransferase activity [39, 40].

CLA has been reported to be a potent ligand activator of PPAR-α [41, 42], however, further studies are necessary to evaluate the role of *trans–trans* CLA in inducing hepatic fatty acid oxidation by ligand activation of PPAR-α. Increased fatty acid oxidation is associated with reduced LDL secretion rate [43], which is in agreement with our findings that show lower serum LDL levels in the obese rats supplemented with *trans–trans* CLA. In addition, it is plausible that hepatic fatty acid synthesis is strongly downregulated by *trans–trans* CLA, which is in agreement with others who reported that polyunsaturated fats strongly downregulated hepatic lipogenesis [44–46]. CLA also enhances the mRNA levels of lipogenic enzymes and their activity with concomitant reduction in the body fat content [47]. However, the *trans–trans* isomer in CLA enriched soy bean oil in our study did not lower the body fat percentage which further supports our hypothesis that *trans–trans* CLA prevents hepatomegaly, lowers the hepatic lipid content and improves the serum lipid profiles by increasing the hepatic fatty acid oxidation rather than compensatory increase in the hepatic lipogenesis.

Conclusion

In summary, dietary supplementation with soybean oil rich in *trans–trans* CLA isomers is effective in lowering serum cholesterol in obese Zucker rats. *Trans–trans* CLA-rich soy oil supplementation also lowered the liver lipid content. Glycated hemoglobin values for rats receiving *trans–trans* CLA were also significantly lower, indicating that *trans–trans* CLA may have a role in regulating blood sugar.

Acknowledgments This study was funded by the Arkansas Biosciences Institute.

Abstract Lipid kinases and phosphatases play essential roles in signal transduction processes involved in cytoskeletal rearrangement, membrane trafficking, and cellular differentiation. Phosphatidic acid (PtdOH) is an important mediator lipid in eukaryotic cells, but little is known regarding its regulation in the parasite *Trypanosoma cruzi*, an agent of Chagas disease. In order to clarify the relationship between PtdOH metabolism and developmental stages of *T. cruzi*, epimastigotes in culture were subjected to hyperosmotic stress (~1,000 mOsm/L), mimicking the environment in the rectum of vector triatomine bugs. These experimental conditions resulted in differentiation to an intermediate form between epimastigotes and trypomastigotes. Morphological changes of epimastigotes were correlated with an increase in PtdOH mass accomplished by increased enzyme activity of diacylglycerol kinase (DAGK, E.C. 2.7.1.107) and concomitant decreased activity of phosphatidate phosphatases type 1 and type 2 (PAP1, PAP2, E.C. 3.1.3.4). Our results indicate progressive increases of PtdOH levels during the differentiation process, and suggest that the regulation of PtdOH metabolism is an important mechanism in the transition from *T. cruzi* epimastigote to intermediate form.

Abbreviations

DAG	Diacylglycerol
DAGK	Diacylglycerol kinase
DGPP	Diacylglycerol pyrophosphate
$InsP_3$	Inositol 1,4,5-trisphosphate
InsPx	Total inositol phosphates
LPP	Lipid phosphate phosphatase
NEM	*N*-ethylmaleimide
PAK	Phosphatidate kinase
PAP	Phosphatidate phosphatase
PLC	Phospholipase C
PtdCho	Phosphatidylcholine
PtdIns	Phosphatidylinositol
PtdIns-4,5-P_2	Phosphatidylinositol 4,5-bisphosphate
PtdIns-4-P	Phosphatidylinositol 4-phosphate
PtdOH	Phosphatidic acid
TLC	Thin-layer chromatography

Introduction

The flagellate protozoan *Trypanosoma cruzi* is responsible for Chagas disease [1], a serious endemic illness and major public health problem in Latin America. The life cycle of this parasite comprises three different morphological and functional forms: amastigotes, epimastigotes, and trypomastigotes [2, 3]. The transformation of epimastigotes to metacyclic trypomastigotes (metacyclogenesis process), leading to forms that are eventually able to

infect mammalian hosts, is of particular interest. In vivo and in vitro metacyclogenesis studies have demonstrated the presence of intermediate forms between epi- and trypomastigotes [3–9]. These intermediate forms were identified morphologically through the position of the kinetoplast relative to the nucleus, similar to the transitional stage described in the reduviid midgut [4, 7, 10, 11]. These forms are characterized by a lengthened flagellum, which is considered to be a pre-adaption for differentiation to the next life-cycle stage, i.e., metacyclic trypomastigote [12]. The biochemical characteristics of these intermediate forms are poorly known. Bourguignon et al. [9] demonstrated that they display electrophoretic mobility similar to that of trypomastigotes, indicating the presence of some specific trypomastigote proteins and surface carbohydrates. On the other hand, the intermediate forms were unable to infect either Vero or 3T3 cells, suggesting that their behavior is similar to that of epimastigotes rather than trypomastigotes [9]. No studies so far have addressed the lipid metabolism of the intermediate forms. Metacyclogenesis can be induced in vitro by incubating epimastigotes in TAU3AAG, a chemically defined medium that mimics the urine of triatomine bugs [13]. However, little is known regarding the exact environmental stimulus leading to intermediate and trypomastigote forms, or the metabolic changes that occur during this process.

Responses of parasites to environmental changes often involve changes in the phospholipid metabolism. Our previous studies have shown that *T. cruzi* epimastigotes respond to external stimuli by the modification of their phospholipid metabolism, in which phosphatidic acid (PtdOH) plays a central role [14–16]. In higher eukaryotic cells, PtdOH is well known as an important second messenger, rapidly produced in receptor-stimulated cells by phospholipase D (PLD, E.C. 3.1.4.4) and/or the combined action of phospholipase C (PLC, E.C. 3.1.4.11) and diacylglycerol kinase (DAGK, E.C. 2.7.1.107) activities [17]. Enzymes that switch off PtdOH signaling are important in the metabolism of this phospholipid. One pathway leading to PtdOH reduction is its degradation to diacylglycerol (DAG) by phosphatidate phosphatase (PAP, E.C. 3.1.3.4), a key enzyme in both lipid synthesis and the generation or degradation of lipid-signaling molecules. PAP enzymes are classified based on cofactor requirement for catalytic activity, i.e., as Mg^{2+}-dependent (termed PAP1, or lipins) or Mg^{2+}-independent (PAP2, or lipid phosphate phosphatases) [18]. In *T. cruzi*, no studies have yet addressed PAP activity, and the possible role of this enzyme in the regulation of PtdOH levels is, therefore, unknown. We previously demonstrated a functional mechanism of PtdOH reduction in epimastigotes in which PtdOH is converted to diacylglycerol pyrophosphate (DGPP) by a phosphatidate kinase (PAK) [15]. DGPP in plant cells appears to be involved in the regulation of cellular responses [19], and this compound may well have a similar function in *T. cruzi* [16].

The possible involvement of PtdOH metabolism in *T. cruzi* differentiation has not yet been studied. We did observe that the activation of both DAGK and PAK in epimastigotes is triggered by peptide 1–40 [16], which can also induce metacyclogenesis [20], suggesting that the regulation of PtdOH levels may play a role in the formation of intermediate forms.

In the present study, we found that lipid kinases (DAGK, PAK) and phosphatases (PAP1, PAP2) are regulated in opposite directions in *T. cruzi* epimastigotes versus intermediate forms. We describe for the first time PAP activity in membrane fractions of *T. cruzi*, and discuss the possible physiological involvement of PtdOH metabolism in the transition from epimastigote to intermediate forms.

Materials and Methods

Organisms and Growth Conditions

T. cruzi Tulahuen strain was used. Epimastigote forms were grown at 28°C in modified Warren medium [21], supplemented with 10% fetal bovine serum (FBS), as described previously [14]. Cells in logarithmic growth phase (day 6) were harvested by centrifugation at $1{,}000\times g$ for 10 min, and washed twice with 25 mM Tris–HCl, pH 7.35, 1.2 mM $MgSO_4$, 2.6 mM $CaCl_2$, 4.8 mM KCl, 120 mM NaCl, and 100 mM glucose [Krebs-Ringer-Tris (KRT) buffer]. To obtain intermediate forms, epimastigote forms were grown in the same culture medium but in the presence of 0.5 M NaCl or 1 M mannitol, and the cells were harvested at day 13 by centrifugation at $1{,}000\times g$ for 10 min and washed twice with KRT buffer.

Optical Microscopy Analysis

Cells were grown as described above and fresh parasite samples were taken at defined times and quantified using a Neubauer's hemocytometric chamber. For morphological studies, parasites were fixed with absolute methanol, stained with 10% Giemsa in 0.1 M sodium phosphate buffer, pH 7.2, and counted (at least 400 organisms per sample) in a Zeiss Axiolab Standard Fluorescence Microscope. Parasites were classified as epimastigotes, trypomastigotes, or intermediate forms based on cell shape, size, and Giemsa staining, as previously published [6, 8, 10].

Determination of Osmolarity

Aliquots of culture medium were taken at various stages of parasite growth, cells were removed by centrifugation, and osmolarity in the supernatant was measured using a Wescor 5500 vapor pressure osmometer.

Preparation of Membranes from Epimastigotes and Intermediate Forms

Washed cells were resuspended in five volumes of 50 mM HEPES (pH 7.4) containing 0.25 M sucrose, 5 mM KCl, 1 mM EDTA, and 4 μg/mL leupeptin. The suspension was frozen at −180°C in liquid nitrogen and thawed; this freeze/thaw cycle was performed three times. Membrane fractions were prepared as described previously [22]. Briefly, the homogenate was centrifuged at 100×*g* for 15 min to remove cell debris, and supernatant was centrifuged at 1,000×*g* for 15 min and at 105,000×*g* for 60 min. Pellets from the two centrifugations were washed, resuspended with 50 mM HEPES (pH 7.4), and used as a source of enzymatic activities.

Determination of Lipid Kinase Activity

Lipid Kinase Assay

PAK and DAGK were assayed simultaneously using endogenous lipids as substrates. The membrane fraction isolated (30–80 μg protein) was added to thermally equilibrated buffer 50 mM HEPES (pH 7.4) containing 0.1 mM EDTA, 0.5 mM DTE, 10 mM $MgCl_2$, 0.1 mM sodium o-vanadate, and 1 mM [γ-^{32}P]ATP (500 cpm/pmol). Endogenous lipid phosphorylation proceeded for 5 min at 30°C in a total volume of 100 μL, and was then terminated by the addition of 1.5 mL chloroform/methanol (1:2, by vol). The protein content of membrane samples was determined by the Bradford method [23], with bovine serum albumin as the standard.

Lipid Extraction and Separation

Lipids were extracted from membranes as described previously [15]. Samples were spotted on silica gel plates coated with potassium oxalate solution and heated at 110°C for 60 min just before use. Thin-layer chromatography (TLC) was developed with chloroform/methanol/acetone/acetic acid/water (40:14:15:12:7, by vol) for the first dimension, and chloroform/pyridine/formic acid (35:30:7, by vol) for the second dimension. The positions of radiolabeled lipids were determined by autoradiography on Kodak film. Spots were scraped off the plates and fractions counted in a liquid scintillation counter.

Determination of PtdOH Mass

Epimastigotes or intermediate forms were grown and harvested as described above. Total lipids were extracted from washed parasites as described previously [14] and aliquots were taken for the determination of total lipid phosphorus. Individual phospholipids were resolved using the TLC procedure described for labeled samples. PtdOH areas were scraped out and the fractions were quantified by phosphorus determination according to Fiske and Subbarow [24]. The experiments, carried out in duplicate, were conducted threefold.

Measurement of PLC Activity

Epimastigotes or intermediate forms were harvested by centrifugation at 1,000×*g* for 10 min and washed twice with KRT buffer. The cells were pre-incubated and gently agitated in a shaking water bath at 28°C for 12 h in KRT buffer plus 0.1% albumin, 10% FBS, 3 mM $MnCl_2$, and 4 μCi myo-[^{3}H]inositol/25 mg of cells. Total [^{3}H]inositol phosphates ([^{3}H]InsPx, the sum of cpm obtained for [^{3}H]InsP, [^{3}H]$InsP_2$, [^{3}H]$InsP_3$, and [^{3}H]$InsP_4$ column fractions) were separated by anion-exchange chromatography on Dowex AG 1-X8, as described previously [25].

Determination of PAP Activity

Preparation of Radiolabeled 1,2-Diacyl-sn-glycerol-3-phosphate

Radiolabeled PtdOH was obtained from [2-^{3}H]-phosphatidylcholine (PtdCho), which was synthesized from bovine retinas incubated with [2-^{3}H]glycerol (200 mCi/mmol), as described previously [26]. Lipids were extracted from tissues as described previously [27], and [2-^{3}H]PtdCho was isolated by TLC and eluted therefrom. [2-^{3}H]-PtdCho was hydrolyzed with PLD, and PtdOH was purified by TLC on silica gel H, developed with chloroform/methanol/acetic acid/acetone/water (9:3:3:12:1.5, by vol). The substrate was eluted from silica gel with neutral solvents to avoid the formation of lyso-PtdOH, and then converted to free acid by washing twice using an upper phase containing 0.1 M sulfuric acid. [2-^{3}H]PtdOH had a specific radioactivity of 0.1–0.2 μCi/μmol. For the determination of type 1 PAP (PAP1) activity, the substrate was prepared by sonicating 3.33 mM [2-^{3}H]-phosphatidate (0.1–0.2 μCi/μmol) and 2.22 mM dipalmitoyl PtdCho in 5.56 mM EGTA and 5.56 mM EDTA. For the determination of type 2 PAP (PAP2) activity, an emulsion was prepared as described above, except that PtdCho was omitted.

Isolation of Radiolabeled PtdOH

Lipids were extracted with chloroform/methanol (2:1, by vol) and washed with 0.2 volumes of 0.05% $CaCl_2$ [27]. Neutral lipids were separated by gradient-thickness TLC on silica gel G and developed with hexane/diethyl ether/acetic acid (35:65:1, by vol). When the chromatogram was developed, [2-^{3}H]-PtdOH and phospholipids were retained at the spotting site. Lipids were visualized by exposing the chromatogram to iodine vapor and scraped off for liquid scintillation counting, followed by the addition of 0.4 mL water and 10 mL 5% OmniFluor in toluene/Triton X-100 (4:1, by vol).

PAP Activity Assay

PAP activities were differentiated based on *N*-ethylmaleimide (NEM) sensitivity [28, 29]. NEM-insensitive PAP activity (PAP2) was determined using an assay mixture consisting of 50 mM Tris–maleate buffer, pH 6.5, 1 mM DTT, 1 mM EDTA plus 1 mM EGTA, 4.2 mM NEM, and 100 μg membrane protein in a volume of 100 μL, with the reaction started by adding 0.6 mM [2-^{3}H]-phosphatidate. NEM-sensitive PAP activity (PAP1) was determined using the same assay mixture but including 0.2 mM Mg^{2+}, with the reaction started by adding 0.6 mM [2-^{3}H]-PtdOH plus 0.4 mM PtdCho.

Parallel incubations were carried out after pre-incubating membrane fractions with 4.2 mM NEM for 10 min. The difference between the two types of activity was labeled as PAP1. All assays for the determination of PAP1 or PAP2 activity were performed for 30 min at 37°C, and were terminated by the addition of chloroform/methanol (2:1, by vol). PAP activity product 1,2-diacyl[^{3}H]glycerol was isolated and measured as described above. PAP activity was expressed as the sum (in nmol) of [^{3}H]diacylglycerol and [^{3}H]monoacylglycerol per h per mg protein.

Sequence Alignment and Phylogenetic Analysis

Sequence analysis was performed using tools provided by the National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov) and the ExPASy Molecular Biology Server (http://us.expasy.org). The *T. cruzi* genome database at GeneDB (http://www.genedb.org/genedb/tcruzi) was searched using Wu-Blast2. Sequence identity was analyzed using BlastP (http://www.ncbi.nlm.nih.gov/blast). Sequences were initially aligned using ClustalW (http://www.ebi.ac.uk/clustalw) with BioEdit Sequence Alignment Editor 4.8.8 [30, 31], and the alignment was then visually refined. Transmembrane segments were determined using TMPred (http://www.ch.embnet.org/software/TMPRED_form.html). Phylogenetic analysis was performed using the neighbor-joining method, with PAM distances computed on 118 reliably aligned sites [32].

Statistical Analysis

The results are shown as mean ± standard error of the mean (SEM) for three or more independent experiments. Statistical analysis of the data was performed using OriginPro 8 software.

Results

Generation of Intermediate Forms in Hyperosmotic Media

Experiments were performed to find out the stress conditions in the culture medium of growing *T. cruzi* epimastigotes similar to those found in the rectum of triatomine bugs, leading to the development of intermediate forms. For this purpose, we added 0.5 M NaCl or 1 M mannitol (which raises the osmolarity to ~1,000 mOsm/L) to medium, and monitored growth curves and morphologic changes of parasites for 13 days.

At day 0, the osmolarity values were 349 ± 27 mOsm/L in control medium, 1,207 ± 50 mOsm/L in NaCl-added medium, and 1,367 ± 68 mOsm/L in mannitol-added medium. In the hyperosmotic media, the proportion of intermediate forms increased steadily, reaching 87 ± 4% in NaCl-added medium at day 13 (Table 1). Morphologic changes observed in NaCl- and mannitol-added media were similar (Fig. 1a–c) and hyperosmolar media did not affect parasite viability. In the control culture, epimastigotes remained the predominant form.

The intermediate forms generated in hyperosmotic media showed increased flagellar length, a 96-h delay in the lag period of the growth curve, increased generation time (twofold), and a reduction in the maximal growth to ~50% of the control value (Fig. 1d).

DAGK and PLC Activities are Increased in the Membrane of Intermediate Forms

Changes in the membrane lipid composition of parasites are often reflected in morphological changes. We showed previously that various stimuli modified the PtdOH metabolism in membrane fractions of *T. cruzi* epimastigotes [15, 16, 22]. In the present study, we looked for correlations between observed morphological changes and PtdOH levels.

We measured the PtdOH mass in both epimastigotes and intermediate forms. The PtdOH amounts were 90.2 ± 1.5 pmol in epimastigotes versus 148.5 ± 2.5 pmol in

Epimastigotes were inoculated in an isosmotic medium (control) or in a hyperosmotic medium obtained by supplement with 0.5 M NaCl or 1 M mannitol. At the indicated times, aliquots were extracted in order to calculate the percent of each parasite stage. Parasites were colored by Giemsa staining and counting under an optical microscope. The data are the mean ± standard deviation (SD) of four experiments performed separately

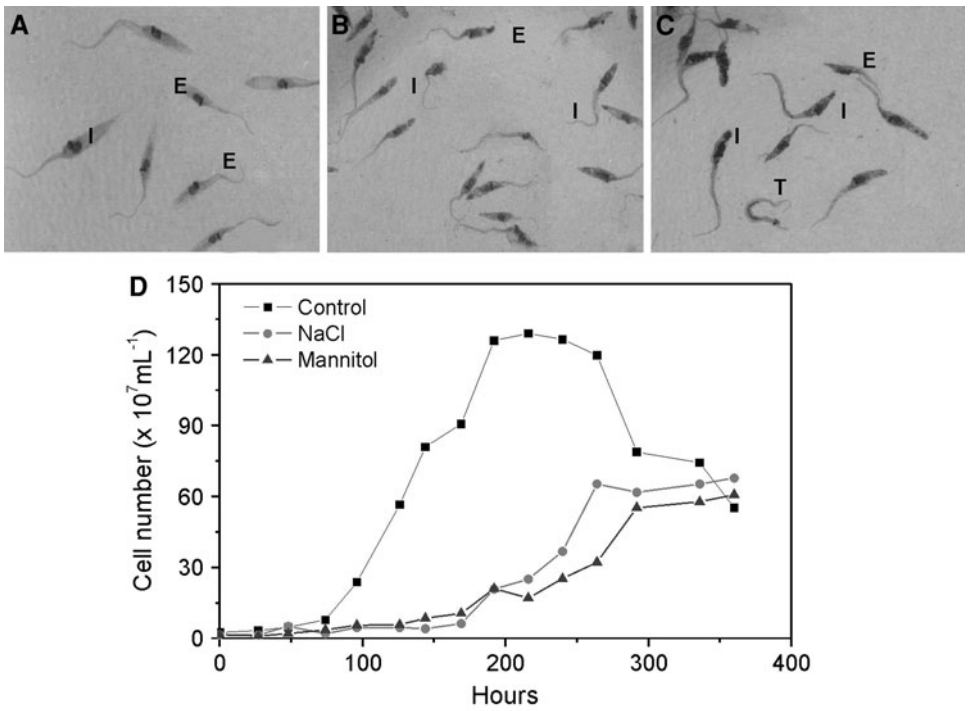

Fig. 1 Morphology and growth curve of *Trypanosoma cruzi* under various osmolarity conditions. Epimastigotes were grown in isosmotic medium (control) or hyperosmotic media (addition of 0.5 M NaCl or 1 M mannitol). An aliquot of each culture was extracted at day 13, subjected to Giemsa staining, and visualized by optical microscopy. **a** Control. **b** NaCl culture. **c** Mannitol culture. *E* epimastigote; *I* intermediate form; *T* trypomastigote. Growth curves were monitored over a period of 13 days (**d**). The parasite number was measured daily by counting in a Neubauer chamber. The data are from a representative experiment out of eight (control) and six (hyperosmotic media) independent experiments

intermediate forms, per nmol of total phospholipids ($n = 3$, $P < 0.05$). Thus, the PtdOH content increased by 64% in intermediate forms, whereas no significant variation in the total amount of phospholipids was detected.

In order to find the origin of the incremented PtdOH, we assayed lipid kinase activities in parasite membranes. [γ-^{32}P]ATP phosphorylation of membrane fractions from epimastigotes resulted in the rapid labeling of chloroform-soluble products. Enzymatic activities of lipid kinases DAGK and PAK were both higher (12.5 and 85%, respectively) in the 1,000×*g* membrane fraction than in the 105,000×*g* membrane fraction (Table 2). Activity values assayed in the 1,000×*g* fraction were 70 pmol/min/mg of protein for DAGK and 25 pmol/min/mg of protein for PAK.

The DAGK activity measured in the 1,000×*g* fraction of intermediate forms was 350 pmol/min/mg of protein, which is fivefold higher than for epimastigotes (Fig. 2a). The DAGK activity in the 105,000×*g* fraction was also roughly fivefold higher for intermediate forms. The difference in PAK activity between intermediate forms and epimastigotes was not significant (Fig. 2a). To elucidate the origin of increased DAGK activity in intermediate forms, we measured the activity of PtdIns-PLC, which yields DAG and inositol 1,4,5-trisphosphate ($InsP_3$) as

Table 2 Lipid kinase activities in 1,000×*g* and 105,000×*g* membrane fractions of *T. cruzi* epimastigotes

Enzyme	Membrane fraction	
	1,000×*g*	105,000×*g*
DAGK	63.10 ± 1.07*	56.40 ± 3.96
PAK	4.80 ± 1.00*	2.60 ± 0.27
Other kinases	32.26 ± 1.78	40.99 ± 2.78

Lipid kinase activities were determinated by phosphorylation with [γ-^{32}P]ATP of epimastigote membrane fractions. The results are expressed as the percentage of the total radioactivity of the organic phase ± standard error of the mean (SEM) ($n = 32$ for 1,000×*g* and $n = 17$ for 105,000×*g* fraction, respectively)

* Statistically significant differences ($P < 0.05$)

products. The accumulation of total inositol phosphates (InsPx) is summarized in Fig. 2b. The levels of these metabolites, representing 0.1–0.2% of cpm incorporated, showed a clear increase (25 ± 5%; $n = 3$, $P < 0.05$) in the intermediate forms compared to epimastigotes. $InsP_3$ levels were also increased (70 ± 5%; $n = 3$, $P < 0.05$), confirming the PtdIns-PLC activity change.

Decrease of PAP Activity in the Membrane of Intermediate Forms

In eukaryotic organisms that contain DGPP, the increase in PtdOH formation which occurs in response to various physiological stresses is often accompanied by increased DGPP [15, 16, 33]. Since PtdOH increase was not correlated with DGPP formation in intermediate forms (Fig. 2a), we considered the possibility that PtdOH might be metabolized by PAP. We differentiated PAP activities on the basis of sensitivity to NEM, a thiol-reactive compound that inhibits PAP1 activity but has no effect on the PAP2 activity. PAP activities were detected in both 1,000×*g* and 105,000×*g* membrane fractions from epimastigotes. In the 1,000×*g* fraction, the specific activity was 77 nmol/h/mg of protein for PAP2 and 25 nmol/h/mg of protein for PAP1. The PAP2 activity was reduced by ~50% in the 1,000×*g* fraction (but not in the 105,000×*g* fraction) of intermediate forms compared to epimastigotes (Fig. 3a). The PAP1 activity was reduced around fivefold in both 1,000×*g* and 105,000×*g* fractions of intermediate forms (Fig. 3b).

Lipid Phosphate Phosphatase Genes Encoded in the *T. cruzi* Genome

PAP2 enzymes are believed to be involved in signal transduction processes. These phosphatases belong to a phosphatase/phosphotransferase family and hydrolyze a

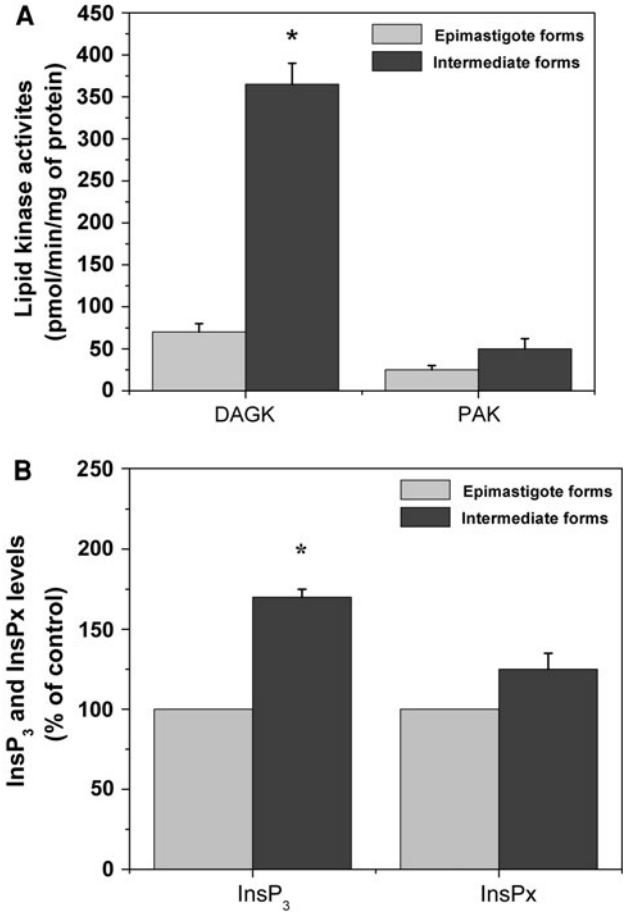

Fig. 2 Lipid kinase and phospholipase C activities. The enzymatic activities of phosphatidate kinase (PAK) and diacylglycerol kinase (DAGK) (**a**) were determined based on [γ-^{32}P] ATP phosphorylation of parasite membrane fractions. Values are mean ± standard error of the mean (SEM) from five independent experiments. [^{3}H] inositol-labeled cells were pre-incubated with 10 mM LiCl for 15 min. $InsP_3$ and InsPx levels (**b**) were analyzed as described in the "Materials and Methods" section. The results are expressed as the percentage of unstimulated control value (defined as 100%) ± SEM, $n = 4$. *$P < 0.05$

broad range of lipid phosphates, including PtdOH and DGPP. The PAP2 enzyme family was renamed "lipid phosphate phosphatases" (LPP) because of a lack of clear substrate preference in vitro and uncertainty regarding their function in vivo [18].

To try to clarify the function of parasite LPP, we conducted a search of *T. cruzi* databases (http://www.genedb.org/genedb/tcruzi) using *LPP* or *PAP* genes from human, plant, and yeast sources as query sequences. This resulted in the identification of three open reading frames, designated at GeneDB as Tc00.1047053511277.359, Tc00.1047053511277.370, and Tc00.1047053511355.30, which showed high similarity to *LPP* genes and were, therefore, termed *TcLPP1*, *TcLPP2*, and *TcLPP3*. The open reading frames of *TcLPP1* and *TcLPP2* are 948 and 879 bp in

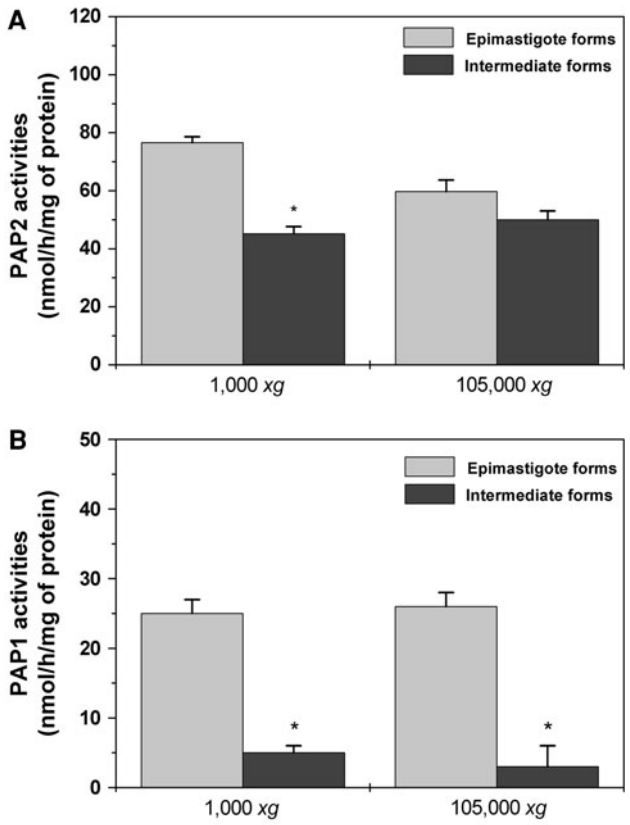

Fig. 3 The enzymatic activities of phosphatidate phosphatases type 2 (PAP2) (**a**) and phosphatidate phosphatases type 1 (PAP1) (**b**) were assayed using [^{3}H]-PtdOH (0.6 mM) plus dipalmitoyl PtdCho (0.4 mM) or [^{3}H]-PtdOH (0.6 mM) as substrates, respectively, and expressed as nmol [^{3}H]-DAG plus [^{3}H]-MAG/h/mg protein. Values are mean ± SEM, $n = 3$. *$P < 0.05$

length and code for putative proteins of 315 and 292 amino acids, here termed TcLpp1 and TcLpp2, respectively. TcLpp1 and TcLpp2 have a molecular mass of 35.3 and 32.2 kDa, respectively, and are both integral membrane proteins and contain six highly hydrophobic regions of sufficient length to be membrane-spanning, here termed TM1–6 (Fig. 4). *TcLPP3* is 954 bp in length and encodes a putative protein, here termed TcLpp3, having 317 amino acids (35.7 kDa) with seven predicted transmembrane helices (TM1–7).

Amino acid sequence analysis showed that TcLpp proteins have the highest identity with human PAP type 2 domain (HsLpp3) (Fig. 4), followed by orthologs of *Arabidopsis thaliana* (AtLpp3) and *Saccharomyces cerevisiae* (ScDpp1) (Table 3). Alignment analysis between TcLpp1, TcLpp2, and TcLpp3 revealed fairly high amino acid identity (33–40%). However, TcLpp3 had a signal peptide predicted in the N-terminal region 22 amino acids in length that did not align with sequences of TcLpp1 or TcLpp2. A phylogenetic tree was constructed for members of the LPP protein family, including TcLpp1, TcLpp2, and TcLpp3 (Fig. 5). The *T. cruzi* proteins were grouped with putative Lpp proteins belonging to other kinetoplastids, such as *T. brucei* (TbLpp) and *Leishmania* (LmLpp, LbLpp).

Discussion

In this study, the transition from *T. cruzi* epimastigotes to intermediate forms stimulated the activities of DAGK and PtdIns-PLC, while the activity of PAK, an enzyme absent in mammalian cells, was unchanged. PAP activity was reduced, suggesting that PtdOH metabolism is involved in this transition process. Intermediate forms generated when epimastigotes were incubated in high-osmolarity conditions were characterized as parasite forms, with nucleus-adjacent kinetoplasts. They also showed increased flagellar length, considered to be a pre-adaptation of epimastigotes for differentiation to trypomastigotes [12]. Carvalho-Moreira et al. [8] reported that epimastigotes incubated in saline solution failed to complete metacyclogenesis, which was interrupted in the intermediate stage, similar to our finding. We observed that NaCl and mannitol treatment evoked similar morphological changes, supporting the idea that increased osmolarity of culture medium, rather than ionic stress, was the factor promoting the formation of intermediate forms. During the course of parasite growth, such morphological alterations, reflected in the changes of membrane phospholipids, may help maintain biophysical properties for optimal membrane function, allowing the parasites to cope with environmental changes. In this sense, it is critical that the intracellular DAG level be tightly regulated, since the conversion of DAG to PtdOH by DAGK is the major route to terminate DAG signaling [22]. PtdOH itself has a broad array of signaling properties distinct from those of DAG. The ability of *T. cruzi* to generate PtdOH through DAGK in intermediate forms provides two ways of terminating the effects of DAG: breaking down DAG metabolically and producing PtdOH. Accordingly, the PtdOH amount was increased in intermediate forms (64%), indicating that the PtdOH metabolism is clearly an important part of the complex mechanism for transition from epimastigotes to intermediate forms in this species.

The presence of DAGK activity in both 1,000×*g* and 105,000×*g* membrane fractions indicates a complex distribution pattern similar to that observed in bacteria and higher eukaryotes [34]. Enzymatic activity in epimastigote 1,000×*g* fraction was comparable to previously reported values [15], but activity in intermediate forms was fivefold higher. This increase was not due to the higher availability of DAG, since the results from experiments with saturating concentrations of exogenous substrates were not significantly different from those in assays with endogenous substrates. Furthermore, the decreased PAP2 activity

TcLpp2	40/54	36/47	28/43
TcLpp3	35/50	31/48	28/48

Percentages of identity (I) and similarity (S) values for *T. cruzi* protein sequences compared with Lpp isoforms from human (HsLpp3), *A. thaliana* (AtLpp3), and *S. cerevisiae* (ScDpp1) proteins, defined by BLAST2 sequence analysis, is shown

recorded in intermediate forms would indicate that DAGK substrate is produced by other pathways. Specific activity of DAGK was highest in the 1,000×*g* fraction of intermediate forms, which is enriched in flagellar membranes (data not shown), suggesting an important role of this enzyme and/or its substrate and product lipids in the self-function of flagellae. Tyler and Engman [12] proposed that epimastigotes react to some stimuli by extending their flagellae in order to adhere to the insect vector hindgut wall and undergo metacyclogenesis.

DAGK enzymes identified in unicellular organisms (bacteria) are structurally different from those in higher

eukaryotes [34 and references therein]. Little is known about regulation of DAGK in parasites. Our search of *T. cruzi* databases (http://www.genedb.org/genedb/tcruzi) identified only a sequence noted as putative DAG kinase-like protein. Mammalian DAGK isoforms are classified into five subtypes based on structural motifs [34 and references therein]. In *T. cruzi*, the above sequence (accession number EAN 99355) showed the highest homology with mammalian DAGKε (data not shown). These isoforms are the only type III enzymes showing an unusual specificity toward acyl chains of DAG, i.e., they strongly prefer unsaturated fatty acids—particularly arachidonate—in the sn-2 (middle) position of the glycerol backbone [35]. Although arachidonic acid (20:4) is not a major component of *T. cruzi* lipids, linoleic acid (18:2) is the major fatty acid of DAG, as well as PtdIns-4,5-P_2 [36, 37]. We hypothesize that DAGK in the parasite plays a role equivalent to that of DAGKε, helping to enrich PtdIns, and, therefore, PtdIns-4-P and PtdIns-4,5-P_2 with unsaturated fatty acids, in membrane microdomains.

Our previous studies demonstrated that *T. cruzi* responds to external stimuli that induce changes in the inositol cycle and calcium signaling [14, 16, 22]. In this situation, DAGK activity causes a dynamic increase of PtdOH, with simultaneous DGPP formation through PAK activation [15, 16]. Since DGPP appears to regulate cellular responses, we considered that increased levels of PtdOH in *T. cruzi* might be metabolized immediately through this pathway. However, the fivefold increase of PtdOH levels by DAGK that we observed in the intermediate forms was not correlated with an increased DGPP level. This finding suggested the existence of another enzymatic activity that utilizes PtdOH as the substrate in order to reduce its signal, consistent with our previous hypothesis that the metabolism of both PtdOH and DGPP is coupled to LPP activity in this parasite [15, 16]. As a test, we determined the activities of two PAP isoforms, PAP1 and PAP2, in parasite membrane fractions, which were decreased in intermediate forms. This result, coupled with the increased PtdOH mass in intermediate forms, indicate a function of PtdOH in this transitional stage. It has been shown that trypanosoma subpellicular microtubules, extended during differentiation, are crosslinked to the plasma membrane through a microtubule-associated protein, p15, which can bind both tubulin and phospholipids in vitro [38], although the nature of the phospholipid participating in the binding is unknown. Since p15 is an amphipathic and positively charged protein, its counterpart in the membrane should be an acidic phospholipid, such as PdtOH. In *T. cruzi*, increased PtdOH mass during differentiation to intermediate forms makes PtdOH a good candidate for that binding and, therefore, an important mediator of microtubular rearrangement. This seems to occur in plant cells, where decreased level of PtdOH causes the release of microtubules from the plasma membrane [17]. Alternatively, PtdOH might be acting as the substrate for *T. cruzi* CDP-DAG synthase (E.C. 2.7.7.41), an enzyme coded in the parasite genome [39]. The latter explanation seems probable, since we found increased PtdIns-PLC activity in intermediate forms, and Tang et al. [35] showed that CDP-DAG is involved in the re-synthesis of PtdIns as a precursor of PtdIns-4,5-P_2. We can not rule out the possible presence of PtdCho-PLC (E.C. 3.1.4.3) activity, which also yields DAG through the hydrolysis of PtdCho, although this enzyme has not been detected so far in *T. cruzi*.

The finding of PAP activity in epimastigotes and intermediate forms of *T. cruzi* is the first biochemical evidence for the presence of LPP in parasitic protozoa. A bioinformatic search of the GeneDB *T. cruzi* database revealed the presence of three putative proteins structurally similar to

the PAP enzymes of yeast, mammalian cells, and plant cells [40]. The candidate proteins TcLpp1, TcLpp2, and TcLpp3 were grouped by phylogenetic analysis into a main branch with other putative PAP of protozoa. The three putative proteins of *T. cruzi* contain a three-domain phosphatase sequence motif that is conserved in Lpp from *S. cerevisiae*, *A. thaliana*, and mammalian cells [41]. TcLpp proteins also showed the presence of conserved amino acid residues important for phosphate phosphatase activity [42], suggesting that the putative proteins are functional. Follow-up studies are needed in order to determine whether the three proteins are expressed in parasites and to identify their substrate specificities.

Our findings help clarify novel aspects of the PtdOH metabolism in *T. cruzi*, the mechanism of phosphorylation/dephosphorylation, and a role of PtdOH in transduction pathways upstream of the trypomastigote stage.

METHODS

Fatty Acid Status Determination by Cheek Cell Sampling Combined with Methanol-Based Ultrasound Extraction of Glycerophospholipids

Mario Klingler · Hans Demmelmair · Berthold Koletzko · Claudia Glaser

Received: 4 January 2011 / Accepted: 19 May 2011 / Published online: 17 June 2011

Abstract Tissue and blood fatty acid compositions are used as biological markers of fatty acid intakes to improve dietary assessments. These approaches are invasive and not well accepted, particularly in infants and young children. We developed a sensitive method for the analysis of fatty acids in cheek cell glycerophospholipids, which includes significant improvements of cell sampling, non-chromatographic isolation of glycerophospholipids and base-catalyzed synthesis of fatty acid methyl esters. Sphingophospholipids are not detected by this method. This enables a highly accurate determination of cheek cell glycerophospholipid fatty acids, even if cell numbers are limited. Coefficients of variation for fatty acids contributing more than 0.3% to total glycerophospholipid fatty acids are below 10% in samples with more than 10^5 cells. Good correlations were shown between docosahexaenoic and eicosapentaenoic acid percentages in cheek cell and plasma glycerophospholipids ($r = 0.83$ and 0.64, respectively; $P < 0.001$) with a linear relationship over the whole concentration range observed in adult study participants ($n = 29$). Cheek cell sampling is non-invasive and can easily be applied in infants. The accuracy and reliability of this new method is comparable to conventional invasive methods for the determination of the n-3 fatty acid status in humans, and it is well applicable in interventional or epidemiological studies.

Abbreviations

ARA	Arachidonic acid
BHT	Butylated hydroxytoluene
CE	Cholesterol ester
CV	Coefficient of variation
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
FA	Fatty acid
FAME	Fatty acid methyl ester
LC-PUFA	Long chain polyunsaturated fatty acid
PL	Phospholipid
SPE	Solid phase extraction
TAG	Triacylglycerols
TLC	Thin layer chromatography
PtdEtn	Phosphatidyletholamine
PtdCho	Phosphatidylcholine

Introduction

Docosahexaenoic acid (DHA) and other long chain polyunsaturated fatty acids (LC-PUFA) play import roles in human health. Increased intake of DHA has been associated with increased DHA content in blood lipids and lower risk for cardiovascular disease [1, 2]. Studies with infants and young children showed that DHA can affect their behavioral and mental development [3]. Studies on fatty acid (FA) intake often rely on food intake questionnaires, which provide information about the type of diet consumed, but they do not allow accurate estimation of the FA status [4]. Analysis of FAs in various body compartments, such as plasma, erythrocytes and adipose tissue, have been used to obtain information on FA status [5]. These

approaches are invasive and not well accepted in population studies, particularly in infants and young children.

McMurchie et al. [6] reported that changes in dietary FA compositions were reflected in cheek cell phospholipids and suggested those as an alternative marker for FA status. Later studies focusing on LC-PUFA uptake confirmed these findings. Diets rich in LC-PUFAs increased infantile DHA and eicosapentaenoic acid (EPA) levels in erythrocytes, plasma and cheek cell phospholipids [7–9]. DHA contents in all compartments were significantly correlated. This was also shown in a study with infants (age <12 months) who received DHA and arachidonic acid (ARA) with an infant formula [10]. Laitinen et al. [11] found differences in cheek cell phospholipid FA compositions associated with eczema in children. A large intervention study in school children showed a positive relationship of n-3 supplementation and cheek cell DHA levels in cheek cell total lipids [12].

The sampling and analytical methods applied in these studies differed widely, which limits the comparison of results [6, 7, 9–14]. Data about cell yield, analytical precision and reliability or storage stability are not available. Therefore, a validated analytical method is needed to utilize cheek cells as FA markers in future interventional or epidemiological studies.

Our group developed a high-throughput method for the determination of FA profiles in plasma glycerophospholipids, which avoids the chromatographic separation of lipid classes and excludes sphingophospholipids [15]. Glycerophospholipid FAMEs were obtained with two single steps. The method is highly selective for glycerophospholipids, and serum samples of more than 1,300 young children were analyzed to provide reference values for clinical practice [16].

This method was adapted for the analysis of glycerophospholipid FA profiles in cheek cells. This article describes the method development and explored factors that may influence the obtained results. Cheek cell and plasma glycerophospholipid FA contents of patients with inborn errors of metabolism were correlated to validate the use of cheek cells as FA status marker.

Materials and Methods

Subjects

Cheek cell samples for method development were obtained from healthy male and female adult volunteers employed at the Dr. von Hauner Children's Hospital, Munich. Cheek cell and plasma samples for correlation analyses were available from a quality of life study comparing adult patients with phenylketonuira and healthy controls. Complete sets of data were available from 17 healthy subjects (40.0 ± 8.5 years, mean ± SD) and 12 patients (37.5 ± 3.5 years). The Ethics Committee of the University of Munich Medical Center had reviewed the study protocol (project number 034-10). Written informed consent was obtained from all study participants prior to the study.

Chemicals and FA Standards

All solvents and chemicals were purchased in the highest available purity from Merck KGaA (Darmstadt, Germany). Sodium methoxide (25 wt% in methanol) and methanolic HCl (3 M) were obtained from Sigma-Aldrich (Taufkirchen, Germany). An internal standard A consisting of dipentadecanolyl-sn-glycero-phosphocholine (Sigma-Aldrich) dissolved in methanol was used for the quantification of glycerophospholipid FAs only. Pentadecanoic acid, cholesteryl pentadecanoate, tripentadecanoin and 1,2-dipentadecanoyl-sn-glycero-phosphocholine dissolved in methanol/chloroform (35:15 by vol.) was used as internal standard B to quantify FA concentrations of individual lipid fractions or total lipids. FA oxidation was minimized by adding 2 g/l 2,6-di-*tert*-butyl-*p*-cresol (butylated hydroxytoluene, BHT; Sigma-Aldrich) to all standard solutions.

Cheek Cell Sampling Procedure

Different methods were tested by a trained adult panel to test sampling procedures for adults and young children. The optimal adult sampling procedure comprised mouth cleaning with tap water three times prior to sampling, followed by rubbing of each inner cheek side with a Gynobrush Plus (Herenz, Hamburg, Germany). Subsequently, the mouth was rinsed with 10 ml pure water (Braun, Melsungen, Germany), and the rinsing solution containing cells washed off the inner cheeks was collected in a tube. The tube with the brush used for scraping inserted was centrifuged at 1,400×*g* for 10 min at 4 °C. The supernatant was discarded, the cell pellet resuspended with distilled water to a total volume of 1 ml, and 25 µl of this volume was used for cell counting. The remaining volume was centrifuged (1,400×*g*, 10 min, 4 °C), the supernatant discarded, and cheek cells either processed immediately or stored at −80 °C until analysis.

The cheek cell sampling procedure for infants <1 year of age was identical, but did not include mouth cleaning before or mouth rinsing after swabbing.

The average cell number obtained by both procedures was estimated by dividing the volunteers ($n = 10$) into two groups: group 1 executed the "children" procedure without mouth rinse, group 2 the "adult" procedure with repeated mouth rinse. After 1 week, sampling was repeated, but

group 1 executed the "adult" procedure and group 2 the "children" procedure. Cells were counted with a hemocytometer (dilution factor 50,000) after staining with trypan blue.

Pooled cheek cell samples were used for method development. Cell samples were collected from each volunteer separately at the same time. Samples were centrifuged at 1,400×*g* for 10 min at 4 °C, supernatants discarded, cell pellets redissolved in 500 µl distilled water and combined in a 15-ml plastic tube. Distilled water was added to a total volume of 10 ml, and the cell suspension shaken vigorously. A 50-µl aliquot was used for cell counting. Based on total cell count, aliquots were obtained with defined cell numbers. Cell sampling for each analysis was conducted at a different day, and numbers of volunteers varied depending on the need of cell numbers; thus, the composition of each cheek cell pool was different, and only the coefficient of variation (CV) can be compared between sample sizes.

The Analysis of Cheek Cell Glycerophospholipid FAs

Glycerophospholipid FAs determinations were based on the method of Glaser et al. [15]; 1.3 ml methanol and 100 µl standard A were added to the cheek cell pellet, the suspension was placed in an ultrasound water bath (120 W, 35 kHz) for 20 min, and precipitated proteins were separated by centrifugation (3,030×*g*, 20 min, 4 °C). Glycerophospholipid containing supernatant was transferred into a 4-ml brown glass vial. Glycerophospholipid FAs were transesterified into FAME after the addition of 50 µl sodium methoxide solution (25 wt% in methanol) at room temperature (21 °C). The reaction was stopped after 4 min with 150 µl 3 M methanolic HCl. FAMEs were extracted twice with 600 µl hexane, dried under a steady nitrogen flow and re-dissolved in 30 µl hexane (containing 2 g/l BHT) for gas chromatographic analysis.

Determination of Cheek Cell TAG and Total Phospholipids

TAG contents in the methanolic supernatant were determined to evaluate their contribution to the total phospholipid content. Briefly, the cell pellet was suspended in 1.4 ml methanol without standard and placed in an ultrasound water bath (120 W, 35 kHz) for 20 min. The precipitated proteins were separated by centrifugation (20 min, 3,030×*g*, 4 °C). After transfer, the methanolic supernatant was dried under nitrogen. The lipid residue was dissolved in 400 µl chloroform-methanol and separated by thin layer chromatography (TLC; SIL G-25, Macherey-Nagel, Düren, Germany) with a mixture of *n*-heptane, diisopropyl ether and acetic acid (60:40:3) as mobile phase [17]. After visualization of the components with 2′,7′-dichlorofluorescein under UV light, the PL and TAG bands were individually scraped off the plate and transferred into brown glass tubes. FAMEs were synthesized in 1.5 ml methanolic HCl at 85 °C for 45 min. Methyl esters were extracted twice with 1 ml hexane, dried under a nitrogen flow and redissolved in 30 µl hexane (containing 2 g/l BHT) for gas chromatographic analysis. Proportions of TAG contents in the PL fraction were calculated by peak area comparison of respective individual FA.

Analysis of Cheek Cell Total Lipids

Glycerophospholipid and total lipid FA concentrations of cheek cells were compared to estimate the glycerophospholipid proportion to total lipids. Briefly, cheek cells were lysed in 2 ml chloroform/methanol (2:1 by vol.) and 25 µl standard B. The solution was placed in an ultrasound water bath (120 W, 35 kHz) for 20 min and centrifuged at 3,030×*g* for 10 min at 4 °C. The supernatant containing total cheek cell lipids was transferred into a 4-ml brown glass vial and dried under a continuous nitrogen flow. The dried lipids were heated to 85 °C for 45 min in 1.5 ml 3 M methanolic HCl transesterifying FAs into their methyl esters. The FAMEs were extracted twice with 1 ml hexane, dried under nitrogen and re-dissolved in 50 µl hexane (containing 2 g/l BHT) for gas chromatographic analysis.

Determination of Plasma Glycerophospholipid FA

Glycerophospholipid contents of plasma and cheek cell FAs were compared in controls and patients with inborn errors of metabolism. Plasma glycerophospholipids were analyzed by the method of Glaser et al. [15].

Gas Chromatography

Individual FAMEs were quantified by gas chromatography with flame ionization detection (GC-FID) on a Agilent 5890 series II GC (Waldbronn, Germany), equipped with a BPX 70 column (25 m × 0.22 mm, 0.25-µm film, SGE, Weiterstadt, Germany).

FAMEs obtained from samples with more than 1.5×10^5 cells were injected at a temperature of 250 °C with a split ratio of 1/30. An optimized temperature program was used. Starting at 150 °C, the oven temperature was increased by 2.5 °C per minute to 180 °C, by 1.5 °C per minute to a final temperature of 200 °C, which was held for 1 min. Helium was used as carrier gas. The initial pressure was set to 0.9 bar, increasing by 0.02 bar per minute to 1.2 bar, 0.05 bar per minute to 1.5 bar, and 0.1 bar per minute to the final pressure of 2.0 bar. The final pressure was held until completion of the temperature program [15].

FAME obtained from samples with fewer than 1.5×10^5 cells were injected at a temperature of 300 °C in splitless mode. While pressure programs for split and splitless mode were identical, the temperature program was adjusted as follows: starting temperature 60 °C, temperature increase by 20 °C per minute without initial hold to 150 °C, 2.5 °C per minute to 185 °C, 0.5 °C per minute to 195 °C and final isothermal period of 2 min.

Data Quantitation

Individual FAMEs were identified by comparison with authentic standards (GLC-569B, Nu-Check Prep, Inc. Elysian, MN). A FAME mixture (GLC-85) was used as external standard, which was analyzed directly by GC and used to determine the response of each FAME relative to pentadecanoic acid methyl ester (internal standard). Peaks were integrated with EZChrom Elite version 3.1.7 (Agilent, Waldbronn, Germany).

Statistical Analysis

The results for FAs with chain lengths of 14–24 carbon atoms were expressed as absolute concentrations (nmol/cell) or percentages of total analyzed FAs (mole%). FA profiles of pooled cheek cell samples were presented as mean ± standard deviation (SD). Intra-assay was performed by measuring individual FA proportions in ten aliquots of three pooled cheek cell samples with different FA compositions and expressed as CV in percent. Inter-assay was done by measuring individual FA proportions in eight aliquots of three pooled cheek cell samples with different FA compositions over a period of 4 weeks and expressed as CV in percent. A linear regression model was used to determine the coefficients of determination to evaluate relationships between cheek cell numbers and FA concentrations. Correlation analysis of FA contents in cheek cells and plasma were performed according to Pearson for normally distributed variables. Differences between cheek cell sampling methods with and without mouth rinsing, and differences between plasma and cheek cell glycerophospholipid FAs were evaluated using paired *t* tests. PASW Statistics for Windows, version 17.0.2 (IBM SPSS), was used for all statistical calculations.

Results

Cheek Cell Sampling

The average cell yield (mean ± SD) with mouth rinsing was $8.3 \times 10^5 \pm 4.3 \times 10^5$ cells, which was significantly higher compared to $5.3 \times 10^5 \pm 2.4 \times 10^5$ cells without mouth rinsing ($n = 10$, $P < 0.001$). The minimal and maximal numbers of cells collected with mouth rinsing were 2.1×10^5 and 1.6×10^6 cells, and without 1.5×10^5 and 9.0×10^5 cells, respectively. Inclusion of mouth rinsing increased the cell yield by approximately 60%.

FA Composition of Cheek Cell Glycerophospholipids

Table 1 shows the FA composition of cheek cell glycerophospholipids present in cell amounts representative for sampling procedures without or with mouth rinsing (5.0×10^5 cells or 8.5×10^5 cells). Results of sample aliquots containing 10^5 cells are included, as this sample size was the smallest that could be analyzed with acceptable variations.

Samples from different subjects were combined for each tested cell number; thus, the FA composition of pooled cell samples varied, and only CV can be compared between sample sizes. CV ranged from 1.4 to 9.7% in samples with 10^5 cells, from 1.3 to 9.4% in samples containing 5.0×10^5 cells and from 0.7 to 8.2% in samples with 8.5×10^5 cells.

Oleic, palmitic, linoleic and stearic acid were the quantitatively dominant FAs, which together comprised approximately 77% of total FAs. Monounsaturated FAs were the largest FA group, followed by saturated FAs, n-6 and n-3 PUFAs (Table 1).

The inter-assay reproducibility was determined by analyzing eight aliquots of pooled cell samples with different cell numbers (10^5, 5.0×10^5 or 8.5×10^5 cells) over a period of 4 weeks (Table 2). The CV of 5.0×10^5 cell samples ranged from 2.6 to 9.1%, and for 8.5×10^5 cell samples from 1.1 to 9.8%, respectively. The CV of samples containing 10^5 cells ranged from 2.0 to 9.3%, except for FAs with a proportion of less than 0.5% of total FAs, the CV values of which were about 14%. Proportions of individual FAs were comparable to results of the intra-assay.

Samples with low cell numbers ($<1.5 \times 10^5$ cells) had to be analyzed in splitless mode because of the low concentrations of some FAs. Solvents and reagents for lipid extraction and FAME synthesis were reduced to half of the standard volume. This was necessary as chemicals were contaminated with traces of palmitic and stearic acid. The reduction in volume reduced the contamination by approximately 50–2.2% for palmitic acid and 3.7% for stearic acid, based on corresponding FA concentrations in 10^5 cheek cells. It was not possible to reduce the background of C14:0 and C20:2n-6; therefore, both FAs were excluded from the analysis.

Table 1 Intra-assay reproducibility of glycerophospholipid FA compositions in cheek cell samples of different size

Linear Relationship of Cell Numbers and FA Concentrations

Aliquots containing 10^5–10^6 cells of a pooled cheek cell sample were analyzed for the determination of the application range. Coefficients of determination were evaluated for absolute values in a linear regression model. The r values for all FAs were higher than 0.995, except for EPA ($r = 0.993$), C22:5n-6 ($r = 0.992$) and C22:0 ($r = 0.995$). CV values calculated for FA proportions were below 10%, with the exception of C22:5n-6 (16.7%). The concentrations of mead acid (C20:3n-9) and C20:3n-3 remained constant despite increasing cell numbers, indicating that the size of the evaluated peaks was compromised by contaminations, which prohibited quantification of these FAs.

Contamination of Phospholipid-Associated FAs by TAG-Derived FA

The total TAG FA content in the methanolic supernatant was determined to estimate its contribution to the total PL FA content ($n = 4$). The degree of contamination depended on centrifugation time. The total TAG FA content averaged 5.4 ± 1.2% of total PL, if the supernatant was centrifuged for 10 min at 3,030×g and 4 °C. Increasing the centrifugation time to 20 min resulted in a reduced total

TAG content of 2.3 ± 0.3% of PL. Individual FAs were affected differently by TAG contamination. Prolonged centrifugation reduced palmitic and stearic acid contaminations from 8.5 and 3.6% to 4.3 and 1.9%, respectively. These figures were 10.7 and 3.3% for C16:1n-7, 4.0 and 1.4% for oleic acid, and 7.9 and 2.0% for linoleic acid. TAG-bound n-3 PUFAs were below the detection limit.

Stability of Cheeks Cell Glycerophospholipid FA Composition at Ambient Temperature

A pooled cheek cell sample was split into equal volumes, centrifuged, and cells kept either in saline solution (NaCl, 0.9%) or distilled water over a period of 48 h at ambient temperatures. Nine aliquots were analyzed. Total glycerophospholipid FAs decreased by about 25% in saline and pure water (Fig. 1). FA patterns did not change over the storage period because the concentrations of individual FAs were evenly affected, as shown by a CV of less than 10% for all FA proportions, except for 22:5n-6 and 18:3n-3 in saline solution (10.6 and 12.9%, respectively), and 22:5n-6 (10.8%) in distilled water.

Comparison Between FA Compositions of Cheek Cell Glycerophospholipids and Total Lipids

Table 3 shows the absolute (nmol/5 × 10^5 cells) and relative (mole%) FA content of total lipids and glycerophospholipid FAs of a pooled cheek cell sample. Approximately 75% of FAs in total lipids were contributed by glycerophospholipids, but major differences were observed for some individual FAs. Proportions of stearic, palmitoleic, oleic, linoleic and γ-linolenic acids were significantly higher in glycerophospholipids compared to total lipids. On the contrary, the proportions of saturated FAs, with the exception of stearic acid, or most FAs with 20 and more carbon atoms were significantly reduced in glycerophospholipids compared to total lipids (paired t test, $P < 0.05$). In cheek cells glycerophospholipid ARA and DHA comprised approximately two-thirds of the total ARA and DHA content.

Comparison of Cheek Cell and Plasma Glycerophospholipid Patterns

Cheek cell and plasma glycerophospholipids were compared in participants of a quality of life study (Table 4). Cheek cells contained mainly monounsaturated FAs (39.1 ± 4.9 mol%), plasma mainly saturated FAs (45.0 ± 1.2 mol%). Oleic acid (29.9 ± 1.5 mol%) was the predominant FA in cheek cells, while palmitic acid (30.7 ± 2.1 mol%) showed the largest percentage in plasma. However, in both compartments the total amount of palmitic, stearic, oleic and linoleic acid

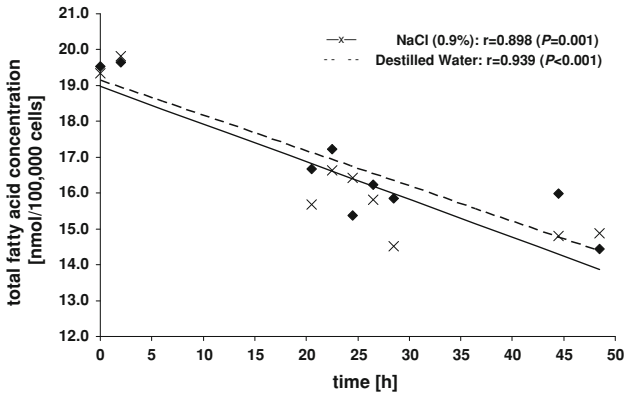

Fig. 1 Glycerophospholipid total FA content in cheek cells kept at ambient temperature in saline solution (NaCl, 0.9%) or distilled water over periods up to 48 h

comprised approximately 78% of the total FAs. ARA and DHA contents were approximately three times higher in plasma than in cheek cells (9.8 vs. 3.39 mol% and 3.12 vs. 0.88 mol%, respectively).

Numerous saturated and polyunsaturated FAs, but not the monounsaturated FAs were significantly correlated between cheek cell and plasma glycerophospholipids (Table 4). The correlation coefficients for DHA and EPA were $r = 0.83$ and 0.64 ($P < 0.001$), respectively; their sum showed a correlation of $r = 0.47$ ($P < 0.010$). The relationships of plasma and cheek cell DHA and EPA appeared linear over the entire concentration range observed (Fig. 2). The correlation coefficients for ARA and linoleic acid were $r = 0.44$ ($P = 0.017$) and $r = 0.58$ ($P = 0.001$), respectively.

Discussion

A strict sampling procedure is important to collect adequate amounts of cheek cell samples of high quality. Studies showed that cleaning the mouth prior to sampling did reduce possible food particle residues, although some cheek cells might get lost through this process [13]. Furthermore, using a brush instead of a cotton swab for cheek cell sampling was superior with respect to the overall cell yield [11], and rinsing the mouth after scraping the inner cheeks led to significantly higher cell yields [13]. We combined these procedures for cheek cell sampling and observed an increased cell yield of up to 60% by the additional mouth rinse after scraping.

Rinsing the mouth is not applicable when collecting cheek cells in infants or young children, which might limit the FA profiling. In a study with preterm infants cheek cells were collected with a cotton swab up to day 14 of life and at week 52 [9]. The average cell yield was

$1.45 \times 10^5 \pm 0.77 \times 10^5$ cells without mouth rinsing. Our tests with adults showed that the average cell yield with a cotton swab is approximately two-thirds compared to the yield with a small endocervical brush (data not shown). The use of a brush might be crucial to collect a sufficient amount of cells ($>10^5$ cells) in young children for a reliable analysis of glycerophospholipid FAs with our method.

Preliminary tests showed that cheek cells are robust and hard to disrupt by isolated applications of detergents, ultrasound or polar solvents. Furthermore, some methods inherently include long processing times (freezing), the risk of contamination (grinding, ultrasound micro tip) or are unsuitable for the analytical procedure (water, detergents). Thus, a combination of methanol and ultrasound was used to disrupt cell membranes. The degree of disruption was >90% (data not shown).

Methanol was chosen as solvent, as it enables the direct transfer of the two-step procedure developed for the selective preparation of FAMEs from glycerophospholipid-bound FAs in plasma [15]. After centrifugation the supernatant contained the polar lipids and only minor amounts of TAG and cholesterol esters (CEs). CEs, non-esterified fatty acids and sphingomyelin do not contribute to synthesized FAMEs, as their FAs are not transesterified under the alkaline conditions applied [15]. However, small amounts of TAG remain in the cheek cell lipid extract, which accounted for 2.3 ± 0.3% of total PLs.

In this regard, it is notable that the centrifugation time affects the TAG content in the supernatant. Increasing the

centrifugation time to 20 min reduced the TAG content of individual FAs by 50–80% compared to 10 min. No further improvements were observed for centrifugation times greater than 20 min. The underlying mechanism is not known, but TAGs are possibly bound to cell fragments with much higher molecular weights.

Methanol is a potent extraction solvent for polar lipids. The recovery rate of plasma phospholipids extracted with methanol compared to chloroform-methanol (2:1) is approximately 90% [15]. Furthermore, losses through the interaction of lipids with a stationary phase are excluded. This might be crucial for small sample volumes as losses of plasma PL separated by solid phase extraction (SPE) or TLC were reported to be 6.5–60% [18–20], although early studies showed recovery rates of almost 100% for PLs [21, 22]. The differences observed may relate to the samples analyzed; high recovery rates were reported for lipid standards only, but not for the complete extraction procedure of plasma PL [19]. Another aspect, which seems to limit the SPE separation of lipids in cheek cells, is the lipid to sorbent ratio, which should be greater than 2.5% [20]. The total PL concentration of cheek cell samples (5.0×10^5–8.0×10^5 cells) averages 60–110 µg; for an optimal PL recovery the sorbent weight needs to be less than 2.4–4.4 mg.

Data on the precision of glycerophospholipid FA analysis have only been published for plasma so far [15]. The described CV for glycerophospholipid FA determinations ranged from 1.0 to 10.5%, which is in accordance to our cheek cell data.

A minimum of 10^5 cheek cells is needed for a precise glycerophospholipid FA profiling. At this level some FA concentrations are below the detection limit, or CVs are greater than 10%. However, proportions of major FAs are equal to those in samples with higher cell numbers; thus, samples with 10^5 cells are still suitable for cheek cell FA profiling. For samples smaller than 10^5 cells, a reliable quantification seems not to be possible with our method. It does not reflect the actual FA profile as contaminations of solvents with palmitic and stearic acid significantly falsify the proportion of all FA.

The identification of false-positive peaks is important for an accurate qualification of FAs. This not only defines the lower limit of the method, it also excludes FAs from analysis. The systematic analysis of blanks gave information about contaminations derived from chemicals or consumables. Mainly palmitic and stearic acid traces were found in solvents, but also a smaller amount oleic acid. Splitless injection of blanks with BHT showed an additional peak, which co-eluted with C14:0. This was identified as a co-product of BHT. Small peaks caused by not identified sample-derived compounds can also cause false-positive peaks. They have been identified by the linear increase of cell numbers (10^5–10^6), i.e., peaks, which did not increase proportionally to the cell concentration were excluded, such as peaks co-eluting with mead acid (20:3n-9) and C20:2n-6. An increased mead acid level in plasma indicates a deficiency of essential FAs [23]. The inability to detect mead acid in cheek cells limits the use of this compartment as an essential FA deficiency marker.

Connor et al. [10] determined the cheek cell PL FA pattern of infants on various diets. The observed distribution of FAs is similar to our results, except for C18:1n-9 and C18:1n-7; both FAs combined contributed a 5–10% higher proportion in our study population. The observed differences might relate to higher dietary oleic acid intakes by our volunteers. Moreover, oleic acid is preferentially incorporated in glycerophospholipids, as shown by Glaser et al. [15]. Data presented by other authors are limited to PL PUFA contents only; saturated and monounsaturated FAs were summarized [7, 11]. Reported PUFA levels are comparable in all studies. However, the sum of saturated FAs tended to be lower in our study. Again, this might reflect dietary differences or the exclusion of sphingophospholipids, but could also be explained by a reduced palmitic and stearic acid contamination in our analyses compared to those previously reported. The average DHA content observed in our study cohort of 0.88 ± 0.29 mol% agrees with previous studies [7, 10, 11].

The concentration of the total PL fraction was reported to be 115 ± 35 μg/10^6 cells by comparison to a standard lipid mixture [13]. This is comparable to the glycerophospholipid total FA concentration of our study, which averaged 317.0 ± 9.4 nmol/10^6 cells (88.6 ± 2.6 μg). Our data suggest that most FAs in cheek cells originate from the glycerophospholipid fraction (75.6 ± 1.6%), which is much higher than the proportion reported by Devereux-Graminski and Sampugna for human buccal cheek cells (11–14%) [13]. They also described a free FA content of 14–23%, which seems to be unusually high. The observed results could relate to phospholipase A_2 activity, which catalyzes the hydrolysis of membrane glycerophospholipids into free FAs and lysophospholipids [24]. In agreement with our results, PLs were found to be the major fraction in cheek cells of pigs [25, 26]. These authors determined the distribution of lipid fractions by photodensitometry and lipid proportions was based on total molar amounts of lipids, including cholesterol. The differences in PL contents observed in comparison to our results might be explained by interspecies differences, but also by the applied analytical methods. The glycerophospholipid content in our study was based on the total FAME content analyzed by GC-FID.

In addition, proportions of ARA, EPA and DHA in glycerophospholipids are lower compared to these LC-PUFAs in total lipid FAs. This seems to be in contrast to erythrocytes where phosphatidyletholamine (PtdEtn) showed higher LC-PUFA proportions than total lipids [27]. On the other hand, the LC-PUFA proportion of phosphatidylcholine (PtdCho) is lower than that of total lipids. Thus, the lower LC-PUFA levels of glycerophospholipids may be related to the different distribution of PtdCho and PtdEtn, which is approximately 2:1 (PtdCho:PtdEtn) in cheek cells [13].

The impact of distilled water and saline solution (NaCl, 0.9%) on the quality of the cheek cell samples was tested over 48 h at room temperature. Interestingly, the total FA concentration decreased over time, but FA compositions did not change. Distilled water had no adverse effect on the stability of cheek cells or the FA concentration. This suggests that the addition of antioxidants to cheek cell samples is not required if only proportions are determined.

Previous studies reported that the cheek cell FA composition reflects the dietary FA intake as well as erythrocyte and plasma levels of essential PUFAs [7, 10–12]. Good correlations were shown for n-3 FAs in plasma and cheek cell PLs, and a trend to lower correlations for ARAs [7, 10, 11]. This is in accordance with our results for glycerophospholipid FAs. Proportions of ARA and DHA differ strongly in plasma and cheek cells, and may limit the latter as a FA status marker. The biological variances in plasma and cheek cells were comparable in our cohort; nevertheless, the precision of the cheek cell method is suitable to detect even small differences in cheek cell glycerophospholipid FA components.

We conclude that this non-invasive method for cheek cell FA analysis is reliable, even if cell numbers are limited. The applied modifications to sampling, non-chromatographic isolation of glycerophospholipids and synthesis of FAME result in a highly accurate determination of cheek cell glycerophospholipid FAs. The precision of this method is comparable to conventional invasive methods determining the n-3 FA status in humans, based on blood lipid FA analyses. Therefore, this novel technique could be used for interventional or epidemiological studies.

Acknowledgments We are truly grateful to the ten volunteers who donated their cheek cells for this work. We also acknowledge the

financial support by the Federal Ministry of Education and Research (project number: 0315680B). B. Koletzko is the recipient of a Freedom to Discover Award of the Bristol-Myers Squibb Foundation, New York, NY. The method for glycerophospholipid FA analysis in cheek cells and plasma described in this article is in patent pending status.

Abstract The association between hypercholesterolemia and elevated serum apolipoprotein B (APOB) has generated interest in APOB as a therapeutic target for patients at risk of developing cardiovascular disease. In the clinic, mipomersen, an antisense oligonucleotide (ASO) APOB inhibitor, was associated with a trend toward increased hepatic triglycerides, and liver steatosis remains a concern. We found that siRNA-mediated knockdown of *ApoB* led to elevated hepatic triglycerides and liver steatosis in mice engineered to exhibit a human-like lipid profile. Many genes required for fatty acid synthesis were reduced, suggesting that the observed elevation in hepatic triglycerides is maintained by the cell through fatty acid uptake as opposed to fatty acid synthesis. Fatty acid transport protein 5 (*Fatp5*/*Slc27a5*) is required for long chain fatty acid (LCFA) uptake and bile acid reconjugation by the liver. *Fatp5* knockout mice exhibited lower levels of hepatic triglycerides due to decreased fatty acid uptake, and shRNA-mediated knockdown of *Fatp5* protected mice from diet-induced liver steatosis. Here, we evaluated if siRNA-mediated knockdown of *Fatp5* was sufficient to alleviate *ApoB* knockdown-induced steatosis. We determined that, although *Fatp5* siRNA treatment was sufficient to increase the proportion of unconjugated bile acids 100-fold, consistent with FATP5's role in bile acid reconjugation, *Fatp5* knockdown failed to influence the degree, zonal distribution, or composition of the hepatic triglycerides that accumulated following *ApoB* siRNA treatment.

Introduction

Elevated LDL cholesterol (LDL-c) promotes atherosclerosis, and it is well established that reducing LDL-c helps to mitigate the risk of developing cardiovascular disease in patients with hypercholesterolemia [1–7]. LDL-c consists of a single apolipoprotein B-100 (APOB-100) molecule, cholesterol, cholesterol-esters and triacylglycerols that are comprised of various dietary and de novo synthesized fatty acids [8]. In the liver, APOB is required for very low density lipoprotein (VLDL) formation and serves as the scaffold to solubilize cholesterol and fatty acids (in the form of triglycerides) for secretion into the blood for circulation [8]. An association between hypercholesterolemia and increased APOB protein levels, together with the observation that reductions in *ApoB* synthesis reduce LDL-c and the incidence of atherosclerosis, has generated interest in APOB as a therapeutic target [9–13]. Both antisense oligonucleotides (ASOs) and small interfering RNAs (siRNAs) targeting *ApoB* reduce LDL-c in mice and in non-human primates [14–18]. In mice, *ApoB* ASOs reduced LDL-c without inducing hepatic steatosis, a liability of microsomal transfer protein (MTP) inhibitors that block triglyceride-rich lipoprotein assembly and secretion [19]. In patients, mipomersen, an *ApoB* targeting ASO, reduces both LDL-c and APOB, demonstrating the potential for an *ApoB*-targeted therapeutic [20–24]. Liver steatosis induced by inhibiting *ApoB*, however, remains an important concern. Recently, mipomersen administration at a sub-maximum efficacious dose was shown to be associated with a trend toward increased intra-hepatic triglyceride (IHTG) content for mipomersen-treated patients with one of the ten patients developing mild steatosis [20]. In addition, mice harboring a base-pair deletion in the coding region of *ApoB* (*ApoB-38.9*) exhibited hepatic triglyceride accumulation [25]. In order to attenuate the risk of liver steatosis associated with an *ApoB*-targeted therapeutic, one approach would be to combine an *ApoB* ASO or siRNA with another therapeutic that increases the clearance of hepatic triglycerides.

Fatty acid transport protein 5 (*Fatp5*/*Slc27a5*) mediates the uptake of long chain fatty acids (LCFAs) to the liver and is involved in bile acid reconjugation during enterohepatic recirculation [26, 27]. *Fatp5* knockout mice exhibit lower levels of hepatic triglycerides and free fatty acids due to decreased liver fatty acid uptake [27]. Furthermore, Doege et al. [25] recently showed that adenovirus-shRNA-mediated silencing of *Fatp5* mRNA not only protected mice from high fat diet-induced liver steatosis but also reversed steatosis once it was established. This suggested that a FATP5 inhibitor may be an attractive combination therapy with an APOB-targeted therapeutic.

Besides of its role in free fatty acid uptake, FATP5 also plays a critical role in reconjugation of bile acids during enterohepatic recirculation to the liver, and complete deletion of *Fatp5* resulted in a significant increase in unconjugated bile acids in both bile and serum [26]. Activation of FXR, a bile acid nuclear receptor, with bile acids or synthetic activators has been shown to reduce the secretion of triglyceride-rich VLDL from the liver in mice, which was associated with a decrease in *Srebp1* and *2* pathway genes [28]. The involvement of FATP5 in bile acid metabolism suggests that it too may play a role in hepatic triglyceride metabolism via FXR. However, the contributions of the bile acid reconjugation activity of FATP5 on hepatic steatosis or the contribution of FATP5 on APOB-induced steatosis are currently unknown. By utilizing two siRNAs specifically targeting *Fatp5* and *ApoB*, we evaluated the ability of *Fatp5* siRNA treatment to alleviate *ApoB* siRNA-induced liver steatosis.

Materials and Methods

siRNA Design

siRNAs were designed to the mRNA transcripts using a previously published design algorithm [34]. siRNA sequences contained the following chemical modifications added to the 2′ position of the ribose sugar when indicated: deoxy (d), 2′ fluoro (f), or 2′ O-methyl (o) [34]. Modification abbreviations are given immediately preceding the base to which they were applied. Passenger strands were capped with an inverted abasic nucleotide on the 5′ and 3′ ends. The control siRNA sequence (Cntrl siRNA) consists of:
iB;fluU;fluC;fluU;fluU;fluU;fluU;dA;dA;fluC;fluU;fluC;
fluU;fluC;fluU;fluU;fluC;dA;dG;dG;dT;dT;iB
passenger strand and
fluC;fluC;fluU;omeG;omeA;omeA;omeG;omeA;omeG;
omeA;omeG;fluU;fluU;omeA;omeA;omeA;rA;rG;rA;omeU;
omeU guide strand sequences.
The *Fatp5*(951) siRNA sequence consists of:
iB;fluC;fluU;dG;fluC;fluC;dA;fluU;dA;fluU;fluU;fluC;dA;
fluU;fluC;fluU;fluU;fluU;dA;fluC;dT;dT;iB
passenger strand and

rG;rU;rA;omeA;omeA;omeG;omeA;fluU;omeG;omeA;
omeA;fluU;omeA;fluU;omeG;omeG;fluC;omeA;omeG;
omeU;omeU guide strand sequences.
The *ApoB*(10168) siRNA sequence consists of:
iB;fluU;fluC;dA;fluU;fluC;dA;fluC;dA;fluC;fluU;dG;dA;
dA;fluU;dA;fluC;fluC;dA;dA;dT;dT;iB
passenger strand and
rU;rU;rG;omeG;fluU;omeA;fluU;fluU;fluC;omeA;omeG;
fluU;omeG;fluU;omeG;omeA;fluU;omeG;omeA;omeU;
omeU guide strand sequences.

siRNA Synthesis

siRNAs were synthesized by methods previously described [35]. For each siRNA, the two individual strands were synthesized separately using solid phase synthesis, and purified by ion-exchange chromatography. The complementary strands were annealed to form the duplex siRNA. The duplex was then ultrafiltered and lyophilized to form the dry siRNA. Duplex purity was monitored by LC/MS and tested for the presence of endotoxin by standard methods.

Preparation of siRNA-Lipid Nanoparticle (LNP) Complex

LNPs were made as described previously [36]. The encapsulation efficiency of the particles was determined using a SYBR Gold fluorescence assay in the absence and presence of triton, and the particle size measurements were performed using a Wyatt DynaPro plate reader. The siRNA and lipid concentrations in the LNP were quantified by a HPLC method, developed in house, using a PDA detector.

In Vivo siRNAs Treatments

All in vivo work was performed according to an approved animal protocol as set by the Institutional American Association for the Accreditation of Laboratory Animal Care. C57Bl/6 mice engineered to be hemizygous for a knockout of the LDL receptor and hemizygous for the overexpression of the human cholesterol ester transfer protein (CETP) driven by the endogenous apoA1 promoter within a C57Bl/6 background [B6-Ldlr<tm1>Tg(apoA1-CETP); Taconic] were used for these studies. Mice ~16–20 weeks of age were fed Lab Diets (5020 9F) starting 2 weeks prior to the start of the study. siRNAs were administered by intravenous (i.v.) injection. Animals were dosed on days 0 and 14 with either 3 mg/kg of a single LNP formulated siRNA or 1.5 mg/kg of two LNP formulated siRNAs for a 3 mg/kg total siRNA combination dose. For siRNA combinations, siRNA were formulated individually and hand-mixed immediately prior to injections. Animals were euthanized by CO_2 inhalation. Immediately after euthanasia, serum was collected using serum separator tubes and allowed to clot at room temperature for 30 min. Liver sections were excised, placed in either RNA Later (Qiagen) (right medial lobe), 10% buffered formalin (10% NBF, left medial lobe), or flash frozen (the remainder), and stored until further use.

RNA Isolation and qRT-PCR

RNA was isolated using an RNeasy96 Universal Tissue Kit (Qiagen) according to the supplied product protocol and as described previously [37]. TaqMan Gene Expression Assays (Applied Biosystems) were performed as described within the product protocol using the following primer probes, Mm00447768_m1 for *Fatp5*, Mm01545154_g1 for *ApoB*, and Cat# 4352339E for the reference, *Gapdh*. All reactions were performed in duplicate, and data were analyzed using the ddCt method with *Gapdh* serving as in [38]. Data represented as the $\log_2$-fold change (ddCt) relative to the control siRNA. For analysis of the selected *Srebp1c* and *Srebp2* pathway genes and *Scd1*, expression was normalized to an average of that of mouse *β-actin* (*Actb*), Glyceraldehyde 3-phosphate dehydrogenase (*Gapdh*), Beta-glucuronidase (*Gusb*), Hypoxanthine–guanine phosphoribosyltransferase (*Hprt1*), Peptidylprolyl isomerase A (*Cyclophilin A*/*Ppia*) and ribosomal protein 113a (*Rp113a*) in each sample. Expression levels of all genes analyzed were normalized to an average of the housekeeping genes (listed above) to obtain dCt. Fold regulation is calculated as: ddCt of gene in treatment group/dCt of gene in control group. Significance (p value) was calculated from a two-tailed t test between control and treatment groups. Accession numbers for the primer/probes used are listed in Supplemental Table 1.

Cholesterol and Triglyceride Analysis

Serum for cholesterol and triglyceride analysis was analyzed using Wako's total and HDL cholesterol kits according to the supplied product protocol and as described previously [37]. Non-HDL, which serves as an approximation for LDL, was calculated by subtracting HDL from total cholesterol measurements. The percent difference relative to the control siRNA was calculated using the following equation $\{100 \times [1-(\text{experimental/control})]\}$.

Histology and Hematology

Mouse livers were fixed with 10% neutral buffered formalin. One hepatic lobe was treated with osmium tetroxide solution, to visualize lipids, overnight at room temperature prior to paraffin embedding and processing. The other

hepatic lobe was embedded and processed in paraffin and hematoxylin and eosin (H&E) stained. Samples were sectioned at a thickness of 5 μm. The osmium-stained samples were digitalized using an Aperio ScanScope XT. Percent area (positive pixel count) was calculated using the positive pixel count algorithm (MAN-0024) supplied with the imaging software (Aperio). Samples were also reviewed by a board-certified veterinary pathologist and scored for inflammation and lipidosis using a semi-quantitative score.

Measurement of Serum APOB

The APOB levels in serum were measured by LC/MS as described previously [29]. The concentration of APOB peptide was calculated by dividing the area under the curve for the analyte by the area of its internal standard and multiplying by the internal standard concentration. The concentration of APOB was then converted to and reported as mg/dL.

LC/MS Sample Preparation and Analysis for Bile Acid Conjugation and Hepatic Triglycerides

Terminal bile samples from each group were collected using the stick and pull method. Samples were diluted 1:1,000 v/v in 50% acetonitrile + 0.1% formic acid/50% water + 0.1% formic acid, followed by the addition of 1 μM total internal standard solution (D_4-TCA, D_4-CA, D_4-GCA) (Sigma-Isotec, St. Louis, MO, USA). The mixture was vortexed for 10 s, centrifuged for 10 min at 15,000*g*, and then stored at −20 °C until LC/MS analysis. Supernatant was injected (10 μL) directly onto the LC/MS system.

A 50-mg slice of frozen liver from each animal was homogenized in 2-mL polypropylene tubes containing a 14-mm ceramic bead using a Precellys 24 homogenizer (Bertin Technologies, Montigny-le-Bretonneux, France). A non-naturally occurring internal standard solution (20 μL) containing TG 51:0 (Sigma Aldrich, St Louis, MO, USA) 0.8 mg/mL along with dichloromethane/methanol (2:1 v/v) was added to each sample prior to homogenization [39]. Samples were homogenized at 5,500 RPM, 2 × 30 s, with a 15 s pause between cycles. In order to generate a two layer liquid separation, 200 μL of distilled water was added, vortexed for 30 s, followed by centrifugation at 20,000*g* at 5 °C for 10 min. 10 μL of the lower layer, containing the lipids, was removed without disrupting the liver tissue homogenate disk. This was followed by dilution of the extracted lipid sample 1/50 in a solvent mixture (65% ACN, 30% IPA, 5% H_2O).

External endogenous calibration standards in buffer solution were used to cover the endogenous concentrations present in the bile and liver tissues. The inlet system was comprised of an Acquity UPLC (Waters, Milford, MA, USA). Bile and lipid extracts were injected (2 μL) onto a 1.8-μm particle 100 × 2.1 mm id Waters Acquity HSS T3 column (Waters). The column was maintained at 55 °C with a 0.4-mL/min flow rate for the lipid analysis and 65 °C with a 0.7-mL/min flow rate for the bile analysis. A binary gradient system was utilized for the analysis of both sample sets. Two different gradient conditions were used. For the lipid analysis, the same conditions were used as previously described [40]. For the bile acid analysis, water + 0.1% formic acid was used as eluent A. Eluent B consisted of acetonitrile + 0.1% formic acid (Burdick & Jackson, USA). A linear gradient (curve 6) was performed over a 13-min total run time. During the initial portion of the gradient, it was held at 80% A and 20% B. For the next 10 min, the gradient was ramped in a stepped linear fashion to 35% B (curve 5) in 4 min, 45% B in 7.5 min and 99% B in 9.5 min and held at this composition for 1.6 min. Hereafter, the system was switched back to 80% B and 20% A and equilibrated for an additional 2.9 min.

The inlet system described was directly coupled to a hybrid quadrupole orthogonal time of flight mass spectrometer (SYNAPT G2 HDMS; Waters MS Technologies, Manchester, UK). Electrospray (ESI) positive and negative ion ionization modes were used. In both ESI modes, a capillary voltage and cone voltage of ±2 kV and ±30 V, respectively, were used. The desolvation source conditions were as follows: for the desolvation gas 700 L/h was used and the desolvation temperature was kept at 450 °C. Data were acquired over the mass range of 50–1,200 Da.

The LC/MS data acquired was processed by the use of a quantitative data deconvolution package (Positive software by MassLynx; Waters, MA, USA). Data are presented as ± standard error of the mean (SEM). Differences between groups were computed by either Student's *t* test or by two-way ANOVA (GraphPad Prism, La Jolla, CA, USA). Post-test analysis for quantifiable variables was conducted using either Bonferroni or Mann–Whitney *U* non-parametric test with two-tailed *p* values. Values of $p < 0.05$ were considered statistically significant.

Lipid Nomenclature

The nomenclature utilized in this manuscript is in accordance with Lipidmaps (http://www.lipidmaps.org). In brief, a triglyceride described as TG 52:2 is interpreted as a triglyceride containing 52 carbons attached to the glycerol back-bone and two double bonds in the fatty acyl chain as described by Fahy et al. [41].

Results

Sustained Knockdown of Both ApoB and Fatp5 mRNA Transcripts was Achieved with siRNAs Administered Either Alone or in Combination

To investigate if we can simultaneously silence both *ApoB* and *Fatp5*, we administered siRNAs specifically targeting *ApoB* and *Fatp5*, alone and in combination, to CETP/LDLR hemizygous female mice (mice exhibiting a human-like lipid profile) fed a low-fat western diet. Changes to the lipid profile were obtained through a hemizygous mutation of the LDL receptor (±LDLR) and the hemizygous over-expression of a mouse apoA1 promoter-driven human CETP transgene (±apoA1-hCETP). This led to an elevation in LDL and a cholesterol profile that more closely resembled the HDL–LDL ratio observed in humans [29]. Female mice were fed a low-fat western diet ad libitum and treated with siRNAs formulated in a lipid nanoparticle (LNP) to achieve delivery to the liver [30]. Animals were dosed on days 0 and 14 with either 3 mg/kg of a single siRNA or 1.5 mg/kg of two siRNAs for a 3 mg/kg total siRNA combination dose. Efficacy was analyzed using qRT-PCR on liver samples collected on day 21. Analysis of mRNA expression levels revealed no appreciable difference in knockdown (KD) between *ApoB* siRNA treatments administered either alone or in combination with the *Fatp5* siRNA (Fig. 1a; ≥90% KD across all groups). Similar results were observed for the *Fatp5* siRNA, where ≥89% knockdown of *Fatp5* was observed (Fig. 1b).

Fatp5 Knockdown Impaired Bile Acid Reconjugation

The ratio of unconjugated/conjugated bile acid in the bile was used as a biological indicator for the loss of FATP5 activity following siRNA treatment to female mice fed a low-fat western diet ad libitum [26]. A significant increase in the proportion of unconjugated bile acids was observed for all *Fatp5* siRNA treatment groups, indicative of the loss of FATP5 activity (Fig. 2a; $p = 0.0003$, t test, Mann–Whitney post-test, cntrl siRNA groups vs. *Fatp5* siRNA groups). The unconjugated/conjugated ratio for the cntrl/cntrl siRNA group and the *Fatp5*/*Fatp5* siRNA group was 0.004 and 2.2, respectively. The ratio was lower for some of the *Fatp5* siRNA treatment groups when combined with the *ApoB* siRNA, but nevertheless exhibited a significant level of target engagement when compared with the control siRNA. Cholic acid in the *Fatp5* groups was the most predominant unconjugated bile acid found in bile (Fig. 2b), which showed a dramatic increase in concentration (0.77 mM in control siRNA vs. 77.95 mM in *Fatp5*) after knockdown of *Fatp5* ($p = 0.0003$, t test, Mann–Whitney post-test). Conjugated bile acids, specifically taurocholic acid (TCA), showed the reverse effect following *Fatp5* knockdown ($p = 0.1304$, t test, Mann–Whitney post-test). The levels of TCA decreased to 43.2 mM in comparison with the cntrl siRNA group 69.7 mM (data not shown). The ratio of unconjugated/conjugated bile acid in the serum reflected that of the bile, with a significant increase in the unconjugated levels (data not shown).

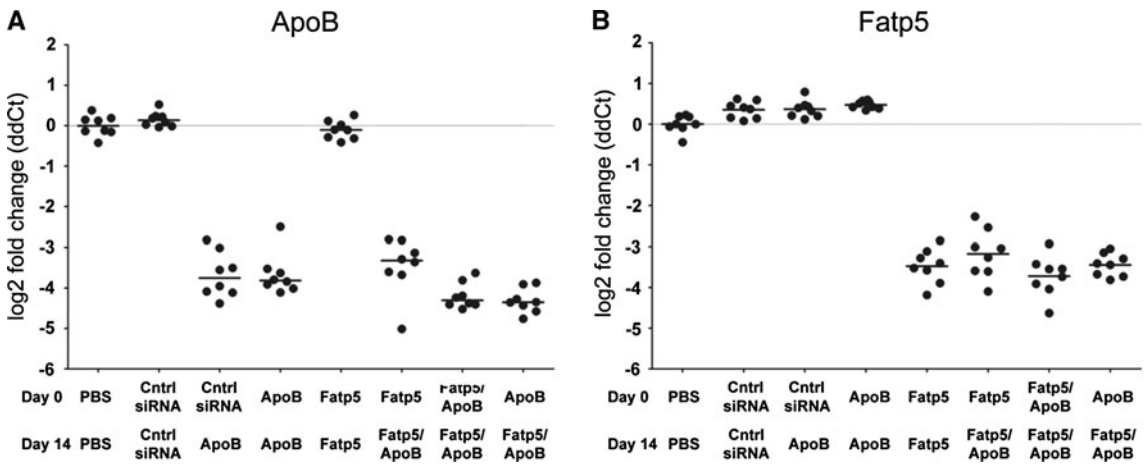

Fig. 1 Similar levels of *ApoB* and *Fatp5* mRNAs were observed for all groups containing siRNAs targeting these genes, either alone or in combination. Mice ($n = 8$/group) were treated with siRNAs targeting *ApoB* and *Fatp5* alone or in combination (*ApoB*, *Fatp5*, *Fatp5*/*ApoB*) at days 0 and 14. Gene expression was analyzed using qRT-PCR (TaqMan) on day 21 (**a**, **b**) post the initial dose. PBS and a control siRNA (*cntrl siRNA*) served as negative controls. Data represented as the log2 fold change (*ddCt*) relative to the cntrl siRNA treatment of individual animals (*circles*) and the group means (*bars*) are shown

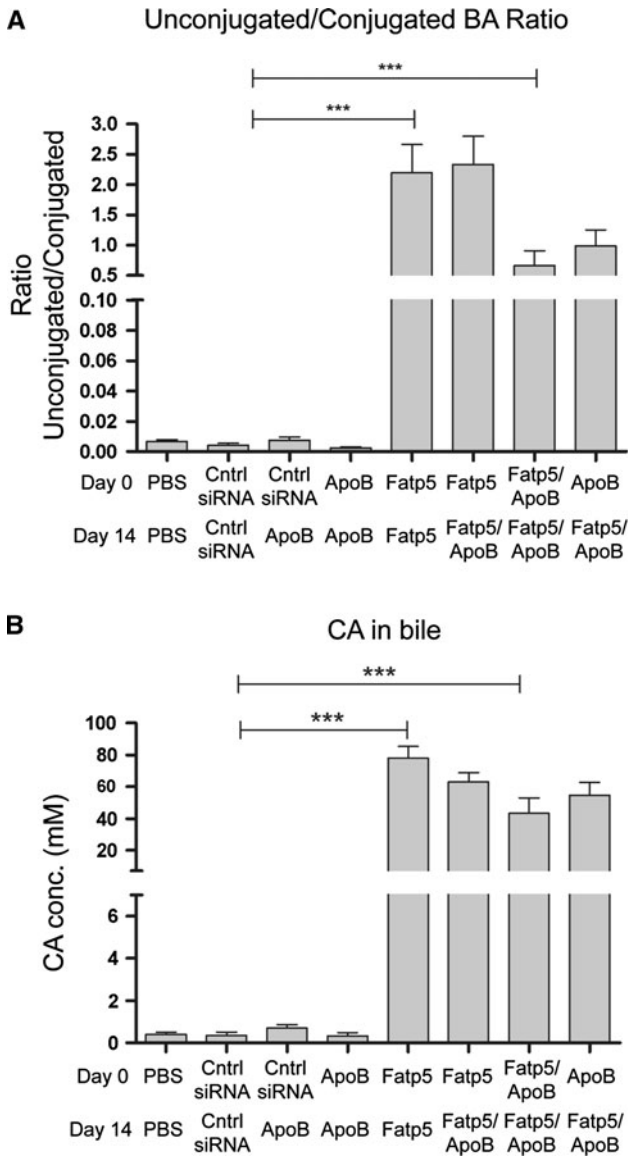

Fig. 2 *Fatp5* knockdown reduces bile acid (*BA*) reconjugation. **a** An increase in the level of unconjugated/conjugated bile acid ratio (***$p \leq 0.001$, *t* test, Mann–Whitney post-test) was observed following *Fatp5* knockdown. **b** Cholic acid (*CA*) concentrations exhibited an increase in the concentration measured (***$p \leq 0.001$, *t* test, Mann–Whitney post-test) by LC/MS after treatment with the *Fatp5* siRNA. Data represented as the group means (*bars*) ± SD ($n = 8$/group)

ApoB siRNA Treatment Led to Significant Reductions in Serum APOB Protein, Cholesterol and Triglyceride Levels Alone and in Combination with a Fatp5-Targeting siRNA

ApoB siRNA treatment, either alone or in combination with a siRNA targeting *Fatp5*, caused a significant reduction ($p \leq 0.001$) in serum APOB levels in female mice fed a low-fat western diet ad libitum (Fig. 3). APOB protein reductions were consistent with the reductions in hepatic

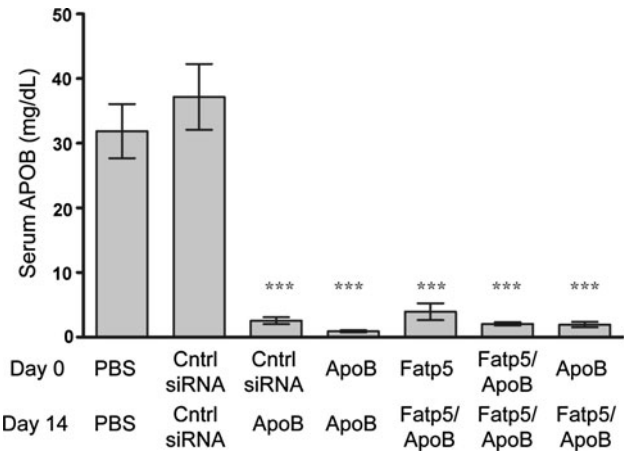

Fig. 3 Serum APOB protein levels were reduced following *ApoB* siRNA treatment. APOB levels in serum were measured by LC/MS on day 21 following days 0 and 14 doses as indicated on the *x*-axis. Data represented as the group means (*bars*) ± SD ($n = 8$/group). Significance (***$p \leq 0.0001$) relative to the siRNA control-treated group was calculated using a one-way ANOVA, Tukey post-test

ApoB mRNA levels (Fig 1a). This led to reductions in circulating cholesterol and triglyceride levels. On day 21, similar reductions in total (76–84%), HDL (67–78%), and non-HDL (79–90%) cholesterol were observed across all *ApoB* siRNA treatment groups (Fig. 4a–c). No significant decrease in cholesterol levels were observed for the *ApoB* + *Fatp5* siRNA combination group relative to the *ApoB* siRNA individual treatment group.

Serum triglycerides were also significantly reduced for *ApoB* siRNA treatments either alone or in combination on day 21 (Fig. 4d). Taken together, these data point to similar and significant changes in serum cholesterol across *ApoB* siRNA treatment groups that correlated with the observed reductions in *ApoB* mRNA and serum protein levels.

Fatp5 siRNA Treatment Failed to Alleviate ApoB siRNA-induced Liver Steatosis

To determine if *Fatp5* siRNA treatment was sufficient to alleviate *ApoB* siRNA-induced liver steatosis, liver sections were processed, sectioned, and stained with either osmium or H&E. Image analysis of the osmium stained slides revealed similar levels of significant lipid accumulation across all *ApoB* siRNA treatment groups relative to the PBS, *Fatp5*, or control siRNA groups (Fig. 5a, b). These data indicated that *Fatp5* siRNA treatment failed to alleviate *ApoB* siRNA-induced liver steatosis in female mice fed a low-fat western diet ad libitum. For the PBS, *Fatp5*, and control siRNA groups, there was some evidence of a periportal to midzonal (zones 1 and 2) distribution of lipid droplets within hepatocytes (Fig. 5b). This contrasted the lipid distribution following *ApoB* siRNA treatment,

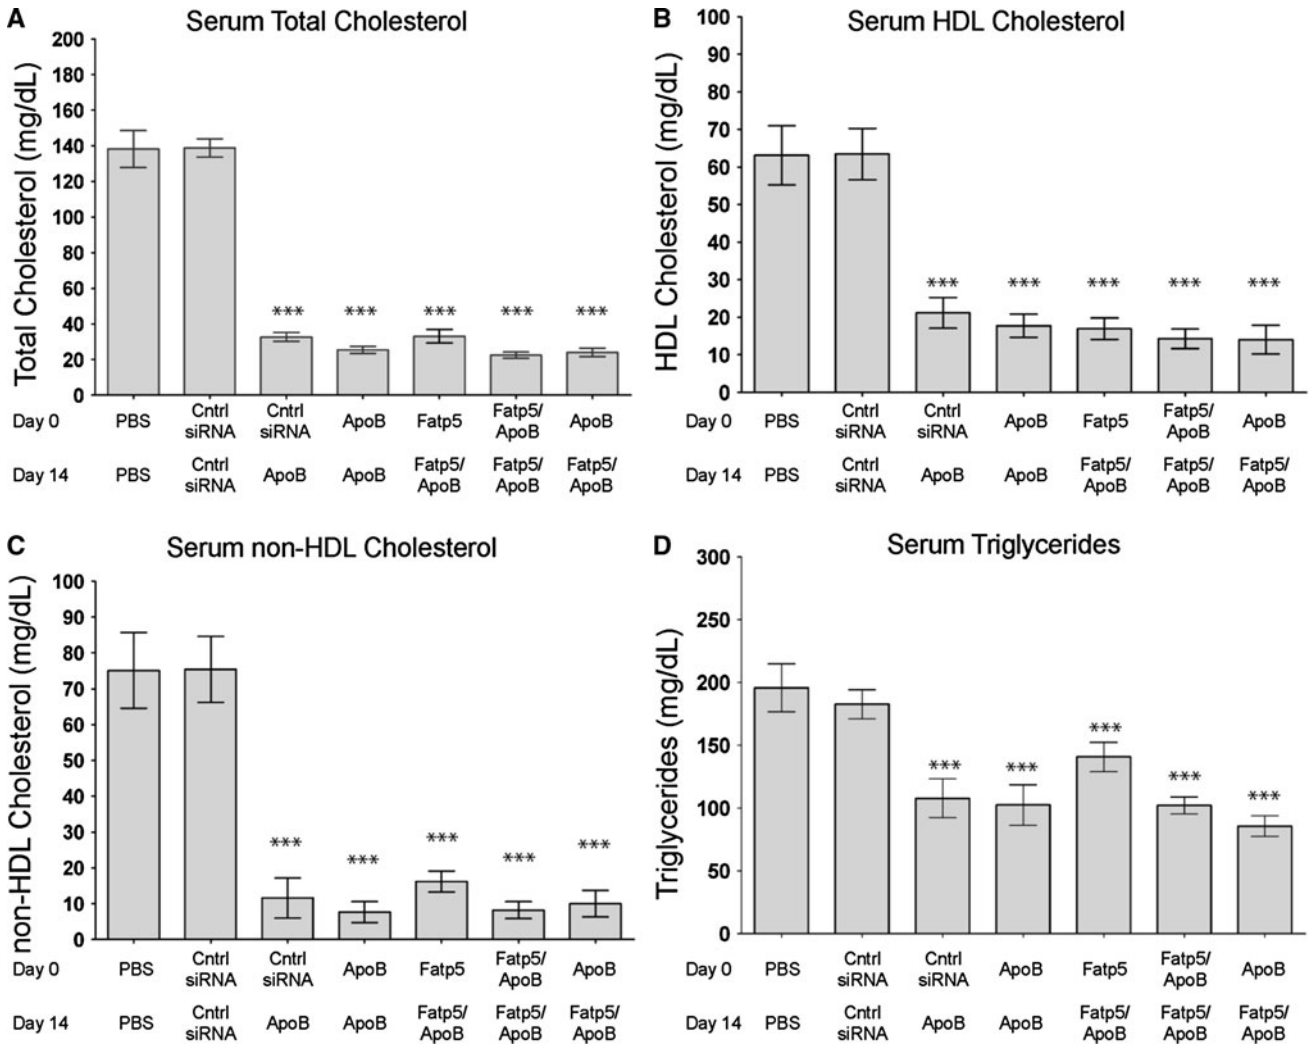

Fig. 4 Comparable levels of serum cholesterol and triglycerides were observed for *ApoB* siRNA treatments either alone or in combination with a siRNA-targeting *Fatp5*. Total cholesterol (**a**), HDL cholesterol (**b**), and triglycerides (**d**) were measured on day 21 following days 0 and 14 doses as indicated on the *x*-axis. Non-HDL cholesterol (**c**) was calculated by subtracting the HDL cholesterol value from the total cholesterol value. Data represented as group means (*bars*) ± SD ($n = 8$/group). The percent difference relative to the control siRNA is shown. Significance (***$p \leq 0.0001$) was calculated using a one-way ANOVA, Tukey post-test, and reported for treated groups relative to the siRNA control (*cntrl siRNA*) treatment

where diffuse infiltration (all zones) was observed (Fig. 5b). The *ApoB*-treated groups displayed lipid droplets that were smaller and more evenly distributed, while fewer but larger lipid droplets were observed for the remaining groups in many instances and as shown in Fig. 5b. By H&E staining, hepatocytes in the *ApoB* siRNA treatment groups appeared diffusely swollen, with granular to vacuolated cytoplasmic spaces (data not shown).

Fatp5 Knockdown Failed to Alter ApoB siRNA-induced Liver Triglyceride levels or Composition

Total triglyceride composition analysis by LC/MS revealed a significant increase in the level of triglycerides found in the liver following treatment with *ApoB* siRNA when compared with siRNA control (Fig. 6a; Cntrl siRNA 7.5 μg/mg of tissue vs. *ApoB* siRNA 35.5 μg/mg of tissue, $p = 0.0002$, *t* test with Mann–Whitney post-test). Comparative measurements between the *ApoB*/*ApoB* and the *Fatp5*/*Fatp5* + *ApoB* groups demonstrated that there was no protection from triglyceride accumulation in female mice fed a low-fat western diet ad libitum. LC/MS indicated that triglycerides 52:2 and 52:3 were significantly higher ($p \leq 0.0001$, two-way ANOVA with Bonferroni post-test) following *Fatp5*/*Fatp5* + *ApoB* treatment relative to *ApoB*/*ApoB* treatment (Fig. 6b). Triglycerides 52:4 and 54:3, although not statistically significant, also showed an increase in the *Fatp5*/*Fatp5* + *ApoB* cohort in

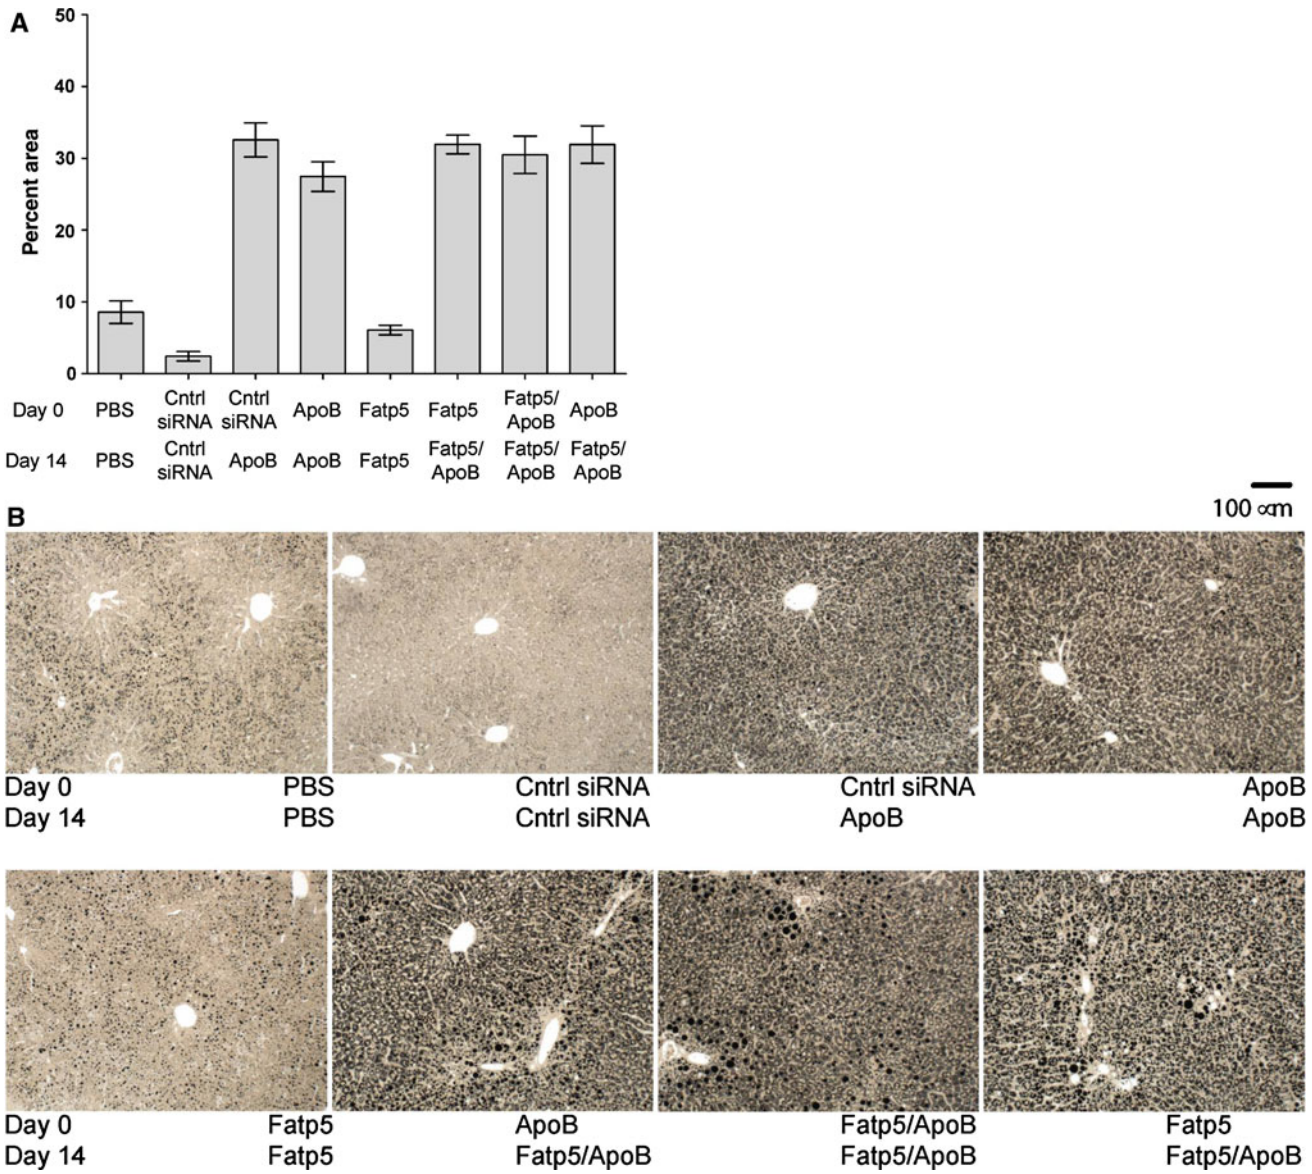

Fig. 5 Similar levels of liver steatosis were observed across all *ApoB* siRNA treatment groups. **a** Osmium-stained images were digitized and pixel intensities were quantitated for day 21. Data represented as the group mean ± SD ($n = 8$/group). **b** Images representative of each of the treatment groups are shown

comparison with the *ApoB*/*ApoB* cohort. Structure elucidation by collision-induced dissociation MS/MS provided information about the possible fatty acid composition for each triglyceride. Triglyceride 52:2 contained 16:0/18:1/18:1, triglyceride 52:3 contained 16:0/18:1/18:2, triglyceride 54:3 contained 18:1/18:1/18:1 and triglyceride 54:3 contained 18:1/18:2/18:1. These triglycerides were confirmed by accurate mass and the use of external standards (data not shown). All of these significantly relevant triglycerides have constituent fatty acids which are non-essential, suggesting that they may be derived from de novo synthesis.

The Hepatic Sterol Response Differed After ApoB and Fatp5 siRNA Treatments

To investigate the hepatic gene response to *ApoB*, *Fatp5* or combination treatments, we performed qRT-PCR analysis on genes involved in the sterol response element binding protein 1 and 2 pathways (*Srebp1* and *Srebp2*). Interestingly, although *ApoB* knockdown induced steatosis, it resulted in a significant decrease in many genes involved in both pathways (Table 1), including genes that are key regulators of fatty acid and triglyceride synthesis (*Fasn*, *Scd*, *Fads1/2*, *Acsl3/5*). As previously described, deletion

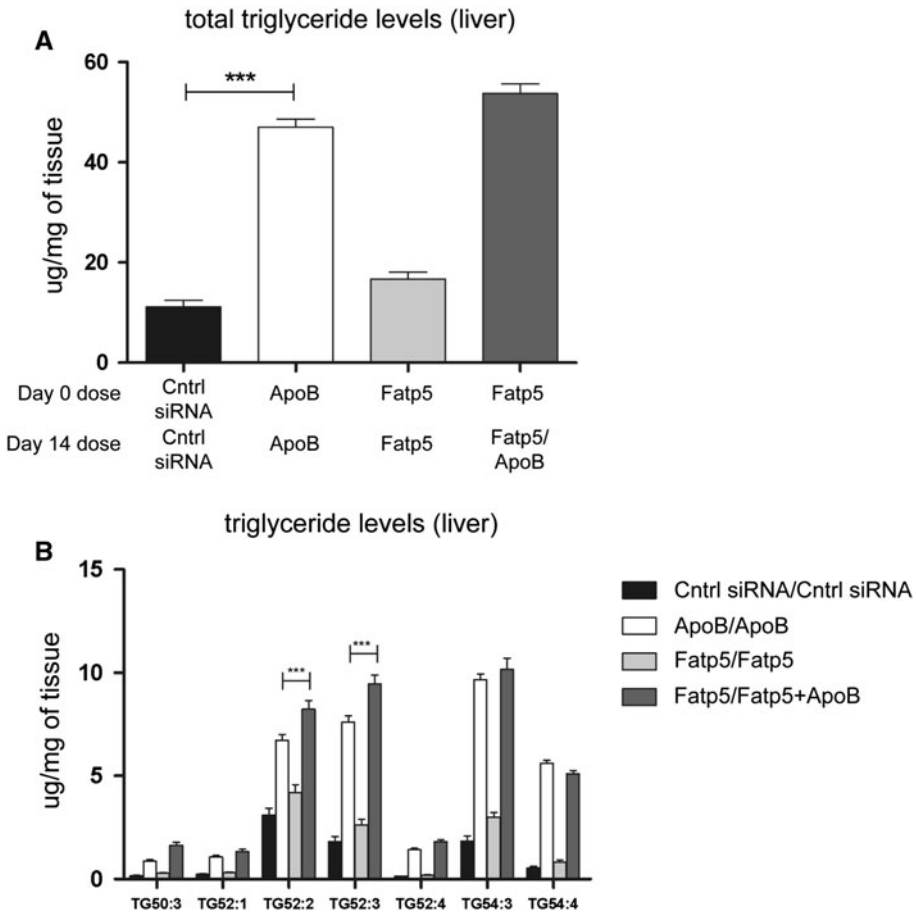

Fig. 6 *Fatp5* siRNA treatment fails to alter *ApoB* siRNA-induced liver triglyceride levels or composition. The total triglyceride pool size and composition was measured for different siRNA administrations (*Cntrl siRNA/Cntrl siRNA*, *ApoB/ApoB*, *Fatp5/Fatp5* and *Fatp5/Fatp5 + ApoB*). **a** A large increase in liver triglycerides was observed for the *ApoB/ApoB* group relative to the control siRNA (***$p = 0.0002$, *t* test with Mann–Whitney post-test). *Fatp5* siRNA treatment (*Fatp5/Fatp5 + ApoB*) did not show protection from *ApoB* siRNA-induced liver steatosis. **b** Specific triglycerides *TG 52:2* and *TG 52:3* showed an increase in their concentrations in both the *ApoB/ApoB* and *Fatp5/Fatp5 + ApoB* groups suggesting that *Fatp5* knockdown fails to alter the triglyceride composition induced by *ApoB* knockdown (***$p \leq 0.0001$, two-way ANOVA with Bonferroni post-test)

[31] or silencing [25] of *Fatp5* caused a reduced uptake of hepatic free fatty acids from serum, which caused a subsequent increase in genes involved in fatty acid synthesis. In contrast to *ApoB* siRNA treatment, Table 1 shows that *Fatp5* siRNA treatment resulted in a significant increase in both *Srebp1* and *Srebp2* pathways. Although bile acid conjugation levels changed and there was a significant increase in cholic acid in bile (Fig 3b), transcription of FXR or key regulators of FXR did not change (data not shown). *ApoB* siRNA treatment appeared to have a stronger effect on the *Srebp1/2* pathways than *Fatp5* siRNA since the simultaneous reductions of both resulted in a hepatic gene signature more similar to that of *ApoB* siRNA treatment alone.

Discussion

In this report, we found that siRNA-mediated knockdown of *ApoB* led to a significant reduction in serum lipids, including HDL, which was associated with an increase in hepatic triglycerides leading to liver steatosis in CETP/LDLR hemizygous mice (a mouse model having a human-like lipid profile). It is worth noting that similar results were observed on day 28 for all end points measured [mRNA knockdown, serum lipids, and histological analysis of hepatic lipid levels (data not shown)].

ApoB siRNA-mediated steatosis contrasts with results reported for ASO-mediated *ApoB* knockdown where only modest but not significant increases in hepatic triglycerides were observed following 6 weeks of biweekly (25 mg/kg) treatment that resolved by week 20 [14]. Crooke et al. reasoned that a compensatory mechanism, which included the activation of AMPK leading to increased fatty acid oxidation and the down-regulation of genes involved in fatty acid synthesis and transport, led to the resolution of hepatic triglyceride accumulation [14]. However, we also observed decreased gene expression within these pathways following the knockdown of *ApoB*. In addition, we observed increased serum ketone levels following *ApoB* siRNA treatment, which is indicative of increased fatty acid oxidation (data not shown). Furthermore, mice harboring a base-pair deletion in the coding region of *ApoB* (*ApoB-38.9*) also exhibited hepatic triglyceride accumulation and decreased expression of genes involved in fatty acid synthesis [25]. Taken together, these data suggest that an alternative mechanism may explain the lack of ASO-mediated steatosis and the discrepancy between *ApoB*

Table 1 *Srebp1c* and *Srebp2* gene expression changes observed following *ApoB*, *Fatp5,* and combination siRNA treatments

Selected *Srebp1* and *Srebp2* pathway genes were analyzed after siRNA treatments. Mice were treated with siRNAs targeting *ApoB* and *Fatp5* alone or in combination (*ApoB*, *Fatp5*, *Fatp5*/*ApoB*) at days 0 and 14. Gene expression was analyzed using qRT-PCR (TaqMan) on day 21. Fold regulation was calculated for the treatment group relative to the control siRNA group.

[a] Indicates a significant induction ($p \leq 0.05$) and [b]a significant reduction ($p \leq 0.05$) in expression relative to the control siRNA group. Significance (*p* value) was calculated using a two-tailed *t* test between control and treatment groups

siRNA and ASO treatments, which could be explained, at least in part, by the fact that we are observing slightly greater *ApoB* knockdown (~90 vs. ~75%) and cholesterol lowering [~80 (non-HDL) vs. 66% (LDL)] relative to the ASO-mediated changes.

From our results, HDL appears lower and serum triglycerides higher than one would initially expect for *ApoB* knockdown. While the cause of the decrease in HDL following *ApoB* siRNA treatment is unknown, it is likely that the HDL components provided by APOB-containing particles are reduced following *ApoB* knockdown leading to a reduction HDL levels, which is consistent with findings by Tadin-Strapps et al. [29, 31]. In addition, while serum triglycerides appear disproportionately higher relative to serum APOB for *ApoB* siRNA-treated groups (Fig. 3 relative to Fig. 4d), some of this apparent discrepancy could be due to the production of larger, more triglyceride-rich, non-HDL particles for the limited number of particles produced. It also remains likely that serum triglycerides are artificially elevated relative to other endpoints, since serum triglycerides are measured enzymatically and glycerol is a reaction intermediate. Thus, any glycerol within the serum would lead to a higher reading than would otherwise be expected.

Fatty acids are either transported into the liver or synthesized de novo. Since fatty acids are required for triglyceride synthesis and *ApoB* knockdown reduced the expression of many of the genes involved in de novo hepatic fatty acid synthesis, we rationalized that liver steatosis induced by *ApoB* knockdown could be maintained, at least in part, by the accumulation of fatty acids taken up by hepatocytes [29]. FATP5 is a transporter of long chain fatty acids (LCFAs) into hepatocytes [27, 32], and we reasoned that reducing LCFA uptake by knocking-down *Fatp5* would reduce hepatic triglyceride levels induced by *ApoB* knockdown. We found that *Fatp5* knockdown does not influence the size, composition, or zonal distribution of the hepatic triglyceride pool generated by *ApoB* siRNA treatment. Lipid levels for the *Fatp5* siRNA treatment alone were too low to reliably assess differences in the hepatic triglyceride population relative to the control siRNA group, although results reported by Doege et al. [27] would

suggest that reductions in FATP5 would disproportionately decrease the saturated and polyunsaturated fatty acid containing triglycerides relative to monounsaturated fatty acid containing triglycerides.

It remains possible that FATP5 may not function as a transporter of fatty acids under our conditions. In the studies reported here, animals were fed a chow diet containing 9% fat ad libitum, whereas *Fatp5* knockout mice fed a similar diet (a chow diet containing 5% fat) exhibited the most dramatic changes in hepatic lipid accumulation under prolonged fasting conditions [32]. One could also argue that *Fatp5* knockdown may induce the expression of other *Fatp* family members, which could compensate for the loss of FATP5 activity under our conditions. However, this is unlikely, since *Fatp5* knockout mice did not exhibit altered expression of *Fatp1-4* or *Fatp6* [32], and we did not observe a change in the expression of either of the two *Fatps* evaluated (*Fatp2* or *Fatp4*, data not shown). Alternatively, both *Fatp2* and *Fatp5* are highly expressed in liver, and *Fatp2* knockdown has also been reported to decrease hepatic fatty acid uptake in mice [33]. Therefore, it remains possible that FATP2 is sufficient to mediate hepatic fatty acid uptake in the absence of FATP5 under our conditions.

Even though *Fatp5* knockdown failed to influence the hepatic triglyceride pool generated following *ApoB* knockdown, it did lead to a 100-fold increase in ratio of unconjugated to conjugated bile acids. The magnitude of the shift within the bile acid pool, from predominately conjugated to predominately unconjugated bile acids, is consistent with FATP5 being required for the majority of bile acid reconjugation during enterohepatic recirculation. Our results are inline with the results reported for *Fatp5* knockout mice and suggest that *Fatp5* siRNA treatment is sufficient to influence FATP5 activity [26]. We expect these changes to have only a minor effect on fat absorption, since, consistent with Hubbard et al. [26], we observed that unconjugated bile acids are found within gall bladder bile. Thus, unconjugated bile acids can be efficiently secreted into bile following *Fatp5* knockdown and should therefore be available for fat absorption. *Fatp5* knockout mice also exhibited secondary metabolic changes leading to decreased food intake. Although, it is unclear if this is due to altered bile acid metabolism via the inhibition of bile acid reconjugation, altered lipid metabolism via the inhibition of fatty acid uptake, or both. While outside the scope of this work, it remains possible to use siRNAs targeting *Fatp5* to address this question, since we observed the inhibition of bile acid reconjugation but not fatty acid uptake under these conditions.

Finally, we have shown that *Fatp5* knockdown resulted in a significant increase in genes involved in hepatic cholesterol biosynthesis (*Srebp2* pathway) and fatty acid synthesis (*Srebp1* pathway). This is consistent with the increase in fatty acid synthase expression and defects in bile acid reconjugation reported for the loss of FATP5 activity [26, 27].

One could, therefore, speculate that changes in bile acid conjugation levels would result in an increase in de novo cholesterol synthesis, requiring more acetyl-CoA, which may promote fatty acid synthesis.

Acknowledgments We would like to thank Duncan Brown for siRNA design, Dipali Ruhela and her group for providing the LNP formulations, Jing Kang and Natalya Dubinina for their help with the 'in-life' portion of these studies, Carla S. Colon and David McLaren for their help with metabolite profiling, Wu Yin for help with the gene expression analysis, Kenny K. Wong, Steven R. Bartz, and Anthony K. Ogawa for helpful discussions, as well as Premier Laboratory for histological services and support with pathology review.

Received: 14 April 2011 / Accepted: 12 September 2011 / Published online: 9 October 2011

Abstract Scientific research is constantly working to find new molecules that are effective in preventing excessive accumulation of body fat. The aim of the present work was to assess the potential agonism on PPARα and PPARγ of a conjugated linolenic acid (CLNA) isomer mixture, consisting of two CLNA isomers (*cis*-9,*trans*-11,*cis*-15 and *cis*-9,*trans*-13,*cis*-15). Secondly, we aimed to analyze the effects of this mixture on triacylglycerol accumulation in 3T3-L1 mature adipocytes. Luciferase transactivation assay was used to analyze whether the CLNA mixture activated PPARs. The expression of several enzymes and transcriptional factors involved in the main metabolic pathways that control triacylglycerol accumulation in adipocytes was assessed by real time RT-PCR in 3T3-L1 adipocytes treated for 20 h with the CLNA mixture. The mixture activated PPRE in cells with PPARα receptor over-expression, but not those with PPARγ over-expression. Decreased triacylglycerol was found in treated adipocytes. The lowest dose (10 μM) increased HSL expression and the highest dose (100 μM) increased ATGL gene expression. The other genes analyzed remained unchanged. The hypothesis of an anti-obesity action of the analyzed CLNA mixture, based on increased lipid mobilization in adipose tissue, can be proposed.

Keywords PPARα · PPARγ · Conjugated linolenic acid · HSL · ATGL · 3T3-L1

Abbreviations

ACC1	Acetyl-CoA carboxylase1
ATGL	Adipose triglyceride lipase
CLA	Conjugated linoleic acid
CLNA	Conjugated linolenic acid
FASN	Fatty acid synthase
HSL	Hormone-sensitive lipase
IBMX	3-Isobutyl-1-methyl-xanthine
LPL	Lipoprotein lipase
PPAR	Peroxisome proliferator-activated receptor
PPRE	Peroxisome proliferator response element
SREBP-1c	Sterol regulatory element binding protein
TAG	Triacylglycerol

Introduction

Being overweight and obesity are a public health problem in developed societies because of their high prevalence, not only in adults but also in children. They generate numerous metabolic disturbances and other associated diseases, such as insulin resistance, diabetes, hypertension and dyslipemia [1]. Scientific research is constantly working to find new molecules, either drugs or dietary ingredients, which are

effective in preventing excessive accumulation of body fat and/or in reducing the fat previously stored.

In recent years a great deal of scientific work has been performed to analyze the anti-obesity effects of conjugated linoleic acid (CLA) and has shown that it strongly reduces body fat in rodents (mice, hamsters and rats) [2–5]. Despite these promising results, CLA testing on humans produced effects which were far less noticeable, and frequently highly controversial. Whereas CLA was not effective in several studies, in others it led to a very weak reduction in body fat [6–9]. Thus, the EFSA (European Food Safety Authority) Panel on Dietetic Products, Nutrition and Allergies, based on the results reported in human studies, concluded that a cause and effect relationship has not been established between the consumption of an equimolecular mixture of CLA isomers, *cis*-9,*trans*-11 and *trans*-10,*cis*-12, and contribution to the maintenance or achievement of a normal body weight [10].

This scientific scenario has directed researchers' attention towards conjugated linolenic acid isomers (CLNA), defined as octadecatrienoic fatty acid isomers with at least two conjugated double bonds. The literature shows that, although in general terms beneficial effects on health are induced by CLNA isomers, important differences exist in terms of anti-obesity action among *cis*-9,*trans*-11,*trans*-13 (α-eleostearic acid) [11], *trans*-9,*trans*-11,*cis*-13 (catalpic acid) [12], *cis*-9,*trans*-11,*cis*-13 (punicic acid) [13–15], *trans*-8,*trans*-10,*cis*-12 (calendic acid) [16] and *cis*-8,*trans*-10,*cis*-12 (jacaric acid) [17]. Based on published results, it has been proposed that punicic acid (*cis*-9,*trans*-11,*cis*-13) will be further developed for regulating blood sugar levels [18] and catalpic acid (*trans*-9,*trans*-11,*cis*-13) for lipid-lowering and anti-obesity applications. The interest in calendic acid (*trans*-8,*trans*-10,*cis*-12) is limited because its effectiveness on body-fat reduction is lower than that of conjugated linoleic acid (CLA) [16]. Jacaric acid (*cis*-8,*trans*-10,*cis*-12) seems not to be useful for these purposes [19].

Taking all these results into consideration, and in the line of searching new CLNA isomers with anti-obesity properties, the present study focused on a CLNA mixture consisting of two CLNA isomers (rumelenic acid *cis*-9,*trans*-11,*cis*-15 18:3 and *cis*-9,*trans*-13,*cis*-15 18:3; 50:50) not extensively investigated yet. In the first part of the present study the potential agonism of these CLNA isomers on PPARα and PPARγ was assessed. Secondly, the effects of this mixture on triacylglycerol (TAG) accumulation in 3T3-L1 mature adipocytes, as well as on the expression of enzymes and transcriptional factors involved in the main metabolic pathways that control TAG accumulation in adipocytes, such as de novo lipogenesis, fatty acid uptake from circulating TAG and lipolysis, were also evaluated. Our research revealed that the analyzed CLNA mixture was able to activate PPARα but not PPARγ. Moreover, it increased the expression of HSL and ATGL but not that of LPL, PPARγ, ACC1, FASN and SREBP-1c. Therefore, our findings suggest that analyzed CLNA mixture may have anti-obesity properties.

Methods and Procedures

Method for Obtaining the CLNA Mixture

The CLNA isomer mixture was prepared by alkali isomerization of hydrolyzed linseed oil using an adaptation of the procedure described by Galvez et al. [21]. The CLNA isomers were isolated from the isomerized product by silver ion thin layer chromatography, according to the method described by Destaillats et al. [22]. The two CLNA isomers were identified as rumelenic acid (*cis*-9,*trans*-11,*cis*-15) and *cis*-9,*trans*-13,*cis*-15 18:3 in a molar ratio of 50:50, previous derivatization with 4-methyl-1,2,4-triazoline-3,5-dione (Sigma, St. Louis, Mo, USA) following the procedure of Destaillats et al. [23].

Reporter Assay

Human Kidney Embryonic HEK293T cells were maintained and transfections were carried out as previously described [24]. HEK293T were transiently transfected with 25 ng of the reporter expression vector under study (PGL2-PPRE-Luc) and with 25 ng of the internal control vector (β-galactosidase), using Lipofectamin 2000® (Invitrogen, Carlsbad, CA, USA), according to the manufacturer's instructions. Cells were divided into two experimental groups: cells with over-expression of PPARα (transfected with 5 ng of PPARα) and cells with over-expression of PPARγ (transfected with 5 ng of PPARγ). WY-14643 (Calbiochem-Merck, Darmstadt, Germany) and rosiglitazone (Cayman Chemical, Michigan, USA) were used as the positive controls of PPARα and PPARγ receptors activation, respectively. After 24 h, cells were treated with the CLNA mixture at different doses (3, 15, 30 μM) during 18 h. CLNA, as well as PPAR ligands, were dissolved in 95% ethanol. At this point luciferase activity was measured. Luciferase activity was normalized for transfection efficiency using a β-galactosidase reporter (RSV β-gal) as an internal control. Experimental data are the mean of at least three independent experiments with luciferase activity normalized to β-galactosidase activity, conducted in triplicate.

β-Galactosidase assays for normalization of PPRE-luciferase activity were performed using 10 μl of cell lysate, 50 μl 2× buffer (1.33 mg/mL 2-nitrophenyl β-D-galactopyranoside, 100 mM 2-mercaptoethanol, 2 mM magnesium chloride, 200 mM sodium phosphate pH 7.5),

and 40 μL water in each well of a clear 96-well plate. All these were purchased from Sigma (St. Louis, MO, USA). The plate was covered and incubated for 30 min at 37 °C, and absorbance at 405 nm was determined with a BioRad Lumimark Plus plate reader. Lysate samples were assayed in triplicate. Lysates from untransfected cells were used as controls for background activity.

3T3-L1 Adipocyte Culture

The 3T3-L1 cells were maintained and cultured as previously described [25]. In brief, cells were cultured at 37 °C in a humidified atmosphere of 5% CO_2/95% air. 3T3-L1 pre-adipocytes were maintained in DMEM (Invitrogen, Carlsbad, CA, USA) containing 10% (v/v) fetal calf serum (FCS; Sigma, St. Louis, MO, USA) and antibiotics (penicillin/streptomycin). Differentiation of the cells was initiated 24 h after confluence by incubation for 2 days in FCS free medium containing 0.25 μM dexamethasone (Sigma, St. Louis, MO, USA), 500 μM 3-isobutyl-1-methyl-xanthine (IBMX; Sigma, St. Louis, MO, USA) and 10 nM insulin (Sigma, St. Louis, MO, USA). Differentiation into adipocytes was visualized under the microscope from the accumulation of lipid droplets. Until day 11 (adipogenic phase) the cells were maintained in a feeding medium (DMEM containing 10% (v/v) FCS and antibiotics, as well as insulin) that was renewed every 3 days.

On day 11 after differentiation, the cells were pre-incubated for 24 h with an insulin-free feeding medium in order to avoid the influence of insulin. On day 12 after differentiation, mature adipocytes, grown in 6-well plates, were incubated with either 0.1% ethanol (95%) (control group) or with the CLNA mixture (10 or 100 μM, diluted in 95% ethanol) for 20 h. Cells were harvested after the treatment and TAG content, normalized by protein content [26], were quantified by using AdipoRed® assay reagent (Lonza, Walkersville, USA). Gene expression was assessed by real time RT-PCR as described below.

Gene Expression Analysis by Reverse Transcription-Quantitative PCR (RT-PCR)

Total RNA was extracted from adipocytes with Trizol (Invitrogen, Carlsbad,CA, USA). RNA samples were then treated with a DNA-free kit (Ambion, Applied Biosystems, USA) according to the manufacturer's instructions, to remove any contamination with genomic DNA. The yield and quality of RNA were assessed by measuring absorbance at 260, 270, 280 and 310 nm and by electrophoresis on 1.3% agarose gels. Then, 1.5 μg of total RNA of each sample was reverse-transcribed to first-strand complementary DNA (cDNA) using iScript® cDNA Synthesis Kit (Bio-Rad, Hercules, CA, USA).

Relative PPARγ, LPL (lipoprotein lipase), ACC1 (acetyl-CoA carboxylase1), FASN (fatty acid synthase), SREBP-1c (sterol regulatory element binding protein), HSL (hormone-sensitive lipase) and ATGL (adipose triglyceride lipase) mRNA levels were quantified using real-time PCR with an iCycler® – MyiQ® Real Time PCR Detection System (BioRad, Hercules, CA, USA). β-Actin mRNA levels were similarly measured and served as the reference gene.

Then, 0.1 μL of each cDNA was added to the PCR reagent mixture (SYBR® Green Master Mix; Applied Biosystems, USA), with the upstream and downstream primers (300 nM each). The PCR parameters were as follows: initially 2 min at 50 °C, denaturation at 95 °C for 10 min followed by 40 cycles of denaturation at 95 °C for 15 s, annealing for 30 s and extension at 60 °C for 30 s. Information concerning specific sense/antisense primers and PCR annealing extension temperatures is described in Table 1.

Table 1 Primers and annealing temperature for PCR amplification of each gene studied

SYBR® Green RT-PCR			
Primers	Sense primer	Antisense primer	Annealing temperature
SREBP-1c	5′-GCGGACGCAGTCTGGG-3′	5′-ATGAGCTGGAGCATGTCTTCAAA-3′	60.9 °C [27]

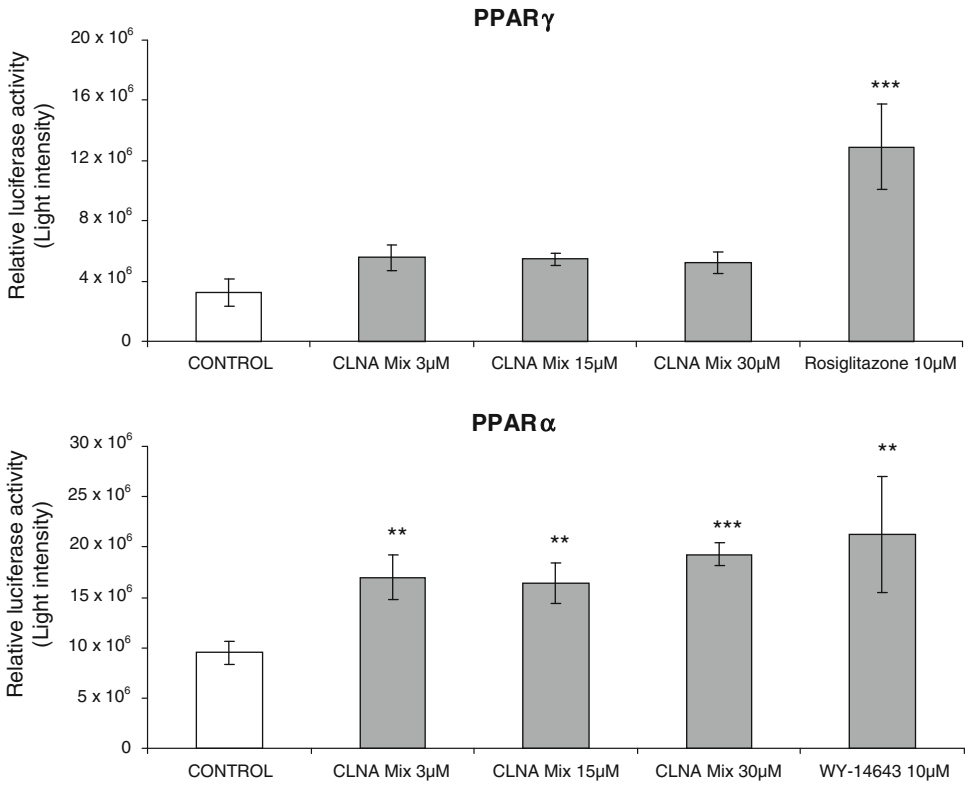

Fig. 1 Effects of 3, 15 and 30 μM CLNA mixture *cis*-9,*trans*-11,*cis*-15 and *cis*-9,*trans*-13,*cis*-15 on peroxisome proliferator response element (PPRE) reporter activity of HEK293T cells with PPARγ/PPARα receptors over-expressed. Values (luciferase activity normalized to β-galactosidase activity) are means with the standard error of the mean, shown by *vertical bars*. 10 μM Rosiglitazone and 10 μM WY-14643 were used as positive control of PPARγ and PPARα receptor activation respectively. Data were analyzed by one-way analysis of variance followed by the Tukey post hoc test. $^{**}P < 0.01$, $^{***}P < 0.001$

mRNA levels were normalized to the values of β-actin and the results expressed as fold changes of threshold cycle (Ct) value relative to controls using the 2-ΔΔCt method [28].

Statistical Analysis

Results are presented as means ± standard errors of the means. Statistical analysis was performed using SPSS 17.0 (SPSS Inc. Chicago, IL, USA). Data was analyzed by one-way analysis of variance followed by the Tukey post hoc test. Statistical significance was set-up at the $P < 0.05$ level.

Results

PPRE Activation on HEK293 Cells

The mixture of CLNA isomers activates peroxisome proliferator response element (PPRE) of cells with PPARα receptor over-expression, but not those with PPARγ over-expression. In the case of the PPARα transcriptional factor the activity increase was as evident as that shown with the positive control (10 μM of WY-14643). No dose-dependent effect among the doses was observed (Fig. 1).

Effect of the CLNA Mixture on Triacylglycerol Accumulation in Nature Adipocytes

The TAG content in the control group was not modified after 20 h of treatment. It was found that 10 and 100 μM of the CLNA mixture decreased TAG content in mature adipocytes (−49 and −39% respectively). As shown in Fig. 2, dose-dependent effects were not found, according to the percentage of reduction.

Effect of the CLNA Mixture on the Expression of Adipocyte-Specific Genes in Mature Adipocytes

With regard to the adipocyte-specific genes, LPL, PPARγ, ACC1, FASN and SREBP-1c remained unchanged (Fig. 3a, b). The expression of the main lipases, HSL and ATGL, was also analyzed. HSL expression was increased with the lower dose (10 μM) and ATGL expression was increased with the higher dose (100 μM) (Fig. 3a).

Discussion

Genes involved in lipid metabolism are controlled by several peroxisome proliferator-activated receptors (PPARs) [29–31]. PPARα, mainly expressed in oxidative tissues such

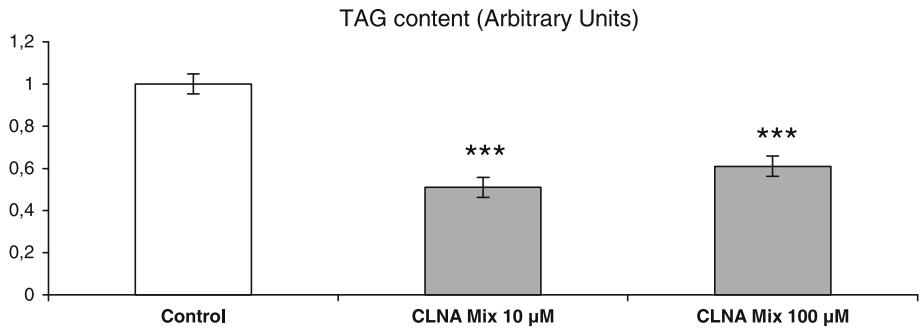

Fig. 2 Triacylglycerol content normalized by protein in mature adipocytes 3T3-L1 treated for 20 h with 10 and 100 µM of the CLNA mixture *cis*-9,*trans*-11,*cis*-15 and *cis*-9,*trans*-13,*cis*-15. Values are means with the standard error of the mean, shown by *vertical bars*. Data were analyzed by one-way analysis of variance followed by the Tukey post hoc test. ***$P < 0.001$

as liver, activates the expression of enzymes involved in fatty acid oxidation [31]. PPARγ, widely expressed in white adipose tissue, regulates genes related to adipogenesis, fatty acid storage as TAG, adipokine release and improves insulin sensitivity [31–33]. Thus, when the anti-obesity and/or anti-diabetic properties of new potential functional ingredients are analyzed it is important to know if they are able to activate these transcriptional factors.

It has been reported that conjugated linoleic acid isomers have the ability to bind PPARα [34, 35] and PPARγ [36, 37]. With regard to conjugated linolenic isomers, Hontecillas et al. [15] observed that punicic acid (*cis*-9,*trans*-11,*cis*-13) activated both PPARγ and PPARα in 3T3-L1 adipocytes transfected with PPAR-Luciferase plasmids. In another study Chuang et al. [11], found that α-eleostearic acid (*cis*-9,*trans*-11,*trans*-13) activated PPARα in a transactivation assay performed with a clone of CHOK1 cells. By contrast, in previous studies from our laboratory, jacaric acid (*cis*-8,*trans*-10,*cis*-12) a CLNA isomer that does not show the sequence *cis*-9,*trans*-11 observed in punicic and α-eleostearic acids, did not activate PPARγ or PPARα in a transactivation assay performed with HEK293T cells [19]. These results suggest that the ability of CLNA isomers for activating PPARs depends on their chemical structure.

In this context, in order to broaden the knowledge about CLNA isomers, the first aim of the present study was to evaluate the potential activation of PPARα and PPARγ by means of a CLNA mixture consisting of two CLNA isomers (rumelenic acid *cis*-9,*trans*-11,*cis*-15 18:3 and *cis*-9,*trans*-13,*cis*-15 18:3; 50:50). This process has not been extensively investigated before. In fact, as far as we know, there is only one paper addressing the effect of these two isomers on lipid synthesis, which specifically concerns their effect on milk fat synthesis in lactating dairy cows [20]. The results concerning the activation of PPARs by CLNA isomers will be very helpful in order to know if these molecules may be good candidates to be used as functional ingredients for obesity, diabetes and dyslipidemia prevention.

The mixture analyzed in the present study activated PPRE of cells with PPARα receptor over-expression, but not those with PPARγ over-expression. By comparing the present results with those published by other authors, by using other CLNA isomers, it can be observed that our mixture shares with punicic acid and α-eleostearic acids the ability for activating PPARα.

As previously explained in this discussion, the activation of PPARα leads to the activation of enzymes involved in mitochondrial and peroxisomal fatty acid oxidation [28, 38, 39]. Thus, the present results suggests that, when administered in vivo, this CLNA mixture could have the capability of reducing steatosis, hypertriglyceridemia, and even body fat accumulation (anti-obesity effect), by increasing fatty acid oxidation [40–45].

The CLNA mixture did not act as a PPARγ agonist; this is a difference from other CLNA isomers, such as punicic acid [15]. The lack of PPARγ activation means that this CLNA mixture is probably not useful for insulin resistance management and glycemic control. In contrast, it could be an interesting prospect for avoiding an increase in adipose tissue because, as explained before, PPARγ activation promotes lipid storage in adipose tissue. Other potential actions of the CLNA mixture on adipocyte metabolism cannot be discarded because changes in the expression of this transcriptional factor, as well as modifications in metabolic pathways that are not regulated by PPARγ, could take place.

In order to obtain more evidences concerning the effect of the CLNA mixture on adipose tissue metabolism, a second experiment devoted to analyze its effects on TAG accumulation in 3T3-L1, as well as on the expression of lipid-related genes, was carried out in the present study. The amount of accumulated TAG was lower in treated cells than in the controls, suggesting that the analyzed CLNA mixture may be of interest as a potential anti-obesity agent, not only by increasing liver fatty acid oxidation through the activation of PPARα, but also by acting directly on other molecular mechanisms in adipocytes.

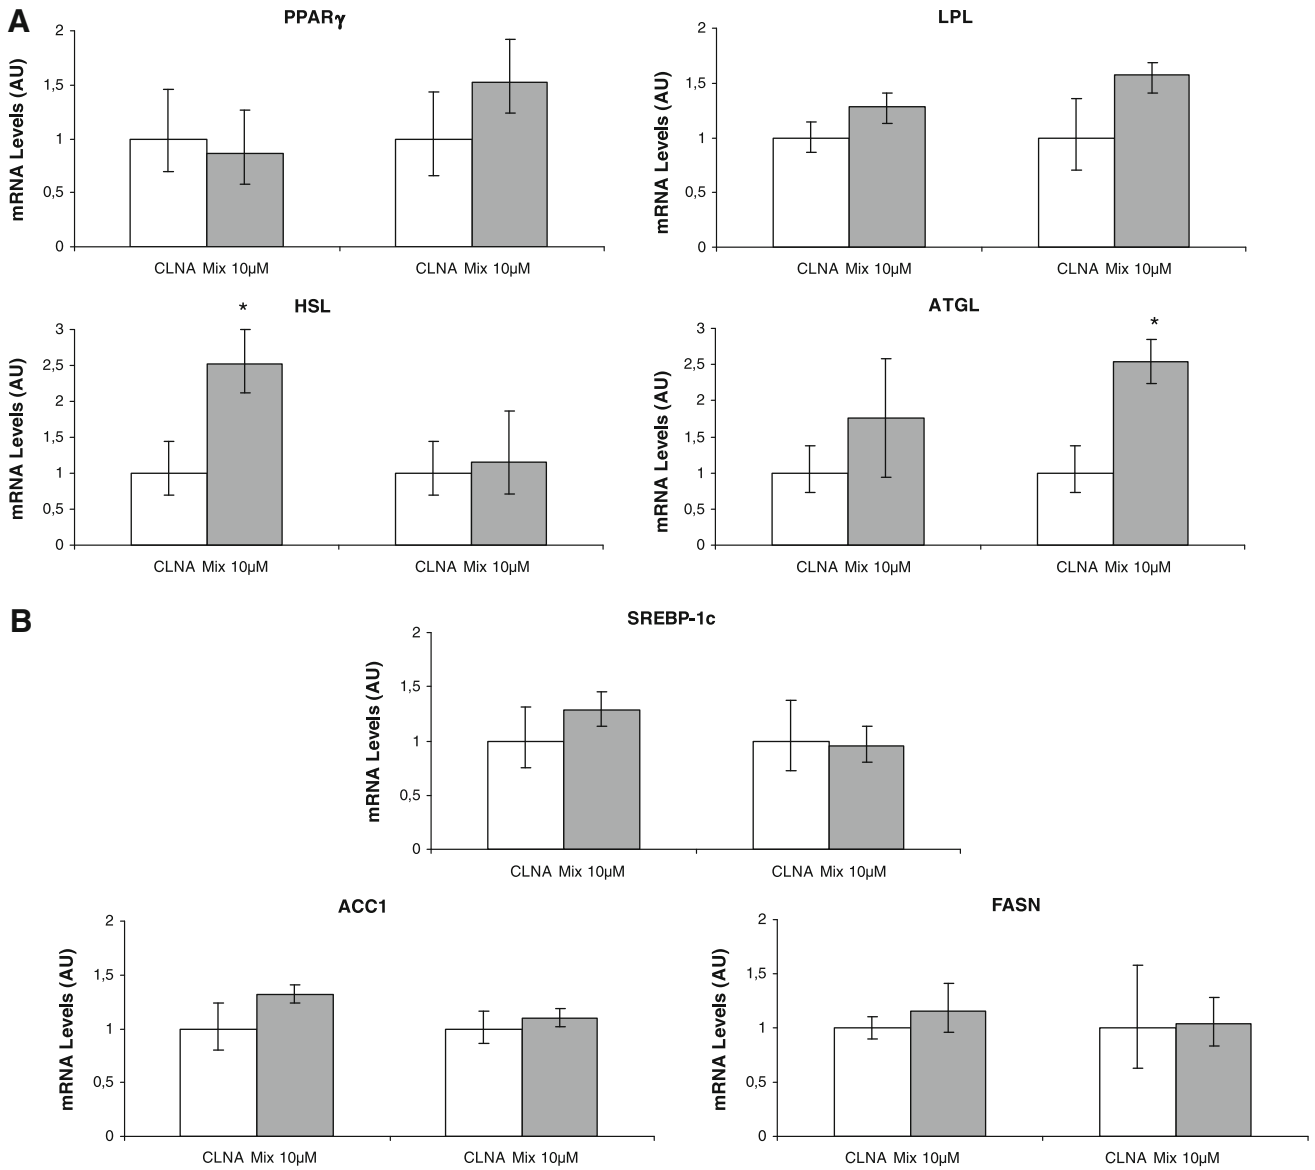

Fig. 3 mRNA levels were measured by Real Time RT-PCR in mature 3T3-L1 adipocytes treated for 20 h with 10 and 100 μM of the CLNA mixture *cis*-9,*trans*-11,*cis*-15 and *cis*-9,*trans*-13,*cis*-15. **a** Genes related to fatty acid uptake from circulating triacylglycerol and lipolysis (LPL, PPARγ, ATGL, HSL) and **b** genes related to lipogenesis (SREBP-1c, FASN, ACC1). Values are expressed relative to control group and results are given as means with the positive and negative error, shown by *vertical bars*. Data were analyzed by one-way analysis of variance followed by the Tukey post hoc test. *$P < 0.05$

In the present study, the effects of the CLNA mixture on the expression of enzymes and transcriptional factors involved in de novo lipogenesis, fatty acid uptake from circulating TAG and lipid mobilization were assessed. No changes were observed in the expression of LPL or PPARγ. These results, together with the absence of activation of this transcriptional factor, suggest that the CLNA mixture does not modify fatty acid uptake from circulating TAG in adipocytes.

The expression of ACC1 and FASN, as well as the transcriptional factor SREBP-1c, also remained unchanged, indicating that the reduction in the accumulation in TAG induced by the CLNA mixture is not due to decreased de novo lipogenesis. With regard to HSL and ATGL, two lipases controlling lipolysis, an increase in their expression was observed in adipocytes treated with the CLNA mixture. These data suggest that the reduction in TAG accumulation can result from increased lipid mobilization.

In summary, on the basis of the present in vitro delipidation effect, the hypothesis of an anti-obesity action of the CLNA mixture, consisting of *cis*-9,*trans*-11,*cis*-15 and *cis*-9,*trans*-13,*cis*-15 isomers, increased lipid mobilization in adipose tissue, can be proposed. These results open the way for further research. Obviously, checking whether this

CLNA mixture indeed induces a reduction in fat accumulation requires further studies performed in animal models as a first step, and later on in humans.

Acknowledgments This study was supported by grants from the Government of País Vasco (IT-386-10; CTP09/R5), Instituto de Salud Carlos III (RETIC PREDIMED) and CYTED (208RT0343). J. Miranda is a recipient of a doctoral fellowship from the Ministerio de Educación y Ciencia. PPAR response element (PPRE) luciferase reporter plasmid (pPPRE-Luc), as well as PPARα and γ receptors expression plasmids, were kind gifts from Dr. Renaud Dentin.

Abstract Nuclear hormone receptors are transcription factors that can be activated by nutrition-derived ligands and alter the expression of various specific target genes. Stearoyl-Coenzyme A desaturase (SCD1) converts palmitic acid (16:0) to palmitoleic acid (16:1n-7) as well as stearic acid (18:0) to oleic acid (18:1n-9). At the same time, elongase 6 (ELOVL6) elongates 16:1n-7 and 18:1n-9 to vaccenic acid (18:1n-7) and eicosenoic acid (20:1n-9). We examined how synthetic selective ligands of nuclear hormone receptors alter the gene expression of hepatic enzymes in mice. In addition, we examined how the regulation of these two enzymes influences fatty acid composition of phospholipids in liver and plasma. Mice were gavaged daily for 1 week with synthetic ligands of peroxisome proliferator-activated receptor (PPAR) α, β/δ, γ, liver X receptor (LXR), retinoic acid receptor (RAR) and retinoid-X receptor (RXR) for 1 week. Phospholipids from liver and plasma were analysed using ESI-MS/MS and GC after saponification. Hepatic gene expression of SCD1 and ELOVL6 was measured using QRT-PCR. SCD1 and ELOVL6 expression increased after the gavage of LXR and RXR ligands. The analysis of fatty acid composition of total phospholipids in plasma and liver showed increased percentage contributions of the SCD1 and ELOVL6 products 18:1n-9, 18:1n-7 and 20:1n-9 after LXR and RXR ligand application. Analysis of total phospholipids from plasma and liver revealed a significant increase in monounsaturated fatty acids bound in phosphatidylcholine (PtdCho) and lysophosphatidylcholine (PtdEtn) after LXR and RXR ligand administration. Increased hepatic gene expression of SCD1 and ELOVL6 after gavage of selective RXR or LXR ligands to mice resulted in increased concentrations of their metabolic products in phospholipids of liver and plasma.

modulate the expression of various specific target genes at the transcriptional level. Peroxisome proliferator-activated receptor α (PPARα) is mainly expressed in the liver, skeletal and heart muscle as well as in blood vessels and the pancreas. PPARα plays an important role in fatty acid uptake, liver steatosis, cardiac lipid accumulation, and is critical for the development of atherosclerosis [1, 2]. PPARβ/δ is ubiquitously expressed, and is involved in HDL-cholesterol metabolism in obese and non-obese mice [2]. PPARγ is mainly expressed in adipose tissue, in macrophages and in low levels in the liver. It is primarily involved in fatty acid uptake and inflammation control [3, 4]. Apart from the synthetic ligands used in our study for each PPAR isoform, mainly monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA) were also reported to be natural activators [5].

Liver X receptor (LXR) is highly expressed in the liver, and to a lesser extent in the adipose tissue and in macrophages. LXR is a key modulator of lipid metabolism, inflammatory signalling and regulation of cholesterol efflux in macrophages. Cholesterol and its metabolites are natural ligands that can activate LXR [6]. Retinoid-X receptor (RXR) and retinoic acid receptor (RAR) are activated by vitamin A derivates like all-*trans*-retinoic acid (ATRA) and its *cis*-isomer the 9-*cis*-retinoic acid (9CRA). This activation can also take place by specific synthetic ligands. Furthermore RXR forms heterodimers with various nuclear receptors including the LXR, RAR and PPARs [3, 7], which is crucial to induce a signal transduction. Alternatively besides natural ligands also synthetic, high specific ligands for LXR, RXR, RAR and PPARs have been developed.

SCD1 is an enzyme mainly expressed in adipogenic tissues including hepatic and adipose tissue [8, 9]. SCD1 desaturates 16:0 and 18:0 to 16:1n-7 and 18:1n-9, respectively. The regulation of SCD1 and its consequences on metabolic disease has been studied in several models. The depletion of SCD1 in SCD1-knock-out mouse models reduces triglyceride synthesis in the liver [10] and further protects against induced hepatic steatosis and adiposity [11]. Elongases extend fatty acids by two additional carbon atoms. The enzyme ELOVL6 extends 16:0, 16:1n-7 and 18:1n-9 to 18:0, 18:1n-7 and 20:1n-9, respectively [12, 13]. It is mainly expressed in brown and white adipose tissue, hepatic tissue and brain [12, 14]. The gene expression of both enzymes is suggested to be regulated by the SREBP1, a transcription factor inducible by the activated nuclear hormone receptors LXR and RXR but not by other hormone receptors like PPARα and PPARγ [15–17].

This study investigated how the nuclear hormone receptors RAR, RXR, PPARs and LXR alter the gene expression of the enzymes SCD1 and ELOVL6 by the application of their specific selective ligands. Due to this alteration of the gene expression the impact on the composition of various phospholipids and the contents of the metabolic products of SCD1 and ELOVL6 had been studied in plasma and liver of mice. The activation of the nuclear hormone receptors RAR, RXR, PPARs and LXR can also occur by various semi-stable and multi-potent endogenous/nutritional-relevant ligands. An induction of these receptors regulates various nutritional relevant pathways like in the present study - the metabolism of monounsaturated and saturated fatty acids. We postulate that an alteration of gene expression of SCD1 and ELOVL6 caused by the application of different nuclear hormone receptor ligands influences the content of MUFAs/saturated fatty acids (SFAs) and therefore indirectly effects the fatty acid composition of phospholipids and membranes.

Materials and Methods

Experimental Design

Animal experiments were performed at the Laboratory Animal Core Facility at the University of Debrecen in Hungary in accordance with Hungarian ethical guidelines. Six to eight week old female C57BL6 mice, purchased from Charles River (Budapest, H), were fed for 2 weeks with chow (VRF1, Altromin, D). After the acclimatization period, animals were gavaged daily for one week with specific synthetic ligands dissolved in 25% Cremophor EL (Sigma-Aldrich, Budapest, H)/water (v/v) (Table 1). The vehicle (cremophor EL) was applied at 5 ml/kg body weight (b.w.). Rosiglitazone a PPARγ ligand was bought at Biomol (Butler Pike, USA) [18] and LG268 an RXR ligand [19] was a gift from Ligand Pharmaceuticals (San Diego, CA, USA). AM580 (RAR ligand) [20], GW7647 (PPARα ligand) [21] and GW0742 (PPARβ/δ ligand) [22] were purchased from Biotrend Chem. GmbH (Cologne, D) and T0901317 (LXR ligand) [23] from the Cayman Chemical Company (Tallinn, EST).

Table 1 Amount of ligands applied to mice by oral gavage

Receptor	Specific ligand	Daily dose
Vehicle	Cremophor/EL	5 ml/kg b.w.
PPARα	GW7647	3 mg/kg b.w.
PPARβ/δ	GW0742	5 mg/kg b.w.
PPARγ	Rosiglitazone	3 mg/kg b.w.
LXR	T0901317	20 mg/kg b.w.
RAR	AM580	10 mg/kg b.w.
RXR	LG268	30 mg/kg b.w.

Ligands: GW7647, GW0742, Rosiglitazone, T0901317, AM580 and LG268 were dissolved in 25% Cremophor/water (v/v) and gavaged once a day

Animal Study

Mice had free access to water and food over the duration of the experiment. They were kept at 22 °C room temperature with a 12 h day/night cycle. All animals were killed by anaesthesia with halothane. Blood collection was carried out by cardiac puncture. The blood was centrifuged for 10 min and plasma was stored at −80 °C. The mice were dissected, and liver samples were weighed and immediately frozen in liquid nitrogen and later stored at −80 °C.

Analysis of Composition of Fatty Acid in Total Phospholipids in Plasma by Gas Chromatography (GC)

For the analysis of plasma fatty acids, frozen plasma samples were thawed and the dipentadecanoylphosphatidylcholine (Phosphatidylcholine Dipentadecanoyl, Sigma-Aldrich, Budapest, Hungary) internal standard was added. Lipids were extracted by the addition of 3 ml chloroform and 1 ml methanol according to the method of [24]. The mixture was vortexed at 3,000 rpm for 15 min. The lower layer was then aspirated into vials and evaporated under an N2 stream. Lipid extracts were reconstituted in 70 µl chloroform and lipid classes were separated by thin layer chromatography (TLC). The solvent-mix for TLC of plasma lipids was as follows: hexane:diethyl ether:chloroform:acetic acid (21:6:3:1, v/v). The bands were stained with dichlorofluorescein, removed by scraping and transesterified in 1 ml of 3 N-HCl-methanol solution (Methanolic HCl, 3 N, Supelco, Budapest, Hungary) at 84 °C for 45 min [25]. Fatty acids were analysed by high-resolution capillary GC using a Finnigan 9001 gas chromatograph (Finnigan/Tremetrics Inc., Austin, TX, USA) with split injection (ratio 1:25), automatic sampler (A200SE; CTC Analytic, Zwingen, CH, USA) and flame ionisation detector with a DB-23 cyanopropyl column of 40 m length (J & W Scientific, Folsom, CA, USA). The temperature program was set to the following parameters: temperature of injector at 80 °C/min up to 280 °C, temperature of detector at 280 °C, temperature of column area at 60 °C for 0.2 min, temperature increase by 40 °C/min up to 180 °C, 5 min isothermal period, temperature increase by 1.5 °C/min up to 200 °C, 8.5 min isothermal period, temperature increase by 40 °C/min up to 240 °C and 13 min isothermal period. The constant linear velocity was 0.3 m/s (referred to 100 °C). Peak identification was confirmed by comparison with authentic mixtures of weighed fatty acid (FA) methyl esters (GLC-463: Nu-Chek Prep, Elysian, MN, USA; and Supelco 37 FAME Mix: Supelco, Bellefonte, PA, USA). Individual FA response factors determined from these weighed standards were used to calculate the percentage by weight for individual FA between 12 and 24 carbon atoms from the percentage of area under the curve.

RNA Isolation from Liver and QRT-PCR

Total RNA was isolated from liver and quantified by QRT-PCR (quantitative real time-PCR). In brief, samples of liver tissue (50 mg) were homogenized in Trizol (10 mg tissue/100 µl Trizol, Sigma-Aldrich, Budapest, Hungary) and extracted with chloroform (20 µl/100 µl Trizol). The aqueous phase was mixed with 700 µl of ethanol (70% v/v) and loaded on the RNA isolation column (GenElute Mammalian Total RNA Miniprep Kit, Sigma-Aldrich, Budapest, Hungary). RNA was isolated from tissues according to the given protocol of Sigma-Aldrich and eluted in nuclease free water. Concentration and purity were measured by Nanodrop (Thermo, Budapest, Hungary), while the RNA quality was examined by agarose-gel-electrophoresis (1%, Sigma-Aldrich, Hungary). cDNA was obtained by reverse transcription (10 min 25 °C, 120 min 42 °C, 5 min 72 °C) and amplified via QRT-PCR (40 cycles: 12 s 94 °C, 45 s 60 °C, 60 s 94 °C). Primer and probe for expression analysis (Taq-Man-Gene Expression Assay) as well as quantitative real-time PCR detection system (ABI-PRISM, 7900HT Sequence Detection System) were purchased from Applied Biosystems (Budapest, Hungary). The expression of genes was normalized to cyclophilin A (house-keeping gene): primer 77"+" 5′-CG ATGACGAGCCCTTGG-3′, primer 142 "−" 5′-TCTGCT GTCTTTGGAACTTTGTC-3′, probe (69+, 96+): FAM-CGCGTCTCCTTCGAGCTGTTTGCA. The amplification signal was detected and analysed by the SDS2.1 program from Applied Biosystems, Budapest, Hungary. The expression of SCD1, ELOVL6 and cyclophilin A was determined in the liver.

Analysis of Lipid Species in Plasma and Liver by ESI-MS/MS

Liver homogenate and plasma were extracted according to the procedure described by Bligh and Dyer et al. [26] in the presence of non-naturally occurring lipid species as internal standards. Lipids were quantified by electrospray ionization tandem mass spectrometry (ESI-MS/MS) in positive ion mode as described previously by Brugger et al. and Liebisch et al. [27–29]. Samples were quantified by direct flow injection analysis using the analytical setup described by Liebisch et al. [28, 29]. A precursor ion scan of *m/z* 184 specific for phosphocholine containing lipids was used for phosphatidylcholine (PtdCho), sphingomyelin (CerPCho) [28] and lysophosphatidylcholine (LysoPtdCho) [30]. Neutral loss scans of 141 and 185 were used for phosphatidylethanolamine (PtdEtn) and phosphatidylserine

(PtdSer), respectively [27]. Ceramide was analyzed similarly to a previously described methodology [31] using *N*-heptadecanoyl-sphingosine as the internal standard. Quantification was achieved by standard addition calibration to liver homogenates or plasma using a number of naturally occurring lipid species for each lipid class. The following non-naturally occurring lipid species were used as internal standards: PtdCho 28:0, 44:0, LysoPtdCho 13:0, 19:0, PtdEtn 28:0, 40:0, PtdSer 28:0, 40:0. Quantification was performed by standard addition calibration to plasma and liver homogenates using several naturally occurring lipid species for each lipid class (PtdCho 34:1, 36:2, 38:4, 40:0; Sphingomyelin 16:0, 18:1, 18:0; LysoPtdCho 16:0, 18:1, 18:0; PtdEtn 34:1, 36:2, 38:4, 40:6 and PtdEtnp16:0/20:4; PtdSer 34:1, 36:2, 38:4, 40:6). All standards were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Isotopic overlap corrections of lipid species as well as data analysis by self programmed Excel Macros were performed for all lipid classes according to the principles described previously [28].

Statistical Analysis

Results were displayed as mean with standard error and statistically analysed by ANOVA followed by the Bonferroni post hoc test using the program SPSS (15.0) (SPSS Inc., Chicago, USA). Statistically significant differences were displayed at a value of $P < 0.05$.

Results

Analysis of Fatty Acids Composition in Plasma Phospholipids

Plasma phospholipids fatty acids for substrates, products and product/substrate ratios of SCD1 and ELOVL6 enzymes in the treatment groups are compared to the vehicle group in Table 2. Palmitic acid (16:0) decreased significantly in treatment groups of LXR, RAR and RXR, whereas significantly increased in the PPARα group. Stearic acid (18:0) percentages decreased significantly in the RXR group and increased significantly in the RAR group. Percentages of palmitoleic acid (16:1n-7) did not differ, whereas vaccenic acid (18:1n-7), oleic acid (18:1n-9) and eicosenoic acid (20:1n-9) percentages increased significantly in the LXR and RXR groups. The product/substrate ratios exhibited significant increases following treatment (with the exception of the 20:1n-9/18:1n-9 ratio). Specifically, a significant increase of the 16:1n-7/16:0 ratio has been observed in the LXR group, of the 18:1n-9/18:0 ratio in the PPARα, LXR and RXR groups and of the 18:1n-7/16:1n-7 ratio in PPARγ and RXR groups.

Substrates, products and product/substrate ratios for steroyl-coenzyme A desaturase and elongase 6 enzymes in plasma phospholipids in mice ($n = 6$). Data are given as means ± standard error of percentage of total fatty acid and statistically compared to vehicle, *$P < 0.05$

Hepatic Gene Expression of SCD1 and ELOVL6

Hepatic SCD1 and ELOVL6 expression significantly increased in animals gavaged with LXR and RXR ligands, while treatment with PPARα, PPARβ/δ and PPARγ ligand did not show any significant alteration. Application of an RAR ligand leads to a slight, non-significant suppression of hepatic SCD1 expression, while the expression of ELOVL6 was not effected (Fig. 1).

Analysis of Composition of Fatty Acids of PtdEtn, PtdCho and LysoPtdCho by ESI-MS/MS

Saturated and monounsaturated fatty acids of selected phospholipid classes phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn) and lysophosphatidylcholine (LysoPtdCho) were determined in plasma and liver by ESI-MS/MS and displayed in mean of % of specific lipid class related to total lipid class (Fig. 2). The composition of phosphatidylethanolamine (PtdEtn) species containing one monounsaturated fatty acid (36:1 and 34:1) was mainly influenced by the application of RXR and LXR ligand leading to an increase of bound monounsaturated fatty acids in liver tissue and plasma (Fig. 2). The oral gavage of the RAR ligand, by contrast, decreased monounsaturated fatty acids (displayed by: 32:1, 34:1) in liver and plasma. As with PtdEtn, an increase of monounsaturated fatty acids (displayed by: 32:1, 34:1 and 36:1) in PtdCho was determined in the liver and plasma after the application of RXR and LXR agonists, while the activation of RAR, PPARα and PPARγ lead to a decrease of phosphatidylcholine (PtdCho) 36:1 in the liver and plasma. Furthermore, RAR activation reduced the content of PtdCho 32:1, 34:1 and 36:1 in liver and plasma. The activation of RXR and LXR by their synthetic ligands altered the composition of lysophosphatidylcholine (LysoPtdCho) in liver and plasma in which monounsaturated fatty acids (16:1 and 18:1) were increased. 16:1 in plasma and 18:1 in liver were additionally increased by application of ligands for RXR and PPARα, respectively. A reduction of 18:1 in liver tissue and 16:1 in plasma and liver was determined after the gavage of the RAR agonist. Additionally, the composition of ceramides and sphingomyelins were investigated and remained unchanged in 16:0, 18:0, 16:1 and 18:1 species. In summary, activation of RXR and LXR by their specific ligands was found to lead to an increase of bound MUFAs.

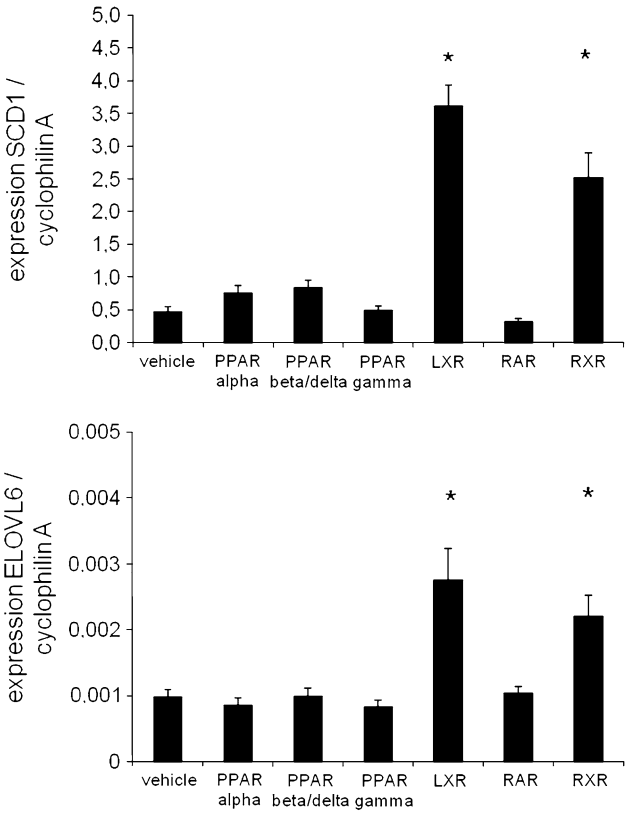

Fig. 1 Expression of SCD1 and ELOVL6 in liver of mice, $n = 6$, measured by QRT-PCR. Expression of SCD1 and ELOVL6 were normalized to cyclophilin A, mean ± standard error of gene expression were displayed and statistically analysed compared to the vehicle, $P < 0.05$(*)

Discussion

In this study, we investigated the influence of nuclear hormone receptor ligand treatment on hepatic SCD1 and ELOVL6 gene expression and the composition of SFA/MUFA bound to phospholipids in liver and plasma. We gavaged specific synthetic ligands of nuclear hormone receptors in concentrations that are able to activate these receptors regarding to previous published studies [18–23]. Our results revealed that the hepatic gene expression of SCD1 and ELOVL6 was significantly increased by LXR and RXR ligand treatment, while RAR and PPARα, β/δ and γ ligands did not significantly alter SCD1 and ELOVL6 gene expression. In addition, metabolic products of SCD1 and ELOVL6 such as 18:1n-7, 18:1n-9 and 20:1n-9 as well as product / substrate ratios 18:1n-9 / 18:0 and 18:1n-7 / 16:1n-7 was significantly increased by RXR and LXR ligand treatments, but not by PPARα, PPARβ/δ or PPARγ ligand treatment.

The nutritional impact of this study is how these nutrient-activated nuclear hormone receptors RXR, RAR, PPARs and LXR are regulating fatty acid metabolism and thereby membrane composition. The connection of food intake and nuclear hormone activations is not very deeply investigated [32, 33], so instead of semi-stable and multipotent natural ligands we used the synthetic ligands specific for these nuclear hormone receptors.

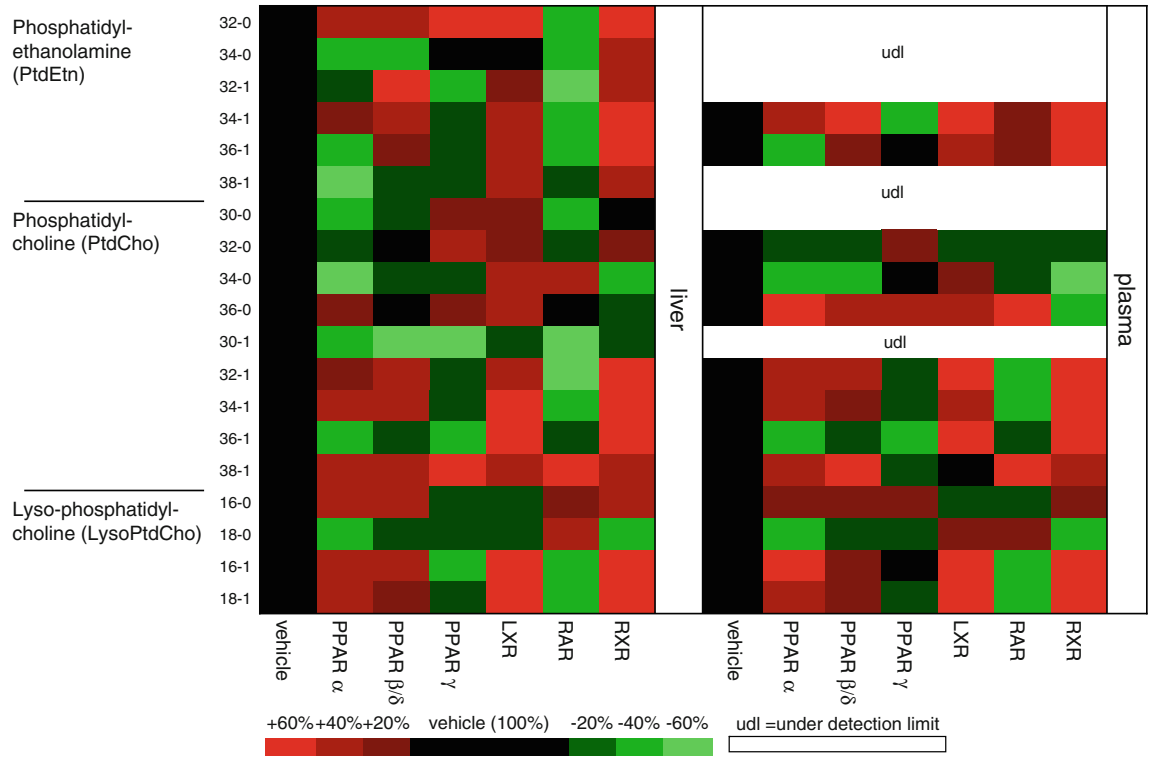

Fig. 2 Analysis of the fatty acids in PtdEtn (phosphatidylethanolamine), PtdCho (phosphatidylcholine) and LysoPtdCho (lysophosphatidylcholine) in liver and plasma of mice, $n = 6$. Percentage of total lipid class and fold change from the vehicle (=100%). *udl* under detection limit

Hepatic SCD1 expression has been extensively investigated and known to be an LXR target gene [10]. Our studies corroborate previous results in mice, namely, that the application of LXR and RXR ligands induces hepatic SCD1 expression. In these same studies, the gavage of PPARα ligands also resulted in an increased SCD1 gene expression, thereby increasing the plasma and hepatic ratios of 16:1n-7/16:0 and 18:1n-9/18:0 [34–37]. Both SCD1 and ELOVL6 are target genes of sterol regulatory element-binding protein 1 (SREBP1). It is a transcription factor inducible by the activation of LXR in hepatic tissue, adipose tissue and intestine [15, 16] and by a synthetic RXR ligand, but not by PPARα or PPARγ ligands [17]. An activation of this transcription factor pathways results in an induction of SCD1 and ELOVL6 [38]. As expected the PPARγ ligand rosiglitazone did not alter hepatic expression of ELOVL6 or SCD1 or phospholipid composition [37–39].

The role of vitamin A in the regulation of SCD1 expression remains controversial. Bioactive vitamin A metabolites like all-*trans*-retinoic acid and *9-cis*-retinoic acid are natural ligands for the activation of RAR, RXR as well as PPARβ/δ mediated pathways [40]. RXR induces SCD1 gene expression, while RAR displayed tendencies to reduce it. The previously reported induction of gene expression of SCD1 by vitamin A has not been specified regarding the responsible nuclear hormone receptor RXR and RAR. RXR can form heterodimers with several nuclear hormone receptors like LXR, which are activated by metabolites of cholesterol and specific synthetic ligands like T091317 [41]. This LXR-RXR heterodimer can also be activated by the synthetic RXR ligand LG268, the potential natural ligand of RXR 9-*cis*-retinoic acid or the selective ligands for LXR and result in an induced expression of LXR specific target genes [42, 43]. In summary, in our study, the activation of LXR by a synthetic LXR-ligand as well as by a synthetic RXR-ligand maybe responsible for the strong induction of the hepatic expression of SCD1 and we postulate that the RXR ligands induced effects are mediated via LXR–RXR pathways. This activation can be inhibited if other nuclear hormone receptors are activated by their ligands. PPARα and LXR are competitors to bind to RXR. This competition leads to a suppression of the SREBP-1c pathway (LXR activated) by the increased formation of PPARα/RXR and decreased availability of LXR/RXR [44].

Following LXR and RXR ligand application 18:1n-7 and 20:1n-9, metabolic products of ELOVL6, as well as product/substrate ratios of 18:1n-7/16:1n-7 but not 20:1n-9/18:1n-9 was significantly increased in plasma phospholipids. In contrast the ratio of 16:1/18:1 in liver of ELOVL6 knock-out mice increased, by reduced conversion of 16:1 to 18:1 compared to wild-type mice [13]. PtdCho, PtdEtn

and LysoPtdCho were analysed separately, and fatty acid composition was determined in order to investigate, which specific phospholipids are influenced by nuclear receptor ligand treatments. PtdEtn and PtdCho contain two esterified fatty acids, while in LysoPtdCho only one fatty acid is contained. In our analysis of the specific phospholipid classes PtdCho and PtdEtn the two bound fatty acids were detected and resulted in an increase of monounsaturated fatty acids incorporated in PtdEtn and PtdCho after the application of LXR and RXR ligands and a tendency to decrease in liver and in plasma by the treatment with an RAR ligand. The increase could be explained by the induction of SCD1 and ELOVL6 in the liver, while the tendency of decrease may be the result of the tendency of suppressed expression of SCD1 by RAR ligand treatment.

In summary, hepatic SCD1 and ELOVL6 expression and product formation was found to be strongly influenced by the activation of LXR–RXR pathways, while RAR and PPARα, PPARγ, and PPARβ/δ pathways exerted minor influence.

Studies directly connecting the activation of nuclear hormone receptors with the formation of phospholipids, reported that the activation of LXR reduced the biosynthesis of PtdEtn by inhibiting the phosphoethanolamine cytidylyltransferase [45]. However, in our study, LXR resulted in an increased total content of PtdCho and PtdEtn in liver and in plasma. Additionally, with the administration of rosiglitazone the synthetic PPARγ ligand is thought to inhibit the formation of PtdCho and PtdEtn in a dose-dependent manner [46]. This could not be confirmed in our studies.

In conclusion, hepatic expression of SCD1 and ELOVL6 was significantly induced by LXR and RXR ligand application, while RAR, PPARα, β/δ and γ ligands did not significantly alter their gene expression. The nutritional relevance of these findings must be examined using various nutritional supplementations [47, 48], which have been shown to activate specific nuclear hormone receptor pathways to elucidate nutritional activation of gene expression pathways. Unfortunately selective activations by nutrients have been reported as difficult [49]. The MUFA incorporated into phospholipids were increased suggesting that the phospholipid MUFA and SFA compositions in plasma and liver are mainly under the control of SCD1 and ELOVL6 pathways.

Acknowledgments This study was conducted with the support of Tamas Röszer and Eva Papp. Ralph Rühl and Johanna Mihály are members of the EU FP7 COST "Mitofood" project. GS and GL were supported by the seventh framework program of the EU-funded "LipidomicNet" (proposal number 202272).

alterations in the numbers and function of macrophage and dendritic cells in visceral fat [2–4]. Inflammation in visceral adipose tissue is thought to play a central role, with the degree of inflammation being demonstrated to inversely correlate with insulin sensitivity [5–8]. Conversely, treatment of inflammation has been shown to reverse insulin resistance and improve indices of whole body glucose homeostasis. The mechanisms by which a dysregulated immune axis may contribute to IR is multifactorial but a key pathway is through the release of pro-inflammatory cytokines (TNFα and IL-6), and immunoattractant chemokines that further contribute to an adaptive immune response [9–16]. Mice that lack TNFα and CCR-2, the receptor for monocyte chemoattractant protein 1 (MCP-1/CCL-2), have improved insulin sensitivity and glucose metabolism when compared to adiposity-matched controls [13, 17]. Recent studies show that the Toll-like receptor 4 (TLR4) may play a central role in the link among insulin resistance, inflammation, and obesity; TLR4 deficiency prevented insulin resistance and obesity-mediated activation of IκB kinase (IKKb) and c-Jun NH2-terminal kinase (JNK), suggesting that TLR4 is a key modulator in the cross-talk between inflammatory and metabolic pathways [18–22].

Alpha lipoic acid (αLA) is a disulfide derivative of octanoic acid that forms an intra-molecular disulfide bond that is readily reduced to dihydrolipoic acid intra-cellularly [23]. Anorectic effects in rodents have been reported for αLA as well as improved hypertriglyceridemia in Zucker diabetic fatty rats [24]. αLA has been reported to increase insulin sensitivity in the skeletal muscle via AMPK activation in obese rats [25] though other researchers have failed to confirm this finding [24]. αLA has been shown to reduce NF-κB activation in human monocytic cells and reduce inflammation [26]. However the impact of αLA on innate immune inflammation and whether these effects lead to coordinate change in indices of IR/glucose homeostasis have not been investigated. We employed a novel model of diet-induced obesity/IR using transgenic reporter mice that express YFP under control of a c-fms reporter (c-fms^{YFP+}) that allows monocyte specific expression of the reporter and unparalleled ability to track these cells in visceral adipose tissue. In carefully performed pair-fed experiments, we demonstrate that αLA improves key metrics of innate immune activation and IR.

Materials and Methods

Animals

Oral αLA Regimen

c-fms^{YFP+} transgenic mice were generated at the Transgenic Animal Service of Queensland, Brisbane, Queensland, Australia by injection of the transgenes into pronuclei of (C57BL/6 × CBA)F_1 (BCBF1) fertilized eggs [27]. The Committee on Use and Care of Animals from the Ohio State University (OSU) approved all experimental procedures. c-fms^{YFP+} mice of the FVB/N strain were bred and genotyped at OSU and housed in cages individually. YFP^+ males at 6 weeks of age were fed a HFD for 8 weeks (42% energy from fat—Harlan Teklad TD88137) prior to randomized to three dietary groups (5 mice/group): ad libitum, αLA-fed, and pair-fed to αLA. Pair-feeding was employed as αLA is well known to modulate central appetite pathways and reduce food intake. Food intake was monitored every other day by weighing the remaining chow; pair-fed mice were then offered the same amount of food as consumed by the αLA-mice. αLA (2 mg/ml; Sigma Aldrich T5625) was administered in the drinking water (ultrapure 18.2 MΩ) at a pH of 8.0 with NaOH. Pair-fed mice were given ultrapure water at a pH of 8.0. αLA was administered for 8 weeks before mice were sacrificed. Mice consumed approximately 6 mg of αLA per day over the course of the study, which was a dose of 167 mg/kg at time zero, and 157 mg/kg after 8 weeks due to weight gain.

Determining an appropriate oral αLA dose was challenging as there were no published data on plasma αLA levels in mice after oral administration. Thus, we used a dose previously shown to be effective in mice on disease processes, that did not have adverse side effects, and which was reasonable in regards to what plasma levels might be expected. Yi and Maeda [28] used approximately 200 mg/kg via addition to the chow and showed significant abrogation of atherosclerotic lesion development. Additionally, if one considers 50 mg/kg injections in mice resulted in modest plasma levels of 7.6 ± 1.4 μg/ml [29], the oral dose of ∼160 mg/kg used in this study is expected to result in <7 μg/ml plasma concentrations due to bioavailability limits and gastrointestinal metabolism.

IP αLA Regimen

Males at 6 weeks of age were fed a HFD for 8 weeks, before being randomized to αLA or vehicle control groups. A solution of sterile αLA in saline (4 mg/ml) was injected intraperitoneally at a dose of 10 mg/kg once daily, 6 days a week. Mice were weighed daily to ensure accurate dosing. αLA dosing in the mouse was done with attention to the concentration reasonably obtained in human plasma by use of conventional dietary supplements. Healthy human subjects given an average oral dose of 8.25 mg/kg (600 mg) of R-αLA sodium salt dissolved in water were shown to have a mean maximum plasma concentration (C_{max}) of 16.03 μg/ml [30]. However, others have reported a much lower oral bioavailability, with 600 mg of racemic αLA via solid supplement resulting in a C_{max} of 2.85 [31] and

2.7 μg/ml [32]. These data suggest that potassium or sodium salt of lipoic acid have higher oral bioavailability, as was administered in this study. Additionally, a human oral dose of 1,200 mg resulted in plasma C_{max} levels of 3.8 ± 2.6 to 10.3 ± 3.8 μg/ml with area under the curve (AUC) levels from 443.1 ± 283.9 to 848.8 ± 360.5 which was similar to a subcutaneous injection of 50 mg/kg αLA in mice which yielded 7.6 ± 1.4 μg/ml and 223 ± 20 AUC [29]. The dose of 10 mg/kg (daily) and 50 mg/kg (acute) used in this report are reasonable if not conservative in this context.

Serum Cytokine Analysis

Blood was collected via heart puncture under CO_2 anesthesia and allowed to coagulate at room temperature followed by centrifugation. Serum cytokine levels were analyzed using BD™ Cytometric Bead Array, Mouse inflammation kit according to the manufacturer instructions.

Epididymal Fat Pad Digestion and Quantification of ATMs

Epididymal fat pads from c-fms^{YFP+} mice at the end of the treatment phase were excised, minced, washed in 1× PBS, and digested with sterile collagenase type II from *Clostridium histolyticum* (1 mg/ml) in DMEM (10% FBS) at 37 °C with shaking (140 rpm) as detailed previously [4, 33]. The digesta was filtered through a 100 μm nylon cell strainer before centrifugation (300×*g*, 10 min). The resulting pellet was defined as the stromal vascular fraction (SVF). Viable adipose tissue mononuclear cells were isolated from SVF using Lympholyte M (Cedarlane Laboratories Ltd, Burlington, NC). Approximately 10^6 cells were incubated with mouse FcR blocking reagent (Miltenyi Biotec Inc., Auburn CA) in FACS buffer (1× PBS, 5% FBS) for 10 min at 4 °C followed by staining with F4/80-PE-Cy5, CD11b-PE, and isotype control antibodies (Biolegend, San Diego, CA). Cells were washed in FACS buffer 3 times and measured (BD FACS LSR II™ flow cytometer, Becton–Dickinson, San Jose, CA). Data were analyzed using BD FACS Diva 6.0.1 software (Becton–Dickinson, San Jose, CA). Gates were set using the appropriate isotype controls.

Live Confocal Microscopy of Unfixed Adipose Tissue

Epididymal fat was removed using sterile techniques and carefully cut into ~3–4 mm pieces. After rinsing with 1× PBS the tissue was incubated with *Griffonia simplicifolia* isolectin GS-IB4 conjugated to AlexaFluor 488 (10 μg/ml—Molecular Probes), BODIPY 558/568 (5 μM—Molecular Probes), and Hoechst 33342 (40 μM—Molecular Probes) for 1 h in 1× PBS supplemented with 1 mM $CaCl_2$. Isolectin has been shown to be an endothelial cell specific stain in the adipose [34]. Tissue was visualized on a Zeiss laser scanning microscope 510 under 40× water immersion.

Monocyte-Vascular Adhesion as Assessed by Intravital Microscopy

Mice were given αLA IP (50 mg/kg body weight) 24 h before the start of the experiment. TNFα was injected IP (1 μg/kg; 0.9% saline with 1.0% BSA) 4 h before visualization. Under ketamine/xylazine anesthesia, the testicular cremaster muscle was exposed using a dissecting microscope (2×; Nikon SMZ 645, Japan). The cremaster muscle was bathed with Ringers Lactate at 37 °C and monocyte-endothelial interaction was assessed in 15–25 vessels using a Nikon Eclipse FN1 microscope (Nikon, Japan) with a 40×/0.80 W water immersed objective at a 2.0 mm working distance. In all experiments video images were captured and digitalized to 12-bit TIF images using Metamorph software (version 7.1.2.0, Metamorph, Downingtown, USA). Rolling YFP^+ cells were counted per minute for different vessel diameters and vessel segments. All YFP^+ cells, per 100 μm of vessel length, that were immobile for at least 30 s were interpreted as adherent cells [35]. Calculations to determine the number of rolling and adherent cells according to vessel diameter were performed using Opti Test (Version 1.4.1.0).

Bone Marrow Derived Macrophage Culture and Differentiation

Bone marrow was isolated from WT or TLR4 deficient mice and grown in DMEM media supplemented with 10% FBS in the presence of L-cell conditioned media for 5 days. The differentiated macrophages were pretreated with αLA (100 μg/ml) 45 min before LPS (0.5 μg/ml) addition. Post absorption, αLA is rapidly cleared from circulation via renal excretion and tissue uptake. While much is excreted, tissues especially the liver, heart, skeletal muscle, and possibly the brain, accumulate αLA and extensively catabolize to a dozen or more metabolites depending on species [36, 37]. There is also evidence the αLA is rapidly reduced by cells in vitro to DHLA and subsequently excreted [37]. Thus, determining in vitro doses that might be physiologically relevant was challenging. 100 μg/ml (~0.5 mM) αLA was previously shown to prevent LPS-induced TNFα expression in mouse monocytes in vitro and was found to be an optimal dose for Akt phosphorylation [38]. This does is higher than would be obtained in mouse serum, thus it most likely super-physiological but is no more than tenfold higher than what is possible in serum. Also, relative to published in vitro

studies using αLA the dose used herein is conservative [39, 40].

Quantitative-Real-Time PCR Detection of Macrophage Activation Status

RNA was isolated using Absolutely RNA®, Stratagene™ according to the manufacturer's instructions including DNase digestion. RNA quality and quantity were assessed by agarose gel electrophoresis and a Nanodrop™ spectrophotometer. cDNA was reverse transcribed using 800 ng of total RNA according the manufacturer's instructions (Invitrogen Life Technologies—M-MLV reverse transcriptase) using random primers. PCR was performed using SYBR Green I master mix (Roche) on a Roche Lightcycler 480. All real-time reactions had the following profile conditions: 10 min hot start at 95 °C followed by 45 cycles of 94 °C 10 s, 60 °C 20 s, 72 °C 20 s. Reference and target gene dilution standards were run in triplicate for each primer set to calculate PCR efficiency using the above profile. The concentration ratios were determined after PCR efficiency correction by relative quantification analysis using Lightcycler 480 software. All target genes were expressed as fold increase compared to control. Melting/dissociation curves were run on each plate to assure the production of one amplicon of the same melting temperature for each primer set. Real time primers (listed below) were designed to span genomic introns, thus avoiding amplification of genomic DNA possibly present in the RNA samples. "No template," cDNA negative controls were included for each gene set in all PCR reactions to detect contamination. Primers used were: TNFα For 5′-caacggcatggatctcaaagac-3′, Rev 5′-agatagcaaatcggctgacggt-3′; CCR2 For 5′-ttgg gtcatgatccctatgtgg-3′, Rev 5′-ccttcctaatcctgtgaccctt-3′; IL-6 For 5′-attaacacatgttctctgggaaatcgt-3′ Rev 5′-tatatccagtttgg tagcatccatca-3′ MCP-1 For 5′-gcagcaggtgtcccaaagaa-3′ Rev 5′-atttacgggtcaacttcacattcaa-3′ Macrophage galactose *N*-acetyl-galactosamine receptor-specific lectin 1 (Mgl1) For 5′-tggatgggaccgactttgagaa-3′; *Mgl1* Rev 5′-gggac cacctgtagtgatgtg-3′; *Glyceraldehyde-3-phosphate dehydrogenase (GAPDH)* For 5′-gtgaagcaggcatctgaggg-3′; GAPDH Rev 5′-cgaaggtggaagagtgggagt-3′

Chemiluminescent Electrophoretic Mobility Shift Assay

Nuclear extracts for use in EMSAs were performed using the previously published protocol [41, 42]. Oligonucleotides probes (NFκB sense 5′-AGTTGAGGGGACTT TCCCAGGC-3′, NFκB antisense 5′- GCC TGG GAA AGT CCC CTC AAC T-3′) were biotinylated using Biotin 3′ End DNA Labeling Kit (Pierce, Rockford IL #89818) according to manufacturer's instructions. Lightshift™ Chemiluminescent EMSA kit (Peirce, Rockford IL #20148) was used to perform the binding reaction and chemiluminescent detection. Briefly, 5 μg of nuclear extract was incubated at room temperature in a binding reaction which included a final concentration of: 1× binding buffer, 50 ng/μl Poly (dI·dC), 0.05% NP-40, 2.5% glycerol, and 5 mM $MgCl_2$ for 15 min prior to addition of the biotinylated probes. The complex was run on a pre-electrophoresed 6% polyacrylamide gel in 0.5× TBE (pH 8.4) at 100 V for approximately 45 min followed by wet-transfer in 0.5× TBE to Amersham Hybond™ –N+ membrane (GE Healthcare) at 380 mA for 30 min. The transferred DNA was cross-linked to the membrane before continuing with protocol according to manufacturer's instructions. X-ray film was exposed to membrane and developed.

Results

Alpha Lipoic Acid (αla) Administration Improved Markers of Systemic and Local Insulin Sensitivity and Triacylglycerol Metabolism

Oral αLA Regimen

At the end of 8 weeks of HFD feeding, c-fms^{YFP+} transgenic mice were markedly insulin resistant demonstrating evidence of fasting hyperglycemia and hyperinsulinemia. Body weight increased approximately 16 g. Following this period mice were assigned to ad libitum treatment (αLA 2 mg/ml drinking water), or pair-fed groups. c-fms^{YFP+} mice administered αLA-fed mice exhibited improved fasting glucose approaching a high normal level (125 ± 10.6 mg/dl) compared to the pair-fed group (179 ± 15.7 mg/dl) (Fig. 1a). Fasting insulin levels were also significantly lower in αLA-fed mice (0.96 ± 0.21 ng/ml) than the pair-fed group (2.03 ± 0.17 ng/ml) and the ad libitum group (2.23 ± 0.63 ng/ml). Food intake suppression was modest and decreased over time with non-significantly different body weights across groups after 8 weeks of feeding (Ad lib 40.9 ± 1.4 g; Pair-fed 39.8 ± 0.9 g; αLA-fed 38.2 ± 0.8 g). Cholesterol and triglyceride levels were unchanged with αLA feeding. αLA feeding resulted in a significant decrease in serum IL-6 levels (Ad lib 11.9 ± 4.3 ng/ml; Pair-fed 7.4 ± 2.6 ng/ml; αLA-fed 1.1 ± 0.2 ng/ml), an insignificant but measured decrease in MCP-1, and no change in circulating IL-12, TNFα, IFNγ, and IL-10 cytokines (Fig. 1c).

IP αLA Regimen

In contrast to the weight-neutral effects of oral αLA, an IP regimen did have significant weight loss effects. In this

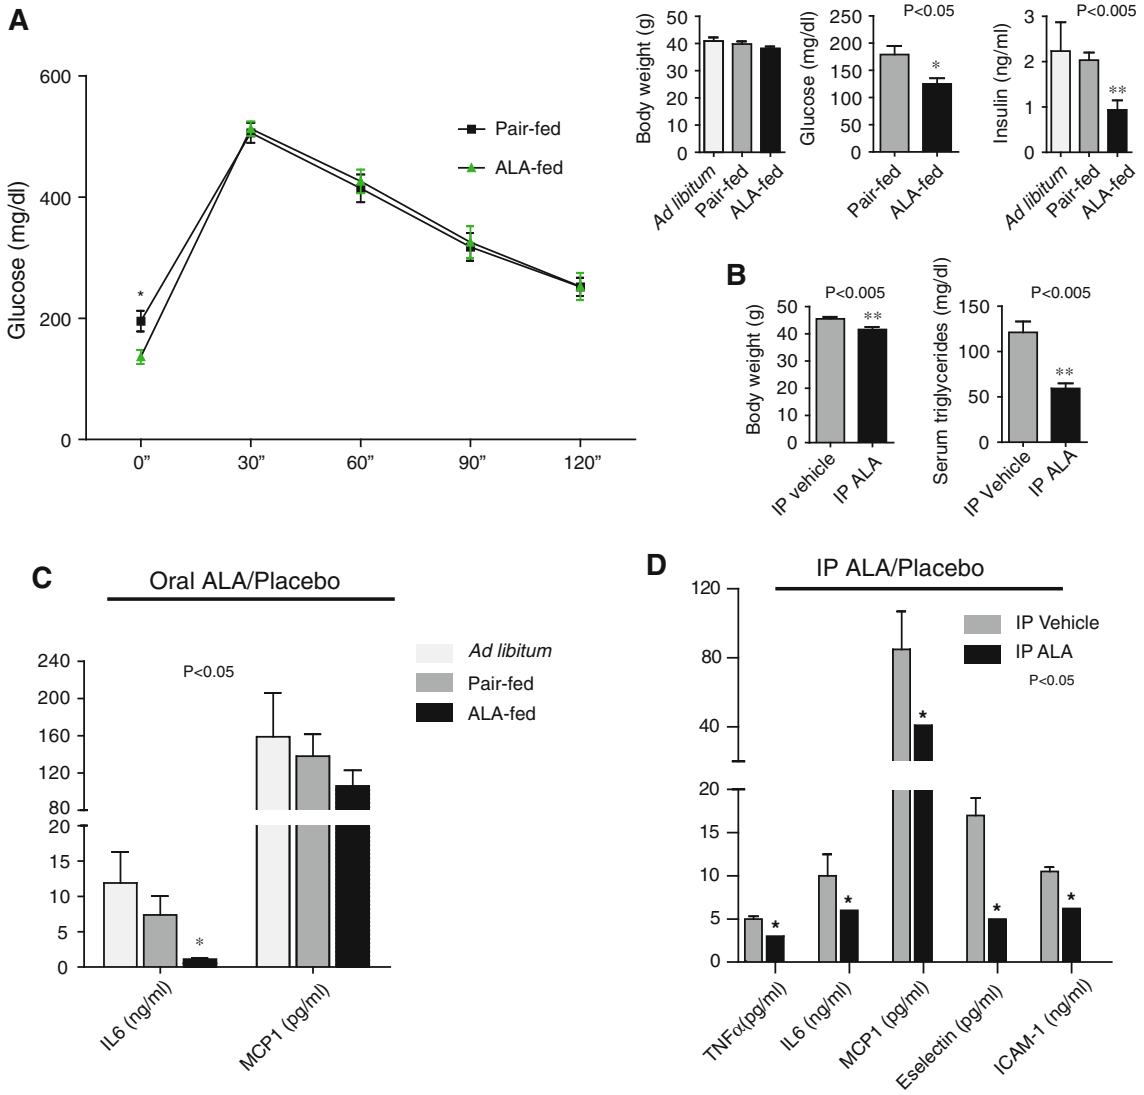

Fig. 1 Effect of α-lipoic acid (αLA) on measures of glucose metabolism. **a** Plasma glucose was measured every 30 min after intra-peritoneal injection of 2 mg/g body weight dextrose after an overnight fast. Fasting glucose and insulin in the αLA-fed mice was significantly lower than the pair-fed control group; $*P < 0.05$; $**P < 0.005$ αLA-fed group compared to pair-fed ($N = 5$/group). However, glucose clearance post-bolus was not improved in the αLA group. **b** IP αLA resulted in significant weight loss, a more dramatic effect on glucose clearance (not shown), and decreased fasting serum triglycerides compared to IP vehicle; $**P < 0.005$. Serum cytokines in HFD fed mice receiving either αLA or placebo by drinking water (**c**) or via intraperitoneal injection (**d**). Oral αLA resulted in a significant decrease in circulating IL6 levels and a nonsignificant decrease in MCP1; there were no changes in serum IL-12, TNFα, IFNγ, and IL-10 cytokine values within the detection the range of the assay. IP αLA administration resulted in a significant decrease in circulating cytokines involved with vascular adhesion and inflammation

experiment as with the oral regimen, after 8 weeks of HFD feeding, mice were randomized to αLA and vehicle control groups. IP αLA resulted in a significant decrease in body weight of 3.9 ± 0.8 g (41.6 ± 0.93 g in IP αLA vs. 45.5 ± 0.73 g in vehicle injected controls). There was no change in plasma total cholesterol but circulating triglycerides were significantly lower in the IP αLA group (59.25 ± 5.7 mg/dl) compared to IP vehicle controls (121 ± 12 mg/dl). IP αLA resulted in significant decreases in serum IL-6, MCP-1, and TNFα. IP αLA also resulted in a significant decrease in serum E-selectin and ICAM-1, markers of monocyte vascular adhesion (Fig. 1d).

In light of its weight neutral effects we proceeded to investigate oral supplementation of αLA at ~160 mg/kg. IP-αLA induced weight loss would have rendered dissociation of weight-loss effects from weight-loss independent effects difficult. Thus continued experimentation focused on the effects of dietary αLA as the effects on food intake

could be more easily addressed and because αLA is most commonly consumed as a dietary supplement.

Dietary αLA Attenuated Visceral Adipose Tissue Macrophage (VATM) Infiltration and In Vivo Macrophage Activation

VATM content of the epididymal adipose of c-fms^{YFP+} mice was quantified using yellow fluorescent protein expression (CD115) in combination with surface staining for CD11b and F4/80, markers for monocytes and mature macrophages, respectively. We found that dietary αLA treatment dramatically decreased the number of YFP$^+$ CD11b$^+$ macrophages per gram of epididymal fat from $6.1 \times 10^5 \pm 0.5$ cells per gram in the ad libitum and $7.4 \times 10^5 \pm 1.7$ in the pair fed group to $1.5 \times 10^5 \pm 0.4$ cells per gram in αLA-fed mice (Fig. 2). This phenomenon was visualized histologically using confocal microscopy of unfixed epididymal adipose collected, stained, and visualized consecutively upon sacrifice. Representative images are provided in Fig. 3a. Assessment of confocal images in the pair-fed mice demonstrate a pattern of crown like structures (CLS) indicative of dead or dying adipocytes [43] and macrophage infiltration. The prevalence of CLS was dramatically decreased in the visceral adipose of the αLA-fed group compared to pair-fed and ad libitum (Fig. 3a). We then examined CD11c$^+$ cells in the stromal vascular fraction of adipose tissue derived from YFP$^+$ animals. αLA-feed significantly attenuated the number of CD11c$^+$ inflammatory macrophages in the visceral adipose with the ad libitum group containing $1.7 \times 10^5 \pm 0.4$ cells per gram, the pair-fed group $1.5 \times 10^5 \pm 0.4$ cells per gram and the αLA-fed group only $0.4 \times 10^5 \pm 0.09$ cells per gram. To further examine the effect of αLA on monocyte/endothelial interactions and monocyte activation pathways, we tested the effects of αLA on TNFα mediated monocyte adhesion using a model of acute inflammation and additionally tested the effects of αLA on monocyte activation in vitro.

αLA Pretreatment Prevented TNFα-Mediated Vascular Adhesion In Vivo

Intravital microscopy of the cremasteric vasculature showed that the number of free-flowing, rolling YFP$^+$ cells was increased by TNFα (Fig. 3b). While αLA did not have an effect of rolling monocytes, αLA pretreatment significantly prevented TNFα-mediated YFP$^+$ cell adherence to vessel walls suggesting that αLA may modulate adhesion molecules involved in firm monocyte adhesion but not

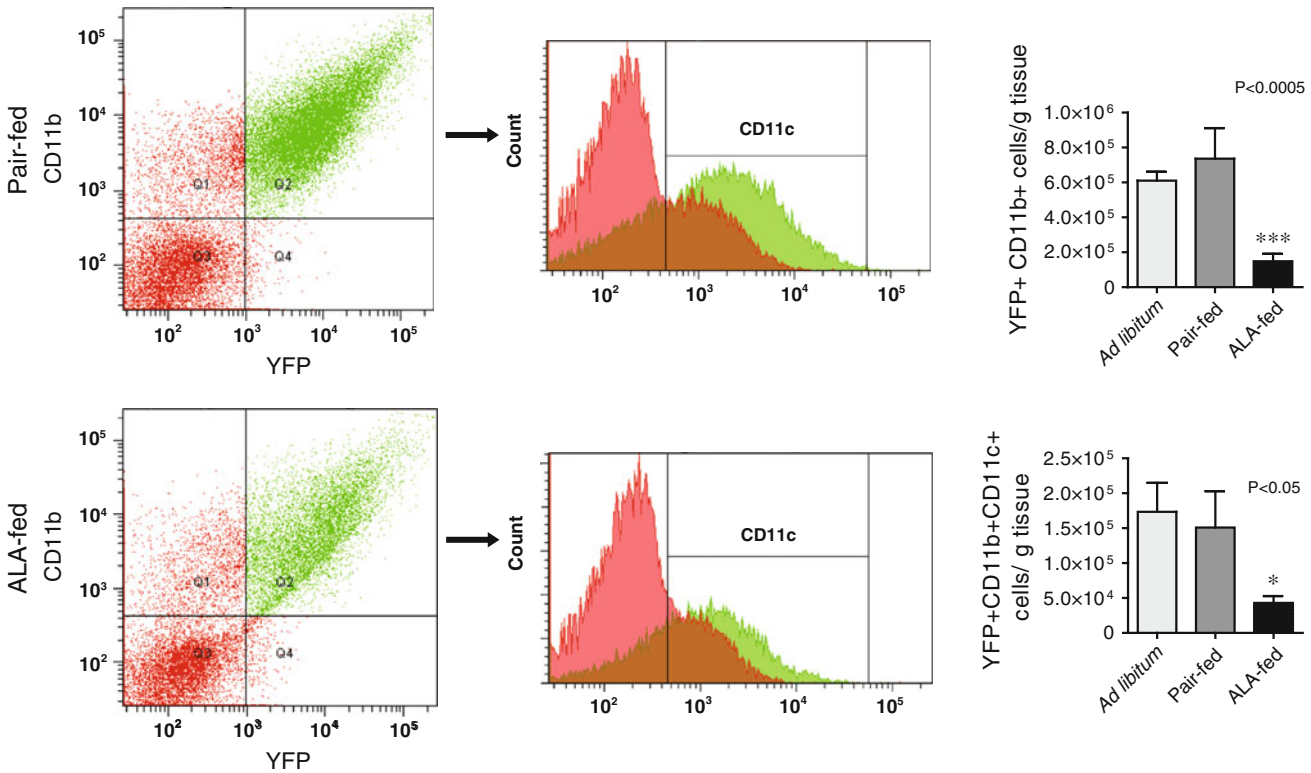

Fig. 2 Macrophage content analysis of the epididymal adipose by flow cytometry. The ad libitum and pair-fed groups had significantly more CD11b$^+$ YFP$^+$ cells per gram of adipose tissue than the αLA fed group, $***P < 0.005$. Oral αLA significantly decreased the number of CD11c positive, inflammatory macrophages, per gram of adipose, $*P < 0.05$ versus pair-fed

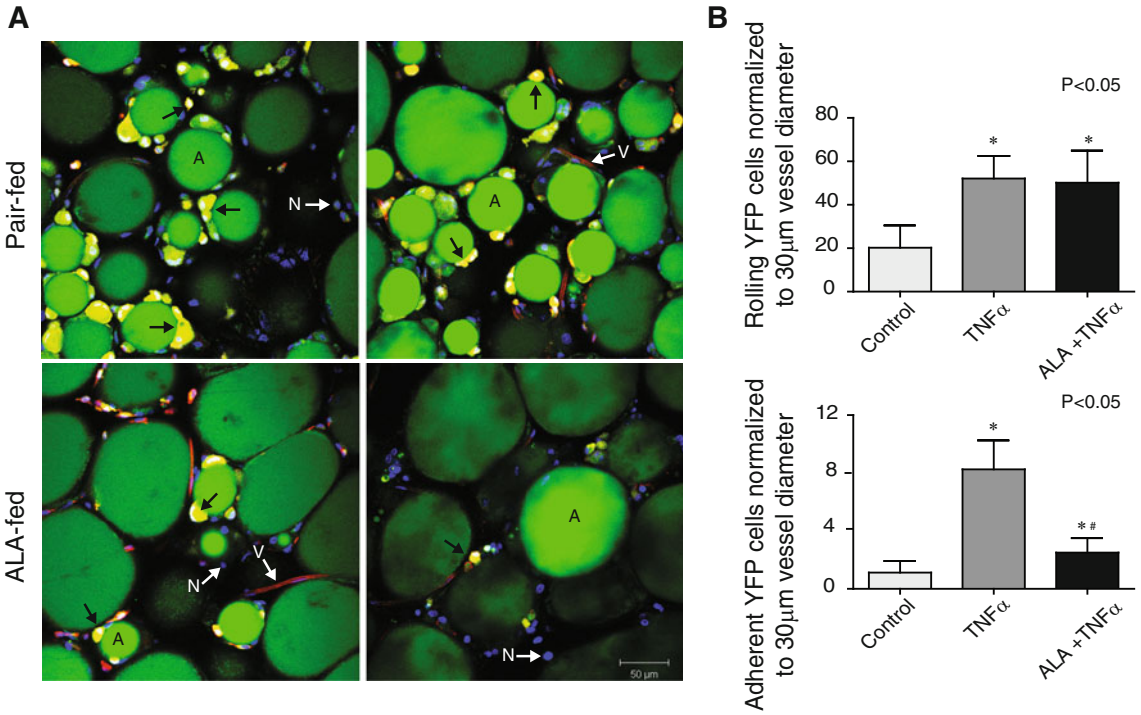

Fig. 3 **a** Representative confocal microscopy images of live epididymal adipose. YFP^+ (*yellow*/indicated by *arrow*) cell infiltration and the prevalence of multiple "crown-like" structures surrounding adipocytes (*green*/indicated by the letter *A*) in the pair-fed and αLA-fed groups. Blood vessels are shown in *red* (indicated by *white arrow V*) due to endothelial staining with *Griffonia simplicifolia* isolectin GS-IB4 conjugated to AlexaFluor 488, most of the YFP expressing cells are outside of the vasculature. The adiposomes are shown in *green* (indicated by the letter *A*) due to BODIPY 558/568 staining and nuclei are *blue* (indicated by *white arrow N*) due to Hoechst 33342 staining. **b** Acute αLA IP pretreatment reduced YFP^+ cell adhesion in cremasteric vessels after injection of TNFα; $^*P < 0.05$ versus control, $^{\#}P < 0.05$ versus TNFα

those involved in rolling. To further examine the effect of αLA on mechanisms by which αLA may modulate excess monocyte infiltration into the adipose we examined the effects of αLA on MCP-1 and CCR-2 in response to a prototypical TLR4 agonist, LPS.

αLA Attenuates MCP-1 Expression on Macrophages via TLR4 Mechanisms

Bone marrow-derived macrophages (BMDM) from wild-type Balb/c mice and toll-like receptor 4 (TLR4) null mice were pretreated with αLA or vehicle control then activated with lipopolysaccharide (LPS), a TLR4 ligand [44]. αLA significantly decreased MCP-1 and TNFα gene expression in response to LPS stimulation but had no effect on IL-6 activation (Fig. 4a). αLA significantly decreased basal TNFα expression in both TLR4 WT and deficient macrophages. The degree of attenuation of LPS-mediated TNFα expression by αLA alone was small but comparable to that seen with $TLR4^{def/def}$. The TNFα and IL-6 response to LPS in $TLR4^{def/def}$ macrophages was significantly blunted compared to the WT cells. MCP-1 induction by LPS was small compared to TNFα and IL6. LPS-mediated MCP-1 expression, however, was potently inhibited by αLA pretreatment. Interestingly, LPS activation had no effect on CCR2 expression, though αLA significantly down-regulated CCR-2 expression in the presence and absence of LPS; suggesting that non-TLR4 pathways are probably involved in CCR2 down-regulation in response to αLA. αLA increased Mgl1 gene expression, a marker of alternative macrophage activation, while LPS decreased expression (data not shown). These data suggest that αLA may function as an anti-inflammatory agent by preventing inflammatory gene expression. Since nuclear factor kappa B (NF-κB) plays a pivotal role in cellular inflammatory processes we decided to assay the effect of αLA on NF-κB-DNA binding in these TLR WT macrophages. An electrophoretic mobility shift assay showed LPS treatment dramatically increased the binding of NF-κB to the oligonucleotide probe. αLA (100 μg/ml) pretreatment of WT BMDM lead to the inhibition of LPS-mediated (0.5 μg/ml) NF-κB activation as measured by binding to probe DNA.

Discussion

Visceral adipose inflammation is believed to play an etiologic role in the development of insulin resistance (IR) in

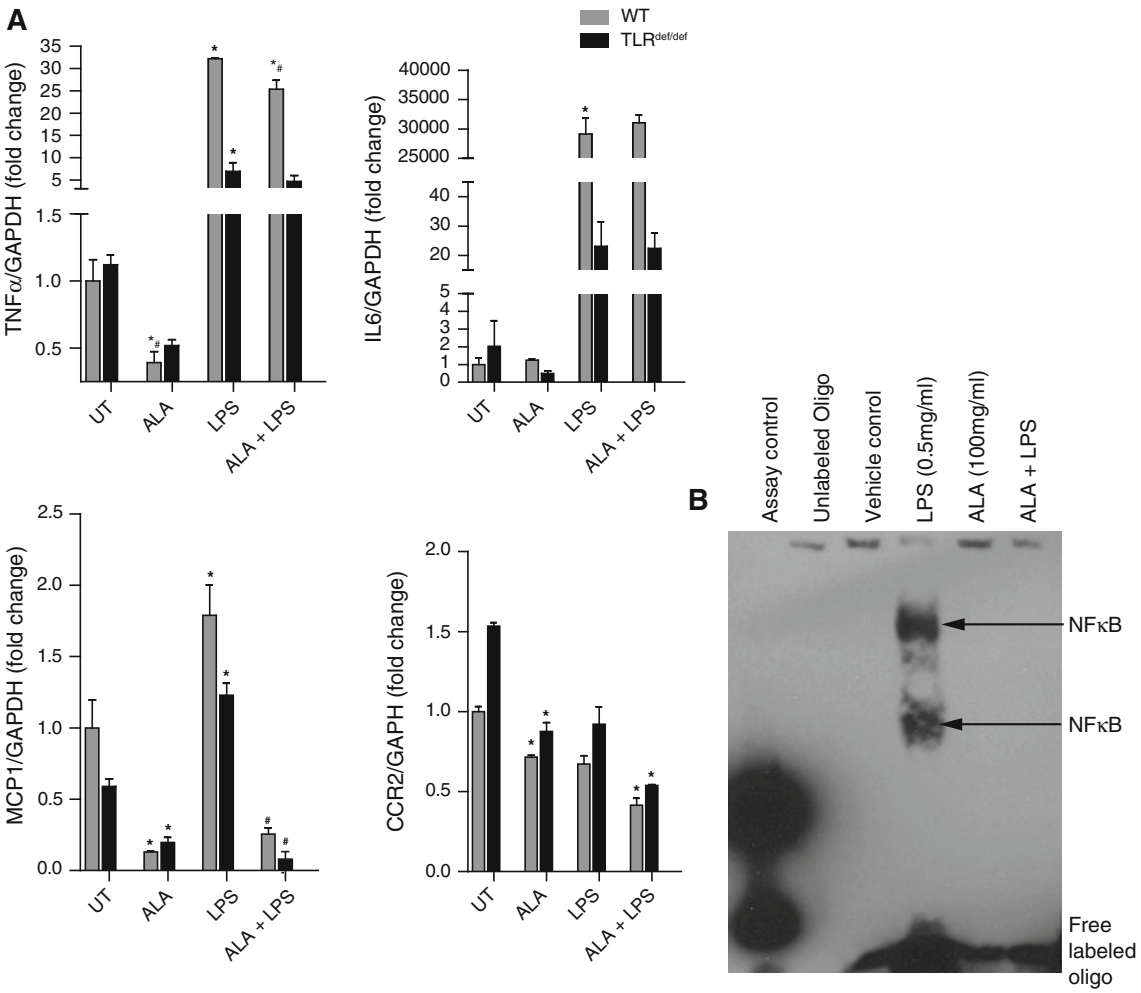

Fig. 4 αLA pretreatment (100 μg/μl) attenuated expression of inflammatory and homing molecules in cultured bone marrow derived macrophages activated with LPS (0.5 μg/μl), $^{*}P < 0.05$ compared to respective untreated (UT) control; $^{\#}P < 0.05$ compared to respective LPS treatment group. TNFα, MCP-1, and CCR2 gene expression is significantly down-regulated by αLA in cultured murine macrophages

obesity and is typified by early, and often dramatic, increases in innate immune cells such as macrophages. With accumulation of neutral lipids in the adiposome, adipocytes hypertrophy and a subset undergo "necrosis-like" cell death resulting in the recruitment of macrophages [45, 46]. The relationship between alterations in innate and adaptive immune cell numbers, their effect on the adipose, and their contribution to the eventual development of obesity is largely attributed to the production and systemic introduction of inflammatory mediators. The pathophysiological processes that develop due to obesity have various putative etiological origins involving multiple tissues, including immune-modulated inflammation of the visceral adipose.

In this study we assessed the effects of αLA on the development of insulin resistance and adipose inflammation in a novel model of murine diet-induced obesity and IR. We demonstrate in pair-feeding experiments that oral αLA exerts beneficial weight loss-independent effects on insulin sensitivity, visceral adipose inflammation, vascular adhesion, and whole body inflammatory cytokine markers. Oral αLA reduced VATM content and activation in insulin resistant, obese mice. αLA also prevented LPS-mediated NF-κB activation and decreased the expression of inflammatory/migratory genes in un-stimulated and LPS-stimulated macrophages. These results suggest that αLA has a potent effect on macrophage activation status and thus may modulate the innate immune response in chronic inflammation in the visceral adipose tissue, a hallmark of type 2 diabetes and the metabolic syndrome.

Though oral αLA was less effective than IP αLA at lowering blood glucose and normalizing markers of insulin resistivity, at the dose used orally, it lacked weight loss effects and obviously prevented its confounding influence in the assessment of results. αLA decreases hypothalamic AMPK activity and causes profound weight loss in rodents by reducing food intake and enhancing energy expenditure [47]. Pair-fed experiments suggest a minimal effect of oral

αLA at ~160 mg/kg on food intake and body weight over 8 weeks in mice. It should be noted that the first week of oral αLA did result in decreased food intake and some weight loss, however, over the subsequent weeks the effect subsided and weights normalized then increased to levels comparable to controls. The reduction in fasting glucose and insulin by oral αLA did not translate into improved glucose bolus clearance, suggesting that αLA did not abrogate the effects of obesity on glucose metabolism in the long term. However, αLA may selectively regulate fasting indices of glucose homeostasis which have been shown to be sensitive to anti-inflammatory measures [48]. Our data suggest that αLA has a moderate effect in already obese mice. The effect may be more dramatic in mice that begin oral αLA prior to a HFD or in mice that are not already overtly insulin resistant.

The marginal effects of post-prandial indices contrasted dramatically with the ability of αLA to reduce the number and activation status of macrophages in the epididymal adipose. Visceral adipose inflammation is a major area of study in obesity and IR, with visceral adipose inflammation being a putative pathophysiological phenomenon with the activation status of VATM being of particular interest. The phenotypic activation state of macrophages is a crucial determinant of functionality and the inflammatory state. Resident tissue macrophages in lean mice display a phenotype that is typical of cells committed to efferocytosis and scavenger functions and are referred to as M2 or "alternatively activated" macrophages expressing anti-inflammatory cytokines (*Il10, Arginase1, Mgl1*) [49] concomitantly with lower levels of M1 genes. High fat diet (HFD) and obesity in mice lead to a M1 or "classically activated" state which have been shown to express CD11c and secrete pro-inflammatory cytokines such as TNFα, IL-6, and IL-12 [4]. This phenotypic shift is now believed to play an important role in the genesis of IR [4]. The dramatic attenuation in VATM numbers and CD11c expression observed by αLA is consistent with an effect on activation status of adipose macrophages. Interestingly, the effects of αLA are similar to those reported in obese CCR2 null mice versus obese wild type (WT) mice [13]. Obese CCR2 null mice also showed a reduction in VATM with a modest decrease in whole body insulin resistance. Our data suggest that modulation of VATM activation and visceral infiltration by αLA in already obese mice decreases systemic markers of inflammation and improves markers of insulin sensitivity.

In separate experiments, we addressed the effects of αLA on the monocyte/macrophage activation state and extravasation by demonstrating that acute αLA administration reduced monocyte adhesion to the endothelium. Homing of macrophages to the visceral adipose may be modified by decreasing vascular adhesion, the first step in extravasation and homing to tissue. Our intravital microscopy data demonstrate a dramatic effect of αLA in reducing monocyte adhesion to venules and supports the hypothesis that αLA may reduce monocyte efflux from the vasculature to tissues due to inflammatory signals. Directly measuring monocyte/macrophage efflux to the epididymal adipose is a preferable method but was not technically possible at the time of these mouse experiments.

To further address the role of αLA on TLR4-mediated macrophage activation and signaling we examined the effects of αLA on bone marrow-derived macrophages from $TLR4^{def/def}$ and WT animals. Recent studies show that the Toll-like receptor 4 (TLR4) may play a central role in the link among insulin resistance, inflammation, and obesity. TLR4 deficiency prevented DIO-mediated insulin resistance and activation of IkB kinase (IKKb) and c-Jun NH2-terminal kinase (JNK), suggesting that TLR4 is a key modulator in the cross-talk between inflammatory and metabolic pathways [18–22]. Recently it was demonstrated that high fat meals can increase circulating LPS levels and may result from increased intestinal permeability to LPS [50, 51]. Additionally, DIO was shown to induce the expression and activation of TLR4 in the adipose of obese rats, while exercise reduced circulating LPS and TLR4 activation [21]. High levels of saturated NEFA, such as palmitate, when combined with hyperinsulinemia, have been shown to activate human monocytes via TLR4 agonism resulting in the production of pro-inflammatory cytokines [52]. Additionally, high glucose conditions may result in oxidative stress-mediated NF-κB activation and subsequent up-regulation of TNFα and MCP-1 [53, 54]. We demonstrated that αLA was an effective inhibitor of NF-κB activation in murine macrophages, a potent transcription factor regulating inflammatory genes including TNFα and IL6 in this cell. We show that αLA pretreatment is capable of preventing TLR4-mediated up-regulation of MCP-1. MCP-1 is the primary cytokine recruiting monocytes, memory T cells, and dendritic cells to sites of tissue injury and inflammation. It has been shown in endothelial cells that αLA prevented high-glucose induced MCP-1 expression via inhibition of reactive oxygen species-mediated NF-κB activation [54]. The cognate receptor for MCP-1, CCR2 is also down-regulated on monocytes by αLA (albeit via non-TLR4 pathways) suggesting that it may make monocytes less responsive to a MCP-1 chemotactic gradient. Interestingly, CCR2 expression was not induced by TLR4 activation, conversely LPS acted synergistically with αLA to further down-regulate CCR2 expression. αLA also potently decreased LPS-stimulated TNFα gene expression demonstrating that αLA can modulated macrophage activation post TLR4 ligation. These data suggest that αLA is a potent modulator of inflammation via TLR4, non-TLR4 and NF-κB pathways.

We acknowledge several important limitations of this study beginning with our focus on adipose-inflammation centric mechanisms. Our study did not investigate the effects of αLA on hepatic glucose generation or adipocyte function. Prior studies with αLA have clearly demonstrated an effect of αLA in improving serum lactate and pyruvate concentrations and improving glucose levels in lean and obese patients with type 2 diabetes [55]. Our experimental design did not clearly examine the effect of αLA on adipocytes themselves. We cannot say whether αLA decreased visceral adipocyte apoptosis and subsequent VATM infiltration or whether αLA prevented monocyte/macrophage activation and infiltration leading to a lower incidence of adipocyte apoptosis. It is also important to note that αLA may have different mechanisms of action based on duration of treatment, route of administration, and maximal plasma concentration thus comparing data between treatment protocols and in vivo and in vitro results is tenuous and must be taken within context. For example, while αLA potently down-regulated TNF, IL6, and MCP-1 gene expression in vitro, the in vivo effects were not nearly as dramatic in the oral αLA group with only IL-6 being significantly down-regulated and more comparable in the IP-αLA mice. It should also be noted that αLA can activate nuclear factor erythroid2-related factor (Nrf2), the principal transcriptional regulator of antioxidant response element (ARE)-mediated gene expression [56] and through these pathways could exert powerful effects on adipose inflammation [57, 58]. Though prior studies have demonstrated important effects on systemic IR and inflammation, a thorough examination of the long-term weight loss-independent effects of αLA on insulin sensitivity and macrophage activation pathways in already obese individuals was needed.

energy balance leading to constant weight gain in the form of fat [2]. Since the discovery of leptin in 1994 by Zhang and colleagues [3], the adipocyte and its products have been profoundly studied. Adipose tissue has an important and critical role in the regulation of energy homeostasis, behaving as an endocrine organ that synthesizes molecules involved in the regulation of metabolism [4]. Alterations of both the expression and activity of these molecules also contribute to the development of obesity among other pathologies [4]. IL-15 has been recently described as a cytokine that has important metabolic effects on adipose tissue [5]. IL-15 has pleiotropic functions because it exerts effects on the proliferation, survival, and differentiation of many more distinct cell types than was originally thought [6, 7]. Since the discovery of this cytokine as an anabolic factor for skeletal muscle, several reports have described its important role as a regulator of energy homeostasis [7, 8]. In-vivo studies have shown that chronic IL-15 administration (seven days) results in a 33% decrease of white adipose tissue (WAT) in healthy rats [6]. Additional studies demonstrate that the effects of the cytokine on WAT are partially caused by inhibition of both lipogenesis [9] and LPL activity [10] and by reduced lipid uptake in this tissue [5]. IL-15 also regulates liver lipogenesis, reducing the lipid content of VLDL particles [10], and thermogenesis in brown adipose tissue [11]. Some of the effects of this cytokine are mediated by upregulation of PPARδ [5, 11] a transcription factor involved in fatty acid oxidation and other metabolic adaptations to environmental changes [12]. In summary, IL-15 could be important in the conversion of fat to lean body composition [4, 8, 10, 13].

Inhibition of adipogenesis by IL-15 in 3T3-L1 cells has been reported, suggesting a direct action of the cytokine in adipose tissue [14]. Moreover, in a study using obese rodent models, a correlation was found between the sensitivity to the fat-inhibiting effects of IL-15 and the fat expression of mRNA for signaling subunits of the IL-15 receptor in WAT [15], confirming that IL-15 has a direct effect on this tissue. Thus, it is known that the cytokine signals by activation of two different subunits also present in the IL-2 receptor, and binds specifically to the α subunit of the receptor [7]. The activation of IL-15 receptor triggers different transduction pathways depending on cellular type. Thus, IL-15-mediated signaling involves proteins such as JAK/STAT, the Src family, PI3-Kinase and Akt, MAPK, NFκB, and AP1 in immune cells [16–19]. Regarding its signal transduction in adipose tissue, only one report has suggested that JAK and PKA act as partial mediators of the lipolytic effect that IL-15 exerts on primary pig adipocytes [20].

Taking into account the important effects of the cytokine on lipid metabolism, the objective of this study was to analyze the effects of IL-15 on adipocyte differentiation using the 3T3-L1 preadipose cell line, and to study the signal transduction pathways mediating the effects of the cytokine.

Materials and Methods

Cell Culture and Adipocyte Differentiation

3T3-L1 preadipocytes (ATCC) were cultured in Dulbecco's modified Eagle's medium (DMEM) with high glucose (Invitrogen) supplemented with 10% (*v*/*v*) fetal calf serum (Invitrogen), 25 mM HEPES pH 7.0, 1,000 U/mL penicillin, 1,000 U/mL streptomycin, and 25 μg/mL fungizone (BioWhittaker). To induce adipocyte differentiation, cells were grown for 2 days postconfluence and then treated for 2 days with differentiation medium of DMEM with high glucose supplemented with 10% (*v*/*v*) fetal bovine serum (Invitrogen), 25 mM HEPES pH 7.0, 1,000 U/mL penicillin, 1,000 U/mL streptomycin, and 25 μg/mL fungizone, plus MDI (0.5 mM isobutylmethylxanthine, 0.25 μM dexamethasone and 5 μg/mL insulin). On day 2 the cells were re-fed with differentiation medium that contained insulin (5 μg/mL) instead of MDI, and every 2 days thereafter with differentiation medium alone. The cells were completely differentiated 14 days after induction. 3T3-L1 cells were treated with 10 ng/mL IL-15 (Peprotech) or with PBS for 7 days before inducing differentiation (referred to hereafter as preadipocytes), for 7 days after inducing differentiation (referred to as 7d-adipocytes), and for 7 days after they were differentiated (referred to as 14d-adipocytes). All experimental groups were analyzed at the end of the treatment.

Protein Extraction and Western Blotting

For protein extraction the cells were scraped into ice-cold buffer containing 10 mM Tris pH 7.5, 10 mM EDTA, 400 mM NaCl, 10% glycerol, 0.5% Nonidet P-40, 5 mM NaF, and 0.01 mM sodium orthovanadate, in the presence of protease inhibitors, and then sonicated for 10 s. The samples were then centrifuged at 13,000 rpm for 10 min and the supernatants were collected and protein concentration was determined by use of the BCA method (Pierce, USA). Equal amounts of protein (50 μg) were heat-denatured in sample-loading buffer (50 mM Tris-HCl, pH 6.8, 100 mM DTT, 2% SDS, 0.1% bromophenol blue, 10% glycerol), resolved by SDS–polyacrylamide gel electrophoresis (10% polyacrylamide, 0.1% SDS) and transferred to Immobilon membranes (Immobilon PVDF, Millipore, USA). The filters were blocked with 5% PBS-non-fat dried milk or 5% BSA and then incubated with polyclonal antibodies: anti-phosphoAKT,

anti-phosphoSAPK/JNK, anti-phosphoJAK1, anti-JAK1, anti-phosphoSTAT5, anti-STAT5 (Cell Signaling Technology, Beverly, USA), anti-AKT, anti-SAPK/JNK1, anti-phosphop38 (Santa Cruz Biotechnology, Santa Cruz, CA, USA), and anti-p38 (Calbiochem, Germany). An anti-tubulin polyclonal antibody (Santa Cruz Biotechnology) was used as a control for the different studies. Donkey anti-mouse peroxidase-conjugated IgG (Jackson ImmunoResearch, West Grove, USA), and goat anti-rabbit horseradish peroxidase conjugate (Bio-Rad, USA) were used as secondary antibodies. The membrane-bound immune complexes were detected by use of an enhanced chemiluminescence system (EZ-ECL, Biological Industries, Israel).

Cell-Proliferation Studies

3T3-L1 cells were seeded in multiwells plates and cultured for 24 h for cell attachment. The cells were then serum-starved for 24 h and treated with 10 ng/mL IL-15 or vehicle solution depending on the experimental group. After 24 h of treatment, 1 μCi methyl-[^{3}H]thymidine (Amersham) was added to each well, and cells were incubated for 24 h for thymidine incorporation into DNA [21, 22]. For measuring the cell-proliferation rate, cells were washed twice with PBS, and DNA was precipitated by use of trichloroacetic acid. Finally, cells were homogenized and the total amount of lysate was dissolved in 4 mL liquid-scintillation fluid for total radioactivity estimation in a liquid scintillation counter.

DNA Extraction and Apoptosis

The studies were carried out on 14d-adipocytes. For DNA extraction, cells were resuspended in Kauffman buffer (0.5 M Tris, 2 mM EDTA, 10 mM NaCl, and 1% SDS) and incubated for 12 h in the presence of 200 μg/ml proteinase K. DNA was extracted with phenol–chloroform [23] and apoptosis was measured by LMPCR (ligation-mediated PCR) [24], using the β-actin gene as control. The PCR samples were checked by 1.5% agarose gel electrophoresis and stained with ethidium bromide. The percentage of DNA fragmentation was quantified by scanning densitometry (Phoretix International, Newcastle upon Tyne, UK).

Oil Red O Staining

In order to assess the stage of differentiation, cells were stained by oil red O dye, lipid content being determined in both 7d-adipocytes and 14d-adipocytes. The cells were fixed with 3% paraformaldehyde and stained with the lipophilic dye oil red O (Sigma) dissolved in isopropanol, as previously described [14]. Stained cells were visualized by bright-field microscopy and photographed. Diameter of lipid droplets was measured by bright-field microscopy at ×40.

Annexin V–Propidium Iodide Staining

The staining was performed on 14d-adipocytes. To determine apoptosis by the annexin–propidium iodide method, cells were seeded on coverslips. After 3T3-L1 differentiation, cells were serum-starved for 24 h followed by 24 h-treatment with IL-15 (100 ng/mL). For annexin V–propidium iodide determination, the cells were fixed and stained by use of a commercial kit (rhAnnexin V/FITC/propidium iodide; Bendermedsystems, Pharmingen, San Diego, CA, USA). Apoptosis was assessed by laser-scanning microscopy with a laser wavelength of 495 nm.

DAPI Staining

DAPI staining was carried out using 14d-adipocytes. For analysis of nuclei condensation, the cells were seeded on coverslips. Twenty-four hours after serum deprivation, cells were treated for 24 h with 100 ng/mL IL-15. The cells were then washed with ice-cold PBS, fixed with 70% ethanol for 10 min, stained with a DAPI solution (1 μg/mL) for 20 min, then washed twice and mounted on glass slides with Vectiscilol (Vectashield® Mounting Medium; Vector Laboratoires H-1000, Southfield, MI, USA). DAPI staining was analyzed by use of an epifluorescence microscope (Leica, Solms, Germany).

Real-Time PCR (Polymerase Chain Reaction)

First-strand cDNA was synthesized from total RNA with oligo dT15 primers and random primers pdN6 by using a cDNA synthesis kit (Transcriptor Reverse Transcriptase, Roche, Barcelona, Spain). Analysis of mRNA levels for the genes from the different proteolytic systems was performed with primers designed to detect the following gene products: PPARδ (5′ GAAGCCATCCAGGACACCAT 3′; 3′ AAGG TCTCACTCTCCGTCTT 5′), leptin (5′ TTCACA CACGCAGTCGGTAT 3′; 3′ CATTCA GGGCTAAGGTC CAA 5′) and 18S (5′ GCGAATGGCTCATTAAAT CAGTTA 3′; 3′ GC ACGTAAATAGTCTAGTTTTGGT 5′). To avoid the detection of possible contamination by genomic DNA, primers were designed in different exons. The real-time PCR was performed using a commercial kit (LightCycler™ FastStart DNA Master^{PLUS} SYBR Green I, Roche, Barcelona, Spain). The relative amount of all mRNA was calculated by using the comparative C_T method. The invariant control for all studies was 18S mRNA.

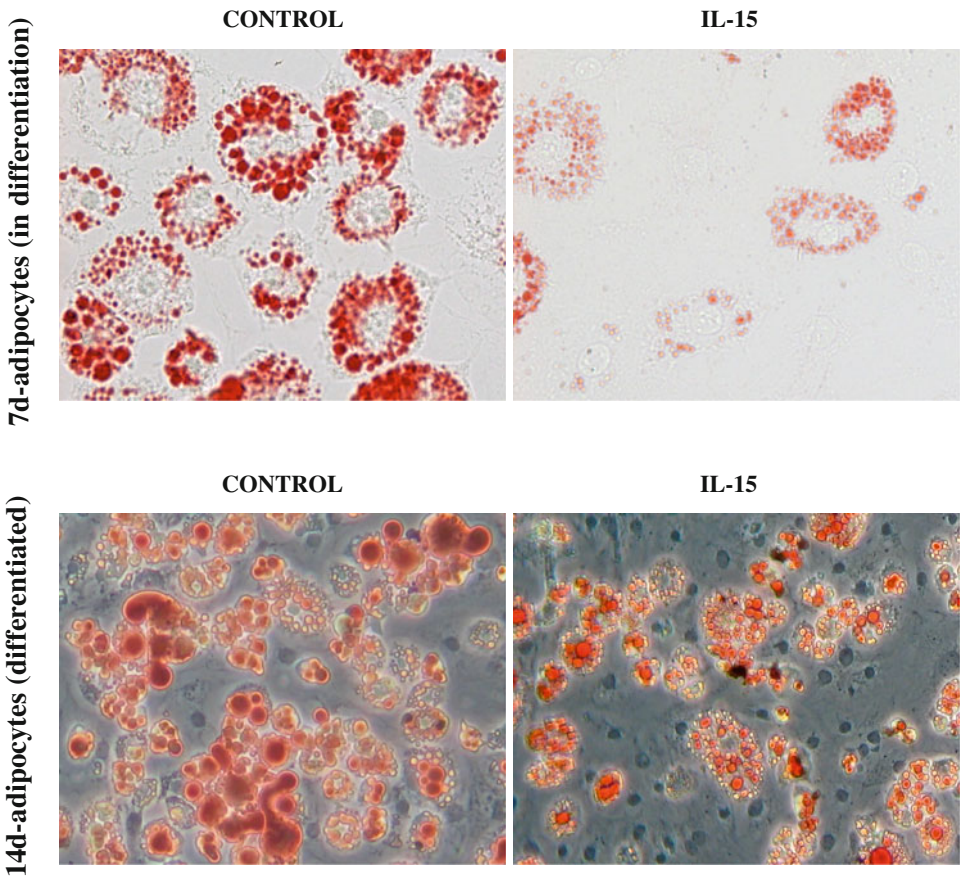

Fig. 1 Oil red O staining of both 7d-adipocytes (in differentiation) and 14d-adipocytes (completely differentiated) after treatment with vehicle or IL-15. Oil red O dye stains lipid content of the cells. These are representative photographs from six independent experiments. The results are means ± SEM for 100 cells and are expressed in μm (diameter of lipid droplets measured by bright-field microscopy at ×40)

Statistical Analysis

All data were analyzed by use of Student's *t* test. Statistical significance of results is indicated by: $*p < 0.05$, $**p < 0.01$, $***p < 0.001$.

Results

To check the degree of adipocyte differentiation, cells were stained with oil red O dye to estimate lipid content (Fig. 1). It can be seen that cells were clearly differentiated and how IL-15 resulted in a significant decrease in lipid content. Levels of different markers (PPAR-γ2 and leptin) also indicated a clear effect of IL-15 on lipid content (Table 1). Because p42/44 MAPK play a central role in the regulation of cell proliferation and cell survival [25–27], their content was analyzed. In preadipocytes, IL-15 treatment caused a significant decrease (60% less than control) of both the phosphorylated form and the total amount of p42/44 MAPK (Fig. 2a) with no differences in the ratio (Fig. 2b). However, IL-15 treatment of early differenciated adipocytes (7 days) caused a strong decrease of the p44 MAPK protein content (84% less than in the control) (Fig. 2a, b). On the other hand, in 14d-adipocytes, IL-15 treatment led to an increase of both forms of p42/44 MAPK (phosphorylated active p44 73% and p42 29%; total amount p44 42% and p42 47%) protein (Fig. 2a).

Table 1 Effects of IL-15 on 7d-adipocytes' mRNA content of the differentiation markers

Experimental group	Control	IL-15
PPARγ	100 ± 48 (5)	26 ± 11 (4)
Leptin	100 ± 30 (5)	17 ± 8 (4)*

For more details see the "Materials and Methods" section. Results are mean ± SEM (*n*) for the number indicated in parentheses. The results are expressed as a percentage of controls. Values that are significantly different by the Student's *t* test from the control group are indicated by $*p < 0.05$

To relate the effects of the cytokine to cell differentiation, the JAK/STAT pathways were examined. The total and activated amount of both JAK and STAT proteins in the different stages of adipocyte differentiation under IL-15 treatment were determined. Despite a significant increase in the total amount of JAK1 and STAT5 proteins in 3T3-L1 preadipocytes (25 and 80% respectively) (Fig. 3a), the ratio between the active or phosphorylated form and the total protein content indicated that there was a significant decrease of active JAK1 protein whereas no significant changes were observed for STAT5 (Fig. 3b). During the

differentiation of 3T3-L1 cells (d7-adipocytes), cytokine treatment induced a decrease in both the active form and the total amount of STAT5 protein, despite no changes were observed in the ratio (Fig. 3a, b). However, in d14-adipocytes, the IL-15 treatment resulted in a significant increase of both JAK1 and STAT5 phosphorylated proteins (127 and 300% respectively) (Fig. 3a) also in the ratio (Fig. 3b), suggesting activation of the JAK/STAT pathway in mature 3T3-L1 adipocytes.

AKT is another important signaling protein for cell proliferation and differentiation [28]. No differences were observed in AKT protein content in 3T3-L1 preadipocytes treated with IL-15 (Fig. 4a). However, treatment with this cytokine induced a significant increase in the total amount of AKT protein (42%) (Fig. 4a) and reduced the ratio (Fig. 4b), therefore modulating the activity of this pathway. Finally, IL-15 caused an increase in both activated and total of AKT protein in 14d-adipocytes (70 and 54%, respectively) (Fig. 4a).

p38 and SAPK/JNK belong to the MAPK signaling pathway and are known to be involved in the regulation of differentiation and cell apoptosis. Interestingly, these proteins can regulate each other [25, 29–32]. In preadipocytes, IL-15 treatment caused a decrease in the total amount of p38 (47%) without affecting its activated phosphorylated form, as shown in Fig. 5a, b. Moreover, in 7d-adipocytes IL-15 treatment also caused a significant reduction in the total amount of p38 (34%), leading to a significant increase of the ratio phospho-p38/p38 (Fig. 5a, b). Finally, in 14d-adipocytes the treatment resulted in a significant decrease in the percentage of activation, but an increase in the total amount of p38 protein (73%). In order to see the effects of IL-15 on the SAPK/JNK pathway, the two proteins that form the dimer (SAPK/JNK54/46) were analyzed. IL-15

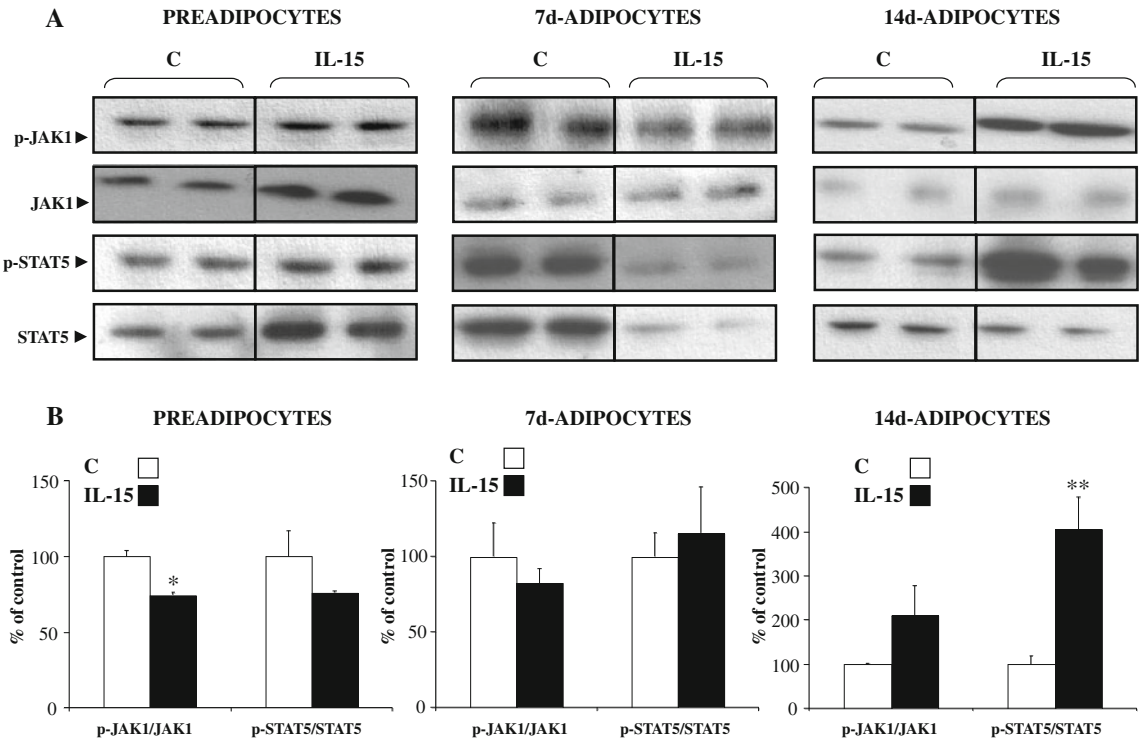

Fig. 3 Effects of IL-15 on JAK1 and STAT5 protein content. *C* control, *IL-15* IL-15-treated cells. **a** Representative Western blot pattern of both phosphorylated and total JAK1 and STAT5. The images were densitometrically analyzed and corrected for tubulin levels as loading control (images not shown). Data were then statistically analyzed (Student's *t* test). **b** Ratio of densitometric analysis of phosphorylated and total form of JAK1 and STAT5 content. The results are means ± SEM for 4 or 5 samples and are expressed as percentages of control values. treatment caused a significant decrease of the ratio between phospho-SAPK/JNK and SAPK/JNK total (in both JNK54 and 46) in preadipocytes (Fig. 5b). Interestingly, during adipocyte differentiation (14d-adipocytes), the ratio between the active and total forms of these proteins was increased (Fig. 5b).

It is important to note that the increase in p38 and SAPK/JNK in mature 14d-adipocytes has been related to increased apoptosis [25, 31]. Thus, to determine if this could be a satisfactory explanation for the observed increase in the p38 protein, apoptosis was studied by the LMPCR method. Figure 6a shows a clear and significant increase of the DNA ladder levels after IL-15 treatment in 14d-adipocytes, supporting increased apoptosis as a result of the cytokine treatment. DAPI and annexin–propidium iodide analysis confirmed the effects of IL-15 on apoptosis (Fig. 6b, c).

Discussion

The accretion of WAT observed in obese patients can be because of an increase in cell size, cell number or both [33], indicating that the molecular mechanisms that regulate preadipose cell growth, adipose differentiation, and lipogenesis in fat cells, have a key role in controlling the energy balance [33]. Cytokines seem to be major regulators of adipose tissue metabolism [34]. Taking this into consideration, IL-15 is a cytokine of special interest because it causes an important reduction of WAT weight by altering several important processes within this tissue, for example lipogenesis [9, 15], LPL activity, or lipid uptake [5, 10]. Furthermore, it is important to note that our results from oil red O staining confirm that IL-15 is able to inhibit adipogenesis in 3T3-L1 cells as previously described [14].

IL-15 signaling pathways have been widely studied in the immune system since this cytokine was firstly described in immune cells in 1994 [35, 36]. However, very few investigations have been focused on the proteins involved in IL-15 signal transduction in adipose tissue or other non-immune system tissues. Ajuwon and Spurlock [20] described the direct regulation of lipolysis by IL-15 in primary pig adipocytes through a pathway regulated in part by PKA and JAK proteins.

In order to study the signaling of IL-15 on adipocytes, we chose the 3T3-L1 cell line. This is an immortal fibroblast line derived from nonclonal Swiss 3T3 cells that are

already committed to the adipocytic lineage [37]. This cellular model has some limitations, because the adipose tissue matrix has an important role in adipocyte differentiation. However, when these cells receive the appropriate hormonal inducers, they undergo differentiation to mature fat cells [37–39]. In fact, the first stage before differentiation is growth arrest, which is achieved in cultured cells by contact inhibition (named in this study as the preadipocyte group). When the cultured cells receive the differentiation cocktail (isobutylmethylxanthine, dexamethasone, and insulin), they begin the next step of differentiation, called clonal expansion. This is followed by a second growth arrest which is associated with several changes in protein expression. After this, the cells acquire a round morphology, accumulate lipid, become insulin-sensitive, and express typical gene markers (for example PPARγ) of completely differentiated adipocytes [40].

In immune cells, IL-15 signals through several molecules, for example MAPK, AKT, or JAK/STAT. Among these, p42/44 MAPK is highly related to the promotion of cell division [27] and this could be the role of this protein in 3T3-L1 preadipocytes. Indeed, IL-15 seems to downregulate p42/44 MAPK levels in preadipocytes, and it could lead to a tendency of a lower proliferation rate.

The JAK/STAT pathway is a predominant signaling cascade for cytokines including the IL-15 signaling pathway [7]. In addition, it has been described that during adipocyte differentiation, expression levels of STAT5 are highly induced and dysregulation of this cell process attenuates induction of this protein [41]. Floyd and Stephens [42] stated that STAT5A ectopic expression in nonprecursor cells led to fat cell differentiation, confirming the importance of this signaling protein in this adipocyte process. As mentioned in the "Results" section, IL-15 treatment resulted in a decrease in differentiation markers in 7d-adipocytes. Interestingly, treatment of 7d-adipocytes with IL-15 clearly resulted in downregulation of the levels of STAT5 protein, indicating that the effects of IL-15 on adipogenesis could be partly mediated through STAT5 protein. Conversely, in mature adipocytes STAT5 protein has been reported to have an antilipogenic role by inhibiting expression of fatty acid synthase, the central enzyme for de-novo lipogenesis [43]. Furthermore, it has been reported that IL-15 induces loss of adipose tissue partly by inhibiting lipogenesis [9]. Indeed, IL-15 treatment of 14d-adipocytes results in a significant increase in the activity of the JAK/STAT pathway and a decrease in lipid content, suggesting that this cytokine

could also act through these proteins to control adipocyte lipogenesis.

There are contradictory reports on the role of p42/44 MAPK in adipogenesis. On the one hand, some studies have implicated these proteins in the differentiation process [44] and, on the other hand, Font de Mora et al. [45] stated that they are not necessary for this process but rather these proteins exert an antagonizing effect on adipogenesis. However, it is important to note that after insulin treatment—as a differentiation stimulus—the MAPK and AKT pathways are activated [46]. Insulin treatment seems to exert a dual effect on 7d-adipocytes, by inducing mitogenesis in growing cells, and differentiation in confluent cells through p42/44 MAPK and AKT respectively. In our study, the observation that IL-15 inhibited p44 MAPK reinforces the role of this protein in the differentiation process. On the other hand, the activation of p42/44MAPK by IL-15 at day 14 could also be correlated with cytokine blockage of the differentiation process, because p42/44MAPK has been involved in inhibition of terminal adipose conversion. Interestingly, sustained activation of p42/44 MAPK has been demonstrated to inhibit terminal adipose conversion by inhibition of PPARγ, at least [47]. IL-15 could act by blocking the final stages of adipogenesis in 14d-adipocytes by increasing the protein level of p42/44 MAPK and consequently could be blocking PPARγ activity. Additionally, and because the AKT pathway has a key role in adipogenesis, it has been reported that constitutive activation of AKT induces spontaneous adipogenesis in 3T3-L1 cells [28]. The IL-15-induced decrease of the activation ratio at day 7 supports the effects of this cytokine on adipogenesis.

Although previous work established a direct relationship between p38 upregulation and apoptosis in 3T3-L1 adipocytes [29], the results of our study showed upregulation of total p38 in mature adipocytes without affecting the activated protein. In addition, in 14d-adipocytes IL-15 treatment caused a significant increase in SAPK/JNK, which seems to lead to an increment in apoptosis levels as shown in the apoptotic assays (Fig. 6). These results agree with the study of Yang et al. [31], who reported that increased levels of SAPK/JNK are also directly related to apoptosis.

In conclusion, this study expands knowledge of the actions of IL-15 on body fat [8, 10] and confirms the anti-adipose tissue actions of the cytokine. IL-15 could, thus, regulate energy homeostasis by affecting adipose tissue in several cell processes including proliferation, differentiation, lipogenesis, and apoptosis. These actions on adipocytes may be mediated by different signaling pathways: p42/44 MAPK in proliferation and final conversion to adipocytes, STAT5 during differentiation process and lipogenesis, and SAPK/JNK in apoptosis in mature adipocytes. Additional studies are needed to further understand the role of IL-15 in adipogenesis.

of important cellular signaling molecules, termed adipokines. These adipokines have consequences ranging from local autocrine and paracrine effects to systemic endocrine actions. Adipokines also vary widely in both their function and mechanisms of control. One such mechanism of control is the fatty acid composition of adipose tissue which can affect cellular signaling, fatty acid trafficking, gene expression and, consequently, metabolism [1]. Adipose tissue composition varies based on two main effectors: energy balance, which regulates the metabolism of free fatty acids within the adipose tissue, and diet, which will alter the fatty acid profile of the adipose tissue. Although the former has been examined extensively, particularly with regard to leptin expression and adipocyte differentiation, the effects of the latter on endocrine function have only recently begun to be investigated.

Adiponectin is the most highly expressed and secreted adipokine, with beneficial effects on metabolism, inflammation, and vascular function. Adiponectin has a paradoxical expression pattern. As adiposity increases, adiponectin expression and secretion decreases within the adipose tissue [2]. It is believed that this paradox is part of the pathology of obesity, and is symptomatic of dysfunctional adipose tissue. Adiponectin plays a role in insulin sensitivity, LDL oxidation, eNOS activation, inflammation suppression and fatty acid catabolism [3–5]. Thus, hypoadiponectinemia is of interest as a biomarker of both cardiovascular disease and metabolic syndrome.

Another important adipokine that could be stimulated by changes in fatty acid profile is leptin. It was first discovered as the protein encoded by the *obese* gene, named for the phenotype of the double knockout mouse. These mice experience no satiety, and thus eat continuously when fed ad libitum, leading to severe diet-induced obesity. In humans, leptin deficiency has been implicated in cases of morbid obesity, as either a genetic factor or a metabolic insufficiency [6, 7]. Leptin's role in hypothalamic-mediated appetite suppression in response to caloric intake is not its only function. Leptin may also be important in the modulation of T cell activity in the early stages of atherosclerotic development as well as other immune cells [8]. In obesity, leptin may be under-expressed by the adipose tissue in response to a consistently high caloric diet, or, leptin receptors may be down-regulated, thus leading to high plasma leptin levels and leptin resistance [9].

Flaxseed has recently gained popularity as a functional food. Alpha-linolenic acid (ALA) comprises approximately 55% of the total fatty acid content of flaxseed fatty acids [10]. ALA-rich diets, including diets enriched with ground flaxseed, have been shown in interventional and experimental trials to reduce both fatal and non-fatal myocardial infarction [11, 12], cardiac arrhythmias [12–15], and the incidence of atherosclerotic lesions [12, 14, 16, 17]. However, the mechanism whereby ALA and flaxseed induce this cardio-protective action is unclear. Previous data have indicated that ALA from a flaxseed enriched diet is deposited in adipose tissue [18]. It is possible, therefore, that this change in adipose tissue fatty acid content may influence adipose tissue function. We hypothesize that the change in lipid composition in adipose tissue in response to a flaxseed supplemented diet may affect the adipokine signaling from the adipocytes. It is possible, therefore, that the beneficial cardiovascular actions of flaxseed previously observed may be associated with changes in adipokine expression.

Materials and Methods

Diet and Feeding

All experiments were conducted in accordance with the guidelines of the Canadian Council on Animal Care. Sixteen male New Zealand White rabbits (2.8 ± 0.1 kg, Southern Rose Rabbitry) were randomly assigned to receive one of four diets. Diets were prepared as previously described [15, 17] by the addition of components to a regular (RG) rabbit diet (CO-OP Complete Rabbit Ration, Federated Co-operatives): 0.5% cholesterol (CH), or 10% ground flaxseed (FX), or both (CF) for 8 weeks ($n = 4$). The chow was stored at 4 °C and protected from light. The diets differed only in total fat content due to the inclusion of the naturally ALA-rich ground flaxseed (Tables 1, 2). The diet fatty acid composition is outlined in Table 2. Addition of flaxseed to the diet significantly increased the amount of C16:0, C18:0, C18:1 (oleic acid) and C18:3 (ALA) provided. The addition of cholesterol had no significant effect on dietary fatty acids provided in comparison to the RG diet. Rabbits were fed 125 g/day of the diet.

Table 1 Crude dietary composition

	RG	FX	CH	CF
Crude protein (%)	21.3	20.5	20.4	20.5

Blood Sampling and Analysis

Blood was drawn from the left marginal ear vein of rabbits that were fasted overnight before starting their experimental diets and at 8 weeks. It was collected in vacutainer tubes containing EDTA (Becton–Dickinson). Blood samples were centrifuged at 4,500×*g* at room temperature for 10 min, and plasma was then stored at −80 °C. Before analysis, plasma samples were thawed and centrifuged at 6,800×*g*. Plasma levels of cholesterol and triglycerides were analyzed using a VetTest 8008 blood chemistry analyzer (IDEXX Laboratories). Fatty acids were extracted from plasma and derivatized, as described previously [15, 18].

Tissue Collection

After 8 weeks of dietary treatment, animals were euthanized by 5% isoflurane gas delivered by face mask, followed by cardiac extraction. Retroperitoneal and epididymal adipose tissue were collected. To prevent RNase contamination, the animal and tools were sprayed with RNaseZap (Ambion) both before and during tissue collection. Adipose tissue was immediately placed in RNAlater, and kept overnight at 4 °C, as indicated in the manufacturer's instructions (Ambion). Preliminary testing indicated that there was successful stabilization of mRNA compared to flash freezing or maintenance overnight at 4 °C (as assessed by agarose gel electrophoresis and subsequent qRT-PCR) despite the high lipid content of this tissue. RNAlater was removed from the tissue by suction, and the samples were then flash frozen in liquid nitrogen and stored at −80 °C.

qRT-PCR

RNA was extracted from the adipose tissue in an RNase-free environment. Adipose tissue was homogenized in Trizol reagent (Invitrogen), and fat was removed. Phenol was separated from the solution by washing the solution twice with chloroform. The RNA was precipitated from solution with ethanol, and added to RNeasy columns for further purification (Qiagen). Extracted RNA was quantified and assessed for quality by spectrophotometer and agarose gel electrophoresis. It was then used for qRT-PCR (Quanta Biosystems) using a iQ5 Real-Time PCR Detection System (Bio-Rad). Primers designed using BLAST software (NCBI) and were as follows: Adiponectin: (Forward 5′ACCAGGACAAGAACGTGG AC3′, Reverse 5′TGGAGATGGAATCGTTGACA3′);

Leptin: (Forward 5′GTCGTCGGTTTGGACTTCATC3′, Reverse 5′CGGAGGTTCTCCAGGTCGTTG3′) [19];

GAPDH: (Forward 5′GATGGTGAAGGTCGGAG TGAA3′, Reverse 5′GGTGAAGACGCCAGTGGATT3′) [20].

Primers were validated using NCBI's BLAST software [21]. Unused samples were stored at −80 °C. cDNA was synthesized from 1 ug of RNA with qScript cDNA Supermix (Quanta) via the manufacturer's directions. qPCR proceeded for 2 min at 50 °C, 95 °C for 8.5 min, then 40 cycles of 95 °C for 15 s and 60 °C for 60 s, at which point the data were captured. A melt curve was obtained after cycling with 95 °C for 1 min followed by 55 °C for 1 min,

and 80 10-s capture cycles of 55 + 0.5 °C/cycle. Results were normalized by GAPDH expression and analyzed by the delta–delta-Ct method using iCycler Real-Time Detection Software.

Fatty Acid Extraction and Methylation

Plasma fatty acids were directly extracted and derivatized using a modification of the original method described by Lepage and Roy [22] and later modified by Garg et al. [23]. Briefly, 100 μL of plasma was combined with 2 mL of 4:1 (v/v) methanol:toluene in a borosilicate glass tube. The methanol:toluene solution contained 0.5 mg/ml of the internal standard, C19:0 (Nu-Chek Prep. Inc.). While vortexing, 200 μL of acetyl chloride was slowly added. Tubes were capped with a Teflon lined lid, weighed and then heated at 100 °C for 1 h. Once cooled to room temperature, tubes were re-weighed to ensure no sample loss had occurred. Five milliliters of an aqueous 6% K_2CO_3 solution was then added to terminate and neutralize the reaction. The sample tube was then centrifuged at 5,000 rpm for 5 min at room temperature after which the upper toluene layer was removed and subjected to gas chromatographic analysis using flame ionization detection (GC-FID). Methylation was verified by thin layer chromatography. Fatty acids from approximately 15 mg of adipose tissue were extracted and derivatized using the method outlined by Lepage and Roy [24].

Gas Chromatography

Fatty acid methyl esters (FAME) were injected onto a Varian CP 3800 gas chromatographic system using a Varian CP 8400 autosampler. Analytes were detected using flame ionization detection and analyzed on a Varian MS Workstation (vrs. 6.9.1). One microliter of sample was injected at 250 °C at a split ratio of 50:1 onto a Varian CP-Sil 88 capillary column (60 m × 0.25 mm × 0.20 μm). Helium gas (ultra pure) was used as the carrier gas at a constant flow rate of 1.5 mL/min. The oven temperature was maintained at 111 °C for 1 min then rapidly increased by 20 °C/min to 170 °C. It was then slowly increased at a rate of 5 °C/min to 190 °C and finally by 3 °C/min up to 225 °C where it was maintained for 10 min. FAME were quantified against an external standard, GLC 462 (Nu-Chek Prep, Inc.).

Quantification of Aortic Atherosclerosis

The aorta from the ascending arch to the iliac bifurcation was isolated from peripheral tissues and washed in cold PBS, then opened longitudinally and pinned flat. The aortic lumen was digitally photographed and luminal images were analyzed with Silicon Graphics Imaging software. Fatty streaks and complicated lesions were expressed as a percentile of total luminal surface area.

Statistics

Results were reported as means ± SE, and analyzed with Sigma-Stat software by one-way ANOVA, using Fisher's LSD test. A significant correlation was identified by a *t* test. $p \leq 0.05$ was considered statistically significant.

Results

Body Weight

After 8 weeks of dietary treatment, mean body weight significantly increased from 2.8 ± 0.06 to 3.7 ± 0.09 kg. However, there was no effect on weight with the experimental diets as compared to control diets (data not shown).

Plasma Lipids

There was no significant change in the plasma cholesterol of animals fed a regular or flaxseed supplemented diet after 8 weeks. Supplementation of the diet with dietary cholesterol for 8 weeks induced severe hypercholesterolemia (Fig. 1a). Addition of dietary flaxseed to a cholesterol-enriched diet did not lower the plasma cholesterol values from those observed in animals fed a diet supplemented with cholesterol alone.

Plasma triglycerides were not significantly affected by any of the diets (Fig. 1b). Addition of milled flaxseed to the diet, providing ALA, induced a 17-fold increase in the percentage composition of ALA in the plasma (Fig. 1c). Simultaneous consumption of flaxseed and cholesterol doubled the amount of ALA in the plasma as compared to the consumption of flaxseed alone, comprising 21% of all plasma fatty acids. an eightfold increase in plasma ALA, despite being provided with only 2 mg of ALA/gram, supporting the observation that cholesterol aids in absorption of ALA [15–18].

Atherosclerosis

Animals fed a regular or flaxseed-supplemented diet for 8 weeks did not develop any quantifiable atherosclerosis in the aortic arch (Fig. 2). Inclusion of 0.5% cholesterol in the diet induced atherosclerotic lesions in the aorta, covering 76.3 ± 8.5% of the aortic lumen ($p < 0.05$ vs. RG, $n = 3$). Addition of ground flaxseed to the cholesterol-supplemented diet ameliorated the atherogenic effects of cholesterol, significantly reducing lesions to 28 ± 4.3% of the aortic lumen ($p < 0.05$ vs. CH, $n = 3$).

Fatty Acid Composition of Adipose Tissue

Total lipids were extracted from two primary sources of visceral fat. Epididymal and retroperitoneal fat consisted of 92.24% lipid by wet weight (range 83.3–99.5%), with no significant changes in total lipid between different dietary treatments, or either adipose source (Tables 3, 4).

The main component of adipose tissue was C18:1, oleic acid, which composed 32.3 ± 1.9% of total fatty acids in the retroperitoneal adipose of RG-fed animals (Table 3). C16:0, palmitic acid, and C18:2, linoleic acid, were also common, comprising 25.2 ± 1.4 and 26.7 ± 1.3% of the total retroperitoneal adipose tissue fatty acid content, respectively. Also stored in appreciable quantities in the retroperitoneal adipose tissue of animals fed a regular diet were ALA (6.34 ± 0.34%), steric acid (6.14 ± 0.57%), palmitoleic acid (2.12 ± 0.08%), vaccenic acid (1.98 ± 0.21%), and myristic acid (1.77 ± 0.12%) (Table 3).

The fatty acid proportions in the epididymal tissue of the animals fed a regular diet were not significantly different than the proportions of fatty acid in retroperitoneal tissue (Table 4). Dietary cholesterol did not significantly affect either total lipids or individual fatty acids as compared to RG. Addition of flaxseed to a regular diet significantly reduced levels of C16:0, C18:1-*cis*, C18:1-*trans*, and C18:2 in the adipose tissue, both in absolute concentrations and relative to total fatty acid content (Tables 3, 4). When consumed in conjunction with 0.5% cholesterol, dietary flaxseed induced a 3.1-fold increase in adipose tissue ALA, a significant increase as compared to RG, but significantly less than animals supplemented only with flaxseed. Dietary cholesterol did not affect any of the other fatty acids observed.

Adipokine Expression

Adiponectin and leptin are the two most highly expressed adipokines in adipose tissue. In epididymal adipose tissue, there was no significant change in either leptin or adiponectin mRNA expression after addition of either flaxseed or cholesterol to the diet (Fig. 3a). Adiponectin expression did not vary with dietary treatment in retroperitoneal adipose tissue (Fig. 3b). However, in retroperitoneal adipose tissue, dietary flaxseed induced a two-fold increase in leptin mRNA ($p < 0.05$ vs. RG). Conversely, dietary cholesterol reduced leptin mRNA expression by about one-half in comparison to control, and the addition of flaxseed to the cholesterol-supplemented diet induced a recovery of leptin expression, increasing expression beyond that of flaxseed alone.

These changes in leptin expression were positively correlated with plasma ALA and adipose ALA levels (Fig. 4). Plasma ALA correlated with leptin expression in the retroperitoneal adipose tissue ($p < 0.05$), but not in epididymal adipose (Fig. 4a). Adipose tissue ALA exhibited a stronger relationship than plasma ALA with leptin expression in retroperitoneal adipose tissue (Fig. 4b).

Relationship of Leptin Expression to Atherosclerosis

All animals that were not fed cholesterol did not exhibit any atherosclerosis. Consequently, in order to determine if there was a significant relationship between leptin expression and the development of atherosclerotic lesions, linear regression was performed only on data obtained from animals fed a cholesterol-supplemented diet. Increased leptin expression in the retroperitoneal adipose tissue significantly correlated ($p < 0.05$) with decreased atherosclerosis (Fig. 5).

Discussion

One of the primary purposes of this study was to determine if diets of very different lipid composition could influence the expression of leptin or adiponectin in adipose tissue when caloric balance was maintained. It is known that leptin expression varies with caloric balance and adiposity [25–28]. The present study was designed to avoid these potential variables by maintaining the diets in a manner which maintained a consistent level of caloric intake while at the same time insuring diversity in lipid composition. The differences in caloric values between the diets were so minor that they did not induce a significant change in body weight. The data obtained in the present study demonstrates that the lipid composition of the diet can have an important role to play in adipokine expression. The changes in adipokine expression were sensitive to the type of lipid in the diet, the adipose tissue examined and the

adipokine studied as well. A high cholesterol diet suppressed leptin expression whereas a diet rich in the omega-3 fatty acid ALA increased leptin expression. Leptin expression was influenced by the diets whereas adiponectin was not. Retroperitoneal but not epididymal adipose tissue was affected by the diets. It is known that the location of the different adipose tissues will influence circulating adipokine levels [29].

The mechanism whereby leptin mRNA expression is regulated by dietary lipids is presently unclear. Although SREBP1c mRNA expression is directly related to polyunsaturated fatty acid content in adipose tissue [30] and an SREBP-like binding element is present in the leptin promoter, it is not responsive to SREBP itself [31]. However, polyunsaturated fatty acids may act as ligands for PPAR gamma to alter adipokine expression [32]. This may occur through an increase in translation [33]. Mason et al. [28] have demonstrated a novel binding site for an adipocyte-specific transcription factor in the -87 position of the leptin promoter which is conserved in both mice and humans, however, the consensus sequence does not match any known transcription factor. This region, termed LP1, presents an interesting possibility for a novel transcription factor which may regulate the response of leptin to dietary lipids in addition to PPAR-gamma.

The observation that the adipose tissue is responding to these diets in a very specific manner suggests that the changes are physiologically important. Increased leptin levels have been identified previously as a risk factor for atherosclerosis [34]. However, data correlating leptin and atherosclerosis have been derived from obese humans and animal models of obesity [35–39]. Our data indicates that in a non-obese population, leptin may have a previously unidentified role in cardioprotection. In support of this hypothesis, leptin expression was significantly correlated in a negative fashion with atherosclerosis. When leptin levels

were high, atherosclerosis was low and when leptin expression was depressed by circulating cholesterol, atherogenesis was stimulated.

Consumption of flaxseed has previously been shown to improve insulin resistance, hyperlipidemia, atherosclerosis and hypertension and decrease the incidence of cardiac arrhythmias [15–17, 40]. These effects of dietary flaxseed have been attributed, in part, to the rich ALA content of flaxseed [15–17, 40]. Dietary flaxseed provided a source of ALA in the present study which subsequently increased ALA both in the circulation and in the adipose tissue. With the addition of cholesterol to the flaxseed-supplemented diet, plasma ALA increased substantially but adipose tissue levels of ALA did not exhibit further increase beyond those observed when the diet was supplemented with flaxseed alone (Table 3). This could be due to one of several factors. ALA may be deposited in other organs preferentially, such as the heart and liver, as previously observed in the hypercholesterolemic rabbit [18]. Alternatively, a cholesterol-rich diet may direct the ALA to be used directly for beta-oxidation, thus reducing the amount of ALA available for storage [41]. Cholesterol may also induce an efflux of ALA from the adipose tissue, which is greater than the influx of ALA from the plasma, leading to a net decrease in ALA [42]. Further study is required to understand the relative lack of storage of ALA in the adipose tissue when it is presented with such high levels of circulating ALA.

Both beneficial and deleterious cytokines from the adipose tissue may be responsible for many of the links between diet, BMI and cardiovascular disease. The present data demonstrate that dietary cholesterol and flaxseed have

the capacity to alter leptin expression. The cardioprotective effects of flaxseed are thought to be provided in part by its delivery of ALA to the body [16, 40]. However, the mechanism to explain the induction of these effects by ALA remains elusive. In the present study, ALA in the adipose tissue was strongly associated with increased leptin expression and the subsequent reduction of atherosclerosis. Our data, therefore, suggests that flaxseed may induce its anti-atherogenic effects in part via an ALA-mediated modulation of the expression of leptin.

Introduction

The accumulation and retention of Apolipoprotein (Apo)B-containing lipoproteins, such as low-density lipoprotein (LDL), within the arterial wall is a major trigger of atherosclerotic plaque development [1, 2]. Along with arterial endothelial activation, LDL retention elicits a chronic inflammatory response whereby monocytes, among other immune cells, are continually recruited to the site of trapped LDL, indicating defective inflammatory resolution [3, 4]. Such monocytes can differentiate into macrophages and, along with those resident in the arterial intima, ingest native and modified forms of LDL through various cellular mechanisms that are usually harnessed in innate immunity to become lipid-rich foam cells [5]. Macrophages were established as critical components of atherosclerotic plaque initiation development in ApoE$^{-/-}$ mice [6]; a well characterized animal model for this disease [7]. The conversion of macrophages into lipid-loaded foam cells is a critical early event in atherosclerosis [1]. The uptake of modified LDL is a key feature of macrophage foam cell formation and involves internalization of modified LDL by a family of scavenger receptors [8, 9] and alternative mechanisms such as macropinocytosis [10] and phagocytosis [11].

There is increasing evidence that dietary intake of long chain n-3 PUFA, such as EPA and DHA, which occur in significant amounts in fish oil, is beneficial against cardiovascular disease. In particular, these fish oil derived n-3 PUFA have been shown to be atheroprotective in different mouse models of the disease [12–16], to reverse defective efferocytosis of apoptotic cells in obese mice [17], to enhance atherosclerotic plaque stability in humans awaiting carotid endarterectomy [18] and to be effective in reducing the risk of cardiac mortality [19, 20]. Nevertheless, despite this evidence, other studies have contradicted some of these results [21–23] although this could be linked to background levels of n-6 PUFA since these can affect the efficacy of n-3 PUFA in atheroprotection [24] and since lowering the n-6:n-3 PUFA ratio in ApoE$^{-/-}$ mice reduces atherosclerotic plaque development [16]. Some of the atheroprotective effects of n-3 PUFA in mice have been shown to involve changes in macrophage function [12, 17] and a recent study found that EPA, delivered from n-3 PUFA ethyl esters, reduced foam cell accumulation in advanced human carotid plaques [25] suggesting that n-3 PUFA not only target macrophage activity but also foam cell formation. It has been found that EPA inhibits cholesteryl ester accumulation in THP-1 [26] and rat peritoneal macrophages [27] with the latter effect attributed to a reduction in acetylated LDL (AcLDL) receptor number. However, it has not been established whether EPA affects direct uptake of modified LDL in human macrophages and whether DHA, another key n-3 PUFA, is also able to regulate this process.

In this present study, we investigated whether the uptake of AcLDL and OxLDL by human macrophages was altered by co-incubation of EPA or DHA. We found that both EPA and DHA inhibited AcLDL uptake in both THP-1 macrophages and primary human monocyte-derived macrophages (HMDMs) whilst DHA, but not EPA, reduced OxLDL uptake. These effects could only partly be explained by changes in the mRNA and protein expression of key scavenger receptors in these cells, thereby suggesting that inhibition of macropinocytosis, as measured by Lucifer Yellow uptake and Syndecan-4 expression, should play an important role in modified LDL uptake.

Materials and Methods

Reagents and Cell Culture

THP-1 cells were maintained in complete RPMI-1640 supplemented with 10% (v/v) heat-inactivated FCS, penicillin (100 U/ml), streptomycin (100 μg/ml) and L-glutamine (2 mmol/l) (all from Invitrogen, Paisley, UK), at 37 °C in a humidified atmosphere containing 5% (v/v) CO_2. HMDMs were isolated from buffy coats supplied by the Welsh Blood service using Ficoll-Hypaque purification [28]. Briefly, blood from the buffy coat was layered over Lymphoprep^{TM} (Nycomed Pharmaceuticals, Oslo, Norway) in Accuspin^{TM} tubes (Sigma–Aldrich, Poole, UK) and centrifuged at 800*g* for 30 min. The resultant mononuclear cell interface was collected and washed 6–8 times in PBS containing 0.4% (v/v) tri-sodium citrate to remove platelets. Monocytes were allowed to adhere to tissue culture plates in complete RPMI-1640 medium containing 5% (v/v) FCS for 10 days to enable macrophage differentiation and permit removal of non-adherent cells. THP-1 cells were differentiated into macrophages using 160 nM phorbol 12-myristate 13-acetate (PMA; Sigma–Aldrich) for 24 h and this ensured high expression levels of scavenger receptors [29]. The stock solutions of EPA and DHA were made up in DMSO at a concentration of 100 mM and were stored at −20 °C. The cells were then incubated for the requisite time with EPA or DHA (both from Nu-Chek-Prep Inc., Elysian, MN, USA) or the same final concentration of DMSO as a vehicle control. For experiments with LY294002, the cells were

pre-treated for 1 h with the inhibitor or vehicle before addition of the lipids.

DiI-AcLDL and Lucifer Yellow Uptake Assays

Cells were incubated for 24 or 48 h with 1,1′-dioctadecyl-3,3,3′,3′-tetramethyllindocarbocyane perchlorate (DiI)-labeled AcLDL (DiI-AcLDL) or oxidized LDL (DiI-OxLDL) (both 10 μg/ml; Intracel, Frederick, MD, USA) or Lucifer Yellow CH dipotassium salt (100 μg/ml; Sigma–Aldrich) in RPMI-1640 containing 0.2% (v/v) fatty-acid free BSA (Sigma–Aldrich) at 37 °C. The concentration of Lucifer Yellow reflects that used routinely in previously reported experiments [30]. DiI-AcLDL and Lucifer Yellow uptake were analyzed by flow cytometry on a FACS Canto (BD Biosciences, Oxford, UK) flow cytometer with at least 10,000 events acquired for each sample. DiI-AcLDL and Lucifer Yellow uptake is represented as a percentage with the DMSO-treated control indicated as 100%.

Real-Time Quantitative PCR

Real-time quantitative PCR analysis was performed using SYBR® Green JumpStart™ *Taq* ReadyMix™ (Sigma–Aldrich) and primers, detailed in the supplementary table, specific for human scavenger receptor (SR)-A (SR-A), CD36, SR for phosphatidylserine and oxidized LDL (SR-PSOX), Syndecan-4, Lipoprotein lipase (LPL), Lectin-like oxidized LDL receptor-1 (LOX-1) and SR-BI using a previously described method [28].

Western Blotting

Total cell lysates were size-fractionated on NuPAGE 4–12% SDS–polyacrylamide gels (Invitrogen) and then analyzed by Western blotting [28]. Antibodies against CD36 (sc-9154) and SR-A (sc-20660) were from Santa Cruz Biotechnology (Santa Cruz, CA) and the antibody to β-actin was from Sigma–Aldrich. Semi-quantitative measurement of Western blots was performed by densitometric analysis using the Gene Tools software (GRI, Braintree, UK).

Fatty Acid Uptake Analysis

Lipids were extracted from cells by a modified Folch method [31] and separated using 1-dimensional thin-layer chromatography on 10 × 10 cm silica gel G plates with double development using toluene/hexane/formic acid (140:60:1, by vol) for the entire plate followed by hexane/diethyl ether/formic acid (60:40:1, by vol) to half height. Plates were sprayed with 0.05% (w/v) 8-anilino-4-naphthosulphonic acid in methanol and viewed under UV light to reveal lipids. The bands corresponding to free fatty acids and total polar lipids were scraped from the TLC plates and their fatty acid compositions and the amounts of incorporated DHA and EPA were determined by gas chromatography using an internal standard of pentadecanoate.

Statistical Analysis

All data are presented as means [± standard deviation, (SD)] on the assigned number of independent experiments. Statistical significance was evaluated using Student's *t* test or by one-way ANOVA with Dunnett's post-hoc test for multiple sample comparison.

Results

EPA and DHA Inhibit AcLDL Uptake by Human Macrophages In Vitro

Macrophage foam cell formation is known to involve the disruption of a homeostatic mechanism that controls cholesterol metabolism and the uptake of modified forms of LDL by macrophages enables rapid, uninhibited conversion into lipid-rich foam cells [5]. One type of modified LDL, AcLDL, is used extensively for in vitro foam cell formation assays since it produces massive intracellular cholesterol accumulation [32]. Considering this, we first investigated the impact of exogenous EPA and DHA incubation (24 h) on the uptake of co-cultured DiI-AcLDL by THP-1 macrophages. Fatty acid uptake analysis showed that 73% of the supplemented EPA and 69% of DHA was taken up by the cells (data not shown). Both acids were partly incorporated into polar lipids and partly located among the pool of cytosolic free fatty acids. EPA and DHA produced a statistically significant decrease in DiI-AcLDL uptake compared to the DMSO-treated control in a concentration-dependent manner (Fig. 1a). The highest concentration, 100 μM, reduced DiI-AcLDL uptake by approximately 40%. Using this same concentration, which lies within the physiological range of human plasma EPA and DHA levels, DiI-AcLDL uptake was also decreased in HMDMs in a statistically significant manner with EPA producing a 28% reduction and DHA a 32% reduction (Fig. 1b). To add to this, EPA produced a comparable reduction in 48 h DiI-AcLDL uptake by THP-1 macrophages (Fig. 1c) whilst DHA was able to produce similar reduction although this change failed to reach significance. In addition, we found that DHA inhibited the uptake of DiI-OxLDL in THP-1 macrophages (Fig. 1d) suggesting that it can also inhibit the uptake of other forms of LDL. Conversely, EPA produced a significant increase in OxLDL uptake (Fig. 1d). These data show that DHA can inhibit both AcLDL and OxLDL uptake by human macrophages

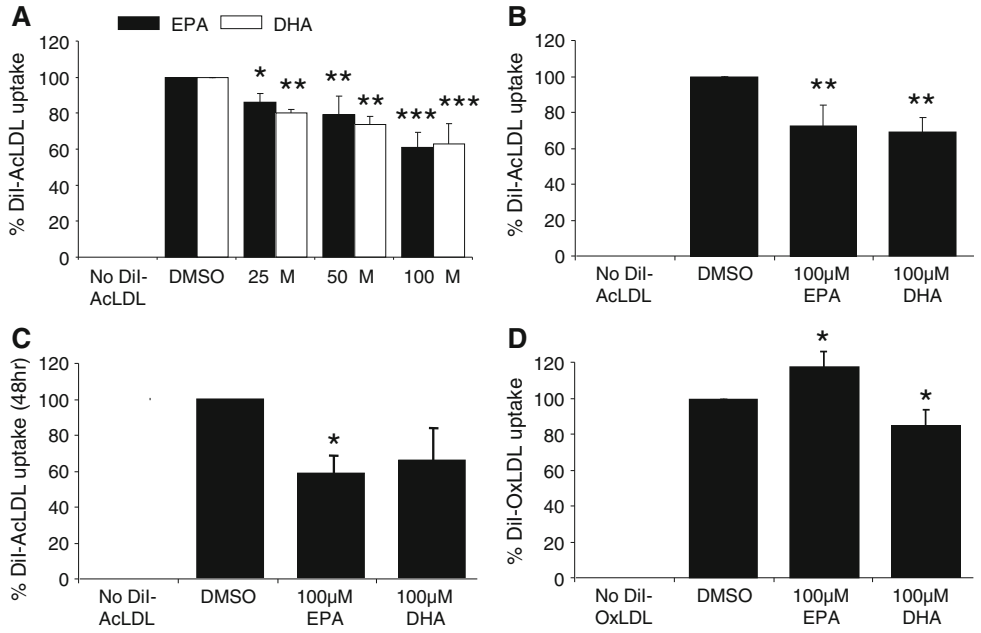

Fig. 1 EPA and DHA regulate the uptake of modified LDL by human macrophages. DiI-AcLDL uptake was measured in 24 h PMA-differentiated THP-1 macrophages following 24 h co-incubation with varying concentrations (25, 50, 100 μM) of EPA (*filled bars*) or DHA (*open bars*) ($n = 4$) (**a**). DiI-AcLDL uptake was measured in 10 day differentiated HMDMs incubated for 24 h with 100 μM EPA or DHA ($n = 4$) (**b**). DiI-AcLDL uptake was measured in 24 h PMA-differentiated THP-1 macrophages co-incubated for 48 h with 100 μM EPA or DHA ($n = 3$) (**c**). DiI-OxLDL uptake was measured in 24 h PMA-differentiated THP-1 macrophages incubated for 24 h with 100 μM EPA or DHA ($n = 4$) (**d**). DMSO was used as a vehicle control in all experiments and the modified LDL uptake in its presence was given an arbitrary value of 100%. Data represent means ± SD. One-way ANOVA with Dunnett's post-hoc test (**a**) or Student's *t* test (**b**–**d**), $*P < 0.05$; $**P < 0.01$; $***P < 0.001$

whilst EPA reduced AcLDL uptake but increased OxLDL in THP-1 cells.

EPA and DHA Do Not Inhibit CD36 and SR-A Expression in Human Macrophages

The uptake of modified LDL into macrophages is principally performed by two scavenger receptors, CD36 and SR-A, which internalize the majority of OxLDL and AcLDL, respectively [8, 9]. We therefore investigated whether the changes in modified LDL uptake in human macrophages by EPA and DHA could be explained by alterations in CD36 and/or SR-A expression. We found that EPA and DHA produced a statistically significant increase in CD36 mRNA levels in THP-1 macrophages and HMDMs but did not produce any significant change in SR-A mRNA expression (Fig. 2a, b). These changes in mRNA expression did not explain the EPA- and DHA-mediated reductions in AcLDL uptake seen in these cells, but may in part explain the observed EPA-mediated increase in OxLDL uptake, particularly since CD36 mRNA expression was increased. We next analyzed the impact of EPA and DHA on the mRNA expression of other scavenger receptors including SR-B1, SR-PSOX and LOX-1, which can take up modified LDL. EPA and DHA did not change the mRNA expression of SR-B1, SR-PSOX and LOX-1 in THP-1 macrophages or HMDMs (Fig. 2a, b). Additionally, EPA and DHA did not alter the mRNA expression of LPL, which is also known to regulate modified LDL uptake (Fig. 2a, b) [33]. Since the reduction in AcLDL uptake by EPA and DHA may involve changes in CD36 and SR-A protein expression rather than mRNA transcripts, we next investigated whether EPA and DHA could inhibit the protein expression of CD36 and SR-A. We found that EPA and DHA increased CD36 protein levels in THP-1 macrophages (Fig. 2c), with the increase by only EPA being statistically significant, but did not alter CD36 protein expression in HMDMs or SR-A protein levels in either THP-1 macrophages or HMDMs (Fig. 2c, d). Collectively, these data show that EPA and DHA do not inhibit CD36 and SR-A expression at either the mRNA or protein level. Therefore, the inhibition of AcLDL uptake by these n-3 PUFA appears to involve a scavenger receptor-independent mechanism in human macrophages whilst EPA may increase OxLDL uptake in THP-1 macrophages via a CD36-dependant mechanism.

EPA and DHA Inhibit Macropinocytosis and Syndecan-4 mRNA Expression

There is evidence documenting scavenger receptor-independent mechanisms of LDL uptake. Native LDL can be

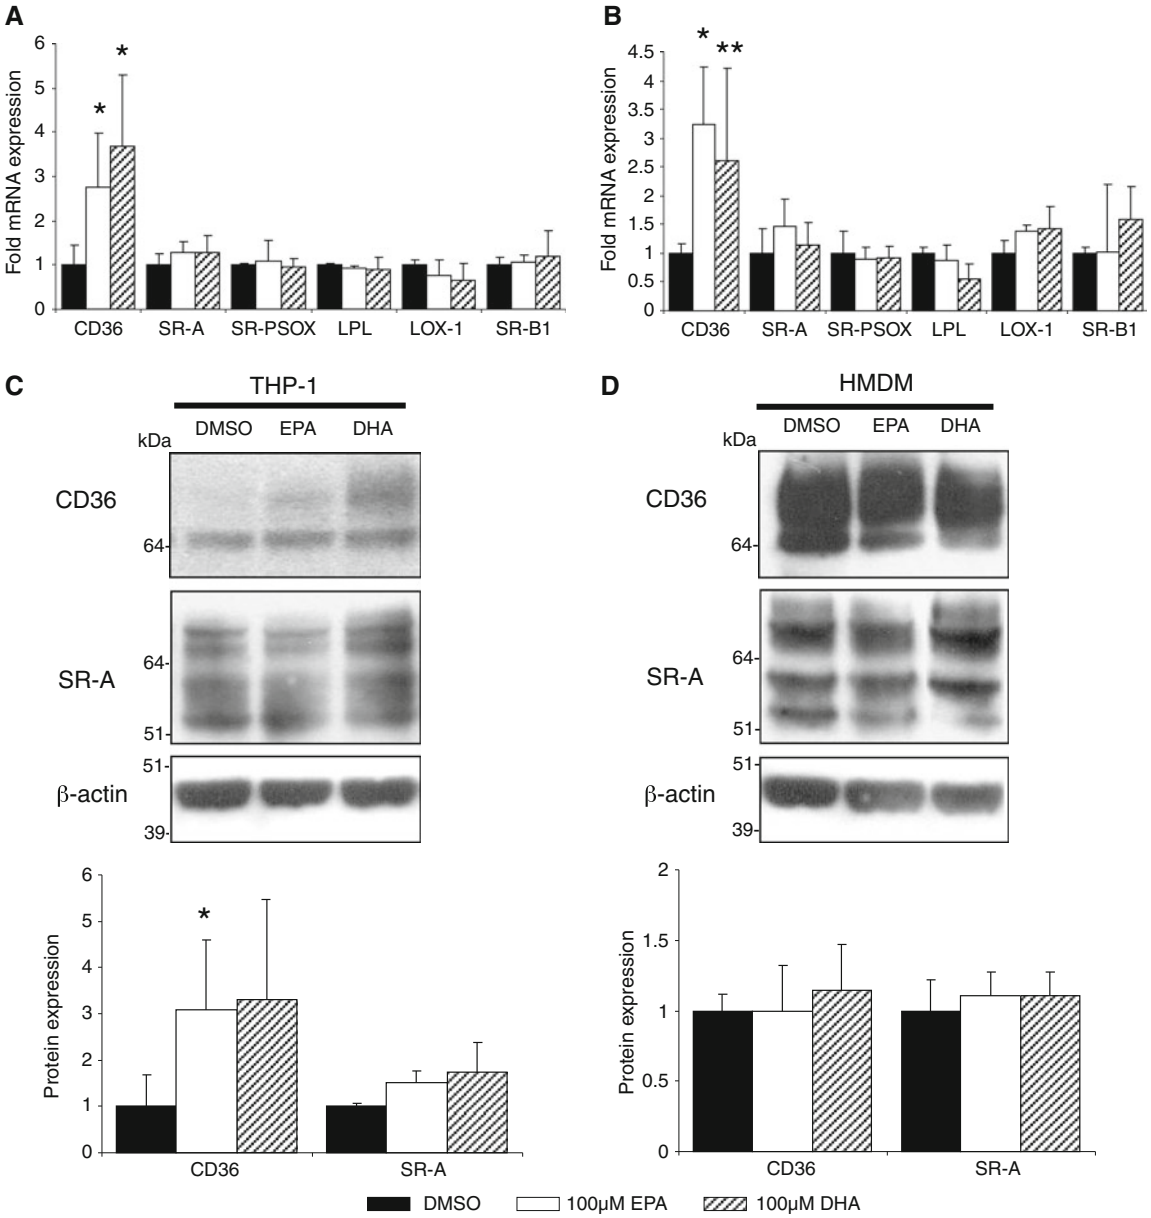

Fig. 2 EPA or DHA do not inhibit mRNA and protein expression of key genes implicated in the uptake of modified lipoproteins in human macrophages. Real-time quantitative PCR for CD36, SR-A, SR-PSOX, LOX-1, LPL and SR-BI was performed on cDNA from 24 h PMA-differentiated THP-1 macrophages (**a**) or 10 day differentiated HMDMs (**b**) incubated for 24 h with DMSO (*filled bars*), 100 μM EPA (*open bars*) or 100 μM DHA (*striped bars*) ($n = 4$). Gene-specific mRNA expression levels were calculated using comparative C_t method and normalized to GAPDH levels with DMSO-treated cells given an arbitrary value of 1. Western blot analysis was performed on total lysates from 24 h PMA-differentiated THP-1 macrophages (**c**) or 10 day differentiated HMDMs (**d**), incubated for 24 h with DMSO (*filled bars*), 100 μM EPA (*open bars*) or 100 μM DHA (*striped bars*) using antibodies against CD36, SR-A or β-actin. Multiple immunoreactive polypeptides for SR-A and CD36 represent different isoforms and/or post-translationally modified products. Semi-quantitative analysis of Western blots was performed by densitometric analysis using the Gene Tools software (GRI) and normalized to β-actin levels (DMSO-treated cells given an arbitrary value of 1). Graphs indicate data from four independent experiments ($n = 4$). All quantitative data represent means ± SD. Student's t test, $^*P < 0.05$; $^{**}P < 0.01$

internalized by the LDL receptor but this mechanism is negatively regulated by rising intracellular cholesterol levels [1]. In addition, it can be taken up by macropinocytosis [34], a form of fluid-phase endocytosis that is phosphoinositide 3-kinase (PI3K)-dependent, involves membrane ruffling and is involved in immune responses such as antigen presentation in dendritic cells [35, 36]. Modified LDLs can also be internalized by macrophages through macropinocytosis [10]. We therefore investigated whether EPA and DHA inhibited macropinocytosis. To do

this, we analyzed the impact of EPA and DHA on the uptake of Lucifer Yellow (LY), a solute marker used to study and quantify macropinocytosis in macrophages [37] by flow cytometry. LY uptake by macrophages was confirmed using confocal microscopy which identified the presence of Lucifer Yellow positive macropinosomes (1–5 μm in diameter) within the cells (data not shown). We found that EPA and DHA inhibited LY uptake by THP-1 macrophages (22 and 24%, respectively) (Fig. 3a) indicating that both EPA and DHA may inhibit macropinocytosis. Furthermore, as seen in Fig. 3b, blockade of macropinocytosis using the PI3 K inhibitor LY294002 [36] completely abolished the EPA- and DHA-mediated inhibition of LY uptake, thereby potentially providing direct evidence for the involvement of macropinocytosis during this process.

In order to further explain these reductions in LY uptake, we next analyzed whether EPA and DHA altered Syndecan-4 expression in these cells. Syndecan-4 is a cell surface heparan sulfate proteoglycan that can be endocytosed through the macropinocytic pathway [38] and can mediate uptake of LPL-enriched LDL [39] and group V secretory phospholipase A_2-modified LDL (GV-LDL) [40]. We found that EPA and DHA produced a statistically significant decrease in Syndecan-4 mRNA expression in THP-1 macrophages (Fig. 3c). The magnitude of this decrease was greater than that seen for LY uptake, which suggested that it might be linked to the inhibition in macropinocytosis. These data suggest that the reduction in macrophage AcLDL uptake triggered by EPA and DHA could involve the inhibition of macropinocytosis and Syndecan-4 expression.

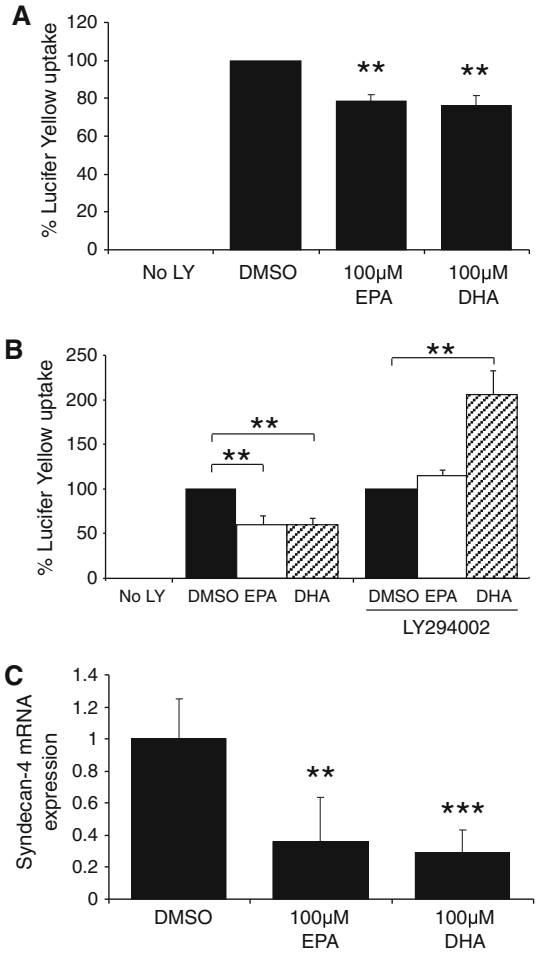

Fig. 3 EPA or DHA inhibit Lucifer Yellow uptake and Syndecan-4 expression in THP-1 macrophages. LY uptake was measured in 24 h PMA-differentiated THP-1 macrophages treated for 24 h with DMSO, 100 μM EPA or 100 μM DHA ($n = 3$–4) (**a**) or DMSO, EPA or DHA in the presence or absence of 100 μM LY294002 stimulation ($n = 3$) (**b**). Lucifer Yellow uptake in the presence of DMSO alone was arbitrarily assigned as 100%. LY294002 produced an approximate 49% inhibition in LY uptake in DMSO-treated cells (i.e., constitutive macropinocytosis). However, to delineate the effect of LY294002 on the EPA- or DHA-mediated inhibition of LY uptake, the relative level of LY uptake in LY294002 treated cells has been arbitrarily assigned as 100%. Syndecan-4 mRNA expression was measured in 24 h PMA-differentiated THP-1 macrophages in response to 24 h treatment with DMSO, 100 μM EPA or 100 μM DHA ($n = 3$) (**c**). Gene-specific mRNA expression levels were calculated using comparative C_t method and normalized to GAPDH levels. The DMSO-treated cells were given an arbitrary value of 1. Data represent means ± SD. Student's t test, $^{**}P < 0.01$; $^{***}P < 0.001$

Discussion

The results reported here supplement evidence describing EPA and DHA, as not only anti-inflammatory but also atheroprotective agents [12–18]. EPA and DHA are known to reduce foam cell accumulation in advanced human carotid plaques [25] and cholesteryl ester levels in THP-1 macrophages [26]. However, here we report that EPA elicits differential effects on the uptake of modified LDL as it reduces the uptake of AcLDL while promoting the uptake of OxLDL. We also report for the first time that DHA is able to regulate a key mechanism in macrophage foam cell formation since it inhibits both AcLDL and OxLDL uptake in human macrophages (Fig. 1). In addition, we show that both EPA and DHA inhibit the uptake of LY by macropinocytosis (Fig. 3).

In our study, the mechanism for EPA- and DHA-mediated inhibition of AcLDL uptake was found to be CD36 and SR-A-independent since their expression was not attenuated by either n-3 PUFA. Indeed, we found that stimulation with EPA or DHA induced the expression CD36 mRNA in both THP-1 macrophages and HMDMs and enhanced CD36 protein expression in only THP-1 macrophages. Clearly, such changes in scavenger receptor expression may be expected to elevate modified LDL uptake. It is possible that the reduction in AcLDL uptake observed in our study may occur as the result of diminished

AcLDL receptor number, as reported in rat peritoneal macrophages [27]. In addition, an inhibition in macropinocytosis and Syndecan-4 expression (Fig. 3) may also explain how AcLDL uptake, and OxLDL uptake in the case of DHA, is reduced independent of changes in the expression of scavenger receptors. Indeed, our data implicate modified LDL as a potential ligand for Syndecan-4 mediated endocytosis since GV-LDL has been identified as a target ligand [40].

As seen in Fig. 2, incubation with EPA induces CD36 mRNA and protein expression in an identical fashion to that observed for DHA. However, this observation contrasts that reported in human monocytic cells [41] and could represent a differential effect of this n-3 PUFA on monocytes compared to macrophages. Nevertheless, increased expression of CD36 mRNA and protein levels could potentially explain the observed increase in OxLDL uptake in response to EPA. Interestingly, EPA has been shown to induce the expression of peroxisome proliferator-activated receptors (PPAR)-α in THP-1 macrophages [26] and numerous studies have used PPAR agonists, such as thiazolidinedione, to delineate an anti-atherogenic role for these ligand-activated transcription factors during foam cell formation [42]. More specifically, it has now been shown that PPAR activation can induce the expression of CD36 [43, 44], which in turn increases the amount of OxLDL internalized [45], while simultaneously promoting cholesterol efflux through the up-regulation of ATP-binding cassette transporter proteins A1 (ABCA-1) and G1 (ABCG-1) in human macrophages [46, 47]. Considering these observations, we may propose that, despite the EPA-mediated up-regulation of OxLDL uptake observed in our study, EPA may still elicit an anti-foam cell phenotype in our system by increasing both OxLDL uptake and cholesterol efflux from the cell, a mode of cholesterol homeostasis also observed during the PPAR-dependant anti-atherogenic actions of interleukin-10 [48]. Furthermore, it has previously been shown that fish oils enhance macrophage reverse cholesterol transport in mice [49], and that AcLDL prepared from LDL isolated from African green monkeys fed on a diet rich in n-3 PUFA increases free cholesterol efflux from THP-1 macrophages [50]. Nevertheless, the role of EPA during cholesterol efflux remains controversial as our own study has shown that EPA does not affect the expression of SR-B1, which contributes to cholesterol efflux, while another study has shown that EPA can reduce ABCA-1-dependent efflux in THP-1 macrophages [51]; a result characteristic of foam cell promoting agents. There have yet to be any reports documenting specific actions of DHA on the above process.

In conclusion, we show that the n-3 PUFA DHA inhibits both AcLDL and OxLDL uptake while EPA reduces AcLDL uptake but increases OxLDL uptake by human macrophages. We also provide data suggesting that DHA and EPA reduce AcLDL uptake, and OxLDL uptake in the case of DHA, through a mechanism that is in part scavenger receptor-independent and may involve inhibition of macropinocytosis and Syndecan-4 expression. Furthermore, despite highlighting a role for CD36 in the EPA-mediated induction of OxLDL uptake, we speculate that EPA has anti-foam cell properties and that both EPA and DHA are capable of inhibiting macrophage foam cell formation. This study adds to evidence describing an atheroprotective role for n-3 PUFA implicating them as potential therapeutic agents for the treatment of clinical atherosclerosis.

confirmed in randomized phase III clinical trials, the consequences could be considerable by opening up the prospect of systematic adjuvant supplementation during cancer treatment, a significant shift in current cancer therapeutic paradigms.

DHA has been hypothesized to sensitize tumors to anticancer treatments through a variety of mechanisms involving alteration of cellular functions in cancer cells and modifications of the tumor microenvironment [1, 4, 5]. Enrichment of tumor cell membranes with DHA is crucial because it is assumed to be the initial step of these processes. On the basis of animal experiments, clinical trials were carried out in humans, where DHA was supplied to tumor tissues through a dietary supplementation during chemotherapy. Studies in rodents have shown that DHA-enriched diets administered for several weeks significantly increased tumor tissue DHA content in autochthonous mammary tumors [6, 7]. However, beside this observation, little is known about incorporation of preformed DHA in tumor tissue. One pilot study showed that the efficacy of chemotherapy was tightly related to DHA level in plasma phospholipids (PL) during dietary DHA supplementation [2]. In this study, the efficacy of chemotherapy was greater in patients with high plasma levels of DHA compared to patients with low plasma levels of DHA [2]. From these observations, it was hypothesized that blood supply of preformed DHA to tumor tissues varied among patients and that DHA supply to tumors was higher when DHA levels were elevated in plasma PL. It was also hypothesized that plasma could be an indirect indicator of DHA level in tumor tissue. Since all of these hypotheses rely on circumstantial evidences, it appears that the conditions of dietary DHA supplementation needed to obtain optimal DHA accumulation in tumor tissue have to be defined to properly design and interpret studies using dietary DHA intervention aiming at sensitizing tumor tissue to anticancer treatments.

To our knowledge, no study has evaluated the influence of the duration of intake or the dose of DHA on tumor tissue content of DHA, or the use of plasma as a surrogate biomarker. Therefore, we used a model of autochthonous mammary tumors induced by a carcinogen in female rats. This model is relevant to address these issues because carcinomas develop autochthonously in the mammary gland, generating a tumor tissue with features mimicking the complexity of common human breast tumors [8, 9]. Phospholipids and triacylglycerol (TAG) are the main tumor lipid fractions in this model. Herein, we report on the response of tumor PL and TAG fatty acid composition to dietary DHA supplementation over time and to increasing dose of DHA. We also investigated whether DHA level in plasma PL can be a proxy for DHA content in tumors.

Materials and Methods

Animal Procedures

All the work with rats was carried out in accordance with the European guidelines for the care and use of laboratory animals and approved by the local Institutional Animal Care Committee (060NH). Female Sprague–Dawley rats received a single dose of NMU (*n*-methyl-*N*-nitrosourea) by an inguinal subcutaneous injection (25 mg/kg of body weight) at 48 days of age to induce mammary carcinogenesis. Detection of the tumors was performed by palpation twice a week. Tumors developed in the mammary tissue approximately 8 weeks after the induction of carcinogenesis. Diets had the same carbohydrate, protein, mineral, vitamin and total fat content but different fatty acid composition (Table 1). Rats were maintained on a palm oil-based diet (diet 0) until tumor area reached 0.8 cm^2. Then, rats were fed either diet 1 (20 g/day) providing 0.8 g DHA/day for 4 weeks (group 1, $n = 4$) or 9 weeks (group 2, $n = 4$) or diet 2 (20 g/d) providing 1.5 g DHA/day for 4 weeks (group 3, $n = 4$). In group 1, transcutaneous biopsies of one tumor per rat and blood collection (0.4 ml) from the tail were performed under general anaesthesia before switching to a DHA-enriched diet (basal, diet 0) and at week 1 during diet 1. At the end of the study, rats were killed by cervical dislocation. Tumors were rapidly excised, frozen and stored at −80 °C. Blood collected during the study or at sacrifice by cardiac puncture was drawn into EDTA tubes, separated into cells and plasma by centrifugation, and plasma was stored at −80 °C. Palm oil was obtained from the Société Industrielle des Oléagineux (Bougival, France) and DHA was obtained from DHASCO oil (Martek Bioscience, Columbia, MD). The daily doses of DHA given to the rats were 4 g/kg body weight for diet 1 and 8 g/kg body weight for diet 2. If conversions used for drugs apply to nutrients, these amounts would correspond to approximately 700 mg/kg and 1,300 mg/kg respectively in man [10]. These very high dosages of DHA were aimed at experimentally investigating the extent of changes that takes place in the level of DHA in the tumor and plasma.

Fatty Acid Composition Analysis

The fatty acid composition of the experimental diets, plasma and tumors was determined by gas chromatography as previously described [2, 11]. Diet, plasma and tumor tissue lipids were extracted using chloroform/methanol (2:1, by vol; containing 50 mg/L BHT) [12]. PL and TAG were separated by one-dimensional silicagel thin layer chromatography. Fatty acids were

transmethylated with 14% boron trifluoride in methanol at 100 °C for 90 and 30 min, respectively for PL and TAG. FAME were extracted with hexane. Fatty acid methyl esters were resolved on an AS 2000 gas chromatograph (ThermoFinnigan, France) equipped with a cold on-column injector and a 60 meters BPX 70 capillary column, with the aid of an automatic injector. The temperature protocol was adapted from reference [13]. FAME were identified by comparison with authentic standards (Supelco, USA). The peak area was determined using ChromQuest software and results are presented as a percentage of the total peak area.

Statistics

GraphPad Prism (version 4, GraphPad Software, Inc., San Diego, USA) was used for statistical analysis. The effects of time on fatty acid composition were assessed by one-way ANOVA completed with the Bonferroni test. The effects of dose on fatty acid composition were assessed by an unpaired *t* test. The Spearman test was used to analyze the relationship between DHA concentration in plasma and in tumor tissue. Significance was defined as $P < 0.05$ (two-sided).

Results

DHA Accumulation in Tumor PL

The fatty acid composition of tumor PL during dietary DHA supplementation is presented in Table 2. DHA level in tumor PL rose to equilibrate between 2 and 4 weeks. DHA level increased by 2-fold after 4 weeks of intake. No further increase was noted after 4 weeks. When the dose of DHA was doubled, the amount of DHA in tumor PL increased by 1.3-fold. There was a time- and dose-dependent increase in tumor PL EPA content and a time-dependent increase in DPA n-3. No significant change was noted in the amount of ALA. Tumor LA content increased in a time-dependent manner with diet 1 and maintained while on diet 2. There was a reciprocal decrease in tumor PL ARA over time that was enhanced by a higher dose of DHA. Since oleic acid was present in large amounts in the diets, an increase in tumor PL oleic acid content was also noted.

DHA Accumulation in Tumor TAG

The fatty acid composition of tumor TAG during dietary DHA supplementation is presented in Table 3. The DHA

Table 1 Composition of diets

	Diet 0	Diet 1	Diet 2

increase in tumor TAG was more progressive and did not equilibrate during the time course of the study compared to tumor PL. The level of 5.5% DHA was reached in 9 weeks in the TAG fraction compared to 4 weeks in the PL fraction. The proportion of DHA in tumor TAG increased 2.6 fold when the dose of DHA was doubled. EPA increased after one week of dietary DHA supplementation to reach a steady state. EPA further increased in response to a higher dose of DHA. DPA n-3 increased in a time- and dose-dependent manner. There was a time-dependent increase in the amount of ALA and LA. Tumor TAG ARA content decreased in a time- and dose-dependent manner. There was also an increase in tumor TAG oleic acid and a decrease in stearic acid.

Relationship Between DHA Concentration in Plasma PL and in Tumor Tissue

DHA increase in plasma PL was rapid and reached a steady state after one week of intake (Table 4). A higher dose of DHA induced a 1.7 fold increase in DHA concentration in plasma PL. The DHA concentration in plasma PL followed a pattern close to that of tumor PL. Changes in EPA and ARA followed a pattern similar to that of tumor PL. An increase of ALA was noted at week 9 during diet 1. The proportion of LA increased during diet 1 but decreased during diet 2 when the amount of LA in the diet was reduced. No significant change in the DPA n-3 level was noticed.

Plasma PL DHA showed a correlation with tumor PL DHA ($r = 0.72$; $P < 0.001$; Fig. 1a) and tumor TAG DHA ($r = 0.64$; $P = 0.003$; Fig. 1b).

Discussion

This study describes the evolution of mammary tumor tissue fatty acids during dietary DHA supplementation over time and with increasing doses of DHA in rats. We found that DHA accumulation in tumor tissue increased in

a time- and dose-dependent manner in response to supplementary dietary DHA and that DHA concentration in plasma PL can serve as a proxy biomarker for tumor DHA.

Enrichment of cancer cell membranes and tumors with DHA has been associated with enhanced efficacy of anticancer treatments and is therefore assumed to be a critical step leading to this effect. Although increased de novo lipogenesis is a property of cancer cells [14], these cells cannot synthesize LCPUFA de novo because mammalian cells cannot introduce double bonds beyond the Δ9 position. Diet is a simple and efficient way to supply DHA to tumors as previously documented in this model [6, 7]. In the present study, we showed that dietary DHA supplementation induced a rapid accumulation of DHA in tumor PL over time. DHA level equilibrated between 2 and 4 weeks of intake in the PL fraction while no steady state was reached within the 9 weeks of intake in the TAG fraction. This suggests that a dietary DHA supplementation for 2–4 weeks would be necessary to significantly increase tumor PL content of DHA. As a practical consequence for future clinical trials, it would be necessary to initiate dietary DHA supplementation at least 2 weeks prior to chemotherapy to ensure optimal DHA accumulation into tumor tissue. When this is not possible, assessment of chemotherapy efficacy should not be performed before one month of dietary DHA supplementation has been achieved.

We provided 0.8 g DHA/day in diet 1 based on previous studies indicating that this dose significantly increased tumor DHA content and sensitized tumors to chemotherapy and radiation therapy in the same model [6, 7]. Despite the saturation of DHA level in tumor PL with this dose of DHA, tumor tissue continued to incorporate DHA in response to the considerable amount of DHA provided by diet 2 (1.5 g/day). DHA accumulation in the TAG fraction was greater than in the PL fraction in response to a higher dose of DHA. These results suggest that tumors have a high propensity to incorporate preformed DHA, even in large amounts. A possible mechanism could be an up-regulation in tumor lipid transporters to meet their high requirement for structural lipids. Whether the rate of growth or proliferation in the tumors could interfere with DHA accumulation in tumor tissue should be examined.

Diet has been considered to be the main source of DHA supplied to tissues including tumors either as preformed DHA or as its precursor, the essential fatty acid α-linolenic acid (18:3n-3, ALA). DHA synthesis from ALA requires elongation, desaturation by Δ6 (EC 1.14.19.3) and Δ5 desaturases (EC 1.14.19.4), and β-oxidation [15]. The activity of the desaturation/elongation pathway in the liver is the most important in terms of supply of ALA metabolites to other tissues. Tumor cells might also contribute to this pathway since several cancer cell lines are capable of processing exogenous essential fatty acids [16, 17]. During diet 0, endogenous synthesis of DHA may be regarded as the likely supply to tumor tissue, since no dietary source of preformed DHA was available. However, this pathway could not have markedly contributed to the increase in DHA level during dietary DHA supplementation because the amount of ALA and the ratio of LA:ALA were approximately similar in diet 1 and diet 0, and diet 2 contained only traces of ALA. The formation of EPA during dietary DHA supplementation, while diets were free from EPA, could be a result of DHA retroconversion [18]. This process mainly takes place in the liver and requires saturation of the Δ4 double bond by Δ4 enoyl CoA reductase (EC 1.3.1.34) and rearrangement of the double bond structure by Δ3, Δ2 enoyl CoA isomerase (EC 5.3.3.8) [19, 20]. The formation of DPA n-3 could be a result of DHA retroconversion or a chain-elongation of the retroconverted EPA. ARA decrease concomitant with increase in LA during dietary DHA supplementation may result from a competition with EPA and a lower conversion

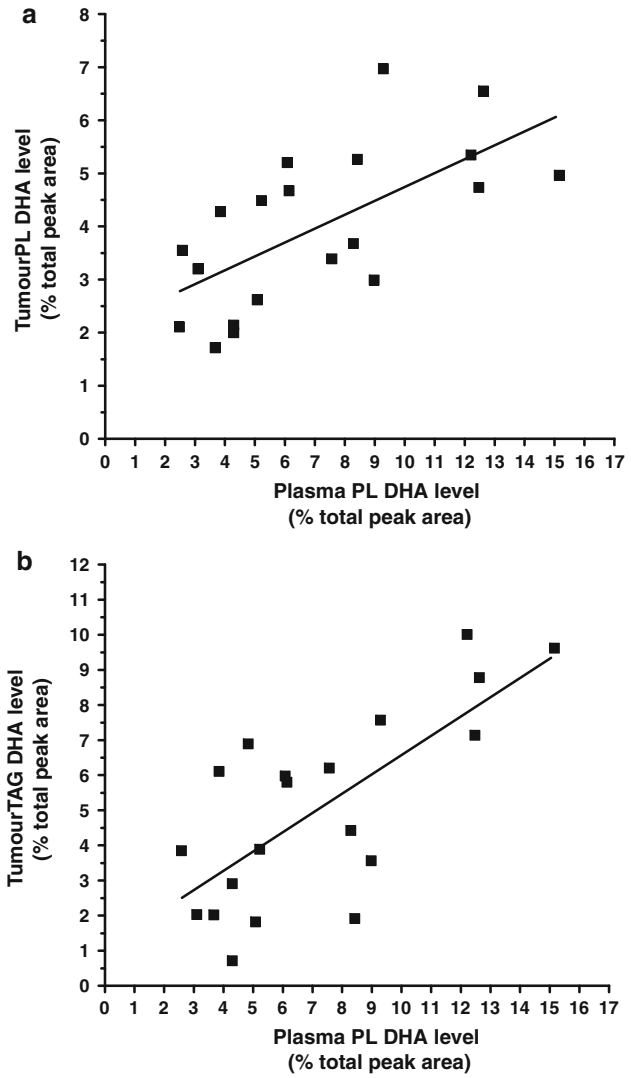

Fig. 1 Positive correlation between tumor PL **(a)**, or TAG **(b)**, DHA levels and DHA concentration in plasma PL. Spearman test results are $r = 0.72$, 95% CI = 0.39–0.88, $P = 0.0003$, $n = 20$ **(a)** and $r = 0.64$, 95% CI = 0.26–0.85, $P = 0.003$, $n = 20$ **(b)**. Lines represent the least-squares regression analysis of best linear fit (GraphPad Prism Software, version 4). Linear regression results are $r^2 = 0.43$, $P = 0.0018$ **(a)** and $r^2 = 0.52$, $P = 0.0003$ **(b)**

from LA. DHA and EPA were shown to downregulate the expression of Δ 5- and Δ 6-desaturases [21]. As a result of ARA changes, there was a dramatic decrease in n-6/n-3 ratio in tumor lipid fractions. Thus, we were able to profoundly modify the fatty acid composition of tumor tissue with a DHA-enriched diet. It is likely that this would have consequences on tumor metabolic pathways, particularly the production of inflammatory eicosanoids.

Blood is the route of delivery of dietary lipids to tissues. Plasma DHA in total lipids has been shown to correlate with DHA accumulation in the brain, retina or liver in experimental animals [22, 23]. We found that DHA accumulation in tumor PL followed a pattern close to that of plasma PL and that DHA in tumor PL and TAG correlated with the DHA level in plasma PL in this model. Studies exploring this issue in cancer patients are difficult to perform because of technical problems and ethical concerns. One study reported that the DHA increase in gastro-intestinal tumors was concomitant with its increase in plasma PL after 5 days of dietary supplementation with fish oil [24]. These results suggest that plasma, beside its use as a biomarker of intake, could be a relevant surrogate biomarker of tumor tissue DHA content.

In conclusion, this study establishes the evolution of tumor tissue fatty acid composition in response to different durations or doses of dietary DHA supplementation and demonstrates that accumulation of preformed DHA into tumor tissue is time- and dose-dependent. These results could provide a basis for a rational design of dietary DHA supplementation in cancer patients.

Acknowledgments DHASCO was graciously provided by Martek Biosciences (Columbia, MD, USA) and palm oil by the Société Industrielle des Oléagineux (Bougival, France). We also thank Pierre Besson for his contribution to this work.

(multi-deficient diet with 7% protein) may influence brain growth spurt, feeding behavior, ontogeny of reflexes, skeletal muscle mechanical properties and locomotor activity in adult rats [5–7].

Developmental plasticity is now observed when an organism is exposed to very high caloric nutrition before birth [4]. In fact, human studies have shown that high-fat diet availability during gestation and lactation, as well as gestational diabetes, may predispose offspring to increased fat mass and incidence of metabolic syndrome as children and adults [8]. In animals, maternal high fat or cholesterol over-feeding during the perinatal period is associated with long-lasting effects on the offspring such as: dyslipidemia, hyperleptinemia, increased adiposity and blood pressure, elevated blood glucose and triglycerides [9, 10]. Litter size reduction (3 pups/litter) resulted in postnatal overfeeding during the suckling period and elevated blood pressure in adulthood [11]. Previous studies have related early adiposity to faster growth and hyperphagia (suppressed orexigenic signals), as seen in 20-postnatal-day offspring from mothers submitted to a high-fat diet during gestation [12]. Out of this context, the main goal of the present study is to evaluate the long-term effects of a palatable high-fat diet during gestation and lactation on the food intake and lipids profiles of offspring.

Materials and Methods

Animals and Diet

The experimental procedures were approved by the Ethical Committee of the Center of Health Science, Federal University of Bahia (protocol no. 018/2008-13), and followed the Guidelines for the Care and Use of Laboratory Animals [13]. Ten pregnant Wistar rats (aged 90–100 days and weighing 180 ± 11 g) were fed either a control diet (*C*, $n = 5$) or a palatable hyperlipidic diet (HL, $n = 5$) during gestation and lactation. The compositions of the diets are shown in Table 1. The fatty acids were analyzed on a gas chromatograph (Shimadzu GC-9A, Japan) with an FID detector. The column was WAX (25 m × 0.25 mm × 0.2 μm), with a flow of 1.3 mL min^{-1} of helium [14]. During the suckling period, the offspring were kept in groups of 8 pups/litter. At weaning (on the 22th day of age), two male offspring from each mother were randomly chosen and assigned to either control (C_p $n = 10$, pups from control mothers) or palatable hyperlipidic diet (HL_p $n = 10$; pups from HL mothers). The offspring were housed 3–4 per cage and received the animals' standard laboratory chow (Nuvilab® CR1, Brasil) ad libitum.

Table 1 Analysis of fatty acid percentage composition of the diets

Ingredients (g/100 g)	Control diet	Hyperlipidic diet
Carbohydrate	57	46
Protein	22	17
Lipids	4	23
Ashes	9	4
Humidity	8	10
Energy (kcal/g)	3.5	4.5
Individual fatty acids (g/100 g of total fatty acid)		
C12:0	ND	13.81
C14:0	ND	5.81
C16:0	15.86	12.65
C18:0	3.31	6.08
C18:1n-9 *cis*	26.24	34.52
C18:1n-9 *trans*	1.18	0.41

C18:3n-3	3.72	0.27
C20:0	ND	0.77
C20:1n-9	ND	0.80
C22:0	ND	1.58
C24:0	ND	1.01
Total fatty acids		
Total SFA	19.17	41.71
Total MUFA *cis*	26.24	35.32
Total PUFA *cis*	53.4	21.95
Total TFA	1.18	0.41
PUFA:SFA	2.78	0.53
n-6:n-3	13.35	80.3

Control diet included commercial chow (Nuvilab® CR1, Brasil). The palatable food included commercial chow (Nuvilab® CR1, Brasil), peanut, milk chocolate bars, and biscuits in the proportion of 3:2:2:1. The main source of fat in the control diet was soybean oil. The main sources of fat in the HL were lard, animal fat, butter and safflower oil

SFA Saturated fatty acids, *MUFA* Monounsaturated fatty acids, *PUFA* Polyunsaturated fatty acids, *TFA* Trans fatty acids, *ND* Not detected

Measurement of Food Intake and Fasting Serum Glycemia and Cholesterol Profile

On day 76, pups were housed individually for 14 days in a metabolic cage. The first 4 days were designed for adaptation to the cage. Next, the animal's daily food consumption was determined by the difference between the amount of food provided (50 g) at the onset of the light cycle and the amount of food remaining 24 h later. Body and food weights were recorded by a Marte Scale (AS-1000), in increments of 0.01 g [15]. At 100 days old, and after fasting (12 h), serum glucose, total cholesterol, high-density-lipoprotein cholesterol (HDL-C) and triglyceride (TG) levels were determined with commercially available kits (BioSystems, Spain—A 25 Clinical Chemistry

Analyse®). Low-density-lipoprotein cholesterol (LDL-C) and very low-density-lipoprotein cholesterol (VLDL-C) were obtained using Friedwald calculations [16].

Statistical Analyses

Results are presented as means ± standard errors of the mean. Data for all analyses were performed using the statistical program Graphpad Prism 5® (GraphPad Software Inc., La Jolla, CA, USA). For statistical analysis of body weight and food intake, a two-way repeated measures ANOVA was used, with the mother's diet (HL) and time (weeks) as factors. Bonferroni's post hoc test was used, and Student's *t* test was used to compare groups in terms of blood biochemical parameters. Significance was set at $P < 0.05$.

Results and Discussion

Offspring's body weight in the HL_p group was higher than that of the control group throughout the weeks of development (Fig. 1a). The effects of a palatable high-fat diet during the perinatal period and the consequences of offspring body weight have also been seen in previous studies [8, 17]. The present study shows that life-time effects on body weight are seen in rats in response to perinatal (gestation and lactation) and that adult animals fed by mothers that were fed a perinatal high-fat diet were permanently heavier than their controls.

The measurement of food intake during a period of 6 days was higher in the HL_p group (Fig. 1b). High food intake can be associated with a high adiposity, high leptinemia and leptin resistance [18]. There is a correlation between high leptin resistance and the relative food intake per gram of body weight [18]. Although the concentrations of leptin were not evaluated in the present study, previous studies have found that a perinatal high-fat diet or gestational diabetes can lead to hyperinsulinism and a malprogramming in central regulators of body weight and metabolism [17].

Serum total cholesterol, LDL-C, HDL-C, TG, VLDL-C and glycemia were higher in the HL_p group than controls group (Table 2). In addition, these animals were markedly heavier and had significantly increased serum concentrations of glucose, cholesterol, and triglycerides, suggesting impairments in carbohydrate and lipid metabolism. Khan et al. [19] reported an increase in plasma triglycerides and a decrease in HDL-cholesterol concentrations in the female offspring born to mothers fed a rich in lard (25.7% fat) diet 10 days before and throughout pregnancy and lactation, although these changes were only apparent in one-year-old offspring. Although previous studies have used different protocols to induce developmental plasticity by a maternal high-fat diet, our results are in accordance with previously reported results in terms of blood lipid profiles [8, 10, 17,

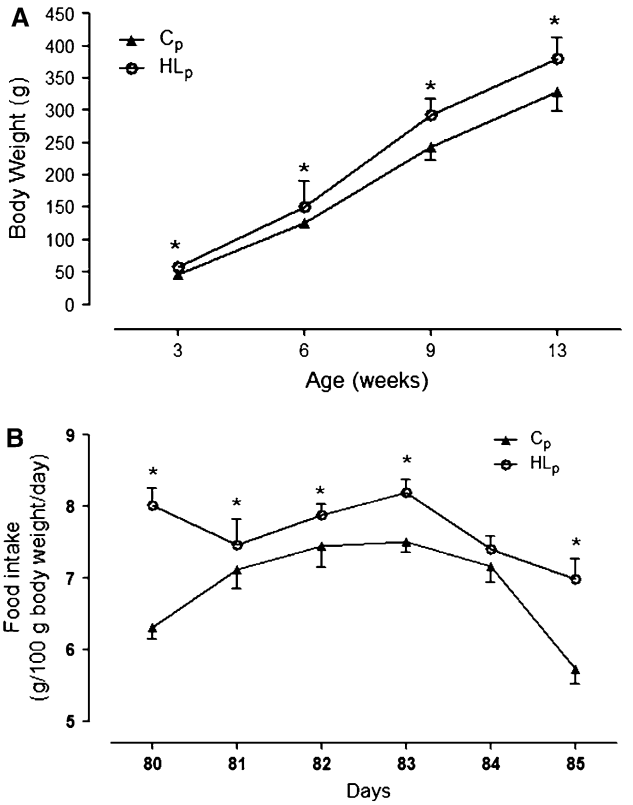

Fig. 1 Body weight of pups from mothers submitted to either a control or a hyperlipidic diet during gestation and lactation (**a**). Body weight was evaluated weekly until the 90th day of life. Food intake by pups at 80 days old from mothers submitted to either a control or a hyperlipidic diet during gestation and lactation (**b**). Food intake was evaluated daily until the 85th day of life. Control (C_p, $n = 10$) and hyperlipidic pups (HL_p, $n = 10$). The values are presented as means + SEM. *$P < 0.05$ using two-way ANOVA and Bonferroni's post hoc test

Table 2 Fasting serum glycemia and cholesterol profile of pups at 90 days old from mothers submitted to either a control or a hyperlipidic diet during gestation and lactation

	C_p	HL_p
Total cholesterol (mg/dL)	35.1 ± 1.0	56.4 ± 3.3*
LDL-C (mg/dL)	9.6 ± 1.1	19.14 ± 2.2*
HDL-C (mg/dL)	16.6 ± 0.7	25.5 ± 1.3*
Triglycerides (mg/dL)	44.2 ± 4.1	58.8 ± 5.5*
VLDL-C (mg/dL)	8.84 ± 0.8	11.76 ± 1.1*
Glycemia (mg/dL)	171.6 ± 11.1	217 ± 10.6*

20–22]. The alterations could be associated with the concentration of saturated fatty acids (41.71%) in the mother's diet, even though the post-weaning diet was balanced for both groups in terms of carbohydrates, lipids and protein. The novelty of the present study is that a perinatal high-fat diet induces altered plasma cholesterol and triglyceride levels in the offspring and can predispose the offspring to developing obesity in a manner that is independent of postnatal diet.

Perinatal nutrition-induced hypercholesterolemia has been previously described in animal models, and the offspring's susceptibility to programmed obesity risk has been shown to be dependent on the timing and severity of diet manipulation [3]. Most models have used malnutrition as a stimulus for developmental plasticity, and relatively few studies have seen the effects of a high-fat diet during gestation and lactation. In this regard, we have presented data that confirm our hypothesis by demonstrating that a palatable high-fat diet during perinatal period increases food intake and induces hypercholesterolemia. In conclusion, our observations extend the evidence that both gestation and lactation are critical periods for the development of metabolic disease in later life.

Acknowledgments This study received financial support from the CNPq and FAPESB.

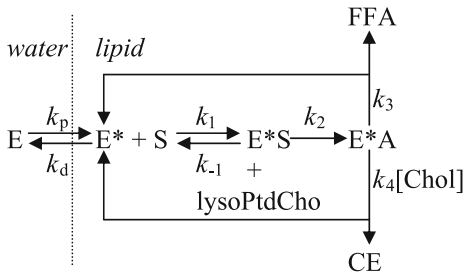
lipid-bound state may influence LCAT activity via enzyme binding with the lipid interface, substrate and enzyme activation [5]. Both LCAT-activating and lipid-binding regions in apoA-I has been suggested to exist. The low lipid affinity of 144–186 region has been suggested to be important in LCAT activation [6]. Despite the numerous studies of LCAT reaction with HDL, the quantitative characteristics of the reaction are absent. The study of Verger et al. [7] on phospholipase A catalysis at interface, the identification of the catalytic triad of LCAT as Ser-Asp-His [8] with Ser181 as nucleophile residue in catalysis [9] and consideration of the influence of an added nucleophile at acyl-enzyme deacylation [10] are the seminal keys in the present effort to describe the LCAT reaction at the lipid-water interface of discoidal HDL as a tool for a mechanism-based analysis of enzyme activation by apolipoproteins and the contribution of the HDL structure.

Materials and Methods

Proposed Model of the LCAT Reaction

Two events underlie the kinetic mechanism of cholesteryl ester formation by LCAT with the discoidal HDL particle: (1) the existence of two consecutive equilibria, i.e. enzyme binding to the particle (penetration) and the LCAT reaction with phosphatidylcholine and cholesterol; (2) this reaction at the water-lipid interface proceeds through three steps that involve the formation of an acyl-enzyme intermediate and cholesterol as a nucleophilic agent can compete with water at the deacylation of acyl-enzyme. Indeed, the kinetic analysis of the interfacial catalysis of pancreatic phospholipase A_2 in phospholipid molecular layers has been done [7]. LCAT, in a reaction analogous to that of classical serine-dependent esterases, initially cleaves the *sn*-2 ester bond of phosphatidylcholine with the formation of lysophosphatidylcholine (lysoPtdCho) and an intermediate oxyester. The serine oxyester donates its fatty acyl group to cholesterol, forming a cholesteryl ester and regenerating the nonacylated enzyme [11]. The kinetic scheme 1 combines these events:



(1)

Kinetic Treatment of the Proposed Model

The balance between different enzyme forms exists (Eq. 2):

$$[E_t] = [E] + [E^*](I/V) + [E^*S](I/V) + [E^*A](I/V) \quad (2)$$

Equations 3–7 satisfy steady state conditions

$$\mathrm{d}[E^*]/\mathrm{dt} = k_p[E] + k_{-1}[E^*S] + (k_3 + k_4[\mathrm{Chol}])[E^*A] - (k_d + k_1[S])[E^*] = 0 \quad (3)$$

$$\mathrm{d}[E^*S]/\mathrm{dt} = k_1[E^*][S] - (k_{-1} + k_2)[E^*S] = 0 \quad (4)$$

$$\mathrm{d}[E^*A]/\mathrm{dt} = k_2[E^*S] - (k_3 + k_4[\mathrm{Chol}])[E^*A] = 0 \quad (5)$$

$$\mathrm{d}[\mathrm{CE}]/\mathrm{dt} = v_i = v_o/(I/V) = k_4[\mathrm{Chol}][E^*A] \quad (6)$$

$$[S] = [S_o]/(I/V) \quad (7)$$

where $[E_t]$ is the total enzyme concentration (mol/volume); $[E]$ is the free enzyme concentration (mol/volume); $[E^*]$ is the penetrated enzyme concentration (mol/surface); $[E^*S]$ is the penetrated enzyme/substrate complex (mol/surface); $[E^*A]$ is the penetrated acyl-enzyme (mol/surface); $[S]$ is the substrate (phosphatidylcholine) concentration (mol/surface); $[S_o]$ is the total substrate concentration in bulk units (mol/volume); [CE] is the product (cholesteryl ester) concentration (mol/surface). I is the total interfacial area (surface) and V the total volume (volume); k_p is the penetration rate constant (volume/surface)(time^{-1}); k_d is the desorption rate constant (time^{-1}); k_1 (mol/surface)$^{-1}$ (time^{-1}); k_{-1} (time^{-1}); k_2 (time^{-1}); k_3 (time^{-1}); k_4 is the second order rate constant (mol/surface)$^{-1}$(time^{-1}); v_i is the interface expression of the velocity (mol/surface·time) and v_o is the bulk expression of the rate (mol/volume·time). Finally (I/V) is the factor for conversion from surface units to bulk units.

Equations 2–7 can be combined to obtain the bulk/interface expression of the velocity v_o/v_i at steady state in terms of the initial surface concentration of substrate $[S]$ (Eq. 8):

$$\frac{v_o}{[E_t]} = \frac{v_i}{[E_t]} \times \frac{I}{V} = \frac{\frac{k_2 \times k_4 \times [\mathrm{Chol}]}{k_2 + k_3 + k_4 \times [\mathrm{Chol}]} \times \frac{I}{V} \times [S]}{\frac{k_3 + k_4 \times [\mathrm{Chol}]}{k_2 + k_3 + k_4 \times [\mathrm{Chol}]} \times K_m^* \times \left(K_d^* + \frac{I}{V}\right) + \frac{I}{V} \times [S]} \quad (8)$$

K_m^* and K_d^* are the interfacial Michaelis–Menten and dissociation constants given by Eqs. 9 and 10, respectively:

$$K_m^* = \frac{k_{-1} + k_2}{k_1} \quad (9)$$

$$K_d^* = \frac{k_d}{k_p} = K_d \times \mathrm{area}_{\mathrm{LCAT}} \times 10^{-14} \times N_A \quad (10)$$

K_d is the dissociation constant of LCAT/disc complex in bulk units (mol/cm^3), $\mathrm{area}_{\mathrm{LCAT}}$ is the accessible area of

LCAT interface recognition region (nm^2), N_A Avogadro' number. K_d should be measured independently.

The interfacial substrate and cholesterol concentrations (mol cm^{-2}) are determined by Eqs. 11 and 12, respectively:

$$[S] = \frac{n_{PC} \times 10^{14}}{(\text{area}_{PC} \times n_{PC} + \text{area}_{Chol} \times n_{Chol}) \times N_A} \quad (11)$$

$$[\text{Chol}] = \frac{n_{Chol} \times 10^{14}}{(\text{area}_{PC} \times n_{PC} + \text{area}_{Chol} \times n_{Chol}) \times N_A} \quad (12)$$

where n_{PC} and n_{Chol} are the number of PC and Chol molecules per disc and area_{PC} and area_{Chol} are the phosphatidylcholine and cholesterol surface areas (nm^2).

Thus the hydrolysis/solvolysis of acyl-LCAT intermediate on the surface of discoidal HDL by water and cholesterol predicts a dependence of the cholesteryl ester formation rate on three variables: the surface substrate concentration [*S*], the surface cholesterol concentration [Chol] and the proportion of interface *I*/*V*. The apparent catalytic rate constant k_{cat}^{app} and Michaelis constant K_m^{app} are defined by Eqs. 13 and 14, respectively:

$$k_{cat}^{app} = \frac{k_2 \times k_4 \times [\text{Chol}]}{k_2 + k_3 + k_4 \times [\text{Chol}]} \quad (13)$$

$$K_m^{app} = \frac{k_3 + k_4 \times [\text{Chol}]}{k_2 + k_3 + k_4 \times [\text{Chol}]} \times K_m^* \left(K_d^* + \frac{I}{V} \right) \quad (14)$$

The individual parameters are derived from double reciprocal plots (Eqs. 15 and 16):

$$\frac{1}{k_{cat}^{app}} = \frac{k_2 + k_3}{k_2 \times k_4} \times \frac{1}{[\text{Chol}]} + \frac{1}{k_2} \quad (15)$$

$$\frac{K_m^{app}}{k_{cat}^{app}} = K_m^* \left(K_d^* + \frac{I}{V} \right) \times \frac{k_3}{k_2 \times k_4} \times \frac{1}{[\text{Chol}]} + \frac{1}{k_2} \times K_m^* \left(K_d^* + \frac{I}{V} \right) \quad (16)$$

Results and Discussion

The raw data of Sparks et al. [12] on apparent kinetic parameters and particle composition for four reconstituted discoidal HDL preparations D4–D26 with two molecules apoA-I per disc were analyzed. The input parameters used in the subsequent calculations are listed in Table 1. It is evident that the interfacial lipid area and the POPC concentration are nearly constant while cholesterol varied at a 6-fold level. The increase in Chol content did not change significantly hydrodynamic diameter of the disks [12]. The k_{cat}^{app} values were normalized to an equal POPC concentration of 2.69×10^{-10} mol cm^{-2}. The $area_{LCAT}$ value calculated with the RVP-net web server [13] for the region between 50 and 74 residues in LCAT sequence, suggested to be involved in interfacial recognition [14], was 6.6 nm^2. The values for molecular surface area area_{PC} and area_{Chol} were chosen as 0.58 and 0.38 nm^2, respectively [15]. These values were obtained for Langmuir-type film at high surface pressures (30–40 mN/m) that mimic a disc bilayer. Even at largest, Chol content in lipid phase of the particle did not exceed 12.5 mol% and Chol-induced POPC area condensation (<5%) was discarded. The bulk K_d value as 3×10^{-10} mol/cm^3, obtained by others [16] for complex analogous to D18, was fixed at the assumption of constant *I*/*V* and [*S*] values for all four complexes. The linear transformation of the input data corresponded well the kinetic mechanism with acyl-enzyme intermediate predicted by Eqs. 15 and 16 (Fig. 1). This treatment allowed the calculation to be made of the complete set of kinetic constants for LCAT-catalyzed cholesteryl ester formation in discoidal HDL (Table 2). The k_2 value is close to phospholipase A_2 LCAT activity with the turnover rate as 40 times/min [17]. The ratio of rate constants of acyl-LCAT hydrolysis/solvolysis by water and cholesterol is 0.66 at 12.5 mol% cholesterol (26 molecules per particle). Cholesterol seems to be an efficient nucleophilic agent at its physiological concentration in discoidal HDL. Also, the amount of cholesterol in native HDL_3 particles varies between 15 and 41 molecules per particle [18], quite comparable to the current values. It should be emphasized that data at high cholesterol content do not indicate a saturation phenomenon, thus giving no evidence for a binding of cholesterol to the enzyme. This would argue against any gross change in the LCAT interfacial recognition region.

Table 1 Compositional and kinetic properties of four discoidal reconstituted HDL

Complex	*I* (nm^2)	POPC $\times 10^{10}$ (mol cm^{-2})	Chol $\times 10^{11}$ (mol cm^{-2})	k_{cat}^{app} (s^{-1})	$K_m^{app} \times 10^8$ (mol POPC cm^{-3})
D4	105	2.82	0.63	0.23	2.2
D8	112	2.79	1.19	0.44	2.5
D18	113	2.69	2.66	0.69	2.5
D26	115	2.62	3.74	0.74	2.5

Numbers in complex name correspond the number of Chol molecules/particle [12]. The raw data for complex composition and for apparent kinetic constants [12] were transformed as input values in Eqs. 15 and 16. The k_{cat}^{app} values were normalized to an equal POPC concentration of 2.69×10^{-10} mol cm^{-2}. POPC and cholesterol surface concentrations were calculated from their molecular areas

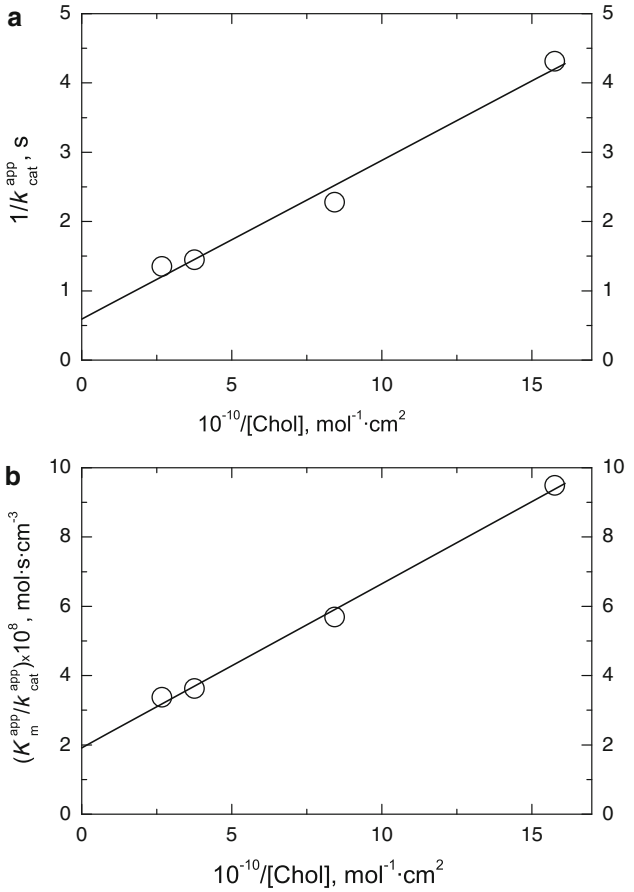


Fig. 1 The relation of apparent kinetic parameters of the LCAT reaction with reconstituted HDL on the cholesterol level. **a** The dependence of the rate constant of cholesteryl ester formation on the cholesterol level in double reciprocal plots. The k_{cat}^{app} values were normalized to an equal POPC concentration of 2.69×10^{-10} mol cm^{-2}. Data were fitted by linear regression $y = a + b \times x$ with $a = 0.59 \pm 0.19$, $b = (2.29 \pm 0.21) \times 10^{-11}$, $r = 0.992$ ($p = 0.008$, $n = 4$); **b** the dependence of kinetic parameters ratio on cholesterol level in double reciprocal plots. The k_{cat}^{app} values were normalized to an equal POPC concentration of 2.69×10^{-10} mol cm^{-2}. Data were fitted by linear regression $y = a + b \times x$ with $a = (1.91 \pm 0.20) \times 10^{-8}$, $b = (4.74 \pm 0.22) \times 10^{-19}$, $r = 0.998$ ($p = 0.002$, $n = 4$)

Table 2 Solvolysis of the acyl-LCAT intermediate by cholesterol and water

k_2 (s^{-1})	k_3 (s^{-1})	$k_4 \times 10^{-11}$ (mol^{-1} cm^2 s^{-1})	K_d^* (cm^{-1})	I/V (cm^{-1})	$K_m^* \times 10^{10}$ (mol cm^{-2})
1.69	3.01	1.22	11.9	93.0	3.08

Errors are ±10%. the K_d^* value was calculated from the bulk K_d and the area of the LCAT interface recognition region. I/V was calculated for the mean value of the bulk K_m and the POPC concentration 2.69×10^{-10} mol cm^{-2}

Early investigations with LCAT also showed that the catalytic activity of the enzyme was sensitive to the amount of cholesterol in the surface of vesicular and discoidal particles [19–21]. In addition, LCAT activity increased at the modest increase of Chol but became independent when Chol level exceeded 20 molecules per particle [22], still comparable with the highest Chol concentration in the present study. Prominent heterogeneity of the complexes in the study of Jonas and McHugh [22] may contribute to the different LCAT kinetics. So, deacylation of acyl-enzyme intermediate by water and cholesterol is not rate-limiting (Table 2) and LCAT activation by apoA-I must involve either activation of the enzyme and/or of the phospholipid molecule. The increased accessibility of the *sn*-2 ester bond of phosphatidylcholine for presentation to the catalytic site of the enzyme may underlie substrate activation by apoA-I [21]. The precise influence of apoA-I domains on phospholipid conformation remains to be established. The calculation of K_m^* value requires the knowledge of K_d^* value determined in turn from the independent measurement of bulk K_d value. K_m^* value agreed well with the analogous parameter for phospholipase A_2 activity toward mixed phosphatidylcholine-detergent micelles when some simplifying assumptions on the dissociation constant, not directly measured, had to be made [23]. However, a difference in K_m^* by two orders of magnitude has been obtained in another study [24] for the same phospholipase A_2-micelle system that weakens the significance of indirectly determined K_d value. The widely used k_{cat}^{app}/K_m^{app} ratio (Eq. 13 divided by Eq. 14) as a measure of LCAT catalytic efficiency is actually a complex function of three rate constants, interfacial Chol concentration and interfacial Michaelis and dissociation constants. All these variables should be introduced into examination of LCAT activity with discoidal HDL. The present analysis may be applied for complexes of apoA-I mutants and other apolipoproteins. This approach will be combined with the consideration of cholesterol radial distribution [25] and apolipoprotein conformational stability [26] in emerging analysis of the contribution of HDL composition and structure into RCT efficiency directed by LCAT at the cholesteryl ester generation step.

number of double bonds, with n-3, n-6 and n-9 indicating the position of the first double bond counting from the methyl end

Introduction

Previous reports have shown that, in the rat testis and spermatozoa, sphingomyelin (CerPCho) and ceramide (Cer) contain a high proportion of very long chain (VLC) polyunsaturated fatty acids (PUFA), this including non-hydroxy (n-) and 2-hydroxy (2-OH) VLCPUFA [1, 2]. The association of these unusual lipids with cells of the spermatogenic lineage was indicated by in vivo studies showing that they appear in the testis only after the onset of spermatogenesis and that they gradually disappear from the testis of healthy adult rats in situations that lead to germ cell deprivation with permanence of Sertoli cells [3, 4].

The amount of both types of fatty acids increases in both lipids from the onset of spermatogenesis to adulthood in both sphingolipids, but species with *only* n-VLCPUFA rise during the first few weeks, the species with 2-OH VLCPUFA being the last to be accrued [2]. Conversely, species with n-VLCPUFA disappear from the adult rat testis *before* those with 2-OH VLCPUFA in situations that are known to be damaging to the immature and rapidly dividing germ cell precursors, like doxorubicin treatment [2] and X-ray irradiation [4]. These in vivo changes found an explanation when the acquisition of each type of VLCPUFA was shown to be associated with germ cell differentiation [5]. Thus, virtually only sphingomyelins and ceramides with n-VLCPUFA may be found in the larger and less differentiated pachytene spermatocytes, whereas species with 2-OH VLCPUFA prevail in the smaller but more mature and numerous round spermatids.

After leaving the testis, spermatozoa are known to undergo a series of structural and functional modifications during their passage through the highly convoluted epididymal duct [6, 7]. Progressive motility, a quality obviously associated with the tail, is one of the last properties to be acquired. Epididymal maturation entails changes in many sperm constituents, including proteins and lipids. In several mammalian species, the content of glycerophospholipids (Gpl) per cell decreases as spermatozoa acquire their definite shape and size during their transit from the caput to the caudal segments, this process being associated with a relative increase in choline glycerophospholipids (ChoGpl) [8–11]. In the rat, this concurs with a reduction in the proportion of the major 22:5n-6 in Gpl, and a concomitant increase in that of 22:4n-9, markedly affecting the ChoGpl, but most especially the plamenylcholines (PlsCho) [12].

In contrast to the significant quantitative and qualitative differences observed for the major Gpl, sphingomyelins and ceramides accompany the gametes with little change in their fatty acid profiles from epididymal caput to caudal regions [2]. Moreover, these lipids show similar features in their fatty acids between testicular round spermatids and spermatozoa from epididymal cauda [5]. Both developmental stages contain sphingomyelins with similar proportions of n- and 2-OH VLCPUFA and, intriguingly, high levels of Cer that exclusively contain 2-OH VLCPUFA [5].

A previous study focusing on the species of CerPCho and Cer with nonhydroxy VLCPUFA showed that, as long as care is taken to avoid "spontaneous" hydrolysis of CerPCho during isolation of rat spermatozoa from the epididymal cauda, these gametes contain virtually no Cer [13]. Thus, using divalent cation-free media, most of the n-VLCPUFA-rich species of CerPCho that can be recovered from spermatozoa were found to be located to the head, not only in rat but in bull spermatozoa [13]. It was then intriguing that whole rat spermatozoa contained relatively high levels of Cer with 2-OH VLCPUFA [14], even if isolated in divalent cation-free media [5].

The aim of the present study was to investigate how the sphingomyelins and ceramides that contain both types of VLCPUFA are distributed between head and tail in rat spermatozoa. A comparison with other lipid classes with which these lipids coexist in each of these two regions, focusing on their fatty acids, was also included. Our results show that not only the major Gpl classes and subclasses tend to be unevenly distributed between these two regions, but that sperm sphingomyelins and ceramides are completely segregated.

Materials and Methods

Spermatozoa and Their Parts

Adult (3–4 month-old) Wistar rats, maintained an manipulated in accordance with the Guide for the Care and Use of Laboratory Animals, Institute for Laboratory Animal Research (ILAR), National Academy of Sciences (Bethesda, MD, 1996) were used to obtain the spermatozoa used in this study. Caudal epididymi were excised, freed of their fat pad and blood vessels, and transferred to small dishes containing PBS. After making a few incisions with a scalpel blade, the epididymi were gently incubated under a 95% O_2—5% CO_2 for 15 min at 34 °C to allow release and diffusion of spermatozoa into the medium. The gametes were obtained from such media by centrifugation at $200\times g$, re-suspended in PBS, and subjected to the fractionation procedures. The divalent metal-ion chelator EDTA was incorporated at a concentration of 2.5 mM in

all media used for sperm isolation, from the initial PBS to the sucrose-containing solutions [13]. The study protocol was approved by the Committee on the Care and Use of Research Animals at the University of the South.

To separate the sperm heads from the tails, the gametes were gently suspended in PBS containing 1 mM phenylmethyl-sulfonyl fluoride (PMSF) and the samples were sonicated at 30-s intervals using a Model 250 Branson Sonifier. It was necessary to pool samples of spermatozoa isolated from several rats to obtain sufficient material for lipid analysis. After sonication, the mixture of separated heads and tails was pelleted at 600×*g* at 4 °C, re-suspended in 65% sucrose, loaded onto a step gradient made up of 65, 70 and 75% (w/v) sucrose in PBS-PMSF, and separated in an ultracentrifuge at 4 °C as previously described [13, 15]. The purity of the fractions was verified by light microscopy (Fig. 1).

Lipid Separation and Analysis

Sperm heads and tails were collected from the gradients, gently washed with PBS and pelleted by centrifugation. Lipid extracts were prepared and partitioned using chloroform–methanol mixtures [16]. After evaporating the organic solvents under N_2, the samples were dissolved in chloroform–methanol (2:1 v/v) and aliquots were taken for total lipid phosphorus and phospholipid composition analyses.

For preparative isolation of lipid classes for further analysis, most of the lipid extracts were spotted on TLC plates (500 µm, silica gel G) under N_2, along with commercial standards (Sigma Chemical Co, MO, USA). The polar lipids remained at the origin of the plates, and the neutral lipids were resolved in two steps. Chloroform/methanol/aqueous ammonia (90:10:2 by vol) was run up to the middle of the plates to resolve the ceramides and then hexane/ether (80:20, by vol) up to the top of the plates to separate free cholesterol from other (minor) neutral lipids. After TLC, the zones containing the lipids of interest were located under UV light after spraying with 2′,7′-dichlorofluorescein in methanol and scraped into tubes for elution. This was done by 3 successive extractions of the silica support with chloroform/methanol/water (5:5:1 by vol.), centrifuging, collecting the solvents, and partitioning with four volumes of water to recover the lipids.

The total polar lipid fraction was subjected to further separations and analyses. Choline and ethanolamine glycerophospholipids (ChoGpl, EtnGpl) were resolved into classes by two-dimensional TLC [17]. They were separated into their major subclasses by taking advantage of the lability to acid of the 1-alk-1′-enyl bond present at *sn*-1 in the corresponding plasmalogens and the stability to alkali of the 1-*O*-alkyl bond present in the corresponding glyceryl-ether derivatives [5]. Briefly, the eluted, dried ChoGpl or EtnGpl were gently agitated for 1 min with a small amount of acid acetonitrile (0.5 N HCl). This produced a

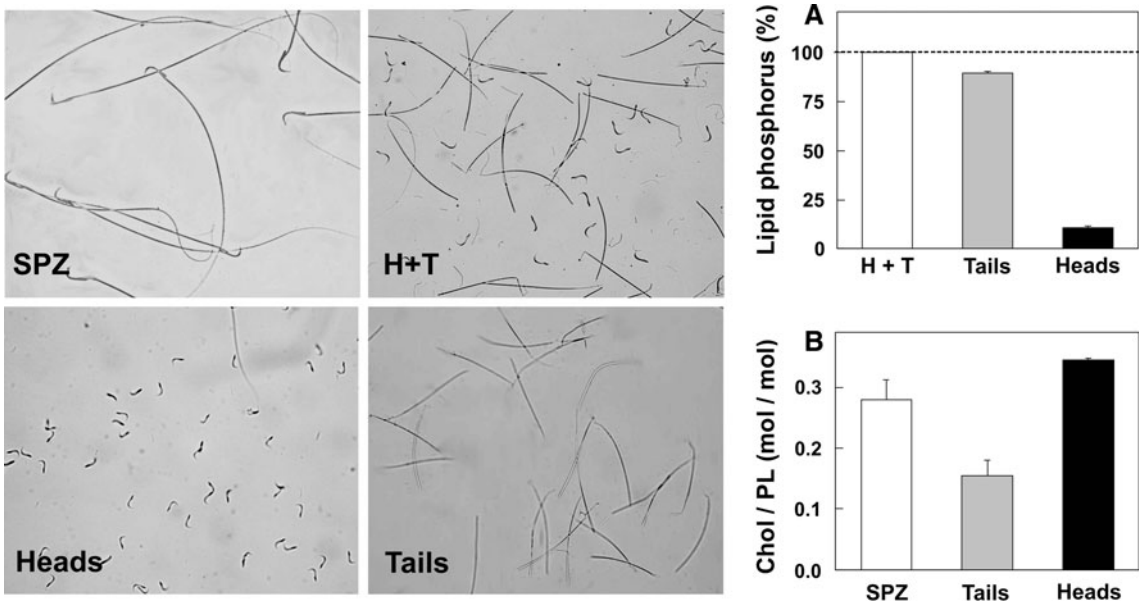

Fig. 1 *Panels on the left*: Phase photomicrographs of intact spermatozoa (SPZ), heads plus tails (H + T), as observed after sperm sonication cycle and before isolation of the two parts, and separate head and tail fractions, obtained after gradient centrifugation. **a** Total lipid phosphorus distribution between head and tail fractions, expressed as percentage of the lipid phosphorus present in the initial H + T fraction. **b** Cholesterol/phospholipid (Chol/PL) ratio in whole sperm and its two main fractions

fatty aldehyde and the corresponding lyso-Gpl, easily separable by TLC (chloroform/methanol/water, 65:25:4, by vol.) from the unchanged lipid (mainly 1,2-diacyl-Gpl plus a small proportion of 1-alkyl-2-acyl-Gpl). After elution, both lipids were subjected to further analysis (phosphorus, fatty acids). An aliquot of the larger band thus obtained was exposed to mild alkali (0.1 N NaOH in methanol) to remove all ester-bound fatty acids, this allowing recovery of the corresponding alkali-stable lysophospholipid, whose phosphorus is representative of the corresponding 1-*O*-alkyl, 2-acyl ChoGpl or EtnGpl subclass.

Sphingomyelin was recovered after TLC using chloroform/methanol/acetic acid/0.15 mM NaCl (50:25:8:2.5 by vol). After elution and drying of this CerPCho (and also of Cer), a similar mild alkali treatment was performed in order to ensure removal from the samples of any potential lipid contaminant containing ester-bound fatty acids [13] and the two lipids were recovered again by TLC.

The fatty acids of all lipid classes were quantified by gas-chromatography (GC). After adding appropriate internal standards, the fatty acids were converted to methyl esters (FAME) by transesterification with 0.5 N H_2SO_4 in anhydrous methanol under N_2 [18], kept overnight at 45 °C in Teflon®-lined, screw-capped tubes. Before GC, FAME were routinely purified by TLC on prewashed (methanol:ethyl ether, 75:25, by vol) silica Gel G plates, using hexane:ether (95:5, by vol for normal FAME and a combination of 80:20 followed by 95:5 by vol of the same solvents) for the cleanup of CerPCho- and Cer-derived FAME and 2-OH-FAME [2]. After elution and drying, the former were analyzed directly by GC and the latter after conversion into O-TMS derivatives.

The nonhydroxy VLCPUFA and the 2-hydroxy VLCPUFA of CerPCho were thoroughly identified by Poulos and colleagues in 1987 and 1992, respectively, using widely accepted lipid methodological procedures including mass spectrometry [19, 20]. More recently, the 2-hydroxy VLCPUFA were also unambiguously characterized in a novel series of glycosphingolipids from mouse testis by Sandhoff and colleagues [21]. Mass spectra of rat germ cell Cer- and CerPCho-derived methyl esters of 28:4n-6 and 30:5n-6 [22] as well as of (intact and hydrogenated) TMS derivatives of 2-OH 28:4 and 2-OH 30:5 [4] appeared in previous articles from our laboratory.

A Varian 3700 Gas Chromatograph equipped with two (2 m × 2 m) glass columns packed with 10% SP 2330 on Chromosorb WAW 100/120 (Supelco, Inc.) was used for fatty acid analysis. The column oven temperature was programmed from 150 to 230 °C at a rate of 5 °C/min for nonhydroxy fatty acids and from 190 to 230 °C in the case of 2-OH fatty acids, the upper temperature being kept for at least 30 min to allow for elution of the longest VLCPUFA (32 carbon in the case of rat testicular lipids). Injector and detector temperatures were set at 220 and 230 °C, respectively, and N_2 (30 ml/min) was the carrier gas. The fatty acids were detected with two flame ionization detectors, operated in the dual-differential mode, connected to a Varian Star Chromatography Workstation (version 4.51).

Statistical analyses- All data are expressed as mean values ± SD, from a number of at least 4 different experiments. Statistical differences between 2 groups were evaluated by unpaired Student's t tests. Statistical analyses were performed using GraphPad Prism 5.0 (GraphPad Software, San Diego, California). All differences tested were statistically significant when assessed at $P < 0.05$.

Results

Spermatozoal Head and Tail Lipids

In comparison with other mammalian species including the mouse, rat spermatozoa are characterized by a long, voluminous tail and a really minute, hook-shaped head (Fig. 1). Of the total lipid phosphorus that was present in the starting homogenate (i.e., the mixture that contained the heads and tails before their separation), the tails contributed on average an 87.5% and the heads a mere 12.5% of the total lipid phosphorus of spermatozoa (Fig. 1a) (tail/head ratio = 7). By the same token, the tails contributed on average a 72% and the heads a 28.5% of the total cholesterol recovered (approximate tail/head ratio = 2.5). In the head, the total cholesterol/total phospholipid ratio (mol/mol) was significantly higher (0.35) than in the tail (0.15), with an intermediate value (0.28) for the whole sperm (Fig. 1b). These data indicate that the concentration of cholesterol with respect to that of phospholipids was more than twice as large in the head as in the tail.

The figures that follow were set to show the quantitative distribution of lipids and their fatty acids between heads and tails. Tables with compositional (%) data may be found in the supplementary material. In the head, choline glycerophospholipids (ChoGpl) constituted the major phospholipid class, followed in a far second place by EtnGpl (60 and 15% of the head phospholipids, respectively) (see supplementary Table 1). In the tail, the proportions of these two lipids were closer but still the ChoGpl predominated (43 and 32%, respectively). The quantitative distribution of phospholipid classes (Fig. 2) showed that all major Gpl appeared in both parts, most predominating in the tail, as expected from the observed head–tail size disparity. The observation that cardiolipin (Ptd_2Gro) was negligible in the head but was the third most abundant phospholipid in the tail fraction (Fig. 2) agrees with the

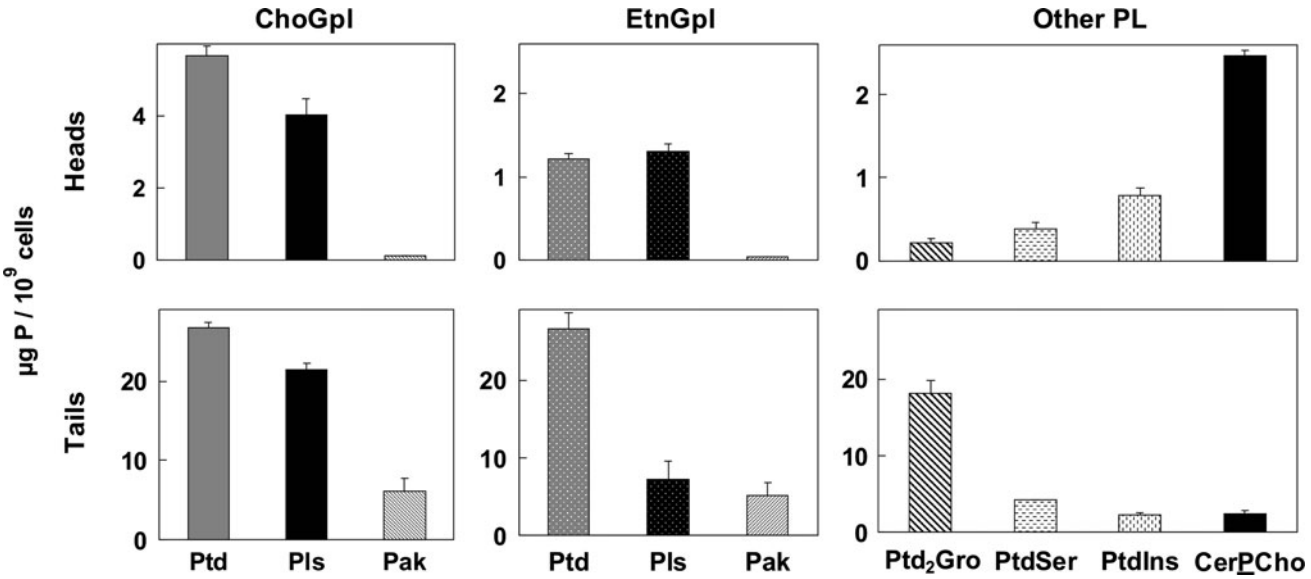

Fig. 2 Distribution of major phospholipids between rat sperm heads and tails. Lipids were quantified on the basis of phosphorus (P) content and expressed on the basis of a given number of cells, taking into account the initial gamete count per sample and the proportion (%) of the total P contributed by each fraction. Note the scale differences. Abbreviations: *ChoGpl* choline glycerophospholipids, *EtnGpl* ethanolamine glycerophospholipids, *Ptd*, *Pls*, and *Pak* the three subclasses (1,2-diacyl-, 1-alk-1′enyl, 2-acyl- and 1-*O*-alkyl, 2-acyl-subclasses, respectively) of ChoGlp or EtnGpl, *Ptd$_2$Gro* diphosphatidylglycerol, *PtdIns* phosphatidylinositol, *PtdSer* phosphatidylserine, *CerPCho* sphingomyelin

fact that the tail contains the middle piece, rich in mitochondria, the inner membrane of which is known to contain cardiolipin.

The different composition of the lipid material present in the two sperm regions was also reflected in the proportions of the three subclasses of ChoGpl and EtnGpl (Fig. 2). Thus, the percentage ratio between phosphatidylcholine (PtdCho), plasmenylcholine (PlsCho), and plasmanylcholine (PakCho) was on average 51:41:8 for whole sperm and quite close (50:39:11) for the tail fraction. The corresponding phosphatidylethanolamine (PtdEtn), plasmenylethanolamine (PlsEtn):plasmenylethanolamine (PakEtn): plasmanylethanolamine (PakEtn) ratios were 64: 27: 9 in whole sperm and 68:19:13 in tails. The proportion of the Pak subclass was somewhat larger in the tail than in whole sperm for both lipid classes because it was virtually undetectable in the head (Fig. 2). The proportion PtdCho:PlsCho and PtdEt:PlsEt in the head were 58:42 and 48:51, respectively. Thus, the head was much richer in plasmalogens than the tail.

In agreement with previous results [13], CerPCho abounded in the head (15% of the phospholipid) but scarcely reached a 2% of total lipid phosphorus in the tail fraction. The amount of CerPCho was therefore similar in tails and heads (Fig. 2), because it comprised a large proportion of the total phospholipid of the (small) head and a small proportion of total phospholipid of the (large) tail.

Distribution of Major Glycerophospholipids

Polyunsaturated fatty acids of the n-6 series with 18–22 carbon atoms collectively constituted the main fatty acids of sperm Gpl (more than half, see Table 2, supplemental material). Although both, heads and tails, were characterized by containing high proportion of 22 carbon PUFA, 22:4n-9 was the main PUFA in the total Gpl of the head fraction, followed by 22:5n-6, while the opposite occurred in the Gpl of the tail, where 22:5n-6 predominated over 22:4n-9. The percentage of species with saturated fatty acids was slightly higher in the total Gpl of heads than of tails, mainly due to 16:0 and 18:0, probably accompanying the mentioned polyenes in Gpl molecules. These characteristics were mostly determined by the fatty acids of the main subclasses of ChoGpl and EtnGpl (Fig. 3).

Although the same fatty acids appeared in PtdCho and PlsCho, their distribution markedly differed between the equivalent lipid of sperm head or tail (Fig. 3). Thus, sperm head PlsCho was markedly richer in 22:4n-9, and showed a much higher 22:4n-9/22:5n-6 ratio, than the PlsCho of the tail. Sperm head PdtCho also contained relatively more 22:4n-9 (and 18:0), and less 22:5n-6 (and 16:0) than the same lipid located in the tail. In quantitative terms, 20% of the total 22:4n-9, in comparison with 10% of the total 22:5n-6 of ChoGpl was in the head (Fig. 3).

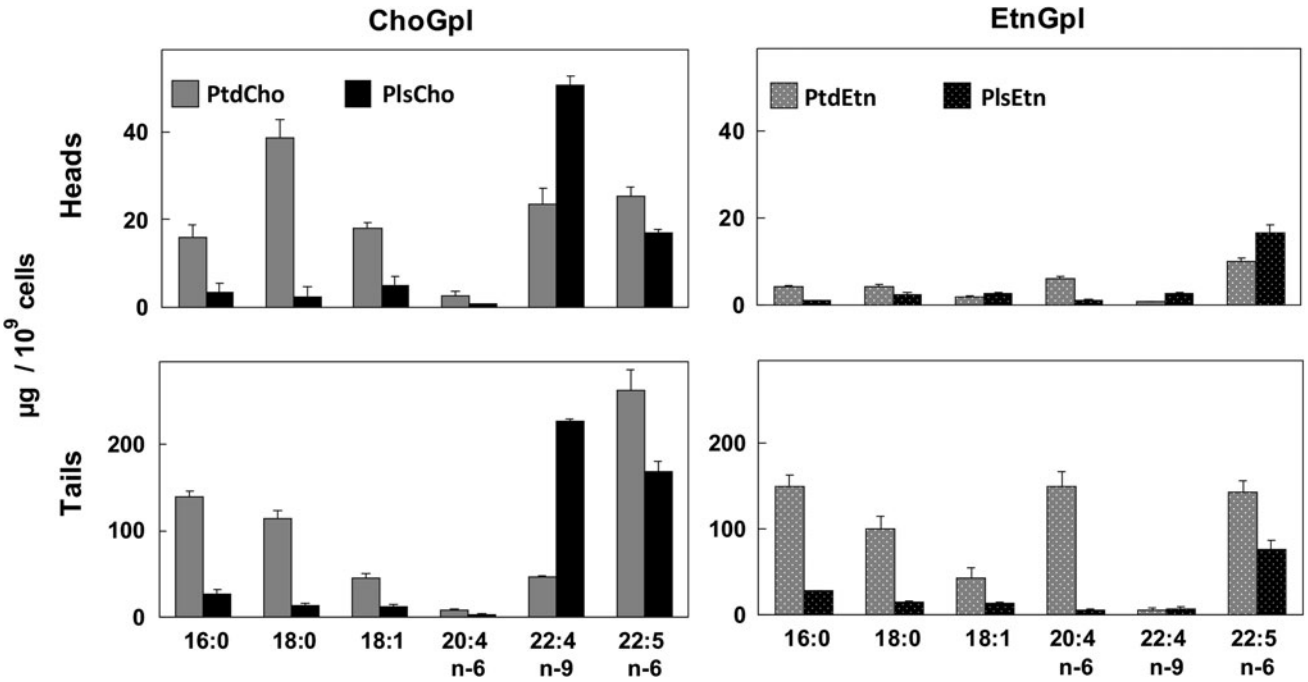

Fig. 3 Amounts of representative fatty acids of the two main subclasses of rat sperm head and tail ChoGpl and EtnGpl. The abbreviations Ptd and Pls indicate phosphatidyl- and plasmenyl-subclasses within each of these lipid classes. Other abbreviations are the same as in Figs. 1 and 2. Note the predominance of 22:5n-6 in tail PtdCho in contrast to that of 22:4n-9 among the PUFA of head PlsCho

The fatty acids of EtnGpl subclasses showed fewer contrasting differences than those of ChoGpl between sperm heads and tails, as long as PlsEtn had 22:5n-6 as its major fatty acid in both fractions. In the tail PtdEtn, 22:5n-6 and 20:4n-6 occurred in similarly large proportions, while 22:4n-9 was a minor fatty acid in relative or absolute terms (Fig. 3).

Distribution of Sphingomyelins and Ceramides

As estimated from its fatty acids, the content per cell of CerPCho was very similar in the head and in the tail (Fig. 4), confirming the distribution of this lipid estimated on the basis of the amount of lipid phosphorus (Fig. 2). However, the fatty acids revealed that the sphingomyelins of the tail contained predominantly saturated fatty acids, while those of the head contained almost exclusively VLCPUFA (Fig. 4). Most of the former were 16:0 and 18:0 (see supplementary Table 3). As for the latter, in addition to the n-VLCPUFA previously reported [13], the 2-OH VLCPUFA were even more abundant (26 and 37% of the total fatty acids, respectively). Both types of VLCPUFA were virtually absent from the CerPCho of the tail and, conversely, little saturates were measurable in the same lipid from the head (Fig. 4).

As previously shown for the ceramides of rat spermatozoa [13], when these gametes were isolated in the presence of EDTA, the total content per cell of Cer was very low in the heads of spermatozoa, as long as the species with n-VLCPUFA are concerned (Fig. 4). However, this did not apply to the Cer present in the tails, which was almost 8 times as high as in the heads, even when both fractions were isolated from the same source and in similar media. Most of this difference was found to be due to the species of Cer that contained 2-OH VLCPUFA as their almost exclusive components (Fig. 4).

As a group, 2-OH VLCPUFA represented more than 80% (see supplementary Table 4) of the fatty acids of the sperm tail-associated Cer in the rat. Considering their large size (Fig. 1), the finding of virtually all of the Cer with 2-OH VLCPUFA located to the tails clarifies why this unique lipid is constitutively so abundant in intact rat spermatozoa (Fig. 4).

The amounts of individual VLCPUFA of Cer and CerPCho involved in this uneven distribution, equivalent on a molar basis to the abundance of the corresponding molecular species, are shown in Fig. 5. The main and virtually only n-VLCPUFA of head CerPCho was 28:4n-6. The main 2-OH VLCPUFA of head CerPCho, and also of

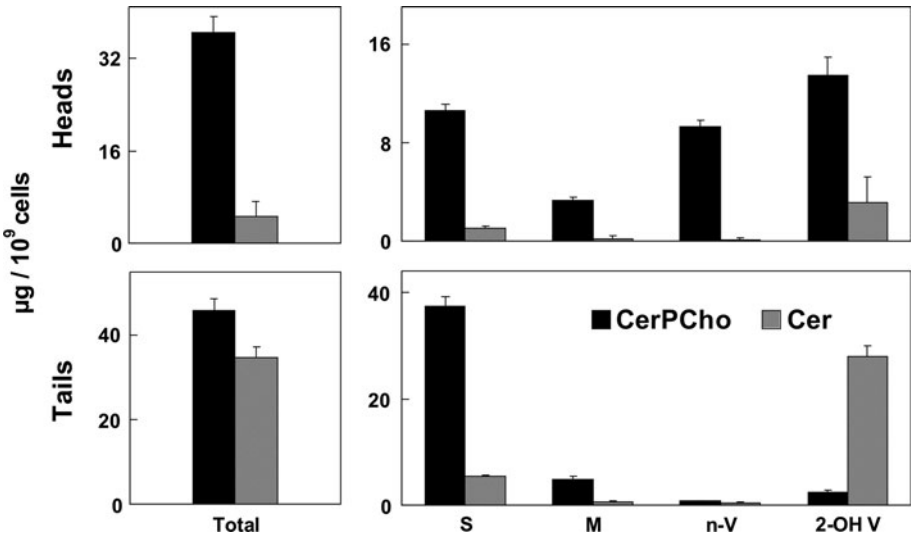

Fig. 4 Amount of sphingomyelins and ceramides, represented by their fatty acids, in rat sperm head and tail fractions. The fatty acids from the two lipids from each fraction were quantified by gas chromatography and are here expressed on the basis of a given number of cells. *Left panels* amounts of total fatty acids; *right panels* amounts of main fatty acids, grouped into saturated (S), monoenoic (M), nonhydroxy VLCPUFA (n-V) and 2-hydroxy VLCPUFA (2-OH V). Note the high total CerPCho/total Cer ratio in the head in comparison to the tail. Note also the predominance of VLCPUFA (n-V plus 2-OH V) in the CerPCho of the head, in contrast to the virtual absence of these fatty acids in the same lipid of tails. The latter contain Cer with almost exclusively 2-OH VLCPUFA

tail Cer, were 2-OH 30:5n-6, 2-OH 28:4n-6, and 2-OH 32:5n-6, in that order (Fig. 5).

Discussion

Because the rat sperm head size is several times smaller than the tail, the fact that the absolute amount of most lipids was larger in the tail than in the head responds to this characteristic. Most lipids of rat spermatozoa showed quantitative and qualitative variations in their proportions and in their fatty acid composition between both regions. A main finding of the present study was that the head contributed virtually all of the VLCPUFA-containing sphingomyelins, while the tail contributed virtually all of the VLCPUFA-containing ceramides, which can be isolated from rat spermatozoa. This observation could be done thanks to the inclusion in the study of the 2-OH VLCPUFA as components of these lipids, and to the strategy of inhibiting the "spontaneous" hydrolysis of membrane lipids, including CerPCho into Cer, by the addition of a divalent cation chelator.

Cholesterol has widespread effects on the behavior of lipid molecules in cell membranes, its best known property being its ability to interact with CerPCho. The relative higher abundance of cholesterol with respect to phospholipids observed here in rat head spermatozoa coincides with the fact that the VLCPUFA-containing species of CerPCho were almost exclusively located to the head, and may in part be a manifestation of this lipid–lipid interaction. However, cholesterol is distributed all over the plasma membrane of spermatozoa, even in the Cer-rich tail, where it interacts also with other lipid classes.

One of the best known functions of sperm sterols, mostly cholesterol, in spermatozoa is to participate in the complex process known as sperm capacitation. Its release to incubation media that contain a suitable cholesterol acceptor (e.g., albumin) during this process is one of the widely accepted prerequisites for sperm capacitation to proceed [23–25]. Zanetti et al. [14] recently showed that during incubation of rat spermatozoa in conditions that lead to their capacitation, the release of cholesterol concurs with a massive hydrolysis of sperm Gpl, with release of plenty of free fatty acids to an albumin-containing medium.

A relatively higher sterol/phospholipid ratio in the head than in the tail has also been observed in gametes from other mammalian species such as the ram and the boar [26], although the opposite seems to be the case in monkey sperm [27]. In addition to obviously wide species-related differences, the diversity of procedures, manipulations and media used in the isolation of the gametes may explain many lipid discrepancies.

The fact that cardiolipin was negligible in the head but abounded in the tail is interpreted to reflect the fact that these lipids normally compose the inner membranes of mitochondria, organelles that remain in the mid-piece that separates together with the tails during the present tail-head separation. It is certainly possible that the CerPCho that contains virtually only saturated and monoenoic fatty acids in the tail (Fig. 4) could also belong to this intracellular

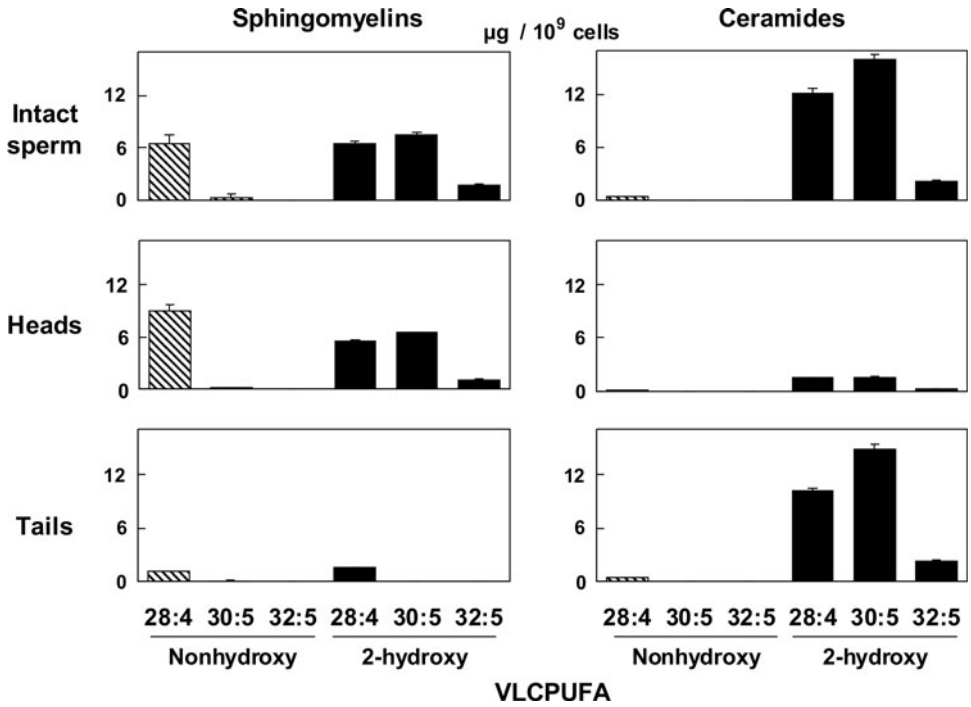

Fig. 5 Amounts of main individual nonhydroxy (*hatched bars*) and 2-hydroxy (*black bars*) VLCPUFA that constitute the CerPCho and Cer of rat spermatozoa and in their head and tail fractions. These (n-6) fatty acids are the main components of the fatty acids that are grouped as n-V and 2-OH V in Fig. 4

structure of the rat tail. The sphingomyelin from a mitochondrial fraction isolated from rat testis showed to be the rich in these two types of fatty acids and poor in VLCPUFA [22]. By the same token, the nuclear and the acrosomal membranes may be expected to contribute their own lipids to the total lipid of the sperm head fraction, in addition to those of the overlying plasma membrane. These intracellular membranes are not easy to isolate and analyze separately in the case of rat sperm head, given its size and fragility of the acrosome. In the case of bovine spermatozoa, sphingomyelin was 10, 13 and 17% of the phospholipids, respectively, in intact spermatozoa, total plasma membrane (i.e., that overlying tails and heads), and the outer acrosomal membrane [28], whereas cardiolipin, originally present in spermatozoa, was absent from both of these membranes.

The high proportion of 22:5n-6 and 22:4n-9 in ChoGpl and the predominance of just 22:5n-6 in EtnGpl, particularly in plasmalogens, is a characteristic of rat spermatozoa. In bovine, ovine, or human spermatozoa, the diacyl- and the abundant alkenyl- subclasses of both lipids, i.e., the four subclasses, are all alike in that they contain 22:6n-3 as their single and predominant PUFA [9, 10, 29, 30]. In this study, the dissimilar fatty acid profiles of ChoGpl and EtnGpl subclasses in rat spermatozoa allowed the observation that they behaved as independent lipids as far as head–tail distribution is concerned (Fig. 3). Notably, the sperm head contained more 22:4n-9-rich PlsCho than did the tail in compositional terms, and the tail contributed more of this Gpl subclass to the total lipid of the gametes in quantitative terms.

In rat sperm, lipid remodeling during epididymal maturation from caput to cauda results in a decrease in sperm head size and total lipid phosphorus, with a concomitant increase in the proportion of plasmenylcholines that contain 22:4n-9 [12]. This specific subclass is absent from the testis, where the PlsCho and PlsEtn of spermatogenic cells increase their proportion of 22:5n-6 with differentiation, but contain no 22:4n-9 [5]. Thus, an important part of the plasmalogens of rat spermatozoa is acquired by these gametes during their passage through the epididymis. The present data allows the inference to be made that this "phospholipid maturation" affects the heads as well as the tails of spermatozoa.

The androgen-dependent epithelial cells of the epididymis contain plenty of peroxisomes and express the enzymes that are required for plasmalogen biosynthesis [31]. Moreover, the synthesis of 22 carbon PUFA that have their first double bond at position 4 (namely, 22:5n-6, 22:6n-3, and also 22:4n-9), requires anabolic enzymes (desaturases, elongases) that are located in the endoplasmic reticulum as well as beta-oxidation enzymes that are located in peroxisomes [32]. In the rat, stearoyl-CoA desaturase 1 (SCD1), stearoyl-CoA desaturase 2 (SCD2), delta5-desaturase, and delta6-desaturase are all actively expressed in the testis and the epididymis [33].

Recently, group III phospholipase A_2 (sPLA$_2$-III), a member of the secreted phospholipase A_2 (sPLA$_2$) family, was shown to be expressed in the mouse proximal epididymal epithelium [34]. Targeted disruption of the gene encoding this protein leads to defects in sperm maturation and fertility. Taken together with the mentioned

biosynthetic activities, this finding suggests that the epididymis may play a role in sperm lipid remodeling by hydrolyzing part of the sperm original Gpl and by delivering PlsCho newly synthesized in situ to the sperm plasma membrane.

After incubation in conditions that lead to sperm capacitation, a significant hydrolysis of ChoGpl occurs that is accompanied by the release of plenty of 22:4n-9 and 22:5n-6 to the media [14], suggesting that plasmalogens participate in this important process. The biological significance that the regionalization of major plasmalogens may have in sperm physiology certainly demands further studies.

The presence of the unique species of Cer that contain 2-OH VLCPUFA in rat sperm tails is consistent with the fact that the proportion of these fatty acids with respect to the rest, and particularly the n-/2-OH VLCPUFA ratio, increase notably in the Cer of whole rat testis from the beginning of spermatogenesis to adulthood [2] and in adults during differentiation from pachytene spermatocytes to spermatids and from these to spermatozoa [5]. Germ cell maturation and differentiation involves the progressive increase in the number and concomitant reduction in size and change in shape from round to elongated forms. In the last phases of spermiation, the size and shape of the head is modified to a larger extent than the tail, which agrees with the fact that the fatty acid composition of Cer is so similar between round spermatids and whole mature spermatozoa [5], and between the latter and isolated sperm tails (present results).

The sharp regionalization observed for these unique species of Cer suggest that they are made in the testis to fulfill a specific function in fertilization that normally involves the sperm tail. One of these functions could be related to sperm motility, as suggested by the fact that mice that lack acid sphingomyelinase have a reduced fertility because their spermatozoa are immotile and have structural defects in their tails [35, 36]. Such a defect was ascribed to an abnormal excess of CerPCho and cholesterol accumulating in the mid-piece, in the tail, or both. The present results reinforce such concept by showing that a certain amount of Cer is required as a normal component of the tail.

The abundance in the sperm head of VLCPUFA-containing sphingomyelins may fulfill a role in sperm physiology that is associated with this region, as it is for instance the acrosomal reaction. It was recently shown [14] that incubation of rat spermatozoa in conditions that evoke this calcium-dependent reaction results in the massive hydrolysis of both (n- and 2-OH VLCPUFA-containing) species of CerPCho, and the concomitant increase in the production of the corresponding species of Cer. The present results, locating these sphingomyelins to the head, are consistent with the acrosomal reaction being a function that exclusively occurs in this sperm area.

The previous finding that the membrane-rich particles known as "residual bodies" of spermiogenesis contain virtually only sphingomyelins with 2-OH-VLCPUFA [5] is consistent with the present results. These structures are formed in the last stages of sperm differentiation in the area of the heads of the condensing spermatids, and are shed from this area as the newly formed spermatozoa are released to seminiferous tubule lumina. The previous observations that epididymal rat spermatozoa [2, 5] constitutively have much more VLCPUFA-containing Cer than CerPCho are also explained by the present findings, since the former are mostly lipids of the large tail, while the latter mostly collect in the small head.

atherosclerosis and diabetes develop over time, and risk factors may be detectable early in life [2–6]. Prevention may therefore be possible by targeting factors leading to CVD early in life.

A lipid profile, with high plasma levels of LDL-cholesterol, triacylglycerols (TAG) and apolipoprotein B100 (Apo-B) and a low concentration of HDL-cholesterol and apolipoprotein A1 (Apo-A), increase the risk of atherosclerosis and CVD [7, 8]. Also, plasma LDL particles are comprised of different sub-fractions, differing in chemical composition, size and density, and studies have suggested that particularly the fraction of small dense LDL particles (sdLDL) is associated with CVD [9, 10]. sdLDL is strongly correlated with plasma TAG, and generally the strong correlation between the different lipid fractions makes it difficult to identify the contribution of the separate fractions to the risk of CVD [7, 8, 11].

Fish consumption and supplementation with n-3 polyunsaturated fatty acids (PUFA) in adulthood have been associated with slightly increased levels of HDL cholesterol, lower TAG concentration, and both a lower relative abundance and particle number of sdLDL [12, 13]. Also, fish oil supplementation during infancy has been found to be associated with a decrease in plasma TAG concentration and an increase in the concentration of plasma LDL and total cholesterol [14, 15]. It is, however, not known whether these effects of n-3 PUFA found early in life can track and program the future lipid profile of the child [16].

Breast feeding has also been shown to increase cholesterol concentration in infancy [17]. These short-term effects of breast feeding are, translated into a long-term decrease in total cholesterol in adulthood [17]. This effect is thought to be caused by the relatively high cholesterol concentration of breast milk, leading to a decrease in the endogenous production of cholesterol. However, breast milk also contains high concentrations of n-3 PUFA, which could potentially influence lipid metabolism. To our knowledge, only one study has looked into the long-term effect of fish oil supplementation during early life on the lipid profile in adulthood [18]. In this study, no association between increased dietary intake of n-3 PUFA during the first 5 years of life and lipid profile at the age of 8 years, was found.

We investigated the hypothesis that supplementation with long chain marine n-3 PUFA during fetal life has an impact on the plasma lipid profile in adolescence. This was done by studying offspring from a randomized controlled trial conducted in 1990, where pregnant women were randomized to fish oil, olive oil or no oil [19]. No association between fish oil supplementation during pregnancy and blood lipid profile in the offspring was found.

Methods

The aim of the original study was to investigate the effect of fish oil supplementation on gestational length. The recruitment and randomization of the original study population has previously been described in detail [19].

Briefly, 533 women in gestational week 30 who attended the Midwife Centre in Aarhus, Denmark, were randomized to four 1 g fish oil capsules (FO) (Pikasol: 32% eicosapentaenoic acid and 23% docosahexaenoic acid, corresponding to approximately 2.7 g marine n-3 PUFA) per day ($n = 266$), four similar capsules with olive oil (OO) ($n = 136$) or no capsules (NO) ($n = 131$) in 1990. The women receiving oil were blinded for study interventions, and the capsules and boxes looked identical. The 533 enrolled and randomized women represented 61% of eligible women.

The offspring from the abovementioned randomized controlled trial constituted the study population in the present study. At the time of the study, the offspring were aged between 18 and 19 years. A total of 517 (97%) mother and child pairs were alive and living in Denmark.

All the mothers were contacted by mail and they invited their children to complete a self-administered web-based questionnaire concerning anthropometric measures, health and lifestyle. The offspring were also asked whether they wanted to receive an invitation for a physical examination. Those accepting and those who did not respond were all invited to the physical examination. A total of 382 filled out the questionnaire and 243 participated in the clinical examination (Fig. 1).

At the physical examination, a fasting venous blood sample was drawn, centrifuged and frozen at −80 °C.

Serum TAG and cholesterol fractions (Total, LDL, HDL) were measured according to standard methods on a Modular P from Roche Diagnostics, Basel, Switzerland. Apo-B was measured using antibody from DAKO, Glostrup, Denmark, on an Advia 1650 from Bayer Diagnostics, NY, USA. Interserial variation was 5.5%. Apo-A was measured using antibody from DAKO, Glostrup, Denmark, on an Advia 1650 from Bayer Diagnostics, NY, USA. Interserial variation was 5%.

For the sdLDL analysis, blood, anticoagulated with K3-EDTA 1.6 mg/ml, was centrifuged and plasma stored until analysis. Plasma, adjusted to 1.067 g/L with 60% iodixanol from Optiprep, Axis-Schield PoC As, Oslo, Norway, was prestained with Coomassie blue, under-layered beneath 9% iodixanol and subjected to ultracentrifugation (2½ h, 65.000 rpm 16 °C (341.000 g) in a near vertical rotor (Beckmann NVT65). A digital photograph of LDL subclass profiles was analyzed using Total Lab 1D gel-scan software (Pharmacis, UK). LDL subclass phenotypes A, B and I (Intermediate) were characterized according to the

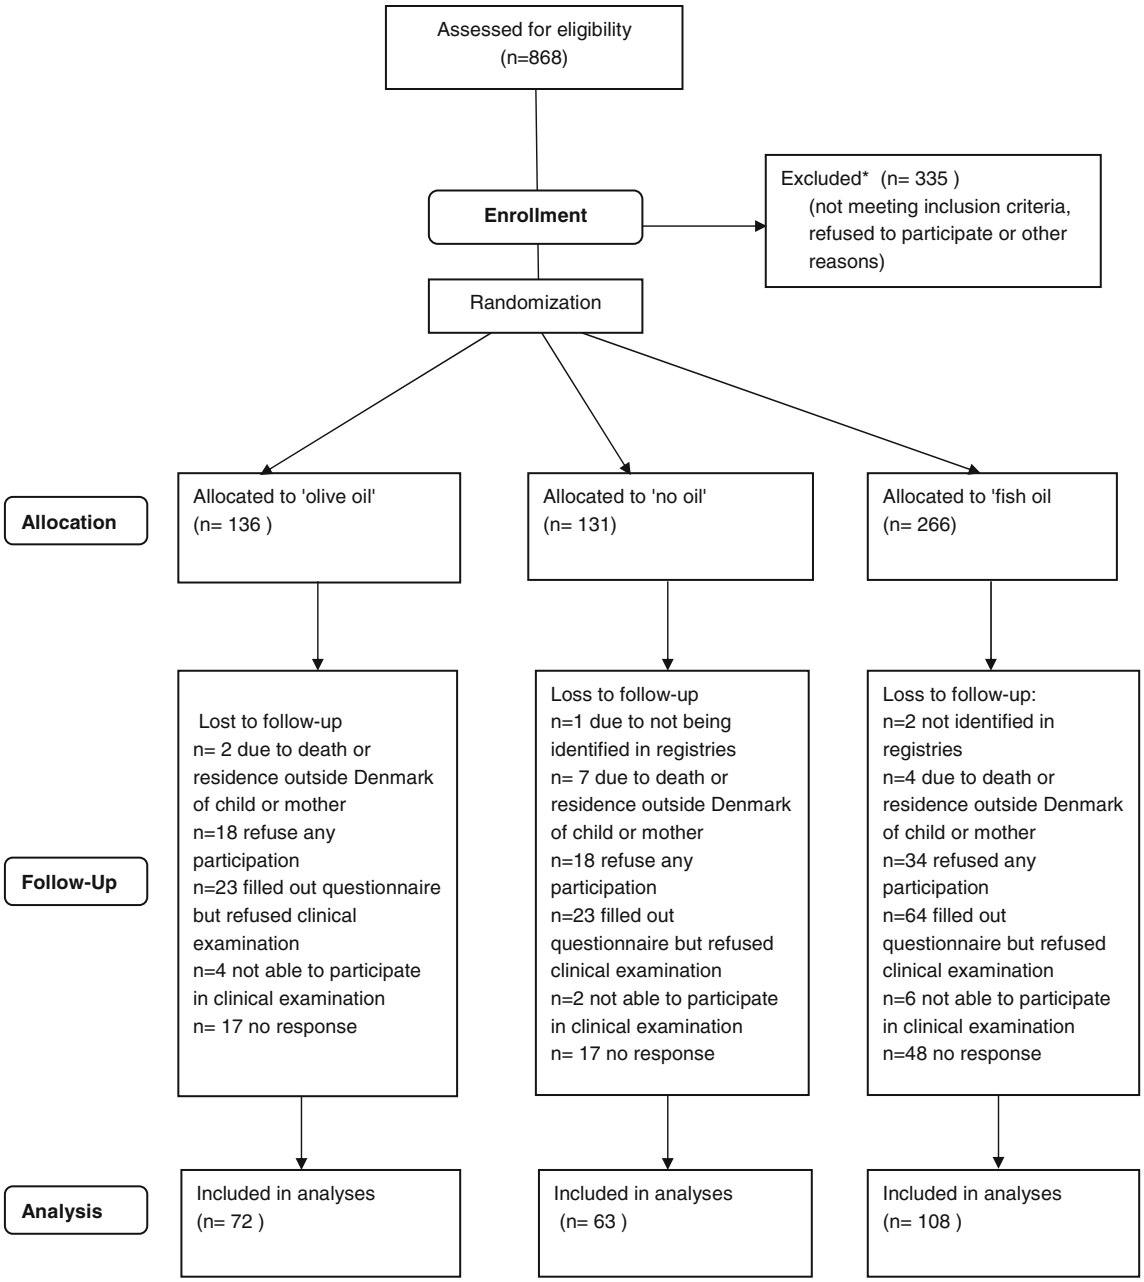

Fig. 1 Flow chart. Nineteen years follow-up of offspring from a randomized controlled trial with fish oil supplementation in pregnancy. Reprinted with permission from Lancet [19] has previously been published [28] and is reprinted with permission from *Am J Clin Nutr*

density and to the area under the curve of B (%AUC B) (sd-LDL) as follows: A: AUC B <40%, I: AUC B 40-50%, B: AUC B >50%. The method has been described in detail previously [20].

Covariates

Information on the mother was collected from the interview and questionnaire during pregnancy. The pregnant women filled out a simple food frequency questionnaire in order to assess their baseline fish consumption, and three categories were defined according to fish consumption. Characteristics of the children were collected from the questionnaire at 18–19 years of age. For this reason, we only had information regarding covariates for the non-participating children who filled out the questionnaire. Information on sex, gestational age and birth weight were collected from medical records.

This study was conducted according to the guidelines laid down in the declaration of Helsinki and all procedures involving human subjects were approved by the local ethics committee (case no.: M-ÅA 20060182) and the

Danish Data Protection Agency (journal no.: 2006-41-6257). Written informed consent was obtained from all subjects.

Statistics

The OO group was used as the reference in the study for the following reasons: (1) the original study showed that blinding worked well in the OO group, indicating that this group was unlikely to have increased their fish consumption during the trial period. (2) It seems reasonable to assume that OO in the supplemented amounts was inert. The results from the NO group are, however, also presented in the tables.

The distribution of biochemical variables was generally skewed, and therefore log transformation was applied to normalize the distribution. Geometric means and interquartile ranges are presented.

Chi-square tests and Student's *t*-tests were used to compare categorical and normally distributed continuous covariates, respectively, between participants and non-participants as well as between the FO and OO groups with two-sided *p*-values <0.05 considered statistically significant. For covariates that were not normally distributed or did not have the same variance in the two groups, Wilcoxon rank sum test was used to test for differences between groups.

Differential programming effects may be found in boys and girls, and therefore the analyses used to estimate the association between fish oil and later lipid profile were initially stratified by sex, using ANOVA. Since the associations were similar in males and females, multiple linear regression modeling adjusting for sex was used to estimate the association. Also, since supplementation with fish oil would be expected to have the largest effect among pregnant women with a low baseline fish intake, the multiple linear regression analyses were also done by only including participants of mothers with a low baseline fish intake ($n = 46$). All associations are reported as percentage difference, since they were all analyzed on the log-scale.

In addition to analyzing the effect on the relative abundance of sdLDL (% of total number of LDL particles) using multiple linear regression, also the effect on the prevalence of LDL subclass B (prevalence of sdLDL >50%) was estimated by logistic regression, adjusting for sex.

Results

Participants

Characteristics of those participating in the clinical examination and the non-participants are given in Table 1. The participants differed from the non-participants with regard to the mother's age during pregnancy, sex and birth weight. Also, the participation rates differed between randomization groups, being lower in the FO group (41%) compared with the OO group (53%). A number of women in the FO group experienced side effects such as gastric reflux during supplementation. When invited to the follow-up, a few mothers reported that they did not think it was relevant for their child to participate since they did not comply with the original study protocol, due to side effects. The women were contacted in writing and the importance of participating was explained, irrespective of compliance. However, among those participating in the clinical examination from the FO group, 1.9% of the mothers took less than 75% of the daily dosage as opposed to 8.6% among non-participants. In the OO group, 2.8% of those participating in the follow-up and 3.2% of non-participants took less than 75% of the daily dosage. There was no information on compliance for 14.6 and 20.9% of the women receiving FO and OO, respectively.

A description of the participants in the three randomization groups is given in Table 2. The three groups were similar with respect to most covariates. The only difference reaching statistical significance was the smoking status in the offspring, with smoking being more prevalent among participants from the OO group compared to the other two groups.

The participants in the study were generally healthy. The median (interquartile range) was 4.0 (3.6; 4.7) mmol/l for total cholesterol, 1.3 (1.1; 1.6) mmol/l for HDL cholesterol, 2.3 (1.8; 2.7) mmol/L for LDL cholesterol and 0.9 (0.6; 1.2) mmol/L for TAG. In light of the recommended lipid levels in healthy subjects from international guidelines a total of 14% had a total cholesterol concentration above 5 mmol/L, 9% an HDL cholesterol concentration less than 1 mmol/L, 18% a LDL cholesterol concentration above 3 mmol/L and only 3% had a TAG concentration above 2 mmol/L.

Fish oil supplementation during pregnancy was not associated with cholesterol concentrations (total cholesterol, LDL, and HDL), TAG concentration or Apo-A1 and Apo-B in the offspring (Table 3). Also, no association was found with relative abundance of sdLDL. However, when restricting the analyses to participants of mothers with a low baseline fish intake, there was a tendency towards a healthier lipid and lipoprotein profile in participants from the FO group compared with the OO group (Table 4). Particularly, TAG, Apo-B and LDL cholesterol tended to be lower in the FO group, but none of the differences were statistically significant.

The distribution of LDL subclass phenotypes A, B and I (Intermediate) in the three randomization groups, stratified by sex, is shown in Fig. 2. There was a tendency towards a

OO olive oil, *NO* no oil, *FO* fish oil

[a] Information collected from a self-administered questionnaire to the pregnant women in week 16 of gestation

[b] Presented as number of participants; % in parentheses

[c] Chi-square test

[d] Presented as mean ± SD

[e] Student's *t* test

[f] Presented as median, inter-quartile range in parentheses

[g] Wilcoxon rank sum test

[h] Information collected from a self-administered web-based questionnaire to the offspring at the age of 18–19. Sex and birth weight collected from medical records

[i] Defined as regular exercise of at least 20 min duration, resulting in breathlessness

lower prevalence of phenotype B and larger prevalence of phenotype I in the FO and NO groups compared to the OO group. However, the difference did not reach statistical significance. Sex was significantly associated with LDL phenotype, with phenotype B being more prevalent among males.

Discussion

We found no association between fish oil supplementation during pregnancy and lipid and lipoprotein profile in the 19-year-old offspring. The LDL phenotype in the FO group tended to be healthier in comparison to the

phenotype of the OO group, but the difference was not statistically significant. Finally, there were indications of a healthier lipid profile among offspring of mothers with a low baseline fish intake in the FO group, but with only 46 participants in this group, the confidence intervals were wide and no statistically significant association could be demonstrated.

Loss to follow-up was present overall but significantly higher in the FO group compared to the OO group. This could potentially have led to bias, assuming that a lower participation rate was associated with an unhealthy lipid profile. Participation per se would not be expected to be directly associated with the lipid profile, since most of the participants probably were unaware of their lipid levels, but an unhealthy lipid profile is often associated with a high BMI, and participation could be negatively associated with BMI. However, according to the questionnaire data (Table 1), participation was not associated with BMI. Hence, it is unlikely that the results were biased for BMI.

The larger loss to follow-up in the FO group may partly be caused by differences in compliance. Compliance was higher among participants in the FO group compared to the non-participants. By primarily including participants with high compliance in the analyses, this would strengthen a possible association between FO supplementation and later lipid profile. Hence, this cannot explain the finding of no association in the present study. However, those complying with the study protocol might be different from those not complying, and hence this could introduce some residual confounding.

Participation was associated with exposure and may also be associated with e.g. lifestyle factors which could

Phenotypes A, B and I were characterized as follows: A: sdLDL <40% of LDL, I: sdLDL 40-50% of LDL particles, B: sdLDL >50% of LDL particles. There was no statistically significant difference in the prevalence of phenotype B between groups

influence lipid profile. Hence, such factors might confound the association between FO supplementation and the lipid profile. In the main analysis we only adjusted for sex. Additional adjustment for offspring smoking and parental overweight did not change estimates.

To our knowledge, no other study has investigated the effect of supplementing with n-3 PUFA during pregnancy on later lipid profile. However, fish oil supplementation during pregnancy has been shown not to affect the lipid profile of the umbilical cord blood speaking against fetal life as the right time window for fish oil supplementation [21]. In another study where term infants were randomized to an intervention aimed at increasing dietary intake of n-3 PUFA and decreasing intake of n-6 PUFA from the time of weaning until the age of 5 years, no association between intervention and lipid profile was found when the children were followed-up at the age of 8 years [18]. The children were, however, very young at follow-up and effects may not be visible until considerably later in life.

Several studies indicate that the lipid profile in adulthood can be influenced, "programmed", by early nutrition. Hence, Barker et al. showed that a low abdominal circumference at birth was associated with higher concentrations of total cholesterol, LDL cholesterol and Apo-B in adulthood [22]. The authors argued that this could be a consequence of impaired liver growth during late gestation due to malnutrition. Accordingly, a study from the Dutch Hunger Winter showed that persons, who were exposed to hunger during early gestation, displayed significantly higher LDL to HDL ratios, and a tendency towards lower plasma concentrations of HDL and Apo-A1 and higher concentrations of LDL and Apo-B compared to persons born before or after the Dutch Hunger Winter [23]. These results, however, contradict results from the Leningrad Siege, where no association between hunger during fetal life or infancy and any of the lipid parameters in adulthood was found [24].

A large body of research on programming of future lipid profile has focused on the effects of breast feeding. The short-term effect of breast feeding in infants is an increase in total cholesterol [17]. However, this effect may be reversed in adulthood, where breastfeeding has been found to be associated with a lower total cholesterol concentration [17]. Hence, a high total cholesterol concentration early in life may be protective later in life.

Also, a study where pre-term infants were randomized to banked breast milk or formulae showed that those receiving banked breast milk had a lower LDL to HDL ratio in adolescence [25]. The mechanism behind the effects of breast-feeding or breast milk on later lipid profile is unknown but may be associated with a lower total energy intake [26] or the higher cholesterol concentration of breast milk compared to infant formulae. The higher cholesterol concentration during early life could potentially suppress endogenous cholesterol production and hence lead to a lower cholesterol concentration later in life [27]. However, breast milk is also high in n-3 PUFA. The short-term effect of supplementing infants with fish oil on serum cholesterol is similar to that of breast feeding [14, 17]. If the effect of breast feeding on later lipid profile is operating through increased cholesterol levels in infancy by inducing decreased endogenous cholesterol production, this could also be the case for fish oil supplementation. Most of the women in the present study had a medium to high baseline fish consumption during pregnancy, and it is possible that this attenuated the effect of fish oil supplementation. Thus, among the offspring of mothers with a low baseline fish intake, there were indications of a beneficial association between fish oil supplementation and later lipid profile. However, as mentioned previously this sub-group analysis contain very few numbers, making it difficult to draw any conclusions. Hence, further studies are needed to confirm this potentially important observation.

Finally, it should be had in mind that very few individuals in early adulthood have an unhealthy lipid profile. Potential benefits of early supplementation with n-3 PUFA on later lipid profile might therefore not be detectable until considerably later in life, and it will be important to follow-up the offspring at later ages.

Conclusion

We found no association between fish oil supplementation during third trimester of pregnancy and offspring plasma lipid and lipoprotein profile in adolescence.

development of infants [1]. For this reason, both DHA and ARA are commonly supplemented in infant formulae. For example, fish oil, which is rich in DHA and eicosapentaenoic acid (EPA, 20:5n-3), is conventionally used as a source of n-3 LC-PUFA in infant formulae in Japan, while DHA-rich microalgal oil (DMO), which is free of EPA, is used to supplement formulae in more than 60 countries worldwide, including the United Kingdom, Mexico, China, United States, and Canada.

A randomized clinical trial has suggested that EPA may be unsuitable for infants because it might reduce ARA levels and delay development [2]. However, maternal milk contains some levels of n-3 LC-PUFA other than DHA, such as 20:3n-3, EPA, and docosapentaenoic acid n-3 (DPAn-3) [3]. Although this suggests that excessive levels of EPA are harmless, the effects of ingestion of trace amounts n-3 LC-PUFA are unknown. Therefore, it is necessary to compare the effects of ingested fish oil and DMO on the fatty acid composition in tissues.

Since available tissue is limited in human studies, animal studies using rodents are useful for elucidating overall LC-PUFA status in target tissues. For example, Moriguchi et al. [4] showed that recovery from the DHA deficiency in the brain and retina caused by n-3 PUFA deficient feeding over two generations takes 8 weeks after initiation of the repletion diet. Animal studies usually employ severe n-3 PUFA deficient conditions, such as long-term n-3 PUFA-deficient diet [4, 5] or artificial rearing conditions with n-3 PUFA-deficient milk [6]. In this study, our interest is the effect of n-3 LC-PUFA on a mildly n-3 PUFA deficient nutritional status because severe n-3 PUFA deficiency is rare in humans, except in such a case as total parenteral nutrition with an inappropriate oil source [7].

In a previous report, we determined the fatty acid composition of serum and liver phospholipids and triglycerides in rat pups from mildly n-3 PUFA-deficient dams who were fed fish oil (FO) or DMO, and found that DMO nearly restored liver EPA levels to those of pups fed a control diet, whereas FO had little effect [8]. However, due to the rapid metabolic turnover in the serum and liver, it is necessary to investigate phospholipid levels in other tissues in order to deduce the overall impact of fish oil and DMO on the LC-PUFA status of human infants.

Here, the fatty acid composition of phospholipids was investigated in five rat tissues, namely the brain, heart,

kidney, spleen and thymus. We elucidated the effect of pre-weaning supplementation of FO or DMO on tissue fatty acid composition compared to the oil supplement-free condition. FO or DMO was fed to mildly n-3-PUFA-deficient rats pre-weaning and the fatty acid composition of the tissues was determined and compared to the control, namely, pups reared by n-3 PUFA-sufficient dams. The results of this study suggest an important way to improve n-3 PUFA deficiency through supplementation of fish oil and DMO before weaning. This finding is an important consideration in determining how best to accomplish n-3 LC-PUFA supplementation through infant formulae.

Materials and Methods

Animals, Diets, and Supplementation

All animal procedures were performed according to the Regulations for Animal Experiments and Related Activities at Tohoku University (June 27, 2007, Regulation No. 122). Pregnant Sprague-Dawley rats (day 4 of gestation) were purchased from Japan SLC, Inc. (Hamamatsu, Japan).

Two diets were prepared: the AIN-93G diet [9] as a control diet and the n-3 PUFA-deficient diet. The AIN-93G diet composition was the following: 397.5 g/kg cornstarch, 200 g/kg casein, 132 g/kg α-cornstarch, 100 g/kg sucrose, 70 g/kg soybean oil, 50 g/kg cellulose, 35 g/kg mineral mix (AIN-93G), 10 g/kg vitamin mix (AIN-93), 3 g/kg L-cystine and 2.5 g/kg choline bitartrate. The n-3 PUFA-deficient diet was based on the AIN93G diet composition and its oil source from soybean oil was replaced by an n-3-deficient oil which consisted of a mixture of peanut and safflower oils (Table 1). Alpha linolenic acid (ALA, 18:3n-3), was the sole n-3 PUFA source in both diets and was present at a concentration of 0.2% in n-3-deficient oil and 7.9% in soy bean oil for AIN-93G diet. The n-6/n-3 ratio of the n-3 PUFA-deficient oil was 278 and approximately 40-fold higher than that of the soybean oil.

Fatty acid supplements were used as sources of n-3 LC-PUFA (Table 2): FO (Nippon Suisan Kaisha, Ltd., Tokyo, Japan) and DMO (Martek Co., Columbia, MD, USA). The DHA content of FO and DMO was 29.3 and 50.0%, respectively, while EPA was 7.3 and 0.1%, respectively. The oils were emulsified in 1% sodium carboxymethyl cellulose (CELLOGEN F; Dai-ichi Kogyo Seiyaku Co., Kyoto, Japan) solution by sonication to a final concentration of 20% (w/w). The emulsions were freshly prepared daily.

Experimental Procedure

The experimental schedule is shown in Fig. 1. On the day of delivery, the pregnant rats were divided into two diet groups (Table 1): the control diet group ($n = 2$) and the n-3 PUFA-deficient diet group ($n = 6$). Dams were fed the experimental diets through the gestation and lactation

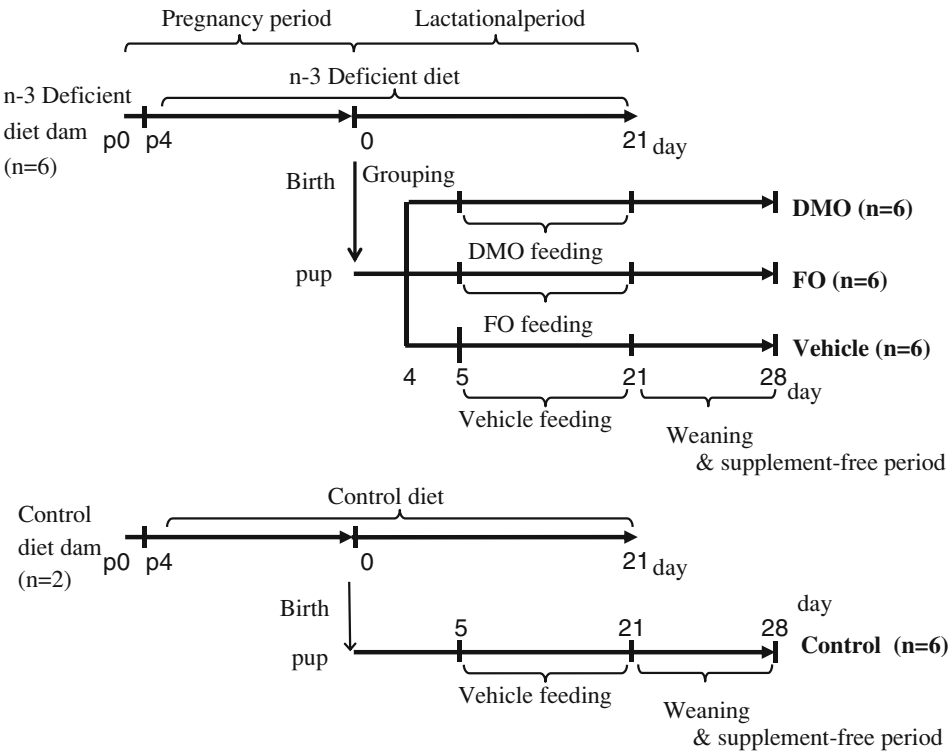

Fig. 1 Schedule of the animal experiment. P0 and P4 indicate days of pregnancy. *DMO* DHA-rich microalgal oil, *FO* fish oil. Vehicle was 1% sodium carboxymethyl cellulose solution

periods. At 4 days of age, pups were weighed and culled to ten individuals from each dam for supplementation experiments. Male pups born to dams fed the n-3 PUFA-deficient diet group were assigned to each of the supplementation treatment groups, and were orally administered fatty acid supplements at 5 μl/g of body weight to pups from 5 to 21 days of age (weaning date): n-3 PUFA-deficient + FO ($n = 6$), n-3 PUFA-deficient + DMO ($n = 6$), and n-3 PUFA-deficient + vehicle ($n = 6$). Male pups ($n = 6$) of dams fed the control diet were also administered the vehicle. The oil or vehicle administration continued for 17 days and ended on the weaning day. After weaning, pups were fed the same diet as their dams for a 1-week without oil or vehicle administration.

After 1-week supplement-free period (28 days of age) pups were sacrificed by decapitation after 12-h food deprivation. Brain, heart, kidney, spleen, and thymus tissues were removed and weighed, and were then immediately frozen and stored at −20 °C until analyzed. For stomach content analysis, pups from another pregnant Sprague-Dawley rat ($n = 10$) fed the control diet ($n = 5$) or n-3 deficient diet ($n = 5$) were bred under the same conditions and sacrificed at 5 days of age.

Fatty Acid Analysis

Total lipids were extracted from stomach contents and tissues using the Bligh-Dyer method [10]. The fatty acid methyl esters (FAME) of lipids from the stomach samples were prepared by treatment with diazomethane followed by sodium methoxide ($NaOCH_3$) [11]. Phospholipids from other tissues were purified by thin layer chromatography (TLC) [12] before preparing FAME using $NaOCH_3$. FAME were analyzed by gas-liquid chromatography (GLC) (GC-380; GL Sciences Inc., Tokyo, Japan) using a CP-Sil 88 WCOT fused silica column (100 m × 0.25 mm i.d., 0.2-m film thickness; Varian, Middelburg, Netherlands) and identified by comparison against commercial external standards. Fatty acid composition was expressed as composition of fatty acid methyl esters.

Statistical Analysis

All data are expressed as the means ± standard deviation (SD). Differences in the stomach content FAME levels of pups from n-3 PUFA-deficient and control groups were detected by the unpaired t test. Dunnett's T3 multiple comparison test was used to determine whether the values of n-3 PUFA deficient + FO, n-3 PUFA deficient + DMO, n-3 PUFA deficient + vehicle, and control groups differed from each other. IBM SPSS Statistic ver. 19 (IBM Corp. Armonk, NY, USA) was used for all statistical calculations.

Results

Stomach Content

Table 3 shows the fatty acid composition of the stomach contents collected from 5-day-old rat pups. The fatty acid composition of the stomach content reflects that of the dam's milk. Pups reared by dams on the n-3 PUFA-deficient diet had significantly decreased levels of ALA, EPA, docosapentaenoic acid (DPAn-3, 22:5n-3) and DHA levels and significantly increased levels of docosapentaenoic acid (DPAn-6, 22:5n-6) compared to 5-day-old pups reared by

Fatty acid composition expressed as composition of fatty acid methyl esters

DMO DHA-rich microalgal oil, *FO* fish oil

Different lower case letters indicate statistically significant differences, as determined by Dunnett's T3 multiple comparison test (*$P < 0.05$)

dams on the control diet. The level of ARA was not significantly different between the groups.

Brain

DHA content of brain phospholipids in 28-day-old pups was 14.56% in the control diet group, but that in the n-3 PUFA-deficient + vehicle group (9.72%) was significantly lower (0.67-fold lower) than in any other group. For pups in the n-3 PUFA-deficient group, supplementation with DMO gave a significantly greater increase in DHA than FO, and neither was significantly different than the control. DPAn-3 and EPA did not differ significantly among the four groups. ARA was approximately 11% in the control and in the n-3 PUFA-deficient groups with vehicle and FO supplementation, but ARA was slightly decreased (0.9-fold lower than control) in the n-3 PUFA-deficient + DMO group ($P < 0.05$). DPAn-6 showed a 3.8-fold increase from 1.66% in the control group to 6.53% in the n-3 PUFA-deficient + vehicle group ($P < 0.05$). DPAn-6 with FO supplementation was significantly decreased compared to the vehicle, but still 1.6-fold higher than that of the control ($P < 0.05$) (Table 4). DMO supplementation significantly decreased the DPAn-6 content to the control level.

Heart

The DHA content of heart phospholipids was 0.32-fold lower in the n-3 PUFA-deficient diet group (2.80%) than in the control diet group (8.55%)—a significant difference. In the n-3 PUFA-deficient diet groups, FO supplementation restored heart DHA to the control level, while DMO supplementation produced levels that were 1.6-fold greater than the control, a significant difference. DPAn-3 was 3.50% in the control and significantly lower in the other groups (Table 5). EPA was not significantly different among the four groups. ARA in the n-3 PUFA-deficient + DMO group was the lowest in the n-3 PUFA-deficient diet group (24.38%; $P < 0.05$). DPAn-6 was 2.25% in the control group and 7.91% in n-3 PUFA-deficient + vehicle group, a 3.5-fold increase ($P < 0.05$). The DPAn-6 content in the n-3 PUFA-deficient + FO group was significantly lower than in the n-3 PUFA-deficient + vehicle group, but still twice that in the control ($P < 0.05$).

nd not detected (less than 0.01%)

DMO DHA-rich microalgal oil, *FO* fish oil

Different lower case letters indicate statistically significant differences, as determined by Dunnett's T3 multiple comparison test (*$P < 0.05$)

DMO supplementation significantly decreased the DPAn-6 content to the control.

Kidney, Spleen, and Thymus

DHA content in the control diet for the kidney (Table 6), spleen (Table 7), thymus (Table 8) phospholipids (2.97, 2.21, 0.81%, respectively) was lower than those for the brain and heart. DHA content in the n-3 PUFA-deficient + vehicle group was 1.09, 0.61, 0.28%, respectively, which is 0.3–0.4-fold lower than in the control group ($P < 0.05$). FO supplementation restored the kidney and thymus DHA levels to the control levels, but the spleen DHA level recovered no further than 0.7-fold that of the positive control ($P < 0.05$). DHA of kidney, spleen, thymus was 1.6, 1.6, 1.9-fold higher respectively for the n-3 PUFA-deficient + DMO group than in the control ($P < 0.05$). Although FO or DMO supplementation significantly restored kidney and spleen DPAn-3 levels compared to the vehicle, was lower than that of the control group ($P < 0.05$). EPA was very low in the n-3 PUFA-deficient + vehicle group in kidney and spleen and was not detected in the thymus. FO or DMO supplementation restored the EPA level in these tissues, and, in particular, the kidney EPA level in the n-3 PUFA deficient + DMO group was not significantly different from the control. Kidney ARA was slightly higher in the n-3 PUFA-deficient diet with vehicle and with FO supplementation than in DMO supplementation group ($P < 0.05$). ARA of spleen and thymus did not significantly differ among the groups. DPAn-6 in the kidney, spleen and thymus was 0.20, 0.44 and 1.43%, respectively, in the control and 2.41, 2.15 and 2.66% in the n-3 PUFA-deficient + vehicle group, representing a 12-, 4.9-, and 1.9-fold increase, respectively ($P < 0.05$). The DPAn-6 content of these tissues in the n-3 PUFA-deficient + FO group was significantly lower than in the n-3 PUFA-deficient + vehicle, but still 4.4-, 3.1- and 1.3-fold that of the positive control. DMO supplementation

significantly decreased the DPAn-6 content compared to the control level.

Discussion

We examined the effect of two common n-3 LC-PUFA supplement sources during the infant period in a rat model. DMO is designed to have the highest breast milk DHA content, i.e. 1.4% of total fatty acids, as reported in a meta-analysis of "DHA and ARA concentrations in breast milk from mothers of term infants" conducted by Brenna et al. [13], as a safe and effective supplemental level. It is difficult to estimate the actual daily fatty acid intake of fat in rat pups that are reared on mother's milk. Based on studies on pups reared on milk replacer [14, 15], 5-day-old pups need 290 mg milk substitute/g body weight with a 12.3% fat content in order to maintain similar body weight to counterparts reared on mother's milk [15]. Based on the calculation that pups at this age ingested 35.7 mg fat/g body weight, the supplementation used in the experiment in this study was set at 1 mg fat/g body weight, corresponding to a 2.8% daily fat intake. The percentage of DHA as a percentage of the total fatty acid intake was calculated to be 1.4% DHA. The supplementation of FO was followed by DMO supplementation and the calculated percentage was 0.82% DHA, 0.04% DPAn-3 and 0.20% EPA of the total fatty acid intake. A supplement-free period at 7 days was set because fatty acids from the oil supplementation are thought to be pooled in the liver and plasma first, it would take more than 4 days to distribute to other tissues [16].

FO supplementation to rat pups of dams fed on a n-3 PUFA-deficient diet nearly restored DHA levels in tissue phospholipids to those of the control group pups; however, tissue phospholipid EPA and DPAn-3 levels did not recover. In addition, the DPAn-6 level, which serves as a reliable index of n-3 PUFA deficiency, did not decrease to the control group level. Taken together, these results indicate that the dosage of FO supplementation to pups in this study was insufficient to completely restore the LC-PUFA status. The low recovery of tissue phospholipid

EPA and DPAn-3 compared to DHA also suggests that these fatty acids might be preferentially metabolized to DHA in rats.

In the case of DMO supplementation, the brain phospholipid DHA level also recovered to that of the control pups, although the other four tissue phospholipid DHA levels exceeded those of the control group. This finding suggests that the dose of DMO used in this experiment slightly exceeded suitable levels and that brain phospholipid DHA content might be regulated by homeostasis. Tissue phospholipid DPAn-6 was lower compared to the vehicle-feeding group level. Taken together, these results indicate that DMO is more effective than FO for restoring n-3 LC-PUFA status, because DMO contains approximately a 1.3-fold greater total n-3 PUFA than fish oil (Table 2).

Our study showed that both FO and DMO supplementation during the nursing period restored the brain DHA level in pups reared by dams fed a n-3 PUFA-deficient diet, although the brain DHA generally has very slow metabolic turnover. For example, Moriguchi et al. [4] studied the DHA supplementation effect on the tissue fatty acid composition of n-3 PUFA-deficient weaned rats and reported that a full recovery of the DHA level in the brain was not obtained until 8 weeks after initiation of the repletion diet. The following difference in our study might explain this apparently conflicting finding. The one reason n-3 PUFA-deficiency in this study is mild is that the decrease in brain DHA is only one-third of the control level. In addition, infant-stage mammals have an immature brain-blood barrier [17]. Therefore, our experimental design might make it conducive to recovering from the n-3 PUFA deficient condition.

It has been proposed that dietary EPA from fish oil hinders infant development by competing with ARA [2]. However, in the present experiment, FO supplementation did not reduce phospholipid ARA content in nearly any of the examined tissues, a result which may be explained by three possible factors. First, the dosage of FO was appropriate and not excessive to allow recovery of DHA levels in

brain phospholipid; second, rat pups could ingest maternal milk that included appropriate levels of ARA; and third, the FO used in this experiment was tuna oil, which has four times more DHA than EPA. Our results are also supported by human studies that have indicated FO with an appropriate level and ratio of DHA and EPA does not affect plasma and erythrocyte ARA status in infants [18, 19].

Contrary to our expectations, DMO supplementation decreased the ARA level in brain phospholipids—0.9% compared to the control level. Although it is unclear whether this slight reduction in brain phospholipid ARA is biologically significant, acute changes in such an important fatty acid would cause metabolic changes in order to maintain fatty acid homeostasis. For example, Kim et al. [20] reported that dietary n-6 PUFA deprivation down-regulates arachidonate metabolizing enzymes in the rat brain such as cytosolic phospholipase A2 and cyclooxygenase-2 decreases ARA consumption. In their experimental conditions, brain ARA content was reduced by 28% [21].

In this study, two sources of n-3 LC-PUFA (FO and DMO) were supplemented to mildly n-3-deficient rat pups to elucidate effects of supplementation on tissue LC-PUFA content. Both FO and DMO improved the DHA level of tissues, particularly the brain. DMO was more effective at increasing tissue DHA status because it is richer in n-3 PUFA than FO. FO had slightly lower PUFA levels than required to completely restore LC-PUFA status to normal levels in this experiment, and EPA did not accumulate in tissues under the conditions tested here. These results demonstrate the effectiveness of ingesting either FO or DMO in the pre-weaning period for improving mild n-3 PUFA deficiency.

Introduction

Fish oil utilization by the aquafeed industry is increasingly recognized by the scientific sector and industry stakeholders as an environmentally unsustainable and economically unviable practice. Thus, a significant global research effort is currently focusing on finding possible remedial strategies; and the use of alternative oils (vegetable oils and animal fats) to replace fish oil in aquafeed formulations is envisaged to be the most practical and easily implemented option [1].

It has been well documented that when fish oil is substituted with alternative oils of terrestrial origin, the resultant fatty acid composition of fish fillet is significantly affected [2, 3]. Specifically, the major detrimental effect of replacing fish oil is the reduction of the overall nutritional qualities of cultured products due to the reduction of health promoting omega-3 long chain polyunsaturated fatty acids (n-3 LC-PUFA; and particularly eicosapentaenoic acid—EPA, 20:5n-3, docosapentaenoic acid—DPAn-3, 22:5n-3 and docosahexaenoic acid—DHA, 22:6n-3) in fish fillet [4]. Therefore, the fatty acid metabolism, and potential fatty acid bioconversion capabilities, of cultured fish is a topic of increasing scientific interest, and major strides have now been achieved in its understanding [5, 6].

On a yearly basis, global salmonid aquaculture is responsible for the exploitation of over 56% fish oil supplies [7]. The high demand for fish oil by the salmonid industry is driven mainly by the market demand/expectation for n-3 LC-PUFA rich products [4, 7], rather than a physiological need of these species. In fact, salmonids such as the Atlantic salmon (*Salmo salar*) and the rainbow trout (*Oncorhynchus mykiss*), are likely better equipped, from a fatty acid metabolism point of view, to cope successfully with fish oil replacement in their diets in comparison to other fish species [8–12]. Rainbow trout in particular, have been shown to be capable of bioconverting large quantities of dietary α-linolenic acid (ALA, 18:3n-3), which can be found in several different vegetable oils, into n-3 LC-PUFA [13]. However, the final n-3 LC-PUFA content of the fillets of trout fed fish oil deprived diets (560 mg per 100 g of fillet) was still significantly lower than that of fish fed with a fish oil-based diet (1,860 mg per 100 g of fillet). Thus, it is important to gain a better understanding of n-3 LC-PUFA biosynthesis in fish, towards more efficiently formulated feeds for maximizing the n-3 LC-PUFA content of fish fillet, when fish oil is not included in dietary formulations.

The enzymes involved in the bioconversion of both n-3 and n-6 C_{18} PUFA to LC-PUFA are the Δ-6 desaturase (EC 1.14.19.3), the Δ-5 desaturase (EC 1.14.19.-) and two elongases (EC 6.2.1.3; Elovl-5 and Elovl-2) [6]. Therefore, it is evident that the proportion of substrate availability (n-3 and n-6 C_{18} PUFA) will ultimately have an effect on the final production of n-3 or n-6 LC-PUFA. As such, it is commonly accepted that the dietary α-linolenic acid (ALA, 18:3n-3)/linoleic acid (LNA, 18:2n-6) ratio plays a major role on fatty acid metabolism. Surprisingly, whilst fish oil deprived diets either rich in 18:3n-3 (i.e. linseed/flaxseed oil, camelina oil, etc.) or 18:2n-6 (i.e soybean oil, sunflower oil, etc.) have been studied in fish in detail [14–16], studies focusing on a sliding 18:3n-3/18:2n-6 ratio are relatively scarce and limited to a few species, including: Coho salmon (*Oncorhynchus kisutch*) [17]; Milkfish (*Chanos chanos*) [18]; silver perch (*Bidyanus bidyanus*) [19]; Eurasian perch (*Perca fluviatilis*) [20]; yellow catfish (*Pelteobagrus fulvidraco*) [21]; and Murray cod (*Maccullochella peelii peelii*) [22, 23]. An early study on rainbow trout also assessed the effect of various 18:3n-3/18:2n-6 ratios in juvenile fish from 0.4 to 4 g of body weight [24]. In this study it was shown that both 18:3n-3 and 18:2n-6 are essential fatty acids for rainbow trout and that trout grew better when receiving a diet richer in 18:3n-3 than 18:2n-6. The authors also suggested that the bioconversion of 18:2n-6 into n-6 LC-PUFA was partially inhibited by dietary 18:3n-3, whilst the bioconversion of 18:3n-3 was also inhibited by dietary 18:2n-6, but to a lesser degree. Importantly, whilst these results are very interesting, it should be noted that in this study, one-month old fish were used, and that prior to the experimentation fish were fed a fat free diet containing fatty acids in a purified free ethyl ester form.

The objective of the present study was to evaluate the effects of different 18:3n-3/18:2n-6 ratios in practical (commercial-like) fish oil deprived diets in rainbow trout over the whole production cycle, with particular attention on the effects on the fatty acid metabolism and the final fatty acid composition of fish fillet.

Materials and Methods

Animals and Husbandry

Juvenile rainbow trout (*Oncorhynchus mykiss*) were obtained from Fisheries Victoria—Department of Primary Industries (Snobs Creek, Victoria, Australia) and transported to Deakin University's Aquaculture Research Facility at the Warrnambool campus. Prior to the commencement of the feeding trial, fish were acclimated to the new environmental conditions in a recirculating aquaculture system (RAS) and maintained on a commercial diet (Skretting, Cambridge, Tasmania, Australia) at 2% of their body weight daily for 5 weeks. The RAS system consisted of 18 (1,000 L) rearing tanks, equipped with inline biological and physical filtration (drum filter with a 60-μm screen; Hydrotech, Vellinge, Sweden), ultra violet (UV) disinfection, oxygen enrichment and temperature and light control. The system was maintained on a 12:12 h light:dark cycle. Fish were held under optimal conditions, the pH (mean 8.26 ± 0.04), dissolved oxygen (mean 9.14 ± 0.30 mg/L) and water temperature (mean 15.0 ± 0.80 °C) were monitored daily. The levels of metabolic waste products, ammonia and nitrite were monitored weekly and recorded values below 0.20 and 0.25 mg L^{-1}, respectively.

Experimental Diets and Study Design

Six iso-proteic and iso-lipidic experimental diets were formulated and manufactured, as previously reported in detail [25], to contain 46% of protein and 18% of lipid and varying only in the dietary lipid source. Fish oil was used as a reference/control diet (CD). Sunflower oil (rich in LA, 18:2n-6) and linseed oil (rich in ALA, 18:3n-3) were blended in variable proportions to obtain five diets with varying ratios of 18:3n-3/18:2n-6, maintaining a constant level of total C_{18} PUFA (58% of total fatty acids). The diets were named ALA72%, ALA54%, ALA36%, ALA18% and ALA2% (indicating the % contribution of 18:3n-3 to total C_{18} PUFA content of the diet). The 18:3n-3/18:2n-6 ratios of five experimental diets were 2.63, 1.19, 0.56, 0.23, and 0.02, respectively.

At the commencement of the experiment, 360 fish with an initial body weight of 29.8 ± 0.21 g were individually weighed and randomly distributed into 18 tanks (20 fish per tank) and randomly assigned to each of the six experimental treatments in triplicate groups.

Fish in each treatment were fed with one of the six experimental diets by hand to apparent satiation twice daily at 0900 h and 1600 h for a 126 day grow out period. Feed consumption was recorded weekly and mortalities were recorded throughout the experimental period.

At the commencement of the experiment, an initial sample of 15 fish was taken and euthanized in excess anaesthetic (AQUI-S, Lower Hutt, New Zealand) for subsequent analysis. Feces were collected during the last week before the termination of the experiment, as previously described in detail [26]. At completion of experimental phase, all fish were individually weighed and eight fish from each tank (24 fish per treatment) were randomly taken, euthanized and stored at −20 °C for future analysis.

All procedures used in this study were approved by the Deakin University Animal Welfare Committee.

Chemical Analysis

Out of the eight fish collected from each replicate tank, four fish per tank were dissected for biometric data and the four left hand fillets were finely chopped, pooled and homogenized before subsequent analysis. The remaining four fish per tank were finely chopped, pooled and homogenized for subsequent chemical analysis. The chemical composition of experimental diets and biological samples was analyzed in triplicate on the pooled samples for each replicate (tank) and conducted according to standard methods. Briefly, moisture was determined by drying samples in an oven at 80 °C to constant weight. Protein content ($N \times 6.25$) was determined using an automated Kjeltech 2300 (Foss Tecator, Geneva, Switzerland). Ash content was determined by incinerating samples (approximately 0.5 g) in a muffle furnace (Wit, C & L Tetlow, Melbourne, Australia) at 550 °C for 18 h. Lipid was determined by chloroform:methanol (2:1) extraction as previously described [27]. Nitrogen free extract (NFE) was calculated by difference and dietary energy content was calculated on the basis of 23.6, 39.5 and 17.2 kJ g^{-1} of protein, fat and carbohydrate, respectively.

Following the lipid extraction, fatty acids were esterified into methyl esters using an acid catalyzed methylation method, and analyzed by gas chromatography according to the methods previously used in the laboratory [27]. Briefly, 0.5 ml of C23:0 (1.5 μg/ml) was added to each sample as an internal standard (Sigma-Aldrich, Inc., St. Louis, MO, USA). Fatty acid methyl esters were isolated and identified using a Shimadzu GC 17A (Shimadzu, Chiyoda-ku, Tokyo, Japan) equipped with an Omegawax 250 capillary column (30 m × 0.25 mm internal diameter, 0.25-μm film thickness; Supelco, Bellefonte, PA, USA), a flame ionisation

detector (FID), a Shimadzu AOC-20i auto injector, and a split injection system (split ratio 50:1). The temperature program was 150–180 °C at 3 °C min^{-1}, then from 180 to 250 °C at 2.5 °C min^{-1} and held at 250 °C for 10 min. The injector and detector temperatures were set at 270 and 280 °C, respectively. The carrier gas was helium at 1.0 ml min^{-1}, at a constant flow. Each of the fatty acids was identified relative to known external standards (37-Component FAME Mix, PUFA No. I-Marine Source, PUFA No. II-Animal Source and PUFA No. III–Menhaden Oil, all from Supleco, Bellefonte, PA, USA). The resulting peaks were then corrected by the theoretical relative FID response factors and quantified relative to the internal standard.

Digestibility and Fatty Acid Metabolism

Chromic oxide in the diets and feces was estimated according to the method of Furukawa and Tsukahara [28]. Estimates of apparent digestibility coefficients (ADC) for dry matter, lipid, total and individual fatty acid were calculated using standard formulas [26].

The in vivo assessment of fish fatty acid metabolism of rainbow trout in this study was performed using the whole-body fatty acid balance method, as described previously in detail [29, 30]. Briefly, this method involves a first step in which the net appearance/disappearance of each individual fatty acid is deduced by means of a mass balance determined by the difference between total fatty acid gain (=final fatty acid content−initial fatty acid content) and the net fatty acid intake (=total fatty acid intake−fatty acid excretion in feces). After the transformation of data from mg to μmol of appeared/disappeared fatty acid per gram of body weight per day, the subsequent second step involves a series of backwards computations along all the known fatty acid bioconversion pathways (n-3 PUFA, n-6 PUFA and SFA + MUFA) so that the fate of each individual fatty acid towards bioconversion, oxidation or deposition, can be determined. Eventually, data relative to apparent in vivo enzyme activity can be reported in absolute terms (μmol g $fish^{-1}$ day^{-1}) or as percentage of substrate availability.

Statistical Analysis

All data were reported as means ± standard error of mean ($n = 3$, $N = 18$). Comparisons amongst treatments were analyzed by one-way analysis of variance (ANOVA) at a significance level of 0.05 following confirmation of normality and homogeneity of variance different statistical tests. Where significant differences were detected by ANOVA, data were subjected to a Student–Newman–Keuls post hoc test for identifying homogeneous subsets. Data were analyzed further by linear regression, where appropriate. The statistical analyses were computed using SPSS v17.0 (SPSS Inc., Chicago, IL, USA).

Results

Diet Compositions

The lipid (∼185 mg/g) and protein (∼465 mg/g) content of the six diets were similar across all treatments, and diets can be considered as iso-proteic, iso-lipidic and iso-energetic (Table 1). The fatty acid composition of the experimental diets reflected the objectives of the formulations (Table 2). CD contained the highest amount of n-3 LC-PUFA, mainly 20:5n-3 (7.6%) and 22:6n-3 (8.9%). The five fish oil deprived experimental diets contained very similar levels of saturated fatty acids (SFA; ∼13.5%), monounsaturated fatty acids (MUFA; ∼23%) and polyunsaturated fatty acids (PUFA; ∼63%). Specifically, total C_{18} PUFA accounted for ∼58%, and the main difference amongst the five diets was the sliding proportion of 18:3n-3/18:2n-6 contributing to total C_{18} PUFA. The resulting 18:3n-3/18:2n-6 ratios were 2.63, 1.19, 0.56, 0.23, and 0.02 for ALA72%, ALA54%, ALA36%, ALA18% and ALA2%, respectively. Amongst these five diets, 20:5n-3 ranged from 2.4 to 2.7% and 22:6n-3 ranged from 2.0 to 2.3% of total fatty acids. These fatty acids were clearly derived from the residual lipid content of the fish meal included in the formulation (Table 2).

Growth Performance, Feed Utilization and Proximate Composition

All experimental diets were readily accepted by fish and no mortality was recorded during the entire feeding trial. No significant differences were found in feed intake, final mean weight or grow rate during the experimental period. Throughout the 126 day experimental period, fish increased their weight by over 1,700% in all treatments. Final mean weights of fish fed the six dietary treatments ranged from 562.2 ± 6.21 to 613.0 ± 7.47 g. FCR was 1.2 in fish fed CD diet and ranged from 1.0 to 1.1 for fish in the other treatments (Table 3). Specific growth rate (SGR) was similar in all experimental groups, varying between 2.3 and 2.4% day^{-1}. No significant differences in condition factor (*K*-value), fat deposition rate (FDR), dress-out percentage (DP), hepatosomatic index (HSI), visceral fat index (VFI) or fillet yield (FY) were found amongst fish fed the different experimental diets (Table 3).

The proximate composition of trout fillets and whole bodies at the commencement and termination of the experiment are reported in Table 4. Small, but statistically

[j] Calculated on the basis of 23.6, 39.5 and 17.2 kJ g^{-1} of protein, fat and carbohydrate, respectively

significant ($P < 0.05$) differences were recorded in ash content of whole bodies and in the moisture, protein and lipid content of fish fillets. The lipid content of fillets of fish fed ALA54% was significantly lower than fish fed ALA72% or CD.

Fillet Fatty Acid Composition

The fatty acid composition of trout fillets at the end of the feeding trial is reported in Table 5. Several statistically significant ($P < 0.05$) differences were recorded and in general the fillet fatty acid make-up was somewhat mirroring that of the corresponding diet. Fillets of fish fed CD contained the highest amount of n-3 LC-PUFA (187.7 ± 0.7 mg g lipid^{-1}), mainly 20:5n-3 (33.9 ± 0.3 mg g lipid^{-1}) and 22:6n-3 (123.1 ± 0.4 mg g lipid^{-1}). The fillets of fish fed the five fish oil deprived experimental diets (from ALA72% to ALA2%) recorded no statistically significant differences in their content of SFA and MUFA, whilst the total PUFA concentration of fish receiving ALA2% (493.2 ± 7.8 mg g lipid^{-1}) was significantly ($P < 0.05$) lower than fish fed ALA72% and ALA54% (536.2 ± 3.7 and 524.9 ± 11.1 mg g lipid^{-1}, respectively). The 18:3n-3 and 18:2n-6 content (and their ratio) in the fillets of fish fed the five fish oil deprived diets were directly proportional to that of their diets with 18:3n-3 varying from 269.2 ± 2.9 to 5.9 ± 0.6 mg g lipid^{-1} and 18:2n-6 varying from 125.2 ± 0.5 to 381.1 ± 8.2 mg g lipid^{-1} in fillets of fish fed ALA72% to ALA2%, respectively.

Despite the five fish oil deprived diets containing almost identical contents of n-3 LC-PUFA, the actual n-3 LC-PUFA of fillets of fish was significantly different with the highest value (110.9 ± 1.7 mg g lipid^{-1}) recorded in ALA72% and the lowest value (50.5 ± 1.2 mg g lipid^{-1}) recorded in ALA2%. The same trend was recorded for individual n-3 LC-PUFA, such as 20:5n-3, 22:5n-3 and 22:6n-3.

[a] See Table 1 for diet abbreviations

[b] See Table 2 for fatty acid class abbreviations

different diets were similar and highly consistent with that of the fillets.

The 20:5n-3, 22:5n-3, 22:6n-3 and total n-3 LC-PUFA content of fillets of rainbow trout fed the experimental diets for 126 days, expressed as mg per 100 g of fillet, are depicted in Fig. 1. As expected, the highest content of these fatty acids was recorded in the fillets of fish fed CD. A clear trend towards an increased content of these fatty acids with the increasing dietary supply of 18:3n-3 was present. For example, the 20:5n-3 and 22:6n-3 content of fish fed

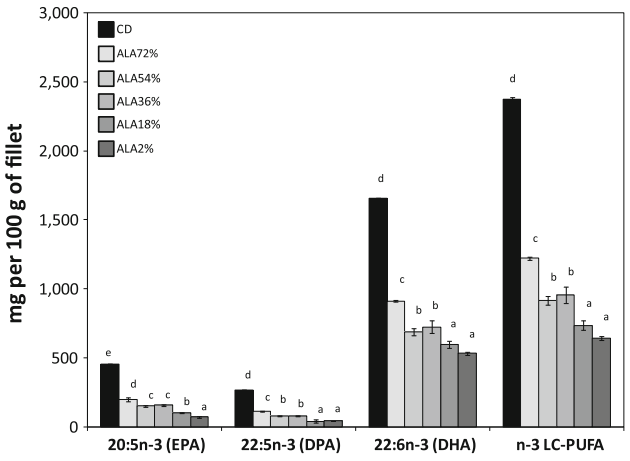

Fig. 1 The EPA (20:5n-3), DPAn-3 (22:5n-3), DHA (22:6n-3) and total n-3 LC-PUFA content of fillets of rainbow trout fed the experimental diets for 126 days (mg per 100 g of fillet)

the ALA2% were 69.2 ± 3.8 and 531.0 ± 12.9 mg per 100 g of fillet, whilst in the ALA72% treatment these values were 197.6 ± 13.6 and 911.3 ± 5.3 mg per 100 g of fillet, respectively.

Lipid and Fatty Acid Digestibility

The dry matter, lipid, total fatty acid and individual fatty acid digestibility are reported in Table 6. In general, all diets recorded high digestibility values, with no significant differences recorded in total dry matter, total lipid and total fatty acid digestibility. Individual fatty acids all recorded relatively high levels of digestibility, and despite a few statistically significant differences, the overall values were numerically similar and within the normal range of values reported for fatty acid digestibility in finfish. The two fatty acids which were quantitatively more variable across all treatments were 18:2n-6 and 18:3n-3, and whilst 18:2n-6 recorded no significant differences in its digestibility across all treatments, 18:3n-3 digestibility in ALA2% (the diet containing the smallest amount of this fatty acid) was significantly lower in comparison to the other diets.

Lipid and Fatty Acid Metabolism

In Table 7 the appearance/disappearance (expressed as mg per fish) of individual fatty acids during the 126 day experimental period are reported. These values are important for the implementation of the whole-body fatty acid balance method but also provide interesting information on its own. In fact, in the five fish oil deprived treatments, 18:2n-6 and 18:3n-3 recorded the highest level of disappearance (proportional to dietary concentration), alongside 20:5n-3. On the other hand, 16:0, 18:1n-9 and 22:6n-3 all recorded a high rate of appearance, clearly indicating that these fatty acids were synthesized by fish during the trial. The resultant apparent in vivo total enzyme activity (μmol g fish^{-1} day^{-1}) in rainbow trout fed the six experimental diets is reported in Table 8. Total apparent in vivo fatty acid de novo biosynthesis was significantly ($P < 0.05$) smaller in the CD treatment compared to the other five treatments, whilst no statistically significant differences were recorded for total apparent in vivo fatty acid β-oxidation. The apparent in vivo fatty acid Δ-9 desaturation was significantly ($P < 0.05$) lower in the CD treatment compared to ALA36%, however, no differences were noted amongst the five fish oil deprived experimental treatments. Total apparent in vivo fatty acid Δ-6 and Δ-5 desaturation both trended towards higher activity in fish receiving higher dietary 18:3n-3 (ALA72% > ALA54% > ALA36% > ALA18% > ALA2%). No apparent in vivo fatty acid Δ-5 desaturation was recorded in fish fed CD.

The apparent in vivo n-6 PUFA and n-3 PUFA bioconversion activity (μmol g fish^{-1} day^{-1}) are reported in Figs. 2 and 3, respectively. Specifically, in these figures the main enzyme activity on the different fatty acid substrates along the n-6 PUFA and n-3 PUFA bioconversion pathway from 18:2n-6 to 22:4n-6 and from 18:3n-3 to 22:6n-3, respectively, are reported. Observing Figs. 2 and 3, it is evident how the enzyme activity was directly proportional to substrate availability: enzyme activity on n-6 PUFA: ALA2% > ALA18% > ALA36% > ALA54% > ALA72%; and enzyme activity on n-3 PUFA: ALA72% > ALA54% > ALA36% > ALA18% > ALA2%. Interestingly, observing Fig. 2, it is evident that the overall enzyme activity was gradually decreasing when moving along the bioconversion pathway (Δ-6 desaturation of 18:2n-6 > elongation of 18:3n-6 > Δ-5 desaturation of 20:3n-6 > elongation of 20:4n-6). This trend was also evident on the n-3 PUFA pathway, but only up to the production of 20:5n-3. In fact, the Δ-6 desaturation of 18:3n-3 was generally higher than the elongation of 18:4n-3, which was higher than the Δ-5 desaturation of 20:4n-3. However, proceeding along the n-3 PUFA bioconversion pathway, the overall elongation of 20:5n-3 to 22:5n-3 was higher than the actual Δ-5 desaturation of 20:4n-3 to 20:5n-3, and similarly, the final elongation, Δ-6 desaturation and chain shortening of 22:5n-3 for the production of 22:6n-3 was even higher. Fish fed the CD treatment recorded an active production of 18:3n-6, 20:3n-6, 22:5n-3 and 22:6n-3, but in no instance was Δ-5 desaturation activity recorded.

In Fig. 4, the Δ-6 desaturase, Elovl-5 elongase Δ-5 desaturase affinity towards n-3 or n-6 fatty acids is reported. Here, the plotted graphs report the relationship between the substrate availability, n-3/n-6 ratio and the ratio of enzyme activity acting on the two substrates (activity on n-3/activity on n-6 ratio). In all three instances, linear regression equations (with a slope of 3.182, 1.122

and 8.097 for Δ-6 desaturase, Elovl-5 elongase Δ-5 desaturase, respectively) best described this relationship. It is clearly demonstrated that the Δ-6 desaturase activity acting on 18:3n-3, across either of the experimental treatments (ALA72%–ALA2%), was higher than the activity acting on 18:2n-6 (evident if compared to the line of equity), clearly indicating that the affinity of the Δ-6 desaturase was 3.2-fold higher for 18:3n-3 in comparison to 18:2n-6. Similarly, the Δ-5 desaturase activity acting on 20:4n-3 was much higher than the activity on 20:3n-6, with its affinity being 8-fold higher for 20:4n-3 in comparison to 20:3n-6. Elovl-5 elongase, on the other hand, seemed to have a more balanced affinity between the two substrates, with 18:4n-3 only slightly preferred to 18:3n-6.

n.d. Not detected

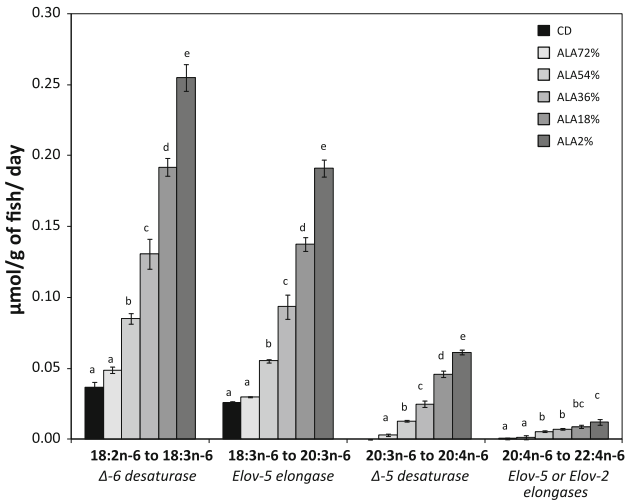

Fig. 2 Apparent in vivo n-6 PUFA bioconversion activity (μmol g fish^{-1} day^{-1}; Δ-6 desaturase, elongase and Δ-5 desaturase) on the different substrates along the n-6 PUFA bioconversion pathway from 18:2n-6 to 22:4n-6 deduced by the whole-body fatty acid balance method

The efficiency of the various apparent in vivo enzyme activities is reported in Table 9 and expressed as product % on total substrate availability (net intake + in vivo production). The efficiency of different enzymes acting on different substrates was somewhat affected by the different dietary treatments, particularly in the two most extreme treatments (CD and ALA2%), whilst values recorded amongst treatments ALA72% to ALA18% were quite consistent.

Discussion

This study could be considered as a practical feeding trial representative of the entire production cycle of rainbow trout, as practical commercial-like experimental diets were used and as juveniles were grown up to commercial size fish (~600 g). However, it also provides specific details towards a better understating of in vivo fatty acid metabolism, and how this can directly impact the final product quality of cultured trout. Thus, it is envisaged that the reported findings could be considered as highly relevant and directly usable by the industry, while at the same time providing valuable insight for researchers investigating fish fatty acid metabolism.

During the feeding trials, fish recorded a weight gain of over 1,700%, with optimal performance (SGR ~2.4 and FCR ~1.1) and no mortality. Whilst some numerical differences were noted amongst various parameters recorded, none were significantly ($P > 0.05$) different, clearly demonstrating that (1) fish oil replacement in rainbow trout practical diets has no negative effect on fish performance, and (2) diets either rich in 18:3n-3 or 18:2n-6 are both equally and favorably utilized by growing trout. These observations are in agreement with the majority of the studies focusing on fish oil replacement in salmonids [2, 3, 8–11, 25] and in several other species, as recently reviewed by Turchini et al. [14]. In direct alignment with the lack of any significant modification to fish performance, there was no effect on overall nutrient digestibility of the different lipid sources recorded in the present study. The individual fatty acid digestibility values recorded were all relatively high (the majority were higher than 95%) and in agreement with the statement that fat and fatty acids are efficiently digested and utilized by fish [31]. In some instances, slight growth retardation has been reported in rainbow trout fed alternative oils, but mainly when the diets were purified or semi-purified, and thus containing little/no fish meal in their formulation [12, 32]. In practical, commercial-like diets, both ALA-rich and LA-rich oils have been suggested to be valid fish oil replacers, as C_{18} PUFA are a good

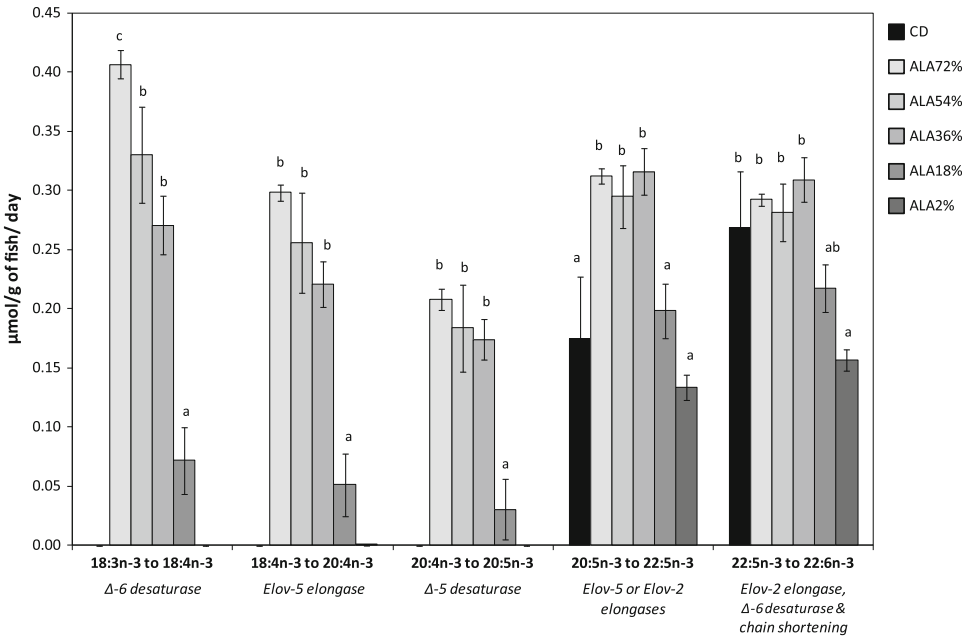

Fig. 3 Apparent in vivo n-3 PUFA bioconversion activity (µmol g fish^{-1} day^{-1}; Δ-6 desaturase, elongase, Δ-5 desaturase and chain shortening) on the different substrates along the n-3 PUFA bioconversion pathway from 18:3n-3 to 22:6n-3 deduced by the whole-body fatty acid balance method

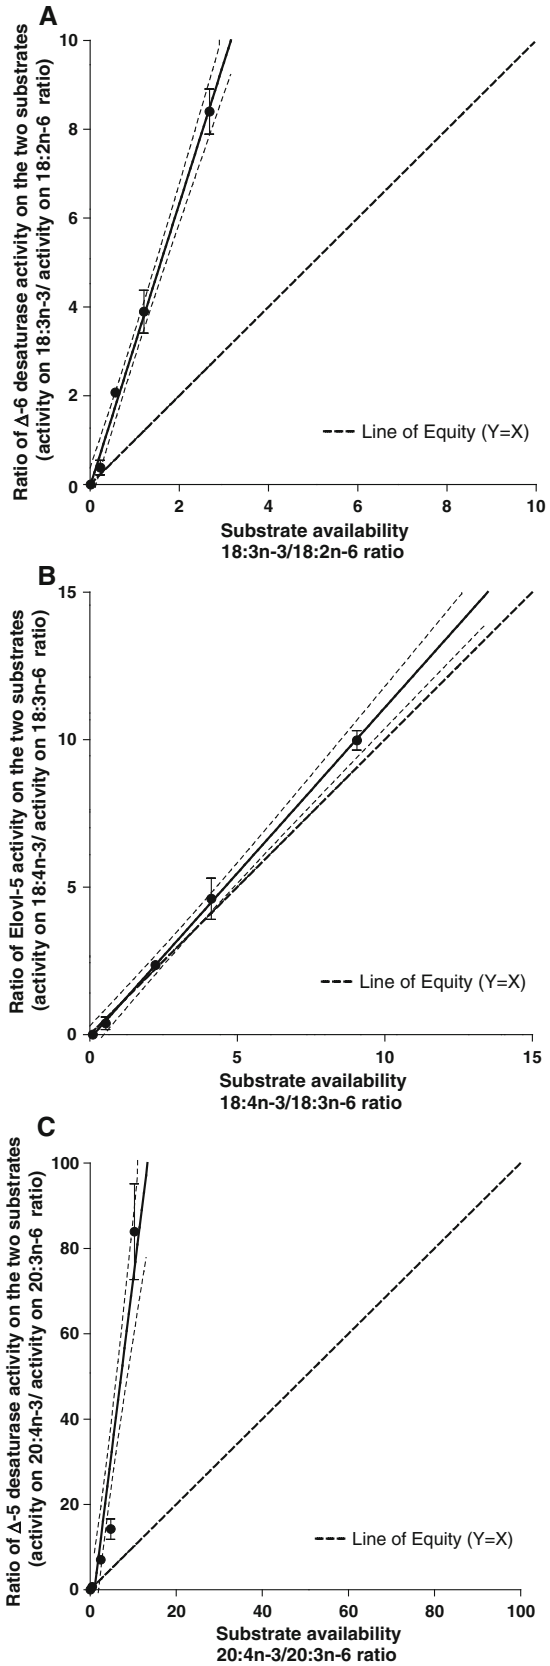
source of available energy for fish growth [15, 16]. However, the dietary availability of 18:3n-3 and 18:2n-6 clearly affects the final fatty acid composition of fish fillets [14], and thus given their different nutritional qualities for human health [33], the use of ALA-rich or LNA-rich oils in aquafeed needs to be carefully evaluated where final eating quality is a concern [4].

Despite numerical differences being noted in the total apparent in vivo β-oxidation of fatty acids in fish under the different dietary treatments, these were, from a statistical point of view, not significantly different. On the contrary, total apparent in vivo fatty acid de novo biosynthesis was markedly and significantly higher in all fish fed the five fish oil deprived diets compared to the fish oil based diet (CD). This was mainly ascribable to a large de novo biosynthesis of SFA and MUFA (which includes fatty acid elongation and Δ-9 desaturation), as previously observed in fish fed diets rich in PUFA and with relatively little dietary SFA and MUFA [12, 34]. Therefore, when making the assumption that the optimal dietary fatty acid composition for a growing animal is the fatty acid composition which minimized in vivo bioconversion and biosynthesis, the theoretical optimal dietary fatty acid composition for farmed rainbow trout should be characterized by a relatively high content of SFA and MUFA, as previously suggested [12].

The PUFA bioconversion pathway in rainbow trout is well established [35, 36], and it is consistent with that of the majority of other vertebrates, involving an alternation of desaturation and elongation steps. The Δ-6 desaturase is the first enzyme involved in the bioconversion of C_{18} PUFA towards longer and more unsaturated LC-PUFA and for this reason it is often considered as the rate-limiting enzyme in the LC-PUFA biosynthetic pathway [37, 38]. However, in the present study it has been shown that a clear trend of progressively less efficient bioconversion of fatty acids to more unsaturated or longer homologues occurs along the n-6 PUFA pathway itself (Fig. 2). This suggests that, more than the existence of a "rate-limiting enzyme", which restricts the LC-PUFA biosynthetic pathway, the pathway has a "funnel-like" efficiency, as previously speculated for rainbow trout [12]. Consistently, it has been reported that the relative activity of each step of the pathway decreases as the chain length increases [39]. Interestingly, this apparent decreasing efficiency was also observed on the n-3 PUFA pathway, but only up to the production of 20:5n-3 (Fig. 3). Hereafter, there was a proportionally higher active production of 22:5n-3 and 22:6n-3 recorded across all treatments (CD included) suggesting an "hourglass-shape" of bioconversion efficiency. This is likely ascribable to the markedly higher substrate availability as all diets contained some 20:5n-3 (the initial substrate for these two last steps) and other n-3 LC-PUFA originating from fish oil in the CD treatment and from the residual oil of the fish meal component of the fish oil deprived experimental diets. This is partially in contrast with a previous study on rainbow trout in which it was reported that the ability of trout hepatocytes to synthesize 22:6n-3 from both 18:3n-3 and 20:5n-3 can be markedly stimulated by eliminating n-3 LC-PUFA from their diets [35]. However, another study on rainbow trout, also reported that fish fed a fish oil based diet, and thus with an abundant dietary supply of 20:5n-3, were still bioconverting this fatty acid up to 22:6n-3 quite efficiently [12].



◀ **Fig. 4** Enzyme affinity (substrate preference) towards n-3 or n-6 fatty acids: the relationship between the substrate availability n-3/n-6 ratio and the ratio of the enzyme activity on the two substrates (activity on n-3/activity on n-6 ratio) deduced by the whole-body fatty acid balance method. **a** Affinity of Δ-6 desaturase: relationship between the substrate availability 18:3n-3/18:2n-6 ratio and the ratio of Δ-6 desaturase activity on the two substrates (activity on 18:3n-3/activity on 18:2n-6 ratio). Regression equation: $Y = 3.182X - 0.04168$; $R^2 = 0.97$; **b** Affinity of Elovl-5 elongase: relationship between the substrate availability 18:4n-3/18:3n-6 ratio and the ratio of Elovl-5 elongase activity on the two substrates (activity on 18:4n-3/activity on 18:3n-6 ratio). Regression equation: $Y = 1.122X - 0.1353$; $R^2 = 0.98$; **c** Affinity of Δ-5 desaturase: relationship between the substrate availability 20:4n-3/20:3n-6 ratio and the ratio of Δ-5 desaturase activity on the two substrates (activity on 20:4n-3/activity on 20:3n-6 ratio). Regression equation: $Y = 8.097X - 8.150$; $R^2 = 0.87$. In all graphs, *error bars* represent SEM, *dotted lines* represent 95% confidence band of the regression line, and the lines of equity ($Y = X$) have also been reported for visual reference. In all three linear regressions (**a**, **b** and **c**) the slope deviation from zero was significant ($P < 0.0001$)

Interestingly, the in vivo efficiency of the different enzymes involved in LC-PUFA biosynthesis (expressed as product % on total substrate availability) were quite different relative to the substrate (i.e. n-3 or n-6 PUFA) and relative to the step in the bioconversion pathway (Table 9). Apart from the two most extreme treatments (CD and ALA2%), values recorded amongst treatments ALA72% to ALA18% were quite consistent for a given fatty acid bioconversion step. Observing the middle treatment (ALA36%), it is possible to exemplify more schematically the recorded differences in enzyme efficiency. The efficiency of the apparent in vivo Δ-6 desaturase activity on C_{18} PUFA was generally higher for 18:3n-3 compared to 18:2n-6. In fact in ALA36%, 12.7% of available 18:3n-3 and only 3.5% of available 18:2n-6 were Δ-6 desaturated. Markedly higher values were recorded for the following elongation, with 68.3% of available 18:3n-6 and 72.4% of available 18:4n-3 was elongated in ALA36%. The efficiency of apparent in vivo Δ-5 desaturase activity was then again remarkably different between n-6 and n-3 fatty acids, as 26.4% of available 20:3n-6 was desaturated to 20:4n-6 and over 75.3% of 20:4n-3 was desaturated to 20:5n-3. Similarly, the following elongation recorded much higher efficiency values for n-3 fatty acids compared to n-6 fatty acids, with only 15.3% of available 20:4n-6 and 73.1% of 20:5n-3 been elongated. The final production of 22:6n-3, which involves an elongation, a Δ-6 desaturation and a chain shortening step, recorded very high efficiency values around ~84%, indicating that in general, 22:5n-3 was very efficiently bioconverted to 22:6n-3.

Given 18:3n-3 and 18:2n-6 are both substrates for the Δ-6 desaturase, its affinity towards one or the other is particularly relevant. The above discussed results relative to enzyme efficiency are in agreement with the generally

n.d. Not detected

accepted notion that fatty acid desaturases have a higher affinity towards n-3 PUFA than n-6 PUFA [39]. Accordingly, previous studies using radio-labelled fatty acids in Atlantic salmon hepatocytes observed that the overall level of LC-PUFA synthesis from 18:2n-6 was less than half of that from 18:3n-3, irrespective of the diet [40, 41]. Similarly, using the whole body fatty acid balance method, a 3.2-fold greater Δ-6 desaturase affinity toward 18:3n-3 over 18:2n-6 was recorded in Murray cod [22, 42]. In the present study, an almost identical relationship between substrate availability and Δ-6 desaturase activity was shown (Fig. 4), suggesting that the overall affinity of this enzyme is 3.2-fold greater for 18:3n-3 over 18:2n-6 in rainbow trout. Elovl-5 elongase acting on C_{18} PUFA recorded no difference in affinity, whilst a remarkable 8-fold greater Δ-5 desaturase affinity toward 20:4n-3 over 20:3n-6 was recorded. Thus, if dietary 18:3n-3 and 18:2n-6 are provided in similar amounts (as in diet ALA54%), the amount of 18:4n-3 produced in vivo will be 3-times larger than 18:3n-6. The following Elovl-5 elongase activity, which showed no difference in its affinity, will produce 20:4n-3 and 20:3n-6 roughly maintaining the same ratio of their substrates availability (in this example 3:1). Then, in consideration that Δ-5 desaturase affinity towards 20:4n-3 was 8-fold higher than that acting on 20:3n-6, theoretically it will ultimately produce (3.2 × 8=) ~25.6-fold more 20:5n-3 than 20:4n-6. This difference in substrate preference of the above mentioned enzymes is consistent with previous indications obtained in trout cell culture [43]. To understand how these differences can affect final fatty acid composition of fish tissues, of course, other metabolic pathways (such as further bioconversion and β-oxidation) also need to be considered. However, according to the above discussed results, it is evident that significantly larger amounts of n-3 LC-PUFA, compared to n-6 LC-PUFA, will be found in fish tissues.

The capability of rainbow trout to bioconvert 18:3n-3 into 22:6n-3 in vivo was previously investigated using deuterated (D5)-18:3n-3 ethyl ester [44]. One of the most notable features of this study was the slow rate at which D5-22:6n-3 was synthesized and deposited in tissues. The authors also suggested that in trout, it takes ~4 weeks for a pulse of 18:3n-3 to be fully metabolized to 22:6n-3 and that given the experimental design, it could not be determined whether the PUFA biosynthetic pathway was substrate limited. However, it was also suggested that if more substrate (18:3n-3) had been available the rate of formation of 22:6n-3 might have been increased. Accordingly, in a following study on the same species, it was shown that a relatively large amount of dietary 18:3n-3 was bioconverted up to 22:6n-3, when the diet was deprived of n-3 LC-PUFA and supplied with abundant 18:3n-3 [12]. The results of the present study further confirm the fact that rainbow trout are quite efficient in bioconverting 18:3n-3 to 22:6n-3, and that clearly the PUFA biosynthetic pathway is substrate limited.

When it comes to the eating quality of cultured fish, one of the most important parameters to be considered is the actual quantity of n-3 LC-PUFA in the fish fillets [4, 45]. As expected, in the present trial, the highest content of 20:5n-3, 22:5n-3 and 22:6n-3 (totaling over 2.3 g of n-3LC-PUFA per 100 g of fillet) was recorded in the fillets of fish fed the CD. However, in fish fed the five fish oil deprived diets, a clear trend towards an increased content of these fatty acids with the increasing dietary supply of 18:3n-3 was present, independent of the fact that they were all fed with almost identical amounts of n-3 LC-PUFA. Rainbow trout have been shown previously to be capable of being a net producer of n-3 LC-PUFA [13], and the present study further confirms this. Importantly, it is commonly accepted that when fish oil is replaced in aquafeed, a significant detrimental reduction of total n-3 LC-PUFA occurs in fish fillets [14]. However, the present study highlights the very pertinent point that not all alternative oils are the same, and oils rich in 18:3n-3 can provide significantly higher amounts of total n-3 LC-PUFA in fish fillets in comparison to oils rich in 18:2n-6. For example (Fig. 1), the 20:5n-3 and 22:6n-3 content of fish fed the ALA2% (sunflower oil) were 69.2 ± 3.8 and 531.0 ± 12.9 mg per 100 g of fillet, respectively, whilst in ALA72% (linseed oil) these values were 197.6 ± 13.6 and 911.3 ± 5.3 mg per 100 g of fillet, respectively. Despite an almost identical dietary supply, the fillets of trout fed the diets richest in 18:3n-3 (ALA72%) contained double the amount of n-3 LC-PUFA in comparison to the fillets of fish fed with the diet containing the lowest content of 18:3n-3 (ALA2%). Basically, it was clearly shown that the substitution of fish oil with a proper alternative vegetable oil in aquafeed is an efficient tool that can be easily implemented which has the possibility to transform the salmonid aquaculture industry from a consumer into a net producer of health promoting n-3 LC-PUFA. This will ultimately assist aquaculture to accomplish its role in conserving wild fisheries in the future. However, it is important to highlight that when fish oil is completely replaced by alternative terrestrial oils, and therefore fish are provided with significantly less dietary n-3 LC-PUFA, a remarkable reduction in the n-3 LC-PUFA content in the final product is still unavoidable. Importantly, whilst this study clearly showed that the final n-3 LC-PUFA content in fish fed fish oil deprived diets can be increased by the provision of an abundant dietary supply of 18:3n-3 and the concomitant reduction of total dietary 18:2n-6, the proper balancing of dietary fatty acids with an appropriate amount of SFA and MUFA is also important to guarantee optimal growth performance.

Acknowledgments The authors express their gratitude to Bob Collins for his general and technical support throughout the research project and to Dr. Richard Smullen (RidleyAquafeed, RidleyAgriProducts, Narangba, QLD, Australia) for kindly providing some of the raw materials used in the experimental diets. This research was supported under the Australian Research Council's Discovery Projects funding scheme (project DP1093570). The views expressed herein are those of the authors and are not necessarily those of the Australian Research Council. The first author, Thanuthong, T. is the recipient of a Thai Government scholarship funded by Thai Government, and this support is gratefully acknowledged.

prey. In spite of this common unique lifestyle and shared morphological features, like a rod shape and a single polar flagellum [3], BALO were found to be a phylogenetically heterogeneous group and, thus, the order *Bdellovibrionales*, to which all BALO belong so far, was split into the two families *Bdellovibrionaceae* and *Bacteriovoracaceae* based on 16S rRNA analyses [4].

The lifecycle of these predatory prokaryotes can be split into several stages, among which the initial interaction between predator and prey determines whether the predator penetrates into the prey or detaches itself. Since the first contact occurs between structures of the cell walls, machineries for attachment, prey recognition and penetration are supposed to be located in the cell wall of the predator. However, the predator–prey interaction mechanisms and therefore the important key structures are still largely unknown.

Beside the outer membrane proteins of BALO [5, 6], lipid structures have previously been analyzed in our group. We elucidated the structures of the lipid A of *B. bacteriovorus* and *B. stolpii*, two distinct BALO strains, and found an unusual structure of the lipid A of *B. bacteriovorus*, which is the first described lipid A structure missing charged residues [7]. *B. stolpii* is a facultative predatory strain that can be grown on prey bacteria but also on rich media. *B. stolpii* possesses a lipid A very different from the *B. bacteriovorus* lipid A, since it carries charged phosphate groups [8]. Very uncommon for prokaryotes, sphingolipids were found in the cell wall of *B. stolpii*, which were shown to be phosphonolipids [9–11]. The only other BALO which has been analyzed so far in respect to its phospholipids is *B. bacteriovorus* [12].

Bacterial cell wall lipids vary to a great extent between organisms, but also between different strains of the same organism. The main phospholipid classes of the model organisms *Escherichia coli* (Gram-negative) and *Bacillus subtilis* (Gram-positive) are phosphatidylethanolamines (PtdEth), phosphatidylglycerols (PtdGro) and cardiolipins (Ptd_2Gro), so these classes are generally believed to be the main membrane-forming lipid classes in all prokaryotes [13]. However, there are bacterial strains containing other phospholipids as major or minor constituents. In some cases, sphingolipids were observed, for the genera *Sphingobacterium* [14] and *Sphingomonas* [15] they are eponymous, but they have also been found in other genera. In the majority of cases, glycerophospholipid structures like phosphatidylcholines (PtdCho) [16], phosphatidylinositol (PtdIns) [17] or amino acid-containing phosphatidylglycerols (PtdGro) or cardiolipins (Ptd_2Gro) [18] are predominant.

In this work we studied the phospholipids of the three BALO strains *B. stolpii*, *B. bacteriovorus* HD100 and *P. starrii*.

Materials and Methods

Bacterial Growth and Lipid Extraction

B. stolpii (DSM 12778) was grown in peptone yeast extract medium at 30 °C for 3–5 days. Cells were harvested by centrifugation. For the obligate prey dependant strains *B. bacteriovorus* HD100 (DSM 50701) and *P. starrii* (DSM 17039), prey bacteria were grown to the stationary phase in liquid Luria-Bertani broth, centrifuged and resuspended in a buffer containing 3 mM ammonium acetate, 3 mM magnesium chloride and 3 mM calcium chloride at pH 7.5. This suspension was infected with the BALO strain. After 2–3 days at 25–27 °C the lysis of the prey bacteria was complete. The cultures were centrifuged at $2{,}000\times g$ for 15 min at 4 °C to minimize the contamination with residual prey bacteria and BALO cells were harvested at $10{,}000\times g$ for 30 min at 4 °C. *B. bacteriovorus* HD100 was grown on *Escherichia coli* K-12 (DSM 423) and *P. starrii* on *Pseudomonas putida* (DSM 50906).

Phospholipids were extracted with the methyl *tert*-butyl ether (MTBE) method described by Matyash et al. [19]. In short, in a glass flask, an aliquot of the cell pellet was resuspended in 0.5 ml of bidistilled water and 3.75 ml of methanol and 12.5 ml of MTBE were added. The mixture was incubated for 1 h at room temperature with shaking. 3.125 ml of bidistilled water were added to separate phases and the organic phase was collected. The water phase was reextracted by addition of 4 ml MTBE, 1.2 ml MeOH and 1 ml bidistilled water. The combined organic phases were evaporated to dryness under a gentle stream of nitrogen.

Analysis of Sphingophosphonolipids

Sphingophosphonolipids (SPNL) were separated from the glycerophospholipid (GPL) species by mild alkaline methanolysis [9] or by incubation of a total phospholipid extract with lipase D (personal communication, Sabine Schiller, Department of Biology, Humboldt-Universität zu Berlin). For the enzymatic assay, 0.3 mg of a total phospholipid extract were dissolved in 183.3 µl of ethyl acetate and 83.3 µl of an acetate buffer (0.2 M sodium acetate, 40 mM calcium chloride, pH 8.0) were added. The solution was heated to 37 °C and 2 µl of a 1 unit μl^{-1} solution of lipase D (Sigma-Aldrich; Steinheim) were added. This mixture was incubated for 2 h at 37 °C. For acetylation, 200 µl of acetic acid anhydride and 2.1 µl of a 5 mg ml^{-1} solution of 4-dimethylaminopyridine in pyridine were added to 420 µl of a solution of SPNL in dry pyridine (approx. 1 mg ml^{-1}). This solution was stirred for 1 h at 60 °C followed by incubation for 16 h at room temperature. The solvent was evaporated under a gentle stream of nitrogen.

The performance of this assay was tested on standard phospholipids (Avanti Polar Lipids, Alabaster).

HPLC–MS

HPLC separation was carried out with an Agilent 1200 system (Agilent, Waldbronn) and a BioBasic-4 column (150 mm × 1 mm i.d., particle size 5 µm, Thermo Scientific, Bremen). Both a LTQ-FT MS Classic equipped with a 6 T superconducting magnet and a LTQ-FT MS Ultra equipped with a 7 T superconducting magnet were used (both Thermo Scientific, Bremen) as detectors. The mass spectrometers were calibrated according to the manufacturer's recommendations and transfer optics were tuned with a lipid standard mixture containing phosphatidylserine (PtdSer; 16:0/18:1), phosphatidylglycerol (PtdGro; 16:0/18:1), phosphatidic acid (PtdOH; 16:0/18:1), phosphatidylethanolamine (PtdEth; 16:0/18:1), phosphatidylcholine (PtdCho; 16:0/18:1) and cardiolipin (Ptd_2Gro; 4×18:1) (Avanti Polar Lipids, Alabaster). The samples were dissolved in acetonitrile/methanol (1:1, by vol.) to a concentration of about 1 mg ml^{-1} and 1–8 µl were injected onto the column.

The HPLC-MS method employed was based on a method by Hein et al. [20]. Eluent A consisted of 95% water and 5% acetonitrile (by vol.), eluent B of 70% acetonitrile, 25% *iso*-propanol and 5% water (by vol.). Both eluents contained 10 mM triethylammonium acetate and 1 mM acetic acid. The gradient elution was started at 70% B and held there for 2 min, after which the % B was linearly increased to 80% in 46 min, then to 100% in 2 min. The % B was held at 100% for 23 min, before it was returned to initial conditions in 2 min, where it was held for 15 min. For more polar lipid classes, the initial conditions of the gradient were changed to 60% B. The separation was performed with a flow rate of 50 µl min^{-1} and the column was heated to 40 °C during separations. All solvents used were of HPLC gradient grade (Mallinckrodt Baker, Deventer). Lipid species were assigned according to their accurate masses in negative electrospray ionization mode and their corresponding fragmentation spectra. The accuracy in the survey scans (FT–MS) was below 2 ppm at all times and fragmentation experiments were carried out in the linear ion trap showing an accuracy of better than ±0.25 Da. All lipid species were detected in the deprotonated form $[M–H]^-$ apart from the PtdCho species, which were detected only as acetate adducts $[M+AcO]^-$. The assignment of the acyl residues to the positions *sn*-1/*sn*-2 was based on intensities of the corresponding fragment ions, as previously published [21].

The mass spectrometric data was processed and evaluated using the Profiler-Merger-Viewer software tool of Hein et al. [22]. Microsoft Excel was used to calculate the masses of the lipid species in the lipid library; PtdSer, PtdGro, PtdIns, PtdOH, PtdEth, mono- and dimethylphosphatidylethanolamines, PtdCho, Ptd_2Gro, sphingophosphonolipids (with AEP, HAEP and APP head group), phosphatidylthreonine, glutamylphosphatidylethanolamine, *N*-acylphosphatidylethanolamine and the corresponding lysoforms were taken into account. Fatty acid (FA) acyl chain lengths from 2–30 carbon atoms with up to 15 double bonds and three hydroxy groups were considered.

Thin-layer Chromatography

One dimensional thin-layer chromatography (1D-TLC) analyses of lipid extracts were carried out on Silica Gel 60 plates (Merck, Darmstadt). The plates were developed with a $CHCl_3$/MeOH/AcOH/H_2O 80:14:12:4 (by vol.) solvent system. Dried plates were stained with a solution of phosphomolybdic acid in ethanol (50 g l^{-1}) and heating. Plates were scanned and images were analyzed densitometrically (ProteomWeaver 2.1.0 software, Definiens AG, München). For re-extraction of the separated lipid classes, dried plates were stained with a solution of primulin in acetone/water 4:1 (by vol.) [23], lipids were re-extracted according to the MTBE protocol described above.

Compositional Analysis

Polar head groups were released by hydrolysis with hydrochloric acid [24]. Fatty acid methyl esters were prepared by dissolving phospholipids in 2 M hydrochloric acid in methanol and stirring for 16 h at 85 °C. Pyrrolidides and picolinyl esters of fatty acids were synthesized as described elsewhere [25, 26]. GC–EI/MS was performed on an electron impact ionization mass spectrometer (Hewlett Packard G1800A) with a fused silica capillary column (HP-5MS, 30 m, inner diameter 0.25 mm, film thickness 0.25 µm). Hydrogen was used as carrier gas at a flow rate of 1 l h^{-1}. Relative abundances were determined from the corresponding peak areas.

Results

Total phospholipid extracts of the organisms *B. stolpii*, *B. bacteriovorus* HD100 and *P. starrii* were separated according to their lipid classes using 1D-TLC (Fig. 1). The relative abundances of the different lipid classes as determined from densitometric analyses of TLC plates are given in Table 1. In all three strains phosphatidylethanolamine, phosphatidylglycerol, and cardiolipin were the most abundant lipid classes. The results for *B. stolpii* are consistent with the data published by Steiner et al. [10]. However, we could not confirm the high proportion of

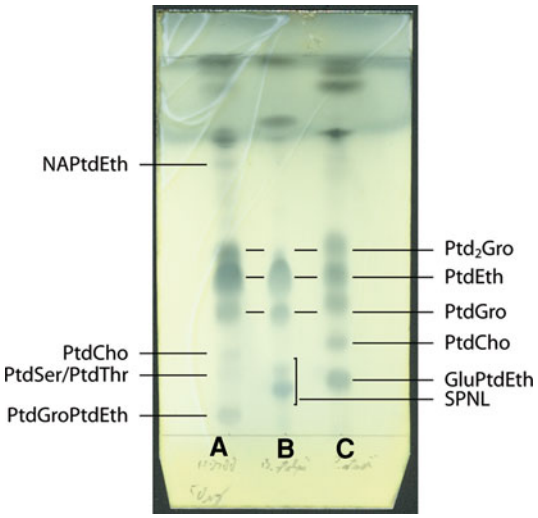

Fig. 1 1D-TLC of total phospholipid extracts of *A B. bacteriovorus* HD100, *B B. stolpii* and *C P. starrii*. The lipids were stained using phosphomolybdic acid. *PtdGroPtdEth* phosphatidylglycerophosphoethanolamine or a phosphatidyl-2(2-aminoethyl)-glycerophosphate, *PtdSer* phosphatidylserine, *PtdThr* phosphatidylthreonine, *PtdCho* phosphatidylcholine, *NAPtdEth* *N*-acylphosphatidylethanolamine, *SPNL* sphingophosphonolipid, *GluPtdEth* glutamylphosphatidylethanolamine, *PtdGro* phosphatidylglycerol, *PtdEth* phosphatidylethanolamine, *Ptd_2Gro* cardiolipin

phosphatidylserine found in *B. bacteriovorus* HD100 by Nguyen et al. [12].

Since the SPNL previously found in *B. stolpii* were associated with the predatory life style [10, 11], the three BALO were tested for the presence of sphingolipids. Therefore, total phospholipid extracts were subjected to a mild alkaline methanolysis [9], which is able to cleave the ester linked acyl chains of glycerophospholipids, but not the amide linked acyl chains of sphingolipids. All sphingolipids found in *B. stolpii* proved to be phosphonolipids by incubation with lipase D as well as mass spectrometric characterization after acetylation. Phospholipase D hydrolyzes the phosphodiester bond on the side of the polar head group [27]. Phosphonolipids are not cleaved by phospholipase D since these possess a phosphorus-carbon bond instead of this phosphodiester bond. Like Jayasimhulu et al. [9], we found SPNL comprising phyto- and dihydrosphingosine structures. In addition to the two SPNL head groups 1-hydroxy-2-aminoethylphosphonate (HAEP) and 2-aminoethylphosphonate (AEP) described by Jayasimhulu et al., SPNL with a 2-amino-3-phosphonopropanate (APP) head group were also identified (Fig. 2, Table 2).

In *B. bacteriovorus* HD100 and *P. starrii* no sphingolipid species could be detected. Nevertheless, other unusual lipid structures were found in these two members of the BALO group. Nguyen et al. already reported phosphatidylserines in *B. bacteriovorus* HD100, as well as an additional lipid class for which the identification as *N*-acylphosphatidylethanolamines (NAPtdEth) was proposed [12]. Experimental proof for this assumption other than accurate masses was not provided. With high-resolution mass spectrometry in combination with additional fragmentation experiments, we were able to validate the previously proposed presence of NAPtdEth in *B. bacteriovorus* HD100. Figure 3 shows a typical fragmentation spectrum of a NAPtdEth species. Interestingly, all *N*-acyl chains found in NAPtdEth contained a cyclopropane ring, while mainly 9,10-methylene hexadecanoyl residues were observed.

Beside PtdSer phospholipids, another lipid class with a head group differing in the mass of one methylene group (CH_2, 14.015 Da) was detected in *B. bacteriovorus* HD100. After hydrolysis a hydrolysis product with a molecular mass of 119.06 Da ($C_4H_9NO_3$) was observed. This sum formula matches threonine, *N*-methylserine and serine methyl ester. The corresponding spectra of the first two were compared (Fig. 4). The third possible structure,

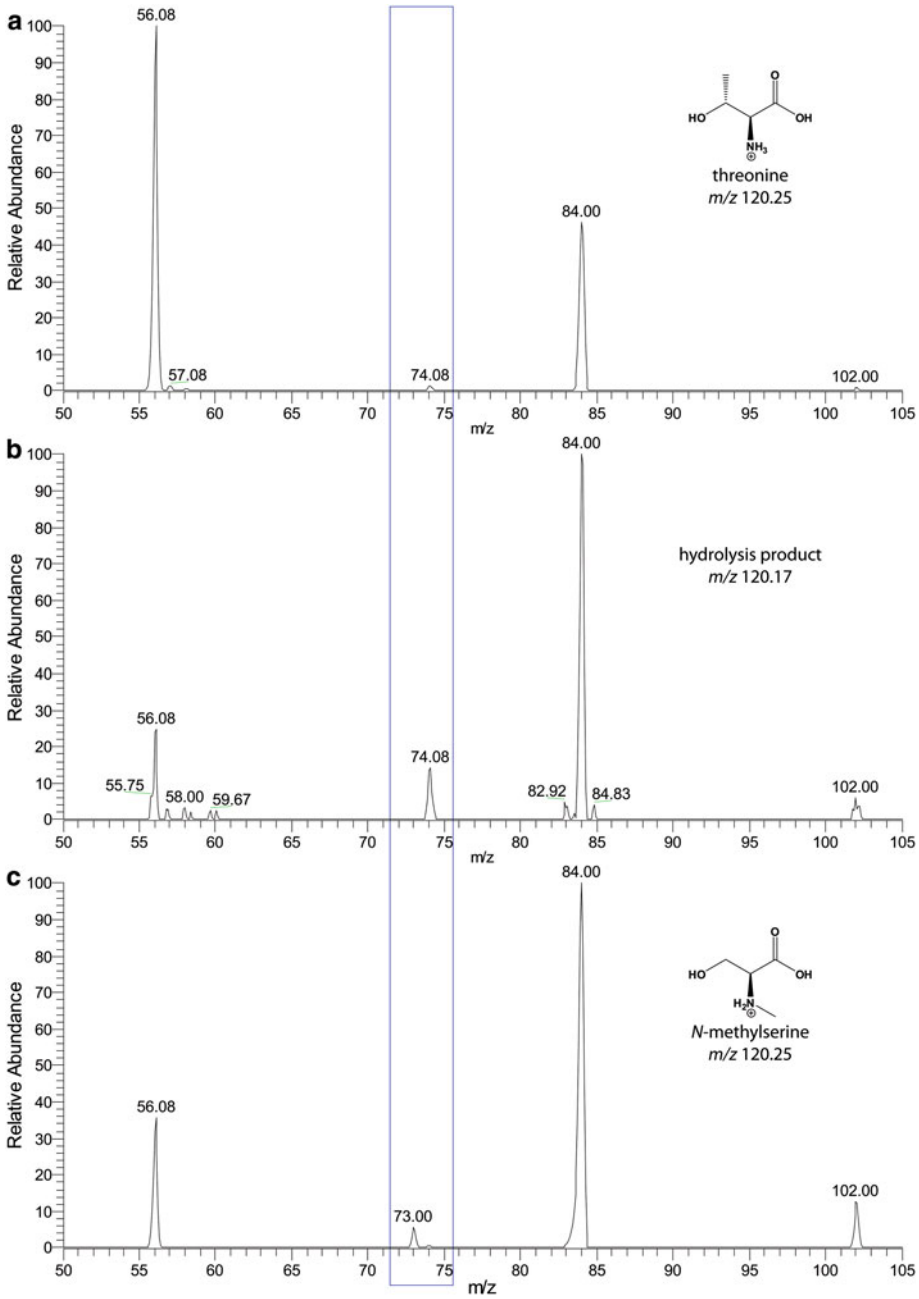

Fig. 4 Comparison of the MS/MS-spectra of **a** threonine, **b** the product with a molecular mass of 119.06 Da of the hydrolysis of the lipid species differing in the mass of one methylene group (CH_2, 14.015 Da) from phosphatidylserines and **c** *N*-methylserine in the positive ion mode

serine methyl ester, was ruled out due to the abundant neutral loss of two water molecules observed in the MS/MS-spectra of the hydrolysis product. By comparison of the fragmentation spectra, the hydrolysis product was identified as threonine and, thus, this new lipid class proved to be phosphatidylthreonines (PtdThr).

Another unknown ninhydrin-positive TLC-spot was apparent after separation of *B. bacteriovorus* HD100 total lipid extracts. In MS/MS-spectra of the reextracted lipids, signals corresponding to PtdGro and phosphatidic acid (PtdOH) could be detected (Fig. 5). Furthermore the loss of ethanolamine (C_2H_7NO, 61.05 Da) and vinylamine (C_2H_5N, 43.04 Da) were apparent. A similar FA distribution in these lipids compared to the PtdGro also supported a structure derived from PtdGro. These findings and the accurate masses of the parent ions strongly suggest PtdGro structures containing an ethanolamine and an additional phosphate residue in the polar head group. In this case either a phosphatidylglycerophosphoethanolamine or a phosphatidyl-2(2-aminoethyl)-glycerophosphate structure (Fig. 6) could be proposed. Additionally, PtdCho species were found in *B. bacteriovorus* HD100 and *P. starrii*.

From *P. starrii* total lipid extracts, TLC spots corresponding to PtdEth, PtdGro, Ptd_2Gro and PtdCho were detected. Furthermore, an additional unknown ninhydrin-positive TLC spot was detected. High resolution MS-spectra

and fragmentation experiments performed with the extracted lipids from this TLC spot indicated PtdEth structures containing an *N*-glutamyl residue (Fig. 7). After hydrolysis of these lipids and comparison of the MS/MS-spectra of the hydrolysis product with the molecular mass of 147.05 Da ($C_5H_9NO_4$) with the corresponding fragmentation spectra of glutamic acid, the identification of this lipid class as glutamylphosphatidylethanolamines (GluPtdEth) was verified.

In addition to the mass spectrometric analyses of the TLC separation, we performed HPLC–MS analyses. The most abundant glycerophospholipid species of the identified lipid classes of the three BALO strains *B. stolpii*, *B. bacteriovorus* HD100 and *P. starrii* detected in these experiments are given in Table 3.

The FA compositions of total phospholipid extracts from the three BALO members were determined by GC–EI/MS (Table 4). The FA compositions of the SPNL and glycerophospholipid species of *B. stolpii* were analyzed separately. The FA were converted to methyl esters and analyzed as pyrrolidides after corresponding derivatization. Phospholipid extracts containing cyclopropane FA were analyzed as picolinyl derivates, as acid-catalyzed methanolysis leads to ring openings and formation of methoxy species [29].

C_{13}- up to C_{19}-FA were detected with this methodology, while mainly non hydroxylated fatty acids were detected. The only hydroxy FA present were 2-hydroxy FA in the SPNL of *B. stolpii*, while *B. bacteriovorus* HD100 and *P. starrii* did not show hydroxy FA at all. This is surprising as the lipid A of *B. bacteriovorus* HD100 also contains hydroxy FA as well as the lipid A of *B. stolpii* to a large extent [7, 8]. Hydroxy FA may be labile under some acidic conditions [28]. Nevertheless, we were able to detect hydroxy FA in GC–MS experiments from SPNL after TLC separation and acidic methanolysis. Furthermore, no indications for hydroxy FA were observed in HPLC–MS and MS/MS experiments, apart

HD100 (12.1%) and *P. starrii* (1.7%). In both of the latter organisms cyclopropane FA in proportions of 42.9% (*B. bacteriovorus* HD100) and 47.4% (*P. starrii*) were found.

Discussion

Besides the known SPNL with HAEP and AEP head groups, SPNL with an APP head group were identified in *B. stolpii* in this study. Lipid-bound APP intermediates were postulated for the biosynthesis of phosphonolipids with AEP head group in various organisms [30, 31], but could not be detected [32–34]. By identifying SPNL with APP and AEP head groups in *B. stolpii*, we were able to detect the proposed lipid-bound APP intermediate of the biosynthesis of the latter. In both of the other analyzed BALO strains, no sphingolipids could be detected. The correlation of the presence of SPNL with the predatory behavior has already been suggested for *B stolpii* [10], but it has been shown that SPNL are not crucial for the predatory behavior of *B. stolpii* [35]. In both *B. bacteriovorus* HD100 and *P. starrii* unusual and previously unidentified lipid structures were found. For the first time, glutamylphosphatidylethanolamines were identified in *P. starrii*. Interestingly, amino acid-containing PtdGro and Ptd_2Gro are known to be present in bacteria, primarily in Gram-positive strains [18], but amino acid-containing PtdEth have not been reported previously. Thus, the presence of glutamylphosphatidylethanolamines in *P. starrii* is unique.

Furthermore, we were able to determine the presence of NAPtdEth in *B. bacteriovorus* HD100, as proposed in another study [12]. In this context, the only amide bound fatty acids found in the NAPtdEth were cyclopropane FA. Additionally, phosphatidylthreonines and another lipid class, probably phosphatidylglycerophosphoethanolamine or phosphatidyl-2(2-aminoethyl)-glycerophosphate, were detected in *B. bacteriovorus* HD100. PtdThr is a rarely observed lipid class, usually found in eukaryotic organisms [24, 36–38]. Nevertheless, the presence of PtdThr lipids has recently been reported in *Clostridium novyi* NT, being the first prokaryotic organism containing PtdThr [39]. Furthermore, in both *B. bacteriovorus* HD100 and *P. starrii* significant amounts of PtdCho have been found.

The role of these under physiological conditions predominant anionic lipids has to be resolved in further studies, especially with regard to a possible involvement in processes relevant for the predatory life style of the BALO. The unusual lipid structures might compose the necessary environment to incorporate important outer membrane proteins (OMP) associated with processes of the predator–prey interaction, or the lipids might even be part of a signalling cascade regulating the OMP function.

From the current point of research, more BALO strains should be analyzed for their lipid composition in order to get a broader view of the presence of specific, partly very unique, lipids in predatory prokaryotes. Although the strains examined so far show distinct lipid structures, a broader view might give insights into the mechanisms of predation and prey recognition employed by predatory prokaryotes.

Introduction

Phosphatidylcholine (PtdCho) is the major phospholipid (PL) constituent of eukaryotic cells. It is mainly biosynthesized through two pathways: the CDP-choline pathway and the *N*-methylation of phosphatidylethanolamine (PtdEtn) [1]. In mammals, this latter pathway is mainly expressed in the liver [2] where it contributes to the biosynthesis of ~30% of PtdCho [3, 4]. Similar hepatic expression of the PtdEtn *N*-methylation pathway was also demonstrated in euryhaline fish and crustaceans [5]. The physiological significance of the PtdEtn *N*-methylation pathway has long been a matter of debate [6–9], since *Pemt* –/– mice fed a normal diet are viable, fertile and display no obvious phenotype with regards to cognitive functions and behavior [10]. It was suggested that the PtdEtn *N*-methylation was an "accessory" pathway for PtdCho biosynthesis, and that it was conserved during evolution to provide PtdCho on demand when dietary intake of choline is insufficient [7]. Data obtained on *Pemt* –/– mice support that physiological function since the animal fed a choline-deprived diet quickly developed liver steatosis and died [9].

However, some observations suggest that the PtdEtn *N*-methylation pathways may have other physiological functions. Hence it was shown that mitogenic activation of lymphocytes induces an activation of PtdCho synthesis through PtdEtn *N*-methylation [11]. Similar activation of this metabolic pathway has been observed in different cell types including rat reticulocytes exposed to catecholamines [12]. The authors of these studies concluded that the activation of PtdEtn *N*-methylation pathway had a role in signal transduction by facilitating interactions between ß-adrenergic receptors and adenylate cyclase [12–14]. However, in a critical rehearsal of data, Vance and de Kruijff questioned the physiological relevance of PtdEtn *N*-methylation in signal transduction [15]. Other studies demonstrated that the PtdEtn *N*-methylation pathway may have a role in the acclimation of euryhaline species during thermal and salinity changes. Hence, it was shown that acclimation of euryhaline fish and crustaceans to elevated temperatures resulted in an activation of the PtdEtn *N*-methylation pathway in the liver and hepatopancreas of these animals [16–19]. Interestingly, the percentage of PtdCho synthesized in fish liver via the *N*-methylation of PtdEtn was more than doubled in fish adapted to 22 °C than to 12 °C [5]. Furthermore, changes in water salinity were shown to impact PtdCho synthesis in the liver of eels *Anguilla anguilla* with ~35 or ~65% of PtdCho made through PtdEtn *N*-methylation in respectively fresh water- or sea water acclimated animals [17]. We recently reported similar observations in two species of euryhaline crabs, *Carcinus maenas* and *Eriocheir sinensis* [20]. In that study, we demonstrated that acclimation to sea water activates the PtdEtn *N*-methylation pathway in the hepatopancreas and that the newly formed PtdCho is exchanged with the hemolymph of animals. We found that this activation of the PtdEtn *N*-methylation pathway plays an important role in the biosynthesis of betaine (an organic osmolyte derived from choline metabolism) which led us to the conclusion that one of the physiological functions of the PtdEtn *N*-methylation pathway is to provide organic osmolytes (such as betaine) when animals are facing salt stress. However, all these studies were performed in animal models that are considered as good osmoregulators. The euryhaline fish species that were used in these experiments are effectively able to keep their blood osmotic concentrations in a near constant range when salinity of the medium increases. The crustacean species used in the reported studies are also able to regulate their hemolymph osmotic concentration at low salinities and to osmoconform at higher salinity ranges [21]. However, some animals have different strategies to cope with salinity. It is the case of osmoconformers whose blood osmotic concentrations display a direct correlation with salt concentrations in their environment [21]. Some marine molluscs such as the mussel *Mytilus galloprovincialis* are typical osmoconformers. At high salinity, these species have to adjust their intracellular osmotic concentrations to avoid cellular shrinkage. To do so, osmoconformers essentially rely on the accumulation/synthesis of organic osmolytes in order to match their intracellular osmotic concentrations with blood. Interestingly, these animals are known to use betaine as a major organic osmolyte. Knowing the importance of the PtdEtn *N*-methylation pathway in the synthesis of this choline-derived osmolyte in crabs, we hypothesized that this pathway may be expressed in osmoconformers such as the mussel *M. galloprovincialis*. Unfortunately, to our knowledge there are no data on PtdEtn *N*-methylation activity in these animals.

Although the expression of lipids in various tissues of a number of bivalve species has been studied [22, 23], data on their metabolism remain fragmentary. Some information is available in different marine mollusc species on the transport of lipids in the hemolymph in which phospholipids represent 70–90% of total lipids [24–28] and on biosynthesis of fatty acids [29]. Experiments with [^{14}C]-labeled fatty acids suggested the existence of lipid transfer from the blood to various tissues in marine bivalves [27, 28]. However, until now few studies on phospholipids metabolism have been performed in marine molluscs. Using [1-^{3}H]-glycerol, Lubet et al. [30] showed that PtdEtn and PtdCho display the highest turnover rate among phospholipids in all tissues of *M. galloprovincialis*. However, this study did not address PtdEtn *N*-methylation activity in the marine mollusc. The goal of this study was thus to characterize the ability of *M. galloprovincialis* tissues to synthesize PtdCho through this metabolic pathway.

Materials and Methods

Materials

All solvents were of analytical grade and were purchased from SDS (Peypin, France) or Sigma-Aldrich (Saint Quentin Fallavier, France). Silica gel G60 thin layer chromatography (TLC) plates were from Merck (Darmstadt, Germany). Aminopropyl columns (LC–NH_2-500 mg) were from Supelco (Saint Quentin Fallavier, France). L-[3-^{3}H]-serine and [1-^{3}H]-ethanolamine (both with a specific activity of 30 Ci/mmol) were from Amersham, UK. [methyl^{3}H]-adenosylmethionine (specific activity of 80 Ci/mmol) was from American Radiolabeled Chemicals (Saint Louis, MO, USA). PtdEtn and phosphatidyldimethylethanolamine standard and other chemicals were from Sigma–Aldrich.

Animal Experiments

The mussels *M. galloprovincialis* were obtained from a rearing farm in the Bay of Lazaret near Toulon (South of France). Animals were collected in May, at the period of sexual maturity, just before spawning. Female mussels of the same IIIA sexual stage [31] and same age (15 months) were kept in 500 l tanks with running sea water (salinity 38‰) at 17 °C for 2 weeks prior to experimentation. Water was well aerated and filtered.

To test the effect of salinity on PtdEtn *N*-methyltransferase (*Pemt)* activity, animals were acclimated to diluted-sea water (salinity 19‰) for 6 days prior to the experiments.

Mussels were injected in the foot with 10 μCi of [1-^{3}H]-ethanolamine dissolved in sterile sea water. Hemolymph was collected after various incubation times (see results) in plastic centrifuge tubes (coated with complexon K3) by cutting the posterior adductor muscle. Hemocytes were separated from hemolymph by centrifugation at 1,500 g_{av} for 15 min at 10 °C. Animals were rapidly dissected to collect gills, digestive gland and mantle which were weighed before lipid extraction.

In Vitro Incubation of Mussel Tissues

Incubations were performed at 20 °C on 100–200 mg fragments of gills, the mantle or the digestive gland in sterilized sea water containing 10 μCi/ml of [1-^{3}H]-ethanolamine or L-[3-^{3}H] serine. Samples were incubated for 3 h, washed with sea water and lipids analyzed as described below.

In Vitro labeling of Hemocytes

Hemolymph was collected from animals as described above. Hemocytes were labeled for 90 min at 20 °C by addition of 2 μCi of [1-^{3}H]-ethanolamine/ml of hemolymph. At the end of incubation, hemocytes were separated from plasma by centrifugation (1,500 g_{av} – 15 min) and washed twice with non-radioactive plasma. The lipids from hemocytes were extracted and analyzed as described thereafter. Pulse-chase experiments were also performed with [1-^{3}H]-ethanolamine in order to determine the putative exchange of lipids from hemocyte to plasma. In order to do so, hemocytes were labeled with 10 μCi of [1-^{3}H]-ethanolamine/ml of plasma at 20 °C. After 60 min of labeling, hemocytes were separated from plasma by centrifugation and washed twice with non-radioactive plasma. Prelabeled hemocytes (t_{0hr}) were then incubated for 90 min in non-radioactive plasma. At that time, hemocytes were separated from plasma (that was kept for lipid analysis), washed twice with non-radioactive plasma and lipids extracted. Radiolabeling distributions within lipids of the cells and plasma were determined.

Lipid Analysis

Lipids were extracted according to the Folch method [32], and washed according to Chapelle et al. [33] with 0.25% KCl aqueous solution (mass/vol) and deionized water. The chloroform phase was evaporated to dryness with a rotative evaporator along with absolute ethanol to remove traces of water. The sample was further dried overnight in a desiccator. Lipids were weighed, dissolved in benzene/methanol (2:1, vol/vol) and kept at −30 °C until analysis.

Phospholipid determination was performed by measuring phosphate [34] after mineralization of the molecules with sulfuric acid/perchloric acid (2:1, vol/vol) containing 0.1% V_2O_4 (mass/vol) [35]. Individual phospholipids were separated by 2-D TLC according to Portoukalian et al. [36], and detected by the phospholipid specific spray of Dittmer and Lester [37]. Individual phospholipids were quantified as described above. Amino phospholipids and choline-containing phospholipids were revealed, respectively, by ninhydrin spray and the *cis*-aconite reagent of Vaskovky and Suppes [38]. Phosphonolipids[1] were detected according to the Stillway and Harmon procedure [39].

[1] Two spots of phosphonolipids were detected on TLC plates when lipids from *Mytilus galloprovincialis* were separated by the 2D-TLC procedure used herein. ESI–MS and MS/MS analysis showed that both compounds are ceramide aminoethylphosphonate. The full characterization of these two compounds (reported as phosphonolipid X and phosphonolipid Y in this manuscript) will be described elsewhere.

Radioactivity in total lipid extracts was determined on aliquots with a Packard Tricarb ß-spectrometer and Picofluor 30 as scintillation fluid (Packard, US). Water soluble radioactivity was determined on samples of the washing phases.

Labeled phospholipids resolved by 2-D TLC and revealed by Dittmer and Lester's reagent were counted by scraping the spots into scintillation vials in which 3 ml of deionized water/ethanol (1:1, vol/vol) and 8 ml Picofluor 30 were added.

The localization of radioactivity within PtdCho and PtdEtn was performed by acetolysis as described by Renkonen [40]. Briefly, the phospholipids were isolated on a 500 mg aminopropyl column by a modification of the method described by Pietsch and Lorenz [41]. Due to the presence of phosphonolipids, PtdCho and PtdEtn fractions were further chromatographed on TLC plates with chloroform/methanol/acetic acid/water (40:10:10:1, by vol) as the solvent system. PtdCho and PtdEtn spots were visualized with iodine and separately scraped into Teflon screw-capped tubes containing 2 ml of acetic acid/acetic anhydride (3:2, vol/vol). Acetolysis was performed for 5 h at 150 °C. After completion of the reaction the formed bases and diacylglycerol acetate derivatives were extracted with chloroform/methanol/water (8:4:3, by vol). Separation of the aqueous and chloroform phases was facilitated by centrifugation. Radioactivity in the polar moiety of phospholipids was determined by liquid scintillation on an aliquot of the aqueous phase. Radioactivity in the phospholipid hydrophobic moiety was determined after separation of diacylglycerol acetate by TLC with heptane/diisopropyl ether/acetic acid (60:30:3, by vol) as solvent system.

Analysis of fatty acids in PtdCho was performed as follows. PtdCho was isolated on a 500 mg aminopropyl-bonded silica gel column according to the method of Pietsch and Lorenz [41]. The fraction containing PtdCho was dried down under nitrogen and further separated by TLC using chloroform/methanol/acetic acid/water (40:10:10:1, by vol) as solvent system. PtdCho was detected with Dittmer and Lester reagent, scraped into Teflon screw-capped tube and transesterified as previously described [42]. The fatty acid methyl esters were analyzed by gas chromatography on a Chrompack CP 9000 apparatus equipped with a flame ionization detector and a 30 m Omegawax 250 glass capillary column. Nitrogen was used as the carrier gas. Fatty acid methyl esters were separated as previously described [43] and peak areas were calculated using the Maestro integration software from Chrompack.

PtdEtn *N*-Methyltransferase Assay

Pemt was assayed on the microsomal fraction according to the method described by Ridgway and Vance [44]. Briefly, homogenates of mussel tissues were prepared in 10 mM Tris–HCl (pH 7.2) containing 150 mM NaCl and 1 mM each of dithiothreitol, EDTA and phenylmethylsulfonyl fluoride. The tissues were homogenized in a Potter–Elvehjem apparatus. The microsomal fraction obtained by ultracentrifugation at 100,000 g_{av} was kept for *Pemt* assay. *Pemt* activity was performed in 125 mM Tris–HCl (pH 9.2) containing 5 mM dithiothreitol, 1 mM triton X-100, 200 µM [methyl-^{3}H]-AdoMet, 2 mM PtdEtn and 0.4 mM of phosphatidyldimethylethanolamine. The samples were incubated at 37 °C for 30 min. The assay was stopped by addition of 4 ml of chloroform—methanol (2:1, v/v). The lipids were washed as described above and PtdCho was separated from other phospholipids (including phosphatidylmonomethylethanolamine and phospshatidyldimethylethanolamine) by 2-D TLC [36]. Phospholipids were revealed with Dittmer and Lester reagent [37], and radioactivity within PtdCho determined by liquid scintillation. *Pemt* activity was determined on tissues isolated from individual mussels excepted for hemocytes for which activity was assayed on samples pooled from several individuals, due to the limited amount of tissue.

Statistical Analysis

Statistical analysis was performed with SAS software after ratios were transformed to their arcsine [45]. Statistical comparisons between means were performed using one and two-way ANOVA. If the test for normality (Kolmogorov–Smirnov) failed, a non-parametric Kruskal–Wallis one-way ANOVA on ranks was used.

Results

We first determined the phospholipid content in the major tissues of *M. galloprovincialis*. We found that total phospholipids represent 1.12 ± 0.08, 1.42 ± 0.13 and 1.99 ± 0.17% of fresh weight in the gills, the mantle, and the digestive gland, respectively. These data are similar to the one reported for *Mytilus edulis* [23, 46] and *M. galloprovincialis* [30]. Individual phospholipids composition is very similar to the one previously reported by Lubet et al. [30], and are thus not reported herein. PtdCho and PtdEtn were the main phospholipids and represented 70–80% of total phospholipids in the main tissues.

We then studied the in vivo incorporation of [1-^{3}H]-ethanolamine within the tissues and lipids of *M. galloprovincialis*. In all organs most of the radioactivity (between 92 and 95% of total radioactivity) was found in the water soluble and lipid fractions. The radioactivity measured in the chloroform/methanol extract insoluble fraction (mainly made of proteins) accounted for only

5–8% of the total radioactivity in the tissues. Figure 1 shows the kinetics and distributions of [1-^{3}H]-ethanolamine-derived labeling within the waters soluble and lipid fractions in hemolymph, the mantle, the digestive gland and gills during the 72 h following the radio-precursor injection. The highest concentrations of [1-^{3}H]-ethanolamine-derived radioactivity were found in the digestive gland followed by the mantle, the gills and hemolymph. In all tissues, a progressive decrease in labeling in the water soluble fraction was observed with a concomitant radioisotope accumulation in the lipid fraction. Again the digestive gland displayed the highest labeling of lipids. In this tissue, a strong and sustained increase in labeling of lipids was observed up to 72 h following [1-^{3}H]-ethanolamine administration. Similar observation was made in gills where lipid labeling was, within 24 h, increased ~ twofold at a level that remained stable till 72 h. In the hemolymph and the mantle, a maximal lipid labeling was observed 24 h following the administration of [1-^{3}H]-ethanolamine. The increase in labeling observed during the first 24 h was followed by a ~50% decrease of radioactivity level during the next 48 h, showing a different kinetic in these tissues when compared to the one in gills and the digestive gland.

We next examined the distribution of [1-^{3}H]-ethanolamine labeling within the lipids (see Table 1). The distribution of [1-^{3}H]-ethanolamine within the lipids remained relatively constant in each tissue throughout the 72 h of experiments, as shown by the small variation of percentages (Table 1). In all tissues, the radioactivity was mainly incorporated into PtdCho and PtdEtn that concentrated from ~79 to ~92% of the total lipid radioactivity. [1-^{3}H]-ethanolamine-derived labeling was observed in PtdCho in all tissues. Plasma displayed a particularly high proportion of labeled PtdCho (~21% of total lipid radioactivity) when compared to other tissues (from ~7 to ~10% of total lipid radioactivity). The percentage of radioactivity recovered within neutral lipids of plasma and hemocytes was also higher than in other tissues.

This labeling of PtdCho with [1-^{3}H]-ethanolamine suggests that PtdEtn *N*-methylation occurs in the tissues of the mussel *M. galloprovincialis*. However, this PtdCho labeling may also be explained by the putative incorporation of catabolic products of ethanolamine into the fatty acyl and/or glycerol moiety of the phospholipid. To test this possibility acetolysis of PtdEtn and PtdCho was performed and radioactivity within the acetyl-diacylglycerol or head group moieties of the molecules determined. Hence, 48 h after [1-^{3}H]-ethanolamine injection, 55 and 75% of labeling into PtdCho of the digestive gland and plasma were found in the choline moiety of the phospholipid (Fig. 2a). In PtdEtn, 80 and 70% of labeling were detected in the ethanolamine moiety of the molecule isolated from the digestive gland and the plasma respectively (Fig. 2b). These results show that the *N*-methylation pathway of PtdEtn to PtdCho takes place at a significant rate in *M. galloprovincialis.*

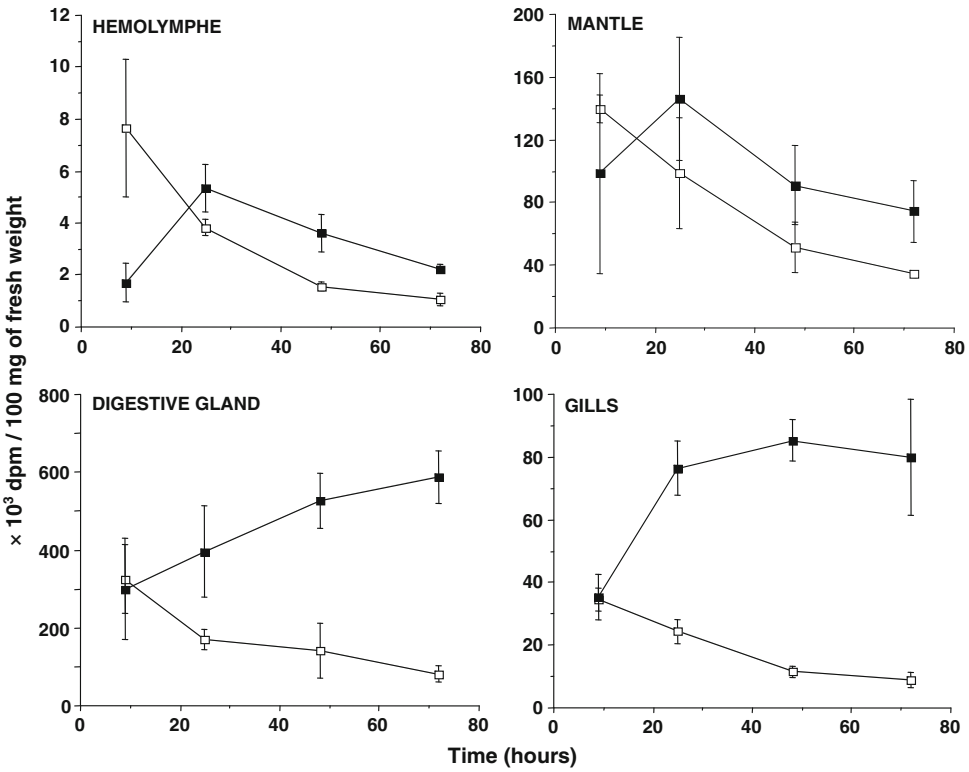

Fig. 1 Distribution of [1-^{3}H]-ethanolamine-derived radioactivity in the water soluble and lipid fractions from *M. galloprovincialis* tissues. Mussels were administered 10 μCi of [1-^{3}H]-ethanolamine as described in the methods section. The different tissues were collected at 9, 24, 48 and 72 h, weighted and lipids were extracted. Radioactivity was determined in the water soluble fraction (*empty squares*) and in the total lipid fraction (*full squares*). Results are averages ± SEM of 5 independent experiments

Table 1 In vivo distribution of [1-^{3}H]-ethanolamine in the lipids *of M. galloprovincialis*

	Mantle	Gills	Digestive gland	Plasma	Hemocytes
Phosphonolipids

Animals were injected with 10 μCi of [1-^{3}H]-ethanolamine as described in the methods section. After 9, 24, 48, and 72 h the tissues were collected and lipids extracted and purified. The lipids were separated by 2-D TLC and radioactivity determined by liquid scintillation. Results are expressed as the percentage of radioactivity within total lipids. As the distribution of the radioactivity remained the same during the 72 h period, the results are expressed as averages ± SEM (20 animals) between the 9, 24, 48, and 72 h labeling periods. Values with a common superscript show a statistical difference ($p < 0.01$) between tissues in the distribution of radioactivity within an individual lipid

We also determined the specific activity of total phospholipids, PtdEtn and PtdCho in the different tissues of *M. galloprovincialis*. The results (see Table 2) show that the highest specific activities in total phospholipids were observed in the digestive gland and plasma. This was also true for PtdCho that displayed in plasma and the digestive gland a specific activity that was ~5 and ~4.5 times higher than in gills and in the mantle. Interestingly, the specific activity of PtdCho in plasma was very similar to the one in the digestive gland (see Table 2), with a ratio of PtdCho specific activities of ~1.1 between plasma and the digestive gland. This strongly suggests that [1-^{3}H]-ethanolamine-derived PtdCho in plasma is synthesized in the digestive gland through PtdEtn *N*-methylation. This relationship is further illustrated in Fig. 2.

As shown in Fig. 2a, the variation of PtdCho specific radioactivity in hemolymph was correlated ($r = 0.47$, $p < 0.01$) to the one in the digestive gland. The PtdCho specific radioactivity ratios (PtdCho SA in plasma/PtdCho SA in the digestive gland) were effectively not statistically different of 1 after Asin transform (ratios were respectively, 0.87 ± 0.16, 1.42 ± 0.29, 1.20 ± 0.21 and 1.36 ± 0.13 at 9, 24, 48 and 72 h following the label injection). At the opposite, differences were observed in PtdEtn specific activities between plasma and the digestive gland 48 and 72 h following [1-^{3}H]-ethanolamine administration (Fig. 2b). The similar specific activity of [1-^{3}H]-ethanolamine-labeled PtdCho between plasma and the digestive gland strongly suggests that the digestive gland exchanges the newly formed PtdCho with plasma.

We next determined the fatty acid composition of PtdCho purified from the different tissues. The results show that, in all tissues, palmitic (16:0), stearic (18:0), arachidonic (20:4n-6) eicosapentaenoic (20:5n-3) and docosahexaenoic acids (22:6n-3) are the major fatty acids in this phospholipid (see Table 3). These fatty acids accounted for ~76 to ~80% of all fatty acids in PtdCho. The percentage of palmitic and stearic acids was ~1.8-fold higher in plasma and the digestive gland when compared to the mantle and gills. At the opposite, the percentage of docosahexaenoic acid was 2.1-fold lower in plasma and the digestive gland when compared to other tissues. The major observation was that fatty acid composition of PtdCho from plasma is similar to the one of PtdCho isolated from the digestive gland. There was a significant positive correlation between plasma and the digestive gland for 22:6n-3 ($r = 0.53$, $p < 0.001$) the sum of the n-3 PUFA ($r = 0.45$, $p < 0.005$) and n-6/n-3 PUFA ratio ($r = 0.47$, $p < 0.002$).

We then tested the ability of the different tissues to synthesize PtdCho through the PtdEtn *N*-methylation pathway In vitro. In the mantle, gills and the digestive gland, most of [1-^{3}H]-ethanolamine labeling of lipids was recovered into PtdEtn. This phospholipid concentrated from ~87 to ~91% of total lipid radioactivity in these tissues (see Table 4). In the digestive gland, a small but significant part of labeling was observed into PtdCho. Acetolysis of PtdCho purified from the digestive gland showed that ~70% of [1-^{3}H]-ethanolamine-derived labeling was recovered in the choline moiety of the molecule. This was not the case in the mantle and gills where most of PtdCho labeling was detected in the diacylglycerol moiety of the phospholipid. These in vitro observations show that the digestive gland is the place of an active PtdCho synthesis through the PtdEtn *N*-methylation pathway. We also studied the in vitro incorporation of [1-^{3}H]-ethanolamine within the lipids of hemocytes. Surprisingly, the distribution of the precursor in the lipids of these cells was very different when compared to other tissues (see Table 4). Most of the radioactivity (~60%) was found in the neutral

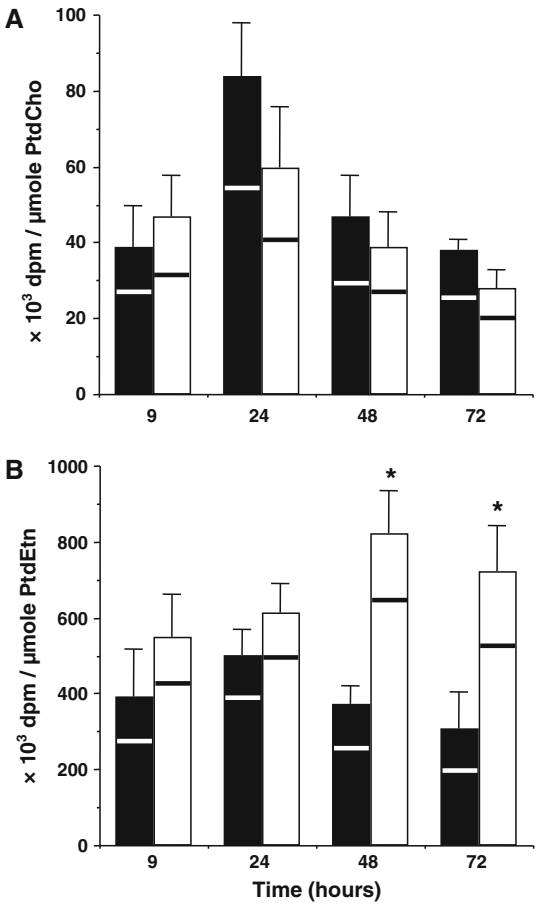

Fig. 2 PtdCho and PtdEtn specific radioactivities in the plasma and the digestive gland of mussels were administered 10 µCi of [1-^{3}H]-ethanolamine as described in methods. Digestive gland and hemolymph were collected at different times after the radio-precursor administration. Plasma was prepared by centrifugation of hemolymph. Lipids were extracted from tissues and phospholipids separated by 2-D TLC. PtdCho and PtdEtn were quantified and radioactivity determined. Panels **A** and **B** respectively, show the specific radioactivities of PtdCho and PtdEtn. Results are averages ± SEM of 5 different experiments and specific radioactivities are expressed as $\times 10^3$ dpm/µmol of PtdCho or PtdEtn. *White* and *black bars* respectively, represent the specific activities in the digestive gland and plasma. The horizontal *black* and *white lines* within the *white* and *black bars*, respectively, represent the extent of labeling recovered within polar head groups (area under the *black* and *white lines*) based on acetolysis of the molecules. *Asterisks* indicate statistical differences between the digestive gland and plasma ($p < 0.01$)

lipid fraction. PtdCho was the phospholipid displaying the highest [1-^{3}H]-ethanolamine-derived labeling along with PtdEtn and the phosphonolipid X. Acetolysis of PtdEtn and PtdCho from hemocytes showed that more than 70% of radioactivity was incorporated into ethanolamine and choline, respectively. These observations demonstrate that, like the digestive gland, hemocytes express an active PtdEtn *N*-methylation pathway. We also found that total phospholipid concentrations are ~5 times higher in hemocytes than in plasma (respectively, 103 ± 69 µg and 17.8 ± 7.8 µg/100 mg of the fresh weight; $n = 5$). Despite this difference we observed that the individual phospholipid composition of hemocytes is similar to the one of plasma except the absence of Diphosphatidylglycerol (Ptd_2Gro) in the latter and that the percentage of Lysophosphatidylcholine (LysoPtdCho) was approximately doubled in plasma compared to cells (see Table 5). We thus performed pulse-chase experiments with [1-^{3}H]-ethanolamine in order to address the occurrence of putative exchange of lipids from hemocytes to plasma. After 60 min of incubation a strong labeling was observed in hemocytes with lipids representing ~1.1% of the total label incorporation (see Table 5). After 90 min of chase in non-radioactive plasma, a transfer of lipids from the cells to the plasma was observed as illustrated by the appearance of radioactivity in the plasma lipid fraction. Interestingly the distribution of [1-^{3}H]-ethanolamine-derived radioactivity within plasmatic lipids was similar with the one in hemocytes at the exception of Phosphatidylinositol (PtdIns) and the phosphonolipid Y that were poorly or not exchanged with plasma (see Table 5). The data also show that the PtdCho synthesized in hemocytes via the PtdEtn *N*-methylation pathway is partly exchanged with plasma inasmuch [1-^{3}H]-ethanolamine-labeled PtdCho was measured in this tissue.

We also performed in vitro labeling experiments with L-[3-^{3}H] serine on the two tissues (digestive gland and hemocytes) in which we observed an active PtdCho synthesis via the PtdEtn *N*-methylation pathway. L-[3-^{3}H] serine was chosen as radio-precursor since it labels a pool of PtdEtn after decarboxylation of Phosphatidylserine (PtdSer). The results in Fig. 3 show that in both tissues an important fraction of L-[3-^{3}H] serine-derived labeling was recovered into PtdCho. Positional analysis of labeling into PtdCho purified from both tissues showed that ~80% of the radioactivity was in the choline moiety of the molecule (Fig. 3). These data show that PtdCho synthesis occurred through the PtdEtn *N*-methylation pathway, confirming the data obtained in vivo and in vitro with [1-^{3}H]-ethanolamine. Figure 3 also demonstrates that in hemocytes most of L-[3-^{3}H] serine labeling was observed into PtdEtn (~73% of total phospholipids labeling), suggesting an active PtdSer decarboxylation in this tissue, at least under our experimental conditions. The phosphonolipids X and Y concentrated also a significant part of L-[3-^{3}H]-serine labeling with respectively ~8 and ~11% of total phospholipids radioactivity in hemocytes and the digestive gland.

We finally determined *Pemt* activity within the tissues of *M. galloprovincialis* acclimated either to sea water or diluted-sea water. Our first attempts on crude tissue homogenates without exogenously supplied PtdEtn and phosphatidyldimethylethanolamine were unsuccessful as

Table 2 Main phospholipids specific radioactivities in the tissues of *M. galloprovincialis*

	Total phospholipids	PtdCho	PtdEtn
Plasma	110.9 ± 15.8	56.4 ± 15	368.6 ± 37.9
Gills	45.6 ± 5.3	11.7 ± 3.1	100.3 ± 11.5
Mantle	63.7 ± 14.9	9.4 ± 3	112.1 ± 11.5
Digestive gland	188.1 ± 25.1	48.8 ± 11.3	655.1 ± 94

Animals were injected with 10 μCi of [1-^{3}H]-ethanolamine as described in the methods section. After 9, 24, 48, and 72 h the lipids were extracted and purified from the different tissues. The phospholipids were separated by 2-D TLC and radioactivity determined by liquid scintillation. Quantification of total lipids, PtdCho and PtdEtn were also performed by phosphate determination as described in the methods section. Specific radioactivity is expressed in $\times 10^3$ dpm/μmol of lipid phosphorus. The values are the means ± SEM (20 animals) of the different determinations undertaken during the 72 h experimental period

22:5n-3	1.7 ± 0.5	2.1 ± 0.3	2.1 ± 0.2	2.7 ± 0.1
22:6n-3	12.2 ± 0.3	14.0 ± 1.9	23.6 ± 2.8	31.2 ± 1.9

Lipids were extracted and purified from mussel tissues. PtdCho was purified by solid phase extraction on an aminopropyl column and TLC. The phospholipid was transesterified and methyl fatty acids were analyzed by gas chromatography as described in the methods section. The results are expressed as percent of total fatty acids and are average ± SEM of six independent experiments

N.D Not detected

the activity was very low (~0.3–0.4 nmol of methyl group transferred/min/mg of protein in the digestive gland). The activity at 37 °C was much higher than at room temperature (i.e., close to the acclimation temperature of animals) and therefore this temperature was used. We thus determined *Pemt* activity on tissue microsomal fraction according to the procedure described by Ridgway and Vance [44]. Figure 4 shows that the highest *Pemt* activities were recovered within the digestive gland and hemocytes. *Pemt* activities determined within the mantle and gills were respectively ~11 and ~17 lower when compared to the digestive gland from sea water acclimated animals (Fig. 4). We also determined *Pemt* activity on tissues isolated from animals acclimated to diluted-sea water. In these conditions, *Pemt* activities were reduced by respectively, ~36, ~45 and ~55% in gills, hemocytes and the digestive gland when compared to sea water acclimated animals. A ~20% but non-significant decrease ($p = 0.16$) in *Pemt* activity was measured in the mantle of diluted-sea water animals.

Discussion

The major observation of this study is that the mussel *M. galloprovincialis* can synthesize PtdCho through the PtdEtn *N*-methylation pathway in at least two tissues, the digestive gland and the hemocytes. The occurrence of PtdEtn *N*-methylation activity in *M. galloprovincialis* may not be surprising if we consider the fact that biosynthesis of PtdCho by *N*-methylation of PtdEtn is widely expressed throughout evolution, from PtdCho biosynthesizing bacteria to mammals, although enzyme sequences differ substantially between prokaryotes and eukaryotes [1, 47]. In higher vertebrates such as mammals, the PtdEtn *N*-methylation pathway is mainly expressed in the liver [2, 4] with discrete activity in some other tissues such as kidney and cell types such as leucocytes and reticulocytes [11, 48, 49]. We previously showed that the liver/hepatopancreas is also the main site of the PtdEtn *N*-methylation pathway in euryhaline fish and crustaceans [5, 17, 20]. However, there

Table 4 Distribution of [1-^{3}H]-ethanolamine in lipids after in vitro incubation of *M. galloprovincialis* tissues

	Mantle	Gills	Digestive gland	Hemocytes

Hemolymph was collected and hemocytes separated from plasma as described in the methods section. The lipids were extracted, phospholipids separated by 2-D TLC and quantified

Phospholipid composition is expressed as percentage of total phosphorus and results are average ± SEM of 5 determinations

Exchange of lipids from hemocytes with plasma was studied as follows. Hemocytes in 10 ml of plasma were labeled with 100 μCi of [1-^{3}H]-ethanolamine for 60 min at 20 °C. Hemocytes were then separated from plasma and washed with non-radioactive plasma. Prelabeled hemocytes (t_{0hr}) were incubated for 90 min in non-radioactive plasma. At that time, hemocytes were separated from plasma, washed and lipids extracted and analyzed. Radiolabeling distribution was determined on the cells and plasma as described in the methods section. [1-^{3}H]-ethanolamine-derived radioactivity is expressed as % of the total radioactivity recovered on the TLC plate. Results are averages ± SD of 3 independent experiments

was no information available on PtdCho biosynthesis by *N*-methylation of PtdEtn in molluscs and the tissues where this metabolic pathway might take place.

The in vivo labeling of *M. galloprovincialis* with [1-^{3}H]-ethanolamine shows that the highest PtdEtn and PtdCho specific activities were observed in the digestive gland and

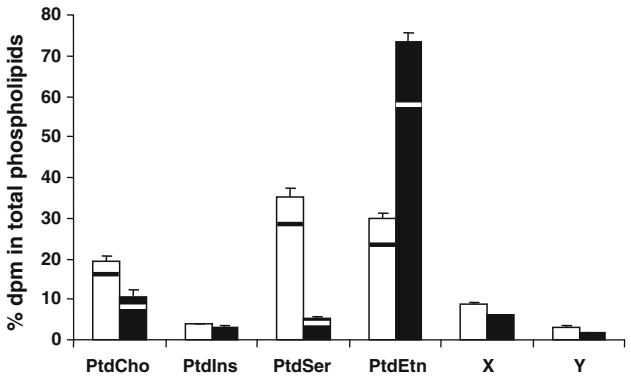

Fig. 3 L-[3-^{3}H]-serine labeling of phospholipids in hemocytes and the digestive gland. The digestive gland and hemocytes were incubated in sterile sea water for 3 h at 20 °C with 10 μCi/ml of L-[3-^{3}H] serine as described in the methods section. The tissues were washed, lipids extracted and phospholipids separated by 2-D TLC. Radioactivity in the different spots was determined by liquid scintillation. *White* and *black* bars respectively, represent the digestive gland and hemocytes. The horizontal *black* and *white lines* within the *white* and *black bars*, respectively, represent the extent of labeling recovered within polar head groups (area under the *black* and *white lines*) based on acetolysis of PtdSer, PtdEtn and PtdCho. The results are averages ± SD of 4 different experiments and the results are expressed as % of total radioactivity recovered in total phospholipids

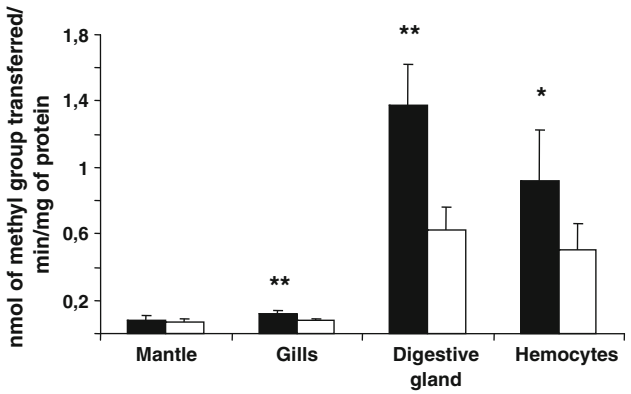

Fig. 4 Effect of salinity on *Pemt* activity in tissues of *M. galloprovincialis* mussels were acclimated to sea water or diluted-sea water for 6 days. Tissues were quickly removed and underwent a *Pemt* assay as described in the methods section. *Black* and *white bars* respectively, represent sea water and diluted-sea water acclimated animals. Data are the averages ± SD of 5 different experiments. *Asterisks* indicate statistical differences between sea water and diluted-sea water acclimated animals (*$p < 0.05$, **$p < 0.001$)

the plasma (Table 2). Phospholipid acetolysis demonstrated that the [1-^{3}H]-ethanolamine-derived labeling was mainly located in the polar head groups of the molecules confirming that the digestive gland can synthesize PtdCho through the PtdEtn *N*-methylation pathway. The PtdCho specific activities in plasma and the digestive gland were very similar suggesting a precursor relationship between these two tissues. We thus compared the kinetics of specific activities into PtdCho from the digestive gland and plasma (Fig. 2a). The results show that, at the opposite of what was observed for PtdEtn (Fig. 2b), no statistical differences could be observed in the specific activities of PtdCho in these two tissues. These observations demonstrate that the [1-^{3}H]-ethanolamine-derived PtdCho, i.e., the PtdCho synthesized by *N*-methylation of PtdEtn in the digestive gland is exchanged with plasma. Our previous results have shown a similar phenomenon in fish and crustaceans where the PtdCho synthesized by *N*-methylation of PtdEtn in the liver/hepatopancreas is exchanged with the plasma of these animals [5, 20]. Interestingly, a role for the PtdEtn *N*-methylation pathway in VLDL lipoprotein secretion has been demonstrated in the liver of *Pemt* –/– mice [50–52]. Fatty acid analysis of PtdCho purified from the digestive gland and plasma also support that there is a precursor relationship between PtdCho synthesized in both tissues of *M. galloprovincialis*. This phospholipid effectively expressed similar fatty acid composition in the two tissues, with a particularly high proportion of palmitic acid and, in contrast, a lower proportion of docosahexaenoic acid when compared to the PtdCho of the mantle and gills (Table 3). Despite these tissue differences in the phospholipid docosahexaenoic acid content, this fatty acid was one of the most expressed, an observation similar to the one reported by others in the mussel *M. edulis* [53]. The metabolic data and PtdCho fatty acid profiles suggest that the digestive gland in the mussel *M. galloprovincialis* insures similar functions in PtdCho synthesis by *N*-methylation of PtdEtn as it is known for the liver in fish and mammals and for the hepatopancreas in crustaceans [20]. The digestive gland is the only tissue where the specific activities of PtdCho and fatty acid composition were similar to the ones in hemolymph.

During in vivo experiments, we also observed a substantial amount of [1-^{3}H]-ethanolamine-derived labeling within Lysophosphatidylethanolamine (LysoPtdEtn) of the digestive gland. In this tissue the lysophospholipid concentrated 3.1 ± 0.4% of radiolabeling. There was no evidence for a LysoPtdEtn-forming activity in other tissues (Table 1) or in vitro (Table 4). The explanation for the specific occurrence of LysoPtdEtn labeling from [1-^{3}H]-ethanolamine within the digestive gland in vivo is not clear. It suggests that the digestive gland may express particularly active metabolic pathway(s) producing this lysophospholipid in vivo. Hax and van Kessel [54] reported the occurrence of LysoPtdEtn within the tissues of the mollusc *Helix pomatia*. Sajiki also reported pH-dependant phospholipase A1 and A2 activities towards PtdEtn in the digestive gland of oysters [55]. Although several biological functions, such as signal transduction, have been attributed to some lysophospholipids (especially lysophosphatidic acid) [56], little is known about LysoPtdEtn [57]. However, antimicrobial activity [58], induction of PC12 cells differentiation [59] and chemotactic migration [60] have been

reported for this lysophospholipid. The occurrence of [1-^{3}H]-ethanolamine-derived labeling within LysoPtdEtn in the digestive gland may simply reflect active remodeling of phospholipids taking place in this tissue which plays a central role in food digestion. Hence LysoPtdEtn expression and labeling in the digestive gland may be the result of concerted actions of phospholipases and reacylation to PtdEtn. A specific LysoPtdEtn acyltransferase has recently been characterized in *Saccharomyces cerevisiae* but the relevance of this observation for animals has still not been established [61].

We also observed that LysoPtdCho relative concentrations in plasma are approximately twice higher than the other tissues (for instance, compare plasma and hemocytes, Table 5). This proportion of LysoPtdCho in plasma is interesting on the basis of what is known about the transport functions that have been ascribed to the lysophospholipid in mammals. When bound to plasma albumin, LysoPtdCho has been shown to be a preferred form of DHA transport to the brain (for a review see [62, 63]). That LysoPtdCho is involved in hemolymph transport of long chain PUFA to tissues in molluscs is thus a tempting hypothesis, but we did not characterize its fatty acid composition.

[1-^{3}H]-Ethanolamine in vitro labeling of tissues strengthens the observations made in vivo. Among the main tissues, the digestive gland was the only one where a significant labeling of PtdCho could be observed, even though the percentage of label recovered within PtdCho was low when compared to in vivo experiments ($\sim$2.8% of total phospholipids radioactivity was recovered into PtdCho when the digestive gland was labeled in vitro versus $\sim$10% in vivo—compare Tables 1 and 4). In vitro, most of the label incorporated into phospholipids was within PtdEtn. Acetolysis of PtdCho isolated from in vitro radiolabeled mantle and gills showed that the low amount of radioactivity recovered in the phospholipid was located in the diacylglycerol moiety of the molecule, the opposite of what was observed in PtdCho purified from the digestive gland.

These different in vitro and in vivo observations point to the digestive gland as the tissue where PtdEtn *N*-methylation is taking place. The in vivo [1-^{3}H]-ethanolamine-derived labeling observed in PtdCho of the mantle and gills may thus be the result of redistribution of the PtdCho synthesized in the digestive gland and exchanged with plasma. Some authors have shown the existence of lipoproteins in the plasma of marine and freshwater bivalves [27, 28]. These authors demonstrated in the pacific oyster (*Crassostrea gigas*) and a freshwater mollusc (*Diplodon delodontus*) that radiolabeled fatty acids were recovered in the plasma lipoproteins and to a lesser extent in hemocytes, and suggested that these structures were involved in lipid transport in molluscs. Our results in *M. galloprovincialis* are in agreement with those reported by these authors on the levels of phospholipids measured in the plasma of *C. gigas* and *D. delodontus*.

However, we were also able to show that, in addition to the digestive gland, PtdEtn *N*-methylation occurs in hemocytes at a significant rate. In vivo radiolabeling of mussels with [1-^{3}H]-ethanolamine showed that $\sim$9.3% of total lipid radioactivity in hemocytes was recovered in PtdCho (see Table 1), with most of the label in the choline moiety of the molecule. In vitro experiments with hemocytes showed that PtdCho concentrated the most [1-^{3}H]-ethanolamine-derived labeling within phospholipids (Table 4). These results demonstrate that an active PtdEtn *N*-methylation pathway is expressed in hemocytes. Pulse-chase experiments with hemocytes indicated that the [1-^{3}H]-ethanolamine-labeled lipids (including PtdCho) synthesized by the cells were partly exchanged with plasma (see Table 5). Thus it appears that plasmatic PtdCho originates from at least two sources: the digestive gland and hemocytes. Unfortunately we were unable to quantify the relative contribution of these tissues in the synthesis of plasmatic PtdCho derived from PtdEtn *N*-methylation. The limited amount of hemocytes enabled us to determine reliably the specific activity of PtdCho in unique samples of these cells. However, it is reasonable to assume that most of [1-^{3}H]-ethanolamine-derived PC in plasma originates from digestive gland because of the close relationship in the specific activities of the phospholipid in these two tissues (Fig. 2a) and because of the low amount of hemocytes in the plasma of *M. galloprovincialis* (we found that less than 1% of hemolymph volume was made of hemocytes).

We also determined *Pemt* activities within the different tissues of *M. galloprovincialis* (Fig. 4). The data confirm that the active PtdEtn *N*-methylation pathway occurs within the digestive gland and hemocytes, strengthening the conclusions based on in vivo and in vitro labeling with [1-^{3}H]-ethanolamine. Acclimation to diluted-sea water caused a reduced *Pemt* activity (Fig. 4). This demonstrates that PC biosynthesis through the PtdEtn *N*-methylation pathway is regulated by environmental salinity, similar to what was reported in fish [5, 19], euryhaline crustaceans [20] and plants facing dryness [64].

Among the few metabolic studies of phospholipids metabolism in molluscs [30, 65, 66] this study is the first to address PtdCho biosynthesis through PtdEtn *N*-methylation in such animals.

Our interest in the PtdEtn *N*-methylation pathway in marine molluscs lies in our previous observations showing that acclimation of euryhaline fish and crustaceans to sea water (i.e., hypertonic conditions with respect to cellular osmolarity) resulted in an activation of *N*-methylation of

PtdEtn into PtdCho that was rapidly exchanged with plasma/hemolymph [5, 17, 20]. We also showed that this PtdCho was used as a precursor for the synthesis of betaine, an important organic osmolyte derived from choline [20]. The PtdEtn *N*-methylation pathway is effectively the only known biosynthetic pathway for choline synthesis in animals [4], whereas plants display active *N*-methylation of phosphorylethanolamine [67]. In the water-stressed barley plant *Hordeum vulgare* Hitz et al. [64] demonstrated a precursor-product relationship between the PtdCho arising from the PtdEtn *N*-methylation pathway and betaine synthesis. In *Pemt* knockout mice a relation between the PtdEtn *N*-methylation pathway and betaine synthesis is suggested by the observations that liver concentrations of this choline metabolite were decreased in female fed a standard diet [68]. Interestingly, *M. galloprovincialis* is known to accumulate high concentrations of betaine when the animal is facing hyperosmotic conditions such as in sea water [69]. These authors demonstrated that moving *M. galloprovincialis* from diluted-sea water (salinity 19‰) to sea water (salinity 38‰) resulted in a 87% increase in tissue betaine concentrations two days after transfer. They also demonstrated that *M. galloprovincialis* displays the ability to synthesize betaine from choline. In similar salinity conditions (see the methods section) we observed a significant effect of salinity on *Pemt* activity (Fig. 4). It is thus tempting to hypothesize that the physiological role described for the PtdEtn *N*-methylation pathway in fish [5, 19] and crustaceans [20] hyperosmotic response may also be relevant in marine molluscs. However, we were unable to measure betaine radiolabeling in plasma during our in vivo experiments due to the small amount of tissue available from animals. The present report characterizing PtdEtn *N*-methylation activity in *M. galloprovincialis* should pave the way to addressing the putative relationship between the PtdEtn *N*-methylation pathway and betaine synthesis in molluscs.

wide range of mono- and disaccharides as well as branched polysaccharides. The optimal temperature for growth is 68 °C (range 50–73 °C) and pH 5.3 (range 4.7–5.8) [2].

The lipid composition of *C. calidirosea* presents a number of unusual features both in the fatty acids and polar lipids. The present publication describes fatty acids of this unique organism, including the discovery of a novel, 5,6-methylene hexadecanoic acid. While polar lipids observed in *C. calidirosea* resembled those reported for *Deinococcus radiodurans*, the polar lipids of the latter contained monoenoic acids only of Δ7, Δ9 and Δ11 series, with up to 11% of unidentified fatty acids [3, 4], and it was highlighted that no cyclopropanoic acids were found [5]. A combination of chemical and instrumental techniques (GC, GCMS, TLC, SPE, preparative HPLC, hydrogenation of unsaturated fatty acids, a cyclopropane ring opening by hydrogenation in glacial acetic acid, formation of DMDS adducts and TMS derivatives, IR, and ^{1}H-NMR) was applied to identify all fatty acids present in the organism at levels above 0.2% of total fatty acids. Characteristic features of *C. calidirosea* seem to be the presence of normal and branched chain *cis*-Δ5 monounsaturated fatty acids and 5,6-methylene hexadecanoic acid. The latter feature makes *C. calidirosea* unique, since cyclopropane fatty acids found in bacteria usually belong to *cis*-9,10-methylene- or *cis*-11,12-methylene families [6], with less common *trans*-4,5-methylene pattern reported for cyanobacteria [7, and references therein].

Materials and Methods

Lipid Extraction

Chthonomonas calidirosea was cultivated as described in [2]. Wet biomass was extracted using the method of Bligh and Dyer [8]. Freeze-dried biomass was extracted by the same method after re-constituting with tenfold excess of water (by weight).

Thin-Layer Chromatography

Neutral lipids were resolved by high performance thin-layer chromatography (HPTLC) on 10 × 10 cm Silica gel 60 glass plates (Merck, Germany) in hexane/diethyl ether/glacial acetic acid (80:20:1, by vol) with the following reference compounds: cholesterol, cholesterol oleate, triolein, 1,2- and 1,3-dipalmitoyl glycerol, 1-monopalmitoyl-glycerol, and oleic acid (Sigma, USA; and IRL own collection of reference lipid compounds). Resolution of diploptene, squalene and partially hydrogenated squalenes was achieved by development of a HPTLC plate with chloroform for 1/3 of height, drying in warm air, followed by development in hexane up to full height [9]. Preparative TLC in hexane was used for isolation of individual neutral lipid classes. Edges of zones were detected by iodine vapours after covering the developed and air-dried plate with a clean glass plate. Zones were each scraped and eluted with 1 ml hexane. Identities of components were established either by direct injections of fractions into GCMS, or by hydrogenation followed by GCMS.

Non-specific detection of organic compounds on TLC plates was performed with the use of iodine vapours or by charring with 5 or 10% (by vol) sulphuric acid in methanol. To improve detection of saturated compounds, charring with molybdate spray [10] was found useful.

Fatty Acids Analysis

Fatty acid methyl esters were prepared from small samples of biomass without lipid extraction and analysed as described by Svetashev et al. [11].

For detailed analysis, fatty acid methyl esters were prepared from the lipid extracts according to the method of Carreau and Dubacq [12], and purified by SPE on a 500 mg Strata SI-1 cartridge (Phenomenex, USA) conditioned with hexane. Hydrocarbons were eluted with 3 ml of hexane and used for diploptene/squalenes detection, and fatty acids methyl esters (FAME) were eluted with 6 ml of hexane-diethyl ether (99:1, by v/v). The method used was identical to the third procedure presented elsewhere [13], with the only exception being the use of a SPE cartridge in place of a Silica gel 60 column.

GC analysis of fatty acid methyl esters was performed on a TraceGC Ultra instrument (ThermoFinnigan, USA), equipped with FID and 30 m, 0.32 mm i.d. BP20 polyethylene glycol capillary column (SGE, Australia). Helium was used as the carrier gas; the split ratio was 1:60. Separation temperature was 195 °C. When non-polar BP1 (60 m, 0.32 mm i.d.) methyl silicone capillary column (SGE, Australia) was used, the separation temperature was maintained at 220 °C. For calculation of equivalent chain length (ECL) of methyl esters of 5- and 6-methyl hexadecanoic acids, the oven temperature was maintained at 150 °C. Fatty acids were identified by the use of reference compounds, the known ECL values for methyl silicone column [14], and by GCMS (see below). Hydrogenation of fatty acid methyl esters was performed according to Appelquist [15]. Dimethyl disulfide (DMDS) adducts formation [16] was used to locate the position of the double bond in monounsaturated fatty acids [17].

To open a cyclopropane ring, hydrogenation of the sample in glacial acetic acid over PtO_2 catalyst [18] was performed for 6 h at room temperature, as described by Saito and Ochiai [19].

Trimethylsilyl derivatives were prepared by dissolving approximately 0.2 mg of the sample in 10 µl of pyridine, and 30 µl of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane (Aldrich, USA). The reaction mixture was maintained for 30 min at 60 °C. The sample was either analysed directly, or was evaporated under a stream of argon and re-dissolved in 0.5 ml of hexane prior to the injection.

GCMS analyses were performed on an Agilent 5890N gas chromatograph equipped with a 5973 Inert mass-spectrometric detector and HP-5 capillary column (30 m, 0.32 mm i.d.; Hewlett-Packard, USA). Helium was used as the carrier gas. Analysis of FAME was initiated at 100 °C (hold for 6 min), with the temperature increased at a rate of 5 °C/min up to 160 °C, followed by a rate of 1 °C/min to 240 °C, and then maintained for 25 min. Neutral lipids (diploptene, squalene, and partially hydrogenated squalenes) were analysed in the following temperature programme: 6 min at 100 °C, with the temperature increased at a rate of 5 °C/min up to 160 °C, followed by a rate of 2.5 °C/min to 300 °C, and then this was maintained for 30 min.

Preparative HPLC separation of the *C. calidirosea* free fatty acids was carried out using a Gilson 321 preparative HPLC pump, an Agilent 1100 photodiode array detector (at 205 nm), C12 column (Synergy 4 µ Max-RP 80A 250 × 30.00 mm) with a guard column (Phenomenex SecurityGuard cartridge C12 15 × 30.00 mm). Data were collected and analysed using Gilson Unipoint 3.20 software. Solvents used were: Solvent A: 85% aqueous methanol with 0.05% acetic acid; Solvent B: methanol with 0.05% acetic acid. The eluent flow rate was 15 ml/min. The concentration of injected sample was 200 mg/ml in chloroform, 0.3 ml was injected. The eluent gradient employed was: 0 to 2 min—100% Solvent A; 24 min—35% Solvent A, 65% Solvent B; 69 min—100% Solvent B.

^{1}H-NMR of fatty acid samples was performed in $CDCl_3$ using a Bruker Avance III 500 MHz instrument. Spectra were recorded with the following instrument settings: spectrometer frequency 499.843 MHz, sweep width 10,302 Hz, 65,536 data points, 30° excitation pulse, 32 transients taken, each with a 1-s delay time and f.i.d. acquisition time of 3.18 s. Spectra were processed with a standard exponential weighting function with 0.3 Hz line broadening before Fourier transformation.

IR spectra were recorded with a Spectrum One (Perkin-Elmer) FTIR spectrometer (solvent—CCl_4).

Results

Lipid Content

The lipid content of *C. calidirosea* samples varied between 0.29 and 0.36% of the wet biomass weight, or 7.6–8.8% in the freeze-dried samples. A bright pink pigment was present in all total lipid extracts.

Neutral Lipids

No free fatty acids, wax or sterol or glycerol esters were observed in the total lipids of *C. calidirosea* in our TLC experiments, suggesting that fatty acids, if any, are present as constituents of polar lipids only. Initial analysis of the mixture produced by transmethylation of bacterial biomass without further purification demonstrated the presence of significant quantities of hydrocarbons in the mixture, apart from fatty acid methyl esters. These hydrocarbons were fractionated by preparative TLC (Fig. 1). Individual components were identified by GCMS of intact and hydrogenated samples as squalene, dihydrosqualene, tetrahydrosqualene, hexahydrosqualene, octahydrosqualene and decahydrosqualene (all of these produced squalane upon hydrogenation), and diploptene (hopane was produced upon hydrogenation). An unidentified component, appearing to be partially cyclised squalene with two rings and four double bonds, was also observed. The mass spectrum of this component was similar to that of a known product of an incomplete cyclisation of squalene, γ-polypodatetraene [20], but no further structure elucidation was performed.

Diplopterol, along with barely detectable levels of the methyl ester of β-hydroxy myristic acid were observed when methanolysis products prepared from total lipids [11] were analysed by GCMS in the form of TMS-derivatives.

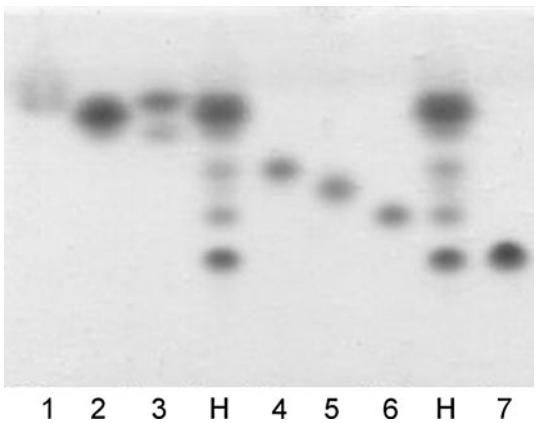

Fig. 1 Fractionation of neutral lipids of *C. calidirosea*. TLC in hexane, detection by iodine vapours. The identities of the components were confirmed by GCMS of fractions before and after hydrogenation (see "Materials and Methods"). *Lanes 1* octahydrosqualene and decahydrosqualene; *2* diploptene and octahydrosqualene; *3* octahydrosqualene, diploptene, and hexahydrosqualene; *H* hexane fraction of *C. calidirosea* neutral lipids; *4* tetrahydrosqualene; *5* unidentified bicyclic tetraene; *6* dihydrosqualene; *7* squalene

Fatty Acids

The only type of unsaturation found in *C. calidirosea* fatty acids was Δ5 with *cis*-configuration. These were identified via GCMS analysis of the DMDS adducts (Fig. 2), and IR spectrometry, resulting in fragments with *m/z* 161, $CH_3SC_5H_7O_2CH_3^+$, and 129 (*m/z* 161-CH_3OH), and no *trans*-unsaturation absorbance at 960–980 cm^{-1} in the IR spectrum.

Comparison of the chromatographic behaviour of the FAME on non-polar and medium polarity phases, along with analysis of hydrogenated samples, allowed the identification of most of the fatty acids present in *C. calidirosea* lipids. Since a BP20 column was unable to separate *ante-iso*-17:0 and *iso*-17:1Δ5 peaks (both components have ECL of 16.68 at 195 °C), a BP1 column was used for fatty acid profiling of cultured samples.

An unidentified fatty acid methyl ester, X, with ECL 16.86 on non-polar column BP1 (Fig. 3), and ECL 17.27 on a medium polarity BP20 column possessed a molecular ion with *m/z* 282, suggesting the presence of a 17:1 fatty acid, but it did not form DMDS adducts and was not affected by mild hydrogenation conditions. MS spectrum of X revealed that it featured an ion pattern characteristic for cyclopropane fatty acids, with the peak at *m/z* 41 of higher intensity than that of *m/z* 43 [21]. ^{1}H-NMR spectra of both polar lipids fraction of *C. calidirosea* lipids, and FAME fraction enriched in X demonstrated a resonance at −0.3 ppm, as well as at 0.6 ppm confirming the presence of a cyclopropane ring with *cis*-stereochemistry [22]. Hydrogenation of X in acetic acid resulted in formation of straight chain 17:0 (ECL 17.00) and two branched FAME with ECL 16.42 and 16.43 on 60 m BP1 column. The former ECL values is close to the one reported by Apon

Fig. 2 Mass-spectrum of DMDS adduct of *i*17:1 methyl ester

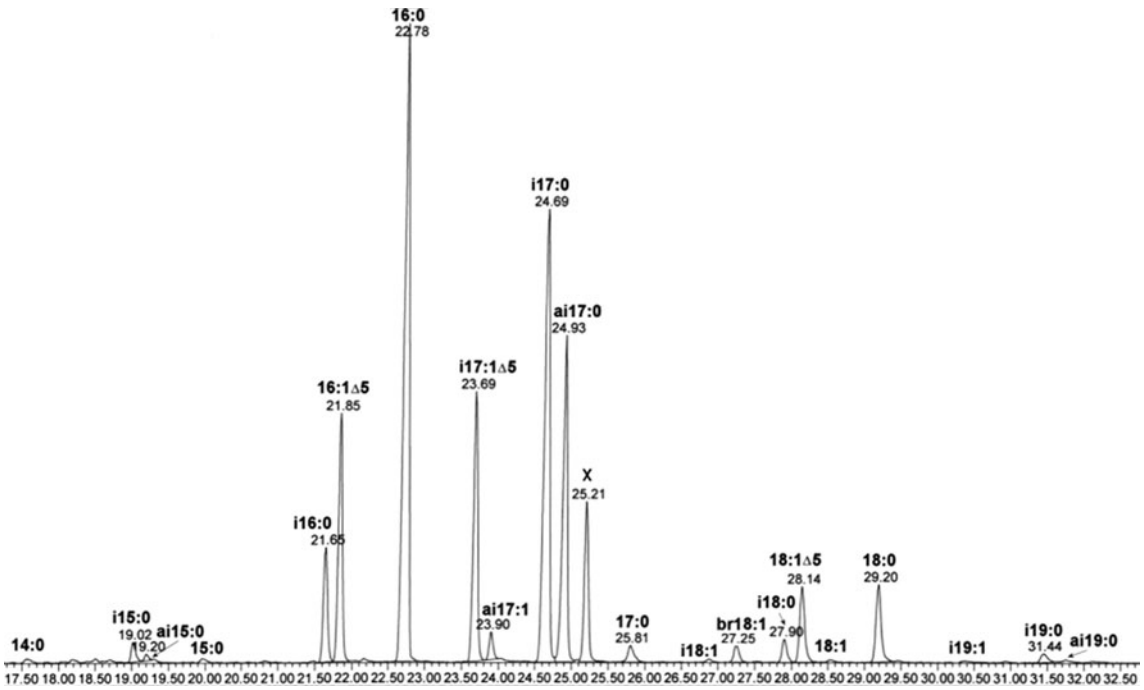

Fig. 3 GC of FAME derived from *C. calidirosea* total lipids on HP-5 capillary column

and Nicolaides [23], who observed the ECL of 16.40 for 6-methyl hexadecanoic acid methyl ester using a home-made 500 or 1,000 ft stainless steel capillary columns coated with Pentasil (a non-polar phase). Unfortunately, they did not report the ECL for 5-methyl hexadecanoic acid methyl ester. In the GCMS experiment these components demonstrated characteristic fragments at *m/z* 115 and 143 (6-methyl 16:0), and at *m/z* 101 and 129 (5-methyl 16:0), correspondingly (Fig. 4), thus confirming 5,6-methylene hexadecanoic acid structure. The presence of a major ion at *m/z* 208 (M-76) in the former spectrum is known to be characteristic for fatty acid methyl esters with a methyl branch at C6 (peak "e" in [18]), while the same fragment may be observed at very low abundance in spectra of 5-methyl- and 7-methyl FAME. A major ion at *m/z* 241 in the latter spectrum originates from the loss of a three carbon fragment from within the chain (ibid.). Overall, MS data for 5-methyl- and 6-methyl-16:0 did match well with those published in Table II of [23], including a peculiar pattern at *m/z* 111 and 112 for 6-methyl-16:0. A satisfactory GC separation of 5-methyl- and 6-methyl hexadecanoic acids was achieved by the use of a 60-m capillary column and reduced temperature of analysis. The level of 5,6-methylene hexadecanoic acid in a solid media-grown sample was 5.2% of total fatty acids (Table 1).

Discussion

Bacterial *cis*-monounsaturated fatty acids of Δ5 series were discovered by Kaneda [24] who found *i*-C16:1Δ5, *n*-C16:1Δ5, *i*-C17:1Δ5, and *ai*-C17:1Δ5 in three species of *Bacillus*, with either *n*-C16:1Δ5 or *ai*-C17:1Δ5 being the major unsaturated component. Later Kaneda commented that the significance of the unusual position of the double bond was not clear, but linked Δ5-unsaturation to aerobic biosynthesis [25].

Cyclopropane fatty acids found in bacteria usually belong to *cis*-9,10-methylene- or *cis*-11,12-methylene families [6]. Less common structures were also reported, e.g., compounds based on *trans*-4,5-methylene pattern were reported for cyanobacteria [7, and references therein]. Since biosynthesis of a cyclopropane ring in fatty acids is accomplished by methylenation of an unsaturated moiety with *S*-adenosylmethionine [26], we expected that the cyclopropane acid found would have a 5,6-methylene

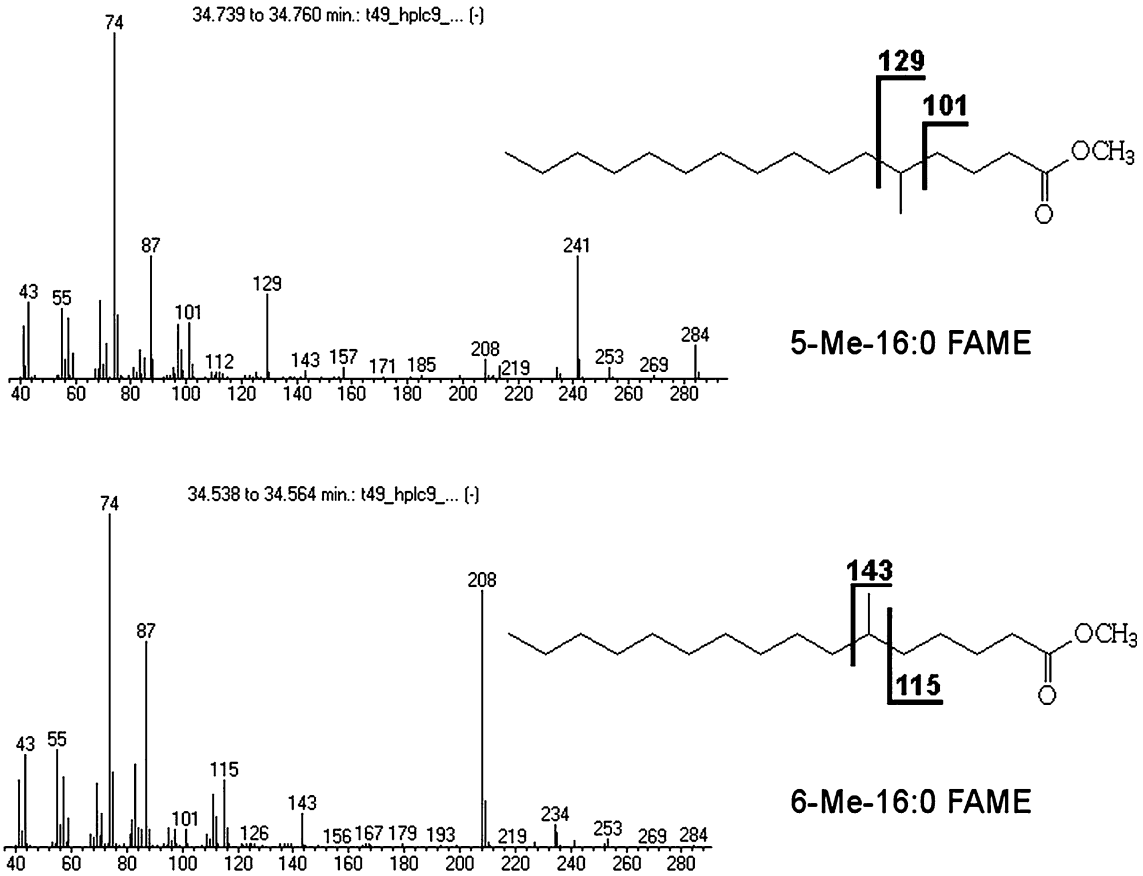

Fig. 4 GCMS of branched acids derived upon cycle opening of compound X: 5-methyl hexadecanoic acid methyl ester (*upper*), and 6-methyl hexadecanoic acid methyl ester (*lower*). The molecular ions of both isomers are situated at *m/z* 284

[a] components also present in media

fragment. Indeed, a ring opening study using GCMS analysis of the products confirmed the presence of 5,6-methylene hexadecanoic acid in *C. calidirosea*.

According to the result of a search performed with the use of Reaxys® (Elsevier Properties SA service) and SciFinder® (Chemical Abstracts service), 5,6-methylene hexadecanoic acid has not been reported yet, but a longer chain homologue, 5,6-methylene octadecanoic acid, was synthesised from the corresponding octadecenoic acid [27]. Interestingly, the 2-hydroxy derivative of 5,6-methylene octadecanoic acid is a component of Cepaciamide A, a fungitoxic compound isolated from *Pseudomonas cepacia* [28].

While polar lipids observed in *C. calidirosea* resembled those reported for *Deinococcus radiodurans* (data not shown), the polar lipids of the latter contained monoenoic acids only of Δ7, Δ9 and Δ11 series, with up to 11% of unidentified fatty acids [3, 4], and it was highlighted that no cyclopropanoic acids were found [5]. The prevalence of Δ5 *cis*-monounsaturated and 5,6-methylene hexadecanoic acid provides *C. calidirosea* with a unique set of lipid biomarkers. The fatty acid profile of *Armatimonas rosea*, the only other cultivated bacterium from the phylum Armatimonadetes [29], lacks these markers and suggests that Δ5 *cis*-monounsaturation and 5,6-methylene hexadecanoic acid may only be specific to the class or genus. Additional data on the fatty acid profile of the other bacteria within the *Chthonomonas* genus will provide chemotaxonomic information on these microorganisms and confirm their prevalence.

Acknowledgments The authors are grateful to Dr. Kevin Mitchell for help with HPLC, Dr. Herbert Wong for NMR-spectra recording, Dr. Owen Catchpole for reviewing the manuscript, Alison Speakman for invaluable help in information retrieval (all—IRL), and anonymous reviewers for helping to make this article better. The authors also thank the Tikitere Trust for their on-going support of this research.

Conflict of interest Authors declare that there is no conflict of interest.

(>12 h). These methods include density gradient ultracentrifugation, nuclear magnetic resonance (NMR) spectroscopy, and polyacrylamide gradient gel electrophoresis (PGGE). Recently, another technique to measure LDL particle size was developed by the Quantimetrix Corporation [9]. This new method, termed the "lipoprint LDL system", allows for the determination of LDL particle size and distribution in <3 h by a polyacrylamide gel electrophoresis system [9]. Although this new method has been used in a variety of clinical trials [10–12], no data on the *agreement* between this new technique and previously validated methods (i.e. PGGE) has been published. Greater insight into the level of agreement between the two methods is of particular importance in view of the increasing application of the lipoprint method in both research and clinical practice. Accordingly, this study evaluated the agreement between LDL particle size and distribution measured by the lipoprint system and PGGE in obese adults at risk for CHD.

Methods

Subjects

Subjects were selected from a 10-week weight loss intervention trial. The study population has been previously described in detail [13]. Inclusion criteria were as follows: males; non-pregnant females; age 35–65 years; BMI between 30 and 39.9 kg/m^2; and not taking glucose or lipid lowering medications. The experimental protocol was approved by the Office for the Protection of Research Subjects at the University of Illinois, Chicago, and all volunteers gave their written informed consent to participate in the trial.

Blood Collection Protocol and Plasma Lipid Analysis

Twelve-hour fasting blood samples were collected between 7.00 am and 9.00 am at baseline (week 1), weeks 3, 6, and 10. Participants were instructed to avoid exercise, alcohol, and coffee for 24 h before each visit. Blood was centrifuged for 15 min at 520×*g* and 4 °C to separate the plasma from the red blood cells. The samples were stored at −80 °C between the time of collection and the time of analysis. Plasma LDL cholesterol and triglyceride concentrations were measured in duplicate using enzymatic kits (Biovision Inc., Moutainview, CA, USA).

Polyacrylamide Gradient Gel Electrophoresis (PGGE)

LDL particle size analysis was performed on whole plasma using nondenaturing 2–16% PGGE, as described previously [14, 15]. All gels were prepared in batches of 8 in our laboratory using a multi-casting chamber (Bio-Rad Laboratories Canada, Mississauga, ON, Canada). Carboxylated latex beads (Duke Science, Palo Alto, CA, USA) were used as standards for molecule size and mass. Plasma samples (3.5 μL) were mixed with a sampling buffer containing 20% sucrose and 0.25% bromophenol blue in a 1:1 (v/v) ratio. Samples were applied to each unique gel in a random fashion. All 64 samples were analyzed in one batch. After a 15-min pre-run, electrophoresis was performed at 150 V for 3 h. Gels were then stained for 1 h with Sudan black (0.07%) and stored in a 0.81% acetic acid/4% methanol solution until analysis. The Imagemaster 1-D Prime computer software (Amersham Pharmacia Biotech, Piscataway, NJ, USA) was used to analyze the gels. Integrated LDL particle size was calculated as the sum of LDL subspecies' diameter multiplied by its relative proportion [14, 15]. The relative proportion of small ($LDL_{<255\ Å}$%), medium ($LDL_{255–260\ Å}$%), and large ($LDL_{>260\ Å}$%) particles was obtained by computing the relative area of the densiometric scan (<255 Å, 255–260 Å, and >260 Å, respectively) [14, 15]. A second batch of plasma samples were analyzed to evaluate the coefficient of variation (CV) between batches. This analysis revealed that measurement of integrated particle size was highly reproducible between batches with a CV of <2%.

Quantimetrix Lipoprint LDL System

This system separates LDL subfractions by a polyacrylamide gel electrophoresis technique [9]. The lipoproteins are separated on the basis of net surface charge and size [9]. The dye used in the lipoprint system binds proportionally to the relative amount of cholesterol in each lipoprotein. High-resolution 3% polyacrylamide gel tubes were used for electrophoresis. LDL subfractionation was performed as described in the lipoprint LDL system product insert. Briefly, 25 μL of sample was mixed with 200 μL of liquid loading gel. All 64 samples were analyzed in duplicate in one batch. The loading gel contained Sudan black dye to stain the lipoproteins. The resulting mixture was added to the top of precast 3% polyacrylamide gel tubes. After photopolymerization at room temperature for 30 min, samples were electrophoresed for 1 h (3 mA/gel tube). The electrophoresis was followed by resting the tubes in the dark for 1 h. Lipoware computer software (Quantimetrix, Redondo Beach, CA, USA) was used to analyze the gels. The software divides the LDL particles into small ($LDL_{<255\ Å}$%), medium ($LDL_{255–260\ Å}$%), and large ($LDL_{>260\ Å}$%) particles. A second batch of plasma samples were analyzed to evaluate the coefficient of variation (CV) between batches. This analysis revealed that measurement of integrated particle size was highly reproducible between batches with a CV of <3%.

Statistics

Results are presented as means ± standard deviations (SD). The intra-subject reliability of the lipoprint duplicate measurements was tested on all samples by calculating the technical error of measurement (TE) as [TE = $\sqrt{(di^2/2N)}$], where *di* represents the difference between measurements on the *i*th sample, and where *N* is equal to the number of samples [16]. Pearson's correlational analysis was implemented to calculate the association between lipoprint and PGGE techniques for integrated LDL particle size, and the proportion of large, medium and small LDL particles. A paired *t* test was used to test for differences in LDL particle size parameters between the lipoprint and PGGE methods. The Bland-Altman test [17] was employed to evaluate the agreement between the two techniques. Tests for normality were undertaken for each variable. A level of statistical significance of $P < 0.05$ was used in all analyses. Data were analyzed using SPSS software (version 18.0 for Mac OS X; SPSS Inc, Chicago, IL, USA).

Results

Sixteen subjects (4 men/12 women) completed the 10-week trial, and LDL particle size was analyzed at 4 different time points. Thus, in total, 64 samples were analyzed by the lipoprint system and PGGE. The mean age and BMI of the subjects at baseline was 46.0 ± 2.4 years and 33.7 ± 1.0 kg/m^2, respectively [13]. Subject ethnicities were as follows: $n = 8$ African Americans, $n = 2$ Caucasians, and $n = 6$ Hispanic Americans. Body weight decreased from 96 ± 5 kg to 91 ± 5 kg over the course of the trial [13]. LDL cholesterol concentrations fell from 102 ± 9 mg/dL to 72 ± 8 mg/dL, while triglyceride levels decreased from 125 ± 15 mg/dL to 88 ± 15 mg/dL [13].

Mean TE for duplicate lipoprint and PGGE measurements was 0.2 ± 0.1 Å (range 0–0.6 Å) and 0.2 ± 0.1 Å (range 0–0.4 Å), respectively, for integrated particle size. These TE values suggest highly reproducible findings for the lipoprint and PGGE techniques. The lipoprint LDL system gave significantly different values for integrated LDL particle size ($P = 0.003$) when compared to the PGGE method (Table 1). In contrast, the two methods gave similar findings for the proportion of large ($P = 0.201$), medium ($P = 0.056$), and small LDL particles ($P = 0.167$). Results of the Bland–Altman test are reported in Fig. 1. The lipoprint system was shown to slightly overestimate integrated LDL particle size by 1.1 ± 3.0 Å. As for the proportion of large, medium, and small LDL particles, there was good agreement between the two methods (i.e. mean difference was <3% for each parameter).

Table 1 LDL particle size as determined by the lipoprint LDL system and polyacrylamide gradient gel electrophoresis (PGGE)

	Lipoprint	PGGE	*P* value[a]
Integrated LDL particle size (Å)	268.9 ± 6.8	267.8 ± 6.0	0.003
Proportion of large LDL particles (%)	70.1 ± 14.6	71.7 ± 17.0	0.201
Proportion of medium LDL particles (%)	19.5 ± 9.2	16.9 ± 8.7	0.056
Proportion of small LDL particles (%)	9.6 ± 7.8	11.4 ± 9.4	0.167

Mean values ± SD of the $n = 64$ samples analyzed

[a] *P* value for difference between methods (Paired *t* test)

Correlational analysis revealed a strong relationship between lipoprint and PGGE for integrated LDL particle size ($r = 0.89$, $P < 0.0001$). Similarly, good relationships between lipoprint and PGGE values were shown for the proportion of large ($r = 0.81$, $P < 0.0001$), medium ($r = 0.67$, $P < 0.0001$), and small ($r = 0.73$, $P < 0.0001$) LDL particles. The bias between lipoprint and PGGE measurements was not correlated with age, body weight, BMI, LDL cholesterol or triglyceride concentrations. Moreover, no difference in the relationship between the two methods was noted when samples with higher concentrations of LDL cholesterol were compared to samples with lower concentrations of LDL cholesterol.

Discussion

Findings from the present validation study suggest that, when compared to the PGGE technique, the lipoprint LDL system is adequate for estimating the proportion small ($LDL_{<255\ Å}$%), medium ($LDL_{255–260\ Å}$%), and large ($LDL_{>260\ Å}$%) particles, but may overestimate integrated LDL particle size. Specifically, we showed here that the mean difference between the two methods for each LDL size subfraction was <3% and non-significant. On the other hand, the lipoprint system was shown to significantly overestimate integrated LDL particle size by 1.1 Å when compared to PGGE. Thus, lipoprint may be an acceptable method for assessing the distribution of LDL particles, but not the absolute size.

To date, three other studies [9, 18, 19] have examined the adequacy of the lipoprint LDL system for the measurement of LDL particle size. For instance, Hoefner et al. [9] and Ensign et al. [18], tested the ability of lipoprint versus PGGE to classify subjects into LDL size phenotypes. In both studies [9, 18], phenotype A was defined as a predominance of large buoyant LDL particles, while phenotype B was defined as a predominance of small dense

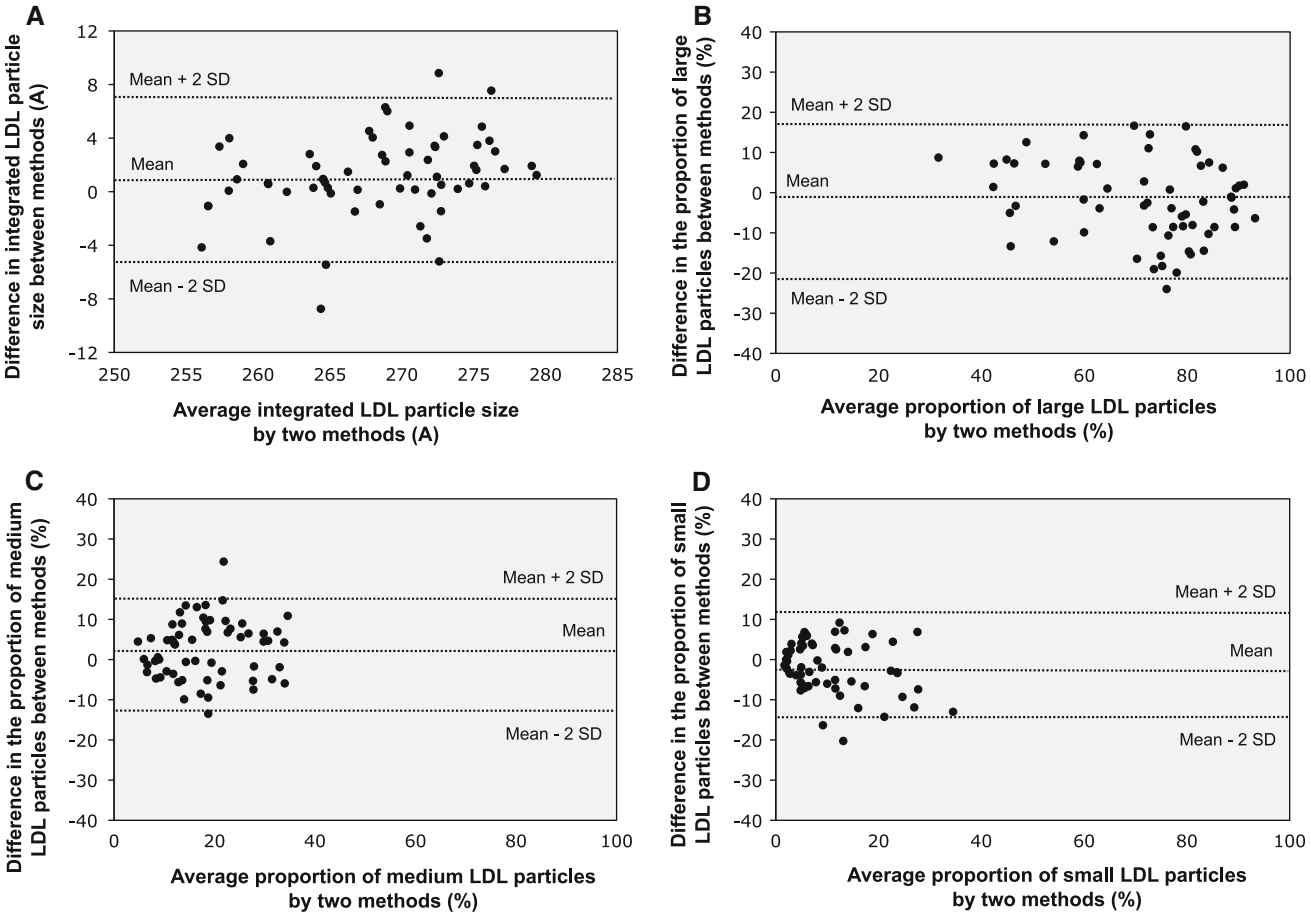

Fig. 1 Bland–Altman plot of the differences between integrated LDL particle size (**a**), and proportion of large (**b**), medium (**c**), and small LDL particles (**d**), predicted by the lipoprint LDL system versus polyacrylamide gradient gel electrophoresis (PGGE). Values for $n = 64$ samples analyzed. Difference between methods calculated as PGGE minus lipoprint values. *Dotted middle line* represents mean difference between methods (bias), and the *outside dotted lines* represent the upper and lower limits of agreement (±2 SD of the mean bias)

LDL particles. Findings from the study by Hoefner et al. [9] revealed a strong correlation between the two methods for their ability to classify individuals as phenotype A, but not as phenotype B. In contrast, Ensign et al. [18] showed a very weak association between methods for LDL size phenotyping. In the trial by Hirany et al. [19], LDL subfractionation was compared between lipoprint and PGGE techniques. Strong correlations between methods were observed for the distribution of large, medium, and small LDL particles in the 102 samples analyzed [19]. Although previous studies have attempted to validate the lipoprint system, it is difficult compare the present findings to what has been reported previously [9, 18, 19] for two main reasons. Firstly, none of the previous trials evaluated integrated particle size, thus a comparison between past and present findings cannot be made for this parameter. Secondly, these previous studies only examined the *association* between the two methods, and not the level of *agreement*. A strong correlation between two methods is simply a sign that the study includes a widespread sample, and gives no indication as to the level of agreement between the two techniques [17]. Since agreement was not measured in any of these previous trials, this statistic cannot be compared between studies. Future studies in this area should therefore aim to implement tests of agreement to complement correlational analyses to compare LDL subfractionation methodologies.

Interestingly, this cohort displayed a very low proportion of small LDL particles (<10%), and a very high proportion of large LDL particles (>70%). One possible explanation for this may be the ethnic distribution of the sample employed. Our cohort consisted of $n = 8$ African Americans, $n = 2$ Caucasians, and $n = 6$ Hispanic Americans. Recent research has shown that African Americans have a more favorable lipoprotein profile (i.e. lower proportion of small LDL particles, and higher proportion of large LDL particles) than Caucasians, despite a higher prevalence of coronary heart disease risk factors

[20]. Since half of the subjects in the study were African American, this may explain why we observed a more favorable lipoprotein profile than what would be expected if the population consisted primarily of Caucasians.

In summary, our findings demonstrate that the lipoprint system may be used as an alternative to the PGGE method for the assessment of LDL size distribution. As for the measurement of absolute size, the validity of the lipoprint system with PGGE is still uncertain. However, it is well known that LDL distribution (particularly the proportion of small LDL particles) is a stronger predictor of CHD risk than absolute size. Thus, this lower concordance between lipoprint and PGGE for absolute LDL size may not be that critical. Moreover, the lipoprint LDL system has several advantages over the PGGE method in that it is less labor-intensive, more cost-effective, faster, and not subject to inter-individual interpretation. Therefore, the lipoprint technique may be viewed as an attractive alternative to PGGE for laboratories that routinely measure LDL particle size distribution for the assessment of CHD risk. Nevertheless, since this study employed a fairly small sample size, more research is required before solid conclusions can be reached.

Acknowledgments We would like to thank the study participants who contributed their time and effort. Departmental grant, Kinesiology and Nutrition, University of Illinois, Chicago.

lecithin cholesterol acyl transferase mediate the synthesis of CE within cells and in high-density lipoprotein, respectively [5, 6]. Based on the importance of plasma levels of free and esterified cholesterol, it is likely that plasma levels of specific molecular species of CE may have utility as predictors of atherosclerosis, diabetes mellitus, coronary heart disease and cancer [7–9]. It should also be noted that within cells the appearance of CE-enriched lipid droplets is a consequence of impaired metabolism or overnutrition [9, 10]. Furthermore, elevated tissue CE levels are observed in tumors [11].

Mass spectrometry potentially affords rapid high-throughput chemical analysis to interrogate the role of lipids in cellular, tissue and systemic physiological and pathophysiological processes [12, 13]. However, mass spectrometry (MS) of CE is complicated by the presence of other lipids having common isobaric molecular ions (e.g., diacylglycerols), which hinders both the identity and quantification of individual CE by single stage mass spectrometry. Soft ionization techniques have been used in the past for CE analyses, specifically the use of matrix-assisted laser desorption/ionization [14] and electrospray ionization (ESI) [15–17]. It is recognized that ESI can provide efficient quantification of lipid species in complex matrices without the need for derivatization. Although, ammoniated adducts of CE have been used for detection of molecular species using ESI–MS, this adduct produces only moderate levels of MS/MS fragmentation [18, 19]. In this study, ESI–MS/MS strategies were developed and optimized for the species-selective analysis of multiple CE molecular species using sodiated adducts. In comparison to ammoniated adducts of CE, fragmentation of sodiated adducts of a CE result in the loss of a cholestane as a neutral fragment. Based on this fragmentation, neutral loss scanning was developed to quantify sodiated adducts of CE molecular species. This technique was subsequently applied to examine CE molecular species in mouse macrophages supplemented with either linoleic acid or arachidonic acid, as well as in the plasma of mice fed specific diets.

Materials and Methods

Standards and Solvents

Fatty acids and CE molecular species standards, including myristate (14:0), palmitate (16:0), palmitoleate (16:1), heptadecanoate (17:0), stearate (18:0), oleate (18:1), linoleate (18:2), arachidonate (20:4), and docosahexaenoate (22:6) were purchased from NuChek Prep (Elysian, MN). Distearin (18:0–18:0 or 36:0) and diarachidin (20:0–20:0 or 40:0) were also purchased from NuChek Prep (Elysian, MN). Chloroform and methanol were of HPLC grade and were purchased from Burdick and Jackson (Muskegon, MI).

Electrospray Ionization-Mass Spectrometric Analysis

Direct-infusion electrospray ionization mass spectrometry of CE was performed in positive ion mode using a Thermo Fisher TSQ Quantum Ultra with Xcalibur data acquisition software. Samples were analyzed at a flow rate of 3 μL/min. Tune parameters were optimized for CE analyses, and were set at spray voltage = 3,800 V, sheath gas = 8 (arbitrary units), ion sweep gas pressure = 0.5 (arbitrary units), auxiliary gas pressure = 5 (arbitrary units), and capillary temperature = 270 °C. Spectra for survey scans were acquired for five min with a scan rate of 0.5 scans/s. In each MS/MS mode, the collisional energy for the analyses of CE molecular species was set at 25 eV. Spectra for MS/MS scan modes were acquired over 3 min with a scan rate of 0.5 scans/s.

Fatty Acid Supplementation of J774 Cells

J774 cells were a generous gift from Dr. George Rothblat (Children's Hospital of Philadelphia). Mouse J774 monocyte-derived macrophages were maintained at 37 °C with 5% CO_2 in RPMI-1640 (Sigma) supplemented with 10% v/v fetal bovine serum (Atlanta Biologicals) and 1× antibiotic/antimycotic (Sigma). For the fatty acid supplementation, either 50 μM linoleic or arachidonic acid were suspended in media as an ethanol injectate (ethanol <0.1% v/v), and cells were treated with these fatty acids for 24 h followed by a second supplementation with the same concentration of either fatty acid for an additional 24 h. Negative control conditions for the fatty acid-supplementation condition included incubating cells with vehicle-treated media only. Cells were then extracted in the presence of 17:0 CE internal standard by a modified Bligh-Dyer technique [20] with saline in the aqueous phase. The collected chloroform phases were sequentially dried under nitrogen, resuspended in 250 μL of chloroform, and stored under N_2 at −20 °C until analysis. For direct-infusion ESI analysis, 50 μL of the resuspended lipid solution (in chloroform) was added to 200 μL of methanol. NaOH was added to each sample at a concentration of ~10 μM. The ion intensity of each CE molecular species was divided by the ion intensity of the internal standard (CE 17:0), and the mass of each molecular species was determined using parameters from response calibration lines determined for each molecular species in comparison to 17:0 CE. Values for CE molecular species are normalized to cell protein (Bio-Rad Laboratories, Inc., Hercules, CA).

Mouse Feeding Studies

Six week old female C57BL6 mice were started on Western diets (Harlan Teklad 88137) and they remained on this diet for 14 weeks. Control, age-matched female mice were

fed regular chow diet (Teklad 2018S) for the same interval. Blood was collected at the end of this interval by cardiac puncture, and plasma was prepared by centrifugation. Ten microliters of mouse plasma was extracted in the presence of 17:0 CE internal standard by a modified Bligh-Dyer technique [20] with saline in the aqueous phase. Plasma lipid extracts were then subjected to direct infusion ESI–MS for the analyses of CE molecular species.

Preparation of Oxidized Unsaturated CE

Selected CE molecular species (1 nmol) were dried under nitrogen in 12 × 100 mm borosilicate test-tubes and were either immediately resuspended in 250 μL methanol/chloroform (4/1) or were exposed to ambient air for 6 or 15 h prior to being resuspended in 250 μL methanol/chloroform (4/1). For each sample, 1 nmol of 17:0 CE was added as an internal calibrant. Precursor CE molecular species and their oxidized products were subsequently examined by neutral loss scan of 368.5 employing the parameters described above. The CE and CE oxidation species were monitored as sodiated adducts following the addition of NaOH.

Results

Direct Infusion ESI–MS of Sodiated Adducts of Individual CE Molecular Species

As a first step to examine the feasibility of using sodiated adducts of CE for their quantification by mass spectrometry, survey scan spectra and collisionally-activated dissociation (CAD) spectra were collected for 16:0 and 18:2 CE. Data shown in Fig. 1 show the survey scans of sodiated adducts of both 16:0 and 18:2 CE (Panels A & B), and the collisionally-activated dissociation (CAD) spectra of each molecular species with both the cholestane (*m*/z 369.2) and sodiated fatty acid ions (279.04 and 303.08) observed (Panels C & D, Fig. 1). While others have shown that CAD of molecular ions of ammonium adducts of CE yields a robust cholestane positive ion [16, 21, 22], these results show that the sodiated adduct only forms a weak cholestane positive ion and preferentially loses this residue as a neutral in concert with the appearance of an abundant sodiated fatty acyl positive fragment ion. Panels E & F of Fig. 1 show the parent ion (PI) scans using the product ion of the sodiated ion fatty acid (e.g., PI 279.04 and 303.08 for 16:0 CE and 18:2 CE of the sodiated adducts, respectively). It is important to appreciate that the fragmentation of the sodiated CE molecular species to their respective metal ion fatty acyl fragment represents the loss of the neutral fragment cholestane, and this neutral loss can, thus, be potentially useful in uniformly detecting CE. Indeed, Fig. 2 shows the neutral loss (NL) scan of 368.5 of an equimolar mixture of CE molecular species. Importantly, it should be noted that CE with varying degrees of unsaturation have different ionization efficiencies. Positive ions of sodiated adducts of CE molecular species have a greater intensity as the degree of unsaturation increases for sodiated adducts of CE. Accordingly, ionization of the sodiated adduct of each CE molecular species was compared to that of 17:0 CE to determine their relative responses. In addition, 17:0 CE was used in subsequent studies as an internal standard to quantify CE molecular species in biological samples. Table 1 shows the individual calibration constants for the sodiated CE molecular species. Examination of these calibration constants reflect the increased ionization intensities of polyunsaturated CE molecular species with these molecular species having increased slopes compared to the monounsaturated and saturated molecular species. Corrections for disparate ion intensities of these CE molecular species are predominantly dependent on the response factor (slope of calibration lines), and the impact of the *y*-intercepts is generally negligible.

Resolving CE Molecular Species from Isobaric Ions Using the NL 368.5 Scan Mode

NL scanning for 368.5 was used to examine CE in the presence of isobaric diacylglycerol (DAG) molecular species to assess the utility of this NL 368.5 approach for the specific detection of CE molecular species. For this analysis, 16:0 CE and distearin (18:0-18:0 DAG) were examined as sodiated adducts, which both have molecular ions at 647 (Fig. 3). Panels A and D of Fig. 3 show the survey scan and NL 368.5 scan, respectively, for a mixture of 16:0 and 17:0 CE, which have molecular ions at *m*/*z* 647.6 and 661.6, respectively. Panels B and E show the same scans for the analyses of a mixture of 18:0-18:0 DAG and diarachidin (20:0-20:0 DAG), which have molecular ions at 647.5 and 703.6, respectively. These sodiated adducts of the DAGs are not detected with the CE-specific NL 368.5 scan mode (Panel E). Panels C and F show the survey scan and NL 368.5 scan, respectively, for the analyses of all four CE and DAG species in one mixture. In this isobaric mixture, a large *m*/*z* 647 ion was observed in the survey scan (Panel C) due to the presence of the two isobaric lipids. Note that the ion at 647 in the survey scan (Panel C) is greater in intensity than the two internal calibrants (17:0 CE and 20:0-20:0 DAG). However, only the CE molecular species were detected in the NL 368.5 scan (Panel F), and yielded equal ion intensities for this analysis since the saturated CE were present at equimolar concentrations. Thus, these data demonstrate that NL 368.5 scanning can be used to distinguish isobaric CE from DAG molecular species using sodiated adducts.

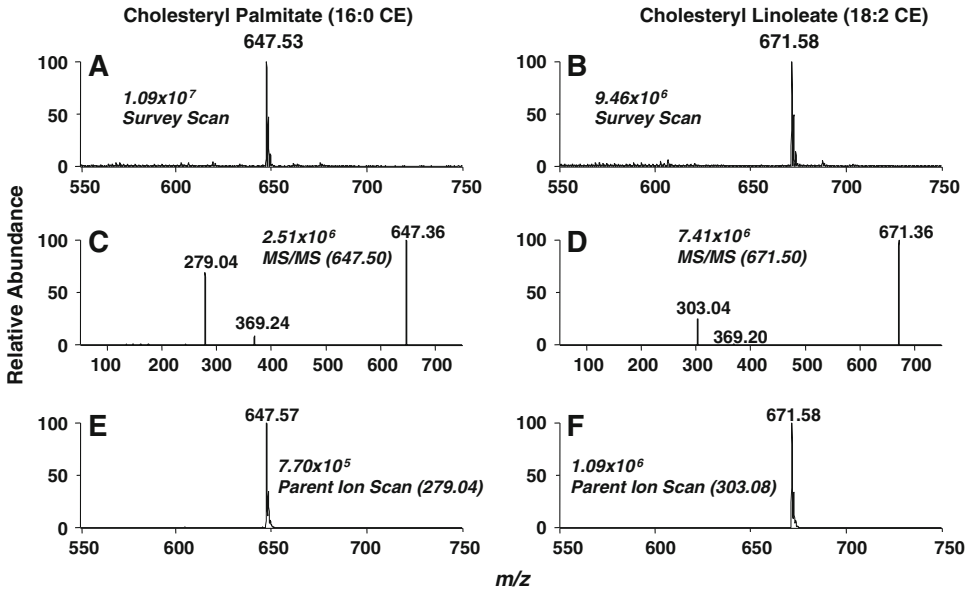

Fig. 1 Survey, CAD, and parent ion scans of sodiated cholesteryl palmitate (16:0 CE) and linoleate (18:2 CE) using direct-infusion ESI–MS analysis. Survey scans (**a**, **b**) were acquired for five min over the *m*/*z* range of 550–750. The CAD analysis (**c**, **d**) was performed at a collisional energy of 25 eV. Parent ion scans (**e**, **f**) were acquired from the sodiated fatty acyl fragment (25 eV). The concentrations of 16:0 and 18:2 CE were 10 μM. The NaOH added prior to ESI analysis was 10 μM

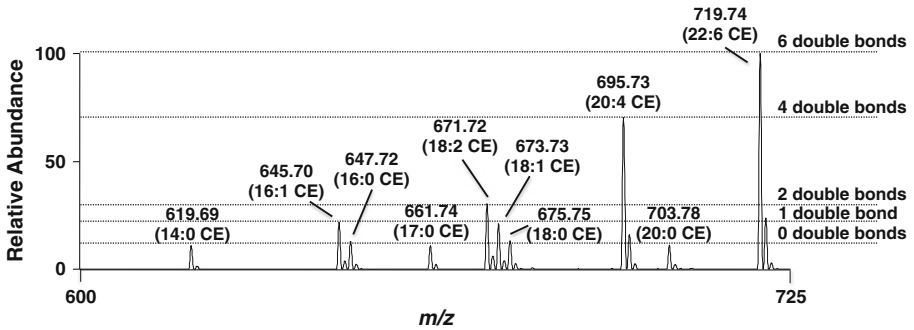

Fig. 2 Neutral loss of 368.5 MS/MS analyses of an equimolar mixture of the cholesteryl esters (each at 2 μM) as sodiated adducts. Spectra were obtained using the neutral loss 368.5 at a collisional energy of 25 eV as described in "Materials and Methods". *Horizontal dashed lines* highlight the disparate ionization efficiencies associated with CE molecular species containing different levels of unsaturation

CE Molecular Species in J774 Cells Supplemented with Specific Fatty Acids in Cell Culture Media

To test the NL 368.5 scan as a technique to quantify CE molecular species of sodiated adducts in biological samples, we treated mouse monocyte-derived macrophages (J774 cells) with media that was supplemented with specific fatty acids to delineate the fatty acid incorporation into CE molecular species. The mass spectra using NL 368.5 for cells without fatty acid treatment revealed that 18:1 CE (673.73) was predominantly present in J774 cells grown in the cell culture media with minimal levels of 18:2 and 20:4 CE present in these cells (Fig. 4, Panel A). In the spectra shown in Fig. 4, *m*/*z* 661.7 is the sodiated adduct of the internal standard, 17:0 CE. Figure 4, Panel B demonstrates that J774 cells supplemented with linoleic acid in the media have increased levels of intracellular 18:2 CE (671.73). Interestingly, as shown in Fig. 4 (Panel C), J774 cells incorporate arachidonic acid into CE pools (*m*/*z* 695.72), and also apparently elongate 20:4 to 22:4 and 24:4 under these cell culture conditions leading to the appearance of 22:4 and 24:4 CE (e.g., 723.76 and 751.84, respectively). Additional analyses showing the accumulation of 22:4 and 24:4 CE molecular species were performed with the addition of both 17:0 CE and 18:3 CE added as internal calibrants (Supplemental Figure). The inclusion of 18:3 CE did not impact the relative spectral intensities of the endogenous CE as well as the 17:0 CE standard. (Supplemental Figure). The amounts of specific CE for J774 cells treated with either linoleic or arachidonic acid compared to cells with no fatty acid treatment are summarized in Fig. 5. With both fatty acid supplementations to the cell culture media, the respective CE molecular species increased with an accompanied decrease in the amount of 18:1 CE. The total CE levels only marginally changed in cells treated with fatty acids due to the accumulation of new molecular species being offset by the decrease in 18:1 CE levels.

Table 1 Calibration line parameters for sodiated adducts of CE molecular species

CE	NL 368.5 $[M + Na]^+$	Line parameters
14:0	619.54	$y = 0.8503x - 0.0073$
16:0	647.57	$y = 1.0642x - 0.0057$
16:1	645.56	$y = 2.3832x + 0.0088$
18:0	675.61	$y = 1.1076x - 0.0258$
18:1	673.59	$y = 1.9934x + 0.0094$
18:2	671.57	$y = 2.7519x - 0.0151$
18:3	669.56	$y = 3.4011x + 0.0379$
20:4	695.57	$y = 4.6394x - 0.1213$
22:6	719.57	$y = 4.8166x - 0.1237$

Linear regression of ion intensity responses for each CE molecular species over a concentration range of 0.1–10 μM was determined. In all cases, the coefficient of determination (R^2) was greater than 0.99. The internal standard, 17:0 CE was constant at 2 μM

Mouse Plasma CE Molecular Species

To further illustrate the utility of NL 368.5 scanning for CE using sodiated adducts, we examined the CE molecular species in the lipid extracts prepared from plasma isolated from female mice fed either normal chow (Panels A & B of Fig. 6) or a Western diet (Panels C & D of Fig. 6). Survey scans in the positive ion mode (Panels A & C) showed CE molecular species amongst other isobaric positive ions, which potentially may preclude an accurate quantification of the CE molecular species. Panels B & D are the same lipid extracts but were subjected to NL 368.5 scanning for CE identification. From these scans, it was readily appreciated that the overall plasma CE levels were elevated and that the CE molecular species profile was much more diverse in mice fed the Western diet (comparing Panels B & D of Fig. 6). Figure 7 summarizes the quantitative data for the plasma CE in mice fed these two diets. In particular, the Western diet led to large increases in both 16:1 and 18:1 CE molecular species. These changes may reflect either increased production of monounsaturated fatty acids that are subsequently incorporated into the CE pool or, alternatively, enrichment of oleic acid in the Western diet (Teklad diet data). Interestingly, the Western diet is not enriched with palmitoleic acid. Also, it should be noted that the Western diet was enriched with cholesterol in comparison to the normal chow diet, which was likely responsible for the almost two-fold increase in total CE levels present in the plasma of these mice.

Oxidative Modification of Unsaturated CE Molecular Species

Studies with arachidonic acid supplementation of J774 cells unexpectedly revealed that arachidonic acid addition led to an increase in elongated CE molecular species, which were observed in the CE pool (Fig. 4). This finding was rapidly determined using the NL 368.5, which is CE class-specific. Similarly this technique was used to examine air oxidation of CE with varying degrees of unsaturation (Fig. 8). NL 368.5 scans of 18:0 CE exposed to ambient air for 15 h indicated that this saturated molecular species was not degraded in an oxidizing environment (Fig. 8, Panel A). In contrast, 18:2, 20:4 and 22:6 CE molecular species were significantly oxidized after exposure to ambient air for 15 h (Panels B–D). Note that in these same analyses, 17:0 CE was added prior to ESI–MS analyses to allow relative

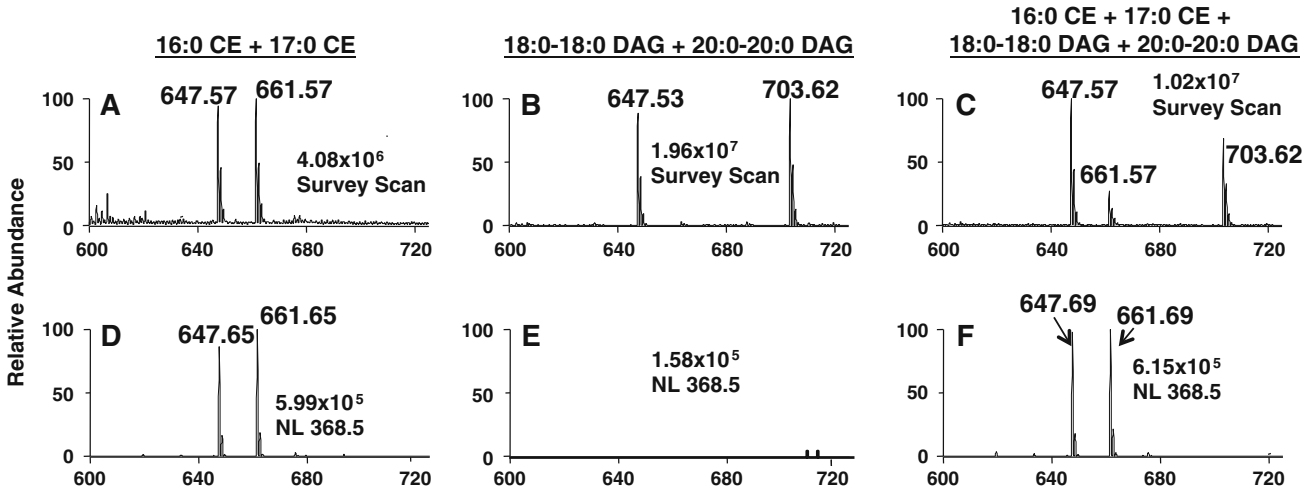

Fig. 3 MS and MS/MS analyses of CE and DAG sodiated adducts. 16:0 CE (*m/z* 647) and 17:0 CE (661) (**a**, **d**), 18:0-18:0 DAG (*m/z* 647) and 20:0-20:0 DAG (703) (**b**, **e**), and a mixture of both CE and DAGs (**c**, **f**) (all lipids present at a concentration of 5 μM) were subjected to direct-infusion ESI–MS analysis. Panels **a**–**c** are survey scans of each lipid mixture over an *m/z* range of 600–725 for five min. Panels **d**–**f** are scans for the neutral loss of 368.5, which were acquired for three min. The collisional energy for the MS/MS analysis of the CE molecular species was 25 eV. The NaOH added prior to ESI analysis was 10 μM

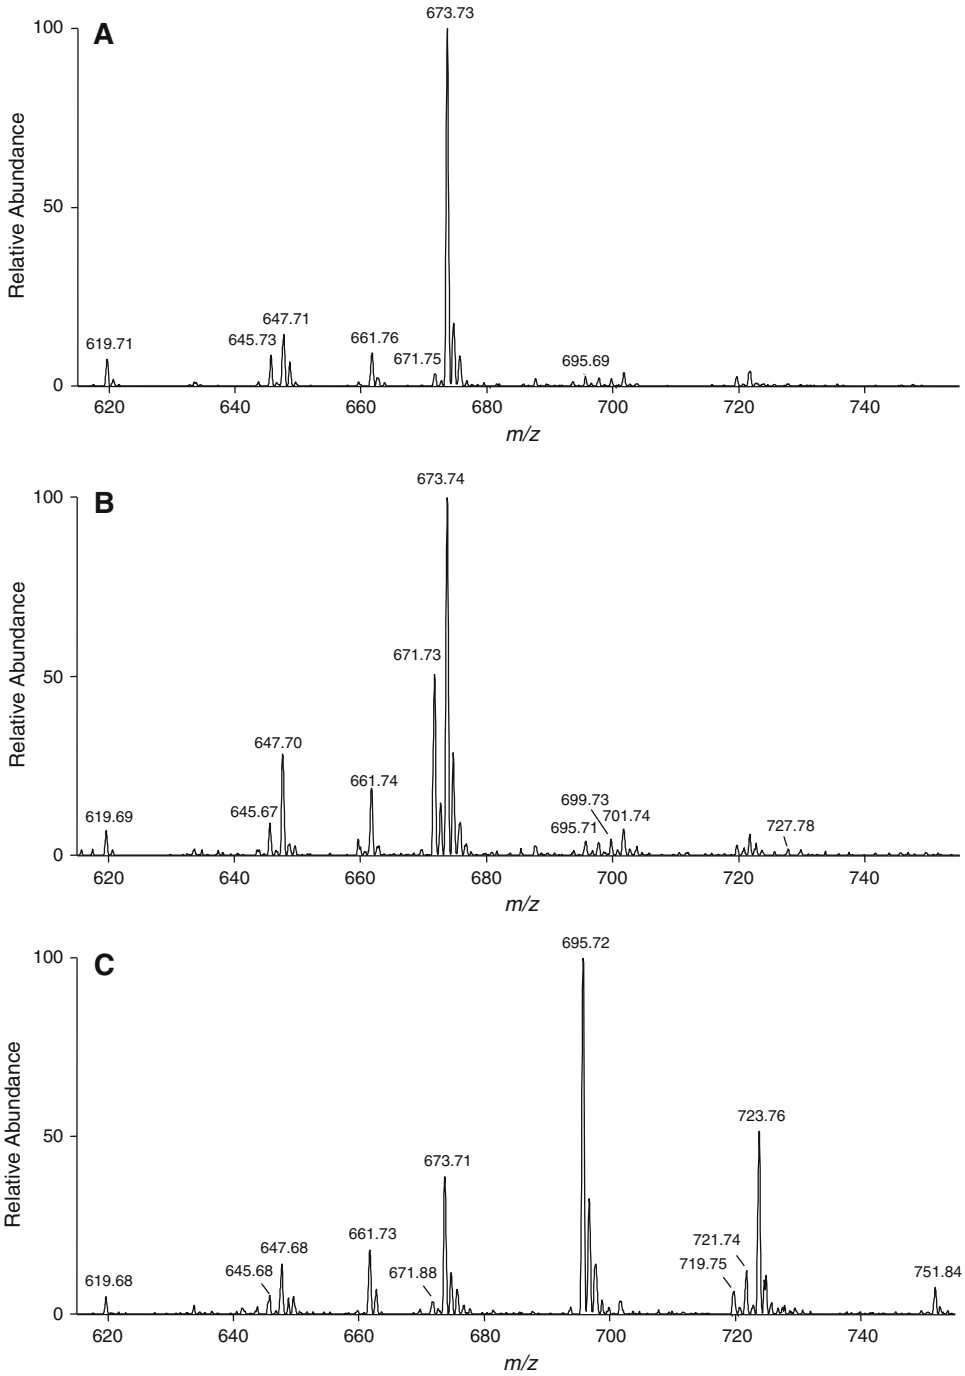

Fig. 4 NL 368.5 scans of sodiated CE present in J774 cells. J774 cells were cultured in the presence of either no fatty acid supplementation (**a**), linoleic acid supplementation (**b**) or arachidonic acid supplementation (**c**). At the end of the cell culture treatment interval, lipids were extracted from J774 cells with 17:0 CE added as an internal standard as described in detail in "Materials and Methods". Neutral loss scans were acquired for five minutes at a collisional energy of 25 eV. NaOH added prior to ESI analysis was 10 μM

comparisons of the parent CE loss due to air oxidation. Close examination of the NL 368.5 scans of 18:2 CE exposed to ambient air revealed oxidation of the parent sodiated adduct of 18:2 CE (671.80) and the appearance of species enriched with one oxygen (*m/z* 685.80 and 687.80) and two oxygens (*m/z* 701.79 and 703.79) (Fig. 8, Panel B). These oxidized molecular species likely reflect the incorporation of oxygen into the parent molecule with 14 and 16 amu increases that likely represent the formation of oxo-ODE and epoxide species, respectively [8, 23]. It is also clear from these studies that as the degree of unsaturation increases in CE (e.g., 20:4 CE and 22:6 CE), the relative rate of CE oxidation increases (Fig. 8). It is envisioned that this rapid analytical method has utility in assessing the oxidation of unsaturated molecular species of CE that are added exogenously in experimental models. Furthermore, the fragmentation of specific species produced in vivo under oxidizing conditions could potentially be detected with this NL technique particularly in conjunction with chromatography.

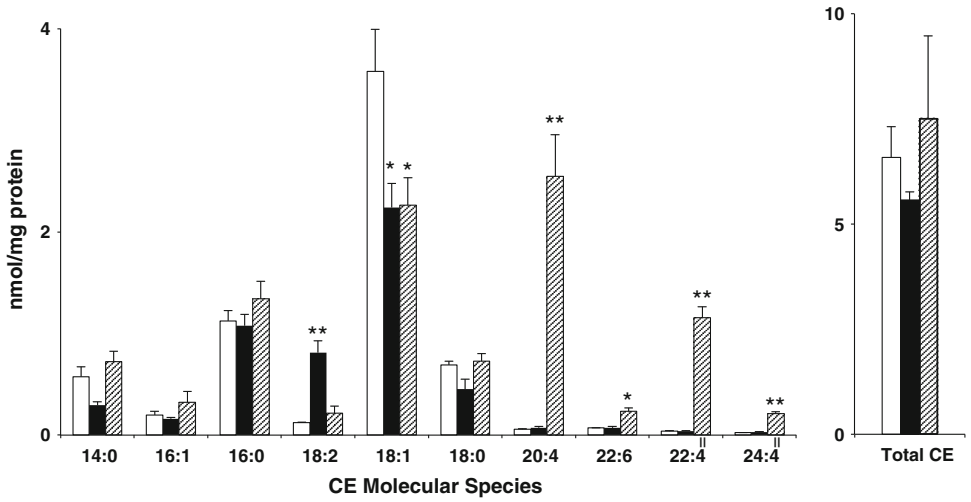

Fig. 5 CE molecular species present in J774 cells. J774 cells were cultured in the presence of either no fatty acid supplementation (*open bars*), linoleic acid supplementation (*black bars*) or arachidonic acid supplementation (*hatched bars*). At the end of the cell culture treatment interval, lipids were extracted from J774 cells with 17:0 CE added as an internal standard, and were subsequently subjected to ESI–MS using NL 368.5 scanning as described in detail in "Materials and Methods". Values are the means + SEM for $n = 3$. All values were corrected by calibration constants in Table 1 with the exception of those indicated (‖), which were corrected with the response factor (slope) of the corresponding shorter chain fatty acid with the same degree of unsaturation. For example, 22:4 and 24:4 CE were corrected using the 20:4 response factor. These elongated CE molecular species were not available to derive response curves. * and ** indicate $p < 0.05$ and $p < 0.005$ for comparisons between no fatty acid supplementation and indicated fatty acid supplementation conditions

Discussion

CE is predominantly found in the core of lipoproteins and lipid droplets [7, 8, 10]. Total plasma cholesterol and its association with specific lipoproteins is an important indicator of cardiovascular risk. Total plasma cholesterol is comprised of both free and esterified cholesterol. Both free cholesterol and CE is carried in plasma by lipoproteins. Despite the importance of CE as an indicator of cardiovascular disease, determining the specific aliphatic fatty acid associated with the CE is often overlooked in both clinical and experimental analyses, which is typically determined by removing the fatty acid by cholesteryl esterase, and then coupling cholesterol oxidase with a colorimetric readout. Using MS, CE molecular species form relatively poor protonated ions compared to other lipids containing class-specific functional groups that ionize [12, 24]. Previous studies have used ammonium acetate to create $[M + NH_4]^+$ ions of lipids using ESI–MS [15–17, 25]. Several groups [16, 21, 22] have examined ammoniated adducts of CE, which under CAD conditions results in predominant cholestane cation fragment. In comparison to the fragmentation of ammoniated adducts of CE, the sodiated adduct had an intense sodiated fatty acid fragment from the neutral loss of the cholestane residue. In addition, lithiated adducts of CE have also been shown to preferentially form lithiated fatty acid fragments in comparison to the cholestane cation observed with ammoniated adducts [26]. It should be appreciated though that the use of sodium to form adducts of CE enables faster workup of samples and is less problematic compared to the use of lithium, which requires extensive back extractions to remove sodium from biological samples.

Overall the goal of this study was to develop an electrospray ionization MS/MS method that could be readily used to quantify CE in biological samples and overcome potential interference and inaccuracies associated with other positive ions that are present in the mass range of biologically relevant CE ($\sim$ m/z 600–750 for sodiated adducts). Data shown in Fig. 3 clearly shows that NL 368.5 scanning specifically detects CE and does not detect isobaric DAG molecular species. Furthermore comparisons of positive ion survey scans and NL 368.5 scans shown in Fig. 6 from lipid extracts of mouse plasma demonstrates the utility of NL 368.5 scanning for detection of CE in complex biological matrices. Similar to other CE adducts that have been assessed in the past [16, 26], CE molecular species with varying degrees of unsaturation were shown to have different ionization efficiencies. CE have a weak dipole that is enhanced in the presence of sodium, and, similar to the dipole of triglycerides and CE with other adducts, the dipole in sodiated CE is dependent on the aliphatic chain length and more specifically the degree of unsaturation of the aliphatic group [12, 15, 16, 27]. Due to the varying degree of chain length and unsaturation for CE present in complex biological samples, it was necessary to generate individual calibration lines for each CE molecular species to correct for disparate responses compared to that of the internal standard (17:0 CE).

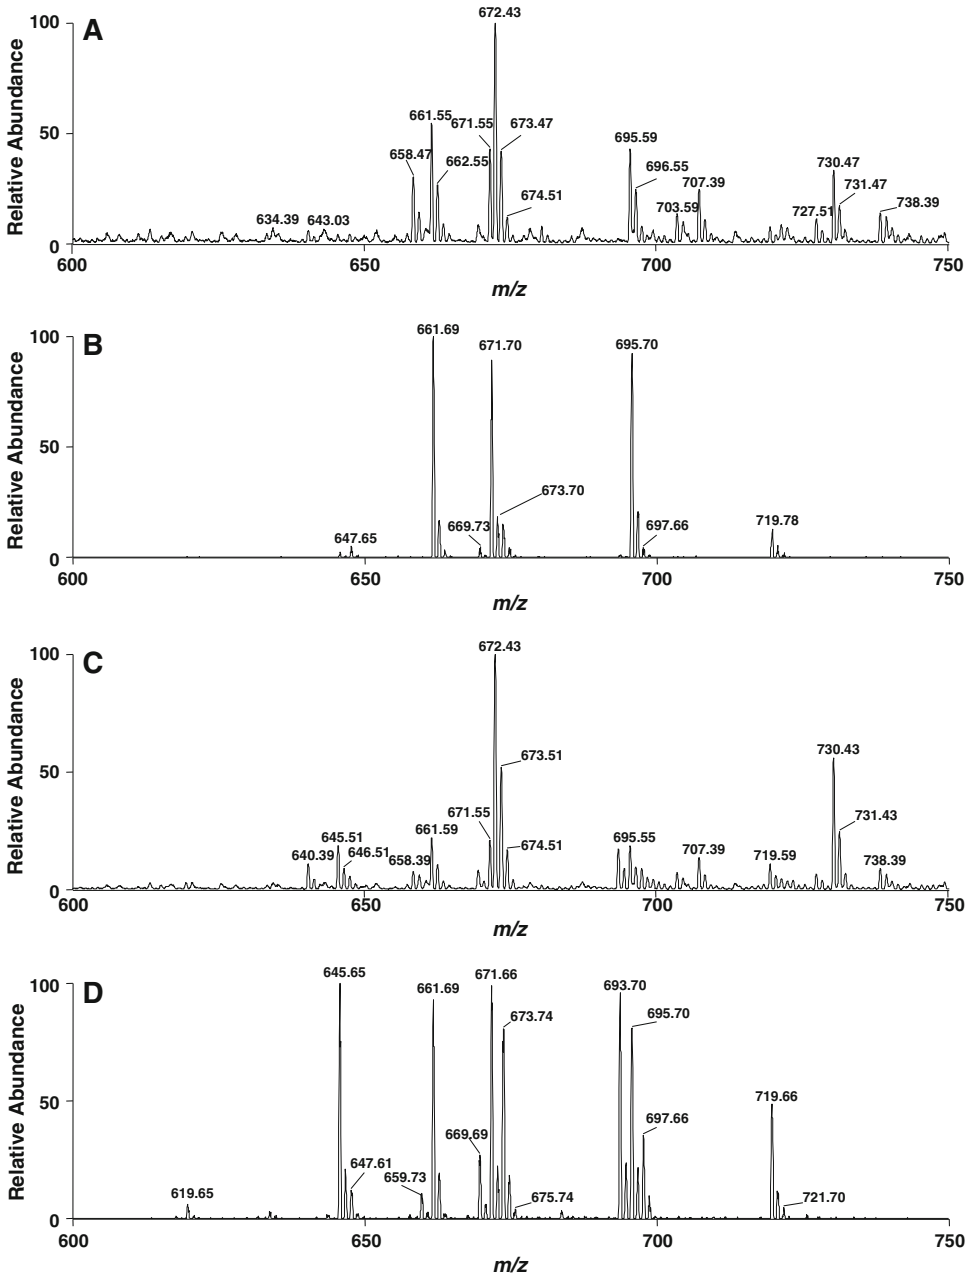

Fig. 6 Survey and NL 368.5 scans of sodiated cholesteryl esters present in mouse plasma. Female mice were fed a diet of either normal chow (**a**, **b**) or Western diet chow (**c**, **d**) for 14 weeks, and plasma was subsequently collected for the analyses of CE molecular species as described in detail in "Materials and Methods". Survey scans (**a**, **c**) and NL 368.5 scans (**b**, **d**) at a collisional energy of 25 eV were each acquired for five min. The NaOH added prior to ESI analysis was 10 μM

It should be appreciated that the use of neutral loss 368.5 scanning for the detection of CE molecular species can also be applied to rapidly determine alterations in the CE molecular species within biological samples, as well as assess fatty acyl decomposition of CE. We performed three experiments that demonstrate the utility of this technique. In the first study, J774 cells were treated with physiological concentrations (50 μM) of either linoleic acid or arachidonic acid, and then we assessed their effect on cellular CE composition. The predominant CE in J774 cells under normal cell culture conditions (control) was 18:1 CE. With addition of either linoleic or arachidonic acid to the cell culture media there was as drop in 18:1 CE levels accompanied by an increase in 18:2 or 20:4 CE respectively. Analyses using NL 368.5 scanning also revealed the somewhat unexpected finding that fatty acid chain elongation products were present in the CE pool of J774 cells treated with arachidonic acid (i.e., 22:4 and 24:4 CE were present). It should be noted that arachidonic acid has previously been shown to undergo elongation, and interestingly 22:4 CE is the predominant CE in the adrenal gland [28, 29]. In the second study, female mice were fed either a normal chow or Western diet for 14 weeks, and plasma CE levels were examined. In the normal chow fed female mouse, the predominant plasma CE were 18:2 and 20:4 CE. In comparison to the chow fed female mice, female

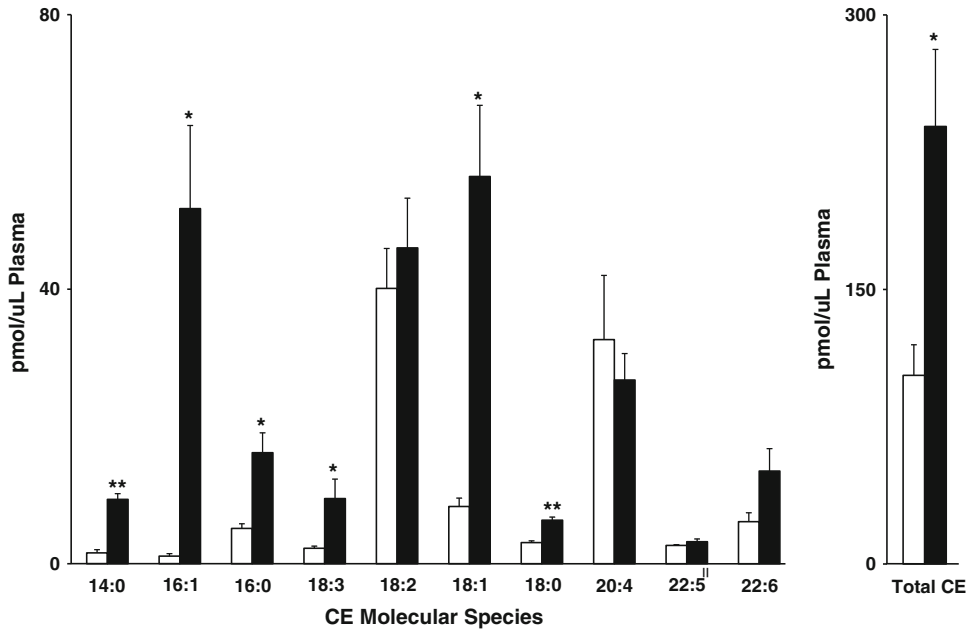

Fig. 7 Plasma CE molecular species in female mice fed either normal chow diet or Western diet. Female mice were fed a diet of either normal chow (*open bars*) or Western diet chow (*black bars*) for 14 weeks, and plasma was subsequently collected for the analysis of CE molecular species using NL 368.5 scans as described in detail in "Materials and Methods". All values were corrected by calibration constants in Table 1 with the exception of 22:5 CE (‖), which was corrected with the response factor (slope) of 20:4 CE. Values are the means + SEM for $n = 3$. * and ** indicate $p < 0.05$ and $p < 0.005$ for comparisons between normal chow diet and the Western diet

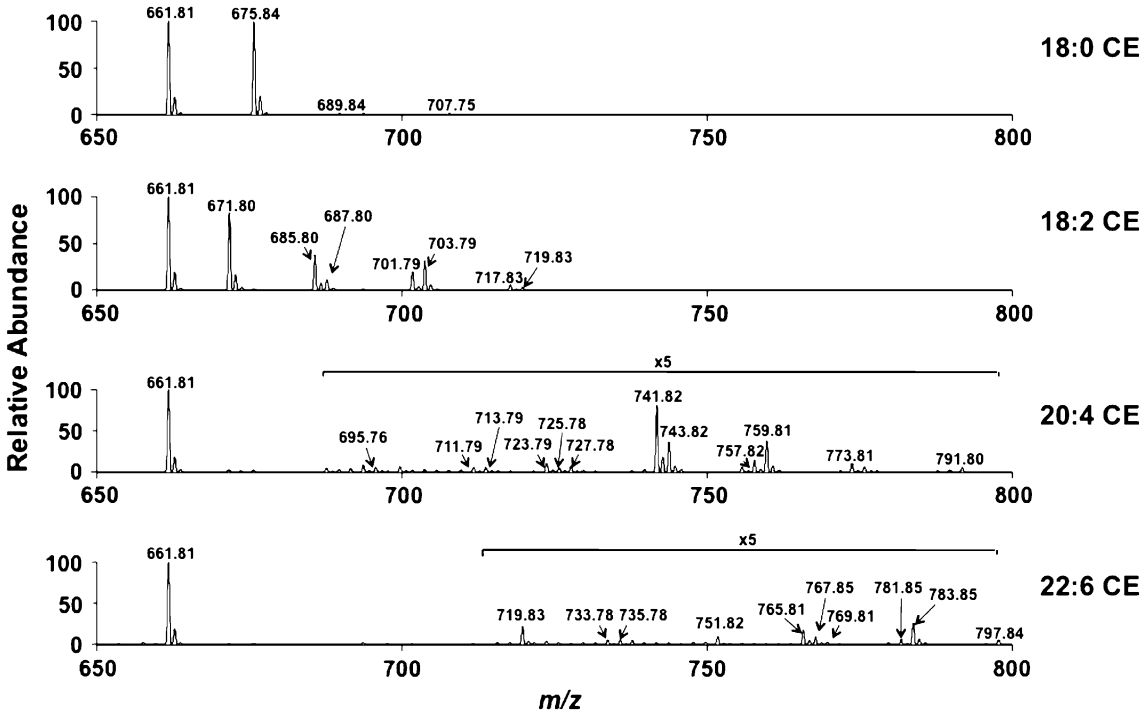

Fig. 8 Comparative oxidation of saturated and unsaturated CE. Indicated CE molecular species (18:0, 18:2, 20:4, and 22:6 molecular species) were dried individually and exposed to ambient air for 15 h. Treatments were terminated by resuspending CE in methanol/chloroform (4/1) containing equimolar 17:0 CE added as an internal calibrant. Each treated CE was subsequently subjected to direct-infusion ESI–MS analyses using neutral loss 368.5 scanning of sodiated adducts as described in "Materials and Methods". In the absence of oxidizing conditions, NL 368.5 analyses showed precursor CE were not decomposed and no oxidized products were observed

mice on a Western diet had nearly the same levels of 18:2 and 20:4 CE, but had a large increase in both 18:1 and 16:1 CE leading to a doubling of the total CE level. In the third study, we examined the air oxidation of several CE standards using the NL 368.5 scan mode to monitor the specific oxidation of CE molecular species. Oxidation of polyunsaturated species of CE is a concern both in the food industry since oxidized CE contribute to the rancid nature of spoiled oils [30], and from a health perspective since oxidized CE molecular species present in lipoproteins are a key contributor to the development of early atherosclerotic fatty streaks [8, 23]. Data herein demonstrates that the neutral loss technique can be used to quantitatively assess the loss of the CE molecular species to oxidation as well as the concomitant qualitative visualization of the oxidized products. It should be appreciated that CE that contain increasing levels of unsaturation are much more susceptible to air oxidation, and saturated CE are relatively stable when exposed to air under the conditions employed. These oxidation studies focused on the oxidation of the aliphatic chain of polyunsaturated molecular species of CE, and not the oxidation of the sterol nucleus. Sterol nucleus oxidation would probably not be detectable by the neutral loss of the cholestane fragment since the cholestane residue would be modified. Additionally, quantifying the oxidized species of CE will require comparing authentic oxidized CE molecular species to an internal standard to obtain species-specific response factors. Taken together, these three experimental approaches illustrate the utility of NL 368.5 scans of the positive ion sodiated adducts of CE in biological samples as well as the verification that the polyunsaturated fatty acid constituents of CE are intact and not oxidized.

In summary, these studies demonstrate the feasibility of forming sodiated adducts of CE molecular species, which can then be specifically detected by NL scanning of 368.5. Sodiated adducts can be readily formed in biological matrices extracted in the presence of saline in the aqueous phase and with the addition of micromolar concentrations of NaOH to samples subjected to direct infusion ESI–MS. Furthermore, since this is a lipid class-specific technique, direct infusion ESI–MS/MS can be used to quantify CE molecular species accurately in the presence of isobaric species in complex or crude biological lipid extracts.

sample, for example oleic acid (w/w) [1]. The majority of standard methods proposed by organizations such as the American Oil Chemists Society (AOCS) [2], international Union of Pure and Applied Chemistry (IUPAC) [3] etc., are based on acid–base titration. These methods are time consuming, laborious, have relatively high detection limits and are far from being fully automated [4, 5]. Another shortcoming of the standard methods is the use of toxic solvents, which is not only responsible for increasing the cost of the analysis but also represents a source of potential health risks and environmental pollution [6].

Over the last decade, several methods have been proposed for determining FFA in oils in order to overcome the drawbacks of the official methods. The instrumental determination of individual FFA is carried out usually by gas chromatography (GC), high performance liquid chromatography (HPLC) or capillary electrophoresis (CE), where the sample is subjected to pre-treatments such as liquid–liquid extraction (LLE) or solid-phase extraction and derivatization [7, 8]. Such treatments are necessary either to increase the volatility of the analytes for GC or improve the sensitivity of analytes for HPLC and CE methods.

Recently, Fourier transform infrared (FT-IR) spectroscopy has attracted interest as a method for the determination of FFA in edible oils [9, 10]. However, there are drawbacks to this method. Ismail et al. [11] also proposed a FT-IR method requiring high sample volumes and does not provide the level of speed necessary. Here the main limiting factor is that edible oils have high viscosity.

In recent years, flow injection analysis (FIA) has found wide application as a tool for routine analysis in several fields, including edible oils [1]. The advantages of flow techniques, such as versatility, simplicity and low cost make these procedures excellent choices for the analysis of edible oils because it becomes possible to perform analyses in an organic medium with low liquid waste, in a short period of time and with very high precision [7]. However, few flow injection (FI) methods for the analysis of edible oils and fats have been published. This situation is due to (i) the physical properties of oil samples, (ii) the difficulty of the operation in non-aqueous media, and (iii) difficulty in providing repeatability.

Velasco-Arjona and co-workers [12] described a fully automated robotic method for the determination of acid value (AV) based on the extraction of free fatty acids from olive oil samples into an immiscible phase and subsequent AV determination by monitoring the pH of the sample reagent emulsion using a combined glass-calomel electrode. The method consumes high reagent and sample volumes and requires a long time to complete the analysis, so the use of this method is not recommended. The method proposed by Ekstrom [13] was based on copper soap colorimetry, using one extraction to achieve a reaction of the FFA with copper ions and another to recover copper ions that are subsequently monitored. This method was also modified by others [14, 15] using a phase or membrane separator, and channels and oil samples were injected after being pre-diluted and homogenized with toluene. Nouros et al. [16] suggested an automated FI titrimetric method for the determination of olive oil acidity.

In the present study using a modified HPLC system, a novel method was developed using FIA for the assessment of FFA in corn and sunflower oil samples. An olive oil aliquot was injected into a carrier stream of *n*-propanol containing KOH and a phenolphthalein indicator, and the absorbance of the resulting mixture was monitored continuously. Quantification was performed by taking peak areas measurements into account. The sampling rate was 30–100 h^{-1}, while *n*-propanol consumption was 3–7 mL per run. Almost all of the above-mentioned methods used for FFA determination require some pre-treatments such as dilution with appropriate solvents.

Experimental Section

Samples, Chemicals and Reagents

The chemicals and solvents of chromatographic purity were obtained from Merck (Darmstadt, Germany) and Sigma (St. Louis, USA). Edible oil samples were obtained from the Helvacizade Food Company, manufacturer of edible vegetable oils in Turkey. Oil samples were stored at 4 °C in brown glass bottles and were brought to room temperature before use.

Spectrophotometric Analysis

Initial analyses were performed using a UV detector in order to determine the appropriate wavelength. For this purpose, potassium hydroxide (KOH) and phenolphthalein (PHP) in different concentrations were prepared by dissolving both in *n*-propanol.

Standard Method Analysis

To determine the FFA content in oil samples, the AOCS standard method (Ca-5a-40) was used. According to this method, 0.1000 or 0.2500 N NaOH solutions were used as titrants, and potassium acid phthalate was also used as the primer standard substance to adjust the titrant concentration. The titrant solutions were dissolved in 95% ethyl alcohol, and the indicator solutions (1% PHP) were prepared by dissolving 1 g phenolphthalein in 100 mL 95% ethyl alcohol.

Flow Injection Analysis (FIA)

For the FFA content determination, *n*-propanol was the carrier phase, and KOH and PHP solutions were used as reagents at different concentrations.

Working References Materials (WRM)

Working reference materials supplied by Helvacizade Food Company (Konya, Turkey) were used in the FIA analysis. The contents of FFA% in four sunflower reference oils were 0.07, 0.40, 0.74, 1.40 while in eight corn reference oils the levels of FFA% were 0.09, 0.25, 0.50, 0.75, 1.00, 1.50, 2.00 and 2.42.

Modified HPLC System for FIA Analysis

FIA experiments were performed by using a modified HPLC system (Agilent Technologies Inc., USA) consisting of a G1379A model degasser (B), G1311A model quaternary pump (D), a 7725i model Rheodyne manual injector system with a 20-μL loop (E) and a G1314A model variable wavelength UV detector (I). The temperature of the column was controlled by a G1316A model thermostatted column compartment (F). Data were recorded by a Chemstation 2001 data processor. In addition, a 2-position/6-port selection valve (H) and different reaction coils (G) made in our laboratory from PEEK tubing were adapted into the system. The tubing and fittings used to create the system were obtained from Agilent. Reaction coils are flexible and easy to cut into the desired lengths for the desired degree of reaction. The properties of these coils are given in Table 1. One of the other coils, labeled K in the system, was used to provide the connections. When required for chromatographic analysis, this part of the connection was also used. Coils, shown by the J and K labels in the system, were adapted for later analysis of other oil characteristics. In this study, only G was activated for the formation of the reaction. The single-line manifold system used for determining FFA% content in oil samples is shown in Fig. 1.

Concept of Flow Injection (FI) Analysis for FFA Determination

An alkaline solution, including KOH and PHP, was prepared by dissolution in *n*-propanol and was used as a carrier phase. The method is based on monitoring of changes in the absorbance of the indicators from the basic–acidic–basic form (pink–colorless–pink for PHP) as a result of neutralization of the KOH in the carrier phase by the injected FFA sample. Since the basic properties of the carrier phase decreased in a short time frame, a negative peak occurred. This decrease in the absorbance is proportional to the content of FFA%. Due to the continuous flow of the carrier phase, the absorbance value was increased to the initial absorbance value after a short duration. The negative peak height (h), half-peak width (w) and the area under the peak (A) were utilized to determine the FFA% of the oil samples. The data obtained from the peaks are proportional to the amount of FFA% in the oil samples; the greater the FFA% content in the sample, the more the peak absorbance decreases.

Table 1 Properties of reaction coils used in the FFA% determination tests

	Number of turns of the spiral	Coil length (l) (cm)	Inner diameter of coil (id) (mm)	Inner diameter of tube wrapped of coil (ID) (cm)
Coil 1	74	174	0.50	0.5
Coil 2	42	71	0.50	0.3
Coil 3	19	128	0.25	1.5

Optimizing Experimental Parameters

FIA parameters such as the flow rate of the carrier phase, length, geometry and inner diameter of the reaction coils, and the reagent concentration were optimized. The optimization experiments were performed with sunflower oils with FFA% values ranging between 0.07 and 1.40 and corn oils with FFA% values ranging between 0.09 and 2.42. The analysis was repeated at least five times. The carrier phase flow rate optimization studies were carried out using five different flow rates (0.1, 0.5, 1.0, 2.0, 3.0 mL min^{-1}). In the reaction coil optimization experiments, the effect of three reaction coils (tubing) with different inner diameter, length and geometry was investigated. In the reagent concentration optimization experiments, the effects of the base (KOH) and indicator (PHP) concentrations in the carrier phase were investigated. Reagent concentrations are given in Supplemental Table 1.

Generally, optimization studies investigating the effects of different parameter values on the FFA% experiments were conducted in parallel in order to give a better determination of the cumulative effects of the parameters.

Validating the FIA Method for FFA% Determination

In order to determine the suitability of the FIA method developed for FFA% determination, method validation studies were performed by measuring basic parameters such as precision, accuracy, linear region, LOD and LOQ.

Comparing Standard Methods with the Proposed FIA Method

In order to check the performance of the FIA method, the developed method was applied to real samples and

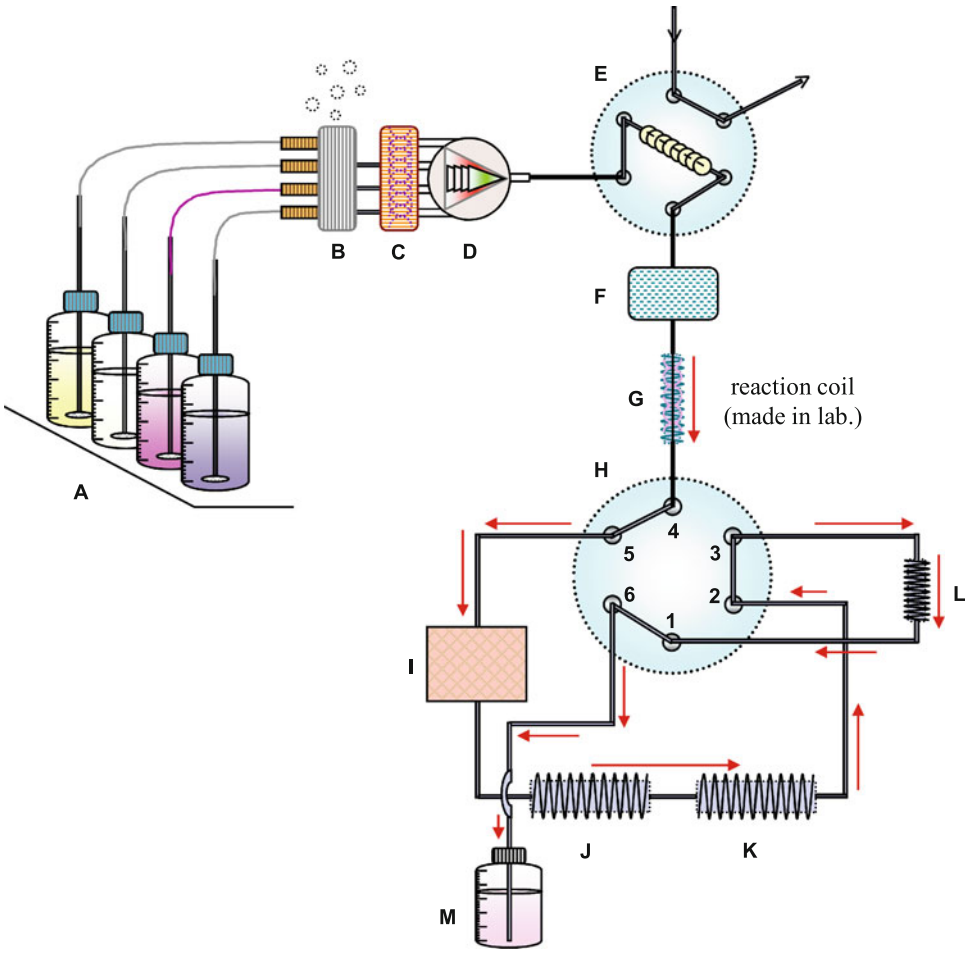

Fig. 1 Modified HPLC system with manual injection for determining FFA% *A* carrier/solvent tray, *B* degasser unit, *C* mixer, *D* quaternary pump, *E* manual injection port, *F* thermostatted column oven, *G* reaction coil (id: 0.25 mm, ID: 1.5 cm), *H* 2-position/6-port selection valve, *I* UV detector, *J–K* 1 mL stainless steel loop (id: 0.76 mm), *L* 50-μL stainless steel loop (id: 0.51 mm), *M* waste

reference material samples of sunflower and corn oils. For real samples, the results were cross checked by the standard AOCS titration method. Data obtained with the two methods were compared using statistical *t* and *F* tests. The *t* test comparing the average values of data groups and the *F* test comparing the variance values of data groups was used for comparison of the methods. The tests were performed using XLSTAT 2010 and statistiXL programs. These tests, applied in accordance with null and alternative hypotheses, were performed as double-sided with a 95% confidence level ($p = 0.05$), and calculated *t* and *F* values were compared with critical *t* and *F* values.

Results and Discussion

Spectrophotometric Analysis

Spectrum scans were collected with a UV detector over a 190–600 nm range. A wavelength of 580 nm showed maximum absorbance and was thus accepted as the appropriate wavelength for FFA measurements.

Flow Injection (FI) Analysis for FFA%

Experiments were carried out with the flow injection system protected from the atmosphere and light, both very important in terms of the reliability of the analysis results. For example, carbon dioxide in the air affects the indicator function due to its acidic properties. Light also triggers the degradation reactions of the oil and may increase the amount of FFA. *n*-Propanol containing the reagent KOH, and indicator (PHP), were used as the carrier phase, and 20-μL oil samples not subjected to any pre-processing were injected into the FIA system. The continuously flowing mobile phase had high absorbance due to the characteristic property of the indicator in basic media. The injected sample reacts with the base (KOH) in the carrier phase and the pH of the carrier phase is lowered for a short period of time. After completion of free fatty acid reactions with the equivalent amounts of base, absorbance returned to the initial value due to the constant stream of fresh carrier phase. The transitory absorbance change presents as a negative peak and is used to calculate the FFA% content since peak intensity increases negatively in proportion to the increased FFA% content.

Optimizing Carrier Flow Rate

The carrier phase flow rate is related directly to the formation of the desired reaction, peak shape, peak size and peak resolution. For this reason, the flow rate of the carrier phase was usually the first parameter optimized in both chromatography and FIA experiments. The peak shape measures the reaction between the analyte and a carrier or reagent. When the desired reaction did not occur, rectangular rather than Gaussian curve-shaped peaks were observed. Although Gaussian-shaped peaks are preferable in chromatography and flow injection analysis, rectangular peaks are also used effectively. Flow rate, peak shape, size and differences in peak absorbance were optimized. After carrying out optimization experiments at five flow rates (0.1, 0.5, 1.0, 2.0, 3.0 mL min^{-1}), the appropriate value for quantitation of FFA was determined to be 2.0 mL min^{-1}. With flow rates lower than 2.0 mL min^{-1}, the desired reaction did not occur and the resultant peaks were spread out too far. When the flow rate was >2.0 mL min^{-1}, the area and height of the obtained peaks decreased. Peaks obtained from the flow rate optimization experiments for each reaction cell are shown in Figs. 2, 3. FFA versus flow rate graphs showed that the highest correlation between measured and reference FFA contents, regardless of oil properties, was obtained with reaction coil 3, the flow rate was 2.0 mL min^{-1} (Table 2).

Optimizing Reaction Coils

The natural properties of oils, especially their viscosity, require that reaction conditions are set up very precisely. For this reason, the type of FIA reaction coils used is very important. Experiments designed to select the best reaction coil were done with various flexible tubes wrapped in a spiral on a cylindrical support. Turbulence associated with a spiral structure accelerated formation of the desired reaction and facilitated the desired degree of dispersion. Also, the internal volume of the tube (reaction coil), the inner diameter of material wrapped around the tube are extremely important factors for selecting the reaction coil. The results revealed that for the reaction to occur to the desired extent, the ratio of the tube's inner diameter (id) to wrapped material's diameter (ID) should be approximately

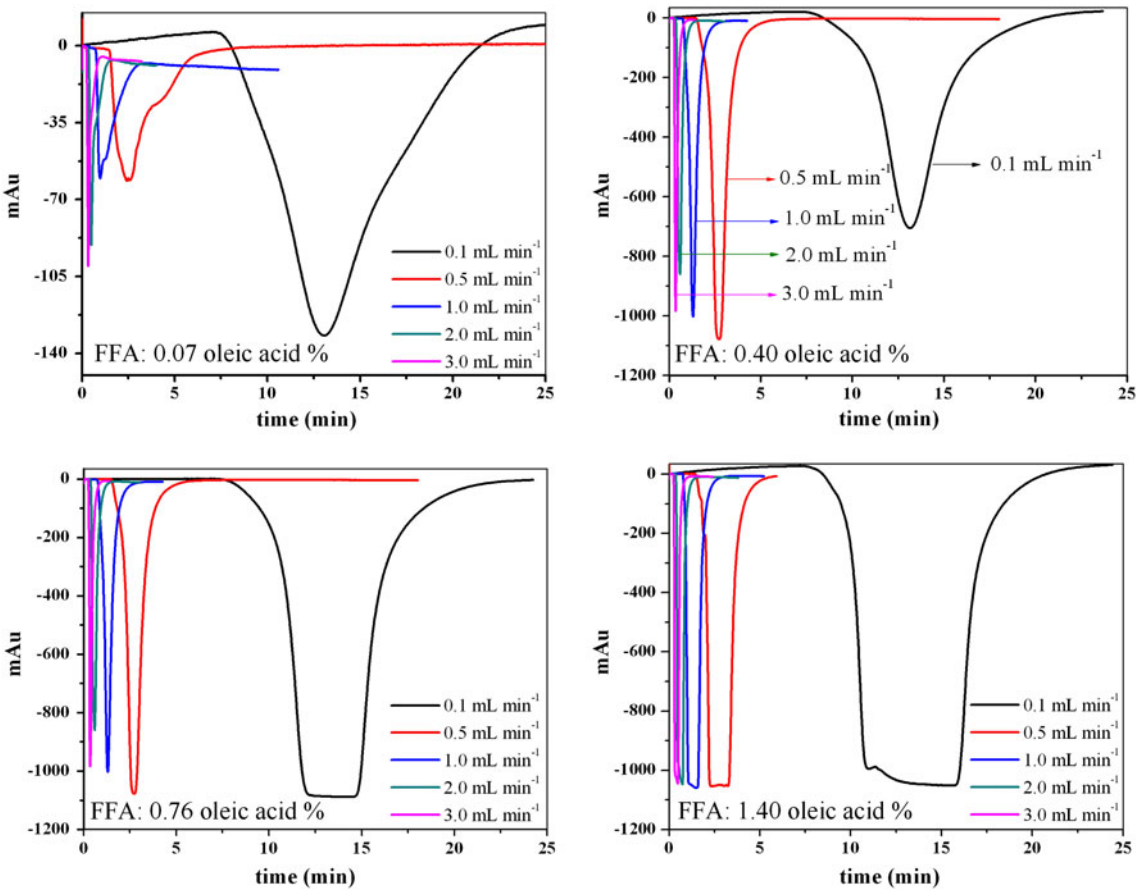

Fig. 2 Peaks obtained from flow rate optimization experiments for sunflower oil samples using coil 1. *Wavelength:* 580 nm

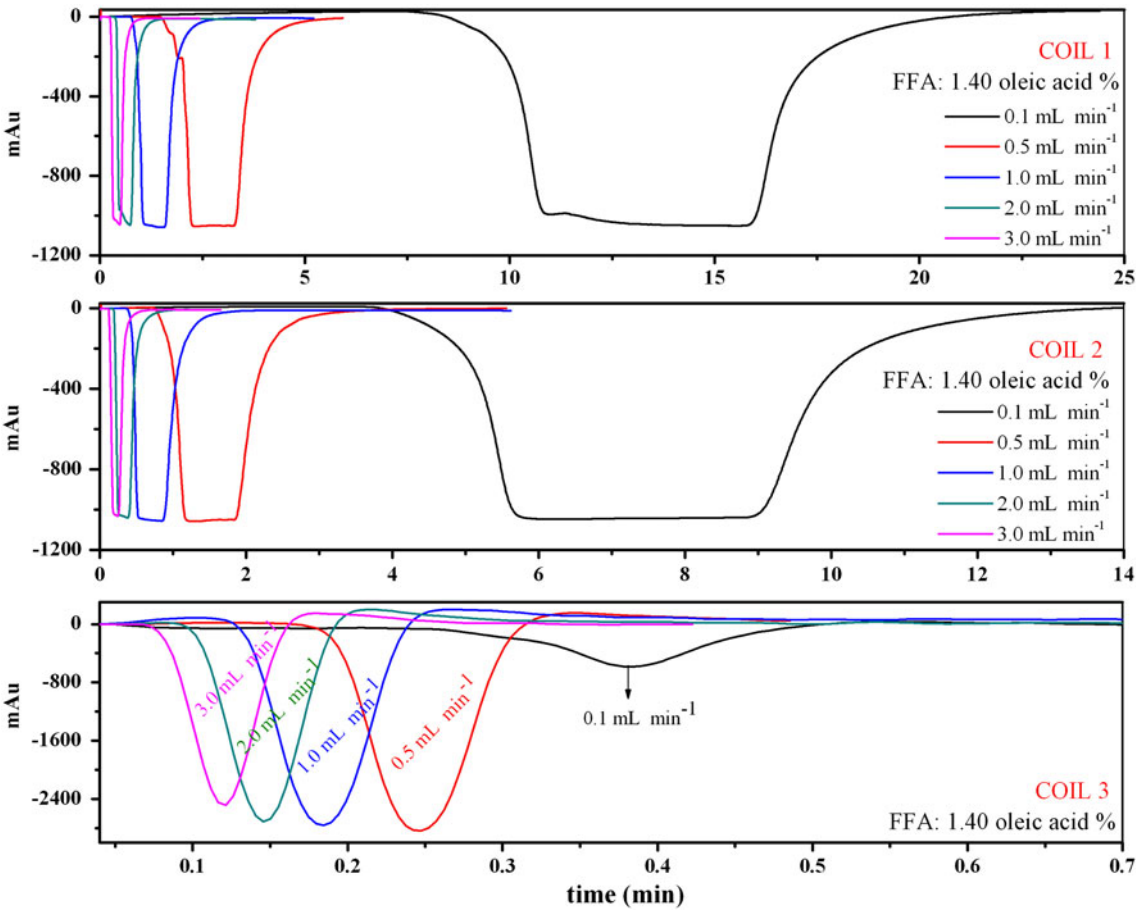

Fig. 3 Peaks obtained from flow rate optimization studies for sunflower oil samples with different reaction coils. *wavelength:* 580 nm

Table 2 Correlation coefficients obtained from Area-FFA% graphs plotted for flow rate and reaction cell studies

	Correlation coefficients of FFA%—flow rate graphs[a]		
Flow rate (mL min^{-1})	Coil 1	Coil 2	Coil 3
0.1	$R^2 = 0.951$	$R^2 = 0.960$	$R^2 = 0.995$
0.5	$R^2 = 0.995$	$R^2 = 0.867$	$R^2 = 0.998$
1.0	$R^2 = 0.989$	$R^2 = 0.859$	$R^2 = 0.997$
2.0	$R^2 = 0.983$	$R^2 = 0.830$	$R^2 = 0.999$
3.0	$R^2 = 0.988$	$R^2 = 0.828$	$R^2 = 0.998$

[a] The experiments were performed using sunflower oils with FFA% values ranging between 0.07 and 1.40 and corn oils with FFA% values ranging between 0.09 and 2.42

1/10. With these conditions, sufficient turbulence can occur and dispersion of the substances can be achieved. Another important factor is the length of the coil. Data obtained with three reaction coils with different lengths and internal diameters, data obtained from these studies show that coil 3, having 19 turns of the spiral, was the most appropriate cell for determining FFA% in different oils (Fig. 3 and Table 2). When coil 1 and coil 2 were used as reaction cells, the peaks necessary for evaluating the results could not be obtained. Namely, oils containing high amounts of FFA did not react sufficiently with the base in the carrier phase. Oils with low amounts of FFA gave distorted peaks due to the length of the reaction cells (Fig. 2).

Optimizing Reagent Concentration

Reagent concentration studies performed with corn oil samples, with FFA% values ranging from 0.09 to 2.42; show that the use of KOH and PHP as reagent and indicator is extremely important to determine the FFA% by FIA. Reagent concentrations used in the experiments must clearly demonstrate peak reductions with increasing FFA content. Reagent concentration studies were carried out with coil 3 at the selected flow rate, 2.0 mL min^{-1}. Many things were taken into consideration when evaluating the results, such as peak separation, symmetry, slope and regression coefficient values of measured FFA% values across samples. Reagent concentration optimization studies were performed using various solutions, with base

concentrations from 2.12×10^{-3} M to 5.00×10^{-3} M and indicator concentrations between 10.63×10^{-5} M and 25.00×10^{-5} M. As can be seen from the peaks plotted for different reagents, best results were obtained when Reagent 2 ($\sim 2.50 \times 10^{-3}$ M KOH and 25.00×10^{-5} M PHP) was used as the reagent (Fig. 4).

Validating the FIA Method for FFA% Determination

Method validation studies were performed by examining basic assay parameters such as precision, accuracy, linear region and dynamic range. The limit of detection (LOD) and the limit of quantification (LOQ) were found from the results of at least five repeat experiments. In order to test the accuracy of the FIA method for the determination of FFA%, three samples of corn and sunflower oil within the range of the calibration curve were analyzed. Accuracy of the FIA method was expressed as relative error (E_r), calculated on the basis of the mean (X_i) and actual values (X_t) of the FFA obtained from five repeated experiments. The mean measured values obtained from the studies were within ±5% of the actual value, thus proving the accuracy of the FIA method. Repeatability of the experiments was determined by carrying out repeat tests in two stages, including intra-day and inter-day tests. Repeatability was measured as the standard deviation (s), relative standard deviation (RSD), variance (s^2) and coefficient of variation (CV), and confidence intervals ($p = 0.05$) for each series (Supplemental Table 2). Regression analysis was carried out by means of a one-way ANOVA analysis and statistical descriptions for the linear range of FIA were obtained (Supplemental Table 3). The scatter plot with fit and residual plot obtained from ANOVA is also shown in Supplemental Fig. 1. The linear measurement ranges for the sunflower and corn oils used in the FFA% analysis were determined to be 0.07–1.40 and 0.09–1.50, respectively. In the calculation of LOD and LOQ, calibration graphs (Area-FFA%) were used, with points plotted for each oil sample. The standard deviations of the areas and FFA% values were calculated by using the slope and intercept of the graph and coefficient of variation (CV) values. FFA values, corresponding to three and ten times the calculated standard deviation value, were regarded as LOD ($3 \times s$) and LOQ ($10 \times s$), respectively. Accordingly, LOD values for corn and sunflower oils were calculated as 7.53×10^{-4} and 7.11×10^{-4} oleic acid %, and LOQ values were calculated as 2.28×10^{-3} and 2.23×10^{-3} oleic acid %, respectively.

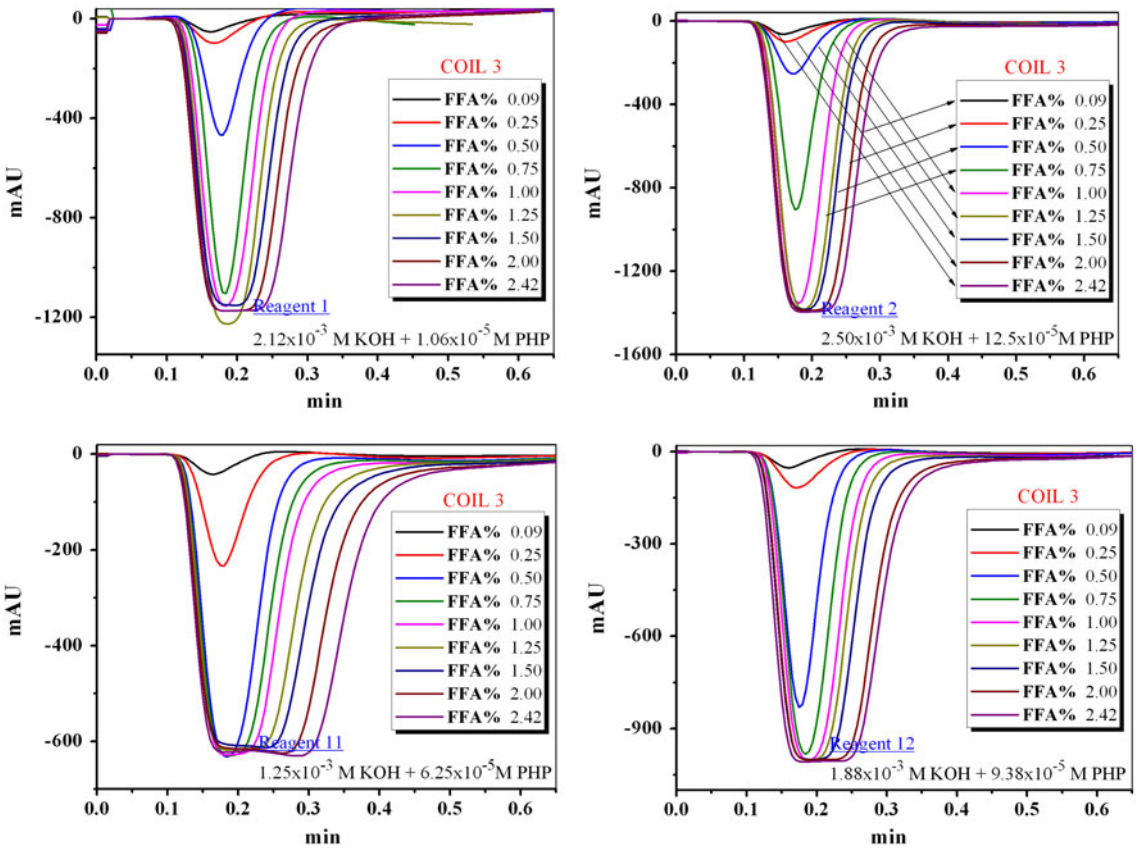

Fig. 4 Peaks obtained from the optimization of reagent concentration studies for corn oil samples

Evaluating the FIA Method on Working References Materials

The results of the method were also verified on WRM of sunflower and corn oil. Our developed method gave satisfactory results which were comparable to the labelled FFA contents. Therefore, a wide range of FFA contents was covered by analyzing both real samples obtained from industries and the WRM.

Comparing the Standard Method with the Proposed FIA Method

Performance of our developed FIA method was compared statistically with the standard method. Double-sided statistical tests conducted in accordance with Null and alternative hypotheses were found to have a 95% confidence level ($p = 0.05$). The data calculated separately for corn and sunflower oil samples showed that the t and F values calculated from experimental studies were smaller than the critical t and F values ($t_{\text{calculated}} = 0.09 < t_{\text{critical}}$ 2.12 and $F_{\text{calculated}} = 0.97 < F_{\text{critical}} = 4.43$ for corn oils and $t_{\text{calculated}} = 0.08 < t_{\text{critical}}$ 2.12 and $F_{\text{calculated}} = 0.94 < F_{\text{critical}} = 4.43$ for sunflower oils). Consequently, it is very clear from Table 3 that there is no significant difference between the data obtained by the FIA method and the standard method and there is a good correlation between the two methods for both oils ($R^2 = 0.996$ for corn oil and $R^2 = 0.994$ for sunflower oil).

Conclusions

The proposed method was applied successfully to the determination of FFA% content in corn and sunflower oil samples. This novel single-line FIA system is capable of performing many additional important oil analyses such as peroxide value, anisidine value, and iodine value. The developed method, based on a continuous-flow system with manual injection, provides an alternative procedure for quality control of FFA in edible oils compared to the standard reference method. The proposed FIA method requires only 1 ml *n*-propanol, 20 μL of oil sample per analysis and permits the analysis of 120 samples per hour. The superiority of the FIA method presented here is evident in comparison to the total amount of solvent and sample consumed by the standard method (~10 g of oil sample, 50–100 mL ethanol or diethyl ether). Furthermore, the results obtained with the proposed FIA method are highly compatible with those obtained with the standard method ($R^2 = 0.996$ for corn oil and $R^2 = 0.994$ for sunflower oil). Another important advantage of the proposed method is that the oil samples can be injected directly into the system without any pre-treatment. Since our method is simple, accurate, precise, rugged, rapid, cost effective and environmentally friendly, it is directly and easily applicable to other vegetable oils. The procedure is therefore a suitable alternative to the tedious classical method for FFA% determination, and can potentially eliminate more sources of experimental errors. We believe that the proposed method has great potential for a variety of on-line measurements such as peroxide value, anisidine value, and iodine value determination in edible oils. We also suggest that auto injector systems should be examined for their potential to automate FFA analysis.

Acknowledgments This study, a part of Ph.D. thesis entitled "*Improvement of Edible Oil Analysis Methods by Flow Injection Systems*" was supported by Selcuk University Coordination of Scientific Research with SU-BAP 08-101029 project numbers. The authors wish to thank the Principal of Selcuk University and Scientific Research Projects Coordination.

Conflict of interest The authors declare that there is no conflict of interest.
