ANNOUNCEMENT

Springer in the International Year of Chemistry 2011

As a leading international publisher in Chemistry, Springer enthusiastically supports the goals of the International Year of Chemistry 2011. The objectives of the IYC include enhancing the public appreciation of chemistry in meeting world needs and also celebrating the achievements of chemistry and its contribution to the well-being of mankind. As a step towards these objectives, Springer constantly develops innovative ways to bring information about chemistry and related sciences to a wide audience, not only of specialists in a given area, but also to researchers and teachers in other areas, students and others. Increasingly online media play the key part in worldwide dissemination of Springer's publications. Springer's online Chemistry and Materials Science package provides 24/7 access to 200 peer-reviewed journals and over 2,000 eBooks, with some 200 new eBook titles added per year. Additionally, Springer offers publications in the area of chemical and molecular sciences that are included in Springer's other eBook collections in areas such as life sciences, medicine, environment and energy. Overall, Springer currently offers over 2,000 online journals and 40,000 ebooks.

Springer has a range of new products to support students and young scientists.

- A newly launched book series "Lecture Notes in Chemistry" will make information at the forefront of research accessible to advanced students.
- Springer Theses, publishes exceptional theses from leading research institutions around the world, providing an international forum for outstanding young scientists at the start of their careers.
- Students and staff of institutions in North America and several European countries, that have purchased one or more Springer eBook collections, are now offered the opportunity to order their personal printed copy of an eBook at a fixed price of 24.95 USD/EUR. These so-called MyCopy books are black-and-white, paperback, print-on-demand books, and can be ordered directly from SpringerLink.

Through its extensive range of journals, books, reference works and databases, Springer plays a leading part in the broad dissemination of information on chemistry and its applications in all areas of human activity.

REVIEW

Oxidative Stability of Marine Phospholipids in the Liposomal Form and Their Applications

F. S. Henna Lu · N. S. Nielsen · M. Timm-Heinrich · C. Jacobsen

Received: 31 March 2010 / Accepted: 26 October 2010 / Published online: 19 November 2010

Abstract Marine phospholipids (MPL) have attracted a great deal of attention recently as they are considered to have a better bioavailability, a better resistance towards oxidation and a higher content of eicosapentaenoic (EPA) and docosahexaenoic acids (DHA) than oily triglycerides (fish oil) from the same source. Due to their tight intermolecular packing conformation at the *sn*-2 position and their synergism with α-tocopherol present in MPL extracts, they can form stable liposomes which are attractive ingredients for food or feed applications. However, MPL are still susceptible to oxidation as they contain large amounts polyunsaturated fatty acids and application of MPL in food and aquaculture industries is therefore a great challenge for researchers. Hence, knowledge on the oxidative stability of MPL and the behavior of MPL in food and feed systems is an important issue. For this reason, this review was undertaken to provide the industry and academia with an overview of (1) the stability of MPL in different forms and their potential as liposomal material, and (2) the current applications and future prospects of MPL in both food and aquaculture industries with special emphasis on MPL in the liposomal form.

Introduction

The present imbalance in the intake of n-3 and n-6 polyunsaturated fatty acids (PUFA) has a serious negative impact on health in the general population [1–3] and there is a strong desire to improve the situation by introducing new products on the market with a higher level of n-3 PUFA and a lower level of n-6 PUFA. Currently, the global food and dietary supplement market for n-3 fatty acids (EPA and DHA) is estimated to be 15,000–20,000 tons, derived from a total world production of fish oil of approximately 300,000 tons per year. Marine phospholipids (MPL) from, e.g., krill represents an alternative source of n-3 PUFA, but the market for MPL is still in its infancy even though an increasing activity in this field has been observed recently [4]. A number of companies are preparing market introduction of either natural MPL, derivatives of natural MPL, or synthetic MPL. The leading MPL product on the market at the moment is a krill extract with approximately 35% PL [5]. There are also MPL products that are made from fish processing by-products and salmon roe. It is expected that the MPL market will follow the general trends of n-3 fish oils. MPL are new on the market and their range of applications has yet to be determined. However, MPL are believed to have potential applications in human and animal nutrition, in pharmacology, and in drug delivery. The most well-documented applications of MPL are related to liposomes. Liposomes made from MPL have been developed as a test system for antioxidants and as model systems for oxidation of biological membranes [6–9].

Many studies have been performed on n-3 triacyglycerols (TAG) enriched functional foods [10] while limited studies have been carried out on MPL enriched functional foods either in their pure form or in liposomal form. Furthermore, the current applications of phospholipid liposomes are limited to lecithin from soy bean or phosphatidylcholine (PC) from egg yolk and no attempts to use MPL based liposomes for food purposes have been reported in the literature [11–13]. However, some studies [14–19] have investigated the use of MPL such as herring roe or krill PL for larvae feed in the aquaculture industry. The limited application of MPL and liposomes in both food and aquaculture industries can be attributed to several reasons (1) lack of knowledge especially related to the behavior of MPL in food and feed systems, (2) limitations in large scale production of liposomes without using organic solvents and (3) the requirement of expensive equipment for liposome production. Nevertheless, there is ongoing research in this area [20–28]. With the growing understanding of the following areas regarding (1) the physicochemical properties of MPL, (2) the oxidative stability of MPL or MPL based liposomes under gastrointestinal condition and (3) emerging technologies for liposome production without using organic solvents such as microfluidization and pro-liposomes method [29], it may soon become feasible to use MPL in both the food and aquaculture industries. This review gives an overview of our current knowledge on the above mentioned aspects.

Classification and Sources of MPL

PL can be divided into three classes: glycerophospholipids, ether glycerolipids and sphingophospholipids. Glycerophospholipids represent the most widespread phospholipid class and they differ in their polar head groups. For example, phosphatidylcholine (PC) has choline as a head group, while phosphatidylethanolamine (PE) has ethanolamine as a head group, etc. as shown in Fig. 1. In addition, PL from different sources also have different fatty acid profiles in the *sn*-1 and *sn*-2 positions (Fig. 2a). Thereby, the chain length and degree of unsaturation may vary from source to source. For example, PL originating from plants such as soy bean do not have fatty acid chain lengths longer than 18 carbon atoms and contain only one to three double

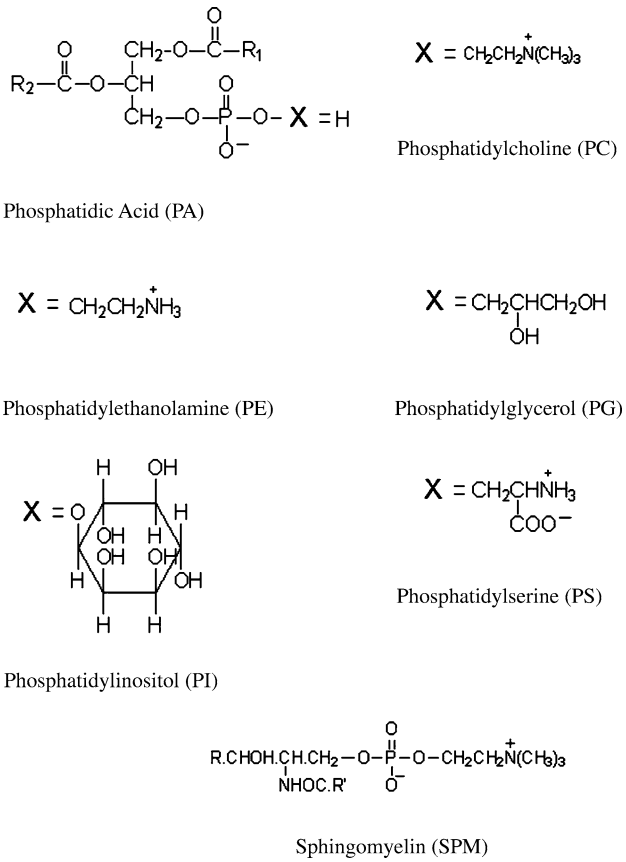

Fig. 1 Chemical structures of PL compounds with names and abbreviations

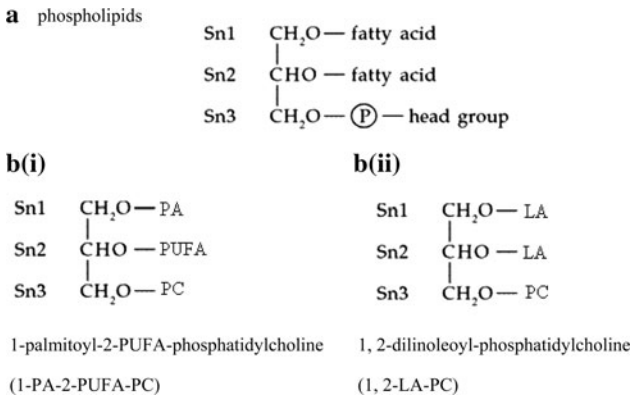

Fig. 2 **a** General structure of a phospholipid, **b** i) 1-palmitoyl-2-PUFA-phosphatidylcholine ii) 1,2-dilinoleoyl-phosphatidylcholine.

bonds, while PL originating from egg yolk or marine sources additionally have chain lengths of 20 and 22 carbon atoms with four to six double bonds e.g. as found in fatty acids of EPA and DHA. However, egg yolk only contains small amounts of EPA and DHA while marine sources are high in EPA and DHA. As far as marine sources are concerned, PL are found relatively abundant in roe, fish heads and offal such as viscera [30]. The most predominant PL in marine source such as salmon, tuna, rainbow trout and blue mackerel is phosphatidycholine (PC) as shown in Table 1. The second most abundant is phosphatidylethanolamine (PE). Phosphatidylinositol (PI), phosphatidylserine (PS), sphingomyelin (SPM) and lysophosphatidylcholine (LPC) are usually found in smaller amounts in marine sources, except for the relatively high level of sphingomyelin (SPM) found in tuna species [31–36]. Furthermore, krill such as *Euphausia superba* and *Euphausia pacifica* are other rich source of MPL [37, 38]. Almost half the lipid content of both types of krill is present in phospholipid form, mainly around 35% PC and 16% PE in *Euphausia superba* and 29% PC and 26% PE in *Euphausia pacifica*, respectively. Currently, Neptune Krill oil (a concentrate of MPL from *Euphausia superba*) is a leading commercial krill oil on the market.

Similar to the production of egg yolk PL, production of MPL in industry uses a combination of organic solvents such as hexane and acetone, isopropanol and ethanol for extraction of wet or dried biomass [36]. Non-polar solvents are used to extract TAG while polar solvents are used to extract PL. However, extraction of lipids using organic solvents may bring adverse health effects. Recently, a more promising method without using an organic solvent, supercritical fluid extraction (SFE) has been used for the extraction and fractionation of lipids [39–42]. The extraction can be carried out at low temperature by using CO_2. However, CO_2 can only extract neutral lipids from lipid mixtures, and a generally recognized as safe (GRAS) co-solvent such as ethanol must also be used to extract PL for the food industry. For instance, the addition of about 5–10% of ethanol to CO_2 is necessary to achieve the extraction of PL from egg yolk [42–44]. Additionally, krill oil has been extracted by a patented cold vacuum extraction process that can protect the biomass from exposure to heat, light or oxygen. Thereby, the oil is protected throughout the production process and the original nutrients of the krill are maintained intact.

Health Benefits of MPL

Many studies have shown that MPL are more efficient carriers of n-3 PUFA than TAG (normal fish oils) in terms of n-3 PUFA absorption in different tissues [45–47]. Thus, MPL not only contains more n-3 PUFA than TAG from the same source [31, 48, 49], but also provide better absorption in most tissues. This may be due to the amphiphilic properties of PL resulting in better water dispersability and

their greater reactivity towards phospholipases compared to the glycerolysis of triglycerides [49]. For this reason, supplementation of foods with n-3 PUFA rich PL has recently emerged as an interesting way of increasing the assimilation and thereby the health benefits of EPA and DHA. EPA and DHA have numerous well-documented health benefits, which have been reviewed extensively by Narayan et al. [50]. The more recent studies on these health benefits include a reduction of coronary heart diseases, inflammation, autoimmune diseases, hypertension, cancer, diabetes, susceptibility to mental illness and neurological diseases such as depression and Alzheimer's disease, as well as improved brain and eye functions in infants [51–59].

Apart from the benefits obtained from their favorable fatty acid composition, MPL may also provide health benefits due to their polar head groups [60, 61] or to a unique combination of the two in the same molecules. The latter explanation is supported by the following observations; the use of n-3 fatty acids (EPA and DHA) in PL form (either from marine or synthetic origin), instead of the triglyceride form, together with a vegetable oil containing n-6 fatty acids in a nutritive lipid emulsion, gave even lower blood triglyceride and cholesterol levels of patients as compared to the same amount of n-3 fatty acids given as fish oil [62]. The same observation was also obtained by Bunea et al. [63] who investigated the effect of krill oil (mainly present as PL) on hyperlipidemia. In addition, they reported that high doses of krill oil significantly reduced low-density lipoproteins (LDL) level and increased high-density lipoproteins (HDL). Their study concluded that krill oil was more effective at improving blood lipids and lipoproteins than fish oil. Apart from that, several studies have also shown that krill oil has many beneficial health effects such as it may has therapeutic value for metabolic syndrome, non-alcoholic fatty liver disease, attention deficit/hyperactivity deficit disorder (AD/HD), premenstrual syndrome (PMS) and it also showed anti-inflammatory effect [64–68]. Sampalis et al. [67] reported that phospholipid krill oil was more effective than triglyceride fish oil at improving both the physical and emotional symptoms of PMS while Deutsch [66] reported that the intake of krill oil at a daily dose of 300 mg can significantly inhibit inflammation and reduce arthritic symptoms within a short treatment period of 7 and 14 days. According to Maki et al. [64], 4 weeks of krill oil supplementation increased plasma EPA and DHA of overweight and obese men and women and was well tolerated without adverse effects on safety parameters. Besides that, Hayashi et al. [69] also showed that n-3 PUFA from salmon roe phosphatidylcholine may be beneficial in treatment of chronic liver diseases while Taylor et al. [70] showed that MPL is a promising new dietary approach to tumor-associated weight loss. Due to these numerous health benefits, there is an increasing desire to offer MPL containing n-3 PUFA to a wider market, e.g. for human foods and also to the general feed and aquaculture industry.

Introduction to Liposomes

Liposomes or lipid vesicles are aggregates formed from aqueous dispersions of amphiphylic molecules such as polar lipids that tend to produce bilayer structures [71]. They are useful microscopic carriers for nutrients and have a great potential for applications in both food and aquaculture industries. Besides that, liposomes have been recognized as a powerful tool in the treatment of diseases by the pharmaceutical industry. Their use as drug delivery vesicles and their medical applications such as in anticancer therapy, vaccination, gene therapy, and diagnostics have been reported in literature [72]. According to Watwe et al. [73], liposomes can be divided into three main classes: (a) multilamellar vesicles (MLV), contain more than a single bilayer membrane with a size range of 0.1–6.0 μm, (b) small unilamellar vesicles (SUV) and (c) large unilamellar vesicles (LUV) which both contain only a single bilayer membrane with sizes range of 0.02–0.05 μm and >0.06 μm, respectively. LUV are the most useful liposomes because they are more homogeneous than MLV and have higher encapsulation efficiency [74]. MPL or MPL based liposomes have obtained considerable attention and their oxidative stability has been studied extensively as shown in Table 2. Generally, MPL have been found to have a higher oxidative stability than TAG as will be discussed in the following.

Oxidative Stability of MPL

Mechanism of Oxidation for MPL

The PUFA chains in PL are the primary targets of oxidation. Similar to the oxidation of TAG, phospholipid oxidation may occur through radical and non-radical reactions involving enzymes such as lipoxygenase and myeloperoxidase or non-enzymatic systems such as ·OOH, ·OH, Fe^{2+}, Cu^{+} and radiation [75]. Due to the low dissociation energy of bisallylic carbon–hydrogen in double bonds of PUFA, a hydrogen atom can easily be removed. The first steps in the lipid peroxidation consist of hydrogen abstraction, rearrangement of double bonds and addition of triplet oxygen leading to highly reactive peroxyl radicals. These radicals can undergo a large variety of consecutive reactions including further reaction with other PL, fragmentation and generation of truncated PL and different

Table 2 Chemical and physical stability of MPL and MPL-based liposomes

Sources of phospholipids (PL)	Brief summary of findings	References
TL, NL and PL (from muscle of blue fish)	Antioxidant activity in salmon oil system supplemented with: 2.5% or 5% PL > 0.02% BHT 5% PL > 5% TL or 5% NL	King et al. [87]
Lipid fractions (from muscle, viscera and skin of sardine and mackerel fish)	Oxidative stability of lipid fractions: Muscle > viscera and skin Presence of higher PL (PE and PC) and α-Toc in muscle and synergistic effect of PE with α-Toc	Ohshima et al. [105]
Salmon roe PC, soybean PC	Oxidative stability of both PC in aqueous solution 1) Catalyzed by Fe^{2+}-ascorbic acid; salmon roe PC > soybean PC 2) Under influence of emulsifier: egg albumin > Tween 20 > deoxycholic acid sodium salt Reason: high stability of salmon roe PC is due to the conformation of PC molecule and the phase behavior of PC aggregation	Miyashita et al. [90]
Squid: muscle TL, viscera TL, eye TL; Tuna orbital TL, trout egg TL and bonito TAG	Oxidative stability of lipids fraction: Squid viscera TL or squid muscle TL > squid eye TL > trout egg TL > bonito TAG > tuna orbital TL Reason: higher stability is due to the presence of PL in squid tissue lipids and trout egg TL	Cho et al. [21]
DHA, PC, PE, TG	Oxidative stability of DHA in lipids: 1-DHA-2-palmitoyl-PE or 1-palmitoyl-2-DHA-PE or 1-DHA-2-palmitoyl-PC or 1-palmitoyl-2-DHA-PC > DHA + 1,2-palmitoyl-PC (1:1) > 1,2-diDHA-PC + 1,2-dipalmitoyl-PC (1: 1) or 1,2,3-triDHA-TAG DHA was most protected against oxidation when it was incorporated at one position of either PC or PE	Lyberg et al. [9]
Fish roes: salmon and herring, commercial fish oils: crude tuna oil and sardine oil	Oxidative stability of lipids Herring roe lipids > salmon roe lipids > commercial fish oils The higher oxidative stability is mainly due to the presence of PL in fish roe lipids and the synergistic effect of PL on the antioxidant activity of α-tocopherol	Moriya et al. [25]
Salmon roe PC, chicken egg PC and commercial soybean PC	Oxidative stability of PC in: a) Aqueous micelles: Salmon roe PC > chicken egg PC > soybean PC b) Liposomes: Chicken egg PC and salmon roe PC > soybean PC Reason: Higher stability is due to the presence of PUFAs in chicken egg PC and salmon roe PC which are esterified at the *sn*-2 position	Nara et al. [6]
Salmon roe PC, chicken egg PC and commercial soybean PC	Oxidative stability of liposomes containing DHA enriched TAG: Salmon roe PC > chicken egg PC and commercial soybean PC Addition of CHO; DP, SA, chicken egg albumin and Toc improved oxidative stability of salmon roe PC liposomes	Nara et al. [7]
68% PC, 23% PE, 2% PI, 2% PS and 1% SPM, 27% CHO and 4% TAG	Low pH led to an instantaneous vesicle aggregation of MPL-liposomes and shortened the release time of vitamin B1	Cansell et al. [20]
68% PC, 23% PE, 14% EPA, 31% DHA	MPL-liposomes exhibited relative high membrane physical and chemical stability in the gastric digestion condition indicating that MPL-liposomes could be used as oral administration vectors	Nacka et al. [28]
68% PC, 23% PE, 2% PI, 2% PS and 1% SPM	Acidification caused liposomes size and shape changes while maintaining the bilayer structure indicating that MPL-liposomes could be used as oral administration vectors	Nacka et al. [27]
68% PC, 23% PE, 14% EPA, 31% DHA	α-Toc uptake after oral delivery: MPL liposomes > sardine oil digestion Under gastrointestinal condition, α-Toc incorporation improved chemical stability of liposome suspension with best oxidative stability at (5 mol%)	Nacka et al. [26]

Table 2 continued

Sources of phospholipids (PL)	Brief summary of findings	References
Cod roe PL	Lipids oxidation is proportional to [Fe^{2+}] and [PL] but was dependent on pH with a maximum between pH 4 and 5 Addition of salt decreased the rate of lipid oxidation	Mozuraityte et al. [22]

types of low molecular weight compounds such as aldehydes and ketones. However, enzymatic oxidation of PL can be eliminated in the MPL during their thermal production. Besides that, different PL oxidation products can be formed depending on the predominating oxidative process [76]. Oxidation products can be classified into three main categories such as: (1) long chain products that preserve the PL skeleton, and which may result from insertion of oxygen followed by rearrangement or cleavage of the PL hydroperoxides leading to epoxy, polyhydroxy, hydroxy, or keto derivatives of PL, (2) short-chain or truncated products, formed by cleavage of the unsaturated fatty acids. These products include ketones, aldehydes, unsaturated carboxylic acids, (keto)hydroxyl-aldehydes, (keto)hydroxyl-carboxylic acids, lyso-phospholipids and lyso-phospholipid halohydrins, and (3) adducts, formed by reaction between oxidation products and molecules containing nucleophilic groups, this include the products usually formed by cross-linking reactions between PL oxidation products with carbonyl groups and amino groups present in neighboring biomolecules such as peptides, proteins and phosphatidylethanolamine.

Dangers of Auto-Oxidation of MPL

Oxidation of MPL can not only deteriorate the quality of MPL enriched foods and affect the flavor, but also promote the development of neurodegenerative diseases. Many reported studies [75, 77–83] have shown that oxidized PL cause harmful effects to human health as they play physiopathological roles in developing diseases such as age-related and chronic diseases, acute lung injury, atherosclerosis, inflammation and decrease immune response. PL oxidation products such as hydroperoxyl, hydroxyl, aldehyde and epoxy groups that are potentially important in the progression of atherosclerosis and inflammation [80]. For instance, by activating the receptor for the platelet-activating factor (PAF), oxidized PL induce platelet aggregation [84–86]. Oxidized PL can also induce monocyte adhesion to endothelial cells, accumulate in atherosclerotic lesions, and play a role in inflammation and signaling inflammatory response. The dangers of the oxidized PL have been reviewed extensively and will not be further discussed in this review.

Antioxidant Effect of PL

King et al. [87] investigated the role of PL and the degree of fatty acid unsaturation on lipid oxidation in a salmon oil model system. Their findings showed that addition of a 2.5% (wt/wt) or a 5% (wt/wt) PL fraction extracted from bluefish to salmon oil increased its stability during heating at 55 and 180 °C as compared to the control salmon oil, or salmon oil to which 0.02% (wt/wt) of BHT or 5% (wt/wt) of other lipid fractions from bluefish such as total lipid or neutral lipid had been added. The PL fraction with 34% DHA was found to exhibit higher oxidative stability than other lipid fractions with 15% DHA. Subsequently, they investigated the antioxidant properties of individual PL in a salmon oil model system [88]. They found that nitrogen-containing PL such as PE, PC, LPC, and SPM were equally effective as antioxidants and they were more effective than PS, PG and PI. Their studies did not postulate any mechanism or reasons for the antioxidant properties of the different PL classes. In both studies by King and colleagues, the oxidative stability of the salmon oil model system was investigated through 2-thiobarbituric acids (TBARS) assay and the decreases in the ratio of DHA to PA (C22:6/C16:0). Boyd et al. [89] investigated the effect of 0.5% (by weight) PL toward lipid oxidation of 2.5 g salmon oil and menhaden oil model systems respectively, through the more sensitive headspace gas chromatographic analysis. Their study also showed that addition of PL significantly reduced the production of volatile compounds in both oil model systems.

Conformations of PUFA at the *sn*-2 Position of PL

Miyashita et al. [90] showed that salmon roe PC had a higher oxidative stability than soybean PC in an aqueous solution dispersed with chicken egg albumin although the degree of unsaturation in the salmon roe PC was higher

than in the soybean PC. They suggested that the high stability of salmon roe PC was mainly correlated with the conformation of the PC molecule and the phase behavior of PC aggregation. The main molecular species of soybean PC was 1,2-dilinoleoyl-phosphatidylcholine (1,2-diLA-PC), while for salmon roe PC it was 1-palmitoyl-2-PUFA-phosphatidylcholine (1-PA-2-PUFA-PC) as shown in Fig. 2b. Hence, the presence of this main molecular species in salmon roe PC (with most of the PUFA located at the *sn*-2 position of PC) may provide a more tightly packed molecular conformation as compared to the soybean PC and thereby increase resistance of PC towards oxidation. The findings of Miyashita et al. [90] corroborated the original work of Applegate and Glomset [91] who reported that DHA in the *sn*-2 position of diacylglycerol (DAG) containing a saturated acyl chain in the *sn*-1 position could form a tighter intermolecular packing conformation as will be further discussed below.

Conformations of DHA at the *sn*-2 Position in a DAG Model

Applegate and Glomset (1986) used a molecular modeling approach to search for conformations of DHA that might uniquely influence acyl chain packing in cell membranes. Their DHA conformations of lowest energy as shown in Fig. 3 were extended conformations in which six double bonds projected outward from the methylene axis (a) in two nearly perpendicular planes to form an extend angle-iron shaped structure or (b) at nearly 90° intervals to form a helical structure, respectively. Studies of packed arrays of these hexaenes with or without saturated hydrocarbons showed that tight packing arrangements were possible especially for angle iron-shaped molecules as a consequence of back-to-back, intermolecular contacts involving these chains. Applegate and Glomset [92, 93] further concluded that different unsaturated fatty acids at the *sn*-2 position of *sn*-1,2-diacylglycerols (DAG) may promote different packing and conformations. For instance, 1-stearoyl-2-DHA-DAG and 1-stearoyl-2-AA-DAG can assume a regular shape and tight packing while 1-stearoyl-2-oleoyl-DAG adopt a highly irregular shape and much looser packing. The simulations by Applegate and Glomset were done without reference to potential effects of polar headgroups, water of hydration and applied thermal energy. However, the molecular areas obtained for the model of DAG are in good agreement with that of the *sn*-2 polyunsaturated phosphoglycerides [94, 95]. This raises the possibility that corresponding natural phosphoglycerides may be able to pack closely together in monolayers and bilayers if their headgroups do not interfere. The findings of Applegate and Glomset were supported by Albrand et al. [96] who also agreed with the existence of the extended-helical conformations of DHA in PL. However, they also suggested several coiled conformations for DHA, tightly back-folded helical conformations with 1.2 and 1.5 spirals appearing to be the most stable as shown in Fig. 3.

More Recent Studies on the Conformation of PUFA at the *sn*-2 Position of PL

Nara et al. [6, 7] further compared the oxidative stability of PC from salmon roe, soybean and chicken egg in aqueous micelles and also in the form of liposomes with and without encapsulation of lipophilic substances. In aqueous

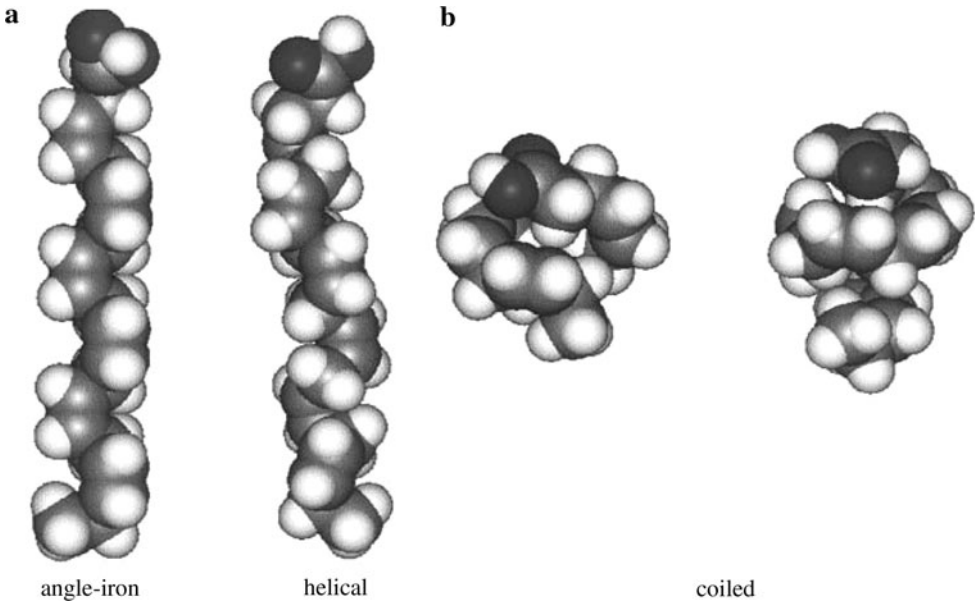

Fig. 3 Extended conformations of DHA in (**a**) angle-iron shaped and helical form, (**b**) coiled form

micelles, salmon roe PC was found to have the highest oxidative stability as evaluated by the highest content of un-oxidized PUFA, followed by chicken egg PC and soybean PC. Their findings are in agreement with the findings of Miyashita et al. [90]. No significant difference was found in oxidative stability between chicken egg PC and salmon roe PC when in the pure form of liposomes. However, for liposomes encapsulating with DHA enriched TAG resulted in the highest oxidative stability of both TAG and PC when salmon roe PC was used as the encapsulation material [7]. This unusual order of oxidative stability could be expected to be closely related to the conformation of PUFA at the *sn*-2 position in PC molecules as mentioned earlier [91]. Consequently, it is difficult for free radicals and oxygen to attack PUFA in bilayers of tighter conformation in salmon roe PC liposomes. Nara et al. [7] also suggested the possibility of using salmon egg PC as a liposomal material for the prevention of the oxidation of encapsulated fish oils.

Furthermore, Araseki et al. [8] also reported the characteristic oxidative stability of PC liposomes prepared from synthesized PC containing palmitic acid (PA), linoleic acid (LA), arachidonic acid (AA) and docosahexaenoic acid (DHA) in known positions. When the oxidative stability of 1-PA-2-LA-PC or 1-PA-2-AA-PC was compared with that of a 1:1 (mol ratio) mixture of 1,2-diPA-PC + 1,2-diLA-PC, or 1,2-diPA-PC + 1,2-diAA-PC respectively, the PC were more oxidatively stable than the latter corresponding PC mixtures in all oxidation systems despite the fact that the degree of unsaturation was the same in 1-PA-2-PUFA-PC and the corresponding mixture of PC. This was suggested to be due to the different conformation of PC bilayers which refer to the location of PUFA at the *sn*-2 position and the different rate of hydrogen abstraction by free radicals from intermolecular and intramolecular acyl groups. Their finding did not support a study by Lyberg et al. [9] who reported that the stability of DHA was improved independent of its position (*sn*-1 or *sn*-2) in PC or PE. Besides that, the more recent experiments and simulations [97–102] emphasized various degrees of flexibility of the DHA chain that gives looser packing of lipids bilayer. Their NMR analysis showed that the mobility of the hydrophobic part of the DHA molecule is higher than that of LA in liposome formation. These two competing views were portrayed in a review by Gawrish et al. [103]. However, according to Saiz and Klein [100], the flexibility of DHA chain conformation gives looser packing of the membrane at the lipid water interface and causes high water permeability. The presence of water molecules near DHA molecules lowers the density of the bisallylic hydrogen and inhibits the hydrogen abstraction from double bonds of PUFA during the propagation stage of autoxidation. As a conclusion, the higher water permeability of DHA and its specific conformation may be a reason for higher oxidative stability of DHA or other PUFA containing liposomes.

However, as compared to the study mentioned earlier by Miyashita et al. [90], contradictory results have also been reported by Monroig et al. [15, 16, 19] in their efforts to develop PUFA-rich liposomes for fish feed. They found that liposomes made from krill PL with 67% PC, 9% PE and a high content of PUFA showed lower oxidative stability as compared to liposomes made from soybean lecithin with 95% PC. The contradictory findings may be due to the different experimental conditions in the two studies, liposomes in model system versus liposomes in *Artemia* enrichment condition. In the model system, liposomes were formulated with pure PC containing fatty acid chains in known positions of the glycerol moiety and the oxidation was carried out in a very well-defined condition (temperature of 37 °C, in the dark and without agitation). On the contrary, the *Artemia* enrichment conditions were as follows: enrichment was carried out at 28 °C with strong aeration and 21 h of incubation.

Synergism Between PL and α-Tocopherol

Many studies have shown that the higher stability of PL may be due to the presence of antioxidants such as α-tocopherol in the PL mixture or synergistic effects of PL together with α-tocopherol [21, 25, 87, 88, 104–107]. The mechanism responsible for the synergy of tocopherols and PL is not very well understood. However, Hildebrand et al. [108] postulated that the mechanism involved in synergism of PE, PC and PI with tocopherol in the autoxidation of soybean oils were as follows: (1) amino groups of organic bases in PE and PC molecules and reducing sugar in the PI molecule facilitate hydrogen or electron donation to tocopherol and (2) these PL extend the antioxidant efficacy of tocopherol by delaying the irreversible oxidation of tocopherol to tocopherylquinone. Additionally, Saito et al. [106] reported that antioxidant activity of PL was found to be attributable not only to side chain amino groups such as choline and ethanolamine, but also to the hydroxyl group in the side chain.

Oshima et al. [105] studied the oxidative stability of sardine and mackerel lipids with respect to synergism between phospholipids and α-tocopherol. They investigated the oxidative stability of lipid fractions from different parts of sardine and mackerel; tissue from white and red muscles, viscera and skin of the fish. The oxidative stability was determined through the measured changes of the peroxide value (PV), fatty acid composition, α-tocopherol content and the oxygen uptake of lipids during an incubation period at 37 °C. Muscle lipids, which contain α-tocopherol and larger amounts of PL (PE and PC) than

other tissues, showed good oxidative stability despite their high content of PUFA. It was postulated that the synergistic effect of PE with α-tocopherol was the main reason for this phenomenon. Cho et al. [21] compared the oxidative stability of lipid fractions from marine organisms, squid muscle total lipids (TL), squid viscera TL, squid eye TL, tuna orbital TL, trout egg TL and bonito TAG. The fatty acid compositions, lipid classes, tocopherol contents and average number of bisallylic positions in each lipid fraction are shown in Table 3. Higher oxidative stabilities of three kinds of squid tissue TL and trout egg TL compared to those of bonito TAG and tuna orbital TL were observed as shown in Fig. 4. The authors suggested that the presence of PL in lipid fractions from squid tissue and trout egg was responsible for this increased oxidative stability. In addition, bonito TAG was found to be less susceptible to oxidation than tuna orbital TL and this could be due to the presence of a higher tocopherol content in bonito TAG.

Moriya et al. [25] compared the oxidative stability of fish roe lipids (salmon roe and herring roe) with that of lipids from commercial fish oils (crude tuna oil and crude sardine oil). As shown in Table 4, fish roe lipids contain higher levels of PL, EPA and DHA, and lower levels of tocopherol while lipids from commercial fish oils contain higher levels of TAG, tocopherol and lower EPA and DHA levels. Judging from these data, fish roe lipids were presumed to have lower oxidative stability. However, the opposite was observed as shown in Fig. 5 and it was proposed that the higher oxidative stability of fish roe lipids was mainly due to their high content of PL. It was also suggested that the synergistic effect of PL on the antioxidant activity of tocopherol was the main reason for this phenomenon. The higher oxidative stability of herring roe as compared to salmon roe was suggested to be due to synergism between PE and tocopherol. As shown in Table 4, the PE content in herring roe lipids was 6.6%, but there was no PE in salmon roe. Furthermore, herring roe also contained higher levels of PS and lysoPC than salmon roe and this may also have caused differences in their oxidative stability. The presence of antioxidants other than tocopherols in fish roe lipids such

as astaxanthin, coenzyme Q10 and lutein might contribute to this extraordinary stability as well.

Other studies [104, 107, 109] reported that the synergistic effect of PE with α-tocopherol was higher than that of PC. Bandarra et al. [104] investigated the antioxidant synergy of α-tocopherol (0.04%) with several PL fractions (0.5%) such as PE, PC and cardiolipin (CL) in a refined sardine oil model system. Their results showed that PC was the most effective individual antioxidant when it was compared to PE, CL and α-tocopherol while PE provided the highest synergistic effect with α-tocopherol. Higher synergism of PE as compared with that of PC could be due to the easier hydrogen transfer from the amino group of PE to tocopheroxyl radical and regeneration of tocopherol or the secondary antioxidant action of PE in reducing quinones formed during oxidation of tocopherols [109]. Since MPL may contribute to better oxidative stability than marine TAG, it can be expected that enrichment of foods or food emulsions with MPL could lead to n-3 PUFA enriched foods that have better oxidative stability than foods enriched with n-3 TAG.

Stability of MPL Based Liposomes Under Gastrointestinal Conditions

MPL based liposomes were designed with the purpose of increasing the PUFA bioavailability and also to protect entrapped compounds from digestive degradation. However, liposome characterization with respect to vesicle composition and membrane integrity under various gastrointestinal conditions are needed before considering liposomes as a useful oral dosage form. Many studies have shown that MPL liposomes could be used as an oral administration vector [6, 7, 20, 26–28]. This is because bilayer structures of MPL based liposomes were still maintained even under acid stress or gastrointestinal conditions despite of slight morphological modifications. Nacka et al. [28] investigated the in vitro behavior of MPL based liposomes under the influence of pH from 1.5–2.5 (stomach) to 7.4 (intestine) at physiological temperature (37 °C) in the presence of bile salts and phospholipase A_2 (Table 2). Their study showed that acidification induced instantaneous vesicle aggregation of MPL based-liposomes, which was partially reversed when the external medium was neutralized. Acidification also caused a complex morphological bilayer rearrangement and led to the formation of small aggregates. Nevertheless, Nacka et al. [27, 28] reported that the pH and temperature dependent structural rearrangement is mainly due to the osmotic shock and chemical lipid alterations such as oxidation and hydrolysis. Hydrolysis of the liposomes was amplified under the influence of an acid medium and high temperatures (Table 2).

Cansell et al. [20] investigated the physical stability of MPL-based liposomes containing vitamin B1 under acidic conditions simulating the stomach conditions. Encapsulation of vitamin B1 in the liposomes was carried out through passive encapsulation and active loading methods. They observed that vitamin B1 was totally released from liposomes after 24 h storage in a neutral medium and the time of release was shortened to 1 h in acidic condition (pH 1.5). According to their study, this liposome instability could result from the external medium osmolarity that forced water to flow out of the liposomes and simultaneously dragged vitamin B1 molecules through the bilayer. Furthermore, protons may also destabilize the lipid membrane by their interaction with PL via structural membrane rearrangement as previously mentioned. However, their study also proved that addition of xanthan gum improved the encapsulation efficiency and also the retention of vitamin B1 in liposomes regardless of the encapsulation

method used. They suggested that this increase is due to the adsorption of hydrocolloid to the outer surface of the liposomes that not only trapped part of the external vitamin but also formed a strong xanthan gum coating around the liposome surface. They postulated that this coating resulted from strong lipid–hydrocolloid interactions occurring during the centrifugation steps of liposome preparation.

The Effect of Lamellarity, pH, Temperature, Ionic Strength, Presence of Pro-oxidants and Chelators on MPL-Based Liposomes' Stability

Chemical and physical stability of liposomes are closely related to the mechanical strength and lipid bilayer conformation. Strong and well-packed lipid bilayers or multilamellar layers can protect the entrapped substance, decrease the changes of size distribution, fusion or other changes in the mechanical properties of lipid bilayers. For this reason, factors such as lamellarity, pH, temperature, ionic strength, dissolved oxygen content within the formulation, the presence of antioxidants and chelators are believed to affect mechanical properties of lipid bilayers and thereby affect the physical and chemical stability of MPL-based liposomal products [22, 23].

Nacka et al. [27] showed that the sensitivity of MPL based liposomes towards harsh condition such as acidic condition depends on their size and lamellarity (Table 2). They found that filtered liposomes with higher lamellarity and a protective effect against aggregation showed a slower size rearrangement. This finding supported a study by Monroig et al. [19] who, in addition, reported that liposomes with multilamellar vesicles seem to be more suitable than liposomes with unilamellar vesicles in the encapsulation of free methionine. They found that methionine dissolved in the more internal intermembrane spaces of multilamellar liposomes would remain encapsulated, whereas methionine from the aqueous compartments located between the more outer membranes would leak out

into the external medium when the liposomes were subjected to harsh conditions. However, this result contradicts another study by this group [15] where unilamellar liposomes were found to be more stable than multilamellar liposomes. The apparent discrepancy in these two studies is probably due to different experimental conditions and materials used for the liposomes preparation.

Mozuraityte et al. [22] examined the lipid oxidation rate of liposomes made from cod PL under influence of factors such as the temperature, the amount of added Fe^{2+}, the lipid concentration, pH, the concentration of NaCl, and the dissolved oxygen. Their study showed that the rate of lipid oxidation was proportional to the iron and lipid concentrations. Furthermore, lipid oxidation was dependent on pH, with a maximum observed between pH 4 and 5. Addition of NaCl decreased the rate of lipid oxidation. However, contradictory results were reported in another study [110] which showed that addition of NaCl had no effect or even increased iron-catalyzed oxidation of a sodium dodecyl sulfate-stabilized salmon oil emulsion.

Mozuraityte et al. [23] examined the effect of zeta potential on the lipid oxidation rate of liposomes made from cod PL under the influence of pH and different cations such as Na^+, K^+, Ca^+, Mg^+ and anions such as $H_2PO_4^-$ and Cl^- (Table 2). Their data showed that cations did not influence the rate of oxidation in the tested range of the ionic strength from 0 to 0.14 M whereas the opposite was the case for anions. Both phosphate and chlorides have an additive antioxidative effect on the oxidation in liposomes. Phosphate was shown to be more effective in reducing the oxidation rate than chloride. The inhibition of Fe^{2+} induced oxidation of liposomes by phosphate might be due to the phosphate chelation of iron [111, 112]. Furthermore, they also concluded that addition of salts and changes in pH affected the zeta potential of the liposomes. However, absolute values of the zeta potential alone cannot be used to predict oxidation rates.

Improvement of MPL Based Liposomes' Oxidative Stability

Many studies have been conducted to improve the oxidative stability of liposomes. Most of the studies focus on the use of cholesterol in improving the oxidative stability of liposomes [12, 113–115]. For example, a study conducted by Nara et al. [7] showed that addition of cholesterol and ingredients such as diacetyl phosphate (DP) and stearylamine (SA) improved the oxidative stability of salmon roe PC liposomes. Furthermore, in the effort of developing liposomes as feed supplement in larva culture. Monroig et al. [15] also showed that addition of cholesterol to liposomes made from krill PL or 1,2-PA-PC or soy PC improved the oxidative stability of the liposomes. Cholesterol has a condensing effect on the PC bilayer arrangement over its phase transition temperature and thus improves the physical stabilization of PC liposomes [116]. Addition of cholesterol can increase the rigidity of 'fluid state' liposomal bilayers and the retention of entrapped hydrophilic substances [117]. It counteracts lipids phase transition and increases resistance to in vivo liposomes degradation [118–120]. An interaction mechanism between bilayer forming PL and cholesterol has been proposed. This is due to the formation of hydrogen bonds between the three hydroxyl group of cholesterol and fatty acyl esters of PL at both *sn*-1 and *sn*-2 positions [121, 122]. These physico-chemical effects of cholesterol on liposomes may contribute to the increased oxidative stability in liposomes with cholesterol.

α-Tocopherol is widely known for its antioxidative effect [123]. However addition of high concentrations of α-tocopherol may also cause prooxidative effects [124, 125]. The most effective concentration of α-tocopherol in the prevention of lipid oxidation in salmon roe PC liposome

suspensions was 0.25 μM in a study conducted by Nara et al. [7]. Nacka et al. [26] investigated the most efficient amount of α-tocopherol for liposomes incorporation under gastrointestinal-like conditions. Their findings showed that the best oxidative stability was obtained for liposomes that were prepared at a ratio of 5 mol% of α-tocopherol of the total marine lipids. This concentration of α-tocopherol produced liposomes with the lowest concentration of propanal as an oxidation product of n-3 PUFA and required the longest time of oxidation induction phase. They also found that incorporation of α-tocopherol induced liposome structural modifications, evidenced by turbidity and the production of lysophospholipids from PL chemical hydrolysis.

Nara et al. [6, 7] investigated the effect of addition of diacetyl phosphate (DP), stearylamine (SA) and chicken egg albumin, and soybean protein on improving the oxidative stability of MPL based-liposomes. DP and SA give a negative or positive charge to the liposomes respectively and thus protect the liposomes from aggregation. An improved oxidative stability of liposomes after addition of this ingredient was observed and suggested that it was due to the physical stabilization of the PC liposomes. Furthermore, added proteins such as chicken egg albumin and soybean protein improved the oxidative stability of liposomes by protecting the PC bilayer from the attack of free radicals. Proteins have the ability to absorb at PC–water interfaces and this adsorption of proteins would closely relate to its antioxidant activity [6]. However, albumin acted as a more effective inhibitor of the oxidation of PC containing DHA than PC containing LA [90].

Determination of Oxidation Products from MPL

As discussed above MPL has been found to exert antioxidative effects toward lipids oxidation. However, many of the lipid oxidation studies [6–8, 21, 90, 105] were performed using simple analyses such as TBARS, PV, determination of the un-oxidized lipids (PUFAs) content through gas chromatography, or determination of only one secondary volatile compound, propanal (as a marker of n-3 PUFA oxidation) by headspace GC–MS analysis [25], etc. In many of these oxidative stability studies, there is a lack of determination of the entire spectrum of volatile oxidation products or identification of specific oxidation products which are responsible for sensory off-flavors of the marine lipids. Furthermore, there are no studies providing the sensory data or statistical correlation between instrumental analysis and sensory data for oxidation of MPL. These data are particularly important in the studies of MPL for foods enrichment and additional studies in this area are clearly needed. Due to the low odor threshold, the presence of volatile secondary oxidation products, even at low concentrations, can significantly decrease the sensory quality of marine lipids or marine lipids containing foods.

In the recent years, the oxidation products of PL have attracted intensive research interest due to their biological functions in human pathophysiology. Similar to other lipids such as TAG, many methods can be used to study the oxidation of PUFA containing PL such as (1) measurement of lipid hydroperoxides through spectrophotometric determination of PV or conjugated dienes (CD). Lipid hydroperoxides may also be determined by sample derivatization followed by HPLC with chemiluminescence detection, (2) measurement of breakdown products of hydroperoxides, such as the aldehydes, malondialdehyde, etc. through anisidine value (AV), 2-thiobarbituric acid value (TBARS), etc., (3) measurement of secondary volatile compounds through more sensitive instrumental methods such as GC–MS, (4) measurement of long chain oxidation derivatives of PL through MS. Electrospray ionization (ESI) is gaining in popularity in this area nowadays for this purpose [76]. ESI is a soft ionization technique that does not cause fragmentation and allows detection of intact PL classes without sample derivatization. ESI can readily be coupled to reverse phase LC and allow the analysis of oxidized PL [126–129]. Interfacing reverse phase LC to ESI–MS has the advantage as oxidized PL elutes earlier than their native counterparts due to their higher hydrophilicity. Spickett et al. [127] used the positive ion ESI–MS for detection of hydroperoxide in PC vesicles after treatment with *tert*-butylhydroperoxide and Fe^{2+} while Yin et al. [129] used ultra performance liquid chromatography (UPLC) coupled with negative ion electrospray ion trap MS to identify the intact oxidation products of glycerophospholipids in vitro and in vivo such as hydroxyeicosatetraenoates (HETE) and isoprostanes (IsoP). Other soft ionization methods include matrix-assisted laser desorption ionization (MALDI) and tandem mass spectrometry (MS/MS). As a conclusion, the future direction for research and development could focus on the investigation of oxidative stability for MPL by using advanced MS analysis.

Potential of MPL as Liposomal Material

A variety of liposome preparation methods are available nowadays ranging from traditional methods using solvent extraction such as thin film hydration, detergent dialysis, reverse-phase evaporation, etc. to emerging technologies without using an organic solvent such as pro-liposome, supercritical fluid extraction, and microfluidization. Each method has its own advantages and drawbacks as reviewed by Taylor et al. [130]. Among these technologies, pro-liposome and microfluidization are recommended to produce liposomes for food applications. Pro-liposome is a

simple method for mass production of liposomes without using large amounts of energy, solvents and complex equipment. This method is based on the idea that addition of water to an appropriate mixture of ingredients leads to the spontaneous formation of liposomes [29]. On the other hand, microfluidization is a method using a microfluidizer (a high pressure homogenizer) that can rapidly produce large volumes of liposomes in a continuous and reproducible manner. The average size of the liposomes can be adjusted through this technology and the solutes to be encapsulated are not exposed to sonication, detergents or organic solvents. Furthermore, this technology enables the production of stable liposomes with high encapsulation efficiency [74]. Recently, Thompson et al. [131–133] used a microfluidization technique to produce liposomes from milk fat globule membrane PL in the food industry. Studies showed that liposomes prepared via microfluidization have high encapsulation efficiencies, smaller size, a narrower size distribution and a higher proportion of unilamellar vesicles as compared to methods such as thin film hydration. PL from soybean and egg yolk, either in purified form, crude form or hydrogenated form are widely used for liposome production in both the food and aquaculture industries. The use of MPL-based liposomes has gained attention recently in the aquaculture industry and there is much ongoing research in this area as shown in Table 5. Several studies have shown the use of MPL such as herring roe or krill PL for larvae feed in the aquaculture industry [14–19] but no attempts to use MPL based liposomes for food purposes have been reported in the literature so far.

One potential advantage of using MPL-based liposomes for food application is that they may provide better bioavailability of encapsulated nutrients [26, 134, 135] as compared to TAG. Nacka et al. [26] showed that MPL-based liposomes facilitated α-tocopherol uptake after oral delivery as compared to sardine oil digestion. Furthermore, Hossain et al. [136] also showed that MPL-based PC liposomes (squid PC and starfish PC) enhanced the permeability, transportation and uptake of PL in Caco-2-cells. It is also known that the fluidity of liposomes increases with increasing contents of highly unsaturated PUFA such as AA and DHA, showing the advantage of PC containing AA or DHA for use in drug or nutrient delivery systems [100, 101].

Application of PL Liposomes in the Food Industry

The uses of liposomes in the food industry can be summarized as follows (1) use of liposomes to encapsulate food ingredients in order to provide better protection or to hide the bitter taste of entrapped substances and (2) use of liposomes to control the delivery of functional components by delaying the release of the encapsulated materials. Liposomes have been used to entrap thermally sensitive compounds such as vitamins, enzymes, flavorings, PUFA from fish oils, antimicrobial peptides (lysozyme, nisin) and other nutrients [13, 137–144]. Hydrophilic substances can be entrapped in the internal water core of the liposomes while lipophilic compounds can be efficiently enclosed in the PL bilayer at the same time through a pro-liposomes approach [29]. For this reason, liposomes can be used for the formulation of functional foods or drinks such as energy drinks, sport drinks, fortified milk, etc. Arnaud et al. [145] reported that PC from egg or soybean has been used in development of liposome-based functional drinks. With the use of PC-based liposomes in food industry, consumers not only benefit from the health benefits of water soluble nutrients that are entrapped in the liposomes but also benefit from the nutritional benefits of PL in liposomes. In the production of cheese, PL liposomes may be used to delay the release of encapsulated proteinases [146, 147] or to protect encapsulated enzyme such as protease and lipases with the purpose of improving the texture and sensory properties of cheese [148–152]. Liposomes have also been used to encapsulate vitamin D with the purpose of increasing the vitamin D content of cheese [153].

Application of PL Liposomes in the Aquaculture Industry

Besides food incorporation, recent studies have also indicated that liposomes rich in n-3 PUFA can offer a range of benefits when used for fish larvae feed. Due to the high consumer demand and limited natural stocks of fish species such as salmon, trout and eel, much effort has recently been spent by researchers on developing cost effective aquaculture methods for farming such species. Generally, the main problems faced by aquaculture industry are low survival rate of the hatched fish larvae of the farmed species and the difficulty in supplying live prey organisms which provide nutritionally adequate feed for these larvae. Live prey such as Rotifers *Brachionus plicatilis* and *Artemia* nauplii provide adequate amounts of protein and energy. However, they do not provide lipid profiles that cover the requirements for EPA and DHA, which are essential for optimum survival, growth and development of larvae [154–157]. Thus, to provide prey organisms with such a composition of n-3 PUFA, it is necessary to cultivate these organisms in the presence of enrichment products with high EPA and DHA contents, preferably in an easily digestible, highly bio available form, such as MPL. During the enrichment process, enrichment products are passively filtered by *Artemia* nauplii and their digestive tract becomes loaded with these enrichment products. A wide

	No size changes of liposomes during the experimental period			

1,2-PA-PC, dipalmitoyl phosphatidylcholine; *PL*, phospholipids; *CHO*, cholesterol; *LUV*, large unilamellar vesicles; *MLV*, multilamellar vesicles; *EFA*, essential fatty acids; *PG*, phosphatidylglycerol; *SS*, Super Selco (Artemia Systems, INV E, Ghent) as control; *PT*, Tuna oil orbital oil emulsified with 12% herring roe polar lipids; *L*, liposomes with the composition, (40%)1,2-PA-PC (40%)PC(20%)CHO; *PS*, phosphatidylserine; *CFE*, cod fish extract; *PHS*, physiological saline; *Toc*, α-tocopherol

variety of enrichment products are available nowadays such as microalgae, microcapsules [158] and oil emulsion products [159].

PL especially MPL are considered to be a better way for providing EPA and DHA for larvae than TAG fish oil due to reasons such as: (1) marine fish larvae commonly ingest and assimilate better natural diets rich in PL than TAG [160–162]. The ratio of DHA:EPA in the PL naturally consumed by larvae is generally higher as compared to the corresponding ratio in TAG fish oil [156], (2) studies also showed that PL facilitate the absorption of lipids in the larvae gut [163] and thus promote growth and survival of larvae [164], and (3) PL have been shown to exert antioxidant properties against oxidation [87, 88].

Mcevoy et al. [14, 165] showed the advantage of using PC from soybean and marine fish eggs in enrichment of *Artemia* nauplii. They found that a mixture of DHA rich fish oil and PC (90:10) resulted in *Artemia* nauplii which were markedly enriched in DHA, and with minimal peroxidation in an aerated mixture during 18 h of enrichment. This is because the added PC functions as a natural emulsifying agent and a natural protectant against oxidation. They also showed that PC from marine egg sources was superior to soy PC in terms of n-3 PUFA content. This is presumably due to the presence of readily assimilable DHA and EPA in a ratio of 2:1 in marine roe lipids as compared to LA in soy PC. Their study corroborated the original work of Kanazawa et al. [166] using soy and bonito PC as feed supplements for larval sea bream and aye.

As mentioned earlier, there are several forms of enrichment products commercially available nowadays for live prey. However, as compared to an emulsion, liposomes provide more advantages. This is due to their ability to encapsulate lipids as well as water soluble components. For example, liposomes have been successfully used to encapsulate vitamin C [19] or water soluble antibiotics [167] in *Artemia* nauplii enrichment. In addition, liposomes can also be used to encapsulate hydrophobic components such as vitamin A [19] and free amino acids such as methionine [19, 168] or glycine [169]. Many studies have also shown that it is possible to encapsulate considerable amounts of n-3 PUFA into liposomes for *Artemia* enrichment [14, 15, 170].

Future Prospects and Conclusion

MPL may offer more advantages to consumer, food, and aquaculture industries as compared to fish oils. Particularly, the use of MPL-based liposomes is expected to provide benefits such as better oxidative stability, higher bioavailability and higher fluidity as compared to other PL-based liposomes. However, the use of MPL-based liposomes is just starting to be explored in both aquaculture and food industries and no current use of MPL-based liposomes for food applications has been reported. The next frontier in liposome application in the food industry will probably focus on the use of MPL for the development of n-3 PUFA enriched functional foods or the use of MPL-based liposomes as nutrient delivery system in foods and feed. Additionally, another area of study that needs further exploration is the use of liposomes for encapsulation of flavor, aroma and natural coloring compound in foods. However, due to the high content of n-3 PUFA in MPL, foods containing MPL are highly susceptible to lipid oxidation, which results in oxidative products that not only cause deterioration of food quality but also increase the risk of certain degenerative diseases as mentioned earlier. Therefore, it is expected that many more studies will be carried out in the future to explore the oxidative stability and sensory properties of MPL or MPL liposomes prior their potential uses in both food and aquaculture industries.

ORIGINAL ARTICLE

Elucidation of Phosphatidylcholine Composition in Krill Oil Extracted from *Euphausia superba*

Bjørn Winther · Nils Hoem · Kjetil Berge · Léon Reubsaet

Received: 9 June 2010 / Accepted: 30 August 2010 / Published online: 17 September 2010

Abstract High performance liquid chromatography-electrospray tandem mass spectrometry was used to elucidate the phospholipids in krill oil extracted from *Euphausia superba*, an emerging source for human nutritional supplements. The study was carried out in order to map the species of the choline-containing phospholipid classes: phosphatidylcholine and lyso-phosphatidylcholine. In addition, the prevalent phosphatidylcholine class was quantified and the results compared with prior analysis. The qualification was performed with separation on a reverse phase chromatography column, while the quantification was obtained with class separation on a normal phase chromatography column. An Orbitrap system was used for the detection, and pulsed-Q dissociation fragmentation was utilized for the identification of the species. An asymmetrical exclusion list was applied for detection of phospholipid species of lower concentration, significantly improving the number of species observed. A total of 69 choline-containing phospholipids were detected, whereof 60 phosphatidylcholine substances, among others seven with probable omega-3 fatty acids in both *sn*-1 and *sn*-2. The phosphatidylcholine concentration was estimated to be 34 ± 5 g/100 g oil ($n = 5$). These results confirm the complexity of the phospholipid composition of krill oil, and the presence of long chained, heavily unsaturated fatty acids.

Abbreviations

EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
lyso-PtdCho	Lyso-phosphatidylcholine
NPLC	Normal phase liquid chromatography
PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
PtdIns	Phosphatidylinositol
PtdSer	Phosphatidylserine
PL	Phospholipid
RPLC	Reverse phase liquid chromatography

Introduction

Krill oil has emerged as an important source of omega-3 fatty acids for human consumption during the last decade, and the amount sold on the world market is rapidly increasing. In contrast to traditional omega-3 supplements on today's market, which are based on omega-3 fatty acids bound to triglycerides (such as cod liver oil and fish oil) or bound as ethyl esters (Omacor/Lovaza), krill oil contains a high proportion of omega-3 fatty acids bound to phospholipids.

Krill oil has been investigated in several preclinical and clinical studies [1–4], and there is growing evidence that the molecular form of the omega-3 fatty acids (i.e. triglycerides, ethyl-esters, phospholipids) might be of importance for their biological effect as well as distribution of the omega-3 fatty acids in the body. In one animal study,

it was demonstrated that when krill oil and fish oil were administrated to Zucker rats with an equimolar dose eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA), krill oil had stronger and in some instances different effects than fish oil on specific parameters related to the metabolic syndrome [1]. The lipid level in both heart and liver was significantly lower in rats treated with krill oil, when compared to rats fed the fish oil diet. The authors suggest that this difference may be linked to differences in the incorporation of omega-3 fatty acids into membranes, and consequently a reduction of inflammatory molecules and endocannabinoids, which might be relevant for the differences observed between fish oil and krill oil. Further, in the same study, it was demonstrated that the level of DHA in the brain increased significantly after krill oil administration, but not after fish oil administration, when compared to control animals [2]. Thus, omega-3 fatty acids linked to phospholipids may be differently distributed in the body compared to omega-3 fatty acids in other molecular forms. Moreover, in a clinical safety study, the presence of EPA and DHA in the blood plasma was determined after daily administration of 2 g krill oil or 2 g menhaden oil for 4 weeks [3]. The authors concluded that EPA and DHA from krill oil are absorbed at least as well as that from menhaden oil.

The aim of the current study was to characterize the phospholipids in krill oil in more detail to evaluate the composition of the fatty acids present in the phospholipids. The composition was determined using LC/ESI–MS(/MS), a technique which has lately played an important role in characterization of the lipidome in tissues and organisms [5]. An inherent limitation in the use of ESI for the ionization of long chained fatty acids has been described by Koivusalo et al. [6]. The study showed that the instrument response is affected by the acyl chain length. This is a consideration which is important particularly in the quantification of the lipids.

The elucidation of the phospholipid species is often performed either by doing a precursor ion scan or a neutral loss scan with triple quadrupole instrumentation [7–9], or with MS^n fragmentation with systems based on ion traps [10–13]. Normal phase liquid chromatography (NPLC) and reverse phase liquid chromatography (RPLC) are both frequently used for the separation of the components [10, 14–17]. Of these two separation techniques, RPLC has been shown to be more suitable for species separation and characterization [8].

Different ionization and fragmentation techniques can be used for the evaluation of phospholipids. Ionization of the phospholipids may be performed in negative- and positive-ionization mode. In general, fragmentation of phospholipids in the positive mode provides information about the phospholipid head group, while fragmentation in the negative mode is the source of structural information. For phospholipids containing choline-headgroups, the choline-specific fragment *m/z* 184 has been used in precursor ion scanning operating in the positive ionization mode for class determination [7, 18]. Also in the negative mode, class-specific fragments may be used in the characterization. All phospholipid classes, except those containing choline, yield molecular ions $[M-H]^-$ when a formate-based mobile phase is used. On the other hand, the choline-containing classes form stable adducts with formic acid in the mobile phase, yielding $[M + FA-H]^-$ ions ($m/z = M + 45$) [19, 20]. With fragmentation, this adduct dissociates with the loss of ($HCOO + CH_3$) into the fragment ion $[M-CH_3]^-$. This is in particularly useful in methods utilizing RPLC for separation. Although the chromatographic class information is lost in such setups, the class-specific fragments may be used in the characterization of the species [11].

Two ion activation techniques may be used for MS analysis utilizing ion traps: collision-induced dissociation (CID) and pulsed-Q dissociation (PQD) techniques. While CID has a low mass cut off below 28% of the *m/z* for the precursor ion, the novel PQD technique eliminates the potential loss of low mass fragments [21, 22]. This difference could be crucial in the fragmentation of larger molecules into low mass, specific fragments, as shown with detection of iTRAQ fragments with a linear ion trap [23].

The fatty acid composition of phosphatidylcholine (PtdCho) from krill oil has previously been investigated by Le Grandois et al. [24]. This study was performed with a method based on the ESI operated in the positive mode with triple quadrupole detection of lithium adduct ions, and showed the presence of a higher number of PtdCho species with long chained unsaturated fatty acids, than seen in egg yolk, ox liver and soy.

We believe the current study verifies previously presented findings and offer new insights into the composition of krill oil. In addition; it shows the advantage of performing an additional fragmentation using an exclusion list in the identification of low prevalent species.

Experimental Procedures

Chemicals

Phospholipid standards of lyso-phosphatidylcholine (lyso-PtdCho), PtdCho, phosphatidylethanolamine (PtdEtn), phosphatidylinositol (PtdIns) and phosphatidylserine (PtdSer) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Lyso-PtdCho, PtdCho and PtdEtn were lyophilized powders obtained from egg yolk, whereas the PtdIns source was *glycine max* and the PtdSer source was

bovine brain. EPAX 6000 TG® fish oil was donated by EPAX (Ålesund, Norway), and Superba™ krill oil was obtained from Aker BioMarine (Oslo, Norway). All other chemicals were of MS grade.

Instrumentation

The chromatography was carried out on a Dionex system consisting of an Ultimate 3000 pump, an Ultimate 3000 RS autosampler, and an Ultimate 3000 flow manager. Detection was obtained using a linear ion trap LTQ XL coupled to an Orbitrap Discovery, LC-operation, data acquisition and processing were carried out using Chromelion SDK 6.80 SP2 Build 2327 and Xcalibur version 2.0.7 coupled with DCMS^{Link} 2.5 (all Instrument-Teknikk AS, Østerås, Norway).

Mass Spectrometry

The LTQ Orbitrap system was operated with a spray voltage of 5.00 kV, nitrogen as the sheath gas with flow rate set to 30 arbitrary units, and helium as the collision gas. The quantification of the PtdCho class was performed with a scan from $m/z = 400$ to $m/z = 1{,}000$ operated in negative ionization mode. MS^n experiments for identification of the choline-containing phospholipids were performed using data dependent PQD for the first fragmentation step. The molecular ion selected for each fragmentation in this step, was the most intense ion detected by the Orbitrap analyzer with target mass resolution of 30,000 and a scan window from $m/z = 400$ to $m/z = 1{,}000$. The normalized collision energy was 200 and the isolation width 2.00 Da. Subsequently, the most intense fragment ion detected was further fragmented using CID, with the normalized collision energy at 35 and an isolation width of 2.00 Da (MS^3). The LTQ was utilized for the detection of the fragments and the m/z range was relative to the m/z of the molecular ion. An alternative method was used in order to be able to observe species that were not selected for fragmentation in this way. The overall setup of this method was as described above, with the distinction of adding an asymmetric exclusion list. The exclusion list was generated with the purpose of the LTQ to ignore already identified substances. The list was based on the m/z of the molecular ions, with an exclusion window from this mass-to-charge ratio, up to $m/z + 1$. The width of the exclusion window was selected in order to diminish the detection of isotopes of the molecular ions.

Chromatographic Conditions RPLC

Chromatographic separation was performed on a ZORBAX Eclipse Plus C18 column with particle diameter of 5 μm and the column dimensions were 150 × 2.1 mm i.d.

The mobile phase A consisted of 90 parts 1% TEA and 0.2% formic acid in water, and 10 parts mobile phase B (*v*/*v*). Mobile phase B consisted of 1% TEA and 0.2% formic acid in 60 parts methanol and 40 parts acetonitrile (*v*/*v*).

A linear gradient was used for the separation. The system was first kept isocratic at 65% mobile phase B for 5 min after injection of sample. The gradient was then run from 65 to 100% mobile phase B in 5 min and was kept isocratic at 100% mobile phase B for 20 min, before it was returned to the initial condition in 0.1 min. The column was regenerated with 65% mobile phase B for 16 min. The mobile phase flow was set to 0.2 mL/min and the injection volume was 20 μL throughout the study.

Chromatographic Conditions NPLC

NPLC was performed on a HiCHROM LiChrospher 100 DIOL column with a particle diameter of 5 μm and column dimensions of 250 × 2 mm i.d. Mobile phase C was 100% chloroform, and the mobile phase D consisted of 0.05% TEA, 0.05% ammonia and 0.1% formic acid in methanol (*v*/*v*). For the class separation of the phospholipids, a linear gradient was used. The gradient was run from 5 to 27.5% mobile phase D in 15 min, followed by a rise to 80% in 2 min to flush the column. This concentration was kept isocratic for 4 min, before it was returned to the initial condition in 2 min. The column was regenerated with 5% mobile phase D for 12 min. The mobile phase flow was set to 0.3 mL/min, and the injection volume was 20 μL throughout the study.

Sample Preparation

Samples of krill oil and stock solutions of standards were prepared by dissolving the lipids in a mixture of chloroform and methanol at a ratio of 2:1. These solutions were stored at −32°C and excessive heating cycles were avoided. Samples were prepared by further dilution with solvents compatible with the mobile phases used. For NPLC, this was achieved with chloroform:MeOH 95:5, while it was attained by dilution in mobile phase A for RPLC.

Calibration Curve

For the quantification, a calibration curve was established with samples of PL free fish oil (EPAX®) spiked with a PtdCho standard purified from egg yolk to concentrations of 100 μg/mL. The spiking of PL free fish oil was performed in order to produce comparable matrixes in the standards and the krill oil samples. Stock solutions were made by dissolving PtdCho standard, PL free fish oil and krill oil separately in mixtures of chloroform:MeOH 2:1. The concentration of krill oil and PtdCho standard was

1 mg/mL and for PL free fish oil 10 mg/mL for these solutions. Respectively, 100 μL of PtdCho standards and of krill oil was added to 900 μL of the PL free fish oil, producing samples with concentrations of 100 μg/mL. For the calibration curve, the PtdCho standard samples were consecutively diluted to the desired concentrations of 10.0, 5.00, 2.50, 1.00, 0.50, 0.25, and 0.10 μg/mL ($n = 5$) with a mixture of chloroform:MeOH 95:5. The krill oil samples were diluted in the same way to a concentration of 1.00 μg/mL in order to measure the PtdCho content within the linear area of response of the calibration curve.

Results

Selection of MS-Mode for PtdCho-Classification

Initial experiments with standards of PtdEtn, PtdIns, PtdSer, PtdCho and lyso-PtdCho, were performed in both positive- and negative- ion mode using the LTQ Orbitrap as a detector. Separation of these substances on a NPLC column yielded class-specific baseline separation (data not shown). The results of these tests indicated a minor difference in the signal intensities obtained between the two settings, with a slightly higher response in negative mode.

Identification of Choline-Containing Phospholipids in Krill Oil

Since krill oil, as established in Fig. 1, is predominantly composed of choline-containing phospholipids, the emphasis of the work was focused on the elucidation of the species in the PtdCho and lyso-PtdCho classes. In NPLC, class separation of the phospholipids is achieved. A clear tendency of the elution order from the column was seen from high *m/z* to lower *m/z*. PtdCho class species eluted from 6.5 to 8 min, and the elution of the lyso-PtdCho class occurred between 10.5 and 12 min. Some species separation

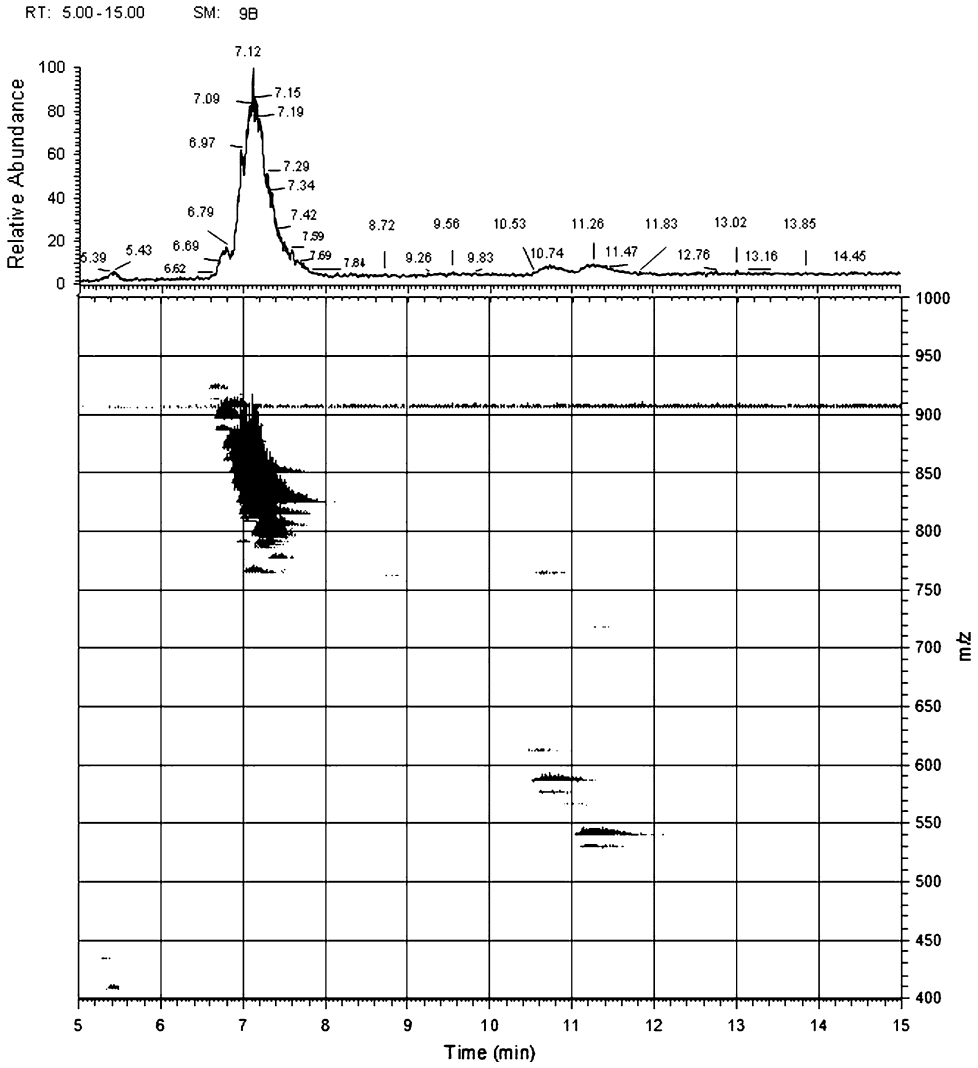

Fig. 1 Base peak chromatogram and three dimensional (*3D*) map of phospholipid class separation of krill oil, performed with a linear gradient NPLC/ESI–MS on a HiCHROM LiChrospher 100 DIOL column (250 × 2 mm i.d., 5 μm). MS was operated in the negative ionization mode and set to scan *m/z* 400–1,000. Only the relevant part of the chromatogram is shown (5–15 min). For the major part of the species, the map show adduct ions in the form of $[M + FA–H]^-$

was seen within the PtdCho class, however, this was not adequate for identification of the diverse species within the classes.

As the identification of the components is performed with data dependent fragmentation, chromatographic separations of the substances are critical for detection of the less prominent species. Hence, the separation for characterization of the species was performed utilizing a RPLC C18 column as described under "Experimental Procedures". This improved the chromatographic performance for species separation compared to NPLC (Fig. 2). As lyso-PtdCho only carry one fatty acyl group, these components elute earlier in the chromatogram than the PtdCho species. Lyso-PtdCho dominate the region between 12.0 min and 14.5 min in the chromatogram, while the heavier PtdCho components dominate the chromatogram after 14.5 min.

The identification of the species was performed utilizing a MS^3 data dependent fragmentation method, with an initial PQD fragmentation resulting in the loss of methyl formate, followed by a CID fragmentation. Analysis of the fragmentation spectra obtained typically revealed the identity of the substances without ambiguity. However, co-elution of isobaric compounds could potentially complicate the interpretation of the spectra. This challenge is minimized by applying a set of criteria for reliable identification. The following criteria were applied for reliable interpretation of a choline-containing phospholipid: based on the mass-to-charge ratio of the molecular ion, it is likely to be a choline-containing phospholipid (i.e. *m*/*z* being an even number). Following the first CID with PQD, a daughter ion should be produced by the loss of ($HCOO + CH_3$) as 60 Da. Further fragmentation with CID of the resulting product should produce specific fragments revealing the nature of the fatty acyl groups in both the *sn*-1 and the *sn*-2 position, either by the occurrence of the fragment for the fatty acyl group itself, or by the presence of the corresponding fragments of the lyso-compound. The sum of the fatty acyl groups elucidated in this matter should yield a mass matching the initial molecular mass. This is illustrated in Fig. 3, showing the elucidated fragment identity for the fragmentation of the 20:5–22:6 diacyl PtdCho.

The spectra were generally dominated by fatty acyl fragments from both the *sn*-1 and the *sn*-2 positions in addition to their corresponding fragments of the lyso-compound, ensuring identification of the species. The lyso-PtdChoand PtdCho substances identified by applying this method are presented in Tables 1 and 2. The relative intensity of the molecular ions is also presented.

As described earlier, the use of signal intensities in MS, for concentration comparison of the different substances, is only semi-quantitative. However, it provides a valuable indication of the composition of the PtdCho and lyso-PtdChoclasses. Chromatograms and fragmentation patterns are presented in Figs. 4 and 5 for the 10 foremost substances characterized from the PtdCho class.

As data dependent fragmentation methods are, by nature, biased in the selection of the most prevalent substances, the experiments where repeated with the use of an asymmetric exclusion list added to the MS-method. The exclusion list was based on the data sets obtained with the initial settings (i.e. Tables 1, 2). This method allowed the detection and identification of the additional substances presented in Table 3.

Quantification of PtdCho-Class in Krill Oil

Krill oil predominantly contains phospholipids from the PtdCho class (Fig. 1). It was therefore attempted to quantify the absolute concentration of this class by use of class separation with NPLC. Quantification of the PtdCho class was performed with a method developed "in-house" with a LTQ Orbitrap mass spectrometer for the detection.

In the construction of the calibration curve, PtdCho concentrations above 1.00 μg/mL resulted in a relative decrease in the MS signal response, yielding a quadratic polynomial curve ($y = ax^2 + bx + c$) where $a = -9{,}766$, $b = 330{,}360$ and $c = 4763.8$ with $r^2 = 0.9995$. From 0.10 μg/mL to 1.00 μg/mL, the calibration curve showed a high degree of linearity ($r^2 = 0.9995$) with a linear regression curve ($y = bx + c$) where $b = 368{,}737$ and $c = -16{,}547$.

The latter area was chosen for quantification purpose. From this, the PtdCho content of the undiluted krill oil was determined to be 34 ± 5% (*w*/*w*) ($n = 5$). Comparisons of the mass spectrum of the sample with the spectrum of the PtdCho standard indicated a difference in PtdCho class composition (Fig. 6). From the results, the average acyl chain lengths appear to be higher in krill oil than in egg yolk. This has also previously been shown by others [24]. As mentioned above, instrument response is affected by the acyl chain length of the PtdCho. These differences in chain lengths could therefore influence the quantification of the PtdCho class as discussed later. The quantitative results were compared with an earlier analysis of the krill oil, performed by the accredited analytical company Nofima (Bergen, Norway). They reported the PtdCho concentration in the krill oil sample to be 35 g/100 g oil.

Discussion

The fact that fatty acyl chain lengths of the PtdCho species are relatively long, affects both the choice of fragmentation technique and the effect of standards used for quantification purposes. Due to the low mass cut-off limit at 28% of the molecular ion mass with CID fragmentation in ion

traps, fragmentation utilizing PQD in the positive ionization mode was chosen as the first fragmentation step. In addition, utilizing PQD in the first fragmentation step of a MS^3 method, operating with negative mode ionization, also yields class elucidation of phospholipids with choline head groups. This is achieved by the detection of the $[M-CH_3]^-$ fragment formed after ($HCOO + CH_3$) loss from formate-molecular ion adducts. Consequently, performing a mode shift from the positive to the negative ionization mode is not necessary for the overall identification of lyso-PtdCho and PtdCho class phospholipids. PQD with a normalized collision energy at 200 produced the $[M-CH_3]^-$ fragments, without extensive fragmentation to secondary fragment ions. Higher collision energies produced secondary fragments that could be used as a source of structural information; however, this was better achieved with CID as a second fragmentation step. The CID was operated with a normalized collision energy of 35, for further fragmentation of the $[M-CH_3]^-$ ion. This value was not optimized for the individual species, and additional structural information could potentially have been achieved by specie specific optimization of this setting.

With the described method for separation and fragmentation of the phospholipids, typical fragmentation patterns were obtained, as shown in Fig. 3. The spectra were dominated by fatty acyl fragment ions originating

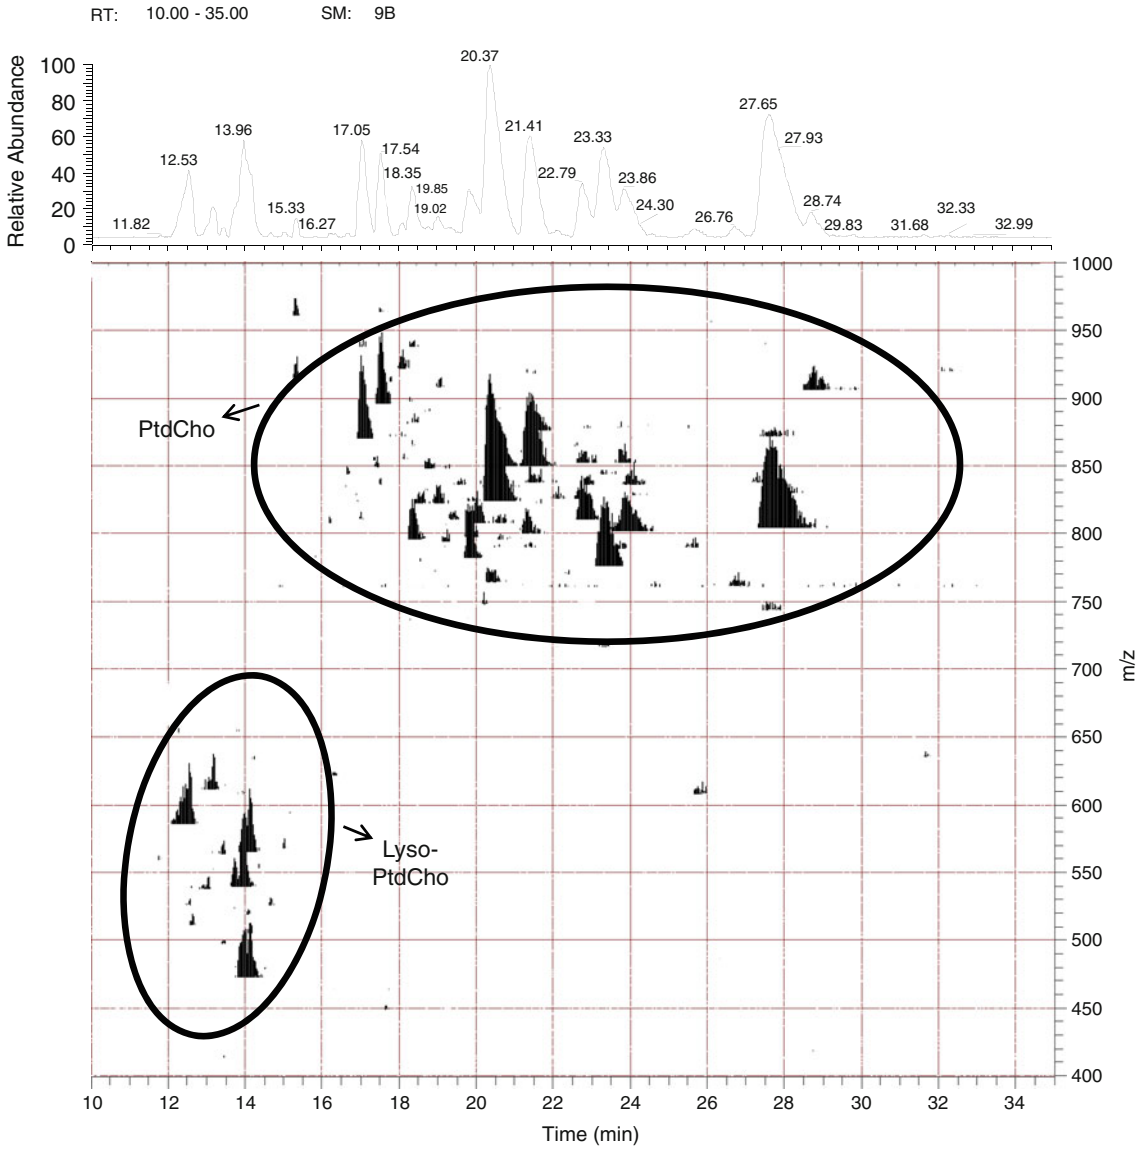

Fig. 2 Base peak chromatogram and three dimensional (*3D*) map of phospholipid specie separation of krill oil, performed with RPLC/ESI–MS on a ZORBAX Eclipse Plus C18 column (150 × 2.1 mm i.d., 5 μm). MS was run in negative the ionization mode and set to scan from *m*/*z* 400 to *m*/*z* 1,000. Only the most relevant part of the chromatogram is shown (10–35 min). Adduct ions in the form of $[M + FA–H]^-$ is seen throughout the map

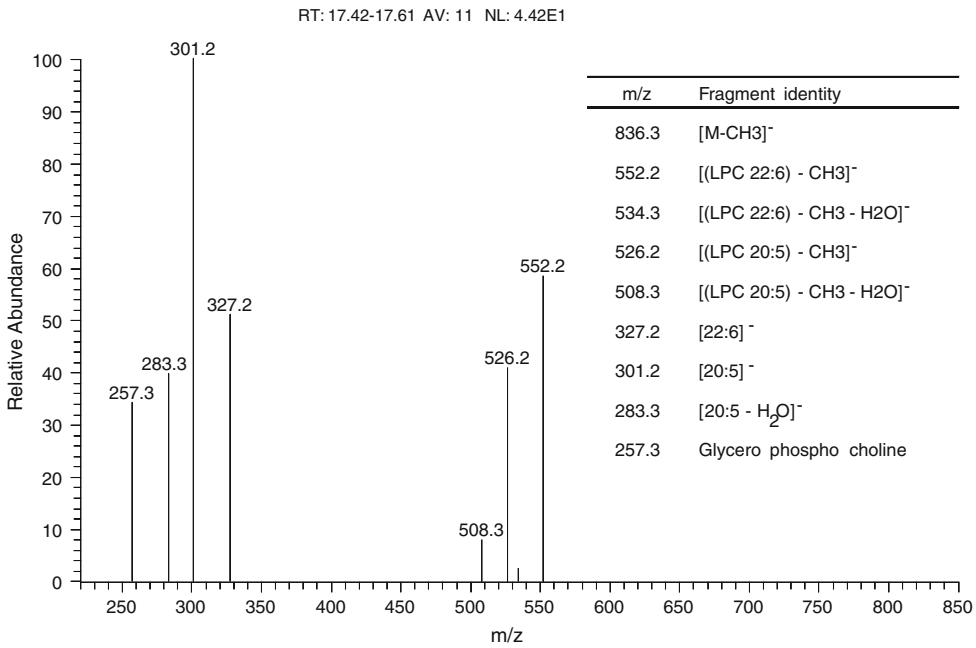

Fig. 3 MS^3 product ion spectrum of 22:6–20:5 diacyl PtdCho obtained in negative ionization mode. The molecular ion of *m/z* 896.6 was selected for PQD fragmentation; this yielded a fragment ion of *m/z* 836.3 which was further fragmented with CID resulting in the presented spectrum. Fragment identity is explained in the table on the *right hand side*, indicating the high level of certainty in the characterization

Table 1 Identified lyso-phospholipid species with choline head group in krill oil

Class	Mass	*m/z*[a]	Molecular specie	Relative intensity

from both *sn*-1 and *sn*-2, except in the fragmentation of alkyl–acyl species, where only a single fatty acyl fragment ion was observed. In addition, the corresponding fragment ions of the lyso-PtdCho compound were prevalent, confirming the characterization of the species. The fragments associated with the lyso-PtdCho compounds were either in the form of $[\text{lyso-PtdCho–CH}_3]^-$ or $[\text{lyso-PtdCho–CH}_3\text{–H}_2\text{O}]^-$. Furthermore, fragments specific for phospholipids carrying a choline head group were often registered. These dissociation products were *m/z* 257, *m/z* 242 and *m/z* 223, representing [Glycero phospho choline]$^-$, $[\text{Glycero phospho choline–CH}_3]^-$ and $[\text{Glycero phospho choline–CH}_3\text{–H}_2\text{O}]^-$, respectively. The identification of the phospholipid class was made based on the loss of 60 Da in the PQD fragmentation step. However, fragments specific for phospholipids carrying a choline head group affirms this interpretation. In spectra obtained from the dissociation of species carrying a 20:5 fatty acyl group, an ambiguous $[20:5–H2O]^-$ fragment ion with *m/z* 283 can often be detected. This ion can potentially be misinterpreted as the fatty acyl fragment $[18:0]^-$, but meeting the criteria for reliable identification will rule out this erroneous conclusion.

In some incidences, a molecular ion could be explained by either being a diacyl-, or an alkyl–acyl-compound. In these cases, the possible identification of alkyl–acyl PtdCho species was based on the presence of a relatively high MS-signal for a single fatty acyl fragment ion and the corresponding lyso-PtdCho compound. In addition, there should be a total absence of signals (i. e. both fatty acyl-, and lyso-PtdCho-ions) potentially explained by fragmentation of an ester bond in the opposite *sn*-position. An example of this is *m/z* 764.6 (spectrum shown in Fig. 5f) which could originate from both O16:0–20:5 alkyl–acyl PtdCho and 15:0–20:5 diacyl PtdCho. The presence *m/z* 466 $[\text{(lyso-PtdCho O16:0/15:0)–CH}_3]^-$, 448 $[\text{(lyso-PtdCho O16:0–15:0)–CH}_3\text{–H}_2\text{O}]^-$ and 301 $[20:5]^-$ indicate a fatty acyl group of 20:5, while there is no fragment indicating a fatty acyl group of 15:0 in the opposite *sn*-position. This is therefore assumed to be a PtdCho-specie with an alkyl-acyl composition of O16:0–20:5. Altogether, seven different potential alkyl-acyl PtdCho species were characterized. For all these species, the fatty alkyl chains were either hexadecanoic or octadecanoic, and either saturated or with a single double bond.

No further attempt was made to clarify the stereospecificity of the species. It is important to keep in mind that

Table 2 Identified phospholipid species with choline head group in krill oil

[a] m/z for $[M + FA–H]^-$ adduct

stereoisomers would be difficult to separate and specifically identify. Therefore, the relative intensity values presented in Table 2 will in many cases be the sum of the signal intensities of the two stereoisomers. The ratio between the stereoisomers will vary among the different species. However, an interesting observation was that several of the *n*-3 acylated species appear to carry the *n*-3 fatty acyl group in the *sn*-1 position, based on the fragment ratios in the fragmentation spectra (e.g. 22:6–18:1 diacyl PtdCho).

In total, 58 species were characterized without the use of the exclusion list, whereof seven were from the lyso-PtdCho class and 51 from the PtdCho class. An additional 11 species were detected by applying the asymmetric exclusion list. Of these latter, two were identified as lyso-PtdCho and nine as PtdCho compounds, yielding an overall total of nine lyso-PtdCho class species and 60 PtdCho class species elucidated. Seven species yielded signals for highly probable fatty acyl *n*-3 groups in both the *sn*-1 and *sn*-2 positions (i.e. the diacyl PtdCho species 18:4–20:5, 18:4–22:6, 20:5–20:5, 20:5–22:6, 20:5–23:5, 22:6–22:6 and 20:5–22:5). Those species and the detection of more exotic species such as 22:6–23:5 and 20:5–26:4 diacyl PtdCho, show the complexity of krill oil.

Prior to analysis of the krill oil, the total fatty acid composition, wherein information on the concentration of individual fatty acids and their *n*-3 content was obtained and provided by Nofima, with the method AOCS Ce 1b-89 (data not shown). The sum of polyunsaturated (*n*-3) fatty acids was reported to be 18.5 g/100 g oil. The assumed homologous distribution of the fatty acid composition between triacylglycerols, free fatty acids, and the lyso-PtdCho- and PtdCho-classes, combined with the described relative intensities of the known species (Tables 1, 2), makes it possible to estimate the prevalence of *n*-3 fatty acids in one or both *sn* positions of the PtdCho species. For the PtdCho class, approximately 58% of the components contained a single *n*-3 fatty acid, and 10% held an *n*-3 fatty acid in both *sn*-1 and *sn*-2 positions. Of the species in the lyso-PtdCho class, approximately 35% contained an *n*-3

fatty acid. The phospholipid composition might potentially give better insight into the mechanism and distribution of krill oil in the body.

In the analysis performed by Nofima, the PtdCho concentration of the same krill oil as was used in the current study was reported to be 35 g/100 g oil (Nofima internal method N A88, based on [25, 26]). With the method developed for this work, the PtdCho concentration was estimated to be 34 ± 5 g/100 g oil. This shows that, in spite of the difference between the methods, the correlation of the values obtained with the two methods is relatively high. Dissimilarity between the standards used for calibration and the actual composition of the phospholipid classes in the sample could influence the quantification. In this work, we utilized a PtdCho standard originating from egg yolk. The difference in the PtdCho profile between this standard and the krill oil (Fig. 6) could potentially result in an underestimation of the PtdCho content of the sample. This is a result of krill oil containing long chained fatty acids in the phospholipid components, which are less prone

[a] m/z for $[M + FA–H]^-$ adduct

to ionization with ESI as described earlier. Hence, the use of a PtdCho standard originating from krill oil would have been preferred. However, this type of standard was not commercially available when the study was performed.

Krill oil has been analyzed by a novel method and numerous molecular species were found that were previously not known to be present in krill oil. To our knowledge, there has previously only been one report showing the fatty acid composition in PtdCho from krill oil [24] The method used in that study was comparable to the platform used in the current study, however, their detection was based on the formation of lithium adducts, detected with a triple quadrupole. The krill oil used in that study was delivered by Nestec SA (Lausanne, Switzerland), and the composition of the two krill oils might therefore not be directly comparable in respect to composition. However, in both studies the following three PtdCho species were among the five most prevalent: (16:0–20:5) (16:0–22:6), and (16:0–18:1). On the other hand, they detected high levels of other PtdCho species that are low or absent in our study, such as: (18:1–20:5) and (18:0–18:2). Le Grandois et al. detected neither fatty acids longer than 22 carbons nor ether-linked fatty acids. Moreover, in our study, a higher number of PtdCho species was detected. Whether these differences are due to a different composition of the two krill oils, or the methodology is not known, but might indicate that the detection method used in the current study is more sensitive.

The method used for quantification purposes in this study was optimized for specific quantification of the PtdCho class, and quantification of other PL classes was not attempted. However, it would be of great interests and an aid in the field of lipidomics, to develop standardized and validated LC–MS methods that meet the need for quantification of all phospholipid classes in complex matrixes like krill oil. One of the potential challenges in the development of such strategies would be the choice of suitable standards for the calibration curves.

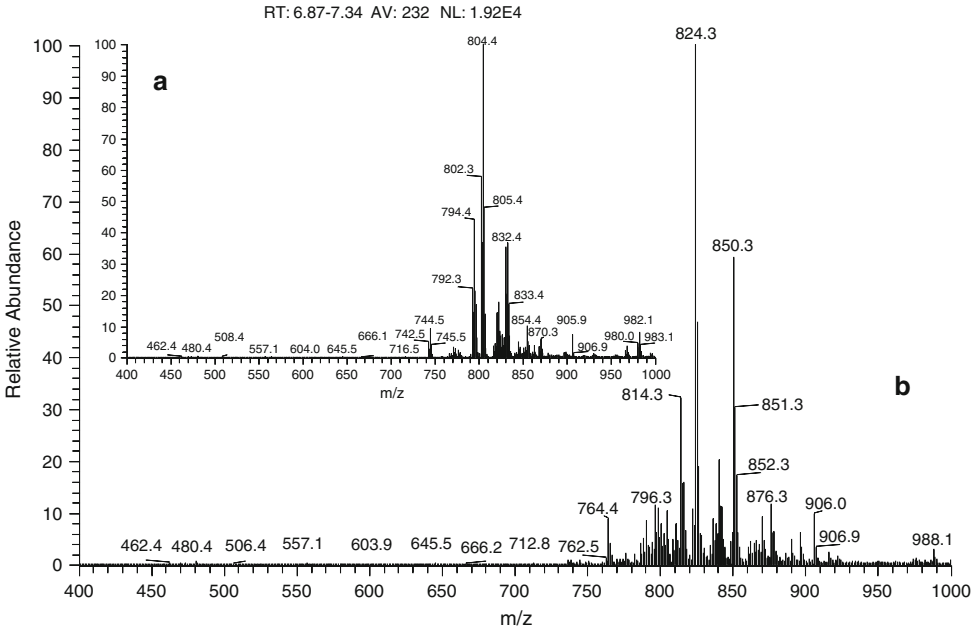

Fig. 6 **a** Mass spectrum of PtdCho class standard used as calibrant for quantification. **b** Mass spectrum of the krill PtdCho class. Both spectra were obtained with NPLC/ESI–MS operated with negative mode ionization, and show $[M + FA–H]^-$ adduct ions. The *mass spectra* indicate a higher occurrence of long chained fatty acyl groups in PtdCho species originating from krill than in the PtdCho standard from egg yolk

Acknowledgments The authors would like to thank Dr. Inge Bruheim and Dr. Åsmund Larsen for their helpful input and valuable discussions during the method development. This work was partially funded by Aker BioMarine ASA.

Abstract The purpose of the present study is to investigate the effects of krill oil and fish oil on serum lipids and markers of oxidative stress and inflammation and to evaluate if different molecular forms, triacylglycerol and phospholipids, of omega-3 polyunsaturated fatty acids (PUFAs) influence the plasma level of EPA and DHA differently. One hundred thirteen subjects with normal or slightly elevated total blood cholesterol and/or triglyceride levels were randomized into three groups and given either six capsules of krill oil ($N = 36$; 3.0 g/day, EPA + DHA = 543 mg) or three capsules of fish oil ($N = 40$; 1.8 g/day, EPA + DHA = 864 mg) daily for 7 weeks. A third group did not receive any supplementation and served as controls ($N = 37$). A significant increase in plasma EPA, DHA, and DPA was observed in the subjects supplemented with n-3 PUFAs as compared with the controls, but there were no significant differences in the changes in any of the n-3 PUFAs between the fish oil and the krill oil groups. No statistically significant differences in changes in any of the serum lipids or the markers of oxidative stress and inflammation between the study groups were observed. Krill oil and fish oil thus represent comparable dietary sources of n-3 PUFAs, even if the EPA + DHA dose in the krill oil was 62.8% of that in the fish oil.

Keywords Plasma lipoproteins · Plasma lipids · Dietary fat · Nutrition, n-3 fatty acids · Lipid absorption · Phospholipids

Abbreviations

EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
FA	Fatty acid
PL	Phospholipids
PUFA	Polyunsaturated fatty acid
TG	Triglycerides

Introduction

An association between consumption of fish and seafood and beneficial effects on a variety of health outcomes has been reported in epidemiologic studies and clinical trials [1–5]. These effects are mainly attributed to the omega-3

long-chain polyunsaturated fatty acids (n-3 PUFAs) abundant in fish and seafood, and in particular to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The effects of marine n-3 PUFAs on various risk factors of cardiovascular disease (CVD) are in particular well documented. In large systematic reviews of the available literature, consistent reductions in triglyceride (TG) levels following consumption of n-3 PUFAs have been demonstrated as well as increases in levels of high-density lipoprotein (HDL) cholesterol [6, 7]. The net beneficial effects of these changes have been disputed, although several large intervention studies indicate that n-3 PUFAs reduce mortality in patients with high risk of developing coronary heart disease (CHD) [8]. Moreover, guidelines published by the American Heart Association for reducing CVD risk recommend fish consumption and fish oil supplementation based on the acknowledgement that EPA and DHA may decrease the risk of CHD, decrease sudden deaths, decrease arrhythmias, and slightly lower blood pressure [9].

Reports on health benefits have led to increased demand for products containing marine n-3 PUFAs. Since fish is a restricted resource, there is growing interest in exploiting alternative sources of marine n-3 PUFAs. Antarctic krill (*Euphausia superba*) is a rich source of n-3 PUFAs. Krill is by far the most dominant member of the Antarctic zooplankton community in terms of biomass, which is estimated to be between 125 and 750 million metric tons (according to the Food and Agriculture Organization of the United Nations; http://www.fao.org/fishery/species/3393/en), and thus attractive for commercial harvest. The DHA content of krill oil is similar to that of oily fish, but the EPA content is higher [10]. The overall fatty acid composition resembles that of fish. In fish, the fatty acids are mainly stored as TG, whereas in krill 30–65% of the fatty acids are incorporated into phospholipids (PL) [10]. Whether being esterified in TG or in PL impacts on the absorption efficiency of FAs into the blood and on effects on serum lipid levels are issues for discussion. In a study by Maki et al. [11] comparing the absorption efficacy of n-3 PUFAs from different sources it was shown that EPA and DHA from krill oil were absorbed at least as efficiently as EPA and DHA from menhaden oil (TG) [11], and studies in newborn infants have indicated that fatty acids in dietary PL may be better absorbed than those from TG [12–14]. Studies addressing the compartmental metabolism of dietary DHA have indicated that the metabolic fate of DHA differs substantially when ingested as TG compared with phosphatidylcholine, in terms of both bioavailability of DHA in plasma and accumulation in target tissues [15]. Only a limited number of studies addressing health outcomes following ingestion of krill oil as compared with fish oil are currently available, but some of these have shown promising effects of krill oil on serum lipids and on markers of inflammation and oxidative stress (reviewed in [10]).

The aim of this study is to investigate the plasma levels of EPA and DHA, and the effects on serum lipids and on some biomarkers of inflammation, oxidative stress, and hemostasis, after krill oil and fish oil administration in healthy subjects after a 7-week intervention period. Safety was evaluated based on assessment of hematology and biochemistry parameters, and registration of adverse events.

Experimental Procedures

Study Subjects

The 129 subjects included in the study were healthy volunteers of both genders with normal or slightly elevated total blood cholesterol (<7.5 mmol/L) and normal or slightly elevated blood triglyceride level (<4.0 mmol/L). Subjects with body mass index (BMI) >30 kg/m^2, hyperlipidemia, hypertension, coronary, peripheral or cerebral vascular disease were excluded from participating in the study. No concomitant medication intended to influence serum lipid level was permitted. All study subjects were informed verbally and in writing, and all subjects signed an informed consent form before entering the study. The study was approved by the Regional Ethics Committee.

Study Design

The study was an open single-center, randomized, parallel group designed study. Screening of subjects ($N = 149$) was performed at the first visit to include subjects that satisfied the eligibility criteria ($N = 129$). These were randomized into three study groups. Seven participants were lost before the baseline visit. The remaining 122 participants were given either 3 g krill oil daily ($N = 41$), 1.8 g fish oil daily ($N = 40$) or no supplementation ($N = 41$) for a period of 7 weeks. A total of 115 participants finished the study. The disposition of the subjects is illustrated in Fig. 1. None of the subjects regularly ate fatty fish more than once a week prior to inclusion or during the 7-week intervention period. None were using cod liver oil or other marine n-3 supplements during the study or at least 2 months prior to inclusion. All the participants were instructed by a nutritionist to keep their regular food habits during the study.

Study Products

The krill oil capsules contained processed krill oil extracted from Antarctic krill (*Euphausia superba*). The product was

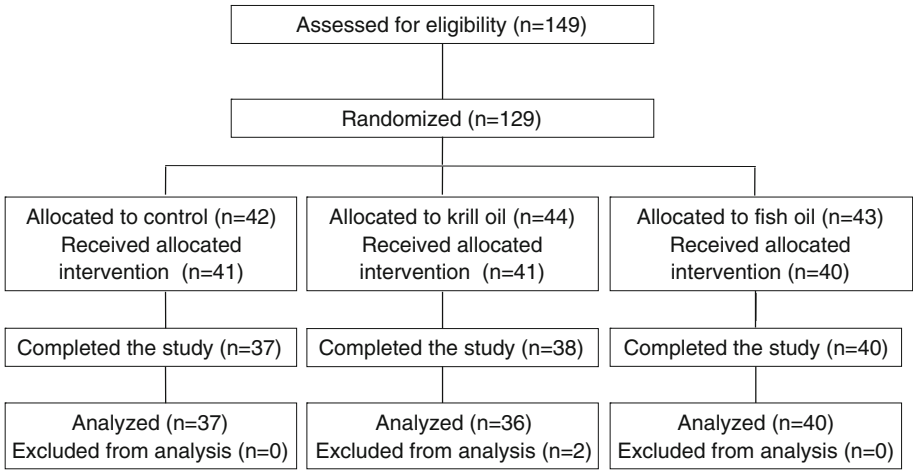

Fig. 1 Disposition of subjects

manufactured by Aker BioMarine ASA. Each capsule contained 500 mg oil that provided 90.5 mg EPA and DHA, and a total of 103.5 mg n-3 PUFAs. The capsules were made of gelatin softened with glycerol. The daily study dosage was six capsules (each of 500 mg oil). The comparator omega-3 fish oil product was manufactured by Peter Möller AS, Oslo, Norway. The daily study dosage was three capsules each containing 600 mg fish oil that provided 288 mg EPA and DHA, and a total of 330 mg n-3 PUFAs. The capsules were made of gelatin softened with glycerol. The fatty acid profile of the study products is presented in Table 1. The daily dose of EPA, DHA, and total n-3 PUFAs in the krill oil and fish oil groups is presented in Table 2. The daily EPA + DHA dose in the krill oil group was 62.8% of the dosage given in the fish oil group. DL-α-tocopheryl acetate (vitamin E), retinyl palmitate (vitamin A), and cholecalciferol (vitamin D) were added to the product.

Table 1 Relative content of fatty acids in the study products

n-6	2.9	2.5

Clinical Assessment

Demographic characteristics (gender, age, height, and weight), concomitant medication, and medical history were recorded at the screening visit. In addition, all subjects went through a physical examination to confirm satisfaction of the eligibility criteria.

Changes in concomitant medication from screening, smoking and alcohol habits, and clinical symptoms before intake of the study products were also registered.

Serum Lipids and Blood Safety Parameters

Blood from venipuncture was collected after an overnight fast (≥12 h) at baseline and at final visit. The subjects were instructed to refrain from alcohol consumption and from vigorous physical activity the day before the blood sampling. Serum was obtained from silica gel tubes (BD Vacutainer), kept at room temperature for at least 30 min until centrifugation at 1,300 × *g* for 12 min at room temperature. Serum analysis of total, low-density lipoprotein

Table 2 n-3 fatty acid contents of the study products

Study product	Daily study dose	Daily dose EPA	Daily dose DHA	Daily dose EPA + DHA	Daily dose n-3 PUFAs
Fish oil	3 capsules (1.8 g oil)	450 mg	414 mg	864 mg	990 mg
Krill oil	6 capsules (3.0 g oil)	348 mg	195 mg	543 mg	621 mg

(LDL), and HDL-cholesterol, TG, apolipoprotein A1, and apolipoprotein B was performed at the routine laboratory at Department of Medical Biochemistry at the National Hospital, Norway using standard methods. Blood samples for analysis of hematology and serum biochemistry parameters including hemoglobin, leukocytes, erythrocytes, thrombocytes, hematocrit, glucose, calcium, sodium, potassium, urea, creatinine, alkaline phosphatase, alanine aminotransferase, bilirubin, albumin, and total protein were collected and analyzed at the routine laboratory at Department of Medical Biochemistry at the National Hospital, Norway using standard methods.

Plasma Fatty Acid Composition

Plasma was obtained from ethylenediamine tetraacetic acid (EDTA) tubes (BD Vacutainer) kept on ice immediately and within 12 min centrifuged at 1,300 × *g* for 10 min at 10°C. Plasma samples were kept frozen at −80°C until analysis. Plasma fatty acid composition was analyzed by Jurilab Ltd., Finland using a slight modification of the method of Nyyssonen et al. [16]. Plasma (250 μL), fatty acids, and 25 μL internal standard (eicosane 1 mg/mL in isopropanol) were extracted with 6 mL methanol–chloroform (1:2), and 1.5 mL water was added. The two phases were separated by centrifugation, and the upper phase was discarded. To the chloroform phase, 1 mL methanol–water (1:1) was added, and this extraction was repeated twice. The chloroform phase was evaporated under nitrogen. For methylation, the remainder was treated with 1.5 mL sulfuric acid–methanol (1:50) at 85°C for 2 h. The mixture was diluted with 1.5 mL water and extracted with light petroleum ether. The fatty acids from the ether phase were determined using a gas chromatograph (Agilent Technologies 6890)/mass spectrometer (Agilent Technologies 5973) with electron impact ionization and a HP-5ms capillary column (Hewlett Packard). For retention time and quantitative standardization, fatty acids purchased from Nu-Chek-Prep (Elysian, MN, USA) were used. All work was carried out under a certified ISO 9001/2000 quality system.

Plasma α-Tocopherol

Human plasma (100 μL) was diluted with 300 μL 2-propanol containing the internal standard tocol and butylated hydroxytoluene (BHT) as an antioxidant. After thorough mixing (15 min) and centrifugation (10 min, 4,000 × *g* at 10°C), an aliquot of 1 μL was injected from the supernatant into the high-performance liquid chromatography (HPLC) system. HPLC was performed with a HP 1100 liquid chromatograph (Agilent Technologies, Palo Alta, CA, USA) with a HP 1100 fluorescence detector (emission 295 nm, excitation 330 nm). Tocopherol isomers were separated on a 2.1 × 250 mm reversed-phase column. The column temperature was 40°C. A two-point calibration curve was made from analysis of a 3% albumin solution enriched with known concentration of tocopherols. Recovery is >95%, the method is linear from 1 to 200 μM at least, and the limit of detection is 0.01 μM. Relative standard deviation (RSD) is 2.8% (17.0 μM) and 4.6% (25.1 μM).

Urinary F2 Isoprostanes

Fasting urine samples were analyzed for 8-iso-prostaglandin $F_{2\alpha}$ (8-iso-$PGF_{2\alpha}$) by a highly specific and validated radioimmunoassay as described by Basu [17]. Urinary levels of 8-iso-$PGF_{2\alpha}$ were adjusted by dividing the 8-iso-$PGF_{2\alpha}$ concentration by that of creatinine.

Markers of Inflammation and Hemostasis

Plasma interleukin-6 (IL-6), tumour necrosis factor-alpha (TNFα), monocyte chemotactic protein-1 (MCP-1), thromboxane B_2 (TxB_2), interferon-gamma (INFγ), soluble E-selectin and P-selectin, soluble intracellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1) were determined by Fluorokine® MAP kits (R&D Systems, Inc., Minneapolis, MN, USA). Plasma leukotriene B_4 (LTB_4) and thromboxane B_2 (TxB_2) were assessed as described by Elvevoll et al. [18]. High-sensitivity C-reactive protein (hsCRP) evaluation was performed at the routine laboratory at Department of Medical Biochemistry at the National Hospital, Norway using standard method.

Statistics

All continuous variables were summarized by product group and visit number and described using standard statistical measures, i.e., number of observations, mean,

standard deviation (SD), median, minimum, and maximum. Absolute and percentage change from baseline to the week-7 visit are presented as summary statistics. All categorical (discrete, including ordinal) variables are presented in contingency tables showing counts and percentages for each treatment group at all time points. Continuously distributed efficacy laboratory parameters (lipids, EPA, DHA, and docosapentaenoic acid (DPA)) were analyzed by analysis of covariance (ANCOVA) using the following model: change in parameter value = baseline value + treatment + gender + age + error.

Change from baseline to week 7 was used as a dependent variable in the model. A linear model using SAS GLM with gender as fixed effect, subject as random effect, and baseline value and age as covariates was applied. A reduced ANCOVA model with baseline value and treatment was used for the secondary efficacy parameters. Significant treatment effects were analyzed by pairwise tests. Changes from baseline to end of intervention were tested by paired *t*-test.

Results

Subject Characteristics at Baseline

Figure 1 shows the disposition of all subjects. One hundred fifteen of 129 randomized subjects completed the study. Withdrawal rates were similar in all three groups (three withdrawals in the fish oil group, six withdrawals in the krill oil group, and five withdrawals in the control group). Three subjects discontinued the study due to clinical symptoms (all in the krill group), three subjects violated the exclusion criteria (two in the fish oil group and one in the krill oil group), and one subject in each group was lost to follow-up. Two subjects in the control group were withdrawn due to concomitant treatments, and three subjects withdrew their consent (one subject in the krill oil group and two subjects in the control group). Clinical symptoms included symptoms of common cold or gastrointestinal symptoms. During database clean-up, it was detected that two subjects (in the krill oil group) had been allowed to enter the study although they violated the entry criteria. They where therefore excluded from the per protocol subjects. The statistical analyses of efficacy were performed on the data collected from 113 per protocol subjects (Fig. 1).

The study groups were comparable in terms of weight, height, BMI, gender, and age at baseline (Table 3). Vital signs including systolic and diastolic blood pressure and heart rate were within normal ranges. More females than males were included in all study groups.

Table 3 Demographic information and body measurements

Parameter, mean (SD)	Study groups		
	Fish oil ($N = 43$)	Krill oil ($N = 44$)	Control ($N = 42$)
Age (years)	38.7 (11.1)	40.3 (14.8)	40.5 (12.1)
Height (cm)	171.2 (7.8)	171.3 (8.6)	172.2 (9.4)
Weight (kg)	71.7 (12.0)	69.8 (13.7)	71.7 (12.0)
BMI (kg/m^2)	24.4 (3.0)	23.6 (3.3)	23.9 (3.0)
Gender			
Female (*n*)	34 (79.1%)	31 (70.5%)	28 (66.7%)
Male (*n*)	9 (20.9%)	13 (29.5%)	14 (33.3%)

Fatty Acid Composition in Plasma

Plasma levels of EPA, DHA, and DPA increased significantly from baseline to the end of the intervention phase in the groups receiving fish oil and krill oil, but not in the control group. The changes in EPA, DHA, and DPA differed significantly between the subjects supplemented with n-3 PUFAs and the subjects in the control group, but there was no significant difference in the change in any of the n-3 PUFAs between the fish oil and the krill oil groups (Table 4).

There were significant within-group changes in individual FAs from start to end of intervention, but no clear trends in changes in the plasma FA composition were apparent in any of the study groups (Table 4).

The level of arachidonic acid (C20:4n-6) increased from baseline in the krill group, whereas a decrease was observed in the fish oil group. The changes in arachidonic acid between the fish oil and the krill oil groups, and the control group differed significantly ($p = 0.001$). Pairwise comparisons showed that the mean increase in arachidonic acid in the krill oil group was significantly different from the mean decreases in the fish oil and control groups, but there was no significant difference between the mean changes in arachidonic acid level between the fish oil and control groups.

Serum Lipids

Small changes in the levels of HDL-cholesterol, LDL-cholesterol, and TG were observed in all study groups from start to end of the intervention phase, but only the within-group increase in LDL-cholesterol seen in the fish oil group ($p = 0.039$) was statistically significant. The tests comparing the differences between the study groups gave no statistically significant results (Table 5). The HDL-cholesterol/TG ratio and the change from start to end of the intervention were calculated for all study groups. No significant changes in the HDL-cholesterol/TG ratio from start to end of the interventions were detected in the fish oil or

[a] Test of within-group changes

[b] Test comparing change from start to end of intervention between the fish oil, krill oil, and control groups

control groups. In the krill oil group, however, there was a significant increase in the HDL-cholesterol/TG ratio. The test for differences between the study groups gave no significant results (Table 5).

Although the interventions did not significantly change TG levels a reduction was seen in those subjects in the krill oil group having the highest baseline values (Fig. 2).

The changes in levels of Apo B-100 from baseline to end of study were minor in all study groups. Moreover, the test for differences between the study groups in changes in Apo A1 was not significant. However, the within-group changes of Apo A1 levels from start to end of the interventions were statistically significant in the krill oil group.

[a] Test of within-group changes

[b] Test comparing change from start to end of intervention between the fish oil, krill oil, and control groups

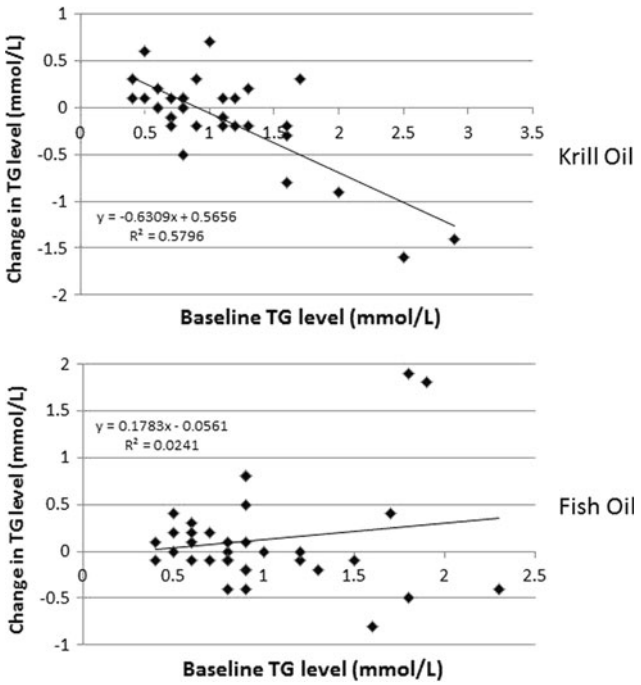

Fig. 2 Correlation between baseline TG levels and change in TG levels after 7 weeks of intervention with krill oil or fish oil

Oxidative Stress, Markers of Inflammation, and Hemostasis

α-Tocopherol is considered an antioxidant, and an increase in PUFAs may lead to increased oxidative stress. Although α-tocopherol was added to both supplements, no significant change in levels of α-tocopherol was detected (Supplementary Table). A tendency towards a reduced level of α-tocopherol was observed in all study groups. F2-isoprostanes, formed from free-radical-induced peroxidation of membrane-bound arachidonic acid, are considered a reliable biomarker of oxidative stress. However no differences were observed in urine F2-isoprostane, suggesting that there was not an increase in oxidative stress. No significant changes were observed in levels of hsCRP, markers of inflammation or hemostasis (Supplementary Table).

Discussion

The primary finding of the present study was that plasma concentrations of EPA, DPA, and DHA increased significantly in both the krill oil and fish oil groups compared with the control group following daily supplementation for 7 weeks. There was no statistically significant difference between these two groups in the levels of the increases in EPA and DHA. Since the subjects in the krill oil group received 62.8% of the total amount of n-3 PUFAs received by the subjects in the fish oil group, these findings indicate that the bioavailability of n-3 PUFAs from krill oil (mainly PL) is as, or possibly more, efficient as n-3 PUFA from fish oil (TG). This supports the results of a previous study with krill oil and menhaden oil in humans [11]. In the study performed by Maki et al., plasma EPA increased 90% and DHA increased 51% from baseline levels. In the current study EPA increased 146% and DHA increased 43% from baseline levels. The small discrepancy between these two studies might be related to different levels of EPA and DHA in the oils used, different treatment time (7 versus 4 weeks), and different dose used (3 g oil versus 2 g). It has been hypothesized that PL improve the bioavailability of lipids, which may facilitate absorption of EPA and DHA from marine PL compared with TG, but the extent to which this contributes to the efficient absorption observed in the krill oil group is unknown.

AHA dietary guidelines for long-chain n-3 PUFAs and fish for primary prevention of coronary diseases are two servings of fatty fish per week [9]. This recommendation will provide the order of 250–500 mg EPA + DHA per day [19]. In the present study we have shown that daily intake of 3 g krill oil containing 543 mg EPA + DHA increases the plasma level of EPA and DHA to the same extent as intake of fish oil containing 864 mg EPA + DHA. A food-based approach for achieving adequate intake of n-3 PUFAs is recommended [20]. However, for some individuals nutritional supplements may be needed, such as those who do not like fish or for other reasons choose not to include fish in their diet. This study demonstrates that supplementation with krill oil will be a good source of EPA and DHA in their daily diet.

Serum TG and HDL-cholesterol have been observed to be inversely related [21]. Although the metabolic relation that exists between HDL-cholesterol and TG is not fully understood, the ratio between TG and HDL-cholesterol has been shown to be a powerful risk predictor for CHD [22, 23]. In the present study, no statistically significant differences in HDL-cholesterol, TG or HDL-cholesterol/TG ratio were observed between the study groups. However, the change in the HDL-cholesterol/TG ratio in the krill oil group was statistically significant (Table 5). This observation supports the impression of a more pronounced effect of krill oil supplementation on HDL-cholesterol and TG compared with other n-3 PUFA supplements. However, to verify these effects of krill oil, they should be studied in a population with elevated blood TG levels and lowered HDL-cholesterol, i.e., in a population with markers of metabolic syndrome. The increase in HDL-cholesterol was slightly higher in the krill oil group than in the fish oil group (8.7% versus 3.2%), although not significantly so ($p = 0.061$). Compared with fish oil, krill oil contains a high amount of astaxanthin, which has been indicated to

increase HDL-cholesterol as well as decrease TG in humans [24]. Moreover, intake of PL may increase HDL-cholesterol [25]. The small increase in LDL-cholesterol, but no effect on HDL-cholesterol, in the fish oil group is in accordance with previous findings [7].

The analysis of the changes in the plasma fatty acid composition following 7 weeks of intervention with n-3 PUFAs showed that the levels of arachidonic acid and behenic acid significantly increased from baseline in the krill oil group as compared with the fish oil and control groups. Moreover, arachidonic acid was significantly decreased in the fish oil group. Intake of n-3 PUFAs from fish oil can be incorporated in cell PL in a time- and dose-dependent manner at the expense of arachidonic acid [26]. The explanation and importance of this finding are not clear. However, one possible explanation might be that arachidonic acid is mobilized from the cell membranes to the blood by EPA and DHA linked to the PL in the krill oil. However, the changes in plasma arachidonic acid were small compared with the changes in EPA and DHA, and there was no significant difference in the increase in EPA/arachidonic acid ratio between the two intervention groups.

The CRP level did not change during the study in any of the study groups, and no significant changes were observed in the other markers of inflammation and hemostasis (data not shown). This is in accordance with others who have examined the effect of fish oil among apparently healthy individuals [27–31]. Moreover, no statistically significant differences were found in α-tocopherol levels and F2-isoprostanes in urine, suggesting that no oxidative stress occurred.

The safety analysis revealed no clear patterns in the changes in any of the hematological or serum biochemical variables, vital signs or weight that might indicate a relation with administration of any of the studied products. Clinical symptoms registered during the study included mainly symptoms of common cold or gastrointestinal symptoms. However, one subject in the fish oil group experienced moderate bruises, and one subject in the krill oil group withdrew from the study because of an outbreak of rash that was possibly related to intake of the study products. Safety laboratory parameters and other safety observations such as occurrence of adverse events indicate that krill oil is well tolerated. There were no apparent differences in the rate of adverse events or blood safety parameters between the krill oil, fish oil or control groups.

In conclusion, the present study shows that n-3 PUFAs from krill oil in the form of PL are readily and effectively absorbed after ingestion and subsequently distributed in the blood. The krill oil supplement is safe and well tolerated. Krill oil thus represents a valuable source of n-3 PUFAs.

Acknowledgments The authors would like to thank the volunteers who participated in this study. This work was partially funded by Aker BioMarine ASA.

ORIGINAL ARTICLE

A High Omega-3 Fatty Acid Diet has Different Effects on Early and Late Stage Myeloid Progenitors

Melinda E. Varney · James T. Buchanan · Yulia Dementieva · W. Elaine Hardman · Vincent E. Sollars

Received: 24 May 2010 / Accepted: 18 October 2010 / Published online: 31 October 2010

Abstract The effects of the polyunsaturated omega-3 (n-3) and omega-6 (n-6) fatty acids (FA) on hematopoiesis are complex in that both FA forms are processed into leukotrienes, eicosanoids, and prostaglandins, which can have independent effects. These FA have antagonistic effects in that n-6 FA prostaglandins tend to be pro-proliferative and pro-inflammatory, while the effects of n-3 FA prostaglandins are the opposite. We have previously shown that diets high in n-3 FA reduce the size of the middle to later stage myeloid progenitor compartment in FVB X sv129 F_1hybrid mice. To assay the effects of high n-3 FA diets on earlier stages of myelopoiesis, we fed C57BL/6J mice diets high in n-3 FA or levels of n-3/n-6 FA similar to western diets and assayed the effects on myelopoiesis with flow cytometry and colony forming cell assays. Results indicate an expansion of the common myeloid progenitor cell compartment in high n-3 FA diets, which does not persist into later stages where the number of progenitor cells is actually lower in high n-3 FA fed animals. Investigations in vitro with the hematopoietic stem cell line EML-clone 1 indicate that cells cultured with eicosapentaenoic acid (n-3 FA) or arachidonic acid (n-6 FA) have no differences in cell viability but that arachidonic acid more rapidly produces progenitors with low levels of the macrophage developmental marker, F4/80.

Introduction

The examination of omega-3 (n-3) and omega-6 (n-6) fatty acids (FA) effects on hematopoiesis is important to patient care. The inhibitory effect of n-3 FA on inflammation has led to the use of fish oils that are high in these FA in the management of several inflammatory and autoimmune diseases [1]. n-3 FA affect hematopoietic differentiation by influencing myeloid progenitor cells [2]. n-3 FA are known to affect immune system function by reducing several aspects of neutrophil, monocyte, and lymphocyte function [1]. Suppression of n-6 derived eicosanoids has been proposed as a strategy for chemoprevention and as an adjunct for treatment of cancer [3–6].

n-3 and n-6 FA are incorporated into cell membranes either directly or after elongation and then desaturation by Δ6 and Δ5 desaturases. Dietary linoleic acid (LNA, 18 carbons, n-6 FA) is generally considered to be the major source of tissue arachidonic acid (ARA, 20 carbons, n-6 FA) although meat fat can be a direct source of ARA [7]. n-3 FA have greater affinity for the Δ5 and Δ6 desaturases than n-6 FA. Consequently, increasing dietary intake of n-3 FA reduces the desaturation of LNA and reduces the production of ARA [8]. All three major n-3 FA—α linolenic acid (ALA, 18:3, n-3)—eicosapentaenoic acid (EPA, 20:5, n-3), and docosahexaenoic acid (DHA, 22:6, n-3), directly inhibit the production of ARA from LNA [8].

Both ARA and EPA can be cleaved from the cell membrane phospholipids stores by phospholipase A_2 and acted on by cyclooxygenases (either the constitutive COX1 or the inducible COX2) to produce prostaglandin precursors which are isomerized by prostaglandin synthases to produce prostaglandins. COX activity on ARA forms the two-series prostaglandins that tend to be pro-proliferative and pro-inflammatory in most tissues [9]. Micromolar concentrations of prostaglandin E2 increase human myeloid progenitor cell proliferation [2]. However, COX activity on EPA forms the three-series prostaglandins that tend to have anti-proliferative and anti-inflammatory properties [9]. In addition to prostaglandins, leukotrienes and eicosanoids are formed from FA through activity of various lipoxygenases. These have been shown to have varying and sometimes controversial effects on either hematopoietic stem cell or myeloid progenitor cell differentiation [2, 10]. A model system approach is needed to effectively dissect the net effect of dietary fatty acids on hematopoiesis in vivo.

In this study, we examined the effects of n-3 and n-6 fatty acids in vivo in the mouse, with an analysis at the level of stem and progenitor subtypes. Our results indicate that, compared to diets rich in n-6 FA, diets rich in n-3 FA induce lower levels of later stage myeloid progenitor cells in mice, but that there is a higher frequency of the earliest stage myeloid progenitor cells in these mice. Our in vitro results indicate that aspects of the in vivo effects of n-3 and n-6 FA can be modeled using the EML cell culture system to ascertain the mechanisms involved.

Materials and Methods

Animals

Mice were housed in the AAALAC accredited animal facilities of the Marshall Universitiy School of Medicine. All animal use and care was approved by the Marshall University Institutional Animal and Use Committee. The mice were housed 3–4 in a cage and individually numbered for identification. Mice were fed either a fish oil diet ($n = 8$) or a corn oil diet ($n = 8$) from 6 weeks of age until 20 weeks of age (100 days on diet).

Diet

The base diet was an AIN-76A diet modified by substitution of 5% sucrose for 5% more oils to contain a total of 10% w/w oil (Tables 1, 2). The fish oil diet contained 3.65% n-3 FA and 1.3% n-6 FA. The corn oil diet contained 0.1% n-3 FA and 6.1% n-6 FA. Diets were prepared in the Marshall University School of Medicine animal diet prep room. Diet composition is shown in Table 1 and was formulated to be isocaloric, isonutrient, and relevant to human consumption. The AIN-76A diet is adequate for the nutritional support of the mice [11]. The dry ingredients of the diet were obtained in bulk from MP Biomedicals (Solon, OH, USA), sugar, corn, and canola oil were purchased locally (100% canola oil, 100% corn oil, no additives or preservatives). The n-3 supplement (OmegaRx Liquid) was purchased from Zone Labs, Danvers, MA. Batches of diet were prepared as needed, about every 2 weeks. The diet mixture was pressed into trays. Food (25–30 g) was stored in sealed containers at −20 °C to prevent oxidation of the fat and bacterial growth in the food. Mice had free access to food and water and were fed fresh food 5 days per week. Food removed from cages was discarded.

Table 1 Modified AIN-76A diet composition

Ingredient	Diet composition	
	wt%	Amount/100 g
Casein (protein)	20	20
Sucrose	45	45
Corn starch (carbs)	15	15
Alphacel (fiber)	5	5
Choline bitartrate	0.2	0.2
DL-Methionine	0.3	0.3
Mineral mix	3.5	3.5
Vitamin mix	1.0	1
Fat	10	10
Total	100	100
Total fat		10
Total protein		20
Total carbohydrate		60

The base diet is an AIN-76A diet modified by substitution of 5% sucrose for 5% more oils to contain a total of 10% w/w oil. The mouse food recipe contains 10% fat in each diet supplied through these oils

Colony Forming Cell (CFC) Assays

CFC assays were performed upon bone marrow isolated from the mice as previously discussed [12, 13]. Briefly, bone marrow was harvested by flushing from the femurs with Iscove's modified Dulbecco's medium and cells were counted and seeded in 4-well plates at a density determined empirically by a pilot study conducted with a broad and consistent range of seeding densities. After linear response of colony production to seeding density was insured by the pilot study, seeding densities were chosen to produce 10–30 colonies for each well (4-well plates). Bone marrow was cultured in 1% semi-solid Methocult M3434 (StemCell Technologies), supplemented with 0.4% autochthonous sera. Cells were incubated for 6–7 days to allow colony formation. Colonies with a minimum cell number of 20 were scored as positive using an inverted microscope at 40× magnification. Colonies were counted based on morphological features that are associated with each progenitor type.

Cell Cycle Analysis

EML cells were seeded at 2×10^5 cells/mL and treated with vehicle, 60 μM ARA (Sigma–Aldrich, cat # A3555), and 60 μM EPA (Sigma–Aldrich, cat # E2011). Cell counts were taken at 24 and 48 h. After 48 h, cells were collected, centrifuged (500*g*) and washed once with PBS. The cells were then resuspended in PBS (without Ca^{2+} or Mg^{2+}) and incubated with 70% EtOH for >2 h, at which time they were again centrifuged (500*g*) and washed once with PBS. The cells were then resuspended in PBS (without Ca^{2+} or Mg^{2+}) containing 50 μg/mL of propidium iodide and 250 μg/mL of RNase A (both purchased from Sigma, St. Louis, MO, USA) and incubated at 37 °C for 30 min. Cells were then analyzed for fluorescence by flow cytometry on a BD FACSAria.

Flow Cytometry

The preparation of bone marrow for flow cytometry was performed as previously described [12]. EML cells were prepared by washing twice with FACS buffer (PBS supplemented with 0.5% bovine serum albumin and 2 mM EDTA) and collecting by centrifugation. Thereafter, samples of both type were incubated with 2% autochthonous sera obtained from cardiac puncture just before marrow harvest to prevent nonspecific binding by blocking the Fc receptors for half an hour at 4 °C. The cells were washed again and labeled with antibodies for 30 min on ice. The following antibodies were used in the bone marrow studies with Streptavidin-Pacific Blue to detect biotinylated antibodies: PE-Cy7 conjugated Sca-1 (clone D7, eBiosciences #25-5981-81), APC-eFluor 750 conjugated CD117 (clone 2B8, eBiosciences #47-1171-80), biotinylated lineage panel (BD Biosciences #559971), biotinylated IL-7Rα (clone B12-1, BD Biosciences #555288), APC conjugated $F_CR\gamma$ (clone 93, eBiosciences #17-0161-81), and PE

Table 2 Compositions of dietary fats (approximate %)

	Saturated FA	Linoleic acid (omega 6)	Total omega 3	Monounsaturated FA
Corn oil[a]	13	61	1	26
Canola oil[a]	6	20	10	62
n-3 supp[b]	9	6	63	21

The corn oil diet is the low n-3:n-6 FA diet containing 10% w/w corn oil as the source of all fat. The fish oil diet is our high n-3:n-6 FA diet containing 5% w/w canola oil and 5% w/w n-3 FA supplement. The corn oil diet contains 0.1% n-3 FA and 6.1% n-6 FA, which is a relative ratio of n-6 to n-3 of 61:1. The fish oil diet contains 3.65% n-3 FA and 1.3% n-6 FA, which is a relative ratio of 1:2.8

conjugated CD34 (clone RAM34, BD Biosciences 551387). The following antibodies were used in labeling the EML-clone1 cells in labeling pairs with Streptavidin-APC (BD Biosciences #554067) to detect biotinylated antibodies: biotinylated Ly6G/C (clone RB6-8CS, BD Biosciences #553125) + PE conjugated CD117 (clone 2B8, BD Biosciences #553355), biotinylated CD11b (clone M1/70, BD Biosciences #553309) + PE conjugated Sca-1 (clone D7, BD Biosciences #553108), and biotinylated CD45 (clone RA3-6B2, BD Biosciences #553086) + PE conjugated F4/80 (clone BM8, Caltag #MF48004). Data acquisition was performed using BD FACS Aria I sorter and data analysis/compensation was performed using FlowJo v. 7.6 software (Treestar, Ashland, OR, USA) with super-enhanced *D*max subtraction analysis for determination of differences in histograms.

In Vitro Culture and Differentiation

EML C1 cells were the kind gift of Dr. Schickwann Tsai and were maintained in Iscove's modified Dulbecco medium (IMDM,) supplemented with 20% horse serum (American Type culture collection, ATCC, Manassas, VA, USA) and 10% BHK/MKL-conditioned medium [14]. For differentiation studies, EML cells were induced to differentiate into myeloid cells with 10 μM all-*trans* retinoic acid (ATRA; sigma, St. Louis, MO, USA), 10% BHK conditioned medium (source of stem cell factor) and 15% WEHI conditioned medium (source of interleukin-3a) for 3 days. EML-clone1 cells were seeded at 2×10^5 cells/mL and cultured for 24 h in 60 μM FA (same formulations as stated previously) in standard growth medium (20% horse serum, 70% Dulbecco's modified eagle medium, and 10% BHK conditioned medium). After 24 h cells were placed in differentiation medium with 60 μM FA at 2.0×10^5 cells/mL. Cell counts were performed using trypan blue at 24, 48, 72, and 96 h. After 96 h cells were processed for flow cytometry analysis.

FA Metabolism Studies

Cells were seeded at 2×10^5 cells/mL and treated with vehicle or 60 μM FA (same formulations as stated previously). Cell counts were performed at 24, 48, 72, and 96 h using trypan blue. At each time point, half the total volume of the culture was taken as a sample and replaced with untreated growth media. Each sample was centrifuged (500*g*), the supernatant removed and the pellet store at −20 °C until analyzed by gas chromatography.

At the time of gas chromatography, cells were homogenized in 0.1% butylated hydroxytoluene in 70% methanol/distilled water to prevent FA oxidation. Lipids were extracted with chloroform/methanol and methylated. Methylated lipids were separated and identified using gas chromatography as previously published [15]. FA methyl ester standards (Nu-Chek-Prep, Elysian, MN, USA) were used for peak identification. The FA methyl esters were reported as the percent of the total methylated FA (area under the curve).

Statistical Analysis

Statistical analyses were run using SAS software release 9.2 (SAS Institute Inc. Cary, NC, USA). Student's *t* tests were used to detect differences between the experimental groups (corn versus fish diet) of colony forming cells ($n = 8$ for each group) and between the experimental groups (corn vs. fish diet) in flow cytometry assays ($n = 8$ for each group). To determine statistical significance in gas chromatography experiments and differentiation studies the levels of fatty acids of a particular type were analyzed using either one-way analysis of variance (ANOVA) or by one-way Kruskal–Wallis analysis of variance on ranks. Dunnett multiple comparison tests were used for testing if any treatments are significantly different from a single control for all main effects means in the MEANS statement.

Results

Fish Oil Diets Induce Changes in the Frequency of Various Myeloid Progenitor Cell Types in the Bone Marrow

In our previous investigations of the effect of fish oil diets on murine hematopoiesis, we found a down-regulation in the frequency of myeloid progenitor cells in bone marrow in mice fed fish oil diets compared to those on corn oil diets [16]. Other investigators have reported that bone marrow of rodents readily changes composition based upon dietary FA sources [17]. However, our investigations using colony forming cell assays limited our ability to assay the frequency of more immature cell types, such as the common myeloid progenitor (CMP) and hematopoietic stem cell (HSC). In order to assay the effects of high n-3 FA diets on these cell types, we verified that the effects seen in hybrid F_1 animals were also seen in C57BL/6 mice where flow cytometry markers for examining these rare cell types have been verified [18]. In the experiments presented here, mice were fed diets rich in n-3 FA (fish oil diet) or rich in n-6 FA (corn oil diet) from 6 weeks of age until 20 weeks of age (Tables 1, 2, 100 days on diet). Bone marrow was then harvested and analyzed by colony forming cell assay and flow cytometry. There was no difference in density of cells in the bone marrow (Fig. 1a). Our results (Fig. 1b)

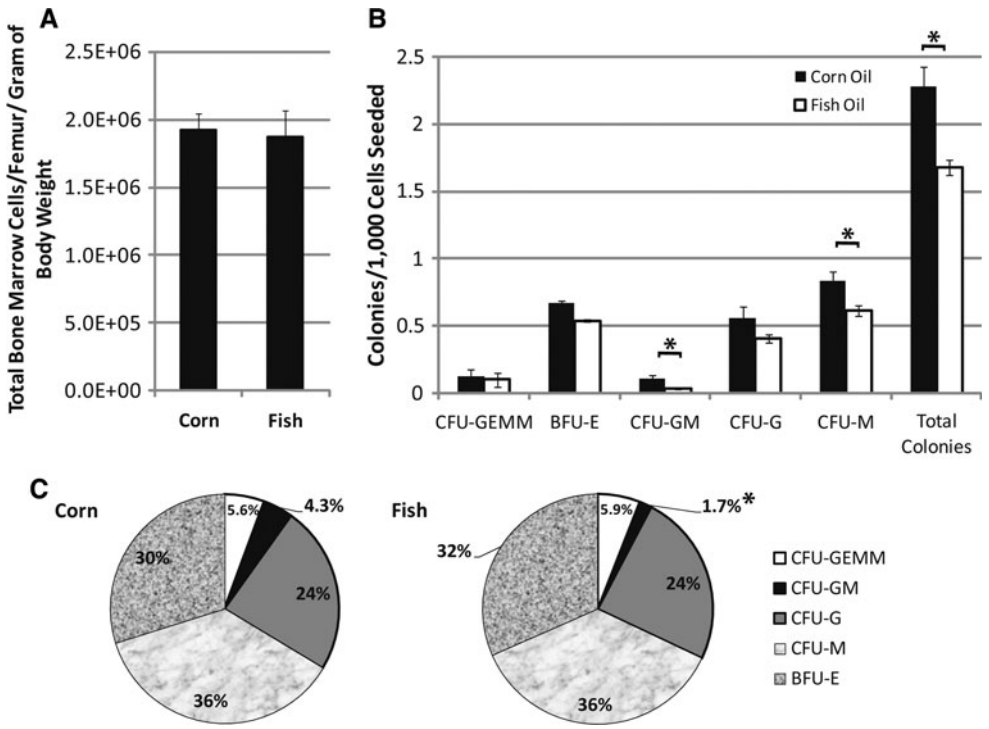

Fig. 1 Reduction in middle to latter stage myeloid progenitor cell types by high n-3 diet. Mice were fed either corn oil or fish oil diets for *x* days followed by harvesting of bone marrow from femurs. The number of cells harvested from the mice on the different diets were similar (**a**). Colony forming cell assays were performed to enumerate the frequency of middle to latter stage progenitor types. The frequency of each progenitor cell type (**b**) and the relative distribution of progenitor types (**c**) in the total progenitors assayed are shown. Significant differences as measured by Student's *t* tests ($p < 0.05$) are indicated by *asterisk*. *Error bars* represent SEM ($n = 8$). SEMs in **c** for the corn oil diet data are BFU-E, 2.4%, CFU-GEMM, 0.8%, CFU-GM, 1.1%, CFU-G, 2.7%, CFU-M, 1.8% and for the fish oil diet are BFU-E, 2.4%, CFU-GEMM, 0.6%, CFU-GM, 0.5%, CFU-G, 2.1%, CFU-M, 2.1%. *CFU* colony forming unit, *BFU* blast forming unit, *GEMM* granulocyte erythrocyte monocyte macrophage, *E* erythrocyte, *GM* granulocyte monocyte, *G* granulocyte, and *M* macrophage

indicated an overall lower frequency of mid to late stage progenitors when mice were fed n-3 FA rich diets compared to those that were fed diets rich in n-6 FA rich diets. There was a significantly lower (26%, $p < 0.01$) overall myeloid progenitor cell frequency, with significant reductions ($p < 0.05$) in colony forming unit granulocyte–macrophage (CFU-GM) and colony forming unit macrophage (CFU-M).

When we examined the relative contributions of each progenitor cell type to the overall myeloid progenitor cell pool in the bone marrow (Fig. 1c), we found that there is a significant reduction in CFU-GM proportion in mice on the fish oil diet ($p < 0.05$). The comparison of proportions of subtypes of myeloid progenitors is different than what we observed in FVB X sv129 F_1 hybrid mice [16], where we observed an overall shift to more later stage progenitor types [16]. Thus, though there was a reduction in myeloid progenitor cell frequencies in the marrow and a twofold reduction in proportion of CFU-GM, there was little shift in proportions of the other progenitor subtypes. This may be due to particular characteristics of the C57BL/6 inbred strain that are not seen in F_1 hybrid animals, due to the lessening of homozygous recessive mutations in hybrid animals. We have shown that mice vary significantly in myeloid progenitor cell frequencies in a previous publication [12]. These data indicate that C57BL/6 mice responded to high n-3 FA diets with a reduction in overall myeloid progenitors cell frequencies, and significantly altering the proportions of the CFU-GM present.

The Frequency of the Common Myeloid Progenitor Fraction is Increased in Mice Fed Fish Oil Diets

In order to assay the frequencies of earlier stage stem and progenitors cells in mice fed corn and fish oil diets, flow cytometry studies were conducted using established gating parameters for the assay of HSC, CMP, granulocyte–macrophage progenitors (GMP), and megakaryocyte–erythrocyte progenitors (HSC) in C57BL/6 mice[18] (Fig. 2a). Bone marrow was first gated by excluding high and low forward scatter cells along with those labeled positively for one of the differentiation antigens in the lineage panel or IL-7Rα, which marks lymphoid cells. These FSC^{mid}IL-7R$\alpha^{-}Lin^{-}$ were further separated into stem (FSC^{mid}IL-7R$\alpha^{-}Lin^{-}$Sca-1^{+}c-Kit^{+}) and progenitor (FSC^{mid}IL-7R$\alpha^{-}Lin^{-}$Sca-1^{-}c-Kit^{+}) cell fractions by

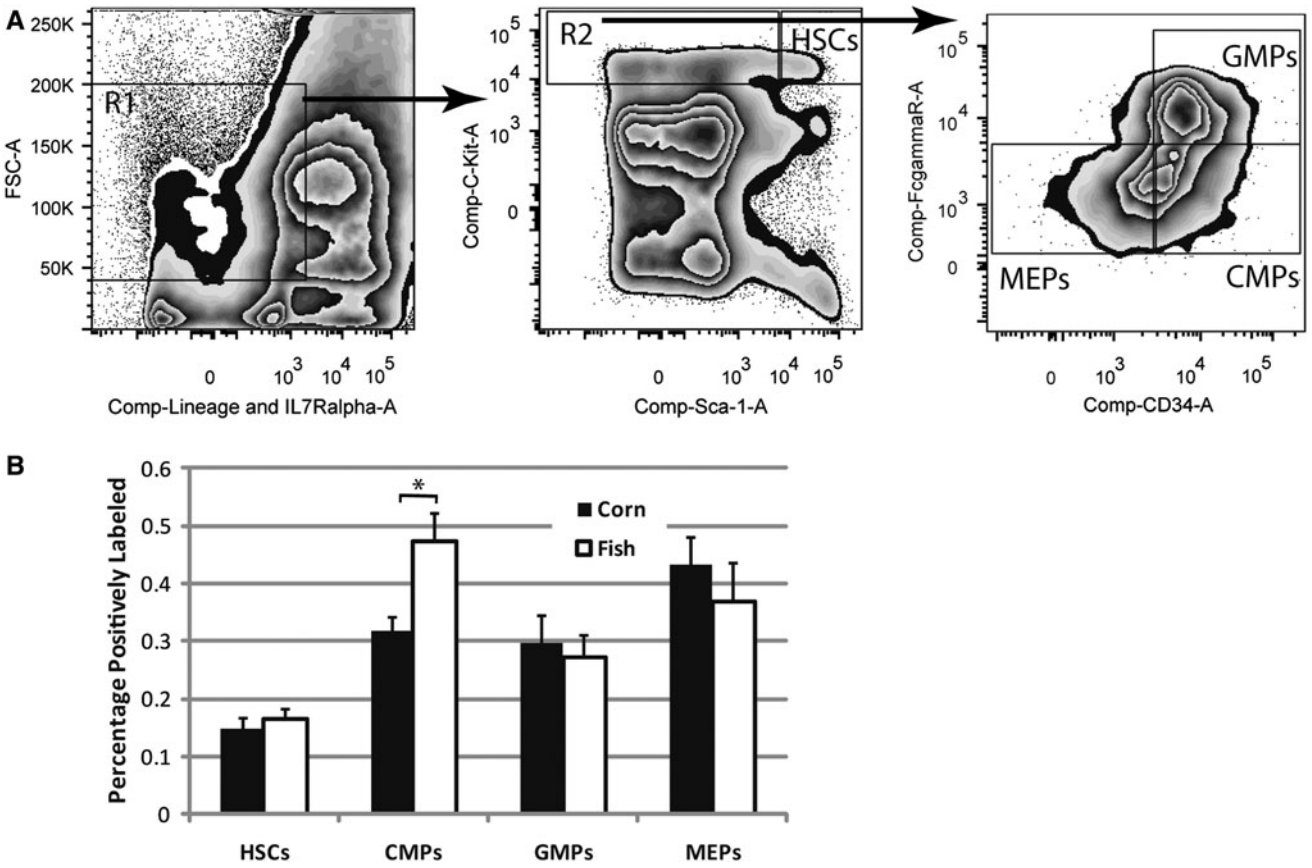

Fig. 2 Increase in early myeloid progenitors by high n-3 diets. Mice were fed either corn oil or fish oil diets for *x* days followed by harvesting of bone marrow from femurs. Bone marrow was analyzed by flow cytometry first by FSC X lineage panel + IL7Rα, then by C-kit and Sca-1 expression, followed by FcγR X CD34 expression to differentiate between various stem or progenitor cell types (**a**). The percentage of the total marrow cells labeling positive for each fraction are shown (**b**). Significant differences as measured by Student's *t* tests ($p < 0.05$) are indicated by *asterisk*. *Error bars* represent SEM ($n = 8$). *HSC* hematopoietic stem cells, *CMP* common myeloid progenitors, *GMP* granulocyte macrophage progenitors, and *HSC* megakaryocyte erythrocyte progenitors

expression of c-Kit and Sca-1 as shown. The progenitor pool was also separated based upon the expression of CD34 and FcγR to delineate CMP ($FSC^{mid}IL\text{-}7R\alpha^{-}Lin^{-}Sca\text{-}1^{+}$ $c\text{-}Kit^{+}Fc\gamma R^{lo}CD34^{+}$), GMP ($FSC^{mid}IL\text{-}7R\alpha^{-}Lin^{-}Sca\text{-}1^{+}$ $c\text{-}Kit^{+}Fc\gamma R^{hi}CD34^{+}$), and HSC ($FSC^{mid}IL\text{-}7R\alpha^{-}Lin^{-}$ $Sca\text{-}1^{+}c\text{-}Kit^{+}Fc\gamma R^{lo}CD34^{-}$). These data show a 50% increase ($p = 0.01$) in the frequency of the CMP fraction in mice fed fish oil diets (Fig. 2b). There were no significant differences in frequency of HSC, GMP, or MEP fractions indicated in these studies. These data suggest that the frequency of the CMP has been increased by administration of a diet containing high levels of n-3 FA.

FA Applied to EML Cell Culture Medium are Incorporated and Processed

In order to study the observed effects of n-3 versus n-6 FA on early myeloid progenitor cells in more detail, we examined the effects of the polyunsaturated fatty acids EPA and ARA on EML cells in culture. We chose to compare these two FA because EPA (20:5, n-3) is the fatty acid most molecularly similar to ARA (20 carbons, n-6 FA) available. DHAn-3 (22:6, n-3) has two more carbons in the chain. The EML cell line is a stem cell factor dependent multipotent cell line with erythroid (E), myeloid (M), and lymphoid (L) potential. It was established from DBA/2 mouse bone marrow infected with a retroviral vector (LRARα403SN) harboring a dominant negative retinoic acid receptor [14]. It is a suspension cell line consisting of mostly blast like cells with 20–30% hand mirror shaped cells. EML cells serve as an excellent model to study hematopoietic differentiation. It can be induced to differentiate towards granulocyte/monocyte progenitors by high concentration of all-*trans* retinoic acid (ATRA) in the presence of interleukin-3 (IL-3).

To verify the incorporation and processing by EML cells of FA placed in the culture medium, we spiked the culture medium with 60 μM ARA (Fig. 3a) or 60 μM EPA (Fig. 3b) and analyzed the levels of various FA present in the cells over the course of 4 days. Cells were analyzed

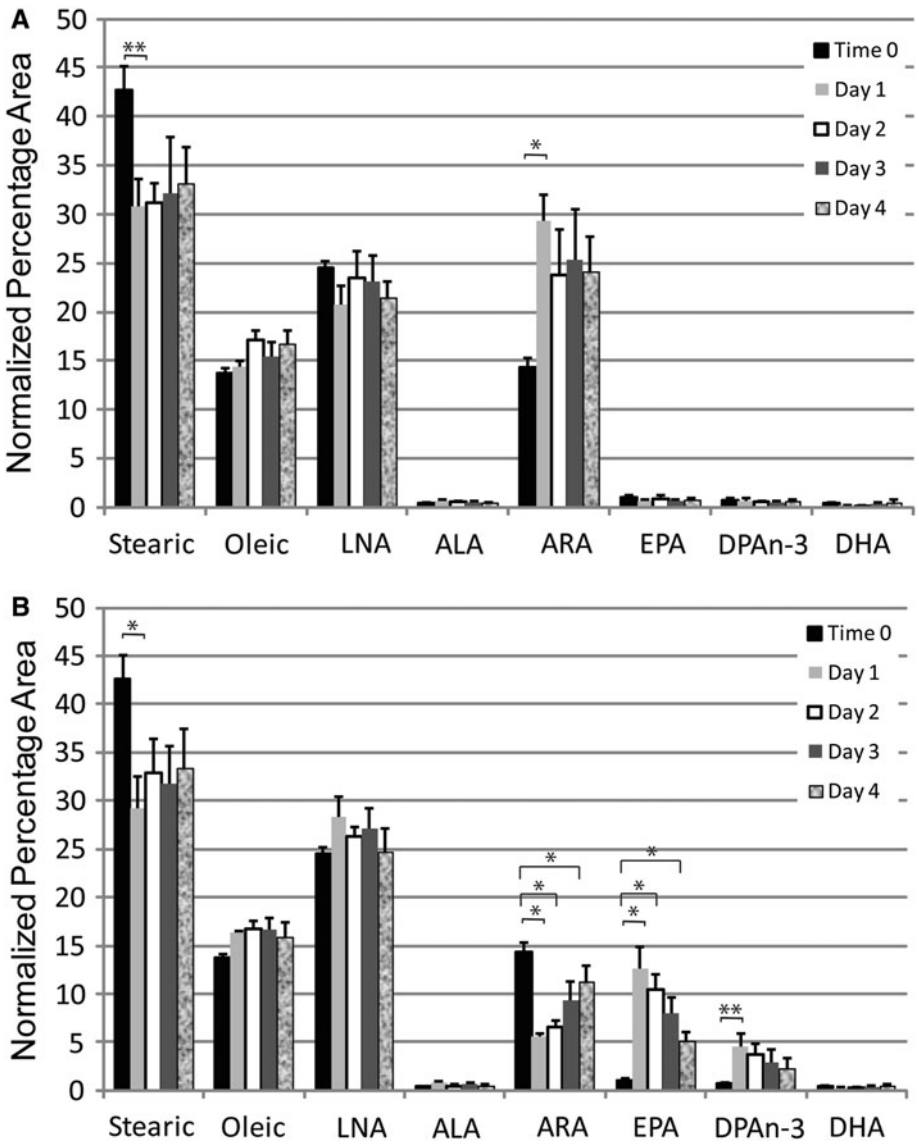

Fig. 3 EML cells take up and metabolize FA. EML cells were placed in growth medium containing 60 μM arachidonic (**a**) or eicosapentaenoic (**b**) acid. The uptake and processing of these FA was assayed over the course of 4 days. Samples were taken just before addition of the FA ($t = 0$), 24, 48, 72, and 96 h for analysis by gas chromatography. The gas chromatography data for each FA is shown above for the five data points in temporal order. Data displayed are the results of three independent experiments with the mean and SEM displayed. *LNA* linoleic acid, *ALA* alpha-linolenic acid, *ARA* arachidonic acid, *EPA* eicosapentaenoic acid, *DPA* docosapentaenoic acid, and *DHAn-3* docosahexaenoic acid. * indicate statistically significant ($p < 0.05$) differences based on one-way ANOVA test or Kruskal–Wallis test with Dunnett multiple comparisons adjustment. ** indicate statistically significant ($p < 0.05$) differences based on Student's *t* test or Mann–Whitney rank sum test without multiple comparison adjustment

with gas chromatography daily to determine the uptake and processing of FA. The major FA in untreated EML cell membranes are steric acid, oleic acid, LNA, and ARA (time 0). There are only faint traces of n-3 FA such as ALA, EPA, docosapentaenoic acid (DPA), and DHA in EML cell membranes under normal culturing conditions (time 0). In both cultures, the percentage of the major constituent of cell membranes (steric acid) is reduced as this is replaced by either ARA or EPA (Fig. 3a, b, 24 h). Thus, FA supplied in culture medium were being incorporated into cellular membranes and this occurs within 24 h. Supplementation of ARA in the medium caused an increase in the already substantial levels of ARA in cellular membranes (Fig. 3a). There was a significant ($p < 0.05$) two-fold increase in ARA at 24 h that drops to a 66% increase at 48 h and was maintained for the remainder of the 4 days. The addition of EPA to the culture medium caused a significant ($p < 0.001$) increase in the n-3 FA EPA and elevated levels (p value significant before correction for multiple comparisons) of the EPA elongation metabolite DPA, with a corresponding significant ($p < 0.001$) decrease in ARA by 24 h (Fig. 3b). Interestingly, there was no increase in DHA, which is the Δ4 desaturase metabolite of DPA, indicating EML cells do not have this enzymatic activity. Thus, addition of FA to the cell medium resulted in incorporation of these FA into cellular membranes and processing of these FA by 24 h.

Incubation of EML Cells with FA has Effects on Immunophenotype and Cell Viability

To determine if the effects of n-3 versus n-6 FA seen in our in vivo experiment are due to viability/proliferation differences induced by the FA, we analyzed the effect of n-3

and n-6 FA on EML cells in culture (Fig. 4a) for 2 days, since we have shown the greatest levels of incorporation of fatty acids supplied through the culture medium occur at 24 h according to the gas chromatography. EML cells in their native state are a model for hematopoietic stem cells. We found that cultures treated with 60 μM ARA had significantly reduced ($p < 0.05$) cell counts after 1 day compared to the vehicle control. EPA treated cultures had slightly lower cell counts at day one, but the difference was not statistically significant. Neither of the treated cultures had statistically significant differences from the control at day 2, indicating that the effects of treatment with ARA were transitory. These results are consistent with the in vivo results, where we saw no difference in the stem cell compartment of fish oil (high n-3) versus corn oil (high n-6) fed mice.

To observe cell autonomous effects of n-3 versus n-6 FA on cell viability and proliferation during the GMP myeloid progenitor cell differentiation stage we primed EML cells for 24 h with 60 μM EPA or ARA, then induced differentiation into macrophage/granulocytic lineages with ATRA, stem cell factor (SCF), and IL-3. After 72 h in the differentiation medium, cell counts were performed on these EML cell cultures. Viability/proliferation was measured by trypan blue exclusion (Fig. 4b). The viability of the cell cultures was very similar with the various treatments at each stage with a fairly consistent viability as the cultures differentiated (measured by non-stained cells/total cells, data not presented). All cultures were proliferating robustly with a doubling time starting at 18 h and shortening as differentiation proceeded (data not presented). The major finding of this study was a significant reduction ($p < 0.05$) in cell counts in the EPA treatment group at days 2 (11% reduction) and 3 (21% reduction) with a suggestive reduction at day 1 (Fig. 4b). There was no reduction in viability of the cultures at these time points, suggesting the difference was due to cell proliferation. These results are consistent with our in vivo results that show a higher frequency of middle-later stage myeloid progenitors with high n-6 diets.

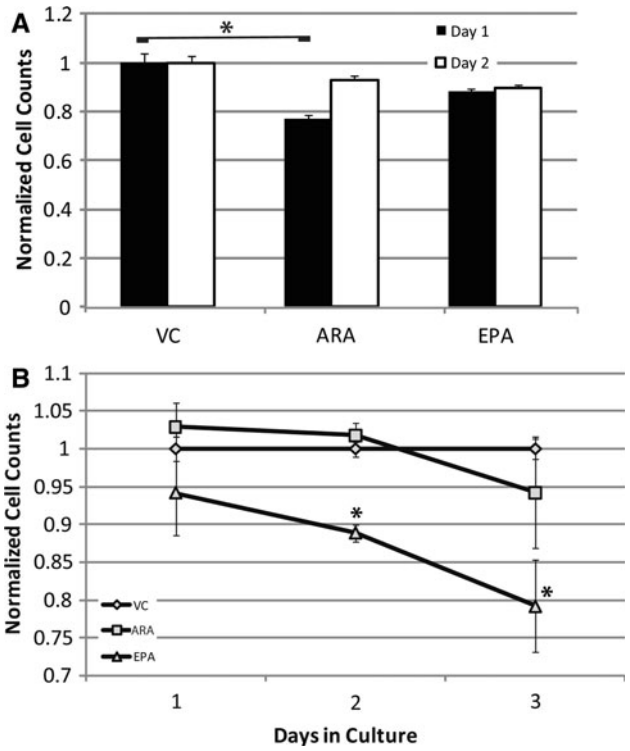

Fig. 4 In vitro culture of EML cells shows a slight increased viability in n-3 versus n-6 augmented cultures. EML cells in standard culture were augmented with either vehicle control, arachidonic acid (n-6), or eicosapentaenoic acid (n-3) for 48 h with cell counts performed at 24 and 48 h to determine viability (**a**). EML cells were cultured in either vehicle control, arachidonic acid (n-6), or eicosapentaenoic acid (n-3) for 24 h then induced to differentiate for another 72 h down myeloid lineages (**b**). Data displayed are the results of two (**a**) or three (**b**) independent experiments with the mean and SEM displayed of culture counts normalized to the vehicle control. * indicate statistically significant ($p < 0.05$) difference based on one-way ANOVA test with Dunnett multiple comparisons adjustment

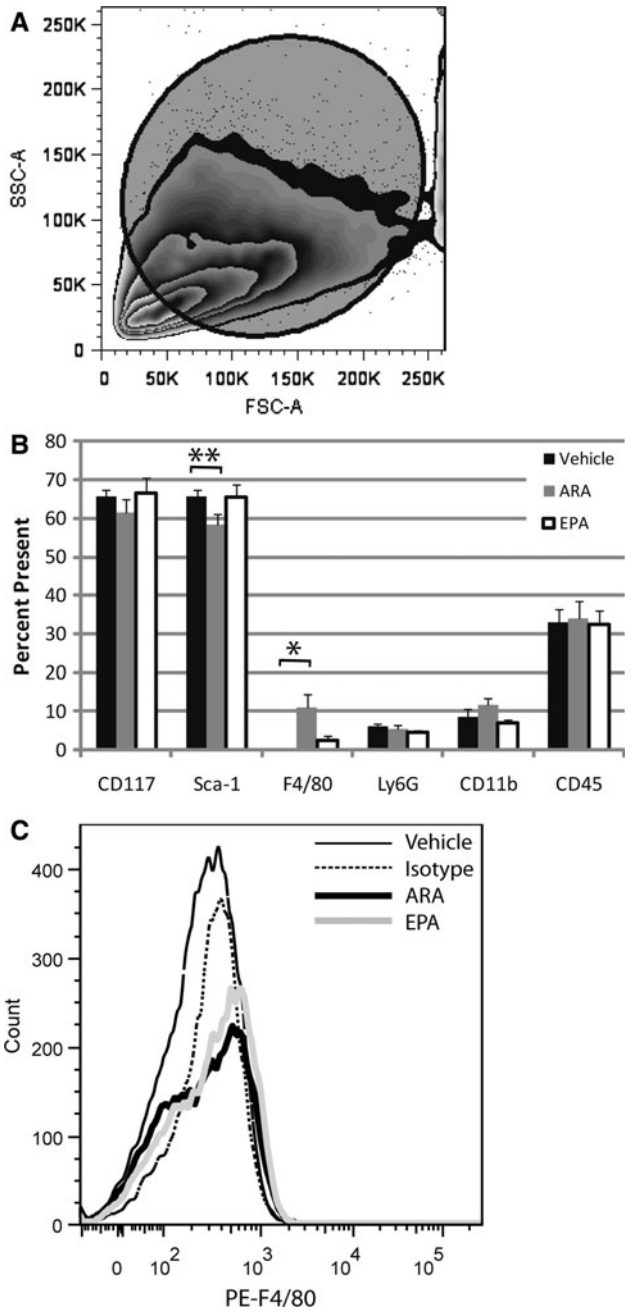
Fig. 5 No significant differences in myeloid progenitor cell maturation rate between n-3 and n-6 FA. EML cells were cultured in either vehicle control, arachidonic acid (n-6), or eicosapentaenoic acid (n-3) for 24 h then induced to differentiate for another 72 h down myeloid lineages. Flow cytometry was performed analyzing the larger FSC population of non-apoptotic cells (**a**). The percentage of cells displaying various markers of differentiation are shown for each culture type (**b**). Representative histograms are displayed for the isotype control (*black*, *narrow line*), vehicle control (*dotted line*), EPA treated cultures (*gray line*), and ARA treated cultures (*black*, *thick line*) (**c**). Both fatty acid treated culture display a shift over to low level expression (a small increase in fluorescence) of the antigen, but the ARA treated cultures show a greater shift (more cells present in the higher fluorescence channels). Data represents the results from five independent experiments with the mean and SEM displayed. * indicates statistically significant ($p < 0.05$) difference based on one-way Kruskal–Wallis analysis of variance on ranks followed by Dunnett test. ** indicates statistically significant ($p < 0.05$) difference based on Student's *t* test without multiple comparison adjustment

To observe cell autonomous effects of n-3 versus n-6 FA on myeloid progenitor cell differentiation we primed EML cells for 24 h with 60 μM EPA or ARA, then induced differentiation into macrophage/granulocytic lineages with ATRA, stem cell factor (SCF), and IL-3. After 72 h in the differentiation medium, EML cells were immunophenotyped for the early markers Sca-1 and CD117, as well as the differentiation markers Ly6G, CD11b, CD45, and F4/80 (Fig. 5b). There were no significant decreases in Sca-1 levels (the first sign of differentiation in this model) with treatment, though the decrease with ARA treatment is suggestive (*p* value significant before correction for multiple comparisons, but not after the appropriate Dunnett multiple comparison correction) when comparing treatments to vehicle control. There was significant ($p < 0.05$)



difference in the percentage of cells labeling with the F4/80 antigen in the ARA treatment group compared to the vehicle control. The sizeable increase in F4/80 positive cells coupled with the suggestive decrease for the Sca-1 antigen in the treatments with ARA compared to vehicle (Fig. 5b) indicates the production of a granulocyte/macrophage progenitor population with ARA treatment. These two results are consistent in that there is a lower frequency of the marker for stem cells and an increase in frequency of the differentiation marker F4/80. This result is also consistent with the in vivo data that found an increase in production of granulocyte and macrophage progenitor subtypes at later stages. The expression of F4/80 appears to be at a low abundance on a per cell basis in both ARA and EPA treated samples, but much more prevalent in ARA treated samples (Fig. 5c). Thus, our model suggests that the differences seen in the CMP compartment seen in our in vivo experiment are not due to changes in rate of differentiation in the bone marrow and that n-6 FA supplementation produces a shift to macrophage/granulocytic lineages as seen in vivo.

Discussion

Our primary objective in this study was to determine if the reduction of later myeloid progenitor subtypes by diets high in n-3 FA seen previously [12] was the continuation of differences induced at earlier stages of myeloid progenitor development. The data from these experiments indicate that this is not the case. The effect of lowering the frequency of myeloid progenitors of the later stages in mice fed n-3 FA rich diet was recapitulated in the present study, but we did not see a lowering of the stem/early progenitor cell fractions in the bone marrow. Conversely, we observed an increase in the common myeloid progenitor cell fraction with flow cytometry. Thus, the effects of n-3 FA on stem/progenitor cell biology in bone marrow are not a simple lowering of the overall frequency of these cell types. Determination of the exact mechanism of n-3 FA effects will entail studies at multiple levels of maturation in bone marrow. Possible mechanisms include effects through metabolites such as leukotrienes, resolvins, incorporation into cell signaling molecules such as hedgehog, or production of prostaglandins. Our data suggest that these mechanisms are eventually triggering a slowed differentiation between the early and middle myeloid progenitor phases resulting in an increase in early progenitors and a decrease in later stage progenitors in high n-3 diets. Understanding the mechanisms involved will enable targeted therapies to hematopoietic disorders involving problematic differentiation.

Our in vivo studies indicate that diets rich in n-3 FA when compared to n-6 FA have an effect of increasing the frequency of CMP, but no effect on HSC (Fig. 2). The changes seen in early stem/progenitor cell biology are then reversed, in that diets rich in n-6 FA produce more later stage progenitor cells of the granulocyte and macrophage lineage (Fig. 1). The results of our stem cell culture model found no lasting effects on stem cell viability or proliferation when cultured in n-3 versus n-6 fatty acids (Fig. 4a), similar to that seen in vivo. It is interesting that we did not see an increase in HSC with the corn oil diet containing high n-6 FA levels considering the recent results indicating one of the products of n-6 FA, prostaglandin E_2, can

increase HSC production in vivo [19–22]. This may be due to the complex metabolism of FA and use of them in biomolecules or the genetics of the C57BL/6 model. We found a low level expression of F4/80 antigen upon treatment with ARA treatment, characteristic of macrophage progenitor development [23–26], consistent with these progenitors being greater in vivo in corn oil fed mice compared to fish oil fed mice (Fig. 1). No other significant changes were seen in differentiation state upon treatment with ARA or EPA in comparison to vehicle controls. We observed a lower proliferation rate during differentiation of EML cells while cultured in EPA compared to vehicle controls that was not seen with ARA treatment. This is consistent with an overall lowering of middle-later stage myeloid progenitor cell numbers in mice fed fish oil diets relative to corn oil diets (Fig. 1). An important consideration in extrapolating these in vitro experiments to our in vivo results is that the EML cell model only takes into account cell autonomous factors. The stem cell niche is an important part of stem cell biology and this is not recapitulated in this model.

These data indicate that the effect of n-3 FA in the diet of mice on reducing later stage myeloid progenitors is not a simple reduction of HSC in the bone marrow relative to n-6 FA fed mice. n-3 FA appear to have a diverse effect depending upon the stage of progenitor cell development. Understanding the mechanisms involved will allow a more targeted approach to using n-3 FA clinically in differentiation therapies. We are currently investigating whether the use of n-3 fatty acids as a mechanism of induced differentiation is applicable to reduction of the progression of chronic myelogenous leukemia (CML) to the lethal blast crisis phase in a murine model as well as clinical trials with B-cell malignancies ([27] and unpublished results).

Received: 22 July 2010 / Accepted: 21 October 2010 / Published online: 20 November 2010

Abstract The Omega-3 Index, a measure of long-chain omega-3 fats in red blood cell membranes, predicts heart disease mortality in adults, but its association with cardiovascular risk factors in younger populations is unknown. We determined the Omega-3 Index in adolescents participating in the Western Australian Pregnancy (Raine) Cohort, assessed associations with diet, lifestyle and socioeconomic factors, and investigated independent associations with cardiovascular and metabolic risk factors. Red blood cell fatty acid analysis was determined for 1,301 adolescents aged 13–15 years. Risk factors examined were blood pressure, fasting blood insulin and glucose concentrations, and fasting blood lipids including ratios. The mean Omega-3 Index was $4.90 \pm 1.04\%$ (range 1.41–8.42%). When compared with categories identified in adults, 15.6% of adolescents were in the high risk category (Index $< 4\%$). Age ($P < 0.01$), maternal education ($P < 0.01$) and BMI ($P = 0.05$) were positively associated with the Omega-3 Index. The Index was positively associated with dietary intakes of eicosapentaenoic and docosahexaenoic acid ($P < 0.01$), protein ($P < 0.01$), omega-3 fats ($P < 0.04$), and food groups of fish and wholegrains (both $P < 0.01$), and negatively associated with intakes of soft drinks and crisps (both $P < 0.01$). In boys, the Omega-3 Index was independently associated with total ($\beta = 0.06$, $P = 0.01$) and HDL-cholesterol ($\beta = 0.03$, $P = 0.01$), and diastolic blood pressure ($\beta = -0.68$, $P = 0.04$). The predictability of the Index for the risk of cardiovascular disease later in life warrants further investigation in the adolescent population.

EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
RBC	Red blood cell
HDL	High density lipoprotein
LDL	Low density lipoprotein

Introduction

The Omega-3 Index has been suggested as a physiologically relevant, modifiable, and independent risk factor for cardiovascular disease [1]. The Index is equal to the content of long-chain omega-3 fatty acids—eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3)—in red blood cell (RBC) membranes, as a percentage of the total fatty acids. The omega-3 fatty acid content of RBC membranes reflects the fatty acid content of cardiac membranes [2]. Dietary intake of fats is thought to modify the Index [3], and supplementation with long-chain omega-3

fatty acids has been shown to increase the Omega-3 Index in a randomised trial [4]. Other factors such as age and smoking habits may also affect the Index [3].

Long-chain omega-3 fatty acids in RBC membranes exert beneficial metabolic effects, in part, by altering membrane characteristics and the activity of membrane-bound proteins [5]. They reduce the risk of cardiovascular disease through their strong anti-inflammatory effects, their capacity to reduce platelet adhesiveness, and by benefitting blood pressure and vascular reactivity, cardiac function, lipid metabolism, platelet and leukocyte function, cytokine production and oxidative stress [6–9]. Harris and von Schacky have shown, through analyses of epidemiological and randomised controlled trials, that an Omega-3 Index of <4% is associated with a high risk, 4–8% an intermediate risk and >8% a low risk of coronary heart disease mortality in adults [5].

Existing literature on investigations of the Omega-3 Index is predominantly focussed on adults [10–12]. To our knowledge, there have been no reports describing associations between the Omega-3 Index and cardiovascular and metabolic risk, dietary, lifestyle and socioeconomic factors in an adolescent population. To assess its potential value as an early predictor of adult cardiovascular and metabolic disease, we have investigated cross-sectional associations between cardiometabolic risk factors and the Omega-3 Index in a large population-based adolescent cohort in Western Australia.

Materials and Methods

Subjects

As a longitudinal observational study, the Raine Study recruited 2,900 pregnant women from May 1989 to November 1991 through the public antenatal clinic at the King Edward Memorial Hospital and private clinics in Perth, Western Australia. Further details on the Raine Study have been previously published [13]. Of the initial cohort of 2,868 live births, assessments occurred at birth and at ages one, two, three, five, eight, ten and 14 years. This study utilises data collected at the 14-year follow-up when assessments of RBC fatty acids and dietary intake were conducted. The ethics committees of King Edward Memorial Hospital and Princess Margaret Hospital approved the protocol for all aspects of the study. Each adolescent, as well as their parent or guardian, provided written consent for participation in the study.

Red Blood Cell Analysis

Fatty acids of interest for this study were EPA and DHA. RBC fatty acid analysis was performed as previously described [14]. Briefly, chloroform:methanol (2:1) was used to extract total lipids and fatty acid methyl esters were prepared by treatment of extracts with 4% H_2SO_4 in methanol at 90 °C for 20 min. Samples were analysed by gas chromatography using an Agilent 7890A gas chromatograph. The column was a BPX70 (25 m × 0.32 mm, 0.25 μm film thickness) (SGE, Ringwood, Victoria, Australia) with programmed temperatures of 150–210 °C at 4 °C/min. N_2 was used as the carrier gas at a split ratio of 30:1. Peaks were identified by comparison with a known standard mixture. Reproducibility for duplicate analysis was ~10–20%. Coefficients of variation were 2% for DHA and 4% for EPA. The fatty acids were expressed as a percentage of the total fatty acids measured (C_{14}–C_{22}).

Assessment of Cardiovascular Factors

Blood pressure readings were taken using a Dinamap ProCare 100 automatic oscillometric blood pressure recorder (GE Healthcare Technologies, Rydalmere, Australia) while subjects were seated after a 5-min rest. Over a 10-min period, six blood pressure measurements were taken. The first was disregarded and blood pressure was calculated as the mean of the next five measurements. Trained phlebotomists visited the adolescents at their homes and obtained fasting blood samples prior to breakfast. The biochemistry assays for the study were conducted by PathWest Laboratories at Royal Perth Hospital. Serum triglycerides were measured using the Cobas MIRA analyser (Roche Diagnostics, Basel, Switzerland). Glucose was measured using an automated Technicon Axon Analyzer (Bayer Diagnostics, Sydney, Australia) and insulin was measured on an Immunlite 2000 Insulin Analyzer (Siemens Medical Solutions Diagnostic, LA, USA). Insulin resistance was determined using the homeostasis model assessment of insulin resistance (HOMA-IR), calculated as fasting plasma insulin (mU/L) × plasma glucose (mmol/L)/22.5 [15]. High density lipoprotein (HDL) cholesterol was determined on a heparin–manganese supernatant [16]. Cholesterol ratios were calculated for total/HDL, low density lipoprotein (LDL)/HDL and triglycerides/HDL [17, 18].

Dietary Intake

Dietary intake at this follow-up was assessed from three-day food records in household measures, as previously reported [19]. In brief, subjects were provided with a record booklet with instructions and a set of metric measuring cups and spoons. Food records were individually checked by a dietitian as they were returned in order to clarify any ambiguous or potential omissions [20]. The Australian Food and Nutrient database through the

FoodWorks dietary analysis program (Professional Version 5, 2007, Xyris Software, Brisbane) was used to analyse the food record data. Individual nutrients as well as overall diet was considered from the food diaries, with dietary patterns used to investigate overall diet. Using exploratory factor analysis, two major dietary patterns were identified: a 'healthy' pattern high in fresh fruit, vegetables, whole grains and grilled or canned fish, and a 'western' pattern high in takeaway foods, confectionery, soft drinks, crisps and fried potato [21]. Each adolescent received a *z*-score for both western and healthy dietary patterns. A positive score indicated a greater intake of foods representative of that pattern. To assess differences in the Omega-3 Index due to early infant feeding, information on breastfeeding cessation was obtained from the year 1, 2 and 3 Raine follow-up questionnaires. At the time of these follow-ups it was not mandatory for infant formulas to be enriched with long-chain omega-3 fatty acids in Australia.

Additional Factors

Anthropometry and Puberty

Adolescents were dressed in running shorts and singlet tops for anthropometric measurements. Height was measured to the nearest 0.1 cm with a Holtain Stadiometer, and body weight was measured to the nearest 100 g using a Wedderburn Digital Chair Scale. The body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared. The Tanner stages of pubic hair development [22, 23] was used to assess puberty; adolescents selected their corresponding developmental stage in a questionnaire completed privately. Adolescents were asked to choose from a set of standard drawings depicting the different Tanner stages from two (sparse) to five (adult) (stage one was omitted as this corresponds to pre-pubescent age younger than 10 years).

Sociodemographic and Family Characteristics

Family income, mother's age at conception and mother's education level were obtained by parent report. Maternal education was assessed by the highest school year completed. Current family income, defined as the annual income for the household before tax at the time of the follow-up, was determined as ($AUD): <$35,000 pa, $35,000–70,000 pa, or >$70,000 pa. Family history of cardiovascular disease was assessed as either yes or no, depending on whether a biological parent or sibling of the adolescent had been medically diagnosed with diabetes mellitus, hypertension, hypercholesterolemia, or other cardiac condition.

Fitness

The Physical Working Capacity 170 (PWC 170) test was applied to estimate aerobic fitness [24]. PWC170 was measured using a bicycle ergometer to determine the power output (watts) required at a heart rate of 170 beats per minute. This measure of fitness is highly correlated with self-reported physical activity level in the Raine cohort at the 14-year follow-up [25].

Statistical Analysis

Independent *t* tests or cross-tabs analysis were used to compare characteristics of Raine Study adolescents between Omega-3 Index risk categories, with low and intermediate categories combined due to the small number of subjects in the low category. Mann–Whitney tests were used to assess significance of dietary intakes of omega-3, the omega-6 to 3 ratio and EPA + DHA due to the skewed distribution of these variables. Associations between continuous variables and the Omega-3 Index were described with Pearson's or Spearman's correlations. Linear regression was used to examine associations between Omega-3 Index as a continuous independent variable and cardiovascular risk factors as dependent variables. General Linear Modelling was used to analyse associations with Omega-3 Index categories and cardiovascular risk factors. Log values were used for HOMA, triglycerides, and insulin due to their skewed distribution. To evaluate the relationship between the Omega-3 Index and cardiometabolic risk factors, parsimonious models were created which adjusted for age, sex, BMI, maternal education, total energy intake and family history of cardiovascular disease or diabetes, based on the relationship of the variables with the risk factors and the Omega-3 Index. Other variables considered for the model included puberty, aerobic fitness, physical activity, family income, single parent family, maternal age, but were excluded due to strong correlation between covariates or lack of association with risk factors and the Index. Subjects who were on cardiac or diabetes related medications ($n = 4$) or diagnosed with diabetes ($n = 9$) were excluded from analysis investigating cardiometabolic disease risk factors. The Statistical Package for Social Sciences for Windows, Rel.15.0.0. 2006 (Chicago: SPSS Inc) was used for analyses; statistical significance was set at $P \leq 0.05$.

Results

From the initial Raine Study cohort of 2,868 live births, 1,861 subjects completed at least one aspect of the 14-year

follow-up (mean age 14.0 ± 0.2 years, range 13.0–15.0 years), with the remainder lost to follow-up, withdrawn or temporarily deferred from the study ($n = 975$), or deceased ($n = 32$). RBC fatty acids were determined for 1,301 subjects. The mean ± SD Omega-3 Index was 4.90 ± 1.04% (range 1.41–8.42%). Relative to the published Omega-3 Index risk categories [5], 15.6% of adolescents were in the high risk category (<4%), 84.0% were in the intermediate risk category (4–8%) and 0.4% were in the low risk category (>8%). Omega-3 Index values in the population were normally distributed, while dietary intake of EPA and DHA was not (Fig. 1). Characteristics of this sample across high and low/intermediate Omega-3 Index risk categories are shown in Table 1.

When associations with subject characteristics were examined with the Omega-3 Index as a continuous variable, age at assessment ($r = 0.12$, $P < 0.01$) and maternal education ($r = 0.09$, $P < 0.01$) showed significant correlations with the Index. BMI showed borderline significance ($r = 0.05$, $P = 0.05$). The Omega-3 Index as a continuous variable showed significant positive associations with healthy eating pattern scores ($r = 0.14$, $P < 0.01$), energy adjusted dietary intakes of EPA + DHA ($r = 0.22$, $P < 0.01$), protein ($r = 0.12$, $P < 0.01$) and total omega-3 fats ($r = 0.08$, $P = 0.04$), and a significant negative association with western eating pattern scores ($r = -0.13$, $P < 0.01$) (data not shown). The significant association with EPA + DHA was also observed in comparison of Omega-3 Index risk categories ($P < 0.01$), along with a positive association with glycemic index ($P = 0.02$) (Table 1).

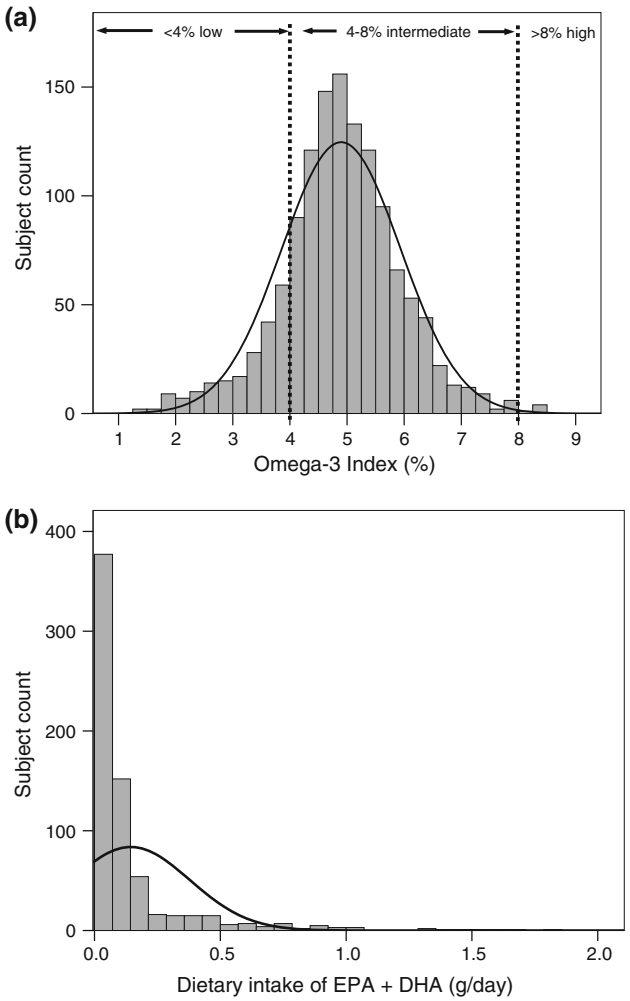

Fig. 1 **a** Histogram of Omega-3 Index in Raine Study adolescents ($n = 1{,}301$), showing Omega-3 Index risk categories (5), and **b** subjects who also reported dietary intake of EPA plus DHA from completed and followed-up 3-day food records ($n = 689$)

Several food group intakes were correlated with the Omega-3 Index (Fig. 2). Fish and seafood ($r = 0.18$, $P < 0.01$), wholegrain foods such as multigrain bread, brown rice and pasta ($r = 0.11$, $P < 0.01$) and vegetables ($r = 0.10$, $P < 0.01$) showed the strongest positive associations with the Omega-3 Index. Intakes of soft drinks ($r = -0.11$, $P < 0.01$) and crisps ($r = -0.10$, $P < 0.01$) were negatively correlated with the Omega-3 Index.

After adjustment for potential confounding factors in a linear regression model, the Omega-3 Index was positively associated with total cholesterol ($\beta = 0.064$, $P = 0.01$) and HDL-cholesterol ($\beta = 0.029$, $P = 0.01$) in boys and girls (Table 2). There were no significant associations with other cardiovascular or metabolic risk factors. When analysed according to gender, significant associations were observed with boys for total cholesterol ($\beta = 0.074$, $P = 0.03$), HDL-cholesterol ($\beta = 0.036$, $P = 0.01$) and diastolic blood pressure ($\beta = -0.684$, $P = 0.04$); insulin ($\beta = -0.019$, $P = 0.05$) and HOMA-IR ($\beta = -0.019$, $P = 0.07$) showed borderline significance. No significant associations were observed with girls. Associations with risk factors were also examined according to Omega-3 Index risk categories [5]. General linear modelling suggested boys and girls in the low/intermediate risk category were more likely to have lower HDL-cholesterol levels, with borderline significance ($\beta = -0.057$, $P = 0.07$); no other risk factors were significant when boys and girls were analysed together or separately (data not shown).

Discussion

Due to variation in the methods used for red blood cell analysis in different laboratories, direct comparison of results is not possible. However, we found that the mean Omega-3 Index in the Raine Study adolescents (4.9 ± 1.0%) was consistent with the value of 4.7 ± 0.4% previously reported in a smaller control sample of healthy Australian children and adolescents aged 9–18 years [26]. Our value is also similar in value to that reported in US

Table 1 Characteristics and energy adjusted dietary intakes of Raine Study adolescents in high risk ($n = 203$) compared with low/medium risk ($n = 1{,}098$) Omega-3 Index risk categories [5]

Characteristic	Omega-3 Index Category		P*
	High risk (<4%)	Low/intermediate risk (≥4%)

Models adjusted for age, sex (where applicable), BMI, maternal education, daily energy intake, and family history of cardiovascular disease or diabetes

Dietary fish intake was the strongest food group predictor of the Omega-3 Index in the Raine adolescents ($P < 0.01$), and has previously been shown to be a determinant of the Index in older US adults [3]. Fish is a good source of dietary EPA and DHA, and this finding is consistent with trials showing increased dietary EPA and DHA leads to higher concentrations of RBC omega-3 fatty acids [4, 31]. Further, our results showed daily intake of EPA + DHA positively correlated with the Omega-3 Index ($P < 0.01$). Fish is also a good source of protein, along with legumes, nuts and eggs which may have contributed to the positive association observed with protein and Omega-3 Index. The wholegrain food group showed the next strongest positive association with the Omega-3

Index ($P < 0.01$). Wholegrains contain omega-3 fats in the form of alpha-linolenic acid (18:3n-3) in the bran outer layer of the grain. Interestingly, refined grain products that are missing the bran layer were also observed to have a significant positive association with the Omega-3 Index ($P < 0.05$). This may be partially due to the consumption of DHA enriched white bread observed in the Raine Study cohort at this follow up [19]. However, given the additional positive associations with vegetables and fruit, it is more likely that these associations with the Omega-3 Index are related to an overall 'healthy' pattern of eating. Similarly, a high intake of soft drinks and crisps, along with a high dietary glycemic index, may reflect a less 'healthy' eating pattern. This is reflected in the associations observed with the dietary pattern scores identified in this cohort: the Index showed a positive association with the healthy pattern score and a negative association with the western pattern score. Food groups loading on the healthy pattern included fresh fruit, vegetables, wholegrains and grilled or canned fish, while the 'western' pattern score represented a higher intake of takeaway foods, crisps and soft drinks [21]. Although soft drinks do not contain fat, their consumption has been shown to result in a rapid increase in glucose and insulin concentrations in adolescents [32], and the fructose component of sucrose in soft drinks may lead to enhanced fatty acid synthesis, contributing to higher circulating triglycerides [33]. Higher GI diets, as observed in subjects in the high risk Omega-3 Index category, may also contribute to higher plasma triglycerides [34]. Together, these dietary factors may play a role in alteration of the fatty acid content of RBC membranes.

Results of our study also extend the findings of previous research in adults [3, 31] by confirming that higher dietary intake of EPA and DHA through consumption of fish is associated with a higher Omega-3 Index in adolescents. However, the difference in distributions of dietary EPA and DHA compared to Omega-3 Index values (as shown in Fig. 1) highlight the contribution that non-dietary factors may also make in determination of the Omega-3 Index.

The Omega-3 Index has been proposed to predict coronary heart disease mortality in adults [5]. Our data show it is also associated with total and HDL-cholesterol concentrations and diastolic blood pressure in boys in our adolescent cohort. The positive relationship between increasing Omega-3 Index and higher HDL-cholesterol supports Australia's National Heart Foundation's position statement that marine omega-3 PUFA supplementation increases HDL-cholesterol levels [35]. This result is also consistent with previous research in adult populations [36]. In contrast, the Omega-3 Index was not significantly associated with HDL-cholesterol or other cardiovascular risk factors in a study of overweight and obese European adults [29], although borderline significance was observed with lower LDL. The findings, however, may have been influenced by weight status, as our results suggest that the BMI is positively associated with the Omega-3 Index ($P = 0.05$). Consistent with previous research showing a positive association between age and the Index [3], the adults in the European study had a noticeably higher Omega-3 Index than we observed in our adolescent population ($7.0 \pm 1.9\%$ vs. $4.9 \pm 1.0\%$), which may have affected associations with disease risk. Although high total cholesterol is commonly considered a risk factor for cardiovascular disease, high HDL-cholesterol is beneficial [37], and the two measures are related as HDL-cholesterol contributes to total cholesterol. Ratios may therefore be considered more useful as indicators of cardiovascular disease risk [17], however we found no significant associations between the Index and ratios of total/HDL-cholesterol, LDL/HDL-cholesterol or triglycerides/HDL-cholesterol.

The significant negative association observed with diastolic blood pressure in boys in our cohort supports a role for omega-3 fatty acids in optimisation of blood pressure. Omega-3 fatty acids have been shown to have a variety of actions that can lead to improved vasodilation and arterial compliance, including increased membrane fluidity, suppression of vasoconstrictors, and changes in mobilisation of intracellular calcium [9, 38, 39].

In our adolescent cohort, we observed a gender difference in the relationship between Omega-3 Index and risk factors for cardiovascular and metabolic disease. Analysis with boys showed significant or borderline associations with measures of cholesterol, blood pressure, and insulin resistance, whereas no significant associations were observed for measures in the girls analysis. Boys were more likely to be in the high risk category of Omega-3 Index (<4%) compared to the low risk (≥4%, $P = 0.10$), and similar gender differences have previously been identified in the long-chain omega-3 fatty acid composition of RBC membranes in rats, with a link between ovarian hormones and DHA composition proposed [40]. Sex hormones may play a role in modification of the omega-3 content of tissues, possibly by altering expression of enzymes in the liver [41], while also contributing to gender specific pathophysiological differences in cardiovascular and metabolic disease [42].

To our knowledge, this is the first study to evaluate the Omega-3 Index with cardiovascular and metabolic risk factors in a large cohort of adolescents. Interpretation of our study results is limited by the cross-sectional study design, however an important strength of our study is that it represents a large, population based cohort and has data on a wide range of cardiometabolic, socioeconomic and dietary variables. Our results demonstrate a significant and independent association between the Omega-3 Index and

total and HDL-cholesterol, as well as blood pressure, in Australian adolescent boys. Although the Omega-3 Index did not demonstrate a statistically significant association with the cholesterol ratios, it is considered to be a risk factor in its own right and has not been shown to mediate through effects on traditional risk factors. Therefore the Index may still be useful in the prediction of cardiovascular disease later in life, and our results support further long term investigation of this concept.

Acknowledgments We would like to express our gratitude to all the Raine Study participants and their families, and the Raine Study Team for cohort co-ordination and data collection. We thank Royal Perth Hospital laboratories for conducting biochemistry assays and Mr. Peter Jacoby for statistical assistance. We acknowledge the NH&MRC for their long term contribution to funding the study over the last 20 years, and the University of Western Australia (UWA), Raine Medical Research Foundation, UWA Faculty of Medicine, Dentistry and Health Sciences, The Telethon Institute for Child Health Research and the Women and Infants Research Foundation for providing funding for Core Management of the Raine Study. We also acknowledge support from the Telstra Research Foundation, the Western Australian Health Promotion Foundation, the Australian Rotary Health Research Fund and the National Heart Foundation of Australia and Beyond Blue. Biological specimens were funded by NH&MRC (Beilin et al., ID 403981) and RBC fatty acid analysis was funded from the NH&MRC Program Grant (Stanley et al., ID 003209).

Conflict of interest The authors have no conflict of interests to disclose.

Received: 12 February 2010 / Accepted: 28 September 2010 / Published online: 29 October 2010

Abstract Hepoxilins are epoxy alcohols synthesized through the 12-lipoxygenase (12-LO) pathway in animal cells. The epidermis is the principal source of hepoxilins in humans. Here we report on the formation of novel hepoxilin regioisomers formed by the 15-LO pathway in human cells. The Hodgkin lymphoma cell line L1236 possesses high 15-lipoxygenase-1 (15-LO-1) activity and incubation of L1236 cells with arachidonic acid led to the formation of 11(*S*)-hydroxy-14(*S*),15(*S*)-epoxy 5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3 11(*S*)) and 13(*R*)-hydroxy-14(*S*),15(*S*)-epoxy 5(*Z*),8(*Z*),11(*Z*) eicosatrienoic acid (14,15-HxB_3 13(*R*)). In addition, two hitherto unidentified products were detected and these products were collected and analyzed by positive ion electrospray tandem mass spectrometry. These metabolites were identified as 11(*S*),15(*S*)-dihydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid (14,15-HxA_3-C) and 11(*S*),15(*S*)-dihydroxy-14(*R*)-cysteinyl-glycyl-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid (14,15-HxA_3-D). Incubation of L1236 cells with synthetic 14,15-HxA_3 11(*S*) also led to the formation of 14,15-HxA_3-C and 14,15-HxA_3-D. Several soluble glutathione transferases, in particular GST M1-1 and GST P1-1, were found to catalyze the conversion of 14,15-HxA_3 to 14,15-HxA_3-C. L1236 cells produced approximately twice as much eoxins as cysteinyl-containing hepoxilins upon stimulation with arachidonic acid. Human eosinophils, nasal polyps and dendritic cells selectively formed 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*) stereoisomers, but not cysteinyl-containing hepoxilins, after stimulation with arachidonic acid. Furthermore, purified recombinant 15-LO-1 alone catalyzed the conversion of arachidonic acid to 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*), showing that human 15-LO-1 possesses intrinsic 14,15-hepoxilin synthase activity.

Introduction

Hepoxilins (Hx) are a family of hydroxy epoxides which are formed by rearrangement of 12(*S*)-HPETE [1]. Murine 12/15-lipoxygenase (LO) (earlier called leukocyte-type 12-LO), the ortholog to human 15-LO-1, can catalyze the metabolism of arachidonic acid via 12(*S*)-HPETE to 8(*R*/*S*)-hydroxy-11(*S*),12(*S*)-epoxy-5(*Z*),9(*E*),14(*Z*)-eicosatrienoic acid and 10(*R*/*S*)-hydroxy-11(*R*),12(*R*)-epoxy-5(*Z*),8(*Z*),14(*Z*)-eicosatrienoic acid, termed HxA_3 and HxB_3, respectively [2, 3]. Hydrolysis of these metabolites leads to the formation of trihydroxy-8,11,12-eicosatrienoic acid (trioxilin A_3, $TrxA_3$) and trihydroxy-10,11,12-eicosatrienoic acid ($TrxB_3$), respectively [4]. HxA_3 can also be converted into a glutathione conjugate, named HxA_3-C [5]. The enzyme γ-glutamyl transpeptidase catalyzes the conversion of HxA_3-C into HxA_3-D [6]. In contrast to murine 12/15-LO, human platelets which exhibit high 12(*S*)-LO activity can not convert arachidonic acid to HxA_3, probably due to low peroxide tonus in the cell [7]. However, 12(*R*)-LO and epidermal lipoxygenase-3 (eLOX3) are expressed in human skin and these enzymes are involved in the formation of the stereospecific HxA_3 8(*R*) in human epidermis [8–10].

The hepoxilins exert a variety of biological actions in different type of cells, likely mediated via changes in intercellular concentrations of calcium and potassium and alterations in the secondary messenger systems [2]. Several lines of evidence indicate that hepoxilins might play a role in the water-impermeable barrier of the outer epidermis [1, 11]. Genetic studies of inherited ichthyosis have demonstrated that mutations of 12(*R*)-LO and/or eLOX3 is connected to autosomal recessive congenital ichthyosis in man [12, 13]. Animal studies have also shown that 12(*R*)-LO deficiency leads to an ichthyosis form phenotype [14]. The formation of 12(*R*)-HETE and hepoxilins is increased in affected psoriatic skin [9, 15]. HxA_3 and HxB_3 have been reported to stimulate insulin secretion from rat langerhans islets [16] and calcium release [2]. HXA_3 has also been found to cause vascular contraction [17] and increased vascular permeability in rat [18]. In human neutrophils, the biological actions of HxA_3 are indicated to be receptor mediated [19], and this metabolite has been found to stimulate human neutrophils to migrate across intestinal epithelia [20]. HxA_3-C has been reported to induce vascular contraction in guinea pig isolated trachea [21] and increase vascular permeability in rat skin [18].

Human 15-lipoxygenase type 1 (15-LO-1) is mainly expressed in human airway epithelial cells, macrophages, reticulocytes, eosinophils and mast cells [22–26]. The amount and activity of 15-LO-1 is increased in the bronchial tissue of patients with asthma or chronic bronchitis compared to healthy subjects [26–29]. Eoxins (EX, also called 14,15-leukotrienes) are recently identified endogenous metabolites of arachidonic acid, formed through the 15-LO-1 pathway in human eosinophils, mast cells and nasal polyps [30]. 15-LO-1 catalyzes the conversion of arachidonic acid to EXA_4 which can be further metabolized to EXC_4, after conjugation with glutathione. EXC_4 and its metabolites EXD_4 and EXE_4 induce increased permeability of vascular endothelial cell monolayer in vitro, indicating that eoxins are pro-inflammatory mediators [31]. The Hodgkin cell line Ll236 possesses high 15-LO-1 activity and we have recently reported that these cells have a high capacity to produce EXC_4, EXD_4 and EXE_4 [31].

14,15-Hepoxilins of both A and B type are formed from arachidonic acid via the 15-lipoxygenase pathway in garlic root [32]. Human airway epithelial cells have been found to produce 14,15-HxB_3 [33]. Since most studies, however, have been focused on the formation of hepoxilins catalyzed by the animal enzyme 12/15-LO which possesses mainly 12-lipoxygenase activity, we thought it was of interest to reinvestigate which type of hepoxilins could be produced by human cells which express the ortholog 15-LO-1. In contrast to the animal 12/15-LO, the human enzyme possesses mainly 15-lipoxygenase activity. For that purpose, we used L1236 cells as a model system since this cell line possesses high 15-LO-1 activity [31]. Furthermore, we also investigated whether the corresponding metabolites were formed in human eosinophils, nasal polyps and dendritic cells.

Experimental Procedure

Materials

The [1-^{14}C] arachidonic acid (56.0 mCi/mmol) was obtained from Amersham Biosciences (Uppsala, Sweden) and unlabeled arachidonic acid was from Nu-Chek prep (Elysian, USA). Synthetic 14(*S*),15(*S*)-epoxy-5(*Z*),8(*Z*),10(*Z*),12(*E*)-eicosatetraenoic acid (EXA_4), 14(*R*)-glutathionyl-15(*S*)-hydroxy-5(*Z*),8(*Z*),10(*Z*),12(*E*)-eicosatetraenoic acid (EXC_4) and 14(*R*)-cysteinyl-glycyl-15(*S*)-hydroxy-5(*Z*),8(*Z*),10(*Z*),12(*E*)-eicosatetraenoic acid (EXD_4) were purchased from BIOMOL (Plymouth Meeting, USA). [1-^{14}C] 15(*S*)-hydroperoxy-5(*Z*),8(*Z*),11(*Z*),13(*E*)-eicosatetraenoic (15(*S*)-HPETE), 11(*S*)/(*R*)-hydroxy-14(*S*),15(*S*)-epoxy-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid (14,15-HxA_3), 11(*S*),15(*S*)-hydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-C), 13(*S*)/(*R*)-hydroxy-14(*S*),15(*S*)-epoxy-5(*Z*),8(*Z*),11(*Z*)-eicosatrienoic acid (14,15-HxB_3) was synthesized as described in the Supplement. 11(*S*)-hydroxy-14(*R*)-cys-gly-15(*S*)-hydroxy-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-D) was made in house from 14,15-HxA3-C with γ-glutamyl transpeptidase (Sigma, Sweden). All solvents used were of HPLC grade.

Cell Experiment

The Hodgkin cell line L1236 (50–60 × 10^6 cells/sample) was suspended in PBS and pre-warmed for 2 min at 37 °C prior to addition of arachidonic acid (final concentration 30 μM) and labelled arachidonic acid (final concentration 9 μM). Incubation was stopped after 2 and 10 min, respectively, with the addition of one volume of cold methanol. L1236 cells were incubated, under similar experimental conditions, with EXA_4, 14,15-HxA_3 and 14,15-HxB_3, respectively. EXA_4 (37 μM) and 14,15-HxA_3 (42 μM) and 14,15-HxB_3 (48 μM) were incubated for 5, 10 and 10 min, respectively. Sonicated L1236 cells were incubated with [1-^{14}C]-15-HPETE (20 μM, 5 min). The sonicated cell suspensions were supplemented with glutathione (final concentration of 5 mM) and a protease inhibitor (Complete mini, Roche Diagnostics GmbH, Germany). Dendritic cells, eosinophils and nasal polyps (chopped up) were isolated as described [30, 34] and these cells/tissues were incubated in the same manner as described for the L1236 cells, with the addition of indomethacin (1 μM) to inhibit cyclooxygenase activity. This study was approved by the local ethic committee of the Karolinska University Hospital.

Enzyme Incubations

Human GST M1-1, M2-2, M3-3, M4-4, M5-5, P1-1(Ile105), P1-1(val105), T1-1, A1-1, A2-2, A3-3 and A4-4 are soluble recombinant glutathione transferases prepared by heterologous expression as previously described [35]. Two allelic forms of GST P1-1 were used [36]. Expression constructs (Bac-to-Bac Baculovirus expression system, Gibco/Life Technologies) for LTC_4 synthase was a kind gift from Dr. Jakobsson (Karolinska Biomic Center, Karolinska University Hospital and Karolinska Institutet, Sweden). The LTC_4 synthase membrane fraction was isolated as described [37]. Enzymatic conjugation of glutathione with 14,15-HxA_3 was studied as follows. Glutathione transferases (4 μg) in PBS (50 μL) were pre-warmed for 2 min at 37 °C followed by addition of 14,15-HxA_3 (228 μM) and glutathione (5 mM final concentration). Subsequently, the cells were incubated for 10 min and the incubation was terminated by addition of one volume acetonitrile/methanol/acetic acid (50:50:1, by vol).

Similar experimental conditions were used when recombinant 15-LO-1 (5 μg) was incubated with arachidonic acid (30 μM) and [1-^{14}C]-arachidonic acid (9 μM) combined. The incubation was stopped after 15 min by addition of one volume cold methanol.

HPLC-Analysis with UV and Radioactivity Detection

Cells and cell debris were removed by centrifugation (1,400×g, 6 min). The supernatant was diluted with water and then transferred to a washed and equilibrated extraction cartridge, Oasis HLB 1 cc 10 mg (Waters, Sweden). The extracted metabolites were washed with water and eluted with 200 μL methanol. Reverse-phase HPLC was performed on a Waters Alliance 2690 with a Nova Pak C18 column (2.1 × 150 mm, Waters AB, Sweden). The initial mobile phase was 100% A (0.01% acetic acid adjusted to pH 5.6 with ammonia) at a flow rate at 0.4 mL/min A linear gradient was started after 5 min, reaching 36% B (60:40 acetonitrile/methanol, by vol) at 20 min The mobile phase was isocratic at A/B (64:36, by vol) for 100 min. Column effluent was monitored using diode array detection (PDA 996, Waters AB, Sweden) and radioactivity monitoring (β-RAM, INUS-systems, USA). UV spectra were acquired between 200 and 340 nm. The eluting metabolites were collected with a fraction collector (FC II, Waters AB, Sweden) and further analyzed by mass spectrometry. The collected fractions were dried under N_2 and subsequently dissolved in methanol/water (1:1, by vol).

Nanospray Mass Spectrometry Analysis

Mass spectrometry was performed on a Quattro Ultima triple quadrupole mass spectrometer (Micromass, Manchester, UK) operating in positive ion mode for glutathione-containing metabolites and in negative ion mode for the other hepoxilins with a capillary voltage at 2.2 and 1.8 kV, respectively. MS/MS spectra were obtained using collision energy of 20 eV using argon as the collision gas.

Synthesis of Reference Substances

Four epoxy alcohols were prepared from 15(*S*)-hydroperoxy-5(*Z*),8(*Z*),11(*Z*),13(*E*)-eicosatetraenoic acid (15(*S*)-HPETE) by slight modification of a method previously described for synthesis of *erythro* and *threo* epoxy alcohols having trans epoxide stereochemistry [38], i.e. methyl 14(*S*),15(*S*)-epoxy-13(*S*)-hydroxy-5(*Z*),8(*Z*),11(*Z*)-eicosatrienoate and methyl 14(*S*),15(*S*)-epoxy-13(*R*)-hydroxy-5(*Z*),8(*Z*),11(*Z*)-eicosatrienoate. In addition to these major compounds, smaller quantities of the corresponding allylic epoxy alcohols, methyl 14(*S*),15(*S*)-epoxy-11(*S*)-hydroxy-5(*Z*),8(*Z*),12(*E*)-eicosatrienoate and methyl 14(*S*),15(*S*)-epoxy-11(*R*)-hydroxy-5(*Z*),8(*Z*),12(*E*)-eicosatrienoate, were also obtained. All four methyl esters were saponificated with lithium hydroxide to form the carboxylic acid. Glutathione conjugates, 11(*S*),15(*S*)-dihydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid and 11(*R*),15(*S*)-dihydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid, were prepared by reacting glutathione thiolate with 14(*S*),15(*S*)-epoxy-11(*S*)-hydroxy-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid and 14(*S*),15(*S*)-epoxy-11(*R*)-hydroxy-5(*Z*),8(*Z*),12(*E*)-eicosatrienoic acid, respectively. For further information see supplementary information.

Quantification of 14,15-HxA_3-C and EXC_4 by LC–MS/MS

Quantification was performed on a Surveyor MS pump coupled to a TSQ Quantum Ultra triple quadrupole mass spectrometer (Thermo Scientific, Sweden). Reverse phase LC was performed using a Zorbax Eclipse Plus 3.5 μM C18 column 2.1 × 50 mm (ChromTech, Sweden) with the flow rate constantly held at 400 μL/min. Mobile phase A consisted of 2% acetonitrile in water and 0.1% acetic acid, and mobile phase B consisted of 80% acetonitrile in water and 0.1% acetic acid. Isocratic elution at 90% A for 1.5 min was followed by a 6.5 min linear gradient reaching 100% of B. The system was washed at 100% B for 4 min and subsequently equilibrated at 90% A for 4 min. The mass spectrometer was operated using an electrospray atmospheric pressure ionization source in positive mode. The spray voltage was set to 4,500 V, capillary temperature was 375 °C and sheath and auxiliary gas were optimal at 40 and 5, respectively (arbitrary units). Skimmer offset was at 10 V and tube lens 121 V. To quantify formed 14,15-HxA_3-C and EXC_4 multiple reaction monitoring, MRM, was utilized. The transitions utilized were 644.3 *m/z* to 526.0 and 479.2 *m/z* and 626.2 *m/z* to 301.0 and 205.0 *m/z* at collision energies between of 17 and 22 eV.

Standard calibration curve at ten levels was prepared in PBS (1 mL) and in the following interval; 2.5–1,000 nM for 14,15-HxA_3-C and 1–800 nM for EXC_4. Warfarin (Sigma, Sweden) was used as internal standard at 16 nM and one qualitative control in triplicate of 14,15-HxA_3-C and EXC_4 at 50 and 40 nM, respectively. The standard samples were extracted with the same solid phase method as the L1236 cell incubation samples. The following transitions was used for warfarin detection: 309.0 *m/z* to 251.2 and 163.1 *m/z* at a collision energy of 19 and 17 eV, respectively. One standard series was analyzed in the beginning and one at the end of the analysis list.

Results

Metabolism of Arachidonic Acid in L1236 Cells

The Hodgkin cell line L1236 has been found to produce eoxins and a series of 8,15-DiHETE metabolites after incubation with arachidonic acid [31]. In this study we detected other major unidentified metabolites in the radioactivity chromatogram after incubation of L1236 cells with ^{14}C-arachidonic acid (Fig. 1). These compounds were called metabolites I and II. Metabolites I and II did not have a UV-absorbance maximum above 200 nm, hence they did not contain any conjugated double bonds. Therefore, there were no corresponding metabolites detected in the UV chromatogram at 280 nm (Fig. 1). Maximal

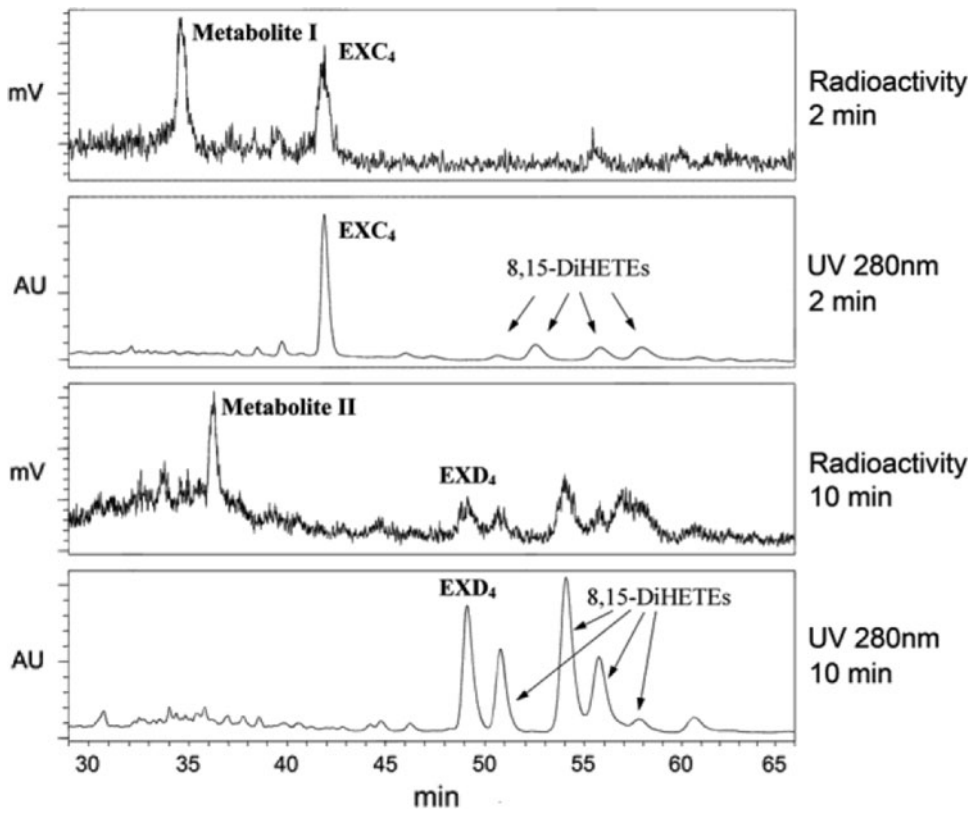

Fig. 1 L1236 cells incubated with arachidonic acid. Radioactivity and UV (280 nm) chromatograms of the products formed by L1236 after incubation with ^{14}C-labelled arachidonic acid (40 μM) for 2 and 10 min, respectively. The retention times of metabolites I and II, EXC_4, EXD_4 and 8, 15-DiHETEs are all indicated in the chromatograms. Metabolite I and EXC_4 dominated after 2 min of incubation and metabolite II and EXD_4 after 10 min. EXC_4 and EXD_4 were visible in the both UV and radioactivity chromatogram. Metabolites I and II were not detectable in the UV chromatogram at 280 nm

amounts of metabolites I and II were detected after 2 and 10 min of incubation, respectively. A similar time-course was observed for the formation of EXC_4 and EXD_4.

Incubation of L1236 cells with either arachidonic acid or 15(*S*)-HPETE, but not with EXA_4, led to the formation of metabolites I and II (data not shown). This indicates that the metabolites I and II are formed through the 15-LO-1 pathway but that these metabolites are not eoxins. Analyzing the two metabolites by mass spectrometry revealed that both metabolites I and II had a molecular weight of plus 18 (equivalent to H_2O) in comparison to EXC_4 and EXD_4, respectively. Together, these results suggest that the metabolites contain an additional hydroxyl group, in comparison to the eoxins, and contain three non-conjugated double bonds. Positive ion MS/MS spectrum of metabolite I showed a fragment ion with *m*/*z* 308 (Fig. 2), this may arise by cleavage of the carbon–sulfur bond with the charge retention on the peptide part as described for LTC_4 [39]. Analysis of the MS/MS spectra of metabolite II and EXD_4 demonstrated that both metabolites contain a fragment ion at *m*/*z* 179 (Fig. 3), representing the cysteinyl-glycine complex. These fragment ions make it clear that the material in metabolite I contains a conjugated glutathione metabolite and that the material in metabolite I is converted to metabolite II by the removal of glutamate, analogous to the conversion of EXC_4 to EXD_4. Since most fragments present in the MS/MS spectra for metabolite I and II are derived from the peptide and few from the lipid-containing part (as for EXC_4 and EXD_4 fragmentation), the position of the extra hydroxyl group in comparison to eoxins was not obvious.

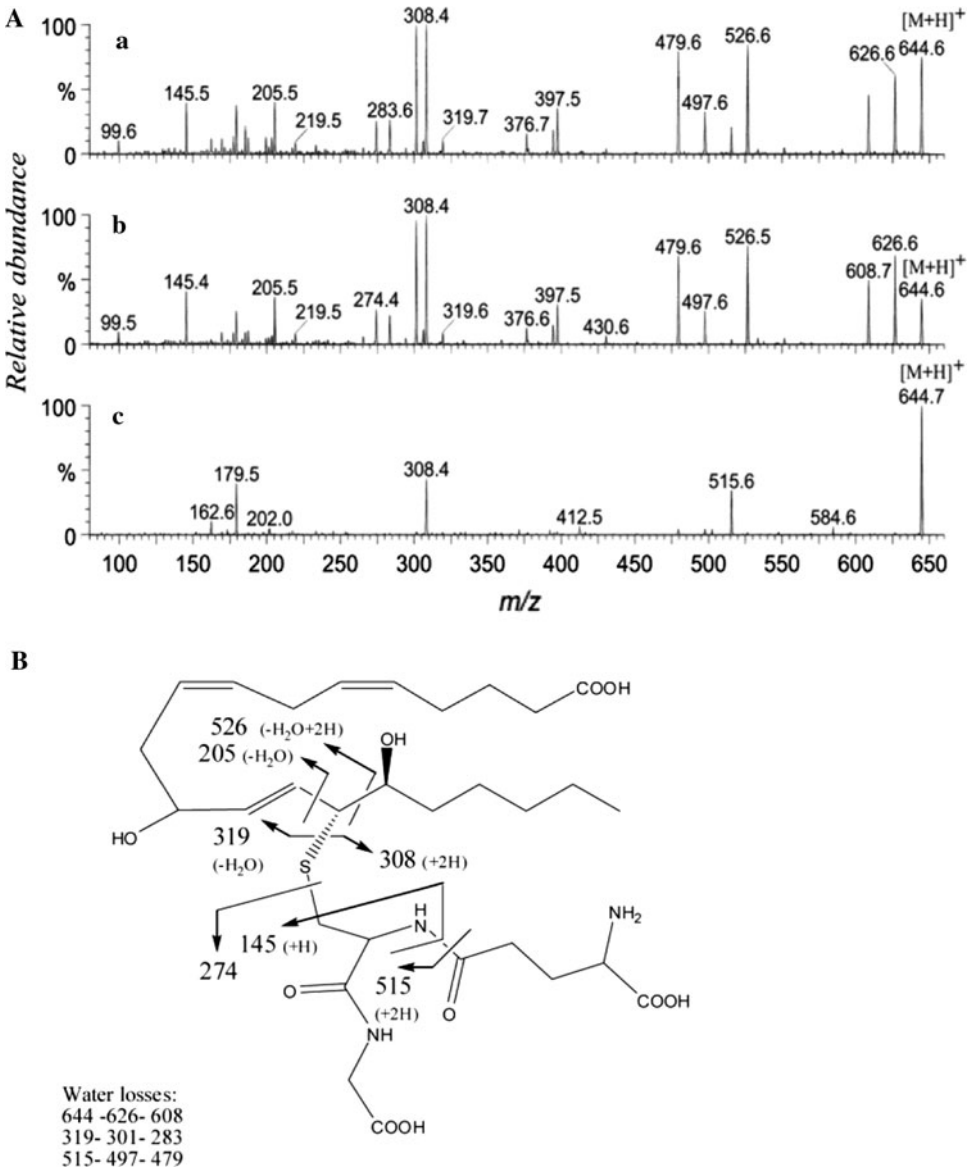

Fig. 2 **a** MS/MS spectra of metabolite I. Positive ion MS/MS spectra of $[M + H]^+$ at 644 *m*/*z* was recorded on a triple quadrupole mass spectrometer. MS/MS of (*A*) metabolite I formed by the L1236 cells compared to (*B*) synthetic 14,15-HxA_3-C and (*C*) synthetic 14,15-HxB_3-C. MS/MS spectra of 14,15-HxA_3-C and metabolite I were identical and show characteristic water losses. **b** Structure of the14,15-HxA_3-C with possible fragment ions present in the positive ion MS/MS spectrum indicated

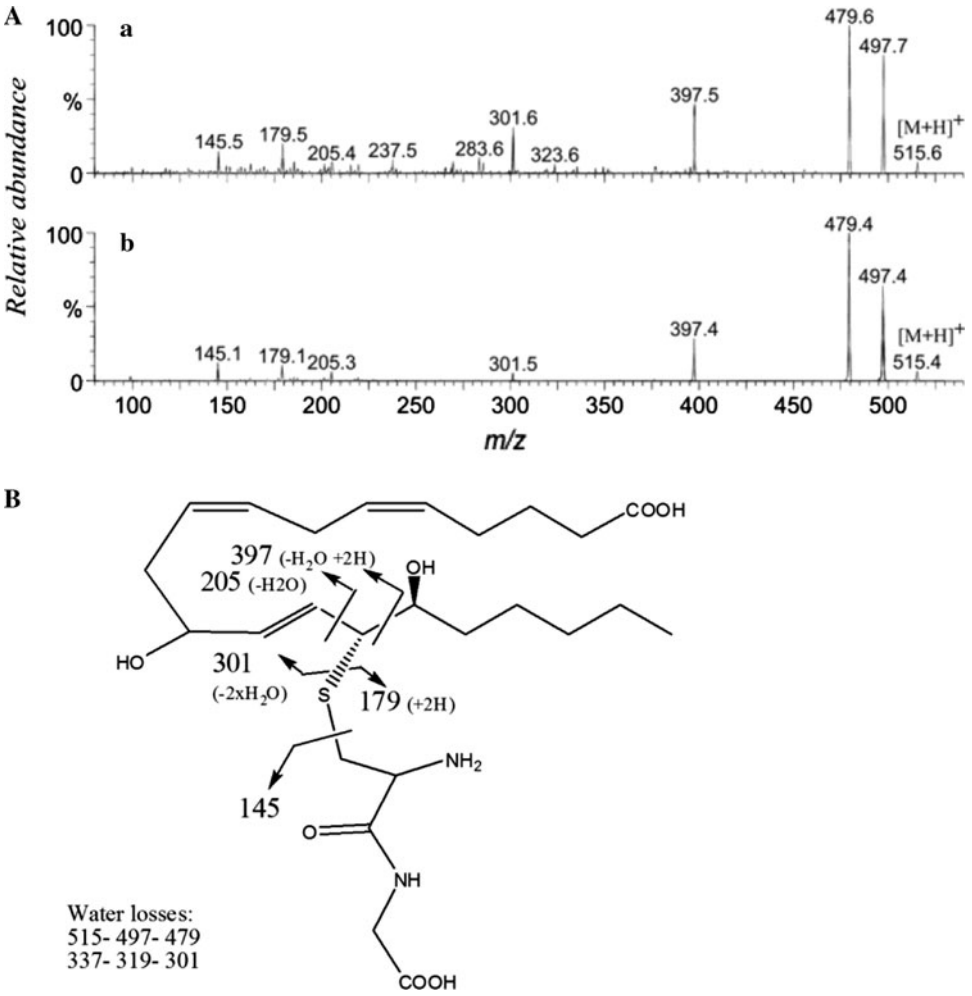

Fig. 3 **a** MS/MS spectra of metabolite II. Positive ion MS/MS spectra of $[M + H]^+$ at 515 *m/z* were recorded on a triple quadrupole mass spectrometer. MS/MS spectrum of (*A*) metabolite II formed by L1236 cells compared to (*B*) synthetic 14,15-HxA_3-D. **b** Structure of 14,15-HxA_3-D with possible fragment ions present in the positive ion MS/MS spectrum indicated

Chemical Structure of Metabolite I

13(*R*/*S*)-Hydroxy-14,15-epoxyeicosatrienoic acid also known as 14,15-Hepoxilin B_3 (14,15-HxB_3) is a previously characterized metabolite produced through the 15-LO-1 pathway in human airway epithelial cells [33]. A candidate structure for metabolite I was therefore 14,15-HxB_3 conjugated with a glutathione (14,15-HxB_3-C). Synthetic 14,15-HxB_3 with the hydroxyl group at position 13 in either *S* or *R* configuration was prepared. These compounds were incubated with L1236 cells leading to formation of 14,15-HxB_3-C. This metabolite, with the hydroxyl group in the 13(*R*) configuration, co-eluted with metabolite I but the MS/MS spectrum was not identical to the spectrum of metabolite I. Many fragments present in the MS/MS spectrum for metabolite I were not present in the 14,15-HxB_3-C spectrum such as losses of water from the protonated molecule (Fig. 2), showing that metabolite I was not identical to 14,15-HxB_3-C.

11(*R*/*S*)-Hydroxy-14,15-epoxyeicosatrienoic acid also known as 14,15-Hepoxilin A_3 (14,15-HxA_3) is also formed through the 15-LO-1 pathway, produced in garlic root [32]. 14,15-HxA_3 is more unstable than 14,15-HxB_3, and therefore more difficult to isolate since it is sensitive to acid and is easily degraded non-enzymatically to trihydroxy acids. Both enantiomers of 14,15-HxA_3 were synthesized containing the hydroxyl group at carbon 11 in either *S* or *R* configuration. These were then incubated with L1236. 14,15-HxA_3 with the hydroxyl group at position 11 in *S* configuration and a conjugated glutathione, 14,15-HxA_3-C 11(*S*), co-eluted and exhibited an essentially identical spectrum as metabolite I (Fig. 2). In contrast, 14,15-HxA_3-C with the hydroxyl group at position 11 in R configuration eluted faster than metabolite I. The structure of 14,15-HxA_3-C explains the facile losses of water evident in the MS/MS spectrum since removal of water produces a favourable conjugated double bond structure of a triene or a tetraene (Fig. 2).

14,15-HxA_3 is a *trans* epoxide in *S* configuration and the glutathione is probably conjugated in *R* orientation forming 11(*S*),15(*S*)-hydroxy-14(*R*)-glutathione-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-C 11(*S*)) (**1**). This synthetic product co-eluted and had the same MS/MS spectrum as metabolite I produced endogenously in the cell line. In

comparison, the synthetic 11(*R*),15(*S*)-dihydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-C 11(*R*)) did not co-elute with metabolite I. Incubation of 14,15-HxA_3 11(*S*) with purified enzyme GSTM1-1, a soluble glutathione transferase expressed in the L1236 cells (Feltenmark et al., to be published), also resulted in a identical MS/MS spectrum as for metabolite I.

Chemical Structure of Metabolite II

Metabolite II appeared to be formed by removal of glutamate from metabolite I. Therefore the identity of metabolite II was probably 11(*S*),15(*S*)-dihydroxy-14(*R*)-cysteinyl-glycine-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-D) (**2**). The product formed after incubation of synthetic 14,15-HxA_3-C 11(*S*) with L1236 cells or γ-glutamyl transpeptidase had the same retention time on HPLC and similar MS/MS spectra as metabolite II (Fig. 3), demonstrating that the structure of the material in metabolite II was 14,15-HxA_3-D 11(*S*).

Comparison of the Amounts of 14,15-HxA_3-C and EXC_4 Formed by L1236 Cells

The amount 14,15-HxA_3-C and EXC_4 formed in arachidonic acid (40 μM) incubations with different L1236 cell densities (1, 5, 10, 20 and 50 million cells/mL) was quantified by LC–MS/MS. The amounts of 14,15-HxA_3-C and EXC_4 produced per million cell were similar at different cell densities but with a tendency to decreased ratio EXC_4 versus 14,15-HxA_3-C by increased cell density (Fig. 4). The L1236 cells produced 15.4 ± 8.5 pmol 14,15-HxA_3-C/million cell and 30.2 ± 8.2 pmol EXC_4/million cell ($n = 4$) at a cell density of 10 million cells/mL.

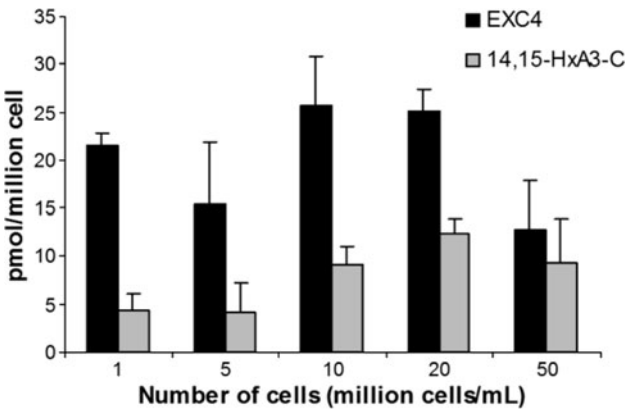

Fig. 4 Comparison of 14,15-HxA_3-C and EXC_4 formed from arachidonic acid by the L1236 cells. L1236 cells were incubated with arachidonic acid (40 μM) for 2 min at 37 °C at different cell densities i.e. 1, 5, 10, 20 and 50 million cells/mL. Quantification was performed by LC–MS/MS multiple reaction monitoring on a triple quadrupole mass spectrometer (TSQ Quantum). Each value represents the mean ± SD of three independent experiments

Soluble GSTs Catalyze the Conversion of 14,15-HxA_3 to 14,15-HxA_3-C

Subcellular fractionation of L1236 cells demonstrated that the 100,000 g supernatant but not the 100,000 g pellet converted 14,15-HxA_3 and EXA_4 to 14,15-HxA_3-C and EXC_4, respectively (data not shown). We therefore investigated the capacity of different soluble glutathione transferases to catalyze the conversion of 14,15-HxA_3 to 14,15-HxA_3-C. Earlier studies performed in our laboratory have shown that L1236 cells express high levels of GSTM1-1 (Feltenmark et al., to be published). Recombinant GST M1-1b, M2-2, M3-3, M4-4, M5-5, P1-1(Ile), P1-1(val), T1-1, A1-1, A2-2, A3-3 or A4-4 and LTC_4 synthase was solved in PBS followed by addition of 14,15-HxA_3 (228 μM) and glutathione (final concentration of 5 mM) followed by incubation for 15 min. GST M1-1 (520 pmol/μg), P1-1(Ile) (350 pmol/μg), M2-2 (250 pmol/μg) and P1-1(val) (230 pmol/μg) had the highest capacity to conjugate glutathione to 14,15-HxA_3 11(*S*). In comparison, LTC_4 synthase was less efficient than GST M1-1 to convert 14, 15-HxA_3 to 14,15-HxA_3-C (Fig. 5).

14,15-Hepoxilin Formation in Eosinophils, Nasal Polyps and Dendritic Cells

Besides the glutathione conjugated 14,15-hepoxilins, the L1236 cells also stereoselectively produced 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*) upon challenge with arachidonic acid (Fig. 6b–c). These metabolites were identified by

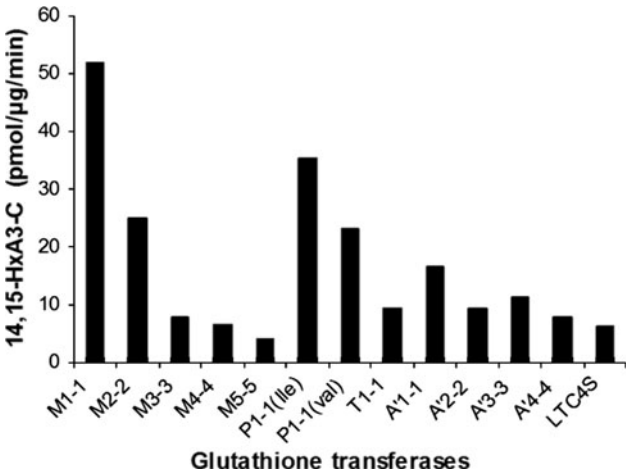

Fig. 5 Metabolism of 14,15-HxA_3 to 14,15-HxA_3-C by various glutathione transferases (GSTs). 14,15-HxA_3 11(*S*) (228 μM) was incubated with 12 different soluble glutathione transferases (4 μg), GST M1-1, M2-2, M3-3, M4-4, M5-5, P1-1(Ile), P1-1(val), T1-1, A1-1, A2-2, A3-3 and A4-4 and LTC_4 synthase for 10 min at 37 °C. The 14,15-HxA_3-C product was quantified by reverse phase HPLC coupled with UV detection (210 nm). Each value represents the mean of two independent experiments

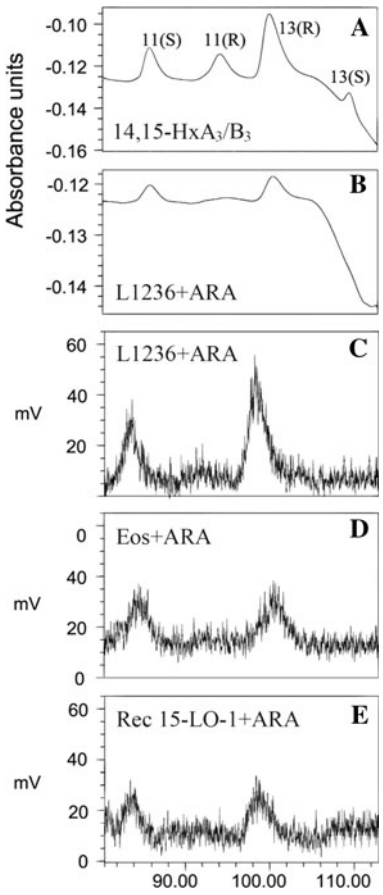

Fig. 6 Formation of isomers of 14,15-HxA_3 and 14,15-HxB_3. Standard 14,15-Hx isomers were separated as shown in the UV (210 nm) chromatogram (**a**). UV (210 nm) and radioactivity chromatograms of the L1236 cell line incubated with arachidonic acid are displayed in panels **b** and **c**, respectively. The cells produced exclusively 11(*S*)-hydroxy-14(*S*),15(*S*)-epoxy-5,8,12 (*Z*,*Z*,*E*)-eicosatrienoic acid (14,15-HxA_3 11(*S*)) and 13(*R*)-hydroxy-14(*S*),15(*S*)-epoxy-eicosatrienoic acid (14,15-HxB_3 13(*R*)). The same isomers were selectively formed in eosinophils and by recombinant 15-LO-1, and corresponding radioactivity chromatograms are shown in panel **d** and **e**

MS/MS spectra (data not shown) and retention times on column were compared with synthetic standards. In order to elucidate if other human cells or tissues, which express 15-LO-1, could produce 14,15-hepoxilins, eosinophils, dendritic cells and nasal polyps were incubated with [1-^{14}C] arachidonic acid, with or without glutathione, and analyzed using a radioactivity detector. The major formed hepoxilins in these cells/tissues were 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*), however no glutathione-conjugated 14,15-hepoxilins were detected. Fig. 6d shows the formation of these metabolites in eosinophils. Similar results were obtained with dendritic cells and nasal polyps (data not shown). Incubation of recombinant 15-LO-1 with arachidonic acid also led to formation of 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*) (Fig. 6e), demonstrating that human 15-LO-1 has an intrinsic hepoxilin A_3 and B_3 synthase activity. The hepoxilins represent 5–10% of the total peak area in the radio chromatograms.

Discussion

We had previously shown that the Hodgkin cell line L1236 exhibits high expression of 15-LO-1 and can convert arachidonic acid to eoxins [31]. In this study we have identified two other hitherto unknown cysteinyl-containing arachidonic acid metabolites formed through the 15-LO-1 pathway in L1236 cells. Based on MS/MS spectra of endogenous formed metabolites and corresponding synthetic compound, the unknown metabolites were identified as 11(*S*),15(*S*)-dihydroxy-14(*R*)-glutathionyl-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-C) (**1**) and 11(*S*),15(*S*)-dihydroxy-14(*R*)-cys-gly-5(*Z*),8(*Z*),12(*E*) eicosatrienoic acid (14,15-HxA_3-D) (**2**) (Figs. 2, 3).

The 14,15-hepoxilins are described as hydroperoxide isomerase products [40] or as non-enzymatic degradation products of 15(*S*)-hydroperoxy-eicosatrienoic acid (15-HPETE) [41]. In rabbit aorta, a CYP2J2 is suggested to function as a 15-HPETE isomerase forming the 14,15-HxA_3 [42], and in the garlic root a hydroperoxide isomerase is described [32]. The origin of the 14,15-hepoxilins are enzymatic since formation of 14,15-HxA_3 and 14,15-HxB_3 is stereospecific. 14,15-HxA_3 11(*S*) and 14,15-HxB_3 13(*R*) were the major isomers formed in L1236 cells and also in eosinophils, dendritic cells and in nasal polyps (Fig. 6). This is consistent with the results from human epithelial cells where the 14,15-HxB_3 with the hydroxyl group in *R* configuration is the most prominent isomer [33]. These stereospecific products were formed when arachidonic acid was incubated with recombinant 15-LO-1, demonstrating that 15-LO-1 alone can catalyze the formation of the 14,15-hepoxilins. Thus, human 15-LO-1 possesses an intrinsic 14,15-hepoxilin activity without the presence of an isomerase. It had been demonstrated earlier that purified lipoxygenase from rabbit reticulocytes can convert arachidonic acid into 15-HPETE and 14,15-HxB_3 [43]. The 12-LO Fe^{3+} is described to catalyze the formation of the arachidonic acid peroxide radical which rearranges to give HxB_3 [10]. The biosynthesis of 14,15-hepoxilins was proposed to occur by a free radical mechanism. The 15-HPETE hydroperoxide forms an oxygen radical by homolytic cleavage catalyzed by the 15-LO-1 Fe^{2+}. Spontaneous cyclization forms an epoxyallylic radical having electron density principally at carbons 11 and 13. Oxygen rebound at these carbons results in the formation of 14,15-HxA_3 and 14,15-HxB_3, respectively. Although human epidermis appears to be the principal source of 12-lipoxygenate derived hepoxilins, there is evidence that human intestinal epithelial cell lines can also produce

HxA_3 [20, 44]. The enzyme which catalyzes the formation of this metabolite in these cells is not clear. However, it is possible that human 15-LO-1 also can, to a limited extent, catalyze the formation of hepoxilins, although human 15-LO-1 possesses a relatively low 12-lipoxygenase activity (ratio 15-HETE vs. 12-HETE 9:1 after incubation with arachidonic acid).

In summary, 14,15-HxA_3 and 14,15-HxB_3 were stereospecifically formed with the 11 or 13 hydroxyl group in *S* and *R* configuration, respectively, in human cells such as L1236, eosinophils, nasal polyps and dendritic cells. These metabolites were formed promptly upon stimulation with arachidonic acid. This fatty acid is mainly esterified in membranes in non-activated cells but during inflammatory processes, the level of free arachidonic acid can markedly increase. The metabolite 14,15-HxA_3 has not previously been described to be formed by human cells. The 14,15-HxA_3-C and the 14,15-HxA_3-D were novel identified metabolites of arachidonic acid produced by L1236 cells (Fig. 7). It is noteworthy that LTC_4 as well as EXC_4 in eosinophils are formed by membrane-bound LTC_4 synthase [30] but the synthesis of 14,15-HxA_3-C in L1236 cells is apparently catalyzed primarily by the soluble GST M1-1. This GST is abundant in this cell type, but in other cells GST P1-1 may be more important. GST M1-1 is polymorphic with a frequent null allele [45] and it is obvious that the relative contributions of the different GSTs expressed in a given cell will determined the amounts present. For clarification of the enzymology of 14,15-HxA_3-C formation in different tissues, it will be necessary to quantify the expression of soluble GSTs as well as the membrane-bound LTC_4 synthase in future studies.

The biological effects of the hepoxilins, formed by animal cells and in human epidermis, are still unclear although it has been reported to causes a rise in cytosolic calcium in human neutrophils [32], migration of neutrophils across intestinal epithelial [20], and relaxation of precontracted rabbit aorta [40]. HxA_3-C has been reported to induce vascular contraction of guinea pig isolated trachea

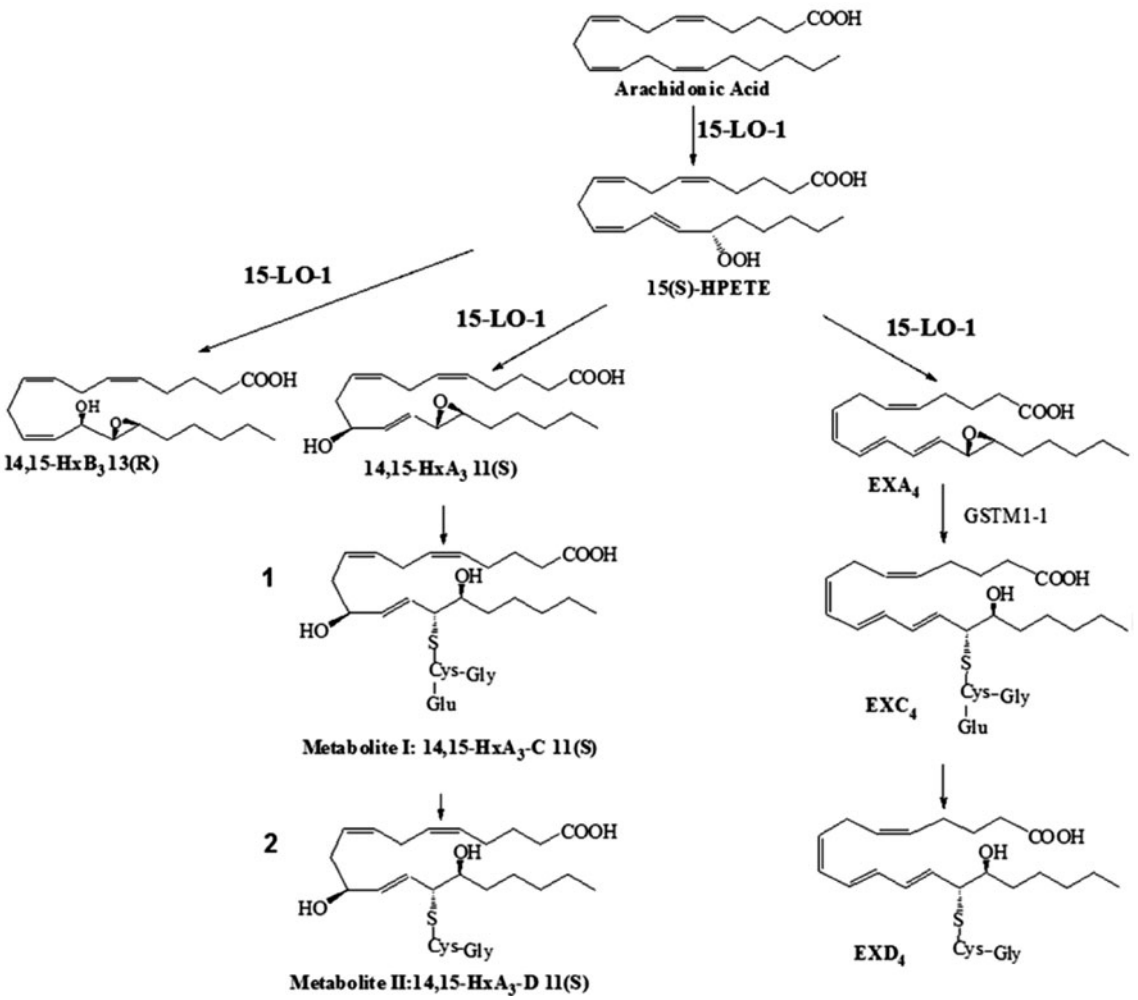

Fig. 7 Overview of the biosynthesis of 14,15-hepoxilins and eoxins in the Hodgkin lymphoma cell line L1236

and increase vascular permeability in rat skin [18, 21]. Therefore it will be of great interests to investigate the biological effects of these newly identified cysteinyl-containing 14,15-hepoxilins produced by human cells.

Received: 12 April 2010 / Accepted: 11 October 2010 / Published online: 16 November 2010

Abstract Two new eicosanoids with a unique isovalerianic acid ester group at C-12, named dichotellates A (**1**) and B (**2**), were isolated from the gorgonian *Dichotella gemmacea* collected from the South China Sea using bioassay-guided fractionation. Their structures were established on the basis of extensive spectroscopic analysis including one-dimensional (1D) and two-dimensional (2D) NMR as well as high-resolution ESI-MS experiments. These two compounds were evaluated for their lethal activity toward brine shrimp *Artemia salina* and both showed weak activity.

Keywords Gorgonian · *Dichotella gemmacea* · Eicosanoid · Dichotellate A · Dichotellate B

Abbreviations

COSY	Correlation spectroscopy
DEPT	Distortionless enhancement by polarization transfer
ESI	Electrospray ionization
HMBC	Heteronuclear multiple bond correlation
HMQC	Heteronuclear multiple quantum correlation
IR	Infrared
MS	Mass spectrometry
NMR	Nuclear magnetic resonance

Introduction

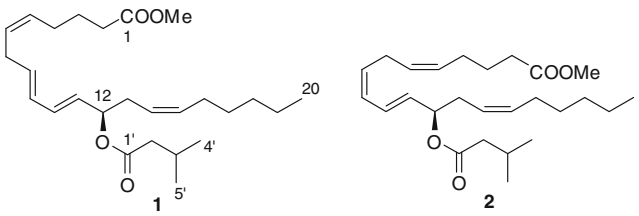
Polyunsaturated fatty acids (PUFA) have played important roles in the pharmaceutical and biochemical fields because of their biological properties including antimalarial activity, mycobactericidal activity, and antifungal activity [1–3]. They also have significant functions in animal systems as intermediate products, such as eicosanoids derived from C20 PUFA that regulate cell differentiation, immune responses, and homeostasis [4].

Coral is a notable source of eicosanoids, for example, cyclopropyl eicosanoids from the gorgonian *Plexaura homomalla*, (8*R*)-8-hydroperoxyeicosatetraenoic acid and 11(*R*)-hydroxy-eicosatetraenoic acid from *Plexaura homomalla* and *Plexaurella dichotoma*, respectively [5–7]. In the course of our program to search for bioactive metabolites from marine invertebrates, the petroleum ether extract of the gorgonian *Dichotella gemmacea* collected from the South China Sea showed lethal activity toward brine shrimp *Artemia salina*. Bioassay-guided fractionation of the active extract led to the isolation of two new eicosanoids, dichotellates A and B (**1**, **2**) (Scheme 1), containing a unique isovalerianic acid ester group at C-12. Herein, we report the isolation and structure elucidation of the two metabolites and their lethal activity toward the brine shrimp *A. salina*.

Materials and Methods

General Experimental Procedures

Optical rotations were measured with a Horiba SEAP-300 spectropolarimeter. IR (KBr) spectra were obtained on a Nicolet Nexus 470 infrared spectrophotometer. ^{1}H, ^{13}C, and 2D NMR spectra were recorded on a JEOL JNM-ECP



Scheme 1 Chemical structures of **1** and **2**

600-MHz NMR spectrometer with tetramethylsilane (TMS) as internal standard. MS spectral data were obtained on a Micromass Q-TOF spectrometer for ESI-MS. High-performance liquid chromatography (HPLC) separation was performed using a Waters 1525 preparative HPLC system coupled with a Waters 2996 photodiode array detector. A Kromasil C18 preparative HPLC column (250 × 10 mm, 5 μm) was used. Silica gel (200–300 mesh) for column chromatography and GF_{254} for TLC were made by the Qingdao Marine Chemical Factory, Qingdao, China.

Animal Material

The gorgonian *D. gemmacea* was collected at a coral reef in the South China Sea, Sanya, Hainan Province, China, in April 2006 and identified by Prof. Ren-Lin Zou, South China Sea Institute of Oceanology, Chinese Academy of Sciences, China. A voucher specimen was deposited in the Key Laboratory of Marine Drugs, Ministry of Education, School of Medicine and Pharmacy, Ocean University of China, Qingdao, China, with access code HN-SYM-20060032.

Extraction and Isolation

The fresh material (2.8 kg wet weight) was extracted with 95% EtOH three times (3 × 5 L) at room temperature, and the solution was evaporated to dryness under vacuum. The residue was suspended in H_2O (500 mL) and partitioned with petroleum ether (1,000 mL) three times. The petroleum ether extract (14.0 g) was subjected to silica gel column chromatography (CC), using petroleum ether/acetone (from 100:0 to 0:100) as eluent. The fractions were further subjected to Sephadex LH-20 CC and eluted with petroleum ether/$CHCl_3$/MeOH (2:1:1) and purified by semipreparative HPLC using MeOH/H_2O (90:10) as mobile phase to obtain compounds **1** (3.0 mg) and **2** (4.6 mg).

Dichotellate A (**1**)

Colorless oil, $[\alpha]_D^{25}$ −0.21° (*c* 0.5, $CHCl_3$). IR (KBr) ν_{max} 2,956, 2,927, 2,856, 1,736, 1,458, 1,370, 1,292, 1,242, 1,188, 1,096 cm^{-1}; NMR spectral data see Table 1; ESI-MS (+) *m/z*: 441 $[M + Na]^+$; High-resolution ESI-MS *m/z*: 441.2972 ($C_{26}H_{42}O_4Na$, calcd. 441.2981).

Dichotellate B (**2**)

Colorless oil, $[\alpha]_D^{25}$ −0.35° (*c* 0.5, $CHCl_3$). NMR spectral data see Table 1; ESI-MS (+) *m/z*: 441 $[M + Na]^+$; High-resolution ESI-MS *m/z*: 441.2983 ($C_{26}H_{42}O_4Na$, calcd. 441.2981).

Bioassays

The brine shrimp lethality assay was performed on *A. salina* according to the published protocols [8, 9].

The isolated compounds were screened for cytotoxic activity against KB and KBv200 cell lines using the method of microculture tetrazolium (MTT) [10].

Results and Discussion

The gorgonian *D. gemmacea*, collected from a coral reef of Sanya, Hainan Province, China, in April 2006, was extracted with 95% EtOH three times, and the extract was suspended in H_2O and partitioned with petroleum ether. The petroleum ether was subjected to silica gel column chromatography followed by separation on Sephadex LH-20. Further purification by semipreparative HPLC of fractions from petroleum ether extract yielded two new metabolites (**1**, **2**).

Compound **1**, isolated as a colorless oil, $[\alpha]_D^{25}$ −0.21° (*c* 0.5, $CHCl_3$), gave an $[M + Na]^+$ ion peak at *m/z* 441.2972 (calcd. 441.2981) by HR-ESI-MS, which indicated that the compound has molecular formula $C_{26}H_{42}O_4$ with 6° of unsaturation. The IR spectrum of **1** showed strong carbonyl group absorption at 1,736 cm^{-1}. In its ^1H NMR spectrum, eight olefinic proton signals were found at δ_H 6.23 (1H, dd, $J = 15.0$, 10.3 Hz), 6.02 (1H, dd, $J = 15.0$, 10.6 Hz), 5.70 (1H, m), 5.51 (1H, dd, $J = 15.4$, 7.4 Hz), 5.44 (2H, m), and 5.35 (2H, m), while three methyl groups signals were observed at δ_H 0.94 (6H, d, $J = 6.6$ Hz) and 0.88 (3H, t, $J = 7.0$ Hz) and one methoxyl group signal at δ_H 3.67 (3H, s). The ^{13}C NMR spectrum of **1** revealed 26 carbon signals. Furthermore, DEPT spectrum confirmed that this compound has 3 methyls, 1 methoxyl, 10 methylenes, 10 methines, and 2 quaternary carbon atoms. The six elements of unsaturation of **1** were accounted for eight olefinic carbon signals and two carbonyl groups (δ_C 174.0 and 172.4). A ^1H NMR spin system from H-2 to H-20 was completely revealed by analysis of its ^1H–^1H COSY spectrum (Table 1; Fig. 1). A sharp triplet at δ_H 2.31 with $J = 7.4$ Hz was caused by the C-2 methylene protons as in other oxylipins [11]. The above data implied that compound **1** is a long-chain unsaturated

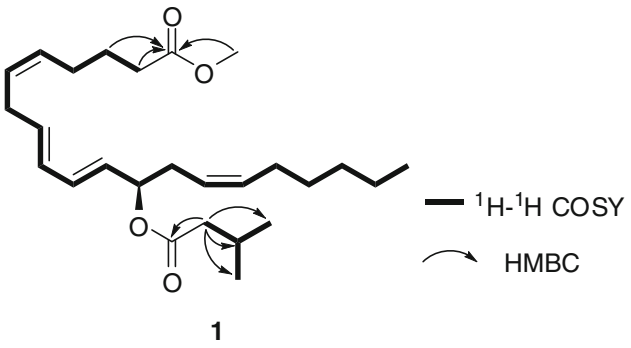

Fig. 1 ^{1}H–^{1}H COSY and selected HMBC correlations for **1**

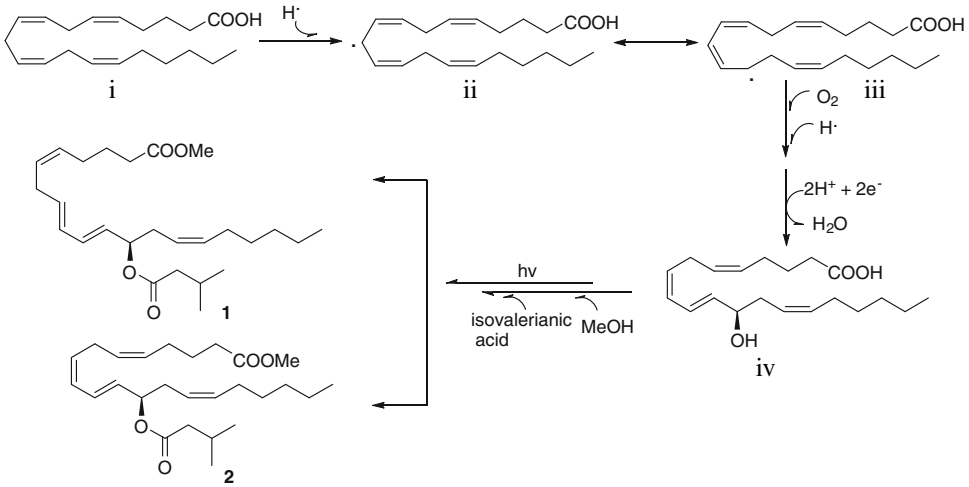
eicosanoic acid derivative. From the HMQC spectrum data, all proton signals were assigned to their directly attached carbons, and the full assignments of chemical shift data of C-2 to C-20 were further confirmed by HMBC spectra (Table 1; Fig. 1). Since the HMBC correlation between the methoxyl group at δ_H 3.67 and C-1 at δ_C 174.0 was detected, compound **1** was presented as an methyl ester. The correlations of H-23/H-24/H-25, H-26 in the ^{1}H–^{1}H COSY spectrum together with the HMBC correlations from H-23 to C-22, C-24, C-25/C-26 and from H-25/H-26 to C-23, C-24 suggested that an isovalerate unit was located at C-12, an oxygenated carbon with chemical shift value at δ_C 73.7. The *trans–trans* relationships of H-8 and H-9, H-10 and H-11 were assigned by the coupling constants ($J_{8,9}$ = 15.0 Hz and $J_{10,11}$ = 15.4 Hz) while the *cis*-geometries of the other two double bonds were determined by the diallylic and allylic carbons, observed at δ_C 30.4 (C-7) and 27.1 (C-16), respectively [12, 13]. Based on the optical rotation of compound **1** together with those in the literatures for enantiomerically pure 12-HETE, its absolute configuration at C-12 was tentatively determined as *R* [14–16]. On the basis of these results, the full structure of **1** was elucidated as (5*Z*,8*E*,10*E*,12*R*,14*Z*)-methyl 12-(3-methyl-1-oxobutoxy)-5,8,10,14-eicosatetraenoate and named as dichotellate A.

Compound **2** was obtained as a colorless oil, $[\alpha]_D^{25}$ – 0.35° (*c* 0.5, $CHCl_3$) with a pseudomolecular ion peak

Scheme 2 Possible formation of **1** and **2** from arachidonic acid



presented as an $[M + Na]^+$ ion at *m/z* 441 in ESI-MS. Its HR-ESI-MS ($[M + Na]^+$ *m/z* 441.2983, calcd. 441.2981) implied **2** has molecular formula $C_{26}H_{42}O_4$, which is the same as compound **1**. Possessing similar ^{1}H NMR data and patterns as for compound **1**, compound **2** has the same carbon skeleton as **1** (Table 1). The ^{13}C NMR and DEPT spectra revealed **2** has 26 carbon signals attributing to 3 methyls, 1 methoxyl, 10 methylenes, 10 methines, and 2 quaternary carbon atoms. The chemical shift value of C-7 at δ 26.1 and the H-8 and H-9 coupling constant of $J_{8,9} = 11.0$ Hz indicated that the configuration of C-8 and C-9 was at *cis* position to each other [13]. The carbons and protons were assigned unambiguously by analyzing its 2D NMR spectral data. The absolute configuration at C-12 in **2** was also tentatively determined as *R* [14–16]. Hence, the structure of compound **2** was established as (5*Z*,8*Z*,10*E*,12*R*,14*Z*)-methyl 12-(3-methyl-1-oxobutoxy)-5,8,10,14-eicosatetraenoate and named as dichotellate B.

A unique isovalerianic acid ester group at C-12 is the main characteristic of the two eicosanoids (**1** and **2**) isolated from gorgonian *D. gemmacea*. To the best of our knowledge, they are the first examples from nature of eicosanoids esterified by isovalerianic acid.

Taking into account the structures of compounds **1** and **2**, they may be derived from arachidonic acid, and a possible process for compounds **1** and **2** is proposed in Scheme 2 based on the literature [17–19]. The precursor arachidonic acid (**i**) was firstly abstracted at 10-*pro*-(*R*) hydrogen atom and converted into two resonance forms (**ii** and **iii**) with the radical at either C-10 or C-12. The resonance form **iii** was then oxidized at C-12, followed by peroxidase reduction, resulting in the corresponding hydroxyeicosatetraenoic acid (intermediate **iv**). After esterification and *cis–trans* isomerization, the intermediate **iv** was finally transformed into **1** and **2**.

Compounds **1** and **2** were evaluated for their lethal activity toward brine shrimp *A. salina*. At concentration of 50 μg/ml, compounds **1** and **2** showed weak lethality to the brine shrimp *A. salina* with lethal rates of 19% and 33%, respectively. These two compounds were also tested for cytotoxicity against KB and KBv200 tumor cell lines and shown to be inactive ($IC_{50} > 50$ μg/ml).

Two uncommon eicosanoid metabolites with a unique isovalerianic acid ester group at C-12 have been isolated and identified from gorgonian *D. gemmacea*. Their possible biosynthetic pathway was also proposed. The chemical investigation of *D. gemmacea* may be used as foundation for further studies on eicosanoid metabolites in gorgonian.

Modeling the Primary Oxidation in Commercial Fish Oil Preparations

Received: 5 July 2010 / Accepted: 4 November 2010 / Published online: 23 November 2010

Abstract The quality of commercial fish oil products can be difficult to maintain because of the rapid lipid oxidation attributable to the high number of polyunsaturated fatty acids (PUFA), specifically eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). While it is known that oxidation in fish oil is generally the result of a direct interaction with oxygen and fatty acid radicals, there are very few studies that investigate the oxidation kinetics of fish oil supplements. This study uses hydroperoxides, a primary oxidation product, to model the oxidation kinetics of two commercially available fish oil supplements with different EPA and DHA contents. Pseudo first order kinetics were assumed, and rate constants were determined for temperatures between 4 and 60 °C. This data was fit to the Arrhenius model, and activation energies (E_a) were determined for each sample. Both E_a agreed with values found in the literature, with the lower PUFA sample having a lower E_a. The oil with a lower PUFA content fit the first-order kinetics model at temperatures ≥20 °C and ≤40 °C, while the higher PUFA oil demonstrated first-order kinetics at temperatures ≥4 °C and ≤40 °C. When the temperature was raised to 60 °C, the model no longer applied. This indicates that accelerated testing of fish oil should be conducted at temperatures ≤40 °C.

Introduction

Fish oil dietary supplements have been gaining popularity in recent years due to the health benefits provided by the polyunsaturated fatty acids (PUFA) they contain. The primary PUFA in fish oil are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). These fatty acids (FA) have been shown to be important factors in cardiovascular health as well as brain and eye development in babies [1–6] while deficiencies in PUFA have been associated with a number of negative health conditions including dermal conditions, attention deficit disorder and clinical depression [4]. Because most people do not consume the recommended 2–3 servings of fatty fish per week as recommended by the World Health Organization [7], fish oil supplements have become a popular alternative. Unfortunately, due to their large number of double bonds, PUFA in fish oil are subject to rapid oxidation which produces fishy off-flavors and can make supplements unpalatable.

The type of oxidation most commonly seen in commercial fish oil products is a result of direct interactions between fatty acid radicals and molecular oxygen. This process is initiated by reaction of singlet oxygen with lipids [8] to generate free radicals that in turn, initiate chain reactions of oxidation. Oxidation of PUFA leads to the formation of the primary oxidation products, lipid hydroperoxides, which then break down into secondary oxidation products including aldehydes, ketones, acids, and alcohols. Hydroperoxides are stable at room temperature, but readily decompose at elevated temperatures or in the presence of transition metals [9]. The rate of formation and degradation of hydroperoxides increases with increasing temperature [10]. Hydroperoxides are an important measure of oil quality as they are an indicator of the future levels of secondary oxidation products that negatively impact sensory

parameters. There are a variety of other factors, including fatty acid composition, lipid class composition, concentrations, and type of oxygen present, antioxidants and light, that can influence oxidation, and make accurate comparisons between oxidation studies difficult [9].

Tests of oxidative stability are commonly used to evaluate the shelf life of fish oils, but in order to complete testing in a reasonable amount of time, elevated temperature is frequently used to accelerate oxidation. The goal of this accelerated testing is to obtain results that can then be used to predict the shelf life of fish oil products that are stored under normal conditions [11]. For this to be possible, the kinetics of the oxidation reaction must be determined. Theoretically, oxidation rates can be monitored by following the degradation of specific FA. Though this has been attempted in fish oils [12], these oils have a complex FA profile and application of these techniques may not give an accurate representation of oxidation that is occurring in the oil as a whole. At normal oil storage temperatures the change in fatty acid profile happens very gradually and fatty acid analysis may not be sensitive enough to detect the minute changes in fatty acid concentration, making this method impractical to use for monitoring oxidation of fish oils. Rather than monitoring fatty acid composition of fish oils, other studies use oxygen concentrations to assess oxidation [e.g. 13, 14], a technique that may be more accurate for fish oil oxidation though it does not directly take into account the formation of oxidation products that could impart negative flavors into the oil. No studies could be found that attempt to decipher the kinetics of fish oil oxidation using a common oxidation indicator. The present study uses peroxide values (PV) to assess oxidation because these compounds are formed directly from lipids and therefore, the amount of hydroperoxides present can be directly related to the amount of oxidized lipid present at early stages of oxidation.

This study evaluates the stability of two commercially available liquid fish oil supplements for oxidative stability by monitoring hydroperoxide formation at a number of different temperatures, ranging from 4 °C to 60 °C to determine if oxidation of fish oil follows the Arrhenius model. This information is important to fish oil manufacturers as it will enable the application of accelerated stability data to real-time conditions, thereby reducing the time required to perform stability studies from years to weeks.

Experimental Procedures

Materials

Two different types of commercially available liquid fish oil supplements were obtained from a retail outlet. The first was NutraSea, a typical "18:12" fish oil, containing approximately 18% EPA and 12% DHA as proportions of total FA. The second was NutraSea HP, a fish oil "concentrate" containing approximately 30% EPA and 10% DHA. Both products were produced by Ascenta Health and contained winterized fish oil (97.86%), natural flavor (2%), alpha tocopherol (0.04%) and green tea catechins (0.1%). Amber bottles (200 ml) and lids were supplied by Ascenta Health. These products were marketed as fish oils and contained triacylglycerols (TAG) as the primary lipid at 70–75%. Monoacylglycerides (MAG) and diacylglycerides (DAG) were also preset at 20–25% and <5%, respectively.

Potassium iodide, 1% starch indicator, sodium chloride, butyl hydroxytoluene, boron trichloride-methanol, anhydrous sodium sulfate, Optima acetic acid and Optima isooctane were obtained from Fisher Scientific (Ottawa, ON). Optima chloroform was obtained from VWR (Mississauga, ON). An Isotemp 100 Series Model 126G oven (Fisher Scientific) was used to incubate samples. Methyl tricosenoate, methyl eicosapentaenoate, and methyl docosahexaenoate were obtained from Nu-Chek Prep (Elysian, MN).

Methods

Fatty Acid Analysis

Both fish oils were analyzed for EPA and DHA via GC-FID. Triacylglycerols were converted to methyl esters (ME) following the modified Global Organization for EPA and DHA Voluntary Monograph for Omega-3 [15], using methyl tricosenoate as an internal standard, as well as external standards for EPA and DHA. ME were separated using a column coated with (50% cyanopropyl)-methylpolysiloxane (30 m × 0.25 mm × 0.25 μm film thickness) and helium was used as the carrier gas at a flow rate of 1.0 ml/min. The oven temperature was initially held for 2 min at 153 °C then increased at 2.3 °C/min to 205 °C and held for 8.3 min. The total run time was approximately 32 min. The FID was maintained at 270 °C, and the injector (split mode 1:100, 4 mm liner) at 250 °C.

Stability Studies

Both oils were incubated in the dark at 4, 20, 40, and 60 °C. The 18:12 oil was also incubated at 30 °C. Three bottles were used for each incubation temperature. Bottles were capped but not purged with nitrogen after the initial opening. PV were measured in triplicate, with each bottle sampled at each time point, following AOCS Official Method Cd 8-53 [16]. Samples stored at 4 °C were initially tested weekly, but then were tested monthly after 3 months of testing. Samples stored at 20 °C were tested weekly, while samples stored at 30 and 40 °C were tested every 3 days. Samples stored at 60 °C were analyzed daily. Different

sampling periods were necessary to capture the variation in PV with changing oxidation rates. After removing an aliquot for sampling, each bottle was recapped and returned to the test temperature. Testing was stopped when an average peroxide value of 5 mequiv/kg was reached, as this is the maximum accepted value for fish oil as recommended by the Global Organization for EPA and DHA [15].

Determination of Rate Constants and Shelf Life Prediction

Kinetic analysis of data was carried out using methods adapted from Labuza [17], Labuza and Bergquist [18], Spears et al. [19] and Tan et al. [20]. Pseudo-first order conditions were assumed with the oil substrate in excess so that

$$-\mathrm{d}[\mathrm{O}_2] = \mathrm{d}[C]/\mathrm{dt} = kC \quad (1)$$

where C is the concentration of oxidation products, in this case the PV, and k is the rate constant. Integration leads to the classic relationship in first order kinetics:

$$\ln C = \ln C_\mathrm{o} + kt \quad (2)$$

where C_o is the initial concentration of oxidation products (PV at initial times) and t is time in days. Plots of ln PV versus time were linear with slopes of k for most trials. Rate constants derived from linear plots were then fit to an Arrhenius model:

$$\ln k = \ln A - E_\mathrm{a}/RT \quad (3)$$

where A is the prefactor, R is the universal gas constant, T is the absolute temperature and E_a is the activation energy in J/mol.

Because the ultimate goal of this study was to investigate the validity of shelf life prediction by extrapolating rate constants from high temperature to low temperature studies, we therefore examined the exponential relationship between the time require to reach the upper limit of acceptability (t_rej) and temperature, according to

$$t_\mathrm{rej} = ae^{T} \quad (4)$$

where a is a constant and t_rej is the time required to reach PV = 5 mequiv/kg, as the upper limit of acceptability for fish oil oxidation. Integration of this relationship gives

$$\ln t_\mathrm{rej} = a + \ln T \quad (5)$$

suggesting that a plot of ln t_rej versus T should be linear.

Results and Discussion

Fatty Acid Analysis

The amounts of EPA and DHA present in both the 18:12 and concentrate oils (Table 1) differed, as expected from their label claims. The 18:12 oil had a label specification of 269 mg/g while the concentrate specified 430 mg/g. Upon testing, both samples exceeded label claims for EPA and DHA with values of 286 and 499 mg/g, respectively. We therefore considered these oils to have significantly different PUFA contents. Complying with label claims was also important to establish that these oils were typical of commercial products currently available; the purpose of this study was to monitor oxidation in commercial products with added antioxidants and flavors that contained FA at expected levels.

Table 1 EPA and DHA content (mean ± SD) of 18:12 oil and concentrate oil compared to the label claim

	18:12	Concentrate
Omega-3 claim (mg/g)*	269	430
Actual EPA content (mg/g)	151 ± 0.97	349 ± 1.23
Actual DHA content (mg/g)	135 ± 1.23	150 ± 0.42
Total EPA + DHA content (mg/g)	286 ± 1.56	499 ± 1.30

* Manufacturer guarantees only the total sum of EPA+DHA, not the individual fatty acid content

Stability Studies

In the experimental design, pseudo-first order kinetics was assumed. For the initial setup, each bottle contained approximately 180 ml of fish oil with approximately 20 ml of headspace. This corresponds to approximately 0.6 mol of FA and 2×10^{-4} mol of O_2, with FA present in excess of 3,500 times the amount of O_2. This ensures that O_2 is limiting, a necessary criteria of pseudo-first order reactions. Even in the samples that had the longest testing period (22 time points, with 5 ml of oil being used at each point), this situation was maintained with 70 m of oil, and 130 ml of air. This is equivalent to 0.23 mol of FA and 1.3×10^{-3} mol of O_2, ensuring that FA were still present in excess of 176 times the amount of O_2. Resulting plots of PV versus time were therefore expected to increase exponentially over time (Fig. 1a, b) with linear fits for the corresponding regressions of ln PV versus time (Table 2). It should be noted that kinetics are typically modeled by monitoring the breakdown of reactants, while this study monitors the formation of oxidation products. Oxidation products have been used by a number of research groups including Labuza and Bergquist [18], Mancebo Campos et al. [21], and Gomez-Alonso et al. [22] to successfully model oxidation kinetics.

Despite ensuring that pseudo-first order conditions were met, the reaction was obviously not first order for several of the sample-temperature combinations. For example, at 4 °C the 18:12 oil showed a clear lag in the onset of oxidation (Fig. 1a) that did not fit the expected model. In fact,

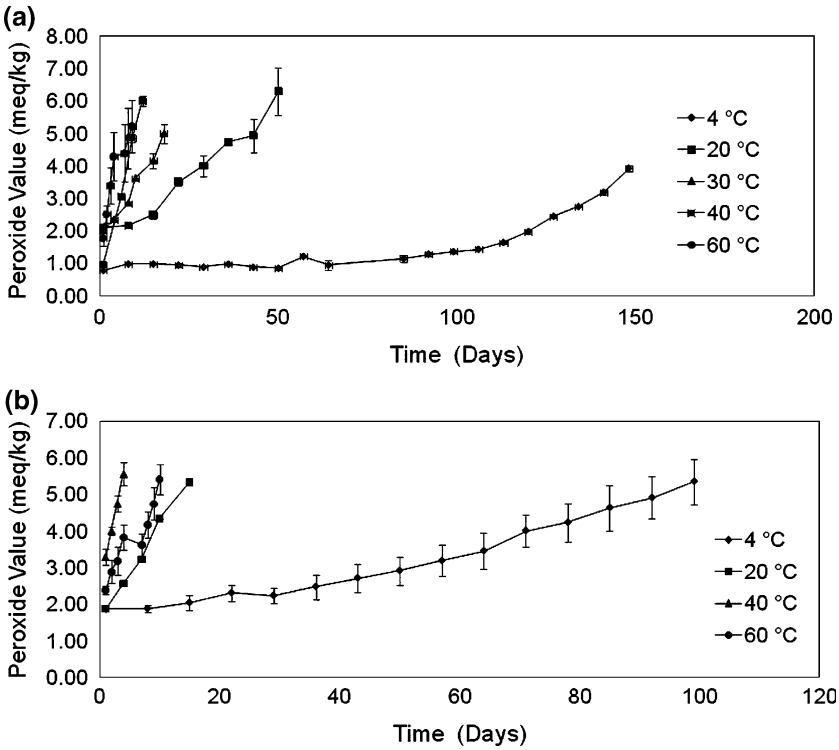

Fig. 1 Change in hydroperoxide value (mean ± SD, $n = 3$) at different temperatures over time. **a** 18:12 oil and **b** fish oil concentrate

[b] Excludes 4 and 60 °C data (18:12) or 60 °C data (concentrate)

modeling with zero and second order kinetics did not show any improvement at that temperature. Interestingly, the concentrate oil did follow a first order model quite well at 4 °C (Fig. 1b; Table 2), likely because of the absence of a prolonged lag phase. Both oils also deviated from the expected first-order model at 60 °C. This was less surprising as it is well accepted that the mechanisms for a complex chain reaction such as lipid oxidation may vary with increasing temperature [11]. For the purpose of this study, it was assumed that peroxide derivatives of fatty acids do not degrade; however, a large variety of secondary oxidation products are formed from these compounds as oxidation progresses. It may be that the increase in temperature increased the rate of both peroxide formation and breakdown; thus, the low rate constant derived at 60 °C for both oils suggests that peroxides are decomposing faster than they are being formed [9, 11]. Additionally, at elevated temperatures, lipid oxidation is more dependent on the concentration of oxygen. At high temperatures, the solubility of oxygen decreases, and becomes a limiting factor in lipid oxidation reactions as oxygen is rapidly consumed [11].

First-order kinetics were expected because of the experimental design, but all data was also evaluated for fit to a zero- and second-order model (Table 3). For a zero-order model, regression of PV versus time is linear, while for second-order models, one expects plots of 1/PV versus time to be linear. Coefficients of determination were simply used to assess fit (Table 3). In most cases it is quite obvious that a first-order model is as good as or better than other models (e.g., 18:12 oil at 20 and 30 °C). In other cases it is less obvious. For example, at both 40 and 60 °C for the 18:12 oil, a zero-order model has a slightly better fit to the data, while at 4 °C, the second order model has the best fit for the same oil. This is likely related to the high content of rapidly oxidizing PUFA that are present in fish oil.

Table 3 Coefficients of determination for 18:12 and concentrate fish oils when zero, first and second-order models were considered

Temperature (°C)	# of points	Zero-order	First-order	Second-order
18:12 Oil		r^2		
277	20	0.6993	0.8142	0.8648
293	8	0.9596	0.9429	0.9703
303	6	0.9752	0.9801	0.9572
313	4	0.9941	0.9539	0.8546
333	7	0.8777	0.8027	0.7052
Concentrate Oil		r^2		
277	15	0.9561	0.9876	0.9863
293	5	0.9429	0.9706	0.9105
313	4	0.9993	0.9969	0.9817
333	8	0.8812	0.8866	0.8603

All trials were stopped when the upper level for acceptability for fish oil, PV = 5 mequiv/kg, so that the duration of the experiment grew shorter as temperature increased. With daily sampling, this meant that fewer data points were acquired as temperature increased, making it difficult to fully capture the change in oil quality with time. The situation reached an extreme at 40 °C with both oils only requiring 4 days to exceed the upper limit of acceptability. Had sampling continued beyond this time point, the change in slope that is expected with first-order kinetics may have been captured. As plotted here, it is likely that only a small linear portion of a larger curve is being shown. Because we were only trying to model kinetics until the quality limit was reached and first-order kinetics fit well for 20 and 30 °C, it seemed appropriate to continue to model with first-order kinetics at the other temperatures. In addition, we were very reluctant to fit the data to a zero-order model in any situation. Zero-order kinetics dictates that reaction rate is independent of substrate concentration. Though both oils contain the same amount of fatty acid structures, the concentrate sample contained more PUFA, or substrate, that could be oxidized. Rates were obviously higher in the concentrate oil (Fig. 2; Table 2) so zero-order kinetics were ruled out immediately as an increase in PUFA increased the rate of peroxide formation. Finally, a first-order model was expected because others have found that oils containing antioxidants follow such models [17]. All this evidence pointed to the use of a first-order model when any ambiguity in model fit was encountered.

Arrhenius Behavior and Shelf Life Prediction

Rate constants for both oils were lower at 60 than at 40 °C; this result, combined with their poor fit to the first-order model, led to their exclusion from the Arrhenius plot. Similarly, because of the obvious lag time for onset of

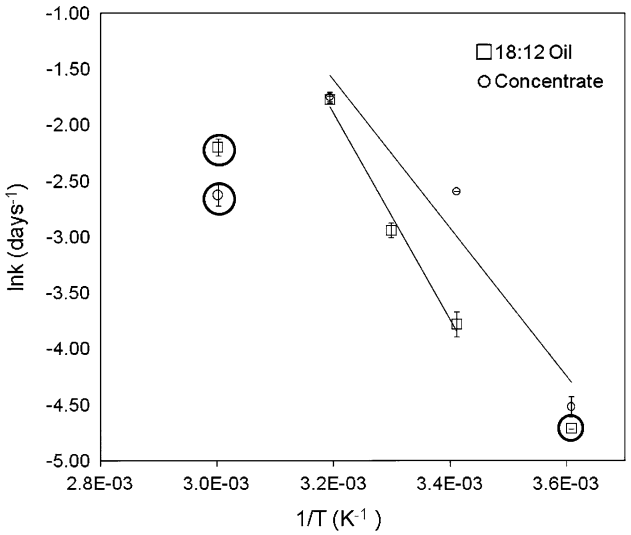

Fig. 2 Arrhenius plots for 18:12 oil (R^2 0.9871) and concentrate oil (R^2 0.9384). *Circled points* are not included in regression. Data are means ± SD

oxidation of 18:12 oil at 4 °C, the data collected at this temperature was also omitted from the plot for 18:12 oil, leaving only 3 data points for each oil. Despite the low sample numbers, we still see a good fit for both oils, with differing slopes. From the slopes, E_a of oxidation for the 18:12 and concentrate oils were calculated as 76 and 55 kJ/mol, respectively. The lower E_a for the concentrate oil was expected because less energy should be required to initiate oxidation due to the higher PUFA content. If the 4 °C data point is included in the 18:12 analysis (data not shown), the slopes are virtually identical, giving a very similar and highly unlikely E_a. This further points to the appropriateness of omitting the 4 °C data point in the 18:12 set. The E_a determined here are similar to those reported by Labuza [23] for lipid oxidation by free radical mechanisms (63–105 kJ\mol). With pure triglycerides (TAG), consisting of esterified DHA, Yoshii et al. [14] found similar E_a ranging from 77 to 97 kJ/mol, depending on the level of antioxidant added, and clearly showed that E_a increases with increased concentration of rosemary extract. With added antioxidants, both the fish oils examined here and those containing high levels of PUFA studied by Yoshii et al. [14], had E_a more similar to the stable vegetable oil from canola [24], pointing to the clear advantage of employing antioxidants to prevent oxidation.

The objective of this study was to determine the real time shelf life of these products by extrapolating from accelerated data. Data from experiments above 40 °C were therefore omitted from the shelf life plots (Fig. 3). This also agrees well with the recommendation by Frankel [11] that the temperature used for accelerated fish oil stability studies should not exceed 40 °C. This has obvious implications for fish oil stability studies that involve the use of

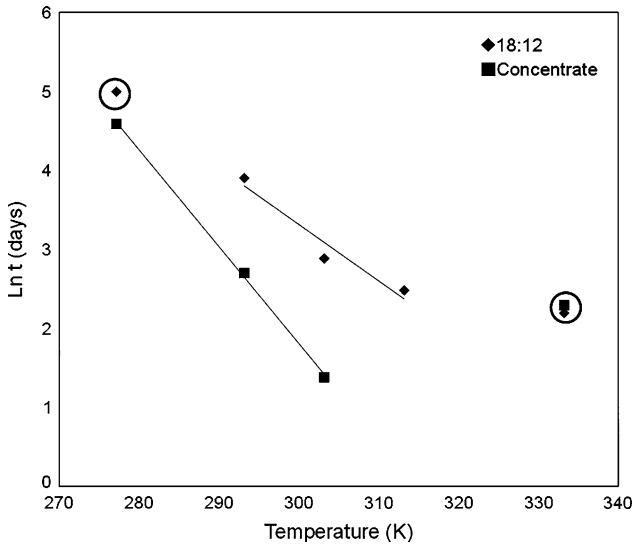

Fig. 3 Shelf life plots for 18:12 and concentrate fish oils. *Circled points* are not included in regression

oxygen absorption methods at elevated temperatures such as such as the Rancimat and Oxidative Stability Index (OSI) [25–27]. It is clear from the present study that PV of oils stored under Rancimat or OSI conditions will not be related to the PV of the same oils stored at temperatures <60 °C. Knowing that, the data for 4 °C in the 18:12 oil did not follow first order kinetics also led to its omission from the shelf life plot. Without that data, it is of course not possible to predict shelf life at temperatures <20 °C and >4 °C by interpolation. However, if the 4 °C data was included, the slope of the line would only change subtly so that the shelf life would be predicted at 143 days rather than the measured 148 days. This represents an error <4% and when considering data between 4 and 20 °C, the impact would be proportionally and absolutely less. Thus, one may cautiously extrapolate beyond the linear portion of the curve for 18:12 oil, knowing that the predicted shelf life would be under-estimated by no more than 4%. It is important to note that these equations only hold true for these specific products. Oils that have different fatty acid or lipid class profiles or use different antioxidants will likely have different rates of oxidation.

This study was designed to mimic the oxidation that might take place after a consumer has purchased a bottle of fish oil and has begun consuming it. The shelf lives measured here for storage at 4 °C for both oils (148 and 99 days for 18:12 and concentrate, respectively) agrees well with typical manufacturers' recommendations of 90 days in refrigeration. An obvious contrast is with freshly bottled fish oils, purged with inert gas, usually nitrogen. Exclusion of air in such products promotes much longer-term oxidative stability and we would not expect the kinetics of oxidation to be similar to those reported here. Studies to monitor such products would be logistically difficult to organize simply because sealed containers of oil could only be sampled once; after opening, the sample would be in contact with air and, even if again purged with nitrogen, rates of oxidation would be expected to vary. Thus, a very large amount of individually bottled oil would be required.

The lack of kinetic data between 4 and 20 °C is the largest flaw in this study. Had we included at least one data point in this range, we would have been much better able to characterize both the Arrhenius behavior and shelf life prediction. This is critical because it would have set a lower limit on temperatures to which we could interpolate without introducing a known minimum error. It would also have been useful to examine other measures of oxidation. Frankel [28] used volatile oxidation products to examine the kinetics of fish oil oxidation. Anisidine values are also recommended in the GOED Voluntary Monograph [15] as a quality measure of fish oil. These tests could allow us to investigate the relationship between primary and secondary oxidation and could help to determine if hydroperoxides are in fact breaking down at 60 °C. A substantial increase in either anisidines or volatile oxidation products would support our hypothesis of peroxide breakdown. Additionally, monitoring secondary oxidation would allow for the creation of shelf life plots that could potentially correlate with sensory characteristics of the oils and give a better indication of how consumers will perceive the oils. However, both parameters are difficult to accurately measure in commercial oils that have added flavors. Our experience has shown that flavor compounds co-elute with oxidation products in gas chromatographic analysis of volatiles, especially when headspace analysis techniques are utilized. While selective ion monitoring could potentially be used to monitor oxidation in co-eluting peaks, these techniques are beyond the scope of this paper. Flavor compounds also interfere with the *p*-anisidine test, causing drastic overestimation of the measure, sometimes outside the range of measurement. Thus, monitoring change in secondary kinetics with *p*-anisidine test would only be feasible in unflavored oils, which would not necessarily be relevant for shelf life studies of commercial dietary supplement.

Fish oil is a popular dietary supplement taken by many people for its health benefits. Because of the high PUFA content, the oil oxidizes rapidly. At temperatures ≥20 °C and ≤40 °C, 18:12 fish oil appears to follow first-order kinetics. Fish oil concentrate demonstrates first-order kinetics at temperatures ≥4 °C and ≤40 °C. At 60 °C both oils oxidized more rapidly, likely because of hydroperoxides breaking down faster than they could form. This confirms that accelerated stability studies using fish oil should be conducted at temperatures no higher than 40 °C. Accelerated temperature data can then be used to predict

shelf-life at lower temperatures; however, extrapolation of data should be done with caution as the rate of reaction may not hold true at low temperatures. This was the case for 18:12 oil as clearly demonstrated in this study.

METHODS

Rapid Quantitative Analysis of Lipids Using a Colorimetric Method in a Microplate Format

Yu-Shen Cheng · Yi Zheng · Jean S. VanderGheynst

Received: 11 August 2010 / Accepted: 15 October 2010 / Published online: 11 November 2010

Abstract A colorimetric sulfo-phospho-vanillin (SPV) method was developed for high throughput analysis of total lipids. The developed method uses a reaction mixture that is maintained in a 96-well microplate throughout the entire assay. The new assay provides the following advantages over other methods of lipid measurement: (1) background absorbance can be easily corrected for each well, (2) there is less risk of handling and transferring sulfuric acid contained in reaction mixtures, (3) color develops more consistently providing more accurate measurement of absorbance, and (4) the assay can be used for quantitative measurement of lipids extracted from a wide variety of sources. Unlike other spectrophotometric approaches that use fluorescent dyes, the optimal spectra and reaction conditions for the developed assay do not vary with the sample source. The developed method was used to measure lipids in extracts from four strains of microalgae. No significant difference was found in lipid determination when lipid content was measured using the new method and compared to results obtained using a macro-gravimetric method.

Keywords Sulfo-phospho-vanillin · Microalgae · Macro-gravimetric

Introduction

Lipids are an important group of compounds that provide several biological functions such as energy storage, cell membrane structure and signaling [1, 2]. For this reason, lipid analyses are performed routinely in many different research areas. For example, the screening of oleaginous organisms has extensive application in both research and industry settings for identifying and producing food supplements and renewal biofuels [3–5]. In addition, in aquaculture processes analysis of lipid content in animals and microorganisms assists with monitoring the health conditions of the culture and developing growth strategies [6, 7]. Several methods have been developed to quantify total lipids. The most common approach is a macro-gravimetric method in which lipids are extracted from a sample, the extraction solvent is evaporated and the retained material is measured as the lipid content [8, 9]. This traditional gravimetrical method requires a relatively large quantity of sample and is time-consuming and labor-intensive when analysis of many samples is needed. Spectrofluorometric analysis of lipid, which uses the fluorescent dye Nile red, was originally developed by Greenspan et al. [10] and has also been modified for quantification of total lipids [11–14]. While this approach is high-throughput, environmental factors and other components in the cell cytoplasm, such as proteins and pigments, interfere with the assay and the fluorescence intensity varies between samples [14–16]. For

this reason accurate quantification of lipids using this approach requires that the optimal spectra and reaction conditions be determined for each type of sample prior to fluorescent measurements [13, 17].

The colorimetric sulfo-phospho-vanillin (SPV) method developed by Chabrol et al. [15, 18] is an attractive alternative for lipid measurement because of its fast response and relative ease in sample handling. The SPV method has been modified for diverse applications such as the determination of total lipids in serum, food and ecological samples [16, 19–23]. A micro scale modification of the SPV assay was developed by Van Handel [24] for determination of total lipids in a single mosquito, and assessed by several investigators as a more time and labor efficient approach compared to gravimetric methods [25–27]. In Inouye's report [25], 0.25 ml sample, 0.1 ml sulfuric acid and 2.4 ml vanillin reagent (1.2 mg vanillin per ml 68% phosphoric acid) were required for the micro-colorimetric assay. Similarly, in a report published by Lu et al. [27] 0.1 ml sample, 2.5 ml sulfuric acid and 5 ml vanillin reagent were needed to conduct the SPV assay on a micro scale. Both methods were completed in 13 × 100 mm culture tubes. Transfer of reactants to proper containers was required for absorbance measurement. Since color develops continuously, careful sample handing and control of color development are critical using this micro-scale approach.

The present work reports on an adaptation of the SPV method for completion of lipid quantification in a 96-well microplate for higher throughput and reduced costs. The adapted method involves an assay in which the reagent mixture is confined to one microplate for the entire assay. This enables faster measurement of multiple samples with easy background correction and more consistent monitoring of color development. As an example, total lipids in extracts from microalgae, which contain a dark green background, was successfully measured using this assay approach with corn oil as a standard.

Materials and Methods

Materials

Concentrated sulfuric acid, *o*-phosphoric acid (85%), chloroform and methanol, all ACS grade, were purchased from Thermo Fisher Scientific Inc (Waltham, MA, USA). Vanillin (≥98%) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Commercial corn oil, canola oil, flax oil, sunflower oil and cod liver oil were obtained from local markets. A cholesterol standard for clinical work was purchased from MP biomedicals (Solon, OH, USA). Flat bottom, polystyrene 96-well microplates (Costar 3370) were obtained from Corning Incorporated (Corning, NY, USA).

Preliminary Assessment of General Assay Conditions

A preliminary microplate test was performed to determine the initial assay conditions. The general assay steps followed are presented in Fig. 1. The volume of reagents per well in the preliminary study included 100 µl of concentrated sulfuric acid and 100 µl vanillin–phosphoric acid reagent. Three concentrations of vanillin were examined (1, 0.5, and 0.1 mg vanillin per ml 68% phosphoric acid) to determine the suitable concentration for assay in a microplate format. Standard samples were prepared by mixing corn oil in solvent (chloroform:methanol = 1:1) at 15 mg/ml. Standards were added into each well of the microplate by varying the volume (0.5–30 µl) and then 100 µl concentrated sulfuric acid was added after the solvent was evaporated at 90 °C for about 10 min. The microplate was then incubated on a dry heating bath (Isotemp 125D, Thermo Fisher Scientific Inc.) at 90 °C for 10 min and cooled to room temperature on ice water (~2 min). A microplate reader (Model VMax, Molecular Device, Sunnyvale, CA, USA) with compatible software, Softmax v 2.43, was used to measure background absorbance. Then, 100 µl vanillin–phosphoric acid reagent was added for

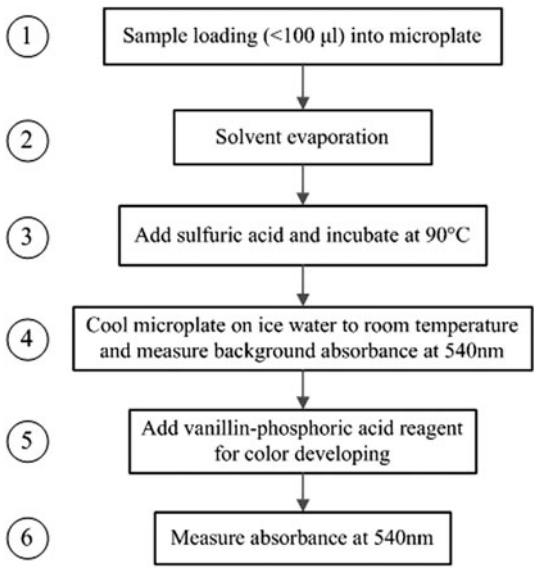

Fig. 1 General analysis procedures of SPV method in a microplate. Volumes of sulfuric acid and incubation times in *step 3*, and vanillin–phosphoric acid reagent levels and color development time in *step 5* were varied to determine the ideal assay conditions for high throughput microplate analysis of lipid

color development. Absorbance at 540 nm was measured after 5 min of color development.

Examination of Solvent Ratios for Sample Preparation

Solvent mixtures including four different ratios of chloroform and methanol (chloroform only, chloroform:methanol = 2:1, 1:1 and 1:2) were tested to determine the effect of sample preparation on the assay. Samples containing corn oil in solvent mixtures (15 mg corn oil per ml solvent) were pipetted into the microplate wells by varying the volume from 1 to 15 μl. The solvent was evaporated at 90 °C (~10 min), and then 100 μl concentrated sulfuric acid was added. The microplate was then incubated on a dry heating bath at 90 °C for 20 min. Absorbance at 540 nm was measured as background after the microplate was cooled to room temperature on ice water. Then, 100 μl vanillin–phosphoric acid reagent (0.5 mg vanillin per ml 68% phosphoric acid) was added for color development. Absorbance at 540 nm was measured after 5 min of development.

Examination of Vanillin and Phosphoric Acid Concentrations

After the sample preparation method was determined, concentrations of vanillin and phosphoric acid were investigated to determine their influence on the assay and if lower concentrations could be used in a high-throughput format. All assays used 100 μl vanillin–phosphoric acid reagent for color development. Four vanillin concentrations in 68% phosphoric acid were first tested at 0.5, 0.375, 0.25 and 0.125 mg/ml. After an ideal concentration of vanillin (0.25 mg/ml) was determined, four different concentrations of phosphoric acid (17, 34, 51 and 68%) were tested. To examine the possibility of further reducing vanillin in the assay, the vanillin concentration was optimized after the suitable concentration of phosphoric acid had been determined.

Volume of Vanillin Phosphoric Acid Reagent and Concentrated Sulfuric Acid

In an attempt to reduce water use and final volume, different volumes of vanillin phosphoric acid reagent were tested. Four volumes of vanillin phosphoric acid reagent (20, 25, 50, 100 μl) containing an equivalent amount of vanillin were first investigated to determine whether the volume of the reagent could be reduced by increasing the vanillin concentration. After the vanillin concentration in the phosphoric acid reagent and volume of vanillin phosphoric reagent in the assay were determined, the effect of concentrated sulfuric acid volume (100, 150 and 200 μl) on digestion was tested.

Examination of Reaction Time and Stability of Absorbance Linearity

To investigate the effect of reaction time on the assay, standard samples (10 mg corn oil per ml solvent) were loaded at varying volumes (12, 8, 4, 1 μl) in the assay with 100 μl concentrated sulfuric acid. The reaction time was varied from 10 to 60 min by carefully transferring samples from the original microplate to a new one at 10 min intervals. The new microplate was maintained on ice water until all the samples were transferred. After all samples had been cooled and background absorbance had been measured, 50 μl of vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) was added to each well. To test the stability of absorbance linearity, absorbance measurements made at 540 nm were recorded from 5 min to 3.5 h after vanillin–phosphoric acid reagent addition.

Relative Absorbance and Linearity of Different Lipid Samples

To survey the applicability of the assay, six different lipid samples, including corn oil, canola oil, flax oil, sunflower oil, cod liver oil and cholesterol, were tested in the range 5–150 μg by varying loading volume of standard solutions (10 mg lipid per ml solvent). After the solvent was evaporated, 100 μl concentrated sulfuric acid was added to each well and then the microplate was incubated at 90 °C for 20 min. 50 μl of vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) was added to each well for color development. Absorbance at 540 nm was measured after 10 min of development.

Applicability of the Assay for Measuring Lipid Extracted from Microalgae

Four different strains of microalgae, *Chlorella vulgaris* UTEX 259, *Chlorella sorokiniana* UTEX 2805, *Chlorella minutissima* UTEX 2341 and *Chlorella* sp. NC64A were obtained from The Culture Collection of Algae (UTEX) and American Type Culture Collection (ATCC). *Chlorella* UTEX 259 and UTEX 2805 were cultured in inorganic N8 medium, and *Chlorella* UTEX 2341 and NC64A were cultured in N8Y medium prepared by adding 0.1% yeast extract in N8 medium. All strains were cultured at 25 °C with either ambient air supply at 1 vvm or 2% CO_2 at 0.5 vvm in 1-l glass bottles and irradiated with fluorescent light at ~2,000 Lux on a 16:8 h light/dark cycle. Cultures were harvested in the late log phase of growth, centrifuged

at 2,000*g* and the retained pellet was lyophilized. The lipid extraction and purification methods were according to Folch [9] with slight modifications. Samples of purified lipid extracts were mixed with twice the volume of methanol for the colorimetric assay in a microplate, and the results were compared with the total lipid measured using the macro-gravimetric method [25].

Data Analysis

Linearity was determined by plotting absorbance versus lipid amount in the assay and examining the R^2 value upon linear regression of the data. Analysis of covariance (ANCOVA) and Tukey's HSD test were used to assess differences in the mean slope obtained upon linear regression of absorbance versus lipid amount. A paired *t* test and a graphical statistic paired test based on Bland's method [28] were performed to evaluate the agreement between the developed method and the macro-gravimetric method when lipid samples from microalgae were analyzed. Paired *t* tests, ANCOVA and Tukey's HSD tests were performed using JMP IN v.8.0 (SAS Institute Inc. Cary, NC, USA).

Results and Discussion

Preliminary Test of Assay Conditions

A preliminary microplate test was performed to determine a suitable range of vanillin in the assay. All tested concentrations (1, 0.5, and 0.1 mg vanillin per ml 68% phosphoric acid) gave good linearity of absorbance ($R^2 > 0.95$) at 540 nm in the range of 15–120 μg lipid (Data not shown). Vanillin concentration at 0.5 mg/ml gave a sufficient and relatively linear result, and therefore was selected as the starting point for optimization. Although the preliminary test showed very good linearity, there were some samples with noticeable film development and corrosion in the bottom of the wells of the microplate that might interfere with the reaction between lipid and sulfuric acid and affect color development. Therefore, different solvent ratios were also included in the development of the method.

Development of Reaction Conditions

Sample Preparation in Different Solvent Combinations

Only the samples prepared in a chloroform:methanol ratio of 2:1 had clear reactions and differences in color development (Fig. 2). In some of the tests using chloroform:methanol ratios of 2:1 and 1:1, corrosion and film development occurred in the bottom of wells. The corrosion might indicate intolerance of polystyrene to these solvent combinations, although the solvent was completely evaporated in a very short time (<10 min). The test of lipid measurement using chloroform only did not show any corrosion, however, a very thick and sticky layer formed when sulfuric acid was added, and color development was less than tests of lipid in other solvent combinations (Fig. 2). This phenomenon was also observed when the assay was performed in polypropylene microtubes, which suggests that the lipid layer might form because of overdrying when the solvent is evaporated rather than solvent intolerance of the assay container. Although the thick and sticky lipid layer could be dissolved after intensive mixing, this would not be suitable for an assay in a microplate where intensive mixing may be difficult to perform.

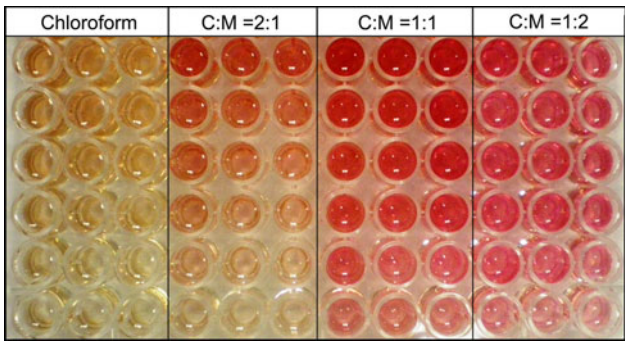

Fig. 2 Influence of solvent combinations on reaction and color development. *C* chloroform, *M* methanol. Samples (corn oil in solvent, 15 mg/ml) were added from 1 to 15 μl and incubated with 100 μl concentrated H_2SO_4 at 90 °C for 20 min. 100 μl vanillin–phosphoric acid reagent (0.5 mg vanillin per ml 68% phosphoric acid) was added for color development. Absorbance measurements were made after 5 min of color development. Sample loading volumes from top to bottom are 15, 12, 9, 6, 3, and 1 μl)

Concentration of Vanillin and Phosphoric Acid

Four different vanillin concentrations were tested based on the results from the preliminary test described earlier. When concentrated sulfuric acid addition was fixed at 100 μl, all concentrations of vanillin in 68% phosphoric acid tested in this study gave an even linearity of absorbance at 540 nm in the range 7.5–120 μg lipid (Fig. 3). In order to balance the conservation of vanillin use and sufficiency of absorbance, 0.25 mg/ml vanillin in 68% phosphoric acid was selected for the following optimization of phosphoric acid concentration. The purpose of testing different phosphoric acid concentrations was to investigate the possibility of using a lower amount of phosphoric acid while retaining linearity and sufficient absorbance. According to a previous report [18], when phosphoric acid concentration was varied between 17.6 and 70.4%, the

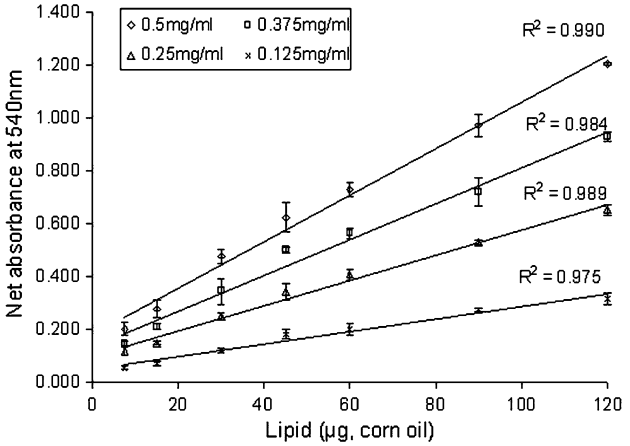

Fig. 3 Influence of vanillin concentration in vanillin–phosphoric acid reagent on color development. The vanillin–phosphoric acid reagent was prepared with 68% phosphoric acid. Samples were incubated with 100 µl concentrated H_2SO_4 at 90 °C for 20 min. 100 µl vanillin–phosphoric acid reagent was added for color development. Absorbance measurements were made after 5 min of color development. *Data points* and *error bars* represent the mean and standard deviation of three replicate samples

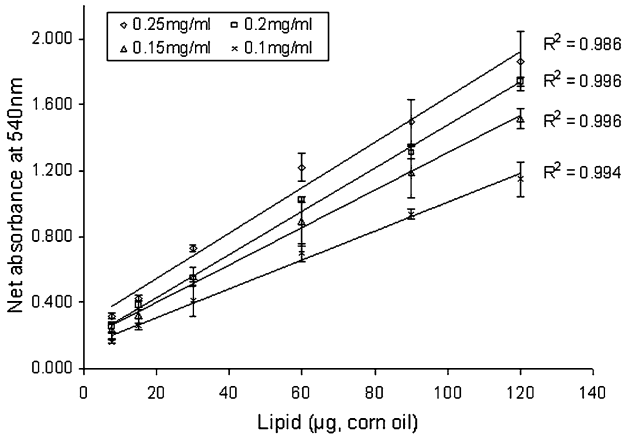

Fig. 5 Optimization of vanillin concentration in vanillin–phosphoric acid reagent for color development. The vanillin–phosphoric acid reagent was prepared with 17% phosphoric acid. Samples were incubated with 100 µl concentrated H_2SO_4 at 90 °C for 20 min. 100 µl vanillin–phosphoric acid reagent was added for color development. Absorbance measurements were made after 5 min of color development. *Data points* and *error bars* represent the mean and standard deviation of three replicate samples

higher concentration provided a greater and more stable color response. Thus, four different concentrations in this range were selected for testing. Figure 4 shows that lower phosphoric acid concentration gave a higher absorbance. This is in contrast to previous reports. The result suggests that the water content in the reagent might play a role in promoting the color response and an increase in the stability. Based on this result, the concentration of vanillin was further optimized. Figure 5 shows that the reduced vanillin concentration in 17% phosphoric acid provided equivalent absorbance linearity at 540 nm. Thus, vanillin concentration at 0.1 mg/ml was selected for the next study.

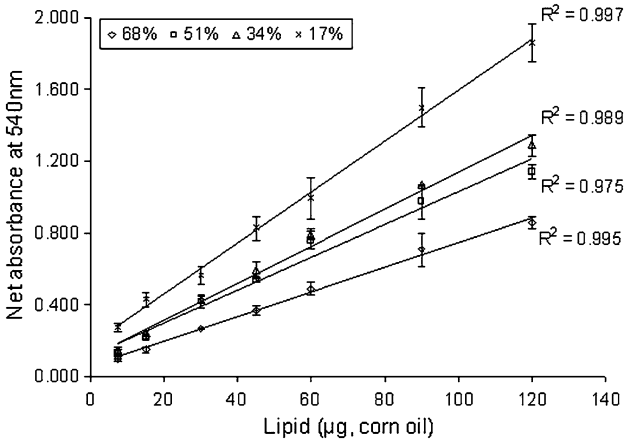

Fig. 4 Influence of phosphoric acid concentration in vanillin–phosphoric acid reagent on color development. The vanillin concentration was fixed at 0.25 mg/ml. Samples were incubated with 100 µl concentrated H_2SO_4 at 90 °C for 20 min. 100 µl vanillin–phosphoric acid reagent was added for color development. Absorbance measurements were made after 5 min of color development. *Data points* and *error bars* represent the mean and standard deviation of three replicate samples

Volumes of Vanillin–Phosphoric Acid Reagent and Concentrated Sulfuric Acid

In an attempt to reduce water use associated with the vanillin reagent, four volumes containing an equivalent amount of vanillin in 17% phosphoric acid were examined. Volumes of 100 µl (0.1 mg/ml) and 50 µl (0.2 mg/ml) provided fairly even linearity of absorbance compared to 20 µl (0.4 mg/ml) and 25 µl (0.5 mg/ml) (Fig. 6).

The volume of concentrated sulfuric acid might affect the reaction quality. In one report, the results were more consistent when the volume of concentrated sulfuric acid was more than 100 µl [25]. Therefore, sulfuric acid volumes of 100, 150 and 200 µl were examined to determine the effect of sulfuric acid loading volume on the color response and stability. Figure 7 shows that higher sulfuric acid volume did not result in better linearity and color development. The results suggest that a moderate ratio between water and sulfuric acid is important for color development.

Reaction Time and Stability of Absorbance Linearity

In the published format of the micro-scale assay, samples were incubated with concentrated sulfuric acid at 100 °C for 10 min. Previous reports also indicated that the heating temperature will affect the color response [19]. Because of

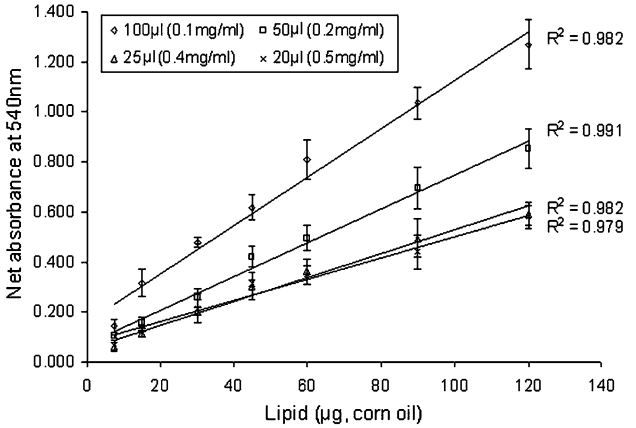

Fig. 6 Influence of the volume of vanillin–phosphoric acid reagent for color development. Vanillin–phosphoric acid reagents were prepared in 17% phosphoric acid. Samples were incubated with 100 μl concentrated H_2SO_4 at 90 °C for 20 min. Vanillin–phosphoric acid reagent was added for color development. Absorbance measurements were made after 5 min of color development. *Data points* and *error bars* represent the mean and standard deviation of three replicate samples

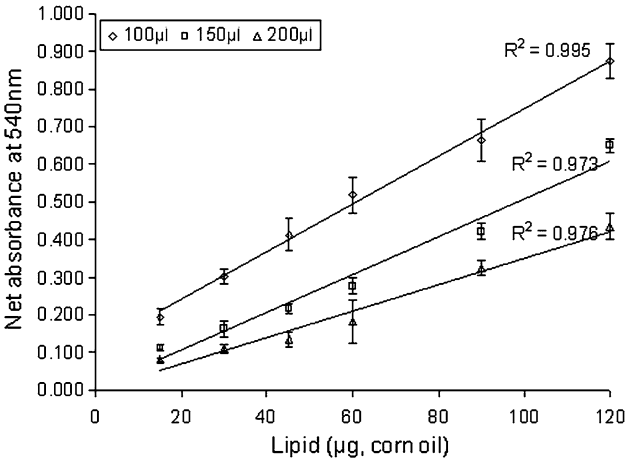

Fig. 7 Influence of volume of concentrated sulfuric acid for color development. Samples were incubated at 90 °C for 20 min. 50 μl Vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) was added for color development. the temperature limitation of polystyrene, the reaction temperature was set at 90 °C and longer incubation times were used to compensate for the temperature difference. Figure 8a shows that at a reaction time of 20 min, the absorbance increased with color development time. Linearity in absorbance was stable for 3.5 h and the results from different reaction times showed a similar pattern. While longer reaction times produced higher background absorbance (Data not shown), the total absorbance was only slightly increased (Fig. 8b). Since color develops

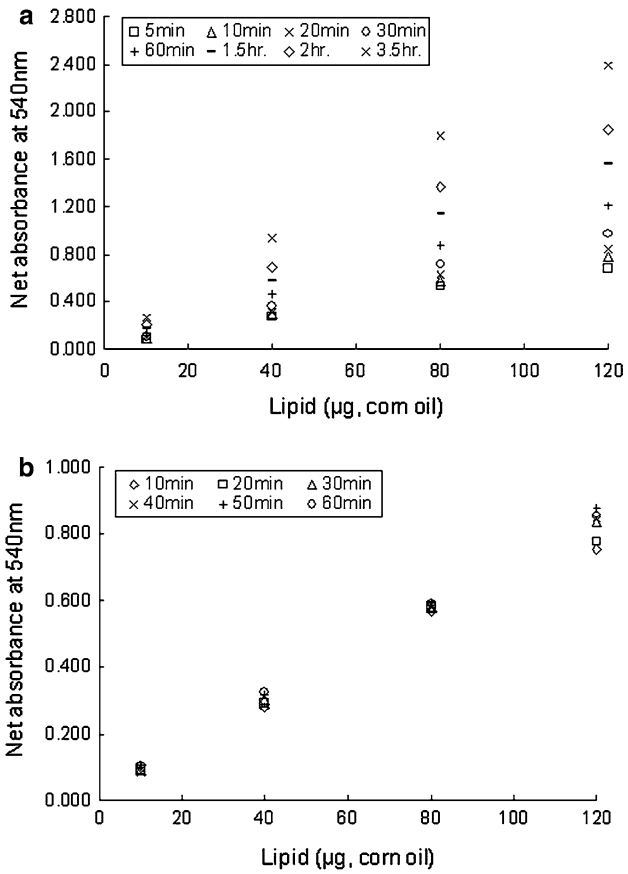

Fig. 8 Test of reaction time and stability for color development. **a** 20 min reaction time with color development from 5 min to 3.5 h, **b** 10–60 min reaction time with 10 min color development. 50 μl vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) was added for color development. *Data points* represent the mean of three replicate samples

continuously, laborious transfer of the reaction mixture for absorbance readings causes considerable error when large numbers of samples need to be measured. In the developed assay, because the samples and standards are on the same sample plate and read at the same time, the timing error is minimized.

Relative Absorbance and Linearity of Pure Lipid Samples

Previous reports indicated that selecting an appropriate standard was important for assessing lipid content in different types of samples [18, 19, 29]. Thus, different types of oil and cholesterol were tested using the new assay format (Fig. 9). The slope of the standard curve was significantly affected by lipid type ($p < 0001$). Standard slopes for cod liver oil and cholesterol were significantly lower than slopes for plant oils (Table 1). There were no significant differences in slopes among the plant oils, except flax oil which was different from all other oils

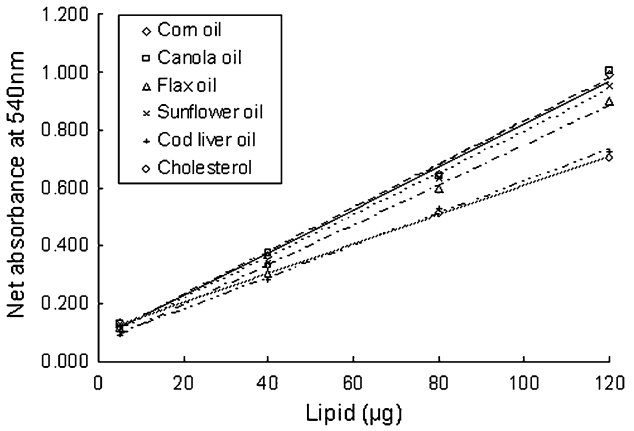

Fig. 9 Absorbance linearity of different lipid types. Samples were incubated with 100 µl concentrated H_2SO_4 at 90 °C for 20 min. 50 µl vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) was added for color development. Absorbance measurements were made after 10 min of color development. Data points represent the mean of three replicate samples

Table 1 Mean slopes from standard curves measured using developed method

Lipid type	Mean slope (Au/µg)*
Canola oil	0.00755 A
Corn oil	0.00746 A
Sunflower oil	0.00721 AB
Flax oil	0.00685 B

* Means followed by the same letter within columns are not significantly different according to Tukey's HSD means comparison test ($n = 3$), $p < 0.05$

except sunflower oil. Cod liver oil and cholesterol were also statistically equivalent (Table 1). Like other methods, standard selection should be based on the source of the sample (i.e., plant or animal) for the microplate method.

Final Microplate Procedure

The final procedure involves the addition of <100 µl of samples and standards that contain 5–120 µg lipids directly into the bottom of microplate wells. After the solvent is evaporated at 90 °C, 100 µl of concentrated sulfuric acid is added to each well. Then, the microplate is incubated at 90 °C for 20 min. Background absorbance at 540 nm is measured when the microplate is cooled to room temperature on ice water (~2 min). 50 µl of vanillin–phosphoric acid reagent (0.2 mg vanillin per ml 17% phosphoric acid) is added to each well for color development for 10 min, and then absorbance is measured at 540 nm. Since the heating and cooling steps will affect the absorbance, evenly heating and cooling the reaction mixtures are critical for having good absorbance linearity. Thus, performing the incubation in a microplate dry heating module or on a water bath with careful handling is recommended.

Applicability of the Assay for Measuring Solvent Extracted Lipid from Microalgae

Since the SPV method has been reported to have a variable response to varying sources of lipids [30], lipids extracted from four different strains of green microalgae were analyzed using the macro-gravimetric method and compared to the new microplate assay. Corn oil was used as the standard for the colorimetric method because microalgal lipids usually have a higher unsaturated ratio and are relatively close in composition to vegetable oil [16, 31–34]. The determined total lipids were converted to lipid percentage of dry algal biomass. Figure 10a shows the correlation of lipid percentage between the microplate format of the SPV method and the macro-gravimetric

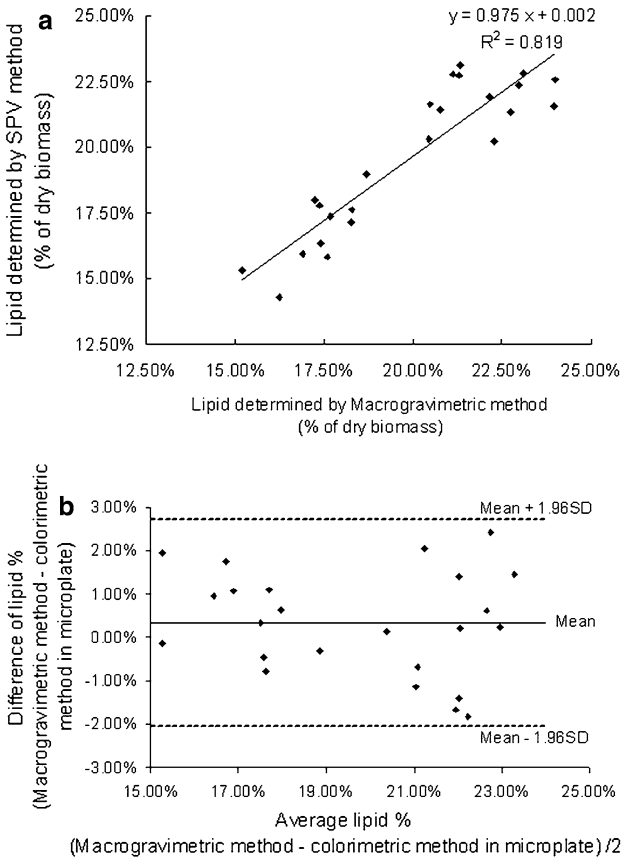

Fig. 10 **a** The correlation between lipid percentage of algae determined using the microplate colorimetric method and macro-gravimetric method. **b** Difference against average of macro-gravimetric and microplate format colorimetric measurement of lipid percentage with 95% limits of agreement (*dashed lines*)

method; there is a strong correlation between the macro-gravimetric method and the microplate format SPV method ($R^2 = 0.819$, $F = 99.72$, $p < 0.0001$). Figure 10b shows that the mean difference and standard deviation are 0.33 and 1.21% (test pairs = 24), respectively, and all differences fall between the 95% limits of agreement. Moreover, the matched paired t test is 1.35 ($p = 0.19$, two tails), which provides evidence that there is no significant difference between the microplate format of the SPV method and the macro-gravimetric method. This result is consistent with an earlier report [29] and suggests that the new SPV method in a microplate format can be applied for the quantification of total lipids from different types of microalgae samples with proper standard selection.

Conclusion

Total lipid quantification is frequently performed in many research areas with different types of samples. The present work reports on a modified colorimetric method for quantitative analysis of total lipid using a high-throughput microplate format. The presented method uses extracted and purified lipid samples. The extraction step minimizes interferences associated with other components in the sample and allows different samples from a variety of research areas to be analyzed using the same conditions. This approach could be very useful when screening the lipid content in different cell cultures and plants. With the development of high-throughput cell disruption technologies such as 96-well plate bead beaters and microwave extraction [35], lipid extraction from large numbers of samples could be done in minutes.

The new assay method possesses many advantages: (1) it requires a small amount sample and the sample volume can be adjusted to fit in the standard range, (2) it requires less time (<1 h) and less labor when a large number of samples is analyzed, and (3) the color development is more consistent with modifications of reagent concentrations. Moreover, the reagents are confined in the microplate through the entire assay procedure, which enables fast and accurate reading of multiple samples. In the final procedure, it is recommended that the volume of the sample should be less than 100 µl in order to ensure a complete reaction with the sulfuric acid. In addition, uniform heating and cooling are important for consistency in the reaction. The method was validated against the macro-gravimetric method. When corn oil was used as a standard, statistically equivalent results were achieved when both methods were used to measure total lipids in four different strains of *Chlorella*.

Acknowledgments Support for this research was provided by Chevron Technology Ventures and the University of California Energy Institute. The authors wish to thank Orn-u-ma Tanadul for assistance with preparation of algae and assays.

REVIEW

The Health Promoting Properties of the Conjugated Isomers of α-Linolenic Acid

Alan A. Hennessy · R. Paul Ross · Rosaleen Devery · Catherine Stanton

Received: 3 September 2010 / Accepted: 3 November 2010 / Published online: 15 December 2010

Abstract The bioactive properties of the conjugated linoleic acid (CLA) isomers have long been recognised and are the subject of a number of excellent reviews. However, despite this prominence the CLA isomers are not the only group of naturally occurring dietary conjugated fatty acids which have shown potent bioactivity. In a large number of in vitro and in vivo studies, conjugated α-linolenic acid (CLNA) isomers have displayed potent anti-inflammatory, immunomodulatory, anti-obese and anti-carcinogenic activity, along with the ability to improve biomarkers of cardio-vascular health. CLNA isomers are naturally present in high concentrations in a large variety of seed oils but can also be produced in vitro by strains of lactobacilli and bifidobactena through the activity of the enzyme linoleic acid isomerase on α-linolenic acid. In this review, we will address the possible therapeutic roles that CLNA may play in a number of conditions afflicting Western society and the mechanisms through which this activity is mediated.

Introduction

Numerous investigations have attributed bio-functional properties to a range of conjugated fatty acids of which the conjugated linoleic acid (CLA) isomers are best characterized [1–3]. The health promoting attributes of the CLA isomers have been reported in detail, however, there are currently few reviews which address the other major group of naturally occurring conjugated fatty acids, the conjugated α-linolenic acid (CLNA) isomers. CLNA isomers combine the conjugated double bond system of CLA with the octadecatrienoic fatty acid (C18:3) structure of α-linolenic acid, conferring these fatty acids with a high bioactive potential. Structurally, CLNA isomers are positional and geometric isomers of α-linolenic acid, and similar to

CLA isomers, are characterized by having one or more double bonds in the *cis* (*c*) or *trans* (*t*) conformation, which are separated by simple carbon–carbon linkage as opposed to being separated by a methylene group (Fig. 1).

In nature, CLNA isomers are readily found in abundance in pomegranate seed (*c*9,*t*11,*c*13 CLNA), tung seed (*c*9,*t*11,*t*13 CLNA), bitter gourd seed (*c*9,*t*11,*t*13 CLNA), snake gourd seed (*c*9,*t*11,*t*13 CLNA), parwal seed (*c*9,*t*11,*t*13 CLNA), catalpa seed (*t*9,*t*11,*c*13 CLNA), and pot marigold seed (*t*8,*t*10,*c*12 CLNA) (Table 1). The presence of these conjugated fatty acids in seed oils is primarily as a result of the action of divergent forms of the enzyme, fatty acid conjugase on linoleic or α-linolenic acids [4, 5] (Fig. 2). Additionally, the *c*9,*t*11,*c*15 CLNA and *t*9,*t*11,*c*15 CLNA isomers may be produced through the isomerisation of α-linolenic acid by intestinal and ruminal bacteria via the action of the enzyme linoleic acid isomerase [6–8].

Research has shown that conjugated fatty acids are associated with potent anti-carcinogenic, anti-inflammatory and anti-atherosclerotic properties both in vitro and in vivo, and how their efficacy against a particular condition may vary substantially between the individual isomers [1–3, 9]. Thus, the conjugation process can result in the production of a range of fatty acids with diverse biogenic profiles [1–3, 9]. The mechanisms behind the health promoting properties of conjugated fatty acids range from their ability to modulate the expression of genes associated with disease pathogenesis, to their ability to compete with pro-inflammatory ω-6 fatty acids such as linoleic and arachidonic acids for incorporation into the cell membrane. In addition, there is evidence to suggest that CLNA isomers may undergo elongation and desaturation reactions similar to α-linolenic acid [10, 11]. This process results in the production of conjugated derivatives of EPA and DHA, which may also possess potent biogenic properties [9, 12]. Indeed, synthetically produced conjugated EPA isomers have displayed potent anti-carcinogenic and anti-adipogenic properties [9, 13–15], while conjugated DHA isomers have shown potent anti-carcinogenic properties [16].

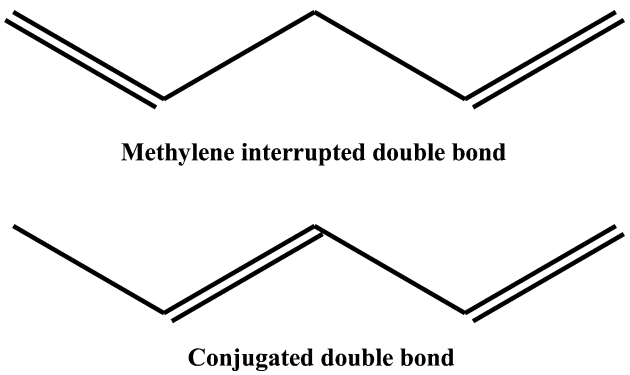

Fig. 1 Structure of conjugated double bonds

The Role of CLNA in Inflammatory Response and Immune Function

Structurally, CLNA isomers have much in common with the ω-3 fatty acid, α-linolenic acid, and the group of fatty acids known as the CLA isomers (*c*9,*t*11 and *t*10,*c*12 CLA isomers). In a number of studies, α-linolenic acid and the CLA isomers have been directly associated with anti-inflammatory and immune enhancing properties [17–19]. Investigations into the mechanisms through which these activities are mediated have highlighted the importance of (a) the down-regulation of eicosanoid production (prostaglandins and leukotrienes) [20, 21]; (b) increased peroxisome proliferator-activated receptor (PPAR) mediated anti-inflammatory response [22]; (c) suppression of inflammatory response through the regulation of the cell transcription factor Nuclear factor kappa B (NF-kB) [23, 24]; and (d) the reduced expression of pro-inflammatory proteins such as Tumor necrosis factor α (TNF-α), interleukin-6, and interleukin-1 beta, [22, 25, 26]. Additionally, both α-linolenic acid and the CLA isomers have been associated with improving the immune response in both animals and humans. In this regard, CLA isomers have been associated with reducing mitogen-induced T lymphocyte activation in humans [27] and improving immunoglobulin (Ig) profiles in both humans and animals [28, 29]. Similarly, α-linolenic acid has also been associated with improving immune response, reducing the proliferation of peripheral blood mononuclear cells without impacting on the concentration of helper and suppressor cells or T and B lymphocytes [30, 31].

The extent and range of the anti-inflammatory and immune enhancing activities shown by α-linolenic acid and the CLA isomers have prompted investigations into what impact, if any, CLNA isomers have on inflammation and immune response (Table 2). It was found that pomegranate seed oil (83% *c*9,*t*11,*c*13 CLNA) enhanced the function of B-cells, which play a prominent role in the humoral immune response [32]. In the study, increased production of IgG and IgM, two key immunoglobulins involved in the antigenic response and produced by B-cells was observed. During investigations into the affect of feeding a range of vegetables to mice on interferon-γ (IFN-γ) and interleukin-4, Ike et al. (2005) discovered the ability of bitter gourd to induce IFN-γ production in mice treated with heat inactivated *Propionibacterium acnes* [33]. IFN-γ is directly associated with Th1 T-helper cells, which play a crucial role in the cellular immune response, maximizing the killing efficacy of the macrophages and the proliferation of

cytotoxic CD8+ T cells [33]. Further investigations into the activity of bitter gourd demonstrated that while the pulp yielded the highest increases in IFN-γ, the peel and seed (sources of the *c*9,*t*11,*t*13 CLNA isomer) also resulted in increased IFN-γ production. Given these observations, more detailed investigations into the effect of the CLNA isomers on inflammation and immune response merit further study, particularly in light of the activity displayed by α-linolenic acid and the CLA isomers.

The Role of CLNA in Obesity

As one of the major health concerns facing the Western World, obesity and strategies to combat the condition have received substantial attention. In a number of studies, both α-linolenic acid and in particular the *t*10,*c*12 CLA isomer have proven themselves to be effective anti-adipogenic agents [3, 34–36]. The anti-adipogenic activity of α-linolenic acid has been attributed to factors such as (a) the high proportion of the fatty acid which undergoes β-oxidation [37–39], (b) the less efficient storage of α-linolenic acid in adipose tissue [40, 41], (c) the higher mobilization of stored α-linolenic acid from adipose tissue relative to linoleic acid [42] and d) the ability of α-linolenic acid to regulate genes associated with fatty acid metabolism [43–48]. Similarly, the anti-adipogenic activity of CLA has been attributed to (a) increased cellular β-oxidation [34], (b) the ability of the fatty acid to modulate the production of enzymes involved in fatty acid metabolism (particularly lipoprotein lipase and carnitine palmitoyltransferase) [49, 50], and (c) reduced proliferation and differentiation of preadipocytes [51, 52]. Interestingly, despite the strong evidence of the anti-adipogenic activity of the *t*10,*c*12 CLA isomer, the *c*9,*t*11 isomer has been significantly less effective in mediating anti-adipogenic activity [53–56].

N.D. Not determined, *N.S.* Not stated

The promise shown by α-linolenic acid and CLA isomers in the control of obesity has prompted investigations into the effect of the various CLNA isomers on the condition [1, 3, 57] (Table 3). Koba et al. (2002) found that the dietary intake of CLNA, prepared from α-linolenic acid via alkaline isomerisation, by Sprague–Dawley rats resulted in reductions in perirenal and epididymal adipose tissue and increased mitochondrial and peroxisomal *β*-oxidation [58]. Dietary pomegranate seed oil, rich in the *c*9,*t*11,*c*13 CLNA isomer has also been shown to reduce omental white adipose tissue weights in lean Long–Evans Tokusima Otsuka (LETO) rats but not abdominal white adipose tissue weights in obese, hyperlipidemic Otsuka Long Evans Tokushima Fatty (OLETF) rats [59]. Studies into the mechanisms behind the anti-adipogenic activity of the *c*9,*t*11,*c*13 CLNA isomer, using genetically modified rapeseed (2.5% of total fat was *c*9,*t*11,*c*13 CLNA) and ICR CD-1 mice, highlighted that dietary exposure to the isomer reduced leptin production and increased carnitine palmitoyl-transferase activity relative to the non-genetically modified control [60]. There is also evidence that the *t*8,*t*10,*c*12 CLNA isomer may decrease the body fat content of male mice [61]. Indeed, mice fed the isomer had a significantly lower percentage body fat than animals on the control diet. However, when the effects achieved with the *t*8,*t*10,*c*12 CLNA isomer were compared to those achieved with the *t*10,*c*12 CLA isomer, the reductions in body fat observed with the *t*10,*c*12 CLA isomer were found to be significantly greater.

There is some evidence to suggest that the anti-adipogenic activity of CLNA may stem not only from its ability to affect proteins such as leptin but also based on its ability to activate the nuclear receptor proteins, PPARs, and in particular PPARα. PPARα plays a key role in the activation of enzymes involved in lipid catabolism, and both the *c*9,*t*11,*t*13 CLNA isomer and *t*9,*t*11,*c*13 CLNA isomer have been directly associated with its activation [62]. Moreover, these CLNA isomers have been shown to increase the activity of acetyl-CoA carboxylase, a key enzyme involved in the peroxisomal *β*-oxidation of lipids under the control of PPARα.

The Role of CLNA in Cardio-Vascular Health

The dietary intake of α-linolenic acid, the non-conjugated parent form of the CLNA isomers has been associated with improving platelet function, cardiac arrhythmia, and atherosclerosis, all of which lend themselves to improved cardiovascular health [37, 38, 63–65]. Indeed, claims for this health promoting activity have been supported by a number of epidemiological studies, dietary trials and meta-analyses [37, 38, 66, 67]. These activities have been

N.D. Not determined

attributed to the impact of the fatty acid on eicosanoid production, sodium ion channels and low density lipoprotein (LDL) receptor activity [68–76]. Despite this evidence, further dietary trials and meta-analyses have drawn into question the claims of improved cardiovascular health while others have questioned the design of a number of the existing epidemiological studies [77–81]. In a number of in vitro and in vivo studies, the CLA isomers have displayed anti-atherosclerotic activity, though a consensus on the significance of this activity in humans is yet to be reached [82–85]. The existing evidence would suggest that any anti-atherosclerotic activity is mediated through effects on the expression of genes such as the LDL receptor gene and on acyl-coenzyme A:Cholesterol acyltransferase [86–88] and/or by their impact on the production of pro-inflammatory eicosanoids [21, 89, 90].

Like α-linolenic acid and the CLA isomers, the CLNA isomers have shown properties associated with improved cardiovascular health and in particular anti-hypercholesterolemic activity. In one such study, the *c*9,*t*11,*t*13 CLNA isomer was associated with significantly lowering total and non-high density lipoprotein (HDL) cholesterol in diabetic rats [91]. This activity may be mediated through the impact of the CLNA isomers on the secretion of apo-lipoprotein B100 and on PPARα (Table 4). Apo-lipoprotein B100 is an essential component of both very low density lipoprotein (VLDL) and LDL cholesterol types, which are associated with increased risk of coronary artery disease. Human hepatoma cells treated with the *c*9,*t*11,*c*13 CLNA isomer have been shown to produce less apo-lipoprotein B100 than cells treated with an equivalent concentration of α-linolenic acid [92]. Perhaps more significant is the increased activation of PPARα by CLNA given its role in lipid uptake and metabolism [93, 94]. Indeed, activators of PPARα such as fibrates have been directly associated with lowering serum cholesterol levels [95]. However, other studies such as that of Dhar et al. (1999) [96] have found no differences in plasma total, HDL, and non-HDL cholesterol when rats were fed *c*9,*t*11,*t*13 CLNA, relative to animals on the control diet. These results may suggest that the positive impact of CLNA on plasma cholesterol is limited to diabetic subjects.

Lipoprotein oxidation in vivo has been increasingly associated with the development and progression of atherosclerosis [97]. A number of natural compounds such as garlic oil, fenugreek, ferulic acid and CLA have been shown to possess antioxidant properties which may combat the oxidation of these lipoproteins. These observations have prompted investigations into the potential of CLNA to reduce lipoprotein oxidation during in vitro and in vivo studies (Table 4). In one such study, male albino rats fed a diet containing 0.5% by weight *c*9,*t*11,*t*13 CLNA were found to be significantly less susceptible to lipoprotein

Table 4 Assessing the effect of the conjugated isomers of α-linolenic acid (CLNA) on cardio-vascular disease

Model	Isomer (purity)	Dose and duration	Function	Potential mechanism of action	References
Cardio-vascular disease					
Male albino rats with alloxan induced diabetes	Bitter gourd seed oil (*c*9,*t*11,*t*13 CLNA) (55.7%)	0.5% wt diet, 6 weeks	↓ plasma total and non-HDL cholesterol, ↓ LDL and erythrocyte lipid peroxidation	Free radical scavenging	[91]
Male 4 week old C57BL/6 N mice	Pomegranate seed oil (*c*9,*t*11,*c*13 CLNA) (83.1%)	0.12–1.2% wt diet, N.S.	↑ plasma total cholesterol, significantly ↑ plasma TAG	N.D.	[32]
HepG2 human hepatoma	Bitter gourd seed oil (*c*9,*t*11,*t*13 CLNA)	100 μM/ml, 6–24 h	↓ apolipoprotein B100 secretion, ↓ TAG synthesis	Potentially reduces VLDL production	[92]
Male albino rats with alloxan induced diabetes	Bitter gourd seed oil (*c*9,*t*11,*t*13 CLNA) (51.1%)	0.5–10% wt diet, 4 weeks	↓ lipoprotein peroxidation, ↓ erythrocyte lipid peroxidation	Free radical scavenging	[96]
Diabetic and non diabetic human blood samples	Bitter gourd seed oil (*c*9,*t*11,*t*13 CLNA) (57.7%)	0.05–0.1% wt diet, N.S.	↓ plasma lipid peroxidation, lipoprotein peroxidation and erythrocyte membrane lipid peroxidation in both	Free radical scavenging	[98]
F344 rats with azoxymethane induced colonic aberrant crypt foci	Catalpa seed oil (*t*9,*t*11,*c*13 CLNA)	1.0% wt diet, 4 weeks	↓ serum triglyceride conc	N.D.	[138]

peroxidation and peroxidation of erythrocyte membrane lipids [96]. In rats with alloxan-induced diabetes mellitus, the *c*9,*t*11,*t*13 CLNA isomer also proved effective in reducing the oxidation of LDL cholesterol and of erythrocyte membrane lipids [91]. The antioxidant effect of *c*9,*t*11,*t*13 CLNA in relation to plasma lipoprotein is not exclusive to murine models. In a recent study, the in vitro antioxidant activity of the isomer in the blood of diabetic and non-diabetic humans was assessed [98]. The results showed that *c*9,*t*11,*t*13 CLNA significantly reduced plasma lipid peroxidation, lipoprotein peroxidation and erythrocyte membrane lipid peroxidation in both diabetic and non-diabetic blood samples.

The Role of CLNA in Cancer

α-Linolenic acid displays potent inhibitory effects on various cancer cell lines, such as colon cancer cells [99, 100], mammary cancer cells [101–104], melanoma cells [105] and hepatoma cells [106]. While reductions in the expression or cellular concentrations of cyclooxygenase-2 (COX-2) and prostaglandin synthesis were reported as contributing factors in the anti-carcinogenic activity of α-linolenic acid against most tumor types, other various tissue specific mechanisms were also identified [100, 103, 106, 107]. Reductions in the incidence of colon cancer in mice as a result of dietary inclusion of α-linolenic acid have been inversely associated with the concentration of *β*-catenin and protein kinase C-ζ [100]. Redistribution of *β*-catenin to its more 'normal' location in the membrane impairs activation of the nuclear Tcf/Lef transcription factor targeting proliferative genes. The anti-carcinogenic activity of α-linolenic acid against mammary cancer has been associated with reductions in expression of the oncogenes fatty acid synthase and human epidermal growth factor receptor 2 [108, 109] and also with the down-regulation of insulin-like growth factor 1 [102, 110, 111]. Vecchini et al. (2004) [106] associated the apoptotic activity of α-linolenic acid against hepatoma cells with reductions in the expression of sterol regulatory element binding proteins (SREBP), nuclear transcription factors which regulate lipid metabolism and lipogenic enzymes including fatty acid synthase. Interestingly, although the evidence pertaining to the anti-proliferative activity of α-linolenic acid is strong, a number of studies and meta-analysis have highlighted the potential increased risk of prostate cancer associated with increased α-linolenic acid intake [67, 112–114]. However, a large number of studies have found no significant relationship between dietary, blood and adipose tissue concentrations of α-linolenic acid and prostate cancer [115–118].

The CLA isomers have also been strongly linked with anti-carcinogenic properties against a range of tumors including those of the mammary gland, colon, skin and liver [1, 3, 119]. Much work has been conducted with regard to elucidating the mechanisms behind this anti-carcinogenic activity. The results have identified CLA isomers as effective modulators of (a) the expression of pro and anti-apoptotic oncogenes such as bcl-2, bax, bak, bad, p53, and p21, (b) eicosanoid synthesis (via their impact on COX-2 and cell membrane composition), and (c) the activity of cell transcription factors such as NF-kB and PPAR [1, 3, 119]. Additionally, conjugated fatty acids such as the CLA isomers, when incorporated into the membranes of cancer cells, can undergo lipid peroxidation leading to cellular apoptosis as a result of the increased oxidative stress [120, 121].

In light of the potent activity which both α-linolenic acid and the CLA isomers have displayed against a range of cancer types, much research has been directed towards identifying the effect that the various CLNA isomers have on cancer, both in vitro and in vivo. These investigations indicate that the various CLNA isomers differ substantially in their anti-carcinogenic properties and in the mechanisms through which this anti-carcinogenic activity is mediated (Table 5).

Pomegranate seed oil, rich in *c*9,*t*11,*c*13 CLNA, has been associated with inhibiting the incidence and multiplicity of chemically induced colonic aberrant crypt foci in male F344 rats via increased concentrations of the *c*9,*t*11 CLA isomer and expression of PPARγ in the colonic mucosa [122]. Pomegranate seed oil has also been associated with reducing the proliferation and invasion of the MCF-7 mammary cancer cell line and increasing apoptosis of the MDA-MB-435 mammary cancer cell line [123]. This anti-carcinogenic activity was potentially mediated through the anti-angiogenic properties of pomegranate seed oil and its ability to inhibit prostaglandin synthesis [124, 125]. Hora et al. (2003) [126] suggested that pomegranate seed oil could be a safe and effective chemopreventive agent against skin cancer. During their investigations, the oil was found to significantly reduce the incidence and multiplicity of chemically induced skin cancer, potentially through reduced ornithine decarboxylase activity.

Interestingly, pomegranate oil has also been associated with suppressing the proliferation and invasion of human prostate cancer despite the association of α-linolenic acid with the condition [67, 127] (Table 5). In one such study, dietary pomegranate seed oil rich in *c*9,*t*11,*c*13-CLNA was found to possess anti-proliferative activity against a range of prostate cancers in vivo, while in another, *c*9,*t*11,*c*13-CLNA was found to significantly reduce the invasiveness of the PC-3 prostate cancer cell line [128, 129].

One of the first investigations into the anti-carcinogenic activity of CLNA found that tung seed oil (67.7% *c*9,*t*11,*t*13 CLNA) was cytotoxic to a range of cancer cell lines at concentrations greater than 25 μM [130] (Table 5). Since that time, a range of further investigations have demonstrated that oils rich in *c*9,*t*11,*t*13 CLNA have anti-proliferative and apoptosis inducing activity against a range of cancers and in particular those of the colon [131–134]. A number of mechanisms have been suggested for this activity including the increased expression of PPARγ and the cell cycle arrest genes GADD45 and p53, along with decreased expression of the apoptosis suppressor Bcl-2 [131–133, 135]. In addition, increased lipid peroxidation within cancer cells, as a result of the uptake of *c*9,*t*11,*t*13 CLNA, has been proposed as contributing to the anti-carcinogenic effect of the isomer [134, 136]. A number of studies have compared the anti-carcinogenic properties of the *c*9,*t*11,*t*13 CLNA isomer or oils rich in the *c*9,*t*11,*t*13 CLNA isomer with that of CLA or certain anti-cancer drugs. When *c*9,*t*11,*t*13 CLNA was compared with both the *c*9,*t*11 and *t*10,*c*12 CLA isomers, the CLNA isomer was found to have stronger anti-carcinogenic activity against the DLD-1 colon cancer cell line than the CLA isomers [134]. Similarly, the *c*9,*t*11,*t*13 CLNA isomer was found to have a higher anti-carcinogenic activity than the PPARγ ligand, troglitazone [131, 132]. However, not all studies have observed the anti-carcinogenic properties of the *c*9,*t*11,*t*13 CLNA isomer. Kitamura et al. (2006) [137] assessed the impact of the isomer on chemically induced mammary and colon carcinogenesis in female Sprague–Dawley rats. The results indicated that treatment with the isomer resulted in only slight reductions in the incidence, multiplicity and volume of tumors.

The *t*9,*t*11,*c*13 CLNA isomer, the predominant conjugated fatty acid found in catalpa seed oil, has also been shown to possess anti-carcinogenic properties (Table 5). One of the first studies to highlight this anti-carcinogenic activity reported the cytotoxicity of the *t*9,*t*11,*c*13 CLNA isomer on transformed mouse fibroblast cell lines and on the human monocytic leukemia cell line U-937 [136]. Further investigations by the same group into this anti-carcinogenic activity showed the *t*9,*t*11,*c*13 CLNA isomer reduced the incidence of chemically induced colonic aberrant crypt foci in rats, increasing apoptosis and reducing proliferation of cancer cells [138]. These studies have inferred the role of increased lipid peroxidation and reduced expression of the enzyme COX-2 as mechanisms for this anti-carcinogenic activity. Interestingly, dietary supplementation of rats with catalpa seed oil (*t*9,*t*11,*c*13 CLNA rich) resulted in increased concentrations of *t*9,*t*11 CLA isomer in the colonic mucosa and liver. The *t*9,*t*11 isomer has previously been shown to decrease expression of Bcl-2, the anti-apoptotic oncogene, and may play a role

N.D. Not determined

in the apoptotic effect found with catalpa seed oil [120]. Yasui et al. (2006b) [133] compared the anti-proliferative and pro-apoptotic properties of the *t*9,*t*11,*t*13 CLNA isomer with that of the *c*9,*t*11,*c*13 CLNA isomer using the Caco-2 colon cancer cell line. Comparatively, the *t*9,*t*11,*t*13 CLNA isomer was significantly more cytotoxic to the Caco-2 colon cancer cell line than the *c*9,*t*11,*c*13 CLNA isomer. In this study, it was found that exposure of the Caco-2 cells to the *t*9,*t*11,*t*13 CLNA isomer stimulated cellular apoptosis via increases in cellular DNA fragmentation, increased expression of the pro-apoptotic oncogene bax, and decreased expression of Bcl-2. Increased lipid peroxidation was also shown to play a role in this anti-carcinogenic activity. However, the observation that the *t*9,*t*11,*t*13 CLNA isomer remained active even in the presence of elevated concentrations of the anti-oxidant α-tocopherol is suggestive that cancer cell apoptosis triggered by increased cellular lipid peroxidation is not at least the predominant mechanism behind the anti-carcinogenic activity of the *t*9,*t*11,*t*13 CLNA isomers.

The *t*8,*t*10,*c*12 and *t*8,*t*10,*t*12 CLNA isomers derived from pot marigold have also been shown to possess some anti-carcinogenic properties (Table 5). The *t*8,*t*10,*c*12 CLNA isomer has displayed apoptotic activity against a range of cancers including the human monocytic leukaemia cell line U-937 and the Caco-2 colon cancer cell line [133, 136]. Investigations into the oxidative stability of the fatty acid and the impact of the antioxidants BHT and α-tocopherol led the authors to conclude that the anti-carcinogenic activity of the isomer was related to lipid peroxidation (Table 5). The anti-carcinogenic activity of the *t*8,*t*10,*t*12 CLNA isomer has also been investigated using the Caco-2 cell line [133]. In this study,*t*8,*t*10,*t*12 CLNA exhibited substantial cytotoxicity to the Caco-2 cell line and caused a substantial increase in the level of DNA fragmentation. However, the mechanism behind this anti-carcinogenic activity remained unclear and could only partially be attributed to increased cellular lipid peroxidation, as the *t*8,*t*10,*t*12 CLNA isomer remained active even in the presence of α-tocopherol.

Comparatively, the anti-carcinogenic activity of the CLNA isomers varies substantially. When the cytotoxicity of the *c*9,*t*11,*c*13, the *c*9,*t*11,*t*13, and the *t*9,*t*11,*c*13 CLNA isomers were compared to that of the *t*8,*t*10,*c*12 CLNA isomer using the U-937 monocytic leukemia cell line and the SV-T2 transformed mouse fibroblast cell line, the 9, 11, 13-CLNA isomers displayed much greater activity [136]. Yasui et al. (2006b) assessed the impact that the trans content of CLNA had on its apoptotic activity using the Caco-2 cancer cell line. The results showed that all trans CLNA isomers (*t*9,*t*11,*t*13 and *t*8,*t*10,*t*12) were more inhibitory to Caco-2 growth than their partial trans counterparts (*t*9,*t*11,*c*13 and *t*8,*t*10,*c*12). When compared to the CLA isomers (*c*9,*t*11 and/or *t*10,*c*12 CLA), tung and bitter gourd seed oils (rich in the *c*9,*t*11,*t*13 CLNA isomer) and pomegranate seed oil (rich in the *c*9,*t*11,*c*13 CLNA isomer) displayed higher anti-carcinogenic activities against colon cancers than the CLA isomers [122, 131, 134]. These investigations highlight the impact of bond position, bond number and bond conformation on the properties of these conjugated fatty acids.

CLNA Metabolism in Vivo

Investigations into the metabolism of CLNA have suggested that mammals rapidly convert 9,11,13-CLNA isomers to 9,11-CLA via a Δ^{13}-saturation reaction catalyzed by a NADPH dependent enzyme [122, 135, 138–140]. Hence, it may be CLA rather than CLNA which exerts its bioactivity in vivo. Interestingly, when rats were supplied with equivalent concentrations of CLA or CLNA, it was CLNA which caused the highest increase in CLA concentrations in both the non-lesional mucosa and liver, potentially explaining the higher anti-carcinogenic activity seen with CLNA. Despite this evidence, not all studies have witnessed the high conversion of CLNA to CLA in vivo. Plourde et al. (2006) [11] found that when Wistar rats were fed a mixture of CLNA isomers (i.e. *c*9,*t*11,*c*15 and *c*9,*t*13,*c*15 isomers), CLNA could be detected in the liver, blood plasma and adipose tissue, while the *c*9,*t*11 CLA isomer could not. This might suggest that n-5 CLNA isomers such as the 9,11,13-CLNA typically found in plants and seed oils, and n-3 CLNA isomers such as 9,11,15-CLNA produced by bacteria may have very different metabolic fates and hence, their activity on disease and health may differ substantially.

Conclusions

The ability to produce conjugated fatty acids is shared by certain plants and microbes, which though different in their chemical structure, often share common bioactivity. This is also true of the various conjugated isomers of CLNA which have been shown to display potent inflammatory and immune modulating properties, reduce the risk of obesity, improve cardiovascular health, and mediate strong anti-carcinogenic activity during in vitro studies and in animal models. These diseases represent some of the greatest mortality risks to humans in the Western world and have been inextricably linked with diet. Thus far, the information pertaining to the mechanisms through which the CLNA isomers impart their bioactivity show strong parallels to that of the CLA isomers. Indeed, in this regard both the CLNA isomers and the CLA isomers have been

shown to impart activity both at an endoplasmic (eicosanoid synthesis) and nuclear levels.

Although there is a plethora of evidence from in vitro studies and animal models to support the bioactive properties of CLNA, there are very limited data from human studies involving these isomers. Consequently, it is difficult to clearly establish the role of biologically active CLNA isomers in improving human health. Moreover, as certain CLA isomers have previously been associated with adverse activities in humans, a better understanding of the impact of CLNA isomers in the human diet is of paramount importance before any recommendations regarding their dietary intake can be made. In conclusion, better controlled human studies are required before CLNA or CLNA enriched foods can be recommended to humans with any degree of certainty that improved health and well-being can be achieved without any negative effects [128, 141–146].

Abstract The well-documented link between α-synuclein and the pathology of common human neurodegenerative diseases has increased attention to the synuclein protein family. The involvement of α-synuclein in lipid metabolism in both normal and diseased nervous system has been shown by many research groups. However, the possible involvement of γ-synuclein, a closely-related member of the synuclein family, in these processes has hardly been addressed. In this study, the effect of γ-synuclein deficiency on the lipid composition and fatty acid patterns of individual lipids from two brain regions has been studied using a mouse model. The level of phosphatidylserine (PtdSer) was increased in the midbrain whereas no changes in the relative proportions of membrane polar lipids were observed in the cortex of γ-synuclein-deficient compared to wild-type (WT) mice. In addition, higher levels of docosahexaenoic acid were found in PtdSer and phosphatidylethanolamine (PtdEtn) from the cerebral cortex of γ-synuclein null mutant mice. These findings show that γ-synuclein deficiency leads to alterations in the lipid profile in brain tissues and suggest that this protein, like α-synuclein, might affect neuronal function via modulation of lipid metabolism.

Introduction

The synuclein family comprises three small, closely-related, natively unfolded proteins, α-, β- and γ-synuclein, that are expressed predominantly in neural tissues. Alpha- and β-synucleins are abundant in the neurons of the central

nervous system (CNS) and concentrated within presynaptic terminals where they are loosely associated with synaptic vesicles. γ-Synuclein is mainly cytosolic and expressed in the neurons of the peripheral nervous system (PNS) and certain populations of CNS neurons. γ-Synuclein is also expressed in some malignant tumours and may be involved in tumorigenesis and metastasis [1].

Aggregated and fibrillated forms of α-synuclein are major components of Lewy bodies, histological hallmarks of hereditary and idiopathic forms of Parkinson's disease (PD). Moreover, several mutations in SNCA, a gene encoding α-synuclein, are associated with early onset autosomal dominant PD [2–7] and polymorphisms of this gene are risk factors for PD and other diseases associated with α-synuclein aggregation [8–12]. The accumulation of aggregation intermediates, i.e. partially or fully soluble oligomeric forms of α-synuclein, is believed to be the principle pathogenic event responsible for neuronal dysfunction [13–16] and interactions with lipids play an important role in oligomerisation of α-synuclein [17–19]. Interestingly, β- and γ-synucleins may act to suppress α-synuclein aggregation and toxicity [20].

In immortalised cell lines and primary neuronal cultures, both WT and PD mutant α-synuclein could be found associated with the phospholipid surface layer of lipid droplets [21] and are enriched in lipid rafts [22]. In the rafts, α-synuclein was associated with specific PtdSer species containing polyunsaturated fatty acids (PUFA) [23] or with gangliosides [24, 25]. Moreover, polyunsaturated fatty acyl groups were shown to promote multimerisation of α-, β-, and γ-synucleins [26] and lipid-associated oligomers of α-synuclein have been detected in the brain of patients with α-synucleinopathies [27, 28]. It has been suggested that α-synuclein—PUFA interactions can reciprocally regulate neuronal PUFA levels and the oligomerisation stage of α-synuclein in normal and disease nervous system [27, 28].

The importance of PUFA in brain structure and functions is well established [29]. These fatty acids, especially arachidonic acid (C20:4n-6, ARA) and docosahexaenoic acid (C22:6n-3, DHA), are enriched in certain brain phospholipids, for example, in PtdIns and PtdEtn, respectively [30]. In animal models, an inadequate supply of n-3 fatty acids during prenatal and early postnatal development decreases DHA levels in the brain. As a result, adult animals develop learning and memory deficits, which can be improved by dietary supplementation of DHA or other n-3 PUFA, e.g. α-linolenic acid (C18:3n-3, LnA) [31–33]. In humans, mental development may be improved by dietary DHA supplementation during infancy [34]. Conversely, low levels of DHA in human brains are associated with the risk of developing neurological diseases such as generalised peroxisomal disorders [35] and Alzheimer's disease (AD) [36, 37]. In contrast, elevated levels of DHA, docosatetraenoic acid and linoleic acid have been shown in those brain areas of PD patients that contain α-synuclein inclusions [28].

Although the precise mechanism of DHA-enriched phospholipid action on cognitive function is still poorly understood, possible effects on the blood–brain barrier, membrane fluidity, activity of certain enzymes, neural signalling, ionic channels, and control of nerve growth factor have all been suggested [38]. Recently, a neuroprotective action of the n-3 PUFA, DHA and LnA, in PD has been also demonstrated using rat and mice models of this disease [39, 40]. Interestingly, expression of genes encoding α-synuclein and γ-synuclein increased in brains of rats fed high n-3 PUFA diets [38]. In turn, an important role of α-synuclein in brain lipid metabolism as well as for fatty acid uptake and metabolism has been documented [41–43].

In contrast to the well-studied role of α-synuclein in lipid metabolism in the normal and diseased nervous systems, very little is known about the involvement of γ-synuclein in these processes. Nevertheless, some recent studies demonstrated that γ-synuclein is directly involved in lipid metabolism in mature adipocytes ([44, 45] and our unpublished observations). Therefore it was logical to investigate a possible link between γ-synuclein and lipids in the nervous system.

Here we analysed lipid composition and fatty acid patterns of individual lipids from brain regions of γ-synuclein null mutant (gammaKO) mice. We found that the level of PtdSer is increased in the midbrain whereas no changes in the relative proportions of membrane lipid classes were observed in the cerebral cortex of these animals. In addition, higher percentages of DHA were found in both PtdSer and PtdEtn from the cerebral cortex of gammaKO mice. These data suggest a role for γ-synuclein in lipid metabolism in the nervous system and are discussed in relation to what is known about alterations of lipid metabolism in α-synuclein-deficient animals.

Experimental Procedures

Materials

FA standards were obtained from Nu-Chek-Pre. Inc. (Elysian, MN) and silica gel G plates were from Merck KGaA (Darmstadt, Germany). Lipid standards were from Sigma (Poole, UK). Other reagents were of the best available grades and were from Fisher Scientific (Loughborough, UK).

Experimental Animals

All animal work was carried in accordance with the United Kingdom Animals (Scientific Procedures) Act (1986). Production of γ-synuclein null mutant mice on a pure (C57Bl6J, Charles River) genetic background and the method of animal genotyping by PCR have been described previously [46, 47]. For this study, male γ-synuclein null mutant mice and their WT littermates were kept in individual cages from the age of 9 weeks with access to water and food ad libitum. Animals were fed special diet DOI 58Y2 with 10% energy from fats (LabDiets). No significant differences in animal weight and food uptake were observed between groups of mutant and WT animals throughout the experimental period. In order to evaluate the effect of γ-synuclein deficiency on the lipid composition in the fully-developed nervous system, tissues of young but fully mature (21 week-old) adult mice were analysed.

Lipid Analysis

At the age of 21 weeks animals were fasted for 4 h before killing by lethal injection of phenobarbital. Lipids were extracted immediately from dissected brain regions by a modified Folch method [48]. In this procedure [originally developed for mitochondrial lipids such as cardiolipin (Ptd_2Gro)] efficient extraction even of highly polar compounds is ensured.

Polar lipids were separated by two-dimensional TLC on 10 × 10 cm 1.2% boric acid-impregnated silica gel G plates using chloroform: methanol: ammonium hydroxide (65:25:4; v/v/v) in the first dimension and then *n*-butanol: acetic acid: water (90:20: 20; v/v/v) in the second. Plates were sprayed with 0.05% (wt/vol) 8-anilino-4-naphthosulphonic acid in methanol and viewed under UV light to reveal lipids. Preliminary identification was made by reference to authentic standards and confirmed using specific colour reagents [49]. Additionally, the structural identification of lipids was confirmed by mass spectrometry (see next paragraph for details). Non-polar lipids were separated using 1-dimensional TLC on 10 × 10 cm silica gel G plates with double development using toluene: hexane: formic acid (140:60:1, v/v/v) for the entire plate followed by hexane: diethyl ether: formic acid (60:40:1, v/v/v) to half height. Individual lipids were scraped from the TLC plates and their fatty acid compositions and contents were determined by gas chromatography using an internal standard of pentadecanoate (for details, see "Fatty Acid Analysis" section below) [49].

Mass spectrometry was performed on an Applied Biosystems 4000 Q-Trap. Lipid extracts were diluted in methanol and introduced at 10 μl/min into the electrospray source operating in the negative ion mode. All scans were obtained using an ionspray voltage of −4,500 V and a declustering potential of −140 V. Q1 scans were performed scanning a mass range of 600–1,000 amu over 4 s, with 10 scans acquired and averaged. MS/MS scans using the ion trap mode of the Q-Trap were run at a scan rate of 1,000 amu/s with collision energies of −50 and −60 V, and a linear ion trap (LIT) fill time of 150 ms with Q0 trapping enabled. Again 10 scans were acquired and averaged and the data analysed using the software Analyst 1.4.1.

Fatty Acid Analysis

Fatty acid methyl esters (FAME) were prepared by transmethylation with 2.5% H_2SO_4 in dry methanol/toluene (2:1, by vol.). FAME were separated using a Clarus 500 gas chromatograph (Perkin-Elmer, Norwalk, Connecticut) fitted with a 30 m × 0.25 mm i.d. capillary column (Elite 225, Perkin Elmer). The oven temperature was programmed: 170 °C for 3 min, heated to 220 °C at 4 °C/min, held at 220 °C for 15 min. FAME were identified routinely by comparing retention times with fatty acid standards (Nu-Chek Prep. Inc., Elysian, USA) but confirmation of the structure of the major fatty acids had also been made by MS. Quantification was made with an internal standard of pentadecanoate.

Statistics

Statistical significance between groups was assessed by Student's *t* test.

Results

Fatty Acid Composition of Diet

The fatty acid composition of the diet used is presented in Table 1. It contained oleic acid as a major compound (35% of total diet FA) followed by linoleic (25%), palmitic (20%) and stearic (13%) acids. The relative amount of α-linolenic (an essential n-3 fatty acid) was low and did not exceed 2.5% of total FA. Thus, the ratio of n-6/n-3 fatty acids was high giving a value of 13 whereas a balanced human diet is believed to range from 1:1 to 1:4 [50]. Lipids accounted for 10% of total energy in this diet.

Fatty Acid Composition of Plasma

Fatty acid composition of plasma from WT and γ-synuclein null mutant mice (gammaKO) is present in Table 1. Palmitic, stearic, oleic, linoleic and arachidonic acids were the

Data as means ± SD ($n = 3$ for diet and $n = 5$ for plasma)

Fatty acids are indicated with the number before colon showing the number of carbon atoms, the figure afterwards denoting the number of double bonds. The position of the first double bond is shown in brackets. Only the major fatty acids (≥0.5%) are listed

n.d. none detected; *tr* trace <0.5%

The asterisk (*) indicates a significant effect of γ-synuclein deficiency when compared with WT ($p < 0.05$)

major fatty acids in plasma together with a moderate amount of DHA in both, WT and gammaKO mice. The relative amount of oleic acid was increased significantly in the plasma of gammaKO mice compared to WT (Table 1).

Cortex and Midbrain Fatty Acid Composition of the Total Polar Lipids in WT and γ-Synuclein Null Mutant Mice

Table 2 shows the FA profile of the total polar lipid fractions from cortex or midbrain in WT and gammaKO mice. Palmitic and stearic acids were dominant FA in cortex followed by DHA, oleic acid and ARA. In midbrain, stearic and oleic acids were the major compounds followed by palmitic, DHA and ARA. The percentages of palmitic, arachidonic and DHA in total polar lipids were significantly higher in the cortex region compared to midbrain in both WT and gammaKO mice, whereas proportions of oleic and nervonic (C24:1) acids were higher in this lipid fraction from midbrain. There were no statistically significant differences in the relative proportions of fatty acids from the total polar lipid fraction between WT and gammaKO mice in either brain region.

The hash (#) indicates significant differences between midbrain and cortex in WT animals ($p < 0.05$)

Polar Lipid Composition of Cortex and Midbrain Regions from WT and gammaKO Mice

The relative proportions of different polar lipids in the two brain regions are shown in Fig. 1. Three phospholipids, namely phosphatidylcholine (PtdCho), ethanolamine phospholipids and PtdSer, were the major polar lipids in both brain regions (accounting for about 70–80% of the total polar lipids). Phosphatidylinositol (PtdIns), sphingomyelin (CerPCho), Ptd_2Gro as well as sulfatide and cerebroside were present in smaller proportions and were each less than 5% of the total polar lipids. Sulfatides and cerebrosides were identified by electrospray ionisation tandem mass spectrometry (ESI–MS-MS) [51, 52]. The relative amounts of polar lipids did not vary much between midbrain and cortex samples from WT animals, although the levels of sulfatides and PtdCho were higher and lower, respectively, in the midbrain region (Fig. 1). In this brain region, γ-synuclein deficiency resulted in a statistically significant (∼40%) increase in the relative proportion of PtdSer compared to WT animals, whereas the proportions of other lipids were not altered significantly (Fig. 1). No differences in the polar lipid composition were found in the cortex of WT compared to gammaKO mice (Fig. 1). Also, no differences in the concentrations of total polar lipids and triacylglycerols (TAG) were observed for these brain regions as a result of γ-synuclein deficiency (data not shown).

See legend to Table 1 for identification of fatty acids

Effect of γ-Synuclein Deficiency on the Fatty Acid Composition of Individual Polar Lipid Classes in Cortex and Midbrain

Figures 2, 3 and Table 3 show data on the fatty acid composition for the major polar lipids in cortex and midbrain from WT and gammaKO mice. These data show a fatty acid distribution typical of that for murine brain tissues.

PtdCho in both cortex and midbrain is characterised by a domination of palmitate (about 48 and 40% in cortex and midbrain, respectively), stearate (14 and 16%) and oleate (21 and 24%) with much lower levels of the two major brain long-chain polyunsaturated fatty acids, ARA and DHA (Table 3). In the cortex, the relative concentrations of ARA and DHA in PtdCho were about 6 and 3%, respectively. In the midbrain, about 4% of each of ARA and DHA was found in PtdCho. The levels of all above mentioned fatty acids were significantly different between the two brain regions. In contrast, there were no significant differences in these parameters between WT and gammaKO mice.

PtdIns is enriched with two fatty acids, stearic (around 44% in both cortex and midbrain) and ARA (37 and 34% in cortex and midbrain, respectively). DHA is a minor component in PtdIns and its relative concentration was about 2% in cortex and 4% in midbrain, these being significantly different. γ-Synuclein deficiency resulted in an increased level of ARA in PtdIns in cortex but did not affect the fatty acid profiles of this lipid in midbrain (Table 3).

Oleic and ARA were the major acids found in brain Ptd$_2$Gro. In this lipid, another C18:1 isomer, *cis*-vaccenic acid, was also present in appreciable amounts especially in the midbrain (around 11 vs. 7% in cortex). The relative concentration of ARA was higher in Ptd$_2$Gro from the cortex than in Ptd$_2$Gro from the midbrain (18 and 13%,

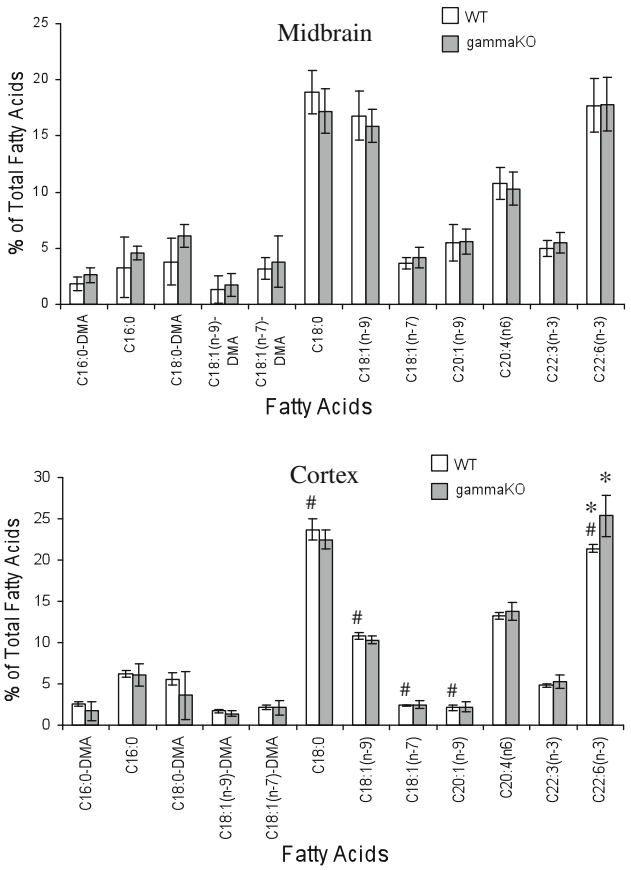

Fig. 3 Fatty acid and dimethylacetal composition of ethanolamine phospholipids from midbrain or cortex in wild-type (WT) and γ-synuclein null mutant (gammaKO) mice. Values represent mean ± SD, $n = 5$. The *asterisk* (*) indicates a significant effect of γ-synuclein deficiency when compared with WT, and the *hash* (#) indicates significant differences between midbrain (*top panel*) and cortex (*bottom panel*) in WT animals ($p < 0.05$ for both)

respectively). In comparison to other polar lipids isolated from the brain, Ptd_2Gro contains higher levels of C16 and C18 monoenic acids, namely C16:1n-7 (up to 5%), C18:1n-9 (up to 38%) and C18:1n-7 (up to 15%). The proportion of the latter was significantly higher in the midbrain than in cortex at the expense of arachidonic acid (Table 3). No statistically significant changes were found when comparing Ptd_2Gro fatty acid profiles in the cortex between WT and gammaKO animals, whereas in midbrain the proportion of C18:1n-7 was increased in gammaKO mice compared to WT (Table 3).

CerPCho from both cortex and midbrain contains stearic acid as its main fatty acid (up to 81% of total FAs in cortex, and up to 65% of that in midbrain). The presence of two very long chain acids, lignoceric (C24:0) and nervonic (C24:1n-6), is also characteristic for this lipid. Their levels were higher in midbrain than cortex. CerPCho fatty acids were unchanged as a response to γ-synuclein deficiency in

Data as means ± SD ($n = 6$–7)

See legend to Table 1 for other details

The asterisk (*) indicates a significant effect of γ-synuclein deficiency when compared with WT ($p < 0.05$). The hash (#) indicates significant differences between midbrain and cortex in WT animals ($p < 0.05$)

the cortex whereas in the midbrain decreased percentages of C18:0 was found.

Fatty acids from both sulfatides and cerebrosides did not show any differences between cortex and midbrain. γ-Synuclein deficiency resulted in a decreased proportion of lignoceric acid in sulfatides and cerebrosides in the cortex (Table 3). In midbrain region, a reduced relative proportion of behenic acid (C22:0) was found in cerebrosides in gammaKO mice (Table 3).

The fatty acid composition of PtdSer and PtdEtn which, in brain tissues, represent two lipid classes significantly enriched with the n-3 PUFA, DHA, are shown in Figs. 2 and 3, respectively. For PtdSer, the levels of both C18:0 and DHA were higher in cortex compared to midbrain while oleate was reduced (Fig. 2). Moreover, the level of DHA in PtdSer was significantly increased in the cortex of gammaKO mice compared to WT animals (30.0 and 25.8% of total FA, respectively) with a concomitant decrease in the proportion of stearate (C18:0) (Fig. 2). PtdEtn contained both ARA and DHA as major fatty acids and, similar to PtdSer, the proportion of DHA was enhanced significantly in cortex tissue (25.4%) in gammaKO mice as compared to control (21.4%). The proportions of ARA were unaffected by γ-synuclein deficiency in PtdEtn from both cortex and midbrain tissues (Fig. 3). In addition to fatty acids from the diacyl form of PtdEtn, we also analysed the profile of dimethylacetal (DMA) derivatives that represent aliphatic chains from ether derivatives (mainly plasmalogens) of PtdEtn (Fig. 3). Four DMA were identified with a domination of C18:0-DMA, but no significant changes in the relative proportion of these compounds in cortex and midbrain were found between WT and gammaKO mice.

In addition to the polar lipid classes described above, a C2-ceramide, *N*-acetylsphingosine, was present in lipid extracts from both cortex and midbrain in small but significant amounts [53]. The structure of this ceramide was elucidated by using ESI–MS (data not shown).

Discussion

The importance of lipids in neural tissue physiology and cell signalling has been demonstrated by the association of lipid imbalances and/or deregulated lipid metabolism with the development of various CNS disorders, including Alzheimer's disease, Parkinson's disease, Niemann–Pick disease, multiple sclerosis, Huntington's disease, amyotrophic lateral sclerosis, schizophrenia, bipolar disorders and epilepsy [54]. Recently, relationships between glucosylsphingosine accumulation due to mutations in the glucocerebrosidase gene (*GBA*) and Parkinsonism as well as dementia with Lewy bodies, have been reported [55, 56]. Because alterations in brain lipid biochemistry have been previously linked to the α-synuclein deficiency [41, 57] and since γ-synuclein and α-synuclein are closely-related proteins, whose functions are potentially redundant [47, 58, 59], it was clearly important to evaluate if γ-synuclein might also be involved in brain lipid homeostasis. In our study we examined the lipid composition of two brain regions, the midbrain that exhibits relatively high level of γ-synuclein expression, and the cerebral cortex, where expression level of this protein is substantially lower [46, 60].

No effect of γ-synuclein deficiency on the total polar lipid content and TAG accumulation in the cerebral cortex and midbrain was revealed in our work (data not shown). This contrasts to studies with α-synuclein deficient mice where an increase in TAG content of the whole brain has been demonstrated [41].

The mitochondria-specific phospholipid, Ptd_2Gro, which was found in both regions studied (4% of the total polar lipids), was not affected by γ-synuclein deficiency (Fig. 1). The fatty acid profile of Ptd_2Gro was also almost the same (Table 3). This was different from α-synuclein deficient mice that had a reduced total brain Ptd_2Gro content with a strongly altered acyl chain composition, a mitochondrial lipid abnormality possibly associated with electron transport chain impairment in the brain of PD patients [42].

Therefore, it is unlikely that the γ-synuclein deficiency affects mitochondrial function in the nervous system.

Similar to α-synuclein deficiency [41], γ-synuclein deficiency did not change the level of ethanolamine phospholipids (Fig. 1). The plasmenyl species of PtdEtn are important phospholipid components of most electroactive cellular membranes, such as cardiac sarcolemma and neuronal cell membranes. Between one-half and two-thirds of the ethanolamine phospholipids in the whole brain are in plasmalogen form, and 11–12% of myelin phospholipids are plasmalogens [61]. A deficiency of ethanolamine plasmalogens has been shown to be associated with aging and some degenerative diseases, especially those associated with peroxisomal disorders [62–64]. The absence of ethanolamine plasmalogen alterations is consistent with only mild alterations in normal neural function in both α-synuclein and γ-synuclein deficient mice. However, further comparative studies of aging mice would be important, due to various effects of aging on their nervous systems [65].

Among polar lipids, only the relative proportion of PtdSer changed in gammaKO in comparison to WT mice (Fig. 1). This change was evident only in the midbrain region where expression of γ-synuclein is much higher than in the cerebral cortex [46]. Although this increase was relatively minor in the whole midbrain tissue, the changes in PtdSer content may be much more pronounced in specific neuronal populations since γ-synuclein has been shown to be expressed only in a subset of midbrain neurons [46]. Previously, increases in PtdSer have been noted in plasma membrane phospholipids from affected regions of AD brains [63] where they may induce formation of amyloid fibers [66]. It is also of note, that PtdSer has roles in apoptosis, in the regulation of many enzymes and in control of the channel function of the acetylcholine receptor [62, 67, 68]. Thus, alteration in PtdSer may have implications for neuronal cell functions. However, the changes observed were not sufficient for triggering pathological alterations in the nervous system of γ-synuclein deficient mice [46, 47, 59].

Three lipid classes in brain contain high levels of PUFA. Whereas PtdSer and PtdEtn are enriched in DHA, PtdIns contains substantial amounts of ARA. When comparing midbrain and cortex regions, the latter was enriched in ARA but depleted in DHA (Table 2). These differences may be partly explained by higher content of PtdCho (Fig. 1), which possesses elevated levels of ARA, in the cerebral cortex (Table 3). Interestingly, statistically significant changes were found in the relative amount of PtdSer in the midbrain region of γ-synuclein null mutant mice (Fig. 1) and in the DHA content of both PtdSer (Fig. 2) and ethanolamine phospholipids (Fig. 3) in the cerebral cortex. Because only a limited number of cortical neurons normally express γ-synuclein, changes of DHA levels in these cells might be much more profound than those revealed by analysis of total cortex phospholipids. It is noteworthy that although α-synuclein null mutant mice had slightly decreased levels of DHA in the whole brain PtdEtn and PtdSer, an increased uptake of this fatty acid into brain phospholipids has also been reported [69]. It is well known that DHA is essential to perinatal neurological development during which it increases in the CNS. The high demand for DHA in the brain is maintained either by dietary supply or by biosynthesis from α-linolenate within the liver [33]. Since no very long-chain PUFA were present in the diet, and no changes in the liver (data not shown) or plasma PUFA profiles (Table 1) were found, we suggest that the differences in DHA levels are most likely related to possible effects of γ-synuclein deficiency on DHA metabolism in the developing brain. Alternatively, complete absence of γ-synuclein might trigger systemic changes, including alterations in adipose and other tissues normally expressing this protein, that activate compensatory mechanisms during brain development.

There is a growing body of evidence about the importance of PUFA in brain function where its deficiency is associated with cognitive decline during aging and with neurodegenerative diseases [70]. The beneficial neurophysiological role of DHA most probably relates to metabolites such as eicosanoids and other autacoids which are important as modulators of membrane microdomain composition, receptor signalling and gene expression [71]. Recent studies demonstrated a role for neuroprotectin D1 (NPD1) in the homeostatic regulation of brain cell survival and repair involving neurotrophic, anti-apoptotic and anti-inflammatory signalling in AD [70]. Unfortunately, there is no information about the possible involvement of such DHA metabolites in PD. But the gammaKO mutants, which exhibit higher levels of DHA accumulation in certain brain regions, may be a useful model for future research in this area.

Acknowledgments This work was supported by the Wellcome Trust Programme Grant to VLB. We are also grateful for equipment funding provided by the Wellcome Trust (VO'D, JLH).

Abstract Cardiovascular safety of cyclooxygenase (COX)-2-selective inhibitors and nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) is of worldwide concern. COX-2 inhibitors and NSAIDs act by inhibiting arachidonic acid metabolism to prostaglandins. They confer a cardiovascular hazard manifested as an elevated risk of myocardial infarction. Mechanisms underlying these cardiovascular effects are uncertain. Here we determine whether interference with cytosolic phospholipase A2 (cPLA-2) or COX-2 through pharmacologic blockade or silencing RNA impacts expression of scavenger receptor CD36 and scavenger receptor A, both involved in cholesterol uptake in monocytes and macrophages. THP-1 human monocytes and human peripheral blood mononuclear cells were exposed to celecoxib, a COX-2 selective inhibitor currently in clinical use, and to arachidonyl trifluoromethyl ketone (AACOCF3), an arachidonic acid analog that selectively inhibits cPLA-2. Celecoxib and AACOCF3 each upregulated expression of CD36, but not scavenger receptor A, as determined by quantitative PCR and immunoblotting. Silencing of cPLA-2 or COX-2 had comparable effects to pharmacologic treatments. Oil red O staining revealed a profound increase in foam cell transformation of THP-1 macrophages exposed to either celecoxib or AACOCF3 (both 25 μM), supporting a role for the COX pathway in maintaining macrophage cholesterol homeostasis. Demonstration of disrupted cholesterol balance by AACOCF3 and celecoxib provides further evidence of the possible mechanism by which COX inhibition may promote lipid overload leading to atheromatous lesion formation and increased cardiovascular events.

Keywords Cyclooxygenase · Atherosclerosis · Gene transcription · Cholesterol · Arachidonic acid

Abbreviations

AACOCF3	Arachidonyl trifluoromethyl ketone
COX	Cyclooxygenase
cPLA-2	Cytosolic phospholipase A2
FCS	Fetal calf serum
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
IFN	Interferon
HRP	Horseradish peroxidase
LDL	Low density lipoprotein
NSAIDs	Nonsteroidal anti-inflammatory drugs
PBMC	Peripheral blood mononuclear cells
PMA	Phorbol 12-myristate 13-acetate
RCT	Reverse cholesterol transport
ScR-A	Scavenger receptor A
TGF	Transforming growth factor

Introduction

Atherosclerosis is a leading cause of death and impairment in developed countries and is the underlying cause of myocardial infarction, stroke, and peripheral artery disease

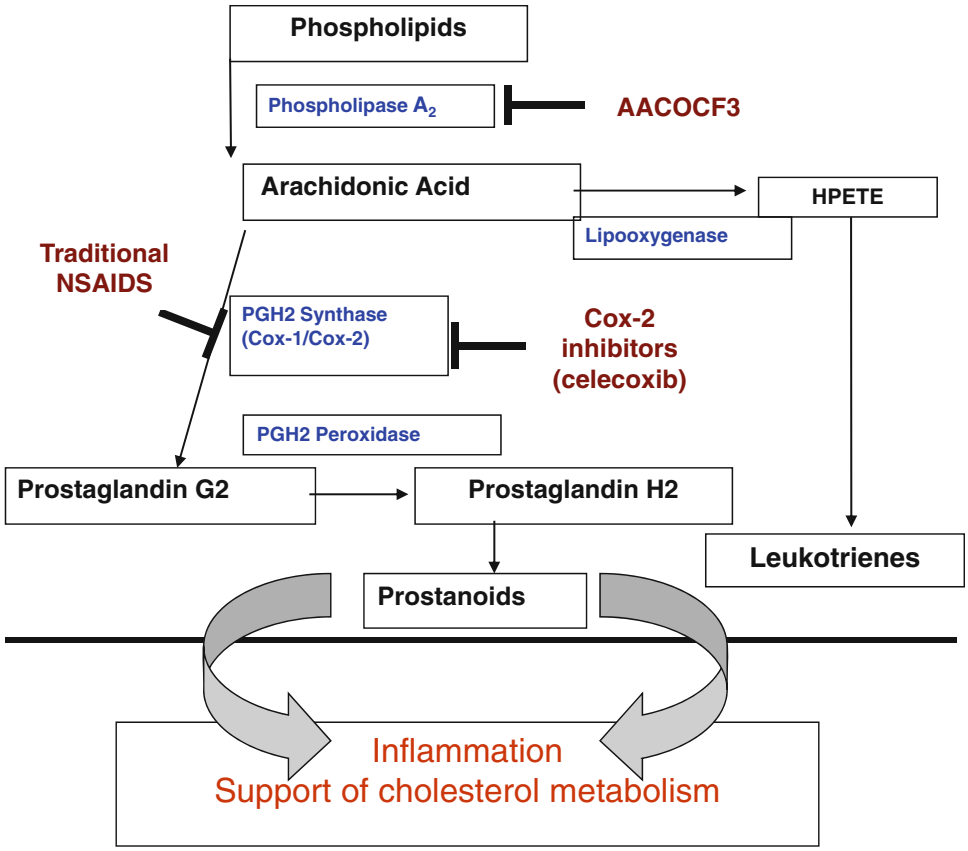

Fig. 1 Molecular pathway for formation of eicosanoids and prostanoids and where different drugs have their effects. cPLA-2 catalyzes the release of arachidonic acid from cell membrane phospholipids. Specific blockade of cPLA-2 with AACOCF3 abrogates eicosanoid synthesis through the arachidonic acid pathway. COX converts arachidonic acid to endoperoxide-containing intermediates to produce prostanoids–prostaglandins and thromboxanes. NSAIDs and COX-2 specific inhibitors reduce formation of these prostanoids, bioactive lipid mediators that support normal cholesterol flux

[1, 2]. It is characterized by accumulation of cholesterol and its esters in the vessel wall, either within macrophage foam cells or as extracellular lipids, including free cholesterol crystals. Unlike the classical low density lipoprotein (LDL) receptor, which is downregulated by increasing cellular cholesterol levels, the ability of scavenger receptors on the macrophage surface to take up modified LDL is not inhibited by increasing cellular cholesterol [3]. Substantial quantities of modified forms of LDL may be internalized by macrophages via scavenger receptors whose expression is not controlled by cholesterol loading, leading to foam cell formation [4, 5]. Lipid-laden foam cells are found within the sub-endothelial space of the arteries in fatty streak lesions, which are the first recognizable atherosclerotic lesions, as well as in more-advanced unstable atherosclerotic plaques.

It is now well-established that endocytic uptake of atherogenic lipoproteins by macrophages or macrophage-derived cells is mainly mediated by scavenger receptors, including scavenger receptor A (ScR-A) and CD36 [6]. The CD36 scavenger receptor is specific for nitrated LDL and oxidized LDL, the most atherogenic forms of modified LDL.

Inhibition of cyclooxygenase (COX) by either non-steroidal anti-inflammatory drugs (NSAIDs), which inhibit both COX-1 and COX-2 isoforms, or by COX-2 specific inhibitors (coxibs) provides analgesia and anti-inflammatory efficacy [7]. Coxibs and NSAIDs have been associated with increased frequency of cardiovascular toxicity and an elevated risk of acute myocardial infarction [8, 9]. The COX-2 inhibitors rofecoxib and valdecoxib have been withdrawn from the market, and two other coxibs failed to receive approval due to cardiovascular concerns [10–12].

The mechanisms underlying cardiovascular effects of coxibs are uncertain [13]. Our laboratory has previously demonstrated that both the NSAID indomethacin and the COX-2-selective inhibitor NS398 suppress expression of cholesterol 27-hydroxylase and ABCA1, proteins involved in reverse cholesterol transport (RCT) from the periphery to the liver for metabolism [14, 15]. This observation led us to propose that interference with normal cholesterol outflow from macrophages accelerates atheroma development, contributing to the cardiovascular consequences of coxib administration and that these effects may be reversible. In the present study, we extend our examination to determine whether interference with the COX/arachidonic acid pathway impacts expression of scavenger receptor genes involved in cholesterol uptake in human monocytes/macrophages. Our study used the COX-2 specific inhibitor celecoxib as well as arachidonyl trifluoromethyl ketone (AACOCF3), a cell-permeable trifluoromethyl ketone analog of arachidonic acid that selectively inhibits cytosolic phospholipase A2 (cPLA-2) (Fig. 1).

The effect of COX-2 and cPLA-2 inhibition on CD36 is measured against known effects of specific cytokines. In a follow-up to our previous reports that the pro-atherogenic cytokine interferon (IFN)-γ suppresses RCT proteins and increases foam cell formation in THP-1 human macrophages [16–18], we compare the impact of IFN-γ to COX/arachidonic acid pathway inhibition on the expression of CD36 and ScR-A1. Since the cytokine TGF-β may be involved in cardiovascular pathophysiology and has been reported to downregulate expression of scavenger receptors ScR-A and CD36, in human macrophages [19, 20], TGF-β was used as a known control in these studies.

Experimental Procedures

Cell Culture

THP-1 monocytes (American Type Culture Collection, Manassas, VA) were cultured in RPMI 1640 supplemented with 10% fetal calf serum (FCS), 2 mM L-glutamine and 50 μg per ml of penicillin–streptomycin at 37 °C in a 5% CO_2 atmosphere to a density of 10^6 cells per ml. Cell culture media and supplementary reagents were obtained from Invitrogen (Grand Island, NY). Differentiation of the monocytic THP-1 cells into adherent macrophages was stimulated by 48 h of exposure to 100 nM phorbol 12-myristate 13-acetate (PMA), obtained from Sigma–Aldrich (St. Louis, MO). When differentiated phenotype was achieved, the PMA-containing medium was removed, and replaced with complete RPMI 1640, supplemented with 10% FCS. The macrophages were cultured for another 24 h before treatment. THP-1 in both monocyte and macrophage states were subjected to the experimental conditions described below.

Human peripheral blood mononuclear cells (PBMC) were isolated from fresh blood obtained from healthy donors. The investigation conforms with the principles outlined in the Declaration of Helsinki. Approval for use of human blood was granted by the Winthrop University Hospital Institutional Review Board. Blood was collected in EDTA treated tubes, adjusted to a density of 1.120 g/ml with the addition of OptiPrep Density Gradient Media (Sigma–Aldrich, St. Louis, MO), according to the manufacturer's instructions. The blood was then overlaid with a 1.074 g/ml density solution composed of complete RPMI 1640 containing 10% FCS and OptiPrep Gradient Media. A layer of complete RPMI containing 10% FCS was then overlaid on top to prevent monocytes from sticking to the plastic tube. The blood was centrifuged at 750*g* for 30 min at 4 °C, then the monocyte interphase was collected from between the 1.074 g/ml and RPMI layers. The collected cells were diluted with two volumes of complete RPMI and harvested by centrifugation. The pellet was resuspended in complete RPMI. The monocytes were then counted with a hemocytometer and plated at a density of 2×10^6 cells/well in 6-well plates. Cells were maintained in complete RPMI 1640, supplemented with 10% FCS and were subjected to the experimental conditions described below.

Experimental Conditions

THP-1 monocytes, THP-1 macrophages and PBMC were incubated in six-well plates at 37 °C in a 5% CO_2 atmosphere for 18 and 24 h in RPMI media under the following six conditions: (1) no additions (untreated control); (2) DMSO vehicle (solvent control); (3) IFN-γ (500 U/ml); (4) celecoxib (25 μM); (5) AACOCF3 (25 μM); (6) transforming growth factor (TGF)-β (120 pg/ml).

AACOCF3 was purchased from Sigma–Aldrich (St. Louis, MO). Recombinant human IFN-γ and TGF-β were purchased from R&D Systems, Inc. (Minneapolis, MN). Celecoxib was obtained from Pfizer (New York, NY). AACOCF3 and celecoxib were dissolved in DMSO (Sigma, Indianapolis, IN) to form 100X stock solutions [21, 22].

Immediately after the incubation period, the cells were collected and centrifuged at 1,500 rpm at room temperature, media was aspirated, and cell protein and RNA were isolated.

Transfection of Small Interfering (si) RNA

Transfection of THP-1 monocytes was carried out when they achieved 70% confluence, approximately 24 h after seeding. Transfection was performed in serum-free medium using siRNA transfection reagent (Santa Cruz, CA, sc-29528). Cells were transfected for 6 h with 100 nM of human COX-2 and cPLA-2 small interfering RNA (siRNA) (Santa Cruz, CA, sc-29528 and sc-29280), or irrelevant non-targeting control siRNA-A (Santa Cruz, CA, sc-37007) according to the manufacturer's protocol. Cells were then further incubated for 24–72 h under standard growth conditions. At 24–72 h post-transfection, depletion of COX-2 was confirmed and expression of CD36 and ScR-A1 were analyzed by quantitative real-time (QRT)-PCR and immunoblotting.

RNA Isolation and cDNA Preparation

Total RNA was isolated using 1 ml per 10^6 cells of Trizol reagent (Invitrogen, Grand Island, NY). The quantity of total RNA from each condition was measured by absorption at 260 and 280 nm wavelengths by ultraviolet spectrophotometry (Hitachi U2010).

All reverse transcription reactions were carried out in an Eppendorf Mastercycler®-personal PCR thermocycler (Eppendorf, Hamburg, Germany). All reagents for reverse transcription and PCR were purchased from Applied Biosystems (Chicago, IL). For each reverse transcription reaction, 1 μg of total RNA was reverse transcribed using 50 units of Murine Leukemia Virus (MuLV) reverse transcriptase in the presence of 20 units of RNase inhibitor in a final volume of 20 μl. The reaction mixture contained 5 mM $MgCl_2$, 0.4 mM of each dNTP, 2.5 μM oligo dT primers and random hexamers. The reaction mixtures were incubated at 42 °C for 90 min. This was followed by heating at 95 °C for 5 min and cooling to 4 °C for 5 minutes. Final cDNA was diluted 10 times for the following QRT-PCR reaction.

Analysis of CD36 and ScR-A1 Message by QRT-PCR

QRT-PCR analysis was performed using the FastStart SYBR Green Reagents Kit according to the manufacturers' instructions on the Roche Light Cycler 480 (Roche Applied Science, Indianapolis, IN). 8 μl of cDNA were amplified using CD36 (forward primer 5′-GAGAACTGTTATGG GGCTAT-3′, reverse primer 5′-TTCAACTGGAGAG-G CAAAGG-3′) [23, 24] and ScR-A1 (forward primer 5′-CT CGTGTTTGCAGTTCTCA-3′; reverse primer 5′-CCATG TTGCTCATGTGTTCC-3′) [25] specific primers. Primers used in amplification reactions were generated by Sigma-Genosys (The Woodlands, TX).

Each reaction was done in triplicate. The amounts of PCR products were estimated using software provided by the manufacturer (Roche Applied Science). To correct for differences in cDNA load among samples, the target PCRs were normalized to a reference PCR involving the endogenous housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Specific primers were used for GAPDH amplification: forward primer 5′-ACCATCATC CCTGCCTCTAC-3′, reverse primer 5′-CCTGTTGCTGT AGCCAAAT-3′.

Non-template controls were included for each primer pair to check for significant levels of any contaminants. A melting-curve analysis was performed to assess the specificity of the amplified PCR products.

Protein Isolation and Western Blot

Cellular extracts were prepared for Western immunoblotting using radioimmunoprecipitation assay (RIPA) lysis buffer (98% PBS, 1% Igepal, 0.5% sodium deoxycholate, 0.1% SDS), supplemented with 10 μl per ml of protease inhibitor cocktail (Sigma–Aldrich). Protein content was measured in triplicate using the BCA Protein Assay Kit by absorption at 562 nm (Pierce Biotechnology Inc., Rockford, IL).

Protein samples (10 μg/lane) were boiled for 5 min, and fractionated on 8% SDS-PAGE, and transferred onto a nitrocellulose membrane (Bio-Rad, Hercules, CA). The membrane was stained with Ponceau red (Sigma–Aldrich) to verify uniformity of protein loading in each lane.

The membrane was blocked for 1 h at room temperature in blocking solution [3% nonfat dry milk (Bio-Rad) in 1X Tris-buffered saline/1% Tween 20 (TTBS)] and then immersed in a 1:500 dilution of primary antibody overnight at 4 °C. The following day, the membrane was washed and then incubated in a 1:5,000 dilution of ECL horseradish peroxidase (HRP)-linked species-specific whole antibody in blocking solution.

The immunoreactive proteins were detected using Pierce ECL Western Blot substrate system, and film development in SRX-101A (Konica Minolta Holdings, Inc., Tokyo, Japan). Stripping and reprobing of the membranes were performed according to the manufacturer's protocol (ECL kit instructions, Thermoscientific, Rockford, IL).

Mouse anti-human CD36 IgM primary antibody (sc-7309) and goat anti-mouse HRP conjugated IgM secondary antibody (sc-2064) were obtained from Santa Cruz Biotechnology (Santa Cruz, CA).

Goat anti-human macrophage ScR-A1 IgG polyclonal antibody (P21757) was purchased from Millipore (Billerica, MA). Donkey anti-goat IgG-HRP conjugated secondary antibody (sc-2020) was obtained from Santa Cruz Biotechnology (Santa Cruz, CA).

As a loading control, on the same transferred membrane, β-actin was detected using mouse anti-β-actin (diluted in 1:1,000) (Abcam, Cambridge, UK). IgG-HRP conjugated antibody was used as a secondary antibody (GE Healthcare Biosciences, Piscataway, NJ).

Band intensities for Western blot protein samples were quantified using Kodak Digital Science 1D, version 2.0.3, after imaging with Kodak Digital Science Electrophoresis Documentation and Analysis System 120.

Foam Cell Formation

THP-1 cells (10^6 cells per ml) were transferred into 8-well glass-chamber slides, then treated with PMA (100 nM, 48 h, 37 °C) to stimulate differentiation into macrophages. Cells were cholesterol-loaded with 50 μg/ml acetylated LDL or 50 μg/ml oxidized LDL (Inracel, Frederick, MD), then further incubated in RPMI 1640 for 48 h under the following five conditions: (1) untreated control, (2) IFN-γ (500 U/ml); (3) celecoxib (25 μM); (4) AACOCF3 (25 μM); (5) TGF-β (120 pg/ml). Following incubation, media was aspirated, slides were washed with PBS and fixed in 4% paraformaldehyde in water for 10 min. Cells were then washed in distilled water and stained with 0.2%

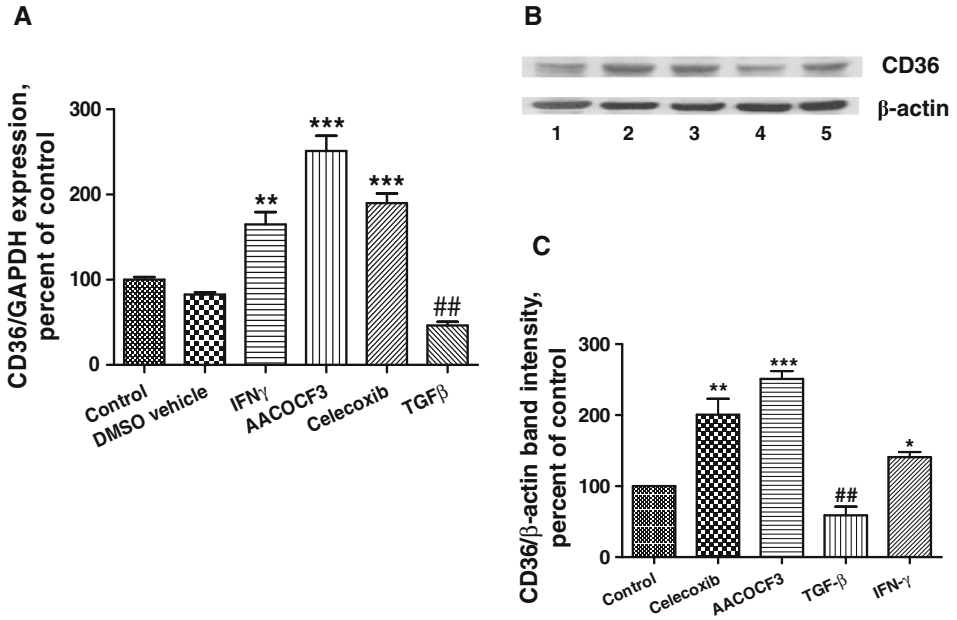

Fig. 2 Effect of COX-2 inhibition by celecoxib and cPLA-2 inhibition by AACOCF3 on CD36 expression in THP-1 macrophages. **a**. Relative CD36 mRNA abundance increases upon exposure to celecoxib or AACOCF3. THP-1 macrophages were incubated for 18 h under the following six conditions: (1) media alone, (2) vehicle (DMSO), (3) IFN-γ (500 U/ml), (4) AACOCF3 (25 μM), (5) celecoxib (25 μM), (6) TGF-β (120 pmol/ml). Total RNA was isolated from cells exposed to each condition. RNA was reverse transcribed and CD36 message was analyzed by QRT-PCR. Gene expression levels were graphed as relative mRNA expression. The expression of CD36 was normalized to that of GAPDH. The data represent the mean and SEM of five independent experiments ($n = 5$). $^{**}P < 0.01$ versus controls, $^{***}P < 0.001$ versus controls, $^{\#\#}P < 0.01$ versus IFN-γ, celecoxib, AACOCF3. **b** Western blot analysis using CD36-specific antibody. Oil Red O (Sigma) for 30 min. After the PBS wash, cell nuclei were stained with hematoxylin (Sigma) for 5 min. After a final wash with PBS, coverslips were mounted on slides using Permount solution (Sigma).

Foam cells, recognized as macrophages stained with Oil Red O, were visualized via light microscopy (Axiovert 25; Carl Zeiss, Gottingen, Germany) with 40× magnification and photographed using a DC 290 Zoom digital camera (Eastman Kodak, Rochester, NY). Number of foam cells formed in each condition was calculated in triplicate manually and presented as a percentage of the total cells.

Data Analysis

Statistical analysis was performed using Graphpad Prism, version 5.01 (GraphPad Software, San Diego, CA). All data were analyzed by one-way analysis of variance, and pairwise multiple comparisons were made between control and treatment conditions using Bonferroni correction. P values less than 0.05 were considered significant.

Results

Celecoxib and AACOCF3 Exposure Increase CD36, But Not ScR-A1 Expression in THP-1 Macrophages and Monocytes

Celecoxib significantly increased CD36 message in THP-1 macrophages. In these mRNA and protein studies, we compared treated THP-1 macrophages to untreated control cells with mRNA and protein expression for untreated control set at 100%. Celecoxib (25 μM) raised CD36 mRNA to 186.77 ± 25.43% of control ($P < 0.001$, $n = 5$). Solvent control reduced CD36 message slightly to 87.64 ± 4.6% (Fig. 2a). AACOCF3 treatment had an effect comparable to celecoxib on CD36 expression in THP-1 macrophages. 25 μM AACOCF3 at 18 h of incubation markedly stimulated expression of CD36 (251.03 ± 39.99%, $P < 0.001$, $n = 5$) (Fig. 2a).

The concentration of celecoxib used was in the range of prior in vitro cell culture studies [26, 27]. Significant upregulation of CD36 message in THP-1 macrophages was

THP-1 macrophages were incubated for 24 h under the following five conditions: (1) media alone, (2) celecoxib (25 μM), (3) AACOCF3 (25 μM), (4) TGF-β (120 pmol/ml), (5) IFN-γ (500 U/ml]. β-actin was detected on the same membrane as a loading control. **c** Graphic representation of immunoblot results for ScR-A1 protein expression with normalization to β-actin. Conditions are the same as in part B. The data represent the mean and SEM of three independent experiments ($n = 3$), NS

detected at celecoxib concentrations as low as 10 μM, simultaneously with abrogation of COX-2 expression (supplementary data Figure 1, not shown). Incubation of THP-1 macrophages with celecoxib at concentrations exceeding 25 μM had a toxic effect on the cells.

Protein expression, as determined by Western blot, confirmed the same pattern of alterations in CD36 expression after celecoxib and AACOCF3 treatment. Thus, celecoxib increased protein expression of CD36 by 100.7 ± 12.9% and AACOCF3 by 151.1 ± 11.9% versus expression in untreated THP-1 macrophages, as normalized to β-actin expression ($P < 0.01$ and $P < 0.001$, $n = 3$, respectively) (Fig. 2b, c).

Consistent with the previously shown pro-atherogenic properties of IFN-γ [17, 18, 28], incubation of THP-1 macrophages with IFN-γ for 18 h resulted in upregulation of CD36 expression to 164.9 ± 32.1% ($P < 0.01$, $n = 5$) for the message and to 140.9 ± 12.6% ($P < 0.05$, $n = 3$) for the protein (Fig. 2).

In contrast to the documented changes in CD36 expression in THP-1 macrophages after celecoxib and AACOCF3 treatment, ScR-A1 expression was not significantly affected by these compounds. Only incubation of THP-1 macrophages with TGF-β, our known control, for 48 h had a significant impact on the ScR-A1 message. We observed a decrease in ScR-A1 expression to 29.93 ± 3.38% of untreated THP-1 macrophages and 91.1 ± 0.29% of DMSO vehicle ($P < 0.05$, $n = 5$) (Fig. 3a). Nevertheless, none of the treatments significantly changed the protein expression of ScR-A1 (Fig. 3b, c).

Equivalent results were obtained in THP-1 monocytes under the conditions described above (supplemental data Figure 2, not shown).

Celecoxib and AACOCF3 Treatment Increases CD36, but Not ScR-A1 in PBMC

Exposure to either celecoxib or AACOCF3 caused a significant increase in CD36 message in human PBMC (Fig. 4a). In these mRNA studies, we compared treated PBMC to untreated control PBMC with mRNA for untreated control set at 100%. Incubation with celecoxib (18 h, 25 μM) resulted in upregulation of the CD36 message to 206.550 ± 32.3% versus untreated PBMC ($P < 0.01$, $n = 3$). AACOCF3 (18 h, 25 μM) stimulated expression of CD36 to 214.83 ± 36.2% ($P < 0.01$, $n = 3$).

Incubation of PBMC with IFN-γ for 18 h upregulated CD36 mRNA expression to 176.90 ± 17.6% ($P < 0.05$, $n = 5$) (Fig. 4a).

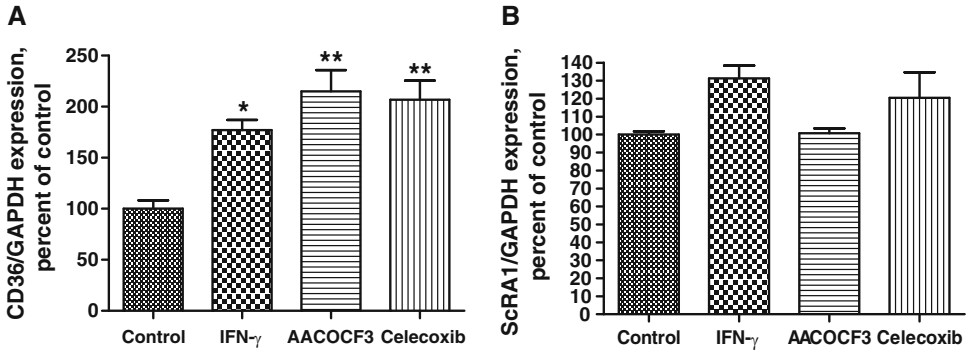

Fig. 4 Effect of COX-2 inhibition by celecoxib and cPLA-2 inhibition by AACOCF3 on CD36 and ScR-A1 mRNA expression in human PBMC. Monocytes from human peripheral blood were incubated for 18 h under the following four conditions: (1) media alone, (2) IFN-γ (500 U/ml), (3) AACOCF3 (25 μM), (4) celecoxib (25 μM). Following incubation, total RNA was isolated from cells exposed to each condition. RNA was reverse transcribed, CD36 and ScR-A1 messages were analyzed by QRT-PCR. The expressions of target genes were normalized to that of GAPDH. **a** CD36 gene expression graphed as relative mRNA expression and compared with results obtained from untreated PBMC. The data represent the mean and SEM of three independent experiments ($n = 3$), $^{*}P < 0.05$ versus PBMC control cells in media alone, $^{**}P < 0.01$ versus control cells. **b** ScR-A1 gene expression graphed as relative mRNA expression and compared with results obtained from untreated PBMC. The data represent the mean and SEM of three independent experiments ($n = 3$), NS

As in the THP-1 monocyte/macrophage system, incubation of PBMC with either celecoxib or AACOCF3 had no significant effect on the expression of ScR-A1 (Fig. 4b).

COX-2 or cPLA-2 Silencing in THP-1 Monocytes Upregulates CD36

Treatment of THP-1 monocytes with 100 nM of COX-2 and cPLA-2 siRNAs (48 h) downregulated the expression of COX-2 mRNA to 45.6 ± 3.48% and 48.97 ± 5.31% respectively, compared to control siRNA transfected cells ($P < 0.01$ and 0.01, $n = 3$ for each, respectively,) (data not shown). Both silencing of COX-2 and silencing of cPLA-2 resulted in upregulation of CD36 message to 156.7 ± 13.68% and 169.5 ± 15.77% respectively, versus mock transfected cells ($P < 0.01$ and 0.01, $n = 3$ for each, respectively) (Fig. 5a).

Incubation of THP-1 cells with COX-2 siRNA and cPLA-2 siRNA for 56 h resulted in significant stimulation of CD36 protein expression (Fig. 5b, c). Thus, transfection with COX-2 siRNA resulted in enhancement of CD36 expression to 139.2 ± 10.68% of mock-transfected control ($P < 0.01$, $n = 3$), which is comparable to the effect of celecoxib treatment on THP-1 monocytes for 24 h (150.1 ± 12.56%, $P < 0.01$, $n = 3$). cPLA-2 siRNA-mediated pathway inhibition and AACOCF3 treatment for 24 h resulted in 197.3 ± 34.67% and 192.7 ± 24.77% upregulation of CD36 protein expression, respectively ($P < 0.001$ and 0.001, $n = 3$ for each). Again, the pharmacologic blockade achieved enhancement of CD36 almost equivalent to the effect observed with silencing of the same target.

Celecoxib and AACOCF3 Augment Foam Cell Transformation in Lipid-laden THP-1 Macrophages

Acetylated LDL-treated THP-1 macrophages showed a significant increase in foam cell transformation in the presence of either celecoxib or AACOCF3 (Figs. 6, 7). Incubation of lipid-laden THP-1 macrophages with celecoxib resulted in 49.7 ± 5.773% of macrophages becoming foam cells vs. 25.57 ± 7.37% foam cells formed in untreated THP-1 macrophages, ($P < 0.01$, $n = 4$) (Fig. 7a). AACOCF3 treatment similarly promoted foam cell transformation in 59.11 ± 3.83% versus 25.57 ± 7.37% of cells in untreated THP-1 macrophages, ($P < 0.001$, $n = 4$) (Fig. 7). Comparable results were observed when THP-1 macrophages were pre-incubated with oxidized LDL (supplementary data Figure 3, not shown).

As additional evidence for the pro-atherogenic nature of IFN-γ, consistent with our previous reports [16, 17], we observed a significant elevation of foam cells to 50.37 ± 3.83% in IFN-γ treated THP-1 macrophages versus 25.57 ± 7.37% of foam cells formed in untreated THP-1 macrophages ($P < 0.01$, $n = 4$) (Figs. 6, 7).

Exposure of lipid-laden macrophages to TGF-β did not significantly alter the percentage of foam cells (Fig. 7).

Discussion

We report here that CD36 expression in human monocytes increases with inhibition of the arachidonic acid/COX pathway and specifically by celecoxib. To our knowledge,

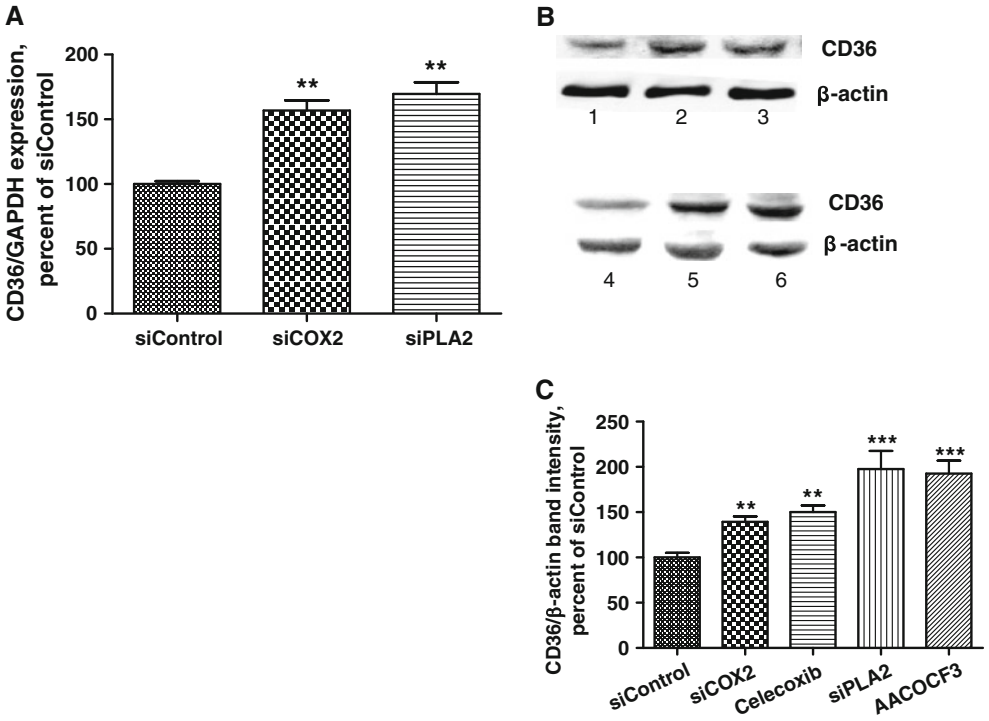

Fig. 5 Effect of COX-2 knockdown by COX-2 and PLA-2 siRNA on CD36 expression in THP-1 monocytes. **a** Relative CD36 mRNA abundance increases upon exposure to siCOX-2 and siPLA-2. THP-1 monocytes were transfected with 100 nM of: (1) siControl, (2) siCOX-2, (3) siPLA-2 and cultured for 48 h. Total RNA was isolated from cells exposed to each condition. RNA was reverse transcribed and CD36 message was analyzed by QRT-PCR. Gene expression levels were graphed as relative mRNA expression. The expression of CD36 was normalized to that of GAPDH. The data represent the mean and SEM of three independent experiments ($n = 3$). $^{**}P < 0.01$ versus siControl transfected cells. **b** Western blot analysis using human CD36-specific antibody. THP-1 monocytes were incubated for 56 h post-transfection of siControl, siCOX-2, siPLA-2 and for 24 h in the presence of celecoxib and AACOCF3. Total protein extracts were analyzed by Western blot for CD36 protein expression: (1) siControl, (2) siCOX-2, (3) celecoxib (25 μM), (4) siControl, (5) siPLA-2, (6) AACOCF3 (25 μM). β-actin was detected on the same membrane as a loading control. **c** Graphic representation of immunoblot results for CD36 protein expression with normalization to β-actin. Conditions are the same as in part B. The data represent the mean and SEM of three independent experiments ($n = 3$). $^{**}P < 0.01$ versus siControl, $^{***}P < 0.001$ versus siControl

this is the first demonstration that CD36 is regulated by a COX-2 inhibitor currently in use in humans. CD36 is a transmembrane, highly N-linked glycosylated glycoprotein expressed on the cell surface of monocytes/macrophages where it is the major receptor responsible for high-affinity recognition of oxidized LDL by macrophages and where it is thought to play important functions in inflammation and vascular biology [29, 30]. CD36 is responsible for over 50% of total modified LDL uptake into human monocyte-derived macrophages [31, 32]. In transgenic mice, knocking out CD36 on the pro-atherogenic apoE-null background reduces atherosclerosis [33]. These double-null mice show a 70–80% reduction in aortic lesion size when compared to apoE null mice. Further, macrophages from CD36-deficient mice exhibit a reduced uptake of modified LDL and are resistant to foam cell formation [33, 34]. Peripheral monocyte-derived macrophages from humans with genetic deficiency of CD36 have reduced uptake and degradation of oxidized LDL. Cholesteryl ester mass accumulation following exposure to oxidized LDL was reduced by approximately 40% in the macrophages from CD36-deficient subjects as compared to cells from normal controls [31]. Anti-CD36 monoclonal antibody reduced by 50% the specific binding of oxidized LDL to human peripheral blood monocyte-derived macrophages [35]. Upregulation of CD36 may contribute to the pathological process of atherosclerosis by promoting macrophage lipid overload and also by fostering cytoskeletal rearrangements that enhance cell spreading and inhibit emigration from lesions [31, 36]. It is likely that the observed phenotype of COX2/cPLA-2 inhibition is the result of multiple lipid regulation pathways gone awry. We previously reported on the suppression of lipid efflux by COX-2 inhibition [14]. Now, additionally, we report CD36 upregulation with COX2/cPLA-2 inhibition. This upregulation has the potential to further exacerbate the cellular lipid load.

Demonstration of disrupted cholesterol homeostasis by AACOCF3 and celecoxib provides further evidence of the possible mechanism through which COX inhibition by traditional NSAIDs or COX-2 specific inhibitors may cause

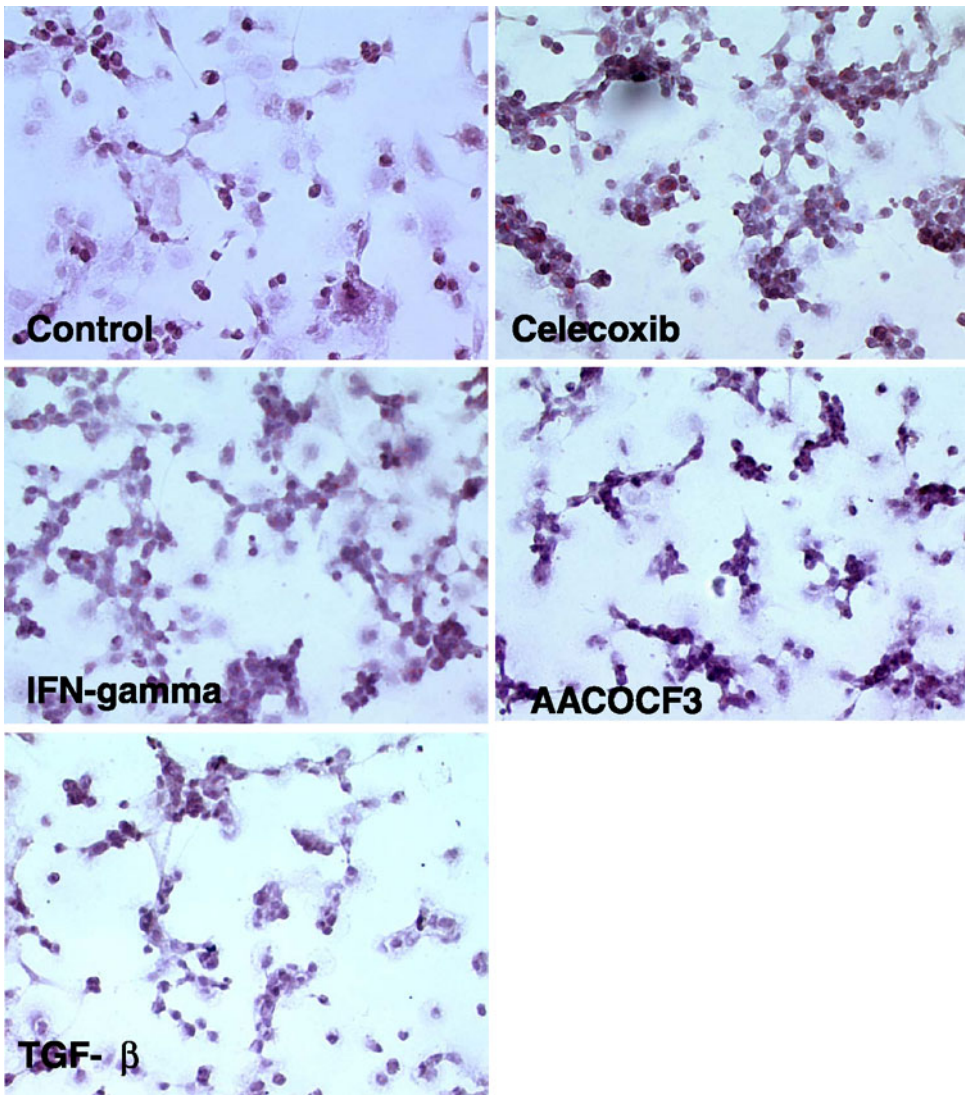

Fig. 6 Foam cell formation in THP-1 macrophages under cholesterol loading conditions is augmented by celecoxib or AACOCF3. THP-1 differentiated macrophages were treated with acetylated LDL (50 μg/ml, 48 h). Cells were then exposed for 48 h to the following five conditions: (1) untreated control, (2) IFN-γ (500 U/ml); (3) celecoxib (25 μM); (4) AACOCF3 (25 μM); (5) TGF-β (120 pg/ml). Representative light photomicrograph at magnification ×40 of Oil red O staining to detect foam cells

early atheromatous lesions leading to increased cardiovascular events.

The contribution of the leukotriene pathway, generated from arachidonic acid and not blocked by COX-2 inhibitors, must be considered. Although the role of leukotrienes in atherosclerosis is not clearly defined, they play a key role in aneurysm formation in mice [37, 38]. It has been shown that enzymes responsible for the biosynthesis of leukotrienes are highly expressed in human atherosclerotic lesions. There is also evidence that the 5-lipoxygenase and leukotriene A4 hydrolase expression, and hence, leukotriene production, are higher in patients with vulnerable atherosclerotic plaques as opposed to patients with stable lesions [39, 40]. Furthermore, it has been reported that all human cell types involved in atherosclerosis have leukotriene B4 receptors. Future studies involving specific blockade of the leukotriene pathway will illuminate its importance in macrophage lipid homeostasis.

One noted consequence of COX-2 inhibition that has been implicated in cardiovascular toxicity is disruption of the balance of thromboxane/prostaglandin I2 [41]. Namely, COX-2 inhibition suppresses prostaglandin I2 and prolonged suppression of prostaglandin I2 leads to deletion of its specific Gs-coupled I prostanoid receptor. A balance between thromboxane and prostaglandin I2 modulates vascular wall-platelet interactions. Thromboxane amplifies the aggregatory responses of platelets to all known agonists, whereas prostaglandin I2 impedes aggregation. Additionally, prostaglandin I2 has been shown to afford protection against oxidant injuries. Prostaglandin I2 appears to contribute to atheroprotection.

The relationship between COX and CD36 has been explored previously. In 2003, Sennlaub and colleagues [42]

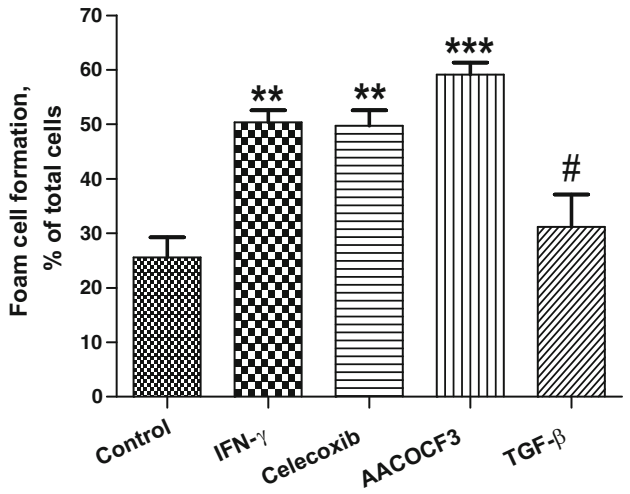

Fig. 7 Effect of celecoxib and AACOCF3 on foam cell transformation in THP-1 macrophages under cholesterol loading conditions. THP-1 macrophages were treated with acetylated LDL (50 μg/ml, 48 h). Cells were then exposed for 48 h to the following five conditions: (1) untreated control; (2) IFN-γ (500 U/ml); (3) celecoxib (25 μM); (4) AACOCF3 (25 μM); (5) TGF-β (120 pg/ml). Cells were stained with Oil red O to detect foam cells. Graphic representation of percentage foam cells shows a significant increase in foam cell transformation with celecoxib, AACOCF3 or IFN-γ ($n = 4$). $^{**}P < 0.01$ versus control cells, $^{***}P < 0.001$ versus control cells, $^{\#}P < 0.05$ versus celecoxib, AACOCF3

reported CD36 upregulation by the COX-2 inhibitor etodolac in a rat model of ischemic proliferative retinopathy. Our present results are consistent with the study by Viñals et al. [43] demonstrating that aspirin produces an increase of CD36 expression in THP-1 macrophages, possibly by decreasing production of PGE2 and the study by Chuang et al. [44] showing that CD36 levels are reduced in peritoneal macrophages derived from endometriosis patients, possibly due to excess prostaglandin E2. In the Chuang study, COX-1 or COX-2 inhibition increased CD36 message in cultured murine peritoneal macrophages.

In what may be a protective homeostatic mechanism, Bujold et al. [45] found that in cultured murine peritoneal macrophages activation of CD36 increases the expression of COX-2 through the activation of the extracellular signal-regulated kinase 1/2 pathway. Enhanced COX-2 expression then promotes cholesterol efflux, possibly by increasing intracellular levels of the PPARγ activator 15-deoxy-Δ12, 14-prostaglandin J2. PPARγ activation transcriptionally upregulates genes involved in cholesterol efflux including liver X receptors, ATP binding cassette transporters and cholesterol 27-hydroxylase [46].

The mechanisms of CD36 upregulation by COX inhibition are unknown. Further studies are needed to define the pathways involved and to determine which specific prostaglandin(s) are responsible for keeping CD36 levels in check.

Strategies to prevent atherosclerosis aimed at blocking upregulation of CD36 activity in patients taking NSAIDs or coxibs long-term may provide a novel therapeutic approach to improving the safety profile of these drugs. Further studies are needed to define the pathways involved and to determine whether CD36 expression may have prognostic value in evaluating cardiovascular toxicity of specific drugs in individuals. CD36 may be a feasible and attractive target for pharmacologic intervention [47, 48].

Abstract Fish oil (FO) supplementation could cause an increase in the concentration of plasmatic free fatty acids and, consequently, could compete with pro-inflammatory arachidonic acid (ARA) derived from brain biomembranes metabolism in the cerebrospinal fluid. Essential fatty acids (EFA) (n-3) have been reported by their antioxidant and neuroprotective properties, and therefore the influence of the FO supplementation on the reserpine-induced motor disorders was studied. Wistar rats were orally treated with FO solution for 5 days, and co-treated with reserpine (*R*; 1 mg/kg/mL) or its vehicle for 3 days (every other day). Reserpine-induced orofacial dyskinesia and catalepsy ($P < 0.05$) were prevented by FO ($P < 0.05$). Biochemical evaluations showed that reserpine treatment increased the lipid peroxidation in the cortex and striatum ($P < 0.05$), while the FO supplementation prevented this oxidative effect in both brain regions ($P < 0.05$). Our results showed the protective role of FO in the brain lipid membranes, reinforcing the beneficial effect of n-3 fatty acids in the prevention of degenerative and motor disorders.

Keywords Fish oil · n-3 Essential fatty acids · Reserpine · Motor disorders · Lipid peroxidation

Abbreviations

ALA	α-Linolenic acid
ARA	Arachidonic acid
DA	Dopamine
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid
EFA	Essential fatty acid(s)
EPA	Eicosapentaenoic acid
FO	Fish oil
FT	Facial twitching
LNA	Linoleic acid
MAO	Monoamine oxidase
NF-κB	Nuclear factor kappa-light-chain-enhancer of activated B cells
PUFA	Polyunsaturated fatty acids
SO	Soybean oil
TBARS	Thiobarbituric acid reactive substances
VCM	Vacuous chewing movements
VMAT	Vesicular monoamine transporter

Introduction

Families of n-3 and n-6 fatty acids are important constituents of neuron cell membranes and are considered essential fatty acids (EFA) because mammals are incapable of synthesizing fatty acids with a double bond past the Δ-9

position [1–3]. These EFA include α-linolenic acid (ALA, 18:3) and its metabolites docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3), which are members of the n-3 series, as well linoleic acid (LNA 18:2n-6) and its metabolite arachidonic acid (ARA; 20:4n-6), which are members of the n-6 series. While the n-3 polyunsaturated fatty acids (n-3 PUFA) are abundant in fish oil (FO) (EPA and DHA) and in smaller amounts in vegetable oils (ALA), the n-6 fatty acids are abundantly obtained from most types of vegetable oils including soybean oil. The intake of these EFA in the diet can affect the brain physiological functions [4]. An unbalanced diet in EFA may change cell permeability, synaptic membrane fluidity [5], density of receptors and function of ion channels. Furthermore, the activity of neurotransmitters is particularly modified [6], especially the dopamine (DA) system [7, 8]. In this sense, experimental studies correlated behavioral abnormalities with diets unbalanced in PUFA [9], while human studies showed a relation between abnormal levels of PUFA in the plasma and/or erythrocytes of subjects suffering from diseases of the central nervous system, such as motor disorders [10], confirming the influence of the diet in the function of neuronal membranes and their functions [11]. Furthermore, a connection between the EPA levels in liquor and Parkinson's disease was recently observed, suggesting the involvement of this fatty acids in neurodegenerative motor processes [12].

Reserpine is a catecholamine depletor that exerts a blockade on the vesicular monoamine transporter (VMAT) for neuronal transmission or storage, promoting dopamine-autoxidation and oxidative catabolism by monoamine oxidase (MAO) [13], which has been closely related to the oxidative stress process [14, 15]. Due to these effects, reserpine has been experimentally used to study movement disorders [16–22] as well as to evaluate new therapeutic approaches [23]. Of particular importance, basal ganglia are brain areas rich in monoamines and consequently more vulnerable to oxidative damage [24], which is frequently related to the development of movement diseases such as Huntington, Parkinson and tardive dyskinesia [25–27]. In this sense, the brain is more susceptible to OS when compared to other systems [28] due to its high level of membrane lipids and autoxidizable neurotransmitters. The neuronal phospholipid membrane is formed by PUFA which are more prone to lipid peroxidation by reactive oxygen species than other lipids such as cholesterol and saturated fatty acids [29]. On the other hand, the enzyme action on n-3 EFA generates less inflammatory docosanoids and eicosanoids than that originated from n-6 ARA [30]. Thus, the n-3 fatty acid supplementation becomes especially important because the majority of the diets contain abundance of n-6 and scarcity of n-3 fatty acids. Considering that n-3 has showed protective action on the neuronal lipid membranes, here we propose to study the effects of FO on reserpine-induced oxidative stress in an animal model. Behavioral and biochemical evaluations were performed to quantify the development of movement disorders and oxidative damage in brain tissues involved in motor control.

Methods

Twenty-eight male Wistar rats weighing 270–320 g (about 3 months of age) were kept in Plexiglas cages with free access to food and water in a room with controlled temperature (22–23°C) and in a 12 h-light/dark cycle with lights on at 7:00 a.m. The animals were maintained and used in accordance with the guidelines of the Committee on Care and Use of Experimental Animal Resources, School of Veterinary Medicine and Animal Science of the University of São Paulo, Brazil, which are in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No 80-23) revised in 1996.

In order to assess the influence of n-3 fatty acids on the reserpine-induced movement disorders, FO was used as source of n-3 EFA, and SO, which contains high levels of n-6 fatty acids, was used as control. FO capsules (Softcaps®, Cotia (SP), Brazil) contained 1 g of oil/capsule rich in n-3 PUFA (35%), which are formed of EPA (20%; 20:5n-3), DHA (6%; 22:6n-3), ALA (0.4%; 18:3n-3) and DPA n-3 (1.2%; 22:5n-3), besides a low content of n-6 PUFA (1.7%) and undetectable levels of *trans* fatty acids. The SO had a high content of ω-6 PUFAs (about 50%), a low content of n-3 PUFA, and a very low content of *trans* fatty acids. Both FO and SO were evaluated by capillary gas chromatography (in the Núcleo Integrado de Desenvolvimento em Análises Laboratoriais-NIDAL-UFSM). Thus, FO and SO were incorporated daily in tap water through a 1% polysorbate 80 (Tween 80®) and offered to the rats in place of drinking water in dark bottles, avoiding contact with the light. Considering the daily intake of each rat (average 40 mL/rat/day), the n-3 fatty acids daily dose was estimated at 14 mg/rat/day for FO-treated rats. This dosage is equivalent to the daily recommendations for human consumption (between 3 and 4 g/adult/day) of n-3 fatty acids.

Reserpine (methyl reserpate 3,4,5-trimethoxybenzoic acid ester-Sigma Chemical) was dissolved in glacial acetic acid and then diluted to a final concentration of 0.5% acetic acid with distilled water. The vehicle consisted of a 0.5% acetic acid solution.

Wistar rats were divided into two groups of 14 animals each and treated with FO or SO solution for 5 days. In the 6th day the groups were re-divided and treated with

reserpine solution (1 mg/kg/mL; sc) (R and FO + R groups) or vehicle (C and FO groups) for 3 days (every other day). During this time the rats were maintained with FO solution or SO solution. One day (24 h) after the last injection of R or V, the rats were placed individually in cages (20 × 20 × 19 cm) containing a mirror under the floor and another one behind the back wall of the cage to allow behavioral quantification when the animal was facing away from the observer. To quantify the occurrence of orofacial dyskinesia, which is characterized by involuntary movements of the orofacial region, observers blinded to the drug treatment recorded the vacuous chewing movement frequency (VCM) and facial twitching time (FT) for three sets of 6 min with intervals of 5 min (a total of 18 min). In a preliminary study (using 5 control and 10 rats treated with reserpine) of interrater reliability, we found that the use of this method of observation for the parameters evaluated usually resulted in >93 agreement between the three different observers. The calculated value was significant for $P < 0.05$.

Immediately after the orofacial dyskinesia observation, rats treated with reserpine (R and FO R) were individually placed on the inclined wire grid (25 × 30 cm, inclined 45° relative to the bench top) for quantification of catalepsy time. This behavioral parameter is characterized by positional passivity, which is observed through failure to correct an uncomfortable imposed posture. Each rat was placed with its forepaws near the edge of the grid and the amount of time spent in this atypical position was recorded for three times, with an interval of 5 min between them. At the end of the three replications, the mean time spent by the rat without moving was calculated for each test. One day (24 h) after the behavioral observations the rats were anesthetized with thiopental (50 mg/kg of body weight, i.p.) and euthanized by exsanguination (blood was collected by cardiac puncture). After removal, the brains were put on ice and cut coronally at the caudal border of the olfactory tubercle. Lipid peroxidation was determined through the pink chromogen produced by the reaction of thiobarbituric acid (TBA) with aldehydes, measured spectrophotometrically at 535 nm, in accordance with Ohkawa et al. [31]. The cortex and striatum were homogenized in Tris/acetic acid buffer (pH 7.4) and centrifuged at 1,310×g for 10 min. The supernatants (10% w/v) were boiled (100 °C) in trichloroacetic acid (TCA-10%) and thiobarbituric acid (TBA-0.67%) for 60 min, cooled and centrifuged. The absorbance of the supernatant was read at 535 nm.

Data were analyzed by one or two-way ANOVA followed by Duncan's multiple range test when appropriate. Pearson's correlation coefficient was calculated between the orofacial dyskinesia parameters (VCM frequency and TF duration) and lipid peroxidation (TBARS levels). Data were analyzed using Statistica 11.0 and expressed as means + SEM. P-values lower than 0.05 were considered statistically significant.

Results

Rats' body weight gain and food/suspension intake were not different among the treatments, and no mortality occurred during the study (data not shown).

The effects of reserpine treatment on orofacial movements are shown in Table 1. Two-way ANOVA revealed a significant main effect of reserpine [$F(1,24) = 74.25$; $P < 0.001$], FO [$F(1,24) = 7.36$; $P < 0.05$], and a significant reserpine × FO interaction [$F(1,24) = 6.42$; $P < 0.05$] for VCM frequency. For duration of FT, two-way ANOVA revealed a significant main effect of reserpine and a significant reserpine × FO interaction [$F(1,24) = 36.62$; $P < 0.001$ and 8.38; $P < 0.05$, respectively].

Univariate ANOVA followed by Duncan's test showed that reserpine treatment (1 mg/kg) caused evident signs of orofacial dyskinesia, which were observed by an increase in the VCM frequency and FT duration (Table 1). The co-administration of FO solution (FO + R group) caused a reduction of 36% and 52% of these behavioral parameters, respectively. In fact, rats treated with FO showed similar VCM and FT as compared to the control group.

One-way ANOVA showed that reserpine treatment (1 mg/kg) caused catalepsy in rats and co-treatment with FO reduced about 21% of this immobility time (Table 1). In this behavioral evaluation, rats not treated with reserpine (C and FO groups) showed no catalepsy and therefore were not included in the "Results" and "Discussion" section.

Two-way ANOVA of cortical TBARS levels revealed a significant effect of reserpine [$F(1,24) = 10.50$; $P < 0.001$] and FO [$F(1,24) = 22.27$; $P < 0.001$], as well

Table 1 Effects of fish oil oral treatment on behavioral parameters (vacuous chewing movements, facial twitching and catalepsy time) of rats treated with reserpine solution (1 mg/kg, sc, every other day, for 3 days)

Groups	VCM (frequency)	FT (seconds)	Catalepsy (seconds)
C	26.7 ± 4.9	0.42 ± 0.4	–
FO	25.3 ± 7.6	1.50 ± 0.9	–
R	116.4 ± 10.8$^{**,\#\#}$	9.82 ± 1.4$^{**,\#\#}$	49.9 ± 2.3
FO + R	74.2 ± 8.6$^{**,\#\#,+}$	4.74 ± 1.1$^{*,\#,+}$	39.3 ± 4.0$^{\#}$

Values are means ± SEM ($n = 7$)

VCM vacuous chewing movements; *FT* facial twitching; *C* control, *FO* fish oil and *R* reserpine

$^{*}P < 0.05$, $^{**}P < 0.001$, differences from control group (C); $^{\#}P < 0.05$, $^{\#\#}P < 0.001$, differences from fish oil (FO) and $^{+}P < 0.05$, differences from reserpine group (R)

as a significant reserpine × FO interaction [$F(1,24) = 12.15$; $P < 0.05$]. Two-way ANOVA of striatal TBARS levels revealed a significant main effect of FO [$F(1,24) = 31.21$; $P < 0.001$] and a reserpine × FO interaction tendency ($P = 0.059$). Duncan's multiple range test showed that reserpine treatment (1 mg/kg) caused an increase in the cortical and striatal TBARS levels (Fig. 1a, b). The co-treatment with FO caused a reduction of 61% and 53% of this lipid peroxidation measure in both brain regions, respectively. Interestingly, statistical analyses revealed a significant positive correlation between VCM frequency ($r = 0.47$, $P < 0.0.05$, Fig. 2a) and FT duration ($r = 0.45$, $P < 0.05$, Fig. 2b) with striatal lipid peroxidation, confirming that motor disturbances and oxidative stress may result from the pro-inflammatory and oxidative cascade induced by reserpine.

Discussion

Our results demonstrate that FO rich in n-3 fatty acids reduced the reserpine-induced parkinsonism symptoms, observed through orofacial dyskinesia parameters, catalepsy time and lipid peroxidation. Sarsilmaz et al. [1] hypothesized that n-3 EFA could affect the oxidant/antioxidant status of the brain by stabilizing the neuronal membranes, acting as an antiapoptotic agent in brain neurons [32] with neuroprotective functions [33, 34]. In fact, n-3 fatty acids have a potential to reduce damages in the neuronal membranes, whose dysfunction may affect the dopaminergic and serotonergic neurotransmission [35]. In dopaminergic structures such as striatum, DA itself may be one of the key contributors to oxidative stress, mainly because it generates dopamine-quinones and hydrogen peroxide by autoxidation and MAO metabolism. In this sense, reserpine is known to exert a monoamine-depleting action by blocking the ATP-dependent uptake mechanism of the storage organelles, resulting in the accelerated presynaptic turnover of the cytoplasmic DA. This mechanism of reserpine was studied by Sussman et al. [36], who showed that reserpine administration causes a decrease in striatal DA levels and an increase in the metabolites of DA ratios (DOPAC/DA and HVA/DA) in rats. The reserpine-induced movement disorders have been suggested as a putative animal model of tardive dyskinesia and parkinsonism [14, 37] which has been used by different research groups [17–19, 38].

Abbreviations: control (*C*); fish oil (*FO*); reserpine (*R*). Data are reported as means + SEM. $^{*}P < 0.05$, $^{**}P < 0.001$, difference from C group; $^{++}P < 0.001$, difference from *R* group

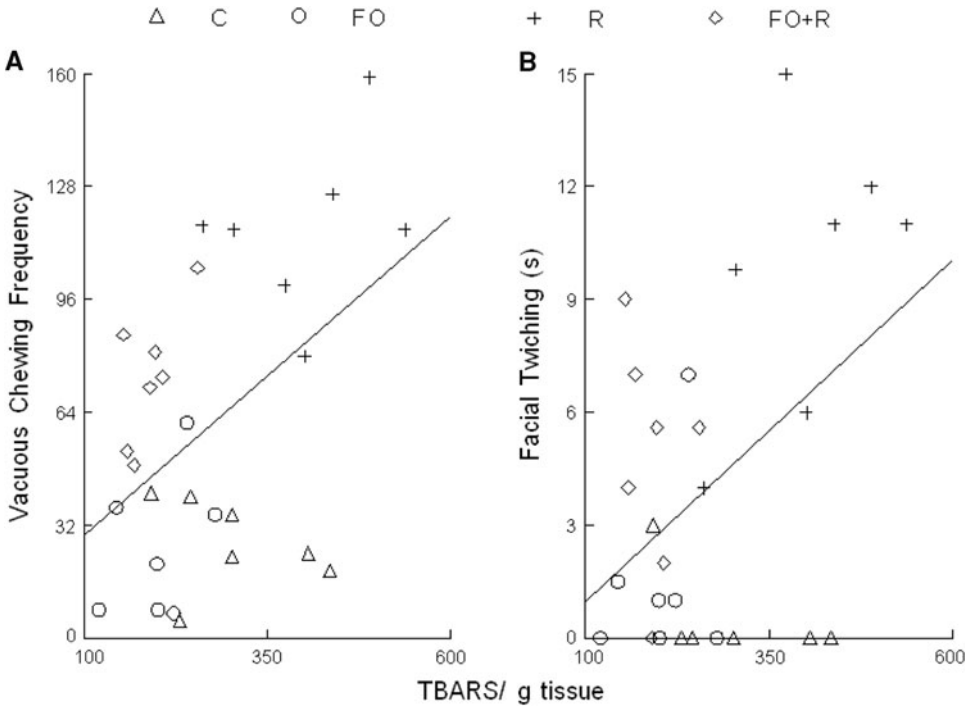

Fig. 2 Linear regression analysis between vacuous chewing frequency, facial twitching and striatal lipid peroxidation induced by reserpine treatment (1.0 mg/kg, sc, every other day, for 3 days) following 5 days of oral treatment with fish oil (ad libitum). Abbreviations: control (*C*); fish oil (*FO*); reserpine (*R*). Linear regression was evidenced by Pearson's coefficient ($r = 0.47$ and 0.45, respectively, $P < 0.05$)

In addition, it has also been used as an animal model of brain oxidative stress [13, 15, 23]. Apart from the names, these animal models are not contradictory, mainly because parkinsonism and tardive dyskinesia are closely related to oxidative stress and neurotoxicity [19, 39]. Recently, we showed a negative relationship between the glutamate transporter and the manifestation of orofacial dyskinesia in rats exposed to reserpine or haloperidol [19], strengthening the relation between oxidative stress, excitotoxicity and movement disorders.

Some studies have shown that deficiencies of n-3 PUFA may decrease the vesicular monoamine transporter (VMAT-2) [40] as well as alter DA vesicle density in frontal cortex [41] and mesolimbic pathway [42] but not in striatum [43, 44]. Unlike these results, our study was not conducted with a lack but with a supplementation of n-3 fatty acids, which showed a beneficial effect on reserpine-induced behavioral and biochemical parameters. Since reserpine acts on the VMAT-2 [13], we can assume that n-3 PUFA supplementation does not prevent its monoamine depleting effects, but attenuates the oxidative cascade resulting from monoamine metabolism. Our findings suggest that n-3 EFA plays a role as an neuroprotective agent. N-3 fatty acids supplementation allows its higher bioavailability for enzymatic activities (cyclooxygenase and lipoxygenase), which degrade the ARA (n-6 EFA) displaced from neuronal phospholipid membranes. So, both n-3 (from supplementation or diet) and n-6 EFA (from membrane phospholipids) compete for the common cyclooxygenase and lipoxygenase enzymes, but ARA produces more potent inflammatory and pro-aggregatory eicosanoids [45], which are also related to the generation of free radicals and development of oxidative damage, while the neuroprotectins derived from these n-3 EFA retard neuroinflammation, oxidative stress and apoptotic cell death in brain tissue [46]. Up to now, different hypotheses have been raised to explain the influence of n-3 EFA on inflammatory and oxidative processes: DHA (and, to a lesser degree, EPA) reduces chronic inflammation by attenuating nuclear factor kappa-light-chain-enhancer of activated B cells (NF-$_\kappa$B), in turn modulating the expression of pro-inflammatory cytokines. These fatty acids may decrease the phosphorylation of specific interleukins (I$_\kappa$B) modulating the availability of NF-$_\kappa$B. Importantly, this process can modulate the expression of the pro-inflammatory genes for COX-2 beyond other molecules of adhesion and signalizing [47]. These genes control the availability of lipid mediators such as prostaglandins, leukotrienes and thromboxanes, which modulate the intensity and duration of immune responses, which are also involved in neuroinflammatory processes. Of particular importance, DHA and its derivatives are themselves intimately involved in cell signaling processes [48]. Although EPA has been explored as a therapeutic agent to treat neurological diseases in recent years [49, 50], its uptake and incorporation in the brain is not clear. A recent study showed a low concentration of EPA in brain phospholipids after intracerebroventricular infusion of ^{14}C-EPA in rats, suggesting a fast β-oxidation (14% per day) of this fatty acid [51]. In this sense, FO, which contains DHA and other EFA, has

shown beneficial effects. A recent study on Parkinson's disease showed that short-term administration of DHA reduced the extent of levodopa-induced dyskinesia by about 40% in a non-human primate model of parkinsonism [52]. On the other hand, animal models showed the involvement of prostaglandins derived from ARA in orofacial dyskinesia [53] and cataleptic behavior [54] development. In addition, we recently showed the beneficial effect of FO on orofacial dyskinesia and oxidative stress induced by typical neuroleptics [55], confirming the protective role of n-3 fatty acids on brain phospholipid membranes [56].

Concerning the length of FO supplementation, different studies have shown the therapeutic properties of n-3 fatty acids after short-term treatment (5–14 days) [10, 32, 57]. Besides these experimental designs, a human study performed during antidepressant treatment showed the beneficial effects of 3 week FO supplementation [58]. In this sense, it is important to emphasize that, as the temporal relationship between humans and animals is very different, a relatively longer time of treatment is needed for animals as compared to humans. In fact, we believe that the demonstration of n-3 fatty acids incorporation in neuronal membranes may be conclusive, but the mechanisms by which the brain uptakes PUFA are not agreed upon. Several models regarding the uptake of PUFA by the brain have been proposed: via receptor mediated transporter (esterified PUFA in the form of a lipoprotein) or via passive diffusion (unesterified PUFA), whose rates of incorporation in brain membrane phospholipids vary with experimental conditions [59, 60]. In short, although brief treatment with n-3 fatty acids is not supposed to change significantly the composition of brain membranes (although this possibility cannot be ruled out), it could cause an increase in the concentration of plasmatic free fatty acids and, consequently, in the cerebrospinal fluid, that could compete with pro-inflammatory ARA derived from brain bio-membranes metabolism.

In conclusion, here we have shown that n-3 fatty acids may protect brain motor structures against reserpine-induced oxidative damage, and its supplementation or inclusion in the diet may prevent the development of motor disorders related to oxidative damages.

Low Levels of the Omega-3 Index are Associated with Sudden Cardiac Arrest and Remain Stable in Survivors in the Subacute Phase

Received: 6 April 2010 / Accepted: 20 November 2010 / Published online: 14 January 2011

Abstract In previous studies, low blood levels of n-3 fatty acids (FA) have been associated with increased risk of cardiac death, and the omega-3 index (red blood cell (RBC) eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) expressed as weight percentage of total FA) has recently been proposed as a new risk factor for death from coronary artery disease, especially following sudden cardiac arrest (SCA). As blood samples often haven been harvested after the event, the aim of our study was to evaluate the stability of RBC fatty acids following SCA. The total FA profile, including the omega-3 index, was measured three times during the first 48 h in 25 survivors of out-of-hospital cardiac arrest (OHCA), in 15 patients with a myocardial infarction (MI) without SCA and in 5 healthy subjects. We could not demonstrate significant changes in the FA measurements in any of the groups, this also applied to the omega-6/omega-3 ratio and the arachidonic acid (AA)/EPA ratio. Furthermore, we compared the omega-3 index in 14 OHCA-patients suffering their first MI with that of 185 first-time MI-patients without SCA; mean values being 4.59% and 6.48%, respectively ($p = 0.002$). In a multivariate logistic regression analysis, a 1% increase of the omega-3 index was associated with a 58% (95% CI: 0.25–0.76%) reduction in risk of ventricular fibrillation (VF). In conclusion, the omega-3 index remained stable after an event of SCA and predicted the risk of VF.

SCD	Sudden cardiac death
STEMI	ST-elevation myocardial infarction
TnT	Troponin-T
VF	Ventricular fibrillation
VT	Ventricular tachycardia

Introduction

The first clinical evidence of a possible protective effect of n-3 fatty acids (FA) against sudden cardiac death (SCD) came from the publication of the GISSI-Prevenzione trial in 1999 [1]. In this study, supplementation with 1 g/day of n-3 FA following a myocardial infarction (MI) resulted in a 45% reduction of sudden deaths during 3.5 years of follow-up. This finding has been supported by the demonstration of low levels of blood n-3 FA in patients suffering SCD [2, 3] or a fatal cardiac event [4]. In addition, our research group has recently presented evidence for an increased risk of ventricular fibrillation (VF) during the acute ischemic phase of an MI in patients with low levels of cellular n-3 FA [5]. In our study, as well as in a previous investigation [3], blood samples were harvested after the episode of sudden cardiac arrest (SCA). To obtain a reliable result with this method, we have to assume that the blood composition of FA remains stable following the event, or else we need to correct for changes induced by the event itself in selected case–controls.

Previous studies have demonstrated significant changes in FA composition of serum [6] and plasma lipids [7] in the early stage of an MI. Recently, the red blood cell (RBC) FA composition has been found to reflect the cardiac omega-3 content [8, 9]. Even though stable in rats for 24 h after the induction of an MI [7], the only evaluation of post-MI RBC FA in humans demonstrated a statistically significant change in the investigated FA during a 7 day period [10]. As most episodes of cardiac arrest appear during the early course of an MI, these findings are of interest when assessing the FA profile of SCD/SCA-patients.

In patients with SCA, the event itself, as well as the resuscitation, might potentially affect the measurements. Stress-induced or injected adrenalin can activate phospholipases, releasing FA from cell membrane phospholipids leading to falsely low post-resuscitation measurements. The only evaluation of this question has so far been performed in animal studies, in which no significant effect of adrenalin on the FA composition in RBC [3] or serum lipids [11] has been observed. FA stability after an episode of cardiac arrest has previously not been reported in humans, and this was the primary aim of our study.

Based on the proposed post-MI changes in FA, we wanted to compare the time-related profile of RBC FA in SCA-patients with that of MI-patients without a cardiac arrest. We also wanted to evaluate whether the level of RBC eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) (the omega-3 index) might be related to VF, as previously demonstrated in another group of SCA patients [5].

Materials and Methods

Study Subjects and Design

This study was performed at Stavanger University Hospital, Stavanger, Norway. The inclusion criteria were; age >18 years and out-of-hospital cardiac arrest (OHCA) of assumed cardiac origin. Patients with permanent return of spontaneous circulation (ROSC) had 6 mL of EDTA-blood drawn on hospital admission. Further blood sampling was repeated after 8–12 h and after 24–48 h. At this point, most patients were on a respirator at the intensive care unit, and blood samples were collected from an already established arterial crane. For the few patients who woke up immediately after resuscitation, blood sampling was performed as part of the hospital's routine. Echocardiography was performed shortly after admission for the evaluation of the ejection fraction (EF). Survivors gave written informed consent before discharge. If the patient stayed unconscious until death, the family was asked for consent on the patient's behalf.

From February 2007 until June 2009, blood samples for evaluation of RBC FA were collected from 25 patients with documented VF. Patients were divided into three groups based on the mechanism of their ventricular arrhythmia; (1) SCA without a present MI, (2) SCA with a first-time MI and (3) SCA with recurrent MI. The presence or absence of an MI was determined from the release pattern of troponin-T (TnT), using ST-segment analysis of the electrocardiogram (ECG) for the definition of ST-elevation MI (STEMI) or non-ST-elevation MI (NSTEMI). For one case, there were only two in-hospital samples available, and this patient was only included in the analysis of risk.

For the evaluation of MI related FA changes, 15 subjects with an acute MI (AMI) without SCA were recruited. In this group, MI was defined by a maximal TnT >0.03 μg/L and a typical release pattern. EDTA-blood from most of these patients was collected as part of the hospital's routine at admission or at coronary angiography and during the subsequent 48 h, employing the same time points as described for the SCA-patients. After collection of blood and baseline characteristics, the identity of these patients was destroyed and all samples treated anonymously. The

selection of the MI-patients was not sufficiently random for them to serve as controls for the assessment of risk.

To rule out a biological variation of the FA profile, we also analyzed a subsequent set of three blood samples in 5 healthy subjects, 3 men and 2 women, with an age of 34–72 years. The first and last (after 24 h) blood samples were drawn after an overnight fast, the second sample was in the fed state 8–12 h after the first one.

For risk evaluation, we compared the admission omega-3 index in the SCA-patients with first-time MI with our previous control-population of 185 first-time MI patients from the Risk factors in Acute Coronary Syndrome (RACS, ClinicalTrials.gov identifier: NCT00521976) study [5]). In that study, patients with chest pain or otherwise suspected acute coronary syndrome (ACS) were included at the same hospital from November 2002 until September 2003. Blood samples for the analysis of the omega-3 index were harvested immediately after admission, without subsequent sampling during hospitalization. Controls were selected based on the absence of VF or sustained ventricular tachycardia (VT) for at least 30 days of follow-up.

The present study was approved by the Regional Board of Research Ethics and the Norwegian Health Authorities and conducted in accordance with the Helsinki Declaration of 1975, as revised in 1983.

Laboratory Methods

Storage of blood samples prior to preparation was allowed for 24 h at room-temperature and 48 h in a refrigerator. RBC for analysis of FA were prepared from EDTA-blood after centrifugation at 2,500*g* for 10 min in room temperature. Plasma was extracted and the buffy coat discarded, after which sedimented RBC were washed twice with phosphate buffered saline (PBS), followed each time by centrifugation at 2,500*g* for 3 min. All samples were stored at –70 °C until extraction of FA could be performed. At this temperature, the composition of RBC FA has been demonstrated to remain stable for at least 4 years [12].

For the FA analysis a 50-μL sample of thawed packed RBC was placed on a filter paper disc (Whatman grade 1, 3.0 cm diameter) that had been pre-treated with butylated hydroxytoluene (50 mg/L) according to Marangoni et al. [13]. Dried blood spots were shipped to the US and the FA composition analyzed in the laboratory of W. S. Harris by flame ionization gas chromatography (GC9A, Shimadazu Corporation, Columbia, MD, USA), as previously described [5]. FA in dried RBC-samples remain stable during storage and shipment in cooled conditions for at least 1 week, as previously described [14]. We have also shown that dried RBC-samples can be stored at −70 °C for 1.5 years with no reduction in the omega-3 index ($n = 22$) (unpublished data). The coefficient of variation (CV) for the omega-3 index was 6%. Laboratory personnel performing the analyses were blinded with respect to clinical events.

Statistical Analyses

Characteristics of cases and controls are given as means ± standard deviations (SD) for normally distributed variables and as medians with interquartile range (25th–75th percentile) when the assumption of normality was violated. Differences between groups at baseline were tested by the Mann–Whitney *U* Test and the Kruskal–Wallis Test for non-normally distributed variables with the independent samples *t* test and the one-way between group analysis of variance (ANOVA) as the parametric alternative. Categorical variables were evaluated using the Chi-square test, or in the case of few expected observations, the *p* value was derived from Fisher's exact probability test. The sample sizes of the subgroups of SCA-patients were, however, too small to test for differences in inter-group frequencies.

For the evaluation of FA stability following an event of SCA and/or AMI we used one-way repeated measures ANOVA to compare the omega-3 index and individual FA at admission, after 8–12 h and after 24–48 h in the four different groups of patients; (1) SCA without an AMI ($n = 6$), (2) SCA with an AMI (both first and recurrent) ($n = 18$), (3) AMI without SCA ($n = 15$) and (4) healthy subjects ($n = 5$). The analysis was performed for each group with time as the only within-subject factor at three levels. The Mauchly's test of sphericity was used to check that the correlations and variances of the observations remained constant at all time points. The within-subject CV was calculated from the mean and SD of the three subsequent omega-3 index measurements, according to the method described by Harris and Thomas [15].

To evaluate the association between the omega-3 index and risk of VF we performed logistic regression analyses adjusting for age and sex. In addition, high-sensitivity C-reactive protein (hsCRP), EF and previous angina pectoris were included as potential confounders in a backward elimination procedure, and stayed in the final model if they were significant in the first step. Based on the existing knowledge of STEMI and anterior location as potential risk factors for VF during the course of an AMI [16, 17], we performed separate analyses for STEMI-patients only and for patients with anterior location of their infarction. We chose not to include maximal TnT as a measure of infarct size due to the possibility of this parameter being differentially affected by the mechanical manipulation of the heart, by coronary hypoperfusion during resuscitation [18, 19] as well as by later percutaneous coronary intervention (PCI) therapy [20]. The Odds Ratio (OR) for VF is

presented with 95% confidence interval (CI). The statistical analyses were performed with the statistical package SPSS version 17.0, with p values derived from the logistic regressions using the Wald chi-square test. All tests were 2-sided with a significance level of 5%.

Results

Characteristics of SCA-Patients

Out of the 25 patients admitted after an event of OHCA, 19 experienced their VF during the initial course of an AMI. The remaining 6 patients had no evidence of a present MI and their arrhythmia was classified as primary VF with the need for an implantable cardioverter defibrillator (ICD) prior to discharge. Patient characteristics for the different SCA-groups are given in Table 1.

Fourteen out of the 19 AMI-patients, 12 men and 2 women, experienced their first MI. These patients were relatively young (median age 52.5 years, range 41–78 years) and had a predominance of STEMI located to the anterior wall of the heart and mainly one-vessel disease evaluated by coronary angiography (Table 1). Retrospectively, 3 patients had evidence of pre-infarction angina, but none of them had received any treatment for this condition.

Characteristics of Control Subjects

The characteristics of the 185 control subjects (134 men and 51 women) are presented in Table 2. As compared to the group of SCA-patients with first-time MI they were significantly older, had a higher frequency of NSTEMI at admission, and at baseline hsCRP was significantly higher and s-glucose significantly lower. For the remaining baseline characteristics, including infarct location, previous history, presence of risk factors, use of medication, EF and degree of coronary artery disease (CAD), there were no statistically significant differences among the two groups.

Serial Measurements of Individual FA and the Omega-3 Index

A plot of the means of the omega-3 index with 95% CI in SCA patients with and without an AMI, in AMI-patients without SCA and in healthy subjects is presented in Fig. 1. Among patients with SCA, mean time from event to first sample was 1.3 ± 0.6 h. The time from admission until first, second and third sample was 0.5 ± 0.4, 11.1 ± 2.3 and 39.3 ± 6.0 h, respectively. After removing from the analysis one patient with chest pain for at least 74 h before the occurrence of cardiac arrest, patients with SCA during the course of their AMI had a mean duration of symptoms of 3.3 ± 5.7 h (range 0.6–21.0 h) at the time of the first sample. For AMI-patients without SCA, time from symptom onset until first sample was 3.4 ± 2.5 h (range 0.8–9.7 h) and from admission to subsequent sampling 0.3 ± 0.4, 10.2 ± 3.1 and 35.6 ± 6.8 h, respectively. Healthy subjects had samples taken at time 0, after 8.1 ± 0.1 and 23.4 ± 0.4 h. The repeated measures ANOVA (sphericity assumed) showed no statistically significant time-dependent effect on the omega-3 index in any of the groups. The within-subject CV differed from 16.7% in SCA-patients with an AMI to 10.4% in SCA-patients with no AMI. The corresponding values for AMI-patients without SCA and for healthy subjects were 11.7 and 12.9%, respectively.

Similar comparisons were performed for the individual FA. As shown in Table 3 the FA profile remained stable irrespective of sampling time in each subject group. Accordingly, the ratio between the omega-6 and omega-3 FA was also found to be stable, including the arachidonic acid (AA) to EPA ratio.

Omega-3 Index and Risk of VF

The mean omega-3 index among SCA-patients with first-time AMI was 4.59% as compared to 6.48% in controls. In the main logistic regression analysis age, sex, hsCRP and EF were included as covariates, 12 cases and 177 controls were enrolled based on available measurements. The omega-3 index turned out to be a highly significant predictor of VF during the course of a first-time AMI with an OR of 0.42 (95% CI; 0.24–0.75, $p = 0.003$). Of the other covariates included in the analysis, only EF (OR 0.94, 95% CI: 0.89–0.99) and hsCRP (OR 0.61, 95% CI: 0.39–0.95) contributed to the risk of VF.

When restricting the analysis to patients admitted with STEMI and to those with anterior location of their infarction, the omega-3 index still remained an independent predictor of VF with an OR of 0.53 (95% CI: 0.29–0.96), $p = 0.037$, in STEMI-patients ($n = 91$) and 0.50 (95% CI: 0.27–0.93), $p = 0.028$, among those with anterior infarctions ($n = 92$) (Fig. 2).

Discussion

We have demonstrated that the RBC FA, including the omega-3 index, remained stable after SCA and during the post-MI period. In healthy subjects, we have also ruled out any significant biological variability, largely confirming previous observations on reproducibility over time [15].

There has been diverging results in previous studies regarding the effect of an AMI on FA composition of phospholipids [6, 7, 10]. Our findings are consistent with

Table 1 Characteristics of patients suffering SCA

results from an experimental study in rats by Shearer et al. [7]. Kark et al. [10] sampled 20 MI-patients up to 7 days after the event. Decreasing values of EPA were evident after 42 h, whereas DHA started to increase 7 h after admission. In that study there were no statistical analyses for composite indexes, but we would expect that increasing values of DHA (the major contributor to the sum of EPA + DHA) would reflect an increasing omega-3 index after the initial 7 h of admission, a finding not confirmed in our study. The observed decrease in EPA after 42 h could, however, have been missed by our investigation, as our mean time to last sample was 35.6 h following admission. The time between onset of symptoms and first blood sample was similar in the two studies. In contrast to the study of Kark et al., our STEMI patients were treated invasively, but there is no indication that this difference in the treatment strategy may influence the FA composition in phospholipids.

Unique to our study is a separate evaluation of the effect of SCA on FA composition in humans. The so-far existing research has been performed on primates [3] and rats [11]. In the study by Siscovick et al. [3] RBC membrane levels of EPA + DHA (corresponding to our omega-3 index) were altered only slightly (0.33%) from the pre-mortem to the post-mortem state, suggesting a non-significant effect on these FA by the cardiac arrest itself. Jurand et al. [11] injected rats with noradrenaline, but could not demonstrate any variation in serum FA. Our study confirms the findings

in these animal studies, and is strengthened by similar results obtained in SCA-patients both with and without an AMI. Although the latter group only consisted of 6 patients, these subjects represent a population in which we could evaluate the effect of the cardiac arrest itself without any interference from an AMI. Also, there was no evidence

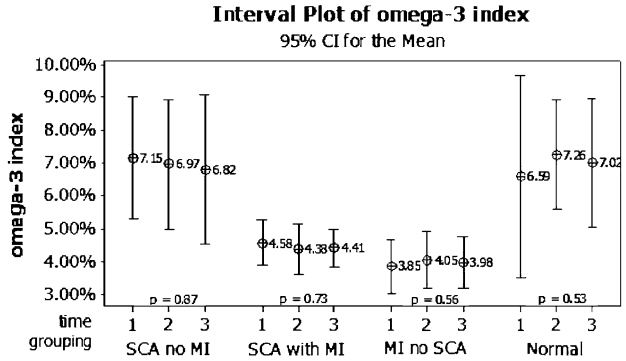

Fig. 1 Mean of the omega-3 index with 95% confidence interval (CI) at admission (time 1), after 8–12 h (time 2) and 24–48 h (time 3). Values given for sudden cardiac arrest (SCA) patients with and without an acute myocardial infarction (MI), MI-patients without SCA and healthy subjects (normal). *p* values for variance of the omega-3 index in each group derived from the ANOVA analysis with time as the only within-subject factor at three levels

of a decreased omega-3 index at admission in patients given adrenaline prior to hospitalization (5.60%, $n = 14$) as compared to those not receiving this medication (5.01%, $n = 11$).

Our findings suggest that any sample obtained within the first 48 h after an event of cardiac arrest, is representative of the total FA status, including the omega-3 index and AA/EPA ratio, of the individual prior to the event. Proof of that assumption would, however, require a measurement just prior to the event, but that would hardly be achievable in a clinical setting. The other option would be blood samples obtained in advance in large prospective cohort studies, but in those settings dietary changes may have taken place between the time of sampling and the event. As a second-best choice, our study was designed to harvest the first sample as close to the event as possible, based on the assumption that it may take some time for the cellular changes to appear. The first sample taken at admission was harvested at a mean time of only 1.3 h after the SCA event. Furthermore, the mean time from symptom onset was 3.3 h in AMI-patients with SCA as compared to 3.4 h in AMI-patients without a cardiac arrest. A possible effect of the cardiac arrest on the FA profile, has been one of the main objections to case–control studies demonstrating an increased risk of SCD/SCA with low levels of n-3 FA [3, 5]. However, these objections are not supported by our present results.

We had previously demonstrated that a 1% increase of the omega-3 index reflects a 48% reduction in risk of VF during the ischemic phase of an AMI [5]. In the present case–control study we have recruited a similar group of SCA-patients with first-time MI, with the use of the same control subjects in both study settings. As in our previous investigation, we found a large difference in the omega-3 index values between cases and controls at admission. Furthermore, the logistic regression analysis confirms an inverse relation between the omega-3 index and risk of VF; a 1% increase in this index reflecting a 58% reduced risk of VF (95% CI: 25–76%). Even though EF and hsCRP contributed to the risk of VF, the omega-3 index was the strongest predictor. The omega-3 index also remained an independent predictor of risk, but was slightly attenuated, in the subgroup analyses of STEMI-patients and anterior infarctions. Contrary to other investigations, both of our studies have documented ventricular fibrillation at the time of resuscitation, supporting the proposed antiarrhythmic mechanism of n-3 FA [21–23], especially in ischemia-induced VF. Theoretically, the antiarrhythmic mechanism of n-3 FA is based on an increase of the arrhythmic threshold in the ischemic zone of the myocardium, due to an indirect effect of the FA on sodium and calcium ion-channels in the myocardial membrane [22, 24].

The group of SCA patients without the presence of an AMI is highly different from the first-time MI population. Their high omega-3 index of 7.15% does not contradict the above finding, as their VF is mainly considered to be a result of myocardial scarring and heart failure. For arrhythmias generated by such mechanisms, n-3 FA might not be protective, as suggested by the discrepant results of n-3 FA in ICD-patients [25, 26]. Also, chronically ill patients may have changed their lifestyle according to an assumed protection by n-3 FA, ingesting an increased amount of fish and omega-3 supplements.

Limitations

Our evaluation of a time-dependent change in the FA profile following an event of SCA and/or AMI is limited by the relative low number of patients in each category, reducing our power to confidently exclude a small change. Statistically, power calculations are difficult to perform with repeated sampling, but the use of serial samples without any detectable change in healthy individuals and in different patient groups strengthen our conclusion. As our patient populations had highly different omega-3 index values, the present study furthermore supports the stability of this analysis in patients with both high and low n-3 FA levels.

The main objection to the present case-control study might be the different time-periods for inclusion of cases and controls. Whereas controls were participants in the RACS-study [5], sampled between November 2002 and September 2003, our new cases had their blood samples taken between February 2007 and June 2009. Both studies were, however, performed at Stavanger University Hospital, the only hospital available for the CAD and SCA

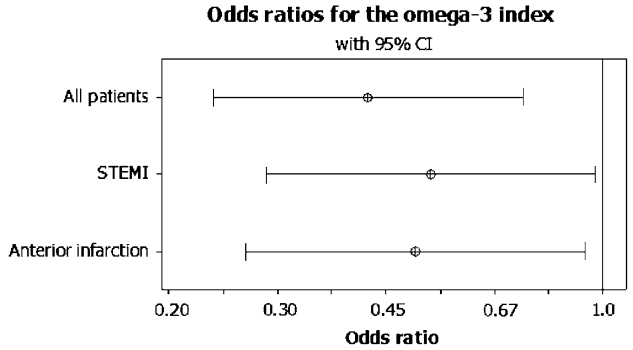

Fig. 2 Result of the multivariate logistic regression analysis in the total population (all patients) and in the subgroups of ST-elevation myocardial infarctions (STEMI) and anterior infarct location adjusting for age, sex, high sensitivity C-reactive protein and ejection fraction. Odds ratios (ORs) given with 95% confidence interval (CI)

populations in this region of Norway. The source-population should therefore be similar for both studies and there is no reason to believe that their way of living, including diet, would have changed significantly during a 5 year period. The results of our study are, however, only valid for the range of omega-3 index values included in the analyses.

Furthermore, we do not know for certain whether the omega-3 index in admitted SCA-patients differ from those of OHCA-patients where ROSC was not obtained. Also, the urgent situation during resuscitation and admission sometimes resulted in missing samples for admitted SCA-patients.

Conclusion

Our study supports an association between low levels of n-3 FA and the risk of VF during the ischemic phase of an AMI in hospitalized patients. The results are strengthened by our demonstration of the stability of RBC FA within the first 48 h after an episode of SCA or AMI, suggesting that the validity of risk assessment is maintained within this time frame.

Acknowledgments Study grants from the Regional Health Authorities in Western Norway, The Research Foundation at Stavanger University Hospital and The Laerdal Foundation for Acute Medicine are gratefully acknowledged. The FA analyses were performed by William S. Harris who is a consultant to companies with interests in omega-3 FA, including GlaxoSmithKline, Reliant Pharmaceuticals and the Monsanto Company. No pharmaceutical company supported this study financially. There are otherwise no financial or other relationships associated with the manuscript that might lead to a conflict of interest.

Abstract The goal of this study was to determine the mechanisms of n-3 polyunsaturated fatty acids (n-3 PUFA) on anti-arrhythmias and prevention of sudden death. The calcium-tolerant Sprague–Dawley rat ventricular myocytes were isolated by enzyme digestion. Effects of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) on action potentials and transient outward potassium currents (I_{to}) of epicardial ventricular myocytes were investigated using whole-cell patch clamp techniques. Action potential durations (APDs) and I_{to} were observed in different concentrations of DHA and EPA. APD_{25}, APD_{50}, and APD_{90} with 0.1 μmol/L DHA and EPA were prolonged less than 15% and 10%. However, APDs were prolonged in concentration-dependent manners when DHA and EPA were more than 1 μmol/L. APD_{25}, APD_{50}, and APD_{90} were 7.7 ± 2.0, 21.2 ± 3.5, and 100.1 ± 9.8 ms respectively with 10 μmol/L DHA, and 7.2 ± 2.5, 12.8 ± 4.2, and 70.5 ± 10.7 ms respectively with 10 μmol/L EPA. I_{to} currents were gradually reduced with the increased concentrations of DHA and EPA from 1 to 100 μmol/L, and their half-inhibited concentrations were 2.3 ± 0.2 and 3.8 ± 0.6 μmol/L. The results showed APDs were prolonged and I_{to} current densities were gradually reduced with the increased concentrations of DHA and EPA. The anti-arrhythmia mechanisms of n-3 PUFA are complex, however, the effects of n-3 PUFA on action potentials and I_{to} may be one of the important mechanisms.

Keywords n-3 Polyunsaturated fatty acid · Docosahexaenoic acid · Eicosapentaenoic acid · Action potential · Action potential duration · Transient outward potassium current

Abbreviations

PUFA	Polyunsaturated fatty acids
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
I_{to}	Transient outward potassium currents
APDs	Action potential durations
APD_{25}	Action potential duration of 25% repolarization
APD_{50}	Action potential duration of 50% repolarization
APD_{90}	Action potential duration of 90% repolarization
HP	Holding potential
V_{max}	Maximal velocity of action potential depolarization
APA	Action potential amplitude
OS	Overshoot

Introduction

Fatty acids, especially polyunsaturated fatty acids (PUFA), play an important role in cardiac activities. For example,

PUFA are essential fuels for mechanical, electrical, and synthetic activities of the heart; and the dietary PUFA are very beneficial to heart functions [1, 2]. Recently, the beneficial effects of PUFA, particularly the n-3 series, have been reported for cardiovascular diseases [3–6]. n-3 PUFA have been shown to reduce cardiovascular mortality, in part, due to their anti-arrhythmic mechanisms that are not fully understood up till now [7, 8].

n-3 PUFA mainly include docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). The vital importance of the n-3 PUFA, so called because of the location of the first double bond (at carbon no.3, from the methyl end of the carbon chain), is becoming widely recognized in human physiology. Many studies suggest that n-3 PUFA have beneficial effects on human health. Recently, more attentions have been paid to their beneficial effects on cardiovascular diseases, especially in their anti-arrhythmias and prevention of sudden cardiac death [9–13]. Although the underlying mechanisms of which are still not completely known, the effects of n-3 PUFA on action potentials and ionic channels might contribute to this phenomenon [14].

The typical action potentials consist of 5 phases or stages, i.e., 0, 1, 2, 3, and 4. The transient outward potassium current (I_{to}) is a major repolarizing ionic current of action potentials in ventricular myocytes of many mammals. Because of its immediate activation by depolarization and its transient nature, I_{to} plays an important role in the early repolarization of action potentials. It influences the height of the plateau potential and the action potential durations (APDs), especially in the early phase. Accordingly, its inhibition leads to a significant prolongation of APDs. It has been reported that APDs magnitude depends on the origin of the myocytes and is regulated by a number of physiological and pathophysiological signals [15, 16].

To investigate the underlying mechanisms of n-3 PUFA in anti-arrhythmias and prevention of sudden cardiac death, the magnitude of I_{to} and APDs were studied in rat ventricular myocytes of endocardial, mid-myocardial and epicardial origin using whole-cell patch clamp recordings. The aim of this study was to test the hypothesis that a differential distribution of I_{to} is the most important cause of different action potential waveforms in endocardial, mid-myocardial and epicardial myocytes, and the effects of n-3 PUFA on action potentials and I_{to} may be one of the important mechanisms of anti-arrhythmias. Since I_{to} may not be uniformly expressed in the ventricle [17], we have only investigated the epicardial cardiomyocytes in order to avoid experiment errors. These results may provide some experimental evidences for rational applications of n-3 PUFA to prevent and treat arrhythmias in clinical practice.

Experimental Procedures

Major Experimental Instruments

The instruments used were: MultiClamp 700B patch clamp amplifier (Axon Instruments, USA), D/A and A/D converter (DigiData 1322, Axon Instruments, USA), Pclamp 9.0 pulse software (Axon Instruments, USA), MP-285 motorized micromanipulator (Sutter Instruments, USA), IX71 inverted microscope (Olympus, Japan), SA-OLY/2 and DH-35 culture dish heater (Warner Instruments, USA), P-97 micropipette puller (Sutter Instruments, USA).

Reagents, Solutions and Drugs

The reagents, solutions and drugs used were: DHA (Sigma, USA), molecular weight 328.5, and EPA (Sigma, USA), molecular weight 302.45; 100 mmol/L stock solutions were prepared respectively by being dissolved in absolute ethanol and protected from light in a refrigerator at −20 °C. The experimental concentrations of DHA and EPA were obtained by dilution of stock solutions before each experiment. For the recording of action potentials, the internal solution (in mmol/L) contained KCl 120, $CaCl_2$ 1, $MgCl_2$ 5, Na_2ATP 5, EGTA 11, HEPES 10, glucose 11, pH 7.3 adjusted with KOH. The external solution was Tyrode's solution [18]. For the recording of I_{to}, the external solution (in mmol/L) contained NaCl 140, KCl 4, $CaCl_2$ 1.5, $MgCl_2$ 1, $CdCl_2$ 0.5, HEPES 5, glucose 10, pH 7.4 adjusted with NaOH. The internal solution (in mmol/L) contained KCl 140,$MgCl_2$ 1,K_2ATP 5, EGTA 5, HEPES 10, pH 7.4 adjusted with KOH. KB solution (in mmol/L) contained L-glutamic acid 50, KCl 40, KH_2PO_4 20, Taurine 20, $MgCl_2$ 3, KOH 70, EGTA 0.5, HEPES 10, glucose 10, pH 7.4 adjusted with KOH.

Cell Isolation

The investigation was approved by our institute ethics committee and conformed to the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (NIH publication No. 85-23, revised 1996). Healthy Sprague–Dawley rats of both sexes, aged 8–12 weeks and weighing approximately 200 g, were provided by the Experimental Animal Center of Soochow University (Suzhou, China). Animals were anesthetized with pentobarbital sodium intraperitoneally (i.p.), Hearts were removed and retrograde perfusion through the aorta was performed as described previously [19]. After retrograde perfusion, epicardial, mid-myocardial, and endocardial ventricular myocardium were obtained respectively by cutting with eye scissors and plyers. Isolated cells were kept at room temperature in KB solution and used within 6 h; only relaxed, striated, and rod-shaped cells were used.

Recordings of Action Potentials and I_{to} with and Without DHA and EPA

Currents in whole-cell voltage clamp configuration were recorded following the method of Hamill et al. [20]. Cardiomyocytes were transferred to a 1-ml chamber (DH-35 culture dish heater, Warner Instruments, USA) with external solution on the stage of an inverted microscope. The chamber was continuously perfused at a rate of 1–2 ml/min with external solution. Electrodes were prepared from borosilicate glass (Clark Instruments, UK) using a P-97 micropipette puller with resistances typically between 2 and 4 MΩ when filled with internal solution. Whole-cell voltage-clamp experiments were performed with a MultiClamp 700B amplifier. Whole-cell capacitance and series resistance were compensated by 60–80%. Experiments were performed at 36–37 °C. Voltage clamp pulses were generated via an IBM-compatible computer connected to Digidata 1322. Data acquisition and analyses were performed using pCLAMP software. To obtain action potentials, a 5-ms depolarizing pulse with 900pA, 1 Hz in current-clamp configuration was applied. DHA and EPA at 0.01, 0.1 , 1, 10, and 100 μmol/L were perfused for 10 min respectively to observe the effects on APDs. To obtain I_{to}, 600-ms depolarizing pulses in the range −40 mV to +70 mV were applied to the ventricular myocytes every 5 s in +10 mV increments from −40 mV holding potential (HP). Recordings of action potentials and I_{to} were performed in the physiological temperature range (36–37 °C). DHA and EPA at various concentrations were applied to investigate the effects on I_{to}.

Statistical Analysis

Continuous variables were expressed as means ± standard error ($\bar{x}$ ± SE). SPSS11.5 SPSS Inc, Chicago, IL, USA) was used for statistical analysis. Comparisons among groups were performed by repeated measurement analysis of variance (ANOVA) and least-significant difference contrast. Control and drug data for individual groups were compared by a Paired t test. $P \leq 0.05$ was considered significant. OriginPro 7.5 software (OriginLab, USA) was utilized to calculate the half-inhibited concentration (IC_{50}).

Results

Characteristics of Action Potentials and I_{to} of Rat Ventricular Myocytes

Action potentials of epicardial, mid-myocardial and endocardial ventricular myocytes were recorded respectively with action potential stimulus protocol. The action potential configurations were different in epicardial, mid-myocardial and endocardial ventricular myocytes (Fig. 1). APD_{25}, APD_{50}, and APD_{90} were gradually prolonged from epicardial to endocardial ventricular myocytes. APD_{25}, APD_{50}, and APD_{90} were 3.6 ± 1.2, 10.3 ± 2.1, and 46.3 ± 4.8 ms in epicardial ventricular myocytes ($n = 50$); 6.4 ± 1.8, 14.7 ± 2.4, and 69.4 ± 8.3 ms in mid-myocardial ventricular myocytes ($n = 58$) and 13.8 ± 2.1, 45.3 ± 10.2, and 152.1 ± 33.4 ms respectively in epicardial ventricular myocytes ($n = 62$). There were statistical significance of APDs' variations in cardiomyocytes of different layers ($P < 0.05$); however, there were no remarkable changes in the maximal velocity of action potential depolarization (V_{max}), amplitude (APA), and overshoot (OS) in epicardial, mid-myocardial and endocardial ventricular myocytes. V_{max} were 228.3 ± 14.5 V/s ($n = 71$), 10.3 ± 2.1 V/s ($n = 63$), and 46.3 ± 4.8 V/s ($n = 70$) in epicardial, mid-myocardial and endocardial ventricular myocytes ($P > 0.05$). APA were 110.7 ± 10.1 mV ($n = 71$),

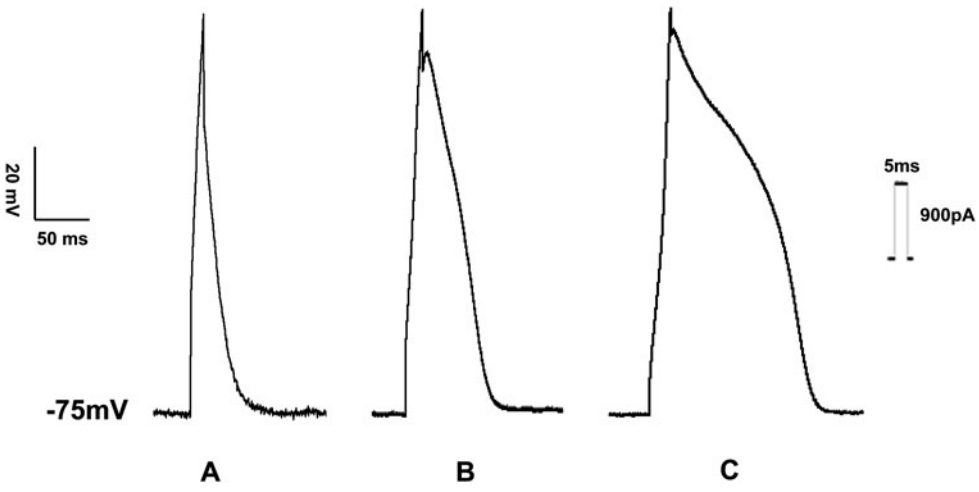

Fig. 1 Action potential configurations of rat ventricular myocytes. *A*, *B* and *C* were action potentials in epicardial, mid-myocardial and endocardial ventricular myocytes, respectively. Action potential durations were gradually increased from epicardial ventricular myocytes to endocardial ventricular myocytes

111.9 ± 9.3 mV ($n = 63$), and 109.8 ± 8.9 mV ($n = 70$) in epicardial, mid-myocardial and endocardial ventricular myocytes ($P > 0.05$). OS were 31.5 ± 5.4 mV/s ($n = 71$), 32.4 ± 6.3 mV ($n = 63$), and 30.8 ± 4.8 mV ($n = 70$) in epicardial, mid-myocardial and endocardial ventricular myocytes ($P > 0.05$). I_{to} current tracings at various test potentials were elicited by 600 ms depolarization in the range of −40 mV to +70 mV pulses applied to the ventricular myocytes every 5 s in +10 mV increments from −40 mV HP. The current densities of epicardial, mid-myocardial and endocardial ventricular myocytes at +70 mV were 59.5 ± 16.0 , 29.2 ± 5.5, and 12.3 ± 3.6 pA/pF, respectively.

The current–voltage curves of I_{to} were plotted with current densities at each test potential. The threshold potential of I_{to} channel opening was −30.3 ± 2.8 mV, i.e., I_{to} channel began to activate at more than −30 mV. I_{to} currents were gradually enhanced with the increase of test potentials. The activation of I_{to} channel was very rapid, and only needed about 10 ms, nonetheless, its inactivation was relatively slow. The time constants of epicardial, mid-myocardial, and endocardial ventricular myocytes were almost the same at each test potential. They were 31.8 ± 1.7, 32.9 ± 2.4, and 33.2 ± 2.9 ms, respectively, at +70 mV test potential ($P > 0.05$).

Effects of DHA and EPA on Action Potentials

DHA and EPA at 0.01, 0.1, 1, 10, and 100 μmol/L were applied to epicardial ventricular myocytes, respectively. The results showed that: ① APDs were gradually prolonged with the increase of DHA and EPA concentrations, whereas APD changes were not significant at low concentrations of DHA and EPA (<1 μmol/L). The prolongation of APD_{25}, APD_{50}, and APD_{90} was less than 15% compared with the control (0 min) when 0.1 μmol/L DHA was applied, and less than 10% with 0.1 μmol/L EPA application (Fig. 2). ② APDs were prolonged in concentration-dependent manners when DHA and EPA were more than 1 μmol/L. APD_{25}, APD_{50}, and APD_{90} were 7.7 ± 2.0, 21.2 ± 3.5, and 100.1 ± 9.8 ms respectively after 10 μmol/L DHA was used for 5 min (Fig. 3C), and 7.2 ± 2.5, 12.8 ± 4.2, and 70.5 ± 10.7 ms respectively with 10 μmol/L EPA application for 5 min (Fig. 3C1). APD_{25}, APD_{50}, and APD_{90} were 15.2 ± 4.0, 45.7 ± 6.8, and 215.6 ± 15.7 ms respectively when 100 μmol/L DHA was utilized for 5 min (Fig. 3D), and 13.1 ± 5.4, 48.2 ± 9.1, and 132.3 ± 21.2 ms respectively with 100 μmol/L EPA for 5 min (Fig. 3D1), which were significantly prolonged compared with those without addition of DHA and EPA ($P < 0.05$).

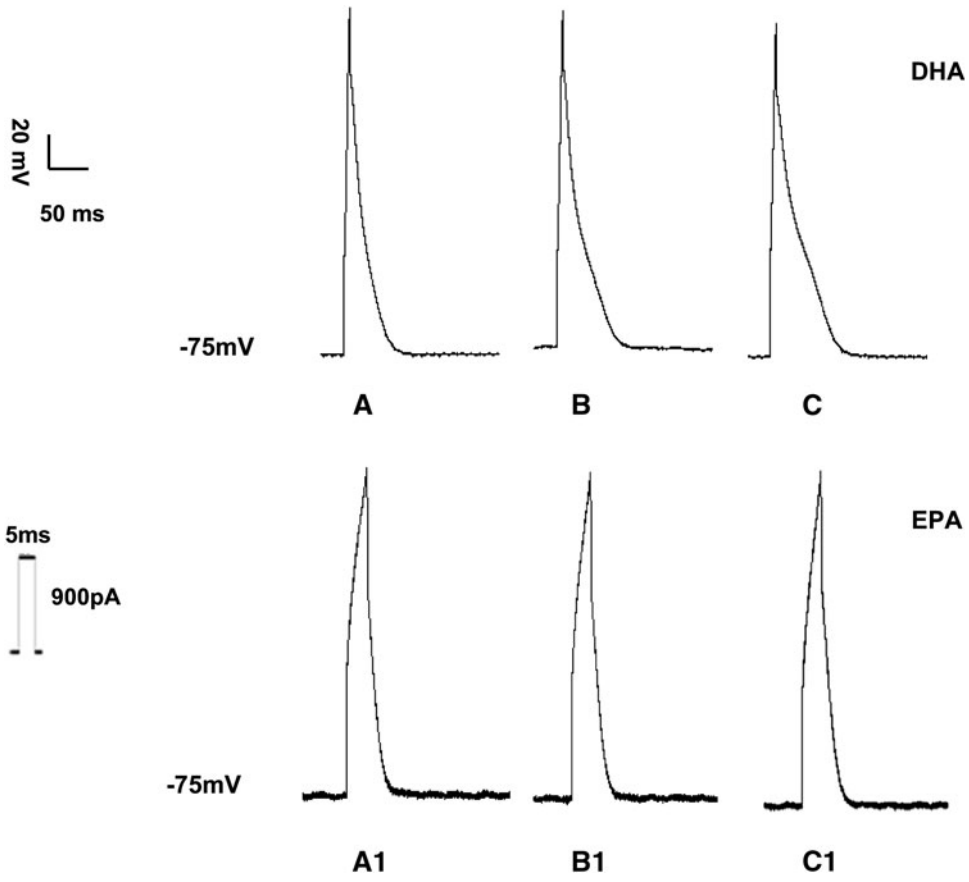

Fig. 2 Action potential changes of rat ventricular myocytes at 0.1 μmol/L DHA and EPA. *A*, *B*, and *C* were configurations of action potential when 0.1 μmol/L DHA was applied at 0, 1, and 5 min, respectively. The action potential duration was increased; however, compared with the control (0 min), the prolongation of action potential duration was less than 15%. *A1*, *B1*, and *C1* were configurations of action potential when 0.1 μmol/L EPA was applied at 0, 1, and 5 min, respectively. The action potential duration was increased; however, compared with the control (0 min), the prolongation of action potential duration was less than 10%

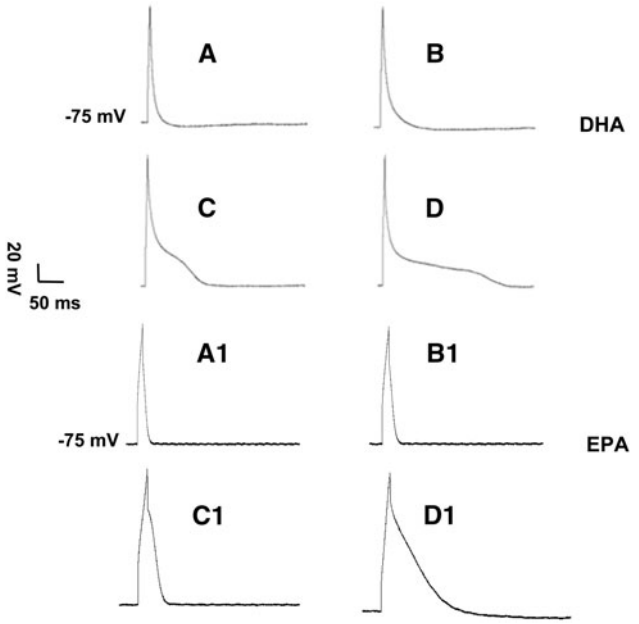

Fig. 3 Action potential changes of rat ventricular myocytes at different concentrations of DHA and EPA. *A*, *B*, and *C* were the applications of 10 μmol/L DHA at 0, 1, and 5 min. *D* was DHA at concentration of 100 μmol/L for 5 min. Action potential durations were significantly prolonged in concentration-dependent manners when DHA concentrations were more than 10 μmol/L. *A1*, *B1*, and *C1* were the applications of 10 μmol/L EPA at 0, 1, and 5 min. *D* was EPA at concentration of 100 μmol/L for 5 min. Action potential durations were significantly prolonged in a concentration-dependent manner when EPA concentrations were more than 10 μmol/L

Effects of DHA and EPA on I_{to}

DHA and EPA at 0.01, 0.1, 1, 10, and 100 μmol/L were applied, respectively. I_{to} currents were blocked by DHA and EPA in concentration-dependent manners. Current densities were gradually decreased with the increases of DHA and EPA concentrations. The I_{to} current densities at +70 mV in different concentrations of DHA and EPA were illustrated in Table 1. The representative current tracings blocked by DHA and EPA at 100 μmol/L were shown in Fig. 4. IC_{50} of DHA and EPA on I_{to} were fitted with Hill function and calculated by OriginPro 7.5 software, which were 2.3 ± 0.2 and 3.8 ± 0.6 μmol/L (Fig. 5).

Discussion

The typical action potentials consist of 5 phases or stages, i.e., 0, 1, 2, 3, and 4. The present study has showed that there are no typical action potential configurations of rat ventricular myocytes. APDs are the shortest in epicardial ventricular myocytes, and repolarization rapidly appears after depolarization, demonstrating no platform phase [21]. The phenomenon of "spike and dome" [22] sometimes can

Table 1 I_{to} current density changes in different concentrations of DHA and EPA

Concentrations (μmol/L)	I_{to} current densities (pA/pF)	
	DHA	EPA
0	59.5 ± 16.0	59.5 ± 16.0
0.01	58.4 ± 15.2	59.1 ± 14.3
0.1	57.1 ± 14.1	59.0 ± 13.2
1	49.3 ± 10.2	52.3 ± 10.5
10	35.4 ± 8.0	40.0 ± 9.2
100	30.1 ± 7.2	32.7 ± 8.1

be seen, however, this phenomenon does not appear in endocardial ventricular myocytes. Action potential repolarization in endocardial ventricular myocytes is slow, showing a relative standard action potential profile. The action potential configurations of mid-myocardial ventricular myocytes are between epicardial and endocardial ventricular myocytes [23, 24], but action potential repolarization is still rapid, and has the tendency of the platform phase, compared with the epicardial ventricular myocytes. The reasons why these alterations appear are that there are regional differences of I_{to} in epicardial, mid-myocardial and endocardial ventricular myocytes. The I_{to} channels are the most abundant in rat epicardial ventricular myocytes and then by turns in mid-myocardial and endocardial ventricular myocytes. The I_{to} current densities in epicardial, mid-myocardial and endocardial ventricular myocytes were different in this study, which further illustrates that I_{to} channels of rat ventricular myocytes have regional differences. I_{to} channels in epicardial myocytes are extremely abundant, and therefore, I_{to} currents are the largest, which makes action potential repolarization rapid, calcium inflow time and APDs short. In contrast, I_{to} channels in endocardial myocytes are few or absent, and therefore, APDs prolong. V_{max}, APA, and OS are formed mainly by 0 phase depolarization. Because regional differences of I_{to} channels do not affect depolarization of ventricular myocytes, and thus, there are no significant differences of V_{max}, APA, and OS in epicardial, mid-myocardial and endocardial myocytes [25].

The Ca^{2+}-insensitive but 4-aminopyridine-sensitive I_{to} currents play a major role in modulating cardiac electrical activity [26]. It underlies phase 1 repolarization, and thus, by setting the voltage of the early plateau phase, it influences activation and inactivation of other plateau currents that affect repolarization. It has also been reported in several studies that I_{to} channels are potentially important targets for both neuromodulatory control [27] and antiarrhythmic drug actions [28]. This current has been suggested to contribute significantly to the regional electrophysiological heterogeneity within the ventricular wall,

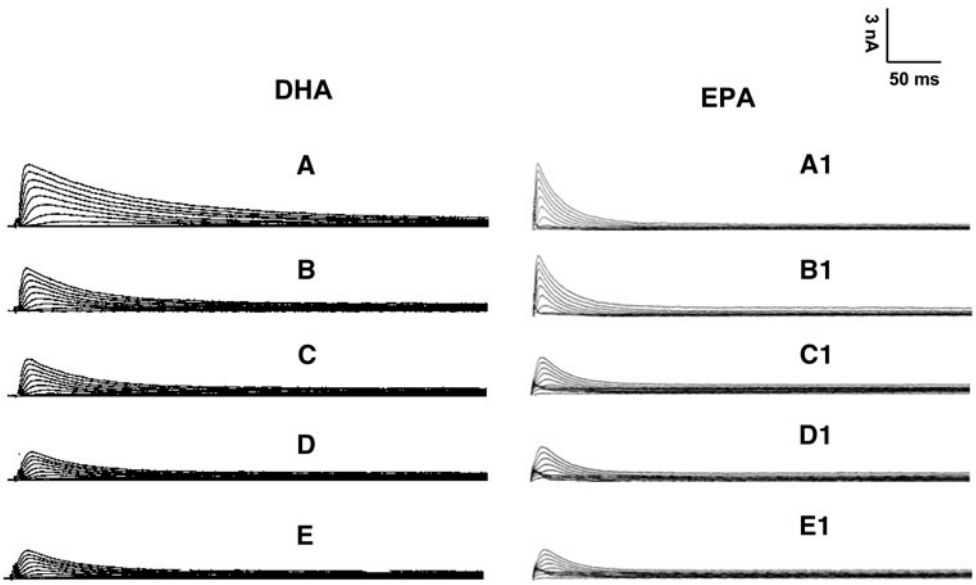

Fig. 4 Alterations of transient outward potassium currents after DHA and EPA at 100 μmol/L were applied. *A*, *B*, *C*, *D*, and *E* were representative transient outward potassium current tracings with DHA at 0, 1, 5, 10, and 15 min, respectively. Transient outward potassium currents were remarkably blocked by DHA. *A1*, *B1*, *C1*, *D1*, and *E1* were representative transient outward potassium current tracings with EPA at 0, 1, 5, 10, and 15 min, respectively. Transient outward potassium currents were significantly blocked by EPA

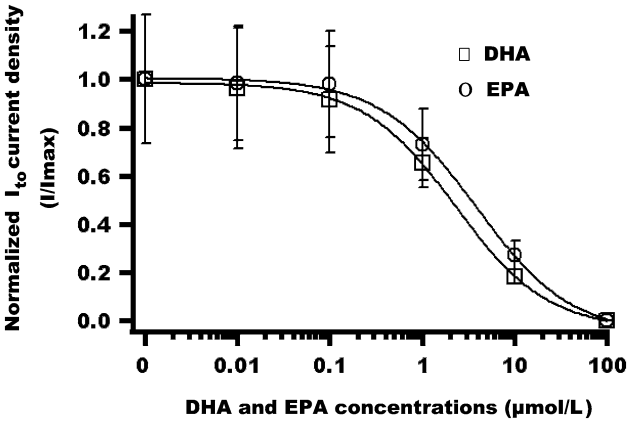

Fig. 5 Half-inhibited concentrations of DHA and EPA on transient outward potassium currents of rat ventricular myocytes. Half-inhibited concentrations of DHA and EPA on transient outward potassium currents were fitted with Hill function, which were 2.3 ± 0.2 and 3.8 ± 0.6 μmol/L

a fact considered to be responsible for T-wave polarity. The heterogeneous distribution of I_{to} thus appears to be essential in causing the transmural electrical gradients necessary for proper repolarization of cardiac action potentials. It is expected that changes in I_{to} distribution and availability can be expressed in the ECG by typical J-wave and T-wave alterations and may lead to cardiac arrhythmias during evolving heart diseases.

The present study results have shown that there are regional differences of action potentials and I_{to} amplitude and configuration of rat epicardial, mid-myocardial and endocardial myocytes. Regional differences of action potentials and I_{to} should be considered when rats are chosen as the experimental animal. We should try to obtain same regional ventricular myocytes to avoid experiment errors when we perform cellular electrophysiological studies. Consequently, in this study, we only chose epicardial myocytes to investigate the effects of DHA and EPA on action potentials and I_{to}.

There have been many reports about the electrophysiological effects of n-3 PUFA on potassium channels of cardiomyocytes and vascular smooth muscle cells in recent years [29–33]. Interestingly, it seems that n-3 PUFA inhibit or block potassium channels of cardiomyocytes [29–31], whereas they activate potassium channels of vascular smooth muscle cells [32, 33]. So far, n-3 PUFA protect against arrhythmia and sudden cardiac death using largely unknown mechanisms [34–36]. In order to investigate the mechanisms of n-3 PUFA on anti-arrhythmias and prevention of sudden death, we performed this experiment to study the effects of DHA and EPA on the action potential and I_{to} of rat ventricular myocytes. The reasons that we chose the rat as the experimental animal are not only because the rats have many advantages, e.g. cheap, strong vitality, and easily bred, but also because there are many similar electrophysiological characteristics between rat and human cardiomyocytes [17, 37].

After DHA and EPA at various concentrations were applied, APDs were gradually prolonged and I_{to} current densities were decreased by degrees with the increased concentrations of DHA and EPA. DHA and EPA could inhibit I_{to} currents, prolong APDs, and extend effective refractory period of cardiomyocytes [38]. The effects of DHA and EPA on action potentials and I_{to} may be one of their anti-arrhythmia mechanisms.

Figure 4 clearly showed that DHA and EPA could inhibit I_{to} currents. However, from the morphologic changes of action potentials in Fig. 3, we found that the morphologic changes of action potentials mainly appeared in phase 2 and phase 3 with the increased concentrations of

DHA and EPA. In contrast, there were no significant changes in phase 1 of action potential formed mainly by I_{to} current efflux. This means DHA and EPA may have effects on other ion currents in addition to the I_{to} current.

The present study has some limitations, e.g., we only investigated the effects of DHA and EPA on action potentials and I_{to} of rat ventricular myocytes. The effects of DHA and EPA on other ion currents such as I_{Na}, $I_{Ca\text{-}L}$, I_K, and I_{K1} still need to be studied further. Only if we explore the anti-arrhythmia mechanisms of n-3 PUFA completely, can we apply them correctly in clinical practice to prevent and treat cardiovascular diseases [39–43].

In summary, the present findings obtained by the patch-clamp technique have clearly shown that APDs are prolonged, and I_{to} current densities are gradually reduced with the increased concentrations of DHA and EPA. DHA and EPA have the similar effects on action potentials and I_{to} of ventricular myocytes. The effects of n-3 PUFA on action potentials and I_{to} may be one of the important mechanisms of anti-arrhythmias.

Abstract Dietary levels of n-3 PUFA are believed to influence the immune system. The importance of the source of n-3 PUFA is debated. This study addressed how the content and source of n-3 PUFA in the maternal diet influenced tissue FA composition and the immune response to ovalbumin (OVA) in mice pups. From the day of conception and throughout lactation, dams were fed diets containing 4% fat from linseed oil (LSO), fish oil (FO) or a n-3 PUFA-deficient diet (DEF). Pups were injected with OVA within 24 h of birth and sacrificed at weaning (day 21). Overall, the content of n-3 PUFA in milk, liver and spleen reflected the source and only minor differences were observed in brain phospholipid 22:6n-3. The source had only limited influence on the n-3 PUFA accretion in peripheral tissue, with most pronounced differences in the spleen. The marine PUFA-group had reduced levels of total OVA-specific antibodies and OVA-IgG1 titers in the pup blood, while the response in the LSO-group did not differ from that in the DEF-group. There were no statistical differences in the cytokine responses to OVA-stimulated splenocytes, but the decrease in IgG1 was paralleled by an increase in IFNγ-production and a decrease in IL-6-production. Our results indicate that maternal intake of FO, but not of LSO, changes the offspring's antigen-specific response and potentially increases Th1-polarization.

Keywords n-3 long-chain polyunsaturated fatty acid · Tissue fatty acid incorporation · Immune maturation · Sensitization · Diet · Programming

Abbreviations

DEF	The n-3 PUFA-deficient group
20:5n-3	Eicosapentaenoic acid (individual fatty acids are named by number of carbon atoms: number of double bonds followed by the position of the last double bond)
FO	The fish oil group
Ig	Immunoglobulin
IL	Interleukin
IFNγ	Interferon-γ
LCPUFA	Long-chain PUFA
LSO	The linseed oil-group
OVA	Ovalbumin
PC	Phosphatidylcholine
PE	Phosphatidylethanolamine
TAG	Triacylglycerol
Th	T-helper lymphocytes
TNFα	Tumor necrosis factor-α

Introduction

An adequate supply of essential fatty acids during pregnancy and lactation is crucial for optimal fetal and

postnatal development. It is well known that n-3 PUFA are required for growth and development of the central nervous system of the fetus and infant [1]. Long-chain n-3 PUFA (n-3 LCPUFA) have in studies with adults been shown to be immunosuppressive and to exert beneficial effects in a variety of inflammatory disorders [2]. Dietary n-3 LCPUFA have, in both human and animal experiments, been shown to affect a wide range of immune functions, including lymphocyte proliferation, cytokine production, NK-cell activity, adhesion molecules expression, and antigen presentation in adults [3]. However, the effect of maternal n-3 PUFA intake on immune function in the offspring is less well characterized and only few experimental studies have addressed this topic [4].

The immune system of the newborn has not fully matured and is believed to be more sensitive to environmental conditions, including diet. Such conditions have been hypothesized to influence the polarization of T-helper lymphocytes (Th1/Th2) of the immune system and accordingly the risk of allergy development [5]. The processes of importance for shaping the immune system take place already in utero and in the early postnatal period, and the immune system is therefore particularly susceptible to changes in diet and external stimuli to the fetus/newborn [6]. To this end, human studies with fish oil-supplementation of pregnant women have been shown to affect immune function in the neonate [7, 8]. We have previously shown that fish oil-supplementation during lactation resulted in a higher predisposition of the blood from the children to produce Interferon-γ (IFNγ) upon polyclonal stimulation [9, 10], indicating a higher intake of n-3 LCPUFA is associated with faster immune maturation and Th1-polarization. An association between a high maternal n-3 PUFA intake and a decreased risk of infant allergy is supported by recent randomized trials [11, 12]. In mice, maternal fish oil has been shown to lead to lower levels of prostaglandin E_2 in pups' lung and increased survival to infection compared to offspring of dams on a corn oil diet [13] and in another study manipulation of the ratio of n-6 to n-3 PUFA in the maternal diet showed better induction of oral tolerance in neonatal mice with a high relative intake of n-3 PUFA [14].

Even though mammals can convert α-linolenic acid (18:3n-3) to eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), it is controversial whether a dietary intake of 18:3n-3 is as efficient as fish oil as a means to affect disease risk. Fish oil [11–13] as well as α-linolenic acid [14] have been used in the various human and animal studies, but since different doses and experimental designs have been used, the effect of the two sources is difficult to compare. In the present study, we hypothesized that maternal n-3 PUFA intake from fish oil0or plant oil during gestation and lactation affects the Th1/Th2-polarization early in life and that this is reflected in the antibody and cytokine production against food allergens encountered postnatally. We fed groups of female mice fish oil or linseed oil from mating until weaning of their offspring, and tested the antibody response to ovalbumin (OVA) injected in the offspring on day 1.

Experimental Procedure

Animals

The experiment was approved by the Danish Committee for Animal Experiments. BalbC mice from Taconic M&B (Ll. Skensved, Denmark) 8–10 weeks of age were housed in plastic cages in a temperature (21 °C) and humidity (50%) controlled environment on a 12 h/12 h light/dark cycle with a standard nonpurified diet (Altromin No. 1324, Chr. Petersen A/S, Ringsted, Denmark) and water freely available. They were acclimatized to the housing conditions for 7 days before conception. The mice were then allocated to individual cages and randomized to the three dietary treatments from the time of mating and throughout the pregnancy and lactation periods. In this feeding experiment, 3 dams on fish oil diet (FO) gave birth to 17 pups, 4 dams on n-3 PUFA-deficient diet (DEF) to 13 pups, and 2 dams on a linseed oil based diet (LSO) to 11 pups. An additional feeding experiment was performed with the same diets, since the first experiment resulted in fewer pregnancies than expected. This resulted in birth of further 12 pups in the FO groups, 11 in the DEF-group, and 10 in the LSO-group, from 2 dams in each of the groups. No differences were found in milk gland TAG fatty acid composition from the two feeding periods, so the results from the two experiments were pooled.

Diets

The overall composition of the three dietary groups was as follows: 56 g/100 g corn starch (Bestfoods Nordic A/S, Skovlunde, Denmark); 20 g/100 g casein (Miprodan milk-proteins, Arla Foods amba, Viby, Denmark), 10 g/100 g sucrose (Danisco Sugar, Copenhagen, Denmark), 5 g/100 g salt mixture (including trace elements), 4 g/100 g fat, 4 g/100 g cellulose powder (MN 100, Machery-Nagel GmbH & Co, Düren, Germany), 0.5 g/100 g vitamin mixture, and 0.5 g/100 g choline chloride (Merck, Darmstadt, Germany). The vitamin and salt mixtures were composed as described by Aaes-Jørgensen and Hølmer [15].

One group was given a DEF, in which fat was supplied as a 78:10-mix of coconut fat (Aarhus United A/S) and safflower oil (Urtekram A/S, Mariager, Denmark). The

other four groups were given n-3 PUFA sufficient diets with equal amounts of n-3 PUFA, but in the form of α-linoleic acid (18:3n-3) from linseed oil (Unikem, Copenhagen, Denmark) mixed with safflower oil, olive oil (FDB, Albertslund, Denmark), and coconut fat (43:13:25:19) (LSO) or n-3 LCPUFA from fish oil (Aarhus United A/S, Aarhus, Denmark) mixed with safflower oil (79:21) (FO). All diets had an equal content of n-6 PUFA (Table 1). All diets were supplied ad libitum. The diets were powdered, stored at –20 °C and provided fresh every day.

Immunization and Organ Collection

All neonatal mice were immunized both intraperitoneally and subcutaneously with 20 μL 10 mg/mL OVA within the first 24 h of life. 3 weeks after birth, blood from the offspring was drawn from retro-orbital venous plexus using calibrated 25 μL heparinized micropipettes. Blood was immediately diluted in 375 μL PBS and stored at −20 °C until antibody determination.

Dams and pups were weighed weekly and when pups were 3 weeks of age, all mice were anesthetized with 0.06 mL/10 g body weight of a mixture composed of Hypnorm (Janssen Pharmaceutica, Beerse, Belgium): Dormicum (Hoffmann-La Roche AG, Basel, Switzerland):sterile water (1:1:2), thereafter death was assured by cervical dislocation. Spleens were removed, and leucocytes were immediately after isolation and used for determination of the fatty acid composition and for OVA-specific cell proliferation and cytokine production. Brains, eyes, and livers were also removed from pups and milk glands from the dams and all organs were immediately frozen in liquid nitrogen. The organs were stored at −80 °C until analysis.

Table 1 Fatty acid composition of diets

	n-3 PUFA-deficient (DEF)	Linseed oil (LSO)	Fish oil (FO)
SFA	71.4	26.6	23.1
MUFA	10.0	30.5	34.3
n-6 PUFA	18.5	18.1	19.3
18:2n-6	18.5	18.1	18.9
20:4n-6	0.0	0.0	0.4
n-3 PUFA	0.1	24.6	23.2
18:3n-3	0.1	24.6	2.4
20:5n-3	0.0	0.0	6.1
22:6n-3	0.0	0.0	9.9
n-6/n-3 PUFA	185	0.7	0.8

Data are given as g/100 g

Analysis of Diets and Tissue Lipids

Lipid from diets and tissues were extracted with chloroform and methanol according to Folch et al. [16]. Fatty acid composition of the dietary fat and the structure of the TAG, represented by the fatty acid composition in *sn*-2 MAG, were measured as described previously [17]. TAG from milk glands were isolated by TLC with heptane–isopropanol–acetic acid (95:5:1, v/v/v) and methylated with a modified BF_3 procedure [18], as were the lipid extracts from the pup livers. Phospholipid classes in pup brain, eyes and spleen (from brain: phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine and PC and PE from eyes and spleen) were separated by TLC with chloroform–methanol–hexane–acetic acid–boric acid (40:20:30:10:1.8, v/v/v/v/w), visualized with 2,7-dichlorofluorescein (0.2% in ethanol), scraped off and methylated with BF_3 [19]. The resulting fatty acid methyl esters were analyzed by GLC in a Hewlett–Packard 5890 chromatograph equipped with a split/splitless injector, SP2380 capillary column (60 m, ID. 0.25 mm; Supelco Inc., Bellefonte, PA), flame-ionization detection and helium as carrier gas. The GLC conditions were as follows: injector temperature 270 °C, flame-ionization detector 270 °C, helium carrier gas at 1.2 mL/min, injector split ratio 1:11, initial oven temperature 70 °C, which was held for 5 min and the increased by 15 °C/min until 160 °C, 1.5 °C/min until 200 °C that was then maintained for 15 min followed by a finally temperature rise to 225 °C maintained for 10 min. The initial oven temperature for the fatty acid determinations in milk gland TAG was 50 °C. Peak areas were calculated using a Hewlett–Packard integrator and the fatty acids were identified by comparing the retention time with standards of known fatty acid composition (Nu-Chek-Prep, Elysian, MN).

Spleen Cell Preparation and Ex-Vivo-Stimulated Cytokine Production

Single-cell suspensions were prepared from spleens pooled from 2 to 3 offspring within a litter in DMEM (Gibco, Life Technologies, Scotland). Red blood cells were lyzed with ammonium chloride buffer (0.83% NH_4Cl). For the measurement of cytokine production, cells were washed and resuspended in X-VIVO 10 (serum free medium, Bio Whitaker, USA) at a final concentration of 2×10^6 cells/ mL and were cultured with 550 μL/well in flat-bottom 48-well tissue culture plates (Nunc, Denmark). Cells were stimulated with 0.5 mg OVA/well (0.9 mg/mL) or with medium in triplicates, and supernatants were collected after 72 h of culture. Supernatants were stored at −80 °C until determination of IFNγ, tumor necrosis factor-α (TNFα), interleukin (IL)-6, IL-10, IL-5 and IL-12 by commercial ELISA

kits from R&D systems Europe (Abingdon, UK) according to manufactures instructions (Duosets DY 485, DY 410, DY 406, DY 417, DY 405, DY 419). Cytokine concentrations were quantified relative to standard curves representing a range of dilutions of recombinant cytokine using 4-parameter curve fit analysis (Kineticalc software, version KC4 Rev 29, Biotek instruments). Limits of detection for these assays were 31 pg/mL (IFNγ), 16 pg/mL (TNFα), 16 pg/mL (IL-6), 31 pg/mL (IL-10), 16 pg/mL (IL-5) and 31 pg/mL (IL-12).

Determination of OVA-Specific Antibodies in Pups' Plasma

Presence of total immunoglobulins (Ig) and IgG_1 plasma antibodies specific for OVA was tested by ELISA. In brief, micro-titer plates (Nunc, Denmark) were coated with OVA overnight at 4 °C and plasma and controls were serially diluted in the washed plates. Bound OVA-specific Ig was detected with peroxidase-conjugated rabbit anti-mouse Ig (DAKO, Denmark). OVA-specific IgG_1 and IgG_{2a} were detected with rabbit anti-mouse IgG_1 and IgG_{2a} antibodies (Zymed, CA, USA) followed by peroxidase-conjugated swine anti-rabbit Ig (DAKO, Denmark). Hydrogen peroxide and tetramethylbenzidine (TMB, Merck, Germany) were used as substrates and the reaction was stopped after 10 min by the addition of phosphorous acid (2 M). Plates were measured spectrophotometrically at 450 nm using 690 nm as reference on an ELISA-reader (Bio-kinetics reader, EL 340, Biotek instruments). Controls, monoclonal antibodies against OVA (of IgG_1 and IgG_{2a} isotypes) and a pool of plasma from OVA-immunized animals were included on each plate. The antibody titers were expressed as $\log_2$ titers and defined as the interpolated dilution (4-parameter analysis, Kineticalc software, KC4 Rev 29, Biotek instruments) of a blood sample leading to an absorbance on 0.2 above background.

Statistics

Results were expressed as means ± standard errors (SEM). Differences in fatty acid compositions between groups were tested by one-way ANOVA (GraphPad PRISM version 3.02, GraphPad software, San Diego, CA). Tukey's Multiple Comparison post hoc test was used to determine the exact nature of the differences. The level of statistical significance was $P < 0.05$.

Results

Dams weighed 23 ± 0.5 g (mean ± SEM) at the beginning and 30 ± 0.6 g at the end of the 7 weeks study. During the course of the study all mice gained more weight due to pregnancy, which they lost again at delivery. The pups increased their weight by a factor 1.8–3.4 from birth until sacrifice at 3 weeks of age. The increase in weight was dependent on the number of pups in the litter, but there was no significant difference in pup litter size (3–7 pups/group in FO-group, 2–6 in DEF-groups, and 3–8 in the LSO-group) and weight between the dietary groups (results not shown).

The n-3 PUFA content in the milk gland TAG reflected the fatty acid composition of the maternal diets (Table 2). Milk gland TAG from both of the n-3 PUFA sufficient groups, LSO and FO, had a significantly higher content of n-3 PUFA relative to the DEF-group. In the LSO-group this was due to an increase in the content of 18:3n-3 and 20:5n-3, whereas also 22:6n-3 was increased in the FO-group. It is noteworthy that although approximately 25% of dietary fatty acids in the LSO-diet were 18:3n-3, only 2% of the milk gland TAG fatty acid was 18:3n-3. The n-6 PUFA-content of the milk glands was not affected by an increased intake of n-3 PUFA, whereas that of MUFA was decreased in the FO-group compared to that in the DEF-group. The composition of PUFA in the pup liver lipid in turn reflects that in the milk gland TAG (Table 3). Pups from both the FO- and the LSO-group had pronouncedly increased liver levels of n-3 PUFA, increased levels of PUFA as such, and lower levels of n-6 PUFA. These changes were more pronounced in the FO-group, but the two groups responded similar with respect to changes in

Statistical analysis by ANOVA and post hoc group comparisons, if overall $P < 0.05$: values in a row with different superscripts differ significantly ($P < 0.0001$)

the overall n-6 to n-3 PUFA-ratio, the content of 20:5n-3 and 22:5n-3, and the observed deceases in the content of the n-3 PUFA-deficiency markers, 22:4n-6 and 22:5n-6.

The phospholipid PUFA-composition of pup tissues was also affected by the n-3 PUFA-content of the maternal diet. All types of n-3 LCPUFA were increased in both PC and PE in both brain and spleen, whereas the n-6 PUFA-content of the tissue phospholipids decreased. The n-6 PUFA-decrease was most pronounced for 22:5n-6, which is the dominant of the two n-3 PUFA-deficiency markers and which decreased to the same extent in the LSO- and FO-group (Table 4). The dietary n-3 PUFA-induced decrease in the tissue phospholipid n-6 PUFA-content was generally larger in the spleen than in the brain. The phospholipid PUFA-incorporation of the LSO- and FO-group only differed significantly in the PE-pool of the tissues, whereas the two groups were very comparable with respect to the composition in PC in brain but exhibited a minor difference in total n-3 PUFA in spleen PC (Table 4). Brain phosphatidylserine PUFA-incorporation was changed in the same way as that of PC and PE, with only minor differences between the LSO- and FO-group (data not shown). Furthermore, the observed diet-induced changes in eye PC and PE PUFA-composition were as those in the brain, except that no differences were found in the PUFA-composition of the LSO- and FO-group (data not shown).

OVA-immunization gave rise to a significant increase in the plasma concentration of OVA-specific antibodies and of OVA-IgG1, which in non-immunized mice of the same age was 6.0 ± 0.07 and 5.5 ± 0.06, respectively. The observed OVA-antibody titers reflect a Th2-polarization of the response, since the IgG1 titers corresponded to the titer measured for all antibody classes. It was not possible to obtain IgG2a titers (representing aTh1-polarization) that were significantly above the background (data not shown), possibly due to the much lower level of antibodies involved in this type of responses. The OVA-Ig titers were significantly reduced in FO group as compared to the DEF-group, whereas the LSO-group did not differ from the DEF-group ($P < 0.01$, Fig. 1). The results for OVA-IgG1 were similar to those of IgG (data not shown).

The cytokines produced in spleen cells from the same mice upon stimulation with OVA did not reveal any significant differences between the different groups (Table 5). The responses were for most of the analysed cytokines only slightly over the detection levels and rather variable and it was thus not possible to show any statistically significant differences between the groups. The high variation within groups may be ascribed to the fact that a proportion of cell cultures within each group did not result in cytokine productions above the background (for IFN-γ, 50, 60 and 40% were detectable in the FO, LSO and DEF-group, respectively). However, a trend towards an increasing IFNγ- and TNFα-production and a decreasing production of IL-6 with increasing incorporation of n-3 LCPUFA in spleen cells was observed. The production of IL-12 and IL-5 could not be detected in any of the groups. There were no significant differences in the spleen cell proliferation or in CD69-expression on the cultured spleen cells from the pups in the dietary groups (data not shown).

Discussion

The present study showed a reduction in total OVA-specific antibodies and in the IgG1 titers in the blood in the neonatal mice from dams in the fish oil-fed group. As we were not able to measure OVA-specific IgG_{2a} antibodies in the plasma, we cannot establish whether this reduction is caused by a general reduction in the ability to respond to an antigen or an increased Th1-polarization. However, although our results were not significant, the decrease in the Th2-facilitated IgG1-response was paralleled by an increase in IFNγ-production and a decrease in the production of IL-6 in OVA-stimulated spleen cells ex vivo, indicating an increase in Th1-cells in the spleen in FO-group compared to control. The response in the LSO-group did not differ from that in the DEF-group. This is supported by the study of Rayon et al. [13], who showed that maternal intake of menhaden oil resulted in a higher survival in rat pups towards group B *Streptococcal* infection. This was correlated with a lower PGE_2 production in the lungs as compared to the corn oil-fed group, indicative of conditions favoring a Th1- over Th2-polarization [20]. Korotkova

et al. [14] have shown that a high maternal n-3 PUFA intake affected the induction of tolerance against orally administered OVA in neonatal rats, thus also supporting a critical need for n-3 PUFA in the perinatal period. Although the results of these two studies are not

comparable, they both point toward a role of n-3 PUFA in directing the immature immune system towards responses which are considered to be beneficial. Furthermore, our results also support our earlier findings in humans, where intake of fish oil in infancy or milk from fish oil-supplemented mother were associated with an increase in IFNγ-production in ex vivo stimulated blood cells also indicative of a Th1-polarization [9, 10]. As regards the effect of fish oil on allergy development in infancy, some studies suggest a protective role of n-3 LCPUFA [21, 22]. Whether a higher ex vivo IFNγ and a reduction in antigen-specific IgG1 antibodies directly can be compared to human studies on infant allergy is, however, purely speculative.

Not surprisingly we found that the milk gland TAG fatty acid composition was reflecting that of the diet, the PUFA-composition in the pup liver lipid in turn reflected that of the milk and that the tissue phospholipid PUFA-composition reflected that in the liver. Furthermore, the present study showed that the source of dietary n-3 PUFA, plant oil 18:3n-3 or marine n-3 LCPUFA, had only limited influence on the accretion of n-3 LCPUFA in the peripheral tissue, but with more pronounced differences in spleen than in brain. Intake of both fish oil and linseed oil gave rise to an increased incorporation of 22:6n-3 compared to that in the DEF-group, but the 22:6n-3 incorporation was more specific in the FO-group as intake of linseed oil also gave rise to pronounced increases in both 20:5n-3 and 22:5n-3. The accumulation of these intermediate n-3 LCPUFA is in agreement with many previous results and a key issue in the debate on whether intake of 18:3n-3 is an optimal way to fulfill requirements [23]. The difference in brain phospholipid 22-6n-3 content was however only minor, where as that in spleens was more pronounced. Brain phospholipid has been shown to saturate with 22:6n-3 at lower levels of intake than other tissues [24, 25]. The present study did not examine the dose response relationship but only compared the two sources of n-3 PUFA at levels well over levels of deficiency (2.5E% from n-3 PUFA) with that from a DEF (0.01E%, 2E% from n-6 PUFA). The level of 18:3n-3 and 22:5n-3 has been shown to increase in the brains of suckling rat pups when the mothers were fed diets with high compared to low levels of 18:3n-3 [26, 27]. A previous four-generation study in rats that compared incorporation of n-3 PUFA from marine oils with that from plant oils at an overall fat intake of 20 g/100 g (39 E% from fat, hereof around ¼ from n-3 PUFA) also found better n-3 LCPUFA-incorporation in brain PE and PS [28]. One of the strengths of this study is that we used intake levels that are similar to that in ordinary mouse chow (11E% from fat). We were unfortunately not able to get milk samples from the mice and used the fatty acid composition of mammary gland TAG as a proxy to the milk fatty acid composition. Several studies have determined the fatty acid composition of mouse milk after oxytocin injection and milking [25, 29, 30]. Although different dietary regimes were used in these studies the overall reported fatty acid composition of mice milk, including the relative content of the MCFA that are characteristic for milk, was comparable to the milk gland TAG composition in the present study. Most of the milk lipids are TAG, but there is however some phospholipid in milk and we expect these to be enriched in LCPUFA. It is therefore, possible that our results may be an exact estimate of the differences in milk-LCPUFA between the FO- and LSO-group. The levels of 22:6n-3 that we found in the milk glands of these mice and the range that we induce by the dietary changes are comparable to the variation in human milk. The average 22:6n-3 content in human milk in populations with a low fish intake such as the Australian or American is typically around 0.1–0.2% of the fatty acids [1] and has in some Chinese milk been found to be as high as 3.6% [31].

This study showed that maternal fish oil intake was associated with a decrease in plasma concentrations of OVA-induced IgG1in the pups and tended to show a Th1-polarization also in the ex vivo cytokine response to OVA in spleen cells, whereas no immuno-modulating effects were observed after intake of 18:3n-3 from linseed oil. Both types of n-3 PUFA were associated with an increase in milk and tissue n-3 LCPUFA-incorporation, although a slightly lower incorporation of 22:6n-3 was seen after 18:3n-3. Early growth is associated with a high n-3 LCPUFA accretion in the central nervous system and therefore a high requirement of n-3 PUFA. Other tissues may therefore be more susceptible to differences in the n-3 LCPUFA intake during the perinatal period than there are later in life. Since early processes play an important role in the long-term shaping of the immune system, the immune system may be especially vulnerable towards suboptimal intakes during the perinatal period. The acute and potential programming effects of an increased intake of n-3 LCPUFA early in life is not well characterized and this study indicate a need for more thorough investigation especially with respect to their potential effects on the immunological development.

Acknowledgments We acknowledge the late CE Høy, who was involved in the funding and planning of this study. We greatly appreciate the technical help of Karen Jensen, Lillian Vile, Charlotte Vajhøj, and Anni Mehlsen. The study was supported by The Danish Research and Development Program for Food and Technology (FELFO) and Center for Advanced Food Studies (LMC). None of the authors have any conflict of interest to disclose in connection with the submitted material.

Arachidonic Acid Induces Production of 17,20β-Dihydroxy-4-pregnen-3-one (DHP) via a Putative PGE2 Receptor in Fish Follicles from the Eurasian Perch

E. Henrotte · S. Milla · S. N. M. Mandiki · P. Kestemont

Received: 16 August 2010 / Accepted: 19 November 2010 / Published online: 24 December 2010

Abstract The effects of docosahexaenoic, eicosaenoic and arachidonic acids (DHA, EPA and ARA, respectively) on sex-steroid and prostaglandin (PG) production were investigated in Eurasian perch (*Perca fluviatilis*) follicles using an in- vitro incubation technique. Only ARA was able to induce the production of 17,20β-dihydroxy-4-pregnen-3-one (DHP), the hormone produced by vitellogenic follicles undergoing final meiotic maturation, as well as the production of PGE2 and PGF2α by the follicles. This work also investigated, using a preliminary pharmacological approach, the presence of a functional PGE2-like receptor in fish follicles. Exogenous PGE2 and butaprost (specific agonist of the EP2 receptor) stimulated DHP production. A second experiment assayed the cyclic adenosine monophosphate (cAMP) production by the follicles after 24 h of incubation with the agonist and antagonist of the EP2 receptor. As observed in mammals, we concluded that the cAMP produced in response to PGE2 was probably mediated by an intracellular mechanism via a PGE2-like receptor. This is the first pharmacological indication of this type of receptors in fish follicles. This study also indicates that ARA, and its derivatives, PGE2 and PGF2α, may act on final follicle maturation in Eurasian perch.

Introduction

Currently, difficulties in the supply of high quality eggs and fry are amongst the main constraints in the development of new species in aquaculture [1]. In an effort to improve egg quality and larval survival, attention should be given to establish the best dietary levels of docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA) and arachidonic acid (ARA) for breeders [2]. DHA is particularly important during fish early ontogeny for normal development of neural and visual functions. Henrotte et al. [3] have shown that a high dietary EPA/ARA ratio could induce lower reproductive performances, especially regarding the larval survival and resistance to an osmotic stress in Eurasian perch, *Perca fluviatilis*. ARA is the chief precursor of the eicosanoids, including two-series prostaglandins (PGs).

However, EPA competitively interferes with eicosanoid production from ARA catalyzed by cyclooxygenase and lipoxygenase. In fish as in mammals, eicosanoid production is thus influenced by the cellular ratio of EPA/ARA [4].

Although several studies describe the action of ARA and its derivatives, on follicle ovulation and/or steroidogenesis in vitro in teleosts [5–10], nothing is known about the effects of those molecules on final follicle maturation and ovulation in the Eurasian perch, one of the most promising species for diversification in European inland aquaculture [11]. ARA alone stimulated sex-steroid production via its conversion into PGE2 and by increasing cAMP production in ovary and testis of goldfish *Carassius auratus* [7, 10], while EPA and DHA inhibited gonadotropin-stimulated testosterone production in goldfish and rainbow trout, *Oncorhynchus mykiss* [7]. In the European sea bass, *Dicentrarchus labrax,* ARA induced maturation in a dose- and time-dependent manner, while EPA and DHA were ineffective [9].

In mammals, pharmacological approaches have been used to demonstrate the existence of a variety of prostanoid receptors, which comprise five major subtypes: DP, FP, IP, TP and EP receptors named in accordance with their selectivity for the prostanoids PGD2, PGF2α, PGI2, TXA2 and PGE2, respectively. The actions of PGE2 are mediated by EP receptors comprising four subtypes: EP1, EP2, EP3 and EP4 [12]. Only few studies focused on those receptors in fish. Busby et al. [13] first demonstrated, by a pharmacological approach, the existence of the EP2 receptor in the liver of rockfish, *Sebastes caurinus*, involved in the regulation of glucose metabolism. PGE2, via EP1 and EP2, also interact with the NaCl transport across the opercular epithelium of killifish, *Fundulus heteroclitus* [14]. But there is no information yet on the presence of EP2 or FP receptors in ovarian follicles of fish linked to reproductive processes. In mammals, the effects associated with EP2 and EP4 receptors are considered relaxant and are believed to be associated with a stimulation of adenylate cyclase and an increase in the levels of intracellular cAMP [15, 16]. The role of cAMP in the stimulation of steroid hormone biosynthesis is well-recognized [17] and eicosanoid signal transduction pathways are highly conserved across vertebrate species [18]. Hizaki et al. [19] showed that ovulation was impaired and fertilization dramatically reduced in EP2-deficient mice, leading to the hypothesis that the reproductive failure during early pregnancy in COX-2 deficient mice was due to lack of PGE2 ligands available to bind to the EP2-receptor. Moreover, Narumiya and Fitzgerald [20] concluded thanks to knockout studies in mice that EP2, but not EP1, EP3 or EP4 was associated with reproductive failures. Given the reproductive stimulatory effects of PGs in fish and of PGs/EPs in mammals, one can suppose that such receptor exist in the gonad of fish and exert some positive actions in the final stages of oogenesis including sex-steroid synthesis in relation to cAMP production.

Our objective was to study the impact of polyunsaturated fatty acids (PUFA), and the derivatives of ARA, on sex-steroid and PG production by the Eurasian perch follicle, during the final stages of oogenesis, in order to understand their role on the follicle physiology. The second objective was to evaluate the presence of PGE2-like receptors in this fish species thanks to a pharmacological approach (use of the mammalian EP2 agonist butaprost and EP2 antagonist AH6809). This work was the first to investigate the presence of a PGE2-like receptor in fish ovary linked to the reproductive processes.

Materials and Methods

Research involving animal experimentation were conformed to the principles for the use and care of laboratory animals, in agreement with the Belgian and European regulations on animal welfare (FELASA).

Chemicals

All chemicals and fatty acids were purchased from Sigma–Aldrich (Belgium). Cortland medium was first selected to observe follicle maturational processes in response to a stimulation with hCG 100 UI mL^{-1}. Successful gonadotropin responsiveness of cultured follicles was observed by adapting the media composition, pH and duration of incubation (data not shown). Cortland medium chosen for follicle incubation consisted of the following (g/L): 7.25 NaCl, 0.38 KCl, 0.23 $CaCl_2$ $2H_2O$, 1.00 $NaHCO_3$, 0.41 NaH_2PO_4 H_2O, 0.23 $MgCl_2$ $6H_2O$, 0.23 $MgSO_4$ $7H_2O$, 5.20 Hepes, 1.00 BSA, 0.03 Penicillin and 0.05 Streptomycin, at pH 7.4. ARA, EPA, DHA, butaprost, AH6809 and PGE2 were first dissolved in ethanol and subsequently diluted with Cortland medium to the desired concentration. The final concentrations of ethanol in follicle incubation did not exceed 0.1%. Control incubations contained 0.1% ethanol.

Effect of PUFA and Derivatives on DHP and PG Production during the Final Follicle Maturation

Fish

Three sexually mature Eurasian perch fed with live food were collected in early March 2007 from a cage placed in a culture pond at the University of Namur (Belgium), maintained under natural conditions of temperature and photoperiod. Perch were killed by decapitation on the day

of sampling, and the ovaries were removed and dissected in Cortland medium adjusted to pH 7.4 at 15 °C.

Ovarian Follicle Incubations

The ovaries were dissected into small pieces containing 10–15 prematurational follicles attached to the surrounding extrafollicular tissue. Prematurational stage was defined as post-vitellogenic follicle, with no signs of yolk clarification or lipid droplet coalescence. Eight ovarian pieces per females were placed in triplicates in a 6-well plastic dish (Cellstar, Greiner Bio-One, Belgium) with 3 mL of Cortland medium per well. Follicles were allowed to stabilize at 15 °C for 30 min prior to treatment. All plates were then incubated at 15 °C under intermittent agitation for 48 h. Every 12 h, all from a group of 10–15 follicles of each replicate were treated with an follicle-clearing solution of ethanol:formalin:acetic acid (6:3:1) and examined immediately using an optical microscope to determine the survival of the follicles. A follicle was considered alive when the ooplasm was clear, tainted in light pink and in the center of the follicle, while dead cells were characterized by a grey color, with the outline of the ooplasm being heterogeneous. Survival was 96% after 48 h of follicle incubation, whatever the tested treatment. The media were replaced every 12 h with new experimental media and were placed in test tubes to be stored at −20 °C for a subsequent radioimmunoassay (RIA). Media tested were: ARA, EPA and DHA (100 μM); PGE2 (1, 100 and 1,000 ng mL^{-1}); butaprost (0.1, 1 and 10 μM) for hormone assays.

Hormone Assays

Sex-steroid hormone in culture media was assayed using RIA according to Fostier and Jalabert [21], following two extractions with cyclohexane/ethyl acetate (v/v). Goetz et al. [22] reported that yellow perch (*Perca flavescens*) follicles show first signs of ovulation predictably by approximate 34 h. We decided therefore to assay RIAs in the media after 36 h of incubation. Only 17,20β-dihydroxy-4-pregnen-3-one (DHP) was assayed, due to its important roles in final follicle maturation. The DHP antiserum and tracer were provided by Dr A. Fostier (INRA, Rennes, France). The intra-assay coefficients of variation was 9.60% ($n = 15$ replicates) and the detection limit was at 4–5 pg mL^{-1}.

Follicles were incubated with ARA, EPA or DHA 100 μM in order to assay PGs in the culture media after 36 h. PGE2 and PGF2α from the culture media were first purified on specific minicolumns (RPN 1903, Amersham, Biosciences) following the procedure of the manufacturer. RIA kits for PGE2 and PGF2α were purchased from Izotop (RK-25 M and RK-15 M, Hungary), the intra-assay coefficients of variation were 4.58 and 9.30% for PGE2 and PGF2α, respectively ($n = 15$).

Preliminary Pharmacological Study on the PGE2-Like Receptor

The study of PGE2-receptor was initiated in 2009 and completed in 2010.

Fish

Three sexually mature Eurasian perch were caught from a pond located in the north of France in early March 2009 and in total 12 females from the river Meuse in 2010. Perch were killed by decapitation few days before expected ovulation, and the ovaries were removed and dissected in Cortland medium adjusted to pH 7.4 at 15 °C.

Ovarian Follicle Incubations

Dissection and incubation conditions were performed as described in point 2. In a first set of experiments conducted in 2009, the media tested were: PGE2 (1,100 and 1,000 ng mL^{-1}); EP2 agonist, butaprost (0.1, 1 and 10 μM); EP2 antagonist, AH6809 (0.01, 1 and 10 μM) and the combination of AH6809 (0.01, 1 and 10 μM) with butaprost (1 μM). The incubation duration was 24 h in this set of experiments and the antagonist AH6809 was added 30 min prior to the addition of the agonist butaprost.

In a second set of experiments conducted in 2010, the treatments tested were: (1) PGE2 (1,000 ng mL^{-1}) in combination with AH6809 (1 μM). The antagonist AH6809 was added 30 min or 12 h prior to the addition of the agonist PGE2; (2) only butaprost (1 μM) testing three incubation periods (30 min, 3, 24 h) and the combination of AH6809 (1 μM) with butaprost (1 μM) when the antagonist AH6809 was added 30 min, 3 or 18 h prior to the addition of the agonist butaprost. The final concentrations of ethanol in follicle incubation did not exceed 0.1%.

cAMP Assay

After the incubation, the culture media were frozen to −80 °C and were diluted to 1:20 in 0.1 M HCl the day of the assay. cAMP concentration was quantified in the culture media by ELISA using a cAMP kit (Biovision, Gentaur, Belgium) according to the manufacturer's protocol. This method included an acetylation step which makes the cAMP assay much more sensitive and avoid the interferences of many components in unpurified samples.

Statistical Analysis

From three to eight females were used in these experiments. Measures in the follicle incubations were realized in triplicates for each females. The data were compared between treatments and over the time of incubation by analysis of variance (one-way ANOVA) followed by a Sheffé's test. A Hartley's test was used for homogeneity verification, and parameters that did not fulfill the assumptions of ANOVA were log-transformed before calculations by statistical software (STATISTICA 5.5). The effects of treatments on cAMP production were sometimes tested by a Wilcoxon non-parametric test because the assumption of normality and/of homogeneity of variance were not always obtained despite adequate transformations. Differences were considered significant at $P < 0.05$. Results are given as means ± standard error.

Results

Physiological Effects of PUFA

Ovarian fragments from sexually mature Eurasian perch were incubated with 100 µM ARA, EPA or DHA. ARA was the only FA able to stimulate DHP synthesis (Fig. 1), with DHP levels up to 25-fold higher to values found for DHA and EPA incubations ($P < 0.05$). As observed with DHP, PGE2 and PGF2α production were significantly higher than in controls only with incubation with ARA ($P < 0.05$) (Fig. 2).

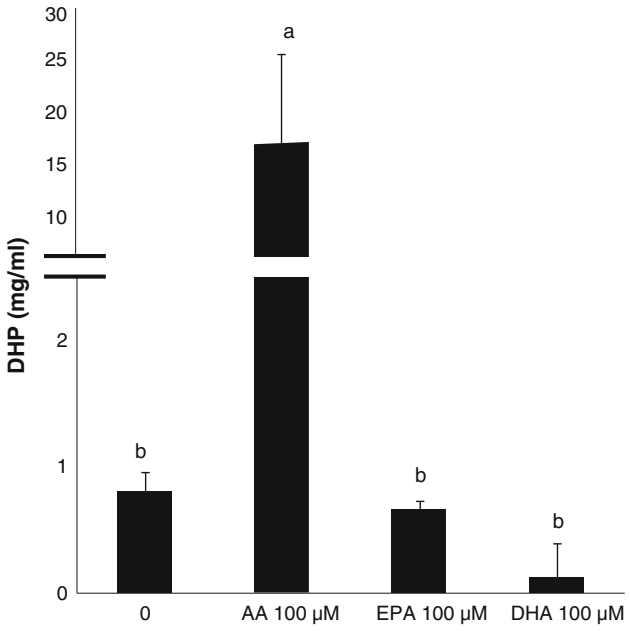

Fig. 1 17,20β-Dihydroxy-4-pregnen-3-one (DHP) levels in the media culture after 36 h of follicle incubation with arachidonic acid (AA), eicosaenoic acid (EPA) and docosahexaenoic acid (DHA) (100 µM). Values are means + SEM ($n = 3$). Significant differences ($P < 0.05$) are indicated with *different letters*

Physiological Effects of Prostaglandin

Follicles were incubated with different doses of PGE2 (1,100 and 1,000 ng mL^{-1}) during 36 h. PGE2 at a concentration of 1,000 ng mL^{-1} provided results comparable to ARA 100 µM in terms of DHP synthesis ($P > 0.05$) (Fig. 3). Nevertheless, due to a high variability, no significant differences were observed in terms of DHP production between the control and the different PGE2 concentrations.

Preliminary Results on the PGE2-Like Receptor

Firstly, one specific EP2 agonist was tested: butaprost (tested at 0.1, 1 and 10 µM). The results showed that DHP

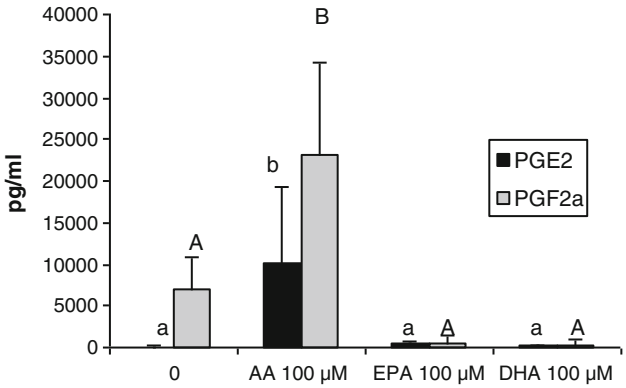

Fig. 2 Effects of arachidonic acid (AA), eicosaenoic acid (EPA) and docosahexaenoic acid (DHA) (100 µM) on the synthesis of PGE2 and PGF2α after 36 h of incubation. Values are means + SEM ($n = 3$). Significant differences ($P < 0.05$) are indicated with *different letters*. *Small letters* concerned PGE2, *capital letters* concerned PGF2α

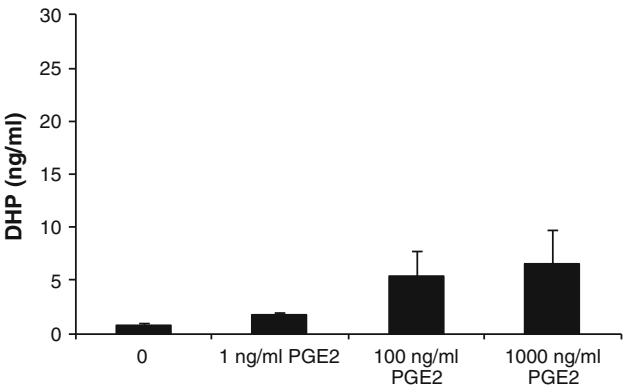

Fig. 3 17,20β-Dihydroxy-4-pregnen-3-one (DHP) levels in the media culture after 36 h of follicle incubation with PGE2 (1,100 and 1,000 ng mL^{-1}). Values are means + SEM ($n = 3$)

synthesis (Fig. 4) was significantly induced by 10 μM butaprost. Thereafter, cAMP production was measured in the media after incubation with PGE2, butaprost and AH6809. Increasing PGE2 or butaprost concentrations in the media increased the cAMP level in a dose-dependent way ($P < 0.05$) (Figs. 5 and 6). Unexpectedly, AH6809 enhanced cAMP production when added alone in the culture media (Fig. 6). But it significantly reduced the cAMP production when added together with butaprost (1 μM), after 30 min of incubation, whatever the antagonist concentration in the first set of experiment, and after 18 h of incubation in the second one (Fig. 8) ($P < 0.05$). During this latter, AH6809 decreased the cAMP production observed with an incubation of follicles with PGE2 1,000 ng mL^{-1}, when it was added 12 h before PGE2 ($P < 0.05$) (Fig. 7). The agonist effect of butaprost was verified by incubating the follicles with this molecule during 30 min, 3 or 24 h (Fig. 8), and the cAMP production was equally stimulated whatever the duration of the incubation period ($P < 0.05$).

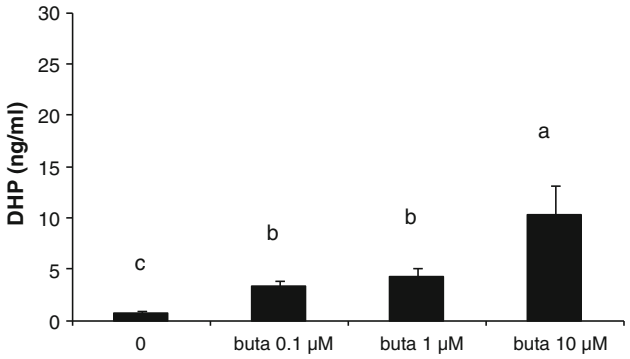

Fig. 4 17,20β-Dihydroxy-4-pregnen-3-one (DHP) levels in the media culture after 36 h of follicle incubation with butaprost (buta) at different concentrations. Values are means + SEM ($n = 3$). Significant differences ($P < 0.05$) are indicated with *different letters*

Discussion

Follicle development in fish is divided into the phases of follicle growth and maturation. Vitellogenesis plays an important role in follicle growth and is estradiol-dependent, while the process of follicle maturation is characterized by the initiation of meiosis, migration, and breakdown of the germinal vesicle (GVBD), coalescence of lipid droplets and yolk globules in the cytoplasm, a rapid size increase of the follicle caused by hydration which is accompanied by an overall increase in follicle translucency [1]. In Eurasian perch, DHP seems to be the main steroid involved in the control of this final follicle maturation [23, 24]. Among the tested fatty acids tested in the present study, only ARA seemed to be able to participate in DHP production in vitro in Eurasian perch. Our results are consistent with previous studies on ARA and its metabolites, PGE2 and PGF2α, concerning their effects on steroidogenesis in goldfish [7, 8], European sea bass [9], and Atlantic croaker, *Micropogonias undulates* [6]. Studies on in vitro effects of EPA and DHA on follicle maturation and steroidogenesis are scarce. In the present study, both EPA and DHA were unable to induce the synthesis of DHP by the follicle, indicating that EPA and DHA were probably less active than ARA in participating to the triggering of final follicle maturation in perch. In agreement with this hypothesis, an in vitro study showed that EPA and DHA were ineffective to induce final follicle maturation at all doses tested in a marine teleost, the European sea bass [9]. Moreover, these FAs inhibited gonadotropin-stimulated testosterone production in the goldfish [7]. Thus, EPA and DHA does not appear to be strong regulators of fish follicle maturation and their respective roles in oogenesis are still confused. As EPA and DHA mainly constitute the PUFA composition in Eurasian perch eggs [25], they control the fluidity of membranes and consequently enzymatic activities, linkage between molecules and receptors, cellular interactions and nutrients transports [26]. In consequence, EPA and DHA could play a more energetic and structural role than ARA in fish membranes. Further studies are needed in order to understand the role of those two PUFA in the physiological process of oogenesis in teleosts. In vivo studies consisting in giving different dietary DHA/EPA/ARA ratios to perch breeders showed that fertilization and hatching rates were not influenced by the diets, but larval resistance to an osmotic stress was clearly lower for diets with a high EPA/ARA ratio [3] than in those with low dietary EPA/ARA ratio. High levels of EPA seem to have less impact on follicle maturation in Eurasian perch, but may interfere rather on larval survival.

ARA was the only FA able to stimulate PGE2 and PGF2α production by the follicles via the cyclooxygenase, as already demonstrated in vitro in goldfish by Mercure and

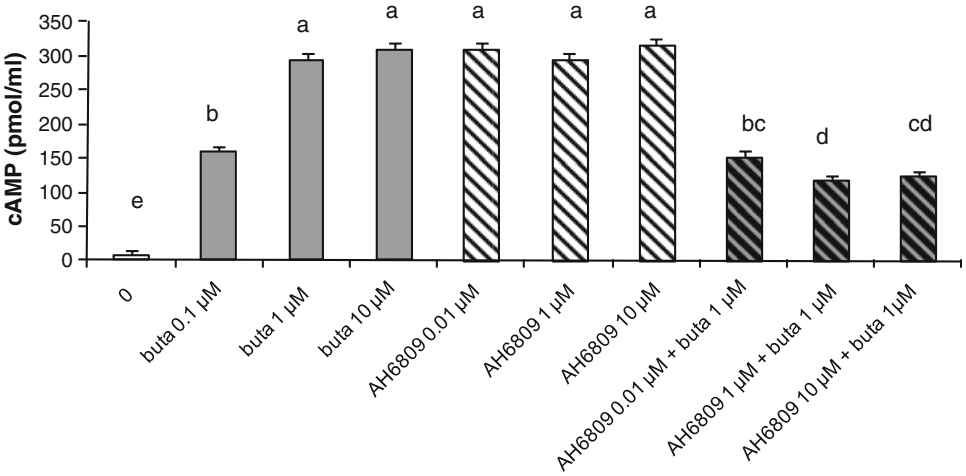

Fig. 6 cAMP levels in the media culture after 24 h of follicle incubation with the agonist of the EP2 receptor, butaprost (buta), with the antagonist of the EP2 receptor, AH6809 (AH), or with agonist and antagonist, at different concentrations. In the case of incubation with both agonist and antagonist, AH6809 was added 30 min before butaprost. Values are means + SEM ($n = 3$). Significant differences ($P < 0.05$) are indicated with *different letters*

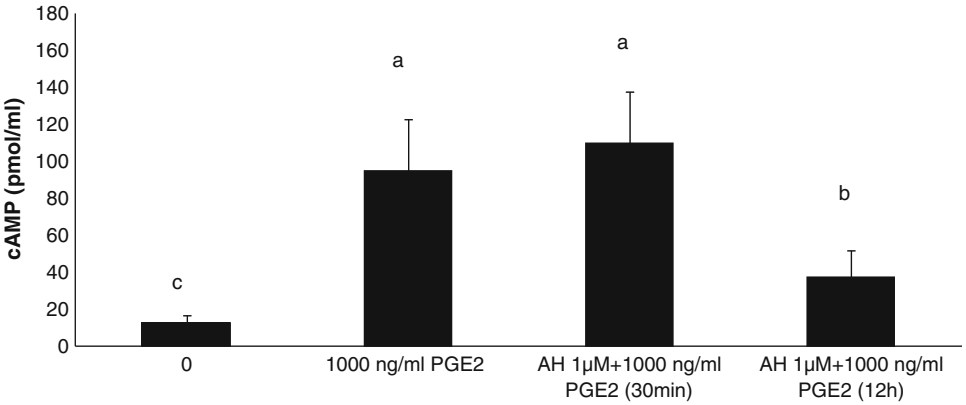

Fig. 7 cAMP levels in the media culture after 24 h of follicle incubation with PGE2 (1,000 ng mL^{-1}) with or without AH6809 (AH, the antagonist). In this case, AH6809 was added 30 min or 12 h before PGE2. Values are means + SEM ($n = 8$). Significant differences ($P < 0.05$) are indicated with *different letters*

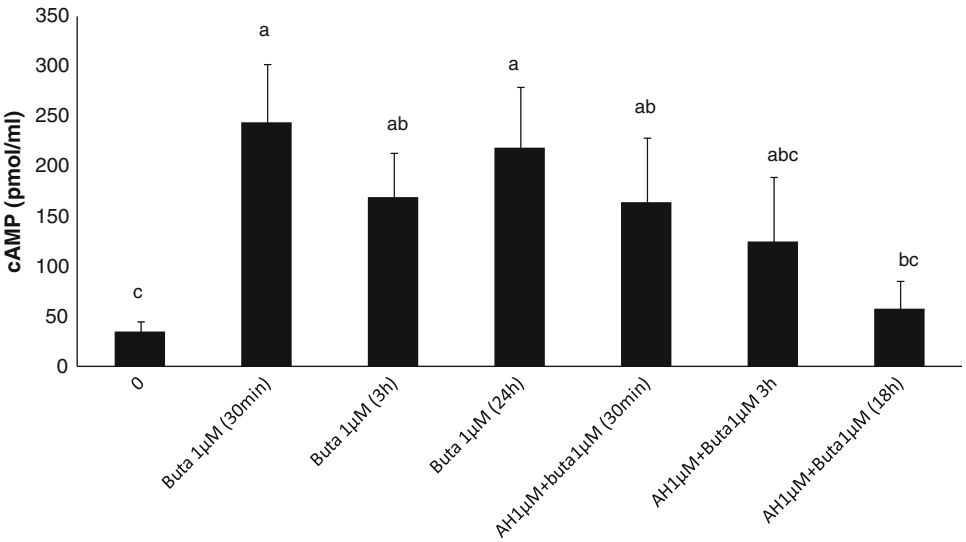

Fig. 8 cAMP levels in the media culture of follicle incubation with an agonist of the EP2 receptor, butaprost (buta, 1 µM) with or without AH6809 (AH, the antagonist). Follicles were incubated with butaprost alone during 30 min, 3 or 24 h. In the case of incubation with butaprost and AH6809, total incubation time was 24 h, and AH6809 was added 30 min, 3 or 18 h before butaprost. Values are means + SEM ($n = 4$). Significant differences ($P < 0.05$) are indicated with *different letters*

Van Der Kraak [8]. This was not surprising since ARA is the chief precursor of PGs from the two-series, not EPA and DHA. In agreement with this, in the present study, it appeared that ARA, but neither EPA and nor DHA, could enhance the follicle final maturation and ovulation, directly or indirectly (via PGE2), by stimulating the synthesis of DHP. PGE2 may also induce DHP production since PGE2 at a concentration of 1,000 ng mL^{-1} provided results comparable to ARA 100 µM. Studies using goldfish testicular tissue treated with PGs of the E-series indicated that they were the most potent stimulators of steroid production when compared to other cyclooxygenase-derived eicosanoids

[10], while lipooxygenase products of ARA metabolism had no effect on this production.

In mammals, ARA may be liberated from phospholipids by a Ca^{++}-dependent process involving phospholipase A2. PGE2 is a major metabolite of ARA synthesized by the cyclooxygenase pathway and regulates uterine functions such as contraction and relaxation of the uterine smooth muscles and the induction of labor [15, 27]. These actions of PGE2 are exerted through its binding to specific receptors on cellular membranes [28]. For example, the EP2 receptor plays critical roles in these processes, especially in ovulation and fertilization, in mice [29, 30]. The effects associated with EP2 and EP4 receptors are believed to be associated with a stimulation of adenylate cyclase and an increase in the levels of intracellular cAMP [31, 32]. In goldfish, ARA and PGE2 stimulated testosterone production in ovarian follicles by increasing cAMP production [7, 10]. From this, we can hypothesize that such type of receptors may exist in fish. Busby et al. (2002) [13] first demonstrated, by a pharmacological approach, the existence of the EP2 receptor in the liver of rockfish, *Sebastes caurinus*, involved in the regulation of glucose metabolism, but there is no information yet on the presence of EP2 receptor in ovarian follicles of fish linked to reproductive processes. In the present study, PGE2 and butaprost, the specific agonist of EP2 receptor in mammals, stimulated DHP synthesis in follicles. Moreover, PGE2 and butaprost both enhanced cAMP production. This is a first indication of PGE2-like receptors involvement in this process. The agonist effect of butaprost on cAMP induction was counteracted in presence of AH6809 when added after 30 min or 18 h of incubation. By contrast, our findings with this antagonist alone are unexpected because AH6809 appeared to be full agonist of the PGE2-like receptor in the absence of butaprost. The reason for this is unclear because AH6809 has been proven to be a specific antagonist of EP2 receptor in ovary of mammals [33, 34]. The agonist comportment of a molecule in fish which is normally considered in mammals as a specific antagonist is not new. For example, Sturm et al. (2005) [35] tested in rainbow trout the specific antagonist of mineralocorticoid receptor (MR), spironolactone, and observed that when the antagonist was tested alone, the transcription activity of MR was enhanced, and the transcription decreased if the antagonist was tested together with the agonist of the receptor (aldosterone). In the present study, as butaprost and PGE2 are less able to further induce cAMP rise in presence of AH6809, we also deduce that the regulation of cAMP by PGE2 implies, at least in part, the PGE2-like receptor transduction pathway in follicles, as observed in mammals. To support this conclusion, both cAMP and DHP production could be stimulated in a concentration-dependent manner by the EP2-selective agonist butaprost, as observed by Harris et al. [36], at least for the cAMP production, in human granulosa-lutein cells. All together, our data thus indicate the presence of PGE2-like receptors (probably including EP2 receptors) in perch ovary. It is the first pharmacological approach of this type of receptor in fish follicles, and further investigations are needed to confirm its existence, for example by using labeled antibodies or by studying the expression of those receptors by PCR analysis. Nevertheless, the failure of the EP2 antagonist AH6809 to completely abolish the cAMP response to butaprost indicates that this agonist may be acting through other receptor subtypes in fish follicles. EP4 is another receptor that could also be implied in those mechanisms, since this receptor is coupled to adenylate cyclase and generate cAMP that activates the protein kinase A signaling pathway [32]. In chicken, EP2 and EP4 were shown to be potently activated by PGE2 in vitro [37]. Otherwise, we can speculate that the level of butaprost used in the present work was in excess and mobilized a part of the available PGE2-like receptors, despite the fact that the antagonist was added more than 30 min before the agonist in the culture media. In mammals, it has been shown also that the affinity of AH6809 for the EP2 receptor was lower than affinity of butaprost [34]. This could explain why there was a remainder of cAMP in the medium when butaprost and AH6809 were added simultaneously. In that way, we observed that the duration of antagonist exposure influences the antagonist effect of AH6809. By contrast, the duration of agonist exposure does not seem to modify the stimulation of cAMP production by butaprost. In rockfish hepatocytes, cAMP production reached a maximum 2 min after PGE2 incubation and then remained high and steady during the 15 first minutes [13]. We can thus suspect significant changes in cAMP production within the first 30 min of agonist exposure of incubation, including a sudden and linear elevation in the first minutes. Finally, follicle incubations with butaprost together with the antagonist, AH6809, were done once in 2009, and another test with time points was done in 2010. Both experiments showed that AH6809 partly counteracted the stimulation of cAMP by PGE2 or butaprost. But the incubation time needed with the antagonist alone before the addition of butaprost, in order to observe such effect, differed in both experiments (30 min in 2009 vs. 18 h in 2010). The fact that the experimental conditions were not exactly the same (meteorology, fish origin,…) certainly explains this difference. The set of time points used in the present study, in order to evaluate the impact of our treatment on the cAMP production, allowed us to study these effects in a short time (30 min) or in a longer time.

In conclusion, the results of the present study confirm that PUFA act on the physiology of the follicle. Especially, ARA, via its conversion to PGE2 and PGF2α, may have a stimulating role in the final follicle maturation, by

enhancing the production of DHP. Moreover, this study allowed the observation of the stimulating and inhibiting effect of the EP2 receptor agonist and antagonist on DHP and cAMP production processes, which indicates the putative presence of PGE2-like receptor in the follicle membrane of Eurasian perch, as observed in mammals. This interaction has to be further studied in the future, and it remains to be determined whether fish follicles have different functional PGE2 receptor subtypes.

Acknowledgments Emilie Henrotte is grant holder of the "Fonds pour la Formation à la Recherche dans l'Industrie et dans l'Agriculture" (FRIA). Thanks are due to Jonathan Poncin, for his valuable help during data collection. The authors would like to express their gratitude to Dr Alexis Fostier for his comments on a first version of the manuscript.

Abstract As lipid deposition tissue in fish, the white adipose tissue (WAT) has important functions related to reproduction and the challenges of long-term fasting. In the study reported here, we infused fish fed a high-carbohydrate diet with two doses of insulin for 5 days in order to explore the effects of this hormone on lipogenesis and beta-oxidation-related enzymes. We demonstrated the presence of some of the main lipogenic enzymes at molecular, protein and activity levels (ATP-citrate lyase and fatty acid synthase). However, while ATP-citrate lyase was unexpectedly down-regulated, fatty acid synthase was up-regulated (at protein and activity levels) in an insulin dose-dependent manner. The main enzymes acting as NADPH donors for lipogenesis were also characterized at biochemical and molecular levels, although there was no evidence of their regulation by insulin. On the other hand, lipid oxidation potential was found in this tissue through the measurement of gene expression of enzymes involved in β-oxidation, highlighting two carnitine palmitoyltransferase isoforms, both down-regulated by insulin infusion. We found that insulin acts as an important regulator of trout WAT lipid metabolism, inducing the final stage of lipogenesis at molecular, protein and enzyme activity levels and suppressing β-oxidation at least at a molecular level. These results suggest that WAT in fish may have a role that is important not only as a lipid deposition tissue but also as a lipogenic organ (with possible involvement in glucose homeostasis) that could also be able to utilize the lipids stored as a local energy source.

Keywords Insulin · Fish · Dietary carbohydrates · White adipose tissue · Lipogenesis · Lipid oxidation

Abbreviations

6PGDH	6-Phosphogluconate dehydrogenase
ACLY	ATP citrate lyase
CPT	Carnitine palmitoyltransferase
EF1α	Elongation factor 1 alpha
FFA	Free fatty acids
G6PDH	Glucose 6-phosphate dehydrogenase
HOAD	3-Hydroxyacyl-CoA dehydrogenase
HSL	Hormone-sensitive lipase
ICDH	Isocitrate dehydrogenase
LPL	Lipoprotein lipase
ME	Malic enzyme
NAPDH	Nicotine adenine dinucleotide phosphate, reduced
TAG	Triacylglycerols
TNF	Tumor necrosis factor-alpha
WAT	White adipose tissue

Introduction

White adipose tissue (WAT) has a role in energy storage and as insulation from environmental temperature and trauma, storing lipids in the form of triacylglycerols (TAG)

and in mobilizing them via breakdown into free fatty acids (FFA) and glycerol [1]. In mammals, several studies have been able to document the presence of lipogenic enzymes and the conversion of glucose into fat in insulin-stimulated adipocytes [2], although very little is known about WAT lipid oxidation capacities [3]. FFA originating from dietary intake or de novo synthesis are stored as TAG. With its storage capacity and its ability to hydrolyze TAG, WAT provides a FFA buffering system for other organs [4].

WAT is one of the most important lipid stores in several teleosts, although the liver and muscle also constitute lipid storage organs in some species [5]. In salmonids, WAT is distributed primarily in the abdominal cavity, in association with the mesenteric and pyloric caeca [6]. In fish, as in mammals, the development of WAT and accumulation of lipids is a continuous process that depends on nutritional [7, 8] and reproductive status [9]. The WAT provides capital for fish reproduction [10] as well as for the challenges of long-term fasting [7].

As the enzymatic machinery responsible for lipid mobilization and deposition in fish, WAT is similar to that found in mammals [6], and both lipoprotein lipase (LPL) [11, 12] and hormone-sensitive lipase (HSL) [13, 14] have been characterized. However, other aspects of lipid metabolism such as the lipogenic and lipid oxidation potential have not been fully explored in fish WAT. Early studies have shown the presence of lipogenic enzyme activities in visceral fat in the eel [15], channel catfish [16] and coho salmon [17]. More recent studies have also investigated the presence of NADPH-donor enzymes involved in lipogenesis in gilthead seabream [18]. However, on the basis of findings in the rainbow trout, in which the liver accounts for more TAG synthesis than the adipose tissue [19], and the lower levels of lipogenic enzyme activity in WAT present in coho salmon [17], Henderson and Sargent [20] proposed a minor role for WAT in the whole fish lipogenic potential. The lipid oxidation capacities of fish WAT are poorly understood, although β-oxidation was recently reported to be regulated by different fatty acids in vivo [21] and in vitro [22] in Atlantic salmon. Functional data are scarce, and only gene expression of carnitine palmitoyltransferase (CPT) has been described in the WAT of rainbow trout [23] and salmon [24], while no expression was found in gilthead seabream [25]. Other enzymes involved in lipid oxidation are also expressed in salmon WAT, including acyl-CoA oxidase and acyl-CoA dehydrogenase, although they are not regulated by the nature of the oil present in the feed [24].

Lipid metabolism in fish WAT is regulated by several endocrine factors, such as insulin, GH and somatolactin, [26], glucagon [27] and norepinephrine [28], and also by other factors such as TNF-α [13, 29]. Clearly, most of the studies on endocrine control of lipid metabolism in fish WAT have been focused on the insulin action [12, 27, 30, 31]. Unfortunately, all these studies were carried out in order to understand the regulation of key enzymes involved in lipid storage and mobilization such as LPL and HSL (see above), and no information about hormone control of lipogenesis or lipid oxidation is available for fish WAT. On the other hand, insulin action on other tissues such as the liver and white skeletal muscle has been widely studied, with the predominant lipogenic and anti-lipolytic action of this hormone [30, 32]. We recently reported similar results at the molecular level in fasted rainbow trout infused with bovine insulin for 4 days [33], although details regarding the WAT were not available in that study. Insulin receptors have also been studied in rainbow trout WAT, showing the first evidence of insulin regulation of lipid metabolism in this tissue [34].

In order to characterize the lipogenic potential and its regulation by insulin in fish WAT, rainbow trout were infused with two different doses of bovine insulin for 5 days. We assessed two of the main enzymes involved in lipogenesis at enzymatic, protein and molecular levels (ACLY (ATP citrate lyase) and FAS (fatty acid synthase)) as well as the main enzymes acting as NADPH donors, including 6PGDH (6-phosphogluconate dehydrogenase), G6PDH (glucose 6-phosphate dehydrogenase), ICDH (isocitrate dehydrogenase) and ME (malic enzyme). RNA levels of two enzymes involved in lipid oxidation were also assessed, including HOAD (hydroxyacyl-CoA dehydrogenase) and CPT-1 isoforms. WAT insulin sensitivity was studied on the basis of the phosphorylation status of Akt, and fish were fed a high carbohydrate diet in order to counteract the insulin-induced hypoglycemia caused by the pump infusion [35] and to induce lipogenesis, as in other fish tissues [16, 36–38].

Materials and Methods

Fish

Rainbow trout (*Oncorhynchus mykiss* Walbaum) were obtained from the INRA experimental fish farm facilities of Donzacq (Landes, France). Fish were maintained in tanks with well-aerated water at 17 °C and a controlled photoperiod (LD12:12), and fed a standard trout commercial diet during the acclimatization period (T-3P classic, Trouw, France). Fish weight was 200 ± 10 g. The experiments were conducted in accordance with the Guidelines of the National Legislation on Animal Care of the French Ministry of Research (Decret N° 2001-464, May 29, 2001) and were approved by the Ethics Committee of INRA (according to INRA 2002-36, April 14, 2002).

Experimental Protocols

For sustained hormone infusions, fish were food-deprived for 48 h and then implanted with 1003D Alzet® mini-osmotic pumps (Alza, USA) containing either saline (control, $n = 6$) or bovine insulin solution at two different concentrations ($n = 6$) ($\sim$27 units/mg; Sigma Chemical Co.). Fish were first anesthetized and weighed, and pumps were then inserted into the peritoneal cavity through a 1.0-cm incision made in the ventral midline at ca. 2.0 cm rostral of the pelvic fins. The incision was closed with one stitch and an antibiotic gel was applied topically to the incision area. Pumps were implanted in the morning and fish were allowed to recover. The next morning (24 h later), fish were fed a diet containing a high-level of carbohydrate (30% dextrin, 57% fish meal and 10% fish oil) for 5 days and sampled 6 h after their last meal. Pump flow rate was established at 0.39 µl h^{-1}, which at 17 °C should provide sustained release of 0.35 (Ins1x) or 0.7 (Ins2x) IU kg^{-1} day^{-1} insulin for 11 days. The doses chosen were based on previous studies carried out in fasted rainbow trout [35, 39].

Tissue and Blood Sampling

Trout were sacrificed by a sharp blow on the head. Blood was removed from the caudal vessels and centrifuged (3,000*g*, 5 min); the plasma recovered was immediately frozen and kept at −20 °C pending analyses. Gut content of each fish was systematically checked to confirm that the fish sampled had in fact consumed the diet. The perivisceral WAT was collected and frozen in liquid nitrogen and kept at −80 °C pending analyses.

Molecular and Biochemical Analyses

Plasma glucose (Biomérieux, France), triglycerides (Biomérieux, France) and FFA (Wako Chemicals GmbH, Germany) levels were determined using commercial kits adapted to a microplate format. Bovine insulin levels were measured using a bovine-specific commercial ELISA kit (Mercodia, Sweden) as in [35].

Tissue mRNA levels of proteins involved in lipid metabolism were determined by real-time quantitative RT-PCR (q-PCR) [33]. The transcripts assessed FAS, G6PDH, ACLY, HOAD, CPTIA, CPTIB, CPTIC, CPTID, ME, 6PGDH and ICDH. Primers (Table 1) were designed to overlap an intron where possible (Primer3 software) using known sequences found in trout nucleotide databases (Genbank and INRA-Sigenae) as previously described [33]. Quantification of the target gene transcript level was performed using *ef1α* gene expression as reference [40], which was found to be stable in this study. Quantification of the target gene transcript in relation to the *ef1α* reference gene transcript was performed following the Pfaffl method [40].

Protein extraction (20 µg) and Western blotting were undertaken using anti-phospho-Akt Ser^{473} (Cell Signaling Technology), anti-FAS (Santa Cruz Biotechnology), anti-β-tubulin (Cell Signaling Technology) and anti-ACLY (Cell Signaling Technology) against human proteins.

Tissue used to assess enzyme activities was homogenized with 10 vol of ice-cold buffer consisting of 20 mmol l^{-1} Tris

(pH 7.4), 250 mM sucrose, 2 mmol l^{-1} EDTA, 10 mmol l^{-1} β-mercaptoethanol, 100 mM NaF and 0.5 mM EDTA. The homogenate was centrifuged for 20 min at 17,000*g* and the supernatant was used immediately for enzyme assays at 37 °C in pre-established conditions. HOAD was assessed as in [41], while G6PDH (final substrate concentration 0.5 mM glucose-6-phosphate) and FAS (final substrate concentration 50 μM malonyl-CoA) were assessed following the method described by Figueiredo-Silva et al. [42] adapted to trout tissues. ME, ICDH and 6PGDH were assessed as in [43], adapting the conditions to the WAT. ACLY activity was determined as in [44]. Levels of enzyme activity are expressed in terms of mg protein. Protein concentration was determined using a Bradford protein assay kit (Bio-Rad, Germany) with BSA as standard.

Statistical Analysis

The results are expressed as means ± SEM ($n = 6$). Data were analyzed by one-way ANOVA. When necessary, data were log-transformed to fulfill the conditions of the analysis of variance. Post-hoc comparisons were made using a Student–Newman–Keuls test, and differences were considered statistically significant at $P < 0.05$.

Results

Plasma triglyceride levels (Fig. 1a) were unaffected by the insulin infusion. In contrast, FFA levels in plasma (Fig. 1b) were reduced after the insulin infusion regardless of the dose. Bovine insulin levels were constant in all trout with insulin pumps, averaging 3.11 ± 0.34 and 6.36 ± 0.65 ng ml^{-1} for 1x and 2x, respectively. Plasma glucose levels were lower than in the controls in the Ins1x group (7.67 ± 0.42 mM), while glycemia was similar in the Ins2x group (9.02 ± 0.44 mM) to the saline-infused group (9.08 ± 0.42 mM).

The phosphorylation status of Akt (at Ser^{473}) is shown in Fig. 2. A twofold increase in phosphorylation of the kinase was observed when fish were infused with the higher insulin dose when compared with the saline-treated fish.

ACLY and FAS enzyme activity and protein and mRNA transcript levels are shown in Fig. 3. ACLY in particular was affected by insulin at the protein level, with lower levels in fish infused with either insulin dose than in the control group. In contrast, mRNA levels were only reduced with the Ins1x dose, while activity was down-regulated by the higher insulin dose. The main differences were found at the protein level, since insulin was able to reduce ACLY levels by more than 50%. In this study FAS was positively affected by insulin infusion at activity, protein and gene expression levels. The effect on activity was dose dependent, while

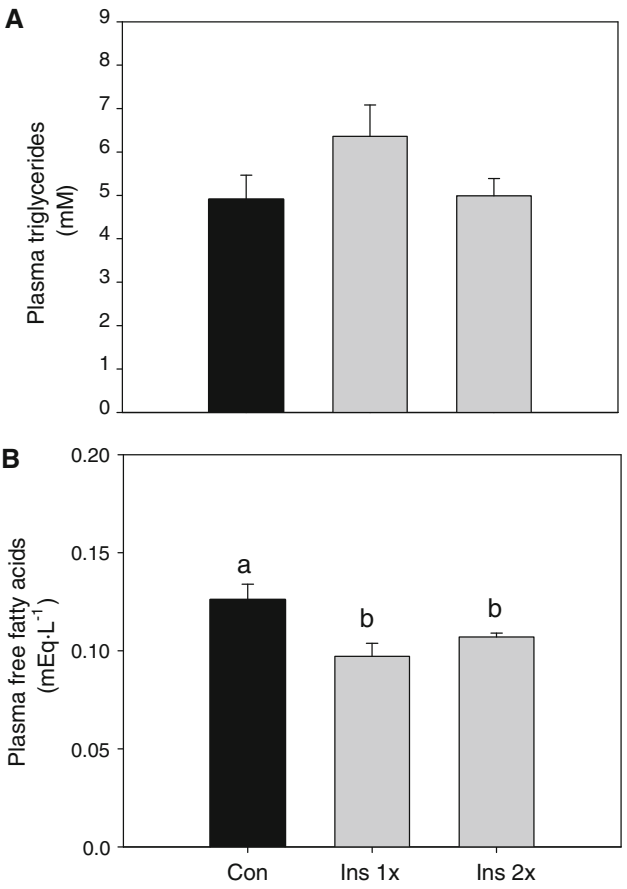

Fig. 1 Plasma triglyceride (**a**) and free fatty acid (**b**) levels in rainbow trout fed a carbohydrate-enriched diet and sacrificed 6 h after the last meal. Fish were implanted with pumps containing saline (control) or two insulin doses: Ins1x (0.35 IU kg^{-1} day^{-1}) and Ins2x (0.7 IU kg^{-1} day^{-1}) and then fed for 5 days. Results are expressed as means ± SEM ($n = 6$) and were analyzed by one-way ANOVA followed by Student–Newman–Keuls multiple comparison test. *Different letters* indicate significant differences among groups ($P < 0.05$)

mRNA levels were less affected. Protein FAS levels were increased up to fourfold when insulin was infused (regardless of the dose infused). On the other hand, WAT FAS activity (0.32–0.97 mU mg^{-1} protein = 4–11 mU g^{-1} tissue) was higher than in other studies involving fish liver [38, 41], although lower than in liver samples from the present study, ranging from 0.25 to 1 mU mg^{-1} protein = 29–86 mU g^{-1} tissue.

Changes in enzyme activity and mRNA levels of proteins acting as NADPH donors are shown in Fig. 4. The four enzymes studied were affected by insulin in different ways: no changes in 6PGDH or ICDH were found at either biochemical or molecular levels. G6PDH mRNA levels were reduced only with the Ins1x dose, with no impact on activity, which remained unchanged by the treatments. Finally, ME mRNA levels increased 2-fold when the Ins2x dose was infused in comparison with the control group.

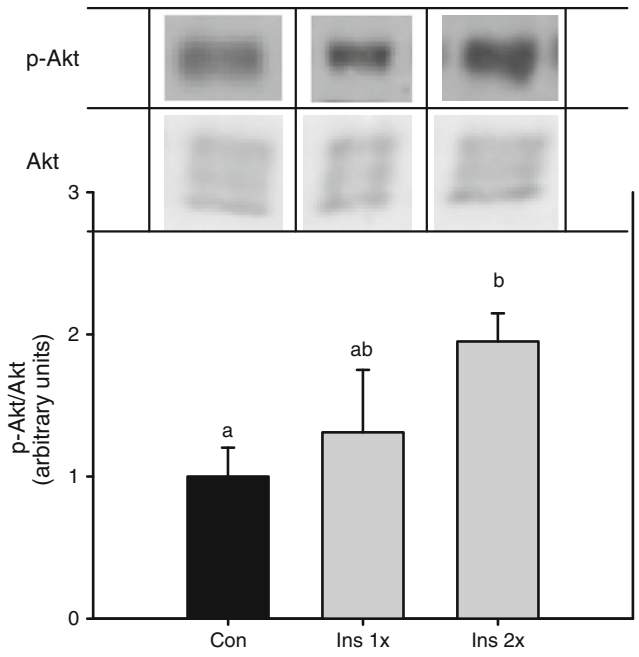

Fig. 2 Effects of insulin infusion (5 days) on WAT Akt phosphorylation status (Western blot analysis) in trout fed a high carbohydrate diet. Gels were loaded with 20 μg total protein per lane. Protein and phosphorylation levels were normalized to total tissue Akt levels and are indicated as fold-change compared with the saline-treated group. Results are expressed as means ± SEM ($n = 6$) and were analyzed by one-way ANOVA followed by Student–Newman–Keuls comparison test. *Different letters* indicate significant differences among groups ($P < 0.05$)

These changes were not followed by enzyme activity, that showed higher levels than the control group only when fish were infused with the Ins1x dose.

mRNA levels of the main enzymes involved in β-oxidation are presented in Fig. 5. No changes were observed in mRNA levels of HOAD. However, the different isoforms of CPT were regulated by insulin. No significant expression was found for CPT1A or CPT1B (data not shown). In contrast, the mRNA levels for CPT1C and D were affected by the treatment, an effect that was particularly clear in the latter isoform, responding to both insulin doses, while in the former reduced mRNA levels were found only with the Ins1x dose.

Discussion

The effects of insulin on fish WAT lipid metabolism are little known and, although the storage of TAG has been demonstrated, the lipogenic role of this tissue has been traditionally considered as minor compared with that of the liver [30]. In the present study we confirmed the presence of the main enzymes responsible for de novo lipid synthesis at a biochemical level in fish, and demonstrated important findings at both protein and molecular levels. We also present original findings showing the molecular expression of key enzymes involved in the β-oxidation of lipids in the WAT.

Insulin Effects on Plasma Parameters and Sensitivity of White Adipose Tissue

The main and well known effect of insulin in fish lipid metabolism is to decrease FFA levels in plasma (reviewed by [32]). The reduced levels of plasma FFA in our study confirm this insulin action as well as the physiological effects of insulin dose as applied in this experiment. Further confirmation of insulin action can be demonstrated by plasma glycemia and the phosphorylation status of a key protein in the insulin signalling pathway, such as Akt. In our study, Akt phosphorylation in the WAT was increased with the higher insulin dose, providing supporting evidence of insulin sensitivity of this tissue in the trout, as previously demonstrated by other authors [34, 45]. Bouraoui et al. (2010) [45] demonstrated the involvement of insulin in the development of adipocytes and also in glucose metabolism. The fact that Akt phosphorylation status can be significantly affected by insulin in vivo, as in the present study, confirms that insulin can activate its own signalling pathway in this tissue, suggesting an important role in WAT metabolism. It was recently demonstrated in rat adipocytes that Akt activity is required for the effects of insulin on lipid metabolism [46]. In this model, Akt was essential in the antilipolytic action of insulin and, when inhibited, the lipogenic role of insulin was counteracted. We can therefore hypothesize that the insulin-induced Akt phosphorylation in this fish model could be related to both increased lipogenic and decreased lipid oxidation potential in the WAT of rainbow trout, as discussed below.

Lipogenesis in White Adipose Tissue

Carbohydrates consumed in excess of energy requirements and of hepatic glycogen storage capacity must be converted into lipids for subsequent storage. De novo lipogenesis is the metabolic pathway that synthesizes fatty acids from excess carbohydrates to be incorporated into TAG for energy storage. In mammals the WAT is the main lipid-storing tissue [47], while in fish the liver has been traditionally considered as the main tissue responsible for lipogenesis [17, 20]. Due to this minor role in lipogenesis, this pathway has been little studied in fish WAT and therefore very little information is available in the literature.

Enzymes central to the process of lipogenesis are those that catalyze fatty acid biosynthesis, i.e. ACC, FAS and ACLY, which is involved in the transfer of acetyl-coenzyme A (acetyl-CoA) from the mitochondrion to the cytosol,

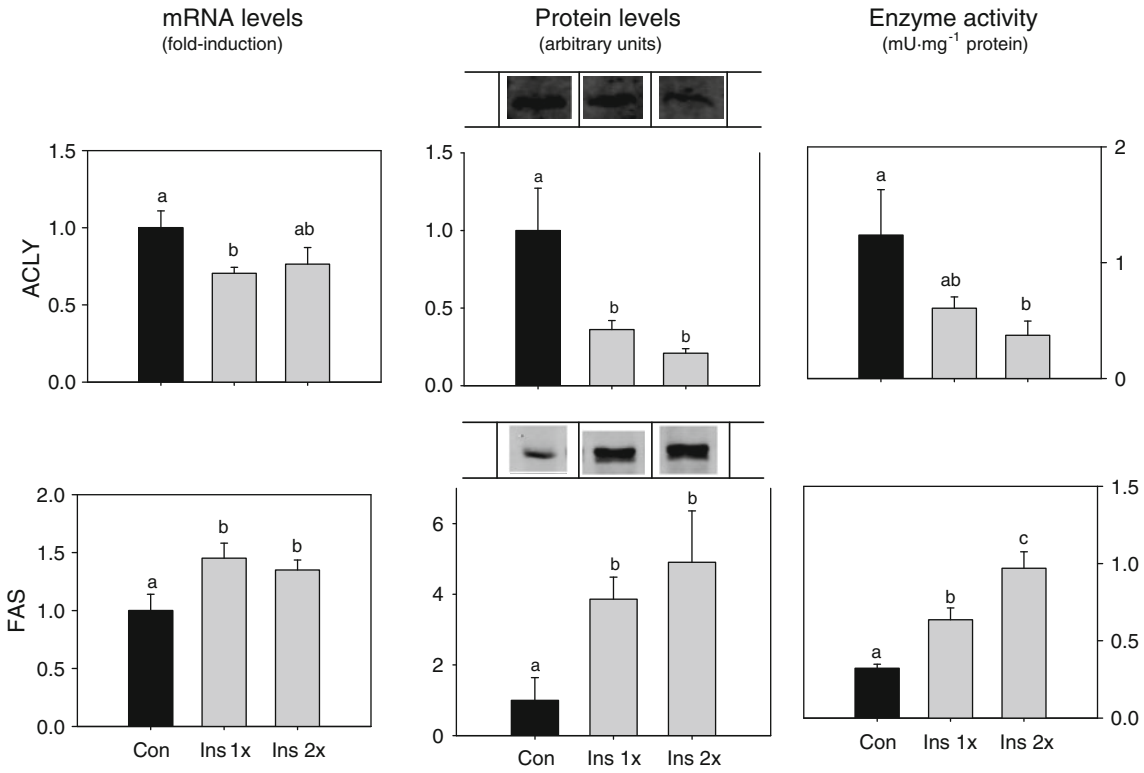

Fig. 3 Effects of insulin infusion (5 days) on ATP-citrate lyase (ACLY) and fatty acid synthase (FAS) mRNA levels, protein levels and levels of enzyme activity in WAT of trout fed a high-carbohydrate diet. mRNA levels were estimated using real-time RT-PCR. Expression levels were normalized to elongation factor 1α (EF1α)-expressed transcripts which did not change under the experimental conditions and are presented as fold-change against the saline solution-treated group set at 1. Enzyme activity units (mIU) are defined as nmol of substrate converted to product, per min, at 37 °C, were expressed/mg protein. Protein (20 μg per lane) and phosphorylation levels were normalized to tissue β-tubulin levels and are indicated as fold-change compared with the saline-treated group. Results are presented as means ± SEM ($n = 6$) and were analyzed by one-way ANOVA followed by Student–Newman–Keuls comparison test. *Different letters* indicate significant differences among groups ($P < 0.05$). More details in Fig. 1

where fatty acid synthesis occurs [48]. ACLY has only been described previously in coho salmon WAT, although its activity was unaffected by different diets [17]. In the present study ACLY was inhibited by insulin, especially at the protein level. This is the first time that this enzyme has been fully characterized in fish WAT. Insulin regulation of ACLY in mammals is not fully understood, and although this hormone is able to stimulate lipogenesis in rat adipocytes, ACLY activity and mRNA levels are often unaffected [49, 50]. Although intriguing, our results are not surprising in view of the fact that in other lipogenic tissue in the trout (the liver) ACLY is not regulated at the molecular level by either nutritional status [51] or insulin [33]. In fact, the inhibition of ACLY by insulin in the trout shows that this step of lipogenesis in fish WAT is regulated in a different way from that described in mammals. In mammals ACLY is phosphorylated by Akt into serine 455, abolishing the homotropic allosteric regulation by citrate and enhancing the catalytic activity of the enzyme [52]. This differential level of regulation compared to the mammalian model is further supported by the increased Akt phosphorylation with the higher insulin dose in the present study. We also analyzed FAS mRNA, protein and activity levels. Although FAS has been widely studied in the fish liver, information regarding the WAT is scarce [16, 17]. In the study presented here we showed similar levels of activity to those previously reported in salmon WAT [17] and higher levels than those reported in the trout liver, the traditional lipogenic organ in fish [38, 41]. Moreover, in accordance with the findings reported in mammals [47], FAS mRNA levels and protein and activity levels were stimulated by insulin, in line with the increased Akt phosphorylation status, which in mammals is considered to be essential to the insulin-stimulated lipogenesis in adipocytes [46]. This is the first time that insulin-induced lipogenic potential has been described in fish WAT, in agreement with the stimulating effects of dietary carbohydrates shown in catfish [16].

This study demonstrated that some of the main lipogenic enzymes are significantly expressed at both mRNA and protein levels in WAT and that the levels of activity are consistent with a biologically significant lipogenic pathway. Insulin-stimulated FAS regulation thus seems to be as

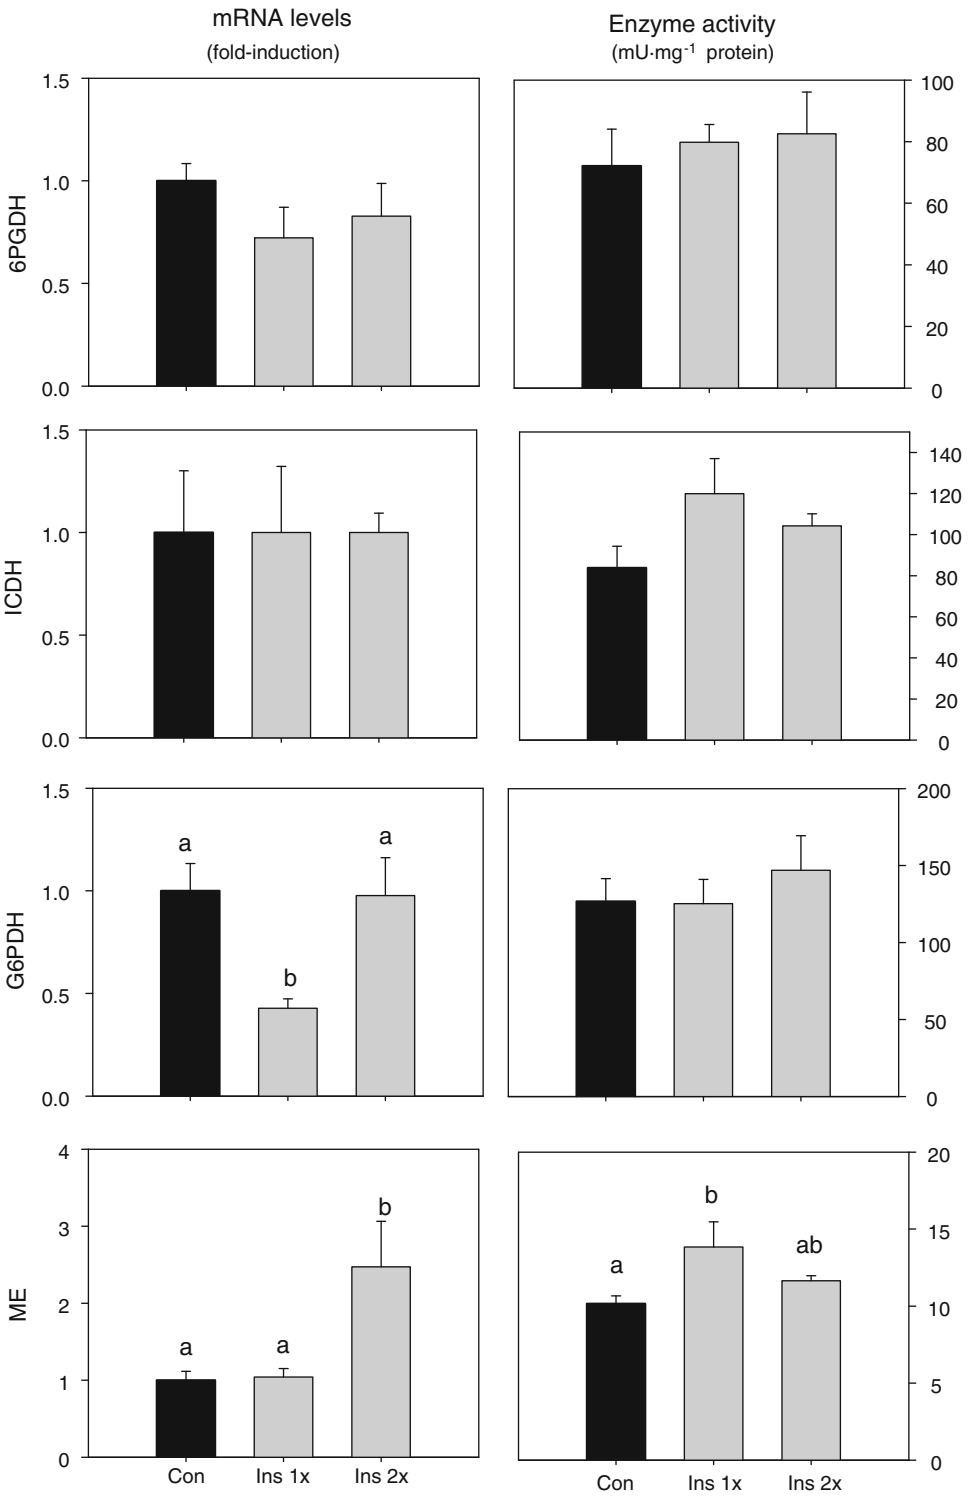

Fig. 4 Effects of insulin infusion (5 days) on glucose 6-phosphate dehydrogenase (G6PDH), 6-phosphogluconate dehydrogenase (6PGDH), isocitrate dehydrogenase (ICDH) and malic enzyme (ME) mRNA and levels of enzyme activity in WAT of trout fed a high-carbohydrate diet. mRNA levels were estimated using real-time RT-PCR. Expression levels were normalized to elongation factor 1α (EF1α)-expressed transcripts which did not change under the experimental conditions and are presented as fold-changes against the saline solution-treated group set at 1. Enzyme activity units (mIU) are defined as nmol of substrate converted to product, per min, at 37 °C, were expressed/mg protein. Results are presented as means ± SEM ($n = 6$) and were analyzed by one-way ANOVA followed by Student–Newman–Keuls comparison test. *Different letters* indicate significant differences among groups ($P < 0.05$). More details in Fig. 1

expected, in view of the anabolic action of insulin in fish [30] and the insulin-induced lipogenesis in hyperinsulinemic rats [53, 54]. However, the global inhibition of ACLY by insulin is surprising although consistent, since it was found at all the levels studied. More studies are needed to clarify whether this pathway is fully functional in fish WAT. On the other hand, the fact that lipogenesis can be up-regulated in trout WAT when fish are fed an excess of dietary carbohydrates also suggests a possible role in glucose metabolism and homeostasis. Lipogenesis in the liver in rainbow trout also fed with carbohydrates [38] was shown to be induced by the anti-diabetic drug metformin,

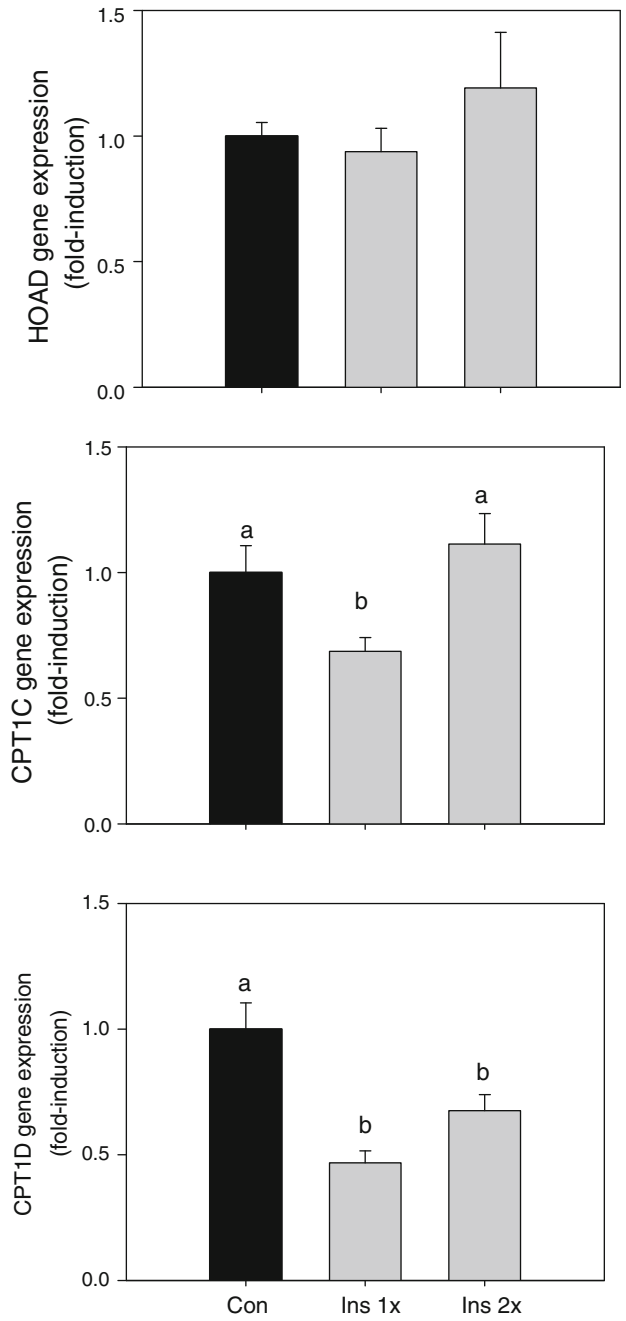

Fig. 5 Effects of insulin infusion (5 days) on 3-hydroxyacyl-CoA dehydrogenase (HOAD),carnitine palmitoyltransferase 1B (CPT1B), CPT1C and CPT1D and mRNA levels in WAT of trout fed a high-carbohydrate diet. mRNA levels were estimated using real-time RT-PCR. mRNA levels were normalized to elongation factor 1α (EF1α)-expressed transcripts which did not change under the experimental conditions and are presented as fold-changes against the saline solution-treated group set at 1. Results are presented as means ± SEM ($n = 6$) and were analyzed by one-way ANOVA followed by Student–Newman–Keuls comparison test. *Different letters* indicate significant differences among groups ($P < 0.05$). More details in Fig. 1

improving the glycemic profile and glucose homeostasis. The induction of WAT lipogenesis by the lower insulin dose in the present study may also be involved in the hypoglycemic effect of this hormone, thus improving control of glycemia in this "glucose intolerant" species [55].

NADPH Donors in White Adipose Tissue are Poorly Regulated by Insulin

The de novo synthesis of lipids in the cytoplasm of vertebrate tissues requires a carbon source (acetyl CoA), reducing equivalents (NADPH) produced by one or more of four cytoplasmic dehydrogenases (G6PDH, 6PGDH, ME and ICDH). We present here for the first time in fish the molecular and biochemical regulation by insulin of the four enzymes in the trout WAT. When compared with other fish species the reducing power generated in trout WAT (5.3 nmol NADPH min^{-1} g^{-1} = 347 nmol NADPH min^{-1} mg $protein^{-1}$) lipogenesis is variable and related to the species and the assay temperature. Trout WAT generates up to 4.5-fold more NADPH than the eel (assessed at 20 °C) [15] and catfish (assessed at 25 °C) [16] visceral adipose tissue. When compared with the salmon (assessed at 18 °C) [17], the difference is tenfold higher. Taking into account the assay temperatures and species-dependence of the findings described above, we can suggest that the WAT in trout has a similar lipogenic potential to other fish species such as the catfish and eel, but higher than that of other salmonids. Overall, it seems that the generation of reduction potential for lipogenesis in trout WAT is high enough to sustain lipogenic activity, although its potential is lower than in the liver. In view of the relative contributions of the different enzymes assessed as NAPDH donors, it should be noted that the ME activity was about 9.5-fold lower than that of the others, and thus its relative contribution to the total NADPH is probably low, as in the liver. These results are similar to those described in the fish species cited above, in which ME also presents low levels of activity. The activity levels of other enzymes involved in the generation of NADPH are relatively high, similar to levels found in the liver [41] and about tenfold higher than in other species studied [15–17]. However, despite this high potential NADPH production capacity, only minor changes in ME were found in trout WAT. The fact that the enzymes exhibiting higher levels of activity were unaffected by insulin suggests that the NADPH production pathway does not constitute the limiting step for lipogenesis in trout WAT.

Beta Oxidation Pathway in White Adipose Tissue: Regulation by Insulin

In this study, we examined two key enzymes involved in regulating FFA oxidation in trout WAT and the effects of insulin infusion at the molecular level. CPT-I is considered to be a key regulatory enzyme in FFA oxidation. It

catalyzes the formation of long-chain acyl-carnitine, the transportable form of activated FFAs, thus committing FFAs to oxidation in the mitochondria [56]. In fish, FFA oxidation takes place mainly in the liver and cardiac and skeletal muscle, where CPT-I is present [23, 25] and regulated by insulin [33]. However, information about CPT-I in fish WAT is limited: CPT-I gene expression has been described in the rainbow trout [23, 57], although no transcripts were found in seabream [25]. As far as we are aware, this is the first study in which WAT CPT-I regulation is explored in fish, especially in relation to insulin. Very interestingly, we found that the two major CPT-I isoforms expressed in the liver and muscle of rainbow trout (CPT-IA and CPT-IB) [33] were not significantly expressed in the WAT. Moreover, the main isoforms found in this tissue were CPT-IC (brain type) and D (larval type) (personal observations). The expression patterns of trout CPT-I compared to those of mammals, where the CPT-I-M (the muscle type) is the predominant isoform in the adipose tissue [58], were especially interesting. Overall, we found that the two isoforms expressed in the WAT were down-regulated by the insulin infusion, although no relationship with insulin dose was found. This finding agrees with the global anabolic role (anti-lipolytic effects) of insulin in fish [27, 59] and the down-regulation of CPT-IA and CPT-IB transcripts in muscle of fasted trout infused with insulin [33]. This is in accordance with the findings reported in rat adipocytes, in which the presence of insulin in the medium down-regulates CPT-I mRNA levels [3]. However, the relative contributions of the isoform transcripts studied to the total pool of CPT-I activity in WAT remain unidentified and further studies must therefore be conducted to clarify the regulation of this enzyme in fish WAT. Finally, we present here the presence of transcripts for the HOAD enzyme involved in the β-oxidation of lipids. Lipid oxidation in the WAT has been little explored in fish to date [21, 22] and, although the expression of HOAD does not seem to be regulated by insulin, its presence suggests the utilization of this substrate as a local energy source.

Conclusions and Perspective

Although the role of the WAT in fish as a lipid deposition organ is well recognized [6], both the lipogenic capacity and lipid energy metabolism have been traditionally considered to be of minor importance, and its biological significance and regulation have remained undemonstrated [20]. We present here original findings regarding lipid metabolism in the WAT of rainbow trout fed a high carbohydrate diet and infused with insulin that emphasize the functions of this tissue, mainly as energy storage for long-term periods of fasting [7] and for reproduction purposes [10]. In these conditions, we found the presence of some of the main enzymes required for lipogenesis at molecular, protein and activity levels, such as ACLY and FAS. The up-regulation of FAS activity by insulin in a dose-dependent manner reinforces the lipogenic role of WAT in the trout. We may thus hypothesize that this increased lipogenic potential can help trout to control glycemia when fed high-carbohydrate diets, as this pathway has been shown to be involved in control of glucose homeostasis in this species [38, 39]. Moreover, the presence of the major NADPH donors for lipogenesis with relatively high rates of activity (equivalent to those found in the liver in this species) supports this lipogenic role of WAT. However, the lack of response to insulin infusion suggests that NADPH production is not a lipogenesis limiting step in this tissue. On the other hand, lipid oxidation potential was found through the mRNA levels of enzymes involved in β-oxidation, such as HOAD, the brain isoform of CPT-IC, and an exclusive isoform of this tissue, CPT-ID. Although no levels of activity were assessed for these enzymes, a novel oxidation potential can be suggested in the WAT of rainbow trout, probably for local use. We found that insulin acts as an important regulator of trout WAT lipid metabolism as a whole, as recently proposed by Bouraoui et al. (2010) [45], inducing the final stage of lipogenesis and suppressing β-oxidation at a molecular level. Although preliminary, these results suggest that the WAT in fish may have an important role not only as lipid deposition tissue, but also as a lipogenic organ, that could also be able to utilize lipids stored as a local energy source.

Acknowledgments This study was supported by research grants from the Agence Nationale de la Recherche (ANR-08-JCJC-0025-01) and INRA PHASE Department. SP was recipient of a postdoctoral fellowship from the Xunta de Galicia (Program Ángeles Alvariño). We thank the technical stuff (Y. Hontang, F. Sandres, and F. Terrier) of the INRA experimental fish farm of Donzacq for supplying the experimental animals.

COMMUNICATION

Stereochemistry of Hydrogen Removal During Oxygenation of Linoleic Acid by Singlet Oxygen and Synthesis of 11(*S*)-Deuterium-Labeled Linoleic Acid

Mats Hamberg

Received: 23 August 2010 / Accepted: 23 November 2010 / Published online: 16 December 2010

Abstract Exposure of unsaturated fatty acids to singlet oxygen results in the formation of hydroperoxides. In this process, each double bond in the acyl chain produces two regioisomeric hydroperoxides having an (*E*)-configured double bond. Although such compounds are racemic, the hydrogen removal associated with the oxygenation may, a priori, take place antarafacially, suprafacially or stereorandomly. The present study describes the preparation of [11(*S*)-^{2}H]linoleic acid by two independent methods and the use of this stereospecifically labeled fatty acid to reveal the hidden stereospecificity in singlet oxygenations of polyunsaturated fatty acids. It was found that linoleic acid 9(*R*)- and 13(*S*)-hydroperoxides formed from [11(*S*)-^{2}H] linoleic acid both retained the deuterium label whereas the 9(*S*)- and 13(*R*)-hydroperoxides were essentially devoid of deuterium. It is concluded that polyunsaturated fatty acid hydroperoxides produced in the presence of singlet oxygen in e.g., plant leaves are formed by a reaction involving addition of oxygen and removal of hydrogen taking place with suprafacial stereochemistry. This result confirms and extends previous mechanistic studies of singlet oxygen-dependent oxygenations.

Keywords Singlet oxygen · Oxygenation · Hydroperoxide · Linoleic acid · Oxylipins

Introduction

Lipoxygenases are non-heme dioxygenases which catalyze the incorporation of molecular oxygen at a 1(*Z*),4(*Z*)-pentadienyl moiety of polyunsaturated fatty acids forming optically active hydroperoxy fatty acids having a pair of (*E*),(*Z*)-configured conjugated double bonds [1–3]. The same type of fatty acid hydroperoxides is formed by autoxidation of polyunsaturated fatty acids by ground state (radical) dioxygen ($^{3}O_2$). In this case oxygenation takes place without control of regiochemistry and the hydroperoxides are racemic. A third possibility of generating hydroperoxides from unsaturated fatty acids is to expose them to singlet oxygen ($^{1}O_2$). This unstable, non-radical form of dioxygen can be generated from ground state oxygen by light irradiation in the presence of a photosensitizer. $^{1}O_2$ is also produced in certain oxygen-evolving reactions such as the oxidation of hydrogen peroxide by hypochlorite and during the thermal decomposition of phosphite ozonides and other oxygenated compounds (see Ref. [4] and references cited therein). In the process, each double bond in the acyl chain will produce two regioisomeric, racemic hydroperoxides.

Mechanistically, the vast majority of lipoxygenase-catalyzed oxygenations proceed with antarafacial stereochemistry, i.e. the initial hydrogen removal and the subsequent attack by $^3O_2$ take place from opposite sides of the plane of the 1,4-pentadiene moiety [2]. Autoxidation, on the other hand, is a stereorandom process where the carbon-centered radical formed following hydrogen removal can be attacked from both sides with equal probability [5]. Mechanistic studies of $^1O_2$ oxygenations of simple model alkenes have indicated a suprafacial process [6, 7], however, it was of interest to extend such studies to a biologically relevant substrate. The present report is concerned with singlet oxygenation of a polyunsaturated fatty acid having the characteristic methylene group-interrupted (*Z*),(*Z*)-diene partial structure. [11(*S*)-^{2}H]Linoleic acid prepared by two different methods was used for this purpose, and the regio- and stereoisomeric hydroperoxides formed during its exposure to $^1O_2$ were analyzed for isotope content using GC–MS.

Experimental Procedures

[11(*R*,*S*)-^{2}H]Linoleic Acid

The deuterated linoleic acid was synthesized by acetylene coupling followed by partial hydrogenation of the resulting deuterated octadecadiynoic acid. Briefly, 2-octynal (2.5 g; Sigma-Aldrich, Stockholm, Sweden) was reduced to [1-^{2}H]2-octyn-1-ol using sodium borodeuteride in methanol. The bromide (2.73 g) prepared by refluxing with PBr_3 was coupled to methyl 9-decynoate in the presence of CuI and Cs_2CO_3 [8]. Following purification on a silica gel column, 90% pure methyl [11(*R*,*S*)-^{2}H]9,12-octadecadiynoate (4.4 g; yield from 2-octynal, 75%) was obtained. An aliquot was subjected to partial hydrogenation using P-2 nickel as the catalyst [9]. The resulting deuterated methyl linoleate was purified by RP-HPLC, saponified, and further purified by a second RP-HPLC run to provide >99% pure [11(*R*,*S*)-^{2}H]linoleic acid.

[11(*S*)-^{2}H]Linoleic acid (**5**): Method A

It is well known from previous studies that soybean lipoxygenase-1 stereospecifically abstracts the *pro-S* hydrogen from the ω8 bisallylic methylene group of linoleic acid and other polyunsaturated fatty acids [10], and that substitution of this hydrogen for deuterium is accompanied by a large kinetic isotope effect (k_H/k_D about 40, see [11]). Thus, if [11(*R*,*S*)-^{2}H]linoleic acid is incubated with soybean lipoxygenase, the 11(*R*)-^{2}H-labeled enantiomer will be rapidly consumed whereas the 11(*S*)-^{2}H-labeled acid will largely remain not converted. Method A was based on these facts and involved stirring at 0 °C under oxygen atmosphere of [11(*R*,*S*)-^{2}H]linoleic acid (192 mg) in 300 mL of 0.1 M sodium borate buffer pH 10.4 with soybean lipoxygenase-1 (Sigma-Aldrich type IV, 60 μL (250,000 units) [unit definition: as defined by the manufacturer, 1 U will cause an increase in A_{234} of 0.001/min at pH 9.0 at 25 °C when linoleic acid is the substrate in 3.0 mL volume (1 cm light path)]. After 19 min, additional enzyme was added [20 μL (83,000 U)]. The reaction was followed spectrophotometrically by recording the absorbance at 234 nm and interrupted after 32 min (53% conversion according to UV spectrometry). From the mixture, [11(*S*)-^{2}H]linoleic acid was obtained in >99% pure form following preparative RP-HPLC. The isotope composition was 98.1% deuterated and 1.9% undeuterated molecules. In agreement with the labeling, re-incubation of an aliquot of the [11(*S*)-^{2}H]linoleic acid with soybean lipoxygenase-1 resulted in a very slow conversion and the formation of 13(*S*)-HPODE which was essentially devoid of deuterium.

The above method for enzymatic resolution of [11(*R*,*S*)-^{2}H]linoleic acid has been used in a previous study [11].

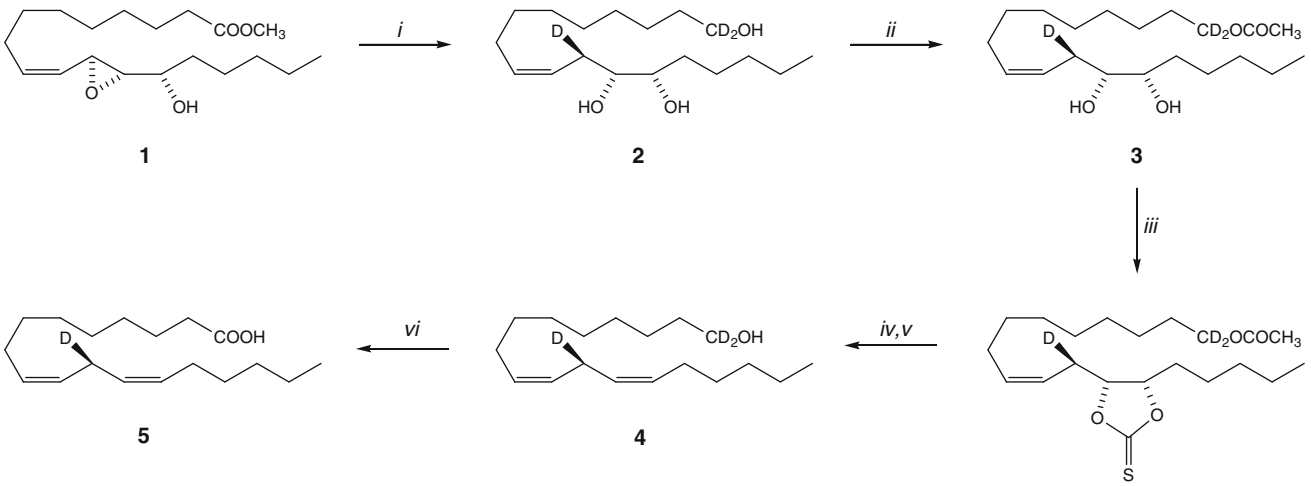
[11(*S*)-^{2}H]Linoleic acid (**5**): Method B

In Method B, a series of stereospecific transformations were used to convert the readily obtainable epoxy alcohol methyl 11(*S*),12(*S*)-epoxy-13(*S*)-hydroxy-9(*Z*)-octadecenoate (**1**) into the desired labeled linoleate (Scheme 1). Thus, **1** (250 mg [12]) in diethyl ether (10 mL) was stirred with lithium aluminium deuteride (155 mg, Sigma-Aldrich) at 23 °C for 5 h affording triol **2** as a white solid [214 mg (92%)]; mass spectrum (Me_3Si derivative) showing *m*/*z* 429 (2%; M^+–Me_3SiOH), 346 (26; M^+–Me_3SiO^+=CH–C_5H_{11}), 275 (100; Me_3SiO^+=CH–CH($OSiMe_3$)–C_5H_{11}), and 173 (Me_3SiO^+=CH–C_5H_{11}). Monoacetylation of **2** using acetyl chloride and 2,4,6-trimethylpyridine [13] afforded diol acetate **3** in quantitative yield; mass spectrum (Me_3Si derivative) showing *m*/*z* 474 (1%; M^+–CH_3), 316 (55; M^+–Me_3SiO^+=CH–C_5H_{11}), 275 (92; Me_3SiO^+=CH–CH($OSiMe_3$)–C_5H_{11}), and 173 (100; Me_3SiO^+=CH–C_5H_{11}). The *erythro*-12,13-diol function of **3** was deoxygenated via the cyclic thionocarbonate using previously described methodology [14]. Following saponification and purification on a silica gel column [1,1,11(*S*)-$^2H_3$]9(*Z*),12(*Z*)-octadecadienol **4** was obtained as a colorless oil [65 mg (32% from epoxy alcohol **1**)]; mass spectrum showing *m*/*z* 269 (7%; M^+), 251 (1; M^+–H_2O), 96 (59), 82 (87), and 68 (100). Oxidation using pyridinium dichromate (273 mg) in dimethylformamide (2.5 mL) containing water (26 mg) and butylated hydroxytoluene antioxidant (2 mg) at 40 °C for 15 h afforded the title compound **5** [23 mg (11% from **1**)]. The

pure compound was obtained following silica gel column chromatography and RP-HPLC. The mass spectrum (methyl ester) showed *m/z* 281 (20%; M^+), 250 (11; M^+–OCH_3), 96 (63), 82 (88), and 68 (100) and an isotopic composition of 2.0% unlabeled and 98.0% monodeuterated molecules. The purity of the sample was in excess of 99% as judged by GLC analysis (Fig. 1). Importantly, this analysis was carried out with the 9(*E*),12(*Z*)- and 9(*Z*),12(*E*)-octadecadienoate isomers as standards and proved that the two double bonds of **5** were both "*Z*".

High-Performance Liquid Chromatography (HPLC)

Purification of **5** and its methyl ester was performed by reversed-phase (RP) HPLC using a column of Nucleosil C_{18} 100-7 (250 × 10 mm; Macherey–Nagel, Düren, Germany) and solvent systems of acetonitrile–water (85:15, by vol) (**5** methyl ester) or acetonitrile–water–acetic acid (75:25:0.005, by vol) (**5**) at a flow rate of 4 mL/min. Regioisomeric hydroxyoctadecadienoic acids were separated by straight-phase (SP) HPLC using a column of Nucleosil 50-7 (250 × 10 mm, Macherey–Nagel, Düren,



Scheme 1 Synthesis of [11(*S*)-^{2}H]linoleic acid **5** from epoxy alcohol **1**. (*i*) $LiALD_4$, diethyl ether; (*ii*) CH_3COCl, 2,4,6-trimethylpyridine; (*iii*) thiophosgene, 4-dimethylaminopyridine; (*iv*) 1,3-dimethyl-2-phenyl-1,3,2-diazaphospholidine; (*v*) NaOH, aq. ethanol; (*vi*) pyridinium dichromate, dimethylformamide, water

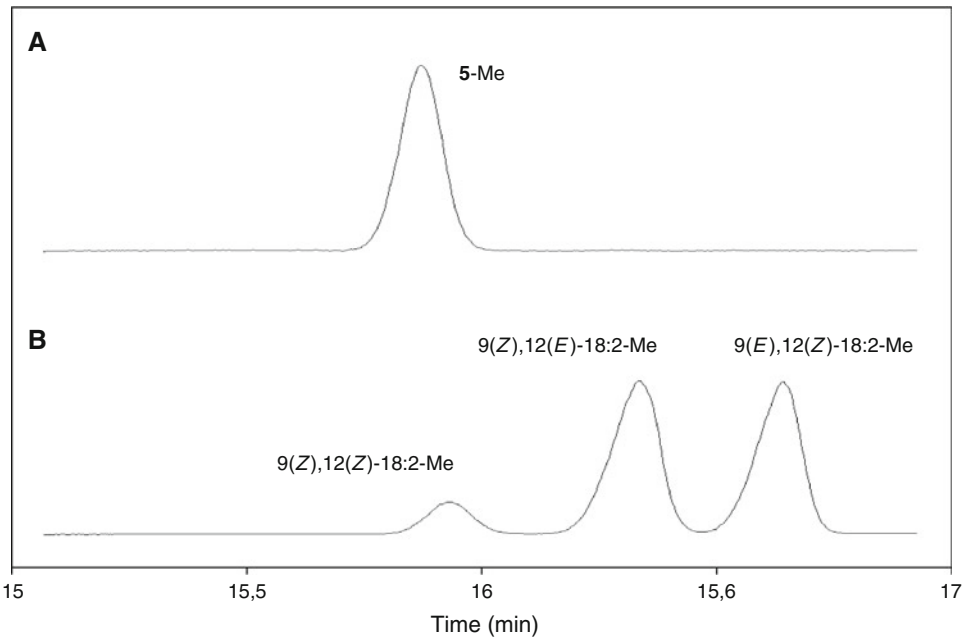


Fig. 1 GLC analysis of the methyl ester of **5** (**a**). The methyl esters of 9(*Z*),12(*Z*)-, 9(*Z*),12(*E*)- and 9(*E*),12(*Z*)-octadecadienoates were used as references (**b**). A methyl silicone capillary column (25 m, 0.33 μm film thickness) was used with helium as the carrier gas. Column temperature, 180 °C

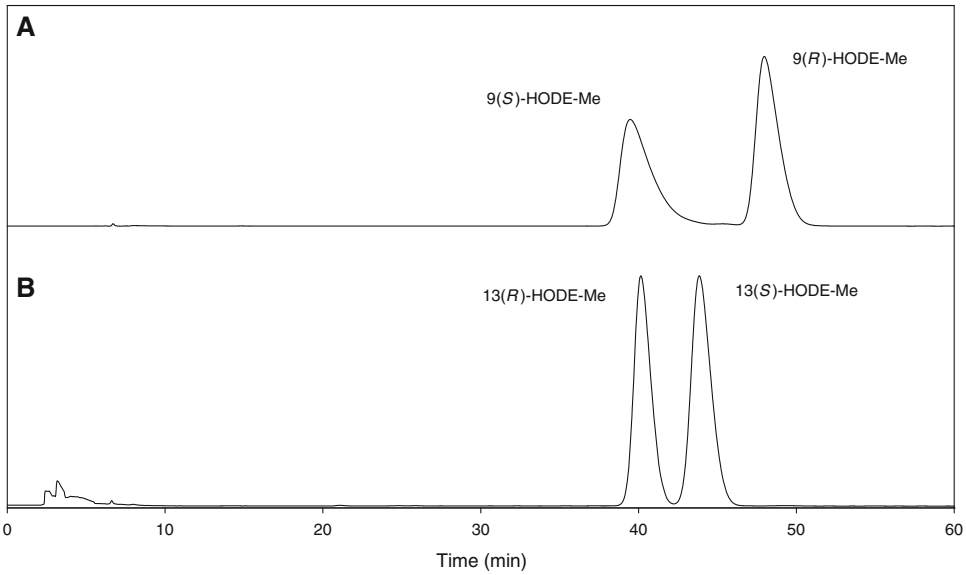

Fig. 2 Separation by CP-HPLC of the methyl esters of 9-HODE (**a**) and 13-HODE (**b**) obtained by singlet oxygenation of **5**. A Chiralcel OB-H column (250 × 4.6 mm) eluted with 2-propanol/hexane (1.5:98.5, v/v) at 0.5 mL/min was used. Detection by UV (234 nm)

Germany) and a solvent system of 2-propanol-hexane-acetic acid (2:98:0.01, by vol) at a flow rate of 4 mL/min. The column effluent was passed through serially connected detectors for measurement of UV absorbance (210 or 234 nm) and refractive index. Methodology for separation of enantiomers of the methyl esters of 9- and 13-HODE by chiral phase (CP) HPLC has been described in detail [15, 16].

Oxygenation Procedure and Isolation of Products

[11(*S*)-^{2}H]Linoleic acid (4.7 mg) was dissolved in methanol (6 mL) containing methylene blue (3 mg). The solution was stirred at 5–8 °C under continuous bubbling of O_2 and irradiated by a 250 W halogen lamp giving a light intensity of approximately 30,000 lx. After 100 min, the solution was cooled on ice and treated with $NaBH_4$ (15 mg). Water was added, and the material extracted with diethyl ether was subjected to SP-HPLC (refractive index detection). Four peaks were observed due to 13-HODE (29%; 42.7 mL effluent), 12-HODE (21%; 51.3 mL), 10-HODE (21%; 57.0 mL), and 9-HODE (29%; 73.1 mL). The 9- and 13-hydroxyoctadecadienoates were methyl-esterified and individually resolved into enantiomers using CP-HPLC (Fig. 2). Derivatization of the methyl esters into Me_3Si derivatives [16] was performed prior to analysis by GC–MS.

GC–MS

A Hewlett–Packard model 5970B mass selective detector connected to a Hewlett–Packard model 5890 gas chromatograph was used. For determination of the isotope content of methyl ester–Me_3Si derivatives, the instrument was operated in the selected ion monitoring mode using the following ions: *m/z* 382.3/383.3 (M^+), 311.2/312.2 (Me_3SiO^+=CH–CH=CH–CH=CH–$(CH_2)_7$–$COOCH_3$), and 225.1/226.1 (Me_3SiO^+=CH–CH=CH-CH=CH–$(CH_2)_4$–CH_3).

Results and Discussion

Shown in Table 1 are results of GC–MS analyses of 9- and 13-hydroxyoctadecadienoates isolated following exposure of [11(*S*)-^{2}H]linoleic acid to singlet oxygen. It is clear that most of the deuterium label was retained in the 9(*R*)-and 13(*S*)-hydroxy derivatives, and that the 9(*S*)- and 13(*R*)-hydroxy compounds had lost most of the label. Thus, the first-mentioned pair was formed by stereospecific elimination of the 11(*R*)-hydrogen, whereas the 11(*S*)-deuterium was lost in the formation of the latter pair. This means that the stereochemical relationship between oxygen addition and hydrogen abstraction is suprafacial in the formation of all four stereoisomers, a finding which confirms and extends previous studies carried out using simple synthetic

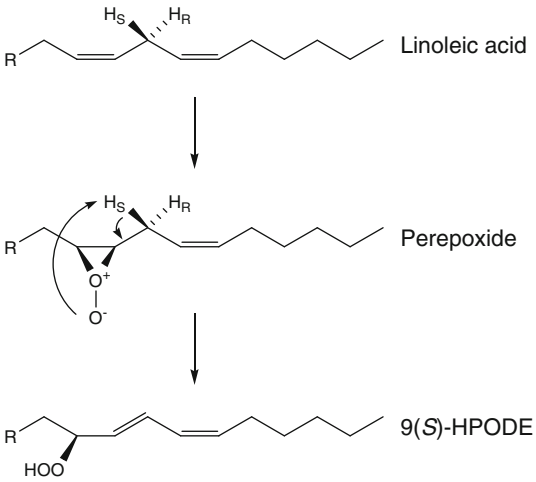
Table 1 Deuterium-content of 9- and 13-hydroxyoctadecadienoates formed by $^1O_2$ oxygenation of [11(*S*)-^{2}H]linoleic acid (**5**)

Hydroxyoctadecadienoate[a]	Monodeuterated molecules (%)	
	Exp 1[b]	Exp 2[c]
9(*R*)-HODE	97.1	96.9
9(*S*)-HODE	3.5	2.3
13(*R*)-HODE	3.4	2.5
13(*S*)-HODE	97.2	97.1

[a] The deuterium label was fully retained in the 10- and 12-hydroxyoctadecadienoates

[b] **5** prepared from [11(*R,S*)-^{2}H]linoleic acid was used

[c] **5** prepared from epoxy alcohol **1** was used



Scheme 2 Possible mechanism in the formation of 9(*S*)-HPODE from linoleic acid in the presence of singlet oxygen

alkenes [6, 7]. Although the detailed mechanism of singlet oxygenation is still being discussed [17–19], it appears that the most plausible one consists of initial addition of $^1O_2$ to the C=C bond to form a doubly charged perepoxide, in which the geometrical configuration of the two carbon atoms is retained (e.g., a (*Z*) double bond gives rise to a *cis*-configured epoxide group) [7]. As illustrated for the linoleic acid → 9(*S*)-HPODE conversion (Scheme 2), suprafacial abstraction of a proton from the allylic methylene by the negatively charged perepoxide oxygen, opening of the epoxide ring and creation of an (*E*)-configured double bond completes formation of the hydroperoxide.

Fatty acid peroxidation in biological systems can take place by lipoxygenase-catalyzed oxygenation, autoxidation, or oxygenation by singlet oxygen, and such oxygenations frequently take place in parallel. This has been best studied in plant leaves, which possess lipoxygenase activity, can initiate $^3O_2$-dependent autoxidation, and produce $^1O_2$ during photosynthesis [20, 21]. Whereas the first- and second-mentioned oxygenations take place antarafacially and stereorandomly, respectively, the present report shows that oxygenation of polyunsaturated fatty acids by singlet oxygen proceeds suprafacially. The distribution of regio- and stereoisomeric hydroperoxides formed by the three oxygenation pathways differ, and determination of specific hydroxide isomers by GC–MS or HPLC has been used to assess the relative importance of the different modes of fatty acid peroxidation in leaves [20]. Conceivably, a further aid in such studies could be provided by isotope analysis of the various hydroxide isomers if a stereospecifically deuterated fatty acid precursor is included as a probe.

Finally, singlet oxygenation has been reported to be accompanied by a weak intramolecular deuterium isotope effect (k_H/k_D 1.4 or less) [7]. An isotope effect would lead to a preponderance of the 10- and 12-hydroxyoctadecadienoates at the expense of the 9- and 13-hydroxy isomers, however, this was not observed using SP-HPLC (refractive index-based detection) or during analysis of the reaction product by GC–MS. Also, as seen in Fig. 2, the ratio of the enantiomers of 9- and 13-hydroxyoctadecadienoates observed on CP-HPLC was close to 1.

EDITORIAL

Are You a Good Citizen of Science?

Eric J. Murphy

In the past I have pondered this important, but perhaps a bit nebulous question: Am I a good citizen of science? So I ask you: Are you a good citizen of science? This is an intriguing and interesting question on which we should all reflect and one that I would hope receives a resounding, "you bet I am!", from everyone. (For those unfamiliar with the movie Fargo, in the upper Midwestern part of the United States that would be a "you betcha!") But are you and I really good science citizens? What exactly does a good citizen of science do, or, on the contrary, not do?

Science citizenship can take on many different forms, from citing papers from a competing scientist to agreeing to review yet another paper on top of the many other commitments one has on hand; from mentoring young colleagues, to offering a colleague a helping hand, to sharing reagents with a no-strings-attached policy, and working to enhance one's own field by doing the drudgery of society work. In the end, good science citizenship is offering our precious time in a selfless manner to help others in our respective fields. Yet, are we good citizens?

This brings me to one of the fundamental cornerstones of science, peer-review. I wish I had a quarter, whether it be in Euros, US, or Canadian currency, every time someone uttered: "I have a grant due in 2 months, so I cannot review that manuscript." Or "I have a meeting in 2 weeks; sorry I just cannot review that manuscript." Amazingly, many individuals who are too busy and too overcommitted to review a manuscript, have no problem burdening the peer-review system with their own manuscripts. They have no problem if their equally busy peers who have meetings to attend, grants to write, and a family with which they might want to see, take time to review a manuscript of theirs. Yet, isn't this a profession in which being overcommitted, understaffed, and underfunded is the norm? So why do many of our colleagues think they should forgo participating in the peer-review process, yet subject others to reviewing their own manuscripts? Perhaps it is selfishness or just plain old-fashioned greed for more time devoted to their own pursuits? Regardless, this is a growing problem not just at *Lipids*, but at many other journals, and something with which editorial board members have repeatedly dealt and uttered complaints about dealing with so many reluctant reviewers.

So, to each reader I offer a suggestion to actively participate in the peer-review process. My "Golden Rule" for peer review is quite simple: Review at least four times the number of manuscripts that you submit in a year. When you are truly pressed for time, discuss with a young colleague, a student or a post-doctoral fellow in your lab the possibility of taking on a peer-review assignment. I have found that many early career scientists—including graduate students—make the best reviewers. Taking this approach will actually expand the vista of your citizenship as you help mentor a young scientist in the peer-review process. This helps educate them on the process as well as providing real experiential learning on how to write (or not to write) a manuscript.

So are you a good science citizen? I hope you are and if not, perhaps you'll see the value of being a good citizen and you'll start down the path of recovery so that you, too, can again feel that exhilaration of being a science citizen in good standing.

REVIEW

Dietary Monounsaturated Fatty Acids Are Protective Against Metabolic Syndrome and Cardiovascular Disease Risk Factors

Leah G. Gillingham · Sydney Harris-Janz · Peter J. H. Jones

Received: 5 November 2010 / Accepted: 21 December 2010 / Published online: 10 February 2011

Abstract Over 50 years of research has sought to define the role dietary fat plays in cardiovascular disease (CVD) risk. Although optimal dietary fat quantity has been keenly pursued over past decades, attention has recently centered on the value of dietary fat quality. The purpose of the present review is to provide a critical assessment of the current body of evidence surrounding efficacy of dietary monounsaturated fatty acids (MUFA) for reduction of traditional risk factors defining metabolic syndrome (MetS) and CVD. Due to existing and emerging research on health attributes of MUFA rich diets, and to the low prevalence of chronic disease in populations consuming MUFA rich Mediterranean diets, national dietary guidelines are increasingly recommending dietary MUFA, primarily at the expense of saturated fatty acids (SFA). Consumption of dietary MUFA promotes healthy blood lipid profiles, mediates blood pressure, improves insulin sensitivity and regulates glucose levels. Moreover, provocative newer data suggest a role for preferential oxidation and metabolism of dietary MUFA, influencing body composition and ameliorating the risk of obesity. Mounting epidemiological and human clinical trial data continue to demonstrate the cardioprotective activity of the MUFA content of dietary fat. As the debate on the optimal fatty acid composition of the diet continues, the benefit of increasing MUFA intakes, particularly as a substitute for dietary SFA, deserves considerable attention.

Introduction

Considerable scientific interest has focused on the impact of dietary fat in the development of metabolic disorders, leading to cardiovascular disease (CVD) [1, 2]. The complications associated with metabolic syndrome (MetS) are the primary foundation of CVD morbidity and

mortality. Dyslipidemia, hypertension, hyperglycemia, insulin resistance and obesity, namely abdominal obesity, are critical factors contributing to MetS. As MetS is a combination of modifiable risk factors, dietary intervention is targeted in primary prevention and secondary treatment therapies. Cumulative scientific evidence suggests that dietary monounsaturated fatty acids (MUFA) effect reductions in key risk factors for MetS [3–5]. Dietary MUFA promote a healthy blood lipid profile, mediate blood pressure, and favorably modulate insulin sensitivity and glycemic control. Conversely, the detrimental effects of diets rich in saturated fatty acids (SFA) have been widely recognized [6, 7]. Thus, national dietary guidelines with a primary focus on cardiovascular health have emphasized the need to reduce consumption of SFA as compared to a decrease in total dietary fat. With emerging research on the health attributes of MUFA rich diets, and the low prevalence of chronic disease in populations consuming MUFA rich Mediterranean diets [8], recommendations have been made to replace SFA intakes with unsaturated fats [9]. However, questions still remain as to the optimal dietary replacement for SFA, comparing MUFA intakes to those of polyunsaturated fatty acids (PUFA) and carbohydrates (CHO). Despite PUFA numerous cardiovascular benefits, intakes have been limited to $\leq$10% of energy due to potential adverse effects, including reduction of high-density lipoprotein cholesterol (HDL-C) levels and increased susceptibility of low-density lipoprotein (LDL) to oxidation [4, 10]. Furthermore, the replacement of dietary SFA with CHO may result in challenges in glucose metabolism and insulin resistance, as well as blood triglyceride (TAG) and HDL-C levels [11, 12]. Thus, potential health attributes of increasing MUFA intakes, particularly at the expense of dietary SFA, deserve careful attention. In light of the recent attention challenging the cardioprotective benefits of MUFA [13, 14], professional organizations continue to recommend dietary MUFA for the prevention of CVD [15, 16]. The purpose of the present review, therefore, is to critically assess the current evidence from human clinical trials surrounding the efficacy of dietary MUFA in the reduction of risk factors for MetS, ultimately targeting a reduction in CVD.

Metabolic Syndrome; Definition and Prevalence

The rising prevalence of chronic disease is related to unhealthy lifestyle choices, including atherogenic diets and lack of physical activity. Metabolic syndrome is defined by a collection of metabolic disorders occurring in an individual and associates with an increased risk of developing type 2 diabetes mellitus (DM-II) and CVD [17–19]. The primary clinical endpoint of MetS is CVD morbidity and mortality. Since the term was first classified by Reaven [20], the definition has evolved to include specific diagnostic criteria by several professional organizations. Recently, the National Cholesterol Education Program's Adult Treatment Panel III (NCEP ATP III) defines MetS as an individual possessing any three or more of the following five risk factors; elevated TAG [$\geq$150 mg/dL (1.7 mmol/L)], reduced HDL-C [<40 mg/dL (1.03 mmol/L) in men or <50 mg/dL (1.29 mmol/L) in women], elevated fasting glucose [$\geq$100 mg/dL (5.6 mmol/L)], hypertension ($\geq$130/85 mmHg or drug treatment), or obesity [waist circumference $\geq$102 cm (40 in) in men or $\geq$88 cm (35 in) in women] [20], with ethnicity specific values for waist circumference outlined by the International Diabetes Federation [21]. Furthermore, emerging risk factors for MetS include a proinflammatory and prothrombotic state [20]. Initially it was hypothesized that insulin resistance was the main risk factor for MetS [22], however, recent definitions propose abdominal obesity to be the predominate risk factor underlying MetS [20, 21, 23, 24]. The prevalence of MetS ranges worldwide [25], impacted by cultural differences associated with population dietary and lifestyle patterns. For example, the prevalence of MetS in the United States (34.5%) is approximately threefold that of Mediterranean countries [25–27]; predominated by the epidemic growth of obesity in the United States [28]. Currently, approximately 66% of the United States population are classified as overweight (BMI > 25 kg/m^2) and 33% obese (BMI > 30 kg/m^2) [29]. The components of the Mediterranean diet are fundamental to the lower prevalence of MetS [30]. Although the Mediterranean diet is complex in nature, rich in fruits, vegetables, and whole-grains, the MUFA content of Mediterranean diets accounts for 16–29% of energy [4], with olive oil providing 15–30% of energy [8]. Therefore, incorporating MUFA into Western dietary patterns, particularly at the expense of SFA, may target a reduction in risk for MetS and CVD.

Monounsaturated Fat; Structure and Sources

Monounsaturated fatty acids are classified as fatty acid chains containing one double bond. Monounsaturated fatty acids possess higher melting points than PUFA, which contain two or more double bonds. Both MUFA and PUFA are liquid at room temperature, whereas MUFA exist as semi-solids or solids when refrigerated. Conversely, SFA contain no double bonds and are solid at room temperature. Structurally, the common MUFA, palmitoleic acid (16:1n-7) and oleic acid (OLA; 18:1n-9), are both *cis* isomers of MUFA. The major dietary *trans* isomer of MUFA is elaidic

acid (*trans*18:1n-9). Oleic acid is the predominate MUFA in the diet, representing ~92% of *cis*MUFA [4]. Table 1 outlines the fatty acid content of food rich in MUFA. Of the MUFA rich dietary oils, the most commonly consumed are olive and canola oil. Furthermore, over the last decade an increase has occurred in commercial production of high OLA modified dietary oils with increased stability for the use in food processing, as a replacement to dietary oils rich in SFA and *trans* fatty acids (TFA) [31].

Current and Recommended Intakes of Dietary Fatty Acids

The total fat intake from Western diets is similar to that of the Mediterranean diet (Table 2), however, the type of dietary fat, specifically MUFA, differs vastly. In the United States, MUFA intakes are 13–14% of energy, SFA intakes are in excess at 11–12% of energy, and PUFA intakes are ≤7% of energy, of which 85–89% of PUFA intakes are

[c] Based on a ~2,000 kcal/day

omega-6 PUFA, principally linoleic acid (LNA) [4, 32, 33]. Conversely, the majority of total fat intake (33–40% of energy) in the Mediterranean diet is represented by MUFA, ranging from 16 to 29% of energy, with olive oil as the principal fat [4, 34, 35]. The high MUFA intake of the Mediterranean diet is at the expense of SFA, with intakes of SFA <8% of energy. Thus, an inverse relationship between the Mediterranean diet and coronary heart disease (CHD) risk has been substantiated in both epidemiological studies and randomized clinical trails [1].

Cardiovascular disease, the clinical outcome of MetS, remains the leading cause of mortality in the Western population [29] and therefore, several professional health organizations have outlined target fatty acid intakes to reduce MetS, DM and CVD risk (Table 2) [9, 36–41]. Recently, the recommendations focus on dietary fat quality versus fat quantity with less emphasis on high CHO diets. The American Diabetes Association (ADA) have modified their previous dietary recommendations for individuals with diabetes, which consisted of high CHO intakes and restricted total fat to ≤30% of energy, with SFA, MUFA, and PUFA at ≤10% of energy [42]. The ADA currently recommends that 60–70% of total calories in diets of those affected with DM-I and -II should be obtained from MUFA and CHO, emphasizing individualization of macronutrients by healthcare professionals [43, 44]. Moreover, the most recent position statement on dietary fatty acids from the ADA and Dietitians of Canada allows for total fat between 20 and 35% of energy, enhancing MUFA intakes up to 25% of energy [36]. The upper limit of total fat at 35% of energy is to minimize intakes of SFA, as well as an upper limit of PUFA intake at 10% of energy due to inconclusive scientific evidence supporting higher intakes of LNA for individuals with DM. Furthermore, the NCEP ATP III, endorsed by the American Heart Association (AHA), has recommended dietary guidelines for primary and secondary prevention of CHD with emphasis on monitoring total dietary fat and targeting a reduction in SFA. Similar to the ADA, earlier recommendations by the AHA, NCEP Step I and II diets, limited total fat intake to ≤30% and MUFA intake to ≤15% of energy [45]. However, in 2001 the NCEP released revisions to the ATP III guidelines [9] increasing total fat to 25–35% of energy, allowing a specific increase in MUFA intakes of up to 20% of energy, with a recommendation for replacing CHO with unsaturated fats for individuals with DM or MetS. Of interest, the current NCEP ATP III recommendations mirror the dietary fat profile of the Mediterranean diet (Table 2) [4, 34, 35]. Recently, the Joint FAO/WHO Expert Consultation on Fats and Fatty Acids in Human Nutrition recommended that MUFA intakes be 15–20% of energy, according to total fat intakes [46]. Unlike other fatty acids with a recommended limit, MUFA intakes should be determined by calculating the difference, i.e. MUFA (% energy) = Total Fat (% of energy) − SFA (% of energy) − PUFA (% of energy) − TFA (% of energy). Thus, MUFA intakes will range with respect to the total fat and fatty acid composition of the diet.

As mentioned, olive oil is the predominate fat in the Mediterranean diet, and although olive oil use is not as common in Western diets, MUFA rich canola oil use in the United States has increased 5.5-fold from 1985 to 1994 [32]. Canola oil, originally naturally bred from rapeseed oil and low in erucic acid, has grown to become the third largest consumed vegetable oil in the world and, next to soybean oil, canola oil is the second most consumed

vegetable oil in the United States. Canola oil can be regarded as one of the most healthy consumed vegetable oils with an attractive fatty acid profile distinctively low in SFA, and rich in MUFA and n-3 PUFA α-linolenic acid (ALA) (Table 1). Consequently, in 2006 the United States Food and Drug Administration (FDA) authorized a qualified health claim stating that canola oil (~19 g daily) may reduce the risk of CHD due its unsaturated fat content, recommending direct caloric replacement of dietary SFA with canola oil [47]. A recent dietary modeling study revealed that replacing common dietary fats in the United States with canola oil and canola-based spreads would increase the percentage of Americans complying with current dietary intake recommendations for fatty acids, namely SFA, MUFA, and ALA, but not for LNA [48]. More specifically, a 50% substitution of fats with canola oil would decrease SFA intakes by 4.7%, whereas a 100% substitution would decrease SFA and LNA intakes by 9.4 and 44.9%, respectively, while increasing MUFA and ALA intakes by 27.6 and 73.0%, respectively. Based on the emphasis of increasing the intakes of MUFA in the diet, particularly at the expense of SFA, it is timely and appropriate to explore the efficacy of MUFA rich diets in the prevention of MetS and CVD.

Monounsaturated Fat and Blood Lipids

Numerous randomized controlled trials have investigated the impact of dietary intervention on changes in circulating lipids [49–52]. The NCEP ATP III guidelines have outlined risk factors that increase CHD risk over a 10 year period. Traditionally, elevated LDL-C [>100 mg/dL (2.6 mmol/L)] remains the strongest primary factor in predicting CHD and therefore is a primary target of therapy [53]. However, as circulating TAG and HDL-C concentrations are critical risk factors in MetS, the TC:HDL-C ratio has been considered a more valuable marker in determining CHD risk [52]. Although the hypolipidemic effect of reducing dietary SFA is well-known and remains the primary target of dietary intervention [7], the debate as to whether MUFA, PUFA or CHO should replace SFA in the diet continues.

Effects of Monounsaturated Fat Compared with Saturated Fat

Evidence from randomized controlled trials has substantiated the deleterious effects of dietary SFA on circulating lipids and lipoproteins [49–51]. When MUFA isocalorically replace SFA in the diet there are improvements in the TC:HDL-C ratio, namely associated with a decrease in serum LDL-C levels and preservation of HDL-C levels. Recently, attention has focused on the lipidemic effects of individual SFA, as stearic acid (STA, 18:0) is considered to have neutral or hypolipidemic effects on circulating lipids compared with other SFA, namely lauric (12:0), myristic (14:0) and palmitic (16:0) acids [52, 54]. Although only a few studies have directly compared OLA to STA intakes, Hunter et al. [54] collectively showed that when OLA replaced STA, LDL-C levels decreased by 5–13% in 3 of 8 studies, however, had no effect in 5 other studies. HDL-C levels increased in one study between 5 and 7%, with no effect in 7 of 8 studies. Triglycerides decreased 20–37% in 2 studies; with no effect in 6 other studies. Finally, an estimated directional decrease in TC:HDL-C ratio was observed in 6 of the 8 studies when OLA replaced STA. Overall compared to OLA, STA tended to increase LDL-C and TAG levels, lower HDL-C levels, and resulted in an increase in the TC:HDL-C ratio. Thus, novel modified dietary oils with a high OLA content have been developed by agricultural and food industries to replace partially hydrogenated oils rich in TFA and SFA for use in food preparation, including frying, baking, and blending with other fats [31]. However, as there are specific food applications that require a solid fat (i.e. shortenings and baked goods), a high STA fat may provide an alternative to fat-containing TFA [54].

Dietary Monounsaturated Fat Versus Carbohydrate for Replacement of Saturated Fat

The effects on CHD risk with substitution of SFA by other macronutrients continue to be a primary focus of public health agendas [14, 52, 55]. Diets rich in CHO, PUFA and MUFA have been compared to those rich in SFA in assessing the ability of each dietary strategy to favorably alter plasma lipids. In studies conducted with healthy subjects comparing high MUFA diets to high CHO diets, those on high MUFA diets showed significant reductions in TAG levels [56–58]. Likewise, overweight and obese subjects [59], those with DM-II [5, 60, 61], and MetS [62] also benefitted from the substitution of MUFA rich diets, as compared to CHO rich diets, in improving plasma TAG levels. One of the main cardioprotective activities of high MUFA diets is the ability of MUFA to either preserve or increase HDL-C levels when compared to CHO rich diets which mostly produce decreases in HDL-C levels [5, 56, 60, 62, 63]. As compared to high CHO diets, high MUFA diets more favorably affect the TC:HDL-C ratio, emphasized by a reduction in LDL-C and TAG levels, while increasing HDL-C levels [52]. Recently, Cao et al. [64] conducted a meta-analysis of 30 controlled-feeding studies in subjects with and without diabetes, comparing moderate fat (MF) (30.2–50% of energy; mean MUFA intake 23.6%

of energy) versus lower fat (higher CHO) diets (LF) (18.3–30.2% of energy; mean MUFA intake 11.4% of energy). In all subjects, reductions in LDL-C levels were similar between the MF and LF diets. However, the MF diet increased HDL-C levels (2.28 mg/dL; 95% CI 1.66–2.90 mg/dL) and decreased TAG levels (−9.36 mg/dL; 95% CI −12.16 to −6.08 mg/dL) versus the LF diet. Moreover, in subjects with diabetes, a further decrease in TAG levels (−24.79 mg/dL) was observed after the MF diet, as well as a decrease in the TC: HDL-C ratio (−0.62) and non-HDL-C (−5.39%) versus the LF diet. The authors concluded that MF diets reduced predicted CHD risk by 6.37% in men and 9.34% in women, including subjects with diabetes, compared with the LF diet. Therefore, MUFA versus CHO replacement for SFA may be more beneficial for individuals predisposed to MetS or with DM-II [5, 53].

Dietary Monounsaturated Fat Versus Polyunsaturated Fat for Replacement of Saturated Fat

Comparison studies and reviews have also examined the action of PUFA rich versus MUFA rich diets on plasma lipid modulation [4, 52, 65–67]. Evidence supports the notion that MUFA rich diets have slightly less or comparable TC and LDL-C lowering effects to those of PUFA rich diets. Whereas n-3 PUFA rich diets may additionally reduce serum TAG [68], MUFA rich diets have more favorable effects on HDL-C concentrations. The ability to effectively target an increase in plasma HDL-C is critical in patients with MetS, DM-II and the prevention of CVD [69, 70]. When PUFA and MUFA rich diets were compared for replacement of dietary SFA in healthy adult subjects, those consuming MUFA rich diets demonstrated a preservation of HDL-C levels to a greater extent with only a 4% decrease in HDL-C levels compared to those consuming PUFA rich diets, which decreased HDL-C levels by 14% [71]. Thus, due to the preservation of HDL-C with MUFA versus PUFA rich diets, effects on the TC:HDL-C ratio where comparable when either MUFA or PUFA replaced dietary SFA [52, 71].

Dietary Monounsaturated Fat and Blood Pressure

Evidence from human clinical studies have shown that dietary MUFA either have neutral or hypotensive effects when compared to diets rich in CHO, n-6 or n-3 PUFA, notably reporting consistent reductions in blood pressure when MUFA are compared to SFA rich diets (Table 3). A study comparing hypertensive subjects consuming MUFA and PUFA rich diets revealed that virgin olive oil high in OLA resulted in significant decreases in total blood pressure [72]. The hypotensive effect of MUFA also alleviated the need of anti-hypertensive drug therapy by 48%, whereas all subjects on a PUFA rich diet required further drug therapy. In contrast, a study conducted by Mutanen et al. [73] failed to observe hypotensive effects of either MUFA or PUFA rich diets in normotensive subjects. Among the studies comparing MUFA and PUFA rich diets, hypotensive benefits of MUFA rich diets are observed in individuals predisposed to MetS in 2 clinical trials, whereas 4 of 5 clinical trials observed no difference between MUFA and PUFA diets in healthy individuals (Table 3).

The effects of MUFA versus CHO rich diets on blood pressure were compared in a meta-analysis by Shah et al. [74]. Of the 10 intervention trials assessed, MUFA rich diets were associated with a slight reduction in blood pressure, specifically systolic blood pressure, compared to the CHO rich diets. Similarly, in this review, 3 of 6 clinical trials observed hypotensive benefits with MUFA rich diets compared to CHO rich diets in individuals predisposed to MetS (Table 3). Muzio et al. [75] compared consumption of high MUFA diets to high CHO diets in 100 obese subjects with MetS over 5 months. At study cessation, while both groups showed significant reductions in all components of MetS, only the diet high in MUFA produced a significantly lower systolic blood pressure, as well as lowered heart rate. In the large randomized, crossover Omni Heart Trial, 164 subjects with prehypertension or stage-1 hypertension consumed diets varying in dietary fats for 6 weeks to determine their subsequent risk of hypertension [76]. Compared to a high CHO diet, consumption of high protein and MUFA diets produced significant reductions in systolic blood pressure and additional benefits in TAG and HDL-C levels.

Considering prospective cohort studies, the SUN (Seguimiento Universidad de Navarra) study of nearly seven thousand subjects reported that high intake of olive oil for an average of 28.5 months was associated with a decrease in the incidence of hypertension in men, but not women [77]. Similarly, in the Greek EPIC (European Prospective Investigation into Cancer and Nutrition) study, olive oil consumption was a primary dietary factor in the Mediterranean diet preventing hypertension [78]. More specifically, a reduction in both systolic and diastolic blood pressure was noted with olive oil consumption, even after controlling for vegetable intake. Alongside, there was an inverse relationship between blood MUFA:SFA ratio and arterial blood pressure. Indeed, olive oil in Mediterranean diets has potent hypotensive effects [79]. However, the OLA content of olive oil, independent of its other components, has been shown to be directly associated with a reduction in blood pressure [80]. As such, strong support can be obtained from clinical trials of the blood pressure

Table 3 Human clinical trials investigating the effects of monounsaturated fat and hypertension

Reference	Subject characteristics	Study design/ duration	Diets	Outcome
Individuals predisposed to metabolic syndrome				
Gulseth et al. [125]	MetS subjects ($n = 486$)	Randomized, parallel 12 weeks	MUFA 39% fat; 10% SFA, 19% MUFA, 7% PUFA SFA 40% fat; 18% SFA, 13% MUFA, 6% PUFA H-CHO 30% fat; 9% SFA, 12% MUFA, 6% PUFA H-CHO + n-3 PUFA 29% fat; 9% SFA, 11% MUFA, 6% PUFA, 1.6 g/d EPA + DHA	No difference in systolic BP or diastolic BP between diets ↓ Pulse pressure with MUFA vs. SFA in men
Brehm et al. [94]	Overweight or obese with DM-II subjects ($n = 124$)	Randomized, parallel 12 months	MUFA 38% fat; 14% MUFA H-CHO 28% fat; 8% MUFA	No difference in diastolic BP between diets
Muzio et al. [75]	Hypercholesterolemic obese subjects with MetS ($n = 100$)	Randomized 5 months	H-CHO 22% fat; 5% SFA, 14% MUFA, 3% PUFA MUFA 33% fat; 9% SFA, 21% MUFA, 4% PUFA	↓ Systolic BP and HR with MUFA vs. H-CHO
Appel et al. [76]	Pre-HT or HT (stage 1) subjects ($n = 164$)	Randomized, crossover 6 weeks	H-CHO 27% fat; 6% SFA, 13% MUFA, 8% PUFA Protein 27% fat; 6% SFA, 13% MUFA, 8% PUFA MUFA 37% fat; 6% SFA, 21% MUFA, 10% PUFA	↓ Systolic and diastolic BP with MUFA and protein vs. CHO in all subjects
Shah et al. [126]	DM-II subjects ($n = 41$)	Randomized, crossover 6 weeks, then 14 weeks	H-CHO 30% fat; 10% SFA, 10% MUFA, 10% PUFA MUFA 45% fat; 10% SFA, 25% MUFA, 10% PUFA	No difference in BP between diets at 6 weeks ↑ Diastolic BP and heart rate at 14 weeks with H-CHO vs MUFA
Piers et al. [106]	Overweight or obese men ($n = 8$)	Randomized, crossover 4 weeks	SFA 40% fat; 24% SFA, 13% MUFA, 3% PUFA MUFA 40% fat; 11% SFA, 22% MUFA, 7% PUFA	↓ Mean arterial pressure and diastolic BP with MUFA vs. SFA
Ferrara et al. [72]	HT subjects ($n = 23$)	Randomized, crossover 6 months	MUFA 27% fat; 6% SFA, 17% MUFA, 4% PUFA PUFA 27% fat; 6% SFA, 11% MUFA, 11% PUFA	↓ Systolic and diastolic BP with MUFA vs. PUFA ↓ HT drug treatment with MUFA but not PUFA

Monounsaturated Fats, Insulin Resistance and Diabetes Mellitus-II

With the rising prevalence of DM worldwide [81], MUFA have gained attention for their ability to regulate glycemic response and improve insulin sensitivity. Similar to the detrimental effects on circulating lipids, SFA have been shown to impair glycemic control and insulin sensitivity [12], specifically in skeletal muscle cells [82]. Therefore, clinical trials replacing dietary SFA with MUFA have noted improvements in insulin sensitivity and glycemic response in individuals predisposed to insulin resistance [83–86], as well as healthy people [87–91] (Table 4). The KANWU (Kuopio, Aarhus, Naples, Wollongong and Uppsala) Study of 162 healthy subjects reported a reduction in insulin sensitivity following consumption of a SFA rich diet for 3 months, and that replacement of SFA with a MUFA rich diet improved insulin sensitivity [89]. More specifically, when total daily fat intake was <37% of energy, an 8.8% increase in insulin sensitivity was observed with the MUFA rich diet, whereas the SFA rich diet decreased insulin sensitivity by 12.5%. However, these effects were not observed when total daily fat intakes exceeded 37% of energy. In the development of DM-II, pancreatic β-cells that secrete insulin to counteract postprandial rises in blood glucose become overwhelmed and as a result, fail to effectively provide the necessary insulin to regulate glucose levels [92]. Recently, MUFA was shown to have a direct action on β-cell function and lower

Table 4 Human clinical trials investigating the effects of monounsaturated fat on glucose and insulin responses

Reference	Subject characteristics	Study design/ duration	Diets	Outcome
Individuals predisposed to metabolic syndrome				
Brehm et al. [94]	Obese and overweight subjects with DM-II ($n = 124$)	Randomized 1 year	H-CHO 28% fat; 7–9% MUFA MUFA 38% fat; 14–15% MUFA	No differences in glucose and insulin sensitivity between groups
Due et al. [83]	Nondiabetic obese subjects ($n = 46$)	Randomized, parallel 6 months	SFA 32% fat; 15% SFA, 10% MUFA, 4% PUFA MUFA 39% fat; 7% SFA, 20% MUFA, 8% PUFA Low-fat 23% fat; 8% SFA, 8% MUFA, 5% PUFA	↓ Fasting glucose, insulin, and insulin resistance score with MUFA vs. other diets ↓ HOMA-IR with MUFA vs. other diets
Paniagua et al. [84]	Obese DM-II subjects ($n = 11$)	Randomized, crossover 28 days	SFA 38% fat; 23% SFA, 9% MUFA, 6% PUFA MUFA 38% fat; 9% SFA, 23% MUFA, 6% PUFA H-CHO 20% fat; 6% SFA, 8% MUFA, 6% PUFA	↓ Fasting glucose with MUFA and H-CHO vs. SFA ↑ Insulin sensitivity (↓ HOMA-IR) with MUFA vs. other diets ↑ Postprandial GLP-1 with MUFA vs. H-CHO
Shah et al. [85]	DM-II subjects ($n = 11$)	Randomized, crossover 15 days	SFA 50% fat; 26% SFA, 20% MUFA, 5% PUFA MUFA 50% fat; 7% SFA, 39% MUFA, 5% PUFA n-6 PUFA 50% fat; 4% SFA, 8% MUFA, 39% PUFA n-3 PUFA 50% fat; 9% SFA, 15% MUFA, 44% PUFA	↓ Postprandial insulin response with MUFA and n-3 PUFA vs. SFA and n-6 PUFA ↔ Postprandial glucose response between diets
Vega-Lopez et al. insulin resistance in a study of 14 healthy men using a randomized, crossover design [87]. Data revealed that MUFA improved insulin sensitivity and β-cell function when compared with SFA. With the incremental substitution of MUFA for SFA, direct linear decreases in insulin resistance were observed.

As a replacement for dietary SFA, high MUFA diets have been compared to high CHO diets for preventing insulin resistance and DM-II risk [3, 5]. An earlier meta-analysis of 10 randomized controlled trials by Garg [5], assessing the effects of high MUFA diets in patients with either DM-I or DM-II, reported improvements in glycemic control, as well as lipoprotein profiles, as compared to high CHO diets. Ros [3] reviewed the evidence on dietary MUFA and metabolic control in DM-II following the comprehensive meta-analysis by Garg [5] and observed similar beneficial metabolic effects of MUFA rich diets. Following these analyses, Paniagua et al. [84, 93] demonstrated that compared to SFA or CHO rich diets, insulin resistant subjects consuming a MUFA rich diet exhibited improvements in insulin sensitivity, as well as other hormonal and metabolic parameters. Similarly, when compared to high CHO and high SFA diets, diets high in MUFA have been shown to significantly decrease fasting glucose by 3% and insulin by 9.4%, and improve insulin sensitivity by 12.1% [83]. In contrast, clinical trials with healthy subjects have observed no difference between MUFA and CHO rich diets in markers of glucose–insulin homeostasis [88, 94, 95]. However, due to other metabolic abnormalities associated with high CHO diets, such as the deleterious effects on plasma TAG and HDL-C levels [11] high MUFA diets may be more beneficial for ameliorating the risk of DM-II. Taken together, evidence from prospective cohort studies have reported that dietary MUFA are not associated with increased risk of DM-II in men [96] or women [97] after adjustment for other dietary fats, age and BMI.

Monounsaturated Fat in Weight Maintenance and Obesity

There is a perception that fat, rich in calories as compared to CHO or protein, is associated with body weight gain leading to obesity [98]. However, a strong argument also exists that dietary fat is not the primary cause of the high prevalence of obesity [99, 100]. Moreover, fat quality may have a stronger correlation to weight gain than fat quantity [101]. Considering fat quality and specific effects of dietary fatty acids for risk of obesity, evidence from prospective cohort studies have reported that MUFA intake is not associated with increases in waist circumference or body weight gain [101, 102]. In the Health Professionals Study of 16,587 men over a 9 year period, replacement of 2% energy of PUFA or CHO with MUFA was not associated with any change in waist circumference, whereas replacement with TFA or SFA led to an increase [102]. Similarly, in the Nurses' Health Study, consumption of MUFA, as well as PUFA, was not associated with an increase in body weight, while TFA and SFA positively correlated with weight gain after 8 years [101]. Large prospective cohort studies in the Mediterranean region have revealed that high intakes of olive oil [103] or nuts [104], both rich sources of MUFA, or adherence to a Mediterranean diet [105] were not associated with an increase in weight or risk of obesity over the longer term [103, 104].

With respect to human clinical trials, Paniagua et al. [93] have demonstrated that compared to CHO rich diets, insulin resistant subjects consuming a MUFA rich diet showed significantly increased fat oxidation rates and decreased abdomen-to-leg adipose ratios, thus preventing central body fat distribution [93]. This finding has important implications for those at risk for MetS since the increase in central adiposity was associated with a reduction in adiponectin expression and insulin sensitivity following the CHO rich diet as compared to the MUFA rich diet. An inverse relationship has been shown between circulating adiponectin levels and body fat percentage as well as central body fat accumulation, specifically visceral adiposity. Similarly, Piers et al. [106] substituted a SFA rich diet with MUFA for 4 weeks in eight overweight and obese men using a randomized crossover design to determine the effects on body weight and composition. Assessment of body composition by dual energy X-ray absorptiometry (DEXA) revealed a significant decrease in body mass (-2.1 ± 0.4 kg; $p = 0.0015$) and fat mass (-2.6 ± 0.6 kg; $p = 0.0034$) following the MUFA compared to the SFA rich diet, albeit no differences in total energy or fat intake were noted between diets. Furthermore, the changes in body mass and fat mass were accompanied with a decrease in waist-to-hip ratio after the MUFA rich versus the SFA rich diets. The favorable modifications in body composition and amelioration of weight gain after consumption of MUFA compared to SFA have also been observed in healthy subjects [107].

Of interest and as extensively reviewed by Bergouignan et al. [82], MUFA is the primary fat composing adipose tissue, however, there appears to be no direct relation between MUFA intake and MUFA levels in adipose. Rather SFA intake seems to be more closely associated with endogenous MUFA levels [108, 109]. Bergouignan et al. [82] hypothesized that in vivo desaturation of SFA may be related to an increase in MUFA versus SFA in adipose tissue. Furthermore, OLA preferentially accumulates in subcutaneous fat versus visceral fat, whereas the reverse exists with palmitate [110, 111]. Thus, since a direct correlation exists between visceral fat and risk factors for metabolic syndrome [112], OLA concentrating in subcutaneous fat versus visceral fat may be less atherogenic. Moreover, dietary MUFA may be preferentially oxidized as compared to other dietary fatty acids, as the degree of fatty acid chain length and unsaturation may

contribute to the partitioning of dietary fat to energy expenditure versus energy storage [107, 113–116]. Furthermore, the metabolism of dietary fat stimulates behavioral changes in food intake preference [117]. Indeed, evidence suggests that different dietary fats may elicit varying effects on satiety and total energy intake [118]. Taken together, dietary MUFA consumption is associated with maintenance of body weight and favorable shifts in reducing central body fat adiposity, potentially ameliorating obesity risk.

Monounsaturated Fats and Cardiovascular Risk; Epidemiological Evidence

As effects on risk markers may not directly translate into effects on clinical outcomes of disease, it is thus critical to assess effects of dietary MUFA on the primary clinical endpoint of MetS, that is CVD morbidity and mortality. Randomized controlled trials are considered the gold standard for evaluating the causal relationship between dietary intervention and chronic disease endpoints in humans; however, to date no randomized controlled trials have investigated dietary MUFA on CVD morbidity and/or mortality as the clinical endpoint [1]. Consequently, Rudel et al. [119] have challenged the cardioprotective effects of MUFA, observing equal coronary artery atherosclerotic effects between dietary MUFA and SFA in nonhuman primates. However, it is acknowledged that results from experimental animal models may not always extrapolate to humans. Considering the substantial evidence presently reviewed supporting the beneficial effects of dietary MUFA on risk factors for MetS and CVD, additional evidence is needed to uncover the discrepancy between human epidemiological evidence and experimental animal models. The following literature discusses the evidence from ecological and prospective cohort studies on effects of MUFA and CVD risk.

Ecological Studies

In a landmark epidemiological trial of 11,579 men aged 40–59 in the Seven Countries study, Keys et al. [8] presented important data revealing that areas consuming a Mediterranean diet rich in OLA from olive oil, even though higher in total fat (33–40% of energy), exhibited lower incidence of CHD mortality. Indeed, in this 15 year follow-up trial, data continued to emphasize the strong inverse relationship between dietary MUFA, as well as the ratio of dietary MUFA to SFA, and incidence of CHD mortality. Conversely, Hegsted and Ausman [120] reported a positive correlation between dietary MUFA and CHD mortality in men aged 35–74 from 18 countries. It is important, however, to note the authors emphasized a rather high correlation between MUFA and SFA intakes and stated that SFA as a confounding variable compromised conclusions linking dietary MUFA with increase risk of CHD.

Prospective Cohort Studies

Large prospective cohort studies are considered to be the strongest source of evidence of the observational studies. Recently, a systematic review of 507 prospective cohort studies confirmed the relationship between a Mediterranean diet and decreased risk of CHD (RR = 0.66; 95% CI 0.57–0.75), evidence that was further confirmed as effective through pooled analysis of 94 randomized control trials [1]. Of interest, analysis of the prospective cohort studies revealed strong evidence of an inverse relationship between dietary MUFA and CHD risk (RR = 0.81; 95% CI 0.68–0.93). Conversely, Mente et al. also identified that consumption of foods high in TFA and glycemic load were attributed to increased CHD risk (RR = 1.32; 95% CI 1.16–1.48; and RR = 1.33; 95% CI 1.13–1.52, respectively). In a 14 year follow-up of 80,082 women in the Nurses' Health Study, a 5% increase in energy intake from MUFA was associated with a relative risk of CHD of 0.81 (95% CI 0.65–1.00) [121]. Furthermore, it was estimated that a 5 or 2% energy replacement of SFA or TFA with MUFA decreased risk of CHD by approximately 30 and 50%, respectively, whereas a 5% energy replacement of MUFA with CHO increased risk of CHD by approximately 25%. Results of the Finnish ATBC (Alpha-Tocopherol, Beta-Carotene) Cancer Prevention Study revealed that after adjustment for vitamin E, C, and β-carotene intakes, an inverse association existed between MUFA intakes and CHD mortality (RR between the extreme quintiles = 0.73; 95% CI 0.56–0.95) [122]. Conversely, a pooled analysis of 11 American and European cohort studies conducted by Jakobsen et al. [14] failed to identify a causal link between MUFA intake and decreased CHD risk. These authors reported that a 5% energy substitution of MUFA for SFA resulted in a hazard ratio of 1.19 (95% CI 1.00–1.42) for CHD events and 1.01 (95% CI 0.73–1.41) for CHD deaths. The authors, however, discussed that the association of MUFA intakes with CHD risk may be confounded by incomplete adjustments for TFA intakes, as MUFA intakes in Westernized diets are primarily from meat, dairy and hydrogenated oils [123]. Moreover, data from the Nurses' Health Study reported a strong correlation between MUFA intakes and SFA ($r = 0.81$) and TFA ($r = 0.55$) [121]. Taken together, observational evidence supports dietary MUFA for

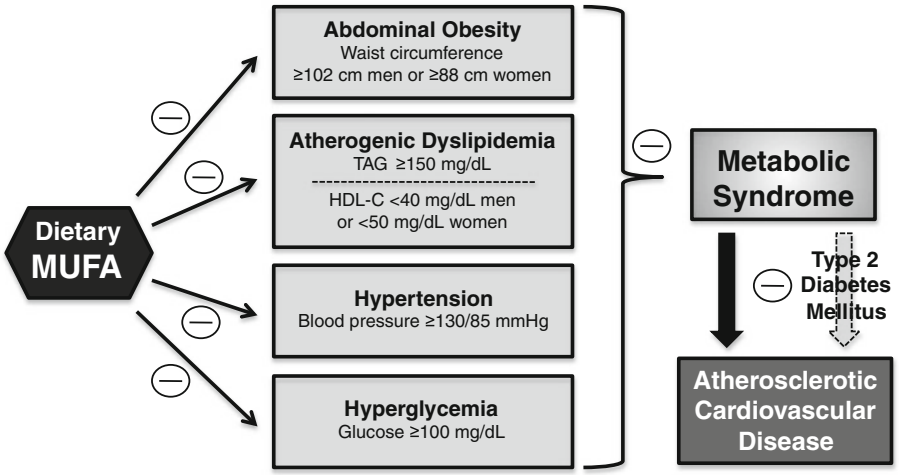

Fig. 1 Dietary monounsaturated fats for the prevention of metabolic syndrome and atherosclerotic cardiovascular disease risk

reduction of CVD risk, however, results from large randomized controlled trials are crucial to substantiate the cardioprotective effects of dietary MUFA.

Conclusion

As dietary intervention remains the primary strategy for the prevention of CVD risk, professional organizations continue to ascertain the optimal fatty acid profile for population intake recommendations. This critical assessment of randomized controlled trials demonstrates that dietary MUFA prevent or ameliorate MetS and CVD risk by favorably modulating blood lipids, blood pressure and insulin sensitivity. Moreover, MUFA preferential oxidation and metabolism influence body composition and potentially ameliorate the risk of obesity (Fig. 1). Considering dietary replacement of SFA, as compared to CHO, MUFA are effective at preserving HDL-C levels, lowering TAG levels, and improving insulin sensitivity; benefits which are especially important in individuals with MetS and DM. As compared to PUFA, MUFA have slightly less or comparable plasma LDL-C and TC lowering effects, however, ameliorate reductions in HDL-C levels, and potentially provide hypotensive effects. The majority of epidemiological data favor the cardioprotective activity of dietary MUFA. More specifically, strong evidence from prospective cohort studies suggests that dietary MUFA are associated with a 20% reduced risk in CHD events [1]. It has also been well established that the intake of a Mediterranean diet rich in MUFA contributes to reducing CHD in both healthy adults and those with established chronic disease.

In North America, where consumption of SFA and TFA are in excess, a dietary movement is occurring to reduce the content of these deleterious fats from commercial production of foods. With the escalating use of MUFA rich canola oil, replacing common dietary fats with canola oil and canola-based spreads would increase the percentage of North Americans complying with current dietary intake recommendations for fatty acids [48]. Consumer awareness of the health implication of dietary fats is increasing [124] and there is a demand for modified dietary oils with a high OLA content for the use in cooking and food preparation in replace of partially hydrogenated oils rich in TFA and SFA [31]. Novel dietary oils rich in OLA with enhanced oxidative stability, such as high-oleic canola oil, provide an attractive healthful alternative to increase dietary MUFA and reduce SFA in commercial food use. With epidemiological and human clinical research substantiating the cardioprotective value of dietary MUFA, increasing population consumption of MUFA, specifically as a substitute for SFA, will embark beneficial implication for MetS, CVD and overall health.

Conflict of interest The authors have no conflict of interest to declare.

Aerobic Training in Rats Increases Skeletal Muscle Sphingomyelinase and Serine Palmitoyltransferase Activity, While Decreasing Ceramidase Activity

Agnieszka Błachnio-Zabielska · Piotr Zabielski · Marcin Baranowski · Jan Gorski

Received: 11 September 2010 / Accepted: 1 December 2010 / Published online: 22 December 2010

Abstract Sphingolipids are important components of cell membranes that may also serve as cell signaling molecules; ceramide plays a central role in sphingolipid metabolism. The aim of this study was to examine the effect of 5 weeks of aerobic training on key enzymes and intermediates of ceramide metabolism in skeletal muscles. The experiments were carried out on rats divided into two groups: (1) sedentary and (2) trained for 5 weeks (on a treadmill). The activity of serine palmitoyltransferase (SPT), neutral and acid sphingomyelinase (nSMase and aSMase), neutral and alkaline ceramidases (nCDase and alCDase) and the content of sphingolipids was determined in three types of skeletal muscle. We also measured the fasting plasma insulin and glucose concentration for calculating HOMA-IR (homeostasis model assessment) for estimating insulin resistance. We found that the activities of aSMase and SPT increase in muscle in the trained group. These changes were followed by elevation in the content of sphinganine. The activities of both isoforms of ceramidase were reduced in muscle in the trained group. Although the activities of SPT and SMases increased and the activity of CDases decreased, the ceramide content did not change in any of the studied muscle. Although ceramide level did not change, we noticed increased insulin sensitivity in trained animals. It is concluded that training affects the activity of key enzymes of ceramide metabolism but also activates other metabolic pathways which affect ceramide metabolism in skeletal muscles.

Keywords Serine palmitoyltransferase · Sphingomyelinase · Ceramidase · Sphingolipid intermediates · Skeletal muscle · Training

Abbreviations

Cer	Ceramide
dhCer	Dihydroceramide
Sph	Sphingosine
SPA	Sphinganine
S1P	Sphingosine-1-phosphate
SPA1P	Sphinganine-1-phosphate
SPT	Serine palmitoyltransferase
nCDase	Neutral ceramidase
alCDase	Alkaline ceramidase
nSMase	Neutral sphingomyelinase
aSMase	Acidic sphingomyelinase

Introduction

Sphingolipids are an important lipid class that is present in all higher organisms. Ceramide (Cer) is the key compound on the crossroads of sphingolipid metabolism. Ceramide mediates a number of biological processes, including apoptosis, proliferation, differentiation, growth arrest, inflammation and heat stress response [1–4]. The variety of cellular effects of ceramide can be attributed to its ability to alter the activity of kinases, phosphatases and transcription factors [5–7]. Other sphingolipid intermediates, such as sphingosine (Sph), sphingosine-1-phosphate (S1P), ceramide-1-phosphate are also important second messengers [8–12]. The cellular content of ceramide is determined by a balance between the rate of its formation and degradation.

There are two major types of ceramides production. One of them is hydrolysis of sphingomyelin and the other one is de novo biosynthesis. Sphingomyelin is located in the plasma membrane, in lysosomes, and in endosomes. Its hydrolysis is catalyzed by the neutral and acid sphingomyelinase (n- and aSMase). De novo synthesis is initiated by condensation of serine with palmitoyl-CoA to generate 3-ketosphinganine [13]. This, the rate-limiting step in de novo sphingolipid biosynthesis is catalyzed by the enzyme serine-palmitoyltransferase (SPT). 3-Ketosphingosine is rapidly reduced to sphinganine (SPA) by the action of the enzyme 3-ketosphinganine reductase. Next, SPA is acylated to form dihydroceramide by the action of dihydroceramide synthase. The last step of ceramide synthesis is conversion of dihydroceramide to ceramide by insertion of a 4,5-*trans*-double bond into dihydroceramide. This reaction is catalyzed by the enzyme dihydroceramide desaturase [13]. Ceramide is hydrolyzed by the enzyme ceramidase (CDase) to yield a free fatty acid and sphingosine. There are three isoforms of ceramidase: acid (aCDase), neutral (nCDase) and alkaline (alCDase). By the use of enzymatic assay and Northern blot analysis almost no activity or mRNA of aCDase was found in skeletal muscle [14].

Ceramide has been shown to be present in skeletal muscle [15–17]. Its content in the muscles depends on the muscle type. The higher content of ceramide was observed in muscle composed mostly of oxidative fibers than in muscle composed mostly of glycolytic fibers [16]. Skeletal muscles are responsible for 70–80% of whole body insulin-stimulated glucose uptake [18, 19]. Recent evidence suggests that the accumulation of intramuscular lipids is involved in the induction of insulin-resistance [20, 21]. One candidate for this action is ceramide [17]. The intracellular level of ceramide is increased in the muscles of obese, insulin-resistant Zucker rats [22] and obese insulin-resistant humans [17]. Adams et al. reported that ceramide content increased nearly twofold in skeletal muscles of obese humans. It is also well known that trained subjects are more insulin sensitive than sedentary subjects [23, 24].

A previous study showed that endurance training decreases the total content of sphingomyelin and ceramides, increases the content of sphinganine, does not affect the sphingosine content, and increases nSMase activity [25]. Moreover, sphingolipid content and the activity of enzymes of ceramide metabolism both depend on the duration of exercise and muscle type [26]. In the mentioned study, the ceramide level decreased after 30 min of running but increased after exhaustive exercise [26]. Data obtained from human skeletal muscle showed that training did not change either ceramide content or nSMase activity [27]. There was no data on the effect of training on the activity of SPT, acid sphingomyelinase and ceramidases in rat skeletal muscles. Therefore the aim of the present study was to examine the effect of training on the activity of key enzymes of ceramide metabolism and selected sphingolipid intermediates in skeletal muscle.

Materials and Methods

Animals and Study Design

The investigation was approved by the Ethical Committee for Animal Experiments at the Medical University of Bialystok. The experiments were carried out on male Wistar rats (200–250 g) fed ad libitum on commercial food pellets for rodents. Animals were housed in standard conditions (21 ± 2 °C, 12 h light/12 h dark cycle) with free access to tap water and food pellets. The animals were randomly divided into two groups ($N = 8$ in each group): (1) sedentary (control) (2) trained for 5 weeks on an electrically driven treadmill according to the following protocol [28]: 1st week 1 h daily at a speed of 960 m/h. The same running time was applied during successive weeks but the running speed was increased as follows: 2nd week 1,200 m/h, 3rd week 1,440 m/h, 4th–6th week 1,680 m/h. This type of training was previously found to affect ceramide metabolism in both cardiac and skeletal muscle of the rat [25, 29]. Twenty four hours after the last exercise bout in the training program, the rats were anaesthetized along with the controls with pentobarbital sodium administered intraperitoneally at a dose of 80 mg/kg. The soleus and the red and white sections of the gastrocnemius were excised, cleaned of any visible adipose tissue, nerves, and fascias and frozen in liquid nitrogen. These muscles are composed predominantly of slow-twitch oxidative, fast-twitch oxidative-glycolytic, and fast-twitch glycolytic fibers, respectively [30, 31]. We used a homeostasis model assessment for calculating insulin resistance (HOMA-IR) in both groups.

The Content of Sphingosine, Sphinganine and Sphingosine-1-phosphate

The content of Sph, SPA and S1P was measured using the method previously described by Min et al. [32]. Internal standards (C17-sphingosine and C17-S1P, Avanti Polar Lipids) were added to the samples before homogenization and ultrasonication. The dried lipid residues were redissolved in ethanol and sphingoid bases were converted to their *o*-phthalaldehyde derivatives and analyzed on an HPLC system (ProStar, Varian Inc.) equipped with a fluorescence detector and C18 reversed-phase column (Varian Inc. OmniSpher 5, 4.6 × 150 mm). The isocratic eluent composition of acetonitrile (Merck): water (9:1 v/v) and a flow rate of 1 ml/min were used. The column temperature

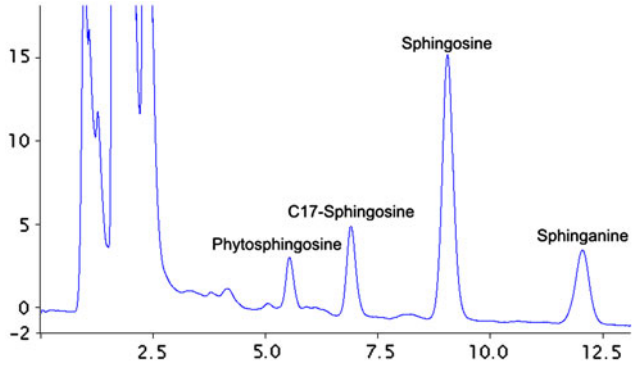

Fig. 1 HPLC chromatography separation of sphingolipids

was maintained at 33 °C. Figure 1 presents a chromatogram showing the separation of sphingolipids. Figure 2 shows the standard curve of SPA, Cer, Sph and S1P.

The Content of Ceramide and Dihydroceramide

A small volume of the chloroform phase containing lipids extracted as described above was transferred to a fresh tube containing 31 pmol of C17-sphingosine as an internal standard. The samples were evaporated under a nitrogen stream, redissolved in 1 M KOH in 90% methanol and heated at 90 °C for 60 min to convert ceramide into sphingosine. This digestion procedure does not convert complex sphingolipids, such as sphingomyelin, galactosylceramide or glucosylceramide, into free sphingoid bases [33]. Samples were then partitioned by the addition of chloroform and water. The upper phase was discarded and the lower phase was evaporated under nitrogen. The content of free sphingosine liberated from ceramide was then analyzed by means of HPLC as described above. The calibration curves were prepared using *N*-palmitoylsphingosine and *N*-palmitoylsphinganine (Avanti Polar Lipids, Alabaster, AL, USA) as standards. The chloroform extract used for the analysis of Cer and dhCer levels also contains small amounts of free sphingoid bases. Therefore, the content of ceramide and dihydroceramide was corrected for the level of free sphingosine and sphinganine, respectively, as determined in the same sample.

The Activity of Sphingomyelinases

The activity of n- and aSMase was determined according to Liu and Hannun [34]. The activity of both sphingomyelinases was measured with the use of radiolabeled substrate [*N*-methyl-^{14}C]-sphingomyelin (Perkin-Elmer Life Sciences). The product of reaction—^{14}C-choline phosphate—was extracted with $CHCl_3$:methanol (2:1, v/v), transferred to scintillation vials and counted using a Packard TRI-CARB 1900 TR scintillation counter.

The Activity of Ceramidases

The activity of alCDase and nCDase was measured by the method of Nikolova-Karakashian and Merrill [35]. The activity of the enzymes was determined with the use of radiolabeled [*N*-palmitoyl-1-^{14}C]-sphingosine (Moravek Biochemicals) as a substrate. Unreacted ceramide and liberated ^{14}C-palmitate were separated with basic Dole solution (isopropanol:heptane:1 N NaOH, 40:10:1, v/v/v). Radioactivity of the ^{14}C-palmitate was measured by scintillation counting.

The Activity of Serine Palmitoyltransferase

The activity of SPT was examined as described by Merrill [36] with the use of a radiolabeled substrate, [^{3}H]-L-serine (Moravek Biochemicals). Briefly, rat skeletal muscle microsomal fraction was obtained by ultracentrifugation at 150,000*g* for 40 min. Microsomes were incubated for 10 min at 37 °C in the reaction buffer (100 mM HEPES (pH 8.3), 5 mM DTT (dithiothreitol), 2.5 mM EDTA (pH 7.0), 50 μM pyridoxal phosphate, 200 μM palmitoyl-CoA and 2 mM L-serine, 44,000 dpm/nmol). The labeled lipid product 3-ketosphinganine was extracted with $CHCl_3$:methanol (1:2, v/v) and the radioactivity was measured by scintillation counting.

Plasma Insulin and Glucose Concentration

The plasma insulin concentration was determined using an ELISA kit (Mercodia Insulin ELISA kit). The plasma glucose concentration was measured using the Glucose Ox Liquid Kit (Pointe Scientific).

Plasma Free Fatty Acids (FFA) Concentration

The FFA concentration was determined using the Wako NEFA C kit (Wako Chemicals).

Statistical Analysis

All data are presented as means ± SD. Data were analyzed by one-way analysis of variance (ANOVA), followed by the Newman–Keuls post hoc test. p values <0.05 were taken to indicate statistical significance.

Results

Plasma FFA, Glucose and Insulin Concentration and HOMA-IR

The cellular ceramide level depends on the availability of plasma FFA. Circulating FFA must be converted to their

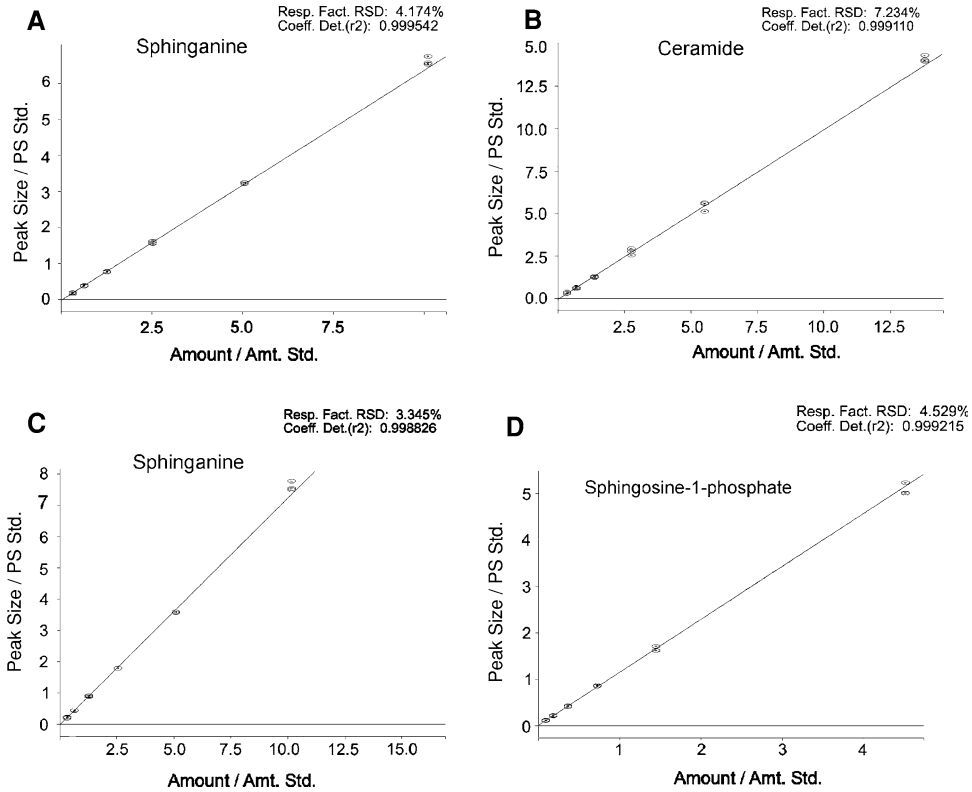

Fig. 2 Standard curve of sphinganine (**a**), ceramides (**b**), sphingosine (**c**), sphingosine-1-phosphate (**d**)

active form—fatty acyl coenzyme A—after entering the cell in order to participate in further metabolic processes. Acyl-CoA is used as a substrate in the de novo sphingolipids biosynthesis. In our study the plasma FFA concentration decreased from 260 ± 17 nmol × ml^{-1} (control group) to 111.06 nmol × ml^{-1} ($p < 0.01$) (training group) (Table 1). To estimate the insulin sensitivity we measured fasting plasma insulin and glucose concentration for HOMA-IR calculation. The equation for calculating HOMA-IR was as follows: HOMA-IR = (fasting plasma glucose × fasting plasma insulin)/2,430, where fasting plasma glucose was in mg/dl and fasting plasma insulin in μU/ml [37]. Both plasma glucose and insulin concentration were significantly lower in the trained group compared to the sedentary group (Table 1). We found that HOMA-IR values were lower in the trained group ($HOMA\text{-}IR_{trained}$ = 0.54) than in the sedentary group ($HOMA\text{-}IR_{sedentary}$ = 1.13) which means that exercised animals were more insulin sensitive than sedentary rats.

Table 1 Effect of training on plasma free fatty acid, glucose and insulin concentration

	Control	Training
Plasma FFA concentration (nmol × ml^{-1})	260 ± 17	111.06 ± 15[b]
Plasma glucose concentration (mg/dl)	140.76 ± 16.6	90.18 ± 11.8[a]
Plasma insulin concentration (μU/ml)	19.6 ± 2.4	14.6 ± 2.1[a]
HOMA-IR	1.13 ± 0.10	0.54 ± 0.04[b]

Values are means ± SD ($n = 8$ in each group). The rats were either sedentary (control) or trained on the electrically driven treadmill as described in the methods

HOMA-IR = [fasting glucose (mg/dl) × fasting insulin (μU/ml)]/2,430

The Content of Skeletal Muscle Sphingolipids (Table 2)

Sphingolipids, especially ceramides, are very active biologically and mediate a number of biological processes. It seems that ceramides play an important role in the induction of different diseases states such as insulin resistance [38, 39]. Data from our previous study showed that ceramide metabolism changes with the duration of single-bout exercise [26]. In the present study we wanted to examine how training affects sphingolipids content and enzymes activities implicated in ceramide metabolism in skeletal muscle. Therefore we measured the content of the following sphingolipids: sphingosine, sphingosine-1-phosphate, sphinganine, sphinganine-1-phosphate (SPA1P), ceramides and dihydroceramide (dhCer). The content of Sph (Fig. 3a) and S1P (Fig. 3b) did not change in any

studied muscle after endurance training. SPA level increased by 52% ($p < 0.01$) and 41% ($p < 0.01$) in the soleus and red section of the gastrocnemius, respectively, compared to the control group. There was no difference in the SPA content in the white section of the gastrocnemius between trained and sedentary groups (Fig. 3c). The content of sphinganine-1-phosphate increased in both sections of the gastrocnemius in trained animals. In the red section of the gastrocnemius the SPA1P level was 50% ($p < 0.01$) higher than in the same muscle in the control group. In the white section of the gastrocnemius the SPA1P level was almost four times higher ($p < 0.001$) then in the same muscle from the sedentary group (Fig. 3d). The content of ceramide and dhCer did not change in any studied muscle from the trained group (Fig. 3e, f).

The Enzymes of Ceramide Metabolism (Table 3)

The activities of the key enzymes implicated in ceramides metabolism: SPT, nSMase, aSMase (enzymes responsible for ceramides generation) and nCDase and alCDase (enzymes responsible for ceramides degradation) were measured. There are limited data about the activity of the above-mentioned enzymes in skeletal muscle. The only available data on the activity of all the enzymes in muscle refer to the enzymes' activity at rest, after a single-bout of exercise [26], from diabetic and healthy animals with increased plasma FFA concentration [40] and from animals fed high fat diets [41]. In the present study the activity of SPT increased in each studied muscle in the trained group. The enzyme activity was almost two times ($p < 0.001$), three times ($p < 0.001$) and almost four times ($p < 0.001$) higher in the soleus, red, and white section of the gastrocnemius, respectively, compared to the control group (Fig. 4a).

In the soleus, there was no difference in nSMase activity between the control and trained groups. In the red and white sections of the gastrocnemius, the activity of nSMase increased by 30% ($p < 0.01$) and by 41% ($p < 0.001$), respectively, compared to the control group (Fig. 4b).

The activity of the aSMase increased in each studied muscle in the trained group. The enzyme activity was 1.5 ($p < 0.001$), 2.5 ($p < 0.001$) and 2.3 times ($p < 0.001$) higher in the soleus, red and white sections of the gastrocnemius respectively, compared to the control group (Fig. 4c).

The activity of nCDase decreased by 19% ($p < 0.05$) and by 30% ($p < 0.05$) in the soleus and white section of the gastrocnemius respectively, compared to the control group. The enzyme activity did not change in red section of the gastrocnemius (Fig. 5a).

The activity of alkaline ceramidase (alCDase) decreased by 21% ($p < 0.05$), 24% ($p < 0.05$) and 34% ($p < 0.01$) in

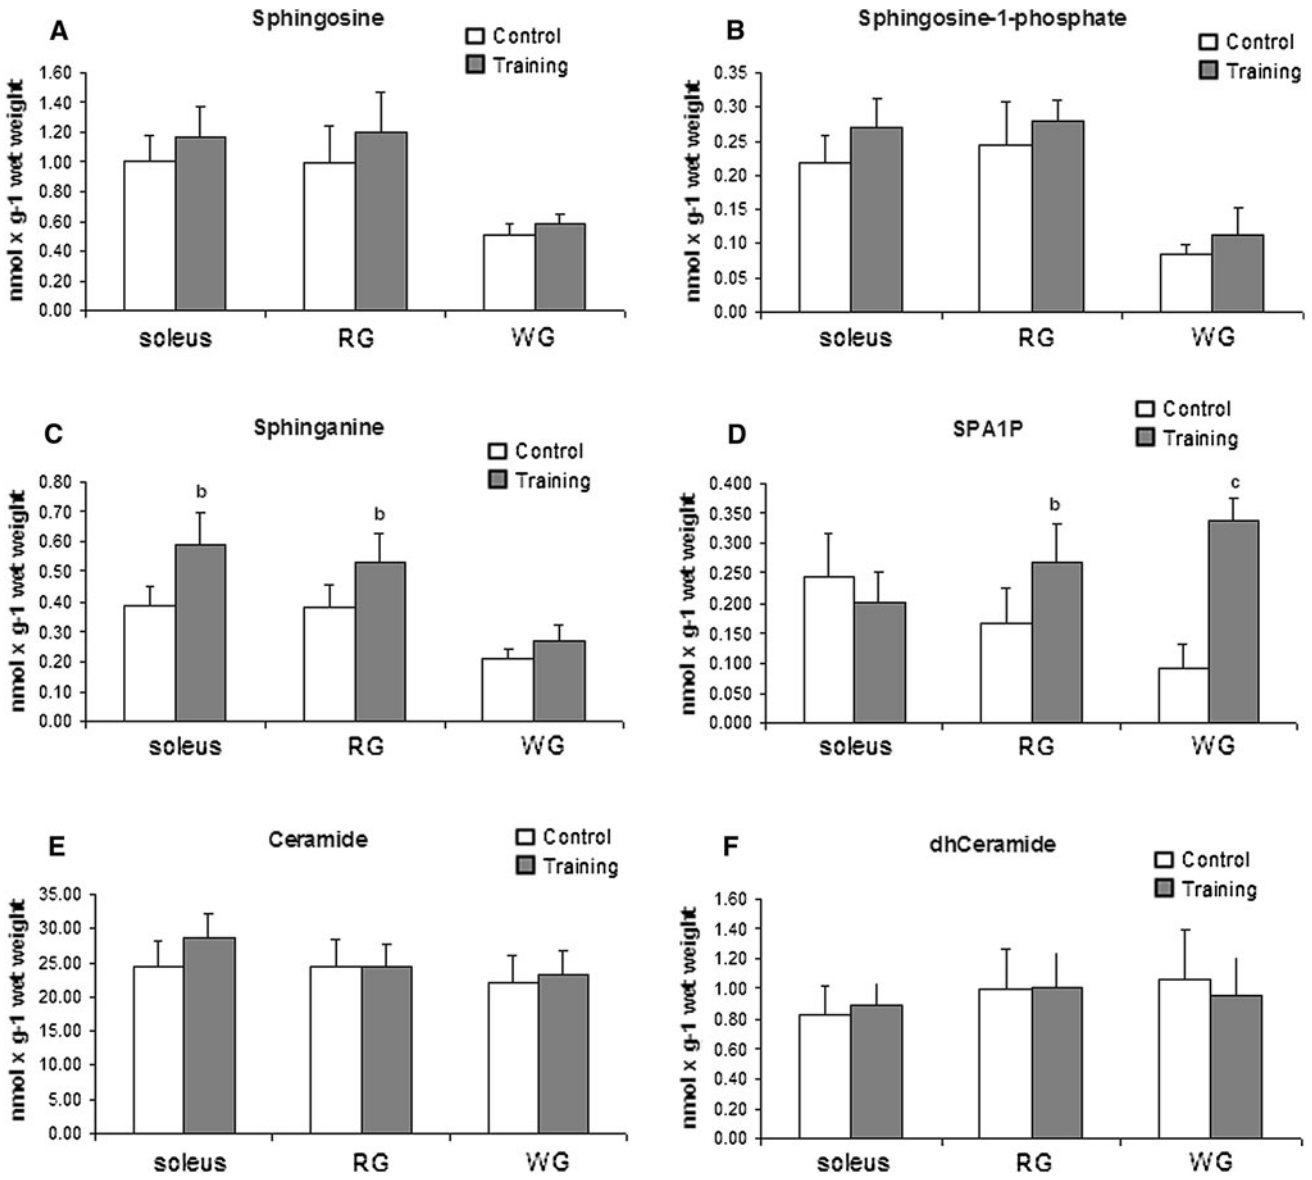

Fig. 3 Effect of training on the content of sphingosine (**a**), sphingosine-1-phosphate (**b**), sphinganine (**c**), sphinganine-1-phosphate (**d**), ceramide (**e**) and dihydroceramide (**f**) in three types of rat skeletal muscles. Values are means ± SD ($n = 8$ in each group). the soleus, red and white sections of the gastrocnemius respectively, compared to the control group (Fig. 5b).

Discussion

Endurance training induces several changes in lipid metabolism in skeletal muscles. The major change is an increased capacity of the muscles to utilize free fatty acids as a source of energy. Certain changes in phospholipid content and composition and the content of triacylglycerols have been also described [42, 43]. Recent research has provided information on the role of sphingolipids in induction of insulin resistance. Therefore, knowledge of how the ceramide metabolism can be changed seems to be very important for the invention of new treatments to prevent ceramide accumulation. Ceramide metabolism is changed in muscle in rats fed a high fat diet [41], diabetic and healthy animals with increased plasma FFA concentration [40], and also after a single-bout of exercise [26]. There are very few data in the literature concerning the effect of training on the activity of the key enzymes of ceramide metabolism in skeletal muscle. Our results suggest that the regulation of ceramide metabolism depends on

Table 3 Effect of training on the activity of enzymes implicated in sphingolipids metabolism in rat skeletal muscle

the type of exercise. We found that the short-time exercise caused a reduction in ceramide content but exhaustive exercise led to an elevated ceramide content in muscle [26]. Data from the current study show that training affects the ceramide metabolism in a different way to single-bout exercise. The ceramide level does not change in the trained group although the activities of the key enzymes of ceramide metabolism changed. The data regarding the content of ceramide are in agreement with the results reported previously, where 8 week training did not affect the ceramide content in rat gastrocnemius muscle [44]. In human skeletal muscle, training did not change the total ceramide

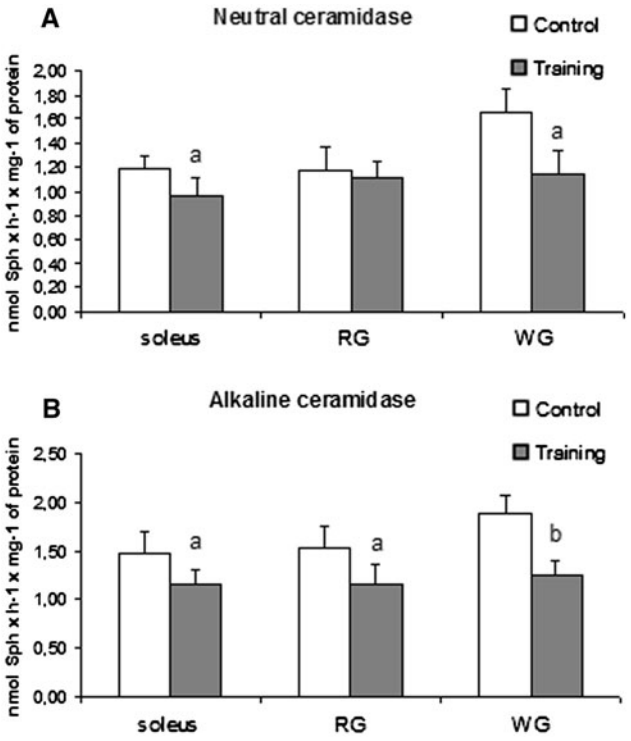

Fig. 5 Effect of training on the activity of neutral (**a**) and alkaline (**b**) ceramidase in rat skeletal muscle. Values are means ± SD ($n = 8$ in each group). content [27]. However, there are also conflicting data on the ceramide content in trained muscle. Experiments performed on obese subjects showed that endurance training reduces ceramide content and improves glucose tolerance [45, 46]. It must be mentioned that in these cases, obese people were examined and the ceramide metabolism in obesity can be different than in lean subjects. However, in the literature, there are also data showing that ceramide content decreases in muscle from trained rats [25]. The possible explanation of this discrepancy could be different analytical techniques used for measurement of the ceramide level in these two studies. In the mentioned work, ceramide content was measured by means of gas–liquid chromatography (GLC) after transmethylation of the ceramide fatty acids. Ceramide was purified by means of thin layer chromatography (TLC). The total content of different ceramides was measured including species containing: sphingosine, sphinganine, phytosphingosine, and homologs as a sphingoid base.

In our work, we have demonstrated that ceramide generation increased (increased activity of SPT, nSMase and aSMase) and decreased ceramides degradation (decreased activity of both CDases isoforms). Because of increased activity of enzymes responsible for ceramide production and decreased activity of enzymes responsible for ceramides degradation, we would expect to have an elevated ceramide content in the muscle, but we did not notice any changes in the ceramides level. We also did not observed any changes in muscle dihydroceramide content between trained and sedentary groups. This suggests that in the trained muscle other enzymes responsible for ceramides degradation/conversion are activated. We suspect that ceramide kinase, sphingomyelin synthase or glucosylceramide synthase are activated. Contribution of these pathways to regulation of ceramide content has not been recognized, so far.

Presently, we reported increased activity of SPT (enzyme catalyzing the reaction of condensation of serine and palmitoyl-CoA) and elevated content of sphinganine (main intermediate in sphingolipids de novo biosynthesis) in trained muscle. The elevation in the activity of SPT and the SPA content during exercise strongly indicates that physical exercise augments de novo sphingolipids synthesis in the muscles. The accumulation of SPA in the skeletal muscles of trained rats was observed also in the former study [25]. In our work we have observed an increased content of sphinganine-1-phosphate. It seems that sphinganine is directed to SPA1P instead of dhCer in the de novo synthesis pathway. Unfortunately, we have been unable to compare results from SPT activity and SPA1P content with any others because there is no information about SPT activity and SPA1P content in trained muscle.

Moreover, we also noticed increased activity of both isoforms of sphingomyelinases. We assume that increased nSMase activity is the effect of an increased content of TNF-α. During exercise TNF-α concentration increases and this agent is well known as an SMase activator [47]. Increased activity of nSMase was also previously observed in trained rat muscles [25]. In the literature there are also conflicting results related to nSMase activity. Data from trained muscle in human subjects showed that training does not affect nSMase activity [27].

Besides increased activities of enzymes responsible for ceramide production (SPT, n- and aSMase), we have simultaneously observed decreased activity of both isoforms of CDases. We cannot compare this result with any others studies because this is the only study when the enzymes activities were measured in trained muscles. In our work we did not observe any changes in Sph content and this result is in line with the results obtained previously [25].

It is well known that accumulation of ceramides, diacylglycerols and LCACoA in skeletal muscle is responsible for induction of insulin resistance. In our work, although ceramide content did not change in trained muscle, increased insulin sensitivity was observed—HOMA-IR

values were significantly lower in trained animals compared to sedentary rats (Table 1).

In summary, ceramide content does not change in the trained group although the animals were more insulin sensitive, Moreover, the activity of enzymes responsible for ceramide production (SPT, nSMase, aSMase) increased and the activity of enzymes responsible for ceramide degradation (nCDase, alCDase) decreased. These results suggest that in trained muscle other metabolic pathways are activated and have an effect on the ceramide content.

Abstract This study was conducted to examine dietary tea catechins (TC) supplementation on the fatty acid composition of muscle and ruminal bacteria in goats fed a maize stover-based diet. Forty goats, 8 months old (16.2 ± 1.2 kg), were randomly divided into four equal groups (10 animals in each group) and assigned to four experiment diets with TC supplementation at four levels (0, 2,000, 3,000 and 4,000 mg TC/kg feed, namely TC0, TC2000, TC3000 and TC4000, respectively). After a 60-day feeding period, all the goats were slaughtered and sampled. The results showed that dietary TC inclusion increased the average daily gain (ADG), protein content in the *semimembranosus* muscle and dry matter in the *longissimus dorsi* muscle (LD). Dietary TC supplementation increased the ratio of n-6 to n-3 fatty acid, the ratio of polyunsaturated fatty acids to saturated fatty acids was higher in TC3000 and TC4000 than in TC0 and TC2000 for LD. The current results implied that dietary inclusion of a suitable TC dose could improve the growth performance and increase the proportions of unsaturated fatty acids in muscle, and the biohydrogenation of ruminal microorganisms might change the profiles of fatty acids in the muscle of growing goats.

Keywords Goats · Tea catechins · Fatty acids · Biohydrogenation

Abbreviations

ADF	Acid detergent fiber
CLA	Conjugated linoleic acid
CP	Crude protein
DM	Dry matter
GM	Gluteus medius muscle
IMF	Intramuscular fat
LD	*Longissimus dorsi* muscle
MUFA	Monounsaturated fatty acid(s)
ME	Metabolizable energy
NDF	Neutral detergent fiber
OM	Organic matter
PUFA	Polyunsaturated fatty acid(s)
SFA	Saturated fatty acid(s)
SM	*Semimembranosus* muscle
TC	Tea catechins
UFA	Unsaturated fatty acid(s)

Introduction

Ruminants have a relatively high ratio of saturated to unsaturated fat acids in their body lipids. A low intake of saturated fat and an increased polyunsaturated to saturated fatty acid ratio (PUFA:SFA) in the diets are associated with a low risk of human coronary heart disease [1]. However, the level of PUFA consumed by the general population is

currently considered to be inadequate [2]. Hence, many animal scientists have been focusing on how to produce PUFA fortified animal products (meat, eggs and milk) for human beings.

In the past decades, the interest has been focused on the effects of antioxidants on nutrient digestibility, microbial nitrogen synthesis, and fatty acid profiles of meat in ruminants [3]. Dietary supplementation of antioxidants could improve total carbohydrate, neutral and acid detergent fiber (ADF and NDF) digestibility, and the amount of digested feed nitrogen converted to microbial nitrogen in dairy cows [4]. Furthermore, antioxidant supplementation could result in ruminal microbial metabolic changes, which were beneficial to cellulolytic activity [4] and growth of rumen microbes [5]. Researchers have demonstrated that dietary antioxidants might increase the PUFA content of meat in ruminants. Vázquez-Añón et al. [4] suggested that inclusion of dietary antioxidants could protect fatty acids from further peroxidation with a reduction in the toxic effect of unsaturated fatty acids on rumen microbes. Meanwhile, antioxidants might act as electron donors to provide the electrons for the reduction of some UFA, and be metabolized to these donors by microorganisms in the rumen [6].

Tea catechins (TC), a predominant group of polyphenols in green tea leaves (*Camellia sinensis* L.), comprise mainly four compounds namely (−)-epicatechin (EC), (−)-epicatechin gallate (ECG), (−)-epigallocatechin (EGC), and (−)-epigallocatechin gallate (EGCG) [7]. The TC have many biological functions, especially the anti-oxidative function. Its anti-oxidative properties as the dietary supplement have already been studied in dairy [5], chicken [8] and pig [9] using in vivo or vitro experiments. However, few trials have been conducted to study the effect of dietary TC supplementation on enhancing PUFA content of goat meat in a practical feeding system. The objective of this study was to investigate the effect of dietary TC supplementation on fatty acids profiles of ruminal bacteria and relevant tissues in goat kids.

Materials and Methods

The experiment was conducted according to the animal care and the use guidelines of the Animal Care Committee, Institute of Subtropical Agriculture, The Chinese Academy of Sciences, Changsha, China.

Reagent and Materials

All commercial kits used were obtained from Jiancheng Biology Co., Nanjing, China. All other general laboratory chemicals used for analysis were "AnalaR" grade. Tea catechins (TC) (purity of 80.86%) were extracted from green tea leaves (*Camellia sinensis* L.) by using high pressure liquid chromatography (HPLC) (Model Waters600, Waters Corp., Milford, USA) analysis according to the procedure reported previously [10] at Hunan Agriculture University, Changsha, Hunan, China. The TC were mainly composed of, by weight, caffeine (CAF) (0.75%), (+)-catechin and (−)-catechin (DL-C) (1.61%), EC (5.77%), EGC (0.47%), ECG (13.03%), (−)-gallocatechin gallate (GCG) (1.56%), and EGCG (57.67%).

Animal Management and Diet Preparation

Forty castrated Liuyang black male goats (a local breed) with an average age of 8 months ± 10 days, an average initial body weight of 16.2 ± 1.2 kg and the same genetic background were randomly divided into four equal groups (10 animals in each group) and assigned to four experiment diets for 60 days of the feeding trial, respectively. The control group (TC0) was fed the basal diet without TC supplementation. The other three groups were fed the basal diet with dietary TC supplementation at the levels of 2,000 (TC2000), 3,000 (TC3000) and 4,000 (TC4000) mg TC kg^{-1} feed (on DM basis). The ingredients and chemical composition of the basal diet, formulated according to NRC (1981) [11], are given in Table 1. Before the commencement of the trial, each group was allowed a 2-week adaptation period to the diets, respectively, and the average voluntary feed intake was measured. During the formal feeding period, each kid was fed twice daily (08:00 and

Table 1 The ingredients and chemical composition of the basal diet

[a] Contained per kg: 227 g $MgSO_4 \cdot H_2O$, 12.5 g $FeSO_4 \cdot 7H_2O$, 2.8 g $CuSO_4 \cdot 5H_2O$, 12.2 g $MnSO_4 \cdot H_2O$, 13.4 g $ZnSO_4 \cdot H_2O$, 20 mg Na_2SeO_3, 50 mg KI, 35 mg $CoCl_2 \cdot 6H_2O$, 90,000 IU vitamin A, 17,000 IU vitamin D, and 17,500 IU vitamin E.

[b] Metabolic energy (ME) was calculated according to NRC (1981) [11]

20:00 hour) with the amount of 578 g DM diets (determined by the average voluntary feed intake) and recorded the orts daily. Each goat was assigned to a single finishing barn as an experiment unit with an average room temperature of 24 ±1 °C with free access to fresh water. After 60 days of the feeding period, all goats were humanely slaughtered and samples were collected.

Slaughtering Procedure and Samples Preparation

After 60 days of feeding period, all kids were weighed (average weight was 17.5 ± 1.4 kg) and slaughtered under the commercial procedures, which was maintained according to the animal ethic committee of the Institute of Subtropical Agriculture. After slaughter, the goat carcasses were hung to remove the skin, head (at the occipito-atlantal joint), fore feet (at the carpal-metacarpal joint), hind feet (at the tarsal-metatarsal joint), gastrointestinal tract and visceral organs such as lung, liver, heart and kidney. About 1,000 g rumen fluid contents (mixed well) were collected from the rumen of the freshly slaughtered goat. Then, carcasses were cooled at 4 °C for 1 h in total darkness, and the left half-carcass was used for meat quality measurement. Muscles were separated from the carcass, and all external fat and connective tissue were removed within 24 h postmortem. About 200 g of left LD (from the 6th to 10th rib), 200 g gluteus medius muscle (GM) and 200 g *semimembranosus* muscle (SM) were sampled, respectively. Then, 100 g LD, GM and SM were, respectively, freeze-dried for analysis of intramuscular fat (IMF), crude protein (CP), ash and DM, and 50 g LD was taken and cut into slices and stored at −20 °C for determination of the fatty acid composition.

Analytical Procedure

At the beginning and end of the feeding trial, the weight of the goats was measured, which was used to measure the average daily gain of goats. The DM, CP, IMF and ash contents of LD, GM and SM were determined according to the method of the Association of Official Analytical Chemists [12]. Samples of LD were analyzed for fatty acid composition according to the following procedure. Tissue samples were homogenized and lipids were extracted from LD with chloroform/methanol (2:1). About 2 g of a muscle sample was combined with 10 ml of extraction solution (chloroform/methanol, 2:1, by vol) and 3 ml distilled water, and then extracted for 2 h at room temperature. After vacuum filtration, residues were rinsed with 10 ml of chloroform and then again filtered. The filtered solution was centrifuged at 5,000 rpm for 10 min. The upper layer (methanol and water layer) was removed and the bottom layer was sucked into the test tubes. These tubes were placed in a water bath at 37 °C for evaporating the chloroform using dry nitrogen. Then the extracts were stored at −40 °C until required for analysis. After extraction of the fat, fatty acid methyl esters were prepared for gas chromatography analysis. Briefly, 2 mg of extracted lipids were placed in a glass vial, and then 1.5 ml hexane, 100 µl methyl acetate and 100 µl sodium methoxide were added to the vial and thoroughly mixed. The mixture was kept for 20 min at 20 °C, and then 10 min at −20 °C in a refrigerator. Afterward, the vial was taken out of the refrigerator, and 60 µl of oxalic acid was added quickly. After centrifuging at 5,000 rpm for 10 min and discarding the deposit, the supernatant solution was dried over Na_2SO_4 and stored for future injection.

According to Kramer et al. [13], gas chromatography analyses of methyl esters were performed with the Agilent Technologies 6890N gas chromatograph (Agilent Technologies Inc., Palo Alto, CA, USA), fitted with a flame ionization detector. Separation was carried out on a CP-Sil88 fused silica open tubular capillary column (100 m × 0.25 nm) (Chrompack, Bridgewater, NJ, USA). The oven temperature started at 45 °C for 4 min, it was raised 13 °C/min to 175 °C; held for 27 min at 175 °C; increased 4 °C/min to 215 °C and held for 35 min at 215 °C. Injector and detector temperatures were 250 °C. The carrier gas was hydrogen at a flow rate of 30 ml/min. Identification of fatty acid methyl esters was accomplished by comparing their retention time with a GC reference standard (GLC 463, Nu-Chek Prer Inc, Elysian, MN).

Four specific isomers of conjugated linoleic acid (CLA) (18:2c9,t11, 18:2t10,c12, 18:2c9,c11 and 18:2t9,t11; Matreya LLC, USA) were used for CLA identification according to the procedure described by Destaillats and Angers [14]. Fatty acid methyl esters were quantified by determining areas under the identified peaks. Results were expressed as a proportion of each fatty acid methyl ester in relation to the total methyl esters detected.

The fatty acid composition of the ruminal solid-associated bacteria was measured according to the following procedure modified by Bas et al. [15]. 200 ml ruminal samples collected from each goat were pooled the rest of the group immediately and squeezed using four layers of cheesecloth. The liquid phase was centrifuged at 800×*g* for 15 min at 4 °C. The precipitate was added to the particles retained on the cheesecloth, then particles were blended (200 g of particles plus 200 ml of 0.9% cold NaCl) in a blender for 1 min, squeezed through four layers of cheesecloth, and then washed with 200 ml of 0.9% cold NaCl and squeezed again. The filtrates were centrifuged at 27,000×*g* for 30 min at 4 °C to obtain a pellet that contained solid-associated bacteria. Bacterial isolates were freeze-dried and ground using a mortar and pestle for later analysis of the fatty acid composition of the ruminal bacteria.

Statistical Analysis

All data were subjected to analysis of variance (ANOVA) using the generalized linear model procedure of SAS (2002). The main effect tested was the TC supplementation level for all variables. The following statistical model was used for data analysis:

$$Y_{ij} = \mu + T_i + e_{ij}$$

where Y_{ij} is dependent variables, μ is the overall mean, T_i is the effect of treatment ($i = 1, 2, 3, 4$), and e_{ij} is the random residual error. Where the effects of treatment were significant, differences among means were tested with Duncan's multiple range tests. Statistical significance was declared at $P \leq 0.05$.

Results

Chemical Composition of Fresh Meat

Effects of TC supplementation on chemical composition (fresh basis) of muscle are listed in Table 2. The TC supplementation decreased (linear, $P < 0.01$; quadratic and cubic, $P < 0.001$) moisture content of LD, and TC2000 treatment was found to have the highest DM content among all the groups. Dietary TC inclusion had a cubic effect ($P < 0.05$) on IMF content of SM, the least value occurred at TC3000 treatment. The ash content of LD in TC groups decreased significantly ($P < 0.05$) compared to control group, TC inclusion had a quadratic effect ($P < 0.01$) on ash content of SM. The CP content of SM linearly increased ($P < 0.05$) in response to TC supplementation, and control group had the lowest value. On the other hand, the average daily gains of TC0, TC2000, TC3000 and TC4000 groups were observed for 14.2, 17.2, 28.4 and 27.5 g/day, respectively. The results showed that TC supplementation had a linear and a cubic increase effect ($P < 0.001$) on the ADG of goats. All TC supplementation groups had a higher ADG than the control group ($P < 0.05$), and TC3000 and TC4000 had higher values than the TC2000 treatment.

Fatty Acid Composition of the *Longissimus Dorsi* Muscle

Effect of TC supplementation on the fatty acid composition of LD is presented in Table 3. For SFA, TC supplementation had no significant effect on the fatty acid proportions of 10:0, 12:0, 14:0, 16:0, 17:0, and 18:0, but the proportion of 15:0 decreased linearly ($P < 0.001$) with increasing TC supplementation levels; TC3000 and TC4000 had lower

* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$

proportions of SFA when compared to the control group. For MUFA, there was no significant effect on the fatty acid proportions of 14:1, 16:1, 9t18:1, 11t18:1 and 12c18:1 with TC supplementation; but TC3000 had higher proportion of 11c18:1, TC2000 had a lower proportion of 11c20:1, and all TC treatments had higher proportions of 9c18:1 and MUFA. For PUFA, TC supplementation had no significant effect on fatty acid proportions of 9c12c18:2, 20:3, 20:5,

22:4, 22:5 and 22:6; when compared to the control group, TC2000 had lower 20:4 and total n-3, TC3000 had higher proportion of α-18:3n-3, TC4000 had higher proportion of total n-6, TC2000 and TC3000 had higher proportions of 9t12t18:2, TC3000 and TC4000 had higher proportions of PUFA. For CLA, TC inclusion had no significant effect on fatty acid proportions of 11c13tCLA and 8c10c/11c13cCLA, whilst total CLA proportion decreased linearly ($P < 0.001$); TC2000 and TC3000 had lower proportions of 10t12cCLA when compared to the control group. In general, dietary TC supplementation increased (linear, $P < 0.001$) the ratio of n-6 to n-3 fatty acid in LD, the ratio of PUFA to SFA was higher ($P < 0.05$) in TC3000 and TC4000 than in TC0 and TC2000.

Fatty Acid Composition of Rumen Bacteria

Effect of TC supplementation on fatty acid composition of rumen bacteria attached to the solid particles is given in Table 4. For SFA, TC supplementation had no significant effects on the proportions of 14:0, 15:0, 16:0, 17:0 and SFA, but TC2000 had a higher ($P < 0.05$) proportion of 18:0, TC2000 and TC4000 had higher ($P < 0.05$) proportion of 20:0, and TC3000 and TC4000 had higher ($P < 0.05$) proportion of 12:0. For MUFA, there were no significant effects on fatty acid proportions of 16:1, 9t18:1, 9c18:1, 11c18:1, 12c18:1, 11c20:1 and MUFA among all experimental groups, but the proportion of 11t18:1 increased quadratically ($P < 0.05$) with increasing dietary TC levels. For PUFA, TC supplementation had no significant effects on fatty acid proportions of 20:3, 20:5, 22:4, and the ratio of n-6 to n-3; when compared to the control group, TC2000 had a higher proportion of 22:6, TC3000 had a lower proportion of 22:5, TC4000 had a higher proportion of total n-3, TC2000 and TC3000 had lower ($P < 0.05$) proportions of 9c12c18:2, TC2000 and TC4000 had higher ($P < 0.05$) proportions of 20:4, TC3000 and TC4000 had higher ($P < 0.05$) proportions of PUFA, n-6 and a higher ratio of PUFA to SFA. There were quadratic effects ($P < 0.05$) on the proportion of α-18:3n-3 with the greatest value being for TC2000 and TC4000. For CLA, TC inclusion had no significant effects on fatty acid proportions of 9c11tCLA and 8c10c/11c13cCLA; when compared to the control group, TC3000 had a higher proportion of 11c13tCLA, TC4000 had higher proportions of 10t12cCLA and total CLA.

Discussion

The ADG is the most important index which reflects the growth performance of animals. In this study, we found that the high TC dosage in the diets could improve the growth rate of growing goats. The reason for the increasing ADG may be attributed to TC supplementation, as a growth promoter, presumably acting on the intestinal and ruminal microorganism leading to higher nutrient digestion [5]. Tea polyphenols, especially the catechins, are effective antimicrobial and antioxidant agents [16]. Therefore, dietary TC inclusion could enhance the animal growth performance through regulating the physiological function of rumen microorganisms.

Consumers have given more attention to meat quality during recent years because of the high incidence of disease related to diet, especially related to fatty acid composition of meat. Our results demonstrated that TC supplementation could increase the CP content in SM. This might be supported by the previous results of Kondo et al. [17], in which dietary inclusion of green tea waste containing the rich antioxidant increased N retention in goats. Although it has been generally accepted that a higher IMF level is positively related to the sensory experience associated with meat [18], TC supplementation did not affect the IMF deposition in LD and GM in this study. The current results indicated that dietary antioxidant was not a main factor in regulating IMF content of muscle. It has been proven that TC has an antimicrobial property, which make it a potential alternative to antibiotics to manipulate microbial activity in the rumen [19]. Many plants can produce secondary metabolites which might have antimicrobial properties, e.g., tannin and saponin. These secondary metabolites have been shown to modulate the rumen fermentation to improve nutrient utilization [20]. Hence, it might be the potential explanation for the improvement of N retention when TC was added in the diets of ruminants. As for the increase of CP in SM but not in LD or GM, it might need further studies in the future.

Banskalieva et al. [21] reviewed similar results to this study concerning the main SFA, MUFA and PUFA of meat. Our results indicated that suitable dosages of dietary TC inclusion could increase the proportions of MUFA and PUFA in LD. These results were supported by the findings of Dal Bosco et al. [22], who reported that dietary antioxidant could increase PUFA and decrease SFA in rabbit meat. Sant'Ana et al. [23] also reported that addition of antioxidants in vivo could improve the composition of PUFA in fish fillets. According to our previous findings [24], TC addition in the diets was effective in inhibiting peroxidation in goat. If free radicals exceed the capacity of the cellular intrinsic free radical scavenging systems, they will become cytotoxic to cells by attacking fatty acids, and the reactions caused by exceeding radicals lead to lipid peroxidation of membranes. As an antioxidant, TC could protect the peroxidation of oxidative-labile MUFA and PUFA rather than that of more stable SFA. These results were consistent with the findings of Herlie et al. [25] in

cultured cardiomyocytes. Alternatively, the extensive biohydrogenation of ingested PUFA by rumen microorganisms might lead to the low PUFA:SFA ratio in ruminant meat [26]. Chikunya et al. [6] reported that dietary antioxidant could protect the UFA in milk from biohydrogenation in the rumen, and they concluded that antioxidants might act as electron donors to provide the electrons for the reduction of some UFA and be metabolized to these donors by microorganisms in the rumen. Vasta et al. [27] also reported that the addition of

antioxidant could reduce the biohydrogenation through inhibiting the activity of rumen microorganisms. Therefore, we suggested that the possible mechanism should be that dietary TC inclusion exerts its function in the protection of polyunsaturated acids in feed and tissues. With high TC supplementation, the proportion of PUFA n-6 increased and the proportion of PUFA n-3 was not affected. A similar result was reported by Donaldson [28].

There was no more information about the effect of dietary TC inclusion on fatty acid composition of ruminal microorganism. Our results showed that suitable doses of TC supplements could increase the composition of PUFA, PUFAn-6, PUFAn-3 and CLA. The main fatty acid 18:1 as MUFA, 18:2 of rumen bacteria was close to the previous findings reported by Williams and Dinusson in bovine ruminal bacteria [29], but our results showed higher 16:0 and lower 18:0 proportions than those Williams and Dinusson reported. The higher 16:0 and lower 18:0 proportions might be a result of the different sources of rumen microorganisms which might be derived from different breeds of animals, and different feeding regimes, because the fatty acid composition is remarkably different for different sources of ruminal microorganisms and is significantly affected by feeding type [15].

Furthermore, numerous studies showed that different nutritional conditions can change lipid fatty acid composition of muscle, such as PUFA and total n-6 [30]. The profiles of fatty acids of digesta arriving at the proximal duodenum were different from those of the diets ingested in ruminants. The composition of fatty acids in muscle might partially be co-determined by the biohydrogenation and de novo synthesis by microorganisms in the rumen. The synchronous increase of UFA in muscle fat and ruminal bacteria, and the decrease of SFA in muscle with dietary TC inclusion in this study, probably implied that rumen microorganism could contribute a substantial part to the UFA of muscle.

Conclusion

In summary, dietary TC supplementation could improve the growth performance, and increase the proportions of MUFA and PUFA, and the ratio of PUFA to SFA in muscle, and increase the proportion of PUFA and the ratio of PUFA to SFA of ruminal bacteria in growing goats. As an antioxidant, dietary inclusion of the suitable TC dose (3,000 mg/kg) could change the fatty acid profile of goat meat through enhancing the contents of unsaturated fatty acids.

Acknowledgments The authors would like to express their sincere gratitude and appreciation to the Ministry of Science and Technology of China (2006BAD04A15; 2008BADA7B04) for providing the financial support.

N-Acylated Bacteriohopanehexol-Mannosamides from the Thermophilic Bacterium *Alicyclobacillus acidoterrestris*

Tomáš Řezanka · Lucie Siristova · Karel Melzoch · Karel Sigler

Received: 20 July 2010 / Accepted: 23 September 2010 / Published online: 21 October 2010

Abstract Identification of molecular species of various *N*-acylated bacteriohopanehexol-mannosamides from the thermophilic bacterium *Alicyclobacillus acidoterrestris* by semipreparative HPLC and by RP-HPLC with ESI is described. We used triple-quadrupole type mass spectrometer, ^{1}H and ^{13}C NMR for analyzing this complex lipid. CD spectra of two compounds (model compound—7-deoxy-D-*glycero*-D-*allo*-heptitol obtained by stereospecific synthesis, and an isolated derivative of hopane) were also measured and the absolute configuration of both compounds was determined. On the basis of all the above methods, we identified the full structure of a new class of bacteriohopanes, represented by various *N*-acylated bacteriohopanehexol-mannosamides.

Introduction

Bacteriohopanepolyols (BHpolyols) are pentacyclic triterpenoids, which are present as membrane constituents in

many bacteria [1]. They perform a regulating and rigidifying function in membranes analogous to that of some sterols in eukaryotes [2–4]. BHpolyol side chains form many structures, which differ in terms of the number, position and nature of the functional groups [2, 5]. The side chain is responsible for the charge and the function of the molecule [6].

The most commonly occurring BHpolyols in bacteria contain four functional groups in the side chain, typically three hydroxyl groups at 32*R*, 33*R*, 34*S* [7, 8] with the C-35 position occupied by either another OH or an amino group [2].

In numerous strains belonging to various taxonomic groups (e.g. purple nonsulfur bacteria, methylotrophs, or cyanobacteria) the bacteriohopane (BH) derivatives are not present as free polyols but are linked to various polar moieties like glucosamine or *N*-acylglucosamine, anhydrogalacturonopyranosides, α-amino acids such as tryptophan and ornithine, adenosine, cyclitol ethers or other polar entities the structures of which are still unidentified [2, 9]. BHpolyols have been found in many other structural variations including double bonds in the ring system or substitution by methyl groups in ring A. Furthermore, BHpolyols with five and six functional groups in the side chain, i.e. BHpolyols with additional one or two OH group(s) at C-30 and/or C-31 position(s) were identified [10–14, 40]. These structures are restricted to a limited number of organisms or occur in an explicit group of organisms and can serve as specific bacterial marker information [2, 5].

To date there have been only a few hexafunctionalized side chain structures reported from nature. The basic structure has five hydroxyl groups and NH_2 functionality at C-35, and has only been observed in Type I methanotrophic bacteria [14, 15]. Further, BHhexol cyclitol ether was identified in sediments of two lakes from Antarctica [16], soils from Northern England [17], and BHhexol in sediments from the popular Loch Ness (UK) [2].

This report is part of our investigation of thermophilic bacteria, mainly of the genus *Alicyclobacillus*. We extended our analysis from glycophospholipids [18], unusual acylphosphatidylglycerols [19], and *O*-acyl glycosylated cardiolipins [20] to hopanoids. The structure of *N*-acylated BHhexol-mannosamides was confirmed not only by ESI–MS, but, after isolation, also by measurement of ^{1}H-, ^{13}C-NMR, and CD spectra, including synthesis of a model compound.

Experimental

Instrumentation

The liquid chromatograph was the semipreparative Gradient LC System G-1 (Shimadzu, Kyoto, Japan) with two LC-6A pumps (0.5 ml/min), an SCL-6A system controller, an SPD ultraviolet detector an SIL-1A sample injector and a C-R3A data processor, with a preparative normal phase HPLC column Supelcosil LC-Si HPLC column 5 µm particle size, length × I.D. 25 cm × 21.2 mm with mobile phase containing hexane–isopropanol-0.05% triethylamine in water (99.5:0:0.5, v/v/v) to hexane–isopropanol-0.05% triethylamine in water (20:78:2 v/v/v) for 40 min, a flow rate of 9.9 ml/min, and monitored by a variable wavelength detector at 210 nm (HP 1040M Diode Array Detector).

The HPLC equipment consisted of a 1090 Win system, PV5 ternary pump and automatic injector (HP 1090 series, Hewlett Packard, USA) and two Ascentis® Express HILIC HPLC column 2.7 µm particle size, L × I.D. 15 cm × 2.1 mm (Supelco, Prague) in series were used. This setup provided us with a high-efficiency column—approximately 30,000 plates/30 cm. LC was performed at a flow rate of 300 µl/min with a linear gradient from the mobile phase containing methanol/acetonitrile/aqueous 1 mM ammonium acetate (60:20:20, v/v/v) to methanol/acetonitrile/aqueous 1 mM ammonium acetate (20:60:20, v/v/v) for 40 min. The whole HPLC flow (0.37 ml/min) was introduced into the ESI source without any splitting.

The detector was an Applied Biosystems Sciex API 4000 mass spectrometer (Applied Biosystems Sciex, Ontario, Canada) using electrospray mass spectra. The ionization mode was negative, the nebulizing gas (N_2) pressure was 345 kPa and the drying gas (N_2) flow and temperature were 9 l/min and 300 °C, respectively. The electrospray needle was at ground potential, whereas the capillary tension was held at 4,000 V. The cone voltage was kept at 250 V. The mass resolution was 0.1 Da and the peak width was set to 6 s. For an analysis, total ion currents (full scan) were acquired from 200 to 1,600 Da.

CID ions mass spectra were acquired by colliding the Q1 selected precursor ions with Ar gas at a collision target gas and applying collision energy of 50 eV in Q2. Scanning range of Q3 was *m/z* 200–1,600 with a step size of *m/z* 0.3 and a dwell time of 1 ms. A peak threshold of 0.3% intensity was applied to the mass spectra. The instrument was interfaced to a computer running Applied Biosystems Analyst version 1.4.1 software.

Gas chromatography–mass spectrometry of FAME was done on a GC–MS system consisting of Varian 450-GC, Varian 240-MS ion trap detector with electron impact ionization, and CombiPal autosampler (CTC, USA). The sample was injected onto a 25 m × 0.25 mm × 0.1 µm Ultra-1 capillary column (Supelco, Czech Republic) under a temperature program: 5 min at 50 °C, increasing at 10 °C/min to 320 °C and 15 min at 320 °C. Helium was the carrier gas at a flow of 0.52 ml/min. All spectra were scanned within the range *m/z* 50–600. The spectra was identified manually, se also Siristova et al. [18].

The oven temperature for identification of the acetylated alcohols BH (degradation products) was programmed from 50 to 275 °C at 10 °C/min and further at 5 °C/min to 350 °C and further with 8 min isothermal elution. The others conditions of GC–MS apparatus were identical.

Saccharides were separated on a single HILIC HPLC column (see above) by isocratic elution with acetonitrile and 0.1% acetic acid in water at a ratio of 40:60. They were identified by comparing their retention times with those of commercially obtained standards (galactosamine, glucosamine and mannosamine) and single ion monitoring at m/z 180 ($[M + H]^+$).

NMR spectra were recorded on a Bruker AMX 500 spectrometer (Bruker Analytik, Karlsruhe, Germany) at 500.1 MHz (^1H) and 125.7 MHz (^{13}C). Optical rotations were measured with a Perkin-Elmer 243 B polarimeter. The circular dichroism measurement was carried out under dry N_2 on a Jasco-500A spectropolarimeter at 24 °C. HR-FAB-MS (positive ion mode) were obtained with a PEG-400 matrix using a VG 7070E-HF spectrometer. All compounds were purchased from Sigma–Aldrich (Prague, Czech Republic).

Cultivation, Isolation and Identification

Alicyclobacillus acidoterrestris CCM 4660 (Czech Collection of Microorganisms, Brno, Czech Republic) was cultivated in an alicyclobacillus medium containing (g/l): yeast extract 6.0, glucose 5.0, $CaCl_2 \cdot 2H_2O$ 0.25, $MgSO_4 \cdot 7H_2O$ 0.5, $(NH_4)_2SO_4$ 0.2, KH_2PO_4 3.0 and 1 ml/l of trace element solution ($ZnSO_4 \cdot 7H_2O$ 0.1 g/l, $MnCl_2 \cdot 4H_2O$ 0.03 g/l, H_3BO_3 0.3 g/l, $CuCl_2 \cdot 6H_2O$ 0.2 g/l, $CaCl_2 \cdot 2H_2O$ 0.01 g/l, $NiCl_2 \cdot 6H_2O$ 0.02 g/l, $Na_2MoO_4 \cdot 2H_2O$ 0.03 g/l), pH was adjusted to 4. A volume of 600 ml of inoculum was prepared in 500-ml round-bottom flasks on a temperature controlled shaker at 45 °C and 200 rpm. The biomass was cultivated in a 5-l mechanically stirred fermentor with the aim of obtaining inoculum for a 50-l fermentor. Inoculum was cultivated for 12 h under aerobic conditions with aeration rate 0.8 VVM. The stirrer frequency was 300–400 rpm and the cultivation temperature was 45 °C.

The strain main cultivation was carried out in a 50-l mechanically stirred fermentor for 15 h, under aerobic conditions with an aeration rate of 1 VVM. The stirrer frequency was 350–400 rpm and the cultivation temperature was 45 °C. Cells were harvested in the log phase when the optical density of the culture was maximal. The dry biomass was 1.49 g/l media.

The extraction procedure was based on the method of Bligh and Dyer [21]. The alcohol-water mixture was cooled and one part chloroform was added and the lipids were extracted for 30 min. Insoluble material was sedimented by centrifugation and the supernatant was separated into two phases. The aqueous phase was aspirated off and the chloroform phase was washed three times with two parts 1 M KCl each. The resulting chloroform phase was evaporated to dryness under reduced pressure.

First, total lipid extracts were applied to Sep-Pak Cartridge Vac 35 cc (Waters; with 10 g of aminopropyl-silica-based polar bonded phase), and from the cartridge were subsequently eluted chloroform–methanol mixture (98:2) [22] for removing of non-polar lipids, and polar lipids, but not phospholipids were further eluted by an acetone. The eluate was reduced in volume and subjected to normal phase HPLC.

The aliquot of total BHs (5 mg) was stirred for l h at room temperature with periodic acid (H_5IO_6; 3 mg) in tetrahydrofuran/water (3 ml; 8:1 v/v). The vicinal diols were oxidized to yield aldehyde products. After addition of water (10 ml) the mixture was extracted with petroleum ether (3 × 5 ml). The combined extracts were evaporated and further stirred for l h at room temperature with sodium borohydride ($NaBH_4$; 1 mg) in ethanol (3 ml) to produce alcohols. The excess of $NaBH_4$ was destroyed by water and the mixture was extracted with petroleum ether (3 × 5 ml). The extracts were evaporated and acetylated, see below.

The total extract was acetylated overnight at room temperature with acetic anhydride/pyridine (30 ml; 1:1 v/v). The peracetylated BHs were evaporated and further analyzed.

The fraction of *N*-acylated BHhexol-glycoside after semipreparative HPLC was treated for 16 h at 100 °C with a 10% solution of dry HCl in CH_3OH. The reaction mixture was taken to dryness, suspended in water, the pH was regulated by 5% NaOH to 9, BHhexol was extracted by diethyl ether, the water mixture was acidified by 5% HCl to pH 4, free fatty acids were extracted by $CHCl_3$ and water phase was after lyophilization was silylated, see above. The fatty acid methyl esters were prepared by reaction of the free fatty acids with methanol, see Rezanka et al. [23].

Preparation of 7-Deoxyheptitol

D-*glycero*-D-*allo*-Heptose (**8a**) and D-*glycero*-D-*altro*-heptose (**8b**) were prepared from KCN and D-allose (**6**) according to procedures described previously [24, 25]. Briefly, the pH of an aqueous solution (15 ml) of potassium cyanide (269 mg, 4.14 mmol) was lowered to 7.2 by dropwise addition of aqueous acetic acid (3 M) with rapid stirring at room temperature. An aqueous solution (10 ml) of D-allose **6** (248 mg, 1.38 mmol) was slowly added, with addition of acetic acid (3 M) or sodium hydroxide (1 M) as appropriate to maintain a pH of 7.2–7.5 during addition of D-allose and subsequent reaction, which was allowed to proceed for 1.5 h. The reaction mixture was analyzed by TLC (cellulose sheets, 90:10 acetone–water) to reveal a

complete conversion of D-allose (**6**) (R_f 0.67) into the aldonitriles (**7a** and **7b**) (R_f 0.8–0.9). The pH of the aldonitrile solution was lowered to 4.7 by dropwise addition of acetic acid (3 M) and the solution was stored at 4 °C for ca. 1 h. Further, the pH of the solution was again lowered to 4.2 by dropwise addition of acetic acid (3 M). Following addition of prereduced 5% palladium on barium sulfate (86 mg = 4.3 mg, 0.04 mmol Pd), the flask was evacuated three times and flushed with hydrogen. Vigorous stirring under an atmosphere of hydrogen was then allowed to proceed at room temperature for ca. 15 h. The reaction mixture was analyzed by TLC (90:10 acetone–water) to reveal a complete reduction of the aldonitriles (**7a** and **7b**) (R_f 0.8–0.9) into the imines (R_f 0.4–0.6). The catalyst was removed over Celite and the pH of the resultant filtrate was lowered from pH 4.4 to ca. pH 3.0 by repeated batch-wise treatment with Dowex® 50WX2 hydrogen form 200–400 mesh (4 × 4 g). The final filtrate was analyzed by TLC (95:5 acetone–water) and no imine was detected. The water was removed by lyophilization to leave the epimeric mixture of **8a** and **8b** as a pale yellow oil; the yield of epimeric sugars was 243 mg (84%) and they were separated by semi-preparative TLC.

Aldrich Analtech TLC Uniplates™ with spherical particles (size 50 μm) of α-cellulose matrix, size 20 cm × 20 cm, layer thickness 250 μm, fluorescent indicator were used. The mobile phase was acetone–water (95:5, v/v), D-glucose being used as standard. Identification under UV light gave the following R_f values for the compounds: D-*glycero*-D-*allo*-heptose (**8a**) (0.35), D-glucose (0.51) and D-*glycero*-D-*altro*-heptose (**8b**) (0.63). The yield of D-*glycero*-D-*allo*-heptose (**8a**) was 106 mg, with $[\alpha]_D^{23}$ +12.8 (1 day, c = 0.15), lit. data: $[\alpha]_D^{21}$ +14.1 [26], $[a]_D$ +10.7 (24 h) (c 1.6, H_2O) [27], $[a]_D$ +7.2 (3 min) → +12.7 (24 h) (c 4.6, H_2O) [28]; ^{13}C NMR (125 MHz, D_2O) δ major: 93.8 (C-1), 73.8, 72.1, 71.3, 71.2, 67.7, 61.8; minor: 92.7 (C-1), 72.0, 71.7, 67.6, 67.1, 66.9, 62.1 [27, 28]; ^{13}C NMR δ 94.4, 72.9, 72.0, 71.9, 74.6, 68.5, 62.6 (the values for C-1 → C-7 of β-pyranose), the values for C-1 were 93.4 (α-pyranose), 94.4 (β-pyranose), 96.8 (α-furanose), and 101.4 (β-furanose) [29]. Our data measured for mixture of four forms at C-1 were 93.2 (α-pyranose), 94.5 (β-pyranose), 97.0 (α-furanose), and 101.5 (β-furanose) and the following values are for the major form: ^{13}C NMR (125 MHz, D_2O) δ 94.5 (C-1), 73.3 (C-2), 72.5 (C-3), 71.6 (C-4), 73.8 (C-5), 68.4 (C-6), and 62.2 (C-7); HR-FAB-MS (m/z): 211.0823 $[M + H]^+$, calc. for $[C_7H_{14}O_7 + H]^+$ 211.0818.

D-*glycero*-D-*allo*-Heptose diethyl thioacetal = (2*S*,3*R*,4*S*,5*S*)-7,7-bis(ethylthio)heptane-1,2,3,4,5,6-hexaol. A mixture of D-*glycero*-D-*allo*-heptose (**8a**) (105 mg) and concentrated HCl (5 ml) was shaken for about 10 min to dissolve most of the sugar and then, as the solution began to assume a reddish color, 5 ml of ethylthiol was added and shaking was continued for 2.5 h. The product was allowed to stand overnight in the refrigerator. About 5 ml of cold water was added, the dithioacetal filtered, and washed with cold ethanol. The yield, after one recrystallization from ethanol, was 100 mg (63.3%). Very surprisingly, this compound (**9**) has not yet been described. $[a]_D$ +10.7 (c 0.16, MeOH); ^{1}H-NMR (500 MHz, CD_3OD) δ 4.92 (1H, *d*, J = 1.6, H-7), 4.93 (1H, *dd*, J = 1.6, 5.5, H-6), 5.06 (1H, t, J = 5.5, H-5), 5.19 (1H, t, J = 5.5, H-4), 4.71 (1H, t, J = 5.5, H-3), 4.65 (1H, *ddd*, J = 5.5, 3.2, 8.2, H-2), 4.52 (1H, *dd*, H = 11.0, 3.2, H-1a), 4.42 (1H, *dd*, J = 11.0, 8.2, H-1b), 2.89 (2H, m, $SC\underline{H}_2$), 2.89 (2H, m, $SC\underline{H}_2$), 1.22 (6H, m, $CH_2C\underline{H}_3$); ^{13}C NMR (125 MHz, CD_3OD) 56.1 (C-7), 74.2 (C-6), 73.3 (C-5), 71.2 (C-4), 74.6 (C-3), 72.8 (C-2), 64.4 (C-1), 64.8 ($S\underline{C}H_2$), 15.0 ($CH_2\underline{C}H_3$); HR-FAB-MS (m/z): 317.1099 $[M + H]^+$, calc. for $[C_{11}H_{24}O_6S_2 + H]^+$ 317.1092.

7-Deoxy-D-*glycero*-D-*allo*-Heptitol, i.e. (2*R*,3*R*,4*S*,5*S*,6*S*)-heptane-1,2,3,4,5,6-hexaol (**10**). Reductive desulfurization of similar dithioacetals has already been described [30]. To a solution of the derivative **9** (95 mg, 0.30 mmol) in dioxane (5 ml) was added Raney Ni (300 mg). The suspension was heated at 80 °C for 1 h with stirring to give the derivative **9**. Crystallization from absolute ethanol yielded 43.5 mg (74%) of the desired desoxyheptitol as clusters of needles, with an m.p. at 124–125 °C and $[\alpha]_D$ +1.7 (c 0.16, MeOH); ^{1}H-NMR (500 MHz, CD_3OD) δ 3.65 (1 H, *dd*, J = 10.1, 11.5, 1a-H) and 3.84 (1 H, *dd*, J = 3.4, 11.5, 1b-H), 3.77 (1 H, *ddd*, J = 2.2, 3.4, 10.1, 2-H), 3.70 (1 H, *dd*, J = 3.9, 2.2, 3-H), 3.92 (1H, *dd*, J = 3.9, 3.4, 4-H), 3.62 (1 H, *dd*, J = 3.4, 5.2, 5-H), 3.94 (1 H, *dq*, J = 5.2, 6.5, 6-H), 1.21 (3 H, *d*, J = 6.5, 7-H); ^{13}C NMR (125 MHz, CD_3OD) 19.1 (C-7), 70.4 (C-6), 73.2 (C-5), 71.7 (C-4), 74.2 (C-3), 72.7 (C-2), 64.1 (C-1); HR-FAB-MS (m/z): 197.1025 $[M + H]^+$, calc. for $[C_7H_{16}O_6 + H]^+$ 197.1025. Again, though it is hard to believe, this compound has not yet been described.

General Procedure for Bichromophoric Derivatization

Anthroylation

To an ice cooled suspension of the 9-anthracenecarboxylic acid (0.1 mmol, 22.2 mg) and fluoro-*N,N,N′,N′*-tetramethylformamidinium hexafluorophosphate (TFFH, 0.1 mmol, 26.4 mg) in a minimum of CH_2Cl_2 (ca. 5 ml) was added Et_3N (0.5 mmol, 50.5 mg, 70 μl) resulting in a clear solution with some heat evolution. After stirring for 30 min at 20 °C the alcohol (**10**) (0.1 mmol, 19.6 mg) and a catalytic amount of DMAP (0.01 mmol, 1.22 mg) were added and the reaction mixture was stirred at 20 °C overnight. Water (5 ml) was added and the mixture extracted with CH_2Cl_2 (3 × 3 ml). The combined organic extracts were dried ($MgSO_4$),

filtered and concentrated in vacuo. The resulting crude residue was purified by SPE with silica gel (MeOH/CH_2Cl_2, 1:9) to yield the desired ester (**11**) [yield 33.6 mg (84%)]. HR-FAB-MS (*m/z*): 401.1606 $[M + H]^+$, calc. for $[C_{22}H_{24}O_7 + H]^+$ 401.1600. The eluate was concentrated, the mixture was separated by normal phase HPLC (Supelcosil™ LC-Si HPLC Column 5 µm particle size, L × I.D. 25 cm × 10 mm, EtOAc-hexane, 3:7; 2 ml/min; 311 nm UV detection), and used for the next step, cinnamoylation.

The preparation of the anthroyl derivative of BHhexol (**13**) was performed similarly as with (**11**). From the 9-anthracenecarboxylic acid (1 µmol, 222 µg), TFFH (1 µmol, 264 µg) in CH_2Cl_2 (200 µl), Et_3N (5 µmol, 505 µg, 0.7 µl) and the alcohol (**3**) (1 µmol, 578 µg) with catalytic amount of DMAP (1 µmol, 122 µg) compound **13** was obtained after purification by SPE with silica gel (MeOH-CH_2Cl_2, 2:98) in a yield of 610 µg (78%). HR-FAB-MS (*m/z*): 783.5199 $[M + H]^+$, calc. for $[C_{50}H_{70}O_7 + H]^+$ 783.5204.

Cinnamoylation

To an ice cooled suspension of the p-methoxycinnamic acid (712 mg, 4 mmol) and fluoro-*N,N,N′,N′*-tetramethylformamidinium hexafluorophosphate (TFFH, 5 mmol, 1.32 g) in a CH_2Cl_2 (35 ml) was added Et_3N (25 mmol, 2.52 g, 3.48 ml) resulting in a clear solution with some heat evolution. After stirring for 30 min at 20 °C the anthroyl derivative (**11**) (30 mg, 75 µmol) and a catalytic amount of DMAP (0.1 mmol, 12.2 mg) were added and the reaction mixture was stirred at 20 °C overnight. H_2O (10 ml) was added and the mixture extracted with CH_2Cl_2 (3 × 5 ml). The combined organic extracts were dried ($MgSO_4$), filtered and concentrated in vacuo. The resulting crude residue was purified by SPE with silica gel (MeOH/CH_2Cl_2, 1:9) to yield (66.6 mg, i.e. 74%) the desired ester (**12**). HR-FAB-MS (*m/z*): 1,201.4221 $[M + H]^+$, calc. for $[C_{72}H_{64}O_{17} + H]^+$ 1,201.4226.

The preparation of cinnamoyl derivative of BHhexol (**14**) was performed similarly as with the derivative (**12**). From the p-methoxycinnamic acid (712 µg, 4 µmol), TFFH (5 µmol, 1.32 mg) in CH_2Cl_2 (0.1 ml), Et_3N (25 µmol, 2.52 mg, 3.5 µl) and the alcohol (**13**) (0.77 µmol, 603 µg) with catalytic amount of DMAP (0.1 µmol, 12 µg), 915 µg (75%) of compound (**14**) was obtained after purification by SPE with silica gel (MeOH-CH_2Cl_2, 2:98). HR-FAB-MS (*m/z*): 1,583.7816 $[M + H]^+$, calc. for $[C_{100}H_{110}O_{17} + H]^+$ 1,583.7820.

Results

A. acidoterrestris was cultivated in a 50-l fermentor as described previously [20]. The total lipids were obtained by Bligh-Dyer extraction [21] of lyophilized cells and a part of the total lipids was cleaved by H_5IO_6 followed by $NaBH_4$ reduction. This releases mainly a mixture of alcohols arising from the BHpolyol derivatives, identical in GC retention times and mass spectra with the previously described alcohols which were used for the identification of BHpolyols from sediments [31]. Three alcohols were identified by GC–MS, i.e. bishomohopanol representing BHtetrols, homohopanol belonging to BHpentols, and the BHhexol hopanol. The detection of hopanol suggests the presence of a hopanoid with a hexafunctionalized side-chain in the total lipid extract.

Further, part of the total lipids was fractionated by means of cartridges with aminopropyl silica-based polar bonded phase, which were rinsed in a chloroform–methanol mixture (98:2) [22] for removing non-polar lipids. Polar lipids, but not phospholipids, were further eluted by acetone. Polar non-phospholipids (25% of total lipids, i.e. 385 mg) were further separated by normal phase HPLC, as described by Moreau et al. [22]. Briefly, non-phospholipids were subjected to semi-preparative normal phase HPLC with a linear gradient in for 40 min and with detection at 210 nm, as described by Fox et al. [1]. Table 1 gives the data obtained after normal phase semipreparative HPLC. The relative amounts of the C32, C31 and C30 alcohols, i.e. the relative contributions of tetra-, penta-, and hexafunctionalized side-chains were in a 2:1:1 ratio, which is in agreement with data from Table 1. This table also summarizes appropriate classes of hopanoids, i.e. tetrols, pentols, and hexols, whereas minority derivatives of BHs (up to 2% of total lipids) were omitted.

Table 2 gives the data obtained after RP-HPLC from the fraction of per-acetylated *N*-acylated BHhexol-glycosides,

which had the broadest interval of molecular weights. A total of 8 peaks were separated by LC–MS/ESI on narrow-bore columns connected in series. The chromatogram is given in Fig. 1.

Diagnostic fragment ions for hexafunctionalized bacteriohopane structures include the ion at *m/z* 771 resulting from the loss of the terminal group at C35 (either OH or any other moiety linked to C35 via oxygen [32]) and *m/z* 711, 651, 591, 531 and 471 from sequential loss of the remaining 5 acetylated OH groups from C30 to C34. The ESI/MS spectrum (Fig. 2) of a proposed acetylated *N*-acyls glycoside of BHhexol (**2**, $n = 3$) includes all these diagnostic ions as well as a further series *m/z* 579, 519, 459, 399, 339 and 279 from neutral loss of the A and B rings (i.e. loss of 192 Da) after a loss of one to six of the acetylated hydroxyls [32]. The composite hexafunctionalized structure **2** is proposed on the basis of observation of the diagnostic ions *m/z* 771 (etc.) and ions at *m/z* 554 (etc.), indicating the mass of the terminal group, and by comparison with spectra reported for the penta- and hexafunctionalized cyclitol ethers, see also Table 3.

The structure of pentacyclic nucleus including the side chain was essentially determined by ^{1}H-NMR spectroscopy using COSY, ROESY, HMQC, and HMBC experiments. The ^{1}H-NMR spectrum (data see Table 4) of acetylated hopanoids (**2**) showed signals in the methyl region typical of bacteriohopane derivatives. Both signals, including the ^{13}C NMR, are in agreement with previously published papers [7, 14, 33].

The ROESY spectrum displayed a number of correlation peaks between methyl groups and ring protons in the 1,3 diaxial relationship. Thus, 24-Me, H-6ax, 25-Me, 26-Me, and 13-H were shown to be all located on the upper face of

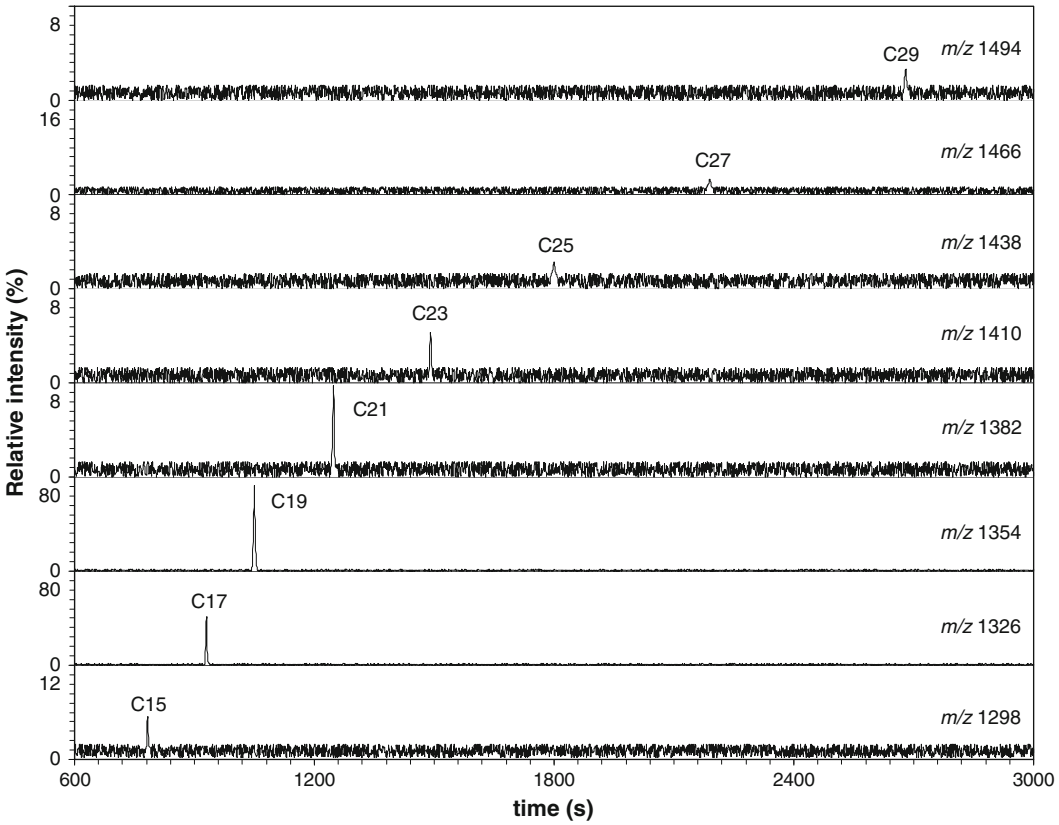

Fig. 1 LC–MS/ESI SIM chromatograms of *N*-acylated BHhexol glycosides from total lipids of *A. acidoterrestris* after normal phase HPLC; fraction of *N*-acyls-mannosamine-BHhexol is shown. The SIM traces depict $[M + H]^{+}$ masses, see *m/z* values

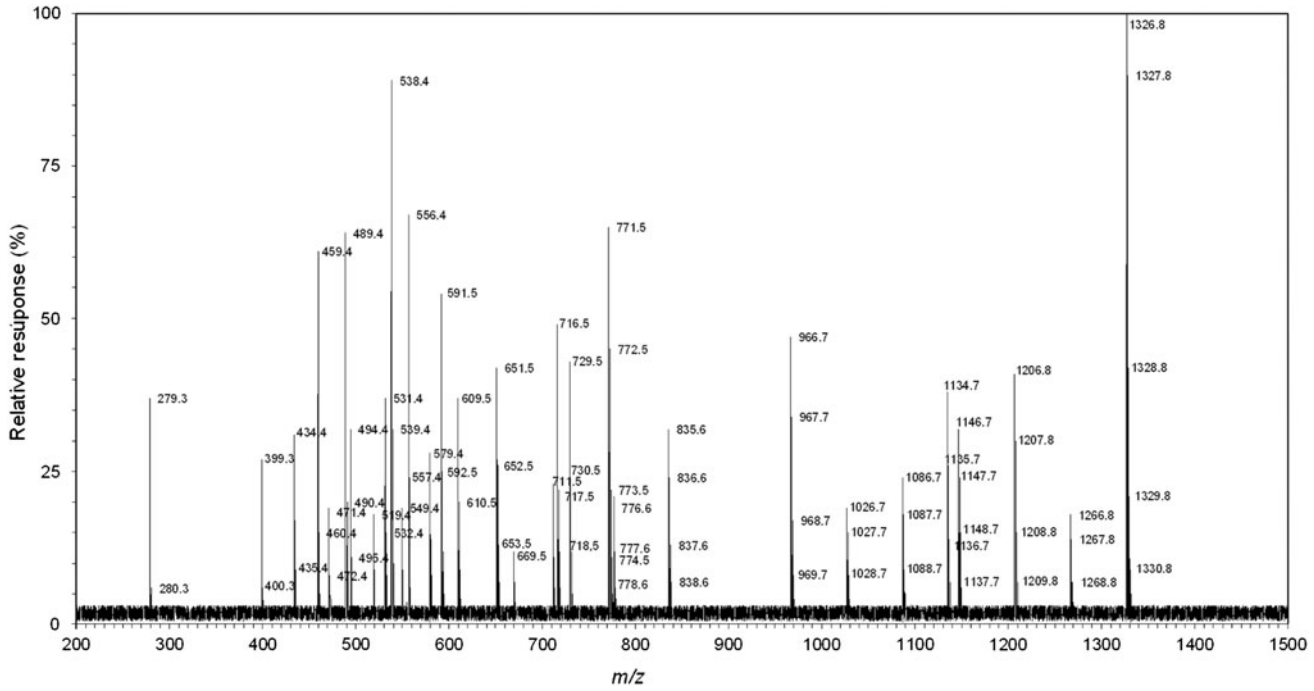

Fig. 2 The tandem quadrupole ESI product-ion spectrum of the $[M + H]^+$ ion of *N*-C17-mannosamine-BHhexol at *m/z* 1,326

the molecule, whereas 27-Me, 28-Me, H-5ax, and H-9ax were all on its lower face. Also the four-bond couplings (W coupling) of an angular methyl group with a ring proton in the COSY were observed. These couplings are only possible when the dihedral angle between the methyl group and the ring proton is near 180° and these couplings confirmed a trans connection of all the rings, hence the stereochemistry of compound **2** was the same as in previously isolated bacteriohopanoids. This was confirmed by HMBC correlations between Me groups and carbons of the ring system. Thanks to this fact the ^{13}C-resonance (see δ_C values in Table 5) of the five cycle moiety could be determined [7, 14, 33].

The ^{1}H-NMR spectrum of the octaacetate of compound (**2**) shows that the signals of the protons at C30 to C34 are nearly identical to those of the corresponding protons of the synthetic tetraacetate glycoside [33] and/or isolated pentaacetate of aminoBHtetrol [14] and are easily identifiable. Decoupling experiments performed on the C34 proton permitted an assignment of the signals of the two C35 protons which are nearly equivalent and appear as two doublets at 3.68 and 3.98 ppm. The fact that the signals of the C35 protons as well as the signal of the C35 carbon atom were shifted in comparison to the signals of the corresponding atoms of acetylated BHpolyol [9] indicated that a sugar moiety was located on the oxygen atom at C35. From the ^{1}H-NMR spectrum eight acetoxy groups are present: five at C30 to C34 and three on the residue linked at C35. Decoupling experiments initiated on the exchangeable NH proton of the acylamide group as well as dimensional proton/proton correlation allowed the whole pattern of the substituent to be established as compatible with the structure of an acylated sugar.

The large vicinal coupling constants, $^3J_{3',4'} = 9.5$ Hz and $^3J_{4',5'} = 9.5$ Hz, and the NOE between H-3′ and H-5′ indicated that H-3′, H-4′ and H-5′ protons were located at an axial position. The observation of NOE between H-4′ and 2′-NH proton suggested that 2′-NH was oriented in an axial position. These data indicate that the monosaccharide is a mannosamine in pyranose form; α configuration was determined by a large coupling constant, $^1J_{C\text{-}1',H\text{-}1'} = 166.1$ Hz [34] and small $^3J_{H\text{-}1'\text{-}H\text{-}2'} = 1.8$ Hz [35]. This implies also that the linkage between the BHhexol and the mannosamine moiety is an *O*-glycosidic bond.

HMBC analysis indicated that 2-NH′ of the mannosamine was esterified by a fatty acyl group by the correlation peak between H-2′ (δ 4.63) and C-1′′ (δ 172.8) of the fatty group and that 3-OH′, 4-OH′, and 6-OH′ of the mannosamine moiety were esterified by acetates by the correlation peaks between H-3′ (δ 5.38), H-4′ (δ 5.06), and H-6′ (δ 4.30, 4.14) and the other three carbonyl carbons (δ 170.7, 170.6, 170.2). The key HMBC are showed in Fig. 3.

The components of *N*-acylated BHhexol-mannosamide were also analyzed after hydrolysis (Fig. 4). The hydrolyzate contained BHhexol as the aglycone moiety and mannosamine was the only sugar which was detected by GC–MS in this fraction. Mannosamine had $[\alpha]_D^{25}$-4.1, compared to the literature data, $[\alpha]_D^{25}$ -4.2 for D-mannosamine

Table 3 The main molecular species of *N*-acylated BHhexol glycoside (**2**) from *A. acidoterrestris*

(2-amino-2-deoxy-D-mannopyranose) [36]. The mixture of homologous ω-cyclohexyl fatty acids, isolated from the hydrolyzate, was also determined by GC–MS. The fatty acid composition obtained by GC–MS was nearly identical with the results obtained from ESI analysis (see Table 2).

Bisseret and Rohmer [37], who synthesized the eight possible diastereomers of BHtetrols, established the absolute stereochemistry of the side chain on the basis of their ^{1}H-NMR spectra. Since the 32 diastereomers for BHhexols have not yet been synthesized, we had to use the CD exciton chirality method [38] that has been applied to sugar polyols [39] and/or different acyclic polyols such as BHpolyols [40] with up to five contiguous OH groups, or aminoBHpentols [41, 42]. These CD studies clearly showed that with flexible

available saccharide D-allose (**6**) appropriate 7-deoxy-D-*glycero*-D-*allo*-heptitol (**10**) via the D-*glycero*-D-*allo*-heptose (**8a**) according to Fig. 5. This helped us remove the obstacle mentioned by Zhou et al. [41], viz. that configurational determination of aminoBHpentol is not straightforward due to the lack of reference hexols.

The original version of the Kiliani-Fischer synthesis was modified according to several authors [24, 25]. Instead of conversion of the cyanohydrin (aldonitrile) to a lactone, the cyanohydrin is reduced with hydrogen (palladium on barium sulfate) in water to an imine that quickly hydrolyzes at pH 4.2 to an aldehyde; thus the final sugars are produced in just two steps rather than three and, moreover, the final sugars are separated instead of the lactones. We used semipreparative TLC on cellulose plates and employed a previously described solvent system (acetone–water 95:5, v/v) with D-glucose as standard. The compound with an R_f lower than glucose was D-*glycero*-D-*allo*-heptose (**8a**) while that with an R_f higher than glucose was D-*glycero*-D-*altro*-heptose (**8b**), see also paper [25]. The measurement of ^{13}C-NMR spectra of (**8a**) showed that, in keeping with literature data [27], this compound is present as a mixture of four forms, i.e. α and β pyranoses and α and β furanoses in a ratio of 15:75:5:5. Experimental part gives only the values for the most copious form, i.e. β-pyranose.

Heptose (**8a**) was converted first to the diethyl thioacetal (**9**), and then, by reductive desulfurization with Raney nickel, to 7-deoxy-D-*glycero*-D-*allo*-heptitol (**10**). This desoxyheptitol was esterified by selective anthroylation of primary hydroxyl by anthracene-9-carboxylic acid to (2*R*, 3*R*, 4*S*, 5*S*, 6*S*)-2,3,4,5,6-pentahydroxyheptyl anthracene-9-carboxylate (**11**). To make sure that we had indeed the appropriate and pure epimer (viz. the separation of heptoses by TLC after reduction) we used a separation of this compound by means of normal phase HPLC, see also Wiesler and Nakanishi [43]. They reported that mixtures of saccharides (after cyanohydrin synthesis) could be directly subjected to anthroylation, after which separation of the fluorescent monoesters was greatly simplified. The secondary hydroxyls of anthroyl derivative (**11**) were per-p-methoxycinnamoylated to an appropriate "bichromophoric" derivative (**12**) and CD spectrum of this compound was measured, see Fig. 6. The curve for L-*allo* (**12**) is plotted as a mirror image of the D-series, see also Zhou et al. [39].

On the basis of all above mentioned spectra (including CD spectrum of synthetic compound **12**), we confirmed that the configuration of the side chain is 30*R*, 31*R*, 32*R*, 33*S*, 34*S* (D-*glycero*-D-*allo*) and the components of this fraction are *N*-acylated-mannosamine-BHhexols which contain—α-D-2-amino-2-deoxymannopyranose esterified by ω-cyclohexyl fatty acids from C-15 to C-29. The correct name of the glycoside with C-17 fatty acids is 11-cyclohexyl-*N*-((2*S*,3*S*,4*R*,5*S*,6*R*)-2-((2*S*,3*S*,4*R*,5*R*,6*R*,7*S*)-7-((3*S*,3a*S*,5a*R*,

5b*R*,7a*S*,11a*S*,11b*R*,13a*R*,13b*S*)-5a,5b,8,8,11a,13b-hexamethylicosahydro-1*H*-cyclopenta[a]chrysen-3-yl)-2,3,4,5,6-pentahydroxyoctyloxy)-4,5-dihydroxy-6-(hydroxymethyl) tetrahydro-2*H*-pyran-3-yl)undecanamide (**1**).

Discussion

To the best of our knowledge, this is the first report of BHhexol from a specific bacterium. Bacteriohopanoids having hexol in the side chain, including their composite derivatives, have so far been identified only in sediments but their configuration has been unknown [2, 16, 17]. Based on the comparison with the synthesized model compound (**12**), we determined its absolute configuration by using CD. Still, the identification of a novel hopanoid from *A. acidoterrestris* is not too surprising since only several tens of bacterial and cyanobacterial genera have been tested for the presence of hopanoids [16]. Although the biological significance of our compound is not yet clear; it is probable that in *A. acidoterrestris* the long chain ω-cyclohexyl FAs, which are bound by an amidic bond to

the amino group in position 2 of the appropriate monosaccharide, play an important role in the thermophilicity of this bacterium.

Different monosaccharide derivatives have been found to be bound glycosidically to the primary C35 hydroxyl: Simonin et al. [44] described galacturonic and altruronic acids while all other studies describe 2-amino-2-deoxyglucose and one study reports on 6-amino-6-deoxyglucose [44]. We assume that the change in the configuration of the amino group on C2 (mannose is a 2-epimer of glucose), i.e. axial to equatorial, alters the planarity of the whole molecule.

The last result of our study is the heretofore undescribed large variability of chain lengths. Only ω-cyclohexyl FA with 17 and 19 carbon atoms have so far been described [18]. Solely in *N*-acyl glycoside of BHtetrol did Talbot et al. [5] succeeded in identifying by ESI also other homologues, one shorter (C15) and one longer (C21). We have extended the range of homologues by other longer-chain members—odd-numbered C23 to C29.

In conclusion we can state that, by using modern analytical methods, we succeeded in identifying one of the possible sources of BHhexol in sediments, i.e. *A. acidoterrestris*, and determined the absolute configuration of the side chain of BHhexol by CD and by its comparison with the synthetic model compound 7-deoxy-D-*glycero*-D-*allo*-heptitol, i.e. (2*R*,3*R*,4*S*,5*S*,6*S*)-heptane-1,2,3,4,5,6-hexaol (**10**), which has not yet been described.

Acknowledgments The research was supported by projects of the *Ministry of Education, Youth and Sports of the Czech Republic* (no. 1M06011; GACR P503/10/P182), and by *Institutional Research Concepts* AV 0Z 502 0910 and MSM6046137305.

ORIGINAL ARTICLE

The Absolute Configurations of Hydroxy Fatty Acids from the Royal Jelly of Honeybees (*Apis mellifera*)

Tetsuya Kodai · Takafumi Nakatani · Naoki Noda

Received: 20 June 2010 / Accepted: 22 October 2010 / Published online: 17 November 2010

Abstract 9-Hydroxy-2*E*-decenoic acid (9-HDA) is a precursor of the queen-produced substance, 9-oxo-2*E*-decenoic acid (9-ODA), which has various important functions and roles for caste maintenance in honeybee colonies (*Apis mellifera*). 9-HDA in royal jelly is considered to be a metabolite of 9-ODA produced by worker bees, and it is fed back to the queen who then transforms it into 9-ODA. Recently we found that 9-HDA is present in royal jelly as a mixture of optical isomers (*R*:*S*, 2:1). The finding leads us to suspect that chiral fatty acids in royal jelly are precursors of semiochemicals. Rather than looking for semiochemicals in the mandibular glands of the queen bee, this study involves the search for precursors of pheromones from large quantities of royal jelly. Seven chiral hydroxy fatty acids, 9,10-dihydroxy-2*E*-decenoic, 4,10-dihydroxy-2*E*-decenoic, 4,9-dihydroxy-2*E*-decenoic, 3-hydroxydecanoic, 3,9-dihydroxydecanoic, 3,11-dihydroxydodecanoic, and 3,10-dihydroxydecanoic acids were isolated. The absolute configurations of these acids were determined using the modified Mosher's method, and it was revealed that, similar to 9-HDA, five acids are present in royal jelly as mixtures of optical isomers.

Introduction

The so-called "queen substance," 9-oxo-2-decenoic acid (9-ODA), was isolated from the honeybee queen mandibular glands by Butler et al. [1]. This compound is a well-known semiochemical which has various important functions, such as queen recognition and inhibition of ovary development in worker bees for caste maintenance in honeybee colonies [2].

In 1965, Johnston and co-workers reported that 9-ODA was rapidly metabolized to 9-hydroxy-2*E*-decenoic (9-HDA) or 9-hydroxydecanoic acids [3]. They further postulated a "pheromone cycle," in which worker bees would receive 9-ODA from the queen and convert it into 9-HDA. The metabolite would then be transported to the worker mandibular glands where it would be passed back to the queen through royal jelly. The queen would then convert it back into the active oxo-form, 9-ODA. In fact, significant amounts of 9-HDA have been found in royal jelly, but 9-ODA has not yet been detected. Furthermore, our previous study revealed that 9-HDA is present as a mixture of optical isomers (*R*:*S*, 2:1) in royal jelly [4]. This interesting finding is important with regard to searching for precursors of unknown semiochemicals in royal jelly.

The present study was undertaken to examine the constituents of royal jelly in the hope of discovering precursors of unknown queen substances. We conducted a more

detailed survey of the components, particularly the fatty acid fraction, and isolated seven chiral fatty acids in the pure state. The absolute configurations of the chiral acids were determined using the modified Mosher's method [5–7]. Similar to 9-HDA found in royal jelly, five acids are present as mixtures of optical isomers.

Experimental Procedure

Materials

Lyophilized royal jelly powder was supplied by Yamada Apiculture Center Inc. (Okayama, Japan). A voucher specimen was deposited in the Faculty of Pharmaceutical Sciences, Setsunan University.

Instrumentation

Optical rotations were measured at 25 °C with a JASCO DIP-140 polarimeter (JASCO, Tokyo, Japan). ^{1}H- and ^{13}C-NMR spectra were recorded on JEOL JMN GX400 or ECA 600SN spectrometers (JEOL, Tokyo, Japan), using tetramethylsilane (TMS) as an internal reference. All samples were measured at a probe temperature of 35 °C. The two-dimensional heteronuclear multiple bond connectivity (HMBC) spectrum was recorded at 600 MHz with 64 scans ($^{2,3}J_{CH} = 8$ Hz). Fast atom bombardment mass spectrometry (FAB-MS) including high-resolution mass was recorded on a JEOL JMS-700T spectrometer (JEOL). (Accelerating voltage, 5 kV; matrix, glycerin or triethanolamine; collision gas, He). Column chromatography was carried out on Diaion HP-20 (Mitsubishi Chemical Co., Tokyo, Japan), Sephadex LH-20 (Amersham Pharmacia Biotech AB, Uppsala, Sweden), silica gel (Kiesergel 60, Merck), and Cosmosil 75C_{18}-OPN (Nacalai Tesque, Inc., Tokyo, Japan). Preparative HPLC was conducted over Mightysil RP-18 GP (5 μm, 4.6 × 250 mm, Kanto Chemical Co. Inc. Tokyo, Japan) and Inertsil ODS-3 (4 μm, 4.6 × 100 mm, GL Sciences Inc., Tokyo, Japan) columns with a JASCO 980-PU (JASCO, Tokyo, Japan). The elution profile was monitored by a refractive index detector, RI504R (GL Sciences Inc., Tokyo, Japan).

Isolation of Compounds, 1–7

Lyophilized royal jelly powder (1 kg) was percolated with chloroform to remove a major component, 10-hydroxy-2*E*-decenoic acid. The residue was extracted with chloroform/acetone (1:1, vol/vol), and the solvent was removed in vacuo to give an extract (36.1 g). This was chromatographed on silica gel and eluted successively with chloroform/methanol/water (7:2:0.2 → 7:3:0.5 → 6:4:1 by vol) to give four fractions, fr. 1 (30.0 g), fr. 2 (1.8 g), fr. 3 (0.9 g), and fr. 4 (0.5 g). Fr. 2 was chromatographed on Sephadex LH-20 (methanol) and Cosmosil 75C_{18}-OPN (methanol/water, 1:1 vol/vol → methanol) columns to give three fractions, fr. 5 (115 mg), fr. 6 (314 mg), and fr. 7 (340 mg). Fr. 5 was subjected to preparative HPLC on a reversed-phase column (Inertsil ODS-3) using acetonitrile/water/trifluoroacetic acid, 30:70:0.25 by vol to give compound **1** (7.6 mg). Fr. 3 was chromatographed on Sephadex LH-20 (methanol) and Cosmosil 75C_{18}-OPN (methanol/water, 3:7 → 1:1 by vol → methanol) columns to give four fractions, fr. 8–11. Fr. 8 (31.2 mg) was subjected to preparative HPLC on a reversed-phase column (Mightysil RP-18 GP) using a mobile phase (methanol/water/trifluoroacetic acid, 25:75:0.5 by vol) to give compounds **2** (11.7 mg) and **3** (1.3 mg). Fr. 9 (499 mg) was separated by an Inertsil ODS-3 column using a mobile phase (methanol/water/trifluoroacetic acid, 25:75:0.5 by vol) to give compounds **5** (5.4 mg) and **7** (118 mg). Fr. 10 was subjected to HPLC on an Inertsil ODS-3 column using a solvent (methanol/water/trifluoroacetic acid, 37:63:0.5 by vol) to give compounds **4** (3.4 mg) and **6** (4.2 mg). Compound **7** was identified as 3*R*,10-dihydroxydecanoic acid by comparison of the NMR and FABMS spectroscopic data with those of an authentic sample [4].

Preparation of 2-Methoxy-2-(trifluoromethyl)phenylacetyl (MTPA) Ester Derivatives

Compounds **1** through **6** (*ca.* 1 mg) were each treated with diazomethane in diethyl ether. (−)- and (+)-MTPA Chlorides (Tokyo Kasei Kogyo Co. Ltd., 20 mg each) were separately added to a solution of the above product in carbon tetrachloride (0.3 mL) and pyridine (1.0 mL), and the mixture was stirred at room temperature for 12 h. After removal of the solvent under a nitrogen stream, the reaction

mixture was subjected to silica gel column chromatography (chloroform) to give a MTPA derivative.

Bis[(−)-MTPA] Ester of Methyl Ester of **1** (**1a**) ^{1}H-NMR ($CDCl_3$, 600 MHz) δ: 1.18–1.17 (8H, m, $CH_2 \times 4$), 2.12 (0.5H, dt, $J = 7.2$, 7.2 Hz, H_2-4 of *S*-form), 2.16 (1.5H, dt, $J = 7.2$, 7.2 Hz, H_2-4 of *R*-form), 3.42 (2.25H, m, OCH_3 of *R*-form), 3.44 (2.25H, m, OCH_3 of *R*-form), 3.48 (0.75H, m, OCH_3 of *S*-form), 3.49 (0.75H, m, OCH_3 of *S*-form), 3.73 (3H, s, CO_2CH_3), 4.27 (0.75H, dd, $J = 4.8$, 12.0 Hz, Ha-10 of *R*-form), 4.30 (0.25H, dd, $J = 6.0$, 12.0 Hz, Ha-10 of *S*-form), 4.54 (0.75H, dd, $J = 3.0$, 12.0 Hz, Hb-10 of *R*-form), 4.62 (0.25H, dd, $J = 3.0$, 12.0 Hz, Hb-10 of *S*-form), 5.28–5.32 (1H, m, H-9), 5.79 (0.25H, d, $J = 15.6$ Hz, H-2 of *S*-form), 5.80 (0.75H, d, $J = 15.6$ Hz, H-2 of *R*-form), 6.92 (0.25H, dt, $J = 15.6$, 7.2 Hz, H-3 of *S*-form), 6.93 (0.75H, dt, $J = 15.6$, 7.2 Hz, H-3 of *R*-form), 7.33–7.40 (6H, m, H-ph), 7.43–7.50 (4H, m, H-ph).

Bis[(−)-MTPA] Ester of Methyl Ester of **2** (**2a**) ^{1}H-NMR ($CDCl_3$, 400 MHz) δ: 1.22–1.72 (10H, m, $CH_2 \times 5$), 3.53–3.55 (6H, m, $OCH_3 \times 2$), 3.74 (1.5H, s, CO_2CH_3 of *R*-form), 3.76 (1.5H, s, CO_2CH_3 of *S*-form), 4.24–4.34 (2H, m, H_2-10), 5.57–5.60 (1H, m, H-4), 5.86 (0.5H, d, $J = 15.6$ Hz, H-2 of *R*-form), 5.98 (0.5H, d, $J = 15.6$ Hz, H-2 of *S*-form), 6.78 (0.5H, dd, $J = 6.0$, 15.6 Hz, H-3 of *R*-form), 6.84 (0.5H, dd, $J = 6.0$, 15.6 Hz, H-3 of *S*-form), 7.38–7.42 (6H, m, H-ph), 7.49–7.52 (4H, m, H-ph).

Bis[(−)-MTPA] Ester of Methyl Ester of **3** (**3a**) ^{1}H-NMR ($CDCl_3$, 400 MHz) δ: 0.86-1.61 (11H, m, H_3-10 and $CH_2 \times 4$), 3.52–3.57 (6H, m, $OCH_3 \times 2$), 3.74–3.76 (3H, m, CO_2CH_3), 5.04–5.13 (1H, m, H-9), 5.51–5.60 (1H, m, H-4), 5.85 (0.29H, d, $J = 15.6$ Hz, H-2 of 4*R*9*R*-form), 5.86 (0.21H, d, $J = 15.6$ Hz, H-2 of 4*R*9*S*-form), 5.96 (0.37H, d, $J = 15.6$ Hz, H-2 of 4*S*9*R*-form), 5.98 (0.13H, d, $J = 15.6$ Hz, H-2 of 4*S*9*S*-form), 6.76 (0.29H, dd, $J = 5.6$, 15.6 Hz, H-3 of 4*R*9*R*-form), 6.78 (0.21H, dd, $J = 5.6$, 15.6 Hz, H-3 of 4*R*9*S*-form), 6.81 (0.37H, dd, $J = 5.6$,

15.6 Hz, H-3 of 4*S*9*R*-form), 6.83 (0.13H, dd, $J = 5.6$, 15.6 Hz, H-3 of 4*S*9*S*-form), 7.39–7.43 (6H, m, H-ph), 7.50–7.53 (4H, m, H-ph).

(−)-MTPA Ester of Methyl Ester of **4** (**4a**) ^{1}H-NMR ($CDCl_3$, 400 MHz) δ: 0.88 (3H, t, $J = 7.2$ Hz, H_3-10), 1.18–1.58 (12H, m, $CH_2 \times 6$), 2.58 (1H, dd, $J = 4.8$, 16.0 Hz, Ha-2), 2.65 (1H, dd, $J = 8.0$, 16.0 Hz, Hb-2), 3.56 (3H, m, OCH_3), 3.59 (3H, s, CO_2CH_3), 5.48 (1H, m, H-3), 7.37–7.43 (3H, m, H-ph), 7.52–7.54 (2H, m, H-ph).

(+)-MTPA Ester of Methyl Ester of **4** (**4b**) ^{1}H-NMR ($CDCl_3$, 400 MHz) δ: 0.87 (3H, t, $J = 7.2$ Hz, H_3-10), 1.20–1.67 (12H, m, $CH_2 \times 6$), 2.61 (1H, dd, $J = 4.8$, 16.0 Hz, Ha-2), 2.70 (1H, dd, $J = 8.0$, 16.0 Hz, Hb-2), 3.55 (3H, m, OCH_3), 3.66 (3H, s, CO_2CH_3), 5.48 (1H, m, H-3), 7.37–7.41 (3H, m, H-ph), 7.52–7.54 (2H, m, H-ph).

Bis[(−)-MTPA] Ester of Methyl Ester of **5** (**5a**) ^{1}H-NMR ($CDCl_3$, 600 MHz) δ: 1.25 (2H, d, $J = 6.6$ Hz, H_3-10 of 3*R*9*S*-form), 1.33 (1H, d, $J = 6.6$ Hz, H_3-10 of 3*R*9*R*-form), 1.31–1.66 (10H, m, $CH_2 \times 5$), 2.55 (0.33H, dd, $J = 4.8$, 16.2 Hz, Ha-2 of 3*R*9*R*-form), 2.56 (0.67H, dd, $J = 4.8$, 16.2 Hz, Ha-2 of 3*R*9*S*-form), 2.63 (0.33H, dd, $J = 7.8$, 16.2 Hz, Hb-2 of 3*R*9*R*-form), 2.64 (0.67H, dd, $J = 7.8$, 16.2 Hz, Hb-2 of 3*R*9*S*-form), 3.51–3.56 (6H, m, $OCH_3 \times 2$), 3.59 (3H, m, CO_2CH_3), 5.10–5.14 (1H, m, H-9), 5.43–5.48 (1H, m, H-3), 7.37–7.42 (6H, m, H-ph), 7.50–7.53 (4H, m, H-ph).

Bis[(+)-MTPA] Ester of Methyl Ester of **5** (**5b**) ^{1}H-NMR ($CDCl_3$, 600 MHz) δ: 1.24 (1H, d, $J = 6.6$ Hz, H_3-10 of 3*R*9*R*-form), 1.32 (2H, d, $J = 6.6$ Hz, H_3-10 of 3*R*9*S*-form), 1.11–1.65 (10H, m, $CH_2 \times 5$), 2.58 (0.67H, dd, $J = 4.8$, 16.2 Hz, Ha-2 of 3*R*9*S*-form), 2.59 (0.33H, dd, $J = 4.8$, 16.2 Hz, Ha-2 of 3*R*9*R*-form), 2.68 (0.67H, dd, $J = 7.8$, 16.2 Hz, Hb-2 of 3*R*9*S*-form), 2.69 (0.33H, dd, $J = 7.8$, 16.2 Hz, Hb-2 of 3*R*9*R*-form), 3.53–3.56 (6H, m, $OCH_3 \times 2$), 3.66 (3H, m, CO_2CH_3), 5.08–5.13 (1H, m, H-9), 5.42–5.48 (1H, m, H-3), 7.36–7.40 (6H, m, H-ph), 7.51–7.54 (4H, m, H-ph).

Bis[(−)-MTPA] Ester of Methyl Ester of **6** (**6a**) ^{1}H-NMR ($CDCl_3$, 600 MHz) δ: 1.18–1.68 (14H, m, $CH_2 \times 7$), 1.25 (2.25H, d, $J = 6.0$ Hz, H_3-12 of 3*R*11*S*-form), 1.33 (0.75H, d, $J = 6.0$ Hz, H_3-12 of 3*R*11*R*-form), 2.57 (1H, dd, $J = 4.8$, 15.6 Hz, Ha-2), 2.64 (1H, dd, $J = 7.8$, 15.6 Hz, Hb-2), 3.52 (3H, m, OCH_3), 3.54 (3H, m, OCH_3), 3.59 (3H, s, CO_2CH_3), 5.11–5.16 (1H, m, H-11), 5.45–5.49 (1H, m, H-3), 7.38–7.41 (6H, m, H-ph), 7.52–7.53 (4H, m, H-ph).

Bis[(+)-MTPA] Ester of Methyl Ester of **6** (**6b**) ^{1}H-NMR ($CDCl_3$, 600 MHz) δ_H: 1.38–1.65 (14H, m, $CH_2 \times 7$), 1.25 (0.75H, d, $J = 6.0$ Hz, H_3-12 of 3*R*,11*R*-form), 1.33 (2.25H, d, $J = 6.0$ Hz, H_3-12 of 3*R*11*S*-form), 2.61 (1H, dd, $J = 4.8$, 15.6 Hz, Ha-2), 2.70 (1H, dd, $J = 8.4$, 15.6 Hz, Hb-2), 3.54 (3H, m, OCH_3), 3.57 (3H, m, OCH_3), 3.66 (3H, s, CO_2CH_3), 5.11–5.17 (1H, m, H-11), 5.44–5.49 (1H, m, H-3), 7.38–7.40 (6H, m, H-ph), 7.53–7.54 (4H, m, H-ph).

The ratio of *R* to *S* was determined by the intensity of the signals arising from both enantiomers.

Results

The total lipid fraction obtained from lyophilized royal jelly powder (1 kg) was separated repeatedly by silica gel column chromatography with various solvents to give the crude fatty acid fraction. This fraction was further separated with HPLC, and seven compounds **1**–**7** were isolated in pure form (see "Experimental Procedure").

The molecular formula of **1**, $C_{10}H_{18}O_4$, was established using high resolution FAB-MS. The ^{1}H-NMR spectrum of **1** showed *trans* olefinic (δ_H 5.80 and 6.89), oxymethine (δ_H 3.57), and allylic (δ_H 2.21) groups together with non-equivalent methylene signals. The ^{13}C-NMR spectrum showed one oxy methine (δ_C 73.1) and one oxy methylene (δ_C 67.3) units together with carboxyl (δ_C 171.4) and olefinic (δ_C 123.7 and 149.5) carbons. The COSY and HMBC spectra showed significant correlation peaks between H_2-10/H-9, H-2/C-1, and H-3/C-1, respectively. These findings revealed that **1** was 9,10-dihydroxy-2*E*-decenoic acid. The absolute configuration of C-9 was determined using the modified Mosher's method.[1]

Methylation of **1** with diazomethane, followed by treatment with (−)-MTPA chloride gave the (−)-MTPA ester (**1a**). The ^{1}H-NMR spectrum of **1a** showed two sets of signals in a ratio of *ca* 3:1 due to optical isomers. The $\Delta\delta$ values [δ (−)-MTPA ester – δ (+)-MTPA ester] of the major characteristic H-2 and H-3 protons were +0.011 and +0.013 ppm, respectively, whereas those of Ha-10 and Hb-10 were −0.025 and −0.076 ppm, respectively, indicating the 9*R* configuration. Hence, **1** was revealed to be a mixture of 9*R*,10- and 9*S*,10-dihydroxy-2*E*-decenoic acids in a ratio of *ca* 3:1 (Fig. 1).

The high resolution FAB-MS of **2** showed an $[M-H]^-$ ion peak at *m*/*z* 201.1118, consistent with the same molecular formula, $C_{10}H_{18}O_4$, as that of **1**, and indicating that **2** is an isomer of **1**. The ^{1}H-NMR spectrum of **2** showed similar *trans* olefinic (δ_H 5.97 and 6.92) signals due to protons H-2 and H-3, and equivalent H_2-10 (δ_H

[1] To establish whether the modified Mosher's method is applicable to compounds possessing a 1,2-diol, we firstly examined this method using 3-(octadecyloxy)-1,2*S*-propanediol. The $\Delta\delta$ values of the corresponding (−)- and (+)-MTPA esters were consistent with those predicted for *S* configuration.

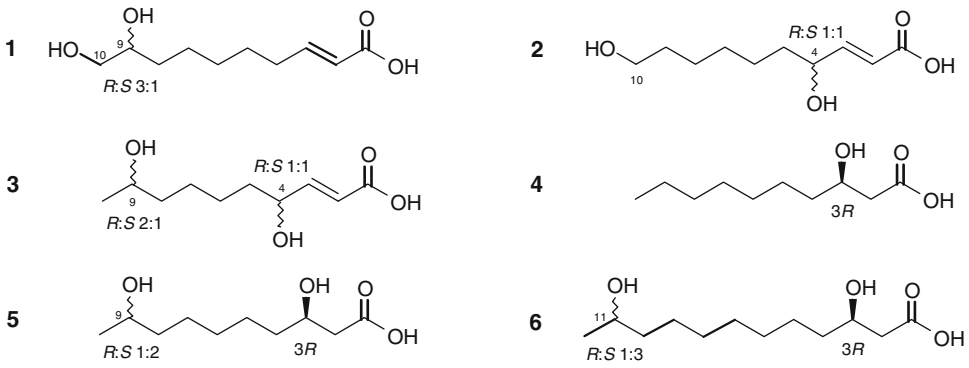

Fig. 1 Structures of chiral fatty acids **1–6**

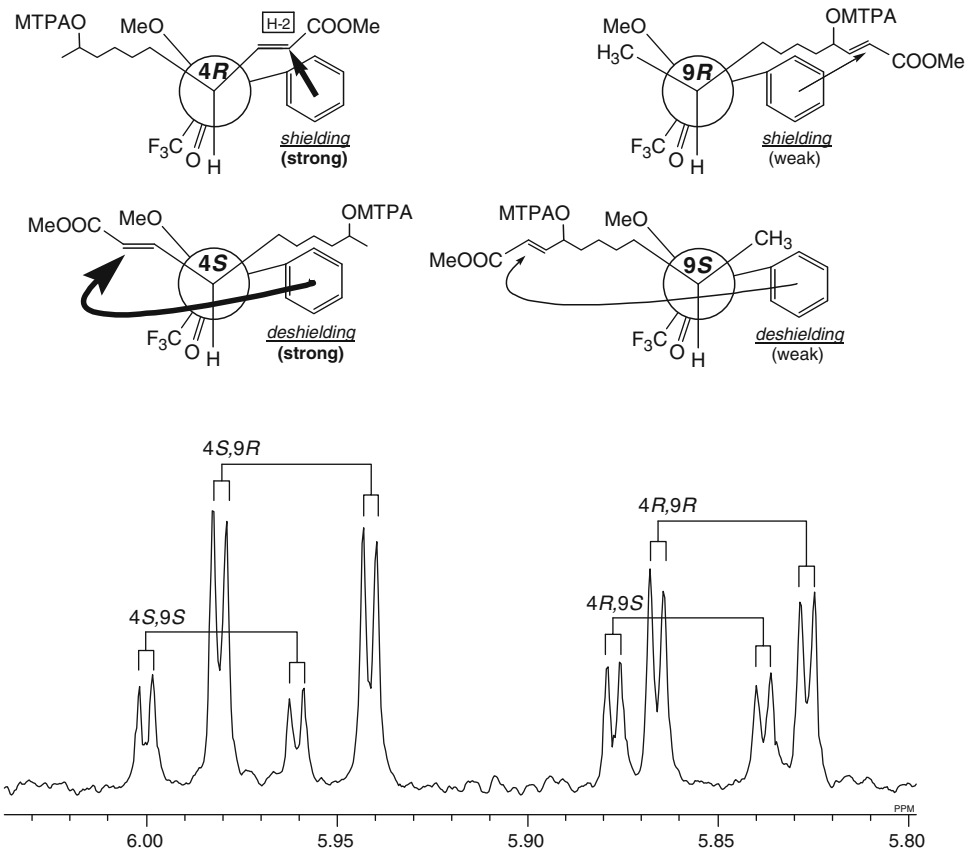

Fig. 2 ^{1}H-NMR spectrum of H-2 of **3a** and anisotropic effects of two MTPA groups

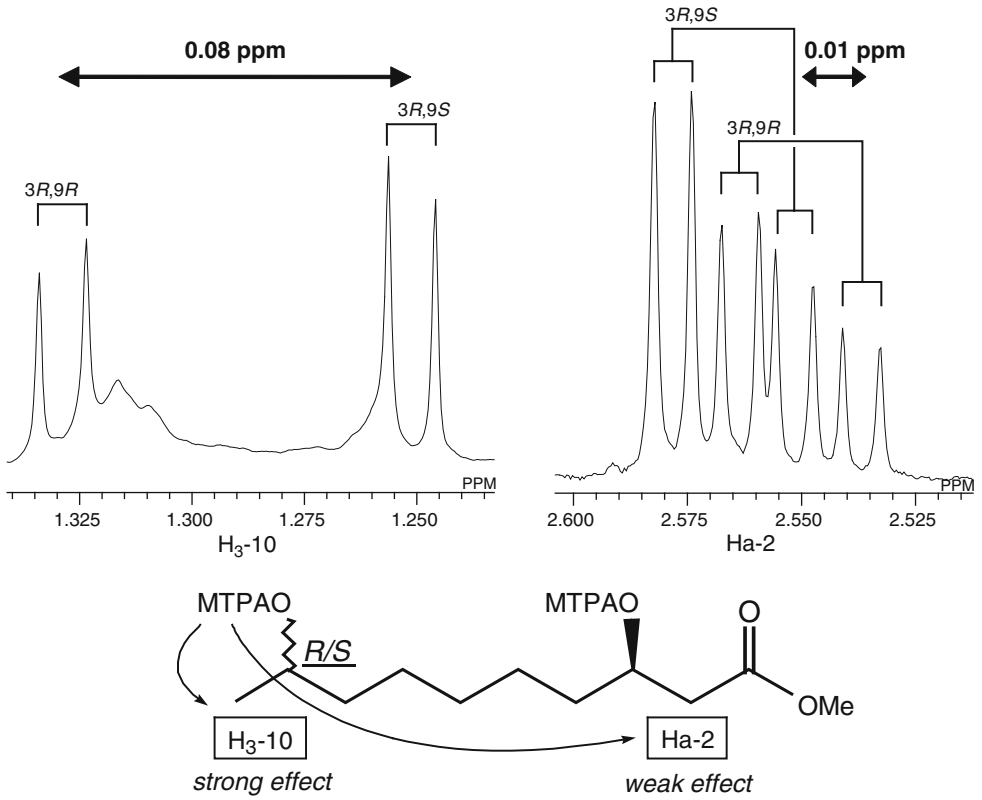
3.54) signals together with an oxy methine (δ_H 4.22) group coupled with H-3. These findings revealed that **2** was a positional isomer of **1**; that is, **2** differed in the position of the secondary hydroxyl group placed at C-4 instead of C-9 as in **1**, and hence the structure was determined to be 4, 10-dihydroxy-2*E*-decenoic acid. Methylation of **2** with diazomethane followed by esterification with (−)-MTPA chloride gave the (−)-MTPA ester (**2a**). The ^{1}H-NMR spectrum of **2a** showed, similar to that of **1a**, two sets of signals assignable to optical isomers, but, in a ratio of ca. 1:1. From these findings, it was determined that **2** was a mixture of 4*R*,10- and 4*S*,10-dihydroxy-2*E*-decenoic acids, in a ratio of ca. 1:1 (Fig. 1).

Compound **3** ($C_{10}H_{18}O_4$) was found, using two dimensional ^{1}H-NMR (COSY and HMBC) spectroscopic analyses, to be another isomer, 4,9-dihydroxy-2*E*-decenoic acid. The ^{1}H-NMR spectrum of (−)-MTPA ester (**3a**) showed, in contrast to those of **1a** and **2a**, four sets each of signals due to protons H-2 and H-3, indicating that **3a** is a mixture of four isomers (4*R*9*S*, 4*S*9*R*, 4*R*9*R*, and 4*S*9*S*). As can be seen in Fig. 2, the olefinic signal for proton (H-2) of the 4*R*9*R* isomer should appear at the highest field because of the anisotropic effect of the two phenyl groups of the MTPA esters (strong shielding by the near 4*R*-MTPA+ weak shielding by the far 9*R*-MTPA). The signal observed at the second highest field could be assigned as proton H-2

Fig. 3 ^{1}H-NMR spectrum of **5a**



of the 4*R*9*S* isomer (strong shielding by the near 4*R*-MTPA + weak deshielding by the far 9*S*-MTPA). Again, employing the modified Mosher's method as described above, olefinic signals due to the four isomers were successively discriminated, and thus **3** was revealed to be a mixture of 4*S*9*R*-, 4*R*9*R*-, 4*R*9*S*-, and 4*S*9*S*-dihydroxy-2*E*-decenoic acids, in a ratio of ca. 9:7:5:3. On comparison with those of **2a**, the $\Delta\delta$ values for protons H-2 and H-3 were consistent with the assignment of configurations (Fig. 4).

Analysis of the NMR and FAB-MS spectra of **4** ($C_{10}H_{20}O_3$) revealed the structure to be 3-hydroxydecanoic acid. The ^{1}H-NMR spectrum of (−)-MTPA ester (**4a**) showed, unlike those of **1a**–**3a**, signals due to one optical isomer. We then prepared the (+)-MTPA ester (**4b**). The $\Delta\delta$ value for protons H_2-2 showed that the configuration at C-3 was *R* (Fig. 4).

The ^{1}H-NMR spectrum of **5** ($C_{10}H_{20}O_4$) showed two oxy methine signals (δ 3.71 and 3.97), and similar to that of **4**, no signals due to olefinic protons. One oxy methine was coupled with the terminal methyl, H_3-10, and the other was coupled with the nonequivalent protons, H_2-2. From this information, it was clear that the two hydroxyl groups were located at the C-3 and C-9 positions, and hence the structure of **5** was defined as 3,9-dihydroxydecanoic acid. To clarify the absolute configuration, **5** was converted into the (−)-MTPA derivative (**5a**). The ^{1}H-NMR spectrum of **5a**, in contrast to that of **3a**, showed two signals for protons H_2-2, and accordingly **5** was regarded as being a mixture of enantio- and/or diastereoisomers. We then prepared the (+)-MTPA ester (**5b**). If compound **5** was a mixture of enantiomers [(3*R*9*R* and 3*S*9*S*) or (3*R*9*S* and 3*S*9*R*)], the chemical shifts of all signals arising from the (+)- and (−)-MTPA esters would reverse each other, and similar to those of **2a**, the $\Delta\delta$ values would have the opposite sign (Fig. 4). However, the signals in the spectra of **5a** and **5b** gave different chemical shifts. Based on these findings, compound **5** was revealed to be a mixture of diastereomers. The anisotropic effect of the phenyl group of the MTPA ester decreases with increasing numbers of methylene groups between it and the chiral center. In the ^{1}H-NMR spectrum of **5a**, the difference in the chemical shifts for the Ha-2 group (0.01 ppm) was less than that for the H_3-10 group (0.08 ppm) (Fig. 3). Therefore it was determined that the C-9 position has two (*R* and *S*) configurations, while the C-3 carbon has only one. Since the $\Delta\delta$ values for the H_2-2 protons in both the (+)- and (−)-MTPA esters showed the same minus sign, the configuration of the C-3 position could be assigned as *R*. On the basis of the results obtained above, compound **5** was found to be a mixture of 3*R*9*R*- and 3*R*9*S*-dihydroxydecanoic acids, in a ratio of ca. 1:2.

The ^{1}H-NMR spectrum of **6** was quite similar to that of **5**, including signals due to two methines and one terminal methyl group. Its negative ion FAB-MS showed

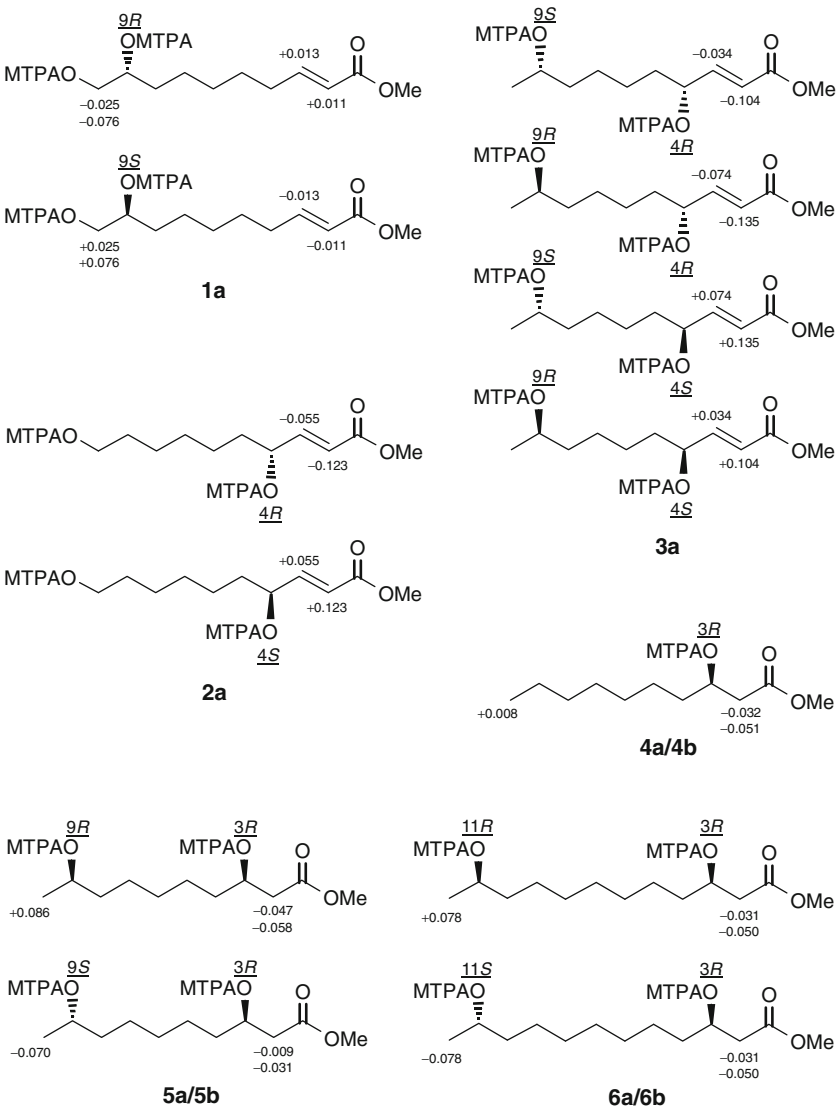


Fig. 4 $\Delta\delta$ values of ^{1}H-NMR chemical shift difference (ppm) for MTPA esters

an $[M-H]^-$ ion peak at *m/z* 231, which was 28 mass units more than that of **5**, while in the ^{13}C-NMR spectrum, two additional methylene signals were observed. From these findings, **6** was revealed to be 3,11-dihydroxydodecanoic acid. The absolute configurations of the two secondary hydroxy groups were determined in the same manner as described for **5**. With the $\Delta\delta$ values and signs of the diagnostic signals, similar to those of **5**, the C-3 position was determined to be the *R* configuration, while the C-11 carbon was found to have both forms (Fig. 4). Accordingly, **6** was identified as a mixture of the isomers, 3*R*11*R* and 3*R*11*S* in a ratio of 1:3.

Discussion

Seven hydroxy fatty acids were isolated in the pure state from the royal jelly of honeybees (*Apis mellifera*). Compounds **1**–**3** and **5** are the first hydroxy fatty acids isolated from royal jelly, although **5** has already been detected in human urine by Tserng et al. [8]. Compound **6**, was recently isolated from royal jelly, by Melliou and co-workers [9], however, the absolute configuration remains unclear. Similar to 9-HDA in royal jelly, the chiral acids obtained in this study are revealed to be mixtures of enantio- or diastereo-isomers (Fig. 4).

It should be noted that the absolute configurations of the secondary hydroxy groups located at C-3 of the chiral acids are all the *R* form, while those at positions C-4, C-9, and C-11 have both forms.

A recent study of the genome sequencing of the honeybee, *A. mellifera*, demonstrated that the species has more odorant receptors than other insects, such as *Drosophila melanogaster*, *Anopheles gambiae*, and *Bombyx mori*, indicating that the honeybee lifestyle involves enhanced pheromone communication [10].

Considering the above information together with the relationship between 9-ODA and 9-HDA, it is believed that the chiral acids isolated in the present study are precursors of unknown semiochemicals, and that their corresponding oxo-forms may play physiologically important functions and roles in the hierarchy of honeybee colonies. We are now synthesizing these oxo-derivatives in order to examine the biological activities of these compounds.

Acknowledgments The authors wish to thank Dr. K. Hashimoto, Institute for Bee Products & Health Science, for supplying the royal jelly. This study was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

A New Mechanism for Photo- and Radiation-Induced Decomposition of Sphingolipids

Alexandra G. Lisovskaya · Oleg I. Shadyro · Irina P. Edimecheva

Received: 2 October 2010 / Accepted: 10 November 2010 / Published online: 8 December 2010

Abstract Data have been obtained showing regularities in product formation following radiolysis of serinol, lysosphingomyelin and photolysis of *N*-(2-hydroxypropyl)hexanamide, sphingomyelin, which point to the possibility of photo- and radiation-induced destruction of the named substrates via a C–C bond rupture. The key stage of this process is the formation and decomposition of N-centered radicals generated from the starting compounds.

Introduction

Lipids are known to undergo various free-radical transformations on irradiation. Of these processes, the most extensively studied one is lipid peroxidation [1]. In cases of hydroxyl-containing lipids, such as cardiolipin and phosphatidylinositol, the radiation may induce free-radical fragmentation, in which the key stage is the decomposition of α-hydroxyl-containing carbon-centered radicals formed from the starting molecules [2, 3]. Unlike glycerophospholipids, the radiation-induced transformations of sphingolipids have been studied to a much less extent, and only sporadic publications on this issue can be found in the literature. At the same time, sphingolipids, the structural components of which are sphingosine bases, represent one of the most diversified kinds of lipids, as regards chemical structure and functional activity. They are indispensable components of cell membranes and therefore play an important role in biosystem functioning. In plasmatic membranes of mammals, the major part of sphingolipids is localized, together with cholesterol, in definite areas of biomolecules, usually named "lipid rafts" [4]. The "lipid rafts" containing high concentrations of sphingomyelin (CerPCho) are believed to have the potential to accumulate significant amounts of CerPCho, which leads to the formation of high local concentrations of ceramide, an important participant in apoptosis processes [5]. Lysosphingolipids, such as lysosphingomyelin (SPPtdCho) and sphingosine-1-phosphate, are regarded as a new class of signaling molecules. They are formed during physiological and pathological processes and are responsible for activating various signaling cascades [6].

The aforesaid may serve as a serious motivation for studying photo- and radiation-induced transformations of sphingolipids.

Materials and Methods

Materials

In the present study, composition of the product mixtures formed on radiolysis of 2-aminoglycerol (serinol) or SPPtdCho was examined, as well as that of photolysis products of *N*-(2-hydroxypropyl)hexanamide (HPHA) and CerPCho. Structures of the compounds under study are shown in Fig. 1.

CerPCho from *Sigma* and serinol from *Aldrich* were used in the study. SPPtdCho was prepared by deacylation of CerPCho [7]. Synthesis of HPHA was performed according to a procedure based on acylation of amino alcohol with complex capric/*n*-butylcarbonic acid anhydride in a solvent system containing tetrahydrofuran and acetonitrile (1:2), with the addition of 15 μL of triethylamine per 10 mL of the mixture [8]. Structures of the synthesized compounds were confirmed by ^{1}H- and ^{13}C-NMR spectroscopy.

Preparation of Liposomes from Lipids

Multilayer liposomes were prepared by dispersing thin lipid films in phosphate buffer [9]. To do this, the solvent was removed on a rotor evaporator from solutions of the respective lipids in chloroform, and the film samples obtained were kept under a vacuum for at least 1 h to complete the process of solvent removal. To the lipid film thus obtained, a definite amount of phosphate buffer was added ($c = 0.05$ mol/L; pH 7.4), pre-deaerated by bubbling argon (99.9%) for 45 min. The mixture was shaken for 15 min on a Vortex mixer at 50 °C. The obtained multilayer liposomes were sonicated for 3 min at 24 kHz (50% vibration amplitude, cycling mode 0.3) on an ultrasound unit UP 200H. Lipid concentration in the liposomes was 2×10^{-2} mol/L.

Preparation of Solutions of the Compounds Under Study

Freshly twice-distilled water was used for preparation of 0.1 M aqueous solutions of serinol and HPHA. The necessary pH values of serinol solutions were achieved by adjusting with perchloric acid or sodium hydroxide. Oxygen was removed from the solutions obtained by bubbling argon through them for 45 min.

Irradiation of Samples

The prepared samples were irradiated on a γ-unit equipped with ^{60}Co source; the dose rate was 0.45 ± 0.1 Gy/s. The absorbed dose range for serinol solutions and SPPtdCho liposomes was 0.54–2.70 kGy.

CerPCho dispersions and HPHA solutions were irradiated with a continuous spectrum of a high pressure mercury arc lamp (DRT-100). The sample distance from the source was 20 cm. The dose rate in the wavelength range

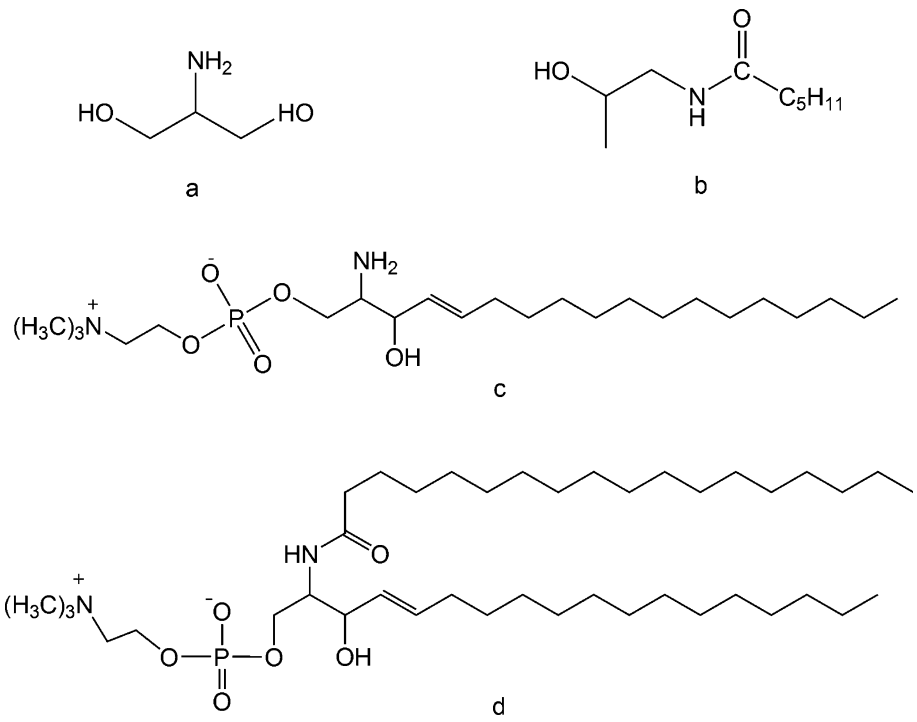

Fig. 1 Structures of the compounds studied, **a** serinol; **b** *N*-(2-hydroxypropyl) hexanamide (HPHA); **c** lysosphingomyelin (SPPtdCho); **d** sphingomyelin (CerPCho)

230–320 nm was 6.8×10^{15} photons s^{-1} mL^{-1}. The irradiation period for HPHA was varied from 10 to 100 min, and that for CerPCho liposomes was 15–160 min.

LC Analysis of Ammonia in Serinol Solutions

The ammonia content of serinol solutions was determined by means of the liquid chromatography technique as described in [10] using sodium citrate buffer pH 10.1 as eluent.

HPLC Analysis of Carbonyl-Containing Products

Analysis of carbonyl-containing products (formaldehyde, acetaldehyde, glycolic aldehyde, β-hydroxypropionic aldehyde, hydroxyacetone) formed on radiolysis or photolysis of the substrates being studied was carried out, after derivatization of the named compounds with 2,4-dinitrophenylhydrazine, by means of the high performance liquid chromatography technique using a Shimadzu LC-10AD_{VP} instrument equipped with a UV detector. The chromatographic conditions were as follows: NUCLEOSIL 120-5 C_{18} column (length 250 mm, ID 4 mm); eluent: methanol/water (60:40); eluent flow rate: 0.6 mL/min; temperature: 37 °C; detection wavelength 360 nm; injection volume: 4 μL.

GC–MS Analysis of Radiolysis Products Formed from Lipid Liposomes

2-Hexadecenal, stearamide and hydrocarbon contents of irradiated lipid liposomes were determined using the chromatography-mass spectrometry technique on a Shimadzu GCMS-QP2010 instrument (electron impact at 70 eV; ion source temperature 250 °C). The products were separated on an Equity™-5 capillary column (30 m, 0.25 mm ID, 025 μm thickness of the liquid phase layer). The GC oven temperature was increased from 60 to 280 °C at a rate of 5 °C/min. The samples were extracted from the liposomes with methanol.

Radiation-chemical yields of formation for the respective products were calculated from the data on radiolysis product accumulation as function of the dose absorbed. The figures given the tables are average values from at least three measurements. Within the absorbed dose range used, concentrations of radiolysis products increased linearly with the irradiation dose.

Results

The parent compound for sphingolipids is sphingosine, which contains a 2-aminoglycerol moiety in its structure (Fig. 1a). For this reason, we investigated the composition and determined yields of the products formed on radiolysis of deaerated 0.1 M serinol solutions in water and deuterium oxide (D_2O) as function of the solution pH (Table 1). The data obtained show that the main radiolysis products of serinol are ammonia and various carbonyl-containing substances, which are formed on deamination and C–C destruction of the starting compound. The yields of these products are significantly affected by pH of the starting solutions, as well as by replacement of H_2O by D_2O.

Radiolysis of aqueous SPPtdCho dispersions (Fig. 1c) results in formation of compounds with lower molecular mass than that of the starting substrate. Using the GC–MS method, we have detected 2-hexadecenal among radiolysis products formed in 0.02 M aqueous SPPtdCho dispersions. Figure 2 shows the mass spectrum of a product present in the reaction mixture obtained after radiolysis of SPPtdCho. The spectrum is consistent with the structure of 2-hexadecenal, an unsaturated C_{16} aldehyde [11].

Accumulation of 2-hexadecenal proceeds proportionally to the dose absorbed (Fig. 3). This fact indicates that the named compound is a primary product of SPPtdCho radiolysis.

Table 1 Radiation-chemical yields (G, molecule/100 eV) of product formation on radiolysis of deaerated 0.1 M serinol solutions in water and D_2O as function of pH

Products	G, molecule/100 eV	
	pH 7.0	pH 11.0
NH_3	2.94 ± 0.05	3.03 ± 0.12
$HOCH_2CH_2CHO$	(0.82 ± 0.06)/(1.54 ± 0.04)	(0.54 ± 0.04)/(0.24 ± 0.05)
$HOCH_2C(O)CH_3$	(0.03 ± 0.01)/–	(0.23 ± 0.01)/(0.01 ± 0.01)
CH_2O	(0.20 ± 0.03)/(0.05 ± 0.03)	(0.40 ± 0.06)/(0.14 ± 0.04)[a]
CH_3CHO	(0.04 ± 0.01)/(0.02 ± 0.01)	(0.29 ± 0.05)/(0.05 ± 0.02)
$HOCH_2CHO$	(0.05 ± 0.04)/(0.01 ± 0.02)	(0.36 ± 0.03)/(0.03 ± 0.01)

[a] The formaldehyde yield value given in the Table at pH 11.0 may be lower than the actual one since formaldehyde at alkaline pH values can undergo condensation reactions

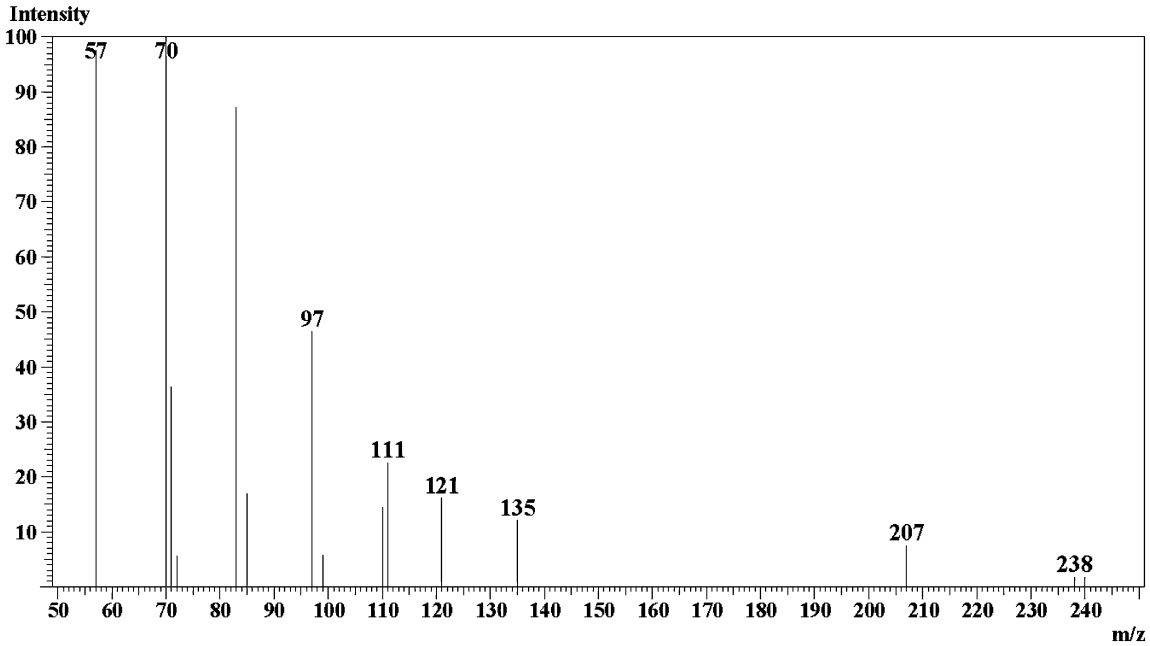

Fig. 2 Mass spectrum of 2-hexadecenal present in irradiated SPPtdCho dispersions

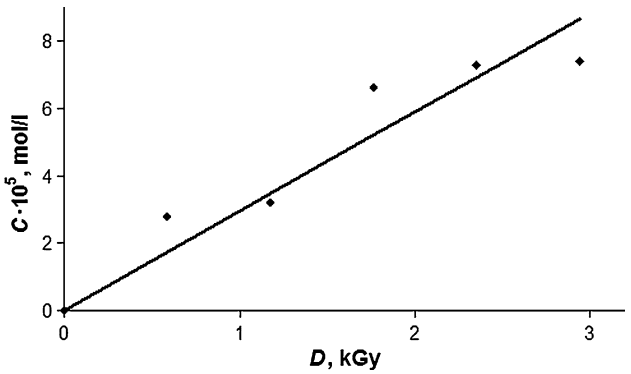

Fig. 3 Accumulation of 2-hexadecenal on irradiation of aqueous SPPtdCho dispersions ($c = 0.02$ mol/L, pH 7.4) as function of dose absorbed

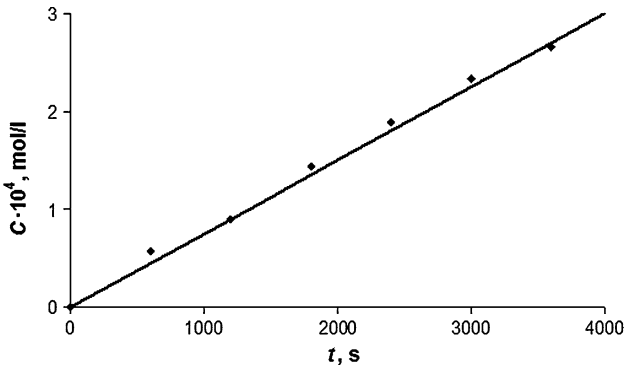

Fig. 4 Accumulation of acetaldehyde in UV-irradiated 0.1 M HPHA solutions as function of irradiation time

The radiation-chemical yield of 2-hexadecenal calculated from the data shown in Fig. 3 for 0.02 M aqueous SPPtdCho dispersions amounted to 0.22 ± 0.04 molecule/100 eV.

Furthermore, photolysis of 0.1 M HPHA solutions and 0.02 M CerPCho dispersions were performed in this study. Thereafter, composition of the product mixtures was examined and quantum yields determined for the respective photolysis products.

On photolysis of deaerated aqueous 0.1 M HPHA solutions, we have detected pentane and acetaldehyde. Accumulation of the latter occurred in direct proportion to UV irradiation time (Fig. 4).

Photolysis of deaerated aqueous 0.02 M CerPCho dispersions results in formation of the corresponding hydrocarbons and 2-hexadecenal.

Quantum yields of the photolysis products obtained after UV-irradiation of HPHA and CerPCho are presented in Table 2.

Along with the CerPCho destruction products formed via C–C bond cleavage, we have also detected stearamide, a deamidation product of the starting substance (Table 2).

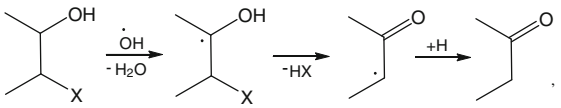
Discussion

A characteristic feature of the chemistry of free radicals generated from bi- and polyfunctional organic compounds

Table 2 Quantum yields of formation (Φ, molecule/photon) of photolysis products for the compounds under study

Starting substances	Photolysis products	Φ, molecule/photon
Deaerated aqueous 0.1 M HPHA solution	Acetaldehyde	1.5×10^{-3}
	Pentane	3.2×10^{-4}
Deaerated aqueous 0.02 M CerPCho dispersions	2-Hexadecenal	3.5×10^{-4}
	Stearamide	5.3×10^{-5}
	Hydrocarbons	4.4×10^{-5}

is their tendency towards decomposition via the stage involving formation of carbon-centered radicals according to the following scheme [12]:

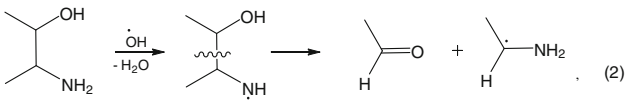


X= OH, NH_2, OR, OCOR (1)

Realization of reaction (1) on the radiolysis of serinol results in the formation of ammonia and 3-hydroxypropionic aldehyde. Based on the yields obtained for ammonia, one can conclude that the radiation-induced deamination is the prevailing process in the case of serinol. Radiation-induced deamination of serinol is accompanied by the formation of hydroxyacetone and 3-hydroxypropanal. This fact suggests the possibility of ammonia elimination by two pathways, and the pH of the starting solution appears to have a deciding influence on the probability of their realization.

At the same time, the probability of product formation via rupture of C–C bonds in serinol molecules appears to be quite high, especially in alkaline media.

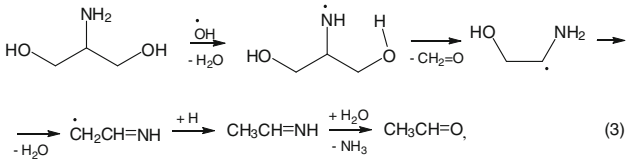
It has been shown while studying radiolysis of amino alcohols and diamines [12] that the radiation-induced destruction of amino-containing bifunctional compounds proceeds according to a mechanism shown below:



(2)

The probability of reaction (2) being realized should increase in alkaline media, where the amino group is deprotonated, making the abstraction of a hydrogen atom from it by the electrophilic ·OH radical easier. Indeed, the yields of serinol breakdown products such as formaldehyde, acetaldehyde and glycolic aldehyde increase significantly when changing to alkaline solutions. The probability of forming nitrogen-centered radicals should decrease if the radiolysis is performed in D_2O, because the amino group will be deuterated in this case, and abstraction of deuterium requires more energy.

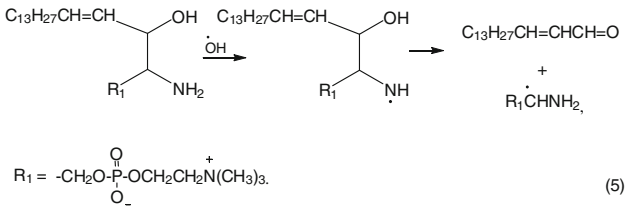
The facts established in this study allow the following schemes to be proposed for the product formation resulting from the destruction occurring on radiolysis of serinol:



(3)

(4)

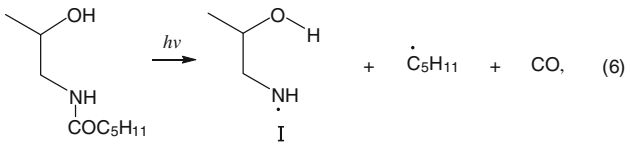
The attack of the ·OH radical formed on radiolysis of water on the amino group of SPPtdCho should also induce destruction of the latter involving cleavage of the C–C bond:



(5)

Identification of 2-hexadecenal among the products formed on the radiolysis of SPPtdCho may serve as a confirmation for the process of radiation-induced C–C destruction being realized with the starting substance.

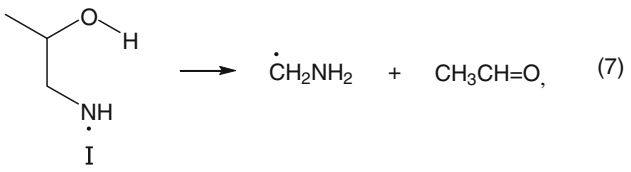
Unlike substances belonging to the amino alcohol class, their amide analogues absorb UV radiation. This leads to their destruction according to the Norrish type I scheme, which, in the case of HPHA, can be represented in the following way:



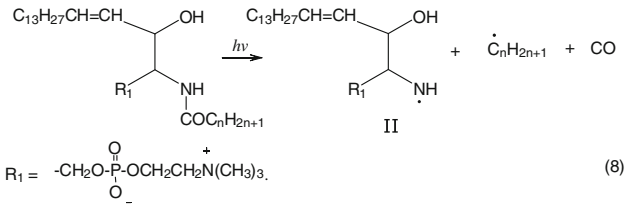
(6)

Realization of photochemical reaction (6) should lead to the generation of aminyl radicals (I), and hence to the appearance of products resulting from their subsequent destruction via C–C bond rupture.

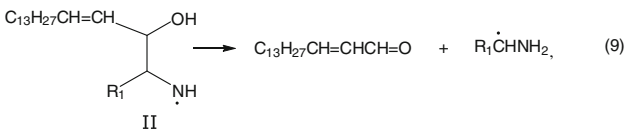
Indeed (see Table 2), among the photolysis products of HPHA, we have identified pentane, evidencing realization of the Norrish destruction (6), as well as acetaldehyde. Formation of the latter is possible due to C–C destruction of the species I:



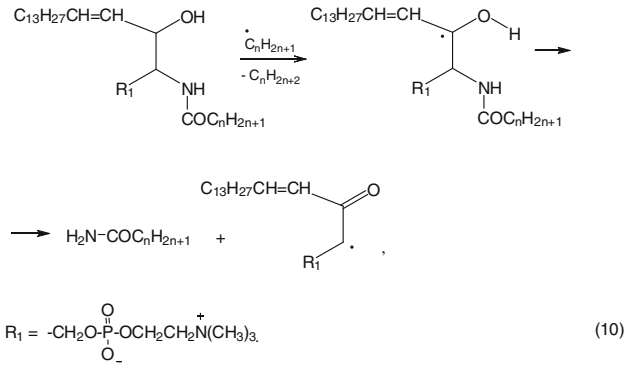
The established fact of photo-decomposition of CerP-Cho, due to the biological importance of this substance, is of particular interest. After photon absorption, CerPCho will undergo the Norrish type I decomposition:



Subsequently, the nitrogen-centered radicals II should decompose to form 2-hexadecenal:



The alkyl radicals formed according to reaction (8) are capable of abstracting an H atom from the starting molecule and initiating the deamidation process, as described in [13].



Analysis of the reaction mixture obtained after photo-induced destruction of CerPCho (see Table 2) revealed the presence of 2-hexadecenal, stearamide and hydrocarbons, which may serve as confirmation for the reactions (8–10) taking place.

Thus, the data presented in this paper point to the realization of γ- and UV-induced fragmentation of sphingolipids involving C–C bond cleavage, which has not been described previously.

In Vitro Intestinal Bioaccessibility of Alkylglycerols Versus Triacylglycerols as Vehicles of Butyric Acid

Diana Martín · María I. Morán-Valero · Francisco J. Señoráns · Guillermo Reglero · Carlos F. Torres

Received: 30 August 2010 / Accepted: 17 December 2010 / Published online: 12 January 2011

Abstract Butyric acid has been the subject of much attention last years due to its bioactivity. However, the potential advantages of butyrate are limited by the problem to reach enough plasma concentrations; therefore, pro-drugs have been proposed as an alternative to natural butyrate. A comparative study on in vitro intestinal digestion of 2,3-dibutyroil-1-*O*-octadecyl glycerol (D-SCAKG) and tributyrin (TB), as potential pro-drugs of butyric acid, was performed. Aliquots were taken at different times of digestion for studying the extent and rate of hydrolysis of both substrates. The micellar phase (MP) and oily phase (OP) formed in the digestion media were separated and their composition in lipid products was analyzed. Initially, it was confirmed that the in vitro model reproduced physiological results by testing against olive oil as a standard lipid. The progress of in vitro intestinal digestion of D-SCAKG was slower than that of TB. TB hydrolyzed completely to butyric acid, whereas D-SCAKG mainly yielded 2-butyroil-1-*O*-octadecyl glycerol (M-SCAKG), followed by butyric acid and 1-*O*-octadecyl glycerol (AKG). The MP from both substrates mainly consisted of butyric acid. Minor levels of M-SCAKG and AKG were also found in the MP after hydrolysis of D-SCAKG, the M-SCAKG being mainly distributed in the OP. Therefore, D-SCAKG produced a stable form of esterified butyric acid as M-SCAKG after in vitro intestinal digestion, unlike TB. Additionally, such a product would integrate both bioactive compounds, butyric acid and alkylglycerol, within the same molecule. Free butyric acid and AKG would be also released, which are lipid products of interest as well.

Keywords Alkylglycerols · Butyric acid · Lipid digestion · Micellar phase · Structured lipids · Pro-drugs

Abbreviations

AKG	1-*O*-octadecyl glycerol
DAG	Diacylglycerol
DB	Dibutyrin
D-SCAKG	2,3-dibutyroil-1-*O*-octadecyl glycerol

Introduction

Butyric acid has been the subject of much attention over the last years due to its bioactivity. Besides having physiological role as the main metabolic fuel for colonocytes and control of colonic inflammation, butyrate seems to interfere with the pathogenesis of diverse cancers, such as colorectal cancer, hepatocarcinoma, leukemia, breast and

prostate cancer, by inhibiting cell proliferation or inducing apoptosis [1–5]. However, the potential application of butyrate as antitumor agent is limited by the problem to reach enough plasma concentrations required to exert its antiproliferative/differentiating actions. Moreover, it is rapidly metabolized, showing a short half-life [3, 6]. Therefore, there is a current interest on overcoming these drawbacks in order to allow its application as therapeutic agent. Pro-drugs, such tributyrin (TB), have been proposed as alternative of natural butyrate [3, 7].

Recently, structured triradylglycerols as potential vehicles of butyric acid in the form of alkylglycerols (2,3-dibutyroil-1-*O*-octadecyl glycerol; D-SCAKG) have been synthesized by Torres et al. [8] (Fig. 1). Besides butyrate, the own alkylglycerol backbone is of current interest by itself. Alkylglycerols, alkylglycerophospholipids and their derivatives, namely ether lipids, are membrane components and cellular signaling molecules. They have been related to antitumor, antineoplastic and cellular differentiation properties and increased immune responses. Furthermore, alkylacetylglycerols are precursors of the platelet-activating factor, which is biologically active phospholipid with diversity effects on cells and tissues [9–12]. Therefore, additionally to TB, the structured lipid in the form of D-SCAKG might have the double advantage of alkylglycerols as potential lipid vehicle of butyrate and the bioactivity of each individual compound, alkylglycerol and butyrate, within the same molecule.

One of the problems that arise is to elucidate which of these two lipids, alkylglycerols or triacylglycerols, would be more effectively transported and chemically stable in the plasma, diffuse through biological membranes, or show more effective intracellular metabolism and, specially, would be more bioaccessible during gastrointestinal digestion, as the first step before any other physiological action beyond colon or intestinal tissues.

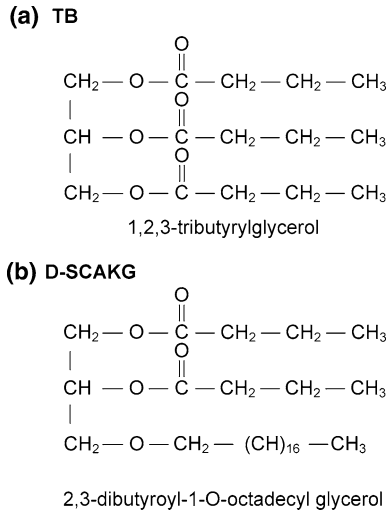

Fig. 1 Triradylglycerols sterified with butyric acid

In vitro intestinal models of lipid digestion are an interesting approach for obtaining preliminary and valuable information concerning digestion of lipid species. A huge diversity of in vitro intestinal models of lipid digestion can be found in the scientific literature trying to simulate pseudo-physiological conditions [13, 14]. However, the fact is that the composition of the reaction media used to be diverse concerning most variables, such as the ratio enzyme/substrate, bile salts/lecithin, the volume or time of reaction, the pH, or the composition and ionic strength of the used buffer. Since there is no standardized method, we considered that the selection of the model that closely simulate in vivo conditions was especially essential when performing in vitro lipid digestion of novel or unknown lipids, in order to accurately understand obtained results and to avoid misinterpretations due to the own used methodology.

The study of intestinal lipid digestion under in vitro conditions is frequently completed by the subsequent study of the different phases of the digestive media containing the released lipid products. During intestinal digestion of dietary fat, the intraluminal content has been shown to be structured as an oily phase (OP) dispersed in a micellar bile salt solution (MP) [15]. The OP mainly contains undigested triacylglycerols (TAG) and released diacylglycerols (DAG), whereas the MP contains bile salt and the poorly soluble end products of enzymatic hydrolysis, namely monoacylglycerols (MAG) and fatty acids, structured as mixed micelles, micelles, vesicles or emulsion droplets [13, 16]. Absorption of lipid products takes place supported by this MP, which enhances the transport of lipid products to enterocytes throughout the unstirred water layer close to the microvillus membrane, where they are absorbed [17]. The analysis of lipid products of these phases contributes to the study of bioaccessibility. The term bioaccessibility defined according to Fernandez-Garcia et al. [18], as the fraction of a compound that is released from its matrix in the gastrointestinal tract and thus becomes available for intestinal absorption. The intraluminal behavior of short-chain TAG during intestinal digestion is rather different. Thus, short-chain fatty acids released by pancreatic enzymes do not need to be included in the micellar structures, but they are easily solubilized in the aqueous media and the unstirred water layer close to enterocytes for absorption [17, 19]. On the other hand, to the best of our knowledge, previous information concerning the distribution of alkylglycerides, both free and esterified, within the intraluminal phases during intestinal digestion has not been previously reported. In fact, the general information on the process of intestinal absorption of alkylglycerides is scarce. Nevertheless, evidence that 1-*O*-alkyl-*sn*-glycerols derived

from dietary ether glycerolipids are completely absorbed by intestine without cleavage of the ether bond exists [20]. After reaching the targets, alkylglycerols were directly utilized to synthesize membrane alkylglycerolipids and plasmalogens, according to the normal metabolism described for this kind of lipids [20]. However, the exact mechanism of absorption is unknown.

The aim of the present research was to perform a comparative study about the intestinal digestion of TB and D-SCAKG under in vitro conditions, in order to show differences in the rate and extent of reaction, generation of lipid products and their potential bioaccessibility. Firstly, the in vitro intestinal digestion model was tested against a standard lipid, in order to be certain that the model reflected physiological intestinal lipid digestion and to reject that any artifact or the own conditions of the digestion method would not interfere with the results obtained for TB and D-SCAKG hydrolysis.

Materials and Methods

Reagents and Materials

The D-SCAKG was synthesized according to a methodology previously described by our group [8], TB (Ref. T8626) was purchased from Sigma-Aldrich Chemie GmbH (Steinheim, Germany) and olive oil as the standard lipid was from Inmaculada Murga Arenas (Toledo, Spain). Trizma (Ref. T1503), maleic acid (Ref. M0375), pancreatin (Ref. P1750), bile salts (Ref. B8756) and phosphatidyl choline from egg yolk (Ref. 61771) were purchased from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). Hydrochloric acid, sodium sulfate anhydrous, sodium chloride (Ref. 141659.1211), calcium chloride (Ref. 141221.1211) were from Panreac (Barcelona, Spain). *n*-Dodecane for synthesis was purchased from Merck (Darmstadt, Germany). All solvents used were of HPLC grade from Lab-Scan (Dublin, Ireland).

In Vitro Lipid Digestion

The in vitro lipid digestion model was based on Martin et al. [21]. Since this model was rather preliminary and basic, some improvements were performed in the present study, in order to reach closer physiological results by using the closest physiological conditions. Such modifications included the increase in the ratio enzyme/substrate, bile salts and phospholipids concentrations, the preemulsion of the substrate and the preparation of fresh pancreatic extract [13]. On the other hand, in our former method [21] and in many in vitro models of lipid digestion [13], the pH of the process used to be maintained to that physiological by continuous addition of NaOH to the reaction media. Since we detected non-physiological acyl migration of 2-MAG to 1-MAG in the presence of NaOH (36.7 and 80.0% of total MAG as 2-MAG in presence and absence of NaOH, respectively), the use of alkali was avoided and the ionic strength of the pH 7.5 buffer was increased instead. Under this condition, a physiological ratio 2-MAG to 1-MAG was kept and the pH of the media varied from 7.2 to 6.5, which was within the optimum and physiological range of pancreatic lipase activity [15, 22].

The final conditions of the amended in vitro digestion model will be described briefly. Sample (1 g) was mixed with 0.5 g of bile salts, 0.2 g of lecithin, 5 mM $CaCl_2$, 150 mM NaCl and 54 mL of Trizma-maleate buffer (0.1 M for olive oil and 1 M for TB and D-SCAKG) pH 7.5. The mixture was homogenized (Ultra-Turrax IKA T18) for 20 min at 7,000 rpm. The homogenized mixture was placed in a thermostatically controlled vessel (37°C) under continuous stirring by magnetic stir bar at 1,000 rpm. Simulation of intestinal digestion was started by addition of fresh pancreatin extract (1 g of pancreatin in 6 mL of Trizma-maleate buffer pH 7.5 stirred for 10 min and centrifuged at 1,600×*g* for 15 min). In order to study the evolution of lipid products throughout the hydrolytic process, aliquots (450 mg) were taken at 0, 2, 4, 10, 20, 30 and 60 min of reaction. In vitro digestion of each sample was performed in triplicate.

Separation of Phases After In Vitro Lipid Digestion

The digestion medium was submitted to centrifugation at 4,000 rpm, for 40 min, at 20°C (5810R Eppendorf Iberica, Madrid, Spain) according to Soler-Rivas et al. [23]. After centrifugation, an upper OP, a lower aqueous phase (MP) and a minor precipitated pellet were obtained. Aliquots (450 mg from the aqueous phase or 50 mg from the oily phase) were taken for studying their composition on lipid products.

Lipid Extraction

The total lipids from samples were extracted by 1,450 μL of hexane/methyl-*tert*-butyl ether (50:50, by vol) in polypropylene tubes of 2,000 μL. Furthermore, this medium was acidified by hydrochloric acid (150 mM) in order to stop the enzymatic reaction and to enhance the recovery of butyric acid in the case of TB and D-SCAKG digestions [24]. *n*-Dodecane (10 mg) was added as internal standard for analysis of TB and D-SCAKG lipid products. The mixture was vortexed for 1 min and centrifuged for 10 min at 15,000 rpm. Organic phase containing separated lipids was collected and anhydrous sodium sulfate was added before further analysis. A second lipid extraction

was performed on the remaining aqueous phase in the polypropylene tube in the case of olive oil.

Analysis of Lipid Products

Hydrolysis products of olive oil were determined by high-performance liquid chromatography (HPLC) according to Torres et al. [25] on a Kromasil silica 60 column (250 mm × 4.6 mm, Analisis Vinicos, Tomelloso, Spain) coupled to a CTO 10A VP 2 oven, a LC-10AD VP pump, a gradient module FCV-10AL VP, a DGU-14A degasser, and an evaporative light scattering detector (ELSD-LT) from Shimadzu (IZASA, Spain). The column temperature was maintained at 35°C. 20 µL of the diluted samples (4 mg/mL) were injected. Quantification was based on calibration curves performed with appropriate standards (Sigma-Aldrich Chemie GmbH, Steinheim, Germany).

Hydrolysis products of TB and D-SCAKG were determined according to Torres et al. [26] by gas chromatography (GC) (Hewlett-Packard 5890 series II) with on-column injection using a 7 m 5% phenyl methyl silicone capillary column (Quadrex Corporation, New Haven, CT, USA), 0.25 µm i.d. A deactivated column of 12 cm 530 µm i.d. was used as pre-column. Injector and detector temperature was 43 and 360°C, respectively. The temperature program was as follows: starting at 40°C and then heating to 250°C at 42°C min^{-1} with 10 min hold, followed by heating from 250 to 325°C at 7.5°C min^{-1} with 30 min hold. Helium was used as the carrier gas at a pressure of 5.2 psi. The peaks were computed using GC chemstation software (Agilent Technologies, Santa Clara, CA, USA) and quantified according to the internal standard.

Results

In Vitro Intestinal Digestion of the Standard Lipid

Previous to in vitro digestion of D-SCAKG and TB, we first tested the intestinal digestion model on a standard lipid, in order to be certain that the in vitro model reflected more physiological intestinal lipid digestion, and to reject that any artifact or the own conditions of the digestion method would not interfere with the results obtained for TB and D-SCAKG hydrolysis. Olive oil was chosen as the standard lipid because it is a well-known, simple, natural and abundant oil. As reference of physiological levels of lipid products after in vivo intestinal digestion, we considered the outstanding results reported by Hofmann and Borgstrom [15] in one of the first relevant and complete studies performed on the lipid composition of the intraluminal phase during fat digestion in man.

A huge diversity of in vitro intestinal models of lipid digestion can be found in the scientific literature trying to simulate pseudo-physiological conditions, the complexity of the composition of the media being diverse [13, 14]. In a first attempt, the in vitro lipid digestion of the standard lipid was performed under an in vitro model previously reported by ourselves on fish oils [21]. Since such a model was rather preliminary and basic, some improvements were performed in the present study, in order to reach closer physiological results by using the closest physiological conditions. Such modifications, and the final conditions of the amended in vitro digestion model, were those described in "Material and Methods". The yield in lipid products of the adapted method closely reflected those physiological previously found in the intraluminal phase in man during fat digestion [15] (Fig. 2a, c), so this model was used for simulating lipid digestion of D-SCAKG and TB under pseudo-physiological conditions.

In Vitro Intestinal Digestion of D-SCAKG and TB

The course of in vitro intestinal digestion of D-SCAKG and TB is shown in Fig. 3a, b, respectively. The progress of the in vitro intestinal digestion of the standard lipid has

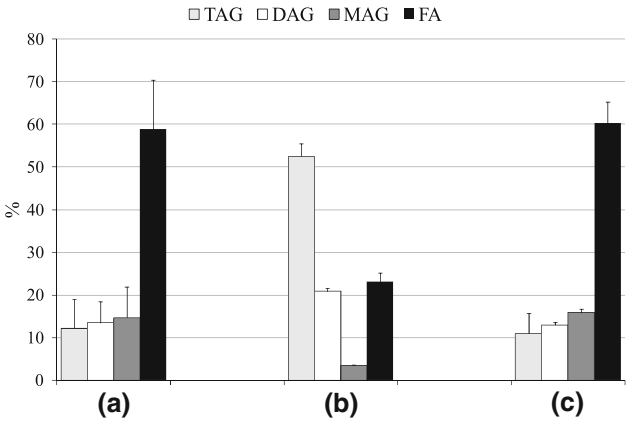

Fig. 2 Lipid products of **a** the in vivo intraluminal phase in man during fat digestion (adapted from Hofmann and Borgstrom [15]) (Mean of lipid products of samples taken from intraluminal content of five men during fat digestion at different collection interval and intestinal site.), **b** the in vitro intestinal digestion of olive oil following the method of Martin et al. [21] without modifications[2] (Mixture of 1 g of sample, 54 mL of 50 mM Trizma-maleate pH 7.5, 5 mM $CaCl_2$, 150 mM NaCl. Addition of fresh pancreatin solution (20 mg in 6 mL of Trizma-maleate buffer, 50 mg lecithin, 250 mg bile salts, stirred for 10 min). Continuous stirring at 37°C and continuous addition of NaOH 1 M to maintain pH at 7.5.) and **c** the in vitro intestinal digestion of olive oil after modification of the method of Martin et al. [21] (Homogenization of 1 g of sample, 54 mL of 100 mM Trizma-maleate pH 7.5, 5 mM $CaCl_2$, 150 mM NaCl, 200 mg lecithin, 500 mg bile salts. Addition of fresh pancreatin solution (1,000 mg in 6 mL of Trizma-maleate buffer, stirred for 10 min and centrifuged at 1,600×g 15 min). Continuous stirring at 37°C)

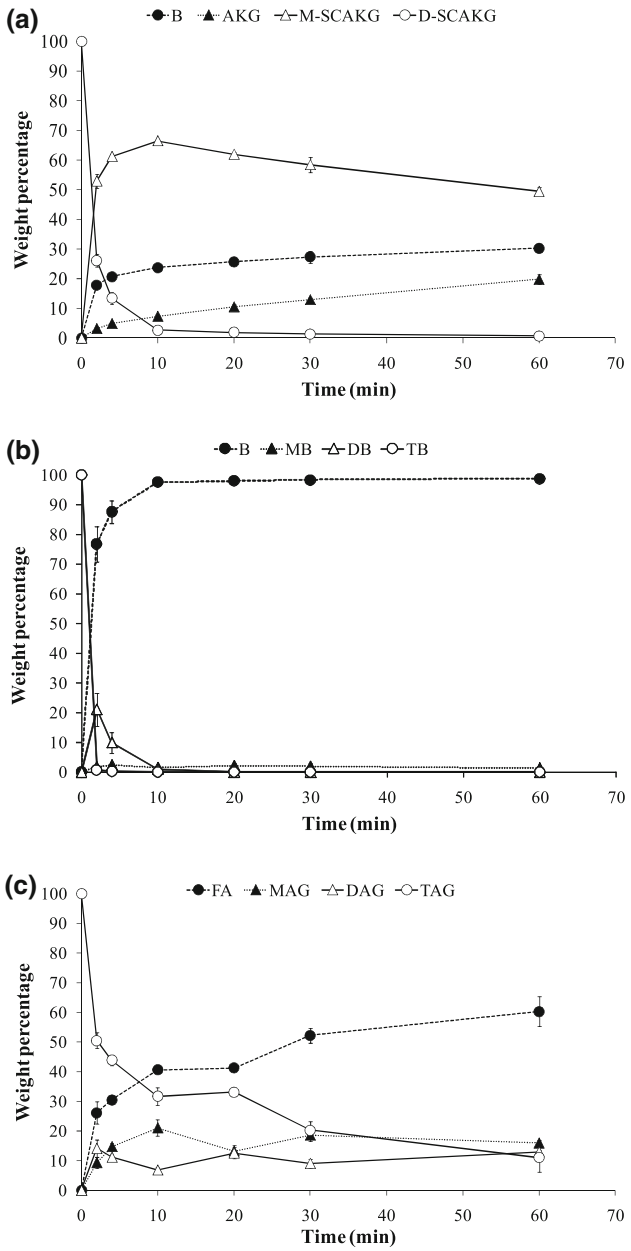

Fig. 3 Evolution of lipid products throughout in vitro intestinal digestion of **a** D-SCAKG, **b** TB and **c** olive oil. *D-SCAKG* 2,3-dibutyroil-1-*O*-octadecyl glycerol; *TB* tributyrin

been also included (Fig. 3c). Pancreatic enzymes effectively recognized the substrate D-SCAKG, but led to diverse differences on the course of hydrolysis respect to TB. The progress of in vitro intestinal digestion of D-SCAKG was slower than that of TB. An almost total hydrolysis of TB was detected just at 2 min of reaction (99.4%), whereas the extent of D-SCAKG hydrolysis was 73.9% at the same moment. After 20 min of in vitro intestinal digestion, the complete hydrolysis of TB and its derived glyceride products, namely dibutyrin (DB) and monobutyrin (MB), was reached, yielding butyric acid as the only final lipid product. In the case of alkylglycerols, the complete hydrolysis of D-SCAKG was also observed, but only after longer times of in vitro digestion (60 min), and yielding 2-butyroil-1-*O*-octadecyl glycerol (M-SCAKG) as the main lipid product, followed by butyric acid and 1-*O*-octadecylglycerol (AKG). Therefore, compared to MB, the released M-SCAKG was quite stable throughout the course of in vitro intestinal digestion, although a low, but progressive decrease after 10 min of reaction was observed. An additional in vitro digestion was performed for D-SCAKG beyond 60 min. After 240 min of in vitro digestion, the level of M-SCAKG was still 39.2%.

Lipid Composition of the Separated Phases After In Vitro Intestinal Digestion of D-SCAKG and TB

The lipid composition of the separated MP and OP after in vitro digestion of the standard lipid is shown in (Fig. 4a). Approximately, 94 and 6% of total lipids distributed in the MP and OP, respectively. The results obtained were in agreement with the lipid composition of the intraluminal phases during in vivo fat digestion in man [15].

The lipid composition of the separated MP and OP after in vitro digestion of D-SCAKG and TB is shown in Fig. 4b and c, respectively. Approximately, 40% of the total lipid products distributed in the MP in the case of the hydrolysis of D-SCAKG. Such MP mainly consisted of butyric acid and minor proportions of M-SCAKG and AKG. The remaining 60% of total lipid products from hydrolyzed D-SACKG distributed in the OP, the M-SCAKG being its major component. Concerning AKG, this lipid product seemed to be distributed in both MP and OP. Similar to D-SCAKG, the total butyric acid from hydrolyzed TB was found in the MP (Fig. 4c). Due to the complete hydrolysis of glycerides species from TB, there was no separation of OP [14].

Discussion

The course of in vitro intestinal digestion of TB observed in the present assay was in agreement with the classic described process of gastrointestinal digestion of short-chain TAG. These kinds of lipids are rapidly and completely hydrolyzed to fatty acids and glycerol by digestive enzymes, such as the *sn*-1,3 specific gastric lipase and pancreatic lipase, whereas long-chain TAG are mainly hydrolyzed by the *sn*-1,3 specific pancreatic lipase to yield 1,2-DAG, which is later on hydrolyzed to fatty acid and 2-MAG [27, 28]. Taking into account the specificity of digestive enzymes to *sn*-1,3 locations, the complete hydrolysis of short-chain TAG has been explained in most

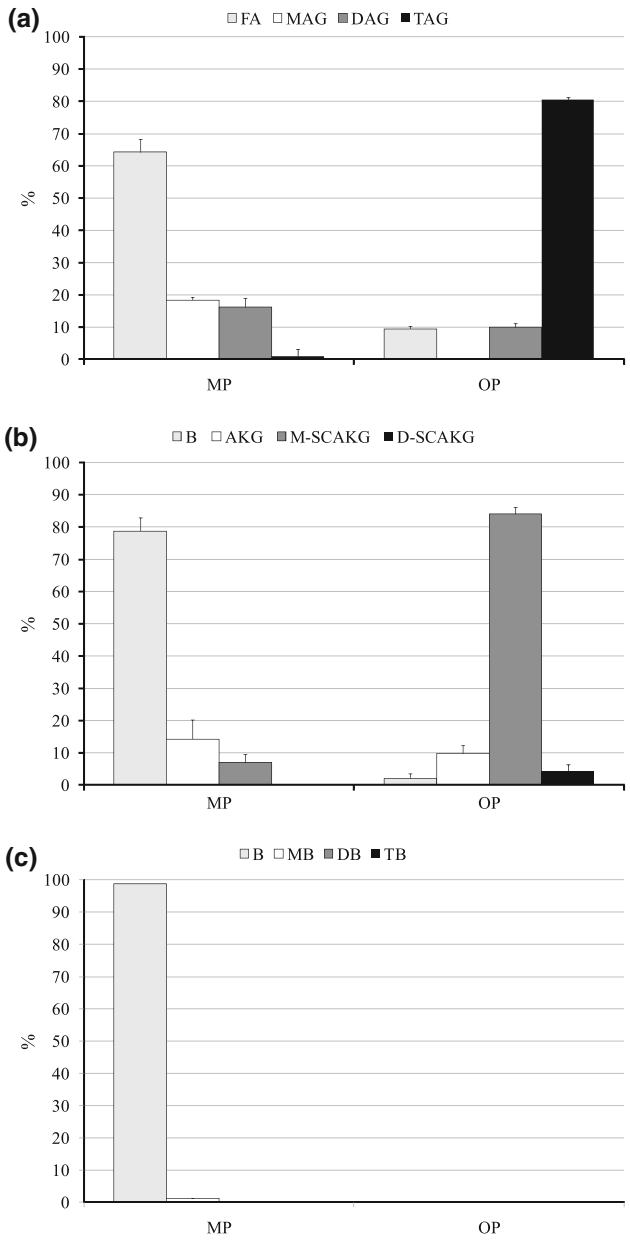

Fig. 4 Lipid composition of the MP and OP after in vitro intestinal digestion of **a** olive oil, **b** D-SCAKG and **c** TB. *D-SCAKG* 2,3-dibutyroil-1-*O*-octadecyl glycerol); *TB* tributyrin

studies by acyl migration phenomena. Thus, the formed 1,2-DAG or 2-MAG rapidly isomerizes to outer positions to give 1,3-DAG or 1-MAG, where the 1,3 specific pancreatic lipase acts, yielding fatty acids and glycerol [29].

Despite the gastric phase of lipid digestion was not being included in the in vitro model, it should be pointed out that the action of gastric lipase, previous to the hydrolysis by pancreatic lipase, might contribute to the overall hydrolysis of short-chain lipids, both TB and D-SCAKG. This is because gastric lipase shows a higher activity on short-chain lipids compared to longer fatty acids [27–29]. Further studies with a more complex in vitro model including simulation of the gastric phase of lipid digestion would contribute to the knowledge of the digestion of these molecules.

In the case of M-SCAKG, the progressive decrease observed after 10 min of in vitro intestinal digestion (Fig. 3a) might suggest that acyl migration of esterified butyric acid from the *sn*-2 to the *sn*-3 location could also take place, but after longer times and at slower rate than MB. Furthermore, the disappearance of M-SCAKG did not begin until the hydrolysis of D-SCAKG was almost complete, whereas the disappearance of MB was simultaneous to the hydrolysis of TB (Fig. 3b). This different course of hydrolysis/acyl migration between M-SCAKG and MB during in vitro intestinal digestion might be due to the own structure of the alkylglycerol backbone, in which the *sn*-1 location is not available due to the etherified octadecyl alcohol, and the *sn*-3 outer position of the M-SCAKG being the only chance of acylmigration for internal butyric acid. The proposed mechanism of acylmigration for explaining the hydrolysis of D-SCAKG is illustrated in Fig. 5, compared to the normal hydrolysis process of TB. Other reasons related to the own etherified alkyl chain, the hydrophobicity of the whole molecule or the steric structure, might influence the interaction of the enzyme with alkylglycerols and explain the different course of reaction respect to TB [30, 31].

Previous information concerning catalyzed-hydrolysis of alkylglycerols by pancreatic lipase is scarce. A lower rate of hydrolysis for long-chain PUFA diesterified alkylglycerols compared to the analogous TAG by pancreatic lipase was reported by Endo et al. [31], in agreement with the results obtained. Similarly, a resistance to pancreatic lipase of diacyl glyceryl ethers isolated form the muscle of the fish *Stromateus stellatus* was found by Sato et al. [32]. On the other hand, the lipase-catalyzed ethanolysis of the same substrates of the present study was previously performed by Vazquez et al. [33]. Despite this, such a trial was carried out in a simple non-aqueous media, unlike the aqueous and more complex media of the present study, these authors reported differences in the course of reactions of D-SCAKG and TB similar to those observed in the present study. Thus, the rate of lipase-catalyzed ethanolysis of D-SCAKG by lipase B from *Candida antarctica* was lower than that of TB, the ethanolysis of TB was more complete, the M-SCAKG was the major product from D-SCAKG and the level of this lipid product kept almost constant during the course of reaction.

Regardless of the specific mechanism of in vitro intestinal digestion of D-SCAKG, the observed differences in the present study between TB and D-SCAKG, in the course of hydrolysis and levels of lipid products, showed interesting implications. One of the problems of the application of butyrate as an antitumor agent is due to the limitation of

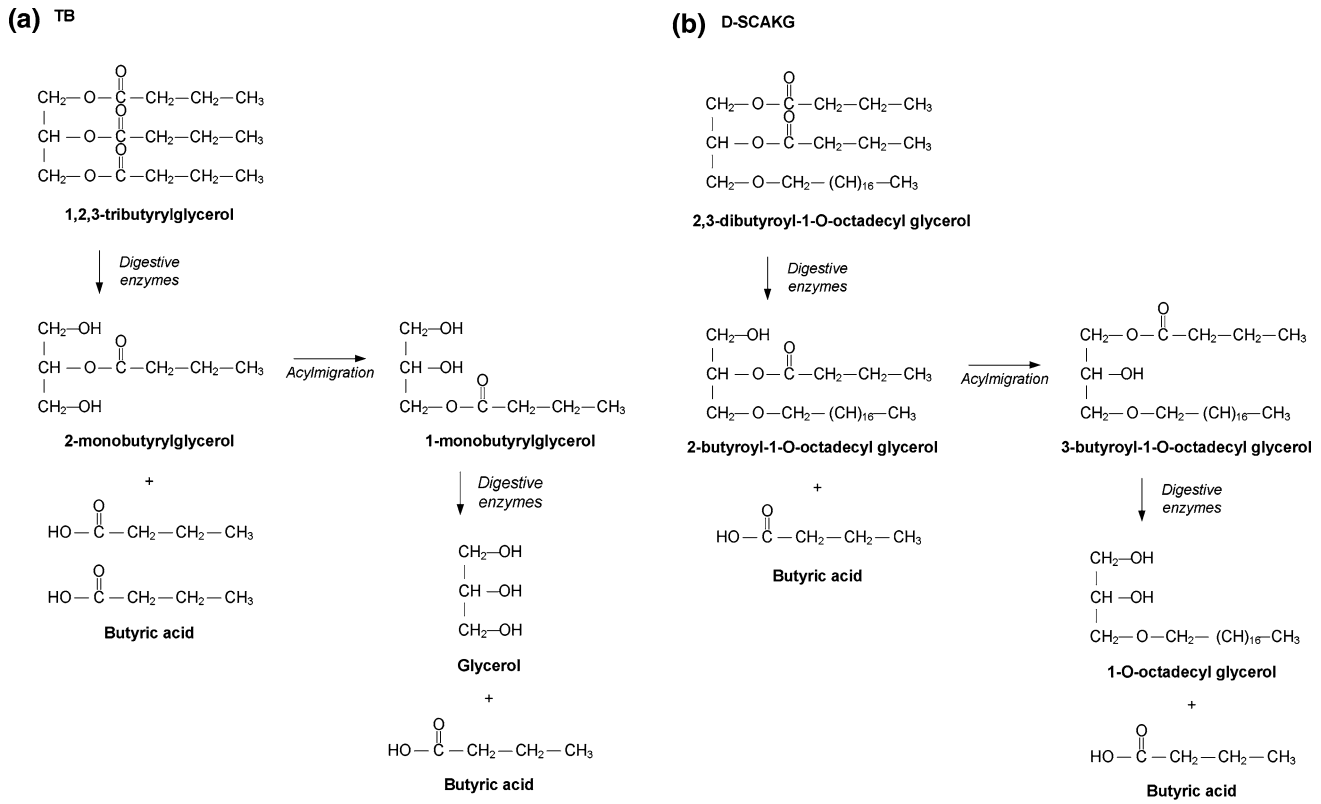

Fig. 5 Hydrolysis and released lipid products of triradylglycerols of butyric acid by digestive enzymes (proposed mechanism in the case of D-SCAKG). *TB* tributyrin; *D-SCAKG* 2,3-dibutyroil-1-*O*-octadecyl glycerol

reaching the enough plasma concentrations required to exert its antiproliferative/differentiating actions [3, 6]. This is because the normal metabolism of short-chain fatty acids inside enterocytes after absorption is the local use as a fuel for the enterocytes or their transport to the liver by the portal bloodstream, whereas only trace amounts enter the general blood circulation and they are rapidly oxidized in peripheral tissues where they arrive there [28, 34]. Diverse studies have successfully evidenced higher levels of butyrate in peripheral tissues after administration in the form of TB [35, 36], but the problem of the extremely short half-life of butyrate in plasma remained [28]. Efficient prodrugs of butyrate should have a sufficiently stable bond between the carrier and the drug molecule to increase its in vivo half-life [1]. The experimental D-SCAKG assayed in the present study showed such behavior during in vitro lipase-catalyzed hydrolysis, since most butyric acid remained esterified in the *sn*-2 location throughout digestion as M-SCAKG, unlike the analogous MB.

On the other hand, alkylglycerols are of interest by themselves due to their own functional properties [9–11]. Therefore, in addition to TB, the structured lipid in the form of D-SCAKG would have the double advantage of alkylglycerols as a potential lipid vehicle for butyrate and the bioactivity of each individual compound, alkylglycerol and butyrate, within the same molecule. Furthermore, the released AKG after in vitro intestinal digestion of D-SCAKG would be another option to take advantage of the bioactivity of alkylglycerols, this product being minor at initial times of digestion (3.2% at 2 min) but progressively increasing up to 19.8% at 60 min or 33.0% at 240 min of enzyme-catalyzed intestinal digestion.

Therefore, the present study showed that, after in vitro intestinal digestion of D-SCAKG, diverse potential bioactive products might be obtained, namely butyric acid, esterified butyric acid, mono-esterified alkylglycerol and non-esterified alkylglycerol, the proportion of each product being different at short-term or long-term times of digestion. Despite the interest in these molecules beyond the intestinal tract, it should be pointed out that, some of these breakdown metabolites might be of interest within the intestinal tract. Most of them might contribute to the intraluminal level of butyrate, with the importance of its implication as one of the main metabolic fuels for colonocytes, and interfere with the control of colonic inflammation or the pathogenesis of colorectal cancer [27, 28]. On the other hand, esterified butyrate with AKG, or the simultaneous presence of both lipid products as individual metabolites, might be evaluated on the bioactivity of these molecules within the intestinal tract.

Concerning the distribution of lipids products in the different phases of the digestion medium, the findings of the present study showed that the major hydrolysis product, namely M-SCAKG, was mainly distributed in the OP (Fig. 4b). This result might be partially explained by the poor solubility of this molecule in the micellar structures, related to the etherified octadecyl alcohol of the alkylglycerol moiety. It has been found that long-chain saturated fatty acids, either free or esterified, are poorly absorbed, because these fatty acids and their MAG are poorly solubilized in mixed micelles, and show a strong tendency to form insoluble calcium soaps at the alkaline pH of intestine [17, 37, 38]. Nevertheless, it has been shown that the absorption of insolubilized lipids might be increased when fed together with unsaturated fatty acids. This is because the inclusion in MP seems to be enhanced when micelles are expanded by the incorporation of MAG and fatty acids of unsaturated nature [13, 38]. This premise might be also considered for alkylglycerols. Thus, it could be hypothesized that the co-administration of D-SCAKG and unsaturated fats might enhance the incorporation of released M-SCAKG into micelles. In fact, this might be the likely situation in a real meal in which fats of diverse nature and saturation degree use to be ingested together. To the best of our knowledge, information concerning the distribution of alkylglycerides, both free and esterified, within the intraluminal phases during intestinal digestion has not been previously reported. In fact, the general information of the process of intestinal absorption of alkylglycerides is scarce. Nevertheless, there is evidence that 1-*O*-alkyl-*sn*-glycerols derived from dietary ether glycerolipids are completely absorbed by the intestine [20]. However, the exact mechanism of absorption is unknown. As example of effective absorption of alkylglycerols in rodents and human, Das et al. [20] showed that alkylglycerols liberated from dietary ether lipids in the lumen are readily absorbed without cleavage of the ether bond, transported to the liver and other organs, where they were directly utilized to synthesize membrane alkylglycerolipids and plasmalogens.

Concerning AKG, this lipid product seemed to be distributed in both MP and OP, regardless of the presence of octadecyl alcohol (Fig. 4b). The lack of esterified butyric acid might lead to a higher polarity of this molecule with respect to M-SCAKG, in which both esterified butyric acid and etherified octadecyl alcohol might contribute to the lower polarity of the whole molecule.

In conclusion, the present study showed that the structured lipid 2,3-dibutyroil-1-*O*-octadecyl glycerol might be proposed as a potential vehicle of butyrate, since it produced a stable esterified form of butyric acid as 2-butyroil-1-*O*-octadecyl glycerol after simulation of intestinal lipid digestion. In contrast, the analogous TB, was completely hydrolyzed to butyric acid. Furthermore, structured alkylglycerols would have additional properties, since they might integrate two bioactive compounds, alkylglycerol and butyrate, within the same molecule. Their own alkylglycerol backbone would be a third bioactive lipid product released after hydrolysis catalyzed by pancreatic enzymes.

Further in vivo studies concerning the potential of structured alkylglycerol as a pro-drug of butyrate are worthwhile, in order to elucidate whether these compounds, especially 2-butyroil-1-*O*-octadecyl glycerol, would be effectively absorbed, reach the plasma at high enough bioactive concentrations, would show an adequate half-life or if interactions on bioactivity between alkylglycerol and butyric acid exist. Specially, the bioaccessibility of lipid products containing the alkylglycerol moiety should be studied in depth, since the present research showed a limitation of their inclusion within the bioaccessible micellar structures. Whether this finding was a result of the sole presence of alkylglycerol in the digestion medium, and if the co-administration with fat of a different saturation degree would improve the bioaccessibility of lipid products, needs to be examined.

Acknowledgments The work was supported by the Ministerio de Ciencia e Innovacion, Spain (AGL2006-02031/ALI and AGL2008-05655) and the Community of Madrid, Spain (ALIBIRD-CM S-2009/AGR-1469). Received: 2 May 2010 / Accepted: 19 October 2010 / Published online: 13 November 2010

Abstract Prostate cancer is the second leading cause of male deaths due to cancer in the United States. Hydrogenated vegetable oils have been suspected of inducing adverse health effects, including atherosclerosis and cancer. Here we report that a selectively hydrogenated soybean oil (SHSO) containing a high quantity of conjugated linoleic acids showed remarkably strong anticarcinogenic activity against prostate cancer in the rat model (Copenhagen rats with MAT-LyLu syngeneic rat prostate cancer cells) study in vivo and human prostate carcinoma cell lines studies in vitro, as compared with native soybean oil. A 5% dietary supplementation with SHSO inhibited the growth of prostate cancer by 80% in vivo. The TUNEL method and immunohistochemical staining assays of bax, bcl-2, and survivin clearly showed that SHSO induced prostate cancer cell apoptosis in the tested rats. DNA fragmentation analysis in vitro further confirmed the apoptotic activity of SHSO on the MAT-LyLu prostate cancer cells. The SHSO also showed strong cytotoxicity on human prostate cancer cells (DU145 and PC3). This represents the first report demonstrating the significant anticancer activities of hydrogenated vegetable oils at low levels of dietary supplementation.

TUNEL	Terminal deoxynucleotidyl transferase dUTP nick end labeling
MTT assay	Method of transcriptional and translational assay

Introduction

Prostate cancer is the second leading cause of male deaths due to cancer in the United States. Each year roughly 230,000 men are diagnosed with prostate cancer in the United States, with more than 30,000 deaths occurring [1]. Various environmental factors appear to influence the development and progression of prostate cancer. It has been generally accepted that the dietary amount of fat is the strongest environmental factor.

Hydrogenated vegetable oils are widely consumed worldwide in foods such as salad and cooking oils, margarines, shortenings and confectionery fats. The health effects of hydrogenated vegetable oils have been studied extensively [2, 3], with the previous studies showing their adverse effects on health such as hypercholesterolemia, atherogenesis and coronary heart disease. The hydrogenated vegetable oils have been also suspected to be related with cancer development [4–6]. Their reputations

for negative effects on health are mainly attributable to their high contents of *trans*-fatty acids and saturated fatty acids. The fatty acid composition of hydrogenated vegetable oils can be manipulated by controlling the hydrogenation conditions. We originally reported that an exceptionally high level of conjugated linoleic acids (CLA), which are beneficial functional compounds, can be formed during commercially selective hydrogenation of soybean oil, and that the quantity of CLA (98–230 mg/g oil) in the selectively hydrogenated soybean oil (SHSO) was the highest ever reported in foods [7–9]. CLA have been recognized for their ability to inhibit carcinogenesis in multiple systems at several levels, including initiation [10–13], promotion [14, 15], and progression [16] and metastasis [17, 18]. Other physiological benefits of CLA include a reduction in the severity of atherosclerosis [19, 20], improvement in glucose tolerance [21, 22], and reduction in body fat [22–26]. The major dietary source of CLA was ruminant animal meats and dairy product, which contain small quantities of CLA (4–7 mg/g oil) [9, 27]. Thus, normal food lipids containing CLA have not been used in tumorigenesis studies because their low concentration of CLA have prevented them from being added directly to experimental diets. The CLA used in the previous researches were obtained by the alkali-induced isomerization of linoleic acid. This isomerization induces almost exclusively two isomers (*cis*-9 *trans*-11- and *trans*-10 *cis*-12-) along with small portions of other minor isomers [28]. Most studies have focused on the functionalities of these two isomers. The composition of CLA isomers in SHSO differs greatly from that produced by alkali isomerization. Twenty-one different CLA isomers in a triacylglycerol form were found in SHSO, as determined by a combination of silver ion-impregnated HPLC and a GC-ion impacted mass spectrometry of DMOX derivatives of the CLA isomers [9, 31]. The individual CLA isomers reportedly have different activity on their biological functionalities [22, 24, 25, 29, 30]. Currently, the activities of most of the CLA isomers present in SHSO are not clearly defined. Moreover, although it has been reported that SHSO contains a high level of CLA, its anticancer activities has not been studied previously.

The objective of this research was to find out whether SHSO containing a large quantity of CLA exerts anticancer effects against prostate cancer in an animal model in vivo and in human prostate carcinoma cell lines in vitro, as compared with native soybean oil, which is the most consumed vegetable oil worldwide. The apoptotic activities of SHSO were also studied by TUNEL analysis, immunohistochemical analysis of bax, blc-2, and survivin, and DNA fragmentation analysis.

Materials and Methods

Materials

Six-week-old Copenhagen rats (body weight about 200 g) were obtained from Harlan Sprague–Dawley (Indianapolis, IN). A rat prostate cancer cell line of MAT-LyLu was purchased from the European Collection of Cell Cultures (ECACC). Human prostate carcinoma cell lines of PC-3 and DU145 were purchased from the Korean Cell Line Bank (Seoul, Korea). The antibodies of anti-bax and anti-blc-2 antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA), and anti-survivin antibodies were purchased from Alpha Diagnostic International Inc. (San Antonio, TX). Soybean oil was obtained from a local edible oil refinery (Heinz Korea, Incheon, Korea).

SHSO with High CLA

Hydrogenation was performed in a 1-L capacity hydrogenator equipped with temperature, pressure and stirring-rate controller to obtain the SHSO with a large quantity of CLA [8, 9]. Six hundred and fifty gram of soybean oil was hydrogenated for 40 min with a commercially available selective Ni catalyst (0.5%, nickel, based on the oil mass) under the condition of a reactor temperature of 230 °C, a hydrogen pressure of 0.5 kg/cm^2, and a 300-rpm stirring rate.

Fatty Acid Methyl Esterification

The fatty acids in the triacyl moiety of the SHSO were methylesterified with a 1.0 mL of 0.25 N sodium methoxide in methanol at 55 °C for 30 min [9]. The fatty acid methyl esters (FAME) were extracted from the reacted samples with 2,2,4-trimethyl pentane.

Gas Chromatography

For the separation and quantification of individual fatty acids and CLA, 2–6 μL FAME sample was injected into a gas chromatograph equipped with a flame ionization detector [9]. The column used was a highly polar fused silica capillary column (cyanopropyl siloxane phase, SP2380 100 m × 0.25 mm, 0.25 μm thickness, Supelco Inc., Bellefonte, PA). A 100:1 split injection was used for sample injection. Helium was used as carrier gas with a head pressure of 300 kPa. Temperature of the injector and detector were 230 and 250 °C, respectively. The initial oven temperature was 170 °C, which was held for 1 min and then increased at 0.8 °C/min to 200 °C.

Silver Ion-Impregnated High Performance Liquid Chromatography

Silver ion-high performance liquid chromatographic analysis of CLA was carried out with an HPLC (Shimazu, Tokyo, Japan) equipped with a 20 μL injection loop (Waters) and UV detector operated at 233 mm. Three analytical silver-impregnated columns (ChromSpher 5 Lipid, 250 mm × 4.6 mm i.d., 5 μm, Chrompak, Bridgewater, NJ) were used in series [9, 31, 32]. The mobile phase was 0.1% acetonitrile in hexane, operated isocratically at a flow rate of 1.0 mL/min.

In Vivo Anticancer Activity

The effects of the SHSO on prostate cancer growth were studied using the well-known model of male Copenhagen rats with syngeneic rat prostate cancer cells (MAT-LyLu). All animal experiments were carried out in Hallym University (Chuncheon-Si, Gangwon-Do, Korea) after the approval of Institutional Animal Care and Use Committee (IACUC) of Hallym University (IUCUC Approval Number, Hallym-1-60, 28 October, 2008). The 6-week-old rats were fed ad libitum with AIN-76A diet and water for 1 week before the experiments. The experiments were done in wire-bottomed cages in a temperature- (20–25 °C) and humidity-(60–70%) controlled room with a 12:12-h light:dark cycle. The 7-weeks-old rats were divided into four groups ($n = 10$ per group) by a randomized complete block design, and were fed isocaloric AIN-76A diets for 3 weeks with the following fat composition: 5% soybean oil (0% SHSO diet group), 1.5% SHSO + 3.5% soybean oil (1.5% SHSO diet group), 3% SHSO + 2% soybean oil (3% SHSO diet group) and 5% SHSO (5% SHSO diet group). On day 8 of the feeding program, 2×10^5 MAT-LyLu prostate cancer cells were injected subcutaneously into the right flank on each animal. After being fed the experimental diets for an additional 2 weeks, the rats were killed by cervical dislocation under general anesthesia with diethyl ether in the presence of a veterinarian. Tumors were excised and weighed, and tissue specimens from tumors were fixed in 10% buffered formalin and embedded in paraffin.

Immunohistochemistry for bcl-2, bax and Survivin Protein Expressions

The expression of bcl-2, bax, and survivin protein expressions were evaluated using an immunohistochemical staining assay. Paraffin-embedded thin sections (4 μm thickness) were mounted on slides, deparaffinized, rehydrated and washed with TBS-T. The intrinsic peroxidase activity was inhibited by 0.3% H_2O_2 for 20 min, and nonspecific binding was blocked with normal goat serum (1:5, DAKO kit, Dako co. Ltd, Kyoto, Japan) for 1 h. Primary antibodies were diluted 1:50 and incubated with the sections overnight at 4 °C. The primary antibodies used were anti-bax, anti-bcl-2, and anti-survivin. A secondary antibody, biotinylated link antibody (Dako Co. Ltd, Kyoto, Japan), was incubated with the sections for 20 min, and the sections were treated with streptavidin peroxidase for 15 min, and then stained with DAB. The sections were counterstained with Meyer's hematoxylin, and then washed with distilled water.

TUNEL Method

TUNEL staining was done with an in-situ apoptosis kit (Takara Shuzo Co., Kyoto, Japan), according to the manufacturer's instruction. The apoptosis index was determining by counting the percentage of TUNEL-positive cells in the total cell counts.

In Vitro Cell Proliferation

SHSO was dissolved in ethanol, and the solution was added into the DME media. Cancer cell lines were cultured for 48 h at 37 °C in CO_2 incubator. The proliferations of the cells were assayed by MTT [33] and trypan blue dye exclusion methods [34]. Apoptosis of cell line was determined by DNA fragmentation.

Statistical Analysis

Duncan's multiple range tests and paired *t* test were used to assess the statistical significance between the treated groups, using the SAS System [35].

Results

CLA Composition in SHSO

Native soybean oil did not contained detectable amounts of CLA. The manufactured SHSO contained CLA at 210.6 mg/g oil in its triacylglycerol moiety as measured by gas chromatography, which is about 40 times higher than the contents in dairy products and ruminant meats [8, 27]. Native soybean oil contained 11.33% palmitic acid, 4.29% stearic acid, 22.19% oleic acid, 1.33% *cis*-C18:1, 52.99% linoleic acid, 0% CLA, 0.63% unconjugated $C_{18:2}$, 6.17% linolenic acid, 0.37% arachidonic acid, and 0.70% behenic acid. The fatty acid composition of the SHSO was 11.53% palmitic acid, 6.18% stearic acid, 20.28% oleic acid, 5.56% *trans* $C_{18:1}$, 2.39% *cis* $C_{18:1}$, 20.70% linoleic acid, 22.97% CLA, 7.48% unconjugated $C_{18:2}$, 1.07% linolenic acid, 0.65% linolenic acid isomers, 0.42% arachidic acid, and 0.77%

behenic acid, as determined by gas chromatography. The individual isomers were identified by silver-ion impregnated HPLC and confirmed by ion-impacted mass spectroscopy of their DMOX derivatives (Table 1). The relative composition of individual CLA isomers in SHSO was as follow: 13t,15t (2.65%), 12t,14t (3.36%), 11t,13t (6.40%), 10t,12t (11.83%), 9t,11t (12.09%), 8t,10t (6.39%), 7t,9t (2.75%), 12t,14c (1.54%), 12c,14t (1.11%), 11t,13c (1.97%), 11c,13t (4.23%), 10t,12c; 10c,12t (14.33%), 9c,11t; 9t,11c (17.58%), 8t,10c; 9c,10t (4.91%), 7t,9c; 7c,9t (0.93%), 11c,13c (1.31%), 10c,12c (2.73%), 9c,11c (2.77%), and 8c,10c (1.10%).

In Vivo Inhibition of Prostate Cancer Growth

Figure 1a shows that the dietary SHSO supplements greatly inhibited the prostate cancer growth in vivo. The quantitative effects of dietary SHSO supplements on the growth of prostate cancer in the rats are shown in Fig. 1b. The SHSO supplements inhibited the prostate cancer growth in a dose-dependent manner: the tumor weights in the groups supplemented with the 0, 1.5, 3, and 5% SHSO were 8.07 ± 0.99, 7.91 ± 2.53, 5.05 ± 1.64, and 1.60 ± 0.29 g, respectively. No overt toxic symptoms were observed in these groups during the experiments. The effects of dietary SHSO on growth performance of rats inoculated with Mat-LyLu cancer cells are given in Table 2. The food intake of rats in the 0, 1.5, 3 and 5% SHSO dietary groups during the feeding experiment were

10c,12c	2.73
9c,11c	2.77
8c,10c	1.10

17.43 ± 0.07, 16.66 ± 0.55, 16.79 ± 0.54, and 17.36 ± 0.54 g, respectively. The mean body weight gains in the 0, 1.5, 3, and 5% SHSO groups were 25.86 ± 1.64, 19.37 ± 3.16, 21.49 ± 2.29, and 16.85 ± 1.38 g, respectively.

Immunohistochemistry

To assess the modulation of the expression of proapoptotic and antiapoptotic proteins by SHSO, we performed immunohistochemical staining assays with tumor tissues obtained from control and SHSO treated groups (Fig. 2 and Table 3). Figure 2 shows the pictures of immunohistochemical staining for bax, blc-2 and survivin proteins with samples from control (a) and 5% SHSO groups (b). The SHSO treated groups showed greatly higher expression of bax (proapoptotic protein) than control. The increased amount of the SHSO treatment, the higher the expressions of bax were observed (Table 3). SHSO treated groups showed greatly lower expressions of bcl-2 and survivin (antiapoptotic protein) (Fig. 2). The down regulation activities of SHSO on the expressions of bcl-2 and survivin were dose-dependent (Table 3).

Table 2 Effects of SHSO on growth performance of rats inoculated with Mat-LyLu cancer cells

	Treatments			
	Control	1.5% SHSO	3% SHSO	5% SHSO
Initial body weight (g)	209.74 ± 4.49	207.66 ± 4.77	207.54 ± 3.09	207.66 ± 3.86
Final body weight (g)	235.60 ± 5.97	227.03 ± 3.07	229.03 ± 4.78	222.51 ± 4.59

Body gain (g)	25.86 ± 1.64^{a}	19.37 ± 3.16^{ab}	21.49 ± 2.29^{ab}	16.86 ± 1.38^{b}

Values are means ± SD

Values with different superscripts within a row are significantly different from each other at $p < 0.05$ by Duncan's multiple range ANOVA test

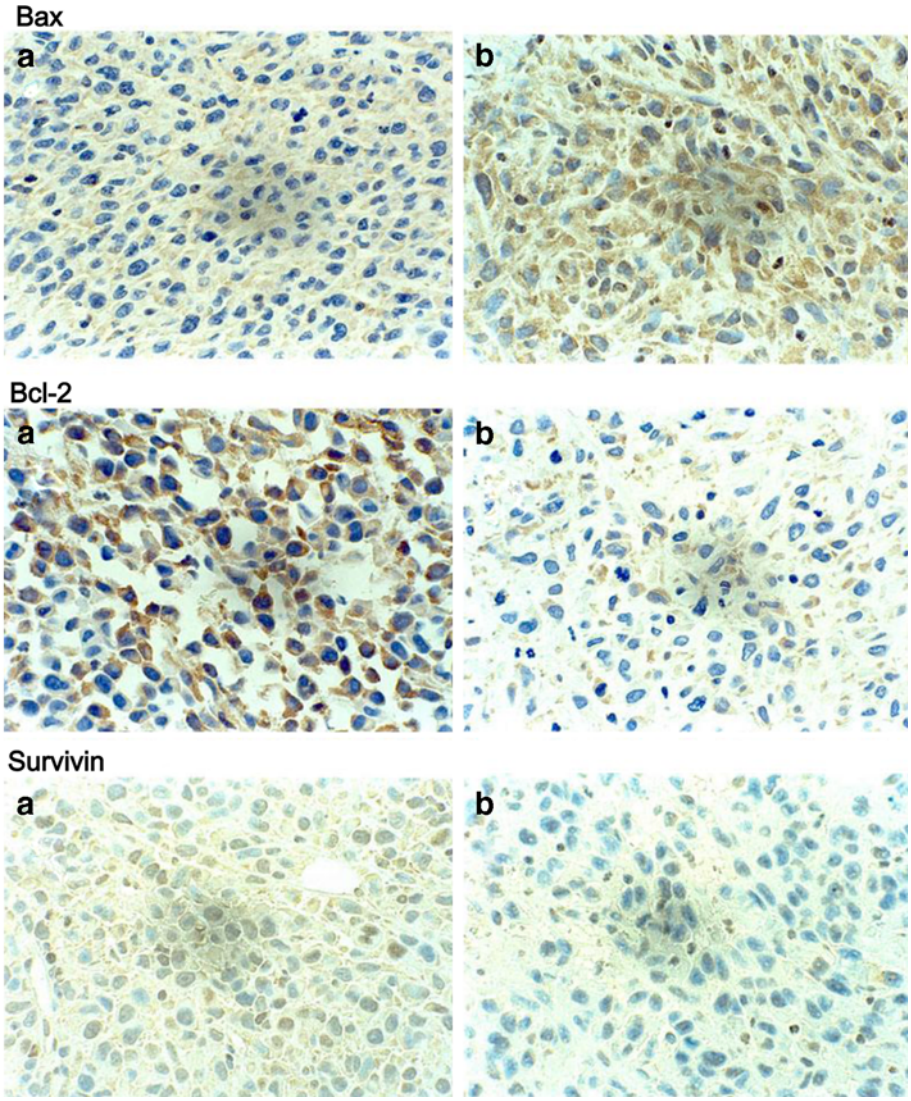

Fig. 2 Immunohistochemical staining of bax, bcl-2, and surviving obtained from tissues in prostate cancer from Copenhagen rats treated with different level of SHSO administrations: **a** tissues from control group, **b** tissues from 5% SHSO group

TUNEL Assay

Figure 3 shows the in situ TUNEL staining of tumor tissues obtained from the 0, 1, 3 and 5% SHSO groups. The results clearly show that the amount of apoptosis induced increased with SHSO, which is consistent with the result from the immunohistochemical staining assay. The apoptotic index was calculated by counting the percentage of apoptotic cell in total cell counts (Table 4). The apoptosis indexes of the 0% SHSO (control), 1.5% SHSO, 3.0%

Table 4 Apoptotic index obtained from TUNEL assay from prostate cancer in rats

Diets	Number of samples	Apoptotic index[a,b] Mean ± SD (%)
Control diet	5	2.60 ± 1.19[a]
SHSO 1.5% diet	5	5.09 ± 0.39[b]
SHSO 3% diet	4	10.00 ± 0.90[c]
SHSO 5% diet	5	14.54 ± 1.16[d]

[a] Apoptotic index : (number of TUNEL-positive cell/number of total cell) × 100

[b] Values of different subscripts are significantly different at $p < 0.0001$ by Duncan's multiple range test

SHSO, and 5.0 SHSO groups were 2.60 ± 0.19, 5.09 ± 0.39, 10.0 ± 0.9 and 14.54 ± 1.16%, respectively. The results suggested that the in vivo anticancer activity of SHSO in the Copenhagen rat model with transgenic prostate cancer cell could be explained, at least in part, by the induction of apoptosis of the MAT-LyLu.

In Vitro Assays for Antiproliferation and Apoptosis in the MAT-LyLu Prostate Cancer Cell Line

To confirm the apoptotic activity of SHSO, we studied its antiproliferation and DNA fragmentation analysis of SHSO on the prostate cancer cell line. We incubated the prostate cancer cells (Mat-LyLu) with 300 μg/mL (equivalent to CLA TG 82 μM) of SHSO for 48 h to check the cytotoxicity of SHSO in vitro. The SHSO showed significant in vitro cytotoxicity at this concentration. The inhibitions of the MAT-LyLu cell proliferation by SHSO as measured by MTT and trypan blue assays were 11.3 ± 2.8 and 14.2 ± 1.1%, respectively. However, native soybean did not show any significant in vitro cytotoxicity on MAT-LyLu, showing 4.2 ± 3.1 and 2.9 ± 4.8% inhibitions at 300 μg/mL as measured by MTT and trypan blue assays, respectively. No cytotoxicity of the SHSO on normal, non-cancer cell line (3T3, fibroblasts) was observed at the tested concentration (300 μg/mL) (data not shown). Instead, SHSO slightly promoted the normal human cell (3T3) proliferation. The effect of CLA on DNA fragmentation in MAT-LyLu cells are shown in Fig 4. The results show that SHSO induced the apoptosis of the prostate cancer cell line at the levels of 200 and 300 μg/mL (equivalent to CLA TG 55 and 82 μM, respectively), as shown in Fig 4. However, native soybean oil at 300 μg/mL (equivalent to CLA TG 0 μM) did

not show DNA fragmentation, indicating no apoptotic activity (data not shown).

In Vitro Assays for Antiproliferation on Human Prostate Cancer Cell Lines

The effects of SHSO on the proliferation of human prostate cancer cell lines (DU145 and PC-3) were also studied to check the cytotoxic activity of SHSO on these human cancer cell lines. SHSO at 300 μg/mL (equivalent to CLA TG 82 μM) significantly reduced the proliferation of both DU145 and PC-3 cell lines in vitro: by 33.3 ± 1.7 and 43.3 ± 2.7%, respectively, as measured by MTT assay. In contrast, native soybean oil at of 300 μg/mL (equivalent to CLA TG 0 μM) inhibited the proliferation of DU145 and PC-3 by only 13.7 ± 5.0 and 18.8 ± 5.4, respectively, as measured by MTT assay. The cytotoxicity of SHSO on the DU145 and PC-3 cell lines was further confirmed by the trypan blue dye exclusion method, which showed that 300 μg/mL (equivalent to CLA-TG 82 μM) SHSO inhibited the proliferation of DU145 and PC-3 by 22.3 ± 2.7 and 27.4 ± 2.4%, respectively.

Discussion

Our study shows that SHSO exerted markedly strong anticancer effects on the prostate cancer in vivo, as compared with native soybean oil. Dietary supplementation with 5% SHSO induced an 80% inhibition of prostate tumor weight in rats. The individual food intakes of rats in 3 and 5% SHSO groups were not significantly different from those in control during the feeding experiment (Table 2). This result clearly showed that the anticarcinogenic activity of (SHSO) was not due to the changes in caloric intake. The mean body weight gains in the 3 and 5% SHSO groups were significantly lower than that in control group (0% SHSO), and this was mainly attributable to the differences in their tumor weights; there was no significant difference in body weight gains after correcting for the tumor weight. Note that the mean tumor weights of control, 3% SHSO, and 5% SHSO groups were 8.07 ± 0.99, 5.05 ± 1.64 and 1.60 ± 0.29 g, respectively (Fig. 1b). SHSO dietary supplementation up-regulated the expression of bax, and down-regulated the expressions of bcl-2 and survivin in a dose-dependent manner. The results obtained from the TUNEL assay were consistent with the immunohistochemical staining of bax, bcl-2, and survivin, indicating the positive in vivo apoptotic effects exerted by SHSO against Mat-LyLu prostate cancer cells.

SHSO also showed antiproliferation activity against the growth of MAT-LyLu and human prostate carcinoma cell lines (DU145 and PC-3) in vitro. The in vitro DNA fragmentation data further confirmed that SHSO possessed apoptotic activity on Mat LyLu. It is interesting that the antiproliferation activities of SHSO on human prostate carcinoma cell lines (DU145 and PC-3) were much higher than that on MAT-LyLu at the same concentration. This result suggests that SHSO might be also effective in reducing the risk of prostate cancer in human. SHSO showed cell-specific cytotoxicity, in that it did not inhibit the growth of the normal 3T3 cell lines (human fibroblasts), indicating that the SHSO was not cytotoxicity to a normal cell line.

This is the first report demonstrating significant anticancer and apoptotic properties of a hydrogenated vegetable oil on prostate cancer rat model in vivo and human cell line studies in vitro. Our in vitro result obtained from cell line proliferation studies showed that native soybean oil did not exert any significant antiproliferation activities on Mat-LyLu, and much lower effects on DU145 and PC-3 cells than SHSO. From these results, it is reasonable to postulate that the active components of SHSO are the CLA formed

during hydrogenation. The SHSO contained 22.97% CLA in their triacylglycerol structures, and so the 5% SHSO diet was equivalent to approximately 1.0% CLA supplementation. CLA are geometric and positional isomers of octadecadienoic acid that are known to be present in trace amounts in ruminant meats and dairy products. These fatty acids have been shown to be effective in inhibiting carcinogenesis in multiple systems and at several levels, including initiation, promotion, progression, and metastasis [10–18, 27, 29]. CLA supplementation as a fatty acid form at 1% level reportedly exerted anticancer effects independently from the level and types of other fat treated [15]. It also has been reported that 1% CLA sodium salt (mixture of c9,t11- and t10,c12) significantly reduced the growth of prostate tumors in SCID mice [17]. It has been reported that 100 mM CLA increased the level of mRNA for glutathione peroxidase and reduced the diacylglycerol contents in human prostate cancer cells (PC3) [35]. Ochoa et al. [36] reported that CLA mixture (c9 t11:t10 c12) was able to decrease PC-3 proliferation at 100 and 150 μM (19.9% of control and 59.3% of control, respectively). Masso-Welch et al. [37] reported that *cis*-9, *trans*-11 and *trans*-10, *cis*-12 CLA isomers were effective in inhibiting angiogenesis in a dose-dependent manner. Even though the CLA have been reported to have various anticancer activities with a single or a mixture of its isomers as a fatty acid form (obtained from alkali isomerization from linoleic acid), the anticancer activities of hydrogenated vegetable oils with a high quantity of CLA have not been previously reported. The CLA in SHSO used in this study were present as an esterified form in a triacylglycerol structure, not as a fatty acid. Furthermore, the SHSO was obtained by the hydrogenation of soybean oil, which is a classical food process that has been used for over a century for the production of margarine, shortening, and confectionery fats. The isomeric distribution of CLA in the SHSO used in our study was greatly different from those CLA isomers studied previously. The CLA produced by alkali isomerization from linoleic acid contains mainly two isomers of *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers (more than 85%) along with minor proportion of other isomers [28]. But the SHSO contained various types of isomers with a wide distribution, as indicated in Table 2. It has been reported that the bioactivities of the CLA isomers were different with different isomers. The bioactivities of only few isomers (including c9,t11- and t10,c12- isomers) have been well elucidated. We previously identified 21 CLA isomers in SHSO [31], but the bioactivities of most of the CLA isomers present in SHSO have not been studied. The relative distributions of *trans/trans, cis/trans* or *trans/cis*, and *cis/cis* isomers in SHSO were 45.5, 46.6, and 7.9%, respectively (Table 2). The high proportion of *trans/trans* isomers in the CLA products in the present study is in contrast to trace of *trans/trans* isomers in CLA produced by alkali isomerization. The high distribution of *trans/trans* isomers in SHSO might play an important role in its anti-prostate cancer activity. Park et al. [30] compared the cytotoxic effects of four CLA isomer (10t,12c-, 9c,11t-, 10t-,12t- and 9t,11t-) on the gastric cancer cell line (NCI-N87). The authors reported that 9t,11t and 10t,12t- isomers (*trans/trans* isomers) showed stronger cytotoxic activity on the NCI-N87 cancer cell line proliferation than 10t, 12c- and 9c,11t-CLAs (*cis/trans* isomers). Hydrogenated vegetable oils have earned reputations for negative effects on human health mainly due to their high contents of *trans* fatty acids and saturated fatty acids. The increased concern about the effects of *trans* fatty acids on health led to regulations requiring the nutrition facts panel on all food labels to indicate the *trans* fat content by 1 January, 2006. It is interesting to note that CLA are a type of *trans* fatty acids, in a chemical view point. We previously demonstrated that the fatty acid composition of hydrogenated vegetable oils could be manipulated by controlling the reaction conditions such as temperature, catalyst type and amount, hydrogen pressure, and agitation rate [8, 9]. The present study showed a clear evidence that hydrogenated vegetable oils with high conjugated linoleic acids, which were obtained by carefully controlled hydrogenation condition, have great potential as a prototype functional food ingredient for the chemoprevention of prostate cancer. Previously, we reported that SHSO with CLA also showed body fat reducing activity (deleted—and antiatherosclerotic) properties in rats [38]. Prostate cancer is the second leading cause of male death due to cancer in the United States. Given that hydrogenated vegetable oils have been extensively consumed for about a century, this novel approach may be particularly appealing to those people who are unwilling to change their eating habits (in terms of fat consumption), but still desire alternative food choices for cancer prevention.

METHODS

Improved Methods for the Fatty Acid Analysis of Blood Lipid Classes

Ken'ichi Ichihara · Kumiko Yoneda · Ayuko Takahashi · Noriko Hoshino · Motoyoshi Matsuda

Received: 6 October 2010 / Accepted: 14 January 2011 / Published online: 7 February 2011

Abstract Two improved methods have been developed for preparation of fatty acid methyl esters (FAME) from major *O*-ester lipid classes in blood, i.e., cholesterol ester, triacylglycerol, and glycerophospholipids. The methods involve simple operations, and use neither harmful solvents such as chloroform or benzene nor highly reactive volatile reagents such as acetyl chloride. The FAME synthesis reaction proceeds under mild temperature conditions. The methods include (1) extraction of lipids from 0.2 ml of blood with 0.2 ml of *tert*-butyl methyl ether and 0.1 ml of methanol, (2) separation of the total lipids into lipid classes using a solid-phase extraction column or thin-layer chromatography, and (3) methanolysis of each lipid class at room temperature or at 45 °C. In all the operations, solvent concentration is performed only once prior to gas–liquid chromatography (GC). No noticeable differences in composition determined by GC have been found between FAME prepared by the present methods and those prepared by a conventional method involving lipid extraction with chloroform/methanol. The mild reaction and simplified procedures of the present methods enabled safe and reproducible analysis of the fatty acid compositions of the major ester-lipid classes in blood.

GPL	Glycerophospholipids
GroPCho	Glycerophosphocholine
GroPEtn	Glycerophosphoethanolamine
PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
SPE	Solid phase extraction
TAG	Triacylglycerol(s)
TLC	Thin-layer chromatography

Introduction

The major ester-lipid classes in blood are cholesterol esters (CE), triacylglycerols (TAG), and glycerophospholipids (GPL). The fatty acid compositions of these lipid classes are among the indicators related to human health and nutritional status, and they have been used in many clinical and epidemiological studies [1–6]. While convenient methods have been presented for preparation of fatty acid methyl esters (FAME) from blood total lipids [7–10], the preparation of FAME from individual lipid classes in blood is both labor-intensive and time-consuming. The first step in conventional preparation of FAME from lipid classes is extraction of total lipids from blood with chloroform–methanol, phase separation, and concentration of the chloroform solution. However, the trihalomethane solvent is toxic for humans and its carcinogenicity is a considerable

health risk for researchers in laboratories [11]. Chloroform may also contaminate the environment. It has been noted that labile lipid species can be chemically modified with the phosgene formed by decomposition of chloroform [12]. Chloroform has another disadvantage in phase separation, in that it forms a lower layer because of its high density (1.48 g/cm^3). When the lower solvent layer is collected with a pipette, it can be contaminated with solid impurities floating in the interface between the upper and lower layers [13]. Therefore, chloroform should be replaced with a less harmful, non-chlorinated, low-density solvent. The second step is isolation of individual lipid classes by silica gel thin-layer chromatography (TLC) or column chromatography. The procedure of this step varies between groups, and there is still no unified protocol for isolation. The third step is formation of FAME from the isolated individual lipid classes by methanolysis or by saponification followed by methylation. Although FAME have been mostly synthesized at temperatures higher than 70 °C, the operation of methanolysis under lower, mild temperatures must be adopted for safety of researchers and to allow simplification of the apparatus used. BF_3 and 3-(trifluoromethyl) phenyltrimethylammonium hydroxide are often used as catalysts for methanolysis of isolated lipid classes [14, 15], but fluorine compounds are restricted for the global environment by local drainage laws. Environmentally friendly alternatives to fluorine compounds should be used as catalysts. HCl is a widely used acid catalyst, and anhydrous HCl/methanol can be prepared from acetyl chloride and methanol [16]. However, the volatile acid halide is an extreme irritant to the eyes, and care must also be taken to prevent violent reaction with methanol. From a safety standpoint, it is desirable to avoid use of this reagent. Benzene, which has been used in the preparation and extraction of FAME [7, 17], may cause leukemia, and it should therefore be replaced by an alternative solvent. Purification of the synthesized FAME is necessary to remove impurities for capillary gas–liquid chromatography (GC) at the last step of preparation, but the procedure is variable and is not standardized. During these operations, concentration of solvents is often repeated, but the number of concentration steps must be minimized for simplification.

We attempted to develop and establish simplified procedures for routine fatty acid analysis of blood CE, TAG, and GPL, and also to minimize possible hazards during chemical manipulation in laboratories and to reduce environmental burden of waste products. Here, we propose two methods and the corresponding protocols for preparation of FAME derived from the blood lipid classes. The first includes a procedure using a solid-phase extraction (SPE) column for separation of blood lipids into lipid classes and is suitable for simultaneous treatment of many samples or robotic systems, and the other includes a TLC procedure, which has been used most frequently to date.

Materials and Methods

Reagents

Cholesteryl oleate and dierucoyl glycerophosphocholine (GroPCho) were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Cholesteryl erucate, trierucoyl glycerol, and the FAME standard mixture for GC were purchased from Nu-Chek-Prep (Elysian, MN, USA). Trioleoyl glycerol was obtained from Sigma-Aldrich (St. Louis, MO, USA). Dioleoyl glycerophosphoethanolamine (GroPEtn) was from Wako Pure Chemical Industries (Osaka, Japan). Dioleoyl GroPCho was synthesized from GroPCho and oleic acid [18]. Acetone, chloroform, hexane, and methanol were purchased from Wako Pure Chemical Industries or Nacalai Tesque (Kyoto, Japan) as glass-distilled solvents for analysis of residual pesticides and herbicides. Metal Na, KOH, 50% BF_3 in methanol, *tert*-butyl methyl ether (*tert*-BME), methyl acetate, and heparin sodium salt were of reagent grade. Methanolic CH_3ONa solutions of 1.2 M and 2.0 M were prepared by diluting 25% (w/w; 4.37 M) methanolic CH_3ONa, which was purchased from Sigma-Aldrich, with methanol or prepared by dissolving metal Na in methanol. A reagent for methylation of FFA, 0.8 M HCl in 95% methanol, was prepared by diluting conc. HCl (12 M) 15-fold with methanol. TLC plates of silica gel (0.25 mm thick, No. 105715) and SPE columns packed with 200 mg of silica gel (LiChrolut, No. 102021) were products of Merck (Darmstadt, Germany). The SPE columns were previously washed with 10 ml of hexane and 6 ml of acetone to remove plasticizers and impurities, and then dried in vacuo (1.3 kPa) for 16 h. Microcentrifuge tubes (1.5 ml; Greiner Bio-One, Kremsmünster, Austria) made of homopolymer polypropylene and translucent were soaked in hexane overnight to remove plasticizers. Transparent tubes made of the copolymer polypropylene contained more plasticizers and were not used for lipid extraction. Most solvent systems for lipid extraction and TLC contained 0.001% 2,6-di-*tert*-butyl-*p*-cresol as an antioxidant. Small volumes ($\leq$1 ml) of organic solvents were measured with positive displacement pipettes (Microman M-100 and M-250; Gilson, Middleton, WI, USA). M-1000 was also used for solvents other than chloroform.

TLC and GC

Reaction products of methanolysis were analyzed by silica gel TLC. Developed lipids on TLC plates were visualized

by spraying with 50% (w/w) sulfuric acid and then heating at 137 °C. Phospholipids were also detected with the Dittmer and Lester reagent [19]. For preparation of FAME from lipid classes, methanolic 0.001% primulin was sprayed on plates and lipids were detected under ultraviolet light at 365 nm. FAME prepared were analyzed with a Shimadzu 2014 gas chromatograph equipped with flame ionization detectors and columns of DB-23 (0.25 mm × 30 m) and SUPELCOWAX 10 (0.53 mm × 30 m) at an isothermal column temperature of 200 °C or 215 °C in N_2 gas.

Conventional Method for Preparation of FAME from Blood Lipid Classes

Lipids were extracted from 0.2 ml of blood plasma containing heparin with 4 ml of chloroform/methanol (2:1, v/v) by the Folch method [20]. Total lipids thus obtained were developed on silica gel plates (5 cm in width × 10 cm in height) to 2 cm from the origin with acetone and then redeveloped with hexane/*tert*-BME (90:10, v/v) to 8 cm from the origin. Lipids were detected with primulin, and those located at the origin of the plate were regarded as GPL. Silica gel bands corresponding to lipid classes were scraped off and suspended in 2 ml of methanol/toluene (4:1, v/v). After addition of acetyl chloride (0.2 ml), the mixture was heated at 100 °C for 1 h in a screw-capped glass test tube [7]. FAME formed were extracted with hexane.

Method I (SPE Column Method)

Extraction of Lipids and SPE Column Fractionation (*Fig. 1a*)

Total lipids were extracted from 0.2 ml of whole blood in small glass test tubes or in 1.5-ml polypropylene microcentrifuge tubes by vortexing for 1 min with 0.2 ml of *tert*-BME and 0.1 ml of methanol. The tubes were centrifuged for 1 min and 0.1 ml of the upper ether layer formed was slowly applied at the center of the upper-frit surface of a dry SPE column packed with 200 mg of silica gel. The upper frit put on the silica gel matrix was washed with 0.02 ml of hexane. The silica gel charged with blood total lipids as a *tert*-BME solution containing methanol and water was allowed to stand for 5 min and dried for 1 h or overnight in vacuo (1.3 kPa). CE was eluted with 3.4 ml of 1% (v/v) methyl acetate in hexane, and the volume of eluate was 3.0 ml. TAG was then eluted with 3 ml of 2.5% (v/v) methyl acetate in hexane. After the column was washed with 3 ml of acetone to remove cholesterol and pigments, GPL were eluted with 4 ml of methanol.

(a) Extraction of blood total lipids and isolation of lipid classes by an SPE column

Blood 0.2 ml
- ← 0.2 ml of *tert*-BME and 0.1 ml of methanol
- vortexed for 1 min
- centrifuged for 1 min

tert-BME layer (0.1 ml from 0.14 ml in total)
- applied to a silica gel SPE column

Silica gel SPE column
- washed with 0.02 ml of hexane
- allowed to stand for 5 min
- dried in vacuo for 1 h or overnight
- eluted with 3.4 ml of 1% methyl acetate in hexane (CE)
- eluted with 3 ml of 2.5% methyl acetate in hexane (TAG)
- washed with 3 ml of acetone
- eluted with 4 ml of methanol (GPL)

CE, TAG, and GPL fractions

(b) Preparation of FAME from lipid classes

CE fraction (3 ml of 1% methyl acetate/hexane)
- ← 1.5 ml of acetone and 0.6 ml of 2 M CH_3ONa
- vortexed and allowed to stand for 30 min at room temperature
- ← 0.1 ml of acetic acid and 3 ml of water

Hexane layer
- washed twice with 3 ml each of water
- applied to an SPE column
- eluted with 3 ml of 1% methyl acetate/hexane

Eluate (FAME from CE)
- concentrated

GC

TAG fraction (3 ml of 2.5% methyl acetate/hexane)
- ← 0.1 ml of acetone and 0.1 ml of 2 M CH_3ONa
- vortexed for 30 s at room temperature
- ← 0.02 ml of acetic acid and 3 ml of water

Hexane layer
- washed twice with 3 ml each of water
- applied to an SPE column
- eluted with 3 ml of 1% methyl acetate/hexane

Eluate (FAME from TAG)
- concentrated

GC

GPL fraction (4 ml of methanol)
- ← 0.6 ml of 2 M CH_3ONa
- vortexed and allowed to stand for 7 min at room temperature
- ← 0.1 ml of acetic acid, 3 ml of hexane, and 3 ml of water

Hexane layer
- washed with 3 ml of water
- applied to an SPE column
- eluted with 3 ml of 1% methyl acetate/hexane

Eluate (FAME from GPL)

Fig. 1 Flow chart for Method I

Preparation of FAME from Lipid Classes in Eluates (*Fig. 1b*)

The CE solution (3 ml) was mixed with 1.5 ml of acetone and 0.6 ml of 2 M CH_3ONa, the final concentration of which was 0.24 M. The mixed solution, which formed a single phase, was allowed to stand for 30 min at room temperature. Methanolysis was stopped with 0.1 ml of acetic acid, and then 3 ml of water was added to the solution. After mixing, the hexane layer formed was washed twice with 3 ml of water each time and applied to a silica gel SPE column conditioned with 2 ml of hexane for removal of the byproduct cholesterol and small amounts of FFA. The flow-through fraction was discarded, and FAME were then eluted with 3 ml of 1% methyl acetate in hexane. Cholesterol and FFA were retained in the column. The FAME solution was concentrated in vacuo for GC analysis.

To the TAG solution (3 ml) were added 0.1 ml of acetone and 0.1 ml of 2 M CH_3ONa, and the mixed solution of two separate phases was vortexed for 30 s at room temperature. The reaction was terminated by addition of 0.02 ml of acetic acid, and the solution was mixed with 3 ml of water. The hexane layer was washed twice with water and FAME were purified by the same procedures as described above.

The methanolic GPL solution (4 ml) was mixed with 0.6 ml of 2 M CH_3ONa. Methanolysis was completed within 7 min at room temperature. After addition of 0.1 ml of acetic acid and 3 ml of water to the reaction mixture, FAME were extracted with 3 ml of hexane. The separated hexane layer was washed with 3 ml of water and FAME were purified with a silica gel column to remove non-acylated compounds similar to GPL in polarity as described above.

Method II (TLC Method)

Extraction of Lipids and Fractionation by TLC (*Fig. 2a*)

An area (4 cm in width × 1 cm in height) of a 5 × 10 cm silica gel TLC plate was spotted with 0.1 ml of a *tert*-BME solution of total lipids extracted from 0.2 ml of whole blood by the same procedures as described for lipid extraction in Method I. The plate was dried in vacuo (1.3 kPa) for 15 min, developed with acetone to 3 cm from the bottom of the plate, dried in vacuo for 5 min, and redeveloped with hexane/*tert*-BME (90:10, v/v) to 9 cm from the bottom. Bands of CE and TAG were located by spraying with primulin solution followed by visualizing under an ultraviolet lamp at 365 nm, while GPL remained at the spotted area. Each silica gel band was scraped off and placed in a glass test tube (16.5 mm × 125 mm) for TAG and GPL or in a screw-capped glass test tube (16.5 mm × 105 mm) for CE.

Preparation of FAME from Lipid Classes on Silica Gel (*Fig. 2b*)

CE on silica gel was vortexed with 0.5 ml of toluene/acetone (1:1, v/v) and 1 ml of 1.2 M CH_3ONa for 10 s, and methanolysis was carried out at 45 °C for 30 min. To the reaction mixture was added 3 ml of 0.8 M HCl in 95% methanol, and the test tube was incubated at 45 °C for 20 min for methylation of FFA byproducts. Two phases were formed by the addition of 1 ml of hexane and 2 ml of water to the acidic solution, and the hexane layer was washed with 2 ml of water. The hexane solution thus obtained was applied to a silica gel SPE column. The adsorbed FAME were eluted with 3 ml of 1% methyl acetate in hexane, and the eluate was concentrated for GC analysis.

TAG on silica gel and GPL on silica gel were vortexed with 0.5 ml of toluene/acetone (1:1, v/v) and 1 ml of 1.2 M CH_3ONa for 30 s, and then the mixture was allowed to stand for 1 min at room temperature. Methanolysis was terminated by addition of 0.1 ml of acetic acid. Then, 1 ml of hexane and 2 ml of water were added to the solution for extraction of FAME. The hexane layer was washed with 2 ml of water, and FAME were purified by the same procedure as described for methanolysis of CE.

Assessment of Lipid Extraction with *tert*-BME/Methanol

Whole blood (0.2 ml) was vortexed with 0.2 ml of *tert*-BME and 0.1 ml of methanol, and the mixture was centrifuged. The upper *tert*-BME layer was removed, and the surface of the lower layer was gently washed with 0.1 ml of *tert*-BME. These *tert*-BME solutions were combined. Lipids that were not extracted with *tert*-BME and remained in the lower water/methanol layer were extracted twice with 0.2 ml and with 0.1 ml of chloroform. For comparison, blood (0.2 ml) was diluted with 0.3 ml of 0.5 M KH_2PO_4 and lipids were extracted with 1.5 ml of chloroform and 0.5 ml of methanol by vortexing for 2 min [21]. The chloroform layer was removed, and the surface of the water/methanol layer was gently washed with 1 ml of chloroform. The two chloroform solutions were combined. Lipids in the water/methanol layer were re-extracted twice with 1 ml and with 0.5 ml of chloroform. Extracted lipids were analyzed by TLC. The plate was first developed in chloroform/methanol/water/acetic acid (65:35:4:1, v/v/v/v) to 3 cm from the origin, dried in vacuo, and then redeveloped in hexane/*tert*-BME/acetic acid (85:15:0.5, v/v/v) to 8 cm from the origin.

Acid-Catalyzed Methanolysis

Although this study focused on the fatty acid analysis of ester lipids, FAME from both *O*-acyl and *N*-acyl lipids were also prepared (Fig. 3). An 8% (w/v) solution of HCl in methanol/water (85:15, v/v) was prepared by diluting 10 ml of conc. HCl with 42.8 ml of methanol [10]. Blood total lipids were extracted with *tert*-BME/methanol and lipid classes were isolated by TLC. Toluene (0.2 ml), methanol (1.5 ml), and the 8% HCl solution (0.3 ml) were added sequentially to each lipid class/silica gel. The final concentration of HCl was 1.2% (w/v), and the solution contained 2.2% (w/v) water derived from conc. HCl. Methanolysis was carried out at 100 °C for 1 h. The reaction mixture was neutralized with 2 ml of 0.5 M $NaHCO_3$, and products were extracted with chloroform for TLC. When FAME were analyzed by GC, they were extracted with hexane without neutralization.

Results and Discussion

Extraction of Total Lipids and Yields of FAME

tert-BME is immiscible with water and its density is lower than water. It has moderate polarity and moderate volatility with boiling point of 55 °C. Its toxicity is lower than chloroform. It is not prone to peroxide formation. It is commercially available as a reagent of high purity in reasonable prices. Thus, *tert*-BME was selected as an alternative solvent to chloroform for lipid extraction. The compositions of blood total lipids extracted by two

different solvent systems, the present *tert*-BME/methanol system and a modified Folch method that uses chloroform/methanol, were compared by TLC, but no differences in lipid composition were found (Fig. 4). The lower water/methanol phase formed on extraction with *tert*-BME was extracted with chloroform to confirm lipid classes remaining in the lower phase that should be discarded. Small amounts of lipids were distributed to the lower layer, but the lipid compositions of the two layers were very similar to each other on the TLC plate. Matyash et al. [13] also reported that *tert*-BME gave good recoveries for extraction of major lipid classes and was comparable to chloroform used in the Folch method [20] or the Bligh and Dyer method [22].

Extraction efficiencies were compared between the above two solvent systems based on data from an experiment performed in triplicate. An internal standard, methyl erucate, in *tert*-BME or in chloroform was added to blood at the time of lipid extraction. FAME were prepared from the total lipids by HCl-catalyzed methanolysis at 45 °C [10] and analyzed by GC. There was no significant difference in total yield of FAME between *tert*-BME/methanol extraction and chloroform/methanol extraction, and the fatty acid compositions of these FAME preparations were very similar to each other. These findings indicated that *tert*-BME/methanol compares favorably with chloroform/methanol for extraction of blood total lipids as reported previously in lipidomics research [13].

Methanolysis of Lipid Classes Separated by Silica Gel SPE Columns (Method I)

In the 1980s, SPE columns were used for separation between non-polar lipids and phospholipids [23]. Figure 5a shows that CE, TAG, and GPL could be fractionated from total lipids by SPE columns. Methanolysis was carried out at room temperature without concentration of the lipid solutions, and FAME derived from each lipid class were purified to a single spot on TLC (Fig. 5b).

Methanolysis of TAG proceeds in a solvent mixture of hexane and methanol containing a base catalyst, and it requires vortexing for 2 min at room temperature in the absence of acetone [24]. Addition of acetone to a mixture of the TAG eluate and CH_3ONa/methanol stimulated the reaction, and TAG was converted into FAME within 30 s by vortexing at room temperature (Fig. 5b, lanes 5, 6). Hexane and methanol are immiscible, while methanolysis occurs in the lower methanol phase in which a base catalyst, e.g., CH_3ONa or KOH, is dissolved. As TAG, which is a non-polar lipid, is soluble in hexane but slightly soluble in methanol, it is distributed unevenly to the hexane phase when dissolved in a mixed solvent of hexane and methanol. The concentration of TAG in the methanol phase is low, and hence methanolysis proceeds slowly. When a small volume of acetone is added to a mixture of hexane and methanol, acetone is miscible with methanol and the two polar solvents form a lower phase. As acetone is a good solvent for TAG, the concentration of TAG increases in the lower phase where methoxide ions are present and methanolysis occurs. FAME formed are more hydrophobic than TAG and are transferred immediately to the upper hexane phase. FAME are, therefore, not hydrolyzed by alkali dissolved in the methanol/acetone phase. This is probably why methanolysis of TAG is stimulated with acetone.

CE is more hydrophobic and less soluble in methanol than TAG, and methanolysis of CE does not proceed under the conditions for TAG [25, 26]. Various solvents have been used to increase the solubility of CE in methanol to enhance its reactivity. For example, good yields of FAME are obtained in 1 h at 37 °C or at room temperature by reaction in diethyl ether/methyl acetate/methanol containing 1 M CH_3ONa (50:1:1, v/v/v) or in methyl propionate/methanol containing 0.84 M NaOH (2:3, v/v), respectively [25, 26]. A mixture of CE eluate (3 ml of 1% methyl acetate in hexane), 1.5 ml of acetone, and 0.6 ml of 2 M CH_3ONa/methanol formed a single homogenous phase of the solvents, and methanolysis was completed in 30 min at room temperature (Fig. 5b, lane 2). This improved reactivity of CE was also due to its high solubility in the solution containing acetone.

To a methanol eluate (4 ml) of GPL was added 0.6 ml of 2 M CH_3ONa/methanol to form a 0.26 M CH_3ONa

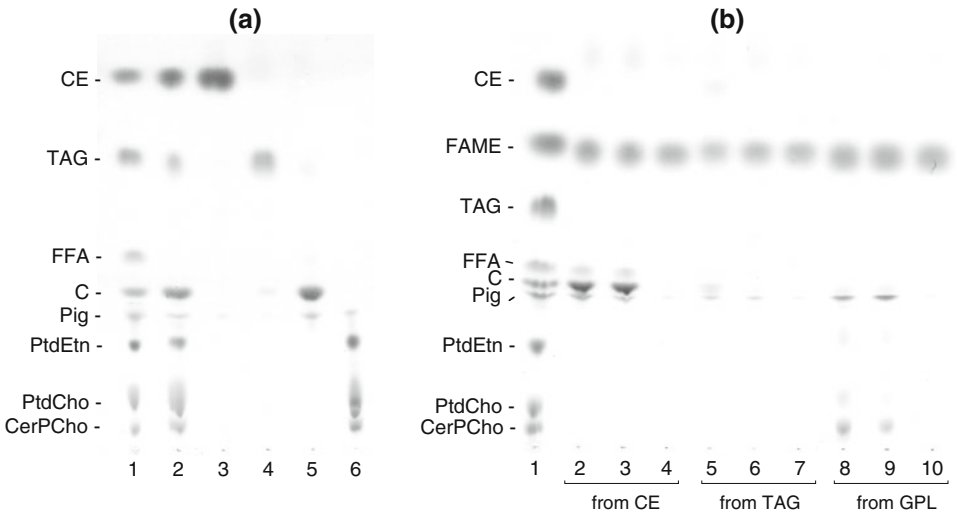

Fig. 5 **a** Isolation of CE, TAG, and GPL by a silica gel SPE column. Total lipids were extracted from whole blood with *tert*-BME/methanol (*lane 2*) and separated into three lipid classes, CE (*lane 3*), TAG (*lane 4*), and GPL (*lane 6*) by an SPE column. *Lane 5* is the acetone eluate that contains cholesterol and pigments. Reference lipids were developed in lane 1. **b** Preparation of FAME from lipid classes. Reaction products of the isolated lipid classes by methanolysis were extracted with chloroform (*lanes 2, 5, 8*) or with hexane (*lanes 3, 6, 9*). The hexane extracts were purified by SPE columns (*lanes 4, 7, 10*). Lane 1 is a mixture of authentic lipids. The conditions of TLC were the same as those in Fig. 4

solution, which was allowed to stand for 7 min at room temperature. As GPL are polar lipids and sufficiently soluble in methanol, the reaction proceeded rapidly in methanol (Fig. 5b, lane 8). The reaction time of 7 min at room temperature was sufficient for transesterification of GPL bearing *O*-ester linkages. The pale spot detected near the position corresponding to PtdEtn after methanolysis was not a phospholipid, and another pale spot found near the position of PtdCho was lysoplasmalogen. Sphingomyelin, which has no ester-linked acyl residue, remained unchanged as expected. The fatty acid composition of sphingomyelin is considerably different from those of glycerophospholipids, and it must be determined using acid-catalyzed methanolysis after isolation.

Acetone is known to reacts with aminophospholipids to form Schiff's bases under mild conditions [27, 28], but the influences of acetone complexes on the preparation of phospholipids and analysis of fatty acid composition were not considered in the present study.

Methanolysis of Lipid Classes Separated by Silica Gel TLC (Method II)

CE, TAG, and GPL were isolated by silica gel TLC from *tert*-BME extracts (Fig. 6). Methanolysis in the presence of silica gel has some disadvantages compared to the reaction in the absence of silica gel, especially for CE; i.e., the reaction proceeds slowly and FFA are produced. However, these disadvantages could be alleviated by optimizing reaction conditions. A reaction medium consisting of 0.25 ml of toluene, 0.25 ml of acetone, and 1 ml of methanolic 1.2 M CH_3ONa forms a single organic phase, in which the concentration of CH_3ONa is 0.8 M. This solvent system containing the base catalyst was able to dissolve all three lipid classes and was used for methanolysis.

Each value is the average obtained from three FAME preparations. Values that share common superscript letters in each row are significantly different at $P < 0.01$. Minor components and C_{24} acids are omitted

In the absence of silica gel, TAG can be readily derivatized to FAME in two solvent phases composed of hexane and methanol [24]. Acetone in the methanol phase enhances the reaction rate, as described for methanolysis of TAG isolated by SPE columns. Silica gel interfered with the reaction, and under the conditions used for the two-phase solvent system, conversion of TAG to FAME resulted in low yields. However, methanolysis of TAG was completed in 90 s at room temperature with trace amounts of FFA byproducts, when silica gel that adsorbed TAG was treated with the homogeneous solution of 0.8 M CH_3ONa in toluene/acetone/methanol (Fig. 6, lanes 6–8).

CE on silica gel was also incubated with CH_3ONa solution (Fig. 6, lanes 2–5). CE disappeared within 30 min at 45 °C or 45 min at 37 °C, but considerable amounts of FFA were produced, as reported previously [25]. The compositions of the FFA were not different from those of FAME formed by methanolysis. FFA in the reaction mixture were scavenged by adding 3 ml of 0.8 M HCl in 95% methanol. Most of the FFA were methylated at 45 °C for

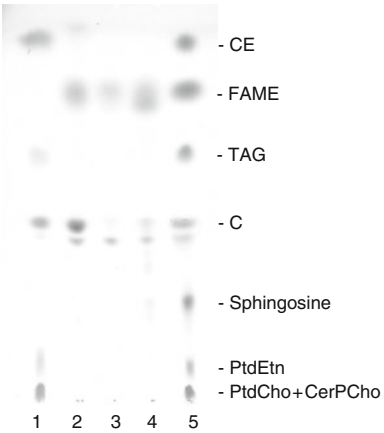

Fig. 7 Methanolysis of blood lipid classes with 1.2% HCl/methanol/toluene in the presence of silica gel. See "Materials and Methods" for details on preparation of FAME. The TLC plate was developed to 3.5 cm from the origin in chloroform/methanol/15 M NH_3 (80:20:1, v/v/v), and then redeveloped in hexane/*tert*-BME (90:10, v/v). *Lane 1* blood total lipids; *lanes 2–4* products of CE, TAG, and phospholipids, respectively; *lane 5* authentic lipids

20 min. Remaining FFA and cholesterol derived from CE were removed by SPE columns prior to GC.

FAME were formed from GPL within 90 s at room temperature by the same procedures as described for TAG, but they were contaminated with sphingomyelin, lysoplasmalogen, pigments, and other impurities (Fig. 6, lanes 9–12). Sphingomyelin and lysoplasmalogen in the reaction mixture showed little extraction by hexane. Pigments and other impurities were derived from the original GPL preparation and were removed by SPE columns.

Purification of FAME by Silica gel SPE Columns

Methanolysis of CE inevitably produces free cholesterol as a byproduct. As methanolysis of acyl lipids is accompanied by a side reaction, saponification or hydrolysis, in the presence of water, small amounts of FFA are formed during the reaction. FAME products obtained under the present conditions of methanolysis were contaminated by cholesterol, FFA, and other impurities, such as pigments. These impurities were removed by SPE columns (Figs. 5, 6). Purification of FAME is thus recommended, but FAME products can be injected immediately into GC columns without purification to speed up analysis as adopted in most methods reported previously [1–3, 7]. Reactions of blood lipids in HCl/methanol at high temperatures are accompanied by the formation of two major artifacts derived from CE and cholesterol [29, 30], i.e., 3,5-cholestadiene and cholesteryl methyl ether, the latter of which cannot be removed by silica columns. Base-catalyzed methanolysis used in the present method does not generate these artifacts.

Fatty Acid Compositions of Lipid Classes and Yields of FAME

The three major *O*-acyl lipids of blood, CE, TAG, and GPL, were isolated by silica gel SPE columns or TLC, and converted into FAME. The fatty acid compositions of these lipid classes were determined by GC and they were compared with each other and with those obtained by a conventional method (Table 1). There were no remarkable differences in fatty acid composition among these methods, although some small but significant differences were found. To assess the validity of the present methods, the yields of FAME were compared between the present methods and a conventional method including Folch extraction followed by isolation of lipid classes by TLC. Total lipids were extracted with the *tert*-BME or chloroform solvents containing three internal standards, i.e., cholesteryl erucate, glyceryl trierucate, and dierucoyl GroPCho. In GC analysis of the FAME thus prepared, similar yields were obtained for the two present methods and the conventional method (data not shown). These findings support the validity and reliability of the present methods. Although fatty acid analysis of lipid classes in whole blood was reported here, plasma and serum can also be analyzed.

Some fatty acid species are acid- and heat-labile. For example, conjugated linoleic acids that occur predominantly in dairy products and show physiological activities are associated human plasma lipids in small quantities [31]. As these acids are unstable under acidic conditions, Methods I and II, which include base-catalyzed methanolysis under mild temperature conditions, will be useful for determination of these acid-labile fatty acid species in plasma lipid classes.

When the combined fatty acid compositions of both *O*-acyl and *N*-acyl phospholipids including sphingomyelin are required, acid-catalyzed methanolysis must be used. Even in this case, a combination of lipid extraction from blood with *tert*-BME/methanol and methanolysis at 100 °C with 1.2% HCl/methanol prepared from aqueous conc. HCl and methanol [10] is recommended for safety and convenience (Fig. 3). Figure 7 shows methanolysis products obtained by this combination. A pale spot found near the solvent front in lane 2 is probably 3,5-cholestadiene, a decomposition product of cholesterol.

In conclusion, the present protocols for preparation of FAME from lipid classes of blood do not include chloroform in the lipid extraction and TLC steps. The reactions of all three lipid classes, CE, TAG, and GPL, proceed at room temperature or at 45 °C. Method I in which lipid classes isolated by SPE columns may be more readily automated than Method II in which silica gel bands corresponding to individual lipid classes on TLC plates must be manually

scraped off. TLC, on the other hand, has been commonly used for separation of blood total lipids into lipid classes. In each method, the protocols proposed are thus safer for researchers and have less impact on the environment than those adopted previously. Moreover, the reaction conditions are mild for lipids. In the future, it may be worthwhile to further develop these methods to simpler and time-saving direction.

Acknowledgments We thank Dr. Kouhei Yamamoto (Osaka Prefecture University) for his advice on GC analysis of blood fatty acids. EDITORIAL

Citations: The Rules They Didn't Teach You

Eric J. Murphy

Citations, so many citations, so what is right and what is wrong? As an editor-in-chief, as a reviewer, and as an author of my own journal articles I have personally dealt with this question on multiple levels. At times, the emergence of PubMed has resulted in a citation explosion and a resulting quagmire as many authors are just not selective about referencing papers and tend to be a bit over zealous in citing more and more papers many of which are not on the topic. In such cases, I often question whether these authors have read anything more than just the titles of these papers that they cite left and right to support their own work. Last August, Dr. William J. Pearce authored an intriguing opinion piece in *The Scientist* entitled "Citations: Too Many, or Not Enough" (*The Scientist* 24(8):29). In this piece he waxed somewhat nostalgic regarding the use of *Index Medicus,* bringing back fond memories of how we found citations in the "old days". Of course, of late, I have been referred to as a dinosaur. Although I am not "Singin' the Dinosaur Blues" (a reference to a Steven Fromholz song sung by Jerry Jeff Walker), I do think it is indeed an important point to understand what are the best practices for citing the literature. Dr. Pearce also brought forth additional points about the current use of citations in the literature such as the number of citations in a manuscript, the quality of citations used, the appropriateness of these citations, and the use of reviews as a substitute for the primary literature. These are all extremely important issues that are a concern for many in the field and are addressed herein.

How do you find a citation? How do you know if a citation is appropriate? Prior to the invention of PubMed and Google as a means to search the scientific literature and back when people recognized such names as *Index Medicus* or *Current Contents*, we would start with several papers on the topic of interest. After thoroughly reading and understanding the content of these papers, the references would lead us to the next round of papers from the literature that were deemed to be pertinent. Scampering off to the library and pulling these 20–30 new papers to read we determined if these papers could be used as citations in the burgeoning manuscript that we were composing. Someone skilled in the art of citation seeking would then have another round of papers to pull as these 20–30 papers would lead to new potentially citable papers in the literature.

There are several important themes in this process that may be absent today. First, papers were read completely because that was the only way to really determine if there were important references contained in the paper being read that could be potentially useful. Second, there was a need to really understand and comprehend what was being discussed in the paper being read to make an informed decision whether it was indeed worth citing in your manuscript. Hence, decisions were made based upon a lot of time devoted to reading and understanding the literature. What concerns me is the emerging practice of authors having not really read the papers that they cite, but an even greater concern is whether authors have read anything more than the title of a paper that they are citing. Hence, these authors have not really made any decision on citing a particular paper based upon a true comprehension of that paper, but rather are citing that paper based upon a rather superficial understanding of it based solely upon the title or abstract.

In this type of authors' defense, it is a really quick process to get the citation. But should it be? In the past, finding citations took time, but it also meant reading papers and being more judicious in selecting papers on the topic to cite, reducing the superfluous citations that are common today. As a graduate student coming of age at that time, the citations of another laboratory's work in the literature or the repeated reference to a particular paper would bolster my confidence that this paper was truly worth reading and that it might serve as a solid citation in my own manuscript. This confidence was a key point in teaching yourself to place a value on the quality of the work presented in potential citations and to pick only those that met an ever evolving selectivity.

Does this mean that Google and PubMed should not be used to find citations? Absolutely not as these are modern and useful tools for searching through the ever growing literature. However, there is something to be said about having to go the library to see the newest copy of *Lipids*, *Biochemistry*, *Journal of Neurochemistry*, or *Journal of Lipid Research* to see what the newest papers are in each issue. This used to be accomplished by a weekly trip to the library to actually look at something called a printed copy of these journals. Hence, there was an effort to actually look at the literature, not merely use a computer search to find a particular topic. In the past, this was how we often found important papers that otherwise might have been overlooked. Today of course we have the table of contents for our favorite journals sent to us by e-mail, which enables us to look through the various papers published in an issue and select ones to print off or to save as a PDF to our computer. The question then is whether or not these printed or saved papers are ever really read and fully digested by the reader.

This brings me to the ever increasing citation of reviews as if they were primary literature. In the past, reviews were written by absolute leaders in the field who where imparting to the readers years of knowledge in the field and putting the current status of the field into perspective. Hence, there was a sense of validation to the papers that were cited in the review as you knew that the author was indeed one of the world's leading experts on that topic. Is that still the case today? Over the past few years, I often find reviews written by people who I don't recognize as a leader in the field and may not recognize them at all. This causes a major credibility gap, but more importantly, it suggests that less well-known individuals recognize that reviews, good or bad, will get cited by individuals who are unwilling to bother with reading the primary literature.

Let me give you a personal example as I am currently composing a review on fatty acid binding proteins (FABP) in the brain. I have used PubMed to look for potential missing key papers, which was more or less not overly productive. However, reading the literature, which when combined with the PubMed search, led to about 35 novel papers. After reading these papers, I generated another list of about 15 or more papers to acquire and then read prior to initiating writing of that review. While I know this literature quite well, I was amazed by the number of papers I didn't have in my collection and these papers I came to via reading the literature and looking for unique citations in these papers that would be useful and pertinent to the review. However, this is a bit of a tangent, nonetheless an important one about composing a review, yet it includes the ideas of reading the papers being cited as well as using someone else's citations to find previously unknown literature to you on the topic of interest. This newly acquired literature was located despite doing a thorough PubMed search, which of course depended upon me picking the correct key words as well as the authors picking the correct key words. While I figure that the authors might have chosen correctly, my confidence in myself on this point is less than overwhelming.

However, does a review on, let's say FABP in the brain, suffice for a reference for the role of FABP3 in brain fatty acid uptake? No. A review might be useful to cite as a global vision on the role of FABP in brain function, yet the actual paper(s) in which the observation regarding fatty acid uptake was illuminated should be cited. This is where I find many authors repeatedly making this mistake, assuming that citing a review is sufficient, but it is absolutely not sufficient nor is such a citation correct.

Why is this so critical? Well for two overlapping reasons. First, it fails to give credit to the individuals who make a particular discovery and report this in the literature. The author of the review may not have made that observation, so why give them credit? So many times I see a repeated citation of a review by multiple authors over several years, yet when looking at the actual review I find it has little to do with what it is credited to report. Hence, it is especially important not to start an inappropriate base for others to continue to make an incorrect citation, but not giving credit where credit is due does exactly that. Second, citing a review does not permit an individual to grow the number of references to their work nor to the journal in which it was originally printed. This can impact many aspects of career development such as promotion and salary, but for a journal it impacts how well a journal is perceived by the greater science community. Thus, in the end, I guess the "Golden Rule" again comes into play, cite others' work properly as you hope others will cite your work properly.

Yet amazingly, editors love to publish reviews because this type of publication is often highly cited and that will drive up a journal's impact factor. Whether such a citation

is right or wrong is based upon the willingness of the individuals doing the citing actually to read the review and the primary literature cited therein. Well-written reviews offer an incredible resource to a novice in the field giving a historical background and a current perspective by a leader in the field. Well-written reviews offer readers an up-to-date literature review and a great starting-off point to begin collecting the most pertinent literature that they can begin to read. Undoubtedly, this will give them an additional insight into particular discoveries as well as offer a new source for potential pertinent references not contained in the review. Hence, reviews are crucial for every field in science, but the use of reviews as the key citation for this or that discovery is not proper as such citations should go back to the original literature.

While Dr. Pearce highlighted the increase in the number of citations per paper using the *American Journal of Physiology* as an example, he noted that the average number of citations per paper grew from 29 in 1989 to 37 in 1999 and then to 42 in 2009 [1], I really don't see much of a problem with this trend. As the literature expands, it is my expectation that authors will need to cite more and more papers from the literature to be complete. Adding an additional 13 papers cited on average over a 20 year period is not overwhelming nor is the growth of 5 papers over the last 10 years. I would rather see an author include 10–15 additional references in a manuscript that are all deemed important rather than pick and choose which work is cited or even worse use one or two reviews to fill this void. So, in the end I think it is important to cite papers that bring into perspective for the reader the important background required to introduce the topic properly, the methods used in the study, and the required citations to have a proper discussion of how the author's work fits into the field. This of course includes citations that both support the author's conclusions as well as those that might dispute the author's conclusions.

This editorial condenses down to my rather simple rules for citations. These rules may not be all-comprehensive, but I have done the best I can to be inclusive. Here they are:

1. Read and comprehend all of the literature that you are citing in your manuscript
2. Cite the primary literature and the actual papers to which a particular discovery is attributed; if multiple citations need to be made, do so
3. Cite the literature that agrees as well as that which disagrees with your point-of-view; be fair to multiple points-of-view
4. Be as inclusive as possible, but know where to draw the line, citing the most pertinent literature and the original papers
5. Use reviews judiciously in your manuscript and use them properly
6. Do NOT cite reviews in lieu of citing the original literature
7. Remember that PubMed goes back to 1966, but many worthwhile discoveries were made prior to that time and it is important to be historically accurate in your citations
8. When citing your own work, do so to support your point-of-view or to put the current work into the proper context for the reader. Do not attempt to grow your own citation base solely on the dreaded "self-citation"

Following these simple rules will certainly help limit the use of improper, superfluous citations because you have actually read the literature. An additional advantage is that by reading the literature, you will be able to find those elusive, yet important papers on your topic of interest. This adds importance and perhaps makes an Introduction and Discussion much more relevant and inclusive. By avoiding merely citing your own work and including work of others as well as those papers with a different point-of-view, you are in the end being a good citizen of science and working to recognize the contribution of your colleagues in the field. In the end, following these simple rules avoids many of the issues brought forth in this editorial and in the article by Dr. Pearce. So if you have been a citation abuser, try this 8-step program.

ORIGINAL ARTICLE

Activation of AMP-kinase by Policosanol Requires Peroxisomal Metabolism

Subhashis Banerjee · Sarbani Ghoshal · Todd D. Porter

Received: 10 December 2010 / Accepted: 3 February 2011 / Published online: 27 February 2011

Abstract Policosanol, a well-defined mixture of very long chain primary alcohols that is available as a nutraceutical product, has been reported to lower blood cholesterol levels. The present studies demonstrate that policosanol promotes the phosphorylation of AMP-kinase and HMG-CoA reductase in hepatoma cells and in mouse liver after intragastric administration, providing a possible means by which policosanol might lower blood cholesterol levels. Treatment of hepatoma cells with policosanol produced a 2.5-fold or greater increase in the phosphorylation of AMP-kinase and HMG-CoA reductase, and increased the phosphorylation of Ca^{++}/calmodulin-dependent kinase kinase (CaMKK), an upstream AMP-kinase kinase. Intragastric administration of policosanol to mice similarly increased the phosphorylation of hepatic HMG-CoA reductase and AMP-kinase by greater than 2-fold. siRNA-mediated suppression of fatty aldehyde dehydrogenase, fatty acyl-CoA synthetase 4, and acyl-CoA acetyltransferase expression in hepatoma cells prevented the phosphorylation of AMP-kinase and HMG-CoA reductase by policosanol, indicating that metabolism of these very long chain alcohols to activated fatty acids is necessary for the suppression of cholesterol synthesis, presumably by increasing cellular AMP levels. Subsequent peroxisomal β-oxidation probably augments this effect.

Keywords Policosanol · AMP-kinase · Peroxisomes · HMG-CoA reductase · Hepatoma cells · Ca^{++}/calmodulin-dependent kinase kinase

Abbreviation
CaMKK Calcium-calmodulin-dependent kinase kinase

Introduction

Policosanol is a well-defined mixture of very long-chain alcohols (C26-C32) derived most commonly from the wax of processed sugar cane [1]. A number of early clinical studies indicated that policosanol at 5–20 mg/day could lower blood cholesterol levels [2–4], although several more recent, larger studies have been unable to replicate this benefit, even with doses up to 80 mg/day [5–7]. Our previous studies [8] showed that policosanol decreases cholesterol synthesis in rat hepatoma cells by up to 30% at concentrations relevant to clinical dosing regimens, providing a possible mechanism to lower blood cholesterol. This inhibition is mediated at or above HMG-CoA reductase, the regulatory step in cholesterol synthesis, but policosanol does not directly inhibit this enzyme nor does it decrease enzyme levels as measured by immunoquantitation [8]. Similar results were obtained with fibroblasts in vitro [9, 10], and two studies with whole animals similarly showed that policosanol treatment decreases hepatic cholesterol synthesis [11, 12]. However, two studies with hamsters were unable to demonstrate an effect of policosanol on cholesterol synthesis in vivo [13, 14].

Policosanol treatment of hepatoma cells increases the phosphorylation of AMP-kinase at Thr172 [8, 15], a

modification known to activate this kinase, providing a possible mechanism by which policosanol might down-regulate HMG-CoA reductase activity and decrease cholesterol synthesis without directly inhibiting the enzyme or reducing its expression: AMP-kinase is the principal regulatory kinase for HMG-CoA reductase, catalyzing the phosphorylation of HMG-CoA reductase at Ser872 [16]. This phosphorylation decreases HMG-CoA reductase activity by 70–80% [17] and is thought to provide a rapid means to modulate cholesterol synthesis in response to cellular ATP levels and other stimuli. The present studies were undertaken to test this hypothesis that policosanol treatment promotes the phosphorylation of HMG-CoA reductase and to identify the mechanism by which policosanol activates AMP-kinase.

Materials and Methods

Chemicals

Lesstanol Brand Natural Policosanol OCTA-60 was kindly provided by Garuda International, Inc. (Lemon Cove, CA). Alcohol content, determined by gas chromatography/flame ionization detection (average of two independent determinations), yielded 66% octacosanol (C28), 17% triacontanol (C30), 6% hexacosanol (C26), 5% dotriacontanol (C32), 2% tetracosanol (C24), and 1% tetratriacontanol (C34). Tricosanol (C23) and heptacosanol (C27) each constituted less than 1% of the mixture, and eicosanol (C20), docosanol (C22), and nonacosanol (C29) constituted less than 0.1%; total alcohol content was 98%. Dulbecco's modified Eagle's medium (DMEM), penicillin-streptomycin-glutamine (PSG), fetal bovine serum (FBS), and trypsin were purchased from Invitrogen (Carlsbad, CA). Acadesine (AICAR), 1,1-dimethylbiguanide hydrochloride (metformin), ionomycin, sodium acetate, and protease inhibitor cocktail were obtained from Sigma (St. Louis, MO). HALT phosphatase inhibitor and the BCA protein assay kit were purchased from Roche Diagnostics (Indianapolis, IN) and Pierce/Thermo Scientific (Rockford, IL) respectively. McA-RH7777 rat hepatoma cells were obtained from American Type Culture Collection (Manassas, VA) and used between passages 12 and 22.

Cell Culture and Preparation of Lysates

McA-RH7777 rat hepatoma cells were cultured in DMEM supplemented with 10% FBS and 1× PSG in six-well plates at 37 °C under a humidified atmosphere of 5% CO_2. After 48 h the medium was replaced with fresh medium with the addition of policosanol (10–25 μg/ml in 50% ethanol) and incubation was continued for 3 h. Control cells received an equal volume of 50% ethanol, which did not exceed 1% final concentration in the medium. Cells were washed once with phosphate-buffered saline (pH 7.4), scraped from the plates, pelleted by low-speed centrifugation, and lysed by two cycles of freeze-thawing (dry ice/ethanol and 37 °C water bath) in 0.25 M Tris–HCl buffer (pH 7.5) containing protease and phosphatase inhibitors at 2× standard concentration. The lysates were cleared by centrifugation (18,300×*g*, 10 min, at 4 °C) and the supernatant was stored in aliquots at −80 °C.

Animal Treatments

Experiments involving the use of animals were performed following protocols approved by the Institutional Animal Care and Use Committee of the University of Kentucky and were in accordance with all policies for the use and care of laboratory research animals as stipulated by the NIH. Seven-to-eight week-old female C57BL/6 J mice (∼15–17 g) were purchased from Jackson laboratories (Bar Harbor, ME) and maintained in a temperature-, humidity-, and light-controlled facility with free access to water and food for one week prior to experimentation. After an overnight fast, mice in groups of 5 were gavaged with 150 μl of policosanol in 50% ethanol in doses of 25, 50 or 100 mg/kg body weight. Control animals received an equal volume of 50% ethanol only. Access to food was restored, and at 0, 3, 6, 12, and 18 or 24 h the mice were euthanized by CO_2 asphyxiation and the liver and intestine were removed and portions promptly frozen in liquid nitrogen and stored at −80 °C until use.

Preparation of Tissue Homogenates

Hepatic and intestinal homogenates were prepared as follows: Approximately 25 mg of tissue was transferred into 4 volumes of ice-cold RIPA homogenization buffer (50 mM Tris–HCl, pH 7.4, 150 mM NaCl, 1 mM PMSF, 1 mM EDTA, 5 μg/ml aprotinin, 5 μg/ml leupeptin, 1% Triton X-100, 1% sodium deoxycholate, and 0.1% SDS) and homogenized using a Potter-Elvehjem homogenizer. The samples were then subjected to two cycles of freeze–thawing (dry ice/ethanol and 37 °C water bath) and then cleared by centrifugation (18,300×*g*, 10 min, 4 °C). The supernatant was stored in aliquots at −80 °C. Protein concentration was determined by BCA assay.

Gel Electrophoresis and Immunoblotting

Thirty micrograms of protein from cell lysate or tissue homogenate was fractionated by SDS-polyacrylamide gel electrophoresis on 8% gels and electroblotted to nitrocellulose (Bio-Rad, Hercules, CA). The membrane was

blocked with 0.05% Tween-20 and 5% defatted milk for 1 h at room temperature and then incubated in this same buffer with rabbit antibody to total AMP-kinase (anti-AMPK α-pan, 1:2000; Upstate/Millipore, Billerica, MA) or to phosphorylated AMP-kinase (anti-phospho-AMPKα, 1:500; Upstate/Millipore) overnight at 4 °C with gentle shaking. The immunoblot was developed with a secondary antibody conjugated to horseradish peroxidase for 1 h at room temperature and the chemiluminescent image (Supersignal West Pico Chemiluminescent Substrate, Pierce/Thermo Scientific) captured by autoradiography on a Kodak Image Station or on film and analyzed for mean intensity above background. Band intensity on film was measured with Image J software on the scanned image with background subtraction. The same procedure was followed for detecting total HMG-CoA reductase (anti-HMG-CoA reductase, 1:1000, Millipore) and phosphorylated HMG-CoA reductase (anti-phospho-HMG-CoA reductase, 1:500; Millipore).

Immunoprecipitation

To determine the level of phosphorylation of the kinases LKB1 and calcium-calmodulin-dependent kinase kinase (CaMKK), cell lysates or tissue homogenates were incubated for 1 h at 4 °C with 20 μl of mouse monoclonal antibody to phosphoserine/phosphothreonine/phosphotyrosine (Abcam, Cambridge, MA). Antibody conjugates were precipitated with 35 μl of protein A or G Plus-Agarose (Calbiochem/EMD Chemicals, Gibbstown, NJ) for 1 h at 4 °C as follows: After centrifugation at 12,000×*g* for 20 s at 4 °C, the immunoprecipitated phosphoproteins were released from the agarose beads by heating at 95 °C for 4 min in 25 μl of 2× gel loading buffer [0.5 M Tris–HCl, pH 6.8, 4.4% SDS, 20% (v/v) glycerol, 2% (v/v) 2-mercaptoethanol, and bromophenol blue in deionized water]. After removal of beads by centrifugation at 12,000×*g* for 20 s at 4 °C, the phosphoproteins were fractionated by SDS-gel electrophoresis and electroblotted to nitrocellulose as described above. Phosphorylated protein content was detected and quantified with an antibody to LKB1 (anti-LKB1, 1:1000; Sigma Chemical) or CaMKK (anti-CaMKK, 1:1000; BD Transduction, San Jose, CA) followed by a secondary antibody conjugated with horseradish peroxidase as described above.

siRNA Plasmid Transfection and RT-PCR Analysis of Expression

Plasmids for the expression of siRNA (SureSilencing™ shRNA, SABiosciences, Frederick, MD) to fatty aldehyde dehydrogenase 3A2 (ALDH3A2), peroxisomal acyl-CoA synthetase long-chain family member 4 (ACSL4), and peroxisomal acetyl-CoA acyltransferase 1 (β-ketothiolase, ACAA1) were prepared by standard techniques from *Escherichia coli* DH5α and used to transfect hepatoma cells plated in 6-well plates at a density of 8×10^4 cells per cm^2 as follows: On the day following plating, plasmid DNA was mixed with Fugene 6 transfection reagent (Roche Diagnostics) according to the manufacturer's instructions at a ratio of 1 μg DNA:5 μl reagent and complexes were allowed to form for a minimum of 30 min at room temperature. The cell culture medium then was replaced with antibiotic-free medium containing 10% FBS and the transfection mixture was added drop-wise to the cells with gentle swirling. Four plasmids with unique siRNA sequences were provided for each gene; all four were tested for efficacy by RT-PCR as described below (data not shown), and the plasmid providing the greatest suppression of mRNA expression for each gene was selected for use (Table 1). A plasmid containing a scrambled siRNA sequence served as the negative control.

Total RNA was isolated from cells with the use of TRIzol reagent (Invitrogen) at 2, 4, 6, 8, and 10 days post-transfection and the concentration of RNA was determined spectrophotometrically with the use of a Nanodrop instrument (Thermo Scientific). First strand cDNA synthesis was performed using 200 units of Superscript II Reverse Transcriptase (Invitrogen) with 200 ng of random primers, 1 μl RNaseOUT (Invitrogen), 5 μg of total RNA, 2 μl of 0.1 M DTT, and 1 μl of dNTP mix (200 μM each nucleotide) in a total volume of 12 μl in diethylpyrocarbonate-treated water.

Table 1 siRNA plasmid sequences and PCR primers

Gene	GeneID	siRNA sequence	PCR primers
ALDH3A2	65183	TCACTGATGTTGACCCTAACT	Fw: 5′-GCGAGAGAAGGACATCTTGG-3′

Scrambled control		GGAATCTCATTCGATGCATAC	

The reaction was incubated at 25 °C for 10 min, followed by 50 min at 42 °C and then inactivated by incubation at 70 °C for 15 min. Synthesized single-stranded cDNA was quantified by Nanodrop measurement. Gene-specific primers for real-time polymerase chain reaction (PCR) were designed using Primer 3 software (http://frodo.wi.mit.edu/primer3/) and are shown in Table 1. Each 20-µl PCR reaction mixture contained 0.1 µg of single-stranded cDNA or template, 0.5 µl of gene-specific primers (10 µM each), 3 µl of dNTP mix (200 µM each nucleotide) and 1× SYBR Green PCR buffer (Applied Biosystems, Carlsbad, CA). Cycling conditions were: 2 min at 50 °C to activate, initial denaturation for 10 min at 95 °C, followed by 50 cycles of denaturation for 15 s at 95 °C and 1 min of annealing/extension at 55 °C. In order to detect nonspecific amplification, dissociation curves were established for each PCR product. The detection and quantitation of nucleic acid levels was done by using the comparative delta-delta ct method [18].

Statistical Analysis

Image intensity values for each blot were normalized, setting the control (untreated) value at 100 after background subtraction. Results are presented as the mean and standard deviation with significance determined by one-way analysis of variance (ANOVA) with either Dunnett's or Tukey's post-hoc test, setting $p < 0.05$, using Prism (GraphPad Software, La Jolla, CA).

Results

Previous results from our laboratory demonstrated that policosanol activates AMP-kinase in hepatoma cells [8]. To confirm and extend those findings, we carried out dose-response and time-course experiments. Policosanol increased AMP-kinase phosphorylation in hepatoma cells by more than 2.5-fold after a 3-h treatment (Fig. 1a), with maximal stimulation occurring between 15–25 µg/ml. These increases were comparable to those seen with AICAR and metformin, both of which are known to promote phosphorylation of AMP-kinase and served as positive controls. No change in the level of total AMP-kinase protein levels were observed over the 3-hr period of the experiment. As shown in Fig. 1b, policosanol treatment rapidly activated AMP-kinase, with an increase in phosphorylation evident at 30 min; phosphorylation peaked at 1.5 h and stayed elevated through 3 h.

The activation of AMP-kinase by policosanol was concomitant with the phosphorylation of HMG-CoA reductase in hepatoma cells, as shown in Fig. 2. HMG-CoA reductase phosphorylation was increased in a dose-dependent manner with 10–25 µg/ml of policosanol. Treatment of

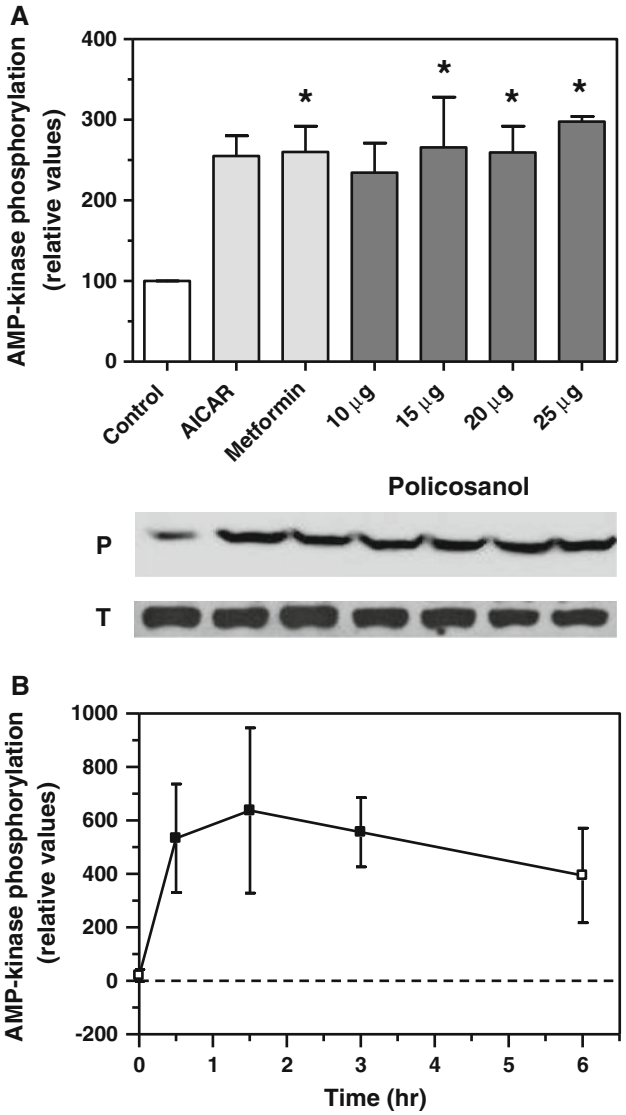

Fig. 1 Policosanol activates AMP-kinase in vitro. **a** Phosphorylated AMP-kinase in hepatoma cells was measured by immunoquantitation with an antibody specific for the phosphorylated protein after a 3-h treatment with 10–25 µg/ml of policosanol. The AMP-kinase activators AICAR and metformin (1 mM each) served as positive controls. Values represent the mean and standard deviation of three experiments; *asterisks* indicate values statistically different from control (ANOVA with Dunnett's post-hoc test, $p < 0.05$). Representative immunoblots of phosphorylated (P) and total (T) AMP-kinase are shown below the graph. **b** AMP-kinase phosphorylation in hepatoma cells at various times after treatment with 15 µg/ml of policosanol. Values represent the mean and standard deviation of three experiments; *closed symbols* are statistically different from the zero-time value

cells with AICAR or metformin yielded a similar increase in phosphorylated HMG-CoA reductase. Total HMG-CoA reductase protein levels did not change over the course of this experiment.

To extend these studies to whole animals in vivo, the phosphorylation of AMP-kinase and HMG-CoA reductase

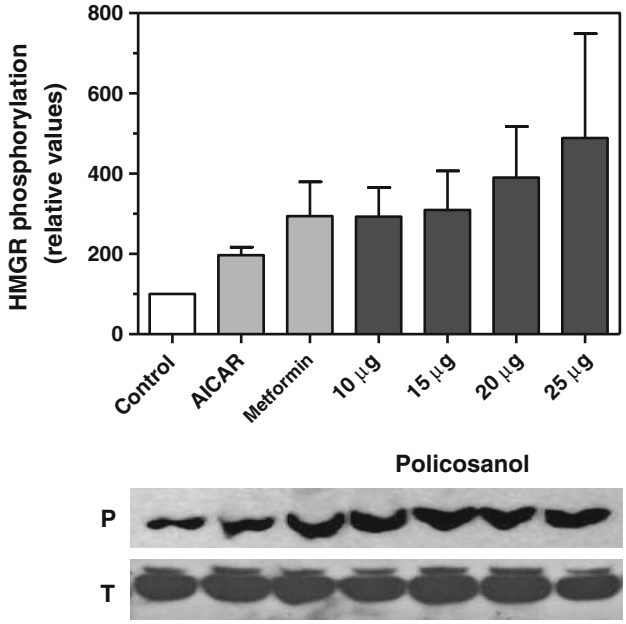

Fig. 2 Policosanol inactivates HMG-CoA reductase in vitro. Phosphorylated HMG-CoA reductase in hepatoma cells was measured by immunoquantitation with an antibody specific for the phosphorylated protein after a 3-h treatment with 10–25 μg/ml of policosanol. AICAR and metformin (1 mM each) served as positive controls. Values represent the mean and standard deviation of three experiments. Representative immunoblots of phosphorylated (P) and total (T) HMG-CoA reductase are shown below the graph

was assessed in the livers of mice gavaged with a single dose of policosanol at 10, 25, 50, and 100 mg/kg. As shown in Fig. 3, policosanol increased the phosphorylation of AMP-kinase and HMG-CoA reductase at 25 and 50 mg/kg by 2 to 4-fold as early as 3 h after dosing. No increase in phosphorylation was seen at lower (10 mg/kg) or higher doses (100 mg/kg), and no change in the total AMP-kinase or HMG-CoA reductase was observed at each of time points and the dosing regimens tested (data not shown). Policosanol had no effect on AMP-kinase in the duodenum of mice gavaged with 25 or 50 mg/kg (data not shown), suggesting that intestinal cholesterol synthesis, which can account for up to 25% of circulating cholesterol, is resistant to suppression by these fatty alcohols.

As AMP-kinase is itself activated by upstream kinases, we wanted to determine if policosanol acted on these upstream kinases. The principal AMP-kinase kinase is LKB1, but AMP-kinase can also be activated by CaMKKβ [19]. As both kinases are activated by phosphorylation, we monitored their phosphorylation in hepatoma cells and in mouse liver by immunoblotting after policosanol treatment. LKB1 phosphorylation was increased about 3-fold in hepatoma cells by policosanol (Fig. 4), slightly less than that seen with metformin, a known activator of LKB1, although neither increase was statistically significant. LKB1 phosphorylation was not increased in mouse liver after gavage with policosanol. CaMKK phosphorylation was increased in hepatoma cells about 2.5-fold by policosanol, and to a slightly greater extent than that seen with ionomycin, an activator of CaMKK; both increases were statistically significant. CaMKK phosphorylation also was increased up to 4-fold in mouse liver at 6 h post-dosing, and remained elevated up to 18 h, although these increases did not reach statistical significance. These results support the activation of AMP-kinase by policosanol both in cell culture and in vivo, and suggest that CaMKK contributes to this activation.

Long-chain fatty alcohols are substrates for the 'fatty alcohol cycle' which converts these alcohols to their corresponding fatty acids [20]. To determine if metabolism of policosanol by this pathway was necessary for the activation of AMP-kinase, we used siRNA to suppress the expression the second enzyme in this pathway, fatty aldehyde dehydrogenase 3A2, in hepatoma cells. As shown in Fig. 5, the siRNA plasmid suppressed ALDH3A2 mRNA expression nearly completely at 4 and 6 days post-transfection. The corresponding ability of policosanol to promote AMP-kinase phosphorylation at 4, 6, and 8 days post-transfection was reduced by greater than 50% in these cells, and phosphorylation of HMG-CoA reductase was nearly extinguished. These results reveal that the very long chain alcohols that make up policosanol must be converted to fatty acids in order to activate AMP-kinase.

To determine if peroxisomal metabolism of policosanol was also required for activation of AMP-kinase, we used siRNA to suppress the expression of peroxisomal acyl-CoA synthetase long-chain family member 4 (ACSL4) and peroxisomal acetyl-CoA acyltransferase 1 (β-ketothiolase, ACAA1) in hepatoma cells; these enzymes catalyze the activation of long-chain fatty acids and the last step in peroxisomal β-oxidation, respectively. As shown in Fig. 6, mRNA levels for both enzymes were suppressed by greater than 80% on days 4 and 6 post-transfection, similar to that seen with ALDH3A2. The ability of policosanol to stimulate the phosphorylation of AMP-kinase and HMG-CoA reductase was fully prevented in cells transfected with either siRNA plasmid. The ability of metformin to activate AMP-kinase and promote HMG-CoA reductase phosphorylation was not affected by these siRNAs, demonstrating that the AMP-kinase pathway itself was not impaired by the suppression of peroxisomal fatty acid catabolism.

As the principal metabolite of fatty acid β-oxidation is acetyl-CoA, we determined if addition of acetate to cells would similarly increase the phosphorylation of AMP-kinase. As shown in Fig. 7a, addition of sodium acetate (0.12 mM) increased AMP-kinase phosphorylation by 2–3-fold, similar to that seen with AICAR, metformin, and policosanol. To determine if acetate activated AMP-kinase

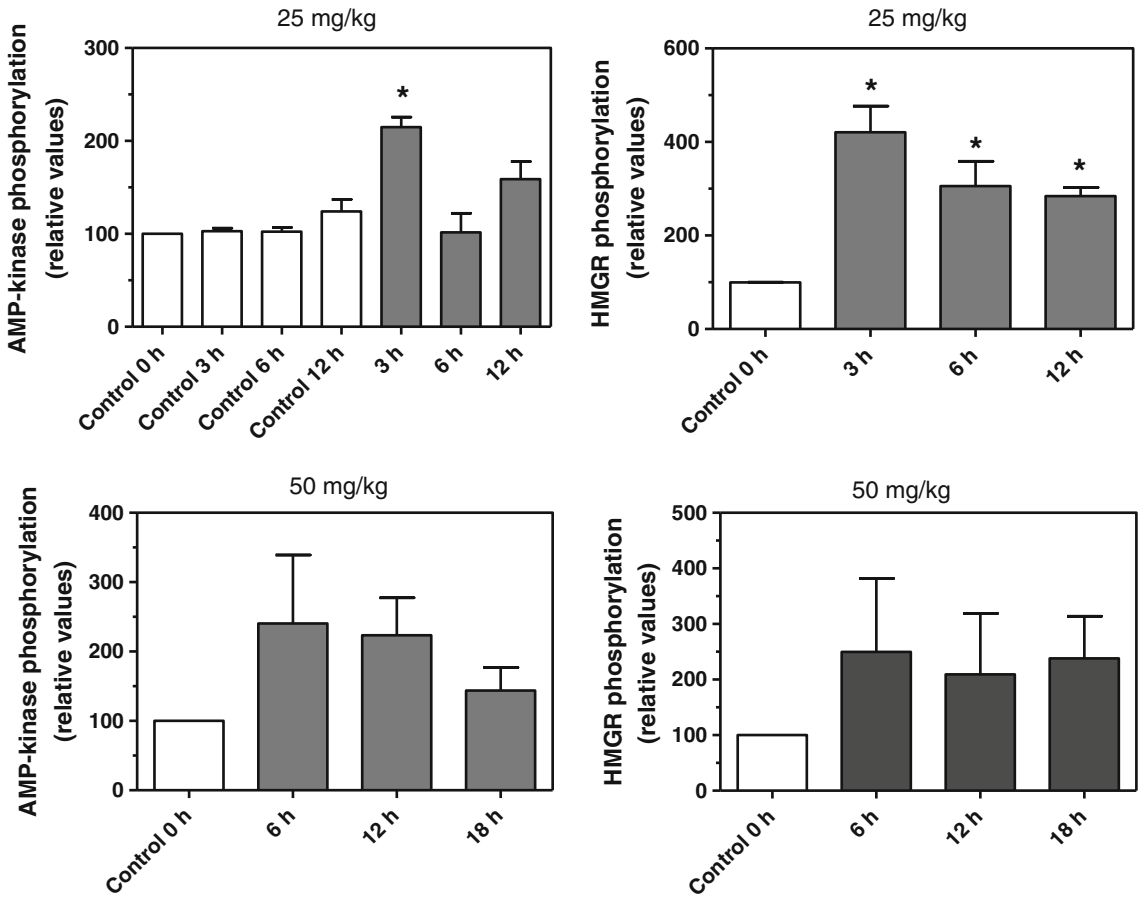

Fig. 3 Policosanol increases the phosphorylation of AMP-kinase and HMG-CoA reductase (HMGR) in vivo. Mice were gavaged with policosanol (25 or 50 mg/kg) and phosphorylated AMP-kinase and HMG-CoA reductase were measured in liver homogenates by immunoquantitation. Values represent the mean and standard deviation of 2–3 experiments; values that are statistically different from untreated controls are indicated with *asterisks*. Statistical significance was determined by ANOVA with Dunnett's post-hoc test, $p < 0.05$

by the same pathway as policosanol, the effect of acetate treatment on CaMKK phosphorylation and LKB1 phosphorylation was measured. As seen with policosanol, acetate increased CaMKK phosphorylation by nearly 3-fold (Fig. 7b), but did not increase LKB1 phosphorylation (Fig. 7c).

Discussion

The present studies reveal that the activation of AMP-kinase by policosanol is dependent upon the oxidation and peroxisomal metabolism of these very long-chain alcohols. It was anticipated that these alcohols would be metabolized by this route [21, 22]; moreover, the ability of long chain fatty acids to activate AMP-kinase is well established [23]. These findings thus provide a biochemical mechanism to explain the observed ability of policosanol to decrease cholesterol synthesis, through the activation of AMP-kinase and subsequent inactivation of HMG-CoA reductase [8, 15]. It is worth noting that D-003, a mixture of very long chain fatty acids also derived from sugarcane wax, has similarly been shown to decrease cholesterol synthesis in cultured fibroblasts [24]. These results do not exclude the possibility that policosanol acts through other HMG-CoA reductase kinases as well, such as a protein kinase C or a calmodulin-dependent protein kinase, as both have been shown to be capable of phosphorylating HMG-CoA reductase in vitro [25].

Metformin, a widely used drug in Type II diabetes, is a potent activator of AMP-kinase [26] and is well known to modestly lower blood lipid levels in patients. The present results are consistent with the possibility that policosanol could act via this same mechanism to lower blood cholesterol levels. However, although we show here that policosanol is able to increase the phosphorylation of HMG-CoA reductase in mouse liver after intragastric administration, the ability of therapeutically recommended doses of policosanol to decrease blood cholesterol levels by this pathway remains in doubt. The doses used in our study, ranging from

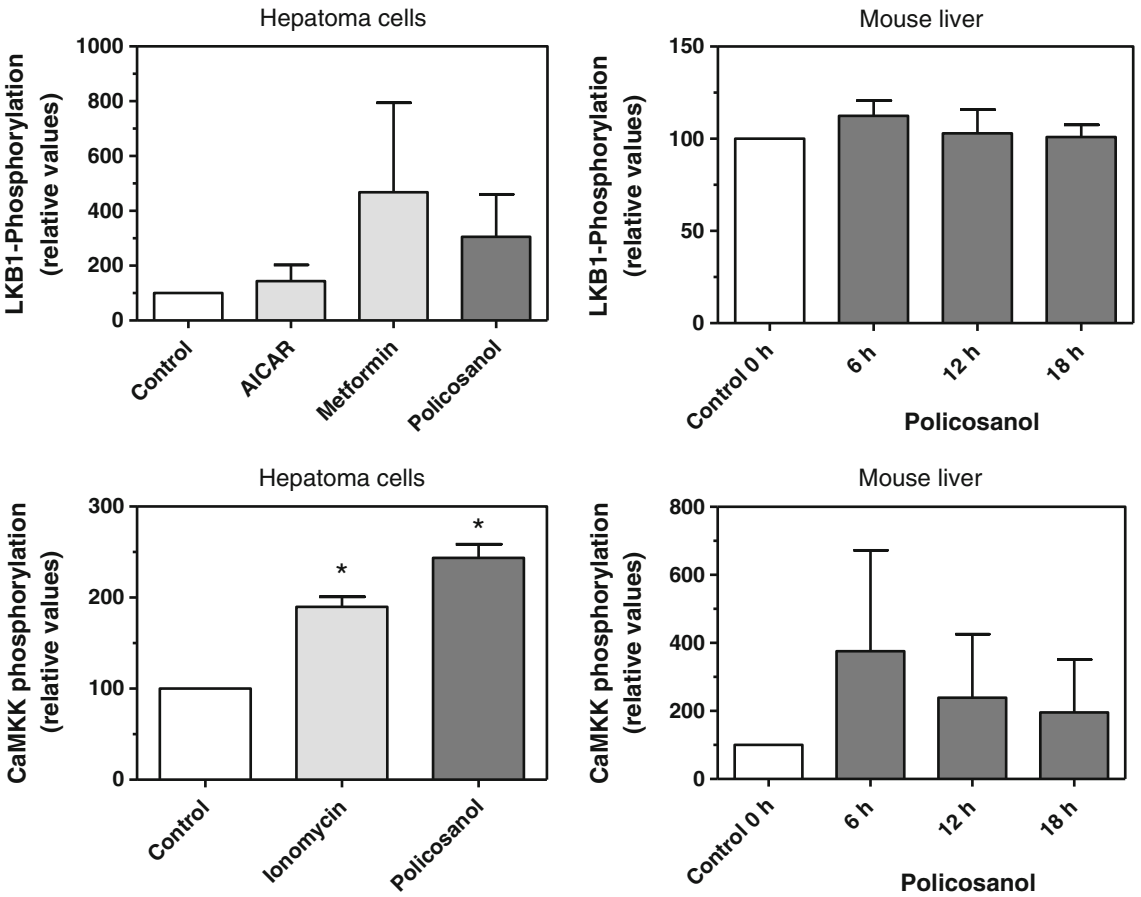

Fig. 4 Policosanol activates CaMKK and LKB1. Phosphorylated LKB1 and CaMKK were immunoprecipitated from hepatoma cell lysates or mouse liver homogenates with an antibody to phosphoserine/phosphothreonine/phosphotyrosine and then quantified by immunoblotting with an antibody to LKB1 or CaMKK. Metformin (1 mM) served as a positive control and AICAR (1 mM) as a negative control for the LKB1 assays; ionomycin (1 μg/ml) was a positive control for the CaMKK assay. Hepatoma cells were incubated with 15 μg/ml of policosanol for 3 h; mice were gavaged with 50 mg/kg body weight of policosanol and the livers removed at 6, 12, and 18 h post-dosing. Values represent the mean and standard deviation of 2–3 experiments; values that are statistically different from controls are indicated with *asterisks*. Statistical significance was determined by ANOVA with Dunnett's post-hoc test, $p < 0.05$

10 to 100 mg/kg by body weight, are considerably higher than those used in clinical studies, where the typical dose is between 5 to 80 mg per day. Assuming that the typical patient weighs 70 kg, a minimal 10 mg/kg dose would require a 35-fold higher dose than that typically used (up to 1 g/d), and this calculation does not consider differences in intestinal absorption between mice and men. Nonetheless, long-chain alcohols are a common constituent of human diets [27], and no significant adverse effects have been noted for policosanol in animal or clinical studies.

CaMKK is thought to be a principal AMP-kinase kinase in brain, but is considered to be an alternative to LKB1 in the liver [28]. In our studies policosanol produced a statistically significant increase in CaMKK phosphorylation in hepatoma cells, suggesting that activation of this upstream kinase by policosanol contributes to the phosphorylation of AMP-kinase. CaMKK phosphorylation was also increased 4-fold in mouse liver after gavage, although this increase was not statistically significant. CaMKK also appeared to be activated by addition of acetate to hepatoma cells, which would bypass the requirement for peroxisomal metabolism; either acetate per se, or its activation to acetyl-CoA or subsequent metabolism would appear to be sufficient to activate this kinase. Notably, Za'tara et al. [23] have shown that non-metabolizable analogs of long-chain fatty acids are also able to activate AMP-kinase, but that this requires activation with coenzyme A. The CoA synthetases that activate these fatty acids to acyl-CoAs generate AMP; AMP is an allosteric regulator of AMP-kinase that facilitates its phosphorylation by LKB1, but not, interestingly, by CaMKK [19, 28]. Thus, β-oxidation of very long chain fatty acids may not be required if they are present in sufficient abundance to generate elevated levels of AMP by activation with coenzyme A.

Our studies with siRNA-mediated suppression of fatty alcohol cycle (ALDH3A2) and peroxisomal enzymes

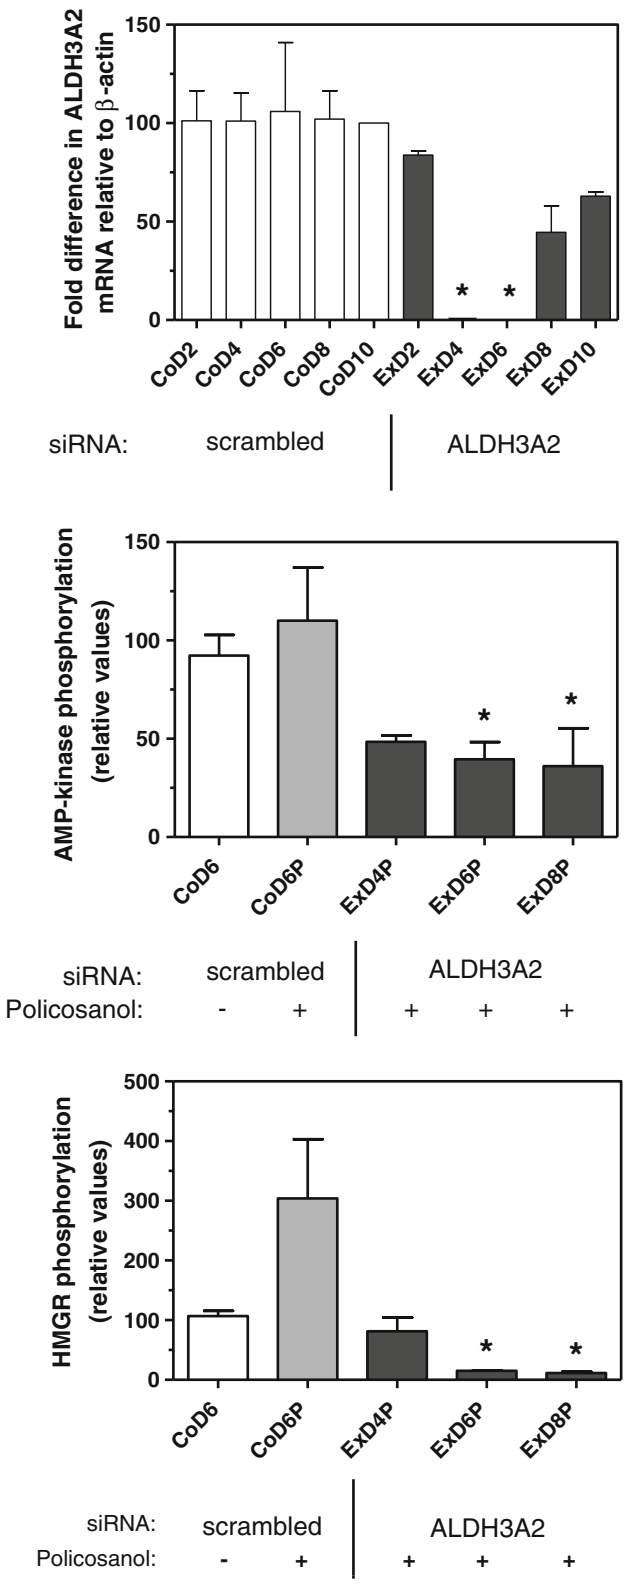

Fig. 5 siRNA-mediated suppression of fatty aldehyde dehydrogenase 3A2 (ALDH3A2) prevents the increase in phosphorylation of AMP-kinase and HMG-CoA reductase by policosanol. ALDH3A2 mRNA was quantified by RT-PCR with the primers listed in Table 1; control cells contained a plasmid with a scrambled siRNA sequence. Phosphorylated AMP-kinase and HMG-CoA reductase were measured by immunoquantitation. Cells were incubated with 15 μg/ml of policosanol for 3 h as indicated. Values represent the mean and standard deviation of 2–3 experiments; values that are statistically different from the corresponding day control (mRNA levels) or the policosanol-treated control are indicated with *asterisks*, as determined by one-way ANOVA with Tukey's post-hoc test, $p < 0.05$. *Co* control cells, *Ex* cells transfected with ALDH3A2 siRNA plasmid; 'D' indicates day post-transfection; 'P' indicates policosanol treatment

(ACSL4, ACAA1) demonstrate that peroxisomal metabolism of policosanol is necessary for the activation of AMP-kinase in hepatoma cells. This requirement for β-oxidation, as shown with ACAA1 suppression, suggests that repeated chain-shortening with subsequent activation by ketothiolase is necessary to generate sufficient AMP to increase AMP-kinase phosphorylation. However, the suppression of peroxisomal β-oxidation not only blocked the effect of policosanol, but also reduced the phosphorylation of AMP-kinase and HMG-CoA reductase below the level seen in non-suppressed (control) cells. This suggests that peroxisomal metabolism contributes to the basal level of AMP-kinase activation under normal physiological conditions. It is thus formally possible that the activation of policosanol-derived fatty acids to acyl-CoAs is sufficient to increase AMP-kinase phosphorylation and activity, without further metabolism by β-oxidation, as found by Za'tara et al. [23]. Nonetheless, under normal circumstances the subsequent peroxisomal metabolism of these activated very long chain fatty acids would greatly increase the generation of AMP and amplify this signaling pathway.

This peroxisomal pathway for the activation of AMP-kinase by policosanol in hepatoma cells can be extrapolated to the liver in an intact animal. However, the observation made here and earlier [29] that acetate, the product of β-oxidation, leads to the activation of AMP-kinase, raises the possibility that policosanol does not need to be absorbed intact to activate hepatic AMP-kinase. Although there is good evidence that the very long-chain alcohols of policosanol are absorbed into the systemic circulation, the fractional absorption is very low [22, 30, 31]. It can be considered that a significant portion of these alcohols may be metabolized in the colon by gut bacteria to generate chain-shortened metabolites, including acetate, propionate, and butyrate, which are readily absorbed and transported to the liver [reviewed in 32]. Moreover, a number of studies have reported that propionate produced in the gut can decrease hepatic cholesterol synthesis [32]. These chain-shortened metabolites would bypass peroxisomal metabolism and serve as direct substrates for cytosolic acyl-CoA synthases, thereby generating AMP; the ability of intraperitoneal administration of acetate to increase AMP levels in hepatocytes and in the liver [33, 34] supports this hypothesis. It was also reported that

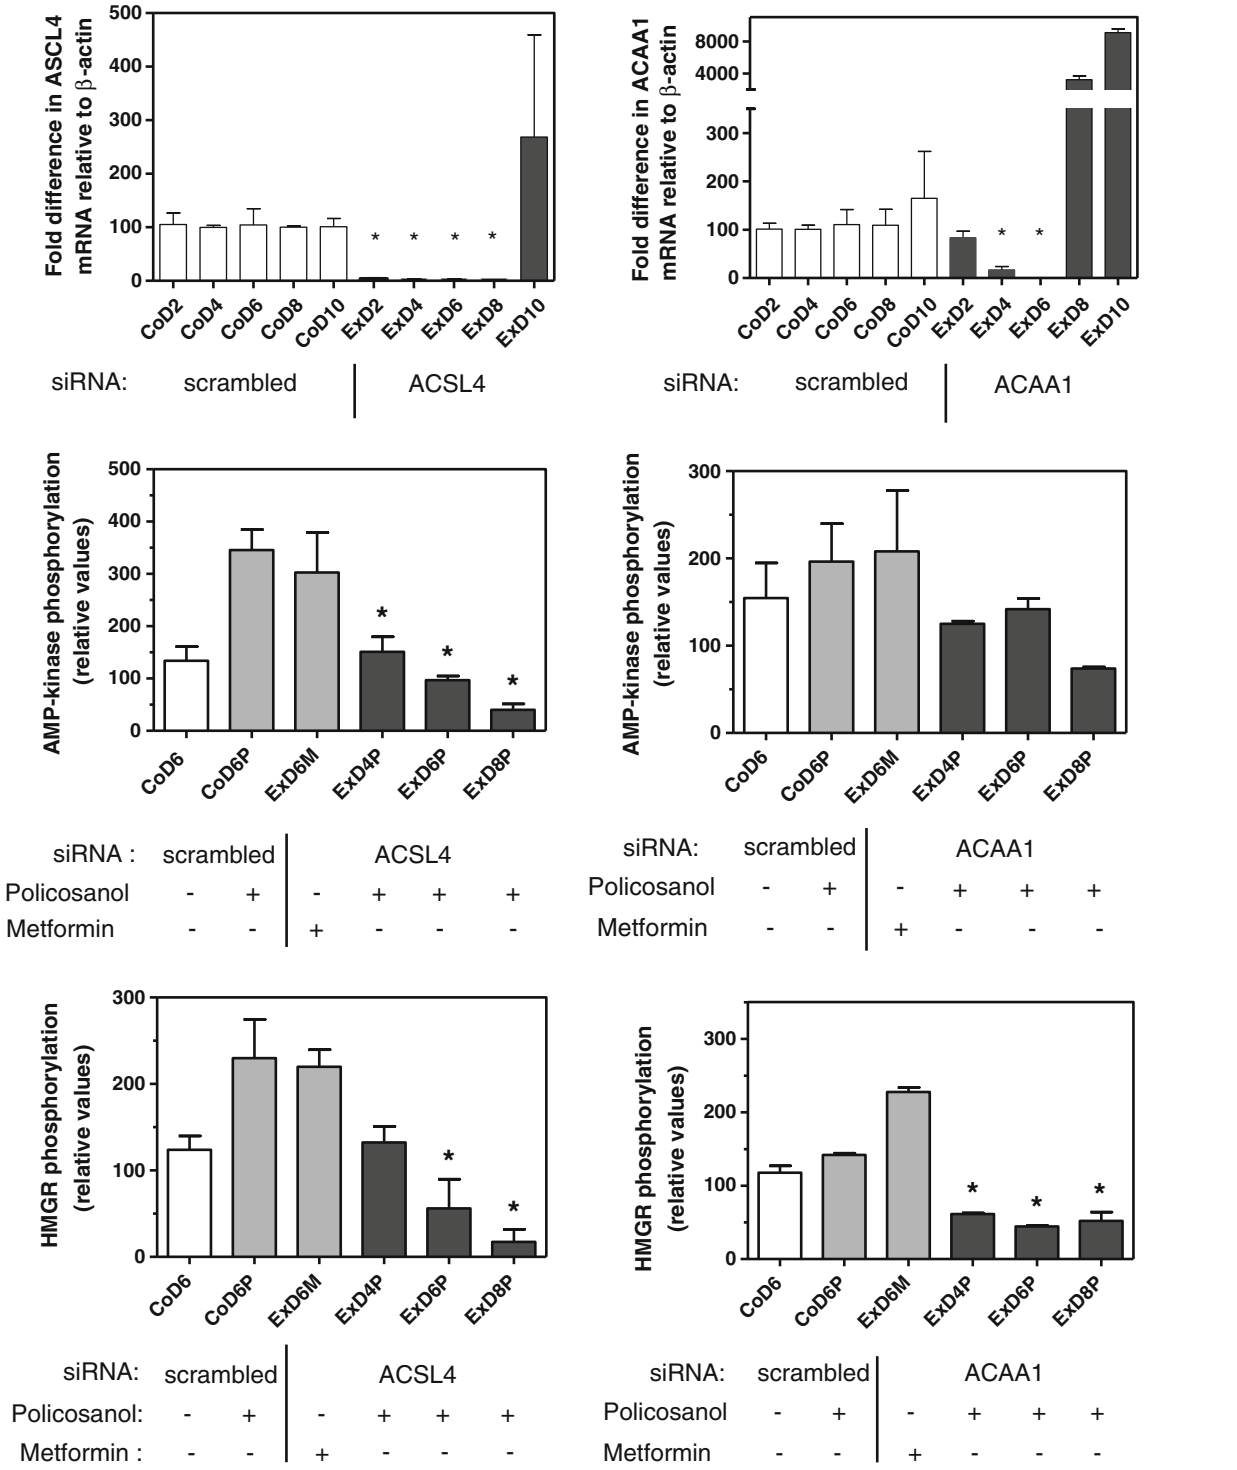

Fig. 6 siRNA-mediated suppression of peroxisomal fatty acyl-CoA synthetase 4 (ACSL4) or acetyl-CoA acyltransferase 1 (ACAA1) prevents the increase in phosphorylation of AMP-kinase and HMG-CoA reductase by policosanol. ACSL4 and ACAA1 mRNA was quantified by RT-PCR with the primers listed in Table 1; control cells contained a plasmid with a scrambled siRNA sequence. Phosphorylated AMP-kinase and HMG-CoA reductase were measured by immunoquantitation. Cells were incubated with 15 μg/ml of policosanol or 1 mM metformin for 3 h as indicated. Values represent the mean and standard deviation of 2 experiments; values that are statistically different from the policosanol-treated control are indicated with *asterisks*, as determined by one-way ANOVA with Tukey's post-hoc test, $p < 0.05$. *Co* control cells; *Ex* cells transfected with ACSL4 or ACAA1 siRNA plasmid; 'D' indicates day post-transfection; 'M' indicates metformin treatment; 'P' indicates policosanol treatment

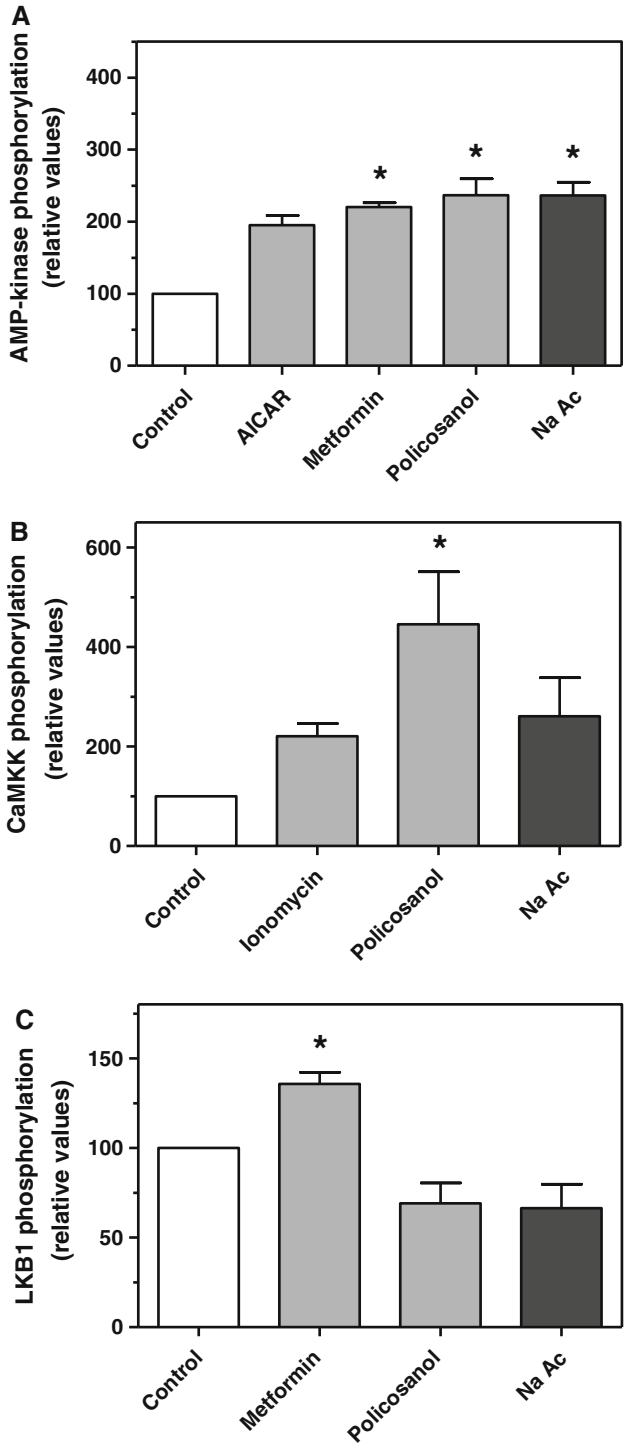

Fig. 7 Treatment of hepatoma cells with sodium acetate promotes the phosphorylation of AMP-kinase through CaMKK. Phosphorylated AMP-kinase (**a**), CaMKK (**b**), and LKB1 (**c**) were measured by immunoquantitation in hepatoma cells three hours after treatment with sodium acetate (0.12 mM), AICAR (1 mM), metformin (1 mM), policosanol (15 μg/ml) or ionomycin (1 μg/ml). Values represent the mean and standard deviation of 2–3 experiments; values that are statistically different from the control are indicated with *asterisks*, as determined by one-way ANOVA with Dunnett's post-hoc test, $p < 0.05$

acetate treatment of hepatocytes decreased SREBP-1 mRNA levels [29], which could lead to decreased expression of HMG-CoA reductase. Taken together, these observations suggest that there are multiple pathways by which policosanol might generate elevated hepatic acyl-CoA and AMP levels to activate AMP-kinase and suppress cholesterol synthesis.

Presence of Apolipoprotein C-III Attenuates Apolipoprotein E-Mediated Cellular Uptake of Cholesterol-Containing Lipid Particles by HepG2 Cells

Received: 15 September 2010 / Accepted: 26 October 2010 / Published online: 16 November 2010

Abstract Apolipoprotein C-III (apoC-III) decreases the apolipoprotein E (apoE)-mediated uptake of lipoprotein remnants by the liver, and a high plasma concentration of apoC-III in VLDL is associated with hypertriglyceridemia and the risk of coronary heart disease. In this study, we prepared lipid emulsions containing triolein, phosphatidylcholine and cholesterol as model particles of lipoproteins, and examined the roles of apoC-III in apoE-mediated uptake of emulsions by HepG2 cells. Cholesterol in emulsion particles enhanced the apoE-mediated uptake via heparan sulfate proteoglycan and LDL receptor-related protein pathways. The amount of apoE bound to emulsion particles was increased by the presence of cholesterol at the particle surface, whereas cholesterol had no effect on the binding amount of apoC-III. Surface cholesterol alleviated the inhibitory effect of apoC-III on apoE incorporation into the emulsion surface. However, ApoC-III almost completely inhibited the apoE-mediated uptake of cholesterol-containing emulsions despite sufficient binding of apoE to emulsions. These findings suggest that apoC-III attenuates the binding of apoE to the lipoprotein surface and apoE-mediated cellular uptake of lipoprotein remnants. Furthermore, cholesterol may affect these functions of apoC-III and apoE involved in the clearance of lipoprotein remnants.

TAG	Triacylglycerol

Introduction

Apolipoprotein C-III (apoC-III) in VLDL and LDL is an independent risk factor for coronary heart disease [1–3]. A high concentration of apoC-III-containing VLDL is associated with the delayed catabolism of triacylglycerol (TAG) in VLDL and hypertriglyceridemia [4, 5]. ApoC-III enhances the conversion from light LDL to dense LDL [6, 7]. ApoC-III deficiency (by ~50% of normal levels) confers a favorable lipid profile and reduced subclinical coronary artery atherosclerosis [8]. Recently, it has been reported that polymorphisms in the apoC-III gene promoter are associated with plasma apoC-III concentration, plasma TAG concentration, lipoprotein profile, cardiovascular health, nonalcoholic fatty liver disease, insulin sensitivity, and longevity [9, 10].

Apolipoprotein E (apoE), a 299-amino acid plasma apolipoprotein, is a ligand for the LDL receptor, LDL receptor-related protein (LRP) and the VLDL receptor, and binds to cell surface heparan sulfate proteoglycans (HSPG) [11]. The liver produces the vast majority of plasma apoE, and apoE promotes the internalization of TAG-rich lipoprotein remnants by hepatocytes. ApoE knockout mice have high levels of plasma cholesterol, which is a result of the impaired clearance of lipoprotein remnants, and readily develop atherosclerosis [12, 13].

ApoC-III is a 79-amino acid glycoprotein synthesized mainly in the liver and to a minor extent in the intestine as a component of chylomicrons, VLDL, LDL and HDL [11]. In normotriglyceridemic subjects, apoC-III is associated primarily with HDL, whereas there is redistribution of apoC-III to chylomicrons and VLDL in the postprandial state and hypertriglyceridemia [14, 15]. Human apoC-III transgenic mice exhibit markedly elevated levels of chylomicron and VLDL TAG [16]. In addition, a synergistic interaction between the human apoC-III transgene and LDL receptor defects produces large quantities of VLDL and LDL and enhances the development of atherosclerotic lesions in mice [17]. ApoC-III is known to be a potential inhibitor of lipoprotein lipase activity [18]. ApoC-III also inhibits the apoE-mediated hepatic uptake of TAG-rich lipoproteins through LDL receptor and LRP [19, 20], but the mechanism of this inhibition has not been characterized in detail.

Emulsion particles are used as protein-free models for plasma lipoproteins. Our previous studies demonstrated that apoC-III reduced the apoE-mediated uptake of emulsion particles by HepG2 cells [21]. We also showed that free cholesterol in the emulsion surface enhanced the apoE-mediated uptake by J774 macrophages by increasing the amount of apoE bound to emulsion particles [22]. In this study, to elucidate the influence of apoC-III on apoE-mediated uptake of lipoprotein remnants, we investigated the uptake of lipid emulsions by HepG2, human hepatoma, cells and the binding of apoE and apoC-III to the emulsion surface.

Materials and Methods

Materials

Egg yolk phosphatidylcholine (PtdCho) was generously provided by Asahi Kasei (Tokyo, Japan). Triolein, cholesterol, heparinase I, and BSA were purchased from Sigma-Aldrich (St. Louis, MO, USA). 1-Pyrenemethyl 3β-(*cis*-9-octadecenoyloxy)-22,23-bisnor-5-cholenate (PMC oleate) was obtained from Molecular Probes (Eugene, OR, USA). Bovine lactoferrin was purchased from Wako Pure Chemicals (Osaka, Japan). All other chemicals used were of the highest reagent grade.

Preparation of Emulsions

The lipid emulsions were prepared by the method described previously using a high-pressure emulsifier (Nanomizer System YSNM-2000AR; Yoshida Kikai, Nagoya, Japan) [23]. Briefly, mixtures of triolein, PtdCho and free cholesterol were suspended in 10 mM Tris–HCl buffer (pH 7.4), containing 150 mM NaCl, 1 mM EDTA, and successively emulsified under 100 MPa of pressure at 40–60 °C. Depending on the purpose of the experiment, PMC oleate, which has been used as a tracer of lipoprotein endocytosis and as a general nonexchangeable membrane marker [24, 25], was added to the lipid mixtures at a ratio of 1 mol% of triolein. After the removal of contaminating vesicles by ultracentrifugation (55,000*g*, 60 min), homogeneous emulsion particles were obtained. The mean particle diameter of each emulsions was about 120 nm determined from dynamic light scattering measurements using a Photal LPA-3000/3100 (Otsuka Electronics, Hirakata, Japan) equipped with a He–Ne laser at a wavelength of 632.8 nm. The concentrations of triolein, PtdCho and cholesterol were determined using enzymatic assay kits purchased from Wako. As a result, we confirmed that the composition of PtdCho and cholesterol in the isolated emulsions was the same as that in the starting lipid mixtures, and the isolated emulsions contained the expected amount of cholesterol (molar ratio of PtdCho/cholesterol = 3/2). The molar ratios of core triolein to surface PtdCho for isolated triolein-PtdCho and triolein-PtdCho/cholesterol (3/2) emulsions were 4.76 $\pm$ 0.29 and 4.99 $\pm$ 0.12, respectively.

ApoE and ApoC-III

Recombinant human apoE (isoform E3) was provided by PeproTech (London, UK). Recombinant apoE was previously shown to have similar physical and biological properties to native human plasma apoE [26]. Purified apoC-III from human plasma was purchased from Chemicon (Temecula, CA, USA). To minimize self-association, apoE and apoC-III were added to 6 M guanidine hydrochloride solution and dialyzed extensively against Tris–HCl buffer.

Cell Cultures

HepG2 cells were grown in a humidified incubator (5% CO_2) at 37 °C in DMEM supplemented with 10% heat-inactivated FBS, L-glutamine, penicillin, and streptomycin. The FBS was replaced with 1% BSA 15 min before each experiment. Experiments were carried out in DMEM containing 1% BSA.

Cell Uptake Assays

The lipid emulsions were preincubated with apoE and apoC-III at 37 °C for 30 min, allowing sufficient time for equilibrium binding [27]. Treatment with heparinase was performed by preincubating the cells at 37 °C for 45 min in the presence of 10 units/ml heparinase. HepG2 cells were incubated with PMC oleate-labeled emulsions (250 μM triolein) containing apolipoproteins at 37 °C for 2 h. After incubation, the cells were chilled on ice and washed twice with ice-cold Hepes buffer containing 0.2% BSA and then washed twice with ice-cold Hepes buffer alone. Cells were then dissolved in 0.2% Triton X-100. To evaluate the particle uptake, the fluorescence intensity of PMC oleate (excitation 342 nm, emission 377 nm) was measured with a Hitachi F-4500 spectrofluorometer, and the concentration of cellular protein was measured by the method of Lowry. By this method, uptake means binding and internalization by the cells.

Apolipoprotein Binding Assay

Lipid emulsions (250 μM triolein) were incubated with apoE and apoC-III at 37 °C for 30 min, which allowed sufficient time for equilibrium binding [27]. The mixtures were subjected to ultracentrifugation (55,000*g*, 60 min) to separate both emulsions and lipid-bound apolipoproteins from free apolipoproteins. The concentration of triolein in the top fraction was measured using an enzymatic assay kit. This apolipoprotein–emulsion complex was diluted to 2.5 mM triolein in 1% Triton X-100 and treated with sample buffer. Apolipoproteins were separated by 10–20% SDS PAGE. Following silver staining, the amounts of apoE and apoC-III were quantified by densitometric scanning calibrated with standard solution of each apolipoprotein. The binding of apolipoproteins had no effect on the size of emulsion particles [28].

Statistical Analysis

The statistical significance of differences between mean values was analyzed using the non-paired *t* test. Differences were considered significant at $P < 0.05$. Unless indicated otherwise, results are given as means ± SE ($n = 3$).

Results

ApoE-Mediated Uptake of Lipid Emulsions by HepG2 Cells

To investigate the role of cholesterol in the apoE-mediated uptake of emulsion particles by HepG2 cells, we prepared two types of emulsions: triolein-PtdCho and triolein-PtdCho/cholesterol (molar ratio of PtdCho/cholesterol = 3/2). Triolein-PtdCho/cholesterol emulsions were used as models for lipoprotein remnants. As shown in Fig. 1, apoE enhanced the uptake of both emulsions by HepG2 cells in a dose-dependent manner. There was no significant difference between triolein-PtdCho and triolein-PtdCho/cholesterol emulsion uptake in the absence of apoE. The uptake of triolein-PtdCho/cholesterol emulsions was 2.7-fold higher than that of triolein-PtdCho emulsions in the presence of 4 μg/ml apoE, indicating that the apoE-mediated uptake was markedly enhanced by the presence of cholesterol at the emulsion surface.

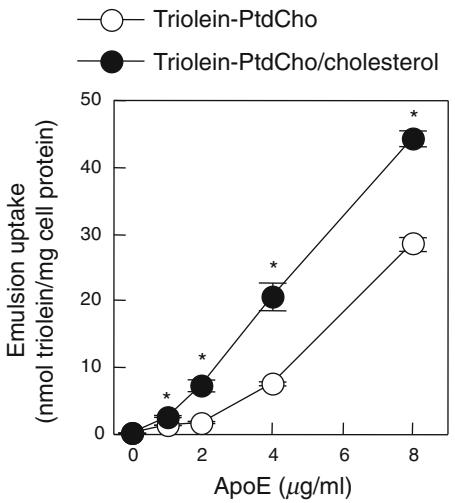

Fig. 1 ApoE-mediated uptake of emulsion particles by HepG2 cells. HepG2 cells were incubated for 2 h at 37 °C with triolein-PtdCho (*open circles*) or triolein-PtdCho/cholesterol (3/2) (*closed circles*) emulsions (250 μM triolein) in the presence of the indicated amounts of apoE. Values represent the means ± SE of three measurements. *$P < 0.05$, significantly different from triolein-PtdCho emulsions

To examine if known lipoprotein receptors on HepG2 cells are involved in the emulsion uptake, we conducted experiments using inhibitors of lipoprotein receptors. HSPG and LRP play important roles in apoE-enriched remnant uptake, and HSPG participate in the uptake, either associating with LRP or acting alone as a receptor [29]. Heparinase released the sulfated glycosaminoglycan side chains from HSPG [30]. In this study, heparinase treatment significantly inhibited both triolein-PtdCho and triolein-PtdCho/cholesterol emulsion uptake by HepG2 cells in the presence of 8 μg/ml apoE (Fig. 2). Lactoferrin interacts with HSPG and LRP, and inhibits the uptake of lipoprotein remnants by preventing their binding to HSPG and subsequent transfer to LRP [31]. In the presence of 8 μg/ml apoE, lactoferrin (5 mg/ml) also markedly prevented the uptake of triolein-PtdCho and triolein-PtdCho/cholesterol emulsions by HepG2 cells (Fig. 2). Thus, HSPG and LRP were mainly involved in the apoE-mediated uptake of triolein-PtdCho and triolein-PtdCho/cholesterol emulsions by HepG2 cells.

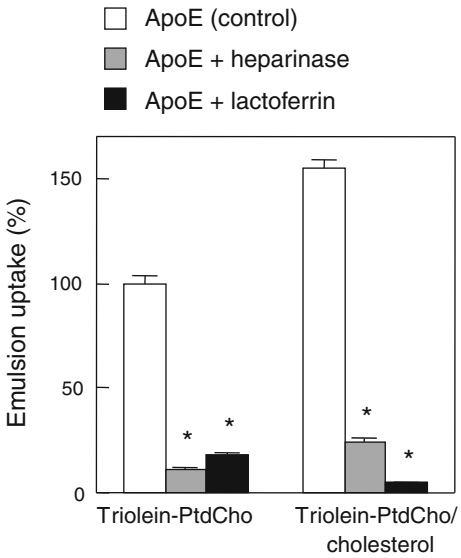

Fig. 2 Effects of heparinase and lactoferrin on apoE-mediated uptake of emulsion particles by HepG2 cells. Treatment with heparinase was performed by preincubating the cells at 37 °C for 45 min in the presence of 10 units/ml heparinase (*gray bars*). HepG2 cells were incubated for 2 h at 37 °C with triolein-PtdCho or triolein-PtdCho/cholesterol (3/2) emulsions (250 μM triolein) with 8 μg/ml apoE in the absence (control; *white bars*) or presence of 5 mg/ml lactoferrin (*black bars*). Results are expressed as the percentage of triolein-PtdCho emulsion uptake measured in the presence of 8 μg/ml apoE. Each *bar* represents the mean ± SE of three measurements. $^*P < 0.05$, significantly different from the control

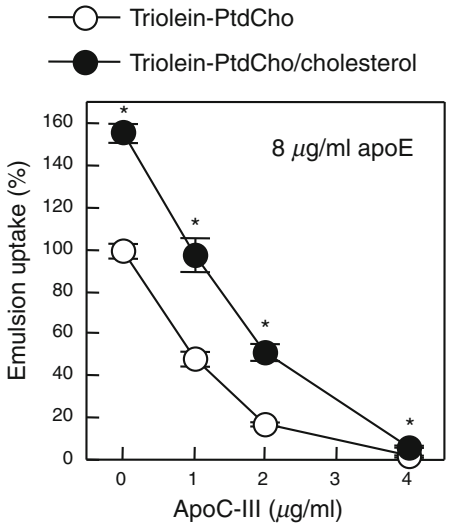

Fig. 3 Effects of apoC-III on apoE-mediated uptake of emulsion particles by HepG2 cells. HepG2 cells were incubated for 2 h at 37 °C with triolein-PtdCho (*open circles*) or triolein-PtdCho/cholesterol (3/2) (*closed circles*) emulsions (250 μM triolein) in the presence of 8 μg/ml apoE and the indicated amounts of apoC-III. Results are expressed as the percentage of triolein-PtdCho emulsion uptake measured in the presence of 8 μg/ml apoE without apoC-III. Values represent the means ± SE of three measurements. $^*P < 0.05$, significantly different from triolein-PtdCho emulsions

Effects of ApoC-III on ApoE-Mediated Uptake by HepG2 Cells

We assessed the uptake of triolein-PtdCho and triolein-PtdCho/cholesterol emulsions by HepG2 cells in the presence of apoE and apoC-III. Figure 3 shows that the apoE-mediated uptake of both emulsions decreased with the apoC-III concentration. The uptake of triolein-PtdCho/cholesterol emulsions was higher than that of triolein-PtdCho emulsions in the presence of both apoE and apoC-III. At a higher concentration (4 μg/ml) of apoC-III, the cellular uptake of triolein-PtdCho and triolein-PtdCho/cholesterol emulsions was very low (97.5 ± 0.1 and 95.8 ± 0.2% inhibition, respectively), indicating apoC-III almost completely abolished the stimulatory effect of apoE on the emulsion uptake. Possible mechanisms of the inhibition of apoE-mediated uptake by apoC-III are: (1) apoC-III displaces apoE from emulsion surfaces; (2) apoC-III directly interacts with apoE bound to emulsion particles.

Binding of ApoE and ApoC-III to Emulsion Particles

To examine the effects of surface cholesterol on the binding of apoE and apoC-III to the emulsion particles, we compared the amount of apoE or apoC-III bound to triolein-PtdCho and triolein-PtdCho/cholesterol emulsions. In accord with our previous report [22], the incorporation of cholesterol into the emulsion surface caused a significant increase in the binding amount of apoE (Fig. 4a). However, the amounts of apoC-III bound to triolein-PtdCho and triolein-PtdCho/cholesterol emulsions were nearly the same (Fig. 4b). These results indicated that the presence of cholesterol at the emulsion surface enhanced the binding of apoE. In contrast, the binding amount of apoC-III was not affected by surface cholesterol.

We next explored the competitive binding of apoE and apoC-III to emulsion particles. As shown in Fig. 5a, apoC-III reduced the binding of apoE to triolein-PtdCho and triolein-PtdCho/cholesterol emulsions. In the presence of 2 μg/ml apoC-III, the binding of apoE to triolein-PtdCho/cholesterol emulsions was significantly larger than that to triolein-PtdCho emulsions, whereas the binding amount of apoC-III was similar between triolein-PtdCho and triolein-PtdCho/cholesterol emulsions (Fig. 5b). At 4 μg/ml apoC-III, the apoC-III binding to triolein-PtdCho/cholesterol emulsions was slightly higher than triolein-PtdCho emulsions. Figure 5c shows that the binding amount of apoE was found to correlate inversely with the binding amount of apoC-III to triolein-PtdCho and triolein-PtdCho/cholesterol emulsions ($r = -0.980$ and $r = -0.988$, respectively). The slope of the plot for triolein-PtdCho emulsions (−3.45 ± 0.50) was lower than that for triolein-PtdCho/cholesterol emulsions (−2.00 ± 0.23), indicating that apoC-III inhibited the apoE binding to

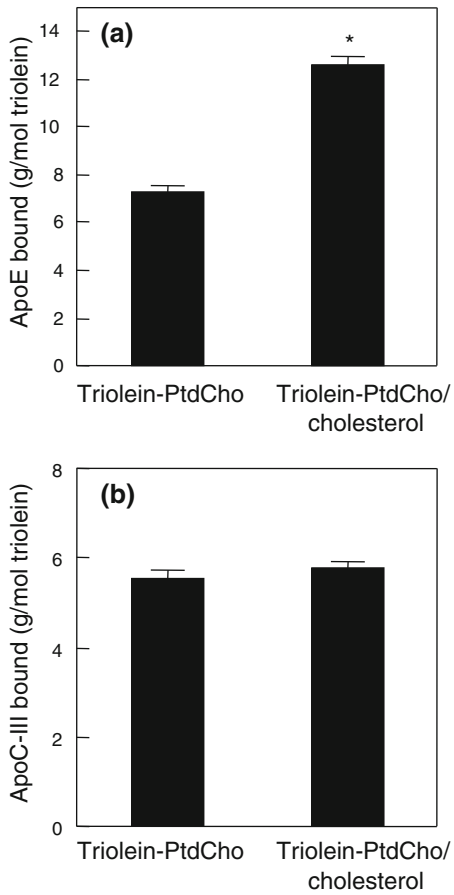

Fig. 4 Effects of cholesterol on the binding of apoE **a** and apoC-III **b** to emulsion particles. Triolein-PtdCho and triolein-PtdCho/cholesterol (3/2) emulsions (250 μM triolein) were incubated with 4 μg/ml apoE or 2 μg/ml apoC-III for 30 min at 37 °C. Each *bar* represents the mean ± SE of three measurements. $^*P < 0.05$, significantly different from triolein-PtdCho emulsions

triolein-PtdCho emulsions more effectively than that to triolein-PtdCho/cholesterol emulsions. ApoC-III decreased the total binding of apoE and apoC-III to triolein-PtdCho emulsions compared to the binding of apoE alone (Fig. 5d). The total binding amount of apoE and apoC-III to triolein-PtdCho/cholesterol emulsions was larger than that to triolein-PtdCho emulsions. The total binding of apoE and apoC-III to triolein-PtdCho/cholesterol emulsions was not significantly different from that of apoE alone (Fig. 5d), because the loss of apoE bound to triolein-PtdCho/cholesterol emulsions by apoC-III was largely offset by the amount of apoC-III bound to triolein-PtdCho/cholesterol emulsions (Fig. 5a, b).

Relationship between Cellular Uptake and Binding of ApoE and ApoC-III

To determine if the binding of apoE or apoC-III is responsible for the emulsion uptake, we studied the relationship between the emulsion uptake by HepG2 cells and the binding amounts of apoE and apoC-III. The apoE and apoC-III concentrations in the incubation media used in apolipoprotein binding assays and cell uptake assays are summarized in Table 1. As shown in Fig. 6a, excluding the case of triolein-PtdCho/cholesterol emulsions in the presence of both apoE and apoC-III (closed circle, closed inverted triangle and closed square), the emulsion uptake was positively correlated with the amount of apoE bound to emulsions ($r = 0.996$). Compared with triolein-PtdCho/cholesterol emulsions in the presence of 4 μg/ml apoE (emulsion uptake, 72.7 ± 7.0%; apoE bound, 12.6 ± 0.4 g/mol triolein; closed triangle), the uptake of triolein-PtdCho/cholesterol emulsions in the presence of 8 μg/ml apoE and 4 μg/ml apoC-III (closed square) was markedly lower (6.5 ± 0.3%) despite the fact that similar amount of apoE bound to the emulsions (12.2 ± 2.0 g/mol triolein). As depicted in Fig. 6b, at 8 μg/ml apoE, there were inverse correlations between the emulsion uptake and the binding of apoC-III ($r = -0.997$ for triolein-PtdCho and $r = -0.987$ for triolein-PtdCho/cholesterol emulsions). Thus, apoC-III bound to emulsion particles may prevent the apoE-mediated uptake.

Discussion

The concentrations of apoE and apoC-III in human plasma are 50–80 and 80–120 μg/ml, respectively [9, 10, 32, 33]. Homozygosity of the A-641C allele in the apoC-III gene promoter is associated with significantly lower serum levels of apoC-III [9], whereas the variant alleles in the apoC-III gene promoter (C-482T and T-455C) cause a 30% increase in the fasting plasma apoC-III concentration compared with the WT homozygotes [10]. The normal plasma TAG concentration is <1.5 mg/ml (<1.69 mM) in the fasting state. In the present study, the concentrations of apoE (0–8 μg/ml), apoC-III (0–4 μg/ml) and triolein (250 μM) in the media were not physiological but optimal conditions to investigate the functions of apoE and apoC-III [21–23].

In this study, we used the lipid emulsions as protein-free lipoprotein models. However, the emulsions may not necessarily represent the nature of TAG-rich lipoproteins owing to the lack of other apolipoproteins, notably apolipoprotein B. Apolipoprotein B plays a crucial role in the maintenance of the lipoprotein structure, the cellular uptake of lipoproteins through the LDL receptor, and the development of atherosclerosis [34, 35]. At present, apolipoprotein B cannot be properly reconstituted on emulsion particles. However, the lipid emulsions are useful to elucidate the roles of exchangeable apolipoproteins in lipoprotein metabolism because they enable easy control of the lipid and protein constituents and the size of the particles.

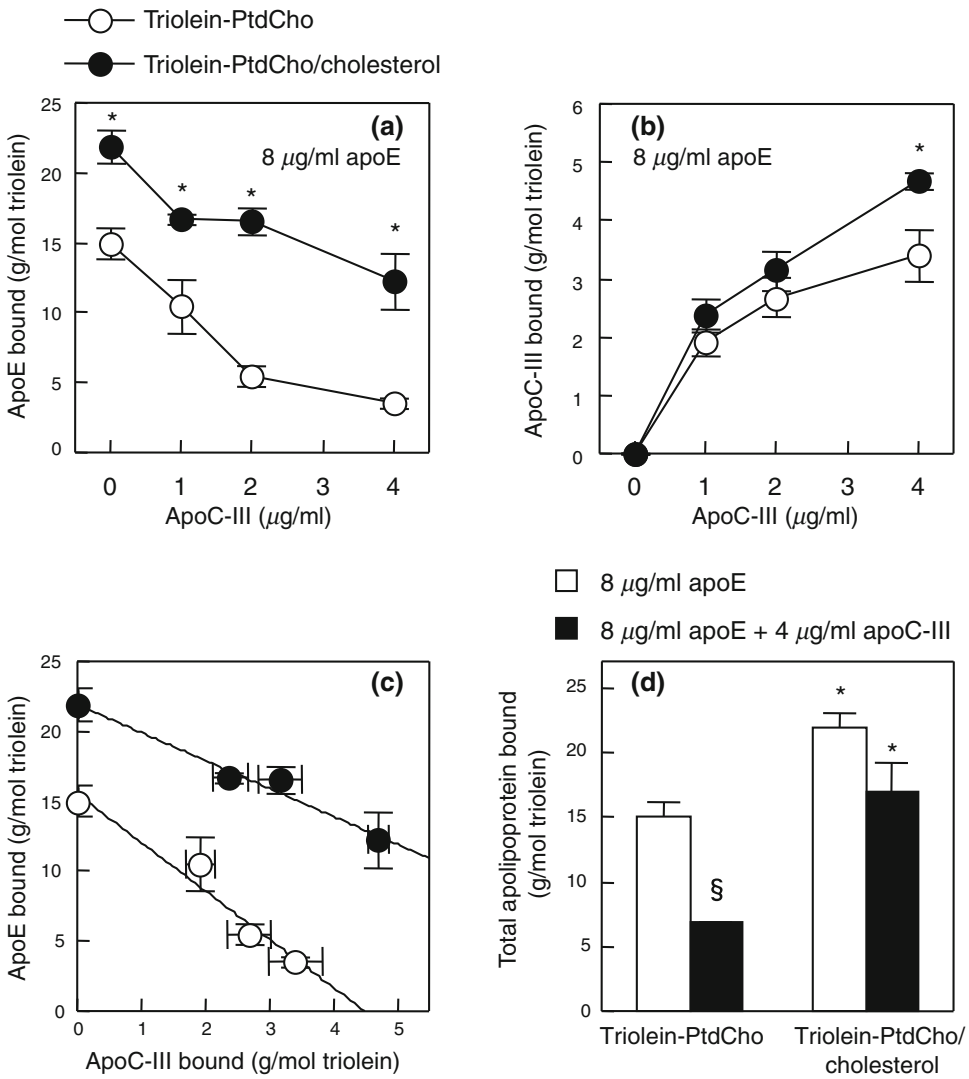

Fig. 5 Competitive binding of apoE and apoC-III to emulsion particles. Triolein-PtdCho and triolein-PtdCho/cholesterol (3/2) emulsions (250 μM triolein) were incubated with 8 μg/ml apoE and the indicated amounts of apoC-III for 30 min at 37 °C. **a** The amounts of apoE bound to triolein-PtdCho (*open circles*) and triolein-PtdCho/cholesterol (3/2) (*closed circles*) emulsions in the presence of apoC-III. **b** The amounts of apoC-III bound to triolein-PtdCho (*open circles*) and triolein-PtdCho/cholesterol (3/2) (*closed circles*) emulsions in the presence of apoE. **c** Plot of the binding of apoE versus the binding of apoC-III to triolein-PtdCho (*open circles*) and triolein-PtdCho/cholesterol (3/2) (*closed circles*) emulsions. It has been suggested that apoC-III is made of two helical domains. The N-terminal domain of apoC-III is important in the modulation of lipoprotein lipase activity, and the binding of apoC-III to surface phospholipid is mediated by the C-terminal helix [33, 36]. Gangabadage et al. [37] have reported the three-dimensional NMR structure of apoC-III in complex with SDS micelles, in which 6–10-residue amphipathic helices wrap around the micelle surface, three positively charged residues line the polar faces of helices 1 and 2, and an array of negatively charged residues lines the polar faces of helices 4 and 5 and the adjacent flexible loop.

It has been demonstrated that apoE contains two independently folded domains, the 22-kDa N-terminal domain and 10-kDa C-terminal domain [11]. The C-terminal domain has a high affinity for lipid and is responsible for lipoprotein binding and preference [38, 39]. The N-terminal domain exists in the lipid-free state as a four-helix bundle and contains the LDL receptor-binding region [40]. The cluster of arginine and lysine residues located

Table 1 ApoE and apoC-III concentrations in incubation media used in apolipoprotein binding assays and cell uptake assays

The molecular masses of apoE and apoC-III are 34.0 and 8.8 kDa, respectively

between residues 136–158 represents the binding site for LDL receptor. The segment comprising the receptor-binding portion of apoE (residues 130–149) interacts with ligand-binding clusters of LRP [41, 42]. Both domains of apoE contain heparin-binding sites, but the N-terminal site plays a dominant role in the binding to heparin [43]. The cluster of positively charged amino acids between residues 136–150 is also involved in the heparin interaction. The four-helix bundle in the N-terminal domain undergoes a conformational opening upon lipid binding, leading to the receptor-active conformation of apoE [11, 44]. In this conformation, the positive electrostatic potential in the receptor-binding region of apoE is enhanced [45, 46]. The leucine zipper motif confers stability to the helix bundle conformation of the N-terminal domain, which serves to maintain apoE in a receptor-inactive state [47].

The lipoprotein surface is mainly formed by phospholipids (PL) and cholesterol together with apolipoproteins. The amount of cholesterol in lipoproteins regulates their metabolism. The cholesterol/PL ratios in VLDL and LDL are 0.78 and 0.73, respectively [48]. When chylomicrons are converted to chylomicron remnants by the action of lipoprotein lipase, there is an increase in the relative content of cholesterol in the remnants [49]. The cholesterol/PL ratio of the remnant fraction of human serum in the postprandial state is close to 1 [50]. In the present study, triolein-PtdCho/cholesterol (3/2) emulsions can be applied as a model for TAG-rich lipoprotein remnants [22]. Emulsions rich in cholesterol were metabolized like chylomicron remnants [51]. Cholesterol can distribute between the surface and core phases in lipid emulsions and lipoproteins. From the surface-core phase equilibrium, over 80% of cholesterol is accommodated in the surface phase in TAG-PtdCho emulsions [52]. Cholesterol induces a motional restriction of PtdCho and a rigidification of the TAG-PtdCho emulsion surface with increasing content [52]. Cholesterol is associated with surface PL but located deep in the inner hydrocarbon region [52]. Our previous report showed that cholesterol enrichment on the emulsion surface led to PtdCho head group separation and hydration, and markedly increased the apoE binding maximum without changing the binding affinity [22]. There was a correlation between the degree of PL head group separation and the apoE binding maximum. It was also demonstrated that the acyl chain packing was not a determining factor in apoE binding, suggesting that apoE binds to emulsion particles through

insertion between the PL head groups but not deep penetration into the hydrocarbon interior [22]. In this study, cholesterol in the emulsion surface increased the amount of apoE bound to the particles, but had no effect on the binding amount of apoC-III (Fig. 4), suggesting that the binding of apoC-III is insensitive to the degree of PtdCho head group separation at the emulsion surface. Our current data also demonstrated that cholesterol reversed the inhibitory effect of apoC-III on apoE incorporation into the emulsion surface, and increased the total binding of apoE and apoC-III (Fig. 4). We consider that cholesterol at the emulsion surface increases the number of the apoE binding sites rather than the apoC-III binding sites.

Our results show that in the presence of apoE and apoC-III, the uptake of cholesterol-containing emulsions by HepG2 cells was higher compared with that of cholesterol-free emulsions (Fig. 3), consistent with the facilitated uptake of cholesterol-containing emulsions by the liver [53]. Increased levels of apoC-III on the lipoprotein particles would displace apoE, which would result in decreased remnant clearance [54]. It has been proposed that apoCs induce conformational alteration of the N-terminal domain of apoE and modulate the receptor binding properties [55]. ApoC-III completely abolishes the apolipoprotein B-mediated binding of lipoproteins to LDL receptor, suggesting that this inhibitory action of apoC-III on lipoprotein binding is due to a masking of the receptor domain of apolipoprotein B by apoC-III [56]. In the present study, we showed that despite sufficient amount of apoE bound to cholesterol-containing emulsions, apoC-III almost abolished the cellular uptake of the emulsions via HSPG and LRP pathways (Fig. 6a). It is possible that at the cholesterol-containing particle surface, apoC-III leads to the receptor-inactive conformation of the apoE-N-terminal domain or masks the cluster of positively charged amino acids of apoE involved in the binding to LRP and HSPG, in addition to the attenuation of apoE binding to the particle surface.

ApoC-III delays the metabolism of TAG-rich lipo proteins by inhibiting lipoprotein lipase activity and apoE-dependent hepatic uptake, which has been suggested to increase the probability of cholesterol deposition of lipoprotein particles in the vessel wall [3, 4]. ApoC-III may inhibit apoE incorporation into the lipoprotein surface and apoE-mediated cellular uptake of lipoprotein particles through HSPG and LRP pathways. In addition, cholesterol at the surface of lipoprotein remnants would modulate these atherogenic functions of apoC-III.

Abstract Oxidative stress is thought to play an important role in atherogenesis. The statin group of cholesterol-lowering drugs have been shown to reduce cardiovascular events and possess antioxidant properties. We aimed to assess the effects of simvastatin on a novel measure of prooxidant–antioxidant balance (PAB) in dyslipidemic patients. The PAB assay can measure the prooxidant burden and the antioxidant capacity simultaneously in one assay, thereby giving a redox index. We treated 102 dyslipidemic individuals with simvastatin, or a placebo in a double-blind, cross-over, placebo-controlled trial. PAB values were measured before and after each treatment period. Seventy-seven subjects completed the study. We found that statin therapy was associated with a significant reduction in PAB values ($P < 0.001$). This effect appeared to be independent of the cholesterol-lowering effects of statins. We conclude that serum PAB values are decreased by simvastatin therapy. Regarding previous reports on the elevation of PAB in conditions associated with oxidative stress, the PAB assay, along with other markers of oxidative stress, may be applied to estimate the extent of oxidative stress in patients, assessment of the antioxidative efficacy of medication such as statins and perhaps also for the identification of those individuals who need antioxidant therapy.

Keywords Simvastatin · Prooxidant–antioxidant balance (PAB) · Dyslipidemia

Abbreviations

BMI	Body mass index
CVD	Cardiovascular disease
eNOS	Endothelial nitric oxide synthase
FBS	Fasting blood sugar
HDL-C	High-density lipoprotein cholesterol
HMG-CoA	3-Hydroxy-3-methylglutaryl-coenzyme A
LDL-C	Low density lipoprotein cholesterol
NADPH	Nicotinamide adenine dinucleotide phosphate

ox-LDL	Oxidized low density lipoprotein cholesterol
PAB	Prooxidant–antioxidant balance
ROS	Reactive oxygen species
SAS	Statistical analysis software
SD	Standard deviation
TC	Total cholesterol
TG	Triglycerides
TMB	3,3′,5,5′-Tetramethylbenzidine

Introduction

Oxidative stress is an imbalance between the production of pro-oxidants and antioxidant defenses in favor of pro-oxidants. Oxidative stress is usually related to the increased formation of reactive oxygen species (ROS), and is thought to play an important role in the pathogenesis of cardiovascular disease (CVD) and its complications. Recently oxidative stress [1] and inflammation [2] have been proposed to be significant risk factors for CVD, and the lipid oxidation hypothesis provides one mechanism by which oxidative stress may be implicated [3].

It is also suggested that oxidative stress may be a strong and independent prognostic predictor of cardiovascular events [4].

Low density lipoprotein cholesterol (LDL-C) has been associated with several pro-atherothrombotic processes through the development of endothelial dysfunction, inflammation and foam cell formation [5]. Indeed, individuals with relatively normal LDL levels but high exposure to oxidative stress such as those with hypertension [6], are at increased risk of developing CVD via the formation of pro-inflammatory and pro-atherogenic molecules associated with the formation of oxidized-LDL (ox-LDL). Ox-LDL has been shown to accumulate in the arterial wall and this is associated with the development of endothelial dysfunction [7, 8]. Thus, reduction in plasma levels of LDL and ox-LDL may represent a useful approach for preventing from atherosclerotic diseases.

Statins are a group of lipid-lowering agents which block the rate limiting step in cholesterol biosynthesis, the conversion of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) to mevalonic acid. The LDL-cholesterol lowering property of statins is associated with a reduction of cardiovascular endpoints including definite coronary events (specified as nonfatal myocardial infarction or death from coronary heart disease), definite nonfatal myocardial infarctions; death from definite plus suspected coronary heart disease and death from all cardiovascular causes [9]. However, it has been argued that the benefits obtained with statin therapy in patients with a wide range of cholesterol levels may be due to their "pleiotropic" non-cholesterol-lowering effects. These pleiotropic effects of statins include: improving endothelial function, decreasing oxidative stress (by lowering ROS production and increasing the resistance of LDL-C to oxidation), inhibiting platelet adhesion, reducing inflammation, and enhancing the stability of atherosclerotic plaques [10].

Until now, many methods have been developed that can separately determine the total pro-oxidant and antioxidant capacities and are therefore hard, time consuming, expensive, and imprecise. We have recently used a simple, rapid and inexpensive method [11] to measure the PAB directly, by using 3,3′,5,5′-tetramethylbenzidine (TMB) and two different kinds of reaction, an enzymatic reaction where the chromogen TMB is oxidized to a colored cation by peroxides, and a chemical reaction in which the colored TMB cation is reduced to a colorless compound by antioxidants. A redox index is thereby derived from these two reactions. The assay has been calibrated against the most significant known oxidants and antioxidants and its response has been found to be a linear decrease against antioxidants and a linear increase against oxidants. The method was also, validated in depth by other known oxidative stress markers [11]. In this study, we aimed to evaluate the effect of simvastatin on PAB values by a modified PAB assay [12] in a randomized, double blind, cross-over trial in dyslipidemic patients.

Methods

Subjects

One hundred and two men and women, aged 20–88 who were not originally taking lipid-lowering agents were recruited from the lipid clinics at the Qaem hospital, Mashhad, Iran. In addition to a history of not taking statins, other inclusion criteria were any of the following conditions (based on the NCEP-ATP III guidelines [13]): (1) patients with <2 risk factors (except diabetes mellitus) for coronary heart disease (CHD) and 160 mg/dL < LDL-C < 190 mg/dL, or (2) patients with ≥2 risk factors (except diabetes mellitus) for coronary heart disease (CHD) and 130 mg/dL < LDL-C < 160 mg/dL. Cardiovascular risk factors were defined as age >65 years, hypertension (defined as taking any anti-hypertensive medication; or systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg), diabetes mellitus (defined as fasting blood sugar (FBS) ≥ 126 mg/dL), positive family history of CVD, smoking, male sex and obesity [defined as body mass index (BMI) ≥ 30 kg/m^2].

The exclusion criteria were; malignancy or history of malignancy, infections, connective tissue disorders or treatment with immunomodulatory drugs (e.g. corticosteroids), liver or renal disease, leukocytosis (white blood cell count >10,000 10^9/L), thrombocytosis (platelet count >450,000 10^9/L) and anemia (hematocrit <40%). Each subject gave informed written consent to participate in the study, which had previously been approved by the Mashhad University of Medical Science Ethics Committee. In addition, subjects were advised to continue their normal medication schedule.

Study Design

This study was designed as a randomized, double blind, cross-over trial in which each patient received simvastatin or a placebo and then crossed over to the alternate regimen. Each treatment period was 30 days and there was a 2-week washout interval in between the regimens. The dose of simvastatin and all other medication remained unchanged during the experimental period, and the patients were advised not to change their lifestyle during the study. At the first visit, patients were randomized for one of two treatment regimens, 51 patients were provided with simvastatin 40 mg/day for 30 days and other 51 patients received a placebo (simply prepared by filling empty capsules—which were matched for size and color with simvastatin capsules—with starch instead of simvastatin) for 30 days. After another 2-week wash-out period, patients crossed over to the other form of treatment.

Anthropometric Measurements

Anthropometric parameters including weight, height, and BMI were measured. Weight was measured with the subjects dressed in light clothing after an overnight fasting using a standard scale. BMI was calculated as weight (kg) divided by height squared (m^2).

Blood Sampling

Blood samples were collected four times for each subject (before and after starting each period). Blood samples for laboratory assays were obtained on the day of sampling after 12 h of fasting. Following venipuncture, blood samples were collected in Vacutainer® tubes and centrifuged at 10,000*g* for 15 min at 4 °C. After separation, aliquots of serum were frozen at −80 °C until analysis.

Routine Biochemical Analysis

A full fasted lipid profile comprising total cholesterol, triglycerides, high-density lipoprotein cholesterol (HDL-C) and LDL-C was determined for each subject. Serum lipid and FBS concentrations were measured enzymatically with the use of commercial kits.

Chemicals

TMB powder (3,3′,5,5′-tetramethylbenzidine, Fluka), peroxidase enzyme (Applichem: 230 U/mg, A3791,0005, Darmstadt, Germany), chloramine T trihydrate (Applichem: A4331, Darmstadt, Germany), hydrogen peroxide (30%) (Merck). These chemicals and all the other reagents used were reagent grade and were prepared in double distilled water.

Prooxidant–Antioxidant Balance (PAB) Assay

A modified PAB assay was applied based on a previously described method [11, 12]. The standard solutions were prepared by mixing varying proportions (0–100%) of 250 μM hydrogen peroxide with 3 mM uric acid (in 10 mM NaOH). TMB powder (60 mg) was dissolved in 10 mL DMSO. For preparation of the TMB cation, 400 μL of the TMB/DMSO solution was added to 20 mL of acetate buffer (0.05 M buffer, pH 4.5), and then 70 μL of fresh chloramine T (100 mM) solution was added to this 20 mL. The solution was mixed well and incubated for 2 h at room temperature in a dark place. Then 25 U of peroxidase enzyme solution was added to 20 mL of TMB cation solution, dispensed in 1 mL and stored at −20 °C. In order to prepare the TMB solution 200 μL of TMB/DMSO was added to 10 mL of acetate buffer (0.05 M buffer, pH 5.8) and the working solution was prepared by mixing 1 mL TMB cation with 10 mL of TMB solution. This working solution was incubated for 2 min at room temperature in a dark place and used immediately. Ten microliters of each sample, standard or blank (distilled water) were mixed with 200 μL of working solution in each well of a 96-well plate, which was then incubated in a dark place at 37 °C for 12 min. At the end of the incubation time, 100 μL of 2 N HCl was added to each well, and the optical density (OD) was measured in an ELISA reader at 450 nm with a reference wavelength of 620 or 570 nm. A standard curve was provided from the values relative to the standard samples. The values of the PAB are expressed in arbitrary units, this is the percentage of hydrogen peroxide in the standard solution. The values of the unknown samples were then calculated based on the values obtained from the above standard curve.

Statistical Analysis

Values were expressed as means ± SD or, in the case of non-normally distributed data, as median and inter-quartile

range. The comparison between pre and post treatments was done using the paired t test or the Wilcoxon signed rank test. Data obtained from independent variables analyzed using Student's t test (for those with normal distribution) or Mann–Whitney U test (for those without normal distribution). Categorical data were compared using χ^2 test. Correlations between changes in serum PAB and LDL-C levels were assessed using the Pearson correlation coefficient. Mixed model analysis of variance for 2×2 cross-over studies were fitted when assumption for normality were met. All analysis were performed with the Statistical Analysis Software (SAS version 8). A two-sided P value of <0.05 was considered statistically significant.

Results

From 102 subjects who entered our study, 25 (24.5%) did not complete the study, leading to a final sample size of 77 (78.18%). The reasons for drop-outs were non-compliance with the study protocol ($n = 21$), drug intolerance ($n = 2$) and moving to anothercity ($n = 2$) (Fig. 1). To rule out the possibility of a carryover effect from one treatment period to the other treatment period, we compared baseline values before the first treatment period to those before the second treatment period. No significant difference was found in the analysis ($P > 0.05$). The mean age and BMI of subjects were 46.61 ± 13.95 and 29.94 ± 6.08, respectively, with 72.1% being female. The prevalence of smoking, diabetes mellitus and hypertension were 7.0, 14.0 and 9.3%, respectively.

Effect of Administration of Simvastatin Versus Placebo on Weight, BMI and FBS

FBS was not significantly affected by simvastatin nor by the placebo ($P > 0.05$). However, mean baseline values for BMI and weight were significantly different between the first and second periods of treatment ($P = 0.019$ and $P = 0.003$, respectively) (Table 1).

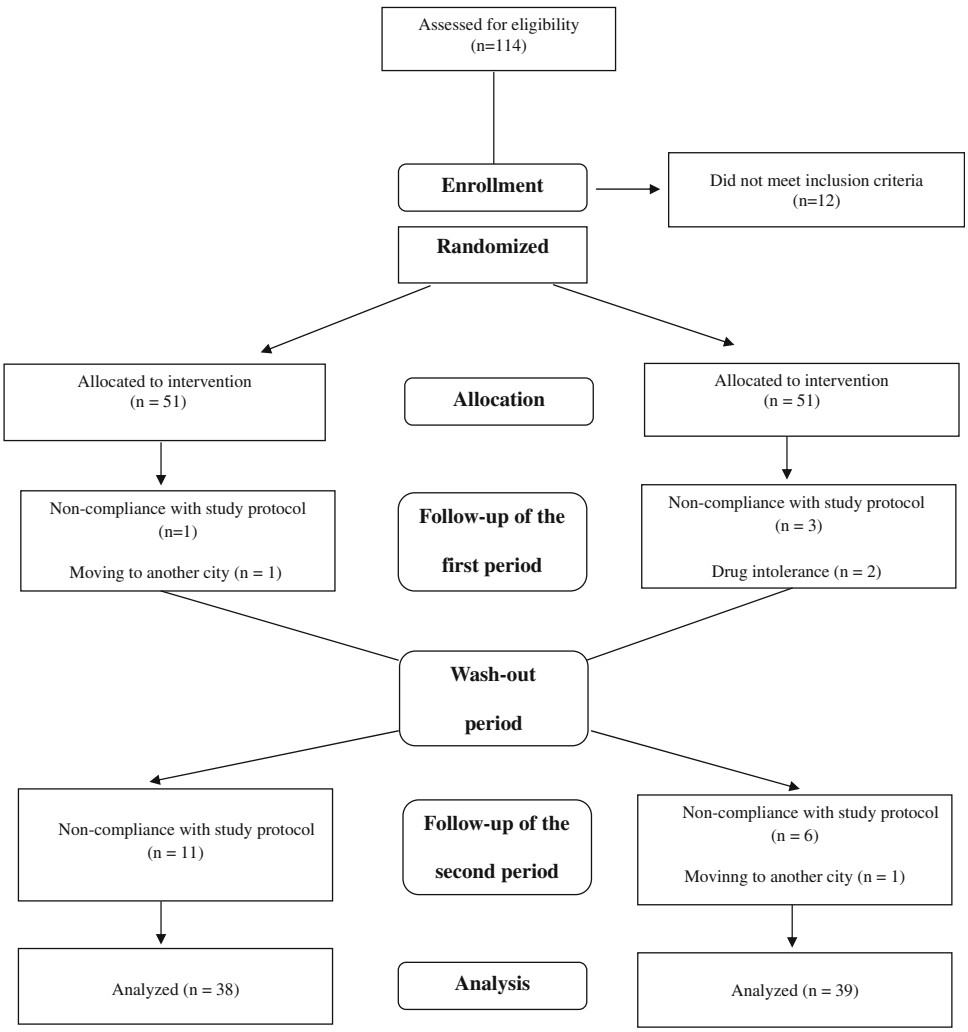

Fig. 1 Flow chart of the trial

Table 1 Effect of simvastatin and placebo therapy in two groups of subjects

	Study groups	First Pre treatment	Period Post treatment	Second Pre treatment	Period Post treatment	Period effect[a]	Treatment effect (S vs. P)
FBS (mg/dl)	Statin–placebo	86.46 ± 19.52	85.58 ± 17.12	81.28 ± 15.83	81.09 ± 13.65	($P > 0.05$)	($P > 0.05$)
	Placebo–statin	104.36 ± 47.61	101.71 ± 45.86	103.5 ± 45.55	99.10 ± 33.28		
Weight (kg)	Statin–placebo	71.59 ± 22.02	72.42 ± 19.24	73.80 ± 18.60	75.27 ± 18.55	($P = 0.003$)	($P > 0.05$)
	Placebo–statin	78.04 ± 16.63	77.17 ± 16.30	76.99 ± 15.50	76.71 ± 16.41		
BMI (kg/m^2)	Statin–placebo	28.83 ± 6.18	28.30 ± 6.19	28.95 ± 5.90	29.09 ± 5.91	($P = 0.019$)	($P > 0.05$)

Values are expressed as means ± SD for normally distributed data and median and interquartile range. Statin-placebo group took statin at first, while placebo-statin group received statin following placebo

BMI body mass index, *FBS* fasting blood sugar, *TC* total cholesterol, *HDL* high-density lipoprotein, *LDL* low-density lipoprotein, *TG* triglycerides, *PAB* prooxidant–antioxidant balance

[a] Defined as comparison of mean values between the first and second periods

Effect of Administration of Simvastatin Versus Placebo on Lipid Parameters

As expected, total cholesterol, LDL-C and triglycerides were reduced significantly after 4-weeks of treatment with simvastatin ($P < 0.001$). However, HDL-C did not change significantly with either treatment ($P > 0.05$) (Table 1).

Effect of Administration of Simvastatin Versus Placebo on PAB Values

Treatment with simvastatin 40 mg/day for 4 weeks caused a statistically significant reduction in the mean PAB values ($P < 0.001$) (Fig. 2).

Correlation Between Changes in PAB Values with Changes in LDL-C Levels

Statistical analysis showed that there was no significant correlation between changes in PAB values and serum LDL-C levels in any of the periods, neither in the placebo-statin nor in the statin-placebo group ($P > 0.05$, Table 2). The only exception was a significant correlation between PAB changes and serum total cholesterol changes in the placebo-statin group ($P < 0.05$, Table 2).

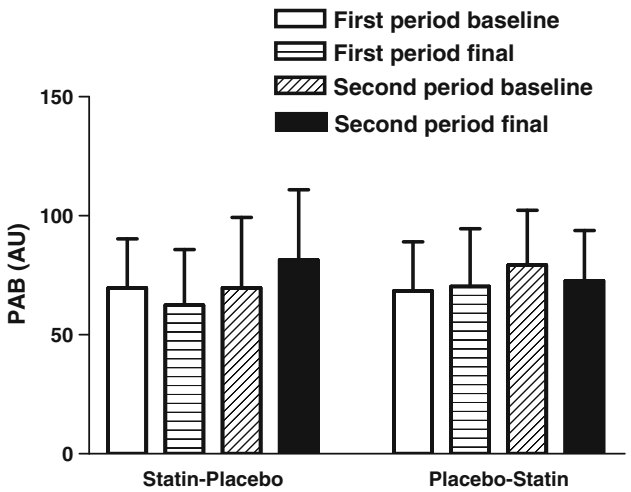

Fig. 2 Effect of simvastatin versus placebo on serum PAB values. Period effect: $P > 0.05$; treatment effect: $P < 0.001$

Discussion

In the present study we found that simvastatin therapy for 4 weeks caused a statistically significant reduction in mean PAB values, showing that statin therapy may be associated with a reduction in levels of oxidative stress. Our finding confirms the results of other studies evaluating the effect of statins on plasma measures of oxidation status. Fluvastatin therapy was found to reduce superoxide radical generation

Table 2 Correlations between changes in serum PAB and LDL-C levels

	LDL-C		Total cholesterol	
	r	*p*	*r*	*p*
Placebo–statin				
First period	0.197	>0.05	0.335	<0.05
Second period	0.005	>0.05	−0.016	>0.05
Statin–placebo				
First period	0.050	>0.05	0.031	>0.05
Second period	−0.356	>0.05	−0.360	>0.05

Correlations were assessed using the Pearson correlation coefficient

PAB prooxidant–antioxidant balance

and the susceptibility of LDL to oxidation in cholesterol-fed rabbits [14]. Moreover, simvastatin was reported to lower superoxide generation in human macrophages [15]. Furthermore, oxidative stress of different patients has been shown to decrease after treatment with atorvastatin, simvastatin, pravastatin, fluvastatin, and lovastatin [16–18]. In addition, treatment with these statins was followed by a prolonged lag time of LDL oxidation [19–21]. Statin therapy also causes a significant reduction in plasma levels of ox-LDL [17] and it has also been reported that in hypercholesterolemia or mixed type hyperlipidemia, atorvastatin can increase total plasma antioxidant status, leading to a lower LDL oxidation capacity [19].

There appear to be several mechanisms whereby statins may reduce oxidative stress. Apart from their hypocholesterolemic effects and the subsequent reduction of oxidation substrate, statins are known to exert radical scavenging activity and decrease the generation and release of ROS through different mechanism such as inhibition of Rac1GTPase and NADPH-oxidase [22].

Nicotinamide adenine dinucleotide phosphate (NADPH) oxidases are as one of the important sources of superoxide in human coronary artery, and their activities have been reported to be increased in patients with CVD [23]. Statins have been reported to reduce NADPH dependant superoxide formation by monocyte-derived cell lines in culture [24]. Atorvastatin has been reported to inhibit angiotensin II-induced superoxide formation by NADPH oxidase in rats in vivo [25]. Statin therapy has been also suggested to inhibit ox-LDL induced NADPH oxidase expression and superoxide anion formation [26]. The anti-inflammatory properties of statins make them able to inhibit macrophage growth and foam cell formation stimulated with ox-LDL [27], leading to a reduction in influx of inflammatory cells, which consecutively results in a decreased release of ROS and the LDL oxidation.

Statins may also act as an antioxidant via different mechanisms, for instance, there are some reports, though not consistent, indicating that statins are able to increase the activity and/or expression of antioxidant enzymes such as catalase, paraoxonase and glutathione peroxidase, while decreasing those of NADPH oxidase [28–31]. It is also reported that statins can increase the release of NO [32], and also several statins have the ability to increase eNOS expression in the blood vessels of treated animals [33], resulting in the restoration of endothelial function. Moreover, atorvastatin has been reported to increase paraoxonase activity and decrease the enhanced cellular uptake of ox-LDL of monocytes differentiating into macrophages [34]. Finally some statin metabolites are considered to possess antioxidant properties and prevent lipid peroxidation [35] (Fig. 3).

In our study, we did not find a significant correlation between changes in PAB values with changes in serum levels of LDL-C, implying that antioxidant activity of statins may be at least partly due to other pleiotropic properties rather than just lipid-lowering effects of these drugs. It is suggested that the underlying cholesterol independent effects relates to the inhibition of isoprenoid intermediates of the cholesterol synthesis pathway [36].

The aforementioned studies together with the findings of the present study support the notion that oxidative stress could be used as a significant risk predictor in the atherosclerotic process. Statins have pleiotropic properties as endothelial protective, anti-inflammatory, and antioxidative agents, and suggest that other markers such as

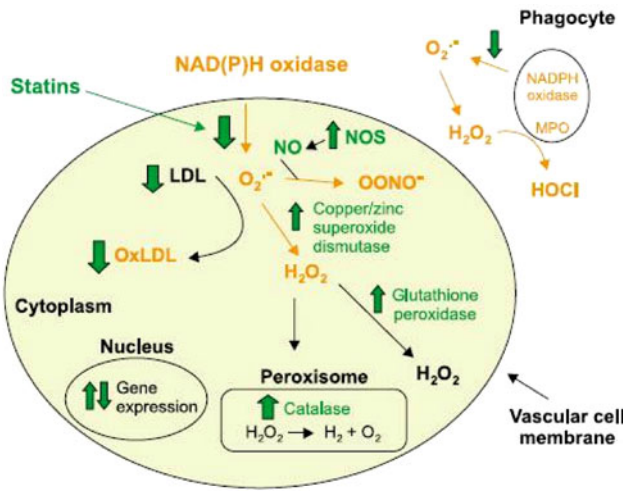

Fig. 3 Some antioxidant mechanisms of statins. Statins inhibit the assembly of NAD(P)H oxidase in both vascular cells and phagocytes, thus preventing the formation of superoxide ($O_2^{\cdot-}$). *Bi-directional arrows* associated with gene expression indicate upregulation of expression of antioxidant enzymes (eNOS and catalase) and down-regulation of oxidants (NAD[P]H components and cyclooxygenase-2). C-reactive protein, oxidative biomarkers and isoprenoid intermediates might be used in conjunction with serum cholesterol levels to assess the therapeutic benefits of statin therapy better.

In previous studies using the PAB assay, it was reported to be elevated in a number of conditions associated with oxidative stress including diabetes mellitus [11], coronary artery disease [12], acute coronary syndrome [37], exfoliative glaucoma [38], and stroke [39]. PAB values have been also reported to decrease following antioxidant vitamins (E and C) [11] and selenium consumption [40]. The PAB assay may be useful as a CVD risk predictor [12, 37] and could help to identify patients with higher oxidative stress in order to introduce interventions for the prevention of vascular disease earlier. In the present study, we showed that this assay may serve as a useful method to assess the effect of statin therapy in CVD, indicating that the PAB assay, along with other known markers of oxidative stress, may be used to estimate the extent of oxidative stress in high-risk groups, identify subjects who need antioxidant therapy, and evaluate the antioxidative efficacy of different supplements and medications. Finally, further clinical research is required based on a larger healthy population, as well as on various physiological and pathological states associated with oxidative stress, and by multiple laboratories in order to substantiate the potency of the assay to become a clinical laboratory test.

Study Limitations

The present study had several limitations. First, 25 subjects did not complete the study due to non-compliance with the study protocol or drug intolerance. Second, simvastatin was administered at a dose of 40 mg/day for a limited period (30 days), and longer term studies are necessary to show that this effect is sustained. Finally, using several doses of statins could have been useful to determine whether the observed effects of simvastatin are dose-dependent and whether higher doses exert more dramatic effects.

Acknowledgments We are particularly grateful to the patients and their family members who volunteered to participate in this study. This work was financially supported by the Iran National Science Foundation and Mashhad University of Medical Science (MUMS), Mashhad, Iran.

Ezetimibe Treatment Lowers Indicators of Oxidative Stress in Hypercholesterolemic Subjects with High Oxidative Stress

Received: 31 October 2010 / Accepted: 4 February 2011 / Published online: 26 February 2011

Abstract Ezetimibe effectively reduces low-density lipoprotein cholesterol (LDL-C). In this study, we tested the hypothesis that ezetimibe monotherapy may also decrease markers of oxidative stress in subjects with hypercholesterolemia. Subjects with hypercholesterolemia and no evidence of cardiovascular disease were randomly allocated to open-label ezetimibe monotherapy 10 mg/day (EZT group) or therapeutic lifestyle changes (TLC group). At baseline and 12 weeks post-treatment serum lipoprotein and apolipoprotein levels as well as oxidative stress parameters, including oxidized LDL (ox-LDL), 8-isoprostanes (8-epi-PGF2a) and reactive oxygen metabolites (d-ROMs) levels, were blindly determined. A total of 60 patients were included; 30 in each group. Despite a significant decrease in ox-LDL levels (by 20.8%, $p < 0.001$ vs. baseline; $p < 0.001$ vs. TLC group) in the EZT group no change in the ratio ox-LDL to LDL-C was noticed following ezetimibe treatment. No significant change in 8-epiPGF2a and d-ROMs levels was observed in the EZT group. Of note, a significant decrease in 8-epiPGF2a and d-ROMs levels (by 20.4% and 18.2%, respectively, $p < 0.01$ vs. baseline for both), was noted among patients in the EZT group who exhibited 'high oxidative stress' at baseline. No change in any of oxidative stress parameters was noted in the TLC group. Ezetimibe may decrease markers of oxidative stress in hypercholesterolemic subjects. This benefit may be more profound among patients who exhibit 'high oxidative stress' at baseline.

Keywords Ezetimibe · Oxidative stress · Oxidized LDL · 8-Isoprostanes · Reactive oxygen metabolites · Pleiotropic actions · Hypercholesterolemia

Abbreviations

ANCOVA	Analysis of covariance
Apo	Apolipoprotein
d-ROMs	Reactive oxygen metabolites
EZT	Ezetimibe
HDL-C	High-density lipoprotein cholesterol
HOMA	Homeostasis model assessment
LDL-C	Low-density lipoprotein cholesterol
NCEP	National Cholesterol Education Program
Ox-LDL	Oxidized low-density lipoprotein
RISCC	Ratio of ingested saturated fat and cholesterol to calories
TC	Total cholesterol
TAG	Triacylglycerol
TLC	Therapeutic lifestyle changes
8-epiPGF2a	8-Isoprostane

Introduction

Lowering levels of low-density lipoprotein cholesterol (LDL-C) plays an important role in cardiovascular disease prevention and comprises the main target of hypolipidemic therapy [1]. Statins are considered the most effective drugs in terms of improving serum lipid profile [2]. Treatment with statins has been associated with improved outcomes

either in the primary or the secondary prevention of cardiovascular disease [3]. This benefit has been attributed not only to the lipid-lowering potency, but also to various pleiotropic anti-atherosclerotic properties of these drugs (namely anti-inflammatory, anti-oxidative and anti-thrombotic) [4].

Ezetimibe potently inhibits the intestinal absorption of cholesterol from dietary and biliary sources by blocking the Niemann–Pick C1-like 1 protein for cholesterol transport [5]. Clinical studies showed that ezetimibe either as monotherapy or in combination with statins decreases LDL-C levels and beneficially modifies serum lipid profile [6, 7]. However, there is a lack of convincing evidence that ezetimibe may prevent cardiovascular disease [8–11]. It also remains questionable whether ezetimibe shares some of the pleiotropic properties of statins [12].

Oxidative stress, mostly by giving rise to endothelial dysfunction and pro-inflammatory processes, plays a major role in atherogenesis [13]. Several biomarkers, including oxidized LDL (ox-LDL), 8-isoprostane (8-epiPGF2a) and reactive oxygen metabolites (d-ROMs), are useful for the assessment of oxidative stress in clinical practice [14]. Hyperlipidemia and increased oxidative stress often coexist and their combined unfavorable effects may result in increased atherogenicity [13].

To date, limited data suggest that ezetimibe may reduce various markers of oxidative stress [15–17]. As with other possible pleiotropic actions, it remains unclear whether these effects are associated with the LDL-C lowering capacity of this drug. In the present study, we sought to investigate the effects of ezetimibe monotherapy on serum markers of oxidative stress in subjects with primary hypercholesterolemia.

Materials and Methods

Study Population

Subjects with mild-to-moderate hypercholesterolemia consecutively attending the Outpatient Lipid Clinic of the University Hospital of Ioannina, Ioannina, Greece, were included in the present study. Exclusion criteria consisted of: (1) age <18 years, (2) coronary heart disease (unstable angina, acute myocardial infarction, coronary artery bypass graft, or percutaneous transluminal coronary angioplasty within the last 3 months), (3) type 2 diabetes [fasting blood glucose >126 mg/dL (6.93 mmol/L)], (4) renal function impairment as defined by serum creatinine levels higher than 1.8 mg/dL (158.4 μmol/L) and/or total protein urinary (UTpr) excretion >150 mg/24 h, (5) liver disease (as defined by alanine and/or aspartate aminotransferase levels >3 times the upper limit of normal in more than two consecutive measurements), (6) raised thyroid-stimulating hormone (TSH) levels (>5 IU/mL), (7) childbearing potential for women, (8) psychiatric disease with defects in judgement, (9) known allergic reaction to ezetimibe, (10) heavy alcohol consumption (>3 drinks per day) or (11) lipid-lowering therapy (including statins, fibric acid derivatives, nicotinic acid, cholestyramine, or ω-3 fatty acids) or other treatment that could possibly affect lipid metabolism, renal or hepatic function, as well as parameters examined in this study.

After a 6 week dietary lead-in, eligible patients were randomly allocated to receive either open-label ezetimibe 10 mg/day (EZT group) or continue therapeutic lifestyle changes (TLC group). Compliance with study medication was assessed at week 12 with questionnaires and pill count; patients were considered compliant if they took 80–100% of the prescribed number of tablets. All patients gave written informed consent and the study protocol was approved by the Institutional Ethics Committee.

In order to validate the measurements of oxidative stress markers and distinguish patients with 'high oxidative stress' at baseline, we evaluated a 'control group' of 30 subjects who were selected among volunteers attending a Primary Care Family Screening Program. The same exclusion criteria were applied to the control group.

Clinical Evaluation

At baseline as well as 12 weeks post-treatment body weight and height measurements were performed in every individual to calculate body mass index [BMI = body weight (in kilograms)/height (in m^2)]. Waist circumference and blood pressure measurements were also obtained. A food record rating score was calculated from 3-day diaries kept by participants to assess compliance to dietary intervention throughout the study. The mean total daily intake of energy, carbohydrates, protein, fat, saturated fat, and cholesterol was calculated from these diaries by a modified Nutritionist V diet analysis (First Databank, San Bruno, CA, USA), which was amended to include traditional Greek recipes. From these data, the dietary RISCC (ratio of ingested saturated fat and cholesterol to calories) rating was determined [18]. The RISCC rating condenses the saturated fat, cholesterol, and energy intakes into one value, which summarizes the serum lipoprotein-raising potential of a diet [18]. For example, the RISCC rating of a typical diet (fat intake of 35–40% of total energy) is between 24 and 28. All participants were instructed to keep a dietary pattern similar to that of the NCEP (National Cholesterol Education Program) Step I diet, which is characterized by a reduced fat intake scoring from 13 to 18[19]. Stability in RISCC ratings over time provides evidence for stability of background dietary patterns.

Laboratory Investigations

Blood samples were obtained at baseline and after 12 weeks following a 12-h overnight fast to determine serum lipid and non-lipid metabolic parameters as well as oxidative stress markers. All samples were blindly assessed with regard to treatment allocation.

Non-Lipid Metabolic Parameters

Serum glucose, insulin, creatinine, creatine kinase, aminotransferases, and thyroid function tests were performed shortly after blood sampling by use of conventional methods. The Homeostasis Model Assessment (HOMA) a marker of insulin resistance (IR) [$HOMA_{IR}$ = insulin (μU/mL) × glucose (mg/dL)/405] was also assessed.

Lipid Determinations

Measurements of serum lipids [total cholesterol (TC), triacylglycerols (TAG) and high-density lipoprotein cholesterol (HDL-C)] were performed shortly after blood sampling. The concentrations of TC and TAG were determined enzymatically on the Olympus AU 600 clinical chemistry analyzer (Olympus Diagnostica, Hamburg, Germany). HDL-C was determined by a direct assay (Olympus Diagnostica, Hamburg, Germany). LDL-C was calculated using the Friedewald formula.

For the determination of apolipoprotein (apo) variables, samples were frozen and stored at −80 °C, and all samples were analyzed in the same run at the end of the study. ApoA1, apoB, apoE and Lp(a) were measured with a Behring Nephelometer BN100, and reagents (antibodies and calibrators) from Dade Behring Holding GmbH (Liederbach, Germany). The apoA1 and apoB assays were calibrated according to the International Federation of Clinical Chemistry (IFCC) standards.

Oxidative Stress Markers

To assess oxidative stress, serum levels of 8-epiPGF2a, ox-LDL and d-ROMs were measured. Serum levels of 8-epiPGF2a were determined by means of a competitive ELISA using a commercially available kit (Cayman Chemicals, Ann Arbor, MI, USA), as previously described [20]. This method has a specificity of 100% for 8-epiPGF2a, while having minimal cross-reactivity with other compounds, mostly 8-isoPGF3α. Concentrations of ox-LDL were assayed with the noncompetitive immunoassay (Mercodia AB, Uppsala, Sweden), which uses an antibody (4E6) that was obtained after immunization of mice with copper-oxidized LDL [21, 22]. As a measure of the equilibrium between free radical production and antioxidant defense, serum levels of d-ROMs were determined using a commercial kit (d-ROMs test Diacron International, Grosseto, Italy) on a Free Radical Analytical System (FRAS 4, Diacron, Grosseto, Italy) [23–25]. The reactive oxygen metabolites, primarily hydroperoxides are able to generate alkoxyl and peroxyl radicals in the presence of iron released from plasma proteins by an acidic buffer in accordance to the Fenton's reaction. Such radicals are, in turn, able to oxidize an alkyl-substituted aromatic amine (*N*,*N*-diethyl-*para*-phenylendiamine) to the corresponding radical cation, which can be quantified spectrophotometrically at 505 nm. The concentration of d-ROMs is positively directly correlated with color intensity and is expressed as Carratelli Units (1 CARR $U = 0.08$ mg hydrogen peroxide/dL). In normal subjects carr U values range from 250 to 300 [23, 24].

Statistical Analysis

It was estimated that a sample size of 54 would give a 95% power to detect a 15% difference in the reduction of 8-epiPGF2a between the 2 groups at an alpha of 0.05. We included 60 patients allowing for a drop-out rate of ∼10%.

Preliminary analysis was performed to ensure no violation of the assumptions of linearity and normality. The Shapiro–Wilk test was used to evaluate whether each parameter followed a Gaussian distribution. Values are expressed as mean ± standard deviation (SD) and median (range) for normally and non-normally distributed variables, respectively. In-group comparisons of continuous variable values prior to and post-treatment were performed by a paired two-tailed Student's test for parametric variables and Wilcoxon's ranks test for non-parametric distributed ones.

Relationships between variables were assessed by the Pearson's and Spearman correlations coefficients for parametric and non-parametric variables, respectively. Analysis of covariance (ANCOVA), adjusted for baseline values, was used for comparisons between treatment groups. Logarithmic transformations were performed for non-parametric variables. All comparisons were also held into subgroups of hypercholesterolemic patients either exhibiting 'high oxidative stress' or 'normal oxidative status' at baseline. In hypercholesterolemic patients, 'high oxidative stress' was defined as levels of 8-epiPGF2a equal or greater than the mean value of 8-epiPGF2a plus a standard deviation in controls.

Differences were considered significant at a value of $p < 0.05$. All analyses were carried out with SPSS 16.0 (SPSS Inc, Chicago, IL, USA).

Results

Demographics

A total of 60 subjects were enrolled, 30 in the EZT group and 30 in the TLC group. The demographic, clinical and laboratory characteristics of the study population are shown in Table 1. No differences between the EZT and TLC group were recorded with regard to baseline clinical and laboratory parameters.

Safety and Compliance

All patients completed the study protocol without any withdrawals. Small elevations of aminotransferase activities (<3 times the upper limit of normal) were observed in two patients in the EZT group and of creatine kinase (<5 times the upper limit of normal) in one patient in the same group. Enzyme activities returned to normal with continuing treatment in all cases. Mean compliance was above 90% during the study period.

Clinical Evaluation

No alterations in clinical parameters, including BMI, waist circumference and blood pressure were noted in either group. Likewise, RISCC scores remained unchanged at the end of the follow-up in both treatment arms (data not shown).

Changes in Lipids and Apolipoproteins (Table 1)

TC and LDL-C levels were reduced by 13.2 and 18.1%, respectively, following ezetimibe treatment ($p < 0.001$ vs. baseline and $p < 0.001$ vs. TLC group for both comparisons) (Table 1). No significant change with regard to HDL-C and TAG levels was observed in the EZT group. A decrease in non-HDL-C levels by 14.5% was recorded ($p < 0.001$ vs. baseline and $p < 0.05$ vs. TLC group) in the EZT group (Table 1). None of these variables was significantly altered from baseline in the TLC group. Ezetimibe induced significant reductions in apoB and apoE levels by 16.5% ($p < 0.001$ vs. baseline and $p < 0.01$ vs. TLC

group) and 15.4% ($p < 0.001$ vs. baseline and $p < 0.01$ vs. TLC group), respectively, while apoA1 concentration remained unchanged (Table 1). No change in apolipoprotein levels was noted in the TLC group.

Evaluation of Baseline Oxidative Stress in Hyperlipidemic Patients and Controls

Hyperlipidemic patients exhibited higher levels of ox-LDL, 8-epiPGF2a and d-ROMs as compared with controls ($p < 0.01$ for all comparisons) (Table 1). 'High oxidative stress' as assessed by increased baseline 8-epiPGF2a levels (i.e., ≥64 pg/mL) was noted in 17/30 patients of the EZT group and 18/30 patients of the TLC group (57 vs. 60%, respectively, p = NS for the comparison between groups).

Changes in Oxidative Stress Markers

A significant reduction of ox-LDL levels by 20.8% was observed following ezetimibe treatment ($p < 0.001$ vs. baseline and $p < 0.001$ vs. TLC group) (Table 1). However, ezetimibe treatment, by producing comparable decreasing effects on ox-LDL and LDL-C levels, did not affect the ratio of ox-LDL to LDL-C (from 0.64 ± 0.23 to 0.62 ± 0.21, p = NS). No significant alterations in 8-epiPGF2a and d-ROMs levels were noted in the EZT group after 12 weeks of treatment (Table 1). No change was observed in the TLC group in any of the above measured oxidative stress markers.

Correlations of Oxidative Stress Markers

Baseline ox-LDL levels were correlated with baseline TC ($r = 0.72$, $p < 0.001$), non-HDL-C ($r = 0.74$, $p < 0.001$), LDL-C ($r = 0.65$, $p < 0.001$) and apoB ($r = 0.77$, $p < 0.001$) levels. The post-treatment decrease in ox-LDL levels observed in the EZT group was positively correlated with age ($r = 0.50$, $p < 0.05$), baseline levels of ox-LDL ($r = 0.41$, $p < 0.05$) as well as with the decreases in TC ($r = 0.48$, $p < 0.05$) and LDL-C levels ($r = 0.57$, $p < 0.01$). Baseline levels of 8-epiPGF2a were significantly correlated with baseline TC levels ($r = 0.41$, $p < 0.05$). Only baseline 8-epiPGF2a levels ($r = 0.52$, $p < 0.05$) were correlated with the reduction in 8-epiPGF2a concentration following ezetimibe treatment, which was independent of any post-treatment changes in lipid and apolipoprotein levels. Baseline d-ROMs concentration was correlated with baseline TAG ($r = 0.43$, $p < 0.05$), non-HDL-C ($r = 0.43$, $p < 0.05$) and Lp(a) ($r = 0.60$, $p < 0.01$) levels. The decrease in d-ROMs levels in the EZT group was positively correlated with age ($r = 0.498$, $p < 0.05$) and inversely with baseline TC levels ($r = -0.57$, $p < 0.01$).

Differential Changes of Oxidative Stress Parameters in Ezetimibe-Treated Patients Exhibiting 'High' or 'Normal' Oxidative Stress at Baseline (Table 2)

Both groups exhibited similar serum lipid profile at baseline. No differential effect of ezetimibe on serum lipid and apolipoprotein levels was observed between groups. In patients who exhibited 'high oxidative stress' at baseline ($n = 17$) ezetimibe treatment significantly reduced ox-LDL levels by 19.1% ($p < 0.01$ vs. baseline), whereas the ratio of ox-LDL to LDL-C did not change (from 0.64 ± 0.31 at baseline to 0.63 ± 0.29 post-treatment, p = NS). In the same subgroup of patients ezetimibe was associated with a significant decrease in the levels of 8-epiPGF2a and d-ROMs by 20.4 and 18.2% ($p < 0.01$ vs. baseline for all comparisons), respectively. Spearman's correlations coefficients revealed that the post-treatment decreases in 8-epiPGF2a and d-ROMs levels in the 'high oxidative stress' patients was independent of any change in lipid and apolipoprotein levels. The decrease in d-ROMs levels was significantly associated only with baseline d-ROMs concentration ($r = 0.68$, $p < 0.05$).

In the subgroup of patients with 'normal oxidative stress' at baseline ($n = 13$) ezetimibe treatment was associated with a significant decrease of ox-LDL levels by 18.9% ($p < 0.01$ vs. baseline). This decrease was not significantly different from that observed in patients with 'high oxidative stress'. Contrarily to the patients with 'high oxidative stress', no post-treatment changes in 8-epiPGF2a and d-ROMs levels were observed among hyperlipidemic patients with 'normal oxidative stress' at baseline ($p < 0.05$ for the comparison between groups). Also, TLC resulted in no significant changes in any of the examined oxidative stress markers in patients with either 'normal' ($n = 12$) or 'high' ($n = 18$) oxidative stress at baseline.

Discussion

The present study provides evidence that a 12-week ezetimibe treatment may reduce oxidative stress markers in subjects with primary hypercholesterolemia. This benefit is reflected by a decrease in the levels of 8-epiPGF2a and d-ROMs, which was observed among patients with 'high oxidative stress'. Decreases in ox-LDL levels following ezetimibe treatment were closely related with the degree of LDL-C lowering. Therefore, the levels of ox-LDL to LDL-C ratio did not change. No differential effect of ezetimibe on ox-LDL was detected in patients with either 'high' or 'normal' oxidative stress at baseline.

Ezetimibe is a potent inhibitor of cholesterol intestinal absorption and effectively decreases LDL-C levels. However, it remains uncertain whether this drug may affect

Table 2 Differential changes of laboratory parameters in ezetimibe-treated patients with 'high' or 'normal' oxidative stress at baseline

atherosclerosis progression or improve clinical outcomes [8–11]. Given the potency of ezetimibe to effectively reduce LDL-C levels, the possible pleiotropic antiatherosclerotic actions of ezetimibe have been posed under question [12]. Several studies have come with contradictory results with regard to the effect of ezetimibe on inflammatory markers and endothelial function indices [12, 26, 27]. The anti-oxidative potential of this drug is also under consideration. In this study, we tested the hypothesis that ezetimibe treatment may decrease markers of oxidative stress in subjects with primary hypercholesterolemia. Markers used for the evaluation of oxidative stress were ox-LDL, 8-epiPGF2a and d-ROMs.

Ox-LDL, the product of oxidative modification of LDL, when impedes into the arterial wall induce endothelial dysfunction and gives rise to a cascade of inflammatory and proliferative processes leading to atherosclerotic plaque formation [14, 28]. High levels of ox-LDL have been recognized as an independent risk predictor for cardiovascular disease [29]. Ezetimibe treatment significantly decreased ox-LDL levels in our study (by 20.8%, $p < 0.001$) an observation that accords with recently published results showing that ezetimibe treatment reduced ox-LDL levels in 30 hyperlipidemic patients after a 3-month period [30]. Our results further showed that there is a significant positive correlation of post-treatment change in ox-LDL levels with the corresponding changes in LDL-C. Consequently, the ratio of ox-LDL to LDL-C remained unchanged, implying that the ezetimibe-induced decrease in ox-LDL levels may be primarily attributed to its effect on LDL-C levels.

8-epiPGF2a result from free-radical attack of cell membrane phospholipids or circulating LDLs. 8-epiPGF2a levels comprise a marker of lipid peroxidation and have been recognized as one of the most valid markers of in vivo oxidative stress. Increased levels of 8-epiPGF2a have been associated with increased risk for cardiovascular disease [31]. In our study a significant decrease of 8-epiPGF2a levels was observed in patients with 'high oxidative stress' (by 20.4%, $p < 0.01$ vs. baseline). This effect of ezetimibe was independent of the degree of LDL-C lowering. Our findings are consistent with a decrease in 8-epiPGF2a levels associated with a 3-month ezetimibe treatment in 30 hyperlipidemic patients in the previously mentioned study [30].

The d-ROMs test is a novel available test for the determination of organic peroxides [31]. High concentrations of lipid peroxides may produce an imbalance between nitric oxide and reactive oxygen species in vascular endothelium. This process results in endothelial dysfunction which comprises a critical step in the atherosclerotic process [32]. In the present study, ezetimibe induced a small (by 10%) but not significant decrease in d-ROMs levels. Of note, this decrease was significant in patients

with 'high oxidative stress' at baseline (by 18.2%, $p < 0.01$ vs. baseline). This effect was independent of any post-treatment change in lipid parameters. The ezetimibe-related reduction of d-ROMs in our study is comparable to that induced by a 22-week ezetimibe treatment (by 11%) in 14 high-risk patients with hypercholesterolemia who were on stable treatment with statins [16].

Study Limitations and Strengths

Limitations of the current study include the open-label design, the absence of a 'true' placebo group and the relatively short duration. Also, it should be acknowledged that it is very difficult to correctly quantify lipid peroxides and is impossible to quantify reactive oxygen species in vivo, due to their reactivity. We determined ox-LDL, dROMs and 8-epiPGF2a levels which are only markers of oxidative stress. In addition, 8-epiPGF2a levels would depend on the amount of arachidonic acid in the diet. To this regard, the determination of arachidonic acid would be useful and the concentration of 8-epiPGF2a should have been expressed per equivalent of plasma 20:4.

On the other hand, we assessed oxidative stress by the determination of various parameters, we included a TLC group and we blindly assessed endpoints.

Conclusion

In patients with primary hypercholesterolemia ezetimibe may reduce markers of oxidative stress, including ox-LDL, 8-epiPGF2a and d-ROMs levels, especially in those who exhibit 'high oxidative stress' at baseline. This action of ezetimibe, especially the decrease in ox-LDL levels, could be at least partially mediated through its lipid-lowering potency. However, the possibility that ezetimibe may decrease 8-epiPGF2a and d-ROMs levels independently of its lipid-lowering capacity cannot be excluded. Further studies are needed to explore the underlying mechanisms for the anti-oxidative actions of ezetimibe.

Conflict of interest This study was conducted independently; no company or institution supported it financially.

Abstract Women with diabetes are faced with a higher risk of dyslipidemia and cardiovascular disorders than men with diabetes. We aimed to study the role of gender and menopausal status in serum Lp(a) levels in patients with type 2 diabetes. We quantified serum Lp(a) levels in a group of 477 patients with type 2 diabetes (men, premenopausal and postmenopausal women with diabetes), as well as in 105 controls. We stratified the patients into two groups of low Lp(a) levels (Lp(a) <35 mg/dl) and elevated Lp(a) levels (Lp(a) >35 mg/dl). Patients with diabetes had higher serum Lp(a) levels than the controls. Serum Lp(a) levels was significantly higher in women with diabetes than men with diabetes. Lp(a) levels did not differ between male and females in the control group. Premenopausal and postmenopausal women with diabetes did not differ significantly in serum Lp(a) levels. The odds ratio of having a serum Lp(a) level higher than 35 was 5.85 in premenopausal women with diabetes, 5.08 in postmenopausal women with diabetes, 2.41 in men with diabetes and 1.9 in the women in the control group compared to the men in the control group, after adjustment for age and BMI. This observational study clearly indicated that serum Lp(a) levels were significantly higher in women and men with diabetes. The increase in women was independent of menopause. The level of serum Lp(a) had no correlation with lipid parameters in men or women.

Abbreviation

Apo (B)	Apoprotein B-100
BMI	Body mass index
HDL-C	High density lipoprotein cholesterol
LDL-C	Low density lipoprotein cholesterol
Lp(a)	Lipoprotein(a)
TG	Triglyceride
VLDL	Very low density lipoprotein cholesterol

Introduction

While cardiovascular disease mortality is currently decreasing in the general population [1], mortality in women with diabetes is increasing [2]. Both metabolic syndrome and diabetes pose a significant increase in the risk of mortality in postmenopausal women [3]. However, the traditional risk factors for coronary heart disease like, hypertension, elevated serum cholesterol, smoking habit and diabetes dyslipidemia [4], do not explain the excessive prevalence of coronary heart disease among women with diabetes [5–7].

Lipoprotein a [Lp(a)] is a modified form of low density lipoprotein in which apoprotein B-100 [apo (B)] is linked to a unique glycoprotein, named apoprotein (a) [8]. It is mainly determined genetically, depending on apoprotein (a) genotype [9, 10]. The direct association between serum Lp(a) levels and the risk of cardiovascular disorders is well established [11, 12]. Elevated levels of serum Lp(a) is also associated with an increased risk of coronary heart disease in patients with diabetes [13, 14]. It is also a predictor of non-proliferative retinopathy in these patients [15–19]. Lp(a) is present in the arterial wall at sites of atherosclerosis in humans and results in both atherogenesis and thrombosis (3). Elevated levels of Lp(a) are associated with aortic dissection [20], occlusion of large cerebrovascular arteries [21] and silent cerebrovascular infarction in hemodialysis patients [22].

To date, we are unaware of any study demonstrating the impact of diabetes and menopausal status on serum Lp(a) levels. This is debatable due to the wide variability of serum Lp(a) levels in the general population, its highly skewed distribution and the role of gender particularly on its association with diabetes [23–26]. In this observational study, we aimed to evaluate serum Lp(a) levels, in males, premenopausal and postmenopausal females with diabetes.

Method

We performed a cross-sectional analysis of the serum samples of 477 patients with type 2 diabetes who were consecutively selected from the diabetes clinic of Vali-Asr hospital affiliated with Tehran University of Medical Science plus 105 controls. Controls were healthy volunteers from the patients' concomitants or hospital staff. Healthy controls were selected from those without any known disease including type 2 diabetes, hyperlipidemia, ischemic heart disease, and malignancy. The patients were divided into 3 groups of 115 women in premenopausal state, 144 women in postmenopausal state and 218 men. Diabetes was diagnosed according to the criteria of the American Diabetes Association [27]. Exclusion criteria were pregnancy, acute or chronic renal failure, glomerulonephritis, congestive heart failure, thyroid disorders, acute infections, stroke, diabetic ketoacidosis, non-ketonic hyperosmolar diabetes and hospital admission in recent months. The age of menopause and the time of elapse after menopause were recorded in the questionnaire. None of the studied participants had overt diabetes complications; none of the studied patients had a history of ischemic heart disease. The frequency of insulin therapy was similar between men and women with type 2 diabetes (15–20%). Based on our clinical experience, we rarely have diabetic patients on either oral contraceptive agents or hormone replacement therapy. Therefore, we think this will not influence on our results. The groups were also matched according to statin therapy. Nearly 40–60% of the patients were on statin therapy. Furthermore, our clinical experiences indicate that niacin treatment may reduce Lp(a) levels at a very high doses. None of the participants in our study were using niacin at high doses.

Demographic and anthropometric data including age, sex, duration of diabetes, height, weight in light clothing and blood pressure in the sitting position were recorded. Blood pressure was remeasured twice after an average of 5 min. The body mass index (BMI; kg/m^2) was calculated according to the Quetelet formula. All participants gave written informed consent before participation. The research was carried out according to the principles of the Declaration of Helsinki; the local ethics review committee of Tehran University of Medical Science approved the study protocol.

Blood Samples

Blood samples were collected after 12 h of fasting and, serum creatinine, fasting blood sugar (FBS), total cholesterol, triglycerides (TG), high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C) and HbA1C were measured. Glucose measurements [intra-assay coefficient of variants (CV) 2.1%, inter-assay CV 2.6%] were carried out using the glucose oxidase method. Cholesterol, HDL-C, LDL-C and TG were determined using direct enzymatic methods (Parsazmun, Karaj, Iran). HbA1C was estimated by high-pressure liquid chromatography (HPLC) Method. Apo (B) and Lp(a) were measured by multiple standard non-linear immunoturbidimetry with a Cobas-Mira device. All the kits used were supplied by Parsazmun Co., Karaj, Iran.

Statistical Analysis

The statistical package SPSS 16 for Windows (Chicago, IL, USA), was used for analysis. The Kolmogorov–Smirnov test was employed to test the normality of the variables in each group. Variables distributed normally are presented as means ± standard deviation of mean (SD). Variables with skewed distribution are presented as the median [interquintile range]. For comparison of serum Lp(a) level, lipid profile and other variables between patients with type 2 diabetes and controls and also between men and women within in each group, Mann–Whitney *U* test (for variables deviated from normal distribution), and student *t* tests (for normally distributed variables), were employed. Partial correlation coefficients were calculated to demonstrate the

association of serum Lp(a) and apo (B) level with other studied variables, after adjustment for age and BMI. Plasma Lp(a) levels vary over 100 fold in the population, ranging from <0.1 mg/dl to >100 mg/dl [21]. Threshold levels of serum Lp(a) for the development of atherosclerosis varies from 20 to 45 mg/dl [21]. To provide a measure of association of high Lp(a) levels and cardiovascular risk factors the patients were stratified into two groups of low Lp(a) levels (<35 mg/dl) and elevated Lp(a) levels (>35 mg/dl). Logistic regression analysis was employed to predict the odds of a patient having a serum Lp(a) level higher than 35 mg/dl in each group, after adjustment for age and BMI. General linear models were employed to study serum Lp(a) levels in premenopausal and postmenopausal state when controlling for age, duration of diabetes and BMI. Significance was set at $p < 0.05$.

Results

Demographic data of participants are shown in Table 1. The mean of age, BMI, total cholesterol, LDL-C and diastolic blood pressure was similar for patients and controls. Patients with diabetes had significantly higher serum Lp(a), apo (B), TG and HDL-C levels than the controls (Table 1). Men and women in the control group were similar in all studied variables except that the women had a higher HDL-C level. There was a significant difference between men and women with diabetes in BMI, lipid profile and diastolic blood pressure. Women with diabetes had higher serum Lp(a) levels than men with diabetes (Table 1). The distribution of serum Lp(a) levels in controls, men with diabetes, premenopausal and postmenopausal women with diabetes are illustrated in Fig. 1.

Postmenopausal women had significantly higher levels of apo (B), LDL-C, total cholesterol, and systolic blood pressure than premenopausal women, however, they did not differ significantly in serum Lp(a), FBS, TG, HDL-C, diastolic blood pressure and HbA1C levels (Table 2). Serum Lp(a) levels did not differ significantly between premenopausal and postmenopausal women with diabetes, even after adjusting for age, duration of diabetes and BMI. There were no difference sin serum Lp(a) levels before ($n = 29$) and after ($n = 36$) menopause in controls.

Partial correlation analysis demonstrated that serum Lp(a) levels had a significant correlation with FBS in men and women of control group, when controlling for age and BMI (Table 3). It did not have any significant correlation with the lipid profile, HbA1c, systolic and diastolic blood pressure in the studied groups.

The Lp(a) level was more than 35 (mg/dl) in 31% of women in the control group, 21% of men in the control

The *numbers* above the *bars* represent the percentage of participants with a high serum level of lipoprotein(a)

than 35 was 5.85 in premenopausal women with diabetes, 5.08 in postmenopausal women with diabetes, 2.41 in men with diabetes and 1.9 in women of the control group compared to men of the control group, when adjusting for age and BMI (Table 4).

Discussion

In this observational study, we present results that clearly indicate that the frequency distribution of Lp(a) levels in our studied population was highly skewed and ranged from very low toward high levels, which was more notable in patients with diabetes (Fig. 1). Patients with diabetes had higher serum Lp(a) levels than the controls. We showed that serum Lp(a) levels were higher in women with diabetes than men with diabetes. There was no gender difference in serum Lp(a) levels in the control group. Serum Lp(a) levels were higher in men with diabetes than men and women in the control group. The risk of having a serum Lp(a) levels above 35 (mg/dl) did not change according to menopausal status.

There are controversial reports on the effect of diabetes on serum Lp(a) levels. In agreement with our findings, some studies have shown increased levels of serum Lp(a) in patients with diabetes [28–30]. Koschinsky et al. [28] demonstrated higher levels of serum Lp(a) in patients with diabetes. Similarly, Labudovic et al. [29] showed increased serum Lp(a) levels in patients with diabetes which predicted the risk of atherosclerosis in these patients. Serum Lp(a) concentration also decreased by insulin treatment in non-obese patients with type 2 diabetes [30]. Some earlier case control studies found no difference in serum Lp(a) levels between patients with diabetes and controls [31–33]. Rainwater et al. [34] demonstrated lower serum Lp(a) levels in patients with type 2 diabetes. A recent meta-analysis, showed a lower serum Lp(a) level in patients with diabetes compared to controls [35]. They analyzed the results of 35 studies of which none were specifically focused on the populations with type 2 diabetes. The reference value of Lp(a) levels was determined to be 12.6 (4.9–32.1) which is in line with Lp(a) levels in our control group. They approximated that patients with diabetes have about 11% (4–17%) lower serum Lp(a) levels compared to the reference values. However, this result is not in line with most of the studies which have directly measured serum Lp(a) levels in patients with diabetes [28–30], including the present study.

Table 4 The odds ratio of having a serum lipoprotein(a) level higher than 35 (mg/dl) in different groups in comparison with normal men, after adjustment for age and BMI

	P value	Odds ratio	95% confidence interval	
			Lower	Upper
Men with diabetes	0.040	2.412	1.040	5.593
Premenopausal women with diabetes	<0.001	5.857	2.432	14.107
Postmenopausal women with diabetes	<0.001	5.085	2.103	12.293
Women in control group	<0.169	1.953	0.752	5.075

High serum Lp(a) levels are a powerful risk factor for coronary artery disease both in the general population and patients with diabetes [14, 36–39]. Since women with diabetes have a higher rate of mortality from cardiovascular disorders than men [7], it could be hypothesized that increased levels of serum Lp(a) in women with diabetes, may be one of the mechanisms for this observation. On the other hand, one could think that these results are affected by the gender effect on serum Lp(a) levels which is demonstrated by population based studies [40]. We showed that the odds ratio of having a serum Lp(a) level higher than 35 was 5.85 in premenopausal women with diabetes, 5.08 in postmenopausal women with diabetes, 2.41 in men with diabetes and 1.9 in women of the control group compared to men of the control group, when adjusting for age and BMI. Therefore, if our findings are confirmed by large longitudinal studies, serum Lp(a) levels could be considered as a powerful marker of coronary artery disease in men and especially in women with diabetes.

Previous studies have suggested that the postmenopausal state in women is associated with higher plasma LDL-C, VLDL, TG, apo (B) and lower HDL-C concentrations than premenopausal women of comparable age [41, 42]. However, we did not found any study addressing the question whether menopausal status has any effect on serum Lp(a) levels in patients with diabetes or not. In the current study, we clearly demonstrated that, irrespective of other lipid measures, serum Lp(a) levels do not differ between pre- and postmenopausal women, even after adjusting for duration of diabetes, age and BMI. This is notable because some experimental studies have shown an effective role for estrogen in lowering serum Lp(a) levels [43]. Nakagani et al. showed that ovariectomy increases serum Lp(a) levels in transgenic mice, whereas a continued replacement of 17 beta estradiol reverses the changes. They suggested that estrogen negatively regulates both plasma Lp(a) levels and Lp(a)-induced vascular remodeling [43]. In a large prospective study conducted by Shilpack et al. [44] Lp(a) was an independent risk factor for recurrent coronary heart disease in postmenopausal women and treatment with estrogen and progestin lowered its serum levels. Similar studies have also shown that estrogen therapy improves serum Lp(a) levels in the postmenopausal state [45–47]. Whether these findings are caused by the impact of diabetes or other confounding factors such as accelerated aging in premenopausal women with diabetes [48], has to be studied in the future.

In conclusion, we have shown a profound increase of serum Lp(a) levels in women with type 2 diabetes, irrespective of menopausal state. This may add to the understanding of the lipid metabolism in patients with diabetes. The limitations of the study are those inherent in a cross-sectional analysis which precludes the determination of the direction of causality. Nonetheless, this study took the advantage of a relatively large sample size and close similarity between groups in most of the affecting variables. Evaluating the association of the serum Lp(a) level with microalbuminuria in patients with diabetes may be an interesting topic for future studies.

Acknowledgment This study was not funded and was designed based on the questions we encountered during clinical practice.

Conflict of interest The authors declare they did not have any conflicts of interest.

Abstract The aim of this study was to investigate the effects of *GCKR* polymorphism on the prevalence of overweight and obesity in Chinese female subjects using a gene-wide tagging- single nucleotide polymorphism (tSNP) strategy. We conducted a genetic association study in the Taizhou Retiree Women Cohort, a sub-cohort of the Taizhou longitudinal study. We genotyped four tSNPs (rs4425043, rs780094, rs814295, and rs8179206) of the *GCKR* gene using the Taqman assay in 2,851 female subjects and investigated their associations with overweight and obesity. Odds ratios and their 95% confidence intervals (CIs) were derived from ordered logistic regression model. We observed significant association between rs4425043 and body-mass-index-defined overweight and obesity. The frequencies of A allele of the rs4425043 exhibited a significant increasing trend from normal weight (13.20%), overweight (15.08%), to obese subjects (17.10%) ($P = 0.006$). Individuals with the GA or AA genotypes showed a 31% excessive risk to develop overweight or obesity (95% CI: 1.12–1.52, $P = 0.001$). In addition, we observed significantly increased levels of fasting plasma glucose associated with variations of both rs780094 and rs814295 (5.03, 5.09, and 5.15 mmol/L for rs780094 AA, GA and GG genotypes, respectively, and 5.03, 5.11, and 5.20 mmol/L for rs814295 AA, GA and GG genotypes, respectively). In conclusion, a novel polymorphism (rs4425043) in the *GCKR* gene increases the risk of overweight and obesity in Chinese women. Previous report that other polymorphisms in the *GCKR* gene are associated with glucose levels have also been confirmed.

Introduction

Overweight and obesity are important modifiable risk factors for cardiovascular disease and associated conditions, including type 2 diabetes, hypertension, hypercholesterolemia, coronary heart disease, and stroke [1]. Excessive body weight is also associated with an increased risk for other health consequences, such as osteoarthritis, gall bladder disease, and some cancers [2, 3]. In Europe, the prevalence of obesity in women varies from 6.2 to 36.5% [4]. In recent decades, with the rapid economical growth in China, the prevalence of overweight and obesity has been increasing [2, 5]. In 2006, the prevalence of obesity was 7.2%, representing a 3.6-fold increase from 1996 [6].

Obesity demarcates an imbalance between energy intake and energy expenditure, and excess energy has been stored in fat cells that enlarge and increase in number resulting in elevated secretion of free fatty acids and numerous peptides [7]. Glucokinase (GCK) is a key regulatory enzyme in the pancreatic-cells, and it plays a crucial role in determining the threshold for glucose-stimulated insulin secretion [8]. GCK activity, at least in the liver, is closely regulated by the glucokinase regulatory protein (GCKR) [9]. The *GCKR* gene is localized on chromosome 2p23.2–3 [10], a genomic region previously linked to metabolic traits like fat mass and circulating lipid concentrations [11]. Animal studies indicated that *GCKR*-knockout mice show a parallel loss of GCK protein levels and activity in the liver, leading to altered glucose metabolism and impaired glycemic control [12].

Recently, a single nucleotide polymorphism (SNP) rs780094 in the *GCKR* gene was found to be associated with metabolic phenotypes in Caucasians or Japanese [13–18]. To appraise systematically the effect of *GCKR* genetic variation on these phenotypes, we conducted a genetic association study using a gene-wide tagging-SNP (tSNP) strategy. This method might save cost since only a small proportion of tSNPs of the studied gene give sufficient information to capture most of the haplotype structures in the high linkage disequilibrium (LD) regions [19].

Subjects and Methods

Study Subjects

The Taizhou longitudinal study (TZL), which was initiated in July 2007, was an open-ended prospective study with very broad research aims. The design and baseline characteristics of the study have been described previously [20]. The Taizhou Retiree Women Cohort is a sub-cohort of the TZL. This sub-cohort includes women who were born between 1944 and 1958 (aged 50–64 years). After baseline survey, 7,786 retired women without a history of cancer, stroke, and myocardial infarction were recruited for long-term followed up includes Taizhou is a prefecture of Jiangsu province in China. From the perspective of population size and economic development, Taizhou is a mid-sized city in China. The women in Taizhou retire at least 5 years earlier in age than men. Like women living in other mid-sized cities of China, the retired women in Taizhou are subject to much lower stress in life than their male counterparts. The Taizhou Retiree Women Cohort survey aims to investigate the relationship between the women's lifestyle and the incidence of metabolic and cardiovascular diseases.

A random sample of 2,851 women from the above-mentioned Taizhou Retiree Women Cohort was drawn for this genetic association study. Subjects who reported a history of autoimmune diseases, tuberculosis, and abnormal thyroid function, were excluded from this study since these conditions may affect the level of metabolic phenotypes. The study was approved by the Human Ethics Committee of Fudan University. Written informed consent was obtained from all participants.

Protocol and Measurements

All participants had a face-to-face interview and a physical examination. Body weight and height were measured to calculate the BMI (the ratio of weight in kg to the square of height in m). The waist circumference (WC) was measured midway between the caudal point of the costal arch as palpated laterally and the iliac crest. A blood specimen was drawn after overnight fasting and subjected to centrifugation within 3 h and analyzed within 8 h for measuring triglycerides (TG) and fasting plasma glucose (FPG). The normal weight group, overweight group, obesity group were defined as 18.5 up to 23.9, from 24 to 27.9, and greater than 28 kg/m^2, respectively, according to the Chinese criteria [21]. Hypertriglyceridemia was defined as TG $\geq$ 1.7 mmol/l. Type 2 diabetes mellitus was defined as FPG $\geq$ 7.0 mmol/l.

Selection of tSNPs

Haplotype-tagging SNPs of the *GCKR* gene were selected using the Chinese Han sample in Beijing, China, available from the International HapMap databank (public data release 21 a/phase II, Jan. 2007; http://www.hapmap.org/cgi-perl/gbrowse/hapmap_B35/). To identify common haplotype tSNPs, eligible SNPs were entered into the tagger program that has been implemented in Haploview version 3.32 [22]. We defined the common variants as those with a heterozygosity of >5% and set a threshold of

0.8 for the LD analysis r^2. In total, four tSNPs (rs4425043, rs780094, rs814295, rs8179206) in the *GCKR* gene capturing 13 genotyped alleles were selected.

Genotyping

Blood samples were collected in EDTA-containing receptacles and genomic DNA was extracted using a standard method. Genotyping of the selected tSNPs was conducted using the Taqman assay (Applied Biosystems, Foster City). Sample DNA (10 ng) were amplified by PCR following the recommendations of the manufacturer. Fluorescence was detected using an ABI 7900HT and the alleles were scored using sequence detection software (Applied Biosystems, Foster City, CA, USA). Allele-specific probes used in the TaqMan assay were designed for each of the polymorphic sites. The genotyping success rates for *GCKR* rs4425043, rs780094, rs814295, rs8179206 were 97.9, 99.7, 99.2 and 98.1%, respectively. Sequencing was implemented to test the validity of genotyping.

Statistical Analysis

The deviation from the Hardy–Weinberg expectation for the variants was tested by a Chi-square statistic. Differences of mean BMI, WC, FPG, TG across genotype groups were tested using an ANOVA method. Allelic and genotypic frequencies were compared among the normal weight, overweight, and obesity groups using the Chi-square test or Fisher's exact test. The odds ratios (ORs) and the corresponding confidence intervals (95% CIs) were estimated by ordered logistic regression models under the dominant genetic model assumption, to test the association between SNPs and BMI-defined overweight/obesity where appropriate due to the low frequency of a minor allele. The three categories of dependent variable were treated as ordered values (normal weight as 0, overweight as 1, and obesity as 2), and probabilities modeled were cumulated over the lower ordered values. A score test was used for testing the proportional odds assumption. For haplotype construction, the genotype data were used to estimate inter-marker linkage disequilibrium by measuring pairwise D' and r^2 and by defining LD blocks. Haplotype inferring and haplotype association testing were conducted using the Haploview software [22]. All analyses were performed using SAS statistical software (release 8.2, SAS Institute Inc, Cary, NC, USA).

Results

The clinical and metabolic characteristics of the studied subjects by BMI categories are summarized in Table 1. Compared with normal weight subjects, the overweight and obesity subjects had significantly higher WC, FPG, and TG. Genotypes at all loci were consistent with Hardy–Weinberg expectation. Allelic and genotypic frequencies of the four tSNPs for the overweight, obesity and normal weight subjects are shown in Table 2. The allelic and genotypic frequencies at rs780094, rs814295 and rs8179206 did not differ significantly among overweight, obesity, normal weight subjects. However, the rs4425043 was significantly associated with body mass indices (BMI) defined as overweight/obese. The frequency of the A allele of the rs4425043 increased from normal weight subjects (13.20%), overweight (15.08%) subjects, to obese subjects (17.10%). Individuals with the GA or AA genotypes had a 31% excessive risk (95% CI: 1.12–1.52, $P = 0.001$) of developing overweight or obesity (normal weight subjects as controls) or developing obesity (subjects of normal weight or overweight as controls) in a dominant model of A allele. The significance remained after adjusting for age, or further adjusting for FPG, and TG (Table 3).

We further explored whether the tSNPs affect the level of metabolic phenotypes in the subjects who had a BMI less than 28 kg/m^2. We further excluded those subjects whose TG $\geq$ 1.7 mmol/l and/or FPG $\geq$ 7.0 mmol/l. As shown in Table 4, rs780094 and rs814295 variations were significantly associated with increased FPG levels ($P = 0.034$ and $P = 0.002$, respectively). The level of

LD analysis of rs4425043, rs780094, rs814295, rs8179206 revealed that the SNP rs780094 was in moderate LD with rs814295 which were about 2 kb apart ($D' = 0.97$, $r^2 = 0.51$). Haplotype analysis of rs780094 and rs814295 did not find major haplotypes conferring the risk of overweight/obesity (data not shown).

Discussion

In this study, we explored the relationship between four tSNPs in the *GCKR* gene and the risk of overweight/obesity defined by BMI in the Taizhou Retiree Women Cohort. We observed a dose–response effect of A allele in rs4425043 conferring an increased risk for overweight or obesity. To the best of our knowledge, this is the first study to correlate *GCKR*-rs4425043 with the risk of overweight and obesity in Chinese females.

GCKR, including 19 coding exons, spans 26.8 kb on chromosome 2. SNP rs4425043 is located at the 16th intron of the *GCKR* gene. The functional significance of rs4425043 is still unknown. As can be calculated from the data of Han Chinese (CHB) in the International Hapmap database, rs4425043 tags five SNPs located in a region from the 5th to the 11th intron. This positive SNP is likely a genetic marker which is in LD with a casual variant located within this region. It is noteworthy that we did not find significant association of this polymorphism with BMI levels in the non-obese female subjects. Different modifying effects of this polymorphism on the pathological status of obesity and physiologic level of BMI may be the explanation. Since only 1,356 non-obesity subjects were included in the association analysis for quantitative traits, false-negative association of rs4425043 with BMI levels may also be an alternative explanation due to insufficient statistical power.

Recently, two important SNPs in the *GCKR* gene were reported to be associated with specific metabolic phenotypes. SNP rs780094, located at intron 16 of the *GCKR* gene, is in strong LD with a non-synonymous SNP rs1260326 (P446L) located at exon 15 [13]. In two genome

wide association studies, the A allele of rs780094 was found in association with decreased concentration of plasma glucose and increased TG in Caucasians [14, 15]. Later, the A allele of rs780094 was found to be linked to decreased risk of type 2 diabetes in Japanese [16]. In 12 independent cohorts comprising 45,000 individuals of Caucasians, Asians, and African Americans, SNP rs780094 was found to be associated with decreased concentration of plasma glucose but increased TG level [17]. Sparsø et al. observed that the A allele of rs780094 polymorphism is associated with elevated fasting serum triacylglycerol, reduced fasting and OGTT-related insulinemia, and a reduced risk of type 2 diabetes. More recently Qi et al. [23] observed that the A allele of rs780094 is associated with a reduced risk of diabetes, and a decreased risk of BMI related obesity in Chinese subjects. Further, it was also associated with increased TG levels and decreased BMI and WC in this study [23]. A potential explanation of the different effects on glucose and TG observed in these studies is the opposite and overriding effects of increased glucose utilization and glycolytic flux on liver glucose and lipid metabolism [17]. Similar to these studies, we observed that the A allele of rs780094 decreased the level of plasma glucose (FPG was 5.15, 5.09, and, 5.03 for GG, GA, and AA, respectively). However, we did not observe that the rs780094-A allele increases the level of TG, as the aforementioned studies did [19–23]. We also did not observe that the rs780094-A allele increases the BMI and WC, as Qi et al. observed [23]. Genetic and phenotypic heterogeneity of these traits may be a reason for the lack of significant associations in our study. The lack of statistical power due to insufficient sample size, differences in gender (our sample comprised only women) and age (the ages of our sample ranged from 50 to 64 years) from other studies may also be other possible reasons.

In this study, we observed another SNP, rs814295, to be associated with the FPG level (FPG was 5.03, 5.11, and, 5.20 for AA, GA, and GG of rs814295, respectively). This SNP is located at the 17th intron of the *GCKR* gene and is in moderate LD with rs780094 ($r^2 = 0.50$), which is located at intron16. We could not exclude the possibility that the glucose decreasing effect of both the A allele of rs814295 and the A allele of rs780094 results from the effect of rs1260326 (P446L), which is in strong LD with rs814295. However, since there were only 69 diabetes subjects in the study, we did not have the statistical power to explore the effect of rs780094 and rs81429 on the prevalence of diabetes. Fortunately, Taizhou Retiree Women Cohort is an ongoing prospective study of old women which will be used to validate the genotype–phenotype association discovered in the baseline cross-sectional studies. The present study had other

limitations. For example, we did not consider the effects of dietary intake or physical activity on the studied metabolic phenotypes since we did not include measurement of these factors in this Retiree Women Subcohort. Fortunately, we did include these exposures in the community based sub-cohort of TZL, which can be analyzed in future studies.

In summary, we have reported a novel polymorphism (rs4425043) in the *GCKR* gene linked to the risk of overweight or obesity in Chinese women. We also confirmed the previous finding that polymorphisms in the *GCKR* gene are associated with the glucose level in a Chinese women cohort. Since our cross-sectional case–control design was based only on a baseline stage of an ongoing prospective study, our exploratory results need to be validated in future prospective studies.

Acknowledgments This study is supported by grant from the National Science Fund (30973595, 81072358), a grant from Independent Innovation Foundation of Shandong University, IIFSDU. We also thank the members of the survey teams and the participants for their contribution to this study.

Dietary Cocoa Butter or Refined Olive Oil Does Not Alter Postprandial hsCRP and IL-6 Concentrations in Healthy Women

Tine Tholstrup · Kim-Tiu Teng · Marianne Raff

Received: 25 August 2010 / Accepted: 27 December 2010 / Published online: 2 February 2011

Abstract Contrary to other long chain saturated fatty acids (SFA), fats high in stearic acid do not raise plasma cholesterol concentrations, however, a slight elevation in inflammatory markers, plasma fibrinogen and interleukin-6 (IL-6), has been observed in the fasting state. The effect of stearic acid on inflammation in the postprandial state has not yet been reported. We conducted a single blind cross-over, randomized, postprandial study to compare the effects of a fat load of cocoa butter high in stearic acid and olive oil in ten healthy women. The test meals contained 1 g of fat per kg body weight (mean 62 g). Blood samples were collected at 0 (fasting), 4 and 6 h. Both diets resulted in a significant increase in serum triacylglycerol (TAG) concentration over time ($P = 0.003$) and a decrease in serum IL-6 concentration after 4 h followed by an increase to post absorptive values after 6 h ($P < 0.001$); whereas serum high sensitivity C-reactive protein (hsCRP) concentration was not affected. There was no difference between diets in effects on serum TAG, hsCRP and IL-6 concentrations and no association between postprandial lipemia and inflammatory markers. High intake of dietary fats increase postprandial serum TAG, however, may not affect inflammatory markers postprandially. Thus, fat rich in stearic acid does not seem to increase postprandial inflammation.

Keywords Postprandial lipemia · C-reactive protein · Interleukin-6 · Stearic acid · Triacylglycerol

Abbreviations

hsCRP	High-sensitivity C-reactive protein
IL-6	Interleukin-6
OL	Olive oil
CB	Cocoa butter
%E	Percentage of energy
TAG	Triacylglycerol
TNF-α	Tumor necrosis factor-α
SFA	Saturated fatty acids
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
BMI	Body mass index
CAM	Cellular adhesion molecules

Introduction

It is recognized that fats high in stearic acid are considered more beneficial than other long chain saturated fatty acids (SFA), as they do not raise plasma cholesterol concentration [1–3]. In addition, earlier studies from our group and others demonstrated that stearic acid given as a synthetic, interesterified fat resulted in a lower postprandial lipemia and factor VII coagulant activity than test fats high in unsaturated fatty acids [4, 5]. However, stearic acid may lead to a slight but consistent increase in fasting plasma fibrinogen, a marker of inflammation [6, 7]. A single study demonstrated a slight increasing effect of stearic acid compared to carbohydrate on fibrinogen, as well [8]. The main regulator of hepatic synthesis of acute phase reactants

such as C-reactive protein (CRP) is associated with future cardiovascular disease in apparently healthy individuals [9–12]. In the postprandial state, as well as in the fasting state, inflammatory events may increase atherogenesis. It was reported that an increase in plasma IL-6 was observed in response to postprandial lipemia in humans, however, no changes could be detected in plasma cell adhesion molecules (CAM) concentrations after a high fat meal [13].

Specific dietary fats may influence the expression of inflammatory markers in postprandial state differently. Results from a study investigating influence of postprandial TAG-rich lipoprotein on lipid mediated gene expression demonstrated that intake of butter compared to refined olive oil increased postprandial mRNA expression of tumor necrosis factor-α (TNF-α) in smooth muscle cell of the human coronary artery [14]. This is in agreement with a decrease in postprandial IL-6 and TNF-α concentrations in mononuclear cells after consuming olive oil and walnut meals compared to butter meal [15]. A recent study in healthy men, however, concluded that acute changes in the dietary content of saturated and unsaturated fatty acids had no adverse effect on postprandial circulation of the adipose-related factors such as adiponectin, IL-6, TNF-α, or hsCRP [16], although a transient increase in IL-6 after 6 h was observed after both type of fats.

The detrimental effects of hydrogenated fats to health have been confirmed by extensive epidemiological and clinical studies. The mandatory '*trans* fatty acids' labelling on packaged food products effective on 2006 has driven the food manufacturers to look for alternatives for hydrogenated vegetable oils. Hence, fats high in stearic acid may be used as a suitable replacement for hydrogenated vegetable oils with similar functionality by proving its health effects. To the best of our knowledge, no study has been conducted to examine the effect of a high stearic acid fat, cocoa butter (CB) as SFA source compared to olive oil (OL) on serum hsCRP and IL-6. Thus, we performed a pilot study to investigate the postprandial effect of olive oil and cocoa butter on serum TAG, hsCRP and IL-6 in healthy women.

Materials and Methods

Study Design

We conducted a randomized, crossover, postprandial study with refined OL and CB. The study participants ($n = 10$) were given two test meals separated by a minimum of 3 days. After an overnight fast, participants reported to the study center at 8:00 a.m. A venous blood sample was taken and the participants consumed test meals within 15 min. Blood samples were drawn at 4 and 6 h after the meal had begun. The participants were instructed to maintain same level of physical activity throughout the study period. They were allowed to consume water ad libitum. The Scientific Ethics Committee of the City of Copenhagen and Frederiksberg Municipality approved the research protocol (protocol no. HB-2008-056 additional protocol). All participants gave informed consent before the study was commenced.

Subjects

We recruited ten female participants from Department of Human Nutrition, Faculty of Life Sciences, University of Copenhagen, Denmark by advertisement. The participants were apparently healthy as indicated by interview, non-smoking, not taking medication and without history of cardiovascular diseases. Baseline characteristics of study participants are presented in Table 1. The study participants were advised to consume low fat diet and refrained from alcohol intake the day proceeding the study day. All participants recorded their food intake the evening before blood samples were drawn. To ensure the participants consume the same meals for dinner the evening before each intervention day, they were instructed to record all foods eaten for dinner the night before the first test meal, and to eat the same the evening before the second meal.

Test Diet

The test meals contained 1 g of fat per kg body weight (mean 62 g). The study participants consumed a high fat meal which consisted of OL or CB with the following %E: fat 76, carbohydrate 21 and protein 3, respectively. The nutrient composition of both test meals is shown in Table 2. OL consisted mainly of oleic acid (73.3% wt), whereas both oleic acid (34.1% wt) and stearic acid (34.7% wt) were the major fatty acids composition in CB. The high-fat meals were prepared using instant mashed potatoes (Coop Danmark, Hadsten, Denmark). Each test

C18:3	0.5	0.1

OL olive oil, *CB* cocoa butter, *SFA* saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids

meal consisted of 1 g test fat and 1 g mashed potato powder per kg body weight of the participant and was mixed with 3 ml of boiling water per g of mashed potato powder. The average energy intake per test meal was 2.6 MJ with 76% E fat. For OL refined olive oil was provided by Karlshamns BV, Zaandijk, The Netherlands whereas for CB cacao butter was provided by Urtekram A/S International, Mariager, Denmark.

Blood Collection

We collected venous fasting blood into plain tubes in the morning at 8:00 a.m. and after 4 and 6 h after the test meal. The tubes were clotted for 30 min and centrifuged at 2,200×*g* for 15 min at 4 °C. Aliquots of serum were harvested and stored at −80 °C until analyses.

TAG, hsCRP

Serum TAG was analyzed using enzymatic procedure (ABX Pentra Triglycerides CP kit) on an ABX Pentra autoanalyzer, Horiba Group, France. We measured serum hsCRP concentrations according to the procedure of a high sensitivity latex-enhanced immunoturbidimetric assay (ABX Pentra CRP CP kit) using ABX Pentra autoanalyzer, Horiba Group, France. The intra assay CV for TAG was 3.1% ($n = 6$) and 5.0% ($n = 6$) for hsCRP.

IL-6

We measured IL-6 using an enzyme-linked immunosorbent assay (ELISA) kit (Quantikine HS6000, R&D System Europe). All samples were assayed in duplicate within a plate. A standard procedure of ELISA was performed according to manufacturers' instruction. Intra assay value was 5.3% ($n = 31$).

Statistics

Outcome variables were analyzed using mixed model ANCOVA and baseline values were used as covariates. Variables were set as fixed effect and participant ID was random effect. Data was log-transformed to obtain variance homogeneity. Descriptive data of baseline characteristics of study participants are presented as means ± SD (range), and other data are presented as mean ± SEM. All analyses were conducted using SAS 9.0, SAS Institute, Cary, NC, USA. Age, BMI and the order in which the participants received the test meals were tested for influence on the results, and were found to have no influence. hsCRP measurements from one participant after one test meal (cocoa butter) were excluded from the analyses due to increased hsCRP values which reflected a cold; this exclusion did not influence the results. Two values from one test meal (cocoa butter, 4 and 6 h) were not detectable. In regard to IL-6 data were log-transformed to obtain variance homogeneity. One observation was excluded from the analysis (6 h, olive oil) to obtain variance homogeneity; this exclusion did not change the results.

Results

No drop-out or non-compliance was reported. There was a significant increase in plasma TAG over time for both test meals ($P = 0.003$), but there was no difference in response between the two test meals ($P = 0.41$) (Fig. 1a). There was no significant difference between the effects of the two test meals ($P = 0.53$) on the postprandial hsCRP response (Fig. 1b). A significant difference in plasma IL-6 was found over time after both meals ($P < 0.001$), but there was no difference between the two test meals ($P = 0.19$) for IL-6 (Fig. 1c). Likewise, it was necessary to exclude one very high observation from the analysis (OL, 6 h) to obtain variance homogeneity. This did not change the overall results.

Discussion

Although the fatty meals induced a considerable increase in postprandial lipemia the pro-inflammatory marker hsCRP was not activated after either of the two test fats in our study. This agrees with findings by others, a single study with a mixture of SFA, MUFA and PUFA [17], with the effects in healthy participants in trials including fat loads either low or high in SFA [16, 18], together with a study

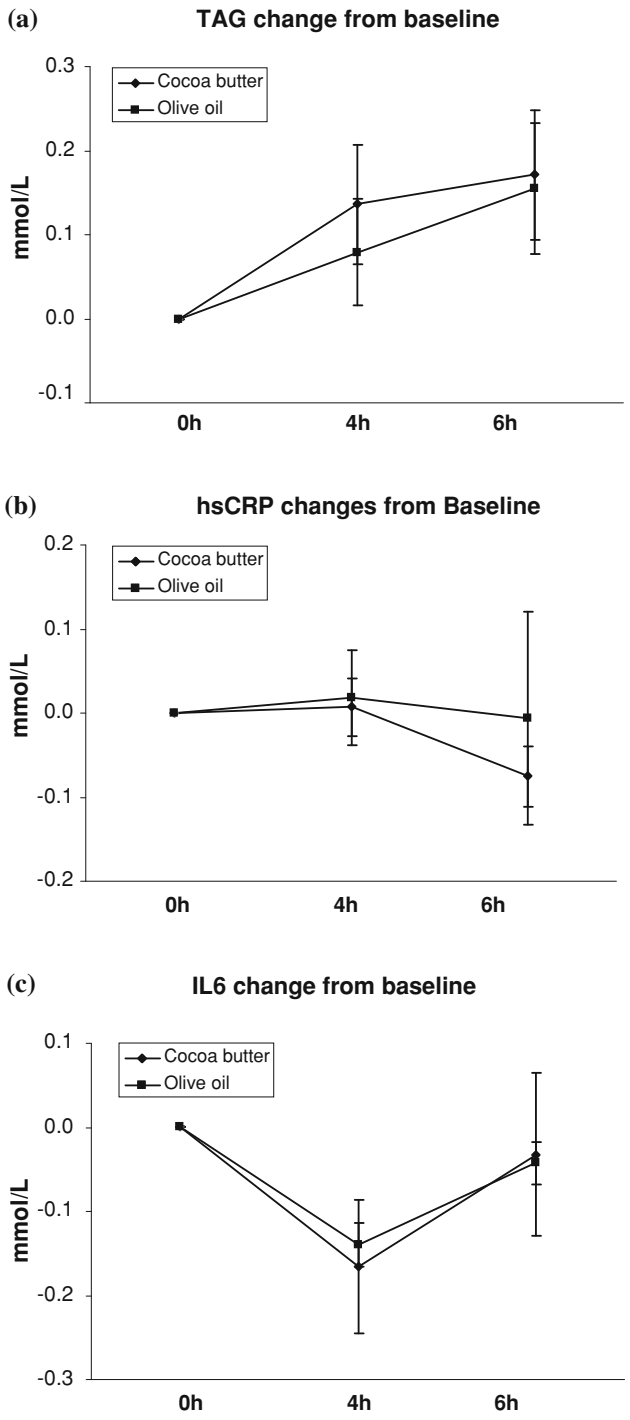

Fig. 1 Mean change of serum. **a** TAG, **b** hsCRP and **c** IL-6 from baseline ± SEM. Baseline values were included as covariates. **a** There was no difference in the effect of the test meals (Mixed model ANCOVA), but a significant increase was found over time for both test meals ($P = 0.003$), but there were difference between the two test meals ($P = 0.41$). **b** There were no significant difference between the effect of the two test meals ($P = 0.53$) on the postprandial hsCRP response. **c** A significant difference was found over time for both test meals ($P < 0.001$), but there were no difference between the two test meals ($P = 0.19$)

including participants with the metabolic syndrome in which ratio n-6/n-9 was modified [19]. Taken together results from these studies indicate that high fat meals irrespective of fatty acid composition do not increase postprandial hsCRP values.

With regard to IL-6 we observed a transient decrease after 4 h followed by an increase to postabsorptive values. The response pattern with a lack of increase in IL-6 over the day in our study is not in agreement with observations from other studies on fat load, which reported a postprandial increase in IL-6 in healthy individuals [13, 16, 18, 20–22]. It is noteworthy that also intake of carbohydrate was shown to increase IL-6 [21] and specifically potatoes raised IL-6 more compared to all bran meal [20]. In addition, there were no differences in the rate at which IL-6 concentrations increased after fatty meals compared with water [19]. Haack et al. [23] reported that diurnal variations of IL-6 levels may be confounded by blood drawing procedures. It is unknown why the postprandial response in IL-6 differed between our study and studies by others. We speculate, if the postprandial increase in IL-6 reported in more studies is due to diurnal variation, and that oleic acid (and stearic acid), the two dominating fatty acids of the test fats in our study, may have had a more neutral or even an attenuating role in regard to plasma IL-6. The cocoa butter meal contained 26.4% E as stearic acid, but also 20% E palmitic acid and 26% E oleic acid (Table 1). Since cocoa butter contains as much oleic acid as stearic acid, there is no objective reason to suppose that stearic acid in the cocoa butter meal could play the same neutral or attenuating role as that of oleic acid in the olive oil meal. Accordingly, it may be supposed that oleic acid at 26% E in the cocoa butter meal (only twice less compared to the olive oil meal) was sufficient by itself to prevent postprandial increases of inflammation markers. The two meals essentially differed by their ratio of total SFA to MUFA. A rationale for this idea is finding from in vitro studies. Thus, contrary to results from human intervention studies a different gene expression in pro-inflammatory markers after consumption of different dietary fat types was reported. Butter compared to olive oil and walnut increased postprandial mRNA expression of TNF-α and IL-6, in human coronary artery cells [15]. Another study reported an increased expression of inflammatory genes, TNF-α after butter compared to olive oil and vegetable/fish oil [14]. A recent in vitro study demonstrated that presence of as little as 1/10 ratio of oleic acid to that of stearic acid attenuates stearic acid-included pro-inflammatory responses in endothelial cells by reducing cellular stearic acid incorporation and NF-κB activation [24]. It is therefore, possible that a lack of differences between cocoa butter and refined olive oil on serum TG, IL-6 and hsCRP is mainly due to attenuation of stearic

acid-induced responses by the presence of substantial amounts of oleic acid in the cocoa butter. However, there is no previous evidence suggests that fatty acid quality affects postprandial IL-6 response or other inflammatory markers in human studies. In addition, although dietary fatty acid composition may regulate gene regulation to some extend, observed differences from in vitro studies may not be applicable to the in vivo situation.

We hypothesized that there would be an association between the postprandial lipemia and inflammatory markers, as suggested by others [21], however, we were not able to confirm this relation. This lack of association agrees with the results in healthy individuals [13], which did not demonstrate significant correlations between postprandial plasma TAG and IL-6, and CAMs. Based on our results and the results by others who included inflammatory markers as CAMs and TNF-α, we suggest that postprandial increase in plasma TAG may not be the only player during postprandial activation. Interestingly, the increased inflammatory activity reported induced by high fat meals was partly inhibited by antioxidant vitamins in one study [21], which may be due to some involvement of oxidative mechanism. Although there may be some affiliation the role of increased postprandial lipemia on pro-inflammatory activation is at the present not fully elucidated and lipemia may not be the main player in regard to inflammatory markers as agreed by others [16, 19].Taken together there are rather few studies on acute effect of dietary fatty acid composition on pro-inflammatory markers in humans, and although available data suggest that there may be some activation of fat load, this is not always the case. Moreover, this activation is not demonstrated to be dependent on fat quality in humans. More human intervention studies are needed to clarify a possible relation.

Conclusion

In our study, fat loads with cocoa butter high in stearic acid did not increase hsCRP and IL-6, both markers of inflammation compared to olive oil postprandially. There was no difference in postprandial response in plasma TAG and inflammatory markers after intake of cocoa butter and olive oil. In addition, we were not able to confirm any association between postprandial lipemia and markers of inflammation in healthy women. Overall, the study is an explorative pilot study which may inspire others to perform a larger study within this important research field. A larger sample size study may be warranted to observe a significant change in postprandial lipemia

Received: 23 July 2010 / Accepted: 14 November 2010 / Published online: 1 February 2011

Abstract Macrophages in arterial walls accumulate lipids leading to the development of atherosclerotic plaques. However, mechanisms underlying macrophage lipid accumulation and foam cell formation are often studied without accounting for risk factors such as dyslipidemia. We investigated the effect of varying concentrations of triglyceride (TG) within physiological range on macrophage fatty acid (FA) accumulation and expression of cholesterol efflux proteins. Human monocytes were cultured in media supplemented with 10% sera containing low (0.7 mmol/L) to high (1.4 mmol/L) TG. The resulting macrophages were harvested after 10 days for analysis of FA content and composition and expression of genes involved in lipid metabolism. Exposure to higher TG and lower HDL concentrations in media increased macrophage lipid content. Macrophages exposed to higher TG had increased total FA content compared with controls (876 μg/mg protein vs. 652 μg/mg protein) and greater proportions of C16:0, C18:1 and C18:2. Macrophage expression of both ABCA1 and ABCG1 cholesterol efflux proteins were reduced when higher TG concentrations were present in the media. Expression of scavenger receptor CD36, involved in lipoprotein uptake, was also downregulated in macrophages exposed to higher TG. Culturing macrophages in conditions of higher versus lower TG influenced macrophage FA content and composition, and levels of regulatory proteins. Replicating in vitro levels of dyslipidemia encountered in vivo may provide an informative model for investigation of atherogenesis.

Keywords Dyslipidemia · Triglyceride · Macrophage · Fatty acids · Unsaturated fatty acids · Atherogenesis

Abbreviations

ABCA1	ATP-binding cassette transporter A1
ABCG1	ATP-binding cassette transporter G1
CD36	Cluster of differentiation 36
CLRP	Chylomicron remnant-like particles
CVD	Cardiovascular disease
FA	Fatty acid
FFP	Fresh frozen plasma
HDL	High density lipoprotein
hMDM	Human monocyte-derived macrophage
LDL	Low density lipoprotein
LPL	Lipoprotein lipase
LXR	Liver X receptor
PPARγ	Peroxisome proliferator-activated receptor gamma
SCD	Stearoyl-CoA desaturase
SR-A	Scavenger receptor A
TG	Triglyceride
VLDL	Very low density lipoprotein

Introduction

Atherosclerosis is the pathology underlying cardiovascular disease (CVD) and accounts for up to 50% of deaths in those with CVD [1]. A central step in atherogenesis occurs when monocytes adhere to endothelium and transmigrate into the subendothelial space where they differentiate into macrophages and express scavenger receptors CD36 and scavenger receptor-A (SR-A). These scavenger receptors take up lipids in the form of modified low-density lipoprotein (LDL) [2] and also regulate the uptake of free fatty acids (FA) [3]. Macrophage lipoprotein uptake is balanced by cholesterol efflux regulated by members of the ATP-binding cassette transporter family A1 and G1 (ABCA1 and ABCG1) [4]. Progression of foam cell formation to fatty streak and atherosclerotic plaque development reflects the cumulative effects of cholesterol and fatty acid accumulation from very low density lipoprotein (VLDL) and LDL uptake, balanced against anti-atherogenic cholesterol efflux into the reverse cholesterol pathway via apolipoprotein A-1 (apoA-1) and high-density lipoprotein (HDL) [4]. Hyperlipidemia especially hypercholesterolemia coupled with low HDL is a major risk factor for CVD [5]. Accumulating evidence suggests that elevated triglyceride (TG) levels are an independent risk factor for CVD [6]. However, the mechanisms by which hypertriglyceridemia increases development or progression of atherosclerosis are not fully understood.

Monocytic cell lines such as THP-1 and U937 which are differentiated into macrophages by the addition of phorbol 12-myristate 13-acetate provide a model of foam cell formation and lipid metabolism. However, they are not necessarily representative of the processes occurring in vivo [7, 8]. Human-derived macrophages (hMDMs) are more representative models, however, they tend to be cultured under generic conditions or with supplementation of modified LDL to supraphysiological levels to create a model of the diseased/pathological state [9, 10]. Data are lacking to demonstrate the effects of variation in lipid concentrations particularly TGs within the physiological range on mechanisms of macrophage lipid accumulation. To better understand how hypertriglyceridemia occurring might modulate macrophage lipid accumulation, we examined hMDMs grown in an environment which reflected varying degrees of hypertriglyceridemia encountered in vivo. We sought to test the hypothesis that subtle changes in TG levels would increase macrophage lipid accumulation altering FA content and composition and regulating proteins involved in both lipid uptake and cholesterol efflux.

Materials and Methods

Reagents

Chemicals and reagents used are listed below with the supplier. All solvents were high performance liquid chromatography grade (Mallinckrodt). Enhanced chemiluminescence (ECL) reagent; Full range Rainbow Molecular Weight Marker (GE healthcare, formerly Amersham Biosciences). RPMI 1640; L-glutamine; penicillin/streptomycin; phosphate buffered saline (PBS) (Invitrogen). Heptadecanoic acid and Nile red (SIGMA). Peroxisome proliferator-activated receptor γ (PPARγ) rabbit polyclonal antibody; SR-A; stearoyl-CoA desaturase (SCD) and beta-actin (goat polyclonal antibodies); RIPA lysis buffer (Santa Cruz). ABCA1; ABCG1; and CD36 (rabbit polyclonal antibody) (Novus Biologicals). Bio-Rad Protein Assay; bisacrylamide 30%; bovine serum albumin (BSA) (Bio-Rad). Aprotinin; Phenylmethylsulfonyl fluoride; FastStart SYBR Green Master mix (Roche Diagnostic). Glutaraldehyde; and analytical- or HPLC-grade solvents (Merck, formally BDH). TRIsure (Bioline).

Cell Culture and Serum Preparation

Human-derived macrophages were grown at 37 °C in a 5% CO_2 atmosphere. hMDMs were prepared from white buffy coat concentrates from healthy donors as described [11]. Briefly buffy coats obtained from the Australian Red Cross Blood Service (ARCBS) were diluted with PBS, layered over Ficoll-Paque and centrifuged for 30 min at 1,000×g at room temperature. The white blood cell layer was collected, pelleted at 700×g for 10 min at 4 °C, washed and re-suspended in RPMI media to allow purification of monocytes by adhesion. Monocytes at a concentration of 1.5×10^6 cells/mL were cultured in RPMI-1640 medium containing 10% (v/v) heat-inactivated whole human serum from healthy volunteers for 2 days. The cells were washed and incubated for a further 8 days in RPMI 1640 containing 10% (v/v) heat-inactivated pooled serum supplemented with penicillin/streptomycin 100 U/100 μg/mL and L-glutamine (2 mM) with replacement of media every 3 days. For experiments, serum was prepared using heat-inactivated pooled fresh frozen plasma (FFP) which was stood for 30 min and centrifuged at 16,000×g for 10 min before collection of the serum supernatant. The sera were pooled into four groups (A, B, C and D) according to varying TG, HDL and total cholesterol concentrations (Table 1). FFP was kindly provided by Transfusion Medicine, Fremantle Hospital. The protocol was approved by the South Metropolitan Area Health Service Human Research Ethics Committee.

Table 1 Biochemical analysis of pooled-sera with varying TG, HDL and cholesterol concentrations, termed A, B, C and D

	A	B	C	D
Triglyceride (mmol/L)	0.75	0.85	1.05	1.4
Cholesterol (mmol/L)	4.8	4.3	3.35	3.15
HDL (mmol/L)	1.2	0.9	1.15	0.8
LDL (mmol/L)	3.26	3.02	1.72	1.71

Monocytes were differentiated into macrophages in culture media containing 10% normal human sera for 2 days followed by culturing in media containing 10% sera of either A, B, C and D for a further 8 days. Pooled-sera A represented a control lipid profile, B, C and D represented profiles with higher TG and lower HDL levels

Nile Red Staining and Visualization of Lipids

Nile red stains neutral lipids such as TG and cholesterol esters and can be visualized with fluorescence microscopy. After 8 days incubation in experimental media, hMDMs were washed with PBS. Glutaraldehyde (1.5%) was added to each well and left to incubate at 4 °C for 5 min to fix cells. The wells were washed several times with PBS before Nile red in PBS (100 ng/mL) was added to each well and left to incubate at room temperature for 5 min. The cells were washed with PBS before visualization under fluorescence microscopy at yellow gold fluorescence (excitation 450–500 nm, emission >528 nm).

Fatty Acid Extraction and Gas Chromatography

On day 10 of culture, total FA content and FA composition for both media and hMDMs were extracted and measured by gas chromatography (GC) as previously described [11]. Samples were analyzed in a gas chromatograph (Hewlett Packard 5890) using a 25 cm BPX70 capillary column (SGE Scientific) of 0.35 mm internal diameter. The FA quantified were C16:0, C18:0, C18:1, C18:2 and C20:4. As SCD converts stearic acid (C18:0) to oleic acid (C18:1), the ratio of C18:1 to C18:0, known as the desaturation index, was calculated as an indicator of macrophage SCD activity where an increased ratio would indicate increased activity [12].

Biochemical Analysis

Fasting glucose, serum total cholesterol (TC), HDL-cholesterol and TGs were measured using the Cobas Integra 800 analyser (Roche Diagnostics, Australia) following assay methodologies previously described [11]. LDL-cholesterol levels were calculated using the formula LDL = TC – HDL − (TG/2.22) [13].

Macrophage RNA Extraction

Total RNA was isolated on day 10 of culture using TRIsure reagent, according to the manufacture's instructions. RNA samples were treated with DNase I (DNA-*free*™ Kit; Ambion, Inc.) and stored at −80 °C. The quantity and quality of RNA was determined on a NanoDrop 1000 Spectrophotometer (Thermo Fisher Scientific).

Reverse Transcription and Quantitative Real Time-PCR

First strand cDNA was synthesised from 1 μg of total RNA using oligo(dT)$_{20}$ primers with the SuperScript™ III First-Strand Synthesis System for RT-PCR (Invitrogen). Quantitative real time-PCR was performed on the Corbette Rotorgene system (Rotorgene Research, Australia). Each 20 μl PCR reaction amplified 1 μl of cDNA using FastStart SYBR Green Master mix and gene-specific primers. The sequences of the primers used were as follows: ABCA1: 5′-AGACGC AACACAAA AGTGG-3′ and 5′-TGG GTAGCTCAGCCGAACAG-3′, ABCG1: 5′-GAGGGATT TGGGTCTGAAC-3′ and 5′-GCAGCCTTCCATGGAC GA-3′, SCD: 5′-ATGCCG GCCCACTTGCTG-3′ and 5′-CGAATGTCGTCTTCCAAG-3′, CD36: 5′-CTGGGG CTGTCATTGGTG-3′ and 5′-TGTGGATTTTGCACAT CA-3′, LPL: 5′-GAGCCAA AAGAAGCAGCAAAA-3′ and 5′-CCACGGTGCCATACAGA G-3′, LXRα: 5′-CC CTGTGCCTGACATTCC-3′ and 5′-AGCAGGGCTGTG GGCTCT-3′, PPARγ: 5′-TCT CTCCGTAATGGAAGA CC-3′ and 5′-GCATTATGAGACAT CCCCAC-3′ and β-actin: 5′-CTGGCACCACA CCTTCTA-3′, and 5′-GGT GGT G AAGCTGTAGCC-3′. Standard curves were created using serial dilutions of reference plasmids containing full-length cDNA transcripts of ABCG1 (pcDNA4/*myc*-His.hABCG1 kindly provided by Dr. I Gelissen, University of New South Wales, Australia), PPARγ (pCR3.1.hPPARγ1 kindly provided by Prof. B Spiegelman, Dana-Farber Cancer Institute, Boston) and β-actin (pMET-mβ-actin kindly provided by Dr. S Busfield, University of Western Australia, Australia) or partial cDNA transcripts of ABCA1, SCD, CD36 (cloned into the pCRII-TOPO vector, Invitrogen) and LPL mRNAs (cloned into the pGEM—T Easy vector, Promega). Melting point analysis and ethidium bromide-stained gel electrophoresis were performed to confirm PCR product purity and size.

Western Analysis

On day 10 hMDMs were lysed in a buffer containing 50 mM Tris pH 7.4, 2% SDS, 5 mM EDTA, 1 mM DTT, 2 μg/ml aprotinin and 0.5 mM phenylmethylsulfonyl-fluoride, incubated on ice for 1 h, centrifuged at 14,000 rpm

for 10 min at 4 °C and stored in aliquots at −80 °C. Protein concentration was quantified using BCA protein assay kit (Pierce) and measuring absorbance at 580 nm. SDS-PAGE was performed using 50 μg of protein lysate per lane followed by semi-dry blot transfer. Membranes were blocked with 5% skim milk powder in TBS-T (20 mM Tris pH 7.4, 150 mM NaCl, 0.1% Tween-20) before sequential incubations with antibodies to detect CD36, SCD, ABCA1 and ABCG1. Actin was used as a loading control. ECL was performed with GE Healthcare ECL Western blotting detection reagents according to the manufacturer's protocol.

Statistical Analysis

Data are presented as either means ± standard deviation (SD) or means ± standard error of the means (SEM) of means from multiple independent experiments. Analysis was performed using one-way ANOVA. A two-tailed p value of <0.05 was considered significant.

Results

Lipid Content and Composition of Sera and Media

Eight units of FFP were processed and pooled into four sera conditions (A, B, C and D) with varying TG, HDL and cholesterol levels (Table 1). Conditions A to D were arranged according to increasing concentrations of TG (0.74–1.39 mmol/L), decreasing levels of HDL (1.2–0.8 mmol/L) and decreasing levels of cholesterol (4.79–3.14 mmol/L). The media used to culture hMDMs was supplemented with 10% of the pooled sera for each condition A–D. There were no significant differences in total FA content of the media between each of the conditions A–D (Fig. 1i). The media contained more saturated FAs than monounsaturated, and polyunsaturated FAs (Fig. 1ii). Media from condition D had less palmitic acid (C16:0) than media from condition A (117 ± 10 vs. 131 ± 5 ng/μg media, $p = 0.008$) (Fig. 1ii). Media from condition B had more stearic acid (C18:0) than media from condition A (109 ± 11 vs. 94 ± 8 ng/μg media,

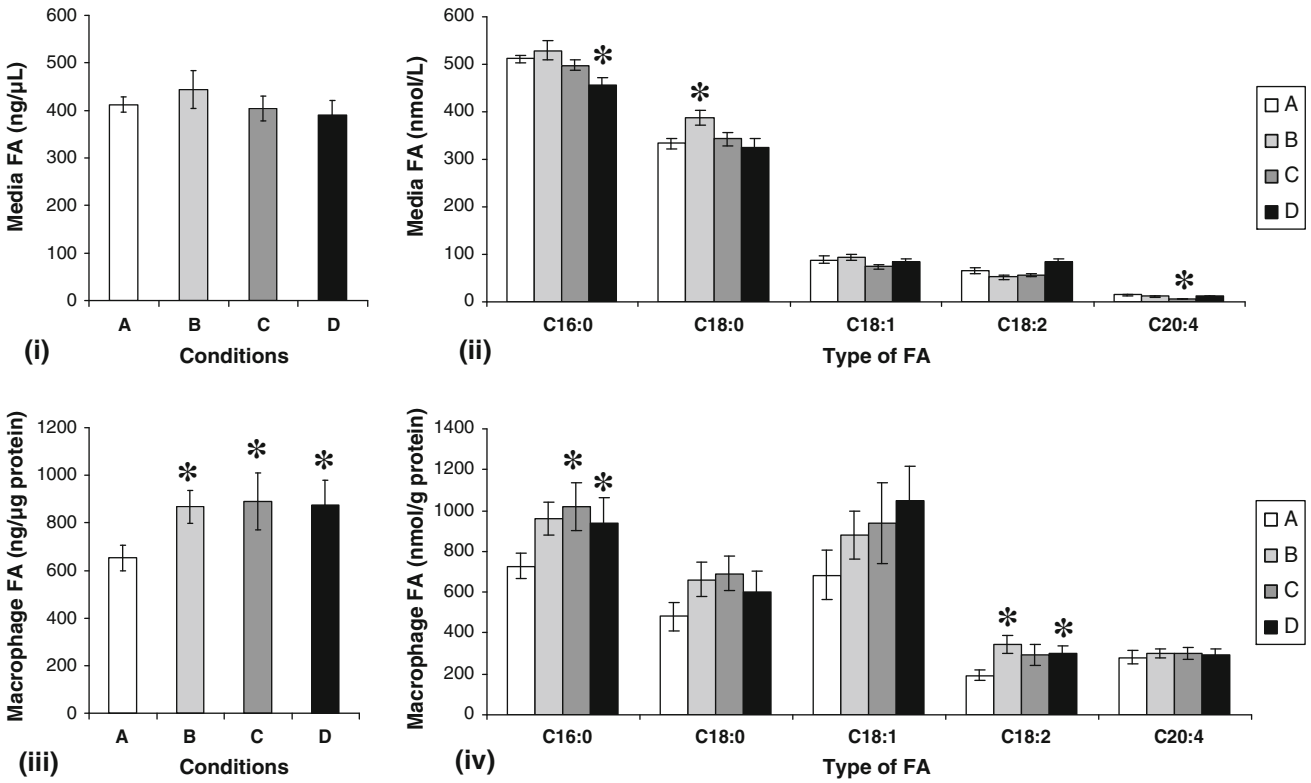

Fig. 1 Macrophages were cultured in media with 10% of sera A (*white bar*), B (*light grey bar*), C (*dark grey bar*) and D (*black bar*) and FA extraction performed on day 10. **i** and **iii**; total fatty acid content of media and cells, respectively. **ii** and **iv**; specific fatty acid composition of media and cells, respectively. Results for media are expressed in ng total FA content/μL media or nmol/L of individual FA and shown as mean ± SD of three independent experiments done in duplicates. Results for hMDM are expressed in ng total FA content/μg protein or nmol of individual FA/μg protein and shown as mean ± SE of five independent experiments done in triplicates. FA, fatty acids; C16:0, palmitic acid; C18:0, stearic acid; C18:1, oleic acid, C18:2; linoleic acid; C20:4, arachidonic acid. One-way ANOVA versus condition A; *$p < 0.05$

$p = 0.017$) (Fig. 1ii). Media from condition C had less arachidonic acid (C20:4) than media from condition A (2.2 ± 0.4 vs. 4.3 ± 0.9 ng/μg media, $p = 0.003$) (Fig. 1ii).

Effect of Dyslipidemia on Macrophage Lipid and Fatty Acid Content

During the period of culture in vitro, monocytes became adherent, increased in size and changed shape from being spheroid to being flatter with some macrophages being round and some being spindle-shaped in tissue culture. To test monocyte differentiation into macrophages, cells were incubated with latex bead particles and phagocytosis of latex beads occurred consistent with macrophage function (Fig. 2i). Macrophages also consistently showed strong CD68 immunostaining after 10–14 days of culture (Fig. 2ii, iii). Macrophages were cultured with the four pooled sera (A–D) with varying TG, HDL and cholesterol levels, and stained with nile red on day 10 or after 8 days in experimental media. Macrophages cultured in conditions B, C and D stained more intensely than controls A indicating more lipid accumulation (Fig. 2a–d). Macrophages grown in the four conditions were harvested and total FA content assayed via GC for quantitative analysis (Fig. 1iii, iv). Total fatty acid content was increased in macrophages grown in conditions B, C, D compared to A with D containing significantly more FAs compared to A (876 ± 102 vs. 652 ± 55 ng/μg protein, $p = 0.02$, respectively) (Fig. 1iii).

Effect of Dyslipidemia on Macrophage Fatty Acid Composition

Human-derived macrophages had a different FA profile to the media in which they were cultured in. Compared to the media, hMDMs had proportionately more monounsaturated and polyunsaturated FAs (Fig. 1ii vs.iv). The increase in total FA content in hMDMs cultured in conditions B, C and D was evident in the increase of individual FA C16:0, C18:0, oleic (C18:1) and C18:2 compared to hMDMs cultured in condition A (Fig. 1iv). The amount of C16:0 in hMDMs cultured in conditions C and D was significantly higher than hMDMs cultured in condition A (261 ± 30 and 240 ± 33 vs. 186 ± 16 ng/μg protein, $p = 0.04$ and 0.03,

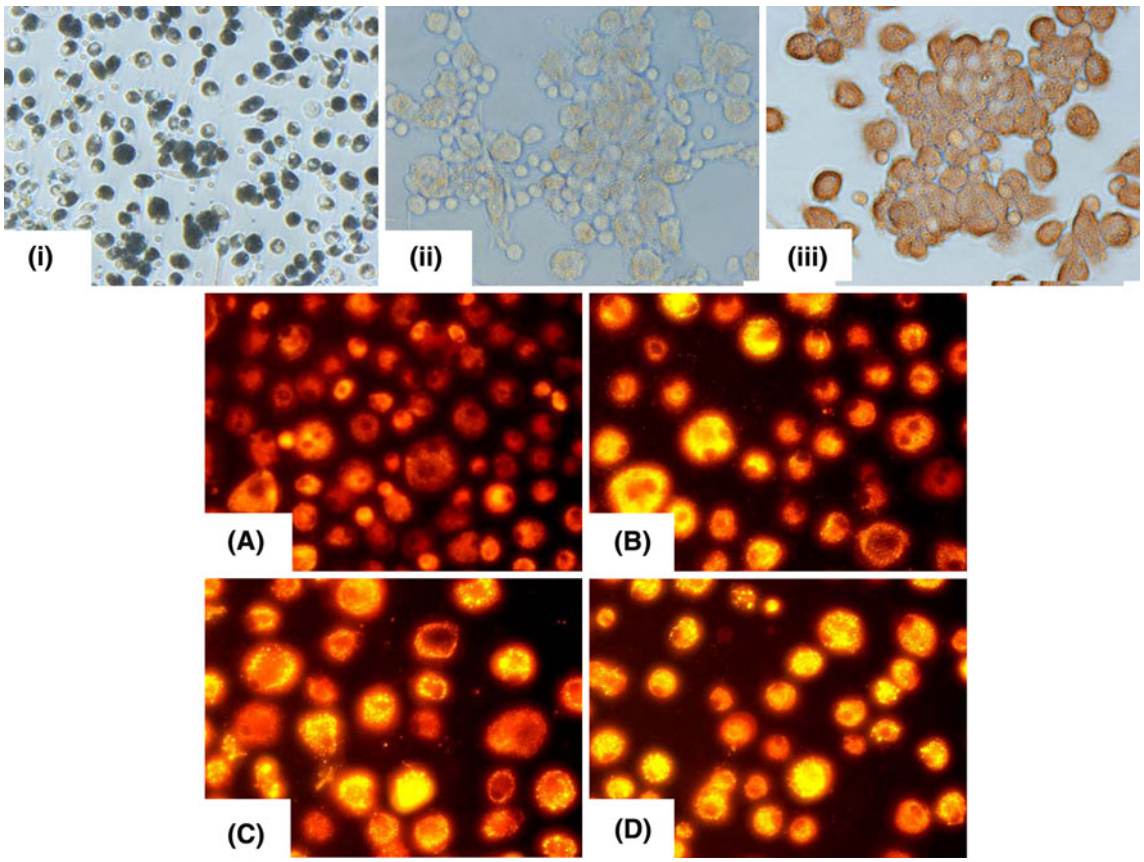

Fig. 2 Macrophages exhibited phagocytosis of latex beads (**i**) and immunostaining for negative control (**ii**) or the macrophage marker CD68 (**iii**). Macrophages were grown in media conditions A, B, C and D with varying concentrations of TG and HDL, and were stained with Nile red on day 10 to demonstrate differences lipid content (**a–d**)

respectively) (Fig. 1iv). There was a trend for the amounts of C18:0 and C18:1 in hMDMs grown in conditions B, C, and D to be higher than A (Fig. 1iv). The amount of C18:2 in macrophages grown in conditions B, C and D were higher than A, however, only conditions B and D were significantly increased compared to A (97 ± 12 and 83 ± 11 vs. 53 ± 7 ng/μg protein, $p = 0.03$ and 0.005, respectively) (Fig. 1iv). All conditions contained similar amounts of C20:4 (arachidonic acid) (Fig. 1iv).

Increased Ratio of C18:1 to C 18:0 FAs in Macrophages Exposed to Elevated TG

As SCD converts stearic acid (C18:0) to oleic acid (C18:1), the ratio of C18:1 to C18:0 was calculated as an indicator of macrophage SCD activity where an increased ratio would suggest increased activity [12]. There was no significant change in the ratio of C18:1/18:0 in media, however, the ratio of C18:1/18:0 was significantly increased in macrophages grown in condition D compared to A (0.74 ± 0.11 vs. 0.60 ± 0.10, $p = 0.004$).

Gene Expression in Macrophages Exposed to Varying TG Levels

RNA extracted from hMDMs cultured in conditions A–D was analysed using reverse transcription and real-time PCR (Table 2). mRNA levels were normalized to β-actin and expressed as a ratio relative to condition A. ABCA1, ABCG1, SCD and CD36 mRNA levels in hMDMs cultured in conditions B, C and D were found to be significantly reduced compared to condition A (Table 2). LXRα and PPARγ mRNA levels in hMDMs cultured in conditions C and D were significantly reduced compared to condition A (Table 2). There were no significant changes in LPL mRNA levels in hMDMs cultured in conditions A–D (Table 2).

Table 2 Expression ABCA1, ABCG1, SCD, CD36 LXRα, PPARγ and LPL in hMDMs cultured for 2 days in media with 10% normal human sera and a further 8 days in media supplemented with 10% sera A–D

mRNA expression was analysed by reverse transcription and real-time PCR. β-actin was used as a loading control and results were normalized to control A = 1.0. Results are expressed as mean ± SE of 2 independent experiments performed in triplicates. One-way ANOVA versus condition A; *$p < 0.05$

Protein extracted from macrophages cultured in conditions A to D were analyzed using Western analysis. Both representative blots as well as quantitative data from replicate experiments of ABCA1, ABCG1, SCD and CD36 proteins are shown in Fig. 3. Protein levels were normalized to actin and expressed as a ratio relative to condition A. ABCA1 protein was significantly decreased in conditions B and C compared to conditions A (0.45 ± 0.07 and 0.35 ± 0.12 vs. 1.0 ± 0.23, $p = 0.04$ and 0.03, respectively) (Fig. 3). Protein levels of ABCG1 were reduced in conditions B, C and D compared to A (0.60 ± 0.10; 0.42 ± 0.05 and 0.55 ± 0.12 vs. 1.0 ± 0.04, $p = 0.004$; <0.001 and 0.005, respectively) (Fig. 3). There were no significant changes in macrophage SCD protein levels (Fig. 3). Protein levels of CD36 were significantly decreased in conditions B and C compared to A (0.54 ± 0.08 and 0.65 ± 0.07 vs. 1.0 ± 0.03, $p = 0.0002$ and 0.001, respectively).

Discussion

Cultured macrophages are an accepted model for elucidating cellular mechanisms relevant to atherosclerosis [9, 10], however, these models have not been used previously to evaluate contributions of subtle dyslipidemia to modulate foam cell formation. Our study addresses an important issue of whether or not exposure to varying levels of TG in culture media would alter the phenotype of macrophages in relation to lipid accumulation. We found that macrophages exposed to sera with higher levels of TG had increased lipid content and altered expression of regulatory proteins, both plausible mechanisms which could contribute to foam cell formation and hence atherogenesis and CVD in patients with hypertriglyceridemia. Of note, these phenotypic differences were observed in macrophages grown in media containing varying concentrations of TG. Levels of TG in the sera (A–D) were within the physiological range and were further diluted 1:10 in the culture media.

Higher TG concentrations in the experimental media resulted in macrophages with greater intracellular lipid content compared with macrophages exposed to lower levels of TG. We have previously shown that macrophages cultured in autologous serum from patients with type 2 diabetes and controls, had significant differences in FA composition [11]. In that study, serum levels of TC and HDL between control and diabetic men and women were comparable whereas TG concentrations of subjects with diabetes had almost twice that of controls. However, the limited amount of blood sampled from each individual restricted the number of macrophages that could be grown

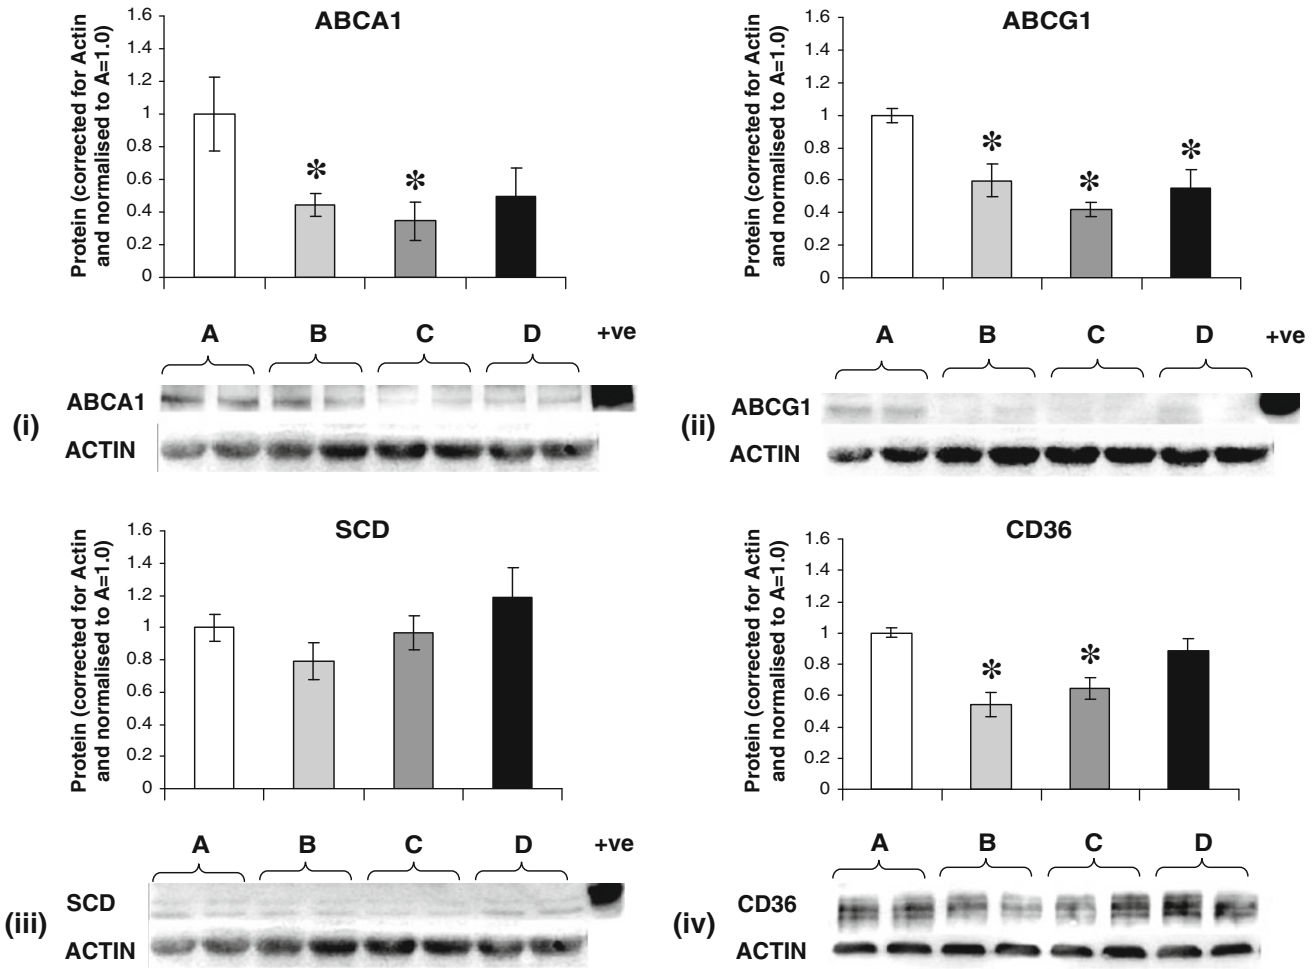

Fig. 3 Macrophages were grown for 2 days in 10% normal human serum 8 days in media supplemented with conditions A (*white bar*), B (*light grey bar*), C (*dark grey bar*) and D (*black bar*) before analysis. Protein lysates were analysed by Western blot and protein expression of ABCA1 (**i**), ABCG1 (**ii**), SCD (**iii**) and CD36 (**iv**) measured. hMDM treated with T0901317, which increases expression of ABCA1, ABCG1 and SCD was used as positive control. Results are shown as a representative blot from one experiment done in duplicates. β-actin was used as a loading control and results were normalized to control $A = 1.0$. Results were expressed as mean $\pm$ SD of three independent experiments performed in duplicates. One-way ANOVA versus condition A; $^{*}p < 0.05$

and hence the experimental work possible in that study. Furthermore, it was unclear whether the differences in macrophage FA composition were due to the origin of the macrophages from patients with and without diabetes or resulted from the differences in TG concentration in serum. By using a common source of monocytes, differentiating these cells over 2 days in the presence of normal human serum and exposing them to experimental sera from days 2 to 10, we found that relatively modest differences in TG concentrations in culture media resulted in significant changes in macrophage fatty acid composition and reduced expression of genes involved in lipid metabolism. Therefore, while the present study utilised pooled sera (A–D) for experiments rather than serum samples from multiple donors, advantages of this approach were that experimental conditions were constant, results were confirmed in multiple independent experiments each performed with replicates and characterization of the macrophage phenotype was more extensive, extending to analysis of FA content and composition, mRNA levels and protein levels via Western analysis. While the results are attributable to exposure to the different experimental sera, additional studies would be needed to confirm that sera from different individuals would yield similar results.

The role TG in CVD has been debated but higher TG is now accepted as a risk factor for coronary heart disease [6]. Increased plasma TG levels appear to increase risk of cardiovascular events independently of LDL concentrations [6, 14]. The effect of varying TG within serum in culture media to promote FA accumulation provides a mechanistic link between higher TG levels and atherosclerosis. The predominant class of lipoproteins in hypertriglyceridaemic serum is chylomicrons and VLDL which contains chylomicron remnant-like particles (CRLP).

CRLP are pro-atherogenic being able to induce macrophage to form foam cells without prior oxidation [15]. Therefore, our work is consistent with previous studies in which CRLP enriched with saturated and monounsaturated FA are taken up more rapidly by macrophages, resulting in greater lipid accumulation of saturated FA [16]. The findings that ABCA1 as well as ABCG1 mRNA and protein levels decreased are consistent with the observation of Moore et al. [17] in which lipid accumulated after exposure of macrophages to CRLP is resistant to efflux. Of note, total FA content in the various media was stable even though the TG levels varied. This is likely due to the fact that cholesterol level (mainly cholesterol esters) was lower in the group with higher TG as was HDL which contains substantial amounts of FA in the form of phospholipids and diacylglycerol.

Compositional analysis of FA revealed that hMDMs cultured in the presence of sera with higher TG had more C16:0 and to a certain extent more C18:0 than those with low TG. These differences are of interest given the range of cellular and metabolic functions which are influenced by saturated FA (for review, see [18]). Reverse cholesterol transport (RCT) is believed to be the primary mechanism by which HDL and its major protein apoA-I protect against atherosclerosis [4]. While all cells are capable of effluxing cholesterol, cholesterol efflux from macrophages critical step of RCT [4]. ABCA1 and ABCG1 mediate the transport of cholesterol and phospholipids from macrophages to apoA-1 and eventually HDL in the reverse cholesterol pathway. Unsaturated FA palmitoleate, oleate, linoleate, and arachidonate but not the saturated FA palmitate and stearate decrease ABCA1 expression in cells by increasing its protein degradation rate [19]. Furthermore, these unsaturated FA were shown to accelerate ABCA1 protein turnover through phospholipase D2 pathway, increased protein kinase C activity and the phosphorylation of ABCA1 serine residues [20]. We found that exposure to media with higher TG decreased macrophage ABCA1 and ABCG1 at both mRNA and protein levels. Therefore, destabilization of macrophage ABCA1 or ABCG1 protein by FA is not the sole mechanism by which cholesterol efflux pathways are downregulated.

CD36 belongs to the class B scavenger receptor family and is an integral membrane protein found on the surface of macrophages. In macrophages, CD36 binds oxidized LDL, native lipoproteins, oxidized phospholipids [21] and long-chain FA [3]. CD36 expression on macrophages is regulated by different molecules in vivo and in vitro. It is positively regulated by transcriptional factors such as PPARγ ligands [22], cytokines such as macrophage stimulating factor [23] and interleukin 4 [23], as well as lipid and lipid components such as cellular cholesterol, oxidized and modified LDL [24], and unsaturated FA (oleic, linoleic, eicosapentaenoic and docosahexaenoic acids) [25]. It is negatively regulated in response to cholesterol efflux [26], interferon-γ [27], transforming growth factor-β1 (TGF-β1) and TGF-β2 [28]. CD36 mRNA levels were lower in macrophages in B, C and D. In line with this CD36 protein levels were lower in B and C. These findings suggest that moderate variations in TG levels in culture media may affect macrophage expression of receptors involved in lipoprotein uptake as well as proteins involved in cholesterol efflux. Therefore, the observed increase in macrophage lipid content and composition could be due to reduced efflux or to uptake by other scavenger receptors [29].

Stearoyl-CoA desaturase catalyzes the critical committed step in the biosynthesis of monounsaturated FA from saturated FA [18]. This reaction involves the introduction of the cis- double bond in between carbons 9 and 10 of palmitoyl-CoA and stearoyl-CoA, which are converted into palmitoleoyl-CoA and oleoyl-CoA, respectively [30]. The roles of monounsaturated FA are diverse and crucial in living organisms. Oleic acid is found to be the major monounsaturated FA of membrane phospholipids, TG, cholesterol esters, wax esters and alkyl-1,2-diacylglycerol. A proper ratio of saturated to monounsaturated FAs contributes to membrane fluidity, while changes in cholesterol esters and TG affect lipoprotein metabolism [31]. Wang et al. [19] have shown that increasing SCD through LXR ligands destabilized ABCA1. We wanted to explore the possibility that with subtle variations in TG concentrations in the media would lead to increased SCD activity in our model of macrophage foam cell development leading to destabilization of ABCA1. We found that macrophages exposed to sera with the highest concentration of TG exhibited an elevated desaturation index suggesting an increase in SCD activity. However, protein quantification of SCD through Western analysis did not show any significant change in SCD protein levels. Therefore, as C16:0, C18:0 and C18:2 are increased, in addition to C18:1 in macrophages cultured in B, C and D, it appears that there is generalized increase in both saturated and unsaturated FA rather than a specific increase in conversion via SCD.

Whilst FA profiles were analysed for sera and macrophages, we did not analyse the FA composition of TG separately. The roles of saturated and polyunsaturated FA to influence phenotypes could be further explored, for instance they differentially modulate inflammatory responses in macrophages [32].

In our study, macrophages from the same source were cultured in media containing the various pooled sera, therefore the changes in FA accumulation and gene expression are attributable to the differences in the serum to which the macrophages were exposed during culture. We used pooled sera, instead of generic sera supplemented with chemically modified or supraphysiological levels of

lipoproteins. This approach provides an experimental model more closely reflecting physiological differences occurring in vivo. A limitation of this study is the fixed amount of pooled-serum A-D collected, all of which was used up during experimentation. While cholesterol content and efflux might have been informative, we did not have additional sera for further experiments. Macrophage cholesterol loading increases cholesterol efflux, partly via accumulation of oxysterols, which in turn activate LXR to increase expression of ABCA1 and ABCG1 [33, 34]. The reduced ABCA1 and ABCG1 mRNA and protein levels in macrophages under conditions C and D with lower LDL levels compared with A might reflect reduced macrophage cholesterol loading. However, macrophages in A and B were exposed to similar LDL levels but those in B had altered gene expression and increased lipid accumulation as a possible consequence of exposure to higher TG or lower HDL levels.

Compared with macrophages grown in A, those exposed to B, C and D had comparably increased lipid and FA accumulation and similar alterations in gene expression. Therefore, the altered macrophage phenotype appears to correspond more closely to higher TG and lower HDL-cholesterol levels rather than differences in total and LDL-cholesterol levels. Higher TG and lower HDL-cholesterol levels in the absence of grossly elevated LDL-cholesterol is characteristic of the metabolic syndrome or diabetic dyslipidemia [35]. In the Multi-Ethnic Study of Atherosclerosis, subjects with reduced HDL ($\leq$1.0 mmol/L in men, $\leq$1.3 mmol/L in women), LDL $<$4.1 mmol/L and TG $\geq$1.7 mmol/L represented 15% of the study population and had increased risk of prevalent coronary artery calcification [36]. Our results link dyslipidemia with altered macrophage phenotype favouring foam cell formation. However, further investigation is needed to clarify whether increased TG or reduced HDL is the primary factor underlying this association, and to clarify whether qualitative rather than quantitative alterations in LDL or HDL might play a role in this context [37].

Conclusions

Moderate variations in TG and cholesterol levels in culture media result in altered macrophage FA content and composition, and changes in the expression of proteins involved in cholesterol efflux and lipoprotein uptake. Hypertriglyceridemia may increase the risk of CVD via direct actions on macrophages favoring foam cell formation, thus leading to the development of atherosclerotic plaque. These findings indicate that replicating in vitro degrees of dyslipidemia encountered in vivo provides an informative model for investigation of atherogenesis.

Palm Olein and Olive Oil Cause a Higher Increase in Postprandial Lipemia Compared with Lard but Had No Effect on Plasma Glucose, Insulin and Adipocytokines

Received: 26 October 2010 / Accepted: 7 December 2010 / Published online: 1 January 2011

Abstract Postprandial lipemia impairs insulin sensitivity and triggers the pro-inflammatory state which may lead to the progression of cardiovascular diseases. A randomized, crossover single-blind study ($n = 10$ healthy men) was designed to compare the effects of a high-fat load (50 g fat), rich in palmitic acid from both plant (palm olein) or animal source (lard) versus an oleic acid-rich fat (virgin olive oil) on lipemia, plasma glucose, insulin and adipocytokines. Serum triacylglycerol (TAG) concentrations were significantly lower after the lard meal than after the olive oil and palm olein meals (meal effect $P = 0.003$; time effect $P < 0.001$). The greater reduction in the plasma non-esterified free fatty acids levels in the lard group compared to the olive oil meal was mirrored by the changes observed for serum TAG levels ($P < 0.05$). The magnitude of response for plasma glucose, insulin and adipocytokines [interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β) and leptin] were not altered by the type of dietary fats. A significant difference in plasma IL-1β was found over time following the three high fat loads (time effect $P = 0.036$). The physical characteristics and changes in TAG structure of lard may contribute to the smaller increase in postprandial lipemia compared with palm olein. A high fat load but not the type of fats influences concentrations of plasma IL-1β over time but had no effect on other pro-inflammatory markers tested in the postprandial state.

Keywords Postprandial lipemia · Adipocytokines · Free fatty acids · Palmitic acid

Abbreviations

IL-1β	Interleukin-1β
IL-6	Interleukin-6
MUFA	Monounsaturated fatty acids
NEFA	Non-esterified free fatty acids
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
TAG	Triacylglycerol
TNF-α	Tumor necrosis factor-α

Introduction

Extensive studies have demonstrated the effects of different types of dietary fats on postprandial lipemia [1–4]. The positional distribution of fatty acids in the triacylglycerol (TAG) structure is believed to affect lipid metabolism [5–7]. Fats from plant origin such as palm oil have palmitic acid distributed in the outer positions of the TAG molecule, namely *sn*-1 and *sn*-3 positions and oleic acid in the *sn*-2 position [8]. However, palmitic acid is found abundantly in the *sn*-2 position in fats with an animal origin, such as lard and human breast milk. Evidence from animal and human infant studies suggests that palmitic acid is better absorbed when found in the *sn*-2 position compared with the *sn*-1 and *sn*-3 positions and hence affects the metabolism of lipids [9]. Hence, it is noteworthy that dietary fats with similar

fatty acid composition may have different biochemical and physical characteristics dependent on their TAG structure which may influence the metabolism of lipids [9]. It has been well established that dietary oleic acid may be neutral to cardiovascular heart disease with regard to its plasma total cholesterol and LDL cholesterol-reducing effects. However, saturated fatty acids (SFA) such as palmitic acid are thought to be cholesterol-raising [10]. Palm olein with oleic acid almost exclusively in the *sn*-2 position may be less cholesterolemic compared to animal fat like lard.

A prolonged and elevated postprandial lipemic response is associated with an increased risk of cardiovascular diseases by a variety of mechanisms such as endothelial function [11], inflammation [12], insulin resistance [13] and oxidative stress [14]. A high fat load with different dietary fats acutely impairs plasma glucose and insulin levels in both healthy and diabetic subjects [13, 15]. Human clinical studies have demonstrated an inverse association between activation of pro-inflammatory cytokines and plasma insulin levels [16, 17]. Increased levels of adipocytokines such as interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β) and leptin were reported in obese [18] and type 2 diabetes patients [19] after consuming a high fat meal. Earlier studies by our group [20] and others [21] reported that specific dietary fats with different fatty acid compositions alter plasma IL-6, TNF-α, E-selectin, and high sensitivity C-reactive protein (hsCRP) but the effect was not seen in the postprandial state [22].

Hence, given the fact that palm olein and lard have similar proportion of SFA and monounsaturated fatty acids (MUFA) content but differ in the structure of TAG and physical properties of fats, we hypothesized that these physical characteristics may determine the extent to which lard and palm olein affect postprandial lipemia. The current study sought to investigate the effects of two palmitic acid-rich fats, one from a plant source (palm olein) and one from an animal fat (lard) with similar SFA content but differing in physical characteristics and TAG structure versus oleic acid-rich fat (virgin olive oil) on postprandial changes in lipemia, plasma glucose, insulin and certain adipocytokines (IL-6, TNF-α, IL-1β and leptin). To the best of our knowledge, no study has been conducted to investigate the effect of a meal rich in palmitic acid from palm olein or lard compared to oleic acid on the pro-inflammatory cytokines and leptin in the postprandial state.

Methods

Subjects

Ten healthy male subjects aged 21.9 ± 0.7 years were recruited from the University Putra Malaysia student population. Exclusion criteria included history of cardiovascular disease, diabetes, body mass index (BMI) <18.5 or >30 kg/m^2, plasma cholesterol >5.2 mmol/L, TAG >1.7 mmol/L, hypertension, current use of medication and smoking. Fasting plasma lipid profile, body weight, blood pressure, blood cell count, liver function were confirmed to be within the prescribed limit as assessed by a physician. Baseline characteristics of study subjects are presented in Table 1.

Table 1 Baseline characteristics of study participants

Variables	Values
Male (*n*)	10
Age (years)	21.9 ± 0.7
BMI (kg/m^2)	21.0 ± 1.6
Systolic BP (mmHg)	126.8 ± 8.6
Diastolic BP (mmHg)	71.3 ± 4.9
Waist (cm)	79.5 ± 6.2
Total cholesterol (mmol/L)	4.8 ± 0.7
TAG (mmol/L)	0.9 ± 0.7
LDL cholesterol (mmol/L)	2.6 ± 0.8
HDL cholesterol (mmol/L)	1.6 ± 0.4
Glucose (mmol/L)	5.2 ± 0.5
Insulin (μIU/mL)	3.6 ± 1.6

Values are means with SD

BP blood pressure

Study Design

A randomized, single-blind, crossover postprandial study was conducted. Each study subject received three experimental meals separated by a minimum of 3-day wash out. Study subjects were provided with a standardized low fat dinner (mee soup, containing <10 g of fat) to consume as their evening meal the day preceding their postprandial day. The subjects were advised to refrain from consuming high fat foods, caffeinated drinks and alcohol. The subjects were asked to refrain from strenuous exercise before the study day. After an overnight fast, subjects reported to the study center at 07:30 morning. A venous blood sample was taken and the subjects consumed the test meals within 15 min. Further venous blood samples were obtained at 30 min, 1, 2, 3 and 4 h. During the postprandial period, subjects were asked to consume water at a regular interval throughout. The Medical Ethics Committee, University Malaya Medical Centre approved the study (Reference number 732.22). The study was conducted according to the guidelines laid down in the Declaration of Helsinki. The study was registered at ClinicalTrial.gov (NCT01124487). All subjects gave written informed consent before the study was commenced.

Test Meals

The test meal consisted of 60 g of mashed potatoes, 180 g of baked beans, 50 mL of skimmed milk, 200 mL of orange juice and 50 g of the test fat (virgin olive oil, palm olein or lard). The test meal was formulated to provide 683 kcal of which 7% of energy was protein, 33% of energy was carbohydrate and 60% of energy was fat. The nutrient composition of test meals is presented in Table 2. The olive oil-enriched diet consisted of 45% energy as MUFA, supplied by Unilever Bestfoods Italia s.r.l, Italy. Palm olein consisted of 24% of energy as SFA with 21% of energy from palmitic acid as provided by Wilmar International Limited, Singapore. Lard consisted of 29% of energy as SFA with 15% of energy from palmitic acid and 10% of energy from stearic acid (purchased from Sainsbury's, UK).

Blood Collection

Fasting venous blood samples of 20 mL were collected in vacutainers (Beckton Dickinson, UK). Serum samples for lipid analysis (TAG and total cholesterol) were collected in 10-mL plain tubes. Blood sample was allowed to clot for 30 min and centrifuged at 1,300*g* for 15 min at 4 °C. For plasma NEFA and pro-inflammatory markers, blood sample was collected into EDTA containing vacutainers and separated by centrifugation at 1,300*g* for 15 min at 4 °C. Blood sample for glucose analysis was collected into 4 mL fluoride oxalate tubes, and blood sample for insulin analysis was collected into 2 mL lithium heparin tubes, both were centrifuged at 1,300*g* for 15 min at 4 °C. Samples for all analyses were collected at hourly intervals. Samples for glucose and insulin were collected at 30 min, and then at hourly intervals after subjects had consumed the high fat meal. Aliquots of blood samples were harvested and stored at −80 °C until analysis.

Table 2 Nutrient composition of meals

	Olive oil	Palm olein	Lard

PUFAs	6.2	8.6	5.9
C18:2	5.6	8.4	5.5

Values are means of double determinations

TAG and Total Cholesterol

Serum TAG and total cholesterol were measured using enzymatic procedures (triglycerides GPO-PAP and cholesterol CHOD-PAP kits; Roche Diagnostics GmbH, Mannheim, USA). Both assays were analyzed using a Hitachi 902 analyzer, Roche Diagnostics GmbH, Germany. The intra-assay CV for TAG was 2.2% ($n = 5$) and 1.7% ($n = 5$) for total cholesterol.

Non-esterified Fatty Acids

Plasma NEFA were measured using non-esterified fatty acids detection 500 Point kit (Zen-Bio Inc., Research Triangle Park, NC, USA) according to standard procedures provided by manufacturer. All samples were assayed in duplicate within a plate. The intra-assay value was 2.8% ($n = 20$).

Plasma Glucose and Insulin

Plasma glucose (glucose GOD-PAP kit; Roche Diagnostics GmbH, Mannheim, USA) was analyzed using an enzymatic colorimetric assay procedure (Hitachi 902 analyzer, Roche Diagnostics GmbH, Germany). Insulin levels were measured using Immulite 1000 ver. 5.16, US (Immulite 1000 Insulin kit; Siemens Healthcare Diagnostics, Deerfield, USA). The intra-assay CV for glucose and insulin were 2.5% ($n = 8$) and 4.1% ($n = 9$), respectively.

IL-6, TNF-α, IL-1β and Leptin

Serum adipocytokines were analyzed using Procarta® Cytokine Assay kit, Panomics Inc., USA. The assays used the xMAP® technology with multi-analyte profiling beads to detect and quantify multiple protein targets simultaneously. The intra-assay values were 6.6% for IL-6 ($n = 20$), 3.0% for TNF-α ($n = 15$), 5.3% for IL-1β ($n = 20$) and 6.6% for leptin ($n = 20$).

Statistics

A sample size of ten subjects will have 80% power at $P = 0.05$ to detect a change of 0.28 mmol/L in plasma TAG concentrations from the baseline between groups. Outcome variables were analyzed using repeated measures ANOVA corrected with the baseline values. Descriptive data of baseline characteristics of study subjects are presented as means ± SD, and other data are presented as means ± 95% confidence interval. All analyses were

conducted using PASW statistics 18.0, Chicago, IL, USA and GraphPad Prism 5.03 for WINDOWS (GraphPad Software, San Diego, CA, USA). Incremental area under the curves (iAUC) were calculated using GraphPad Prism 5.03 using the trapezoid rule. Treatment and time were within-subject factors and age, BMI and the order in which the subjects received the test meals were between subject factors. Bonferroni adjustment was used for multiple comparisons.

Results

A total of 18 subjects were screened and 10 subjects fulfilled the inclusion criteria. All ten subjects completed the study. No drop-out or non-compliance was reported.

Postprandial Lipemia

Serum TAG concentrations were significantly lower after the lard-enriched meal than after the olive oil and palm olein meals (meal effect $P = 0.003$, Fig. 1a). The iAUC for serum TAG was 56 and 49% higher after the olive oil and palm olein meals than after the lard, respectively ($P < 0.05$, $P < 0.01$, respectively). Concentrations of TAG peaked at 3 h after the olive oil and palm olein meals but at 2 h after the lard-enriched meal (time effect $P < 0.001$). Plasma NEFA decreased after meal and displayed a transient increase after 1 h (time effect $P < 0.001$, Fig. 1b). Lard elicited a smaller increase in plasma NEFA at 2 h and 3 h (meal × time interaction, $P = 0.003$) as compared to olive oil ($P < 0.05$).

Postprandial Plasma Glucose and Insulin

There was a significant change in plasma glucose and insulin over time for the three meals ($P < 0.001$, for both meals; Fig. 2a, b, respectively), but there was no difference in response between the three meals. No differences in iAUC plasma insulin values were observed between the diets.

IL-6, TNF-α, IL-1β and Leptin

There was no significant difference between the effects of the three test meals on the postprandial plasma IL-6, TNF-α and leptin (Fig. 3a, b, d, respectively). There were also no significant changes over time for the markers measured. A significant difference in plasma IL-1β was found over time after the three meals ($P = 0.036$), but there was no difference between the meals (Fig. 3c).

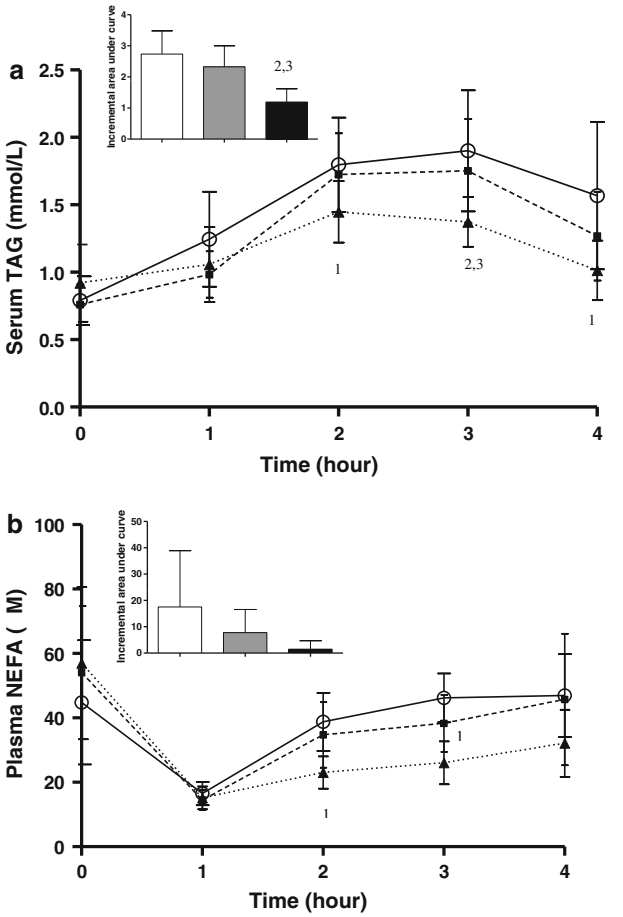

Fig. 1 Mean plasma **a** TAG and **b** NEFA concentrations and 95% CIs in healthy men ($n = 10$) after test meals containing 50 g test fat. Olive oil (*open circles*), palm olein (*filled squares*) and lard (*filled triangles*). Deviations from fasting values were analyzed by repeated measure ANOVA, with the three meals and time (0–4 h) as factors: **a** meal effect ($P = 0.003$), time effect ($P = 0.000$), and meal × time interaction ($P = 0.212$); **b** meal effect ($P = 0.072$), time effect ($P = 0.001$), and meal × time interaction ($P = 0.003$). Incremental area under the curve (0–4 h) values are inset and presented as mean and 95% CIs ($n = 10$) for olive oil (*open squares*), palm olein (*brackets*) and lard (*filled squares*). **a** *1* $P < 0.05$, significantly different from olive oil; *2* $P < 0.01$, significantly different from olive oil; *3* $P < 0.05$, significantly different from palm olein **b** *1* $P < 0.05$, significantly different from olive oil (Bonferroni multiple comparison test)

Discussion

The present study demonstrated that lard resulted in a lower postprandial TAG response in comparison with olive oil and palm olein. The lower postprandial level of lipemia following lard in the present study is in agreement with results reported from a previous study [23] comparing interesterified palm olein versus native palm olein but is not in accordance with other studies [5, 7]. The similar trend of increase over time for palm olein and olive oil concurs with findings from other studies [24, 25]. Rate of lipolysis and

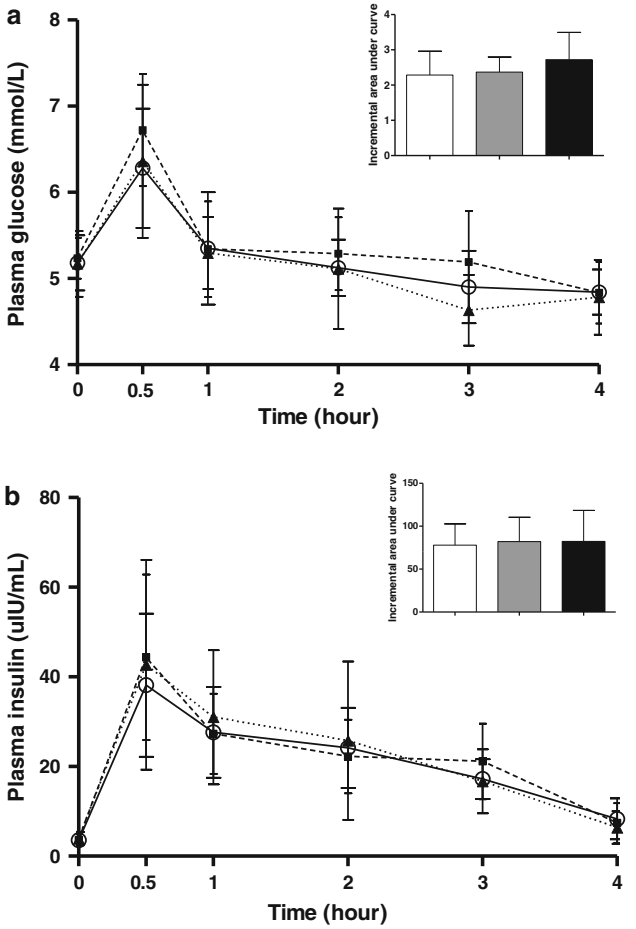

Fig. 2 Mean plasma **a** glucose and **b** insulin concentrations and 95% CIs in healthy men ($n = 10$) after test meals containing 50 g test fat. Olive oil (*open circles*), palm olein (*filled squares*) and lard (*filled triangles*). Deviations from fasting values were analyzed by repeated measure ANOVA, with the three meals and time (0–4 h) as factors: **a** meal effect ($P = 0.475$), time effect ($P = 0.000$), and meal × time interaction ($P = 0.719$); **b** meal effect ($P = 0.740$), time effect ($P = 0.000$), and meal × time interaction ($P = 0.711$). Incremental area under the curve (0–4 h) values are inset and presented as means and 95% CIs ($n = 10$) for olive oil (*open squares*), palm olein (*brackets*) and lard (*filled squares*); **a**, **b** no significant differences were observed

clearance of chylomicrons are unlikely contributed to the markedly lower response of lipemia after lard intake as a study has reported that lipoprotein lipase activity is similar following high fat loads with different types of fatty acid composition [25]. Although lard and palm olein have almost similar SFA content (24% in palm olein, 29% in lard), they differ significantly in the positional distribution of the fatty acids in the TAG molecule. Almost all of the palmitic acid in lard is present in the *sn*-2 position of TAG. Palm olein contains only 7–11% of palmitic acid in the *sn*-2 position, the predominant fatty acid in the *sn*-2 position is oleic acid (~70%). The position of fatty acids in the TAG molecule determines the physical properties of fat. Hence, it is probable that differences in the physical characteristics of fats and changes in TAG structure (for both lard and palm olein) may influence the level of postprandial lipaemia [9]. Lard which contains a higher proportion of solid fat at 37°C compared with olive oil and palm olein may be emulsified less readily and is less absorbed due to its higher melting point, resulting in a slower increase in serum TAG levels [1, 23].This finding would suggest that lard containing SFA in the *sn*-2 position might be cleared from the circulation slower than dietary fat containing SFA in the *sn*-1, 3 positions. This may lead to a more prolonged postprandial lipemia.

The greater reduction in the plasma NEFA levels after the lard meal compared to olive oil and palm olein was mirrored by the changes observed in serum TAG levels. In contrast with the current finding, previous studies have demonstrated that MUFA and polyunsaturated fatty acids (PUFA) suppressed plasma NEFA more than SFA [26, 27] and the increase in plasma NEFA following the initial suppression after a meal was markedly higher following a SFA-rich meal than MUFA, n-6 and n-3 PUFA [15]. However, a study reported that palmitic + myristic acid displayed higher and stearic acid lower in plasma NEFA levels in comparison with palmitic acid, MUFA and PUFA-rich high fat loads [25]. Taken together the results suggest that fatty acid composition per se influences plasma NEFA response in a different manner.

Several studies have demonstrated that dietary SFA impair postprandial glucose and insulin levels but the results are not consistent [13, 15, 23, 28]. The current study did not demonstrate any differences between the three meals on insulin and glucose levels over time. Direct examination in muscle cells in vitro indicates that SFA cause insulin resistance whereas unsaturated fatty acids improve insulin sensitivity [29]. However, observed differences from in vitro studies may not be applicable to the in vivo situation. The lack of significant response between meals could be partly explained by the relatively young and healthy individuals recruited in the present study. Obese subjects demonstrated exaggerated insulin responses compared with normal weight healthy individuals [30]. The single high fat load may not affect the changes in plasma glucose and insulin levels. Hence, a longer exposure of feeding may be needed to induce the changes by consuming high fat meals with different fatty acid composition. However, our results are in agreement with a large scale chronic study (RISCK study) comparing the consumption of SFA and MUFA which shows that SFA and MUFA show similar in insulin response [31]. Although the dietary fats in our study altered postprandial lipemia markedly, the magnitude of response in the pro-inflammatory cytokines, IL-6, TNF-α and IL-1β was not altered. This is in agreement with findings reported by other

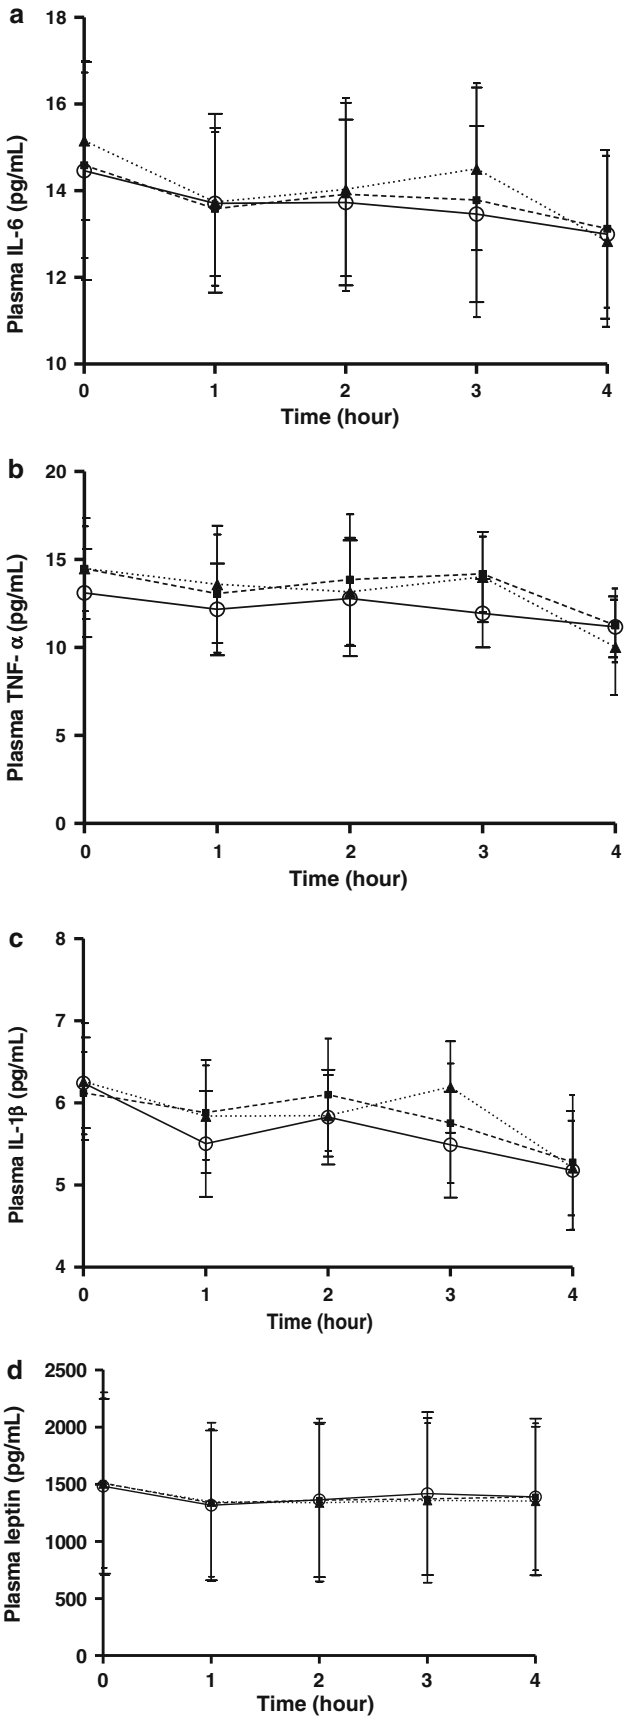

Fig. 3 Mean plasma **a** IL-6, **b** TNF-α, **c** IL-1β and **d** leptin ▶ concentrations and 95% CIs in healthy men ($n = 10$) after test meals containing 50 g test fat. Olive oil (*open circles*), palm olein (*filled squares*) and lard (*filled triangles*). Deviations from fasting values were analyzed by repeated measure ANOVA, with the three meals and time (0–4 h) as factors. **a**, **b**, **d** No significant differences were observed for meal, time and meal × time effects. **c** no significant differences were observed for meal and meal × time effects, but a significant time effect was observed ($P = 0.036$). Mean incremental area under the curve (0–4 h) values and 95% CIs were as follows: **a** olive oil (0.83; −0.14, 1.81), palm olein (0.47; −0.21, 1.14) and lard (0.23; −0.08, 0.53); **b** olive oil (12.6; −10.1, 35.2), palm olein (0.95; −0.40, 2.30) and lard (25.5; −29.8, 80.8); **c** olive oil (0.37; 0.05, 0.69), palm olein (0.65; 0.09, 1.20) and lard (0.57; 0.03, 1.11); **d** olive oil (175.0; −163.1, 513.2), palm olein (53.1; −4.98, 111.1) and lard (43.4; −7.69, 94.5); **a**–**d** no significant differences were observed

studies. In contrast with the present study, long term dietary intervention studies reported an increase in IL-6, E-selectin [21], hsCRP and IL-8 in healthy subjects after consuming a meal enriched with trans fatty acids in comparison with an oleic acid-enriched meal [20]. These findings suggest that a prolonged stimulation of an inflammatory state may be required in order to trigger a pro-inflammatory response in the body. Hence, repeated exposure to high fat diets may induce inflammatory activity in the body with regard to fatty acid composition per se. In regard to plasma IL-6 and TNF-α, the lack of increase over time in the present study is not in agreement with findings reported by other studies [18, 19, 32]. The lack of response might also be due to the relatively young and lean subjects who were recruited in the present study which may not trigger a significant response over time for plasma IL-6 and TNF-α. Overweight or obese subjects with increased adipose tissue are more vulnerable to enhanced pro-inflammatory cytokines increase after meals rich in fat load [18]. Excess adipose tissue may contribute to a substantially higher secretion of IL-6 and TNF-α as shown by other studies [18]. It is to be noted that the relatively small sample size may not produce significant differences between diets after a high fat load. The sample size was calculated based on the true difference of serum TAG on dietary treatments. A further study with a larger population may be needed to observe a significant change in plasma pro-inflammatory markers.

IL-1β, however, showed a significant change over time following the three high fat loads. The novel observation of a transient decrease at 1 h of plasma IL-1β concentrations in the present study is in accordance with an increase in the plasma insulin level at 1 h after the three meals. One likely explanation for this observation is that insulin activity is reported to possess anti-inflammatory and antioxidant properties [33] which may attenuate the pro-inflammatory response. The release of insulin is stimulated by IL-1β with the activation of protein kinase C and production of

diacylglycerol in an in vivo study [17]. With regard to this, IL-6 was also reported to enhance insulin-mediated glucose uptake [16]. IL-6 may directly affect insulin signalling by the induction of a suppressor of cytokine signalling-3 which inhibits insulin-dependent insulin receptor autophosphorylation.

The present study did not demonstrate that the activity of leptin is altered by high fat loads differing in fatty acid composition. This observation is in agreement with earlier findings [30, 34]. However, it is noteworthy that the postprandial leptin response is lower after a carbohydrate meal in obese women than in lean subjects, suggesting an impairment of postprandial leptin regulation in obese but not in lean subjects [30, 34]. This may explain the non-activated leptin levels in the present study. The evidence suggests that leptin, together with other adipocytokines (IL-6, TNF-α, IL-1β and other pro-inflammatory markers secreted from adipose tissue) and NEFA, displays a positive relationship with insulin resistance [35]. Leptin is thought to promote fatty acid oxidation and reduce ectopic fat accumulation in non-adipose tissues, thereby increasing insulin sensitivity which is probably mediated by the activation of 5′-AMP-activated protein kinase [36].

In conclusion, this study demonstrated that lard behaves differently from palm olein although both contain similar proportions of SFA in comparison with oleic acid-rich fat in postprandial lipemia. Positional distribution of fatty acids in the *sn*-2 position may play a role in postprandial lipemia. Palm olein and olive oil displayed similar effects on postprandial lipemia. There were no differences in plasma glucose, insulin and pro-inflammatory markers between the three meals suggesting that a high fat load but not fatty acid per se influences the trend of response of pro-inflammatory markers.

Acknowledgments We thank our colleagues, Fatmawati, Wong Weng Yew and Che Hui Ling from the Malaysian Palm Oil Board for technical assistance.

LETTER TO THE EDITOR

Supplementation of Monounsaturated and Polyunsaturated Fatty Acids in Non-Alcoholic Fatty Liver Disease and Metabolic Syndrome

Anna Alisi · Carlo Agostoni · Valerio Nobili

Received: 21 February 2011 / Accepted: 21 February 2011 / Published online: 16 March 2011

To the Editor

Metabolic syndrome is the result of a combination of risk factors, including abdominal obesity, hyperlipidemia, hypertension, and insulin resistance. Dietary fat intake may play a critical role in the development of the metabolic syndrome. It is now clear that it is not so much the amount of lipids introduced by the diet, but rather the type of fatty acid that is able to interfere with the development of the disease [1]. In fact, in a recent review published in this journal [2], the authors provided a critical evaluation of the evidence supporting the impact of dietary monounsaturated fatty acids (MUFA) on plasma lipidome. Furthermore, several studies highlight the efficacy of MUFA in improving insulin sensitivity and regulating glucose levels, thus reducing the risk of metabolic syndrome and cardiovascular disease [2].

Recently, metabolic syndrome has been also associated with non-alcoholic fatty liver disease (NAFLD) [3]. NAFLD is a multifactorial disease ranging from simple fatty liver to non-alcoholic steatohepatitis (NASH), with or without fibrosis [4]. The coexistence of metabolic syndrome and NAFLD represents an increased risk factor for type-2 diabetes and cardiovascular disease [3, 4]. There are currently no available therapies for NAFLD and NASH. Recently, lipotoxicity and plasma lipidome have emerged as novel targets for potential therapeutic strategies [5, 6]. Furthermore, several authors showed that n-3 polyunsaturated fatty acids (PUFA) may have beneficial effects in preventing the complications of lipotoxicity [6]. PUFA dietary intake has positive effects on intra-hepatic fat accumulation in patients with NAFLD [7]. In a recent study conducted on 60 children with biopsy-proven NAFLD, we demonstrated that docosahexaenoic acid (DHA), an n-3 long-chain PUFA, is able to decrease liver fat content, change the lipidomic profile, reduce insulin resistance, thus improving some of the metabolic signatures of obesity [8].

It is noteworthy that all these findings support the role of highly saturated fatty acids, and the n-6/n-3 ratio as modulators of these metabolic parameters, and suggest that early markers of developing metabolic syndrome may be ameliorated by the administration of n-3 long-chain PUFA and MUFA even if controversy still exists on the different effects of n-6 and n-3 PUFA, as well as on the interacting effect of dietary saturated and monounsaturated fat.

National dietary guidelines are increasingly recommending dietary MUFA, primarily at the expense of saturated fatty acids (SFA), the so-called Mediterranean diet.

As the debate on the beneficial dietary fatty acid combination continues, the mechanisms involved in the effects of MUFA and PUFA on metabolic syndrome and NAFLD, deserves considerable attention and further human studies. Nevertheless, we believe that the take home message is that if therapeutic MUFA-based strategies are effective in prevention of metabolic syndrome and are also applicable to NAFLD; and vice versa, then there is a good hope with regard to the possibility of successful implementation of PUFA as a therapy for both diseases. Finally, the inclusion of MUFA and PUFA supplements in the diet of individuals with metabolic syndrome and NAFLD should be warranted, in view of their potential to reduce the risk of cardiovascular disease.

ORIGINAL ARTICLE

PGE_2 Release from Tryptase-Stimulated Rabbit Ventricular Myocytes is Mediated by Calcium-Independent Phospholipase $A_2\gamma$

Janhavi Sharma · Jane McHowat

Received: 16 February 2011 / Accepted: 16 March 2011 / Published online: 2 April 2011

Abstract Inflammation is associated with cardiovascular disease, including myocardial infarction, atherosclerosis, myocarditis and congestive heart failure. Mast cells have been implicated in inflammation, but their precise role in cardiac inflammation remains unclear. Mast cells contain a variety of pre-formed granule-associated mediators, including tryptase. We have previously demonstrated that the majority of the phospholipase A_2 (PLA_2) activity in isolated rabbit ventricular myocytes is membrane-associated, calcium-independent and selective for plasmalogen phospholipids. We hypothesized that tryptase stimulation of rabbit ventricular myocytes would increase $iPLA_2$ activity, leading to increased arachidonic acid and prostaglandin E_2 (PGE_2) release. Isolated rabbit ventricular myocytes were stimulated with tryptase and $iPLA_2$ activity, arachidonic acid and PGE_2 release were measured. Tryptase stimulation increased $iPLA_2$ activity after 5 min. Activation of $iPLA_2$ was accompanied by increased arachidonic acid and PGE_2 release in tryptase-stimulated myocytes. However no increase in platelet activating factor was observed with tryptase stimulation. To distinguish between different $iPLA_2$ isoforms in the myocardium, we pretreated ventricular myocytes with the (*R*)- and (*S*)-enantiomers of bromoenol lactone (BEL) to selectively inhibit $iPLA_2\gamma$ and β respectively. Pretreatment with (*R*)-BEL resulted in complete inhibition of tryptase-stimulated $iPLA_2$ activity, arachidonic acid and PGE_2 release, suggesting the $iPLA_2\gamma$ is the predominant myocardial isoform activated by tryptase. These studies demonstrate that PGE_2 release from tryptase stimulated rabbit ventricular myocytes is mediated primarily by $iPLA_2\gamma$.

Keywords Heart · Mast cell · Inflammation

Abbreviations

BEL	Bromoenol lactone
COX	Cyclooxygenase
ECM	Extracellular matrix
$iPLA_2$	Calcium-independent phospholipase A_2
MMP	Matrix metalloprotease
PAF	Platelet activating factor
PGE_2	Prostaglandin E_2
PMA	Phorbol 12-myristate 13-acetate

Introduction

It is estimated that one in three American adults has one or more types of cardiovascular disease [1], the leading cause of mortality and morbidity in the US. The pathology of many cardiovascular diseases, including myocardial infarction, atherosclerosis, congestive heart failure and myocarditis, are associated with myocardial inflammation [2]. Mast cells are normally present in heart tissue, and lie in close proximity to blood vessels and in between myocytes in the myocardium [3]. Previous studies have demonstrated a pathological role for mast cells in the heart, whereby following degranulation they cause myocardial tissue injury, contractile dysfunction and are proarrhythmic [4, 5]. Mast cell degranulation releases many harmful mediators such as histamine, chymase, tryptase and eicosanoids that can contribute to inflammation [5]. Mast cells

have also been shown to contribute to fibrosis via the release of various profibrotic cytokines. Additionally, tryptase has been shown to stimulate fibroblast proliferation and collagen deposition [6, 7]. Tryptase is known to degrade denatured collagen and activate matrix metalloproteases (MMPs) that are responsible for extracellular matrix integrity. It also degrades a number of bioactive peptides and lipoproteins [8].

Previous studies from our laboratory have demonstrated that mast cell tryptase activates calcium-independent phospholipase A_2 ($iPLA_2$) in endothelial and epithelial cells, resulting in increased inflammatory phospholipid metabolite accumulation and propagating the inflammatory process [9, 10]. PLA_2 are a large family of esterases responsible for the hydrolysis of *sn*-2 esterified fatty acids from membrane phospholipids, resulting in the production of free fatty acid, including arachidonic acid and a lysophospholipid. These can serve as important precursors for metabolites that have been shown to initiate or propagate inflammation. For example, arachidonic acid can be converted to prostaglandins by the action of cyclooxygenases (COX). The liberated accompanying lysophospholipid can be acetylated at the *sn*-2 position to produce platelet-activating factor (PAF). Both, arachidonic acid metabolites and PAF have a well established role in the inflammatory process [11].

Several PLA_2 isoforms have been identified in the myocardium. Secretory phospholipase A_2 require millimolar amounts of calcium for their catalytic activity and act extracellularly. Intracellular phospholipases are divided into two groups- cytosolic PLA_2 ($cPLA_2$) and $iPLA_2$. All known $cPLA_2$, except for $cPLA_2\gamma$, require micromolar concentrations of Ca^{2+} for their translocation from the cytosol to intracellular membranes. They do not, however, require Ca^{2+} for their catalytic activity. As their name suggests, $iPLA_2$ do not require Ca^{2+} for their activity or substrate binding. Even though all three groups of PLA_2 have been identified in the myocardium, several studies show that the majority of myocardial PLA_2 activity is Ca^{2+}-independent [12].

The $iPLA_2$ family of enzymes contains at least seven members amongst which, $iPLA_2\gamma$ and $iPLA_2\beta$ are the most abundant in mammalian tissue and have been shown to be important for regulating myocardial function [13]. An inhibitor selective for $iPLA_2$, bromoenol lactone (BEL), has been useful in demonstrating the role of this enzyme in various settings. The separation of BEL into its enantiomers, (*R*)-BEL and (*S*)-BEL has further allowed us to discriminate between the major isoforms of $iPLA_2$, since they are ten fold selective for $iPLA_2\gamma$ and $iPLA_2\beta$ respectively [14].

In this study we examined the effect of tryptase stimulation on rabbit ventricular myocyte $iPLA_2$ activity, and the subsequent production of arachidonic acid, PGE_2 and PAF.

Methods

Rabbit Ventricular Myocyte Isolation and Culture

All studies using vertebrate animals were carried out under the approval of the Animal Care and Use Committee at Saint Louis University as outlined in protocol # 1207. Adult rabbits of either sex weighing 2–3 kg were anesthetized with intravenous pentobarbitone sodium (50 mg/kg) and the heart rapidly removed. The heart was mounted on a Langendorff perfusion apparatus and perfused for 5 min with a Tyrode solution containing (mmol/L) NaCl 118, KCl 4.8, $CaCl_2$ 1.2, and glucose 11; the Tyrode solution was saturated with $95\%O_2/5\%CO_2$ to yield a pH of 7.4. This was followed by a 4-min perfusion with a Ca-free Tyrode solution containing EGTA (100 μM) and a final perfusion for 20 min with the Tyrode solution containing 100 μM Ca^{2+} and 0.033% collagenase. The heart was removed from the perfusion apparatus, the atria were removed and the remaining ventricles were cut into small pieces and incubated in fresh 0.033% collagenase solution at 37 °C in a shaking water bath for 4 successive harvests of 20 min. Individual myocytes were washed with HEPES buffer containing (mmol/L): NaCl 133.5, KCl 4.8, $MgCl_2$, $CaCl_2$ 0.3, KH_2PO_4 1.2, glucose 10 and HEPES 10 (pH 7.4). Extracellular Ca^{2+} was increased to 1.2 mM in three stages at intervals of 20 min. Myocytes were incubated overnight in M199 medium with 10% fetal calf serum at 37 °C and then washed three times with 1.2 mM Ca^{2+} HEPES solution.

Phospholipase A_2 Activity

Myocytes were suspended in 1 mL buffer containing (mmol/L): sucrose 250, KCL 10, imidazole 10, EDTA 5, dithiothreitol (DTT) 2 with 10% glycerol, pH 7.8 (activity buffer). The suspension was sonicated on ice six times for 10 s (using microtip probe at 20% power output, 500 Sonic Dismembrator, Fisher Scientific) and the sonicate centrifuged at $20{,}000\times g$ for 20 min to remove cellular debris and nuclei. The supernatant was then centrifuged at $100{,}000\times g$ for 60 min to separate the membrane fraction from the cytosolic fraction. The membrane fraction was washed twice to minimize contamination with cytosolic protein by resuspending in activity buffer, and centrifuging at $100{,}000\times g$ for 60 min. The final membrane fraction was resuspended in activity buffer. Purity of the membrane fraction for sarcolemma and sarcoplasmic reticulum membranes was verified by verifying the presence of K^+-*p*-nitrophenyl phosphatase and NADPH-cytochrome *c* reductase and the absence of glucose 6-phosphate dehydrogenase and cytochrome *c* oxidase. PLA_2 activity in membrane fractions was assessed by incubating enzyme (8 μg

membrane protein) with 100 μM (16:0, [^{3}H]18:1) plasmenylcholine substrate in assay buffer containing (mmol/L): Tris 10, EGTA 4, 10% glycerol, pH 7.0 at 37 °C for 5 min in a total volume of 200 μL. The radiolabeled phospholipid substrate was introduced into the incubation mixture by injection in 5 μL ethanol to initiate the assay. Reactions were terminated by the addition of 100 μL butanol and released radiolabeled fatty acid was isolated by the application of 25 μL of the butanol phase to channeled Silica Gel G plates, development in the petroleum ether/diethyl ether/acetic acid (70/30/1, v/v) and subsequent quantification by liquid scintillation spectrometry. Protein content of each sample was determined by the Lowry method utilizing freeze dried bovine serum albumin as the protein standard.

Measurement of Total Arachidonic Acid Release

Arachidonic acid release was determined by measuring [^{3}H] arachidonic acid released into the surrounding medium from ventricular myocyte suspensions labeled previously with [^{3}H] arachidonic acid. Briefly, myocyte suspensions (10^6 myocytes in 10 mL culture media) were incubated at 37 °C with 3 μCi [^{3}H] arachidonic acid for 18 h. This incubation resulted in >70% incorporation of radioactivity into the myocytes. After incubation, myocyte suspensions were washed three times with Tyrode solution containing 0.36% bovine serum albumin to remove unincorporated [^{3}H] arachidonic acid. Myocytes were incubated at 37 °C for 15 min before being subjected to experimental conditions. At the end of the stimulation period, myocyte suspensions were centrifuged, and the supernatant was removed. Myocyte pellets were solubilized in 10% sodium dodecyl sulfate, and radioactivity in both supernatant and pellet was quantified by liquid scintillation spectrometry.

Measurement of PGE_2 Release

Rabbit myocytes were washed twice with Hanks balanced salt solution (HBSS) containing, in mmol/L, 135 NaCl, 0.8 $MgSO_4$, 10 HEPES (pH 7.6, 1.2 $CaCl_2$, 5.4 KCl, 0.4 KH_2PO_4 and 6.6 glucose. After washing, 0.5 mL of HBSS with 0.36% BSA was added to each culture well. Myocytes were then stimulated with the appropriate tryptase concentrations. The surrounding buffer was removed from the cells after selected time intervals, and PGE_2 release was measured immediately using an immunoassay kit (R&D Systems, Minneapolis, MN).

PAF Assay

Isolated rabbit ventricular myocytes were washed twice with Hanks' balanced salts solution containing NaCl 135 mM, $MgSO_4$ 0.8 mM, HEPES (pH = 7.4) 10 mM, $CaCl_2$ 1.2 mM, KCl 5.4 mM, KH_2PO_4 0.4 mM, Na_2HPO_4 0.3 mM and glucose 6.6 mM and incubated with 50 μCi [^{3}H] acetic acid for 20 min. After the selected time interval for incubation with the appropriate agents, lipids were extracted from the cells by the method of Bligh and Dyer. The chloroform layer was concentrated by evaporation under N_2, applied to a silica gel 60 TLC plate, and developed in chloroform/methanol/acetic acid/water (50/25/8/4 vol/vol). The region corresponding to PAF was scraped and radioactivity quantified using liquid scintillation spectrometry. Loss of PAF during extraction and chromatography was corrected for by adding a known amount of [^{14}C] PAF as an internal standard. [^{14}C] PAF is synthesized by acetylating the *sn*-2 position of lyso-PAF with [^{14}C] acetic anhydride using 0.33 M dimethylaminopyridine as a catalyst. The synthesized [^{14}C] PAF is purified by HPLC.

Statistical Analysis

Statistical comparison of values was performed by Student's *t* test or one way analysis of variance with post hoc analysis performed using Dunnett's test. All results are expressed as means ± SEM. Statistical significance was considered to be $P < 0.05$.

Results

Effect of Tryptase on PLA_2 Activity

To determine the contribution of $iPLA_2\beta$ and $iPLA_2\gamma$ to total $iPLA_2$ activity in rabbit ventricular myocytes, membrane protein was incubated with increasing concentrations of (*R*)-BEL or (*S*)-BEL and PLA_2 activity was measured in the absence of calcium (4 mM EGTA) using (16:0, [^{3}H]18:1) plasmenylcholine as substrate. Incubation with concentrations of (*R*)-BEL greater than 0.1 μM resulted in a significant inhibition of membrane-associated $iPLA_2$ activity (Fig. 1). Incubation of membrane protein with (*S*)-BEL resulted in a significant inhibition of $iPLA_2$ activity at concentrations greater than 1 μM (Fig. 1). Incubation with (*R*)-BEL inhibited $iPLA_2$ activity to a greater extent than incubation with (*S*)-BEL at all concentrations examined, suggesting that the majority of ventricular myocyte $iPLA_2$ activity is $iPLA_2\gamma$.

Isolated rabbit ventricular myocytes stimulated with tryptase (20 ng/mL) demonstrated a significant increase in $iPLA_2$ activity 5 min after stimulation, which returned to basal level after 10 min (Fig. 2). Ventricular myocytes pretreated with (*R*)-BEL (2 μM, 10 min) resulted in complete inhibition of tryptase-stimulated $iPLA_2$ activity (Fig. 2). However, pretreatment with (*S*)-BEL (2 μM,

10 min) did not significantly affect tryptase-stimulated iPLA$_2$ activity (Fig. 2). These data suggest that tryptase stimulation caused an increase in iPLA$_2$ activity in myocytes, most likely due to activation of iPLA$_2\gamma$.

Effect of Tryptase on Arachidonic Acid Release

Since iPLA$_2$ mediated membrane hydrolysis results in the production of free fatty acid from the *sn*-2 position, rabbit ventricular myocytes were stimulated with tryptase (20 ng/mL) and arachidonic acid release was measured. Tryptase stimulation resulted in a significant increase in arachidonic acid release after 2 min. Stimulation for a longer period resulted in a five-fold increase in arachidonic acid (Fig. 3). Pretreatment of ventricular myocytes with (*R*)-BEL (2 μM, 10 min) completely inhibited tryptase-stimulated arachidonic acid release whereas pretreatment with (*S*)-BEL (2 μM, 10 min) inhibited arachidonic acid release by approximately 40% (Fig. 3). This suggests that iPLA$_2\gamma$ is primarily responsible for arachidonic acid release in response to tryptase stimulation in rabbit ventricular myocytes.

Effect of Tryptase on PGE$_2$ Release

Free arachidonic acid can be metabolized to PGE$_2$ by the sequential actions of cyclooxygenase (COX-1 or COX-2) and prostaglandin E synthase. An increase in PGE$_2$ release was observed when rabbit ventricular myocytes were stimulated with tryptase (20 ng/mL, Fig. 4). In agreement

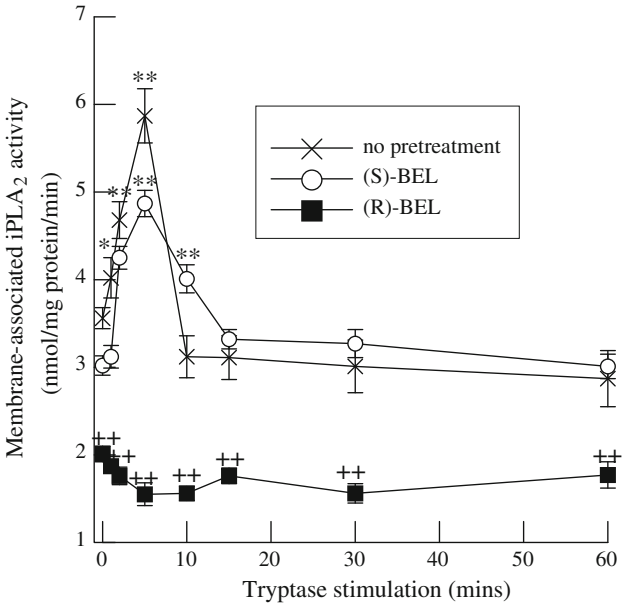

Fig. 2 Calcium-independent phospholipase A$_2$ (iPLA$_2$) activity in rabbit ventricular myocytes stimulated with tryptase (20 ng/mL) with or without pretreatment with (*R*)- or (*S*)-BEL (2 μM, 10 min). $^{*}p < 0.05$, $^{**}p < 0.01$ when compared to untreated controls. $^{++}p < 0.01$ when comparing tryptase stimulated results in the presence or absence of (*R*)-BEL. $N = 6$

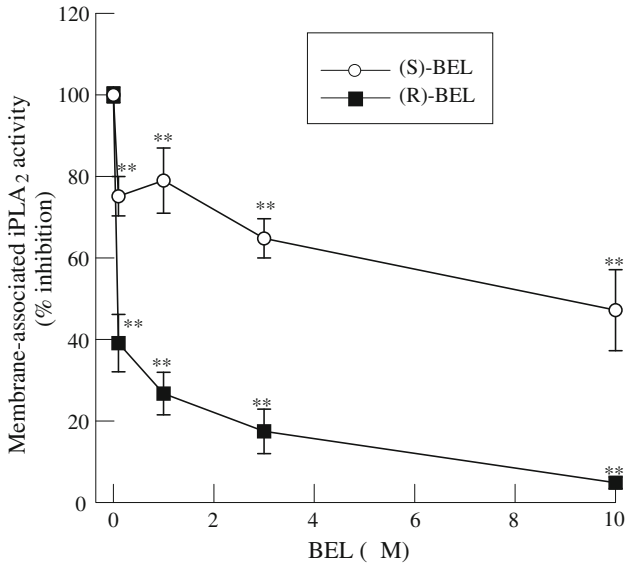

Fig. 1 Inhibition of calcium-independent phospholipase A$_2$ (iPLA$_2$) activity in rabbit ventricular myocytes treated with (*R*)- or (*S*)-BEL. Isolated membrane fractions were incubated with bromoenol lactone (BEL, 10 min) prior to assay of PLA$_2$ activity, measured using 100 μM (16:0, [^{3}H]18:1) plasmenylcholine in the presence of 4 mM EGTA. Untreated iPLA$_2$ activity was 6.1 ± 0.1 nmol/mg protein/min, $N = 9$. $^{*}p < 0.05$, $^{**}p < 0.01$ when compared to activity measured in the absence of BEL

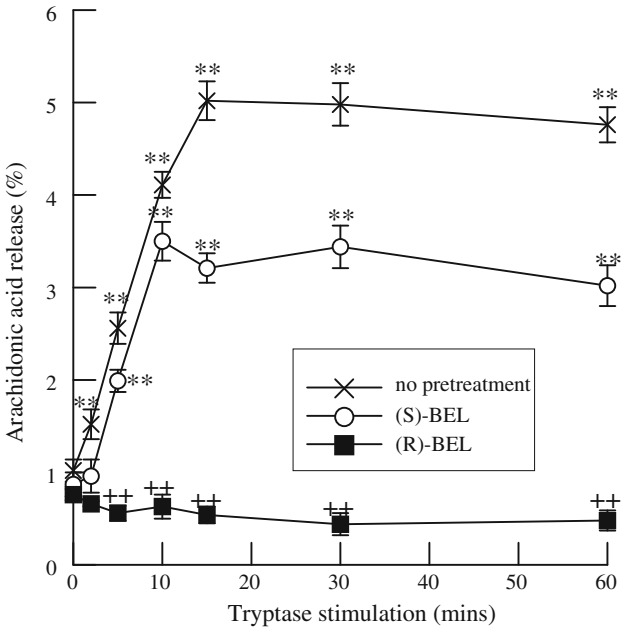

Fig. 3 Increase in arachidonic acid release from tryptase-stimulated (20 ng/mL) rabbit ventricular myocytes with or without pretreatment with (*R*)- or (*S*)-BEL (2 μM, 10 min). $^{**}p < 0.01$ when compared to unstimulated release. $^{++}p < 0.01$ when comparing tryptase stimulated results in the presence or absence of (*R*)-BEL. $N = 6$

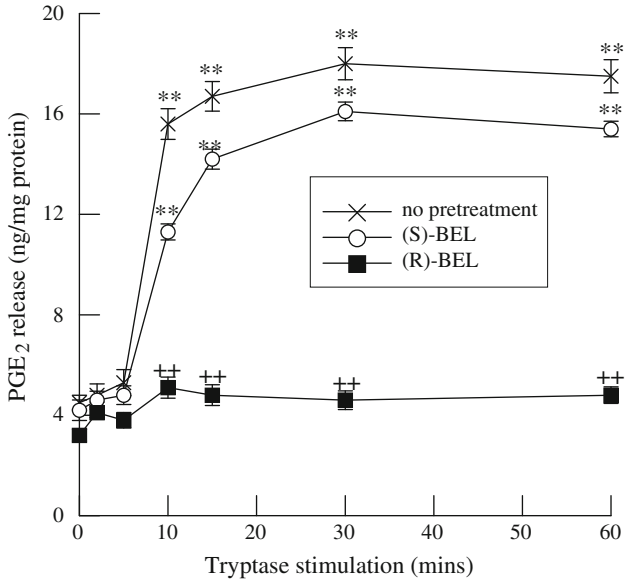

Fig. 4 Increase in prostaglandin E_2 (PGE_2) release from tryptase-stimulated (20 ng/mL) rabbit ventricular myocytes with or without pretreatment with (*R*)- or (*S*)-BEL (2 μM, 10 min). $^{**}p < 0.01$ when compared to unstimulated release. $^{++}p < 0.01$ when comparing tryptase stimulated results in the presence or absence of (*R*)-BEL. $N = 6$

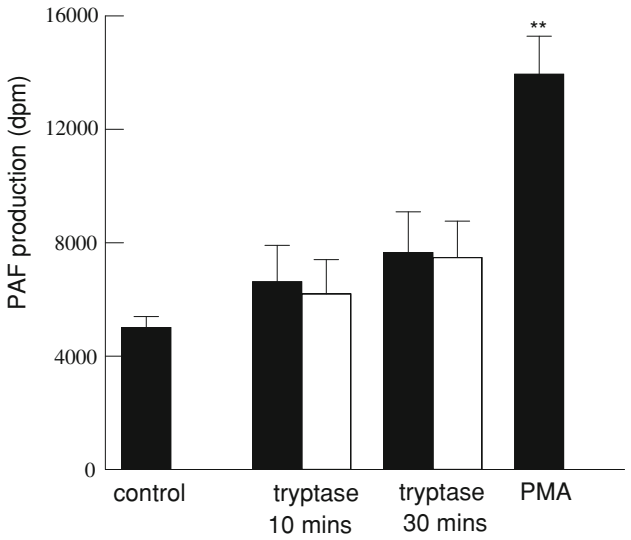

Fig. 5 Platelet-activating factor (PAF) production in rabbit ventricular myocytes stimulated with tryptase (20 ng/mL) or PMA (100 nm, 10 min) with (*open bars*) or without (*filled bars*) BEL pretreatment (2 μM, 10 min). $^{**}p < 0.01$ when compared with unstimulated values. $N = 8$

with our previous findings, PGE_2 release was inhibited completely with (*R*)-BEL, indicating that $iPLA_2\gamma$ activation is mostly responsible for PGE_2 production in tryptase stimulated rabbit ventricular myocytes (Fig. 4).

Effect of Tryptase on PAF Production

Previous studies from our laboratory have demonstrated an increase in PAF production in epithelial and endothelial cells in response to tryptase-stimulated $iPLA_2$ activity. We measured PAF production in rabbit ventricular myocytes following tryptase stimulation and observed no increase after 10 or 30 min stimulation (Fig. 5). However, treatment with PMA (100 nM, 10 min), caused a significant increase in PAF production (Fig. 5). Thus, though capable of producing PAF, tryptase-mediated stimulation of $iPLA_2$ does not appear to increase PAF production in ventricular myocytes.

Discussion

Prostaglandins are synthesized from membrane phospholipids by the sequential action of phospholipase A_2, COX and PG synthase enzymes. They are biologically active mediators which regulate heart rate, coronary blood flow, coronary microvascular permeability and left ventricular contractility [15]. In cardiac myocytes, PGE_2 production exceeds the production of all other PGs [16]. The production of arachidonic acid, a polyunsaturated fatty acid residing in cell membranes, is the rate limiting step for prostaglandin synthesis. Arachidonic acid is liberated from membrane phospholipids via the hydrolysis of the *sn*-2 bond by phospholipase A_2 enzymes and is acted upon by the cyclooxygenases to form PGG_2 and PGH_2, and subsequently converted to PGE_2 by PGE synthase Since PLA_2 determines the amount of arachidonic acid released from cell membranes, it also determines the amount of eicosanoids produced [17].

All major human organ systems, such as gastrointestinal, reproductive, neuroendocrine and immune systems, require PGE_2 to regulate their function [18]. Depending on their site of action, the effects of PGE_2 could be homeostatic, inflammatory or even anti-inflammatory [17]. PGE_2 has diverse actions in inflammation, such as having vasodilatory or vasoconstrictive effects based on various conditions [18]. These conflicting functions and effects make it challenging to elucidate the role of this eicosanoid in physiology and pathology. The receptors via which PGE_2 exerts its action are the prostaglandin E receptors (EP1-4), which are a set of G-protein-coupled receptors that differ in their tissue distribution, structure and signaling pathways [19]. It is suggested that this family of receptors is most likely responsible for the differing actions of PGE_2.

Previous studies from our laboratory have shown that mast cell tryptase activates $iPLA_2$, leading to the upregulation of arachidonic acid and prostaglandin production in epithelial [10] and endothelial cells [9, 11]. Mast cells are known to have a crucial role in a variety of disorders,

however their exact contribution to cardiovascular pathology is still unclear. One of the most distinctive morphological features of mast cells is the presence of numerous electron-dense secretory granules containing various preformed mediators [20]. In humans, mast cells are generally classified according to the type of protease enzymes they contain: tryptase (MC_T), chymase (MC_C) or both tryptase and chymase (MC_{TC}) [21]. It has been reported that the human heart contains 90% MC_{TC} type mast cells [22]. In the heart, mast cell tryptase is known to promote cardiac remodeling by altering the extracellular matrix (ECM) and increasing fibroblast proliferation [4]. Tryptase activates MMPs known to be associated with plaque destabilization and rupture in atherosclerosis and fibrosis associated with myocarditis [2, 23]. In cardiovascular inflammation tryptase levels are known to be elevated [24, 25], thus it is likely that mast cell tryptase directly affects cardiac myocytes following degranulation.

In rabbit ventricular myocytes, we have shown that majority of the PLA_2 activity is calcium-independent, membrane associated and selective for arachidonylated plasmalogen phospholipids [26]. Further, full length sequences of rabbit iPLA$_2\beta$ and γ were determined and found to be 91 and 88% identical to the corresponding human isoforms. We have previously demonstrated the presence of iPLA$_2\gamma$ in microsomes isolated from rabbit heart and ventricular myocytes [27]. Multiple iPLA$_2\gamma$ protein products are localized to intracellular compartments, including the plasma membrane, mitochondria and peroxisomes [28]. Rabbit microsomal iPLA$_2\gamma$ is approximately 88 kDa, which is the long form of iPLA$_2\gamma$ [26, 27]. We determined activation of iPLA$_2\gamma$ in the membrane fraction of ventricular myocytes, which contains sarcolemma and sarcoplasmic reticulum membranes. $iPLA_2$ activity measured in the cytosolic and mitochondrial fractions isolated from ventricular myocytes was not significantly increased by tryptase stimulation (data not shown). Thus, we hypothesize that tryptase stimulation of ventricular myocytes likely activates iPLA$_2\gamma$ localized in the sarcolemma at short intervals of stimulation.

Rabbit myocyte $iPLA_2$ is activated by thrombin in a similar time course to that observed here with tryptase [28]. We have previously observed comparable time courses of $iPLA_2$ activation in response to thrombin and tryptase in human coronary artery endothelial cells [11]. As with endothelial cells, thrombin activation of cardiac myocyte $iPLA_2$ is quicker than with tryptase, suggesting that cell signaling events between $iPLA_2$ activation and protease activated receptor-1 (PAR-1, cleaved and activated by thrombin) or PAR-2 (cleaved and activated by tryptase) are different. We have demonstrated that $iPLA_2$ activation by thrombin is mediated by protein kinase C, possibly via phosphorylation of the enzyme [29]. Pretreatment of tryptase-stimulated ventricular myocytes with GF 109203X (100 nM, 10 min) to inhibit protein kinase C resulted in inhibition of membrane-associated $iPLA_2$ activation (4.2 ± 0.3 nmol/mg protein/min vs. 3.8 ± 0.4 nmol/mg protein, $N = 6$). These data suggest that thrombin or tryptase stimulation results in similar increases in $iPLA_2$ activation and membrane phospholipid hydrolysis and that the presence of PAR-1 and PAR-2 increases the range of proteases to which ventricular myocytes can respond.

In the present study, (*R*)- and (*S*)-BEL were used to ascertain the specific contributions of iPLA$_2\beta$ and γ in ventricular myocytes in response to tryptase stimulation. The majority of membrane associated $iPLA_2$ activity in rabbit ventricular myocytes was inhibited by (*R*)-BEL, indicating that iPLA$_2\gamma$ was responsible. Membrane fractions of ventricular myocytes pretreated with (*R*)-BEL did not show an increase in $iPLA_2$ activity in response to tryptase stimulation. However, pretreatment with (*S*)-BEL did not inhibit tryptase-stimulated $iPLA_2$ activity. Tryptase-stimulated increases in arachidonic acid and PGE_2 release were completely inhibited by pretreatment of ventricular myocytes by (*R*)-BEL, indicating the dependence of these responses on iPLA$_2\gamma$ activation. While it has been determined that PLA_2 is a key enzyme in PGE_2 production, the exact contribution of $iPLA_2$ to this biosynthetic process in cardiac myocytes had not been illustrated. It is of particular interest to know the role of $iPLA_2$ in these settings since majority of the PLA_2 activity in cardiac myocytes is attributable to membrane associated $iPLA_2$. The lysophospholipid produced when arachidonic acid is released from membrane phospholipids by $iPLA_2$ can be acetylated to form platelet activating factor (PAF). PAF has various effects in the cardiovascular system where it is known to decrease cardiac output and affect vascular tone in addition to its direct influence on cardiac myocytes [30]. Previous studies from our laboratory have shown an increase in PAF production in endothelial cells following $iPLA_2$ activation [31, 32]. However, tryptase stimulation of myocytes for up to 30 min did not affect PAF production even though stimulation with PMA resulted in a significant increase in PAF in these cells. This suggests that while cardiac myocytes are able to produce PAF, this process is most likely independent of tryptase stimulation. In a previous study we have determined that thrombin stimulation of rabbit ventricular myocytes failed to increase PAF production [33]. Taken together, these data suggest that thrombin and tryptase activate ventricular myocytes $iPLA_2$ to release arachidonic acid from membrane phospholipids, but the accompanying lysophospholipid is not acetylated to form PAF.

In conclusion, our data suggest that in response to tryptase stimulation, majority of the $iPLA_2$ activity in rabbit ventricular myocytes is due to iPLA$_2\gamma$. This results in increased arachidonic acid and PGE_2 production, but does not affect PAF production in tryptase-stimulated myocytes.

Oral Docosapentaenoic Acid (22:5n-3) Is Differentially Incorporated into Phospholipid Pools and Differentially Metabolized to Eicosapentaenoic Acid in Tissues from Young Rats

Bruce J. Holub · Patricia Swidinsky · Eek Park

Received: 30 August 2010 / Accepted: 13 January 2011 / Published online: 6 March 2011

Abstract The present study assessed the effect of oral supplementation with docosapentaenoic acid (DPA, 22:5n-3) on the levels of serum and tissue lipid classes and their fatty acid compositions including individual phospholipid types in rat liver, heart, and kidney. Sprague–Dawley rats received daily oral gavage over 10 days as corn oil without (controls) or with purified DPA in free fatty acid form (21.2 mg/day). The DPA group exhibited significantly lower serum lipid concentrations. The concentrations in μmol/100 g serum or μmol/g tissue of DPA in the total lipid (TL) were higher by 2.3-, 2.4-, 10.9-, and 5.1-fold in the DPA group of serum, liver, heart, and kidney, respectively, with the phospholipids (PL) being the major DPA reservoir (45.2–52.1% of the DPA in the TL). No significant differences in DHA (22:6n-3) amounts in TL appeared. The highest relative mol% values as DPA were in heart tissue (means of 11.1% in PL and 16.2% in phosphatidylinositol) and lowest in kidney. The EPA (20:5n-3) concentrations were markedly higher in the DPA group and most pronounced in the kidney (5.1 times higher in the TL as compared to controls) relative to liver and heart yielding an estimated apparent % conversion of DPA to EPA of 67% and EPA:DPA ratios reaching 5.74 in kidney phosphatidylethanolamine. The serum lipid-lowering potential of dietary DPA and its impact in the kidney with the derived EPA warrants investigation.

Introduction

Docosapentaenoic acid (DPA, 22:5n-3) as present in seal meat, whale meat/blubber, plus some fish/fish oils to a lesser extent is a significant component of the long-chain omega-3 fatty acids found in the Inuit diet [1]. While eicosapentaenoic acid (EPA, 20:5n-3) plus docosahexaenoic acid (DHA, 22:6n-3) are credited for the apparent cardioprotective effects of diets rich in marine fats [2],

higher levels of DPA in the circulation have been associated with a lower risk for coronary heart disease in population studies [3]. Furthermore, DPA has shown the ability to inhibit human platelet aggregation in vitro and to suppress thromboxane formation [4]. Intervention trials using seal oil containing DPA in addition to EPA/DHA have exhibited beneficial effects on selected cardiovascular disease risk factors in healthy volunteers [5, 6]. The much lower intakes of DPA in the diets of populations who consume small amounts of fish are derived mostly from meat plus poultry [7].

Very recently, supplementation with DPA in rats has indicated that it is both elevated and partly retroconverted to EPA in liver, adipose, heart, and skeletal muscle based on total lipid analyses along with data suggesting that dietary DPA can be converted to DHA in the liver [8]. We have extended the previous work herein by measuring the effect of DPA-supplementation in the rat on the levels of various serum and tissue lipids and their fatty acid profiles as well as the fatty acid compositions of various lipid fractions including individual phospholipids in liver, heart, and kidney. This present study differs from previous work [8] which was restricted to total lipid analyses only in selected tissues and excluded the serum and kidney. The present findings reveal dramatic differences in the resulting fatty acid compositions between individual lipid/phospholipid classes upon DPA supplementation and indicate a particularly high capacity for the retroconversion of DPA to EPA in the kidney.

Experimental Procedure

Animals and Study Design

This study was approved by Animal Care Services, Office of Research, University of Guelph (Animal Utilization Protocol No. 96R093). Seventeen male Sprague–Dawley weanling rats (Charles River Canada, St. Constant, P.Q.) having an average body weight of 49.6 ± 0.6 g and approximately 21 days of age were randomly housed in stainless steel cages with 12 h light–dark cycle and a constant room temperature of 25 °C. All animals were fed (ad libitum) Purina Laboratory Chow (Purina Mills Inc., St. Louis, MO), devoid of long-chain n-3 fatty acids including DPA, and given either 500 μL per day of corn oil alone (control group; Mazola Corn Oil, Corn Products Inc., St. Louis, MO) or an equal volume of corn oil containing a small amount of purified DPA [Nu-Chek Prep Inc., Elysian, MN, U-101-A (free fatty acid form), >99% DPA devoid of 20:5n-3 and 22:6n-3] via oral gavage. The fatty acid composition of the two oral gavages, namely corn oil versus corn oil-DPA, contained mostly oleic acid (28.9 and 26.5 wt%) and linoleic acid (55.0 and 53.4 wt%) with DPA representing 0 and 4.24 wt%, respectively, of total fatty acids. The oral gavages were administered for a period of 10 days after which time the animals were sacrificed and various tissues (plus serum via blood centrifugation) were taken for analyses. The dietary conditions and compositions (including oral gavage) for the DPA group (DPA-supplemented rats) were estimated to provide approximately 2.5% of the total fat intake (oral gavage plus dietary chow) as DPA which is in the general range as reported historically for the Greenland Inuit population [9]. In absolute amounts, the DPA dose was 21.2 mg/day which is higher than Inuit intakes on a body weight basis.

Lipid and Fatty Acid Analyses

Total serum cholesterol levels were determined by a microcolorimetric method [10]. The individual lipid classes were separated by thin-layer chromatographic (TLC) procedures following lipid extraction using methods similar to those described [11, 12]. The TLC plate developed in the neutral lipid system provided for the separation of triacylglycerols (TAG), total phospholipids (PL), non-esterified fatty acids (NEFA), and cholesteryl esters (CE) whereas development in the polar lipid system provided isolations of the individual phospholipids including phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn), phosphatidylinositol (PtdIns), phosphatidylserine (PtdSer), and sphingomyelin (CerPCho) as described [11, 12]. The addition of known amounts of an internal standard (odd-carbon fatty acid) to the total lipid (TL) extracts and the isolated lipid fractions provided for determination of both the individual and total fatty acid amounts plus the relative wt% of total fatty acids following transmethylation and gas–liquid chromatographic analyses [11, 12].

Statistical Analyses

The experimental data were analyzed for statistical significance by Student's t-test [13].

Results

The initial and final body weights (following 10 days of oral gavage treatment) for all animals ($n = 17$) were 49.4 ± 0.4 (mean ± SE) and 102.2 ± 2.4 g, respectively. Weights of liver, heart, and kidney were 5.13 ± 0.17, 0.47 ± 0.01, and 0.57 ± 0.02 g, respectively. Total serum fatty acid amounts in the TL of the DPA-supplemented rats were significantly lower (by 15.7% overall) relative to controls (Table 1). Moderately lower levels were also found for the PL (by 13.4%) and the CE (by 15.9%)

Table 1 Concentrations (μmol/g serum) of total fatty acids in serum lipids from control and DPA-supplemented rats

Lipid class	Control	DPA
Total lipid (TL)	4.71 ± 0.25	3.97 ± 0.13[a]
Total phospholipids (PL)	2.02 ± 0.05	1.75 ± 0.05[b]
Triacylglycerols (TAG)	0.93 ± 0.13	0.73 ± 0.12
Non-esterified fatty acids (NEFA)	0.24 ± 0.02	0.27 ± 0.02
Cholesteryl esters (CE)	1.13 ± 0.06	0.95 ± 0.06[a]
Total cholesterol (TC), μmol sterol/g serum	2.17 ± 0.07	1.91 ± 0.04[b]

Data are mean values ± SE for 8 rats from each group

Statistical significance (DPA vs. control): [a]$P < 0.05$, [b]$P < 0.01$

whereas this was not statistically significant in the case of the TAG where the mean level was 21.5% lower as compared to the controls. Total serum cholesterol levels were moderately lower (by 12.0%) and statistically significant ($P < 0.01$) for the DPA group relative to controls (Table 1). The absolute amount of DPA in TL (μmol/100 g serum) increased by 2.28-fold in the DPA-supplemented rats relative to controls (Fig. 1) with considerable increases apparent in all the individual lipid classes. The single major reservoir of DPA following DPA supplementation was in the PL at a mean of 3.66 μmol/100 g serum (49.2% of DPA in TL) with the TAG, NEFA, and CE contributing 32.0, 13.1, and 5.3%, respectively. The corresponding concentrations (μmol/100 g serum) for EPA in the TL of the control versus DPA groups were 5.65 ± 0.50 and 12.13 ± 0.69, respectively, with a P value of <0.001. Interestingly, the single major reservoir of EPA was in the serum CE at 6.55 ± 0.46 μmol/100 g serum which represented 54.0% of the EPA in the TL for the DPA group. The absolute levels (μmol/100 g serum) of DHA in serum TL (Fig. 2) were not significantly different with values of

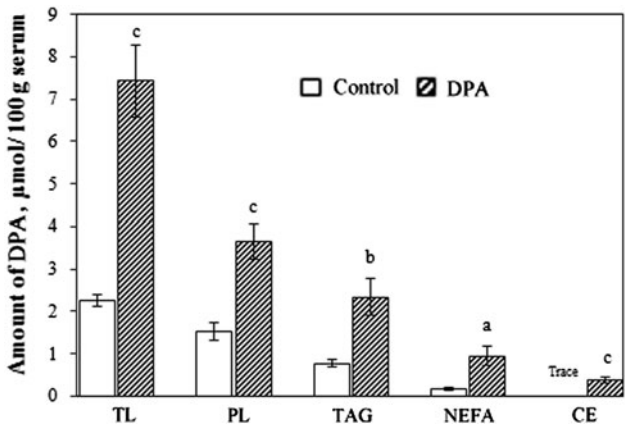

Fig. 1 Concentrations of DPA (22:5n-3) in serum lipids from control and DPA-supplemented rats. Statistical significance (DPA vs. control): [a]$P < 0.05$, [b]$P < 0.01$, [c]$P < 0.001$

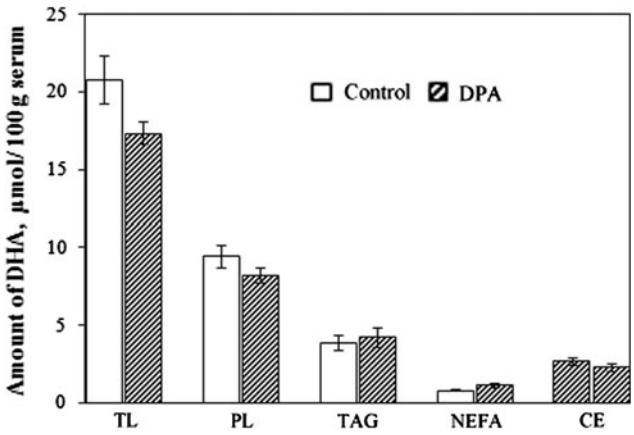

Fig. 2 Concentrations of DHA (22:6n-3) in serum lipids from control and DPA-supplemented rats. No statistically significant differences were found between the DPA versus control group

20.79 ± 1.55 and 17.38 ± 0.76 for the control and DPA groups, respectively. Significantly lower concentrations ($P < 0.001$) of ARA but not 18:2n-6 were found in the TL of the DPA group (48.70 ± 4.70) relative to the controls (87.88 ± 3.74).

The relative mol% of total fatty acids as DPA following supplementation was moderately higher in the TAG fraction as compared to the serum PL with the lowest level being in the CE (Table 2). A moderately higher level of DHA ($P < 0.05$) was found only in the TG upon DPA supplementation although the absolute amounts of DHA (in μmol/g serum) were not significantly different between the control and DPA group for any of the lipid fractions (data not shown). Significantly higher levels of EPA (Table 2) were found in the DPA group—particularly in the TAG and CE fractions. Markedly lower levels of arachidonic acid (ARA, 20:4n-6) but not linoleic acid (18:2n-6) were found in the TAG, PL, and CE within the DPA group relative to controls.

The total fatty acid amounts in TAG were considerably lower in the liver TAG of the DPA group relative to control (1.49 ± 0.28 vs. 4.07 ± 0.94, μmol/g tissue) and in the kidney TAG (2.30 ± 0.25 vs. 4.93 ± 0.56) whereas no statistically significant differences were found in the heart TAG or in the PL for any of the three tissues. The absolute concentrations of DPA in the total lipids of liver, heart, and kidney were dramatically higher (by 2.4-, 10.8-, and 5.1-fold, respectively) in the DPA group relative to controls without any statistically significant differences in the DHA contents (Table 3). The tissue concentrations of DPA in the PL fraction for the DPA group contributed 1.26 ± 0.11 (mean ± SE), 1.17 ± 0.05, and 0.54 ± 0.03 μmol/g tissue which represented 52.1, 45.2, and 51.9% of the DPA amounts in TL for liver, heart, and kidney, respectively. EPA levels were higher in the DPA group by 3.9-, 2.2-, and 4.1-fold, respectively. Considerably lower levels of ARA

were found in the liver and kidney upon DPA supplementation relative to controls with no significant differences appearing in heart tissue. No significant differences in the absolute amounts of 18:2n-6 were found in any tissue between the DPA and control groups (data not shown). The relative mol% of total fatty acids as DPA was found to be significantly higher in the TL, PL, and TAG for all three tissues in the DPA group (Tables 4, 5, 6). The DPA rose to similar levels (mean values of 2.93–3.62 mol%) in liver TL, PL, and TAG upon DPA supplementation with the highest level by far of DPA in the PL of all tissues being in the heart (11.09 mol%). In the case of TAG, the highest level of DPA following DPA-supplementation was in the kidney (5.33 mol%) followed by the heart and liver. The DHA levels as mol% were significantly higher in the DPA group relative to controls in the TAG but not the PL of all three tissues. In heart tissue, the DHA level was actually significantly lower in the PL fraction of the DPA group. Following DPA supplementation, the mol% of EPA was considerably higher in the PL as compared to the TAG fraction for all tissues and, in the case of the kidney, the mol% as DPA markedly surpassed that of DPA itself. In all three tissues, the PL exhibited a significant lowering of the mol% as ARA in the DPA group which was even more pronounced in the case of 22:5n-6.

The relative mass distribution (based on μmol/g tissue) for the esterified DPA (DPA group) found in association with the individual phospholipid types in the three tissues (Fig. 3 a–c) indicates that the major reservoir of DPA was almost equally distributed between PtdCho (39.3–46.4% of total) and PtdEtn (38.0–44.7% of total). The highest mol% of fatty acids as DPA for each individual phospholipid (Table 7) was found in heart tissue (relative to liver and kidney). In contrast, the levels of EPA for all individual phospholipids were considerably higher in kidney compared to the corresponding phospholipids in the other

tissues (Table 7). The highest EPA:DPA molar ratios for all individual phospholipids were found in the kidney ranging from 1.03 in PtdIns to 5.74 in PtdEtn. The corresponding ratios across individual phospholipids were lowest in heart tissue (0.03–0.08) with intermediary ratios being found in the liver (0.15–0.91).

Discussion

Previous studies involving the feeding of dietary seal oil to human subjects have demonstrated a significant elevation in the level of DPA in the circulating lipid fractions [5, 6] as well as a significant rise in DPA concentrations in tissue lipid in animal studies [14]. Such effects cannot be directly attributed to the consumption of DPA since it represents approximately 5% of the fatty acids in seal oil with the higher level of EPA having the capacity to generate considerable amounts of DPA via chain elongation [15, 16]. In addition, previous studies in humans on the effects of dietary seal on circulating lipids [5, 6] cannot be attributed to the effects of DPA specifically since EPA plus DHA are more predominant components of such oils. In their newly released review, Kaur et al. [17] have updated the current knowledge available on the metabolism and the biological effects of DPA. The recently published study by Kaur et al. [8] evaluated the effect of purified dietary DPA directly in rats on the fatty acid compositions of liver, adipose, heart, skeletal muscle, and brain. The present study has measured changes in plasma and tissue lipid levels and fatty acid

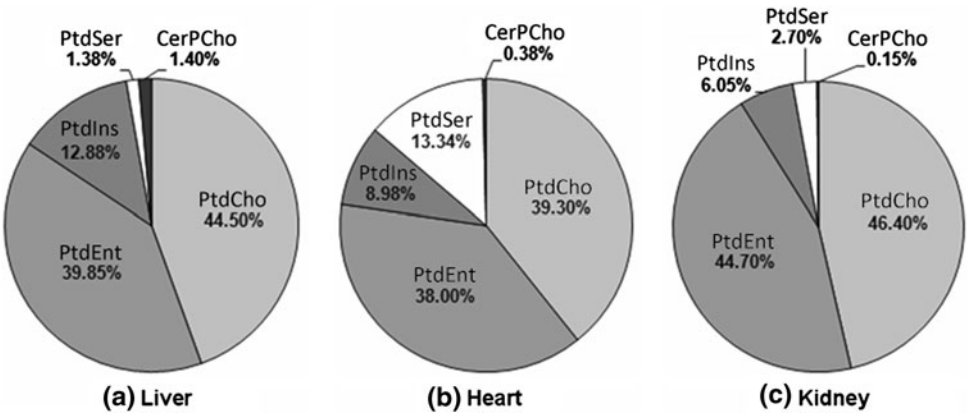

Fig. 3 The relative % distribution (based on μmol/g tissue) for the esterified DPA (DPA group) found in association with the individual phospholipid types in the liver, heart, and kidney

compositions resulting from DPA ingestion including an extensive analyses of the resulting fatty acid alterations in the liver, heart, and the kidney and individual phospholipid types therein.

The moderately lower levels of total lipid (based on total fatty acid concentrations) in the serum lipid of the DPA group (Table 1) was accounted for by significantly lower levels of the summed fatty acid as PL and CE while the lower levels as TAG did not reach statistical significance. Such measurements of circulating lipids were not reported in the recent publication by Kaur et al. [8]. Moderately lower levels of total serum cholesterol were also found in the present study as was found for plasma cholesterol levels in rats following dietary treatment with concentrated DHA [16]. In the circulation, serum PL was the single predominant reservoir of esterified DPA whereas the TAG fraction showed a moderately greater enrichment (as mol% of total fatty acids) in DPA as compared to PL (Table 2). Interestingly, the very low level of accumulation of DPA in serum CE (0.41%) upon supplementation (Table 2) resulted in the DPA:ARA molar ratio in serum CE to be only a small fraction of that in the corresponding PL (0.012 vs. 0.23). Since serum CE is derived from LCAT (lecithin:cholesterol acyltransferase) activity [18, 19] and tissue (liver) ACAT (acyl-CoA:cholesterol acyltransferase) activity [20], such esterification reactions appear to discriminate against substrates containing DPA. Previous human studies on plasma LCAT have suggested a preferential utilization of EPA-containing species of phospholipid (lecithin) relative to DHA species [21] which appears in keeping with the much higher levels of EPA (relative to DHA) in the serum CE relative to the PL of the DPA supplemented rats (Table 2). It is not yet known if the relative participation of DPA species in the LCAT reaction may influence its apparent role in reducing atherosclerosis [19]. It is noted that higher intakes of DPA in humans and higher levels of DPA in the circulation have been associated with protection against carotid atherosclerosis [22] and coronary heart disease [3].

Data are mean values ± SE for each group or mean values only (EPA:DPA ratio)

The considerably lower concentrations of TAG in the liver (by 64%) and kidney (by 53%) in the DPA-supplemented rats as found herein are consistent with the TAG-lowering effect of fish oils containing EPA plus DHA in these same tissues as reported [11, 23]. Potential mechanisms for such a suppression in tissue TAG levels with dietary DPA likely involve a diminution in lipogenic enzyme activities and corresponding gene expression, a significant suppression in 1,2-diacylglycerol conversion to TAG via CoA:1,2-diacylglycerol acyltransferase, and/or increased fatty acid oxidation [11].

In addition to the markedly higher concentrations of DPA in the TL and individual lipid types relative to controls in the DPA group, considerably higher levels of EPA were also found in the TL of serum, liver, heart, and kidney along with considerable heterogeneity in the magnitude of such elevations across the various lipid classes (Fig. 1; Tables 3, 4, 5, 6). The DPA concentration in liver averaged 2.42 μmol/g tissue (Table 3) which was approximately 20% lower than that reported upon DPA supplementation in the recent paper by Kaur et al. [8] which likely reflects the lower dose in our study (21.2 vs. 50 mg/day) and differences in animal body weights. We found a moderately higher rise in concentration of DPA in heart as compared to liver as observed by others [8] which may reflect a preferential uptake of DPA by cardiac tissue. In their study, Kaur et al. [8] observed increased concentrations of EPA, in addition to DPA, in liver, heart, and skeletal muscle which they attributed to the process of DPA retroconversion into EPA in vivo as described by others and attributed to involve the peroxisomal acyl-CoA oxidation [24, 25]. The former authors [8] estimated the extent of apparent retroconversion of DPA to EPA as [ΔEPA × 100/Δ(DPA + EPA)] and reported such to be 28% in liver and 4% in heart. Using such an approach from our data (Table 3), our corresponding estimates are generally similar to the aforementioned and amount to 41 and 5%, respectively. The moderately higher estimated percentages from our data may be due in part to the longer (10 day) supplementation regimen in our research as compared to 7 days by the other group [8]. It is particularly interesting that the estimated % conversion of DPA to EPA based on our kidney data (Table 3) is 67% and dramatically higher than that reported for all other tissues by us herein plus the previous work [8]. It is possible that the kidney may have an unique affinity for the uptake of EPA; however, this appears unlikely since it has been observed that the feeding of purified EPA to rats resulted in a lower mean EPA % in the kidney as compared to liver lipids [16]. It is likely that the kidney has a particularly high capacity for the retroconversion of DPA to EPA which accounts for the predominance of EPA over DPA following DPA supplementation in the total lipid, total phospholipid, and major phospholipid fractions (Tables 3, 6, 7).

The significantly lower percentages of fatty acids as ARA in the PL of all tissues with DPA supplementation (Tables 4, 5, 6), and as DHA in heart PL, likely represents competition from DPA and the derived EPA for esterification via acyltransferase activities. The relative cellular availability and preferential utilization of DPA versus other long-chain n-3 and n-6 fatty acids plus its enzymic competition with such for entry into individual phospholipid

types via various de novo biosynthetic, deacylation-reacylation, and transacylation reactions [26, 27] likely contribute to the fatty acid profiles in PtdCho, PtdEtn, PtdIns, and PtdSer following DPA ingestion (Table 7). The particularly high enrichment of heart PtdIns, PtdEtn, and PtdSer with DPA upon supplementation (Table 7) may possibly arise from a preferential utilization of DPA-CoA by the corresponding acyltransferase reactions and/or other reactions in the biosynthetic pathways. The marked differences in such compositions indicate that much heterogeneity exists in the regulation of DPA levels along with other long-chain polyunsaturates (PUFA) between individual phospholipid types and tissues. The extent to which these compositions influence the formation and functioning of bioactive products resulting from DPA such as hydroxylated derivatives via lipoxygenase activities [28] including cellular mediators from ARA, EPA, and DHA [29] upon their enzymic release from these PL reservoirs remains to be studied.

The observed serum lipid-lowering potential of DPA and other physiological effects will need evaluation in human trials as concentrates of DPA (devoid of EPA/DHA) become available in bulk amounts. Our current results strongly suggest a particularly high capacity for the apparent retroconversion of DPA to EPA in the kidney which is worthy of further investigation with respect to mechanisms and potential significance to renal functioning in health and disease.

Dietary n-3 Fatty Acid Deficiency in Mice Enhances Anxiety Induced by Chronic Mild Stress

Akiko Harauma · Toru Moriguchi

Received: 8 September 2010 / Accepted: 21 December 2010 / Published online: 7 February 2011

Abstract Docosahexaenoic acid (DHA), is the major polyunsaturated fatty acid in the brain and is important for both the structure and the function of the nervous system. Mice were fed either an n-3 fatty acid deficient (n-3 Def) or adequate (n-3 Adq) diet for two generations. The mice were housed under two conditions, as a group or in isolation and the major point of the study was to determine whether n-3 fatty acid deficiency would enhance isolation-induced anxiety. Isolation stress was assessed using the novelty suppressed feeding paradigm (NSF) after a 3-week period and the test lasted a maximal duration of 10 min. The number of successful mice consuming food pellets within 5 min in the n-3 Def diet group was low in both housing conditions (group housing, 33% and isolated, 30%), but was 92% in the group housed and 50% in the isolated group when fed the n-3 Adq diet. In the subsequent 5 min period, the isolated housing group consuming the n-3 Adq diet increased up to 79% and the group housed animals fed the n-3 Def diet increased to 67%. However, those that consumed the n-3 deficient diet combined with isolation stress exhibited no increase. These results suggested that the n-3 deficient mice had increased anxiety that was enhanced by the chronic mild stress of social isolation.

DHA	Docosahexaenoic acid, 22:6n-3
PUFA	Polyunsaturated fatty acid(s)

Introduction

The n-3 fatty acids, α-linolenic acid (ALA, 18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) are nutritionally essential polyunsaturated fatty acids and cannot be synthesized de novo in mammals. These fatty acids, particularly DHA, exist mainly in the form of membrane phospholipids which are known to be crucial for maintaining normal brain structure and function [1]. It has been well documented that animal model of dietary n-3 fatty acids deprivation produces a loss of brain function. Several rodent studies have reported that lower DHA levels in the brain led to poorer performance on a variety of cognitive and learning tasks [2–5]. There have recently been several reports concerning various mental functions including mood variations and underlying mechanisms. For example, epidemiological studies of healthy people and postpartum women indicate a negative correlation between dietary n-3 PUFA intake and mental illness including serious mood disorders, aggression, depression, and bipolar disorder [6–9]. These findings suggest that mental illness may be associated with reduced dietary intake of n-3 fatty acids. In animal studies, Delion et al. [10] indicated that an n-3 fatty acid deficient diet specifically affects the monoaminergic system in brain.

Kodas et al. [11] showed that dietary n-3 deficiency induced changes in the synaptic levels of 5-HT. On the other hand, it has been known that monoamine level in the brain are altered by chronic mild stress which may be induced by such animal housing conditions as lack of bedding, wet bedding, a tilted cage etc. [12, 13]. These lines of inquiry together suggest that n-3 fatty acid deficiency and stress are both factors that can modulate aspects of mental illness such as depression and anxiety.

In this study, the effects of n-3 fatty acid deficiency and social isolation stress were tested in mice using the novelty suppressed feeding paradigm (NSF) with the hypothesis that the combination of these factors would lead to the highest level of anxiety [14]. The NSF test has been considered useful for assessment of anxiety as it has lower sensitivity to changes in cognitive factors and thus has been used to evaluate anti-anxiety and anti-depressant drugs [15–17].

Materials and Methods

Animals and Study Design

Female CD-1 (ICR) mice were obtained at 3 weeks of age from Charles River Japan, Inc. and fed an n-3 deficient (n-3 Def) or n-3 adequate (n-3 Adq) diet (see experimental diet, Table 1). They were maintained within our animal facility under conventional conditions with controlled temperature (23 ± 3 °C), humidity (55 ± 10%), and illumination (12 h; 0700–1900). At 7 weeks of age, they were mated with 8-week-old males of the same strain (experimental scheme presented in Fig. 1). Their litters were culled to ten pups and the pups were weaned onto the same diet as their mothers. Each individual in a cage of five mice was from a different litter. When the male offspring (second generation) were 8 weeks old, half of them in the each diet group were maintained in a cage containing five mice (group housed), the other half were housed individually for 3 weeks (isolation group). Behavioral experiments were conducted when the male mice were 11 weeks of age. Spontaneous motor activity was first measured for each mouse and after following a 15-h fast, each animal was given the NSF test [15–17].

After the behavioral experiments, they were killed by decapitation and the brain and blood were collected. Blood was spun in a refrigerated centrifuge at 2,300×*g* for 15 min at 4 °C. An aliquot of the upper plasma phase was transferred to another tube. The plasma and brain samples were frozen at −80 °C prior to lipid extraction and measurement of fatty acid composition. This experimental protocol was approved by the Animal Care and Use Committee of the Wakunaga Pharmaceutical Co. in Japan.

Table 1 Composition of experimental diets

Ingredient	Amount (g/100 g diet)	
	n-3 Def.	n-3 Adq.
Casein, vitamin free	20	20
Carbohydrate	60	60
Cornstarch	15	15
Sucrose	10	10
Dextrose	19.9	19.9
Maltose-dextrin	15	15

TBHQ	0.002	0.002
Fat	10	10
Hydrogenated coconut oil	8.1	7.75
Safflower oil	1.9	1.77
Flaxseed oil	None	0.48
Fatty acid composition[a]		
Saturates	80.3	76.7
Monounsaturates	3.8	5.2
18:2n-6	15.7	15.0
18:3n-3	0.14	2.5
n-6/n-3	112	5.9

The two experimental diets, an n-3 fatty acid adequate diet (n-3 Adq) and an n-3 fatty acid deficient diet (n-3 Def), were based on the AIN-93 formulation with several modifications to obtain the extremely low basal level of n-3 fatty acid required in this study

[a] The 20:4n-6, 20:5n-3 and 22:6n-3 fatty acids were less than 0.01%

Experimental Diet

The two experimental (n-3 Def and n-3 Adq) diets used were based on the AIN-93G diet recommendations for rodents (Table 1). The fat sources were altered to provide for the low n-3 fatty acid content required. The only difference between the n-3 Def and the n-3 Adq diets was the amount of n-3 fatty acids. This was achieved by adding a small amount of flaxseed oil to the n-3 Adq diet. The basal fat ingredients used were hydrogenated coconut and safflower oils for the n-3 Def diet. The fat content in both diets was 10/100 g diet and the amount of n-3 fatty acids as ALA in the n-3 Def and the n-3 Adq diets were 0.14 and 2.5% of total fatty acids, respectively. There was no difference in the total n-6 fatty acids between the two diets (n-3 Def, 15.7%; n-3 Adq, 15.0%). This diet was custom prepared and pelleted using low heat conditions (about 65 °C), then stored at 4 °C to prevent lipid oxidation (Oriental Yeast, Chiba, Japan) and the fatty acid distributions of the entire diet was quality assured within our own laboratory.

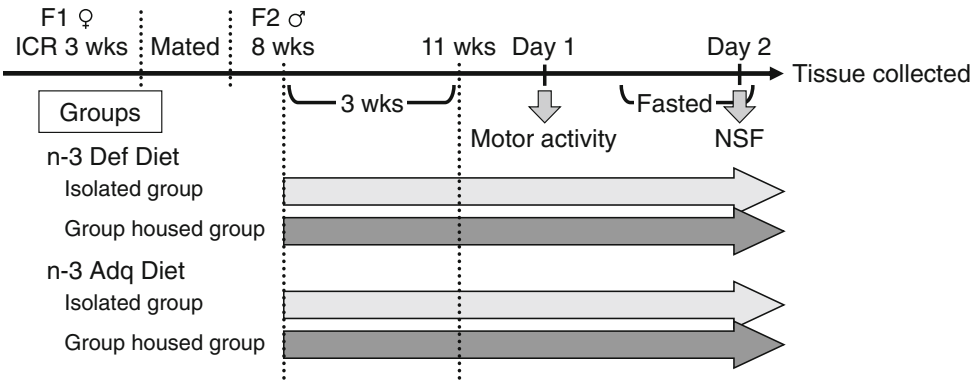

Fig. 1 Schematic diagram illustrates study design. Half of the mice in the each diet group were switched to the isolated housing condition from 8 weeks of age for 3 weeks. NSF was conducted the day following measurement of motor activity at 11 weeks of age. After NSF, the mice were killed by decapitation and plasma and brain collected and the tissues analyzed for fatty acid composition

Behavioral Experiment

The behavioral experiments including motor activity and NSF were performed in the morning (0900–1200 hours). Motor activity was measured using an activity sensor (Model NS-AS01, Neuroscience, Inc., Tokyo Japan). Each mouse was individually placed into a cage (22 × 34 × 14 cm), and the ambulatory time was measured during spontaneous motor activity for 30 min. After the measurement of motor activity, each mouse was returned to its home cage. The NSF was conducted the day following measurement of motor activity. All diet in the home cage was removed for 15 h prior to NSF testing. The NSF procedure was modified from that previously reported [15–17]. The test chamber was composed of an acrylic box (50 × 50 × 20 cm), and the floor was covered with approximately 2 cm of wooden bedding. At the time of testing, a single pellet of diet (n-3 Def or n-3 Adq diet) was placed on a platform positioned in the center of the box. A mouse was placed in a corner of the chamber and the session was recorded by video camera (HDR-SR1, SONY, Tokyo, Japan) until the mouse began to eat the pellet. The measurement time was set for 5 min and was extended to 10 min if eating behavior did not occur within the first 5 min. The parameters measured were the time to initially touch the food pellet, the latency of beginning to eat the pellet (defined as the mouse sitting on its haunches and biting the pellet with the use of forepaws) and the number of mice that were successful in eating (they ate within the measurement period). When the mouse failed to eat the pellet within 5 or 10 min, the latency was calculated as, 300 or 600 s, respectively. After starting to eat the pellet, the mouse was immediately transferred to a new cage in order to control for the time spent in the testing cage. The amount of food consumed over the 5 min period was measured. The feeding drive of each mouse was assessed by returning it to the familiar environment of its home cage immediately after the NSF test and measuring the amount of food subsequently consumed over a 5 min period.

Lipid Extraction, Transmethylation and Gas Chromatography

Tissue samples were thawed, weighed, and homogenized in methanol–hexane and methylated in acetyl chloride according to the modified method of Lepage and Roy [18]. Varying amounts of the internal standards methyl docosatrienoate (22:3n-3 for brain) or methyl tricosanoic (23:0 for plasma) were added to each sample to compensate for differences in tissue weight and lipid concentration (70 μg/250 mg brain, 20 μg/100 μl plasma). As an aid in preventing lipid oxidation during the procedures, 50 μg/ml of butylated hydroxytoluene was added in the methanol. The hexane extracts were concentrated into micro vials for gas chromatographic (GC) injection.

Fatty acid methyl esters were analyzed with a GC-2010 Network Gas Chromatograph (Shimadzu CO.LTD, Kyoto, Japan) equipped with a split injector, an AOC-20i automatic liquid sampler and an FID detector. The instrument was controlled and data was collected with GC solution (Shimadzu Co. Ltd, Kyoto, Japan). The GC column was a DB-FFAP 15 m × 0.10 mm i.d. × 0.10 μm film thickness (J&W Scientific from Agilent Technologies, California, US). The detector temperature was set at 260 °C and the injector at 250 °C. The oven temperature program began at 150 °C with a 0.25 min hold, and then ramped at 35 °C/min to 200 °C, then 3 °C/min to 225 °C with a 2.0 min hold, and finally ramped at 80 °C/min to 245 °C with a 25 min hold. Helium was used as carrier gas at a linear velocity of 56 cm/s [19]. A custom-mixed, 28-component, quantitative methyl ester standard containing 10–24 carbons and 0–6 double bonds was used for assignment of retention times and to ensure accurate quantification (Nu Chek Prep 462, Elysian, MN). The amount of each fatty acid was

expressed as the mole percentage (mol%) of total fatty acid content.

Statistical Analysis

All data are expressed as the mean ± the standard error of the mean (SEM). First touch time, food consumption and lipid composition in the plasma and brain were analyzed by Tukey test after one-way ANOVA. Latencies until eating the diet were evaluated using the Mann–Whitney *U* test, the number of successful mice were evaluated by Fisher's exact probability test (Statistica, Statsoft Japan, Tokyo, Japan).

Results

In this study, two types of diets were used including an n-3 Adq diet containing both n-6 (about 15% linoleic acid) and n-3 fatty acids (about 2.5% ALA) and an n-3 Def diet with the same level of linoleic acid but nearly devoid in n-3 fatty acids (0.14%). These diets produced no significant differences in body weight gain between dietary groups during the testing period (Table 2). Prior to starting the NSF measurements, mice were subjected to a single 30 min motor activity trial in which their moving time was recorded. There were no significant differences between any of the dietary groups in spontaneous motor activity (data not shown).

In the time of first touch of the food pellet in the NSF experiment, there was no significant difference between the n-3 Def and n-3 Adq groups in either housing condition (Table 2). The latency to eat diet in the n-3 Adq-group housed group in the first 5 min was 179.9 ± 20.7 (sec) and was significantly shorter than that of the other three groups (the n-3 Def-isolated group, 264.0 ± 24.0, $P < 0.05$; the n-3 Def-group housed, 248.8 ± 22.1, $P < 0.05$; the n-3 Adq-isolated group, 250.3 ± 19.9, $P < 0.05$). Also, these differences continued to be evident when measured after 5 min (Table 2).

The proportion of successful mice, those eating a food pellet within the first 5 min, was 30% (3/10 animal) in the n-3 Def-isolated housing group, 33% (5/15) in the n-3 Def-group housed, 50% (7/14) in the n-3 Adq-isolated group and 92% (12/13) in the n-3 Adq-group housed group, respectively (Fig. 2a). Most mice in the n-3 Def-isolated group were not able to perform the task, but the n-3 Adq-group housed animals were very successful. These proportions indicated a significant difference ($P < 0.01$) between the n-3 Def and n-3 Adq diet groups in the control breeding condition, i.e., group housed animals, but there was no significant difference between dietary groups in the isolated housing groups. Also, there was a significant difference between the isolated and group housed animals who consumed the n-3 Adq diet ($P < 0.05$), but this difference was not detected between the groups consuming the n-3 Def diet.

When the analysis of the measurement time was extended to its maximum of 10 min, the proportion of successful mice in each group increased to 67% (10/15) in the n-3 Def-group housed and to 79% (11/14) in the n-3 Adq-isolated, thus increasing to a level similar to that of the n-3 Adq-group housed animals (Fig. 2b). It was of importance that only the n-3 Def-isolated group remained at the same low level of success (30%) even when the trial was extended to 10 min. There was a significant difference between the n-3 Def and n-3 Adq diet groups in the isolated housing groups ($P < 0.01$). The significant difference between dietary groups in the group housed condition which was detected in the 5 min evaluation disappeared during the extended period. Also, there was the tendency for a difference between housing conditions in the n-3 Def diet group, although this was not observed in the 5 min evaluation. There was no appreciable difference between any of the groups in food consumption at the 5 min time point during NSF testing (data not shown).

The mice were killed and plasma and brain collected after the behavioral testing was completed. The lipid composition in these tissues was analyzed in order to

Table 2 Enhancement of the level of anxiety by n-3 fatty acid deficiency and mild stress on the novelty suppressed feeding paradigm

Group	No. of mice	Body weight (g)	First touch (s)	First 5 min latency 1 (s)	Max. 10 min latency 2 (s)

[#] $P < 0.05$, vs. n-3 Adq group housed (Mann–Whitney *U*-test)

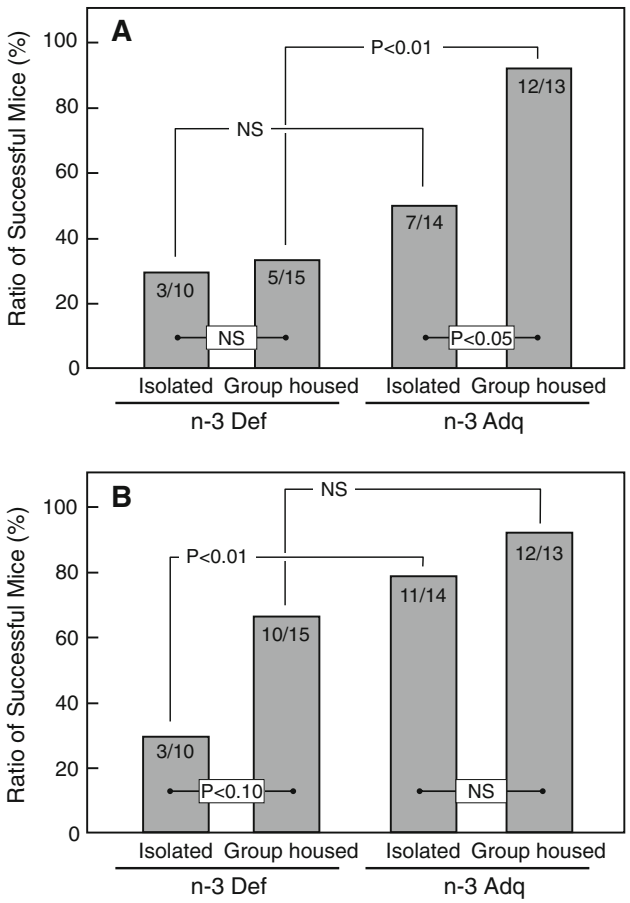

Fig. 2 The influence of the n-3 fatty acid deficiency and isolated housing on the anxiety level of mice. The measurement time was set initially for 5 min (**a**) and was extended to 10 min (**b**), if mice could not eat the food pellet within the first 5 min. The ratio of successful mice (mice who found the food and began to eat it) was calculated for each group. Significant differences between groups were analyzed by Fisher's exact probability test ($n = 10$–15 animals per group)

confirm the expected effects of the dietary fatty acid (Tables 3, 4). In both plasma and brain, there were no striking differences within the families of saturated or monounsaturated fatty acids nor the amount of total fatty acids between the n-3 Def and n-3 Adq groups in either housing condition. However, the n-3 Def group showed a marked increase in three n-6 fatty acids, 20:4n-6, 22:4n-6, 22:5n-6, and a decrease in two n-3 fatty acids, 22:5n-3 and 22:6n-3, in both tissues when compared to the n-3 Adq group and in both housing conditions. As expected, the ratio of n-6/n-3 fatty acids in the n-3 Def group markedly increased with a concomitant change in the level of n-6 and n-3 fatty acids. When animals in the two different housing conditions were compared, there were no significant differences in brain, although there were rather small differences in some plasma saturated, monounsaturated and n-6 fatty acids.

Discussion

In this study, effects of n-3 fatty acid deficiency and isolation stress on anxiety were studied. In all four groups, there was no significant difference in motor activity and the time of first touch on the NSF task, important controls for motor function, general level of arousal and motivation. However, the latency of eating the diet in the n-3 Adq group housed animals was significantly shorter than that of the other three groups in both evaluation periods ($P < 0.05$). In the first 5 min, the ratio of successful mice in the n-3 Def group was clearly lower than that of the n-3 Adq group in the group housed case ($P < 0.01$). Also, in the 10 min evaluation, the ratio of successful mice in the n-3 Adq group was greater than that of the n-3 Def group in the isolation stressed groups ($P < 0.01$). These results suggested that the n-3 Def mice had a higher anxiety level than the n-3 Adq mice. The proportion of successful mice was a better indicator than the latency to consume diet when comparing experimental diets or housing conditions.

The evaluations using two different periods (5 and 10 min) in the NSF test produce a change in the level of difficulty or what may be considered the sensitivity of the test since 10 min is long enough to allow for eating behavior in most mice. In the longer evaluation period only, the number of successful mice in the n-3 Def-group housing condition was increased and there was a tendency for a difference according to housing condition for the proportions of successful mice ($P < 0.10$). These results indicated that the anxiety level of the n-3 Def mice was increased in the isolated housing case.

Fedorova and Salem studied the anxiety level of n-3 fatty acid deficient mice exposed to sound stress using elevated plus maze performance [5]. In both n-3 fatty acid adequate and deficient dietary groups, the number of entries into the open arms and the time spent in the open arm decreased in the high-stress condition (a loud noise of 120 dB) but there was no difference between dietary groups under low-stress conditions. However, these parameters were markedly decreased in the n-3 deficient group relative to the n-3 adequate group [5, 20]. This result suggests that the n-3 fatty acid deficient animals exhibit an enhanced vulnerability to acute stressors. Nakashima et al. [21] demonstrated that n-3 fatty acid deficient mice (supplemented with safflower oil) tended to spend more time in the open arm relative to an n-3 adequate group (perilla oil) in the elevated plus maze task. However, in this task, a decline in cognitive function in the n-3 deficient animals may be an important factor rather than solely an increase in anxiety. Also the safflower oil group exhibited no change in drug sensitivities to scopolamine and pentobarbital, drugs known to alter behavior. From these considerations, it may be surmised that n-3 Def animals have a decrease

Table 3 Effects of n-3 fatty acid deficiency on fatty acid composition of mouse plasma (mol% of total fatty acids)

in the threshold or an enhancement of vulnerability to stressors, a factor independent of any acute social stress induced by isolation. It is important to note here though that the balance of these factors likely depends upon the details of the conditions of each behavioral experiment as they determine the intensity of the stress.

The n-6 fatty acids increased and the n-3 fatty acids markedly decreased in the n-3 Def group compared with the n-3 Adq group in both brain and plasma. There was a marked decline in brain DHA with a concomitant increase in n-6 fatty acids including 22:5n-6, 22:4n-6 and 20:4n-6 as a result of the n-3 fatty acid dietary deficiency. However, there was no change in fatty acid composition between groups given different types of housing, even though we detected significant differences in the anxiety level between the isolated and group housed animals. Vancassel et al. [12] reported a change in monoamine content in the mouse brain when exposed to unpredictable chronic mild stress (UCMS) in various housing conditions including no-bedding, wet-bedding, a tilted cage, water in the home

Fatty acid methyl esters from 14:0 to 24:1n-9 were analyzed. Each parameter is presented as the mean ± SEM. $^{*}P < 0.05$, $^{**}P < 0.01$ compared between n-3 Def and n-3 Adq diet groups in each housing condition. (one-way ANOVA and Tukey test)

cage, switching the light/dark cycle, etc. The UCMS induced a significant decrease of norepinephrine in the frontal cortex and striatum and tissue levels of serotonin. Moreover, Kodas et al. [11] demonstrated that chronic n-3 fatty acid dietary deficiency induced changes in the synaptic levels of 5-HT and subsequent provision of n-3 fatty acid was able to restore both biochemical and neurochemical factors altered by the n-3 deficient diet. Therefore, our results may be due in part to stress-induced alterations in brain monoamines that can alter emotional behavior. It is likely then that a decline in brain DHA and the level of stress are important factors modulating anxiety-related behavior.

In the present study, we demonstrated that the anxiety level of n-3 Def mice was greater than that of n-3 Adq mice and was enhanced by the social isolation stress of individual housing. These results suggest that n-3 fatty acid deficiency may decrease the threshold to stress and, conversely, that increased intake of dietary n-3 fatty acids may suppress the risk of emotional disorders. The relationship between various brain monoamines and behavioral performance in n-3 fatty acid deficient animals requires further investigation.

ORIGINAL ARTICLE

Long-Term Administration of Cod Liver Oil Ameliorates Cognitive Impairment Induced by Chronic Stress in Rats

Emil Trofimiuk · Jan J. Braszko

Received: 30 June 2010 / Accepted: 4 March 2011 / Published online: 26 March 2011

Abstract Cod liver oil (CLO) is a rich source of omega-3 fatty acids (FA), especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The existing data suggest that EPA and DHA are the active agents of fish oil. In this study, we tested a hypothesis that the active constituents of CLO alleviate the negative impact of prolonged restraint stress on cognitive functions of male Wistar rats. Specifically, we attempted to characterize the preventive action of long-lasting treatment with CLO [0.375 ml/100 g body weight (equivalent to a dose of 300 mg/kg DHA and 225 mg/kg EPA), p.o. for 21 days] against an impairment caused by chronic restraint stress (2 h daily for 21 days) on recall as tested in a passive avoidance situation and on the spatial reference and working memory tested in a Barnes maze as well as on locomotor activity and anxiety behavior tested respectively in an open field and elevated plus-maze. We found that CLO administration statistically significantly ($p < 0.01$, both) prevented the deleterious effects of chronic restraint stress on recall and the spatial memory.

Keywords Cod liver oil · Stress · Open field · Elevated plus maze · Passive avoidance · Barnes maze · Spatial memory

Abbreviations

AD	Alzheimer's disease

Introduction

Neuropsychological dysfunctions, including learning and memory impairments, are the usual outcome of an exposition to prolonged stress [9, 31]. It is recognized that chronic stress is an important risk factor for the development of several cognitive deficits involving reference and working memory [10]. Although experimental studies identified many potentially effective neuroprotective agents, no clinically effective therapeutic strategy has yet been found to treat stress-induced cognitive impairment. Therefore, the search for substances that could be safe and effective in the prevention and treatment of the negative effects of stress on cognition is an urgent priority.

Docosahexaenoic acid (DHA, 22:6n-3) has been found to improve several brain functions including memory. DHA plays crucial role in maintaining structural and functional integrity of biological membranes [12, 13, 33]. In the brain and retina, DHA comprises, respectively, more

than 20 and 50%, of the membrane phospholipids [11]. DHA is essential for normal neurological function [18]. In the mammalian brain, lipids make up 10% of their fresh weight and 50% of dry weight, and DHA and arachidonic acid [20:4(n-6)] are the major polyunsaturated fatty acids (PUFA) in neuronal membranes [32]. Most DHA accumulation in the brain takes place during brain development from the beginning of the third trimester of gestation to 2 years after birth in humans and from prenatal day 7 to postnatal day 21 in rats [21, 26]. However, brain DHA levels decrease with age [14, 17] and are reduced in Alzheimer's disease (AD) [30]. Deficiency of brain DHA is associated with reduced learning ability and memory in rats [18] and with memory loss in AD patients [35]. Once incorporated into the phospholipids of the cell membrane, DHA modulates neurotransmitter release, membrane-bound enzymes and ion channel activity, gene expression, and synaptic plasticity [5, 23]. Numerous peripheral and central nervous system disorders have been associated with an imbalance in n-6 to n-3 PUFA, mainly arachidonic acid and DHA, respectively [12, 23, 33]. Dietary supplementation with fish oil containing standardized concentrations of EPA and DHA has been recommended by the American Heart Association for patients with documented chronic heart disease [13].

Whether oral administration of CLO, a principle dietary source of DHA and EPA, also could be effective in preventing the consequences of prolonged stress is not known. To our knowledge, no study has investigated the potential beneficial effects of fish oil in preventing stress-induced cognitive dysfunction. Therefore, the objective of the present study was to investigate whether prolonged treatment with a commercially available, standardized fish oil preparation is effective in alleviating the cognitive impairment and neurodegeneration caused by stress in rats. The specific hypothesis is that DHA treatment may protect brain cells from the stress-evoked damage, and the use of a standardized, high-grade DHA-containing fish oil formulation may be a safe, effective, and readily available means of preventing or even treating the negative consequences of stress on cognition. In this study, we tested this hypothesis in rats using a passive avoidance situation and Barnes maze paradigms. To control for unspecific influence of locomotor activity and anxiety we used open field and elevated plus-maze tests, respectively.

Materials and Methods

Animals

Seventy-five male, 6 week old Wistar rats, weighing 120–140 g at the beginning of the experiments, were used. The rats were kept in a temperature- (23°C) and humidity-(50–60%) controlled vivarium in groups of five under a constant 12/12 h light/dark schedule (lights switched on at 7:00 a.m.) with free access to standard lab chow and tap water.

Drugs

A standardized CLO formulation (Cod Liver Oil, Lysi HF, Island) was used. Each 5 ml contained 400 mg DHA, 300 mg EPA, and 4.6 mg vitamin E (artificial antioxidant), 0.23 mg vitamin A and 0.0046 mg vitamin D. CLO was administered by gavage in a volume of 0.375 mL/100 g body weight. Doses of DHA, EPA, and vitamins E, A and D contained in this volume of CLO were 300 [34], 225, 3.45, 0.175 and 0.00345 mg/kg, respectively. Control rats received 0.009% Cremophor (Sigma, Germany) as a vehicle [16].

Animals were divided into four groups treated daily as follows: (1) 20 rats received 0.009% Cremophor (Control); (2) 17 rats received 0.009% Cremophor followed by stress procedure described below (Stress); (3) 20 rats received 0.375 ml/100 g body weight CLO (CLO); (4) 18 rats received 0.375 ml/100 g body weight CLO followed by stress procedure (Stress + CLO).

The experimental procedures were carried out according to the European Council Directive of 24 November 1986 (6/609/EEC) and were approved by the Local Ethics Commission for Animal Experimentation.

Stress Procedure

Two groups of animals (19 rats and 16 rats) were subjected to chronic restraint stress [3], 2 h daily for 21 days. The restraint was imposed during the light phase from 0900 to 1100 hours. The restrainer was made of transparent perforated plastic tube, 20 cm long, and 7 cm in diameter. A rat was eased into the restrainer, head first, and once in the tube it was closed with a plexiglas lid. The animals fit tightly into the restrainers and it was not possible for them to move or turn around. Non-stressed control rats were at the same time briefly handled and returned to their home cages.

Behavioral Tests

Open Field

The next day after ending of the 3 week administration of CLO or vehicle animals were tested in an open field for assessment of their locomotor exploratory activity. Open field was a square 100 × 100 cm white floor divided by eight lines into 25 equal squares and surrounded by a

47 cm high wall [6]. Four plastic bars, 20 cm high, were designed as objects of possible animal's interest and fixed perpendicularly, parallel to each other, in four line crossings, in the central area of the floor. A rat was placed in the center of the floor and, following 1 min of adaptation, crossings, rearings and bar approaches were counted manually for 5 min.

Elevated 'Plus' Maze

Anxiety was evaluated in the same group of rats, next day after assessment of their open field performance. It was measured in an elevated plus-maze (made of gray colored wooden planks) consisted of four arms, 50 × 10 cm (length x width). Two arms (closed) had 40 cm high walls, covered with removable lid, and two remaining arms (opened) had no walls, such that the open or closed arms were opposite to each other. The maze was elevated to a height of 50 cm from the floor. Rats were placed for 5 min in a pretest arena (60 × 60 × 35 cm, constructed of the same material) prior to exposure to the maze. This step allowed facilitation of exploratory behavior. The experimental procedure was similar to that described by Pellow et al. [29]. Immediately after the pretest exposure rats were placed in the center of the elevated plus-maze facing one of the open arms. During the 5 min test period the following measures were taken: the number of entries into the open and closed arms and the time spent in the open and closed arms. An entry was defined as all four feet into one arm. An increase in open arms entries and increase in time spent in open arms were interpreted as indicative of potential anxiolytic activity.

Passive Avoidance

Passive avoidance (PA) behavior was studied in a one trial learning, step-trough situation [1], which utilizes the natural preference of rats for dark environments. The apparatus consisted of the platform (250 × 80 mm) connected to a dark compartment—a metal box (400 × 400 × 400 mm) with an opening (60 × 100 mm) in the middle of the front wall length. After a 2 min habituation to the dark compartment, the rat was placed on the illuminated platform and allowed to enter the dark compartment. Two more approach trials were given on the following day with a 2 min interval. At the end of the second trial unavoidable scrambled electric foot shock (0.25 mA, AC, 2 s) was delivered through the grid floor of the dark compartment (learning trial). Twenty-four hours later retention of the passive avoidance response was tested by placing the animal on the platform and measuring the latency to re-enter the dark compartment to a maximum of 300 s. Two rats were excluded from testing retention because they did not effectively learn the rules of the test.

Barnes Maze

On the first day of testing, the animals (40 rats, different from those used for PA) were brought in the testing suite and allowed to enter the goal box through one of the holes in the maze. Once the animal entered the hole, a black Plexiglas cover was positioned over the hole to prevent escape. A 4 min habituation in the goal box was given prior to the first training trial. Next, the animal was placed for 30 s in a 20 cm diameter by 30 cm high round non-transparent holding box that was positioned in the center of the maze. The holding box was then removed, a timer begun, and the experimenter moved behind the curtain.

An escape was counted when all four paws of the animal were in the goal box. Following successful location of the goal box, the animals were allowed to stay there for 60 s. A maximum of 4 min was allowed for each trial and if an animal did not locate in the goal box during this 4 min period it was removed from the maze and placed in the goal box for 60 s. During the 60 s period in the goal box, the maze was wiped with a paper towel to remove any feces or urine prior to the beginning of the next trial. The test paradigm consisted of two trials per day for 5 days. Prior to the start of the second trial the animal was returned to its home cage for 1 min and then placed again in the holding box in the center of the maze to start the second trial as described above. The maze was then rotated a random number of holes (between one and eight holes using a random numbers table) in order to prevent use of odor trails in solving the task. Following the rotation of the table, the procedure was repeated with the next animal.

Two measures were recorded on each trial. The first was the latency to find the goal box. The second was the number of errors committed by each animal. An error was defined as a head poke or exploration of any hole other than the hole above the goal box and including perseverative investigations of the same hole. At the end of each day the maze was cleaned using a 70% ethanol solution [4].

Statistical Analysis

Data were presented as means ± standard error of mean (SEM). One-way analysis of variance (ANOVA), followed by Bonferroni test for chosen group comparisons, was applied for mean performance of the rats in the open field, elevated plus-maze, passive avoidance; and two way analysis of variance (ANOVA II) (treatment × days) with repeated measures, followed by the post hoc Newman–Keuls test for multiple comparisons, was used for latencies to enter the escape hole and number of errors in the Barnes Maze (BM). The probability level less than 0.05 was accepted as significant.

Results

Effects of Stress and CLO on Locomotor Exploratory Activity of Rats in the Open Field

ANOVA of the results obtained in the open field (Fig. 1) yielded no statistically significant differences in the numbers of crossings $F(3,34) = 1.466$ ($p > 0.05$), rearings $F(3,34) = 1.681$ ($p > 0.05$) and bar approaches $F(3,34) = 1.107$ ($p > 0.05$). It indicates that stress and CLO administration did not affect musculo-skeletal aspects of the rats' psychomotor performance.

Effects of Stress and CLO Administration on Anxiety Behavior in the Elevated Plus-Maze

ANOVA of the results obtained in the elevated plus-maze test yielded no statistically significant differences in the times spent by rats in open arms $F(3,34) = 0.3771$ ($p > 0.05$) and in the numbers of open arms entries $F(3,34) = 0.2910$ ($p > 0.05$; Fig. 2). It means that stress and our treatments and procedures did not appreciably affect the emotional aspects of the rats' psychomotor performance.

Effects of Stress and CLO Administration on Passive Avoidance Behavior

ANOVA of the results obtained in the passive avoidance test yielded $F(3,35) = 13,167$ ($p < 0.001$) statistically significant differences between the groups in the re-entry latencies in the passive avoidance situation (Fig. 3). Post-hoc comparisons in preselected pairs with Bonferroni test revealed that stressed rats re-entered the dark part of the apparatus significantly earlier then all remaining groups: control ($p < 0.05$), treated with CLO ($p < 0.01$) pretreated with CLO and then stressed ($p < 0.001$) rats. This pattern showed that significant adverse effect of stress on retrieval of PA behavior was abolished by parallel CLO administration to the stressed animals.

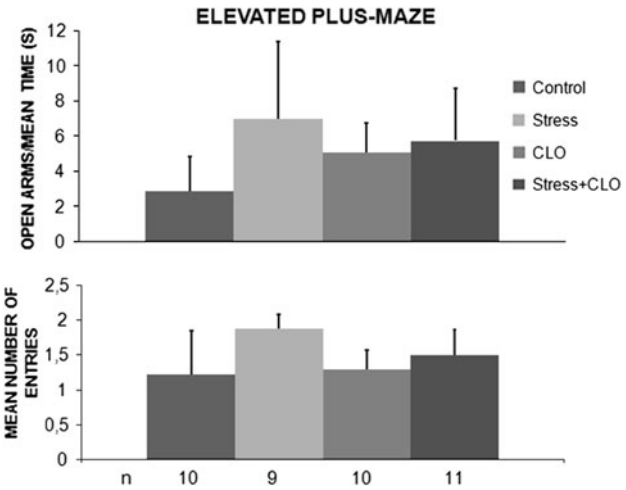

Fig. 2 Effects of stress and long-term CLO administration on the time spent by rats in, or the number of entries to the open arms of an elevated plus-maze. *Columns* represents means ± SEM of the values obtained from *n* rats indicated at the *bottom* of the figure

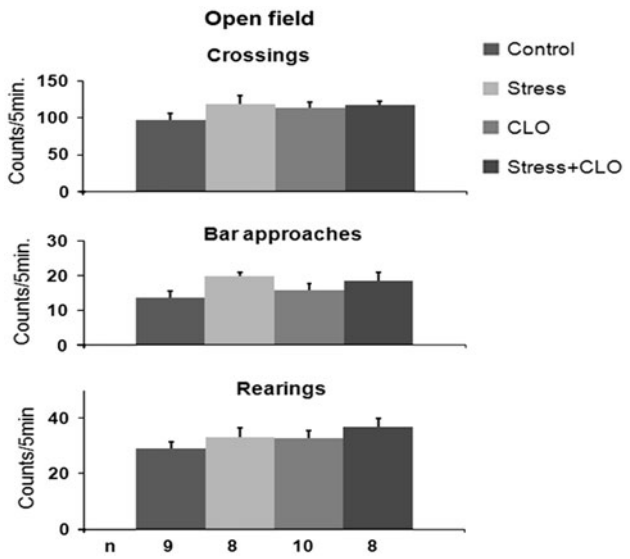

Fig. 1 Effects of stress and long-term CLO administration on the locomotor activity of rats in open field. *Columns* represent means ± SEM of the number of crossings, *rearings* or *bar* approaches obtained from *n* rats indicated at the *bottom* of the figure

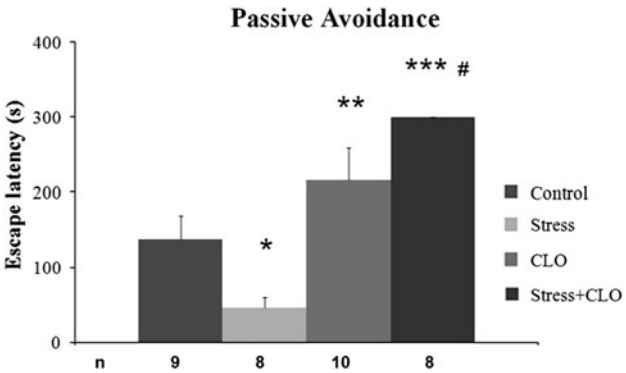

Fig. 3 Effects of chronic stress and CLO on the re-entry latencies in the passive avoidance situation. *Columns* represent means ± SEM of the values obtained from *n* rats indicated at the *bottom* of the figure. The two groups demonstrated significantly different results in re-entry latencies in comparison with Control: $*p < 0.05$ versus Stress, $\#p < 0.01$ versus Stress + CLO. The statistically significant differences were also in $**p < 0.01$ versus Stress, and $***p < 0.001$ versus Stress

Effects of Stress and CLO on Performance of Rats in the BM Test

ANOVA II of the mean numbers of errors made by rats in the BM revealed a significant treatment effect ($F(3,36) = 7.240$, $p < 0.001$), and also a significant day effect ($F(4,12) = 32.263$; $p < 0.001$) but no significant treatments × days interaction ($F(12,144) = 1.496$, $p > 0.05$) (Fig. 4). It means that all rats effectively learned the task over 5 days and specific treatment effect was detected. Further post hoc comparisons made with Bonferroni test revealed that the stressed rats made significantly more errors than the controls ($p < 0.05$), those treated with CLO ($p < 0.01$) and the rats pre-treated with CLO and subsequently stressed ($p < 0.001$).

ANOVA II of the mean latencies to enter the escape hole in the BM yielded a significant treatment effect ($F(3,35) = 5.495$; $p < 0.01$) and also a significant day effect ($F(4,12) = 51.299$; $p < 0.001$) and also a significant treatment × days effect ($F(12,144) = 2.796$; $p < 0.01$) (Fig. 5). It means that all rats effectively learned the task over 5 days and specific treatment effect and also treatment × days interaction were detected. Post hoc comparisons in preselected pairs with the Bonferroni test revealed that chronic stress ($p < 0.01$) significantly increased latency to finding the escape hole in comparison to control. Also, the animals treated with CLO ($p < 0.001$), pre-treated with CLO and subsequently stressed ($p < 0.001$) were faster in finding the escape hole in comparison with the stressed group.

Discussion

In this study we showed that CLO effectively restored examined cognitive functions impaired by stress. Specifically, CLO significantly reduced stress-related forgetting in

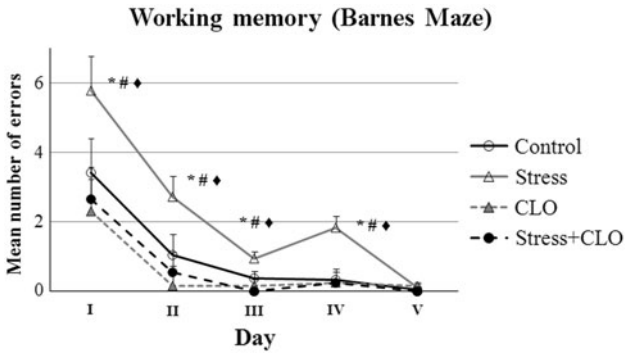

Fig. 4 Effects of chronic stress and CLO supplementation on performance in BM task. Each *graph* represent the mean ± SEM number of errors (two trials per day of 5 days) obtained from 9–11 rats per each group. The three group demonstrated significantly different results in making of errors in comparison with Stress: Control (*$p < 0.05$), CLO + Stress (#$p < 0.01$) and CLO (◆ $p < 0.001$)

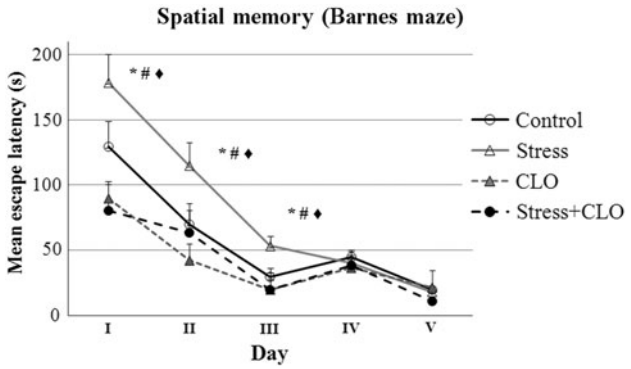

Fig. 5 Effects of chronic stress and CLO administration on performance in spatial memory test of BM. Each *graph* represent the mean escape latency ± SEM (two trials per day of 5 days) obtained from 9–11 rats per each group. The three group demonstrated significantly different results in making of errors in comparison with Stress: Control (*$p < 0.05$), CLO + Stress (#$p < 0.01$) and CLO (◆ $p < 0.001$)

rats and alleviated negative effects of stress on spatial memory.

In order to study the a possible influence of chronic stress related anxiety on the results of cognitive tests, the elevated plus-maze test was applied as it is known that cognitive processes may be impaired by anxiety [20]. Interestingly, in our study no influence of chronic mild stress or CLO treatment on anxiety as measured in the elevated plus-maze was seen.

Spontaneous open filed activity includes a variety of responses that could be interpreted as indices of exploration, arousal, locomotion, anxiety, and emotionality. In particular, increased locomotion (horizontal or forward or ambulatory activity) and vertical activity (rearing) characterize the rat's behavioral response to novelty. In this study we found that chronic stress and CLO administration is not associated with changes of locomotor activity in rats.

In studies employing DHA supplementation in a mouse model of Alzheimer's disease or in aged animals, learning and memory were improved by DHA [7, 22]. Reduced brain DHA levels are associated with poor spatial reference memory [24] which is restored by administration of exogenous DHA or docosapentaenoic acid [25].

Because most previous studies have examined memory in DHA-deficient animals [27], it was important to determine whether spatial reference memory or working memory can be enhanced in normal rats. Most previous studies have focused on whole brain DHA recovery and improved reference memory in DHA-deficient animals given a fish oil supplement. Chung et al. [8] examined the effects of fish oil administration to FA deficient rats. They found that recovery of brain DHA levels significantly improved both spatial reference and working memory. Moreover, comparison of escape latencies in Morris water maze (MWM)

test between control and control treated with fish oil groups showed that fish oil supplementation enhances spatial reference and working memory also in normal rats. In our study we did not observe nootropic effects of CLO administration in non-stressed rats. It is worth mentioning that in PA, an aversively motivated recall task, similarly as in the MWM used by Chung et al. [8], but not as in the Barnes maze (less stressful) we observed better performance in rats stressed and treated with CLO than in the control animals.

Admittedly, in some studies learning and memory improvement was observed in normal rats after repeated oral administration of DHA (300 mg/kg per day) when tested in the radial maze task [19, 34]. Their dose of DHA was the same as that used in our study, except for our DHA being not alone but as an ingredient of CLO.

Wu et al. [37] found that the DHA dietary supplementation increases activation of Akt in the hippocampus. Akt signaling is a crucial step by which BDNF exerts its action on synaptic plasticity, involving NMDA receptor stimulation [38]. In addition, Akt signaling is an important intermediate factor by which DHA influences neuroplasticity [2]. A DHA-enriched diet modulates hippocampal CaMKII activation and CaMKII is another signaling system whose action is critical for learning and memory [15], and plays a role in the DHA hippocampal-dependent cognitive enhancement [36].

Long-term potentiation (LTP) has long been recognized as a typical example of synaptic plasticity and is considered to represent a neuronal basis of learning and memory involving NMDA activation. Nishikawa et al. [28] reported that DHA potentiated the NMDA-induced response, suggesting a possible role of DHA in LTP formation. Furthermore, the beneficial effect of DHA (300 mg/kg per day for 12 weeks) on learning and memory measured in the radial maze was related to increased Fos expression in the hippocampus [34].

There are also few reports on the effects of pure EPA on cognition. Chronic administration of pure EPA attenuates memory impairment induced by interleukin 1β administration but does not enhance memory in control rats. Hashimoto et al. [22] suggests that EPA, as a precursor of DHA, ameliorates learning deficits associated with Alzheimer's disease and that these effects are modulated by the expression of proteins involved in neuronal plasticity.

In conclusion, the present study demonstrates that prolonged treatment with a standardized, high-concentration DHA- and EPA-containing fish oil reduces stress-induced retention deficit (amnesia) as measured in the PA task as well alleviates spatial reference and working memory impairments evoked by chronic stress. The present findings not only confirm the few to-date findings concerning the behavioral effects of DHA but also demonstrate for the first time that the use of a CLO facilitates functional recovery after stress evoked cognitive deficits.

Acknowledgments This study was supported by the Medical University of Bialystok (3-66775L).

Received: 20 December 2010 / Accepted: 15 March 2011 / Published online: 5 April 2011

Abstract We investigated the effect of saury oil on the alleviation of metabolic syndrome in mice. Saury oil contains 18% (w/w/) n-3 polyunsaturated fatty acids (n-3 PUFA) and 35% (w/w) monounsaturated fatty acids (MUFA). Diabetic KKAy mice were fed a 10% soybean oil diet (control) or a 10% saury oil diet for 4 weeks, and diet-induced obese C57BL/6J mice were fed a high-fat diet containing 32% lard (control) or 22% lard plus 10% saury oil for 6 weeks. After the intervention periods, the levels of glucose, insulin and lipids in plasma had decreased significantly for the saury oil diet group, and insulin sensitivity had improved. These favorable changes may be attributed to the increased adiponectin and decreased TNFα and resistin levels in plasma. The saury oil diet also resulted in downregulated expression of the lipogenic genes (*SREBP-1*, *SCD-1*, *FAS*, and *ACC*) as well as upregulation of the fatty acid oxidative gene, *CPT-1*, and the energy expenditure-related genes (*PGC1α* and *PGC1β*) in white adipose tissue for the diet-induced obese C57BL/6J mice. An increase in n-3 PUFA levels and the concomitant decrease in the n-6/n-3 PUFA level ratio in serum, white adipose tissue, and liver with a saury oil diet are likely to be involved in the beneficial changes to the metabolic indicators. MUFA may also play a positive role in remodeling lipid composition. Based on these mice models, our results suggest a potential use for saury oil for improving metabolic abnormalities.

Introduction

Metabolic syndrome (MetS) is a major and growing public health problem and is characterized by a group of metabolic risk factors for cardiovascular disease and diabetes

that includes hypertension, glucose intolerance, dyslipidemia and abdominal obesity [1]. The causes of MetS are unknown, although they are considered to involve both genetic and environmental factors, including diet [2].

Alteration of the type of dietary lipids is an important way of preventing and treating obesity-associated MetS. Studies have demonstrated that the health benefits of fish oil, which is rich in n-3 polyunsaturated fatty acids (n-3 PUFA) such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), include its ability to prevent heart disease, inflammation, dyslipidemia and diabetes via multiple mechanisms [3]. Studies in rats and mice fed a high-fat or lipogenic, sucrose-rich diet have shown that n-3 PUFA have beneficial effects on obesity and insulin resistance [3, 4]. Several studies have also demonstrated a decrease in adiposity in obese humans and improved glucose metabolism in human subjects after n-3 PUFA supplementation [5, 6].

Fish lipids generally contain varying amounts of different types of fatty acids in addition to n-3 PUFA [7]. Consistently high levels of monounsaturated fatty acids (MUFA) are found in the lipids of some pelagic surface fish species, such as saury [8], capelin [9], sprats [10], and herring [11], whose lipids originate from their food source, such as zooplankton [12, 13]. It has been established that ingestion of fish oil rich in MUFA increases peroxisomal beta-oxidation [14] and promotes the synthesis of long-chain essential fatty acids [15]. Additionally, Osterude et al. [16] demonstrated that a seal/cod liver oil mixture and whale oil both increased high-density lipoprotein cholesterol (HDL-C) levels, and furthermore, cod liver oil reduced triacylglycerol (TAG) levels in healthy humans. Because all these fish oils contain a considerable amount of MUFA in addition to n-3 PUFA, some of these effects may be attributable to MUFA. All of these studies suggested a possible beneficial effect of MUFA for the treatment of MetS.

Saury, a seawater fish from the family Scomberesocidae, is one of the most highly consumed fish in Japan. Saury oil contains n-3 PUFA, such as EPA and DHA, as well as considerable amounts of MUFA (C20:1 and C22:1). Given the positive effects on glucose and lipid homeostasis by n-3 PUFA, and the findings that MUFA may have an impact on the treatment of MetS, we evaluated the effect of saury oil on glucose and lipid metabolism using diabetic KKAy mice and diet-induced obese C57BL/6J mice for our animal model. Our research revealed that saury oil intake reduced insulin resistance and plasma levels of glucose, insulin, and lipids. This effect may be attributable to favorable changes in the plasma adipokine profile and lipid metabolism-related gene expression. Our research constitutes the first investigation of the effect of saury oil ingestion on glucose and lipid metabolism, and our findings suggest that saury oil may have a favorable impact on MetS.

Materials and Methods

Animals and Diets

All animal experiments were conducted in complete compliance with the National Institutes of Health: Guide for the Care and Use of Laboratory Animals, and were approved by the Institutional Animal Care and Use Committee at Nihon Bioresearch Inc. (Gifu, Japan), where the animals were housed for the entire experimental period. Five-week-old spontaneously diabetic male KKAy mice were obtained from CLEA Japan Inc. (Shizuoka, Japan), and 5-week-old male C57BL/6J mice were from Charles River Laboratories Japan Inc. (Yokohama, Japan). Mice were housed 1/cage at 23 ± 1 °C with a 12-h light/dark cycle, and provided with free access to water and standard mouse chow CRF-1 (Oriental Yeast Co. Ltd., Tokyo, Japan) for an acclimatization period of 1 week.

The fatty acid composition of the dietary oils is shown in Table 1. Saury oil (Nippon Suisan Kaisya, Ltd., Tokyo, Japan) contained 34.7% MUFA (20:1 and 22:1 isomers) and 18% of EPA and DHA combined. Following the acclimatization period, the KKAy mice were randomly assigned into two groups for a 4-week feeding experiment. The control group ($n = 10$) was fed on AIN-93G growth diet (Oriental Yeast Co., Tokyo, Japan) containing 10% soybean oil, and the saury oil group ($n = 10$) was fed the same basal diet supplemented with 10% saury oil. The two groups were pair-fed throughout the experiment. The

ND not detected

C57BL/6J mice were randomly divided into two groups for a 6-week pair-feeding period. The control group was fed on a high-fat diet (D12492 Rodent Diet with 60 kcal% Fat; Research Diets, Inc., New Brunswick, NJ, USA) containing 32% lard (corresponding to 60% energy from fat; $n = 10$), and the saury oil group was fed a saury oil-supplemented diet (22% lard plus 10% saury oil, corresponding to 60% energy from fat; $n = 10$). The compositions of the experimental diets are shown in Table 2. All diet feeds were stored at −20 °C and were provided fresh daily to the mice. Body weight and food intake were monitored throughout the study.

At the end of the intervention periods, the KKAy mice and C57BL/6J mice were anesthetized with 4% sodium pentobarbital (Dainippon Sumitomo Pharma, Osaka, Japan) in the early light phase of the light–dark cycle (fed condition), and blood was collected by abdominal vein puncture. Plasma was obtained by centrifugation at 3,000 rpm for 15 min and stored at −80 °C pending further analysis. Liver and mesenteric adipose tissue (WAT) were snap-frozen in liquid nitrogen after weighing for further analysis.

Lipid Extraction and Fatty Acid Analysis

The fatty acid composition of plasma, WAT, and liver in the C57BL/6J mice was determined as described [17]. Lipids were extracted by homogenizing the tissue samples in a 4:1 (v/v) methanol/hexane solution supplemented with 50 μg/ml butylated hydroxytoluene (BHT) as an antioxidant. Fatty acids methyl esters were obtained by transmethylation of the lipids (500 μl) with acetyl chloride (200 μl) and heating at 80 °C for 1 h under a nitrogen atmosphere. Methyl docosatrienoate (22:3n-3) at a final concentration of 0.4 μg/mg for WAT and liver, and methyl tricosanoate (23:0) at a final concentration of 0.2 μg/μl for plasma were added to each sample as internal standards. Gas chromatographic analysis of fatty acid methyl esters was performed on an Agilent 6890N Network Gas Chromatograph System (Agilent Technologies Japan, Ltd., Japan) equipped with a split injector, FID detector and a fused silica capillary column (30 m × 0.25 mm ID × 0.25 μm film thickness, J & W Scientific, Agilent Technologies). Data were collected with GC Chemstation (Agilent Technologies). Fatty acid methyl esters were identified by co-chromatography with purified standard mixture (Nu-Chek Prep 462, Elysian, MN), and fatty acid data were expressed as the percentage peak area corresponding to the weight of individual fatty acids.

Table 2 Composition of the diets for the KKAy and C57BL/6J mice

Component (%)	KKAy mice		C57BL/6J mice	
	Soybean oil diet	Saury oil diet	Lard diet	Saury oil diet
Casein	20	20	25.8	25.8
L-Cysteine	0.3	0.3	0.4	0.4
Corn starch	49.9	49.9	–	–
Maltodextrin 10	–	–	16.2	16.2
Sucrose	10	10	8.9	8.9
Cellulose	5	5	6.5	6.5

Choline bitartrate	0.3	0.3	0.3	0.3
Soybean oil	10	–	3.2	3.2
Lard	–	–	32	22
Saury oil	–	10	–	10

Insulin Tolerance Test

For the KKAy mice on the control diet and the saury oil diet, the insulin tolerance test was performed at the end of 3 weeks. Each mouse received an intraperitoneal injection of insulin (0.75 U/kg body weight, Humulin R U-100, Eli Lilly, Japan) after fasted for 6 h with free access to water. Blood samples were taken from the retro-orbital venous plexus prior to the insulin injection (0 min time point) and at indicated time points after the injection. The blood samples were centrifuged at 3,000 rpm for 15 min, and plasma glucose concentration was measured using a glucose test kit (Glucose CII-test, Wako Pure Chemicals Industries, Japan).

Biochemical Analysis of Plasma

The plasma concentrations of glucose, total cholesterol (TC), HDL-C, TAG, and nonesterified fatty acids (NEFA) were measured using a Glucose CII-Test, a Cholesterol E-Test, a HDL-Cholesterol E-Test, a TG E-Test and a NEFA C-Test, respectively (Wako), and low-density lipoprotein cholesterol (LDL-C) levels were calculated as TC−HDL-C−TGA × 0.2. Plasma insulin levels were determined using an Insulin ELISA kit (Morinaga Institute of Biological Science, Inc., Japan). Plasma concentrations of adipokines, including adiponectin, resistin, tumor necrosis factor-alpha (TNFα), and leptin, were measured using the following respective enzyme immunoassay kits: mouse adiponectin ELISA kit (Otsuka Pharmaceutical Co., Ltd., Japan), Mouse Resistin ELISA kit (Shibayagi Co. Ltd., Japan), Mouse TNF-α ELISA kit (Shibayagi) and Mouse Leptin ELISA kit (Morinaga).

Analysis of mRNA Expression Using Real-Time Reverse Transcription Polymerase Chain Reaction (RT-PCR)

For the C57BL/6J mice fed high-fat diets, total RNA was isolated from mesenteric WAT using TRIzol reagent (Qiagen, Tokyo, Japan) according to the manufacturer's protocol. The first strand of cDNA was generated from total RNA using a PrimeScript II 1st strand cDNA Synthesis kit (TaKaRa Bio, Otsu, Japan) using oligo dT-adaptor primers, and 1–2 μg of total RNA as the template. The resulting cDNA pool was used for real-time RT-PCR amplification and specific sequence detection on an Applied Biosystems 7300 Real-Time PCR System (Life Technologies Co., Japan). The forward and reverse PCR primers shown in Table 3 were used at final concentrations of 10 μM. SYBR Premix Ex Taq (TaKaRa Bio) was also used. The PCR cycling parameters were: 30 s at 95 °C; followed by 40 cycles of 5 s, 95 °C, 34 s at 60 °C; and a final melting curve of 15 s at 95 °C, 1 min at 60 °C, 15 s at 95 °C. Gene expression was scaled to the expression of the housekeeping gene encoding 18S ribosomal RNA.

Statistical Analysis

All data are expressed as means ± SE. Statistical differences between two groups were determined using Student's *t* test. The value was considered to be significantly different for values of $P < 0.05$.

Results

Fatty Acid Composition of Plasma, WAT and Liver

Plasma, mesenteric WAT, and liver fatty acid compositions in C57BL/6J mice fed the control diet (lard) or saury oil-supplemented diet are shown in Table 4. PUFA and MUFA percentages were significantly different in the saury oil group compared to the control group although there were no large differences in the levels of saturated fatty acids (SFA) between the two diet groups. The saury oil-supplemented diet resulted in reduced levels of arachidonic acid (C20:4 n-6) in plasma, WAT and liver by 33.8% ($P < 0.05$), 39.3% ($P < 0.01$), and 53.7% ($P < 0.001$) respectively, and reduced the total n-6 PUFA levels significantly in WAT and liver by 8% ($P < 0.05$) and 29.2% ($P < 0.05$), respectively. Ingestion of saury oil increased EPA levels significantly in both plasma and liver by 130% ($P < 0.05$) and 1118.5% ($P < 0.001$), respectively, and also increased DHA levels significantly in WAT and liver by 835.3% ($P < 0.001$) and 85% ($P < 0.001$), respectively. Compared to the control group, the total n-3 PUFA levels in the saury oil diet group increased significantly in plasma, WAT and liver by 35.9% ($P < 0.05$), 162.2% ($P < 0.001$), and 141.8% ($P < 0.001$), respectively. The decrease in n-6 PUFA and increase in n-3 PUFA with the saury oil diet resulted in significant decreases in n-6/n-3 PUFA ratios in plasma, WAT and liver by 39.7% ($P < 0.05$), 64.9% ($P < 0.001$), and 69% ($P < 0.001$), respectively. A different pattern of changes in lipid composition was observed for the MUFA levels with the saury oil diet. Compared to the control diet group, C22:1 levels in the saury oil group were significantly higher in plasma, WAT and liver by 110.3% ($P < 0.05$), 266.7% ($P < 0.001$), and 450% ($P < 0.01$), respectively. Also, C20:1 levels in WAT were significantly elevated (by 66.7%, $P < 0.001$) with the saury oil-supplemented diet. In contrast, saury oil intake decreased oleic acid (C18:1) levels markedly in WAT and liver, by 16.8% ($P < 0.01$) and 27.2% ($P < 0.05$), respectively.

Effect of Saury Oil on Plasma Glucose Levels in an Insulin Tolerance Test

The plasma glucose concentrations in an insulin tolerance test are shown in Fig. 1 for KKAy mice fed a soybean oil (control) or saury oil diet. Plasma glucose levels in the saury oil group declined ($P = 0.14$) at 60 min, and then significantly decreased by 25.3% ($P < 0.05$) at 80 min after insulin injection, compared to the control group.

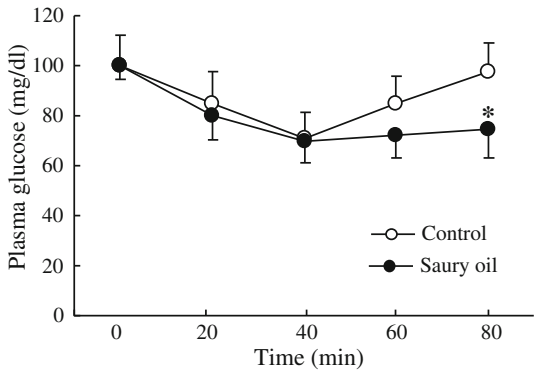

Fig. 1 The effect of saury oil on insulin sensitivity. An insulin tolerance test was performed at the end of 3 weeks to KKAy mice fed a 10% soybean oil diet (control) or 10% saury oil diet. Values are mean ± SE ($n = 10$) and are normalized relative to the control group. *$P < 0.05$ compared to controls

Effect of Saury Oil on Metabolic Variables in Plasma

The body weight, mesenteric WAT mass, and plasma concentrations of glucose, insulin, and lipids in KKAy mice and diet-induced obese C57BL/6J mice are shown in Table 5. After 4 weeks of feeding KKAy mice the saury oil diet, the mesenteric WAT mass in the saury oil group was 10.4% ($P < 0.05$), plasma concentrations of glucose were 13.7% ($P < 0.05$), insulin were 45.4% ($P < 0.01$), TC were 39.4% ($P < 0.001$), LDL-C were 76.4% ($P < 0.001$), and NEFA were 23.1% ($P < 0.01$) lower than in the control soybean oil group. Plasma TAG concentrations also tended to be lowered by the saury oil diet ($P = 0.14$).

Each value represents the mean ± SE ($n = 10$). KKAy mice were fed a 10% soybean oil diet (control) or a 10% saury oil diet for 4 weeks. C57BL/6J mice were fed a 32% lard diet (control) or a 22% lard plus 10% saury oil diet (saury oil diet) for 6 weeks

WAT white adipose tissue, *TC* total cholesterol, *LDL-C* low-density lipoprotein cholesterol, *TAG* triacylglycerol, *NEFA* nonesterified fatty acid

* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ compared to controls

There was no difference in body weight between the saury oil group and the control group. Similarly, ingestion of saury oil also decreased the plasma concentrations of glucose in C57BL/6J mice by 13.6% ($P < 0.01$), of insulin by 35.2% ($P < 0.05$), of TC by 18.6% ($P < 0.01$), of LDL-C by 27.3% ($P < 0.05$), and of TAG by 19.4% ($P < 0.001$), although the mesenteric WAT mass did not differ between the saury oil group and the control group.

Effect of Saury Oil on Adipokine Levels in Plasma

Intake of saury oil increased the concentration of adiponectin in plasma by 28.7% ($P < 0.01$) in KKAy mice and by 23.6% ($P < 0.01$) in C57BL/6J mice (Fig. 2a). Plasma resistin concentrations were decreased by 28.5% ($P < 0.05$) and 9.5% ($P < 0.05$) with a saury oil diet in KKAy mice and C57BL/6J mice, respectively (Fig. 2b). Ingestion of saury oil also decreased plasma TNFα concentrations by 59.5% ($P < 0.01$) in KKAy mice (Fig. 2c) and plasma leptin concentrations by 66.9% ($P < 0.01$) in C57BL/6J mice (Fig. 2d).

Effect of Saury Oil on the Expression of mRNAs Related to Lipid Metabolism in WAT

The saury oil-supplemented diet downregulated the mRNA expression of lipogenic genes *SREBP-1* (sterol regulatory element binding protein 1), *SCD-1* (stearoyl-coenzyme A desaturase 1), *FAS* (Fatty acid synthase), and *ACC* (Acetyl-CoA carboxylase) by 65% ($P < 0.05$), 72% ($P < 0.01$), 70% ($P < 0.05$), and 74% ($P < 0.05$), respectively, compared to the control lard diet group (Fig. 3a), and upregulated expression of the oxidation-related gene *CPT-1* (Acetyl-CoA carboxylase Carnitine palmitoyltransferase-1), the energy consumption-related genes *PGC1α* (Peroxisome proliferator-activated receptor gamma coactivator 1-alpha) and *PGC1β* (Peroxisome proliferator-activated receptor gamma coactivator 1-beta) by 123% ($P < 0.05$), 171% ($P < 0.05$), and 176% ($P < 0.05$), respectively (Fig. 3b), in diet-induced obese C57BL/6J mice.

Discussion

The present study has demonstrated that ingestion of saury oil alleviates MetS in type II diabetic KKAy mice and diet-induced obese C57BL/6J mice by improving glycemic and lipid control. To understand the possible mechanisms of the hypoglycemic and hypolipidemic effects of saury oil, we investigated adipokine levels. As a key adipokine, adiponectin has received considerable attention due to its anti-inflammatory, antiatherogenic and antidiabetic properties [18, 19]. There is increasing evidence supporting the positive association of higher adipocyte-derived adiponectin with glycemic control, lipid profile, and inflammation [20]. By contrast, elevated levels of circulating NEFA and other adipokines such as TNFα, resistin, and leptin are associated with insulin resistance [21–26]. Therefore, the increase in plasma levels of adiponectin, as well as the decreases in plasma levels of NEFA, TNFα, resistin, and leptin with a saury oil diet are possibly associated with the improvement of hyperglycemia, hyperinsulinemia, and hyperlipidemia relative to insulin resistance.

Saury oil intake decreased mesenteric WAT mass significantly in KKAy mice, and several lines of evidence indicate that a lower content of WAT is associated with a

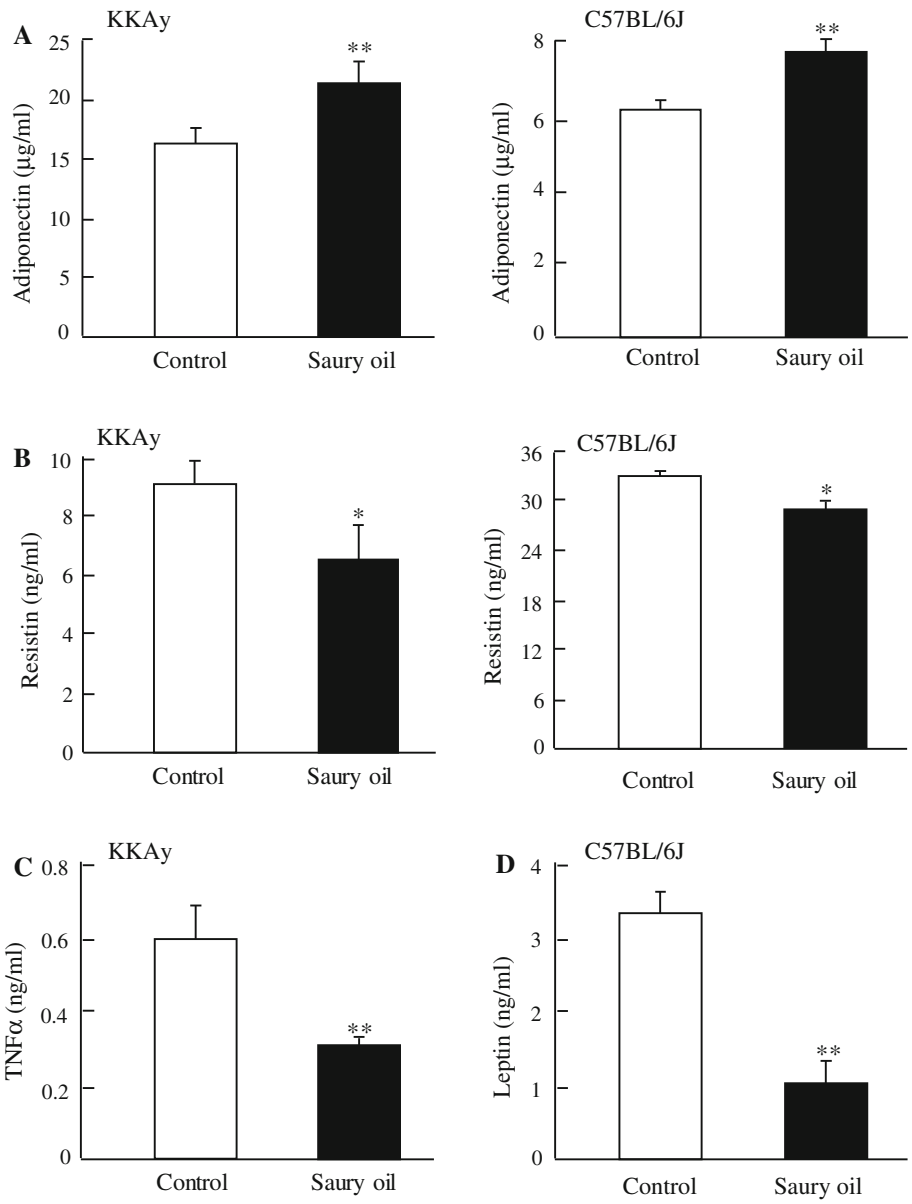

Fig. 2 The effect of saury oil on plasma adipokines. Plasma adipokine concentrations in KKAy mice (*left*) and in diet-induced obese C67BL/6 J mice (*right*) for: **a** adiponectin, **b** resistin, **c** TNFα, and **d** leptin. KKAy mice were fed a 10% soybean oil diet (control) or a 10% saury oil diet for 4 weeks. C57BL/6J mice were fed a 32% lard diet (control) or 22% lard plus 10% saury oil diet (saury oil group) for 6 weeks. After the feeding period, plasma adipokine levels were measured in duplicate by ELISA. Values are mean ± SE ($n = 10$). *$P < 0.05$, **$P < 0.01$ compared to controls

favorable profile of adipokines as well as a lower MetS risk [27]. Saury oil intake did not change WAT mass in diet-induced obese C67BL/6J mice, however, although there were favorable changes in plasma adipokines associated with a favorable metabolic profile. It is therefore suggested that adipose tissue mass loss is not the only essential factor for the improvement of metabolic disarrangement in diet-induced obese C57BL/6J mice fed a saury oil diet. Notably, Saraswathi et al. [28] demonstrated that by feeding fish oil to LDL receptor-deficient mice, WAT-specific inflammation and insulin sensitivity were improved and macrophage infiltration was reduced despite an increase in adipose tissue mass.

The n-3 PUFA levels in plasma, WAT and liver increased significantly in the saury oil group compared to the control group for C57Bl/6J mice. It has been demonstrated that EPA increases adiponectin secretion in rodent models of obesity and in human obese subjects, in part through TNFα downregulation in macrophages [29, 30]. n-3 fatty acids also decrease TNFα, resistin and leptin levels, all of which are implicated in insulin insensitivity [31–33]. The beneficial effect of saury oil in producing a more favorable adipokine profile and easing the onset of MetS may be partly attributed to the increase in n-3 PUFA.

SREBP-1 and its target genes *SCD-1*, *FAS* and *ACC* are involved in adipogenesis, and *SREBP-1* has a key role in regulating fatty acid synthesis [34]. Insulin-induced expression of *SREBP-1* mRNA can be prevented by the n-3 PUFA [35]. n-3 PUFA also prevented insulin induction of the downstream lipogenic enzyme targets *FAS* and *ACC*,

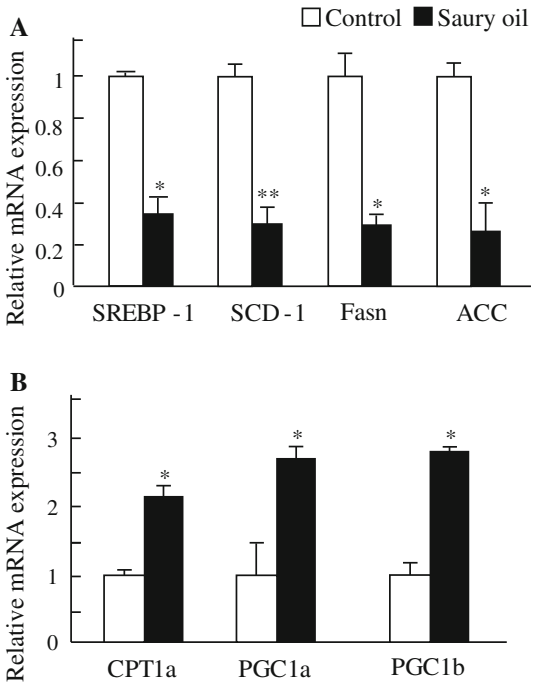

Fig. 3 The effect of saury oil on the mRNA expression levels of genes involved in lipid metabolism in mesenteric WAT. **a** mRNA expression of markers of lipogenesis (*SREBP1*, *SCD-1*, *FAS* and *ACC*). **b** mRNA expression of markers of lipid oxidation (*CPT1a*), and energy expenditure (*PGC1α* and *PGC1β*). C57BL/6J mice were fed a 32% lard diet (control) or a 22% lard plus 10% saury oil diet for 6 weeks. After the intervention period, mRNA levels in mesenteric WAT were measured by real-time RT-PCR. Values for expression levels were normalized to that of 18S ribosomal RNA and expressed relative to the control group. Values are means ± SE ($n = 10$). $^{*}P < 0.05$, $^{**}P < 0.01$ compared to controls

and reduced de novo lipogenesis [36]. Enzyme CPT-1 is rate limiting for fatty acid β-oxidation in mitochondria [37], and PGC1α is a molecular marker of energy expenditure via regulatory function for mitochondrial biogenesis and oxidative metabolism [38–40]. Flachs et al. [41] demonstrated that the antiadipogenic effect of an EPA/DHA concentrate (6% EPA and 51% DHA) may involve a metabolic switch in adipocytes that includes enhancement of β-oxidation with increase in mRNA expression of *CPT-1* and upregulation of mitochondrial biogenesis with an increase in the expression of genes encoding PGC1α and nuclear respiratory factor-1 (Nrf-1). Suppression of adipogenesis and promotion of fatty acid oxidation, as well as energy expenditure in mRNA levels with a saury oil diet are associated with improvement of glucose and lipid metabolism, and this is potentially derived from a significant increase in n-3 PUFA with an intake of saury oil.

In contrast to the increase in n-3 PUFA, there were marked reductions in n-6 PUFA including arachidonic acid, along with a corresponding decrease in the n-6/n-3 PUFA ratio, with the saury oil diet. n-6 PUFA, which compete with n-3 PUFA for several physiological processes, can increase inflammatory signals and have been associated with metabolic/cardiovascular disorders and cancer [42–44]. A decrease in the n-6/n-3 PUFA ratio can enhance glucose tolerance in healthy animals [45], and prolong survival of type I diabetes model non-obese diabetic mice by retaining the beta cell mass [46]. Thus, a decrease in n-6 PUFA, as well as in the n-6/n-3 PUFA ratio, contributes to the beneficial effects of saury oil on glucose and lipid metabolism in a saury oil diet.

In addition to n-3 PUFA, diets rich in MUFA are recommended for individuals with type 2 diabetes mellitus, and studies suggest the beneficial effect of dietary oleic acid on insulin sensitivity [47]. Levels of 18:1 in WAT and liver decreased significantly with a saury oil diet, however, suggesting a minor role for 18:1 in the improvement of MetS with saury oil treatment. Because a considerable fraction of the fatty acids in saury oil is comprised of MUFA (35% of C20:1 and C22:1), some of the beneficial effects of saury oil on metabolic control of hyperglycemia and hyperlipidemia observed in the present study may be associated with MUFA.

Whale oil is rich in MUFA—28% of it is comprised of C20:1 and C22:1 aliphatics—but contains only 54% of combined EPA/DHA found in cod liver oil and 68% of that found in seal oil. Despite this difference, Osterud et al. [16] demonstrated that the consumption of these three oils by healthy subjects increased the content of n-3 fatty acids in serum lipids significantly to a comparable degree and also reduced the arachidonic acid levels similarly for all three oils. Similarly, in another study by Halvorsen et al. [15] feeding rats fish oil fractions rich in MUFA (80% of C20:1 and C22:1), the level of EPA in the plasma lipids was increased while the content of arachidonic acid was reduced compared with that of rats fed lard. The increase in n-3 PUFA and the improved ratio of n-6 PUFA to n-3 PUFA, which contributes to the improvement of glycemic and lipid metabolism in diet-induced obese C57BL/6J mice fed a saury oil-supplemented diet, may therefore be partly attributable to MUFA. In addition, it has been demonstrated that MUFA-enriched whale oil supplementation reduces TNFα generation in lipopolysaccharide-stimulated blood [16]; this supports our finding that reduced blood TNFα levels correlated with improved insulin resistance in KKAy mice fed a saury oil diet. Taken together, these results are interesting and suggest a possible synergistic effect between n-3 PUFA and MUFA in the improvement of MetS.

Very limited data exist defining the health beneficial actions of saury oil, and the current study showed the beneficial effects of saury oil in reducing risk factors for metabolic syndrome in spontaneously diabetic mice and diet-induced obese mice. On the other hand, the mechanism by which MUFA boosts the effect of n-3 PUFA and whether

MUFA has a specific effect on metabolic disorders themselves still needs to be elucidated. This is of importance if the development of functional lipids from fish and MetS treatment with a diet rich in saury oil are to be pursued.

Growth Temperature and Salinity Impact Fatty Acid Composition and Degree of Unsaturation in Peanut-Nodulating Rhizobia

Natalia S. Paulucci · Daniela B. Medeot · Marta S. Dardanelli · Mirta García de Lema

Received: 6 July 2010 / Accepted: 21 February 2011 / Published online: 10 March 2011

Abstract Growth and survival of bacteria depend on homeostasis of membrane lipids, and the capacity to adjust lipid composition to adapt to various environmental stresses. Membrane fluidity is regulated in part by the ratio of unsaturated to saturated fatty acids present in membrane lipids. Here, we studied the effects of high growth temperature and salinity (NaCl) stress, separately or in combination, on fatty acids composition and de novo synthesis in two peanut-nodulating *Bradyrhizobium* strains (fast-growing TAL1000 and slow-growing SEMIA6144). Both strains contained the fatty acids palmitic, stearic, and *cis*-vaccenic + oleic. TAL1000 also contained eicosatrienoic acid and cyclopropane fatty acid. The most striking change, in both strains, was a decreased percentage of *cis*-vaccenic + oleic (≥80% for TAL1000), and an associated increase in saturated fatty acids, under high growth temperature or combined conditions. Cyclopropane fatty acid was significantly increased in TAL1000 under the above conditions. De novo synthesis of fatty acids was shifted to the synthesis of a higher proportion of saturated fatty acids under all tested conditions, but to a lesser degree for SEMIA6144 compared to TAL1000. The major adaptive response of these rhizobial strains to increased temperature and salinity was an altered degree of fatty acid unsaturation, to maintain the normal physical state of membrane lipids.

Introduction

Increased agricultural production plays a key role in enhancing food supply, economic growth, and the overall standard of living in developing countries. Bacteria termed "rhizobia", which have the ability to fix atmospheric nitrogen in symbiosis with roots of legumes, are economically important for increasing the yield of legume crops. Peanut is an important legume crop used for direct human

consumption and a variety of food products. It is a major agricultural crop in many countries such as China, United States and Argentina. Peanut is nodulated by the slow growing strain *Bradyrhizobium* sp. SEMIA6144 [1]. In addition, peanut is also nodulated by *Bradyrhizobium* sp. TAL1000 [2]. In peanut, the rhizobial infection mechanism differs from other legumes since rhizobia penetration into the root occurs without intracellular infection thread formation and involves intercellular penetration (crack entry) [3].

Environmental conditions, e.g., temperature and salinity, affect the symbiosis between rhizobia and host plant. Suboptimal temperatures reduce the competitiveness of rhizobia for nodulation [4], delay root infection and inhibit nodule development and nitrogenase activity [5]. Application of 100 mM NaCl to peanut plants completely inhibited nodule formation by *Bradyrhizobium* strains ATCC10317, TAL1000, and SEMIA6144 [6].

Survival of bacteria in stressful conditions is often determined by their capacity to adapt by altering the composition of the lipid bilayer of the cell surface membranes, which regulate or integrate many vital processes [7, 8]. The primary lipid components of the bilayer are phospholipids (PL). In bacterial membranes PL play key roles in energy transduction, signal transduction, solute transport, and cell–cell recognition [9]. Many microorganisms have been shown to modify lipid composition in order to maintain membrane fluidity within an optimal range [10]. In general, perturbation of membrane fluidity by extrinsic chemical agents or other factors initiates an active response based on intrinsic chemical changes such as the modification of existing lipids and the de novo synthesis that tend to counteract the perturbation [11, 12].

Previous studies of our laboratory demonstrated that, both PL composition and synthesis were modified by salt and temperature stresses in the peanut-nodulating *Bradyrhizobium* sp. SEMIA6144. The amount and the labeling of each individual PL was increased by NaCl, while they were decreased by temperature stress. The amount of PtdCho, PtdEtn, and PtdGro under the combined stresses decreased, as in the temperature effect [13]. Similar PL changes in response to salt and temperature stress have been observed in other microorganisms [8, 14]. Additional mechanisms to stabilize membrane fluidity in bacteria involve changes in fatty acids (FA), the major component of PL. Such mechanisms, which may occur in combination, involve changing the ratio of saturation to unsaturation; *cis* to *trans* unsaturation; branched to unbranched structures, type of branching; acyl chain length and formation of cyclopropane FA [15, 16].

Increased degree of unsaturation in response to reduced temperature has been described for many microorganisms [17, 18], and can be regarded as a universally conserved adaptation response [19]. In *Aeromonas*, alteration of growth temperature induced changes in unsaturation, branching, and chain length of the FA. At temperatures below 15 °C or above 25 °C, three species of *Aeromonas*, *A. caviae*, *A. hydrophila* and *A. sobria*, showed significant decrease of *cis*-vaccenic acid (*cis*-11-C18:1) content. In cells exposed to high NaCl concentration, maintenance of growth ability was related to a reduced ratio of unsaturated to saturated FA, reflecting membrane rigidification [20].

How the FA composition of membrane lipids is altered in response to change of growth temperature depends on the mechanism of unsaturated FA (UFA) synthesis [21]. In bacteria, UFA synthesis involves both anaerobic and aerobic mechanisms. UFA synthesis in response to low temperature was characterized in vivo for the gram-positive bacteria *Bacillus subtilis*, which desaturates palmitate to delta 5-hexadecenoate [22]. The molecular mechanism of UFA synthesis in response to temperature change has been well studied in the gram-negative bacteria *Escherichia coli*. Since membrane of *E. coli* lacks of PtdCho, its composition is quite different from that of the rhizobia [23]. However, little is known regarding the control of FA synthesis in legume-nodulating rhizobia under abiotic stress.

The FA composition profiles of *Bradyrhizobium* and *Rhizobium* are quite different, and have been used for chemotaxonomic purposes [24]. Effects of growth phase [25, 26] and low temperature [4, 27] on FA synthesis and composition in these genera have been studied, but not the effects of high temperature or high salinity.

While we have previously determined the composition of PL in SEMIA6144 [13], in this study we describe for the first time the composition of FA and the effect of high growth temperature and salinity on the FA composition and FA synthesis in this strain and in TAL1000, peanut-nodulating rhizobia. We also describe the composition of PL in TAL1000 and the effect of high growth temperature and salinity on this composition and on the survival of this strain. Our purpose was to clarify the role of cell membrane modifications in resistance and adaptation of these rhizobia to environmental stresses. The results may identify new strategies for increasing symbiotic efficiency between rhizobia and peanut.

Materials and Methods

Bacterial Strains and Culture Conditions

The fast-growing strain TAL1000 was kindly provided by NifTAL Microbiological Resource Center, Paia, HI (USA), and the slow-growing strain SEMIA6144 was provided by MIRCEN/FEPAGRO (Brazil). The strains were kept on yeast extract mannitol plates [2] at 28 °C, with the pH of

the medium adjusted to 7 before autoclaving. For the determination of bacterial growth, viability and biochemical parameters, the strains were grown in B^- medium [28] for 24 h (TAL1000) or 120 h (SEMIA6144) with an initial optical density of 0.1 (620 nm), in a shaking water bath at 28 °C or 37 °C for high growth temperature. Based on differential NaCl tolerance of each strain (data not shown), the medium was supplemented with 300 mM NaCl (TAL1000) or 50 mM NaCl (SEMIA6144) for saline stress experiments. Viable TAL1000 cells were counted (CFU) by removing samples at intervals, as described by da Silva [29].

Incorporation of Labelled Acetate

[1-^{14}C]acetate, sodium salt (43 mCi mmol^{-1}, New England Nuclear), sterilized, was added to the medium (1 μCi ml^{-1}) at the time of inoculation. Cells were harvested at the late exponential phase (24 h for TAL1000 and 96 h for SEMIA6144) by centrifugation at 6000×*g* for 10 min, in a Beckman Allegra 64R refrigerated centrifuge. Pellets were washed twice with 0.9% NaCl and used for further studies. The same procedures and conditions were used for unlabelled samples.

Lipid Extraction

Lipids were extracted from washed bacteria with chloroform/methanol/water [30]. The lower phase, containing lipids, was dried under N_2, and dissolved in appropriate volume of chloroform/methanol 2:1 (v/v).

Separation and Quantification of ^{14}C-labelled Phospholipids

Aliquots of total lipid extracts were analyzed by Analtech thin layer chromatography (TLC) plates (silica gel HLF, 250 μm) using chloroform/acetone/methanol/acetic acid/water (40:15:14:12:7, by vol) as solvent. All solvents were of analytical or HPLC grade. Lipids were detected by iodine vapors and separated lipids were identified by comparison with purified standards (Sigma Chemical Co., St. Louis, MO, USA). TLC bands were scraped, 3 mL Optiphase Hisafe 2 (PerkinElmer, USA) was added to each vial, and radioactivity was measured by liquid scintillation counter (Beckman LS 60001 C, USA) [31].

Separation and Quantification of ^{14}C-labelled Fatty Acids Based on the Degree of Unsaturation

Fatty acid methyl esters (FAME) were prepared from total lipid extracts with 10% BF_3 in methanol [32], and resolved according to number of double bonds on TLC plates impregnated with $AgNO_3$ (10%, w/v), using hexane/ethyl ether/acetic acid (94:4:2, by vol) as solvent. FAME bands were detected under UV light after spraying the plates with dichlorofluorescein, elution [33], and drying in counting vials as described above.

Analysis of Fatty Acids by GC-FID

FAME prepared as above were analyzed using a Hewlett Packard 5890 II gas chromatograph (GC) equipped with a methyl silicone column (length 50 m; inner diameter 0.2 mm; film thickness 0.33 μm) and a flame ionization detector (FID).

GC conditions: injector temperature 250 °C; detector temperature 300 °C; carrier gas nitrogen. Temperature program: 180 °C, 25 min isothermal; 3 °C min^{-1} to 250 °C. Peak areas of carboxylic acids in total ion were used to determine relative amounts.

Fatty acids were identified by comparison of retention times with commercial standards. (Sigma Chemical Co., St. Louis, MO, USA).

Statistical Analyses

Data were compared by one-way analysis of variance (ANOVA) test.

Results

Effects of High Growth Temperature (37 °C) and Salinity on TAL1000 Survival

Viability of TAL1000 (measured as CFU ml^{-1}) was reduced by NaCl stress alone, and by a combination of NaCl stress and high growth temperature (Fig. 1), although TAL1000 was able to survive in these conditions. Lowest CFU values were obtained with 300 mM NaCl. Viability at high growth temperature, 37 °C, was not significantly affected.

Effect of High Growth Temperature and Salinity on TAL1000 Phospholipid Metabolism

[1-^{14}C]acetate sodium salt was incorporated mostly (90–92%) into PL, and the rest into neutral lipid fraction. The predominant labeled PL was phosphatidylcholine (PtdCho), followed in descending order by phosphatidylglycerol (PtdGro), phosphatidylethanolamine (PtdEtn), dimethyl phosphatidylethanolamine (DMPtdEtn), cardiolipin (Ptd_2Gro), and lysophosphatidylethanolamine (LPtdEtn) (Table 1).

PL phospholipids, *PtdCho* phosphatidylcholine, *DMPtdEtn* Dimethyl phosphatidylethanolamine, *LPtdEtn* lysophosphatidylethanolamine, *PtdEtn* Phosphatidylethanolamine, *Ptd_2Gro* cardiolipin, *PtdGro* phosphatidylglycerol, *NL* neutral lipids

* Difference from control (28 °C) value statistically significant at $P < 0.05$ level

PL patterns for TAL1000 were qualitatively similar for all experimental conditions, but quantitative changes were observed for individual PL. High growth temperature caused an increase in PtdCho from 44 to 49.4% and combined conditions increased PtdCho from 44 to 54%. Compared to the control condition (28 °C), the amount of radiolabel in LPtdEtn (identity confirmed by ninhydrin spray reagent) increased about twofold in response to salt stress and increased about threefold in response to high growth temperature.

Decreased labeling was observed for PtdEtn under high growth temperature from 13.7 to 7.6% and combined conditions from 13.75 to 8.1%, for PtdGro under combined conditions from 17.5 to 12.4% and for Ptd_2Gro by high growth temperature from 4.2 to 3%. Under combined conditions, the ratio of zwitterionic to anionic PL (Z/A) increased (data not shown).

Fatty Acid Composition of TAL1000 and SEMIA6144

Major FA detected in TAL1000 and SEMIA6144 were *cis*-vaccenic (18:1n-7) + oleic (18:1n-9), stearic acid (18:0) and palmitic acid (16:0). Eicosatrienoic acid (20:3n-6) and cyclopropane fatty acid ($19:0_{cyclo}$) were only detected in TAL1000, while palmitoleic acid (16:1n-7) was only detected in SEMIA6144 (Table 2).

Effect of Growth Conditions on Fatty Acid Composition of TAL1000 and SEMIA6144

FA composition of the two strains under experimental conditions tested is shown in Table 2. In TAL1000 the FA showing greatest change in response to tested conditions was 18:1n-7 + 18:1n-9, whose percentage declined from 63.3 to 8.2% under high growth temperature, and to 4.3% under temperature plus NaCl stress. Conversely, 16:0 increased from 8.4 to 20% at 37 °C, and to 16.1% under the combined conditions. The other saturated FA, 18:0, increased from 12.6 to 24% at 37 °C, and to 29% under combined conditions. $19:0_{cyclo}$ increased from 3.4 to 10% at 37 °C and to 14.5% under combined conditions. The changes in FA percentages led to alteration of the ratio between unsaturated to saturated FA (U/S in Table 2), which decreased in all experimental conditions.

Of all the tested conditions, the growth temperature increase was the one causing the most significant changes in the level of FA in TAL1000.

Notably, in SEMIA6144, 18:1n-7 + 18:1n-9 decreased from 84 to 73.5% under temperature stress, and to 68.5% under combined stresses, while 16:0 increased from 11 to 18.6% under temperature stress, and to 19.7% under combined stresses. FA values under NaCl stress alone were not significantly different from control values. The U/S ratio for SEMIA6144 decreased under all experimental conditions, but not as markedly as in TAL1000.

Effect of Growth Conditions on Fatty Acid Metabolism of TAL1000 and SEMIA6144

[1-^{14}C]acetate sodium salt was used as precursor for study of FA metabolism. Radioactivity distribution of various FA in TAL1000, separated by TLC according to degree of unsaturation, is shown in Fig. 2. Under control conditions (28 °C), labeling in TAL1000 was found predominantly in monounsaturated FA, followed by triunsaturated, saturated, and diunsaturated fractions. Consistent with findings for

Lipids were extracted, and fatty acids of total lipid were converted to methyl esters and analyzed by GC, as described in the text

Percentage of each fatty acid is relative to total fatty acids defined as 100%. Values represent means ± SEM of three independent experiments

ND not detected

[a] Correspond to two peaks of retention times of 36 min and 37.4 min. Such peaks could correspond to FA of more than 18 carbon atoms

[b] Ratio between sum of unsaturated and sum of saturated fatty acids

* Difference from control (28 °C) value statistically significant at $P < 0.05$ level

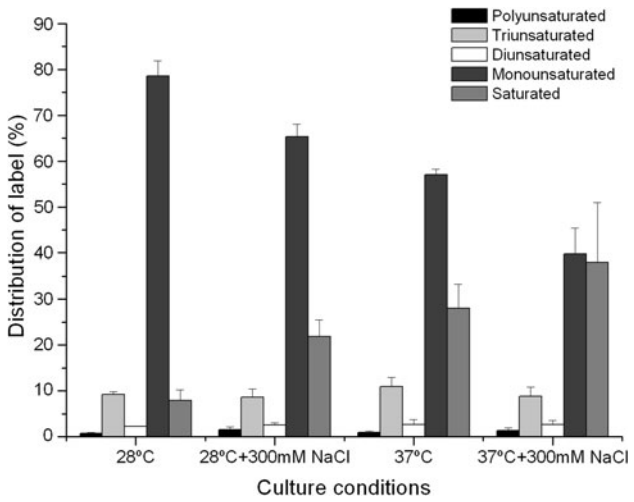

Fig. 2 Effect of NaCl and temperature on incorporation of [1-^{14}C]acetate in fatty acids of *Bradyrhizobium* TAL1000. FAMEs were prepared from total lipids, and separated according to unsaturation degree using TLC plates impregnated with 10% $AgNO_3$. Results are expressed as the percentage of total radioactivity incorporated in each FA fraction. Values represent means ± SEM from three independent experiments

FA composition (Table 2), high growth temperature and combined conditions decreased the [1-^{14}C]acetate incorporation in monounsaturated FA, 27.4 and 49.4% respectively. [1-^{14}C]acetate incorporation in saturated FA increased 3.5-fold by high growth temperature and 4.7-fold by combined conditions. [1-^{14}C]acetate incorporation in monounsaturated FA decreased from 78 to 65% and that of saturated FA increased from 8 to 22% by NaCl stress. Based on modified incorporation of labelled acetate, the U/S ratio decreased from 11.5 to 3.5 for NaCl stress, from 11.5 to 2.5 for high growth temperature, and from 11.5 to 1.6 for combined conditions.

Incorporation of [1-^{14}C]acetate in FA of SEMIA6144 was also tested. Labeling was observed primarily in monounsaturated FA, followed by saturated, diunsaturated, and triunsaturated FA. [1-^{14}C]acetate incorporation in saturated FA increased 28% under NaCl stress, 39% at 37 °C, and 45% under combined conditions. In contrast, radioactive incorporation in diunsaturated FA decreased 73% under NaCl stress, 66% at 37 °C, and 82% under combined conditions. As a consequence of these changes, the U/S

ratio decreased from 14.7 to 11.5 for NaCl stress, from 14.7 to 10.7 for high growth temperature, and from 14.7 to 10 for combined conditions.

Discussion

Our previous biochemical studies showed that *Bradyrhizobium* SEMIA6144, exhibited reduced viability and increased levels of PtdCho, when exposed to 37 °C, NaCl 50 mM and combined conditions [13]. In the present study we found that, viability of TAL1000 was reduced by NaCl 300 mM and by combined conditions (NaCl 300 mM plus 37 °C). Viability of salt-tolerant TAL1000 was unaffected by high temperature, consistent with studies that indicate a relationship between salt tolerance and temperature tolerance in rhizobial strains [34].

Adaptive mechanisms induced in cells in response to changes in environmental conditions, to maintain membrane fluidity involve modification of PL at the level of FA components and PL head groups [15, 35]. Behavior of SEMIA6144 PL labeling in response to stress [13] differed from those of TAL1000, resulting in different degree of modification in the Z/A ratio. We suggest that the two strains, although possessing similar PL composition, have different mechanisms for stabilizing membrane fluidity. The other adaptive mechanism developed by bacteria is alteration of membrane FA [36]. The FA composition of total lipids in the two strains was different, since TAL1000 contained 20:3n-6 and 19:0_{cyclo} FA, which were not present in SEMIA6144. Since the FA profile of TAL1000 is similar to that reported for *Rhizobium* [24], and both growth velocity and FA profile of TAL1000 differ from those of *Bradyrhizobium*, the taxonomic classification of TAL1000 may need to be reconsidered. High growth temperature and combined conditions caused significant reduction of 18:1 and increase of 18:0 and 16:0 (in TAL1000), or 16:0 (in SEMIA6144). These changes that were more pronounced in TAL1000, provoked modifications at the level of FA unsaturation degree coincident with results obtained for other rhizobia in which different environmental changes caused modifications in the U/S ratio [4, 26].

TAL1000 at 37 °C showed a decreased in the U/S ratio and enhanced formation of 19:0_{cyclo} (Table 2). Cyclic FA in the membranes of rhizobia could represent a mechanism to reduce membrane fluidity, similar to lactobacillus [37]. SEMIA6144, showed change in degree of FA unsaturation and increased 16:0/18:0 ratio under temperature stress, which may reflect decreased chain length and it may alter transition temperature for change from gel to liquid crystalline phase [19]. Results using [1-^{14}C]acetate labeling are consistent with FA composition studies and similar with studies in other gram-negative bacteria [38, 39] since showed synthesis of both saturated and monounsaturated FA. Tested experimental conditions altered incorporation of labeled acetate in FA of both rhizobial strains. We found no studies on effects of abiotic stress on FA synthesis in rhizobia, but a study showing increase of saturated FA synthesis at high temperature in *Bacillus subtilis* was consistent with our results [22].

We conclude that peanut-nodulating rhizobia strains are able to adapt to tested environmental conditions through FA modification, and that fast-growing TAL1000 is more efficient in this respect than slow-growing SEMIA6144. The most important mechanism for maintaining physical properties of the membrane is modification of the FA unsaturation degree. The ability of TAL1000 to alter its content of FA 19:0_{cyclo} may account for its tolerance of high temperature, while adaptation to environmental stresses in SEMIA6144 may involve shortening of the FA chain length [20].

The FA composition of strains of rhizobia used in commercial formulations should be considered as an indicator of whether or not an organism can adapt to changing environmental conditions, since differences in the capacity of rhizobia to adapt to environmental conditions may be related to differences in the FA composition.

Mild Testicular Hyperthermia Transiently Increases Lipid Droplet Accumulation and Modifies Sphingolipid and Glycerophospholipid Acyl Chains in the Rat Testis

Received: 8 October 2010 / Accepted: 23 December 2010 / Published online: 13 February 2011

Abstract Spermatogenesis is known to be vulnerable to temperature. The aim of this study was to investigate the effects on testicular lipids of the transient germ cell loss that is induced by mild testicular hyperthermia. Adult rat testes were exposed once a day to 43 °C for 15 min for 5 days and the effects were followed for several weeks. Two week after the last heat exposure, spermatocytes and early spermatids had virtually disappeared and the seminiferous tubules were populated mostly by mature spermatids and spermatozoa. One week later, the latter were also absent and mostly Sertoli cells populated the tubules. During these 3 weeks, glycerophospholipids (Gpl) and triacylglycerols with long-chain polyunsaturated fatty acids (PUFA) (e.g., 22:5n-6) and species of sphingomyelin and ceramide with nonhydroxy and 2-hydroxy very long-chain (VLC) PUFA (e.g., 28:4n-6, 2-OH 30:5n-6) decreased alongside the germ cells. Concomitantly, the amounts of cholesteryl esters and ether-linked triglycerides increased, both lipids accumulating long-chain and very-long-chain polyenes. This concurred with a considerable buildup of lipid droplets in Sertoli cells, evidently containing these neutral lipids, apparently formed during germ cell-derived membrane lipid catabolism. Between week 4 and week 6, new cohorts of spermatocytes appeared, and by week 12 most cell changes were reversed. Accordingly, as germ cell differentiation proceeded, 22:5n-6-rich Gpl augmented and spermatocyte-associated sphingolipids with nonhydroxy VLCPUFA appeared before their 2-hydroxy counterparts. The unique fatty acids of rat testicular lipids after mild hyperthermia reveal lipid catabolic and biosynthetic reactions that occur in normal spermatogenesis.

Keywords Ceramide · Cholesteryl esters · Ether-linked glycerolipids · Germ cells · Glycerophospholipids · Lipid droplets · Sphingomyelin · Sertoli cells · Very-long-chain PUFA

Abbreviations

ADG	Ether-linked triglycerides (alkyl- plus alkenyl- diacylglycerols)
Cer	Ceramide
CE	Cholesteryl esters
ChoGpl	Choline glycerophospholipids
EtnGpl	Ethanolamine glycerophospholipids
FAME	Fatty acid methyl esters
Gpl	Glycerophospholipids
PUFA	Polyunsaturated fatty acids
TAG	Triacylglycerols
CerPCho	Sphingomyelin
VLCPUFA	Very long-chain polyunsaturated fatty acids (n- and 2-OH are used as prefixes to denote nonhydroxy and 2-hydroxy VLCPUFA, respectively)

Introduction

In mammals, increased testicular temperature is known to result in reduced fertility or sterility due to the loss of spermatogenic cells. Exposure of the testis to abdominal temperature in experimental cryptorchidism and transient

exposure of the testis to moderate hyperthermia (43 °C, 15 min) results in the activation, within a few hours, of apoptotic mechanisms in germ cells [1–6]. Primary spermatocytes and early spermatids are the cells most susceptible to temperature [1, 3, 7]. Thus, exposure to moderate heat induces the partial or total disappearance of cohorts of these early spermatogenic cells, which may be predicted to result, a few weeks later, in reduced numbers or total absence of their more differentiated cell descendants including spermatozoa. After returning the testis to its normal temperature, this germ cell nadir may be followed by the gradual repopulation of the seminiferous epithelium with new spermatogenic cell generations, originated in those stem spermatogonia that were not affected or had tolerated the heat episode. Whereas many studies have examined the causes and mechanisms of heat-induced germ cell death, research following its consequences for several weeks until they are reversed is relatively scarce.

In a previous study [8], the selective reduction in germ cell numbers from adult rat testes exposed to the corporal temperature by the surgical operation of placing the testis in the abdominal cavity was shown to concur with the virtual disappearance of sphingomyelin (CerPCho) species with very long chain (VLC) (C_{24}–C_{32}) polyunsaturated fatty acids (PUFA) and with an intensely reduced amount of glycerophospholipid (Gpl) species with 22:5n-6. Such selective reduction was an indication that these particular species of CerPCho and Gpl were originally specific membrane constituents of germ cells, a fact that was recently confirmed [9]. During cryptorchidism-induced germ cell loss, the concentration of testicular neutral lipids like triacylglycerols, triglycerides with an ether bond, and cholesteryl esters (TAG, ADG, and CE, respectively) increased markedly. The finding that CE accumulated 22:5n-6 and VLCPUFA suggested that this neutral lipid was formed in Sertoli cells, after phagocytosis of apoptotic bodies derived from former germ cells, with temporary esterification of membrane-derived free cholesterol with fatty acids arising from phospholipid catabolism [8]. Because spermatogonia and Sertoli cells stay alive under these conditions, all these temperature-dependent, cell-associated lipid changes were proposed to be potentially reversible, with spermatogenesis starting again provided that the testis could be returned in time to its normal position and temperature.

The purpose of the present study was to follow for some weeks the changes in testicular lipid classes as a consequence of applying a series of direct daily exposures of rat testes in vivo to transient mild heat episodes. This model was useful to follow the induction, and subsequent reversion, of the heat-associated effects on testicular cells and their main polar and neutral lipids with highly unsaturated long-chain and very-long-chain fatty acids, demonstrating the almost complete reversibility of the temperature-induced effects on lipids with germ cell recovery.

Materials and Methods

Animals and Study Design

Four-month-old male Wistar rats were housed in a standard animal facility under controlled temperature (22 °C) and photoperiod (12L:12D) with ad libitum access to food and water. Testicular warming was conducted as described previously [10], by immersing the rat scrota into a water bath at 43 °C for 15 min, with the modification that this procedure was performed once a day for five consecutive days in animals restrained with acepromazine (5 mg/kg) in order to obtain a more drastic and more reproducible germ cell depletion, in an attempt to mimic in part the effects of experimental cryptorchidism. Control rats were subjected to restraint and scrotal immersion in water at room temperature (22 °C). They showed no significant differences in subsequent cell or lipid analyses with untreated animals, and were used as zero-time controls in Figs. 1, 2, 3, 4, 5 and 6. The experimental animals were sacrificed 1, 2, 6, and 12 weeks after the last heat exposure and the testes were removed. Some of the testes were fixed in 10% formaldehyde, embedded in paraffin, and cut into 3 μm sections. The sections were stained with hematoxylin–eosin. The study protocol was approved by the Committee on the Care and Use of Research Animals at the University of the South.

Lipid Separation and Analysis

After weighing, capsules and visible vessels were removed from testes and lipids were extracted after homogenization in mixtures of chloroform–methanol [11]. All solvents used in this study were HPLC-grade (JT Baker, NJ, USA; UVE, Argentina), and most procedures were carried out under N_2.

Aliquots of lipid extracts were taken to determine total lipid phosphorus content and phospholipid composition, with quantification of main phospholipid classes and subclasses, and to isolate polar and neutral lipid classes for further analysis. For phospholipid quantification, aliquots were spotted on high performance TLC plates (Merck, Germany) along with commercial standards and resolved with chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol.). The plates were exposed to iodine vapors, the spots scraped off, and the phospholipid classes quantified by phosphorus analysis [12].

Neutral lipids were separated from total phospholipids and resolved into classes in two steps. Chloroform/

methanol/aqueous ammonia (90:10:2 by vol.) was run up to the middle of the plates to separate the ceramide. After drying, a mixture of *n*-hexane/diethyl ether (80:20, by vol.) was run up to the top of the plates to resolve cholesteryl esters (CE), triacylglycerols (TAG), and triglycerides with an ether bond (abbreviated ADG to include 1-alkyl- and 1-alk-1′-enyl-diacylglycerols). After TLC, lipid bands were located under UV light by spraying with 2′,7′-dichlorofluorescein in methanol and scraped into tubes for elution. This involved thorough extraction (three successive times) of the scraped silica with a mixture of chloroform/methanol/water (5:5:1 by vol.). After collecting the eluates, they were partitioned with four volumes of water and centrifuged to recover the lipids.

The total phospholipid fraction that remained at the origin of the TLC plates was recovered and subjected to further separations. Aliquots were taken to study the total content and composition of Gpl fatty acids. The Gpl were resolved into classes by two-dimensional TLC [12] to isolate choline and ethanolamine glycerophospholipids (ChoGpl and EtnGpl). These were in turn separated into their two major (phosphatidyl- and plasmenyl-) subclasses by exposing the eluted, dried ChoGpl or EtnGpl for 1 min to a solution of 0.5 N HCl in acetonitrile [13] and immediately separating the products by TLC using chloroform/methanol/water (65:25:4, by vol.). The acid released the fatty aldehydes contained in the plasmalogen subclasses, allowing recovery of the corresponding 2-acyl-GPL, which were separated from the major 1,2-diacyl-Gpl (phosphatidylcholine, phosphatidylethanolamine) by TLC and both were subjected to fatty acid analysis.

Sphingomyelin (CerPCho) was resolved using chloroform/methanol/acetic acid/0.15 mol/L NaCl (50:25:8:2.5 by vol.) [14]. After isolation, CerPCho and Cer samples were subjected to mild alkali treatment to remove any potential lipid contaminant containing ester-bound fatty acids as previously described [8]. Briefly, both lipids were dried and treated (under N_2) with 0.5 N NaOH in anhydrous methanol at 50 °C for 10 min. This mild alkaline treatment was also used to obtain, as methyl esters, the fatty acids ester-bound to total Gpl, thus excluding from this fraction the fatty acids amide-bound to CerPCho.

Fatty Acid Analysis

For fatty acid quantification, methyl heneicosanoate and methyl 2-OH lignocerate were added as internal standards before methanolysis to the CerPCho and Cer samples, and just methyl heneicosanoate to the rest of the rat testicular lipids (which do not contain 2-OH fatty acids). Fatty acid methyl esters (FAME) were prepared from all lipid classes and subclasses by transesterification with 0.5 N H_2SO_4 in anhydrous methanol under N_2 [15] by keeping them overnight at 45 °C in Teflon®-lined, screw-capped tubes.

Before GC, all FAME were routinely purified by TLC using silica Gel G plates that had been pre-washed with methanol/ethyl ether (75:25, by vol.) and dried. The FAME from testicular lipids other than CerPCho and Cer were directly purified using hexane/ether (95:5, by vol.). The 2-hydroxy and non-hydroxy FAME from CerPCho and Cer were run with hexane/ether (80:20, by vol.) up to the middle of the plates, followed by hexane/ether (95:5, by vol.) up to near the top [16]. All FAME were eluted from the silica support by thoroughly mixing it with water, methanol and hexane (1:1:1, by vol.), centrifuging to recover the upper hexane layer, and repeating twice the hexane extractions.

Before GC, the 2-OH FAME from sphingomyelin and ceramide were converted into *O*-trimethylsilyl (O-TMS) derivatives [16]. A mixture of *N*,*O*-bis (trimethylsilyl)trifluoroacetamide (BSTFA) and 5% trimethylchlorosilane (TMCS) (Fluka reagent, Sigma-Aldrich) was added to the dried samples in small silanized glass tubes. After adding N_2 and capping the tubes, CerPCho and Cer samples were kept overnight at 45 °C with the reactants. The latter were evaporated and the TMS ethers, taken up into hexane, were subjected to GC. The VLCPUFA of CerPCho and Cer were identified by procedures and criteria described in detail in previous work [16–18].

For fatty acid quantification, a Varian 3700 Gas Chromatograph equipped with two (2 m × 2 mm) glass columns packed with 10% SP 2330 on Chromosorb WAW 100/120 (Supelco, Inc.) was used. Injector and detector temperatures were set at 220 and 230 °C, respectively, and N_2 (30 ml/min) was the carrier gas. For fatty acid detection and analysis, two flame ionization detectors, operated in the dual-differential mode, connected to a Varian Star Chromatography Workstation (version 4.51) were used. The column oven temperature was programmed from 150 to 230 °C at a rate of 5 °C/min for nonhydroxy fatty acids from all lipids and from 190 to 230 °C for 2-OH fatty acids from CerPCho and Cer, and then kept at the upper temperature long enough to elute FAME of different lengths.

Lipid Droplet Detection

Rat testes were fixed in 4% paraformaldehyde, rinsed in PBS containing 30% sucrose overnight at 4 °C, and placed in a small amount of optimal cutting temperature (OCT) compound (Crioplast®, Biopack) on plastic stubs. Preparations were frozen, cut into 5–7 μm sections using a cryostat, and processed for Nile Red staining as previously described [18]. All samples were observed in a laser scanning confocal microscope (Leica DMIRE2) with a 63 water objective. Images were collected and processed with LCS software (Leica) and Photoshop 8.0 (Adobe Systems, San Jose, CA).

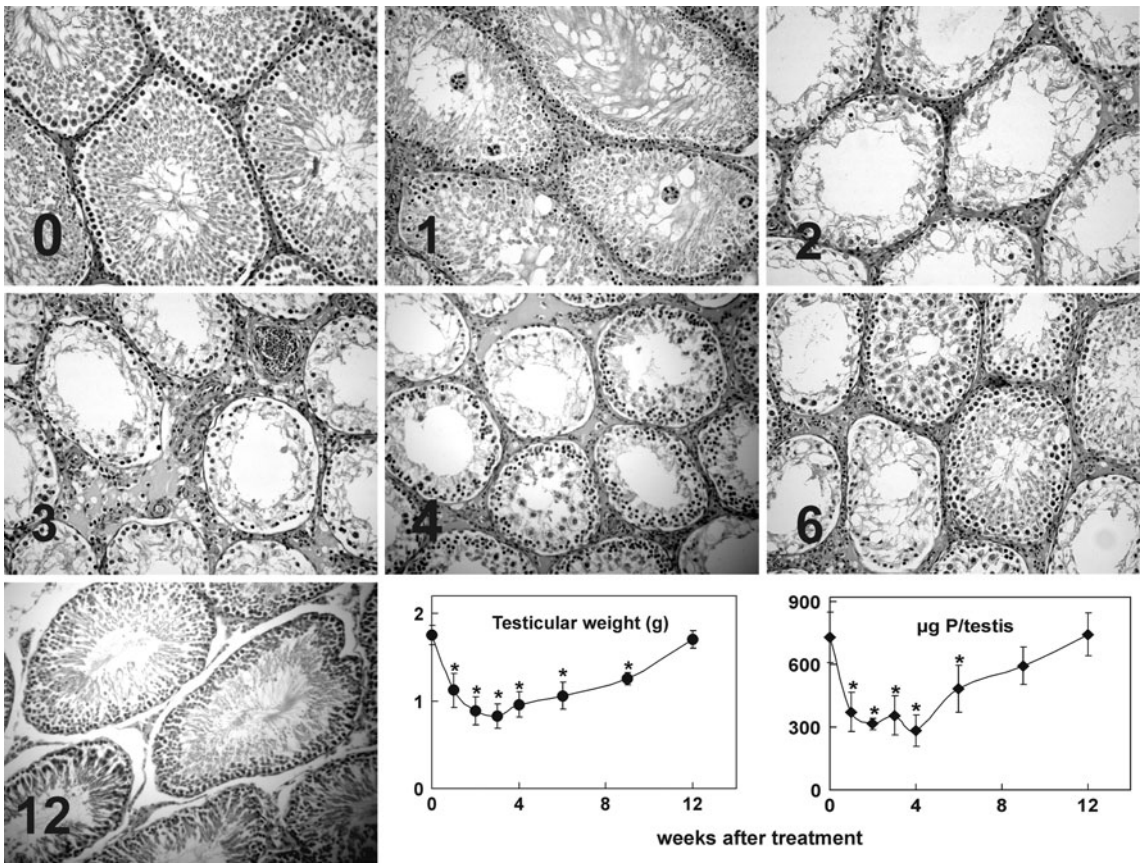

Fig. 1 Cellular changes in rat seminiferous tubules after mild hyperthermia. The micrographs depict hematoxylin-eosin stained sections prepared from rat testes that were subjected for 5 consecutive days to one daily exposure to 43 °C during 15 min, and were analyzed at the periods indicated (0, 1, 2, 3, 4, 6 and 12 weeks after the last day of exposure) (×200). On the *lower right panel*, the effect of these cell changes on the testicular weight and total lipid phosphorus are shown

Statistical Analyses

All data are presented as mean values ± SD, $n = 4$. In the figures, asterisks indicate statistically significant differences compared to non-treated testes at each time point ($p < 0.05$). Data analysis was done using one-way ANOVA followed by the Dunnett′s test.

Results

Testicular Histology and Weight

Episodes of mild hyperthermia applied to the rat testis as described here resulted in a significant reduction in the number of germ cells within seminiferous tubules (Fig. 1). One week after the last episode of heating (i.e., 12 days after the first one), the seminiferous epithelium had lost most of its pachytene spermatocytes and early spermatids, being still populated by remainders of the relatively more heat-tolerant elongated forms of spermatids and testicular spermatozoa, in reduced numbers with respect to controls. Interestingly, at this time point, giant multinucleated cells appeared in the epithelium of many tubules (Fig. 1). These cells are formed from developing round spermatids that are released together from their location around Sertoli cells (normally, there is cytoplasmic continuity between germ cells of a clone through small intercellular bridges, forming a so-called symplast) and are frequently found in the testis after any type of disturbance that destabilizes the cytoskeletal apparatus and leads to the opening of the intercellular bridges between round spermatids [19]. The reduced numbers of spermatids and spermatozoa that occupied the seminiferous tubules at week 1 were no longer present at weeks 2 and 3 post-treatment. At these time points, the cells populating the tubules were mostly Sertoli cells, exhibiting their intact typical nuclei (Fig. 1), plus some undifferentiated spermatogonia. At week 4, new cohorts of recently formed spermatocytes began to develop from the latter. At week 6 most tubules had increased in size with respect to the previous weeks to accommodate a new generation of pachytene spermatocytes and some, still relatively scarce, spermatids. By week 12 the tubules (although not yet the interstitium) looked similar to those

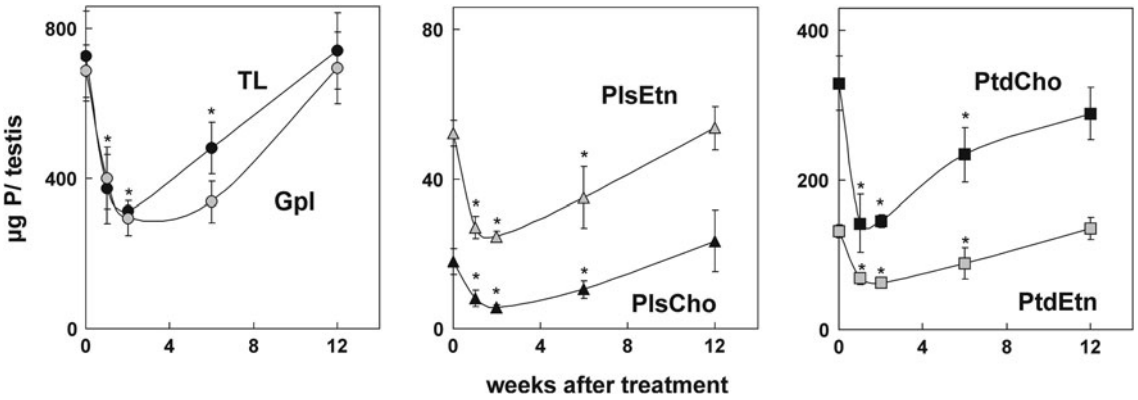

Fig. 2 Consequences of heat exposure on the phosphorus content of total lipids (*TL*) and glycerophospholipids (*Gpl*) of rat testis. The Gpl were resolved into classes to obtain the choline and ethanolamine GPL, and these were then resolved into phosphatidyl- and plasmenyl-subclasses. *Ptd-Cho* phosphatidylcholine, *Ptd-Etn* phosphatidylethanolamine, *Pls-Cho* plasmenylcholine, *PlsEt* plasmenylethanolamine

of untreated animals. In the first phase of germ cell number reduction, Sertoli cells apparently performed an efficient phagocytosis and elimination of the degenerating germ cells, whereas in the second phase of germ cell proliferation and differentiation Sertoli cells reassumed their main role as supporters and organizers of spermatogenesis. The described cellular changes were responsible for the rapid decrease of testicular weight that occurred in the first three weeks after heat treatment, and the gradual weight regain that occurred thereafter (Fig. 1). The total lipid phosphorus virtually paralleled these changes.

Total Phospholipids, Major Glycerophospholipid Classes and Their Fatty Acids

The heat-induced loss of germ cells within seminiferous tubules was accompanied by a 50 and a 57% drop in the total content of lipid phosphorus per testis at weeks 1 and 2 post-treatment, respectively (Fig. 2). Because testicular weight and lipid phosphorus decreased almost in parallel, the concentration of lipid phosphorus per gram of tissue did not change significantly.

The reduction in the amount per testis of total Gpl (Fig. 2) was mostly responsible for the decrease in total lipid (TL) phosphorus. In turn, the two major Gpl classes, ChoGpl and EtnGpl, were mostly responsible for the decrease in total Gpl phosphorus.

The diacyl- subclasses were mostly responsible for the decrease in ChoGpl and EtnGpl (Fig. 2), phosphatidylcholine decreasing more than phosphatidylethanolamine in relative and absolute terms. Although the plasmalogens of both Gpl also decreased, in this case plasmenyl ethanolamine decreased more than plasmenylcholine during the first two weeks following the heat treatment.

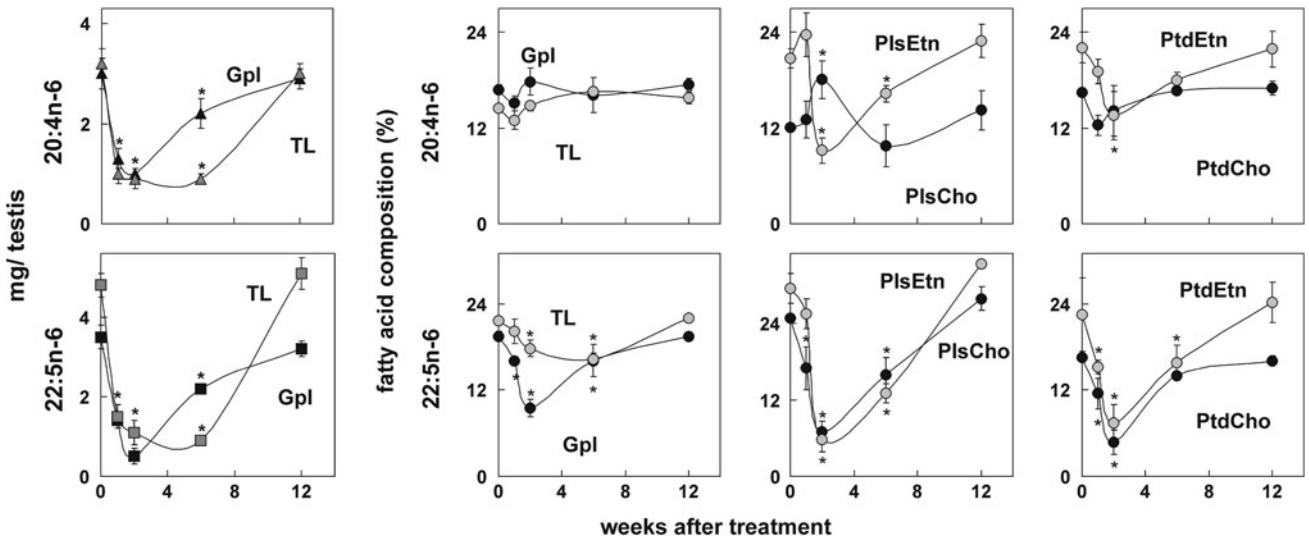

Fig. 3 Consequences of heat treatment on the amounts and percentages of arachidonic and docosahpentaenoic acids in testicular total lipids (*TL*), glycerophospholipids (*Gpl*), and the two major choline and ethanolamine glycerophospholipid subclasses

The decrease in lipid phosphorus was paralleled by a decrease in Gpl fatty acids. However, species with different types of fatty acids decreased at different rates, and there were even differences among species with the two major PUFA, as shown in the left panel of Fig. 3 for the amounts of 20:4n-6 and 22:5n-6. Although both fatty acids decreased dramatically, the amount of 20:4n-6 decreased less than that of 22:5n-6. The former reached its minimum at week 1, which was maintained for the next week, whereas the latter continued to decrease deeply between weeks 1 and 2 post-treatment. The amounts of Gpl species that contain both PUFA had started to recover at week 6, a period of intense new cell generation and concomitant membrane lipid biosynthesis, and were totally restored by week 12.

The *percentage* of 20:4n-6 and 22:5n-6 with respect to the total fatty acids (Fig. 3), show that the decrease of species containing these two PUFA was selective, considering that their proportions were significantly reduced in a decreasing mass of TL and Gpl, with their minima at week 1 and 2 post-treatment, respectively.

The fatty acid composition of phosphatidyl- and plasmenyl-subclasses of ChoGpl and EtnGpl (Fig. 3) shows this even more dramatically. The species of both lipids that contain 20:4n-6 decreased earlier than, and recovered before, the species containing 22:5n-6. Considering the quantitative data in Figs. 2 and 3, at week 2 post-treatment the amount of 20:4n-6 had decreased 3.5- and 4.6-fold, and that of 22:5n-6 10- and 8-fold, in phosphatidylcholine and phosphatidylethanolamine, respectively. Similarly, at week two, 20:4 had decreased 6- and 2-fold, and 22:5n-6 14- and 4-fold, in plasmenylethanolamine and plasmenylcholine, respectively.

Sphingomyelins, Ceramides and Their Fatty Acids

As did the major Gpl, the amount of total testicular CerP-Cho and Cer decreased concomitantly with the progressive loss of germ cells after heat exposure (Fig. 4). The species of these two lipids that contain VLCPUFA decreased up to their virtual disappearance between weeks 1 and 3 after the last heat exposure. The separation of the VLCPUFA of both lipids into nonhydroxy and 2-hydroxy VLCPUFA (n-V and HO-V in Fig. 4) allowed the additional observation that species of CerPCho and Cer with n-VLCPUFA decreased earlier than species with 2-OH VLCPUFA (their nadir occurred at weeks 1 and 2 post-treatment, respectively). This finds an explanation in the type of germ cell that is sequentially affected after heat treatment, considering that at week 1 pachytene spermatocytes had already disappeared from the testis, which still contained some elongated spermatids and spermatozoa (Fig. 1). Pachytene spermatocytes were recently shown to be rich in CerPCho and Cer with n-VLCPUFA, while the more differentiated spermatids and mature gametes are in turn much richer in CerPCho and Cer with 2-OH VLCPUFA [9].

The disappearance of germ cells during the first three weeks post-treatment resulted in a significant increase in the percentage of CerPCho as one of the remarkable changes in the phospholipid composition of the testis (from

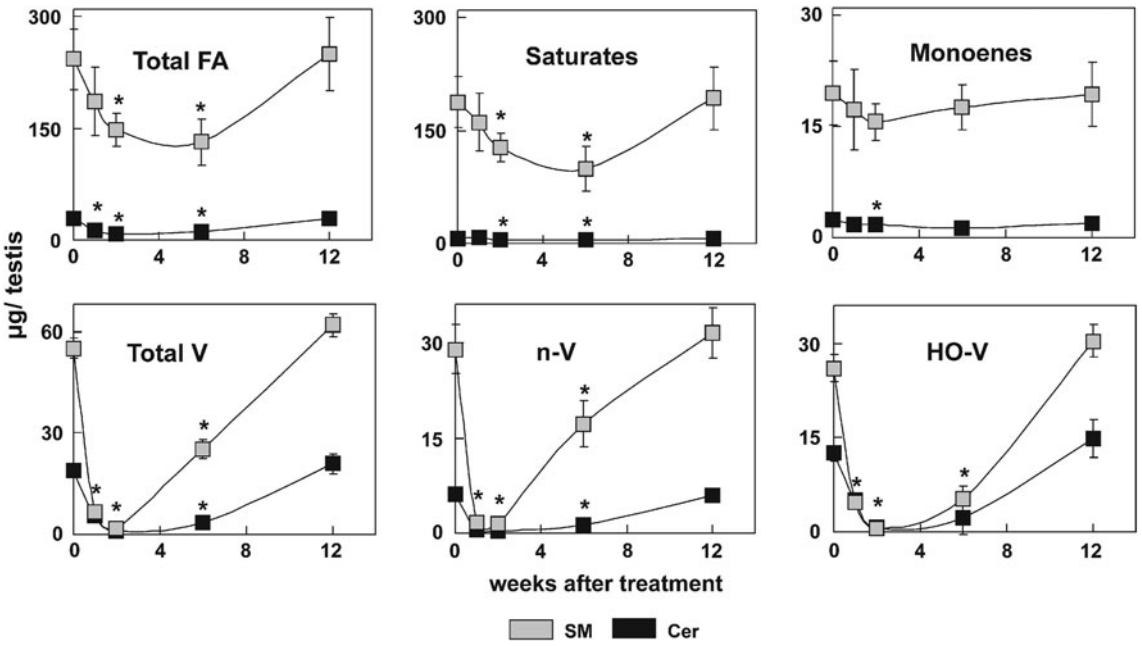

Fig. 4 Time-course of the in vivo changes after heat exposure in the amounts of rat testicular sphingomyelins and ceramides and their fatty acids. n-V, nonhydroxy VLCPUFA; 2-OH V, 2-OH VLCPUFA. Total V represents the sum of both types of VLCPUFA

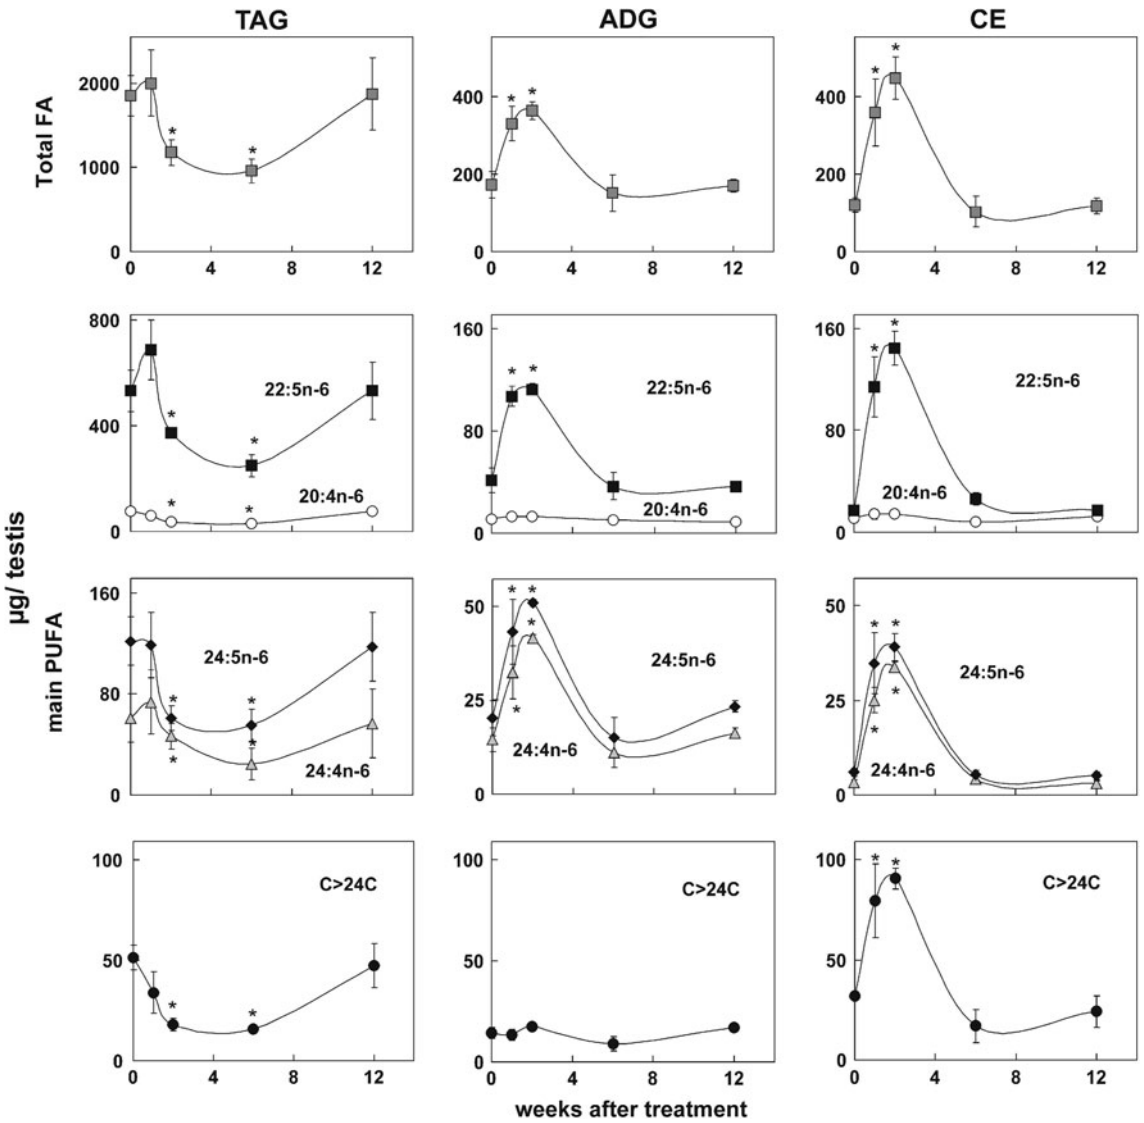

Fig. 5 Consequences of testicular heat exposure on the amount per testis of major neutral lipids and their polyenoic fatty acid constituents. *TAG*, *ADG* and *CE*: triacylglycerols, ether-linked triglycerides and cholesteryl esters, respectively. *Top panels* total fatty acids. *Bottom panels* main C_{20} to C_{32} carbon (n-6) tetraenoic and pentaenoic fatty acids in each lipid. Polyenoic fatty acids with chains longer than C24 are depicted as >24C

a 5 to a 10% of the total phospholipids at post-treatment weeks 1 and 2, not shown). This increase was associated, on the one hand, to the large decrease undergone by the major germ cell associated Gpl, and on the other, to the fact that Sertoli cells contain considerably more sphingomyelin than germ cells [9, 20]. On the basis of its total fatty acids (Fig. 4), 1 and 2 weeks after ending the treatment, the amount per testis of total CerPCho had decreased by 10 and 25%, respectively. Interestingly, at the same time as the sphingomyelins that contain saturated fatty acids were reduced by 12 and 24%, respectively, those that contain n-VLCPUFA were by reduced 90 and 100% and those that contain 2-OH VLCPUFA were reduced by 75 and 100%, respectively. These results agree with the fact that the sphingomyelins of Sertoli cells do not contain VLCPUFA but are instead rich in saturated, followed by monoenoic fatty acids [9], and explain the fact that these sphingomyelins decreased after heating much less than did the species that contain VLCPUFA (Fig. 4).

Neutral Lipids and Their Fatty Acids

The time course of the changes that occur after mild testicular hyperthermia in neutral lipids, focusing on species that contain PUFA of 20 to 32 carbon atoms, is shown in Fig. 5. This revealed a marked contrast between triacylglycerols (TAG) on the one hand and the other two neutral lipids of this study on the other, triglycerides with an ether

bond (abbreviated ADG to include alkyl- and alkenyl-diacylglycerols) and cholesteryl esters (CE) (Fig. 5).

In contrast to the marked reduction undergone by Gpl, the amount per testis of TAG remained unchanged during the first week after the last exposure to heat (Fig. 5). Interestingly, this lipid decreased abruptly (50%) between weeks 1 and 2, and remained at this low level for four additional weeks. Thus, only after post-treatment week 6 TAG started to increase, to return to control values by week 12. The quantitative importance of TAG is self-apparent from the data in Fig. 2, mostly explaining the post-treatment difference between the recovery of total Gpl and that of the total lipid in the testis.

The marked decrease undergone by the amounts of testicular TAG after week 1 in the heat-exposed testes involved predominantly their major species, i.e., those containing 22:5n-6 (Fig. 5), followed by species with 24:4n-6 and 24:5n-6 and also with longer polyenes. The time course of the changes, with persistence of TAG during the early germ cell loss phase, and with reappearance at a late period of the restoration phase, indicates that these TAG species bear an association with the most highly differentiated cells of the spermatogenic lineage.

In clear contrast with TAG, the ADG and CE exhibited an intense accumulation (twofold and fourfold, respectively) during the first two weeks after finishing the heat treatment (Fig. 5). By week 6, the amounts of both lipids had already returned to levels close to those of controls and continued at those relatively low levels for the next 6 weeks (Fig. 5).

Although ADG and CE collected an assortment of fatty acids (including saturates, 18:1 and 18:2, not shown), it was clearly apparent that they also accumulated tetraenoic and pentaenoic fatty acids (Fig. 5). Of these, 22:5n-6 was the single fatty acid that increased the most in quantitative terms in both neutral lipids during the first two weeks post-treatment. In ADG there was also a significant increase in that period of species that contain VLCPUFA with 24 carbon atoms (Fig. 5), but no changes in polyenoic fatty acids longer than C24. In contrast, VLCPUFA with 24 to 32 carbon atoms were collected in CE (Fig. 5).

Lipid Droplets

In histological sections of testicular tissue from untreated adult rats, where seminiferous tubules at different stages of the spermatogenic cycle can be observed, some of the tubules mostly contain spermatocytes at different stages, while others clearly contain mostly spermatids and spermatozoa in formation. In all of the tubules, the relatively minor and permanent population of Sertoli cells, located near the basement membrane of the tubules, can be observed. In control testis preparations, two types of lipid

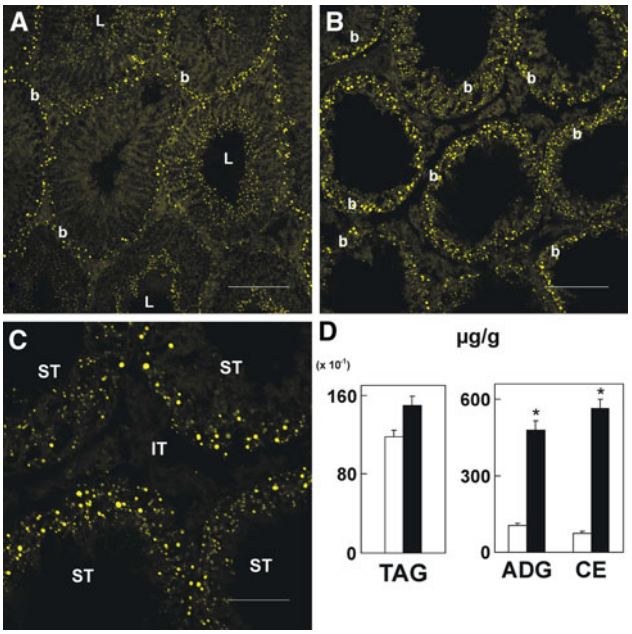

Fig. 6 Lipid droplets of rat testis, as revealed with Nile Red. **A** Control rat testis, showing the intense concentration of small lipid droplets near the lumen (*L*) in some seminiferous tubules and the more disperse and larger lipid droplets located near the basal (*b*) membrane in other tubules (*Bar* 150 µm); **B** Rat testis 2 weeks after the last heat exposure, showing large and abundant *L* and *S* lipid droplets near the (*b*) base of Sertoli cells (*Bar* 150 µm); **C** Enlarged field of another sample in the latter condition (*Bar* 50 µm) showing that lipid droplets were located within seminiferous tubules (*ST*) rather than in the interstitial tissue (*IT*). **D** Concentration (note that it is expressed as µg per gram of tissue) of the three neutral lipids surveyed in this study 2 weeks after daily transient exposures to 22 or to 43 °C (*white and black bars*, respectively)

inclusions were present, which were discriminated using Nile Red as previously described [18]. A population of small lipid droplets, located in the area of the epithelium facing the lumena of most of the tubules (i.e., mostly extracellular), was normally the most abundant (Fig. 6a). These droplets, recently shown to be TAG-rich [9], mostly correspond to the small but abundant lipid-laden "residual bodies" that are normally shed from elongated spermatids in differentiation to spermatozoa. The second type of lipid inclusion, a population of somewhat larger (but normally less numerous) lipid droplets, was observable near the peripheral basement membrane in some of the tubules (Fig. 6a), mainly included in Sertoli cells.

In the present study, 2 weeks after the last heat exposure (i.e., 3 weeks after the first), when virtually no germ cells but mostly Sertoli cells remained in the tubules, the small and the large type of lipid droplets were all concentrated in the latter cells (Fig. 6b). This extensive accumulation occurred exclusively within the seminiferous epithelium, not in the interstitium (Fig. 6c). The lipid profiles at this precise post-treatment time point, with maximum concentrations of TAG, ADG and EC (note that the results are

expressed as the amount per gram of tissue, not amount per testis in this case) (Fig. 6d) suggest that the small and the large lipid droplets observed in Sertoli cells contained these neutral lipids.

Discussion

The presented data demonstrate that repeated episodes of mild testicular hyperthermia applied to the rat testis result in virtually equivalent consequences as experimental cryptorchidism [8] on spermatogenic cells and their typical species of polar lipids, represented by their unique fatty acids, with drops to very low levels of Gpl species that contain 22:5n-6 and of CerPCho and Cer species that contain VLCPUFA. Similar decreases have been observed weeks after treatment with other germ cell apoptosis-inducing agents, such as administration of the antineoplastic agent doxorubicin [21] and X-ray irradiation [18]. In contrast with these two latter conditions, in which repopulation of the testis by new cohorts of germ cells does not occur, in the present experimental model it was possible to see these cells and their membrane lipids to spontaneously reappear in the testis by week 6 after the last heat exposure and reach their normal levels by week 12 post-treatment.

The observation that after heat-induced stress the sphingomyelins and ceramides that contain nonhydroxy-VLCPUFA disappeared *earlier* than the corresponding species of both lipids that contain 2-hydroxy VLCPUFA is consistent with the timed order of germ cell disappearance, considering the difference in fatty acid composition major germ cell types display in the rat testis [9]. Thus, the cells that in this study had vanished by week 1 post-heat treatment, pachytene spermatocytes, are exceedingly rich in sphingolipid species with n-VLCPUFA, in contrast to the more differentiated spermatids and spermatozoa, rich in species with 2-OH VLCPUFA. These cells were precisely the *last* to be lost from the heat-stressed seminiferous epithelium, in agreement with the fact that elongated spermatids are more resistant to thermal stress than primary spermatocytes and round spermatids [22]. The order of re-emergence of the two groups of species of both sphingolipids with time after reinitiating spermatogenesis was also consistent with (n-VLCPUFA-rich) spermatocytes reappearing before spermatids, their more mature (2-OH VLCPUFA-rich) counterparts.

The major Gpl are shown in the present study to loose most of their species with the major PUFA, 22:5n-6, in larger proportion than species with any other fatty acid, including the closely related 20:4n-6, during the first 2 weeks after the last heat exposure. Normally both fatty acids, in a nearly 1:1 proportion, are the main PUFA of the major Gpl of pachytene spermatocytes, while the 22:5n-6/20:4n-6 ratio is significantly higher in Gpl of spermatids and spermatozoa [9]. Thus, the marked decrease in the amount of both fatty acids observed here 7 days after the last heat exposure was associated with the virtual disappearance of spermatocytes, with elongated spermatids and spermatozoa still being present, in that period. The deep valley (in amount and percentage) of 22:5n-6-rich Gpl observed at week 2 post-heating concurs with a profound loss from the testis of virtually *all* germ cell types, and practically a "Sertoli cell only" seminiferous tubule system. Part of this drop at week 2 may be associated to the fact that the heat-tolerant spermatids that were still present at week 1 probably completed their differentiation to spermatozoa during this second week, and that these last gametes left the testis to be transported to the epididymis. This interpretation is consistent with the fact that heat impacts first the testis, then the epididymis. Thus, 7 days after a single episode of testicular heating (43 °C for 15 min), rat testicular weight declines to 70% of control, whereas epididymal weight does not decrease significantly until day 26 [7].

In contrast to the massive decrease of 22:5-rich Gpl observed during the first week after the last heat exposure, the amounts of 22:5n-6-rich TAG did not change significantly. These species of TAG are normally formed in elongating spermatids at the last stages of spermiogenesis and are highly concentrated in the particles known as "residual bodies" [9]. Taken together with the present results, this suggests that 22:5n-6-rich TAG continued to be produced throughout the period of heat exposure. This would explain that TAG levels per testis were still high during the first week after the last heat episode, in concomitance with the last round of spermiogenesis. The TAG concentration in the Sertoli-cell-rich testis at week 2 post-treatment, and the accumulation in these cells of the small lipid droplets representative of residual bodies (Fig. 6), suggests that this process apparently continued at its nearly normal pace by differentiation of pre-existing temperature-tolerant elongated spermatids. Eventually, the latter were also depleted, by transformation into spermatozoa, which left the testis normally in the course of the next week.

In its effects on neutral lipids, the period of two weeks of cell depopulation provoked by the five daily episodes of transient hyperthermia was comparable to the 10 days of unilateral experimental cryptorchidism previously reported [8]. Both had in common a significant buildup of CE species with specific PUFA (e.g., 22:5n-6) and VLCPUFA (e.g., 28:5n-6) in rat testes. Because this accumulation occurred concomitantly with vulnerable germ cell disappearance from, but sparing heat-tolerant Sertoli cells in, seminiferous tubules, it is clearly apparent that CE accumulation is a feature of the latter, not the former cells. The apoptotic bodies derived from heat-damaged germ cells

may be expected to have been phagocytosed by Sertoli cells, this being rapidly followed by hydrolysis and further processing of the ingested materials. Besides proteins and nucleic acids, these materials obviously comprised former germ cell membranes and their lipids (free cholesterol and phospholipids including Gpl and sphingomyelins). The temporary accumulation of 22:5- and VLCPUFA-rich species of CE is interpreted to occur mostly as a consequence of lipid catabolism in Sertoli cells.

One possible explanation for the heat-related CE accumulation, which we proposed in previous work [8], was biochemical, i.e., that this could in part be ascribed to reduced CE hydrolysis due to heat-induced inhibition or inactivation of HSL (*H*ormone *S*ensitive *L*ipase), or to increased CE synthesis due to activation of ACAT (acyl-CoA-cholesterol acyl transferase) in Sertoli cells. However, we now have more of a cellular conception, considering that Sertoli cells are active phagocytes, and that accumulation of 22:5n-6-rich CE in testis also occurs at physiological temperatures, as a consequence of diverse situations whose only common feature is that they are pro-apoptotic to germ cells while sparing Sertoli cells [doxorubicin treatment [21], X-ray irradiation [18], and ischemia-reperfusion (Zanetti SR and Aveldaño MI, unpublished observations)]. We favor the possibility that Sertoli cells habitually form CE, using ACAT as any phagocyte would do, after phagocytosing biological materials whose breakdown leads to an excess of free cholesterol and fatty acids.

The accumulation of 22:5-rich and VLCPUFA-rich species of CE is interpreted to reflect a phagocytic cell-typical activity of Sertoli cells that is always present, but that is markedly intensified in the presence of factors (like temperature) that increase the death of germ cells. This may include a lethal rapid destruction of some cells and the sublethal damage with survival but eventual degeneration of others. Thus, the buildup in Sertoli cells of an excess of germ-cell derived free cholesterol, and (after phospholipid hydrolysis) free fatty acids, may be naturally prevented in these cells by producing CoA esters of the latter and collecting them both in the form of innocuous CE. These CE may be temporarily set aside in their cytoplasm—in the form of lipid droplets—before their ultimate disposal, i.e., until all fatty acids can be oxidized to produce ATP [23] and/or until all that extra cholesterol can be effluxed, which requires ATP-driven transporters [24].

Almost in parallel to CE, the amounts per testis of ADG also increased significantly as a consequence of mild hyperthermia. Considering the reduced testicular weight, the concentration of both neutral lipids increased several fold in Sertoli cells during the first 2 weeks following heat exposures (Fig. 6). This also agreed with previous observations in the cryptorchid rat model [8], since in both temperature-induced situations significant accumulations of ADG with PUFA (largely 22:5n-6, and to a lesser extent 24:4n-5 and 24:5n-6), occurred in concomitance with the depletion of germ cells and the corresponding decrease of 22:5n-6 rich Gpl, including plasmalogens.

In physiological conditions, the ether linked triglycerides (mostly 1-*O*-alkyl, 2,3 diacyl-*sn*-glycerols) could somehow be related to the biosynthesis ether-linked lipids such as PAF or seminolipid, or be precursors of plasmalogens [25]. However, in pathological conditions like the present temperature-related massive germ cell loss, considering that ADG accumulate PUFA, their buildup during the first 2 weeks suggests a relation to catabolism rather than to biosynthesis of plasmalogens. By a similar self-defense reason as CE are accumulated in Sertoli cells, as a strategy to limit any excess of (cell toxic) free cholesterol and free fatty acids, ADG may represent a form of temporarily capturing potentially harmful or disturbing excesses of free PUFA and (diradyl) diglycerides derived from Gpl hydrolysis, in the form of innocuous (non-toxic, cell-signalling inactive) triglycerides. In other words, PUFA- and VLCPUFA-rich CE and ADG seem to be normal, transient by-products formed in Sertoli cells after they ingest and process apoptotic bodies derived from spermatogenic cells that die from *any* cause, whether pathological or physiological.

Physiologically, the same mechanisms operating during the normal spermatogenic cycle provide an explanation to the function of the PUFA- and VLCPUFA-rich CE and ADG previously reported to be present in seminiferous tubules of untreated rats [25]. Thus, Sertoli cells habitually perform phagocyte-typical activities at different stages of the spermatogenic cycle. Firstly, because they have a limited germ cell support capacity, they control the numbers of early germ cells (which are normally overproduced) by inducing their apoptosis [4] and then phagocytosing the resulting apoptotic bodies [26]. Secondly, although at a different stage of the spermatogenic cycle, Sertoli cells are also known to perform on a regular basis the phagocytosis of the myriad of residual bodies that are shed from spermatids during spermiogenesis. These particles were recently shown to be loaded with 22:5n-6-rich TAG, free cholesterol, 22:5n-6-rich Gpl and 2-OH VLCPUFA-rich sphingomyelins [9], lipids whose final destination is also Sertoli cells for eventual hydrolysis and disposal of their acyl chains.

The period that goes between weeks 4 and 6 post-treatment is an excellent phase in which to study biochemical aspects of germ cell development. From a germ cell deprived testis, there is a relatively long period in which pachytene spermatocytes predominate in seminiferous tubules, resembling in many aspects the onset of spermatogenesis at pubertal ages. This phase appears promising to study in vivo

aspects of the biosynthesis of PUFA and n-VLCPUFA, such as the expression and activity of fatty acid desaturases and elongases, and the pathways of incorporation of these fatty acids into the corresponding phospholipids and sphingolipids. The appearance of the first spermatids, with no interference from the presence of their more differentiated counterparts, may be useful to determine the cellular location and mechanism of the 2-hydroxylation that is responsible for the biosynthesis of the 2-OH VLCPUFA of rat testicular CerPCho and Cer. Lastly, the phase of fully restored spermiogenesis may allow the study of the 22:5n-6 rich TAG that is so actively synthesized by differentiating spermatids.

Concluding remarks

This study does not focus on those cells that were directly damaged by temperature: such cells were killed by apoptosis (a process that takes just 12–16 h) and disappeared from the testis in a day or two (the time required for Sertoli cells to phagocytize and completely eliminate apoptotic germ cells). These facts and the mechanisms involved have been comprehensively studied by other authors. It rather deals with those cells that, not having been lethally affected by temperature initially, or having succeeded to endure and overcome its damaging effects, managed to continue with their functions. During the first weeks, the marked decrease in the content of PUFA-rich species of Gpl and VLCPUFA-rich species of sphingolipids was caused mostly by the immediate death of vulnerable germ cell line *precursors* (e.g., pachytene spermatocytes), which led to the subsequent nonexistence of their whole progeny, but also by the eventual death of those cells that had been sublethally targeted by temperature but died at later stages of their differentiation. This phase seems to be a good period in which to study the biochemistry involved in many as yet unknown details of the catabolism of lipids with PUFA of diverse chain lengths and unsaturation (including 22:5n-6 and 2-OH VLCPUFA) in Sertoli cells. In turn, the phase of gradual germ cell repopulation after recovery from mild hyperthermia, with long-chain PUFA synthesized and incorporated into Gpl including plasmalogens, and with n-VLCPUFA restored before 2-OH VLCPUFA and both reappearing amide-bound to Cer and CerPCho, offers a good opportunity to study aspects of the expression of genes and activity of enzymes that take part in the biosynthesis of the unique lipid molecular species that germ cells contain in the adult rat testis.

Acknowledgments The authors gratefully thank Dr. Eduardo N. Maldonado for his helpful comments on the manuscript. METHODS

Efficient Synthesis of the Very-Long-Chain n-3 Fatty Acids, Tetracosahexaenoic Acid (C_{24}:6n-3) and Tricosahexaenoic Acid (C_{23}:6n-3)

Abstract Tetracosahexaenoic acid (C_{24}:6n-3, THA, **3**) is an essential biosynthetic precursor in mammals of docosahexaenoic acid (C_{22}:6n-3, DHA, **1**), the end-product of the metabolism of n-3 fatty acids. THA **3** is present in commercially valuable fishes, such as flathead flounder. Tricosahexaenoic acid (C_{23}:6n-3, TrHA, **2**), an odd-numbered-chain fatty acid, has been identified from marine organisms such as the dinoflagellate, *Amphidinium carterae*. To date, few studies have examined THA **3** and TrHA **2** due to difficulties in detecting and identifying these compounds, so their chemical and biological properties remain poorly characterized. Only one methodology for the chemical synthesis of THA **3** has been presented, and no method for the synthesis of TrHA **2** has been reported. We report here the efficient synthesis of THA **3** in four steps in 56% overall yield, and the synthesis of TrHA **2** in six steps in 48% overall yield. We also present the synthesis of Δ^2-THA **4**, an intermediate of β-oxidation of THA **3** to DHA **1**, in three steps in 73% overall yield.

TAG	Triacyl-*sn*-glycerol

Introduction

The polyunsaturated fatty acid, docosahexaenoic acid (C_{22}:6n-3, DHA, **1**), is largely found in neuronal tissues such as brain and retina [1]. DHA **1** is an essential component of neuronal membranes, is a precursor of potent neuroprotective mediators, and is important in helping to prevent both cardiovascular disease and metabolic syndrome [2, 3]. Mammals obtain DHA **1** directly from dietary sources, especially fish, but can also generate DHA **1** in the liver from n-3 fatty acid precursors obtained from eating plants [4–6]. The capacity of the human liver to produce DHA **1** may become critical for maintaining normal levels of DHA **1** in the brain and retina [4, 6–8] if insufficient DHA **1** is available from the diet, as is often the case in modern societies [9].

The pathway for DHA biosynthesis in the liver is shown in Fig. 1. α-Linolenic acid (18:3n-3, ALA) is converted to eicosapentaenoic acid (20:5n-3, EPA), which is converted into docosapentaenoic acid (22:5n-3, DPA) and then into tetracosahexaenoic acid (24:6n-3, THA, **3**). Desaturase and elongase enzymes are localized in the endoplasmic reticulum of the hepatocyte and act on n-3 fatty acids. Desaturase progressively introduces double bonds, and elongase

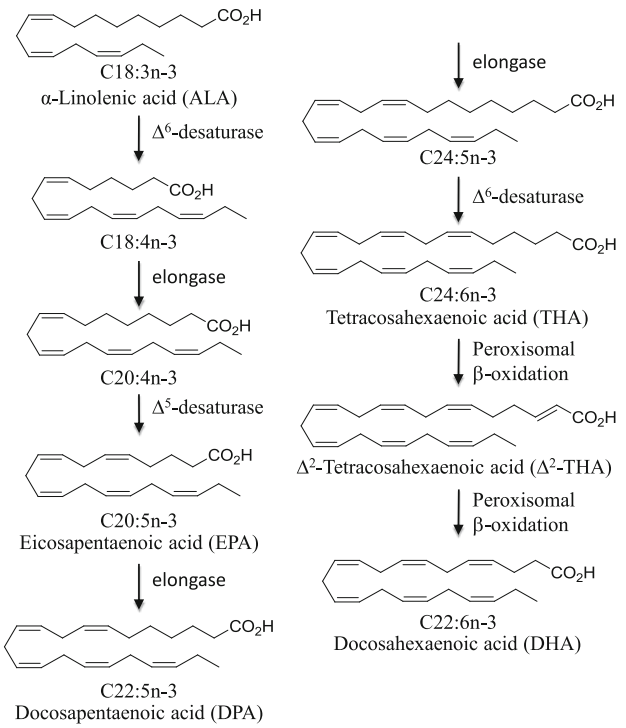

Fig. 1 Metabolic pathway of bioconversion of n-3 polyunsaturated fatty acids

extends shorter-chain n-3 fatty acids by two-carbon units, thereby generating very-long-chain THA **3** [10]. THA **3** is then transported into the peroxisomes and converted to DHA **1** by β-oxidation reactions that involve several specific enzymes: acyl-coenzyme A oxidase, D-bifunctional protein, and peroxisomal thiolases [11–14]. DHA **1**, the end-product of the metabolism of n-3 fatty acids, is delivered to the brain by the circulatory system and accumulates in the brain membranes. In contrast, THA **3** is not incorporated into the brain membranes but is an essential precursor of DHA **1**. Recently, Piomelli's group reported that levels of DHA precursors, particularly ALA and THA **3**, are elevated in the livers of patients with Alzheimer's disease, whereas expression of peroxisomal D-bifunctional protein, which catalyzes the conversion of THA **3** to DHA **1**, is reduced [15]. Piomelli et al. concluded that deficient liver biosynthesis of DHA **1** correlates with cognitive impairment in Alzheimer's patients. Thus, the critical importance of THA **3** in mammals is becoming clearer.

THA **3** is found in various marine organisms [16–18]. Nichols et al. [19] reported that THA **3** constitutes 9.3% of the total fatty acids in the jellyfish *Aurelia* sp. Recently, Tomita and Ando reported that THA **3** is found preferentially at the *sn*-2 position (1.6–23.3 mol%) of triacyl-*sn*-glycerols (TAG) from flathead flounder flesh [20]. Flathead flounder is extensively consumed by humans; therefore, we intake THA **3** in the form of TAG concentrating THA **3** at the *sn*-2 position. Odd-numbered very-long-chain

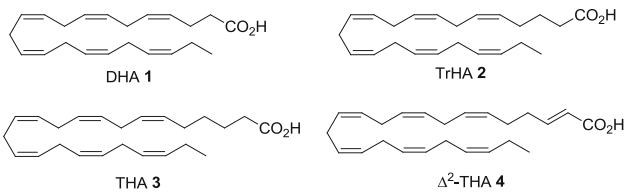

Fig. 2 Chemical structures of the fatty acids discussed in this paper. Docosahexaenoic acid (**1**), tricosahexaenoic acid (**2**), tetracosahexaenoic acid (**3**) and Δ^2-tetracosahexaenoic acid (**4**)

polyunsaturated fatty acids have also been identified from marine organisms [21]. Odd-chain fatty acids can be used in lipid metabolism [22]. The C_{23} fatty acid, tricosahexaenoic acid (C_{23}:6n-3, TrHA **2**), is found in the dinoflagellate, *Amphidinium carterae* [23]. To date, few studies have examined THA **3** and TrHA **2** due to difficulties in detecting and identifying these compounds, so their chemical and biological properties remain poorly characterized. To our knowledge, only one chemical synthesis method for THA **3** has been reported [24, 25], and none for TrHA **2**. In the course of our synthetic and structural biological studies of polyunsaturated fatty acids [26–30], we attempted to derive very-long-chain n-3 fatty acids from DHA ester. In this paper, we report the efficient chemical synthesis of THA **3**, TrHA **2**, and an intermediate of β-oxidation of THA **3** to DHA **1**, Δ^2-THA **4** (Fig. 2).

Materials and Methods

General Experimental Procedures

DHA ethyl ester **5** was a kind gift from the Maruha Nichiro holdings (Tsukuba, Japan). All the other reagents were purchased from commercial sources and used without further purification. Organic solvents used were dried by standard methods. All reactions were performed under a nitrogen atmosphere. Silica gel (wako gel C200) was used for column chromatography, and pre-coated silica gel $60F_{254}$ plates (0.25 mm, Merck) were used for TLC. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) were recorded using a Bruker AV300 instrument in $CDCl_3$ solution with TMS as an internal standard and the chemical shifts are given in δ values. Splitting patterns are indicated as follows: s, singlet; d, doublet; t, triplet; q, quartet; quint, quintet; m, multiplet. Mass spectra were recorded on a JEOL MS700 spectrometer using NBA as positive-ion FAB matrix.

(4*Z*,7*Z*,10*Z*,13*Z*,16*Z*,19*Z*)-Docosa-4,7,10,13,16,19-Hexaenal (**6**)

To a stirred solution of DHA ethyl ester **5** (157 mg, 0.440 mmol) in CH_2Cl_2 (1 mL) was added 1.0 M

diisobutylaluminium hydride (DIBAL-H) in toluene (523 μL, 0.523 mmol) at −78 °C and the mixture was stirred for 1 h. The reaction was quenched with 1 N HCl aq. and the mixture was extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (9 g, 5% EtOAc–hexane) to give aldehyde **6** (117 mg, 85%). A large scale preparation of **6** was performed using 10.1 g of DHA ester **5** under the similar conditions and 7.45 g of pure compound **6** was obtained (84% yield).

^{1}H NMR ($CDCl_3$) δ: 9.78 (1 H, m, H-1), 5.33–5.44 (12 H, m, H-4, 5, 7, 8, 10, 11, 13, 14, 16, 17, 19, 20), 2.78–2.92 (10 H, m, H-6, 9, 12, 15, 18), 2.51 (2 H, m, H-2), 2.40 (2 H, m, H-3), 2.08 (2 H, quint, $J = 7.5$ Hz, H-21), 0.97 (3 H, t, $J = 7.5$ Hz, H-22); ^{13}C NMR ($CDCl_3$) δ: 201.9, 132.0, 129.4, 128.6, 128.4, 128.29, 128.27, 128.1 (2 carbons), 127.90, 127.86, 127.7, 127.0, 43.7, 25.64 (3 carbons), 25.59, 25.5, 20.6, 20.1, 14.3; HRMS (FAB): Calcd for $C_{22}H_{33}O$ $[M + H]^+$: 313.2531; found: 313.2537.

Methyl (2*E*,6*Z*,9*Z*,12*Z*,15*Z*,18*Z*,21*Z*)-Tetracosa-2,6,9,12,15,18,21-Heptaenoate (**7**)

To a stirred suspension of sodium hydride (0.71 g, 29.6 mmol) in THF (6 mL) was added trimethyl phosphonoacetate (4.25 mL, 29.6 mmol) at 0 °C and the mixture was stirred for 10 min. A solution of aldehyde **6** (4.63 g, 14.8 mmol) in THF (45 mL) was added to the mixture. The reaction mixture was stirred at 0 °C for 1 h, then quenched with water at 0 °C and extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (60 g, 0.5% EtOAc–hexane) to give 2*Z*-**7** (0.39 g, 7%) and 2*E*-**7** (4.71 g, 87%) in this order.

2*E*-**7** $R_f = 0.51$ (10% EtOAc-hexane). ^{1}H NMR ($CDCl_3$) δ: 6.96 (1 H, dt, $J = 15.6$, 6.6 Hz, H-3), 5.84 (1 H, d, $J = 15.6$ Hz, H-2), 5.28–5.46 (12 H, m, H-6, 7, 9, 10, 12, 13, 15, 16, 18, 19, 21, 22), 3.73 (3 H, s, H-CO_2Me), 2.78–2.91 (10 H, m, H-8, 11, 14, 17, 20), 2.25 (4 H, m, H-4, 5), 2.08 (2 H, quint, $J = 7.5$ Hz, H-23), 0.97 (3 H, t, $J = 7.5$ Hz, H-24); ^{13}C NMR ($CDCl_3$) δ: 167.0, 148.6, 132.0, 129.1, 128.6, 128.29, 128.26, 128.22 (2 carbons), 128.08, 128.06, 128.02, 127.9, 127.0, 121.3, 51.4, 32.1, 25.7, 25.6 (3 carbons), 25.5, 20.6, 14.3; HRMS (FAB): Calcd for $C_{25}H_{37}O_2$ $[M + H]^+$: 369.2794; found: 369.2780. 2*Z*-**7** $R_f = 0.65$ (10% EtOAc-hexane). ^{1}H NMR ($CDCl_3$) δ: 6.22 (1 H, dt, $J = 11.5$, 7.5 Hz, H-3), 5.79 (1 H, dt, $J = 11.5$, 1.7 Hz, H-2), 5.26–5.45 (12 H, m, H-6, 7, 9, 10, 12, 13, 15, 16, 18, 19, 21, 22), 3.70 (3 H, s, H-CO_2Me), 2.68–2.91 (12 H, m, H-4, 8, 11, 14, 17, 20), 2.22 (2 H, m, H-5), 2.07 (2 H, quint, $J = 7.5$ Hz, H-23), 0.97 (3 H, t, $J = 7.5$ Hz, H-24); ^{13}C NMR ($CDCl_3$) δ: 166.7, 149.8, 132.0, 128.8 (2 carbons), 128.6, 128.25, 128.23, 128.18, 128.16, 128.09 (2 carbons), 127.9, 127.0, 119.7, 51.0, 28.8, 26.6, 25.6 (4 carbons), 25.5, 20.6, 14.3; HRMS (FAB): Calcd for $C_{25}H_{37}O_2$ $[M + H]^+$: 369.2794; found: 369.2792.

Methyl (6*Z*,9*Z*,12*Z*,15*Z*,18*Z*,21*Z*)-Tetracosa-6,9,12,15,18,21-Hexaenoate (**8**)

To a solution of 2*E*/2*Z* mixture **7** (32 mg, 87 μmol) in MeOH (0.5 mL) was added Mg turnings (20 mg, 0.84 mmol) at 0 °C and the mixture was stirred for 3.5 h at room temperature. After addition of H_2O, the mixture was extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (10 g, 1% EtOAc–hexane) to give **8** (26 mg, 81%). A large scale preparation of **8** was performed using 1.07 g of 2*E*/2*Z* mixture **7** under the similar conditions and 820 mg of pure compound **8** was obtained (76% yield). ^{1}H NMR ($CDCl_3$) δ: 5.28–5.56 (12 H, m, H-6, 7, 9, 10, 12, 13, 15, 16, 18, 19, 21, 22), 3.67 (3 H, s, H-CO_2Me), 2.73–2.92 (10 H, m, H-8, 11, 14, 17, 20), 2.32 (2 H, m, H-2), 2.08 (4 H, m, H-5, 23), 1.65 (2 H, quint, $J = 7.7$ Hz, H-3), 1.40 (2 H, quint, $J = 7.7$ Hz H-4), 0.98 (3 H, t, $J = 7.5$ Hz, H-24); ^{13}C NMR ($CDCl_3$) δ: 174.1, 132.0, 129.7, 128.6, 128.4, 128.3, 128.19, 128.16, 128.12, 128.10, 128.0, 127.9, 127.0, 51.5, 34.0, 29.0, 26.9, 25.6 (4 carbons), 25.5, 24.6, 20.6, 14.3; HRMS (FAB): Calcd for $C_{25}H_{39}O_2$ $[M + H]^+$: 371.2950; found: 371.2954.

(6*Z*,9*Z*,12*Z*,15*Z*,18*Z*,21*Z*)-Tetracosa-6,9,12,15,18,21-Hexaenoic Acid (THA **3**)

A solution of **8** (1.19 g, 3.23 mmol) in 5% KOH/MeOH–H_2O (19:1, 16 mL) was stirred at 50 °C for 1 h. The reaction mixture was neutralized with 10% HCl aq. and extracted with EtOAc. The organic layer was washed with water, dried over $MgSO_4$, and evaporated. The residue was chromatographed on silica gel (110 g, 50% EtOAc–hexane) to give THA **3** (1.01 g, 87 %). ^{1}H NMR ($CDCl_3$) δ: 5.27–5.55 (12 H, m, H-6, 7, 9, 10, 12, 13, 15, 16, 18, 19, 21, 22), 2.74–2.91 (10 H, m, H-8, 11, 14, 17, 20), 2.36 (2 H, t, $J = 7.4$ Hz, H-2), 2.08 (4 H, m, H-5, 23), 1.66 (2 H, m, H-3), 1.42 (2 H, m, H-4), 0.98 (3 H, t, $J = 7.5$ Hz, H-24); ^{13}C NMR ($CDCl_3$) δ: 179.9, 132.0, 129.6, 128.6, 128.4, 128.3, 128.22, 128.18, 128.1, 128.03, 127.96, 128.9, 127.0, 33.9, 29.0, 26.8, 25.6 (4 carbons), 25.5, 24.3, 20.6, 14.3; HRMS (FAB): Calcd for $C_{24}H_{37}O_2$ $[M + H]^+$: 357.2794; found: 357.2790.

(2*E*,6*Z*,9*Z*,12*Z*,15*Z*,18*Z*,21*Z*)-Tetracosa-2,6,9,12,15,18,21-Heptaenoic Acid (Δ^2-THA **4**)

A solution of 2*E*-**7** (100 mg, 272 μmol) in 5% KOH/iPrOH–H_2O (19:1, 10 mL) was stirred at 50 °C for 3 h.

The reaction mixture was neutralized with 10% HCl aq. and extracted with EtOAc. The organic layer was washed with water, dried over $MgSO_4$, and evaporated. The residue was passed through a short silica gel column (1 g, 70% EtOAc–hexane) to give Δ^2-THA **4** (95 mg, 99 %). ^{1}H NMR ($CDCl_3$) δ: 7.07 (1 H, dt, $J = 15.6$, 6.6 Hz, H-3), 5.84 (1 H, d, $J = 15.6$ Hz, H-2), 5.28–5.46 (12 H, m, H-6, 7, 9, 10, 12, 13, 15, 16, 18, 19, 21, 22), 2.77–2.91 (10 H, m, H-8, 11, 14, 17, 20), 2.20–2.36 (4 H, m, H-4, 5), 2.08 (2 H, quint, $J = 7.5$ Hz, H-23), 0.97 (3 H, t, $J = 7.5$ Hz, H-24); ^{13}C NMR ($CDCl_3$) δ: 171.9, 151.3, 132.0, 129.2, 128.6, 128.3 (2 carbons), 128.2, 128.13, 128.08 (2 carbons), 128.0, 127.9, 127.0, 121.1, 32.2, 25.6 (4 carbons), 25.5, 20.5, 14.3; HRMS (FAB): Calcd for $C_{24}H_{35}O_2$ $[M + H]^+$: 355.2637; found: 355.2624.

(4*Z*,7*Z*,10*Z*,13*Z*,16*Z*,19*Z*)-Docosa-4,7,10,13,16,19-Hexaen-1-ol (**9**)

To a stirred solution of DHA ethyl ester **5** (6.17 g, 17.3 mmol) in CH_2Cl_2 (40 mL) was added 1.0 M DIBAL-H in toluene (51.5 mL, 51.5 mmol) at 0 °C and the mixture was stirred for 1.5 h. The mixture was quenched with 1 N HCl aq. at 0 °C and extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (100 g, 10% EtOAc–hexane) to give alcohol **9** (5.06 g, 93%). ^{1}H NMR ($CDCl_3$) δ: 5.28–5.47 (12 H, m, H-4, 5, 7, 8, 10, 11, 13, 14, 16, 17, 19, 20), 3.66 (2 H, t, $J = 6.4$ Hz, H-1), 2.85 (10 H, m, H-6, 9, 12, 15, 18), 2.16 (2 H, quint, $J = 6.4$ Hz, H-3), 2.08 (2 H, quint, $J = 7.5$ Hz, H-21), 1.65 (2 H, quint, $J = 6.4$ Hz, H-2), 0.98 (3 H, t, $J = 7.5$ Hz, H-22); ^{13}C NMR ($CDCl_3$) δ: 132.1, 129.4, 128.6, 128.5, 128.30, 128.27, 128.20, 128.16, 128.1 (2 carbons), 127.9, 127.0, 62.5, 32.5, 25.65 (2 carbons), 25.63, 25.60, 25.5, 23.6, 20.6, 14.3; HRMS (FAB): Calcd for $C_{22}H_{35}O$ $[M + H]^+$: 315.2688; found: 315.2686.

(4*Z*,7*Z*,10*Z*,13*Z*,16*Z*,19*Z*)-Docosa-4,7,10,13,16,19-Hexaen-1-yl 4-Methylbenzenesulfonate (**10**)

A mixture of alcohol **9** (5.06 g, 16.1 mmol) and *p*-toluenesulfonyl chloride (4.61 g, 24.2 mmol) in pyridine (25 mL) was stirred at 0 °C for 13 h. After addition of water, the mixture was extracted with EtOAc. The organic layer was washed with 1 N HCl aq., saturated $NaHCO_3$ aq. and brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (110 g, 5% EtOAc–hexane) to give tosylate **10** (6.71 g, 89%). ^{1}H NMR ($CDCl_3$) δ: 7.79 (2 H, d, $J = 8.3$ Hz, H-Ar), 7.34 (2 H, d, $J = 8.3$ Hz, H-Ar), 5.29–5.42 (12 H, m, H-4, 5, 7, 8, 10, 11, 13, 14, 16, 17, 19, 20), 4.03 (2 H, t, $J = 6.5$ Hz, H-1), 2.75–2.87 (10 H, m, H-6, 9, 12, 15, 18), 2.44 (3 H, s, H-Ph-Me), 2.04–2.12 (4 H, m, H-3, 21), 1.71 (2 H, quint, $J = 6.5$ Hz, H-2), 0.97 (3 H, t, $J = 7.5$ Hz, H-22); ^{13}C NMR ($CDCl_3$) δ: 144.7, 133.2, 132.0, 129.8 (2 carbons), 129.4, 128.6, 128.29, 128.26 (2 carbons), 128.1 (2 carbons), 128.0, 127.9 (4 carbons), 127.0, 69.9, 28.8, 25.6 (3 carbons), 25.5 (2 carbons), 23.0, 21.6, 20.6, 14.3; HRMS (FAB): Calcd for $C_{29}H_{41}O_3S$ $[M + H]^+$: 469.2776; found: 469.2777.

(5*Z*,8*Z*,11*Z*,14*Z*,17*Z*,20*Z*)-Tricosa-5,8,11,14,17,20-Hexaenenitrile (**11**)

A mixture of tosylate **10** (6.71 g, 14.3 mmol) and KCN (1.31 g, 20.1 mmol) in DMSO (40 mL) was stirred at 70 °C for 2.5 h. After addition of H_2O at 0 °C, the mixture was extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$, and evaporated. The residue was chromatographed on silica gel (100 g, 5% EtOAc–hexane) to give cyanide **11** (4.51 g, 97%). ^{1}H NMR ($CDCl_3$) δ: 5.32–5.40 (12 H, m, H-5, 6, 8, 9, 11, 12, 14, 15, 17, 18, 20, 21), 2.78–2.87 (10 H, m, H-7, 10, 13, 16, 19), 2.34 (2 H, t, $J = 7.2$ Hz, H-2), 2.01–2.14 (4 H, m, H-4, 22), 1.66 (2 H, m, H-3), 1.42 (2 H, m, H-3), 0.98 (3 H, t, $J = 7.5$ Hz, H-23); ^{13}C NMR ($CDCl_3$) δ: 132.0, 130.3, 128.6, 128.4, 128.3 (2 carbons), 128.1, 128.0, 127.9, 127.8, 127.3, 127.0, 119.6, 26.0, 25.7 (4 carbons), 25.5, 25.3, 20.6, 16.5, 14.3; HRMS (FAB): Calcd for $C_{23}H_{34}N$ $[M + H]^+$: 324.2691; found: 324.2696.

(5*Z*,8*Z*,11*Z*,14*Z*,17*Z*,20*Z*)-Tricosa-5,8,11,14,17,20-Hexaenal (**12**)

To a stirred solution of cyanide **11** (2.53 g, 7.86 mmol) in CH_2Cl_2 (1 mL) was added 1.0 M DIBAL-H in toluene (10.1 mL, 10.1 mmol) at −20 °C and the mixture was stirred for 1 h. The mixture was quenched with 10% aqueous potassium sodium tartrate at 0 °C and the mixture was extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (55 g, 3% EtOAc–hexane) to give aldehyde **12** (1.93 g, 75%). ^{1}H NMR ($CDCl_3$) δ: 9.87 (1 H, t, $J = 1.6$ Hz, H-1), 5.23–5.48 (12 H, m, H-5, 6, 8, 9, 11, 12, 14, 15, 17, 18, 20, 21), 2.78–2.91 (10 H, m, H-7, 10, 13, 16, 19), 2.45 (2 H, td, $J = 7.3$ Hz, 1.6 Hz, H-2), 2.02–2.18 (4 H, m, H-4, 22), 1.71 (2 H, quint, $J = 7.3$ Hz, H-3), 0.97 (3 H, t, $J = 7.5$ Hz, H-23); ^{13}C NMR ($CDCl_3$) δ: 202.4, 132.0, 129.1, 128.8, 128.6, 128.3, 128.23, 128.19, 128.12 (2 carbons), 128.08, 127.9, 127.0, 43.8, 26.9, 25.7 (2 carbons), 25.6 (2 carbons), 25.5, 21.9, 20.6, 14.3; HRMS (FAB): Calcd for $C_{23}H_{35}O$ $[M + H]^+$: 327.2688; found: 327.2696.

Methyl (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*,20*Z*)-Tricosa-5,8,11,14,17,20-Hexaenoate (**13**)

A mixture of aldehyde **12** (1.93 g, 5.92 mmol), KOH (864 mg, 15.4 mmol) and I_2 (1.95 g, 7.70 mmol) in MeOH (75 mL) was stirred at 0 °C for 1 h. After addition of 10% solution of aqueous $Na_2S_2O_3$, the mixture was extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel (40 g, 2% EtOAc–hexane) to give methyl ester **13** (1.91 g, 91%). ^{1}H NMR ($CDCl_3$) δ: 5.28–5.44 (12 H, m, H-5, 6, 8, 9, 11, 12, 14, 15, 17, 18, 20, 21), 3.67 (3 H, s, H-CO_2Me), 2.76–2.90 (10 H, m, H-7, 10, 13, 16, 19), 2.32 (2 H, t, $J = 7.4$ Hz, H-2), 2.04–2.12 (4 H, m, H-4, 22), 1.70 (2 H, quint, $J = 7.4$ Hz, H-3), 0.98 (3 H, t, $J = 7.5$ Hz, H-23); ^{13}C NMR ($CDCl_3$) δ: 174.0, 132.0, 128.9, 128.8, 128.6, 128.25, 128.24, 128.19, 128.15, 128.09 (2 carbons), 127.9, 127.0, 51.5, 33.4, 26.5, 26.63 (4 carbons), 25.5, 24.8, 20.6, 14.3; HRMS (FAB): Calcd for $C_{24}H_{37}O_2$ $[M + H]^+$: 357.2794; found: 357.2790.

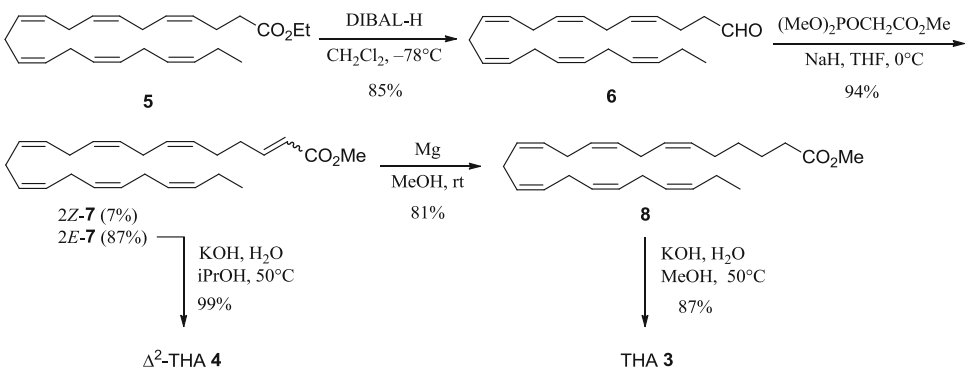
(5*Z*,8*Z*,11*Z*,14*Z*,17*Z*,20*Z*)-Tricosa-5,8,11,14,17,20-Hexaenoic Acid (TrHA **2**)

A solution of ester **13** (1.19 g, 3.34 mmol) in 5% KOH/MeOH–H_2O (19:1, 16 mL) was stirred at 50 °C for 1 h. The reaction mixture was neutralized with 10% HCl aq. and extracted with EtOAc. The organic layer was washed with water, dried over $MgSO_4$, and evaporated. The residue was chromatographed on silica gel (110 g, 50% EtOAc–hexane) to give TrHA **2** (1.01 g, 88 %). ^{1}H NMR ($CDCl_3$) δ: 5.27–5.44 (12 H, m, H-5, 6, 8, 9, 11, 12, 14, 15, 17, 18, 20, 21), 2.76–2.91 (10 H, m, H-7, 10, 13, 16, 19), 2.37 (2 H, t, $J = 7.4$ Hz, H-2), 2.02–2.17 (4 H, m, H-4, 22), 1.70 (2 H, quint, $J = 7.4$ Hz, H-3), 0.97 (3 H, t, $J = 7.5$ Hz, H-23); ^{13}C NMR ($CDCl_3$) δ: 179.9, 132.0, 129.0, 128.8, 128.6, 128.27, 128.20, 128.19, 128.15 (2 carbons), 128.09, 127.9, 127.0, 33.4, 26.5, 25.6 (4 carbons), 25.5, 24.5, 20.6, 14.3; HRMS (FAB): Calcd for $C_{23}H_{35}O_2$ $[M + H]^+$: 343.2637; found: 343.2643.

Results and Discussion

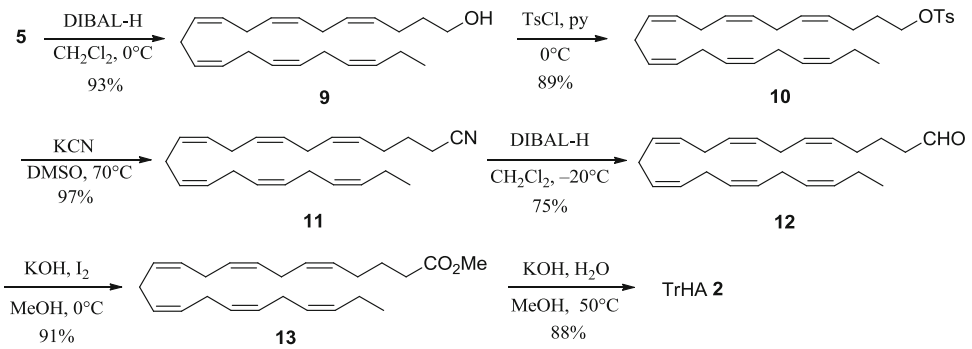
Two fatty acids, THA **3** and Δ^2-THA **4**, were synthesized using DHA ethyl ester **5** as the starting material as shown in Scheme 1. Ester **5** was reduced with 1.2 equivalents of diisobutylaluminium hydride (DIBAL-H) at −78 °C to afford aldehyde **6** in 85% yield. Aldehyde **6** was subjected to the Horner–Wadsworth–Emmons reaction using trimethyl phosphonoacetate [31] to give two-carbon elongated α,β-unsaturated ester **7** in 94% yield as a mixture of 2*E*-isomer (87%) and 2*Z*-isomer (7%). These two isomers were separated easily by silica gel column chromatography. Regioselective hydrogenation of α,β-unsaturated ester **7** was achieved by reduction using Mg turnings in MeOH to provide **8** in good yield (81%) [31–33]. Ester **8** was treated with 5% KOH/MeOH–H_2O (19:1) to provide desired compound THA **3** in 87% yield. On the other hand, Δ^2-THA **4** was obtained in 99% yield upon treatment of 2*E*-**7** with 5% KOH/iPrOH–H_2O (19:1). Thus, THA **3** was synthesized in four steps in 56% overall yield and Δ^2-THA **4** was synthesized in three steps in 73% overall yield. Kuklev et al. [24] reported the synthesis of THA **3** from DHA methyl ester, via a malonic ester derivative as a precursor of two-carbon-elongated fatty acid; he reported a 21% overall yield achieved in five steps. Thus, our synthetic route is more facile and efficient than the previously reported route.

TrHA **2** was synthesized from DHA ethyl ester **5** as shown in Scheme 2. Ester **5** was reduced with DIBAL-H at 0 °C to afford alcohol **9** in 93% yield. Alcohol **9** was then treated with TsCl to give tosylate **10** in 89% yield. Tosylate **10** was treated with KCN at 70 °C to afford one-carbon-elongated cyanide **11** in 97% yield. Cyanide **11** was reduced with DIBAL-H to afford aldehyde **12** in 75% yield. Aldehyde **12** was converted to ester **13** in 91% yield by alkaline-iodine oxidation, a reaction previously developed by our group [34]. Ester **13** was treated with 5% KOH/MeOH–H_2O (19:1) to provide desired compound TrHA **2** in 88% yield. Thus, TrHA **2** was synthesized in six steps in 48% overall yield. To our knowledge, this is the first report of the chemical synthesis of TrHA **2**.



Scheme 1 Synthetic route from DHA ester to tetracosahexaenoic acid (**3**) and Δ^2-tetracosahexaenoic acid (**4**)

Scheme 2 Synthetic route from DHA ester to tricosahexaenoic acid (**2**)



In conclusion, we have developed efficient chemical methods for the synthesis of the very-long-chain n-3 polyunsaturated fatty acids, THA **3**, Δ^2-THA **4** and TrHA **2**. Using these synthetic compounds, we are now investigating their biological activities and metabolism.

METHODS

Mild Method for Preparation of 4,4-Dimethyloxazoline Derivatives of Polyunsaturated Fatty Acids for GC–MS

Vasily I. Svetashev

Received: 25 October 2010 / Accepted: 7 March 2011 / Published online: 3 April 2011

Abstract A mild and convenient method has been developed for preparing 4,4-dimethyloxazoline (DMOX) derivatives of fatty acids for GC–MS analysis. First, fatty acid methyl esters are converted to corresponding amides by incubation overnight at room temperature with 2-amino-2-methyl-1-propanol and a catalytic amount of sodium methoxide. The resulting 2-(methylpropanol) amides were isolated by partition between hexane–diethyl ether and water, and then converted to 4,4-dimethyloxazoline derivatives by treatment with trifluoroacetic anhydride under mild conditions (50 °C for 45 min). Structures of 2-methylpropanol amide and a DMOX derivative of oleic acid were confirmed by GC–MS. This method was applied to different FAME prepared from animal, plant or microbial lipids. The suggested method is most suitable for structure analysis of polyunsaturated fatty acids (PUFA) and for acids with double bonds in close to terminal positions. Application of the method is illustrated with spectra of the DMOX derivatives of 16:1(n-13), 24:5(n-6) and 24:6(n-3) acids.

Keywords GLC-MS · DMOX derivatives · Fatty acid structure analysis

Abbreviations

AMP	2-amino-2-methyl-1-propanol
DMOX	4,4-dimethyloxazoline
FAME	Fatty acid methyl ester(s)
FFA	Free fatty acid(s)
PUFA	Polyunsaturated fatty acid(s)
TFAA	Trifluoroacetic anhydride
TL	Total lipids
THA	Tetracosahexaenoic acid
TPA	Tetracosapentaenoic acid
GLC	Gas-liquid chromatography
MS	Mass spectrometry
TLC	Thin layer chromatography
NMR	Nuclear magnetic resonance
BSTFA	Bis(trimethylsilyl) trifluoroacetamide

Introduction

Fatty acid methyl esters (FAME) are generally accepted derivatives of fatty acids for analysis by GLC and GLC–MS. Methods for FAME preparation are now routine on a small scale and they have excellent chromatographic properties. FAME are most suitable for quantitative analysis, but have limited significance for structure analysis by mass spectrometry [1]. Methyl esters are useful for localization of some branching patterns (iso-, anteiso-), or oxygenated acid functions (2-OH, 3-OH) by MS. Polyenoic fatty acids often give a distinctive mass spectrometric fingerprint, which permits us to differentiate acids of n-3, n-6 and n-9 series, but does not prove the exact positions of double bonds. However, it is usually considered that methyl ester derivatives are not suitable for locating double bonds, especially in monoenoic fatty acids [1]. The main reason for this limitation is the bond migration in the unsaturated fatty acid alkyl chain during ionization. As a result, a number of nitrogen-containing derivatives have been suggested for GC–MS, because of the ability of nitrogen atom to stabilize the charge distribution, thus improving the information value of the spectra.

Of numerous nitrogen derivatives, mainly pyrrolidides [2, 3], DMOX [4, 5] and picolinyl esters [6] have found their use in GC–MS elucidation of fatty acid structure. Each derivative has advantages for GC–MS of fatty acids of a particular type; they are prepared by distinct methods, have different gas chromatographic properties and informativity of mass spectra. A recent review [1] provides comparative information for different derivatives useful in structure analysis of fatty acids.

There are several methods for the preparation of the respective derivatives; these methods have been thoroughly reviewed by Christie [7]. Preparation of acylpyrrolidides from FAME and glycerolipids is a relatively mild procedure [2]. At the same time, the usual direct one-step method for preparation of DMOX derivatives at 170–180 °C overnight [8] gives rise for concern about the risk of PUFA isomerization and/or degradation. This reaction is often incomplete, and on chromatograms some peaks were detected similar to target component mass spectra [9]. It has been also found that some FA can undergo isomerization upon such treatment. For example, *trans*-3-hexadecenoic acids, an essential component of plant phosphatidylglycerol, is mainly converted into *cis*-2-hexadecenoic acid [10]. Later, lengthier mild two-step methods for the preparation of oxazolines and DMOX derivatives [11, 12] have been developed. Methods based on the conversion of FAME or TL to free fatty acids and then to mixed anhydrides or acid chlorides with a subsequent reaction with ethanolamine or AMP. Resulting amides are cyclized by treatment with trifluoroacetic anhydride to target alkyl oxazolines or 4,4-dimethyloxazolines. Recently, a mild one pot-one step method for conversion carboxylic acids to range of amides and oxazolines has been reported [13]. In this method benzoxazoline, DMOX and 4-phenyloxazoline derivatives were prepared from FFA, a corresponding amine and fluorinating reagent Deoxo-Fluor at 0 °C. We present in this paper a mild and convenient method for preparation of DMOX derivatives starting from FAME.

Materials and Methods

Materials

Oleic acid, oleic acid methyl ester, methyl-2-hydroxytetradecanoate, trioleoylglycerol, (Sigma, USA), 2-amino-2-methyl-1-propanol, trifluoroacetic anhydride (Fluka, Germany) were used in the experiments. Chloroform, methanol, hexane, acetone, diethyl ether and benzene were redistilled. AMP was used as a 50%, (w/v) solution in benzene; it was stable at 5 °C for at least for 2 months. A 1% Na solution in methanol was prepared by careful dissolving sodium metal in cold methanol in a fume cupboard. The reagent is stable in tightly closed amber bottles for several months. Extracts of total lipids of the Alcyonaria *Gersemia rubiformis* and the fern *Polystichum subtripteron* were used in the experiments.

Extraction of Lipids and Preparation of FAME

Lipids were extracted from biological materials with chloroform/methanol [14]. FAME were prepared by the routine method [15] and purified by TLC in benzene or hexane/diethyl ether (9:1, by v/v).

Thin Layer Chromatography

Progress in the synthesis of the FA derivatives was controlled by TLC on aluminum sheets 10 × 10 cm with Silica gel 60 F_{254} Merck (Germany). The solvent system hexane/acetone (8:2, by v/v) was used for separation of FAME, FFA, acyl-2-methylpropanol amides, and DMOX derivatives. Spots on the chromatogram were visualized using iodine vapor or charring at 110 °C after spraying with 5% sulfuric acid in methanol.

Gas Chromatography and Gas Chromatography–Mass Spectrometry

GC and GC–MS analyses were performed on a GC 2010 chromatograph with a flame ionization detector and a gas chromatograph–mass spectrometer GCMS-QP5050, both Shimadzu (Japan). Fused silica capillary columns Supelcowax 10 and MDN-5S (both columns 30 m, 0.25 mm ID, 0.25 μm film, Supelco, USA) were used in the apparatus. FAME and DMOX derivatives were analyzed on Supelcowax 10 columns at 200 and 210 °C, respectively. On a nonpolar MDN-5S column, the temperature program started from 200 to 260 °C, 2 °C/min. Helium was used as the carrier gas at a linear velocity of 30 cm/sec. Mass spectra were recorded at 70 eV. Spectra were compared with the NIST library and internet fatty acid mass spectra archive site [7].

Preparation of DMOX Derivatives

To 1–3 mg of FAME or glycerolipids in a 2-ml vial with tightly fitting cap, were added 60 μl 50%, (w/v) AMP in benzene, this was mixed and 10 μl of $NaOCH_3$ reagent was added. After mixing, the vials were flushed with argon and incubated in the dark overnight at room temperature. Acyl-2-methylpropanol amides were isolated by partition between 0.5 ml hexane–diethyl ether 9:1, (v/v) and 0.5 ml water. Extraction was repeated with 0.5 ml hexane–ether. After solvent evaporation, acyl-2-methylpropanol amides were converted to DMOX by adding 150 μl TFAA and

incubated at 50 °C for 45 min. TFAA was evaporated under an argon stream. Derivatives were dissolved in hexane and washed with water to remove the residues of the reagents. Samples prepared from FAME were ready for GC or GC–MS. Samples prepared from total lipids, phospholipids or triacylglycerols needed additional purification by TLC or on a small silica gel column.

Results and Discussion

The current study presents a new method for the preparation of DMOX derivatives of fatty acids. The general plan of the synthesis is shown in Scheme 1. We used a modified method for the preparation of fatty amides or ethanolamides by low temperature aminolysis of FAME and laurel oil, catalyzed by sodium methoxide [16, 17]. The first experiments demonstrated that incubation of MEFA with AMP gives either no or very low yields of amides at room temperature or at 60 °C even after 24 h. An addition of a catalytic amount of $NaOCH_3$ resulted in conversion of FAME to the respective amides at room temperature overnight (Fig. 1). TLC analysis also demonstrated that FAME are more stable to catalytic amidation than triacylglycerols, TL and PL are, and therefore all experiments were conducted on methyl oleate. The use of methyl esters is especially convenient, since FAME are generally accepted derivatives in GC analysis. The proposed method has two main advantages. First, acyl-2-methylpropanol amides were prepared at room temperature and conversion to DMOX derivatives completed at 50 °C. Second, the method is simple, because it does not involve preparation of FFA and then acid halides or mixed anhydrides from TL or MEFA as the two-step method does [11–13]. The samples prepared for GC–MS contain only traces of MEFA.

The structure of oleoyl-2-methylpropanol amide was characterized by H^1NMR and after derivatization with BSTFA by GC–MS (data not shown). DMOX derivatives were characterized by TLC and GC–MS (see Figs. 1, 2). All spectra support the structures depicted in Scheme 1.

Figure 2a shows the spectrum of the DMOX derivative of the Δ3 isomer of hexadecenoic acid from the TL extract of the fern *Polystichum subtripteron*. The spectrum of this acid is very similar to those of Δ3-16:1 [10], and Δ3-18:1 [18] with the main characteristic peaks at *m/z* 152 (base) and 166. Since the peak with *m/z* 110 characteristic of acids

Fig. 1 TLC of starting materials, an intermediate (oleoyl-2-methylpropanol amide), and the final product (oleic acid DMOX). *Lane 1* standard FFA and ME of oleic acid, *Lane 2* oleoyl-2-methylpropanol amide, *Lane 3* DMOX derivative of oleic acid. Solvent system: chloroform/acetone (8:2, by v/v). Detection: charring at 110 °C after spraying with 5% H_2SO_4 in methanol

with a double bond at position 2 [18] was not observed, it seems, no isomerization took place during the DMOX preparation. The method described here has also been used successfully for PUFA of fish oil. Besides the usual acids of the n-3 series, we have also found an acid with a spectrum similar to the DMOX derivative of 16:4(n-1) (data not shown). Therefore, this method can be applied to fatty acids with a terminal position of the double bond.

Figures 2b and c show mass spectra of two tetracosapolyenoic acids, 24:5(n-6) and 24:6(n-3), that were prepared from total lipids of the Alcyonaria *Gersemia rubiformis*. Earlier, these very-long-chain PUFA were found in marine representatives of the phylum Cnidaria [19]. In both spectra, the double bond in position 6 was evident by the characteristic fingerprint of ions at *m/z* 126

Scheme 1 Preparation of DMOX derivatives from FAME

(base), 152, 166 and 180 [18]. The locations of the remaining double bonds were revealed by a gap of 12 amu, as shown on Figs. 2b and c.

Our attempt to prepare DMOX derivative from methyl-2-hydroxytetradecanoate by the suggested method was unsuccessful. A previous effort to synthesize DMOX derivatives of saturated 2-hydroxy fatty acids by the two-step method has also failed [7].

This method can probably be applied for the preparation of other nitrogen-containing derivatives of fatty acids suitable for GC–MS.

METHODS

Quantitative Analysis of Phospholipids Using Nanostructured Laser Desorption Ionization Targets

Abstract Since its introduction as an ionization technique in mass spectrometry, matrix-assisted laser desorption ionization (MALDI) has been applied to a wide range of applications. Quantitative small molecule analysis by MALDI, however, is limited due to the presence of intense signals from the matrix coupled with non-homogeneous surfaces. The surface used in nano-structured laser desorption ionization (NALDI) eliminates the need for a matrix and the resulting interferences, and allows for quantitative analysis of small molecules. This study was designed to analyze and quantitate phospholipid components of liposomes. Here we have developed an assay to quantitate the DPPC and $DC_{8,9}PC$ in liposomes by NALDI following various treatments. To test our method we chose to analyze a liposome system composed of DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine) and $DC_{8,9}PC$ (1,2-bis(tricosa-10,12-diynoyl)-*sn*-glycero-3-phosphocholine), as $DC_{8,9}PC$ is known to undergo cross-linking upon treatment with UV (254 nm) and this reaction converts the monomer into a polymer. First, calibration curves for pure lipids (DPPC and $DC_{8,9}PC$) were created using DMPC (1,2-dimyristoyl-*sn*-glycero-3-phosphocholine) as an internal standard. The calibration curve for both DPPC and $DC_{8,9}PC$ showed an R^2 of 0.992, obtained using the intensity ratio of analyte and internal standard. Next, DPPC:$DC_{8,9}PC$ liposomes were treated with UV radiation (254 nm). Following this treatment, lipids were extracted from the liposomes and analyzed. The analysis of the lipids before and after UV exposure confirmed a decrease in the signal of $DC_{8,9}PC$ of about 90%. In contrast, there was no reduction in DPPC signal.

Keywords NALDI · MALDI · Mass spectrometry · Lipids · Quantitation · Drug delivery

Abbreviations

9-AA	9-Aminoacridine
$DC_{8,9}PC$	(1,2-bis(tricosa-10,12-diynoyl)-*sn*-glycero-3-phosphocholine)
DHB	2,5-Dihydroxybenzoic acid
DIOS	Desorption ionization on silica
DMPC	1,2-Dimyristoyl-*sn*-glycero-3-phosphocholine
DPPC	1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine
ESI	Electrospray ionization
GALDI	Graphite-assisted laser desorption/ionization
GC	Gas chromatography
HPLC	High-performance liquid chromatography
LC	Liquid chromatography
LDI	Laser desorption ionization
MALDI	Matrix-assisted laser desorption/ionization

Introduction

Chromatography has been the traditional technique of choice for the analysis of lipids. Thin-layer chromatography [1] and liquid chromatography [2] have been the most widely used methods in the field, especially in combination with UV detection [3]. Those techniques are well-established and robust but they are also time-consuming, because they often involve steps of derivatization and long separation times [4]. Spectroscopic methods, such as IR and NMR, have been applied in the lipid analysis field as well [3]. The first use of mass spectrometry for the analysis of lipids was reported by Gohlke in 1959 [5] using gas chromatography mass spectrometry (GC–MS). Mass spectrometry provides information on the molecular weight of the species of interest that can be useful for identification purposes. Since then GC–MS has been applied to many analytical questions regarding the biology and chemistry of lipids [6], however GC–MS may require derivatization when the analyte is not volatile and thermally stable [7]. While derivatization may help, in some cases it results in additional steps that can complicate the entire analysis [8].

In recent years with the introduction of the so-called "soft ionization" techniques, electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI), [9] that allow for the analysis of intact lipids [10], mass spectrometry has gained importance in the analysis of lipid mixtures [11] and in the rapidly growing field of mass spectrometry tissue imaging [12]. Electrospray ionization is the most frequently used mass spectrometry technique for lipid analysis, but MALDI represents a powerful tool in this field, because the time necessary for the analysis can be reduced to less than one minute per sample [10]. ESI mass spectrometry in association with liquid chromatography (LC) allows for separation and identification of molecular species, however analysis times can be long and the buffers used for LC/MS are often incompatible with lipid solubility.

In MALDI, the sample is mixed with a solution of matrix that absorbs the laser energy. The mixture is allowed to dry to form co-crystals on the surface of target. The homogeneity of the solid crystals on the plate is essential for the reproducibility of the analysis, therefore accurate sample preparation is necessary [10]. In most cases, the matrix is soluble in the same organic solvents as the lipid analytes, so very homogenous co-crystals are produced facilitating the analysis.

The choice of the most suitable matrix is often quite challenging. While water soluble analytes have a wide range of useful matrices [13], only a few matrices have been utilized for lipid analysis due to their lipophilic nature. Recently Teuber et al. [14] compared a series of matrices for lipids. Along with the most commonly used DHB (2,5-dihydroxybenzoic acid), other matrices showed interesting characteristics, especially a newly synthesized compound, α-cyano-2,4-difluorocinnamic acid, for analysis of charged phospholipids, and 9-aminoacridine (9-AA) for both positive [14, 15] and negative ion analysis [16–19]. In particular the interest in 9-AA, as a matrix for lipids analysis in MALDI, has recently been applied by Benaddellah et al., for lipid negative ion analysis in a tissue imaging study that compares MALDI-TOF and secondary ion mass spectrometry [20]. For small molecule analysis it is necessary to choose a matrix that does not generate polymers by photochemical reactions (e.g. sinapinic acid), because the polymerization products will saturate the detector [4] and suppress the signal from the analytes. In addition the presence of interfering peaks due to matrix adducts (e.g. DHB with Na^+), [21] in the lower *m/z* range is a crucial issue in the analysis of small molecules, therefore other approaches have been taken into consideration. Some studies suggested the use of high molecular weight matrices such as *meso*-tetrakis(pentafluorophenyl)porphyrin [22–24] for the analysis and quantification of fatty acids. In this case the signals due to molecular ions of the matrix or its impurities, adducts or clusters are in a higher mass range and do not overlap with the analyte signal.

Recently matrix-free laser desorption ionization (LDI) has become a promising approach in the field of small molecules. In this case the sample is applied onto a surface that absorbs the laser energy without the use of additional compounds. The direct deposition of the sample involves minimal sample preparation and practically no signal from the support surface [21]. Silicon has been one of the first materials to be used as a suitable support for matrix-free LDI [25]. Its surface can be easily oxidized and modified to trap the analyte and it has high absorptivity in the UV, therefore it can act like the matrix itself. This technique, termed desorption ionization on silica (DIOS), has been applied to a number of small molecule analytes [26]. The use of silicon as a LDI mass spectrometry support has evolved with the recent introduction of silicon nanowires [27]. Muck et al. [28] provided evidence of the superiority of this approach compared with other traditional techniques that use energy absorbing matrices of questionable purity and stability. Other nanostructures have interesting characteristics. Carbon nanotubes have shown low signal background and good capability to transfer energy to the analytes [29–31]. Carbon nanotubes often have solubility issues, however. Ren et al. [31] used oxidization to improve solubility and produced a more homogeneous phase with reproducible analysis.

Graphite, a polymorph of the element carbon, has been applied by several groups to MALDI analysis. Graphite-assisted laser desorption/ionization (GALDI) has been successfully used in different applications [32], in particular for protein and peptides [33] and small molecules such as triterpenes [34, 35]. More recently colloidal graphite has been introduced as a support for MALDI imaging studies of small metabolites from fruits and plants [36, 37] and cerebrosides from direct analysis of rat brain tissue [38].

An issue with the use of nano-structured materials is that they are produced by a random process [26] that cannot always guarantee a homogeneous surface where the sample should be applied. In contrast, ZnO nanowires can be selectively grown on a substrate, are easy to synthesize, and their orientation can be controlled, so that on a flat substrate they can be organized as vertical wire arrays with defined dimension and structure [39]. ZnO presents characteristics that are particularly suitable for many industrial applications [40, 41]. It is a semi-conductive material that can absorb energy from the laser in wavelengths typically used in MALDI and transfer it to the analyte. ZnO nanoparticles have been successfully applied to the desorption/ionization of several small molecules, from drugs to lipids [42]. Kang et al. [41] compared a suspension of analyte/ZnO nanowires and the direct deposition of the analyte onto the surface of a nanowire chip. The nanowire chip showed better performance and a potential applicability to quantitative analysis.

There are few examples in the literature of matrix-free LDI applications for lipids. Other small molecules, such as fatty acids, have been analysed by DIOS [43] and with silicon nano-wires in association with lithium hydroxide [28]. Diamond-like carbon matrix-free targets have been proven to be capable of absorbing laser energy and transferring it to a wide range of analytes, including lipids [44]. Another interesting application of a matrix-free approach for lipids analysis is the one proposed by Vidova et al. [45] for mice kidney tissue imaging experiments. This study makes use of a commercially available nanostructured surface (NALDI^{TM} chip, Bruker Daltonics) as a support in LDI MS and allows the identification of a slightly higher number of lipids species compared to analysis performed with alpha-cyano-4-hydroxy cinnamic acid as matrix in MALDI.

In this study we demonstrate how a NALDI^{TM} chip can be used as a support for desorption/ionization applied for small molecule quantitative analysis. We have examined two phospholipids, DPPC and $DC_{8,9}PC$, that have been recently used for development of photo-triggerable liposomes [46–48]. Our system represents a novel and elegant method to determinate the concentrations of the two phospholipids of interest in the liposomes. This methodology bears the potential for future applications for the analysis of molecules with similar chemical and physical properties.

Methods and Materials

Liposome Preparation and Treatment

Liposome Reagents

DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine) and DMPC (1,2-dimyristoyl-*sn*-glycero-3-phosphocholine) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL) as solutions in chloroform. $DC_{8,9}PC$ (1,2-bis(tricosa-10, 12-diynoyl)-*sn*-glycero-3-phosphocholine) was synthesized by Dr. Alok Singh at the Naval Research Laboratory (Washington, DC) using a previously published procedure [46]. Methanol HPLC grade was purchased from OmniSolv (EMD Chemicals, Inc., Gibbstown, NJ), while Chloroform ACS was from Fisher Scientific (Pittsburgh, PA).

Preparation of Liposomes

Liposomes were prepared using the probe sonication essentially as described [46]. Briefly, DPPC:$DC_{8,9}PC$ (80:20 mol%) lipid mixtures were mixed in a glass tube. The lipid film was formed by removing the solvent under nitrogen and any residual chloroform was removed by placing the film overnight in a vacuum desiccator. To encapsulate calcein, the lipid film was reconstituted in HEPES buffer (HBS, 10 mM HEPES, 140 mM NaCl, pH 7.5) containing self-quenched concentration of calcein (0.1 M at pH 7.2–7.6). Unilamellar vesicles were formed by sonication at 4 °C for 5–10 min (1 min pulses and 1 min rest) using a Probe Sonicator (W-375 Heat Systems-Ultrasonics, New York, USA). The samples were centrifuged to remove any titanium particles and larger aggregates. Solute-loaded liposomes were separated from unentrapped calcein using a size exclusion gel chromatography column (Bio Gel A0.5 m, 1 × 40 cm, 40 ml bed volume).

UV Treatment

Liposomes were placed in a 96-well plate (total volume of 0.2 ml) as described [47], and irradiated with a UV lamp (UVP, short wave assembly, 115 V, 60 Hz) at 254 nm in a distance of 1 inch for 45 min. We routinely examined calcein leakage and $DC_{8,9}PC$ photo-crosslinking to confirm the modification in our liposome preparations as previously described [46, 47]. For mass spectrometry analysis (see below) lipids were extracted according to the Bligh/Dyer method [49].

Mass Spectrometry Analysis

Reagents

Methanol was HPLC grade (OmniSolv, EMD Chemicals, Inc., Gibbstown, NJ). Chloroform was HPLC grade from Chromasolv (Sigma–Aldrich, St. Louis, MO). Water was LC–MS grade from J. T. Baker (Mallinckrodt Baker Inc., Phillipsburg, NJ). Cesium chloride (CsCl, 99.9%) was purchased from Sigma–Aldrich (St. Louis, MO).

Sample Preparation

Sample preparation used only glassware and Wiretrol disposable glass micropipettes (Drummond Scientific Company, Broomall, PA). The lipid films obtained from Bligh–Dyer extraction were reconstituted in 200 μL of chloroform, then diluted 1:10 in a mixture methanol/chloroform, 1/1, v/v. Standard solutions for each lipid were prepared in methanol/chloroform, 1/1, v/v. DMPC was used as an internal standard at a concentration of 25 ng/μL in methanol/chloroform, 1/1, v/v. A CsCl solution, 50 mM in methanol, was used as a matrix additive to promote formation of [M + Cs] pseudo molecular ions for the lipids studied. Calibration curves were created for the phospholipid combination by mixing $DC_{8,9}PC$ in equal volume (5 μL) with the corresponding dilution of DPPC, followed by addition of 5 μL of DMPC 25 ng/μL and 15 μL of CsCl 50 mM. Concentration ranges for DPPC and $DC_{8,9}PC$ were 10–200 and 2.5–100 ng/μL, respectively. We washed the NALDI target twice with HPLC grade chloroform and allowed to dry prior to use. The standard solutions were mixed and 3 μL spotted onto the surface of a NALDI chip (Bruker Daltonics, Billerica, MA). Standards were spotted in triplicate. In a similar fashion, 10 μL of the diluted sample solutions were mixed with DMPC 25 ng/μL (5 μL) and CsCl 50 mM (15 μL) and 3 μL of each solution spotted in triplicate onto the surface of the same target where the corresponding standard solutions were spotted.

Mass Spectrometry Analysis

All spectra were acquired on a Bruker Ultraflex III TOF/TOF mass spectrometer (Bruker Daltonics, Billerica, MA). Spectra of intact lipids were acquired in positive ion reflector mode, with no ion extraction delay. Ion source voltage 1 was 25 kV, ion source voltage 2 was 21.30 kV and lens voltage was 9.52 kV. Reflectron and reflectron 2 were 29.50 and 13.84 kV, respectively. Deflection was set at 600 Da. Monoisotopic masses were determined using FlexAnalysis 3.0 (Bruker Daltonics) with the SNAP peak picking algorithm. The instrument was calibrated in reflector mode using peptide standards of the Bruker peptide calibration kit (Bruker Daltonics, Billerica, MA). Data acquisition and peak analysis were completely automated with an accumulation of 1,200 shots using a random walk pattern. To create the calibration curves, intensity ratios of the analyte signal relative to the intensity of the internal standard were calculated and averaged from the three measurements at each concentration.

Results and Discussion

Phospholipids are the basis of cellular structures and because of their amphiphilic properties, they have the natural tendency to form a bilayers in an aqueous system [3]. These unique properties allowed A.D. Bangham to formulate the first preparation of liposomes with encapsulated materials in 1965 [50]. Since then, scientists have concentrated their efforts to take advantage of the characteristics of liposomes to understand the biophysical properties of membranes, study lipid interactions and to create efficient drug delivery systems [48, 51–54]. The evolution of this concept led Yavlovich et al. [46] to design an innovative liposome formulation for potential use as an efficient drug release system in appropriate organs and at the appropriate times. They were able to co-assemble several phospholipids (e.g. DPPC and EggPC) and $DC_{8,9}PC$ in the liposome bilayer. $DC_{8,9}PC$, a phospholipid with reactive diacetylenic groups, is known to undergo a photo cross-linking reaction when treated with UV radiation (254 nm) [55, 56]. Similar photo-crosslinking was observed when $DC_{8,9}PC$ was embedded in DPPC bilayers at mole ratios 1:9 and above leading to release of entrapped liposome contents [46]. It was hypothesized that photo cross-linking generates local defects in the liposome membrane that can promote drug release.

The detailed analysis of the individual lipids in these liposomes is critical to understand the nature of molecular interactions that result in photo-crosslinking and such information may improve design of these formulations. Initially, we set out to develop a quantitative method for the analysis of these lipids by MALDI mass spectrometry. MALDI-TOF MS has not been considered the first choice for quantitative analysis of lipids or other small molecular weight molecules for two main reasons: first the presence of matrix peaks and adducts in the low molecular range can interfere with analyte peak detection and second, inhomogeneity of the matrix/sample crystallization process reduces shot-to-shot reproducibility. Therefore, a matrix-free approach was chosen to avoid the disadvantages of the matrix and selected nanowire targets which had been

shown to be applicable to quantitative analysis of small molecules [41, 57].

In our initial method development we observed in the lipid spectra the presence of multiple peaks related to the analyte of interest—protonated and sodiated adducts—and realized this could present difficulties in data analysis and reproducibility of the assay. Considering the work of Schiller et al. [58], we decided to use CsCl as a cationization agent. Using CsCl, the MS signal of the phospholipids was shifted by 133 Da corresponding to the atomic mass of cesium. Other groups chose cesium acetate [24] and they were also able to obtain dominant cesiated adducts. Our analytes, dissolved in a mixture of chloroform/methanol, were mixed with a methanolic solution of cesium chloride prior to spotting on the NALDI target. Cesium chloride is soluble in water but not in chloroform/methanol; therefore we prepared a stock solution of 1 M cesium chloride in water and diluted to our working concentration—50 mM—in methanol, so it would be miscible with our analyte dilution buffer (chloroform/methanol, 50/50, v/v). We tried to use other, less volatile solvents to facilitate the sample dilution procedure, but a decrease in the quality of the spots was observed, and consequently of the analysis, probably due to solubility issues related to the lipophilic nature of the analytes.

The choice of organic solvents such as chloroform and methanol necessitated the use of glassware and glass micropipettes for the sample preparation. We observed an advantage in the use of volatile solvent systems: the rapid evaporation of the solvent mixture promoted an efficient co-crystallization of lipids and cesium chloride, resulting in homogeneous spots, as previously observed by other investigators [59]. Homogenous spots, along with triplicate analyses, allowed us to control variability issues, such as shot-to-shot, region-to-region and sample-to-sample [59, 60] variability. The possibility of bias acquisition was considered and therefore we opted for a completely automated acquisition of data collecting 1,200 shots, in a random walk pattern and with an intensity of laser between 15 and 60% in order to avoid saturation of the instrument. A better reproducibility was observed with the average of 1,200 spectra, rather than with a smaller number of acquisitions for each spot.

Release of contents from DPPC: $DC_{8,9}PC$ 4:1 liposomes occurs as a result of UV-triggered $DC_{8,9}PC$ polymerization in the bilayer [46]. Therefore the liposomes were loaded with 50 mM calcein and its release was monitored after treatment with UV (254 nm) for 45 min using a fluorescent micro plate reader (Methods section). Before and after UV treatment liposome lipids were extracted and analyzed by the NALDI mass spectrometry method.

MALDI signals for DPPC and $DC_{8,9}PC$ were linear over the selected ranges and the calibration curves resulted in coefficient of determinations (R^2) = 0.99, as shown in Fig. 1. Figure 2 shows two examples of spectra obtained from the lipids extracted and treated as described above. The decrease in intensity of the signal of the pseudo molecular ion for $DC_{8,9}PC$ after UV treatment is evident. We were able to determine the concentration for both DPPC and $DC_{8,9}PC$ using the equation from the linear regression for each compound. Figure 3 compares the concentration, expressed in μM, for both species before and after UV treatment. The concentration of DPPC remained constant (260 μM) while $DC_{8,9}PC$ decreased from 120 μM in the starting liposome to 12 μM in the liposome treated with 254 nm irradiation.

It is important to mention that the possibility of ion suppression and ionization efficiencies of the individual lipids we analyzed was considered. This is a common drawback in any mass spectrometry assay and we attempted to overcome this issue with the use of DMPC as the internal standard as it is structurally similar to the analytes of interest. The use of internal standards for quantitative analysis is standard practice [24, 61–63] and it is of crucial importance in any MALDI approach to these types of analyses. However in some cases a suitable internal standard may not be available, but reasonable quantitation may still be possible [64]. For optimal results, the use of a stable isotope analog of the analyte of interest would be the primary choice [63] for an internal standard, but in our case the available stable label analog of DPPC was not of sufficient purity for use as an internal standard so we chose a slightly smaller saturated PC as our internal standard.

By application of this novel MS method to the analysis of the phospholipids extracted from liposomes prepared and treated as described by Yavlovich et al. [46], we were

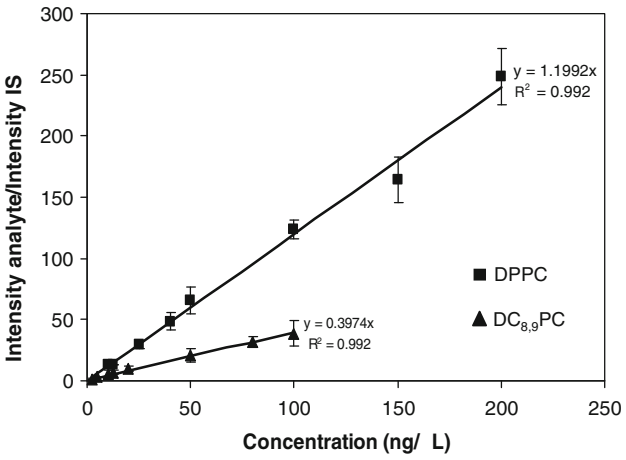

Fig. 1 Calibration curves for DPPC and $DC_{8,9}PC$. Concentration ranges for DPPC and $DC_{8,9}PC$ were respectively 10–200 ng/μL and 2.5–100 ng/μL

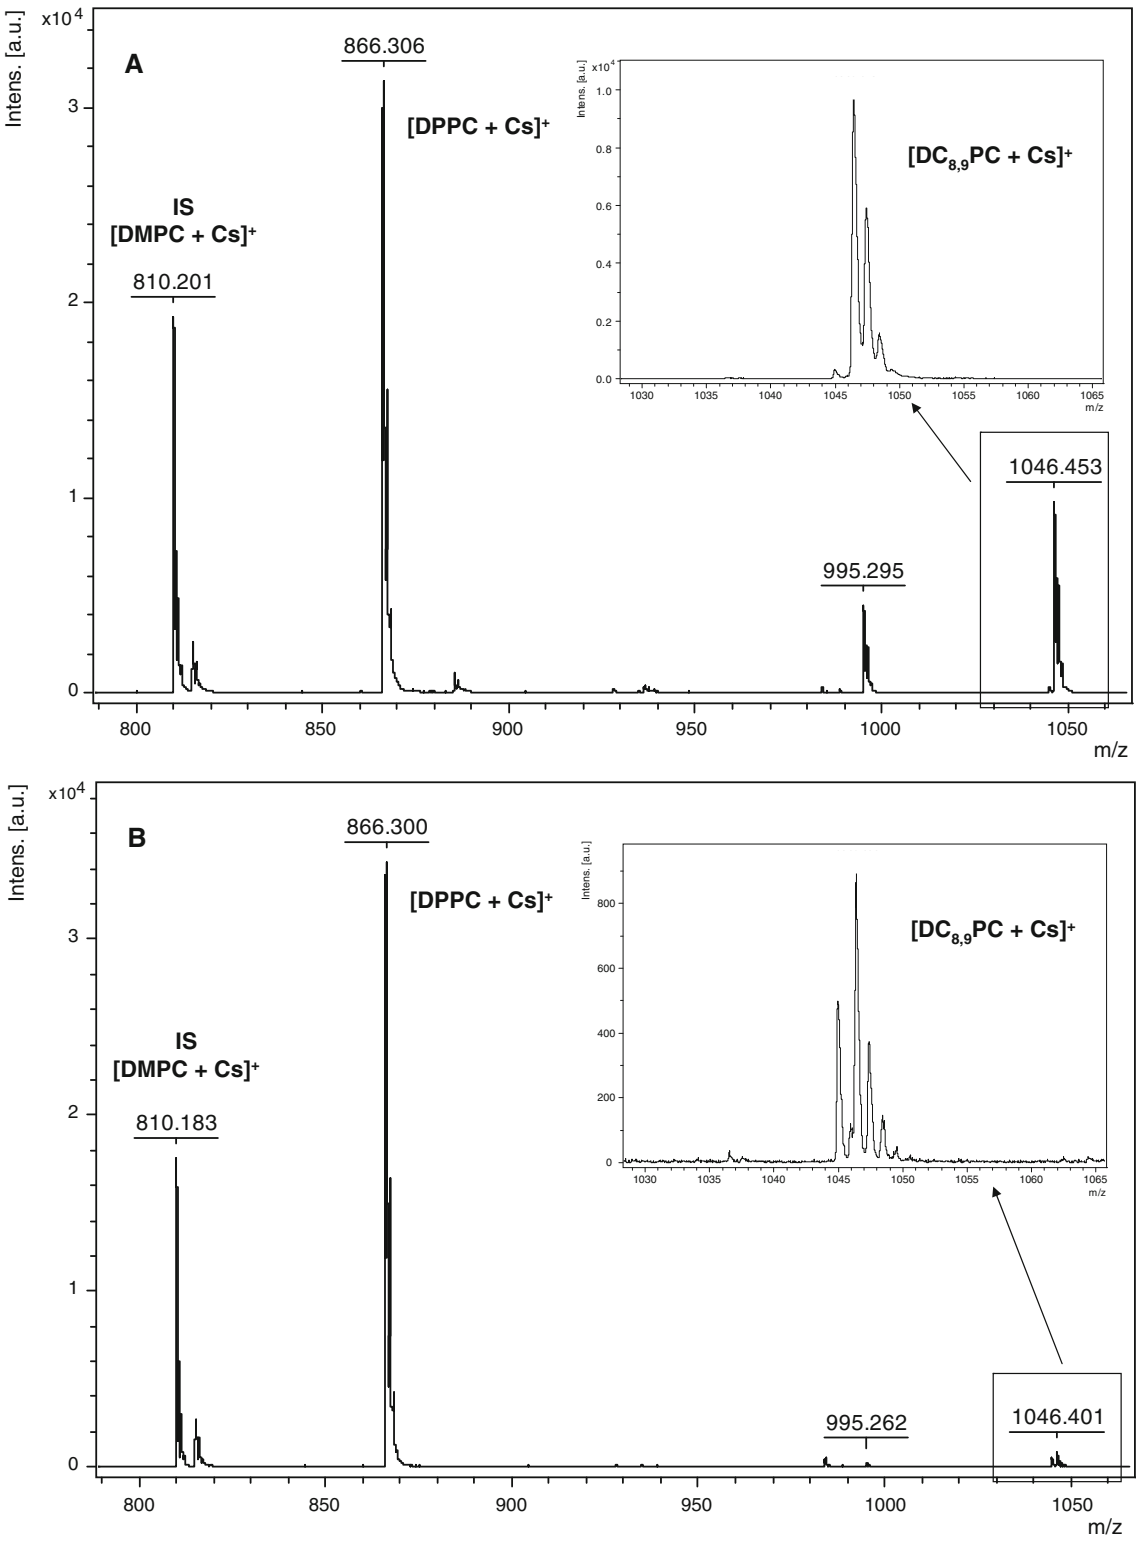

Fig. 2 Mass spectra of phospholipids from liposome before (**a**) and after (**b**) UV treatment (254 nm)

able to confirm the decrease of $DC_{8,9}PC$ from 120 μM to 12 μM, before and after the UV treatment (Fig. 3). As expected DPPC concentration did not change. It has been demonstrated that $DC_{8,9}PC$ liposomal photo-triggering by UV light occurs via direct photopolymerization mechanism [46].

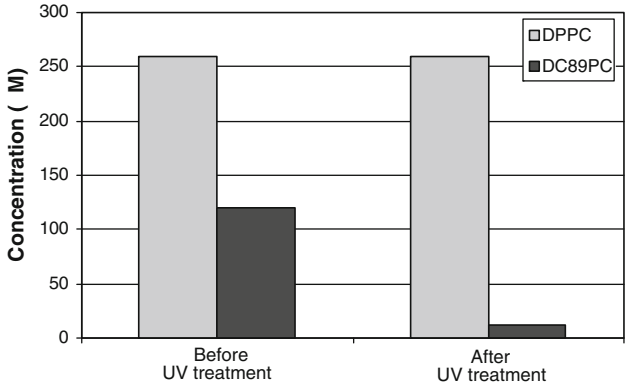

Fig. 3 Quantitative comparison of DPPC and $DC_{8,9}PC$ in liposome before and after UV treatment. A decrease of $DC_{8,9}PC$ from 120 μM to 12 μM, before and after the UV treatment, was observed, while the concentration of DPPC remained unchanged following exposure of the intact liposome at 254 nm irradiation

Conclusion

The NALDI-based analysis of the phospholipids presented here provides a fast and reproducible approach for the quantitative analysis of lipids in relatively complex mixtures. We have demonstrated that our method is sufficiently specific for the lipids of interest because it was not necessary to use tandem mass spectrometry as suggested by other investigators [21, 62, 65]. The use of the NALDI targets allows for greatly simplified sample preparation and eliminates the matrix-associated issues of inhomogeneous crystals and matrix adducts. This approach should also be possible to for a wide range of lipids and structurally similar molecules.

Receptor Mediated Elevation in FABP4 Levels by Advanced Glycation End Products Induces Cholesterol and Triacylglycerol Accumulation in THP-1 Macrophages

Received: 6 August 2010 / Accepted: 8 February 2011 / Published online: 20 February 2011

Abstract Excessive formation of advanced glycation end products (AGE) and lipid accumulation in macrophages play a pivotal role in the progression of atherosclerosis in diabetes mellitus. This study aimed to determine the molecular link between AGE-induced fatty acid binding protein 4 (FABP4) expression and macrophage lipid accumulation. AGE–BSA markedly increased macrophage FABP4 expression via engagement of RAGE, a 35-kDa transmembrane receptor that is able to bind extracellular AGE and responsible for the corresponding signal transduction, whereas knockdown of RAGE significantly reversed the FABP4 up-regulation. This effect was further paralleled with elevated intracellular total cholesterol and triacylglycerol levels. Finally, administration of FABP4 inhibitor totally abolished the increased lipid contents in response to AGE–BSA. These results indicate that FABP4 up-regulation is responsible for the enhanced macrophage lipid accumulation by AGE, which may underlie the accelerated formation of foam cells and development of atherosclerotic cardiovascular diseases in diabetic patients.

Abbreviations

AGE	Advanced glycation end products
aP2	Adipocyte protein 2
BSA	Bovine serum albumin
DMSO	Dimethyl sulfoxide
esRAGE	Endogenous secretary RAGE
FABP4	Fatty acid binding protein 4
FABP5	Fatty acid binding protein 5
FBS	Fetal bovine serum
LOX-1	Lectin-like oxidized low-density lipoprotein receptor 1
MSR	Macrophage scavenger receptor
OD	Optical density
ORO	Oil red O
oxLDL	Oxidized low-density lipoprotein
PBS	Phosphate-buffered saline
PMA	Phorbol 12-myristate 13-acetate
RAGE	Receptor for advanced glycation end products
sRAGE	Secretary RAGE
TAG	Triacylglycerol
TC	Total cholesterol

Introduction

Accelerated atherosclerosis accounts for about 80% of morbidity and mortality in patients with diabetes [1, 2]. Increased formation of advanced glycation end products (AGE) is recognized as an important player in diabetic vascular complications [3, 4]. After longstanding exposure to hyperglycemic milieu, proteins and lipids in blood and tissues undergo non-enzymatic Maillard reaction, and finally give rise to the irreversible formation of AGE [4].

AGE exert adverse effects largely through engagement of receptor for AGE (RAGE) on the cell membrane of vascular wall [5–7]. Postmortem studies have consistently shown that RAGE expression was mainly localized in macrophages within or around necrotic cores of atherosclerotic plaques, and was substantially increased in diabetic patients [8].

Macrophages actively participate in atherogenic processes, including formation of lipid-laden foam cells and atheromatous lipid cores [9]. FABP4, also known as adipocyte protein 2 (aP2), is highly expressed in macrophages [10]. It functions in cellular lipid metabolism, cholesterol trafficking and other biologic responses [11, 12]. Expression of FABP4 in THP-1 monocytes/macrophages was greatly increased upon treatment with phorbol 12-myristate 13-acetate (PMA) and oxidized low-density lipoprotein (oxLDL), while transformation of THP-1 monocytes into foam cells was significantly suppressed by FABP4 inhibitor, a small synthetic molecule designed to competitively prevent FABP4 from binding fatty acids [13, 14]. Likewise, inhibition of FABP4 expression either by macrophage-specific gene deficiency or administration of FABP4 inhibitor in vivo led to a protection from the development of atherosclerosis [15]. Iwashima et al. [6] observed that macrophage lipoprotein receptors, including CD36, macrophage scavenger receptor (MSR) class A and lectin-like oxLDL receptor 1 (LOX-1) were up-regulated in response to AGE stimulation, whereas key proteins localized on the cell membrane that mediate macrophage cholesterol efflux, including ABCA1 and ABCG1, were down-regulated or destabilized [16, 17].

It is still unclear, however, whether macrophage FABP4 remains, equally or to a greater extent, an active pro-atherogenic participator in the context of diabetes where AGE are greatly enriched. In this study, we tested the hypothesis that AGE-induced FABP4 expression in THP-1 macrophages was potentially associated with an increase in intracellular lipid levels. The assessment of lipid contents after FABP4 inhibitor administration was also performed.

Materials and Methods

Cell Culture

Human monocytic leukemia THP-1 cells were obtained from ATCC and cultured in Gibco RPMI 1640 medium supplemented with 10% heat-inactivated fetal bovine serum (FBS), 50 U/ml penicillin and 50U/ml streptomycin (Gibco, Auckland, New Zealand) at 37 °C in 5% CO_2. THP-1 monocytes were differentiated into macrophages by induction of 100nM phorbol 12-myristate 13-acetate (Sigma-Aldrich, MO) for 48 h. Cells were then incubated in the presence or absence of bovine serum albumin (BSA; fatty acid free, catalog no. 126575; Calbiochem, CA) or AGE–BSA (catalog no. 121800; Calbiochem, CA) for the indicated time intervals. FABP4 inhibitor (Calbiochem, CA) dissolved in dimethyl sulfoxide (DMSO) at the indicated concentrations was administrated for study purpose.

Transfection of RAGE-Specific siRNA

Transient transfection of THP-1 macrophages with RAGE-specific and negative control siRNA (Ambion CA) was scheduled as follows: Silencing RAGE expression was performed using human RAGE-specific siRNA and siRNA transfection reagent (Lipofectamine 2000, Invitrogen, CA) to macrophages. Macrophages grown in 6-well plates were transfected with various concentrations of siRNA according to the manufacturer's protocol. The RAGE-specific siRNA (100 pM) for reducing RAGE expression was added 48 h before AGE stimulation; macrophages were then exposed to BSA or AGE–BSA (Calbiochem CA) for 24 or 48 h for RNA or protein analysis and ORO-staining, respectively.

Assessment of Intracellular Lipid Contents

Cultured and transfected macrophages were washed twice in phosphate-buffered saline (PBS, Gibco, Auckland, New Zealand) and then fixed in 4% paraformaldehyde for 30 min. After rinsing with ddH2O, macrophages were incubated with filtered Oil Red O solution (0.6 g/L ORO in 60% isopropanol) (ORO, Sigma-Aldrich, MO) for 10 min and with 1 mL of Mayer's hemalum (Merck, Darmstadt) for 1 min. After rinsing with PBS four times, intracellular lipid droplets were evaluated under Olympus DP-71 microscope. Spectrophotometric quantification of the staining was performed as described previously [18]. Briefly, stained oil droplets were dissolved in 100% isopropanol for 10 min. Then optical density was measured at 500 nm and equalized with the cell numbers estimated by microscope. Quantifications of intracellular total cholesterol and triacylglycerol levels were performed following the protocols from the manufacture (Biovision, CA) and analyzed with a microtiter plate reader (Ex/Em = 538/587 nm). Total cholesterol and triacylglycerol concentrations were expressed as micrograms per milligram protein and nanomoles per milligram protein sample, respectively.

Quantitative Real-Time PCR Analysis

Total RNA was isolated using Trizol reagent (Invitrogen, CA). For reverse transcription, 1 μg of the total RNA was converted to first strand complementary DNA in 20-μl reactions using a reverse transcription kit (Promega, WI). Quantitative real-time PCR analysis was performed

(StepOne, Applied Biosystems) using SYBR Green (Takara, Dalian, China). The thermal cycling program was 10 s at 95 °C for enzyme activation and 40 cycles of denaturation for 5 s at 95 °C, 31 s 60 °C for annealing and extension. The comparative cycle threshold (CT) method was used to determine relative mRNA expression of genes as normalized by β-actin housekeeping gene. Primers used are as follows: 5′-TGGGATGGAAAATCAACC-3′ for FABP4-F, 5′-TCTCTCATAAACTCTCGTGG-3′ for FABP4-R, 5′-GGCAGAAAAACTCAGAC-3′ for FABP5-F, 5′-GACACACTCCACCACTAA-3′ for FABP5-R, 5′-GCTGGTGTTCCCAATAA-3′ for AGER-F, 5′-AGTGTGAAGAGCCCTGT-3′ for AGER-R, 5′-CGTGGACATCCGCAAAG-3′ for β-actin-F, and 5′-TGGAAGGTGGACAGCGA-3′ for β-actin-R.

Western Blot

Total proteins were prepared by standard procedures and assessed by microplate protein assay (BSA; Pierce, IL). Thirty micrograms of protein per sample and known molecular weight markers were loaded onto a 12% SDS-polyacrylamide gel. After SDS-polyacrylamide gel electrophoresis, proteins were transferred to PVDF membranes (Millipore, MA). The blocked membranes (5% nonfat milk in TBS buffer containing 0.1% Tween 20) were incubated with anti-FABP4 (1:1000; Santa Cruz Biotechnology, CA), anti-RAGE (1:1000; Abcam, MA) and anti-β-actin antibody (1:1000; Cell Signaling Technology, MA) for overnight at 4 °C. The membranes were then treated with horseradish peroxidase-conjugated rabbit anti-goat, goat anti-rabbit or goat anti-mouse antibodies (1:5000; Bio-Rad, Hercules, CA). After washing, immunodetection analysis was accomplished using the Immobilon Western Chemiluminescent HRP Substrate (Millipore, MA).

Statistical Analysis

Data are expressed as means ± SEM. The mean values for biochemical measurements from each group were compared using Student's t test. A $P < 0.05$ was considered statistically significant.

Results

AGE–BSA-Induced Up-Regulation of FABP4 Expression

After incubation with AGE–BSA for 24 h at various concentrations (from 25 to 200 μg/ml), FABP4 expression was substantially up-regulated, and reached the maximum level

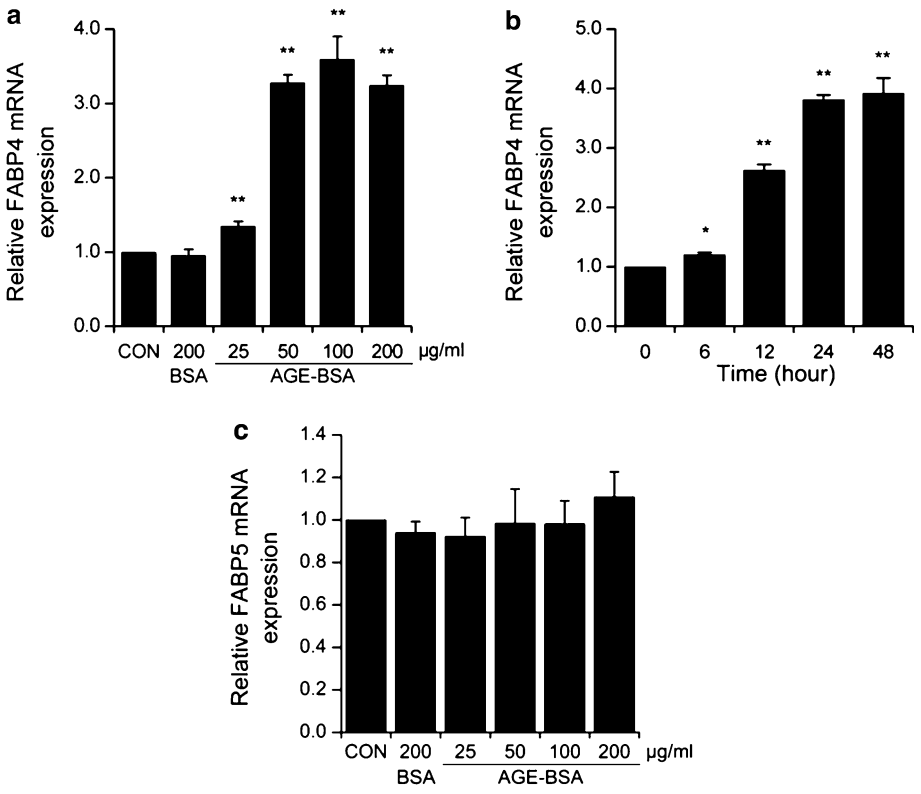

Fig. 1 Up-regulation of FABP4 mRNA expression by AGE–BSA. **a**, **c** THP-1 macrophages were treated with indicated doses of BSA or AGE–BSA for 24 h. **b** Macrophages were either untreated or treated with 100 μg/ml AGE–BSA for various time intervals. FABP4 and FABP5 mRNA levels were detected by quantitative real-time PCR; data are expressed relatively to untreated cells, arbitrarily set at the level of 1, and are the means ± SEM of at least three independent experiments. *$P < 0.05$ and **$P < 0.01$ when compared with untreated cells

at 100 μg/ml (3.59 ± 0.53-fold vs. con; $P = 0.001$), whereas BSA did not affect FABP4 expression significantly (0.95 ± 0.14-fold vs. con, $P = 0.577$; Fig. 1a). A 3.9-fold increase in FABP4 expression was observed by 48 h of incubation ($P = 0.0003$; Fig. 1b). FABP5, another fatty acid binding protein expressed in macrophages, was not affected by AGE (Fig. 1c).

RAGE Mediates AGE–BSA-Induced FABP4 Expression

AGE–BSA moderately increased RAGE expression by 1.2-fold in cells transfected with non-specific negative control siRNA ($P = 0.010$, Fig. 2a). After gene silencing of RAGE, AGE exposure no longer affected FAPB4 expression both at mRNA (1.38 ± 0.24-fold vs. BSA, $P = 0.069$; Fig. 2b) and protein (Fig. 2c) levels when compared with negative control-treated groups (2.78 ± 0.36-fold vs. BSA, $P = 0.001$).

AGE–BSA-Induced Macrophage Lipid Accumulation

Oil red O (ORO) staining of lipid droplets was most evident at 100 and 200 μg/ml of AGE–BSA (Fig. 3a, b). A similar trend was also obtained for intracellular TC (100 μg/ml AGE–BSA: 37.20 ± 2.52 μg/mg, $P = 0.0002$; 200 μg/ml AGE–BSA: 29.89 ± 4.67 μg/mg, $P = 0.0066$ vs. con: 15.10 ± 1.61 μg/mg; Fig. 3c) and TAG levels (100 μg/ml AGE–BSA: 4.35 ± 1.35 nmol/mg, $P = 0.0252$; 200 μg/ml AGE–BSA: 2.89 ± 0.75 nmol/mg, $P = 0.0463$ vs. con: 1.64 ± 0.08 nmol/mg; Fig. 3d). RAGE knockdown markedly reduced lipid contents in response to AGE exposure (TC, 21.92 ± 3.09 μg/mg vs. BSA: 17.23 ± 2.20 μg/mg, $P = 0.0980$; TAG, 5.64 ± 1.43 nmol/mg vs. BSA: 1.85 ± 1.10 nmol/mg, $P = 0.0220$) when compared with negative control-treated cells, as demonstrated by ORO staining (Fig. 3e, f), TC (Fig. 3g) and TAG (Fig. 3h) quantification.

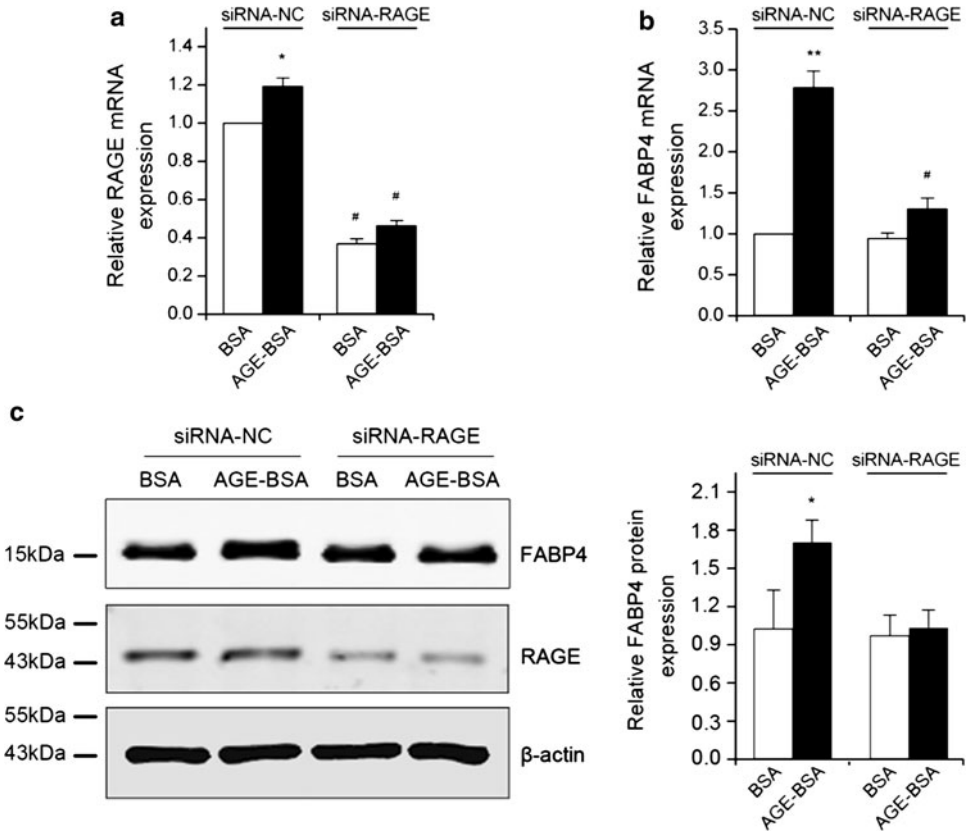

Fig. 2 Effect of RAGE knockdown by siRNA transfection on FABP4 expression. Macrophages were transfected with negative control or RAGE specific siRNA for 48 h and exposed to BSA or AGE–BSA, respectively, at the concentration of 100 μg/ml. Then mRNA expression levels of RAGE (**a**) and FABP4 (**b**) were determined using quantitative real-time PCR; data are expressed relatively to untreated cells, arbitrarily set at the level of 1, and are the means ± SEM of at least three independent experiments. **c** Protein expression levels of FABP4 and RAGE in each group were analyzed by Western blot. β-actin demonstrated equal loading. The right panel shows the average densitometric analysis of three independent experiments. Data are expressed in arbitrary units. $^{*}P < 0.05$ and $^{**}P < 0.01$ compared with BSA-treated cells in the same group. $^{\#}P < 0.01$ versus cells with the same BSA or AGE–BSA treatment in negative control group

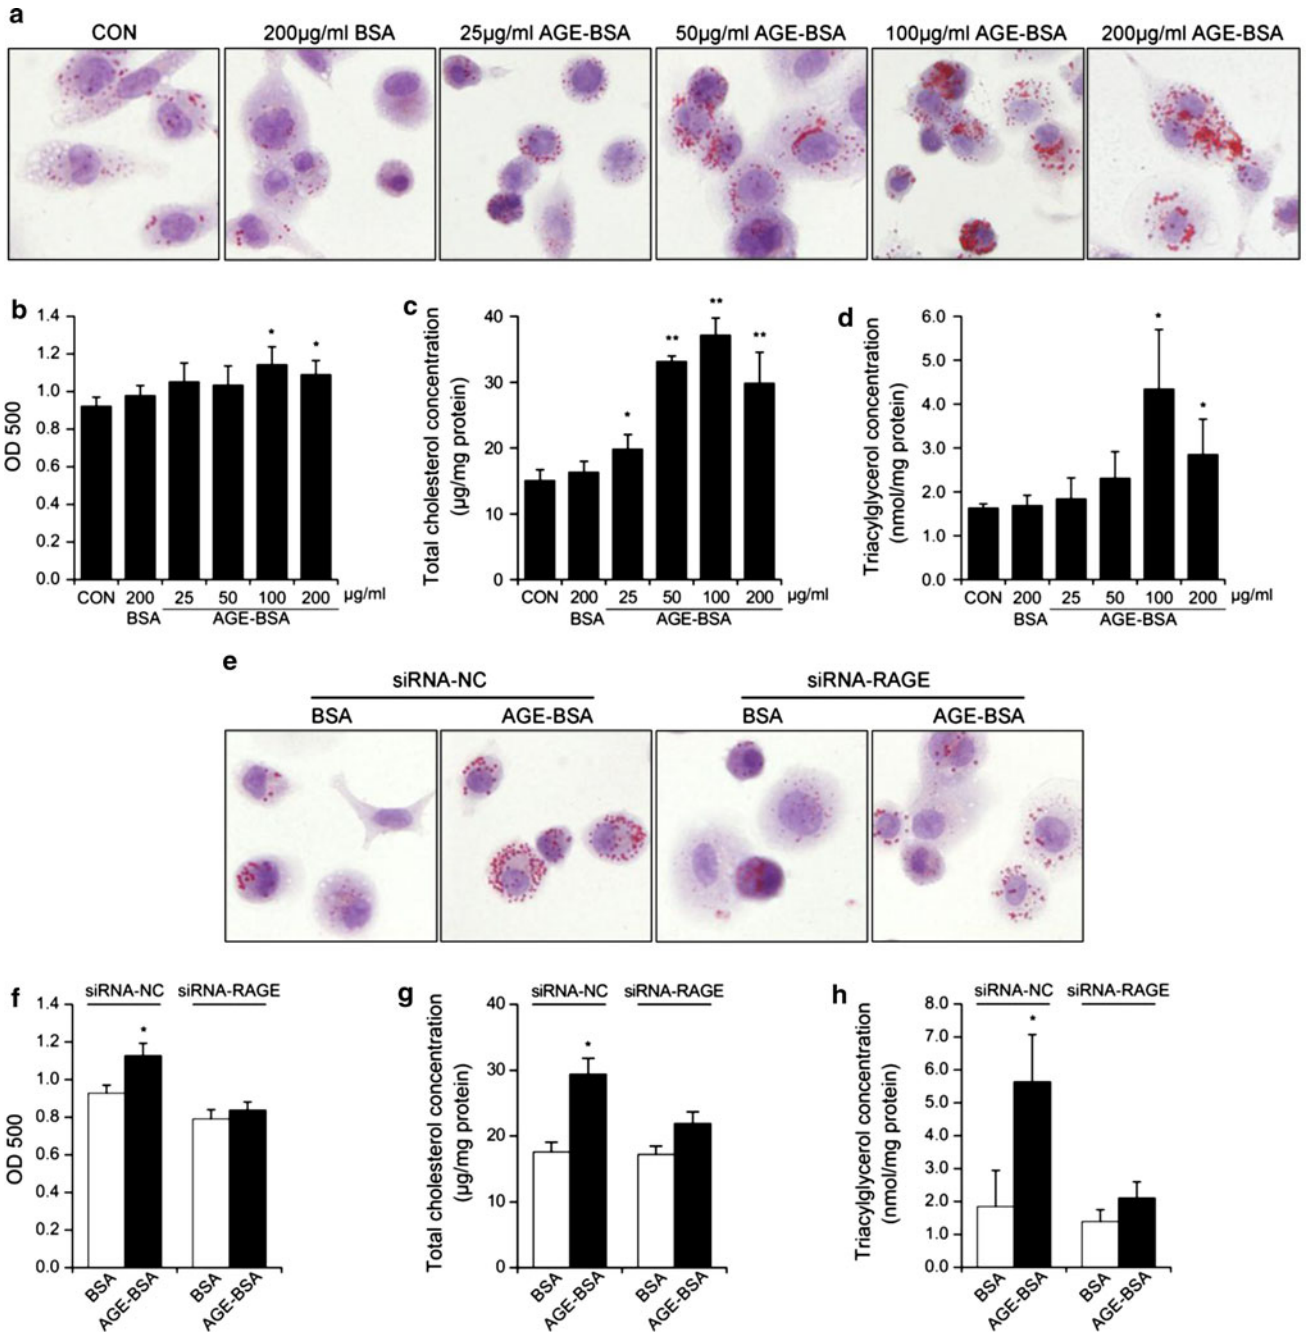

Fig. 3 Up-regulation of lipid contents by AGE–BSA via RAGE. **a**–**d** Macrophages were either untreated or treated with indicated doses of BSA and AGE–BSA for 48 h. **e**–**h** Macrophages were transfected with negative control or RAGE specific siRNA for 48 h and then exposed to BSA or AGE–BSA, respectively, at the concentration of 100 μg/ml. **a**, **e** Intracellular lipid droplets were observed through light microscope after ORO staining; pictures acquired at the magnification of 400× and processed using identical conditions are representative of three independent experiments. **b**, **f** Spectrophotometric quantifications of ORO staining by optical density at 500 nm were shown. Intracellular total cholesterol (**c**, **g**) and triacylglycerol (**d**, **h**) concentrations were determined using a fluorometric method; data are presented as micrograms of total cholesterol per milligrams of protein or nanomoles of triacylglycerol per milligrams of protein ± SEM of three independent experiments. $^{*}P < 0.05$ versus untreated cells (**b**, **c**, **d**) or BSA-treated cells in the same group (**f**, **g**, **h**). $^{**}P < 0.01$ versus untreated cells

Changes After Incubation with FABP4 Inhibitor

After incubation with FABP4 inhibitor for 48 h, AGE-induced lipid accumulation in macrophages was substantially suppressed and reached the maximum effect at 40 μM as demonstrated by ORO staining (Fig. 4a, b), TC (14.92 ± 1.54 μg/mg vs. BSA: 14.56 ± 0.81ug/mg, $P = 0.7356$; Fig. 4c) and TAG (0.79 ± 0.35 nmol/mg vs. BSA:

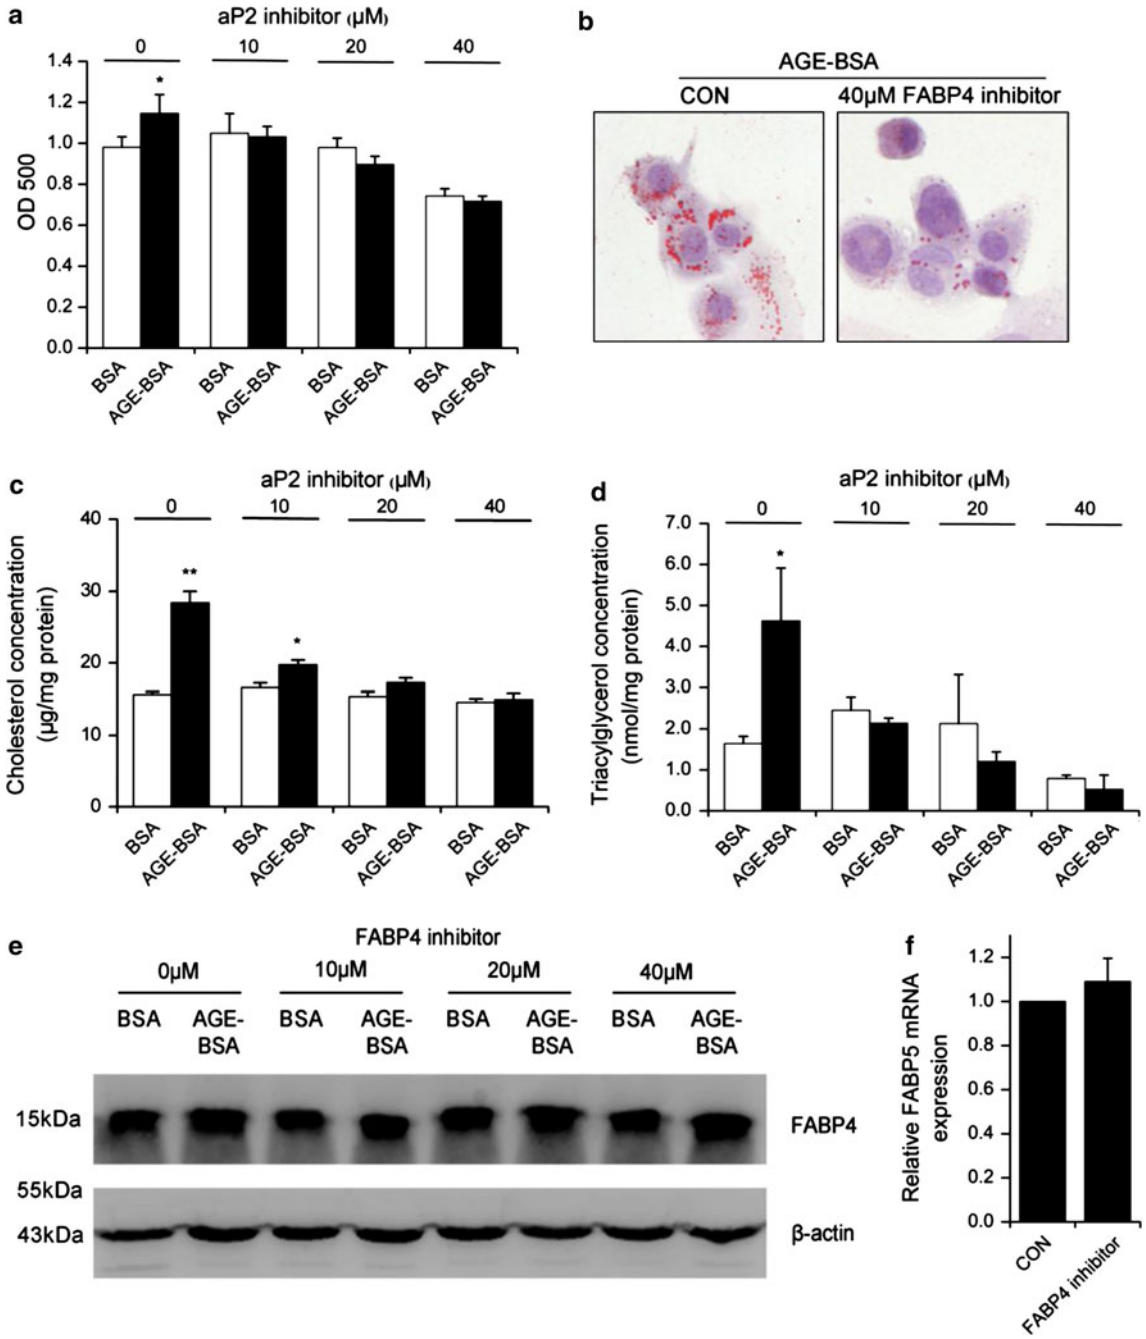

Fig. 4 Effect of FABP4 inhibitor on AGE–BSA-induced lipid accumulation. Macrophages were treated with 100 μg/ml BSA or AGE–BSA in the absence or presence of indicated doses of FABP4 inhibitor for 48 h. **a** Intracellular cellular lipid droplets were stained with ORO and quantified by optical density at 500 nm or **b** observed through light microscope; pictures acquired at the magnification of 400× and processed using identical conditions are representative of three independent experiments. Intracellular total cholesterol (**c**) and triacylglycerol (**d**) concentrations were determined using a fluorometric method; data are presented as micrograms of total cholesterol per milligrams of protein or nanomoles of triacylglycerol per milligrams of protein ± SEM of three independent experiments. **e** FABP4 protein expression levels in each group were analyzed by Western blot. *β*-actin demonstrated equal loading. **f** THP-1 macrophages were treated with or without 40 μM FABP4 inhibitor for 48 h. FABP5 mRNA levels were detected by quantitative real-time PCR; data are expressed relatively to untreated cells, arbitrarily set at the level of 1, and are the means ± SEM of at least three independent experiments. $*P < 0.05$; $**P < 0.01$ versus BSA-treated cells in the same group

0.52 ± 0.24 nmol/mg, $P = 0.2656$; Fig. 4d) quantification when compared with macrophages without FABP4 treatment. AGE–BSA up-regulated FABP4 protein levels irrespective of FABP4 inhibitor at each concentration (Fig. 4e). FABP5 expression was not affected by FABP4 inhibitor (Fig. 4f).

Discussion

In THP-1 macrophages, AGE-induced FABP4 expression via a RAGE-dependent signaling pathway resulted in increased intracellular lipid levels, which could be attenuated by FABP4 inhibitor.

AGE are increasingly regarded as an indispensable factor for severity and progression of atherosclerosis in patients with diabetes [8]. AGE-albumin, a further glycation modified protein derived from Amadori adduct exerts more severe pathogenic influence. Elevated serum AGE-albumin and decreased serum endogenous secretary RAGE (esRAGE) levels highly correlated with the extent of angiographic severity in patients with type 2 diabetes [19, 20]. In contrast, in vivo studies showed that administration of soluble RAGE (sRAGE), another truncated form of RAGE acting as a decoy for AGE, completely suppressed diabetic atherosclerosis in glycemia- and lipid-independent manners [21]. Other approaches utilizing inhibitors for AGE formation, including aminoguanidine and an AGE cross-link breaker ALT-711, also led to a striking reduction in atherosclerotic lesions in diabetic apoE-deficient mice [22].

Despite the important contribution of AGE to the accelerated atherosclerosis in diabetes, the specific molecular mechanisms in response to AGE within a macrophage (a central player in atherogenesis) remain unclear. In this study, we discovered that exposure of THP-1 macrophages to AGE was time-dependently associated with a significant elevation of FABP4 expression, reaching its maximum level when 100 μg/ml AGE–BSA was used. At the same time, the enhanced expression of FABP4 was paralleled with increases in intracellular TC and TAG levels. RAGE-specific gene silencing led to reversions both in FABP4 expression and lipid contents, suggesting that AGE-elicited atherogenic effects in macrophages were, at least partly, RAGE-dependent. Finally, this increase in lipid levels was totally abolished by simultaneous administration of FABP4 inhibitor.

Our study is the first to show that macrophage FABP4 expression, a critical participant in atherogenesis, is further enhanced in the context of diabetes. In an animal experiment, Gerrity et al. [2] observed that FABP4 deficiency protected against the development of insulin resistance, diabetes, and atherosclerotic cardiovascular disease. Recent population studies revealed that genetic variations at the FABP4 locus in humans led to lowered serum triglyceride levels, and a markedly reduced risk of coronary heart disease in type 2 diabetes [23]. These anti-atherosclerotic effects were mainly attributed to the improvement of glucose control, insulin resistance and dyslipidemia [24, 25]. In this study, we demonstrated that exposure of macrophages to AGE was capable of increasing intracellular FAPB4 levels and lipid contents, similar to that when transforming macrophages to foam cells in the presence of oxLDL stimulation [14]. These observations suggest that excessive formation of AGE could render diabetic patients under high risk of developing atherosclerosis like those with dyslipidemia. [26–28].

Furthermore, our results imply that FABP4 might be a potential therapeutic target for the treatment of diabetic patients with atherosclerosis. In this study, mild doses of FABP4 inhibitor (10–20 μM) greatly attenuated AGE–BSA elicited macrophage lipid accumulation, whereas lipid levels in the absence of AGE were not affected. These findings indicate that FABP4 inhibitor may not disturb physiological lipid metabolism in macrophages, but, on the contrary, suppresses exclusively pathological excessive lipid accumulation.

This study does not specify the mechanisms by which lipid contents and trafficking are affected by AGE besides the elevated FAPB4 level. Deficiency of FABP4 enhanced CD36-mediated lipoprotein entry and, at the same time, activated ABCA1-dependent lipid efflux to a greater extent, thereby lowering intracellular lipid contents [29]. Likewise, AGE stimulation on macrophages could increase SRA-1 and CD36 and decrease ABCG1 protein levels [6, 16, 17]. Thus, enhanced expression of FABP4 by AGE might extensively affect lipid influx and efflux, directly or indirectly, at the same time to increase lipid accumulation. Further studies including analysis of lipid trafficking in macrophages from FABP4-deficient mice and blocking lipoprotein transporters by their specific siRNA or antibodies, are needed to elucidate the mechanisms.

In conclusion, this study demonstrates a causal molecular link between AGE and FABP4 in macrophage lipid accumulation. FABP4 inhibitor may be useful for suppressing the atherosclerotic process in patients with diabetes.

Abstract In this study, cells from the stromal vascular fraction of human subcutaneous tissues were induced to differentiate toward adipose cells in vitro for 2 weeks. During adipogenic differentiation, we followed the chronological changes in their morphology with Coherent anti-Stokes Raman scattering (CARS) microscopy and checked the PPAR-γ and UCP-1 expression with RT-PCR. On day 4 after inducing adipogenic differentiation, CARS imaging showed multiple small lipid droplets (LD) distributed peripherally along the cellular membrane. PPAR-γ began to express at this time and increased until day 14 at a steady rate. On day 7, the cells appeared as brown adipocytes with numerous small LD throughout the cytoplasm, and the mRNA level of UCP-1 rose abruptly by 6- to 7-fold. After an additional 7 days, CARS imaging showed the development of a large LD, which is characteristic of white adipocytes, and the mRNA level of UCP-1 slumped significantly. These results demonstrate the possibility that ADSC pass through a brown adipocyte-like stage while differentiating into white adipocytes.

SVF	Stromal vascular fraction
UCP-1	Mitochondria-uncoupling protein-1
WAT	White adipose tissue

Introduction

Adipose tissue has been classified into two distinct types in mammals: WAT and BAT [1]. WAT is mainly involved in energy storage [2], while BAT forms heat using accumulated lipids [3] and the thermogenic capability depends on the presence of UCP-1 which is unique and specific to brown adipocytes [4, 5]. Although both of them are important to control the energy balance, they are regarded as distinct tissues and thought to develop independently for several reasons. One of the reasons is that white adipocytes do not express UCP-1 during adipogenesis, which was supported indirectly by an experiment using double transgenic mice [6].

Adipogenesis is a complicated process, which eventually results in the expression of various adipocyte-associated genes as well as an increased capacity of the cell for lipid-filling [7, 8]. For the past 20 years, many studies of adipogenesis have been conducted using preadipocyte clonal lines from rodents [8–10].

Although the results of studies using established cell lines have been invaluable, they are limited in their applicability to an in vivo human context because of their aneuploidy, unipotency, site-restriction and the species–species differences between humans and mice [9, 11]. Recently, a new era has started after the identification of human ADSC, mesenchymal stem cells isolated from adipose tissue. ADSC have a self-renewal capacity and multi-lineage potential toward adipocytes, osteoblast, chondrocytes, myoblasts and neuronal cells [12, 13]. Additionally, they are easily processed from lipoaspirated fat and can provide a significant quantity of multipotent stem cells [14]. Compared to clonal cell lines from mice, human ADSC may be much more appropriate for studies of adipocyte differentiation because they can offset the disadvantages of previous models and can better reflect the in vivo human context.

CARS microscopy is an advanced technique for the real-time imaging of live cells. It requires neither fixation nor a fluorescent probe. In the CARS process, a "pump" beam at a higher frequency (ω_p), a "Stokes" beam at a lower frequency (ω_s) and a "probe" beam (ω'_p) at the same frequency as the pump beam interact with a sample to generate an "anti-Stokes" beam, presented in the form of the equation $2\omega_p - \omega_s$. These signals are maximized by tuning the frequency difference ($\omega_p - \omega_s$) to the vibration of specific chemical bonds, which provides chemical selectivity in CARS microscopy [15]. In particular, CARS microscopy shows high sensitivity to the C–H vibration of lipid-rich molecules. Thus, CARS microscopy has been used to visualize lipids, axonal myelin sheaths and lipid-rich cells [16, 17]. Moreover, it was shown to be effective for imaging LD, in which the fatty acyl group is highly accumulated, in live cells without fixation [18].

In this study, we isolated the stromal-vascular fraction (SVF) cells from human subcutaneous tissue which contains ADSC and induced the cells to differentiate toward adipose tissue in vitro. To characterize the morphologic and molecular change of the cells during adipogenic differentiation, we serially imaged live cells with CARS microscopy and examined the PPAR-γ and UCP-1 expression with RT-PCR. On day 7 of adipogenesis, these cells transiently appeared multilocular with numerous small LD with an abrupt increase of UCP-1, thus suggesting that stem cells passes through a brown adipocytes-like stage while differentiating to white adipocytes.

Materials and Methods

Isolation and Culture of Human ADSC

Before the study, the protocols for fat collection were reviewed and approved by the institutional research board of the Seoul National University Hospital Clinical Research Institute, and informed consent was obtained from the human subjects. Liposuction aspirates from abdominal subcutaneous tissue were acquired from three healthy female donors undergoing elective procedures under tumescent anesthesia. The lipoaspirates were washed with PBS and were subsequently finely minced. The extracellular matrix was digested with 0.075% collagenase type I (Sigma-Aldrich, St. Louis, MO). Enzyme activity was neutralized with DMEM containing 10% FBS and the tissue was centrifuged for 10 min at 1,200g at room temperature. The supernatant, containing mature adipocytes, was aspirated. The pelleted SVF cells were collected and then plated in 175 cm^2 flasks (Becton–Dickinson AG, Basel. Switzerland) in a control medium which consisted of DMEM, 10% FBS, and 1% penicillin/streptomycin 5,000 U/ml (Invitrogen AG, Bagel, Switzerland). After that, they were incubated overnight at 37 °C in 5% CO_2. The resulting cell population includes human ADSC. [12, 13]. This initial passage was referred to as passage 0 (P0). After they achieved 90% confluence, the cells were passaged repeatedly until P8 by trypsin (0.05%, Invitrogen AG, Basel, Switzerland) in the same way.

Flow Cytometry

Cells at passage 4 were harvested and labeled with the following anti-human antibodies: anti-CD29-FITC (Santa Cruz Biotechnology, Santa Cruz, CA), anti-CD44-FITC (Dako, Carpinteria, CA), anti-CD31-FITC, and anti-CD34-FITC (Becton–Dickinson, San Diego, CA). Mouse isotype antibodies served as controls. Cells were analyzed using a FACS Calibur flow cytometer (Becton–Dickinson) [19].

Multilineage Differentiation of Human ADSC in Vitro

Human ADSC at passage 4 were analyzed to confirm their capacity to differentiate toward the adipogenic, osteogenic, and chondrogenic lineages. To induce the respective differentiations, ADSC were cultured with previously described lineage-specific induction media [12, 20, 21], as detailed in Table 1. To induce adipogenic and osteogenic differentiation, cultures in respective lineage-specific media were maintained at 37 °C in 5% CO_2 for 2 weeks. Chondrogenic differentiation was determined using a slight modification of a previously described pellet culture technique [22]. Briefly, ADSC were placed in 15 ml polypropylene conical tubes, centrifuged at 1,500 rpm for 5 min, and then cultured in chondrogenic medium (CM) at 37 °C in 5% CO_2 for 4 weeks. ADSC maintained in the control medium were analyzed as negative controls. During the culturing process, the medium was changed every 2 days.

Table 1 Media supplementation for lineage-specific differentiation

Medium	Media	Serum	Supplements
Adipogenic (AM)	DMEM	10% FBS	0.5 mM isobutyl-methylxanthine (IBMX), 1 μM dexamethasone, 10 μM insulin, 200 μM indomethacin, 1% antibiotic/antimycotic
Osteogenic (OM)	DMEM	10% FBS	0.1 μM dexamethasone, 50 μM ascorbate-2-phosphate, 10 mM β-glycerophosphate, 1% antibiotic/antimycotic
Chondrogenic (CM)	DMEM	10% FBS	1.08 μM insulin, 0.23 nMl TGF-β1, 50 nM ascorbate-2-phosphate, 1% antibiotic/antimycotic

Histological Analysis

Differentiated ADSC were confirmed using histological assays [12]. Oil red O stain was used for adipogenesis, alkaline phosphatase (AP) activity and von Kossa stain for osteogenesis, and Safranin O stain for chondrogenesis. For Oil red O stain, cells were fixed with a 3.7% solution of formaldehyde, washed with distilled water, and stained with Oil red O solution for 10 min. AP activity was detected by fixing the cells with a 3.7% solution of formaldehyde and staining with AP solution including 1% naphthol ABSI phosphate. For von Kossa staining, the cells were fixed with 1% paraformaldehyde for 15 min and overlaid for 15 min with a 5% silver nitrate solution in the dark at room temperature. Then, they were left under UV light for 20 min, followed by incubation with sodium thiosulfate for 2 min. For Safranin-O staining, the tissue sections were deparaffinized with xylene and ethanol. Then 1% aqueous Safranin-O was added for 30 min and 0.2% fast green was added for 3 min. After that, the sections were washed with distilled water and with serial concentrations of 70, 80, and 95% ethanol.

Coherent Anti-Stokes Raman Scattering (CARS) Microscopy

For the CARS image measurements, the pump and the Stokes beams were generated from two synchronized 76-MHz near-infrared mode-locked lasers. An Nd:Vanadate laser with a pulse duration of 7 ps (PicoTRAIN, High Q Laser Production GmbH, Hohenems, Austria) was used as the Stokes beam at 1,064 nm, and a pump beam with a duration of 6 ps at 776 nm was generated from an intracavity doubled optical parametric oscillator (Levante, APE GmbH, Berlin, Germany) that is synchronously pumped by the Nd:vanadate laser. The power levels of the pump and the Stokes beams were kept around 50 and 25 mW, respectively. A multiplexed pump beam of 30 nm bandwidth at 817.2 nm was produced from a femtosecond Ti:sapphire laser (Micra-10, Coherent Inc., Santa Clara, CA) with an average power of 900 mW, whose output pulse train was synchronized with that of the 1,064 nm picosecond laser by using an electronic cavity feedback module (SynchroLock-AP, Coherent Inc.). The Raman shift value set in the laser wavelengths was nearly in resonance with the CH-stretching vibrational modes of the sample. The synchronized three laser beams were then collinearly combined and sent to and inverted optical microscope (IX81, Olympus, Tokyo, Japan). The CARS excitation beams were then focused onto a sample by a 1.2-NA water immersion objective lens (UPLSAPO/IR 60X, Olympus). The forward CARS signal in the lipid window (644–683 nm) was collected by a 0.55-NA condenser lens and directed to the photomultiplier tube (R3896, Hamamatsu Photonics, Hamamatsu, Japan). The CARS images having a maximum field of view of 250 × 250 μm^2 were acquired by performing raster scans of the laser beams on the sample.

Reverse Transcription-Polymerase Chain Reaction (RT-PCR) Analysis

Adipogenic differentiated cells were collected at defined time points (day 1, 4, 7 and 14), and non-induced cells were also examined as a negative control. Total RNA from each cell group was extracted by TRIzol reagent (Invitrogen) and was reverse transcribed using the TaqMan Gold RT-PCR kit (Applied Biosystems, Foster City, CA, USA). All real-time PCR measurements were performed using an ABI 7000 real-time PCR system (Applied Biosystems) according to the standard temperature cycling protocol for the relative quantification assays. The expression of PPAR-γ and UCP-1 was quantitated and the primer pairs used were as follows: PPAR-γ: 5′-ATGACAGCGACTTGG CAA-3′ (forward primer) and 5′-AATGTTGGCAGTG GCTCA-3′ (reverse primer); UCP-1: 5′-AGAGCCATCT CCACGGAA-3′ (forward primer) and 5′-CCAGGATCCA AGTCGCAA-3′ (reverse primer). The expression of human glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used to normalize the gene expression levels.

Image Analysis

We used the IMT morphology program (iMT technology, Bucheon, Korea) to count the number of LD and to estimate the size of each LD.

Statistical Method

Statistical significance was determined using the Student's *t*-test and a p value of <0.05 was considered significant.

Statistical analysis was performed using SPSS version 17.0 (SPSS, Chicago, IL, USA).

Results

Primary Culture and Phenotypic Characterization of SVF Cells

SVF cells including ADSC extracted from the lipoaspirates adhered to the tissue culture dish and grew into spindle-shaped cells, while non-adherent cells such as red blood cells were removed by changing the media. SVF cells proliferated rapidly and exhibited a relatively consistent population doubling rate from passage 0–8 (data not shown). At passage 4, these cells appeared to have a fibroblast-like shape. To examine the immunophenotype of these cells, we characterized the cell population according to its CD marker profile using flow cytometry. The results demonstrated that cells at passage 4 expressed CD29 (99.5%) and CD44 (97.6%) but did not express hematopoietic lineage markers CD31 (6.1%) and CD34 (5.4%) (Fig. 1).

Multi-lineage Differentiation of ADSC

To verify the ADSC, we tested the multilineage capacity of the cultured cells. Cells were differentiated toward the adipogenic, osteogenic, and chondrogenic lineages using lineage-specific induction media, and the instances of differentiation were assessed by histology (Fig. 2). Our cells were cultured in AM for 2 weeks and developed lipid-containing droplets which were stained by Oil Red O, which is consistent with the phenotype of mature adipocytes. Cells treated with OM formed a dense and extensive network. They expressed the increased AP activity by which an osteoblast was characterized and calcification as detected by von Kossa staining. Finally, Safranin-O staining showed distinct proteoglycan production, which indicated chondrogenic differentiation, in cells cultured in CM by the pellet technique. These indicated that ADSC composed the SVF cells from human lipoaspirates.

Serial Observation of Human ADSC in Adipogenic Differentiation

SVF cells including ADSC were cultured in control medium and then switched to AM at passage 4. Using Oil red O stain and CARS microscopy, we observed the chronological change of morphology during the adipogenic differentiation of human ADSC on day 0, 1, 7, and 14 after induction. Treatment with AM generally resulted in enlarged cell morphology and a time-dependent increase in intracellular LD (Fig. 3). Details are as follows: on day 0, the cells were elongated and fibroblast-like. Oil red O staining was negative, and the CARS image showed a centered nucleus with low signal intensity and a ground glass-appearing cytoplasm with multiple medium signal intensity spots.

On Day 1, there appeared to be no significant changes in the morphology of the cells. Cells were still elongated and not stained with Oil red O. The CARS finding was somewhat similar to that on day 0. The characteristic changes began to be observed only after 4 days. The ADSC had become rounder, and Oil red O staining showed sparse positively stained LD. Additionally, multiple 1–3 μm sized high signal globules were distributed in a lace-like pattern peripherally along the cell border in the CARS image.

On day 7, slightly enlarged, rounder cells were observed. They had several enlarged and positively stained LD with Oil red O. The CARS image demonstrated a number of 4–6 μm high signal globules that filled the entire cytoplasm. The nucleus was spared and positioned in the center or on the slight periphery. These morphologic features in CARS image are similar to those of the brown adipocytes [1].

Treatment of AM for additional 7 days enlarged the cells much more. On day 14, Oil red O staining showed large and densely positive LD. On CARS microscopy, the ADSC resembled white adipocytes with a large globule approximately 10 μm in size that had been generated from aggregation of adjacent LD. The nucleus was distorted and leaned onto the cytoplasmic membrane. The number of LD per cell decreased compared to that on day 7.

Monitoring Adipogenesis with Real-Time qPCR

Real-time qPCR demonstrated that PPAR-γ was expressed at an essentially steady rate since it was detected initially on day 4 (Fig. 4a). The mRNA level of UCP-1, a specific marker of brown adipocytes, rose 6- to 7-fold abruptly on day 7 (Fig. 4b), however, slumped significantly on day 14.

Discussion

To reflect an in vivo human context better, we undertook this study using cells from human subcutaneous tissue. Before inducing these cells to differentiate toward adipose tissue, we showed that SVF cells exhibit a stable proliferation rate and a self-renewal capacity, and were positive for mesenchymal cell markers CD29, CD44 but negative for CD31, CD34. This indicates that our cells were not contaminated with progenitors from bone marrow or hematopoietic lineage cells from blood vessels. In addition, we demonstrated the multipotentiality of our cells at passage 4

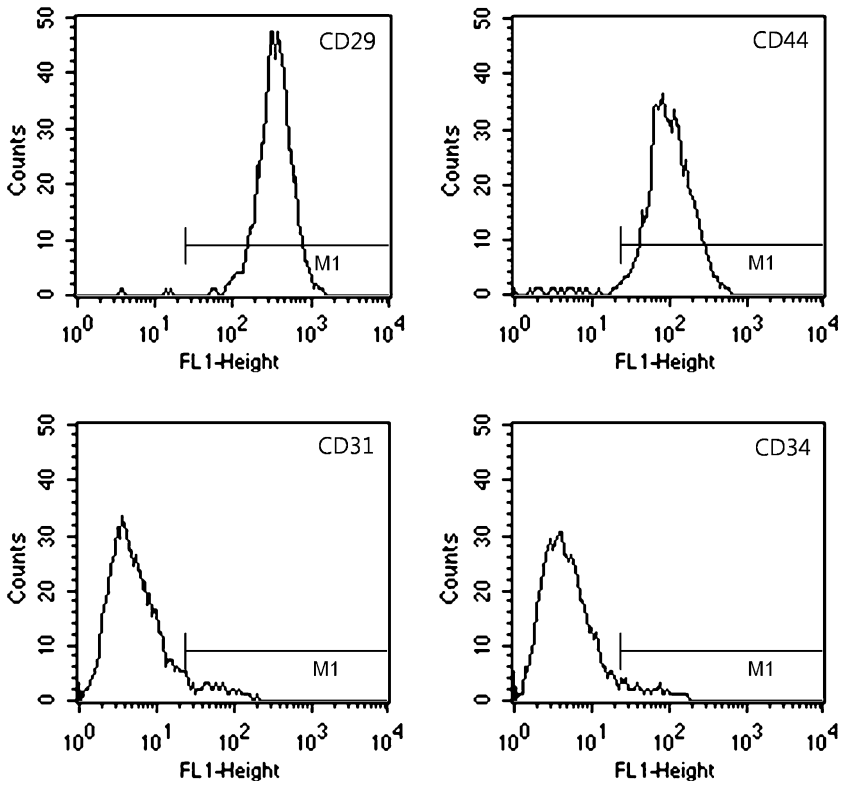

Fig. 1 Phenotypic characterization of human SVF cells. Cells at passage 4 were harvested and flow cytometric analyses of the expression of CD29, CD31, CD34 and CD44 were performed

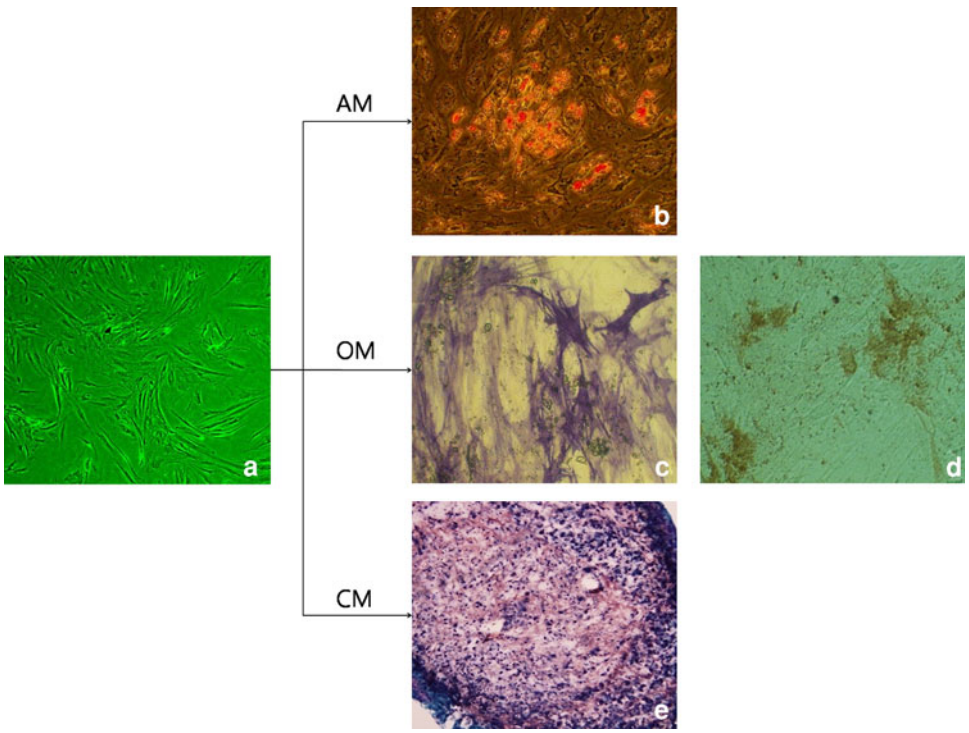

Fig. 2 Multi-lineage differentiation of SVF cells in vitro. SVF cells (**a**) were cultured in lineage-specific media respectively: adipogenic media (*AM*), osteogenic media (*OM*), and chondrogenic media (*CM*). Adipogenic differentiation was confirmed by Oil red O staining (**b**), osteogenic differentiation by alkaline phosphatase activity (**c**) and von Kossa staining (**d**), and chondrogenic differentiation by Safranin O staining (**e**). These indicated that the SVF cells contained ADSC

through differentiating them into osteoblasts, adipocytes, and chondrocytes using lineage-specific induction media. Thus, we concluded that the cultured cells included previously known ADSC. Afterward, the cells including ADSC were induced to differentiate into adipocytes as described previously [12, 20]. In the adipogenic media, IBMX and dexamethasone turn on the transcriptional factor PPAR-γ to direct the transcription of the lipid synthesis

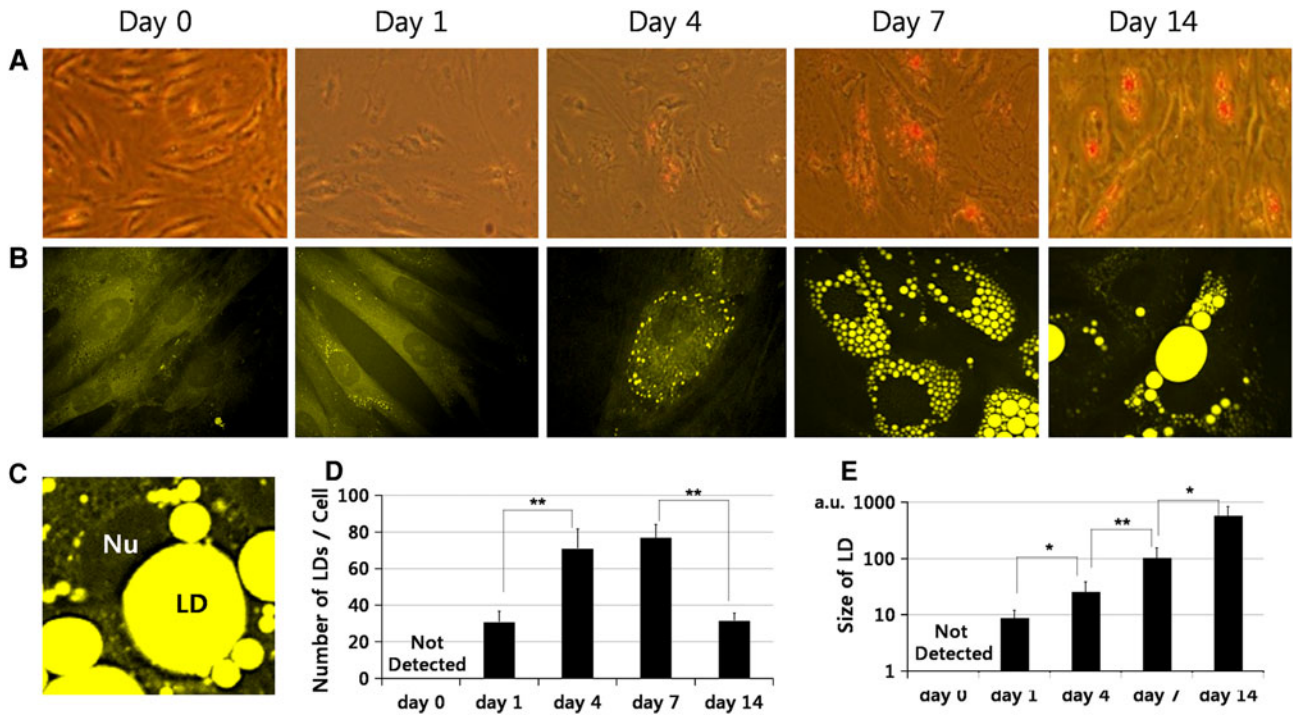

Fig. 3 Chronological observation of adipogenic differentiation with Oil red O staining (**a**) and CARS microscopy (**b**). Lipid droplets (LD) began to be stained sparsely on day 4 and showed a continuous increment of staining by Oil red O (**a**). CARS imaging also demonstrated that multiple 1–3 μm LD were distributed at the periphery of the cells on day 4, which then enlarged to 4–6 μm on day 7 with a centrally placed nucleus. On day 14, a few 10 μm LD pushing the nucleus to the periphery developed (**b**), and this was clearer in the magnified figure (**c**). The number of LD per cell decreased on day 14 compared to that on day 7 (**d**), while the mean size of LD increased (**e**). *LD* lipid droplet, *Nu* nucleus, *a.u.* arbitrary unit). $*p < 0.05$ and $**p < 0.01$

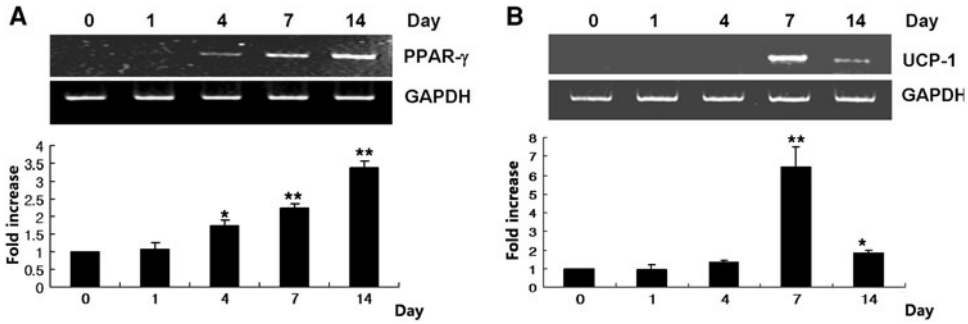

Fig. 4 Assessment of gene expression in adipogenesis. The mRNA level of PPAR-γ increased steadily since it was detected initially on day 4 (**a**). UCP-1 showed an abrupt six–sevenfold increment on day 7 though this regressed on day 14 (**b**). $*p < 0.05$ and $**p < 0.01$ versus day 0

gene, and insulin facilitates glucose uptake and promotes adipocyte differentiation of ADSC [23]. We continuously used this media for 2 weeks.

During adipogenic differentiation, we used CARS microscopy to image ADSC. Traditionally, LD, characteristic structures in adipocytes, can be labeled with Oil red O and imaged using fluorescent microscopy [24]. However, these methods are only applicable to a fixed sample; they disturb LD structures significantly when organic solvents such as ethanol and acetone are used for fixation [25]. Even with formalin fixation, aggregation, fusion, deformation and growth in size of LD arise [18, 26], preventing adipogenesis from being precisely evaluated. In contrast, CARS microscopy allows selective imaging of LD in unstained live cells with a very high contrast, as LD are aggregates of neutral lipids, mainly triglycerides rich in C–H bonds. Consequently, compared to conventional methods, we were able to observe adipogenic differentiation of live ADSC in real-time without fixing and without perturbing the cells.

In addition to the images of high-signal-intensity LD from day 4, CARS images on day 7 were reminiscent of brown adipocytes with numerous scattered small LD showing a multilocular appearance with a very recognizable nucleus, which was either central or somewhat displaced at the periphery of the cell in accordance with the

amount of LD. These features were strikingly similar to those of brown adipocytes in human newborns [27]. However, on day 14, a single large LD was eventually formed perhaps through the coalescence of numerous small LD, pushing the nucleus to the side, which is a typical morphology of mature white adipocytes. The result from the real-time qPCR of UCP-1, which is considered to be the single and best characterized means to distinguish clearly both cell types thus far [5, 6, 28], was consistent with the morphological change of ADSC in adipogenesis; UCP-1 showed a sudden peak on day 7 with a brown adipocyte-like appearance of ADSC, slumping on day 14 with a white adipocyte-like appearance.

As described previously, WAT and BAT has been thought to develop independently for several reasons. First, the developmental patterns of both adipose cells are different, as BAT occurs during late gestation and possesses all the features of mature tissue at birth whereas WAT development takes place mainly after birth [1]. Second, it has been assumed that functional BAT is absent in healthy adults. Third, in vitro precursor cells isolated from WAT or BAT are already committed and therefore differentiate primarily into white or brown adipocytes, respectively [29–31]. However, recent studies have shown that brown adipocytes are dispersed throughout human adipose tissue and are metabolically active [32]. It was also found that BAT activity occurs in healthy men during exposure to cold [33]. Additionally, large depots of BAT development were observed in a patient with a pheochromocytoma that secretes catecholamines [34], although it remains undetermined whether this was reactivation of remnant BAT from neonatal depots or conversion from WAT. Regarding the conversion of white adipocyte to brown adipocyte tissue, Tiraby et al. [35] suggested that it is possible to induce a metabolic shift in white fat cells with PPAR-γ coactivator 1α (PGC-1α) experimentally. Furthermore, upon chronic exposure to rosiglitazone, a specific PPAR-γ agonist, ADSC-derived white adipocytes are able to switch to brown adipocytes by expressing UCP-1 [28]. Our results also support that WAT and BAT do not develop independently, suggesting that white adipocytes undergo a momentary brown adipocyte-like stage during their development. Even if this is not the case, it remains possible that a certain association exists between the developmental processes of both adipocytes.

This study has some limitations. The SVF cells usually represent a very heterogeneous population, which means that every cell we dealt with was not a multipotent stem cell. However, ADSC seems to be mostly responsible for the changes during adipogenic differentiation including transient increase of UCP-1 because cells other than ADSC do not show adipogenic differentiation when cultured in AM. Another limitation is that the morphology of ADSC on day 14 during adipogenesis was not completely identical to that of mature lipid cells. There still remained several small LD although a distinctively large globule developed. However, we think that ADSC would show unilocular LD finally if observation were extended a few days more.

In summary, we observed and characterized the chronological stages of SVF cells including ADSC during adipogenic differentiation. On day 7 of adipogenesis, cells appeared multilocular with numerous small LD according to CARS imaging and the level of UCP-1 increased significantly. However, on day 14, they showed a unilocular appearance with a large single LD and the level of UCP-1 decreased markedly. Based on this morphological change and on the transient expression of UCP-1, we suggest that ADSC passes through a brown adipocyte-like stage while differentiating to white adipocytes.

Growth Hormone Enhances Arachidonic Acid Metabolites in a Growth Hormone Transgenic Mouse

Received: 16 August 2010 / Accepted: 4 March 2011 / Published online: 27 March 2011

Abstract In a transgenic growth hormone (GH) mouse model, highly elevated GH increases overall growth and decreases adipose depots while low or moderate circulating GH enhances adipose deposition with differential effects on body growth. Using this model, the effects of low, moderate, and high chronic GH on fatty acid composition were determined for adipose and hepatic tissue and the metabolites of 20:4n-6 (arachidonic acid) were characterized to identify metabolic targets of action of elevated GH. The products of Δ-9 desaturase in hepatic, but not adipose, tissue were reduced in response to elevated GH. Proportional to the level of circulating GH, the products of Δ-5 and Δ-6 were increased in both adipose and hepatic tissue for the omega-6 lipids (e.g., 20:4n-6), while only the hepatic tissues showed an increase for omega-3 lipids (e.g., 22:6n-3). The eicosanoids, PGE_2 and 12-HETE, were elevated with high GH but circulating thromboxane was not. Hepatic PTGS1 and 2 (COX1 and COX 2), SOD1, and FADS2 (Δ-6 desaturase) mRNAs were increased with elevated GH while FAS mRNA was reduced; SCD1 (stearoyl-coenzyme A desaturase) and SCD2 mRNA did not significantly differ. The present study showed that GH influences the net flux through various aspects of lipid metabolism and especially the desaturase metabolic processes. The combination of altered metabolism and tissue specificity suggest that the regulation of membrane composition and its effects on signaling pathways, including the production and actions of eicosanoids, can be mediated by the GH regulatory axis.

Keywords Growth hormone · Arachidonic acid · Fatty acid composition

Abbreviations

ARA	Arachidonic acid
cDNA	Complementary DNA
COX	Cyclooxygenase
DHA	Docosahexaenoic acid
ELISA	Enzyme-linked immunosorbent assay
FADS	Fatty acid desaturase
FAS	Fatty acid synthetase
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GH	Growth hormone
HETE	Hydroxyeicosatetraenoic
HPLC	High-performance liquid chromatography
MMLV-RT	Moloney murine leukemia virus-reverse transcriptase
mRNA	Messenger ribonucleic acid
oMt1a-oGH	Ovine metallothionein 1a promoter driving ovine GH transgene construct
PCR	Polymerase chain reaction
PGE2	Prostaglandin $E_{2\alpha}$
PTGS	Prostaglandin H synthase
qPCR	Quantitative real time polymerase chain reaction
SCD	Stearoyl-coenzyme A desaturase
SOD	Superoxide dismutase
SREBP	Sterol regulatory element binding protein

Introduction

The fatty acid composition of membrane phospholipids plays an important role in the structural, functional, and signaling properties of biological membranes and has been implicated in regulation of immunologic, physiologic, reproductive and metabolic processes and the functions of tissues from liver to adipose [1]. Arachidonic acid (C20:4n-6, ARA), the most abundant long chain polyunsaturated fatty acid in membranes, appears to be the primary biologically active polyunsaturated species mediating signaling in a variety of peripheral tissues Similarly, the n-3 polyunsaturated fatty acid docosahexaenoic acid (C22:6n-3, DHA) has a role in neural and optical signaling [2].

The negative consequences of deficiencies or excesses of polyunsaturated fatty acids correlate with ARA levels [3–5]. For example, alteration in tissue arachidonate levels can quantitatively account for many of the effects of dietary fish oils due to the omega-3 fats replacing the omega-6 fats in the membranes [3, 6–8] and metabolic deficiencies of arachidonate affect the cardiovascular and immune systems [9]. Whereas all the metabolic, physiologic and immunologic roles of ARA are not yet known, the majority of recognized effects of ARA are thought to be mediated by its conversion to biologically active signal molecules, the eicosanoids [10]. ARA oxygenation by cyclooxygenases produce thromboxane and prostaglandins, while lipoxygenases produce the hydroxyeicosatetraenoic acids (HETE) and leukotrienes (reviewed in [11, 12]). ARA can be also metabolized by cytochrome P450 monooxygenases to yield the epoxyeicosatrienoic acids. These oxygenated derivatives of ARA function to maintain a variety of physiological systems, such as ion exchange in the kidney [13], gaseous exchange in the lung, vascular smooth muscle tone [14], immune cell recruitment and function [10, 15], and activation or inhibition of endocrine glands [16]. While important in specific roles of physiological functions, elevated eicosanoids are considered to be detrimental contributing to a variety of degenerative and inflammatory disease states. As a result of this link, minimizing eicosanoid synthesis is the basis for many therapeutics aimed at controlling inflammation, thrombosis, and pain. Eicosanoids are also a target for proliferative disorders including various cancers, vascular dysfunctions, and autoimmunity.

In vivo, the limiting step for eicosanoid synthesis is the availability of ARA. Although ARA levels are regulated highly within individuals, the absolute amounts vary significantly among a population. Nonetheless, little is known about the basic mechanisms that control the absolute and relative quantities of ARA within cellular membranes. While traditionally most attention has focused on diet, recent observations that polymorphisms of the various desaturase genes are associated with altered fatty acid composition of membranes and various health outcomes has redirected attention on the mechanisms by which fatty acids are metabolized, incorporated into membranes, and converted into bioactive signaling molecules [17]. The limiting steps to membrane composition are still not clear, with both diet and genotype appearing to be important [18, 19]. The importance of hormonal signaling to this interaction has not been defined.

Elevated circulating growth hormone (GH) in a growth hormone transgenic mouse model (the oMt1a-oGH transgenic mouse) reduced essential precursors of long chain polyunsaturated fatty acids (18:2n-6 and 18:3n-3) and increased desaturation and elongation products 20:4n-6 and 22:6n-3 indicating increased activity of the Δ-5 and Δ-6 desaturation enzymes [20]. These mice with chronically elevated circulating GH, relative to wild-type control mice, exhibit about a two-fold increase of ARA content in the phosphatidyl choline phospholipid pool of hepatic membranes. The phosphatidyl ethanolamine component of membrane phospholipids, while not as great a constituent of membrane phospholipids on a percentage basis as phosphatidyl choline pools, also show a modest though significant increase in ARA abundance in response to GH [20]. Arachidonate hydrolyzed from membrane phospholipids of the phosphatidyl choline compartment by phospholipase A2 can be metabolized to eicosanoids thereby serving as local or paracrine effectors [13]. A shift toward a greater proportion of ARA in membrane compartments that are the source of liberated ARA used for subsequent metabolism should correspond to an increase in ARA metabolites. The metabolites of ARA have a wide range of physiological, immunological, neurological and reproductive functions. Therefore, a GH-specific increase in ARA could alter many biological activities, even potentiating the various negative consequences associated with inappropriately elevated eicosanoids.

Dependent upon the degree of transgene induction in the oMT1a-oGH transgenic mouse model, differential adipose phenotypes can be generated: chronically highly expressed circulating GH generates a physically larger, leaner animal [21] while minimal expression of the transgene results in mice of normal in body weight but having enlarged fat depots [22] and moderate transgene stimulation induces an intermediate level of circulating oGH corresponding to a physically larger, yet obese animal [21]. These findings suggest that circulating GH affects growth and adipose

accretion profiles differentially, dependent upon the concentration of circulating GH. Because highly elevated GH induces a change in the fatty acid composition of membranes toward a more unsaturated profile [20, 23], we wanted to determine the extent of GH action on those membranes. Therefore, we asked if long-term different levels of circulating GH, known to alter body composition and fat mass, could change lipid characteristics, and alter the products derived from the arachidonate phosphatidyl pools. Further, we assessed whether genes predicted to respond to changes in the desaturation of tissue lipids were also affected.

Materials and Methods

Animals

Mice used in this study were produced by mating wild-type C57Bl/6 × CBA female mice with males hemizygous for the oMt1a-oGH transgene. This mating scheme produces an average of 50% hemizygous transgenic progeny and 50% homozygous wild-type (i.e., non-transgenic wild-type control) animals. A single copy of the transgene acts in an autosomal dominant fashion to elevate GH expression when stimulated by adding zinc sulfate to the drinking water [24]. Mice were toe-notched for identification and genotyping [25] at 10 days of age and weaned at 21 days of age. All mice were maintained in an AAALAC approved facility in accordance with NIH animal use guidelines under conditions of constant temperature (21°C), humidity (55%), and a 14:10 h light:dark cycle. The study protocol and all procedures were reviewed and approved by the Institutional Animal Care and Use Committee at the University of California, Davis.

Experiment 1

To characterize the role of GH on adipose and hepatic lipid profiles, five to six females were randomly assigned to each of three transgene stimulus groups within a genotype (wild-type or transgenic): 25, 15, or 0 mM $ZnSO_4$ in the drinking water to yield different circulating GH concentrations. Females were chosen to corroborate the lipid alterations observed in studies of male oMt1a-oGH mice [20, 23]. Mice were housed two per cage and provided food (Formulab Chow 5008, Purina Mills, St. Louis, MO) and drinking water ad libitum. Mice were weighed weekly until 10 weeks of age at which time the mice were killed by CO_2 narcosis and gonadal fat pads, blood, and livers collected. Plasma was isolated from blood samples collected at time of animal collection and plasma circulating ovine GH concentrations (resulting from transgene expression) were assayed in duplicate using a double-antibody radioimmunoassay; ovine somatotropin standards were used (NIADDK O-GH-I-3) and a rabbit anti-ovine GH antisera (NIDDK-anti oGH-2) [26].

Lipid Analyses

To determine the effect of GH on modifying the unsaturated lipid pool, the fatty acid class composition was quantified for the phosphatidyl choline fraction of adipose and hepatic tissue as previously described [20]. Briefly tissue lipids were extracted from 200 mg tissue with H_2O/SDS/EtOH/hexanm (1:1:2:2, v/v). Phospholipids were separated by high performance thin layer chromatography using a $CHCl_3$/MeOH/acetic acid/H_2O (50:37.5:3.5:2.0, v/v) solvent system. Samples and standards (Sigma Chemical Co., St. Louis, MO) were visualized and specific lipid-containing bands collected for methylation and gas chromatography separation. The analytical methods used [27] were the most appropriate to quantify the absolute amounts of lipid species present and were designed to be highly quantitative with a cocktail of internal standards and surrogates added quantitatively to each sample. The extractions, derivatizations, and analyses were conducted on platforms to minimize quantitation problems associated with ionization efficiency. Additional hepatic tissue was flash frozen and stored at −80 °C for mRNA analyses.

RNA Analyses

The mRNA levels of genes associated with fatty acid profiles were also assessed: FADS2 (Δ-6 desaturase), fatty acid synthetase (FAS), SCD1 (stearoyl-coenzyme A desaturase 1), and SCD2 (also named Δ-9 desaturase). Several enzymes regulate the production of ARA metabolites, therefore genes expected to change in response to alterations in the desaturation status of tissue lipids were also assessed: prostaglandin H synthase (PTGS) 1 and 2 (also known as cyclooxygenase (COX-1 and 2), and superoxide dismutase 1 (SOD1). RNA was analyzed by Northern blot analysis for SCD2, FAS, SOD1, and COX-1. All reagents, unless noted, were from Sigma Chemical Company (St. Louis, MO). The RNA probes were as follows: SCD2 was as described [28], FAS was a gift from S.D. Clarke [29], Cu–Zn SOD (SOD1) was from the American Type Tissue Collection, and a 1,257 bp fragment of the murine COX-1 (PTGS1) was synthesized using 5′-TTCCTGATTCAAAAGAAGTTCTGG-3′ as the forward primer and 5′-ATGGTGGCTGTTTTGGTAGGCTGT-3′ as the reverse primer on reverse transcribed RNA isolated from murine liver using published methodology [30]. Hepatic FADS2 (Δ-6 desaturase) and SCD 1 mRNA levels were assessed by quantitative real time PCR using

published primers [31, 32], respectively) and mouse specific primers for COX-2 (PTGS2, NM_011198.3) were designed using the NCBI Primer-blast tool: forward 5′-GGCTGTTGGAATTTACGCAT-3′ and reverse 5′-CAGGGCCTTCAAAATGTCTA-3′. The internal endogenous control was GAPDH and used published primers [33]. Primers were fluorescently labeled and the mRNA was transcribed to cDNA with the iScript cDNA synthesis kit (Bio-Rad, Hercules, CA) containing oligo d(t) and random-hexamer primers following the manufacturer's recommendations. All real-time qPCR reactions were run in 96-well plates using UDG-Supermix^{TM} (Invitrogen, Carlsbad, CA). Each reaction contained 10 μM of each primer (forward and reverse), and 5 μl diluted cDNA, in a final volume of 50 μl. The samples were amplified in an MJ Research Chromo 4TM Detector (BioRad, Hercules, CA) and fluorescence was collected during each plate read immediately following the annealing period at 60°C. All reactions were run in triplicate and average values used in quantifying the relative expression of the genes. Levels of mRNA for the genes evaluated were not different across zinc treatments in the wild-type animals ($p > 0.1$) and therefore the data were pooled and the relative quantification of the target genes was determined by the comparative Ct (ΔΔCT) method using the wild-type animal samples as the calibrator. Both the calibrator and samples from the transgenic animals were normalized to GAPDH.

Experiment 2

To explore the consequences of increased ARA levels in tissue, lungs which represent an excellent model to evaluate the production of lipoxygenase metabolites were collected from three adult male transgenic and three adult male wild-type mice maximally stimulated to express GH (25 mM $ZnSO_4$) for 7 days. Nakumura et al. [23] reported a 2.5-fold increase in liver and adipose Δ-6 desaturase activity within 7 days; therefore, this time frame was selected to evaluate the short term consequences on the products derived from the arachidonate phosphatidyl pools. Lungs were homogenized in four volumes of 0.05 M phosphate buffer (pH 7.4) and incubated for 10 min at 37°C. The lipoxygenase metabolite 12-hydroxyeicosatetraenoic acid (12-HETE) was extracted and analyzed by HPLC and diode array detection as described [34]. The effects of GH on circulating prostaglandin $E_{2\alpha}$ (PGE2) and thromboxane were determined for 15 adult male transgenic and 15 adult male wild-type mice supplemented with 25 mM $ZnSO_4$ for 3 weeks. An additional 15 adult male transgenic mice were supplemented with 0 mM $ZnSO_4$ for the same time period. The objective was to evaluate the effects of the transgenically derived GH and as such all wild-type mice received the transgene stimulus to control for any potential zinc effects on PGE2 or thromboxane. Male mice were used to avoid the confounding estrogen effects. Blood samples were collected by cardiac puncture immediately after sacrifice, plasma processed, derivatized and assayed using commercially available ELISA kits according to manufacturer's directions (Amersham, UK). Circulating GH was determined as described.

Statistical Analyses

Data were analyzed by least-squares analysis of variance procedures using PROC GLM of SAS (Version 9.1, 2004) with fixed effects of genotype, zinc stimulation level, and their interaction. Data are presented as means ± standard error of the mean. Post-hoc analysis was done using a *t* test with a Bonferroni adjustment. Significance was defined as $p < 0.05$.

Results

Experiment 1

Circulating ovine (transgene derived) GH in these transgenic mice was correlated directly with the concentration of zinc stimulus. Circulating ovine GH was 750.53 ± 43.83, 131.98 ± 40.40, and 49.22 ± 37.68 ng/ml for 25, 15, and 0 mM $ZnSO_4$, respectively. Zinc, regardless of the level (0, 15, or 25 mM), did not significantly alter body weight nor fat pad depots in the wild-type control mice used in the present study. The body weights associated with the circulating GH were 32.5 ± 0.4, 31.7 ± 0.6, and 22.2 ± 0.4 g for 25, 15, 0 mM $ZnSO_4$, respectively; wild-type mice across all zinc levels weighed 22.6 ± 0.4 g. This was reported in a previously published study of these mice [21].

Adipose Lipid Profiles

The composition of phosphatidyl choline esterified fatty acids was calculated as a mole percent for each lipid species. All three zinc treatments (0, 15, and 25 mM $ZnSO_4$) did not significant alter the adipose lipid profiles in the wild-type animal ($p > 0.1$); as such, the values for wild-type animals were pooled regardless of the zinc treatment given. The fatty acid composition of adipose lipids is presented in Table 1. In most cases, the profile for wild-type animals was generally equivalent to that for the transgenics without transgene stimulation (0 mM $ZnSO_4$) with some exceptions. In particular, the fatty acids typically associated with de novo lipogenesis, 14:1n-7 and 16:1n-7, were elevated significantly while 18:0 was reduced. These same fatty acids were also significantly

Table 1 Adipose lipid profile as mole percent for wild-type (WT) mice and transgenic (TG) mice supplemented with either 0, 15, or 25 mM $ZnSO_4$ to induce variable levels of chronic circulating GH

Fatty acid species	WT ($n = 9$)	TG + 0 mM $ZnSO_4$ ($n = 5$)	TG + 15 mM $ZnSO_4$ ($n = 4$)	TG + 25 mM $ZnSO_4$ ($n = 5$)	Model significance
14:0	2.27 ± 0.06	2.19 ± 0.09	2.22 ± 0.09	1.97 ± 0.08	$p < 0.13$
