Fig. 4 Triacylglycerol content in liver (a) and gastrocnemius muscle (b) in rats fed chow or high-fat diets. Rats were randomly divided into four groups with six animals each, receiving either chow ± 22SHC or

high-fat diet (HFD) ± 22SHC for 21 days. Tissue samples were prepared as described in “Materials and methods”. Data are presented as means ± SEM ($n = 6$). * $p \leq 0.05$ versus control

expression in skeletal muscle [17]. It has been suggested by in vivo experiments that Ucp3 is involved in fatty acid translocation [17]. Previous research in brown adipose tissue and skeletal muscle from rodents described a strong association between Ucp2 and Ucp3 expression and lipid metabolism [18], and that PPAR γ and PPAR α , transcription factors regulated by lipid metabolites, regulated the expression of Ucp2 and Ucp3 [19, 20]. Further, mice over-expressing human Ucp3 were lean despite overeating, had increased metabolic rate and their skeletal muscle mitochondria showed increased proton conductance [21]. In line with this, Choi et al. [22] have recently shown that wild-type mice fed a high-fat diet were markedly insulin resistant, while mice over-expressing Ucp3 in skeletal muscle were completely protected against lipid-induced defects in insulin signaling and action. These data suggest that the effect on body weight and changes in TAG levels we observed after treatment with 22SHC could partly be mediated through increased expression of Ucp3.

Ectopic accumulated fat, especially in liver and skeletal muscle, promotes the development of mitochondrial

Fig. 5 Glucose transport in soleus muscle strips from rats fed a high-fat diet. Rats were randomly divided into two groups with six animals each, receiving high-fat diet (HFD) ± 22SHC for 21 days. Insulin-stimulated glucose uptake was measured in soleus muscle strips on day 21. Data are presented as means ± SEM ($n = 6$)

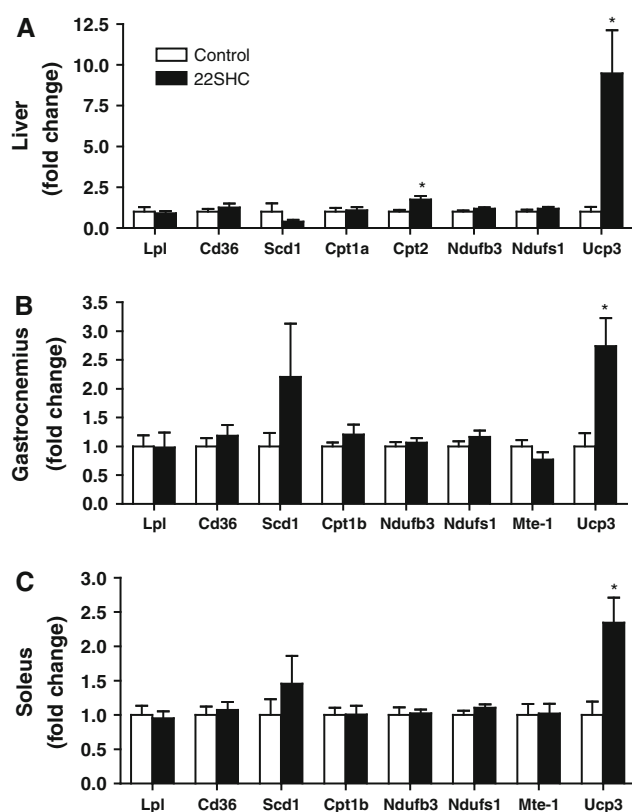

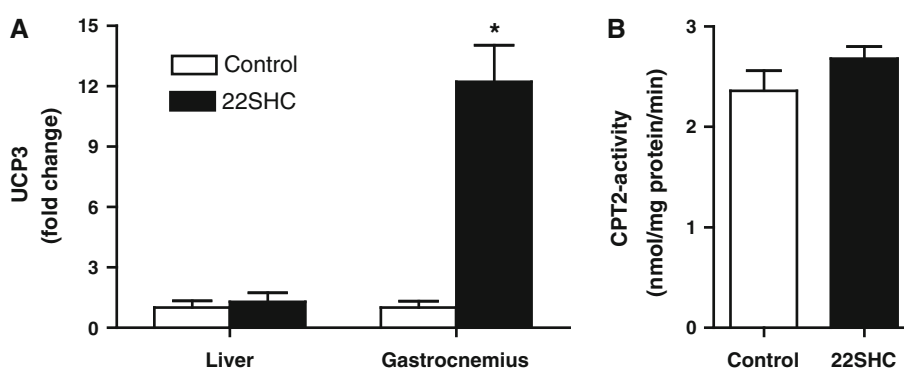

Fig. 6 Gene expression in liver (a), gastrocnemius (b) and soleus muscles (c) from rats fed a high-fat diet. Rats were randomly divided into two groups with six animals each, receiving high-fat diet (HFD) \pm 22SHC for 21 days. Tissue samples were prepared as described in “Materials and methods”. Total RNA was extracted, reversely transcribed and analyzed by RT-qPCR. Results are normalized to levels of GAPDH and presented as means \pm SEM ($n = 6$). *Lpl* lipoprotein lipase, *Cd36* fatty acid transporter, *Scd1* stearoyl-CoA desaturase, *Cpt1a* carnitine palmitoyltransferase 1a, *Cpt1b* carnitine palmitoyltransferase 1b, *Cpt2* carnitine palmitoyltransferase 2, *Ndufb3* NADH dehydrogenase (ubiquinone) 1 beta subcomplex 3, *Ndufs1* NADH dehydrogenase (ubiquinone) subcomplex 1, *Mte-1* mitochondrial thioesterase-1, *UCP3* uncoupling protein 3. * $p \leq 0.05$ versus control

dysfunction and metabolic syndrome [23–25]. Fabbrini et al. [26] have shown that increased level of intrahepatic triacylglycerol (TAG) is an independent indicator of

multiorgan insulin resistance, and that intrahepatic TAG by itself could be directly involved in the pathogenesis of dyslipidemia associated with non-alcoholic fatty liver disease. Therefore, it is possible that visceral adipose tissue itself is not harmful, but is simply an innocent bystander that tracks with intra-hepatic TAG. In our study we observed that the animals receiving only HFD had elevated serum TAG levels while this was not observed for the rats that were treated with 22SHC in combination with the HFD. Interestingly, 22SHC treatment reduced accumulation of TAG in liver compared to control animals, and there was a tendency for reduction in TAG content in gastrocnemius muscle. This is in concordance with recent in vitro data showing reduced de novo lipogenesis in both HepG2 cells (liver cells) and human skeletal muscle cells after 22SHC treatment [6]. Further, the reduction in TAG content was negatively correlated with protein levels of UCP3. This may imply that 22SHC induced a more efficient lipid metabolism by removing TAG from plasma and by increasing fatty acid oxidation and energy dissipation possibly through increased *cpt2* and *Ucp3*-activity. In support of our findings, Changani et al. [27] have shown with MRI technology that UCP3-overexpressing mice weighed less than the control group and most interestingly, since *Ucp3* is mainly expressed in skeletal muscle, they showed no increase in intramuscular fat like the control group. Also, a study on chow-fed UCP3 $^{+/-}$ and UCP3 $^{-/-}$ mice showed that progressive reduction of UCP3 levels resulted in insulin resistance and decreased fatty acid oxidation accompanied by reduced levels of PPAR δ and *Cpt1* [28]. These results also support that UCP3 might be important for an efficient lipid metabolism in vivo.

In vivo *Ucp3*-overexpression animal models with both 2- and 20-fold increase have shown reduced fasting blood glucose [29, 30]. We could neither observe reduced serum glucose in non-fasted animals nor an increase in insulin-stimulated glucose uptake in epitrochlearis muscle strips from rats fed HFD in combination with 22SHC. The lack of effects on glucose metabolism might be caused by the relatively short duration of this in vivo experiment.

Fig. 7 UCP3 protein level (a) and CPT2-activity (b) in tissues from rats fed a high-fat diet. Rats were randomly divided into two groups with six animals each, receiving high-fat diet (HFD) \pm 22SHC for 21 days. Tissue samples were prepared as described in “Materials and methods”. Data are presented as means \pm SEM ($n = 5-6$). * $p \leq 0.05$ versus control

In summary, this study showed that treating rats with 22SHC for 3 weeks resulted in a reduced body weight gain, prevention of an increased concentration of TAG in serum when fed a HFD and a reduction of TAG in liver compared to control animals. We also observed increased gene expression of Ucp3 and Cpt2 in liver and skeletal muscle and increased protein level of Ucp3 in skeletal muscle after 22SHC treatment. To fully understand these results we need a better general understanding of the role of Ucp3 in regulating energy metabolism. Although the mechanisms behind the observed metabolic changes need to be further elucidated, 22SHC seems to be an interesting model substance in the search of treatments for disorders involving lipid aberrations.

Acknowledgments We thank Anne Randi Enget, Mari-Ann Baltzersen, Camilla Stensrud, Kari Williams, Jorid T. Stuenæs and Ada Ingvaldsen for excellent technical assistance. We thank Richard Porter and Lars Henrik Manzke (Trinity College Dublin) for providing us with the UCP3 antibody. Hilde Hyldmo is also thanked for excellent technical assistance with handling of the animals and Vitas AS for analyzing blood samples. This work was supported by grants from the Norwegian Research Council and Birkeland Invention/Inven2 (Project 184019/I10).

Abstract In these studies, we focused on finding the mechanism(s) underlying the bitter melon (*Momordica charantia* L.) methanol fraction (MF)-dependent reduction in the concentration of hepatic triacylglycerol (TAG) and cholesterol in the rat. Rats were fed diets containing low (5 %) fat for 2 weeks (experiment 1), or low (5 %) and high (15 %) fat for a longer period of 8 weeks (experiment 2). MF was supplemented at 1 % level in both experiments. After feeding, rats were sacrificed, and their livers were

prepared as slices and hepatocytes, followed by incubation with [1(2)-¹⁴C] acetate or [1-¹⁴C] oleic acid (18:1 n-6). Under these conditions, we found that rats fed diets containing MF, as compared to those without MF, showed: (1) no adverse effects on food intake and growth, (2) a decreased hepatic TAG and total cholesterol, irrespective of the difference in dietary fat level or feeding period, and (3) a decreased incorporation of [1(2)-¹⁴C] acetate and [1-¹⁴C] oleic acid into TAG of liver slices and hepatocytes. MF-supplemented rats also showed no altered incorporation of labeled acetate into cholesterol and cholesterol ester, an increased fecal excretion of neutral steroids, but not of acidic steroids, and an enhanced mRNA abundance of carnitine palmitoyltransferase I, which is the rate-limiting enzyme for fatty acid oxidation. These results suggest that dietary MF decreases hepatic TAG synthesis while enhancing fatty acid oxidation, thereby reducing the concentration of hepatic TAG. The liver cholesterol-lowering effect of MF, however, is probably mediated through an increased fecal excretion of neutral steroids, without an effect on cholesterogenesis.

A preliminary part of this study was presented at 11th European Nutrition Conference, Spain, 2011.

Introduction

Bitter melon (*Momordica charantia* L.), which is cultivated in countries located in tropical and subtropical areas such as India, Asia, and South America has been traditionally used as a folk medicine for the treatment of diabetes. More recently, favorable effects on glucose metabolism have been demonstrated in cell culture, animal models and human studies [1–8]. It has also been reported that feeding of bitter melon and/or its extract was beneficial in preventing lipid disorders such as hyperlipidemia and diabetic dyslipidemia in both normal rats and in rats with chemically induced diabetes [9]. In a previous series of experiments, we also reported, to our knowledge for the first time, that the freeze-dried powder of bitter melon and its methanol fraction (MF) have potent liver triacylglycerol (TAG)- and cholesterol-lowering activities in rats fed diets with and without cholesterol supplementation [10, 11]. We have also previously examined whether effects of dietary MF on lipid metabolism are reproduced in hamsters fed diets with and without cholesterol supplementation, and found that MF had a potent and dose-dependent lipid-lowering activity in serum, but not in liver, especially in the animals fed diets with cholesterol [12]. Together these data show that bitter melon and its extracts, such as MF, contain bioactive components which favorably modulate TAG and cholesterol metabolism in experimental animals, although there are species-specific differences.

To date, very little information has been reported about the mechanism(s) responsible for the reduced concentration of serum and/or hepatic lipids observed with bitter melon. Bitter melon juice appears to inhibit the synthesis and secretion of TAG in the form of apoB lipoprotein, as well as decrease microsomal transfer protein (MTP) mRNA expression in HepG2 cells [13, 14]. On the other hand, it has been reported that bitter melon extract activates the peroxisome proliferator-activated receptor (PPAR α), and upregulates the expression of acyl CoA oxidase gene in rat hepatoma cells H4IIEC3 [15]. These observations suggest that the triglyceride-lowering effect of bitter melon extract(s) is due to a reciprocal response of TAG synthesis and fatty acid oxidation. There is also a possibility, as reported by Oishi et al. [16] that bitter melon-dependent hypotriglyceridemic action is exerted through an inhibitory effect on digestive enzyme activity in the intestinal tract.

Regarding the mechanism(s) of the hypocholesterolemic and/or liver cholesterol-lowering effects of bitter melon, reduced cholesterol synthesis in the liver and/or increased fecal excretion of steroids seem plausible. However, so far, no information is available to confirm or refute this hypothesis.

In the present studies, we demonstrated for the first time that dietary MF has favorable and independent effects on

TAG and cholesterol metabolism. We also carried out a more detailed mechanistic examination of the effects of dietary MF on TAG and cholesterol metabolism, by using in vitro techniques of liver slices and hepatocytes in the presence of radiolabelled acetate and oleic acid (18:1n-6).

Materials and Methods

The bitter melon methanol fraction (MF) was prepared according to the method described previously [10–12]. [1(2)- 14 C] sodium acetate (2.18 GBq/mmol) and [1- 14 C] oleic acid (18:1 n-9, 2.5 GBq/mmol) were purchased from Amersham Life Sciences (Buckinghamshire, England), and other chemicals were from Wako Chemicals (Osaka, Japan).

Male Sprague–Dawley rats, purchased from a local breeder (Kyudo Co., Kumamoto, Japan), were acclimatized for several days in a temperature and light controlled room (22–24 °C, light on 0700–1900 h). During this period they were fed a pelleted stock chow (Type CE-2, Clea Japan, Tokyo, Japan). They were then divided into two groups (experiment 1) or four groups (experiment 2) with equal body weight (body weight 158 ± 2 g in experiment 1 and 86 ± 1 g in experiment 2). The control diet in experiment 1 was prepared according to the recommendations of the American Institute of Nutrition [17], and contained (by weight): casein, 20 %; corn oil, 5 %; vitamin mixture (AIN 76), 1 %; mineral mixture (AIN 76), 3.5 %; DL-methionine, 0.3 %; choline bitartrate, 0.2 %; cellulose, 5 %; corn starch, 15 %; and sucrose to 100 %. The control diet in experiment 2 was the same as in experiment 1, except for dietary fat levels. In experiment 2, diets were prepared with either 5 % fat (lard 4 % and corn oil 1 %) or 15 % fat (lard 14 % and corn oil 1 %). The fat level in the latter diet was increased at the expense of sucrose. The experimental diet was prepared by adding MF at the 1 % level to the control diets at the expense of sucrose in both experiment 1 and experiment 2. Rats had free access to the diets and water for 2 weeks in experiment 1, and for a longer period of 8 weeks in experiment 2. Food intake and body weight were recorded every other day. In experiment 1, approximately half of the animals were subjected to the liver slice experiments (seven rats for control and eight rats for experimental groups) and the others to hepatocyte experiments (six rats each for control and experimental groups). In experiment 1, the animals were decapitated between 9:00 a.m. and 12:00 p.m., blood was collected, and serum was harvested after centrifugation at 4 °C. The livers were removed immediately, rinsed, dried on filter paper, and weighed. A portion of each liver was cut into small blocks ($1.5 \times 1.5 \times 1$ cm), sliced (0.5 mm thickness) using a tissue slicer, and immediately transferred to opaque flasks containing ice-cold and oxygenated Krebs–Ringer–Bicarbonate buffer (pH 7.4) and

[1(2)- ^{14}C] sodium acetate. Incubation was carried out for 2 h at 37 °C after flushing with a mixture of $\text{O}_2:\text{CO}_2$ (95:5, by vol), and was terminated by addition of 0.1 ml of acetic acid. In the hepatocyte experiments, the rats from control and experimental groups were anesthetized with pentobarbital sodium (64.8 mg/kg BW), and their livers were isolated by a two-step collagenase digestion method [18]. Briefly, anesthetized rats were cleaned and sanitized and placed inside a bio-safety cabinet. The hepatic portal vein was cannulated and the liver was perfused in situ with Krebs–Henseleit buffer (pH 7.4) using a peristaltic pump. A cut was made in the abdominal vena cava just above the level of the kidneys to have an outlet for the drainage of the perfusate. The perfusion was continued until all the lobes of the liver were visibly cleared of blood and blanched. Then the abdominal vena cava was clamped and the thoracic vena cava was cannulated through right atrium and a collagenase solution (0.05 % w/v) in Krebs–Henseleit buffer (pH 7.4) was re-circulated for 10–20 min until the liver lobes gets mildly dispersed. Liver lobes were collected into a sterile beaker with the buffer and sliced. The undispersed parts were filtered out using sterile gauze and the cells were collected into a centrifuge tube. Hepatocytes thus obtained were washed in Hanks buffer and re-suspended in Krebs–Henseleit buffer (pH 7.4) with 10 mM glucose and 2 % bovine serum albumin (fatty acid free, Wako Chemical Co., Japan). All incubations were performed in duplicate for 1 h at 37 °C, in the presence of either [1(2)- ^{14}C] sodium acetate or [1- ^{14}C] oleic acid, under $\text{CO}_2:\text{O}_2$ (5:95, by vol) gas. After incubation, cells and medium were separated by low-speed centrifugation (600 rpm for 1 min), followed by washing three times with PBS; cells were then homogenized with a Teflon homogenizer and stored at -80°C until further analysis for radioactivity in the lipid fractions. Cell viability, as determined by the trypan blue exclusion test, always exceeded 85 %.

All experimental protocols and procedures were approved by the Animal Care and Use Committee of the University of Miyazaki, Japan.

The lipids in the liver and serum were extracted and purified according to the method of Folch et al. [19]. TAG, cholesterol, and phospholipid contents in the lipid extract were measured chemically [10–12]. In the liver slice and hepatocyte experiments, lipids were also extracted by the method of Folch et al. [19] and various lipid fractions were separated by thin layer chromatography on Silica Gel 60G, with a solvent mixture of *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol). The bands corresponding to cholesterol ester, TAG, free fatty acid, partial glycerides (mono- and di-glycerides), and phospholipid were identified with iodine vapor and were scraped into counting vials containing a toluene-based scintillation cocktail. Radioactivity derived from [1(2)- ^{14}C] acetate and [1- ^{14}C] oleic acid in

these lipid fractions was measured in a Wallac 1409 DSA liquid scintillation counter (Wallac Co., The Netherlands). For [1- ^{14}C] acetate incorporation into total fatty acid and digitonin precipitable sterol (DPS), the lipid extract was saponified in methanolic KOH at 75 °C for 30 min, and nonsaponifiable matter was extracted with *n*-hexane three times. After removal of the nonsaponifiable matter, the extracts were acidified with concentrated HCl, and the fatty acids were extracted with *n*-hexane three times. DPS were isolated and purified according to the procedure described previously [20, 21]. Radioactivities for total fatty acid were counted in a toluene-based scintillation cocktail and those for DPS were counted in 1 ml of methanol and Insta Gel.

Feces collected for 2 days before the end of experiment 2 were lyophilized and analyzed for neutral and acidic steroids, as described in detail previously [22].

In experiment 2, the mRNA expression level of liver carnitine palmitoyltransferase I (CPT I) was also measured. Total RNA was extracted from 300 mg of liver, using a TRI ZOL Reagent (Invitrogen, Tokyo, Japan). Extracted RNA was treated with DNase to remove any genomic DNA (gDNA) TaqMan[®] Gene Expression Assays (Applied Biosystems, Tokyo, Japan), Assays-on-Demand[™], Gene Expression Products (Rn00580702_m1 for CPT I, Hs99999901_s1 for 18S RNA; Applied Biosystems, Tokyo, Japan) were used for quantitative real-time RT-PCR analysis of CPT I and 18S RNA expression in the liver. The manufacturer specifies that the assay probes spans an exon junction in the case of CPT I primers and that the assay will not detect gDNA in the case of 18S RNA primers. The amplification was performed with a real-time PCR system (ABI Prism 7000 Sequence Detection System, Applied Biosystems). Results were expressed as a relative value after normalization to 18S RNA expression.

Data were analyzed by Student's *t* test in experiment 1, and by one-way analysis of variance, followed by multiple comparisons with Tukey–Kramer's test (StatView software, Sas Institute, USA) in experiment 2. The statistical significance of the difference of the means in these two experiments was evaluated at the level of $p < 0.05$. In addition, the significance of the interaction of the two treatments was also analyzed by two-factor ANOVA (StatView software, Sas Institute, USA).

Results

Effects of Dietary Bitter Melon Methanol Fraction (MF) on Lipid Metabolism After 2 Weeks of Administration (Experiment I)

Effects of dietary MF, fed for 2 weeks, on growth parameters and the concentration of serum and liver lipids are

Table 1 Effects of *Momordica charantia* methanol fraction (MF) on growth and lipid parameters

| | Control (7) | 1 % MF (8) |
|---------------------------|-------------|--------------|

summarized in Table 1. Although dietary MF had no effect on food intake and growth, relative liver weight tended to be lower in rats fed diets with MF than in those fed diets without MF. Effects of dietary MF on serum lipid parameters were marginal; however, dietary MF significantly decreased the concentration of hepatic TAG and total cholesterol by 54.4 and 24.6 %, respectively. The percentage of cholesterol ester in the liver was significantly lowered in rats fed diets with MF as compared to those fed diets without MF. However, the free cholesterol level remained unchanged between the groups, indicating that the marked reduction in hepatic total cholesterol in rats fed diets with MF is due to decreased cholesterol ester. Liver phospholipid concentration was comparable between the groups.

Since hepatic lipid synthesis is one of the regulatory factors responsible for determining the lipid concentration, we first estimated hepatic lipid synthesis by measuring the rate of incorporation of radiolabelled acetate and oleic acid into lipids of both liver slices and hepatocytes prepared from rats fed diets supplemented with and without MF. As shown in Table 2, in the liver slice experiment, the incorporation of [1(2)- ^{14}C] acetate into TAG was 53.1 % lower in rats fed diets with MF compared to those fed diets

^a Incorporation of radiolabelled acetate into lipid fractions of liver slices are expressed as kBq/g liver. The values are given as mean ± SE of seven rats for control and eight rats for MF group

without MF. The extent of reduction in its incorporation was similar to that of the reduction in liver TAG concentration (54 % reduction in TAG concentration and 53 % reduction in incorporation of [1(2)- ^{14}C] acetate into TAG). On the other hand, incorporation of [1(2)- ^{14}C] acetate into free- and esterified-cholesterol was comparable between the groups, while incorporation of labeled acetate into phospholipids was significantly elevated (1.4-fold) following feeding of MF. Incorporation into free fatty acid fraction tended to be higher in rats fed diets with MF than in those fed diets without MF, but the difference was not significant.

In the hepatocyte experiment, incorporation of [1(2)- ^{14}C] acetate into TAG was 47.3 % lower in liver cells prepared from rats fed diets with MF as compared to those without MF (Fig. 1), while incorporation into both free and esterified cholesterol was comparable between the groups (data not shown). Any effect of dietary MF on the incorporation of [1(2)- ^{14}C] acetate into free fatty acid fraction was also not apparent (data not shown). In this experiment, we further examined the effects of dietary MF on the metabolism of exogenous free fatty acid by using hepatocytes; for this, we used [1- ^{14}C] oleic acid as an exogenous substrate complexed with fatty acid free albumin, and administered to the cells prepared from livers of rats fed with and without dietary MF; dietary MF caused a significantly lowered incorporation of [1- ^{14}C] oleate into TAG fraction (21 % decrease relative to rats fed an MF-free diet) (Fig. 1). On the other hand, no significant differences were observed in incorporation into phospholipids and cholesterol esters between the two groups (data not shown). These results suggest that dietary MF appears to have a potent and specific inhibitory effect on the esterification step of TAG synthesis, but not on de novo synthesis of fatty acids.

Fig. 1 Effect of bitter melon methanol extract (MF) on hepatic TAG synthesis (hepatocyte experiment). Hepatocytes from livers of rats fed diets with and without MF for 2 weeks were incubated in the presence of either $[1(2)\text{-}^{14}\text{C}]$ sodium acetate or $[1\text{-}^{14}\text{C}]$ oleic acid for 1 h. The values are given as means \pm SE of 6 rats per group. *Significantly different from the control group at $p < 0.05$

Effects of Dietary MF on Lipid Metabolism After 8 Weeks of Administration (Experiment 2)

It is known that the level and type of dietary fats are one of the modifying factors for the concentration of serum and liver lipids; in general, high fat diet compared to low fat causes elevated serum and liver lipids. In experiment 2, we examined the effects of dietary MF in rats fed on different fat levels (5 and 15 % fat level) and for prolonged feeding period of 8 weeks. Food intake was comparable in the four groups of rats, as shown in Table 3. However, the final body weight was significantly greater in rats fed high-fat diets than in those fed low-fat diets. Supplementation of MF in the high fat diet, but not in the low fat diet, tended to reduce weight gain. Relative liver weight tended to be lower in rats fed diets with MF, whether rats were fed the high-fat or the low-fat diet. Perirenal and epididymal adipose tissues were significantly heavier in rats fed high-fat diets than in those fed low-fat diets, although supplementation of MF did not influence these parameters. Serum TAG levels were significantly elevated in rats fed high-fat diets compared with those fed low fat diets. Dietary MF in combination with the high-fat diet, but not with the low-fat diet, reduced serum TAG. Neither the concentrations of total- and HDL-cholesterol nor that of phospholipids were influenced by the dietary fat levels or MF supplementation.

Hepatic TAG concentrations were elevated by 1.5-fold in rats fed the high-fat diet compared to those fed the low-fat diet, while supplementation of MF in the low and high-fat diet groups caused reductions in TAG concentration of 44.7 and 52.3 % respectively. The high-fat diet was also associated with an increased concentration of total cholesterol (1.4-fold elevation). Supplementation of MF in the low- and high-fat diets caused reductions of 19.0 and

40.6 %, respectively, in this lipid molecule. The reduction in the concentration of total cholesterol was due to decreases in the concentrations of both free and esterified cholesterol. Phospholipid concentrations were comparable among rats fed high-fat and low-fat diets containing MF and those fed diets without MF.

Fecal excretion of neutral and acidic steroids is shown in Table 4. Fecal weights tended to be heavier in rats fed high-fat diets than in those fed low-fat diets, a further increase in fecal weights was noted in MF-supplemented rats. Although the excretion of bile acids into feces was not different among the groups, that of neutral steroids (coprostanol and cholesterol) was significantly increased in rats fed diets supplemented with MF. The extent of the increase was greater in the high-fat diet group (1.8-fold increase in low-fat diet and 2.3-fold increase in high-fat diet groups, respectively).

In experiment 2, as in experiment 1, we estimated the hepatic lipid synthesis by measuring the incorporation of $[1(2)\text{-}^{14}\text{C}]$ acetate into various lipid fractions. Incorporation of labeled acetate into all lipid fractions in the liver was significantly lower in liver slices prepared from rats fed high-fat diets compared to those fed low-fat diets (Table 5). The extent of this reduction was 65.3 % for TAG and 48.8 % for phospholipids. Supplementation of MF in the low fat, but not the high fat diet group resulted in a typical profile of $[1(2)\text{-}^{14}\text{C}]$ acetate incorporation into various lipid fractions. Thus, dietary MF caused a significant reduction (45.7 %) in incorporation of labeled acetate into the TAG fraction but incorporation into other fractions (partial glycerides, free- and esterified-cholesterol, and phospholipids) was not affected. In addition, there was no change of incorporation into the free fatty acid fraction between the control and MF groups. To

investigate this unexpected finding, we estimated de novo synthesis of fatty acid and cholesterol in liver slices by measuring incorporation of [1(2)-¹⁴C] acetate into total free fatty acid and DPS. Increased dietary fat levels significantly lowered the incorporation of radiolabelled acetate into the total fatty acids and DPS, while there were no significant differences in the incorporation of acetate into total fatty acids due to dietary MF (23.2 ± 3.88 kBq/g for low-fat without MF vs. 21.7 ± 1.53 kBq/g for low-fat

with MF, 10.6 ± 1.73 kBq/g for high-fat without MF vs. 15.1 ± 1.45 for high-fat with MF) and DPS (0.17 ± 0.02 kBq/g for low fat without MF vs. 0.23 ± 0.03 kBq/g for low fat with MF, and 0.05 ± 0.01 kBq/g for high fat without MF vs. 0.10 ± 0.02 kBq/g for high fat with MF). We also checked the expression of CPT I mRNA and found enhanced mRNA abundance following feeding of MF particularly in the low-fat group (data not shown).

Discussion

In the present studies, we show that the methanol fraction (MF) prepared from bitter melon (Koimidori variety), at a 1.0 % dietary level, has potent liver TAG- and cholesterol-lowering activity in rats fed diets containing low (5 %) and high (15 %) fat. In a series of experiments with rats fed diets containing 5 % fat supplemented with or without cholesterol, we had previously reported that feeding of freeze-dried powder prepared from various varieties of bitter melon, especially that from Koimidori, at a 1.0 % dietary level, exhibits potent liver TAG- and cholesterol-lowering potentials, and that its major active principle(s) was localized almost exclusively in the fraction extracted by methanol from Koimidori freeze-dried powder [10, 11]. On the other hand, Ahmed et al. studied the effects of long term feeding (10 wk) of bitter melon juice on plasma and liver lipid profiles in normal and streptozotocin (STZ)-induced Type I diabetic rats, and found that this dietary ingredient exhibits a potent hypolipidemic effects in the STZ-induced diabetic rat [9]. In addition, they also observed the liver TAG-lowering effects of bitter melon juice in non-diabetic normal rat, but not in diabetic rat [9]. These results suggest that bitter melon and/or its extract may be effective in preventing fatty liver and hyperlipidemia caused by high-cholesterol and high-fat diets, as well as the hyperlipidemia induced by diabetes mellitus.

As most studies investigating the biological activity of bitter melon are focused on effects pertaining to plasma glucose and diabetes, or on the mechanism of its hypoglycemic activity [23–25], information regarding the mechanism(s) of its action on serum and/or hepatic lipids is sparse. The present studies therefore focused on understanding the mechanism(s) responsible for the dietary MF-dependent reduction in the concentration of liver TAG and cholesterol. The liver is a major organ regulating the concentrations of serum and/or liver TAG and cholesterol,

through various synthetic and degradative processes (e.g., fatty acid synthesis and oxidation for determining the TAG level, and cholesterologenesis and its elimination into the feces as neutral and acidic steroids for cholesterol level). In the present studies, we calculated the de novo synthesis of lipids by measuring the rate of incorporation of radiolabelled acetate into lipids in liver slices and hepatocytes prepared from rats fed diets with and without MF. In addition, we calculated TAG synthesis by measuring the rate of esterification of exogenous [1-¹⁴C] oleate into the TAG fraction in hepatocytes prepared from these same animals. The appearance of radioactive carbon in hepatic lipids reflects the activation of acetate added to the liver slices and/or hepatocytes to its coenzyme A ester and their subsequent incorporation into glycerolipids and cholesterol. Thus, measuring the rate of incorporation of radioactive acetate into hepatic lipids in the liver slices and hepatocytes is an index of hepatic lipid synthesis and yields valuable information regarding this process, in spite of some limitations such as dilution [26, 27]. In addition, incorporation of [1(2)-¹⁴C] acetate and [1-¹⁴C] oleic acid into hepatic lipids into the liver slices and hepatocytes prepared from rats fed diets with and without MF indicates that these in vitro models of the liver function adequately with respect to lipid synthesis. As shown in Table 1, a marked decrease in TAG concentration in the livers of rats fed diets with MF was concomitantly associated with a decreased incorporation of [1(2)-¹⁴C] acetate into this lipid molecule; the extent of reduction was similar. Further, in experiment 2, this response was reproduced in the liver slices of rats fed, for a longer period of 8 weeks, diets with MF in combination with a low, but not with a high, fat content. On the other hand, incorporation of [1(2)-¹⁴C] acetate into free fatty acid fraction (Tables 2, 4) as well as that into the total fatty acids was not different between the liver slices prepared from rats fed diets with and without MF, suggesting that MF may not be an inhibitor of de novo

fatty acid synthesis. On the other hand, the decrease in the esterification process, as estimated by incorporation of labeled oleate into TAG in hepatocytes, suggested that MF exerts an inhibitory effect on TAG synthesis, rather than fatty acid synthesis. There is no data regarding the effect of bitter melon on fatty acid synthesis, but a few studies have been reported for TAG synthesis. For example, Nerurkar et al. recently reported that HepG2 cells treated with bitter melon juice exhibited reduced cellular TAG synthesis and secretion of TAG into the medium [13, 14]. They also observed that in HepG2 cells treated with bitter melon juice, mRNA expression of MTP was inhibited. MTP plays a pivotal role in the assembly and secretion of apoB-containing lipoproteins, and induces sterol regulatory element-binding protein-1c, which is one of the nuclear transcription factors responsible for modulating lipid and lipoprotein metabolism. The results of these in vitro studies further confirmed in vivo experiments showing that this juice lowers plasma apoB-100 and B-48 in C57BL/6 mice fed high-fat diets [14]. Recently, Chao and Huang observed that bitter melon extract activates PPAR α : an important transcription factor involved in lipid and glucose homeostasis, and upregulates the expression of the acyl CoA oxidase gene in rat hepatoma cells H4IIEC3 [15]. Considering these previous observations in the context of our present results, the mechanism responsible for the observed reduction in the concentration of hepatic TAG by dietary MF is likely to be reduced synthesis of TAG and enhanced fatty acid oxidation.

In these studies, we also measured mRNA expression of carnitine palmitoyltransferase I, which is the rate-limiting enzyme for hepatic mitochondrial fatty acid oxidation. We found, for the first time, that expression of CPT I is enhanced following feeding of MF, particularly in combination with a low fat diet. These results suggest that the diminished concentration of hepatic TAG is directly related to fatty acid oxidation, since an inverse relationship between hepatic TAG content and fatty acid oxidation has been shown [21, 22, 28]. Thus, the mechanism(s) responsible for the observed reduction in the concentration of hepatic TAG may, in part, be attributed to the concomitant elevation of CPT I expression. At present, there has been no direct demonstration that increased enzyme activity accompanies this increase in expression; further studies are needed to determine enzyme activity in animals fed diets with and without MF.

The dietary MF-dependent reduction of hepatic total cholesterol was not accompanied by reduced cholesterol synthesis, as estimated by incorporation of [1(2)- ^{14}C] acetate into both free and esterified cholesterol. Only the reduction in the concentration of cholesterol ester is attributed to decreased synthesis. As shown in Table 4, dietary MF increased fecal excretion of neutral steroids, but

not of acidic steroids, in rats fed low- and high-fat diets, suggesting that MF may influence cholesterol metabolism at the initial stage by inhibiting the absorption of endogenous and exogenous cholesterol. Bitter melon has been reported to contain saponin as an active component [29, 30]; saponin is a known inhibitor of cholesterol absorption in the intestine [31, 32], and thus increases fecal excretion of neutral steroids. Thus, the MF-dependent reduction in the concentration of liver cholesterol may be a consequence of increased fecal excretion of neutral steroids, rather than of altered cholesterologenesis, although further studies are required to elucidate the mechanism.

In summary, bitter melon has active components which may be able to ameliorate the severity of lipid disorders such as hyperlipidemia and fatty liver. The mechanism responsible for the action of bitter melon extracts such as MF is probably the reduced synthesis of liver TAG with a concomitant elevation of fatty acid oxidation. On the other hand, the MF-dependent reduction of liver cholesterol is due to an increase in fecal excretion of neutral sterols. Further studies aimed at characterization of the active component in MF and the precise mechanism(s) responsible for the observed reductions in the liver TAG and cholesterol should be carried out, and this work is in progress in our laboratory.

Acknowledgments G. V. K. Senanayake would like to acknowledge and thank the Japanese Government and the University of Miyazaki for the provision of a Monbusho scholarship grant. The authors wish to thank Mitsuru Maruyama for her excellent technical assistance. We also thank Dr. Melissa Clark in the department of Comparative Biosciences, College of Veterinary Medicine, University of Illinois, Urbana-Champaign, IL, USA, for her valuable comments and for revision of the English in the manuscript.

Conflict of interest The authors declare that there is no conflicts of interest.

Abstract The aim of the study was to determine the effects of different dietary fatty acids during the first half of pregnancy on the fatty acid composition of maternal adipose tissue and of maternal and fetal plasma at mid- and late-pregnancy. Pregnant rats received soybean-, olive-, fish-, linseed- or palm-oil diets from conception to day 12 of gestation. Virgin rats receiving the same treatments were studied in parallel. At day 12, some rats were sacrificed and others were returned to the standard diet and studied at day 20. At day 12, the concentrations of most fatty acids in plasma reflected the dietary composition and individual fatty acids in lumbar adipose tissue of pregnant rats correlated with those in the diet. At day 20, the plasma concentration of each fatty acid was higher in pregnant than in both virgin rats and day-12 pregnant rats. The composition in 20-day pregnant (but not in virgin) rats resembled the diet consumed during the first 12 days. Fatty acid concentration in fetal plasma was also influenced by the maternal diet during the first 12 days of pregnancy, and long-chain polyunsaturated fatty acid (LC-PUFA) concentrations correlated with those in the mothers. In conclusion, during the first half of pregnancy maternal adipose tissue stores dietary-derived fatty acids, which are released into blood during late pregnancy enabling LC-PUFA to become available to the fetus.

Keywords Dietary fatty acids · Early pregnancy · Soybean oil · Olive oil · Fish oil · Linseed oil · Palm oil · Rat · Long-chain polyunsaturated fatty acids

Abbreviations

| | |
|---------|---------------------------------------|
| ALA | Alpha-linolenic acid, 18:3 (n-3) |
| ARA | Arachidonic acid, 20:4 (n-6) |
| DHA | Docosahexaenoic acid, 22:6 (n-3) |
| EFA | Essential fatty acid |
| EPA | Eicosapentaenoic acid, 20:5 (n-3) |
| F | Fish oil |
| L | Linseed oil |
| LA | Linoleic acid, 18:2 (n-6) |
| LC-PUFA | Long chain polyunsaturated fatty acid |
| LPL | Lipoprotein lipase |
| NEFA | Non-esterified fatty acid |
| O | Olive oil |
| P | Palm oil |
| S | Soybean oil |
| TAG | Triacylglycerol |
| VLDL | Very low density lipoprotein |

Introduction

Evidence in humans suggests that fetal growth is most vulnerable to maternal dietary inadequacies during early pregnancy [1], and recently it has been shown that a high-quality diet in the first trimester of pregnancy is associated with an increase in birth weight and length [2]. In fact, maternal metabolism during pregnancy adapts to benefit the growth and development of the fetus and can be divided into two phases. During the initial two-thirds of gestation, when fetal energy demands are limited, maternal fat stores

increase, both in women [3, 4] and in experimental animals [5, 6]. This is attributable in part to maternal hyperphagia together with increased responsiveness of adipose tissue to insulin [7] and subsequent increased lipoprotein lipase (LPL, EC 3.1.1.34) activity in adipose tissue [8, 9]. During the latter stages of pregnancy this anabolic state switches to a state of catabolism with a marked increase in adipose tissue lipolytic activity and the development of maternal hyperlipidemia, coinciding with the phase of maximal fetal growth [10].

Essential fatty acids (EFA), linoleic acid (LA, 18:2 n-6) and α -linolenic acid (ALA, 18:3 n-3), and their long-chain polyunsaturated derivatives (LC-PUFA) like docosahexaenoic acid (DHA, 22:6 n-3) and arachidonic acid (ARA, 20:4 n-6) are essential for the formation of new tissues during fetal and postnatal development. During intrauterine life, EFA and LC-PUFA must be obtained from maternal circulation by passage across the placenta [11–13]. We previously compared pregnant sows given a dietary supplement of either fish oil (rich in DHA) or olive oil during the first half of gestation only. We found that the proportion of DHA in maternal plasma was higher in the fish oil-fed sows even during the first week postpartum, some 60 days after the supplement had been withdrawn [14].

In the present study, we investigated how differences in the fatty acid composition of diets with normal fat contents offered to rats during the first 12 days of pregnancy, could influence the fatty acid profile in maternal plasma and lumbar adipose tissue. After 12 days, all the animals received the standard pellet diet and we determined how this action modified maternal and fetal plasma fatty acid profiles at day 20 of pregnancy.

Materials and Methods

Animals, Diets, and Experimental Design

Female Sprague–Dawley rats were obtained from the animal quarters at the University San Pablo-CEU, Madrid. The experimental protocol was approved by the Animal Research Committee of the University San Pablo-CEU in Madrid, Spain. The rats were initially fed a standard non-purified diet (B&K Universal, Barcelona, Spain) and housed under controlled light and temperature conditions (12-hour light/dark cycle; 22 ± 1 °C). Rats were mated when they were 3 months old. On the day sperm cells appeared in vaginal smears (day 0 of pregnancy) they were randomly divided into 5 groups, the experimental diets of which contained a characteristic type of non-vitamin fat. In the “S” group, the diet contained 9% soybean oil (rich in LA); in the “O” group, the diet contained 9% olive oil (rich in oleic acid, 18:1 n-9); in the “F” group, the diet

contained 8% fish oil (rich in DHA and Eicosapentaenoic acid, EPA, 20:5 n-3) plus 1% sunflower oil (rich in LA); in the “L” group, the diet contained 8% linseed oil (rich in ALA) plus 1% sunflower oil; and in the “P”, diet contained 8% palm oil (rich in saturated fatty acids, 16:0) plus 1% soy oil. Sunflower oil or soy oil was added to some diets to ensure that the minimum requirement for EFA was met. The experimental design is summarized in Fig. 1. The experimental diets were isoenergetic (4.1 kcal/g) and their composition and the proportional fatty acid profiles are shown in Tables 1 and 2, respectively. In addition, values for the major FA in the diets, expressed as % of total energy intake, are also included in Table 2. The composition of each diet complied with the recommendations of the American Institute of Nutrition [15]. The diets were prepared at the beginning of the experiment and were kept at -20 °C in daily portions until use. Every 24 h fresh diet was provided and the daily food intake was estimated periodically. After 12 days on an experimental diet (day 12 of pregnancy), 6–8 rats from each group were sacrificed; the remaining rats were given the standard pellet diet until day 20, when they too were sacrificed. Rats were always housed in collective cages (3–4 per cage) and had free access to the assigned diet and tap water. Age-matched virgin female rats (V), subjected to the same dietary regimens as the pregnant rats, were studied in parallel. One further group of virgin female rats, that were age-matched to the pregnant rats at the onset of the experiment and that received only the standard pellet diet, was also studied and considered to be the basal group (V0). Rats were sacrificed by decapitation and trunk blood was collected into receptacles containing 1 g $\text{Na}_2\text{EDTA/L}$. The two uterine horns were immediately dissected and weighed with their contents to obtain the maternal weight free of conceptus.

EXPERIMENTAL PROTOCOL DESIGN

| Linseed oil | – | – | – | 80.0 | – |
| Palm oil | – | – | – | – | 80.0 |

The experimental diets provided 405 kcal/100 g distributed between carbohydrates (59.7%), proteins (20.7%) and lipids (20%)

^a Salt mix (g/kg diet): copper sulfate 0.1; ammonium molybdate 0.026; sodium iodate 0.0003; potassium chromate 0.028; zinc sulfate 0.091; calcium hydrogen phosphate 0.145; ammonium ferrous sulfate 2.338; magnesium sulfate 3.37; manganese sulfate 1.125; sodium chloride 4; calcium carbonate 9.89; potassium dihydrogen phosphate 14.75

^b Vitamin mix (mg/kg diet): retinyl palmitate 2.4; cholecalciferol 0.025; menadione sodium bisulfite 0.8; biotin 0.22; cyanocobalamin 0.01; riboflavin 6.6; thiamin hydrochloride 6.6; α -tocopherol acetate 100

Lumbar adipose tissue was dissected, placed in liquid nitrogen, and after weighing, kept at -80°C until analysis. In 20-day pregnant rats, fetuses were weighed and decapitated, and the blood collected as indicated above. Fetal liver samples were dissected, immediately placed in liquid nitrogen then stored at -80°C until analysis. Samples from all of the fetuses of the same dam were pooled and processed in parallel to the samples of the adults. Plasma was separated from fresh blood by centrifugation at 1500g for 15 min at 4°C .

Processing of Samples

Plasma triacylglycerols (TAG) and non-esterified fatty acids (NEFA) were determined enzymatically using commercial kits (Spinreact Reactives, Spain and Wako Chemicals, Germany, respectively).

Nonadecenoic acid (19:1) (Sigma Chemical Co.) was added as the internal standard to fresh aliquots of each diet and of frozen plasma, lumbar adipose tissue and fetal liver, which were used for lipid extraction and purification [16]. The final lipid extract was evaporated to dryness under vacuum and the residue resuspended in methanol/toluene and subjected to methanolysis in the presence of acetyl chloride at 80°C for 2.5 h as previously described [17]. Fatty acid methyl esters were separated and quantified on a Perkin-Elmer gas chromatograph (Autosystem) with a

flame ionization detector and a 20 m Omegawax capillary column (internal diameter 0.25 mm). Nitrogen was used as carrier gas, and the fatty acid methyl esters were compared with purified standards (Sigma Chemical Co.). Quantification of the fatty acids in the sample was performed as a function of the corresponding peak areas compared to that of the internal standard. Coefficient of variation values expressed as percentages ranged between 0.0–6.0, giving a mean \pm ES value of $2.28 \pm 0.26\%$ for an arbitrary set of fatty acid analysis. To assess the fatty acid distribution of the different lipid classes (e.g., phospholipids, NEFA, TAG and esterified cholesterol), extracted lipids were separated by thin layer chromatography using Silicagel 60 F₂₅₄ plates (Merck, Darmstadt, Germany) with *n*-heptane/diisopropyl ether/acetic acid (70:30:1, by volume) as the solvent. The bands were visualized with 2',7'-dichlorofluorescein (Supelco, Bellafonte, PA) and eluted from the plate with methanol/toluene and subjected to methanolysis and fatty acid analysis as above.

Statistical Analysis

The values are quoted as mean \pm standard error of the mean (S.E.). Statistical analysis was carried out using SPSS version 17.0 (SPSS Inc., Chicago, IL). Distributions of the studied variables were identified as normal after examination with the Shapiro–Wilk test; therefore, parametric analyses

^a Experimental diets provided 20% of total energy as fat and standard diet provided 17.2% of total energy as fat

were applied. One-way analysis of variance (ANOVA) was used to compare different diets and three-way ANOVA with physiological status (pregnant or virgin), time (12 or 20 days) and diets as factors was used to compare mean fatty acid values from different dietary treatments. When treatment effects were significantly different ($P < 0.05$), Newman–Keuls simultaneous tests were used to establish statistical differences between individual dietary interventions. Fatty acid compositional data between virgin and pregnant rats were analyzed using an unpaired t test. The Spearman rank correlation analyses were used to investigate associations between fatty acid compositions of experimental diets with those of maternal and fetal plasma, and between maternal plasma and maternal adipose tissue.

Results

Body weight and food intake in pregnant rats were higher than in virgin rats, but no difference was found between the groups of pregnant or of virgin rats receiving the different dietary treatments (data not shown). Both total and conceptus-free body weight in pregnant rats at day 12 (301 ± 3 and 296 ± 4 g; data shown as mean \pm SEM) and at day 20 of pregnancy (395 ± 6 and 315 ± 6 g) were significantly higher ($P < 0.001$) than in age-matched virgin rats on the same day of experimental treatment (267 ± 3 g at day 12 and 273 ± 3 at day 20). Neither the number of embryos or fetuses per dam, nor the body weights of the fetuses, differed between the groups (data not shown).

As shown in Table 3, plasma concentrations of either TAG or NEFA did not differ between groups of virgin rats receiving the dietary treatments. In pregnant rats at day 12, neither TAG nor NEFA values in plasma were significantly different from those found in either the V0 or any of the virgin groups at day 12; nevertheless, values of both variables significantly increased at day 20 compared to day 12 values for all groups. The change was particularly striking in the case of the F group for TAG and of the S group for NEFA.

Figure 2 summarizes the plasma concentrations of the different structural groups of fatty acids. The data are organized by the different dietary groups, which show distinct differences in their responses.

The Soy Oil Diet

At day 12, when they were still receiving the experimental diets, those virgin rats (labeled as V12 in the figure) fed the S diet showed no differences in the concentrations of the different groups of fatty acids when compared with the basal group (V0), whereas in pregnant rats (labeled as P12) n-3 PUFA were higher than in either V12 or V0 rats. The switch to pellets from day 12 to day 20 did not modify the different fatty acid groups in virgins at day 20 but did increase the concentrations of all fatty acid groups in pregnant rats, the greatest increase occurring in the n-3 PUFA, which mainly corresponded to DHA (Table 4).

The Olive Oil Diet

At day 12, in rats fed the O diet, no difference was found in any of the fatty acid groups in either virgin or pregnant rats when compared to the basal group (V0), except for a significant decline in n-6 PUFA (Fig. 2), which mainly corresponded to ARA (Table 4). By day 20, 8 days after reverting to the pellet diet, there was no significant change in any of the fatty acid groups in the plasma of virgin rats, but in pregnant rats all the fatty acid groups showed a significant increase in their concentrations.

The Fish Oil Diet

In the F diet group, at day 12, both virgin and pregnant rats showed major changes in the fatty acid concentrations, with a significant decrease in n-6 PUFA (Fig. 2), mostly ARA, and increases in n-3 PUFA, the difference corresponding to both EPA and DHA (Table 4). By day 20, the concentrations of fatty acid groups in the virgin rats had returned to values found in the basal group (V0), whereas in pregnant rats all the concentrations had increased significantly compared to the corresponding values at day 12, and was evident in virtually all the measured fatty acids,

Table 3 Plasma concentrations of triacylglycerols (TAG) and non-esterified fatty acids (NEFA) of virgin (V) and pregnant rats (P) at days 0 (basal), 12 and 20 of the study

Values correspond to mean \pm SEM ($n = 6-8$). Statistical comparisons between days on the diet within the same diet are shown by lower-case superscript letters; comparisons between diets on the same day of the study are shown by upper-case superscript letters (different letters indicate $P < 0.05$)

Fig. 2 Concentration of groups of fatty acids in the plasma of virgin (V) and pregnant (P) rats at 12 and 20 days of the study. Rats were given soy oil-, olive oil-, fish oil-, linseed oil- or palm oil-based diets for 12 days, then from day 12 until day 20 they were given a standard pellet diet. V0 corresponds to age-matched virgin female rats at the onset of the experiment (basal group). Values correspond to mean \pm SEM of 6–8 rats per group. Statistical comparisons between the groups for each fatty acid group are shown by lower-case letters (different letters indicating $P < 0.05$) and comparison between pregnant and virgin rats at the same day of experiment is shown by asterisks (* $P < 0.05$ and ** $P < 0.001$). Saturated fatty acids were calculated as the sum of 14:0, 16:0 and 18:0; monounsaturated fatty acids as the sum of 16:1 (n-7), 18:1 (n-9) and 20:1 (n-9); n-6 PUFA as the sum of 18:2 (n-6), 18:3 (n-6) and 20:4 (n-6); and n-3 PUFA is the sum of 18:3 (n-3), 20:5 (n-3), 22:5 (n-3) and 22:6 (n-3)

Values correspond to mean ± SEM ($n = 6-8$). Statistical comparisons within the same dietary group (e.g., soy oil group V12 versus V20 versus P12 versus P20) are shown by lower-case superscript letters. Statistical comparisons between dietary groups at the same time of the study (e.g., V12 soy oil diet versus V12 olive oil diet versus V12 fish oil diet versus V12 linseed oil diet versus palm oil diet) are shown by upper-case superscript letters (different letters indicate $P < 0.05$).

ND not detected, V12 virgin rats at day 12 of study, V20 virgin rats at day 20 of study, P12 pregnant rats at day 12 of study, P20 pregnant rats at day 20 of study. MUFA monounsaturated FA, PUFA polyunsaturated FA, LA linoleic acid, ARA arachidonic acid, ALA α -linolenic acid, EPA eicosapentaenoic acid, DHA docosahexaenoic acid

including both LA and ARA in case of the n-6 PUFA and ALA, EPA and DHA in case of n-3 PUFA (Table 4).

The Linseed Oil Diet

Rats on the L diet presented a similar picture to that seen with the F diet in terms of their plasma fatty acid profiles. At day 12 no difference was found in the concentrations of saturated or monounsaturated fatty acids of either virgin or pregnant rats compared to the basal group, and there was a significant decline in n-6 PUFA (Fig. 2), again mostly ARA, and increases in n-3 PUFA, the difference corresponding to both ALA and EPA (Table 4). At day 20, all plasma fatty acids in virgin rats (as on the F diet) returned to basal values, and in pregnant rats there were significant increases compared to the values at day 12. The exception was the n-3 PUFA in the plasma of pregnant rats; the concentration in plasma of pregnant rats at day 20 remained practically the same as in the pregnant rats at day 12. This is accounted for by a decline in EPA and an increase in DHA (Table 4).

The Palm Oil Diet

After 12 days of receiving the P diet, virgin rats did not show any change in fatty acid profile, values remaining stable also at day 20, except for a small but significant decline in monounsaturated fatty acids (Fig. 2). In pregnant rats, however, at day 12 of being on the P diet, higher concentrations of monounsaturated fatty acids (oleic acid) and lower concentrations of both n-6 PUFA and n-3 PUFA were observed (Fig. 2), the difference mainly corresponding to LA and DHA respectively (Table 4). At day 20, pregnant rats of the P group showed increases in the plasma concentrations of all fatty acid groups (Fig. 2); the difference was significant ($P < 0.05$) for virtually all the individual fatty acids, and was especially striking in the case of DHA, which was 3-fold higher than at day 12 (Table 4).

Having described the different responses of pregnant and virgin rats at day 12 and day 20 of the dietary manipulations and taking into account the fact that the experimental diets were only given to the rats during the first 12 days of the 20-day experiment, it is possible to examine the differential responses to the different diets. As shown in Table 4, on the last day of receiving the experimental diets (day 12), most of the changes in plasma fatty acid profile, in both virgin and pregnant rats, mimicked the profiles found in the respective diets, with the exception the values for ARA. ARA is found at very low concentrations in all the diets and at much higher concentrations in all the day-12 plasmas, the effect being less pronounced in the F and L groups. After being fed with standard pellet diet for the last 8 days of experiment (i.e., until day 20), the plasma fatty acid profile in the virgin rats returned to values approaching those observed before the experiment (V0); this is not the case in pregnant rats. Saturated fatty acids were the exception in that they were similar in all the groups. The concentration of monounsaturated fatty acids was highest in the two groups whose diets also contained the most oleic acid, O and F. The two groups with the lowest plasma ARA concentrations were L and F, which also had the highest values of DHA. The day-20 pregnant rats on the L diet had the highest proportions of ALA. None of the rats, with the obvious exception of those on the F diet, had very low plasma levels of DHA, although in pregnant rats of the L group at day 20 were notably higher than the remaining three groups (e.g., S, O and P).

It is to be expected that these different fatty acid profiles in maternal plasma would be reflected in the fetuses at day 20 (see Table 5). Palmitic- and oleic-acid concentrations were highest in the fetuses of dams fed the P diet, the other four groups all being similar to each other. No difference between the groups was found in LA concentrations, whereas ARA was lowest in the fetuses of dams fed either F or L diet, which were also those with the highest values of both EPA and DHA. Concentrations of ALA were

Table 5 Concentrations of specific fatty acids in plasma of 20-day fetuses of dams that were fed an experimental diet during the first 12 days of pregnancy and standard pellet diet from day 12 until day 20

| Fatty acid (mg/L) | Soy oil diet | Olive oil diet | Fish oil diet | Linseed oil diet | Palm oil diet |

Values correspond to mean ± SEM ($n = 6-8$). Statistical comparisons are shown by the superscript letters (different letters indicate $P < 0.05$) LA linoleic acid, ARA arachidonic acid, ALA α -linolenic acid, EPA eicosapentaenoic acid, DHA docosahexaenoic acid

highest in fetuses of the S group followed by the L, as compared to the other groups, but were much lower than those of LA in all the groups. In order to determine the potential influence of maternal fatty acids on fetal ones, linear correlation analysis of the concentrations of individual fatty acids between the two sites (Tables 4, 5) was carried out. It was found that only ARA, EPA and DHA showed a significant correlation ($n = 30$, $P < 0.05$, <0.05 and <0.001 , respectively). The proportional distribution of fatty acids in fetal liver of 20 day pregnant rats fed the different diets is shown in supplementary Table 1. The most relevant finding is a lower proportion of ARA and n-6 docosapentaenoic acid and a higher proportion of EPA, n-3 docosapentaenoic acid and DHA in fetuses of the L and F groups as compared to the others. The consistent increase in the concentration of practically all fatty acids in maternal plasma at day 20 compared to all the other groups and the different profiles found in their fetuses, prompted an analysis of the lipid classes that could be carrying them in the plasma.

As shown in Table 6, the lipid class in maternal plasma of all the groups showing the highest proportion of saturated fatty acids was NEFA followed by phospholipids, with smaller proportions in TAG and even smaller in the esterified cholesterol fraction. In the case of monounsaturated fatty acids, the circulating lipid fraction having the highest proportion was TAG, followed by NEFA, then esterified cholesterol or phospholipids. Very differently, the circulating lipid class with the highest proportion of n-6 PUFA (corresponding mainly to ARA) was always esterified cholesterol, followed by either TAG or phospholipids, and the smallest being in the NEFA. In case of n-3 PUFA, phospholipids contained the highest proportion fraction, followed by TAG, esterified cholesterol or NEFA.

In the plasma of fetuses from these same dams (Table 6), none of the fatty acids were detectable as NEFA, but their distribution in the other lipid classes was similar to those in their mothers, albeit with some significant differences. The phospholipids fraction always contained the highest proportion of saturated fatty acid, followed by TAG and esterified cholesterol, which proportion was always higher than in the esterified cholesterol in the corresponding maternal plasma. In fetal plasma, the lipid fraction having the highest proportion of monounsaturated fatty acids was TAG followed by esterified cholesterol and phospholipids; however, the proportion of n-6 PUFA (mainly ARA) in fetal plasma was highest in phospholipids and in esterified cholesterol followed by TAG, and n-3 PUFA represented a higher proportion of the phospholipid fatty acid moieties than did those of esterified cholesterol or TAG, the proportion in NEFA being the lowest. Nevertheless, the proportion of n-3 fatty acids present in each

of the lipid classes analyzed was always lower than the proportions of the other fatty acid families.

In order to test whether maternal adipose tissue represented a store of dietary fatty acids during early pregnancy, the fatty acid profile of lumbar adipose tissue was determined in pregnant rats on the last day of receiving the experimental diet (day 12), and compared to the profile from the basal (V0) group that had received only standard pellets. The results are shown in Table 7. Adipose tissue of the rats on the S diet had higher LA and ALA concentrations than the V0 group; those on the O diet had higher oleic acid but lower LA, ARA and DHA; the rats on the F diet had higher EPA and DHA and lower LA; those on the L diet had higher ALA and EPA; and those on the P diet had higher palmitic acid and oleic acid and lower LA and DHA concentrations than the V0 group.

The similarities observed between the fatty acid composition of the diets (Table 2) and of the lumbar adipose tissue at day 12 of the rats (Table 7) led us to compare the two measurements statistically. A significant linear correlation was found for all the fatty acids except for ARA (which is virtually absent from diets and present at low concentrations in adipose tissue), P values being <0.05 in case of saturated fatty acids and <0.001 for the others (oleic acid, ALA, EPA and DHA).

Discussion

The experiment reported here has shown for the first time that giving rats iso-energetic diets with different fatty acid compositions during just the first 12 days of pregnancy (full term is 22 days) influences the fatty acid profile of maternal adipose tissue greatly, and that these fatty acids are released during late pregnancy even though the rats were returned to a standard diet the second “half” of pregnancy. The experiment further showed that the LC-PUFA in maternal plasma were available to the fetus. This was especially evident when maternal diet during early pregnancy was abundant in n-3 LC-PUFA or n-3 EFA (e.g. ALA), as was the case for the fish oil and linseed oil diets, respectively. In these cases the diet caused a decline in plasma ARA concentrations, which was particularly evident in the fetus.

During the first 12 days of pregnancy in rats, the mother is in an anabolic condition, as shown here by the increased maternal body weight (free of the conceptus) compared to age-matched virgin female rats. Thus, during this early stage of pregnancy, maternal adipose tissue becomes a store of dietary-derived fatty acids, as indicated by the significant linear correlations between the fatty acids in fat pads of day 12 pregnant rats and the composition of the diets as described in the Results section. At this early stage

Table 6 Proportional distribution of groups of fatty acids in different lipid classes in plasma of 20 day-pregnant rats and their fetuses given different experimental diets during the first 12 days of gestation, followed by the standard pellet diet until day 20

Values are the % composition of fatty acid type within each of the lipid classes and are shown as mean ± SEM ($n = 6-8$). “Saturated” is the sum of the acids 14:0, 16:0 and 18:0; “monounsaturated” is the sum of the acids 16:1 (n-7), 18:1 (n-9), 20:1 (n-9) and 22:1 (n-9); n-6 PUFA are the sum of the n-6 polyunsaturated fatty acids 18:2, 18:3 and 20:4; n-3 PUFA is the sum of n-3 polyunsaturated fatty acids (18:3, 20:5, 22:5, and 22:6). Statistical comparison for each fatty acid group in the different lipid class between dietary groups is shown by superscript letters (different letters indicate $P < 0.05$)

Values correspond to mean ± SEM ($n = 6-8$). Basal (V0) corresponds to sex- and age-matched virgin rats at the onset of the experiment. The statistical comparison between groups for each fatty acid is shown by superscript letters (different letters indicate statistical difference between the groups, $P < 0.05$)

LA linoleic acid, ARA arachidonic acid, ALA α -linolenic acid, EPA eicosapentaenoic acid, DHA Docosahexaenoic acid

of pregnancy, when lipolytic activity in adipose tissue is low due to its increased sensitivity to insulin [7], the fatty acid profile in plasma is the result of three main effects: what has been absorbed from the diet; what is taken up from the blood by the different tissues; and what is released to the blood by the liver, where the highest rate of conversion of EFA to LC-PUFA takes place [18]. Indeed the fatty acid profile in plasma of day 12 pregnant rats indicates that an active conversion of EFA to LC-PUFA is occurring at this stage. Thus, while the linseed oil diet had the highest proportion of ALA and practically no EPA, both virgin and especially pregnant rats on this diet had plasma EPA concentrations that were higher than in all the other groups except those on the fish oil diet, suggesting an active conversion of ALA to EPA. This issue regarding conversion in humans of ALA to longer chain n-3 fatty acids is still subject to significant debate. However, the efficient conversion of ALA to longer chain n-3 fatty acids has been shown to be especially active in women of childbearing age compared to males [19–22]. It has also been shown that estrogen exposure in women increases the conversion of ALA to DHA [20]. Our finding that this conversion is increased in late-pregnant rats is consistent with reports that late pregnancy is a condition where high circulating levels of estrogen are present both in women [23–25] and in rats [26].

Similarly, ARA is practically absent from any of the diets used here, but it was present in the plasma of all the groups, suggesting an active endogenous synthesis from its EFA precursor, LA. However, plasma ARA levels at day 12, in both virgin and pregnant rats, were lower in the fish oil and linseed groups than in any of the other groups. The F and L groups were the ones with the highest contents of n-3 LC-PUFA, either EPA or DHA or both. An inhibitory effect of both of these LC-PUFA on the $\Delta 6$ -desaturase, the key enzyme for ARA synthesis from its essential precursor, LA, has been reported [27, 28]. The findings reported here therefore indicate that the same inhibitory action is

effective in vivo in our rats given the fish oil or the linseed oil diet.

The results from the pregnant rats that were studied at day 20 of pregnancy are of particular interest; the experimental diet of these rats had been discontinued for 8 days and replaced by the standard diet. As well as an increase in both plasma NEFA and TAG, a significant increase in the plasma concentrations of most fatty acid groups was found, when compared to values found both in the virgin rats groups and in pregnant rats at day 12 of gestation. These findings clearly suggest an increased adipose tissue lipolytic activity, which must have contributed to the net release of the dietary fatty acids that were stored in adipose tissue during the first 12 days of pregnancy.

A few exceptions deserve comment, mainly relating to the groups on the fish oil and linseed oil diets. In the fish oil group, plasma EPA concentrations in 20-day pregnant rats decreased compared to values found in 12-day pregnant rats. As the fish oil diet contains very little ALA, the EFA precursor for EPA synthesis, but it is rich in EPA itself, it is proposed that the lower concentration of this fatty acid in 20-day pregnant rats on the F diet could be a consequence of its conversion into DHA, the concentration of which in plasma is about three times higher than in 12-day pregnant rats. Similar reasoning could be used for the situation in the linseed oil group, even though this diet is the richest in ALA. The lower concentration of this fatty acid in 20-day pregnant rats is also followed by a decline in plasma concentrations of EPA and a 5-fold increase in DHA, again suggesting an active synthesis of DHA. The potential effect of high estrogen levels on these activities, referred to above, deserves further direct studies.

These LC-PUFA are transported in maternal plasma mainly as their various esterified forms, such as phospholipids, TAG and esterified cholesterol, with small proportions in the form of NEFA. This agrees with previous findings both in pregnant women [8] and in rats [29], showing that PUFA are carried in plasma associated with the

different lipoprotein fractions rather than in their non-esterified form. This further indicates that, although released from maternal adipose tissue in the form of NEFA, they are rapidly taken up by the liver where they are esterified and incorporated into VLDL to be returned to the circulation. As already proposed [13, 29], maternal lipoproteins seems to be the mechanism of transport by which PUFA arrive at the placenta, where they are taken up and, after hydrolytic release, are transferred to the fetal circulation.

The concentrations of LC-PUFA in fetal plasma and even the proportional distribution of fatty acids in fetal liver were found to be influenced by those in maternal circulation, the relationship being especially evident in the case of the fetuses of dams given PUFA-rich diets during early pregnancy (i.e., soy-, fish- or linseed-oil diets). The same does not appear to be true for the rats given diets rich in saturated and monounsaturated fats (i.e., the palm oil and olive oil diets). The finding probably reflects the fact that the rat fetus carries out fatty acid synthesis *de novo* at this stage of intrauterine life [30], resulting in fetal synthesis of both saturated and monounsaturated acids and presumably lower requirements for their placental transfer.

In conclusion, the findings presented here show that the maternal adipose tissue of rats has the ability to store dietary derived fatty acids during the first half of gestation, which are released into the plasma during late pregnancy from where LC-PUFA become available to the fetus. Although extrapolation of this conclusion to the human condition should be made with caution for obvious reasons, alterations in dietary fatty acid composition during early pregnancy may have consequences in terms of which fatty acids reach the fetus during the stage of its most rapid growth and consequent greatest need of LC-PUFA.

Abstract *Camelina sativa* is an oilseed plant rich in n-3 and n-6 fatty acids and extruding the seeds results in high protein meal (~40%) containing high levels of n-3 fatty acids. In this study, we examined the effects of feeding extruded defatted camelina meal to commercial laying hens, measuring egg production, quality, and fatty acid composition. Lohmann White Leghorn hens (29 weeks old) were randomly allocated to three dietary treatment groups ($n = 25$ per group) and data was collected over a 12 week production period. All the treatment groups were fed a corn soy based experimental diet containing 0% (control), 5, or 10% extruded camelina meal. We found no significant differences in percent hen-day egg production and feed consumed per dozen eggs. Egg shell strength was significantly higher in both camelina groups compared to the controls. Egg total n-3 fatty acid content increased 1.9- and 2.7-fold in 5 and 10% camelina groups respectively relative to the control. A similar increase in DHA content also occurred. Further camelina meal did not alter

glucosinolate levels and no detectable glucosinolates or metabolic product isothiocyanates were found in the eggs from either the 5 or 10% camelina groups. These results indicate that camelina meal is a viable dietary source of n-3 fatty acids for poultry and its dietary inclusion results in eggs enriched with n-3 fatty acids.

Introduction

There is an increasing interest in converting oil produced from oil seed crops into biofuels in response to the Energy Policy Act, 2005 [1]. However, oil seeds and oil seed meals are used as a source of crude protein and energy in poultry rations. Therefore, the increase in bio-fuel production has created a need to develop ways to use the meal produced following oil extraction that can benefit the poultry industry by producing alternative meals that do not compete with the human diet yet provide an adequate source of energy and protein.

Camelina sativa, also known as gold-of-pleasure or false flax, is an ancient crop native to Northern Europe and Central Asia. The plant belongs to the family Brassicaceae and is considered a versatile crop that requires a low amount of inputs [2, 3]. This annual oil seed crop can be grown with success under different climatic conditions,

making it an ideal crop for bio-fuel feedstock. Camelina oil contains high amounts of unsaturated fatty acids with alpha-linolenic (ALA, 18:3n-3) and linoleic (LNA, 18:2n-6) acids accounting for approximately 35 and 15% of the total, respectively [2]. Camelina meal, the by-product of oil extraction, has a crude protein content of 40% and oil content of 10–12% oil of which approximately 5% of the remaining oil is enriched in n-3 fatty acid [4]. Camelina meal can be used as a substitute for soybean meal in animal feeds [4].

Glucosinolates are anti-nutritive compounds generally present in the plants belong to Brassicaceae family which may have negative effects on feed consumption [5, 6]. A reduction in feed intake was reported in turkey poults when camelina meal was included in turkey starter diets at a concentration of more than 5% [7]. In most foods consumed that have glucosinolates these compounds are generally rapidly converted to a variety of degradation products during the course of ingestion and digestion. The most prominent metabolites are isothiocyanates and nitrile forms which are generally believed to have potential biological effects [5, 6]. Low glucosinolate content of camelina makes it a desirable animal feed relative to other Brassicaceae species [4].

Egg yolk composition depends on the dietary nutrient provision. Altering the dietary fatty acid intake of a laying hen can either directly [8] or indirectly due to further acyl chain elongation and desaturation in the liver [9] alter the fatty acid composition of the egg yolk. Feeding poultry diets rich in n-3 fatty acids increases the content of these fatty acids in the egg yolk. [10–17]. Because camelina meal is a rich source of essential fatty acids, it can be incorporated in laying hen diets to enrich the n-3 fatty acid content in eggs.

The modern Western diet is low in n-3 fatty acids resulting in a n-6 to n-3 fatty acid ratio ranging from 15:1 to 20:1 [18], which is proposed to increase the incidence of cardiovascular disease, rheumatoid arthritis, and cancer [18, 19]. There is substantial evidence illuminating health concerns caused by low dietary intake of n-3 fatty acids as well beneficial effects of supplementing diets with long-chain n-3 fatty acids [20–23]. The American Heart Association (AHA) recommends increasing the intake of dietary n-3 fatty acids to reduce the risk of coronary heart disease [24]. Because the available sources of long-chain n-3 fatty acids are limited, additional sources of highly nutritious products must be made available. Because egg fatty acid composition can be increased by altering the poultry diet [8, 9] addition of n-3 rich meals will increase n-3 fatty acid content of eggs. Flax seed is traditionally used to enrich eggs with n-3 fatty acids [14–17], however alternative, lower-cost options are needed. Herein, we propose that extruded defatted camelina meal is an excellent alternative

to flax meal as a source of n-3 fatty acids and protein for laying hen diets. Further, we hypothesize that the inclusion of extruded defatted camelina meal containing 10% residual oil, at levels of 5 and 10% will not alter feed consumption, body weight, egg production, internal egg quality, or sensory quality of eggs, but will increase egg n-3 fatty acid content.

Materials and Methods

One hundred, 25 week-old Lohmann White Laying hens, purchased from Feather Crest Farms, were placed individually into 100 laying hen cages. After a three-week acclimation period, 25 birds were randomly allocated to each of the three treatment blocks at the start of the trial, for a total of 75. Individual bird weights (g) were recorded at day 0 and at the end of each 28 day period (3 periods in total). Birds were caged on one tier in a laying hen house with open windows on two sides and an exhaust fan on one end. An additional fan was placed at the opposite end of the house to provide positive airflow towards the exhaust fan. All the methods used in this study were approved by the Texas A&M University Institutional Animal Care and Use Committee (AUP 2007-250).

A commercial type, phase 1 laying hen diet was formulated according to NRC Poultry [25], (Table 1) including control diet (no camelina meal) and diets that contained 5 and 10% camelina meal. All diets were formulated to be iso-nitrogenous and iso-caloric relative to the basal control diet (Table 1). Diets were formulated based on actual chemical analysis of the mechanically pressed defatted camelina meal (supplied by Great Plain Oil and Exploration) used in this study (Table 2). Feed mixtures were made fresh just prior to each 28 day period. Feed and water were offered ad libitum. No concomitant drug therapy was used during the study. Daily observations were made with regard to general flock condition, temperature, lighting, water, feed, and unanticipated events in the house. Pens were also checked daily for mortality.

The treatment group/block was the unit of measure for egg production and feed consumption. There were 5 hens per treatment within each block for a total of 75 hens. Egg measurements were taken on individual eggs. Weekly egg production was recorded. Egg weight, shell thickness and breaking strength, measured in triplicate, were determined for all eggs laid on one day of each week. Feed consumed per dozen of eggs was calculated based on 28-day periods. During the 2nd feeding period, eggs were collected for determination of interior egg quality. Color and Haugh Units were determined using an Egg AnalyzerTM (Orka Food Technology) at time zero and after 1 and 2 weeks of storage at 4 °C.

Procedures Used to Measure Egg Lipid Content

Reagents

HPLC grade *n*-hexane, 2-propanol, and anhydrous methanol, methyl formate, and concentrated sulfuric acid were purchased from EM Science (Gibbstown, NJ). Reagent grade sodium methoxide (25 wt%) and ferric chloride hexahydrate was purchased for Sigma-Aldrich (St. Louis, MO). Fatty acid methyl ester and cholesterol standards were purchased from Nu-Chek-Prep (Elysian, MN). All samples were stored at -80°C and sample extracts were stored in *n*-hexane/2-propanol (3:2, by Vol.) at -20°C prior to use.

Sample Extraction

Yolk samples (0.8–1.0 g) from hard boiled eggs were extracted in *n*-hexane/2-propanol (3:2, by vol.) using a Potter–Elvehjem tissue homogenizer equipped with a Teflon pestle [26]. The final lipid extract was concentrated to zero under a steady-stream of N_2 at 45°C then re-dissolved in 40 mL *n*-hexane/2-propanol (3:2, by vol.) immediately prior to analysis.

Table 2 Nutrient profile of camelina meal

| | Units | Amount |
|--------------------------------|---------|-----------|

Fatty Acid Quantitation and Gas Chromatography

Fatty acid content in the yolk extract was measured in triplicate using a modified method [27]. Briefly, samples were concentrated to zero residual solvent under a steady-stream of nitrogen at 45°C then transesterified in 2.5% sodium methoxide at 40°C for 30 min. The reaction was

stopped with the addition of methyl formate and the fatty acid methyl esters were extracted with *n*-hexane. Triheptadecanoin was used as an internal standard to calculate fatty acid mass. Fatty acid content was measured using a Shimadzu 2010 gas chromatograph (Kyoto, Japan) equipped with a flame ionization detector and a capillary column (SP 2330; 30 m × 0.32 mm i.d., Supelco, Bellefonte, PA). Sample runs were initiated at a column temperature of 180 °C followed by a temperature gradient to 200 °C over 8 min starting at 2 min from the beginning of the run. The temperature was held at 200 °C until the end of the run at 20 min. Fatty acid methyl ester standards were used to establish relative retention times and response factors. The internal standard, methyl heptadecanoate, and the individual fatty acids were quantified by peak area analysis and linear regression analysis (Class VP 7.2.1 Datasystem, Kyoto, Japan). The detector response was linear, with correlation coefficients of 0.998 or greater within the sample concentration range for all standards.

Cholesterol Content

The cholesterol content in the yolk lipid extract was measured in triplicate using a colorimetric assay [28]. Briefly, an aliquot of the yolk lipid extract was concentrated to zero under a steady-stream of nitrogen at 45 °C then dissolved in 3 ml absolute ethanol (Pharmco, Brookfield, CT). A 3-ml aliquot of iron working reagent was added to the sample then vigorously mixed for 10 min to bring the reaction to completion. The absorbance of each sample was measured at 550 nm and the concentration was calculated by comparing sample absorbencies to freshly prepared standard curves using linear regression analysis.

Procedures for the Detection of Egg Glucosinolate Content

Methods: Sample Extraction

For HPLC analysis, typically between 0.25 and 0.5 g of defatted chicken feeds, defatted ground camelina seed meals, and defatted freeze dried whole egg powders were extracted with 2–5 mL of methanol. For glucosinolate recovery experiments, 100 µl of a 1.8 µg/µl solution of sinigrin was added to three 5% camelina feed meals and to egg powders. For isothiocyanate analysis, whole egg powders were extracted with dichloromethane.

HPLC Analysis and Quantitation

For intact glucosinolate quantitation, the extract was run on a Shimadzu (Columbia, MD) HPLC System. The column was a C18 Inertsil 250 mm × 4.6 mm; RP C-18, ODS-3,

5µ, column. The glucosinolates were detected by monitoring at 237 nm. The initial mobile phase conditions were 40% methanol/60% aqueous 0.005 M tetrabutylammonium bisulfate (TBS) at a flow rate of 1 ml/min. After injection the initial conditions were held for 40 min, and then up to 100% methanol over another 10 min. Intact glucosinolates were identified by retention time compared to standards and by LC–MS analysis. Extracts from egg powders were confirmed as not having any intact glucosinolates by HPLC and by LC–MS analysis.

Preparation of Glucosinolate Isothiocyanates

The seed meal was defatted with hexane in a Soxhlet extractor for 24 h, after which the residual seed meal was allowed to dry completely. Defatted seed meal (10-g samples) were mixed with 25 ml of 0.05 M Tris buffer, pH 10.0 to convert the glucosinolates into isothiocyanates. Fifty milliliters of dichloromethane was then added to each flask and the flasks were placed in an incubator shaker set at 25 °C and 200 rpm for 8 h. Following hydrolysis, 10 g of sodium chloride and 10 g of anhydrous sodium sulfate were added. The dichloromethane was decanted and filtered, the residual seed meal was extracted for an additional three times with excess dichloromethane. The combined crude dichloromethane extracts were analyzed by gas chromatography–mass spectrometry (GC–MS).

GC–MS Analysis of Isothiocyanates

Gas chromatography–mass spectrometry was performed using a Hewlett-Packard (HP) 6890 GC system attached to an Agilent Systems HP 5972A Mass Selective Detector. The column used was a fused silica HP-5MS capillary (0.25 µm film thickness, 30 m × 0.25 mm ID). The GC operating parameters were as follows: splitless injection mode; temperature programmed from 50 to 325 °C at 10 °C/min with a 5 min interval and final temperature hold; Helium carrier gas flow rate at 1.0 ml/min, with the injector temperature set at 325 °C. Spectra were compared with purified standards prepared in this laboratory. Dichloromethane extracts of camelina seed powders and meals and egg powders were examined by this method and no detectable isothiocyanates were found.

Sensory Evaluation of Eggs

A panel of 28 untrained evaluators (11–68 years of age), who were blinded to treatment groups did sensory evaluation of eggs. All the tasters ate half of a hard-boiled egg, rinsed their pallet and then ate another egg sample. All three treatment groups were eaten in random order. Panelists were asked to rate the taste and aroma of the eggs.

Statistics

Data were analyzed as a one-way ANOVA with 3 treatments using SPSS [29]. Significant differences among treatment means were separated using Duncan's multiple range test at $P < 0.05$.

The fatty acid content of the individual egg samples was measured then these values were used to calculate the average content of fatty acid per sample group. The fatty acid data were analyzed by using one-way ANOVA and a Tukey's post hoc test.

Results

Production

The egg production rate was greater than 95% for all groups with no significant difference in percent hen-day egg production (Table 3). Feed consumed per production of dozen eggs was 1,521, 1,460 and 1,472 g for Control, 5% camelina and 10% camelina groups, respectively. There was no statistical significant difference for the feed consumption and body weight (Table 3). No mortality was observed in any of the treatment groups during the experimental period.

Egg Quality Characteristics

There was no significant difference in egg weight between the Control and 10% camelina groups, however a significant reduction in the egg weight was observed in the 5% camelina group eggs (Table 4). We found a significant difference in the shell strength of eggs among all the groups (Table 4). Egg shell strength was significantly lower for the Control group and higher for the 5% camelina group. Shell thickness for the eggs from 5% camelina group was significantly higher than that of the Control and the 10% camelina groups (Table 4). Overall, shell strength and shell thickness were higher in the 5% group relative to the Control group, whereas shell strength was higher and shell thickness was lower in 10% group relative to control group. There was no significant difference among the treatments in yolk color when analyzed by the Egg analyzerTM at time

Table 4 Effect of camelina meal in laying hen diets on egg characteristics

| | Egg weight (g) | Shell strength (Breaking force) (kg) | Shell thickness (mm) |
|--------------|---------------------|--------------------------------------|------------------------------|
| Control | 60 ± 4 ^a | 4.5 ± 1.0 ^a | 0.4019 ± 0.02 ^{a,b} |
| 5% Camelina | 58 ± 4 ^b | 5.0 ± 1.1 ^c | 0.4049 ± 0.02 ^a |
| 10% Camelina | 60 ± 5 ^a | 4.7 ± 1.1 ^b | 0.3997 ± 0.02 ^b |

± Standard deviation

^{a,b,c} Means with no common superscript in the same column differ significantly ($P < 0.05$)

zero, one week of cold storage and 2 weeks of cold storage at 4 °C (Data not shown). However, when analyzed for Haugh Unit and Grade, at time zero, eggs from the 5 and 10% camelina groups were graded better [AA] relative to the control eggs [A]. We found no significant difference in the grade when measured after 1 and 2 weeks of cold storage at 4 °C (Table 5).

Egg Fatty Acid Composition

Detailed fatty acid profile of the eggs from three treatment groups is outlined in Table 6. There was a significant increase in the total n-3 fatty acids in the eggs from the 5 and 10% camelina groups, as compared to the Control group. The ratio of n-6 to n-3 fatty acids was also significantly lower in the 10% camelina group (4.3), relative to the 5% camelina group (6.0) and the Control group (12.4). Eggs from the 10% camelina group had on average of 78 mg of DHA per yolk, as compared to 59 mg/yolk from the 5% camelina group and 32 mg/yolk from the Control group. There was a nearly threefold increase in deposition of ALA in the 10% camelina group eggs when compared to the Control group eggs. Cholesterol content of the yolk did not differ significantly between the 5 and 10% camelina groups compared to the Control eggs (data not shown).

Glucosinolate Levels

There were no detectable camelina-derived glucosinolates found in eggs.

Sensory Evaluation

No overt reactions were noted, i.e., facial expressions of poor tasting eggs or really bad tasting eggs, by the panelists. Two individuals noted that the 10% camelina group had a bit of a fishy taste.

Discussion

In this study, we evaluated the use of extruded defatted camelina meal as a protein source rich in n-3 fatty acids on

egg production and quality. In a previous study, when *Camelina sativa* seed oil is added at a level of 5% in laying hen diets, the n-3 fatty acid content of the eggs is increased [30]. Also, the functional properties and sensory quality of the eggs were not negatively affected by the 5% concentration of seed oil demonstrating that the camelina seed oil group scored better than the test group fed with flax seed oil diet [30]. This investigation suggests that *Camelina sativa* seed oil can increase n-3 fatty acid levels in eggs without imparting the same off flavor and odor as flax meal and oil. This is consistent with the results observed in this study.

Camelina meal as a potential feed ingredient in turkey diets at levels above 5% is not recommended as reduction in feed consumption occurs [7]. Feeding camelina meal at levels of 5 or 10% to broilers to enrich tissue n-3 fatty acid content, depresses feed intake and feed conversion ratio during starter phase (0–14 days) while camelina meal did not have any adverse effect on the sensory quality of the meat [31]. Camelina seed does not depress feed consumption at a levels up to 15% in rabbits [32]. Similarly, in our study there was no reduction in the percent hen day production, feed consumption or was there a reduction in hen body weight in the camelina meal fed groups. Because percent hen day egg production is an excellent indicator of health and well-being, the lack of change suggests that neither level of camelina meal had adverse effects on health.

Pekel et al. [33] reported that increasing levels of camelina meal in laying hen diets results in decreased feed consumption, egg production and body weight, however this effect was not observed when camelina meal is fed up to 9% between 22 and 34 weeks. In another report, feeding camelina meal to laying hens at concentrations of 5, 10, and 15% results in a reduction in hen-day egg production at the 15% concentration [34]. This group also reported that yolk weight expressed as a percentage of egg weight was lower for the 10 and 15% camelina groups, but albumin weight expressed as a percentage of egg weight, was higher for these same eggs. Herein, we report that feeding camelina meal up to 10% between 28 and 40 weeks and had no detrimental effects on performance parameters or on egg quality.

We observed a significant difference in the egg weight, shell thickness and shell strength in the 5% camelina group eggs relative to the control group. Our results of egg weight, shell thickness are in contrast to the other study [34], who reported no significant difference in egg weight or shell thickness. The observed reduction in egg weight, increased shell strength and shell thickness in 5% camelina group in the present study may be due to individual bird variation, unknown nutrient interactions or other unexplainable genetic factors because there was no strain difference in the birds used in this study.

As hypothesized, when camelina meal with approximately 12% residual oil is included in hen diets, there is a concomitant increase in total n-3 fatty acid composition from 0.32% in the control eggs to 2.54, 2.69 and 2.99% in 5, 10 and 15% camelina group eggs, respectively [34]. In our study, feeding camelina meal with residual oil content of 10% resulted in a total n-3 fatty acid composition of 2.5 and 3.7% in 5 and 10% camelina group eggs relative to the 1.1% of the control eggs. The net change in total n-3 fatty acids was not the result of a reduction in n-6 fatty acids (Table 6), indicating that inclusion of camelina meal in the diets provided adequate n-6 fatty acid intake. Similar to the other study [34], we also observed a net reduction in saturated fatty acids, but these changes all occurred in a manner that did not alter egg production or egg quality. Diets with moderate levels of ALA and high levels of LA produced increased deposition of DHA in the egg yolk, but not EPA [35]. In the study [35], authors suggested that the increased deposition of DHA may be due to the saturation of the different Δ -unsaturases depending on the level of dietary fat or due to impairment in the conversion of EPA to DHA. However, in the present study we also observed an accretion in the deposition of EPA, but to a very low extent compared to the deposition of DHA. This may be due to the specific action of desaturases to the different dietary source of fat or to the concentration of dietary fat.

Many studies were conducted to investigate the effects of n-3 rich dietary sources in laying hen diets. Using fish meal and fish oil in laying hen diets, both high in n-3 fatty acid content, produced n-3 enriched eggs [11–13, 36–38]. Similarly flax seed meal added to laying hen diets also increases the n-3 fatty acid content although is reported to impart a fishy odor in the egg [14–17]. Herein we propose that camelina meal is a better alternative to flax meal because it is a crop that is much less weather dependent, has more consistent yields, and is cheaper to produce [39]. Thus, camelina meal may offer a less expensive feed ingredient to enrich n-3 fatty acid content in eggs, compared to flax meal.

Addition of camelina meal to laying hen diets at a concentration of 5 and 10% didn't have any detrimental effects on feed consumption and egg production; and there were no detectable glucosinolates in eggs from either treatment groups. Isothiocyanates and nitrile forms are the metabolites of glucosinolates and these are the forms that could possibly have been accumulated in the eggs, but we found no indication of their presence.

Our results indicate that camelina meal can be added as an ingredient to laying hen diets as a source of energy, protein and n-3 fatty acids. Addition of mechanically pressed defatted camelina meal to laying hen diets up to a concentration of 10% did not have any detrimental effects on feed consumption, on hen body weight, on egg production, on

interior quality of eggs and on sensory quality of eggs, while producing n-3 fatty acid enriched eggs.

Acknowledgments This study was funded by Great Plain Oil and Exploration. Camelina meal used in this study was supplied by Great Plain Oil and Exploration.

Abstract Large population studies show that polyunsaturated fatty acids are important for human health, but determining relationships between the health benefits and the fatty acid content has been hampered by the unavailability of labor-effective high-throughput technologies. An automated high throughput fatty acid analysis was developed from a previous procedure based on direct transesterification including the automation of chemical procedures, data acquisition and automatic data processing. The method was validated and applied to umbilical cord serum samples in an epidemiological study. The method

was linear in the range of 1–600 µg/mL serum with $r^2 \geq 0.99$. The within-run CV was <5.4% for 23 fatty acids and a range of recoveries over three concentrations were 76–119% in a low-lipid matrix with the exception of 14:0. The fatty acid concentration as measured by the robotic method for human plasma was in good agreement with the Lepage & Roy method. The fatty acid profile in umbilical cord serum from American subjects ($n = 287$) showed an average of 38.0, 24.9, 32.0 and 4.6% of total fatty acids for saturates, monounsaturates, n-6 and n-3 polyunsaturates, respectively. This is the first report of a complete, validated, cost-effective, automated, high throughput fatty acid measurement method along with application to a population-based study. Automated fatty acid analysis coupled with automated data processing greatly facilitates the high throughput, 72 samples transesterified in 6 h, required for large population-based studies.

Introduction

The content of dietary polyunsaturated fatty acids (PUFA) has been notably associated with human health as reported in several epidemiological studies [1–6] over the past 10 years. In particular, inadequate n-3 PUFA have been implicated in suboptimal neural development [7], increased risk of cardiovascular disease [8], neurodegenerative diseases [9], psychiatric disorders [10], suboptimal IQ [2], as well as other public health related issues [11].

However, the dietary intake of PUFA was usually estimated using food frequency questionnaires [2] which can overestimate and/or underestimate food intake by 20% or more [12]. The relationships between health benefits and n-3 and n-6 PUFA intake and human blood fatty acid content are much needed. The development of the fingertip prick blood sampling [13] and microwave irradiation partial transesterification methodologies [14, 15] has greatly increased the potential for large scale screening of fatty acids in human blood. The further simplification of a one-step, direct transesterification method greatly increased the throughput of fatty acid assays for glycerophospholipids [16]. Nevertheless, the unavailability of automated methodology for labor-saving, high throughput, quantitative and cost-effective fatty acid analysis and the lack of automated data processing have limited the scope of complex n-6 and n-3 fatty acid related clinical studies.

Over the years, we have been developing several techniques to make large scale fatty acid analysis feasible, including a fast gas chromatographic (GC) method [17] and a basic robotic system for the transesterification procedure [18]. This study further developed the robotic procedure and robotic operating script into a working automated, high throughput method for 24 fatty acids in human plasma and serum, and created a Visual Basic Application (VBA) script to automate the data processing. Furthermore, we applied this automated, high throughput technology to umbilical cord sera as part of an epidemiological study.

Materials and Methods

Chemicals and Reagents

All chemicals were of analytical reagent grade and screened for interference with the baseline of chromatograms. Fatty acid standards were purchased from Nu-Chek Prep (Elysian, MN), including docosatrienoic ethyl ester

(22:3n-3) as internal standard (ISTD) and GC reference standard GLC-462 containing 28 fatty acid methyl esters (FAME) of equal weight. GLC-462 was used as the source of individual fatty acid standard in the quality control (QC) samples and validation experiments. Acetyl chloride (Category # 114189) and decane were purchased from Sigma-Aldrich (St. Louis, MO). Toluene and hexane were from EMD Chemicals Inc. (Gibbstown, NJ). Methanol and pentane were from Burdick & Jackson (Muskegon, MI). Stock solutions of standards were prepared in bulk (1–20×) with the addition of butylated hydroxytoluene (BHT, 25 µg/mL) as antioxidant, aliquoted and stored at –80 °C. All solvents were purchased commercially and used without further purification.

Low-Lipid Matrix

A low-lipid matrix was prepared from human serum. The serum lipids were removed using a method modified from Blix [19]; human serum was precipitated with pre-chilled acetone (1:6, by vol) while vortexing, and immediately centrifuged at 1,700g for 3 min at 4 °C. The supernatant fluid was saved and the precipitate was treated twice with the same volume of acetone at –20 °C for 30 min. The pooled precipitates were freeze dried overnight, and stored at –80 °C as a powder for further application in the subsequent experiments. The powder was termed a “low-lipid serum powder”. This powder was dissolved in 0.9% sodium chloride to form a matrix solution with a concentration of 30 mg/mL, containing 8.4% of the original total fatty acids of serum as determined by GC. This matrix solution was applied in QC samples and validation experiments. The supernatant collected as described above was dried under nitrogen, and the total lipid in dried residue was extracted using the Folch method [20]. An aliquot of the extracted total lipids was transesterified, stored at –80 °C and used as a GC reference standard (Ref-LMBB07) along with GLC-462 to identify the retention time of FAME on chromatograms from unknown samples.

Quality Control

Low-lipid matrix serum spiked with fatty acid standards at a low (20 µg of each fatty acid per mL sample), intermediate (100 µg) and high (300 µg) amounts served as QC samples. Reference samples were prepared from 200 mL human serum obtained from a single research blood donor in the Clinical Center of the National Institutes of Health, and then aliquoted and stored at –80 °C. They were measured in 47 replicates in one run, and also in single runs in 12 separated experiments to obtain the mean value of each significant fatty acid. This sample served as a reference sample to monitor the assay performance with a physiological level of fatty acids.

Instrumentation

Automation Liquid Handling System

A Freedom Evo Instrument 200 (TECAN Trading AG, Switzerland) was utilized for automated liquid handling for the transesterification of fatty acids and operated via EVOware® software (v2.0, SP1, Patch3). It is referred to as The Robot, and the configuration was as described in detail in a previous report [18]. In brief, the robotic system equipped with a liquid handling arm (LiHa) is placed in a customized fume hood meeting performance criteria described in NIH Design Requirements Manual Chapter 6, Sect. 6-1-00 D.7.d. The robot components are, in order from left to right, a wash station, carriers for disposal tips and samples, reaction blocks, solvent troughs, and GC vial station on a 2-m platform.

The optimal liquid handling parameters required to process each type of liquid, such as aspirate and dispense speeds, pump mechanics, the air gaps separated liquids, and the characteristics of liquids (viscosity, volume, conductivity) etc. were included in liquid class defined within the EVOware script. Each liquid class is identified by a generic name, such as Serum, Solution. In this assay, liquid classes were established for the blood sample and solutions involved during entire run. The liquid class named pressure monitored pipetting-Serum (PMP-Serum) was for sampling serum or plasma, which also included clot detection for possible clots in samples. PMP-Solutions A, B, C, D were for four types of solutions involved in various steps and their respective pipetting parameters. PMP-Extraction was for extracting FAME after direct transesterification through 25 repetitions of mixing by aspiration and dispensing. PMP-FAME was for transferring FAME from reaction test tubes to GC vials prior to being concentrated at 55 °C. The system received preventive maintenance twice a year by the manufacturer and daily maintenance by the trained staff. Robotic pipetting accuracy was calibrated by weighing the deionized water pipetted under the same conditions as those set up for each liquid class. A routine practice was that eight aliquots of solution A-Startup was retained and weighed periodically to verify the accuracy of the ISTD amount.

Gas Chromatography

Three fast gas chromatography (6890 Plus LAN) systems with flame ionization detectors (FID; Agilent Technologies, Inc.; Santa Clara, CA) coupled with customized fused-silica, narrow-bored high-efficiency DB-FFAP capillary columns (Agilent 127-32H2, 15 m × 0.1 mm ID × 0.1 µm film thickness) were employed for chromatographic separation and to acquire the signal of the FAME

as reported previously [17]. GC inlet: 250 °C (split ratio: 50:1), detector: FID (250 °C) with hydrogen 40 mL/min, air 450 mL/min. Carrier gas: hydrogen with pressure of 355 kPa. Make-up gas: nitrogen constant at 10 mL/min. Temperature program: initially 150 °C with a 0.25 min hold with ramp at 35 °C/min to 200 °C, further 8 °C/min to 225 °C with 3.2 min hold, and then 80 °C/min to 245 °C with a 9 min hold to bake off column. Twenty-four fatty acids were eluted in about 8 min in a total run of about 17 min. Typically, GC analyses were completed overnight or were run simultaneously with robotic derivatization for the next batch of samples.

With good sample preparation and chromatographic separation, all the identified peaks were auto-integrated using the ChemStation (B.01.01) built-in integrator. The threshold values for integration parameters, including baseline correction, slope sensitivity, peak width, area reject, height reject, etc. were selected so as to integrate all signals on one chromatogram simultaneously. The merged peaks, sharing the same baseline, were integrated using non-Gaussian calculation. Manual integration was applied for very small peaks where the peak area was <0.05 area unit.

Lepage and Roy Fatty Acids Analysis

One-step direct transesterification developed by Lepage and Roy [21] was applied as a reference fatty acid method. Briefly, 100 µL of plasma or serum were added to 16 × 100 mm disposable borosilicate glass tubes placed in ice containing 1.6 mL of methanol, 0.4 mL of hexane, and 200 µL of acetyl chloride. 10 µg of 22:3n-3 ethyl ester was used as ISTD. The test tubes were capped under nitrogen, heated at 100 °C for 60 min. Afterwards, the tubes were cooled on ice for 10 min and then neutralized by the addition of 5 mL of 6% of Na₂CO₃ solution followed by centrifugation at 1,700g for 4 min. The upper phase containing FAME was collected and the volume was reduced to ~30 µL. An aliquot of 1–3 µL was injected into the GC inlet.

Automatic High Throughput Fatty Acids Analysis

Automation of plasma or serum fatty acid analysis, referred to as the robotic fatty acid assay, was developed from a previous procedure [18] based on Lepage & Roy's direct transesterification in a one-step reaction [21]. The outline of the assay procedure for the current working method and the composition of the various solutions are presented in Fig. 1. The robotic operation script is supplied as Supplemental Material 1.

Solutions were freshly made, stored at room temperature within sealed containers and transferred to solvent troughs

PROCEDURES

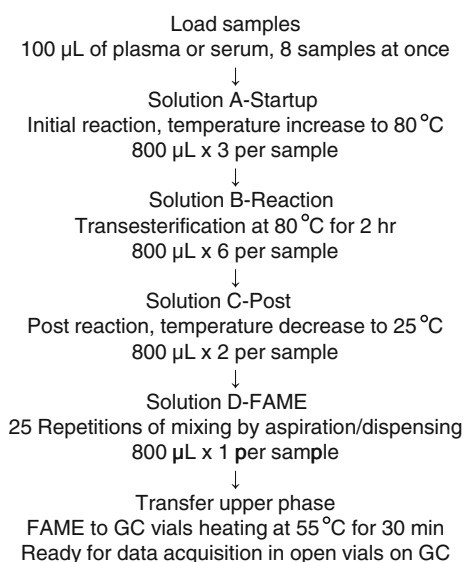

Fig. 1 Outline of the robotic fatty acid analysis procedure. The compositions of four solutions are as followed. A-Startup: methanol (BHT 25 µg/mL):toluene:acetyl chloride (2.0:0.3:0.1; by vol) containing ISTD; B-Reaction: methanol:toluene:acetyl chloride (4.1:0.6:0.1); C-Post:methanol:water (1.4:0.2); D-FAME: decane:pentane (0.08:0.72). FAME fatty acid methyl esters; GC gas chromatography; BHT butylated hydroxytoluene; ISTD internal standard

docked on the automation platform just before the start of the experiment. This guaranteed the accuracy of the concentrations of the ISTD and acetyl chloride. Acetyl chloride was added dropwise to prepare solutions at 0 °C with continuous stirring. Solutions A-Startup, B-Reaction, D-FAME were modified from Stock solutions in the previous procedure [18]. Solution C-Post (methanol:water, 7:1, by vol) was added for a complete reaction and as a key to balance the total reaction time among samples in various locations on the heating block. This also led to a better separation of upper decane/pentane phase containing FAME from the lower aqueous phase which made possible the transferring of the FAME solution to GC vials. BHT was applied as an antioxidant during open tube reactions and remained in the final FAME preparation.

Dissolved plasma or serum in containers was placed in sample carriers. Eight samples of 100 µL of plasma or serum were simultaneously loaded into 13 × 100 mm disposable borosilicate glass tubes preset in Reaction Heating Blocks, referred to as one set of samples. The transesterification reaction started after the addition of solution A-Startup followed by increasing the heating block temperature. The heating block was turned off prior to the addition of solution C-Post. The difference in reaction time between the first set of samples and the last was minimized. There is a maximal 1.6 min difference between

two adjacent sets ($n = 8$ per set) over a 3 h total reaction period. The entire experimental time for the robotic transesterification procedure was nearly independent of the number of samples analyzed, which was about 6 h for up to 72 samples.

Method Validation

The validation and quality control for laboratory robotic fatty acid assay were established in part to be consistent with the Bioanalytical Method Validation in Guidance for Industry by FDA [22] and Clinical Laboratory Improvement Amendments of 1988 [23]. Precision, stability, linearity, recovery and accuracy were examined as follows.

The within-run precision was determined by analysis of 24 fatty acids in 47 replicates of the reference sample. The between-run precision was from one reference sample in each of 12 independent experiments over a 3-month period. The linearity was evaluated by spiking a known amount of fatty acid standard in the low-lipid serum preparation at the concentrations of 1, 5, 10, 25, 50, 100, 200, 400, 600 µg/mL along with 10 µg of ISTD. The peak area ratios of fatty acid to ISTD were determined (endogenous fatty acid amounts from the low-lipid serum were subtracted) and plotted against the concentrations of the added fatty acid. Regression equations and coefficients were then generated. For a routine assay, a one point calibration was applied. The recovery was assessed by spiking a known amount of fatty acid at 20 (low), 100 (intermediate) and 300 µg/mL (high) into the low-lipid serum solution with eight replicates at each concentration. The accuracy was examined by comparing the repeated measurements of human plasma fatty acid concentrations determined by the robotic method ($n = 96$) with the Lepage & Roy method ($n = 16$). The stability of FAME preparations of serum was examined at 1, 2, 3, 8, 12, 18, 24, 30, 60, 90 days after transesterification of 16 reference samples.

In addition, the accuracy and precision for robotic pipetting were also calibrated according to the manufacturer's guidelines.

Epidemiological Study and Subjects

The samples were from the subjects recruited in the Tracking Health Related to Environmental Exposure (THREE) Study. This study was approved by Johns Hopkins University School of Medicine Institutional Review Board (Protocol # 04-04-22-02), reviewed under # NA_00028885 (June 02, 2009). Eligible subjects were singleton, live birth deliveries in the labor and delivery suite at the Johns Hopkins Hospital, Baltimore, Maryland area, during 26 November 2004 and 16 March 2005. Newborns with major congenital anomalies, or whose

mother either gave birth to multiple children, or delivered a single child with an initial twin gestation with fetal loss at ≥ 20 weeks were excluded. Trained clinical staff collected blood from the umbilical cord vein of newborns immediately following delivery. Blood was stored at 4 °C and within 3 h serum was separated by centrifuging at 1,000g for 15 min. Samples were centrifuged to obtain cord serum, aliquoted and stored at -80 °C. Frozen samples were then shipped on dry ice to NIH for fatty acid analysis. Of the 300 samples in the study, 287 had a sufficient quantity of serum to be analyzed for fatty acids. Samples were anonymized so that they could not be linked back to the subjects' identities. Further details regarding methods and population characteristics were reported in a previous publication [24].

Calculation and Automated Data Processing

All the experiments or data described were performed using the robotic method unless otherwise indicated in the text. Data were expressed as the mean concentration \pm standard deviation as μg of fatty acid per mL plasma or serum ($\mu\text{g/mL}$), or % of each fatty acid of the total weight of the identified fatty acids in each sample (wt%). The fatty acid concentrations in the plasma/serum were calculated by comparing the integrated areas of each fatty acid peak with that of a known amount of ISTD. The percent difference (%Diff) of two experimental values was calculated by dividing the absolute difference of the two values by the average of the two values. Linear regression was analyzed using Microsoft® Excel 2003 (Microsoft Corp.; Seattle, WA). The descriptive frequencies analyses were performed in SPSS 13.0 for Windows (SPSS Inc.; Chicago, IL).

The data processing was performed as follows; a calibration table was established providing the GC information for each fatty acid of interest in the reference sample, including peak retention time, signal abundance, integrated area, ISTD amount, etc. According to the number and starting location of the double bonds in the fatty acid carbon chain, a unique identification code was assigned to each fatty acid in the order of elution, as illustrated in Fig. 2a. The Agilent ChemStation software (B.01.01) applied this calibration table to identify fatty acids of interest in all samples in one offline or online sequence and generated a summary report in a text file for all data acquired for further calculation. The above summary reports were imported into an Excel spreadsheet. Fatty acid results were then automatically generated through macro programming (Supplemental Material 2) with Microsoft VBA 6.3 (Microsoft Corp; Seattle, WS), including both concentration ($\mu\text{g/mL}$) and the proportion of each fatty acid in total fatty acids (wt%).

Results

Robotic High Throughput Fatty Acid Assay Validation

Robotic Pipetting Accuracy and Precision

The calibration parameters offset and factor for the robotic disposal tips were applied to calibrate the net volume specified in the robot script, expressed as calibrated dilutor movement (actual volume) = (net volume \times factor) + offset. The factor for 100 μL is 1.0248, offset as 0; for 2.4 mL is 1.079 and 0. With the calibrated volume, for pipetting of a 100 μL sample, the within-run CV for eight tips was 0.4% with volume 99.9 ± 0.4 μL (mean \pm SD, $n = 5$ for each of eight tips); the between-run CV for five tips was 0.2%, volume ranging from 99.2 to 100.3 μL ($n = 5$). For pipetting 2.4 mL of Solution A, the intra CV was 0.1% with 2.407 ± 0.003 mL ($n = 6$); inter CV 0.4%, volume ranging 2.405–2.411 mL ($n = 6$).

Chromatographic Interference

Noise on the GC chromatograms was significantly reduced in the current robotic method (Fig. 2a) after having replaced the source of the acetyl chloride, the major contributor to the interference observed in Fig. 2b. The chromatogram between 1 and 2.7 min in panel 2a is flatter and has many fewer noise peaks than in panel 2b. The flatter baseline improved the accuracy of automated integration of peaks on one chromatogram and made it possible to automate data processing. In order to evaluate the introduction of extraneous peaks in the blank samples, extensive analyses were performed of all materials used (tubes, pipette tips, etc.), all reagents and solvents and robotic conditions (temperature, duration of reactions, etc.). It was determined that the acetyl chloride reagent was the source of the extraneous peaks and the issue was resolved by switching to a different reagent quality from the same supplier.

A custom, high efficiency capillary column with 10,000 theoretical plates (compared to 4,300 of a conventional column) gave good resolutions for the majority of fatty acid peaks after proper conditioning. The only partial peak co-elution noted were that of 16:1n-7 with an unidentified peak and 18:1n-9 with 18:1n-7, as presented in the insets to Fig. 2a.

Precision and Stability

Measurements of within-run precision indicated a CV $< 5.4\%$ for the concentrations of the measured fatty acids with the exception of 14:0 (14%) (Table 1). Measurements of between-run precision indicated an average CV of

Fig. 2 Gas chromatograms of fatty acid methyl esters from rat plasma using the robotic assay with: **a** newly selected reagents, **b** previously employed reagents. A unique code was assigned to each identified fatty acid. A00 series represent saturates, B00 series for monounsaturates, C00 series for n-6, D00 series for n-3, E00 series for n-9 polyunsaturates. A-i, A-ii, A-iii are insets for **a**. All identified

peaks were auto-integrated using an Agilent ChemStation (B.01.01) built-in integrator. Integration parameters setup was: 1 for slope sensitivity, 0.02 for peak width, 0.05 for area reject, 0.3 for height reject, baseline correction sets advanced, and shoulders set off. *FID*, flame ionization detector

$4.6 \pm 2.0\%$ ($n = 12$) for the wt% of all measured fatty acids (except 14:0, 22:0 and 20:2n-6). The CV values were largely independent of fatty acid concentration, which ranged from 1 to 552 $\mu\text{g/mL}$ serum. The stability of the resultant FAME preparation in decane over 90 days for PUFA and over 30 days for saturates and monounsaturates (stored at -80°C between injections) is presented in Table 1. It was noted that saturated fatty acids and some monounsaturates had decreased beyond 30 days after transmethylation possible due to evaporation during storage. The CV for PUFA concentrations over 90 days was

$2.3 \pm 0.8\%$ with the exception of 5.6% for 20:2n-6, a very small peak that was more difficult to integrate properly. Minimal changes in fatty acid concentrations over a period of 30 days indicate that samples do not have to be analyzed by GC immediately in the case of short-term delays caused by GC malfunction or processing delays.

Linearity

Within the concentration range of 1–600 $\mu\text{g/mL}$ of fatty acids, the r^2 for the calibration curves were >0.996 for

Table 1 Precision, stability and recovery in robotic fatty acid analyses

PUFA and 0.995 or greater for monounsaturated and saturated fatty acids with the exceptions of 14:0 and 16:0, which were 0.985 and 0.991. As plotted in Fig. 3, 20:4n-6 and 22:6n-3 are presented as the representatives of key PUFA along with examples of saturated (22:0) and monounsaturated (20:1n-9) fatty acids. The slope (*a*), intercept (*b*) and *r*² for the other fatty acids are presented in the same figure. The established calibration curves cover the expected fatty acid concentration range in unknown plasma/serum samples. A few samples with higher concentrations were diluted and re-assayed to increase accuracy.

Recovery and Accuracy

The recoveries ranged from 76 to 119% at low, medium, high concentrations for all fatty acids with the exception of 14:0 which had a low recovery rate (68%) at the high concentration. For PUFA, averages of 97.5 ± 6.4, 103.6 ± 4.8 and 95.9 ± 1.8% for low, intermediate, and high concentrations were observed, respectively (Table 1). The %Diff between the fatty acid concentrations in either decane or hexane was <2.5% (*n* = 5 per group) for 22 fatty acids with the exception of 14:0 (4.7%) (22:5n-6, not available).

Fig. 3 Linear ranges for the robotic fatty acid assay. The area ratios (fatty acid peak referenced to the internal standard) were plotted against the added fatty acid concentrations of 1, 5, 10, 25, 50, 100, 200, 400, 600 $\mu\text{g/mL}$. The regression lines, equations and r^2 of 20:1n-9 and 22:0 were presented in **a** as the examples for the monounsaturates and saturates; 20:4n-6 and 22:6n-3 in **b** are examples for n-6 and n-3 polyunsaturates, respectively. The parameters for the remaining fatty acids are listed alongside the plots. *a* and *b* indicate coefficients for $y = ax + b$. PUFA, polyunsaturated fatty acids

The fatty acid results from the accuracy assessment showed good agreement between the Lepage & Roy method and the robotic method except for some minor fatty acids, as presented in Table 2. The %Diff between lab bench analyses ($n = 16$) and robotic replicates ($n = 96$) was $<5\%$ for the mean values of total saturates, monounsaturates, n-6 highly unsaturated fatty acids (HUFA), n-3 HUFA and total fatty acids. %Diff was $<10\%$ for the majority of fatty acids with the exception of some minor fatty acids—22:0, 18:3n-6, 22:5n-6, 20:3n-9 (10–18%). The 20- and 22-carbon fatty acids with three or more double bonds are categorized as HUFA.

Fatty Acids Profile of Umbilical Cord Serum

The fatty acid profile of the umbilical cord serum from 287 human neonates, as presented in Table 3, had an average of 452 $\mu\text{g/mL}$ (range 272–802) for saturated fatty acids; 298 $\mu\text{g/mL}$ (149–613) for monounsaturated fatty acids; 380 $\mu\text{g/mL}$ (195–636) for n-6 PUFA; 54 $\mu\text{g/mL}$ (24–130)

for n-3 PUFA. These fatty acid classes accounted for 38.0, 24.9, 32.0 and 4.6%, respectively, of all fatty acids measured. Among the essential fatty acids (EFA), the major n-3 fatty acid, docosahexaenoic acid (DHA; 22:6n-3) was 47 $\mu\text{g/mL}$ (21–114), accounting for 4.0% of total fatty acids. Its precursor, 18:3n-3, was 1.8 $\mu\text{g/mL}$ (0.4–18.2) accounting for 0.15% of all fatty acids. The concentrations (in $\mu\text{g/mL}$) of 20:5n-3 was 1.7 and 22:5n-3 was 3.3. However, arachidonic acid (AA; 20:4n-6) averaged 176 $\mu\text{g/mL}$ (84–300), 15.0% of all fatty acids and its precursor, 18:2n-6, was 140 $\mu\text{g/mL}$ (54–390), accounting for 11.6% of all acids. The concentrations (in $\mu\text{g/mL}$) of 20:3n-6 was 33.9 and 22:5n-6 was 12.9. The frequencies of concentration for each PUFA are presented in Fig. 4 as histograms with their Gaussian curves. The percentage of n-3 fatty acids in total HUFA averaged $18.0 \pm 3.5\%$ with a range of 11.3–32.8%. In contrast, the % n-6 in HUFA was $79.7 \pm 3.1\%$ with the highest quintile as 83.5%, and the lowest at 74.9%. The ratio of 20:4n-6 to 20:3n-9 was significantly different between the upper (60.3) and lower (14.9) quintiles.

Table 2 Comparison of repeated measurements of human plasma fatty acid concentrations obtained by either the robotic or Lepage & Roy method

| Analytes | Lepage & Roy assay | | Robotic assay | | Difference (%) |
|-------------------|--------------------|--------|---------------|--------|----------------|
| | (n = 16) | CV (%) | (n = 96) | CV (%) | |

Data are expressed as means ± SD (μg/mL)

Plasma was obtained from a donor at the NIH Clinical Center; 100 μL was used for each assay

The percent difference was calculated by dividing the absolute difference of the two values from the Lepage & Roy and the robotic methods by the average of the two values

HUFA, highly unsaturated fatty acid, indicating 20C or 22C and ≥3 double bonds

Discussion

Here, for the first time, we demonstrated that a complete, validated, automated high throughput method for fatty acid analysis together with the utility of automated data processing can be applied to an observational epidemiology study as an initial step toward demonstrating utility in large population-based studies.

Robotic Fatty Acid Analysis Technical Development

One of the major challenges of this automation assay was to replace traditional vortex mixing in bench-top assays with repeated aspiration and dispensing of the mixture. Our current system had difficulties with repeated cycles of aspiration/dispensing as error messages were generated. This could be remedied by changing the tip but this was a

PUFA, polyunsaturated fatty acids

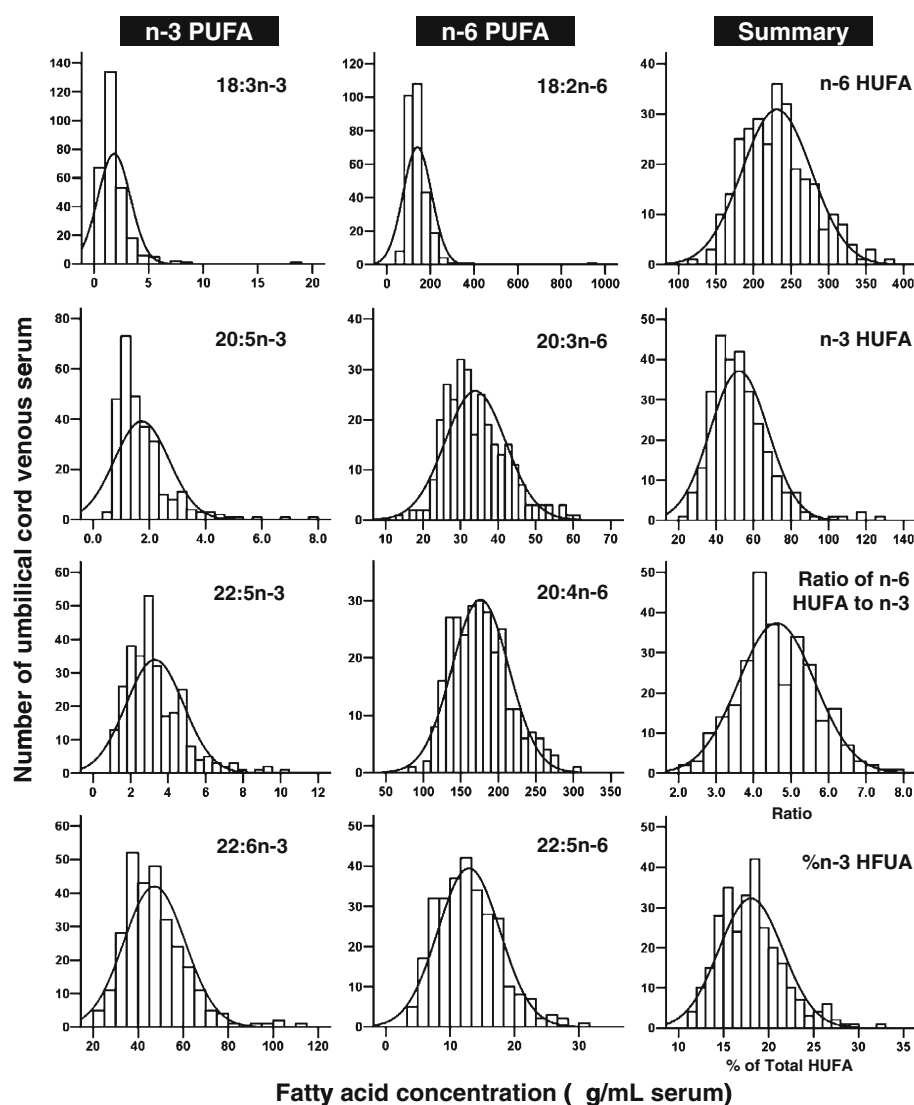

HUFA, highly unsaturated fatty acid, indicating 20C or 22C and ≥ 3 double bonds

slow and expensive solution. This issue was resolved by lowering the under-pressure limit default setting by over tenfold (from -400 to $-5,000$) during the repeated aspiration/dispensing cycle.

The pressure-based liquid level detection (pLLD) is configured for the liquid classes PMP-Serum and PMP-FAME. This detects the liquid surface through a change of

pressure in the air gap between the sample and the system liquid when the pipette tip enters or exits the liquid. One difficulty with our robotic system was that pipetting solution D led to solution dripping and an inaccurate transfer. The dripping could be prevented by pre-rinsing the tip. However, this created a malfunction in the pLLD procedure. This issue was resolved by adding a 5 s delay

Fig. 4 The frequency distribution of polyunsaturated fatty acids (PUFA) in umbilical cord serum ($n = 287$). The concentrations ($\mu\text{g/mL}$) or percentage of n-3 or n-6 in total highly unsaturated fatty acids (HUFA) was plotted as histograms with their normalized curves

following the pre-rinse, which allowed the recovery of pressure in the air gap and provided for normal pLLD.

Acetyl chloride was used as a catalyst for the transesterification with complete derivatization of non-esterified fatty acid, triacylglycerol, cholesterol ester, phospholipid, and sphingomyelin [21]. However, acetyl chloride generates HCl gas that corroded the robot mechanics and electronics. This corrosion was greatly reduced by several steps as follows: addition to two additional preventive maintenance procedures conducted by manufacturer, increasing the air flow of the fume hood enclosing the robot platform; wiping robotic mechanical parts with alcohol before and after assay; parking LiHa rest position near the ventilation exit; removing the used tips and solvent B-Reaction immediately after use. In the longer term, it would be desirable to find an alternative derivatization reagent that is less volatile and/or to significantly reduce the reaction time in the open tube.

Method Validation

A linearity with a regression fit with $r^2 \geq 0.99$ (Fig. 3) demonstrated that this method could be applied for the measurement of endogenous fatty acids in plasma/serum samples over a wide range of concentrations. Good agreement was observed for the fatty acid concentrations determined by the robotic assay compared to those by the reference method with %Diff <10% for the majority of fatty acids and $\leq 2\%$ for n-6 HUFA and n-3 HUFA except 22:5n-6 (Table 2). The much higher concentration for the very minor 22:1n-9 peak in the robotic assay was likely due to an error in peak identification in this specific experiment.

The within-run precision of <5.4% [with the exception of 14:0 (14%)] is well within the range of 1.1–7.9% obtained by GC/FID fatty acid analysis [25] and 4–14% by gas chromatography/mass spectrometry (GC/MS) fatty acid analysis [26]. A higher between-run CV compared to

the within-run was observed in this robotic method as 1.5–12% [with the exceptions of 14:0 and 20:2n-6 (16%)]. It was in comparable to that observed for GC/MS fatty acid analysis (7–17%) [26].

The validation of fatty acid recoveries in plasma samples is inherently difficult due to the widely varying concentrations of various fatty acids within a particular sample. For this reason, recovery experiments were performed at three different concentrations and a plasma matrix with a low lipid content was employed in order to make such an experiment possible. The recoveries thus obtained were comparable to those observed by Quehenberger [26] of 78–115% using a negative chemical ionization GC/MS approach.

Epidemiological Study

The distributions of the various PUFA and the fatty acid compositions were given for the umbilical cord venous serum samples in Fig. 4 and Table 3, respectively, from the Three Study conducted in Baltimore, Maryland. The average concentration of DHA in total lipids in umbilical cord serum was 47.3 ± 13.6 $\mu\text{g/mL}$ (mean \pm SD, $n = 287$) with a median of 45.5. It accounted for $4.0 \pm 0.9\%$ of the weight of total fatty acids. This is in the range of DHA concentrations observed in the umbilical cord plasma/serum total lipids as analyzed by various manually processed fatty acid methods: 40.7 $\mu\text{g/mL}$ ($n = 11$) in the study by Gil-Sanchez et al. [27], 49.9 ($n = 10$) by Lewis [28], and 65.5 $\mu\text{g/mL}$ ($n = 21$) in the study by Denkins [29]. Similarly, for AA, the average concentration was 176 ± 38 $\mu\text{g/mL}$ (15 ± 1.9 wt%) with a median of 174 (15 wt%) and this was again in the range between 79.3 [28] and 271 $\mu\text{g/mL}$ [29]. These values were comparable to those observed in other rather large studies of phospholipid DHA and AA content by Donahue et al. [30] and Kohlboeck [31] as they reported the values of 4.2% (DHA) and 15.5% (AA) in Project Viva ($n = 449$), 7.2% (DHA) and 18.0% (AA) in LISAPLUS Study ($n = 416$). However, both DHA and AA were higher in wt% than the values reported by Pankiewicz [32] of 2.8% DHA and 9.9% AA in total lipids ($n = 38$). The differences in DHA and AA contents are largely dependent on the dietary intake of PUFA among various populations studied and such variations are therefore expected.

Limitation

The robot capital cost, frequent maintenance and the requirement for operation by a well-trained chemist familiar with the operation of GC instruments as well as proficient with automated data calculation would be the major constraint for the establishment of this approach in an analytical laboratory. Multiple fast GC instruments coupled with high efficiency capillary columns are required

to accommodate the larger number of samples that are generated. Manual pipetting would be needed for samples with a very limited volume.

The GC/FID fatty acid assay is generally semi-quantitative since typically one or two internal standards are used for over 20 fatty acids which occur over a wide range of concentrations in a particular plasma sample. More rigorous quantitation may be achieved using a stable isotope labeled analog of a particular fatty acid as internal standard when coupled with GC/MS analysis [26]. In addition, other methodological improvements may also be included in the future. For example, automated sample tracking would speed up work flow, backflushing of the GC injector would serve to shorten the GC run time. The microwave irradiation could potentially reduce the heating and reaction times of transesterification and thus greatly increase the sample throughput and reduce the acid-induced mechanical damage to the robot arm. An automated solid phase extraction separation could be employed to generate fatty acid data for various lipid classes.

Present and Future Applications

In the present application, three fast GC instruments running overnight were needed to support the sample output from a single transesterified robotic system. A single well-trained analyst could operate the robot and GC systems as well as process the data in an automated fashion. The sample output from a typical week was 360 samples analyzed.

This robotic assay has been applied to the fatty acid analyses of 1,600 human sera from active-duty military personnel in a case-control study [33] and 9,581 blood samples from new-born infants and 7-year-old children in a large population study, the Avon Longitudinal Study of Parents and Children (ALSPAC) [34]. The integration of finger prick sampling, robotic derivatization and extraction, fast gas chromatography, and the automated data processing will greatly facilitate fatty acid research. Our present study provides a “proof of principle” that research scale laboratories can perform the thousands of assays per year necessary to support large scale population-based studies concerning the relationship of fatty acid composition to human health and disease.

Acknowledgments This research was supported, in part, by the Intramural Research Program of the National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health; and the National Oceanic and Atmospheric Administration. Thanks to Dr. Shui-Lin Niu for helping with the preparation of the low lipid serum, and Mr. Brian Brown for his assistance with manuscript editing.

Conflict of interest The authors declare that there are no conflicts of interest.

Abstract Basic aspects in the handling of fatty acid-data have remained largely underexposed. Of these, we aimed to address three statistical methodological issues, by quantitatively exemplifying their imminent confounding impact on analytical outcomes: (1) presenting results as relative percentages or absolute concentrations, (2) handling of missing/non-detectable values, and (3) using structural indices for data-reduction. Therefore, we reanalyzed an example dataset containing erythrocyte fatty acid-concentrations of 137 recurrently depressed patients and 73 controls. First, correlations between data presented as percentages and concentrations varied for different fatty acids, depending on their correlation with the total fatty acid-concentration. Second, multiple imputation of non-detects resulted in differences in significance compared to zero-substitution or omission of non-detects. Third, patients' chain length-, unsaturation-, and peroxidation-indices were significantly lower compared to controls, which corresponded with patterns interpreted from individual fatty acid tests. In conclusion, results from our example dataset show that statistical methodological choices can have a significant influence on outcomes of fatty acid analysis, which emphasizes the relevance of:

(1) hypothesis-based fatty acid-presentation (percentages or concentrations), (2) multiple imputation, preventing bias introduced by non-detects; and (3) the possibility of using (structural) indices, to delineate fatty acid-patterns thereby preventing multiple testing.

Keywords Multiple imputation · Non-detectable values · Undetectable · Peroxidation index (PI) · Unsaturation index (UI) · Chain length index · Eicosapentaenoic acid (EPA) · Docosahexaenoic acid (DHA) · Polyunsaturated fatty acids (PUFA) · Recurrent major depressive disorder

Introduction

Clinical fatty acid (FA)-research is becoming increasingly performed, but basic statistical methodological issues have remained largely underexposed in scientific literature thus far. We aim to address three of these issues in the handling of FA-data, and provide quantitative examples of their imminent confounding impact on results of FA-analyses, which may confuse the understanding of the roles FA play in (patho)physiology.

First, FA are reported in two ways: as absolute concentrations, or as percentages of the total FA-concentration. The implications of these different presentations have been scarcely addressed. Importantly, the few studies that have investigated this question showed significant differences between both approaches [1–3]. This is conceivable, because an increase in the percentage of one FA automatically results in the decrease in the relative percentage of another FA, even when its absolute concentration remains unchanged [4, 5]. Nevertheless, recent research still seems to opt rather randomly for either presentational method.

A second methodological issue is how to handle non-detectable FA-concentrations. In contrast to other research fields [6], FA-research thus far has not addressed this problem. Therefore, possible important analytical consequences remain uninvestigated, which may potentially cause biases in the interpretation of FA-data.

Third, because of the great number and variety of FA, the risk exists that multiple testing induces type-I errors, or the need for strict correction [7, 8]. A solution to this problem could be meaningful data-reduction, decreasing the number of tests needed. One possible way to achieve data-reduction might be the use of indices, delineating distinct FA-patterns by incorporating several FA-concentrations into one variable [9]. Examples of important patterns in FA-research are chain length, unsaturation, and peroxidizability of FA, because these characteristics modulate membrane fluidity and susceptibility to radical attack and are thereby conceivably involved in the pathogenesis of e.g. recurrent depression [10, 11]. Using indices, e.g. the unsaturation index (UI), chain length index (CLI) or peroxidation index (PI) [9], would allow testing of these more complex hypotheses on FA-patterns involving multiple FA, thereby obviating the need to interpret analyses of every individual FA to test your hypothesis. Thus far, most FA-research did not correct for multiple testing [7], and tested indices only in addition to the individual FA. This might potentially have resulted in type-I errors, and thereby bias in the interpretation of FA-analyses.

In this paper, the conceivable confounding effects of these three statistical methodological issues are examined, by providing quantitative examples in a practical research setting, using an example dataset of FA-concentrations of recurrently depressed patient and healthy controls, described previously [10]. This was done on the basis of the following research questions: (1) what is the influence of presentation of results in percentages or concentrations, and how does this differ for different FA, (2) what is the influence of the approach used for missing/non-detectable FA-concentrations on the significances of outcome differences; and (3) what is the influence of the use of indices for data-reduction on outcome differences?

Materials and Methods

To investigate our research questions, we reanalyzed an example dataset consisting of washed erythrocyte FA-concentrations (pmol/ 10^6 erythrocytes) from 137 recurrently depressed patients and 73 age- and sex-matched controls, determined by capillary gas chromatography, described in more detail previously [10, 12, 13].

Percentages or Concentrations

To investigate the effects of presentational method, we expressed FA-concentrations both in concentrations (pmol/ 10^6 erythrocytes) and molecular percentages (individual FA's concentrations divided by the total FA-concentration). Subsequently, to quantify the difference between the two presentational methods for each FA, we calculated the correlation between its presentation as a percentage or as a concentration using Pearson's r ($r_{\text{absolute-percentage}}$; Table 1). A $r_{\text{absolute-percentage}}$ of 1.00 (perfect correlation) indicates no difference between the two types of FA presentation, while a $r_{\text{absolute-percentage}}$ closer to zero indicates larger differences.

To learn how, for individual FA, presentation as concentrations or percentages results in differential biases, we investigated whether the difference between the two types of presentation (expressed as $r_{\text{absolute-percentage}}$) depended on individual FA-characteristics. Therefore, we performed a second-level analysis exploring the relation between characteristics of the different individual FA and their observed $r_{\text{absolute-percentage}}$. We first calculated each FA's mean concentration ($\text{mean}_{\text{FA}(i)}$; Table 1). Subsequently, for each FA, we calculated the absolute value (non-negative) of the correlation between the specific FA-concentration and the total FA-concentration for an individual subject ($|r|_{\text{FA}(i)\text{-concentration-FA-total}}$; Table 1). Finally, we determined the influence of these individual FA-characteristics ($\text{mean}_{\text{FA}(i)}$ and $|r|_{\text{FA}(i)\text{-concentration-FA-total}}$) by entering these in a stepwise linear regression model as predicting variables with $r(i)_{\text{absolute-percentage}}$ (after Fisher r -to- Z transformation [14]) as dependent variable.

Handling of Non-detectable Values

To examine the influence of the handling of non-detectable/missing values, we compared: (1) substituting non-detectable values with zero, and omitting missing values; (2) omitting both non-detectable and missing values; and (3) using multiple imputation (MI) to estimate both non-detectable and missing values, using the software package Amelia II [15]. Simulation research previously demonstrated that MI was able to provide highly valid estimations of non-measured values, while incorporating the uncertainty involved [6, 16]. MI has been used on missing FA-concentrations before [17, 18], but not on non-detectable FA-concentrations.

To impute non-detectable/missing values, we used information on sex, age, marital status, educational level, social class, Hamilton Depression Rating Scale score, weight, length, waist and hip circumference, smoking, and salivary cortisol and dehydroepiandrosterone sulphate, folic acid, vitamin B₆ and B₁₂, homocysteine, and all other

Table 1 Effects of method of presentation (percentages or concentrations) and handling of non-detectable/missing values on fatty acid (FA) results in example dataset of 137 recurrently depressed patients and 73 non-depressed controls

All correlations were calculated using Pearson's r

¹ Correlations between results presented in absolute concentrations (pmol/10⁶ erythrocytes) or relative percentages (FA_(i) concentration divided by the total FA-concentration). All correlations were significant with $P < 0.001$

² Mean concentrations (pmol/10⁶ erythrocytes)

³ Modulus of the correlation between mean FA_(i) concentration and total FA concentration

Differences in concentrations between patients and controls, calculated using independent Student's t tests, after: ⁴ substitution of non-detectable values with zero, ⁵ omission of non-detects, and ⁶ multiple imputation of missing and non-detectable values

Significant compared to controls with ⁷ $P < 0.001$, ⁸ $P < 0.01$, and ⁹ $P < 0.05$

measured FA-concentrations. In addition, for non-detectable values, we assigned range priors in Amelia II indicating that a non-detectable FA concentration must lie between 0.001 and the detection limit of that FA (99 % confidence).

We used differences in erythrocyte FA-concentrations between patients and controls as example outcomes, calculated with independent Student's t tests. We compared

the results of these different approaches to handle non-detectable/missing values to demonstrate their impact.

Calculation of Indices

To investigate the influence of the use of indices on outcome differences we compared two methods. First, we compared the 29 individual FA concentrations in our

example dataset between patients and controls using Student's t tests and a Bonferroni correction. We interpreted the outcome differences to detect patterns of differences in chain length, unsaturation or peroxidizability between patients and controls.

As an alternative to the interpretation of these multiple individual FA-tests, we applied data-reduction using indices, which we compared between patients and controls using Student's t tests. We selected three indices specifically designed to delineate patterns in chain length, unsaturation or peroxidizability.

1. The chain length index (CLI), providing information about FA-chain length. We calculated the CLI by adding the products of each FA's concentration and the number of carbon atoms in their carbon chain and dividing this with the total FA-concentration;
2. The unsaturation index (UI), indicating the number of double bonds per FA. Calculated as follows: $(1 \times \text{monoenics} + 2 \times \text{dienics} + 3 \times \text{trienics} + 4 \times \text{tetraenics} + 5 \times \text{pentaenics} + 6 \times \text{hexaenics}) / \text{total FA-concentration}$;
3. The peroxidation index (PI), showing FA's susceptibility to peroxidation. Calculated as follows: $(0.025 \times \text{monoenics} + 1 \times \text{dienics} + 2 \times \text{trienics} + 4 \times \text{tetraenics} + 6 \times \text{pentaenics} + 8 \times \text{hexaenics}) / \text{total FA-concentration}$.

Subsequently, we compared the results of these index tests to the patterns that emerged from the interpretation of the differences between patients and controls in the individual FA. For this, we compared the index test results to the individual FA-tests on multiply imputed data, and also constructed the indices from imputed data. In this way, we prevented missing values in the original dataset causing many missing values among the indices, which would have reduced statistical power.

Statistical Software

We used PASW statistics 18.0 (SPSS, Inc., 2009, Chicago, IL, USA). MI was performed using Amelia II [15], available via the R software package [19].

Results

Correlation between Percentages and Concentrations

Table 1 shows the difference between percentages and concentrations (expressed as $r_{\text{absolute-percentage}}$) for each FA. Correlations ranged from 0.30 for 18:0 to 1.00 for 16:1n-9.

In the second-level analysis, linear regression showed that $\text{mean}_{\text{FA}(i)}$ was associated with $r(i)_{\text{absolute-percentage}}$

($\beta = -0.685$; $t_{(207)} = -4.882$; $P < 0.001$). This indicates that results presented in percentages or concentrations differed more for FA with higher concentrations.

Furthermore, when $|r|_{\text{FA-concentration-FA-total}}$ was also included in the regression model, it had an independent negative influence on $r_{\text{absolute-percentage}}$ ($\beta = -0.824$; $t_{(207)} = -5.486$; $P < 0.001$; Fig. 1). The influence of $\text{mean}_{\text{FA}(i)}$ on $r_{\text{absolute-percentage}}$ was no longer significant. This indicates that differences between results presented in percentages and concentrations were significantly greater for those FA that have a stronger correlation with the total FA-concentration, and that this influence explained the effect of high FA concentrations on differences between results presented in percentages or concentrations.

Handling of Non-detectable Values

In our example dataset, 21 patients and 8 controls had missing FA-results due to technical reasons. The non-detectable percentage ranged from 0 % for 16:0-24:0, 22:5n-3, 22:6n-3, C18:2n-6, 20:3n-6, 22:4n-6, 22:5n-6, 18:1n-7, 18:1n-9 and 24:1n-9, to 60.5 % for 22:2n-6. The mean non-detectable percentage was 11.1 %.

The impact of different methods to handle missing/non-detectable values on example outcomes are demonstrated in Table 1. Compared to results obtained after MI, substitution of non-detectable values with zero resulted in

Fig. 1 Second level analysis stepwise partial regression plot of the relationship between $|r|_{\text{FA-concentration to FA-total}}$ [the absolute (non-negative) value of the correlation between the FA-concentration and total FA concentration for an individual subject] with $r(i)_{\text{absolute-percentage}}$ [the correlation between the presentation of a FA as a percentage or as a concentration calculated using Pearson's r (as an indicator of the difference between the two presentational methods)] after Fisher r -to- Z transformation in an example dataset of 29 FA concentration of 137 recurrently depressed patients and 73 healthy controls. Lines represent linear fit and 95 % CI. FA fatty acid, UI unsaturation index, CLI chain length index, PI peroxidation index, MI multiple imputation

different significance-levels for comparisons between patients and controls. Using zero substitution, the difference between patients and controls in 20:5n-3 was not significant, and differences in 20:3n-6 and 16:1n-9 were less significant. Other FA results were comparable, with lower concentrations for FA with non-detectable values, reflecting the expected bias toward zero.

When non-detectable values were omitted and not used in the analyses, the differences between patients and controls in 18:4n-3, 20:5n-3, 18:3n-6, 20:3n-6 were less or no longer significant, while significant differences in 20:1n-7 and 22:1n-9 emerged and differences in 22:2n-6 could not be tested, all compared to results obtained after MI.

Using Indices to Describe FA Patterns

The tests on the 29 individual FA after multiple imputation are listed in the right columns of Table 1. First, a Bonferroni correction for multiple comparisons was performed resulting in a corrected α of $0.05/29 = 0.0017$. After this correction, differences between patients and controls for 20:5n-3, 20:3n-6, 16:1n-7 and 16:0 were no longer significant. Other differences remained significant, with lower concentrations in patients for 22:5n-3, 22:6n-3, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, 14:1n-5, 16:1n-9, 24:1n-9, 20:0, 22:0 and 24:0. Concentrations of 18:4n-3, 18:3n-6, 22:2n-6, 16:1n-7, and 16:0 were higher in patients compared to controls. In analogy to our previous interpretations [10], these results fitted with patterns of reduced chain length, unsaturation and peroxidation for FA of the patients.

After data-reduction using the CLI, UI, and PI, differences between patients and controls were calculated (Table 2). The mean FA values for patients were less unsaturated ($P \sim 1.2 \times 10^{-18}$; Cohen's $d = 2.35$), shorter ($P \sim 7.1 \times 10^{-19}$; Cohen's $d = 1.46$), and less peroxidizable ($P \sim 4.0 \times 10^{-15}$; Cohen's $d = 1.83$).

When comparing the index results to the results of the multiple individual FA-tests, pattern outcomes were similar, with reduced chain length, unsaturation and peroxidation for FA of patients. Using indices resulted in fewer tests, but provided no information on differences in individual FA concentrations between patients and controls.

Discussion

Our results indicate that: (1) presentation of FA in either percentages or concentrations yields different results, particularly for those FA with a stronger correlation with the total FA-concentration, (2) differences in the approach used for non-detectable/missing values influence significance-levels of outcomes of FA-analysis, and (3) the use of the CLI, UI and PI showed differences between patients and controls in FA-patterns, in agreement with interpretations from individual FA-tests.

Differences between data presented in concentrations and percentages imply that these methods are not simply interchangeable. Moreover, differences between percentages and concentrations depended on individual FA-characteristics ($|r|_{\text{FA-concentration to FA-total}}$). This dependency could inflict differential biases in individual FA results. Therefore, our findings emphasize the importance of a hypothesis driven choice of which method to use. Percentages could be used as a measure of the relative importance of a FA set against the total FA concentration; while absolute concentrations could be used for the measurement of a FA itself, independent of the concentration of other FA [3–5, 20].

The appropriate method of presentation could theoretically differ for each research question [21]. For example, concentrations could be most useful to distinguish depressed patients from controls, while percentages might predict disease progression. Therefore, the appropriate presentation method may depend upon which presentation is more (patho)physiologically to the research question under investigation. However, the dearth of research comparing both approaches so far, may—at present—hamper the formation of a hypothesis about which method be more (patho)physiologically relevant. If so, comparison of both methods of presentation could provide a guideline for future research.

Our results show that the way non-detectable/missing values are handled could potentially bias results, because significance levels of differences in example outcomes differed depending on which method was used. However, it should be noted that not only significances of differences, but also magnitudes of differences determine the bias

Table 2 Mean chain length, unsaturation and peroxidation indices compared between recurrently depressed patients and controls

| | Patients | SEM | Controls | SEM | <i>t</i> | df | <i>P</i> value |
|--------------------|----------|--------|----------|--------|----------|-------|----------------------------|
| Chain length index | 18.32 | 0.0181 | 18.55 | 0.0119 | 10.96 | 226.5 | $\sim 7.1 \times 10^{-19}$ |
| Unsaturation index | 1.29 | 0.0068 | 1.39 | 0.0059 | 11.14 | 90.21 | $\sim 1.2 \times 10^{-18}$ |
| Peroxidation index | 1.10 | 0.0093 | 1.22 | 0.0090 | 9.241 | 101.5 | $\sim 4.0 \times 10^{-15}$ |

All differences were calculated using independent Student's *t* test on indices of 137 recurrently depressed patients and 73 controls

SEM standard error of the mean, *df* degrees of freedom

introduced. Nevertheless, if non-detects occur, knowledge of the way they were handled, and discussion of any possible bias that may be inflicted as such, could prevent interpretation errors. Because other research fields already showed superiority of MI compared to other ways of handling non-detectable/missing values [6], this may soon be adapted as the preferred method to handle missing/non-detectable FA-concentrations as well.

By applying data reduction using indices—the CLI, UI and PI—we tested differences between patients and controls in FA-patterns. Index results were similar to the interpretation of the multiple tests on individual FA [10]. This suggests that indices could provide meaningful data-reduction in FA research. Furthermore, from a statistical viewpoint, the use of indices enabled us to test pattern hypotheses more efficiently by using only one outcome variable (CLI, UI or PI), instead of tests of many individual FA. This precluded the need for correction for multiple tests. In our example dataset this was not of specific analytical concern, because differences in individual FA-tests were large and mostly survived the Bonferroni correction. Nevertheless, this advantage may be beneficial in smaller samples or in diseased populations with smaller differences compared with controls. In addition, the indices facilitated quantitative testing of pattern hypotheses, in contrast to the qualitative interpretation of the individual FA tests. The disadvantage of integrating information on multiple FA-concentrations in one index, could be that it might undesirably simplify the underlying complexity of FA-metabolism. In such situations the relevance of an individual FA could be obscured, because differences in individual FA are not tested.

Whether indices should be used in FA-research seems to depend on the hypothesis under investigation. If FA are analyzed in order to test a pattern [e.g. membrane fluidity; unsaturation or peroxidizability; estimated enzyme activity; (inflammation regulating) FA ratios], indices could be used to first test this general pattern hypothesis. Subsequently, based on the index results, new specific hypotheses concerning selected individual FA could be tested. This would reduce the risk for type-I errors, or the need for strict correction for multiple testing [8]. A recent example of the possible usefulness of applying indices is the observation of bimodal distributions of FA unsaturation and chain length patterns in recurrently depressed patients [22]. However, if FA are analyzed to test a hypothesis concerning a specific FA (e.g. EPA), indices have no use, and should not be tested additionally since this would only increase the problem of multiple testing. Future studies are needed to further clarify the applicability of indices in FA-research.

Some additional limitations should be noted. The examples of the possible influences of the presented statistical methodological issues have been presented on the

basis of only one dataset. However, although the size of the biasing effects may differ between different datasets, the basic principles of the issues addressed concern analysis of FA data in general. Second, our example dataset has a moderate sample size when compared to epidemiological studies. This could have influenced the stability of correlation coefficients, and therefore the results. Third, the data presented only concern these three statistical methodological issues, and do not investigate other important factors that may also influence results, e.g. chemical analytical methods, and the nature of the sample (tissue, cell type, lipid fraction, e.g. cholesteryl esters, triacylglycerol, phospholipids) [4]. Finally, because differences in outcome measures were large in our example dataset, the disadvantages of multiple testing—and thereby the advantages of data reduction—could not be clearly exemplified and remain to be further explored in different datasets.

Nevertheless, our study addresses recurrent basic issues in practical FA research. Using a second-level analysis we were able to quantitatively demonstrate the consequences of the various methods of presentation. In addition, we suggested a novel way to handle non-detectable FA-values, using MI. Finally, we showed, to our knowledge for the first time, that indices could be used to delineate differences in FA patterns between depressed patients and controls.

In conclusion, a hypothesis-based choice of the method of FA-presentation (percentages or concentrations) could prevent bias in future FA-research. If it is not clear which method is preferable a priori, comparison of both methods could guide subsequent investigations. Furthermore, MI might prevent bias potentially inducible by missing/non-detectable values. Finally, indices could assist theory based data-reduction, thereby preventing type-I errors associated with multiple testing. Awareness and cautious handling of these statistical methodological issues in future FA-research may further improve interpretation of FA-analyses, and thereby deepen the understanding of the roles FA play in health and disease.

Abstract A large proportion of the Chinese population is now at risk of non-alcoholic fatty liver disease (NAFLD). We aimed to investigate the relationship between plasma phospholipids (PL) fatty acids and the risk of NAFLD. One hundred NAFLD patients and 100 healthy subjects were recruited in Hangzhou, China. Plasma PL and selected biochemical and hematological parameters were analyzed by using standard methods. Stepwise logistic regression was used to identify independent risk factors of NAFLD. Plasma PL total saturated fatty acid (SFA), C20:3n-6, serum alanine aminotransferase, high-density lipoprotein cholesterol, and body mass index were independent risk factors of NAFLD. The risk of NAFLD was significantly increased with higher quartiles of plasma PL total SFA (P for trend = 0.028) and C20:3n-6 (P for trend <0.001); plasma PL docosahexaenoic acid (C22:6n-3) was significantly lower in NAFLD patients than in controls (P = 0.032) and the OR of NAFLD in the highest quartile of C22:6n-3 was 0.41 (95 % CI = 0.17–0.97) compared with the lowest quartile. In conclusion, plasma PL total SFA and C20:3n-6 are positively correlated with the risk of NAFLD, while C22:6n-3 is negatively correlated with the risk of NAFLD.

Introduction

Non-alcoholic fatty liver disease (NAFLD) is a liver disorder characterized by fatty changes of the liver with no apparent history of habitual alcohol intake and is recognized as one of the most common forms of liver diseases [1]. NAFLD encompasses a spectrum of liver disorders

characterized by macrovesicular hepatic fat accumulation (simple steatosis) or accompanied by signs of hepatocyte injury, mixed inflammatory cell infiltrate, and variable hepatic fibrosis in pericellular distribution (non-alcoholic steatohepatitis, NASH) [2, 3]. NAFLD is associated with obesity, type 2 diabetes mellitus, cardiovascular diseases and insulin resistance [4–6], and is therefore considered as the hepatic manifestation of the metabolic syndrome (MS) [7, 8]. The prevalence of NAFLD ranges from 20 to 30 % of the general population in North America, and NAFLD was once assumed to be mainly confined to Western countries [1]. However, the prevalence of NAFLD in China and Japan has nearly doubled in the past two decades [9]. A large proportion of the Chinese population is now at risk of developing NAFLD as the prevalence of obesity, type 2 diabetes mellitus, dyslipidemia, hypertension and MS in China is steadily increasing [9, 10].

Dietary fat and fatty acids regulate hepatic lipid metabolism by modifying gene transcription and might play an important role in people with NAFLD [11]. Dietary saturated fatty acid (SFA) was reported to be positively correlated with NAFLD [12] and dietary n-3 polyunsaturated fatty acids (PUFA) were negatively correlated with NAFLD [13, 14]. Randomized controlled trials [15, 16] showed beneficial effect of n-3 PUFA supplementation on NAFLD. Plasma PL total n-3 PUFA was inversely associated with insulin resistance and MS in the Chinese population [17, 18]. However, the relationship of PL fatty acids with NAFLD in Chinese population is still unclear.

The aim of this study was to investigate the association between plasma PL fatty acids and the risk of NAFLD in a Chinese population in Hangzhou.

Materials and Methods

Subjects and Study Design

The study protocol was approved by the Ethics Committee, College of Biosystem Engineering and Food Science, Zhejiang University, China, and written consent was provided by all the subjects prior to the study.

All the subjects with NAFLD were recruited from Zhejiang Hospital for a health check program during the period of April 2006 to December 2006. The determination of NAFLD was according to the definition of Chinese Liver Disease Association, and the NAFLD was diagnosed when meeting the first five criteria and either the sixth or seventh criterion: (1) those with no alcohol consumption or alcohol consumption <140 g/week for men and <70 g/week for women [19]; (2) those without certain diseases, such as viral hepatitis and drug induced liver disease, which would lead to fatty liver disease; (3) Except for

clinical manifestation of primary disease, nonspecific symptoms such as debilitation, dyspepsia, dull pain in liver and hepatosplenomegaly were allowed; (4) components of metabolic syndrome such as overweight, central obesity, high fasting blood glucose, dyslipidemia and high blood pressure were allowed; (5) Serum transaminase and gamma-glutamyl transferase (GGT) could be moderately increased (less than fivefold), which mainly referred to the increase in alanine aminotransferase (ALT); (6) liver imaging conforming to the imaging diagnosis criteria of diffuse fatty liver; (7) liver biopsy conforming to the histopathological diagnosis criteria of fatty liver. Finally a total of 100 subjects with NAFLD were included and 100 healthy subjects were randomly enrolled as controls. The exclusion criteria of all the NAFLD patients and controls were: (1) those with alcohol consumption ≥ 140 g/week for men and ≥ 70 g/week for women; (2) those with a history of renal disease, cardiovascular disease, diabetes, thyroid disorder and other endocrine diseases; (3) use of weight loss or lipid-lowering medications.

All the enrolled subjects underwent anthropometric measurements including height, body weight and body mass index (BMI) by an interviewer.

Blood Collection

Subjects arrived at the Zhejiang Hospital in the morning following an overnight fast and relaxed for 10 min. Blood pressure was then measured and 10-mL venous blood samples were taken in plain and EDTA vacuum tubes with 20-gauge needles. Serum and plasma were obtained and stored at -20°C for laboratory analysis.

Laboratory Measurements

Plasma lipids, glucose, serum uric acid, creatinine, blood urea nitrogen (BUN), total bilirubin (TBil), indirect bilirubin (IBil), direct bilirubin (DBil), albumin, immunoglobulin, total protein, ALT, GGT, alkaline phosphatase (ALP) were determined on an autoanalyzer (Olympus AU2700, Tokyo, Japan), via commercially available kits (Olympus). The total lipid content of plasma was extracted with chloroform:methanol (1:1, by vol), and the plasma PL fraction was separated from the total lipids by thin-layer chromatography. The methyl esters of plasma PL fatty acids were prepared by saponification with potassium hydroxide (0.68 mol/L in methanol), which was followed by transesterification with boron trifluoride in methanol [20]. Gas–liquid chromatography was used to separate fatty acid methyl esters as described previously [20].

Definition of MS was according to Fan et al. [2], and the diagnosis of the MS was made when three or more of the following criteria were met: (1) obesity, as BMI ≥ 25 ; (2)

high blood pressure, as blood pressure $\geq 130/85$ mmHg; (3) low high-density lipoprotein-cholesterol (HDL-C), as HDL-C < 1.03 mmol/L for men and HDL-C < 1.29 mmol/L for women; (4) High triacylglycerol (TG), as TG ≥ 1.7 mmol/L; (5) high glucose, as fasting plasma glucose ≥ 6.1 mmol/L.

Statistical Analyses

Continuous variables were presented as means \pm SD. The Kolmogorov–Smirnov test was used to examine the normal distribution of continuous variables. In addition, an independent samples *t* test (for normally distributed variables) or Mann–Whitney *U* test (for non-parametric tests were required) was performed. The Chi-square test was used to compare categorical variables.

Stepwise multivariate logistic regression analysis was used to investigate the independent risk factors associated with risk of NAFLD using the variables which is significant in the univariate analyses, and a total of 20 variables were chosen. Age was introduced into the model as a potential confounder. Glucose, GGT, and TG showed severely skewed distributions and were log-transformed for the logistic regression. To examine the distinctions between NAFLD and MS and their association with plasma PL fatty acids, both the risks of MS and NAFLD according to different quartiles of plasma PL fatty acids (SFA, C20:3n-6, C22:6n-3) were analyzed using a logistical regression model, adjusting for age and gender. Statistical analyses were conducted using SAS for Windows, version 9.1 (SAS Institute). $P < 0.05$ (2-tailed test) was considered statistically significant.

Results

Subject Characteristics and Univariate Analysis

All the subjects enrolled were from the Chinese Han population between 26 and 76 years. As shown in Table 1, there were 100 subjects (85 % male, mean age 44.97 ± 11.27) with NAFLD included in this case–control study, and another 100 subjects (53 % male, mean age 43.37 ± 12.24) were chosen as healthy controls.

The following were significantly higher in the NAFLD group for BMI ($P < 0.001$), total cholesterol (TC, $P = 0.018$), TG ($P < 0.001$), glucose ($P = 0.012$), uric acid ($P < 0.001$), systolic blood pressure (SBP, $P < 0.001$), diastolic blood pressure (DBP, $P = 0.002$), GGT ($P < 0.001$), ALT ($P < 0.001$), ALP ($P = 0.017$), DBil ($P = 0.05$) and creatinine ($P = 0.028$) concentrations, and significantly lower in NAFLD group for high-density lipoprotein cholesterol concentration (HDL-C, $P < 0.001$) compared with the control group. For plasma PL fatty acids (Table 2),

compositions of total SFA ($P = 0.001$) and C20:3n-6 ($P < 0.001$) were significantly higher in NAFLD group than in control group; and docosahexaenoic acid (DHA, C22:6n-3) ($P = 0.032$), C18:1n-7 ($P < 0.001$) and delta-5 desaturase activity (C20:4n-6/C20:3n-6) ($P < 0.001$) in NAFLD group was significantly lower than in the control group.

Multivariate Analysis

Stepwise logistic regression revealed five independent risk factors of NAFLD. The odds ratios (OR) for BMI, ALT, and HDL-C were 1.56 (95 % CI = 1.28–1.90), 1.05 (95 % CI = 1.02–1.09) and 0.05 (95 % CI = 0.01–0.24) respectively. Plasma PL C20:3n-6 (OR = 2.31, 95 % CI = 1.26–4.23) and total SFA (OR = 1.44, 95 % CI = 1.11–1.88) were also risk factors of NAFLD in this study.

Multivariate adjusted analyses (Table 3) showed that the risk of NAFLD was significantly increased with higher tertiles of BMI (P for trend < 0.001) and ALT (P for trend = 0.008), while the risk of NAFLD was lower when HDL-C increased (P for trend = 0.012). For plasma PL fatty acids, age and gender adjusted ORs of NAFLD were increased with higher quartiles of SFA (Fig. 1, P for trend = 0.028) and C20:3n-6 (Fig. 2, P for trend < 0.001). And the OR of NAFLD was 0.41 (95 % CI = 0.17–0.97) for the highest quartile of C22:6n-3 compared with the lowest quartile (Fig. 3).

MS and NAFLD

The prevalence rates of MS and MS components were all significantly higher in the NAFLD group than in the control group (Fig. 4). Age and gender adjusted OR of NAFLD was 17.47 (95 % CI = 4.84–63.04) for MS, 2.10 (95 % CI = 1.00–4.36) for high blood pressure, 4.00 (95 % CI = 2.05–7.80) for high TG, 3.30 (95 % CI = 1.60–6.83) for low HDL-C, and 6.70 (95 % CI = 3.26–13.79) for high BMI (Fig. 5). Multivariate adjusted analyses indicated that OR of MS by quartiles of PL SFA and C22:6n-3 was not significant (P for trend = 0.107 and 0.091, respectively) (data not shown), but for PL C20:3n-6, it was significant (P for trend = 0.028) (data not shown).

Discussion

Epidemiological and dietary intervention studies have shown that the fatty acid profiles of platelet and plasma/serum PL reflected an individual's type of dietary fat intake [21, 22]. This study revealed that plasma PL total SFA and C20:3n-6 were positively correlated with the risk of NAFLD. High plasma PL C22:6n-3 was negatively correlated with the risk of NAFLD.

Table 1 Comparison of clinical and biochemical characteristics in subjects with and without non-alcoholic fatty liver disease (NAFLD)

| Variables | Subjects with NAFLD (<i>n</i> = 100) | Subjects without NAFLD (<i>n</i> = 100) | <i>P</i> value |

Dietary SFA intake has a great impact on the development of both raised plasma low-density lipoprotein cholesterol (LDL-C) levels and the genesis of NAFLD [23, 24], and it was demonstrated that increased plasma LDL-C by SFA was mainly attributed to reduced hepatic clearance of LDL [24, 25]. Further, increased plasma cholesterol by a high intake of SFA may be a result of down-regulation of hepatic LDL receptor expression, especially through the modulation of activity of SREBP2 gene expression [26]. Previous studies have reported that SFA or percent dietary fat intake was significantly higher for NAFLD than controls [8, 12]; the present study was consistent with previous results [12] and indicated that plasma PL total SFA composition was significantly higher in NAFLD group compared with healthy control group, and also an independent risk factor of NAFLD in the Chinese population. The risk of NAFLD decreased in the quartile 4 compared with quartile 3;

it might be that the sample size is not large enough to get a linear association between SFA and NAFLD risk; however the *P* value for trend was still significant.

N-3 PUFA could stimulate peroxisome proliferator-activated receptor- α activity, which could lead to an increase in TG transportation from hepatocytes; and hepatic lipogenesis could also be inhibited by n-3 PUFA through down-regulation of SREBP1 expression [27]. Results from observational studies [14, 28] and randomized controlled trials [15, 16, 29] also supported that n-3 PUFA may be preventive nutrients for NAFLD. Our results supported that high plasma PL n-3 PUFA (C22:6n-3) was inversely associated with NAFLD risk.

In contrast to n-3 PUFA, PL n-6 PUFA (C20:3n-6) in this study was an independent risk factor of NAFLD. Decrease of delta-5 desaturase activity in subjects with NAFLD might contribute to the increase of C20:3n-6 in the

present study. Araya et al. [30] reported a marked increase of n-6/n-3 PUFA in the liver of NAFLD patients, and liver PL 20:4n-6 and total long-chain n-6 PUFA were also significantly higher in NAFLD patients than controls. The positive relation between n-6 PUFA and NAFLD was not surprising as n-6 PUFA was reported to be inversely associated with insulin sensitivity [17], and subjects with MS also had significantly higher n-6 PUFA concentration [18]. And both insulin sensitivity and MS are closely related with NAFLD [4, 31]. Further, unbalanced intake of n-6 and n-3 PUFA, which contributed to enhancement of tissue n-6/n-3 PUFA, may inhibit fatty acid from oxidation and secretion and leading to the storage of TG, and then hepatic steatosis [30].

Puri et al. [32] reported that compared with lean normal controls, non-alcoholic fatty liver (NAFL) and NASH subjects had significantly higher plasma C16:1n-7, C18:1n-9, C18:3n-6 and C20:3n-6 contents; plasma C22:5n-3 was also significantly higher in NAFLD subjects compared with controls. However, only C20:3n-6 was found to be significantly higher in NAFLD subjects compared with controls in the present study. It might be that the degree of NAFLD in the present study was different from the previous one; further, different genetic backgrounds of participants may also contribute to the different results in the present study compared with previous ones.

ALT was an independent risk factor of NAFLD in the present study, and this was consistent with previous reports [4, 33, 34]. ALT was once used as a surrogate marker for liver steatosis and to detect NAFLD in the general population [35], however, prevalence of NAFLD may be underestimated by using liver enzymes as a marker of NAFLD [36], and the prevalence of presumed NAFLD was subject to the cut-off ALT value used [37]. The present study showed that the number of subjects with and without an abnormal ALT level (ALT > 30 U/L for men, ALT > 19 U/L for women) was similar in NAFLD patients (49 % of the subjects had abnormal ALT), and this indicated that ALT may be not sensitive enough to predict NAFLD.

People with MS have an increased risk of developing diabetes mellitus, cardiovascular disease and all cause mortality [4–6]. The prevalence rate of MS ranges from 24 to 44 % in the US population [38] and 10 to 30 % in the Asian population [7, 39, 40], but it was significantly higher in people with NAFLD ranging from 41 to 47 % [8, 41, 42]. Obesity and dyslipidemia are two risk factors of NAFLD [2, 9], and these risk factors have also been identified in the present study. Of note, obesity and dyslipidemia are both MS components. NAFLD is a good predictor for the clustering of risk factors for MS [7]. Although the pathogenesis of MS among patients with NAFLD and their interactive impact on survival rate are still unclear, clinically, patients with NAFLD should be screened regularly for the occurrence and development of MS [9]. Another issue of concern in the present study is the ORs across quartiles of plasma PL fatty acids might reflect only the same pathology or successive stages in the same pathology, such as MS. However the prevalence of MS in NAFLD subjects is only 35 % in the present study, less likely to affect the association of NAFLD with plasma PL fatty acids; further, ORs of MS across different plasma PL fatty acids is different from that of NAFLD; for example, there was no significant trend association of plasma PL SFA with MS risk, while it was significant for NAFLD risk.

There are some limitations to this study. First, the sample size chosen was not large enough to get a more definite conclusion, and included a number of women in the NAFLD group that was limited. However, significant differences of many metabolic factors were determined between the two groups and independent risk factors were also identified in the study. In addition, most of the results were gender adjusted, minimizing the effect of gender. Second, using plasma PL fatty acid as the biomarker of dietary fatty acid intake could not reflect the true dietary intake. However the plasma PL fatty acid composition is a common biomarker used to examine the relationship between dietary fatty acid intake and diseases [17, 18], and the correlations between diet and plasma fatty acids remained relatively constant regardless of whether participants were overweight, possessed chronic diseases, were alcohol drinkers or were cigarette smokers [43].

In conclusion, the present study showed that plasma PL total SFA and C20:3n-6 are positively correlated with the risk of NAFLD, while C22:6n-3 is negatively correlated with the risk of NAFLD. Further confirmation of these associations in large randomized controlled studies are needed.

Acknowledgments The study was funded by the National Natural Science Foundation of China (NSFC, No. 30972464), the National Basic Research Program of China (973 Program: 2011CB504002), Natural Science Foundation of Zhejiang Province (Y205709) and Zhejiang University (No. H20091920).

Conflict of interest The authors have declared that there is no potential conflict of interest with respect to this manuscript.

Abstract The present work studies the potential restorative effect of polyunsaturated fatty acids (PUFA, 5 μ M/24 h) on the dimethoate (DMT)-induced inhibition of testosterone biosynthesis in Leydig cells isolated from rat testes. Various fatty acids (FA) from the n-6 (18:2, 20:3, 20:4, 22:4 and 22:5) and n-3 (18:3, 20:5, 22:5, 22:6) series were assayed in Leydig cells, alone (as delipidated BSA complexes) and in combination with DMT (1 ppm). The n-6 FA stimulated lipid peroxidation (LPO) and inhibited the activities of steroidogenic enzymes (3β - and 17β -hydroxysteroid dehydrogenases). The n-3 FA exerted an anti-oxidant effect, decreasing the production of thiobarbituric-acid reactive substances (TBARS) and inhibiting phospholipase A₂ activity. The biosynthesis of testosterone in DMT-treated cultures was completely normalized by ARA (20:4n-6) and partially restored by the addition of 20:3n-6, increasing ARA content inside the mitochondria. The other FA assayed failed to restore androgenesis. COX-2 protein and prostaglandin F₂ α and E₂ production were stimulated by 20:3n-6, ARA, 18:3n-3 and 20:5 n-3. COX-2 protein decreased upon addition of 22:5n-3 and 22:6n-3. StAR protein was increased by ARA and partially increased by 20:3n-6, likely due to its metabolic conversion into ARA. Both FA increased the mitochondrial cholesterol pool available for testosterone biosynthesis. The rate of androgenesis is likely the result of various regulatory

factors acting concomitantly on the physiology of Leydig cells.

Keywords Arachidonic acid · COX-2 · Dimethoate · Oxidative stress · Prostaglandins · Rat interstitial cells · StAR · PUFA

Introduction

The increasing experimental evidence documenting endocrine dysfunction in the testis has led to the hypothesis that

environmental contaminants adversely affect the male reproductive system [1, 2]. This hypothesis is causally related to the decline in sperm quality observed in developed countries where agrochemicals are used intensively [3]. Many authors have reported that environmental chemicals can mimic estrogen action and also disrupt androgen signaling pathways [4].

Worldwide, dimethoate (DMT) is one of the most commonly used organophosphorus insecticides in horticulture, serving as a systemic insecticide and acaricide for treating gardens, vineyards, and field crops and also applied externally for the control of fly larvae in cattle [5]. Experimental evidence indicates that it impairs fertility, suppresses libido, causes testicular degeneration, and deteriorates semen quality [5].

We found that sub-chronic (5 weeks) administration of DMT to male Wistar rats at low doses (15 mg/kg weight, i.p.) produced evidence toxic effects on testis and modifications in sperm quality [6]. The dosage, similar to the level of pesticide residues in food, caused considerable changes in the appearance, volume and consistence of testes. In agreement with the findings of Sayim et al. [7, 8], the effects included moderate to severe seminiferous tubule degeneration such as sloughing, atrophy and germ cell degeneration, and partial arrest of spermatogenesis. As previously described by Thomas et al. [9], we also found that DMT administration gave rise to a significant increase in the level of circulating gonadotrophins in response to the lower testosterone production. However, previous research proposed that DMT exerts a direct cytotoxic effect unassociated with alterations in LH, FSH, or other hormonal mechanism(s) implicated in androgen biosynthesis [5, 6, 10, 11].

Dimethoate disturbs the pro-oxidant/anti-oxidant balance, causing oxidative stress (OS), a well-known effect of intoxication with environmental contaminants, especially agrochemicals [12–14]. Some of the detrimental effects caused by pesticides in the male reproductive system may therefore be a consequence of the exacerbated free radical production (ROS) [15]. It has been proposed that many pesticides act as pseudosubstrates for the generation of free radicals, which in turn can damage P450 enzymes [4]. However, some research groups dismiss this suggestion since antioxidant supplementation failed to restore testosterone biosynthesis after intoxication by, for example, octylphenols [13]. Our previous results indicated that cultures of interstitial cells isolated from DMT-treated rats have a clear OS condition hallmarked by a general loss of antioxidant capacity and elevation of biomarkers of OS damage [6]. In particular, lipid peroxidation (LPO) is now considered to be the main mechanism by which ROS causes damage leading to impaired cellular function in testis [16]. Mammalian spermatozoa are rich in PUFA,

highly susceptible to OS [4, 8], and the same may be assumed for Leydig cells which are also very rich in PUFA [17]. Induction of OS by DMT has been a focus of research over the last decade in view of its possible role in infertility [4, 18].

We also observed that dimethoate treatment caused a significant loss of PUFA in interstitial cells, especially of 20:4n-6 (ARA), 22:5n-6 and 22:6n-6 fatty acids [6]. As is well known, C₂₂ PUFA are involved in spermatogenesis [19] while ARA is directly linked to the androgenic activity of Leydig cells [20, 21]. Chronic OS may therefore be an important mechanism for the ARA-dependent loss of steroidogenic ability since this fatty acid (FA) is essential for the biological activity of the steroidogenic acute regulatory protein (StAR) [22]. The level of ARA in Leydig cells is controlled by a complex regulatory mechanism involving an acyl-CoA synthetase (ACS4) and a mitochondrial acyl-CoA thioesterase (Acot2). Recent findings show that in steroidogenic cells, ARA release does not operate through the activation of the phospholipase A₂ pathway [23]. In fact, experimental evidence supports the idea that ARA is released from the cholesteryl-ester pool and immediately converted into arachidonoyl-CoA by ACS4 [21]. This thioester binds to the acyl-CoA binding protein (DBI), which in turn binds to the translocator protein (TSPO) located in the outer mitochondrial membrane and possibly facilitates the direct transfer of arachidonoyl-CoA to the mitochondria [22]. In addition, ARA is transformed into lipoxigenated products which induce the transcription of the StAR gene [6, 22]. The conversion of cholesterol to testosterone is limited by the transport of cholesterol from the outer to the inner mitochondrial membrane, which is controlled by StAR activity [24, 25] and the level of ARA [23, 26].

We previously demonstrated that both ARA and cholesterol concentrations are lower in cells isolated from DMT-treated rats [6]. Reduction of ARA, which in turn leads to the reduction of mitochondrial cholesterol content, could be produced by the oxidative destruction of PUFA owing to DMT-induced OS, or increased ARA utilization by the COX-2 pathway (very active in interstitial cells [27]) as the precursor of prostaglandins (PG) G₂, H₂, E₂, D₂ and F_{2 α} [27]. Previous studies performed in mitochondrial fractions subjected to LPO conditions support the assumption that PUFA content can be effectively depleted by overproduction of free radicals [28]. In addition, recent studies from our laboratory indicate that the plasmalogen subfraction is particularly enriched in ARA and highly sensitive to OS [29]. Cyclooxygenase isoenzyme types I (COX-1) and II (COX-2) are key enzymes that function coordinately and are controlled differentially by regulating the amount of ARA and LPO [30]. We observed a significant increase in the level of COX-2 protein in cells

isolated from DMT-treated animals which correlated with the higher concentrations of both PGE₂ and PGF_{2α}. Concomitantly, StAR protein was diminished at both the gene expression and protein levels. Administration of rofecoxib almost restored the hormonal levels to control values. This specific inhibitor of COX-2 was unable to modify the LPO or the OS condition [6], leading us to conclude that the main target of DMT is related to the increment in COX-2 activity that gives rise to the diminution of ARA, the overproduction of PGE₂ and PGF_{2α} and the subsequent inhibition of the StAR regulatory mechanism.

In the present work we therefore sought to study the possible restorative effect of polyunsaturated fatty acids (PUFA, 5 μM/24 h) in cultures of rat Leydig cells on the main mechanistic aspects of the DMT inhibitory effect: (1) LPO status, (2) steroidogenic enzymes activities, (3) mitochondrial cholesterol and ARA levels, (4) PG biosynthesis and (5) StAR and COX-2 expression. We also investigated whether ARA has a specific role in the mechanism of action of DMT or whether there is another long-chain n-6 or n-3 FA that could be biologically active in neutralizing DMT-induced testosterone inhibition. We explored the restorative effect of various fatty acids independently of their relative abundance in the intact cells, since it is well known that in many biological systems there is interaction between the biological effects of members of the two essential series. It is also known that the fatty acid composition of testis (and specifically of interstitial cells) is modified by the quality and quantity of dietary fatty acids. Thus, the final effect on the steroidogenic route depends not only on fatty acid abundance at the basal state, but also on the modifications induced by the fatty acids acquired from the blood stream.

Experimental Procedure

Chemicals

All chemicals used were of reagent grade and obtained from Sigma Chem. Co. (CA, USA, or Buenos Aires, Argentina) or Merck Laboratories (Darmstadt, Germany). Organic solvents were from Carlo Erba (Milano, Italy). Other chemicals employed were of analytical grade and purchased from local commercial sources. Dimethoate (DMT, 2-dimethoxyphosphonylthio-*N*-methylacetamine) was obtained as a gift from INTA (Castelar, Argentina). Pure fatty acids (FA) were obtained from Nu-Chek Prep. (Elysian, MN, USA). All acids were stored in benzene under nitrogen atmosphere at –20 °C. Concentrations and purities were routinely checked by capillary gas-liquid chromatography as described in a previous paper [31].

Animals

Male Wistar rats weighing 180 ± 20 g with specific pathogen-free certified status were used. Upon arrival, the rats were allowed to acclimatize for a week before commencing the experiment, during which time they were maintained under controlled conditions of temperature (25 ± 2 °C) and a normal photoperiod of 12 h dark and 12 h light. They were fed with standard Purina chow from Ganave S.A. (Santa Fe, Argentina) and water ad libitum. Clinical examination together with body weight evaluation was performed throughout the entire adaptation period. Animal maintenance and handling were in accordance with the NIH guide for the care and use of laboratory animals. All procedures were approved by the local Laboratory Animal Bioethics Committee, Facultad de Ciencias Médicas, UNLP, Argentina.

Cell Culture and Treatment

After killing the rats by rapid decapitation, testes were excised and washed under sterile conditions. The technical procedure for Leydig cell isolation was described in detail in a previous report [32]. Briefly, Leydig cells were removed from the interstitial space of testicular tissue by mechanical shaking with collagenase (Sigma Chem. Co., type IV) in a metabolic incubator, at 34 °C, according to Suescon et al. [33]. Cells were suspended in Krebs–Ringer bicarbonate glucose (KRBG) buffer (pH 7.4), examined for viability (90 %) by trypan blue exclusion [34], and counted in a hemocytometer to adjust cell concentration. Aliquots of cell suspensions were subjected to total cellular protein (TCP) determination by the micromethod of Bradford [35]. The homogeneity of cell preparations was assessed by means of the observation of smears fixed in acetone and stained with hematoxylin–eosin. Interstitial cell preparations consisted of 85 % Leydig cells and 15 % spermatids, spermatocytes and small cytoplasmic fragments. Control or DMT-treated cells were divided into experimental sets each containing 6.10^6 cells per sterilized/siliconized Erlenmeyer flask with 20 mL of culture medium in a humidified and oxygenated culture chamber. Flasks with cell suspensions were subjected to soft metabolic agitation in a shaker at 35 °C. At zero time, the cells were supplemented with the assayed FA vehiculized as a complex with delipidated serum albumin (FA:BSA; 5:1) at a final concentration of 5 μM for 24 h. The FA:BSA complexes were sterilized by Millipore (0.22 μm) ultrafiltration and prepared according to the procedure previously described [36]. Cells treated with FA were divided into two series of 6 flasks each and one series was simultaneously treated with DMT (1 ppm) dissolved in 10 % PEG-400 in PBS (pH 7.40) as vehicle. Aliquots of the added supplements never exceeded 100 μL per incubation flask.

Cell Viability Tests

Cell viability was assessed at zero time and at the end of the incubation period (24 h) by two methods. Cell suspensions were assayed using exclusion of trypan blue dye according to Jauregui et al. [34]. Samples of culture medium were subjected to centrifugation at 10,000g for 15 min and then ultrafiltered through Millipore membranes (0.22 μ M) in order to discard cell debris, following which they were analyzed by lactate–dehydrogenase (LDH) leakage in the supernatant [34] (Optima-UV-LDH assay kit from Winner Labs., Rosario, Argentina).

Lipid Peroxidation

LPO was assayed as thiobarbituric acid reactive substances (TBARS) and expressed as nmol malondialdehyde (MDA)/mg protein [37].

Immunoblotting

Cells were homogenized by sonication as previously described [6] in Tris/HCl/sucrose buffer with 1 % antiprotease cocktail (Sigma Chem. Co, Bs. As., Argentina) and 2 % SDS. After heating the samples (20 μ g) at 95 °C for 3 min with 10 % mercaptoethanol, aliquots were supplemented with 10 % glycerol and 0.01 % bromophenol blue and loaded on 12 % SDS-PAGE mini-slabs (Mini protean II, Bio-Rad, Hercules, CA, USA). Proteins were electrophoretically transferred overnight to PVDF membranes (Bio-Rad, Hercules, CA, USA) using a transfer buffer containing 25 mM Tris, 190 mM glycine and 20 % methanol. COX-2 protein levels were analyzed using a polyclonal antibody (Santa Cruz Biotechnology Inc., CA, USA) and StAR protein was detected with a rabbit polyclonal antibody generated against amino acids 88–98 of the 30 kDa StAR protein prepared according to Clark et al. [38]. Blots were re-analyzed for α -tubulin as reference protein to control both loading and transfer processes using a polyclonal anti- α -tubulin antibody from Oncogene (San Diego, CA, USA). Immunocomplexes were revealed with peroxidase-labeled secondary antibodies from Amersham Pharmacia Biotech AB (Uppsala, Sweden). Semi-quantitation of Western blots was performed using the GeneGenius gel documentation system and GeneTools software from Syngene (Cambridge, UK). Results were normalized to α -tubulin signal and expressed as “fold change” relative to the control (basal assay), which was assigned a value of 1.

PGF_{2 α} and PGE₂ Assays

For assessment of PGF_{2 α} and PGE₂ content in the interstitial cells, homogenates were centrifuged at 15,000 \times g for

30 min at 2 °C. Supernatants were filtered through Millipore 0.22 μ m filters and concentrated by lyophilization in a Telstar apparatus, Lyobeta Model (Madrid, Spain). The residues were dissolved with HCl 2 N adjusting the pH to 3.5, injected into a 200 mg C₁₈ reverse phase Sep-columns (Peninsula Lab, Belmont, CA, USA) and then eluted with ethyl acetate. The eluted fractions were evaporated to dryness under a nitrogen stream and reconstituted in buffers for enzyme-immuno assay (EIA) determinations. PG were determined using commercially available kits (Prostaglandin F_{2 α} EIA Kit and Prostaglandin E₂ Express EIA Kit from Cayman, Migliore Laclustra S.R.L. (Buenos Aires, Argentina) with a minimum detection of 4 and 30 pg/mL, respectively. Intra- and inter-assay coefficients of variation were in the range of 8–12 % for both kits.

Lipid Analysis

Aliquots of cell lysates were used to prepare mitochondrial fractions using a combination of low (600 g) and high-speed (11,000 g) centrifugation procedures in a buffer containing HEPES 10 mM/pH 7.50 plus mannitol 200 mM, sucrose 70 mM and EGTA 1 mM according to the recommendation of the kit manufacturer (MITO-ISO1 from Sigma Chem. Co., Buenos Aires). The purity and integrity of the fraction was checked using a CYTOCOX1 kit (Sigma). Total lipids from mitochondrial suspensions were extracted by the method of Folch et al. [39]. The phospholipid fraction was separated from the Folch extracts by the micro-column chromatography method described elsewhere [40] and quantified as phosphorus content [41] after mineralization of an aliquot from the silicic acid partition. GLC of the FAME (fatty acid methyl esters) was performed as indicated in our previous paper [42] except that in this case we used a capillary column mounted on a Hewlett Packard HP 6890 Series GC System Plus (Avondale, PA, USA) equipped with a terminal computer integrator and data station. The FAMES were identified by comparison of their relative retention times with authentic standards and mass distribution was calculated electronically by quantification of the peak areas. To quantify FA content, 21:0 was used as internal standard. Cholesterol (CHOL) content was enzymatically measured according to Allain et al. [43] using a commercial kit from Wiener Lab. (Rosario, Argentina). Testosterone (Te) measurements were performed using a commercial kit KS24CT from Radim (Radim SpA, Pomezia, Italy).

Steroidogenic Enzyme Activities

Appropriate aliquots of homogenate supernatants were employed to determine 3 β -hydroxysteroid-dehydrogenase (3 β HSD) and 17- β -hydroxysteroid-dehydrogenase (17 β

HSD) [EC 1.1.1.51] enzyme activities following the method of Marugesan et al. [44]. In brief, sonicated interstitial cells were centrifuged ($12,000\times g$, 15 min, $1-2^{\circ}\text{C}$). Supernatants were mixed with charcoal in order to remove the endogenous steroids and the samples were again centrifuged ($12,000\times g$ 15 min, 2°C). The reaction conditions were defined in preliminary experiments in which enzyme activities were tested by varying the incubation times and concentrations of substrates, protein, and cofactors. Assays were performed under initial velocity conditions in a reaction mixture (250 μL final volume) containing 10 μM of the steroid substrate (Δ^4 -androstenedione or pregnenolone for 17β HSD and 3β HSD, respectively), 1 mM NADPH (17β HSD) or 0.2 mM NAD^+ (3β HSD), and 0.1 M phosphate buffer (pH 7.4). Mixtures were incubated under air in a spectrophotometric cell holder thermostatted at 37°C . The reactions were started by the addition of the supernatant aliquots and OD changes of the nicotinamide cofactor(s) were measured. The incubation mixture deprived of substrate(s) was used as a reagent blank.

PLA₂ Activity

Phospholipase A₂ (PLA₂) activity was determined with [^{14}C] arachidonoyl-phosphatidylcholine (ARA-PC) (24.0 mCi/mmol, 99 % pure) as substrate according to the method of Hirata et al. [45] with the modifications described in our previous paper [31]. Briefly, cellular homogenates were centrifuged at $15,000\times g$ for 30 min at 2°C and 20 to 40 μg protein was incubated at 37°C in a metabolic shaker with 0.5 mL of 50 mM TRIS/glycylglycine buffer (pH 8.0), 0.1 mM Mg Cl_2 , 5 mM *N*-acetylcysteine, and 1 mM ARA-PC biosynthetically prepared in our laboratory. The lipid was previously scattered, under carefully controlled temperature, in cold potassium buffer plus 0.1 mM sodium deoxycholate (grade II, from Sigma Chem. Co.) by means of three 20-s sonication periods with a Heat System-Ultrasonic Sonicator model W-220F (Plainview, NY, USA) equipped with a 1/8-inch diameter microtip at 50 % output. After preincubation at 37°C for 1 min, the assay was started by the addition of the aliquot assayed. Under these conditions, the reaction was completely linear up to 30 min. It was stopped after 10 min incubation time by the addition of 3 mL isopropyl alcohol/heptane/1 N H_2SO_4 (40:10:1, by vol) followed by 2 mL distilled water plus 2 mL of hexane (Carlo Erba, Milan, Italy) containing 5 μg /tube unlabelled arachidonic acid, thorough mixing and incubation for 10 min at room temperature. Unlabeled acid was added as a carrier to facilitate quantitative extraction. Labeled fatty acids, released by the action of phospholipase A₂, were recovered from the upper phase (at least 95 % yield) and counted by liquid

scintillation (ACS II Scintillation Cocktail, Amersham Pharmacia Biotech., Buckinghamshire, England) using a Wallac Rackbeta Liquid Scintillation Counter (Turku, Finland) with 90 % efficiency for ^{14}C . Blanks consisted of equivalent aliquot samples boiled at 100°C for 5 min. Formation of unlabeled lyso-PC was routinely checked by recovering the phospholipid components followed by thin-layer chromatography and radio-scanning (radio-TLC) in a TLC-proportional radioactivity scanner system (Berthold LB-2832, Wildbad, Germany) equipped with a Hewlett-Packard 3396-A Data Station.

Statistical Analysis

Results were analyzed by one way analysis of variance (ANOVA) followed by the Tukey multiple comparison test. Data were expressed as the mean \pm standard deviation (SD) of six independent determinations. They were considered to differ from control data at a level of significance of $*p < 0.01$. Calculations were made with the aid of Systat (version 12.0 for Windows) from SPSS Science (Chicago, IL, USA) and/or Sigma Scientific Graphing Software (version 9.0) from Sigma Chem. Co. (St. Louis, MO, USA).

Results

Each FA assayed was run in parallel with the following control flasks: C (no additions); BSA (delipidated BSA 1 μM) and PEG (an equivalent aliquot of the vehicle used to supplement the flask with DMT). Since there were no statistical differences between the assays, the results routinely refer to C values as the control experiment.

Influence of Treatments on Cell Viability

None of the experimental treatments with DMT alone or in combination with any of the FA assayed in the form of BSA: FA complexes produced significant changes in cell viability by means of either LDH leakage or trypan blue dye exclusion tests (data not shown). Cell viability remained at 95–98 % throughout the incubation period (24 h).

Lipid Peroxidation and Parameters Involved in Lipid Metabolism

DMT produced a significant increase in the TBARS concentration determined in cellular homogenates, confirming previous results from our laboratory (Table 1). TBARS were also higher in mitochondrial suspensions isolated from DMT-treated Leydig cells, increasing from a basal value of 1.9 ± 0.2 nmol MDA/mg mitochondrial protein

to 4.8 ± 0.3 ($P < 0.01$, $n = 6$ independent determinations). TBARS overproduction was sustained in all assays using n-6 FA in combination with DMT, demonstrating a pro-oxidative condition exacerbated by the addition of these kinds of FA. However, n-3-PUFA produced the opposite effect, neutralizing the elevation of TBARS by DMT treatment to almost control values (Table 1). Total lipid extract from mitochondrial fraction was analyzed in terms of the absolute content of CHOL and ARA using a coupled enzymatic procedure with cholesterol oxidase and quantitative capillary gas–liquid chromatography, respectively. The analysis of whole-cell phospholipids demonstrated that total inorganic phosphate content/mg protein was unaffected by dimethoate treatment (data not shown). Similar results were obtained for the phospholipid fraction isolated from the mitochondrial fraction. However, mitochondrial cholesterol content decreased after DMT treatment, this effect being more noticeable in the co-treatment with three FA (18:2n-6, 18:3 n-3 and 20:5 n-3) (Table 1). Addition of 20:3n-6 restored the cholesterol level to control values, whereas ARA was able to significantly increase the concentration of this sterol. ARA content in the phospholipid subfraction extracted from mitochondrial suspensions was almost 30 % lower in DMT-treated cells compared to control data (Table 1). Addition of 20:3n-6 tended to restore the level of ARA and as expected, supplementation with ARA raised the FA concentration ~ 20 % above control values. Incubation in the presence of 18:3n-3 or 20:5n-3 alone (without DMT) produced a slight—although significant—decrease in ARA content compared to control data. Phospholipase A₂ activity was not significantly modified by treatment with DMT or n-6 FA; however, supplementation with n-3 FA alone or in combination with DMT produced significant inhibition of the enzyme activity (Table 1).

Steroidogenesis and Prostaglandin Production

As previously demonstrated in our laboratory, DMT-treated cells exhibit a reduction in 3β and 17β HSD activities (Table 2). The addition of n-6 FA alone produced inhibitory effects per se in both enzymes, reinforced by adding DMT under co-incubation conditions (FA + DMT). However, n-3 FA displayed the opposite effect, stimulating the basal activity of both enzymes and restoring the values to those of the control data or even producing an increase in the presence of DMT. Both prostaglandins (F2 α and E2) increased significantly after DMT treatment. Addition of n-6 FA produced no further changes, with the exception of the 20:3n-6 and ARA FA, whose levels of both PG increased above those of cells with no additions. Incubation with 18:3 and 20:5 FA from the n-3 series increased PG F2 α and E2 whereas the other FA of the same series caused

a decrease in PG concentration compared to control data (Table 2). Under co-incubation conditions with DMT, 20:3n-6 and ARA increased the level of PG E2 compared to that observed with DMT alone. Addition of 22:5n-3 and 22:6n-3 caused a decrease in both PG compared to DMT-treated cells. On the contrary, addition of 20:5n-3 to DMT-treated cells produced a further increase in PG F2 α and E2.

Testosterone Biosynthesis

The concentration of testosterone in Leydig cells was 56 % lower in DMT-treated cells than in the controls. Some FA added alone produced a slight but significant decrease in testosterone biosynthesis (18:2n-6, 22:4n-6 and n-3 FA except 18:3n-3) whereas others (20:3n-6 and ARA) increased the hormone concentration. In co-incubation with DMT, 20:3n-6 tends to normalize Te production whereas ARA not only restores but also stimulates the biosynthesis of androgen beyond control values. All n-3 FA assayed failed to counteract the inhibitory effect displayed by DMT (Table 3).

StAR and COX-2 Expression

The expression of StAR (Fig. 1) and COX-2 (Fig. 2) proteins was tested by Western blotting. Relative quantification of the signals demonstrates that the observed effects strongly depend on the kind of FA tested, whether alone or in combination with DMT. The StAR protein is strongly stimulated by ARA and partially stimulated by its metabolic precursor (20:3n-6). Addition of ARA completely reversed the inhibitory effect caused by DMT. None of the other FA were able to produce this reversion. In the case of 20:5n-3 we also found a more pronounced inhibitory effect than that observed in control cells, especially when the acid was added in combination with DMT. COX-2 protein increased under DMT treatment. Eicosa-8,11,14-trienoic acid also stimulated COX-2 protein over basal levels. In the case of ARA, this stimulation exceeded that observed with DMT treatment. Addition of 18:3n-3 and 20:5n-3 also stimulated COX-2 protein and when the supplemented FA was eicosapentaenoic acid, the effect was additive. On the contrary, treatment with 22:5n-3 and 22:6n-3 FA decreased the COX-2 protein.

Discussion

Previous studies from Carlsen et al. [2] warn about the worldwide decline in semen quality over the past five decades. Retrospective studies performed independently in sperm banks in Paris [46] and London [47] have confirmed

Table 1 Effect of fatty acid (FA) additions on TBARS production, mitochondrial (MIT) araquidonate and cholesterol (CHOL) concentrations, and phospholipase A₂ (PLA₂) activity in rat Leydig cells treated with or without dimethoate (DMT)

| Additions | FA | DMT | Parameters | | | |

this conclusion. All the experimental and epidemiological evidence points to agrochemicals as the main environmental factor responsible for the decline in sperm quality, especially in those countries where the use of agrochemicals is most widespread [3, 4]. It is almost impossible to draw up an exact scenario of the consequences of environmental pollution on male reproductive functions owing to the lack of adequate data on the level of exposure and precise knowledge of the mechanism of pesticide action on the metabolism of Leydig, Sertoli, and other cells of the germinal and non-germinal series [4, 48].

In the specific case of Leydig cell metabolism, it is well established that there are key events that could produce deleterious effects on the multiple physiological functions of the cells: (1) ROS production in response to toxicants [4, 49], (2) enhancement of COX-2 activity and ARA consumption leading to an increase in F2α and E2 PG [50, 51] and (3) inhibition of StAR activity which internalizes CHOL and regulates the biosynthesis of Te [20, 38]. These factors converge in a complex and not fully understood regulatory mechanism in which ROS, PG and COX-2 (and their metabolites) control the production of Te [12, 21, 50–

52]. In addition, StAR is sensitive to many pesticides [21] and DMT specifically disturbs StAR gene expression in testes [6, 24].

The present work demonstrates that very low doses of DMT added in vitro to Leydig cells were able to produce strong modifications in all the key factors described above that determine the rate of androgenic activity. Interestingly, external supplementation with various n-3 and n-6 FA introduces partial modifications in one or more of the regulatory factors under consideration.

A clear pattern of ROS production was observed in which n-3 FA behave as anti-oxidants and n-6 as pro-oxidants, a finding that is corroborated by other laboratories [53, 54]. As previously stated, detrimental effects of pollutants on the male reproductive system have traditionally been explained in terms of the overproduction of ROS [12–14]. LPO is considered one of main mechanisms by which ROS impairs cell function in testis [16]. Moreover, it has been reported that antioxidants such as curcumin, ascorbate and α-tocopherol [55] may neutralize the androgen imbalance produced by organophosphorates. This hypothesis is supported by the fact that the antioxidant

protection of PUFAS, in particular ARA, is directly correlated with better spermatogenesis [19] and androgenic activity in Leydig cells [20, 21]. However, these findings do not correlate with results obtained from our [6] and other [13] laboratories and appear to be an extreme simplification. We previously found that TROLOX[®], administered as a potent antioxidant, provides no substantial protection against DMT-induced changes. In fact Rofecoxib[®], a COX-2 specific inhibitor, partially attenuates DMT-treatment damages [6], leading us to focus on the ARA signaling cascade as another key regulatory feature within the complex scenario of the DMT-inhibition of Te production.

Our findings relating to the changes caused by some FA on COX-2 activity and PG production, in particular the stimulatory effect of ARA and 20:3n-6 [56] and the inhibition exerted by 22:5n-3, 22:6n-3 and 20:5n-3 FA [56–60], have been corroborated by other laboratories. FA are regulators of COX-2 transcription [61] through the PPAR-dependent signaling route. Previous evidence demonstrated that the biosynthesis of androgens is strongly linked to ARA metabolism [20, 21, 62, 63] and it was reported that n-6 PUFA decrease the quality of the sperm without decreasing the number of Leydig cells, probably by altering the ARA cascade [64]. Interestingly, infertile men have

higher levels of n-6 PUFAS in testis and spermatozoa [53]. Studies also demonstrate that the quality and quantity of dietary FA may determine the pattern of PG in testis and fertility performance in men [53, 64, 65], as corroborated in in vitro studies [58, 66]. In addition, 5 α -reductase—a key enzyme in the androgenic pathway—is strongly influenced by the balance between n-3 and n-6 FA [67]. This mechanistic scheme is even more complicated if we consider that PUFA may modify the specific activity of two of the main steroidogenic enzymes, 3 β HSD and 17 β HSD [29, 68]. As previously described by Murugesan [12, 44, 69] and Kostic [70], overproduction of ROS by any mechanism, including PUFA peroxidation, can also inhibit these enzymes. In addition, certain fatty acids per se may influence the activity of these dehydrogenases. In vivo and in vitro experiments on testis and interstitial cells isolated from rats show that a diet of soybean oil reduces 3 β HSD and 17 β HSD activity as compared with a diet containing equivalent amounts of linoleic acid but without significant amounts of linolenic acid (grape seed oil) [29, 71], strongly suggesting that n-3 fatty acids could inhibit 3 β and 17 β steroidogenic activity as reported by other authors [72]. We also demonstrated that independently of the essential series to which they belong, and unlike saturated or monounsaturated fatty acids, PUFA inhibit steroidogenic enzymes

Table 3 Effect of fatty acid (FA) additions on testosterone production of rat Leydig cells treated with or without dimethoate (DMT)

[29, 71]. This experimental evidence would appear to indicate that ARA decreases testosterone level; however, the inhibitory effect on steroidogenic enzyme activity, although significant, was completely surpassed by the stimulatory action on other main factors determining testosterone biosynthesis, mainly StAR activation.

Availability of ARA depends on its release from phospholipid stores. Although no significant modification in the pool of mitochondrial phospholipids was detected, n-3 PUFA—but not n-6 PUFA—reduced phospholipase A₂ activity to different extents. This finding is in agreement with previous experimental evidence [57, 60] but in apparent contradiction with epidemiological data indicating a reduction of n-3 FA in infertile men [53]. Our results may therefore contribute to understanding why certain n-3 PUFA may have an anti-androgenic effect in Leydig cells.

Many events appear to converge on the central activity of the StAR protein, which ultimately exerts control over the mitochondrial cholesterol pool available for testosterone biosynthesis. The steroidogenic rate is sensitive to small changes in StAR protein activity [24]. It is well

established that translocation of cytoplasmic cholesterol into the mitochondria is controlled by StAR activity [24] and also by the level of ARA [23, 26]. In addition, Diemer et al. [25] reported that ROS per se are able to inhibit StAR activity. Furthermore, PGF2 α significantly depresses StAR activity in porcine, man, rat and human tissues [73–76] and down-regulates 17 β HSD (77). Inhibition of COX-2, on the other hand, significantly increases StAR protein and steroidogenic activity [6, 77].

Whereas our previous findings suggested that the main target of DMT on the steroidogenic route was COX-2 activity, which ultimately modulates the activity of the StAR protein, our present findings lead us to conclude that the mechanism of DMT-induced damage on testosterone biosynthesis in Leydig cells is a multifactorial event with cross-talk among many variables. The resulting rate of biosynthesis is determined by a complex balance between the various factors schematically presented in Fig. 3 (graphical abstract), most of which produce contrary effects, making the final impact difficult to assess. For example, n-3 FA clearly inhibit PLA₂ activity, decreasing the availability of ARA to stimulate the StAR protein, but they simultaneously reduce the overproduction of ROS

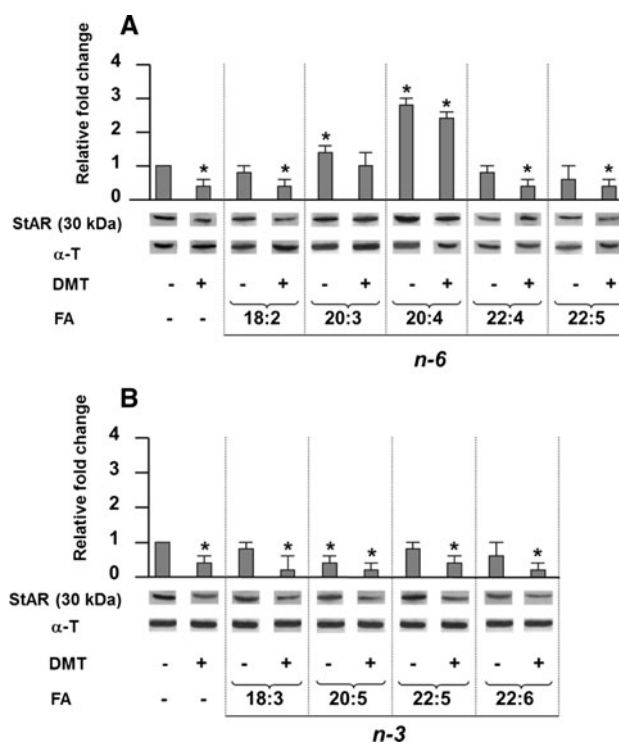

Fig. 1 StAR protein level in interstitial cells treated (24 h) with different fatty acids from n-6 series (panel a) or n-3 series (panel b) added alone as BSA complexes (5 μ M) or in combination with DMT (1 ppm). Results are representative of six different incubations run in duplicate. See details in “Experimental Procedure”. (Asterisk) Significantly different with respect to the corresponding control assay (minus DMT)

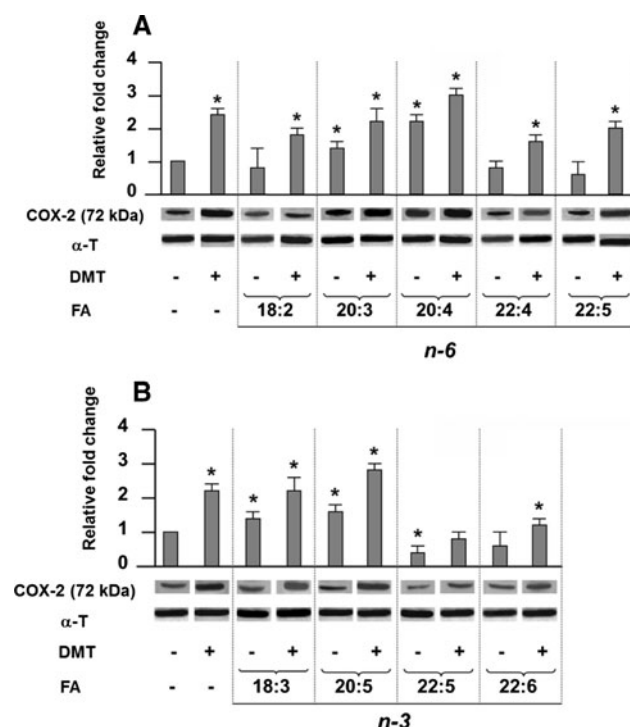

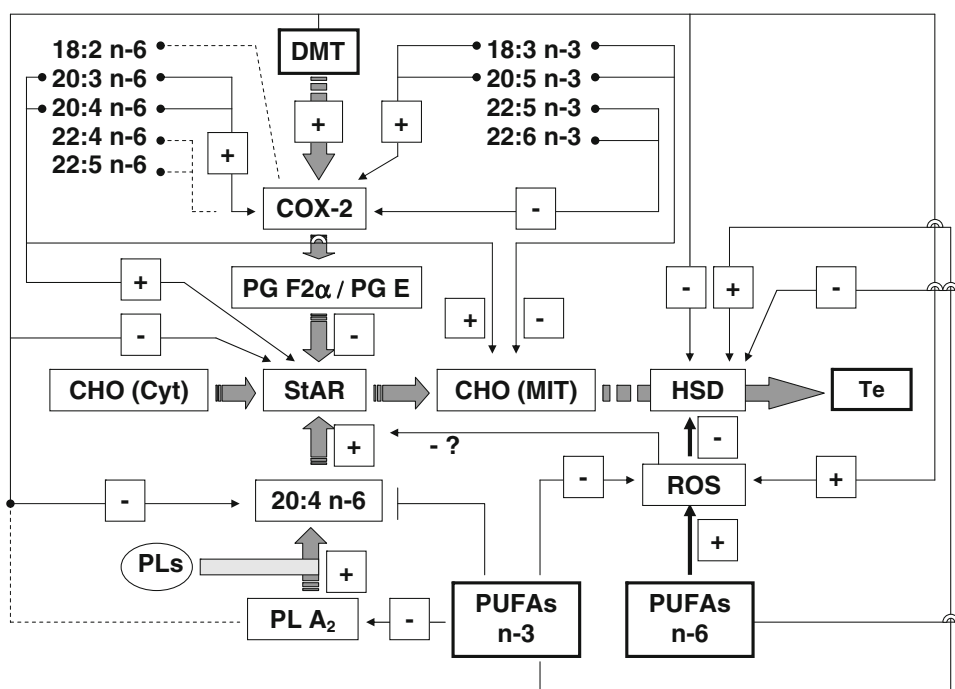

Fig. 2 COX-2 protein level in interstitial cells treated (24 h) with different fatty acids from n-6 series (panel a) or n-3 series (panel b) added alone as BSA complexes (5 μ M) or in combination with DMT (1 ppm). Results are representative of six different incubations run in duplicate. See details in “Experimental Procedure”. (Asterisk) Significantly different with respect to the corresponding control assay (minus DMT)

induced by DMT treatment, thus directly and indirectly facilitating the biosynthetic activity of HSD enzymes. Similarly, two of the n-3 FA stimulate COX-2 activity and raise the production of PG F2 α and E2, which in turn inhibit the StAR protein, whereas the other two have no effect on COX-2 activity but decrease the mitochondrial pool of cholesterol. We also consider that ARA's ability to neutralize the deleterious effect of DMT is mainly a consequence of higher StAR activity and increased ARA availability, causing the import of cholesterol into the mitochondria to appear to be much higher. These effects appear to predominate over others with the potential capacity to counteract their beneficial action, such as the pro-oxidative effect and the stimulation of COX-2 activity together with a slight—but significant—inhibition of HSD enzymes. It is clear that further research is required to localize the exact point at which the action of FA on the DMT-induced inhibition of steroidogenic biosynthesis occurs. The actual scenario is likely to be a complex system with many points of focus regulated by multiple factors, some acting in opposite ways, whose combined effect is difficult to predict based on the currently available information. Whether the beneficial effect of 20:3 n-6 derives from its own action *per se* or from its metabolic conversion to ARA in living cells, which have Δ 5 desaturase activity, is a further area to be investigated. Our preliminary conclusion is that ARA has a specific capacity not observed with any of the other assayed PUFA.

Fig. 3 Graphic summary of the multiple effects of DMT treatment and addition of n-6 or n-3 fatty acids on the main factors determining the rate of testosterone biosynthesis. Solid lines represent positive or negative effects as indicated with the corresponding symbols. Dashed lines represent no significant changes. COX-2 cyclooxygenase II, CHOL cholesterol, DMT dimethoate, HSD hydroxysteroid dehydrogenases, MIT mitochondria, PG prostaglandins, PUFA polyunsaturated fatty acids, ROS reactive oxygenated species, StAR steroid acute regulatory protein, Te testosterone

Clarification of the complex pattern of events that emerges from the present paper may have important connotations in other areas. Disruption of StAR protein activity and the restorative action of PUFA could have implications that go beyond questions of fertility. StAR plays a key role in many other tissues such as adrenal glands, brain, lungs and ovaries, so it is possible that the biosynthetic pathways that regulate mineralo- and glucocorticoids also impact on carbohydrate metabolism, immune function, neuroprotection, water and mineral balance, among others. Further research will help elucidate the detrimental effects of environmental pollutants and their connection with the quantity/quality of PUFA in toxicant-targeted tissues [24, 78–82].

Acknowledgments This study was supported by a grant from Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina. We would like to thank Mrs. Agustina Zardis de Cobeñas, Eva Illara de Bozzolo, and Norma Cristalli for their excellent technical assistance.

Chylomicron Formation and Secretion is Required for Lipid-Stimulated Release of Incretins GLP-1 and GIP

Abstract Glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP) are incretins produced in the intestine that play a central role in glucose metabolism and insulin secretion. Circulating concentrations of GLP-1 and GIP are low and can be difficult to assay in rodents. These studies utilized the novel intestinal lymph fistula model we have established to investigate the mechanism of lipid-stimulated incretin secretion. Peak concentrations of GLP-1 and GIP following an enteral lipid stimulus (Liposyn) were significantly higher in intestinal lymph than portal venous plasma. To determine whether lipid-stimulated incretin secretion was related to chylomicron formation Pluronic L-81 (L-81), a surfactant inhibiting chylomicron synthesis, was given concurrently with Liposyn. The presence of L-81 almost completely abolished the increase in lymph triglyceride seen with Liposyn alone ($P < 0.001$). Inhibition of chylomicron formation with L-81 reduced GLP-1 secretion into lymph compared to Liposyn stimulation alone ($P = 0.034$). The effect of L-81 relative to Liposyn alone had an even greater effect on GIP secretion, which was completely abolished ($P = 0.004$). These findings of a dramatic effect of L-81 on lymph levels of GLP-1 and GIP support a strong link

between intestinal lipid absorption and incretin secretion. The relative difference in the effect of L-81 on the two incretins provides further support that nutrient-stimulation of GIP and GLP-1 is via distinct mechanisms.

Introduction

Glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP) are intestinal peptide hormones that are responsible for the incretin effect. The incretins are released after meals and augment postprandial insulin secretion [1]. Glucagon-like peptide-1 is secreted by enteroendocrine L cells located predominantly in the distal small intestine while GIP is secreted by K cells found mainly in the duodenum and jejunum. Both incretins are released into the circulation in response to enteral carbohydrate, fat or mixed nutrient meals [2–4]. Recent findings support an essential role for the incretins in nutrient metabolism and glucose tolerance [5], and advances in pharmacology have led to application of incretin-based drugs to the treatment of diabetes [6].

Glucagon-like peptide-1 and glucose-dependent insulintropic polypeptide circulate in the plasma in picomolar concentrations and can be difficult to measure accurately in the fasting state. Moreover, GLP-1 does not reach very high concentrations even after meal stimulus. Thus obtaining sufficient blood for serial measurements of GIP and GLP-1 in rodent studies has been challenging. We have established a novel in vivo approach of monitoring GLP-1 and GIP secretion utilizing the lymph fistula rat model.

Using this approach, we have recently demonstrated [7, 8] that the intestinal lymph is enriched with the gastrointestinal hormone GLP-1 before and after meal intake. We have also demonstrated that the concentrations of GIP and GLP-1 are substantially higher in intestinal lymph than in portal venous plasma [7, 9]. These findings suggest that lymph draining the gut may be a medium through which the function of K and L cells can be examined.

While many studies have focused on the biological effects of GLP-1 and GIP, the mechanisms regulating the release of the incretins in response to nutrients remain to be elucidated. To date, several studies have demonstrated that GIP secretion requires the absorption of glucose in the gut, while GLP-1 release has been reported by some to be stimulated by contact of nutrients with the intestinal lumen and shown by others to require the absorption of nutrients [2, 4, 10–15].

The aim of this study was to examine the role of chylomicron formation and secretion on lipid-stimulated GLP-1 and GIP release in vivo. Chylomicrons are synthesized in the intestinal enterocytes during active fat absorption and transported into the lymph. Intestinal formation and transport of chylomicrons is inhibited by a hydrophobic surfactant, Pluronic L-81 (L-81) [16–19]. L-81 is a condensation polymer of polyoxypropylene, which forms a hydrophobic chain that is flanked by the hydrophilic polyoxyethylene. L-81 has been shown to significantly impair the lymphatic transport of triglycerides (TG) [20, 21]. However, L-81 does not inhibit the uptake of lipolytic products of digestion by enterocytes or the reesterification of monoglyceride and fatty acid to form TG [20]. L-81 seems to cause an accumulation of TG in the smooth endoplasmic reticulum and prevents the movement of prechylomicrons from the endoplasmic reticulum into the Golgi complex. A recent report by Fatma et al. [22] showed that L-81 may inhibit the formation of chylomicrons by inhibiting the activity of microsomal triglyceride transfer protein.

Both Pluronic L-81 and Pluronic P-85 (P-85) are difunctional block copolymer surfactant terminating in primary hydroxyl groups. They are both nonionic surfactants composed of a central hydrophobic chain flanked by two hydrophilic chains. L-81 and P-85 have the same sized hydrophobic portion of the molecule, but P-85 has a larger hydrophilic portion than L81. Both Pluronic block copolymers L-81 and P-85 have been examined together in the same studies including lipid-Pluronic interactions [23], cellular uptake of proteins [24], and functional activity of multidrug resistance-associated proteins [25]. Both non-ionic surfactants have also been shown to inhibit intestinal P-glycoprotein efflux [26, 27]. In this study, we investigated the effect of the inhibition of chylomicron formation by L-81 and P-85 on the secretion of GLP-1 and GIP, as well as the role of free fatty acids (FFA) on incretin release.

Materials and Methods

Animals

Adult male Sprague–Dawley rats, weighing 240–350 g (Harlan, Indianapolis, IN), were used. Animals were allowed to acclimate to the animal facility for two weeks prior to the experiment. During this period, the animals were fed regular rodent chow (TEKLAD LM485-7912) and housed in a room with a 12/12 light/dark cycle. Both the temperature and the humidity of the room were kept constant.

Surgical Preparation

All procedures were approved by the University of Cincinnati Internal Animal Care and Use Committee and complied with the NIH Guide for the Care and Use of Laboratory Animals. Installation of the lymph duct and intraduodenal cannulae was performed as previously described [8]. Briefly, under halothane anesthesia, the superior mesenteric lymph duct was cannulated with soft vinyl tubing [medical grade; 0.5 mm inner diameter (ID) and 0.8 mm outer diameter (OD) Biocorp Australia Pty Ltd., Melbourne, Australia] according to the method of Bollman et al. [28] with slight modification. Instead of using suture to tie off the lymph duct, a drop of Krazy glue was used to secure the cannula in place. Intraduodenal cannulation was performed by inserting a silicone tube (1.6 mm OD) about 2 cm into the duodenum via a fundal incision of the stomach and the incision was tied off with a purse-string tie and further sealed with a drop of Krazy glue. Post-operatively, animals were kept in Bollman restraining cages and infused with 5% glucose in saline (145 mM NaCl, 4 mM KCl, 0.28 M glucose) at a rate of 3 ml/h and then switched to saline infusion overnight prior to the nutrient absorption study on the following morning. Lymph samples were collected in 0.5 M EDTA and 500 kallikrein inhibitor units/ml aprotinin (Sigma, St. Louis, MO) [7]. Fasting lymph was collected for 1 h before nutrient infusion and then at 30-min intervals for 1 h and then hourly over the subsequent 6 h.

Nutrient Infusate Preparation

Three groups of animals were tested and infused intraduodenally with a single bolus of 3 ml of one of the following four infusates. Except for the saline control group, the infusate for the other three groups had a caloric content of 4.43 kcal/3 ml. The three infusates were: (1) saline (0.9%, control group), (2) Liposyn consisting of 2.215 ml of Liposyn (20%, 2 kcal/ml) and 0.785 ml of saline, (3) L-81 plus Liposyn (12 mg/ml of L-81 in above Liposyn

and saline mixture) this group had an infusion of L-81 alone starting 60 min before the combination of L-81 and Liposyn), (4) P-85 plus Liposyn (12 mg/ml of P-85 in above Liposyn and saline mixture) with an infusion of P-85 alone starting 60 min prior. The caloric load used was based on previous studies which demonstrated that this is sufficient for a robust stimulation of incretin release into lymph [7, 8]. Animals receiving L-81 with their lipid meal were pretreated for 1 h with L-81 alone based on preliminary studies showing that L-81 works most effectively when it is introduced prior to the administration of the L-81 plus Liposyn mixture. L-81 was sonicated together with the appropriate volume of 19 mM sodium taurocholate (NaTC) to form a micellar solution. The L-81 plus Liposyn mixture was sonicated to form an emulsion which was then administered intraduodenally as a single bolus. The P-85 plus Liposyn mixture was also sonicated to form an emulsion and administered in the same manner as the L-81 mixture. P-85 was used as a control to L-81 effect on TG transport and on incretin secretion. Nutrient infusions were followed by infusion of saline at 3 ml per hour. Liposyn (20%) (Abbott Laboratories, North Chicago, IL) consisted of equal amounts of safflower and soybean oil with a caloric content of 2 kcal/ml. L-81 and P-85 were kindly provided to us by BASF (Parsippany, NJ).

GLP-1 Radioimmunoassay

Glucagon-like peptide-1 concentrations in lymph were determined by a commercially available radioimmunoassay (RIA) kit (LINCO Research, St. Louis, MO) as described previously [8]. This kit uses a rabbit anti-GLP-1 serum, GLP-1 (7–36) amide as the standard and ^{125}I -GLP-1 (7–36) amide as tracer. The antiserum used in this RIA recognizes the C-terminus of GLP-1, including both amidated and non-amidated forms (LINCO Research); therefore the assay detects all of the major circulating forms of GLP-1 including GLP-1 (7–36), GLP-1 (7–37), GLP-1 (9–36), GLP-1 (9–37), GLP-1 (1–36) and GLP-1 (1–37) amides in biological fluids.

GIP ELISA

Glucose-dependent insulintropic polypeptide was determined by ELISA assay kit provided by Linco (St. Louis, MO) that detects both intact GIP and its major metabolite GIP_{3–42}. Briefly, lymph samples were added to wells of a microtiter plate pre-coated with anti-GIP monoclonal antibodies as previously described. A second biotinylated anti-GIP polyclonal antibody was added and then conjugated to streptavidin–horseradish peroxidase. The enzyme activity is measured spectrophotometrically by absorbency at 450 nm.

Chemical Assays

Lymph triglycerides were measured according to the protocol provided by Randox (Randox Laboratories Ltd., Crumlin, UK). This enzymatic assay measured the released glycerol resulting from the hydrolysis of triglycerides. Briefly, 5 μl of lymph was added to 200 μl reagent. After 20 min of incubation at 37 °C, optical density was read at 500 nm. Triglycerides concentration was calculated from the standard solution provided by Randox. Free fatty acids were assayed by a commercial kit from Wako (Wako Diagnostics, Richmond, VA). This enzymatic method involves the acylation of coenzyme A (CoA) by the fatty acids in the presence of added acyl-CoA synthetase. The acyl-CoA product is then oxidized by the added acyl-CoA oxidase to generate hydrogen peroxide. In the presence of peroxidase, a purple colored adduct is formed and can be measured colorimetrically at 550 nm.

Statistical Analysis

All values are expressed as means \pm SE. Two-way repeated-measures ANOVA with Tukey's as a post-test analysis was used to compare all the groups, e.g. L-81 plus Liposyn and Liposyn, throughout the 6 h infusion. The analyses examine the statistical significance between groups and also compare multiple time points within each group. A difference was considered significant if the *P* value was <0.05 . All statistical analyses were performed with the statistics program SigmaStat version 3.5 (SPSS).

Results

Lymph Flow

The lymph flow rate following Liposyn infusion was significantly increased when compared to the saline control group, as reflected by the 30-min time point measure of 4.45 ± 0.38 ml/h for the Liposyn group compared to that of 2.88 ± 0.48 ml/h for the control group ($P = 0.007$, Fig. 1). By 60 min, lymph flow had decreased in the Liposyn group, but at 120 min it was significantly elevated versus the saline control group ($P = 0.001$). The increase remained significant through 180 min ($P = 0.003$) at the rate of 3.84 ± 0.25 ml/h. Addition of L-81 to the Liposyn infusion reduced lymph flow compared to Liposyn alone. In fact, throughout the duration of the 6 h study, the mean lymph flow rate of the L-81 plus Liposyn group, 2.04 ± 0.23 ml/h, was not significantly different from that of the saline control mean, 2.57 ± 0.23 ml/h; however, it was significantly lower than that of the mean flow rate of the Liposyn only group, 3.10 ± 0.25 ml/h ($P = 0.017$).

Fig. 1 The lymph flow rate during the 6 h period following administration of intraduodenal infusion of Liposyn (filled boxes), L-81 plus Liposyn (filled triangles), P-85 plus Liposyn (open triangles) or Saline (filled diamonds). Liposyn ($n = 6$), L-81 plus Liposyn ($n = 7$), P-85 plus Liposyn ($n = 4$) or Saline ($n = 6$). Data are presented as means \pm SEM. Asterisks indicate significant differences between the saline group and the Liposyn or P-85 plus Liposyn group, respectively, at specific times. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$

Infusion of P-85 plus Liposyn slightly increased the lymph flow rate but it was not significant compared to the saline control except at 180 min. The mean lymph flow rate of the P-85 plus Liposyn group, 2.85 ± 0.17 ml/h, was not significant from that of the control.

Effect of L-81 on Lymphatic Triglycerides and Free Fatty Acids Output

Administration of Liposyn alone induced a significant increase in lymph TG which was evident by 60 min and which peaked at $2,095 \pm 298$ mg/dL 5 h after the bolus of enteral lipid ($P < 0.001$; Fig. 2a). Addition of L-81 (12 mg/ml) together with Liposyn completely abolished the increase in lymph TG, resulting in a profile which was not significantly different from the saline control group. Compared to the L-81 plus Liposyn group, P-85 administration with Liposyn demonstrated a significant increase in lymph TG versus the saline control animals at 180 min ($P = 0.005$) and the increase was sustained and peaked at 300 min ($P < 0.001$) similar to the trend of the Liposyn group. There was a significant difference in lymph TG between the L-81 plus Liposyn and the P-85 plus Liposyn groups starting at 60 min ($P = 0.017$) and all the subsequent time points in this study. The overall mean of the 6 h study for the Liposyn group, $1,206 \pm 67$ mg/dL, was greater than that of the L-81 plus Liposyn group, 59 ± 62 mg/dL ($P < 0.001$). A similar significant difference was observed between the 6 h time course mean of the P-85 plus Liposyn group, 721 ± 82 mg/dL, and that of the L-81 plus Liposyn group ($P < 0.001$).

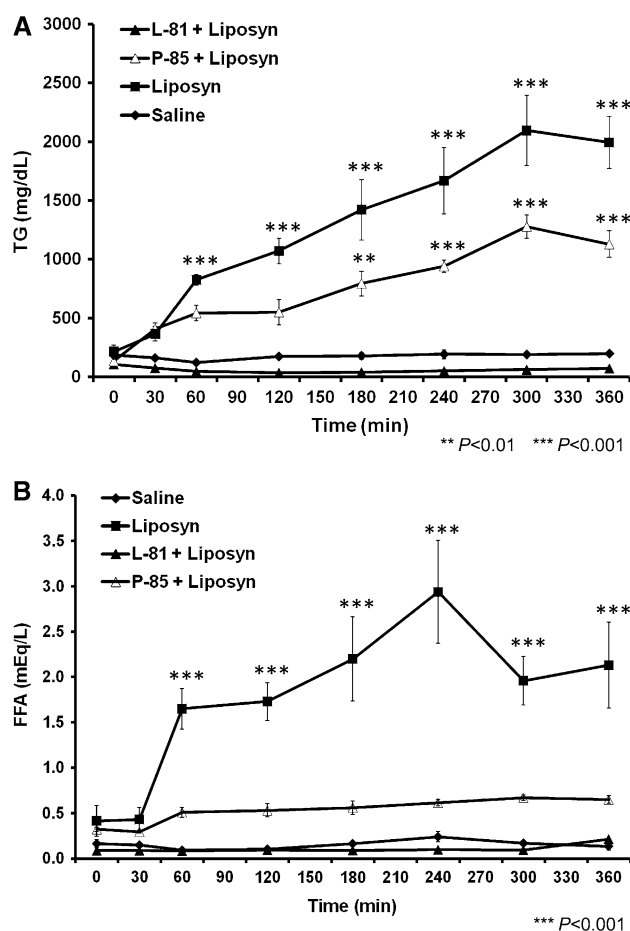

Fig. 2 a Triglycerides content in lymph collected at 30 min and hourly following saline control (filled diamonds) or isocaloric and isovolumetric intraduodenal infusion of Liposyn (filled boxes), Pluronic L-81 (L-81) plus Liposyn (filled triangles) or Pluronic P-85 plus Liposyn (open triangles). Data are means \pm SEM. Asterisks indicate significant elevations of Liposyn group or P-85 plus Liposyn group over the saline values at that time: ** $P < 0.01$, *** $P < 0.001$. **b** Comparison of stimulation of free fatty acids concentrations in response to saline (filled diamonds) or isocaloric and isovolumetric treatment of Liposyn (filled boxes), L-81 plus Liposyn (filled triangles) or P-85 plus Liposyn (open triangle). Data are means \pm SEM. Asterisks indicate significant differences between the saline group and the Liposyn group at specific times: *** $P < 0.001$

Intraduodenal administration of Liposyn alone also stimulated a rapid rise in lymph FFA by 60 min after an initial 30 min period of FFA stability (Fig. 2b). The increase in FFA peaked at 2.93 ± 1.01 mequiv/L 4 h after the Liposyn bolus. The presence of L-81 together with Liposyn completely inhibited the increase in lymph FFA seen with Liposyn alone with the result that levels of FFA in the combined L-81 plus Liposyn group were similar to those in the saline control group which had an average of 0.15 ± 0.15 mequiv/L ($P = 0.891$) over the 6 h study. P-85 infusion with Liposyn showed increased lymph FFA levels after 30 min compared to the saline control and L-81

plus Liposyn but the difference was not significant. The overall mean of the P-85 plus Liposyn group was 0.519 ± 0.16 mequiv/L and the mean of the saline control group was 0.152 ± 0.14 mequiv/L ($P = 0.322$).

Effect of L-81 on Lymph GLP-1 Concentrations and Output

Intraduodenal bolus infusion of Liposyn alone stimulated a rapid peak GLP-1 concentration of 176 ± 29 pM at 30 min (Fig. 3a) and GLP-1 levels remained significantly elevated compared to the saline control through 120 min ($P = 0.042$). The presence of L-81 with Liposyn delayed the postprandial GLP-1 response, resulting in a peak GLP-1 concentration at 120 min rather than 30 min as seen with Liposyn alone. The GLP-1 concentration, although somewhat reduced compared to Liposyn during the first hour, was still significantly higher than the saline controls at all the time points studied up to 240 min with the biggest difference at 120 min when GLP-1 concentration for the combined L-81 plus Liposyn group was 163 ± 47 pM whereas GLP-1 concentration for the saline control was 32 ± 3 pM ($P < 0.001$). Following the combined P-85 plus Liposyn administration, GLP-1 concentration was elevated after 30 min and peaked at 120 min reaching 199 ± 69 pM ($P < 0.001$). Glucagon-like peptide-1 levels were significantly increased versus the saline control from 30 min ($P = 0.001$) through 180 min ($P = 0.005$). The effect of P-85 plus Liposyn on lymph GLP-1 concentration was similar to that of L-81 plus Liposyn both peaking at the same time and had a similar pattern over the 6 h study.

To calculate lymphatic GLP-1 output, post-meal concentrations of the peptide were multiplied by lymph flow. Since lymph concentration of a substrate or of hormones is a function of the release of peptide into the lymph and lymph flow, the lymphatic output serves as a better index of incretin secretion. GLP-1 output following Liposyn administration exhibited a rapid increase by 30 min, peaking at 784 ± 141 fmol/h (Fig. 3b), and then remained elevated for 240 min before decreasing to baseline rates. L-81 plus Liposyn significantly reduced GLP-1 output compared to Liposyn alone initially. At 30 min, when GLP-1 output had reached its maximum in the Liposyn only group, the addition of L-81 decreased GLP-1 secretion by about 75% ($P < 0.001$). However, there was no significant difference between L-81 plus Liposyn and Liposyn groups at 60 min ($P = 0.063$) and subsequent time points. Infusion of P-85 plus Liposyn enhanced GLP-1 secretion to levels similar to Liposyn at 30 min and during the 6 h study. The P-85 plus Liposyn treated animals had greater GLP-1 secretion compared to the saline control group during the first 180 min. The effect of P-85 plus Liposyn was quite similar to that Liposyn alone compared to the

effect of L-81 plus Liposyn on GLP-1 secretion. Cumulative lymph GLP-1 secretion during the six hours of the study was calculated by summing the secretion during each hour. The total GLP-1 released following Liposyn alone, Liposyn plus L-81, Liposyn plus P-85, and saline were $2,530 \pm 195$, $1,737 \pm 351$, $2,705 \pm 203$, and 649 ± 52 fmol/h, respectively (Fig. 5a). While L-81 significantly reduced the secretion of GLP-1 in response to Liposyn ($P = 0.034$), the cumulative output was still much greater than the saline controls ($P = 0.005$). Administration of P-85 plus Liposyn generated cumulative GLP-1 output

that was similar to Liposyn by itself and greater than either the L-81 plus Liposyn ($P = 0.042$) or saline control ($P < 0.001$).

Effect of L-81 on Lymph GIP Concentrations and Output

The intraduodenal administration of Liposyn induced a rapid increase in lymph GIP concentration, peaking at 60 min with GIP levels at 488 ± 140 pg/ml. Glucose-dependent insulintropic polypeptide levels remained elevated throughout the 6 h of study (Fig. 4a). Inhibition of chylomicron formation by the administration of L-81 and Liposyn had a dramatic effect on lymph GIP

concentrations, which changed minimally and did not differ significantly from levels recorded for the saline controls. The mean for the L-81 plus Liposyn group was 93 ± 34 pg/ml compared to the mean for the saline group at 91 ± 40 pg/ml over the entire 6 h time course. Administration of a Pluronic surfactant, which at the same concentration as L-81, has no effect on chylomicron formation such as P-85 together with Liposyn demonstrated no inhibitory effect on lymphatic GIP concentrations. P-85 plus Liposyn induced a rapid increase in GIP levels from 77 ± 22 at fasting to 497 ± 75 pg/ml within 60 min reaching a peak concentration of 529 ± 41 pg/ml at 120 min (Fig. 4a). The P-85 plus Liposyn was significantly elevated compared to the L-81 plus Liposyn group ($P < 0.001$) and to the saline control group ($P < 0.001$) at 60 min. Similar levels of increase were observed for the Liposyn group compared to the L-81 plus Liposyn and saline groups. At 120 min, both the P-85 plus Liposyn and Liposyn groups were still elevated versus the L-81 plus Liposyn and saline control groups ($P < 0.001$). Compared to the L-81 and saline groups, the P-85 plus Liposyn remained increased at 180 min while the Liposyn group started to decrease. The mean for the 6 h time course study of the P-85 plus Liposyn group, 287 ± 45 pg/ml, was also similar to that of the Liposyn group, 289 ± 34 pg/ml.

Glucose-dependent insulintropic polypeptide secretion was calculated based on the GIP concentration and lymph flow rate. The Liposyn group stimulated a rapid increase in GIP secretion during the first 30 min rising to $1,392 \pm 234$ pg/h and peaked at $1,589 \pm 147$ pg/h by 120 min. Administration of P-85 plus Liposyn induced a more gradual increase in GIP secretion but reached a higher peak of $1,798 \pm 185$ pg/h at the same time point as the Liposyn group at 120 min. Glucose-dependent insulintropic polypeptide secretion was blocked in the presence of L-81. The L-81 plus Liposyn group only reached a maximum of 348 ± 112 pg/h at 120 min. During the entire time course, the level of GIP secretion stimulated by the L-81 plus Liposyn group was similar to that of the saline control group with overall means of 188 ± 110 and 241 ± 131 pg/h, respectively. There was no difference between the means of the L-81 plus Liposyn and saline control groups with a P value of 0.989. The GIP secretion rate of the Liposyn group was significantly higher than either the L-81 plus Liposyn or saline control group at 30, 60, and 120 min ($P < 0.001$) as well as at 180 min ($P = 0.001$). Without the inhibitory effect of L-81 on chylomicron formation, the surfactant P-85 plus Liposyn demonstrated similar effect as Liposyn showing significant stimulation of GIP secretion rate from 60 to 180 min. The overall means of the P-85 plus Liposyn, 864 ± 147 , and Liposyn, 939 ± 111 pg/h, were also similar having no significant difference ($P = 0.98$). However, the overall

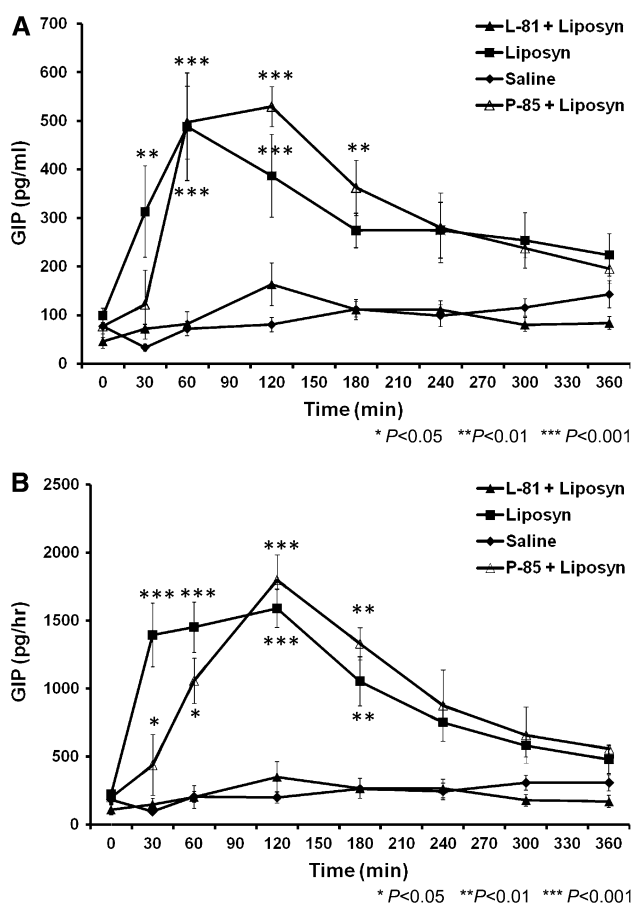

Fig. 4 a Concentrations of GIP in lymph following intraduodenal infusions of Liposyn (filled boxes), L-81 plus Liposyn (filled triangles), P-85 plus Liposyn (open triangles) or saline (filled diamonds). Data are presented as means \pm SEM. Asterisks denote significant differences between the saline group and the Liposyn or P-85 plus Liposyn group, respectively, at that time. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$. **b** Lymphatic GIP secretion rate in response to saline (filled diamond) or isocaloric and isovolumetric treatment of Liposyn (filled box), L-81 plus Liposyn (filled triangle) or P-85 plus Liposyn (open triangle). Data are means \pm SEM. Asterisks indicate significant differences between values of the saline group and the Liposyn or P-85 plus Liposyn group, respectively, at that time: * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$

mean for the 6 h time course of the P-85 plus Liposyn group was much greater than that of the L-81 plus Liposyn group ($P = 0.008$) or the saline control group ($P = 0.024$).

The effect of L-81 on GIP output confirmed the anticipated effect of L-81 in abolishing the secretion of this incretin (Fig. 4b). Furthermore, cumulative lymphatic GIP output in the Liposyn group was $7,510 \pm 1,249$ pg over 6 h whereas the presence of L-81 greatly decreased the output to $1,678 \pm 393$ pg ($P = 0.001$) during the same period (Fig. 5b). Total GIP secretion in the saline control group was $1,929 \pm 258$ pg and was not significantly different from L-81 plus Liposyn ($P = 0.998$). Administration of P-85 together with Liposyn showed similar cumulative

GIP output of $6,909 \pm 1,115$ pg compared to Liposyn ($P = 0.978$). The P-85 plus Liposyn group induced greater lymph GIP output versus that of the L-81 plus Liposyn group ($P = 0.012$) or the saline control group ($P = 0.028$).

Discussion

In previous studies, we showed that the lymph fistula rat model is a useful model for studying the secretion of GLP-1 and GIP in response to glucose and lipid administration. The changes in the concentrations of incretins in intestinal lymph paralleled the changes in plasma levels following carbohydrate, lipid, or mixed nutrient meals [7–9], although lymph concentrations were at much higher levels, suggesting that this model provides a sensitive way of studying gut hormone secretion. In the present study, we took advantage of this newly established conscious rat model to gain insight into the mechanism by which chylomicron formation in the gut stimulates the secretion of incretins by the enteroendocrine cells. By blocking chylomicron formation using Pluronic L-81 (blocking the trafficking of lipoprotein particles from the endoplasmic reticulum to the Golgi apparatus), a relatively distal step in lipid handling by enterocytes, we were able to completely abolish GIP secretion but not GLP-1. Although overall GLP-1 secretion was significantly reduced, the most notable reduction occurred in the initial phase of GLP-1 secretion (first 30 min). The latter phase of GLP-1 secretion was less affected by L-81. The fact that GLP-1 and GIP responses differ is consistent with previous studies suggesting that secretion of the two incretins in response to enteral nutrients occurs via different mechanisms [12].

The near absence of lymph TG when Liposyn was administered in combination with L-81 confirms previous findings which have demonstrated the efficacy of this compound to inhibit the formation and secretion of chylomicron from the small intestine to the lymph [20, 21]. When the incorporation of absorbed TG into chylomicrons is inhibited, the absorbed lipid accumulates in the intestinal epithelial cells as large lipid droplets [20]. Fat digestion and absorption have been shown to occur primarily in the proximal intestine [29–31]. Following the digestion of lipid in the small intestine, free fatty acids and monoglycerides are absorbed by the intestinal enterocytes and re-esterified to TG droplets in the smooth endoplasmic reticulum (ER). L-81 does not affect any of the aforementioned steps, and so, for GIP, the exposure, the uptake, and the re-esterification of the lipid digestion products to form TG is not sufficient to stimulate the K cells to secrete GIP. Our data are consistent with several previous reports that enteral administration of L-81 effectively blocked the postprandial rise in GIP following ingestion of long-chain triglycerides

[32, 33]. Taken together with these findings, our observations that L-81 abolishes the lipid-stimulated rise in GIP indicate that inhibition of chylomicron formation prevents K-cell secretion of GIP.

Under normal circumstances, the TG formed in the ER from absorbed lipid are transported to the Golgi apparatus where the secretory vesicles containing nascent chylomicrons are formed and migrate to the lateral cell membrane. These vesicles subsequently fuse with the lateral plasma-membrane and release the nascent chylomicrons into the intercellular spaces, from where they enter the intestinal lymphatics. In the presence of L-81, however, the trafficking between ER and the Golgi apparatus is prevented which leads to an accumulation of large lipid droplets observable under electron microscopy in distended tubules of smooth endoplasmic reticulum in the apical portion of the enterocytes [20, 34]. Recent data by Fatma et al. [22] showed that L-81 inhibits the microsomal triglyceride transfer activity, a critical component in the trafficking and formation of pre-chylomicrons. This process has a dramatic effect on the secretion of GIP. It is interesting that GIP, produced and secreted almost entirely in the upper intestine, is more affected by L-81 than GLP-1 which is synthesized more distally in the gut. The obvious correlate is that lipid absorption and chylomicron formation is also predominantly a duodenal, upper jejunal process. While we cannot speak to the mechanism whereby GIP, and to a lesser extent GLP-1, secretion is inhibited by L-81, since enteroendocrine cells are not thought to package absorbed lipids into chylomicrons, this effect is likely to be indirect. One plausible explanation is that enterocytes release a factor(s) which stimulate secretion from K-cells. If this is true, the isolation of this factor could be extremely important, not only as it relates to our understanding of the regulation of incretin secretion by macronutrients, but it may also potentially offer a pharmaceutical target for the development of anti-diabetic drugs.

From previous experience we know that L-81 has a profound impact to block chylomicron formation and reduce postprandial TG in lymph and plasma. In this study L-81 reduced incretin secretion, GLP-1 marginally and GIP substantially. Therefore we think it is unlikely that L-81 has an independent effect to stimulate incretin secretion. Even in lymph, concentrations of GIP and GLP-1 are low in the fasting state, and it is unclear that basal secretion has an important physiologic role. Therefore we are not certain that any effect of L-81 alone to reduce incretin secretion would be detectable. For example note the 0 min GLP-1 and GIP levels in the saline and L-81 plus Liposyn groups. The levels are very similar despite infusion of L-81 for 60 min. While not definitive this suggests that administration of L-81 to fasting animals does not have a significant effect on incretin secretion.

The results of our study demonstrated that Pluronic L-81 blocked chylomicron formation induced by Liposyn and the transport of TG to the intestinal lymph. Another Pluronic copolymer examined in the study, P-85, exhibited no inhibitory effect on lymph TG transport at the same dosage administered as L-81. Both L-81 and P-85 have been investigated together in many studies involving cellular uptake of proteins, inhibition of multidrug resistance-associated protein, lipid-Pluronic interactions, and intestinal P-glycoprotein efflux [23–27]. In our study, Pluronic P-85 did not abolish GIP secretion stimulated by Liposyn as Pluronic L-81 did. Pluronic P-85 behaved similarly to Liposyn in stimulating GIP secretion, while Pluronic L-81 behaved similarly to the saline control. The cumulative GIP output induced by P-85 plus Liposyn over the 6 h time course was 4.1 fold greater than that by L-81 plus Liposyn, while cumulative GIP output stimulated by Liposyn alone was 4.5 fold greater than that by L-81 plus Liposyn. Unlike Pluronic L-81, Pluronic P-85 also did not cause a decrease in the initial phase of GLP-1 secretion in response to Liposyn stimulation. The cumulative GLP-1 output induced by P-85 plus Liposyn during the 6 h study was significantly greater than that by either L-81 plus Liposyn or saline control.

In addition to blocking chylomicron secretion, L-81 also prevented the increase in lymphatic free fatty acid output associated with fat absorption as shown in Fig. 3. This raises the possibility that local concentrations of fatty acids in the intestinal mucosa activate K-cells to release GIP. Although possible, we do not believe this to be particularly likely because when we examined lymphatic GIP secretion and lymphatic free fatty acid secretion in a normal animal as depicted in Figs. 4a and 2b, we found that lymphatic GIP secretion peaked much earlier than free fatty acid secretion and also that while lymphatic FFA output gradually increased and before reaching a plateau at 240 min, lymphatic GIP secretion had already started to decrease back to the pre-feeding state before 240 min.

As reflected both by our lymphatic GLP-1 concentration data as well as our GLP-1 secretion data, the presence of L-81 reduced the early phase of GLP-1 secretion by the endocrine cells normally stimulated by fat absorption. While the mechanisms of nutrient-coupling to L-cell secretion are not well understood, it is generally believed that indirect mechanisms account for the early phase of GLP-1 release because GLP-1-producing L-cells are located predominantly in the distal small intestine but plasma levels increase rapidly, within 10 min after meal ingestion [35–37], long before chyme containing the nutrients would be expected to reach the lower gut. Several studies have suggested that neural or humoral mediators are activated by nutrients in the upper gut to signal the release of GLP-1 distally [38–45]. In our study, we found a marked inhibition of GLP-1 secretion during the first 60 min in the

presence of L-81, but the effect of L-81 seemed to diminish from 60 min onwards. From this data, it seems that while the formation and secretion of chylomicrons plays a role in the stimulation of GLP-1 secretion, other factors connected with lipid absorption are important as well. Some have pointed to the activation of G protein coupled receptor 120 by long chain unsaturated fatty acids such as oleic acid and alpha-linolenic acid as one possible mechanism in GLP-1 secretion [45–47]. G protein coupled receptor 120 is distributed widely in the gastrointestinal tract [39]. Bile acids have also been reported to stimulate the release of GLP-1, a process which appears to be mediated by the G protein coupled receptor TGR5 [48]. It is also important to note that only the early secretion of GLP-1 was significantly affected by the presence of L-81. It has been proposed that GIP stimulates the secretion of GLP-1 through activation of the vagus nerve [45]. Because our results show that the increase in GIP secretion following intestinal fat absorption was completely abolished by the addition of L-81, we propose that the lack of the increase in GIP secretion actually resulted in a reduction in the early release of GLP-1 by the endocrine L cells. Thus, L-81 could be a useful tool for the dissection of the relative importance of the different pathways involved in the macronutrient induced secretion of GLP-1. Additional studies would have to be performed to support or refute this interesting notion.

In summary, we have demonstrated that the stimulation of GIP secretion by lipid absorption in the small intestine is dependent on the efficient formation and secretion of chylomicrons and that the inhibition of chylomicron formation by L-81 completely abolishes this stimulation. In contrast, we have shown that GLP-1 secretion by the L-cells is only partially inhibited by L-81, mostly in the early phase of GLP-1 secretion. Another Pluronic copolymer, P-85, examined in our study did not reveal the effect of inhibition of GIP secretion, lymph TG, and the partial reduction of early-phase GLP-1 secretion observed with L-81. We propose that the reduction in the early phase of GLP-1 secretion, believed to be mediated neuronally, is probably a result of the inhibition of GIP secretion. Lastly, our data would suggest that L-81 could be an important and interesting tool in determining the relative importance of the various factors which modulate GLP-1 secretion by intestinal fat absorption.

Abstract Natural killer (NK) T cells are well known to play important roles in both tumor rejection and the defense against infectious. Therefore, the antitumor potential of NKT cell-activating antigens have been the focus for the development of NKT cell-based immunotherapies. Up to now, several studies have revealed that the administrations of glycolipids (e.g. α -galactosylceramide) can successfully treat certain metastatic tumors. However, liver injuries appeared upon the application of these antigens. We previously examined the potential of using β -glucosylceramide (β -GlcCer) to inhibit tumor metastasis to the liver. The aim of this study was to determine the antimetastatic effects of β -GlcCer and its impact on the activation of NKT cells. Intraperitoneal administration of β -GlcCer enhanced the production of interferon- γ from hepatic lymphocytes containing NKT cells, and increased

the cytotoxicity of hepatic lymphocytes against tumor cells. Moreover, β -GlcCer administration suppressed the hepatic metastasis of tumors in wild type (WT) mice, but not in $CD1d^{-/-}$ or $J\alpha 18^{-/-}$ mice. The drawback associated with the other glycolipids in liver injury was not noted in WT mice treated with the continuous daily administration of β -GlcCer for 2 weeks. The present study demonstrated that β -GlcCer treatment activates invariant NKT cells, thus resulting in the inhibition of tumor metastasis.

aspects of cancer biology [1, 2]. We previously demonstrated that ceramides with a chain length shorter than C8, but not longer than C12, show tumor-specific cytotoxicity [3]. Glycosylceramide has been shown to induce antitumor immune responses in various cancer models via the activation of natural killer (NK) T cells, which are important immune regulators that can either promote or suppress immunity [4–6]. It has been believed that NKT cells play roles not only in tumor rejection and defense against infectious agents, but also in the regulation of autoimmunity [7]. NKT cells are distinguished from conventional T lymphocytes by their function and T cell receptor (TCR) usage [8]. Most NKT cells recognize glycolipid antigens in the context of the monomorphic major histocompatibility complex class I-like molecule, CD1 [9]. CD1d-restricted NKT cells are further divided by their functions into Types I and II [7, 10, 11]. The antitumor activities of NKT cells have mainly been attributed to the Type I cells, which express an invariant V α 14-J α 18/V β 8 TCR in mice (V α 24-J α 18/V β 11 in humans) and strongly react with the marine sponge-derived glycolipid, α -galactosylceramides (α -GalCer). The administration of α -GalCer results in the rapid and massive activation of NKT cells, and the production of a burst of typical Th1 and Th2 cytokines such as interferon- γ (IFN- γ) and interleukin-4 (IL-4) from these cells [7, 12, 13]. In mice, NKT cells activated by this compound also down-regulate the TCR and NK-1.1 molecule, a NK cell marker, on their cell surface [14, 15], resulting in the apparent disappearance of NK-1.1 positive T cells in vivo.

In most studies for the development of NKT cell-based immunotherapies, the antitumor potential of NKT cell-activating glycolipids has been focused on α -GalCer [16]. Treatment with α -GalCer has been successful for certain metastatic tumors in various studies [17–19]. However, it has been demonstrated that α -GalCer administration can lead to significant liver damage [18, 20, 21]. These liver injuries appear to be a critical drawback to the application of α -GalCer for immunotherapeutic use. Numerous studies have since focused on the development of effective and safe NKT cell-based immunotherapeutics using various compounds, e.g. synthetic analogues of α -GalCer, naturally occurring ligands, and β -anomers of glycosphingolipids. However, the safe and effective ligands that activate NKT cells have not yet been established for the development of NKT cell-based immunotherapies.

β -GlcCer, a naturally occurring glycolipid, is a metabolic intermediate of glucosphingolipids [22]. In our previous study, we demonstrated that β -GalCer (C18:0) and β -GlcCer (C16:0) exert tumor-specific cytotoxicity in vitro [3]. We also reported that intraperitoneal (i.p.) administration of β -GlcCer isolated from malt feed induced a decrease in the proportion of hepatic NK-1.1⁺ T cells in mice, and suppressed the hepatic metastasis of EL-4

lymphoma cells in mice. We therefore suspected that β -GlcCer could contribute to developing NKT cell-based immunotherapies for metastatic tumors. In the present study, we investigated whether treatment with β -GlcCer could enhance antitumor immunity through NKT cells activation, resulting in the suppression of experimental tumor metastasis.

Materials and Methods

Ceramides

Pure ceramides (C4:0 and C8:0), β -GalCer (C18:0), and β -GlcCer (C16:0) were purchased from Avanti Polar Lipid, Inc. (Alabaster, Alabama, USA). In this study, KRN7000 (Kirin Brewery Co., Ltd., Japan) was used as α -GalCer. Malt-feed-derived β -GlcCer (mf- β -GlcCer) was purified as previously described [3]. Chemical structures of these glycosylceramides are summarized in Fig. 1. The ceramides were dissolved in ethanol, and stored at -30°C until use. In this study, 2 and 200 μg of α -GalCer and the other ceramides were used in a single injection, respectively.

Animals

C57BL/6 (B6) mice (12–16 weeks old) and *CD1d*^{−/−} mice (11–20 weeks old, on a B6 background) were bred and maintained at the University of the Ryukyus and Niigata University, respectively. The *Ja18*^{−/−} mice (14–18 weeks old) on a B6 background were kindly provided by Dr. M. Taniguchi (RIKEN Yokohama Institute, Kanagawa, Japan). All mice were maintained under specific pathogen-free conditions, and given food and water ad libitum. Animal experiments were performed in accordance with the ethical principles and guidelines for the care and use of experimental animals at each university. Their serum and liver were collected at the end of the experiment. The serum IFN- γ levels and the indicator of hepatopathy were measured using commercial ELISA kits purchased from R&D Systems, Inc. (MN, USA) and commercial enzymatic kits (Wako Pure Chemical Industries, Ltd., Osaka, Japan), respectively.

Tumor Metastasis

EL-4 cells, a T-cell lymphoma cell line from a B6 background, were used in this study. These cells (5×10^5 cells/mouse) were intravenously (i.v.) inoculated into B6, *CD1d*^{−/−}, and *Ja18*^{−/−} mice. The mice were administered i.p. injections of ceramides suspended in 200 μL PBS containing 5 % ethanol, 3 days before and on the day of tumor inoculation. A volume of 200 μL of the vehicle

Fig. 1 Chemical structures of glycosylceramides using in this study. In mf- β -GlcCer, Chemical structure of the major-GluCer extracted from malt feed are shown

solution was given as a control at each administration time point. On day 14 after tumor inoculation, the number of tumors visible on the surface of the liver was counted.

Flow Cytometry

The monoclonal antibodies (mAb) used in this study included a FITC-conjugated anti-mouse CD3 ϵ chain (145-2C11) mAb, PE conjugated anti-mouse NK-1.1 (PK136) mAbs, and a biotin-conjugated anti-mouse CD69 (H1.2F3) antibody, which were all purchased from BD Biosciences (CA, USA). The biotin conjugated mAb were detected with Streptavidin-Allophycocyanin reagents (BD Biosciences). To prevent nonspecific Fc receptor-mediated binding of mAbs, the hepatic MNCs were pre-incubated with an anti-CD32/CD16 mAb (2.4G2, BD Biosciences) before staining with the labeled mAbs. The stained cells were analyzed on a FACSCalibur Flow Cytometer and the CellQuest software program (BD Biosciences) was used to analyze the results after gating for cells with the forward and side scatter properties of lymphocytes. Dead cells were excluded by propidium iodide gating.

In Vivo Responses to β -GlcCer in the Liver

At different time points after i.p. treatment with glycosylceramides, the livers were excised from the WT mice. Isolated hepatic MNCs from untreated or treated mice were stained with mAbs followed by a flow cytometric analysis,

or were plated in 96-well round-bottom microculture plates at 5×10^5 cells per well in RPMI-1640 medium (Sigma-Aldrich, Inc.) with 10 % heat-inactivated fetal bovine serum. To assess the levels of cytokine production by the cultured MNCs, the culture supernatants of the MNCs were harvested after 24 h of culture, and the cytokine levels in the culture supernatants were measured.

Cytotoxicity of Hepatic Lymphocytes

NK cell-sensitive YAC-1 lymphoma cells and EL-4 lymphoma cells were used as target cells. Hepatic MNCs (as effector cells) were purified from B6 mice 36 h after i.p. injection of 200 μ g of mf- β -GlcCer, and were suspended in RPMI-1640 medium without Phenol Red (Sigma-Aldrich, Inc.). The serially diluted effector cells were mixed with 1×10^4 target cells in 96-well round-bottom microculture plates. The plates were centrifuged and incubated for 4 h at 37 °C. The lactate dehydrogenase (LDH) released from the target cells was colorimetrically measured with an LDH Cytotoxic Test Kit (Wako Pure Chemical Industries). To induce cytotoxicity, poly (I:C), a ligand of toll like receptor 3, was injected (100 μ g/mouse) intraperitoneally into mice 12 h before the cytotoxicity assay.

IFN- γ mRNA Expression in Hepatic NK-1.1⁺ T Cells

Eighty six mice were sacrificed 24 h after i.p. administration of 200 μ g of mf- β -GlcCer. The isolated hepatic MNCs

were stained with fluorescently labeled anti-CD3 ϵ and anti-NK-1.1 mAbs as described above. The NK-1.1⁺ T cells were then sorted using a FACS Aria II Flow Cytometer (BD Biosciences). Using reverse transcriptase (High Capacity RNA-to-cDNA Kit; ABI, CA, USA), first-strand cDNA was synthesized from 1 μ g of total RNA from the sorted NK-1.1⁺ T cells. The specific primers used in the quantitative real-time PCR analysis were as follows: IFN- γ sense (5'-GAACGCTACACACTGCATC-3'), IFN- γ antisense (5'-GAGCTCATTGAATGCTTGG-3'); β -actin sense (5'-CAGAAGGAGATTACTGCTCTGGCT-3'), and β -actin antisense (5'-GGAGCCACCGATCCACACA-3'). The amplifications were performed with a commercial real-time PCR system (StepOne Real-Time PCR System; ABI). All samples were normalized to the amount of β -actin transcript in each sample.

Recognition of Glycolipid Binding CD1d-Dimer Molecules

Dimeric CD1d molecules (CD1d-dimer) were purchased from BD Biosciences. CD1d-dimer loaded with glycolipids was prepared with a 3- to 10-fold molar excess of glycosylceramides. To detect iNKT cells, hepatic MNCs were labeled with a FITC-conjugated anti-mouse TCR β chain (H57-597) mAb (BD Bioscience) and PE-labeled CD1d-dimer loaded with glycolipids according to the manufacturer's protocol.

Statistical Analyses

All values are expressed as the means \pm S.E.M. The significance of differences in the means between two groups was determined by Student's *t* test. To determine the significance of the differences between means for more than three groups, the data were analyzed by one-way ANOVA,

and then the differences among the mean values were inspected using Tukey-Kramer's multiple comparison tests. Differences were considered to be significant at $P < 0.05$.

Results

We first investigated whether the selective cytotoxicity of ceramides contributes directly to suppressing the metastasis of EL-4 lymphoma cells in B6 mice. The degree of tumor metastasis in mice treated with unglycosylated ceramides showed no significant difference from that in control mice (Fig. 2a, b). However, the treatment with a commercially available pure β -GalCer (C18:0) or β -GlcCer (C16:0) led to the inhibition of tumor metastasis in the liver (Fig. 2c).

As shown in Fig. 3, the proportion of hepatic NK-1.1⁺CD3⁺ cells was significantly decreased in mice treated with α -GalCer. Within the population of NK-1.1⁺CD3⁺ cells (NK cells), the number of CD69 positive cells was also increased. Treatment with mf- β -GlcCer induced a transient decrease in the hepatic NK-1.1⁺CD3⁺ cells proportion and an increase in the proportion of CD69⁺ NK-1.1⁺CD3⁺ cells.

Although the treatment with α -GalCer induced a burst increase in the serum IFN- γ level, the serum IFN- γ level was not altered by mf- β -GlcCer treatment at any of the experimental time points examined in the present study (Fig. 4a). The burst increases in serum IFN- γ and ALT levels induced by α -GalCer treatment were alleviated by the co-administration of mf- β -GlcCer (Fig. 4b). In the mice treated with mf- β -GlcCer, it was observed that there was an increase in the IFN- γ secretion from hepatic MNCs in the mice that were sacrificed 36 h after treatment (Fig. 5a). Using YAC-1 cells as target cells, the cytotoxicity of hepatic MNCs in mice treated with mf- β -GlcCer was significantly enhanced in

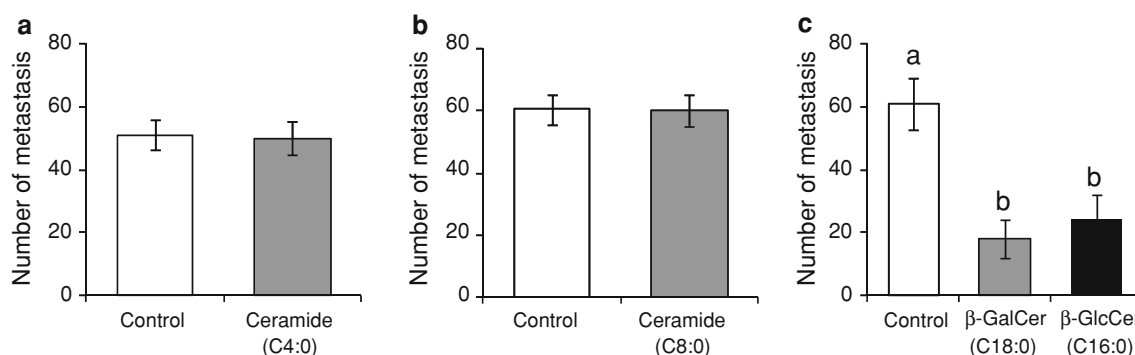

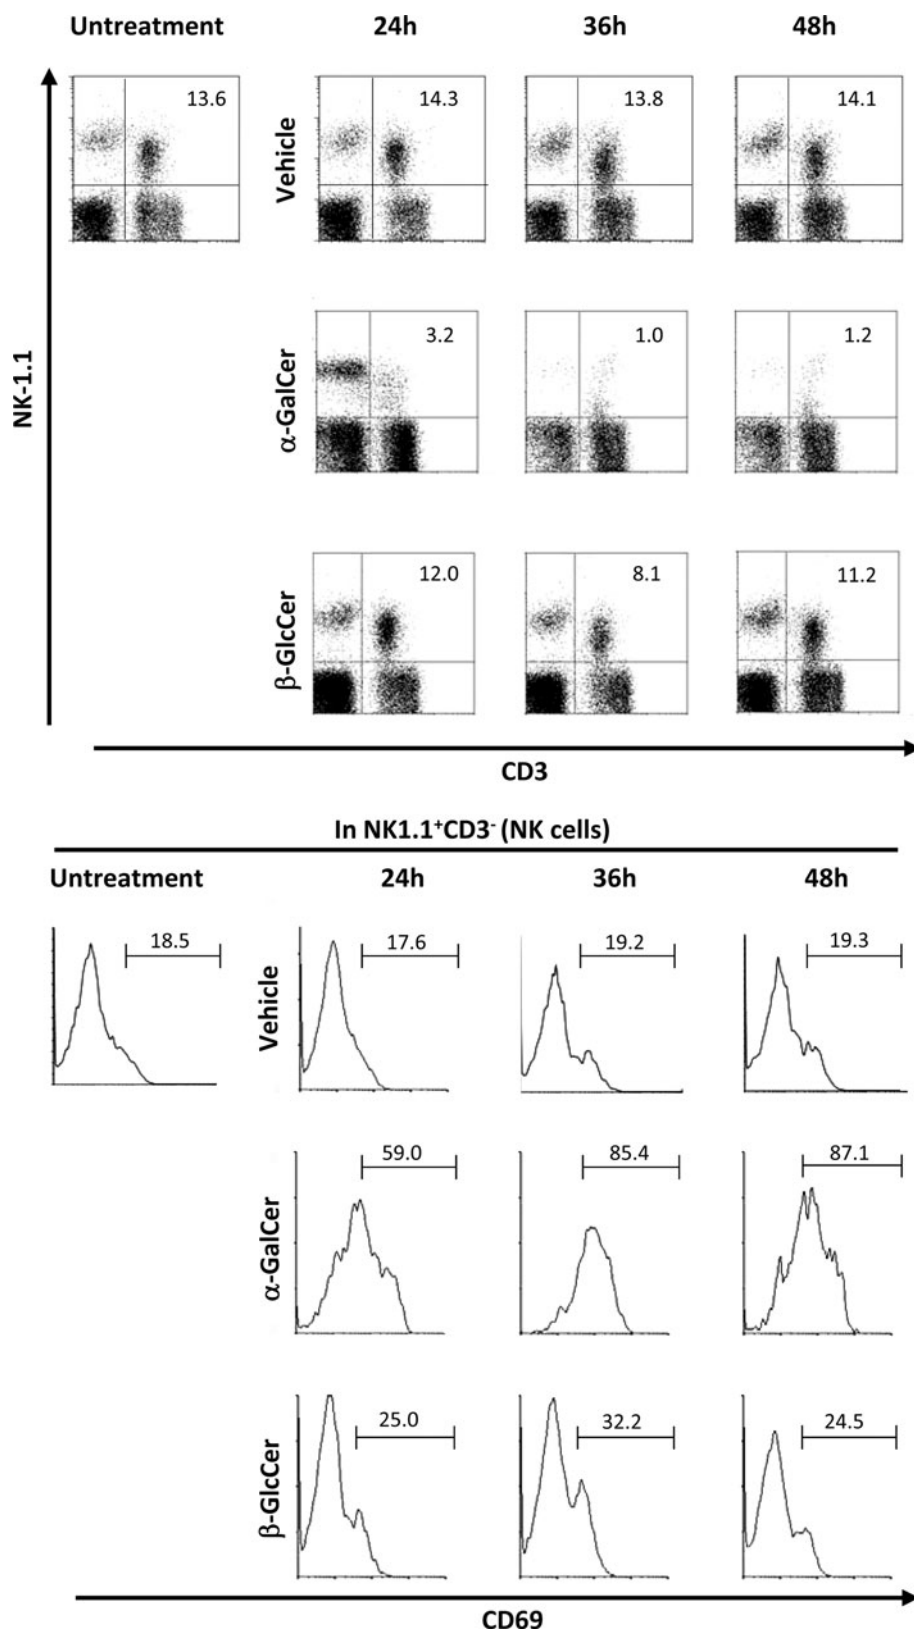

Fig. 2 The antimetastatic activities of ceramides. B6 mice were injected intraperitoneally with 200 μ g of ceramide 3 days before and on the day of intravenous inoculation of EL-4 lymphoma. The mice were then treated with unglycosylceramide with C4:0 and C6:0 fatty acids (a and b, respectively), and with β -GalCer (C18:0) or β -GlcCer

(C16:0) (c). The number of metastatic tumors visible on the liver surface was counted on day 14 after tumor inoculation. The data are presented as the means \pm S.E.M. for six mice. Different letters show significant differences between each experimental group of B6 mice ($P < 0.05$)

Fig. 3 The response of intrahepatic NKT and NK cells to β -GlcCer treatment in B6 mice. Lymphocytes were isolated from the liver at each time point after glycolipid injection. Three color staining for CD3, NK-1.1, and CD69 was conducted. The numbers in the figure indicate the percentages of fluorescence-positive cells in the corresponding areas. The results from one representative experiment out of three are shown

comparison with that in vehicle-treated control mice (Fig. 5b). Similar effect was observed when EL-4 lymphoma cells were used as target cells.

To confirm that β -GlcCer administration activated intrahepatic NKT cells, the IFN- γ production in NKT cells was examined. We thus examined the IFN- γ mRNA

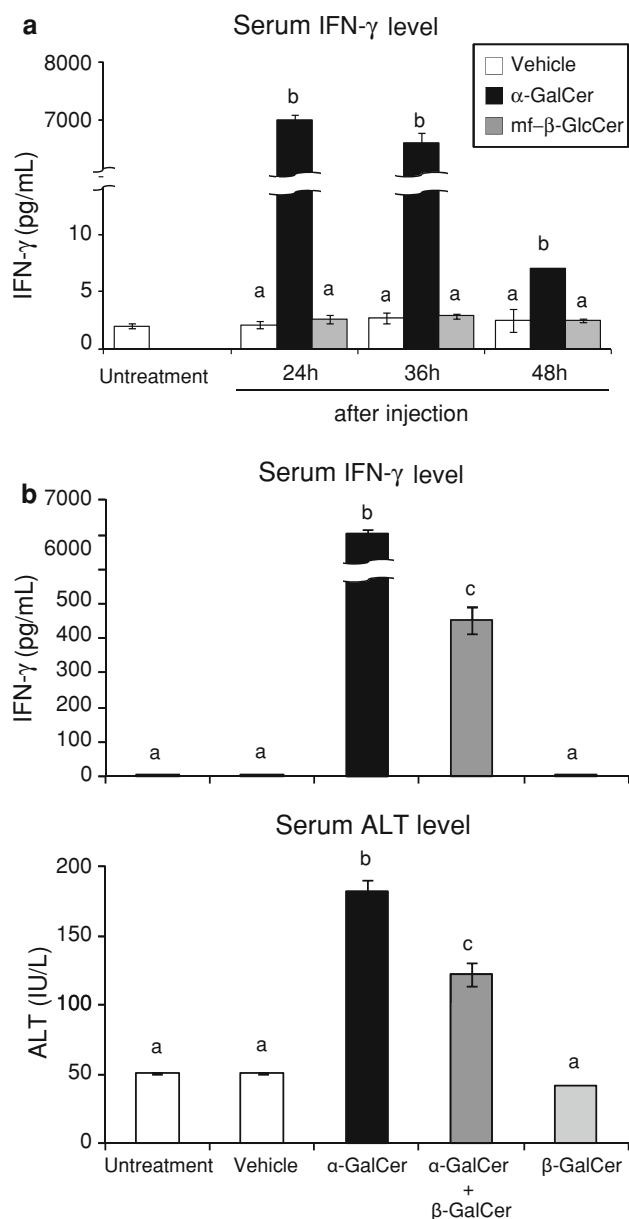

Fig. 4 The in vivo response to β -GlcCer treatment. Sera were collected at each time point after a single i.p. injection of ceramide (a) and 24 h after coadministration of α -GalCer and mf- β -GlcCer to B6 mice (b). The data are expressed as the means \pm S.E.M. for three mice. Different letters show significant differences between each experimental group of B6 mice ($P < 0.05$)

expression in intrahepatic NK-1.1⁺CD3⁺ cells. In this study, all flow cytometry sorting experiments showed >97 % purity (Fig. 6a). Although the mRNA expression of IFN- γ in the sorted NK-1.1⁺CD3⁺ cells was not affected by vehicle treatment, the i.p. injection of mf- β -GlcCer induced a significant enhancement of the IFN- γ mRNA expression (Fig. 6b). In in vitro experiments, the dimeric CD1d molecules loaded with α -GalCer could recognize

invariant NKT cells (Fig. 6c). However, the CD1d-dimer loaded with mf- β -GlcCer did not stain the hepatic MNCs.

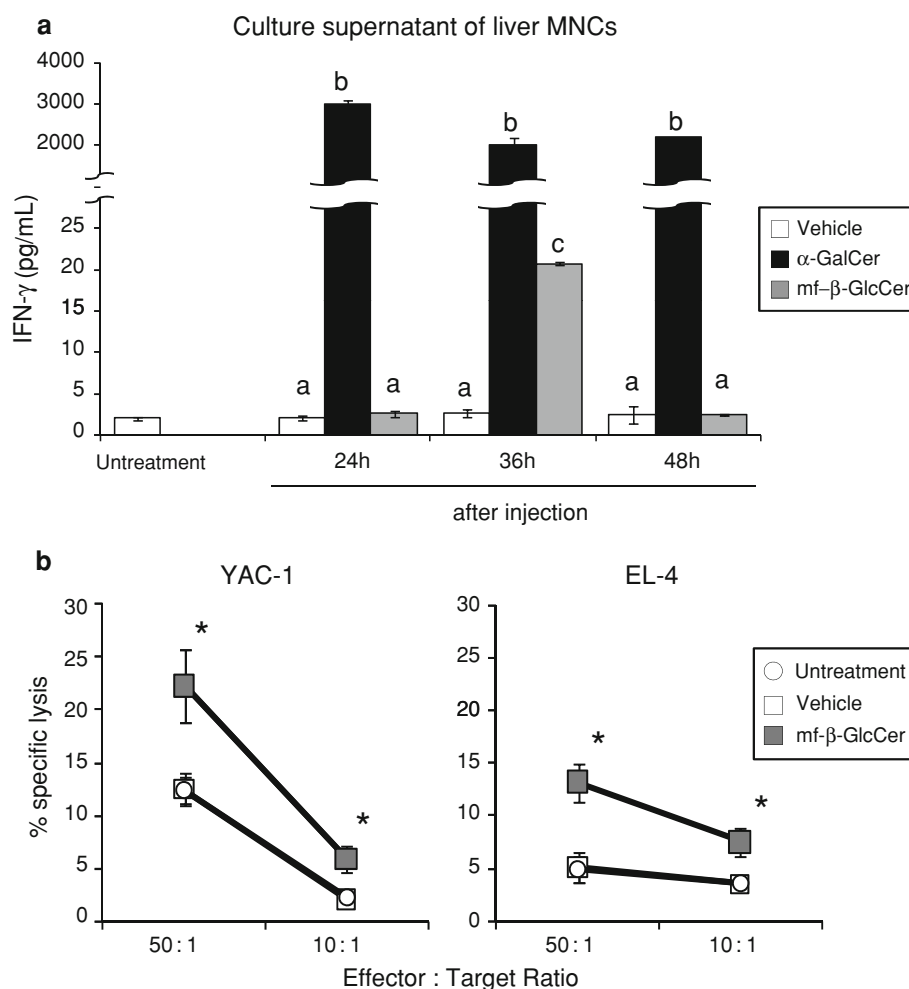

Upon the activation of NKT cells by α -GalCer, CD1d and the V α 14-J α 18/V β 8 TCR are essential molecules on antigen presenting and invariant NKT cells, respectively. Although treatment with mf- β -GlcCer in B6 mice significantly suppressed the number of metastatic tumors on the liver (Fig. 7a), no strong metastatic inhibition by mf- β -GlcCer treatment was observed in the *CD1d*^{-/-} or *Ja18*^{-/-} mice. The daily injection of mf- β -GlcCer (200 μ g/mouse/day) for 7 days did not affect the serum ALT and AST levels in WT mice (Fig. 7b). We also did not note any changes in the histology of the liver during a microscopic evaluation compared to the untreated mice (data not shown).

Discussion

In the present study, the administration of β -GlcCer enhanced the tumor-specific cytotoxicity of hepatic lymphocytes, and the IFN- γ mRNA expression in intrahepatic NKT cells. The β -GlcCer treatment also significantly inhibited the metastasis of experimental EL-4 lymphoma to the liver in WT mice, but not in *CD1d*^{-/-} or *Ja18*^{-/-} mice. The daily administration of β -GlcCer for 7 days did not induce any significant hepatocellular injury, nor any tissue damage as determined by a histological examination. These findings suggest that β -GlcCer, which is widely distributed in the plant kingdom, inhibits an experimental tumor metastasis through NKT cell activation without the critical drawback associated with the application of other antigens for activation of CD1d-restricted NKT cells.

In our previous study [3], the antimetastatic actions of mf- β -GlcCer were suggested to be attributable to two potential mechanisms; the first being their selective cytotoxicity, and the second being the induction of antitumor immunity. Moreover, we did not fully dismiss the possibility that compounds other than β -GlcCer could also contribute to the inhibition of metastasis. We previously reported that unglycosylated ceramides with chain lengths shorter than C8 (C4:0 and C8:0) have more selective cytotoxicity than β -GlcCer [3]. For example, the hepatic metastasis of tumors was inhibited by treatment with glycosylceramides, but not by treatment with unglycosylated ceramide (Fig. 2). The antimetastatic actions of β -GlcCer were not observed in mice with CD1d or J α 18 deficiencies (Fig. 7). These results support that the hypothesis that selective cytotoxicity of β -GlcCer is not required for its antimetastatic activity. This suggests that β -GlcCer injection inhibits tumor metastasis in the liver by enhancing the antitumor immunity.

Fig. 5 The cytokine production and antitumor cytotoxicity of hepatic lymphocytes in response to β -GlcCer treatment in B6 mice **(a)** Hepatic lymphocytes were isolated from B6 mice at each time point after glycolipid injection. The isolated lymphocytes were cultured for 24 h, then the cytokine levels in the culture supernatants were quantified by ELISA. **(b)** Hepatic lymphocytes were isolated from B6 mice 36 h after mf- β -GlcCer injection. To induce cytotoxicity, Poly (I:C) (100 μ g/mouse) was intraperitoneally injected into mice just before the cytotoxicity assay. Each value represents the mean \pm S.E.M. of triplicate cultures. Different letters show significant differences between each experimental group of B6 mice ($P < 0.05$). The asterisks show a significant difference to exist between the vehicle and mf- β -GlcCer treatment groups ($P < 0.05$)

The potential antitumor applications of NKT cell-activating glycolipids have been focused so far on α -GalCer [16]. Treatment with α -GalCer has been shown to successfully decrease the growth of certain metastatic tumors [17–19]. With regard to the antimetastatic activity of α -GalCer in the liver, NK cells are known to be the principal effectors. For example, Nakagawa et al. [18] reported that the IFN- γ produced by α -GalCer-stimulated hepatic NKT cells plays an essential role in the increase in both the innate antitumor cytotoxicity of NK cells and the adaptive antitumor response of CD8 $^{+}$ T cells, thus resulting in the inhibition of tumor metastasis to the liver. Similar to the observations following α -GalCer treatment, the proportion of hepatic NK-1.1 $^{+}$ T cells transiently increased (Fig. 3). Treatment with mf- β -GlcCer also enhanced the IFN- γ mRNA expression in intrahepatic NK-1.1 $^{+}$ T cells (Fig. 6b). The expression of CD69, an activation marker, was slightly increased in hepatic NK cells of B6 mice treated with mf- β -GlcCer. As shown in Fig. 5b, the antitumor cytotoxicity of hepatic MNCs against NK cell-sensitive YAC-1 cells was significantly increased in the mice treated with mf- β -GlcCer. The antitumor cytotoxicity of

these cells was also shown when EL-4 lymphoma was used as the target cells. These results suggest that the tumor-specific cytotoxicity of hepatic lymphocytes including NK cells is enhanced by the IFN- γ secreted from the activated NKT cells as a result of β -GlcCer administration.

We noted that β -GlcCer treatment inhibits tumor metastasis in WT mice, but not in *CD1d* $^{-/-}$ and *Ja18* $^{-/-}$ mice (Fig. 7). Therefore, our findings suggest that invariant TCR-expressing T lymphocytes restricted by CD1d molecules, generally referred to as invariant NKT (iNKT) cells, are pivotal effector cells required for the antimetastatic action of β -GlcCer, similar to the observations of α -GalCer treatment in other studies [17, 18]. Several glycolipids and phospholipids have been identified as natural and endogenous CD1d ligands for NKT cells [23, 24]. For example, Ilan and colleagues examined the effects of β -GlcCer treatment on various animal models. Treatment with β -GlcCer in vivo has been reported to attenuate the tissue damage mediated by Th1-type immune responses in rodent models, including Con A-induced hepatitis, chemically induced hepatic fibrosis, immune-mediated colitis, OVA-induced asthma, and diabetes [25–29]. They also indicated

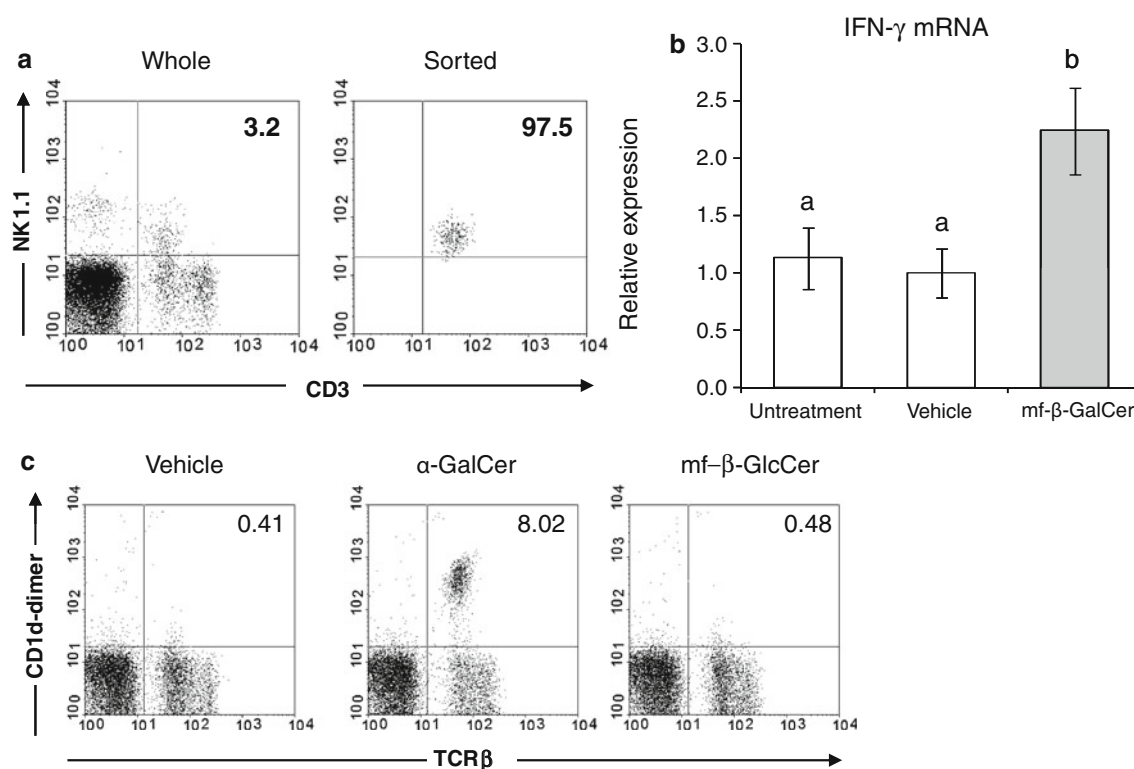

Fig. 6 In vivo response of hepatic NKT cells to β -GlcCer treatment. Hepatic lymphocytes were isolated from B6 mice 24 h after mf- β -GlcCer injection. **a** Two color staining for CD3 and NK-1.1 was conducted, and the NK-1.1⁺CD3⁺ cells were sorted. The numbers in the figure indicate the percentages of fluorescence-positive cells in the corresponding areas. **b** The total RNA was extracted from hepatic NK-1.1⁺ T cells sorted from B6 mice 24 h after treatment, and was

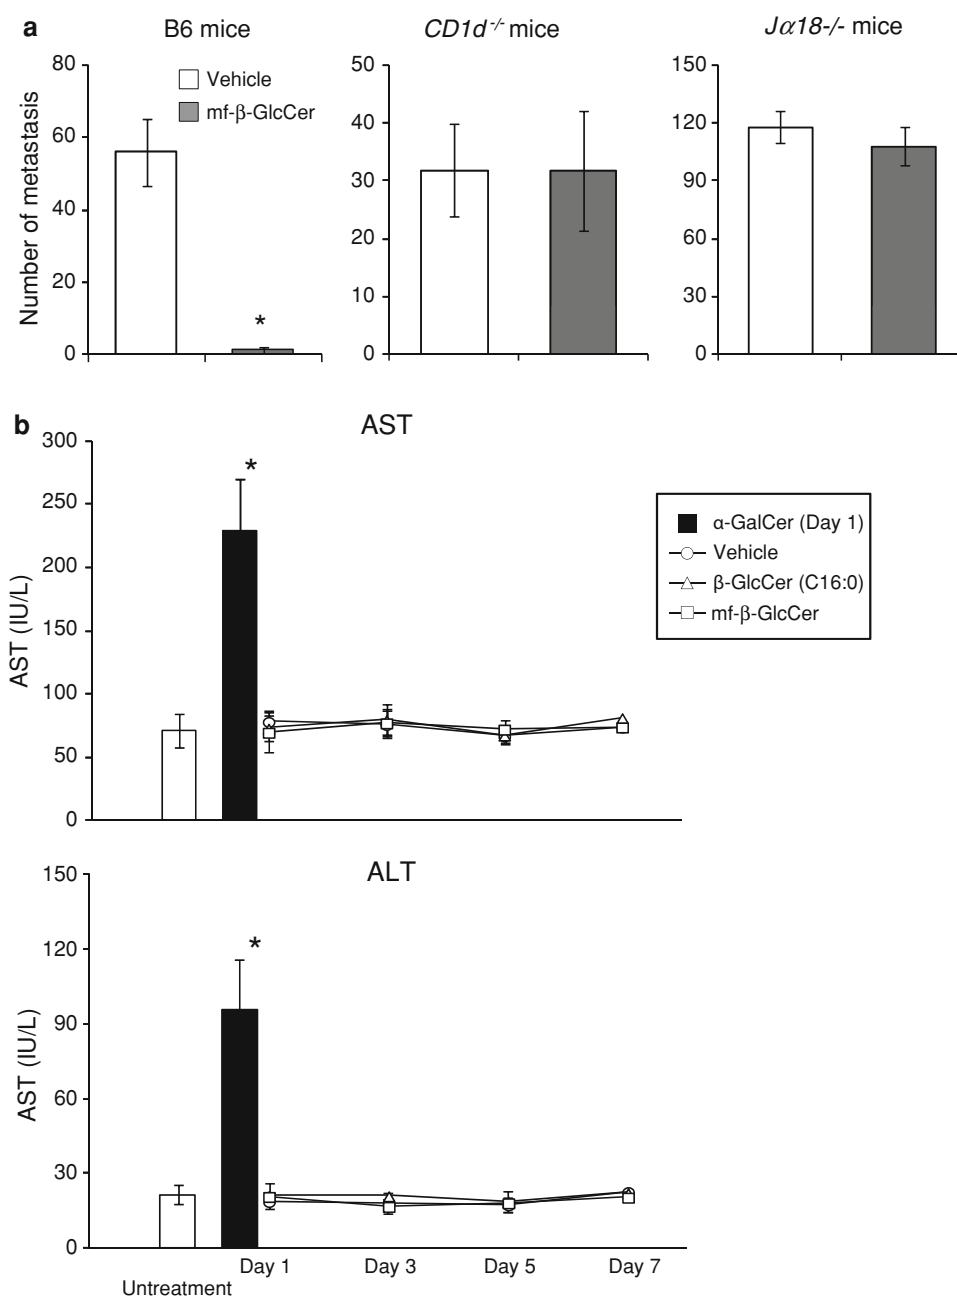

analyzed for the relative expression level of IFN- γ mRNA. The data are expressed as the means \pm S.E.M. for five mice. Different letters show significant differences between each experimental group of B6 mice ($P < 0.05$). **c** Hepatic MNCs were stained with anti-TCR β -FITC mAbs and PE-labeled dimeric CD1d molecules loaded with the indicated glycolipids. The numbers indicate the percentage of cells within each quadrant. The data are representative of two separate experiments

that the daily i.p. administration of β -GlcCer significantly inhibited in vivo transplanted tumor growth in mice [30]. In mammals, lactosylceramide (LacCer), which consists of β -GlcCer and a galactose residue, is metabolized to isoglobotrihexosylceramide (iGb3) by iGb3 synthase. Since several studies have demonstrated that iGb3 shows in vitro stimulatory activity toward both human and mouse iNKT cells [31, 32], it was suggested that iGb3 may be important for iNKT cell activation. However, the normal development and function of iNKT cells was still observed in mice with iGb3 deficiency [33]. However, Stanic et al. [34] revealed that β -GlcCer synthase deficiency causes the defective presentation of iNKT cells in mice, and found that β -GlcCer binds to CD1d1 but that their complexes are not recognized by human NKT hybridomas. Hence, they predicted that β -GlcCer may be a precursor for the biosynthesis of a natural CD1d-restricted antigen for iNKT cells in mammals. As shown in Fig. 4, the co-administration of mf- β -GlcCer alleviated the burst increase in the serum IFN- γ and ALT levels. Dimeric CD1d loaded with mf- β -GlcCer was not recognized by NKT cells (Fig. 6c).

However, Zigmmond et al. [35] demonstrated that in vitro β -GlcCer treatment induces a significant increase in the IFN- γ /IL-4 ratio from double-negative NKT hybridoma cells. Further studies will be needed to fully understand whether β -GlcCer or their metabolites are responsible for the antimetastatic actions resulting from β -GlcCer treatment.

It was indicated that the growth of transplanted tumors is suppressed in mice treated with β -GlcCer (C12), but not in those treated with β -GlcCer (C8) [30]. Although there is some uncertainty in the chemical structure of the mf- β -GlcCer used in this study in terms of its sphingoid base (Fig. 1), they are mostly composed of the longer saturated fatty acids (>16 carbons) as shown in our previous study [36]. The largest fatty acid component was α -hydroxyeicosanoic acid, which comprises about 50 % of the total amide-linked fatty acids. In this study, antimetastatic activities were observed when mice were administered the pure β -GlcCer (C16:0). Our findings therefore suggest that treatment with β -GlcCer, which are composed of unsaturated fatty acids with more than 16 carbons, has the

Fig. 7 The administration of β -GlcCer exerts antimetastatic activity in wild type mice, but not in $CD1d^{-/-}$ or $Ja18^{-/-}$ mice, and did not induce liver injuries. **a** The mice were injected intraperitoneally with 200 μ g of mf- β -GlcCer 3 days before and on the day of EL-4 lymphoma intravenous inoculation. The number of metastatic tumors visible on the liver surface was counted on day 14 after tumor inoculation. **b** The mice were administered the indicated glycosylceramides by i.p. injection for 7 days. The data are expressed as the means \pm S.E.M. for five or six mice. The asterisk shows a significant difference between the untreated mice and the glycolipid treatment group ($P < 0.05$)

potential to inhibit tumor metastasis through the activation of CD1d-restricted NKT cells, without any significant side effects. With regard to the chemical structure of sphingolipids, a sphingoid base and an acyl chain may be important for their NKT cell activation and for determining their binding affinity of the CD1d/antigen complex [37, 38]. Further studies will be needed to elucidate which chemical structure(s) of β -GlcCer are the most effective. It will also be necessary to understand the exact mechanisms underlying the antimetastatic action of β -GlcCer treatment. In conclusion, the present study demonstrated that intraperitoneal treatment with β -GlcCer activates invariant NKT

cells, resulting in the inhibition of tumor metastasis, and that this apparently lacks the toxicity associated with other glycolipid-based treatments.

Abstract A bioassay-guided fractionation and chemical investigation of a MeOH extract of the Korean wild mushroom *Boletus pseudocalopus* resulted in the identification of three new fatty acid esters, named calopusins A–C (**1–3**), along with two known fatty acid methyl esters (**4–5**). These new compounds are structurally unique fatty acid esters with a 2,3-butanediol moiety. Their structures were elucidated through 1D- and 2D-NMR spectroscopic data and GC–MS analysis as well as a modified Mosher's method. The new compounds **1–3** showed significant inhibitory activity against the proliferation of the tested cancer cell lines with IC₅₀ values in the range 2.77–12.51 μ M.

Introduction

In our continuing search for structurally interesting and bioactive metabolites from Korean wild mushrooms [1–5], we have collected scores of endemic Korean mushroom species in the mountainous areas during the hot humid summer and prepared MeOH extracts of them for antitumor-activity screening tests. Among the collected wild mushrooms, the extract of *Boletus pseudocalopus* (Boletaceae) showed significant cytotoxicity against three human tumor cell lines (A549, Hs746T, and H3122) using a sulforhodamine B (SRB) bioassay [6]. *B. pseudocalopus* is an inedible mushroom with toxicity that is recognized by its yellow fruiting bodies and the blue staining when the fruit-bodies are cut or brushed [7], which is presumably due to the presence of the characteristic bolete pigments such as xerocomic acid, variegatic acid, and variegatorubin [8]. The isolation of cytotoxic grifolin derivatives was reported in a recent phytochemical study of this mushroom [8]. Bioassay-guided fractionation and chemical investigation of the MeOH extract of the fruiting bodies of *B. pseudocalopus* resulted in the isolation of three new fatty acid esters (**1–3**) with a 2,3-butanediol moiety, together with two known fatty acid methyl esters (**4–5**) (Fig. 1). In this study, we describe the isolation and structural elucidation of the three new fatty acid esters (**1–3**) from *B. pseudocalopus*, and the cytotoxic activities of the isolates (**1–5**).

Materials and Methods

General Experimental Procedures

Optical rotations were measured on a Jasco P-1020 polarimeter (Jasco, Easton, MD, USA). IR spectra were

recorded on a Bruker IFS-66/S FT-IR spectrometer (Bruker, Karlsruhe, Germany). Electrospray ionization (ESI) and high-resolution (HR)-ESI mass spectra were recorded on a SI-2/LCQ DecaXP liquid chromatography (LC)-mass spectrometer (Thermo Scientific, West Palm Beach, FL, USA). Electron-ionization (EI) mass spectra were obtained on a JEOL JMS700 mass spectrometer (JEOL, Tokyo, Japan). Nuclear magnetic resonance (NMR) spectra were recorded on a Varian UNITY INOVA 500 NMR spectrometer (Varian, Palo Alto, CA, USA) operating at 500 MHz (^1H) and 125 MHz (^{13}C), with chemical shifts given in ppm (δ). Preparative high performance liquid chromatography (HPLC) used a Gilson 306 pump (Gilson, Middleton, WI, USA) with a Shodex refractive index detector (Shodex, New York, NY, USA). Low-pressure liquid chromatography (LPLC) was carried out over a LiChroprep Lobar-A Si 60 column (240×10 mm i.d.; Merck, Darmstadt, Germany) with a FMI QSY-0 pump (Teledyne Isco, Lincoln, NE, USA). Column chromatography was performed with silica gel 60 (Merck, 230–400 mesh). The packing material for molecular sieve column chromatography was Sephadex LH-20 (Pharmacia, Uppsala, Sweden). Merck precoated silica gel F₂₅₄ plates and reversed-phase (RP)-18 F_{254s} plates (Merck, Darmstadt, Germany) were used for thin-layer chromatography (TLC). Spots were detected on TLC under UV light or by heating after spraying with anisaldehyde-sulfuric acid.

Mushroom Material

The fresh fruiting bodies of *Boletus pseudocalopus* Hongo were collected on Mt. Gaya, Hapcheon-Gun of Gyeong-sangnam-do, Korea, in August, 2006. The mushroom was

identified by one of the authors (K.R.L.), according to the taxonomic key of Imazeki and Hongo [9]. A voucher specimen (SKKU 2006–08) was deposited in the herbarium of the School of Pharmacy, Sungkyunkwan University, Suwon, Korea.

Extraction and Isolation

The air-dried (30–40 °C for 20 h) and powdered fruiting bodies of *B. pseudocalopus* (139 g) were extracted twice with 80% aqueous MeOH (each 1.5 L \times 2 day) at room temperature and filtered. The filtrate was evaporated under vacuum to obtain a crude MeOH extract (10 g), which was suspended in distilled water and then successively partitioned with *n*-hexane, CHCl_3 , and *n*-BuOH, yielding 600, 700, and 2,100 mg of residues, respectively. Each fraction was evaluated for cytotoxicity against three human tumor cell lines (A549, Hs746T, and H3122) using an SRB bioassay. We selected the CHCl_3 -soluble fraction for the current phytochemical study, since the CHCl_3 -soluble fraction showed significant cytotoxic activity against the tested tumor cell lines. The CHCl_3 -soluble fraction (700 mg) was separated on a silica gel (230–400 mesh) column chromatography [50 g, 1.5×25 cm, eluted with CHCl_3 –MeOH, 10:1 (1.0 L) and 5:1 (1.0 L)] to yield six fractions [Fr. A, 10:1, 0.3 L; Fr. B, 10:1, 0.3 L; Fr. C, 10:1, 0.4 L; Fr. D, 5:1, 0.3 L; Fr. E, 5:1, 0.3 L; and Fr. F, 5:1, 0.4 L]. Fraction A (350 mg) was subjected to fractionation with Sephadex LH-20 column chromatography [320 g, 3×60 cm, eluted with CH_2Cl_2 –MeOH, 1:1 (2.0 L)] to give three subfractions [Fr. A1, 1:1, 0.7 L; Fr. A2, 1:1, 0.3 L; and Fr. A3, 1:1, 1.0 L]. Subfraction A2 (150 mg) was applied to LPLC on a LiChroprep Lobar-A Si gel 60 column (240×10 mm i.d., 40–63 μm) with a solvent system of CHCl_3 –MeOH (25:1, 800 mL) to give two fractions (A21–A22). Subfraction A21 (50 mg) was purified by preparative normal-phase HPLC using an Apollo Silica column (Alltech, 250 \times 10 mm i.d., 5 μm) with a solvent system of *n*-hexane–EtOAc (15:1, each 800 mL, flow rate; 2 mL/min) to obtain compounds **4** (5 mg) and **5** (7 mg). Subfraction A22 (65 mg) was purified by preparative normal-phase HPLC using an Apollo Silica column (Alltech, 250 \times 10 mm i.d., 5 μm) with a solvent system of *n*-hexane–EtOAc (5:1, each 800 mL, flow rate; 2 mL/min) to afford compounds **1** (4 mg), **2** (3 mg), and **3** (4 mg).

Calopusin A (**1**)

Colorless gum, $[\alpha]_{\text{D}}^{25} -10.7$ (*c* 0.14, CHCl_3); IR (KBr) ν_{max} 3,356 (OH), 2,943, 1,720 (C=O), 1,280, 1,028 cm^{-1} ; ^1H (500 MHz) and ^{13}C (125 MHz) NMR data, see Table 1; ESI-MS (positive mode) m/z 405 $[\text{M} + \text{Na}]^+$; HRESIMS m/z 405.3353 $[\text{M} + \text{Na}]^+$ (calcd. for $\text{C}_{24}\text{H}_{46}\text{NaO}_3$, 405.3345).

Calopusin C (3)

Colorless gum, $[\alpha]_{\text{D}}^{25} +13.8$ (*c* 0.18, CHCl_3); IR (KBr) ν_{max} 3,355 (OH), 2,943, 1,721 (C=O), 1,280, 1,028 cm^{-1} ; ^1H (500 MHz) and ^{13}C (125 MHz) NMR data, see Table 1; ESI-MS (positive mode) m/z 407 $[\text{M} + \text{Na}]^+$; HRESIMS m/z 407.3507 $[\text{M} + \text{Na}]^+$ (calcd. for $\text{C}_{24}\text{H}_{48}\text{NaO}_3$, 407.3501).

Alkaline Hydrolysis of **1–3**

Hydrolysis of **1–3** (each 1.0 mg) was performed with 5% KOH in MeOH (10 ml) under reflux for 2 h. After cooling,

each reaction mixture was diluted with H_2O and extracted with CHCl_3 . The organic layer was washed with H_2O and filtered. The filtrate was chromatographed by a silica gel Waters Sep-Pak Vac 6 cc (Waters) with a solvent system of *n*-hexane–EtOAc (15:1) to give the fatty acid part. Methyl ester derivatives of fatty acids from **1–3** were prepared by refluxing fatty acids with 1% H_2SO_4 in MeOH (10 ml) for 1 h. The methyl ester mixture was analyzed with GC–MS. The GC–MS analyses were carried out using a Hewlett Packard 6,890–5,973 N GC–MS system operating on electron impact mode (equipped with a HP-5MS UI 60 \times 0.25 mm, 0.25 μm film thickness capillary column). Helium (1.5 ml/min) was used as the carrier gas. The initial temperature of the column was 60 $^\circ\text{C}$, and then heated to 280 $^\circ\text{C}$ at a rate of 3 $^\circ\text{C}/\text{min}$. The identification of the fatty acid esters was based on comparison of their EI-mass spectra with the NIST/NBS, Wiley library spectra. The aqueous layer was neutralized by passage through an Amberlite IRA-67 column (Rohm and Haas) and was repeatedly evaporated to give each 2,3-butanediol moiety.

The 2,3-butanediol from **1** and **3** showed the negative optical rotation, $[\alpha]_D^{25} - 16.3$ (c 0.07, CHCl_3) and the ^1H -NMR data was consistent with commercial sample (*R,R*)-2,3-butanediol. The ^1H -NMR data of the 2,3-butanediol, $[\alpha]_D^{25} + 10.8$ (c 0.05, CHCl_3) from **2** was consistent with commercial sample, *meso*-2,3-butanediol.

Preparation of the (*R*)- and (*S*)-MTPA Ester Derivatives of **1–3**

To a stirred solution of **1** (1.0 mg) in pyridine (400 μL) was added 4-(dimethylamino)pyridine (1 mg) and (*S*)-(+)- α -methoxy- α -(trifluoromethyl)phenylacetyl chloride (MTPA-Cl, 10 μL). The mixture was stirred at room temperature for 16 h. The reaction mixture was then passed through a silica gel Waters Sep-Pak Vac 6 cc and eluted with *n*-hexane–EtOAc (15:1) to give the respective (*R*)-Mosher ester **1r**. Treatment of **1** (1.0 mg) with (*R*)-MTPA-Cl (10 μL) as described above yielded the corresponding (*S*)-MTPA ester **1s**. Similarly, treatment of **2** and **3** with (*S*)- and (*R*)-MTPA-Cl afforded the respective Mosher esters **2r**, **2s**, **3r**, and **3s** (Table 2).

Cytotoxicity Testing

A sulforhodamine B (SRB) bioassay was used to determine the cytotoxicity of each compound against four cultured human tumor cell lines [6]. The assays were performed at the Korea Research Institute of Chemical Technology. The cell lines used were A549 (lung carcinoma), Hs756T (stomach carcinoma), H3122 (non-small cell lung carcinoma) and HUVEC (human umbilical cord endothelial cells). The cancer cell lines such as A549, Hs756T, and H3122 cells were provided by the National Cancer Institute (NCI). A normal cell line, HUVEC, was purchased from the American Type Culture Collection. Etoposide (purity $\geq 98\%$, Sigma) was used as a positive control. The cytotoxicities of etoposide against the A549, Hs756T, and H3122 cell lines were IC_{50} 0.24, 0.12, and 0.84 μM , respectively. Tested compounds were demonstrated to be pure as evidenced by NMR and HPLC analyses (purity $\geq 95\%$).

Results

The fruiting bodies of *B. pseudocalopus* were extracted with 80% aqueous MeOH. The methanolic extract showed cytotoxicity against some human tumor cell lines using a SRB bioassay in our screening procedures. Bioassay-guided fractionation and chemical investigation of the extract using successive column chromatography over silica gel and Sephadex LH-20, and preparative HPLC resulted in the isolation and identification of three new fatty acid esters (**1–3**), together with two known fatty acid methyl esters (**4–5**) (Fig. 1). Their structures were elucidated as follows.

Compound **1** was isolated as a colorless gum. The molecular formula of **1** was determined to be $\text{C}_{24}\text{H}_{46}\text{O}_3$ by positive mode HRESIMS data at m/z 405.3347 $[\text{M} + \text{Na}]^+$ (calcd. for $\text{C}_{24}\text{H}_{46}\text{NaO}_3$, 405.3345). The IR spectrum indicated that **1** possessed hydroxyl ($3,355\text{ cm}^{-1}$) and carbonyl ($1,721\text{ cm}^{-1}$) groups. The ^1H -NMR spectrum of **1** (Table 1) was similar to that of **4** [10], except that the proton and carbon resonances of a methoxy group in **4** were absent, and the resonances of a 2,3-butanediol moiety at δ_{H} 4.77 (1H, m, H-2'), 3.75 (1H, m, H-3'), 1.19 (3H, d, $J = 6.5\text{ Hz}$, H-1'), and 1.17 (3H, d, $J = 6.5\text{ Hz}$, H-4'); δ_{C} 74.8 (C-2'), 70.3 (C-3'), 19.3 (C-4'), and 16.5 (C-1') were present in **1** [11]. This structure was confirmed by the HMBC spectrum (Fig. 2), where HMBC correlation between H-2' (δ_{H} 4.77) and C-1 (δ_{C} 173.7) indicated the linkage of the 2,3-butanediol unit at C-1. Alkaline hydrolysis of **1** afforded a 2,3-butanediol moiety and a fatty acid unit. The fatty acid unit after esterification with methanol was analyzed as a methyl ester using GC–MS and was identified as methyl 11(*Z*)-eicosenoate (**4**). The double bond position was further confirmed by analysis of the mass fragmentation in the EIMS data (Fig. 2). The absolute configuration of the 2,3-butanediol unit was determined using a modified Mosher's method [12]. Treatment of **1** with (*R*)- and (*S*)-MTPA-Cl gave the (*S*)- and (*R*)-MTPA esters **1s** and **1r**, respectively. The ^1H -NMR signals of the two MTPA esters (Table 2) were assigned on the basis of their ^1H – ^1H -COSY spectra, and the $\Delta\delta$ values ($\delta_{\text{S}} - \delta_{\text{R}}$) were then calculated (Fig. 3). The results indicated that the

Fig. 2 Key HMBC connectivities and EIMS fragmentation of **1**

absolute configuration of **1** was 3'*R*. Moreover, the chemical shifts for H-2' (δ_{H} 4.77) and H-3' (δ_{H} 3.75) suggested that these protons have a *cis*-orientation, which was in agreement with that of the monoacetate of *dl*-butane-2,3-diol [δ_{H} 4.75 (H-2) and δ_{H} 3.73 (H-3)] [11] and the 2,3-butanediol obtained by hydrolysis of **1** showed the negative optical rotation, [α]_D²⁵ = 16.3 (*c* 0.07, CHCl₃), in agreement with that of (*R,R*)-2,3-butanediol [13, 14]. Thus, the absolute configuration at C-2' was confirmed to be *R*. In conclusion, the structure of **1** was elucidated as shown in Fig. 1, and named calopusin A.

Compound **2** was obtained as a colorless gum. The molecular formula of **2** was deduced to be C₂₄H₄₆O₃ by positive mode HRESIMS data at m/z 405.3353 [M + Na]⁺ (calcd. for C₂₄H₄₆NaO₃, 405.3345). The ¹H-NMR data of **2** (Table 1) was very similar to that of **1**, except for the chemical shift and splitting pattern of H-2' (δ_H 4.87) and H-3' (δ_H 3.87) in **2** instead of those of H-2' (δ_H 4.77) and H-3' (δ_H 3.75) in **1**, which suggested that compound **2** possessed a *meso*-butane-2,3-diol unit on the basis of the chemical shifts of the monoacetate of *meso*-butane-2,3-diol [δ_H 4.86 (H-2) and δ_H 3.88 (H-3)] [11]. This was further supported by the identical ¹H-NMR data of the 2,3-butanediol obtained by hydrolysis of **2** to commercial sample, *meso*-2,3-butanediol. Analysis of the HMQC and

HMBC correlations led to the establishment of the structure for **2**. As described for **1**, the absolute configuration of **2** was determined using a modified Mosher's method [12], which proved the *S*-configuration for C-3' (Fig. 3). Then, the absolute configuration of C-2' was determined to be the *R*-configuration because compound **2** contained a *meso*-butane-2,3-diol unit. Thus, the structure of **2** was assigned as shown in Fig. 1, and named calopusin B.

Compound **3** was isolated as a colorless gum, and had a molecular formula of $C_{24}H_{48}O_3$, as determined by positive mode HRESIMS at m/z 407.3507 $[M + Na]^+$ (calcd. for $C_{24}H_{48}NaO_3$, 407.3501). The 1H and ^{13}C -NMR data of **3** (Table 1) were very similar to those of **1**, except for the absence of the chemical shifts attributable to a double bond in **1** [δ_H 5.34 (2H, m, H-11 and H-12); δ_C 130.2 (C-11) and 129.9 (C-12)]. The structure of **3** was confirmed by analysis of 2D-NMR experiments (HMQC and HMBC). As described for **1**, the absolute configuration of **3** was also determined using a modified Mosher's method [12], which proved the *R*-configuration for C-3' (Fig. 3). Then, the absolute configuration of C-2' was assigned as *R* on the basis of the identical chemical shifts for H-2' (δ_H 4.77) and H-3' (δ_H 3.75) of **3** to those of **1**. Thus, the structure of **3** was determined as shown in Fig. 1, and named calopusin C.

The known fatty acid methyl esters were identified as methyl 11(Z)-eicosenoate (**4**) [10] and methyl palmitoleate (**5**) [10] by comparison of their spectroscopic data to previously reported values and analysis of GC-MS.

Discussion

The cytotoxic CHCl₃-soluble fraction from the MeOH extract of *B. pseudocalopus* was separated by repeated column chromatography to obtain compounds **1–5**. Compounds **1–5** were evaluated for their antiproliferative activities against three human cancer cell lines (A549, Hs756T, and H3122) using the SRB bioassay [6]. Compounds **1–3** showed significant inhibitory activity against proliferation of the tested cancer cell lines with IC₅₀ values in the range 2.77–12.51 μM (Table 3). However, the known fatty acid methyl esters (**4–5**) without a 2,3-butanediol group were inactive (IC₅₀ > 20 μM). In previous studies, the antitumor effect of synthetic 2,3-butanediol fatty acid esters was reported and coixenolide with anti-tumor activity was isolated from *Coix lacryma-jobi* seeds, which is a mixed ester of palmitoleinic acid and vaccenic acid with the 2,3-butanediol [15, 16]. To confirm whether the 2,3-butanediol unit itself is cytotoxic against the tested cell lines, both of (*R,R*)-2,3-butanediol and (*R,S*)-2,3-butanediol obtained by hydrolysis of **1–3** were evaluated for cytotoxicity against three human cancer cell lines

^b Etoposide as a positive control

^c Gemcitabine as a reference compound

(A549, Hs756T, and H3122). But they were inactive (IC₅₀ > 20 μM). These results demonstrate that though the 2,3-butanediol itself is inactive, it improves antitumor activity in such fatty acid esters. To establish whether cytotoxicity exhibited by compounds **1–3** was selective between tumor and normal cells, these compounds were tested against a normal human cell line, HUVEC. The results (Table 3) showed that **1–3** were more cytotoxic against tumor cells than normal cells, indicating that **1–3** exhibited selective toxicity. In particular, compound **3** showed the highest selective cytotoxicity for Hs746T cell line since it exhibited the greatest selectivity index (SI) value of 15.1. The SI value was obtained by dividing the IC₅₀ value for the normal cell line by the IC₅₀ value for the tumor cell line.

In conclusion, we focused our investigation on cytotoxic constituents from the fruiting bodies of *B. pseudocalopus* and identified five fatty acid esters including three new compounds, calopusins A–C (**1–3**) showing significant cytotoxicity. Calopusins A–C (**1–3**), which displayed high selective toxicity against the A549, Hs746T, and H3122 cell lines, may be especially promising for developing an effective drug for lung and stomach cancer in this regard.

Abstract The major fatty acids of a novel species of *Thermogemmatispora* sp. (strain T81) from the phylum *Chloroflexi* were identified as *i*18:0 (42.8 % of total fatty acids), *i*19:0 (9.7 %), and *i*17:0 (5.9 %). Also observed was a number of unidentified fatty acids, including a major acid (16.3 %) with ECL of 19.04 (BP1), and 18.76 (TG-WAXMS A). GCMS revealed that this compound is a saturated 20-carbon atom fatty acid. ^1H - and ^{13}C -NMR, with ^1H - ^1H -COSY and ^1H - ^{13}C -HSQC experiments suggested the structure of dimethyl octadecanoic acid with *iso*-branching, and an extra middle-chain methyl group. A pyrrolidide derivative demonstrated the characteristic gaps in GCMS indicating methyl branching at C12 and C17, which was eventually confirmed by a ^1H - ^{13}C -HSQC-TOCSY experiment. This 12,17-dimethyloctadecanoic acid has not been previously detected or described in these organisms. However, a recent description of a phylogenetically related species of *Thermogemmatispora* (Yabe et al., Int J Syst Evol Microbiol 61:903–910, 2010), noted an unidentified 20:0 fatty acid with matching GC behavior and GCMS data to that of strain T81. These data suggest that *Thermogemmatispora* share an ability to synthesize the same fatty acid. A number of other dimethyl-branched fatty

acids, namely 8,14-diMe 15:0; 12,15-diMe 16:0; 10,15-diMe 16:0; 12,16-diMe 17:0; 10,16-diMe 17:0; 12,17-diMe 18:0; 12,18-diMe 19:0; 14,19-diMe 20:0, were also identified in strain T81.

Introduction

Thermogemmatispora sp. T81 (T81 = ICMP 18709^T = DSMZ 45540^T) is a recently described thermophilic, aerobic, Gram-positive bacterium isolated from geothermal soil in Tikitere, New Zealand [1]. It belongs to the phylum *Chloroflexi* in the newly described genus *Thermogemmatispora* in which there are two validly described strains (*T. onikobensis* and *T. foliorum*). Strain T81 grows well on mono and di-saccharide carbon sources as well as lignocellulosic wood pulps, and a wide variety of polysaccharide compounds. The bacteria is able to grow between 45 and 70 °C with an optimum temperature of 50–60 °C, and tolerates pH 3.1–7.1 with an optimum growth pH of

4.6–6.0. Strain T81 differs from the validly described strains of *Thermogemmatispora* in guanine-cytosine content, morphology, salt tolerance, preferred pH, and substrate utilization [unpublished] and is likely to represent a novel *Thermogemmatispora* species.

The fatty acids profiles between strain T81, *T. onikobensis* and *T. foliorum* vary significantly [2]. The major fatty acids in *T. onikobensis* and *T. foliorum*, are *i*17:0 (44.1 and 44.9 %), and *i*19:0 (19.3 and 27.3 %), while in strain T81 these fatty acids are only minor components (5.9 and 9.7 %, respectively). The major fatty acid in T81 is *i*18:0 (42.8 %), which comprises only 2.2 % of the fatty acids of *T. onikobensis* and *T. foliorum*. Both the *T. onikobensis* and *T. foliorum* strains contained relatively high levels of an unidentified fatty acid (26.55 and 14.56 % of total fatty acids, respectively), the methyl ester of which possessed an ECL of 19.032 (on methyl silicone phase). T81 also possesses a number of unidentified fatty acids [3].

The present publication describes fatty acids of this unique organism, including the discovery of a number of novel dimethyl-branched fatty acids, which may be a distinctive feature of *Thermogemmatispora* species.

Materials and Methods

Fermentation

T81 was cultivated under aerobic conditions in both 250-mL Erlenmeyer shake flasks and a 20-L Braun Bioreactor (Biostat C-DCU 20-3 Melsungen, Germany). The growth media used was a modified OP10A liquid mineral salts medium (2.0 g L⁻¹ soluble starch, 1.0 g L⁻¹ yeast extract, 0.8 g L⁻¹ (NH₄)₂SO₄, 0.1 g L⁻¹ KH₂PO₄, 0.04 g L⁻¹ MgSO₄ × 7H₂O, 0.02 g L⁻¹ CaCl₂, 3 mL L⁻¹ FeEDTA solution, 3 mL L⁻¹ methanotrophs trace metal solution, 1 mL L⁻¹ Wolin trace solution) [1]. The biomass produced in the shake flasks which were agitated at 150 rpm and incubated at 60 °C (Infors Multitron 2, Bottmingen, Switzerland) for 72 h. The biomass produced in the 20-L bioreactor was grown at 60 °C with 100 rpm agitation, 5–15 L/min airflow and pH control (5.0) for 72 h. The dry cell weight at the end of 72 h was 1.4 g/L of medium for both shake flasks and bioreactor samples.

Lipid Extraction

The wet biomass from the 100-mL shake flasks was extracted using the method of Bligh and Dyer [4], yielding lipids at 0.2 % by weight. The biomass produced in 20-L fermenters was transmethylated according to Lewis et al. [5].

Fatty Acids Analysis

Fatty acid methyl esters were prepared from small samples of biomass without lipid extraction and analyzed as described by Svetashev et al. [6]. For detailed analysis, fatty acid methyl esters were prepared from the lipid extracts according to the method of Carreau and Dubacq [7], and purified by SPE on a 500-mg Strata SI-1 cartridge (Phenomenex, USA) conditioned with hexane. Hydrocarbons were eluted with 3 mL of hexane, and fatty acids methyl esters were eluted with 6 mL of hexane-diethyl ether (99:1, by v/v). The method used was identical to the procedure presented elsewhere [[8], the third procedure], with the only exception being the use of a solid phase extraction SPE cartridge in place of a Silica gel 60 column. In a separate experiment the lipid extract was fractionated into neutral and polar lipid fractions prior to transesterification. A silica gel SPE cartridge was used, with neutral lipids eluted by chloroform, and polar lipids by methanol.

GLC analysis of fatty acid methyl esters was performed on a TraceGC Ultra instrument (ThermoFinnigan, USA), equipped with FID and 30 m, 0.25 mm i.d. Trace Gold TG-WAXMS A capillary column (Thermo Scientific, USA). Helium was used as the carrier gas; the split ratio was 1:60. Separation temperature was 195 °C. When non-polar BP1 (60 m, 0.32 mm i.d.) methyl silicone capillary column (SGE, Australia) was used, the separation temperature was maintained at 220 °C. Fatty acids were identified by the use of reference compounds, the known ECL values for methyl silicone column [9], and by GCMS (see below). Hydrogenation of fatty acid methyl esters was performed according to Appelqvist [10].

To prepare trimethylsilyl derivatives 30 µL of *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) with 1 % trimethylchlorosilane (Aldrich, USA) was added to approximately 0.2 mg of the sample in 10 µL of pyridine. The reaction mixture was maintained for 30 min at 60 °C. The sample was either analyzed directly, or was evaporated under a stream of argon and re-dissolved in 0.5 mL of hexane prior to the injection.

Pyrrolidides were prepared according to the procedure described in [11]. Briefly, ~0.1 mg of FAME was dissolved in 50 µL pyrrolidine, 5 µL acetic acid and maintained at 100 °C for 1 h. Unreacted pyrrolidine was removed in the stream of argon. The residue was taken up by 2 mL of hexane-diethyl ether (1:1, by v/v) and washed with 4 × 0.5 mL water. The hexane layer was collected, and the solvent removed under a stream of argon. The residue was dissolved in 1 mL hexane and pyrrolidides analyzed by GCMS.

GCMS analyzes were performed on an Agilent 5890 N gas chromatograph equipped with a 5973 Inert mass-spectrometric detector and HP-5 capillary column (30 m,

0.32 mm i.d.; Hewlett-Packard, USA). Helium was used as the carrier gas. Analysis of FAME and pyrrolidides was initiated at 100 °C (held for 6 min), with the temperature increased at a rate of 5 °C/min up to 160 °C, followed by a rate of 1 °C/min to 240 °C, and then maintained for 25 min.

Preparative HPLC separation of the fatty acids methyl esters was carried out using a Gilson 321 preparative HPLC pump, Agilent 1100 photodiode array detector (at 205 nm), C12 column (Synergy 4 μ Max-RP 80A 250 \times 30.00 mm) with guard column (Phenomenex Security-Guard cartridge C12 15 \times 30.00 mm). Data was collected and analyzed using Gilson Unipoint 3.20 software. Solvents used were: Solvent A: water; Solvent B: acetonitrile. The eluent flow rate was 20 mL/min. The concentration of injected sample was 200 mg/mL in ethanol, 1 mL was injected. The eluent gradient employed was: 0 min—80 % Solvent A, 20 % Solvent B; 8–26 min—10 % Solvent A, 90 % Solvent B; 28 min—100 % Solvent B.

NMR Spectroscopy

All ^1H - and ^{13}C -NMR spectra of fatty acids dissolved in CDCl_3 and referenced to internal TMS at 0 ppm were obtained on a Bruker Avance-III 500 Spectrometer equipped with a Bruker 5-mm broadband probe at 303 K. ^1H , ^{13}C frequencies were 499.8, 125.7 MHz respectively and 90° pulses 13.0, 14.0 μs , respectively. Standard Bruker supplied NMR pulse programs were used for recording all spectra. Pulse program COSYGPMFQF was used to record the gradient selected absolute value proton homonuclear double quantum filtered COSY spectrum. Phase sensitive gradient selected pulse programs HSQCETGP and HSQCETGPMML were used for the two-dimensional (2D) inverse detected ^1H , ^{13}C heteronuclear (HSQC) and HSQC-total correlation (HSQC-TOCSY) spectra with isotropic proton mixing respectively [12].

Parameters for the ^1H spectrum were: sweep width 10,302 Hz, 65,536 data points, 30° excitation pulse, 32 transients taken, each with a 1 s delay time and f.i.d. acquisition time of 3.18 s. Spectra were processed with a standard exponential weighting function with 0.3 Hz line broadening before Fourier transformation. Parameters for the WALTZ ^1H decoupled ^{13}C spectrum were: 30° excitation pulse, sweep width 31,250 Hz, 65,536 data points, 4,192 transients taken each with 0.5 s delay time and f.i.d. acquisition time of 1.05 s for a total acquisition time of 2 h. Spectra were processed with a standard exponential weighting function with 5 Hz line broadening before Fourier transformation. Parameters for the WALTZ ^1H decoupled DEPT90- and DEPT135 ^{13}C spectra were: sweep width 7,530 Hz (narrowed down to focus on the protonated carbon signals of interest), 32,768 data points,

2,048 transients taken each with delay time 0.2 s and f.i.d. acquisition time of 2.18 s for a total acquisition time of 1.5 h. Spectra were processed with a standard exponential weighting function with 5 Hz line broadening before Fourier transformation.

Parameters for the proton homonuclear double quantum filtered COSY spectrum were: two transients taken each with delay time 1.69 s and f.i.d. acquisition time 0.46 s, sweep width F2 2,222 Hz in 2,048 data points, sweep width F1 2,222 Hz in 320 slices for a total acquisition time of 25 min. The absolute value spectrum was processed with a sine bell window function in both directions. Parameters for the HSQC-TOCSY spectrum were: 24 transients taken each with delay time 0.96 s and acquisition time 0.46 s, sweep width F2 2,212 Hz in 1,024 real points, sweep width F1 3,142 Hz in 512 slices, MLEV17 mixing at 8.3 kHz for 60 ms. ^{13}C GARP decoupling (globally optimized alternating phase rectangular pulse) at 3.8 kHz during acquisition for a total spectrum acquisition time of 5 h. Data was processed with a squared cosine bell window function in both directions.

Similar parameters were used for the HSQC spectrum except that 16 scans were taken for 320 slices in the indirect dimension for a total acquisition time of 2 h.

ESI-MS

ESI-MS experiments were performed in negative mode with the use of Waters Q-ToF Premier mass spectrometer working under MassLynx version 4.1 software. Calibration was performed with sodium formate solution. Capillary voltage was 2,500 V, cone voltage 50 V, source temperature 80 °C, desolvation temperature 180 °C, mass range 100–1,000 Da. Typical run duration was between 0.5 and 1 min, with scan time 1 s, and interscan time 0.1 s. Cone gas flow was off, desolvation gas flow was 600 L/h. Collision energy in tandem MS experiments was within the 10–50 eV range.

Results

Fatty Acid Composition of T81

Analysis of fatty acid composition of T81 revealed twenty components present at levels exceeding 0.2 % of total fatty acids. All fatty acids were found to originate from polar lipids. The neutral lipids fraction of T81 produced no FAME upon transmethylation, and was shown to consist only of hydrocarbons [unpublished]. Using the reference compounds, ECL values, and GCMS data eleven of these were identified as saturated fatty acids with straight (14:0, 16:0, 17:0, 18:0), and branched (*i*16:0, *i*17:0, *i*18:0, *i*19:0,

i20:0, *ai17:0*, *ai19:0*) chain. Chemical modifications were used in an attempt to gather initial information on the remaining components, which accounted for 25.1 % of total fatty acids. No changes in fatty acid pattern were observed upon hydrogenation of the sample, suggesting that T81 contains no unsaturated fatty acids. The TLC mobility of FAME and the lack of changes in GC behavior after FAME were treated with BSTFA revealed the absence of hydroxy fatty acids in the sample. The sample

grown in the shake flasks contained 7.6 % of straight chain and 67.3 % of *iso*- + *anteiso*-acids (of total fatty acids). Interestingly, the bacterium grown in the 20 L fermenters demonstrated dramatic changes in straight chain, and *iso*-/*anteiso*- acids content during their growth, which requires further investigation (Table 1).

One more known fatty acid, 12-Me-18:0, was identified on the basis of its ECL [13], GCMS of its methyl ester (a prominent peak at *m/z* 199, accompanied by a weaker ion

Only components accounting for ≥0.2 % of total fatty acids are presented

^a A minor component, 14,19-dimethyl-20:0, was also observed by GCMS of pyrrolidides derivatives

^b The ratio of 10,16-diMe-17:0–12,16-diMe-17:0 was approximately 2:3, as revealed by intensities of signals at *m/z* 113 in GCMS of pyrrolidides derivatives

^c For non-polar column, calculated using fractional chain length data from Apon and Nicolaides [16]

^d As observed by Duque et al. [13] with OV-101 column (similar to BP1 used in the current study)

Fig. 1 GC-MS of pyrrolidides of 12-methyl-18:0 acid from T81. 28 Da gaps indicate the exact position of Me-branching

Fig. 2 Fragments of the structure of a methyl ester of a novel fatty acid from T81 suggested by the results of initial NMR experiments. n could vary from 0 to 6. Chemical shifts are given in ppm relative to internal TMS

at m/z 227 expected for FAME of 12-methyl-branched saturated acids), and GCMS of its pyrrolidides (M^+ at m/z 351, and a gap in 28 Da between the ions at m/z 238 and 266, Fig. 1).

Dimethyl-Branched Fatty Acids

The main unknown fatty acid, referred to as “X” in Table 1 was isolated by HPLC with 99 % purity as demonstrated by GC with FID. Its methyl ester possessed an ECL of 19.04 on methyl silicone phase BP1, and 18.76 on a medium polarity phase TG-Wax. GCMS analysis of the corresponding peak (in the form of methyl ester) suggested that this fatty acid is saturated aliphatic twenty carbon atom acid. Negative ion high resolution QToF MS of the free fatty acid anion had an exact mass of 311.2946 that corresponded to $C_{20}H_{39}O_2^-$ (calculated mass 311.2950, difference -1.3 ppm).

A non-integer ECL value for the saturated fatty acid suggested that there was branching present in the molecule. An initial attempt to establish the structure with the use of

GCMS of methyl esters generated a number of alternative structures.

While 21 signals were expected for C_{20} fatty acid methyl ester in a ^{13}C -NMR spectrum, it contained only 20 signals (in ppm, relative to internal TMS: 19.72, 22.65, 24.97, 27.07, 27.34, 27.76, 27.98, 29.16, 29.25, 29.45, 29.59, 29.67, 30.00, 32.76, 34.13, 37.10, 37.14, 39.11, 51.40 (O-CH₃), and 174.32 (COO)), suggesting that there may be two equivalent carbons. 1H -NMR spectrum contained a doublet at 0.836 (3H, 6.6 Hz, -CH₃), a doublet at 0.863 (6H, 6.6 Hz, two CH₃ groups), a poorly resolved group at 1.0–1.4 ppm (26H, CH₂), a symmetrical 9-component multiplet centered at 1.516 ppm (1H, 6.6 Hz), a multiplet at 1.62 ppm (2H, ~ 7.3 Hz, β -CH₂), a triplet at 2.30 ppm (2H, 7.5 Hz, α -CH₂), and a singlet at 3.66 ppm (3H, -OCH₃). Thus, the presence of the putative fragments shown in Fig. 2 was suggested by NMR.

A very helpful resource, <http://lipidlibrary.aocs.org/>, was used in getting reference spectral data. Since initial 1D-NMR experiments alone were unable to provide a definite structure, we used Reaxys® (Elsevier Properties

SA service) and SciFinder[®] (Chemical Abstracts service) to find if there was any spectral information available for fatty acids within the range suggested by NMR (i.e. from 6,17- to 12,17-dimethyloctadecanoic acid). No hits were found for any one of these acids or their derivatives. We also calculated an expected pattern of ions in GC–MS spectra of each possible structure that matched the restrictions presented in Fig. 2, using another page from the above mentioned resource [14]. The best match between calculated four characteristic ions and those present in the experimental spectrum was observed for 12,17-dimethyloctadecanoic acid, with the ions being at m/z 199, 227, and also less intensive ions at m/z 195 (227-MeOH), and 177 (195-H₂O):

GCMS of pyrrolidides (Fig. 3) suggested the structure of 12,17-dimethyloctadecanoic acid as being possible, with 28 Da gaps indicating the points of methyl-branching at C12 and C17. While it was tempting to perceive lower intensity ions at m/z 294 and 308 as another gap indicative of the presence of ethyl- or dimethyl- branching at C14, no evidence of such branching was seen in NMR spectra.

The structural features were investigated further with ¹H-¹H-COSY and ¹H-¹³C-HSQC NMR experiments.

The concerted use of various 1- and 2D-NMR experiments confirmed the structure of 12,17-dimethyl octadecanoic acid. The proton homonuclear 2D correlation (COSY) spectrum is invaluable for tracing connectivity of neighboring protons. Connectivity of the carbon backbone then follows from the proton carbon heteronuclear single quantum (HSQC) spectrum which also confirms the magnetic equivalence of the methylene –CH₂– protons, which is necessary to utilize with confidence, the HSQC-TOCSY spectrum for tracing out the sub-spectral elements of the fatty acid chain. The HSQC-TOCSY results are critical for determining the carbon backbone length between the points of attachment of the methyl groups.

The evidence for the structure assignment of 12,17-dimethyl octadecanoic acid is detailed below. Starting from the ester end of the chain the ¹³C assignment of the carbonyl (C1, 174.32 ppm) and methoxyl (51.40 ppm) can be made on the basis of chemical shift alone. The methoxyl proton signal at 3.66 ppm is easily assigned by the appearance of the intense singlet and confirmed from the HSQC. The characteristic proton signal at 2.30 ppm is readily and uniquely assigned to H2 whereupon the presence of COSY cross peaks progressively identifies H3 (1.61 ppm) and H4 falls into the intractable group of overlapping signals around 1.25 ppm. C2, C3 are then easily identified at 34.1, and 15.0 ppm, respectively from the HSQC spectrum. These values were consistent with those widely published (e.g. in the above mentioned Lipid Library resource).

To assign the C12 to C18 segment of the carbon backbone we initially pinpointed the mid chain attachment point for C19. The intense COSY cross peak to (the three proton integrated intensity, methyl) H19 (0.83 ppm) readily identifies H12 as the broad featureless low intensity hump at 1.35 ppm. The DEPT90 spectrum contains two methine carbons at 28.0 and 32.8 ppm which can be assigned on chemical shift grounds alone to C17, C12 respectively, however conclusive assignment is provided and confirmed from the COSY cross peaks between the attached methyl groups and methine protons, followed by recourse to HSQC.

Carbons C11, C13 can be assigned on chemical shift grounds alone as the almost overlapping pair of signals at 37.10 and 37.15 ppm. This is confirmed by the COSY spectrum from weak cross peaks between H12 (1.35 ppm) to H11 (1.08 ppm) and from H12 to H13 (1.27 ppm). Conclusive discrimination between C11 and C13 rests on the HSQC-TOCSY results to follow. Whilst C11 and C13 are almost overlapping, they are resolvable/discernible at

Fig. 3 GC-MS of pyrrolidides of 12,17-dimethyl-18:0 acid, “X” from T81

high magnification in the HSQC (and HSQC-TOCSY) spectrum.

Starting now from the iso-methyl end of the chain, the H18/H20 (0.86 ppm) proton methyl doublet, H17 is readily assigned to the symmetric 9-component multiplet at 1.516 ppm from the intense cross peak in the COSY spectrum. Similarly H16 (1.16 ppm) is easily and uniquely assigned.

The corresponding carbon assignments for C18/C20, C17 and C16 follow from the HSQC. Although H15 can be identified from the COSY cross peak to H16, it falls into the intractable group of overlapping signals at 1.25 ppm. At this point all that remains is to assign C14 and C15 and the corresponding proton signals. With the confirmed assignment of the carbon backbone extremities from C12- to C18 established, we now resort to results from the HSQC-TOCSY spectrum to complete the identification of the complete backbone segment. For this purpose we seek proton (or carbon) detector signals with intense, sharp, minimalist multiplet patterns to indirectly detect or map out the hoped for continuous chain of totally correlated carbon cross peak signals C18/C20 through to C12 or alternatively traversing the backbone in the opposite direction, from C19 through to C17. Realistically, with the 60 ms proton isotropic mixing time employed in the concatenated TOCSY portion of the pulse program we do not expect to detect a more than five- or six carbon sub spectrum traversal. The methyl doublets H18/H20 or H19 are ideal for this purpose and Fig. 4 shows the corresponding column of ^{13}C cross peaks in the HSQC-TOCSY spectrum. Focusing on the column of cross peaks detected by the very intense H18/H20 methyl doublet, it is noted when looking down at the noise floor that there is no detectable C12 cross peak but a weak cross peak for C13 is visible above the noise. It is therefore reasonable to expect to see the carbon backbone traversal from C18/C20 to C13 but no further. Still focusing on the column of cross peaks detected by H18/H20, the foregoing discussion has detailed the assignments of C18/C20, C17, C16, C13 so ignoring these we are left with two ^{13}C cross peaks at 27.34 and 27.76 ppm which must therefore be C14 and C15. To discriminate between the two it is noted that the 27.76 ppm cross peak is more intense than the 27.34 ppm cross peak so the assignment is C14, C15 at 27.34 and 27.76, respectively.

For the backbone segment from C1 to C11, carbons C1, C2, C3, C11 and their attached protons have already been assigned above. The remaining ^1H signals fall into the intractable region of overlapping signals around 1.25 ppm. Apart from C10, the remaining six carbons fall into the narrow range from 29 to 30 ppm. Assignment of the remaining carbon backbone relies heavily on cross peak intensities in the HSQC-TOCSY spectrum and will not be discussed at length here. Suitable isolated proton detector

Fig. 4 A fragment of DEPT-TOCSY spectrum of the novel acid from T81. Horizontal axis methyl region of ^1H -NMR spectrum, vertical axis DEPT spectrum

signals are H2, H3 and H11. The sharp intense H2 triplet is especially informative and the column of ^{13}C cross peaks in the HSQC-TOCSY spectrum immediately provides assignments for: (ppm) C4 (29.16), C5 (29.25), C6 (29.45) and C7 (29.59). From C11 end of the backbone segment, the column of ^{13}C cross peaks detected by the broad H11 multiplet (1.08 ppm) in the HSQC-TOCSY spectrum readily provides assignments for (ppm): C10 (27.07), C9 (30.00) and C8 (29.67) (Fig. 5).

Fig. 5 NMR chemical shifts assignments for 12,17-dimethyloctadecanoic acid methyl ester based on the results of HSQC-TOCSY experiment

The ^{13}C -NMR chemical shifts determined in the current work are in a good agreement with those reported for branched fatty acids by Knothe and Nelsen [15].

Structures of 8,14-diMe 15:0, 10,15-diMe 16:0, 12,15-diMe 16:0, 10,16-diMe 17:0, 12,16-diMe 17:0, 12,17-diMe 18:0, 12,18-diMe 19:0 and 14,19-diMe 20:0 were confirmed by GC-MS of pyrrolidides. Interestingly, spectra of all mentioned fatty acids, except that of 12,15-diMe 16:0, contained similar low intensity ions corresponding to the fragments between *iso*- and middle-chain branching as observed for 12,17-diMe 18:0 (Fig. 3).

To detect methyl esters of 2-methyl fatty acids as possible precursors of mid-chain branched acids, we extracted gas chromatograms for McLafferty ions with m/z 74 (saturated esters without 2-methyl group), and m/z 88 (2-methyl branched esters). While the majority of saturated fatty acids have a base peak with m/z 74 in their positive ion EI mass-spectra, those with 2-methyl substitution possess the base peak at m/z 88 instead [17]. The trace at m/z 88 exactly repeated the pattern of m/z 74 trace, the former having the intensity of all peaks about 1/15 of the latter trace, thus excluding a possibility of a presence of noticeable levels of 2-methyl fatty acids.

Discussion

An impressive feature of T81 fatty acids is the complete lack of unsaturation, and predominance of branched-chain structures. Interestingly, mid-chain branching was only observed with *iso*-acids, and not in the *anteiso*-acids.

The cell morphology of T81 changed significantly between the methods of growth (lateral agitation of the shake flask versus impeller agitation in the 20-L bioreactor) and age of the culture. When the bacterium was agitated through lateral shaking in a temperature controlled shaker incubator, the mycelia grew sparsely (loose pellets) and measurements of dissolved oxygen (data not shown) indicated that the culture medium was oxygen starved. When the bacterium was cultured in a chemostat stirred bioreactor, the morphology changed from loose pellets to dense pellets as the agitation was increased to maintain dissolved oxygen above 30 % (v/v). While no direct link can be

made, the change in the fatty acid profile may be attributed to the change in morphology and growth conditions.

An unidentified fatty acid, seemingly branched 20:0, at levels of 14.6–26.6 % of total fatty acids was reported by Yabe et al. [2] for two species of bacteria also belonging to the class *Ktedonobacteria* of the phylum *Chloroflexi*. The reported ECL on a methyl silicone phase, 19.032, for these two strains was virtually identical to that of the fatty acid we observed in T81. Moreover, the reported fragments of mass-spectrum of its methyl ester matched our data, making it likely that both T81 and the other representatives of the genus *Thermogemmatospira* share the same 12,17-dimethyloctadecanoic fatty acid. A striking difference between fatty acid profiles of these organisms is that the major fatty acid in both of *Thermogemmatospira* species is *i*17:0, while in T81 the dominant fatty acid is *i*18:0. Mid-chain methyl-branched fatty acids are considered to be indicative of actinomycetes (10-methyl-18:0, tuberculos-tearic acid), or sulfate-reducing bacteria (10-methyl-16:0) [18].

There are two viable options for biosynthesis of mid-chain methyl-branched fatty acids: either these acids are formed by methylation of unsaturated *isolateiso* acids, or by gradual elongation of dimethyl-branched precursors. The former option requires the presence of a corresponding monounsaturated fatty acid, with methyl group supplied by S-adenosyl-methionine [19]. This mechanism is essentially different for the acids with branching close to either terminal methyl or carboxyl group—such fatty acids are synthesized via corresponding primers (short chain branched carboxylic acids, or α -keto-acids for *iso*- and *anteiso*-acids [20], methylmalonic acid for methyl substituents on even-numbered carbons near a carboxyl group [21]). We were unable to detect any unsaturated fatty acids that could serve as precursors for fatty acids containing mid-chain branching in T81.

The latter option requires the participation of a propionate primer at some stage, followed by a series of C2 elongation events. For example, an excess of propionate is required for formation of 2, 4, 6, 8, 10, and 12-methyl tetradecanoic acids, as well as 4,8-dimethyl-substituted acids with chain length from 11 to 15 carbons in mammals [22]. All dimethyl-branched acids we observed in T81

followed one of two patterns: either the acid possessed an odd-carbon chain with an odd number of methylene units between branching points (8,14-diMe 15:0, 10,16-diMe 17:0, 12,16-diMe 17:0, 12,18-diMe 19:0); or an even-carbon chain with an even number of methylene units between branching points (10,15-diMe 16:0, 12,15-diMe 16:0, 12,17-diMe 18:0, 14,19-diMe 20:0). The “odd–odd” pattern may indicate that these acids are synthesized starting from isobutyryl-CoA via a number of C2 elongations followed by formation of methyl-branching due to propionyl-CoA inclusion, followed by a number of C2 elongations. This suggestion is supported by the finding from T81 genome analysis that the organism possesses a complete propionyl-CoA carboxylase set (M. Stott, unpublished data). The “even–even” pattern acids may be synthesized by the similar mechanism, with the only difference being that isovaleryl-CoA serves as a starting block (Fig. 6).

Our data demonstrate that T81 possesses at least four sets of dimethyl branched fatty acids: with branching points separated by two methylene units (12,15-dimethyl-16:0), three methylene units (12,16-dimethyl-17:0), four methylene units (10,15-dimethyl-16:0; 12,17-dimethyl-18:0; 14,19-dimethyl-20:0), and five methylene units (8,14-dimethyl-15:0; 10,16-dimethyl-17:0; 12,18-dimethyl-19:0). The two latter sets suggest that the mid-chain branching is introduced prior to a number of elongation steps. One of the possible precursors for 10,15-dimethyl-16:0/12,17-dimethyl-18:0/14,19-dimethyl-20:0 may be 4,9-dimethyl-decanoic acid, that was reported for halophilic *Bacillus* species [23].

Since fatty acids with three methylene units between specific branching points, namely 4,8-dimethyl-13:0 and 4,8-dimethyl-15:0 were also reported [22], it is not impossible that one yet to be discovered acid, 4,8-dimethyl-9:0, may serve as a precursor for 12,16-dimethyl-17:0. Interestingly, the presence of dimethyl-branched acids was linked to an abnormally soft subcutaneous adipose tissue of lambs reared on diets with a high content of barley [*ibid.*].

Compared with mono-methyl branched and multiple-branched isoprenoid fatty acids, those with two methyl groups are far less reported in the scientific literature. For example, for mycobacteria the acids with one methyl branch in the middle of the chain, or acids with three or four methyl branches at the carboxyl end were reported, but not with two methyl branches [24]. While dimethyl branched fatty acids with one branching point located in the vicinity of carboxyl group and another close to the terminal methyl were relatively more frequently reported for bacteria (e.g. [19]), dimethyl-branched saturated fatty acids with one branching point at the middle of the chain and another close to the terminal methyl are quite rare. Dimethyl-branched fatty acids with three (with 2,6- and 3,7-pattern) and five (with 2,8- and 3,9-pattern) methylene units between the points of branching were reported as constituents of lipids of preen gland in birds [25].

We used Reaxys® (Elsevier Properties SA service) and SciFinder® (Chemical Abstracts service) to find out if there is any information available about 12,17-dimethyloctadecanoic acid. No findings of this fatty acid have previously been reported, while the only hit found listed this acid among 3,172 branched fatty acids claimed suitable for

Fig. 6 Dimethyl-branched fatty acids of T81—possible biosynthetic pathways

a range of cleaning and other industrial applications [26]. No example of the synthesis or isolation from a natural source was given in that patent. Some of the other dimethyl-branched acids mentioned in the present work were also listed in that patent: 8,14-dimethyl pentadecanoic; 10,15- and 12,15-dimethyl hexadecanoic acids; and 10,16-dimethyl heptadecanoic acid. The synthesis of 12,16-dimethyl heptadecanoic acid, for use as a reference compound in identification of polymethyl-branched fatty acids, was described by Sen Gupta and Peters [27]. As for the natural occurrence of the dimethyl-branched fatty acids encountered in our study, Hedrick et al. [28] reported that the polar lipids of subsurface sediments collected at a former uranium processing facility contained on average 0.78 % of 10,15-dimethyl hexadecanoic acid. The same acid was found in the hydrolysis products of Gram-negative bacteria *Marinobacter aquaeolei* when *iso*-nonadecane was added to the media [29]. Finally, an unspecified amount of allegedly 8,14-dimethyl pentadecanoic acid was reported [30] to be present in adipose tissue of semi-feral fallow deer, this acid being one of ten with *iso*-branching, the sum of which accounted for 1.05 % of total fatty acids. The latter finding may need better experimental support to be considered reliable, since the structure was deduced using only GCMS data for a peak containing at least three dimethyl-branched isomers. No reports on either synthesis or discovery of 12,18-dimethyl nonadecanoic and 14,18-dimethyleicosanoic acids were found.

Overall, the presence of a group of dimethyl-branched fatty acids with 12,17-dimethyloctadecanoic acid as a major component may serve as a useful taxonomic marker of *Thermogemmatipora* microorganisms.

Acknowledgments Authors are grateful to Dr. Kevin Mitchell for help with HPLC, Dr Yinrong Lu for QToF MS support, Dr. Owen Catchpole for reviewing the manuscript, Alison Speakman for invaluable help in information retrieval (all—IRL). The authors also thank the Tikitere Trust for their on-going support of this research. The study was performed within IRL Capability Fund project “Natural bioactives from NZ extremophile microorganisms”.

Conflict of interest The authors declare that there is no conflict of interest.

Abstract GC, GC–MS, and HPLC–LLSD analyses were used to identify and quantify cuticular and internal lipids in males and females of the blow-fly (*Lucilia sericata*). Sixteen free fatty acids, seven alcohols and cholesterol were identified and quantitatively determined in the cuticular lipids of *L. sericata*. Cuticular fatty acids ranged from C₆ to C₂₀ and included unsaturated entities such as 16:1n-9, 18:1n-9, 20:4n-3 and 20:5n-3. Cuticular alcohols (only saturated and even-numbered) ranged from C₁₂ to C₂₀ in males and C₁₀ to C₂₂ in females. Only one sterol was found in the cuticular lipids of both males and females. 23 free fatty acids, five alcohols and cholesterol were identified in the internal lipids. Internal fatty acids were present in large amounts—7.4 mg/g (female) and 10.1 mg/g (male). Only traces of internal alcohols (from C₁₄ to C₂₆ in males, from C₁₄ to C₂₂ in females) were found in *L. sericata*. Large amounts of internal cholesterol were identified in *L. sericata* males and females (0.49 and 0.97 mg/g of the insect body, respectively).

Introduction

Lucilia species (Calliphoridae), important pollinators of flowering plants, are distributed worldwide and are the best known species in human infestation in America, Africa, and Asia. These ectoparasites are found in the meat and corpses of animals, and cause myiasis in humans and domestic herbivorous animals [1–3]. In 1826, myiasis caused by *L. sericata* in humans was reported by Magen. It was then that the parasites were isolated from the mouth, eyes, and paranasal sinuses of a hospital patient for the first time.

Unlike the larvae of some other myiasis-causing flies, *L. sericata* larvae rarely invade living healthy tissues surrounding a necrotic wound. Due to this fascinating phenomenon, called facultative myiasis, *L. sericata* larvae have been used since antiquity as a safe and effective wound treatment. The secretions of maggots are known to stimulate in vitro increase in total human fibroblasts [4]

and have antibacterial properties [5]. Although no in vivo reports regarding wound healing mechanisms of maggot therapy are available, recent data show that fly cuticular fatty acids may play a significant role in this process. Fatty acid extracts of dried *L. sericata* larvae called in traditional Chinese medicine “WuGuChong” and used to treat superficial purulent diseases such as furuncle or carbuncle, can promote murine cutaneous wound healing probably resulting from the powerful angiogenic activity of the extracts [6].

The cuticle of all insects is covered with a very thin epicuticular layer of wax. The cuticle consists of several layers, from the outside to the inside: the epicuticle, the procuticle and the epidermis. The insect cuticle is the first barrier against biological or chemical contact insecticides; it is mostly resistant to enzyme degradation and exhibits characteristic water barrier properties [7].

Naturally occurring entomopathogens are important regulatory factors of insect populations. The potential use of fungal pathogens to control insects is well documented, and the use of fungi as control agents against insect pests has been reviewed [8–12]. Susceptibility or resistance of various insect species to fungal invasion may result from several factors, including differences in the structure and composition of the exoskeleton, the presence of antifungal compounds in the cuticle, as well as the efficiency of cellular and humoral defense reactions of the invaded insect [13]. It is believed that the epicuticular lipid profile of the insect host may be one of pivotal factors determining insect susceptibilities or resistance to fungal attack [14]. The mode of action of entomopathogenic fungi involves the attachment of fungal spores to the cuticle, followed by spore germination and, depending on the fungal species, formation of appressorium or penetrative hyphae. Penetration is then initiated, involving both mechanical and enzymatic mechanisms [15]. Once inside the host, the fungus propagates, consuming nutrients and releases metabolites (some of which might be toxic), which results in mycosis and, ultimately, host death [9, 10].

The ability of the fungus to fully degrade the epicuticular hydrocarbon components of its insect host, utilizing them as an exogenous carbon source, was demonstrated by Napolitano and Juarez [16]. The presence of a wax layer potentially affects spore germination by fungilytic or fungistatic toxicity, or by acting as a barrier to the chitin matrix of the insect exoskeleton, effectively preventing the spore from coming into contact with nutrients or other cues that trigger germination. Thus, the waxy layer produced on the cuticle may act as a first line of defense against fungal pathogens. Little information on both, stimulatory and inhibitory effects of cuticular fatty acids on growth and virulence of insecticidal fungi is available. Medium- and short-chain

fatty acids and alcohols have been demonstrated to be toxic to filamentous fungi, including some that have been isolated specifically from insect cuticle [17, 18], but the toxicity of long-chain fatty acids is unknown. Kerwin [19] demonstrated the toxic effects of 6:0, 7:0, 9:0, 10:0, 18:2 and 18:3 fatty acids on *Entomophthora culicis* conidia. However, 18:1 was found to have a positive effect on spore germination and to mitigate the harmful effects of 18:3 acid. The concentration of fatty acids also had an important impact on fungal growth and conidia development: 0.1% 16:1 was toxic to secondary conidia, but positively affected fungal growth. Cuticular lipids were found to have toxic or inhibitory effects on the conidia of *B. bassiana* and *P. fumosoroseus* when the spores were germinated on nutrient agar in the presence of lipids [19]. Eighteen fatty acids identified in the larval cuticle of three insect species representing differing susceptibilities to *Conidiobolus coronatus* infection [20], were thoroughly tested for effects on the in vitro growth and pathogenicity of this parasitic fungus [21].

This paper describes the cuticular lipid composition of *L. sericata* adults. The surface lipids of flies were separated into classes of compounds using HPLC–LLSD. Qualitative and quantitative analyses were done by GC and GC–MS. The determination of the composition of fly lipids and their impact on the development and pathogenicity of *C. coronatus* may have great practical importance and will allow using this fungus or its metabolites to control insect populations.

Materials and Methods

Insects

Lucilia sericata raised from eggs laid on beef by adult flies, were reared at 25 °C with 50% relative humidity and a 12:12 h photoperiod. Maternal generation was maintained in the same conditions. The insects were fed on beef and it took them approximately 7 days from hatching to puparium formation and another 7 days to the appearance of adult. The insects were exposed for 18 h to fully grown and sporulating fungal colonies. Ten flies were kept in each Petri dish (males and females separately). The adults exposed for 18 h to sterile uninoculated Sabouraud agar supplemented with *G. mellonella* larval extract served as a control. After exposure, the insects were transferred to clean Petri dishes with sugar and water and kept under their growing conditions for 10 days. The condition of the exposed animals was monitored daily. Exposure of tested insects to a *C. coronatus* colony for 18 h was found to be most efficient method resembling the natural infection process [22]. In order to avoid pseudo replication, all

assays of fungi vs. insects were performed with the use of flies from different stocks incubated in three different chambers.

A culture of the wax moth, *Galleria mellonella* was maintained and reared in temperature and humidity controlled chambers (30 °C, 70% r.h.) in constant darkness on an artificial diet [23]. Fully grown larvae were collected before pupation, surface sterilized, homogenized and used as a supplement in fungal cultures.

Fungus

Conidiobolus coronatus, isolate number 3491, originally isolated from *Dendrolaelaps spp.*, was obtained from the collection of Prof. Bałazy (Polish Academy of Sciences, Research Center for Agricultural and Forest Environment, Poznań), routinely maintained in 90-mm Petri dishes at 20 °C with cyclic changes of light (L:D 12:12) on Sabouraud agar medium (SAM) with the addition of homogenized *Galleria mellonella* larvae to a final concentration of 10% wet weight. Addition of homogenized *G. mellonella* larvae enhances SAM cultures of *C. coronatus*. The levels of mycelial growth, conidia production, and virulence were good in hundreds of successive transfers [24] suggesting a stimulatory effect of insect proteins, carbohydrates and lipids on *C. coronatus* growth and insecticidal properties.

Extraction of Insects

Figure 1 shows the scheme for preparing the sample and analysis. Male and female specimens of *L. sericata* were extracted first in petroleum ether for 10 s and then a second time in dichloromethane for 5 min [20]. These two extracts (petroleum extract I and dichloromethane extract II) contained cuticular lipids. The third extraction was a long one with dichloromethane for 10 days (III extract). This third extract contained internal lipids. Then, 0.5 ml of the whole extract was placed in a glass flask and then evaporated under nitrogen to determine the dry mass of the remaining extracted lipids. Table 1 lists the number of adult insects, as well as the masses of the extracts.

High Performance Liquid Chromatography

All lipid extracts of the males and females (I, II and III) were separated into several classes of compounds by HPLC in the normal phase using a Shimadzu LP-6A binary pump in gradient mode. A laser light scattering detector was used as the detection system [25]. To obtain large amounts of lipids for GC–MS analysis the separation was repeated five times. All fractions were evaporated, silylated and analyzed by GC and GC–MS.

Gas Chromatography

The investigations were carried out on a Clarus 500 (Perkin Elmer) gas chromatograph equipped with a Rtx 5 fused silica column (30 m × 0.25 mm i.d., film thickness 0.1 µm) was used. The oven temperature was held at 80 °C for 10 min and then increased at a rate of 4 °C/min to a final temperature of 320 °C [25].

Gas Chromatography–Mass Spectrometry

Gas chromatography–mass spectrometry measurements were carried out by coupling an SSQ 710 (Finnigan Mat) spectrometer to a Hewlett-Packard 5890 gas chromatograph. The samples were introduced through the gas chromatograph equipped with a 30 m × 0.25 mm i.d., Optima-5 silica capillary column and with a 0.25 µm thick film. The oven temperature 80 °C (held for 10 min) was increased to 320 °C at 4 °C/min. The injector temperature was 320 °C and the carrier gas was helium. The ion source was maintained at 220 °C.

The lipids were derivatized by methods described previously [20]. All compounds were identified by comparing the retention time of the analyzed compounds with standards and on the basis of silyl derivative ions. The mass spectrum of trimethylsilyl ethers of fatty acids showed the following ions: M^+ (molecular ion), $[M-15]^+$, and fragment ions at m/z 117, 129, 132, and 145. Cholesterol was identified on the basis of the characteristic ions of silyl derivatives (m/z 458 (M^+), 129, 329, 368, 145, 121 and 353). Characteristic ions of alcohols (trimethylsilyl derivatives) were $[M-15]^+$ and m/z 103 [26].

Statistical Analysis

In order to quantitatively determine each of the compounds analyzed, GC analysis was performed with internal standards (19-methylarachidic acid, 1-octacosanol and sitosterol). Data are presented as the means ± standard deviations of three separate analyses performed on different samples. The data obtained were statistically processed by using the *t* pairwise test for determining significant differences in males and females lipids concentration.

Results

Susceptibility of *L. sericata* to Fungal Infection

Exposure of *L. sericata* adults to the sporulating *C. coronatus* resulted in the prompt death of all tested males and females (Table 2). Both, males and females died around the termination of the 18-h exposure to the fungal culture.

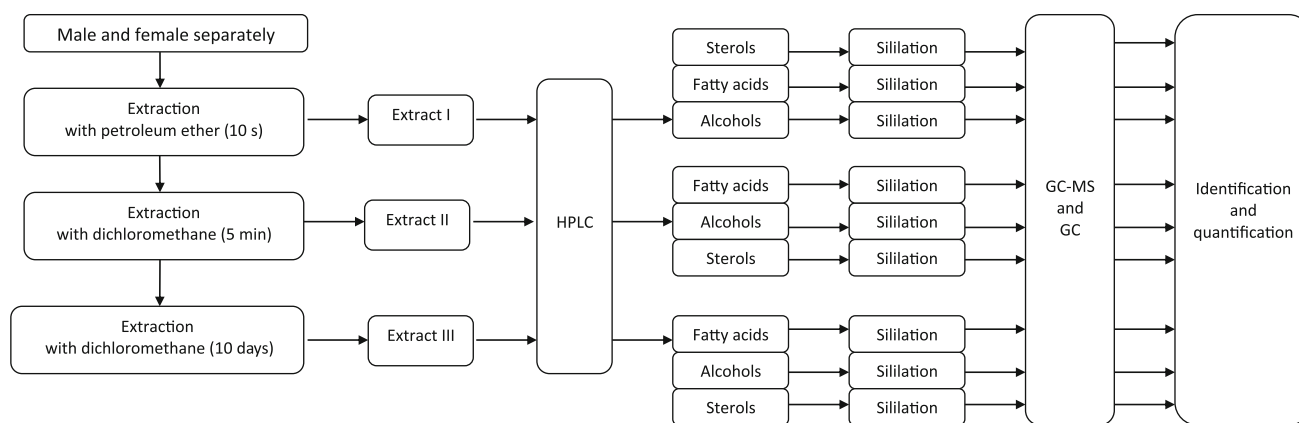

Fig. 1 Scheme of the analysis

Table 1 Quantitative summary of the experiment: numbers and masses of insect; masses of lipids

| | | | | | | | |
|---------------------------------------|--------|----|-----|-----|------|------|------|
| I petroleum extract (10 s) | Male | 75 | 1.7 | I | 5.1 | 0.07 | 3.0 |
| | | | | II | 1.3 | 0.02 | 0.8 |
| | | | | III | 42.3 | 0.56 | 24.9 |
| II dichloromethane extract (5 min) | Female | 80 | 2.3 | I | 3.2 | 0.04 | 1.4 |
| II | | | | 1.6 | 0.02 | 0.7 | |
| III dichloromethane extract (10 days) | | | | III | 45.4 | 0.57 | 19.7 |

The lack of resistance of *L. sericata* males and females on *C. coronatus* infection are confirmed by results obtained with the *t* pairwise test. Based on the *t* pairwise test we did not notice any significant differences in males and females susceptibility to fungal infection.

Extraction of *L. sericata* Lipids

This is the first time that the chemical composition of the cuticular and external lipids in the *L. sericata* has been analysed and identified. Three extractions of male and female *L. sericata* were performed. The petroleum ether

(I) and dichloromethane (II) extracts of males yielded 3.0 and 0.8 mg/g of the insect body, respectively. These two extracts consisted of cuticular lipids, so the quantity of lipids amounted to 3.8 mg/g of the insect body. The quantities of male internal lipids yielded 24.9 mg/g of the insect body (0.56 mg/insect). The quantities of cuticular lipid extracts obtained from female *L. sericata* were smaller than those from the males and amounted 2.1 mg/g of the insect body (1.4 and 0.7 mg/g of the insect body in extracts I and II, respectively). Also, the quantities of female internal lipids were less than in the males and yielded 19.7 mg/g of the insect body, but the quantity of internal lipids per insect was almost the same (0.57 mg/female vs. 0.56 mg/male).

Extracts of lipids from male and female *L. sericata* were separated by HPLC–LLSD into fractions containing general groups of chemical entities. The lipids extracted from the males and females contained four fractions: hydrocarbons, triacylglycerols, free fatty acids (FFA) and sterols. The triacylglycerols were present in the internal lipids of male and female (III extracts). They serve as a source of energy stored in fat body. The hydrocarbons were present in cuticular lipids (I and II extracts) in small amounts. They can play an important role as pheromones. In this study were determined compounds with potential antimicrobial activity, including the free fatty acid, alcohol and sterol fractions. These fractions were further analyzed by GC and

Table 2 The susceptibility of *Lucilia sericata* males and females to fungal infection

| Developmental stage/treatment | Number of insects | Mortality (%) ^a |
|--------------------------------|-------------------|----------------------------|
| Adult females | | |
| Control | 30 | 0 |
| Exposed to <i>C. coronatus</i> | 50 | 100 |
| Adult males | | |
| Control | 47 | 0 |
| Exposed to <i>C. coronatus</i> | 50 | 100 |

^a Adult insects were exposed to sporulating *C. coronatus* colonies as described in the “Materials and Methods” section. The insect susceptibility to fungal infection is expressed as percentage of mortality in tested populations

Cuticular FFA: sum of FFA content in petroleum extract (I), and dichloromethane extract (II)

Data are presented as the means \pm standard deviations of three separate analyses performed on different samples

GC–MS. For qualitative purposes, the instrument was operated in total ion current (TIC) mode and single ion monitoring (SIM) mode for monitoring $[\text{M}-15]^+$ ions (Table 4). Single ion monitoring mode was used to achieve high selectivity and sensitivity. Gas chromatography was used for the quantitative analyses of lipids. Comparisons were made with the lipids extracted from male and female *L. sericata*.

Fatty Acid Composition of Male *L. sericata*

Table 3 summarizes the results obtained during the identification and quantification of FFA in the cuticular lipids of male *L. sericata*. The two cuticular extracts (petroleum ether-I and dichloromethane-II) contained 15 compounds from C_6 to C_{20} . The dominant cuticular fatty acids (all with an even number of carbon atoms) were: 16:1n-9 (10.3%), 16:0 (29.4%), 18:1n-9 (40.6%) and 18:0 (6.7%). The total free fatty acid content in cuticles in males was $14.3 \mu\text{g/g}$

($6.1 \mu\text{g/g}$ in the petroleum ether extract and $8.2 \mu\text{g/g}$ in the dichloromethane extract).

The internal lipids of male *L. sericata* contained 21 FFA (Table 4). The total free fatty acid content in the internal lipids of the male was 10.1 mg/g of the insect body. The fatty acids occurring in the highest concentrations were 16:1n-9 (14.7%), 16:0 (19.5%) and 18:1n-9 (57.4%). The fatty acids 17:1n-10, 18:2n-6, 19:0, 20:1n-6, 20:0, 22:0, 24:0 and 26:0 occurred only in the internal lipids. On the other hand, 10:0 and 11:0 acids occurred only in the cuticular lipids.

Fatty Acid Composition of Female *L. sericata*

The cuticular lipids of female *L. sericata* contained 16 FFA from C_6 to C_{20} (Table 3). Ten FFA from C_8 to C_{18} were identified in the petroleum ether extract (I) and all 16 fatty acids from C_6 to C_{20} in the dichloromethane extract (II). The total free fatty acid content in the cuticle in females was

8.8 $\mu\text{g/g}$ (2.0 $\mu\text{g/g}$ in the petroleum ether extract and 6.8 $\mu\text{g/g}$ in the dichloromethane extract). The percentage contents of fatty acids were very diverse (from traces to 31.2%). The FFA occurring in the highest concentrations were 16:1n-9 (15.2%), 16:0 (31.8%), 18:1n-9 (25.0%) and 18:0 (8.0%).

More fatty acids were present in the internal lipids; they ranged from C₆ to C₂₆ (Table 4) (like the internal lipids in the males). The total free fatty acid content in the internal lipids of the female was 7.4 mg/g of the insect body. Twenty four saturated, monounsaturated and polyunsaturated fatty acids were present in the internal lipids. Saturated (16 compounds) and monounsaturated fatty acids (five compounds) were dominant. The FFA occurring in the highest concentrations were 16:1n-9 (17.5%) 16:0 (21.0%) and 18:1n-9 (53.2%). A similar profile of the major compounds was identified in the cuticular lipids, except that the major compound was 18:1n-9 in the internal lipids and 16:0 in the cuticular lipids. The following acids present in the internal lipids were absent from the cuticular

lipids: 14:1n-9, 17:1n-10, 17:0, 18:2n-6, 19:0, 20:1n-6, 22:0, 24:0 and 26:0. On the other hand, only 11:0 was absent from the internal lipids of female *L. sericata*, whereas the cuticular lipids contains traces of it.

Alcohol Composition of Male *L. sericata*

Table 5 lists the percentage contents of alcohols in the cuticle as well as the alcohol contents calculated per g of insect body. Only five alcohols were found in the cuticular lipids of the males and ranged from C_{12:0} to C_{20:0}. The compound present in the highest concentrations was C_{18:0} (0.37 $\mu\text{g/g}$ of the insect body; relative content 55.2% of total alcohols). The total cuticular alcohol content in male *L. sericata* was only 0.67 $\mu\text{g/g}$. Only traces of five alcohols were found in the internal lipids. These alcohols have more carbon atoms than the cuticular ones, from C_{14:0} to C_{26:0}. The internal lipids contain traces of three alcohols (C_{22:0}, C_{24:0} and C_{26:0}), which were absent from the cuticular

Data are presented as the means \pm standard deviations of three separate analyses performed on different samples

lipids. All the identified alcohols were saturated, with even-numbered carbon chains.

Alcohol Composition of Female *L. sericata*

The cuticular lipids of the female contained seven saturated alcohols with even-numbered carbon chains from C_{10:0} to C_{22:0} (Table 5). The alcohol C_{18:0} was present in the highest concentrations (48.8%) (the same observation as for the male lipids). The total cuticular alcohol content in females of *L. sericata* was 0.80 $\mu\text{g}/\text{g}$ (a little more than in the males). Only three alcohols (C_{14:0}, C_{20:0} and C_{22:0}) were found in traces in the internal lipids of females.

Cholesterol Content in Male and Female *L. sericata*

The cholesterol contents in the cuticular lipids of males and females were 7.6 and 11.4 $\mu\text{g}/\text{g}$ of the insect body, respectively (Table 6). Considerably more cholesterol was present in the internal lipids of these insects. The quantities

of internal cholesterol in female lipids were double those found in males. The cholesterol was identified on the basis of the characteristic ions (as the trimethylsilyl ether).

Discussion

Free fatty acids of *L. sericata* were present not only in the cuticle; large amounts were also detected in the internal lipids. The efficiency of cuticular and internal lipids extraction differed in *L. sericata* males and females. Amounts of cuticular lipids (mg/g of the insect body) extracted with the use of petroleum ether and dichloromethane from males were 2.1 and 1.1 times higher, respectively, than the amounts of extracts obtained from females. Similarly, amounts of internal lipids extracted from males were 1.3 times higher than analogous extracts obtained from females. The total amounts of extracted lipids (cuticular and internal) comprised 2.99% of male and 2.17% of female wet body weight, respectively. From Gilbert [27] it appears that lipid content in male adults of *Calliphora vicina* (formerly *C. erythrocephala*), closely related to *L. sericata*, and is slightly higher than in females (3.4 vs. 3.3% wet weight). In most insect species the female usually contains more lipids than the male, as a lipid is a most efficient substrate for egg development. However, the reverse may be true for many species and this is especially evident when Lepidoptera are considered [27]. Sexual dimorphism in lipid content in the adult stage was studied in detail in the silk moth *Hyalophora cecropia*. The tissues of *H. cecropia* males contain about five times as much lipid per gram of fresh weight as the tissues of the female. The higher concentration of lipids in the male moth

is most likely correlated with mating behavior, since the male moth flies relatively great distances in search of virgin females while the female does only limited flying after emergence. The silk moth male appears to utilize lipid as a primary substrate for flight while female *H. cecropia* converts a large percentage of her endogenous substrate into eggs [27]. In contrast, adults of *L. sericata* utilize carbohydrates as the main source of flight energy [28]. In spite of intensive studies concerning the flight of *L. sericata* and some other Diptera species, no sexual difference in the flight behavior and biochemistry was evidenced [29, 30].

Cuticular fatty acids in male and female extracts made up ca 0.14 and 0.12% of all lipids, respectively. The amounts of FFA in cuticular lipids can vary with respect to sex, stage and living conditions. It has been shown that FFA comprise from 2.04 to 0.50% of the lipids in the exuviae of *Dendrolimus pini* [31] and only trace amounts of FFA were detected in cuticular lipids from nymphs and exuviae of the Silver leaf whitefly, *Bemisia argentifolii* [32], whereas FFA make up 79.40% of the cuticular lipids of *Calliphora vicina* larvae [20]. Cuticular FFA in males and females of *L. sericata* ranged from C₆ to C₂₀; moreover, they consisted of both odd- and even-numbered carbon chains. Similar profiles were identified in closely related *C. vicina* larvae [20]: the fatty acids in this insect ranged from C₅ to C₂₀, although the typical cuticular fatty acids ranged from C₁₂ to C₂₀. For example, fatty acids in this range were found in lipids from *Frankliniella occidentalis* adults and larvae [33], *Acanthoscelides obtectus* males and females [25], *Liposcelis bostrychophila* [34] and *Fannia canicularis* [35]. In our study, the cuticular fatty acids identified in the adult insects were both saturated and unsaturated. Odd- and even-numbered, saturated and unsaturated fatty acids are typically found in many insect species. The presence of polyunsaturated acids 20:4n-3 and 20:5n-3 in cuticular lipids is rather unusual, although these acids were identified in the lipids of the aquatic insect larvae *Stictochironomus pictulus* [36]. In our work, the females contained these compounds in respective concentrations of 1.6 and 1.0%. Moreover, trace amounts of 20:4n-3 and 20:5n-3 acids were present in the male cuticular lipids. The female extract contained C₇ and C₂₀ acids, which were absent from the male extract. On the other hand, C₁₇ acid occurred only in the male extract.

The profiles of predominant cuticular FFA in males and females of *L. sericata* were similar. The predominant components of males and females consisted of 16:0 and 18:0 and also 16:1n-9 and 18:1n-9 fatty acids. Other cuticular fatty acids were present in much smaller quantities. Only four unsaturated fatty acids were present in both males and females. Internal FFA in males and females of *L. sericata* made up 40.4 and 37.7% of all lipids, respectively.

Free fatty acids were extracted from both sexes of *L. sericata* with carbon numbers ranging from C₆ to C₂₆, so the internal free fatty acid profiles of both adult insects were similar. In this case, the acids present in the highest concentrations in the internal extract were 16:1n-9, 16:0 and 18:1n-9. The contents (%) of 20:5n-3 and 20:4n-3 fatty acids of both sexes were similar; there was a significant difference between the amounts (μg/g) of these acids (male: 0.56 mg/g of the insect body and female: 0.38 mg/g of the insect body). The female extract contained 7:0, and traces of 10:0 and 14:1n-9 acids, which were absent, from the male extract. 22:0, 24:0 and 26:0 acids were present in the internal lipids, which were absent from the cuticular male and female extracts.

The alcohols present in the cuticular lipids of insects usually have an even number of carbons and are saturated [32, 37–39]. In our study, the cuticular lipids of females of *L. sericata* contained seven even-numbered, saturated alcohols from C₁₀ to C₂₂, but the cuticular lipids of the males contained only five such compounds, from C₁₂ to C₂₀. C₁₀ and C₂₂ alcohols were present only in female cuticular lipids. However, the remaining alcohols were identified in both samples at similar levels. The alcohol present in the highest concentrations in males and females was C₁₈ (55.2 and 48.8%, respectively). The alcohols found in our study ranged from C₁₀ to C₂₄, and similar profiles were identified in *Locusta migratoria migratoriodes* (from C₁₀ to C₃₄) and *Schistocerca gregaria* (from C₁₀ to C₃₂) [40]. It is known that the amounts of alcohols in the cuticular lipids of an insect may differ significantly between various species. For example, alcohols made up 42% of all cuticular lipids in pupae of *Heliothis virescens* [37], but only 3 and 4% in nymphs and exuviae of *B. argentifolii* [32]. In our work, the cuticular alcohols in male and female *L. sericata* were <1% of all lipids. Internal lipids of females and males of *L. sericata* respectively contained three (from C₁₄ to C₂₂) and five (from C₁₄ to C₂₆) alcohols in trace quantities.

Diverse biological functions of cuticular alcohols have been reported. In the European honey bee, alcohols may protect against parasite attack. Extracts of *Apis mellifera* cocoons containing alcohols of 17–22 carbons induce a strong arrestment response in the mite *Varroa jacobsoni* [41]. A mixture of short chain alcohols, their acetate derivatives, and (Z)-11-eicosenol secreted by the sting apparatus of the worker honey bee are components of bee alarm pheromones [42]. The sex pheromones of the three most important tortricids of European vineyards, *Eupoecilia ambiguella*, *Sparganothis pilleriana* and *Lobesia botrana*, have been chemically investigated and found to contain up to 15 different straight-chain acetates and alcohols [43]. The role of alcohols found in *L. sericata* remains unknown.

In cuticular and internal lipids of *L. sericata*, cholesterol was identified on the basis of the characteristic ions (m/z 129 (100%), 329 (87%), 145 (38%), 121 (36%), 353 (32%) and M^{+} 458) [44] (as the trimethylsilyl ether). Female lipids contained twice as much cholesterol as male lipids. Internal cholesterol in male and female extracts made up 2 and 5% of all lipids, respectively. The respective quantities of cholesterol obtained from male and female *L. sericata* were 0.49 ± 0.02 and 0.97 ± 0.03 mg/g of the insect body, respectively. There was a tenfold higher concentration of cholesterol in internal lipids. Sterols are minor constituents of cuticular lipids [45]. The cholesterol content in cuticular male and female lipids was 7.6 ± 0.4 and 11.4 ± 0.8 μ g/g, respectively. Assuming that sterols are mandatory for egg production and normal embryonic development, a higher concentration of internal cholesterol in *L. sericata* females seems justified. In contrast, the physiological role of cuticular cholesterol remains obscure.

Naturally occurring entomopathogenic fungi are important regulatory factors of insect populations. *Conidiobolus coronatus*, a cosmopolitan soil fungus causing rapid death of susceptible insects, due to the secretion of toxic metabolites [46, 47] was used in current studies. Exposure of *L. sericata* to sporulating fungal colonies resulted in prompt death of both, males and females while larvae and pupae remained unharmed and developed normally. Similarly, the larvae of closely related *C. vicina* showed amazing resistance to *C. coronatus*, while exposure of two lepidopteran larvae, *G. mellonella* and *D. pini*, resulted in their death. Microscopic studies revealed that the conidia of *C. coronatus* did not germinate on the cuticle of *C. vicina* larvae while the cuticles of both lepidopteran larvae were infiltrated by fungal hyphae [47, 48]. The impressive *C. vicina* resistance to fungus is accompanied by a high resistance of the cuticle to degradation by fungal proteases and a high antiproteolytic capacity of insect hemolymph. On the other hand, the immune system of challenged larvae shows very low activity of both, cellular and humoral components. It seems that the significant protection provided by the *C. vicina* cuticle reduces potentially costly defense responses within the hemocoel. Investment in cuticular protection comes at the cost of low phenoloxidase, lysozyme, encapsulation, and phagocytic activities [48]. The cuticular fatty acids profile of *C. vicina* larvae significantly differs from profiles of *D. pini* and *G. mellonella*. Data from in vitro cultures of *C. coronatus* in media supplemented with various fatty acids showed strong fungistatic effects of 18:2n-6, 18:3n-6, 20:1n-3, and 20:0 [21]. It should be pointed out that all these compounds are missing in the cuticular lipids of *L. sericata* adults (traces of 20:0 were detected in females only). On the other hand, 16:1n-9 stimulating fungal virulence [21] is present at high concentrations in both males and females (10.3 and

15.2% of all cuticular lipids, respectively) suggesting that this compound may be responsible for the prompt death of flies exposed to *C. coronatus* colonies. Analysis of cuticular lipids of *L. sericata* larvae and pupae (currently underway in our laboratories) should provide information on whether the high susceptibility of *L. sericata* adults to fungal infection opposed to the resistance of the larvae and pupae is linked with diverse cuticular lipid profiles. Work on the effects of new compounds found in adults of *L. sericata* on the pathogenicity potential of this entomopathogen is in progress. Knowledge of the role of cuticular lipids in fungal interaction with the insect host can be expected to contribute to a better understanding of the nature of fungal pathogenicity.

Abstract The leptocephalus larva of eels distinguishes the elopomorph fishes from all other bony fishes. The leptocephalus is long lived and increases in size primarily through the synthesis and deposition of glycosaminoglycans. Energy stored during the larval stage, in the form of glycosaminoglycan and lipids, is required to fuel migration, metamorphosis and metabolism of the subsequent glass eel stage. Despite the importance of energy storage by leptocephali for survival and recruitment, their diet, condition and lipid content and composition is essentially unknown. To gain further insight into energy storage and condition of leptocephali, we determined the lipid class and fatty acid concentration of larvae collected on a cross-shelf transect off Broome, northwestern Australia. The total lipid concentration of two families and four sub-families of leptocephali ranged from 2.7 to 7.0 mg g wet weight⁻¹, at the low end of the few published values. Phospholipid and triacylglycerol made up ca. 63 % of the total lipid pool. The triacylglycerol:sterol ratio, an index of nutritional condition, ranged from 0.9 to 3.7, indicating that the leptocephali were in good condition. The predominant fatty acids were 16:0 (23 mol%), 22:6n-3 (docosahexaenoic acid, DHA, 16 mol%), 18:0 (8.2 mol%), 20:5n-3 (eicosapentaenoic

acid, EPA, 6.7 mol%), 18:1n-9 (6.4 mol%) and 16:1n-7 (6.3 mol%). The DHA:EPA ratio ranged from 2.4 to 2.9, sufficient for normal growth and development of fish larvae generally. The leptocephali had proportions of bacterial markers >4.4 %, consistent with the possibility that they consume appendicularian houses or other marine snow that is bacteria rich.

Introduction

The life history of elopomorph fishes (i.e. bonefish, ladyfish, tarpon and true eels) differs from that of all other fishes because of the presence of a long lived, gelatinous larval stage known as the leptocephalus [1]. While most fish larvae have a development time of days to a few weeks, leptocephali may live for a few weeks, several months, or >1 year [1–3]. This raises many questions concerning the adaptations of leptocephali enabling such a long pre-metamorphic existence, including predator avoidance behavior and food acquisition. How they feed has been a mystery for centuries [4], as most leptocephali collected in nature have empty guts [5]. It has been suggested that they feed on marine snow, including larvacean tunicate houses [6], perhaps supplemented by direct uptake of dissolved nutrients from seawater solution [5]. New genetic data of gut contents suggests that small leptocephali of the European eel *Anguilla anguilla* feed on a variety of zooplanktonic prey in the Sargasso Sea, dominated by gelatinous taxa such as the hydrozoans, some species of which are commonly known as jellyfish [7].

While there is some knowledge of pre-metamorphic lipid dynamics of the leptocephali of bonefish [8], little is known about the nutritional state or biochemical condition of eel leptocephali in the field. Essentially nothing is known of pre-metamorphic energy storage by eel leptocephali or of changes in lipid and fatty acid content and composition during metamorphosis [9]. Both migration by leptocephali and their metamorphosis into juvenile eels require considerable quantities of energy. Bonefish leptocephali obtain the energy for metamorphosis by catabolizing endogenous reserves, primarily lipids and carbohydrates, which are stored during the pre-metamorphic time period. Most of these reserves are stored in the acellular, gelatinous matrix of the leptocephali [10] which is composed of various sulfated glycosaminoglycans (GAG) [11]. Glycosaminoglycans make up most of the organic mass of bonefish and eel leptocephali, which have a water content >90 % [2, 11]. As leptocephali approach the time of metamorphosis to the glass eel stage, GAG are metabolized, leading to a considerable decrease in water content (ca 80 %) and to body shrinkage by up to 75 % [10]. However, it has been suggested that bonefish leptocephali also lose ca. 50 % of their total lipids during

metamorphosis, providing ca. 80 % of the energy required to undertake this crucial life history transformation [8, 11]. Furthermore, it has been suggested that the endogenous energy reserves of the glass eel stage are provided by the leptocephali depot lipids which remain following metamorphosis [12]. Thus, energy storage during the leptocephalus stage is of crucial importance not only for metamorphosis, but also for the critical post-metamorphic stage, when glass eels may be under nutritional stress [12].

This paper reports the first determination of the lipid class and fatty acid content and composition of eel leptocephali. We explored the following questions of pre-metamorphic leptocephali: (1) what is the total lipid, lipid class and fatty acid content and composition of eel leptocephali? (2) How do lipid and fatty acid content and composition vary among several families and sub-families of leptocephali? (3) Is there evidence of lipid storage, and which lipid classes and fatty acids are accumulated? (4) What is the nutritional condition of the leptocephali? These questions are significant because lipids and fatty acids are important in leptocephalus nutrition, to the fueling of larval metamorphosis [8], and as dietary indicators. The true eels (Anguilliformes) are distributed throughout tropical and temperate waters worldwide [1]. They inhabit ecosystems from the coastal zone to the deep sea, with more than 600 species globally [1]. Eel leptocephali can be highly concentrated in specific oceanic environments, and often many different species of leptocephali can be collected within a relatively small area [1].

Methods

Leptocephali were collected at eight stations from 9 to 15 November 2006 on a cross-shelf transect off Broome, Australia, eastern Indian Ocean (stations 3–10) (Fig. 1). The stations ranged in depth from 87 to 1,699 m (Table 1). This transect was part of leg 7 of the Galathea 3 expedition on board the Danish Navy surveillance frigate “F359” Vædderen.

Water column properties were characterized by a Sea-bird SBE 9/11 CTD Sealogger equipped with 12, 30-l bottles on a rosette sampler. Rosette casts from the surface to within 10 m of the bottom were performed prior to each net tow. Tows for fish larvae were made using a ring net with a mouth diameter of 2 m and a mesh size of 0.55 mm. The gear was lowered from the surface to within 10 m of the bottom, or a maximum of 200 m, and then retrieved. Tow velocity was ca. 1 ms⁻¹ for a duration of 30–45 min, resulting in a range of tow volumes from 5,101 to 14,130 m³ (Table 1). All samples presented in this paper were collected between sunset and midnight.

When the gear was on deck, the cod end contents were immediately washed into plastic buckets and taken to the

Fig. 1 Station locations on the Broome transect off the coast of northwest Australia. Also shown are bathymetric contours, 50, 100, 150, 250, 500 and 1,000 m (map courtesy of R. Brushett). Bathymetry is approximate. For more accurate depth values see Table 1

A map of the station transect is shown in Fig. 1

laboratory for sorting. Within an hour, the leptocephali were sorted and placed in plastic trays containing pre-chilled seawater. The trays were stored in a refrigerator at ca. 5 °C for 1–2 h before further sample processing.

Next, each leptocephalus was removed from its sorting tray and identified to the lowest taxonomic level possible (family or sub-family) following the descriptions of Miller and Tsukamoto [1]. Standard length (SL) was determined to the nearest 0.1 mm using a dissecting microscope with an ocular micrometer. The larvae were then rinsed in filtered seawater and placed into small, plastic weighing boats. Guts were examined for particulate content with a dissecting microscope and documentary photomicrographs taken. After all leptocephali were identified and measured

at a particular station, they were blotted dry and wet weight was determined to the nearest 10 mg. The leptocephali were then placed in a freezer at −20 °C until further processing.

Leptocephali were selected haphazardly from the trays for lipid extraction, making sure to obtain a representative range of body sizes at each station. They were removed from the freezer, rinsed on each side with distilled water and placed in lipid-cleaned, glass test tubes. High performance liquid chromatography (HPLC)-grade chloroform was added sufficient to cover the larvae. The test tubes were then placed on ice until all animals had been processed. The head space of each tube was then purged for 15 s with N₂ and the caps wrapped with Teflon tape to

ensure a tight seal. The purged tubes were stored at -20°C onboard ship, and returned to the laboratory in an insulated container on dry ice. Total system blanks were run at each station to monitor sample contamination.

Laboratory Analyses

Extractions

Lipid samples were extracted according to Parrish [13]. Samples were homogenized in a 2:1 mixture of ice-cold chloroform:methanol using a Polytron PCU-2-110 homogenizer (Brinkmann Instruments, Rexdale, ON, Canada). Chloroform-extracted water was added to bring the ratio of chloroform:methanol:water to 8:4:3. The sample was sonicated for 10 min in an ice bath and centrifuged at 5,000 rpm for 2 min. The bottom organic layer was removed using a double pipetting technique, placing a long lipid-cleaned Pasteur pipette inside a short one, to remove the organic layer without disturbing the top aqueous layer. Chloroform was then added back to the extraction test tube and the entire procedure repeated three times. All the organic layers were pooled into a lipid-cleaned vial. The samples were concentrated using a flash-evaporator (Buchler Instruments, Fort Lee, N.J.).

Lipid class composition was determined using an Iatroscan Mark V thin layer chromatograph with flame ionization detection (TLC-FID), silica-coated Chromarods and a three-step development method [14]. The lipid extracts were applied to the Chromarods and focused to a narrow band using 100 % acetone. The first development system was hexane:diethyl ether:formic acid (99.95:1:0.05). The rods were developed for 25 min, removed from the system for 5 min and replaced for 20 min. The second development was for 40 min in hexane:diethyl ether:formic acid (79:20:1). The final development system had two steps, the first was 100 % acetone for two, 15-min time periods, followed by two 10-min periods in chloroform:methanol:chloroform-extracted water (5:4:1). Before being exposed to each solvent system the rods were equilibrated in a constant humidity chamber. After each development system, the rods were scanned in the Iatroscan and the three scans were joined using the T data scan 3.10 chromatography analysis program (RSS Inc., Bennis, Tenn., USA). The Chromarods were calibrated using standards from Sigma Chemicals (St. Louis, MO, USA). Blanks were run exactly as were the samples, and were subtracted from the sample lipid class values before statistical analysis and plotting. Blank values were generally <1 % of sample values for most lipid classes. Lipids were quantitatively extracted from a known wet mass of sample and individual class amounts were calibrated using standards. The lipid masses were divided by the wet weight of the sample after

blank correction. In this paper, values are reported both as lipid concentration ($\mu\text{g g wet weight}^{-1}$), and as lipid proportion [(mass of each lipid class/mass of total lipids) \times 100 %].

Lipid extracts were transesterified using 14 % BF_3/MeOH for 1.5 h at 85°C . Using TLC-FID, we found that this method derivatized over 90 % of the acyl lipids in leptocephalus larvae. A majority of the fatty acid methyl esters (FAME) were analysed on a HP 6890 gas chromatograph with flame ionization detection (GC-FID) equipped with a 7683 autosampler. The GC column was a ZB wax+ (Phenomenex, USA). The column length was 30 m with an internal diameter of $0.25\text{ }\mu\text{m}$. The column temperature began at 65°C which was maintained for 0.5 min. The temperature ramped to 195°C at a rate of $40^{\circ}\text{C min}^{-1}$, held for 15 min, then ramped to a final temperature of 220°C at a rate of $2^{\circ}\text{C min}^{-1}$. This final temperature was held for 3.25 min. The carrier gas was hydrogen supplied at a rate of 2 ml min^{-1} . The injector temperature started at 150°C and ramped to a final temperature of 250°C at a rate of $200^{\circ}\text{C min}^{-1}$. The detector temperature stayed constant at 260°C . Peaks were identified using retention times from standards purchased from Supelco, 37 component FAME mix (product number 47885-U), bacterial fatty acid ester mix (product number 47080-U), polyunsaturated fatty acid (PUFA) 1 (product number 47033) and PUFA 3 (product number 47085-U). A majority of our fatty acid identifications were based on standards for which we have GC-MS data on file. The remainder were identified with reference to Ackman [15]. Chromatograms were integrated using either the HP ChemStation Chromatography Software (Version B00.00) or Varian Galaxie software (Version 1.9). Individual fatty acids were blank corrected and expressed as a proportion of total fatty acids (mol/mol). Blank values were generally <1 % of sample values for all fatty acids.

Statistics

Lipid, lipid class and fatty acid concentration ($\text{mg g wet weight}^{-1}$) and proportion (% of total lipids or mol% of total fatty acids) are expressed as mean values ± 1 standard deviation. Seven of the 100 lipid class samples were removed from the data set before analysis, due either to accidental loss or insufficient sample weight. Four of the fatty acid samples were removed for similar reasons. Many of the means were non-normally distributed. Therefore, all data were transformed into ranks before statistical analyses (non-parametric). Differences in the mean rank of all variables among taxa were examined using single factor analysis of variance (ANOVA) with six levels (i.e. the taxonomic groups, Table 2). The ANOVA conclusions were double checked using the Brown-Forsythe robust test

which adjusts the F values for unequal variances (Statistical Package for the Social Sciences, SPSS). A post hoc Hochberg's GT2 test was used to determine which taxa had mean values significantly different from one another. The reject criterion for all statistical tests was $p < 0.05$. Statistical analyses were done using SPSS ver. 18.0.2. Figure 2 was made using SigmaPlot ver. 10.0.

Results

The Leptocephali

Total lipid, lipid class and fatty acid data are reported for leptocephali from six eel families or sub-families; Bathymyrinae (Conger eels), Congrinae (Conger eels), Muraenesocidae (Pike Conger eels), Myrophinae (Worm eels), Ophichthinae (Snake eels), and Nettastomatidae (Duck Bill eels) (Table 2). The larvae ranged in SL from 22 to 150 mm and in blotted wet weight (WW) from 0.02 to 2.30 g (Fig. 2). Wet weight increased exponentially with increasing SL. Most of the larvae analyzed for lipids and fatty acids were <75 mm long and <0.3 g WW. The Bathymyrinae were by far the most abundant and common larvae, and were the only family collected at all eight stations, covering the full range of size and weight of all the larvae (Fig. 2).

The Myrophinae were both the shortest and lightest larvae, with a mean SL of ca. 45.8 mm and WW of 0.09 g, whereas the Muraenesocidae were the largest and heaviest, with a mean SL of 132 mm and weight of 1.40 g (Table 3). These mean SL and WW were significantly different from one another. The mean SL of the Bathymyrinae, Nettastomatidae and Ophichthinae ranged from 66.0 to 73.2 mm and were not significantly different from one another.

Fig. 2 Wet weight (g) versus standard length (mm) of eel leptocephali collected on the Broome transect. Note that the X axis begins at a standard length of 20 mm. Data points for leptocephali taxa are: circle Bathymyrinae, square Congrinae, diamond Muraenesocidae, hexagon Myrophinae, diamond up Nettastomatidae, diamond down Ophichthinae. The power equation describing this relationship is $WW (g) = 1.3 \times 10^{-5} SL (mm)^{2.34}$ ($n = 88$, $r^2 = 0.86$)

Except for the above mentioned difference in WW between the Muraenesocidae and Myrophinae, the WW of the remaining four taxa ranged from 0.21 to 0.41 g, and were not significantly different from one another.

Total Lipid Concentration and Lipid Class Composition

The mean total lipid concentration per taxon ranged from 2.7 to 7.0 mg g WW⁻¹, with an overall mean for all samples of 3.7 ± 2.4 mg g WW⁻¹ (Table 3). Assuming that eel larvae are ca. 93 % water [1, 16], this overall mean value of total lipids would be equivalent to ca. 5.2 % of dry weight. The Ophichthinae had the highest mean lipid concentration and the Bathymyrinae the lowest (Table 3).

Table 2 Common names, and adult eel habitat characteristics and migratory behavior of the six families and sub-families of eel leptocephali collected on the Broome transect

| Family | Subfamily | Common name | Habitat | Migrate |
|-------------------------------------|-----------------------------|---------------------|---|---|
| Congridae | Bathymyrinae (shelf) | Conger | Tropical-temperate/sand and mud bottoms/shallow/few species on slope to 2,000 m depth | Short or none/no further than shelf break |
| | Congrinae (shelf) | Conger | Ditto | Ditto |
| Muraenesocidae (coastal) | – | Pike congers | Coastal waters <100 m | ? |
| Ophichthidae (coastal) | Myrophinae | Snake and worm eels | Tropical/intertidal to 750 m/sand, grass, tidal creeks, estuaries | Yes, likely spawn near shelf break |
| | Ophichthinae | | | |
| Nettastomatidae (deep slope) | – | Duckbill | Deep water only/slope | ? |

Information was abstracted from Miller and Tsukamoto [1]. The taxa in bold face are the names that are used in this paper. The “?” indicates cells for which we could not find the pertinent information

Table 3 Mean (\pm sd) standard length, blotted wet weight, and total lipid and lipid class concentrations of six taxa of eel leptocephalus larvae selected haphazardly from ring net samples on the Broome transect (see Table 1; Fig. 1)

| | Bathymyrinae | Congrinae | Muraenesocidae | Myrophinae | Nettastomatidae | Ophichthinae | Overall mean |

Table 3 continued

| | Bathymyrinae | Congrinae | Muraenesocidae | Myrophinae | Nettastomatidae | Ophichthinae | Overall mean |
|---------------------|---------------------|--------------------|--------------------|--------------------|--------------------|---------------------|---------------------|
| SEWE/ SEWE + TAG | 0.07 ± 0.13 [59] | 0.02 ± 0.02 [6] | 0.04 ± 0.03 [6] | 0.32 ± 0.47 [4] | 0.01 ± 0.01 [3] | 0.02 ± 0.02 [14] | 0.06 ± 0.15 [92] |

The values in square brackets are the number of samples used to calculate each mean [*n*] and for lipid classes the values in parentheses represent the mean % of total lipids. The lipolysis index was calculated as $[\text{free fatty acids} + \text{alcohols} (\text{acyl lipids} + \text{alcohols})^{-1}] \times 100$, where acyl lipids = the sum of the concentrations of steryl esters + wax esters, ethyl esters, methyl esters, glyceryl ethers, triacylglycerols, diacylglycerols, free fatty acids, acetone mobile polar lipids and phospholipids. All ratios are w/w and are without units. Numbers in bold face are the three predominant lipid classes in each taxon. Superscripts indicate values not significantly different from one another (single factor ANOVA by ranks). A response variable without superscripts indicates that all means in that particular row are not significantly different from one another. When $n < 4$, the standard deviation was replaced by 50 % of the range of the data

This difference was significant. The mean lipid concentrations of the remaining taxa were not significantly different from one another.

Over all taxa and stations the most abundant lipid classes were phospholipids (PL) (42 % of total lipids), triacylglycerol (TAG) (21 %), sterols (ST) (17 %), acetone mobile polar lipids (AMPL) (9 %) and free fatty acids (FFA) (5.6 %) (Table 3). These five lipid classes accounted for ca. 95 % of total lipids. Across all taxa, ST and PL concentration were most conserved, with coefficients of variation (CV) of overall mean values of 39 and 60 %, respectively. Triacylglycerols and AMPL were most variable, with CV of 112 and 109 %, respectively. Sample contamination and hydrolysis appear to have been minimal, as both hydrocarbons and FFA had overall mean proportions <7 % of total lipids (Table 3). The Bathymyrinae and Myrophinae were the only two families with TAG proportions ≤20 %.

Among the polar lipids, phospholipid (PL) mean concentrations ranged from 1.1 to 2.8 mg g WW⁻¹, but were not significantly different as a function of taxon (Table 3). The PL proportion was essentially identical in five of the six taxa, ranging from 41 to 47 % of total lipids. The Myrophinae was the only taxon with a PL proportion <40 % of total lipids.

Ratios of Lipid Classes

Neutral and polar lipids made essentially equal contributions to the total lipid pool, with taxon-specific mean values ranging from a low of 47 % neutral of total lipids for the Muraenesocidae and Nettastomatidae, to a high of 54 % neutral of total lipids for the Congrinae (Table 3). The differences among the mean values of neutral and polar lipid content were not significantly different among the six taxa.

The TAG:ST ratio is often used as an indication of nutritional condition of heterotrophs, i.e. an index of the energy storage-to-cell structure ratio [17]. The mean

TAG:ST ratio varied ca. fourfold among the six families of leptocephali, from a low of 0.85 for the Myrophinae to a maximum of 3.7 for the Muraenesocidae (Table 3).

The lipolysis index [LI, i.e., $\text{FFA} + \text{alcohols} (\text{acyl lipids} + \text{alcohols})^{-1}$] provides an indication of the breakdown of neutral and polar lipids [18]. The mean LI was uniformly low for the six families of leptocephali, generally <0.10, except for the Myrophinae, which had a mean LI of 0.16 (Table 3). Post hoc analysis indicated that the mean LI for the Myrophinae was significantly greater than was that of the Congrinae and the Muraenesocidae.

Fatty Acids

The six most common fatty acids were 16:0 (overall mean = 23 mol%), 22:6n-3 (docosahexaenoic acid, DHA, 16 mol%), 18:0 (8.2 mol%), 20:5n-3 (eicosapentaenoic acid, EPA, 6.7 mol%), 18:1n-9 (6.4 mol%) and 16:1n-7 (6.3 mol%) (Table 4). Thus, these six fatty acids (FA) accounted for a mean of 67 mol% of total FA. The fatty acids 16:0 and DHA were clearly predominant, together accounting for ca. 40 mol% of total FA. The fatty acids 16:0, 18:0, EPA and DHA were among the six most common in all six leptocephali taxa. The only qualitative difference in the most common FA occurred in the Muraenesocidae and Ophichthinae, in which 16:1n-7 replaced 18:1n-9 as one of the six most common FA (Table 4).

Twenty-four of the 38 FA shown in Table 4 had significant among-taxon differences in mean proportion, including the six most common FA. 16:0 was particularly highly conserved, with a coefficient of variation of the overall mean of only 10 %. The essential fatty acid (EFA) DHA was more variable, with a CV of the overall mean of 23 %. Taxon-specific mean values of DHA proportion ranged from 15 mol% for the Bathymyrinae to 20 mol% for the Congrinae and Nettastomatidae. This difference in DHA proportion was statistically significant.

Table 4 Mean (\pm sd) mol% fatty acids of total fatty acids and fatty acid marker ratios of six taxa of eel leptocephalus larvae selected at random from ring net samples on the Broome transect (see Table 1; Fig. 1)

The number of samples used to calculate each mean is shown in square brackets in row no. 1. Bacterial fatty acid marker = *i15:0* + *ai15:0* + *15:0* + *15:1* + *i16:0* + *ai16:0* + *i17:0* + *ai17:0* + *17:0* + *17:1*. *Sum MUFA* the sum of monounsaturated fatty acids, *Sum PUFA* the sum of polyunsaturated fatty acids, *P/S* the ratio of polyunsaturated to saturated fatty acids, *Sum n-3* the sum of all n-3 fatty acids, *Sum n-6* the sum of all n-6 fatty acids. *C₁₆ PUFA ratio* (a diatom marker) = (16:2n-4 + 16:3n-4 + 16:4n-3 + 16:4n-1)/(16:0 + 16:1n-7 + 16:1n-5 + 16:2n-4 + 16:3n-4 + 16:4n-3 + 16:4n-1) × 100 %. All ratios are mol/mol and are without units. Numbers in bold face are the five predominant fatty acids in each taxon. Superscripts indicate values not significantly different from one another (single factor ANOVA by ranks). If a particular response variable lacks superscripts this indicates that all means in that particular row are not significantly different from one another. A ‘?’ following a particular fatty acid indicates that commercial standards were not available and identification was done by comparison with Ackman [15]

^A The following fatty acids were below detection limits in all samples: 18:2a, 18:2b, 22:2NMIDa?, 22:2NMIDb?

^B The following fatty acids and fatty acid markers were present at proportions <0.99 mol% and were not included in the above table: trimethyltridecanoic acid (TMTD), 14:1, *i15:0*, *ai15:0*, 15:1, pristanic acid?, 16:1n-11?, 16:1n-5, *i17:0*, *ai17:0*, 17:1b, 16:4n-3?, 16:4n-1, 18:1n-11?, 18:3n-6, 19:0, 20:0, 18:5n-3, 20:1n-11?, 20:2n-6, 20:3n-6, 21:0, 22:0, 22:1n-7, 22:1n-11(13), 23:0, 22:4n-6?, 22:4n-3?, and free fatty acids as a % of wet weight

^C Fatty acid or marker with statistically significant difference among means (one way ANOVA by ranks, $p < 0.05$) but only a single homogeneous group using Hochberg’s GT-2 multiple comparison test ($p > 0.05$). Therefore, superscripts could not be assigned to taxonomic groups for these fatty acids and markers

Fatty Acid Sums, Ratios and Markers

The sums of saturated FA and PUFA were essentially equal across all six taxa of leptocephali, each constituting ca. 40 mol% of the total FA (Table 4). This was reflected in the polyunsaturated/saturated (P/S) fatty acid ratio, which had an overall mean value of 0.9. The only significant differences among the taxa were in the sum of PUFA, which was lower in the Bathymyrinae (36 mol%) than in the Congrinae (43 mol%).

The low sum PUFA value for the Bathymyrinae was also reflected in the sum of n-3 FA (25 mol%), which was significantly lower than that of the five other taxa, which was ≥31 mol% (Table 4). The sum of n-6 FA ranged from 7.0 mol% for the Nettastomatidae to 9.3 mol% for the Bathymyrinae. The n-6 FA pool was dominated by the EFA arachidonic acid (20:4n-6, ARA, 2.9 mol%) and 18:2n-6 (3.3 mol%) (Table 4). The sum of n-6 FA for the eel leptocephali collected off Broome was ca. 1/3 that of n-3 FA, giving a range of n-3:n-6 FA of 2.7 for the Bathymyrinae to ≥3.8 for the other five taxa (data not shown).

The DHA:EPA ratio has been shown to be related to egg hatchability and larval development of marine fish, generally with higher ratios being associated with high quality eggs and normal development. The DHA:EPA ratio of the eel leptocephali we collected ranged from 2.4 to 2.7 for all six taxa (data not shown).

The bacterial fatty acid marker (*i15:0* + *ai15:0* + *15:0* + *15:1* + *i16:0* + *ai16:0* + *i17:0* + *ai17:0* + *17:0* +

17:1), and the sum of 18:2n-6 and 18:3n-3, which has been used as a terrestrial plant marker in cold water coastal environments [30, 34], made essentially equal contributions to total fatty acids (i.e. 4.7 and 4.4 mol%, respectively) (Table 4). While the bacterial marker was not significantly different among taxa, the Muraenesocidae had significantly more of the terrestrial FA markers (5.2 mol%) than did the Congrinae (3.6 mol%) and the Myrophinae (4.1 mol%). There was little evidence of carnivory by the leptocephali, as the sum of 20:1n-9 + 22:1n-11 + 22:1n-9 (a proxy for copepod prey) [19] was <1.4 mol% for all taxa (Table 4). The *C₁₆* PUFA ratio (a common diatom marker) [(16:2n-4 + 16:3n-4 + 16:4n-3 + 16:4n-1)/(16:0 + 16:1n-7 + 16:1n-5 + 16:2n-4 + 16:3n-4 + 16:4n-3 + 16:4n-1) × 100 %] was relatively variable within taxa, with an overall mean of 5.0 % (Table 4).

Discussion

The Leptocephali

The eel taxa examined in this study are all strictly marine throughout their life histories, and reside in tropical and sub-tropical continental shelf waters, from near the coast (Ophichthinae) to over the continental slope (Nettastomatidae) [1, 20]. Their migratory behavior is poorly known, but the Ophichthinae may carry out seasonal migration across the continental shelf to spawn near the shelf break

[1]. The size and WW of the taxa collected off Broome are typical of published values for eel leptocephali around the world. Furthermore, the relationship between SL and WW of the taxa we examined is similar to that published for *Paraconger caudilimbatus* from the Gulf of Mexico [2]. For example, the difference in WW predicted by the power equation in Fig. 2 and that of Bishop et al. [2] for a larva 70 mm long is 39 % of the mean value.

Total Lipid Concentration and Lipid Class Composition

Congrid, muraenid and ophichthid leptocephali from the Gulf of Mexico had 2–3 times greater mean lipid concentration than did the larvae we collected off Broome, ranging from 0.8 to 1.0 % of WW [2]. However, leptocephali of *Ariosoma balaericum* collected in the Gulf of Mexico, ranging in length from 20 to 200 mm (very similar to the range in Table 3), had total lipid concentrations ranging from 0.3 to 1.2 % of WW, overlapping values we determined for leptocephali collected on the Broome transect of 0.3–0.7 %. Type II elopomorph larvae are distinguished from the Type I larvae of the other bony fishes primarily by the deposition of large quantities of GAG during the second half of the larval period. Thus, lipid concentration generally decreases in eel larvae with increasing age due to the deposition of large quantities of GAG [16]. However, lipid accumulation rates larva⁻¹ actually increase with increasing age in preparation for the energy demands of metamorphosis [8, 16, 21]. Thus, the relatively low lipid concentrations we have determined suggest that our samples were dominated by relatively old leptocephali with large deposits of GAG. Lipid class and fatty acid data indicate that the low total lipid concentrations were not due to starvation (see below).

The lipid class composition of the leptocephali was similar to that of other fish larvae. PL, ST and TAG were also the top three lipid classes in non-eel fish larvae we have examined recently, accounting for 82–99 % of total lipids in larvae of haddock, Pacific cod, and Atlantic cod [22, 23]. Gadoid PL was generally a higher proportion than in the eel leptocephali (53–85 %); while TAG was generally lower (3–12 %). Thus, although the leptocephali collected off Broome were part of a relatively lipid-poor tropical food web, they accumulated TAG to greater proportions than do the Type I larvae of temperate and boreal gadoids. TAG are generally the most important neutral energy storage depot in marine fish larvae [24].

Ratios of Lipid Classes

Triacylglycerol:sterol ratios <0.2 are generally considered to indicate severe starvation in the early life stages of a variety of marine fish species [17, 25]. Thus, the values we

have determined indicate that all of the taxa except the Myrophinae were in excellent nutritional condition and that none of the leptocephali, including those of the Myrophinae, were suffering severe starvation at the time of sampling.

The LI is defined in Table 3, and provides an index of lipid breakdown. The low values of the LI confirm little lipid breakdown during sample processing, shipment and storage, and likely reflect in situ lipid catabolism by the leptocephali before collection. The relatively high LI of the Myrophinae leptocephali accords with the low TAG:ST ratio noted above, and suggests accelerated catabolism of storage lipids in this taxon in the immediate pre-collection period.

Fatty Acids

We could find no comparative information on the FA composition of leptocephali in the literature. The only information available was for the FA composition of leptocephali of the bonefish *Abula* sp. collected in the Gulf of California, which also had 16:0 and DHA as the two predominant FA (Table 5) [8]. In fact, the FA profiles of the bonefish and eel leptocephali are remarkably similar, with the largest differences being for the relatively minor 18:2n-6, 20:3n-3 and 20:4(n-6?) (Table 5). The fatty acid 16:0 is generally among the most common of marine invertebrates and vertebrates, and was strongly conserved among all six taxa of leptocephali we examined. The EFA DHA was more variable among the leptocephali indicating some degree of nutritional differentiation among the taxa. Within the plankton, DHA originates primarily from flagellates and dinoflagellates [26, and references therein], indicating strong linkage of eel leptocephali off Broome to these microplankton which are abundant at the base of tropical marine food webs. The DHA:EPA ratio is often assumed to reflect nutritional condition in marine heterotrophs, with values >2 considered to indicate good conditions for development and growth. The DHA:EPA ratio of the leptocephali we examined was >2.4, nearly in the middle of the DHA:EPA ratio of bonefish leptocephali in the neutral (1.7) and polar fractions (4.1) [8], and satisfactory for normal development. It also indicates that the leptocephali are relatively high quality prey in terms of DHA content.

Fatty Acid Sums, Ratios and Markers

Both the sum of saturated fatty acids (SFA) and sum of PUFA fall within the published range for bonefish leptocephali (Table 5). The sum of monounsaturated fatty acids (MUFA) was essentially identical with MUFA in the neutral lipid fraction of bonefish leptocephali (Table 5). The high values of SFA and PUFA, and low values of MUFA, are typical of Type I and II marine fish larvae generally [27].

Table 5 Comparison of the fatty acid composition (wt% of total FA) in late stage bonefish leptocephali from Padrón et al. [8] and the overall mean proportions of six taxa of eel leptocephali off Broome, Australia (from Table 4)

| Fatty acid | Bonefish neutral lipids | Bonefish polar lipids | Eels (this study) total lipids |
|------------|-------------------------|-----------------------|--------------------------------|
| 14:0 | 7.1 | 2.4 | 4.4 |
| 14:1 | 1.3 | 0 | – |
| 16:0 | 22 | 38 | 21 |
| 16:1n-7 | 8.2 | 3.0 | 5.7 |
| 18:0 | 4.2 | 9.7 | 8.2 |
| 18:1n-9 | 6.4 | 3.6 | 6.4 |
| 18:1n-7 | 3.0 | 3.3 | 3.6 |
| 18:2n-6 | 2.7 | 1.2 | 3.3 |
| 18:3n-3 | 4.2 | 1.2 | 1.1 |
| 18:4n-3 | 4.8 | 0 | 1.5 |
| 20:3n-6 | 0.9 | 2.7 | – |
| 20:3n-3 | 1.0 | 0.6 | 0.2 |
| 20:4 | 3.0 | 2.1 | 3.2 |
| 20:5n-3 | 10 | 6.0 | 7.1 |
| 22:4n-6 | 1.0 | 0 | – |
| 22:5n-3 | 1.7 | 1.5 | 1.0 |
| 22:6n-3 | 17 | 25 | 19 |
| Saturated | 34 | 50 | 39 |
| Monoenes | 19 | 9.9 | 19 |
| PUFA | 47 | 40 | 42 |
| n-3:n-6 | 8.6 | 8.7 | 3.3 |

Column 1 follows the format and nomenclature of Padrón et al. [8]. Dashed lines indicate FA proportions <1 wt% in all samples

It has been shown that n-3 and n-6 FA have mutually inhibitory effects on incorporation and bioconversion [28]. Thus, the n-3:n-6 ratio has been shown to be important for the development of fish larvae [28]. The values we observed are lower than the mean for bonefish leptocephali (i.e. 8.6–8.7, Table 5), suggesting a relatively high proportion of n-6 FA in the leptocephali off Broome. The n-6 FA are particularly abundant in tropical marine food webs relative to n-3 FA [27, 29], perhaps accounting for the low values of this ratio in the leptocephali we collected. Possible sources of n-6 FA include benthic macroalgae and sea grasses [26, 30], as well as some species of phytoplankton [31].

There were relatively high levels of bacterial and terrestrial FA markers in the leptocephali, perhaps reflecting their near-shore, tropical habitat. In comparison, the primarily herbivorous Arctic copepod *Calanus hyperboreus* had maximum bacterial marker levels of 1.5 % [32] and omnivorous adult *Mysis mixta* and *Acanthostephia malmgreni* from the benthic boundary layer of Conception Bay, Newfoundland, had bacterial FA marker levels ranging from 2 to 6 % and terrestrial FA marker levels

from 1 to 3 % [33]. Thus, the epipelagic leptocephali have similar levels of bacterial FA markers and higher levels of terrestrial FA markers than do near-bottom detritivorous crustaceans. However, a potential confounding factor is the occurrence of 18:3n-3 and 18:2n-6 in some phytoplankton [31] and sea grasses [30]. Although we have shown these FA to be robust makers of terrestrial source material in boreal waters [30, 34], we have not confirmed their efficacy on the Broome transect. The high level of bacterial markers in the eel leptocephali collected off Broome relative to planktonic copepods we have studied [32], is consistent with the possible feeding of leptocephali on bacteria-rich appendicularian houses and marine snow aggregates [6, 7].

The C₁₆ PUFA ratio is a marker of nutrient replete marine diatoms [35]. This ratio was highly variable within the taxa we examined (i.e. CV from 20 to 35 %), and relatively low overall (i.e. an overall mean of 5 %). This value is much lower than that we have determined for herbivorous copepods feeding during the spring bloom (C₁₆ PUFA ratio = 23 %) [36], but similar to a variety of carnivorous invertebrates feeding on sinking spring bloom material (C₁₆ PUFA ratio from 4 to 5 % for the amphipods *A. malmgreni*, *Anonyx* spp. and *Parathemisto* spp., the shrimp *Pandalus borealis*, and the chaetognath *Parasagitta elegans*) [36]. Thus, the leptocephali collected off Broome are only weakly connected with diatom production in the euphotic zone.

Our interest in the lipid and fatty acid content of tropical eel leptocephali (Type II larva) was to better understand their nutrition, energy storage and diet, and thus their ecology and physiological adaptations to an extended larval period. Perhaps not surprising is the complexity of our results, with some biochemical similarities between eel leptocephali and the larvae of non-eel fishes, and some important differences. We determined relatively low total lipid concentrations ranging from 2.7 to 7.0 mg g WW⁻¹, suggesting that the WW of the leptocephali off Broome was dominated by large deposits of GAG. However, PL, TAG and ST were the dominant lipid classes, which is also typical of the Type I larvae we have studied recently.

Although the leptocephali off Broome have an extended life span and had just come through the austral winter, the TAG:ST and DHA:EPA ratios indicated that they were in good condition and were growing and developing normally. The predominant fatty acids were 16:0, 22:6n-3 (DHA), 18:0, and 20:5n-3 (EPA), typical of marine fish larvae feeding at a low trophic level. However, the leptocephali were relatively enriched in n-6 fatty acids and poor in long chain monoenes, both typical of tropical waters. The leptocephali had proportions of bacterial markers >4 %, consistent with the possibility that they may have been consuming bacteria-rich appendicularian houses or other marine snow.

Acknowledgments The present work was carried out as part of the Galathea 3 expedition under the auspices of the Danish Expedition Foundation. We thank the Captain of HMDS 'Vædderen', Carsten Schmidt, and his crew for excellent assistance with our sampling. The authors thank J.T. Christensen, B. Søborg and A. Sampey for technical assistance onboard HMS Vædderen. J. Wells carried out the lipid and fatty acid analyses. The project was supported by grants from Knud Højgaards Fond and the Danish Natural Sciences Research Council, and by a Discovery Grant from the Natural Sciences and Engineering Research Council of Canada (DD). This paper is Galathea 3 contribution no. P87.

Abstract The proximate and fatty acid compositions of the commercially important fish species (*Engraulis encrasicolus*, *Alosa alosa*, *Belone belone*, *Scorpaena porcus*, *Pomatomus saltatrix*, *Mullus barbatus*) from the Sinop region of the Black Sea were examined. The fat contents ranged from 1.26% (for scorpion fish) to 18.12% (for shad). The protein contents were min 14.54% (for red mullet) and maximum 20.26% (for belone). The fatty acid compositions of the fish ranged from 27.83 to 35.91% for saturated fatty acids, 19.50–33.80% for monounsaturated fatty acids and 15.25–40.02% for polyunsaturated fatty acids. Among the saturated fatty acids, palmitic acid (16:0) (17.75–22.20%) was the dominant fatty acid for all the fish species. As a second saturated fatty acid, myristic acid (14:0) was observed in four of the fish species and its content ranged from 4.72 to 7.31%. Whereas, for the other two fish species, the second saturated fatty acid was stearic acid (18:0) ranging between 4.54 and 10.64%. Among the monounsaturated fatty acids, those occurring in the highest proportions were oleic acid (18:1n-9c) (11.67–22.45%) and palmitoleic acid (16:1) (4.50–9.40%). Docosahexaenoic acid (22:6n-3) (5.41–28.52%), eicosapentaenoic acid (20:5n-3) (4.68–11.06) and linoleic acid (18:2n-6) (1.38–3.49%) were dominant polyunsaturated fatty acids, respectively. All the

species, in particular the belone, the anchovy and the shad had high levels of the n-3 series.

Introduction

Fatty acids serve a wide variety of metabolic functions, critical to all forms of life. Polyunsaturated fatty acids (PUFA), particularly the n-3 and n-6 series, play an important role in non-energy-producing biological functions. n-3 PUFA, namely eicosapentaenoic acid, 20:5n-3 (EPA) docosapentaenoic acid, 22:5n-3 (DPA) and docosahexaenoic acid, 22:6n-3 (DHA) plays numerous roles within the human body [1].

The health benefits of the long-chain n-3 PUFA such as 20:5n-3 and 22:6n-3 have been well observed in scientific studies such as the prevention or reduction of human coronary artery disease [2–7], a significant decrease in total cholesterol and high density lipoprotein levels [8], in

peripheral arterial disease, improvement in endothelial functions [9] improvement in depressive symptoms in parkinsonian patients [10], a reduction in the risk of breast cancer [11, 12] and a reduction in the risk of prostate cancer [13].

Long-chain n-3 PUFA cannot be easily synthesized by humans and must be ingested in the diet [14]. Most of the PUFA of fish lipids occur as the n-3 type. The contents of different fatty acids in fish lipids depend on numerous factors, such as diet, the geographic location, the environmental temperature, the time of year, the body length, the lipid content, etc. [15].

Sinop is one of the important port cities on the Black Sea. In particular, anchovy is of utmost importance for commercial fishing in this area. Additionally, the other commercial fish species in this region are bonito, shad, belone, turbot, scorpion fish, horse mackerel, blue fish, red mullet and whiting. Knowledge of the fatty acid composition and nutritional value of commercially important fish species is needed. Therefore, this paper presents the fatty acid compositions and other nutritional values of a variety of commercial fish species found in the Sinop region of the Black Sea.

Materials and Methods

Sample Preparation

For this research, 2 kg each of six different species of commercially important fish were chosen and purchased from the local fish market in January 2011. These were anchovy (*Engraulis encrasicolus*), shad (*Alosa alosa*), belone (*Belone belone*), scorpion fish (*Scorpaena porcus*), bluefish (*Pomatomus saltatrix*), and red mullet (*Mullus barbatus*). The average weights of the fish were 6.18 ± 0.3 g for anchovy, 229.60 ± 10.83 g for shad, 73.31 ± 4.75 g for belone, 87.82 ± 9.91 g for scorpion fish, 110.37 ± 8.17 g for bluefish, and 10.29 ± 0.56 g for red mullet. A minimum of nine fish from each individual species were gutted, filleted and minced for analysis.

Analysis

The moisture and ash contents were determined as described by AOAC [16], and the protein content was determined by the Kjeldahl method [16]. The crude lipid content was performed by acid digestion prior to petroleum ether extraction (boiling point 40–60 °C) in a Soxtec system [17]. These analyses were performed in triplicate. After the fish carbohydrate value was calculated [carbohydrate value = $100 - (\text{water} + \text{lipid} + \text{protein} + \text{ash})$] the energy value was calculated according to the Atwater

method [18]. The fatty acid content was determined using the IUPAC I.D.19 method [19]. The fatty acids were analyzed using a Perkin Elmer Auto System XL gas chromatograph (Perkin-Elmer, Beaconsfield, UK) equipped with a SP-2330 column and a flame ionization detector. The separation of the fatty acids methyl esters was achieved using a fused silica capillary column (30 m \times 0.25 mm \times 0.20 μ m film thickness). The oven temperature was set at 120 °C for 2 min, then increased to 220 °C with a ramp rate of 5 °C/min, and then held for 15 min. The injector and detector temperatures were maintained at 240 and 250 °C, respectively. The carrier gas was helium at 10 psi with a split ratio of 1/50. The air and hydrogen pressures were 338 and 45 ml/min, respectively. The results were determined by the percentage of each fatty acid with respect to the total fatty acids. The fatty acid analyses were conducted in two replicates and the results were expressed in GC area % as mean values \pm standard error. For identification of the fatty acids, their retention times were compared to those of the standard methyl esters (Supelco 37-Component FAME Mix). For conversion of the percentile values to units of weight, the formula recommended originally by Weihrauch et al. [20] and then Paul and Southgate [21] and Soriguer et al. [22] was employed. The formula for fish is as follows: Factor (fish) = $0.933 - (0.143/\text{total fat})$. The conversion factor (CF) for the n-3 FA of *E. encrasicolus*: CF = $0.933 - (0.143/13.90) = 0.92$; $(0.92 \times 28.40)/100 = 0.26$ g/100 g of n-3 (Table 3).

Statistical Analysis

The results of the analyses were presented as means \pm standard errors. Statistical analysis was conducted with the Minitab Statistical Software package (Minitab Release, 13). A one-way analysis of the variance (ANOVA) was used to verify the differences between the species and significance of those differences were tested with the Tukey Test. The significance level was $P < 0.05$.

Results and Discussion

Proximate Composition

Table 1 shows the proximate composition of the six species of fish.

The main chemical components of fish meat are water, crude protein, and lipids. Together they make up approximately 98% of the total mass of flesh. The other constituents, i.e., carbohydrates, vitamins, and minerals, are present in minor quantities. The contents of the main components in the fish body depend primarily on the

(Sample size: 2 kg for each fish species)

species, the stage of maturity, the sex, the spawning cycle, the environment, the season, and the nutritional condition of the animal [15, 23, 24]. Flesh from healthy fish contains 60–84% water, 15–24% protein and 0.1–22% fat; minerals usually constitute 1–2%. The proportions of the constituents are species-specific and the main variations between species are in the fat content. Fish are often classified according to fat content. Lean fish have <0.5% fat, semi-fat fish contain 0.5–2% and fatty fish have more than 2% [25]. In this study, the lipid content ranged from 1.26% for scorpion fish to 18.12% for shad. The scorpion fish could be classified as a semi-fat fish. All the remaining fish could be classified as fatty fish. However, between the fatty fish, the highest fat content was determined in the shad flesh ($P < 0.05$). The fat contents were shad > anchovy > blue fish > red mullet > belone > scorpion fish ($P < 0.05$). Sorting by the moisture content was scorpion fish > red mullet ≥ belone > blue fish > anchovy > shad ($P < 0.05$). In general, there is an inverse relationship between the amount of fat and moisture in the flesh. As shown in Table 1, the moisture content in deep water species (scorpion fish and red mullet) was more than in the pelagic species.

The protein content tends to vary much less widely from one species to another. Most fish contain approximately 20% protein [25]. Also, in this research, the protein content of the fish varied from 14.54 to 20.26%. The ash content ranged from 0.76% for the blue fish to 1.25% for the belone.

The major carbohydrate in fish muscle is glycogen, which is a polymer of glucose. A typical muscle in a live fish may contain between 0.1 and 1% glycogen [25]. In this research, the lowest carbohydrate content was obtained from the red mullet (0.66%) however, it was similar to the carbohydrate value of the other fish except for the anchovy ($P < 0.05$). The energy value of the fish ranged from 82.84 to 243.74 cal ($P < 0.05$), and the fat content together with the energy value, was determined as a linearly relationship ($r = 0.99$).

Similar food compositions for the fish observed in this research have been determined by several other researchers [26–30].

Fatty Acid Composition

Table 2 shows the fatty acid composition of six fish species.

The fatty acids composition of the fish species ranged from 27.83 to 35.91% saturated fatty acid (SFA), 19.50–33.80% monounsaturated fatty acid (MUFA) and 15.25–40.02% PUFA. It was observed that the proportion of these fatty acids changed significantly between the six fish species ($P < 0.05$). Among them, those occurring in the highest proportions were myristic acid (14:0), palmitic acid (16:0) (PAM), stearic acid (18:0) (STA), palmitoleic acid (16:1), oleic acid (18:1n-9) (OLA), linoleic acid (18:2n-6) (LNA), alpha-linolenic acid (18:3n-3) (ALA), eicosapentaenoic acid (20:5n-3) (EPA) and docosahexaenoic acid (22:6n-3) (DHA). These results are in line with previous studies on the fatty acids of other species [27–29, 31–38]. It was also observed that the proportion of these fatty acids vary among the species.

The SFA values were significantly different ($P < 0.05$) for the six fish species. The highest SFA value was obtained from the scorpion fish (35.91%) whose fat content was the lowest in all fish. This was followed by anchovy (35.07%), blue fish (32.86%) and red mullet (30.46%), belone (29.56%) and shad (27.83%). Güner et al. [27] reported SFA ratios 40.77% for anchovy, 38.16% for red mullet, 35.87% for belone, 31.77% for shad. SFA ratios of anchovy by Kaya and Turan [28] were declared as 38.62, 35.20, and 33.57% in November, December and January, respectively. Öksüz and Özyılmaz [29] reported that SFA ratios of anchovy ranged from 37.91 to 34.04% (from October to April). Tanakol et al. [31] determined SFA ratios 42.2% for anchovy, 34.4% for bluefish and 34.7% for belone. Bayır et al. [32] found SFA ratios in bluefish,

Data are the mean values of two replicates ± standard errors

nd Not detected

Within a row values with different superscript letters are significantly different ($P < 0.05$)

anchovy and belone of 38.35, 37.81, and 28.89%, respectively. Palmitic acid was the primary SFA, contributing to 57–66% of the total SFA content of lipids for all the fish species. These result is in line with previous studies on the fatty acids of other species [27–29, 31, 32]. The highest 16:0 content was detected in the scorpion fish, whereas the lowest value was found in the shad. The palmitic acid content in the anchovy and red mullet; belone and the blue fish were similar ($P > 0.05$). Myristic acid was the

secondary fatty acid for the pelagic fish species (anchovy > blue fish > belone > shad, $P < 0.05$), whereas 18:0 was the secondary fatty acid for the deep water species (10.64% for scorpion fish, 4.54% for red mullet).

The MUFA values were significantly different ($P < 0.05$) for all six fish species. The highest MUFA value was obtained from the red mullet (33.80%), followed by the blue fish (30.50%), belone (30.34%) and then the shad (30.26%) ($P > 0.05$), whereas the lowest value was

found in the anchovy (19.50%) ($P < 0.05$). This result is in accordance with Güner et al. [27] who found that anchovy showed the lowest percentage (24.80%) of MUFA in other fish (red mullet, belone and shad). Öksüz and Özyılmaz [29] reported monthly changes (25.91–31.51%) in the levels of the MUFA component throughout the catching season of anchovy. Oleic acid was the most represented of the MUFA, accounting for 60–74% of the total MUFA for all the fish. The highest 18:1n-9 contents were obtained from the blue fish (22.45%) and the shad (22.08%) ($P > 0.05$), followed by belone (20.68%), the scorpion fish (17.32%) and the red mullet (20.49%) ($P > 0.05$), whereas the lowest value was found in the anchovy (11.67%) ($P < 0.05$). While the highest 16:1 value was obtained from the red mullet (9.40%), the lowest value was found for the shad (4.50), and its contents were similar to the anchovy and the blue fish ($P > 0.05$). This two fatty acid (18:1n-9 and 16:1) were determined as the major fatty acids in MUFA in also other studies [27–29, 31, 32].

The PUFA values were significantly different ($P < 0.05$) for the six fish species. The highest PUFA value was obtained from the belone (40.02%), followed by anchovy (32.43%), shad (27.67%), scorpion fish (26.38%), and blue fish (20.15%), whereas the lowest value was found in the red mullet (15.25%). This result is in accordance with Güner et al. [27] who found that red mullet showed the lowest percentage (16.72%) of PUFA in other fish (belone, shad, and anchovy). The major fatty acids, identified as PUFA, were 22:6n-3 and 20:5n-3, respectively. The highest proportion of 22:6n-3 in the total PUFA was obtained from the belone (71%), followed by shad (62%), blue fish (53%) and anchovy (49%), whereas, the scorpion fish (34%) and red mullet (35%) contained lower 22:6n-3 contents. Güner et al. [27] also determined a lower 22:6n-3 content in red mullet than anchovy, belone and shad. It was observed that the proportion of 22:6n-3 in the pelagic fish (belone, shad, blue fish and anchovy) was higher than those in the deep water fish (scorpion fish and red mullet). Similarly, the high proportion of 20:5n-3 was detected in the red mullet (36% of total PUFA) and anchovy (34%), followed by the scorpion fish (23%), blue fish (23%), shad (21%), whereas the belone (12%)

contained lower 20:5n-3 than the other fish. However, the 20:5n-3 values were anchovy > scorpion fish > shad > red mullet > blue fish \geq belone. The 20:5n-3 values in the fish (anchovy, red mullet, belone and shad) studied here were higher than those in the fish (anchovy, red mullet, belone and shad) studied by Güner et al. [27]. Also, the 22:6n-3 values in red mullet, belone and shad except for anchovy were higher than those in the fish studied by Güner et al. [27]. In the PUFA, the 18:2n-6 contents ranged from 1.38% (for red mullet) to 3.49% (for belone). The linoleic acid contents were similar to that of the anchovy (2.52%) with the scorpion fish at (2.41%), shad (2.16%) with blue fish (2.15%), ($P > 0.05$), whereas the 18:3n-3 contents were significantly different in all the fish species, with a content range from 0.41% (for red mullet) to 3.95% (for scorpion fish).

The British Nutrition Foundation [39] recommended that people who have a balanced and healthy diet consume 0.2 g of EPA and DHA daily. The American Heart Association (AHA) recommends that all adults should include fish in their diet at least twice a week, especially oily fish [40–42], and for patients with documented coronary heart disease, the AHA recommends \approx 1 g of EPA + DHA (combined) per day [40, 41]. This may be obtained from the consumption of oily fish or from n-3 fatty acid capsules, although the decision to use the latter should be made in consultation with a physician [40, 41].

Table 3 shows the amounts of EPA + DHA in fish from this research.

As shown in Table 3, the highest EPA + DHA value was obtained from the belone (0.29), followed by anchovy (0.25) and shad (0.21), whereas the lowest values were found for the scorpion fish (0.12), blue fish (0.14) and red mullet (0.15). To meet the EPA and DHA recommendations according to the British Nutrition Foundation, 100 g of belone, anchovy and shad is enough but scorpion fish, blue fish and red mullet should be consumed in amounts higher than 100 g. This research indicates that very oily fish such as anchovy and shad have more EPA + DHA than semi-fat fish such as scorpion fish. However, belone is shown to be a very good source of EPA + DHA, despite the low amount of fat (Table 3).

Table 3 Σ SFA, Σ MUFA, Σ PUFA, EPA, DHA content of fish species (g/100 g fish)

| Species | Lipid (%) | Σ SFA | Σ MUFA | Σ PUFA | n-6 | n-3 | EPA | DHA | EPA + DHA |
|----------------------------------|-----------|--------------|---------------|---------------|------|------|------|------|-----------|
| <i>E. encrasicolus</i> (anchovy) | 13.90 | 0.32 | 0.18 | 0.30 | 0.03 | 0.26 | 0.10 | 0.15 | 0.25 |
| <i>A. alosa</i> (shad) | 18.12 | 0.26 | 0.28 | 0.26 | 0.02 | 0.23 | 0.05 | 0.16 | 0.21 |
| <i>B. belone</i> (belone) | 3.64 | 0.26 | 0.27 | 0.36 | 0.03 | 0.31 | 0.04 | 0.25 | 0.29 |
| <i>S. porcus</i> (scorpion fish) | 1.26 | 0.29 | 0.21 | 0.22 | 0.02 | 0.16 | 0.05 | 0.07 | 0.12 |
| <i>P. saltatrix</i> (blue fish) | 12.29 | 0.30 | 0.29 | 0.19 | 0.02 | 0.15 | 0.04 | 0.10 | 0.14 |
| <i>M. barbatus</i> (red mullet) | 8.32 | 0.28 | 0.31 | 0.14 | 0.01 | 0.11 | 0.05 | 0.10 | 0.15 |

In the present study, it was observed that all the species had high levels of the n-3 series, ranging from 11.60% for red mullet and 34.89% for belone ($P < 0.05$) (Table 2). However, the level of the n-6 series was detected as being low; ranging from 1.49% for the red mullet and 3.49% for belone. The level of the n-6 series of the shad, scorpion fish and blue fish were similar ($P > 0.05$). Excessive amounts of n-6 PUFA and a very high n-6/n-3 ratio, as is found in today's Western diets, promote the pathogenesis of many diseases; including cardiovascular disease, hypertension, depression, cancer, and inflammatory and autoimmune diseases, whereas increased levels of n-3 PUFA (a low n-6/n-3 ratio) exert suppressive effects [1, 43–47]. Because of the low content of n-6 fatty acids in marine fish, the ratio of the total n-3–n-6 fatty acids (essential fatty acid ratio) is high, varying from about 5, and reaching a ratio of more than 10 [48]. In this research, the highest value of n-3/n-6 ratio was obtained from the shad (10.77), followed by belone (10.01) and anchovy (9.91), whereas the lowest values were detected in the scorpion fish (7.87), red mullet (7.79) and blue fish (7.27) (Table 2).

In conclusion, this research indicated that the belone, anchovy and shad in particular, are excellent food sources for EPA + DHA. In addition, the red mullet, blue fish and scorpion fish are also good sources of EPA + DHA.

Oral Supplementation with Dihomo- γ -Linolenic Acid (DGLA)-Enriched Oil Increases Serum DGLA Content in Healthy Adults

Takao Tanaka · Saki Kakutani · Chika Horikawa · Hiroshi Kawashima · Yoshinobu Kiso

Received: 17 January 2012 / Accepted: 28 February 2012 / Published online: 14 March 2012

Abstract Dihomo- γ -linolenic acid (DGLA) is one of the polyunsaturated fatty acids, and is expected to show anti-allergic activity. We examined the effects of supplementation with DGLA-enriched oil (450 mg as free DGLA) for 4 weeks in healthy adults in a randomized controlled study. The DGLA composition in the total fatty acids of serum phospholipids increased from 2.0 to 3.4 %, and returned to the initial level after a 4-week washout. No side effects or changes in blood biochemical parameters were observed. These results indicate that serum DGLA content can be safely increased by supplementation with 450 mg DGLA under these conditions.

Introduction

Dihomo- γ -linolenic acid (20:3n-6; DGLA, 8,11,14-eicosatrienoic acid) is one of the polyunsaturated fatty acids and

a constituent of cell membranes. It is metabolized to eicosanoids, such as 1-series prostaglandins and 15-hydroxyeicosatrienoic acid, which exhibit anti-inflammatory or anti-platelet-aggregation effects [1, 2]. Recently, a new fermentation technique was established using a fungus, *Mortierella alpina*, enabling industrial production of DGLA-enriched triglyceride (DGLA oil) [3]. The DGLA content of this oil is very high, reaching approximately 40 % in total fatty acids. We used this oil to investigate the effects of DGLA administration in rodents. Oral administration of DGLA oil markedly reduced clinical skin severity scores and scratching behavior in NC/Nga mice, the standard model for human atopic dermatitis (AD) [4]. This is consistent with the evidence that the DGLA concentration in serum phospholipids in AD patients was significantly lower than that in healthy volunteers [5]. DGLA was also revealed to have an anti-atherosclerotic effect in apoE-deficient mice [6]. Therefore, the application of DGLA oil for human use is expected. Previously, we found that serum DGLA content in healthy men can increase by supplementation with DGLA oil (50 or 150 mg as free DGLA) [7]. The increase of DGLA composition in serum phospholipids was 0.67 % by supplementation with 150 mg, but there was no significant increase by supplementation with 50 mg. To determine if a higher serum DGLA content can be achieved safely, we investigated the effects of supplementation with DGLA-enriched oil (450 mg as free DGLA) for 4 weeks in healthy Japanese participants in a randomized controlled study.

Materials and Methods

The study design was a randomized, double-blind and placebo-controlled parallel group intervention trial. This study was approved by the Institutional Review Boards of

T. Tanaka · S. Kakutani · C. Horikawa · H. Kawashima (✉) · Y. Kiso

Suntory Ltd. (Osaka, Japan), and performed according to the Helsinki declaration. Healthy Japanese participants (25–44 years old) were recruited after assessment of medical and dietary histories. Each participant provided written informed consent after receiving a thorough explanation of the study. This double-blind, placebo-controlled study included 4-week supplementation and a subsequent 4-week washout, which together formed the test period. The participants were randomly divided into two groups. The DGLA group received six capsules, which contained 1,215 mg of DGLA oil per six capsules per day (corresponding to 450 mg of DGLA per day). The DGLA oil was extracted from a biomass of submerged fermented *M. alpina* and refined by high-purification processes [3]. The placebo group received six capsules containing 1,215 mg of olive oil per day without DGLA. Blood samples were obtained three times, on the day before supplementation began, after the 4 weeks of supplementation, and after the 4-week washout. Sampling was performed from 09:00 to 11:00 after approximately 12 h of fasting. The physical characteristics of participants were measured, and blood and urine were collected for determination of biochemical parameters, fatty acid analysis, and urinalysis. Hematological, blood biochemical, and urinalysis parameters were assayed in the usual manner. Lipids in the serum were extracted by the Folch method [8], and were separated into phospholipids and triacylglycerols by thin-layer chromatography with silica gel 60 (Merck, Darmstadt, Germany). The solvent system consisted of hexane/diethyl ether (7/3, v/v). Fatty acid residues in the phospholipid and triacylglycerol fractions were analyzed as described previously [9]. Findings were examined by repeated ANOVA and Dunnett's test for intra-group comparison and by student *t* test for inter-group

comparison, using the Statistical Package for the Social Sciences for Windows version 17.0 (SPSS Inc., Chicago, IL). *P* value of less than 0.05 was considered to indicate statistical significance.

Results and Discussion

Twenty-six healthy volunteers were originally enrolled. Five of them did not participate because of personal reasons (2 participants) or meeting the exclusion criteria (3 participants). Twenty-one participants (8 males and 3 females in the DGLA group, 7 males and 3 females in the placebo group) were administered the sample, and 20 participants completed the trial (1 male in the DGLA group was withdrawn due to having a cold). There were no significant differences in the baseline characteristics (Table 1). There were no side effects during the study period, and all adverse events observed were considered unrelated to supplementation.

The fatty acid composition of the serum phospholipids is shown in Fig. 1. The mean DGLA composition (±SD) in

Fig. 1 Fatty acid content of DGLA (a), ARA (b), EPA (c) and DHA (d) in total fatty acids of serum phospholipids. Each value represents the mean ± SD (*N* = 10 (placebo group, open circles) and *N* = 10 (DGLA group, closed circles). **P* < 0.05, ***P* < 0.01 versus

baseline in the group (repeated ANOVA and Dunnett's test). ##*P* < 0.01 versus placebo group in the case that the change from baseline is significantly different in each time point (unpaired *t* test)

Fig. 2 Correlation of the DGLA dose and the change in DGLA content in serum phospholipids. *Open circles* are the individual data in this study, and *open triangles* are those in a previous study [7]

total fatty acids of serum phospholipids increased from 1.99 (± 0.43) to 3.36 (± 0.50) % in the DGLA group, whereas it was unchanged in the placebo group over the

test period. The increase in DGLA content was 1.37 % in the DGLA group, which was larger than the increases of 0.67 and 0.46 % by the supplementation with 150 and 50 mg DGLA, respectively [7]. This is also more effective than the supplementation with γ -linolenic acid (GLA), the precursor of DGLA, since the increase in DGLA content was only 1.1 % by the administration of GLA-containing oil (900 mg/day, as free GLA) [10]. After the 4-week washout, the DGLA content returned to 2.12 (± 0.35) %, indicating that DGLA levels can be easily returned to the initial levels by discontinuation of DGLA ingestion, and that continuous DGLA ingestion is needed to maintain an increased DGLA level. The major polyunsaturated fatty acids in the serum phospholipids other than DGLA and arachidonic acid (ARA) were unchanged throughout the test period. The ARA increase was probably due to the conversion of DGLA to ARA, but the activity of conversion seemed not so high under the conditions since the increase (0.76 %) was small. There were no effects on serum contents of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). These data suggest that

Table 2 Blood biochemical and hematological parameters

| Parameter | | Placebo group (N = 10) | | | DGLA-group (N = 10) | | |

supplementation with DGLA oil is very useful in increasing serum DGLA content, because the activity of conversion of both GLA to DGLA and DGLA to ARA seems low in humans. The increase in serum DGLA content (1.37 %) observed in the present study is considered enough to demonstrate clinical efficacy, because GLA administration seemed effective against AD when the increase in serum DGLA content was more than approximately 1 % [11, 12]. Anti-dermatitis effects were also shown in the NC/Nga mice model when the increase in serum DGLA content was approximately 1.5 % [4]. The correlation of the DGLA dose and the increase of serum DGLA is shown in Fig. 2. The plots are individual values in this study and a previous study [7]. Positive correlation was observed, indicating that the increase of DGLA composition in serum phospholipids is 0.255 % per 100 mg supplementation with DGLA for 4 weeks.

Blood biochemical and hematological parameters are shown in Table 2. There were no significant differences between the groups. Some significant differences compared to the baseline values were observed (lactate dehydrogenase, albumin, total cholesterol, red blood cells and hematocrit), but they were within the normal ranges for healthy Japanese adults. Diastolic and systolic blood pressures, coagulation parameters (prothrombin time, activated partial thromboplastin time and antithrombin III) and urinalysis parameters (protein, sugar, and urobilinogen) were also within the normal ranges and showed no significant differences between the groups (data not shown).

In conclusion, these findings show that the human serum DGLA content can be safely increased by supplementation with DGLA oil (corresponding to 450 mg of DGLA per day) for 4 weeks. We can control the human serum DGLA content by supplementation with various doses of DGLA oil, containing from 50 to 450 mg of DGLA as the free fatty acid. Further investigation is expected in supplementation with DGLA oil to patients with atopic dermatitis or symptoms of allergy.

Abstract Epidemiological data have shown an association of the intake of industrial produced *trans* fatty acids (TFA) and sudden cardiac death. The present study examines the impact of elaidic acid (*t*18:1n-9) and linoelaidic acid (*t*18:2n-6) on the human aortic endothelial cell functional response. *Trans* fatty acids predominately incorporated into the phospholipid component while only a minute fraction of the total fatty acids (FA) incorporated into triacylglycerol. *Trans* fatty acids incorporated into the plasma membranes at the expense of the saturated-FA, stearic, palmitic, and to a lesser extent, myristic acid. Both *t*18:1n-9 and *t*18:2n-6 induced a pro-inflammatory response by elevating surface expression of intercellular adhesion molecule-1 (ICAM-1). Neither oleic nor linoleic evoked a pro-inflammatory phenotype under the maximal 50 μ M treatments. Both TFA and stearic acid increased phosphorylation of the ICAM-1 transcriptional regulator, nuclear factor- κ B (NF- κ B), while oleic and linoleic acids did not appear to alter the phosphorylation status. Elaidic acid minimally affected endothelial cell growth, whereas linoelaidic acid completely inhibited growth at 100 μ M and imparted limited cytotoxicity up to 300 μ M. Stearic

acid induced cytotoxicity at concentrations above 75 μ M, while oleic and linoleic acids evoked gradual dose-dependent growth inhibition with cytotoxicity occurring only at linoleic acid concentrations greater than 200 μ M. In conclusion, *t*18:1n-9 and *t*18:2n-6 fatty acids effectively incorporated into the phospholipid component of endothelial cells and subsequently induce a pro-inflammatory phenotype.

Introduction

Trans fatty acid sources are either industrially produced (IP-TFA) or ruminant produced (RP-TFA). Industrially produced-*trans* fatty acids are generated by the partial hydrogenation of vegetable fats and, to lesser extent, fish oils using a high heat source, hydrogen gas, and a metal catalyst. Industrially produced-*trans* fatty acids account for a majority of the *trans* fats in the western diet, and the IP-TFA content of partially hydrogenated fat could reach as high as 60 % [1]. Naturally occurring RP-TFA arise from the bio-hydrogenation in ruminant animals, which are present in beef and sheep products, such as milk and cheese. The RP-TFA present in meat and dairy products comprise a maximum of 6 % of the fat content [1]. In European countries, such as Denmark, aggressive measures have drastically reduced IP-TFA in food products; as a result, their major source of TFA is ruminant produced. The RP-TFA intake in the general Danish population consists of 85 % dairy products and the remaining 15 % in ruminant meat products [2]. Conversely, TFA consumption in the USA population is estimated to account for 4–12 % of the total dietary fat intake, which equates to 13 g of TFA/person/day based on the highest daily intake of TFA [3]. Despite recent trends to drastically reduce *trans* fatty acids from dietary intake in European countries, IP-TFA are readily present in the western diet, particularly in the USA. *Trans* fatty acid intake in Canada was as high as 8.4 g/person/day in the mid-1990s; however, following the health Canada's 2007 request to voluntarily reduce the quantity of IP-TFA by food manufacturers, the average daily intake dropped to 3.4 g/person/day (1.4 % food energy) in 2008 [4]. Even with the significant reduction, the TFA intake continues to exceed the World Health Organizations recommendations of <1 % of food energy consumption.

Epidemiological evidence has established a correlation of TFA consumption with the risk of death from coronary heart disease, primarily due to IP-TFA sources [5–7]. Mozaffarian et al. [8] performed a meta-analysis of four prospective cohort studies investigating the association of TFA intake with the incidence of coronary heart disease (CHD) that resulted in a pooled relative risk of 1.23 (95 % CI, 1.11–1.37; $P < 0.0001$). Furthermore, these investigators evaluated TFA consumption and the risk of nonfatal myocardial infarction in three retrospective case-control studies, which assessed the TFA content in adipose tissue.

With the inclusion of these retrospective studies, the meta-analysis enhanced the association between TFA consumption and the risk of developing CHD (pooled relative risk 1.29; 95 % CI, 1.11–1.49; $P < 0.0001$). Mozaffarian et al. [8] cautions that although the correlation between TFA intake and the risk of CHD are predominantly due to IP-TFA, RP-TFA consumption could be as detrimental if consumed in significant quantities. In a Danish 18-year follow-up study, there was no indication of an association of RP-TFA intake and the risk of CHD in men. In fact, indications of an inverse correlation were observed in women [9]. Additional studies should be performed in this controversial relationship of RP-TFA consumption and the risk of developing cardiovascular disease.

While most investigations have focused on the impact of IP-TFA, Motard-Bélanger and colleagues [10] reported that both IP- and RP-TFA consumption adversely affects cholesterol homeostasis. Mozaffarian et al. [11] reviewed the effects of TFA consumption on CHD. *Trans* fatty acid consumption disrupts cholesterol homeostasis, resulting in increased low-density lipoprotein cholesterol with a corresponding decrease in high-density lipoprotein cholesterol levels. Additional evidence outlined in their review emphasizes the pro-inflammatory impact of TFA, including elevated levels of tumor necrosis factor- α , interleukin-6, and C-reactive protein [11]. Bendsen et al. [12] conducted a 16-week intervention study examining the effect of IP-TFA consumption on biomarkers of inflammation in overweight postmenopausal women. Elevated IP-TFA intake increased TNF- α levels as well as soluble forms of the TNF receptors. The investigators conclude that IP-TFA consumption may involve the activation of TNF- α as a possible mechanism leading to the development of cardiovascular disease.

Saturated fatty acids (SFA), stearic acid in particular, are believed to contribute to CHD by invoking lipid-mediated vascular cell dysfunction [13–17]. In a population-based cross-sectional study aimed at determining the effects of SFA and TFA intake on the mean carotid artery intimal medial thickness, elevated consumption of both of these fatty acid classes were independently associated with increased intimal medial thickness [18]. The authors conclude that elevated intake of SFA and TFA may lead to an increased risk of subclinical atherosclerosis. Based on the limited amount of evidence available, previously published data suggest linoelaidic acid is more responsible for CHD than elaidic acid [11, 19]; however, no direct assessment has been performed in primary cells derived from the vasculature. Endothelial cells (EC) are an integral component of the development and progression of CHD, which is hypothesized to possibly be the end result of chronic systemic inflammation. Previous reports published from our laboratory emphasized the significant role of long-

chain saturated fatty acids in the generation of a pro-inflammatory endothelial cell phenotype [20, 21]. In the present study, we initiated *in vitro* studies to directly evaluate the deleterious affects of two commonly consumed TFA, elaidic and linoelaidic acids, in comparison to their saturated counterpart, stearic acid. As previously reported [22], TFA structurally resemble saturated fatty acids. We hypothesized that TFA-supplemented endothelial cells would develop a pro-inflammatory phenotype similar to cellular responses following long-chain saturated fatty acids, as previously reported [20, 21]. In this investigation, we initiated *in vitro* studies to compare the direct effects of the TFA, elaidic and linoelaidic acids, as well as stearic acid supplementation on the phenotypic and functional responses in human aortic endothelial cells.

Materials and Methods

Materials

Human-derived aortic endothelial cells as well as the growth medium comprised of EGM-2MV bullet kits (endothelial growth medium-2 microvascular) were purchased from Lonza Walkersville Inc. (Walkersville, MD, USA). Fetal bovine serum was obtained from Invitrogen Corporation (Carlsbad, CA, USA). Consumable tissue culture materials were purchased from Fisher Scientific (Pittsburgh, PA, USA). Western blot antibodies were acquired from Cell Signaling Technology (Danvers, MA). Fluorescently coupled antibodies were obtained from BD Pharmingen (San Diego, CA, USA). All fatty acids were purchased from Nu-Chek Prep Inc. (Elysian, MN, USA). Gas chromatography standards were purchased from Restek Corporation, Bellefonte, PA, USA). Additional chemicals and reagents were obtained from Sigma Chemical Company (St. Louis, MO, USA), unless otherwise noted.

Human Aortic Endothelial Cell Culture

Primary human aortic endothelial cells (HAEC) were maintained in endothelial basal medium-2 (EBM2) supplemented with 5 % fetal bovine serum (FBS) and bullet kit materials as specified by the manufacturer. Cell culture passages of less than ten were experimentally utilized at 80–90 % confluence. Human aortic endothelial cells were maintained at 37 °C in a humidified atmosphere in the presence of 5 % CO₂.

Fatty Acid Incorporation into Endothelial Cells

Fatty acid stock solutions (1 mM) were prepared by complexing fatty acid free-bovine serum albumin (BSA) with

individual free fatty acids [23]. Sub-confluent endothelial monolayers were cultured for 24 h in the presence or absence of albumin bound-fatty acids (50 µM). Following treatments, cells were trypsinized and washed in phosphate buffered saline (PBS) supplemented with 0.1 % fatty acid free-BSA. Cell pellets were resuspended in calcium and magnesium-free PBS and sonicated to lyse the cells. Internal standards (C23:0, phospholipid and triglyceride) were added to a known volume of cell lysate, whereas protein content was determined with the remaining lysate using a bicinchoninic acid (BCA) protein assay kit (R and D Systems, Elysian, MN).

Lipids were extracted using the Folch method with chloroform: methanol (2:1) [24]. Fractionation of the lipid classes into phospholipids (PL) and triacylglycerols (TAG) was performed using thin layer chromatography using a hexane: diethyl ether: acetic acid (70:30:1; by volume) solvent system. The scraped lipid fractions were subjected to acid-catalyzed esterification by heating for 90 min at 100 °C in a boron trifluoride-methanol solution (14 %). The fatty acid methyl esters were separated by gas chromatography (Shimadzu GC2010; Shimadzu, Columbia, MD, USA) as previously described [25]. Fatty acid peaks were identified by retention times in comparison to authentic standards. Data were analyzed with Shimadzu's GC solutions software and quantified as the mean quantity of each fatty acid normalized to reflect the protein concentration of each sample.

Lipid Droplet Visualization

Excess triglycerides and cholesterol esters are often packaged and stored intracellularly in the form of lipid droplets. Human aortic endothelial cells were cultured in 4-well Permanox chamber slides in EBM-2 complete medium supplemented with albumin-bound fatty acids for 24 h. The cellular neutral lipids were stained using an oil red O staining kit as described by the manufacturer. These cells were counterstained with modified Mayer's hematoxylin for visualization using an Olympus BX40 upright microscope at 500× magnification with an oil immersion objective.

Flow Cytometric Analysis of HAEC Adhesion Molecule Expression

Treated HAEC were trypsinized, washed in PBS containing 0.5 % BSA, and resuspended in the same buffer for antibody labeling. Cells were labeled with 0.25 µg phycoerythrin (PE)-conjugated intercellular adhesion molecule-1 (ICAM-1), which is also known as CD54, for 20 min at room temperature in the dark. Subsequently, the cells were washed with PBS containing 0.5 % BSA and

resuspended in 300 μ L of the wash buffer. In order to ensure binding specificity, an isotype control was established for each data set. Data analysis was performed on a FACSCalibur flow cytometer (Becton–Dickinson, San Jose, CA, USA) equipped with a 15 mW air-cooled argon-ion laser emitting at a 488 nm wavelength. The PE signal was detected through a 585 nm band pass filter and quantified using CellQuest Software (Becton–Dickinson). Results indicate the mean fluorescent intensity of gated endothelial cells, which excluded cellular debris and particles.

Western Blot Analysis

Subconfluent HAEC were grown in six-well tissue culture-treated plates in the presence or absence of albumin-bound fatty acids in EBM-2 complete medium for 24 h under standard tissue culture conditions. Treated cells were rinsed in cold PBS and lysed on ice for 15 min in a 20 mM Tris–HCl (pH 7.4) buffer containing 137 mM NaCl, 100 mM NaF, 2 mM Na_3VO_4 , 10 % glycerol, 1 % Nonidet P-40, 2 mM PMSF, 1 μ g/ml leupeptin, 0.15 units/ml aprotinin, and 2.5 mM diisopropyl fluorophosphate. Protein content was determined using a BCA protein assay kit following centrifugation of the detergent solubilized extracts to remove insoluble matter. Proteins were electrophoretically separated in 4–12 % polyacrylamide gradient gels and transferred onto nitrocellulose membranes. Membranes were blocked for 30 min at room temperature in 10 % Roche Western Blocking reagent in Tris-buffered saline supplemented with 0.1 % Triton X-100 (TBST). Blots were probed with primary antibodies according to the manufacturer's recommendations. Secondary antibodies were peroxidase-conjugated for protein detection using an enhanced chemiluminescence (ECL) system (Amersham Pharmacia Biotechnology, Piscataway, NJ, USA). Nitrocellulose membranes were stripped in 62.5 mM Tris–HCl (pH 6.8) buffer containing 2 % SDS and 100 mM β -mercaptoethanol for 30 min at 50 °C. Stripped blots were washed six times in TBST, blocked, and reprobed with an alternative antibody.

Growth Inhibition and Cytotoxicity Assay

Determination of the influence of fatty acids on cellular growth inhibition and cytotoxicity was evaluated as previously described [20, 21]. Endothelial cells (5,000 cells/well) were plated in a 96-well flat bottom plate and maintained in EBM-2 complete medium for 6 h to permit cell adherence. A subset of established wells were utilized to determine cellular growth (X; baseline at day zero) by administering WST-1 reagent (10 μ L/well) and recording optical density readings at 450 nm following a 90-minute

incubation under standard tissue culture conditions. All other wells were replaced with EBM-2 complete medium supplemented with varying concentrations of albumin-bound fatty acids. Cell cultures were maintained for an additional 48 h at 37 °C in humidified 5 % CO_2 . Following the addition of WST-1 and 90-minute incubation, optical density values were used to calculate growth inhibition or cell loss based on the day zero baseline readings. Vehicle controls (EBM-2 complete medium supplemented with fatty acid free bovine serum albumin) determined the total growth potential (Y). Cell growth (Z) was normalized to 100 % using the formula $((Y - X) / X) \times 100$. Effects of fatty acid supplementation were ascertained by comparing to Z values. Values from 100 to zero indicated growth inhibition, whereas values less than zero indicated cell loss. Results are expressed as the means \pm standard deviations of at least four determinations.

Apoptosis Detection

Endothelial cells (1.0×10^5) were cultured in six-well plates overnight in EBM-2 complete medium. Spent media was replaced with EBM-2 complete medium supplemented with albumin-bound fatty acids and cultured under typical conditions for 24 h. Following treatments, the cells were rinsed in PBS and trypsinized from the plates. All spent medium, PBS washes, and trypsinized cells were collectively combined to ensure both adherent and non-adherent cells were harvested for analysis. Cell pellets were labeled in a solution containing Annexin V Fluorescein and propidium iodide, which was prepared as described by the manufacturer (Roche Applied Science, Indianapolis, IN). Cell suspensions were labeled in the dark at room temperature for 20 min. Analysis was performed on a FACSCalibur flow cytometer (Becton–Dickinson, San Jose, CA) equipped with a 15 mW air-cooled argon-ion laser emitting at a 488 nm wavelength. Annexin V was detected through a 530 nm band pass filter, while propidium iodide was detected through a 650 nm long pass filter. Data were quantified using CellQuest software (Becton–Dickinson). Data represent the mean \pm standard deviation of three determinations.

Statistical Analysis

Data represent the mean \pm the standard deviation of at least three determinations. Fatty acid profiles were compared between control and experimental groups using Student *t* tests. To account for multiple comparisons to a single control group, significance levels were adjusted using the Bonferroni correction, meaning differences were only considered significant when $P \leq 0.025$. For the apoptosis/necrosis data, where group variances were

similar, analysis of variance (ANOVA) was used for initial comparisons across all groups. If a significant difference was detected across all groups, then Dunnett's multiple comparison test was used to compare each experimental group to control. Group variances for the ICAM-1 expression data were not assumed to be equal, so multiple Student *t* tests for unequal variances (Welch's *t* test) were used to compare treatment groups to control. To account for the multiple comparisons to a single control group, the Bonferroni correction was used to adjust the significance levels. Here differences were only considered significant if $P \leq 0.017$. Significant differences between treatment and control groups are indicated with an asterisk in the tables.

Results

Cellular Incorporation of *Trans* Fatty Acids

Endothelial cells were supplemented for 24 h with *trans* fatty acids (50 μ M) prior to extraction and fractionation into phospholipids and triacylglycerols. Table 1a summarizes the fatty acid distribution in the EC phospholipids. Both elaidic and linoelaidic cellular levels constitute a minor component of the overall fatty acid profile in vehicle-treated cells; however, both of the TFA were readily incorporated into cellular phospholipids (40–54 % of total FA content). This resulted in a 190-fold ($P < 0.025$) and 275-fold ($P < 0.025$) enrichment of ι 18:1n-9 and ι 18:2n-6, respectively. Importantly, this incorporation coincides with noteworthy and significant ($P < 0.025$) decreases in saturated fatty acids (SFA) namely myristic acid (36 % vehicle-treated vs. 17 % TFA-treated), palmitic (32 % vehicle-treated vs. 15 % TFA-treated), +stearic (18 % vehicle-treated vs. 8 % TFA-treated), and monounsaturated fatty acid (MUFA) namely oleic acid (28 % vehicle-treated vs. 10–20 % TFA-treated) levels. The decrease in long-chain polyunsaturated fatty acids (LC-PUFA) was also significant ($P < 0.05$) but it was to a lesser extent than that of SFA and MUFA (approximately 12–25 %). The treatment of ι 18:2n-6 reduced n-3 and n-6 PUFA to approximately an equal extent, whereas effect of ι 18:1n-9 was very minimal on n-6 PUFA reduction than that of n-3 PUFA. Interestingly, the incorporation of TFA did not result in any significant increase in the total fatty acid content in the phospholipid fraction. Table 1b summarizes the fatty acid distribution in the EC triacylglycerols. The fatty acid amounts present in the TAG fraction remained relatively low (2 % of total FA) to that of the phospholipid fraction in vehicle-treated cells. Both TFA were also able to increase incorporation into TAGs by 30–40 % of total fatty acid content. This resulted in an enrichment of ι 18:1n-9 by 33-fold and ι 18:2n-6 by 60-fold. There appears to be a

small decrease (non-significant) in palmitic acid (12–17 %), but this decrease appears to be compensated by an increase in myristic acid, resulting in no overall change in LC-SFA. It therefore appears that unlike their incorporation into phospholipids, the TFA did not incorporate at the expense of other fatty acids; rather they simply accumulated, causing an increase of total FA in TAGs by 40 or 80 % on ι 18:1n-9 or ι 18:2n-6 treatment, respectively. Furthermore, TFA also enhanced some accumulation of LC-PUFA, particularly n-3 PUFA. The overall increase in FA in TAG contributes to an increase of 3–3.5 % of total cellular fatty acids.

Lipid droplet formation is indicative of an accumulation of TAGs being packaged and stored intracellularly. Figure 1 depicts representative oil red O- and hematoxylin-stained EC supplemented with varying fatty acids (50 μ M). Stearic acid-supplemented cells lacked the presence of detectable lipid droplets, which corresponded to the vehicle control cells. As indicated with arrows, lipid droplet accumulation was readily visible in oleic- and linoleic-supplemented EC. The *trans* fatty acids, elaidic and linoelaidic, did present lipid droplets; however, the abundance of these droplets was substantially less apparent than their *cis* fatty acid counterparts.

Effect of *Trans* Fatty Acid Supplementation on Pro-inflammatory Responses in EC

Adhesion molecule surface expression is indicative of the inflammatory status of EC; therefore, our laboratory quantified intercellular adhesion molecule-1 (ICAM-1; CD54) levels in fatty acid supplemented EC. Cultured EC have basal levels of ICAM-1 surface expression under standard tissue culture conditions. Endothelial cells were supplemented with various fatty acids for 24 h prior to flow cytometric analysis. Table 2 summarizes the results of the relative abundance of ICAM-1 surface expression. Our laboratory previously identified the pro-inflammatory impact of saturated fatty acids, namely stearic acid, on HAEC. *Trans* fatty acid-supplementation met or exceeded ICAM-1 expression levels in comparison to stearic acid. The highest level of ICAM-1 expression was observed with elaidic acid (50 μ M); however, it is important to note that the quantity of ICAM-1 basal expression is only a percentage of the cell's ability to respond to cytokine stimulation. *cis* fatty acid supplementation did not significantly elevate basal ICAM-1 expression in comparison to the vehicle.

Although linked to various signaling mechanisms, phosphorylation of NF- κ B has been associated with the pathway leading to ICAM-1 transcription and subsequent deployment to the plasma membrane [20, 21]. Following a 24-hour fatty acid supplementation, EC lysates were

electrophoretically separated, transferred, and probed using a phospho-specific (Ser468) antibody for NF- κ B in comparison to GAPDH loading controls. As shown in Fig. 2, EC supplemented with the TFA, elaidic and linoelaidic, demonstrated dose-dependent increases in NF- κ B phosphorylation. With the exception of only a very slight increase in the

phospho-NF- κ B levels observed following 50 μ M oleic acid supplementation, oleic and linoleic acid-supplementation did not substantially enhance the phosphorylation status of NF- κ B. As previously reported by our laboratory, stearic acid-supplemented HAEC also increased NF- κ B phosphorylation in a dose-dependent manner [20].

Fig. 1 Effect of fatty acid supplementation on the accumulation of neutral lipid storage. Human aortic endothelial cells were supplemented with 50 μM of each individual fatty acid for 24 h at 37 $^{\circ}\text{C}$ in 5 % CO_2 . As described in the methods, lipid droplets containing triacylglycerols were stained with oil red O, and nuclei were counterstained with hematoxylin for cellular definition ($\times 500$ magnification). Treatments included **a** vehicle, **b** stearic acid, **c** oleic acid, **d** elaidic acid, **e** linoleic acid and **f** linoelaidic acid. Lipid droplets are indicated by the arrows. No excess accumulation of lipid droplets was observed when HAEC were co-supplemented with both fatty acids

Effect of *Trans* Fatty Acid Supplementation on HAEC Growth Inhibition and Cytotoxicity

In Fig. 3a the effect of TFA supplementation on EC growth is compared to stearic acid. Stearic acid-induced total growth inhibition was observed at 50 μM and significant cytotoxicity occurred at concentrations greater than 75 μM . While linoelaidic acid did invoke a low degree of EC cytotoxicity at the highest concentrations, a steady dose-dependent effect on growth inhibition was observed at concentrations greater than 25 μM . Elaidic acid minimally impacted EC growth and demonstrated no indication of affecting cellular cytotoxicity. Oleic and linoleic acid, the *cis* counterparts to the TFA, did negatively influence the growth potential of the EC, especially at concentrations greater than 150 μM . Linoleic acid supplementation was more potent than oleic, resulting in cell loss at the highest concentrations.

Fig. 2 Effect of fatty acid supplementation on the phosphorylation of the transcriptional regulator of ICAM-1, NF- κ B. Human aortic endothelial cells were supplemented with varying concentrations of fatty acids for 24 h under typical tissue culture conditions. Endothelial cell lysates (15 μ g/sample) were electrophoretically separated in a 4–12 % polyacrylamide gradient gel and subsequently transferred

onto nitrocellulose membranes. Using phospho-specific antibodies to detect the activation state of the transcriptional activator, NF- κ B, the relative impact of each fatty acid was ascertained. **a** Elaidic and linoelaidic, **b** oleic and linoleic, **c** and stearic acid-supplemented cells were compared. Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) was used as the protein loading control

Effect of Fatty Acid Supplementation on HAEC Apoptosis/Necrosis

To obtain evidence to support the observations in the growth inhibition and cytotoxicity studies, EC were supplemented with fatty acids (either 75 or 100 μ M) for 24 h prior to assessing cell viability. Table 3 compares individual fatty acid treatments with a vehicle control in terms of the percentages of cells classified as viable, apoptotic, or necrotic. The TFA, elaidic and linoelaidic acid, slightly affected the overall viability of the cell population, which corresponded with elevated percentages of apoptotic and necrotic cells, particularly at the 100 μ M dose. Oleic and linoleic supplementation affected cellular viability to a lesser extent with the exception of an unexplained shift in the population dynamics following linoleic acid (75 μ M) supplementation. Stearic acid supplementation clearly demonstrated a significant decrease in cell viability with corresponding increases in apoptotic and necrotic events. This evidence reinforces the findings from the growth inhibition and cytotoxicity studies.

Discussion

Endothelial cells supplemented with either elaidic or linoelaidic fatty acids significantly altered the cellular

profile. Interestingly, these fatty acids incorporated into cellular phospholipids, mainly at the expense of myristic, palmitic, and stearic acids, without causing any net gain in total fatty acid levels. Our laboratory previously reported [20] that stearic acid also incorporated into the phospholipid fraction at the expense of palmitic acid without causing any net increase in total fatty acid content in this fraction. However, in the triacylglycerol fraction, incorporation of TFA was minimal (2–4 μ g/mg proteins) compared to phospholipids (100–150 μ g/mg protein) and did not occur at the expense of any other fatty acid. As shown previously [20], stearic acid incorporation into the TAG fraction was minimal (8 μ g/mg protein) compared to its incorporation into phospholipids (70 μ g/mg protein). In contrast to saturated and *trans* fatty acids, oleic acid, a *cis* fatty acid, incorporated substantially in both phospholipid (80 μ g/mg protein) and TAG (20 μ g/mg proteins) fractions. This data clearly demonstrates that TFA not only structurally resemble saturated fatty acids but they also incorporate into the cell in a similar fashion to that of saturated fatty acids. The fatty acid incorporation results are consistent with the formation of lipid droplets, which are comprised of TAGs and cholesterol esters. Elaidic and linoelaidic fatty acids did generate a few lipid droplets, whereas vehicle and stearic acid supplemented cells were devoid of oil red O-stained droplets. This data suggests that

Fig. 3 Effect of fatty acid supplementation on HAEC growth inhibition and cytotoxicity. Human aortic endothelial cells were supplemented with albumin-bound fatty acids at varying concentrations for 48 h at 37 °C in 5 % CO₂. Cells were administered WST-1 assay reagent, as described in the methods, to ascertain the metabolic activity. Values less than 100, but above 0, represent growth inhibition, whereas values falling below 0 indicate cell loss in comparison to the day 0 initial population. Calculations of these values are described in the methods. **a** Elaidic, linoelaidic, and stearic acids are shown, whereas **b** oleic and linoleic acids portray the *cis* counterparts to the TFA. Data represent the mean \pm the standard deviation of at least four determinations

the polyunsaturated fatty acids, oleic and linoleic, efficiently converted excess fatty acid accumulation into the neutral lipid packages, whereas TFA have a limited capacity for being incorporated into lipid droplets. This further suggests that TFA act more like saturated fatty acids.

Next we compared the functional properties of saturated and *cis/trans* unsaturated fatty acids. We have previously reported the pro-inflammatory effects of long-chain saturated fatty acids, particularly stearic acid [21]. Within this report, we demonstrated that elevated phosphorylation of NF- κ B (Ser468) corresponded with increased ICAM-1 surface expression in non-challenged endothelial cells. Both elaidic and linoelaidic acids induced phosphorylation of the transcriptional regulator, NF- κ B, consistent with stearic acid. The phosphorylation levels corresponded to

Table 3 Effect of fatty acid supplementation on endothelial cell apoptosis/necrosis

| | Apoptosis/necrosis detection (mean percentage \pm SD) | | |

^a Denotes significant differences ($P \leq 0.025$) in comparison to the vehicle control

increased non-challenged ICAM-1 surface expression. Importantly, the TFA enhanced ICAM-1 expression to levels equal to or surpassing those of stearic acid-supplemented cells. The *cis* counterparts did not appear to alter the phosphorylation status or the corresponding ICAM-1 surface expression. These results portray a pro-inflammatory endothelial cell phenotype that is consistent with our previous findings, which focused primarily on linoelaidic acid [25, 26]. Sanadgol et al. [27] reported that elaidic acid supplementation did not diminish tumor necrosis factor- α or lipopolysaccharide-induced upregulation of ICAM-1, whereas oleic acid supplementation suppressed the inflammatory response. This evidence suggests that TFA not only invoke a pro-inflammatory response, but they also assist in maintaining the activation status. Furthermore, Rezamond et al. [28] found elevated mRNA expression of pro-inflammatory markers, including interleukin-1 β and ICAM-1, in bovine mammary epithelial cells supplemented with elaidic acid. In a cross-sectional study of 730 women from the nurses' health study I cohort, TFA intake was associated with elevated plasma levels of C-reactive protein, soluble tumor necrosis factor receptor-2, E-selectin, soluble ICAM-1, and soluble VCAM-1 [29]. The authors

conclude that elevated TFA intake could lead to a chronic pro-inflammatory endothelial cell phenotype, which could progress into CHD.

Consistent with our previous reports, stearic acid-supplemented endothelial cells invoke cytotoxicity at concentrations surpassing 75 μM [20, 21]. Unlike stearic acid, elaidic and linoelaidic acids do not adhere to the same growth inhibition and cytotoxicity observations. Elaidic acid appears to be well tolerated in terms of endothelial cell growth inhibition, whereas linoelaidic acid did significantly inhibit growth at concentrations $>50 \mu\text{M}$ and limited cell loss was apparent at concentrations exceeding 150 μM . Flow cytometric determination of apoptosis and/or necrosis clearly demonstrated the negative impact of stearic acid supplementation on endothelial cell viability; moreover, premature cell loss in the stearic acid-supplemented EC likely skewed the overall percentages, thereby minimizing the negative impact. *Trans* fatty acids did slightly impact endothelial apoptosis/necrosis albeit at relatively low percentage alterations. A recent report by Qiu et al. [30] claimed that relatively high concentrations of elaidic acid induced apoptosis in HUVEC cells. This TFA-induced apoptosis involved the activation of caspases 3, 8, and 9. Zapolska-Downar et al. [31] also assessed TFA's ability to induce apoptosis in HUVEC by comparing both elaidic and linoelaidic fatty acids. They also describe a caspase-3 dependent induction of apoptosis; however, the concentrations used in this study were exceedingly high (up to 5 mM). Consistent with our observations, linoelaidic acid appeared to be potentially more detrimental than elaidic acid.

In conclusion, both elaidic and linoelaidic fatty acids incorporate into endothelial cell phospholipids, and TFA are capable of being incorporated into triacylglycerols to a limited extent. Elaidic acid-supplemented endothelial cells portrayed the most pro-inflammatory phenotype. Furthermore, in contrast to stearic acid (as shown previously) [20], elaidic acid did not negatively impact human aortic endothelial cell growth; however, cellular incorporation of TFA from industrially produced dietary sources into the vasculature could lead to a sustained inflammatory state as elaidic acid is significantly more abundant than linoelaidic in the IP-TFA. The concentration of *trans* fatty acids (5–50 μM) used in the present study were within the physiological range found in fasting 20-years-old non-Hispanic white individuals (30–103 μM) [32]. The pro-inflammatory effects observed in this in vitro study, therefore, suggest an association of dietary TFA with CHD.

Acknowledgments The authors wish to thank Ms. Elaine Bamberlin for the editorial assistance and Mr. Colin Terry for the help in the statistical analysis of the data. The work was supported by a Methodist Research Institute's summer student internship to Mr. Phillip Whitley.

Conflict of interest The authors declare that they have no conflict of interest.

***Trans* Isomers of EPA and DHA in Omega-3 Products on the European Market**

Caterina Sciotto · Svein A. Mjøs

Abstract The levels of *trans* isomers of eicosapentaenoic (EPA) acid and docosahexaenoic acid (DHA) in 77 omega-3 products on the European market have been studied. Fatty acids were analyzed as fatty acid methyl esters by gas chromatography with a flame ionization detector, using a cyanopropyl coated stationary phase. The amount of mono-*trans* EPA isomers relative to the corresponding all-*cis* isomer ranged from 0.19 to 4.5 %. The corresponding values for mono-*trans* DHA relative to the all-*cis* isomer ranged from 0.25 to 5.9 %. There was a strong correlation between the degree of isomerization of EPA and DHA, showing that DHA was 1.26 times more isomerized than EPA. Division of the samples into different product groups showed that samples with a low degree of isomerization were found in all groups, except one. This shows that a high degree of isomerization is avoidable, and also points to deodorization of the oils as the main source of *trans* isomers.

Introduction

Eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) are the two major long chain omega-3 fatty acids in most fats and oils of marine origin. They are known for their positive health effects, such as protection against cardiovascular disease [1, 2] and their critical role in brain function and neurodevelopment [2–4]. There are also claims of reduced inflammation [5, 6], as well as positive effects on psychological and cognitive function [2, 3].

Recommendations for the intake of EPA and DHA vary [2, 7, 8], and so does consumption of fish and other sources of long chain omega-3 fatty acids. But there is a general gap between the recommendations and the average intake of EPA and DHA in western diets [7, 9].

As a consequence, a large number of food supplements and fortified foods containing EPA and DHA in varying amounts are on the market. These products are typically

omega-3 rich fish oils or fish oils where EPA and DHA have been concentrated, e.g., by distilling off shorter fatty acids. Some products are also of algal origin, or contain oils from other marine sources, such as krill. Many of the products are blends of different oils, including common vegetable oils.

It has been shown in previous studies that the processing conditions commonly used for deodorization of oils may lead to the formation of *trans* isomers of EPA and DHA through thermal isomerization [10–13]. Another possible source of these *trans* isomers may be the distillation used for concentrating EPA and DHA in fish oils. Thermal isomerization does not lead to positional isomerism of the double bonds [11–13], and the number of possible *trans* isomers that can be formed is therefore equal to 2^n , where n is the number of double bonds in the molecule, i.e., $2^5 = 32$ for EPA and $2^6 = 64$ for DHA. However, under normal operating conditions, only minor amounts of isomers with more than one *trans* double bond are formed [11–13].

It was shown in [14] that *trans* isomers of EPA or DHA were present in four commercial fish oils and three products of algal origin, but no comprehensive study of the levels in products on the market has been conducted. The purpose of this study has been to evaluate the levels of EPA and DHA *trans* isomers in omega-3 products on the European market, and 77 food supplements or pharmaceutical products claiming to contain EPA and DHA were studied.

Materials and Methods

Samples

Omega-3 products claiming to contain EPA, DHA or both were purchased over the counter in pharmacies or other retail stores in Norway (25 products), Italy (7 products), Spain (13 products), Germany (12 products), UK (15 products) and France (1 product). In addition, four products were purchased over the Internet from Norwegian suppliers. The products were selected so that there would not be replicates of the same product and brand name in the study. However, it is common that products from the same manufacturer are sold under different product and brand names in different markets. It is therefore likely that some of the products in the study may come from the same process and raw material. All products were capsules, except for one of the cod liver oils, which was purchased as a bottled liquid. The products were stored refrigerated and taken out of the refrigerator the day before analysis. All products were within the shelf life when analyzed.

Analysis

Fatty acid methyl esters were prepared from 32 ± 8 mg of the products (1–2 drops, depending on viscosity) by heating at 100 °C for 5 min in 1.5 mL 0.5 N methanolic NaOH followed by heating at 100 °C after addition of 2.0 mL 12 % methanolic BF_3 . Samples were thereafter vortex mixed for 30 s after addition of 1 mL isooctane, 5 mL saturated aqueous NaCl solution was added, the samples were vortexed again and the isooctane layer was collected. The extraction with isooctane was thereafter repeated and the isooctane layer was combined with the first aliquot. The parameters were as described in AOCS Ce 1b-89 [15], except that 5 min reaction time was applied in the BF_3 step and that the saturated methyl ester 21:0 was added as internal standard. Two capsules of each product were analyzed.

The samples were analyzed using an Agilent 7890 gas chromatograph equipped with a flame ionization detector (GC-FID), a split-splitless injection port and a 7673 automatic liquid sampler (Agilent, Santa Clara, CA, USA). The chromatographic conditions were based on the methodology described in [13]. To achieve optimal resolution this reference proposes separate methods for *trans* isomers of EPA and DHA, respectively. Both methods used a BPX-70 column with $L = 60$ m, i.d. = 0.25 mm and $d_f = 0.25$ μm (SGE, Ringwood, Australia). Helium (99.999 %) was used as the carrier gas at an estimated velocity of 26 cm/s, the injector temperature was 250 °C, the detector temperature was 260 °C, and 1 μL sample was injected in the splitless mode. EPA isomers were analyzed by the following temperature program: injection was done at 60 °C, after 4 min the temperature was increased by 30 °C/min to 180 °C followed by 1 °C/min to 220 °C. DHA isomers were analyzed by injection at 60 °C, after 4 min the temperature was increased by 30 °C/min to 160 °C, followed by 1 °C/min to 220 °C. The chromatographic system was controlled by GC Chemstation B.03.02 (Agilent). Integration of chromatographic peaks, quantification and reporting were done in Chrombox C 11-09 (<http://www.chrombox.org>) running under Matlab 6.5 (Mathworks, Natick, MA, USA).

Blank samples and a reference fish oil were prepared daily to check the quality of the reagents. Chromatographic areas were corrected by empirical response factors based on the reference mixture GLC-793 (Nu-Chek Prep. Elysian, MN, USA) that was run as every 10th sample in the analytical sequence. The composition of the reference sample is given as supplementary material (Table S1). Approximately 2 ng of each FAME in the mixture was applied on the column. Response factors of compounds that were not in the reference mixture were calculated from response factors of similar compounds with respect to the

number of double bonds and carbons. The response factors for the EPA and DHA *trans* isomers were set equal to the corresponding *cis* isomers. Qualitative reference mixtures of mono-*trans* EPA and mono-*trans* DHA, prepared as described in [16], were analyzed at regular intervals. The largest peaks in these mixtures corresponded to approximately 3.5 ng on the column.

Because of the great variation of the sample composition it was necessary to analyze the samples twice to adjust the concentration to an appropriate amount for separation and quantification of the peaks. The concentration was scaled after EPA or DHA, depending on which of these that was in largest amounts. The concentration was scaled so that the largest peak corresponded to approximately 15 ng on the column.

To identify the peaks in the region around EPA and DHA, a subset of the samples were also analyzed by gas chromatography–mass spectrometry (GC–MS) at chromatographic conditions described as Program 1 in [17]. The GC–MS system was a HP-5890 GC connected to a HP-5972 mass spectrometer (Agilent). Both short scans (m/z 50–110) and full scans (m/z 50–438) were applied. The peaks were identified in Chrombox Q 11-08 (<http://www.chrombox.org>) using libraries of mass spectra and ECL values downloaded from [18], and by interpretation rules summarized in [19].

Principal component analysis of the fatty acid profiles were performed using Unscrambler 9.8. The variables were standardized prior to the calculation (mean centered and divided by the standard deviation). Other calculations were performed in Microsoft Excel 2002 for Windows.

Results

Chromatographic Resolution

Chromatographic patterns of the region around EPA and DHA of the mono-*trans* reference mixtures and three selected products are shown in Fig. 1. The three products shown were the products with a degree of isomerization closest to the mean value of typical “18/12 oil”, a “33/23 concentrate” and the seal and cod liver oils, which are similar in composition. The three products shown are therefore significantly isomerized, but they are not extreme. See Sect. “Product Groups” for further details.

The resolution shown in Fig. 1 shows the same chromatographic pattern as presented in [16] and [13], and the naming of the mono-*trans* isomers (E1a–d and D1a–e) are according to the same references. The patterns presented in these papers show that the five *trans* isomers of EPA elute in three peaks, and that the six *trans* isomers of DHA elute in five peaks. In these works, the analyses were performed by GC–MS.

As can be seen from the chromatograms, there is a significant overlap between some of the *trans* isomers and other FAME, particularly in the case of EPA. The peaks labelled A–I in the figure has been completely or partially identified by GC–MS using conditions described in [16, 19] and MS libraries and ECL-patterns presented at [18]. Peak A was partially identified as a polyunsaturated FAME, but the quality of the mass spectrum was not sufficient to elucidate further details. Minor amounts of n-4 polyunsaturated fatty acids have previously been reported in marine lipids [17, 19, 20], and a possible structure is 20:4n-4 since it elutes immediately before 20:4n-3, but a non-methylene interrupted 20:4 has also been reported in the same region [18]. Peak B is a mixture of the E1a isomer with 20:4n-3 and 22:1n-11. Both these are common in marine lipids. Peak C is 22:1n-9, which is also a common fatty acid and present in the reference mixture. Peak D was identified as a polyunsaturated FAME, but the quality of the mass spectrum was not sufficient to elucidate further details. A possible structure is 20:4n-1. This fatty acid has previously been reported in marine lipids [17, 19, 21]. Peak E was identified as a monounsaturated FAME. The structure was assigned to the 22:1n-7 based on the distance to the n-9 isomer and ECL values reported at [18]. Peaks F and G are the all-*cis* EPA and all-*cis* DPA (22:5n-3) FAME. Peak H was identified by mass spectrometry as a polyunsaturated FAME. This peak appears in samples that has relatively large amounts of all-*cis* DPA and also a significant degree of isomerization. It has previously been reported as *trans* isomers of DPA corresponding to the E1c/d peak from EPA [13]. Peak I is all-*cis* DHA.

It has been shown that the apparent polarity of cyanopropyl columns increase with temperature [22]. The overlap between the 22:1 monoenes and the *trans* isomers of EPA can therefore be solved by using higher temperature gradients or lower carrier gas velocity, which will increase the elution temperature of the compounds. However, it has also been shown that the chromatographic selectivity on cyanopropyl phases depends basically on the number of *cis* double bonds in the molecule [17]. The overlaps between the 20:4 isomers and mono-*trans* EPA is therefore more difficult to resolve since the molecules have the same number of carbons and *cis* double bonds. Increasing the temperatures to move the EPA isomers away from the 22:1 isomers will lead to a general decrease in separation efficiency and move all-*cis* EPA closer to the E1c/d peak, because all-*cis* EPA have more *cis* double bonds.

Trans isomers of EPA and DHA have previously been separated on BPX-70 [13, 16], SP-2560 [16], CP-Sil 88 [11, 12, 14] and BP-20 [23] capillary columns. None of the previous works has shown that it is possible to separate all the *trans* isomers from possible interferents in a broad range of samples. However, it has been shown in previous

Fig. 1 Chromatographic patterns around EPA and DHA of (a) “18/12 oil”, b “33/23 concentrate”, c seal oil and d the qualitative reference mixtures of mono-*trans* EPA and mono-*trans* DHA. See text in “Chromatographic Resolution” for explanation of the identities of peaks A to I

works that the major *trans* EPA peak E1c/d and the two last *trans* DHA peaks, D1d and D1e, can be expected to be free of interferences [13, 16]. Quantification in this work is therefore based on these peaks.

Quantification and Quality Criteria

It should be emphasized that the chromatographic conditions in the study were optimized for quantification of mono-*trans* EPA and mono-*trans* DHA isomers. Other *trans* fatty acids may be present in low amounts in the products, either as a result of thermal isomerization in fish oil, or because some of the products in the study are blends with vegetable oils, which often contain *trans* isomers of C18 fatty acids. One of the products in the study also had a chromatographic pattern that indicated presence of hydrogenated vegetable oil. Minor amounts of di-*trans* EPA and di-*trans* DHA may also be formed during refining, but amounts are insignificant compared to mono-*trans* isomers [13]. Other *trans* fatty acids than mono-*trans* isomers of EPA and DHA have not been quantified in this study. The term total *trans* in this paper therefore refers to the sum of quantified EPA and DHA mono-*trans* isomers. *Trans* EPA and *trans* DHA refer to the estimated sum of mono-*trans* isomers. For simplicity, *cis* EPA/DHA is used to refer to the naturally occurring all-*cis* isomers.

Because recommendations of daily intake given on packages of omega-3 products are usually adjusted after the content of EPA and DHA the results are reported as percent *trans* isomers relative to the *cis* analog. These

values are denoted $\text{trans EPA}_{\%cis}$ and $\text{trans DHA}_{\%cis}$ for EPA and DHA, respectively. Total content of EPA and DHA *trans* isomers are reported as percent relative to the total fatty acid content and denoted total $\text{trans}_{\%FA}$.

As shown in previous works, three of the mono-*trans* peaks can be expected to be free of interferences and therefore suitable for quantification of trace amounts [13, 16]. This is the largest *trans* EPA peak, eluting after the *cis* isomer (E1c/d), and the two largest *trans* DHA peaks eluting after the *cis* DHA peak (D1d and e). In [13] it was shown that the largest *trans* EPA peak contained approximately 77.4 % of the *trans* EPA isomers, and that the two largest *trans* DHA peaks respectively contained 28.5 and 37.4 % of the *trans* DHA isomers. It was also shown that with a moderate degree of isomerization, these relationships were quite constant. The sums of *trans* EPA were therefore estimated by multiplying the amounts calculated from the last *trans* EPA peak by 1.29 and the sums of *trans* DHA were estimated by multiplying the amounts calculated from two last *trans* DHA peaks with 1.52. These values were thereafter divided by the amounts of the corresponding all *cis* isomers and multiplied by 100 % to get the mass percent *trans* isomers relative to the *cis* isomers ($\text{trans EPA}_{\%cis}$ and $\text{trans DHA}_{\%cis}$). Since the quantification is based on empirically derived correction factors the amounts of all the *trans* peaks relative to the all-*cis* isomers are reported as supplementary material (Tables S2 and S3).

The criterion for the acceptance of the results was that the percentage of *trans* isomers relative to the *cis* analogs should not differ by more than 20 % in the two replicates.

For one of the samples it was not possible to establish acceptable values for the EPA isomers. This was a sample with almost zero *cis* EPA. Results for EPA are therefore reported for 76 samples, compared to 77 samples for DHA.

Degree of Isomerization

The term degree of isomerization (DI) has been used in previous studies of thermal isomerization of polyunsaturated fatty acids as a measure of the fraction or percentage of the original *cis* isomers that have been isomerized [13, 24–27]. The DI of fatty acid *x*, expressed as a percentage, is calculated according to Eq. 1 below:

$$DI_{\%(x)} = 100 \frac{m_{(x)trans}}{m_{(x)cis} + m_{(x)trans}} = 100 \frac{trans\ x_{\%cis}}{100 + trans\ x_{\%cis}} \quad (1)$$

where *m* is the mass of *trans* isomers relative to the corresponding *cis* isomer. As long as the $DI_{\%}$ is low, the value will be close to $trans\ x_{\%cis}$.

The DI of DHA is plotted against the DI of EPA in Fig. 2. As can be expected if the *trans* isomers are formed by the same process, there is a strong correlation between the DI values. The slope of the regression line is 1.26, meaning that DHA in the studied products is 26 % more isomerized than EPA. The isomerization mechanisms of polyunsaturated fatty acids are not fully understood, but studies on the isomer formation of 18:3 acids [25–29], EPA [12–14] and DHA [12–14] have shown that double bonds in different positions isomerize to a different degree. Comparisons of the reaction rates of 18:2 and 18:3 acids [24, 27, 29], as well as EPA and DHA [13, 14] have shown

Fig. 2 Degree of isomerization of DHA versus degree of isomerization of EPA

that reaction rates tend to increase more than the number of double bonds, and that the number of methylene-groups between methylene-interrupted double bonds may be of importance. The relationship 1.26 corresponds well with the ratio of double bond enclosed methylene groups, which is 5/4 for DHA/EPA. However, the slope corresponds less well with the results in [13], which predicts that DHA isomerize 1.6 times faster than EPA. However, these predictions were partially based on experimental conditions that gave extreme DI values compared to those we see in products on the market. Fournier et al. [14] studied four commercial fish oils and found DI_{DHA} over DI_{EPA} varying from 1.26 to 1.53, which is more in accordance with what we observed in this study.

Distributions

The distributions of % *trans* EPA and % *trans* DHA relative to the corresponding *cis* isomers and total *trans* isomers relative to sum fatty acids are shown in Fig. 3, and the values are far from being normally distributed.

$Trans\ EPA_{\%cis}$ ranged from 0.19 to 4.5 % and $trans\ DHA_{\%cis}$ ranged from 0.25 to 5.9 %. The median values were slightly below 1 % for both distributions, meaning that more than half of the products has less than 1 % *trans* isomers relative to the *cis* analogs. But there are also a significant number of samples with severe isomerization. The values for total *trans* relative to total fatty acids show a similar distribution. However, because of the large variation in the content of EPA and DHA in the samples, it is emphasized that samples that are high in $trans\ EPA_{\%cis}/DHA_{\%cis}$ are not necessarily the same samples that are high in total *trans* relative to total FA. In the following discussion, samples within the first quartile of the distribution (lowest 25 %) will be denoted low *trans* and samples in the third quartile (highest 25 %) will be denoted high *trans* (See Fig. 3 for values).

Product Groups

Based on the product labelling, the amount of EPA and DHA in the products (Fig. 4), and principal component analysis of the complete fatty acid profiles, the products were assigned to different product groups. Figure 4 shows four dense groups. One of the groups with 15 objects consists of typical South American “18/12 oils” containing approximately 18 % EPA and 12 % DHA. Three products in the study was labelled salmon oil, but it was not possible to distinguish these products from the 18/12 oils by the principal component analysis of the fatty acid profiles. These were therefore also assigned to the 18/12 oils. Two other dense groups were formed by the cod liver oils (6 objects) and the seal oils (4 objects).

Fig. 3 Distribution and statistics of (a) *trans* EPA isomers relative to *cis* EPA, (b) *trans* DHA isomers relative to *cis* DHA, and (c) sum of *trans* EPA and *trans* DHA isomers relative to total fatty acids

The largest group (25 objects) consists of products with approximately 33 % EPA and 23 % DHA. They are therefore labelled as “33/23 concentrates”. These had

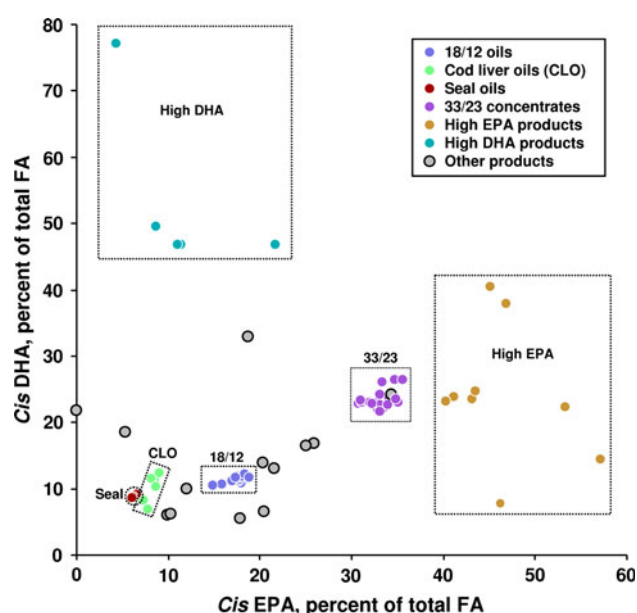

Fig. 4 Weight percent of *cis* EPA and *cis* DHA relative to total fatty acids in the samples

approximately the same EPA/DHA relationships as the 18/12 oils and low levels of short fatty acids, indicating that they are made by distilling off the shorter fatty acids from 18/12 oils.

Products with more than 40 % EPA (9 objects) or more than 40 % DHA (5 objects) were assigned to “high EPA products” and “high DHA products”, respectively. One of the products in the high EPA group also had DHA levels slightly above 40 %. Both these groups had a high variation in the fatty acid profiles, indicating that they are made from different raw materials and by different processes.

Some products (13 objects) could not be assigned to any of these groups based on the fatty acid profile. Inspection of the labelling of these products showed that they were either blends of different marine oils or blends of marine oils with vegetable oils.

Statistics for the different groups are given in Table 1. One of the product groups showed a particularly high degree of isomerization. All four seal oil products were in the high *trans* EPA and high *trans* DHA category, and four of the five most isomerized samples in the study were seal oils. The average *trans* EPA and *trans* DHA levels were 4.0 and 4.8, respectively. However, because the amounts of EPA and DHA in seal oils are rather low compared to the other products in the study, the amount of *trans* isomers relative to total fatty acids were moderate. All seal oil products in the study were purchased on the Norwegian market.

For the other groups there were no trends. There were large variations in the degree of isomerization within each group, and all groups except the seal oils contained objects

with a high degree of isomerization as well as objects with a low degree of isomerization.

Discussion

The strong correlation between DI of EPA and DHA in Fig. 2 indicates that the quantified peaks are free of significant chromatographic interferences. The correlation also indicates that *trans* isomers of EPA and DHA are formed by the same process.

EPA and DHA isomerize rapidly compared to linolenic (18:3n-3) and oleic acids (18:2n-6), of which there have been reports showing significant amounts of *trans* isomers in products on the market [25, 30, 31]. The distributions in Fig. 3 and the number of samples with a DI below 1 % indicates that the majority of manufacturers have focus on the degree of isomerization and are careful when refining the oils, but there are quite a large number of exceptions.

The fact that samples with low *trans* EPA and low *trans* DHA were found in all product groups except the seal oils, shows that products with a large DI can be avoided. The large number of samples with low *trans* EPA and *trans* DHA in the concentrates also show that formation of *trans*

isomers in the distillation process, which requires a high temperature in a short period, is probably insignificant compared to deodorization of the oils. The percentage of samples with low *trans* EPA and low *trans* DHA was higher in the “33/23 concentrates” and “high EPA concentrates” than in the “18/12 oils”.

There is limited information on the biological effects of the *trans* isomers of EPA and DHA. The majority of research on *trans* fatty acids has been carried out on *trans* isomers of C18 fatty acids, and in particular on isomers of 18:1 (oleic acid). Considering the great difference in function of the *cis* analogs, *trans* isomers of EPA and DHA should not be expected to have similar effects as the *trans* C18 fatty acids. Taking into consideration that very small differences in structure and geometry of molecules often have large effects in toxicological studies, the five *trans* EPA isomers and the six *trans* DHA isomers may also differ from each other in function. *Trans* EPA and DHA isomers should therefore be regarded as 11 chemical compounds for which there is limited knowledge about effects. There is some information on biological effects available in the scientific literature, mostly on EPA isomers. *Trans* EPA isomers are elongated and desaturated into *trans* 22:5 and 24:5 fatty acids, and *trans* isomers of

EPA behave differently than *cis* EPA in the eicosanoid synthesis [32]. It has also been shown that *trans* EPA and *trans* DHA have different effects than their *cis* analogs on platelet aggregation [33, 34]. *Trans* isomers of EPA and DHA has been detected in human platelets [35] and in liver lipids of rats [36], possibly as result of intake of 18:3n-3 (alpha linolenic acid) that is elongated and desaturated in the body [35, 36]. Intake of isomerized 18:3n-3 has also led to incorporation of *trans* DHA isomers in the retina and cerebral phospholipids in rats [37, 38]. In this respect it should be emphasized that the *trans* isomers of EPA and DHA that result from metabolism of isomerized 18:3n-3 are basically the isomers with *trans* geometry in the n-3 position (*trans*-17 EPA and *trans*-19 DHA), which are not among the major *trans* isomers formed from heat induced isomerization of EPA and DHA [13].

Currently, we do not have the necessary knowledge to assess whether the levels seen in this study pose any negative effects on human health. There is therefore a need for further studies of the biological effects of *trans* isomers of EPA and DHA. In the meantime there may be good reasons for authorities, consumers and manufacturers to pay attention to the levels of these isomers in the omega-3 products and foods fortified with such products.

Conclusions

The content of mono-*trans* EPA relative to the *cis* isomer (*trans* EPA_{%cis}) varied from 0.19 to 4.5 % in the studied products, with a mean value of 1.31 % and a median value of 0.92 %. Corresponding values for DHA (*trans* DHA_{%cis}) were 0.25, 5.9, 1.61 and 0.99 %. The fact that samples with low *trans* EPA and low *trans* DHA were found in all product groups, except the seal oils, shows that products with large degree of isomerization can be avoided. The distribution also indicates that the process of concentrating EPA and DHA by distillation is not a significant source of *trans* isomers compared to the deodorization of the crude oils. There is currently not enough information about the biological effects of the isomers to assess whether the levels found in this study can have any significant effects on consumer health.

Abstract Mucositis affects about 40 % of patients undergoing chemotherapy. Short chain fatty acids (SCFA), mainly butyrate, are claimed to improve mucosal integrity, reduce intestinal permeability and act as anti-inflammatory agents for the colon mucosa. We evaluated the effects of oral administration of SCFA or butyrate in the 5FU-induced mucositis. Mice received water, SCFA or butyrate during all experiment (10 days) and a single dose of 5FU (200 mg/kg) 3 days before euthanasia. We evaluated inflammatory and histological score by morphometry, and

by activity of enzymes specific to neutrophil, eosinophil and macrophage and TLR-4, TNF-alpha and IL6 expressions. Intestinal permeability and tight junction protein ZO-1 expression were evaluated. Mice from the 5FU (5-Fluorouracil) group presented weight loss, ulcerations and inflammatory infiltration of neutrophils and eosinophils, increased expression of IL6 and TNF-alpha and increased intestinal permeability. SCFA minimized intestinal damage, reduced ulcerations without affecting intestinal permeability. Butyrate alone was more efficient at improving those parameters than in SCFA solution and also reduced intestinal permeability. The expression of pro-inflammatory cytokines and ZO-1 tended to be higher in the SCFA supplemented but not in the butyrate supplemented group. We showed the beneficial effects of butyrate on intestinal mucositis and its promising function as an adjuvant in the treatment of diseases not only of the colon, but also of the small intestine.

Introduction

Short-chain fatty acids (SCFA) mainly acetate, propionate and butyrate are produced by bacterial fermentation, particularly of dietary fiber and carbohydrate in the large intestine. They are readily absorbed and are metabolized in the liver, producing energy. Butyrate, the 4-carbon fatty acid, has been tested as one of the therapeutic options for colon inflammatory diseases but was not previously tested for small intestine conditions, such as mucositis. Several in-vitro and in-vivo studies have shown that butyrate stimulates cell proliferation, inhibits inflammatory mediator production, reduces intestinal permeability and induces apoptosis in colon cancer cells [11, 19, 22, 28]. Moreover, SCFA and butyrate enemas have been considered in the therapy of ulcerative colitis [10, 15, 28].

Mucositis secondary to 5FU chemotherapy is related to alterations in intestinal permeability, causing bacterial translocation and changes in the intestinal immune status. Gut barrier disruption could be related to reduction of cell proliferation or an increase in apoptosis, both influenced by the presence of butyrate in the intracellular milieu. Intestinal paracellular permeability is regulated by the tight junctions [26] which consist of junctional protein complexes located in the apical portion of enterocytes and formed by transmembrane as well as peripheral membrane proteins such as occludin, claudin-1 and zonula occludens (ZO)-1.

Our group has previously shown the beneficial effect of a solution of SCFA (acetate, propionate and butyrate) in the clinical manifestations of ARA-C induced mucositis in mice [20]. In that study, the mechanism of such an action and the specific fatty acid responsible for this effect was not investigated. Due to its metabolic relevance on cell metabolism butyrate is the more promising candidate for such an effect.

Considering the significant clinical impact of mucositis and the beneficial effects of the SCFA solution on the small intestinal mucosa, we aimed to characterize the effects of oral administration of either SCFA or butyrate solutions on

the amelioration of intestinal mucosa after 5-fluorouracil (5FU) administration.

Materials and Methods

Four-week-old female Swiss mice from animal facility of the Federal University of Minas Gerais (Brazil) received water, SCFA or butyrate solutions (replacing drink water) ad libitum for 10 days Table 1. On the 7th day, animals were injected intraperitoneally with a single dose of 5-fluorouracil (5FU, 200 mg/kg, Eurofarma®, Brazil) or PBS. The SCFA solution was prepared according to Ramos et al. [20] and contained 35 mM of acetate, 15 mM of propionate, and 9 mM of butyrate (Sigma-Aldrich, USA). The butyrate solution had a concentration of 9 mM. The pH of all solutions was adjusted to 7.4 by adding sodium hydroxide (50 %).

The animals were subdivided into 6 groups: 1, control group ($n = 12$): no mucositis induction and receiving water; 2, 5FU group: with mucositis and receiving water; 3, SCFA group ($n = 4$): no mucositis induction and receiving SCFA solution; 4, 5FU + SCFA group ($n = 18$): with mucositis and receiving SCFA solution, 5, Butyrate group ($n = 18$): no mucositis induction and receiving butyrate solution and 6, 5FU + butyrate group ($n = 18$): with mucositis and receiving butyrate solution.

On the 10th experimental day, all animals were anesthetized and euthanized for blood and organ collection. Body weight, liquid intake and food intake were measured on the 1st and 10th experimental days. The energy intake was calculated, taking into consideration calories from food and solutions. The protocol was approved by the Animal Care Committee of Universidade Federal de Minas Gerais (UFMG), CETEA # 46/2008.

Histological Analysis

The small intestine and colon were removed from the pylorus to the ileocecal valve and from the cecum to the rectum, respectively. The organs were washed, gently perfused with

Table 1 Experimental groups of Swiss mice receiving water or experimental solutions and chow diet during 10 days

| Group | Liquid intake | Treatment (single dose) |
|----------------|--|-------------------------|
| Control | Water | PBS ^a |
| SCFA | C ₂ (35 mM) + C ₃ (15 mM) + C ₄ (9 mM) ^b | PBS |
| Butyrate | Butyrate (9 mM) | PBS |
| 5FU | Water | 5FU (200 mg/kg) |
| 5FU + SCFA | C ₂ (35 mM) + C ₃ (15 mM) + C ₄ (9 mM) | 5FU (200 mg/kg) |
| 5FU + Butyrate | Butyrate (9 mM) | 5FU (200 mg/kg) |

^a PBS or 5-fluorouracil (5FU) were intraperitoneally administered on the 7th experimental day. The pH of all solutions was 7.4 ± 0.2

^b C₂, acetate; C₃, propionate; C₄, butyrate

PBS and measured with an inextensible millimeter ruler. The intestine was divided into the duodenum, jejunum and ileum and then fixed in paraformaldehyde (4 %) for 15 min. The segments were opened along their longitudinal axes, fixed in Bouin's solution for 6 h, embedded in paraffin and cut into 5 μ m thick sections before being stained with hematoxylin-eosin (H&E). Images were obtained using a JVC TK-1270/RGB microcamera and the KS300 software built into a Kontron Eletronick/Carl Zeiss image analyzer. Ten fields from H&E sections were randomly chosen for villi height measurement.

Alterations of the mucosal architecture (general structure, cell distribution, mucosa and submucosa aspect), ulcerations, inflammation, villus height and inflammatory infiltration were used to determine the histological score. The samples were coded and then scored by a trained pathologist. The score ranged from zero (no alteration) to 3 (severe alteration) according to Soares et al. [24]. The results are presented as the sum of the score obtained for each parameter.

Neutrophil, Macrophage and Eosinophil infiltrations were evaluated by analyzing the enzyme activity of myeloperoxidase (MPO), *N*-acetylglucosaminidase (NAG) and eosinophil peroxidase (EPO), respectively. Samples were homogenized and centrifuged, and precipitates were used for quantification of enzyme activities as previously described [28]. Briefly, precipitates were dissolved in HETAB 0.5 % (Sigma-Aldrich®, USA) in phosphate buffer and centrifuged.

For EPO quantification, 75 μ L of supernatant was added to 75 μ L of OPD (Sigma-Aldrich®, USA), diluted in Tris-HCl and H₂O₂ and incubated at 37 °C for 30 min. The reaction was stopped by adding 50 μ L H₂SO₄ before being read at wavelength 492 nm in a microplate spectrophotometer (TermoPlate, Brazil).

For MPO quantification, 25 μ L of supernatant was added to 25 μ L of TMB in DMSO (Sigma-Aldrich®, USA). After addition of 100 μ L H₂O₂, the solution was incubated at 37 °C for 5 min. The reaction was stopped by adding H₂SO₄ before being read at 450 nm in a microplate spectrophotometer (TermoPlate, Brazil).

For NAG quantification, precipitates were dissolved in 0.1 % Triton X-100 (Sigma-Aldrich®, USA) and centrifuged before the supernatant was added to *p*-nitrophenyl-*N*-acetyl- β -D-glucosamine solution in citrate/phosphate. After incubation, the reaction was stopped by the addition of glycine buffer and read at 400 nm in a microplate spectrophotometer (TermoPlate, Brazil). Results were expressed in arbitrary units (based on absorbance) by 100 mg of tissue.

Study of Intestinal Permeability

We studied intestinal permeability using ^{99m}Tc diethylenetriaminepentaacetic acid (DTPA). Because DTPA is not

absorbed by the healthy small intestine, its presence in the blood is proportional to the increase in the damage of intestinal paracellular permeability. Animals were gavaged with 0.1 mL of DTPA labeled with 3.7 MBq ^{99m}technetium in the form of sodium pertechnetate (Na^{99m}TcO₄), obtained by a ⁹⁹molybdenum/^{99m}technetium generator (IPEN/CNEMA, São Paulo, Brazil) [7]. Four hours after gavage, animals were anesthetized and exsanguinated by the axillary plexus. The radioactivity of the standard dose and blood samples was determined in an automatic pit scintillator (ANSR, Abbott®, USA), and the percentage of recovered dose in each animal was calculated as follows: radioactivity of blood/radioactivity of standard dose \times 100. The average of the control group values was used as a reference. The results were presented as the increase seen in experimental groups over the control group (expressed as a percent).

RT-PCR

The total RNA from the ileum was extracted using the TRIzol® reagent according to the manufacturer's protocol. The reverse transcription was performed using 2 μ g of the total RNA, 200 U of the reverse transcriptase, 2.5 μ L of the 5 \times RT buffer, 1.8 μ L of the 10 mM dNTPs, 0.2 μ L of the 10,000 U/mL RNasin, and 1.0 μ L of the 50 μ M oligo dT. The temperature settings for this reaction were 70 °C for 5 min, on ice for 2 min, 42 °C for 60 min, 70 °C for 15 min and 4 °C for the final step. The resulting cDNA was used for real-time PCR as described below. The specific primers were designed using the Primer Express software and synthesized by IDT. Real time PCR was carried out on a StepOne sequence detection system (Applied Biosystems) using the Power SYBR Green PCR Master Mix (Applied Biosystems). The dissociation curve indicated that only one product was obtained in each reaction. The relative levels of gene expression were determined using the $\Delta\Delta$ Cycle threshold method as described by the manufacturer, in which data for each sample is normalized to the β -actin expression. The PCR results were analyzed with the SDS 2.1 software (Applied Biosystems), and the amount of mRNA of each gene of interest was normalized to the amount of the murine β -actin gene. mRNA expression levels were calculated as the fold difference relative to the housekeeping gene: relative expression = $2^{-(CT[\text{target gene}] - CT[\beta\text{-actin-1}])}$.

The sequences of the primers used are as follows:

TNF α : 5'CGTCGTAGCAAACCAAG3' and 5'GAGATAGCAAATCGGCTGACG3'

IL6: 5'ACAACCACGGCCTTCCTACTT-3' and 5'CA CGATTTCCAGAGAACATGTG3'

TLR4: 5'TGACAGGAAACCCTATCCAGAGTT3' and 5'TCTCCACAGCCACCAGATTCT3'

ZO-1: 5'CCAGCTTATGAAAGGGTTGTTC3' and 5'TCCTCTCTTGCCAACCTTTTCTC3'

β -actin: 5'CTGCCTGACCAAGTC3' and 5'CAAGA AGGAAGGCTGGAAAGG A3'

Statistical Analysis

Statistical analysis was performed using the Graph Pad Prism 7.0[®] software (San Diego CA). The results were tested for outliers (Grubbs' test) and normality using the Kolmogorov–Smirnov test. The one-way ANOVA and the Newman–Keuls multiple comparison post-test were used for all parameters except for architecture alteration and villus height (non-parametric distribution), which were instead analyzed by the Kruskal–Wallis and Dunn's post-test. To compare gene expression of a specific group with the control group, an unpaired *t* test or a Mann–Whitney test was used. A significant difference was defined as $p \leq 0.05$.

Results

Initially we compared the effect of the three control groups (control, SCFA and butyrate groups) on weight gain and intestinal morphology. The results showed that the three groups presented the same weight evolution and intestinal

mucosa aspect (data not shown), demonstrating that SCFA and butyrate administrations do not interfere with intestinal mucosa integrity. For this reason, we omitted data from SCFA and butyrate control groups, presenting only the results of control mice (without SCFA or butyrate supplementation).

Energy and Hydric Intake and Ponderal Evolution

Total liquid intake was similar among all experimental groups, although food intake was reduced in the 5FU group compared to the control group (Fig. 1a, b). Yet, as expected, animals from the 5FU group lost weight. However, animals receiving the SCFA solution lost less weight, and those treated with butyrate did not lose any (Fig. 1c), suggesting that these solutions, mainly butyrate solution, attenuate aggression induced by 5FU. Intestinal length, one of the mucositis characteristics, was reduced in the 5FU group and presented an intermediated level after SCFA and butyrate supplementation (Fig. 1d).

Histological Analyses

Histological analyses of the 5FU group showed the mucositis picture with tissue damage, a reduction in villus height, the presence of inflammatory cells and ulcerations all along the small intestine, which was more

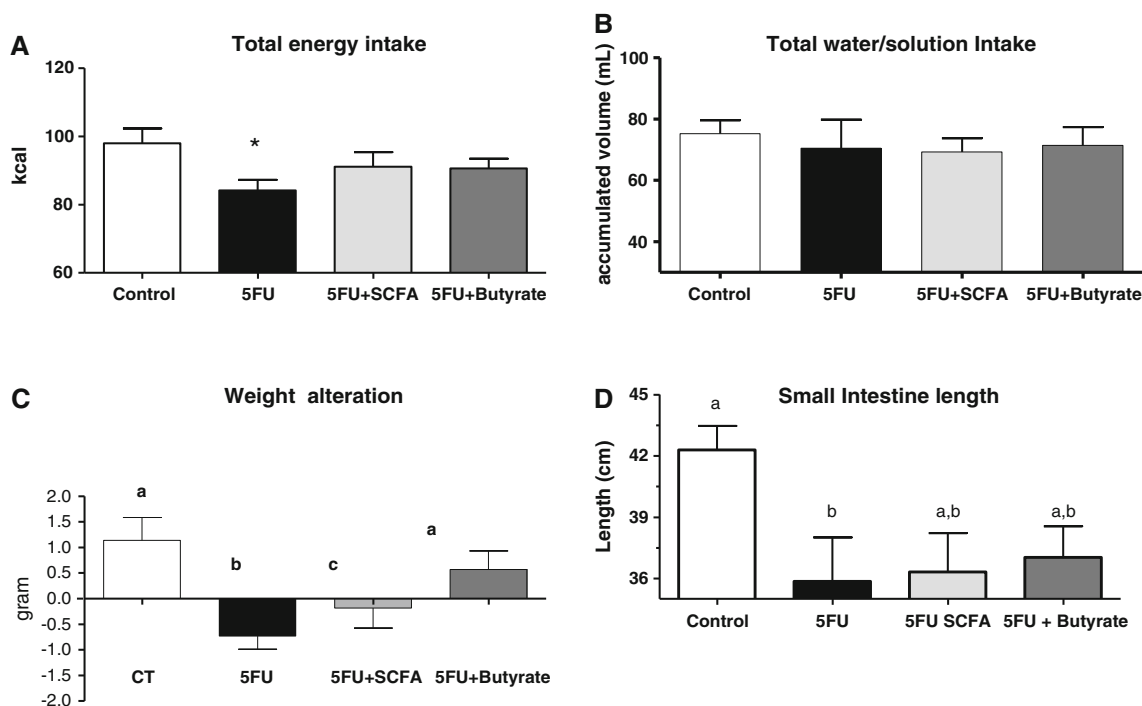

Fig. 1 Energy (a) and liquid (b) intake, weight variation (c) and intestinal length (d) of control mice and mice treated with 5FU (IP) and receiving water (5FU group), SCFA (5FU + SCFA group) or

butyrate (5FU + butyrate group) for 10 days. $n = 15$ – 18 /group. Bars represent average and vertical lines represent standard error. Different letters indicate a statistical difference ($p < 0.05$)

intense in the ileal segment (Fig. 2a). On the other hand, animals receiving SCFA or butyrate solutions presented less intense tissue damage, preservation of villi length in all segments of the small intestine and a lack of mucosa ulceration (Fig. 2a). These results of histological analyses

confirm the more effective protection of butyrate compared to SCFA. Colon histology did not reveal any inflammation (data not shown), reinforcing the fact that the tissue damage driven by 5FU is restricted to the small intestine.

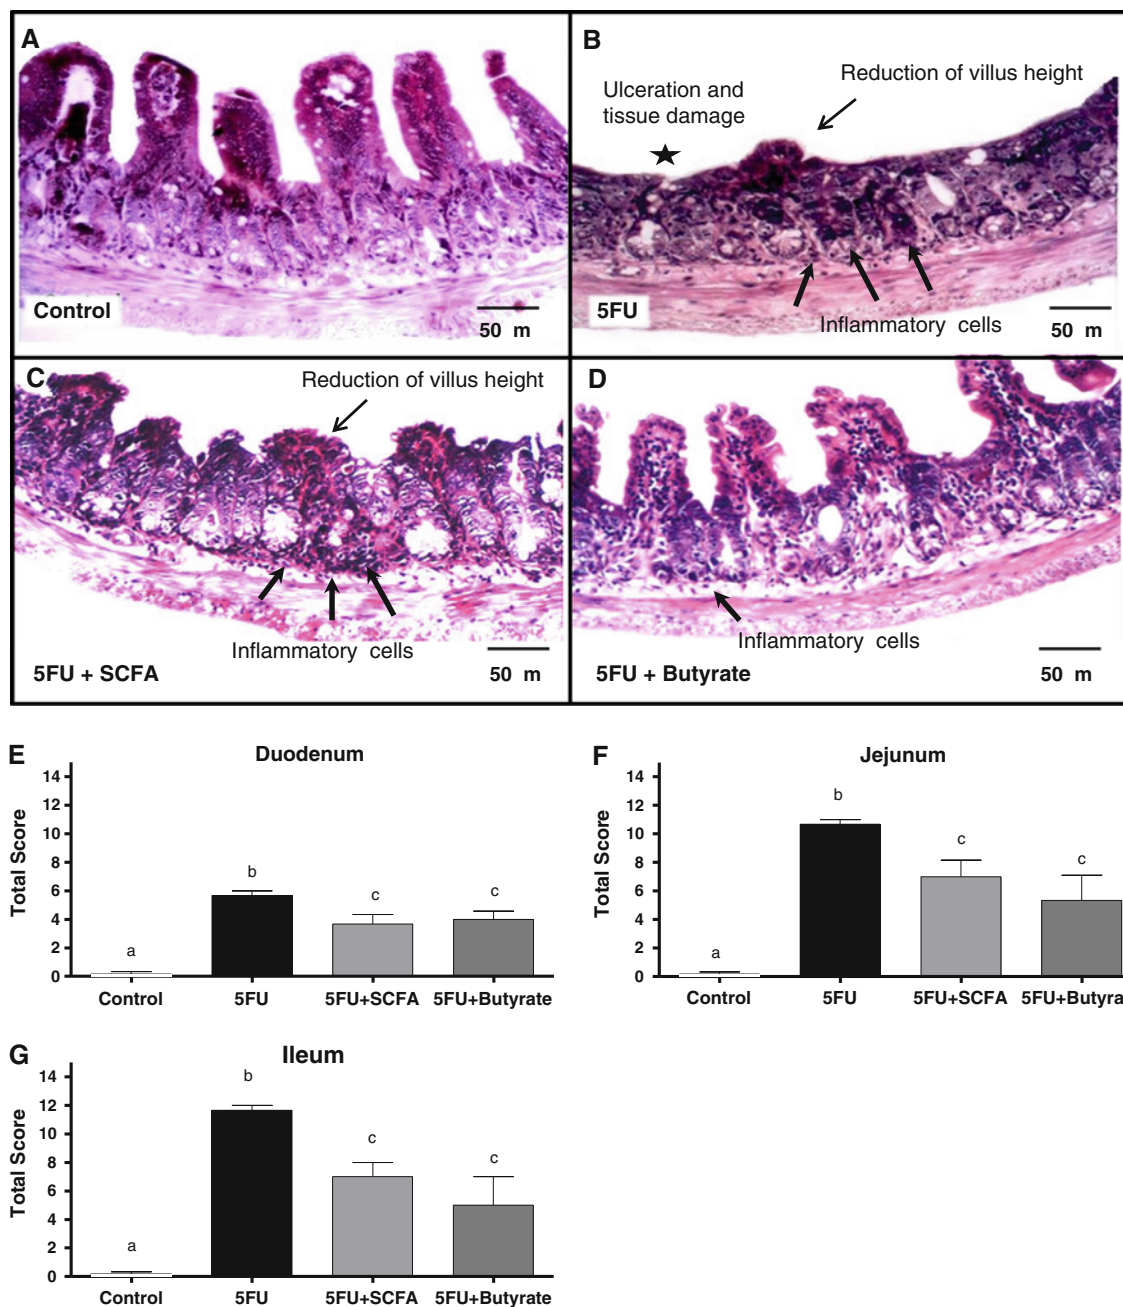

Fig. 2 (Refer to the on-line version for this figure in color) Morphology of the ileum of **a** control mice and mice treated with 5FU (IP) and receiving **b** water, **c** SCFA solution or **d** butyrate solution replacing water for 10 days. In 5FU group: tissue damage with loss of villi, presence of inflammatory cells and ulceration. 5FU + SCFA group: reduction of tissue damage with relative preservation of mucosa villi length and architecture. Inflammatory cells are still seen in mucosa and submucosa. 5FU + butyrate group:

improvement of general architecture and villus height. Inflammatory infiltration (*arrow heads*) is still present in mucosa and submucosa. Histological scores of duodenum (**e**), jejunum (**f**) and ileum (**g**) of control, 5FU, 5FU + SCFA or 5FU + butyrate groups. $n = 6$ per group. In **e**, **f** and **g** the results are the sum of the score obtained for each parameter. Bars represent average and vertical lines represent the standard error. Different letters indicate a statistical difference ($p < 0.05$)

Histological Score

Mucosa improvement was confirmed by the worse histological score for 5FU-treated animals compared to the control animals (Fig. 2b–d). When each intestinal segment was analyzed separately, the duodenum was moderately affected by 5FU treatment, while the inflammation score was intense for both the jejunum and ileum of mice from the 5FU group. Nonetheless, after SCFA and butyrate treatment, the histological score was reduced in all intestinal segments (Fig. 2b, c).

Next, we individually analyzed the four parameters used for the histological score. Mucosa ulceration and general architecture as well as the villus length contribute to the intestinal mucosa recovering following SCFA and butyrate supplementation (Fig. 3). Interestingly, inflammatory infiltration did not decrease after SCFA or butyrate supplementation.

Leukocyte Infiltration and Cytokine Expression

Because no differences were observed in the inflammatory infiltration between groups, we evaluated the activity of neutrophils, macrophages and eosinophils in the intestines of all animals through the determination of MPO, NAG and EPO enzyme activities, respectively. Neutrophil infiltration, as measured by MPO activity was increased as a consequence of 5FU treatment (Fig. 4). Following the results of

the inflammatory score, neither SCFA nor butyrate altered MPO activity (neutrophil infiltration). NAG activity (macrophage infiltration) was similar among groups, including the control group, suggesting it is not relevant to the damage induced by 5FU in this phase of inflammation (Fig. 4). Regarding EPO activity (eosinophil infiltration), it increased 4 times with 5FU treatment compared to the control group. Nevertheless, EPO returned to the control levels after SCFA and butyrate treatments (Fig. 5).

Amplification of mRNA of Pro-Inflammatory Molecules

Gene expression of TLR-4, IL-6 and TNF- α was analyzed by RT-PCR. The TLR4 expression presented a strong tendency ($p = 0.06$) to be higher in 5FU mice compared to controls but it was not different between supplemented groups (Fig. 5a). Regarding TNF- α and IL-6 expressions, a strong tendency ($p = 0.057$) of increased values was seen in 5FU and 5FU + SCFA, but not in 5FU + butyrate (Fig. 5b).

Intestinal Permeability

5FU damage is associated with an increase in intestinal permeability, which can be detected by the blood recovery of ^{99m}Tc -DTPA after an oral dose. For animals in all 5FU groups, intestinal permeability was higher than the control group, which was not reversed by SCFA. However,

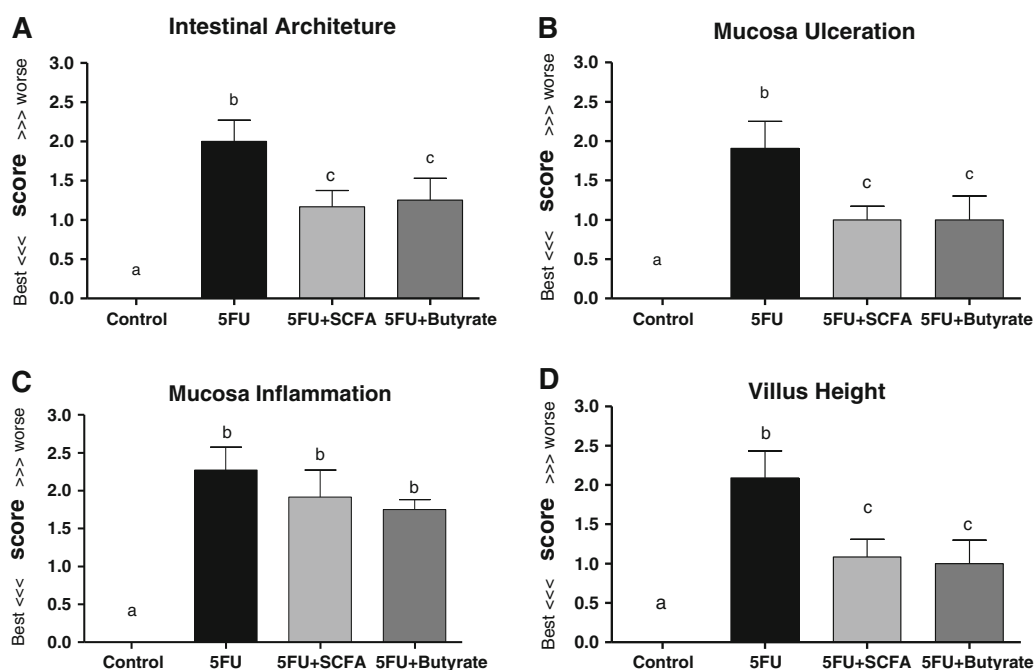

Fig. 3 Evaluation of mucosa architecture alteration (a), mucosa ulcerations (b), inflammatory infiltration (c) and villus height (d) of duodenum, jejunum and ileum of control mice or mice treated with 5FU and receiving water (5FU group), SCFA (5FU + SCFA group)

or butyrate (5FU + butyrate group) for 10 days. $n = 6$ per group. Bars represent average and lines represent standard error. Different letters indicate a statistical difference ($p < 0.05$)

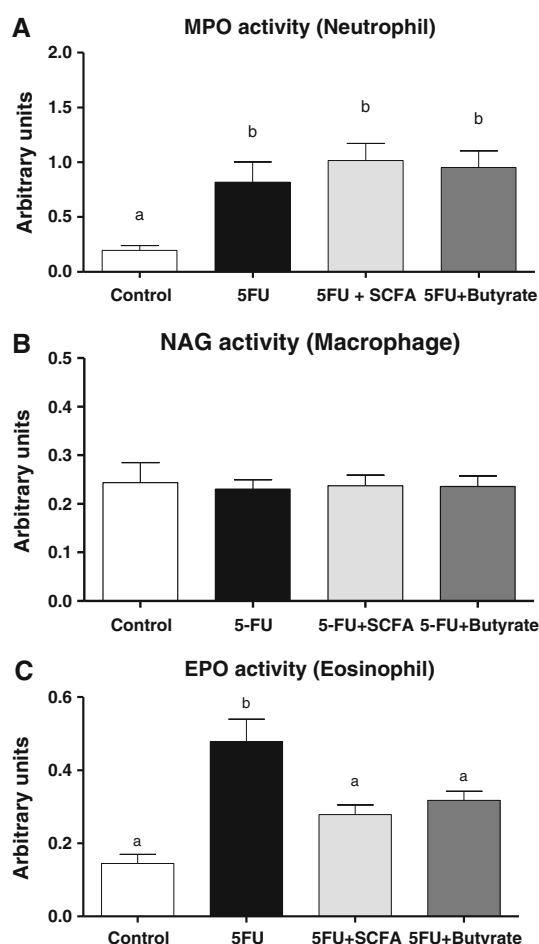

Fig. 4 Evaluation of the enzyme activity of MPO, NAG and EPO, as indirect determination of neutrophil (a), macrophage (b) and eosinophil (c) infiltration, respectively, in the small intestine of control mice or mice treated with 5FU (IP) and receiving water (5FU group), SCFA (5FU + SCFA group) or butyrate (5FU + butyrate group) for 10 days. $n = 7/\text{group}$. Bars represent average and vertical lines represent standard error. Different letters indicate a statistical difference ($p < 0.05$)

butyrate administration reduced intestinal permeability to levels that were closer to those of the control groups (Fig. 6).

Since paracellular permeability is linked to tight junction protein interactions, ZO-1 protein expression was also investigated, also showing a strong tendency to increased expression in 5FU ($p = 0.056$) and 5FU + SCFA ($p = 0.09$) groups. Once again, 5FU + butyrate mice presented ZO-1 expression closer to control ones.

Discussion

In the current study, we have shown that SCFA and, in particular, butyrate are effective in improving mucosa

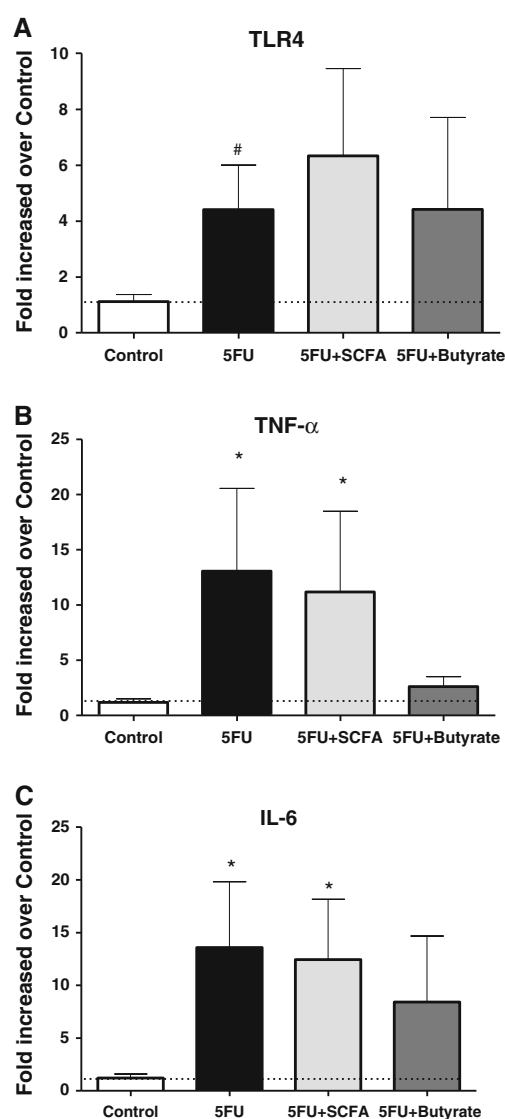

Fig. 5 TLR4 (a), TNF- α (b) and IL-6 (c) mRNA amplifications in the ileum of control mice or mice treated with 5FU (IP) and receiving water (5FU group), SCFA (5FU + SCFA group) or butyrate (5FU + butyrate group) for 10 days. Bars represent average and lines represent standard error. $N = 4/\text{group}$. # $p = 0.061$ and * $p = 0.057$ compared to the control group

integrity and reducing inflammation in an experimental model of mucositis. Moreover, these effects were obtained by the oral supplementation of fatty acids rather than rectal via as is usually done. In a previous study, we showed that SCFA solution improves intestinal manifestation of mucositis [20]. However, we did not evaluate the effects of butyrate used alone and limited our analyses to the histological aspects of the intestinal mucosa. As far as we know, the current study is the first one to address the effect of butyrate supplementation on the evolution of chemotherapy-induced intestinal mucositis.

Role of SCFA and Butyrate on the Intestinal Integrity

Although the SCFA and butyrate solutions had beneficial effects on mucositis, the butyrate solution was the most effective. While it contained the same concentration of butyrate as the butyrate-alone solution, the SCFA solution only partially reduced weight loss and did not prevent permeability alteration or reduced the pro-inflammatory cytokine expression in the intestine. We believe that, rather than presenting deleterious effects, the presence of acetate and propionate in the SCFA solution reduced the intestinal absorption of butyrate via the border brush transporter. The transport of butyrate through monocarboxylate transporters (MCT) is saturable, coupled with H^+ and inhibited by several monocarboxylates, such as acetate, propionate, pyruvate, L-lactate and α -ketobutyrate [8]. We hypothesize that the higher concentration of acetate (35 mM) and propionate (15 mM) in contrast to the lower concentration of butyrate (9 mM) in the SCFA solution could compete with the butyrate transport by MCT and/or another intestinal

transporter, resulting in a smaller absorption and, consequently, a smaller post absorptive effect of butyrate in the SCFA solution compared to the butyrate alone.

Anti-Inflammatory Action

The mucosa analyses showed that neutrophil infiltration, as measured by MPO activity had increased in 5FU-treated animals and that SCFA or butyrate solutions did not interfere in this aspect. Moreover, macrophage infiltration, as measured by NAG activity, was not different in any 5FU-treated groups compared to the control group. This latter result could be explained by the pattern of cell migration towards the inflammatory site. Neutrophils are the first cells arriving at the inflammatory site causing an increase in MPO activity in the first hours after administration of 5FU as seen in the current study [3, 24]. In contrast, macrophages are effector cells, most frequently seen in later inflammatory stages, mainly after 3 days of inflammatory stimulus [30]. Our mice were euthanized 3 days after the administration of 5FU, which may explain the lack of differences in macrophage concentration between the control and 5FU groups. Regarding eosinophils, we found an intense infiltration related to mucositis that was prevented by SCFA and butyrate supplementation. Although the role of eosinophils in mucositis is seldom studied, the detection of eosinophils in the intestinal mucosa of patients with inflammatory intestinal diseases, even in small quantities, has been associated with adverse clinical consequences, such as weight loss, malabsorption and shortening of large intestine crypts [21, 31]. Thus, a reduction of these cells in the groups treated with SCFA and butyrate is considered a sign of a better prognosis.

The expression of the pro-inflammatory molecules TLR4, IL6 and $TNF\alpha$ tended to be higher in the 5FU group. This increase was possibly due to the inflammation caused by 5FU itself and due to the rupture of the intestinal barrier permitting bacterial translocation and LPS-induced TLR4 activation. In concordance to the permeability data and MPO activity, 5FU + butyrate group kept cytokine expression closer to the control group. These data suggest that the better intestinal trophism seen in this group attenuates the inflammatory stimulus secondary to LPS and bacterial translocations, reducing activation of mucosal immune cells.

The absence of differences between the 5FU and butyrate groups for NAG and MPO activities as well as inflammatory score suggest that a trophic rather than immunologic effect is the main mechanism for both butyrate and SCFA protection. Nonetheless, butyrate demonstrated a more intense effect on the intestinal barrier that could be due to its metabolic effect as an energetic source associated to its action on gene expression. The results of

butyrate on cytokines and TLR4 expressions compared to SCFA are in agreement with the improvement of intestinal permeability which will reduce bacterial translocation and LPS induced immune response activation.

Intestinal Permeability

Cell infiltration and intestinal permeability are important markers of tissue damage and mucosal inflammation [2, 17]. We have observed that butyrate reduced the alteration in intestinal permeability that is typically seen in 5FU mice. Our results are in agreement with other in-vitro studies showing the improvement of intestinal permeability with butyrate solutions [14, 19, 27]. The mechanism of this effect can be linked to gene expression of tight junction proteins, since butyrate and trichostatin A, an inhibitor of histone acetylase decreased tight junction permeability in Caco-2 cells via lipoxynase activation [18].

ZO-1 is a TJ protein that interacts with occludin, ZO-2, ZO-3 and actin, reducing intestinal permeability and inducing cell differentiation. Since 5FU treatment induced the increase of intestinal permeability, one would expect a reduction in ZO-1 protein in tight junctions [13, 16, 23]. However, our results showed that ZO-1 expression was increased in groups which presented an increase in permeability (5FU and 5FU + SCFA) compared to the control. We believe that this higher expression of ZO-1 reflects the more intense mucosal repair after 5FU-induced damage. ZO-1 protein and expression are generally tested under conditions of continuous inflammatory stimuli such as cell incubation with pro-inflammatory agents [23] or animal models with chronic inflammatory diseases [13, 16]. This continuous inflammatory stimulus maintains ZO-1 expression down-regulated in those models, avoiding the repair of the intestinal barrier. However, in our mucositis model, 5FU that has a short half-life [4] was given as a single dose 3 days before euthanasia of the mice. Since intestinal mucosa is renewed every 3–4 days, we believe that new intestinal cells formed after 5FU injection overexpressed ZO-1 in order to compensate the important intestinal barrier disruption. In the 5FU + butyrate group, mucosal damage was lower (as seen by the reduction in intestinal permeability and mucosa recovery) compared to the 5FU non-supplemented group, reducing the necessity of a compensatory ZO-1 expression. Probably, ZO-1 expression, intestinal permeability in the 5FU + butyrate group was closer to the control group, reinforcing our hypothesis. Moreover, ZO-1 altered expression in the 5-FU and 5FU + SCFA groups can be related to the ZO-1 translocation from the cell boundary (tight junction location) to the cytoplasm as previously described [23]

Possible Mechanisms of Action

The mechanisms of action of SCFA and butyrate on intestinal cells are not totally understood. Oral administration of SCFA exposes the stomach and small intestine mucosa to these fatty acids before reaching the colon [25, 29] and are transported to the liver [8]. There, they can be metabolized to glutamate, glutamine and acetoacetate [5] important fuels for enterocytes [1, 5, 6]. Butyrate also increases the pancreatic secretion and the activity of jejunal brush-border enzymes [9], increasing availability of nutrients for enterocyte regeneration, stimulates of Glucagon-like peptide-2 (GLP-2) [32], a pleiotropic intestinotrophic hormone that enhances digestive and absorptive capacity [12]. All these components propitiate the mucosa integrity, protecting cells from 5FU damage, including the increase in intestinal permeability. As a consequence, the bacterial translocation is reduced, minimizing the inflammatory response.

In conclusion, the results presented here highlight, for the first time, the potential use of butyrate in inflammatory diseases of the small intestine, such as mucositis. Oral administration of butyrate contributes to rebuilding the intestinal mucosa by quickly repairing ulcerated and inflamed tissue.

Lipid Transfer to HDL is Higher in Marathon Runners than in Sedentary Subjects, but is Acutely Inhibited During the Run

Abstract Although exercise increases HDL-cholesterol, exercise-induced changes in HDL metabolism have been little explored. Lipid transfer to HDL is essential for HDL's role in reverse cholesterol transport. We investigated the effects of acute exhaustive exercise on lipid transfer to HDL. We compared plasma lipid, apolipoprotein and cytokine levels and in vitro transfer of four lipids from a radioactively labeled lipid donor nanoemulsion to HDL in sedentary individuals ($n = 28$) and in marathon runners ($n = 14$) at baseline, immediately after and 72 h after a

marathon. While HDL-cholesterol concentrations and apo A1 levels were higher in marathon runners, LDL-cholesterol, apo B and triacylglycerol levels were similar in both groups. Transfers of non-esterified cholesterol [6.8 (5.7–7.2) vs. 5.2 (4.5–6), $p = 0.001$], phospholipids [21.7 (20.4–22.2) vs. 8.2 (7.7–8.9), $p = 0.0001$] and triacylglycerol [3.7 (3.1–4) vs. 1.3 (0.8–1.7), $p = 0.0001$] were higher in marathon runners, but esterified-cholesterol transfer was similar. Immediately after the marathon, LDL- and HDL-cholesterol concentrations and apo A1 levels were unchanged, but apo B and triacylglycerol levels increased. Lipid transfer of non-esterified cholesterol [6.8 (5.7–7.2) vs. 5.8 (4.9–6.6), $p = 0.0001$], phospholipids [21.7 (20.4–22.2) vs. 19.1 (18.6–19.3), $p = 0.0001$], esterified-cholesterol [3.2 (2.2–3.8) vs. 2.3 (2–2.9), $p = 0.02$] and triacylglycerol [3.7 (3.1–4) vs. 2.6 (2.1–2.8), $p = 0.0001$] to HDL were all reduced immediately after the marathon but returned to baseline 72 h later. Running a marathon increased IL-6 and TNF- α levels, but after 72 h these values returned to baseline. Lipid transfer, except esterified-cholesterol transfer, was higher in marathon runners than in sedentary individuals, but the marathon itself acutely inhibited lipid transfer. In light of these novel observations, further study is required to clarify how these metabolic changes can influence HDL composition and anti-atherogenic function.

Introduction

The beneficial effects of moderate exercise training on the cardiovascular system and on the major risk factors related to cardiovascular disease, such as plasma lipid concentration, have been well established [1]. However, the underlying mechanisms of the protective effects of exercise remain largely unknown [2]. Regular aerobic exercise training decreases low-density lipoprotein cholesterol (LDL-C) and triacylglycerol (TAG) levels and increases high-density lipoprotein cholesterol (HDL-C) levels [3–6]. This leads to a characteristically anti-atherogenic lipid profile and is accompanied by an increase in apolipoprotein (apo) A1 and a decrease in apo B, the main apolipoproteins present in HDL and LDL particles, respectively [7]. Exhaustive, high-intensity exercise, such as that practiced by female marathon runners, elicits strong increases in HDL-C, but unlike moderate exercise, the effects on LDL-C and TAG levels are not significant [8]. This isolated increase in HDL-C is apparently not sufficient to protect from atherosclerosis as it has been shown that marathon runners do not have better coronary artery calcification indexes than sedentary individuals [9]. An important factor influencing exercise-induced plasma lipid changes is the effect of cytokines such as interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF- α), since both cytokines inhibit the activity of lipoprotein lipase and their concentrations increase acutely during exhaustive exercise [10, 11].

HDL-C is an important protective factor against atherosclerosis and an important marker of longevity [12]. The inverse correlation between HDL-C concentration and the likelihood of coronary heart disease (CHD) is well-known, but the protective action of HDL, such as its role in reverse

cholesterol transport, is only partially reflected by its concentration [13, 14]. In reverse cholesterol transport, cholesterol from peripheral tissues is transferred to HDL and transported to the liver, where it is excreted by the bile [15]. HDL also has antioxidant activity—mostly due to paraoxonase 1 (PON 1), which is linked to HDL—and anti-inflammatory, antithrombotic and vasodilatory activities, which may account for the antiatherogenic role of this lipoprotein [16, 17].

HDL metabolism is complex. This lipoprotein is formed in the circulation by the lipidation of apo A1 to produce a disk-shaped nascent form of HDL, which is then transformed into the mature, round form. HDL is continuously remodeled, and lipid transfer to and from this lipoprotein is an essential part of its metabolism and atheroprotective functions, such as the promotion of reverse cholesterol transport [18]. Transfer of lipids is facilitated by transfer proteins such as cholesteryl ester transfer protein (CETP) and phospholipid transfer protein (PLTP), which are involved in the transfer of core lipids (cholesteryl esters and TAG) and surface lipids (PL and free cholesterol), respectively [19–21]. To date, the role of CETP and PLTP in atherogenesis is not completely understood, but HDL-C status is clearly more affected by lipid transfer than very low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) status.

In this study we aimed to investigate whether the transfer to HDL of the four main lipids in the circulation, namely, NEC, EC, PL and TAG, as estimated by an *in vitro* assay [22] is affected by the practice of high-intensity exercise, such as marathon running, and whether marathon running causes an acute change in these transfers. Our results show that there is indeed a marked difference in the lipid transfer process between marathon runners and sedentary individuals. Furthermore, running a marathon acutely inhibits lipid transfer in these athletes.

Materials and Methods

Study Subjects

Fourteen male recreational marathon runners aged 25–50 years and 28 male sedentary individuals were recruited for the study. The two groups were paired for age and BMI (data shown in Table 1). None of the participants were smokers, addicted to alcohol consumption or obese or had systemic arterial hypertension or liver, renal, metabolic, inflammatory or neoplastic diseases. None were using lipid-lowering medications.

The Ethics Committee of the Federal University of São Paulo approved the study, and written informed consent was obtained from all subjects after they were provided with a complete description of the protocol.

Blood samples of the marathon runners were collected at rest (baseline), immediately after and 72 h after the

marathon race. Blood was also collected at rest from sedentary people. Blood draws for all the individuals were performed after 12 h of fasting. marathon runners trained an average of 80–100 km/week to prepare for the race, or an average of 2 h/day. The last training session was performed 24 h before the blood draw. We recommended that all marathon runners ingested 500 mL of water before the marathon. Water was provided by the marathon organizers during the race.

Plasma Lipids

Plasma total cholesterol (measured by the CHOD–PAP method) and total bilirubin levels were determined using commercial kits (Kovalente, São Gonçalo, Brazil), and the results were analyzed with an automated system (Dimension[®] RxL Max[®] Integrated Chemistry System, Siemens, Deerfield, IL). HDL-C and TAG concentrations were determined using commercial kits and an automated analysis system (ADVIA[®] 2,400 Chemistry System, Siemens Healthcare Diagnostics Inc., Deerfield, IL). LDL-C was estimated by the Friedewald formula [23]. Apo A1 and B were measured by rate nephelometry on an Image[®] Immunochemistry System (Beckman Coulter, Brea, CA).

Nanoemulsion Preparation and Lipid Transfer Assay

The lipid donor nanoemulsion used in this study mimics the LDL lipid structure, which consists of a surface monolayer of PL and NEC surrounding a core of

cholesteryl esters also containing residual TAG. The nanoemulsion was prepared from a lipid mixture composed of 40 mg cholesteryl oleate, 20 mg egg phosphatidylcholine, 1 mg triolein and 0.5 mg cholesterol purchased from Sigma Chemical Company (St. Louis, MO). Emulsification of lipids by prolonged ultrasonic irradiation in aqueous media and the two-step procedure of ultracentrifuging the crude emulsion and adjusting its density with KBr to obtain the nanoemulsion was carried out as described previously [22, 24]. The nanoemulsion fraction was dialyzed against 0.9 % NaCl solution. Trace amounts of cholesteryl [1-¹⁴C] oleate and glycerol tri [9, 10 (n)-³H] oleate or [7(n)-³H] cholesterol and L-3-phosphatidylcholine, 1-stearoyl-2-[1-¹⁴C] arachidonyl (Amersham, Little Chalfont, Buckinghamshire, UK) were added to the initial solution.

The in vitro assay to measure lipid transfer from the nanoemulsion to HDL was previously described by Lo Prete et al. [25]; briefly a nanoemulsion labeled with ³H-CE and ¹⁴C-PL or with ¹⁴C-NEC and ³H-TAG is incubated with whole plasma. This incubation is followed by chemical precipitation of the nanoemulsion and apo B containing lipoproteins. The radioactivity of the supernatant containing the lipids that shifted from the nanoemulsion to HDL is then measured by liquid scintillation counting. Transfer of radioactive material from the nanoemulsion to HDL is expressed as the radioactivity in the HDL-containing supernatant as a percentage of the total radioactivity of the nanoemulsion incubated with the plasma [25].

Determination of CETP and PLTP Activity

Serum CETP and PLTP activity was measured using commercially available CETP and PLTP activity assay kits (BioVision Inc, Mountain view, CA) and serum samples of marathon runners collected before (baseline), immediately after and 72 h after a marathon race, following the manufacturer's instructions.

Serum Cytokine Concentration

The concentrations in pg/mL of cytokines IL-6 and TNF- α in the serum of marathon runners collected before (baseline), immediately after and 72 h after a marathon race and in sedentary individuals at rest were measured using the Luminex bead-based system for human cytokines and the LINCOplex kit for simultaneous multi-analyte detection (Linco Research, St Charles, MO).

Statistical Analysis

The Mann–Whitney test was used to determine if the differences between the results for sedentary individuals and those for marathon runners at rest were significant. The Friedman test and Müller–Dunn post-test were used to determine if the differences between the baseline results for the marathon runners and the results immediately after and 72 h after the marathon were significant. The significance level was set to 5 % ($p < 0.05$). Age and BMI data are expressed as means \pm standard deviations. Other parameters evaluated are expressed as median and interquartile range.

Results

As shown in Table 1, there were no significant differences in baseline values of hematocrit, hemoglobin and total bilirubin levels between marathon runners and sedentary individuals.

The results for serum lipids showed that HDL-C concentration was higher in the marathon runners group than in the sedentary group ($p = 0.001$), but there was no statistically significant difference between the two groups for either LDL-C or TAG. When measured in conjunction with HDL-C, levels of apo A1 ($p = 0.04$), which is the major apo in the HDL fraction, were also higher in marathon runners, whereas there was no statistically significant difference in apo B levels between the groups.

Figure 1 shows that transfers of NEC [6.8 (5.7–7.2) vs. 5.2 (4.5–6), $p = 0.001$], PL [21.7 (20.4–22.2) vs. 8.2 (7.7–8.9), $p = 0.0001$] and TAG [3.7 (3.1–4) vs. 1.3 (0.8–1.7), $p = 0.0001$] were higher in marathon runners

than in sedentary individuals but that transfer of EC [3.2 (2.2–3.8) vs. 2.7 (2.2–3), not significant (NS)] was statistically the same.

As hemoconcentration could eventually lead to increased plasma lipid concentration, hematocrit percentages were measured immediately after the marathon and were found to be unchanged (Table 1), indicating that the athletes were adequately hydrated during the race. The increases in hemoglobin levels ($p = 0.01$) and total bilirubin ($p = 0.03$) observed here could be related to acute episodes of hemolysis, which frequently occur in marathon races [26].

As also shown in Table 1, LDL and HDL-C values did not change from baseline to immediately after the marathon, but TAG levels increased by roughly 60 % ($p = 0.001$). Apo B, which is mainly an LDL marker but is also present in VLDL, increased after the race ($p = 0.02$) whereas apo A1 was unchanged.

As shown in Fig. 1, transfers of NEC [6.8 (5.7–7.2) vs. 5.8 (4.9–6.6), $p = 0.0001$], PL [21.7 (20.4–22.2) vs. 19.1 (18.6–19.3), $p = 0.0001$], EC [3.2 (2.2–3.8) vs. 2.3 (2–2.9), $p = 0.02$] and TAG [3.7 (3.1–4) vs. 2.6 (2.1–2.8), $p = 0.0001$] to HDL were all reduced after running a marathon.

It can be seen from Table 1 that all the lipid and apolipoprotein values had already returned to baseline levels 72 h after the marathon ended. The same occurred with the lipid transfer values, which are shown in Fig. 1: transfers of NEC [6.4 (5.8–6.9) vs. 6.8 (5.7–7.2), NS], EC [2.6 (2.1–3.1) vs. 3.2 (2.2–3.8), NS] and PL [20.9 (19.8–22.1) vs. 21.7 (20.4–22.2), NS] were not statistically different from baseline transfer values, except for the transfer of TAG [3 (2.6–3.5) vs. 3.7 (3.1–4), $p = 0.005$], which increased but was still significantly different from baseline values.

Figure 2 shows CETP (a) and PLTP (b) activity in serum of marathon runners on three occasions: at rest (baseline), immediately after and 72 h after the marathon finished. CETP activity was unchanged and PLTP activity ($p = 0.001$) was elevated immediately after the marathon but returned to baseline levels after 72 h.

Figure 3 shows serum concentrations of IL-6 (a) and TNF- α (b) in sedentary individuals at rest and the change in cytokine levels in marathon runners from baseline to immediately after and 72 h after the marathon. IL-6 baseline values for marathon runners and sedentary individuals were statistically equal. However, TNF- α concentrations in marathon runners were lower than in sedentary individuals at rest ($p = 0.001$). Running a marathon race led to a pronounced increase in the concentrations of both IL-6 ($p = 0.0004$) and TNF- α ($p = 0.004$), which returned to baseline levels 72 h after the marathon ended.

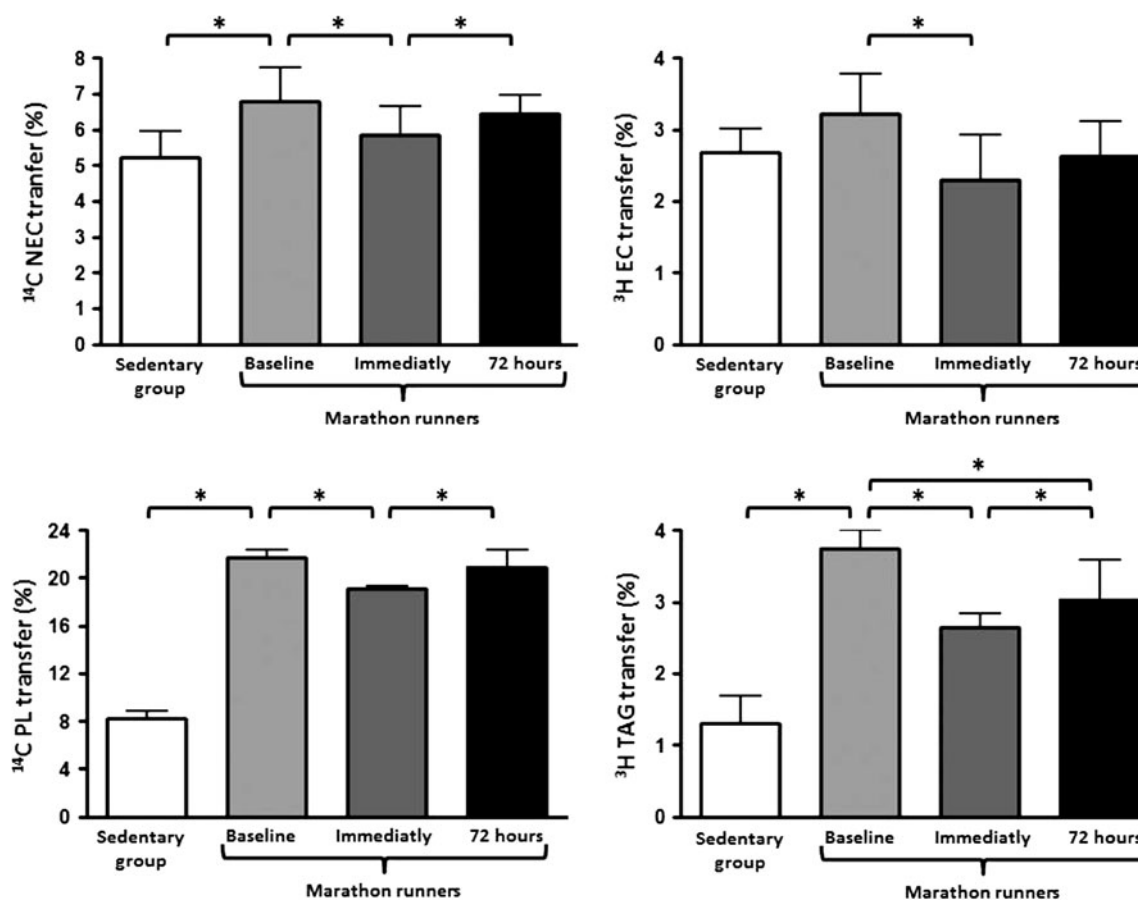

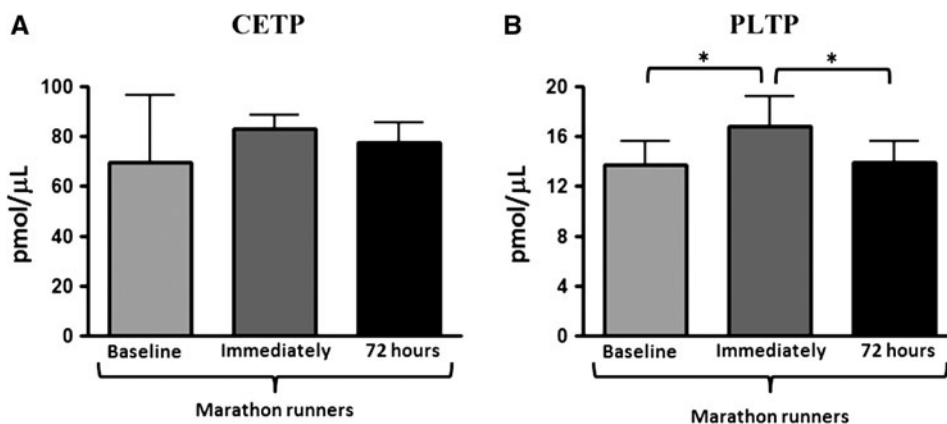

Fig. 1 In vitro transfer of radiolabeled NEC (non-esterified cholesterol) and EC (esterified-cholesterol), PL (phospholipids) and TAG (triacylglycerol) from a donor lipid nanoemulsion to HDL in a group of sedentary subjects at rest and a group of marathon runners

measured on three different occasions: at rest (baseline), immediately after and 72 h after a marathon. Data are presented as medians and interquartile ranges, with a significance level of $*p < 0.05$

Discussion

The results of this study show that while levels of HDL-C and apo A1 (the main HDL apolipoprotein) in marathon runners were different from those in sedentary individuals, LDL-C and apo B were statistically the same. This is in agreement with the findings of other studies showing that regular exercise

training in general and intensive training in particular increase HDL-C [5]. However, training does not guarantee reductions in LDL-C or apo B [27–29], although high-intensity exercise, such as an endurance triathlon, often elicits a decrease in triacylglyceridemia [30, 31]. In the current study, no differences were found in either LDL-C or TAG levels between marathon runners and sedentary individuals.

Fig. 3 Serum concentrations (pg/mL) of cytokines IL-6 (a) and TNF- α (b) in a group of sedentary subjects at rest and in a group of marathon runners measured on three different occasions: at rest (baseline), immediately after and 72 h after a marathon. Data are presented as medians (interquartile range) with a significance level of $*p < 0.05$

It has been reported that, after an ultramarathon or marathon, HDL-C may increase acutely [32] or, as occurred in our study, remain unchanged [33], with large inter-individual variations [32, 33].

A novel finding of this study was that the transfer of lipids to HDL was higher in marathon runners than in sedentary individuals at rest, except for the transfer of EC. This effect could be ascribed to marathon runners having higher HDL-C concentrations, favoring an increase in lipid transfer [25]. It is also possible that increases in CETP and PLTP enhanced the transfers of TAG and PL, respectively. PLTP can also facilitate NEC transfer [34]. While enrichment of HDL with PL is considered beneficial in terms of reverse cholesterol transfer, enrichment with TAG may destabilize the HDL particles [35] and, contrary to what was observed in the present study, lead to a decrease in HDL. However, the fact that more of these lipids were transferred to HDL in marathon runners than in sedentary people does not imply that lipid enrichment occurred, as lipid transfer is bidirectional and in the present study only transfers from the donor nanoemulsion to HDL were measured. Conceivably, compositional changes in the HDL fraction may also change the ability of this lipoprotein to take up lipids from other lipoprotein classes or, as is the case here, from a standard donor nanoemulsion. Recently, our group showed that in subjects that had precocious coronary artery disease the *in vitro* transfer of NEC to HDL was reduced [36, 37]. Since HDL is the main cholesterol esterification site in the circulation and this reaction is essential for stabilization of the plasma cholesterol pool and for reverse cholesterol transport, reduction in NEC transfer to HDL may affect important functions of this lipoprotein, increasing cardiovascular risk. Therefore, we can speculate that the increased transfer of NEC to HDL in marathon runners may play an important role in cardiovascular disease prevention.

The acute effects of running a marathon on lipid and lipoprotein profiles and on lipid transfer to HDL have also been documented. The effects on triacylglycerol-rich lipoproteins such as VLDL were remarkable, as fasting

TAG levels increased more than twofold in female runners [38]. In contrast, HDL-C levels, as well as levels of the HDL marker apo A1, were unchanged and even though previous studies have shown that LDL-C levels were reduced after exhaustive exercise such as an ultra-marathon or bicycle marathon [33, 39], here LDL-C levels were unchanged. Thus, the increase in the LDL marker apo B was due to the marked increase in VLDL, as apo B is also present in the VLDL fraction [40]. The fact that HDL levels were unchanged shortly after the marathon while lipid transfer had decreased suggests that HDL was structurally more stable during the exercise.

Our data confirm previous findings that TNF- α is lower in athletes than in sedentary subjects [41, 42] and that TNF- α and IL-6 increase after a training session of intense exercise [43, 44]. As both TNF- α and IL-6 inhibit lipoprotein lipase [45–50], the transient post-marathon hypertriacylglyceridemia observed in this study can be ascribed to the increase in these cytokines.

HDL-C and apo A1 levels were not acutely changed immediately after the marathon, but the transfer rates of all four lipids to HDL were reduced. Although a decrease in lipid transfer could be attributed to a reduction in CETP and PLTP activity, this did not occur in our study [7, 39, 51]. These findings are similar to those in acute inflammatory response, which elicits an increase in PLTP activity [52] without a change in CETP [53] and interferes with the antioxidant action of HDL, the HDL-associated enzyme paraoxonase-1 (PON1) and apo A1 [53–55]. This effect, also observed in the presence of IL-6 and TNF- α [56] increases phospholipids oxidation [55], possibly leading to a decrease in the capacity of HDL to take up lipids. Another factor leading to decreased lipid transfer to HDL is the increase in triacylglycerol-rich lipoproteins such as VLDL or IDL reflected in marathon-induced hypertriacylglyceridemia [57]. This could have increased the transfer of the nanoemulsion lipids to VLDL at the expense of HDL. An increase in transfers to HDL in conjunction with a return of TAG to pre-marathon levels, as observed 72 h after the run, suggests that this mechanism could have

contributed to the reduction in lipid transfer immediately after the marathon.

While the small number of participants in this study could be considered a limitation, especially when data for the runners at rest are compared with those for the sedentary subjects, the great difference in the results for the lipid transfer assay mitigates this drawback. Furthermore, this is not a limitation in the experiments comparing the acute effects of a marathon run because the data for each participant were compared before and after the marathon, with marked differences found between pre- and post-marathon results for all the individual participants.

In conclusion, lipid transfer to HDL, an important element of HDL metabolism and function, was remarkably increased in individuals who practiced exhaustive exercise. However, running a marathon inhibited lipid transfer transiently, an effect that is possibly related to the increase in serum cytokines. Since HDL has a role in inflammatory processes and is affected by intensive exercise training, our findings may have important physiological implications. Further research is required to establish the mechanisms behind the phenomena described here.

Abstract Racemic 8-[2-(2-pentyl-cyclopropylmethyl)-cyclopropyl]-octanoic acid (DCP-LA), a linoleic acid derivative with cyclopropane rings instead of *cis*-double bonds, contains possible four diastereomers such as α,α -, α,β -, β,α -, and β,β -DCP-LA. The present study examined the effect of racemic and diastereomeric DCP-LA on age-related learning and memory disorders using accelerated-senescence-prone mice 8 (SAMP8) and accelerated-senescence-resistant mice 1 (SAMR1). In the water maze test, the acquisition and retention latencies for SAMP8 mice were significantly longer than the latency for SAMR1 mice, indicating spatial learning and memory impairment for SAMP8 mice. All the racemic (1 mg/kg, *per os*) and diastereomeric DCP-LA (0.25 mg/kg, *per os*) significantly shortened the acquisition latency for SAMP8 mice, and racemic, α,α - and α,β -DCP-LA significantly shortened the retention latency, with the advantage greater than the acetylcholine (ACh) esterase inhibitor galanthamine. The results of the present study show that all the racemic and diastereomeric DCP-LA, has the potential to improve age-related learning and memory deterioration, the potential varying among them.

Introduction

We have synthesized the linoleic acid derivative with cyclopropane rings instead of *cis*-double bonds, 8-[2-(2-pentyl-cyclopropylmethyl)-cyclopropyl]-octanoic acid (DCP-LA), for the purpose of developing an anti-dementia drug [1]. DCP-LA serves as a selective and direct activator of protein kinase C (PKC)- ϵ [2]. DCP-LA stimulates glutamate release from presynaptic terminals in a PKC- and presynaptic $\alpha 7$ ACh receptor-dependent manner, thereby leading to a long-lasting facilitation of hippocampal synaptic transmission [3]. DCP-LA, alternatively, still stimulates the release of γ -aminobutyric acid (GABA) from hippocampal interneurons by targeting $\alpha 7$ ACh receptors under the control of PKC [4]. Moreover, DCP-LA activates Ca²⁺/calmodulin-dependent protein kinase II (CaMKII) by

inhibiting protein phosphatase-1 (PP-1), to promote exocytosis of the α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor subunits GluR1 and GluR2, resulting in the increased membrane surface localization of AMPA receptors on postsynaptic cells in the hippocampus [5]. This DCP-LA action also contributes to facilitation of hippocampal synaptic transmission. DCP-LA improves spatial learning and memory impairment induced by intraperitoneal injection with scopolamine or intraventricular injection with amyloid β_{1-40} peptide and age-related cognitive decline [6, 7]. Additionally, DCP-LA neutralizes and improves impairment of long-term potentiation (LTP), a cellular model of learning and memory, in the in-vivo hippocampus and spatial learning deficits, that are induced by a considerably low dose of mutant amyloid β_{1-42} peptide lacking glutamate-22 [8].

So far, we have carried out those experiments using racemic modification of DCP-LA. Racemic DCP-LA consists of at least four diastereomers such as α,α -, α,β -, β,α -, and β,β -DCP-LA. To assess characteristics of each diastereomer, we have separately synthesized DCP-LA diastereomers (Fig. 1). α,β -DCP-LA selectively and directly activated PKC- ϵ and stimulated release of transmitters such as glutamate, dopamine, and serotonin from rat hippocampal slices in a PKC- and $\alpha 7$ ACh receptor-dependent manner, with the highest potency among four diastereomers [9].

The present study was conducted to assess the effect of racemic and diastereomeric DCP-LA on age-related learning and memory impairment using accelerated-senescence-prone mice 8 (SAMP8), that reveal early onset and irreversible advancement of senescence, and accelerated-senescence-resistant mice 1 (SAMR1) with normal aging [10], and to compare the potential for DCP-LA to improve learning and memory decline with that for galanthamine, an ACh esterase inhibitor, that has been developed as an anti-dementia drug and is now available for treatment of Alzheimer's dementia. We show here that all the racemic and diastereomeric DCP-LA could ameliorate age-related learning and memory deterioration, with the beneficial effect being greater than with galanthamine.

Fig. 1 Structures of racemic and diastereomeric DCP-LA

Materials and Methods

Animal Care

All procedures have been approved by the animal care and use committee at Hyogo College of Medicine and were in compliance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

Animals

Animal preparation: male SAMP8 and SAMR1 mice (age, 22–25 weeks) were obtained from Takeda Pharmaceutical Co. (Osaka, Japan). Mice were individually housed in cages at 23 ± 1 °C, with a 12-h light/dark cycle (light phase beginning at 7:00 a.m.), and had free access to pellet food and water. All the tests here were carried out between 9:00 a.m. and 5:00 p.m.

Construction of Racemic and Diastereomeric DCP-LA

Racemic and diastereomeric DCP-LA were constructed by the method described previously [9]. We previously examined the effect of racemic DCP-LA on synaptic transmission in the in-vivo rat hippocampus at doses ranging from 0.01 to 1 mg/kg, where the most beneficial effect was obtained with intraperitoneal injection with 1 mg/kg of racemic DCP-LA. Racemic DCP-LA contains each diastereomer at the ratio of 1:1:1:1. We, therefore, administered racemic DCP-LA at a dose of 1 mg/kg and each diastereomer at a dose of 0.25 mg/kg to mice in the present experiments.

Administration with DCP-LA or Galanthamine

DCP-LA and galanthamine were dissolved with polyethylene glycol (PEG). Racemic DCP-LA, each diastereomeric DCP-LA, galanthamine, or PEG was directly administered by an oral sonde (*per os*) 1 h prior to each behavioral trial.

Open Field Test

Open field box, that is a cube constructed of 30×30 cm plastic plate, covered with a wooden box to shut out light, was prepared for an open field test. The open-field arena was illuminated at 110 lx by an incandescent lamp fixed on the roof of the box. To avoid outer noise, a fan, producing a noise of 45 dB, was fixed on the wall of the box. Two infrared beams ran from two walls 2 cm above the floor with a 10 cm interval, making cross stripes in parallel with the floor. Numbers to break the beams were regarded as locomotion activity. Twelve infrared beams, on the other

hand, ran 4.5 cm above the floor with a 2.5-cm interval. Numbers to break the beams were regarded as rearing activity. Mice were allowed to move freely in the open-field arena. The test was performed under the light conditions for 10 min. The initial half time of the test was performed under the light conditions, and the latter half time of the test under the dark conditions.

Water Maze Test

A circular plastic water tank 90 cm in diameter and 36 cm deep was used for a water maze test. The entire inside of the pool was painted black, and the pool was filled up to 20 cm from the bottom with murky water containing Indian ink at 22 °C. A platform (11 cm in diameter) painted black was placed in the water, the top sinking 0.5 cm below the water surface. The pool was put in a test room, where there were several marks that mice were able to see from the pool. The position of the marks remained unchanged throughout testing. A platform was located in the constant position, i.e., in the middle of one quadrant, equidistant from the center and edge of the pool. Mice facing the wall of the pool were placed into water at one of five positions selected at random, and time from start to escape onto the platform (acquisition latency) was measured. When they had succeeded, mice were allowed to stay on the platform for 10 s. When mice failed to find the platform within 90 s, the trial was stopped and mice were put on the platform for 10 s. Two trials were carried out a day, and the second trial began 2 min after the end of the first trial. Mice received the task for consecutive 8 days, and the mean latency from 2 consecutive days was calculated. Seven days later, the platform was removed and the retention latency (time from the start to arrival to the place where the platform had been set, 30 s in maximum) was measured.

Passive Avoidance Test

A two-compartment step-through passive avoidance apparatus; a front illuminated chamber (10 × 10 cm floor and a wall height of 20 cm) and a rear dark chamber (10 × 10 cm floor and a wall height of 20 cm) was used for a passive avoidance test. Each chamber was separated by a guillotine door and grids were attached on both the floors. When mice entered the dark chamber, the guillotine door was locked and in turn, electrical stimulation of 0.36 mA for 3 s was applied to their feet, thereafter leaving mice in the chamber for 30 s. Mice were initially put in the light chamber, and moving time from the light chamber to the dark chamber was measured as acquisition latency. The same trial was tested 24 h later, and staying time in the light chamber (maximum, 300 s) was measured as retention latency.

Statistical Analysis

The same mice were used throughout open field test, water maze test, and passive avoidance test. Statistical analysis was carried out using Dunnett's test, analysis of variance (ANOVA), Fisher's Protected Least Significant Difference (PLSD) test, and unpaired *t* test.

Results

Effects of DCP-LA and Galanthamine on Motor Activity

In the open field test to assess motor activity, locomotion and rearing activities under the light conditions for SAMP8 mice significantly increased as compared with the activities for SAMR1 mice ($P = 0.010$ and 0.020 , respectively, unpaired *t* test), while there was no significant difference in the those activities under the dark conditions between SAMP8 and SAMR1 mice (Table 1). This accounts for higher motor activity for SAMP8 mice under the light conditions.

For SAMR1 and SAMP8 mice, racemic DCP-LA (1 mg/kg, *per os*), each diastereomeric DCP-LA (0.25 mg/kg, *per os*), or galanthamine (2.5 mg/kg, *per os*) had no effect on locomotion and rearing activities both under the light and dark conditions as compared with those activities for control mice with PEG administration (Table 1). The locomotion activity for SAMR1 and SAMP8 mice with galanthamine was significantly lower than that for SAMR1 mice with α,β -DCP-LA under the dark conditions ($P = 0.042$, Dunnett's test) or for SAMP8 mice with α,β -DCP-LA under the light conditions ($P = 0.038$, Dunnett's test) and β,β -DCP-LA under the dark conditions ($P = 0.012$, Dunnett's test, Table 1). Moreover, the rearing activity for SAMR1 and SAMP8 mice with galanthamine was significantly lower than that for SAMR1 mice with β,α -DCP-LA under the light ($P = 0.029$, Dunnett's test) and dark conditions ($P = 0.018$, Dunnett's test) or for SAMP8 mice with racemic ($P = 0.009$, Dunnett's test), α,α - ($P = 0.006$, Dunnett's test), β,α - ($P = 0.036$, Dunnett's test), and β,β -DCP-LA under the dark conditions ($P = 0.034$, Dunnett's test, Table 1). Collectively, galanthamine might tend to reduce motor activities, with the potential greater than at least some types of DCP-LA, although galanthamine or DCP-LA does not significantly influence basal motor activities.

Effects of DCP-LA and Galanthamine on Spatial Learning and Memory

To assess spatial learning and memory, water maze test was carried out. There was significant difference in the

$P < 0.05$, unpaired t test;* $P < 0.05$, ** $P < 0.01$,Dunnett's test; Each $N = 5$ mice

acquisition latency between SAMR1 and SAMP8 groups in the ANOVA test, and the latency for SAMP8 mice was significantly prolonged as compared with the latency for SAMR1 mice (Fisher's PLSD test, Fig. 2a). In addition, the retention latency for SAMP8 mice was also significantly longer than the latency for SAMR1 mice (unpaired t test, Fig. 2b). These findings confirm age-related spatial learning and memory impairment for SAMP8 mice.

For SAMR1 mice, β,β -DCP-LA (0.25 mg/kg, *per os*) significantly shortened the acquisition latency (ANOVA followed by Fisher's PLSD test), while racemic DCP-LA (1 mg/kg, *per os*), the remaining DCP-LA diastereomers (0.25 mg/kg, *per os*), or galanthamine (2.5 mg/kg, *per os*) had no effect (Fig. 3a). This suggests that β,β -DCP-LA could serve as a learning enhancer for normal subjects. In contrast, the retention latency for SAMR1 mice was not affected by any DCP-LA or galanthamine (Fig. 3b).

For SAMP8 mice, all the racemic (1 mg/kg, *per os*) and diastereomeric DCP-LA (0.25 mg/kg, *per os*) significantly shortened the acquisition latency as compared with control mice with PEG administration (ANOVA followed by Fisher's PLSD test), but galanthamine (2.5 mg/kg, *per os*) otherwise exhibited no beneficial effect (Fig. 4a). Notably, a significant difference in the acquisition latency for SAMP8 mice was obtained between DCP-LA group and galanthamine group (ANOVA). All the racemic, α,α -, α,β -, β,α -, and β,β -DCP-LA significantly shortened the acquisition latency for SAMP8 mice, with $P = 0.022$ for racemic DCP-LA group and $P < 0.001$ for each diastereomeric DCP-LA group as compared with the latency for galanthamine group (Fig. 4a).

For SAMP8 mice, racemic (1 mg/kg, *per os*), α,α - (0.25 mg/kg, *per os*), and α,β -DCP-LA (0.25 mg/kg, *per os*) significantly shortened the retention latency (Dunnett's

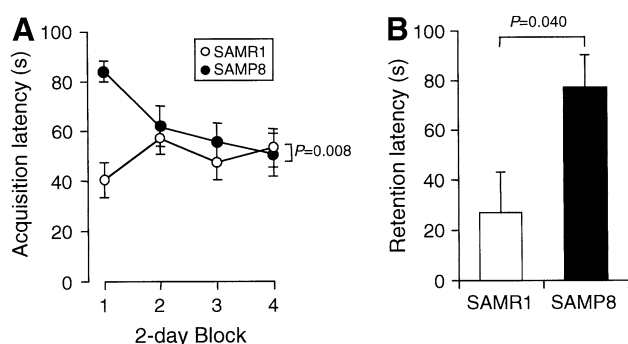

Fig. 2 Spatial learning and memory for SAMR1 and SAMP8 mice. The water maze test was carried out in SAMR1 and SAMP8 mice 1 h after oral administration with 0.1 ml of PEG. **a** Acquisition latency. In the graph, each point represents the mean (\pm SEM) latency from a 2-day block ($n = 5$ mice). P value, Fisher's PLSD test. **b** Retention latency. In the graph, each column represents the mean (\pm SEM) latency ($n = 5$ mice). P value, unpaired t test

test) as compared with control mice with PEG, but no significant effect was found with the remaining diastereomeric DCP-LA (0.25 mg/kg, *per os*) and galanthamine (2.5 mg/kg, *per os*, Fig. 4b). The retention latency for SAMP8 mice with racemic or α,α -DCP-LA was significantly shorter than the latency for mice with galanthamine (Dunnett's test, Fig. 4b). Taken together, these results indicate that all the racemic and diastereomeric DCP-LA could ameliorate spatial learning and memory deterioration for SAMP8 mice, the potential varying among them, with the advantage of efficacy greater than galanthamine.

Effects of DCP-LA and Galanthamine on Anxiety Behavior

In the passive avoidance test to assess anxiety behavior, the acquisition and retention latencies for SAMP8 mice was significantly shorter than the latencies for SAMR1 mice ($P = 0.046$ and $P = 0.033$, respectively unpaired t test, Table 2). This suggests lowered anxiety for SAMP8 mice.

Subsequently, the passive avoidance test was carried out in SAMR1 and SAMP8 mice after oral administration with PEG, racemic DCP-LA (1 mg/kg), each diastereomeric DCP-LA (0.25 mg/kg), or galanthamine (2.5 mg/kg). There was no significant difference in the latencies between control with PEG and any group with racemic DCP-LA, each diastereomeric DCP-LA, or galanthamine (Table 2). This indicates that all the DCP-LA and galanthamine have no effect on anxiety behavior.

The acquisition latency for SAMP8 mice with α,α - (0.25 mg/kg, *per os*) and α,β -DCP-LA (0.25 mg/kg, *per os*), however, was significantly longer than the latency for mice with galanthamine (2.5 mg/kg, *per os*; $P = 0.036$ and 0.009 , respectively, Dunnett's test; Table 2). Moreover, the

retention latency for SAMP8 mice with β,α -DCP-LA (0.25 mg/kg, *per os*) was also significantly longer than the latency for mice with galanthamine (2.5 mg/kg, *per os*; $P = 0.040$, Dunnett's test; Table 2). Overall, galanthamine might tend to enhance age-related anxiety, to a extent greater than at least some types of DCP-LA.

Discussion

Racemic DCP-LA contains four possible diastereomers, and we have established roots for selective optical resolution from racemic DCP-LA and succeeded in synthesizing four diastereomers, namely α,α -, α,β -, β,α -, and β,β -DCP-LA [9]. Each individual diastereomer might exhibit unexpected effects distinct from racemic DCP-LA, as is the case with thalidomide that had been developed as a hypnotic; of two enantiomers such as (*S*)- and (*R*)-form. The (*S*)-form of thalidomide caused the serious side-effect teratogenesis [11]. Accordingly, it is very critical to check the characteristics of each DCP-LA diastereomer.

In the water maze test, the acquisition and retention latencies for SAMP8 mice were significantly longer than the latencies for SAMR1 mice, indicating age-related spatial learning and memory impairment for SAMP8 mice. For SAMP8 mice, all the racemic and diastereomeric DCP-LA significantly shortened the acquisition latency and further, racemic, α,α -, and α,β -DCP-LA significantly shortened the retention latency as compared with the latencies for control mice with PEG, although the potentials varied depending upon DCP-LA types. This implies that racemic and diastereomeric DCP-LA could improve age-related learning and memory deterioration. Interestingly, β,β -DCP-LA significantly shortened the acquisition latency still for SAMR1 mice, while it did not affect the retention latency. This suggests that β,β -DCP-LA could enhance learning ability for normal subjects too.

In the open field test, locomotion and rearing activities under the light conditions for SAMP8 mice significantly increased as compared with the activities for SAMR1 mice, indicating higher motor activities for SAMP8 mice. Racemic and diastereomeric DCP-LA had no remarkable effect on locomotion and rearing activities under both the light and dark conditions for SAMP8 and SAMR1 mice. This interprets that improvement of spatial learning and memory disorder for SAMP8 mice induced by racemic and diastereomeric DCP-LA is not due to alterations of motor activities for SAMP8 mice. Moreover, we had earlier confirmed that eyesight for SAMP8 and SAMR1 mice functions normally [7]. This indicates that improvement of spatial learning and memory disorder for SAMP8 mice induced by racemic and diastereomeric DCP-LA is not due to alterations to the eyesight of SAMP8 mice.

In the passive avoidance test, the acquisition and retention latencies for SAMP8 mice was significantly shorter than the latencies for SAMR1 mice, indicating reduced anxiety for SAMP8 mice. Racemic and diastereomeric DCP-LA had no significant effect on the acquisition and retention latencies for SAMP8 mice. This explains that improvement in spatial learning and memory disorder for SAMP8 mice induced by racemic and diastereomeric DCP-LA is not related to alterations in the anxiety behavior of SAMP8 mice.

Gаланthamine, an inhibitor of acetylcholine esterase, is considered to be a promising drug for treatment with Alzheimer's dementia and it is now available clinically for its treatment [12, 13]. No beneficial effect of gаланthamine

on age-related learning and memory impairment, however, was obtained here. In contrast, racemic and diastereomeric DCP-LA significantly shortened the acquisition and retention latencies for SAMP8 mice more than gаланthamine. This suggests that DCP-LA has the potential to ameliorate age-related learning and memory deterioration, with the advantage of efficacy greater than gаланthamine.

The sites of action for DCP-LA are absolutely different to those for gаланthamine. In explanation for the anti-dementia action, gаланthamine increases ACh concentrations in the synaptic cleft by preventing ACh hydrolysis, thereby facilitating cholinergic transmissions, with no selectivity on G protein-linked muscarinic ACh receptors or nicotinic ACh receptors including $\alpha 7$ ACh receptors.

One of the major action sites for DCP-LA is PKC- ϵ , that is enriched in the presynaptic terminals. DCP-LA increases glutamate release from presynaptic terminals by targeting presynaptic $\alpha 7$ ACh receptors through selective activation of PKC- ϵ , leading to a long-lasting facilitation of hippocampal synaptic transmission [1–3, 9]. This could account for DCP-LA-induced improvement of spatial learning and memory disorders in a variety of animal models, as previously shown [6–8], and again in the present study. Surprisingly, racemic and diastereomeric DCP-LA stimulate the release of not only glutamate but dopamine and serotonin in a PKC- and $\alpha 7$ ACh receptor-dependent manner, although the potential varies depending on the DCP-LA types [9]. This raises the possibility that DCP-LA could have beneficial effects on a variety of forms of dementia including Alzheimer disease, neurodegenerative diseases such as Parkinson disease and diffuse Lewy body disease, extrapyramidal disorders, and psychiatric impairments such as depression, panic disorder, and mental irritation, which are caused by a reduction in or a deficiency of dopamine or serotonin. To address these points, we are currently carrying out further behavioral experiments using different animal models.

In conclusion, the results of the present study show that all the racemic and diastereomeric DCP-LA could ameliorate age-related learning and memory decline, with a beneficial efficacy greater than galanthamine.

Abstract This study investigated the effect of two partially hydrolyzed guar gums (PHGG) on fatty acid and sterol excretion. PHGG were obtained by chemical hydrolysis of guar gum (GG) with H₂O:EtOH (1:1) at 100 °C for 1 h (PHGG1) or 2 h (PHGG2). The viscosity of the PHGG in a 1 % (w/v) aqueous solution corresponded to that of a pseudoplastic fluid and was higher for PHGG1 than PHGG2. Guinea pigs ($n = 8$ per group) were fed high fat diets (17/100 g) that contained 12/100 g of cellulose, PHGG1, or PHGG2 for 4 weeks. Despite the differences in viscosity, the two PHGG exerted similar physiological effects. Compared to the control cellulose group, the body weight gain was lower in animals fed PHGG, although no effect on food consumption was observed. PHGG increased the excretion of fatty acids and neutral sterols, but not bile acids. Consumption of PHGG did not alter the fecal fatty acid profile, while intestinal bioconversion of sterols tended to increase in response to PHGG2. A reduction in the viscosity within the range tested did not correlate with losses in the hypocholesterolemic capacity of PHGG as both were effective in reducing plasma cholesterol. Thus, we conclude that the chemical hydrolysis of guar gum renders the gum suitable for inclusion in food products without significantly altering its beneficial health effects.

Introduction

Guar gum (GG) is a natural polysaccharide that consists of a (1 → 4)- α -D-mannopyranose backbone with single units of linked α -D-galactopyranose. Given its hypolipidemic and hypoglycemic effects, this gum is considered one of the most promising water-soluble dietary fibers [1, 2]. There is

strong evidence that GG decreases the incidence of factor risks associated with cardiovascular diseases, such as high levels of plasma triglycerides and cholesterol, mainly LDL-cholesterol [2, 3]. The hypolipidemic effects of this gum are attributed to its capacity to decrease the absorption of dietary fat and cholesterol, reduce bile acid reabsorption in the small intestine, and produce short chain fatty acids by partial fermentation in the cecum [4, 5].

GG is widely known for its water-soluble characteristics and viscosity [4, 6]. In manufactured or processed foods, gums are commonly used as thickeners and emulsifiers. However, the high viscosity of GG may limit its use at physiologically effective concentrations in some food products [7]. Partial hydrolysis has recently been reported to improve the inclusion of this gum in food products and increase consumer acceptance [8]. For instance, Sunfiber® is a PHGG product that is commercially available and has GRAS status (Generally Recognized As Safe) in the USA [7]. The viscosity of enzymatically hydrolyzed GG can be as low as 10 mPa s in a 5 % aqueous solution, while that of commercially available GG is about 2,000–3,000 mPa s in a 1 % aqueous solution [7]. Nevertheless, it has been reported that the health benefits of partially hydrolyzed GG (PHGG) are similar to those of intact GG [7, 9]. Therefore, it has been proposed that the health benefits of PHGG do not appear to be exclusively dependent on its molecular weight or viscosity and that hypolipidemic mechanisms other than viscosity may be involved [8].

Various studies have reported the capacity of dietary fiber to reduce fat absorption. However, dietary fat exerts a range of effects on lipid metabolism depending on its sterol and fatty acid composition [10]. In general, *trans* fatty acids and most saturated fatty acids (SFA) are considered hyperlipidemic. For instance, lauric (C12:0), myristic (C14:0) and palmitic (C16:0) acids increase the plasma concentration of LDL-cholesterol mainly by decreasing the activity of its receptors in the liver [11]. In contrast to SFA, monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) decrease LDL-cholesterol by a series of mechanisms, such as enhancing the hepatic uptake of LDL particles or the activity of 7 α -hydroxylase [12]. To our knowledge, only a few studies have addressed the effect of functional ingredients on the absorption of individual fatty acids. Interestingly, some of these ingredients exert selective fat-binding capacity, thereby affecting plasma and liver lipid profiles [13, 14]. Given all these considerations, the study of the effect of dietary fiber on each fatty acid is relevant.

Here, we examined the effect of chemically hydrolyzed guar gum on lipid excretion in order to provide new insights into its hypolipidemic mechanism. The effect of PHGG on fat excretion was studied longitudinally and an exhaustive analysis of fecal sterols and fatty acids was

conducted to assess the effect of fiber on fat excretion over time. For this purpose, we used the guinea pig as it is widely accepted as a more reliable model of human lipid metabolism than other more commonly used animals, such as mice or rats, and because, in contrast to hamsters, guinea pigs do not ferment fiber in their stomachs [15].

Materials and Methods

Materials

Fatty acid methyl ester (FAME) standards were of 99 % or higher purity. Oleic acid (C18:1n-9), linolenic acid (C18:3n-3) and heneicosanoate acid (C21:0) were purchased from Larodan Fine Chemical AB (Malmö, Sweden). The remaining FAME standards, bile acids, Sylon BTZ (3:2:3, BSA + TMCS + TMSI) and anhydrous pyridine were from Sigma Chemical Co. (St. Louis, MO, USA). Sterol standards were supplied by Steraloids (Newport, Rhode Island, USA).

Sodium methylate 0.5 N was prepared by dissolving 17 g of sodium in 1 L of dry methanol. *N*-hexane and boron trifluoride (20 % in anhydrous methanol) were purchased from Merck (Darmstadt, Germany). Sodium chloride and anhydrous sodium sulfate were from Panreac (Barcelona, Spain) whereas chloroform, cyclohexane, methanol, ethanol and diethyl ether were purchased from Scharlau Chemie S.A. (Sentmenat, Spain). All solvents and reagents were of analytical grade or higher and double distilled water was used throughout the study.

Production of PHGG

PHGG was obtained by chemical hydrolysis of natural GG from *Cyamopsis tetragonoloba*. The hydrolysis was conducted in a reactor vessel with H₂O:EtOH (1:1) at 100 °C, 4 bar and constant magnetic stirring at 700 rpm. GG was added into the pre-warmed reactor at a concentration of 15 % (w/v) and hydrolyzed for either 1 h (PHGG1) or 2 h (PHGG2). After hydrolysis, the reactor vessel was allowed to cool to 50 °C and samples were passed through a filter plate of porosity No. 2 (40–100 μ m, Vidrafoc, S.A., Barcelona, Spain). The residue was subsequently washed twice with 100 mL of EtOH 95 % and allowed to dry for 5 h at 40 °C in a vacuum oven.

Determination of Viscosity and Rheological Properties of PHGG

The viscosity of 1 % aqueous dispersions of PHGG was determined using a First RM Rheometer from Lamy Rheometers (Champagne au Mont d'Or, France). Homogeneous

polymer dispersions were prepared by sprinkling a given amount of product into deionised water at 40 °C with vigorous magnetic stirring (1,000 rpm). After 1 h of incubation, the preparations were sonicated at 40 °C for 10 min and finally allowed to stand at room temperature for 4 h. The viscoelastic properties of the PHGG dispersions were determined in the same day at 25 °C at shear rates ranging from 1 to 250 s⁻¹.

Diets

Three isocaloric diets were obtained by adding experimental fiber sources (12/100 g of diet) to a non-fiber basal diet prepared by Teklan Harlan (Madison, WI, USA) (Table 1). The fiber used for the control group was cellulose (CE) (Teklan Harlan, Madison, WI, USA) while PHGG1 and PHGG2 were used for the experimental

groups. The fat mix content of diets was olive oil/palm-kernel oil/safflower oil (1:2:1.8). Detailed fatty acid and sterol composition of the diets are present in Table 2.

Animals

Female Dunkin-Hartley guinea pigs were supplied by Harlan Interfauna Ibérica (Barcelona, Spain). Animals weighing 300–400 g were randomly assigned to the treatment groups (8 animals/group) after 1 week of acclimation, when all animals were fed with control CE diet. Two guinea pigs were kept per stainless steel cage, which was wire-bottomed to avoid coprophagia. Animals were housed in a room with a controlled light-cycle (light from 0800 to 2000 hours) at 22 ± 1 °C for 4 weeks of treatment. Food and water were consumed ad libitum. Every 48 h, feces were collected, animals weighed and food consumption controlled. Feces were manually cleaned from sawdust contamination, weighed, homogenized, freeze-dried and

stored at -20°C . After isoflurane anesthesia, non-fasted guinea pigs were killed by heart puncture and blood samples were collected in heparinized tubes. Plasma was separated after centrifugation at $1,500\times g$ for 15 min at 4°C and stored at -80°C until analysis. All procedures were approved by the Animal Care and Use Committee of the University of Barcelona.

Determination of Fatty Acid Content in Feces and Diets

Fatty acids (FA) of diets and feces were determined by gas chromatography. FAME were obtained directly from lyophilized samples by *in situ* basic–acidic derivatization as previously described [16]. Heneicosanoate acid (C21:0) was used as the internal standard.

Determination of Neutral Sterols and Bile Acids

Neutral sterols (NS) and bile acids (BA) were extracted as previously described by Keller et al. [17]. 5α -Cholestane and 23-nor-cholic acid were used as internal standards for NS and BA, respectively. Extracts were evaporated at 30°C under nitrogen flux, dried in a vacuum desiccator overnight and stored at -20°C in a nitrogen atmosphere until silanization and injection. Silanization was carried out by dissolving the samples in an appropriate amount of anhydrous pyridine and adding an equal volume of Sylon BTZ. Samples were injected after silanization for 30 min at room temperature.

GC Conditions

The FAME were analyzed using an Agilent 4890D gas chromatograph, equipped with a flame ionization detector (FID). A split–splitless injector was used with a split ratio of 1:30 and the injection volume was $1\ \mu\text{L}$. The injector and detector temperatures were kept at 270 and 300°C , respectively. FAME were separated in a fused-silica capillary column ($60\ \text{m} \times 0.25\ \text{mm i.d.}$, $0.2\ \mu\text{m}$) from Supelco (Bellefonte, PA, USA). The oven temperature was programmed as follows: an initial temperature of 140°C for 3 min, followed by an increase of $6^{\circ}\text{C min}^{-1}$ to 180°C , then $2^{\circ}\text{C min}^{-1}$ to 200°C and $7^{\circ}\text{C min}^{-1}$ to 240°C and it was finally left to stand for 5 min at 240°C . Helium was used as carrier gas and nitrogen as makeup gas to increase the sensitivity of the detector.

NS and BA were analyzed using a Perkin Elmer Auto-system gas chromatograph equipped with a FID. One microliter of sample and a split ratio of 1:12.5 were used for injection. The injector and detector temperatures were kept at 290 and 350°C , respectively. NS and BA were separated with a 5 % polysilarylene–95 % polydimethylsiloxane capillary column ($60\ \text{m} \times 0.25\ \text{mm i.d.}$,

$0.25\ \mu\text{m}$) from Phenomenex (Torrance, CA, USA). Oven temperature was programmed with an initial temperature of 245°C during 30 s, a rate of 5°C until 290° and it was finally left to stand at this temperature for 30 min.

Chromatographic peaks were identified by comparing the retention times with those of known standards and by co-chromatography. FAME, NS and BA were quantified by the internal standard addition method and using calibration curves with $R^2 > 0.99$.

Determination of Plasma Lipids

Total cholesterol, HDL-chol, LDL-chol and triglycerides were enzymatically determined with a Modular DPE Hitachi auto-analyzer from Roche Diagnostics (Mannheim, Germany).

Statistical Analysis

Data were analyzed by SPSS v.17 for Windows. Significant differences between treatments were determined by one-way ANOVA and the exact nature of the differences between groups by Duncan's multirange test. Differences between initial and final values for each treatment were determined by the Student's *t* test after assessing equality of variances by Leven's test. Results are expressed as means \pm standard error (SEM). A confidence coefficient of 95 % was used.

Results

Viscosity Measurements

The flow curves of 1 % PHGG aqueous solutions at shear rates ranging from 1 to $250\ \text{s}^{-1}$ are shown in Fig. 1. Viscosity of solutions at these rates ranged from 2,884 to 184 and from 1,720 to 110 mPa s for PHGG1 and PHGG2, respectively. The flow curves corresponded to pseudo-plastic fluids as the viscosity was dependent on shear rate, being lower at higher rates. The viscosity of PHGG dispersions was not time-dependent and showed neither thixotropic nor rheopectic behavior.

Body Weight and Food Consumption

All animals gained weight during the study, although the gain was significantly lower in the PHGG groups than the control (Table 3). However, food consumption was not affected by dietary fiber. This observation implies that food efficiency was reduced by PHGG ingestion. Food efficiency was slightly lower in animals fed PHGG1 than those on PHGG2, but differences were not statistically significant.

Fig. 1 Rheological measurements of PHGG dispersions. Values of shear stress (τ) at various shear rates are expressed in mPa for partially hydrolyzed guar gum (1-h hydrolysis) (filled circles) and partially hydrolyzed guar gum (2-h hydrolysis) (filled squares) in 1 % aqueous solution. Values of viscosity are expressed in mPa s for partially hydrolyzed guar gum (1-h hydrolysis) (open circles) and partially hydrolyzed (2-h hydrolysis) (open squares)

Fatty Acid Excretion

Fecal dry weight was not significantly altered by PHGG compared to CE during the study (Table 3). In contrast, FA concentration in feces of the PHGG groups was increased compared to the control group (Fig. 2). SFA and UFA concentration in feces were highly increased by PHGG during the first week of treatment. After this time, the concentration in feces tended to stabilize, although a continuous slight increment in SFA concentration in feces of all groups was observed.

Table 4 shows the concentration of fecal FA at the end of the experiment. SFA concentration in feces was higher than that of UFA. The results reveal a higher excretion of SFA, especially palmitic (C16:0) and stearic (C18:0) acids,

than of UFA. The concentration of all SFA was increased by PHGG1 and PHGG2 compared to CE. Among UFA, fecal MUFA were accounted for mainly by oleic acid (C18:1n-9), whereas linoleic acid (C18:2n-6) was the most abundant PUFA. As observed for SFA, the consumption of the PHGG increased the excretion of MUFA and PUFA. As a result, the FA profile as well as the TSFA/TUFA ratio in feces was not altered by PHGG. The same results were observed for the n-6/n-3 PUFA isomer ratio. In general, the effect of PHGG2 on FA excretion was slightly greater than that of PHGG1, although differences were not statistically significant.

NS Excretion

The concentration of fecal NS is shown in Table 5. The overall excretion was increased in all groups after 4 weeks on high fat diets. However, the increment in animals fed either PHGG1 or PHGG2 was higher than that of CE, reaching final values of 16.07 ± 0.41 , 17.98 ± 0.58 and 10.92 ± 0.73 mg of NS per animal and day for PHGG1, PHGG2 and CE, respectively. PHGG consumption increased the excretion of cholesterol, but especially the excretion of its major metabolic products. We calculated the coprostanol/cholesterol and the secondary metabolites of cholesterol/cholesterol ratios in order to assess the effect of experimental fibers on the intestinal bioconversion of cholesterol. No statistical differences for these parameters were found between treatments, although the bioconversion in feces of animals fed PHGG2 was slightly higher. No effect was observed on phytosterol excretion ($P > 0.05$).

BA Excretion

Fecal BA are shown in Table 6. Secondary BA were the most abundant BA in feces and were accounted for mainly by lithocholic acid. Total BA excretion was only slightly

increased by PHGG1 compared to CE and PHGG2. This increase led to augmented chenodeoxycholic and lithocholic acid excretion. However, differences were not statistically significant. The bioconversion of chenodeoxycholic acid to its secondary metabolite lithocholic acid was increased in PHGG groups; however, this increment was statistically significant only for PHGG2 ($P < 0.029$).

Plasma Lipids

Plasma lipids at the end of the experiment are shown in Table 7. Plasma triglycerides were not significantly altered by PHGG compared to CE. In contrast, total plasma cholesterol was lower in PHGG groups, mainly due to a reduction in LDL cholesterol ($P < 0.05$). As a result, the HDL/LDL ratio was improved in animals fed PHGG diets.

Discussion

The physiological beneficial effects of GG are commonly attributed to its water-soluble and high viscosity characteristics [5, 6]. Several studies have reported that the gel-forming properties of GG reduce the rate of gastric emptying and increase satiation. These effects may decrease food consumption—advocated as the main mechanism responsible for a lower weight gain in animals fed GG [6, 18]. The viscosity of fluids is highly dependent on various factors, such as temperature, pH, pressure, shear rate and time. Given these influences, it is difficult to

compare data from studies that have applied distinct methodologies and conditions. It has been proposed that oral perception of fluid viscosity correlates well with the viscosity of the fluid at a shear rate of 10 s⁻¹ [19]. At this rate, the viscosity of PHGG was significantly different, registering 1,285 and 766 mPa s for PHGG1 and PHGG2, respectively. This difference can be attributed to the higher degree of hydrolysis of the latter. However, the viscosity of PHGG obtained by chemical hydrolysis appears to be considerably higher than that of enzymatically hydrolyzed GG, which has been published to be about 10 mPa s in 5 %

aqueous solution [7]. Chemical hydrolysis of GG allowed us to compare the physiological benefits of two PHGG with distinct degrees of viscosity. The rheological experiments

of 1 % PHGG aqueous solutions revealed pseudoplastic (shear-thinning) behavior. Previous studies have reported similar findings for aqueous solutions of GG [20].

In our study, both PHGG reduced body weight gain to a similar extent. However, this decrease was not correlated with changes in food consumption, which is consistent with the findings of other studies [18]. A reduction in the absorption of nutrients and thus the calories they provide can be partially responsible for the lower food efficiency of diets containing PHGG.

In good agreement with previous reports, fat excretion was increased by ingestion of PHGG [21]. The longitudinal study of PHGG consumption reveals that the effect occurred from the beginning of the treatment and stabilized after 1 week. Therefore, no accumulative effect was observed after the first week.

As previously reported [13], the concentrations of medium and long chain SFA in feces, especially C16:0 and C18:0, were higher when compared to its concentration in diets. This finding is mainly attributed to the low digestibility of these FA [22]. The FA profile in feces was not altered by PHGG consumption in a similar way to other dietary fibers such as pectin [23] and in contrast to others such as hydroxypropyl methylcellulose [14].

Another hypocholesterolemic property commonly attributed to soluble dietary fiber is its capacity to increase the excretion of BA and endogenous and exogenous cholesterol. In vitro [8] and in vivo studies [24] have shown that PHGG conserves the capacity of the native GG to increase cholesterol excretion. In our study, NS excretion was greater after consumption of PHGG, mainly as a result of an increment in cholesterol metabolites such as coprostanol and cholestanol. Thus, the bioconversion of cholesterol tended to increase in animals ingesting PHGG2. Although it is widely accepted that GG increases BA excretion, thus decreasing its reabsorption [24, 25], controversial results have been reported for PHGG. Our results are consistent with the findings of Favier et al. [21], who reported that total BA excretion was not significantly altered by PHGG ingestion. However, as seen for NS, the consumption of PHGG2 increased the bioconversion of primary BA to their secondary metabolites. Similar results on BA bioconversion were observed by Gallaher et al. [26], who reported that the lithocholic/chenodeoxycholic ratio in feces of hamsters fed low viscosity GG was higher than that of animals on native GG. However, that study was performed in hamsters, which partially ferment GG in the pregastric pouch of the stomach [26] and have a distinct BA profile in feces to that of guinea pigs [27]. Our results show that this effect is also present in guinea pigs, a more suitable model for the study of lipid metabolism. GG and PHGG are partially fermented in the intestine, thus favoring increased endogenous bacterial population and activity

[28, 29]. For instance, the growth of intestinal bacteria such *Lactobacillus* spp. and *Bifidobacterium* spp. is enhanced in humans after PHGG consumption [30]. Hence, an increase in bacterial activity may result in greater sterol bioconversion. The lower viscosity of PHGG2 could explain its higher pre-biotic effect as it favors interaction with intestinal microbiota.

Based on these results, the increase in NS excretion appears to be one of the main mechanisms responsible for the lower total plasma cholesterol in animals fed PHGG diets. In addition, it is plausible that the fermentability of PHGG can contribute to its hypocholesterolemic effect due to the production of short chain fatty acids, mainly propionate, which can decrease the endogenous synthesis of cholesterol [29, 31].

On balance, within the degree of hydrolysis tested, a reduction in the viscosity of PHGG did not correlate with a loss of hypolipidemic capacity. Current evidence indicates that consumption of viscous fibers such as GG can alter the viscosity of digesta in the gastrointestinal tract and thereby decrease the bioaccessibility of fat and cholesterol [6, 26, 32]. Nevertheless, it remains questionable whether alterations on in vitro viscosity may result in proportional physiological responses [32, 33]. For instance, Gallaher et al. [32] observed that although only small increments in viscosity were necessary to decrease plasma cholesterol, further increments did not result in larger reductions of plasma cholesterol. In addition, it has been suggested that other mechanisms not attributed to viscosity can be complementarily responsible for the hypolipidemic effect of PHGG. The bioaccessibility of fat and cholesterol was previously studied by Minekus et al. [8] using a dynamic model of the gastrointestinal tract. The authors concluded that PHGG can also reduce lipid absorption by a depletion-flocculation mechanism, which is typical of polymers that do not show surface activity. Since the polysaccharide does not adsorb to the fat droplets, this can result in a region around the droplet where the concentration of the polysaccharide is lower than in the bulk solution. This phenomenon could cause an osmotic pressure that would favor the fat droplets flocculating and coalescing. As a result, it may reduce the emulsifying effect of bile acids and therefore the bioaccessibility of fat and cholesterol.

In conclusion, both PHGG reduced body weight gain and plasma cholesterol, regardless of their in vitro viscosity within the ranges tested. Thus, the chemical hydrolysis can improve the suitability of GG for use in food products without affecting their rheology or palatability and conserving most of its hypolipidemic properties.

Abstract (8*R*)-Hydroperoxy-(9*Z*,12*Z*)-octadecadienoic acid (8-HPODE) is formed by aspergilli as an intermediate in biosynthesis of oxylipins with effects on sporulation. 8-HPODE is transformed by separate diol synthases to (5*S*,8*R*)-dihydroxy- and (8*R*,11*S*)-dihydroxy-(9*Z*,12*Z*)-octadecadienoic acids (5,8- and 8,11-DiHODE). The former is formed by the cytochrome P450 (P450) domain of 5,8-linoleate diol synthase (5,8-LDS or PpoA). Our aim was to characterize the 8,11-diol synthase of *Aspergillus fumigatus*, which is prominent in many strains. The 8,11-diol synthase was soluble and had a larger molecular size (>100 kDa) than most P450. Miconazole, ketoconazole, and 1-benzylimidazole, classical inhibitors of P450, reduced the biosynthesis of 8,11-DiHODE from 8-HPODE (apparent IC₅₀ values ~0.8, ~5, and ~0.6 μM, respectively), but did not inhibit the biosynthesis of 5,8-DiHODE. Analysis of hydroperoxides of regioisomeric C₁₈ and C₂₀ fatty acids showed that the 8,11-diol synthase was specific for certain hydroperoxides with *R* configuration. The suprafacial hydrogen abstraction and oxygen insertion at C-11 of 8-HPODE was associated with a small deuterium kinetic isotope effect ($^Hk_{\text{cat}}/^Dk_{\text{cat}} \sim 1.5$), consistent with P450-catalyzed oxidation. The genome of *A. fumigatus* contains over 70 P450 sequences. The reaction mechanism, size, and solubility of 8,11-diol synthase pointed to PpoB, a homologue of 5,8-LDS, as a possible candidate of this activity. Gene deletion of *ppoB* of *A. fumigatus* strains

AF:Δku80 and J272 did not inhibit biosynthesis of 8,11-DiHODE and recombinant PpoB appeared to lack diol synthase activity. We conclude that 8,11-DiHODE is formed from 8-HPODE by a soluble and substrate-specific 8,11-diol synthase with catalytic characteristics of class III P450.

Introduction

Unsaturated fatty acids can be oxidized to biological mediators in fungi as well as in plants and animals, and some of them are formed by homologous enzymes [1–3]. The animal heme peroxidase gene family contains members which oxidize fatty acids to hydroperoxides, as the

first event in a chain of further transformations. The prototypes are cyclooxygenase-1 and -2 of animals, but the pathogen induced α -dioxygenase (α -DOX) of plants, 7,8-linoleate diol synthase (7,8-LDS) of the Take-all fungus, and psi-producing oxygenase A (PpoA) and C (PpoC) of aspergilli belong to this group [4–8], and possibly also psi producing oxygenase B (PpoB) [7–9].

The biological significance of fungal oxylipins was discovered by Champe et al. [10], who found that oxygenated metabolites of linoleic acid induced premature sexual sporulation of *Aspergillus nidulans*. These hormones were designated precocious sexual inducers (psi), and two were identified as (8*R*)-hydroxy-(9*Z*,12*Z*)-octadecadienoic acid (8-HPODE) and 5*S*,8*R*-dihydroxy-(9*Z*,12*Z*)-octadecadienoic acid (5,8-DiHODE) [10, 11]. The list of fungal oxylipins has since been expanded to include hydroperoxy C_{18} fatty acids, epoxy alcohols, aldehydes, and allene oxides [1, 2, 12, 13].

The fatty acid heme-dioxygenases have a common reaction mechanism, which is based on oxidation of their heme iron with formation of a tyrosyl radical [4, 6, 14, 15]. The substrates and products differ. Cyclooxygenases convert arachidonic acid via an 11-peroxyl radical intermediate to prostaglandin endoperoxides, α -DOX oxidizes a wide range of fatty acids to unstable (2*R*)-hydroperoxy metabolites, whereas 7,8-LDS oxidizes linoleic acid sequentially to 8-HPODE and (7*S*,8*S*)-dihydroxy-(9*Z*,12*Z*)-octadecadienoic acid (7,8-DiHODE) [4, 6, 16]. The latter is formed by the diol synthase of the C-terminal P450 domain of 7,8-LDS [17], which is a member of the class III P450 [17–19].

Cloning and characterization of 7,8-LDS contributed to the discovery of three related proteins of aspergilli, viz., PpoA (also designated 5,8-LDS), PpoB, and PpoC (also designated 10*R*-DOX) [7, 8, 12, 20, 21]. 5,8-LDS forms two of the psi factors described by Champe and colleagues above [12, 20], whereas 10*R*-DOX oxidizes 18:2*n*-6 to 10*R*-hydroperoxy-(8*E*,12*Z*)-octadecadienoic acid (10*R*-HPODE) and 18:1*n*-9 to 8*R*-hydroperoxy-(9*Z*)-octadecadienoic acid (8-HPOME) [12, 22]. 5,8-LDS and 10*R*-DOX have been characterized from *A. nidulans* and *A. fumigatus* by gene deletion and expression [12, 17, 19, 22, 23]. Some aspergilli biosynthesize (8*R*,11*S*)-dihydroxy-(9*Z*,12*Z*)-octadecadienoic acid (8,11-DiHODE) from 8-HPODE [9, 12, 24] and this metabolite is not formed by recombinant 5,8-LDS or 10*R*-DOX. PpoB could possibly be related to biosynthesis of 8,11-DiHODE, at least in some aspergilli. The deduced PpoB protein sequences form a relatively heterogeneous group and the function of PpoB may therefore differ between aspergilli (Supplemental data, Fig. S1).

8,11-DiHODE was first identified in the fungus *Lepidotomitus lacteus* [25]. Enzymes in lamellae of the field mushroom and mycelia of some filamentous fungi were

later found to transform 8-HPODE to 8,11-DiHODE [9, 12, 24, 26, 27]. These investigations showed that 8,11-DiHODE is formed from 8-HPODE in analogy with the intramolecular formation of 5,8-DiHODE [12], as outlined in Fig. 1. The biological function of 8,11-DiHODE in aspergilli has been difficult to evaluate, as we lack information on the 8,11-diol synthase and its gene. 8,11-DiHODE could have effects on sporulation in analogy with the psi factors of *A. nidulans*.

Biosynthesis of 8,11-DiHODE was observed in *A. fumigatus* Fresen., but significant biosynthesis was not detected in the sequenced *A. fumigatus* strain AF293 [12]. Our first objective was to determine whether 8,11-DiHODE biosynthesis occurred in *A. fumigatus* A1163, the second sequenced strain [28], or in other isolates. The second objective was to investigate the biochemical properties of the 8,11-diol synthase of *A. fumigatus* and establish its characteristics in relation to class III P450, which do not require an electron donor [18]. We therefore partly purified the 8,11-diol synthase activity, studied its substrate specificity, oxygenation mechanism, and effects of P450 inhibitors. The third objective was to investigate whether it was possible to link the biosynthesis of 8,11-DiHODE to a specific P450 out of over 70 P450 sequences in the genome. *ppoB* seemed to be a promising gene candidate as discussed above. *ppoB* has been subject to gene deletion, but unfortunately only in *A. nidulans* and *A. fumigatus* AF293, which lack significant capacity to form 8,11-DiHODE [7, 12]. We therefore decided to express recombinant PpoB and to disrupt *ppoB* in strains of *A. fumigatus* with prominent

Fig. 1 Overview of the isomerization of 8*R*-HPODE to 5*S*,8*R*- and 8*R*,11*S*-DiHODE

8,11-diol synthase activity, and we chose to use *Agrobacterium tumefaciens*-mediated transformation [27, 29].

Materials and Methods

Materials

Fatty acids (99 %) and [U-¹³C]18:2n-6 (98 %) were from Merck, Sigma, and Larodan, and stored at 50–100 mM in ethanol (−20 °C). 8*R*-HPODE and [U-¹³C]8*R*-HPODE were prepared by biosynthesis [17], purified by TLC [5], and the integrity was confirmed by LC–MS/MS analysis. 8*S*-HPOME and 11-hydroperoxyocta-(9*Z*)-decenoic (11-HPOME) acids were obtained by autooxidation of 18:1n-9, and purified by NP-HPLC and CP-HPLC [30]. 13-Hydroperoxyoctadeca-(9*Z*,11*E*)-dienoic acid (13-HPODE) and 13-hydroperoxyoctadeca-(9*Z*,11*E*,12*Z*)-trienoic acid (13-HPOTrE) were obtained by biosynthesis and used as internal standards [31]. [11*S*-²H]18:2n-6 (>98 %) and [11,11-²H₂]18:2n-6 (>98 %) were a generous gift of Dr. Hamberg, Karolinska Institutet. Chemically competent *Escherichia coli* (Top10), mouse anti-V5-epitope antibody, Superscript III Kit, hygromycin B, InsectSelect System with pIZ/V5-His, Cellfectin, and phleomycin (Zeocin) were from Invitrogen. Restriction enzymes were from New England BioLabs and Fermentas. Plasmid Midi kit, and QIAquick gel extraction kit were from Qiagen. *Pfu* DNA polymerase and CloneJet PCR cloning kit were from Fermentas. Phusion and Phire DNA Polymerases were from Finnzymes. ECL Advance Western Blotting Detection kit, dNTPs, and horseradish peroxidase labeled anti-mouse IgG antibodies were from GE Healthcare. pGEM7Zf+ was from Promega. pCambia0380 was obtained from CAMBIA (Canberra, Australia). Cefotaxime, RNaseA, ampicillin, kanamycin, 3,5-dimethoxy-4-hydroxyacetophenone, 1-benzylimidazole, ozagrel, fluconazole, ketoconazole, miconazole, troleandomycine, α -naphthoflavone, sulfaphenazole, metyrapone and voriconazole were from Sigma-Aldrich. Ex-Cell 420 insect serum free medium was purchased from SAFC-Biosciences (Hampshire, United Kingdom). Gentamycin sulfate and *Spodoptera frugiperda* (Sf21) cells were obtained locally. Primers were obtained from Cybergene (Huddinge, Sweden). Sequencing was performed at Uppsala Genomic Center (Rudbeck Laboratories, Uppsala University). *Agrobacterium tumefaciens* (strain AGL-1) was kindly supplied by Dr. Sesma (Centre for Plant Biotechnology and Genomics, Madrid, Spain). *A. fumigatus* strains pyrG⁺AF::Delta ku80 (AF:Δku80) and A1163 were from Fungal Genetics Stock Center (FGSC#1151 and FGSC#1163). J272 (CBS 287.95) was a kind gift from Dr. Melin (SLU, Uppsala, Sweden), and

H237 was obtained locally. 7,8-LDS was prepared from mycelium of *Magnaporthe oryzae* as described [27].

Fungal Growth

A. fumigatus strains were grown in malt extract medium, usually for 1–3 days at 37 °C followed by 2–5 days at room temperature under cycles of 8 h in dark and 16 h in fluorescent light (True-light). Mycelia were harvested by filtration through one layer of Miracloth (Calbiochem), and washed with saline. Mycelia were ground into a fine powder in liquid nitrogen, and stored at −80 °C. The nitrogen powder was homogenized (glass-Teflon, 10 passes; +4 °C) in 10 vols. (w/v) of 0.1 mM KHPO₄ (pH 7.3)/2 mM EDTA/0.04 % Tween-20, centrifuged at 13,000×g (2 min, +4 °C). The supernatant was designated nitrogen powder homogenate and used immediately for enzyme assays (biosynthesis of products, test of stability, effects of drugs) and for further purification.

Enzyme Assays

Recombinant PpoB or nitrogen powder homogenate was incubated with 100 μM of unsaturated fatty acid for 40 min on ice, or with 2 μM [U-¹³C]8-HPODE. The reaction (0.3–0.5 ml) was terminated with ethanol (4 vols.), an internal standard (13-HODE) was added in some experiments, and proteins were precipitated by centrifugation. The metabolites were extracted on octadecyl silica (SepPak/C₁₈), eluted with ethyl acetate, evaporated to dryness, and dissolved in 40–50 μl of 75 or 100 % methanol; 5–10 μl was subject to LC–MS/MS analysis. 50–100 μM 18:1n-7, 8*S*- and 11-HPOME were incubated in the same way. The kinetic isotope effect was assayed with 100 μM unlabeled and deuterated linoleic acids ([11*S*-²H]18:2n-6 or [11,11-²H₂]18:2n-6) in separate incubations in triplicate (20 min, +4 °C). After termination, 13*R*-HOTrE was added an internal standard, and the metabolites were extracted and analyzed as above.

Gel Filtration of 8,11-Diol Synthase

The subcellular localization of the 8,11-diol synthase activity (along with the 5,8-diol synthase activity) was determined by differential centrifugation (10,000×g, 15 min; 100,000×g, 60 min; +4 °C) and assayed with [U-¹³C]18:2n-6 as a substrate. The stability of the diol synthase activities at +4 °C were determined with [U-¹³C]8-HPODE as a substrate, and compared with the stability of 8-DOX with [U-¹³C]18:2n-6 as substrate.

Purification of the 8,11-linoleate diol synthase activity was achieved by homogenization (glass-Teflon, 10 passes;

+4 °C) of nitrogen powder in 10 vols. (w/v) of 0.05 mM KHPO₄ buffer (pH 7.35)/0.04 % Tween-20. The homogenate was clarified by centrifugation at 13,000×g (10 min, +4 °C), and the supernatant was filtered and centrifuged (55,000×g, 35 min; +4 °C). The supernatant was loaded onto a Q-Sepharose column (column volume (CV) 12 ml) at a flow-rate of 1 ml/min (ÄKTA FPLC system, GE Healthcare). The column was washed with three CVs 0.05 mM KHPO₄ buffer (pH 7.35)/0.04 % Tween-20 and the protein was subsequently eluted by step-wise increase in the concentration of NaCl (0.25 M, 1 CV; 0.5 M, 1 CV; 0.75 M, 1 CV; 1 M, 3 CV).

Fractions with enzyme activity converting 8-HPODE to 8,11-DiHODE were pooled, and the volume was reduced by ultrafiltration (Amicon Ultracel, 30 kDa) and washed with 0.05 mM KHPO₄ buffer (pH 7.35)/150 mM NaCl/0.04 % Tween-20. The concentrate was separated by size-exclusion chromatography (Superdex 200 HR 10/30, GE Healthcare) with a flow-rate of 0.4 ml/min. 1 ml fractions were analyzed for enzyme activity using [U-¹³C]8-HPODE as a substrate.

Effects of P450 Inhibitors on the Diol Synthase Activities

The effect of a series of P450 inhibitors on the 5,8- and 8,11-diol synthase activities of *A. fumigatus* AF:Δku80 was investigated in triplicate by LC–MS/MS analysis. Miconazole, fluconazole, voriconazole, ketoconazole, ozagrel, 1-benzylimidazole, troleandomycine, α-naphthoflavone, sulfaphenazole, or metyrapone was added to an aliquot of nitrogen powder homogenate in concentrations ranging from 0.3 to 100 μM. The reactions were started by the addition of 100 μM [U-¹³C]18:2n-6, proceeded for 40 min on ice, and were terminated with 4 vols. of ethanol containing the internal standard (13-HODE). The metabolites were extracted as described above. The inhibitory effects of these substances were assessed by LC–MS/MS analysis of the carboxylate anions with monitoring of the ratios of the specific fragment ions (*m/z* 329→224 for [U-¹³C]8,11-DiHODE; *m/z* 329→120 for [U-¹³C]5,8-DiHODE, *m/z* 313→165 for [U-¹³C]8-HODE; and *m/z* 313→193 for [U-¹³C]10-HODE) and the internal standard, 13-HODE (*m/z* 295→195). The inhibition of the 8,11-diol synthase activity was also confirmed with 2 μM [U-¹³C]8-HPODE as a substrate.

Cloning of *ppoB* and Expression in Insect Cells

Total RNA was isolated from nitrogen powder of *A. fumigatus* J272 [22]. The full length cDNA was obtained by PCR technology and cloned into pIZ/V5-His expression vector using KpnI/XbaI generating pIZ_ppoB, with primers listed in the Supplementary data (Table S1).

Plasmid-driven expression was performed by transfection of *Sf21* cells with pIZ_ppoB or pIZ/V5-His_ppoB and Cellfectin as described [32]. Cells were harvested after 48 h, suspended in lysis buffer (50 mM KHPO₄ (pH 7.4)/1 mM EDTA/1 mM GSH/5 % glycerol/0.04 % Tween-20) and sonicated (Branson sonifier cell disrupter B15, max. power 20 %, 3 × 5 s pulses; +4 °C). The cell debris was spun down (15,000×g, 30 min; +4 °C) and the supernatant was used for enzyme assay.

Gene Deletion of *ppoB* and PCR Analysis of Fungal Transformants

Two separate constructs for gene deletion of *ppoB* were prepared in pCambia0380 (Fig. 2). In the first construct, nucleotides 1,247–1,938 of *ppoB*, which include the catalytically important tyrosine residue for hydrogen abstraction, was replaced with a 1,424-bp hygromycin B resistance cassette under the control of the TrpC promoter of *A. nidulans*. The cassette was flanked by sequences of 1,324-bp (upstream) and 1,098-bp (downstream) to ensure homologous recombination and targeted insertion. These flanking sequences were obtained by PCR technology from genomic DNA of *A. fumigatus* by using primers Afum_F-5'-reg/Afum_R-5'-reg and Afum_F-3'-reg/Afum_R-3'-reg, respectively (Table S1). This construct was designated pCAMB_Δ*ppoB*(1). In the second construct, pCAMB_Δ*ppoB*(2), nucleotides 1247–3724 of *ppoB* was replaced with the TrpC/*hph* cassette, flanked by the same upstream sequence as above, and a new downstream sequence

Fig. 2 Overview of two constructs used for deletion of *ppoB*. **a** The construct AfΔ*ppoB*(1) replaced the DOX domain with a hygromycin B cassette under the control of the TrpC promoter of *A. nidulans* (TrpC/*hph* cassette). **b** The construct AfΔ*ppoB*(2) replaced both the DOX and the P450 domains with the hygromycin B cassette and the TrpC promoter

(1,374-bp), amplified using primers Afum_F-3'-2 and Afum_R-3'-2. This ensured that both the DOX domain and the heme binding region of the P450 domain were deleted (Fig. 2).

Fungal conidia were prepared from 8 to 12-days-old mycelia grown on *Aspergillus* minimal medium [33] at 22 °C under 16 h light/8 h dark cycles of fluorescent light (True-light). Conidia were harvested with 4 ml distilled water using a glass spreader and were filtered through Miracloth. Competent *A. tumefaciens* containing either the pCAMB_Δ*ppoB*(1) or Δ*ppoB*(2) constructs were used to transform obtained *A. fumigatus* J272 or AF:Δ*ku80*, respectively, according to Sugui et al. [29] with minor modifications. *Aspergillus* minimal medium agar plates were used, supplemented with 250 μg/ml hygromycin B to select transformed conidia, and 200 μM cefotaxime to eliminate *A. tumefaciens*.

Fungal genomic DNA was prepared by incubating nitrogen powder in an equal amount of extraction buffer (200 mM Tris/HCl (pH 8.5)/250 mM NaCl/25 mM EDTA/0.5 % SDS) at 70 °C for 30 min. Samples were centrifuged, and the supernatant treated with RNaseA, extracted with phenol and chloroform. Genomic DNA was precipitated with isopropanol, collected by centrifugation, and re-suspended in deionized water. Three primer pairs were used to distinguish whether the transformants were the result of homologous recombination with deletion of the *ppoB* gene (Table S1). Primers F-*hph* and R-*hph*, which amplified 971-bp from the *hph* gene, were used for initial screening and were positive in all transformants. Primers F-Δ*ppoB*-Af and R-Δ*ppoB*-Af amplified a fragment of 1,775-bp from transformants resulting from targeted transformation, while F-Δ*ppoB2*-Af and R-Δ*ppoB2*-Af amplified 1,708-bp. These primer pairs would generate different amplicons, or no amplicons at all, in ectopic transformants without simultaneous targeted disruption of *ppoB*. Primers Δ*ppoB*-Af and R-Af-*ppoB*-wt generated amplicons of 1,845-bp from strains containing an intact *ppoB*. Primers F-Δ*ppoB*-Af and R-Δ*ppoB2*-Af amplified a 6,455-bp fragment covering the entire genomic insert, which was subsequently sequenced.

LC/MS Analysis

Reversed phase-HPLC (RP-HPLC) with MS/MS analysis was performed on an octadecyl silica column (5 μm; 2 × 150 mm with a guard cartridge 2 × 4 mm; Phenomenex), which was usually eluted with methanol/water/acetic acid, 800/200/0.05, at 0.3 ml/min, with aid of Surveyor MS pump (ThermoFisher). The effluent was subject to electrospray ionization in a linear ion trap mass spectrometer (LTQ, ThermoFisher). The heated transfer capillary was set at 315 °C, the ion isolation width at 1.5, the collision energy at 50 (arbitrary scale), and the tube lens at

90–130 V. Prostaglandin $F_{1\alpha}$ was infused for tuning. Data were analyzed by the Xcalibur software.

Results

Biosynthesis of 8,11-DiHODE by Strains of *A. fumigatus*

All eight strains of *A. fumigatus* except AF293 oxygenated linoleic acid to significant amounts of 8,11-DiHODE, and all strains formed 5,8-DiHODE (Table 1). The oxygenase activities varied between preparations of the same strain. This made comparison between strains difficult, but we could not find any major differences between the strains (except AF293).

The genomes of AF293 and A1163 have been sequenced [34]. The latter oxidized linoleic acid to 8,11-DiHODE (Fig. 3). This was the only noticeable difference, as both AF293 and A1163 formed 5,8-DiHODE, 8-HODE, and 10-HODE (cf. [12]). We found that growing mycelia of A1163 in a liquid medium at room temperature for a few days yielded pronounced expression of the 8,11-diol synthase activity, as 8,11-DiHODE was often formed as the main metabolite (Fig. 3).

The 8,11-Diol Synthase Activity

As endogenous linoleic acid was oxidized during enzyme preparation, we used [U-¹³C]-labeled substrates. We found that ~90 % of the 8,11-diol synthase activity was present in the cytosolic fraction after differential centrifugation with only ~10 % associated with the microsomal pellet.

We next examined the stability of the 8,11-diol synthase and the 8-DOX and 5,8-diol synthase activities. The 8-DOX activity decreased rapidly and was absent after

– Not detected; + 8,11-DiHODE was formed as a major metabolite

Fig. 3 RP-HPLC–MS/MS analysis of products formed from linoleic acid by *A. fumigatus* A1163. The metabolites were formed by nitrogen powder preparation of mycelia. Peak I, 8,11-DiHODE; peak II, 5,8-DiHODE; peak III contained a mixture of 8- and 10-HODE

24 h on ice as judged from incubations with $[U-^{13}C]18:2n-6$, whereas the 5,8- and 8,11-diol synthase activities with $[U-^{13}C]8\text{-HPODE}$ as substrate appeared to be unaffected. After 72 h on ice, the 5,8-diol synthase activity was lost, while most of the 8,11-diol synthase activity remained.

Substrate specificities of the 8-DOX and the 5,8- and 8,11-diol synthase activities of *A. fumigatus* Fresen have been described previously [12], but we extended the substrate specificities as follows. We found that 18:1n-7 (vacenic acid) was oxidized to 10-HPOME by the AF: $\Delta ku80$ strain and isomerized to 10,13-DiHOME. In contrast to 8*R*-HPOME, we found that 8*S*-HPOME and 11-HPOME were not transformed to 8,11-DiHOME, which demonstrates the substrate specificity of the 8,11-diol synthase.

We compared the rate of oxidation of 18:2n-6, $[11S-^2H]18:2n-6$, and $[11,11-^2H_2]18:2n-6$ to 8,11-DiHODE by nitrogen powder of *A. fumigatus*. The deuterium label at position 11*S* is abstracted in the transformation to 8,11-DiHODE (Fig. 1). With aid of an internal standard, we found by LC–MS analysis of the molecular ions that the primary deuterium kinetic isotope effect was small ($^Hk_{cat}/^Dk_{cat} \sim 1.5$) and the secondary kinetic isotope effect was insignificant. This is in agreement with the non-competitive deuterium kinetic isotope effects of CYP3A4 and the 5,8-diol synthase of PpoA of *A. nidulans* [35, 36].

Effects of P450 Inhibitors on 8,11- and 5,8-Diol Synthase Activities

1-Benzylimidazole, miconazole, ketoconazole, and ozagrel reduced the biosynthesis of $[U-^{13}C]8,11\text{-DiHODE}$ from $[U-^{13}C]18:2n-6$ at μM concentrations. The inhibitory actions of the drugs were confirmed with 2 μM $[U-^{13}C]$

8-HPODE as substrate. The apparent IC_{50} values were ~ 0.6 , ~ 0.8 , ~ 5 , and ~ 30 μM , respectively. The dose-dependent reduction of 8,11-DiHODE biosynthesis by miconazole is shown in Fig. 4. Two related drugs, voriconazole and fluconazole, which lack the imidazole moiety, appeared to be considerably less active ($<20\%$ inhibition at 100 μM). Several drugs did not inhibit the oxygenation of linoleic acid to 5,8- and 8,11-diols by *A. fumigatus* at 100 μM concentrations (metyrapone, sulfaphenazole, alfa-naphthoflavone, and troleandomycin).

In contrast, the biosynthesis of 5,8-DiHODE and 8-H(P)ODE by 5,8-LDS and 10-H(P)ODE by 10*R*-DOX appeared to be largely unaffected by 100 μM of the six inhibitory drugs discussed above. For example, the ratio of $[U-^{13}C]5,8\text{-DiHODE}/[U-^{13}C]8\text{-HODE}$ formed in the presence of 100 μM of a potent inhibitor of 8,11-diol synthase, miconazole, was only 10 % lower than in the controls. We confirmed that these drugs did not reduce the 8-DOX and 7,8-diol synthase activities of 7,8-LDS of *M. oryzae*, suggesting that the potent inhibition by imidazole derivatives could be specific for the 8,11-diol synthase.

Gel Filtration of the 8,11-Diol Synthase Activity

The 8,11- and 5,8-diol synthase activities were followed during anion-exchange chromatography (Q-Sepharose; Fig. 5a). Fractions with detectable diol synthase activities (LC–MS analysis) were combined and reduced to ~ 200 μl by ultrafiltration; an aliquot isomerized $[U-^{13}C]HPODE$ readily to $\sim 80\%$ 8,11-DiHODE and $\sim 20\%$ 5,8-DiHODE. The concentrate was analyzed by gel filtration (Superdex 200 HR) and fractions were assayed for biosynthesis of 8,11-DiHODE. Low 8,11-DiHODE biosynthesis

Fig. 4 Inhibition of 8,11-DiHODE biosynthesis in *A. fumigatus* by miconazole. All incubations of subcellular fractions of strain AF: $\Delta ku80$ were conducted in triplicates with $[U-^{13}C]$ linoleic acid as substrate, corrected for the recovery of the internal standard (13-HODE), and are presented as mean values $\pm SD$ ($n = 3$). Relative activity refers to formation of $[U-^{13}C]8,11\text{-DiHODE}$ without miconazole. The biosynthesis of $[U-^{13}C]8\text{-HPODE}$ was not influenced by the miconazole. The insert shows the structure of miconazole

Fig. 5 Purification of the linoleate diol synthase activities of *A. fumigatus*. **a** Anion-exchange chromatography (Q-Sepharose) of material from AF: Δ ku80. Active fractions (hatched) were combined, concentrated, and analysed for biosynthesis of diols from 8-HPODE. The inset shows that 8,11-DiHODE (black) and 5,8-DiHODE (white) were formed in a ratio of 4:1. **b** Gel filtration. The material from anion-exchange chromatography in **a** was separated by gel filtration (Superdex 200HR), and fractions between the horizontal lines were analyzed for diol synthase activities. The elution volumes of γ -globulin (~156 kDa) and BSA (~67 kDa) are indicated by arrows. **c** Assay of diol synthase activities. The fractions between the vertical lines in **b** and **c** were assayed for diol synthase activities, and the formation of 8,11-DiHODE (black) and 5,8-DiHODE (white), relative to the peak fraction at 12 min, is indicated by the bars

Table 2 Differences in the deduced protein sequences of PpoB of *A. fumigatus* AF293, A1163, and J272. The PpoB of the latter was expressed in this study

| Amino acid position | AF293 | A1163 | J272 |
|---------------------|-------|-------|------|
| 229 | Ala | Pro | Pro |
| 244 | Ile | Val | Ile |
| 663 | Pro | Ala | Pro |
| 1059 | Thr | Ala | Thr |
| 1104 | Ser | Pro | Pro |

GenBank ID: AF293, XP_746438; A1163, EDP47075; J272, HQ832882

was evident in the front fractions, but peak 8,11-DiHODE biosynthesis was noted between 12 and 13 ml with approximately the same elution volume as γ -globulin (~156 kDa, Fig. 5b). Peak 5,8-DiHODE biosynthesis was present at 11–12 ml, suggesting that 5,8-LDS (~120 kDa) mainly eluted as a monomer or dimer. Gel filtration demonstrated that the 8,11- and 5,8-diol synthase activities partly overlapped on this column.

Cloning and Expression of ppoB

With RT-PCR we obtained the full-length cDNA of *ppoB* from J272 (GenBank ID: HQ832882). We found that the intron–exon borders of *ppoB* of J272 were as predicted for *ppoB* of the two sequenced strains, AF293 and A1163. The deduced protein sequence of this PpoB differed at two positions from the PpoB of strain AF293 and three positions from PpoB of strain A1163 (Table 2). Inspection of the J272 sequence shows these replacements were not unique, but PpoB of AF293 differed at two positions (Ala229 and Ser1004) from both of the other two PpoB sequences.

We confirmed that PpoB was expressed in insect cells by Western blot analysis of the V5 epitope, as shown in Fig. 6. We next examined recombinant PpoB for enzymatic activity. We incubated recombinant PpoB expressed in insect cells with linoleic acid, α -linolenic acid, and oleic acid, but we could not detect significant formation of hydroxy- or hydroperoxy metabolites. Attempts to detect diol synthase activities with 8-HPODE as a substrate were also unsuccessful. Recombinant protein expression can give inactive enzymes as expression artefacts, although the insect expression system has worked well for this class of enzymes, e.g., recombinant LDS (*A. fumigatus* [17], *M. oryzae*,¹ and *Gaeumannomyces graminis* [17]) and 10R-DOX (*A. fumigatus* [22]). We therefore decided to delete *ppoB* as this could provide unequivocal information on its relation to 8,11-diol synthase.

¹ Jernerén F., unpublished observation.

Fig. 6 Western blot analysis of PpoB expressed in insect cells. The detected band corresponds approximately to the expected size of ppoB (~133 kDa). An anti-V5 antibody was used for detection, and the markers of the protein ladder are indicated

Gene Deletion of *ppoB*

Gene deletion was performed with two constructs, AfΔ*ppoB*(1) and AfΔ*ppoB*(2), as summarized in Fig. 2. This yielded two gene deletion strains (J272Δ*ppoB* and AF:Δ*ku80*Δ*ppoB*, respectively; Table 1). We confirmed homologous recombination with PCR technology, as illustrated for the largest deletion construct in Fig. 7. In addition, a PCR-fragment, covering the entire genomic insert, was amplified from genomic DNA of a transformant. The targeted insertion of the construct was verified by sequencing of this PCR product.

Incubation of the two Δ*ppoB* strains with linoleic acid consistently showed that the 8,11-diol synthase activity was unaffected, and so were the activities of 5,8-LDS and 10-DOX. We conclude that gene deletion of *ppoB* did not influence the biosynthesis of 8,11-DiHODE. Southern blot hybridization is traditionally used to identify ectopic insertions, but PCR analysis is informative in identifying homologous recombination [37]. Since the biosynthesis of 8-HPODE and 8,11-DiHODE were unaffected by *ppoB* deletion, the possibility of an additional ectopic integration event was not further investigated.

Characteristics of the Δ*ppoB* Mutants

Radial growth rate and asexual sporulation capacity of J272 Δ*ppoB* and AF:Δ*ku80*Δ*ppoB* appeared to be unchanged. These results are in agreement with the effects of *ppoABC*-RNA silencing and *ppoB* gene deletion experiments performed in the AF293 strain [8, 38], which does not produce significant amounts of 8,11-DiHODE (Table 1).

Discussion

We report that 8,11-diol synthase likely belongs to the class III P450 with specificity for certain fatty acid hydroperoxides with *R* configuration. The oxygenation mechanism with a small deuterium kinetic isotope effect and strong inhibition by imidazole derivatives are typical

Fig. 7 PCR analysis of *A. fumigatus* AF:Δ*ku80*Δ*ppoB*. **a** Specific primer pairs were designed to distinguish between targeted gene deletion (primers I + III and VI + VII) and for intact *ppoB* gene (primers I + II) and for integration of the hygromycin B cassette (primers IV + V). **b** PCR was performed with genomic DNA from *A. fumigatus* AF:Δ*ku80* (wt) and gene deletion strain AF:Δ*ku80*Δ*ppoB* [AfΔ*ppoB*(2)], yielding the expected product patterns. See text and Table S1 for details

of P450. The distribution of the 8,11-diol synthase to the soluble cell fraction and its apparent molecular size differ from many class III P450, but not significantly from 5,8-LDS. It was therefore unexpected that 8,11-diol synthase of *A. fumigatus* could not be linked to PpoB in spite of sequence similarities with 5,8-LDS.

Biosynthesis of 8,11-DiHODE has only been observed in aspergilli in connection with 5,8-LDS, which oxidizes 18:2n-6 to the precursor, 8*R*-HPODE. The 8,11-diol synthase activity is prominent in all investigated strains except AF293 (Table 1). The 8,11-diol synthase readily transforms the 8*R*-hydroperoxy metabolite of C₁₈ fatty acids (18:1n-9, 18:2n-6, 18:3n-3) and the 10*R*-hydroperoxy metabolite of vaccenic acid (18:1n-7) to 1,4-diols, but 8*S*-HPOME or

11-HPOME were not transformed. The 8,11-diol synthase thus appears to be both regio- and stereospecific. Pharmacological analysis revealed striking differences between 8-11-diol synthase and 5,8- and 7,8-diol synthases.

We found that miconazole, ketoconazole, and 1-benzylimidazole inhibited the 8,11-diol synthase activity with apparent IC₅₀ values at low μ M concentrations. These drugs are used to treat aspergillosis by inhibition of lanosterol 14 α -demethylase (CYP51) or to reduce platelet aggregation [inhibition of thromboxane synthase (CYP5A)] [39, 40]. The CYP5A inhibitor ozagrel also inhibited the 8,11-diol synthase, but voriconazole and fluconazole were less active. 8,11-Diol synthase was inhibited by drugs with an imidazole as functional group, which blocks catalysis by ligation to the ferric heme iron [40–42]. None of these drugs inhibited the diol synthase activity of 5,8- and 7,8-LDS even at high concentrations (0.1 mM). The selective inhibition of 8,11-diol synthase suggests structural differences in the P450 heme environment of the three diol synthases.

What is the biological function of 8,11-DiHODE? *A. nidulans* is traditionally a model organism for studies of oxylipin effects on sexual and asexual sporulation [10, 43]. *A. nidulans* does not form 8,11-DiHODE, and its biological effects should therefore be investigated in other aspergilli, e.g., *A. fumigatus*, *A. clavatus*, or *A. niger* [9, 12, 24]. 8,11-DiHODE might conceivably affect the sexual cycle of *A. fumigatus*, which was discovered only recently [44], and might be implicated in pathogen-host interactions in analogy with other oxylipins [3].

Recombinant PpoB of *A. fumigatus* J272, which was expressed in insect cells, lacked detectable 8,11-diol synthase activity and did not oxygenate linoleic acid or other unsaturated C₁₈ fatty acids. This insect cell expression system has been used to successfully express 5,8- and 7,8-LDS as well as 10R-DOX [17, 22]. The two sequenced strains of *A. fumigatus*, AF293 and A1163, differ markedly in biosynthesis of 8,11-DiHODE, although their PpoB sequences are similar to PpoB of J272 (Table 2). It therefore seems likely that PpoB may have other catalytic functions, but we cannot rule out loss of activity due to expression artifacts. We therefore chose to study the potential relationship between PpoB and 8,11-diol synthase by gene deletion.

We disrupted *ppoB* with two different constructs, using *Agrobacterium tumefaciens*-mediated transformation, and confirmed the gene deletions by PCR technology and sequencing. Gene deletion of *ppoB* did not affect the biosynthesis of 8,11-DiHODE. This unexpected finding has gained recent support. *A. clavatus* is closely related to *A. fumigatus*, and it has a prominent capacity to synthesize 8,11-DiHODE [9]. While this work was in progress, we found that PpoB of *A. clavatus* contains a serine at the

position of the conserved heme-thiolate (cysteine) residue of its P450 domain [9]. Point mutation of this cysteine residue to serine or alanine is commonly used to abolish P450 catalysis [17, 19, 45]. Replacement of this critical cysteine residue of PpoB during evolution of *A. clavatus* and gene deletion of *ppoB* in *A. fumigatus* both left the biosynthesis of 8,11-DiHODE unaffected.

In addition to 5,8-LDS and 10R-DOX homologues, some aspergilli may also express PpoB and one or two additional DOX-CYP enzymes. These orphan enzymes all contain the characteristic YRWH motif in their DOX domains [13, 24]. In analogy with cyclooxygenases, the Tyr and His residues of this sequence likely represent the catalytically important Tyr residue for hydrogen abstraction and the proximal heme ligand [32, 46]. The orphan DOX-CYP enzymes could therefore be dioxygenases or peroxidases. 9R-HPODE is formed by *A. terreus* [13], and work is now in progress to clone and express its three orphan DOX-CYP enzymes in pursuit of the 9R-DOX activity.

Acknowledgments This work was supported by grants from the Swedish Research Council (03X-06523), the Knut and Alice Wallenberg Foundation (KAW 2004.123), and by Uppsala University. We thank Dr. Melin for the generous gift of aspergilli strains, and Dr. Hamberg for the gift of stereospecifically deuterated fatty acids.

Abstract Several methods are available to extract total lipid and methylate fatty acids from a range of samples including red blood cells (RBC). Fatty acid analysis of human RBC can be undertaken using a two-step extraction and methylation or a combined one-step extraction and methylation procedure. The lipid composition of sheep RBC differs significantly from that of humans and may affect their extraction. The purpose of the current study

was to examine the efficiency of extraction of lipid and detection of fatty acids from sheep RBC using a one-step procedure. Fatty acids were analysed using a one-step extraction and methylation procedure using methanol:toluene and acetyl chloride in comparison with a two-step procedure involving extraction of lipid using chloroform:methanol and separate methylation. Concentrations of saturated fatty acids including C16:0 and C18:0 were significantly higher (42.6 and 33.9 % respectively) following extraction using the one-step procedure compared with the two-step procedure. However, concentrations of some polyunsaturated fatty acids, including C20:5n-3 and C22:6n-3 were not significantly different between either procedure. The improved detection of fatty acids may be related to the ability of different solvents to extract different lipid fractions. The differential extraction of lipids and detection of fatty acids from sheep RBC may have important implications in studies examining the effect of dietary treatment on the possible health benefits of fatty acids.

| SFA | Saturated fatty acids |

Introduction

Concentrations of fatty acids in red blood cells (RBC) reflect long-term dietary intake [1, 2], particularly long-chain omega-3 polyunsaturated fatty acids [LCn-3PUFA] [3]. Changes in the concentrations of LCn-3PUFA in plasma of ruminants have been reported following changes in diet, particularly, after the introduction of grain to sheep and cattle [4, 5]. The effect of diet on the concentrations of LCn-3PUFA in RBC of sheep, however, has not previously been reported.

The analysis of fatty acids in RBC typically involves a two-step procedure, firstly, extraction of lipids and, secondly, saponification and methylation [6]. There are several methods available to extract total lipids from RBC, including the Folch procedure [7], the modified procedure of Bligh and Dyer using altered solvent ratios and volumes [8] and procedures using less toxic solvents, including isopropanol [9, 10]. Lipid samples then have to be methylated separately, which lengthens the time required for analysis. A one-step extraction and methylation procedure is also available for the analysis of fatty acids in a range of tissues, including RBC of humans and rats [11]. The main advantage of this procedure is that it is less time consuming compared with the two-step procedure.

The efficiency of extraction of lipid and analysis of fatty acid methyl esters (FAME) from RBC may be differentially affected by the method of lipid extraction. The analysed concentrations of C16:0 and C18:0 but not C18:2n-6 and C20:5n-3 were significantly higher when fatty acids were analysed in the RBC of humans using the one-step procedure of Lepage and Roy compared with extraction using the Folch procedure [12]. This differential extraction may influence the results obtained when examining the effects of dietary treatments on changes in RBC fatty acid profiles.

The lipid composition of ruminant RBC differs significantly from humans. While human and ruminant RBC are comprised of approximately 26–30 % cholesterol and 50–70 % phospholipid [13, 14], ruminant RBC is comprised predominantly of sphingomyelin and lacks phosphatidyl choline [14]. Sphingomyelin accounts for approximately 54 % of phospholipid and 30 % of total lipids in sheep and cattle RBC [14]. No previous studies have examined the use of the one-step extraction and methylation procedure for the analysis of FAME in RBC of sheep. Therefore, the aims of the current study were, firstly, to determine whether the analysis of fatty acids in sheep RBC could be undertaken using the one-step extraction and methylation procedure developed by Lepage and Roy [11] compared with a two-step procedure and, secondly, to determine whether changes in RBC fatty acids following dietary treatment were affected by the method of analysis.

Materials and Methods

Experimental Design

Animals in the current study were part of a larger study examining the influence of omega-3 polyunsaturated fatty acids (PUFA) on reproductive performance (Gulliver et al. submitted) and were fed one of two dietary treatments differing in total omega-3 and omega-6 PUFA. The current study consisted of two parts. The first part of the study compared two methods for the analysis of fatty acids in sheep RBC at baseline prior to dietary treatment and the second part of the study determined whether changes in RBC fatty acids following dietary treatment differed between analytical methods.

Animals and Feeding

Thirty Merino \times Border Leicester first cross ewes (mean bodyweight = 86.8 ± 1.4 kg) were randomly allocated to one of two groups using a stratified block randomisation procedure with animals stratified to block based on bodyweight. Ewes in Group 1 (high omega-3 PUFA, $n = 15$) were offered a ration containing 100 % cereal silage (n-6:n-3 ratio = 0.36), while ewes in Group 2 (high omega-6 PUFA, $n = 15$) were offered a ration containing 70 % oat grain, 22 % cereal silage and 8 % cottonseed meal (n-6:n-3 ratio = 5.28).

The study was approved by the Charles Sturt University Animal Care and Ethics Committee (Protocol No: 09/123) and was compliant with the NSW Animal Research Act 1985 (as amended) in accordance with the ethical principles that have their origins in the Australian Code of Practice for the Care and Use of Animals for Scientific Purposes [15].

Blood samples were collected from all animals at baseline prior to the introduction of experimental rations and again 2 weeks following introduction. Blood was collected from the jugular vein into a 10-mL VacutainerTM containing lithium heparin. Following centrifugation at $1,500 \times g$ for 10 min, plasma was decanted and RBC were collected as described previously [3].

Reagents and Standards

Chloroform, methanol, toluene, acetyl chloride, potassium carbonate (K_2CO_3) and sodium chloride (NaCl) were all purchased from Sigma. FAME standards were purchased from Nu-Chek Prep (GLC68C, Elysian, MN USA), Supelco (37 Component FAME Mix, Cat No. 47885-U and C18:1n-7, Cat No. 4-6904, Supelco, Bellefonte, PA) and Sigma (C18:3n-6, Cat No. L6503-100MG, C20:5n-3, Cat No. E2012-5MG and C22:2n-6, Cat No. D4034-25MG, St

Louis, MO). The nonadecanoic acid methyl ester (C19:0) internal standard was also purchased from Sigma (Cat No. N5377-1G, St Louis, MO).

Lipid Extraction Using the Folch Procedure

Total lipids were extracted from RBC using the method of Folch [7] with slight modifications. In brief, 200 μL of RBC was added to a round-bottomed centrifuge tube and 5.0 mL of a chloroform:methanol (2:1 v/v) mixture was added to give a final solvent:sample ratio of 25:1 [16]. Tubes were capped and samples were vortexed vigorously for 30 s. Following agitation for 15 min using an orbital shaker, samples were centrifuged for 15 min at $1,500\times g$. The supernatant was transferred to a conical centrifuge tube and 1.0 mL of 0.9 % NaCl added to facilitate the separation of layers. Samples were centrifuged for 10 min at $600\times g$ and the lower chloroform layer containing total lipids was transferred by aspiration to an 8.0 mL glass culture tube with a Teflon-lined lid (Elm Scientific). The remaining solvent was evaporated under nitrogen at 40 °C. The total lipid component was then methylated using the Lepage and Roy procedure outlined below.

Direct Extraction and Methylation—Lepage and Roy

Total RBC lipids were extracted and fatty acids were methylated using the one-step procedure of Lepage and Roy [11]. In brief, 100 μL of RBC (or total lipid extracted using the Folch procedure described above) was added to an 8.0-mL glass culture tube and exactly 2.0 mL of methanol:toluene (4:1 v/v) containing C19:0 (0.02 mg/mL) internal standard was added and vortexed vigorously. Fatty acids were methylated by adding 200 μL acetyl chloride drop-wise while vortexing, followed by heating to 100 °C for 1 h. After cooling, the reaction was stopped by slowly adding 5 mL of 6 % K_2CO_3 while mixing by vortex. The sample was centrifuged at $1,500\times g$ for 10 min to facilitate the separation of the layers. The upper toluene layer containing the FAME was transferred to a 2-mL glass vial and sealed with a Teflon-lined screw-cap for subsequent analysis by gas chromatography.

FAME Analysis

Individual FAME were identified using an Agilent 6890 N gas chromatograph (GC) with a flame ionisation detector (FID). FAME were separated using a fused carbon–silica column, coated with cyanopropylphenyl (BPX70, 30 m \times 0.25 mm i.d. and 0.25 μm film thickness, SGE Analytical Science, Ringwood, Victoria, Australia, P/N 054622). The carrier gas was helium with a total flow rate of

12.4 mL min^{-1} , a split ratio of 10:1 and a column flow of 0.9 mL min^{-1} . The inlet temperature was 250 °C, the inlet pressure was 107.8 kPa and the injection volume was 3 μL into a focus inlet liner (4 mm i.d. SGE Analytical Science, P/N 092002) that was changed at least every 50 injections. The oven temperature was set at 150 °C and held for 0.5 min, increased at 10 °C min^{-1} to 180 °C, increased at 1.5 °C min^{-1} to 220 °C and then increased at 30 °C min^{-1} up to 260 °C and maintained for 5 min to give a total run time of 36.5 min. The FID temperature was set at 280 °C with the following gas flow rates; hydrogen = 35 mL min^{-1} , instrument air = 350 mL min^{-1} and nitrogen make-up gas = 30 mL min^{-1} . Sample FAME peaks were identified by comparing their retention times with those of a standard mixture of genuine FAME (as described above) and quantitated using Agilent Chemstation Version B.01.03 and Microsoft Excel using a four point standard curve for each FAME using C19:0 as the internal standard. In addition, some peaks for branched-chain fatty acids, for which standard FAME were not available, were identified by comparison with published data as described previously [17]. All results were calculated as $\mu\text{g/mL}$ RBC or g/100 g total identified FAME.

The lower limit of detection (LoD) was calculated from three times the standard deviation of the estimated peak area:internal standard peak area ratio for a concentration equal to 0 interpolated from the four standards [18]. The LoD was less than 0.01 $\mu\text{g/mL}$ for all FAME analysed. The co-efficient of variation for the analyses ranged between 3.1–8.2 % for the two-step procedure and 1.1–2.2 % for the one-step procedure.

Statistical Analyses

Prior to analysis, data were assessed for homoscedasticity and normality assumptions using the Scatterplot and Explore options of the Statistical Package for Social Sciences (SPSS) version 14.0 for Windows [19]. Differences in concentrations of FAME between methods at baseline and over time were analysed by repeated measures analysis using the Mixed Model procedure in the SAS statistical program [20]. The restricted maximum likelihood (REML) estimation used “animal” nested within “method” as the individual experimental unit and “animal” nested within “method” as a random effect [3, 21]. The most appropriate covariance structure for each analysis was determined by reference to the Schwarz’s Bayesian Information Criterion (BIC) [22]. The analysis determined the fixed effects of “analytical method”, “dietary treatment” and “time” as well as the interaction between fixed effects. The relationship between RBC FAME concentrations between analytical methods were analysed by Pearson correlation using SAS.

The mean percentage change in each of the major FAME over time following dietary treatment was also analysed using the Mixed Model procedure in SAS. The analysis determined the fixed effects of “analytical method” and “dietary treatment”. Data for percentage change in FAME over time were positively skewed and were transformed prior to analysis ($Y = \log_{10} C18:0 + 17.5$, $Y = \log_{10} C18:2n-6 + 13.5$, $Y = \log_{10} C18:3n-3 + 33.8$, $Y = \log_{10} n-6:n-3 \text{ ratio} + 48.6$) [23].

One ewe offered the high omega-6 PUFA diet refused to eat oats and was, therefore, withdrawn from the study and data from that ewe were excluded from all analyses. An alpha of 0.05 was used for all statistical tests.

Results

Baseline FAME Concentrations

The mean concentration of the major saturated fatty acids (SFA) including C16:0, C18:0 and C22:0 was significantly ($p < 0.01$) higher when RBC FAME were analysed using the one-step procedure compared with the two-step procedure (Table 1). Conversely, concentrations of RBC omega-3 PUFA including C18:3n-3, C20:5n-3 and C22:5n-3 were not significantly ($p > 0.05$) different when RBC FAME were analysed using the one-step compared with the two-step procedure (Table 1). Mean concentrations of C18:0 were underestimated by approximately 26.9 % when fatty acids were analysed using the two-step procedure compared with the one-step procedure of Lepage and Roy, while concentrations of C18:2n-6 were underestimated by approximately 18.9 % using the two-step procedure. The SFA percentage as a proportion of total FAME was higher, while the percentage of monounsaturated fatty acids (MUFA), n-3 and n-6 PUFA were lower when RBC FAME were analysed using the one-step compared with the two-step procedure (data not shown).

Concentrations of RBC FAME analysed using the one-step and two-step procedures were significantly ($p < 0.001$) positively correlated. The relationship between analytical procedures was higher for C18:3n-3 ($r^2 = 0.92$) and C18:2n-6 ($r^2 = 0.78$) compared with C18:0 ($r^2 = 0.57$, Fig. 1).

Change in FAME Concentrations Following Dietary Treatment

Mean concentrations of C18:0 (141.3 ± 2.76 versus 131.7 ± 2.65 , $p = 0.015$) and C18:2n-6 (93.2 ± 2.17 versus 81.2 ± 2.08 , $p < 0.001$) and the ratio of n-6:n-3 fatty acids (3.53 ± 0.07 versus 2.81 ± 0.07 , $p < 0.001$) were significantly higher when sheep consumed a diet high in omega-6 PUFA compared with omega-3 PUFA for

14 days. Conversely, the mean concentration of RBC C18:3n-3 was significantly ($p < 0.001$) lower when sheep consumed a diet high in omega-6 PUFA (11.95 ± 0.47 compared with omega-3 PUFA (17.27 ± 0.45)).

The response to dietary treatment was not significantly different when RBC FAME were analysed using either the one-step or two-step procedure (analytical method \times dietary treatment \times time interaction, $p > 0.05$). The interaction between analytical method and dietary treatment was also not significant in the analysis of percentage change in any FAME over time, however, the percentage decrease in n-6:n-3 ratio when ewes were fed a diet high in omega-3 PUFA (but not the diet high in omega-6 PUFA) was significantly ($p = 0.008$) greater when FAME were analysed using the two-step procedure (re-transformed mean = -35.9%) compared with the one-step procedure (re-transformed mean = -25.5% , Fig. 2).

Discussion

The differential analysis of fatty acids from sheep RBC using the one-step compared with the two-step procedure observed in the current study agrees with previous findings examining the extraction of lipids from a range of tissues. The concentration of a number of fatty acids, in particular SFA, was higher in human RBC [12], milk [24] and plasma [11] when lipids were extracted and FAME were analysed using the one-step procedure compared with extraction of lipid using the Folch procedure.

Concentrations of fatty acids were not always higher when the one-step procedure was employed in the current study, which also agrees with previous comparisons. For example, concentrations of the LCn-3PUFA C20:5n-3 and C22:5n-3 were not significantly different between methods in the current study which is similar to findings with human RBC [12]. The differential detection of SFA compared with MUFA, LCn-3PUFA and LCn-6PUFA resulting in changes in the percentage of FAME as a proportion of total FAME has important implications for the analysis of FAME in RBC. The relationship between RBC FAME and health markers of disease may be affected differentially by the method of analysis used, if the proportions of FAME are considered.

Although concentrations of FAME were significantly different between the two analytical methods, the change in FAME concentrations over the period of feeding experimental diets that differed in omega-3 PUFA and omega-6 PUFA did not differ significantly between methods. The reduction in the n-6:n-3 ratio when ewes consumed a diet high in omega-3 PUFA, however, was significantly greater when the two-step procedure was used compared with the one-step procedure. This differential analysis has important

Table 1 Mean concentration ($\mu\text{g/mL}$) of fatty acid methyl esters (FAME) in the red blood cells of ewes at baseline prior to dietary treatment using the one-step procedure of Lepage and Roy compared with a two-step procedure including Folch lipid extraction

extraction and methylation procedure of Lepage and Roy [11] or the two-step procedure including a Folch extraction [7]. Data are baseline concentrations prior to dietary treatment

implications, particularly in research projects examining the effects of dietary treatment on health benefits of LCn-3PUFA in both animal or human studies, as the n-6:n-3 ratio may be the most closely related marker for several diseases, including cardiovascular disease [25] and mental health disorders such as depression [26].

The differential analysis of FAME from RBC observed in the current study was likely due to the different polarity of solvents used to extract different lipid fractions. The extraction of non-polar lipids such as cholesteryl esters and triglycerides is expected to be greater when a lower polarity solvent mixture is used, such as that used in the Folch extraction (chloroform:methanol (2:1 v/v), dielectric constant = 14.2), compared with a higher polarity solvent mixture used in the Lepage and Roy extraction (methanol:toluene (4:1 v/v), dielectric constant = 26.9) [6]. Conversely, extraction of polar lipids such as phospholipid is expected to be greater when a higher polarity solvent is used.

The proportion of fatty acids that are expected to be contained in different lipid fractions of sheep [27] or cattle

[28] RBC and the expected proportion of different lipid fractions in sheep RBC [14, 27, 29] were estimated from previous studies. These estimates were used to calculate the proportion of each fatty acid likely to be found in the phospholipid fraction of RBC and compared with the differential analysis of fatty acids between methods in the current study (Fig. 3). The improved detection of FAME with the one-step compared with the two-step procedure in the current study was significantly positively correlated ($r^2 = 0.58$, $p < 0.01$) with the estimated proportion of each fatty acid contained in phospholipid (Fig. 3). The detection of C22:0, C24:0 and C24:1n-9 that is contained solely in the phospholipid fraction of RBC was approximately 30 % higher when FAME was analysed with the one-step compared with the two-step procedure.

Similar improvements in the detection of fatty acids contained predominantly in phospholipids have been found in previous studies when higher polarity solvents were used. For example, the concentration of a number of fatty acids including C16:0 and C18:0 in beef [30], human plasma [31] and human RBC [10] was significantly higher

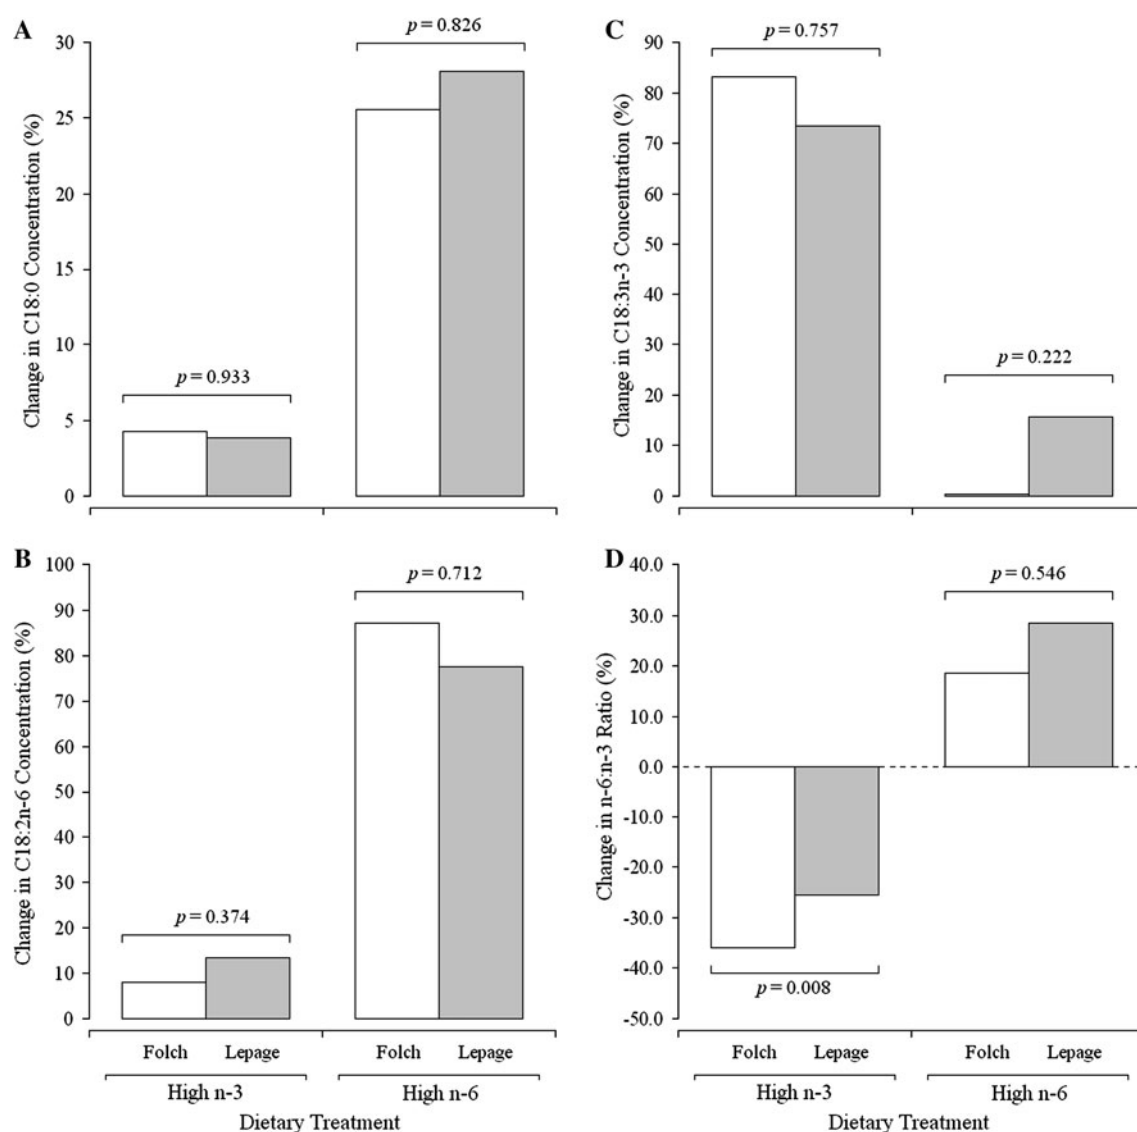

Fig. 2 Mean percentage change in the concentration of **a** C18:0, **b** C18:2n-6, **c** C18:3n-3 and **d** the ratio of omega-6:omega-3 fatty acids (n-6:n-3 ratio) in the red blood cells (RBC) of sheep following the consumption of a diet high in omega-3 or omega-6 polyunsaturated fatty acids for 14 days. Fatty acids were analysed using the one-step extraction and methylation procedure of Lepage and Roy

[11] (shaded bars) or the two-step procedure including a Folch extraction [7] (unshaded bars). Values are re-transformed least squares means (transformations prior to analysis; $Y = \log_{10} \text{C18:0} + 17.5$, $Y = \log_{10} \text{C18:2n-6} + 13.5$, $Y = \log_{10} \text{C18:3n-3} + 33.8$, $Y = \log_{10} \text{n-6:n-3 ratio} + 48.6$)

when methanol or hexane:isopropanol were used compared with chloroform:methanol.

The lower detected concentrations of FAME in RBC when the Folch lipid extraction procedure was used could also be due to physical effects of the solvents on RBC membranes. For example, low polarity chloroform may have led to clotting of membrane-bound proteins and a reduction in the ability of the solvents to extract membrane bound fatty acids [10]. The Folch extraction procedure may need to be undertaken if individual lipid fractions need to be separated, therefore, it may be necessary to improve the extraction of fatty acids using this procedure. The

extraction of total lipid from RBC may be improved if RBC are mixed initially with ice-cold methanol alone and then chloroform is added in the correct proportion following the initial extraction with methanol [13]. The extraction of lipid and SFA may also be improved with additional chloroform washes [16], however, this would add considerable time to an already lengthy procedure. Further research is required to determine whether the extraction of total lipid from sheep RBC can be improved with modifications to the Folch procedure.

There are limitations to the one-step extraction and methylation procedure that need to be addressed during

Fig. 3 Relationship between the proportion of total fatty acid in phospholipid and the percentage increase in fatty acid methyl ester (FAME) concentration at baseline prior to dietary treatment using the one-step extraction and methylation procedure of Lepage and Roy [11] compared with extraction of lipid using the Folch procedure [7]. Increased FAME concentration with Lepage extraction (%) = $[56.2 \times \log_{10} \text{proportion of fatty acid in phospholipid (\%)}] - 78.43$, $r^2 = 0.58$, $p < 0.01$. Proportion of fatty acid in phospholipid derived from data in sheep [27] or cattle (C24:0 and C24:1n-4) [28]

chromatography analysis. For example, the chromatography resolution degrades following multiple injections which can increase the limit of detection. While this degradation in resolution can be overcome by changing the inlet liner at least every 50 injections, this adds an additional cost to the analysis. Different inlet liners can also alter the resolution and, therefore, correct inlet liner selection is critical to the analysis.

Conclusions

The analysis of fatty acids from sheep RBC using the one-step Lepage and Roy procedure resulted in higher analysed concentrations of a number of fatty acids, primarily SFA, compared with lipid extraction using the Folch procedure prior to methylation. The observed difference in fatty acid concentration was most likely due to improved extraction of phospholipids using higher polarity solvents in the one-step procedure. The effect of dietary treatment on RBC FAME was similar when the one-step and two-step procedures were used, however, the effect of dietary treatment on the n-6:n-3 ratio of RBC was significantly different between analytical methods. This differential detection of omega-6 PUFA compared with omega-3 PUFA may have important implications in studies examining the effect of dietary treatment on the health benefits of different fatty acids where the primary outcome of importance is the n-6:n-3 ratio.

Acknowledgments We thank Greg Clark, Steven Huckell, Michael Loiterton, Rex Edis, Craig Rodham, John Wilkins, Susan Robertson, the Gulliver family, Jessica Rose, John Broster and Dr Stephanie Knott for technical assistance during the conduct of the study. We also thank Jamie Ayton for providing assistance with the gas chromatography.

This study was conducted without dedicated external funding. This study was supported by in-kind provision of equipment by the Diagnostic and Analytical Systems division of NSW DPI.

Conflict of interest None.

Abstract Phospholipids and glycolipids from two recently described species belonging to the thermophilic genus *Anoxybacillus* were analyzed by liquid chromatography–electrospray tandem mass spectrometry (LC/ESI–MS/MS). Analysis of total lipids from the facultatively anaerobic *A. bogrovensis* on a HILIC (Hydrophilic Interaction LIquid Chromatography) column succeeded in separating diacyl- and plasmalogen phospholipids. The LC/ESI–MS/MS analysis of the strict aerobe *A. rupiensis* revealed the presence of different unique polar lipids, predominantly alanyl-, lysyl-, and glucosyl-phosphatidylglycerols and cardiolipins. Each of the classes of polar lipids was then analyzed by means of the ESI–MS/MS and more than 140 molecular species of six lipid classes from *A. bogrovensis* and nearly 200 molecular species of nine classes of polar lipids from *A. rupiensis* were identified. Five classes of unidentified polar lipids were detected in both strains. Plasmalogens were thus determined for the first time in a facultatively anaerobic bacterium, i.e. *A. bogrovensis*.

Introduction

Thermophilic bacteria are type extremophiles that are adapted to life at high temperature (optimum growth above 50 °C). They inhabit separate permanently hot niches such as

areas with geothermal and volcanic activity. They were among the first inhabitants of Earth and hold the lowest branches in the global phylogenetic tree of life; their study is thus intimately related with the question of the origin of life and biological evolution. Thermophilic adaptation to severe conditions resulted in the development of several unique mechanisms, one of which is a specific composition of microbial membranes, which form the lipid bilayer permeability barrier of cells. The ability of bacteria to control and modify the biophysical properties of their membrane is achieved by a change of phospholipid composition in response to environmental changes. As an adaptation to the fluidizing effects of increased growth temperature, it is common to observe an increase in the proportion of long chain and saturated fatty acids within the membrane [1].

The efforts to identify new lipids, which may extend the scientific knowledge and have potential practical application, include the isolation and study of new microorganisms in long-known genera. The genus *Bacillus* has a long taxonomic history. Since it was described by Cohn in 1872, its systematics has undergone major revisions [2]. Based on the large number of novel endo-spore forming bacteria described in the 1990-s, Zeigler [3] described 15 genera as *Bacillus* sensu lato (*Bacillus*-like group) and predicted the list of approved *Bacillus*-like genera to expand rapidly during the new decade. One of the recently described genera in this clade is the genus *Anoxybacillus*; its representatives are thermophilic and alkaliphilic or alkalitolerant, chemo-organotrophic bacteria. Though representatives of *Anoxybacillus* have been first identified as anaerobes [4], an additional amendment [5] referred to them as aerotolerant anaerobes. Further, most of these species have been found to be facultative anaerobes and even for some species anaerobic growth was registered only in some conditions [6]. The genus comprises currently 15 species [7] isolated from different geographical areas—Russia, Belgium, Turkey, Mongolia, etc. Two of the species, *A. rупiensis* [8] and *A. bogrovensis* [9] were recently isolated from Bulgarian hot springs and novel molecules of lipids including, e.g., plasmalogens were envisaged in these new microorganisms.

Plasmalogens are any derivatives of *sn*-glycero-3-phosphoric acid that contain *O*-alk-1'-enyl residue attached to the glycerol moiety at *sn*-1 position and a polar head made of a nitrogenous base or glycerol moiety. Their occurrence is limited to strictly anaerobic bacteria and they have not yet been identified in aerobic or facultatively anaerobic bacteria. They are common constituents of animal lipids from invertebrates to humans [10] and are found mostly as plasmalogen phosphatidylcholine, plasmalogen ethanolamine (PlsEtn), plasmalogen phosphatidylglycerol (PlsGro), and plasmalogen phosphatidic acid (PlsOH).

Phosphatidylglycerol (PtdGro) and cardiolipin (Ptd₂Gro) are the major anionic membrane lipids in most bacteria [11].

Forms of PtdGro and Ptd₂Gro modified by different amino acids have been described; for instance, lysyl-phosphatidylglycerol (lysyl-PtdGro) and other aminoacyl esters of PtdGro, such as alanyl-PtdGro, or ornithyl-PtdGro, are major membrane lipids in several Gram-positive bacteria (Firmicutes) [12]. Lysyl-PtdGro constitutes a major membrane lipid in different strains of bacteria [13, 14] such as *Bacillus subtilis* [15], *B. anthracis* [16], and *Listeria monocytogenes* [17]. Alanyl-PtdGro was isolated from *Clostridium perfringens* [14]. A large variety of PtdGro-derived lipids are present in *Enterococcus faecalis* (formerly known as *Streptococcus faecalis*) which probably has alanyl-PtdGro, 2'-lysyl-PtdGro, 3'-lysyl-PtdGro, 2',3'-dilysyl-PtdGro, arginyl-PtdGro, and a diglucosyl derivative of PtdGro [18].

Lysyl-, alanyl-, and glucosyl-Ptd₂Gro have also been described in bacteria [19]. The paper by Peter-Katalinic and Fischer [20], who identified α -D-glucopyranosyl-, D-alanyl- and L-lysylcardiolipin from Gram-positive bacteria (*Streptococcus* sp., *Vagococcus fluvialis* or from *Listeria welshimeri*), can be considered a basic study in the field of mass spectrometry of these polar lipids. A detailed structural study of a cardiolipin and an integral membrane protein was reported for *Rhodobacter sphaeroides* AM260W, which is able to grow heterotrophically via fermentation and aerobic and anaerobic respiration [21].

Identification of these polar lipids is relatively difficult. Many studies using two-dimensional TLC identified only some of the spots while other spots remained unidentified. Other methods of choice are HPLC, especially in combination with mass spectrometry, or mass spectrometry alone, including tandem mass spectrometry [22]. These methods were used for identifying 16 bacterial strains, e.g. *Bacillus subtilis* or *Staphylococcus aureus* [23].

Further, amphiphilic molecules such as phospholipids can be separated on a Hydrophilic Interaction LIquid Chromatography (HILIC) column, but this method has been described in only a few papers, with relatively controversial results concerning especially the elution of individual phospholipid classes [24–26].

This report is part of our investigation of bacterial lipids within the framework of a comprehensive program on the analysis and biosynthesis of lipids [27, 28]. We present here the separation and identification by LC–ESI/MS² of intact plasmalogen phospholipids from diacyl phospholipids of the facultatively anaerobic bacterium *A. bogrovensis*, and nearly 200 molecular species of nine classes of polar lipids from *A. rупiensis*.

Results and Discussion

The total lipid extracts prepared from *A. bogrovensis* by the modified Bligh and Dyer method [29] have been

pre-fractionated by using a cartridge with aminopropyl silica-based polar bonded phase, and further separated on a HILIC column into the individual lipid classes [28]. The chromatographic conditions have been optimized to provide the best separation of all lipid classes. The composition of mobile phase is crucial for the separation of lipid classes. Good resolution of lipid classes was obtained with the mixture of hexane/2-propanol/aqueous ammonium acetate [30] but better selectivity, chromatographic resolution and low background noise were observed in a mobile phase containing methanol–acetonitrile–water with ion-pairing agents such as ammonium salts [24]. The concentration of water and salts including the pH value of mobile phase are crucial parameters for separation and identification of ionic lipids. The use of ion-pairing agents (e.g., ammonium acetate or formate) significantly improves the chromatographic resolution and ionization efficiency of lipids. The best separation and signal intensity have been achieved in mobile phases with 1 mM aqueous ammonium acetate at pH 7 [28]. Lipids from *A. bogrovensis* were separated (Fig. 1) and quantified based on the negative-ion ESI mass spectra [Table 1S (Supplement)]. The retention times of eluted lipids are based on their adsorptions (electrostatic forces) on the HILIC column and showed that lipids with higher polarity or stronger dissociation are more retained. Most lipid classes were baseline separated but some lipids were co-eluted and five peaks were not identified (U1–U5); see Fig. 1 and Table 1S (Supplement).

Individual strains of genus *Bacillus* are being continuously reclassified on the basis of 16S rRNA gene sequence analysis [31]. This is the probable reason why older papers about lipids of bacilli describe considerable heterogeneity in the lipid content [32]. On the other hand, it should be noted that the polar lipids of most bacilli have not yet been

identified. Most of the authors are satisfied with the identification of 3–4 polar lipids on the basis of matching the R_f of two-dimensional TLC [33, 34]. Other spots on the TLC plate remain unidentified; thus Minana-Galbés et al. [33] described eight spots, Khianngam et al. [35] four spots and Kampfer et al. [36] did not identify four, i.e. half of the total number of spots.

The two species of the genus *Anoxybacillus* that we analyzed differ in the composition of their polar lipids. The major phospholipids present are Ptd₂Gro and PtdGro, which confirms that these species belong to the bacilli [12]. Preliminary papers describing the polar lipid composition of the genus *Anoxybacillus* indicated that the strains contain a large number of unidentified polar lipids [33, 37] and share a similar chemical composition. The chemical composition of our two strains also centers around the presence of three polar lipid classes (Ptd₂Gro, PtdGro, PtdEtn), and the dominance of iso- and anteiso-fatty acids (Table 1; see Ref. [8, 9]). Similar observations on *Anoxybacillus* fatty acids were reported by other authors [38, 39].

As seen in Tables 3S–11S, the facultatively anaerobic *A. bogrovensis* was found to contain a total of 12 identified polar lipid classes with 172 molecular species, whereas the aerobic *A. rupiensis* contains six identified polar lipid classes with a total of 195 molecular species. Both species contain five classes of polar lipids that could not be identified. We shall deal in detail only with those Tables that are not given in Supplements.

Individual classes of separated phospholipids were identified by ESI–MS. Based on literature data [40, 41] and our previous results we were able to identify and quantify individual molecular species, see Tables 3–7. The only potential uncertainty concerned the identification of PtdGro

and BMP [26, 42]. However, the HILIC column provided a base-line separation without any problems.

Both phospholipids contain two acids, two glycerol moieties and one phosphodiester and the only difference between them is thus in the position of one of the acyls. For this reason the two phospholipids cannot be distinguished by mass spectrometry alone and it is necessary to use HPLC for their separation [26, 42].

Tandem mass spectrum of PtdGro 15:0/15:0 and BMP 15:0/15:0 in negative-ion mode produced similar fragmentation for both compounds, making specific determination of either lipid in the presence of the other difficult. Intense product ions were observed for the acyl (m/z 241) and for the glycerophosphate fragment at m/z 153. Minor differences in the intensities were observed for the ions at m/z 451 and 469 corresponding to the neutral loss of the $[M-H-ketene]^-$ and $[M-H-RCOOH]^-$. One clear distinction between PtdGro and BMP was the ability of PtdGro to lose the glycerol moiety without the loss of a fatty acid, i.e. a daughter ion of mass $[M-H-74]^-$ was always observed only for PtdGro but not for the compound with retention time 17.1 min. Thus, the neutral loss of 74 Da, i.e. ion at m/z 619, is specific for the 15:0/15:0 PtdGro species [43] and we concluded that this peak must contain BMP, for which it holds that each of the two glycerol moieties is esterified by one fatty acid.

Plasmenyl phospholipids were identified on the basis of our previously described fragmentation [28] and the method described by Hsu and Turk [44]. Briefly, the mass spectrum of all plasmenyl phospholipids is dominated by a set of RCO^- , $[M-H-RCOOH]^-$, $[M-H-R'CH=C=O]^-$,

and $[M-H]^-$ ions that identify the fatty acid substituent. Ions reflecting the 1-*O*-alk-1'-enyl moiety are minor or not present but complete structural characterization of plasmenyl phospholipids can be carried out on the basis of the above ions.

Quantification of individual molecular species of the four classes of plasmalogens is given in Tables 3S–5S. Although the base-line separation of diacyl and alkenylacyl (plasmalogen) of the appropriate class of phospholipid was not successful, we succeeded in quantifying individual molecular species by using the method of Hsu and Turk [44]. Briefly, dissociation of the $[M-H-R_2COOH-polar\ head\ group]^-$ ions from the $[M-H]^-$ ions of plasmalogen phospholipid that have undergone consecutive losses of the fatty acid substituent at *sn*-2 and the polar head group readily gives the structural information about the radical group at *sn*-1, resulting in semiquantification of appropriate molecular species. This is essentially a neutral loss scan with a mass offset that correlates with the mass of the specified neutral losses, i.e. fatty acid at *sn*-2 position and polar head group of the phospholipid.

Analysis of *A. rupsiensis* lipids (Fig. 2) showed that the content of complex lipids is markedly different from that in *A. bogrovensis*. Based on previously published data [45] it can be assumed that the major peaks in the chromatogram are mainly PtdGro and Ptd₂Gro or their derivatives (Figs. 3, 4). As seen from the chromatogram, five other peaks could not be identified. The molecular species of nine identified classes of phospholipids are mentioned in Tables 12S–18S.

Only a few papers are devoted to the analysis of substituted PtdGro or Ptd₂Gro by mass spectrometry in Gram-positive bacteria. Peter-Katalinic and Fischer [20] fundamentally contributed to the identification of cardiolipin derivatives, i.e. Ptd₂Gro substituted on the *sn*-2 hydroxyl of the middle glycerol with α -D-glucopyranosyl- (gluco-Ptd₂Gro), D-alanyl- (alanyl-Ptd₂Gro), or L-lysyl- (lysyl-Ptd₂Gro) moieties. A review describing the presence of glucosyl-Ptd₂Gro, lysyl-Ptd₂Gro, alanyl-Ptd₂Gro, lysyl-PtdGro, etc. was published by Geiger et al. [11].

Analysis of PtdGro and Ptd₂Gro derivatives consisted in their separation on a HILIC column and identification by mass spectrometry. Mass spectra of derivatives of Ptd₂Gro have been described by, e.g., Peter-Katalinic and Fischer [20], who used positive and negative FAB to identify α -D-glucopyranosyl-, D-alanyl- and L-lysylcardiolipins. Negative ionization was more convenient in all cases since, due to the decreased formation of an alkali ion adduct, the negative-ion mass spectrum of the substituted-Ptd₂Gros provided a less complicated pattern than the positive-ion-mode and yielded sufficient information for elucidating the structure of most peaks in the chromatogram.

Based on literature data we assumed that all substituted derivatives of both PtdGro (Table 2) and Ptd₂Gro (Table 3)

Fig. 2 LC/ESI chromatogram of the phospholipids from *A. ruipeensis*

Fig. 3 ESI-mass spectrum of Lys-PtdGro from *A. ruipeensis* in negative ion mode including structure of the major molecular species, i.e. 15:0/17:0-Lys-PtdGro having $[M-H]^-$ at 849 Da

will exhibit similar behavior, i.e. cleavage of a polar substituent—glucose or amino acid. For instance, the MS^2 product-ion spectrum of 17:0/15:0-lysyl-PtdGro (Fig. 5) shows $[M-H]^-$ ion at m/z 849, which was observed in the negative-ESI; this gives rise to the ion at m/z 721 arising from loss of a lysine (128 Da) from deprotonated ion of a substituted-PtdGro.

The MS/MS spectrum of alanyl-PtdGro (15:0/17:0-alanyl-PtdGro) also shows two ions. One of them, at m/z 88, corresponds to the anion of alanine while the other, at m/z 718, arises by neutral loss of 88 Da (alanine) from 15:0/17:0-alanyl-PtdGro ($[M-H]^-$ at m/z 806).

The splitting off of a neutral moiety will transform the unsubstituted PtdGro to a simpler structure and further fragmentation in mass spectrometer is thus identical with

the fragmentation of unsubstituted PtdGro [46] described above.

The structure of lysyl-PtdGro was further confirmed by the presence of ion at m/z 647 originating from the loss of the dehydrated glycerol head group (74 Da), along with the ion at m/z 405, arising from m/z 479 by loss of dehydrated glycerol or from m/z 497 by loss of a glycerol residue (92 Da). The structure was further confirmed by the presence of the ions at m/z 269 and at m/z 241 corresponding to C17 and C15 saturated carboxylate anions, respectively. The ions at m/z 479 and m/z 497 arise from losses of the C15 acyls as an acid or a ketene, respectively, along with the ions at m/z 451 and m/z 469 corresponding to the analogous losses of C17 fatty acid moiety. Differentiation of *sn*-1 and *sn*-2 position was based on the abundance of

Fig. 4 ESI-mass spectrum of Lys-Ptd₂Gro from *A. ruiensis* in negative ion mode including structure of the major molecular species, i.e. 15/17/17/15-Lys-Ptd₂Gro having [M–H][–] at 1,480.05 Da. Asterisk Ion at 1407.02 Da arises by splitting of lysine from [M–H][–] at 1,536.12 Da

Table 2 Lys-PtdGro identified in *A. ruiensis*, the masses of protonated molecules ([M–H][–]), their ACN, and relative quantities of appropriate molecular species (%), including total %

| [M–H] [–] | ACN | Mol spec | % | Mol spec | % | Total % |

two pairs of ions: those at m/z 479/497 were, respectively, more abundant than those at m/z 451/469; this documents that C17 FA is present in position *sn*-1 and C15 FA in position *sn*-2. Based on the above findings, the given molecular species can be determined as 17:0/15:0-lysyl-PtdGro. The situation was complicated by the presence of an isobaric molecule, i.e. 16:0/16:0-lysyl-PtdGro having characteristic ions at m/z 255, 391, 465, 483, etc., see also Fig. 5. Further aminoacyl-PtdGros or aminoacyl-Ptd₂Gros derivatives were identified in a similar way.

The major fragmentation pathway of Lys-Ptd₂Gro (Fig. 6) derivative gives an [M–H][–] ion at m/z 1479, which is shown in Fig. 7. As noted above, both Lys-PtdGro and Lys-Ptd₂Gro undergo the neutral loss of a lysine moiety; the complex lipid (Lys-Ptd₂Gro) has thus in fact been translated into the simplified structure (Ptd₂Gro) and analyzed as previously described [27, 47], see also Fig. 7.

The structure of hexosyl-Ptd₂Gro was deduced on the basis of knowledge of negative mass spectra published previously by several authors [20, 47, 48].

The major derivative of hexosyl-Ptd₂Gro gives an [M–H][–] ion at m/z 1514 and an [M–2H]^{2–} ion at m/z 756. CID of the [M–2H]^{2–} ions at m/z 756 at a collision energy of 50 eV yields two carboxylate anions at m/z 241 and m/z 269, reflecting the two fatty acyl moieties, i.e. both saturated C15 and C17 acids, in the molecule. As observed before in the detection of fragment ions due to the neutral loss of a hexose moiety, a fragmentation type was not detected in the MS/MS experiment using the [M–2H + Na][–] as a precursor ion but only for [M–H][–] [48]. The whole demonstration of hexosyl-Ptd₂Gro structure has thus in fact been translated into the simplified structure (Ptd₂Gro) and analyzed as previously described [47], see also above.

Table 3, which presents 29 molecular species of Lys-Ptd₂Gro, which is in agreement with the content of total FAs. A similar picture emerges in Table 2 describing the content of Lys-PtdGro, which also shows 15/15-, 17/17- and 15/17-Lys-PtdGro as major molecular species.

The peak with retention time 25.0 min (Fig. 2) is assumed to belong to glucosyl-Ptd₂Gro, in which some of the hydroxyls of glucose are esterified by an amino acid (lysine). Due to an insufficient amount of biomass we could not determine the complete structure and its full determination, as well as that of the as yet unknown peaks, will be the topic of our forthcoming study.

So far, not a single paper has appeared which would describe the separation and subsequent identification of any complex lipid having both straight- and branched-chain FAs in the molecule. In a previous study [28] we succeeded in separating synthetic triacylglycerols differing only in straight- and branched chain FAs (specifically 17:0/17:0/17:0 from ai-17:0/ai-17:0/ai-17:0). Unfortunately, because the mass spectra of both triacylglycerols are identical, the

Fig. 5 The tandem ESI product-ion spectrum of the [M–H]⁺ ion of 16/16-Lys-PtdGro and 17/15-Lys-PtdGro including fragmentation

individual molecular species shown in all tables and figures can contain straight- and branched-chain FAs. The only exception is the separation and identification of straight- and branched-chain FAs as methyl esters by GC–MS (Table 2), which presented no problems.

In this study we demonstrated that the ability of one species, i.e. *A. bogrovensis* to grow under facultatively anaerobic conditions quite clearly affects both qualitative and quantitative composition of lipids. The majority of lipids in the two strains under study was qualitatively the same but the strain of *A. ruipeensis* cultivated under aerobic conditions showed a much wider range of polar lipids, i.e. aminoacyl-phospholipids, including as yet undescribed amino-phospho-glyco-lipid. In addition, to our knowledge we are the first to determine plasmalogens in a facultatively anaerobic bacterium. The recent

review about plasmalogens [11] still refers to this as unproven.

We believe that the ability to synthesize many different lipids must also be seen in a taxonomic and evolutionary context of classification of this genus. Our study points to the value of chemotaxonomy within the bacilli and to the need for including such analyses in all future taxonomic work on this and other groups [49].

Experimental

The standard lipid 1-palmitoyl-2-oleoyl-*sn*-glycero-3-[phospho-rac-(1-glycerol)] (16:0, 18:1 PtdGro) used in the experiments to verify the bacterial compound structure was purchased from Avanti Polar Lipids (Alabaster, AL, USA).

Fig. 6 The tandem ESI product-ion spectrum of the $[M-H]^-$ ion of 15/17/17/15-Lys-Ptd₂Gro and 15/16/16/17-Lys-Ptd₂Gro

Fig. 7 The major fragmentation pathways proposed for formation of ions from the $[M-H]^-$ ion of lysyl-cardiolipin (15/17/17/15-Lys-Ptd₂Gro)

Both strains were cultivated in the medium containing 0.2 % peptone and 0.1 % yeast extract on a bath shaker at 240 rpm for 18 h at their optimal pH and temperature.

Anoxybacillus rupiensis was cultivated at pH 6.5 and 55 °C; *A. bogrovensis* was cultivated at pH 8.0 and 65 °C under anaerobic conditions, i.e. in the absence of

atmospheric oxygen. Cells were harvested after centrifugation (4,000 rpm for 20 min) and two washes with distilled water, and lyophilized. The dry biomass after lyophilization of both strains was 0.367 g/L for *A. rупiensis* and 0.233 g/L media for *A. bogrovensis*.

The extraction procedure was based on the method of Bligh and Dyer [29], except that 2-propanol was substituted for methanol, since isopropanol does not serve as a substrate for phospholipases [50]. The alcohol-water mixture was cooled, one part chloroform was added and the lipids were extracted for 30 min. Insoluble material was sedimented by centrifugation and the supernatant was separated into two phases. The aqueous phase was aspirated off and the chloroform phase was washed three times with two parts 1 M KCl each. The resulting chloroform phase was evaporated to dryness under reduced pressure.

First, total lipid extracts were applied to Sep-Pak Cartridge Vac 35 cc (Waters; with 10 g of aminopropylsilica-based polar bonded phase), and from the cartridge were subsequently eluted nonacidic lipids with 40 mL of chloroform-methanol (7:3), and acidic lipids with 30 mL of chloroform-methanol-concentrated aqueous ammonia (70:30:2) containing 0.4 % (w/v) ammonium acetate. The eluate was reduced in volume and subjected to LC-MS.

HPLC equipment consisted of a 1090 Win system, PV5 ternary pump and automatic injector (HP 1090 series, Hewlett Packard, USA), and two Ascentis® Express HILIC HPLC columns [2.7 μ m particle size, L \times I.D. 15 cm \times 2.1 mm (Supelco, Prague)] connected in series. LC was performed at a flow rate of 0.45 mL/min for the phospholipids from the *A. bogrovensis* and 0.58 mL/min for the phospholipids from the *A. rупiensis*, respectively, with a linear gradient from mobile phase containing methanol/acetonitrile/aqueous 1 mM ammonium acetate (50:30:20, v/v/v) to methanol/acetonitrile/aqueous 1 mM ammonium acetate (10:70:20, v/v/v) for 60 min. The whole HPLC flow was introduced into the ESI source without any splitting.

The detector was an Applied Biosystems Sciex API 4000 mass spectrometer (Applied Biosystems Sciex, Ontario, Canada) using electrospray mass spectra. The ionization mode was negative, the nebulizing gas (N_2) pressure was 350 kPa and the drying gas (N_2) flow and temperature were 9.2 L/min and 310 °C, respectively. The electrospray needle was at ground potential, whereas the capillary tension was held at 4,000 V. The cone voltage was kept at 250 V. The mass resolution was 0.1 Da and the peak width was set to 5 s. For an analysis, total ion currents (full scan) were acquired from 80 to 2,000 Da.

Mass spectra of CID ions were acquired by colliding the Q1 selected precursor ions with Ar gas at a collision target gas and applying collision energy of 50 eV in Q2. Scanning range of Q3 was m/z 80–2,000 with a step size of m/z 0.25 and a dwell time of 1 ms. A peak threshold of 0.2 %

intensity was applied to the mass spectra. The instrument was interfaced to a computer running Applied Biosystems Analyst version 1.4.1 software.

Gas chromatography-mass spectrometry of FAME was done on a GC-MS system consisting of Varian 450-GC, Varian 240-MS ion trap detector with external ionization (EI), and CombiPal autosampler (CTC, USA). The sample was injected onto a 25 m \times 0.25 mm \times 0.1 μ m Ultra-1 capillary column (Supelco, Czech Republic) under a temperature program: 5 min at 50 °C, increasing at 10 °C min⁻¹ to 320 °C and 15 min at 320 °C. Helium was the carrier gas at a flow of 0.52 mL min⁻¹. All spectra were scanned within the range m/z 50–600.

Comparison of retention times of commercially obtained standards [Bacterial Acid Methyl Ester (BAME) Mix (Supelco, Prague)] and previously published results [51] were used for identification.

Acknowledgments The research was supported by GACR P503/11/0215, by the Institutional Internal Project RVO61388971, and by a bilateral agreement between the Institute of Microbiology, Bulgarian Academy of Sciences, Bulgaria and Novozymes, Denmark.

Abstract When fatty acids in fish are analyzed, results in percentage form (profile analysis) are mostly reported. However, the much more useful results expressed as mg/100 g (absolute analysis) is the main information required. Absolute methods based on calibration curves are of good accuracy but with a high degree of complexity if applied to a great number of analytes. Procedures based on the sequence profile analysis–total FA determination–absolute analysis may be suitable for routine use, but suffer from a number of uncertainties that have never been really resolved. These uncertainties are mainly related to the profile analysis. In fact, most profile analyses reported in the literature disagree about the number and type of fatty acids monitored as well as about the total percentage to assign to their sum so leading to possible inaccuracies; in addition the instrumental response factor for all FAME (fatty acid methyl esters) is often considered as a constant, but this is not exactly true. In this work, a set of 24 fatty acids was selected and studied on 12 fish species in the Mediterranean area (variable in lipid content and month of sampling): in our results, and in these species, this set constitutes, on average, 90 ± 3 % of the total fatty acid content. Moreover the error derived from the assumption of a unique response factor was investigated. Two different detection techniques (GC-FID and GC–MS) together with two capillary columns (different in length and polarity) were used in order to acquire complementary data on the same sample. With the protocol here proposed absolute analyses on the 12 cited species are easily achievable by

the total FA determination procedure. The accuracy of this approach is good in general, but in some cases (DHA for example) is lower than the accuracy of calibration-based methods. The differences were evaluated on a case by case basis.

Introduction

Fatty acids (FA) are major components of lipids. They are carboxylic acids present as esters in glycerides. In sphingolipids they are linked via an amide bond to a sphingoid base. Double C–C bonds variable in number and in position may be present in the FA molecule (Fig. 1a): in animals and plants, their configuration is prevalently *cis*- (more correctly *Z*-configuration).

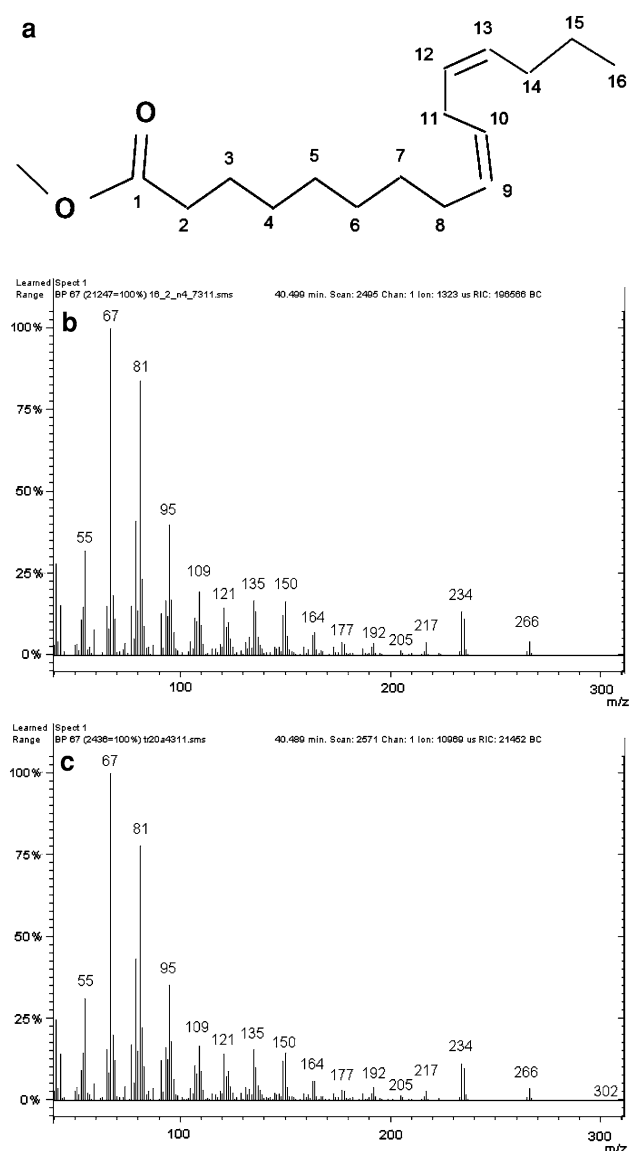

Fig. 1 **a** Molecular structure of the fatty acid 16:2n-4 (or 16:2 ω -4) in methyl ester form. IUPAC name: (9Z,12Z)-hexadecadienoic acid methyl ester. **b** Mass Spectrum of the peak obtained by injecting the authentic methylated standard of 16:2n-4. **c** Mass Spectrum of a peak with the same t_R and obtained by injecting a rainbow trout sample

The consumption of fat in the modern age is remarkable compared to the past and major causes of death in Western societies such as degenerative cardiovascular diseases and cancer are linked to aspects of dietary fat intake. This led to the recommendation that dietary intake of unsaturated FA be increased relative to that of all SFA (saturated fatty acids) [1], together with the reduction of total fat intake [2]. A number of studies reported the benefits derived from the consumption of omega-3 fatty acids and positive effects on health were observed [3]. A great attention was devoted to 20:5n-3 (EPA) and 22:6n-3 (DHA) fatty acids [4] and the recommended dosing that provides maximal cardio

protection [5] is reported. PUFA (polyunsaturated fatty acids) with special emphasis to EPA and DHA, are largely present in fish [6, 7] and fish consumption is associated with a significantly lower risk of fatal and total coronary heart diseases [8]. Recent studies focused on n-6/n-3 PUFA ratio as an important parameter towards a number of pathologies [9, 10]. Other authors suggested that the sum EPA + DHA has to be used instead of the n-6/n-3 ratio being more adequate in evaluating for coronary artery disease risk [11]. It is evident that the content of each fatty acid as mg/100 g edible portion is the main information needed.

In a complex fat matrix like a fish oil up to 100 different fatty acids, or more, can be present and detected, in dependence on the instrumental sensitivity available. In fish lipid analyses only a limited number of them is generally selected (the more important). Quantitative analysis in fish oils can be carried out at two different levels:

1. Profile analysis, that means the determination of each selected FAME as percent of total FAME
2. Absolute analysis, i.e., the assessment of the exact quantity of each selected FAME as mg/100 g edible portion

The level 1 is very often the reported result [6, 7, 12–16]. In fact the profile analysis is relatively easy to carry out if compared with the absolute analysis.

If absolute analysis is achieved with the use of calibration curves [17] it is required that certified quantitative standards are used for calibration, but degradation problems affect PUFA analytical standards when stored, even for a short period of time, and some authors suggest that even by using authentic standards, calibration could be difficult [18]. Absolutely fresh standards should have to be used every time. Moreover, the number of calibrations involved, time, and operator expertise needed make calibration curve approach undoubtedly complex.

A much more affordable method for absolute analysis could be the sequence profile analysis–total FA determination–absolute analysis. Total FA determination can be experimentally achieved by saponification that forms carboxylate ions. Then free fatty acids are reconstituted. This allows that the total fatty acid content as mg/100 g edible portion is known. The same information can also be obtained by applying a widely used conversion factor [19]. However the procedure profile analysis–total FA determination–absolute analysis requires that profile analysis is carried out with great accuracy to avoid errors in the subsequent absolute analysis. However, there is no agreement in the literature on how profile analysis in fish samples has to be conducted. This is an old problem. Due to complexity of requested work various approximations were applied. Most authors selected a number of fatty acids and considered

them as the 100 %. But number and kind of selected FAME vary a lot from one author to another: some considered 33 FAME as 100 % [15] others 17 FAME [16] or 37 FAME [13] as 100 %. Some works considered all peaks in the Chromatograms as FAME, i.e., the 100 % [12], but this is not always true as ascertained in our research by means of mass spectrometry: on 21 fish samples we recognized a mean number of 16 peaks as not-FAME (with a maximum of 32 not-FAME peaks in a European hake sample). Another problem in profile analyses is that the instrumental response factor is often considered as a constant.

In the present work the absolute analysis via total FA determination was carefully set up by executing a complete study of 12 different fish species from the Mediterranean area both of freshwater and marine origin. A set of 24 FAME was selected and compared with all FAME present in samples in order to ascertain the true percentage of their sum over total fatty acids. To our knowledge this is the first time this task has been carried out. The error derived from the assumption of a unique response factor is evaluated.

Materials and Methods

Chemicals and Reagents

The 24 monitored FAME are listed in Tables 3, 4, 5, 7. Methanol, *n*-hexane, potassium hydroxide, ethanol (96° ACS reagent), hydrochloric acid, and chloroform were purchased from Carlo Erba Reagenti, Milano, Italy. Boron trifluoride (BF₃) methanol solution (14 %) and sodium methoxide were purchased from Sigma Aldrich, St. Louis, MO, USA. Ethanolic KOH was prepared weekly by dissolving 10 g of potassium hydroxide in 20 mL of distilled water in a refrigerated 100 mL volumetric flask; after the solution became cool, the volume was brought up to the final 100 mL with ethanol. Analytical standards of triglycerides, individual analytical standards of the 24 FAME studied, FAME mixtures (Me95, Me96), and certified materials (PUFA-1 marine source, PUFA-3 Menhaden oil) were purchased either from Sigma Aldrich, St. Louis, MO, USA or from Larodan, Malmö, Sweden. The Standard Reference Material “1946 lake superior fish tissue” (fillets from adult lake trout, *Salvelinus namaycush*) was purchased from NIST®, National Institute of Standards and Technology, Gaithersburg, MD, USA. The FAPAS® test material T1475, cod liver oil, was from The Food and Environment Research Agency, Sand Hutton, UK.

Fish Samples

Fish samples were collected directly by us or by well-trained personnel, stored on ice, and transported to our

Institute. Here they were filleted as reported in our previous works [6, 7]. Three or more individuals were always pooled in all samplings.

Lipid Extraction

Lipids were extracted from the fish fillets by means of a methanol–chloroform procedure based on the method of Bligh and Dyer [20] modified by Kinsella et al. [21]. A 30–35-g amount of homogenized sample was used for lipid extraction.

Derivatization (Transesterification)

An aliquot of oil coming from the lipid extraction step was derivatized. FA were GC-analyzed as FAME (methyl derivatives): due to the negligible difference the percentage of a single FA was considered as coincident with the percentage of that FA methyl-derivated (FAME). Transesterification (methyl derivatization) was conducted by transferring 10 mg of extracted oil in a 20-mL amber tube with a Teflon-lined screw cap. Then 150 µL of chloroform was added and the tube was shaken by means of a Vortex Mixer (Heidolph, Schwabach, Germany), then 1.5 mL of BF₃ 14 % methanol solution, and 1.5 mL of methanol were added and a second shaking was carried out. The tube was immersed in a water bath for 18 min at 65 °C and then in a tap-water bath: 1.5 mL of distilled water was immediately added while 3 mL of *n*-hexane were added only after the solution had cooled. The tube was shaken and the upper layer was transferred in a 5-mL amber glass vial with a Teflon-lined screw cap and a cone shape at the end, then the solvent was evaporated under a stream of nitrogen.

The 3-mL addition of *n*-hexane in the 20-mL amber tube (and the evaporation from the 5-mL vial, after transferring) was repeated for other two times.

Finally in the 5-mL vial, brought to dryness, 200 µL of *n*-hexane were introduced: this solution was ready for GC injections.

Appropriate derivatizations of blank material were also carried out.

Alternative procedures were tested both for lipid extraction and for derivatization (sodium methoxide) and no differences in fatty acid profile were observed if compared with procedures normally used in this work.

Instrumental

GC-FID (Flame Ionization Detector)

The hexanic solution of FAME coming from derivatization step was injected in a 6890 Agilent gas chromatograph with flame ionization detector (GC-FID), equipped with a

SPBTM PUFA fused silica capillary column (Supelco inc., Bellefonte PA, USA) 30 m × 0.25 mm I.D., 0.20 µm film thickness. Helium as the carrier gas was used in ramp flow mode and was programmed as follows: 0.8 mL/min for 20 min, then increasing to 1 mL/min at a rate of 0.2 mL/min², 20 min hold, then increasing to 1.2 mL/min, at a rate of 0.2 mL/min² until the end of the analysis. Operating conditions for the oven temperature were: initial temperature 50 °C, 2-min hold, increasing to 210 °C, at a rate of 9 °C/min; this last temperature was maintained for 40 min. The post run temperature was 210 °C, 5-min hold. Injector temperature was 200 °C, while FID temperature was 275 °C. Injections were made in split mode (1:50) with an injection volume of 2 µL.

GC–MS (Mass Spectrometry)

The same hexanic solution of FAME coming from derivatization step was injected in GC–MS. Instrument used was a Varian 3900 GC connected to the mass spectrometer Saturn 2100T equipped with an Ion Trap analyzer. The column installed was a CP-WAX 52 CB (60 m × 0.32 mm I.D., 0.50 µm film thickness, 0.45 mm O.D.) from Chrompack, Middelburg, the Netherlands. Injections were made in split mode (1:100) with an injection volume of 0.5 ± 0.1 µL and by using 1 µL of *n*-hexane as a plug. The column oven temperature was settled at an initial value of 50 °C (2 min hold), increased to 140 °C (0 min hold, ramp of 22.5 °C/min), and finally increased to 228 °C (29 min hold, ramp of 2.0 °C/min). Helium as the carrier gas was used at a variable flow regulated by the applied pressure in this way: initial pressure 4.4 psi (0 min hold, observed column flow: 1.0 mL/min), increase to 10.0 psi (0 min hold, ramp of 1.40 psi/min, observed column flow at 10.0 psi: 1.1 mL/min), increase to 14.4 psi (0 min hold, ramp of 0.10 psi/min, observed flow at 14.4 psi: 1.1 mL/min), and finally increase to 29.2 psi (24.90 min hold, ramp of 3.70 psi/min, observed flow at 29.2 psi: 2.5 mL/min). Total runtime was of 79 min. Injector temperature was 220 °C. Mass spectra were obtained in EI (Electron Ionization) mode at 70 eV. Ion trap temperature was 180 °C. For quantitative analyses only full scan chromatograms (TIC: total ion current, also named RIC: reconstructed ion current) were used and the selected mass to charge ratio to acquire was in the 40–440 *m/z* range. SIS (selected ion storage, also named SIM: selected ion monitoring) measures were sometimes used only for qualitative evaluations. In such cases the desired ion mass was selected together with an isolation window of ±2.0 *m/z*. Examples of mass spectra obtained in full scan mode are shown in Fig. 1b and c.

We cite here that most fatty acid libraries are done with a Quadrupole instrument instead of Ion Trap. For this reason we created a “personal” fatty acid library by using

authentic standards with the Ion Trap: this library was used to confirm spectra obtained from peaks in fish samples. In any case no relevant differences were observed between spectra in our personal library and spectra present in the NIST[®] MS database installed on the Varian[®] Workstation.

Total Fatty Acid Determination

A second aliquot of oil (0.1 g) coming from the lipid extraction step was subjected to saponification to experimentally calculate the total FA. Saponification was conducted according to the method of Kinsella et al. [21]. The recovery was assessed by processing a known amount of the standard triglyceride tripalmitolein (tri-16:1n-7): at the end of the analysis the observed recovery was of 99.9 %.

Alternatively the total FA can be calculated by means of a conversion factor without carrying out experimental measures: it relates the total FA amount to the total lipids. This factor was developed by Weihrauch et al. [19] and is also used by the U.S. Department of Agriculture [22].

Results and Discussion

The procedure profile analysis–total FA determination–absolute analysis is based on the accurate percentage assessment of each FA (profile analysis) to be subsequently related with the total FA content in the sample (if, for example, the FA X is 20 % of total FA and the total FA content is 1,000 mg/100 g edible portion then the FA X is 200 mg/100 g edible portion).

Response Factor (RF)

The response factor (RF) is not mentioned at all in many fish fatty acid profile studies [6, 7, 12–16], especially when FID is used as the detector. This implies that a unique FID response factor for all fish fatty acids is tacitly assumed and that area percentage is assumed as coincident with mass percentage. On the other hand some works demonstrated that FID response factors for different FAME are not equal [23], thus contradicting this assumption. The use of an appropriate correction for each FAME in order to convert the percentages of peak areas into mass percentages could be needed or not in dependence of the desired degree of accuracy as clarified later. The EU Commission Regulation 2568/91 [24] reports an example of how such a correction could be made. Obviously the response factor is not a problem if calibration curves are used.

We investigated the FID response factor for 10 representative FAME for which absolutely fresh standards were used. We optimized experimental conditions and, on the basis of observations made by Schreiner [18] and the

AOCS method [25] some precautions were taken. Split injections were used both at GC-FID and GC-MS instrument (1:50 and 1:100 respectively), while the injection temperature was maintained not below 200–220 °C. In addition a WAX-type capillary column and an amount of solvent in the injection syringe, ahead of a 0.5-μL sample, were used in the GC-MS system (1 μL of solvent was loaded in the syringe before sample loading). It has been proposed in fact that the injection technique, especially in vaporizing injectors, is the main source of error in response factor evaluation of long chain PUFA (for example the attribution of a low RF only to FID behavior when also an incorrect injection may contribute). This error can be minimized by reducing discrimination effects in the injector [18]. In Table 1 they are reported RFs measured in this work and RFs measured by Schreiner for three long chain (LC)-PUFA these last normalized to 18:0 RF (normalized RF do not depend from the IS (internal standard) employed in measuring RF, but only from the FAME chosen for normalization; normalized RF are used for general comparisons between different research works). Normalized RF to 18:0 for the same three LC-PUFA but analyzed with our instrumental conditions are reported too: there is a good agreement between the two works.

Our research confirms what previously reported: even when injection errors are minimized we see that the FID response towards different FAME is not exactly the same. The magnitude of this difference can be evaluated. Among the 10 FAME we studied all kinds are comprised (from

short-chain SFA to long-chain PUFA) therefore the set may be considered as representative of FAME in general. We can see in Table 1 that GC-FID response factors for these 10 FAME vary in the range of 4 % RSD (relative standard deviation) with a significant negative deviation from the mean of 22:6n-3 RF.

In the present method a mean error of about 7 % over all FAME analyzed was observed in the final results (Tables 4, 7). With reference to the same Tables 4 and 6, the underestimation on 22:6-3 could be evaluated at about 14–18 % but more frequently the underestimation on 22:6n-3 reaches a value of 20–21 %. This was caused also by the above cited trend of RFs (together with other sources of error). We can affirm, therefore, that using a unique FID response factor for all FAME, as most analysts do and as we did in this work, leads, together with other sources of error, to a mean error of 7 % with the conditions used here. Obviously if other sources of error increase also the final mean error increases (such as, for example, attributing to the studied FAME the 100 % of FAME present in the sample, as is usually done; in some fortunate cases overestimation due to this wrong assumption could be compensated by the underestimation caused by a low response factor considered as constant but this is certainly not a scientific procedure). The inability to isolate the error caused by RF from other sources of error leads us to specify that 7 % is to be intended as the possible maximum mean error derived from RF with the conditions used in this work. This error may be judged as acceptable in most

Table 1 Response factors (RFs)

| FAME | GC-FID response factors measured in the present study | | | | GC-MS response factors measured in the present study | | | | GC-FID response factors normalized to 18:0 (RF _{18:0} = 1): comparison with the work of Schreiner | |

^c $RF = R_A C_S / R_S C_A$ where: R_A = analyte response (peak area), C_S = internal standard concentration, R_S = internal standard response, C_A = analyte concentration

^d 21:0 fatty acid methyl ester was added as IS (internal standard) at a concentration of 492.96 mg/L

nutritional evaluations. If a better accuracy is requested it must be taken into account an increase in procedure complexity. One way can be the assessment and the use of corrections for analytes studied as cited above [24] by employing absolutely fresh standards of FAME: this procedure was applied in the present work to correct DHA. In our conditions we observed that the correction factor to convert the percentage of DHA peak area into mass percentage is equal to 1.26. This factor works very well when the real percentage of the 24 selected FAME is near to 90 % that is the case of most samples (19 on 21 samples, see Table 2). In Tables 4, 5, and 7 there is a separate row with the corrected DHA value.

Another way is the calculation and the use of theoretical response factors [18].

As regards GC–MS full scan response factors they are reported in Table 1 together with GC–FID values. We can see that RFs have the same reciprocal relations on the two instruments; namely, they are different from each other but vary in a not very broad range, with the exception of DHA that confirms a noticeable negative deviation also in GC–MS. The unusual overestimation of GC–FID for the 16:0 FAME, with respect GC–MS, is not caused by a very different MS response factor but it is due to one or more

peaks that coelute with 16:0 on FID column, as shown in Fig. 2 and explained below.

Qualitative Analysis

In this work an investigated FAME had to match the retention time (t_R) of the pure certified standard both on FID column and MS column if the presence of that FAME had to be confirmed. Further verifications completed the identification step, such as the comparison of mass spectrum with that of the pure standard injected by us and with the spectrum present in the NIST® MS database. When necessary injections in SIS, selected ion storage (otherwise named SIM, selected ion monitoring) were carried out for qualitative evaluations.

A double profile analysis FID-based and MS-based was always achieved and this quantitative cross control allowed that the purity of GC–FID peaks was checked, as explained below. First of all we accurately verified that the GC–MS peaks did not coelute with other peaks. Under our conditions, GC–FID and GC–MS generally showed the same percent result for a certain FAME in a chosen sample. Being the GC–MS peaks certainly not interfered it follows that GC–FID peaks are also not interfered, but when a

Results obtained by GC–MS measurements and by applying the (1E) equation

Fig. 2 GC-FID chromatogram of two different fish samples. **a** In this fish sample there are coeluting peaks with 16:0 as revealed by the FID overestimation with respect GC–MS, but they are not visible. **b** In this sample there is the same FID overestimation and one of the coeluting peaks with 16:0 it is also visible

relevant disagreement in the sense of quantitative overestimation by GC-FID is present a GC-FID coelution was detected. With this technique we discovered a frequent GC-FID coelution that can be inferred from Tables 3, 4, and 7 and is shown in Fig. 2. FAME peak coelutions not detectable on GC-FID equipment is cited in the literature as a real event [26]. Alternatively we had the possibility of using the same capillary columns on both instruments: this would make possible a more immediate control of coelutions on GC-FID equipment. Nevertheless, we preferred to use two different columns for qualitative purposes as the following explains. Due to molecular FAME characteristics, EI (electron ionization)-GC–MS often does not show adequate specificity toward particular C–C double bond positional isomers. In some cases, retention times are of primary importance and the double instrumental analysis with the use of two columns different in length and polarity was chosen so as to acquire complementary data, as recommended [24].

The good resolution of GC–MS Chromatograms can be observed in Figs. 3 and 4 (24:1n-9 fatty acid, normally detectable in fish samples, is completely separated from 22:6, with a shorter retention time: it is not visible in Fig. 3 due to its low intensity).

The 24 Selected FAME: Their Total Amount in Samples

The exact percentage of an investigated FAME can be assessed only when the number and the amount of all FAME present in the sample are known. To solve this problem we carried out a complete study on the 12 species shown in Table 2. Mass spectrometry has identification power and sensitivity enough to detect the presence of FAME even in trace quantities. Even if the possible

The same gilthead seabream sample listed in Table 2, second row

^a Number of GC-FID transesterifications = 2, number of GC-FID injections per transesterification = 1

^b Number of GC–MS transesterifications = 1, number of GC–MS injections per transesterification = 1

isomers indicated by the NIST[®] MS database could be more than one, nevertheless, after that Mass Spectrum was examined, the attribution, or not, of the investigated peak to the FAME class was always very clear. By considering all FAME in the sample (with a signal to noise ratio >3) GC–MS chromatograms of fish samples generally showed a number of FAME of about 80, but in some cases this number was 100 or more.

For each species the global amount of the 24 selected FAME was obtained as follows:

$$\begin{aligned} &\text{global amount of the 24 selected FAME (\% of total FAME)} \\ &= \frac{(\text{sum of peak areas of the 24 selected FAME}) \times 100}{\text{sum of peak areas of all FAME revealed}} \end{aligned} \quad (1E)$$

Results are shown in Table 2. For the 12 species examined in this study we may see that the mean

percentage of the 24 selected FAME, over total FAME, is 89.8 ± 2.8 . On the basis of all observations made by us in our work we can round the sum of the 24 selected FAME to 90 ± 3 % of total FAME. This value can be usefully employed whenever one of the 12 species is investigated for the FAME Profile and will be used in any calculation of this work.

Fig. 5 GC-FID chromatogram of the thinlip mullet sample of Table 4

Profile Analysis (Percentages)

The 24 selected peaks represent the 90 ± 3 % of total FAME in samples, as cited above, and this value was used as reference in calculating the amount of each FAME:

$$\text{amount of the investigated FAME in the sample (\%)} = \frac{(\text{peak area of the investigated FAME}) \times 90}{\text{sum of peak areas of the 24 selected FAME}} \quad (2E)$$

In Eqs. (1E) and (2E) area percentages were approximated to mass percentages by taking into account considerations exposed in the response factor paragraph reported above. Table 3 shows the profile analysis for the gilthead sea bream sample of Figs. 3 and 4. Results were obtained by applying the (2E) equation both to GC-FID and GC-MS peak areas. Other Profile analyses are shown in Tables 4 and 7. The good agreement generally observed between percentages coming from GC-FID and coming from GC-MS, made it possible that the profile used to carry out the subsequent absolute analysis was generally that obtained by GC-FID.

Absolute Analysis (mg/100 g Edible Portion)

Total FA Determination

From the results expressed as percentages (profile analysis) the content of each FA in mg/100 g of edible portion can be obtained if the exact amount of total FA in mg/100 g of edible portion is known. We experimentally determined this quantity by means of saponification achieved as reported in “Materials and Methods”. An aliquot of oil, from the total extracted, was taken for saponification. The total FA in mg/100 g of edible portion can be obtained according to the following equation:

$$m = \frac{F}{T} \times P \times 1,000 \quad (3E)$$

where m is the total FA in 100 g of edible portion (mg/100 g of edible portion), T is the aliquot of oil weighed for

Profile used: GC-FID. The samples are the same as those listed in Table 2. Results for thinlip mullet are shown in Table 4

saponification (g), *F* is the total FA found in the aliquot *T* by saponification (g), *P* is the lipids in edible portion weighed (g/100 g).

In Table 4 the total FA content (*m*) was determined in a thinlip mullet sample by applying the Eq. (3E). The value of *m* (total FA) was found to be $3,491.6 \pm 34.5$ mg/100 g of edible portion. If, on the same sample, the factor for finfish derived by Weihrauch et al. [19] is applied (this factor provides the FA amount in a sample without executing the saponification step) we obtain $m = 3,525.2$ mg/100 g. It can be seen that the Weihrauch conversion procedure fits very well with the experimental value so confirming its validity.

Absolute Amount of Each FA

In the same thinlip mullet sample of Table 4 the absolute amount of each FA (mg/100 g of edible portion) was determined by applying the Eq. (4E) reported below:

$$\begin{aligned} &\text{amount of the investigated FAME in the sample (mg/100g)} \\ &= \frac{[\text{percentage of the investigated FAME in the sample (\%)}] \times m}{100} \end{aligned} \quad (4E)$$

In Fig. 5 the GC-FID gas chromatogram obtained for the thinlip mullet sample cited here is shown.

In the 20 remaining fish samples other than thinlip mullet the absolute amount of each FA (mg/100 g of edible portion) was determined by using the factor derived by Weihrauch et al. [19]. Results are listed in Table 5 where the value of *m* for each sample, obtained by using the Weihrauch conversion, is also reported.

Validation and Analytical Quality Control

The certified reference material “FAPAS® T1475-cod liver oil” was used to validate the profile analysis as described in

this paper. It was analyzed in the exact way exposed above (“Results and Discussion”, profile analysis). If we take into account that this material is not strictly within the field of method applicability (cod liver instead of fish fillet) result can be viewed as good (see Table 6) with the expected error either on 22:6n-3 (uncorrected value) and on the other three LC-PUFA.

The Standard Reference Material “NIST® 1946 Lake Superior Fish Tissue” was used to validate the entire approach profile analysis–total FA determination–absolute analysis as proposed in this work. It was analyzed in the exact way exposed above (“Results and Discussion”, absolute analysis). The result is reported in Table 7. In the present research (and with the GC-FID column used) we observed that the 16:0 fatty acid percentage is constantly overestimated by GC-FID with respect GC-MS. This is due to a coelution, see Fig. 2. For example the FID value for 16:0 in the reference material is 14.68 % and the obtained MS value is 12.51 %. The same situation can be observed in Tables 3 and 4.

One of the most important controls we performed was the analysis of the thinlip mullet sample of Table 4 by employing a method calibration curve-based we executed specifically for this purpose. As in the case of the Standard Reference Material NIST® this control was used to validate the entire approach profile analysis–total FA determination–absolute analysis. We used fresh standards and replicate measures. In order to achieve this objective 10 FAME were dissolved in such a way that solutions at four different concentrations were obtained. Each one, of the four concentrations, was prepared in triplicate and GC-FID injected for a total number of 120 dilutions that led to 10 calibration curves (peak area vs. concentration). Recovery analyses were carried out on standard triglycerides that were transesterified as described in “Materials and Methods”. Results showed the same recovery for different FA with a mean value of 45 ± 1 %. Peak areas observed in GC-FID

^a GC-FID: number of transesterifications = 2, number of injections per transesterification = 1^b GC-MS: number of transesterifications = 1, number of injections per transesterification = 1^c Number of total FA determinations by saponification = 5. Total measured FA = 9,316.7 ± 539.4 mg/100 g. Total measured lipids = 10.34 ± 1.30 g/100 g. Total declared lipids = 10.17 ± 0.48 g/100 g

Chromatograms of the thinlip mullet sample of Table 4 were used in combination with calibration curves and measured recoveries to evaluate the content of each FAME

(mg/100 g edible portion). Results obtained with calibration curves were compared with results obtained with the method proposed in this work. Table 4 shows a good

agreement between the two independent techniques, if we except DHA, for which accuracy is at the level discussed in this work. The calibration approach was used also to evaluate the content of 22:6n-3 in the Standard Reference Material NIST® of Table 7: result was of 873 mg/100 g. This means an error of -5 % with respect to the declared value so confirming a better accuracy of methods calibration-based. These validation measures indicate that the procedure profile analysis–total FA determination–absolute analysis as conducted here can be usefully employed as an alternative to the procedure calibration-based when one of the 12 Mediterranean fish species cited above is analyzed. With some advantages and disadvantages to be taken into account. A great advantage lies in complexity reduction: when GC-FID and GC-MS Chromatograms of the sample are obtained is sufficient to apply the value of 90 ± 3 % and the conversion factor of Weihrauch et al. [19] as exposed above to obtain the absolute final result. Absolutely fresh standards of FAME are not necessary in each analysis. This makes it possible that absolute analyses can be readily conducted on a routine basis on fish samples and for a significant number of fatty acids. The main disadvantage is that the method is probably of lower accuracy with respect to methods that are calibration-based, especially in some cases. Nevertheless accuracy is enough for most nutritional evaluations being of the 7 % mean error associated with results under the conditions used here.

Plasma Levels of FABP4, but not FABP3, Are Associated with Increased Risk of Diabetes

Luc Djoussé · J. Michael Gaziano

Received: 24 January 2012 / Accepted: 25 May 2012 / Published online: 16 June 2012
© AOCs 2012

Abstract Little is known about the association between plasma concentrations of fatty acid binding protein 3 and 4 and the risk of diabetes in population-based cohorts. In a prospective nested case–control design, we studied 149 cases of diabetes and 149 matched controls from the Physicians' Health Study. Plasma fatty acid binding proteins were measured on frozen specimens collected between 1995 and 2001 by ELISA. Cases of diabetes were self-reported and validated in a subsample via review of medical records. We used conditional logistic regression to estimate multivariable relative risks. The mean age at baseline was 64.9 years and median plasma fatty acid binding protein 3 and 4 were 2.12 ng/ml (IQR 1.62–2.66) and 15.32 ng/ml (IQR 12.14–18.73), respectively. In separate models, each fatty acid binding protein was positively associated with the risk of diabetes in a conditional logistic regression adjusting for matching variables, smoking, and hypertension. However, upon adjustment for each other, only fatty acid binding protein 4 (but not 3) was positively

associated with the risk of diabetes [relative risk (95 % CI) 1.0 (reference), 2.73 (1.08–6.89), 2.66 (1.11–6.42), and 6.89 (2.83–16.80) across consecutive quartiles of fatty acid binding protein 4, *P* for trend <0.0001]. The FABP4–diabetes association was modified by body mass index (*P* interaction 0.03). Our data showed a positive association between plasma fatty acid binding protein 4 but not 3 and the risk of diabetes in US male physicians. The interaction with body mass index warrants further investigations.

Introduction

Type 2 diabetes (DM) is a major health issue with worldwide health consequences [1–4]. It is estimated that more than 350 million people will be diagnosed with DM by 2030 [5]. Complex secular trends in nutrition and physical activity have led to a dramatic increase in the prevalence of being overweight and obesity [6] with resulting increased prevalence of DM [4, 7, 8]. Adipocytes are known to produce various adipokines, which can influence inflammation, lipids, and glucose metabolism, all of which are relevant in the development of DM [9, 10]. Fatty-acid-

binding proteins (FABPs) are a family of carrier proteins for fatty acids and other lipophilic substances such as eicosanoids and retinoids [11–13]. Of the 9+ members of FABPs [14], FABP4 is mainly expressed by adipocytes and macrophages whereas FABP3 is expressed by skeletal and heart muscle. Mice lacking FABP4 gene gain weight under high-fat diet but do not develop insulin resistance as would be the case in wild type mice [15]. This observation suggests that FABP4 may play a role in the obesity–DM association. Such a hypothesis is supported by the fact that expression of FABP4 leads to insulin resistance in animals [16–18]. While other studies have reported cross-sectional associations between FABP4 and the prevalence of metabolic syndrome [12, 19, 20], only one prospective study has suggested a positive association between plasma FABP4 and incident DM [21]. No previous study has examined the association between FABP3 and the risk of DM and it is unclear whether FABP3 and FABP4 are independently associated with the risk of DM. Hence, we sought to assess whether plasma concentrations of FABP3 and FABP4 are independently associated with the risk of DM in US male physicians.

Materials and Methods

Study Population

Participants in these analyses were members of the Physicians' Health Study I and II who provided blood samples between 1995 and 2001. The Physicians' Health Study I was a completed randomized, double-blind, placebo-controlled trial designed to study the use of low-dose aspirin and beta-carotene for the primary prevention of cardiovascular disease and cancer [22, 23]. The Physicians' Health Study II started in 2001 and was a randomized trial assessing the effects of vitamins on the risk of cardiovascular disease and cancer [24, 25]. Current analyses used a prospective nested case–control design with a risk set sampling technique to select subjects. All eligible subjects were free of DM at the time of blood collection. For each case of incident DM occurring during follow up, we randomly selected a control among participants who were alive and free of DM at the time of diagnosis of the index case (risk set) and matched to the case on age at blood collection (within 1 year), race, year of birth (same), and time of blood collection (within 30 days). From the total pairs identified, we randomly selected 150 pairs for the current study. Because one control did not have data on FABP3 and FABP4, our final sample consisted of 149 matched pairs. Each participant signed an informed consent form and the Institutional Review Board at Brigham and Women's Hospital approved the study protocol.

Measurement of Fatty Acid Binding Protein 3 and 4

Plasma FABP4 was measured using the Human Adipocyte FABP ELISA (Human FABP4 ELISA) from BioVendor LLC (Candler, NC). In this assay, samples and standards are added to microplate wells coated with immobilized polyclonal anti-human AFABP antibody. After incubation and washing, biotin-labeled polyclonal anti-human AFABP antibody is added. Following a second wash, streptavidin-HRP conjugate is added. After a final wash, tetramethylbenzidine is added to the wells. An acidic stop solution terminates the reaction. The optical density of the wells is measured on a SpectraMax spectrophotometer (Molecular Devices, Sunnyvale, CA) at 450 and 630 nm. The intensity of the color formed by the enzymatic reaction is directly proportional to the concentration of FABP4 in the sample and concentration is determined from a standard curve. The inter-assay coefficient of variations were 2.6–5.1 %.

Plasma FABP3 was measured using the Human H-FABP ELISA (Human FABP3 ELISA) from Cell Sciences, Inc (Canton, MA). In this assay, samples and standards are added to microplate wells coated with immobilized anti-human HFABP antibody. After incubation peroxidase conjugated antibody is added. Following a wash, tetramethylbenzidine is added to the wells. An acidic stop solution terminates the reaction. The optical density of the wells is measured on a SpectraMax spectrophotometer (Molecular Devices, Sunnyvale, CA) at 450 and 630 nm. The intensity of the color formed by the enzymatic reaction is directly proportional to the concentration of FABP3 in the sample and concentration is determined from a standard curve.

Ascertainment of Incident DM in the PHS

Ascertainment of DM and other endpoints in the PHS has been achieved using annual follow-up questionnaires. We have validated the diagnosis of self-reported DM in a sample of men by reviewing their medical records. In the PHS, a systematic request of medical records is available for the trial primary endpoints (myocardial infarction, stroke, cancer, death, and pulmonary embolus). For the validation study of DM, we selected all participants who reported a diagnosis of DM on the follow-up questionnaires and had a subsequent diagnosis of myocardial infarction. The rationale for selecting myocardial infarction was that medical records for this event are more likely to contain pertinent information on past medical history, laboratory measurements, and current medications. In contrast, records to confirm cancer or death events are limited mostly to histological reports or death certificates, respectively. Of the 186 subjects who suffered myocardial infarction after a self-reported diagnosis of type 2 diabetes,

we randomly selected half (93 people) for chart review. Medical records were available for 60 subjects. Two physicians independently reviewed these charts. A diagnosis of DM was made if there was sufficient evidence in the chart defined as one of the following: (a) diagnosis of DM on the discharge summary, (b) current treatment with insulin or oral hypoglycemic agents, or (c) fasting glucose above 126 mg/dl or non-fasting glucose above 200 mg/dl. Using these criteria, DM was confirmed in 59 out of 60 cases (98.3 %). There was an excellent agreement between the two examiners ($\kappa = 100\%$).

Other Variables

Demographic information was obtained through self-reports. At baseline, each subject provided information on exercise (how often do you exercise vigorously enough to work up sweat? Possible answers included rarely/never, 1–3/month, 1/week, 2–4/week, 5–6/week, and daily); smoking (never, former, and current smoker); and alcohol intake (rarely/never, 1–3/month, 1/week, 2–4/week, 5–6/week, daily, and 2+/day). Self-reported baseline weight and height were used to compute body mass index (weight in kilograms divided by height in meters squared). Information on prevalent hypertension and coronary heart disease was collected at baseline and through follow-up questionnaires. An endpoint committee of the Physicians' Health Study reviewed the medical records to confirm the diagnosis of myocardial infarction and coronary bypass or angioplasty.

Statistical Analyses

Due to the non-Gaussian distribution of FABP3/4, we use the natural logarithm to normalize their distributions. We created quartiles of log(FABP3) and log(FABP4) using the distribution of these biomarkers in the control series. Means and percentages of baseline characteristics of the study participants are presented according to diabetes status. We used conditional logistic regression to estimate the relative risk of diabetes using the lowest quartile of each biomarker as the reference category. The multivariable adjusted model controlled for matching variables (race, age, time of blood collection, and year of birth), cigarette smoking, hypertension, and mutual control for FABP3 and FABP4. We also evaluated confounding by prevalent coronary heart disease (myocardial infarction, coronary bypass or angioplasty). Additional control for exercise and alcohol consumption did not alter the conclusions (data not shown). Furthermore, we modeled FABP4 and FABP3 as continuous variables using the logarithmic transformed values and estimated relative risks associated with each standard deviation higher log-FABP4 or log-FABP3 using

the models described above. We considered effect measure modification by body mass index given our prior findings of interaction between body mass index and FABP4 in older adults [26], by including product terms of both main exposures (FABP3/4) and body mass index and main effects in the regression model. To obtain a *P* value for linear trend, we created a new variable that was assigned the median value of FABP3/4 in each quartile within the control series and fitted such a variable in the conditional logistic regression. All analyses were performed using SAS (SAS version 9.3, NC) and the alpha level was set at 0.05. All *P* values were two-sided.

Results

The mean age was 64.9 years and 84.6 % were Caucasians. FABP3 and FABP4 were not normally distributed (skewness and kurtosis were 2.92 and 12.2, respectively, for FABP3; corresponding values for FABP4 were 1.84 and 5.60). Subjects who developed DM had a higher body mass index, higher prevalence of coronary heart disease, higher plasma concentrations of FABP3 and 4, lower prevalence of vigorous exercise and hypertension, and were more likely to be current smokers than controls (Table 1). Body mass index was positively correlated with log-transformed FABP4 (Spearman correlation coefficient = 0.44, $P < 0.0001$) but not with log(FABP3) (Spearman correlation coefficient = -0.02, $P = 0.78$). Spearman correlation coefficient between log(FABP3) and log(FABP4) was 0.23 ($P = 0.005$). In a conditional logistic regression model adjusting for matching factors, log(FABP3) was positively associated with diabetes [relative risk (95 % CI) of 1.0 (ref), 0.68 (0.30–1.54), 1.11 (0.56–2.23), and 2.24 (1.09–4.59) across consecutive quartiles of log(FABP3), P for trend 0.008]. Additional adjustment for hypertension and smoking had little effect on the results (P for trend 0.012). Likewise, log(FABP4) was positively associated with DM in the basic model [relative risk (95 % CI) 1.0 (ref), 1.62 (0.73–3.61), 1.84 (0.85–4.01), and 5.20 (2.40–11.27) across consecutive quartiles of log(FABP4), P for trend <0.0001]. Additional adjustment for hypertension and smoking strengthened the results [RR (95 % CI) 1.0 (ref), 2.08 (0.88–4.89), 2.32 (1.01–5.31), and 6.23 (2.75–14.10), respectively]. When both FABP4 and FABP3 were included in the fully adjusted model, FABP4 but not FABP3 was associated with the risk of DM (Table 2). Additional adjustment for prevalent coronary heart disease had minimal effect on the odds ratios [e.g., relative risks were 1.0 (ref), 2.70 (1.06–6.87), 2.87 (1.16–7.01), and 6.87 (2.82–16.76) across consecutive quartiles of FABP4]. Each standard deviation increment of log(FABP4) was associated with 80 % increased risk of

Table 1 Characteristics of 298 male physicians according to diabetes status

| Characteristics | Diabetes cases (<i>N</i> = 149) | Controls (<i>N</i> = 149) |
|--------------------------------------|-------------------------------------|-------------------------------|
| Age (years) ^a | 64.9 ± 8.1 | 64.9 ± 8.1 |
| Race (% Caucasian) ^a | 84.6 | 84.6 |
| Body mass index (kg/m ²) | 28.3 ± 4.6 | 25.5 ± 3.5 |
| log(FABP3) | 0.87 ± 0.58 | 0.75 ± 0.49 |
| log(FABP4) | 2.98 ± 0.42 | 2.73 ± 0.38 |
| Current smokers (%) | 7.4 | 3.4 |
| Former smokers (%) | 41.6 | 41.6 |
| Current alcohol drinkers (%) | 80.1 | 84.5 |
| Vigorous exercise (%) | 48.3 | 68.7 |
| Hypertension (%) | 29.5 | 36.9 |
| Prevalent coronary heart disease (%) | 13.4 | 10.1 |

Data are presented as mean ± standard deviation or percentage

^a Matching variables

DM (95 % CI 37–137 %), Table 2). There was evidence for interaction between body mass index and FABP4 (*P* for interaction 0.03) but not FABP3 (*P* = 0.29) in the fully adjusted model. Unfortunately, we did not have adequate data (i.e. only 17 matched pairs with body mass index <25 kg/m²) for stratified analyses by body mass index.

Discussion

In this prospective nested case–control study, we found a positive and linear association between plasma FABP4 and FABP3 on the risk of DM among United State male physicians when examined individually. However, only

FABP4 (but not FABP3) was independently associated with the risk of DM upon mutual adjustment for the other FABP. The risk of DM was nearly seven fold higher in the fourth compared to the first quartile of FABP4 adjusting for confounders and FABP3. Lastly, the FABP4–diabetes association was modified by body mass index whereas no interaction was seen between body mass index and FABP3. This is the first study to show that FABP4 is positively related to DM risk, independent of FABP3 in a large sample of humans.

Several animal studies have examined the effects of FABP4 insulin resistance and DM risk [13, 15, 16, 27]. However, only limited data is available in humans. In cross-sectional studies, FABP4 was associated with a higher prevalence of metabolic syndrome [10, 12, 19, 20, 28]. Furthermore, in a small Chinese population, a higher concentration of FABP4 was associated with a two-fold increased risk of DM after 10 years of follow up [21]. Those findings are consistent with a positive association between plasma FABP4 and incident DM among US older adults (65+ years at baseline) [26]. However, neither of the previous studies examined the role of FABP3 on the FABP4–DM association for further comparison. The current study suggests that FABP3 may not be as important as FABP4 in the development of DM. The effect modification observed between FABP4 and body mass index is consistent with data from the Cardiovascular Health Study showing similar interaction [26]. We had inadequate data to conduct stratified analyses by body mass index in our study. However, the Cardiovascular Health Study reported a 78 % higher risk of diabetes (95 % CI 13–181 %) per standard deviation higher FABP4 in men with body mass index below 25 kg/m² but no significant relation in overweight [1.03 (0.71–1.49)] or obese [1.43 (0.90–2.28)] men

[26]. It is possible that being overweight/obesity confers a higher background rate for diabetes, thereby making it more difficult to detect a small increment in diabetes risk in such a high-risk population. In contrast, with a lower background risk of diabetes in lean subjects, a small increase in diabetes risk conferred by FABP4 might be readily detectable. Our working hypothesis is that FABP4 is downstream of obesity and future work is needed for further investigation.

Data from the Nurse's Health and Health Professionals Follow-up Studies [17] showed that a functional mutation (T-87C) in the FABP4 gene was associated with a reduced expression of FABP4 in adipocytes and a lower risk of DM (especially among obese subjects). Those data also suggest a possible interaction between body composition and FABP4 on DM risk and are consistent with the interaction observed in the current study. In contrast, other investigators did not show a major effect of FABP4 gene on diabetes risk [29]. At this point, little is known about potential pathways by which FABP4 may influence the risk of DM in humans.

FABP3 and 4 are transport proteins and play an important role in lipid metabolism and perhaps glucose utilization [30, 31]. FABP4-knockout mice remain insulin sensitive despite the development of adiposity under a high-fat diet [15]. In contrast, wild type mice develop insulin resistance and adiposity under a high-fat diet. A working hypotheses could be that FABP4 might mediate obesity-induced insulin resistance and subsequent development of DM. Alternatively, FABP4 may promote lipolysis by removing fatty acids that inhibit hepatic sensitive lipase [27, 32]. Lastly, FABP4 may increase the risk of DM by interfering with key enzymes in the de novo lipogenesis [33, 34]. Unfortunately, we did not have appropriate data to explore further the role of FABP4 on DM risk in our study. At this point, we cannot eliminate the possibility that elevated plasma FABP4 could just be a marker of metabolic derangement associated with metabolic syndrome, obesity, or diabetes. Consistent with this hypothesis, the PREDIMED data suggest that elevated plasma FABP4 predicts atherogenic dyslipidemia in 578 volunteers after a median follow up of 4 years [35]. FABP4 has also been reported as a biomarker of atherogenic dyslipidemia, independent of obesity and insulin resistance [36]. Though our subjects were free of DM at the time of blood collection, we cannot exclude the prevalence of metabolic syndrome or abnormal glucose tolerance at the time of blood collection.

Our study has some limitations. The fact that all participants were male physicians, most of whom were Caucasians, limits the generalizability of the current findings. Our validation of diabetes was limited to a subsample in this cohort, hence, we cannot exclude the possibility of

misclassification of DM. Such misclassification of DM cases is more likely to be non-differential with respect to FABP3 and 4 concentrations and would likely have led to an underestimation of the true association. As an observational study, we cannot rule out chance, residual or unmeasured confounding as alternative explanation of our results. On the other hand, the use of risk set technique, matching to minimize confounding, the availability of several potential covariates, and standardized methods for follow-up and cases ascertainment are strengths of the present study.

In summary, our data suggest that FABP4 but not FABP3 is positively associated with a higher risk of DM. Such an association appears to be modified by body mass index. If confirmed in other studies, FABP4 may offer a new pharmacological targets in the management of diabetes and/or risk stratification.

Acknowledgments Dr Djoussé has full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. We are indebted to the participants in the PHS for their outstanding commitment and cooperation and to the entire PHS staff for their expert and unfailing assistance. The Physicians' Health Study is supported by grants CA-34944, CA-40360, and CA-097193 from the National Cancer Institute and grants HL-26490 and HL-34595 from the National Heart, Lung, and Blood Institute, Bethesda, MD.

A Single Bout of Exercise Increases the Expression of Glucose but not Fatty Acid Transporters in Skeletal Muscle of IL-6 KO Mice

Abstract IL-6 is a biologically active cytokine released during exercise by contracting skeletal muscles. It appears to be highly involved in the regulation of muscles energy substrate utilization. Whether an ablation of IL-6 (IL-6 KO) in mice subjected to a single bout of exercise affects lipid and/or glucose metabolism is currently unknown. In the present study we examined fatty acid (FAT/CD36, FABPpm, FATP-1, FATP-4) as well as glucose (GLUT-1, GLUT-4) transporters expression in IL-6 KO mice. In addition, intramuscular glycogen and lipid content was also evaluated. The expression of all fatty acid transporters (FAT/CD36: +25 %; FATP-1: +31 %; FABPpm: +12.7 %; FATP-4: +7.2 %) was increased in muscles from IL-6 KO mice compared to wild type (WT) mice. Accordingly intramuscular lipid content was also increased in these muscles (FFA: +38 %; DAG: +36 % and TAG: +160 %). Interestingly, IL-6 deficiency had only minor effect on glucose transporters expression (GLUT-1: −4 %, and GLUT-4: −5.1 %), with no apparent difference in muscular glycogen content. A single bout of exercise increased the glucose transporters (GLUT-1: +8 %; GLUT-4: +15 %) as well as FA transporters (FAT/CD36: +13 %; FABPpm: +4.5 %; FATP: +2.5 %, FATP-4: +10 %) expression but only in WT skeletal muscles. In muscles from IL-6 KO mice exercise induced changes only in glucose (GLUT-1: +20 %; GLUT-4: +35 %) but not in the content of FA transporters. Concomitantly, IL-6 KO

mice displayed shorter time toward exhaustion with more pronounced reductions in intramuscular lipid and glycogen content. We may speculate, that IL-6 deficiency provokes more pronounced glucose utilization over lipid oxidation during a single bout of exhausting exercise.

Introduction

In the last few years, evidence has accumulated showing that interleukin-6 (IL-6) is an important molecule involved

not only in immune regulation, hematopoiesis or inflammation but also in glucose and lipid metabolism [1]. IL-6 is synthesized by skeletal muscle and its secretion is markedly augmented during contractile activity [1, 2]. The resultant increase in IL-6 serum concentration positively correlates with increased glucose uptake and fatty acid (FA) oxidation in skeletal muscles. Likely both seem to be mediated by activation of AMPK (AMP-activated protein kinase) [1, 3, 4]. The activation of AMPK, which increases usage of energy substrates is commonly implicated in insulin sensitizing actions in skeletal muscles. However, this view has been recently challenged since serum IL-6 elevation was commonly observed in patients with metabolic disorders such as obesity and/or diabetes [5–7]. There is no evident explanation for this discrepancy. It might be speculated that IL-6 is also a potent activator of SOCS (suppressor of cytokine signaling) and thus increased activation of SOCS3 in skeletal muscles and liver leads to insulin resistance commonly observed in patients with obesity and diabetes [8].

At rest, skeletal muscles use both glucose and fatty acids (FA) as an equivalent energy source [9, 10]. However during exercise, the type of substrate used depends mainly on the intensity and the duration of exercise [2, 11]. It is generally well accepted that, with increased intensity of the exercise, there is a substantial enhancement in glucose utilization. Importantly, a crucial (but not exclusive) rate-limiting process in myocytes glucose utilization, involves transport of glucose across the sarcolemma. The process, that is specifically mediated by membrane glucose transporter proteins belonging to the facilitative GLUT/SLC2A family [12]. In contrary, fatty acids (FA), due to their hydrophobic nature, are able to rapidly traverse the lipid bilayer of the cell membrane by simple diffusion [13]. However, in addition to passive diffusion, a considerable evidence has accumulated to support the existence and importance of a protein-mediated FA transport [14–16]. In skeletal muscles a number of FA transporters have been identified, including (1) a family of fatty acid transport proteins (i.e. FATP-1,4), (2) plasma membrane associated fatty acid binding protein (FABPpm) and (3) fatty acid translocase (FAT/CD36) [17–19].

Given that IL-6 is an important muscle derived factor highly involved in myocyte energy substrate metabolism, we sought to investigate the effect of IL-6 ablation on glucose (GLUT-1, 4) and FA transporters (FAT/CD36, FABPpm, FATP-1,4) expression in skeletal muscle challenged by exercise. Additionally, intramuscular lipids and the glycogen contents were assessed. Aware of the age influence in IL-6 KO phenotype, we investigated the effect of a single bout of exhausting exercise in older mice (12 months).

Materials and Methods

Animals and Experimental Model

Male mice, wild type (C57B4/6J) and IL-6 KO (C57B4/6J IL-6^{tm1 K^{opf} -/-}) were randomly allocated into two groups: sedentary and exercised till exhaustion (swimming). Until the day of experiment (12 months) mice were bred on site in an approved animal holding facility with free access to food and water. The study was conducted in accordance to guidelines of local ethic committee for animal care.

Methods

Genotyping

IL-6 KO mice was tested using genomic DNA and PCR method to confirm deficiency of IL-6 gene as described elsewhere [20, 21]. Briefly, “Genomic mini” kit (A&A Biotechnology, Gdansk, Poland) was used to isolate DNA from mouse tails followed by PCR [applied custom made primers: F 5'-AAGTGCATCATCGTTGTTCATAC3'; R 5'-CCATCCAGTTGCCTTCTTG-3' and commercially available DNA polymerase Taq “Marathon” (A&A Biotechnology, Gdansk, Poland)]. Subsequently DNA was separated on the 1 % agarose gel with ethidium bromide by means of electrophoresis. As a result we gained material from WT animals' encompassed DNA fragments with size ca. 900 bp, whereas DNA fragments originate from knock-out mice (size about 1400 bp) additionally contained a fragment of neomycin cassette.

Exercise Protocol

Animals were used after 7 days of acclimatization to the laboratory conditions. They were maintained in a temperature-controlled environment (22 ± 1 °C) with a 12-h light–dark cycles beginning at 7 a.m. Experiments took place between 1.00 p.m. and 4.00 p.m. in the air-conditioned, sound-isolated room with the possibility of an accurate control of the light intensity. A single bout of exercise was carried out in a tank consisted of a circular, galvanized and painted in white steel pool (120 cm in diameter, 30 cm height) filled up to 26 cm depth with water maintained at 30 ± 1 °C. The mice were submitted to swimming exercise carrying load (lead fish sinkers, attached to the tail) corresponding to 5 % of their body weight. Animals were assessed to be fatigued when they remained under the water surface for 5 s [16].

Intramuscular FA (FAT/CD36, FABPpm, FATP-1,4), Glucose (GLUT-1, GLUT-4) Transporters and pAMPK/AMPK Protein Expression

The protein expression of FAT/CD36, FABPpm, FATP 1, FATP 4 and GLUT-1, GLUT-4 (50 µg) as well as AMPK and pAMPK (90 µg) was determined in muscle homogenates (soleus). Western blotting technique was used to detect the protein content as described by us and others [22, 23]. Briefly, the total protein content in each sample was determined by bicinchoninic acid method with BSA serving as a protein standard. Then, the proteins in each sample were separated using 10 % SDS-polyacrylamide gel electrophoresis and transferred to the nitrocellulose membrane. Equal protein concentrations were loaded in each lane as confirmed by Ponceau staining the blot membrane. In the next step membranes were immunoblotted with selected primary antibodies (FAT/CD36, FATP 1, FATP 4 (Abcam, EU) and GLUT-1, GLUT-4 and β -actin (Santa Cruz Biotechnology, US) as well as AMPK, pAMPK (Thr172) (Cell Signaling, US). Quantification of the selected protein content was achieved by densitometry [Optical Density (OD); Biorad, Poland]. The protein expression (FAT/CD36, FATP 1, FATP 4, GLUT-1 and GLUT-4) was related to β -actin and then to the control (WT sedentary or IL-6 KO sedentary, appropriately as indicated in the legends of figures) that was set to 100 %. Finally, each experimental group was expressed relatively (%) to the control. In addition, AMPK activation was expressed as pAMPK/AMPK ratio. Accordingly, Western Blots were made in triplicates.

Intramuscular Lipid Content

The mice were killed by cervical dislocation and immediately samples of soleus muscle were taken. Afterwards, the samples were rapidly cleaned from any visible non-muscle tissue, frozen in liquid nitrogen and finely powdered. Next the powder was transferred to a glass tube for consequent lipids extraction using the Folch et al. method [24] with modifications of van der Vusse et al. [25]. Gas liquid chromatography (Hewlett-Packard 5890 Series II gas chromatograph, HP-INNOWax capillary column) was used for identification and quantification of individual fatty acid methyl esters, whereas the total FFA, TAG, DAG concentration was estimated as the sum of particular fatty acid species content of the assessed fraction. The value was expressed as nanomoles per gram of wet tissue.

Intramuscular Glycogen Content

Soleus glycogen content was determined as described recently [23, 26]. Skeletal muscles were digested in 30 %

KOH for 20 min and then, a spectrophotometric assay was used to qualify the content of free glucose. Glycogen level is expressed in µmol of glucose/g of wet tissue.

Statistics

All data are expressed as means \pm SEM. Statistical differences between groups were tested with analysis of variance (one way ANOVA) to determine the statistical significance, and appropriate post hoc test. Statistical significance was set at $p \leq 0.05$.

Results

Genotyping confirmed the deficiency of the functional IL-6 gene in the IL-6 KO mice as shown previously [20, 21]. IL-6 KO and wild type (WT) mice displayed no differences in body weight and serum glucose or FFA levels (data not shown, [21]).

Effect of IL-6 KO Genotype on Basal Skeletal Muscle Fatty Acid Transporters Expression and Lipid Content

In sedentary groups, the expression of fatty acid transporters (FAT/CD36: +25 %; FABPpm: +12.7 %; FATP-1: +31 %; $p \leq 0.05$; FATP-4: +7.2 %; $p > 0.05$) was increased in muscles from IL-6 KO mice compared to wild type mice (Fig. 1a–d). Accordingly intramuscular lipid content was also increased in these muscles (FFA: +38 %; DAG: +36 % and TAG: +160 %; $p \leq 0.05$) (Fig. 2a, b).

Effect of IL-6 KO Genotype on Basal Skeletal Muscle Glucose Transporters Expression and Glycogen Content

Interestingly, IL-6 deficiency had only minor effect on: (1) glucose transporters expression (GLUT-1: –4 %, and GLUT-4: –5.1 %; $p > 0.05$; Fig. 3a, b) and (2) glycogen content in soleus muscle compared to control (–7 %; $p > 0.05$; Fig. 3c).

Effect of Single Bout of Exhausting Exercise and IL-6 KO Genotype on Skeletal Muscle Fatty Acid Transporters Expression and Lipid Content

A single bout of exhausting exercise induced a small but significant increase in expression of both FAT/CD36 and FATP-4 (+13 and +10 %; $p \leq 0.05$; Fig. 4a), with no apparent change in FABPpm and FATP-1 (+4.5 and +2.5 %; $p > 0.05$) in WT mice. No significant changes in FA transporters expression induced by exercise were observed in the IL-6 KO group (Fig. 4b).

Fig. 1 The effect of IL-6 deficiency on the expression of fatty acid transporters (**a** FAT/CD36, **b** FABPpm, **c** FATP-1, **d** FATP-4) in soleus muscle of sedentary mice. Representative Western Blots present a relative change in the protein expression related to β -actin content. ($n = 8$; asterisk WT Sed vs. IL-6 KO Sed, $P < 0.05$; OD optical density; control (WT Sed) set at 100 %)

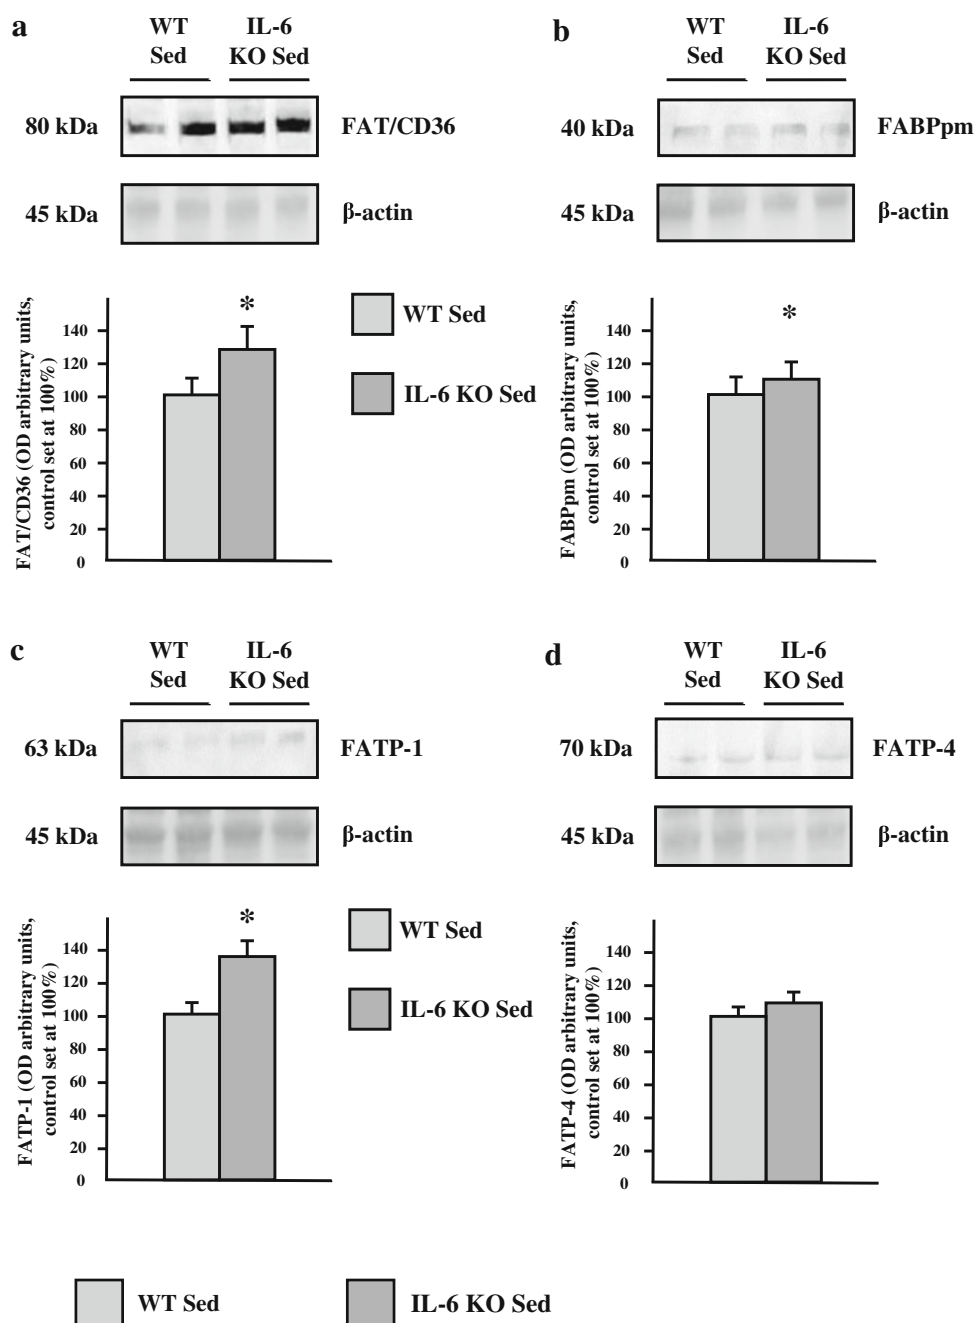

Fig. 2 The effect of IL-6 deficiency on intramuscular lipid content (**a** FFA, DAG; **b** TAG), in soleus muscle tissue of sedentary mice. ($n = 8$; asterisk WT Sed vs. IL-6 KO Sed, $P < 0.05$, FFA free fatty acids, DAG diacylglycerols, TAG triacylglycerols)

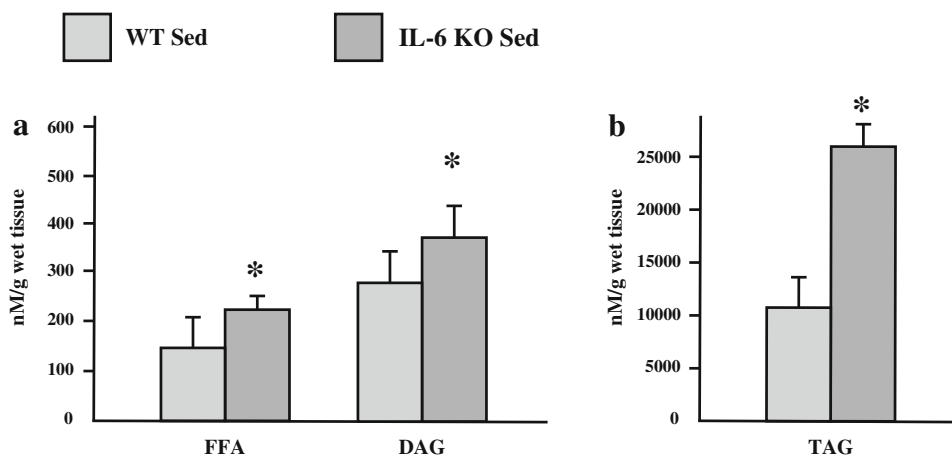

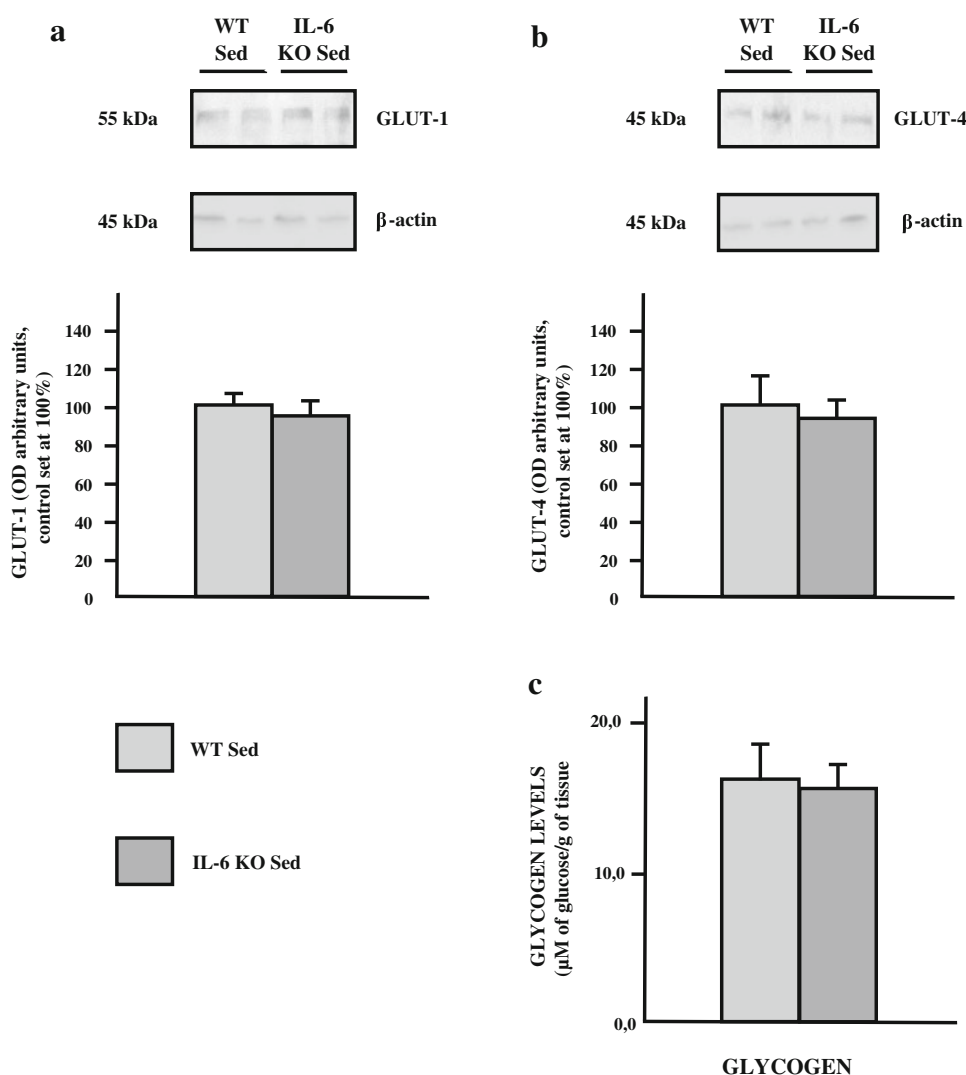

Fig. 3 The effect of IL-6 deficiency on the expression of glucose transporters (**a** GLUT-1, **b** GLUT-4) in soleus muscle of sedentary mice. Representative Western Blots present a relative change in the protein expression related to β -actin content. ($n = 8$; asterisk WT Sed vs. IL-6 KO Sed, $P < 0.05$; OD optical density; control (WT Sed) set at 100 %)

Applied exercise induced a significant reduction in intramuscular FFA and TAG content with more pronounced depletion in IL-6 KO group (−30 and −50 % in WT vs. −45 and −65 % in IL-6 KO group respectively; $p \leq 0.05$; Fig. 5a, b). Apparently, not significant changes were observed in DAG fraction in both groups studied regardless the genotype.

Effect of Single Bout of Exhausting Exercise and IL-6 KO Genotype on Skeletal Muscle Glucose Transporters Expression and Glycogen Content

Exercise induced a significant increase in glucose transporters (GLUT-1: +8 %, GLUT-4: +15 %; $p \leq 0.05$; Fig. 6a) in WT mice, with more pronounced changes in IL-6 KO littermates (+20 and +35 %; $p \leq 0.05$; Fig. 6b).

In both WT and IL-6 KO mice, exhausting exercise induced significant reduction in soleus muscle glycogen level (−30 and 60 %, respectively; $p \leq 0.05$ Fig. 7a, b).

Effect of Single Bout of Exhausting Exercise and IL-6 KO Genotype on Skeletal Muscle AMPK Activation

Exercise-induced AMPK activation as shown by increased the pAMPK/AMPK ratio (+40 %; $p \leq 0.05$; Fig. 8), but only in WT mice, since we observed relatively lower (−10 %; $p > 0.05$; AMPK activation in IL-6 KO mice.

Effect of Single Bout of Exhausting Exercise and IL-6 KO Genotype on Time Performance of Exercise

IL-6 KO mice had a significantly reduced endurance capacity compared to WT mice. The swimming duration time for knock-out animals was much shorter (51 min),

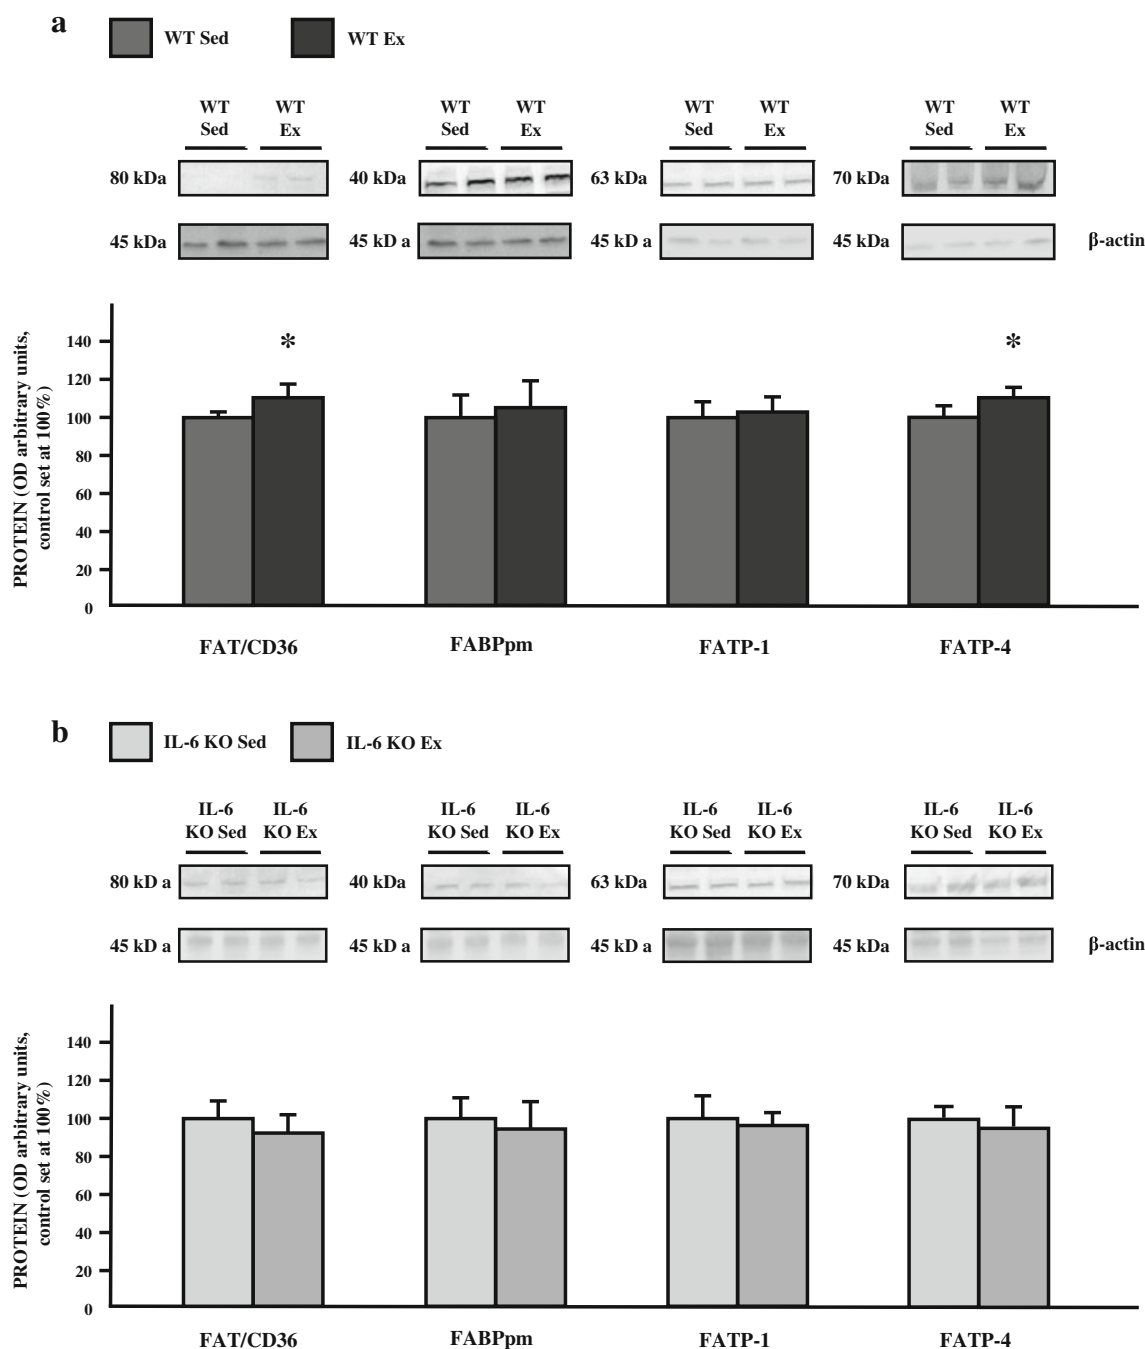

Fig. 4 The effect of a single bout of exhausting exercise on the expression of fatty acid transporters (FAT/CD36, FABPpm, FATP-1, FATP-4) in soleus muscle of WT (**a**) and IL-6 KO mice (**b**). Representative Western Blots present a relative change in the protein

expression related to β -actin content. ($n = 8$; asterisk **a** WT Sed vs. WT Ex, $P < 0.05$; control (WT Sed) set at 100 %); asterisk **b** IL-6 KO Sed vs. IL-6 KO Ex, control (IL-6 KO Sed) set at 100 %)

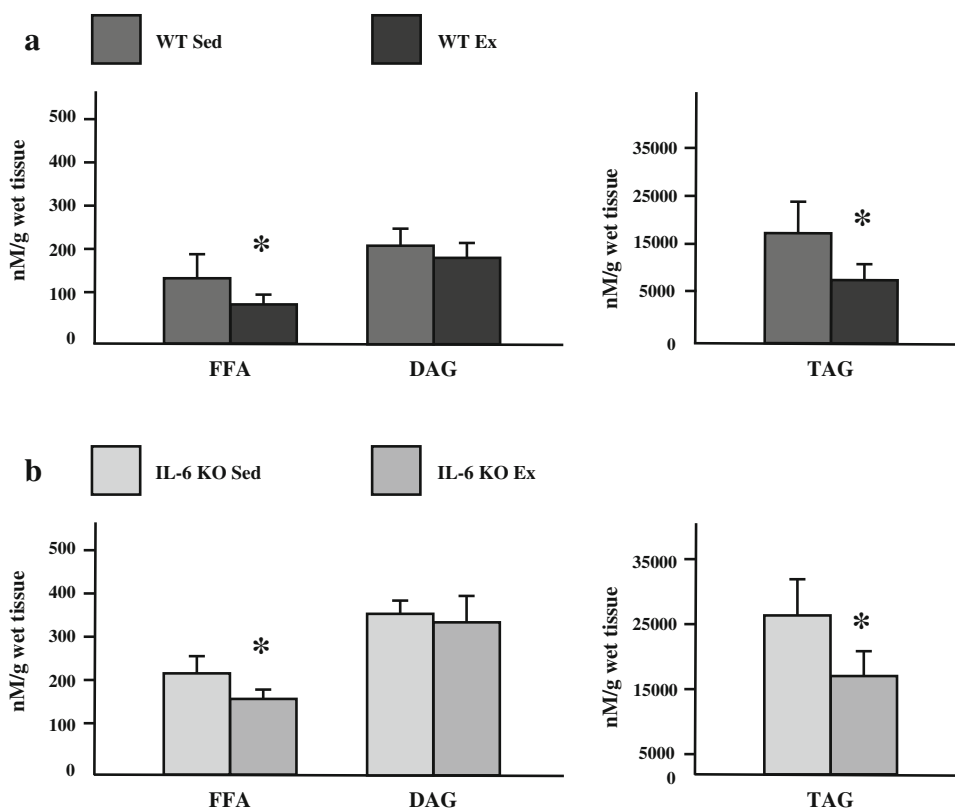

comparing with WT littermates (95 min) ($p \leq 0.05$; Fig. 9).

Discussion

The present study revealed that skeletal muscles from IL-6 deficient mice, when challenged by exercise, respond by:

(1) increased expression of glucose (mainly GLUT-4), but not FA transporters and (2) increased reliance on intra-muscular energy depots (-65% TAG and -60% glycogen reductions). These are accompanied by a lack of significant changes in the expression of AMPK kinase, when compared to WT littermates. Along with the findings, IL-6 KO mice displayed much shorter time till exhaustion

Fig. 5 The effect of a single bout of exhausting exercise on the fatty acid content (FFA, DAG, TAG), in soleus muscle of WT (a) and IL-6 KO mice (b). ($n = 8$; asterisk WT vs. IL-6 KO, $P < 0.05$, FFA free fatty acids, DAG diacylglycerols, TAG triacylglycerols)

during intense swimming. We confirmed also our earlier findings indicating a higher intramuscular lipid content (TAG, FFA, DAG) together with greater FA transport protein expression (FAT/CD36, FABPpm and FATP-1) in IL-6 KO mice [21]. However, despite intramuscular lipid accumulation and increased expression of FA transporters, IL-6 KO mice displayed no other features of obese phenotype (as shown in our previous study) [21, 27].

A growing amount of evidence implicates IL-6 as an important regulator of skeletal muscle metabolism. It seems likely that interleukin-6 exerts its effect on glucose uptake and FA oxidation in skeletal muscles via activation of AMPK (AMP-activated protein kinase) [4, 28]. Studies in vitro [29], ex vivo [30] and in vivo [31, 32] indicate a direct link between IL-6 and AMPK activation. The present study confirmed the existence of such a relations as evidenced by lower activation of AMPK during exercise in IL-6 KO mice comparing to WT littermates. Therefore, we may speculate also that, at rest, lack of functional IL-6 could significantly decreased basal AMPK activation, which in turn, resulted in decreased FA oxidation and subsequent accumulation of intramuscular lipids. This, together with an increased fatty acid transporters expression in skeletal muscle, was likely the cause of fatty acids accumulation in TAG and FFA fractions (present study and [21]). Additionally, functional IL-6 deficiency when

challenged by exercise, induced a smaller reduction in intramuscular lipids that, again, can be attributed to the lack of significant AMPK activation (and AMPK-related FA oxidation). Based on the above, we may speculate that IL-6 deficiency diminishes the AMPK activation during exercise and it seems likely, that exercise-induced activation of AMPK does not directly require IL-6 [33]. During exercise IL-6 serum levels may be increased as much as 100-fold) [34, 35] and in WT mice greater AMPK activation results not only in a response to the increased ratio of AMP/ATP but is additionally triggered by an IL-6 dependent pathway [36]. An open question remains, whether these effects are additive in skeletal muscles. Our findings suggest such a possibility, since, in WT mice, exhausting exercise induced not only a depletion of endogenous energy stores (a reduction in TAG and glycogen), but also induced glucose and fatty acid transporters expression, exacerbating exogenous energy substrates flux into the muscles. It is well known that AMPK activation results in robust energy provision and many studies have shown both: increased FA and glucose oxidation as well as enhanced FA and glucose transporters expression [14, 37, 38]. The present study suggests that with IL-6 deficiency, at least when AMPK activation is diminished, FA flux and subsequent FA oxidation are reduced. Concomitantly, this genetic lack of functional IL-6, associated with diminished

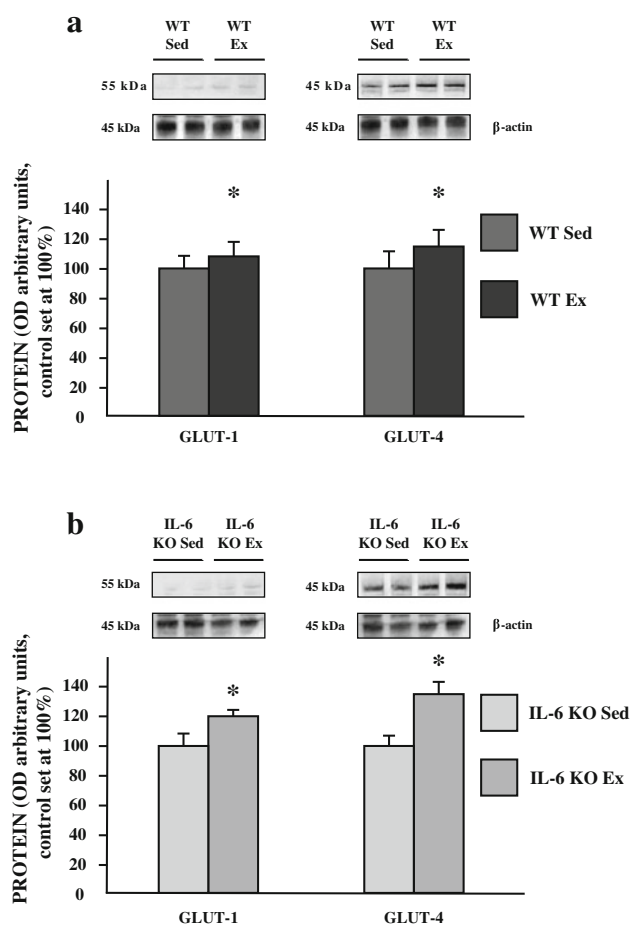

Fig. 6 The effect of a single bout of exhausting exercise on the expression of glucose transporters: GLUT-1, GLUT-4 in soleus muscle of WT (a) and IL-6 KO mice (b). Representative Western Blots present a relative change in the protein expression related to β -actin content. ($n = 8$; asterisk a WT Sed vs. WT Ex, $P < 0.05$; control (WT Sed) set at 100 %); asterisk b IL-6 KO Sed vs. IL-6 KO Ex, control (IL-6 KO Sed) set at 100 %)

exercise-induced AMPK activity, resulted in the increased expression of GLUT-4. It leaves an open discussion for other factors that may also be involved in favoring glucose metabolism over FA oxidation. Furthermore, IL-6 deficient animals exhibited diminished capacity for endurance performance. Likely, it is related to the respiratory exchange ratio (RER), since others reported that during exercise IL-6 KO mice reveal decreased exercise capacity [39]. Likewise, decreased AMPK activation (present study and [39]) could contribute to the shorter time till exhaustion as it was shown in mice expressing a dominant negative AMPK [40].

Along with this idea are studies showing that IL-6 may play a significant role in angiogenesis processes [41]. Thus, IL-6 deficiency may cause a decreased oxygen supply that

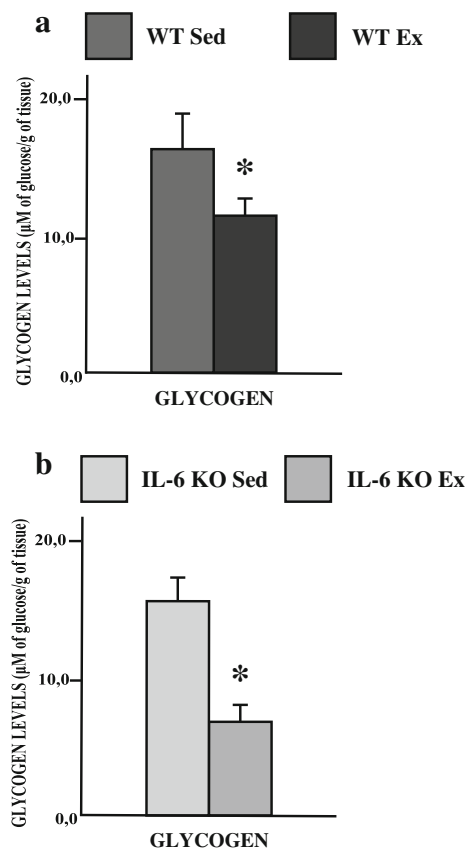

Fig. 7 The effect of a single bout of exhausting exercise on the glycogen content (μM of glucose/g of tissue) in soleus muscle of WT (a) and IL-6 KO mice (b). ($n = 8$; asterisk a WT Sed vs. WT Ex and b IL-6 KO Sed vs. IL-6 KO Ex, $P < 0.05$)

contributes to the decreased lipid utilization [42]. It has also been suggested that IL-6 released from contracting skeletal muscles stimulates the release of glucose and FA from the liver and adipose tissue [1, 2] and lack of functional IL-6 may result in a reduced plasma energy substrate availability. We may speculate this may account for greater reliance on intramuscular energy depots observed in IL-6 KO mice (a higher reduction of intramuscular glycogen and TAG). Nevertheless, the exact mechanism responsible for decreased endurance capacity in IL-6 deficient mice needs to be clarified.

Summing up, the present study has provided several novel findings. We confirmed greater expression of FA transport proteins and accumulation of intramuscular lipids in soleus from IL-6 KO sedentary mice. We found also that IL-6 deficiency results in shorter time till exhaustion accompanied by pronounced intramuscular glycogen depletion, with substantial changes in glucose but not fatty acid transporters expression.

Abstract We have previously shown that a high-protein, carbohydrate-free diet can decrease the production of glycerol-3-phosphate (G3P) from glucose and increase glyceroneogenesis in both brown (BAT) and epididymal (EAT) adipose tissue. Here, we utilized an in-vivo approach to examine the hypothesis that there is reciprocal regulation in the G3P synthesis from glucose (via glycolysis) and glyceroneogenesis in BAT, EAT and liver of fasted rats and cafeteria diet-fed rats. Glyceroneogenesis played a prominent role in the generation of G3P in the liver (~70 %) as well as in BAT and EAT (~80 %) in controls rats. The cafeteria diet induced an increase in the total glyceride-glycerol synthesis and G3P synthesis from glucose and a decrease in glyceroneogenesis in BAT; this diet did not affect either the total glyceride-glycerol synthesis or G3P generation from glyceroneogenesis or glycolysis in the liver or EAT. Fasting induced an increase in total glyceride-glycerol synthesis and glyceroneogenesis and a decrease in G3P synthesis from glucose in the liver but did not affect either the total glyceride-glycerol synthesis or G3P

synthesis from glyceroneogenesis in BAT and EAT, despite a reduction in glycolysis in these tissues. These data demonstrate that reciprocal changes in the G3P generation from glucose and from glyceroneogenesis in the rat liver and BAT occur only when the synthesis of glycerides–glycerol is increased. Further, our data suggest that this increase may be essential for the systemic recycling of fatty acids by the liver from fasted rats and for the maintenance of the thermogenic capacity of BAT from cafeteria diet-fed rats.

Introduction

Liver, white (WAT) and brown (BAT) adipose tissues are directly involved in the maintenance of lipidic homeostasis. In a fed state, the liver stores glucose as glycogen and

excess nutrients are converted into triacylglycerol (TAG), which is then secreted into the bloodstream as TAG-enriched lipoproteins (VLDL) [1]. WAT stores energy as TAG in the post-prandial state and mobilizes fatty acids (FA) in situations of energy demand. More recently, the interest in understanding the WAT physiology has been renewed. This tissue can also participate in the maintenance of the body homeostasis by its capacity to synthesize and to release adipokines [2]. Leptin, the first adipokine described, contributes toward central control of energetic balance, inhibiting food intake and stimulating BAT thermogenesis [2]. Although the physiologic role of BAT in adult humans remains undefined, recent findings indicate that BAT is present and active in a significant number of adults [3]. It is known that the first step in the sequence of metabolic events leading to the activation of BAT thermogenesis is the hydrolysis of endogenous TAG. The FA thus produced, apart from being the main substrates for heat production, are natural uncouplers of oxidative phosphorylation, activating UCP-1, the uncoupling protein specific of BAT mitochondria [3]. The maintenance of adequate stores of TAG is, therefore, essential for a normal functioning of liver, WAT and BAT. TAG production requires a continuous supply of glycerol-3-phosphate (G3P) to esterify newly synthesized or preformed FA. G3P can be formed from three precursors: (1) from glucose via dihydroxyacetone in the glycolytic pathway and conversion to G3P by glycerophosphate dehydrogenase; (2) from glycerol, produced by hydrolysis of stored triacylglycerol (TAG) or taken up by tissue from the circulation, which is converted to G3P by glycerokinase; and (3) from three-carbon intermediates (such as lactate and pyruvate) by glyceroneogenesis, which forms phosphoenolpyruvate via the dicarboxylic shuttle and subsequently produces G3P by a partial reversion of glycolysis (Fig. 1). Only in the last decade, has the importance of glyceroneogenesis as a

supplier of G3P for lipid metabolism been recognized [4, 5]. Recently, in-vivo experiments have indicated that glyceroneogenesis in rat WAT is the major pathway for glyceride–glycerol synthesis [6–8]. In vitro studies have suggested that glyceroneogenesis is also physiologically significant in BAT and liver [9–11].

The experiments described in the present study were motivated by previous findings in rats: (1) adapted to a high-protein, carbohydrate free, (2) fed a cafeteria diet, (3) fasted and (4) diabetic. All these experimental conditions have been used for many years in this laboratory to investigate the nutritional and hormonal control of energy-linked metabolic processes. Our experiments have demonstrated that the adaptation of rats to a high-protein, carbohydrate-free diet induces a reduction in plasma insulin levels [12] and an increase in WAT glyceroneogenic activity, as evidenced by an increased activity of phosphoenolpyruvate carboxykinase (PEPCK) [13] and increased rates of incorporation of non-glucose substrates into TAG-glycerol in vivo [14] and in vitro, in tissue fragments [13] or in adipocytes [15]. Because the use of glucose in vivo and the glycolytic flux are reduced in WAT from rats fed the high-protein, carbohydrate-free diet [16], the increased glyceroneogenesis may represent a compensatory mechanism for the reduced generation of G3P via glycolysis [14]. Similar findings were obtained in BAT from rats fed the high-protein, carbohydrate-free diet [17]. In contrast, cafeteria diet feeding induces a decrease in glyceroneogenesis, which was indicated by reduced PEPCK activity and by decreased rates of ^{14}C -pyruvate incorporation into TAG-glycerol in vitro by isolated white adipocytes or BAT fragments, and an increase in the in-vivo glucose uptake in epididymal adipose tissue (EAT) and BAT [9, 18]. In hepatic tissue, glyceroneogenesis and gluconeogenesis can be simultaneously evaluated in vitro by the rate of incorporation of ^{14}C -pyruvate into glyceride–glycerol and by the amount of glucose released into the incubation

Fig. 1 Sources and pathways of glycerol-3-phosphate generation in adipose tissue and the liver and possible systemic recycling of fatty acids

Table 1 Brown and white adipose tissue weights, free fatty acid and insulin plasma concentrations of fasted, cafeteria-fed or control diet-fed rats

| | Control | Fasted | Cafeteria diet |
|--|-------------|---------------|----------------|
| Interscapular brown adipose tissue (g) | 0.18 ± 0.01 | 0.17 ± 0.01 | 0.36 ± 0.02* |
| Epididymal adipose tissue (g) | 1.00 ± 0.03 | 0.77 ± 0.01* | 2.15 ± 0.11* |
| Free fatty acid (mmol/L) | 0.35 ± 0.03 | 0.97 ± 0.04* | 0.42 ± 0.04 |
| Insulin (μU/mL) | 37.4 ± 4.00 | 14.96 ± 2.60* | 60.78 ± 5.89* |

medium, respectively; both pathways are increased in the liver from fasted and diabetic rats [11]. In both situations, the glycolytic flux (estimated by the amount of ^3H recovered from water after incubation of liver slices in medium containing ^3H -glucose) and the generation of G3P from glucose (assayed by the rate of ^{14}C -glucose incorporation into glyceride–glycerol) are reduced in the liver slices [11]. These primarily in vitro findings from WAT, BAT and liver suggest that glyceroneogenesis and glycolysis would be reciprocally regulated to ensure the generation of G3P that is necessary for FA esterification and TAG synthesis. However, further in-vivo experimentation is needed to firmly establish this hypothesis.

In this work, we examined the in-vivo changes induced by fasting and feeding of a cafeteria diet on glyceroneogenesis and glycolysis in hepatic tissue, EAT and BAT. Fasting and feeding of a cafeteria diet are two physiological conditions that induce opposite effects on the plasma insulin levels (Table 1) and rates of cellular glucose uptake. In addition, fasting results in an increase in adipose tissue lipolysis and FA uptake by the liver. The purpose of this study was to directly assess whether G3P production from glucose or gluconeogenic precursors is reciprocally regulated in liver tissue and adipose tissue.

Materials and Methods

Animals

Male Wistar rats (9–12 animals) were housed in suspended wire-bottom cages in a room maintained at $25 \pm 2^\circ\text{C}$ with a 12 h light/12 h dark cycle. For the fasting experiments, rats weighing 230–250 g were left without food but had free access to water for 48 h. For the cafeteria diet feeding experiments, rats initially weighing 45–55 g were fed a cafeteria diet for 3 weeks, which consisted of a standard balanced diet [Nuvilab CR1, Nuvital, Brazil (22 % protein,

55 % carbohydrate and 4.5 % lipid)] that was supplemented each day with four different lipid-rich, palatable items selected from a list of 12 foods, including bacon, caramel candy, cashew nuts, cookies, cornstarch biscuits, cheese biscuits, chocolate rolls, chocolate wafers, nougat, peanut candy, potato chips, and toast. In addition, the water offered to these rats contained 20 % sucrose. Control rats were only fed a commercial diet, and they consumed water ad libitum. The energy intake of the control rats, estimated from the daily intake and composition of the commercial diet, was $209 \pm 4 \text{ kJ } 100 \text{ g}^{-1} \text{ body weight (bw) d}^{-1}$ (mean ± SEM). In rats that were fed the cafeteria diet, the energy intake, which included the amount and composition of palatable items and the volume of water consumed, was approximately 40 % higher ($293 \pm 13 \text{ kJ } 100 \text{ g}^{-1} \text{ bw d}^{-1}$) than that of the control rats. In cafeteria diet-fed rats, protein contributed $15 \pm 1 \%$, carbohydrate $65 \pm 1 \%$ and lipid $20 \pm 1 \%$ of the total energy intake, compared to contributions of 25, 63 and 12 %, respectively, in rats that were fed the control diet. All rats weighed 220–240 g during the experiments, which were always performed between 08:00 and 10:00 hours. The rat care and treatment protocols received prior institutional approval by the Ethical Committee of the University of São Paulo (protocol number 174/2007).

Label Injection

The labeled molecules [$\text{U-}^{14}\text{C}$]-glucose (10 μCi) and $^3\text{H}_2\text{O}$ (3 mCi) were dissolved in 0.5 mL of saline and injected into non-anesthetized rats, freely moving in its cage, through a catheter that was inserted under anesthesia into the right jugular vein 2 days before the experiments. After flushing the catheter with saline, 0.2 mL blood samples were taken 1, 5, 15, 30 and 60 min after label injection for determination of [$\text{U-}^{14}\text{C}$]-glucose specific activity (SpA). Immediately after obtaining the 60-min sample, which was also used to determine the water SpA ($^3\text{H DPM} \div \text{g atom of water hydrogen}$), each animal was killed by cervical dislocation, and the liver, interscapular BAT (IBAT) and EAT were rapidly removed. IBAT was carefully cleaned free of adhering fat and muscle. All tissue were weighed and suspended in chloroform:methanol (2:1).

Isolation of Tissue Glyceride–Glycerol

The total lipids from liver, IBAT and EAT samples were extracted with 2:1 chloroform:methanol by the procedure described in Folch [19]. Labeled $^3\text{H}_2\text{O}$ was removed from the inferior phases (predominantly chloroform) by washing three times with a superior-phase mixture. After each wash, the tubes were briefly centrifuged to sharpen the phase boundary, and the superior phase was aspirated and discarded. The chloroform phase was evaporated to dryness, and the

saponifiable lipids were hydrolyzed with ethanolic KOH for 1 h at 70 °C. After extraction of the nonsaponifiable lipids and acidification with 6 % H_2ClO_4 , the ^{14}C - ^3H -FA were extracted with petroleum ether, and the extract was evaporated to dryness in a scintillation vial and dissolved in SX22-5 scintillation liquid (Fisher Scientific®). The aqueous hydrolysate containing ^{14}C - ^3H -glycerol was dissolved in SX20-5 scintillation liquid (Fisher Scientific®).

Determination of Plasma Glucose and Water Specific Radioactivity

Plasma was deproteinized with 6 % H_2ClO_4 , and after neutralization, the supernatant was applied to a Dowex column (1 × 8; 100–200 mesh; formate form) to separate [^{14}C]-glucose from [^{14}C]-pyruvate and [^{14}C]-lactate. The compounds that were retained by the column were recovered by thoroughly washing the column with 1 N NaOH. The concentration of plasma glucose was determined enzymatically using a commercial kit from Labtest® (Lagoa Santa, Brazil). Water SpA was determined directly from aliquots of diluted (1:50) plasma dissolved in SX20-5 scintillation liquid (Fisher Scientific®).

Radioactivity Measurements

The degree of quenching in each sample was obtained to enable radioactivity calculation in dpm. Simultaneous liquid scintillation counting of the ^3H and ^{14}C contents of FA or glycerol was performed using a channels ratio method [20] on a Packard Tri-Carb 2100 TR spectrometer.

Experimental Approach

The synthesis of glycerol and FA of glycerides was evaluated in the same animal by simultaneously determining the rate of conversion of ^3H from tritiated water, which estimates the total synthesis from all carbon sources, and ^{14}C from glucose in two fractions (glycerol and FA) of glycerides in the liver, BAT and EAT. The transformation rates of glucose carbon into tissue glyceride-glycerol or glyceride-FA were estimated using the semi-compartmental approach described by Baker and Huebotter [21], which is a modification of the non-compartmental approach of Shipley [22]. The semi-compartmental analysis, which combines features of both the non-compartmental and the compartmental analyses, requires measurement of the SpA time curve for glucose after a single injection of a radioactive tracer (as in the method of Shipley [22]) and measurement of the radioactivity of an “end product” at any time point (60 min in this study). The rates of glyceride-glycerol synthesis from glucose were calculated as described in [21] and [22], using the factor 0.036 to convert

μg of glucose carbon to nmol of glycerol synthesized. The assumptions and supportive arguments for the adequacy of $^3\text{H}_2\text{O}$ for measuring lipid synthesis from all carbon sources have been presented by Windmueller and Spaeth [23] and Jungas [24]. The rates of glyceride-glycerol synthesis from $^3\text{H}_2\text{O}$ were estimated assuming that each glycerol that was incorporated into glyceride contained 3.3 atoms of ^3H when glycerol was formed from glucose via glycolysis [24] and 5 atoms of ^3H when glycerol was formed from non-glucose substrates via glyceroneogenesis [25].

The curves of plasma glucose SpA (corrected by mg of carbon glucose) were fitted to two-term exponential equations (Fig. 2) and whose parameters were used in the calculations [21]. The actual formulae are provided in supplemental material.

Other Methods of Chemical Analysis

Plasma FFA levels were determined by the method described by Dole and Meinertz [26] and the concentration of plasma insulin by radioimmunoassay was measured using a commercial kit (Coat-a-Count Insulin) from DPC (Diagnostic Products Corporation).

Statistical Methods

The results are expressed as means \pm SEM, and the differences between the means were analyzed using the Student's *t* test with $P < 0.05$ as the criterion of significance.

Fig. 2 Plasma glucose (mg mL^{-1}) and plasma glucose specific activity (% of injected dose mg of glucose carbon^{-1}) after intravenous injection of tracer ^{14}C -glucose into either fasted, cafeteria-fed or control diet-fed rats. Each point is the mean \pm SEM of 9–12 rats

Results

Fasting induced an approximately 30 % reduction in EAT weight but did not affect IBAT weight. Conversely, the cafeteria diet induced a significant increase (~ 100 %) in both EAT and IBAT weights. The plasma FFA levels were increased approximately 170 % in fasting rats but did not change in rats fed a cafeteria diet (Table 1). The plasma insulin levels were lower (60 %) in fasting rats and higher (63 %) in cafeteria-diet-fed rats (Table 1).

When compared with rats that were fed the control diet, de novo synthesis of FA was markedly reduced in the liver tissue (~ 74 %), IBAT (~ 59 %) and EAT (~ 65 %) from fasted rats and clearly increased in liver tissue (~ 124 %), IBAT (~ 380 %) and EAT (~ 770 %) from rats fed the cafeteria diet (Fig. 3). G3P generation from glucose and non-glucose sources was evaluated in vivo by simultaneously determining the rate of $^3\text{H}_2\text{O}$ and ^{14}C -glucose incorporation into glyceride–glycerol within the same animal. Total glyceride–glycerol synthesis was significantly increased in the liver tissue (~ 110 %) from fasted rats and in IBAT (~ 78 %) from cafeteria-diet-fed rats compared to control rats (Fig. 4). The increase in total glyceride–glycerol synthesis induced by fasting in the liver tissue was due to an increase in G3P generation via glyceroneogenesis (~ 180 %), despite the decrease in glycolytic flux (~ 66 %) (Fig. 4). In contrast, the increase in total glyceride–glycerol synthesis in IBAT induced by the cafeteria diet was due to an increase in G3P synthesis via glycolytic flux (~ 670 %), even though there was a reduction in synthesis via glyceroneogenesis (~ 42 %) (Fig. 4). Fasting also induced a decrease in glyceride–glycerol synthesis from glucose in IBAT (~ 88 %) and EAT (~ 85 %) without affecting the total synthesis of glyceride–glycerol and glyceroneogenesis (Fig. 4). The cafeteria diet did not affect the rates of glyceride–glycerol synthesis from glucose via glycolysis or from non-glucose substrates via glyceroneogenesis in the liver tissue or in EAT (Fig. 4). During the 60 min experimental period, injected ^{14}C -glucose could be converted into ^{14}C -pyruvate and ^{14}C -lactate. We found that the plasma concentrations of these latter compounds remained constant (approximately 0.07 % of the injected ^{14}C -glucose). Because the consumption of these compounds by tissues was negligible compared with the use of glucose (varying from 1.70 to 0.42 %), we assumed that there was no appreciable turnover of ^{14}C -labeled product during the experimental period.

Discussion

The data presented here clearly show that, compared to glycolysis, the in-vivo glyceroneogenic pathway played a

Fig. 3 Effect of fasting and cafeteria diet feeding on the in-vivo rate of de novo fatty acid synthesis in the liver and brown and epididymal adipose tissues. Bars are means \pm SEM of 9–12 rats. * $P < 0.05$ vs. control

prominent role in the generation of G3P in the liver tissue (73 ± 5 %), IBAT (83 ± 8 %), and EAT (80 ± 6 %) in control rats. Previous in-vivo studies have shown that glyceroneogenesis is the major pathway for G3P synthesis in the WAT of rodents [6–8, 14, 17]. The present work is the first in-vivo evidence that fasting and a cafeteria diet can induce reciprocal changes in G3P generation from glyceroneogenesis and glucose (via glycolysis). Glyceroneogenesis was reduced and glycolysis and total

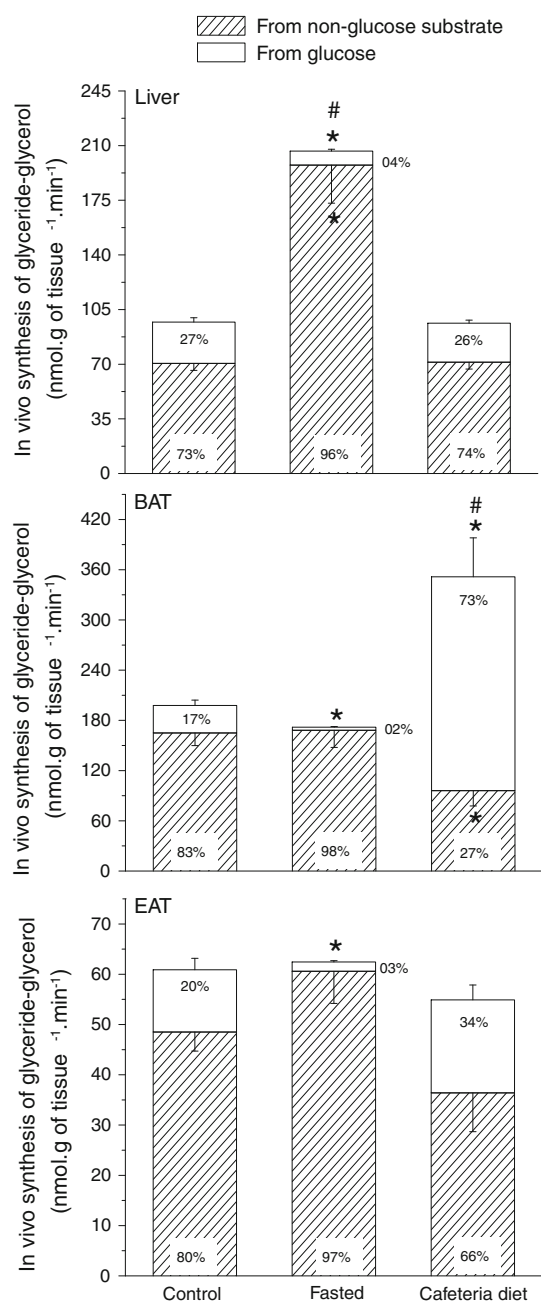

Fig. 4 Effect of fasting and cafeteria diet feeding on the in-vivo synthesis of glyceride–glycerol from glucose (via glycolysis) and non-glucose substrates (via glyceroneogenesis) in rat liver and brown and epididymal adipose tissue. The values in the bars represent the percent contribution of each pathway for the total glyceride–glycerol synthesis. * $P < 0.05$ relative to glycolysis or glyceroneogenesis versus control. # $P < 0.05$ relative to total glyceride–glycerol synthesis versus control

glyceride–glycerol (G3P) synthesis were increased in BAT from rats fed the cafeteria diet, thus the relative contribution of glyceroneogenesis for total G3P synthesis was significantly lower ($27 \pm 5\%$, $P < 0.05$ vs. control, Fig. 4). Glyceroneogenesis and total G3P synthesis were

increased and glycolysis was decreased in the liver tissue of fasted rats, thus the contribution of glyceroneogenesis for total glyceride–glycerol synthesis was $96 \pm 12\%$ ($P = 0.09$ vs. control, Fig. 4). Previous in vitro experiments have shown that a reduction in the G3P generation via glycolysis is accompanied by a significant activation of glyceroneogenesis in liver slices during fasting [11]. We have also previously demonstrated in vitro that G3P synthesis from glucose is increased and glyceroneogenesis is reduced in IBAT from cafeteria-diet-fed rats [9]. The cafeteria diet did not affect either the in-vivo synthesis of G3P from glucose (via glycolysis) or glyceroneogenesis in the liver tissue and EAT (Fig. 4). This finding confirms our hypothesis that there is an in-vivo reciprocal regulation of G3P synthesis between these pathways. This reciprocal change in G3P generation by glyceroneogenesis and glycolysis is important to maintain an adequate supply of the G3P needed for TAG formation and to ensure normal tissue function. In contrast, fasting did not affect either the glyceroneogenesis or the total glyceride–glycerol synthesis in these tissues, although there was a reduction in G3P synthesis from glucose. Previous in vitro studies have shown that fasting induces a reduction in the PEPCK activity and a decrease in the rate of incorporation of [$1\text{-}^{14}\text{C}$] pyruvate into glyceride–glycerol in IBAT and EAT [10, 27, 28]. Recent in-vivo experiments also demonstrated that glyceroneogenesis does not change in EAT in response to 48 h of fasting [8]. The low insulin levels and high FFA levels in fasted rats are expected to increase transcription of the PEPCK gene [29–31], and this increase could stimulate BAT and EAT glyceroneogenesis. However, our findings suggest that there is not a good correlation between gene expression or maximal enzymatic activity and actual flux through the metabolic pathway. Recently, it was demonstrated in vivo that the reduction in plasma insulin levels did not induce changes in EAT glyceroneogenesis in rats fed a low-protein, high-carbohydrate diet [6]. There are several possible explanations for the different responses observed in vivo and in vitro. Notably, in-vivo experiments are capable of evaluating metabolic pathways in conditions that cannot be reproduced in vitro, mainly because a blood supply and sympathetic activity are connected to each tissue.

The effect of the cafeteria diet or fasting on total FA synthesis correlates with the insulin levels in the animals; cafeteria-diet-fed rats showed increases in liver, BAT and EAT, while fasting rats showed decreases in all three tissues (Fig. 3). Using the data for the synthesis of de novo FA and glyceride–glycerol, we can estimate the amount of glycerol used to esterify preformed FA. The fraction of glycerol used for esterification of preformed FA can be obtained by disregarding the glycerol used to esterify de novo synthesized FA, which corresponds to one-third of the glyceride–FA synthesized from $^3\text{H}_2\text{O}$. We assume that

3 mol FA is esterified by 1 mol glycerol because approximately 90 % of the lipids found in adipose tissue are TAG; however, this percentage is lower in the liver. When compared with control diet-fed rats, this estimate shows an increase in the amount of glycerol used to esterify preformed FA in the liver tissue (~ 120 %) of fasted rats ($205 \pm 24 \text{ nmol g}^{-1} \text{ min}^{-1}$ vs. 92 ± 5 in control, $P < 0.05$) and in the IBAT (~ 60 %) of cafeteria-diet-fed rats ($309 \pm 49 \text{ nmol g}^{-1} \text{ min}^{-1}$ vs. 189 ± 22 in control, $P < 0.05$). The cafeteria diet also resulted in an increase in the esterification rate of de novo FA synthesized in the liver tissue, EAT and IBAT, while fasting induced a decrease in the three tissues (Fig. 3). The rate of glycerol used to esterify preformed FA was elevated in liver (~ 90 %), BAT (~ 90 %) and EAT (~ 95 %), even in control rats. Previous studies also showed an elevated rate of glycerol used to esterify preformed FA in liver, BAT and EAT from rats fed a balanced, purified diet (94, 89 and 64 %, respectively) or from rats fed a high-protein, carbohydrate-free diet (96, 96 and 94 %, respectively) [14, 17]. Direct in-vivo measurements of the rates of TAG synthesis and degradation in adipose tissue showed that, despite very active TAG synthesis, lipid degradation occurs at a substantial rate. TAG degradation is approximately 50 % of the lipid synthesis rate in EAT from mice fed a low-fat, high-carbohydrate or high-fat, low-carbohydrate diet [32]. It has been hypothesized that the adipose tissue could play a crucial role in buffering the flux of FA in the circulation in the postprandial period, analogous to the roles of the liver and skeletal muscle in buffering postprandial glucose fluxes. Adipose tissue provides its buffering action by suppressing the release of FFA into the circulation and by increasing TAG clearance [33]. Our results support this hypothesis, indicating that the use of preformed FA, which are recycled after the hydrolysis of endogenous TAG and taken up from the circulating lipoproteins, for glyceride synthesis is markedly high in the liver and adipose tissues.

We agree that the increase in total glycerol synthesis in the liver tissue of fasted rats, which is accompanied by a reduction in the de novo synthesis of FA, is necessary to guarantee the esterification of preformed FA. Fasting induces an increase in the mobilization of WAT FA to meet the energy demands of peripheral tissues. However, a fraction of the FFA is removed from the bloodstream by the liver and converted to TAG, which are either stored in hepatocytes or released from the liver into the circulation as VLDL (Fig. 1). Our results are the first to suggest that this systemic recycling of FA exists in vivo between the WAT and the liver. In contrast, the increase in the total glycerol synthesis in the BAT of cafeteria-diet-fed rats is sufficient to ensure the esterification of preformed FA and de novo synthesized FA, which have increased levels. The cafeteria diet induces BAT thermogenesis [9], stimulating the hydrolysis of endogenous

TAG and subsequently producing FA, which are both substrates and uncoupling messengers for BAT mitochondria. Therefore, the maintenance of adequate TAG stores by the esterification of FA seems to be essential for normal BAT function. Our results indicate that the esterification of de novo synthesized FA is not sufficient to guarantee adequate stores of TAG (and thermogenesis) in the BAT from cafeteria-diet-fed rats and that the reesterification of preformed FA is necessary. The major fraction of preformed FA that are esterified is probably recycled after hydrolysis of endogenous TAG because lipoprotein lipase activity is reduced in the BAT of rats that are fed the cafeteria diet [9].

In summary, the data of our present study, assayed in vivo, suggest that the reciprocal changes in the generation of glycerol-3-phosphate from glucose (via glycolysis) and from glyceroneogenesis occur only when the synthesis of total glyceride–glycerol is increased in the tissue. This increased synthesis seems to be essential for the systemic recycling of FA by the liver from fasted rats and for the maintenance of the thermogenic capacity of the BAT from cafeteria-diet-fed rats.

Abstract Human 15-lipoxygenase-1 (15-LO-1) can metabolize arachidonic acid (ARA) into pro-inflammatory mediators such as the eoxins, 15-hydroperoxyeicosatetraenoic acid (HPETE), and 15-hydroxyeicosatetraenoyl-phosphatidylethanolamine. We have in this study investigated the formation of various lipid hydroperoxide by either purified 15-LO-1 or in the Hodgkin lymphoma cell line L1236, which contain abundant amount of 15-LO-1. Both purified 15-LO-1 and L1236 cells produced lipid hydroperoxides more efficiently when anandamide (AEA) or 2-arachidonoyl-glycerol ester was used as substrate than with ARA. Furthermore, L1236 cells converted AEA to a novel class of cysteinyl-containing metabolites. Based on RP-HPLC, mass spectrometry and comparison to synthetic products, these metabolites were identified as the ethanolamide of the eoxin (EX) C₄ and EXD₄. By using the epoxide EXA₄-ethanol amide, it was also found that platelets have the capacity to produce the ethanolamide of EXC₄ and EXD₄. We suggest that the ethanolamides of the eoxins should be referred to as eoxamides, in analogy to the ethanolamides of prostaglandins which are named prostamides. The metabolism of AEA into eoxamides might engender molecules with novel biological

effects. Alternatively, it might represent a new mechanism for the termination of AEA signalling.

Introduction

Lipoxygenases (LOs) are a family of enzymes catalyzing the positional as well as stereo-specific introduction of molecular oxygen into *cis*-1,4-pentadiene structures found in unsaturated fatty acids or derivatives thereof [1–3] leading to the formation of a hydroperoxide. Oxidation of arachidonic acid (ARA) by 5-lipoxygenase (5-LO) (EC 1.13.11.34), the key enzyme in leukotriene synthesis, leads to the formation of the unstable epoxide leukotriene (LT) A₄. This compound can be conjugated with glutathione to form LTC₄ by LTC₄ synthase (EC 4.4.1.20) [4] or hydrolyzed by LTA₄ hydrolase (EC 3.3.2.6) to form LTB₄. Leukotriene C₄, and its metabolites LTD₄ and LTE₄, are proinflammatory agents, potent bronchoconstrictors and

inducers of plasma leakage [5] whereas LTB₄ is a potent chemoattractant [5]. In analogy to the formation LTC₄, a pathway for the formation of eoxins, a class of structurally related pro-inflammatory lipid mediators, has been described [6, 7]. The oxidation of ARA, catalyzed by human 15-lipoxygenase-1 (15-LO-1) (EC 1.13.11.33), leads in two consecutive steps to the unstable epoxide eoxin (EX) A₄ which can be conjugated to glutathione to yield EXC₄, a reaction very similar to the formation of LTC₄ [6, 8]. The conjugation of glutathione to lipid epoxides is performed by glutathione transferases, including LTC₄-synthase (LTC₄S), microsomal glutathione S-transferase 2 (mGST-2) and soluble glutathione transferases [6, 9–11].

In contrast to 5-LO, less is known about the physiological or pathological role of 15-LO-1. Thus, the finding that eoxins are proinflammatory might shed some light onto the role of 15-LO-1 in inflammatory processes. Furthermore, 15-HPETE and 15-HETE-phosphatidylamine have also been found to possess pro-inflammatory effects [12, 13]. On the other hand, 15-LO-1 metabolites have also been demonstrated to possess anti-inflammatory roles [14]. The expression of human 15-LO is selective and cells such as human eosinophils, airway epithelial cells, reticulocytes, mast cells and dendritic cells has been demonstrated to express 15-LO-1 [7, 15, 16]. The enzyme 15-LO-1, or its rodent ortholog 12/15-LO, has been implicated in pro- as well as anti-inflammatory processes [3, 17]. Two reports describe that ovalbumin sensitized 12/15-LO null mice have reduced airway inflammation, reduced cytokine production and less proliferation of airway epithelial cells after exposure of allergen [18, 19]. Other pathological processes where 15-LO-1 has been suggested to play a role includes cytokine release from airway epithelial cells [20], cardiac inflammation [21], propagation of cancer metastasis [22], atherosclerosis [23–25], Alzheimer's disease [26], insulin resistance and diabetic nephropathy [27, 28]. Furthermore, pharmacological evidence suggests that 15-LO-1 is involved in neuronal cell death induced by oxidative stress [29]. Unlike 5-LO, 15-LO-1 and 12/15-LO has a broad substrate specificity [15] and the enzyme can metabolize membrane bound phospholipids [27] and other conjugated lipids like endocannabinoids and vanilloids to their corresponding mono-hydroxy metabolites [30–35].

Endocannabinoids are a family of endogenous lipid-derived mediators of which arachidonyl ethanolamide (AEA) (anandamide) and 2-arachidonoylglycerol (2-AG) are amongst the most characterized substances. Both AEA and 2-AG are agonists of the G-protein coupled cannabinoid receptors (CB) 1 and 2 [36, 37]. AEA and other endocannabinoids also bind to the vanilloid receptor channel TRPV-1 (VR-1), an ion channel that mediates the pungent effect of the red hot chilli pepper component capsaicin [37, 38].

Oxygenation of endocannabinoids or vanilloids by lipoxygenases has been described in several reports and the monohydroxy derivatives of AEA seem to signal through CB1/2, TRPV-1 and PPAR- α [30–35]. The lipid class *N*-acyltaurines (NAT) was recently discovered and arachidonoyltaurine has also been shown to function as a substrate for lipoxygenases but not for cyclooxygenases [39]. On the other hand, cyclooxygenase-2 (COX-2) (EC 1.14.99.1) has been reported to metabolize AEA and 2-AG to their corresponding prostaglandin-ethanolamide and glycerol esters with high efficiency [40–42]. The pharmacology of these COX-2 metabolites is rapidly being defined and they are now collectively called prostamides [43]. The oxygenation of endocannabinoids by either cyclooxygenases or lipoxygenases is an expanding research area and there is a great likelihood that the oxygenation pathways for endocannabinoids will intersect with eicosanoid pathways [44, 45].

We report herein the in-vitro identification of a novel class of cysteinyl-containing eoxin-like metabolites derived from AEA, i.e. eoxin-ethanolamides, which in analogy to the prostamides are named eoxamides. This pathway of AEA metabolism may lead to a new class of biological active endocannabinoid metabolites or alternatively, a new pathway for terminating AEA signalling.

Materials and Methods

Materials

ARA, AEA and LNA were purchased from NuCheck. HPLC solvents were from Rathburn Chemicals (Walkerburn UK). Synthetic 13-hydroxyoctadeca-9Z,11E-dienoic acid (13-HODE) and 15-hydroxyeicosa-5Z,8Z,11Z,13E-tetraenoic acid (15-HETE) were from Biomol. Diphenyl-1-pyrenylphosphine (DPPP) was from Molecular Probes, Invitrogen. Tissue culture medium, antibiotics, fetal calf serum and Dulbeccos phosphate buffered saline (D-PBS) were from Gibco (Paisley, Scotland, UK). 14,15-epoxy-5,8,10,12 (Z,Z,E,E)-eicosatetraenoyl-EA (EXA₄-EA) was provided by Mats Hamberg (Karolinska Institutet, Sweden). All other chemicals and reagents were from Sigma-Aldrich.

Chemical Synthesis of Eoxin Amides

14-Glutathionyl-15-hydroxy-5,8,10,12(Z,Z,E,E)-eicosatetraenoyl-EA (EXC₄-EA) was synthesized from EXA₄-EA by conjugation to glutathione under alkaline conditions. Briefly, EXA₄-EA was dried under nitrogen and resuspended in 50 mM NaOH and 5 mM GSH to a final

concentration of 1 mM. The reaction was allowed to proceed for at least 3 h at room temperature. The purity and quantization of the produced EXC₄-EA was performed with RP-HPLC and mass spectrometry. 14(*R*)-cysteinylglycyl-15(*S*)-hydroxy-5,8,10,12 (*Z,Z,E,E*)-eicosatetraenoyl-EA (EXD₄-EA) was synthesized as described above with the exception that glutathione was exchanged for Cys-Gly (Sigma-Aldrich, Sweden).

15-LO-1 Fluorescent Enzyme Assay

The 15-LO-1 activity was measured in 96-well black plates (Optiplate, Corning) essentially as described [46]. Briefly, purified 15-LO-1 diluted in D-PBS at 3.18 µg/mL (2.8 µg/mL final concentration) or D-PBS alone was added to each well. Thereafter was 5 µL 2 mM LNA added to each well and the plate was incubated at room temperature for 10 min. The reaction was terminated with 1 volume of methanol containing 0.25 mM DPPP for fluorescent detection of lipid hydroperoxides or with one volume of methanol without DPPP for RP-HPLC-analysis of metabolites as described below. Fluorescence was measured 30 min after the addition of DPPP using a Spectramax Gemini fluorescence plate reader (Molecular Devices) with an excitation wavelength of 363 nm and an emission wavelength of 380 nm.

15-LO-1 Cell-based Assay

The human Hodgkin lymphoma cell line L1236 was grown in a humidified atmosphere at 5 % CO₂ in RPMI 1640 medium supplemented with 10 % heat-inactivated fetal calf serum and L-glutamine. The cells were washed twice in D-PBS before suspension in D-PBS at a final concentration of 10 × 10⁶ cells/mL. Substrate diluted in ethanol was added to yield a final concentration of 50 µM (or as indicated) and the samples were thereafter incubated for typically 2 min at 37 °C. The reaction was terminated by the addition of two volumes of methanol and the samples were stored at –20 °C for at least 60 min before RP-HPLC analysis.

Analysis of Lipoxygenase Products by RP-HPLC

Plates were centrifuged at 2,500 rpm for 5 min to remove precipitated proteins. The resulting supernatants was used for the analysis of monohydroxy acids, eoxins and cysteinyl-containing metabolites of AEA by injecting an aliquot of the supernatant onto a Onyx Monolithic C18 column (100 × 4.6 mm from Phenomenex) at a flow rate of 1.2 mL/min using a Waters Alliance 2795 system. Products were eluted by a 1-min isocratic period followed by a 20-min linear gradient from 20:27:53:0.8 to 35:35:30:0.8 (acetonitrile:methanol:H₂O:acetic acid (pH adjusted to 5.6 with NH₃) (by volume)). The retention times for all metabolites were compared

to authentic standards and qualitative measurements were performed using a 2996 photodiode-array (PDA) detector to verify the spectrum of peaks.

Analysis of products from cellular incubations with EXA₄-EA were performed by injecting an aliquot of the supernatant onto a C18 NovaPak (3.9 × 150 mm) column from Waters coupled to a Waters Alliance 2695 system equipped with a 2996 PDA UV-detector using a flow rate of 1.2 mL/min. Products were eluted by a 4-min isocratic period followed by a 10-min linear gradient from 25:15:60:0.8 to 45:45:10:0.8 [acetonitrile:methanol:H₂O:acetic acid (pH adjusted to 5.6 with NH₃) (by volume)]. In cases with large sample volumes, the supernatants were evaporated under reduced pressure and the residues dissolved in methanol and transferred to a test tube. Samples were thereafter evaporated to dryness under a stream of nitrogen, and finally resuspended in 300 µl of the appropriate mobile phase.

Nanospray Mass Spectrometry Analysis

After termination of incubations, samples were centrifuged (1400×*g*, 6 min) and the supernatants were diluted with water to contain maximum 25 % methanol and transferred to a washed and equilibrated extraction cartridge, Oasis HLB 1 cc 10 mg (Waters AB, Sweden). The columns were washed with water and eluted with 200 µl methanol to retrieve the metabolites. Reverse phase HPLC was performed on a Waters Alliance 2690 with a Nova Pak C₁₈ column (2.1 × 150 mm, Waters AB). The initial mobile phase was 100 % A (0.01 % acetic acid adjusted to pH 5.6 with ammonia) at a flow rate at 0.4 mL/min. A linear gradient was started after 5 min, reaching 36 % B (60:40 acetonitrile: methanol) at 20 min. The mobile phase was isocratic at 64:36, A:B for 100 min. Column effluent was monitored using diode array detection (PDA 996, Waters AB, Sweden). UV spectra were acquired between 200 and 340 nm. The material in the peaks I and II was collected with a fraction collector (FC II, Waters AB, Sweden) and further analyzed by mass spectrometry. The collected fractions were dried to some extent under N₂ and subsequently dissolved in methanol:water (1:1). Mass spectrometry was performed on a Quattro Micro or a Quattro Ultima triple quadrupole mass spectrometer (Micromass, Manchester, UK) operating in positive ion mode with a capillary voltage at 2.2 kV. MS/MS were obtained using collision energy of 20 eV using argon as the collision gas.

Statistical Analysis

Raw data were imported into Graph Pad PRISM 5.0 and all graphs and chromatograms were generated by the use of this software. Statistical analyses were performed by Students two-tailed unpaired paired *t* test.

Results

Comparison of Different Lipid-derivatives as Substrate for Human 15-LO-1

Human 15-LO-1 is known to use a variety of lipids as substrates, albeit with different efficient substrate utilization, i.e. different K_m and V_{max} [47]. We have previously described a fluorescent method for detecting 15-LO-1 derived lipid hydroperoxides [46]. We used this method to investigate different conjugated neutral derivatives of ARA and LNA, i.e. ethanolamides and glycerol esters, as substrates for 15-LO-1. Purified human enzyme was incubated with different substrates as outlined in Fig. 1. The fluorescence intensity obtained with ethanolamide of ARA and LNA was significantly higher than the fluorescence obtained with the free fatty acid. Incubation of the glycerol ester of ARA, but not that of LNA, led to significant higher fluorescence as compared to the free acid. The difference between ARA and AEA as substrate for 15-LO-1 was further investigated in a cellular assay by dose–response curves followed by analysis of the monohydroxy products using RP-HPLC. We have previously described that the Hodgkin lymphoma cell line L1236 express high levels of active endogenous 15-LO-1 and that the cells can produce eoxins [8]. Thus, L1236 cells were incubated with various concentrations of ARA or AEA and as depicted in Fig. 2, both substrates induced a robust formation of 15-HETE and 15-HETE-EA, respectively. The apparent K_m ($K_{m(app)}$) was calculated to 108 or 39 μM when using AEA or ARA, respectively. The difference observed in the formation of lipid-hydroperoxides as judged by fluorescence (Fig. 1) could not be observed in the cell-based assay. The cause

Fig. 1 Formation of lipid hydroperoxides by 15-LO-1. Purified human 15-LO-1 was incubated with 200 μM of the indicated substrate. The reaction was quenched with one volume of methanol containing 125 μM DPPP after 10 min and the lipid hydroperoxide was allowed to react with DPPP for 30 min before the fluorescence was determined. The results are the means \pm SEM from three independent experiments each performed in triplicates. ARA arachidonic acid, 2-AG 2-arachidonoylglycerol, AEA anandamide, LNA linoleic acid, 1-LG 1-linoleoyl-glycerol, LEA linoleylethanolamide

Fig. 2 Formation of monohydroxy metabolites in L1236 cells. L1236 cells (5×10^6 cells/mL) were incubated with the indicated concentrations of ARA or AEA. The amount of 15-HETE or 15-HETE-EA as well as 12-HETE or 12-HETE-EA was quantified by RP-HPLC. The formation of 15- and 12-HETE is presented as the sum of the two metabolites and the results are the means \pm SEM ($n = 3$) from two independent experiments. Open circles indicate the sum of 12- and 15-HETE-EA and solid squares indicate the sum of 12- and 15-HETE

for this might be that the lipid-hydroperoxides were not metabolized in the enzyme assay due to the fact that they were rapidly reduced to the monohydroxy metabolites in the presence of DPPP. The metabolism of the lipid-hydroperoxides in the cell-based assay is most likely very different as compared to the metabolism using purified enzyme. Epoxides could be formed by dehydration or hydroperoxide isomerize activity of 15-LO-1. Furthermore, the epoxides might be non-enzymatically hydrolysed to several dihydroxy products or conjugated to glutathione by a glutathione transferase, as described for the formation of eoxins in L1236 cells [7].

Analysis of Anandamide Metabolites in L1236 Cells

The characterization of ARA metabolites in L1236 cells has been described [8] but no report have so far characterized metabolism of AEA in L1236 cells. In order to characterize the metabolism of AEA in L1236 cells, we investigated the formation of dihydroxy-AEA such as 8(*S*),15(*S*)-, 8(*R*),15(*S*)- and 14(*R*),15(*S*)-dihydroxy-AEA as well as putative cysteinyl-containing AEA metabolites by RP-HPLC after incubation of cells with AEA. As shown in Fig. 3, incubations with AEA led to the formation of metabolites with a characteristic UV-absorbance maximum at 270 nm with two shoulders, thus indicating the presence of a conjugated triene in these samples (Fig. 3, peaks 4–6). These metabolites are thus likely to be dihydroxy-metabolites of AEA. Interesting was the fact that we observed two major and one minor metabolite with an UV-absorbance maximum at 280 nm and two shoulders after incubation of L1236 cells with AEA (Fig. 3, peaks 1–3). These characteristics of the UV-spectrum indicate a triene conjugated with glutathione. The retention time of these mediators were

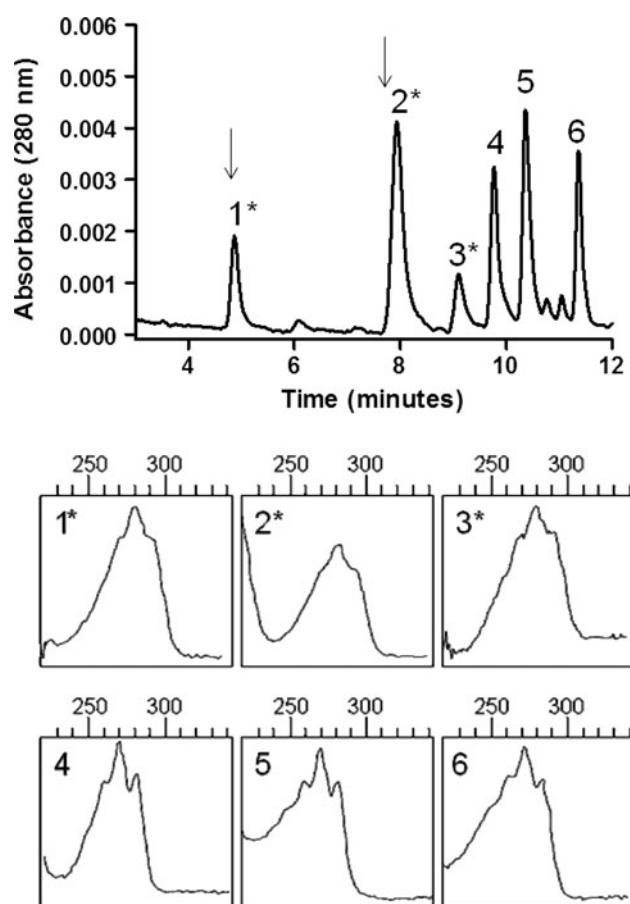

Fig. 3 Chromatographic profile of anandamide metabolites in L1236 cells. L1236 cells (1.0×10^7 cells/mL) were incubated with 50 μ M of AEA. An aliquot of the supernatant (200 μ L) was injected onto a Onyx monolithic C18 column and the formation of eluting cysteinyl-containing metabolites was analyzed by their absorbance at 280 nm. *Upper panel* shows the elution profile and absorbance at 280 nm. Asterisks at peaks 1, 2 and 3 denote products with UV-absorbance maximum at 280 nm. The elution of synthetic EXC₄-EA and EXD₄-EA were analyzed using the same chromatographic system and the elution times are indicated by arrows. *Lower panel* shows the UV-spectra for the indicated peaks

different from other cysteinyl-containing ARA-derivates such as the cysteinyl-containing leukotrienes or the eoxins (data not shown), indicating that these metabolites were unique metabolites of AEA. The most polar AEA metabolite formed with a UV-absorbance maximum at 280 nm (peak 1) was analyzed by mass spectrometry. In a positive ion mode MS scan it had the 669 m/z present, which correspond to AEA conjugated with glutathione. The material in peak 1 gave rise to a MS/MS daughter ion spectrum, containing 308 m/z which correspond to the glutathione part (Fig. 4a). The fragmentation occurred mainly in the peptide part. Thus, this gives no information about the position of glutathione in the fatty acid, although nothing in the MS/MS spectra contradicts the theory that the glutathione is positioned on the omega-7 carbon.

In order to verify the identity of the products in peak 1, we synthesized 14,15-epoxy-eicosatetraenoyl-EA and chemically conjugated glutathione. RP-HPLC and MS/MS analysis of this synthetic compound demonstrated identical retention time and UV-spectrum after RP-HPLC analysis (data not shown) as well as identical molecular mass and similar MS/MS fragmentation pattern (Fig. 4b) to the product in peak 1, thus demonstrating that the product in peak 1 is indistinguishable to synthetic 14-glutathionyl-15-hydroxy-5,8,10,12(*Z,Z,E,E*)-eicosatetraenoyl-EA (EXC₄-EA). The stereochemistry at carbon 14 and 15 has not yet been determined. The stereochemistry of the double bonds is based upon the UV-spectrum and has not yet been experimentally verified.

A second AEA-metabolite with a UV-spectrum similar to EXC₄-ethanol amide and a retention time of 8 min was also observed after incubation of L1236 cells with AEA (Fig. 3, peak 2). The mechanism of formation and metabolism of leukotrienes and eoxins suggested that this metabolite could be the ethanol amide equivalent of EXD₄. Thus, we synthesized EXD₄-EA from 14,15-epoxy-eicosatetraenoyl-EA by conjugating the dipeptide Cys-Gly (by a similar addition as described for the conjugation of glutathione). The product of this reaction displayed a similar retention time and UV-spectrum as observed for the less polar compound eluting at 8 min (data not shown) thus suggesting that this metabolite is the EXD₄-ethanol amide (EXD₄-EA) metabolite of AEA (Fig. 5).

Furthermore, a third metabolite with similar UV-spectrum as the other AEA-metabolites was also detectable in L1236 cells after incubation with AEA (Fig. 3, peak 3). The identity of this minor metabolite is unclear but our hypothesis is that this metabolite is EXE₄-EA. EXE₄, another cysteinyl-containing eoxin, was identified after incubations of L1236 cells with EXA₄ [8]. The retention time and UV-spectrum of the third product suggests that the identity of this metabolite is EXE₄-EA.

Based upon the structural similarity to the eoxins, we suggest that these novel AEA-metabolites should be called eoxamides, in analogy to the nomenclature for prostaglandins and the corresponding prostaglandin-ethanol amides, i.e. the prostamides.

Comparison Between the Formation of Eoxins and Eoxamides in L1236 Cells

In order to compare the capacity of L1236 cells to produce cysteinyl-containing 15-LO-1 metabolites derived from ARA or AEA, we quantified the formation of eoxins and eoxamides by RP-HPLC analysis. Since incubation of 15-LO-1 with 2-arachidonoyl glycerol (2-AG) led to significantly higher fluorescence (Fig. 1) than ARA, presumably through the formation of 2-AG lipid hydroperoxides,

Fig. 4 Identification of anandamide metabolites by MS/MS. L1236 cells were incubated with AEA and the samples were thereafter purified by solid phase extraction and analyzed with RP-HPLC. Peak 1 were collected and further analyzed by mass spectrometry. Peak 1 and synthetic EXC₄-EA had corresponding retention times. The samples were introduced to a triple quadrupole mass spectrometer by nanospray infusion. The MS spectra contained a $[M + H]^+$ at 669

and subsequently MS/MS daughter ion scan at m/z 669 was performed. The MS/MS spectra of the material in peak 1 are displayed in *panel a*. *Panel b* shows spectrum of components in the fraction collected from the HPLC analysis of synthetic EXC₄-EA. The insert in *panel b* also shows the structure and suggested fragments of synthetic EXC₄-EA. Spectra A were recorded on a Quattro Ultima (Waters) and spectrum B on a Quattro Micro (Waters)

we also included 2-AG in our studies of cysteinyl-containing 15-LO-1 metabolites. As summarized in Fig. 6, addition of 50 μ M of substrate to cells led to a robust formation of cysteinyl-containing metabolites of both ARA and AEA. The cells had higher capacity to convert AEA to EXC₄/D₄-EA than to metabolize ARA to EXC₄/D₄. However, considerably lower amount of cysteinyl-containing 2-AG metabolites were detected.

Metabolism of EXA₄-Ethanol Amide by Human Platelets and L1236 cells

Platelets are well-known producers of eicosanoids and especially TXA₂ and 12-HETE through the actions of COX1/TXAS and 12-LO, respectively [48]. Platelets express LTC₄-synthase and can convert exogenous added LTA₄ to LTC₄ [49]. Thus, to further characterize the extent of eoxamide formation in other cells, we incubated human platelets with EXA₄-EA and analyzed the metabolites formed by RP-HPLC. As demonstrated in Fig. 7, platelets readily produced both EXC₄-EA and EXD₄-EA upon incubation with EXA₄-EA as indicated by the presence of two metabolites with an UV-absorbance maximum at 280 nm (Fig. 7, peak 1 and 4) that co-eluted with synthetic standards of EXC₄-EA and EXD₄-EA (indicated by arrows in Fig. 7). Furthermore, several metabolites with UV-absorbance maximum at 270 nm could be detected after incubation of platelets with EXA₄-EA. These metabolites (peaks 2, 3 and 5) are likely to be dihydroxy metabolites of AEA. Figure 8 shows the profile of cysteinyl-containing EXA₄-EA metabolites formed at different incubation

period in both platelets (Fig. 8a) and in L1236 cells (Fig. 8b). The major product formed in platelets at all time points was EXD₄-EA (Figs. 7, 8a). The metabolism of EXC₄-EA and EXD₄-EA in L1236 appeared to be more extensive than in platelets since formation of a third less polar metabolite, presumably EXE₄-EA, was observed to a higher extent in L1236 cells than in platelets (Figs. 3, 7, 8b). This metabolite could only be observed in platelets at incubation times of 10 min or longer, and then only to a low extent. The total formation of cysteinyl-containing metabolites of EXA₄-EA was higher in incubations with L1236 cells than in incubations with platelets. However, the amount of protein is different in L1236 cells as compared to platelets and the values are not corrected for the amount of protein in each cell. Thus, the efficacy of the cells to form eoxamides cannot be judged from these data. Studies using purified glutathione transferases in order to identify enzymes capable of synthesizing eoxamides and to investigate enzyme kinetics are currently ongoing.

Discussion

Endocannabinoids have, since their discovery, been the subject of extensive research as well as pharmaceutical intervention [50]. The tonus of AEA is regulated by de novo synthesis as well as with hydrolyses by FAAH or monoacylglycerol lipases and it has been demonstrated that pharmaceutical blockade of AEA hydrolysis have analgesic effects [51–54]. By blocking the degradation of AEA, one would anticipate higher levels of AEA and thus also

Fig. 5 Pathway for the formation of eoxamides

several applications for these pharmaceuticals in disorders where AEA signalling is involved in the pathophysiology of the disease. Neuropathic pain is one area where intervention of endocannabinoids might prove to be efficacious [55]. Our finding that 15-LO-1 can utilize neutral lipids such as AEA and 2-AG to the same extent, or even better than the corresponding free fatty acid (Figs. 1, 2), indicates that 15-LO-1 mediated oxygenation of endocannabinoids can be extensive as compared to metabolism of ARA in cells expressing 15-LO-1. Furthermore, we describe herein

Fig. 6 Relative cellular formation of cysteinyl-containing metabolites formed from ARA, AEA or 2-AG in L1236 cells. L1236 cells (1.0×10^7 cells/mL) were incubated with 50 μ M of ARA, AEA or 2-AG. An aliquot of the supernatant (200 μ L) was analyzed RP-HPLC. The formation of cysteinyl-containing metabolites were analyzed by their absorbance at 280 nm and by comparison of retention times to synthetic standards. The results are presented as the sum of cysteinyl-containing metabolites \pm SEM ($n = 3$) from three individual experiment, each performed in duplicate

the formation of previously unknown cysteinyl-containing metabolites of AEA by the concerted action of 15-LO-1 and a glutathione transferase (Figs. 3, 4 and 5). The formation of cysteinyl-containing metabolites of AEA exceeded the formation of cysteinyl-containing metabolites from ARA (Fig. 6), supporting the fact that 15-LO-1 mediated metabolism of AEA can be extensive. Apart from the L1236 cells, platelets were also identified as a cellular source of eoxamides (Figs. 7, 8), but only if provided with the epoxide-precursor 14,15-LTA₄-EA. This is analogous to the formation of LTC₄ by platelets after addition of exogenous LTA₄ [56], so-called transcellular metabolism. Cells that express both 15-LO-1 and an appropriate glutathione transferase can indeed synthesize eoxamides from endogenous sources, as seen in L1236 cells. Platelets which lack 15-LO-1 are dependent on transcellular metabolism of EXA₄ for EXC₄ synthesis. If transcellular metabolism also occurs for eoxamides remains to be determined. The fact that there is metabolism of EXC₄-EA to EXD₄-EA and possibly also to EXE₄-EA (Figs. 3, 8) suggests that the pathway for metabolism of eoxamides are similar to the metabolism of cysteinyl-leukotrienes. The metabolism of eoxamides to a stable end-product such as EXE₄-EA could lead to a way to measure the formation of these novel metabolites in vivo.

Endocannabinoids have been described as having multiple effects within the CNS of which some are due to binding of endocannabinoids to cannabinoid-receptor expressing neurons whereas other effects are due to neuroinflammation [50]. The recent finding that monoacylglycerol lipase (MAGL) can hydrolyze 2-arachidonoylglycerol to generate

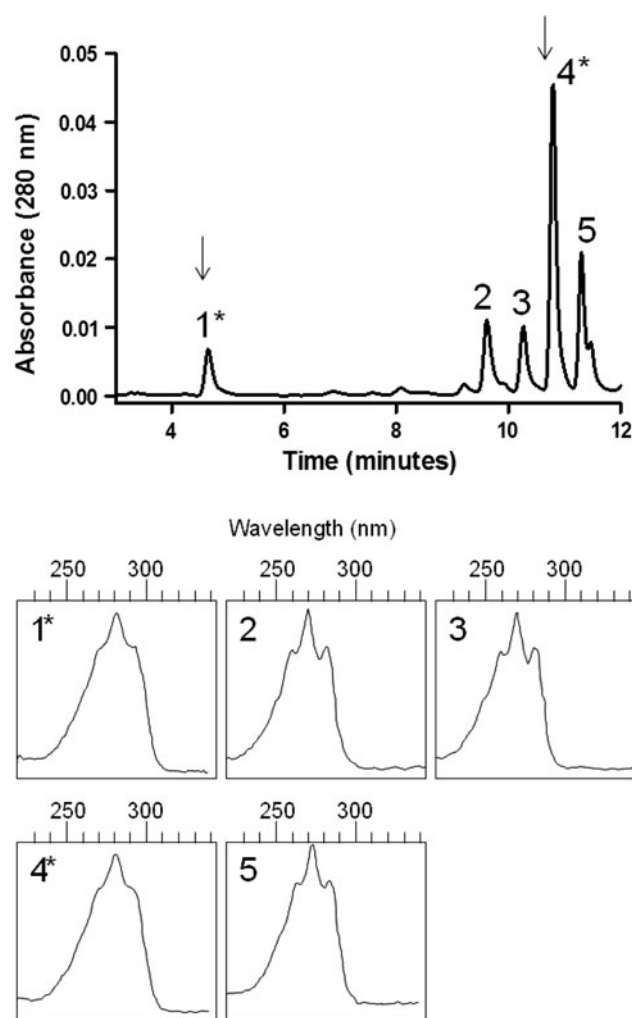

Fig. 7 Chromatographic profile of metabolites formed in platelets after addition of EXA₄-EA. Human washed platelets (approximately 4.0×10^8 cells/mL) were incubated with 50 μ M of EXA₄-EA for 5 min before termination with acidic methanol. After centrifugation, an aliquot of the supernatant (200 μ L) was injected onto a Nova Pak C18 RP-HPLC column. Metabolites were eluted using a different gradient as compared to Fig. 3 (described in “Materials and Methods”). Upper panel shows the elution profile and absorbance at 280 nm. The formation of metabolites was analyzed by comparing their retention times to synthetic standards as well as their absorbance at 280 or 270 nm. Asterisks at peak 1 and 4 denote products with UV-absorbance maximum at 280 nm. The elution times of synthetic EXC₄-EA and EXD₄-EA are indicated by arrows at 4.7 and 11 min, respectively. The lower panel shows the UV-spectra for the indicated peaks

ARA as a precursor for neuroinflammatory prostaglandins has also shed light on the role of endocannabinoids in neuroinflammation [45]. It is noteworthy that 15-LO-1 is expressed within the CNS [26] and that formation of leukotrienes in the CNS has been known for a long time [57, 58]. The recent finding that leukotriene receptor antagonists is effective in an animal model of multiple sclerosis [59]

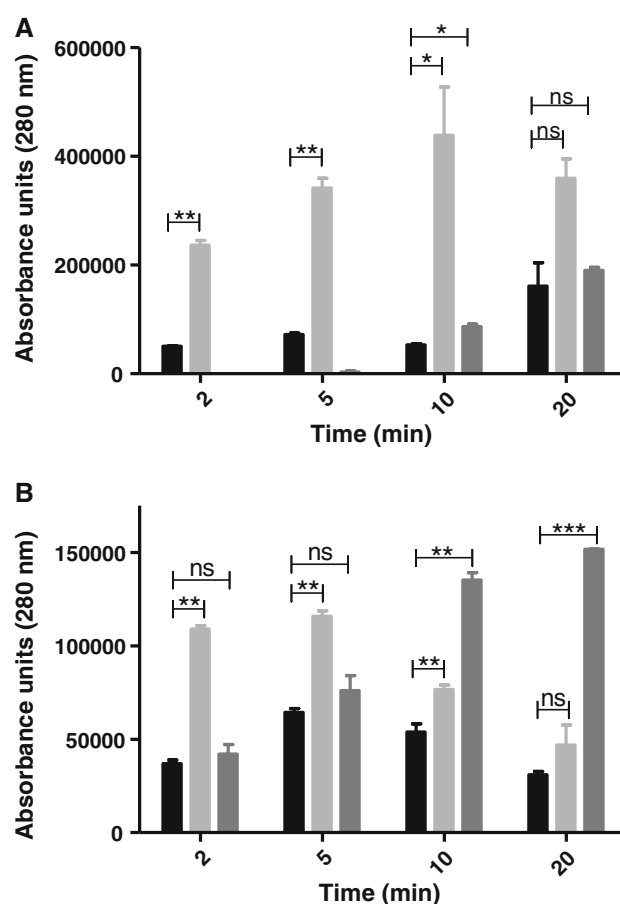

Fig. 8 Comparison between the cellular formation of eoxamides in platelets and L1236 cells after addition of EXA₄-EA. Human washed platelets (approximately 4.0×10^8 cells/mL) (a) or L1236 cells (1.0×10^7 cells/mL) (b) were incubated with 50 μ M of EXA₄-EA for the indicated times before termination with acidic methanol. The formation of cysteinyl-containing metabolites were analyzed by comparing their retention times to synthetic standards as well as their absorbance at 280 nm. The results are presented as the sum of cysteinyl-containing metabolites \pm SEM ($n = 3$) from one representative experiment out of two. Black bars EXC₄-EA, light dark grey bars EXD₄-EA and dark grey bars EXE₄-EA

further highlights the link between CNS, neuroinflammation and cysteinyl-containing leukotrienes.

The Hodgkin lymphoma cell line L1236 has high endogenous expression of 15-LO-1. The expression of 15-LO-1 has also been confirmed in several Reed-Sternberg positive cells by immunohistochemistry [8] and one hypothesis could be that 15-LO-1 plays a regulatory role in controlling immunological responses in the inflammatory process. Apart from their role within the CNS, cannabinoids are also known to be able to affect the immune system and CB1 and 2 are expressed in immune cells with B-lymphocytes being one of the cell types that most abundantly express CB1 and 2 [60, 61]. Polymorphonuclear neutrophils, T-cells and monocytes have also been shown to express CB1 and 2. Thus, the possibility for

immunomodulatory functions for enzymes/receptors involved in endocannabinoid signalling, or termination thereof, is evident. Several pharmacological active compounds that interfere with the endocannabinoid system display plethoric effects affecting both systemic as well as peripheral processes including body weight control, neuropathic pain, inflammation and cytokine release [50]. Our finding of the eoxamides identifies a new pathway for the formation of AEA metabolites. If these unique compounds display any biological role themselves remains to be investigated. However, it is interesting to note that several metabolites of AEA such as the lipoxygenase derived monohydroxy acids [62] or the cyclooxygenases derived prostamides bind to existing receptors or exerts their effect through yet unidentified receptors.

The catabolism of endocannabinoids by FAAH can have a profound effect on pain sensation in animals [53]. The formation of eoxamides is a new example of the catabolism of AEA and the concerted action of 15-LO-1 and glutathione S-transferases or LTC₄-synthase to yield EXC₄-EA might be a new mechanism to terminate AEA signalling. Given the fact that 15-LO-1 has an expression profile restricted to higher primates and rabbits [47], the described metabolism of AEA in this report could be unique to man and other species that express 15-LO-1. We suggest that the described peroxidation and subsequent glutathionylation of AEA should be considered as an alternative pathway to FAAH/MAGL-pathways for elimination and secretion of AEA and as a new pathway for the generation of novel and potentially biological active AEA-metabolites.

Acknowledgments Dr. Mats Hamberg (Karolinska Institutet, Sweden) is gratefully acknowledged for providing synthetic metabolites. This study was supported by grants from the Swedish Cancer Society, Karolinska Institutet and an unrestricted grant from Orexo.

Abstract The particular interest in supplementing human foods with n-3 fatty acids has arisen from the findings that this series of polyunsaturated fatty acids (PUFA) have an impact on neuronal functions. Indeed vertebrates, including humans, preferentially use docosahexaenoic acid (DHA, 22:6n-3) over other long-chain n-3 PUFA for the genesis of their neuronal and retinal membranes. The grey mouse lemur is a nocturnal prosimian primate originating from Madagascar. The increased use of this omnivorous primate in nutritional studies (chronic caloric restriction, n-3 fatty acids supplementation), justifies the interest of determining their fatty acids body composition. In the present study, we report the fatty acid composition in lipid classes from the main target tissues (brain, retina, liver and adipose tissue) of six adult mouse lemurs raised under laboratory nutritional conditions. Among the main findings, n-6-docosapentaenoic acid (n-6-DPA; 22:5n-6) is very low in the brain cortex and retina, whereas there is a very high accumulation of docosahexaenoic acid (DHA, 22:6n-3) in the neural tissues compared to liver and plasma. In particular, DHA accounts for about one half of the total fatty acids in the retina ethanolamine glycerophospholipids. This high concentration clearly indicates that DHA is efficiently

transferred from blood lipids to the outer segment of the mouse lemur retina. We conclude that the mouse lemur n-3 PUFA metabolism efficiently drives DHA to neural tissues, through the blood–brain barrier and the blood–retina barrier.

Introduction

The particular interest in supplementing human foods with n-3 fatty acids has arisen from the findings that this series

of polyunsaturated fatty acids (PUFA) has an impact on neuronal functions. Indeed vertebrates, including humans, preferentially use docosahexaenoic acid (DHA, 22:6n-3) over other long-chain n-3 PUFA for the genesis of their neuronal and retinal membranes (review in [1]). Moreover, when n-3 fatty acids are adequately supplied by the diet, the central nervous system (CNS) membranes of the newborn and adult mammals have higher concentrations in DHA than in n-6 fatty acids, a particular fatty acid composition that is not found in the other tissues. On the other side, if the n-3 fatty acids are chronically low or inadequate in the diet, there is a DHA collapse in the CNS membranes which is almost exactly compensated by the rise of a long-chain derivative of the n-6 series, docosapentaenoic acid (n-6-DPA), to maintain the membrane content of 22C PUFA [2]. This n-6 substitute of DHA is synthesized in the liver from its essential precursor linoleic acid (LNA, 18:2n-6) of oleaginous plant origin, transported in blood lipids and distributed as an end-product to the DHA-deprived tissues including brain and retina [3]. However, the structural replacement of DHA by n-6-DPA has been shown to underlie alterations of retina and brain functions, indicating that the specific accretion of DHA during development is essential for the proper functioning of the mammalian CNS (review in [2]). Regarding the specific roles of DHA, one of the major findings of this decade is that DHA may be converted in response to oxidative stress into oxygenated derivatives which exert potent protective action through the inhibition of pro-apoptotic genes and the induction of anti-apoptotic and anti-inflammatory genes [4]. The synthesis and bioactivity of a lipoxxygenated derivative of DHA, neuroprotectin D1 (NPD1), were formerly evidenced in a rat model of brain ischemia [5]. NPD1 has been also shown to promote retinal pigment epithelial cell survival during oxidative stress [6] and to abrogate genotoxic and oxidative damage in a rat model of liver injury [7].

Docosahexaenoic acid may be directly provided under the esterified form in triacylglycerols (mainly in fish oils and marine products) or may be synthesized from the n-3 precursor, α -linolenic acid (ALA, 18:3 ω 3), through the same hepatic enzyme pathway as that producing ω 6-DPA from LNA upon n-3 deficiency [8, 9]. Therefore, the balance between DHA and ω 6-DPA in blood lipids and in cell membranes, especially those of neurones and retinal cells, will result from both the ratio of n-3 to n-6 in the dietary lipids and from the capacity of liver to convert the plant-issued precursors into their respective long-chain derivatives.

The grey mouse lemur (Fig. 1) is a nocturnal prosimian primate originating from Madagascar. In captivity, this non-human primate has a life expectancy of around 8 years (Languille et al. 2012) [10] and presents specific

Fig. 1 The grey mouse lemur (*Microcebus murinus*)

characteristics, e.g., omnivorous dietary habits and small size and weight (80–120 g). Grey mouse lemurs display a common pattern of cognitive alteration during ageing with humans which makes it a good model to evaluate the effects of dietary treatments on behavioral outcomes, especially in relation to aging or during dietary interventions [11, 12]. Specific tasks have been developed and adapted in our laboratory [10] offering the possibility of evaluating, in this small primate, the impact on longevity or cognitive functions of dietary supplements such as antioxidants [13] or n-3 fatty acids [14].

This nocturnal primate exhibits biological seasonal rhythms that are photoperiodically driven characterized in particular by a winter body mass gain and decreased resting metabolic rate [15]. The increase in body mass can represent close to 50 % of the summer acclimated body mass and is mainly due to fat accumulation [16]. Until now, the tissue fatty acid composition of the grey mouse lemur has not been analyzed and it is thus not known whether the DHA status of this primate raised on an experimental regimen made of milk, eggs, cereals and fruits is adequate. In the present study, we report the fatty acid composition in phospholipids from the main target tissues, brain, retina, liver and adipose tissue of the mouse lemur raised under standard nutritional conditions and acclimated to a winter-like photoperiod.

Materials and Methods

Animals and Ethics Statement

The experiment was performed in accordance with the Principles of Laboratory Animal Care (National Institutes of Health publication 86–23, revised 1985) and the European Communities Council Directive (86/609/EEC). The research was conducted under the authorization # 91–305

from the “Direction Départementale de la Protection des Populations” and the internal review board of the UMR 7179. The experiment was done under personal license (authorization number 91–460, issued 5 June, 2009) delivered by the Ministry of Education and Science. Nociception was minimized as much as possible. Six adult female grey mouse lemurs (*M. murinus*, Cheirogaleidae, primates) acclimated to winter-like photoperiod aged of 23 ± 4 months were raised on fresh fruits and a laboratory daily-made mixture of cereals, milk and egg given ad libitum. The fatty acid composition of this meal is reported in Table 1. It contained about 1 g of total fatty acids per 100 g of meal. PUFA from both series were present, mainly in the form of 18 carbons precursors, LNA (103.8 mg/100 g) and ALA (9.9 mg/100 g). The long-chain PUFA were also present, mainly ARA (3.2 mg/100 g) and DHA (1.4 mg/100 g).

Tissues Collection

Animals were anesthetized by ketamine lethal injection. Blood samples were drawn via the saphenous vein and the animals were killed. The liver and frontal cortex were rapidly removed and frozen in liquid nitrogen then stored at -80°C until analysis. A sample of white adipose tissue was excised from the tail (white adipose tissue being mainly located in the tail during winter mass gain).

The outer retinas (containing the rod outer segments of the photoreceptor cells) were prepared according to the method of Chen et al. [17]. The eyes were removed, and the retinas were detached from the retinal pigment epithelium (RPE) by incubating the eyecups in a calcium-free Ringer buffer (pH 7.4) containing 118 mmol NaCl/L, 4.7 mmol KCl/L, 1.17 mmol KH_2PO_4 /L, 1.17 mmol MgSO_4 /L, 5.6 mmol D-glucose/L, 35 mmol NaHCO_3 /L, and 1 mmol EDTA/L with gentle stirring at room

temperature. The two retinas by animal were pooled and the six preparations were stored at -80°C .

Separation of Phospholipid Classes and Fatty Acid Composition Analysis

The total lipids were extracted from the outer retina and from dilacerated samples of around 50 mg of cerebral cortex and liver with 4 ml of chloroform–methanol (2:1, by vol). The fatty acid composition of the diet was analyzed by the same experimental procedure with a known amount of 19:0-TAG as internal standard. The liver neutral lipids (NL) and the three main phospholipid classes from liver, cerebral cortex and retina, phosphatidylserine (PtdSer), choline glycerophospholipids (ChoGpl), and ethanolamine phosphoglycerolipids (EtnGpl) were isolated by solid-phase extraction on a 500 mg aminopropyl bonded silica cartridge [18]. The cartridges were equilibrated beforehand with eluent I (isopropanol/chloroform, 1:2, by vol). Each sample of total lipids was dried under nitrogen, resolubilized in 250 μl of eluent I and deposited onto a single-use cartridge. It was eluted with 3 ml of eluent I to recover the NL, then with 3 ml of diethylether/acetic acid (98:2, by vol) (discarded), 1 ml of acetonitrile (discarded) and 8 ml of acetonitrile/*n*-propanol (3:1, by vol) to recover the ChoGpl fraction. The cartridge was then eluted with 2 ml of acetonitrile/*n*-propanol (1:1, by vol) (discarded) and 3 ml of methanol to recover the EtnGpl fraction, consisting in a mixture of phosphatidylethanolamine and 1-*O*-alkylenyl-2-acyl glycerophosphoethanolamine. Upon transmethylation (see below), the latter compound generates fatty acid methyl esters from the *sn*-2 position and dimethylacetals (DMA) from the *sn*-1 position. The PtdSer fraction was recovered at the end of the procedure by eluting with anhydrous isopropanol/methanolic HCl 3N (4:1, by vol). The three phospholipid fractions were dried

under a nitrogen flux and transmethylated by methanol at 90 °C in the presence of 10 % BF_3 to generate fatty acid methyl esters and DMA, which were both extracted with hexane. The samples were analyzed by gas liquid chromatography using a 50 m \times 0.20 mm capillary column (CP-Wax 52CB, Varian, Les Ulis, France) and a one-stage temperature program, from 54 to 212 °C at 3 °C/min [19]. The resulting peaks were identified by comparison of their retention times to those of a mix of standard compounds (mix GLC-68A from Nu-Chek-Prep, MN). The proportion of each fatty acid was automatically computed from the ratio of its peak area to the sum of total areas, including DMA, and expressed in mol% (peaks having a surface <0.1 % of total were not computed). The theoretical maximum value of DHA (DHAm_{max}) was calculated as the sum of DHA + n-6 DPA. The desaturation index of n-3 and n-6 series was also calculated. The desaturation index of each series is computed from the content (expressed in % by weight) of the corresponding fatty acid (n-6 or n-3) balanced by the number of its double-bond. The global value obtained within each series results from the sum of the individual indices. It gives an indication of the total unsaturation level in membranes brought about by the n-6 or by the n-3 series.

Statistical Analysis

All values are expressed as means \pm SEM. Paired Student's *t* test analyses were used to ascertain the significant differences in the fatty acid content between tissues. Comparisons were considered to differ significantly with $p < 0.05$. All statistical computations were performed with Prism 5 for Windows XP (Graphpad software).

Results

Adipose Tissue and Plasma (Table 2)

The total lipids of the adipose tissue mainly contains saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA) which together accounts for 96 % of the total fatty acids, reflecting the role of lipid energy storage of this tissue. The PUFA, especially DHA, are extremely low, suggesting that the adipose tissue is not a DHA supplier for other organs. Moreover, the level of the two essential PUFA, linoleic (18:2n-6) and α -linolenic (18:3n-3), were also low, representing 2.1 and 0.2 mol%, respectively. The MUFA are less concentrated in the plasma phospholipids (PL) than in the adipose tissue. DHA and n-6-DPA are both present in the plasma PL (4.6 and 1.2 mol%, respectively) indicating that the blood concentration of DHA issued from metabolism in the present condition of feeding matches

about 80 % of its theoretical maximum value (DHAm_{max}, 5.8 mol%). Eicosatrienoic acid (ETA, 20:3 n-9), a long-chain derivative of the n-9 series marker of total PUFA deficiency, is present at low level.

Liver (Table 3)

The EtnGpl fraction of liver contains 9.8 % DHA and 2.9 mol% n-6-DPA. The relatively high level of n-6-DPA suggests that DHA might reach higher values (theoretically 12.7 mol%) under optimized conditions of n-3 supplies.

The ChoGpl fraction contains DHA and n-6-DPA at lower levels (3.6 and 1.2 mol%, respectively), while the NL contains very low amounts of these long-chain derivatives, 0.2 and 0.1 mol% respectively. The major fatty acids in liver NL are SFA (31.0 mol%) and MUFA (59.3 mol%), mainly present in the form of palmitic acid (16:0) and of oleic acid (18:1n-9). Briefly, the main PUFA in the liver phospholipids are the long-chain derivatives, arachidonic acid (ARA, 20:4n-6) and DHA, while the NL store their respective precursors, LNA (5.7 mol% 18:2n-6) and ALA (0.7 mol% 18:3n-3). The highest contents in ARA and DHA are found in the EtnGpl fraction which consequently has a high level of total unsaturation, with a double-bond index for the n-6 and n-3 series equal to 152 and 83

respectively (vs. 127 and 39 in ChoGpl). There is no substantial accumulation of ETA in liver lipid classes (≤ 0.2 %).

Brain Cortex (Table 4)

The major fatty acids in the ChoGpl fraction from the brain cortex are palmitic acid (52.1 mol%) and oleic acid (17.5 mol%), while DHA is relatively low (4.3 mol%). By contrast, DHA is the major fatty acid in the EtnGpl fraction (32.0 mol%) and the second major fatty acid in PtdSer (24.9 mol%). In the three phospholipid classes, DHA takes account for 98 % of the total n-3 PUFA, a proportion that is

characteristic for neural tissues of mammals. Besides, the brain EtnGpl contains 10-times more DMA in comparison with the liver counterpart, reflecting the specifically high concentration of ether-phospholipids (plasmalogens) in the CNS membranes. In comparison with DHA, the n-6-DPA content is low (1.8 mol% in EtnGpl, $p < 0.001$), indicating that the cerebral needs in DHA are almost fully covered (on the basis that DHA alone takes account for around 95 % of the sum DHA + n-6-DPA). The PtdSer fraction presents the same high DHA content as that in EtnGpl (25.9 mol%), which is a further indication that the brain requirements in DHA are almost fully covered in these animals. The high DHA contents result in high levels of n-3 double-bond index in EtnGpl and PtdSer (178 and 172), values typical for cerebral phospholipids.

Retina (Table 5)

The retina has the highest DHA content (24.7, 37.8 and 47.3 mol% in the ChoGpl, PtdSer and EtnGpl fractions, respectively) whereas the content in n-6-DPA is, in comparison, very low (<2 mol%, $p < 0.001$ for all phospholipids classes). It may be noted that, as in rodents, DHA takes account for almost one half of the whole fatty acids esterified in the retinal EtnGpl of the mouse lemur. This is a clear indication that DHA in the photoreceptor cells of these animals is about at its maximum level. The other major fatty acids are 16:0, 18:0 and ARA in EtnGpl and PtdSer, and SFA and MUFA in ChoGpl. The high DHA content in the retina phospholipids results in very high values of the n-3 double-bond index, i.e., 178 in ChoGpl, 287 in EtnGpl and 258 in PtdSer.

Discussion

This work provides the first analysis of the fatty acid composition in neural and peripheral tissues of the mouse lemur. We examined in particular the DHA status in animals raised on an experimental home-made diet, especially in the brain cortex and retina, the main target tissues, but also in the liver, the main organ ensuring the synthesis of DHA from its precursor.

The home-made diet contained traces of n-6-DPA (0.03 % of total dietary fatty acids), probably from the milk or egg lipids. Notwithstanding, the presence of this long-chain end product of the n-6 series in the hepatic and plasma phospholipids at a substantial level may be indicative of an endogenous synthesis, which would be due to a moderate inadequacy of the amount of n-3 PUFA in diet. α -LNA in the adipose tissue is a marker of dietary α -LNA intake. The very low content of α -LNA in the adipose tissue of the grey mouse lemur (0.2 mol%), compared to

that found in rat fed an α -LNA adequate diet (1 %) [19], is also indicative of a relative inadequacy in n-3 in the diet. However, the very low amount of ETA (a biomarker of PUFA deficiency) indicates that total PUFA intakes are sufficient [19]. In addition, adipose tissue contains very high levels of 16:0 (23.6 \pm 1.7 mol%) and 18:1n-9 (48.5 \pm <0.8 mol%). These amounts of saturated and monounsaturated fatty acids in adipose tissue can be linked to the seasonal fattening and reduced resting metabolic rate exhibited during winter by this species [15, 20]. In addition, it is noteworthy that grey mouse lemurs are seasonal primates that exhibit an important fattening during winter, with an increase in body mass that can represent close to

50 % of the summer acclimated body mass [16]. During the winter, the fat mass represents 35 % of the animal's body weight whereas it represents only 10 % during summer [16]. The present results must be interpreted taking into account that fatty acid compositions have been determined in winter acclimated animals. Very few studies have investigated the fatty acid composition of tropical primates, and more particularly heterotherms. Fietz and colleagues [21] reported the fatty acids composition of the fat-tailed dwarf lemur (*Cheirogaleus medius*), a small primate belonging to the family of *Cheirogaleidae* like the grey mouse lemur. In this species, white adipose tissue contains around 67 % monounsaturated fatty acids, a level higher but comparable to that found in our study (60 %). In both species, 18:1n-9 was the main fatty acid of adipose tissue. As suggested by Fietz et al. [21], because of its high prevalence, 18:1n-9 is probably the main fuel provider during hypothermia in both species.

n-6-DPA is very low in the brain cortex and retina, whereas there is a dramatic biomagnification of DHA in the neural tissues compared to liver and plasma (Fig. 2). In the brain cortex EtnGpl, DHA represents 32.0 ± 1.7 mol%, and 9.8 ± 1.0 in the liver EtnGpl ($p < 0.001$; $t = 25.97$; $df = 5$), and only 4.6 ± 0.9 in the plasma TL ($p = 0.005$, $t = 4.301$; $df = 5$, when compared to liver). In particular, DHA accounts for about one half of the total fatty acids in the retina EtnGpl (47.3 ± 2.5 mol%, $p < 0.001$; $t = 15.63$; $df = 5$, when compared to brain cortex EtnGpl). This high concentration clearly indicates that DHA is efficiently transferred from blood lipids to the outer segment of the mouse lemur retina. It has been demonstrated in the frog and rat retina that DHA is translocated from blood lipoproteins to photoreceptor cells across the choriocapillaris, the Bruch's membrane and the RPE [22]. The RPE cells

release DHA in the interphotoreceptor matrix (IPM) from which it passes into the photoreceptor inner segment where it is incorporated into phospholipids, mainly EtnGpl and PtdSer, for the biogenesis of new membranes, notably those of the photoreceptor disks formed at the outer segment basement. The older disks are phagocytized at the tip of the outer segment by the RPE phagosome, the released DHA molecules being secreted into the IPM for a new cycle of disk biogenesis. RPE cells are capable by themselves of synthesizing DHA from its upstream metabolic precursors (translocated from blood lipids), providing an additional supply for the photoreceptor cells [23]. Thus, the RPE plays a crucial role in the DHA synthesis and recycling, allowing the photoreceptor disks to maintain—in spite of their permanent renewal—the highest DHA concentration of the organism. Similarly to rats, the mouse lemur is a nocturnal species whose vision recruits rod photoreceptor cells [24]. The high concentration of DHA in the outer segment of the mouse lemur retina, similar to that found in that of rats raised on standard diets, strongly suggests that DHA is crucial for the optimum functioning of the lemur rod photoreceptor cells. On the basis of former studies performed on membrane models [25], it may be supposed that DHA-rich phospholipid species (EtnGpl and PtdSer) of the mouse lemur retina ensure a high level of disorder in the membrane environment of the rhodopsin molecules, facilitating the photo-induced conformational change of rhodopsin and the subsequent activation of the G-protein cascade.

The brain cortex phospholipids are also rich in DHA, although at a lower level than in the retina. We have previously shown in rat submitted to a dose-response effect that the retina and brain phospholipids have their own and specific maximum of DHA incorporation (DHAm_{ax}), even though DHA continues to increase in diet [18]. In the rat EtnGpl fraction, the DHAm_{ax} values were equal to 29 % in the frontal cortex and 46 % in the retina. The values which we found in the mouse lemur, 29 and 47 % respectively ($p < 0.001$; $t = 14.75$; $df = 5$), clearly show that the incorporation of DHA into the outer retina is highly similar in the two animal models. Thus, the mouse lemur raised on the home-made diet efficiently metabolizes the dietary n-3 PUFA for the optimum modeling of his cortical and retinal membranes. Therefore, the relative inadequacy of n-3 supplies in the home-made diet, that we may infer from the presence of n-6-DPA in liver and plasma, is fully compensated by the very efficient transfer of DHA to the avid neural tissues, excluding on the contrary n-6-DPA.

However, we recently showed that mouse lemurs receiving the home-made diet supplemented with tuna oil, rich in DHA, had their level of anxiety significantly lowered in comparison with animals receiving a placebo supplementation (olive oil) [14]. The behavioral and cognitive

Fig. 2 Biomagnification of docosahexaenoic acid (DHA, black bars) and arachidonic acid (ARA, grey bars) in the brain and retinal phospholipids of the mouse lemur, in comparison with liver and plasma

tests evidenced a beneficial effect of the tuna oil-supplemented diet on the brain functions of the grey mouse lemur, which may a priori suggest an improvement in their cerebral DHA status. However, on the basis of the present data in animals placed under standard feeding, which have low levels of n-6-DPA in their brain phospholipids and DHA values close to those of the rat DHAmx, it is likely that the requirements for DHA of the neural tissues are almost fully covered with the standard diet. If this speculation is correct, supplementing the diet of adult animals with tuna oil would result in only a modest gain of DHA in the neural tissues. However, our previous study showed that animals fed the tuna oil-supplemented diet had much higher concentrations of EPA, n-3-DPA and DHA in their blood plasma phospholipids than those fed the standard diet [14]. These preformed long-chain n-3 PUFA are potential substrates for the synthesis of an array of bioactive lipids, eicosanoids, docosanoids, maresins and neuroprostanes. Docosanoids mainly include NPD1, a novel DHA-derived stereoselective mediator of signaling, especially in brain and retina cells [4]. It has been shown that NPD1 elicits potent anti-inflammatory actions and prohomeostatic bioactivity, is anti-angiogenic, promotes corneal nerve regeneration, and induces brain cell survival [4]. Whether the lowering of anxiety that we evidenced in DHA-supplemented mouse lemurs is related to activation of the NPD1 signaling pathway and to an improvement of the neuroinflammatory status opens a new field of investigation.

The consumption of n-6 and n-3 fatty acids in equilibrated proportions is crucial in the regulation of cellular physiology and in the prevention of pathologies such as cardiovascular, autoimmune and inflammatory diseases, diabetes and obesity or certain neuropsychiatric affections [2]. Indeed, the dietary intake of n-3 fatty acid (α -linolenate and also DHA) are crucial parameters in the development of retinal and neural function during the perinatal period [2]. On the other hand, a high ratio of n-6/n-3 fatty acids in cell membranes due to an excessive consumption of n-6 fatty acids and a relative n-3 fatty acid deficiency, may promote the pathogenesis of several diseases, including cardiovascular diseases, metabolic syndrome, inflammatory disorders and obesity [1, 4]. These health implications of fatty acids are of major importance when considering that the mouse lemur is becoming an emerging model in nutritional, metabolic and aging studies [10].

We conclude that the mouse lemur n-3 PUFA metabolism efficiently drives DHA to neural tissues, through the blood–brain barrier and the blood–retina barrier. The mouse lemur offers an emerging non-human primate model for n-3 PUFA metabolism studies and nutritional intervention in humans.

Abstract Oleic (OLA) and linoleic (LNA) acids are commonly consumed fatty acids and they can modulate the inflammatory response, in which macrophages play an important role. The aim of this study was to investigate the effects of these two fatty acids on the production of inflammatory mediators by macrophages. Rats received oral administration of water (control), OLA or LNA (0.22 g/kg body weight) daily for 10 days and peritoneal resident macrophages were then isolated. Subsequently, they were seeded in culture plates and the production of various inflammatory mediators was assessed. Oral administration with OLA decreased the production of IL-1 β , IL-6 and CINC-2 $\alpha\beta$ by resident macrophages and LNA decreased the production of IL-1 β , IL-6 and VEGF in the absence of lipopolysaccharide (LPS), although it

accelerated IL-1 β release and decreased IL-10 synthesis when cells were stimulated with LPS. Neither fatty acid affected the production of superoxide anion, hydrogen peroxide, nitrite, TNF- α , PGE₂, LTB₄ or 15(S)-HETE. Thus, OLA and LNA influence the production of several inflammatory mediators by macrophages.

Introduction

Macrophages are mononuclear phagocytes that derive from blood monocytes. They play a central role in the initiation, perpetuation and resolution of inflammatory responses

through the strictly regulated release of inflammatory mediators, such as reactive oxygen species (ROS), reactive nitrogen species (RNS), cytokines, eicosanoids and growth factors [1]. Inflammation is triggered by infection or tissue injury. An effective inflammatory response is key to eliminating pathogens. Resolution of inflammation serves to reduce infiltration and activity of inflammatory cells, to clear apoptotic leukocytes, and to promote wound healing and tissue repair. Non-resolution of inflammation is associated with the development of various pathological states [2].

There is on-going interest in the effects of fatty acids on aspects of inflammation [3–5]. Many in vitro studies with pure fatty acids have been performed. Dietary studies have tended to use fats and oils rich in particular fatty acids or fatty acid classes, with few dietary investigations of pure fatty acids. Oleic (OLA) and linoleic (LNA) acids are abundant fatty acids in western diets [6]. The former is found in meat, eggs, milk and olive oil, whereas the latter is found in soybean, sunflower, safflower and corn oils, which can be used in food manufacture and animal feeding [7, 8]. Effects of pure OLA or LNA on inflammatory processes are poorly explored. Recently, we have observed that oral administration of OLA or LNA to rats improved wound healing and modulated the inflammatory phase of wound repair [9] and influenced the function of neutrophils [10]. Here we continue this work by exploring the effects of oral administration of pure OLA or LNA on macrophage functions.

Materials and Methods

Reagents and Chemicals

Oleic and linoleic acids, lipopolysaccharide (LPS) from *Escherichia coli* serotype 026:B6, phorbol myristate acetate (PMA), sodium bicarbonate, L-glutamine, HEPES, lucigenin, cell growth determination kit, propidium iodide and horseradish peroxidase (HRP) Type II were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). RPMI 1640, penicillin–streptomycin (Pen Strep), fetal bovine serum (FBS) and Amplex[®] Ultrared were purchased from Invitrogen (Carlsbad, CA, USA). DuoSet kits for cytokine determination were purchased from R&D Systems (Minneapolis, MN, USA). Kits for eicosanoid quantification were purchased from Cayman Chemical Co. (Ann Arbor, MI, USA).

Animals and Oral Administration of Fatty Acids

The Animal Care Committee of the Institute of Biomedical Sciences, University of Sao Paulo, approved the experimental procedure (Protocol number: 86). Male Wistar rats (180 ± 20 g) were obtained from the Department of Physiology and Biophysics, Institute of Biomedical

Sciences, University of Sao Paulo, Brazil and were maintained at 23 °C under a light:dark cycle of 12:12 h. Animals received non-purified diet (Nuvital, Curitiba, Brazil; providing 3.0 kcal total metabolizable energy/g), whose composition is presented in Table 1, and water ad libitum. The fatty acid composition of the chow is presented elsewhere [10]. Rats were treated daily for 10 days by gavage with 0.22 g/kg body weight of water (control), OLA or LNA. This supplementation adds 23 and 10 % of OLA and LNA, respectively, to the amount of such fatty acids deriving from chow. Animals were sacrificed approximately 1 h after the last supplementation. The fatty acid administration did not change food, calorie or water intake [10].

Isolation of Peritoneal Resident Macrophages

Peritoneal cells were obtained by intraperitoneal lavage with 50 mL PBS (136.8 mM sodium chloride, 2.7 mM potassium chloride, 0.9 mM potassium phosphate, 6.4 mM sodium phosphate dibasic, pH 7.4). The cells were collected by centrifugation (500g, 4 °C, 10 min). Erythrocytes were lysed in 5 mL hypotonic solution (150 mM ammonium chloride, 10 mM sodium bicarbonate, 0.1 mM EDTA, pH 7.4). Remaining cells were collected by centrifugation, resuspended in 1 mL PBS and counted in a hemocytometer under an optical microscope. Finally cells were again centrifuged and then suspended in RPMI 1640 medium culture supplemented with 10 % FBS, 100 U/mL penicillin, 100 µg/mL streptomycin, 24 mM sodium bicarbonate, 2 mM L-glutamine and 20 mM HEPES. They were then seeded (cell concentration based on the experiment) and maintained in a humidified incubator at 37 °C in an atmosphere of 5 % CO₂. After 1 h, non-adherent cells were removed by washing with culture medium culture; remaining adherent cells were above 90 % macrophages, as described elsewhere [11–13].

Table 1 Composition of the diet

| Nutrients | g/kg diet |
|---|-----------|
| Carbohydrate | 408 |
| Protein | 220 |
| Fat | 45 |
| Fiber | 80 |
| Calcium | 14 |
| Phosphate | 8 |
| Mix of vitamins and minerals ^a | 100 |
| Moisture | 125 |

^a Vitamin A 12,000 UI, vitamin D3 1,800 UI, vitamin E 30 mg; vitamin K3 3 mg, vitamin B1 5 mg, vitamin B2 6 mg, vitamin B6 7 mg, vitamin B12 20 mcg, niacin 60 mg, pantothenic 20 mg, folic acid 1 mg, biotin 0.05 mg, choline 600 mg, iron 50 mg, zinc 60 mg, copper 10 mg, iodine 2 mg, manganese 60 mg, selenium 0.05 mg, cobalt 1.5 mg

Cell Viability Determined by MTT Assay

The MTT assay was used to determine cell viability; the assay reflects functional mitochondria. MTT was added to culture plates of adherent macrophages (4×10^5 cells) and the plates were incubated for 3 h at 37 °C (100 μ L of final volume). Then the medium was removed and 100 μ L 0.1 N HCl in anhydrous isopropanol added. Absorbance was measured at 570 and 690 nm and plotted as the difference between the readings found at the two wavelengths, as specified by the manufacturer.

Determination of DNA Fragmentation

DNA fragmentation in macrophages was determined using propidium iodide staining. Briefly, cells (10^6) were resuspended in 200 μ L lysis buffer (0.1 % sodium citrate and 0.1 % Triton X-100) with 20 μ g/mL propidium iodide and were then incubated in the dark for 30 min. Subsequently, cells were analyzed (10,000 cells/sample) in a flow cytometer (FACSCalibur, Becton–Dickinson, San Juan, CA, USA) using Cell Quest software. Fluorescence was measured using FL2 channel (orange-red fluorescence-585/42 nm).

Lipid Extraction and Determination of Fatty Acid Composition in Plasma by Gas Chromatography

Plasma was collected 1 h after animal treatment. Derivatization of plasma lipid extract was performed according to AOAC Official Methods 996.06 [14], with some modifications. Aliquots of 1 mL from each plasma sample were added to a screw-cap test tube and 5 mg pyrogalllic acid, 0.1 mL standard (5 mg/mL tritridecanoin C13:0 in chloroform), 0.1 mL ethanol, 0.5 mL HCl 8.3 M and some glass beads were added. The tubes were placed in a water bath at 75 °C for 40 min and then cooled at room temperature. Subsequently, 1 mL ethyl ether and 1 mL petroleum ether were added and samples were centrifuged at 10,000 rpm for 5 min. Top phase was transferred to another tube and ether was evaporated under N_2 in a water bath (below 40 °C). Methylation was performed by addition of 1 mL BF_3 (7 % in methanol) and 0.5 mL toluene and subsequent boiling at 100 °C for 45 min. After cooling at room temperature, 2.5 mL water, 1 mL hexane and approximately 0.5 g Na_2SO_4 anhydrous were added. The tubes were left to rest to allow phase separation and then the top phase was transferred to a vial containing anhydrous Na_2SO_4 and evaporated under N_2 . Before injection into the chromatograph, 0.2 mL hexane was added to each sample. Samples were analyzed using gas chromatography on a GC 17A (Shimadzu) equipped with a flame-ionization detector (FID), automatic injector AOC-20 and a

Workstation Class GC10. Fatty acid separation was achieved using a fused-silica column SP-2560 (bis-cyano-propyl polysiloxane) (100 m \times 0.25 mm \times 0.2 μ m; Supelco, Bellefonte, USA). The column temperature was programmed as follows: 140 °C for 5 min; heating at 4 °C/min until 240 °C; 240 °C for 30 min. The injector and detector were at 250 °C, and helium was used as the carrier gas at a 1 mL/min flow rate. The split ratio was 1/10. Two microliters of derivatized lipid extract was injected and the fatty acid methyl ester peaks were identified by comparison of retention times of fatty acid methyl ester standards and the chromatograms viewed in the Ce 1 h-05 methods [15].

ROS Production as Determined by Lucigenin-Amplified Chemiluminescence Assay

The lucigenin-amplified chemiluminescence assay is able to measure ROS, mostly superoxide anion, since lucigenin releases energy in the form of light when excited by superoxide anion. After 1 h incubation of macrophages (4×10^5 cells in a final volume of 200 μ L), the culture medium was discarded and PBS supplemented with 10 % FBS, 10 mM glucose, 1.5 mM magnesium chloride, 1 mM calcium chloride and 1 mM lucigenin was added in the absence or presence of PMA (positive control-10 nM) (250 μ L of final volume). Chemiluminescence was measured in luminometer (Synergy HT Multi-Mode Microplate Reader, BioTek Instruments, Inc., Winooski, VT, USA) during 1 h at 37 °C [16]. Results were expressed as chemiluminescence during 1 h, subtracting blank values.

ROS Production as Determined by Amplex[®] Ultrared Fluorescence Assay

Amplex[®] Ultrared fluorescence assay is also able to measure ROS, but it detects mainly hydrogen peroxide. The product of Amplex[®] (*N*-acetyl-3,7-dihydroxyphenoxazine) oxidation, after HRP-catalyzed reduction of hydrogen peroxide, is named resorufin. This is a red, stable and fluorescent compound that can be measured by fluorometry, indicating the relative amount of hydrogen peroxide in the sample [17]. After 1 h incubation (4×10^5 cells in a final volume of 200 μ L), culture medium was discarded and PBS supplemented with 10 % FBS, 10 mM glucose, 1.5 mM magnesium chloride, 1 mM calcium chloride, 50 μ M Amplex[®] Ultrared and 0.1 U/mL HRP type II was added in the absence or presence PMA (positive control—10 nM) (200 μ L of final volume). The plate was then incubated in the dark for 1 h at 37 °C, followed by measurement in a fluorimeter (Synergy HT Multi-Mode Microplate Reader, BioTek Instruments, Inc., Winooski, VT, USA) (excitation 530 nm/emission 590 nm). Results were expressed as fluorescence during 1 h, subtracting blank values.

Nitrite Quantification

Macrophages (10^6 cells) were incubated in RPMI medium in a final volume of 1 mL for 24 h in the absence or presence of LPS (positive control—5 $\mu\text{g/mL}$). For quantification of nitrite, 100 μL Griess reagent (1 % sulfanilamide in 5 % H_3PO_4 and 0.1 % α -naphthyl ethylenediamine in distilled water, mixed 1:1) was added to 100 μL cell culture supernatant in a 96-well plate. The standard curve was determined by different concentrations of sodium nitrite (0–80 μM) and sample absorbance was measured in spectrophotometer (Synergy HT Multi-Mode Microplate Reader, BioTek Instruments, Inc., Winooski, VT, USA) at 550 nm [18]. Results were expressed as nitrite production (μM).

Cytokine and VEGF Quantification in Culture Supernatants

Macrophages (10^6 cells) were incubated in RPMI medium in a final volume of 250 μL for 5 h or 1 mL for 24 h in the absence or presence of LPS (positive control—5 $\mu\text{g/mL}$). Tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), interleukin-6 (IL-6), cytokine-induced neutrophil chemoattractant-2 $\alpha\beta$ (CINC-2 $\alpha\beta$ /CXCL3), interleukin-10 (IL-10) and vascular endothelial growth factor (VEGF) quantifications were performed in sample supernatants using DuoSet kits (Minneapolis, MN, USA), as described by the manufacturer. Sample absorbance was measured in a spectrophotometer (Synergy HT Multi-Mode Microplate Reader, BioTek Instruments, Inc., Winooski, VT, USA) at 450 nm.

Eicosanoid Quantification in Culture Supernatants

Macrophages (10^6 cells) were incubated in RPMI medium in a final volume of 1 mL for 24 h in the absence or presence of LPS (positive control—5 $\mu\text{g/mL}$). Prostaglandin E_2 (PGE $_2$), leukotrienes B_4 (LTB $_4$) and 15(*S*)-hydroxyeicosatetraenoic acid (15(*S*)-HETE) quantifications were performed in culture supernatants using Cayman kits (Ann Arbor, MI, USA), as described by the manufacturer. Sample absorbance was measured in a spectrophotometer (Synergy HT Multi-Mode Microplate Reader, BioTek Instruments, Inc., Winooski, VT, USA) at 412 nm.

Statistical Analysis

Results are presented as means \pm standard error means (SEM). Comparison between control (C) and fatty acid treated groups was performed using one way ANOVA and Dunnett post hoc test. Significant difference was considered when $p < 0.05$.

Results

Viability of Macrophages

There were no differences between groups with respect to macrophage viability determined by the MTT assay or macrophage DNA fragmentation (data not shown).

Plasma Fatty Acid Composition

Animals treated with OLA presented an increase in plasma OLA by 71 %, whereas treatment with LNA increased plasma LNA by 48 and stearic acid by 40 % (Supplementary Table 1), confirming that oral administration with fatty acids changed plasma fatty acid composition.

ROS and Nitrite Production by Macrophages

There were no differences between groups with respect to production of ROS (Fig. 1) or nitrite (Fig. 2).

Cytokine and VEGF Production by Macrophages

Cytokine and VEGF concentrations were measured in the supernatant of cells incubated for 5 or 24 h and with or without LPS stimulation. There was no significant difference in TNF- α production between groups. Linoleic acid increased IL-1 β release by 34 % when macrophages were stimulated with LPS during 5 h compared with the control group. After 24 h of incubation, unstimulated macrophages from rats that received either OLA or LNA showed a reduction by 50 and 62 %, respectively, in IL-1 β release. Oleic acid decreased by 54 and 45 % IL-6 release, in the absence and presence of LPS, respectively, after 5 h of incubation. Linoleic acid decreased IL-6 production by unstimulated macrophages after 5 and 24 h by 45 and 55 %, respectively. Oleic acid decreased CINC-2 $\alpha\beta$ production by unstimulated macrophages by 43 % after 5 h. Linoleic acid decreased IL-10 production by LPS-stimulated macrophages by 49 % after 24 h (Fig. 3). LPS did not increase VEGF release (data not shown). Neither OLA nor LNA changed VEGF production after 5 h of incubation, whereas after 24 h, LNA caused a reduction by 31 % (Fig. 4).

Eicosanoid Production by Macrophages

Neither OLA nor LNA altered production of PGE $_2$, LTB $_4$ or 15(*S*)-HETE after 24 h (Fig. 5).

Discussion

Oleic and linoleic acids are two commonly consumed fatty acids in the human diet and they can influence the immune

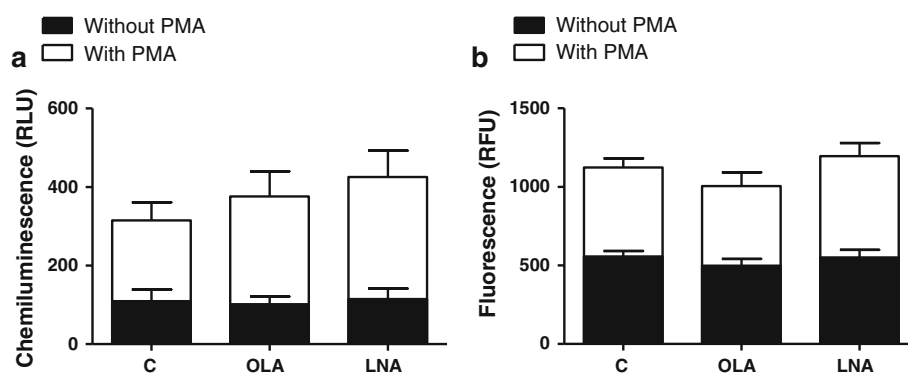

Fig. 1 Effects of oleic or linoleic acids on ROS production by macrophages from the different groups in the absence or presence of PMA. **a** Mainly superoxide is measured. **b** Mainly hydrogen peroxide is measured. Peritoneal macrophages (4×10^5 cells) from rats treated

for 10 days with water (control), oleic or linoleic acids were cultured for 1 h in the absence or presence of PMA (10 nM). Results are presented as means \pm SEM, $n = 9$ –13 samples

Results are presented as mean \pm SEM, $n = 9$ samples

response [3–5]. Moreover, oral administration of either fatty acid improves the wound healing process of rats [9], in which macrophages play an important role. The present study has shown that the oral administration of OLA or LNA modulates macrophage function, i.e., decreases the production of IL-1 β , IL-6, CINC-2 α β , IL-10 and VEGF. The production of superoxide anion, hydrogen peroxide, nitrite, TNF- α , PGE₂, LTB₄ and 15(S)-HETE, however, remained unchanged. The findings are summarized in Table 2.

The lack of effect of fatty acids on the MTT assay and DNA fragmentation indicates that the functional effects of the fatty acids observed here do not relate to an altered viability of the macrophages.

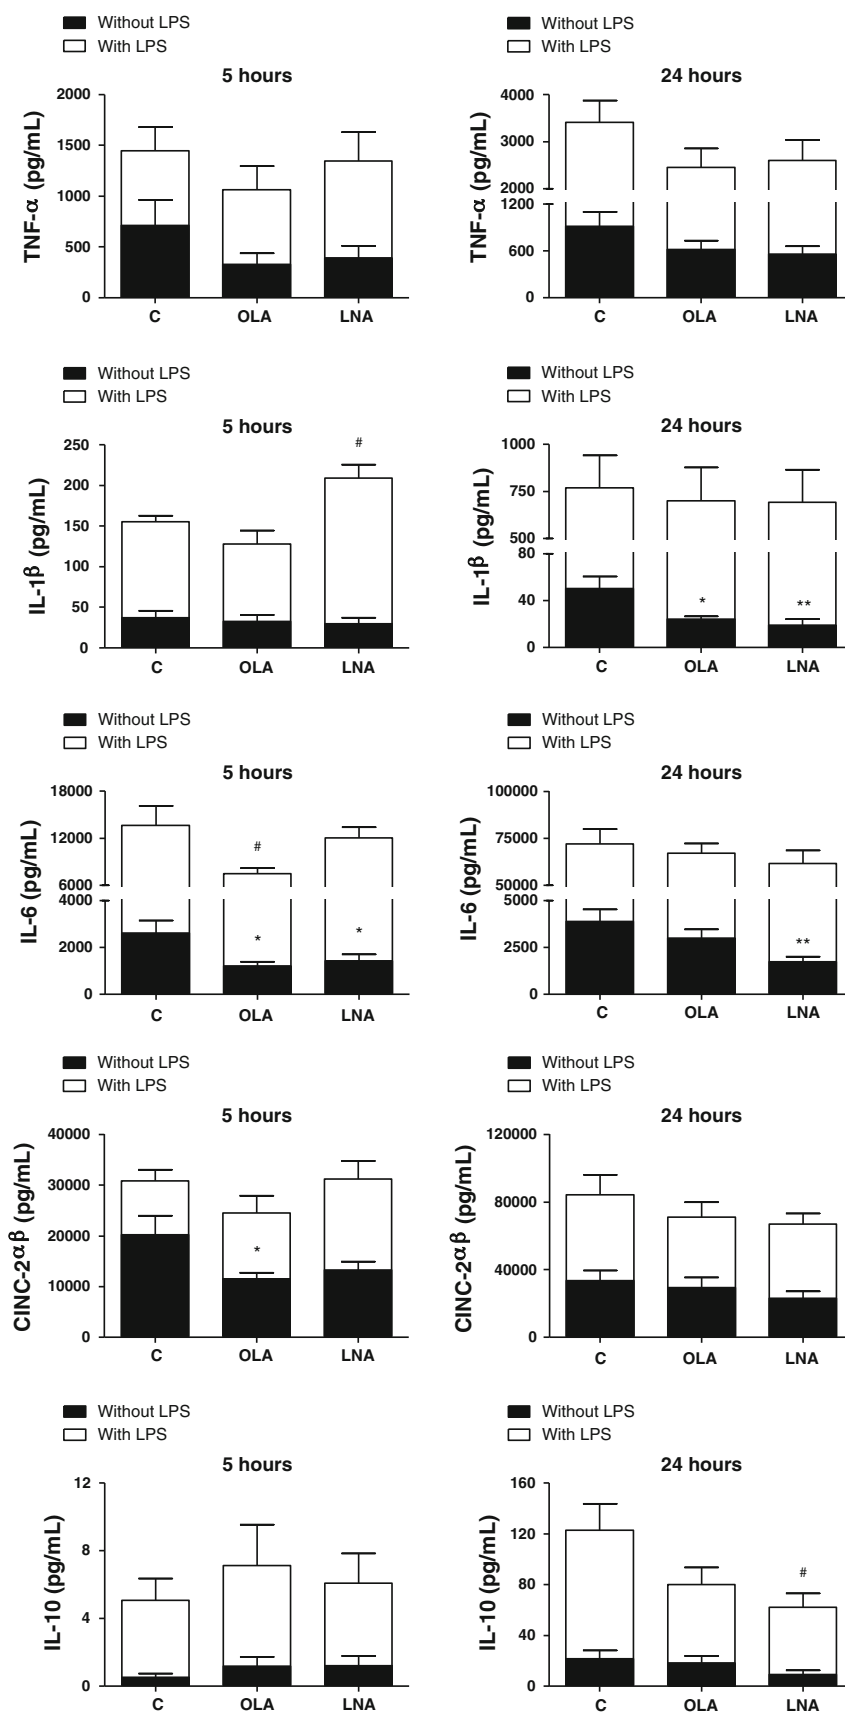

The lack of effect of the two fatty acids on production of superoxide, hydrogen peroxide and nitrite (a surrogate for nitric oxide produced by inducible nitric oxide synthase) indicates that some of the fundamental aspects of host defense associated with macrophages remain intact after

exposure to these two fatty acids. However, these mediators are associated with inflammation, so these components of the inflammatory response seem unaffected by the two fatty acids, as used here. In previous studies, feeding mice olive oil (a source of OLA) or safflower oil (a source of LNA) for a period of 8 weeks increased nitric oxide production by LPS-stimulated peritoneal macrophages [19], whereas feeding for 16 weeks decreased it [20]. Such conflicting observations may be explained by differences in treatment period, consumed doses of fatty acids, or effects of other compounds present in the oils that influence macrophage function.

During the inflammatory response, several cytokines are secreted by macrophages and other cells, as a result of pattern recognition receptor (PRR) activation by microorganisms. TNF- α is one of the first cytokines to be secreted during inflammation and it elicits various reactions in the organism, including leukocyte activation and migration to the inflammatory site, cell proliferation, differentiation and apoptosis [21, 22]. There was no significant difference between cells isolated from control animals and those treated orally with OLA or LNA with regard to TNF- α production. Feeding olive or safflower oils for 6 or 8 weeks reduced TNF- α secretion by thioglycolate-elicited peritoneal macrophages stimulated with LPS [19, 20, 23]. It should be noted, however, that the activation state of the cells influences such response, since peritoneal resident macrophages stimulated with LPS did not present alteration in TNF- α production when animals were fed these same oils [23].

IL-1 β is secreted mainly by macrophages and monocytes and is synthesized as its precursor, pro-IL-1 β [24]. Treatment with LNA accelerated IL-1 β release when macrophages were stimulated with LPS, since despite the increase after 5 h of incubation, IL-1 β level was similar to control after 24 h of incubation. However, in the absence

of LPS, a suppressive effect of OLA or LNA on $\text{IL-1}\beta$ production was only observed after 24 h incubation. Considering that $\text{IL-1}\beta$ is an important mediator of inflammation, since it stimulates signaling pathways that trigger the expression of other cytokines, chemokines, adhesion molecules, acute phase proteins and proteases [25, 26], the acceleration of its release may hasten the resolution of the inflammatory response. Other studies demonstrated that $\text{IL-1}\beta$ release is not altered by macrophages isolated from animals supplemented with olive and safflower oils and stimulated with LPS [19, 23].

In addition to $\text{TNF-}\alpha$ and $\text{IL-1}\beta$, macrophages also produce IL-6 in response to microorganism recognition and together they modulate local and systemic inflammation

[27]. Oleic acid delayed IL-6 production by macrophages stimulated or not with LPS, since its level was lower than control after 5 h of incubation but was similar to control after 24 h. Linoleic acid decreased IL-6 release only in the absence of LPS and this effect was maintained until 24 h. Although several studies have demonstrated a suppressive effect of the *in vivo* treatment with (n-3) fatty acids [28–30] on IL-6 production by macrophages, this is the first in which the same effects have been demonstrated with OLA and LNA. Among several actions, IL-6 stimulates the synthesis of acute phase proteins, modulates cytotoxic T lymphocyte proliferation and differentiation, induces antibody production by B lymphocytes and stimulates the resolution of inflammation. However, its overproduction is

Table 2 Summary of the effects of oleic and linoleic acids on the production of inflammatory mediators by macrophages

associated with Crohn's disease, Castleman's disease, multiple myeloma and rheumatoid arthritis [31, 32].

The release of cytokines such as TNF- α , IL-1 β and IL-6 at inflammatory sites stimulates chemokine expression [33]. Among the different chemokines, the CXC chemokines are the main chemoattractants of neutrophils during inflammation, which then migrate toward areas with higher concentration of chemokines [34]. Oral administration of OLA delayed CINC-2 $\alpha\beta$ production, as observed by the lower concentration compared to control after 5 h of incubation followed by a similar one after 24 h. In contrast, neutrophils from rats treated with LNA showed higher production of CINC-2 $\alpha\beta$ after 4 h of incubation but a reduction in such production after 18 h [10]. A similar response was observed in the wound tissue of animals treated with LNA [9]. Opposite effects on neutrophils and macrophages may assure an appropriate inflammatory response, as they have distinct but complementary features and kinetics [35].

After eliminating microorganisms, macrophages are stimulated to ingest apoptotic cells. This process triggers the release of inflammation-resolving cytokines such as IL-10 and TGF- β [2]. IL-10 is a central cytokine during resolution of inflammation and acts by repressing the pro-

inflammatory response from innate and adaptive immunity and thus prevents tissue damage caused by these cytokines. On the other hand, increased expression of IL-10 has been associated with chronic infectious state, since the inflammatory response is repressed [36]. Therefore, the lower production of IL-10 caused by oral treatment with linoleic acid in the presence of LPS after 24 h incubation may lead to a higher microbicidal activity of these cells. There are very few studies assessing the effect of fatty acids on IL-10 production and most of them used (n-3) fatty acids. Dietary fish oil decreases IL-10 release by murine peritoneal macrophages, when compared to a corn oil diet [37].

The synthesis of VEGF is also essential for the resolution of inflammation and tissue repair, since it stimulates the formation of new blood vessels and thus enables the supply of nutrients and oxygen to the tissue. VEGF is mainly secreted by macrophages and keratinocytes in response to hypoxia and acts on endothelial cells from local blood vessels. Therefore, its synthesis must be strictly controlled, otherwise it can trigger fibrosis and cancer [1, 38, 39]. This is the first study to analyze the effect of fatty acids on VEGF production by macrophages and it was observed that the oral administration of OLA or LNA decreased VEGF production after 24 h incubation.

Lipid mediators are mostly derived from arachidonic acid and also play a central role in the inflammatory response such that those that are synthesized during the beginning of inflammation are gradually switched to others with anti-inflammatory and inflammation-resolving properties [40]. In addition to its effect on the cardinal signs of acute inflammation, PGE₂ also acts as an anti-inflammatory mediator depending on the context, whereas LTB₄ stimulates the recruitment of neutrophils and lipoxins promote resolution of inflammation [40–42]. There was no effect of the *in vivo* treatment with OLA or LNA on eicosanoid synthesis. In agreement with our observations, feeding mice olive or safflower oils had no effect on eicosanoid production by resident macrophages when stimulated with LPS [23]. Likewise, a diet rich in LNA did not change PGE₂ and LTB₄ production by macrophages after infection with *Mycobacterium tuberculosis* [43]. 15(S)-HETE is one of the precursors of lipoxins and its synthesis is catalyzed by 15-lipoxygenase, present in various types of cells including macrophages [44]. Therefore, the effects of fatty acids on 15(S)-HETE production might indicate alterations on lipoxin synthesis. This is the first study to assess the effect of OLA or LNA on 15(S)-HETE production by macrophages. The lack of effect of these two fatty acids on eicosanoid production may mean that arachidonic acid levels in macrophages were not altered by these fatty acids. However, fatty acid composition of the cells was not assessed here, so this explanation cannot be confirmed.

In conclusion, OLA decreased the production of IL-1 β , IL-6 and CINC-2 $\alpha\beta$ by resident macrophages, indicating that this fatty acid may be therapeutically used to control inflammation. Linoleic acid decreased the production of IL-1 β , IL-6 and VEGF in the absence of LPS, although it accelerated IL-1 β release and decreased IL-10 synthesis when cells were stimulated with LPS. The mechanisms of action of the fatty acids in exerting these actions are unknown and were not investigated here. It could be speculated that part of their actions occurs through activation/inhibition of transcription factors, such as NF- κ B, AP-1 or PPARs, but further investigations are needed. The present study makes an important contribution to the elucidation of the effects of OLA or LNA on the production of several inflammatory mediators by macrophages and it is tempting to suggest that they might be used for treating pathological states in which macrophages play a central role, such as wound healing.

Abstract Membrane structural organization is an intrinsic property of a cell membrane. Any changes in lipid composition, and/or any stimuli that affect molecular packing induce structural re-organization. It membrane dynamics provide a means by which changes in structure organization can be determined, upon a change in the membrane internal or external environment. Here, we report on the effect of thermo-stress on membranes containing cholesterol liquid crystal (LC) compounds cholesterol benzoate (BENZO) and oxidized cholesterols. We have (1) revealed that lipid vesicles containing this artificial cholesterol derivative (BENZO) is thermo-responsive, and that this thermo-sensitivity is significantly similar to naturally oxy-cholesterols (2) elucidated the mechanism behind the membrane perturbation. Using Langmuir monolayer experiments, we have demonstrated that membrane perturbation was due to an increase in the molecular surface area, (3) discussed the similarities between cholesterol benzoate in the cholesterol LC state and in lipid bilayer membranes. Last, (4) drawing from previously reported findings, our new data on membrane dynamics, and the discussion above, we propose that artificial cholesterol derivatives such as BENZO, open new possibilities for controlled and tailored design using model membrane systems. Examples could include the development of

membrane technology and provide a trigger for progress in thermo-tropical liquid crystal engineering.

| OxyCHOL | Oxidized cholesterol(s) |

Introduction

Structural organization such as lipid packing, is an intrinsic property of cell membranes, and contributes to biophysical processes such as endo- and exocytosis, that are important for normal cellular function [1]. Cholesterol (CHOL) contributes about 30–40 % (mol%) to the total lipid composition of the membrane lipid bilayer [2]. Any changes in its molecular composition may induce membrane restructuring. In fact, it has been reported that oxidized cholesterol (OxyCHOL) renders membranes unstable more than non-oxidized cholesterol-containing systems [3, 4].

Scheme 1 Cholesterol derivatives. Cholesterol can be oxidized either non-enzymatically or enzymatically. 7-Ketocholesterol (7KC) and 7 β HC are produced by reactive oxygen species. 25-Hydroxycholesterol (25HC) is oxidized enzymatically [5, 16]. BENZO is an artificial cholesterol derivative [18]

In a recent study, we investigated the thermo-responsiveness of OxyCHOL in lipid vesicles [5]. We observed changes in membrane perturbation and we proposed a mechanism behind the change in stability. In this study, we have elucidated the mechanism we had proposed. Further, we have investigated the effect of an artificial cholesterol derivative, cholesterol benzoate (BENZO, Scheme 1), on membrane stability. Since BENZO can form a cholesterol liquid crystal (LC) state, when in the presence of other natural cholesterol derivatives such as Cholesterol oleyl carbonate (CHOL OC) and Cholesterol pelargonate (CHOL PA) (Scheme 2) [6, 7] we aimed to investigate its effect on membrane dynamics. In particular, our choice was motivated by the similarities in structure between DOPC lipid and CHOL PA, CHOL OC. We investigated how the dynamics may relate to those induced by physiologically relevant OxyCHOL and the possible implications.

Membrane structural re-organization and re-packing can be induced by various forms of stimuli such as oxidation, light, and temperature [5, 8–12]. Rafts are considered to be a form of order–disorder phase separation that develop due to the interaction between lipid molecules. Ordered domains are cholesterol rich domains [1, 12, 13], and CHOL is one of the most important components of biological membranes. Oxidation of lipids, lipid peroxidation is a biomarker of cellular oxidative stress [14]. It has long been recognized as contributing to oxidative damage resulting from inflammatory processes, chemical and

Scheme 2 Similarity of structure between cholesterol liquid crystal CHOL PA and CHOL OC and phospholipid DOPC. Some natural cholesterol derivatives have been known to form cholesterol liquid crystal state. These include, CHOL OC (b) and CHOL PA (c). The structure of DOPC (a) acyl chains is similar to structure of esters in CHOL PA and CHOL OC with sterol backbones

reperfusion injury, and chronic diseases such as atherosclerosis and cancer [15]. Recent studies have suggested that cholesterol is an important target of oxidative stress in

membrane components [8, 14, 15]. Auto-oxidation of cholesterol at the C7 position produces 7-ketocholesterol (7KC), and 7 β -hydroxycholesterol (7 β HC), the major oxidized cholesterol species in atherosclerotic plaques [6]. Enzymatically oxidized derivatives of cholesterol are generated mainly on the iso-octyl side chain makes some products such as 24- and 25-hydroxycholesterols (Scheme 1) for production of these OxyCHOL [16]. Some cholesterol derivatives have been known to generate a LC phase [6, 17]. These compounds are used in fluorescence films for membrane technologies, exploiting their liquid crystalline properties [18]. We imagined that properties of membranes containing liquid crystals might be affected by temperature. Heterogeneous membrane containing cholesterol glycol lipid derivatives were reported to be thermo-responsive compounds [19].

In a recent study, Akiyama and colleagues investigated the effect of cholesterol glycolipids, at various temperatures, on domain stability [19]. Another group reported that increased levels of OxyCHOL in brain areas undergoing neuroinflammation may enhance exocytosis and neurotransmitter release, thereby aggravating excitotoxicity [20]. However, there is lot yet to be understood about membrane dynamic processes. Cell-sized lipid vesicles have been used to study the effect of different types of stresses on membrane stability [5, 8, 9, 21–24]. The cell-sized vesicles allow real-time observation of dynamic morphological changes to be clearly visualized, without compromising the “controllable” analytical advantage [2]. They also mimic the physiological environment closely in terms of the spatio-temporal scale at which interactions take place, thus allowing understanding and clarification of mechanisms [22, 25, 26]. In this study, we used such vesicles.

We had reported that 7KC was one of major derivatives of cholesterol after oxidative stress [5]. It has been reported that this OxyCHOL is related to crystal formation on macrophages and even muscles [27]. The crystal domain has been investigated on model membranes and cultured cells [28, 29]. Further, phase transitions of cholesterol derivatives were observed to influence liquid order domain stabilities [30]. However, as far as we are aware, membrane vesicular dynamics of BENZO known to form the LC state have not been reported. Here, we studied the dynamics of vesicles containing BENZO upon a slight increase in temperature. Using the Langmuir monolayer experiment, we analyzed changes in the molecular area in response to applied pressure by measuring the Π – A curve. We discussed the common mechanism between the lipid vesicles containing BENZO and those with OxyCHOL.

Materials and Methods

Materials

1,2-Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and cholesterol (CHOL) were purchased from Avanti Polar Lipids (Alabaster, USA). Cholesterol benzoate (BENZO), 7 β -hydroxycholesterol (7 β HC), 7-ketocholesterol (7KC) and 25-hydroxycholesterol (25HC) were purchased from Sigma-Aldrich (USA). Chloroform was purchased from Kanto chemical (Japan). Methanol was from Nacalai Tesuque (Japan). Deionized water obtained from a Millipore Milli-Q purification system was used to prepare the reagents.

Preparation of Lipid Vesicles

Lipid vesicles were prepared by the natural swelling method from dry lipid films [5, 8]. Lipid mixtures (DOPC, CHOL, BENZO) dissolved in chloroform or chloroform/methanol (2:1, vol/vol) in a glass test tube. They were dried under a vacuum for 3 h to form thin lipid films. The films were then hydrated overnight with deionized water at room temperature (RT) to final concentrations of 0.2 mM lipids. During the course of this study, RT was approximately 22.0 ± 2.0 °C.

Microscopic Observation Conditions

The lipid vesicle solution (5 μ L) was placed in a silicon-well (0.2 mm) on a slide glass, and covered with a smaller cover slip. We observed changes in membrane morphology with a phase-contrast microscope (Olympus BX50, Japan), at RT. The silicon-well and the cover slip ensured that evaporation of the solution did not occur over the duration of the experiment. The images were recorded on a hard-disc drive at 30 frames/s.

Effect of Temperature on Membrane Fluctuation

We prepared two membrane systems composed of DOPC/CHOL (DOPC/CHOL (1:1 molar ratio), BENZO (DOPC/CHOL/BENZO 100:87.5:12.5). Lipid vesicles were prepared and observed as above. While on the stage, temperature was carefully changed using a thermal controller (Tokai-Hit MATS-5550RA-BT; Japan), from 22 to 40 °C. The samples were subjected to a temperature increase at a rate of 1.0 °C/min from 25 to 40 °C [5].

Effect of Temperature on Molecular Area of Monolayer Membranes

A Filgen LB-400 (Aichi, Japan) instrument (Kuhn type) was used to measure the π -A isotherms [32]. DOPC/CHOL (1:1) was dissolved in chloroform to a final concentration of 2 mM lipids and 5 μ L of this solution was added to 100 ml of Milli-Q pure water at each temperature. Temperatures were controlled by attaching the system to the instrument. Waiting for least 10 min, after each temperature was confirmed, the π -A isotherms were measured. Their π -A isotherms were measured using the same procedure and conditions as those of DOPC, DOPC/CHOL/BENZO (50:43.75:6.25), DOPC/CHOL/7KC (50:43.75:6.25), DOPC/CHOL/7 β HCH (50:43.75:6.25), DOPC/CHOL/25HC (50:43.75:6.25) and OXY is DOPC/CHOL/7 β HCH/7KC (50:43.75:3.75:2.5).

Results

Thermo-responsiveness of BENZO-containing Lipid Vesicles

First we prepared lipid vesicles containing BENZO at 6.25 % (molar ratio) of total lipids. We then investigated the thermo-responsiveness of the lipid vesicles containing BENZO. In this paper, we use the term thermo-responsiveness to describe the response by the lipid vesicles induced by the change in temperature [5]. Lipid vesicles were prepared using a natural swelling method [8] to a final lipid concentration of 0.2 mM. An unsaturated phospholipid 1,2-Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) constituted 50 % of the total. The other 50 % was

composed of cholesterol (CHOL) for DOPC/CHOL vesicles. For DOPC/CHOL lipid vesicles with BENZO or other cholesterol derivatives, the derivatives constituted 6.25 %, in line with our previous findings [5]. Scheme 1 shows the structures of the lipids, cholesterol and cholesterol derivatives used in this study. Figure 1 shows typical images of lipid vesicles containing DOPC/CHOL/BENZO and DOPC/CHOL upon increases in temperature. The bottom graphs show the degree of membrane fluctuation at 22 °C (black), 23 °C (gray) as a function of radius and its distribution. We plotted the value of radius of $r - \langle r \rangle$ in each θ ($\theta = \pm\pi/n$, $n = 1, 2, 3, \dots, 100$). The images and graphs clearly show that both lipid vesicles were spherical in

Fig. 2 Membrane fluctuation of lipid vesicles. Temperature was increased from RT to 25.0 °C, using a thermo-controller percentage of lipid vesicles, which started fluctuating at a given level of temperature increase, BENZO (black) and CHOL (gray) ($n = 30$)

Fig. 1 Membrane fluctuation of lipid vesicles. Temperature was increased from RT to 25.0 °C, using a thermo-controller. Images of a typical lipid vesicle captured using a phase-contrast microscope. The scale bar is 10 μ m. These graphs show membrane fluctuation at 22 °C (black), 23 °C (gray) as a function of radius and its distribution. Plotted the value of radius of $r - \langle r \rangle$ in each θ ($\theta = \pm\pi/n$, $n = 1, 2, 3, \dots, 100$) [5, 8, 21–23]. BENZO (a) and CHOL (b)

Table 1 The effect of temperature increase on membrane fluctuation. The values represent the increase in temperature (\uparrow temp.) required for 50 % of the lipid vesicles to start fluctuating. Some of data was reported previously [5]. We carried out >30 lipids vesicles per membrane type

| Membrane system | Increase in temperature (\uparrow temp) ($^{\circ}\text{C}$) |
|--|---|
| Cholesterol (CHOL) | 6.4 |
| 7 β -Hydroxycholesterol (7 β HC) | 2.5 |
| 7-Ketocholesterol (7KC) | 1.7 |
| 25-Hydroxycholesterol (25HC) | 1.7 |
| OXY (7 β HC + 7KC) | 0.5 |
| Cholesterol benzoate (BENZO) | 1.1 |

shape at 22 $^{\circ}\text{C}$. At 23 $^{\circ}\text{C}$, the DOPC/CHOL/BENZO vesicles started to fluctuate, in contrast to the DOPC/CHOL vesicle whose stability was not affected at this temperature.

We then studied membrane responses over a wider range of temperatures. Interestingly, even a small increase in temperature ($\Delta T \sim 2.0$ $^{\circ}\text{C}$) was enough to actuate membrane fluctuation in more than half of the lipid vesicles

containing BENZO. We widened our temperature window even further (between 9 and 29 $^{\circ}\text{C}$) in order to establish a response pattern. BENZO-containing membranes were more thermo-responsive than lipid vesicles without BENZO (Fig. 2). The degree of thermo-responsiveness for lipid vesicles containing the BENZO (which forms LC state at RT in mixture with other compounds [6, 7]), was comparable to that of vesicles containing auto- and enzymatically oxidized (that is, of direct physiological relevance) OxyCHOL [5] (Table 1).

Effect of Temperature on the Molecular Area of BENZO-Containing Lipid Membranes

Thermo-tropism of lipid vesicles containing BENZO although not new [18] is interesting when we consider that the vesicular stability was dramatically affected with a small increase in temperature, and the membrane perturbation was observed in real-time. We attempted to further our understanding by investigating the chemo-physical mechanism behind the changes in stability. Previously, we

Fig. 3 Thermal responsiveness of lipid monolayer membranes. DOPC, CHOL [DOPC/Chol (1:1)] and BENZO [DOPC/CHOL/BENZO (50:43.75:6.25)] are shown. Surface pressure (p)–area per molecule (A) at 30 mN/m, at each temperature from 9 to 29 $^{\circ}\text{C}$. **a** Shows the typically p – A curves of membranes at each temperatures 9, 13, 17, 21, 25 $^{\circ}\text{C}$ respectively. Increases in molecular area correspond to the increasing temperature. DOPC (gray) CHOL (white) and BENZO (black) of **b**

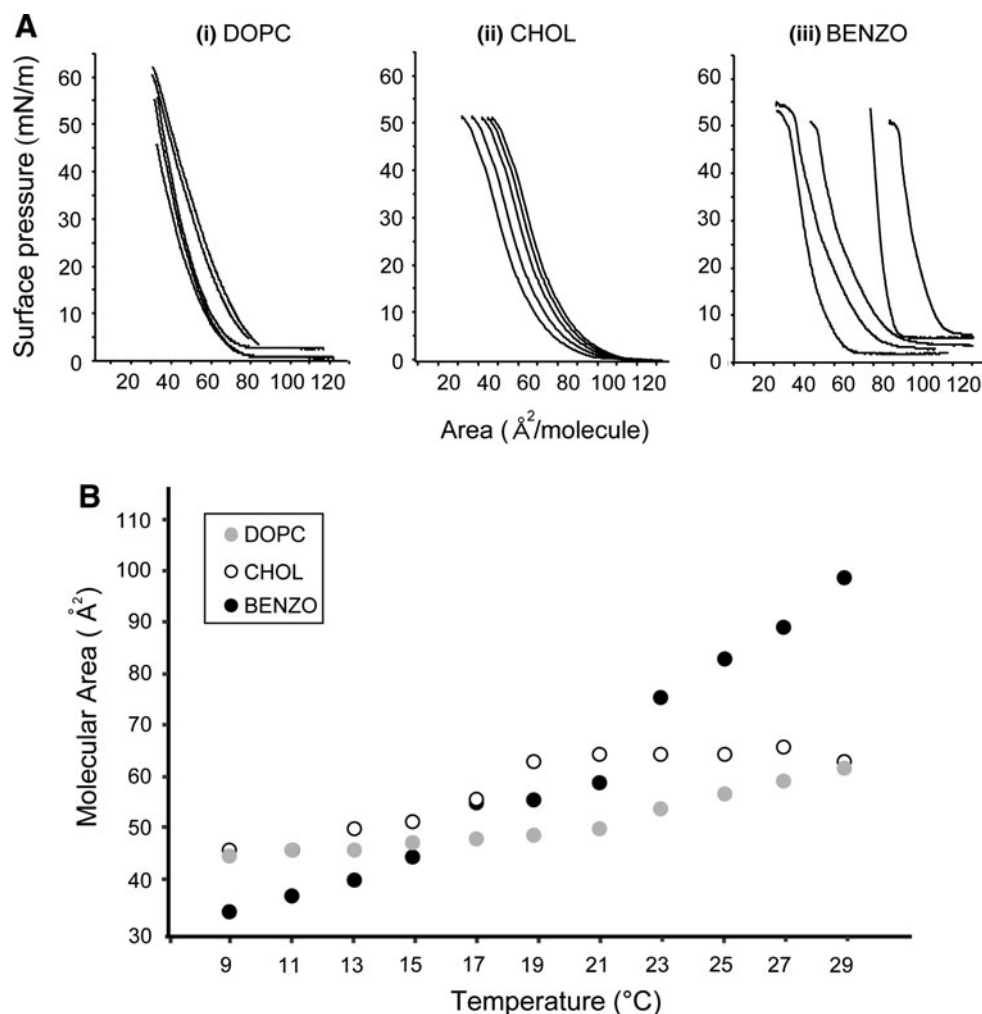

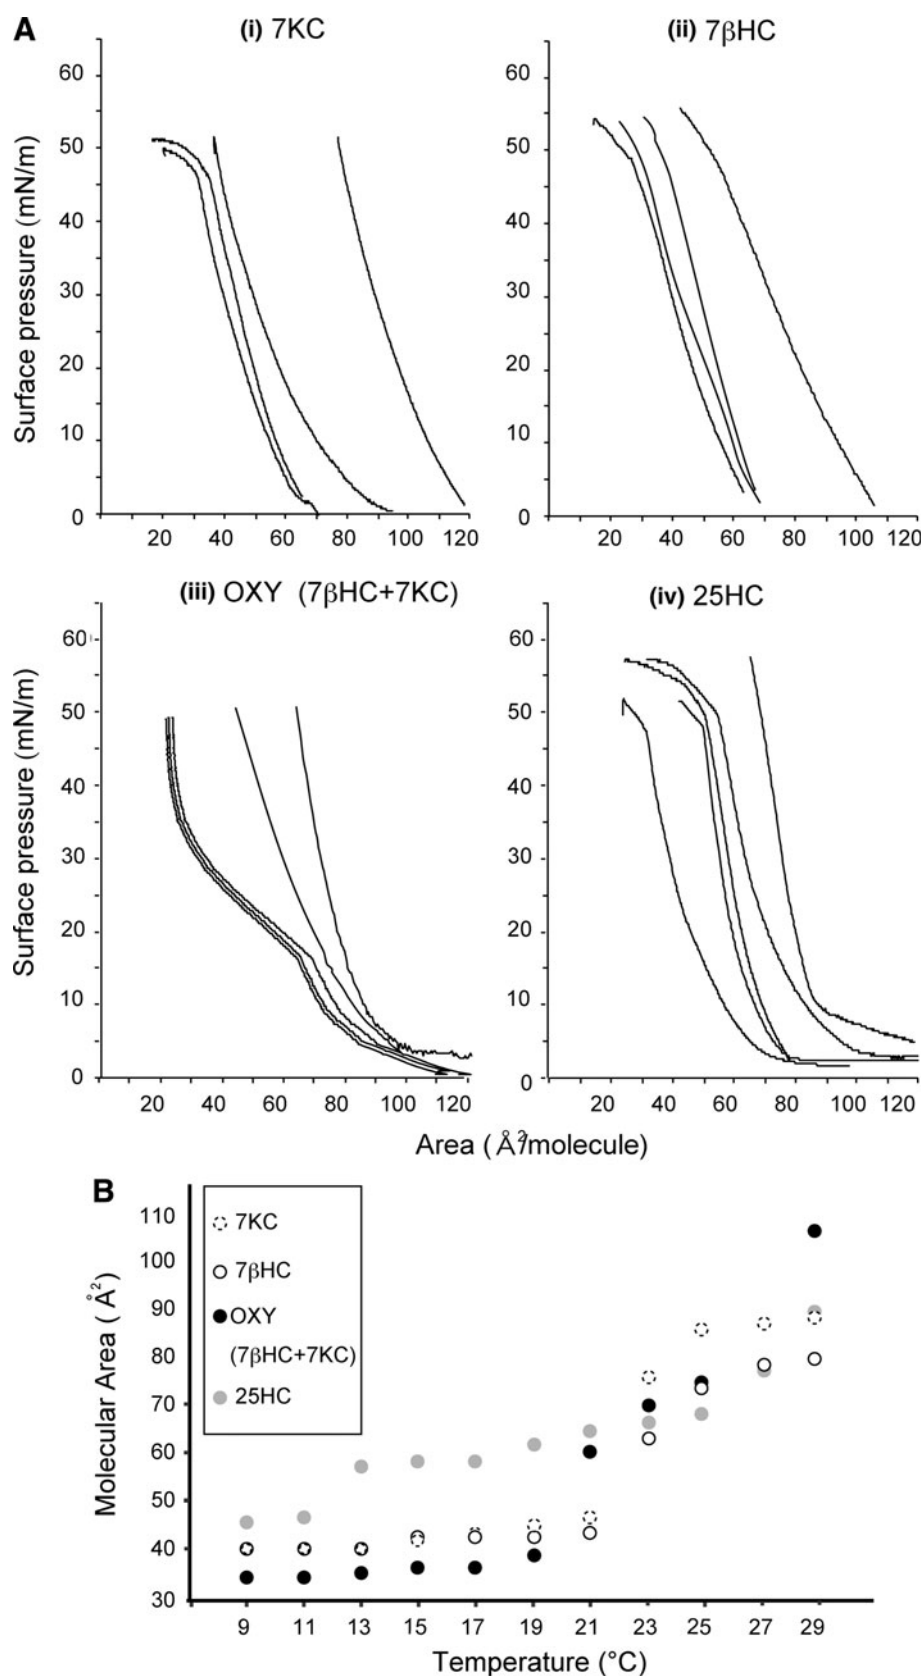

Fig. 4 Typical thermal responsiveness of lipid monolayer oxidized cholesterol-containing membranes, 7KC [DOPC/CHOL/7KC (50:43.75:6.25)], 7 β HC [DOPC/CHOL/7 β HC (50:43.75:6.25)] OXY [DOPC/CHOL/7 β HC/7KC (50:43.75:3.75:2.5)], 25HC [DOPC/CHOL/25HC (50:43.75:6.25)]. Surface pressure (p)–area per molecule (**b**) at 30 mN/m, at each temperature 9–29 °C. **a** Shows the typically P–A curves of a membrane at each temperatures 9, 13, 17, 21, 25 °C respectively ($n = 10$). However, data of 7KC and 7 β HC at 9 °C were nearly equal value, we have omitted data at 9 °C. As increasing shown **b** that are 7KC (*dashed-circles*), 7 β HC (*white-circles*), OXY (7 β HC + 7KC, *black-circles*), and 25HC (*gray-circles*)

had hypothesized that the membrane dynamics induced by changes in temperature, were a consequence of an increase in molecular area [5]. We, therefore, studied the effect of temperature on the molecular area of monolayer membranes using the Langmuir monolayer membrane method. We prepared membrane systems composed of singular (unitary), binary and ternary mixtures of lipids (DOPC, DOPC/CHOL and DOPC/CHOL/BENZO membrane systems). First, we used the DOPC only system as an instrumental control. The control values agreed closely with previous reports (Fig. 3a) [31]. Subsequently, we conducted the monolayer experiments using these membrane systems. Assuming that the bilayer membrane consists of monolayers, the lateral pressure in the lipid bilayer would normally be 30–40 mN/m [32].

BENZO-containing monolayer membranes exhibited a relatively bigger increase in molecular area upon increasing temperature. The response pattern was quasi-linear. In agreement with the vesicular fluctuation reported above, cholesterol-only membrane systems showed only a slight increase in molecular area (Fig. 3b).

Effect of Temperature on Molecular Area of OxyCHOL-Containing Lipid Membranes

Recently, we studied the thermo-responses of lipid vesicles containing OxyCHOL to changes in temperature, and had hypothesized that the membrane perturbation we had observed was due to the increase in temperature [5]. Similar to BENZO-containing lipid vesicles, we followed up on our previous study and investigated the cause, using the Langmuir monolayer experiment. Indeed, we confirmed that thermo-induced fluctuation was due to an increase in molecular surface area (Fig. 4). Further, we established that the thermo-response of these two membrane systems (BENZO- and OxyCHOL-containing) is strikingly similar. Previously, it had been reported that a 3 % increase in a membrane surface area is enough to induce liposome fluctuation [23]. BENZO-containing membranes had a ≥ 3 % molecular area increase at temperatures < 2.0 °C (between 21 and 23 °C). Taken together, the results are in good agreement with the onset of fluctuation upon an increase in temperature (Fig. 2).

Discussion

We can now discuss these similarities of the two membrane systems, and the possible implications. First, we consider the following: (1) BENZO is known to form a LC state, at RT, when in the presence of other natural cholesterol derivatives such as CHOL OC and CHOL PA (Scheme 2) [6, 7]; (2) the self-ordering of the phospholipid bilayer in

membranes is a lyotropic liquid crystalline behavior, that is, phospholipid bilayers form a LC state [33, 34]; (3) the experimental conditions which include a mixing ratio of DOPC/CHOL/Cholesterol derivatives are similar to those of CHOL PA/CHOL OC/BENZO [7]. We calculated the correlation coefficient ($r = 0.83$) between the two membrane systems based on the numbers of carbons, hydrogen, and cholesterol molecule; (4) the structure of DOPC acyl chains is similar to structure of esters in CHOL PA and CHOL OC with sterol backbones (Scheme 2). Despite the knowledge that a cholesterol (twisted nematic) LC state can not exist in a physiological membrane, the facts above strongly suggest that at a molecular level, molecular interactions between BENZO in the DOPC/CHOL membranes are similar to BENZO's association in CHOL PA/CHOL OC. In addition, given our findings that the dynamics of BENZO- and OxyCHOL-containing membrane systems have significantly similar temperature sensitivity, we can now consider the lyotropic nature of BENZO in model membrane systems, and its possible exploitation for tailored design in model membranes.

To summarize, we have (1) succeeded in producing cell-sized membrane containing cholesterol liquid crystal BENZO, (2) revealed that lipid vesicles containing this artificial cholesterol derivative is thermo-responsive, and that this thermo-sensitivity is significantly similar to natural OxyCHOL, (3) elucidated the mechanism behind the membrane fluctuations. Using Langmuir monolayer experiments we have demonstrated that membrane perturbation was due to an increase in molecular surface area, (4) discussed the similarities between BENZO in the cholesterol LC state and in lipid bilayer membranes. Last, (5) drawing from previously reported findings, our new data on membrane dynamics, and the discussion above, we propose that artificial cholesterol derivatives such as BENZO, open new possibilities for controlled and tailored design using model membrane systems.

Acknowledgments We gratefully acknowledge Ms. Ryoko Sugimoto for technical support. We are grateful to Dr. Masaomi Hatakeyama for providing technical assistance with the analysis of membrane fluctuation. Abstract Rumen metabolism (e.g., biohydrogenation) of dietary unsaturated fatty acids (FA) is one of the main reasons why ruminant fats tend to be highly saturated and contain many isomerized FA intermediates. The process by which long-chain (20- to 24-carbon FA) polyunsaturated FA (LC-PUFA) are metabolized by rumen bacteria is not as well understood as that of linoleic or linolenic acids. In order to better understand the fate of LC-PUFA in the rumen several concentrations of docosahexaenoic acid (DHA) were evaluated in in vitro batch incubations ranging from 100 to 1,500 µg per 6 mL of incubation volume using rumen fluid from sheep and incubated for 0, 1, 2, 3, and 6 h. From the results, it was shown that DHA was extensively metabolized at low (100 to 300 µg/6 mL incubation volume), but not at high level of inclusion (800 µg). At 300 µg of DHA most of the depleted DHA was recovered as LC-DHA metabolites within the first 6 h of incubation, and at the lowest levels (100 µg of incubation volume) further metabolism is apparent at 6 h. Using SP-2560 GC columns several LC-DHA metabolites were shown to elute after 24:0 and just past DHA, a region generally free of interfering FA. The present in

vitro study would appear to be a useful method to evaluate the production of DHA metabolites in combination with its depletion.

Introduction

Over the last decade, numerous attempts have been made to enrich beef and milk products with docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) [1, 2], because of the reported health benefits of these long-chain polyunsaturated fatty acids (LC-PUFA) [3]. The results of an extensive review have shown that the transfer efficiency of LC-PUFA into milk averaged about 4.1 % for DHA and 2.6 % for EPA [4]. A low transfer efficiency into meat lipids [5] is also consistent with the low levels of LC-PUFA leaving the rumen and entering the omasal canal in cows fed dietary fish oil supplements [6]. This raises the question of what is happening to LC-PUFA in the rumen to account for its disappearance. Dietary linoleic and linolenic acids are known to be extensively biohydrogenated [7], and a similar isomerization and reduction process to 22:0 have

been suggested recently for DHA [8]. A different process has also been proposed for the metabolism of LC-PUFA that involves the reduction and/or isomerization of double bonds closest to the carboxyl group [9]. To further investigate the metabolism of DHA in the rumen, a preliminary in vitro study was undertaken where several levels of unesterified DHA were incubated with total rumen fluid from sheep over a time period from 0 to 6 h (h) maximum.

Materials and Methods

Animals and Diet

Three dry ewes (2 Assaf and 1 Merino breed) averaging 60 ± 6.2 kg body weight were fitted with ruminal cannula and served as donors of rumen contents. Sheep were fed 1.1 kg dry matter per day of oats hay in one morning meal for over 2 weeks.

In Vitro Incubations

Between 100 and 200 mL of rumen content were collected pre-feeding from each ewe and transferred to the laboratory in pre-warmed thermo flasks. The rumen contents were strained through a double layer of muslin, pooled together (same volume from each ewe), and kept under CO₂ flushing.

Batch-cultures were performed using 15-mL Hungate tubes. The incubated substrate was composed of a proportional mixture of glucose, cellobiose, maltose, corn starch, and casein in order to avoid confounding effects of other fat or carbohydrate sources. Each tube contained 36 mg of the substrate mix (7.2 mg of each ingredient) and unesterified DHA (U-84-A from Nu-Chek Prep, Elysian, MN, USA) dissolved in ethanol (10 µg/µL).

In one trial, 10, 30, and 80 µL of the DHA solution were added to separate sets of tubes. These gave a final DHA content of 100, 300 or 800 µg per tube or 16.7, 50, or 133.3 µg/mL, respectively. The total incubation volume was of 6 mL, composed of 2 mL of rumen fluid plus 4 mL of phosphate-bicarbonate buffer. The buffer solution was prepared as described by Goering and Van Soest [10], with the exception that no trypticase was added. In order to have the same amount of ethanol in all tubes, 70 and 50 µL of ethanol were added to the tubes containing 16.7 and 50 µg of DHA/mL, respectively. As reported by Morgavi et al. [11], these low volumes of ethanol should not affect fermentation, and not considered toxic to the rumen micro-organisms. Each set of tubes (single tube per DHA level and incubation period) was incubated under anaerobic conditions for 0, 1, 2, 3, and 6 h in an incubator set at 39 °C, and tubes were individually agitated every hour.

After each incubation time, the reaction was stopped by placing the tubes in ice-water for 15 min and then storing them at -80 °C. An exception was made for tubes at 0 h in which the appropriate amount of DHA was added after the tubes containing all the other ingredients were placed into the ice-water in order to avoid any possible reaction. An additional tube with no DHA was also frozen at 0 h (control) to determine the natural content of DHA and other fatty acids (FA) in rumen fluid as determined by GC in the region from 24:0 to DHA.

Fatty Acid Analysis

Samples were freeze-dried and, in the same tube, the samples were transesterified using consecutive base and acid catalysts [12] as follows: first 1.5 mL of methanol was added to each tube that was subsequently sonicated for 10 min to rupture cells. After vortexing, the tubes were placed in the sonicator for another 5 min and then 0.4 mL of 0.25 N NaOCH₃ was added, vortexed and tubes were placed in a thermoblock at 50 °C for 30 min. After cooling, 1.5 mL of 10 % (v/v) H₂SO₄ in methanol was added, vortexed and heated at 80 °C for 15 min. After cooling, 1 mL of distilled H₂O was added and the methylated lipids were extracted with 2 mL of hexane. Tubes were then centrifuged at 2,000 rpm (~ 800 g) for 5 min (20 °C) to clarify the layers. The upper hexane layer was transferred to a clean test tube containing approximately 1 g of anhydrous sodium sulphate. The extraction step was repeated with another 2 mL of hexane. The combined hexane was evaporated under a stream N₂ at 37 °C, and the FA methyl esters (FAME) were reconstituted in hexane and analyzed by gas chromatography (GC) (Agilent Technologies 7890A GC System), using a 100 m SP-2560 column (Supelco, Bellefonte, PA, USA). At this point 10 µL of an internal standard (10 µg/µL of 13:0 methyl ester, N-13-M from Nu-Chek Prep, Elysian, MN, USA) was added. Samples were analyzed using the temperature program plateauing at 175 °C [13] and H₂ was used as carrier gas. GC reference standards #463 and #603, and the FAME of 21:0, 23:0 and 26:0 (Nu-Chek Prep Inc., Elysian, MN) were used to identify the FAME peaks. The purity of the DHA was tested after esterifying the free DHA using the aforementioned acid catalyst and analyzing the FAME by GC under the same conditions described above.

Results and Discussion

The partial GC chromatogram from 22:2n-6 to just past DHA for the sheep rumen fluid incubated with 300 µg DHA per tube from 0 to 6 h is shown in Fig. 1. This region was selected because LC-DHA metabolites would be

expected to elute here if the first steps of DHA metabolism involves the formation of one *trans* double bond, loss of 1 or 2 double bonds, or loss of 1 or 2 carbon atoms. Such LC-PUFA metabolites arising from DHA were recently reported to occur in the omasal canal of cows fed fish oil [9]. The GC region from 24:0 to just past DHA at time 0 h showed only minor peaks of 24:0, 15*c*-24:1 and 26:0 both with and without DHA; only the graph with DHA is shown (Fig. 1, 0 h). The DHA used in the incubation studies had only trace amounts of a few DHA isomers (Fig. 1, DHA). It is evident from the GC results in Fig. 1 that numerous peaks in the region from 57 to 70 min appeared during the 6 h incubation, and are suspected to be LC FAME metabolites formed from DHA (or LC-DHA metabolites).

Figure 2 shows DHA depletion (%) and LC-DHA metabolite formation (%) relative to DHA incubated over the 6 h period of incubation. For these calculations baseline DHA and other peak areas at 0 h (control) were subtracted from the rest of the chromatograms. The results show a decrease in DHA and an increase in total LC-DHA metabolites when DHA was added to the incubation tubes.

At the lowest DHA levels approximately 90 % of the incubated DHA was depleted after 6 h with extensive production of LC-DHA metabolites. Most of the depleted DHA was recovered as LC-DHA metabolites within the

first 3 h when 100 µg were incubated per tube. However, after 3 h the content of LC-DHA metabolites dropped which suggests further metabolism to DHA to metabolites which eluted before 24:0. In the present study, the drop was not observed when 300 µg was incubated. In a separate experiment 150 and 1,500 µg per incubation tube were added using the same protocol and conditions. The results using 150 µg were similar to 100 µg in the present study, but at 1,500 µg per incubation tube very little metabolism of DHA was evident even after 6 h (data not shown).

The results of this preliminary study indicate that the amount of DHA incubated with rumen fluid, as well as the incubation times are factors affecting DHA metabolism. A wide range of FA concentrations and lengths of incubation times have been reported in batch studies using total rumen fluid [8, 14–16]. High concentrations of free FA are known to be toxic to rumen microbes [17, 18]. Maia et al. [19] showed that several ruminal bacteria species exhibited growth inhibition at 50 µg/mL of PUFA in the media. This agrees with our study which shows that at the lowest levels of DHA inclusion (100 and 300 µg per tube), the DHA level decreased dramatically. However, higher levels of DHA showed moderate metabolism after 6 h of incubation.

The results of this in vitro study with rumen fluid imply that DHA metabolism is concentration dependent. At low

Fig. 1 Partial GC chromatograms from 22:2n-6 to past DHA selected from rumen incubation with 300 µg DHA per 6 mL over 0, 1, 2, 3, and 6 h. A reference GC standard (GLC 463) was included for comparison as well as the free DHA that was methylated

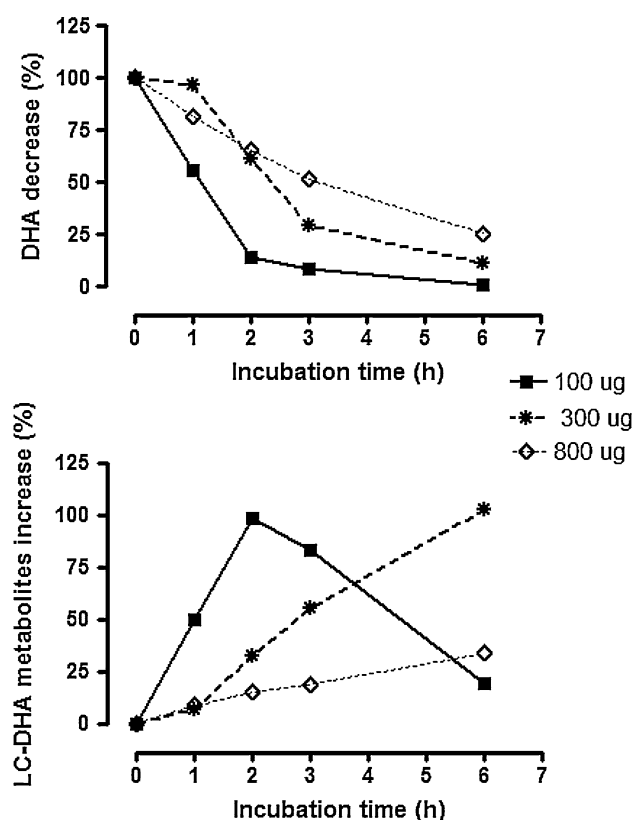

Fig. 2 Calculated DHA depletion (%) and long-chain (LC) DHA metabolite production (%) relative to DHA incubated for each level (100, 300 and 800 µg per tube) and incubation time (0, 1, 2, 3 and 6 h)

levels of DHA addition (≤ 300 µg per tube or 50 µg/mL) extensive metabolism occurred as evident by its depletion and formation of LC-DHA metabolites that elution in the GC region between 24:0 and DHA. There appears to be evidence of further metabolism of the LC-DHA metabolites after 3 h when 100 µg DHA per tube was incubated. It was recently suggested that DHA may be isomerized and reduced to 22:0 by similar pathways as observed for the 18-carbon polyunsaturated FA like linoleic and linolenic acids to 18:0 [8]. However, we did not observe an increase in 22:0 content (data not shown), in agreement with others [9], but that may be due to the much shorter incubation times used in the present study of 6 versus 48 h. Extensive metabolism of DHA at low levels of addition would help to explain the low transfer efficiency of DHA into ruminant tissues, but it is not clear whether a higher supplementation of DHA would result in increased accretion of DHA into meat and milk. Addition of low levels of DHA to the diet of ruminants has recently been used to increase the level of rumenic and vaccenic acids rather than increasing the level of DHA per se [20, 21], because this addition increases the production of *trans*-18:1 isomers in rumen fluid [22]. The 6-h incubation period coupled with analysis of the

LC-DHA metabolites by GC would provide a useful method to evaluate the fate of DHA in ruminants.

Novel Heneicosadienoic and Tricosadienoic Acid Isomers in Ovaries of Marine Archaeogastropods

Hideki Kawashima · Masao Ohnishi

Received: 23 April 2012 / Accepted: 1 June 2012 / Published online: 26 June 2012

Abstract To investigate unusual odd-chain fatty acids (FA) from gonads of archaeogastropods, limpets *Cellana grata* and *Cellana toreuma*, a subfraction enriched in FA with two double bonds extracted from the gonads was obtained by using argentation thin-layer chromatography. The resulting fraction was analyzed by using capillary gas chromatography–mass spectrometry of its methyl esters, 3-pyridylcarbinol esters and pyrrolidide derivatives. Six novel all-*cis* diene isomers were identified as 7,18-heneicosadienoic (21:2Δ7,18), 8,14-tricosadienoic (23:2Δ8,14), 9,15-tricosadienoic (23:2Δ9,15), 7,18-tricosadienoic (23:2Δ7,18), 9,18-tricosadienoic (23:2Δ9,18), and 9,20-tricosadienoic (23:2Δ9,20) acids. In the present study, the differences in the proportion of tricosadienoic acid isomers between the ovary lipids of *C. grata* and *C. toreuma* were recognized.

Introduction

Non-methylene-interrupted (NMI) fatty acids (FA) with even-chain lengths, especially straight-chain NMI dienoic FA with 20 and 22 carbon atoms, are commonly present in small amounts in mollusks, echinoderms, and sponges, but their biological role and function are not fully understood [1]. In contrast to straight even-chain NMI dienoic FA, to date, studies of the occurrence of straight odd-chain NMI dienoic FA with 21 and 23 carbon atoms from living organisms are limited [2–7], because of their usually very minor amounts less than straight even-chain NMI FA. Of the nine different straight odd-chain NMI FA identified from living organisms, both 21:2Δ7,13 and 21:2Δ7,15 as minor components have been reported from the edible bivalve *Megangulus zygonensis* and gonads of limpets *Cellana grata* and *Collisella dorsuosa* [2, 4]. In addition to these isomers, both 21:2Δ5,9 and 21:2Δ7,16 are also found in very small amounts in the limpet gonads of *C. grata* [3], but 21:2Δ5,9 is present in some marine sponges [1]. Four NMI heneicosadienoic acids 21:2Δ5,13, 21:2Δ5,15, 21:2Δ5,16, and 21:2Δ5,20 are distributed in a cold-seep clam of the genus *Calypotgena* [5, 6]. To date, only a straight-chain NMI tricosadienoic acid from marine invertebrates has been identified as 23:2Δ5,9, which is widely distributed in minor amounts (<0.3 % of total FA) in sponges, sea anemones, nudibranchs and limpet gonads [1, 3]. However, other straight-chain NMI

heneicosadienoic and tricosadienoic acids from living organisms may not have been reported.

In our study of the occurrence and structure of NMI FA from the gonads of limpets of marine archaeogastropods, we showed that the structural diversity of NMI FA with 20, 21, 22, and 24 carbon atoms in the ovaries of *C. grata* comprises a wide range of unusual positional isomers [2, 3, 7]. In the present study, to further clarify the detailed odd-chain NMI dienoic FA at relatively low concentrations in the two archaeogastropod limpets *C. grata* and *C. toreuma*, we investigated the structures of these FA by using a combination of argentation thin-layer chromatography (TLC) and capillary gas chromatography–mass spectrometry (GC–MS). Here, we describe the identification of novel heneicosadienoic and tricosadienoic acids detected at trace levels exclusively (<0.05 % of total FA) in ovary lipids and differences in the proportion of tricosadienoic acids between triacylglycerols (TAG) and polar lipids in both limpet species. Furthermore, a possible biosynthetic pathway for novel odd-chain NMI FA is discussed. These findings may provide insight into whether some NMI FA participate in the ecological and physiological roles of marine mollusks.

Experimental Procedures

Reagents

Methyl heneicosanoate (H3265) and tricosanoic acid (T6543) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). All solvents used here were of top grade.

Sampling of Limpets and Extraction of Lipids

Limpets *C. grata* (mean shell length, 37.9 ± 4.6 mm, $n = 95$) and *C. toreuma* (mean shell length, 34.4 ± 2.6 mm, $n = 120$) from Kirikiri, Iwate Prefecture, north-eastern Japan, were sampled between August and October, from 2008 to 2010. After sampling, all limpets were immediately dissected in the laboratory. The sex was determined by microscopic examination, and the gonads were distinguished as male or female. Pooled male or female gonads (15–20 g wet weight) were suspended in 50 mL chloroform–methanol (2:1, v/v) and were homogenized for 1 min at 16,000 rpm by using an IKA Ultra-Turrax T25 basic (IKA Japan KK, Nara, Japan). Lipids were extracted by the method of Bligh and Dyer [8].

Fractionation of TAG and Polar Lipids

Triacylglycerols and polar lipids from lipid extracts were separated on silica gel 60 TLC plates (Merck KGaA.,

Darmstadt, Germany) using *n*-hexane/diethyl ether/acetic acid (80:30:1, v/v/v) as the developing solvent. The lipids were detected by brief exposure to iodine vapor and were marked. TAG and polar lipids were recovered from the scraped silica bands by elution with chloroform/methanol (1:1, v/v).

Preparation of FA Methyl Esters, 3-Pyridylcarbinol Esters and Pyrrolidide Derivatives

Fatty acid methyl esters and 3-pyridylcarbinol esters were prepared as described previously [2]. Pyrrolidide derivatives were prepared according to the method of Andersson and Holman [9].

Fractionation of FA Methyl Esters by Argentation TLC

Fatty acid methyl esters prepared from TAG and polar lipids were separated by argentation TLC (5 % AgNO₃–silica gel 60) into six fractions having zero to five double bonds, using *n*-hexane/diethyl ether (80:20, v/v) as the mobile phase with double development, according to the degree of unsaturation. FA methyl ester bands were located by spraying with a 0.2 % (w/v) solution of 2',7'-dichloro-fluorescein in ethanol and were viewed under UV light at 366 nm. The migration solvent used to confirm geometrical diene isomers was a mixture of *n*-hexane/diethyl ether (90:10, v/v). FA methyl esters were recovered from the scraped silica bands by elution with *n*-hexane [4], and were analyzed by using GLC and GC–MS.

Catalytic Hydrogenation of Unsaturated FA Methyl Esters

An aliquot of fractionated unsaturated FA methyl esters was hydrogenated by stirring at 20 °C for 2 h in *n*-hexane (3 mL) with 18 mg of palladium black (Wako Pure Chemical Industries, Ltd., Osaka, Japan) [4]. The resulting mixture was analyzed by using GLC and GC–MS.

GLC and GC–MS Analyses

FA methyl esters were analyzed by using GLC with a Shimadzu GC-1700 gas chromatograph (Shimadzu, Kyoto, Japan) equipped with an FID and an Omegawax-320 column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA, USA). The column temperature was isothermal at 220 °C. The injector and detector temperatures were 260 °C, and the carrier gas was helium, at a flow rate of 1.0 mL/min.

GC–MS analyses were done by using a Shimadzu GCMS-QP2010 coupled with a Shimadzu 2010 GC equipped with either the same column as described for

GLC analysis on an SAC-5 column (30 m × 0.25 mm i.d., 0.25 µm film thickness; Supelco, Bellefonte, PA, USA). The carrier gas was helium, at a flow rate of either 0.6 or 1.5 mL/min, and pressure programming was used in constant flow mode. The oven temperature was programmed as follows: isothermal at 200 °C for 2 min, increased from 200 to 270 °C (3 °C/min) and maintained at 270 °C for 50 min. Electron impact (EI) mass spectra of FA methyl esters, 3-pyridylcarbinol esters and pyrrolidide derivatives were recorded at an ionization energy of 70 eV and an ion source at 200 °C. Split injection was done with a split ratio of either 1:10 or 1:25. All samples of gonad lipids were analyzed in duplicate.

Results and Discussion

In this study, eight different dienoic FA with 21 carbon atoms, seven of which (21:2Δ5,9, 21:2Δ7,13, 21:2Δ7,15, 21:2Δ7,16, 21:2Δ11,14, 21:2Δ12,15, and 21:2Δ13,16) had been reported by us previously [2, 3], and seven different dienoic FA with 23 carbon atoms, including 23:2Δ5,9 which had been described previously [1, 3], were detected in scanty amounts in gonads of the limpet *C. grata*. Tables 1 and 2 list six novel odd-chain dienoic acids, which were classified as a group of NMI FA, identified by using capillary EI GC–MS of their pyrrolidide derivatives and 3-pyridylcarbinol esters.

The mass spectrum (MS) of the novel methyl ester 21:2Δ7,18 showed a molecular ion at m/z 336 and a fragment ion at m/z 305 due to a loss of OCH_3 , suggesting a heneicosadienoic acid. After complete hydrogenation of the FA, a newly formed peak displayed a molecular ion at m/z 340, assigning a saturated FA with 21 carbon atoms. The retention time and MS of the peak agreed with those of authentic heneicosanoic acid. The structure of 21:2Δ7,18 was

confirmed by the MS of its pyrrolidide derivative, which had a molecular ion at m/z 375, and the double bond position was assigned by gaps of 12 amu between m/z 168 and 180 and between m/z 320 and 332 (Fig. 1a). Similarly, MS data for the 3-pyridylcarbinol ester confirmed the structure of 21:2Δ7,18 at m/z 413 $[\text{M}]^+$, corresponding to a heneicosadienoic acid, and at m/z 206, 232, 358, and 384, indicating the presence of double bonds at Δ7 and Δ18 (Fig. 1b).

The MS of each individual methyl ester of tricosadienoic acid isomers showed a molecular ion at m/z 364 and a characteristic ion at m/z 333 due to a loss of OCH_3 , suggesting a tricosadienoic acid. After complete hydrogenation of the diene isomers, a newly formed peak gave a molecular ion at m/z 368, indicating a saturated FA with 23 carbon atoms. The retention time and MS of the methyl ester of the peak were identical to those of authentic tricosanoic acid. From these results, seven isomers detected in this study were straight-chain dienoic FA isomers with 23 carbon atoms. The MS of all pyrrolidide derivatives of the isomers yielded a molecular ion at m/z 403 that corresponded to a tricosadienoic acid (Table 1). However, of the seven tricosadienoic acids, including 23:2Δ5,9 as a known FA, detected in this study, only one was not identified because of its very small amounts. The MS given in Fig. 2a resembles that of 18:2Δ8,12 as illustrated in the lipid library [10] and that of 18:2Δ8,13 from the sponge *Leuconia johnstoni* [11]. The MS of the pyrrolidide derivative of 23:2Δ8,14 gave gaps of 12 amu between m/z 182 and 194 and between m/z 264 and 276, indicating double bond positions at Δ8 and Δ14. The MS of the pyrrolidide derivative of 23:2Δ9,15 had gaps of 12 amu between m/z 196 and 208 and between m/z 278 and 290, indicating double bond positions at Δ9 and Δ15. This MS of the diagnostic fragment ions was the same for that of 18:2Δ9,15 [12]. In the MS of the pyrrolidide derivative of 23:2Δ7,18, the fragment ions for double bond positions

Fragment ions given in boldface correspond to diagnostic ones

Fig. 1 EI–MS of the pyrrolidide derivative (a) and 3-pyridylcarbinol ester (b) of 7,18-heneicosadienoic acid (21:2 Δ 7,18)

were identical to those of the pyrrolidide derivative 21:2 Δ 7,18 as described above. As shown in Fig. 3a, the MS of the pyrrolidide derivative of 23:2 Δ 9,18 showed gaps of 12 amu between m/z 196 and 208 and between m/z 320 and 332, indicating double bond positions at Δ 9 and Δ 18. Finally, in the MS of the pyrrolidide derivative of 23:2 Δ 9,20, which is a homologue of 21:2 Δ 7,18, as compared to the fragment ions of double bonds for 23:2 Δ 9,15 and 23:2 Δ 9,18, an ion for the double bond at Δ 9 was the same, but a gap of 12 amu for the double bond position at Δ 20 was between m/z 348 and 360. In addition, double bond positions in five novel tricosadienoic acids from limpet gonads were also determined by using capillary GC–MS of their 3-pyridylcarbinol esters. In the mass spectra of the 3-pyridylcarbinol esters of all tricosadienoic acid isomers, their double bond locations were identified by searching for a gap of 26 amu from the fragmentation ions.

Of five mass spectra of the 3-pyridylcarbinol esters of tricosadienoic FA, the spectra of 23:2 Δ 8,14 and 23:2 Δ 9,18, as unusual major FA in limpet gonads (Table 3), are shown in Figs. 2b and 3b, respectively. The MS of the 3-pyridylcarbinol ester of 23:2 Δ 8,14 had diagnostic peaks at m/z 441 [M]⁺ and 220, 246, 302, and 328 for double bond positions at Δ 8 and Δ 14. The MS of the 3-pyridylcarbinol ester of 23:2 Δ 9,18 had a molecular ion at m/z 441, and the double bonds were identified individually by ions that differed by 26 amu from m/z 234 to 260 and 358 to 384. Furthermore, the mass spectra of the 3-pyridylcarbinol esters of 23:2 Δ 7,18, 23:2 Δ 9,18 and 23:2 Δ 9,20 were compared with those of 24:2 Δ 7,17 and 26:2 Δ 9,19 as shown in the lipid library [13]. The mass data clearly show that each individual double bond position in the 3-pyridylcarbinol esters of these isomers was identical to that in the pyrrolidide derivatives.

Fig. 2 EI-MS of the pyrrolidide derivative (a) and 3-pyridylcarbinol ester (b) of 8,14-tricosadienoic acid (23:2 Δ 8,14)

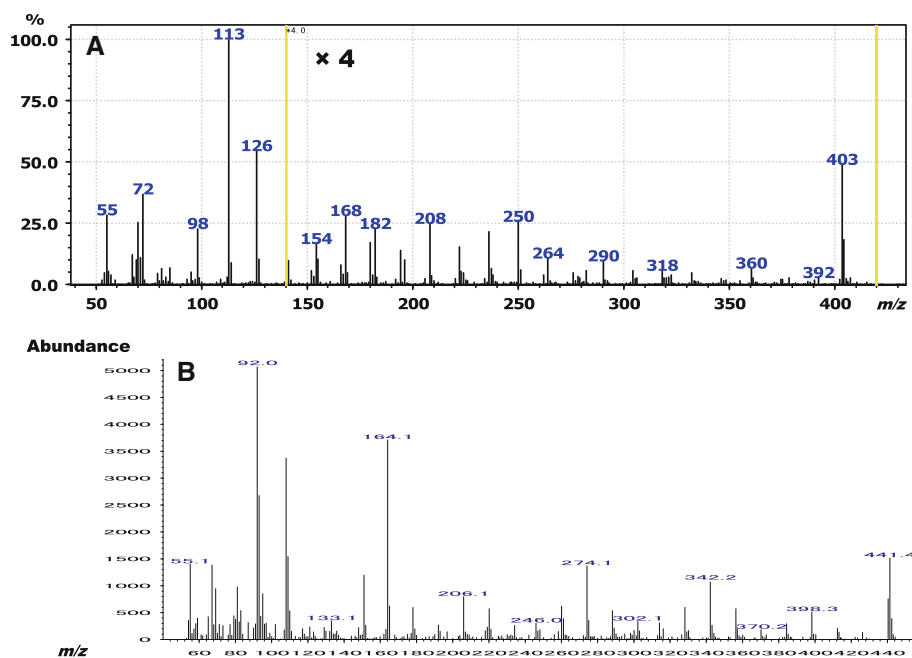

Fig. 3 EI-MS of the pyrrolidide derivative (a) and 3-pyridylcarbinol ester (b) of 9,18-tricosadienoic acid (23:2 Δ 9,18)

In this study, six novel dienoic FA co-eluted with 22:2 Δ 7,13 and 22:2 Δ 7,15 with *cis*-configurations shown by argentation TLC, indicating that their double bonds would have the *cis*-configuration. To the best of our knowledge, these FA were identified from nature for the first time. The most interesting series of the FA was a family of these NMI tricosadienoic acids with first double bonds at either Δ 7, Δ 8, or Δ 9, but 23:2 Δ 5,9, the only NMI tricosadienoic acid isomer in marine invertebrates, had been reported previously [1, 7].

To further clarify the distribution of unusual tricosadienoic acids in TAG and polar lipids (mainly phosphatidylcholine

and phosphatidylethanolamine) of gonads of limpet species, FA of *C. grata* and *C. toreuma* were analyzed. However, tricosadienoic acids from both TAG and polar lipids of all testes were not detected in this study (data not shown). In contrast, clear differences were found in the proportion of tricosadienoic acid composition between the TAG and polar lipids in the two limpet species. The predominant isomer in TAG was 23:2 Δ 9,18 and 23:2 Δ 8,14 for *C. grata* and *C. toreuma*, respectively, but the proportion of 23:2 Δ 9,15 in both *Cellana* species was almost the same (Table 3). Similarly, differences in proportion of

Table 3 Distribution of tricosadienoic acid isomers (%) in ovaries of *C. grata* and *C. toreuma*

| Fatty acid | Triacylglycerols | | Polar lipids | |
|------------|------------------|-------------------|-----------------|-------------------|
| | <i>C. grata</i> | <i>C. toreuma</i> | <i>C. grata</i> | <i>C. toreuma</i> |
| 23:2Δ5,9 | 5.1 | – | – | 50.1 |
| 23:2Δ8,14 | 16.8 | 54.2 | 51.0 | 32.4 |
| 23:2Δ9,15 | 20.0 | 20.9 | 49.0 | 17.5 |
| 23:2Δ7,18 | 11.7 | 6.4 | – | – |
| 23:2Δ9,18 | 33.5 | 18.5 | – | – |
| 23:2Δ9,20 | 10.3 | – | – | – |
| 23:2Δx,y | 2.6 | – | – | – |

The proportion of each isomer was calculated from the total isomers

tricosadienoic acid composition of polar lipids were also recognized, and the abundant isomer was 23:2Δ8,14 and 23:2Δ5,9 for *C. grata* and *C. toreuma*, respectively. The structural variety of odd-chain NMI FA was also recognized in this study, but why a number of unusual NMI FA found only in the ovaries of limpets, which are one of the most primitive gastropod families, is still unknown.

From our results, biosynthetic pathways for the novel tricosadienoic acids belonging to a group of NMI FA were also discussed. The pathway of odd-chain NMI dienoic FA is thought to be basically similar to that of even-chain NMI dienoic FA (Fig. 4). Thus, among tricosadienoic acids, 23:2Δ9,15, 23:2Δ9,18 and 23:2Δ9,20 might be derived from initial precursors 19:1Δ11, 19:1Δ14 and 19:1Δ16, respectively, by Δ5 unsaturation and two successive chain elongation reactions. Similarly, 23:2Δ7,18 might be synthesized from 19:1Δ14, the same initial precursor for 23:2Δ9,18, by chain elongation and sequential Δ5 unsaturation reactions and finally by chain elongation reaction. In contrast, only 23:2Δ8,14 may be formed from 24:2Δ9,15, which is present in limpet gonads [2], by an α-oxidation reaction. But proof or corroboration of this hypothesis requires additional studies.

More interestingly, a 1:2 mixture of all-*cis* dienoic FA, 23:2Δ5,9 and 24:2Δ5,9, isolated from the Turkish sponge *Agelas oroides* inhibits the activity of an enoyl-acyl carrier protein reductase in *Plasmodium falciparum*, which causes

**Fig. 4** Possible biosynthetic pathways for novel tricosadienoic FA. Asterisk not found in organisms

malaria in humans, and in *Escherichia coli* [14]. Furthermore, 23:2Δ14,17 with all *cis*-configuration from the extract of the root of *Angelica dahurica* inhibits a novel proto-oncogenic protein, Shp2, and colony formation of HepG2 cells, and strongly induce poly (ADP-ribose) polymerase cleavage [15]. In our previous study, we showed that a series of rare NMI FA with 24 carbon atoms (24:2Δ5,9, 24:2Δ9,15, 24:2Δ9,17, 24:3Δ5,9,15, 24:3Δ5,9,17, 24:3Δ9,15,18, 24:4Δ5,9,15,18, and 24:5Δ5,9,15,18,21) is especially rich in the ovaries of *C. grata* [8]. Therefore, limpet gonads may be possible marine resources of unique unsaturated FA, but in minor amounts. Because some NMI FA contain further unusual double bond positions in their chemical structures, they could be potential substances for key bioactive compounds, as well as some biomarkers in the marine food web, in future research.

Acknowledgments We are grateful to the two anonymous referees for their helpful comments on the manuscript. This study was supported by the Cooperative Program (No. 118, 2012) of the Atmosphere and Ocean Research Institute, The University of Tokyo.

Abstract Red blood cell (RBC) fatty acid (FA) patterns have been shown to predict risk for cardiovascular and other chronic diseases. As part of a project analyzing RBC samples from the Women's Health Initiative Memory Study (WHIMS) we observed implausibly low levels of highly unsaturated fatty acids (HUFA) suggestive of degradation. This was hypothesized to be due to short term storage (<1 month) at -20°C during sample aliquoting. The purpose of this study was to measure the extent of degradation that occurs under these conditions, and then to use regression calibration equations with multiple

imputations to correct the biases. Samples from the Women's Health Initiative that had always been stored at -80°C were obtained and subjected to similar conditions as the WHIMS samples. General linear mixed models were used to develop bias-corrected calibration equations for each fatty acid. Sample degradation occurred at -20°C with the average HUFA loss of 3.5 to 5.9 % per week depending on aliquot size (250 and 80 μL , respectively). Using the ratio of HUFA to saturated fatty acids (HUFA/SAT) as a marker of degradation, this bias-correction method raised the HUFA/SAT from 0.70 to 0.81, which was similar to that (0.78) seen in another large study with optimal processing. In summary, RBC samples should always be stored at -80°C . The FA compositions of the degraded RBC samples from WHIMS were rehabilitated by application of regression calibration equations and multiple imputations, and these imputed datasets should be used in all future WHIMS studies.

Background

There is an increasing interest in defining the relations between fatty acid patterns and risk for chronic disease. Fatty acids have long been known to have both positive and negative effects on metabolism and physiology. Higher intakes (and thus blood levels) of saturated and *trans* fatty acids exacerbate dyslipidemia and inflammatory processes and increase risk for cardiovascular disease (CVD). The polyunsaturated fatty acids (PUFA) of both the n-3 and n-6 classes reduce risk for CVD [1, 2], and inverse relations between the n-3 levels with prevalent [3] and incident [4] dementia have been reported. Erythrocytes (red blood cells, RBC) have become the sample of choice for assessing fatty acid status because they are readily available, represent the composition of other membranes [5], have low biological variability [6] and reflect relatively long term exposure to fatty acids [7]. Other sample types that have been used to assess n-3 fatty acid status include whole blood, whole plasma, plasma lipid classes (phospholipids, cholesteryl esters, triacylglycerol), platelets, leukocytes and buccal cells.

The Women's Health Initiative Memory Study (WHIMS) was an ancillary study of the Women's Health Initiative (WHI), which was a randomized trial to test the effects of hormone therapy on cognitive outcomes [8]. As part of a project using gas chromatography (GC) to analyze frozen RBC samples collected by the WHI among women who had enrolled in WHIMS, we noticed marked variability in the highly unsaturated fatty acids (HUFA, those fatty acids with 20 or more carbons and three or more double bonds) with a proportion of samples having very low to non-existent HUFA levels (Fig. 1). While low n-3 fatty acid levels (i.e., 20:5n-3 and 22:6n-3) could reflect a low fish intake, very low levels of the most prominent HUFA in RBC membranes, 20:4n-6, cannot be thus explained. Membrane levels of 20:4n-6 are known to be tightly metabolically regulated and largely independent of intake of 18:2n-6, the primary n-6 fatty acid in the diet [9]. This apparent loss of HUFA was most likely due to oxidative degradation since they contain 3–6 methylene-interrupted double bonds.

We hypothesized that a period of storage at -20°C (instead of -80°C), which occurred during the sample aliquoting phase prior to shipment to the research laboratory, may have been responsible for the loss of HUFA. Others have described storage of RBC at this temperature as being a potential problem [10–12]. We also considered the aliquot size as a possible factor since it appeared that the original 80 μL aliquots of RBC were more likely to be affected than the later received 250 μL aliquots. The purpose of this study was to characterize the effects of storage at -20°C on all RBC FA levels for both aliquot sizes used, with a view towards developing regression

calibration equations that could be used to correct the biased measures in the WHIMS data set. Additional experiments using antioxidant preservatives were conducted to document that oxidation was the probable cause of the loss of HUFA in these samples.

Experimental Methods

Subjects

The study design, eligibility criteria, and recruitment procedures of the WHI hormone therapy clinical trial have been described elsewhere [13]. Briefly, in 1992 WHI began enrolling postmenopausal women aged 50–79 at forty clinical centers nationwide to study cardiovascular disease, cancer, and osteoporotic fractures. It included three clinical trials, i.e., dietary modification (low-fat), calcium and vitamin D, and hormone therapy. WHIMS began enrollment in 1996 for women aged 65–80 at 39 of the clinical centers to test the hypothesis that hormone therapy reduces the incidence of dementia and cognitive decline [8]. The National Institutes of Health and the institutional review boards for all participating institutions approved the WHI and WHIMS protocols and consent forms, and all participants provided written informed consent.

Sample Collection and Processing

The following is a summary of the steps used in the collection, shipment, storage, and aliquoting of RBC samples in the WHI:

1. Fasting blood samples were drawn from consenting participants at WHI field centers and processed for plasma, buffy coat, and RBC within 1 h of collection. A single 1.8 mL aliquot (primary vial) of unwashed packed RBC was prepared for each participant.
2. Aliquots were placed in a -70°C freezer within 2 h of collection.
3. Frozen samples were packed on dry ice and shipped on a weekly basis to the central biorepository Fisher, in Rockville, MD.
4. Samples were placed into -80°C freezers at the central repository and stored for up to 16 years.
5. Samples for analysis were pulled from the biorepository and shipped to the sample processing lab (SPL; Seattle, WA) on dry ice.
6. Samples were removed from the shipping box and placed into a -20°C freezer until they were ready for processing (6–16 days).
7. Samples were removed from the -20°C freezer and thawed on ice. An 80- μL aliquot of RBC was

A

B

Fig. 1 Representative chromatograms illustrating the difference between (a) “normal” and (b) “degraded” samples

transferred to a secondary vial (2 mL) and the rest of the primary vial was dispensed in 250- μ L aliquots into 2-mL vials for re-deposit at the biorepository.

8. The 80- and 250- μ L aliquots were again stored at -20°C until shipped to the research laboratory and biorepository, respectively, on dry ice (4–15 days).

9. Upon receipt at the research laboratory and biorepository, the samples were placed in a -80°C freezer.

-80 to -20°C (Pre-Thaw) Experiment

To study the effect of RBC processing step 5 (i.e., shifting the frozen samples from -80 to -20°C), 25 pairs of 1.8 mL fresh RBC samples were collected from subjects undergoing routine clinical testing and frozen for 1 day at -80°C . Then one set of 25 samples was shifted to -20°C , while the other set remained at -80°C . After 14 days all samples were analyzed for fatty acid composition.

Degradation Experiment

In order to determine the combined effects of storage temperature and aliquot size on the apparent loss of HUFA (processing steps 6–7), we obtained 100 RBC samples from women who had consented and had been screened for participation in WHI, but who were ultimately not enrolled. Hence, they had been stored at -80°C just as long as the WHIMS samples. To make the samples even more representative of the WHIMS cohort, they were cross-stratified by subject's race, age, geographic region, and then randomly selected. These 1.8-mL RBC aliquots were shipped directly to the research lab on dry ice. Upon receipt, the samples were placed in a -80°C freezer until the experiment began. At that time, samples were thawed and one aliquot was taken for immediate FA analysis. The rest of the sample was divided into six aliquots: three (80 μL) and

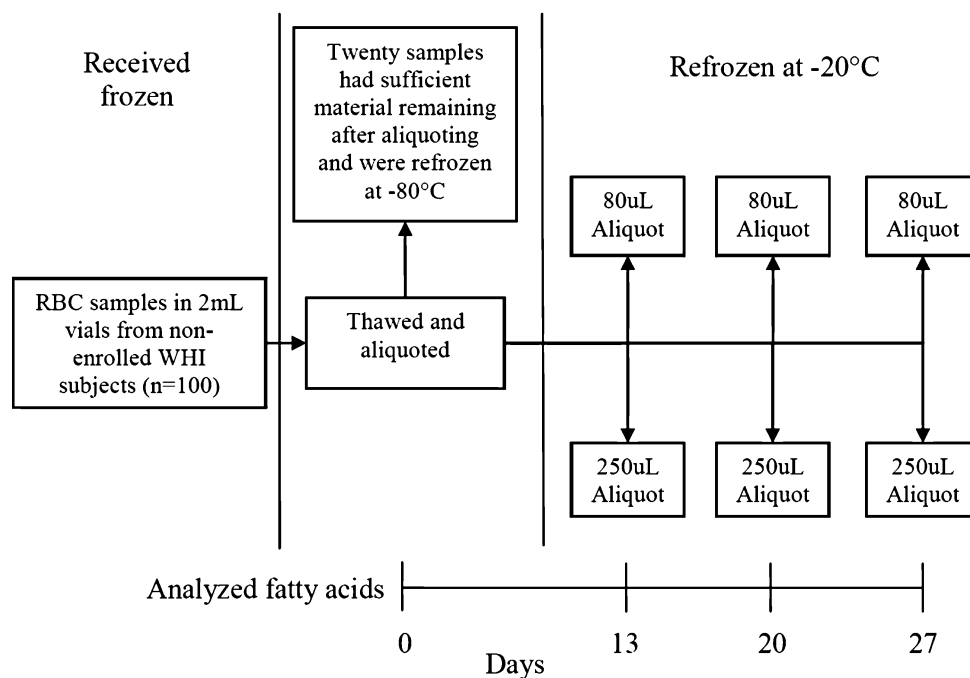

three (250 μL). (The 80- μL aliquot size was used since this was the size originally requested by the investigators, and the analysis required only 25 μL of RBC. The 250- μL aliquot size was used because, once degradation was suspected during the original analysis, we retrieved backup aliquots from the biorepository for repeat testing, and these were 250- μL aliquot sizes. These had also been stored for a time at -20°C like the 80- μL aliquots (see WHI sample processing described in above).

Hence, the final WHIMS RBC FA dataset included 80- and 250- μL aliquots, all of which had been subjected to some storage at -20°C .) The six aliquots were all placed at -20°C , and the 20 samples with RBC left over were immediately re-frozen at -80°C . After 13 days of -20°C storage, one 80- μL and one 250- μL sample were removed and analyzed for FA composition. Other aliquot pairs were removed and analyzed on days 20 and 27. The 20 samples refrozen at -80°C were reanalyzed after 12 weeks of storage (Fig. 2).

Antioxidant Experiment

We conducted an experiment to determine whether inclusion of an antioxidant (BHT) would prevent the RBC HUFA degradation. A 500-mg/L solution of BHT was prepared in methanol and added to the RBC sample (at 4 μL BHT/100 μL RBC) as described by Otto et al. [11]. We obtained five fresh RBC samples and treated each as follows: freeze at -80°C for 1 day, thaw on day 2, analyze for baseline FA composition, and prepare three, 80- μL aliquots. Each sample had one aliquot stored at -80°C

Fig. 2 Degradation (i.e., post-thaw) and -80°C storage experimental design

(control) and the other two at -20°C , with or without BHT. After 20 days of storage, the vials were removed and analyzed for FA composition.

RBC Fatty Acid Analysis

Red blood cells fatty acid composition was analyzed using GC with flame ionization detection using a modification of the direct methylation method of Arajuo et al. [14]. Unwashed, packed RBC (25 μL) were transferred to a screw-cap glass vial. Methanol containing 14 % boron trifluoride (Sigma-Aldrich, St. Louis, MO) and hexane (EMD Chemicals, USA) were added sequentially, 250 μL

summed and referred to as 18:1 *trans*. Fatty acid composition was expressed as a weight percent of total identified fatty acids. The coefficient of variation for the major HUFA (18:2n-6, 20:4n-6, 22:5n-3, 22:4n-6, 22:6n-3, and 20:5n-3) was <6.5 %.

Statistical Methods

The degradation experiment involving storage temperature and aliquot size was conducted to mimic the conditions of the WHIMS RBC samples. As a marker of sample integrity we used the ratio of HUFA to saturated fatty acids (HUFA/SAT).

$$\frac{\text{HUFA}}{\text{SAT}} = \frac{20:3\text{n}6 + 20:4\text{n}6 + 22:4\text{n}6 + 20:5\text{n}3 + 22:5\text{n}3 + 22:5\text{n}6 + 22:6\text{n}3}{14:0 + 16:0 + 18:0 + 20:0 + 22:0 + 24:0}$$

of each. The vial was briefly vortexed and then placed in an aluminum bead hot bath at 100°C for 10 min. After cooling, 250 μL of HPLC grade water was added, the tubes were recapped, vortexed and centrifuged for 3 min at 3,000 rpm to separate layers. A 50- μL aliquot of the hexane (upper) layer was transferred to a GC vial. GC was carried out using a G2010 Gas Chromatograph (Shimadzu Corporation, Columbia, MD) equipped with a SP2560, 100-m fused silica capillary column (0.25 mm internal diameter, 0.2 μm film thickness; Supelco, Bellefonte, PA). Run conditions were: carrier gas, hydrogen; linear velocity, 22.0 cm/s; injector temperature, 230°C ; oven program, initial temperature of 140°C hold for 5 min, ramp temperature at a rate of $4^{\circ}\text{C}/\text{min}$ to 240°C and hold for 15 min (total run time 45 min); detector temperature, 240°C . Fatty acids were identified by comparison with a standard mixture of fatty acids characteristic of RBC (GLC 782, NuCheck Prep, Elysian, MN) which was also used to determine individual fatty acid response factors. The following 24 fatty acids (by class) were identified: saturated (14:0, 16:0, 18:0, 20:0, 22:0 24:0); *cis* monounsaturated (16:1, 18:1, 20:1, 24:1); *cis* n-6 polyunsaturated (18:2, 18:3, 20:2, 20:3, 20:4, 22:4, 22:5); and *cis* n-3 polyunsaturated [18:3, 20:5, 22:5, 22:6]. The omega-3 index is defined as the sum of 20:5n-3 and 22:6n-3. The chromatographic conditions used in this study were sufficient to isolate the 16:1 *trans* isomers and the 18:2 Δ 9t-12c, 9t-12t, and 9c-12t isomers (which were summed and expressed as 18:2 *trans*). However, each individual 18:1 *trans* molecular species (i.e., 18:1 Δ 6 to Δ 13) could not be individually identified but appeared as two blended peaks that eluted just before oleic acid. The areas of these two peaks were

General linear mixed models (GLMM) were used to model the degradation mean response over time by aliquot size for the individual fatty acids and the HUFA/SAT ratio. The models included a random intercept to incorporate the sample clustering among the repeated aliquots. The statistical parameters were estimated using restricted maximum likelihood with the ‘sandwich’ variance estimator; these standard errors are robust to misspecification of the covariance structure [15]. The mean response was modeled allowing a differential slope by aliquot sizes. Fatty acids with mean abundances <1 % were transformed using natural logarithm to improve normality and homoscedasticity of the residuals. General linear mixed models were also used to analyze the HUFA/SAT ratio for the pre-thaw, -80°C storage, and antioxidant experiments.

The negative of the slope estimates from the degradation experiment were used to form calibration equations, to restore the WHIMS samples using lognormal or normal linear regression, corresponding to whether the fatty acid was log transformed or not. Since these equations are estimated rather than known, it is important to include the imprecision due to this estimation in the bias-corrected data. Values were imputed by making stochastic draws from the bias-corrected sampling distributions as described by Rubin [16] for data missing at random. The algorithm for the multiple imputation method is shown in Fig. 3. This was repeated for the entire sample ten times, which has been shown by Rubin to have high relative efficiency compared to an infinite number of imputations even with a large fraction of missing information. Analyses were performed using SAS[®] software (version 9.2; SAS Institute Inc., Cary, NC).

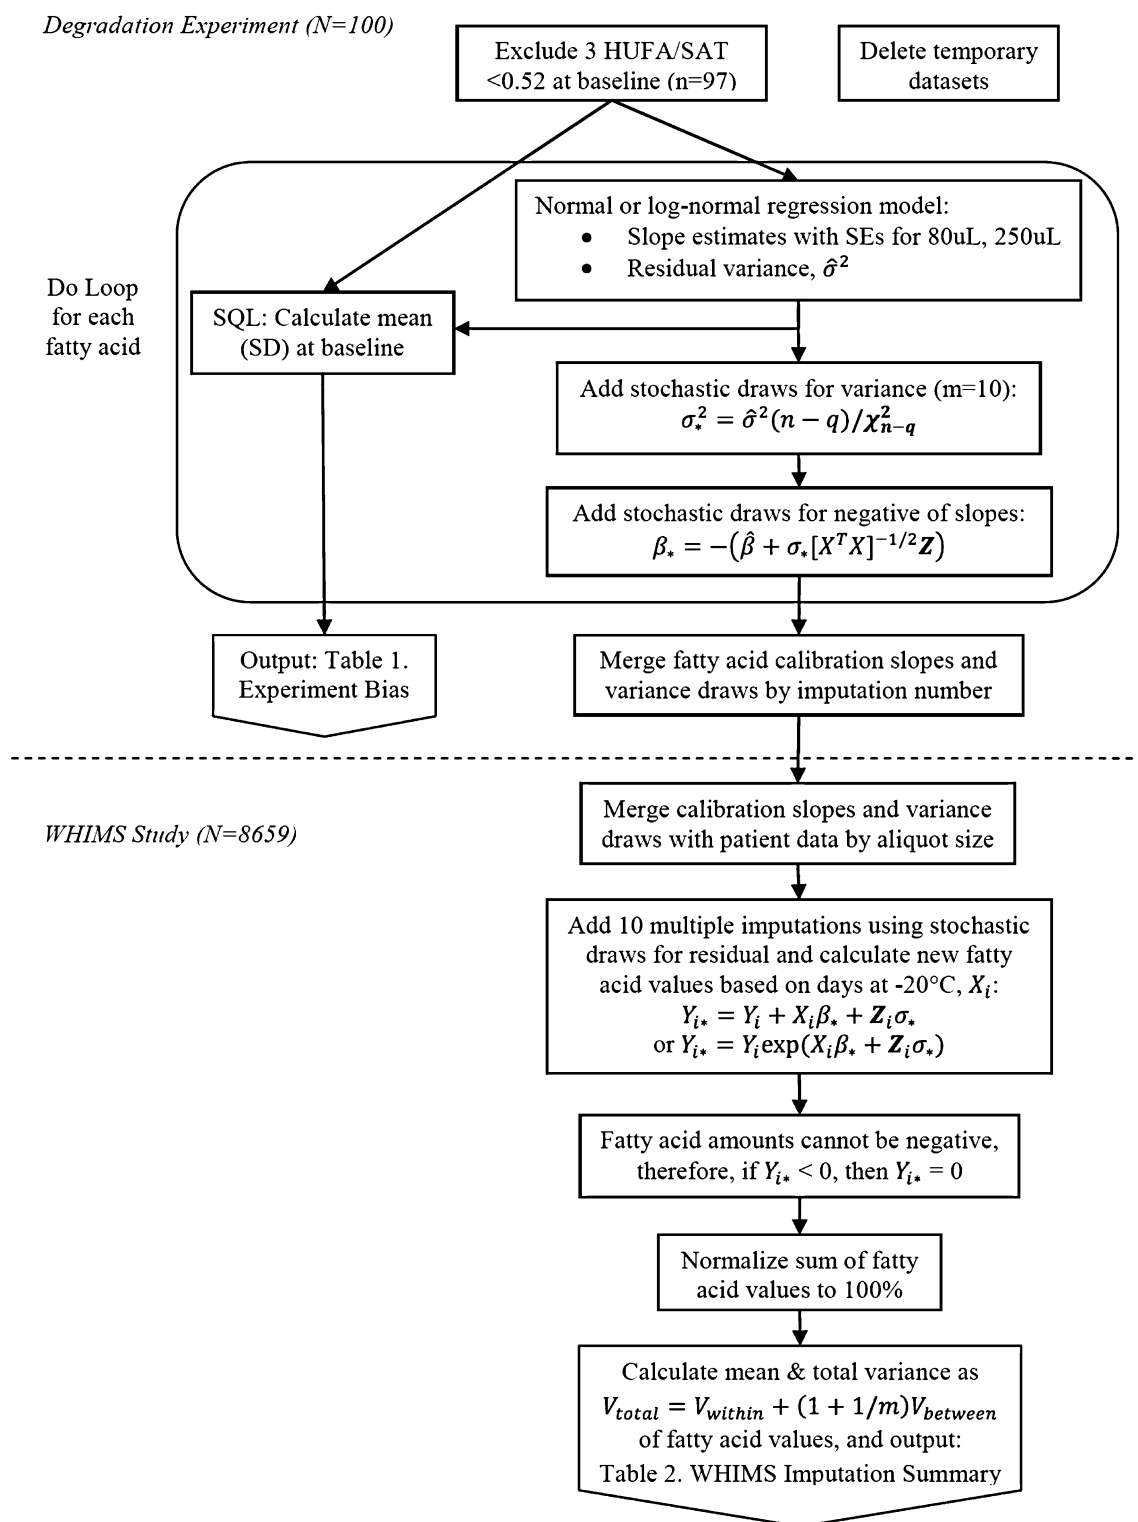

Fig. 3 Statistical methods algorithm for multiple imputations using explicit linear mixed models

Results

A minimum threshold for RBC FA analytical quality was established in a large cohort study (Framingham Heart

Study, $n = 3,197$, unpublished data) where RBC samples were frozen at -80°C on the day of collection and kept at that temperature until the day of analysis about 2 years later. The HUFA/SAT ratio in this dataset was 0.7767 ± 0.0564 .

Fig. 4 Individual response profiles of HUFA/SAT ratio (which is comprised of 13 fatty acids). **a, b** The 80 and 250 μL results were from the degradation experiment at -20°C . Linear regression is shown for weeks 0–2 (solid, bold) and weeks 2–4 (dashed, bold). **c** The 1,800 μL aliquot was from the pre-thaw experiment at -20°C

(see “Experimental Methods”). Over the first 2 weeks the 250- μL post-thaw and 1,800- μL pre-thaw slopes were similar ($p = 0.34$); however, the 80- μL post-thaw may degrade at a faster rate than the 1,800- μL pre-thaw ($p = 0.06$). **d** The last panel shows there was no degradation in samples stored at -80°C for 12 weeks ($p = 0.27$)

In order to establish a minimum HUFA/SAT ratio for use in detecting degraded samples, we employed the process capability index (C_p) [17]. Process capability index is a quality control metric commonly used in manufacturing, and is defined as $C_p = (\text{mean} - \text{lower limit})/3\text{SD}$. Setting the C_p to 1.5, which is recommended for critical parameters of stable processes (like GC analysis of fatty acids), and solving for the ‘lower limit’ returns a HUFA/SAT ratio of 0.52 ($0.7767 - 4.5 \times (0.0564) = 0.52$). Therefore, if the HUFA/SAT ratio is less than 0.52 the sample is deemed to be degraded. Note: this threshold was derived based on the particular RBC fatty acid analysis method given above, and may not be accurate for fatty acid data generated by other analytical methods.

The effects of storage at -20°C on HUFA/SAT ratios are shown in Fig. 4a, b for the 100 WHI RBC samples in 80- and 250- μL aliquot sizes, respectively. There were three samples with HUFA/SAT < 0.52 at baseline, and thus these were excluded from the regression analysis. There were a total of 94 samples with paired data for 80- and 250- μL aliquots at days 0 and 13, three samples did not have 250- μL aliquots due to insufficient material. Out of

these samples, 34 (36 %) of the 80- μL aliquots degraded between days 0 and 13, and 16 (17 %) of the 250- μL aliquots that did the same. Importantly 20 of the degraded 80- μL aliquots had matching 250- μL aliquots that did not degrade, while there were only two samples which degraded in the 250- μL but not the 80- μL aliquot (McNemar’s test $p < 0.0001$). In summary, although a substantial number of samples degraded at -20°C , the 80- μL aliquots were more likely to degrade than the larger 250- μL aliquots.

Some loss of HUFA occurred even in the 1,800- μL aliquot, simply by shifting the frozen vials from -80 to -20°C without thawing to room temperature (Fig. 4c). When comparing the 250 μL (post-thaw processing steps 6–7) to the 1,800 μL (pre-thaw processing step 5) from different experiments at -20°C , the changes were similar in the HUFA/SAT ratios over the first 2 weeks (Fig. 4b, c). The weekly slopes (SE) for the 250 and 1,800 μL were -0.0387 (0.0091) and -0.0566 (0.0090), respectively, $p = 0.34$. However, the 80- μL post-thaw slope (SE) was -0.0919 (0.0092), which may degrade at a faster rate than the 1,800- μL pre-thaw over the first 2 weeks ($p = 0.06$).

Table 1 Bias (% mean change per week) of RBC fatty Acids (by weight%) in -20°C storage degradation experiment, $N = 97$

| | Baseline | | % Bias | |

Negative values are shown in parentheses

Twenty samples from the degradation experiment had sufficient material remaining after making the six aliquots to test their stability when stored at -80°C for 12 weeks. As expected there was no degradation (Fig. 4d) and the mean HUFA/SAT ratio was unchanged ($p = 0.27$). These results, and those from the pre-thaw experiment, indicate that a freeze/thaw cycle did not alter the fatty acid profiles; but the storage temperature did.

Storage of RBC samples at -20°C caused a loss of all HUFA, and the relative proportion of saturated and monounsaturated fatty acids increased (since the total amount of fatty acids is constrained to 100 %) (Table 1). Although the rise in the non-HUFA was presumed to be due to the constraint of reporting FA abundances as a percent of total, it was possible that the rise in their abundance was due to the potential co-elution of some HUFA degradation products with the SATs. This possibility was, however, discounted by analysis of degraded samples by GC-mass spectroscopy which confirmed that no other molecular species were present in the major saturated and monounsaturated fatty acid peaks (data not shown).

The average weekly decreases in HUFA content were -3.5 and -5.9 % for the 250- and 80- μL aliquots, respectively. The two most abundant saturated fatty acids 16:0

**Fig. 5** Triplicate 80- μL aliquots were stored at -80°C (control), -20°C , and -20°C with butylated hydroxytoluene (BHT), an antioxidant, for five RBC samples over 20 days (overall $p = 0.003$). Mean with 95 % confidence intervals are shown**Fig. 6** Distribution of days WHIMS RBC samples were exposed to -20°C storage before and after thawing, by shipping lot identification number ($N = 8,659$)

and 18:0 accounted for about 40 % of the total fatty acids, and demonstrated the inverse effect of the loss of HUFA as noted above. They increased (as a percentage of total) by an average of 1.8 and 3.9 % per week in the 250- and 80- μ L aliquots, respectively.

In the 20-day, 80- μ L antioxidant experiment there was a significant difference among the groups, i.e., -80 (control), -20 , and -20 °C with BHT, $p = 0.003$ (Fig. 5). The HUFA/SAT ratio decreased from 0.68 to 0.43 between the -80 and -20 °C samples (Dunnett adjustment $p = 0.008$), but HUFA/SAT ratios were similar between the -80 and -20 °C + BHT samples ($p = 0.17$). The antioxidant experiment demonstrated that the loss of HUFA in the RBC samples during storage at -20 °C was very likely due to oxidation.

All WHIMS RBC samples ($N = 8,659$) were exposed to some period of -20 °C storage before and after thawing (processing steps 5–7 listed above; Fig. 6). The results from the pre-thaw experiment demonstrated that the 1,800- and 250- μ L aliquot sizes degraded similarly over time at -20 °C. Since the degradation experiment included actual WHI RBC samples representative of the WHIMS samples, the slopes for the individual fatty acids from the 250 μ L were used for the pre-thaw exposure duration in the regression calibration. However, the regression calibration slopes for the post-thaw exposure duration corresponded with their aliquot size, 80 or 250 μ L. Multiple imputations ($m = 10$) of the regression calibration equations were applied to all WHIMS RBC samples. While these techniques are well suited to correct bias, the cost is increased

Table 2 Descriptive statistics for WHIMS RBC fatty acids raw data and imputed values ($N = 8,659$, $m = 10$ imputations)

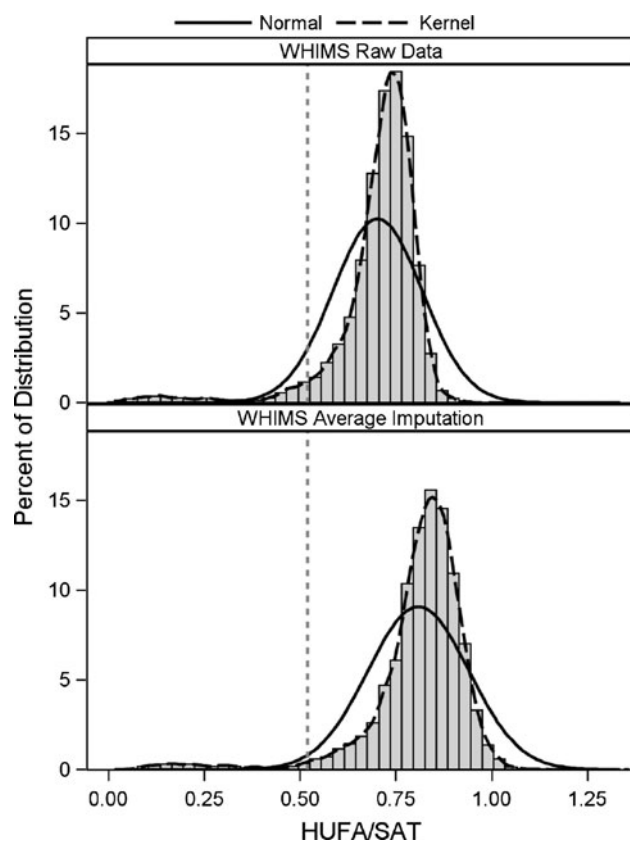

Fig. 7 Histograms including normal and kernel distributions. **a** WHIMS HUFA/SAT original measurements ($N = 8,659$); which included 466 (5.4 %) below the quality threshold HUFA/SAT = 0.52. **b** WHIMS HUFA/SAT averages from ten imputations; 272 (3.1 %) were below the quality threshold

total variability in the imputed data. Since originally the fatty acid measurements summed to 100 %, this constraint was likewise imposed on each imputation. The raw means and standard deviations (SD) are shown in Table 2 by weight% and mol% along with the bias-corrected means and SDs. The distribution of the HUFA/SAT ratio for the entire WHIMS cohort is shown before and after multiple imputations; the mean has been shifted to the right with added variability (Fig. 7). Even after implementing these techniques some samples remained degraded with average imputation HUFA/SAT <0.52 ($n = 272$; 3.1 %).

Discussion

As creators of the fatty acid database for WHIMS, the authors have a responsibility to release a final dataset that can be used in future analyses by other investigators employing standard statistical methods. When significant sample degradation was finally detected and confirmed, we conducted the experiments described here in order to correct the degradation bias with a view towards generating as

accurate a data set as possible. In these experiments, we used well-preserved WHI samples (always kept at -80°C) and exposed them to similar conditions as the WHIMS samples experienced. The explicit regression calibration equations based on this experiment were used for bias correction.

There was marked variation among the WHI experimental samples with respect to their susceptibility to degradation, and the reason why one sample degraded and another did not is unclear. Three of the 100 test samples were degraded before receipt in the laboratory, although they were stored at -80°C in the repository there may have been different handling protocols among the multiple field collection centers. By day 13 of storage at -20°C , 37 and 17 % of samples were degraded in the 80- and 250- μL aliquots, respectively. In an attempt to determine why these samples degraded and the others did not, we examined the fatty acid profiles using multivariate analyses techniques, i.e., principal components analysis and stepwise discriminant analysis (data not shown). We found nothing in the fatty acid profiles that distinguished degraded from preserved samples. One limitation of this study is that we did not measure endogenous levels of RBC antioxidant defense systems (vitamins C and E, glutathione, superoxide dismutase, etc.) [18]. Variations in these factors might have explained the differential susceptibility to degradation that we observed. We also determined in a subset of 3,600 samples that the duration of storage at -80°C (within the range of 10–16 years) did not influence the likelihood of a sample being degraded (data not shown). Presumably the reason why the 80- μL aliquots were more susceptible than the 250- μL aliquots in the 2-mL storage vials relates to greater proportion of surface area to sample volume exposed to air in the smaller aliquot size. The ability of antioxidants to prevent degradation also supports the hypothesis that the loss of PUFA was due to oxidation. As noted earlier, others have reported that storage at -20°C is insufficient for protection of RBC FA composition [10–12], but that this applied even to samples moved from -80 to -20°C without an intervening thaw had not been appreciated.

Since single imputation methods using the best predicted value underestimate variability, multiple imputations were implemented by replacing each fatty acid value with ten instances from a distribution of possible values. Over the last two decades the multiple imputation technique has been used in health care research, and was developed for releasing health care public use datasets [19]. The Third National Health and Nutritional Examination Survey (NHANES III) was completed in 1994 and was the first implementation of multiple imputation ($m = 5$) for that survey, replacing the previous method of reweighting for unit non-response and leaving item non-response values

as missing [20]. Multiple imputation methods have also been implemented in the National Health Interview Survey [19], and are recommended for clinical research [20].

Application of these techniques to the original WHIMS dataset increased the HUFA levels and correspondingly decreased the saturated and monounsaturated FA levels. We believe that these remediated values best represent the fatty acid composition of RBC in WHIMS. The imputed fatty acid datasets generated as described herein should be used in all future studies examining the relationships between RBC fatty acids and any outcomes from WHIMS. A description of how these imputed data sets may be utilized in WHIMS analyses is included in “Appendix 1”. In conclusion, RBC samples destined for fatty acid analysis should always be stored at -80°C .

Appendix 1

This section is specifically for biostatisticians who will be working with the WHIMS RBC fatty acid data sets to test a variety of hypotheses in this study. All samples were exposed to -20°C , which is why all samples were subjected to the calibration equations and multiple imputations. However, some samples remained degraded with average imputation HUFA/SAT <0.52 after correction, and these samples should be excluded from analyses ($n = 272$; 3.1 %). For the remaining samples, standard statistical methods can be applied to the complete data by imputation. For a single inference the set of parameter estimates can be combined into an overall inference by calculating the parameter's average variance over the repeated imputations (within variability) + the variance of the parameter's mean (between variability) multiplied by $(1 + (1/m))$ for a finite number of imputations [21]. For multiple inferences future WHIMS investigators analyzing these RBC data should use the SAS[®] procedure PROC MIANALYZE, which implements Rubin's technique and calculates confidence intervals for the overall inference by using as inputs the covariance matrix and parameter estimates from general linear mixed models or generalized linear models. Rubin developed the multiple imputation method using Bayesian statistics, and then evaluated the technique in randomization-based

statistics using interval estimation [16]. His results show that the final inference is valid as a randomization based confidence interval or a Bayesian probability interval with the same nominal coverage.

Abstract It is known that the ratio, the level of sphingosine-1-phosphate (S1P)/the level of ceramide (CER) determines survival of the cells. The aim of the present study was to examine the effect of myocardial infarction on the level of different sphingolipids in the uninfarcted area. The experiments were carried out on male Wistar rats: 1, control; 2, after ligation of the left coronary artery (infarct) and 3, sham operated. Samples of the uninfarcted area of the left ventricle were taken in 1, 6 and 24 h after the surgery. The level of sphingolipids, S1P, CER, sphingosine (SPH), sphinganine-1-phosphate (SPA1P) and sphinganine (SPA) was determined. The control values were (ng/mg), S1P- 0.33 ± 0.03 , SPH- 1.02 ± 0.13 , SPA1P- 0.11 ± 0.01 , SPA- 0.28 ± 0.04 , total CER- 20.3 ± 1.8 . In infarct, the level of S1P in the uninfarcted area was reduced by ~ 3 times in 1 and 6 h and decreased further in 24 h. The level of SPH decreased in 1 h and returned to the control thereafter. The total level of CER decreased in 6 h after the infarction. Sham surgery also produced changes in the level of certain sphingolipids. The ratio, the level of S1P/the level of CER was markedly reduced at each time point after the infarction. It is concluded that the reduction in the S1P/CER ratio could be responsible for increased apoptosis in the uninfarcted area after the myocardial infarction in the rat.

| SPA | Sphinganine |

Introduction

It has been well documented that sphingosine-1-phosphate (S1P) exerts cardioprotective effect against ischemia as well ischemia/reperfusion injury. On the contrary, another sphingolipid namely ceramide (CER) increases apoptosis of cardiomyocytes in consequence of the procedures. These results were obtained mostly by adding either S1P or a short-chain CER in vitro or in isolated, perfused heart or by changing in the activity of enzymes involved in synthesis/catabolism of the compounds in myocardium [1–4]. Ischemia/reperfusion was shown to reduce the level of S1P in the isolated perfused rat heart by over 50 %, the effect being partially prevented by ischemic preconditioning [5]. In another study ischemia/reperfusion did not affect the heart S1P level. However, it was markedly elevated by ischemic preconditioning. Further elevation in its content was produced by following ischemia/reperfusion procedure [7]. The data concerning the level of CER clearly show that ischemia/reperfusion increases its level in isolated, perfused heart [1, 5, 7, 9, 11] and in the rat heart in vivo [10]. This increase was partially prevented by ischemic preconditioning [5, 8]. Examination of the behavior of individual CER in isolated perfused rat heart after ischemia/reperfusion showed elevation in the level of 7 out of 14 identified species [11].

Ischemia itself also elevated the level of CER in the isolated, perfused heart [7, 8] and in the ischemic area in vivo [10] although no effect was also reported [9].

The uninfarcted portion of the left ventricle is subjected to increased workload as a result of exclusion of the infarcted area from contractile activity. It results in dysfunction of the left ventricle and subsequent elevation in the left ventricular end diastolic pressure and reduction of the left ventricular developed pressure. Surprisingly, there are only very few data available on the metabolism of sphingolipids in the uninfarcted area after myocardial infarction. In one of the above-mentioned studies [9] ischemia/reperfusion was shown not to affect the level of CER in the uninfarcted area. On the contrary, another one [10] reported that the level of CER in the nonischemic area was stable after 30 min ischemia, but it was elevated after subsequent reperfusion as well after 210 min ischemia itself.

The aim of the present study was to examine the level of S1P, CER, sphingosine (SPH), sphinganine (SPA) and sphinganine-1-phosphate (SPA1P) in the uninfarcted area of the left ventricle in 1, 6 and 24 h after ligation of the left coronary artery in the rat.

Methods

The experimental procedure was approved by the Ethical Committee on the Animal Research at the Medical University of Białystok. Male Wistar rats, 200–220 g body weight were used. They were divided into three groups: 1, control; 2, after myocardial infarction (infarct) and 3, after sham surgery (sham). The rats of the infarct group were anaesthetized with thiopental (80 mg/100 g of body weight). The thoracic cavity was opened in the left 5th intercostal space. The lungs were ventilated by frequent air puffs administered manually by means of a small rubber balloon connected with the rat's nose by means of a plastic tube. The heart was exteriorized, the pericardium was cut open and the left coronary artery was ligated with a 6-0 monofilament polypropylene suture thread (Surgipro). Thereafter, the heart was placed back in the thoracic cavity, the thorax was sutured and the rat started to breath spontaneously. After the surgery the rats were placed in their home cages. The same procedure was applied in the sham group with the exception that the coronary artery was not ligated. The rate of survival of the rats subjected to the myocardial infarction was 60 %. In separate rats ($N = 3$) the ischemic area was determined in 24 h after ligation of the left coronary artery using Evans blue dye (1 ml, 2 %, iv). The hearts were excised, frozen and cut into thin slices (2 mm). The ischemic area (expressed as a percentage of left ventricle area) was determined using a stereoscopic microscope (Motic SMZ-143-N2GG, Xiamen, China)

equipped with a digital camera [12]. The ischemic area encompassed 36.3 % of the left ventricle.

At 1, 6 and 24 h after ligation of the coronary artery the rats were anaesthetized again and a sample of the left ventricle next to the interventricular septum, as far as possible from the ischemic area was taken and frozen in liquid nitrogen. In 24 h after the surgery, samples from the center of visible ischemic area were taken from three rats. Also a sample from similar area of a control rat was taken. The samples were fixed in Bouin's fluid for 48 h in +4 °C and embedded in paraffin in a routine way. Next they were cut in 4 µm slices (Leica 2025 Autocut) and stained with haematoxylin–eosin (H + E) for histological examination. Typical pictures are presented at the Fig. 1.

Determination of Sphingolipids

The level of sphingolipids was measured using a UPLC/MS/MS approach according to Blachnio-Zabielska et al. [13]. Briefly, frozen tissue (~20 mg) was homogenized three times in homogenization buffer containing 0.25 M sucrose, 20 mM KCl, 50 mM Tris and 0.5 mM EDTA, pH 7.4. Immediately afterwards 50 µl of the internal standard solution (17C-SPH and 17C-S1P, and 17C16:0-Cer Avanti Polar Lipids) as well as 1.5 ml of an extraction mixture (isopropanol:water:ethyl acetate, 35:5:60 v:v:v) were added to each homogenate. The mixture was vortexed, sonicated and then centrifuged for 10 min at 4,000 rpm. The supernatant was transferred to a new tube and pellet was re-extracted. After centrifugation supernatants were combined and evaporated under nitrogen. The dried sample was reconstituted in 100 µl of LC Solvent A for LC/MS/MS analysis. The following sphingolipids were quantified: Sph, dhSph, S1P, dhS1P, C14:0-Cer, C16:0-Cer, C18:1-Cer, C18:0-Cer, C20:0-Cer, C22:0-Cer, C24:1-Cer, C24:0-Cer. Sphingolipids were analyzed by means of an Agilent 6460 triple quadrupole mass spectrometer using positive ion electrospray ionization (ESI) source with multiple reaction monitoring (MRM). The chromatographic separation was performed using an Agilent 1290 Infinity Ultra Performance Liquid Chromatography (UPLC). The analytical column was a reverse-phase Zorbax SB-C8 column 2.1 × 150 mm, 1.8 µm. Chromatographic separation was conducted in binary gradient using 2 mM ammonium formate, 0.15 % formic acid in methanol Sigma-Aldrich (St. Louis, MO) as Solvent A and 1.5 mM ammonium formate, 0.1 % formic acid in water Sigma-Aldrich (St. Louis, MO) as Solvent B at the flow rate of 0.4 ml/min.

Statistical analysis

The data are presented as means ± SD, $N = 8$. $N = 8$ rats for each time point in either group. Data were analyzed by

Regular arrangement of myocardial fibers is seen. **b**, **c** 24 h after ligation of the left coronary artery. Microscopic images demonstrating the main histopathological changes of the myocardium: interstitial hemorrhage

(asterisks), myofiber degeneration (hypereosinophilia, loss of transversal striation and fragmenting nuclei *arrows*), infiltrating leucocytes and macrophages are apparent. (To view this figure in color, please consult the online version of this paper)

ANOVA with Tukey HSD (Honestly Significant Difference) post hoc test for unequal sample size. $P < 0.05$ is regarded as significant.

Results

Sphingosine-1-phosphate (Fig. 2a)

The infarction (infarct) resulted in a profound reduction in the level of S1P as early as 1 h after. It stabilized in 6 h and declined further in 24 h as compared to 1 h. After sham surgery (sham) the level of S1P in 1 h remained stable and decreased in 6 and 24 h in comparison to the control. It was higher from the respective value in infarct at each time point.

Sphingosine (Fig. 2b)

The level of SPH decreased in 1 h in infarct and returned to the control thereafter. Sham resulted in a $\sim 50\%$ reduction

in the level of the compound in 24 h compared to the control value.

Sphinganine-1-phosphate (Fig. 3a)

The level of SPA1P in infarct decreased in 1 h and then remained stable. There was gradual elevation in the level of the compound in sham.

Sphinganine (Fig. 3b)

The level of sphinganine was unchanged in infarct. In sham, it was reduced in 1 and 24 h after operation. In infarct, the level of sphinganine in 6 and 24 h was higher than the respective value in sham.

Ceramide (Table 1)

The total level of CER in infarct was reduced in 6 h and returned to the control level in 24 h. It remained stable in

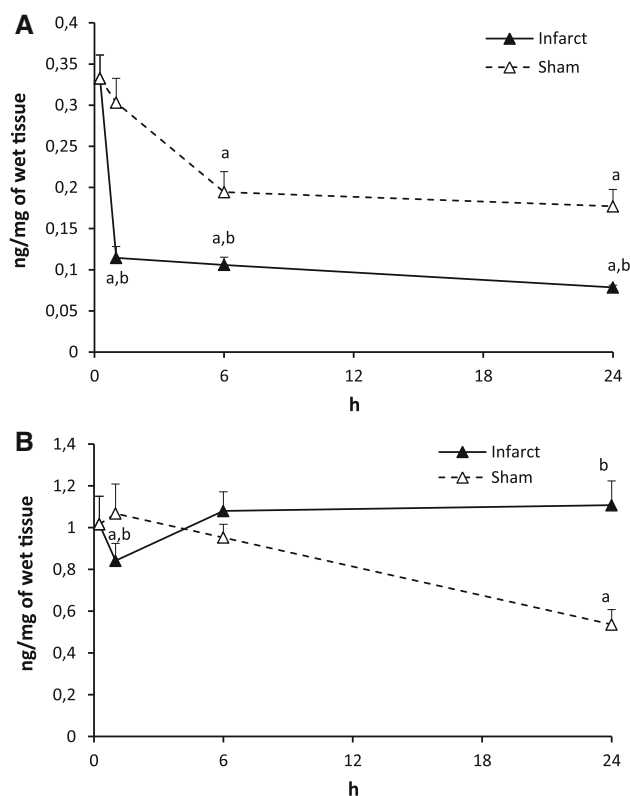

Fig. 2 The impact of myocardial infarction (filled triangles) or sham operation (open triangles) on the level of sphingosine-1-phosphate (a) and sphingosine (b) in the left ventricle of the heart. Black vertical bars represent SD ($N = 8$ per group). ^a $P < 0.05$ as compared to the control, ^b $P < 0.05$ as compared to appropriate sham group

sham. There are also several changes in the level of individual Cer, but they do not form a uniform picture.

Discussion

This is the first study showing a dramatic reduction in the level of S1P in the uninfarcted area of the left ventricle early after the myocardial infarction. S1P is produced by phosphorylation of SPH by the enzyme SPH kinase. It is degraded by two enzymes: sphingoid base-1-phosphate phosphatase and S1P lyase [14, 15]. If the reduction in the content of S1P was a consequence of reduced phosphorylation of SPH one could expect an accumulation of the latter which was not the case with the exception of a small, though significant, elevation in its content in 24 h in infarct group. S1P was shown to be transported from different cells including erythrocytes and platelets, the process being increased upon stimulation [16–19]. It is therefore possible that increased transport of the compound from the cardiomyocytes to the blood was activated in the uninfarcted area resulting in the reduction in its content in the ventricle wall. As mentioned in the introduction elevation in S1P content

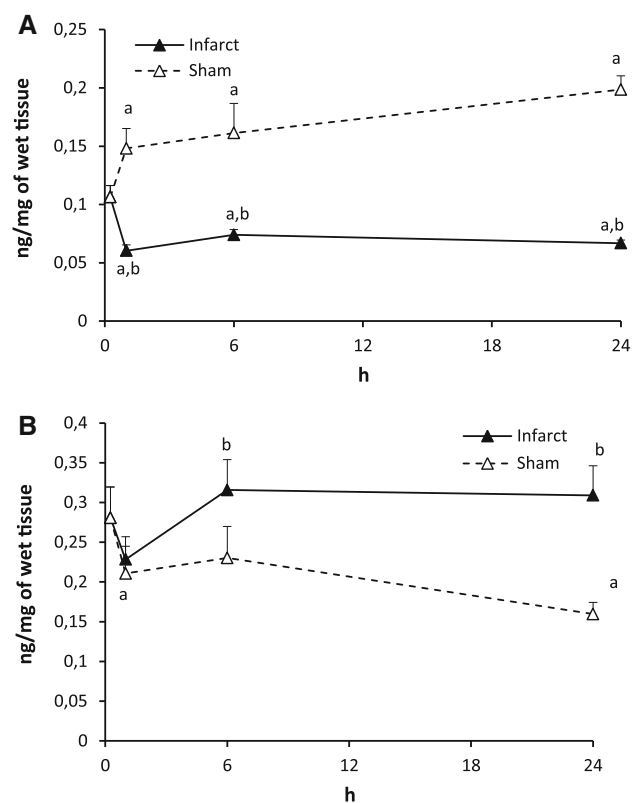

Fig. 3 The impact of myocardial infarction (filled triangles) or sham operation (open triangles) on the level of sphinganine-1-phosphate (a) and sphinganine (b) in the left ventricle of the heart. Black vertical bars represent SD ($N = 8$ per group). When bars not visible, SD smaller than the size of the marker. ^a $P < 0.05$ as compared to the control, ^b $P < 0.05$ as compared to appropriate sham group

was repeatedly shown to protect the heart against ischemia/reperfusion injury, whereas reduction of its level had opposite effect. The cardioprotective impact of S1P includes increased survivability of cardiomyocytes during ischemia in vitro, reduction of the infarct size and left ventricular developed pressure and elevation in the left ventricular end diastolic pressure in isolated, perfused heart subjected to ischemia or ischemia/reperfusion procedure [1–4]. Therefore it may be expected that the profound reduction in the level of S1P in the uninfarcted area of the left ventricle could contribute to the insufficiency of this area after the myocardial infarction.

Sphinganine-1-phosphate is a product of phosphorylation of sphinganine a precursor of CER on the de novo synthesis pathway. We are not aware of any data on the level of SPA1P in the heart. The present data indicate that it is much lower than the level of S1P. Similar relation was reported in plasma, erythrocytes and platelets [17, 20]. The myocardial infarction reduced the level of SPA1P in the uninfarcted ventricle though to a lesser degree than the level of S1P. It was not accompanied by a reduction in the level of sphinganine. It indicates that the reduction in its

^b *P* < 0.05 as compared to the respective value in the sham group

level was rather a consequence of increased transport of the compound from the cells. Interestingly in sham the level of SPA1P increased and the elevation was mirrored by reduction in the level of sphinganine. It would indicate that phosphorylation of sphinganine increased in this case. A mechanism behind these changes remains to be explored. A role of SPA1P is only poorly recognized. It binds to S1P receptors and mimics most effects of S1P [21]. Since its level is much lower than the level of S1P a consequence of its reduction is probably also much weaker.

A factor triggering changes in sphingolipid metabolism in the uninfarcted area of the myocardium remains obscure. It was previously shown that acute exercise produces several changes in sphingolipid metabolism in the heart [22] and skeletal muscles [23]. However, a mechanism responsible for the changes hasn't been studied so far. Increased work output during exercise may be such a factor. As indicated in the introduction, the uninfarcted area of the left ventricle is subjected to increased work load. It may be presumed that this factor is responsible for the changes in the sphingolipid metabolism described presently in the area.

Interestingly, the sham surgery produced also changes in the level of sphingolipids. At present, there are no reliable data for explanation of the phenomenon. However, it is well known that a number of stress factors, cytokines and

steroid hormones affect sphingolipid metabolism [15, 28]. Therefore, it may be presumed that thoracotomy and exteriorization of the heart in the sham group was a stress factor producing the observed changes.

Ligation of the left coronary artery in the rat was shown to induce apoptosis of cardiomyocytes in the uninfarcted ventricular wall and interventricular septum early (3 h) after ligation reached its peak at 1–2 days and decreased thereafter. At 1 day after the infarction a decrease in the expression of bcl-2 and an increase in the expression of bax took place (earlier than 1 day data were not reported). The authors pointed out that an increased mechanical load triggered the programmed cell death [24]. In another study in the rat, increased apoptosis in the uninfarcted area in 3 h after myocardial infarction was observed and the process persisted for 28 days. It was accompanied by activation of caspase-3 and proapoptotic shift of the Bcl-2/Bax ratio [25]. Increased apoptosis of cardiomyocytes in the uninfarcted area of the left ventricle in 24 h after infarction was also reported. Contrary to the above study, it persisted up to 4 weeks [26]. It should be added that 30 min ischemia followed by reperfusion did not increase apoptosis in the nonischemic area either of rabbit [8] or rat heart in vivo [10]. It is well established that CER exerts very strong proapoptotic action [27–29]. A factor triggering apoptosis in the uninfarcted area hasn't been recognized so far.

The present study showed a transient (in 6 h after the infarction) reduction in the level of CER in the examined sample of the ventricle. This would indicate that CER itself could not contribute to the activation of apoptosis in the rat heart reported above. However, the level of pro-survival S1P was deeply reduced at the same time. It was postulated that it is the ratio: the level of S1P/the level of CER which plays a crucial role in regulation of apoptosis [21]. In the present study the ratio decreased by 63.75 % in 1 h, by 61.25 % in 6 h and by 75 % in 24 h after ligation of the artery. Such a shift in the ratio would favor apoptosis. Therefore, it is a good reason to conclude that this mechanism may be responsible for at least early activation of apoptosis in the uninfarcted area of the left ventricle after ligation of the left coronary artery in the rat.

In summary, we showed that myocardial infarction induced profound changes in sphingolipid metabolism in the uninfarcted area of the left ventricle of the rat. Specifically, it deeply reduced the S1P/CER ratio. It is concluded that the reduction in the ratio could be responsible for the early activation of apoptosis in the uninfarcted area of the left ventricle after myocardial infarction.

Acknowledgments This work was supported by UMB grants 113-18664L, 114-18874L. We greatly appreciate Prof. Irena Kasacka for microscopic examination of the myocardium and Dr. Justyna Marciniak for determination of the ischemic area.

Abstract The supplementation of conjugated linoleic acid (CLA) has been shown to improve endurance by enhancing fat oxidation during exercise in rodents and humans. This study was designed to investigate the isomer-specific effects of CLA on endurance capacity and energy metabolism in mice during exercise. Male 129Sv/J mice were divided into three dietary groups and fed treatment diet for 6 weeks; control, 0.5 % *cis*-9,*trans*-11 (*c9,t11*) CLA, or 0.5 % *trans*-10,*cis*-12 (*t10,c12*) CLA. Dietary *t10,c12* CLA induced a significant increase in maximum running time and distance until exhaustion with a dramatic reduction of total adipose depots compared to a control group, but there were no significant changes in endurance with the *c9,t11* CLA treatment. Serum triacylglycerol and non-esterified fatty acid concentrations were significantly lower in the *t10,c12* fed mice after exercise compared to control and the *c9,t11* CLA fed-animals. Glycogen contents in livers of the *t10,c12* fed-mice were higher than those in control mice, concomitant with reduction of serum L-lactate level. There were no differences in non-exercise physical activity among all treatment groups. In addition, the mRNA expression levels of carnitine palmitoyl transferase 1 β , uncoupling protein 2 and peroxisome proliferator-activated receptor δ (PPAR δ) in skeletal muscle during exercise were significantly up-regulated by the *t10,c12* CLA but not the *c9,t11* CLA. These results suggest that the *t10,c12* CLA is responsible for improving endurance exercise capacity by promoting fat oxidation with a reduction of the consumption of stored liver glycogen, potentially mediated via PPAR δ dependent mechanisms.

Keywords Conjugated linoleic acid · Exercise · Fat oxidation · Endurance · Mice

Introduction

One of the major determinants of endurance capacity is increasing fat oxidation, which leads to the sparing of muscle glycogen [1, 2]. Fatty acid β -oxidation in muscle mitochondria followed by aerobic respiration is required to adequately generate ATP for muscular energy during exercise [3]; thus, enhanced fat oxidation, while decreasing carbohydrate utilization as an energy source, results in increased endurance capacity during prolonged exercise.

Conjugated linoleic acid (CLA) is an anti-obesity bioactive compound that plays a key role in enhanced fatty acid β -oxidation in skeletal muscle, suggesting preferential usage of fat over glucose as an energy source in muscle during exercise [4, 5]. In fact, previous short- (1 week) and long-term (10 weeks) feeding studies with CLA showed that dietary CLA enhances maximum swimming or

e-mail: ypark@foodsci.umass.edu

running capacity by increasing fat oxidation in mice [6, 7]. The CLA preparation used in these studies consisted primarily two major CLA isomers, *cis*-9,*trans*-11 (*c9,t11*) and *trans*-10,*cis*-12 (*t10,c12*) isomers. Previous studies suggested the roles and interactions between these two isomers on a number of biological functions of CLA, however, no research has reported the effects of different isomers of CLA on endurance exercise performance and related energy metabolism [8].

Among these two major CLA isomers, the *t10,c12* CLA isomer has been shown to be responsible for body fat reduction along with increased fatty acid oxidation via carnitine palmitoyl transferase 1 β (CPT1 β) and uncoupling protein 3 in skeletal muscle [9, 10]. These reports led us to hypothesize that the *t10,c12* CLA isomer may be responsible for improving endurance capacity as well. Thus we investigated the isomer-specific effects of CLA on endurance capacity and related physiological metabolism in mice as well as determined non-exercise physical activity (NEPA) in this study. This research may provide an important basis for developing CLA as a novel ergogenic aid for future human applications.

Materials and Methods

Materials

cis-9,*trans*-11 (*c9,t11*) and *t10,c12* CLA were provided by Natural Lipids Ltd. AS (Hovdebygd, Norway). The compositions of the CLA isomers were 90 % *c9,t11* isomer (90.1 % *c9,t11*, 3.8 % *t10,c12*, 2.5 % other CLA isomers, and 3.3 % oleic acid) and 94 % *t10,c12* isomer (2.0 % *c9,t11*, 94.4 % *t10,c12*, 2.9 % other CLA isomers, and 0.4 % oleic acid). Semi-purified powdered diet (TD04460, 94 % basal mix) was purchased from Harlan Teklad (Madison, WI). Serum total cholesterol, triacylglycerol (TAG) and glucose assay kits were purchased from Genzyme Diagnostics (Charlottetown, PE, Canada). Non-esterified fatty acid (NEFA) and L-lactate assay kits were purchased from BioAssay Systems (Hayward, CA). Blood urea nitrogen (BUN) and glycogen assay kits were purchased from BioQuant (San Diego, CA) and Cayman Chemical Company (Ann Arbor, MI), respectively. Other chemicals used were purchased from either Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific (Pittsburgh, PA).

Animals and Diet

All animal procedures were approved by the Institutional Animal Care and Use Committee at the University of Massachusetts, Amherst (Protocol ID 2010-0032). Forty

male 129Sv/J mice (5-week-old) were obtained from breeding colonies maintained at the University of Massachusetts Amherst. Animals were housed in individual wire-bottomed cages in a windowless room with a 12-h light–dark cycle. During a 1-week adaptation period, all mice were fed a control diet and were subjected to running exercise three times (velocity of 10 m/min on 0° inclination for 15 min with shock grid OFF, followed by 10 min with shock grid ON) to acclimate to the treadmill. At the end of the adaptation period, all animals were subjected to an endurance test for the measurement of their baselines on the running time to exhaustion. To minimize individual variations on endurance capacity baseline, we selected 18 mice with the closest value to the mean baseline from the original 40. Finally, selected mice were randomly divided into three groups and fed control diet or diet containing 0.5 % of *c9,t11* or *t10,c12* CLA isomer for 6 weeks. The diet composition is shown in Table 1. Body weight and feed intake were recorded weekly. At the end of study, the mice were fasted for 4 h, ran for 40 min according to the endurance protocol, and then immediately sacrificed by CO₂ asphyxiation. Blood was collected by cardiac puncture, and internal organs (liver, heart, kidney, spleen and adipose tissues) were also weighed.

Exercise Training and Endurance Protocol

During the experimental period, all animals were trained three times a week on a motorized treadmill (Columbus Instrument, Columbus, OH). Training was performed for a total 15 min (10 min at 10 m/min, then an increase of 1 m/min every minute for 5 min) on 10° inclination with shock grid ON. Mice were encouraged to run with the use of an electric grid placed at the end of the treadmill (0.97 mA, 1 Hz).

Table 1 Composition of experimental diets

| Ingredient | g/kg |
|--|-------|
| Casein, ‘vitamin-free’ tested | 194 |
| L-Cystine | 3 |
| Sucrose | 87.5 |
| Cornstarch | 373.5 |
| Maltodextrin | 132 |
| Cellulose | 50 |
| Soybean oil | 95 |
| Soybean oil or <i>c9,t11</i> CLA or <i>t10,c12</i> CLA | 5 |
| Mineral mix w/o Ca | 35 |
| CaCO ₃ | 12.5 |
| Vitamin mix | 10 |
| Choline bitartrate | 2.5 |
| <i>tert</i> -Butylhydroquinone | 0.02 |
| Total | 1,000 |

Endurance capacity was determined every other week by placing animals on an individual treadmill at room temperature. The exercise regimen was started with shock grid ON and 10° inclination at 10 m/min for 10 min, speed was increased by 1 m/min up to 25 m/min (15 min with increase speed), and then held at 25 m/min until exhaustion. Based on previous studies, which measured treadmill endurance capacity [11–13], mice were defined as exhausted if they were willing to sustain on the shock grid three times for more than 2 s or remain on the shock grid for five consecutive seconds. At the moment of exhaustion the mouse was removed from the treadmill. The total running time and distance until exhaustion were recorded and used as the index of endurance capacity.

Non-Exercise Physical Activity (Voluntary Movement)

The NEPA was monitored using LoliTrack Quatro Video Tracking Software Version 1.0 (Loligo Systems, Tjele, Denmark) with an infrared camera. The mice were placed in cages (30 × 46 × 40 cm) individually from 12:00 p.m. to 9:00 a.m. the next day with free access to diet and water (provided as HydroGel®, Clear H₂O, Portland, ME) twice during the experimental period. The mice to be tracked were placed against a contrasting background and the software assigned an X, Y coordinate pair to the center of the contrasting objects. The program found all pixels within the range of 640 × 480 pixels and calculated the center X and Y coordinates of these pixels. The time-stamped X, Y-coordinates were written into a data file to 5 times/s, and then the data was imported into Excel for analysis. Movement data for 19 h (light cycle, 2:00 p.m.–6:00 p.m. and next day 6:00 a.m.–9:00 a.m.; dark cycle, 6:00 p.m.–6:00 a.m. next day) except 2 h (12:00 p.m.–2:00 p.m.) of early phase for adapting to surroundings was analyzed. Voluntary movements were expressed as total travel distance (m).

Biochemical Parameters

Serum was separated by centrifugation at 3,000g for 20 min at 4 °C. Serum samples were used for determination of TAG, glucose, total cholesterol, NEFA, L-lactate and BUN using commercial kits as specified by the manufacturer. The glycogen contents in gastrocnemius muscle and liver were measured by the enzymatic method using a commercial kit.

Real Time PCR

Gastrocnemius muscle was homogenized in 1 mL of TRIzol reagent and then total RNA was isolated according to the TRIzol protocol. Total RNA was reverse transcribed

to cDNA using a High Capacity cDNA Reverse Transcription kit (Applied Biosystems, Foster, CA), as described in the manufacture's protocol. cDNA was used as a template for the relative quantitation for the selected target genes [CPT1β (Mm00487200_m1), uncoupling protein 2 (UCP2, Mm00627597_m1), lipoprotein lipase (LPL, Mm00434764_m1), interleukin 6 (IL-6, Mm00446190_m1), peroxisome proliferator-activated receptor δ (PPARδ, Mm00803184_m1)] with predesigned TaqMan gene expression assay kits. Each 20 µL reaction contained 100 ng cDNA, 2× TaqMan Gene Expression Mastermix, forward and reverse primers and TaqMan probe. All reactions were carried out in triplicate with the StepOnePlus Real-Time PCR System (Applied Biosystems, Foster, CA) using the following conditions: 50 °C for 2 min and 95 °C for 10 min followed by forty cycles of 95 °C for 15 s and 60 °C for 1 min. Results were normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH, Mm99999915_g1) as an internal standard, and relative quantities of each gene were presented in terms of $2^{-\Delta\Delta C_t}$, calculated using the ΔC_t and $\Delta\Delta C_t$ values.

Statistical Analyses

Data were analyzed by one-way ANOVA of the SAS software for Windows release 9.2 (SAS Institute Inc., Cary, NC) on the W32_VSHOME platform. For the body weight, feed intake, feed efficiency ratio, endurance time, endurance distance and NEPA data, one-way ANOVA with repeated measures were performed for the data analysis. To test for differences in total adipose depot and organ weight among the experimental groups, analysis of covariance (ANCOVA) with final body mass as covariates was used. Homogeneity of regression assumptions of the ANCOVA model was tested. This assumption was met for organ weight data, but violated for total adipose data. For total adipose depot data, ANCOVA analysis was performed for each of three levels of final body mass (minimum, mean and maximum) [14]. The least squares means option using a Tukey–Kramer adjustment was used for the multiple comparisons among the experimental groups. Data are shown as the mean ± SE. *P* values <0.05 are reported as statistically significant.

Results

Body Weights and Feed Intake

No significant differences were observed in body weights between treatments in regular running-exercised mice during the experimental period (Fig. 1a). Feed intake in the $\tau 10, c12$ CLA fed mice steadily increased from Week 3 and showed a significant difference compared to control group

Fig. 1 Effects of CLA isomers on body weight (a), feed intake (b) and feed efficiency ratio (c). Mice were fed one of the treatment diets for 6 weeks. Feed efficiency ratio was calculated as weight gain (g/mouse/week)/feed intake (g/mouse/week). Values represent mean \pm SE ($n = 6$). *Significantly different from control ($P < 0.05$)

at Week 6, but there was no significant difference in feed intake between the c9,t11 CLA and control groups during the entire experimental period (Fig. 1b). Feed efficiency ratio did not show significant differences among all treatment groups (Fig. 1c).

Adipose Depots and Organ Weights

Adipose tissue weights including epididymal, mesenteric and retroperitoneal fat were adjusted for body size variation at three levels of final body mass (minimum, mean and maximum) as a covariate (Fig. 2). These were necessary since ANCOVA has an underlying assumption of homogeneity of regression, which was not satisfied by our data. This suggests that the dietary effect for adipose tissue weight depends on whole body mass in this study. The ANCOVA analysis showed a significant reduction of adipose depots by the t10,c12 CLA compared to control at the levels of mean and maximum of final body mass, although it was not significant at minimum level. The ANCOVA analysis showed overall increases in organ weights including liver, heart, kidney and spleen in the t10,c12 CLA fed mice compared to other groups (Table 2).

Fig. 2 Effects of CLA isomers on adipose depot. Mice were fed one of the treatment diets for 6 weeks. Adipose depot includes epididymal, mesenteric and retroperitoneal fat. Homogeneity of regression slopes in ANCOVA model was violated (there was a significant interaction between dietary effect on adipose depot and final body mass), and means were adjusted for each of three levels of final body mass (minimum, mean and maximum) [14]. Values represent means \pm SE ($n = 6$). *Significantly different from control (***) $P < 0.001$, **** $P < 0.0001$)

Table 2 Organ weights

| Organ (g) | Dietary group | | |
|-----------|------------------------------|------------------------------|------------------------------|
| | Control | c9,t11 CLA | t10,c12 CLA |
| Liver | 0.86 \pm 0.14 ^b | 0.85 \pm 0.14 ^b | 2.27 \pm 0.16 ^a |
| Heart | 0.11 \pm 0.00 ^b | 0.12 \pm 0.00 ^b | 0.13 \pm 0.00 ^a |
| Kidney | 0.37 \pm 0.02 ^b | 0.38 \pm 0.02 ^b | 0.45 \pm 0.02 ^a |
| Spleen | 0.05 \pm 0.00 ^b | 0.05 \pm 0.00 ^b | 0.08 \pm 0.00 ^a |

Values represent means \pm SE ($n = 6$). Means are adjusted for final body mass using the ANCOVA analysis. Means with different superscripts within the same row are significantly different ($P < 0.05$)

Endurance Capacity and Non-Exercise Physical Activity

Endurance capacities of mice were determined by the maximum running time and distance recorded on the treadmill. The maximum running time and distance were significantly increased in the $\iota 10,c12$ CLA group compared to control mice at Week 2 and Week 6, but there were no significant differences between the $c9,\iota 11$ CLA group and control during the experimental period (Fig. 3a, b). Dietary supplementation of the $\iota 10,c12$ CLA brought on increases of approximately 2.7-fold in maximum time and 4.8-fold in maximum distance at Week 2 compared to their baseline. Control mice showed increases of approximately 1.5-fold (time) and 2.5-fold (distance) at Week 2 compared to their baseline, indicating the effects of other contributing factors such as body weight and running training on endurance capacity.

The NEPA was individually monitored in special cages during both light and dark cycles. In contrast with endurance capacity, the NEPA decreased over time in all treatment

groups, and neither CLA isomer caused significant changes in NEPA of mice during the experimental period (Fig. 4).

Serum Parameters and Glycogen Contents

The serum concentrations of major metabolic substrates after 40 min of endurance exercise are shown in Table 3. There were no marked differences in serum parameters between the control and the $c9,\iota 11$ CLA groups. However, the serum TAG, NEFA and L-lactate concentrations in the $\iota 10,c12$ CLA group were significantly lower than those in the control group. The serum glucose level was the highest in the $\iota 10,c12$ CLA group, but not significant. Supplementation of the $\iota 10,c12$ CLA significantly increased the total cholesterol level compared to other groups, and there were no differences in the serum BUN levels among all treatment groups.

The glycogen concentrations of the gastrocnemius muscle and liver after 40 min of endurance exercise in the $\iota 10,c12$ CLA fed mice tended to be higher than those in other tested mice, although a significant difference compared to control mice was observed only in liver (Table 4).

mRNA Expressions

To determine the mRNA expression levels of key enzymes involved in lipid and energy expenditure metabolism, selected mRNA levels were measured in gastrocnemius muscle after exercise (Fig. 5). The expressions of CPT1 β , UCP2 and PPAR δ in muscle after exercise significantly increased in the $\iota 10,c12$ CLA fed animals compared to those of the control, indicating the $\iota 10,c12$ CLA controls energy metabolism by up-regulating the muscle

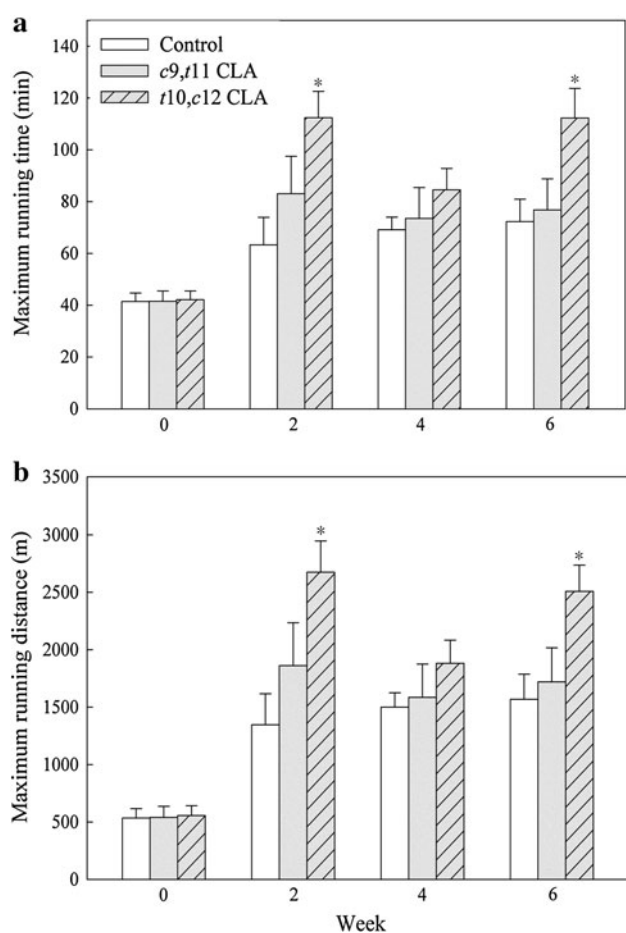

Fig. 3 Effects of CLA isomers on maximum running time (a) and distance (b). Endurance capacity was evaluated with treadmill exercise every 2 weeks. Values represent mean \pm SE ($n = 6$). *Significantly different from control ($P < 0.05$)

Fig. 4 Effects of CLA isomers on non-exercise physical activity. Non-exercise physical activity was monitored in individual clear cages during light and dark cycles (19 h) twice throughout the experimental period. Values represent means \pm SE ($n = 6$)

Table 3 Serum parameters

| mmol/L | Dietary group | | |
|-------------------|--------------------------|---------------------------|--------------------------|
| | Control | <i>c9,t11</i> CLA | <i>t10,c12</i> CLA |
| TAG | 1.39 ± 0.08 ^a | 1.27 ± 0.15 ^a | 0.83 ± 0.07 ^b |
| Glucose | 10.7 ± 1.4 | 10.0 ± 1.3 | 15.0 ± 2.0 |
| Total cholesterol | 2.78 ± 0.16 ^b | 2.93 ± 0.11 ^b | 4.11 ± 0.44 ^a |
| NEFA | 2.08 ± 0.08 ^a | 2.07 ± 0.14 ^a | 1.19 ± 0.04 ^b |
| L-Lactate | 6.83 ± 0.39 ^a | 6.52 ± 0.31 ^{ab} | 5.75 ± 0.10 ^b |
| BUN | 13.8 ± 0.9 | 12.6 ± 0.6 | 11.9 ± 0.5 |

At the end of study, the mice ran for 40 min according to the endurance protocol and were sacrificed by CO₂ asphyxiation. Values represent means ± SE (*n* = 6). Means with different superscripts within the same row are significantly different (*P* < 0.05)

Table 4 Glycogen contents in muscle and liver

| Tissue (mg/g) | Dietary group | | |
|----------------------|-------------------------|--------------------------|-------------------------|
| | Control | <i>c9,t11</i> CLA | <i>t10,c12</i> CLA |
| Gastrocnemius muscle | 0.90 ± 0.21 | 0.79 ± 0.15 | 1.58 ± 0.59 |
| Liver | 22.9 ± 2.3 ^b | 25.8 ± 2.3 ^{ab} | 33.3 ± 3.5 ^a |

At the end of study, the mice ran for 40 min according to the endurance protocol and were sacrificed by CO₂ asphyxiation. Values represent means ± SE (*n* = 6). Means with different superscripts within the same row are significantly different (*P* < 0.05)

Fig. 5 Effects of CLA on expressions of selected genes from skeletal muscle. *CPT1β* carnitine palmitoyl transferase, *UCP2* uncoupling protein 2, *LPL* lipoprotein lipase, *IL-6* interleukin 6, *PPARδ* peroxisome proliferator-activated receptor δ . Relative quantities of each gene were presented in terms of $2^{-\Delta\Delta C_t}$, calculated using the ΔC_t and $\Delta\Delta C_t$ values. Values represent means ± SE (*n* = 6). *Significantly different from control (**P* < 0.05, ***P* < 0.01)

expressions of *CPT1β*, *UCP2* and *PPARδ* during exercise, effects not seen with the *c9,t11* CLA. The expression levels of *LPL* and *IL-6* were not different with treatments of either CLA isomer compared to control.

Discussion

There is much evidence that the wide range of CLA's activities results from interaction between the two major CLA isomers, *c9,t11* and *t10,c12*; additive, independent, or antagonistic effects [8]. In the present study, we investigated the isomer-specific effects of these major CLA isomers on endurance capacity and utilization of metabolic substrates during prolonged exercise. Among these two isomers, the effect of CLA on fatty acid oxidation and body fat reduction is known to be due to the independent effect of the *t10,c12* CLA isomer [9, 15]. Consistently, our current research confirmed that the adipose depots were significantly reduced in *t10,c12* CLA fed mice but not in *c9,t11* fed mice. In addition, our results showed that the *t10,c12* isomer increased endurance capacity in mice.

The body weights did not show differences among all treatment groups during the experimental period, but the feed intake was significantly higher in the *t10,c12* CLA group than other groups at Week 6. These results indicate that the overall balances between energy intake and expenditure were similarly maintained among all treatment groups, when the mice were subjected to the regular exercise in this study. In addition, the reduction of body fat with the constant increases in feed intake in the latter half of the experiment in the *t10,c12* CLA group may potentially indicate overall increases in lean mass as previously suggested [16].

It is well known that increased fat utilization during endurance exercise enables athletes to improve endurance capacity by a sparing effect on the glycogen stores, although the impact of muscle glycogen on endurance is not clear in rodents [17, 18]. The two major repositories of glycogen are the liver and skeletal muscle, and the relative proportion of muscle glycogen is lower, up to tenfold, in mice than in humans [19, 20]. Fernandez et al. [17] suggested that one determining factor for the endurance capacity in mice could be the amount of glycogen stored in liver, rather than that stored in muscle. In the present study, glycogen contents were increased in muscle and liver of the *t10,c12* CLA fed mice, but significance was observed only in liver. This conservation of glycogen consumption accompanied the decreases of serum concentrations of TAG and L-lactate in the *t10,c12* CLA fed mice, suggesting the *t10,c12* CLA could enhance endurance capacity of mice by increasing fat utilization and reducing the consumption of stored liver glycogen. Although we did not include a non-exercise group in this study, Mizunoya et al. [6] showed that the changes of biochemical parameters including serum glucose, TAG and NEFA after prolonged exercise were greater in CLA-fed mice than control mice. Therefore, it is possible that dietary CLA with exercise has a combination effect on biological responses during

exercise. Alternatively, we cannot exclude the possibility that these responses are due to the acute bout of exercise [21].

The CPT1 β is a rate-limiting enzyme of mitochondrial fatty acid β -oxidation, and UCP2 has been shown to be associated with energy expenditure by dissipating the chemiosmotic gradient in mitochondria [22, 23]. In the present study, the mRNA expression levels of CPT1 β and UCP2 were significantly up-regulated by the *t*10,*c*12 CLA, while the *c*9,*t*11 CLA did not induce any significant changes in these genes over the control. Therefore, these results suggest that the *t*10,*c*12 CLA regulates energy metabolism beneficially for the endurance by enhancing fatty acid β -oxidation in muscle during exercise. Additionally, IL-6 is released in large amounts from skeletal muscle during prolonged exercise and IL-6 deficient mice showed reduced endurance and energy expenditure during exercise [24]. Chung et al. [25] reported that the *t*10,*c*12 CLA increases the expression and secretion of IL-6 in human adipocytes, but there was no CLA effect on muscle IL-6 expression in mice in this study.

One of interesting results here is that *t*10,*c*12 CLA significantly up-regulated the muscle mRNA level of PPAR δ . Muscle oxidative capacity is a crucial factor for determining endurance, and PPAR δ is a key regulator of lipid and carbohydrate metabolism in the muscle [26]. In fact, Wang et al. [27] demonstrated that the targeted activation of the PPAR δ gene in muscle leads to muscle fiber transformation to increased mitochondria-rich type I muscle, which mainly uses oxidative metabolism for energy production. In the same report, PPAR δ -null mice showed a remarkably decreased endurance capability compared to their wild type counterparts. Therefore, our present results suggest that *t*10,*c*12 CLA could improve endurance by stimulating oxidative metabolism via PPAR δ regulation in skeletal muscle.

Alternatively, CLA's effect is mediated by AMP-activated protein kinase (AMPK), which is known to be the main regulator of exercise-mediated responses in the skeletal muscle, and PPAR δ is one of the primary downstream targets of AMPK [28–30]. The activation of both AMPK and PPAR δ is associated with the ability to promote endurance [28]. Indeed, it was demonstrated that a PPAR δ agonist and exercise training show synergistic activity of increasing oxidative myofibers and running endurance in mice [28]. Moreover, others recently reported no influence on PPAR δ by CLA [31]. The major difference between our current study and this report is the presence of exercise training in ours. This suggests potential combination/synergistic effects of *t*10,*c*12 CLA with exercise training on improving exercise performance via AMPK and/or PPAR δ -dependent pathways. However, further studies are required to confirm if effects of CLA on endurance capacity involves AMPK and PPAR δ , including its effects on mitochondrial biogenesis.

We have to point out that our results in Fig. 5, only measuring mRNA expressions of selected markers, may be rather limited. However, it has been previously reported that there is a positive correlation between the increased mRNA expression of PPAR δ and its protein expression as well as the correlation between increased mRNA levels of CPT1 β and UCP2 on increased fat oxidation [32, 33]. Nonetheless, we cannot exclude the possibility of regulations of CLA occurring during post-transcriptional and post-translational periods and their activities.

CLA has been shown to enhance energy expenditure, supported by increased oxygen consumption [34, 35] and the expression of uncoupling proteins [36, 37]. Ohnuki et al. [38] reported that the oral administration of a CLA mixture increased serum concentrations of adrenalin and noradrenalin in mice, suggesting stimulation of the sympathetic nervous system. Therefore, CLA isomers may contribute to energy expenditure by inducing the enhancement of NEPA (grooming, feeding, walking around, etc.) as well as exercise performance. However, our data here showed that neither CLA isomer induced a significant change in NEPA during 6 weeks of dietary supplementation. By contrast, CLA supplementation increased NEPA previously when no extensive exercise regime was used [39]. This discrepancy suggests an interaction between NEPA and extensive exercise regime. Thus, further investigations are needed to understand the effects of CLA on NEPA, especially interaction between NEPA and extensive exercise.

There are currently seven human clinical studies reporting on CLA and exercise performance currently [40–46]. Four reported that CLA supplementation resulted in positive effects on at least one of exercise outcomes compared to control [40–43]. Others primarily evaluated effects of CLA on strength or capacity. Blankson et al. [40] reported increased training hours with CLA supplementation, which is consistent with our current observation. The present findings along with the previous studies suggest that CLA could boost the effects of exercise training on endurance capacity, and our results confirmed that the *t*10,*c*12 CLA is responsible for those effects. However, others reported no changes in exercise outcomes with CLA in humans [44–46].

The NEFA is one of major fuels available with glycogen and glucose for oxidative metabolism during exercise [17]. Many researches demonstrated improved endurance capacity by increasing fat utilization during exercise and have shown increased serum level of NEFA during and/or after exercise with improved endurance [17, 47–49]. This might have resulted from increases of lipolysis in white adipose tissue, hydrolysis of very low-density lipoprotein TAG, or hydrolysis of intramyocellular triglyceride stores [17]. However, a previous study using CLA mixture

showed an improved endurance by promoting fat oxidation, with decreased serum concentrations of NEFA [6]. Others have consistently reported, as does this study, that CLA mix or *t10,c12* isomer showed reduced serum levels of NEFA with enhanced endurance by CLA [7]. The decreases of circulating NEFA by CLA supplementation could be most likely explained by the modulation of hepatic lipid metabolisms such as fatty liver. Fatty liver associated with CLA is primarily found in animal studies, and is believed to be due to tremendous fat mobilization from adipocytes and enhanced hepatic lipogenesis [50–52].

In conclusion, the present study demonstrated that *t10,c12*, but not *c9,t11*, CLA supplementation with exercise training enhances the running endurance capacity of mice by increasing muscle fat oxidation and reducing the consumption of stored glycogen during prolonged exercise. The increased expression level of PPAR δ in skeletal muscle indicates enhanced muscle oxidative metabolism by *t10,c12* CLA with exercise training. These findings provide important information for the application of CLA as a novel ergogenic aid.

Abstract The present study examined the effect of 4-[4-(Z)-hept-1-enyl-phenoxy] butyric acid (HUHS2002), a free fatty acid derivative, on $\alpha 7$ acetylcholine (ACh) receptor responses. HUHS2002 potentiated whole-cell membrane currents through $\alpha 7$ ACh receptors expressed in *Xenopus* oocytes in a concentration (1–100 nM)-dependent manner, reaching about 140 % of the original amplitude at 100 nM 50 min after a 10-min treatment. The HUHS2002 effect was prevented by KN-93, an inhibitor of Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII), while it was not affected by GF109203X, an inhibitor of protein kinase C (PKC), or H-89, an inhibitor of protein kinase A (PKA). In the in situ CaMKII assay using cultured rat hippocampal neurons, HUHS2002 activated CaMKII and the activation was abolished by KN-93. In the cell-free assay of protein phosphatase 1 (PP1), HUHS2002 partially inhibited PP1 activity. Taken together, these results indicate that HUHS2002 potentiates $\alpha 7$ ACh receptor responses by indirectly activating CaMKII, possibly via inhibition of PP1.

Introduction

Of neuronal nicotinic acetylcholine (ACh) receptors, a class of ligand-gated cation channels, $\alpha 7$ ACh receptor is preferentially localized at presynaptic terminals in the brain and regulates neurotransmitter release [1–8]. An enhancement in presynaptic nicotinic ACh receptors including $\alpha 7$ ACh receptor induces a long-lasting facilitation of hippocampal synaptic transmission by stimulating glutamate release [1–5]. Alzheimer disease is characterized by impairment in hippocampus-based episodic memory function. The cholinergic systems appear to be selectively disrupted in brain tissues from Alzheimer's patients [9–11]. Intriguingly, amyloid- β peptide, a critical factor proposed for the pathogenesis of Alzheimer disease, is bound to $\alpha 7$

Cell Culture

The hippocampus was removed from the embryonic Wistar rat brain (gestational age, 18 days). Dissociated hippocampal cells were seeded on 96-well plates and grown in a culture medium: neurobasal with the supplement B27 (50:1), 2.5 mM glutamine, 50 μ M glutamate, penicillin (final concentration, 100 U/ml), and streptomycin (final concentration, 0.1 mg/ml) in a humidified atmosphere of 5 % CO₂ and 95 % air at 37 °C. Two days later, cytosine arabinoside (5 μ M) was added to the culture medium to suppress glial cell proliferation.

In Situ CaMKII Assay

CaMKII activity in cultured rat hippocampal neurons after 7 days in vitro was assayed by the method as previously described [24]. Cultured neurons were treated with HUHS2002 in the presence and absence of KN-92 or KN-93 at 37 °C for 10 min in an extracellular solution [137 mM NaCl, 5.4 mM KCl, 10 mM MgCl₂, 0.3 mM Na₂HPO₄, 0.4 mM K₂HPO₄, and 20 mM HEPES, pH 7.2]. Then, cells were rinsed with 100 μ l Ca²⁺-free phosphate-buffered saline (PBS) and incubated at 30 °C for 15 min in 50 μ l of the extracellular solution containing 50 μ g/ml digitonin, 25 mM glycerol 2-phosphate, 200 μ M ATP, and 100 μ M Autocamtide-2 (Lys-Lys-Ala-Leu-Arg-Arg-Gln-Glu-Thr-Val-Asp-Ala-Leu; MW 1,527.8) (Calbiochem, San Diego, CA, USA), a synthetic CaMKII substrate peptide. The supernatants were collected and boiled at 100 °C for 5 min to terminate the reaction. An aliquot of the solution (20 μ l) was loaded onto a reversed phase high-performance liquid chromatography (HPLC) (LC-10ATvp, Shimadzu Co., Kyoto, Japan). A substrate peptide peak and a new product peak were detected at an absorbance of 214 nm (SPD-10Avp UV-vis detector, Shimadzu Co.). Molecular weights for each peak were calibrated from the two standard spectrums, bradykinin (MW 1,060.2) and neurotensin (MW 1,672.9). In the analysis of matrix-assisted laser desorption ionization time of flight mass spectrometry (Voyager DE-STR, PE Biosystems Inc., Foster City, CA, USA), a substrate peak and a new product peak revealed a molecular weight of 1,527 and 1,607, respectively. This explains why a new product peak corresponds to phosphorylated substrate peptide, since a molecular weight of 1,607 is consistent with total molecular weight of unphosphorylated substrate peptide (MW 1,527) plus HPO₃ (MW 80). Areas for unphosphorylated and phosphorylated CaMKII substrate peptide were measured (the total area corresponds to the concentration of CaMKII substrate peptide used here). The amount of phosphorylated substrate peptide (pmol/min/ μ g cell protein) was calculated and used as an index of CaMKII activity.

Cell-Free Assay for CaMKII and PP1 Activity

For cell-free CaMKII assay, a synthetic CaMKII substrate peptide (10 μ M) was reacted with CaMKII (5 U) (Calbiochem) in a reaction medium (25 μ l, pH 8.0) containing 40 mM HEPES, 5 mM Mg-acetate, 0.4 mM CaCl₂, 0.1 mM ATP, 0.1 mM EGTA, 1 μ M calmodulin (Calbiochem) in the presence and absence of HUHS2002 at 35 °C for 10 min. For a cell-free PP1 assay, a synthetic CaMKII substrate peptide (10 μ M) was reacted with CaMKII (5 U) and PP1 (5 mU) (Sigma, St. Louis, MO, USA) in the same reaction medium as for CaMKII assay in the presence and absence of microcystin (Sigma) or HUHS2002 at 35 °C for 10 min. Each reaction was terminated at 100 °C for 5 min. An aliquot of each solution (15 μ l) was injected onto the column (250 mm \times 4.6 mm) (COSMOSIL 5C18-AR-II, Nacalai Tesque, Kyoto, Japan), and loaded onto a reversed phase HPLC system (LC-10ATvp, Shimadzu Co.). Unphosphorylated peptide and phosphorylated peptide were detected at an absorbance of 214 nm (SPD-10Avp UV-vis detector, Shimadzu Co.). Phosphorylated substrate peptide (pmol/min) was used as an index of CaMKII activity. Dephosphorylated substrate peptide (the amount of phosphorylated substrate peptide in the absence of PP1 minus the amount in the presence of PP1 together with and without microcystin or HUHS2002) (Δ pmol/min) was used as an index of PP1 activity. As is the case with DCP-LA [24], much higher concentrations of HUHS2002 in the cell-free system than in the in-situ system were used to detect the activity of CaMKII and PP1.

Statistical Analysis

Statistical analysis was carried out using Fisher's protected least significant difference (PLSD) test and Dunnett's test.

Results

HUHS2002 Potentiates Currents Through $\alpha 7$ ACh Receptors in a CaMKII-Dependent Manner

For *Xenopus* oocytes, expressing $\alpha 7$ ACh receptors, bath-application with ACh (100 μ M) generated inward whole-cell membrane currents at a holding potential of -60 mV (Fig. 2). HUHS2002 (100 nM) potentiated the currents to approximately 150 % of the original amplitude, the effect being evident 50 min after a 10-min treatment (Fig. 2). The potentiating effect of HUHS2002 was concentration (1–100 nM) dependent (Fig. 3).

$\alpha 7$ ACh receptor channels are highly permeable to calcium. In the *Xenopus* oocyte expression system, ACh-evoked currents are composed of currents through $\alpha 7$ ACh receptor channels and endogenous chloride channels that are

Fig. 2 HUHS2002-induced potentiation of $\alpha 7$ ACh receptor currents. $\alpha 7$ ACh receptors were expressed in *Xenopus* oocytes, and ACh (100 μ M) was bath-applied to oocytes for 10 s at a 10-min interval before and after a 10-min treatment with HUHS2002 (HUHS) (100 nM) in Ca^{2+} -containing extracellular solution. The holding potential was -60 mV. Application with ACh is indicated by bars. Typical currents recorded 10 min before and 50 min after treatment with HUHS2002 are shown. In the graph, each point represents the mean (\pm SEM) percentage of the original amplitudes (-10 min) ($n = 8$ independent experiments)

activated by Ca^{2+} influx through $\alpha 7$ ACh receptor channels. HUHS2002 (100 nM) still potentiated ACh-evoked currents in Ca^{2+} -free extracellular solution (Fig. 3). This indicates that HUHS2002-induced potentiation of ACh-evoked currents is due to an enhancement in $\alpha 7$ ACh receptor channel currents but not in Ca^{2+} -sensitive chloride channel currents.

HUHS2002 (100 nM)-induced potentiation of $\alpha 7$ ACh receptor channel currents was significantly inhibited by KN-93 (3 μ M), an inhibitor of CaMKII ($P < 0.001$ as compared with the currents after HUHS2002 treatment in the absence of CaMKII, Fisher's PLSD test), while the potentiation was not affected by GF109203X (100 nM), an inhibitor of PKC, or H-89 (1 μ M), an inhibitor of PKA (Fig. 4). This suggests that HUHS2002 potentiates $\alpha 7$ ACh receptor channel currents by activating CaMKII.

HUHS2002 Activates CaMKII Due to PP1 Inhibition

Our next attempt was to obtain evidence for HUHS2002-induced CaMKII activation. To address this point, we

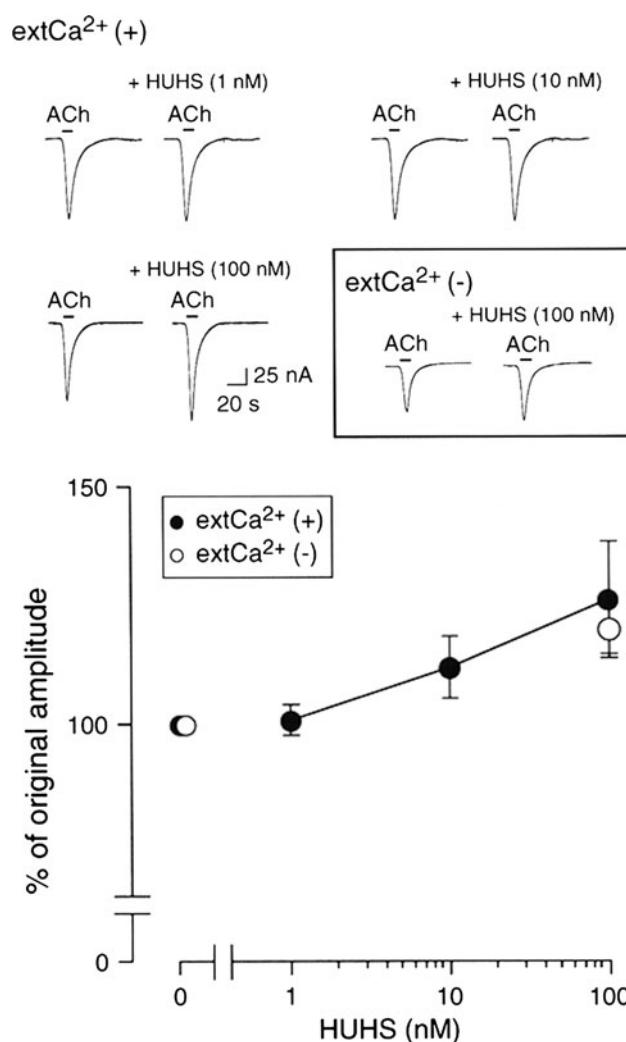

Fig. 3 HUHS2002 concentration-dependent potentiation of $\alpha 7$ ACh receptor currents. ACh (100 μ M)-evoked whole-cell membrane currents were monitored from oocytes expressing $\alpha 7$ ACh receptors 10 min before and 10 min after 10-min treatment with HUHS2002 (HUHS) at concentrations as indicated in Ca^{2+} -containing [ext Ca^{2+} (+)] and -free extracellular solution [ext Ca^{2+} (-)]. Typical currents are shown in the upper panel. In the graph, each point represents the mean (\pm SEM) percentage of original amplitudes (-10 min) ($n = 5$ –8 independent experiments)

assayed CaMKII activity with a reversed phase HPLC. HUHS2002 (100 nM) significantly enhanced CaMKII activity in cultured rat hippocampal neurons, and the HUHS2002 effect was significantly inhibited by KN-93 (3 μ M), an inhibitor of CaMKII, but not KN-92 (3 μ M), an inactive form of KN-93 (Fig. 5a). This provides evidence that HUHS2002 is actually capable of activating CaMKII. In the cell-free system, however, no activation of CaMKII was obtained with HUHS2002 at any concentration ranging from 1 nM to 10 μ M (Fig. 5b). This implies that HUHS2002 does not directly activate CaMKII.

CaMKII is activated through its own autophosphorylation, but otherwise activated CaMKII is inactivated through

Fig. 4 HUHS2002-induced potentiation of $\alpha 7$ ACh receptor currents via a CaMKII pathway. ACh (100 μ M)-evoked whole-cell membrane currents were monitored from oocytes expressing $\alpha 7$ ACh receptors 10 min before and after 10-min treatment with HUHS2002 (HUHS) (100 nM) in the presence of GF109203X (GF) (100 nM), H-89 (1 μ M), or KN-93 (3 μ M). In the graph, each point represents the mean (\pm SEM) percentage of original amplitudes (-10 min) ($n = 5$ independent experiments)

dephosphorylation catalyzed by PP1. Then, we postulated that HUHS2002 might indirectly activate CaMKII by inhibiting PP1. In the cell-free PP1 assay, microcystin (1 μ M), an inhibitor of PP1, markedly suppressed PP1 activity (Fig. 6). Likewise, HUHS2002 (10 μ M) significantly inhibited PP1 activity (Fig. 6). Taken together, the results indicate that HUHS2002 could indirectly activate CaMKII by inhibiting PP1.

Discussion

In the present study, the free fatty acid derivative HUHS2002 potentiated currents through $\alpha 7$ ACh receptors expressed in *Xenopus* oocytes, and the effect was clearly inhibited by the CaMKII inhibitor KN-93. This indicates that HUHS2002 enhances $\alpha 7$ ACh receptor responses via a CaMKII pathway. To our knowledge, this is the first showing CaMKII-dependent enhancement in $\alpha 7$ ACh receptor responses.

To obtain evidence for HUHS2002-induced CaMKII activation, we assayed CaMKII activity. HUHS2002 activated CaMKII in cultured rat hippocampal neurons, but no activation of CaMKII was obtained under the cell-free conditions. This accounts for indirect CaMKII activation by HUHS2002. Then, the question addressing is how HUHS2002 activates CaMKII. PP1 is recognized to dephosphorylate and inactivate CaMKII. In the present study, HUHS2002 reduced PP1 activity under the cell-free conditions, although the inhibition was partial in comparison to the known inhibitor microcystin. This indicates that

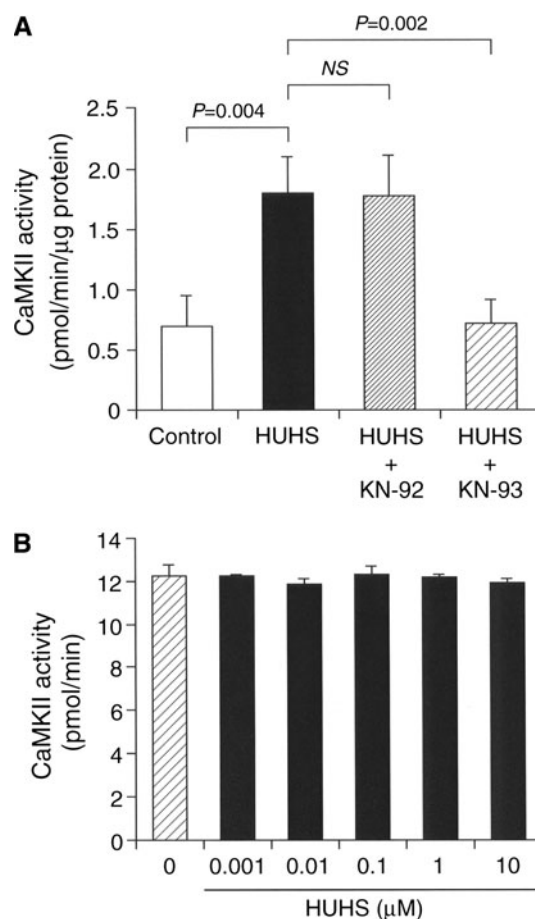

Fig. 5 HUHS2002-induced CaMKII activation. **a** Cultured rat hippocampal neurons were untreated or treated with HUHS2002 (HUHS) (100 nM) in the absence (Control) and presence of KN-92 (3 μ M) or KN-93 (3 μ M). Phosphorylated substrate peptide (pmol/min/ μ g cell protein) was used as an index of CaMKII activity. In the graph, each column represents the mean (\pm SEM) CaMKII activity ($n = 10$ independent experiments). P values, Dunnett's test. NS, not significant. **b** CaMKII activity was assayed under the cell-free conditions in the absence and presence of HUHS2002 (HUHS) at concentrations as indicated. In the graph, each column represents the mean (\pm SEM) CaMKII activity (pmol/min) ($n = 6$ independent experiments)

HUHS2002 is capable of activating CaMKII at least in part by inhibiting PP1. How HUHS2002 inhibits PP1, however, is presently unknown. A plausible explanation for this includes that HUHS2002 directly binds to and inhibits PP1 or HUHS2002 promotes transit from inactive inhibitor-1 to active inhibitor-1 through PKA phosphorylation, to suppress PP1 activity.

$\alpha 7$ ACh receptor has no CaMKII phosphorylation site [25], and therefore, the HUHS2002-induced potentiation of $\alpha 7$ ACh receptor responses is not due to modulation of the receptor channel properties through CaMKII phosphorylation. HUHS2002 might stimulate $\alpha 7$ ACh receptor exocytosis in a CaMKII-dependent manner, to increase membrane surface localization of the receptors, thereby

Fig. 6 HUHS2002-induced PP1 inhibition. PP1 activity was assayed in the cell-free systems in the absence (Control) and presence of microcystin (MC) (1 μ M) or HUHS2002 (HUHS) (10 μ M). In the graph, each column represents the mean (\pm SEM) PP1 activity ($n = 8$ independent experiments). P values, Dunnett's test

enhancing whole-cell $\alpha 7$ ACh receptor responses. A recent study, however, shows that inhibition of plasma membrane calcium-ATPase pump isoform 2 promotes internalization of $\alpha 7$ ACh receptor through a CaMKII-dependent mechanism [26]. It is presently unknown how CaMKII activated by HUHS2002 acts on $\alpha 7$ ACh receptors, to enhance the receptor responses. To address this question, we are probing CaMKII targets responsible for potentiation of $\alpha 7$ ACh receptor responses.

Evidence has pointed to the interaction of *cis*-unsaturated free fatty acids such as arachidonic, oleic, linoleic, linolenic, and docosahexaenoic acid with PKC [19]. We have found that a variety of *cis*-unsaturated free fatty acids and the linoleic acid derivative DCP-LA potentiate nicotinic ACh receptor responses by activating PKC [2, 4, 5, 8, 15–18]. In the preliminary study, HUHS2002 also activated PKC. HUHS2002-induced potentiation of $\alpha 7$ ACh receptor responses here, however, was not inhibited by the PKC inhibitor GF109203X, ruling out the implication of PKC in the HUHS2002 effect. Why PKC activated by HUHS2002 does not participate in potentiation of $\alpha 7$ ACh receptor responses remains to be explored.

In conclusion, the results of the present study suggest that the free fatty acid derivative HUHS2002 potentiates $\alpha 7$ ACh receptor responses by indirectly activating CaMKII at least in part due to PP1 inhibition. This may represent a novel pathway linking lipid signaling to $\alpha 7$ ACh receptor responses.

Macrophages Alter the Differentiation-Dependent Decreases in Fibronectin and Collagen I/III Protein Levels in Human Preadipocytes

Abstract Adipose tissue of obese individuals is characterized by increased fibrosis and macrophage infiltration. Extensive remodeling of the extracellular matrix (ECM) that occurs during adipogenesis can be influenced by macrophages, but it remains unclear how macrophage-secreted factors alter preadipocyte ECM protein expression under non-adipogenic versus adipogenic conditions. Confluent human subcutaneous abdominal preadipocytes were cultured for 14 days, with or without adipogenic inducers, in either control medium, medium conditioned by THP-1 monocytes (THP-1-MonCM), or medium conditioned by THP-1 macrophages (THP-1-MacCM). Under non-adipogenic conditions in THP-1-MacCM, collagen I/III and fibronectin protein levels rose by 40 and 70 %, respectively ($p < 0.05$, $n = 3$; compared to control non-adipogenic medium). When preadipocytes were exposed to adipogenic inducers in THP-1-MacCM, collagen I/III levels increased by 50 %, but those of fibronectin fell by 48 %, both compared to non-adipogenic THP-1-MacCM conditions. The rise in collagen I/III levels contrasts with the 51 % decrease in collagen I/III that occurs with induction of differentiation in control medium, whereas, the decrease in fibronectin is more modest, but consistent in THP-1-MacCM (48 %) and control medium (92 %). A similar effect on fibronectin levels occurred using medium conditioned by LPS-treated human monocyte-derived macrophages (MD-MacCM). Our data indicate macrophage-derived factors regulate levels of collagen I/III and fibronectin in preadipocytes

under non-adipogenic and adipogenic conditions. Further studies are needed to determine if these changes in these ECM proteins contribute to the anti-adipogenic action of MacCM.

Introduction

Under conditions of chronic nutrient excess, adipose tissue expands by hypertrophy and hyperplasia, the latter through a process of recruitment and differentiation of preadipocytes called adipogenesis [1]. A deficit in adipogenesis may arise in this context, resulting in exaggerated adipocyte

hypertrophy that is associated with insulin resistance and inflammation [2, 3]. Macrophages accumulate in adipose tissue of obese individuals [4–6], and they may negatively influence adipogenesis. Indeed, impairment of mouse and human adipocyte differentiation by macrophage-secreted factors has been previously reported by us and others [7, 8]. The mechanisms by which macrophages exert their anti-adipogenic effect remain elusive, but the extracellular matrix (ECM) could be a target.

The ECM is a physiological regulator of adipogenesis and adipose tissue remodeling [9–11]. The preadipocyte ECM consists mainly of fibrillar collagens (types I and III) and fibronectin. Upon differentiation, these proteins are down-regulated, and a laminar basement membrane structure emerges, mainly composed of collagen IV, entactin and laminin [12]. Matrix metalloproteinases (MMPs), tissue inhibitor of matrix metalloproteinases (TIMPs), and adhesion receptors of the integrin family influence adipogenesis [13–15]. Obesity is associated with a progressive elevation in the expression of several collagens, resulting in adipose tissue fibrosis [11].

Previous studies on the effects of macrophage-secreted factors on ECM protein expression have not clearly distinguished between changes occurring in the presence versus the absence of adipogenic inducers [8]. Here, we have examined the influence of human macrophage-secreted factors on the differentiation-associated changes in the levels of fibrillar collagens (I and III), and fibronectin in human preadipocytes. In particular, we have carefully compared the changes in these ECM proteins induced by macrophages under adipogenic versus non-adipogenic conditions.

Experimental Procedure

Cell Culture of Human THP-1 Macrophages and Preparation of MonCM and MacCM

As previously described [7], THP-1 monocytes were resuspended at 1×10^6 cells/mL in RPMI supplemented with 2 mM L-glutamine, 4.5 g/L HEPES, 1 mM sodium pyruvate, 10 % FBS, 0.05 mM β -mercaptoethanol, and antibiotics (100 U/mL penicillin and 0.1 mg/mL streptomycin). THP-1-monocytes were differentiated into adherent macrophages with 100 nM 12-*O*-tetradecanoylphorbol-13-acetate (TPA) for 24 h (>95 % conversion). The medium was then replaced with fresh growth medium (no TPA present) and, after another 24 h, the macrophage conditioned medium (THP-1-MacCM) was collected and centrifuged at $150 \times g$ for 5 min. Supernatants were transferred and frozen at -20°C until use. Medium conditioned by THP-1 monocytes (THP-1-MonCM), as well as medium

never exposed to THP-1 cells (control medium), were processed in parallel as controls.

Isolation and Culture of Monocyte-Derived (MD) Macrophages and Preparation of MD-MacCM

Blood was obtained from three healthy volunteers (approved by the Ottawa Hospital Research Ethics Board #2008445-01H). Blood samples were diluted with PBS supplemented with 2 mM EDTA and layered onto Ficoll-Hypaque (GE Healthcare; Uppsala, Sweden). Peripheral blood mononuclear cells were isolated by density-gradient centrifugation ($400 \times g$ for 30 min). The buffy coat was removed and placed in culture in RPMI supplemented with antibiotics, and monocytic cells were allowed to adhere for 1 h. Floating cells were then removed through several washes with PBS/2 mM EDTA; remaining adherent cells were placed in RPMI supplemented with 10 % FBS and antibiotics in the presence or absence of 1 $\mu\text{g/mL}$ LPS for 24 h to generate MD-MacCM and LPS-MD-MacCM. Each medium was collected, centrifuged at $150 \times g$ for 5 min, and the supernatant was frozen at -20°C until use. Medium supplemented or not with LPS, and not exposed to cells, was processed in parallel as control.

Isolation of Human Abdominal Subcutaneous Stromal Preadipocytes and Adipogenic Induction

Subcutaneous adipose tissue samples were obtained from six weight-stable female patients (age ranged from 34 to 53 years; BMI ranged from 22.4 to 43.1) undergoing elective abdominal surgery (approved by the Ottawa Hospital Research Ethics Board #1995023-01H). Patients receiving insulin or steroid treatment were excluded. Preadipocytes were isolated and differentiated as described [7]. In brief, adipose tissue was dissected away from connective tissue and capillaries, then digested with collagenase CLS type I (600 U/g of tissue). Preadipocytes, obtained following progressive size filtration and centrifugation, were grown in DMEM supplemented with 10 % FBS, antibiotics, and 50 U/mL nystatin (growth medium). For differentiation, preadipocytes were seeded on plastic dishes (immunoblot analysis) or on glass coverslips (immunocytochemistry) at 3×10^4 cells/cm² and grown to confluence in growth medium. Confluent preadipocytes were placed in THP-1-MacCM, THP-1-MonCM, MD-MacCM, or control medium supplemented or not with adipogenic inducers: 5 $\mu\text{g/mL}$ insulin, 100 μM indomethacin, 0.5 μM dexamethasone, and 0.25 mM isobutylmethylxanthine for 14 days. Cells were photographed and processed for triacylglycerol (TG) and protein measurement, followed by immunoblot analysis. Alternatively, cells seeded on coverslips were processed for immunocytochemistry.

Any contamination with macrophage or endothelial cells is <2 % under our culture conditions.

TG Assay

Cellular TG was extracted using a solution of 2:3 (vol/vol) isopropanol:heptane. TG accumulation was quantified using a colorimetric assay [7]. Cellular remains were solubilized in Laemmli buffer [16]. Protein was quantified using the modified Lowry assay (Bio-Rad Protein Assay Kit, Mississauga, Canada) with bovine serum albumin (BSA) as a standard. TG values were normalized to protein content.

Immunoblot Analysis

Following TG extraction, equal amounts of solubilized protein from the cellular remains were resolved by SDS-PAGE and transferred to nitrocellulose membrane. Membranes were blocked, then probed with primary antibodies directed against: collagen I/III (1/500, rabbit polyclonal; EMD Biosciences), fibronectin (1/10,000 mouse monoclonal; BD Biosciences), peroxisome proliferator-activated receptor γ (2 $\mu\text{g/mL}$, PPAR γ , rabbit polyclonal, Santa Cruz), fatty acid binding protein 4 (0.1 $\mu\text{g/mL}$, FABP4/ap2, goat polyclonal, R&D Systems), or extracellular

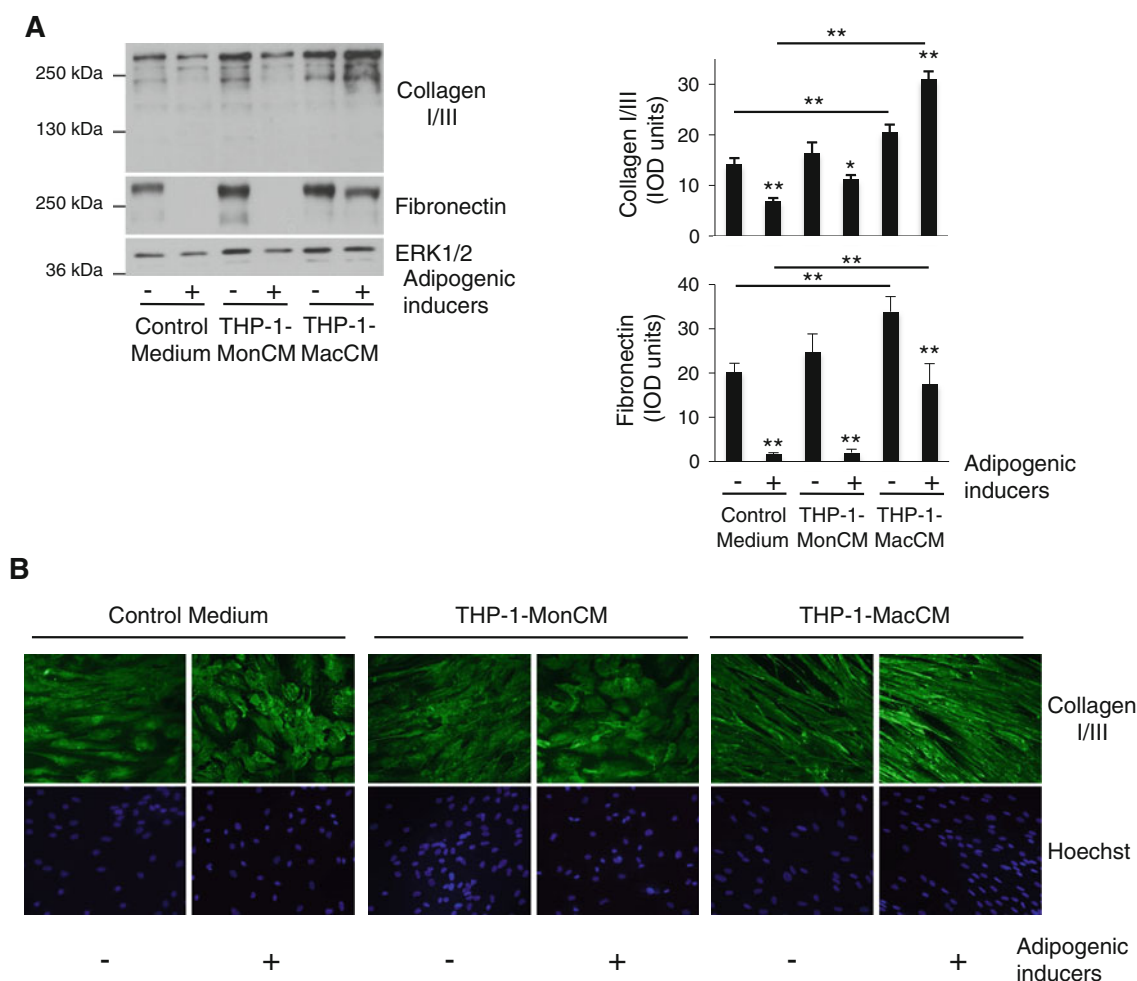

Fig. 1 Changes in levels of collagen I/III and fibronectin protein in preadipocytes cultured in THP-1-MacCM under non-adipogenic and adipogenic conditions. Confluent human abdominal subcutaneous preadipocytes were exposed (+) or not (-) to adipogenic inducers in control medium, THP-1-MonCM, or THP-1-MacCM for 14 days. **a** Solubilized protein was immunoblotted with the indicated antibodies. Representative immunoblots from one patient are shown. ANOVA with replications, followed by Tukey post-tests. ERK1/2 serves as a loading control. **b** Confluent human abdominal subcutaneous preadipocytes were seeded on glass coverslips prior to exposure (+) or not (-) to adipogenic inducers in control medium, THP-1-MonCM, or THP-1-MacCM for 14 days. Cells were fixed and stained with collagen I/III antibodies and Hoechst dye. Immunoreactivity was detected with AlexaFluor488-conjugated IgGs. Representative photomicrographs from one patient sample are shown. Similar results were obtained with three other patients

signal-regulated kinase 1/2 (0.5 $\mu\text{g/mL}$, ERK1/2, rabbit polyclonal, Chemicon). Following incubation with appropriate peroxidase-conjugated secondary antibodies (1:2,000 for PPAR γ , 1:10,000 for collagen I/III, and 1:50,000 for others), signal intensity was assessed by chemiluminescence and a digital imaging system. Quantitative results are expressed as integrated optical density (IOD) units.

Immunocytochemistry

Cells were fixed with methanol:acetone (3:7, v/v) for 15 min. Cells were extensively washed, and antigenic sites were blocked with PBS supplemented with 2 % BSA. Fixed cells were then incubated with collagen I/III antibodies (1:50) or blocking solution (non-specific) binding, followed by incubation with AlexaFluor488-conjugated secondary antibodies (1 $\mu\text{g/mL}$). Nuclei were stained with Hoechst dye, as previously described [17]. Coverslips were mounted on glass slides and fluorescence was visualized with a Zeiss Axioplan 2 microscope.

Results

The Effect of THP-1-MacCM on Levels of Collagen I/III and Fibronectin

We measured levels of collagen I/III and fibronectin protein in human preadipocytes that were cultured either in non-adipogenic or adipogenic conditions in either control, THP-1-MonCM, or THP-1-MacCM (Fig. 1a).

Under non-adipogenic conditions, THP-1-MacCM raised the levels of collagen I/III and fibronectin in preadipocytes, by 40 and 70 %, respectively, versus non-adipogenic control medium. THP-1-MonCM had no effect; the averaged ERK1/2 signal was significantly higher for this condition, but normalization did not alter the result that ECM protein expression is not affected by THP-1-MonCM.

Adipogenic induction in control medium led to a reduction in collagen I/III and fibronectin levels by 51 and 92 %, respectively, versus non-adipogenic control

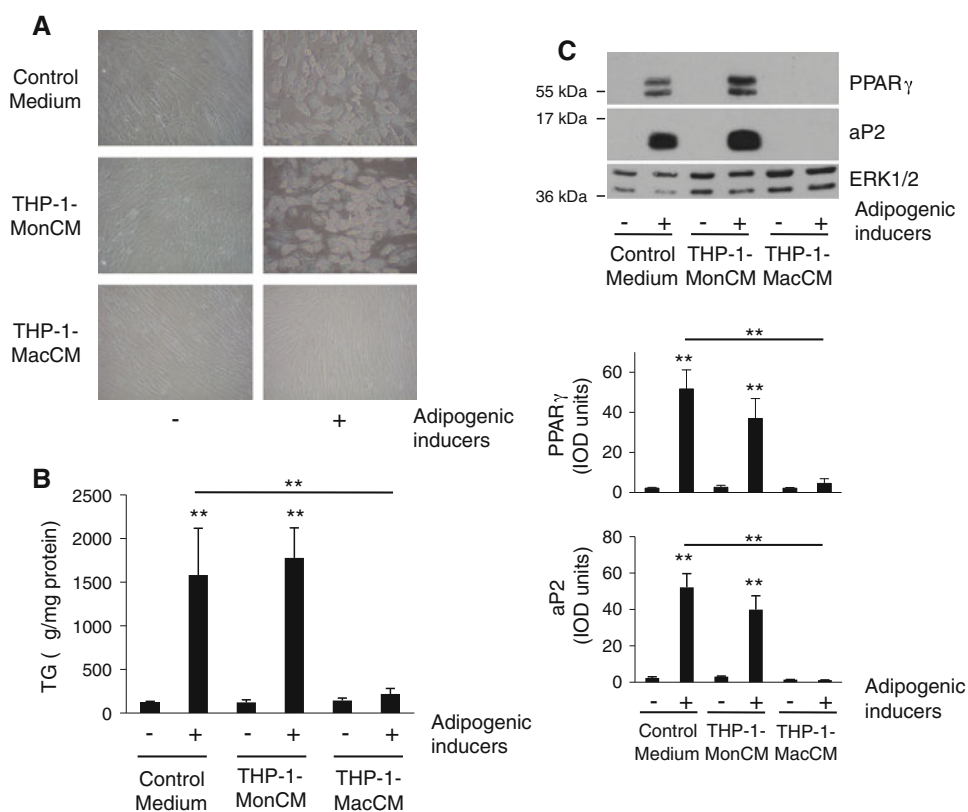

Fig. 2 The effect of THP-1-MacCM on human adipocyte differentiation. Confluent human abdominal subcutaneous preadipocytes were exposed (+) or not (–) to adipogenic inducers in control medium, THP-1-MonCM, or THP-1-MacCM for 14 days. **a** Representative photomicrographs for one patient sample are shown. Similar results were obtained with two other patients **b** TG was extracted, quantified, and normalized to protein content. Results are the mean \pm SE of

three separate patient samples. **c** Solubilized protein was immunoblotted with the indicated antibodies. Representative immunoblots from one patient are shown. Densitometric data are the mean \pm SE of three separate patient samples. $**p < 0.01$ compared to the same condition without adipogenic inducers or between indicated pairs, assessed by two-way ANOVA with replications, followed by Tukey post-tests. ERK1/2 serves as a loading control

conditions. When preadipocytes were exposed to adipogenic inducers in THP-1-MacCM, fibronectin levels followed a similar pattern, but to a more modest degree, falling by 48 %. This level of fibronectin was comparable to that of preadipocytes in non-adipogenic control medium. In contrast, collagen I/III levels did not decrease at all, but instead increased further by another 50 % in the presence of adipogenic inducers, compared to the timed non-adipogenic control condition.

Given the progressive rise of collagen I/III levels even in the presence of adipogenic inducers in the THP-1-MacCM, we assessed collagen I/III organization by immunocytochemistry in human preadipocytes under non-adipogenic and adipogenic conditions (Fig. 1b). Under non-adipogenic conditions, THP-1-MacCM induced a more elongated, spindly morphology of human preadipocytes compared to control or THP-1-MonCM. In the presence of adipogenic inducers, the cells in THP-1-MacCM were even more elongated and organized, in keeping with the progressive increase in collagen I/III noted by immunoblot analysis. Cells in control medium or THP-1-MonCM became more polygonal in shape, consistent with the adipogenic process that occurred under those conditions.

Concomitant with these effects on fibronectin and collagen I/III levels, adipogenesis was potently inhibited by THP-1-MacCM, but not THP-1-MonCM, as assessed by morphology, TG accumulation, and adipogenic gene expression (Fig. 2).

The Effect of LPS-MD-MacCM on Levels of Fibronectin

Although the human THP-1 cell line is a well-accepted model of human monocyte-macrophage biology [18, 19], we extended our studies to examine the effects of conditioned medium from primary human monocyte-derived macrophages that were or were not treated with LPS (Fig. 3).

Under non-adipogenic conditions, LPS-MD-MacCM had no effect on fibronectin levels compared to control medium. Addition of adipogenic inducers to the LPS-MD-MacCM caused fibronectin levels to decrease by 51 %, consistent with, but less potent than the 92 % reduction that occurred with adipogenesis in the control medium. LPS-MD-MacCM effectively inhibited adipogenesis, as assessed by morphology, TG accumulation, and adipogenic markers PPAR γ and aP2 (Fig. 4). MD-MacCM, generated without prior LPS treatment, had no effect on fibronectin levels compared to control medium, with or without adipogenic inducers, consistent with its inability to inhibit adipogenesis.

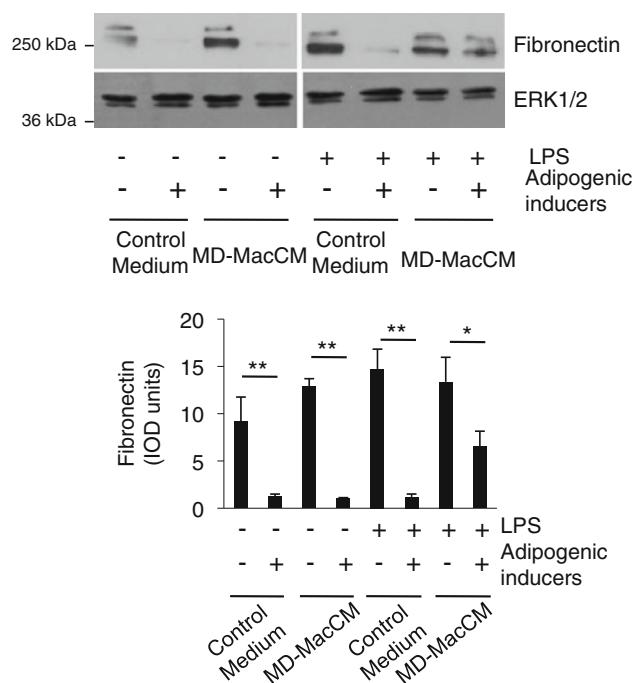

Fig. 3 Changes in levels of fibronectin protein in preadipocytes cultured in MD-MacCM under non-adipogenic and adipogenic conditions. Confluent human abdominal subcutaneous preadipocytes were exposed (+) or not (–) for 14 days, to adipogenic inducers in control medium or CM generated from adherent monocytes (MD-MacCM) activated or not with LPS. Solubilized proteins were immunoblotted with the indicated antibodies. Representative immunoblots from one patient are shown. Densitometric data are the mean \pm SE of three separate patient samples. * p < 0.05 and ** p < 0.01 between indicated pairs, assessed by two-way ANOVA with replications, followed by Tukey post-tests. ERK1/2 serves as a loading control

Discussion

Although the anti-adipogenic action of MacCM has been reported by several groups, using a variety of experimental models, the precise mechanism through which this occurs is not well-understood [7, 8, 20–22]. The ECM proteins produced by adipose cells have been suggested to be targets of MacCM [8, 23]. However, the effect of MacCM on preadipocytes in non-adipogenic versus adipogenic conditions has not been systematically studied. Therefore, we compared collagen I/III and fibronectin levels under both conditions, using human preadipocytes and two human macrophage models, THP-1 macrophages and primary monocyte-derived macrophages.

Previously, human preadipocytes treated with adipogenic inducers in the presence of macrophage-secreted factors for 10–12 days were reported to have higher levels of fibronectin protein compared to cells that were differentiated under control conditions [8]. However, their

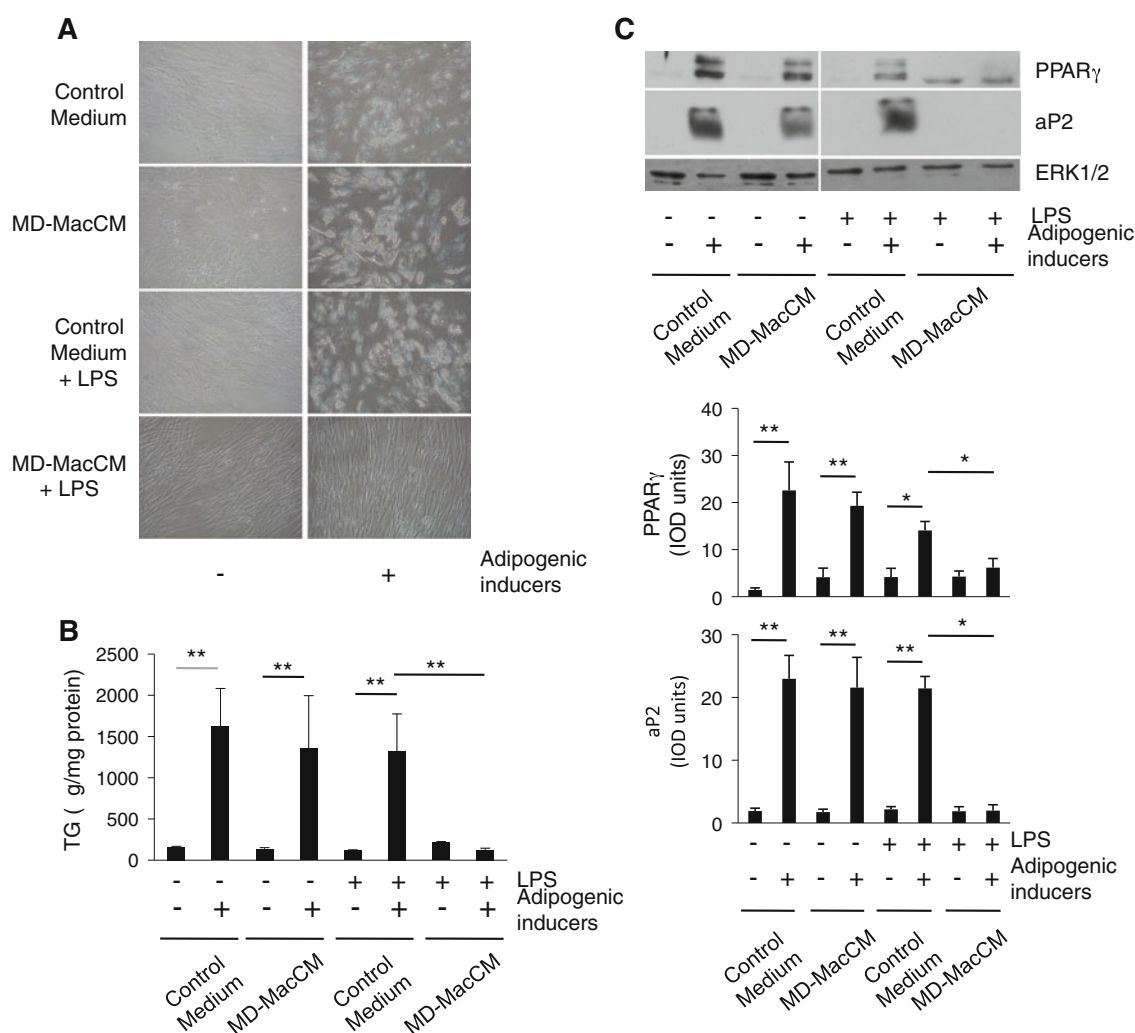

Fig. 4 The effect of human MD-MacCM on human adipocyte differentiation. Confluent human abdominal subcutaneous preadipocytes were exposed (+) or not (–) for 14 days, to adipogenic inducers in control medium or CM generated from adherent monocytes (MD-MacCM) activated or not with LPS. **a** Representative photomicrographs for one patient sample are shown. Similar results were obtained with two other patients. **b** TG was extracted, quantified, and

normalized to protein content. Results are the mean \pm SE of three separate patient samples. **c** Solubilized proteins were immunoblotted with the indicated antibodies. Representative immunoblots from one patient are shown. ERK1/2 serves as a loading control

analysis of the effect of the macrophages on fibronectin levels did not include a timed control study of preadipocytes cultured under non-adipogenic conditions. Therefore, the effect of macrophage factors on cellular fibronectin levels in non-adipogenic versus adipogenic conditions was not assessed. Here, we have undertaken this comparison using either THP-1-MacCM or MD-MacCM.

In the case of THP-1-MacCM, fibronectin levels rose under non-adipogenic conditions, whereas, with MD-MacCM, fibronectin levels remained constant. This difference could be due to variations in the quantity or type of factors released by the two macrophage models. With the results of this non-adipogenic timed control treatment as a comparator, it can be observed that fibronectin levels

are actually lower in preadipocytes cultured in either THP-1-MacCM or MD-MacCM in the presence of the adipogenic inducers. However, the reduction in fibronectin levels that occurs with adipogenic inducers in MacCM is weaker than in control medium. Over time, this results in relatively higher levels of fibronectin in preadipocytes in MacCM, compared to control medium, both under adipogenic conditions. A reduction in fibronectin levels is an established component of the adipogenic program [24]. The attenuation in the fall of fibronectin might be a direct effect of MacCM on fibronectin itself, but might also be an indirect consequence of the overall inhibition of adipogenesis caused by MacCM, perhaps through actions on other targets.

A reduction in fibrillar collagen is also a key part of the ECM remodeling that occurs with adipocyte differentiation [25]. Our comparison of non-adipogenic and adipogenic conditions demonstrates that THP-1 MacCM has a distinct effect on collagen I/III, promoting an ongoing rise in levels, even in the presence of adipogenic inducers. This was observed by immunoblot analysis and supported by cellular imaging. The basis for this divergence in behavior of collagen I/III versus fibrinogen in response to MacCM is not known at present. Examining the levels of these ECM proteins released into the medium by the adipose cells might also be informative. With the small number of donors in this study, there was no apparent effect of age or weight on the responses we measured; it is possible that such potential influences could be detected if the number of donors was larger. Due to detection problems for collagen I/III immunoblots using a smaller number of human preadipocytes to match the limited volume of MD-MacCM, we could not compare collagen I/III versus fibronectin for this model.

The expression of collagen I/III and fibronectin can be regulated by pro-inflammatory cytokines, such as tumor necrosis factor α (TNF α) and interleukin-1 β (IL-1 β), both found in MacCM. However, neutralization of these factors on an individual basis yields only minimal reversal of the inhibition of adipogenesis, despite a reduction in adipose cell inflammation [8, 22]. It remains possible that many factors released by macrophages, including Wnt molecules [26], are competent to prevent adipogenesis. ERK1/2 and NF- κ B signaling pathways are activated in preadipocytes exposed to macrophage-secreted factors, and their pharmacological inhibition reverses the negative effect of MacCM on adipogenesis [20, 27]. These pathways could be involved in the regulation of genes implicated in ECM remodeling. However, at this time, it is not known whether the inhibition of the anti-adipogenic effect of macrophage-secreted factors by interfering with these signaling pathways is linked to normalization of ECM protein levels. More work is needed to determine if the anti-adipogenic effect of MacCM depends on alterations in preadipocyte ECM proteins.

Our data using cell culture models of human macrophages and preadipocytes describe changes in ECM proteins under non-adipogenic and adipogenic conditions. They should be interpreted in context with in vivo adipose tissue remodeling, which involves complex interactions of its cellular population, including adipocytes, preadipocytes, and infiltrating immune cells. Macrophage-secreted factors not only alter the physiology of preadipocytes and adipocytes within the adipose tissue, they also modify the extracellular environment to promote a fibrotic state. The role of the altered ECM environment on preadipocyte growth survival, and differentiation, as well as on adipocyte function requires further investigation, and may be important for metabolic health.

Acknowledgments This work was supported by a grant to AS from the Heart and Stroke Foundation of Canada (Ontario) NA 6634. We thank Fiona Frappier and Dr. J B Angel (OHRI) for assistance with production of MD-MacCM, and patients and surgeons of The Ottawa Hospital for their participation in acquiring adipose tissue samples.

Abstract *Calanus finmarchicus* is the dominant zooplankton species in the North Atlantic. This zooplankton is also of interest for commercial harvesting due to its high abundance and biochemical contents. In the present study, copepodite stage V of *C. finmarchicus* was sampled at different depths from January to June in 2009, 2010 and 2011 in the Trondheimsfjord (63°29'N 10°18'E). The fatty acid composition was analyzed in individual copepods and in the seston. It was found that the fatty acid profile of copepods was related to the fatty acid profile of potential food sources. This study indicates that the onset of vertical migration of stage V, which was observed in May, has a strong link to the production of phytoplankton and lipid accumulation in *C. finmarchicus*. The content of 14:0 and 16:0 fatty acids in the specimens did not increase from February to May in surface waters. This suggests that these fatty acids in the diet were used as precursors for the biosynthesis of 20:1n-9 and 22:1n-11 fatty acids and fatty alcohols. A potential harvesting season of *C. finmarchicus* could be when the species is abundant in surface waters; the content of n-3 fatty acids will vary throughout this season. The peak abundance of *C. finmarchicus* in the spring varied substantially between the years studied.

Introduction

Calanus finmarchicus (Gunnerus, 1765) is the dominant zooplankton species in the Norwegian and Barents Seas [1]. The annual production in the Nordic Seas is roughly estimated to be 74 million tons by wet weight [2]. The copepod has a generation time of 1–2 years in the Norwegian Sea and a dormancy period in deep waters during the winter [3, 4]. *C. finmarchicus* hatch as nauplius larvae and progress through six naupliar stages and five copepodite stages before reaching sexual maturity. The females spawn at the time of the spring bloom, and the offspring feed to obtain large lipid deposits in summer and autumn [5]. The storage lipids of late copepodites and adults are in the form of wax esters, which are fatty acids esterified with fatty alcohols. Wax esters are the most common storage lipids in herbivorous zooplankton feeding on short blooms of phytoplankton followed by long periods of food shortage [6]. The phospholipids mainly consist of phosphatidyl choline and phosphatidyl ethanolamine [7] and contain a high proportion of the fatty acids 22:6n-3 and 20:5n-3 [8, 9].

Due to its abundance and biochemical components, *C. finmarchicus* is a promising marine raw material and an interesting source for commercial use. World aquaculture has grown steadily in the last 50 years, with an annual growth rate of 8.7 % (excluding China) since 1970.

Meanwhile, in the last 10–15 years, most global fisheries have become fully or overexploited, and the maximum sustainable catch has probably been reached, of which 20–30 % is used for animal feed [10]. Further growth in the aquaculture of carnivorous fish and crustaceans will require alternative sources of feed ingredients. Vegetable sources can replace part of the fishmeal and oil used today, but the need for n-3 long chain polyunsaturated fatty acids (LC-PUFA) like 22:6n-3 and 20:5n-3 will require new marine lipid sources [11, 12]. Harvesting zooplankton could be one alternative to meet the increased demand for n-3 LC-PUFA in the aquaculture industry. Atlantic salmon (*Salmo salar*) is capable of utilizing oil from *C. finmarchicus* in its diet [13–16], demonstrating the suitability of *C. finmarchicus* as a new marine ingredient in fish feed. Phospholipids in *C. finmarchicus* have high proportions of 22:6n-3 and 20:5n-3, and could meet the dietary demands of early marine fish larvae, as they require phospholipids [17] in addition to a high content of 22:6n-3 and 20:5n-3 fatty acids [18]. Moreover, there has been increasing awareness of the importance of marine lipids in human nutrition, and beneficial health effects have been documented for the consumption of n-3 LC-PUFA, which are mainly provided by marine lipids [19]. *C. finmarchicus* could also be an interesting additive for human nutrition. Wax esters from *C. finmarchicus* have a low melting point and contain long chain, monounsaturated fatty alcohols, which make this material interesting for cosmetics, lubricants, and pharmaceuticals, as discussed by Sargent and Henderson [20].

In the present study, we examined the size and fatty acid content of copepodite stage V (C5) of *C. finmarchicus* sampled at different depths at a fixed location in the Trondheimsfjord (63°29'N 10°18'E), from January to June in 2009–2011. The main food sources of zooplankton are phytoplankton and protozoa. The stock and condition of *C. finmarchicus* will therefore naturally be affected by changes in phytoplankton composition. In the Trondheimsfjord, the first spring bloom consists mainly of diatoms, while later, dinoflagellates and flagellates dominate the bloom [21]. The dominant fatty acids of diatoms are 16:0, 16:1n-7 and 20:5n-3 [22], whilst dinoflagellates have variable levels of 16:0, 18:4n-3, 18:5n-3, 20:5n-3 and 22:6n-3 [23, 24]. The profile of the fatty acids in the wax esters of *C. finmarchicus* will reflect the fatty acid composition of the dietary phytoplankton [25], but copepods are also dispersed by currents, which provides spatial and depth variation.

In addition to dietary fatty acids, *C. finmarchicus* are capable of de novo synthesis of fatty alcohols from carbohydrates and proteins [26]. Wax esters contain fatty alcohols synthesized de novo, esterified with fatty acids, and the fatty alcohols contain fairly stable content of 20:1n-9 and 22:1n-11 [27, 28] in addition to 14:0 and 16:0, while their fatty acid composition partly reflects the diet of the

copepods. The fatty acids 20:1n-9 and 22:1n-11 are also a prominent component of wax esters [20, 27] and are synthesized de novo by *C. finmarchicus* [26]. However, field observations for documenting biosynthesis are scarce and more detailed information from both field and laboratory studies are needed.

The fatty acid composition of *C. finmarchicus* at different depths could also provide more information on the vertical migration and dormancy of this copepod in the Trondheimsfjord. This zooplankton needs sufficient lipid storage to overcome dormancy and to undertake vertical upward migration, molting and the production of gonads [29]. A threshold lipid level is among several theories suggested as a trigger for vertical migration and dormancy in *C. finmarchicus* [30].

The aim of the present study was to study the lipid variations in *C. finmarchicus* from January to June, before and during the spring phytoplankton blooms, in the Trondheimsfjord. The copepods sampled from different depths were compared on the individual level with regard to fatty acid composition and size, and compared to the fatty acid profile of the phytoplankton present at the time of collection.

Materials and Methods

Sampling Procedure

Plankton samples were collected in 2009, 2010 and 2011 (Table 1) at a fixed position in the Trondheimsfjord (63°29'N 10°18'E) between 10:00 h and 14:00 h, from the vessel R/V Gunnerus. The sample location was chosen because it is fairly representative of the water masses in the main body of the fjord [31]. The samples were collected using a multiple opening and closing net system (patent no. NO318542, square opening 0.0625 m², 200-μm mesh) mounted on a conductivity temperature depth instrument (CTD, Seabird Electronics Inc., USA). The multinet was hauled vertically and each separate net was opened and closed at selected depth intervals (440 (seabed)–300 m, 300–100 m, 100–50 m and 50–0 m) operated by an on-board control unit. The sampling was repeated three times for the subsequent analyses.

Samples for the determination of species, stage composition and enumeration for an estimate of abundance and stage composition were preserved with buffered formalin (4 %) in seawater and stored at room temperature.

Samples for lipid analysis of *C. finmarchicus* were collected as described above, but kept alive in containers with seawater until arrival at the laboratory for further subsampling (10 °C). Viable *C. finmarchicus* from each depth range (5–10 individuals), if available, were then transferred

Table 1 Overview of the sampling dates of copepods for lipid analyses and biometric measurements and the seston for lipid analyses in 2009–2011

to vials and stored at -80°C under a nitrogen atmosphere (N_2) until analysis.

Samples for biometric measurements using image analysis were collected as described above and kept in containers of seawater (approximately 20 L) until arrival at the laboratory for further processing. The containers were placed at 4°C ($\pm 2^{\circ}\text{C}$) until sampling for biometry.

Seston samples for lipid analysis (Table 1) of the surface water were obtained from seawater pumped from a depth of approximately 1.5 m into a reservoir. The water was screened through a plankton net (mesh size $200\text{ }\mu\text{m}$) before feeding into a flow-through centrifuge by gravity at a flow rate of $0.65\text{--}0.85\text{ L min}^{-1}$. The centrifuge was spun at 5,500 rpm, and the seston was removed from the centrifugal bowl ($D = 10.5\text{ cm}$) at intervals. Samples for lipid and fatty acid analysis were immediately frozen and stored

at -80°C under N_2 . Water samples collected at 0, 3 and 10 m for the analysis of chlorophyll *a* (Chl *a*) were collected using Niskin water bottles (30 L), screened with a plankton net (nominal $200\text{ }\mu\text{m}$) and kept in dark containers until filtration. The seston was harvested using Whatman GF/F glass fiber filters.

Analytical Procedure

Live *C. finmarchicus* were classified according to developmental stage under a dissecting microscope (Leica MZ6, Leica Microsystems GmbH, Wetzlar, Germany) based on morphological criteria [32] and size [33]. We did not separate *C. finmarchicus* from *C. helgolandicus* when sorting live copepods, but analyses of the curvature of the basiopod of the fifth pair of swimming legs in *Calanus* sp. from the fixed samples showed a very low abundance of *C. helgolandicus* (0–10 % compared to *C. finmarchicus*) [34, 35].

For biometric analysis *C. finmarchicus* was placed under a dissecting microscope (Leica MZ125, Leica Microsystems, GmbH, Wetzlar, Germany). Images were captured at fixed magnifications with a still-video camera (Sony DFW-SX900, Sony Corp, Japan) controlled by the software Fire-i v.3.01.0.111 (Unibrain Inc., San Diego, USA) operated by a computer after anesthetizing the copepods with tricaine methanesulfonate (FinquelTM, Argent Laboratories, Redmond, USA; 1.5 g/L stock solution in seawater) and orienting them in a fixed position. Biometric analysis of the copepods were done manually using the software ImageJ 1.43u (National Institutes of Health, Bethesda, USA) with the aid of a graphic tablet (Cintiq 12wx, Wacom Co. Ltd., Saitama, Japan). The volume of the oil sac and prosome was calculated according to Miller et al. [36] based on the measurement of the length of the prosome and oil sac as well as the corresponding area of the two compartments. The software was scaled by measuring an image on a calibration slide (E. Leitz, Wetzlar, Germany) captured at the same magnification as the copepods.

Chlorophyll *a* was extracted in methanol and quantified using a fluorometer (Turner Designs) according to Strickland and Parsons [37].

Total lipids of the seston were extracted and determined gravimetrically according to Bligh and Dyer [38] with modifications described by Jakobsen et al. [39]. Fatty acid methyl esters from extracted lipids were prepared according to Metcalfe et al. [40] and were analyzed in duplicate. A modified direct transmethylation procedure from Abdulkadir and Tsuchiya [41] was used to analyze the fatty acids of individual *C. finmarchicus*. Individual copepods were weighed (UMX2 Ultra-microbalance, Mettler Toledo, Columbus, USA), added to 0.5 mL isooctane with C19:0 as an internal standard (Nu-Chek Prep, Japan) followed by

0.2 mL 14 % BF_3 in methanol, and heated for 2 h (100 °C). The tube was cooled on ice, then 0.1 mL isooctane and 0.2 mL distilled water were added and mixed using a vortex mixer for 1 min. After centrifugation (1,640g, 3 min), the upper isooctane phase was transferred to vials and analyzed on a gas chromatograph (Perkin Elmer AutoSystem XL) running TotalChrom v.6.3.1 software (both Perkin Elmer Inc., Waltham, USA). The instrumental conditions were identical to those used in the study by Bergvik et al. [42]. Direct methylation for preparing the fatty acids of individual *C. finmarchicus* was validated by comparing with the conventional methods of Bligh and Dyer [38] and Metcalfe [40]. Five individuals of *C. finmarchicus* were analyzed by direct methylation and three batches with 10 individuals each were analyzed using the conventional method. Direct methylation showed a slightly higher content of total fatty acids compared to the conventional method, indicating that the method was more efficient at extracting fatty acids from *C. finmarchicus*.

Statistics

The Kolmogorov–Smirnov test was used to test for normality. Some groups of samples were not normally distributed even after log transformation, and the homogeneity of variances were not equal. Non-parametric analyses were therefore used for all the statistical analysis in this study. Kruskal–Wallis test was used to compare samples, and the Mann–Whitney *U* test was used to compare all samples for significant differences when the Kruskal–Wallis test indicated a significant difference ($P < 0.05$). The significance level for differences using the Mann–Whitney *U* test was adjusted with the Bonferroni correction and resulted in significance levels of $P < 0.008$ for six groups and $P < 0.013$ for four groups. The sample groups varied in size, and the lowest and highest number included in each group is specified in each figure. All statistical analyses were performed using SPSS Statistics v. 17.0 (SPSS Inc., Chicago, USA). Samples are presented as the mean and error bars indicate standard error of the mean (SEM). All figures were made using SigmaPlot v. 10.0 (Systat Software Inc., San Jose, USA).

Results

C. finmarchicus was sampled from January to June for 3 years (2009–2011) in the Trondheimsfjord at four different depth intervals. The concentration of chlorophyll *a* (Chl *a*) was also measured throughout the sampling period to follow phytoplankton biomass fluctuations. The females spawned early in the spring and the smaller stages of *C. finmarchicus* (copepodite stage 1–3) were registered in

April in all years of the study. The appearance of the smaller stages coincided with the maximum concentration of Chl *a*, although the Chl *a* concentration was low in 2010 compared to the other 2 years (Fig. 1a). The highest abundance of *C. finmarchicus* (sum of all stages) was observed in April

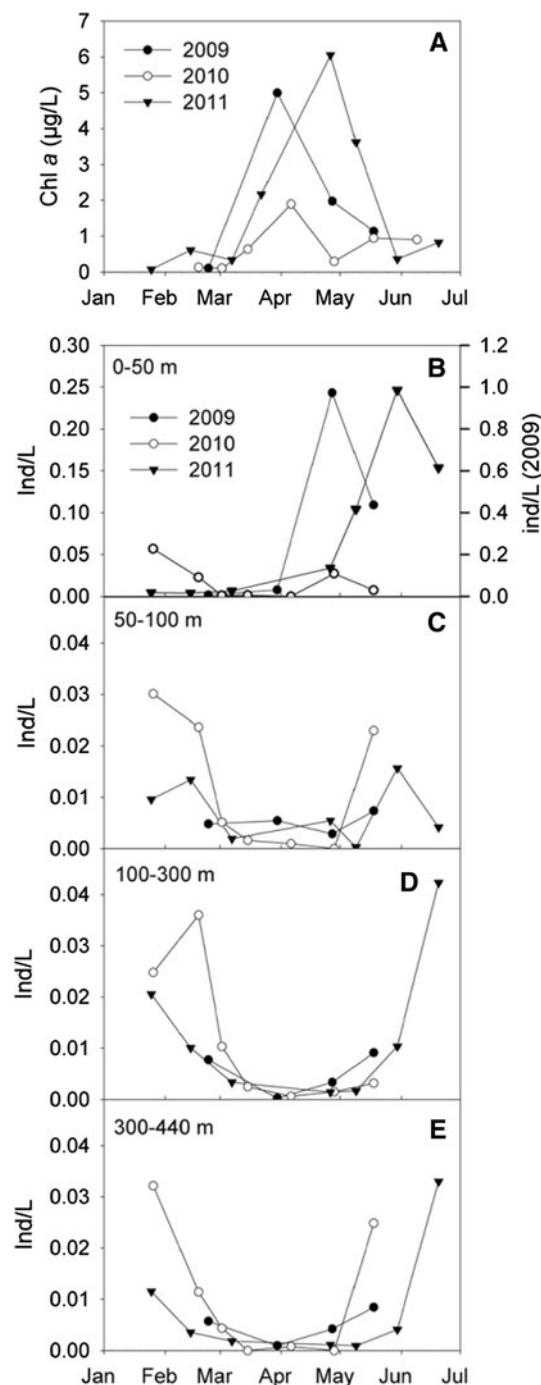

Fig. 1 Concentration of Chl *a* (µg/L) in the upper 10 m from January to June in 2009–2011 **a**. Abundance of *C. finmarchicus* (sum of copepodite stage 4 (C4), copepodite stage 5 (C5), females and males) (ind/L) at 0–50 m **b** from January to June in 2009–2011

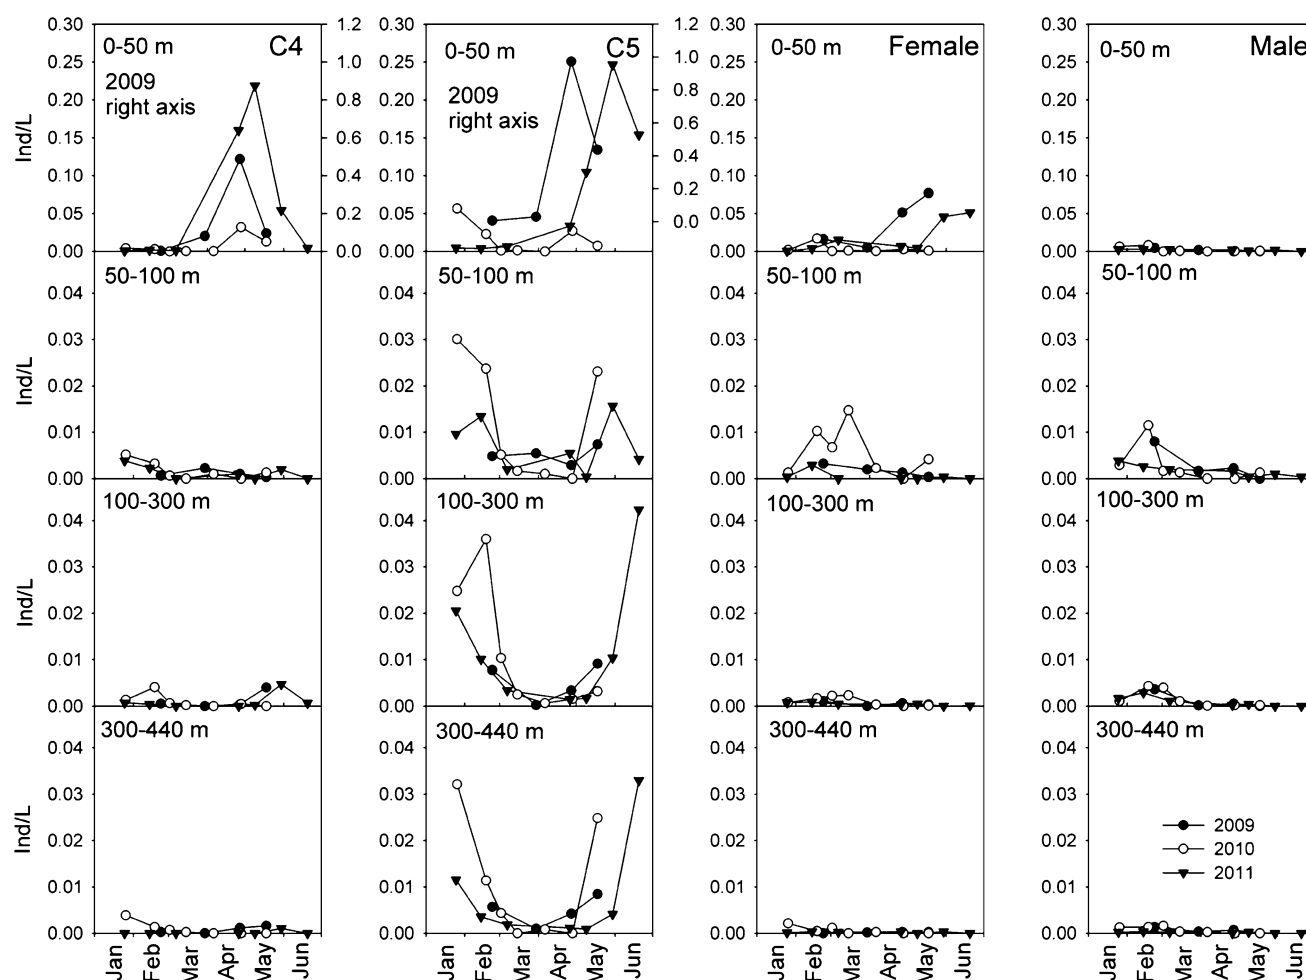

Fig. 2 Abundance of copepodite stage 4 (C4), copepodite stage 5 (C5), females (F) and males (M) (ind/L) at 0–50 m, 50–100 m, 100–300 m and 300–440 m from January to June in 2009–2011

and May in 2009 and 2011 (Fig. 1b), whereas there was a minimal number of *C. finmarchicus* in 2010, similar to the concentration of Chl *a*. The maximum numbers of *C. finmarchicus* were four times higher in 2009 compared to 2011. The concentration of chlorophyll *a* (Chl *a*) in the upper 10 m (Fig. 1a) was positively correlated with the abundance of *C. finmarchicus* in the upper 50 m; the phytoplankton bloom measured as Chl *a* was followed by an increase in the number of *C. finmarchicus*. The abundance of copepodite stage 4 (C4), copepodite stage 5 (C5), females and males (Fig. 2) in the surface (0–50 m) shows that C4 and C5 peaked in late April and May in all years. Following the peak of C5, there was a smaller peak of females, simultaneous with the increase in the number of C5 in deeper waters (50–440 m). The number of males was low and showed little variation, but a small increase was seen in February and March from a depth of 300 m to the surface. The females also showed a small increase in February and March. In January and February of all years, C5 resided mainly in intermediate and deeper layers, and were present

in low numbers in April and May, but increased again from May to June when some of the C5 started their migration to deeper layers. C5 was the dominant stage in the deepest layer. The variation between years in the numbers of C5 at intermediate depths and close to the seabed were not as pronounced, compared to the variation at the surface.

The total lipid content (Fig. 3a) and total fatty acid (TFA) content (Fig. 3b) of the seston showed pronounced variations both through the year and between years. The lipid content was highest in April 2009, in May 2010 and in June 2011 and ranged from 2 to 12 % dry weight (dw). TFA comprised on average 29 % of the total lipids.

The average content of total fatty acids (TFA, mg/g dw) in C5 from both 0–50 m (Fig. 4a) and 300–440 m (Fig. 4b) did not change considerably from January to June in 2009–2011. The dry weight per individual C5 in the upper 50 m increased steadily from February to June (Fig. 4c). The dry weight in January was higher compared to February, but not statistically different from that in April to June (Fig. 4c). The dry weight of C5 close to the seabed

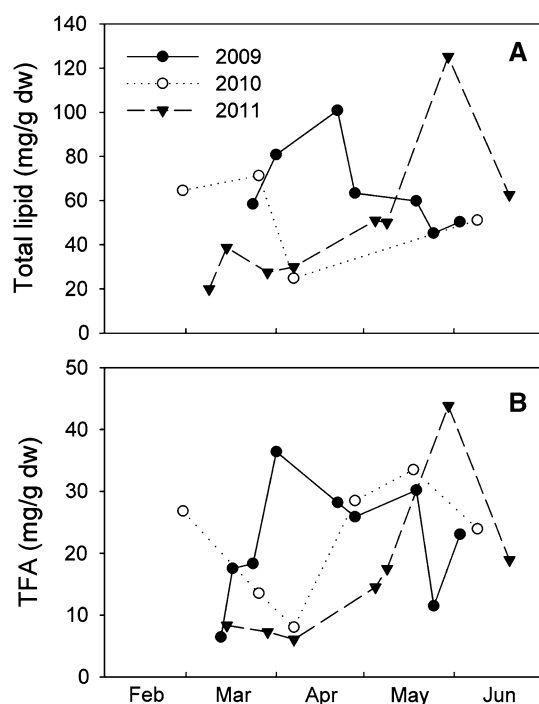

Fig. 3 Content of total lipids (mg/g dw) **a** and total fatty acids (TFA) (mg/g dw) **b** in the seston from March to June in 2009–2011

(300–440 m) also increased from January to May, but showed the same dry weight in June (Fig. 4d). The content of total fatty acids (TFA) per individual at the surface and close to the seabed showed a similar pattern of variation as the dry weight (Fig. 4e, f), and a correlation was found between individual dry weight and TFA content ($r_s = 0.87$, $N = 389$, $P < 0.001$) (Fig. 4g). The body volume of C5 also correlated with the oil sac volume ($r_s = 0.80$, $N = 393$, $P < 0.001$) (Fig. 4h). The dry weights of C5 were significantly lower at the surface (0–50 m) compared to both at intermediate depths and close to the seabed (Fig. 5a). The same trend was apparent for the mean body volume (Fig. 5b) and the individual content of TFA and the oil sac volume, which both increased from the surface toward deeper water layers (Fig. 5c, d).

The fatty acid composition of the seston showed a similar pattern of variation for all years, although with some variation between years (Fig. 6a). The dominant fatty acids in the seston were 22:6n-3, 20:5n-3, 18:4n-3, 16:1n-7, 18:1n-9, 18:0, 16:0 and 14:0. The fraction of the flagellate fatty acid, 18:4n-3 showed the highest variation between years, with a share of 18:4n-3 of 5 % in 2010 and 25 % in 2009. The content of the diatom fatty acid 16:1n-7 showed the same pattern in the spring in all 3 years, with a higher content in the middle of April and at the start of June.

The content of the n-3 polyunsaturated fatty acids (PUFA) 22:6n-3, 20:5n-3 and 18:4n-3 in the surface C5 individuals decreased from January to February, but

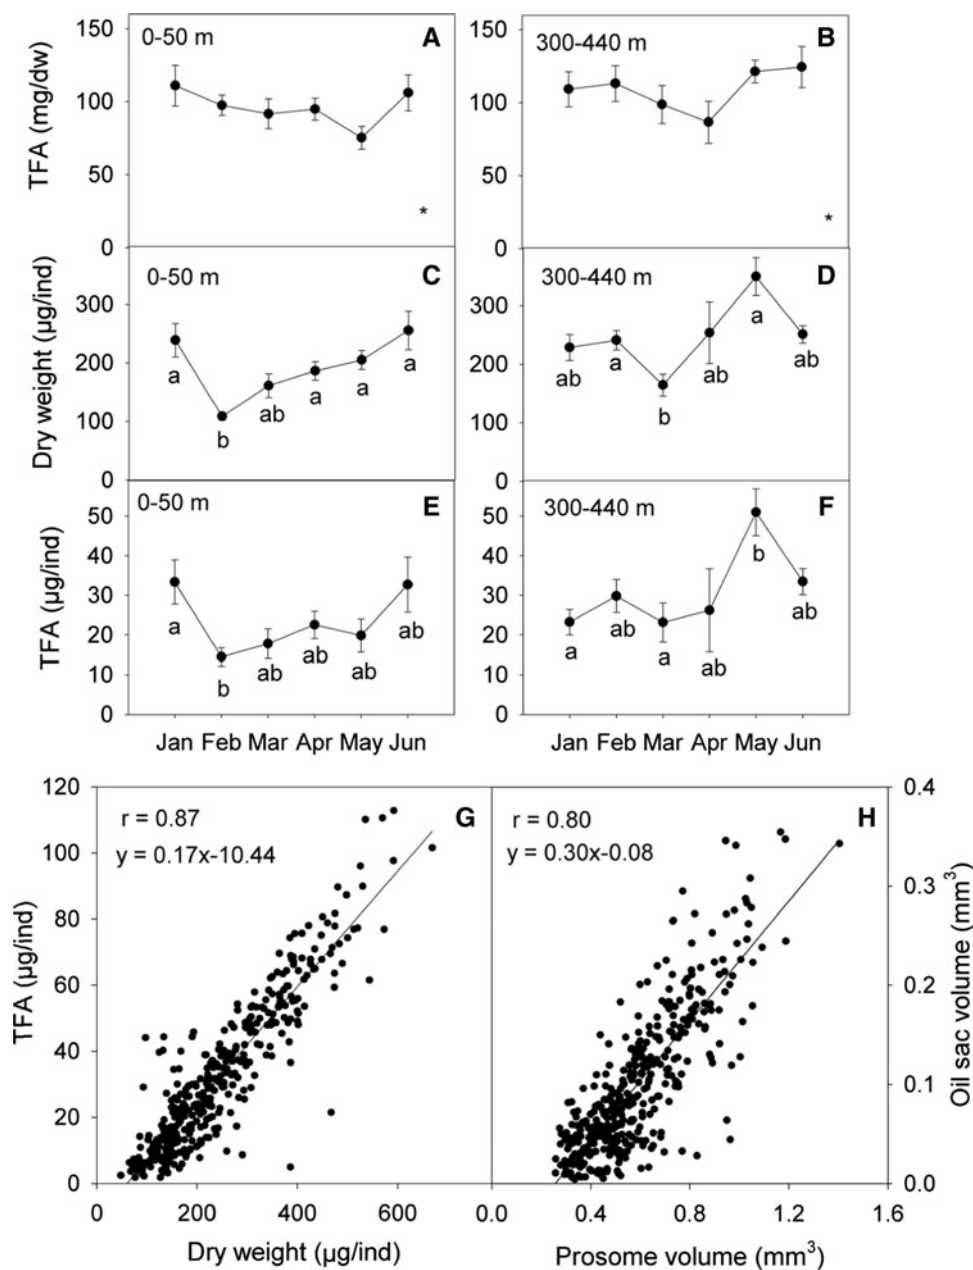

increased from February to March and remained relatively stable until June (Fig. 6b). The content of 16:1n-7, 18:1n-9, 14:0 and 16:0 decreased from January to February and increased again in June. The minor fatty acids constituting on average less than 1 % of TFA are not presented. The content of the different fatty acids in C5 close to the seabed (Fig. 6c) showed a general increase in fatty acids originating from the diet. The fatty acids 16:1n-7 and 18:4n-3 are fatty acids derived from diatoms and flagellates, respectively. Most evident was the increase in 18:4n-3 in April, May and June, reaching 13 % of TFA from zero, suggesting that surface C5 that had grazed on the spring bloom of phytoplankton had migrated toward the seabed. An increase was also seen in the content of 22:6n-3, 20:5n-3 and 16:1n-7 in May. The content of 18:1n-9, 14:0 and 16:0 showed no significant differences from January to June.

The content of 20:1n-9 and 22:1n-11 in C5 at the surface declined from January to February (Fig. 7a, c). From February to June, there were no changes in the content of these fatty acids at a depth of 0–50 m, but we found a higher level of 20:1n-9 and 22:1n-11 close to the seabed (Fig. 7b, d). There was a significant increase in 20:1n-9 and 22:1n-11 from the surface to deeper waters (Fig. 7e).

The fraction of n-3 PUFA of TFA (Fig. 8a) in C5 *C. finmarchicus* declined from January to February, followed by a 61 % increase in March. The percentage composition remained unchanged until a decline took place in June. The decline from January to February was caused by a reduced content of 18:4n-3, while the contents of the fatty acids 20:5n-3 and 22:6n-3 did not change. The fatty acid 20:5n-3 was the cause of the considerable increase in n-3 PUFA from February to March, while 22:6n-3 gradually increased until May. The proportion of mono-unsaturated fatty acids (MUFA) (Fig. 8b) in C5 decreased slightly from January to April, after which it remained unchanged. The percentage content of 20:1n-9 and 16:1n-7 did not change much over this period, but the proportion of 22:1n-11 showed a similar pattern of variation over time as MUFA.

The dry weights of C5 at each depth in the individual months are shown in Fig. 9a. Similar for all months except March, the smallest amounts of C5 were found at the surface, and the largest were found at intermediate depths in January and June. The dynamics of 18:4n-3, 20:5n-3 and 22:6n-3 are shown in Fig. 9b. In January, the content of 18:4n-3 was low at all depths, while the content of 20:5n-3 and 22:6n-3 was higher and stable. In February, the content of these fatty acids decreased at all depths; this pattern was also seen with dry weight and lipid content (Fig. 9a). In March, the same fatty acids increased at the surface as fatty acids became available in the seston. In April, there was an increase in 18:4n-3, 20:5n-3 and 22:6n-3 in the intermediate layers, which could indicate the vertical migration of some C5 from the surface. In May, these fatty acids also

Fig. 4 Average total fatty acids ($\mu\text{g/g dw}$) in *C. finmarchicus* C5 in 0–50 m (a) and 300–440 m (b) from January to June in 2009–2011. Average dry weight ($\mu\text{g/ind}$) of *C. finmarchicus* C5 at 0–50 m c and 300–440 m (d) from January to June in 2009–2011. Average total fatty acids ($\mu\text{g/ind}$) in *C. finmarchicus* C5 at 0–50 m e and 300–440 m (f) from January to June in 2009–2011. Correlation ($r_s = 0.91$, $p < 0.001$, $N = 389$) between dry weight ($\mu\text{g/ind}$) and TFA ($\mu\text{g/ind}$) in all *C. finmarchicus* C5 in this study (g). Correlation ($r_s = 0.80$, $p < 0.001$, $N = 393$) between prosome volume (mm^3) and oil sac volume (mm^3) in all *C. finmarchicus* C5 with biometric measurements (h). Lower case letters indicate significant differences and stars indicate no significant difference. The sample sizes in a, c and e ranged from 10 to 36 individuals, and in b, d and f the sample sizes ranged from 5 to 20 individuals

increased in the deepest layer. The content of the fatty acids 20:1n-9 and 22:1n-11 in C5 (Fig. 9c) was lower at the surface in all months. The content at the surface decreased from January to February, but remained high in deeper layers. In March, the content of 20:1n-9 and 22:1n-11 also decreased in deeper layers. In April and May, the content of these fatty acids increased in deeper layers, but remained low at the surface.

Discussion

The content of lipids and fatty acids in C5 of *C. finmarchicus* in the present work revealed an interaction between

phytoplankton and *C. finmarchicus*, and that lipid and fatty acid accumulation in C5 could be the trigger for vertical migration in the spring. Several theories on the mechanism that triggers the onset of dormancy in *C. finmarchicus* have been suggested, in which food availability, temperature, photoperiod and lipid accumulation are among the suggested cues for entering dormancy [30, 43, 44]. In the present study, there was an increased abundance of C5 in deep waters (300–440 m) in May, indicating the start of vertical migration. We found that the individual size of C5 in surface waters was smaller than the individuals from deep waters, as found in previous studies [5, 45]. The total fatty acid content and volume of the oil sac of C5 also increased from the surface waters toward deeper waters.

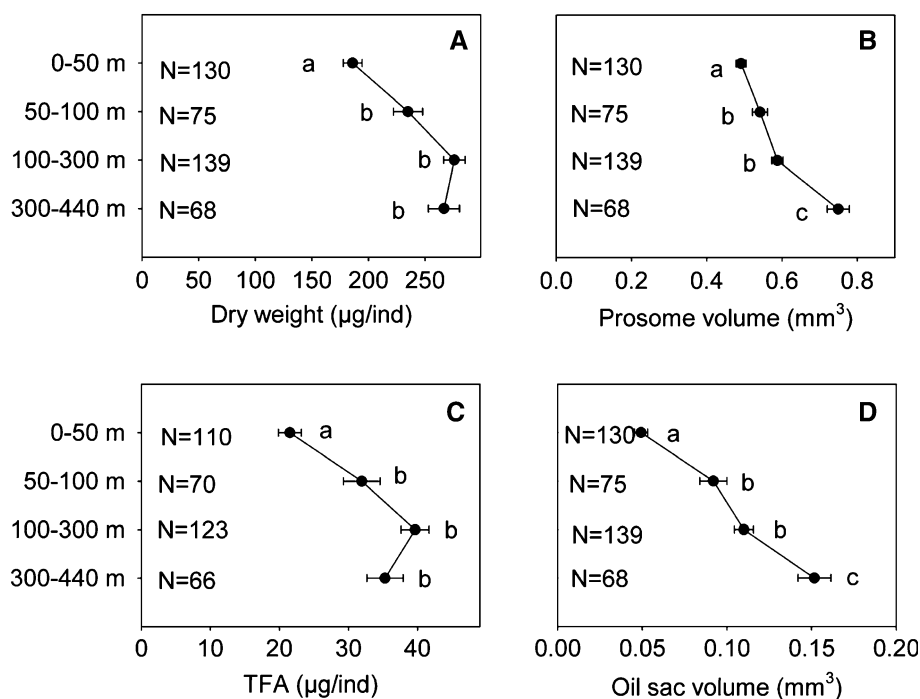

This has been observed previously for both C5 [29, 46, 47] and females [48], and Hirche [45] found larger C5 in deep waters compared to those residing in surface waters. *C. finmarchicus* is dependent on a large lipid reserve to survive dormancy, undertake upward migration, and to have enough energy for molting and gonad formation [29]. The size and lipid content at each depth in May increased both in the deepest layer as compared to the values in April. This suggests that C5 that migrating toward deeper layers had a higher lipid content and were bigger compared to the C5 remaining in the surface waters. The lipid level could thus be the trigger for vertical migration and the onset of dormancy, as discussed by Irigoien [30].

The fatty acid composition of C5 stages of *C. finmarchicus* can also contribute to a better understanding of the onset of dormancy and the relationship between *C. finmarchicus* and the phytoplankton present. The fatty acids of the seston clearly showed the signature fatty acids of diatoms and flagellates over the season (16:1n-7 and 18:4n-3 respectively), revealing a bloom of diatoms at the end of March and a bloom of flagellates at the beginning of June. Sakshaug and Mykkestad [21] found a bloom of diatoms in the Trondheimsfjord at the end of March both in 1970 and in 1971. Spring blooms of dinoflagellates were highly variable between the 2 years of their study, but dinoflagellate blooms followed the diatom blooms in both years. *C. finmarchicus* feeds mainly on phytoplankton, and the signature fatty acids of phytoplankton are directly incorporated in their wax esters [25, 49]. We found that 22:6n-3, 20:5n-3, 18:4n-3 and 16:1n-7 were the dominant fatty acids

Fig. 6 Composition of fatty acids (% of TFA) in the seston (a) from March to June in 2009–2011. Average content of fatty acids ($\mu\text{g}/\text{ind}$) in *C. finmarchicus* C5 from January to June at 0–50 m (b) and 300–440 m (c). In addition to 20:1n-9 and 22:1n-11, the composition of these fatty acids was on average over 1 % of TFA in *C. finmarchicus*. Lower case letters indicate significant differences and stars indicate no significant difference. The sample sizes in b ranged from 10 to 28 individuals and in c the sample sizes ranged from 5 to 19 individuals

from the phytoplankton that were incorporated into the C5 of *C. finmarchicus*. The increase in these fatty acids in *C. finmarchicus* was thereby related to the available fatty acids in the seston, indicating that both diatoms and dinoflagellates were important components of their diet. The importance of diatoms and flagellates in the diet of *C. finmarchicus* revealed as an increased content of the signature fatty acids (16:7n-1 and 18:4n-3 for diatoms and flagellates respectively), have been shown in several studies [47, 50]. The increase in the main n-3 PUFA, 18:4n-3, 20:5n-3 and 22:6n-3, in the deep waters close to the seabed was pronounced in May, suggesting that the deep water C5 had recently fed on phytoplankton at the surface. Most prominent was the content of 18:4n-3, which was nearly absent in January to March close to the seabed, but then reached 15 % of TFA in May. The content of 18:4n-3 and 20:5n-3 was in fact higher in C5 from deep waters compared to those in surface waters. This might suggest that when C5 copepods at the surface reach a certain content of wax esters after the accumulation of phytoplankton, they will migrate toward deeper waters. The onset of migration was about 1 month after the

Fig. 5 Average dry weight ($\mu\text{g}/\text{ind}$) (a), prosome volume (mm^3) (b), TFA ($\mu\text{g}/\text{ind}$) (c) and oil sac volume (mm^3) (d) in *C. finmarchicus* C5 at 0–50 m, 50–100 m, 100–300 m and 300–440 m. Lower case letters indicate significant differences and stars indicate no significant difference. *N* equals the number of replicates

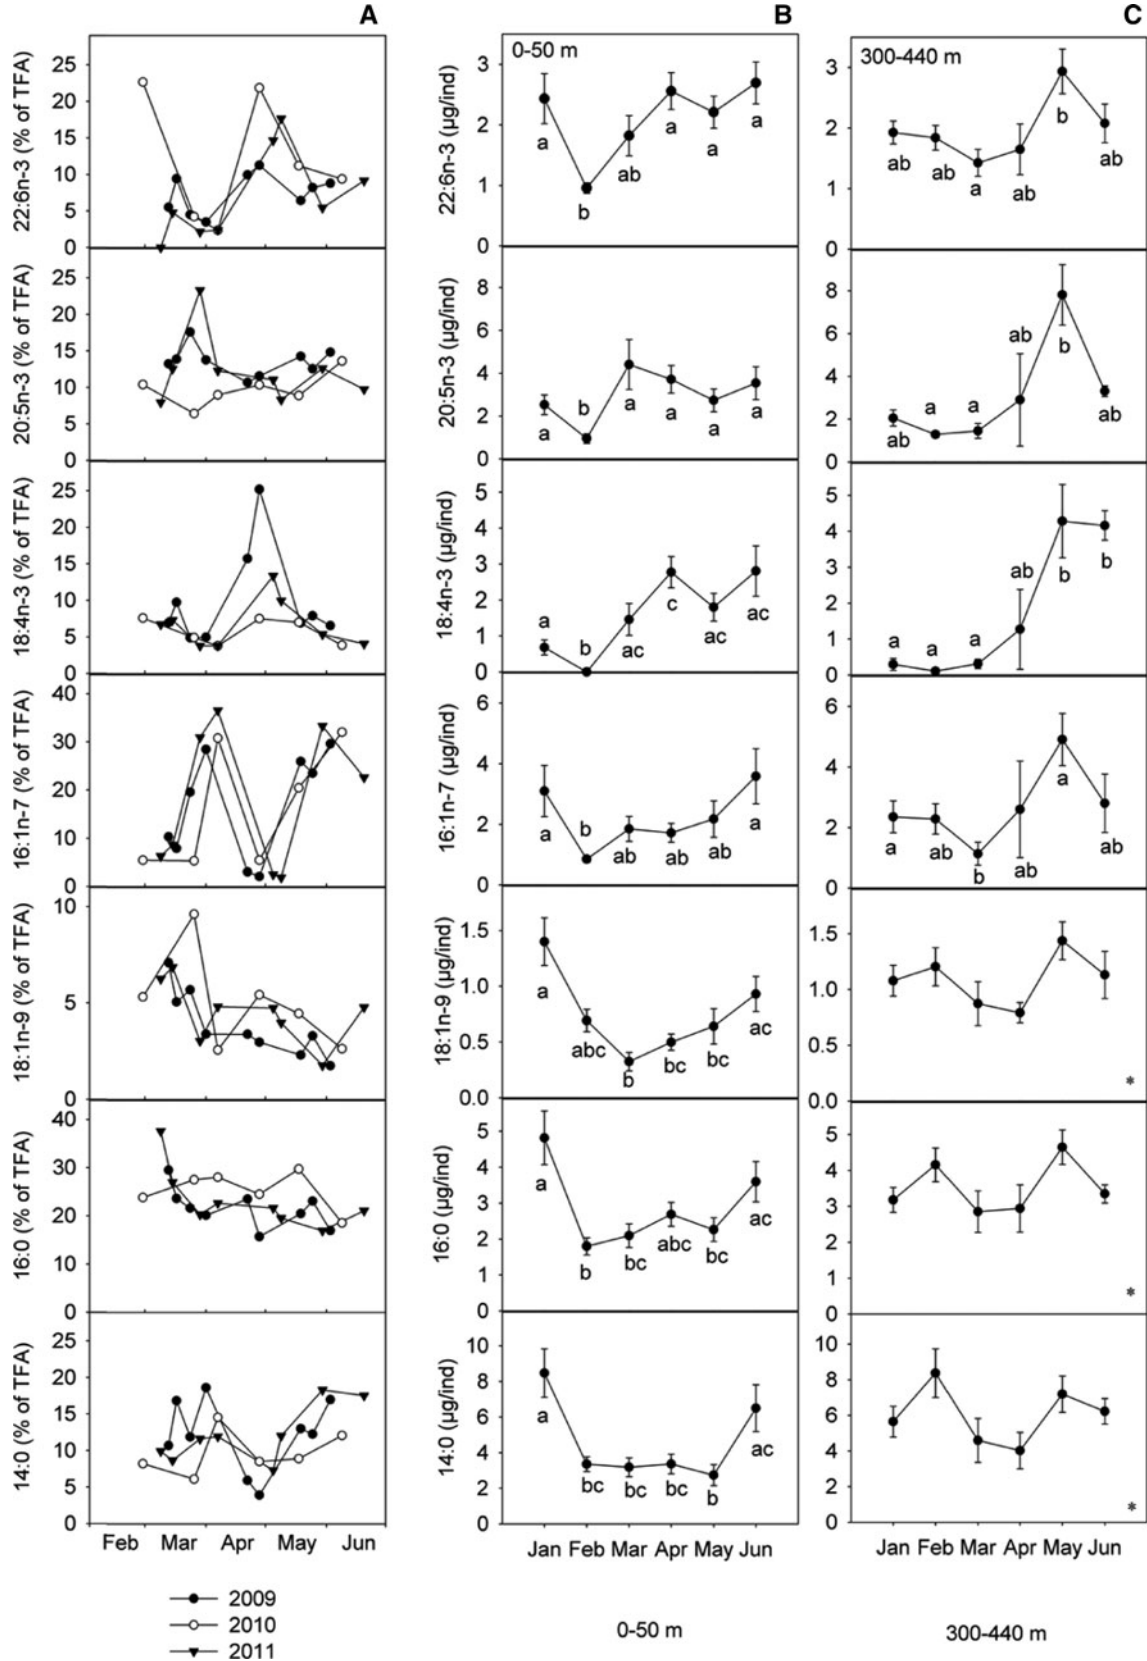

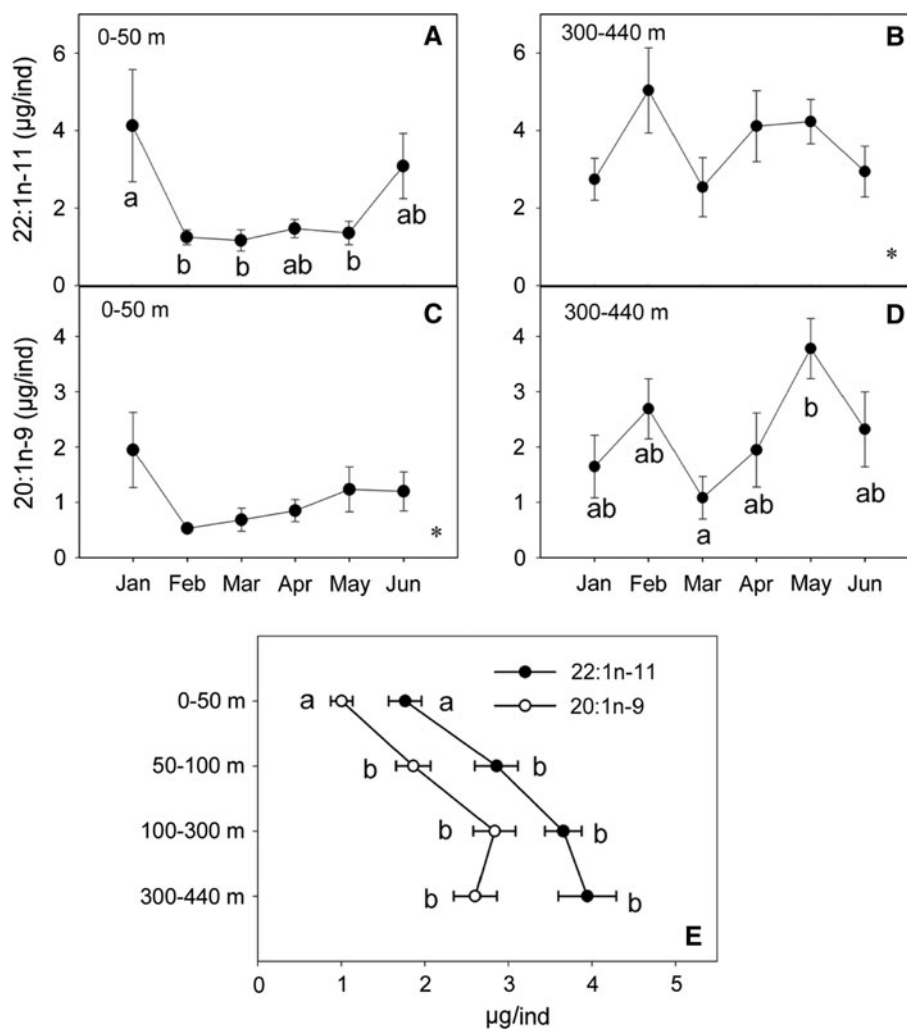

Fig. 7 Average content of the fatty acid 22:1n-11 in *C. finmarchicus* C5 from January to June through 0–50 m (a) and 300–440 m depth (b). Average content of the fatty acid 20:1n-9 in *C. finmarchicus* C5 from January to June through 0–50 m (c) and 300–440 m depth (d). Average content of 20:1n-9 and 22:1n-11 in C5 through all depths: 0–50 m, 50–100 m, 100–300 m and 300–440 m. Lower case letters indicate significant differences and star indicates no significant difference. The sample sizes in a and c ranged from 10 to 28 individuals, in b and d the sample sizes ranged from 5 to 19 individuals and in e the sample sizes ranged from 66 to 123 individuals

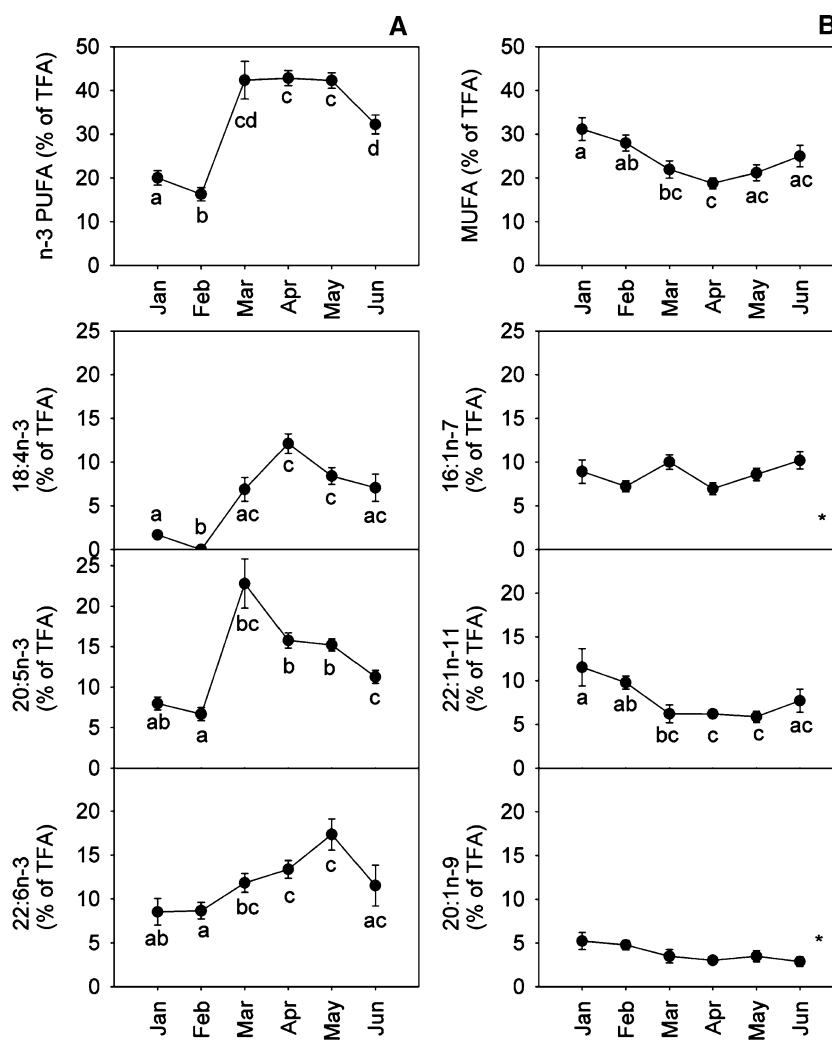

phytoplankton bloom, suggesting a strong link between the production of phytoplankton, lipid accumulation and the onset of migration.

Although some C5 descended to deeper waters in May, there was a concurrent increase in the number of females at the surface. This could indicate that while some C5 start their vertical migration, others molt to females, and was also found in the Irminger Sea [47]. We suggest that the lipid content will decide whether a C5 will migrate or molt. If the lipid content is above a certain level, the C5 will descend to deeper waters. If the requisite lipid level has not been reached, the C5 will molt to females which will start a new generation of *C. finmarchicus*. Miller et al. [36] found that large C5 in the surface waters in December molted to females while the smaller C5 remained in surface waters waiting for food until March, when they again found larger C5 which they attributed to a new generation of C5. The results from our study suggest that lipid accumulation has a strong connection with the onset of dormancy. Johnson et al. [51] did not find an environmental factor that

explained the onset of dormancy in *C. finmarchicus*, and suggested that lipid accumulation could be an explanation.

In our study, most of the fjord population of *C. finmarchicus* had ascended to the surface by March. C5 stages of *C. finmarchicus* that have ascended from deeper water will probably use their lipid reserves to molt into adults and develop gonads. Gatten et al. [52] showed that one half of the wax ester reserves in *C. helgolandicus* were utilized when C5 matured to females and formed gonads. Jonasdottir [29] also suggested that the main part of the lipid reserve was used for vertical migration and gonad formation in *C. finmarchicus*. The lipid content and the size of C5 in our study decreased from January to February, but this could also be the result of a lack of food at the surface. Copepods in surface waters have been shown to have a higher energy demand compared to copepods in deeper waters [5] because metabolism is slow during dormancy in deeper water [45]. Therefore, *C. finmarchicus* would have to catabolize wax esters to meet increased energy demand at the surface [53]. Other authors have also found a

Fig. 8 Fraction of n-3 polyunsaturated fatty acids (PUFA) (a) and monounsaturated fatty acids (MUFA) (% of TFA) (b) in *C. finmarchicus* C5 at 0–50 m from January to June in 2009–2011. The main n-3-PUFA and MUFA are also included. Lower case letters indicate significant differences and stars indicate no significant difference. The sample sizes in a and b ranged from 10 to 28 individuals

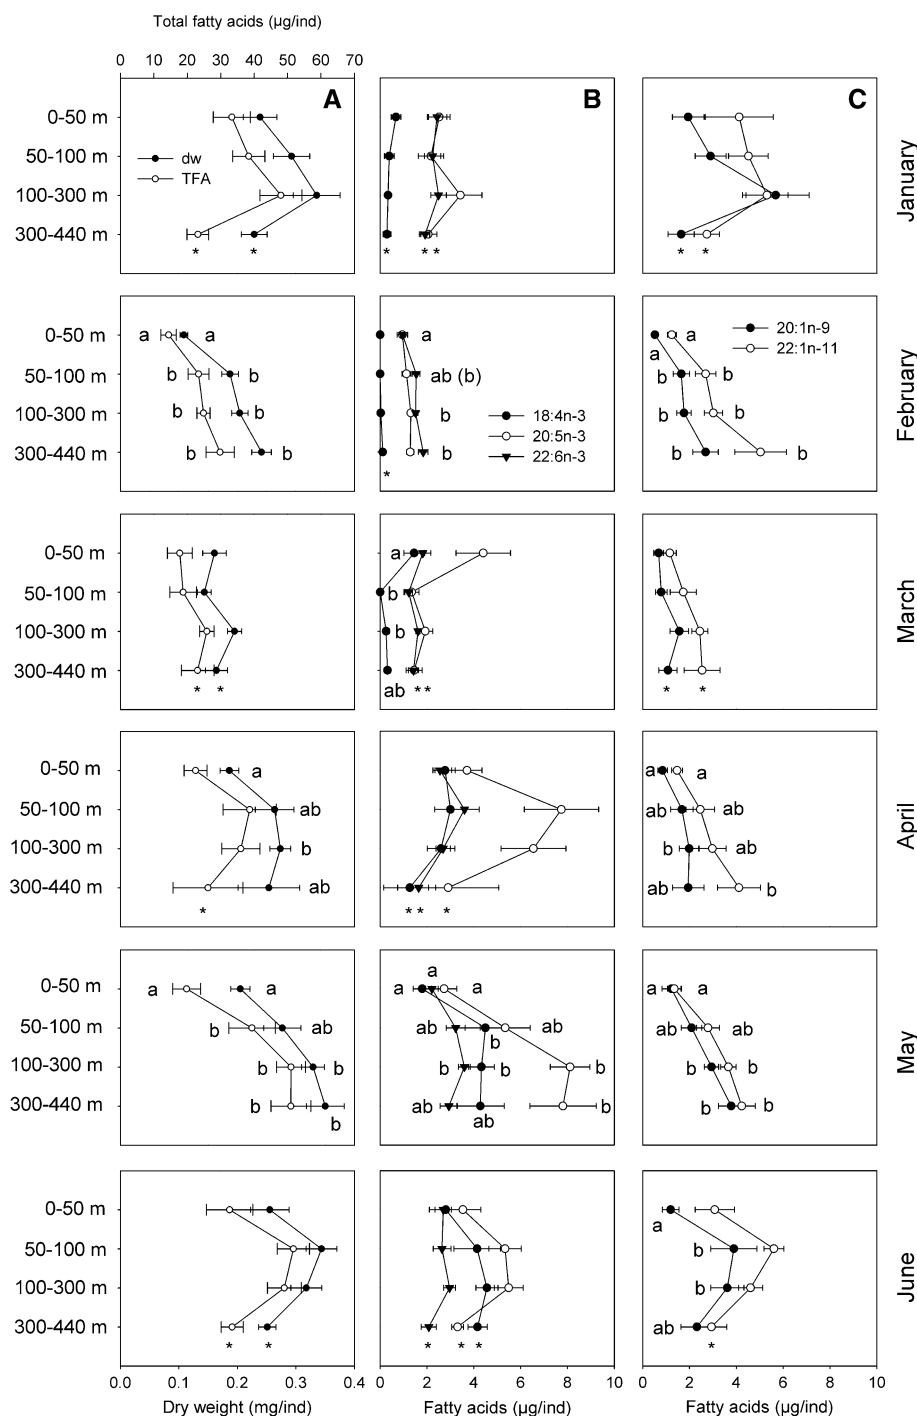

decrease in size and lipid content, but this occurred from December to January [29, 54, 55] and from February to May [46]. Irigoien et al. [56] also found a decrease in the carbon content of *C. finmarchicus* before the spring bloom appeared. Our data show a small increase in females at the surface and in intermediate waters and an increase in males in intermediate waters in February. We suggest that lipid-rich C5 ascend to the surface water and molt into females, while the remaining C5, with a lower lipid content, must wait for phytoplankton production in order to molt. The difference in the time of lipid depletion in the studies mentioned above could have been the result of different locations of study, which could result in a shift in the time for upward migration. An earlier upward migration would lead to an earlier depletion of lipids. Females have been shown to produce eggs prior to the phytoplankton bloom [57], suggesting that the lipid reserves are used for the production of eggs. However, Koski et al. [58] have shown that the fatty acid profile of eggs from *C. finmarchicus* resembled the fatty acid profile of the seston. The smaller copepodite stages (CI–CIII) were observed in April in all

3 years of our study, coincident with the phytoplankton bloom, suggesting that egg production took place before the phytoplankton bloom. The new generation of C5 may be present as soon as late April, given that a sufficient amount of food is present.

The content of the fatty acids 20:1n-9 and 22:1n-11 in individual C5 at the surface was low, but the content was significantly higher closer to the seabed. When *C. finmarchicus* accumulates energy reserves as wax esters in the spring, the formation of fatty alcohols is a necessary step of that synthesis. The proposed route of biosynthesis for fatty alcohols is the synthesis of fatty acids and further conversion of fatty acids into fatty alcohols by fatty acyl coenzyme A oxido-reductase [20, 59]. The production of wax esters by copepods is in fact thought to be limited by this synthesis of fatty alcohols from fatty acids [59, 60]. *C. finmarchicus* contains high amounts of the fatty alcohols 20:1n-9 and 22:1n-11 [27, 28, 61]. The fatty acids 20:1n-9 and 22:1n-11 are synthesized first with subsequent reduction to the corresponding fatty alcohols during lipid accumulation. The content of these fatty acids was scarce

Fig. 9 Dry weight (mg/ind), total fatty acids (TFA, $\mu\text{g}/\text{ind}$) (a), content of 18:4n-3, 20:5n-3 and 22:6n-3 ($\mu\text{g}/\text{ind}$) (b) and content of 20:1n-9 and 22:1n-11 ($\mu\text{g}/\text{ind}$) (c) in C5 of *C. finmarchicus* at 0–50 m, 50–100 m, 100–300 m and 300–440 m from January to June. Note the two x-axes in a, where dry weight is indicated by the lower x-axis and TFA is indicated by the upper x-axis. All numbers are the average of values from 2009 to 2011. The sample sizes ranged from 10 to 15 in January, 13–25 in February, 12–26 in March, 5–27 in April, 19–36 in May and 5–10 in June

during the phase of lipid accumulation in surface waters in the present study, and we can assume that all of the synthesized 20:1n-9 and 22:1n-11 was converted to the fatty alcohols 20:1n-9 and 22:1n-11. When *C. finmarchicus* descends to deeper waters, the copepods have accumulated enough wax esters to enter dormancy and to hibernate through the winter. They no longer require biosynthesis of fatty alcohols and they may instead accumulate the fatty acids 20:1n-9 and 22:1n-11 in their wax esters. The present

study shows that the content of long-chain MUFA increases in copepods at depths of 50–100 m and more.

The fatty acids 20:1n-9 and 22:1n-11 are thought to be synthesized de novo from carbohydrate- and protein precursors [6] with the intermediates 14:0, 16:0 and 18:0, which are further elongated and desaturated to form 20:1n-9 and 22:1n-11. Also, Henderson and Sargent [62] have shown that the carnivorous copepod *Euchaeta norvegica* uses glucose and amino acids in the de novo biosynthesis

of fatty alcohols. In the present study, 14:0, 16:0 and 18:0 were present in the phytoplankton at high levels, e.g. the content of 18:0 was 20 % of TFA in March and April and the content of 14:0 and 16:0 was on average 30–50 % of TFA throughout the sampling period. The content of these fatty acids in the copepods, however, did not increase from February to May and the content of 18:0 was scarce. At the same time, the contents of 18:4n-3, 20:5n-3 and 22:6n-3 in the copepods increased, suggesting that phytoplankton was ingested. The saturated fatty acids 14:0 and 16:0 could then either be catabolized for energy or they could be used as precursors for fatty alcohol synthesis of the longer mono-unsaturated fatty alcohols, 14:0 and 16:0. Some evidence of the incorporation of dietary 14:0 into wax esters has been provided, as well as incorporation into fatty alcohol in *C. helgolandicus* [60]. Sargent and Falk-Petersen [53] suggested the possibility of a further elongation of dietary 14:0 and 16:0, but no evidence was found to support this. Graeve et al. [63] showed that *C. finmarchicus* retained PUFA from a ^{13}C labeled diatom diet, and converted 16:1n-7 from the diet to the corresponding fatty alcohol. This suggests that *C. finmarchicus* selectively accumulates and retains fatty acids in accordance with its metabolic requirements [63]. Sargent and Falk-Petersen [53] also suggested the possibility that the synthesis of wax esters is a flexible system in such a way that zooplankton can switch de novo synthesis in relation to a variable diet.

The individual content of 20:5n-3 and 22:6n-3 decreased from January to February, while the content of the same fatty acids per dry weight was unchanged. From February to March, there was a significant increase in 20:5n-3 and a tendency for an increase in 22:6n-3. The phytoplankton in the surface water contained high fractions of 20:5n-3 and low fractions of 22:6n-3, in agreement with the different increase of these fatty acids in copepods. Phospholipids in *C. finmarchicus* consist mainly of 20:5n-3 and 22:6n-3 in a 1:2 ratio [8, 64]. 22:6n-3 is an essential fatty acid that is important for maintaining specific cellular functions, and Scott et al. [65] have discussed 22:6n-3 as an important factor in the mobility and migration of *C. finmarchicus*. This fatty acid has also been shown to be important in the reproductive capability of copepods [66]. Marine copepods have shown poor capability for the synthesis of 22:6n-3 and 20:5n-3, but the need for n-3 PUFA is vital in their phospholipids and for reproduction. Bell et al. [67] showed that female *C. finmarchicus* have a poor ability to convert 18:3n-3 to 20:5n-3 and 22:6n-3, but this does not rule out the possibility that *C. finmarchicus* can synthesize 22:6n-3 if requirements are not met through the diet. Koski et al. [58] showed that the fatty acid composition of *Calanus* eggs reflected the diet of the females, and furthermore suggested that hatching success was limited by the lipid or PUFA content in the

eggs. This further supports the idea that these specimens did not have the ability to efficiently synthesize n-3 PUFA. Nutritional studies on *C. finmarchicus* should be performed in order to better understand lipid metabolism in this species and the importance of 20:5n-3 and 22:6n-3 during ontogenic development.

We suggest that *C. finmarchicus* could be a new source of marine raw material in the future. *C. finmarchicus* is abundant in surface waters in the spring and summer when phytoplankton or other potential zooplankton food is present, and can be found in very high concentrations. This short time-window is the most likely period for commercial harvest. The content of n-3 fatty acids in *C. finmarchicus* will vary considerably depending on the phytoplankton present during this period. The content of 20:5n-3 will be most dominant during the diatom bloom, and the content of 18:4n-3 and 22:6n-3 will increase later in the spring, caused by a bloom of diatoms and other flagellates (e.g. *Phaeocystis pouchetii*). The content of wax esters will also increase during the spring, indirectly shown as an increase in total fatty acids in the present work. We suggest that C5 will start their vertical migration when a significant lipid level has been reached, and that C5 with lower lipid levels after the phytoplankton bloom will molt to females at the surface and start a new generation. The vertical migration of C5 is in May in the Trondheimsfjord, and a possible harvest should exploit *C. finmarchicus* in the period when it is most abundant and before the majority of the copepods descend to deeper water. However, the concentration of *C. finmarchicus* at the surface can vary greatly between years in the Trondheimsfjord, which may also be the case in other fjords. When this copepod is present in low numbers in a fjord, harvesting can have an impact on the predators of zooplankton, and harvesting of a sparse population would probably not be sustainable. However, when *C. finmarchicus* is abundant, harvesting could even be a positive input for the population, leaving more food for the remaining stock. Our results suggest that fjords are not a suitable harvesting area for *C. finmarchicus*, at least not when the abundance is low.

Acknowledgments This work was supported by the Norwegian Research Council (projects 172641/S40 and 178447). Thanks to the crew of R/V Gunnerus for assisting with sampling and to Ida Fines for performing the biometric analysis. We wish to thank the anonymous reviewers and the associate editor who helped with improving the manuscript.

Abstract This study examined the effects of sesamin inclusion in vegetable oil-based diets fed to Atlantic salmon (*Salmo salar* L.). The diets used differed in n-6/n-3 fatty acid (FA) ratio (0.5 and 1) and sesamin content (high 5.8 g/kg, low 1.16 g/kg and no sesamin). The oils used in the feeds were a mixture of rapeseed, linseed and palm oil. Fish were fed for 4 months. Fatty acids and expression of hepatic genes involved in transcription, lipid uptake, desaturation, elongation and β -oxidation were measured. No major effects on the percentage of DHA in white muscle, liver triacylglycerol and phospholipid fraction were detected. Genes involved in β -oxidation, elongation and desaturation were affected by sesamin addition. Limited effects were seen on any of the transcription factors tested and no effect was seen on the expression of peroxisome proliferator-activated receptors (PPAR). Expression of both SREBP-1 and SREBP-2 increased with sesamin addition. It was concluded that supplementation of fish feed with a high level of sesamin had a negative effect on the growth rate and live weight and did not alter the proportions of DHA in tissues even though gene expression was

affected. Thus, more studies are needed to formulate a diet that would increase the percentage of DHA in fish without negative effects on fish growth.

Introduction

Atlantic salmon (*Salmo salar* L.) is well known for being rich in omega-3 (n-3) long chain polyunsaturated fatty acids (LCPUFA, defined as $\geq C20$) [1, 2]. These n-3 fatty acids (FA) are important for the prevention of cardiovascular disease and brain development, and have anti-inflammatory properties [3].

The expansion in aquaculture production over the last 50 years and the static or even decreasing supply of fish oil (FO) for fish feed production have created a need for alternative vegetable oils (VO) for use in farmed fish feeds. Studies have suggested that replacing FO with VO does not affect fish growth or taste. However, VO are devoid of n-3 LCPUFA and can therefore decrease the amount of these FA in fish muscle [2, 4, 5]. To compensate for the negative effect of lower LCPUFA content, several studies have suggested improving the conversion of α -linolenic acid (ALA, 18:3n-3) to LCPUFA by adding modulators of lipid metabolism to fish feed [2, 6–11]. Sesamin, an oil-soluble lignan found in sesame seeds, is suggested to possess such modulatory properties. In both Atlantic salmon and rainbow trout (*Oncorhynchus mykiss*), the biosynthesis of LCPUFA from ALA to DHA has been well described [12–15]. The genes coding for the enzymes involved in elongation and desaturation have been isolated and characterized in salmonids [16, 17]. In previous studies by our group, a mixture of sesamin/episesamin increased the proportion of docosahexaenoic acid (22:6n-3, DHA) in rainbow trout, [8] and decreased the levels of ALA in Atlantic salmon [18]. Furthermore, in Atlantic salmon hepatocytes, it has been shown that synthesis of n-3 LCPUFA, particularly DHA, increases in the presence of sesamin/episesamin mixture [6]. Sesamin is known to increase gene expression and enzyme activity involved in mitochondrial and peroxisomal β -oxidation [19–25] and to inhibit the $\Delta 5$ -fatty acid desaturation of n-6 FA in rodents [26]. It has been suggested [20, 27] that sesamin triggers these actions through ligand binding to the peroxisomal proliferator-activated receptors (PPARs).

One co-activator of the PPARs is peroxisome proliferator-activated receptor- γ co-activator-1 α (PGC-1 α). PGC-1 α together with PPAR α is involved in the fine-tuning of transcriptional responses in the β -oxidation pathway to environmental variations [28].

In addition, PPAR α has been shown to activate the gene coding for carnitine palmitoyltransferase 1 (CPT-1) by binding to a peroxisome proliferator response elements upstream in the promoter region of the gene, thereby playing an important role in regulating β -oxidation in rodents [29], humans [30] and fish [31]. Similarly, PPAR α activate acyl-CoA oxidase (ACO) the first and rate-limiting enzyme of peroxisomal β -oxidation [30].

Expression of the genes coding for the very long chain fatty acids 5 (ELOVL5) elongase, $\Delta 6$ fatty acid desaturase ($\Delta 6$ fad) and $\Delta 5$ fatty acid desaturase ($\Delta 5$ fad) is regulated by sterol regulatory element binding protein 1c (SREBP-1c). Sterol regulatory element binding protein 2 (SREBP-2) is another transcription factor that regulates lipid homeostasis, including LCPUFA biosynthesis and cholesterol metabolism [32]. Liver X receptor α (LXR α) and LXR β have been shown to activate SREBP-1c in rodents [33, 34]. SREBP-1c, SREBP-2 and LXR α [34] have been isolated and characterized in salmonids.

Recently ELOVL4 has been isolated and characterized in Atlantic salmon. ELOVL4 has been shown to elongate C20 and C22 polyunsaturated fatty acids and to convert eicosapentaenoic acid (20:5n-3, EPA) and 22:5n-3 to 24:5n-3, an intermediate substrate for DHA biosynthesis [35].

In addition, the main high-density lipoprotein (HDL) receptor, scavenger receptor class B1 (SRB-1), responsible for regulating lipid levels from peripheral tissues to the liver [36], has been investigated together with CD36, a gene coding for fatty acid translocase involved in lipid uptake over the membrane [37].

The aim of this study was to investigate possible effects of dietary sesamin in combination with different n-6/n-3 ratios in the diet on post smolt Atlantic salmon muscle and liver in seawater. The different n-6/n-3 ratios were included for comparison of effects by substrate availability on elongation and desaturation.

Fish performance, FA composition and expression of genes involved in lipid pathways were examined. The gene expressions described above were studied in order to determine salmonid responses to sesamin.

Materials and Methods

Animals and Diets

Atlantic salmon were fed seven different experimental diets as shown in Table 1, all produced by Skretting ARC

Feed Technology Plant (Stavanger, Norway). Prior to the trial, the fish were fed a commercial diet (Skretting Transfer 3.0; Skretting, Stavanger, Norway). Each diet was formulated to give an n-6/n-3 FA ratio of either 0.5 (V0.5) or 1.0 (V1), the analyzed n-6/n-3 ratio for V1 was 0.9, however referred to as V1. Different n-6/n-3 ratios were chosen based on the study from Trattner et al. [6] on rainbow trout, which showed increased effects by sesamin at the higher n-6/n-3 ratio. The diets were combined with two different levels of sesamin; high dose (SH) = 5.8 g/kg feed [6], low dose (SL) = 1.16 g/kg feed or a control without sesamin (S0) = 0 g/kg feed. This means that V0.5SL indicates a vegetable oil-based diet with an n-6/n-3 fatty acid ratio of 0.5 and low inclusion of sesamin. The level of added sesamin was chosen to match the concentration of lignan in sesame oil and different dietary levels assuming different dietary inclusion rates. The high level of 5.8 g/kg feed is equivalent to 20 % sesame oil inclusion [6]. The low dose was 20 % of 5.8 g/kg corresponding to 1.16 g/kg. As an additional control, a diet with only fish oil (FO) and no sesamin added was also used.

The dry sesamin powder was added to the feed mix together with the premixes prior to extrusion. Three different batches with increasing sesamin amounts were produced and the different oils were then coated on. Sesamin (98 % purity) was obtained from KEB Biotech (Beijing, China). The experimental diets contained fish meal (Scandinavian LT meal, Skretting, Stavanger) (320 g/kg), wheat gluten (107.4 g/kg), soya concentrate (243.2 g/kg), wheat (89.5 g/kg), premixes (9 g/kg) and sesamin (0, 1.16 and

5.8 g/kg). Fish oil (238.5 g/kg) was added to the control diet (FO) (Skretting, Stavanger), whereas a mixture of vegetable oils was added to diets V0.5S0, V0.5SL and V0.5SH to give 53.5 g rapeseed oil/kg feed (Skretting, Stavanger), 135 g linseed oil/kg feed (Elbe Fetthandel GmbH, Hamburg, Germany) and 50 g palm oil/kg feed (Fritex 24, Aarhuskarlshamn Sweden AB, Karlshamn, Sweden). The other three diets (V1) contained 138.5 g/kg rapeseed oil, 40 g/kg linseed oil and 60 g/kg palm oil. Pellet size was 4 mm. The FA composition of the experimental diets is shown in Table 1.

The feeding trial was carried out at Skretting ARC Fish Trials Station (Stavanger, Norway) in circular tanks (1 m diameter) supplied with flow-through seawater at 12 °C. Each tank was stocked with 35 Atlantic salmon (initial weight 104.6 ± 9.9 g) individually tagged with micro-transponders (Trac ID Systems AS, Stavanger, Norway). The fish were fed in single tanks twice per day for 4 months (November–March) by means of automatic feeders. Fish was fed ad libitum and uneaten feed was removed. At slaughter (average fish weight 553.6 ± 88.1 g), liver and white muscle from eight fish per diet were sampled, frozen in liquid nitrogen and stored at -80 °C for further analysis. The specific growth rate (SGR) was calculated as: $SGR = 100 \times (W_2^{1/3} - W_1^{1/3}) D^{-1}$ with W_2 being final, W_1 the initial weight and D the number of days [38]. The feed conversion ratio (FCR) was calculated as g feed eaten (as fed matter basis) divided by g biomass increase obtained from the 4-month period between samplings. The condition factor (K) was calculated as: $K = 100 \times (WL^{-3})$ with W is live

body weight (g) and L is fork length (cm) of each fish [39]. The liver samples used for gene expression analysis were transferred to RNAlater-ICE (AM7030, Applied Biosystems Part of Life Technologies, Carlsbad, CA, US) directly before storage at -20°C .

Lipid Analysis

The samples were prepared by skinning and deboning the fillets. The white muscle was then dissected from the region between the dorsal and ventral fins. For each group liver ($n = 8$) and muscle ($n = 6$) samples were analyzed in duplicate. Total lipids were extracted according to Trattner et al. [6]. After drying, the lipids were weighed to determine the lipid content and stored in hexane at -80°C until further analysis. All chemicals and other solvents used for analyses were purchased from Merck (Darmstadt, Germany) except for chloroform (Sigma Chemicals Co. St. Louis, MO, USA). The solvents were used without further purification.

Total lipids in muscle tissue and liver were separated by thin-layer chromatography according to Pickova et al. [40]. Fatty acid methyl esters (FAME) from both triacylglycerols (TAG) and phospholipids (PL) were prepared according to the method described by Appelqvist [41].

FAME were analyzed by gas chromatography using a CP 3800 instrument (Varian AB, Stockholm, Sweden) equipped with a flame ionization detector and split injector and fitted with a fused silica capillary column BPX 70 (SGE, Austin, Tex.), length 50 m id. 0.22 mm, 0.25 μm film thickness [42]. The peaks were identified by comparing their retention times with those of the standard mixture GLC-68 A (Nu-check Prep, Elysian, USA). Peak areas were integrated using Galaxie chromatography data system software version 1.9 (Varian AB, Stockholm, Sweden). Fatty acids were quantified using the internal standard (C17:1) methyl-15-methylheptadecanoate (Larodan Fine Chemicals AB, Malmö, Sweden).

Gene Expression Analysis

Gene expression in the liver was investigated by quantitative real-time PCR using an array of target genes coding for enzymes involved in lipid homeostasis.

Total RNA was isolated from the liver of 6 individual fish from each treatment using the spin purification method SV Total RNA Isolation System (Z3105, Promega, Madison, Wisconsin, USA). Each liver was cut in 5×5 mm pieces and approximately 1.7 mg of each liver was randomly collected. Each liver sample was then homogenized and lysed. The isolation and DNase procedures were performed according to the manufacturer's instructions. Total RNA was quantified using a GeneQuantTM 1300 Spectrophotometer (GE Healthcare Life Sciences, Uppsala, Sweden).

Reverse transcription first strand cDNA was synthesized using the High-Capacity cDNA Archive kit (Applied Biosystems Part of Life Technologies, Carlsbad, CA, USA). The protocol was scaled up to from 20- to 100- μl reactions. The kit components were mixed according to the manufacturer's instructions and the reverse transcription reaction was carried out on a Veriti[®] 96-Well Fast Thermal Cycler (Applied Biosystems Part of Life Technologies, Carlsbad, CA, USA). The RT conditions were as follows: 1 cycle at 37°C (60 min) and 1 cycle at 95°C (5 min). The cDNA samples were diluted 1:100 before use.

Real-time PCR analysis of relative abundance of mRNA was carried out using a Fast SYBR[®] Green Master Mix (Applied Biosystems Part of Life Technologies, Carlsbad, CA, USA). The PCR reaction mix (20 μl) consisted of 0.9 μl of each forward and reverse primer (final concentration of 0.5 μM), 6 μl cDNA (approximately 20 ng/sample) and 10 μl master mix diluted with RNase-free water in accordance with the manufacturer's instructions. The primers used for real-time PCR analysis with the corresponding GenBank[®] accession numbers are listed in Table 2. The primers were designed based on available Atlantic salmon sequences from the online version of GenBank[®] (NCBI) using Primer Express[®] software (Applied Biosystems Part of Life Technologies, Carlsbad, CA, USA) [8] or copied from literature references and custom-made at Invitrogen Part of Life Technologies (Carlsbad, CA, USA). Real-time PCR was performed using the StepOnePlusTM Real-time PCR System (Applied Biosystems of Life Technologies, Foster City, CA, USA). The samples were denatured at 95°C for 20 s, followed by 40 cycles of annealing and elongation (95°C for 3 s and 60°C for 30 s) and melt curve analysis to ensure that only a single product was amplified.

All samples were run simultaneously for each gene in triplicate, with a non-template control on each plate. Elongation factor 1a (EF1 α), NADH-ubiquinone oxidoreductase (NUOR), eukaryotic translation initiation factor 3 (ETiF) and RNA polymerase II polypeptide (RPL2) were evaluated for their stability across all experimental variables and samples using the DataAssist software version 2.0 (Applied Biosystems of Life Technologies, Foster City, CA, USA). RPL2 was chosen as the most stable reference gene (results not shown). ΔC_T was calculated by subtracting the C_T for RPL2 from the C_T for the target gene. The relative expression was then calculated by comparing the ΔC_T values for fish fed with or without addition of sesamin using the term $2^{-\Delta\Delta C_T}$ and reported as arbitrary -fold change units [43]. At the end of each real-time PCR run, melt curve analysis was carried out to ensure that only a single product was amplified.

Statistical Analyses

Relative expressions of the different genes, in relation to the reference gene, were determined using the DataAssist software version 2.0 (Applied Biosystems, Foster City, CA, USA). All data are presented as mean values \pm standard deviation (SD) and differences were regarded as significant at $p < 0.05$. Data were analyzed with the general linear model (GLM) procedure (SAS Institute Inc., Cary, NC, USA, version 9.2) [44] with diet as the fixed factor and individual fish as the experimental unit. Tukey's test was used to determine differences between the diets of interest; particularly, VO diets were compared with FO diet, and VOSL/VOSH diets were compared with control VO diets.

Results

Fish Performance

No mortality occurred during the feeding experiment. The mean weight of the fish increased from 104.6 ± 9.9 g to

553.6 ± 88.1 g. The final weight and specific growth rate (SGR) of fish fed with VO diet was not significantly different from that of the FO control. However, there were significant ($p < 0.05$) differences in both final weight and SGR between the control without sesamin (S0) and the high sesamin (SH) group (Table 3). The FCR for the whole trial was similar in all tanks. The average K in the fish at the end of the trial was 1.31 ± 0.09 and was similar in all groups (Table 3).

Fat Content and Fatty Acid Composition

Muscle fat content did not differ between the groups, ranging from 1.4 to 1.8 %. In the liver, lipid content was significantly increased from 5.0 to 7.4 % and 8.0 % in the V0.5SH and V1SH groups, respectively, compared with the groups without sesamin. The FA composition of TAG and PL fractions in white muscle are shown in Table 4 and Table 5, respectively. The FA composition in tissues of control fish fed a fish oil-based diet differed significantly from that of other groups fed vegetable oil-based diets.

Table 3 Initial, final weight (g), specific growth rate (SGR, %/day), feed conversion ratio (FCR, g feed/g body weight increase) and condition factor (*K*) of Atlantic salmon fed seven experimental diets for 4 months, mean values \pm SD, $n = 8$

For abbreviations see Table 1

^{abc} Mean values across rows with different superscripts are significantly different ($p < 0.05$)

White Muscle

Some of the FA in white muscle were significantly affected by sesamin supplementation of the diet, depending on the n-6/n-3 ratio (Table 4). In the TAG fraction of fish fed sesamin and a diet with an n-6/n-3 ratio of 0.5 (V0.5SH), the level of 20:3n-3 increased, while EPA and 22:5n-3 decreased compared with V0.5S0. In the V1SH group (n-6/n-3 = 1; high sesamin level), the content of 18:0 and 18:1n-9 decreased and 18:2n-6 increased (compared with V1S0). When comparing the two n-6/n-3 ratios, V0.5 (n-6/n-3 = 0.5) showed higher levels of 18:0, 18:3n-3, 18:4n-3, 20:3n-3 and 22:1n-11 and lower levels of 18:1n-9 and 20:1n-9 than V1 (n-6/n-3 = 1). The addition of sesamin significantly increased PUFA at the n-6/n-3 ratio of 1. In the PL fraction the proportions of 16:0, 18:1n-9, 18:2n-6, 20:1n-9, 20:3n-6 and 20:4n-6 were significantly lower, while the proportions of 18:3n-3, 20:3n-3 and 22:1n-11 were higher in V0.5 compared with V1. The presence of sesamin in the feed increased the proportion of 20:3n-3 (V0.5SH) and decreased that of 20:5n-3 (V0.5SH), 20:3n-6 (V1SH) and 22:5n-3 (V0.5SH and V1SH) in the muscle PL.

Liver

The FA composition in both TAG and PL fractions of the liver differed considerably between the dietary groups (Table 5). In the TAG fraction and diets with an n-6/n-3 ratio of 0.5, the percentage of 18:2n-6 (V0.5SL), 18:3n-3 (V0.5SL) and 20:3n-3 (V0.5SH) increased and that of 18:0 (V0.5SL) and 22:5n-3 (V0.5SH) decreased with sesamin addition compared with V0.5S0. Diets with an n-6/n-3 ratio of 1 (V1) and containing sesamin decreased the proportion of the following FA: 16:1n-7 (V1SL and V1SH), 18:1n-9 (V1SL, V1SH), 20:3n-6 (V1SH), 22:1n-11 (V1SL), 20:5n-3 and 22:5n-3 (V1SH). The percentage of the FA 18:1n-9 was lower and that of 18:3n-3 and 20:3n-3 higher in the liver from fish fed V0.5 compared with V1. In the PL fraction the level of 14:0 (V0.5SL, V0.5SH) decreased,

while that of 18:1n-9 (V0.5SH) and 18:3n-3 (V0.5SL, V0.5SH) increased after consumption of a sesamin-enriched diet with an n-6/n-3 ratio of 0.5. Diets with an n-6/n-3 ratio of 1 and high sesamin addition resulted in a decreased percentage of 20:3n-6 and 20:4n-6 (V1SH compared with V1S0). In diets with added sesamin, the percentage of 18:2n-6, 20:1n-9 and 20:3n-3 increased significantly, while that of 20:5n-3 and 22:5n-3 decreased with both n-6/n-3 ratios. The proportion of 20:4n-6 was lower and that of 16:0, 18:0, 18:3n-3, 18:4n-3 and 20:3n-3 higher in V0.5 compared with V1. The linoleic acid (LNA, 18:2n-6)/n-6 LCPUFA ratio in the PL fraction increased with the high amount of sesamin and was higher in the V0.5 diet than in the V1 diet. The ALA/(18:4n-3 + n-3 LCPUFA) ratio in the TAG fraction (V0.5SH and V1) and in the PL fraction (V0.5SH) increased after high inclusion of sesamin. PUFA increased in groups with low sesamin addition (V0.5SL) and an n-6/n-3 ratio of 0.5 in both fractions (TAG and PL).

Gene Expression

Transcription Factors

The expression profiles of transcription factors involved in lipid homeostasis (PPAR α , PPAR β 1A, PPAR γ (long/short), PGC-1 α , SREBP-1, SREBP-2 and LXR α) assessed in relation to the reference gene RPL2 are shown in Fig. 1a.

Expression of PPAR α was not affected by any addition of sesamin or by different n-6/n-3 ratios. Similarly, expression of PPAR β 1A was not affected significantly by VO diets with increased n-6/n-3 ratios. However, there was a tendency for lower PPAR β 1A mRNA levels with the VO diet compared with the FO diet. The PPAR β 1A mRNA levels were significantly lower with the higher amount of sesamin in diets with both n-6/n-3 ratios. For the higher n-6/n-3 ratio, the decrease in expression was significant compared with FO, as well as the V1S0 diet. Comparing the PPAR γ long expression rate, a significant increase ($p < 0.05$) was observed for tissue samples from the group fed the highest concentrations of sesamin in combination

Table 4 Fat content (%) and fatty acid composition (%) in the triacylglycerol and phospholipid fractions of white muscle from Atlantic salmon fed seven experimental diets, mean value \pm SD, $n = 6$

For abbreviations see Table 1

SFA include 14:0, 15:0, 16:0, 17:0, 18:0, 20:0, 22:0

MUFA include 14:1, 16:1n-7, 17:1, 18:1n-9, 18:1n-7, 18:1n-5, 20:1n-9, 22:1n-11, 22:1n-9, 24:1

PUFA include 18:2n-6, 18:3n-3, 18:3n-6, 18:4n-3, 20:2n-6, 20:3n-6, 20:4n-6, 20:3n-3, 20:5n-3, 22:5n-3, 22:6n-3

^{a–d} Mean values across rows with different superscripts are significantly different ($p < 0.05$)

^e n-6 desat ratio = 18:2n-6/(20:2n-6 + 20:3n-6 + 20:4n-6)

^f n-3 desat ratio = 18:3n-3/(18:4n-3 + 20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3)

with the highest n-6/n-3 level compared with both the FO control and the V1S0 control.

The mRNA levels for PGC-1 α were significantly downregulated for both n-6/n-3 ratios compared with FO. No change was seen when sesamin was added to the low n-6/n-3 diet. However, for the group fed the diet with an n-6/n-3 ratio of 1 and inclusion of sesamin, the mRNA levels were similar to PGC-1 α expression in the FO diet.

SREBP-1 and SREBP-2 were significantly downregulated in the V0.5S0 group compared with the FO control. In groups fed sesamin together with low n-6/n-3 ratio (V0.5SL and V0.5SH), the mRNA expressions of SREBP-1 and SREBP-2 were significantly upregulated compared with V0.5S0, on the same level or higher than for FO (V0.5SL, V0.5SH and V1SL significantly different from V0.5S0; $p < 0.05$). The highest concentration of sesamin in combination with an n-6/n-3 ratio of 1 (V1) did not result in any significant change in expression of SREBP-1 and -2. The expression levels of SREBP-1 were significantly lower in the V1 groups, but did not change when sesamin was added. Gene expression level for SREBP-2 did not change from that of FO in tissue samples from V1 groups, nor did inclusion of sesamin change the mRNA levels compared with the FO group.

Expression of LXR α in tissues from fish fed V0.5 diets was significantly decreased compared with fish fed the FO diet. However, with addition of sesamin, LXR α was significantly upregulated for both levels, returning to the same level as for fish fed the FO diet. For fish fed V1 diets with or without sesamin, no change in LXR α expression was seen compared with the FO control.

Lipid Uptake

CD36 mRNA levels remained unchanged in tissues from fish fed the VO diet compared with the FO diet. Addition of sesamin decreased expression of CD36 significantly in fish fed the high n-6/n-3 diet compared with both the FO

control and the VO control (V1S0). SR-B1 expression was not affected by changes in n-6/n-3 ratio or addition of sesamin (Fig. 1b).

Desaturation and Elongation

The effects on desaturation and elongation genes are shown in Fig. 1c. Expression of $\Delta 6$ fad and $\Delta 5$ fad was significantly downregulated in the V0.5 diets compared with FO. The levels of $\Delta 6$ fad mRNA were significantly upregulated in liver of fish fed V0.5SL and V0.5SH compared with V0.5S0 and exceeded the levels seen in the FO control ($p < 0.05$). This trend was consistent for the results observed for $\Delta 5$ fad (except for V0.5SL; $p < 0.05$). The V1S0 diet significantly increased expression of $\Delta 6$ fad and $\Delta 5$ fad, compared with FO. However, when sesamin was included in the V1 diet, the levels of $\Delta 6$ fad mRNA decreased ($p < 0.05$).

The levels of ELOVL5b (V0.5S0 and V1S0; $p < 0.05$) and ELOVL2 (V1S0; $p < 0.05$) increased in both VO diets irrespective of the n-6/n-3 ratio. Sesamin also decreased expression of ELOVL5b in V1SL compared with V1S0. Sesamin lowered expression of ELOVL2 in the diets with an n-6/n-3 ratio of 1 (V0.5SH and V1SH; $p < 0.05$).

The transcription level of ELOVL5a was not affected by VO compared with FO. Expression of ELOVL5a was increased by the addition of sesamin for fish fed the diets with lower n-6/n-3 ratio (V0.5SH; $p < 0.05$). No effect of sesamin on ELOVL5a was seen in the diets with higher n-6/n-3 ratio.

When sesamin was added, expression of ELOVL4 was upregulated for V0.5SL and V1SH compared with V0.5S0 and V1S0.

β -Oxidation

CPT1 mRNA expression increased significantly in liver samples from fish fed diets with higher n-6/n-3 ratios. However, when sesamin was added to V0.5 diets (V0.5SL

Table 5 Fat content (%) and fatty acid composition (%) in the triacylglycerol and phospholipid fractions of liver from Atlantic salmon fed seven experimental diets, mean value \pm SD, $n = 8$

^{a–f} Mean values across rows with different superscripts are significantly different ($p < 0.05$)

^g n-6 desat ratio = $18:2n-6 / (20:2n-6 + 20:3n-6 + 20:4n-6)$

^h n-3 desat ratio = $18:3n-3 / (18:4n-3 + 20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3)$

and V0.5SH), the levels of CPT1 mRNA decreased (V0.5SH; $p < 0.05$) (Fig. 1d). There was an equivalent decrease for the highest concentration of sesamin in the V1 diet (V1SH; $p < 0.05$).

Gene expression of ACO increased 2.7-fold when sesamin was added at the higher concentration compared with FO in diets with an n-6/n-3 ratio of 0.5, but decreased 0.6-fold ($p < 0.05$) when the n-6/n-3 ratio was 1.

Discussion

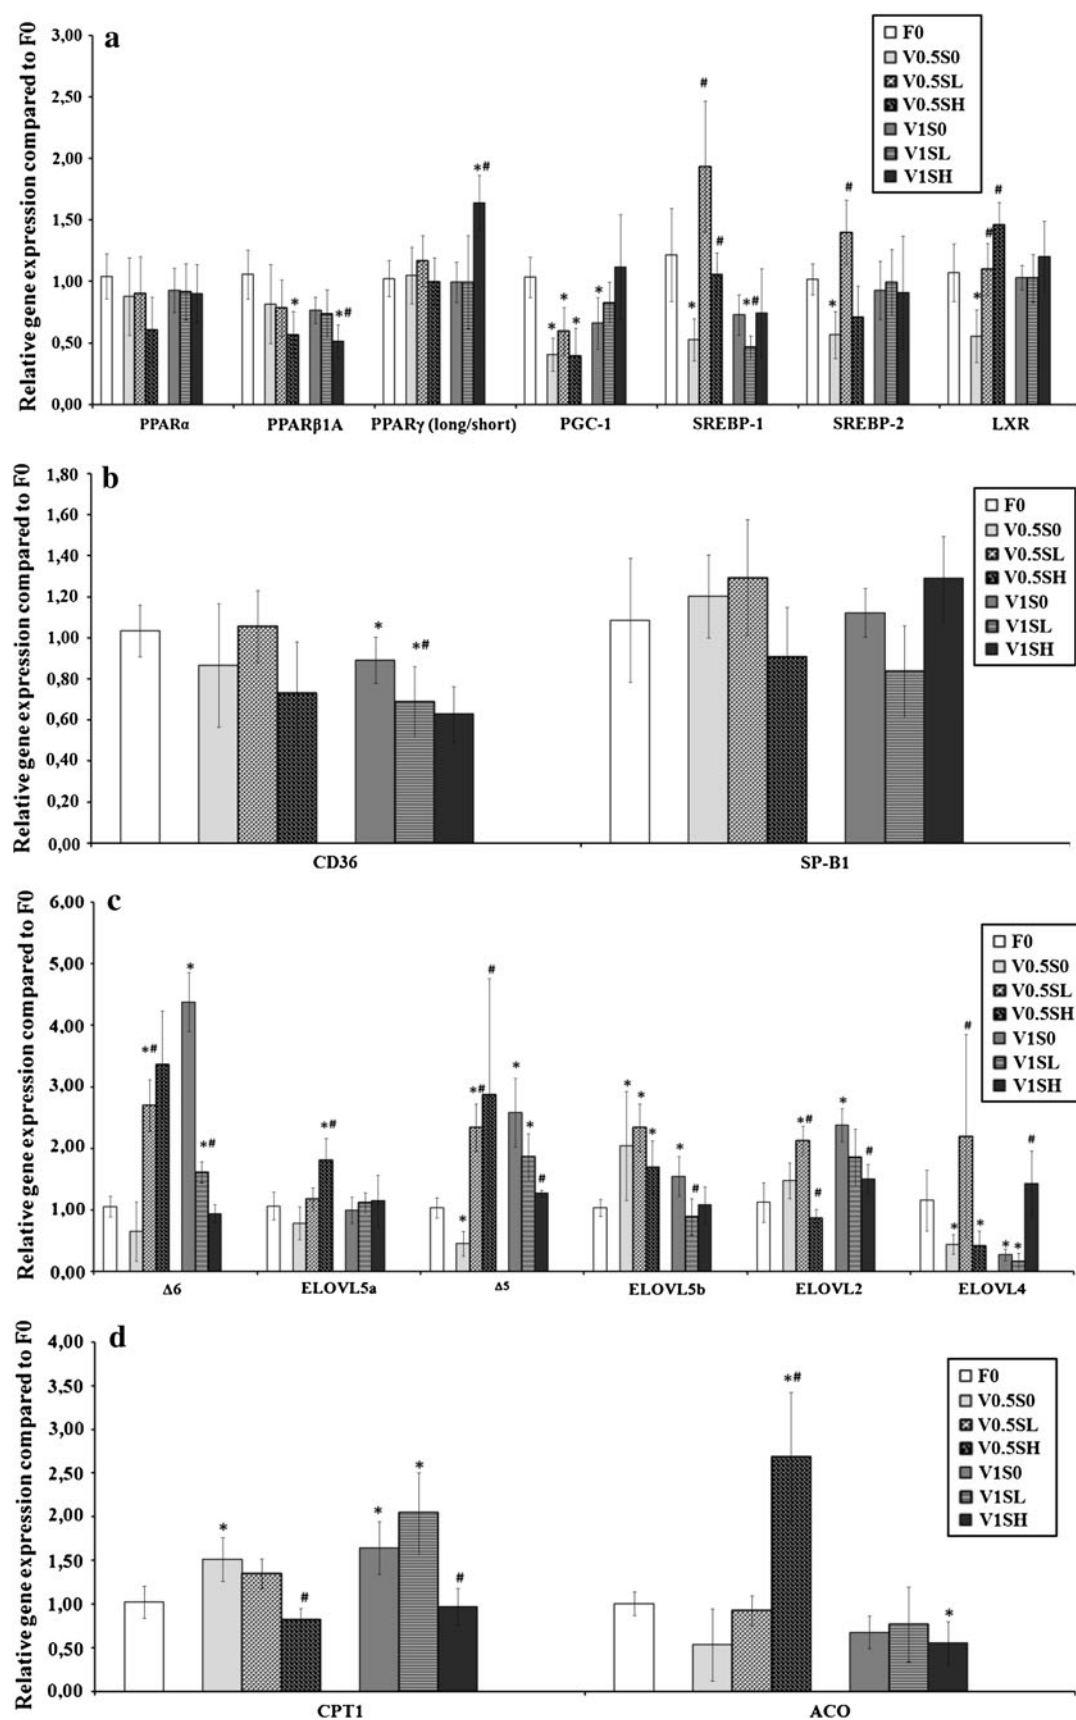

The main objective of this study was to investigate whether Atlantic salmon responded differently to sesamin addition depending on n-6/n-3 ratio in the diet.

Replacement of FO with VO did not affect growth performance measured as weight, K factor and FCR in the present study. Inclusion of sesamin had a dose-dependent negative effect on growth, but only the highest inclusion resulted in significantly reduced weight and SGR of the fish. The results do not suggest diet dependent differences in feed utilization of feeds with and without sesamin (overall K factor was 1.31 ± 0.09). VO has been shown not to affect growth performance in studies on Atlantic salmon [2, 4, 45] and rainbow trout [6]. The inclusion of sesamin showed no effect on growth performance in Baltic Atlantic salmon [46], rainbow trout [6] and carp [47]. The reduced growth in the high sesamin groups is in agreement with studies on other bioactive compounds e.g. dodecylthioacetic acid (DTA) and tetradecylthioacetic acid (TTA) at 5 °C [48], and Moya-Falcon et al. [49] showed that a TTA diet (0.6 % TTA to FO) lowers the body weight of Atlantic salmon at 12 °C. The Atlantic salmon white muscle lipid content was approximately 1.6 % in all groups. No effects on palatability of feeds containing any of these bioactive compounds have been reported so far. Liver fat content was significantly increased by addition of the high level of sesamin, confirming previous findings in rats [18]. In contrast, the liver lipid content is reported to be

unaffected by the addition of TTA to Atlantic salmon diets [49]. As expected, replacement of FO with VO reduced the proportion of DHA five-fold in muscle TAG and ten-fold in liver TAG, but in the PL fraction by only approximately 1.5-fold in both muscle and liver. Sesamin affected FA involved in the synthesis of DHA, e.g. 20:3n-3 increased, EPA and 22:5n-3 decreased and a slight increase in DHA was detected (non significant). Increased levels of 18:2n-6 and 18:3n-3 were also observed as an effect of VO inclusion compared with FO. These results are in agreement with Bell et al. [4], who found that replacement of FO with rapeseed oil (100 %) lowered the proportion of DHA in liver by more than fourfold, but in muscle lipids by only twofold. Similarly, Kleveland et al. [48] showed that dietary TTA increased 18:2n-6 and that DTA increased EPA and 22:5n-3 in white muscle. In the previous study, a significant increase in DHA was observed on addition of a dietary sesamin/episesamin mixture [17].

These different responses to bioactive compounds could be explained by several factors: (1) The physiological response to sesamin may vary between fish size or species. It is well known that in freshwater fish, ALA is converted to EPA and then to DHA [15, 50]. (2) Within the same species, variations in the response to sesamin may depend on age, gender and possibly environmental conditions such as temperature and feed composition. The feeding period could also affect physiological response to sesamin. In the present study, the experimental diets were fed to fish for 4 months, which is longer than in previous studies (8–11 weeks) [6, 18, 47]. Furthermore, seawater stage fish have a lower capacity to convert ALA to DHA than freshwater fish [50–52]. (3) In our study pure sesamin was used,

Fig. 1 Relative expression of genes shown as fold change in liver of fish fed the fish oil (FO) diet and experimental diets with and without sesamin (S). (a) Transcription factors, (b) uptake, (c) elongation, desaturation and (d) β -oxidation. * Denotes significant difference from fish fed the FO diet ($p < 0.05$), n = 6; # Denotes significant difference from fish fed the vegetable oil (VO) diet without sesamin ($p < 0.05$), n = 6. For abbreviations see Tables 1 and 2

whereas Trattner et al. [6, 18] supplemented the fish diet with an equi-mixture of sesamin/episesamin for rainbow trout and Baltic Atlantic salmon. The same mixture was used in a study on Atlantic salmon hepatocytes [8]. It has previously been shown in mammals that episesamin might be more effective in modulating the activity of enzymes involved in lipid metabolism. Therefore, the presence of episesamin in the diet of fish may be important for modulation of FA composition.

The two different n-6/n-3 ratios had an impact on n-3 FA content in fish, mainly in that the higher ratio resulted in lower amounts of ALA. This decrease was not reflected in the percentage of DHA and EPA. The addition of sesamin to diets with low n-6/n-3 ratio increased desaturation index ($\text{ALA}/(18:4\text{n-3} + \text{n-3 LCPUFA})$) in the TAG and PL fractions of liver more than muscle. The desaturation index also increased in the TAG fraction of the liver for diets with high n-6/n-3 ratio. The significant increase in elongation and desaturation index for V0.5 diet could be explained by the higher substrate availability compared with the V1 diet.

Very limited responses were seen for all transcription factors tested. No effect was seen on PPAR α expression. In the case of PPAR γ long, significant upregulation was seen when sesamin was added to higher n-6/n-3 ratio diets, while for PPAR β 1A sesamin decreased the mRNA expression level. This could indicate that the effect of sesamin is not caused by ligand binding to the PPARs. Cloning analysis of the ligand binding regions of PPAR α and PPAR γ genes in Atlantic salmon have revealed that they contain additional amino acid residuals, which could suggest that the ligand binding properties in salmon PPARs can differ from those seen in rodents [53]. This could explain the deviation from findings in rodents [20].

Since both PPAR α and PPAR γ have been shown to induce the transcription of CD36 and SR-B1 [54–56], it was not surprising that the effects on these genes were limited. Only CD36 was significantly downregulated in tissues from fish fed the higher dietary ratio of n-6/n-3 with sesamin added.

Expression of SREBP-1 and SREBP-2 was significantly increased by sesamin addition to the low n-6/n-3 ratio diets, and in fish fed these diets the SREBP target genes desaturases and elongases were also significantly upregulated. It has been shown in liver hepatocytes of rodents that ELOVL5 elongase, $\Delta 6$ fad and $\Delta 5$ fad desaturase expression are regulated by both PPAR α and SREBP-1c [57, 58]. In agreement with this, the present study showed increased expression of SREBP, elongases and desaturases.

The transcription rate of all elongases except ELOVL5a was increased in the liver of salmon fed VO, irrespective of the n-6/n-3 ratio, compared with that of fish fed a FO diet. This is in line with Morais et al. [16] who reported that expression of ELOVL5b and ELOVL2, but not that of ELOVL5a, was significantly increased in both liver and

intestine when Atlantic salmon were fed VO instead of FO. ELOVL5b codes for genes involved in the elongation of C18 to C20 PUFA and ELOVL2 for genes involved in the elongation of C20 to C22 [16, 17]. The increase in ELOVL5b and ELOVL2 in fish fed the VO diet (V0.5) with low sesamin addition was accompanied by upregulation of SREBP-1c and a non significant increase in the amount of 20:3n-3 and DHA in both the TAG and the PL fractions. However, PPAR α expression was not affected by sesamin inclusion. Fish fed the V0.5SL and V0.5SH diets showed increased expression of LXR compared with fish fed the V0.5S0 diet. This could indicate that sesamin acts on SREBP-1c directly, or indirectly by activation of liver X receptor α (LXR α). The increased expression of LXR α and SREBP can also be associated, since LXR α and LXR β have been shown to activate SREBP-1c in rodents [33, 34].

Expression of desaturation and elongation genes increased significantly with addition of sesamin. The effect of sesamin seemed to be influenced by the n-6/n-3 ratio in the feed. For the lower n-6/n-3 ratio sesamin increased desaturation and elongation, while for the higher n-6/n-3 ratio sesamin decreased both desaturation and elongation. This is similar to results reported by Trattner et al. [8]. A possible interaction between feed FA composition and sesamin content could explain the different results between the groups in the present study.

Earlier studies in rats [20, 59] and in salmon hepatocytes [8] found that sesamin positively influenced the activity and gene expression of both ACO and CPT1, which are involved in peroxisomal and mitochondrial β -oxidation, respectively. In the low n-6/n-3 ratio groups we found similar results for ACO but not for CPT1. However, in our study both ACO and CPT1 were significantly downregulated after high sesamin addition in the high n-6/n-3 ratio diet. This might indicate that the n-6/n-3 ratio influenced the response of β -oxidation genes to sesamin.

The lack of correlation between desaturase expression and LCPUFA biosynthesis may also indicate that the effect of sesamin was mediated through other mechanisms not yet understood.

Several studies have shown that the enzymes and the genes involved in the biosynthesis of highly unsaturated FA are upregulated after VO feeding [60, 61]. In our study, sesamin inclusion in both VO diets increased DHA levels in the TAG and PL fractions. This is in agreement with findings reported for Atlantic salmon and rainbow trout [6, 8, 46].

Conclusions

The addition of sesamin to vegetable oil-based diets affected the expression of genes involved in the lipid metabolism and had minor effects on fatty acids. The

response to sesamin was affected by the dietary n-6/n-3 ratio. High sesamin inclusion had a negative effect on growth rate but did not affect the feed conversion ratio or the condition factor.

Abstract Delta (Δ) 5 desaturase is a key enzyme for the biosynthesis of health-beneficial long chain polyunsaturated fatty acids such as arachidonic acid (ARA, C20:4n-6), eicosapentaenoic acid (C20:5n-3) and docosahexaenoic acid (C22:6n-3) via the “desaturation and elongation” pathways. A full length $\Delta 5$ desaturase gene from *Euglena gracilis* (*Eg $\Delta 5D$*) was isolated by cloning the products of polymerase chain reaction with degenerate oligonucleotides as primers, followed by 5' and 3' rapid amplification of cDNA ends. The whole coding region of *Eg $\Delta 5D$* was 1,350 nucleotides in length and encoded a polypeptide of 449 amino acids. BlastP search showed that *Eg $\Delta 5D$* has about 39 % identity with a $\Delta 5$ desaturase of *Phaeodactylum tricornutum*. In a genetically modified dihomogamma-linoleic acid (DGLA, C20:3n-6) producing *Yarrowia lipolytica* strain, *Eg $\Delta 5D$* had strong $\Delta 5$ desaturase activity with DGLA to ARA conversion of more than 24 %. Functional dissection of its HPGG and HDASH motifs demonstrated that both motifs were important, but not necessary in the exact form as encoded for the enzyme activity of *Eg $\Delta 5D$* . A double mutant *Eg $\Delta 5D$ -34G158G* with altered sequences within both HPGG and HDASH motifs was generated and exhibited $\Delta 5$ desaturase activity similar to the wild type *Eg $\Delta 5D$* . Codon optimization of the

N-terminal region of *Eg $\Delta 5D$ -34G158G* and substitution of the arginine with serine at residue 347 improved substrate conversion to 27.6 %.

Introduction

There is increasing interest in the recognized health benefits of long chain polyunsaturated fatty acids (LC-PUFA) such as arachidonic acid (ARA, C20:4n-6), eicosapentaenoic acid (EPA, C20:5n-3) and docosahexaenoic acid (DHA, C22:6n-3) for both humans and animals [1–3]. Since mammals lack delta (Δ) 12- and Δ 15-desaturases, ARA, EPA and DHA cannot be synthesized de novo and must be obtained either in the diet or synthesized through “desaturation and elongation” pathways (Fig. 1) from essential fatty acids linoleic acid (LNA, 18:2n-6) and/or alpha (α)-linolenic acid (ALA 18:3n-3). These LC-PUFA are important fatty acids for human growth and development. For example, ARA, a precursor of EPA, is abundant in the brain and muscles. As a lipid second messenger ARA is involved in cellular signaling and is a key inflammatory intermediate [3]. EPA is a precursor of DHA, and induces a broad anti-inflammatory response [1–3]. DHA is a major ω -3 fatty acid in the mammalian central nervous system and enhances synaptic activities in neuronal cells [1–4]. EPA and DHA are the precursors of E- and D-series resolvins, respectively. These two classes of resolvins have distinct structural, biochemical and pharmacological properties [5, 6]. ARA and DHA together play critical roles for neurological development and health [4, 7]. Dietary EPA and DHA can effectively reduce the level of blood triglycerides in human [8]. Increased intake of EPA-rich

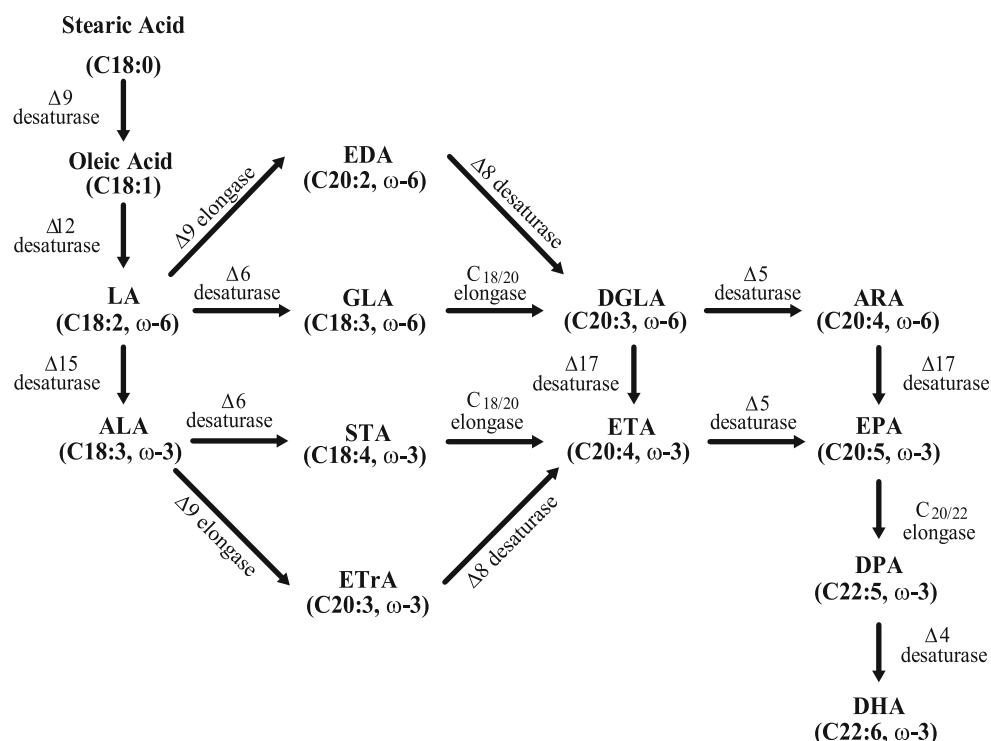

supplement has beneficial effects on coronary heart disease, high blood pressure, inflammatory disorders and mental illness [9, 10].

Currently, the primary source of EPA and DHA is marine fish oil. Most of the EPA and DHA in fish oil are from their cold-water oceanic microalgae food sources. More than 85 % of isolated fish oil is used for aquaculture. In the case of salmon-farming, fish oils from approximately 4 pounds of fish are needed to raise one pound of salmon filet, the fish-in and fish-out ratio is about 4:1. In today’s environment, wild-caught fish often contain contaminants such as methylmercury, polychlorinated biphenyls, dioxins and several other halogenated persistent organic pollutants [11]. With ever-growing human populations, and limited sources of ocean fish, there is growing concern about the quality, quantity and sustainability of fish oil.

In the last two decades, great efforts have been focused on developing different hosts for production of LC-PUFA. Wild type *Mortierella alpina* has been developed for commercial production of ARA [12], while *Cryptocodinium cohnii* and *Schizochytrium* have been developed for commercial production of DHA [13]. The ARA and DHA oils produced from these organisms have been largely used in infant formulas. *Yarrowia lipolytica* has been genetically engineered to contain an EPA biosynthesis pathway [14] allowing for the commercial production of EPA oil, NewHarvest™ (<http://www.newharvest.com>). The EPA oil has been used as a human nutritional supplement. Additionally, EPA-rich *Yarrowia* biomass has been used to feed a brand of farmed salmon, Verlasso™ (<http://www.verlasso.com>), with a fish-in and fish-out ratio of about 1:1. However, the current production scale and cost of ARA, EPA and DHA cannot meet the market demand.

Various organisms use different pathways to synthesize ARA, EPA and DHA. *Cryptocodinium* and *Schizochytrium* synthesize EPA and DHA through a polyketide-based pathway [15], while some species of algae, fungi, and protists synthesize ARA, EPA and DHA through fatty acid “desaturation and elongation” pathways [16, 17]. All “desaturation and elongation” pathways (Fig. 1) require LNA and/or ALA as a substrate, followed by the “ Δ 9 elongase and Δ 8 desaturase” pathway or the “ Δ 6 desaturase and C_{18/20} elongase” pathway to synthesize ARA, EPA and DHA by orchestrated elongation and desaturation reactions. So far, genetic engineering has mainly employed these “desaturation and elongation” pathways to modify hosts such as plants and yeast to produce ARA, EPA and DHA [14, 18–23]. Production of ARA, EPA and DHA through “desaturation and elongation” pathways requires gene expression of Δ 5 desaturase to catalyze the conversion of di-homo- γ -linolenic acid (DGLA, C20:3n-6) to ARA, with a similar activity of converting eicosatetraenoic acid (ETA, C20:4n-3) to EPA. Since the isolation of Δ 5

Fig. 1 Biosynthetic pathways for ARA, EPA and DHA via “desaturation and elongation” pathways

desaturase gene from *Mortierella alpina* (*MaΔ5D*, 24, 25), several $\Delta 5$ desaturase genes have been isolated [26], however, there is little research about their structure/function relationship. Additionally, more efficient $\Delta 5$ desaturase genes are needed to ensure engineered organisms may produce high levels of ARA, EPA and DHA.

$\Delta 5$ desaturases are known as “front-end” desaturases, wherein desaturation occurs between a pre-existing double bond and the carboxyl terminus of the fatty acid [26–29]. Like other desaturases, $\Delta 5$ desaturase is an iron-containing and membrane-bound enzyme that requires both molecular oxygen and an electron transfer to introduce double bonds into an existing acyl chain. Microsomal cytochrome b_5 serves as electron donor to desaturase enzymes [26, 29, 30]. Fatty acid desaturation can be carried out via concerted action of multiple enzymes including NADH reductase, the desaturase enzyme, and cytochrome b_5 reductase. Alternatively, many desaturases contain both a cytochrome b_5 domain and a desaturase domain. For example, $\Delta 4$, $\Delta 5$, $\Delta 6$ and $\Delta 8$ desaturases have a cytochrome b_5 domain at their N-terminus [26]; $\Delta 9$ desaturase has a cytochrome b_5 domain at its C-terminus [30]. The cytochrome b_5 domain of all desaturases has a heme-binding “HPGG” motif. Previous studies using molecular dynamics simulations suggest the “HPGG” motif is important for heme group assembly and desaturase function [31, 32].

The active site of desaturases has been characterized as a diiron cluster that is bound to the enzyme by three regions

of highly conserved histidine-rich (His-rich) motifs [27, 30]. These three His-rich motifs $H(X)_{3-4}H$, $H(X)_{2-3}HH$, and $H/Q(X)_{2-3}HH$ are conserved among all front-end desaturases, and the eight histidine residues of these three motifs are essential for catalytic activity [33]. In the case of $\Delta 5$ desaturase from *MaΔ5D* [24, 25], the exact amino acid sequence of the first His-rich motif ($H(X)_{3-4}H$) is HDASH, which has been suggested as one of the characteristics of $\Delta 5$ desaturases and necessary for its function to convert DGLA to ARA [34]. Recent studies find that several $\Delta 5$ desaturases (GenBank accession #: AAL82631, AAL13311, AAL92562, AAM09687, CAJ07076) do not contain the exact HDASH sequence. Due to the important role of $\Delta 5$ desaturases in LC-PUFA biosynthesis, a detailed understanding of the functional significance of the conserved HPGG and HDASH motifs may contribute to improvements in hosts biologically engineered to produce commercially valuable LC-PUFA.

We report the isolation of a $\Delta 5$ desaturase gene from *Euglena gracilis* (*EgΔ5D*). Expression of *EgΔ5D* in a genetically modified DGLA producing *Y. lipolytica* strain revealed that *EgΔ5D* had strong $\Delta 5$ desaturase activity. Functional dissection of HPGG and HDASH motifs demonstrated that neither the HPGG nor the HDASH motif is necessary in the exact form as encoded for enzyme activity of *EgΔ5D*. Various mutants, within HPGG or HDASH motif alone, or within both HPGG and HDASH motifs, are functionally equivalent or have higher $\Delta 5$ desaturase activity than the wild type *EgΔ5D*. Codon optimization of

the N-terminal region of a double mutant *EgΔ5D-34G158G* and substitution of the arginine with serine at residue 347 effectively improved the enzyme's substrate conversion.

Materials and Methods

Strains, Media and Growth Conditions

E. gracilis was kindly provided by Dr. Richard Triemer of Michigan State University (East Lansing, MI). *Euglena* growth (EG) media (per liter): 1 g sodium acetate, 1 g of beef extract, 2 g of Bacto® tryptone and 2 g of Bacto® yeast extract in 970 mL of water. After filter sterilizing, 30 mL of soil–water supernatant was aseptically added. A 1-mL aliquot of *E. gracilis* culture was transferred into 250 mL of EG Medium in a 500-mL glass bottle. The cultures were grown at 23 °C with a 16 h light, 8 h dark cycle for 2 weeks with no agitation.

Y. lipolytica strain Y2224 is a 5-fluoroorotic acid (FOA) resistant mutant of wild type strain American Type Culture Collection (ATCC, Rockville, MD) #20362 (Fig. 2a) with a mutation in the *URA3* gene (Genbank accession#: No. AJ306421). *Y. lipolytica* strain Y4036U (Zhu et al., unpublished data) is a genetically modified strain with a *Leu*[−] and *Ura*[−] phenotype, also originated from the wild type strain ATCC #20362. Strain Y4036U produced

approximately 18 % DGLA of total fatty acids (Fig. 2b) and is composed of heterologous genes encoding Δ12 desaturase of *Fusarium moniliforme* [35]; C16/18 elongase of *M. alpina* [36]; Δ9 elongase of *E. gracilis* [37] and synthetic mutant of Δ8 desaturase [38] derived from *E. gracilis*. Minimal Media + Leucine (MMLeu), High Glucose Media (HGM) and YPD medium were used as required for *Y. lipolytica* strains and cultured at 30 °C. MMLeu (per liter): 20 g of glucose; 1.7 g yeast nitrogen base without amino acids or ammonium sulfate; 0.1 g proline; 0.1 g leucine; pH 6.1. HGM (per liter): 80 g glucose, 2.58 g KH₂PO₄, 5.36 g K₂HPO₄, pH 7.5. YPD medium (per liter): 10 g of yeast extract, 20 g of Bacto peptone, and 20 g of glucose. Agar plates were prepared by addition of 20 g/l agar to liquid media.

General Techniques for Molecular Biology

Recombinant DNA techniques were used according to standard methods [39, 40]. Site-directed mutagenesis was performed according to the manufacturer's protocol (QuikChange™, Stratagene; San Diego, CA). When PCR or site-directed mutagenesis was involved in the generation of mutants and/or cloning, DNA was sequenced to verify that no additional mutations were introduced.

Total RNA was extracted from the *E. gracilis* cells using the RNA STAT-60™ reagent (Amsbio LLC., Lake forest, CA). 85 μg of mRNA was purified from 1 mg of total RNA using the mRNA Purification Kit (Amersham Biosciences, Piscataway, NJ). Synthesis of cDNA from the *E. gracilis* mRNA was carried out using the adapter primer AP of 3'-RACE kit from Invitrogen (Carlsbad, CA) and the Smart IV oligonucleotide of BD-Clontech Creator™ Smart™ cDNA library kit (Mississauga, ON, Canada) as primers. The reverse transcription was performed with Superscript II reverse transcriptase of Invitrogen.

PCR reactions were carried out in a 50 μl total volume comprising: PCR buffer (containing 10 mM KCl, 10 mM (NH₄)₂SO₄, 20 mM Tris–HCl (pH 8.75), 2 mM MgSO₄, 0.1 % Triton X-100), 100 μg/mL BSA, 200 μM each deoxyribonucleotide triphosphate, 10 pmol of each primer, 10 ng cDNA of *E. gracilis* and 1 μl of Taq DNA polymerase (Epicentre Technologies, Madison, WI). The thermocycler conditions were set for 35 cycles at 95 °C for 1 min, 56 °C for 30 s and 72 °C for 1 min, followed by a final extension at 72 °C for 10 min. The DNA band with expected size was isolated from a 1 % agarose gel and cloned into pGEM-T easy vector (Promega, Madison, WI).

Modified 5' and 3' RACE techniques were used to obtain the full length *EgΔ5D*. The cDNA product from *E. gracilis* mRNA was used as template, and all the primers used in the 5' and 3' RACE are listed in Supplemental Table S1. Specifically, a gene specific primer ODMWP480

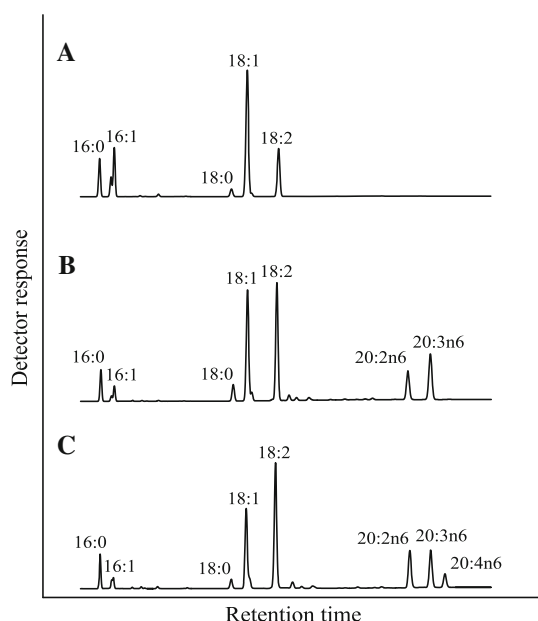

Fig. 2 Chromatograms of the fatty acid profiles. Fatty acid profile of wild type *Y. lipolytica* strain ATCC#20362 (**a**). Fatty acid profile of Y4036U strain, producing about 8 % HGLA (**b**). Fatty acid profile of Y4036U strain transformed with pDMW367-M4, producing about 3.7 % ARA of total lipids (**c**)

and a generic primer CDSIII 5' were used in the first round of 5' RACE. The PCR amplifications were carried out in a 50 μ l total volume, comprising: 25 μ l of *LA Taq*TM pre-mix (TaKaRa Bio Inc., Otsu, Shiga, 520-2193, Japan), 10 pmol of each primer and 1 μ l of Taq DNA polymerase (Epicentre Technologies, Madison, WI). The thermocycler conditions were the same as described above. One micro liter of this product was directly used in a second amplification, which differed from the first only in that the primers used, ODMWP479 and the generic primer DNR CDS 5' were internal to the first set of primers. As no translation initiation codon was found in the product of the first round of 5' RACE, the entire modified 5' RACE protocol was repeated using gene specific primers YL791 and YL792 as primers instead of the primers used in the first round.

A variation of a 3' RACE technique was used to isolate the C-terminal fragment of *EgΔ5D*. The combinations of primers ODMW469 and AUAP, and then YL470 and AUAP were used in the initial amplification and second round reaction, respectively. The PCR reactions were the same as those described for the 5' RACE.

Yarrowia Expression Vector and Transformation

Yarrowia expression vector pDMW367 contained autonomous replication sequence 18 [41] and a *URA3* gene (Genbank accession#: No. AJ306421) of *Y. lipolytica*. It also contains a *FBAIN::EgΔ5D:Pex20* chimeric gene. The FBAIN is a promoter derived from the fructose-bisphosphate aldolase gene (*FBA1*) of *Y. lipolytica* [42]. The *EgΔ5D* is the coding region of a wild type Δ5 desaturase of *E. gracilis*, in which the amino acid at position 347 is arginine. The Pex20 was a terminator sequence of *PEX20* gene (Genbank accession#: AF054613) of *Y. lipolytica*. Transformation of *Y. lipolytica* strain Y4036U was carried out as described by Chen et al. [43].

Cultivation of *Y. lipolytica* Transformants and Fatty Acid Analysis by Gas Chromatography

The *Yarrowia* expression plasmid and its derivatives were used to transform strain Y4036U individually. Transformants from each transformation were streaked onto new MMLeu plates and kept in a 30 °C incubator for 2 days. Cells from streaked plates were cultivated in 24 well blocks with 3 mL MMLeu, and incubated for 2 days at 30 °C with shaking at 200 rpm. The cells were then collected by centrifugation and resuspended in 3 mL HGM. The cells were incubated another 5 days at 30 °C with shaking at 200 rpm.

Fatty acid methyl esters from 1 ml cell culture of *Y. lipolytica* or *E. gracilis* were prepared as described [44],

except that the fatty acid methyl esters were extracted with 0.5 ml of heptane and separated by Agilent 7890A GC using hydrogen as carrier gas supplied by a hydrogen generator (Parker Hannifin, Cleveland, OH). The oven temperature was programmed from 200 to 240 °C at a rate of 25 °C/min. The proportion of each fatty acid was based on the integrated peak area of the corresponding fatty acid methyl ester as a percent relative to the sum of all integrated peaks as calculated by Agilent ChemStation Software.

Results

Isolation of Δ5 Desaturase Gene from *E. gracilis*

Fatty acid profile analyses showed that there were moderate amounts of EDA, DGLA, ARA, EPA, docosapentaenoic acid (DPA 22:5n-3) and DHA produced in *E. gracilis* (data not shown), confirming that there was a “Δ9 elongase/Δ8 desaturase” pathway in *E. gracilis* [16, 38, 45]. The genes encoding the Δ9 elongase, Δ8 desaturase [16, 38], Δ5 desaturase, Δ17 desaturase, C20/22 elongase and Δ4 desaturase [45] were responsible for the production of EDA, DGLA, ARA, EPA, DPA and DHA, respectively (Fig. 1).

After comparison of four Δ5 desaturase genes, *PiΔ5D* from *Pythium irregulare* [46], *PmΔ5D* from *Phytophthora megasperma* (Genbank accession #: CAD53323), *PtΔ5D* from *Phaeodactylum tricornutum* [47], and *DdΔ5D* from *Dictyostelium discoideum* (Genbank accession #: XP_640331) as well as two Δ8 desaturase genes, *EgΔ8D* from *E. gracilis* [16, 38] and *PlΔ8D* from *Pavlova lutheri* [48], two conserved regions, GHH(I/V)YTN and N(Y/F)Q(V/D)EHH (Fig. 3) were selected to design primers to amplify a portion of *EgΔ5D*. To reduce the degeneracy of the primers, four primers (Supplemental Table S1: 5-1A to 1D) were generated for conserved region 1 and four primers (Supplemental Table S1: 5-5AR to 5-5DR) for the anti-sense strand of conserved region 2. One DNA fragment amplified with primers 5-1B and 5-5DR was cloned into pGEM-T Easy vector to generate pT-F10-1. DNA sequence showed that a 590 bp insert of pT-F10-1 encoded an amino acid sequence with 38 % identity and 53 % similarity to the amino acid sequence of the Δ8-sphingolipid desaturase of *Thalassiosira pseudonana* (*TsΔ8D*, Genbank accession #: AAX14502), and 37 % identity and 52 % similarity with *PtΔ5D* [47]. These data suggested that the 590 bp DNA fragment might be a part of a desaturase gene of *E. gracilis*. This gene was designated as putative *EgΔ5D*.

5' and 3' RACE techniques were used to extend the 590 bp region of the putative *EgΔ5D* (Fig. 4). A 797 bp

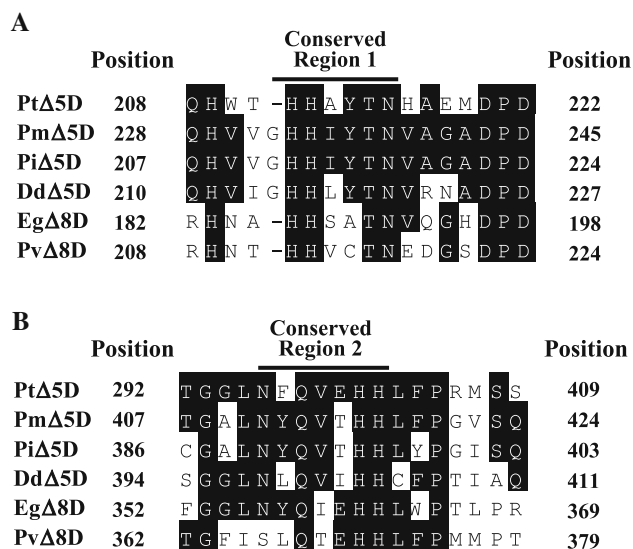

Fig. 3 Alignment of the conserved regions among some Δ5 and Δ8 desaturases. The amino acid sequence alignment was performed with Clustal W analysis (MegAlign™ program of DNASTAR software). Identical residues are shaded in black. PtΔ5D, Δ5 desaturase from *P. tricornutum* (29, GenBank accession #: AAL92562); PmΔ5D, Δ5 desaturase from *P. megasperma* (GenBank accession #: CAD53323); PiΔ5D, Δ5 desaturase from *P. irregulare* (30, GenBank accession #: AAL13311); DdΔ5D, Δ5 desaturase from *D. discoideum* (GenBank accession #: XP_640311); EgΔ8D, Δ8 desaturase from *E. gracilis* (24, GenBank accession #: AAD45877) and PvΔ8D, Δ8 desaturase from *P. lutheri* [48]

DNA fragment with no translation initiation codon was isolated by the first round of 5' RACE. This 797 bp DNA fragment had a 238 bp overlap with the 5' end of the 590 bp fragment of pT-F10-1 and provided 559 bp of 5' upstream sequence. A 273 bp DNA fragment was generated by the second round 5' RACE experiment. This 273 bp DNA fragment had 253 bp overlap with the 5' part of the 797 bp DNA fragment and provided 20 bp of 5' upstream sequence. Seventeen [17] bp of the 20 bp encoded the N-terminal portion of the putative *EgΔ5D*, including the translation initiation codon. A 464 bp DNA sequence was identified by one round of 3' RACE. The first 184 bp of the 464 bp fragment encoded the C-terminal coding region, including the translation stop codon, of the putative *EgΔ5D*.

Assembly of the 5' region, the original 590 bp fragment and the 3' region resulted in a 1,633 bp contig, comprising the complete coding region with additional untranslated 5' and 3' ends (Fig. 4). The coding region of the putative *EgΔ5D* is 1,350 bp in length and encodes a peptide of 449 amino acids. BlastP searches using the full length putative *EgΔ5D* as the query sequence showed that it shares 39 % identity and 56 % similarity with PtΔ5D [47]; 37 % identity and 55 % similarity with TsΔ8D (Genbank accession #: AAX14502). Amino acid sequence alignment performed with the Clustal W analysis (MegAlign™

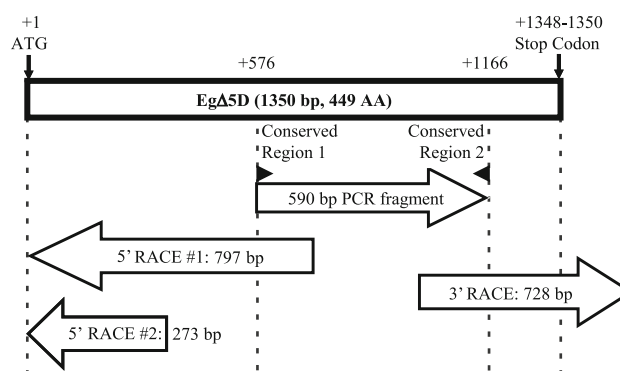

Fig. 4 Graphical representation of the assembly of full length *EgΔ5D*. A 590 bp DNA fragment encoding a portion of *EgΔ5D* was isolated by PCR amplification with degenerate primers. The N-terminal part was isolated by two round of 5' RACE, and the C-terminal portion was isolated by one round of 3' RACE

program of DNASTAR software) showed that *EgΔ5D* has <30 % identity with some represent Δ5 desaturases such as IgΔ5D from *I. galbana* (AEA72469); MaΔ5D from *M. alpina* [24, 25, 34]; PiΔ5D [46]; OtΔ5D from *O. tauri* (Genbank accession #: XP_003082424) and TaΔ5D from *T. aureum* [49]. Further analyses showed that *EgΔ5D* has only 20 % and 25.5 % identity with *EgΔ8D* [16] and *EgΔ4D* [45] desaturases of *E. gracilis*, respectively. It was found that the PCR products for the full length coding region of putative *EgΔ5D* had two versions, both having identical nucleotide sequence except at base pair positions 1,039 and 1,041. This disagreement resulted in a codon change from CGA to AGC. As such, one PCR product indicated arginine at position 347, whereas the second indicated serine. It was hypothesized that this discrepancy was raised at the stage of PCR amplification or during cDNA generation.

Determination of Δ5 Desaturase Activity and Topology Model of *EgΔ5D*

To study the function of the putative *EgΔ5D*, plasmid pDMW367 was generated to express the *EgΔ5D* coding region under the control of the strong constitutive FBAIN promoter [42] from *Y. lipolytica*. The four restriction sites (i.e., *Bgl*II, *Eco*RI, *Hind*III and *Nco*I) inside the coding region of *EgΔ5D* in pDMW367 were removed by site-directed mutagenesis to generate pDMW367-M4 (Supplemental Fig. S1). The amino acid sequence of *EgΔ5D* is identical in pDMW367 and pDMW367-M4 constructs, and the amino acid at position 347 is an arginine.

The pDMW367 and pDMW367-M4 constructs were used to transform DGLA producing strain Y4036U. There was no ARA produced in the parent strain Y4036U (Fig. 2b), while there was about 3.7 % ARA and 11.5 % DGLA produced in transformants of Y4036U with either

Fig. 5 Topology model of *EgΔ5D*. *EgΔ5D* is a membrane diiron protein with three His-rich motifs. The $HX_{(3,4)}H$ motif, HDASH, is located from residues 155 to 159; the $HX_{(2,3)}HH$ motif, HIMRHH, located from residues 190 to 195, and the $(H/Q)X_{(2,3)}HH$ motif,

QIEHH, located from residues 385 to 389. *EgΔ5D* has four transmembrane domains (I–IV) and two hydrophobic stretches (residues from 165 to 187, and 234 to 256). Its N-terminal cytochrome b_5 domain and C-terminal region are located in the cytoplasm

the pDMW367 or pDMW367-M4 construct (Fig. 2c). These results demonstrated that *EgΔ5D* indeed encodes a $\Delta 5$ desaturase. *EgΔ5D* could convert DGLA to ARA with a conversion of about 24.3 %. The conversion of DGLA to ARA was calculated according to the formula: $([ARA \text{ product}]/[DGLA \text{ substrate} + ARA \text{ product}])$. The pDMW367 and pDMW367-M4 constructs were also used to transform strain Y2224, a FOA resistant mutant of wild type strain ATCC#20362. There was no GLA produced in the transformants with either the pDMW367 or pDMW367-M4 construct (data not shown). These results demonstrated that *EgΔ5D* does not have $\Delta 6$ desaturase activity; it is not a bi-functional enzyme.

Like other fatty acid desaturases, *EgΔ5D* is also a membrane-bound enzyme and belongs to a super-family of membrane di-iron proteins with three His-rich motifs: $HX_{(3,4)}H$, $HX_{(2,3)}HH$ and $(H/Q)X_{(2,3)}HH$. These His residues have been predicted to be located in the cytoplasmic face of the membrane and have been shown to be very important for enzyme activity [33]. Within *EgΔ5D*, these 3 His-rich motifs are the HDASH motif located from residue 155 to 159, the HIMRHH motif located from residue 190 to 195, and the QIEHH motif located from residue 385 to 389. The third His-rich motif contains a glutamine substitution that is common to other front-end desaturases. Based on transmembrane domain analysis (TMHMM Server v. 2.0, Center for Biological Sequence Analysis, BioCentrum-DTU, Technical University of Denmark, DK-2800 Lyngby, Denmark) and the location of the His-rich motifs, a topology model of *EgΔ5D* was developed (Fig. 5). The model shows that the N-terminal cytochrome b_5 domain is located in the

cytosol. The topology model also predicts that *EgΔ5D* has a total of four transmembrane regions (amino acid residues 103–125, 130–152, 280–302 and 306–328) and two hydrophobic regions (amino acid residues 165–187, and 234–256). These hydrophobic segments are not membrane-spanning, and may represent hydrophobic patches located closed to the di-iron active site. Because the substrates for the desaturase is highly hydrophobic, they will likely partition into the lipid bilayer. Therefore we purport that the di-iron active site assembled from these His-clusters may occur at or very near the membrane surface.

The HPGG Motif is Important, but not Necessary for $\Delta 5$ Desaturase Activity of *EgΔ5D*

It has been suggested that the highly conserved HPGG motif plays a crucial role in heme group assembly, protein folding and stabilization in cytochrome b_5 proteins, with the histidine residue functioning as an axial heme ligand where a peptide chain reversal occurs [50]. Previous studies have demonstrated that the heme-binding HPGG motif, and in particular, the histidine residue, is essential for enzyme activity of desaturases with cytochrome b_5 domain [51–53]. Although sequence divergence in the vicinity of the HPGG motif is normal, the HPGG motif itself has been conserved throughout the evolution of all the $\Delta 5$ desaturase genes [54]. Thus it was claimed to be a characteristic of $\Delta 5$ desaturases and necessary for its function to convert DGLA to ARA [34].

To assess the functional significance of the HPGG motif (position 33–36) of *EgΔ5D*, we first elected the proline

Table 1 $\Delta 5$ Desaturase activity of *EgΔ5D* with HxGG mutations

| Gene name | Sequence of HPGG motif | $\Delta 5$ Conversion (%) | % of wild type <i>EgΔ5D</i> |

Average of 6 samples for each construct containing different mutations

residue at position 34 (P34) as a target for amino acid substitution. Single amino acid mutations were carried out to generate all 19 amino acid substitution mutants (HxGG). Table 1 shows that the P34 residue could be substituted with several different amino acids without significantly impacting the $\Delta 5$ desaturase activity of *EgΔ5D*. The *EgΔ5D-34A*, *EgΔ5D-34C*, *EgΔ5D-34K* or *EgΔ5D-34W* mutants exhibited >90 % of the wild type *EgΔ5D* activity. The *EgΔ5D-34G* mutant was functionally equivalent to the wild type *EgΔ5D*.

Next, we studied the significance of the second glycine residue at position 36 (G36) within the HPGG motif of *EgΔ5D* using the same approach as that for P34. Table 2 shows that the G36 residue within the HPGG motif could be substituted with several different amino acids without significantly impacting the $\Delta 5$ desaturase activity of *EgΔ5D*. The *EgΔ5D-36S* or *EgΔ5D-36D* mutant had about 100.8 or 99.2 % of $\Delta 5$ desaturase activity when compared to *EgΔ5D*, respectively.

The above functional studies at the P34 and G36 positions within the HPGG motif of *EgΔ5D* demonstrated that the HPGG motif could be changed without impacting the $\Delta 5$ desaturase activity. Specifically, the *EgΔ5D-34G*, *EgΔ5D-36S* and *EgΔ5D-36D* mutants were functionally equivalent to the wild type *EgΔ5D*. Comparison of the

Table 2 $\Delta 5$ Desaturase activity of *EgΔ5D* with HPGx mutations

| Gene name | Sequence of HPGG motif | $\Delta 5$ Conversion (%) | % of wild type <i>EgΔ5D</i> |

Average of 6 samples for each construct containing different mutations

ARA in unesterified fatty acid (FFA), phospholipid (PL) and neutral lipid (NL) pools of *Yarrowia* transformants with *EgΔ5D* and *EgΔ5D-34G* showed that the P34G mutation did not affect the ARA distribution in these pools (Supplemental Fig. S2).

Improvement of $\Delta 5$ Desaturase Activity of *EgΔ5D* by Amino Acid Substitution Within the HDASH Motif

The HDASH motif was also claimed as one of the characteristics of $\Delta 5$ desaturases and necessary for its function to convert DGLA to ARA [34]. To test the hypothesis that the exact sequence of the HDASH motif (position 155–159) of *EgΔ5D* was required, we first selected the alanine residue at position 157 (A157) as a target. The $\Delta 5$ desaturase activity attributed to each mutation at A157 is summarized in Table 3. The data showed that almost all mutations at A157 greatly reduced the $\Delta 5$ desaturase activity of *EgΔ5D*. However, the *EgΔ5D-157G* and *EgΔ5D-157S* mutants retained about 96 and 94 % activity of wild type *EgΔ5D*, respectively.

We also studied the significance of the serine residue at position 158 (S158) within the HDASH motif of *EgΔ5D*. Table 4 shows that the S158 could be substituted with either an alanine or a glycine without substantially

Table 3 $\Delta 5$ Desaturase activity of *EgΔ5D* with HDxSH mutations

| Gene name | Sequence of HDASH motif | $\Delta 5$ Conversion (%) | % of wild type <i>EgΔ5D</i> |
|-------------------|-------------------------|---------------------------|-----------------------------|
| <i>EgΔ5D</i> | HDASH | 24.8 | 100 |

Average of 3 samples for each construct containing different mutations

impacting the $\Delta 5$ desaturase activity of *EgΔ5D*. Specifically, the *EgΔ5D-158A* mutant had about 100.9 % activity of wild type *EgΔ5D*, while the *EgΔ5D-158G* mutation had about 107.7 % activity of wild type *EgΔ5D*. These data demonstrated that the HDASH motif could be changed without significantly reducing the $\Delta 5$ desaturase activity. In fact, the enzyme activity of *EgΔ5D* could be improved by substitution of the S158 within the HDASH motif with a glycine residue.

Both HPGG and HDASH Motifs were not Necessary in the Exact Form as Encoded for $\Delta 5$ Desaturase Activity of *EgΔ5D*

In order to study whether *EgΔ5D* could maintain strong $\Delta 5$ desaturase activity with mutations in both HPGG and HDASH motifs, we generated a series of double mutants. The results (Table 5) demonstrate that $\Delta 5$ desaturases could be constructed having variant HPGG and HDASH motifs that retain at least 64 % of $\Delta 5$ desaturase activity when compared to the wild type.

The proline residue within the HPGG motif can be substituted with glycine with simultaneous substitution of either (1) the alanine residue within the HDASH motif for glycine or (2) the serine residue within the HDASH motif

Table 4 $\Delta 5$ Desaturase activity of *EgΔ5D* with HDAxH mutations

| Gene name | Sequence of HDASH motif | $\Delta 5$ Conversion (%) | % of wild type <i>EgΔ5D</i> |

Average of 3 samples for each construct containing different mutations

for alanine or glycine. The proline residue within the HPGG motif can also be substituted with histidine with simultaneous substitution of the serine residue within the HDASH motif for either alanine or glycine. And, the second glycine residue within the HPGG motif can be substituted with serine with simultaneous substitution of the serine residue within the HDASH motif for either alanine or glycine. Specifically, the *EgΔ5D-34G/157G*, *EgΔ5D-34G/158A* and *EgΔ5D-34H/158G* double mutants had more than 80 % of the $\Delta 5$ desaturase activity of *EgΔ5D*, while *EgΔ5D-34G/158G* had about 97 % $\Delta 5$ desaturase activity of *EgΔ5D*. Further analyses showed that the ARA distribution in FFA, PL and NL pools of *Yarrowia* transformants with *EgΔ5D-34G/158G* was similar to *Yarrowia* transformants with *EgΔ5D-34G* or *EgΔ5D* (Supplemental Fig. S2), suggesting that the simultaneous substitutions (P34G and S158G) within HPGG and HDASH motifs did not change desaturase substrate specificity.

Increased Substrate Conversion of *EgΔ5D-34G/158G* with Double Mutations in HPGG and HDASH Motifs

In order to increase the substrate conversion of *EgΔ5D-34G/158G*, we optimized the codon usage of the

Table 5 $\Delta 5$ Desaturase activity of *EgΔ5D* with mutants simultaneously comprising mutations within HPGG and HDASH motifs

| Gene name | Sequence of HPGG motif | Sequence of HDASH motif | $\Delta 5$ Conversion (%) | % of wild type <i>EgΔ5D</i> |

Average of 6 samples for each construct containing different mutations

N-terminal portion of the gene for expression in *Y. lipolytica*. The codon-optimized *EgΔ5D-34G/158G*, designated as “*EgΔ5M*”, had 48 bp changed in the first 204 bp of the coding region (23.5 %; Fig. 6), which resulted in optimization of 43 codons of the first 68 amino acids within the N-terminus of the protein (63.2 %). The amino acid sequence encoded by the codon-optimized *EgΔ5M* was identical to that of the *EgΔ5D-34G/158G*. *EgΔ5M* was used to replace the *EgΔ5D* of pDMW367-M4 to generate pDMW367-5M, containing a *FBAIN::EgΔ5M::Pex20* chimeric gene.

We then studied the importance of the arginine or serine at position 347 that were found in the original clones of *EgΔ5D*. Based on *EgΔ5M*, the CGA codon for arginine at position 347 was changed to AGC codon to encode for serine, which was designated as *EgΔ5M1*. The synthetic *EgΔ5M1* was used to replace the *EgΔ5D* of pDMW367-M4 to generate pDMW367-5M1, containing an *FBAIN::EgΔ5M1::Pex20* chimeric gene.

The $\Delta 5$ desaturase activity of *EgΔ5D*, *EgΔ5M* and *EgΔ5M1* is summarized in Table 6. GC analyses determined that there were about 3.6 % ARA and 10.8 % DGLA, 4.0 % ARA and 11.2 % DGLA, and 4.1 % ARA and 10.8 % DGLA of total fatty acids produced in the *Yarrowia* transformants with pDMW367-M4, pDMW367-5M, and pDMW367-5M1, respectively. It showed that the wild-type *EgΔ5D* converted about 24.8 % of DGLA to ARA; *EgΔ5M* converted 26.7 % of DGLA to ARA; and, *EgΔ5M1* converted 27.6 % of DGLA to ARA. The fatty acid profile of *Yarrowia* transformants with *EgΔ5M1* was

Fig. 6 Comparison of the 5' portion (204 bp) of *EgΔ5D-34G158G* and its codon optimized version, *EgΔ5M*. The DNA sequence alignment was performed with Clustal W analysis (MegAlign™ program of DNASTAR software). Identical residues are shaded in black

almost identical to the profile of *Yarrowia* transformants with pDMW367-M4 as shown in Fig. 2c, except that more ARA was produced. These data demonstrated that the codon optimization of *EgΔ5D* improved its substrate conversion efficiency. Further, the amino acid at position 347 did affect the $\Delta 5$ desaturase activity of *EgΔ5D*, with a serine residue preferred over an arginine residue.

Discussion

Y. lipolytica has an established history of robust fermentation performance at commercial scale for processes including the production of food-grade citric acid for human consumption and single-cell protein for animal feeds [55]. Recently, *Y. lipolytica* has been used as a host for production of lipid-based compounds [14, 56, 57]. Some *Y. lipolytica* strains are oleaginous organisms that are able to accumulate up to 40 % dry cell weight as oil when starved for nitrogen in the presence of excess glucose as carbon source. However, LNA is the only PUFA that *Y. lipolytica* can synthesize de novo (Fig. 2a). Therefore, it

Table 6 $\Delta 5$ Desaturase activity of *EgΔ5D* and codon optimized *EgΔ5M* and *EgΔ5M1*

| Gene name | Sequence of HPGG motif | Sequence of HDASH motif | Sequence at residue 347 | $\Delta 5$ Conversion (%) |
|---------------|------------------------|-------------------------|-------------------------|---------------------------|

| <i>EgΔ5M</i> | HgGG | HDAgH | R | 26.5 |
| <i>EgΔ5M1</i> | HgGG | HDAgH | S | 27.6 |

Average of 6 samples for each construct containing different mutations

is necessary to isolate genes encoding enzymes for every step of the “desaturation and elongation” pathways (Fig. 1) before genetically engineering *Y. lipolytica* to produce ARA, EPA and DHA oil. $\Delta 5$ desaturase is the enzyme responsible for the conversion of DGLA to ARA, and ETA to EPA. Although several $\Delta 5$ desaturase genes have been isolated from various organisms [26], more effective enzymes may help to improve the production of commercially important LC-PUFA.

Previous studies have indicated that *Euglena* was able to synthesize ARA, EPA and DHA through the “ $\Delta 9$ elongase/ $\Delta 8$ desaturase” pathway [16, 38, 45]. In this report, the gene encoding a $\Delta 5$ desaturase from *E. gracilis* was isolated and characterized. Our results indicated two nucleotide sequences with a difference of two base pairs that would result in either arginine or serine at position 347. This discrepancy was most likely generated from PCR amplification or during cDNA generation. BlastP searches showed that the amino acid sequence of *Eg $\Delta 5D$* shares <40 % identity with any $\Delta 5$ desaturase found in Genbank; *Pt $\Delta 5D$* [47] was the most similar one (about 39 %), suggesting that the primary structure of *Eg $\Delta 5D$* is quite different from those $\Delta 5$ desaturase genes previously isolated. Amino acid sequence alignment also shows that *Eg $\Delta 5D$* has about 20 % identity with *Eg $\Delta 8D$* [16, 38] and about 25.5 % identity with *Eg $\Delta 4D$* [45]. These data suggest that *Eg $\Delta 5D$* is evolutionary closer to $\Delta 5$ desaturase than the $\Delta 4$ or $\Delta 8$ desaturases. Functional analyses of *Eg $\Delta 5D$* in *Y. lipolytica* strains Y4036U and Y2224 revealed that it has strong $\Delta 5$ desaturase activity, with more than 24 % substrate conversion of DGLA to ARA, and it is not a $\Delta 5/\Delta 6$ bifunctional enzyme.

The HPGG motif is expected to be on the cytochrome b_5 surface, in contact with the heme through van der Waals interactions [27]. The conserved HPGG motif was thought to be essential in maintaining cytochrome b_5 electron transfer function, with the histidine serving as a heme axial ligand [50]. Substitution of the histidine residue of the HPGG motif with alanine in the $\Delta 6$ desaturase cytochrome b_5 domain of starflower, rat and algae abolished $\Delta 6$ desaturase activity [51–53]. It is expected that H33 of *Eg $\Delta 5D$* should also be essential for its function.

The HPGG motif itself has a unique structure. The proline residue of the HPGG stretch is located in a turn between two consecutive helices (Fig. 5) and was thought to be important in protein folding and in maintaining cytochrome b_5 protein stability [32]. The three-carbon side chain of proline is bonded to both the nitrogen and the carbon of the peptide backbone to form a five-member ring that greatly restricted its conformational freedom. The nonpolar characteristic of this ring structure may create a hydrophobic spot within the HPGG motif. On the other hand, the glycine possesses the smallest amino acid side

chain, hydrogen, which can allow for greater flexibility in local structure. It is likely that the combination of proline and glycine residues within the cytochrome b_5 HPGG motif is an important factor affecting both the structural position of the hydrophobic heme pocket and the appropriate orientation of the heme group within the heme pocket relative to the desaturase catalytic site. Surprisingly, our results indicate that the proline residue of the HPGG motif is not essential for electron transfer from the heme group of the cytochrome b_5 domain to the catalytic diiron cluster of *Eg $\Delta 5D$* . Most substitution mutants at P34 displayed at least 70 % of the wild type *Eg $\Delta 5D$* activity. The *Eg $\Delta 5D$ -34G* (HgGG) mutant had greater than 98 % of the wild type *Eg $\Delta 5D$* activity, demonstrating that the proline residue of HPGG motif is not required for the enzyme activity of *Eg $\Delta 5D$* (Table 1).

It is noteworthy that aspartate substitutions in *Eg $\Delta 5D$ -34D* and *Eg $\Delta 5D$ -36D* exhibit different effects on desaturase activity. Compared to free cytochrome b_5 , while there are several conserved acidic amino acids, there is a characteristic reduction in the number of aspartate and glutamate residues in the vicinity of the HPGG motif of cytochrome b_5 domain of desaturases. This reduced number of acidic residues around the heme pocket is thought to contribute to stabilizing nonpolar intermolecular interactions between the cytochrome b_5 and desaturase domains [27, 54]. Substitutions involving aspartate or glutamate residues in the HPGG motif may affect the interface geometry of electron donor/acceptor docking that is exhibited in desaturase activity due to altered electron transfer. We also found that substitutions for G36 of *Eg $\Delta 5D$* resulted in mutants with strong $\Delta 5$ desaturase activity. The most functional mutants were the small, slightly polar serine replacement, *Eg $\Delta 5D$ -36S*, and the acidic substitution with aspartate, *Eg $\Delta 5D$ -36D*. The activities of these two mutants are about the same as the wild type *Eg $\Delta 5D$* (Table 2).

The amino acid sequence of the first His-rich motif, HX_(3, 4)H, of *Eg $\Delta 5D$* is HDASH located from residues 155 to 159. The HDASH motif has been suggested as one of the characteristics of $\Delta 5$ desaturases and necessary for its function to convert DGLA to ARA in any transformed organisms [34]. Sequence analyses showed that there are natural variants of the HDASH motif in $\Delta 5$ desaturases, for example, *Pt $\Delta 5D$* [46] has the sequence of HDsSH, the $\Delta 5$ desaturase from *Thraustochytrium* sp. ATCC 21685 (GenBank accession #: AAM09687) has the sequence of HemgH, the $\Delta 5$ desaturase from *Leishmania major* strain Friedlin (GenBank accession #: CAJ07076) has the sequence of HeAgH, the $\Delta 5$ desaturase from Atlantic salmon (GenBank accession #: AAL82631) has the sequence of HDygh, and *Pt $\Delta 5D$* [47] has the sequence of HDAnH in the corresponding location. This suggests that the HDASH

motif is not an invariant characteristic of $\Delta 5$ desaturases, and may be not required for $\Delta 5$ desaturase activity. We suggest that the two His residues of HDASH motif participate in the coordination of the diiron center (Fig. 5), but the other three residues (DAS) residues between the two His residues can be modified.

Systemic substitution studies (Tables 3, 4) at positions A157 and S158 within the HDASH motif of *EgΔ5D* demonstrated that these two residues could be replaced, and the mutants retained good $\Delta 5$ desaturase activity. The *EgΔ5D-157G* and *EgΔ5D-157S* mutants had about 96 and 94 % of the wild type *EgΔ5D* activity, respectively. Since *PiΔ5D* has an HDsSH motif [46], it is not surprising that *EgΔ5D-157S* with sequence HDsSH functioned well in *Yarrowia*. We also found that S158 could be substituted with either alanine or glycine. The alanine, glycine and serine are interchangeable within the HDASH motif of *EgΔ5S*; furthermore, the enzyme activity of *EgΔ5D* could be improved with a motif of HDAGH instead of HDASH (Table 4).

To determine whether at least one motif, HPGG or HDASH, is required for the enzyme activity of *EgΔ5D*, a series of mutants with mutations in both the HPGG and HDASH motifs was generated (Table 5). Some double mutants such as *EgΔ5D-34G/157G*, *EgΔ5D-34G/158A* and *EgΔ5D-34H/158G* had more than 80 % of wild type *EgΔ5D* activity, while *EgΔ5D-34G/158G* had almost the same activity as wild type *EgΔ5D*. Therefore, neither the HPGG nor the HDASH motif is necessary in the exact form as encoded for the activity of *EgΔ5D*.

Distribution analyses (Supplemental Fig. S2) of ARA in FFA, PL and NL pools of *Yarrowia* transformants with *EgΔ5D* shows that more ARA loaded in PL pool than that in FFA pool, suggesting that *EgΔ5D* is also an acyl-lipid desaturase, just like other front-end desaturases from lower plants, fungi and algae [26]. ARA distribution comparison of *Yarrowia* transformants with *EgΔ5D-34G* and *EgΔ5D-34G/158G* with wild type *EgΔ5D* shows that either single mutation within HPGG motif (P34G), or simultaneous mutations within HPGG (P34G) and HDASH (S158G) motifs does not change its fatty acid distribution pattern (Supplemental Fig. S2), and therefore these changes in *EgΔ5D* do not affect its substrate specificity.

An effective $\Delta 5$ desaturase is required for efficient conversion of DGLA to ARA or ETA to EPA (Fig. 1) in engineered *Y. lipolytica* or other organisms to produce commercially valuable LC-PUFA. We employed two approaches to improve the enzyme activity of the double mutant *EgΔ5D-34G/158G*. The optimization (Fig. 6) of the 43 codons of the 68 amino acids within the N-terminal portion of *EgΔ5D-34G/158G*, *EgΔ5M*, improved substrate conversion (Table 6). This improvement may relate to the rate of translation. Recent reports suggest that sequence at

the beginning of a gene can influence translation, and the mRNA structure at the 5' end of an mRNA can affect protein levels [58, 59]. Next, we substituted the arginine residue at position 347 with the serine which was identified in our original PCR products. Surprisingly, this R347S substitution in codon optimized *EgΔ5M1* further improved substrate conversion (Table 6). These data suggest that some un-conserved amino acids among different $\Delta 5$ desaturases may be good targets for protein evolution to generate improved enzymes. At this stage, the improved *EgΔ5D*, both *EgΔ5M* and *EgΔ5M1* should enable us to engineer *Yarrowia* and other organisms to produce high levels of ARA, EPA and DHA.

In conclusion, our studies suggest that the exact sequences of the HPGG and HDASH motifs are not necessary for the function of *EgΔ5D*. Several amino acids within these two motifs can be changed individually, or simultaneously, without significantly reducing the enzyme activity or altering its substrate specificity. In some cases such as *EgΔ5D-36D*, *EgΔ5D-36S*, and *EgΔ5D-158G* mutants, the $\Delta 5$ desaturase activity can be improved. In order to fully understand the function of *EgΔ5D*, the roles of the HX_(2, 3)HH and (H/Q)X_(2, 3)HH motifs as well as the un-conserved amino acids need to be studied in the future.

Acknowledgments We are grateful to Ethel Jackson and Henry Bryndza for their strong support. We thank every member of our Omega-3 team for their suggestions and discussions, Raymond Jackson and the DNA sequencing lab for their technical service, and Kelley Norton and Arthur Kruckeberg for critical reading of this manuscript.

Abstract Autotaxin (ATX) is a glycoprotein that was first identified in the conditioned medium of human melanoma cells as an autocrine motility factor. It possesses lysophospholipase D activity, producing the bioactive lipid mediator lysophosphatidic acid (LPA) from lysophosphatidylcholine. Enhanced expression of ATX mRNA has been reported in various cancer cells and tissues, and it has been speculated that ATX overexpression in cancer cells may be associated with aberrant LPA production. LPA and ATX have been implicated in cancer progression and metastasis, and ovarian

cancer is a representative example. In the present study, we measured the serum ATX antigen levels in patients with ovarian cancer and evaluated the usefulness of this parameter for clinical laboratory testing. The serum ATX antigen levels were not increased in ovarian cancer patients as compared with the levels in healthy subjects, and the serum ATX may not be useful as a biomarker for ovarian cancer.

Introduction

Lysophosphatidic acid (1- or 2-acyl-*sn*-glycero-3-phosphatidic acid, LPA) is a simple lysophospholipid, and is attracting great attention as a lysophospholipid mediator. This bioactive lipid exerts important biological actions, including cell proliferation, migration and survival [1]. The multiple actions of LPA are explained by its binding to and activation of specific G-protein-coupled receptors (LPA1-6), leading to subsequent stimulation of the small GTPases, Ras, Rho and Rac [1–3].

The precise mechanism underlying the extracellular production of LPA has been elucidated in recent studies. In the plasma, autotaxin (ATX) plays a pivotal role in the production of LPA [1, 4]. ATX is a glycoprotein which was

first discovered in the conditioned medium of human A2058 melanoma cells as an autocrine motility factor [1]. Later, it was revealed that ATX possesses lysophospholipase D (lysoPLD) activity, which hydrolyzes lysophosphatidylcholine to produce LPA [4].

LPA has been shown to be involved in several cellular processes such as proliferation, progression and invasion in in-vitro studies [1, 5–7]. On the other hand, enhanced expression of ATX mRNA has also been reported in various metastatic cancer cells and tissues [1, 7–10], and it has been speculated that ATX overexpression in cancer cells may be associated with aberrant LPA production. Together with these findings, not only LPA, but also ATX are likely to play critical roles in the pathophysiology of cancers.

Several studies have indicated that ATX and LPA are also related to the development/progression of ovarian cancer. For example, LPA and ATX have been demonstrated to promote ovarian cancer progression and invasion [6, 7]. ATX has been shown to delay apoptosis induced by carboplatin in ovarian cancer cells [8]. In addition, ATX and LPA receptors have been shown to be expressed in these cells [7, 8]. These studies clearly suggest that ATX and LPA are involved in the onset/progression of ovarian cancer.

Previous studies have investigated whether LPA can serve as a potential biomarker for ovarian cancer. The plasma LPA levels have been found to be increased in patients with ovarian cancer [11]. However, another group reported no difference in the plasma LPA levels between patients with ovarian cancer and healthy controls [12]. At present, whether plasma LPA might serve as a useful marker of ovarian cancer is still controversial. One of the reasons for this discrepancy is the difficulty in plasma LPA measurement. We previously reported that measurement of the plasma LPA concentration for clinical purposes has the critical and difficult problem; plasma levels of LPA can be easily altered during the sample preparation and preservation [13]. Therefore, re-examination conducted under stringent conditions to minimize any increase of the LPA level after sampling is needed for evaluation of the usefulness of plasma LPA measurement for ovarian cancer.

While plasma/serum LPA increases dramatically if samples are not handled properly, the serum ATX/lysoPLD remains relatively stable [13]. Serum ATX measurement seems to allow easier handling of the samples than plasma LPA measurement, and we confirmed that the ATX/lysoPLD antigen concentration and activity were well correlated with the plasma LPA concentration [10, 14–16]. Therefore, the plasma LPA can be estimated from the serum ATX. In the present study, we measured the serum ATX antigen levels in patients with ovarian cancer and evaluated the usefulness of this parameter for clinical laboratory testing.

Methods

The serum samples used in this study were residual samples of those obtained for laboratory analyses (for medical checkups). The study was conducted with the approval of the Institutional Research Ethics Committee of the Faculty of Medicine, the University of Tokyo. Informed consent from the patients was obtained for the use of the samples. Commercially available serum of ovarian cancer patients and healthy subjects were obtained from SLR Research Corporation (Carlsbad, CA, USA), BioTheme Research Solutions, Inc. (Davie, FL, USA) and ProMedDx, LLC (Norton, MA, USA).

The ATX antigen levels in the serum were determined by a two-site immunoenzymetric assay using the ATX assay reagent and the TOSOH AIA system (TOSOH, Tokyo, Japan) [14]. Serum cancer antigen 125 (CA125) levels were also analyzed by a two-site immunoenzymetric assay. The statistical significance of the differences between two groups was determined by an unpaired Student's *t* test. The correlations were evaluated by linear regression analysis. $p < 0.05$ was considered to be indicative of statistical significance.

Results

We first compared the ATX antigen concentrations in residual serum samples between ovarian cancer patients and healthy subjects (Table 1-A). No significant difference in the mean serum ATX level was observed between the patients and healthy subjects ($p = 0.946$). We then examined the correlation between the serum ATX and the serum CA125 in ovarian cancer patients. CA125 is believed to be the best biomarker for ovarian cancer, and is increased to above 35 U/mL in about 80 % of women with epithelial ovarian cancer [17]. No significant correlation was observed between ATX and CA125 ($p = 0.797$, Table 1-A). Similarly, no significant difference of the ATX level was observed between the patients and healthy subjects when commercially available sera were employed ($p = 0.110$, Table 1-B). Slight but significant correlation was detected between ATX and CA125 in commercially available serum ($r = 0.347$, $p < 0.001$) although its significance remains to be solved. When we analyzed the relationship between the serum ATX concentrations and the clinical course in two patients with ovarian cancer, no changes in the serum ATX were detected after chemotherapy, while the serum CA125 levels markedly decreased after chemotherapy (data not shown).

Table 1 Serum ATX concentrations in serum samples from patients with ovarian cancer and healthy subjects

| | No. of patients | Age (years) mean \pm 2SD | ATX antigen levels mean \pm 2SD (mg/L) | CA125 levels mean \pm 2SD (U/mL) | Linear regression analysis | |
|----------------------------------|-----------------|-------------------------------|---|---------------------------------------|----------------------------|----------|
| | | | | | <i>r</i> | <i>p</i> |
| (A) Residual serum samples | | | | | | |
| Ovarian cancer patients | 21 | 53 \pm 24 | 0.856 \pm 0.376 | 438 \pm 969 | 0.060 | 0.797 |
| Healthy subjects | 46 | 37 \pm 18 | 0.859 \pm 0.353 | | | |
| (B) Commercially available serum | | | | | | |
| Ovarian cancer patients | 101 | 64 \pm 30 | 1.122 \pm 0.754 | 970 \pm 4,261 | 0.347 | <0.001 |
| Healthy subjects | 56 | 38 \pm 18 | 1.031 \pm 0.537 | | | |

There was no significant difference in the mean ATX concentration between ovarian cancer patients and healthy subjects, as determined using an unpaired Student's *t* test. No significant correlation between the serum ATX and serum CA125 was observed in ovarian cancer patients in residual serum samples, while significant correlation was detected between these parameters in commercially available serum, as determined using linear regression analysis. The reference value for CA125 is below 30 U/mL.

Discussion

In this study, we measured the serum ATX concentrations in ovarian cancer patients based on our initial supposition that the serum ATX levels might be increased in these cancer patients. However, no significant differences were detected in the serum ATX concentrations between patients with ovarian cancer and healthy subjects (Table 1). No significant correlation was detected between ATX and CA125 in our residual serum samples, while slight but significant correlation was detected when commercially available sera were assayed; its significance remains to be solved based on the fact that no significant differences were detected in the serum ATX concentrations between patients with ovarian cancer and healthy subjects despite a major difference for CA125.

Based on our present data, it seems unlikely that the serum ATX is useful as a tumor marker for ovarian cancer. In this study, we measured only the serum ATX antigen since its concentration is well correlated with the serum lysoPLD activity and since ATX assay is actually more promising than the lysoPLD activity measurement for routine laboratory testing. We, however, admit the limitation of our data since we did not confirm the correlation between the levels of ATX antigen and lysoPLD activity using samples from ovarian cancer patients, which should be important future tasks.

ATX was originally identified as a tumor cell motility factor and has been reported to be expressed in several cancer cells [1, 7–10]. Therefore, it was deemed that the serum ATX may reflect the pathological condition and be elevated in cancer patients. Contrary to this expectation, not many reports have clarified the clinical significance of serum ATX measurement in these patients. The (patho)physiological conditions associated with marked aberrant elevation of the serum ATX induced by cancer cells appear to be limited to follicular lymphoma and

pancreatic cancer, at least at present [10, 18]. In addition to ovarian cancer, we also confirmed that the serum ATX antigen was unsuitable as a tumor marker for prostate cancer (data not shown), as had been shown by measuring lysoPLD activity [9]. Considering the specificity of the rise of the serum ATX in these conditions, measurement of the serum ATX may be extremely useful for the diagnosis of follicular lymphoma and pancreatic cancer.

As described above, we could not confirm the clinical significance of the serum ATX assay in ovarian cancer patients despite that ATX is reportedly involved in the onset/progression of ovarian cancer. Our present data may indicate that ovarian cancer cells do not produce sufficient amounts of ATX to cause an elevation of the serum ATX concentrations. Although the serum ATX is not increased in ovarian cancer patients, this does not exclude the possibility of ATX involvement in ovarian cancer, since ATX, which produces LPA, may locally play an important role in its pathophysiology.

Abstract Because of efforts to decrease *trans* fatty acids (TFA) in the food supply, intake should be assessed in the population to establish a baseline TFA intake. The 1999–2002 National Health and Nutrition Examination Survey (NHANES) was used to identify a benchmark for TFA intake. TFA was estimated by mean, median, and quintile of intake, TFA intake data were weighted using the NHANES 4-year sample weights. The main outcome measures included TFA intake in grams per day and

percentage of energy in the top 25 food sources of TFA. Data are reported for 16,669 individuals ≥ 3 years of age. Median TFA intake was 2.3 % of calories (5 g/day) with 0.9–4.5 % of energy (1.5–13.1 g/day) over different quintiles of intake. Mean TFA intake was 2.5 % of energy (6.1 g/day). The range of TFA intake in the fifth quintile was very large, i.e., 3.5–12.5 % of energy or 8.8–92.4 g/day. Increasing quintiles of TFA intake were associated with increases in total fat (26.7–37.6 % of energy), saturated fat (7.6–10.5 % of energy), and calories (for those >20 years of age: 2,416–2,583 for men and 1,679–1,886 for women). Major food sources of dietary TFA were cakes, cookies, pies, and pastries. Based on current dietary guidance to consume as little industrial TFA as possible, much progress is needed to attain this goal, including food industry efforts to remove TFA from the food supply and educating the public about making healthy food choices.

Introduction

Dietary recommendations have been made in the United States and globally to decrease *trans* fatty acids (TFA) produced by partial hydrogenation of vegetable oils [1, 2]. These recommendations are based on numerous studies demonstrating many adverse health effects of TFA [3]. Multiple strategies have been invoked in the United States to decrease dietary TFA, including nutrition labeling of TFA on the Nutrition Facts Panel (law passed in 2003; enacted in 2006), as well as passage of legislation banning or restricting use of fats and oils containing TFA in some states and cities [4, 5]. In 2009, legislation to limit TFA in the food supply was enacted in 1 state and proposed in 13 states and the District of Columbia [6]. Based on the success of this approach in New York, it seems that legislative strategies may be an effective strategy for decreasing TFA in foods [7]. Mozaffarian and Stampfer [7] estimated that a 1 % reduction in TFA intake could prevent 72,000 cardiovascular disease-related deaths per year. The U.S. Food and Drug Administration (FDA) have also suggested that the removal of TFA from just 3 % of breads and cakes and 15 % of cookies and crackers would save up to US \$59 billion in health care costs over the next 20 years [8]. Consequently, the food industry is actively lowering TFA in the food supply by developing new fats and oils and modifying existing ones [9, 10].

The last comprehensive analysis of TFA intake was published by Allison et al. [11] in 1999, using 1989–1991 data collected from the U.S. Department of Agriculture's (USDA) Continuing Survey of Food Intakes by Individuals (CSFII). At that time, the average TFA intake in the United States was 2.6 % of calories, or 5.3 g/day [11]. Since the work by Allison et al. was published, many food products have had TFA removed and/or reduced appreciably [5, 12]. Much of this has happened as the result of legislation (announced on January 9, 2003) mandating TFA labeling on the Nutrition Facts Panel by January 1, 2006. Clearly, there is a need to evaluate the effects of this announcement and legislation on current TFA intake, and this needs to be done in the context of the most current TFA intake prior to the FDA's announcement. Consequently, it is important to benchmark current TFA intake against intake that is more recent than the 1989–1991 data to evaluate the impact of legislation enacted to decrease TFA intake.

The purpose of this study was to assess TFA intake in different population groups in the United States using more recent intake data from the 1999–2002 National Health and Nutrition Examination Survey (NHANES) just prior to the time that legislation was passed for TFA to be listed on the Nutrition Facts Panel. We also evaluated food sources of TFA in different population groups. A better understanding

of the major food sources of TFA would be helpful for ongoing efforts to markedly lower TFA in the food supply.

Materials and Methods

Estimation of TFA Intake During 1999–2002

To estimate dietary intake of TFA, we used 1999–2002 NHANES consumption data as well as the Foods Analysis and Residue Evaluation Program (FARE) software (v.7.997; Exponent, Washington, DC). FARE is proprietary data processing software that was developed to facilitate the mining of the thousands of individual intake records in the NHANES database. A more detailed description of the analysis done by using the FARE program is described by DiRienzo et al. [13]. FARE is used by the FDA, the USDA, the California Office of Environmental Health Hazard Assessment, and the Health Canada Pest Management Regulatory Agency to derive estimates of food, nutrient, and contaminant intakes based on NHANES and CSFII consumption data.

Dietary assessment in NHANES 1999–2002 was conducted using two 24-h dietary recalls, one in person and a second one by telephone [14]. The TFA content of foods was derived from the NHANES dataset. The NHANES used the *Trans* Fatty Acid Database (laboratory analyses completed between 1990 and 1993) that was released in 1995 as “Special table 1: Fat and fatty acid content of selected foods containing *trans* fatty acids.” This is referred to as the USDA Nutrient Database for Standard Reference (Release 15) which was used to map the *trans* fat content of analyzed foods to the foods reported in the 1999–2002 NHANES. Total dietary TFA intakes were calculated by multiplying the amount of food consumed by the concentration of TFA in that food, and were expressed as a percentage of individual energy intakes per day. The TFA intake data were weighted using the NHANES 4-year sample weights as a means to ensure that the results are representative of the US population (aged ≥ 3 years). Two separate analyses were required to determine the quintile cutoff points for grams per day as well as percentage of energy. The quintiles for the analyses expressed as grams per person per day were calculated based upon grams per day of TFA intake. A second set of population quintile groups was calculated for the percentage of energy analyses based upon the per capita TFA intake expressed as a percentage of energy. The values provided within each quintile are the mean nutrient intakes of that quintile of the population. The inter-quintile ranges of TFA intake from the total diet for each quintile are provided. The un-weighted sample sizes are not exactly the same for each quintile; however, the quintiles are balanced after applying

the statistical weights. Populations were defined by age and gender according to the criteria used by Allison et al. [11] so that results could be compared.

Estimation of Food Sources of TFA

Twenty-five food categories were established based on pre-established food groupings in NHANES (e.g., grains and salty snacks, milk and milk products, etc.) and then further sub-divided to allow identification of categories of foods as eaten (e.g., ready-to-eat breakfast cereals) or that were mentioned in previous studies to be contributors to TFA intakes. The amount of TFA in food (g/100 g) was derived from NHANES recipes as described above.

Results

The mean, median, 90th percentile, and quintiles of TFA intake, as well as other fatty acids, total fat (in grams per day), and energy in the U.S. population (aged ≥ 3 years), are reported for 16,669 subjects (Table 1; Fig. 1) as well as percentages of energy (Table 2). It is apparent that males aged 12–19 years have the highest mean TFA intake expressed as grams per day compared with the other populations for each quintile. When expressed as a percentage of energy, the intake of TFA was similar in all population groups. Subjects were stratified on the basis of total TFA intake as grams per day or percentage of energy, thereby explaining why the number of subjects differs within a quintile between tables for all population groups. The median TFA intake between 1999 and 2002 was 2.3 % of calories (5 g/day) with a range of 0.9–4.5 % of energy (1.5–13.1 g/day) over the different quintiles of intake. The mean TFA intake was 2.5 % of energy (6.1 g/day). There was a remarkable range of TFA intake in the top quintile (3.5–12.5 % of energy, or 8.8–92.4 g/day). Increasing quintiles of TFA intake were associated with increases in total fat (range, 26.7–37.6 % of energy), saturated fat (range, 7.6–10.5 % of energy), as well as calories (for men and women aged >20 years: 2,416–2,583 for men and 1,679–1,886 for women). Interestingly, intakes of *cis*-monounsaturated fatty acid (MUFA) and linoleic acid (both as grams per day and percentage of energy) also increased with increasing TFA intake. Notably, from the first to the fifth quintile, energy intakes increased approximately twofold in each cohort, whereas TFA increased 5- to 8-fold across the quintiles for all cohorts. On a percentage-of-energy basis, TFA increased about 4.5- to 5-fold across the quintiles for all cohorts. This suggests that food choices varied and dietary patterns differed across the TFA quintiles. Likewise, as a percentage of energy, TFA intake also increased concomitant with increases in

percentage of energy from total fat, saturated fatty acids (SFA), MUFA, and polyunsaturated fatty acids, with the increases in TFA being proportionally greater. Specifically, TFA increased 4- to 5-fold across quintiles of TFA intake, whereas energy intake increased from 7 to 17 %. Trends for TFA intakes were similar for all population groups studied (Tables 1, 2), with median TFA intake ranging from 2.1 to 2.5 % of calories (4.4–6.6 g/day). The mean TFA intake ranged from 2.3 to 2.7 % of calories (5.0–7.8 g/day). Intakes of TFA (as a percentage of calories), as well as SFA, oleic acid, linoleic acid, and alpha-linolenic acid, were similar among the different cohorts studied (Fig. 2).

The top 25 food categories that accounted for 79 % of TFA intake in the United States were identified on the basis of gram quantity of TFA consumed (Fig. 3). In our analysis, the major source of dietary TFA in the total population aged ≥ 3 years was cakes, cookies, pies, and pastries (Fig. 3), accounting for approximately 19 % of total TFA intake. Importantly, this food source of TFA was approximately 2-fold higher than the next three leading sources, which include yeast breads, French fries (commercial), and grain mixtures/ethnic mixed dishes. The fifth highest contributor was tortilla chips (accounting for 5.5 % of total TFA). Stick margarine provided 2.9 % of total TFA, and was ranked eighth in TFA intake. The 10 major food sources of TFA across the different population cohorts were very similar (Table 3).

A comparison of the above data with the 1989–1991 CSFII data [11] showed that the mean and median values were similar across cohorts, whereas TFA intake at the 90th percentile was higher (Table 4) in our analysis. In terms of the percentage of calories from TFA in 1989–1991, all cohorts in the 90th percentile of TFA intake consumed approximately 3.2 % of calories. In contrast, using the 1999–2002 NHANES data, TFA intake was 4.1–4.7 % of calories in similar cohorts. These results clearly indicate that consumption of TFA food sources increased considerably between 1991 and 2002 in individuals in the 90th percentile of TFA intake.

Discussion

The mean TFA intake in children and adults in the United States between 1999 and 2002 was 5.0–7.8 g/day (2.3–2.7 % of energy). In all cohorts, the range in TFA intake from the first quintile (1.3–2.0 g/day) to the fifth quintile (9.6–16.5 g/day) varied by approximately 5- to 8-fold. On a percentage-of-calories basis, TFA consumption ranged from 0.8–1.2 % (quintile 1) to 4.4–5.0 % of calories (quintile 5). For all population groups, there was remarkable variation in the range of TFA intake on a

^a Per capita estimates are based on food consumption data for all individuals who responded during the one NHANES survey day, whether they reported eating the food(s) or ingredient(s) of interest. Percentage of energy for total fat and the individual fatty acids should be determined per individual and grouped within quintiles based on *trans* intake as %en. Conducted in FARE version 7.99

^b Quintiles calculated based upon % energy from total *trans* fatty acid consumption. Interquintile range (*IQR*) indicates cutoff values of *trans* fat intake, and mean intake values are reported within each quintile

^c Energy units are kcal/day. The values for each quintile are the mean kcal/day consumed by the participants who consumed the amount *trans* fat as a % of energy listed in the interquintile range

grams-per-day basis, as well as a percentage-of-energy basis in quintile 5. Variation was greatest in males aged 12–19 years, with intake that varied from 12 to 92 g/day in quintile 5. Collectively, these data illustrate that some individuals consume large quantities of TFA (in quintile 5), whereas there are others who eat little TFA (in quintile 1). Interestingly, as TFA intakes increased across quintiles, energy, total fat, and SFA intakes also increased in all populations. However, there were important differences in the magnitude of increases for each of these dietary constituents. Although there were noticeable increases in total fat and SFA intake across quintiles, as well as somewhat

modest increases in energy intake across quintiles (specifically for the fatty acid data presented as percentages of energy in Table 2), the proportional increase in TFA was dramatically greater.

Collectively, our results indicate a change in dietary patterns across quintiles. Specifically, TFA-containing foods were either added to the diet or substituted for non-TFA-containing foods. Given that the proportional increase in dietary TFA was greater than the increase in energy, it seems that substitution of TFA-containing foods was more common. Thus, a high TFA intake reflects a different dietary pattern compared with a lower TFA intake. In fact,

Fig. 2 Fatty acid intake (% of calories) by demographic group. *SFA* saturated fatty acid, *LA* linoleic acid, *ALA* alpha-linolenic acid, *TFA* *trans* fatty acid

Fig. 3 Contribution of 25 food categories to dietary TFA. The Y axis represents the percentage of total TFA contributed by the respective food category

starting with quintile 2, it appears that the dietary patterns are shifting because of increases in the proportions of TFA, SFA, and total fat (as a percentage of energy) relative to the increase in energy intake. However, although all population groups showed similar changes in fatty acids and energy across quintiles, it can be concluded that dietary patterns within a quintile are likely comparable among the different population groups.

It is telling that the results of this study show that the population evaluated in 1999–2002 consumed similar amounts of TFA compared to the U.S. population surveyed in 1989–1991 [11]. In fact, the mean and median TFA intakes are similar in both studies. However, what is striking between the two studies is the increase in TFA intake in the

90th percentile. As Table 4 shows, there were approximately 20 and 27 % higher TFA intakes in men and women, respectively, in the 1999–2002 database versus the earlier survey. Collectively, this finding suggests that there is a relatively large cohort of individuals in the population who have made changes in their diet in a manner that is incongruent with current dietary recommendations. It is important to appreciate that the large gap between the 99.9th and 100th percentiles of TFA intake (34 vs. 92 g/day) most likely represents only a very small group of high-TFA consumers, which would be expected to slightly skew the results for this cohort. Nonetheless, these findings indicate that there are individuals who follow extreme dietary practices, putting them at high risk for chronic disease and malnutrition.

Table 3 Top 10 food group contributors to *trans* fat intake in different population groups

^a CSFII adult data were divided into subgroups of 20–49 and 50–69 years; NHANES reported all adults in one group (≥20 years)

The food sources of dietary TFA are similar among the different population groups studied. The major TFA sources were cakes, cookies, pies, and pastries, as well as yeast breads, French fries, grains and ethnic dishes, and tortilla chips. It is important to note that many food sources of TFA are also major contributors of SFA [8], such as

grain-based desserts, savory snacks, ethnic dishes, and French fries/fried potatoes. Many of these foods are typically classified as discretionary calories and consequently should be limited in the diet. Reducing these foods would not only decrease TFA but also SFA and excess calories.

Our analysis provides useful information about TFA intake and food sources in the United States prior to the onset of legislative action intended to decrease TFA in the food supply. The data presented here are important as a benchmark to track changes in TFA intake in the future as the result of these sweeping legislative mandates to decrease TFA in the food supply. It will be important to monitor changes in fatty acid intake in the population because of the concerted effort to remove TFA from the food supply. Much progress has occurred in food science and lipid chemistry to appreciably decrease industrially produced TFA in the food supply in recent years. In fact, a new study reported an average population intake of 1.3 g/day of industrially produced TFA using analysis of 2003–2006 NHANES data [15]. In many instances, oils high in MUFA are replacing conventional fats that are high in TFA (e.g., for liquid fat food applications), whereas in other situations, fat sources of SFA are replacing solid fats rich in TFA (e.g., for solid fat food applications). One caveat to be mindful of is that efforts to decrease TFA should not result in increases in SFA intake in the population. Consistent with this, the American Heart Association [16] has recommended that TFA and SFA in unmodified foods not be greater than total SFA in modified foods. It is clear that there are currently countless fats that differ in their fatty acid profiles that could be substituted for TFA. It will be important that fats devoid of TFA be selected to achieve current dietary fatty acid guidelines and, thereby, realize a public health benefit. This has been

reported in a recent modeling exercise by Lefevre et al. [17]. The last point that must be emphasized is to acknowledge that many of the foods that deliver industrially produced TFA are “extras in the diet,” and even if they are modified to have a fatty acid profile that is consistent with current dietary recommendations, their intake should be limited within the context of a healthy diet that meets current food-based and nutrient recommendations. Limiting intake of these fatty acid-modified foods will also help control calories, which is a pressing societal need.

A limitation of this study is that the analysis of TFA intake was based on NHANES 1999–2002 data. The TFA data were derived from the 1995 *Trans* Fatty Acid Database and the USDA Nutrient Database for Standard Reference (Release 15). Consequently, changes that were made in foods in the marketplace (with respect to TFA content) between 1993 (when the TFA analyses of foods were completed) and 1999–2002 are not reflected in this analysis. This is a well-recognized limitation of the available nutrient databases and underscores the importance of continuously updating them. Another potential limitation is the use of two 24-h recalls. According to Allison et al. [11], 3 days of intake data provide a better assessment of usual intake. Moreover, the present study only evaluated industrial TFA and not other sources of TFA, which could have important health implications [18]. Despite these limitations, however, this study provides useful information about TFA intake in the population and important food sources prior to collective efforts by the food industry to decrease TFA in the food supply.

In summary, in all population groups studied, TFA intake between 1999 and 2002 was 5.0–7.8 g/day (2.3–2.7 % of energy). Much of the TFA consumed was derived from energy-dense and nutrient-poor foods such as cakes, cookies, pies, pastries, and savory snacks (i.e., chips). Strikingly, there was a population, albeit small, with an extremely high intake of TFA (males aged 12–19 years in the fifth quintile, who consumed 11.8–92.4 g/day) as well as SFA (and also energy). Obviously, this reflects very poor dietary practices. In fact, as TFA intake increased in the population groups studied, there was a trend toward poorer dietary practices. Ongoing nutrition intervention efforts must be directed at decreasing TFA and also promoting healthy dietary patterns.

Abstract Previous experiments in mice showed that dietary *trans*-fats could play a role in non-alcoholic steatohepatitis (NASH) yet little is known about the accumulation *trans*-fats in hepatic lipid pools in relationship to liver injury. NASH is also associated with obesity yet improves with only modest weight loss. To distinguish the role of obesity versus sustained consumption of a *trans*-fat containing diet in causing NASH, mice with obesity and NASH induced by consuming a high *trans*-fat diet for 16 weeks were subsequently fed standard chow or maintained on *trans*-fat chow for another 8 weeks. The accumulation, partitioning and loss of *trans*-fats in the major hepatic lipid pools during and after *trans*-fat consumption were

determined. Obese mice switched to standard chow remained obese but steatohepatitis improved. *trans*-fats were differentially incorporated into the major hepatic lipid pools and the loss of *trans*-fats after crossover to control chow was greatest in the cholesteryl ester pool. In summary, dietary changes can improve the biochemical and histopathological changes of NASH despite persistent obesity in mice. Analysis of hepatic lipids confirmed that dietary *trans*-fats accumulate in the major lipid pools and are released differentially with diet normalization. The substantial loss of *trans*-fats from the cholesteryl ester pool in parallel with improvement in NASH suggests that this pool of *trans*-fats could play a role in the pathogenesis of NASH.

Introduction

Lifestyle modifications that include caloric restriction to achieve both weight loss and increased physical activity

are the primary therapeutic interventions recommended to patients with nonalcoholic steatohepatitis (NASH) [1, 2]. Because clinical case series have identified obesity as a major risk factor for NASH and the degree of obesity correlates with the severity of disease [3, 4], normalization of weight to a healthy range might be needed to achieve significant improvement in liver disease. However, available clinical data suggest otherwise. Several studies have shown that patients can have improved histopathological findings with only a modest weight reduction of 5–10 % [5–7] and a large community intervention trial demonstrated improved nonalcoholic liver disease (NAFLD) measured by magnetic resonance spectroscopy with exercise and just 3 % weight loss [8].

To examine the effects of the rodent equivalent of therapeutic lifestyle modifications on NASH, we normalized the diet for 8 weeks in mice with obesity and NASH induced by the American lifestyle induced obesity syndrome (ALIOS) model for an initial period of 16 weeks. The ALIOS model includes feeding male C57BL/6 mice with high fat, *trans*-fat enriched chow and consumption of high fructose corn syrup resulting in a NASH-like liver histological phenotype [9]. We had previously shown that the *trans*-fat component of the ALIOS model is the primary factor responsible for the development of NASH in the ALIOS mouse model [9] and this has been confirmed by *trans*-fat feeding without inclusion of high fructose corn syrup [10, 11]. The liver pathology that develops in this model may be strain specific as AKR/J mice did not develop significant steatohepatitis when fed a similar diet [12] and the abnormalities may also be dependent on the source of fat used to prepare the partially hydrogenated vegetable oil [13]. In the current study, we show that despite persistent obesity, continued excessive caloric intake and an abnormal adipokine profile, obese ALIOS mice changed to standard rodent chow had marked improvement in the biochemical and histological evidence of NASH. Determination of the incorporation and subsequent release of *trans*-fats in the major hepatic lipid pools during and after *trans*-fat consumption confirmed *trans*-fat incorporation in all major pools but differential release with the cholesterol ester pool of *trans*-fats being the most labile.

Materials and methods

Animal Treatment

Male C57BL/6 mice initially 6–8 weeks old (Harlan, Indianapolis, IN) were treated as approved by the Animal Care Committee of Saint Louis University (protocol #1573). Mice were kept on a 12 h:12 h light:dark schedule

at 23 °C, housed in cages of five, and weighed weekly. All animals received humane care according to the criteria outlined in the “Guide for the Care and Use of Laboratory Animals” prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication 86-23 revised 1985).

ALIOS mice were fed a diet similar in composition to an American fast food diet with 45 % calories in the chow from fat in the form of partially hydrogenated soybean oil (28 % of fatty acids as saturated, 57 % MUFA and 13 % PUFA; *trans*-fat custom diet TD06303, Harlan Teklad). The *trans*-fat content of the partially hydrogenated soybean oil used to prepare the chow was approximately 30 % and mostly in the form of elaidic acid according to the supplier. ALIOS mice were also given high fructose corn syrup equivalent (HFCS, 55 % fructose, 45 % glucose by weight) in their drinking water at a concentration of 42 g/l. The drinking water was provided as gel–water [93 % water, 2.8 % gelatin (Pork skin gelatin, Type A, Sigma, St. Louis) and 4.2 % HFCS] in dishes on the cage floor. In order to discourage physical activity in ALIOS mice, the wire racks were removed from the cages. Control mice were given standard rodent chow containing 13.6 % of calories from fat in the form of soybean oil (15 % of fatty acids as saturated fat, 23 % MUFA and 61 % PUFA; 2018S, Harlan Teklad, Madison, WI). Control mice ($n = 10$) fed standard chow were kept in cages with wire racks and were given gel–water without HFCS. After 16 weeks of ALIOS conditions, one group of mice ($n = 10$) continued with ALIOS conditions for an additional 8 weeks while a second identical group ($n = 10$) was crossed over to control conditions for an additional 8 weeks. Food and water consumption were measured by weighing new and remaining food and water 3 times weekly between treatment weeks 10 and 16 and then again from weeks 19 to 24.

Mice were sacrificed after ketamine and xylazine anesthesia. Plasma prepared with EDTA was separated and frozen at -80°C . Livers were removed, weighed and divided into sections that were either fixed in 10 % phosphate buffered formalin (Sigma Aldrich, St. Louis, MO) or frozen in liquid nitrogen. Formalin fixed, paraffin-embedded tissue was sectioned (5 μm) and stained with hematoxylin and eosin, Sirius red and Masson’s trichrome.

Chemistry

Plasma alanine aminotransferase (ALT), aspartate aminotransferase (AST), total cholesterol (free and esterified), and triglycerides were measured using a calibrated clinical analyzer (Cobas Mira Plus Chemistry Analyzer, Roche Diagnostics, Indianapolis, IN). Liver triglyceride content was measured using an endpoint glycerol phosphate oxidase method (Pointe Scientific, Lincoln Park, MI). Plasma

leptin and resistin were measured by multiplexed immunoassay (Linco Diagnostics, St. Charles, MO).

Plasma and Liver Lipidomics

Samples of liver (40–50 mg) were homogenized in 500 μ l phosphate buffered saline, and lipids were extracted from 100 μ l of the liver homogenate in the presence of internal standards for each lipid class [14]. Lipid classes were separated by thin layer chromatography using silica gel Gas stationary phase and a mobile phase comprised of petroleum ether/ethyl ether/acetic acid (80/20/1, v/v/v) [15]. Subsequently, fatty acid methyl esters (FAME) were prepared by acid methanolysis [15] and subjected to gas chromatography (GC) on an SP-2560 fused silica capillary column (100 m \times 0.25 mm, 0.2 μ m film thickness) with flame ionization detection (FID) [16]. FAME were quantified by comparisons with FAME derived from internal standards added during liver lipid extraction.

Statistical Analysis

The data were analyzed for statistical significance with ANOVA and post hoc two-tailed *t* tests with significance being $P < 0.05$. Results are reported as mean \pm standard deviation (SD).

Results

Mice treated with the ALIOS conditions of a high *trans*-fat and high fructose corn syrup diet for 16 weeks became obese and weighed 31 % more than control mice. Little further weight gain occurred during the ensuing 8 weeks in ALIOS or control mice (Fig. 1). Crossover to control chow and unrestricted activity was not associated with weight loss and crossover mice weights were not significantly different from ALIOS mice at any of the subsequent time points examined. The measured energy consumption based on combined food and HFCS consumption was 24 % higher in ALIOS mice compared to control mice during weeks 10–16 but was similar when measured from weeks 19 to 24 (Table 1). The obese crossover mice had the same energy consumption as the mice continued on the ALIOS diet despite eating control chow.

Despite persistent excessive energy consumption and obesity in the crossover (XO) mice, liver weights and liver triglyceride content were substantially lower after crossover to standard chow and unrestricted activity (Fig. 2). The mean liver weight of ALIOS mice doubled to 2.19 ± 0.56 g compared to control mice at 24 weeks. The liver weight of ALIOS mice at 16 weeks was 1.81 ± 0.41 g as previously reported [9]; the further increase at 24 weeks in these mice

Fig. 1 Mean body weight after crossover from ALIOS conditions to control conditions (standard chow and water, no activity restrictions) for another 8 weeks compared to the weight of mice that remained on ALIOS conditions or were treated with control conditions for the entire 24 weeks. When feeding began at week 0, all mice weighed the same (18.4 ± 0.9 g). By week 16, the ALIOS mice weighed substantially more than control mice [37.2 ± 3.2 g ($n = 30$) vs. 28.4 ± 3.2 g ($n = 20$), $P < 0.001$]. Crossover at week 16 did not result in subsequent weight loss although there was no further weight gain ($n = 10$). A trend towards continued weight gain was evident in mice that remained on ALIOS conditions ($n = 10$). The weights at the final time point tended to be reduced compared to the previous week because of overnight fasting before sacrifice. The mean weights of ALIOS mice and crossover mice were significantly greater than control mice ($n = 10$) at all time points whereas there was not significant differences between ALIOS and crossover mice at any of these time points ($P < 0.05$; $n = 10$ mice in each group, error bars denote SD)

Table 1 Energy consumption by mice before and after crossover to control chow

| | kcal/mouse/day (\pm SD) | | |
|-------------|----------------------------|------------------|----------------|
| | Control | ALIOS | Crossover |
| Weeks 10–16 | 8.9 ± 1.4 | $11.0 \pm 1.7^*$ | |
| Weeks 19–24 | 9.5 ± 1.5 | 10.1 ± 2.2 | 10.1 ± 1.0 |

* $P < 0.001$ compared to control chow consumption during week 10 to 16

was not statistically significant ($P = 0.13$). The liver weight of control mice did increase from 0.91 ± 0.08 g at 16 weeks to 1.09 ± 0.07 g at 24 weeks ($P < 0.001$). The lower liver weight at 24 weeks after 8 weeks of crossover to control conditions compared to mice remaining on the ALIOS diet correlated with substantially lower liver triglyceride content as well, suggesting that the mobilization of liver triglyceride was largely responsible for the loss of liver weight. Similarly, biochemical evidence of hepatocellular injury as assessed by the plasma ALT level was reduced in the crossover group compared to the ALIOS group (Fig. 3). Plasma ALT was fourfold elevated at 24 weeks in ALIOS with a mean of

Fig. 2 Liver weight (a) and triglyceride content (b) at 24 weeks. Crossover to control conditions from weeks 16 to 24 (XO) caused reduction in liver weight and triglyceride content approaching normal levels (* $P < 0.05$ compared to control and crossover, ** $P < 0.05$ compared to control and ALIOS; $n = 10$ mice per group; error bars denote SD)

122 U/l. This was elevated to the same degree as previously described at 16 weeks, a time point at which the mean ALT was 119 U/l [9]. Plasma AST exhibits a high baseline level in mice but was also significantly elevated at 24 weeks of ALIOS conditions to 250 U/l. As observed with ALT, AST levels were nearly normal after 8 weeks of crossover to control feeding conditions.

Changes in total plasma cholesterol and triglyceride levels were discordant during ALIOS treatment and subsequent crossover to control conditions (Fig. 4). Whereas total plasma cholesterol was elevated in ALIOS mice and returned to normal following crossover to control chow, plasma triglycerides were not elevated during *trans*-fat feeding yet became elevated after crossover to control chow. This, in conjunction with decreased levels of hepatic triglyceride after crossover, is supportive of the mobilization of hepatic triglyceride in the crossover mice.

Plasma levels of the adipokines leptin and resistin were elevated in ALIOS mice and remained elevated after treatment with control conditions (Fig. 5), consistent with adipose tissue being the source of these adipokines, and the fact that the crossover mice remained obese. A decline of plasma resistin levels between 16 and 24 weeks was noted in both the control mice and the ALIOS mice.

Examination of liver histology in the ALIOS mice at 24 weeks demonstrated substantial accumulation of steatosis as a mix of large and small droplet fat (Fig. 6, Panel B). Similar to the abnormalities seen at 16 weeks [9], striking zonation of steatosis was noted with large droplet

Fig. 3 Plasma ALT (a) and AST (b) levels were increased after 24 weeks of ALIOS conditions but returned to near normal in crossover mice (* $P < 0.05$ compared to control and crossover; $n = 10$ mice per group; error bars denote SD)

Fig. 4 Plasma total cholesterol levels (a) were increased by 59 % in ALIOS mice at 24 weeks and were near normal in crossover mice (* $P < 0.05$ compared to control and crossover by ANOVA; $n = 10$ mice per group; error bars denote SD). In contrast, plasma triglyceride levels (b) were unchanged in ALIOS mice but were increased by 36 % after 8 weeks of crossover conditions (* $P < 0.05$ compared to control and ALIOS; $n = 5$ mice per group; error bars denote SD)

fat most notably in zone 1 areas and small droplet fat being localized to zone 3 regions. Scattered lobular foci of mixed inflammatory infiltrates were evident. Hepatocellular ballooning and necrosis were not observed by routine light microscopy. In mice crossed over to control conditions for 8 weeks, variable but often substantial resolution of

Fig. 5 Plasma leptin (a) and resistin (b) levels were increased in ALIOS mice at 16 and 24 weeks compared to control levels at the same time point (denoted by asterisks). Levels did not normalize with crossover to control chow. Resistin levels at 24 weeks were lower than at 16 weeks in both the control mice and ALIOS mice ($P < 0.05$). * $P < 0.05$ compared to control at the same time point; $n = 5$ mice per group; error bars denote SD

steatosis was present (Fig. 6, Panel C). Fibrosis was not identified in ALIOS mice at 24 weeks or in mice crossed over to control conditions by Masson's trichrome or Sirius red staining.

The incorporation of dietary *trans*-fats into triglyceride, phospholipid and cholesteryl ester pools in the liver and the clearance of esterified *trans*-fats from these pools following

elimination of dietary *trans*-fats were also evaluated and is reported as the percent of total fatty acids that are *trans* 18:1 plus *trans* 18:2. Other *trans*-fat species were present in comparatively negligible amounts. Extraction of liver lipids followed by separation into free fatty acid, triglyceride, polar lipid (e.g. phosphatidylcholine) and cholesteryl ester pools and analysis of FAME derived from each lipid pool by gas chromatography-flame ionization detection was performed to assess the effect of the ALIOS diet on liver lipids and the reversibility of these changes. The *trans*-fat content in the chow was similarly measured and found to be 30.8 % of fatty acids by weight monounsaturated *trans*-fat acids (*trans* 18:1) and 6.8 % *trans* 18:2, similar to what was reported by the manufacturer. In the mouse livers after 24 weeks of *trans*-fat feeding, the fraction of fatty acids as *trans*-fats in hepatic lipid pools ranged from 5 to 8.9 % (Fig. 7). *trans*-fats were not found in control animal livers consistent with finding that *trans* 18:1 and *trans* 18:2 were each less than 0.1 % of liver fatty acids in normal rats [17]. The polar lipid pool was the most enriched at 8.9 % of fatty acids as *trans*-fats and appeared to be the slowest to turn over with about half the *trans*-fat content after 8 weeks of a *trans*-fat free diet compared to mice fed the *trans*-fat diet for 24 weeks. The cholesteryl ester pool on the other hand appeared to turn over rapidly as the *trans*-fat content after crossover to control chow was only 3 % of that in mice continued on the *trans*-fat diet.

The effect of the ALIOS diet on types of fatty acids in the major hepatic lipid pools was also examined. Both the triglyceride and cholesteryl ester pools were expanded whereas the polar lipid pool, likely comprised primarily of membrane lipids was relatively unchanged (Fig. 8). The

Fig. 6 Representative liver histology from control (a), ALIOS (b) and crossover (c) mice at 24 weeks. ALIOS livers at 24 weeks are characterized by extensive zone 1 macrovesicular steatosis around the portal venules (pv) and microvesicular steatosis are the central venules (cv) similar to that described previously at 16 weeks. Most of

the macrovesicular fat was gone after 8 weeks of crossover to control chow leaving a ring of macrovesicular fat in zone 2 and residual microvesicular fat in zone 3. Hematoxylin and eosin stain, $\times 20$ original magnification

Fig. 7 Incorporation of *trans*-fats into the free fatty acid, triglyceride, polar lipid and cholesteryl ester pools of fatty acid containing hepatic lipids after *trans*-fat feeding for 24 weeks or after *trans*-fat feeding for 16 weeks followed by crossover to control chow for a further 8 weeks. No *trans*-fats were detectable in any of the pools in control mice fed standard chow for the 24 week period (not shown). The polar lipid pool, mostly phosphatidylcholine, was the most *trans*-fat enriched pool in the liver and retained the greatest amount after crossover to control chow. The cholesteryl ester pool by comparison was mostly devoid of *trans*-fats after crossover to control chow, suggesting rapid turnover. The data represents the mean of analyses of 5–9 mice per group, error bars indicate standard deviation; the percent *trans*-fat incorporation into the fatty acids pools was significantly less in the crossover group compared to the ALIOS group for each lipid pool ($P < 0.001$ for all groups)

C16:1/C16:0 desaturation index was markedly increased in the cholesteryl ester and free fatty acid pools indicating increased formation or retention of monounsaturated fatty acids during feeding in these pools. These changes partially reversed after normalization of the diet. By comparison, there was little effect of the diet on the desaturation index of fatty acids incorporated into the triglyceride and polar lipid pools.

Discussion

Even if effective pharmacological therapies are developed for NASH, the initial recommendations for treatment will likely remain lifestyle modifications to reduce caloric intake, improve the quality of food eaten and increase aerobic activity. Although a number of small studies of lifestyle interventions have indicated that this approach is generally effective in reversing NASH if the changes can be maintained, major clinical studies have not been reported to validate this treatment approach [2, 18]. Weight reduction to the point of normalization of body mass index

is difficult to accomplish and is rarely sustained by most overweight individuals [19, 20]. However, available studies that indicate NASH can improve with relatively small amounts of weight loss in the range of 5–10 % [21], although this remains controversial [22].

One goal of these experiments was to determine if changing to a normal diet and activity level could lead to improvement in the extensive hepatic steatosis and elevated ALT levels that are characteristic of NASH and which develop in sedentary mice consuming a diet high in *trans*-fats. Surprisingly, markedly improved liver histology and ALT levels occurred with normalization of the diet for a relatively short period despite the continued consumption of the same number of calories and a lack of weight loss. The failure to lose weight was also observed in a more prolonged diet induced obesity model in rats [23] and has disconcerting implications for success with diet interventions for human obesity. The mechanisms controlling satiety and feeding behavior are only beginning to be understood [24, 25] and further evaluating the role of these mechanisms in preventing weight loss was beyond the scope of this study. Leptin has anorexic effects but leptin levels remained elevated after crossover, suggesting that central nervous system leptin resistance could play a role in preventing the normal response to this adipokine [26].

Despite sustained obesity with elevated resistin and leptin levels, the liver disease in mice crossed over to control conditions improved with reductions in liver fat content and decreased biochemical evidence of hepatocellular injury. This observation indicates that obesity per se and dysregulated leptin responsiveness are not the cause of NASH in this model. Instead, it suggests that ongoing dietary factors or the abnormalities in lipid trafficking related to the diet are primarily responsible. Thus obesity and liver disease may occur as parallel processes in response to a poor diet rather than obesity being a direct cause of liver disease.

Previous analysis of the ALIOS model found that the inclusion of a high level of *trans*-fats in the ALIOS diet is the major determinant of the resultant liver disease while the presence of high fructose corn syrup resulted in slightly greater consumption of the fat-containing chow [9]. Subsequent studies of mice fed *trans*-fats have also demonstrated the development of NASH [10, 11, 27] and an increase in hepatocellular ballooning was noted even with a relatively low dose of dietary *trans*-fats in one study [10]. A subsequent study using AKR/J mice found that *trans*-fat feeding caused elevated aminotransferases but in contrast to the previous studies, significant liver histological changes were not identified in this mouse strain [12]. A potential source of confusion in understanding the effects of *trans*-fat feeding in causing liver disease was a recent report indicating that mice fed *trans*-fats developed

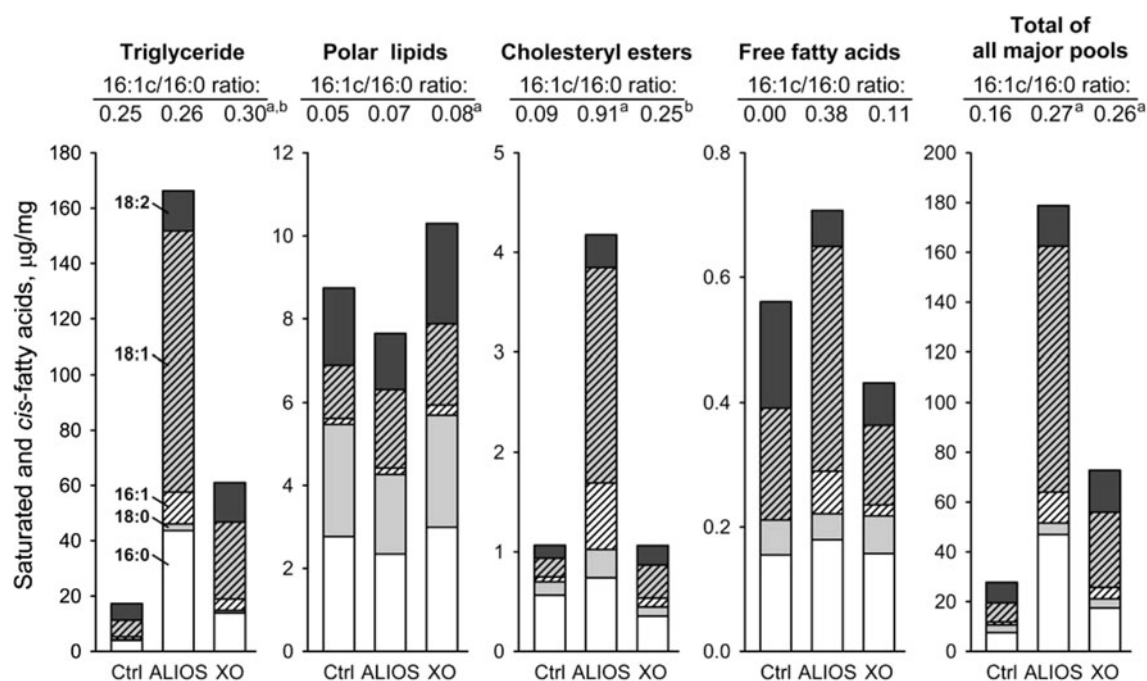

Fig. 8 Saturated and *cis*-unsaturated C16 fatty acids incorporation into triglyceride, polar lipids, cholesteryl esters or present as free fatty acids in the liver in control, ALIOS and crossover (XO) mice at 24 weeks. The identities of species represented by segments of the stacked bars are shown on the left panel. The monounsaturated pool (MUFA) was expanded in the ALIOS mice, especially in the cholesteryl ester pool. The polar lipid pool, representing membrane lipids was relatively unchanged. All pools contracted proportionally after crossover to control chow for 8 weeks. The essential fatty acid

linoleic acid (18:2) was increased in the triglyceride and cholesteryl ester pools and remained increased in the triglyceride pool after crossover to control chow. The desaturation index (the ratio of 16:1c/16:0) was increased in the cholesteryl ester and free fatty acid pools under ALIOS conditions. The data represents the mean of analyses of 5–9 mice per group; *a* the ratio is significantly different from control; *b* TF-HC and XO ratios are significantly different; non-significance is indicated by no letter; significance is defined as $P < 0.05$ by *t* test

features of NASH [28] but the fat source was fully hydrogenated coconut oil containing no detectable *trans*-fats [29].

The causal role of dietary components rather than obesity in causing NASH may also explain why relatively small amounts of weight loss in the range of 5–10 % have been associated with improved NASH in clinical trials. It may be that adhering to a healthier diet with the intent of achieving weight reduction could be directly beneficial to the liver independent of actual weight reduction. Clinical trials testing the hypothesis that *trans*-fats could play a role in lipotoxic liver injury have not been reported. A possible exception is a trial of excessive fast food consumption by student volunteers that led to elevations of serum ALT levels within weeks despite trivial changes in liver fat content [30]. However, the actual *trans*-fat content of this diet was not reported and other dietary factors could play a role in this worrisome finding.

The normal plasma triglyceride levels observed in ALIOS mice suggest that despite substantial hepatic accumulation of fat, either a secretory block prevents its release from the liver as VLDL or robust mechanisms of triglyceride removal from the blood prevent hypertriglyceridemia despite increased secretion. The observation that

plasma triglycerides became elevated in mice after being returned to control conditions supports the former hypothesis because this occurred at a time when hepatic steatosis was resolving.

There is no data on the incorporation and turnover of *trans*-fats in hepatic lipid pools with respect to the associated liver pathology. Previous studies have shown that *trans*-fats may be poor substrates for enzymatic incorporation into triglyceride compared to their *cis* analogues whereas they may be better substrates for peroxisomal oxidative pathways [31, 32]. Earlier studies also suggested that *trans*-fats are less facile substrates for mitochondrial beta-oxidation [31, 33–36], although this has been disputed [32]. The diminished ability of *trans*-fats to be handled by enzymatic pathways may explain the disproportionately low *trans*-fat incorporation into liver lipid pools compared to the dietary exposure in which more than 30 % of the fat was *trans*-fat.

The incorporation of *trans*-fats into the major hepatic lipid pools was evaluated to determine if changes in specific pools correlated with changes in the pathological findings after resumption of regular chow. An earlier study demonstrated incorporation of *trans*-fats into all major lipid pools to varying degrees when given to rats as free

fatty acids [37] but conflicting data suggested that little *trans*-fat was incorporated into triglyceride when given as triglyceride [38]. Studies have also shown that *cis* to *trans* isomerization can be facilitated by thiyl radicals under severe oxidant stress such as occurs with carbon tetrachloride administration to rats or gamma irradiation of tissue homogenates [17]. Whether the trace amounts of endogenously produced of *trans*-fats found in that previous study contributed to the accumulation of *trans*-fats in liver lipid pools in the ALIOS model cannot be determined in the present experiment. Such a contribution would seem unlikely however since the accumulation following substantial free radical stress was still less than 1 %.

The present study demonstrates that with crossover to control chow, the cholesteryl ester pool appeared to be the most labile with near complete loss of *trans*-fat cholesteryl esters after 8 weeks of control chow. By comparison, the polar lipid pool, representing membrane lipids such as phosphatidylcholine, retained its *trans*-fats to a substantial degree. Incorporation of *trans*-fats into membrane phospholipids can have important physiologic effects. For example, *trans*-fats increase membrane cholesterol content and alter G-protein coupled receptor activation [39, 40] and *trans*-fat incorporation into adipocyte membranes was found to impair insulin signaling and regulation of lipolysis [41]. However, the substantial persistence of *trans*-fats in the polar lipid pool at a time when liver injury is markedly improving after crossover to control chow suggests that membrane incorporation of *trans*-fats may not be the primary mechanism of *trans*-fat induced NASH in this model. On the other hand, the *trans*-fat incorporation into the cholesteryl ester pool was substantially diminished with consumption of control chow. The observation that this parallels the improvement in liver injury suggests that the role of *trans*-fat cholesteryl esters deserve further study in the pathogenesis of NASH. Somewhat surprising was the lability of the *trans*-fat content of the triglyceride pool, an observation also made in an earlier study [38]. This suggests that the accumulation and degradation of triglyceride in the liver is a highly dynamic process in contrast to adipocyte triglyceride which has a much slower turnover [42]. If the loss of triglyceride after normalization of the diet simply reflected a flow of fatty acids out of the pool, then the fraction of *trans*-fat in this pool would be relatively stable. Alternatively, triglyceride containing *trans*-fats may be preferentially degraded by the lipases responsible for hepatocyte triglyceride turnover.

Upregulation of stearoyl-CoA desaturase (SCD) is a common feature in diet induced obesity models and metabolic disease [43]. Once thought to play a role in metabolic disease [44, 45], this compensatory response of the liver to handle an increased burden of saturated fat is now thought to play a protective role in the liver by increasing

the ability to store fatty acids inertly by forming triglycerides [46], and thus avert lipotoxic injury from fatty acid metabolites [47]. Increased SCD activity can be estimated by the increased desaturation index of C16 fatty acids [48]. Indeed, mice fed the ALIOS diet demonstrated increased desaturation of C16 fatty acids in the cholesteryl ester pool. By comparison, there was a relative lack of a corresponding increase in the desaturation index of fatty acids incorporated into the triglyceride, polar lipid and free fatty acid pools. Understanding the implications of the uniquely marked increase in desaturation of fatty acids esterified to cholesterol in response to *trans*-fat feeding requires further investigation.

In summary, normalization of diet promoted improvement in NASH caused by a high *trans*-fat diet despite persistent obesity in mice. *trans*-fats were differentially incorporated into hepatic lipid pools and were released from these pools at different rates after stopping *trans*-fat consumption. The significance of these changes in the pathogenesis and potential for reversal of NASH warrants further investigation.

Abstract The varied functional requirements satisfied by *trans* fatty acid (TFA)—containing oils constrains the selection of alternative fats and oils for use as potential replacements in specific food applications. We aimed to model the effects of replacing TFA-containing partially hydrogenated soybean oil (PHSBO) with application-appropriate alternatives on population fatty acid intakes, plasma lipids, and cardiovascular disease (CVD) risk. Using the National Health and Nutrition Examination Survey 24-hour dietary recalls for 1999–2002, we selected 25 food categories, accounting for 86 % of soybean oil (SBO) and 79 % of TFA intake for replacement modeling. Before modeling, those in the middle quintile had a mean PHSBO TFA intake of 1.2 % of energy. PHSBO replacement in applications requiring thermal stability by either

low-linolenic acid SBO or mid-oleic, low-linolenic acid SBO decreased TFA intake by 0.3 % of energy and predicted CVD risk by 0.7–0.8 %. PHSBO replacement in applications requiring functional properties with palm-based oils reduced TFA intake by 0.8 % of energy, increased palmitic acid intake by 1.0 % of energy, and reduced predicted CVD risk by 0.4 %, whereas replacement with fully hydrogenated interesterified SBO reduced TFA intake by 0.7 % of energy, increased stearic acid intake by 1.0 % of energy, and decreased predicted CVD risk by 1.2 %. PHSBO replacement in both thermal and functional applications reduced TFA intake by 1.0 % of energy and predicted CVD risk by 1.5 %. Based solely on changes in plasma lipids and lipoproteins, all PHSBO replacement models reduced estimated CVD risk, albeit less than previously reported using simpler replacement models.

TFA *trans* fatty acid
 USDA US Department of Agriculture

Introduction

On July 9, 2003, the US Food and Drug Administration (FDA) mandated that food manufacturers list the content of *trans* fatty acid (TFA) on the Nutrition Facts panel of foods and dietary supplements by January 1, 2006. Subsequently, additional legislation banning or restricting the use of fats and oils containing TFA has been passed in California as well as major US metropolitan areas such as New York City and Philadelphia, and has been considered in 23 other states [1]. These actions occurred in response to compelling evidence that dietary TFA increases the risk for cardiovascular disease (CVD) [2], most notably by raising total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) while lowering high-density lipoprotein cholesterol (HDL-C) [3].

The food manufacturing and restaurant industries have responded by reformulating products and recipes to minimize their TFA content. Although the ensuing reduction in the population intake in TFA is predicted to reduce the risk for CVD, the extent of this risk reduction is dependent on the choice of TFA replacement fats. In 2005, prior to TFA labeling requirements, per capita availability of margarine and shortening totaled 33.1 lbs/year (15.05 kg/year) or 370 kcal/person/day [4]. Thus, the choice of alternative oils used to replace margarines and shortening has the potential to affect health by changing a substantial portion of the population's fatty acid (FA) intake in addition to that of TFA alone.

The choice of TFA replacements within a given food is constrained by the desired functionality. TFA-containing fats and oils have two desirable properties: thermal stability for use in frying and an appropriate melting profile for use as shortening or margarine when solid fats are required. Consequently, a single replacement option for TFA is unlikely to satisfy the broad array of applications currently filled by TFA-containing oils. Furthermore, TFA replacement oils need to be available in sufficient amounts to meet domestic consumption demands, estimated in 2005 to be 8.6×10^9 billion pounds (3.9×10^9 kg) alone for soybean oil (SBO) used in baking, frying, and margarine applications [5].

As efforts to replace TFA-containing oils continue, guidance is needed with respect to which oils, or combination of oils, would likely provide the greatest improvements in CVD risk. In the present study, we model the effects of five application-appropriate TFA replacement

scenarios on population intakes of FA. The choice of oils used in our replacement scenarios was based on both functional suitability and availability as TFA replacements. Issues of availability limited our choices to replacements based on either soy bean or palm oil. In food applications requiring oils with enhanced thermal stability (e.g., for fried foods) we selected two low linolenic acid soy bean oils alternatives: (1) a low linolenic acid soy bean oil in which the linolenic acid is reduced and replaced with linoleic acid; and (2) a low linolenic acid, mid oleic acid soybean oil in which both the linolenic and linoleic acid are reduced and replaced with oleic acid. In food applications requiring solid fats to provide functional properties (e.g., for pie crusts and margarines), we selected two solid fat alternatives with different fatty acid profiles: (1) palm oil in which the predominant saturated fatty acid is palmitic acid; and (2) interesterified, fully hydrogenated soybean oil in which the predominant saturated fatty acid is stearic acid. This modeling exercise enabled us to predict the effect of these replacement scenarios on reductions in CVD risk mediated by changes in plasma lipid/lipoprotein levels.

Materials and Methods

Modeling of Changes in Dietary FA Intake Following PHSBO Replacement

The methods for estimating SBO intake, TFA intake, and changes in dietary FA intakes following application-appropriate substitution of replacement oils and fats for PHSBO are essentially identical to those previously published [6, 7] and are detailed below.

Estimation of TFA Intake During 1999–2002

Dietary intake of whole foods was estimated using food consumption data from the 1999–2002 National Health and Nutrition Examination Survey (NHANES) [8], which included 9,965 participants in 1999–2000 and 11,039 participants in 2001–2002. All estimates were derived using the NHANES 4-year medical examination center statistical weights and adjusting for survey design.

NHANES researchers used two US Department of Agriculture (USDA) databases—the 1993 *trans* Fatty Acid Database [9] and the Nutrient Database for Standard Reference [10], in which many foods are the same—to map the TFA content of analyzed foods to the foods reported in the 1999–2002 NHANES. All analyses, including the total dietary TFA intakes, were calculated using the NHANES food consumption data and TFA content of individual foods using Foods Analysis and Residue Evaluation

(FARETM) software (version 7.997; Exponent, Washington, DC). TFA consumption for individuals was calculated using the following formula:

$$E_{\text{TFA}} = \sum_i (\text{Fc})_i (\text{TFA}_f)_i$$

where E_{TFA} is the total intake of TFA, i is the number of different food types consumed daily, Fc is the amount of food consumed (g/day), and TFA_f is the TFA content of food (g/100 g food).

Estimation of SBO Content of NHANES Foods

The SBO content of food (including both nonhydrogenated and PHSBO) was determined using the USDA-developed recipes that translate foods reported in the NHANES “as eaten” into their component ingredients (raw agricultural commodities) for purposes of nutrient analysis [8]. The recipes used in the FARE program are based on the USDA recipes but have been made more user friendly for use in additional kinds of intake analyses, including ingredients, additives, or contaminants. For example, the USDA recipes break foods down from the food reported as consumed (e.g., pizza) into the ingredients (e.g., dough, tomato sauce, and cheese). The final recipes were further broken down into the raw agricultural commodities (e.g., wheat flour, tomatoes, olive oil, milk-based fat, etc.). The final recipes have been quality checked and approved by the USDA and are currently used by the FDA.

The calculation for the SBO from foods reported consumed in the NHANES is similar to the formula presented earlier except that the amount of food consumed was multiplied by the amount of SBO in food (derived from NHANES recipes) to estimate individual SBO intakes.

Selection of Food Categories for TFA Replacement Modeling

All NHANES foods were assigned to 1 of 59 broad food categories. These categories are based on the NHANES tiered food coding (i.e., all foods in the diet are grouped into three tiers starting with nine broad food categories and 263 additional subcategories). The selection of these categories was based on prior knowledge of their SBO content and degree of hydrogenation as communicated by the industry members of the ILSI North America Technical Committee on Dietary Lipids. The calculations for total dietary SBO and TFA intake within each food category were estimated as described above but on a food category basis. Based on these analyses, 25 food categories, accounting for 86 % of SBO intake and 79 % of TFA

intake, were further considered for inclusion in our replacement models (Table 1).

Reference Consumption of FA from SBO

For the purposes of this analysis, we defined the consumption of FA from the SBO fraction of foods during the 1999–2002 NHANES survey period as our “reference.” This period was selected because it immediately preceded significant efforts by the food industry to remove TFA from products.

The NHANES database does not include the FA composition of the individual components (e.g., SBO) of foods. The SBO used in foods is either liquid (nonhydrogenated) or partially hydrogenated to a particular level. The FA composition of the SBO will vary depending on the level of hydrogenation. Because it would be impossible to make assumptions regarding the specific TFA composition of the oils used for several thousand foods containing SBO, we simplified our analysis by assigning a SBO with a specified degree of hydrogenation and TFA content to each of the targeted 25 broad food categories. We then used the category-assigned SBO composition to estimate the SBO FA composition for all individual foods within each category.

The 1993 USDA *trans* Fatty Acid Database [9] and the USDA Nutrient Database for Standard Reference (Release 15) [10] were used to assign the FA content (including TFA) of SBO to each of the selected 25 broad food categories. The USDA *trans* Fatty Acid Database has FA profiles for the oil in 214 foods. When this database did not provide the FA profiles for specific varieties of SBO used in target food groups, these FA were estimated using information from the food industry (ILSI North America Technical Committee on Dietary Lipids). The FA data for SBO within the 25 broad food categories were chosen to reflect what was in the food marketplace during the 1999–2002 NHANES survey years (Table 1).

When a specific oil was not listed in a food recipe for oils, margarines, or shortenings, a Monte Carlo approach was used to select an oil for this food. Oil varieties used in the analysis were based on the USDA oil production statistics [11]. The SBO used to estimate reference FA intakes ranged in TFA content from 0.7 % of FA (liquid SBO, not hydrogenated) to 43.3 % of FA (for popcorn) (Table 1).

Individual SBO TFA intakes from both nonhydrogenated and partially hydrogenated SBO (henceforth combined and collectively referred to as PHSBO) were determined and the population was subsequently grouped by quintiles of PHSBO TFA intake. Once an NHANES respondent was assigned to a particular quintile in the reference analysis, we computed the mean intakes of the

Table 1 Fatty acid profiles of soybean oils assigned to broad food categories used for replacement models

| Food categories | NHANES intake | | Assigned soybean oil fatty acid composition (percentage of total fatty acids) | | | | | | Assigned replacement fat |
|--|-----------------|----------------|--|------|-------|--------|--------|-------|--------------------------|
| | TFA (g/day) | SBO (g/day) | 16:0 | 18:0 | 18:1c | 18:2n6 | 18:3n3 | 18:1t | |
| 1. Frozen plate meals with grain mixture as major ingredient ^a | 0.001 | 0.01 | 10.5 | 6.5 | 26.3 | 35.0 | 3.6 | 12.7 | F1A; F2A |

major FA within each quintile of PHSBO TFA intake. Respondents remained in the same population quintile for all subsequent replacement model analyses.

Consumption of FA Following PHSBO Oil Replacement

To determine the dietary impact of substituting new oils for existing partially PHSBO in the diet, five application-appropriate replacement models were considered.

Heat-Stable Model 1 A nonhydrogenated low-linolenic acid SBO was substituted in applications requiring thermal stability (e.g., frying). Foods included were tortilla chips and other corn-based baked snacks; commercially and home fried meat, fish, poultry, eggs, and French fries; home-baked French fries; and potato chips.

Heat-Stable Model 2 A nonhydrogenated mid-oleic, low-linolenic acid SBO was substituted in the same foods as in heat-stable model 1.

Functional Model 1 Palm-based oils were substituted in applications requiring specific functional characteristics (e.g., melting profile and shortening applications). Foods included were stick and tub margarines; shortening; baked goods; crackers, pretzels, and other grain snacks; creamy soups; grain mixed dishes; sweet rolls and biscuits; popcorn; and frozen meals.

Functional Model 2 Fully hydrogenated interesterified (FH-IE)-based SBO, high in stearic acid, were substituted in the same foods as in functional model 1.

Complete Model A 50:50 ratio of the oils used in the heat-stable models 1 and 2 was substituted in thermal applications and a 50:50 ratio of the oils used in functional models 1 and 2 was substituted in functional applications.

To simplify our analyses, only the PHSBO portion of the food within the 25 food categories was subject to replacement modeling. The FA composition of the oils used in the replacement models, along with that of non-hydrogenated SBO and a typical PHSBO, are presented in

Table 2. A review of the TFA content of the 25 categories revealed a number of categories that would have had a low degree of SBO hydrogenation between 1999 and 2002 [12]. These categories included “squeeze or liquid butters,” “soups, broth based,” “salad dressing, oil based,” “salad dressing, creamed based,” “mayonnaise,” and “yeast breads—other than sweet rolls and biscuits” (Table 1). Consequently, the reference FA composition of these categories was retained throughout all replacement scenarios.

Once the PHSBO replacements were made, we computed the predicted mean intakes of each of the FA within each quintile of reference PHSBO TFA intake.

Calculation of 20-Year CVD Risk

Predicted changes in FA intake from reference values were estimated within each PHSBO TFA quintile for each of the five replacement models. Using published regression equations [3], we calculated the predicted mean change in TC, LDL-C, HDL-C, triglycerides, and the TC/HDL-C ratio based on dietary FA replacements. From the TC/HDL-C ratio, we estimated the 20-year risk for developing CVD from equations provided by Anderson et al. [13]. Predicted change in relative risk was defined as follows: (model 20-year CVD risk)/(reference 20-year CVD risk)—1.

Data Management and Statistical Analyses

All NHANES data management, TFA replacement modeling, and estimates of means, medians, and percentile distributions for dietary FA intakes under each replacement model were accomplished using FARE software. Estimates of changes in lipid levels and coronary heart disease risk associated for each replacement model were calculated using an Excel (Microsoft, Redmond, WA) spreadsheet populated with the relevant equations and coefficients.

Table 2 Nutrient profiles of reference SBO and oils used in replacement models

| Replacement oil | Application | C16:0 | C18:0 | C18:1c | C18:2n6 | C18:3n3 | C18:1t |

Results

Population TFA Intake

Based on the USDA *trans* Fatty Acid Database and the USDA Nutrient Database for Standard Reference, the mean population total TFA intake during 1999–2002 was 2.5 % of energy with a 90th percentile intake at 4.3 % of energy (Table 3). Those in the highest quintile of TFA intake had a mean total TFA intake of 4.5 % of energy with a range between 3.5 and 12.5 % of energy.

Estimated mean TFA intake from PHSBO in the top 25 SBO-containing food categories was 1.4 % of energy, accounting for 56 % of the value derived for the population total TFA intake (Table 3). The 90th percentile for PHSBO TFA was 3.0 % of energy (70 % of the value derived for the population total TFA intake). Taking into account naturally occurring TFA from beef and dairy products (estimated at 21 % of total TFA intake) [10], the estimated

mean TFA intake from PHSBO in the top 25 SBO-containing food categories accounted for 71 % of the population total TFA intake from hydrogenated vegetable oils.

Predicted Effects of Application-Appropriate PHSBO Replacement on Product FA Composition

The predicted effects of the replacement of PHSBO with application-appropriate oils on FA classes for selected food product groups are shown in Fig. 1. The food product groups in Fig. 1 were selected to indicate a representative range of predicted changes in FA composition. Net predicted change in TFA content (as a percentage of total FA) ranged from a net reduction of approximately 10 % of FA for tub margarine to >40 % of FA for popcorn with most other products ranging between 20 and 25 % of FA. For popcorn, cakes, cookies, pies, and pastries that require PHSBO for functional properties, replacement of PHSBO with either palm-based oils or FH-IE SBO increased

Table 3 Estimated and modeled per capita intake of TFA for the U.S. population (aged ≥3 years) as a percentage of total energy

FH-IE, fully hydrogenated interesterified; PHSBO, partially hydrogenated soybean oil; SBO, soybean oil; TFA, *trans* fatty acid

^a For quintiles, data are mean (range)

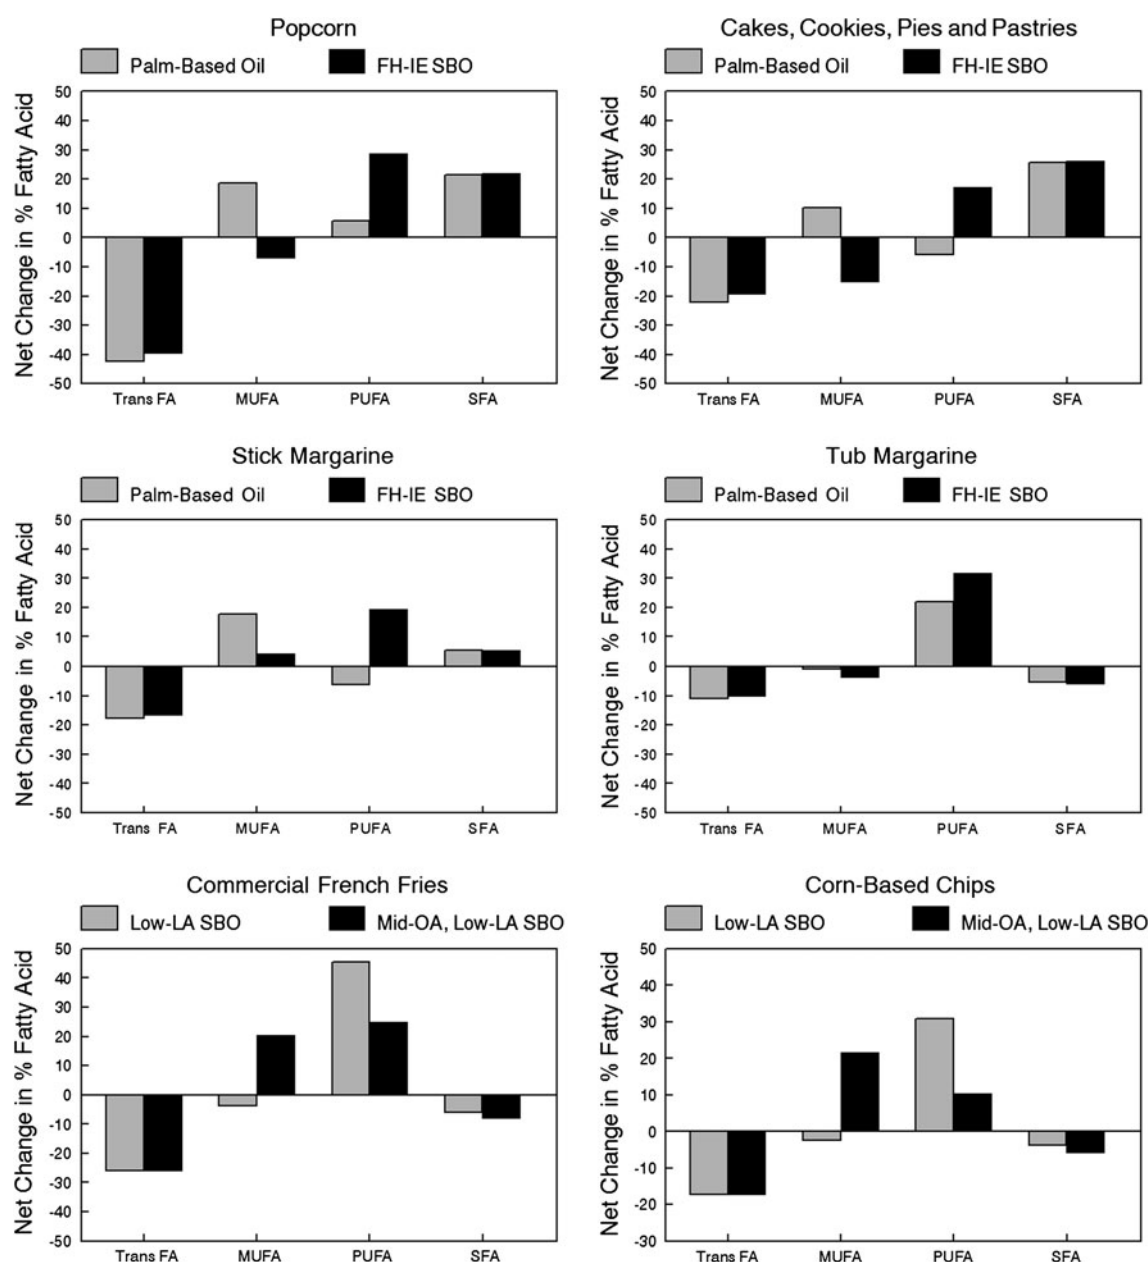

Fig. 1 Predicted change in fatty acid content of selected food categories with replacement of partially hydrogenated soybean oil (PHSBO) with application-appropriate oils. Graphs show the predicted net changes (as a percentage of total fatty acids) in *trans* fatty acid (TFA), MUFA, PUFA, and SFA following replacement of PHSBO with either palm-based oils or fully hydrogenated interesterified

soybean oil in foods requiring a functional fat (popcorn, cakes, cookies, pies, pastries, stick margarine, tube margarine) or with low-linolenic acid soybean oil or mid-oleic, low-linolenic acid soybean oil in foods requiring heat-stable oils (commercial French fries, corn-based chips)

predicted total saturated FA (SFA) by 20–25 % of FA. In contrast, replacement of PHSBO with either palm-based oils or FH-IE SBO in stick margarine is predicted to result in a moderate net increase in SFA by approximately 5 % of FA, whereas in tub margarines SFA are predicted to decrease by approximately 5 % of FA.

For products in which PHSBO is used for thermal stability (French fries, corn chips) replacement of PHSBO with

low-linolenic acid SBO (heat-stable model 1) increased predicted PUFA levels between 30 and 45 % of FA, whereas predicted *cis*-MUFA levels were largely unchanged. In the same applications, replacement of PHSBO with mid-oleic, low-linolenic acid SBO (heat-stable model 2) increased predicted PUFA levels by 10–25 % of FA, whereas predicted MUFA levels increased by approximately 20 %.

Effect of Application-Appropriate PHSBO Replacement on Population FA Intakes

Replacement of PHSBO in applications requiring thermal stability with either low-linolenic acid SBO (heat-stable model 1) or mid-oleic, low-linolenic acid SBO (heat-stable model 2) produced identical predicted reductions in mean PHSBO TFA intakes of 0.3 % of energy (25 % decrease) in the middle and 0.7 % of energy (22 % decrease) in the upper quintile of PHSBO TFA intake (Table 3). Both heat-stable replacement models increased predicted linoleic acid intake, whereas the use of mid-oleic, low-linolenic SBO predictably increased oleic acid intake. Modest reductions in total SFA were predicted in the high TFA consumers, whereas linolenic acid was not predicted to change with either heat-stable replacement oil (Table 4).

Replacement of PHSBO used in functional applications with palm-based oils reduced predicted PHSBO TFA intake by 0.8 % of energy (67 % decrease) in the middle and 2.3 % of energy (72 % decrease) in the upper quintiles of PHSBO TFA intake (Table 3). These predicted reductions in PHSBO TFA were accompanied by 1.0 and 3.0 % predicted increases in energy from palmitic acid in the middle and upper PHSBO TFA intake quintiles (Table 4). Use of palm-based oils also produced slight predicted reductions in linoleic and linolenic acid and increases in oleic acid.

Because of its residual TFA content (as provided for commercial food ingredient products at the time), replacement of PHSBO used in functional applications with FH-IE SBO produced smaller predicted reductions in PHSBO TFA intakes than observed with palm-based oil.

Replacement of PHSBO with FH-IE SBO reduced predicted mean PHSBO TFA intake by 0.7 % of energy (58 % decrease) in the middle and 2.0 % of energy (63 % decrease) in the upper quintiles of SBO TFA intake (Table 3). These predicted reductions in SBO TFA were accompanied by 0.9 and 2.4 % predicted increases in energy intake from stearic acid in the middle and upper quintiles, whereas predicted changes in total SFA were identical to those observed in the palm-based oil replacement model (Table 4). Use of FH-IE SBO also produced predicted reductions in oleic acid and increases in linoleic acid intakes.

Combined replacement of PHSBO used in both thermal and functional applications with equal contributions from each application-appropriate oil produced the greatest predicted reduction in PHSBO TFA intake. Predicted PHSBO TFA intake decreased by 83 % (1.0 % of energy) in the middle quintile, whereas predicted intake decreased by 91 % (2.9 % of energy) in the upper quintile (Table 3). These predicted changes in PHSBO TFA intakes were accompanied by predicted increases in palmitic, stearic, and linoleic acids with virtually no predicted change in either oleic or linolenic acids (Table 4).

Effect of Application-Specific PHSBO Replacement on Estimated 20-Year CVD Risk

From predicted changes in FA intakes relative to reference values, we calculated predicted changes in TC, LDL-C, HDL-C, and the TC/HDL-C ratio. With the exception of replacement with palm-based oil, LDL-C was predicted to decrease in all models (Fig. 2a). All replacement models

Table 4 Estimated mean fatty acid intakes from SBO (including PHSBO) at reference and under five application-appropriate replacement models for the middle and upper population quintiles for PHSBO TFA intake

showed a predicted increase in HDL-C (Fig. 2b) and decrease in the TC/HDL-C ratio (Fig. 2c). Predicted 20-year CVD risk (derived from changes in TC/HDL-C) declined with each of the five replacement models (Fig. 3). Predicted changes in CVD risk were similar with both heat-

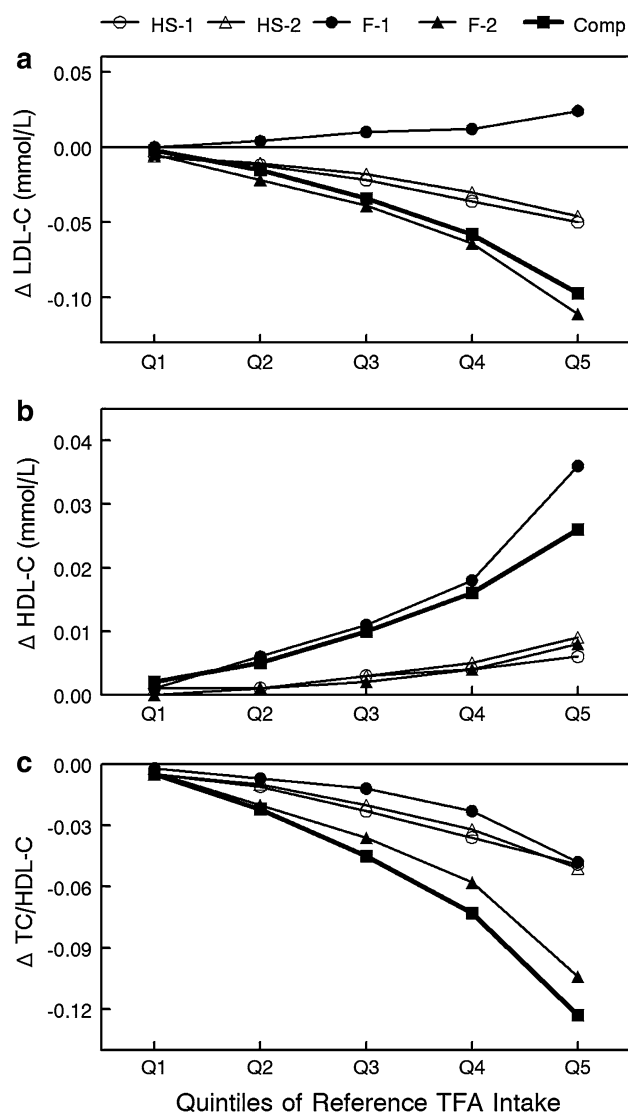

Fig. 2 Predicted change in **a** low-density lipoprotein cholesterol, **b** high-density lipoprotein cholesterol, and **c** total cholesterol/high-density lipoprotein cholesterol ratio for each quintile of reference *trans* fatty acid intake. HS-1, heat-stable model 1 using nonhydrogenated low-linolenic acid soybean oil (SBO) as a replacement in applications requiring thermal stability; HS-2, heat-stable model 2 using nonhydrogenated mid-oleic, low-linolenic acid SBO as a replacement in applications requiring thermal stability; F-1, functional model 1 using palm-based oils in applications requiring specific functional characteristics; F-2, functional model 2 using fully hydrogenated interesterified-based SBO in applications requiring specific functional characteristics; Comp, complete replacement using a 50:50 ratio of the oils used in heat-stable models 1 and 2 and a 50:50 ratio of the oils used in functional models 1 and 2 in their appropriate applications

stable replacement models with risk declining by 0.7–0.8 % in the middle and 1.6–1.7 % in the upper quintiles of SBO TFA intake. In contrast, estimated CVD reduction differed between the two functional replacement models. Use of a palm-based oil reduced predicted CVD risk by 0.4 % in middle and by 1.6 % in the upper quintiles. In contrast, the FH-IE SBO reduced predicted CVD risk by 1.2 % in the middle and 3.4 % in the upper quintiles. The complete replacement model reduced predicted CVD risk by 1.5 % in the middle and 4.0 % in the upper quintiles.

Discussion

Our study shows for the first time the predicted changes in the population intake of dietary FA associated with achievable application-appropriate replacements for PHSBO. With near complete replacement of PHSBO used in thermal and functional applications with an equal mix of likely available options, we predicted that TFA intake would decline by >90 % (2.9 % of energy) in the upper quintile of TFA users with increases in palmitic acid (1.4 %

Fig. 3 Predicted change in 20-year cardiovascular disease (CVD) risk following near complete replacement of partially hydrogenated soybean oil (PHSBO) with application-appropriate oils across quintiles of reference soybean oil *trans* fatty acid intake. Reference risk assumed a 40-year-old man without diabetes, hypertension, or left ventricular hypertrophy with a total cholesterol (TC) level of 200 mg/dL and an high-density lipoprotein cholesterol (HDL-C) level of 45 mg/dL. Changes in risk are based on predicted changes in the TC/HDL-cholesterol ratio subsequent to changes in predicted fatty acid intake following PHSBO replacement. *Low-LA SBO* low-linolenic acid soybean oil, *Mid-OA, Low-LA SBO* mid-oleic, low-linolenic acid soybean oil, *FH-IE SBO* fully hydrogenated interesterified soybean oil; complete, for heat-stable applications: 50:50 use of low-linolenic acid soybean oil and mid-oleic, low-linolenic acid soybean oil and for functional applications: 50:50 use of palm-based oils and fully hydrogenated interesterified soybean oil

of energy), stearic acid (0.7 % of energy), and linoleic acid (1.6 % of energy) intakes and no appreciable change in oleic or linolenic acid intakes. Based exclusively on predicted changes in TC/HDL-C levels, we estimated that these changes in dietary FA would result in a 20-year CVD risk reduction of 1.5 % in the middle and 4.0 % in upper TFA quintiles.

Our choice of using TC/HDL-C as our primary metric is justified based on observations that unlike saturated FA, TFA both increase LDL-C and decrease HDL-C, resulting in uniquely unfavorable increases in the TC/HDL-C [3]. Indeed, the ability of TFA to increase TC/HDL-C has been used as a primary rationale in the call for its reduction in the diet [14]. The use of the TC/HDL-C ratio as the primary metric to evaluate changes in CVD risk associated with replacement of TFA in the diet is also supported in the World Health Organization scientific update on TFA [15].

The time period used for our reference analysis (1999–2002 NHANES survey), coupled with industry data for TFA content of foods in the marketplace at that time, allowed us to estimate the effects of TFA replacement prior to significant product reformulation. Our estimate of a mean total TFA intake of 2.5 % of energy agrees with a previous estimate of 2.6 % of energy from the Continuing Survey of Food Intakes of Individuals data for 1989–1991 [16] and 1994–1996 [12].

The mean SBO TFA content during the reference time period for the foods used in our replacement model was 56 % of that derived from the NHANES data, a difference due to several factors. To simplify our analysis, we focused only on SBO as the TFA source. Thus, partially hydrogenated oils from other sources (e.g., corn, canola, and cottonseed), which may contribute up to 18 % of partially hydrogenated oil consumption [17], were not considered in our analysis. Second, in selecting only the 25 SBO-containing food categories for analysis, we largely excluded TFA from animal sources, which may account for 21 % of TFA intake [12]. Finally, we updated the TFA content of selected foods, including items such as creamy salad dressings and sauces in which the TFA content reported in the USDA *trans* Fatty Acid Database was likely to be substantially higher than what was present in the marketplace during 1999–2002 [12].

Changes in selected food product FA composition in the United States between 2005 and 2008 resulting from replacement of TFA have been reported [18]. Analysis of changes in microwave popcorn FA composition indicated a net reduction of approximately 40 % in TFA and a net increase of 24 % in SFA. This compares favorably with our estimates of a net reduction of 40–42 % in TFA and a net increase of 22 % in SFA. For cakes and cookies, our predicted changes in TFA and SFA are approximately half of that reported to have occurred (estimated 40 % net

reduction in TFA and 60 % net increase in SFA for the United States). These differences could reflect the selection of products higher in TFA for longitudinal FA analysis as opposed to the broader spectrum of foods within the cakes and cookies categories used in our estimates. Finally, our predicted changes in the product categories also are consistent with reported reductions in TFA + SFA and increases in *cis*-unsaturated FA following product reformulation in Canada [19]. With the exception of a predicted modest 3–7 % net increase in TFA + SFA levels in the cakes, cookies, pies, and pastries category, predictions for all other food categories indicated a net decrease in the TFA and SFA levels and a net increase in the *cis*-unsaturated FA levels (data not shown).

Our analysis accounted for approximately 71 % of TFA from vegetable sources. The remaining 29 % likely comes from hydrogenated corn, canola, and cottonseed oil not included in our replacement model. Assuming that these were similarly subjected to replacement would further decrease predicted CVD risk by an additional 40 % relative to our original estimates resulting in a 20-year CVD risk reduction of 2.1 % in the middle and 5.6 % in the upper TFA quintiles. However, even after corrections for unaccounted TFA from vegetable sources, our estimate for CVD risk reduction based on changes in the TC/HDL-C ratio is less than half of that predicted by others (estimated at 6 % for the population average) [2]. Most of this difference can be traced to the choice of specific replacement oils. Earlier studies [2, 20] modeled the health effects of TFA replacement using simpler approaches in which all dietary TFA are replaced with a single class of FA (MUFA, PUFA, or SFA). Although this approach has been useful in providing guidance about the preferred FA to replace TFA to achieve maximum CVD risk reduction, it fails to consider certain practical issues for commercial food production.

Our approach was fundamentally different from previous studies in three respects. First, to reflect the food reformulation process more accurately, the unit of exchange in our analysis was whole oils and not individual FA. This approach adds complexities by taking into consideration changes in FA beyond TFA in terms of what is removed with the TFA-containing oil and what is added with the replacement oil.

Second, our approach considers the functional attributes required of the replacement oil to effectively substitute for TFA-containing oils within a given broad application. Thus, although oils high in PUFA or MUFA may be considered suitable replacements for many frying applications (accounting for approximately 25 % of TFA intake), they would not provide the desired functional characteristics in many baking applications.

Finally, because of the magnitude of TFA usage, particularly as PHSBO, the options for oil replacement are

limited by availability and economics. Although both corn and sunflower oil have been used to replace TFA-containing oils for frying applications, their combined domestic production in 2006 was only 15 % of that of SBO [21] and supply reliability for commercial use is questionable [17]. The emergence of trait-enhanced SBO low in linolenic acid with or without increased oleic acid levels [17] suggests that they will likely constitute a substantial fraction of the oils used to replace TFA in frying applications. For functional applications, palm-based oil replacements have been used in Europe for over a decade and are currently available in sufficient quantities to meet demand [22]. However, because of the magnitude of domestic SBO production, we included FH-IE SBO in our models because it is likely that functional limitations with FH-IE SBO will shortly be overcome and it will be available as an alternative to palm oil.

Our estimates for CVD risk reduction are based only on the predicted effects of changes in individual FA on circulating lipoproteins. Our models do not consider possible effects on other CVD risk factors including inflammation and hemostatic factors, lipoprotein[a], and endothelial function, all of which are affected by TFA and other FA [2]. Thus, the actual reduction in CVD risk associated with TFA replacements may be greater than our estimates. Indeed, employing simpler substitution models, the estimates for CVD risk reduction based on data from prospective studies have been approximately four times higher than that predicted from changes in the TC/HDL-C ratio [2]. Based on changes in FA classes (and not individual FA) and published regression coefficients from prospective studies [23], our data would predict a reduction in CVD events of 11 % in the middle and 29 % in the upper quintiles of TFA users under the complete replacement model.

It is important to note that each of the proposed replacement strategies has uncertainties. The use of less thermally stable frying oils may result in increased consumption of oxidized and thermally degraded FA with potential adverse health effects [24]. Expanded use of low-linolenic SBO beyond that needed for applications requiring thermal stability (e.g., salad and cooking oils) may decrease population intakes of this beneficial n3-FA. Although oils high in oleic acid are generally considered to be healthy, some have cautioned against their increased consumption because of a similar atherogenic potential when compared to saturated fat in animal models [25], and recent data suggest that MUFA may actually increase coronary heart disease risk relative to SFA [26]. As a TFA replacement for functional applications, FH-IE SBO would seem to be preferred, largely because of the high content of

cholesterol-neutral stearic acid. However, very high stearic acid (10.9 % of energy) intakes may increase fibrinogen levels [27]. Furthermore, the randomization of FA in the glycerol moiety of the triglyceride molecule by the inter-esterification process may adversely affect glucose metabolism at very high stearic acid intakes (12 % of energy) [28]. As a tropical oil, palm oil markedly increases LDL-C due to its high palmitic acid content [3]. These uncertainties warrant a continuing assessment of the health effects of new fats and oils introduced into the marketplace.

Finally, not considered in the current study was replacement of TFA-containing foods with other foods, rather than replacing their TFA-containing oils. Indeed, replacement of cakes, cookies, pies, French fries, chips, and other such foods with fruits, vegetables, and whole grains to achieve a dietary pattern consistent with current recommendations [29] would be expected to provide the greatest reduction in CVD risk.

In summary, all TFA replacement strategies evaluated changed the fatty acid profile in a manner that is projected to decrease CVD risk, albeit to different extents based on the specific selection of the replacement oils. The combined use of mid-oleic, low-linolenic SBO for frying applications and fully hydrogenated interesterified SBO for functional application is predicted to provide the greatest reduction in CVD risk. Nonetheless, our estimates of this CVD risk reduction, which are based solely on the predicted changes in plasma lipid profile, are lower than previous estimates due in large part to the real-world constraints associated with the selection of the TFA replacement oils. As more data are developed regarding the quantitative relationship between changes in dietary fatty acid composition and changes in a broader spectrum of CVD risk factors, the modeling employed in this study would be expected to provide even better estimates of the health consequences associated with population-wide changes in the use oils in the food supply. Such detailed modeling would be increasingly valuable as a tool to guide both policy makers and the food industry as further changes in the production, availability and use of alternate dietary oils are contemplated in efforts to provide a healthier food supply.

Abstract Serum small dense low-density lipoprotein (sd-LDL) concentrations were measured in patients with angiographically defined coronary artery disease (CAD) and compared to concentrations in healthy subjects. Five hundred and seventy patients with stable CAD were divided into CAD− and CAD+ based on angiography. Patients in whom stenosis was <50 % in diameter were classified as having a ‘normal’ angiogram (CAD−), otherwise the patients were allocated to the CAD+ group. The CAD+ group was further subcategorized into single-, double- and triple-vessel disease (VD). Serum sd-LDL concentrations were significantly lower in controls compared with CAD+ and CAD− patients ($P < 0.001$). Moreover, CAD+ patients had higher concentrations of sd-LDL than

CAD− patients ($P < 0.01$). sd-LDL levels were not significantly associated with severity of CAD defined by the number of stenosed coronary arteries ($P = 0.245$). All participants were also categorized into subgroups with or without metabolic syndrome. Subjects with metabolic syndrome had higher levels of sd-LDL than subjects without metabolic syndrome ($P < 0.01$). Multiple linear regressions showed that in CAD patients, triacylglycerol, total-cholesterol, body mass index, and waist circumferences were the most important determinants of serum sd-LDL concentrations. We found that sd-LDL levels were significantly higher in patients presenting with symptoms of CAD. Moreover, patients with significant stenosis of their coronary arteries (>50 % stenosis) had higher levels of sd-LDL compared to patients without significant lesions.

Introduction

A high serum low-density lipoprotein cholesterol (LDL-C) is a well established risk factor for cardiovascular disease (CVD) [1]. However, the qualitative features of LDL particles also appear to play an important role in the development of CVD as a novel risk factor, particularly the size spectrum of LDL-C particles and the predominance of small dense LDL (sd-LDL) particles. Several studies have investigated the possible role of sd-LDL in the pathogenesis of CVD and most have reported a positive association between the sd-LDL levels and the presence and severity of CVD [2–6].

It has been previously reported that the mean LDL particle size is smaller in those patients with proven coronary artery disease (CAD) based on angiography than for healthy controls; the authors observed that after multiple regression analysis the presence of high levels of sd-LDL was a significant and independent risk factor for CAD [2]. Moreover, it has been reported that men with an LDL particle size <25.6 nm had a significantly higher (2.2-fold increase) in the 5-year rate of ischemic heart disease compared with those men having an LDL particle size >25.6 nm [6] and hence it has been proposed that the presence of high concentrations of sd-LDL particles is a potent risk factor for CVD [3]. Previous studies have reported that there is a linear correlation between the sd-LDL concentrations and the risk of development of cardiovascular events [4, 5]. It has also been demonstrated that in healthy middle-age individuals the predominance of sd-LDL particles is associated with increased proinflammatory activation of peripheral mononuclear cells [7]. There is also evidence that sd-LDL is associated with the metabolic syndrome [8, 9]. In the present study, we aimed to evaluate the association between sd-LDL concentrations and severity of atherosclerosis defined by number of stenosed vessels in Persian population and also to assess the relationship between sd-LDL concentrations and several components of the metabolic syndrome.

Methods

Study Population

The study participants were selected from those subjects who underwent coronary angiography in the Quem Hospital, Mashhad in the north-eastern region of Iran. Angiography was principally indicated for stable angina, in patients who were positive for at least one objective test of myocardial ischemia including: exercise stress test, dobutamine stress echocardiography, and thallium SPECT (single photon emission computed tomography). The

exclusion criteria for the study were as follows; oral contraceptives or hormone replacement therapy, pregnancy, prior history of coronary angioplasty or coronary artery bypass graft, having overt clinical features of infection or chronic inflammatory disease, and all subjects were negative for viral markers of hepatitis and anti-HIV antibody. Moreover, patients with myocardial infarction within the previous 3 months, renal, hepatic or malignant diseases were excluded. Finally, 570 patients fulfilled the inclusion criteria and blood samples were collected from all of them prior to the procedure. These patients included those with a primary diagnosis of CAD and included diabetic patients. Patients who were diagnosed with CAD were treated with a statin, and those who were diagnosed as diabetic were treated with anti-diabetic drugs. No subjects in the control group were treated with statins, whilst 22.6 and 32.4 % of patients in CAD– and CAD+ group were previously treated with statins respectively.

Coronary angiograms were performed using routine procedures using a femoral approach on patients who were fasted prior to the procedure. Analysis of the angiograms was performed offline by a specialist cardiologist. The presence of one or more stenoses ≥ 50 % in diameter of at least one major coronary artery (left main, right coronary artery, left anterior descending, circumflex) was considered evidence of significant CAD [10]. Patients in whom stenosis was <50 % in diameter were categorized as having a ‘normal’ angiogram (CAD–). The CAD+ patients were sub-classified according to the number of significantly affected stenotic vessels into: single-vessel ($n = 114$), double-vessel ($n = 123$), and triple-vessel ($n = 174$) disease groups. One-hundred and nine healthy volunteers were also recruited as a normal control group. The control group comprised subjects who had never experienced any symptom nor had any signs of CVD. These subjects had no other apparent major disease. Information on smoking, drug use and family history of CAD was obtained via a questionnaire. The study protocol was approved by the Ethics Committee of Mashhad University of Medical Sciences (MUMS) and written informed consent was obtained from each participant.

Definition of Metabolic Syndrome

The American Heart Association/National Heart, Lung and Blood Institute (AHA/NHLBI) guideline was used to categorize subjects into metabolic syndrome-positive and metabolic syndrome-negative subgroups [11]. Metabolic syndrome was defined as the co-occurrence of at least three of the following five metabolic abnormalities: (1) elevated serum fasting glucose (≥ 100 mg/dl) or use of medication for hyperglycemia; (2) elevated serum triacylglycerols (≥ 150 mg/dl); (3) reduced serum high density lipoprotein-

cholesterol (HDL-C) (<40 mg/dl in males and <50 mg/dl in females); (4) elevated systolic (≥ 130 mmHg) or diastolic (≥ 85 mmHg) blood pressure or use of medication for hypertension; and (5) elevated waist circumference (≥ 102 cm in males and ≥ 88 cm in females).

Anthropometric and Other Measurements

Anthropometric parameters including weight, height, and body mass index (BMI) were measured in all subjects. Weight was measured with the subjects dressed in light clothing after an overnight fasting using a standard scale. BMI was calculated as weight (in kg) divided by height squared (in square meters). Blood pressure was measured twice while the patients were seated and rested, using a standard mercury sphygmomanometer. The systolic blood pressure was defined as the appearance of the first sound (Korotkoff phase 1), and the diastolic blood pressure was defined as the disappearance of the sound (Korotkoff phase 5) during deflation of the cuff.

Blood Sampling and Biochemical Analysis

Blood samples were taken from each patient for analysis prior to the procedure. Following venipuncture, blood samples were collected into Vacutainer[®] tubes and centrifuged at 15,000g for 15 min at 4 °C. After separation, aliquots of serum were frozen at −80 °C until analysis. A full fasted lipid profile comprising total-cholesterol, triacylglycerols, HDL-C and LDL-C were determined for each subject. Serum lipid and fasting blood glucose (FBG) concentrations were measured enzymatically with the use of commercial kits using a BT-3000 autoanalyzer (Biotechnica, Rome, Italy). High sensitive C-reactive protein (hs-CRP) was measured by a PEG-enhanced immunoturbidimetry method with an Alcyon[®] analyzer (ABBOTT, Chicago, IL, USA).

Determination of Serum sd-LDL Levels

Serum sd-LDL concentrations were determined using a method previously described in detail by Hirano et al. [12]. Briefly, a precipitation reagent (150 U/ml heparin-sodium salt and 90 mmol/l MgCl_2) was added to 0.5 ml of serum sample, mixed and incubated for 10 min at 37 °C. The samples were placed in an ice bath and allowed to stand for 15 min, and centrifuged at 15,000 rpm for 15 min at 4 °C. An aliquot of the clear supernatant was removed for LDL-cholesterol and apo B analyses. The LDL-C in the heparin- Mg^{2+} supernatant (containing HDL and sd-LDL) was directly and selectively determined by a homogeneous method. The concentration of the sd LDL-apoB in the heparin- Mg^{2+} supernatant was measured by an

immunoturbidimetric assay (Apo-B, Biosystems). In this method, as has been previously described, the cholesterol and apo-B values obtained by the precipitation method were similar to those obtained in the lipoprotein separated by ultracentrifugation, and the authors have found there was an excellent correlation between the two methods for sd LDL-cholesterol and apoB [12]. The coefficients of variation of inter- and intra-assay for the precipitation method were 1.3–1.6 and 1.7–3.7 %, respectively.

Statistical Analysis

All statistical analyses were performed using the SPSS for Windows[™], version 16 software package (SPSS Inc., Chicago, IL, USA). Data were expressed as means \pm SD (for parameters with a normal distribution) or median and interquartile range (for non-normally distributed data). Data that were normally distributed were analyzed using Student's *t* test (for 2 groups) or one-way analysis of variance (ANOVA) (for >2 groups). Data found to be non-normally distributed were analyzed using the non-parametric Mann–Whitney test (for 2 groups) or Kruskal–Wallis (for >2 groups). Categorical data were compared using the Chi-square test. A two-sided *P* value <0.05 was considered statistically significant. A Bonferroni correction was applied in the comparison of sd-LDL values between control, CAD− and CAD+ groups. Bivariate correlations between different parameters and sd-LDL levels were performed using Spearman's rank correlation and Kendall's test. Stepwise multiple linear regression analysis was used to determine which of the conventional risk factors could influence sd-LDL values. The predictor variables classified as dichotomous (1 = yes/0 = no) including diabetes mellitus, hyperlipidemia, hypertension, sex and smoking were entered into the initial model. Height, weight, FBG, waist circumference, hip circumference, HDL-C, LDL-C, systolic and diastolic blood pressure, triacylglycerol and number of narrowed vessels were entered as continuous variables in the same model. The effect of statin therapy was also analyzed as a covariate variable.

Results

Demographic Characteristics

Clinical and biochemical characteristics of all 3 groups (CAD+, CAD−, and control) are summarized in Table 1. LDL-C values were found to be significantly higher in controls than for patients. This may be attributed to the fact that a proportion of the CAD patients were on treatment with a statin, whilst none of controls were on statin treatment. With regard to the subgroups of CAD+ patients with

Table 1 Demographic and clinical characteristics of CAD positive and negative and control participants

| | CAD-positive | CAD-negative | Controls | <i>P</i> value |

* Means before covariate analysis

different number of stenosed vessels [single-vessel disease (SVD), double-vessel disease (2VD), and triple-vessel disease (3VD)], no significant differences in demographic parameters were observed between different subgroups ($P > 0.05$, Table 2) except age. All subjects were divided into those with or without metabolic syndrome, based on AHA/NHLBI criteria. These data have been summarized in Table 3.

Sd-LDL Values Among Different Groups

Median sd-LDL values in the control group were [16.52 (11–27.5) (mg/dl)], being significantly lower than CAD– [30.21 (16.52–46.52) (mg/dl)] and CAD+ patients [34.42 (19.68–53.37) (mg/dl)] (comprising SVD, 2VD and 3VD) ($P < 0.001$). The results remained significant after Bonferroni correction. Moreover, CAD– patients had statistically lower median sd-LDL values in comparison with

patients with SVD, 2VD and 3VD ($P < 0.01$). In the CAD+ group, median sd-LDL values were [36.26 (20.60–54.42) (mg/dl)], [29.16 (18.63–49.16) (mg/dl)] and [35.73 (19.55–57.05) (mg/dl)] in SVD, 2VD and 3VD patients respectively. Median sd-LDL levels were not significantly different among SVD, 2VD and 3VD patients ($P = 0.245$). Gender and smoking status did not alter the sd-LDL values significantly between controls, CAD+ and CAD– patients ($P > 0.05$).

The subjects were also divided into those with or without co-existing metabolic syndrome. As would be expected, the sd-LDL levels were significantly higher in patients with metabolic syndrome [33.9 (19.16–52.31) (mg/dl)] in comparison with patients without metabolic syndrome [27.6 (16.52–45.34) (mg/dl)] ($P = 0.006$). Sd-LDL levels were evaluated based on different components of the metabolic syndrome. In those subjects with several components of the metabolic syndrome such as increased waist circumference,

Values are presented as means ± SD or median (interquartile range). Comparisons between 1VD, 2VD and 3VD patients were performed using ANOVA or Kruskal–Wallis and Chi-square test

CAD coronary artery disease, *sd-LDL* small dense low density lipoprotein, *DM* diabetes mellitus, *HTN* hypertension, *HLP* hyperlipidemia, *WC* waist circumference, *HC* hip circumference, *FBG* fasting blood glucose, *BMI* body mass index, *TC* total-cholesterol, *LDL-C* low-density lipoprotein cholesterol, *HDL-C* high-density lipoprotein cholesterol, *TAG* triacylglycerol, *hs-CRP* high-sensitive C-reactive protein, *SBP* systolic blood pressure, *DBP* diastolic blood pressure, *VD* vessel disease

reduced HDL-C, and hypertension had significantly higher levels of sd-LDL in comparison with those subjects without above components (Table 4). This was not however the case for hyperglycemia and hypertriacylglycerolemia. When the females and males with and without metabolic syndrome were analyzed separately, it was found that females ($P = 0.006$) but not in males ($P = 0.108$), sd-LDL levels were significantly different between patients with and without metabolic syndrome.

Covariate Analysis

The effects of statin therapy were analyzed as a covariate variable. We found that in the present study, statin therapy had a covariate effect in 3 groups of CAD+, CAD– and control subjects, whilst we did not observe this effect in the CAD+ subgroups. After covariate analysis, we found similar results, as CAD+ and CAD– patients had significantly higher levels of sd-LDL than controls ($P < 0.001$).

Moreover, a significant difference was observed between patients with and without metabolic syndrome ($P < 0.05$). Covariate analysis also confirmed our previous results indicating that only in females ($P < 0.01$) but not in males ($P = 0.137$), sd-LDL levels were significantly different between patients with and without metabolic syndrome.

Correlation Between sd-LDL Values and CAD Risk Factors

Among the risk factors for CAD, in the CAD+ group waist and hip circumferences, waist/hip ratio, FBG, LDL-C, HDL-C, triacylglycerol (positively) and systolic blood pressure (inversely) were related to sd-LDL levels, however in CAD– patients sd-LDL levels were not associated with any of the classical CAD risk factors except waist circumference and triacylglycerol. In controls, FBG and triacylglycerol (positively) and LDL-C and hs-CRP (inversely) was associated with sd-LDL levels. No association was

Group comparisons were performed using Kruskal–Wallis test with Bonferroni correction. As statin therapy was as a covariate variable, patients who were treated with stains were analyzed separately

Sd-LDL small dense low density lipoprotein, *MS* metabolic syndrome *HDL-C* high density lipoprotein-C, *WC* Waist circumference

found for traditional CAD risk factors such as diabetes mellitus, smoking, hypertension and hyperlipidemia with sd-LDL in 3 groups (Data have not been shown).

When the association between different biochemical and CAD risk factors with sd-LDL levels were assessed among

the 3 subgroups of CAD patients (SVD, 2VD and 3VD), we found that LDL-C and triacylglycerol (positively) and smoking (inversely) were associated with serum sd-LDL concentrations in patients with SVD. In the 2VD subgroup, only triacylglycerol was associated with the sd-LDL

concentrations; whilst in the 3VD subgroup, waist and hip circumference, waist/hip ratio, FBG, LDL-C, HDL-C, triacylglycerol (positively) and systolic blood pressure (inversely) were associated with the sd-LDL concentrations (Data not shown).

Association Between sd-LDL Values and CAD Risk Factors

Stepwise multiple linear regressions in CAD patients yielded the following equation for the prediction of serum

sd-LDL values [sd-LDL values = 0.115 (triacylglycerol) + 0.154 (total-cholesterol) – 0.891 (BMI) + 0.306 (waist circumferences)] (Table 5). Moreover, in patients with metabolic syndrome, the regression model yielded the following equation for the prediction of serum sd-LDL values in patients with metabolic syndrome [sd-LDL values = 0.149 (triacylglycerol) + 0.173 (total-cholesterol)] (Table 6). In patients without metabolic syndrome, the following equation for the prediction of serum sd-LDL values was found [sd-LDL values = 0.148 (total-cholesterol) + 9.07 (gender) + 0.061 (triacylglycerol) + 0.107

Table 5 Stepwise multiple linear regressions of factors affecting sd-LDL levels in CAD patients

| Independent variable | Before covariate analysis | | | After covariate analysis | | |
|----------------------|---------------------------|-------------|----------|--------------------------|-------------|----------|
| | β | % Variation | P values | β | % Variation | P values |

| Systolic blood pressure | 0.107 | 1.9 | 0.043 | – | – | – |

Diabetes mellitus, hyperlipidemia, hypertension, sex and smoking were entered into the initial model. Height, weight, fasting blood glucose, waist and hip circumference, high and low density lipoprotein-cholesterol, systolic and diastolic blood pressure blood pressure, triacylglycerol and number of narrowed vessels were entered as continuous variables in the same model. Regression analyses were performed before entering the effect of statin consumption as covariate variable

Sd-LDL small dense low density lipoprotein

(systolic blood pressure)] (Table 7). After regression analysis and entering statin consumption as a covariate variable, we found similar results in all three regression analysis, but only in patients without metabolic syndrome systolic blood pressure lost its significance.

Discussion

To our knowledge, the predominance of the sd-LDL phenotype has not previously been studied in Persian CAD patients. We have however recently found higher levels of sd-LDL in SVD versus 3VD patients among 204 patients presenting with acute coronary syndrome [13]. Thus, we aimed to evaluate the possible relationship between the severity of CAD and sd-LDL concentrations within a larger sample size in which CAD was defined angiographically. In the present study, we found higher levels of sd-LDL concentrations in CAD+ patients compared with CAD– and healthy controls. Moreover, the sd-LDL values were significantly higher in CAD– patients, who had no significant stenosis in their coronary arteries based on angiography results, than healthy controls.

There have been previous studies that have reported a positive association between the sd-LDL levels, LDL particle size and the presence and severity of CVD [2–6]. It has also been reported that the mean LDL size was smaller in those patients with proven CAD based on angiography results than the healthy controls; Moreover, after multiple regression analysis, the presence of sd-LDL was found to be an important and independent risk factor for CAD development apart from the traditional cardiovascular risk factors [2]. Furthermore, it has been reported that men with an LDL particle size <25.6 nm had a significant 2.2-fold increase in the 5-year rate of ischemic heart disease compared with those men having an LDL particle size >25.6 nm [6] and it has been proposed that sd-LDL particles and high concentrations of sd-LDL are both important risk factors for CVD [3]. Previous reports indicate that there is a linear correlation between the sd-LDL concentrations and the risk of development of cardiovascular events [4, 5].

It has been proposed that sd-LDL may be involved in the pathogenesis of CVD via several mechanisms. Sd-LDL is one of the most atherogenic lipoprotein classes, and in comparison with larger-sized lipoproteins, sd-LDL particles have (1) a lower affinity for the LDL-receptors [14], (2) higher susceptibility to oxidative modification and (3) lesser antioxidants concentrations [15], (4) longer retention time in the circulation [16] and (5) enter the arterial wall more easily [17].

Although our method is less precise than the recently developed quantitative angiographic techniques such as

those using the Gensini coronary atherosclerosis scores and angiography itself may not accurately measure the CAD severity, but based on the number of stenosed vessels, we did not find any association between sd-LDL levels and severity of CAD; LDL- and total-cholesterol levels were comparable between patients with SVD, 2VD and 3VD. Some studies have reported results consistent with ours. Koba et al. [18] found that LDL size is not related to the severity and extent of coronary lesions determined by Gensini score. In other study by Kwon et al. [2], it was found that patients with more extensive CAD had smaller LDL particles. In other study, both sd-LDL mass concentrations and also sd-LDL particle size were measured simultaneously in patients with CAD and their association with severity of disease (based on Gensini score) was determined. The authors found that high sd-LDL concentrations were closely related to the CAD severity independently of classical coronary risk factors, while LDL particle size was not related. Thus, they suggested that the progression of CAD is closely linked to the amount of sd-LDL but not with the LDL particle size [3].

There is also strong evidence suggesting that sd-LDL is independently associated with the metabolic syndrome; Haffner et al. [19] have reported a decreased LDL size in subjects with multiple metabolic disorders. Moreover, several studies have suggested sd-LDL as a valuable marker for diagnosis and severity of the metabolic syndrome [8, 9]. It has been previously reported that increased plasma triacylglycerol and decreased HDL-C concentrations are usually accompanied by the presence of sd-LDL particles comprising together the atherogenic lipoprotein phenotype [20, 21]. Furthermore, in regard to important role of triacylglycerol in the composition and metabolic fate of lipoproteins, it has been reported that 80 % of patients with serum triacylglycerols above 1.5 mmol/L are characterized by the presence of sd-LDL subfraction pattern [22]. In the present study, as would be expected the subjects with metabolic syndrome had higher levels of sd-LDL values compared with subjects without metabolic syndrome. Moreover, when sd-LDL levels were analyzed with respect to metabolic syndrome components separately and statin therapy analyzed as a covariate variable, we found that all of metabolic syndrome components except hypertriacylglycerolemia and hyperglycemia appear to affect sd-LDL levels significantly. In a recent cross-sectional study by Kathiresan et al. [23], the number of sd-LDL particles was found to be greater in patients with metabolic syndrome and to increase with the number of components of metabolic syndrome.

In addition, multiple linear regressions showed that triacylglycerol, total-cholesterol, BMI, and waist-circumferences were the most important determinants of sd-LDL levels in CAD patients. Increased plasma triacylglycerol

plays a critical role in preponderance of sd-LDL in CAD patients, as our results and other studies support that LDL particle size is associated with serum triacylglycerol level [24]. Hirano et al. [12] have reported that sd-LDL is positively associated with LDL-C and triacylglycerol and inversely with HDL-C. When the females and males with and without metabolic syndrome were analyzed separately, it was found that only in females but not in males, sd-LDL levels were significantly different. As Coresh et al. [25], have previously reported, this finding can be explained by the fact that female subjects had significantly higher levels of HDL-C and lower levels of triacylglycerol in comparison with the male subjects.

In the present study, the regression model showed that sd-LDL levels were negatively associated with BMI in the CAD patients. While it would be expected that patients with a high BMI, would have high levels of sd-LDL, the regression model did not show this in our sample population. This may be explained by this notion that more than 30 % of the subjects in CAD group were treated with statins. Moreover, it has been previously revealed that statin therapy does not decrease the proportion of sd-LDL among total LDL particles, but in fact increases it, while predictably reducing total LDL-C, absolute amounts of sd-LDL, and absolute amounts of large, buoyant LDL [26]. It has been proposed that statins are able to up-regulate the activity of LDL receptor and decreases large, buoyant LDL more than sd-LDL, as statins increase LDL receptor activity; large, buoyant LDL is a better ligand for the LDL receptor than sd-LDL [27]. Hence, it may be concluded that those patients who have higher BMI, are more prone to development of CAD and these patients usually receive statins lifelong. Thus, it could be possible those patients, who have higher BMI and are treated with statins, would have lower sd-LDL values.

In conclusion, we found that sd-LDL levels are significantly higher in patients presenting with symptoms of CAD. Moreover, patients with evident stenosis in their coronary arteries had also higher levels of sd-LDL levels compared with those patients without overt lesions. Due to our results, sd-LDL concentrations are not associated with severity of CAD defined by number of stenosed coronary arteries. In addition to assessing the impact of lipid-lowering agents on sd-LDL size further studies are needed to assess the effect of lipid lowering drugs in reduction of sd-LDL concentrations.

Limitations

This study has a number of limitations; first, it was not possible to control for the dosage, or type of statin in our subgroups of our patients. It is possible that patients with more severe disease were on higher doses of statin, or more

potent statins, and this will cause increasing effects on sd-LDL. We did not examine the size distribution of sd-LDL. It is not clear whether the LDL size profile or sd-LDL concentration is the better risk marker. There was a potential problem of selection bias in our study, as patients included were those with extant CAD rather than an unselected metabolic syndrome population. As we looked at a rather selected group of patients with metabolic syndrome, that may not be representative of all patients with metabolic syndrome. We hope future studies provide more information about this that which one (size or concentrations of sd-LDL) would be more useful in clinical practice.

Acknowledgments The Mashhad University of Medical Science has provided the financial supports for this study. We are particularly grateful to the patients and their family members who volunteered to participate in this study. We are particularly grateful to Ms. Zahra Gharaiie Sheyda for data analysis. The results presented in this work have been taken from Shima Yazdandoust's thesis in Mashhad University of Medical Science.

Conflict of interest None.

Abstract The present study enumerates the synthesis, spectroscopic characterization, and evaluation of anticancer potential of esters of two n-9 fatty acids viz., oleic acid (OLA) and ricinoleic acid (RCA) with 2,4- or 2,6-diisopropylphenol. The synthesis strategy involved esterification of the hydroxyl group of diisopropylphenol (propofol) to the terminal carboxyl group of n-9 fatty acid. The synthesized propofol-n-9 conjugates having greater lipophilic character were tested initially for cytotoxicity in-vitro. The conjugates showed specific growth inhibition of cancer cell lines whereas no effect was observed in normal cells. In general, pronounced growth inhibition was found against the human skin malignant melanoma cell line (SK-MEL-1). The anticancer potential was also determined by testing the effect of these conjugates on cell migration, cell adhesion and induction of apoptosis in SK-MEL-1 cancer cells. Propofol-OLA conjugates significantly induced apoptosis

in contrast to propofol-RCA conjugates which showed only weak signals for cytochrome *c*. Conclusively, the synthesized novel ester conjugates showed considerable moderation of anti-tumor activity. This preliminary study places in-house synthesized conjugates into the new class of anti-cancer agents that possess selectivity toward cancer cells over normal cells.

Introduction

Dietary constituents are reported to be one of the main safety factors in the prevention and pathobiology of cancer [1]. They are now being used effectively as an alternative to the conventional anticancer drugs. A range of natural sources like castor oil, olive oil, almonds, peanuts, red meat, fish oil, etc., contains the *n*-hydroxy unsaturated fatty acids (UFA). These fatty acids have been shown to play an important role in inhibition of various type of cancer and manifest less side-effects when compared to standard chemotherapeutic agents [2, 3]. The UFA are taken up rapidly by tumor cells [4] and their hydrophobic nature facilitates their rapid incorporation into the lipid bilayer of cells [5, 6] resulting in disruption of membrane structure and fluidity [7]. Considering these characteristics of UFA, they are now being used exogenously to enhance the anticancer activity of various chemotherapeutic agents [8, 9] and for tumor-targeting drug delivery.

To achieve effective tumor-specific drug delivery, the UFA have been chemically modified to enhance their specificity, potent biological activity and reduction in toxicity against a range of therapeutic targets [10]. Previously, we had demonstrated efficient synthesis of *n*-6 polyunsaturated fatty acid (PUFA)-esters where PUFA was conjugated with propofol in order to enhance its activity, lipid-solubility, bioavailability, and decrease its side-effects [11]. Propofol (diisopropylphenol) is one of the most popular chemical agents used for induction of anesthesia and is non-toxic to humans at high concentrations (3–8 µg/ml; 20–50 µM) [12]. The presence of two isopropyl groups at the ortho position with respect to the hydroxyl group in propofol exerts a steric hindrance that prevents access of hydrophilic molecules to the hydroxyl group. This makes the molecule highly hydrophobic. Although it is an intravenous sedative-hypnotic agent, propofol also shows preferential scavenging of organo-radical species. Clinically relevant concentrations of propofol are reported to decrease the metastatic potential of human cancer cells [13] and have been shown to induce apoptosis involving both extrinsic and intrinsic pathways [14]. Our preliminary studies showed a noticeable feature of selective inhibition of cancerous cells by the novel PUFA-ester conjugates [11]. These results encouraged the present work, which is directed towards the synthesis of a new class of *n*-9 monounsaturated fatty acid (MUFA)-ester conjugates possessing anticancer activity.

Amongst UFA, the MUFA, despite being crucial to the body, have received less attention than *n*-3 and *n*-6 PUFA counterparts. Primarily, MUFA offer major health benefits

viz., promotes healthy blood lipid profiles, mediates blood pressure, improves insulin sensitivity and regulates glucose levels [15]. The major MUFA in human diets is oleic acid (OLA; *cis*-9-octadecenoic acid). It is found in several animal and vegetable oils; olive oil being its richest source. High concentrations of OLA are found to lower the levels of cholesterol, atherosclerosis and aid in cancer prevention [16–18]. Curiosity has been stimulated in OLA since the discovery of its role in protection from breast cancer [19–23]. Various epidemiological and animal model studies have correlated the consumption of OLA rich olive oil with reduction in cancer incidences [24–27]. In-vitro studies conducted by Menendez et al. [19] have shown the use of OLA in synergistically enhancing the effectiveness of various anticancer agents. The higher concentration of OLA has been revealed to induce DNA fragmentation and loss of membrane structure of various cancer cell lines [28]. Recently, Brinkmann et al. [29] suggested that OLA has a great potential to lyse the membrane of target cells and also induce apoptosis in cancer cells. The augmentation of the antiproliferative effect of OLA can be ascribed partly to its unique structure. The presence of one double bond (monounsaturated) at the 9th position in a 18-carbon chain makes it much less susceptible to oxidation and thereby imparts higher stability.

Ricinoic acid (RCA; *cis*-12-hydroxyoctadec-9-enoic acid), the other MUFA has not yet been investigated for its role in cancer prevention. In yeast, RCA is a possible intermediate in the conversion of oleic acid to linoleic acid [30]. RCA produced through the hydrolysis of castor oil is a pharmacologically active molecule [31]. Structurally RCA is similar to OLA, but with a slight difference, where one hydroxyl group is present at the 12th carbon position. Unlike other UFA, the presence of an additional hydroxyl group provides several interesting properties to RCA by which it can be converted to useful chemical analogs. A study on the biological action of RCA has shown that it does not exert any hyper-analgesic effect towards heat and chemical nociceptive stimuli [32]. These properties render RCA as a promising analgesic and anti-inflammatory agent for local application. The surfactant properties of RCA have been considered to impart its antibacterial activity [33]. Moreover, its chemical structure has been used as a basis for the development of novel capsaicin-like compounds [34].

Here, we report the synthesis of four novel *n*-9 MUFA-ester derivatives (Scheme 1). The conjugates were spectroscopically analyzed to establish their chemical structures, followed by evaluation of their in-vitro anticancer efficacy. These conjugates were tested for their ability on apoptosis, cell migration and cell adhesion.

Materials and Methods

Materials

Oleic acid, ricinoleic acid, 2,6-diisopropylphenol, 2,4-diisopropylphenol, *N,N*-dicyclohexylcarbodiimide (DCC), 4-dimethylaminopyridine (DMAP), Rosewell Park Memorial Institute (RPMI)-1640 medium, Eagle's Minimum Essential Medium (EMEM); 2-[4-(2 hydroxyethyl)piperazine-1-yl]ethane sulfonic acid (HEPES); phenylmethylsulfonyl fluoride (PMSF); EDTA; dithiothreitol (DTT); 3-4, 5-dimethylthiazol-2-yl-2, 5-diphenyl-tetrazolium bromide (MTT), propidium iodide, sodium dodecyl sulphate (SDS) were acquired from Sigma-Aldrich. Fetal calf serum (FCS) was procured from Bio-Whittaker. Thin-layer chromatography plates (60A, 0.2 mm thick) and silica gel (60–120 mesh) were purchased from Fisher Scientific. Dichloromethane (DCM), methanol, ethanol, chloroform, *n*-hexane, diethyl ether, sucrose, KCl, MgCl₂, dimethyl sulfoxide (DMSO) and acetic acid were procured from Merck. Cell migration and adhesion kits were obtained from Cell Biolabs, Inc.

Monoclonal antibodies such as anti-caspase-3, anti-cytochrome *c* and anti- β -actin were purchased from BD Biosciences (San Diego, CA). Secondary anti-mouse peroxidase-conjugated antibody was from Amersham Pharmacia Biotech. A chemiluminescence detection kit was purchased from GE healthcare.

Cell Lines and Culture Conditions

Cell lines SK-MEL-1 (ATCC# HTB-67), HepG2 (ATCC# HB-8065), MDA-MB-361 (ATCC# HTB-27), A549 (ATCC# CCL-185), HL 60 (ATCC# CCL-240) and non-cancerous HFL1 (ATCC# CCL-153) were obtained from the American Type Culture Collection (Rockville, MD). SK-MEL-1 and HepG2 cell lines were maintained in

EMEM whereas MDA-MB-361, A549, HL-60 and HFL1 were maintained in RPMI medium. To make the complete growth medium, both types of media were supplemented with 10 % (v/v) heat-inactivated FCS, 2 mM L-glutamine, 100 U/ml penicillin and 100 μ g/ml streptomycin. All cells were maintained at 37 °C in a 95 % humidified atmosphere containing 5 % CO₂. Cells were screened periodically for mycoplasma contamination.

Synthesis and Purification of Propofol-n-9 Conjugates

A synthesis approach was conceived using the protocol of Siddiqui et al. [35]. However, several modifications were incorporated in our lab for synthesis of the final product [11]. A 1 mmol amount of the respective MUFA was dissolved in 5 ml dichloromethane (DCM). To this mixture, 0.45 mmol of coupling reagent *N,N*-dicyclohexylcarbodiimide (DCC) was added and the reaction mixture was stirred for 10 min at room temperature (23–25 °C). Finally, 1 mmol of one of the propofol isomers (2,6-propofol/2,4-propofol) was added and the reaction mixture was esterified in the presence of a catalyst, 0.152 mmol 4-dimethylaminopyridine (DMAP). The reaction mixture was stirred for a period of 10 h in the dark. The reaction was stopped by filtration and the filtrate was concentrated under reduced pressure to yield the product. The progress of the reaction was monitored on thin layer chromatography (TLC) in iodine vapour. Finally, the synthesized product was purified by silica gel column chromatography with solvent system *n*-hexane and diethyl ether (1:1).

2,6-Diisopropylphenol-Ricinoleic Acid (2,6P-RCA)

Yield 86 %; ^1H NMR (CDCl_3 , δ_{H}): 0.80 (*t*, $J = 6.96$ Hz, 3H), 1.11–1.40 (*m*, 30H), 1.68–1.72 (*m*, 2H), 1.98 (*q*, 2H), 2.1 (*t*, $J = 13.6$ Hz, 2H), 2.54 (*t*, $J = 15.08$ Hz, 2H), 2.8 (*m*, 2H), 3.5 (*m*, 1H), 5.3 (*m*, 1H), 5.5 (*m*, 1H), 6.80–6.82 (*d*, $J = 15.44$ Hz, 1H), 6.9 (*t*, $J = 7.6$ Hz, 1H); ^{13}C NMR (CDCl_3 , δ_{C}): 71.52, 120.6, 123.87, 126.42, 133.67, 139.54, 145.61, 172.40. FAB-MS: $[\text{M}-17]^+$ 441. Anal. calc. for $\text{C}_{30}\text{H}_{50}\text{O}_3$: C, 78.55; H, 10.99. Found: C, 78.98; H, 11.13. IR (KBr, cm^{-1}): 2934, 2869, 1749, 1452, 1364, 1171, 820, 733.

Spectral Analysis of Propofol-n-9 Conjugates

The formation of propofol-n-9 conjugates was confirmed by various spectroscopic studies. The presence of diisopropylphenolate in the synthesized conjugates was

assessed by UV spectroscopy on a UV Mini-1240 spectrophotometer. The absorption spectra were measured between 200 and 600 nm. The infrared spectra of the conjugates were recorded on a Nicolet-6700 FT-IR instrument. An aliquot (ten microliter of $1\text{ }\mu\text{g}/\mu\text{l}$) of the conjugate was deposited exactly within the cell limit and scanned as a thin film after evaporation of solvent. Absorption peaks of synthesized conjugates were observed at 1757.40/1758.73 (2,6P-OLA/2,4P-OLA) and 1740.07/1735.00 (2,6P-RCA/2,4P-RCA). The presence of $\nu(\text{C}=\text{O})$, $\nu(\text{C}-\text{O})$, aromatic C–H (propofol) and aliphatic C–H bond and absence of hydroxyl ($-\text{OH}$) absorption peak corresponds to the data published previously [11]. The formation of new conjugates was elucidated with ^1H - and ^{13}C -NMR spectra on a BRUKER AVANCE II 400 NMR spectrometer. The FAB-MS spectra were recorded on a JEOL SX 102 Mass Spectrometer/Data System using Argon/Xenon (6 kV, 10 mA) as the FAB gas.

Analysis of Growth Inhibition of Cancer Cells

The conjugates were examined for their cytotoxicity against five different types of cancer cell lines viz., SK-MEL-1 (human skin malignant melanoma), HepG2 (human liver hepatocellular carcinoma), MDA-MB-361 (human ductal carcinoma, breast), A549 (human lung carcinoma), HL-60 (human leukemia, acute promyelocytic) as well as one non-cancerous HFL1 (human lung fibroblast) using a standard MTT reduction assay. Cells in exponential growth were seeded into 96-well plates at a concentration of 5×10^5 cells/200 μl /well and allowed to grow in their respective medium containing 5 % FCS. After 24 h, cells were treated with different concentrations of test conjugate or parent controls (OLA and RCA only/propofol only) at a concentration range of 0–15 μM . Vehicle control (ethanol only) and positive control (doxorubicin) cells were cultured using the same conditions. Following 94 h incubation, the medium was removed and replaced with fresh medium. MTT reagent (5 mg/ml in PBS) was added to each well at a volume of 1:10 and incubated for 2–3 h at 37 °C. After treatment, 100 μl of DMSO was added to each well after carefully aspirating the supernatants. Absorbance was measured at 620 nm in a multi-well plate reader. Triplicate wells were prepared for each individual concentration. Dose–response curves were plotted as percentages of the cell absorbance. Drug sensitivity was expressed in terms of the concentration of drug required for a 50 % reduction in cell viability (IC_{50}).

Toxicity Analysis of Propofol-n-9 Conjugates

Preliminary acute toxicity of conjugates was tested through erythrocyte lysis test wherein hemoglobin, released as a

result of membrane leakage or disruption caused by exposure to high doses of the drug, was measured spectrophotometrically [36]. Fresh human blood in heparin was subjected to centrifugation at 1,000g for 15 min at 4 °C. Buffy coat as well as plasma was discarded. The washed erythrocytes were diluted with isotonic buffer (10 mM phosphate buffer, 150 mM NaCl) and 50 % hematocrit was prepared. To study the extent of haemolysis, the suspension of RBCs was incubated with 150 μ M (dose that induces cytotoxicity concentrated ten times) of conjugates, propofol only as well as OLA and RCA only at 37 °C for 1 h. Ethanol was taken as the vehicle control. After 1 h, the reaction mixture was centrifuged at 1,500g and the supernatant was collected and analyzed by UV–Visible spectroscopy ($\lambda_{\text{max}} = 576$ nm) for released hemoglobin.

Analysis of Cancer Cell Migration

Cell migration was performed with CytoSelect 24-Well Cell Migration Assay (Cell Biolabs, Inc.). Under sterile conditions, the 24-well migration plate was allowed to warm up at room temperature for 10 min. The lower well of the migration plate was supplemented with 500 μ l of EMEM containing 10 % fetal bovine serum with or without (control) test conjugates. To the inside of each insert 100 μ l of SK-MEL-1 ($0.5\text{--}1.0 \times 10^6$ cells/ml) cell suspension was added. The plates were incubated for 8 h at 37 °C in a humidified CO₂ incubator. After incubation, the media from inside the inserts was carefully aspirated and the non-migratory cells were removed using cotton-tipped swabs. The inserts were transferred to a clean well containing 400 μ l of cell stain solution and incubated for 10 min at room temperature. The stained inserts were gently washed several times and then transferred again to an empty well. Finally, 200 μ l of extraction solution per well was added and incubated for 10 min on an orbital shaker. From each sample, 100 μ l was taken in a 96-well microtiter plate and the absorbance at 560 nm was read in a plate reader.

Analysis of Cancer Cell Adhesion

The cell adhesion assay was performed with a CytoSelect 24-Well Cell Adhesion Assay kit (Cell Biolabs, Inc.). Under sterile conditions, the ECM adhesion plate was allowed to warm up at room temperature for 10 min. Then 150 μ l of the SK-MEL-1 cell suspension ($0.1\text{--}1.0 \times 10^6$ cells/ml) in serum free media with control or test conjugates was added to each well. The plates were incubated for 30–90 min in a CO₂ incubator. The wells were washed three times with PBS and the adhered cells were stained with 200 μ l of cell stain solution for 10 min at room temperature. The excess stain was removed by washing

4–5 times with distilled water. After air drying the wells, 200 μ l of extraction solution per well was added and then incubated for 10 min on an orbital shaker. Then 150 μ l from each extracted sample was transferred to a 96-well microtiter plate and the absorbance at 560 nm was read in a plate reader. Absorbance of dye in the control (vehicle-treated) cells was regarded as 100 % adherence and the percentage adherence of treated cells was calculated in comparison with that of the control cells.

Apoptosis Assay

Cancer cells (1×10^7 cells per well) were grown in 6-well plates in a serum free culture medium (respective to the cell line used) in a humidified CO₂ incubator at 37 °C. After 24 h, confluent cells were treated with control (ethanol only) or parent control (OLA/RCA only/propofol only) or test conjugates and incubated for 24 h again. Following incubation, cells were harvested and washed twice in PBS. The cells were suspended in 50 μ l of ice-cold TNN buffer containing 50 mM Tris–HCl pH 7.4, 100 mM NaCl, 5 mM EDTA, 0.5 % Nonidet P-40, 1 μ g/ml pepstatin, 0.5 mM EGTA, 200 μ M PMSF, 0.5 mM DTT and 1 μ g/ml of leupeptin and homogenized in a Teflon homogenizer. A post-nuclear fraction was prepared by centrifugation for 5 min at 2,000 rpm at 4 °C. The supernatant was further centrifuged for 20 min at 10,000 rpm at 4 °C and the resultant cytosolic fraction was used for detecting the expression of two apoptotic factors; cytochrome *c* and caspase-3.

Western Blotting

Equal amounts of protein in SDS sample buffer were subjected to 10 % SDS-polyacrylamide gel electrophoresis [37]. Immunoblotting of resolved proteins was done on a nitrocellulose membrane. Nonspecific binding on the nitrocellulose membrane was minimized by blocking for 1 h at room temperature with PBS-T [PBS (pH 7.5) and 0.05 % Tween-20] containing 5 % (w/v) non-fat dry milk. The treated membrane was washed in PBS-T and then incubated overnight at 4 °C with specific primary antibodies (monoclonal anti-cytochrome-*c* or monoclonal anti-caspase-3) in PBS-T containing 5 % (w/v) BSA. The membranes were again washed in PBS-T, anti-mouse peroxidase-conjugated secondary antibodies in PBS-T were added for 2 h, and immunoreactive bands were detected by enhanced chemiluminescence detection kit. Blots were re-probed with an antibody for β -actin to control for equal protein loading and transfer. Densitometric values of protein bands were quantified using Alpha Image Analysis software on Alpha Image Gel Documentation System.

Protein Determination

Protein content was determined by the BCA method [38]. The mixture of solutions A and B (1:49) of BCA reagent was added to the protein sample and further incubated at 37 °C for 45 min. The absorbance was measured at 562 nm and the protein concentration was calculated using a standard curve of BSA.

Statistical Analysis

Results are expressed as the means \pm SD of three experiments for each treatment and were plotted accordingly. Individual treatments were tested against the control by using the Student *t* tests. Significant differences from controls were considered at $P < 0.05$. Analyses were conducted with SPSS version 13.0.

Results

Chemistry

The two isomers of propofol viz. 2,4-propofol and 2,6-propofol were conjugated with OLA and RCA separately. The four novel propofol-n-9 conjugates were obtained from the esterification of hydroxyl ($^1\text{C-OH}$) group of propofol with the terminal carboxylic group of MUFA in the presence of DCC and DMAP. The reaction sequences are outlined in Scheme 1. The newly synthesized ester derivatives of propofol-OLA and propofol-RCA were located at specific *RF* values when subjected to thin layer chromatography analysis (Supplementary Fig. 1). The *RF* values of the products significantly differ from those of the parent controls viz. OLA/RCA and propofol. The conjugates were synthesized in good yield and had a colorless viscous liquid (oily) consistency at room temperature.

Spectral Characterization of Propofol-n-9 Conjugates

UV Absorbance

Propofol-OLA conjugates The spectra of parent OLA (Fig. 1a, b) showed an absorption peak at 268 nm whereas, absorption peaks of 2,4-propofol and 2,6-propofol were observed at 282.8 and 286 nm, respectively. In 2,4P-OLA and 2,6P-OLA conjugates, the characteristic peaks appeared at 263 and 266 nm, respectively.

Propofol-RCA conjugates The spectra of parent RCA (Fig. 1c, d) showed two absorption peaks at 255 and 270 nm whereas, absorption peaks of 2,4-propofol and 2,6-propofol were observed at 281.2 and 285.3 nm,

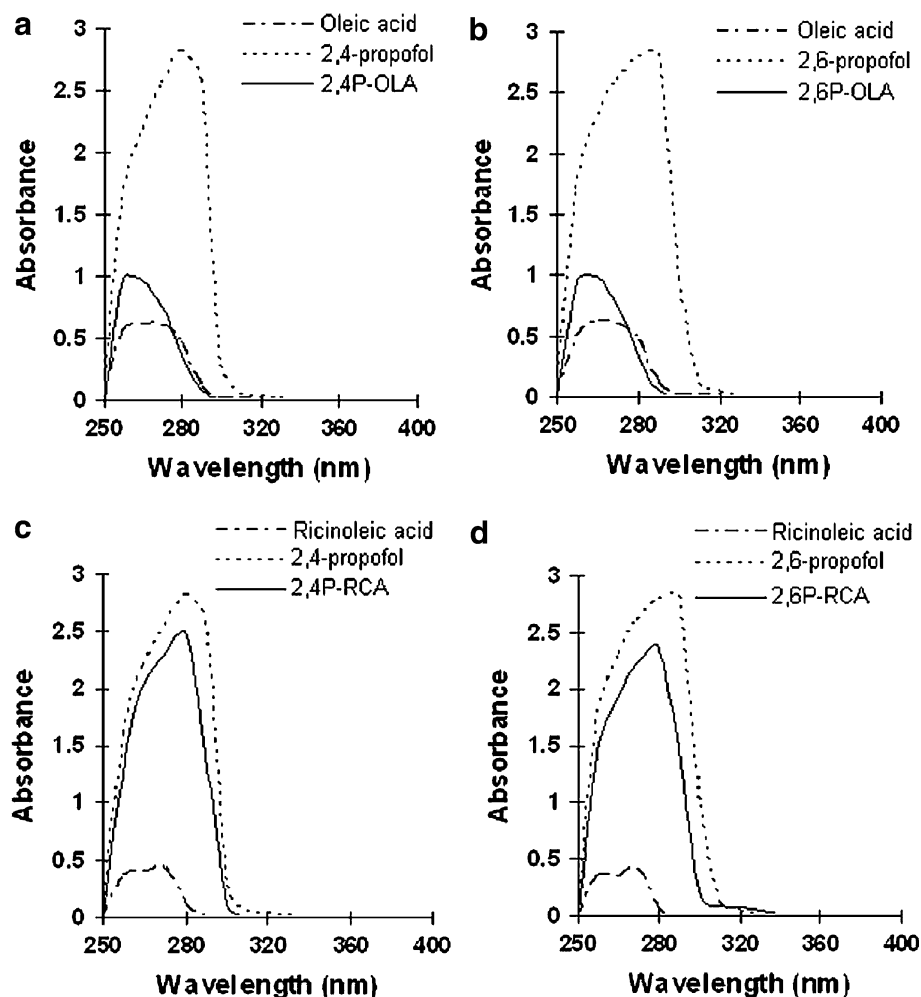

respectively. These peaks were shifted to 278 and 279 nm, for 2,4P-RCA and 2,6P-RCA conjugates, respectively.

Nuclear Magnetic Resonance Spectral Studies

Propofol-OLA and propofol-RCA conjugates The formation of propofol-OLA and propofol-RCA conjugates was further confirmed with the ^1H - and ^{13}C -NMR spectra. Assignments of the signals are based on the chemical shift and intensity pattern. The absence of a signal of the hydroxyl group confirms the synthesis of 2,4P-OLA and 2,6P-OLA (Supplementary Fig. 2a, b, respectively). The two olefinic protons of 2,4P-OLA and 2,6P-OLA (*k* and *i*) were observed as a multiplet at δ_{H} 5.36 while that of 2,4P-RCA and 2,6P-RCA (*l* and *k*) were resonating as multiplet at δ_{H} 5.4 ppm and 5.5 ppm respectively (Supplementary Fig. 2c, d) [39]. Due to the proximity of the hydroxy group to the double bond, the signal of the olefinic protons of 2,4P-RCA and 2,6P-RCA were split, with the downfield signal being assigned to the *k* proton at C-10 and the upfield signal assigned to the *l* proton at C-9 [40]. The $-\text{OH}$ proton is exchangeable with deuterium and might not always be visible as in our case. A triplet was observed at 0.88 ppm corresponding to the terminal methyl protons of the fatty acid chain. A conspicuous multiplet corresponding to the methylene protons of the fatty acid chain appeared in the range 1.25–1.46 ppm. The methyl protons of the isopropyl chain of the ring of 2,4P-OLA were observed as a doublet at 1.20 ppm while the signal corresponding to methyl protons of a isopropyl chain of 2,6P-OLA, 2,4P-RCA and 2,6P-RCA was merged with the methylene protons appearing as a strong multiplet at 1.19–1.48 ppm range. The methylene groups ($-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$) attached to the olefinic carbons were resonating as a quartet at 2.00–2.07 ppm (relatively at lower field) as a consequence of olefinic bond. The methylene protons $-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}(\text{OH})-$ of 2,4P-RCA and 2,6P-RCA were observed at 2.23 ppm as triplet with a coupling of 13.72 Hz. The $-\text{CH}_2-\text{CH}(\text{OH})-\text{CH}_2-$ protons of 2,4P-RCA and 2,6P-RCA resonate at 3.62 ppm as multiplet, since it is attached to the $-\text{OH}$ group, therefore is shifted downfield from the others. The $-\text{COCH}_2-$ protons adjacent to a carbonyl group resonate in the range 2.50–2.60 ppm, while the $-\text{CO}-\text{CH}_2-\text{CH}_2-$ protons were resonating in the range 1.75–1.85 ppm as a multiplet. In the case of 2,4P-OLA and 2,4P-RCA, $\text{Ar}-\text{CH}<$ gives two signals in the range 2.9–2.6 ppm [12] while for 2,6P-OLA and 2,6P-RCA, it gives a single signal at 2.9 ppm [41–43]. The aromatic protons appear in the usual range 6.80–7.30 ppm.

In the ^{13}C -NMR spectra, the assignments of the ^{13}C signal for $>\text{C}=\text{O}$ group of an ester is quite straightforward

Fig. 1 UV absorbance spectra of propofol-OLA and propofol-RCA conjugates. **a** 2,4P-OLA, **b** 2,6P-OLA, **c** 2,4P-RCA, **d** 2,6P-RCA. Absorbance of parent controls is also shown

and were observed in the range of 172.0–173.0 ppm [41, 43, 44]. The terminal methyl groups gave signals in 14–15 ppm range. Olefinic carbons were recorded at 133–125 ppm [39, 40, 45]. The $-\text{CH}(\text{OH})-$ carbon of 2,4P-RCA and 2,6P-RCA was recorded at 71.58 ppm. Assignment of other significant carbon signals has been shown in the Supplementary Fig. 2a–d.

FAB-MS Studies

Propofol-OLA and propofol-RCA conjugates The mass spectrum and fragmentation pattern of the 2,4P-OLA, 2,6P-OLA, 2,4P-RCA and 2,6P-RCA are illustrated in Supplementary Fig. 3a–d, respectively. They are typical in that they have a prominent ion peak at $m/z = 163$, 177, 264, 265 and 281, which are all fragments about the ester group. The molecular ion $[\text{M} + 3\text{H}]^+$ ($m/z = 445$), $[\text{M} + \text{H}]^+$ ($m/z = 443$) and $[\text{M}]^+$ ($m/z = 458$) are easily distinguished. The base peak was observed at $m/z = 177$ with its isotopic peak at $m/z = 178$ and represents a cleavage in the ester group. There is an ion at $m/z = 163$ representing loss

of the terminal carbon as a methylene group from the base peak of propofol [46].

Analysis of Growth Inhibition

Consistent with a previous report [11], the newly synthesized conjugates significantly inhibited cancer cell growth in a dose-dependent manner. All tested cells after treatment with the conjugates showed variable growth inhibitions till a maximum tested concentration of 15 μM was reached, making them potent, less potent or equipotent (IC_{50} values: Table 1). However, SK-MEL-1 was observed to be the most sensitive to all the four conjugates (Figs. 2, 3). The conjugates showed statistically significant ($P < 0.05$) anticancer activity in comparison with the vehicle control. The in-vitro evaluation revealed that structural modifications of propofol and MUFA resulted in conjugates that were non-toxic to non-cancerous HFL1 cells. This feature imparts extra edge to the synthesized products and put them into the class of anticancer agents in terms of selectivity and specificity. Although conjugates of propofol-linoleic acid and

propofol-arachidonic acid, (previously synthesized in our laboratory) [11] were also reported to be significantly cytotoxic to cancer cell lines (Table 1), the propofol-oleic acid conjugates synthesized in the present study were also found to be more potent anticancer molecules.

Toxicity Level of Propofol-n-9 Conjugates

The toxicity levels of conjugates were determined by in-vitro hemolysis testing. Figure 4 displays lysis of erythrocytes by various conjugates expressed as a percentage of total lysis (100 % lysis) induced with Triton X-100. The propofol-OLA conjugates caused negligible RBC lysis as compared to propofol-RCA conjugates. Among various conjugates 2,6P-OLA (~8 % hemolysis) and 2,4P-OLA (~10 % hemolysis) imparted less toxicity to erythrocytes than does 2,6P-RCA (~18 % hemolysis) and 2,4P-RCA (~19 % hemolysis). The intrinsic lytic ability of the propofol only, OLA and RCA only was also tested. RCA (~21 % hemolysis) caused a higher toxicity than OLA (~6 % hemolysis), propofol (~17 % hemolysis) and ethanol (~4 % hemolysis) thereby resulting in significant hemolysis of RBCs.

Note: Further in-vitro evaluations of anticancer efficacy of propofol-n-9 conjugates were done on the SK-MEL-1 skin cancer cell line since it was observed to be more prone to the cytotoxic effect of conjugates.

Effect of Propofol-n-9 Conjugates on SK-MEL-1 Cancer Cell Migration

The results shown in Fig. 5 demonstrate that OLA, RCA and propofol alone had a minimal effect on skin cancer cell migration. On the other hand, propofol-OLA and propofol-RCA inhibited cell migration by about 50 % ($P < 0.05$) and 30 % respectively to that of the control group.

Effect of Propofol-n-9 Conjugates on SK-MEL-1 Cancer Cell Adhesion

We also tested the effect of the propofol-OLA and propofol-RCA conjugates on the adhesion of the skin cancer cells to a fibronectin surface. While, OLA and RCA or propofol alone did not significantly affect skin cancer cell adhesion (Fig. 6), in contrast, propofol-OLA and propofol-RCA inhibited cell adhesion by ~40 % (significant at $P < 0.05$) and 35 %, respectively.

Effect of Propofol-n-9 Conjugates on Induction of Apoptotic Factors

Protein fractions of SK-MEL-1 cancer cells after incubation with n-9 or propofol alone or with test conjugates individually were screened by Western blotting after 24 h of treatment. Propofol-OLA conjugates were able to induce apoptosis in SK-MEL-1 cells at 15 μ M concentration whereby a significant increase in the expression of cytochrome *c* and caspase-3 was distinctly visualized (Fig. 7a, lanes 4 and 5). Whereas, weak signals of cytochrome *c* and no signals of caspase-3 were recorded with propofol-RCA conjugates (data not shown).

Mean densitometric values of individual bands of cytochrome *c* and caspase-3 were quantified using image analysis gel documentation system software. Each value was mean of three experiments. At 15 μ M tested concentration, increased expression of both apoptotic factors was recorded with slight variations in the activity of 2,4P-OLA and 2,6P-OLA conjugates. Release of 32.8 and 36.6 % cytochrome *c* and expression of 28.7 and 34.1 % caspase-3 was observed after treatment with 2,4P-OLA and 2,6P-OLA, respectively (Fig. 7b, c).

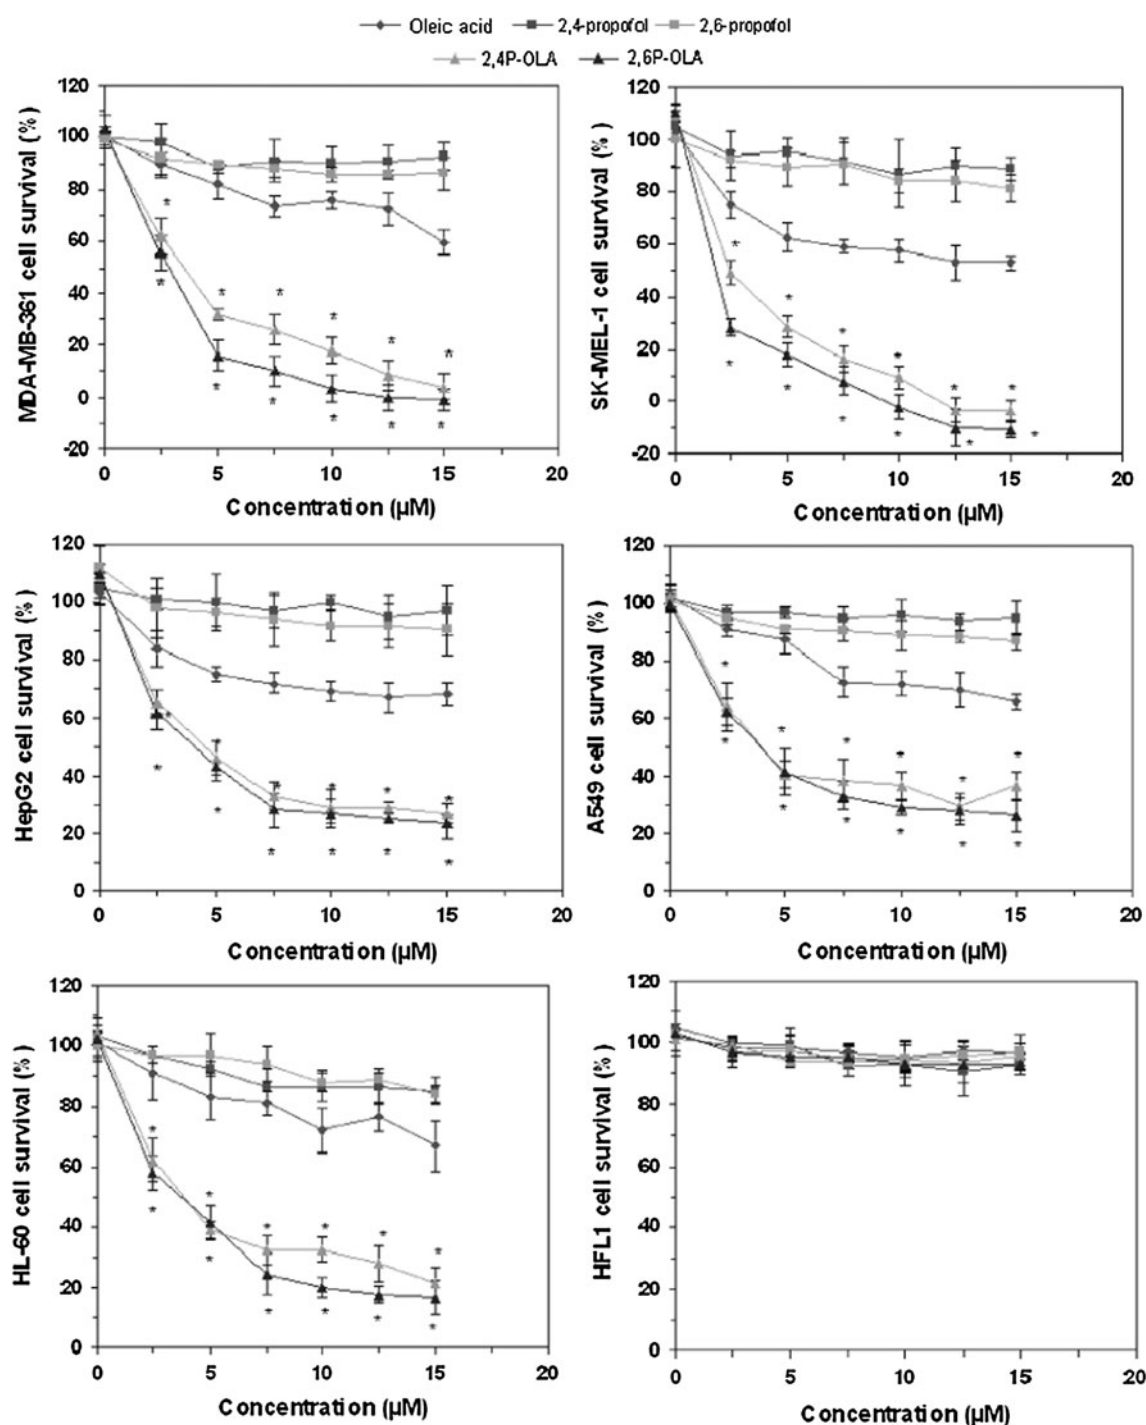

Fig. 2 Viability assessment of various cell lines after treatment with propofol-OLA conjugates. The effects of novel esters along with parent OLA and 2,4-/2,6-propofol are expressed as the means \pm SD of three experiments

Discussion

Efforts made in medicinal and combinatorial chemistry continue to give rise to a wide range of anticancer agents with remarkable therapeutic potential. A number of studies have concluded that chemically modified fatty acid

molecules possess more specific and potent biological activity, in addition to possibly affecting a wider range of therapeutic targets [10]. Over the last decade several attempts have been made to synthesize novel anticancer compounds by conjugating fatty acids with various anticancer drugs [35, 45, 47–49]. Many of these agents have

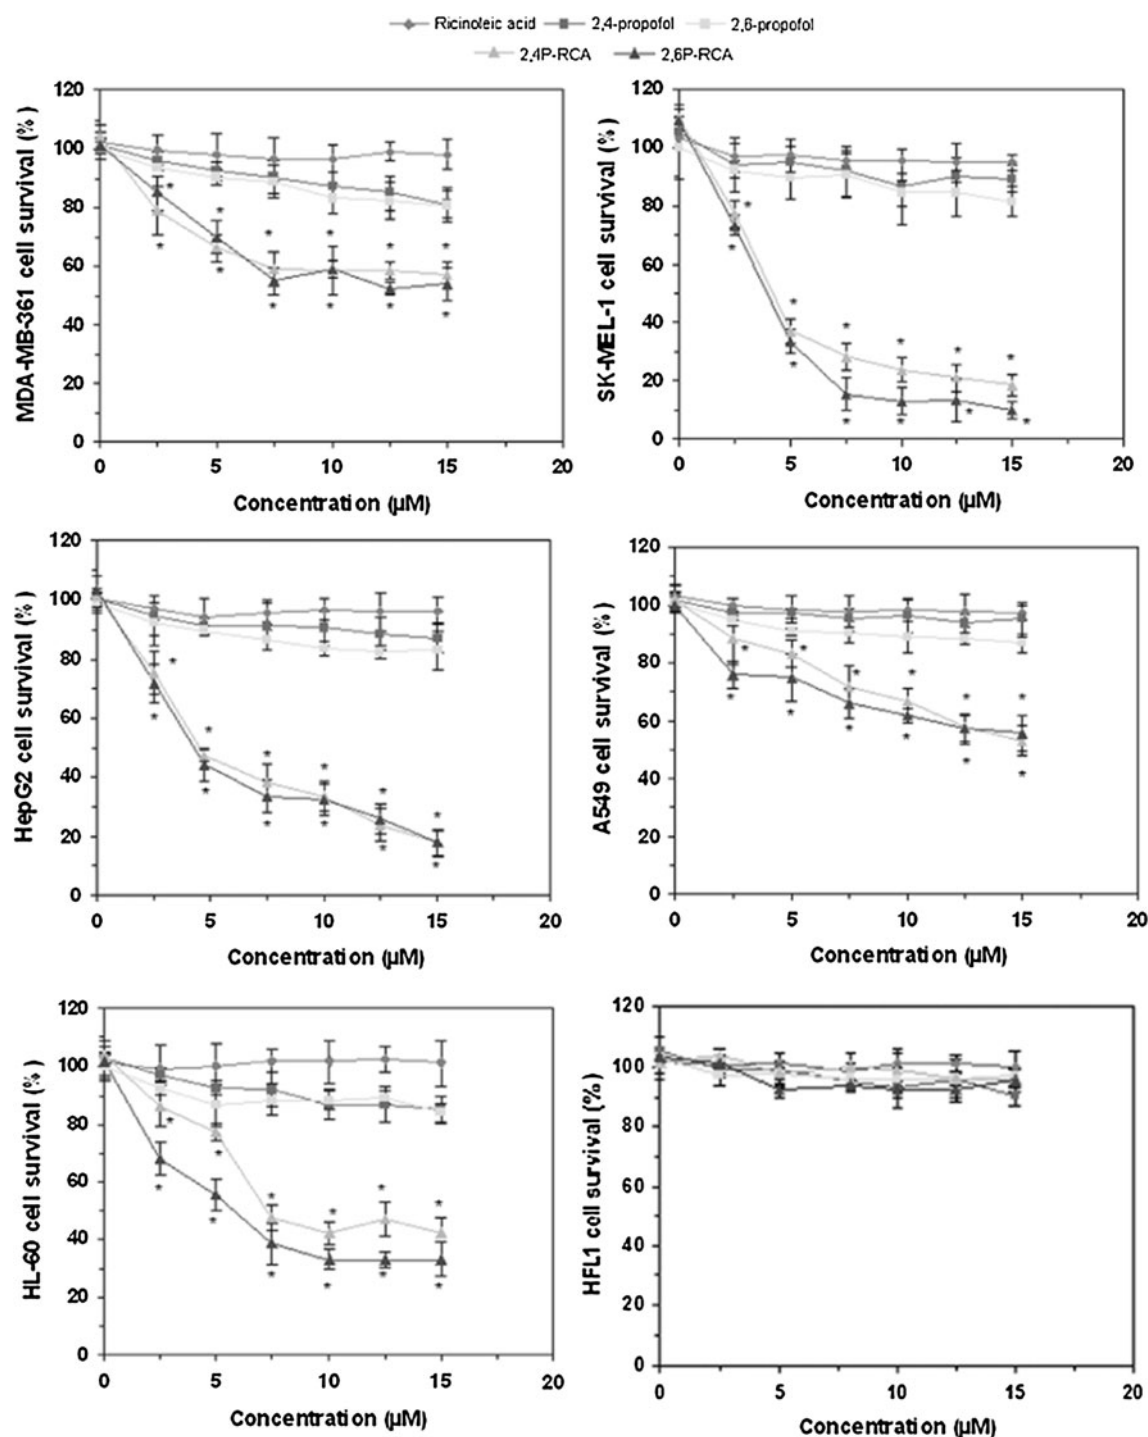

Fig. 3 Viability assessment of various cell lines after treatment with propofol-RCA conjugates. The effects of novel esters along with parent RCA and 2,4-/2,6-propofol are expressed as the means \pm SD of three experiments

solubility, stability or toxicological issues, which hamper their development into viable treatment strategies. To overcome these issues, the administration of antioxidants such as propofol is speculated to enhance the impact of chemotherapy. The co-administration of propofol with chemotherapeutic UFA, is supposed to enhance the

cytotoxicity and inhibit the oxidative damage, thereby inhibiting the growth of tumors. The cytotoxicity of different propofol-fatty acid esters have been investigated previously [11, 35, 50]. The present work is based on the chemical conjugation of MUFA with propofol isomers. The presence of DMAP (catalyst) and DCC (coupling

Fig. 4 The extent of damage caused to blood erythrocytes by propofol-n-9 conjugates was measured as the percentage lysis of the total red blood cells added. The data are the means \pm SD of three sets of different experiments

Fig. 5 Effect of propofol-n-9 conjugates on migration of SK-MEL-1 cancer cells. Results are the means \pm SD for three experiments. The level of significance for various data when compared to control ($P < 0.05$) is indicated with an *asterisk*

reagent) was a pre-requisite for esterification of novel conjugates. The use of the DCC/DMAP method was found to be a more suitable synthetic route under milder reaction conditions, giving a higher yield and providing convenient product purification strategies. The chemical nature of the four novel MUFA-esters reported in this study show absorption peaks in the ultraviolet range, which were quite distinct from the reactant parent controls (Fig. 1). The presence of an ester bond, aromatic C–H bond, and absence of the free –OH group as visualized by FT-IR, confirmed the formation of conjugates. Elemental analysis of conjugates showed the values for ‘CHN’ within ± 0.4 % of the theoretical ones.

Fig. 6 Effect of propofol-n-9 conjugates on adhesion of SK-MEL-1 cancer cells. Results are the means \pm SD for three experiments. The level of significance from the control ($P < 0.05$) is indicated with an *asterisk*

When the NMR signals of the conjugates were compared with the parent propofol [35], the hydroxyl proton signal at about 4.82 ppm in propofol was not visualized in the spectra of conjugates. The absence of hydroxyl group signal in ^1H -NMR spectra of the conjugates confirms the synthesis of new product, distinct from parent controls. The overall shift in signals indicates that the ester bond was formed at C-19 hydroxyl group of propofol. The molecular mass of the novel MUFA-ester derivatives determined by mass spectrometry was very close to the theoretically calculated molecular mass values viz., 442.47 Da for propofol-OLA conjugates and 458 Da for propofol-RCA conjugates.

After establishing the structures of the conjugates, their inherent toxicity in terms of cell membrane lysis was determined. The in-vitro erythrocyte lysis test showed that the newly synthesized esters cause only negligible damage to RBCs (Fig. 5). The four novel MUFA-esters were also screened for potential anticancer activities against a range of human cancer cell lines (Figs. 2, 3). The cytotoxic efficacy of these conjugates is expressed in terms of IC_{50} values, as shown in Table 1. Among various esters synthesized, propofol-OLA conjugates showed greater in-vitro anticancer activity with IC_{50} values ranging from 2.3 μM for SK-MEL-1 cells to 3.9 μM for HepG2 cells. Propofol-RCA conjugates however, moderately inhibited various cancer cells and showed negligible inhibition against MDA-MB-361 and A549 (IC_{50} values ranging from 3.9 μM for SK-MEL-1 cells to 7.4 μM for HL-60 cells). The propofol-n-9 conjugates were non-toxic to the normal HFL1 cells up to the highest concentration screened (15 μM).

Since, the conjugates revealed optimum cytotoxicity against SK-MEL-1 cells; we used this cell line for further studies. Cell migration and adhesion are essential processes in tumor metastasis [51]. In the present study, cell migration and cell adhesion assay revealed that the conjugates were able to inhibit the metastatic potential of SK-MEL-1 cells (Figs. 5, 6) where parent controls were not effective. Selective apoptosis of malignant cells is the most commonly analyzed attribute in chemotherapeutic studies. Modulation of expression of apoptotic factors must be tightly regulated for normal cellular functioning. Therefore, we also analyzed the effect of the conjugates on the induction of apoptosis by assaying for caspase-3 activation and cytochrome *c* release (Fig. 7). The 2,6P-OLA conjugate showed increased expression of both cytochrome *c* (36.6 %) and caspase-3 (34.1 %) in comparison with 2,4P-OLA (Fig. 7b, c). On the other hand, very weak signals for cytochrome *c* were detected when SK-MEL-1 cells were treated with propofol-RCA conjugates (data not shown). Interestingly, no signal of caspase-3 was recorded upon treatment of SK-MEL-1 cells with propofol-RCA conjugates. Thus, among the four conjugates, propofol-OLA conjugates promote apoptotic

cell death at doses of 15 μ M. Our current findings, thus demonstrate that propofol-OLA conjugates can induce the apoptosis by induction of a novel pathway through which n-9 MUFA putatively modulate the aggressive behavior of skin cancer.

Conclusion

The present study has shown the synthesis of four novel propofol-n-9 ester conjugates revealing unique cytotoxic action against various cancer cell lines. The conjugates are able to inhibit the growth of cancer cells in a dose-dependent manner. Positive results in the inhibition of cancer cell migration and adhesion further established their anticancer potential. Although, propofol-RCA conjugates are observed to be weak candidates in initiating apoptosis, the propofol-OLA conjugates induce a cell signaling pathway, that eventually leads to apoptotic cell death in skin cancer cells. Our preliminary data strongly suggest that the synthesized conjugates possess potent anticancer activity. However, the exact mechanism by which these conjugates modulate the apoptotic pathway in cancer cells

selectively, while sparing the non-malignant cells needs further investigation.

Acknowledgments We are thankful to Prof. M. Saleemuddin, Co-ordinator, Interdisciplinary Biotechnology Unit, Aligarh Muslim University, Aligarh, India for providing the central instrumentation facility to carry out the experiments. We also thank the Sophisticated Analytical Instrumentation Facility (SAIF) of the Central Drug Research Institute, Lucknow, India for providing the NMR and mass spectra facility. The study was conducted with the financial support given to Mr. Azmat Ali Khan by the University Grants Commission (India).

Abstract The objective of this study was to examine the therapeutic effect of osthol, a coumarin compound isolated from the fruit of *Cnidium monnieri* (L.) Cusson, on cardiac hypertrophy in rats and investigate its potential mechanisms. The rats with cardiac hypertrophy induced by renovascular hypertension were given osthol orally by gavage for 4 weeks. The results showed that in the osthol 20 mg/kg group, the blood pressure, heart weight index and myocardial malondialdehyde content were lowered ($p < 0.001$, $p = 0.002$ and $p = 0.025$, respectively), the myocardial superoxide dismutase and glutathione peroxidase contents were increased ($p < 0.001$), and the elevated unesterified fatty acids and triacylglycerols in myocardial tissues were decreased ($p = 0.017$ and $p = 0.004$, respectively). At the same time, the myocardial peroxisome proliferator-activated receptor (PPAR)- α and carnitine palmitoyltransferase (CPT)-1a mRNA expressions were increased and the myocardial diacylglycerol acyltransferase (DGAT) mRNA expression was decreased in the osthol 20 mg/kg group ($p < 0.001$). Osthol treatment was associated with a decreased cross-sectional area of cardiomyocytes ($p < 0.001$). These findings suggest that osthol may exert a therapeutic effect on cardiac hypertrophy in rats, and its mechanisms may be related to the improvement of myocardial oxidative stress and lipid metabolism

via regulation of PPAR α -mediated target gene expressions including an increase in CPT-1a mRNA expression and a decrease in DGAT mRNA expression.

Keywords Osthol · Cardiac hypertrophy · Hypertension · Oxidative stress · Lipid metabolism

Abbreviations

| | |
|--------|---|
| CPT-1a | Carnitine palmitoyltransferase-1a |
| DGAT | Diacylglycerol acyltransferase |
| FFA | Unesterified fatty acids |
| GAPDH | Glyceraldehyde phosphate dehydrogenase |
| GSH-Px | Glutathione peroxidase |
| MDA | Malondialdehyde |
| PPAR | Peroxisome proliferator-activated receptor |
| RT-PCR | Reverse transcription polymerase chain reaction |
| SOD | Superoxide dismutase |
| TAG | Triacylglycerol(s) |

Introduction

Hypertension is now recognized as the most common cause of cardiac hypertrophy. The formation and development of cardiac hypertrophy is not only due to an adaptive response of the heart to pressure overload but also be due to myocardial oxidative stress and energy metabolism imbalance [1–3]. In vivo and in vitro studies indicate an association of myocardial oxidative stress with myocardial remodeling [4–6]. Myocardial energy metabolism gradually switches from fatty acids to glucose utilization during the formation of cardiac hypertrophy [2, 3, 7]. This metabolic shift can be viewed as an adaptive response, because it may decrease

oxygen consumption per mole of ATP generated [8]. However, it finally leads to certain maladaptive features including increased lipid accumulation in the heart due to impaired oxidation of fatty acids.

Osthol is a coumarin compound isolated from the fruit of *Cnidium monnieri* (L.) Cusson (Apiaceae), a traditional Chinese medicine. Recently, numerous studies have revealed that osthol exhibits various pharmacological activities such as anti-inflammation [9], anti-osteoporosis [10], an estrogen-like effect [11], hypoglycemic activity [12], inhibition of hepatic oxidative stress [13] and cellular apoptosis [14], and cardiovascular effects including anti-thrombosis and platelet aggregation [15], a decrease in blood pressure [16] and myocardial fibrosis [17]. It was also reported that osthol might be a dual agonist of peroxisome proliferator-activated receptor (PPAR)- α/γ [12, 18, 19], which are known to regulate the myocardial energy and lipid homeostasis [20]. Moreover, osthol could also regulate the downstream target genes of PPAR α/γ , such as carnitine palmitoyltransferase (CPT)-1a and diacylglycerol acyltransferase (DGAT) [13]. The former is a rate-limiting enzyme mediating the entrance of fatty acids into the mitochondria [21], and the latter is a key enzyme in the process of triacylglycerol (TAG) biosynthesis [22].

From these data, we hypothesized that osthol may reduce the cardiac hypertrophy induced by renovascular hypertension via regulation of PPAR α -mediated target genes involved in lipid metabolism and inhibition of myocardial oxidative stress. In the present study, the antioxidant enzymes superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px), as well as a stable terminal metabolite of lipid peroxidation malondialdehyde (MDA) were used as the indicators of oxidative stress.

Materials and Methods

Drugs and Reagents

Osthol was kindly provided by Dr. Jia Zhou of Xi'an Green Fount Natural Product Co. Ltd. (China), the purity was >98 % as determined by high performance liquid chromatography. The assay kits for SOD, GSH-Px, MDA, unesterified fatty acids (FFA) and TAG were manufactured by Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Trizol was a product of Invitrogen (Carlsbad, CA, USA). Reverse transcriptase, dNTP Mix and Taq DNA Polymerase were products of Fermentas (Vilnius, Lithuania). The primers used for amplification by reverse transcription polymerase chain reaction (RT-PCR) were synthesized by Sangon Gene Company (Shanghai, China).

Animals

Sprague–Dawley rats (male, 250 ± 20 g) used in this study were supplied by the Animal Breeding Center of Soochow University (Suzhou, China). Housing conditions of the animals were maintained at a temperature (22–24 °C) and humidity (55–60 %), with a 12 h light/dark cycle. The experimental rats were allowed free access to food and water. The animal study was approved by the Ethics Committee of Soochow University and conducted in accordance with the regulations for the use and care of experimental animals at Soochow University (number of Ethic Committee: 2010-85). These rats were randomized into 4 groups ($n = 8$): namely, control (surgical intervention but not ligation), model (left renal artery ligation), osthol 10 and 20 mg/kg groups (treatment with osthol 10 and 20 mg/kg after left renal artery ligation).

Preparation of Rat Renovascular Hypertensive Model

The rat renovascular hypertensive model induced by two kidney-one clip method was prepared as previously described [23]. For preparation of the animal model, the rats were anesthetized with sodium pentobarbital (i.p. 50 mg/kg). The incision in the left flank was made above the left kidney. A blunt glass needle was used to divide the left renal artery, and then the left renal artery was clipped together with a silver clip (0.2 mm in diameter), which was then removed to generate the renal arteriostenosis and later hypertension. Rats in the control group underwent the same operation but not clipped. After 4 weeks, medicine-treated rats were given osthol 0.2 ml/100 g/day orally by gavage, and the control and model rats were orally given an equivalent volume of 0.5 % sodium carboxymethyl cellulose solution. Ogawa et al. [16] reported that osthol could decrease blood pressure and improve hepatic lipid metabolism in spontaneously hypertensive rats after administration for 4 weeks. Therefore, all of rats were sacrificed after treatment with osthol for 4 weeks. The blood and heart were collected for measurement of design parameters. The partial left ventricles were taken, put into a freezing tube, then weighed and quickly frozen in liquid nitrogen and stored at -80 °C for RT-PCR. The weight of the partial left ventricles equaled the total weight minus the weight of the empty tube. The rest of the heart was obtained and weighed for measurement of related parameters.

Measurement of Systolic Blood Pressure

The systolic blood pressure of rat tail artery was measured in rats that were awake using the CODA 4 tail-cuff non-invasive blood pressure system (Kent Scientific Corporation, Torrington, USA) and once every 2 weeks after

renovascular ligation. The room temperature of the measurement was kept at about 30 °C. The rats were acclimated to the acrylic holders and tail-cuff apparatus, specifically designed for the non-invasive blood pressure system, for 5 min before each rat measurement. The blood pressure measurements were performed at the same time of day (9:00–13:00) in order to avoid the influence of the circadian cycle, and the blood pressure values were obtained by calculation of the average reading of five measurements.

Measurement of Heart Weight Indexed to Body Weight

The heart was immediately excised and weighed. The absolute heart weight was obtained by the calculation, namely, the weight of partial left ventricles plus the weight of the rest of heart. The heart weight index was calculated according to absolute heart weight (g) divided by body weight (g).

Measurement of Myocardial SOD, GSH-Px, and MDA Levels

The heart was excised and partial right ventricles were rapidly cut into pieces in ice-cold saline, then a tissue homogenate (10 %, W/V) was prepared. The contents of myocardial SOD, GSH-Px, MDA and protein were determined by colorimetric methods, respectively. All procedures completely complied with the manufacturer's instructions.

Measurement of Myocardial FFA and TAG Levels

The partial left ventricles were rapidly cut into pieces, the tissue homogenate (10 %, W/V) was prepared using a chloroform/methanol mixed solution (1:1, V:V) to extract the myocardial lipid, the prepared sample was then

centrifuged at 1,200×g for 10 min, the substratum obtained was used for measurement of FFA and TAG levels according to the colorimetric methods following the manufacturer's instructions.

Morphological Observation

The partial specimens of left ventricles were fixed in 10 % formaldehyde solution, embedded in paraffin, and sectioned on a microtome for hematoxylin–eosin staining, and then examined under a light microscope to evaluate the size of cardiomyocytes. The perimeters of 100 cells from every section were traced and analyzed by the Image J 1.44p software system, which was used to calculate the mean cross-sectional area.

RT-PCR

Total RNA was extracted from frozen rat myocardial tissues using trizol reagent, and RT-PCR was performed according to the manufacturer's instructions. The concentration and purity of the RNA were determined spectrophotometrically by the absorbance ratio 260:280 nm. Then total RNA (5 µg) was used for the RT reaction performed in 40 µl of the final volume at 42 °C for 60 min. The PCR was carried out by the following conditions: one cycle of 94 °C for 3 min, followed by 35 cycles of denaturation at 94 °C for 30 s, annealing (the temperature was seen in Table 1) for 60 s, and extension at 72 °C for 30 s. A final extension was 72 °C for 10 min. The RT-PCR was used for measurement of PPARα, CPT-1a, DGAT, and glyceraldehyde phosphate dehydrogenase (GAPDH) mRNA expressions in rat myocardial tissues. The specific primers used for PCR amplification were seen in Table 1. GAPDH was used as an internal control. Data were expressed as a ratio of the signals of interest mRNA to that of GAPDH mRNA.

Table 1 The specific primers used for PCR amplification to determine the gene expression in rat myocardial tissues

| Gene | Primer sequence | bp | Annealing temperature (°C) |
|-----------|------------------------------|-----|----------------------------|

Statistical Analysis

The data are expressed as means \pm SEM. The *F* test and Kolmogorov–Smirnov test were performed to test for homogeneity of variance and normality of distribution, respectively. The normally distributed variables were analyzed using one-way analysis of variance (ANOVA) followed by a post hoc LSD test. The variables that are not normally distributed and/or displayed homogeneity of variance were analyzed using one-way ANOVA followed by a post hoc Games–Howell test. The statistical analysis was conducted using SPSS 18.0 software. $p < 0.05$ was considered statistically significant.

Results

Effect on Systolic Blood Pressure

The results are shown in Table 2. Compared with the control group, the systolic blood pressure in the model group was higher after the second week subsequent to renovascular ligation and steadily maintained at the high level ($p < 0.001$), suggesting that rat hypertension had developed. The systolic blood pressure was reduced with osthol 20 mg/kg/day treatment at 2 and 4 weeks ($p < 0.001$), and the expected reduction in systolic blood pressure was also observed after treatment with osthol 10 mg/kg/day for 4 weeks ($p = 0.023$).

Effect on Heart Weight Indexed to Body Weight

The results are shown in Table 3. The absolute heart weights and heart weights indexed to body weight in the model group were higher than those in the control group ($p = 0.038$ and $p < 0.001$, respectively). Indexed heart weight was lower in the animals treated for 4 weeks with osthol 20 mg/kg/day compared to the model animals ($p = 0.002$).

Table 3 Changes of absolute heart weight, body weight, and heart weight indexed to body weight after treatment with osthol for 4 weeks in renovascular hypertensive rats

| Group | Absolute heart weight (g) | Body weight (g) | Heart weight indexed to body weight (g/g) |
|-----------------|--------------------------------|-----------------|---|
| Control | 1.290 \pm 0.032 | 444.1 \pm 9.4 | 0.00291 \pm 0.00005 |
| Model | 1.390 \pm 0.029 [#] | 440.1 \pm 5.9 | 0.00318 \pm 0.00004 [#] |
| Osthol 20 mg/kg | 1.332 \pm 0.030 | 450.8 \pm 7.5 | 0.00295 \pm 0.00005* |
| Osthol 10 mg/kg | 1.388 \pm 0.044 | 451.4 \pm 4.8 | 0.00308 \pm 0.00010 |

Data are presented as means \pm SEM; $n = 8$

[#] $p < 0.05$ versus control group

* $p < 0.05$ versus model group

Effect on Myocyte Cross-Sectional Area

The results are presented in Fig. 1. Compared with the control group, the myocyte cross-sectional area in the model group was higher ($p < 0.001$). After treatment with osthol 10 and 20 mg/kg/day for 4 weeks, the myocyte cross-sectional area was lower ($p < 0.001$), showing a cardiomyocyte smaller in size.

Effects on Myocardial SOD, GSH-Px, and MDA Contents

The results shown in Table 4 indicate that in the model group, the myocardial SOD and GSH-Px contents were lowered ($p = 0.002$ and $p = 0.027$, respectively), and the MDA content had increased as compared with the control group ($p = 0.019$). After administration for 4 weeks, the SOD and GSH-Px contents in myocardial tissues were increased in the osthol 10 mg/kg ($p = 0.035$ and $p < 0.001$, respectively) and 20 mg/kg ($p < 0.001$) groups, but the MDA content was only lowered in the osthol 20 mg/kg group ($p = 0.025$).

Table 2 Changes of systolic blood pressure of rat tail artery after renovascular ligation for 8 weeks and later treatment with osthol for 4 weeks in rats (mmHg)

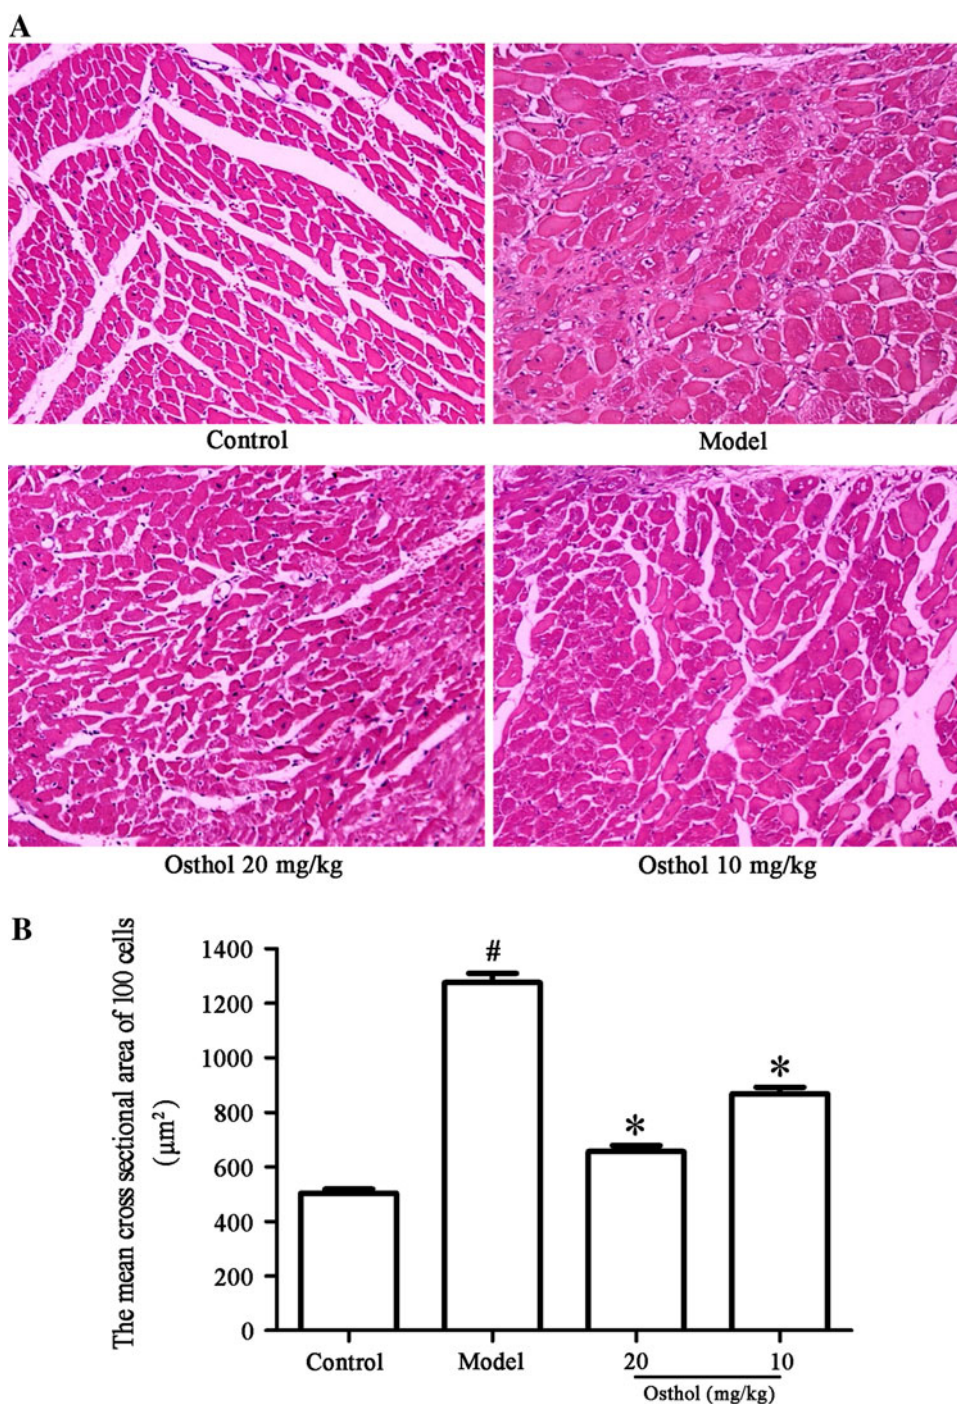

| Group | Pre-treatment with osthol | | | Post-treatment with osthol | |
|-----------------|---------------------------|------------------------------|------------------------------|------------------------------|--------------------------------|
| | 0 | 2nd week | 4th week | 2nd week | 4th week |
| Control | 133.0 \pm 0.6 | 133.9 \pm 1.8 | 125.8 \pm 1.6 | 131.0 \pm 1.7 | 125.2 \pm 1.8 |

Data are presented as means \pm SEM; $n = 8$. $^{\#}p < 0.05$ versus control group; $*p < 0.05$ versus model group

Effects on Myocardial FFA and TAG Levels

The results are presented in Table 5. In the model group, the levels of myocardial FFA and TAG were higher compared with the control group ($p < 0.001$ and $p = 0.008$, respectively). After treatment with osthol for 4 weeks, the elevated FFA and TAG were lowered in the osthol 20 mg/kg group ($p = 0.017$ and $p = 0.004$, respectively), but not affected in the osthol 10 mg/kg group.

Effects on Myocardial PPAR α , CPT-1a, and DGAT mRNA Expressions

As shown in Fig. 2, the myocardial PPAR α and CPT-1a mRNA expressions had been lowered in the model group ($p < 0.001$) and increased in the osthol 10 mg/kg ($p = 0.003$ and $p = 0.012$, respectively) and 20 mg/kg ($p < 0.001$) groups. The myocardial DGAT mRNA expression was increased in the model group compared to

the control group (*p* < 0.001), and decreased in the osthol 20 mg/kg group (*p* < 0.001) and unchanged in the osthol 10 mg/kg group compared to the model group.

Discussion

The two kidney-one clip method is generally acknowledged as a conventional model of hypertension, which may cause an increase in the angiotensin II release via the activation of renin-angiotensin system, and leads to an increase in the blood pressure and oxidative stress, and final cardiac hypertrophy [4, 23, 24]. Our experimental results indicated that in the model group, the blood pressure, heart weight index, myocyte cross-sectional area and myocardial MDA content were increased, the myocardial SOD and GSH-Px contents were decreased, suggesting that the rat cardiac hypertrophy induced by renovascular hypertension had successfully developed, and the animal model might result in myocardial oxidative stress.

Hypertension is generally recognized as a major risk for cardiac hypertrophy. Ogawa et al. [16] observed that osthol could lower the elevated blood pressure in stroke-prone spontaneously hypertensive rats. In the present study, our

**Fig. 2** Effects of osthol on myocardial PPARα, CPT-1a and DGAT mRNA expressions after administration for 4 weeks in renovascular hypertension-induced cardiac hypertrophic rats. Data are presented as means ± SEM; *n* = 5. [#]*p* < 0.05 versus control group; **p* < 0.05 versus model group

experimental results further demonstrated that osthol was effective in lowering blood pressure. The mechanism might be related to its Ca²⁺ channel-blocking property and the elevation of the cGMP level in vascular smooth muscle [25].

Recently, it has been reported that oxidative stress is involved in hypertensive development in the two kidney-one clip animal model [26] and plays a critical role in the progression of cardiac hypertrophy [1, 4, 27–29]. It is known that oxidative stress may lead to the accumulation of the lipid peroxidation product MDA, and cause cellular dysfunction. The antioxidants may play an important role in cellular defense against oxidative stress and it has been proposed that they prevent the development of cardiac hypertrophy [30, 31]. In the present study, the results showed that osthol at 20 mg/kg/day was associated with a reduced MDA content and increased the SOD and GSH-Px contents in the heart, demonstrating an inhibitory effect on the myocardial oxidative stress. The results were in accordance with our previous observation [13], which might be one of mechanisms for the observed antihypertrophic effect.

Under normal physiological condition, the main substrates of myocardial energy metabolism are from fatty acids. Recent studies have shown that the myocardium of cardiac hypertrophy might switch from fatty acids to glucose utilization [2, 3, 7], which results in the decrement of myocardial fatty acid oxidation and the accumulation of fatty acids and TAG in the heart. This conversion may initially be a compensatory mechanism, but the continuous accumulation of fatty acids in the heart may lead to further oxidative stress and severe cardiac hypertrophy [1]. In our present study, the results also showed that the levels of myocardial FFA and TAG were higher in the model group. After treatment with osthol, the elevated lipid levels in myocardium were lower, suggesting that osthol might reduce the cardiac hypertrophy via regulation of myocardial lipid metabolism.

PPAR α plays an important role in regulating lipid metabolic genes including CPT-1a and DGAT [20]. In the present study, we found that after treatment with osthol, the myocardial PPAR α and CPT-1a mRNA expressions were increased, while the myocardial DGAT mRNA expression was decreased, suggesting that osthol might enhance myocardial fatty acid oxidation and suppress myocardial TAG biosynthesis, and that the reduction in myocardial TAG in osthol-treated rats was consistent with reduced DGAT mRNA expression.

In conclusion, our present study demonstrated that osthol is effective at alleviating renovascular hypertension-induced cardiac hypertrophy in rats, and the mechanisms of its effect might be related to the reduction in myocardial oxidative stress and an improvement in myocardial lipid metabolism via regulation of PPAR α -mediated target genes CPT-1a and DGAT. However, there were some deficiencies in the present study. It would be best to investigate the exact effects of osthol on protein expressions of PPAR α , CPT-1a and DGAT. On the other hand, the inflammatory cytokines also participates in the pathogenesis of cardiac hypertrophy [32], thus the therapeutic effect of osthol may be attributed partly to its anti-inflammatory property. Our previous studies have observed that osthol could inhibit myocardial inflammatory factors like nuclear factor- κ B and transforming growth factor β 1 in myocardial fibrotic mice [17]. Therefore, further research is also needed to clarify this.

Abstract Little is known about exogenous inhibitors of low-density lipoprotein (LDL) aggregation. The search for nontoxic and bioavailable inhibitors of LDL aggregation is of interest, especially considering that the suppression of the aggregation of LDL might represent a therapeutic approach. We hypothesized that amphiphilic copolymers of propylene oxide and ethylene oxide, the so-called Pluronic block copolymers, can be used to influence the aggregation of LDL. In this work we used Pluronic® P85, L61 and F68. A comparative study of the effects of Pluronic block copolymers with various hydrophilic–lipophilic properties on the aggregation process of LDL showed that Pluronic copolymers with strong hydrophobic properties (P85 and L61) at concentrations close to or greater than the respective critical concentration of micelle formation inhibited the aggregation process of LDL; however, the “hydrophilic” Pluronic F68 had no effect on the aggregation of

LDL at any concentration. Thus, the study demonstrated for the first time that Pluronic® block copolymers inhibit LDL self-association. The possibility of modulating the aggregation of LDL by various Pluronic copolymers can be regarded as a prerequisite in the creation of new types of anti-atherosclerotic drugs.

Introduction

One of the earliest manifestations of atherosclerosis at the cellular level is the accumulation of lipids, particularly cholesterol esters, in the intima of the arteries [1–4]. The source of the lipids that accumulate in the intima of blood vessels is the low-density lipoproteins (LDL) circulating in the blood [4, 5]. It is known that native LDL circulating in the blood cannot cause lipid accumulation in cultured cells and thus, native LDL are not atherogenic [6–8]. However, modified LDL do become atherogenic [8–11]. In vitro, LDL can be modified by various ways (acetylated, treated with malondialdehyde, vortexed) [8–11].

It is also known that native LDL do not form aggregates and do not possess atherogenic properties, which means LDL do not cause the intracellular accumulation of lipids [12]. Aggregated LDL acquire atherogenic properties as shown in in vitro experiments [10–12]. The binding affinity of LDL (–) to human aortic proteoglycans depends on their aggregation level [13]. It is a general assumption that in vivo, native LDL (which are not modified or aggregated) do not possess atherogenic properties. This explains interest in the search for modulators of the LDL aggregation process.

For this reason, there is heightened interest in the search for modulators of the LDL aggregation process.

There are several known endogenous inhibitors of the aggregation of LDL [10, 14], such as 17 beta-estradiol (E2), a specific ligand to apoB-100, stabilizes apoprotein, and the E2-stabilized LDL is resistant to aggregation [15], lipoprotein-deficient serum, bovine serum albumin (BSA), high-density lipoprotein (HDL) from healthy donors and primary HDL apolipoprotein (ApoA-I). These inhibitors all have amphiphilic properties, and presumably by interacting with hydrophobic regions on the surface of the LDL, these inhibitors prevent an interaction between LDL particles and inhibit aggregation. Little is known about exogenous inhibitors of LDL aggregation. Therefore, the search and studies of nontoxic and bioavailable inhibitors of LDL aggregation are of great interest, especially considering that the suppression of the aggregation of LDL might represent a therapeutic approach.

In this work, we hypothesized that amphiphilic copolymers of propylene oxide (PO) and ethylene oxide (EO), the so-called Pluronic block copolymers, can be used to this end. In this study, we examined the ability of various Pluronic copolymers to influence the aggregation of LDL.

Materials and Methods

We used Pluronic® P85, L61 and F68 (BASF; Wyandotte, MI). The study complied with institutional ethical use protocols. The total LDL fraction was isolated by ultracentrifugation using a two-step density gradient of NaBr from the serum of patients with cardiovascular disease (men aged 40–74 years with early asymptomatic carotid atherosclerosis) [16]. The protein concentration in the LDL samples was determined using the Lowry method.

To study the aggregation of LDL, the suspension was first freed from those in spontaneously formed aggregates by filtering the sample through a filter with a pore diameter of 0.45 µm (Nalgene, USA). LDL at a concentration of 0.5 mg protein/ml were incubated at 37 °C in isotonic phosphate buffer (IFB; GIBCO; Paisley, UK; KCl 0.2 g/l, KH₂PO₄ 0.2 g/l, NaCl 8 g/l, and Na₂HPO₄ 1.15 g/l,

pH 7.2) with constant stirring at 100 rpm. The degree of aggregation of LDL was assessed by recording light transmission fluctuations through a laser light beam at a wavelength of 860 nm using an Aggregometer (Aggregation analyzer; Biola, RF, USA) [17]. The method is based on the fact that the relative dispersion of the optical density fluctuations caused by random changes in the number of particles entering the optical path of the laser beam reflects the deviations from their average size; in other words, the degree of LDL aggregation. At regular intervals, the fluctuation of light transmission was recorded.

The average size of the aggregates formed was estimated by quasi-elastic scattering of the laser on an Autosizer 2 Malvern (Malvern Instruments, UK). For this measurement, samples of LDL at a concentration of 2.5 mg protein/ml were incubated at 37 °C in isotonic phosphate buffer with constant stirring at 1,000 rpm. At regular intervals, the particle size measurement was performed. The addition of EDTA did not affect the association of LDL.

Results

Low-density lipoprotein particles are prone to spontaneous aggregation. The so-called spontaneous aggregation of LDL, which is not induced by external factors, occurs during the incubation of LDL particle suspensions at 37 °C with constant stirring. We used two methods to assess the aggregation of LDL and the influence of Pluronic copolymers on this process, the transmission method and the fluctuations of the quasi-elastic laser scattering method. In all cases, the results obtained using the two methods to evaluate the aggregation of LDL fully coincided. This finding is well illustrated in Figs. 1 and 2.

Fig. 1 Kinetic curves showing changes in the average particle size of LDL under the influence of Pluronic P85. The incubation medium was IFB at pH 7.4, the concentration of LDL was 2.5 mg protein/ml, incubation temperature was 37 °C, and a stirring speed of 1,000 r/min was used. Curve (1), suspension of LDL in the absence of Pluronic P85; curves (2 and 3) in the presence of 0.01 and 0.1 % Pluronic P85, respectively

Fig. 2 Kinetic curves of changes in the fluctuations of light transmission of the suspension under the influence of Pluronic P85. The incubation medium was IFB at pH 7.4, the concentration of LDL was 0.5 mg protein/ml, incubation temperature was 37 °C, and a stirring speed of 100 r/min was used. Curve (1), suspension of LDL in the absence of Pluronic P85; curves (2–4) in the presence of 0.005, 0.1 and 0.01 % Pluronic P85, respectively

We conducted a comparative study of Pluronic block copolymers with various hydrophilic–lipophilic properties on the aggregation process of LDL. For these experiments, we used Pluronic F68, which has a high hydrophilic–lipophilic balance (HLB 29) and pronounced hydrophilic properties, Pluronic L61, which is characterized by a large hydrophobic balance (HLB 3), and Pluronic P85, which has a moderate hydrophilic and lipophilic balance (HLB 16).

Figure 1 shows representative kinetic curves of changes in the average particle size of LDL in the event of spontaneous aggregation and in the presence of Pluronic P85. We observed an increase in the average particle size during spontaneous aggregation that depends on the incubation time (Fig. 1). At the same time, the addition of various concentrations of Pluronic P85 significantly inhibited the formation of LDL aggregates. Therefore, the addition of Pluronic P85 at a concentration of 0.1 % (v/v%) to a suspension of LDL before incubation inhibited the aggregation by 93 % after 4.5 h of incubation (Fig. 1). This suppression effect was dependent on the concentration of Pluronic P85, and when the concentration of Pluronic P85 was used at 0.01 %, aggregation was suppressed by 79 % after 4.5 h of incubation (Fig. 1).

Similar data were obtained in the fluctuations of light transmission. Figure 2 shows typical curves of variation of light transmission fluctuations in the suspension of LDL in the presence of various concentrations of Pluronic copolymers in the incubation medium. As shown in Fig. 2, the lowest concentration of Pluronic P85 (0.005 %) had no effect on the aggregation process of LDL. Thus, it is clear that Pluronic P85 was an inhibitor of the aggregation of LDL only at a concentration close to or greater than

Table 1 Properties of the used pluronics

| Pluronic | Molecular mass (Da) | Critical micelle concentration (%) | Hydrophilic–lipophilic balance |
|----------|---------------------|------------------------------------|--------------------------------|
| L61 | 2,000 | >0.022 | 3 |
| P85 | 4,600 | 0.005–0.05 | 16 |
| F68 | 8,400 | >0.4 | 29 |

the critical concentration of micelle formation (CCM) (Table 1), which is 0.03 % for Pluronic P85.

When Pluronic P85 was added to a suspension of LDL during incubation (when the process of aggregation of the particles had already been initiated), an increase in the average particle size of LDL was inhibited (Fig. 3). Pluronic P85 was added to a suspension of LDL at a concentration of 0.1 % after the first and second hour of incubation. In both cases, no further increase in the average particle size was observed, and aggregation was fully suppressed. It should be noted that the addition of Pluronic P85 did not cause any decrease in the average particle size; therefore, one can assume that the action of Pluronic P85 did not induce disaggregation of the LDL aggregates. Consequently, the aggregation of LDL is irreversible and is likely to merge LDL particles.

In addition to Pluronic P85, we examined the ability of two other Pluronic copolymers to inhibit the aggregation of LDL. It was shown that Pluronic F68, which is characterized by pronounced hydrophilic properties and a high value of HLB, has no influence on the aggregation process of LDL particles. Figure 4 shows representative kinetic curves of changes in light transmission fluctuations in the presence of Pluronic F68 at a concentration of 0.4 % and in the absence of Pluronic copolymers (Fig. 4). In addition, using a higher concentration of Pluronic F68 (4 %) did not

Fig. 3 Kinetic curves of changes in the average particle size of LDL under the influence of Pluronic P85. The incubation medium was IFB at pH 7.4, the concentration of LDL was 2.5 mg protein/ml, incubation temperature was 37 °C, and a stirring speed of 1,000 r/min was used. Curve (1), suspension of LDL in the absence of Pluronic P85; curve (2), in the presence of 0.1 % Pluronic P85 added after 2 h of incubation; and curve (3), in the presence of 0.1 % Pluronic P85 added after 1 h of incubation

Fig. 4 Kinetic curves of changes in the fluctuations of light transmission of the suspension of LDL under the influence of Pluronic F68. The incubation medium was IFB at pH 7.4, the concentration of LDL was 0.5 mg protein/ml, incubation temperature was 37 °C, and a stirring speed of 100 r/min was used. Curve (1), suspension of LDL in the absence of Pluronic F68; and curve (2), in the presence of 0.4 % Pluronic F68

Fig. 5 Kinetic curves of changes in the fluctuations of light transmission of the suspension of LDL under the influence of Pluronic L61. The incubation medium was IFB at pH 7.4, the concentration of LDL was 0.5 mg protein/ml, the incubation temperature was 37 °C, and a stirring speed of 100 r/min was used. Curve (1), suspension of LDL in the absence of Pluronic L61; and curve (2) in the presence of 0.022 % Pluronic L61

lead to inhibition of the aggregation process of LDL (data not shown). However, the application of Pluronic L61, which has pronounced hydrophobic properties and a low HLB value, led to the suppression of the aggregation of LDL. Thus, at a concentration of 0.022 %, Pluronic L61 inhibited the growth of fluctuations in the transmittance of the suspension of LDL after 2 h of incubation at 78 % (Fig. 5). Using a higher concentration of Pluronic L61, 0.22 %, led to an almost complete suppression of LDL aggregation, and the use of a lower concentration, 0.0022 %, had no effect on the aggregation of LDL particles (data not shown). Therefore, Pluronic copolymers with strong hydrophobic properties (P85 and L61) at concentrations close to or greater than the respective CCM

inhibited the aggregation process of LDL; however, the “hydrophilic” Pluronic F68 had no effect on the aggregation of LDL at any concentration.

Discussion

Aggregation of LDL particles can be expressed as a reversible aggregation of particles and as the irreversible fusion of modified LDL particles. The mechanism of LDL particle aggregation is still not completely understood. There is evidence that modifications of LDL change the hydrophilic surface layers of the particles, thereby disturbing their hydrate-solvate shell and leading to increased hydrophobicity of the particles, resulting in the loss of stability in solution [10, 14]. Therefore, it is assumed that the aggregation of LDL particles is due to hydrophobic interactions of modified LDL particles. A number of more recent studies dealing with LDL aggregation have reported findings important for the further understanding of the mechanisms of LDL aggregation. In particular, studies by Parassasi et al. [18], Bancells et al. [13, 19, 20], Greco et al. [21], Llorente-Cortes et al. [22, 23], Oörni et al. [24], Plihtari et al. [25], Lahdesmaki et al. [26] have contributed to enhancing the knowledge on different aspects of the molecular mechanisms involved in LDL aggregation and on the role that LDL aggregation plays in atherosclerosis.

We studied the effect of Pluronic copolymers on the LDL aggregation process. Pluronic copolymers consist of a lipophilic part, which is formed by PO, and a hydrophilic part, which is built with EO, and these copolymers have the following structure: $(EO)_N-(PO)_M-(EO)_N$. This structure defines the basic properties of the Pluronic copolymer, including the ability to interact with biological membranes and induce structural changes [27]. Important characteristics of Pluronic copolymers are the CCM above which the assembly of individual copolymers into micelles occurs and the HLB, which reflects the ratio of hydrophilic and hydrophobic substances. Currently, there are many different Pluronic copolymers that differ in the number of monomers of EO and PO and are characterized by different hydrophilic and lipophilic properties, molecular weight and PFC [28]. Thus, the polymers that are characterized by a significant number of PO molecules and a small number of EO molecules are highly lipophilic and have a relatively low CCM and HLB, such as Pluronic L61. In contrast, Pluronic copolymers with large number of EO are dominated by hydrophilic interactions and are characterized by high CCM values and HLB, such as Pluronic F68. Lastly, there is a group of Pluronic copolymers with intermediate properties, such as P85.

We investigated the ability of Pluronic P85, L61 and F68 with different CCM and HLB characteristics

(Table 1). Our results suggest that the ability of amphiphilic copolymers of propylene oxide and ethylene oxide to inhibit the aggregation of LDL is directly dependent on the degree of hydrophobicity in the Pluronic copolymer. Pluronic copolymers with severe and moderate hydrophobic properties, such as L61 and P85, can significantly inhibit the aggregation of LDL; however, this happens only at concentrations close to the CCM. In this study, we conclude that it is the micellar form of Pluronic copolymers that are capable of inhibiting LDL particle aggregation, and Pluronic individual molecules inhibitory properties do not possess this property. These data support the hypothesis first made by Khoo and coworkers [10] on the role of hydrophobic interactions in the aggregation of LDL. Presumably, during incubation with constant mixing, conformational changes in the structure of LDL occur and lead to exposure of hydrophobic sites on the surface of the particles. Therefore, this change begins an interaction of hydrophobic regions between different particles and leads to the aggregation of LDL. When amphiphilic substances are present in a suspension of LDL, the lipophilic part of the amphiphilic molecules can interact with the hydrophobic domains on the LDL particle surface, which prevents the aggregation process of LDL.

Taking into account the importance of the aggregation of LDL in the pathogenesis of atherosclerosis [9–11], the possibility of suppressing LDL aggregation with Pluronic copolymers can stimulate the development of new approaches in therapy and prevention of atherosclerosis. In addition, actively investigating the possibility of using Pluronic copolymers as carriers of drugs in cases with low bioavailability is another potential role for Pluronic copolymers. For example, in the treatment of multi-drug resistant tumors [29], Pluronic micelles with a medicine show a much higher cytotoxicity toward cancer cells than do the drug without the addition of the Pluronic micelles. Pluronic P85 is also used when the penetration of drugs across the blood–brain barrier is necessary [30].

Various Pluronic copolymers have long been used as “carriers” of drugs, which promote the transport of drugs in an unchanged form; however, their role is much more significant. We studied the mechanisms of action of Pluronic copolymers on multi-drug resistant cells. It was shown that the Pluronic copolymers can reduce the microviscosity of the cell membrane, significantly increase ATP levels in cancer and adjacent cells, and reduce the efflux of drugs among other roles [31]. Furthermore, Pluronic copolymers exhibit diverse biological activities, including the ability to affect lipid metabolism. Therefore, when Pluronic L81 inhibited the assembly and secretion of chylomicrons, it helped to reduce LDL cholesterol and lipoproteins in very low-density lipoproteins (VLDL) and prevented the development of diet-induced

hypercholesterolemia and atherosclerosis in rats [16]. However, it has been reported that Pluronic P-407 causes hyperlipidemia in mice [32].

Obviously, before any Pluronic block copolymer can be considered as an anti-atherosclerotic agent, it would be necessary to investigate whether the association of this Pluronic copolymer to LDL (assuming that it is irreversibly bound) would not interfere with normal LDL metabolism.

Conclusion

This research work demonstrates, for the first time, that Pluronic® block copolymers inhibit LDL self-association. Obviously, further studies are needed in order to examine the applicability of the finding for atherosclerosis therapeutic intervention. The possibility of modulating the aggregation of LDL by various Pluronic copolymers can be regarded as a prerequisite in the creation of new types of anti-atherosclerotic drugs.

Abstract The chemical characterization of the free fatty acid (FFA) fractions of the cuticular lipids of *Calliphora vicina* larvae and pupae was performed by separating the FFA fraction using high-performance liquid chromatography with laser light scattering detection (HPLC–LLSD) and quantitatively analyzing the FFA using gas chromatography–electron impact mass spectrometry (GC–MS). Thirty-two saturated and unsaturated FFA were identified and quantified in the insect lipids. Cuticular FFA profiles of *C. vicina* larvae and pupae were compared. Cuticular FFA of larvae and pupae accounted for 70.8 and 77.8 % of the total lipids, respectively. The cuticular lipids of *C. vicina* larvae contained 24 FFA ranging from 8:0 to 24:0, whereas the cuticular lipids of pupae contained 32 FFA ranging from 6:0 to 26:0. The cuticular lipids of the larvae contained 16 saturated, five monounsaturated, one diunsaturated, and two polyunsaturated FFA. The cuticular lipids of the pupae contained 18 saturated, nine monounsaturated, two diunsaturated, and three polyunsaturated FFA. The major cuticular FFA in *C. vicina* larvae and pupae was 18:1 (47.6 and 41.7 %, respectively). The highest amounts of total cuticular FFA were detected in larvae of *C. vicina* (1.7 mg/g of the insect body). The quantities of total cuticular FFA in pupae were smaller (1.4 mg/g of the insect body).

Introduction

The cuticular lipids constitute the initial passive barrier to desiccation [1] as well as to fungal and bacterial infection [2], and they may reduce the penetration of toxins and chemicals [3]. Cuticular lipids are also involved in various types of chemical communication [4]. For example, insects use components of the surface lipids as contact pheromones when they encounter each other. The cuticular lipids in pheromones are hydrocarbons, short-chain unsaturated aldehydes, ketones, fatty acids, and acetate esters of short-chain unsaturated alcohols.

The insects belonging to the Calliphoridae, Sarcophagidae, and Muscidae families often colonize a human corpse [5], and are often very important elements in forensic investigation. For example, *Calliphora vicina* is considered as a synanthropic species and larvae of this species are used in criminal investigations to determine the post-mortem interval (PMI), i.e., the time from death to discovery of the corpse.

In view of the great importance of *C. vicina*, it was decided to identify and assign the components of the free fatty acid (FFA) mixtures found on the surface layers of the

cuticle in larvae and pupae. Susceptibility or resistance of various insect species to fungal infection may be caused by several factors. The most important of them are differences in the structure and composition of the exoskeleton. The exudation of ammonia and allantoin is very significant in cleansing the insects' microhabitat. The bacteriostatic effects of the heat generated by accumulations of actively feeding larvae, the presence of antifungal compounds in the cuticle, especially FFA [6], as well as the cellular and humoral defense reactions of insect are also important [7, 8]. Susceptibility to penetration by fungal pathogen depends on mechanical barriers which either prevent or reduce infection and chemical barriers which inhibit or kill the pathogen. For example, FFA possess the ability to kill or inhibit the growth of fungi and bacteria [6, 9–13]. The antibacterial and antifungal effects of FFA are frequently observed during bioassay of extracts from a variety of organisms [13–15]. The activity of each FFA is influenced by its structure, especially the length of the carbon chain and the presence, number, orientation, and position of double bonds, and the presence the hydroxyl group is important for the antibacterial activity of FFA [16]. Unsaturated FFA are more active than saturated FFA with the same carbon chain length [16, 17] and unsaturated FFA are more active against Gram-positive bacteria than Gram-negative [18]. Additionally, FFA with the double bonds in the *cis* orientation have greater antibacterial activity than FFA with double bonds in the *trans* orientation [10, 12].

The most popular techniques used for the identification and quantification of cuticular lipids are TLC [19], column chromatography [20], HPLC/LLSD [21], GC–FID [22], GC–MS–TIC [23, 24], GC–MS–SIM [25], and MALDI [26]. For analysis, relatively volatile compounds solid-phase microextraction (SPME) [27, 28] or solid injection (SI) [29] coupled to the GC or GC–MS are often used [30].

This paper describes the qualitative and quantitative comparisons of cuticular and internal FFA profiles of larvae and pupae. These results provide baseline data for further studies on the possible role of FFA in the resistance to microbial attack. The lipids of flies were separated into classes of compounds using high-performance liquid chromatography with laser light scattering detector (HPLC–LLSD). Qualitative and quantitative analyses were done by gas chromatography combined with mass spectrometry (GC–MS).

Methods and Material

Insects

A total of 140 larvae and 302 pupae of *C. vicina* were obtained from the Institute of Parasitology, Polish

Academy of Sciences in Warsaw (Poland). The insects, raised from eggs laid on beef by adult flies, were reared at 28 °C with 70 % relative humidity and a 12:12 h photoperiod. Maternal generation was maintained in the same conditions. For experiments, 1-day-old larvae and freshly emerged pupae were used. All insects were quickly frozen and kept at –20 °C until being used.

Extraction of Lipids

The cuticular and internal lipids were extracted by methods described previously [24]. All larvae and pupae were first extracted separately by stirring in 20 ml of petroleum ether for 10 s (extracts 1L and 1P). All primarily extracted larvae and pupae were separately extracted for a second time in 20 ml of dichloromethane for 1 min (extracts 2L and 2P). Finally, the insects were extracted with 50 ml dichloromethane for 10 days (extracts 3L and 3P). The obtained extract was filtered (0.45 µm) and collected into a glass vial. A 1-ml aliquot of this extract was further taken and placed into a tared glass flask, and then evaporated under nitrogen in order to determine the dry mass of extracted lipids. For example, extracts 1L and 2L contained cuticular lipids, and extract 3L contained internal lipids of larvae.

High-Performance Liquid Chromatography with Laser Light Scattering Detector

The lipids were separated by methods described previously [31]. All lipid extracts (larvae and pupae) were separated using HPLC–LLSD. Separation in the normal phase (five replicates) was performed on a silica gel column (Econosil Silica 5 Micron, Alltech, 25 cm × 4.6 mm i.d.). Binary gradient elution with eluent A (hexane) and eluent B (15 % of acetone in dichloromethane) was applied with a linear gradient from A to B within 35 min. Total flow was maintained at 0.8 ml/min. The FFA fractions obtained by HPLC were silylated with 100 µl of a mixture of 99 % bis(trimethylsilyl)acetamide and 1 % chlorotrimethylsilane (Sigma Aldrich) for 1 h at 100 °C and then analyzed by GC–MS.

Gas Chromatography Mass Spectrometry

GC–MS analysis of each FFA fraction was performed with a Finnigan Mat SSQ 710 mass spectrometer coupled to a Hewlett–Packard 5890 gas chromatograph. Compounds were separated on a 30 m × 0.25 mm i.d., film thickness 0.25 µm, HP-5 capillary column. Helium was used as the carrier gas at a flow rate of 1 ml/min. The injector temperature was 320 °C and the column oven temperature cycle was 60 °C for 10 min, then 60–320 °C at 4 °C/min; the final temperature was then held for 20 min. Electron-impact

ionization (electron energy 70 eV, ion source temperature 200 °C) was used.

In order to quantitatively determine each of the analyzed FFA, GC–MS analysis was performed with an internal standard (19-methylarachidonic acid). The contents of the compounds in the analyzed samples were calculated from the chromatogram peak areas. The results were expressed as mean \pm standard deviation of three GC–MS analyses.

Results

Total Lipids and Free Fatty Acids

The total quantity of cuticular and internal lipids larvae was 20.4 and 461.8 mg, which comprised 0.2 and 5.4 % of the total fresh weight of the biological material, respectively (Table 1). The percentage content of cuticular and internal lipids in pupae was similar. The total quantity of cuticular and internal lipids of pupae was 30.0 and 514.9 mg, which comprised less than 0.2 and 3.1 % of the total fresh weight of the biological material, respectively (Table 1). Cuticular FFA of larvae and pupae accounted for 70.8 and 77.8 % of the total lipids, respectively, whereas internal FFA of larvae and pupae made up 5.2 and 21.3 % of the total lipids, respectively.

Free fatty acid fractions obtained as a result of the HPLC–LLSD separations were then subjected to further GC–MS analysis. GC–MS in total ion current (TIC) mode was used to identify unknown components, and single ion monitoring mode (SIM) to verify recognized molecular ions. FFA in the cuticular and internal lipids of *C. vicina* larvae and pupae were identified on the basis of the characteristic ions: 73, 128, 132, 145, $M-15^+$, and M^+ (molecular ion).

The amount of cuticular FFA isolated from larvae was 1.7 mg/g. The results obtained from pupae were similar: 1.4 mg/g of the insect body. The total mass of internal FFA

was greater in pupae (6.6 mg/g). This last quantity is about twice the average in larvae (2.8 mg/g).

Cuticular Free Fatty Acids in Larvae

Cuticular lipids of larvae contained 24 FFA ranging from 8:0 to 24:0 (Table 2). Among cuticular FFA of larvae, 15 saturated, seven unsaturated with even-numbered, and two unsaturated with odd-numbered carbon chains FFA were present. The major FFA in *C. vicina* larvae were 18:1n-9 (47.6 %), 16:1n-9 (20.0 %), 16:0 (19.4 %), and 18:0 (9.4 %). FFA occurring in smaller quantities (from greater than 0.1 to 1 %) were 12:0 (0.4 %), 14:1n-9 (0.6 %), 14:0 (0.3 %), 17:1n-10 (0.8 %), 17:0 (0.6 %), and 18:2n-6 (0.9 %). The cuticular lipids also contained 14 FFA present in concentrations from traces to less than 0.1 %.

Cuticular Free Fatty Acids in Pupae

Table 2 lists the FFA contents calculated per gram of pupae body. Among 32 cuticular FFA of pupae, 18:1n-9 (41.7 %), 16:0 (19.3 %), 16:1n-9 (16.4 %), 18:0 (8.6 %), and 18:2n-6 (6.9 %) were the most abundant compounds. One fatty acid is present in a smaller amount (14:0, 2.4 %). Other FFA were detected in very small and comparable amounts from 0.7 % (26:1) to less than 0.1 % (e.g., 6:0). Cuticular lipids of pupae contained 18 saturated FFA, among which seven fatty acids are odd-numbered, and also 14 unsaturated FFA, among which three fatty acids are odd-numbered.

Comparison of Free Fatty Acids Composition of Cuticular Lipids of *C. vicina* Larvae and Pupae

The presence of six FFA with 20 carbon atoms in the chain, namely, 20:0, 20:1n-6, 20:2n-6, 20:3n-6, 20:4n-3, and 20:5n-3, in the cuticular lipids of pupae is very interesting. On the other hand, only four FFA with 20 carbon atoms in the chain were present in the cuticular lipids of larvae.

The following free acids present in the cuticular lipids of pupae were absent from the cuticular lipids of larvae: 6:0, 7:0, 19:1n-10, 20:3n-6, 20:2n-6, 22:1n-9, 26:1n-9, and 26:0. The percentage contents of cuticular 14:0 and 18:2n-6 in pupae were significantly higher than those of cuticular lipids in larvae and compromised 2.4 vis 0.3 % and 6.9 vis 0.9 %, respectively.

In cuticular lipids of larvae, the relative content of 16:1n-9 was higher than the relative content of 16:0. On other hand, in cuticular lipids of pupae, the relative content of 16:1n-6 was lower than the relative content of 16:0.

Internal Free Fatty Acids in Larvae

Internal lipids of larvae *C. vicina* contained 26 FFA ranging from 6:0 to 22:0 (Table 2). In the internal lipids 15

Cuticular FFA, sum of FFA content in petroleum extract (1L and 1P) and dichloromethane extract (2L and 2P). Internal FFA, dichloromethane extract (3L and 3P). Data are presented as the mean \pm standard deviation of three separate analyses performed on different samples

saturated, six monounsaturated, one diunsaturated, and four polyunsaturated FFA have been identified. Only three acids are present in high concentrations (more than 10 %): 16:0 (13.6 %), 16:1n-9 (23.2 %), and 18:1n-9 (53.6 %). Other acids amounted to from less than 0.1 to 6.8 %. Among saturated acids, the following are the most abundant: 16:0 (13.6 %), 14:0 (6.8 %), and 18:0 (1.6 %). Among unsaturated acids, the following are the most abundant: 18:1n-9 (53.6 %), 16:1n-9 (23.2 %), and 17:1n-10 (2.3 %). Internal lipids of larvae contained six FFA with 20 carbon atoms in

the chain: 20:0, 20:1n-6, 20:2n-6, 20:3n-6, 20:4n-3, and 20:5n-3.

Internal Free Fatty Acids in Pupae

Internal lipids of pupae *C. vicina* contained 20 FFA ranging from 7:0 to 26:0 (Table 2). FFA occurring in the highest quantities were 16:1n-9 (18.2 %), 16:0 (24.2 %), and 18:1n-9 (40.9 %). Except for 16:1n-9 and 18:1n-9, which occurred in large amounts, the following unsaturated FFA

are present in smaller quantities: 14:1n-9 (1.0 %), 17:1n-10 (1.4 %), 20:5n-3 (0.2 %), and 20:4n-3 (0.2 %). Among saturated free acids, only C16:0 is present in large amount (24.2 %). Four saturated FFA are present from 2.1 % (17:0) to 5.2 % (14:0). Other saturated FFA occur in smaller quantities.

Comparison of Free Fatty Acids Composition of Internal Lipids of *C. vicina* Larvae and Pupae

The following acids present in the larvae lipids were absent in the pupae lipids: 6:0, 11:0, 19:1n-10, 19:0, 20:3n-6, 20:2n-6, 20:1n-6, and 20:0. On the other hand, only 13:0, 24:0, and 26:0 were absent from the internal lipids of larvae *C. vicina*.

In the internal lipids of larvae, the relative content of 16:1n-9 was higher than the relative content of 16:0. However, in the internal lipids of pupae, the relative content of 16:1n-6 was lower than that of 16:0. The same situation is observed in cuticular lipids of larvae and pupae.

Internal lipids of larvae contained six FFA with 20 carbon atoms in the chain but internal lipids of pupae contained only two of those compounds (20:4n-3 and 20:5n-3).

The percentage contents of internal 15:0 and 18:0 in pupae were significantly higher than those of internal lipids in larvae and compromised 5.2 vis 0.7 % and 4.8 vis 1.6 %, respectively.

Discussion

The major components of the cuticular lipid coating of insects are often hydrocarbons, such as *n*-alkanes, monomethylalkanes, dimethylalkanes, and alkenes [32], FFA [31], alcohols [33], aldehydes [34], wax esters [35], fatty acid methyl esters [32], and acylglycerols [36].

In our work, we stated that cuticular lipids of *C. vicina* larvae contained FFA from 8:0 to 24:0 and pupae from 6:0 to 26:0. Table 3 lists the FFA identified in insect cuticular lipids. For example, in the cuticular lipids the following FFA were identified: from 10:0 to 22:1 in *Locusta migratoria migratoriodes* adult [37], from 10:0 to 20:1 in *Schistocerca gregaria* adult [37], from 14:0 to 18:1 in *Frankliniella occidentalis* larvae [32], from 16:0 to 18:3 in *Acanthoscelides obtectus* female [21], and from 16:0 to 36:0 in *Apis mellifera* [38].

In our study, the major cuticular FFA were: 16:1n-9, 16:0, 18:2n-6, 18:1n-9 and 18:0 in pupae and 16:1n-9, 16:0, 18:1n-9 and 18:0 in larvae.

In the other insects species, the major FFA were 14:0 (40 %) in *Acyrtosiphon pisum* [42], 16:0 (25 %) in *L. migratoria migratoriodes* adult, (64 %) in *S. gregaria*

adult, (63 %) in *F. occidentalis* larvae, (36 %) in *Fannia canicularis* adult [40], (38 and 30 %) in *Attagenus megatoma* 6.8- and 32-week-old larvae, respectively [43], 18:0 (58 %) in *A. megatoma* adult [41], (33 %) in *Lasioderma serricornis* larvae [44], (40 %) in *Dendrolimus pini* larvae [6], (49–52 %) in *Galleria mellonella* larvae [6] and (51 %) in *A. obtectus* female [21], 18:3 (28 %) in *Melanoplus sanguinipes* and *M. packardii* adult [36], 24:0 (29 %) in *A. mellifera* [38], and 28:0 (34 %) in *D. pini* exuviae [31]. On the basis of these results, we stated that two major FFA (16:0 and 18:1) were present in many insect species. Other major FFA are atypical (14:0, 24:0, and 24:0). In our study, the major compound in cuticular lipids of larvae and pupae, i.e., 18:1n-9, is typical.

Saturated, unsaturated, and even-numbered FFA ranging from 12 to 20 are typically found in many insect species [30, 33, 45], whereas the presence of FFA ranging from 5 to 11 and from 21 to 26 are unusual. In particular odd-numbered FFA and polyunsaturated FFA such as 15:1n-10, 17:1n-10, 20:5n-3, and 20:4n-3 identified in lipids of *C. vicina* are unusual. Only typical cuticular FFA ranging from 12:0 to 20:0 are present in cuticular lipids of larvae *F. occidentalis* [32], adult *F. canicularis* [40], *L. bostrychophila* [34], and female *A. obtectus* [21].

In our study, the FFA (in the range from 5:0 to 11:0) 8:0, 9:0, 10:0, and 11:0 in larvae and additionally 6:0 and 7:0 in pupae were identified in the cuticular lipids. Similar cuticular lipids ranging from 5:0 to 11:0 were identified in the lipids of *D. pini* exuviae [31], *L. migratoria migratoriodes* adult, *S. gregaria* adult [39], and *A. pisum* [42]. The numbers of fatty acids in this range are not large: one compound in the cuticular lipids of *L. migratoria migratoriodes*, *S. gregaria*, and *A. pisum* and four FFA in *D. pini* exuviae.

Cuticular lipids of *C. vicina* larvae and pupae contained several odd-numbered FFA. Among this group the following acids are present: 9:0, 11:0, 13:0, 15:0, 17:0, and 19:0 in larvae and pupae and additionally 7:0 in pupae. All of these FFA are minor constituents. Those compounds were identified in the cuticular lipids of some insects. For example, 9:0, 11:0, 21:0, 15:0, 17:0, 19:0, and from 23:0 to 33:0 were present in *D. pini* exuviae [31]. The 15:0, 17:0, and 19:0 entities were identified in *S. gregaria* adult [39] and 15:0 and 17:0 were present in the cuticular lipids of *L. migratoria migratoriodes* adult [39].

Among odd-numbered and unsaturated acids only 15:1n-10 and 17:1n-10 in larvae and 15:1n-10, 17:1n-10, and 19:1n-10 in pupae of *C. vicina* are present in small amounts. These FFA (17:1 and 19:1) were also identified in cuticular lipids of *S. gregaria* adult [39]. Moreover, the presence of polyunsaturated and odd-numbered fatty acid (21:3) in cuticular lipids of *L. migratoria migratoriodes* was detected. However, its biological function needs additional research.

Free fatty acids with molecular weight from 20:0 to 26:0 (only even-numbered) are present in cuticular lipids of *C. vicina* larvae and pupae, but all of these compounds are minor constituents: in larvae from traces to 0.1 % and in pupae from less than 0.1 to 0.7 %. Cuticular FFA in range from 20:0 to 26:0 were detected in the cuticular lipids of *M. sanguinipes* adult [36], *G. mellonella* larvae [6], and *S. gregaria* adult [39]. Eight FFA even-numbered and ranging from 22:0 to 36:0 were present in cuticular lipids of *A. mellifera* [38] and three FFA ranging from 22:0 to 26:0 were identified in cuticular lipids of *A. megatoma* 6.8- and 32-week-old larvae [43] and also two compounds are present in *A. megatoma* larvae [41] and *L. serricorne* larvae [44].

In our previous work [6] it was shown that the cuticular fatty acid profiles of *C. vicina* larvae (last-instar wandering larvae) differ from the profile of *C. vicina* larvae analyzed here. The major difference was the content of 18:1n-9 and 18:2n-6 in the cuticle. In our previous work, the relative content of 18:1 and 18:2 was 23.2 and 24.0 %, respectively, whereas in the present work, the relative content of 18:1n-9 and 18:2n-6 was 47.6 and 0.9 %, respectively. The concentrations of FFA of last-instar wandering larvae were circa eight times higher than those of the final instar larvae. Changes in the composition of cuticular lipids during development have been studied in only a few insects. For example, total cuticular lipid of *A. megatoma* increased from 4.1 to 13.7 µg/larvae for the 6.8- and 32-week-old larvae, respectively [43]. The amount of 16:0 and 18:0 decreased while 18:1 increased in the older *A. megatoma* larvae. The presence of 18:2 and 20:0 in 32-week-old larvae of *A. megatoma* is interesting, whereas these compounds were absent in the 6.8-week-old larvae. Additionally, the FFA profile in the adult insects is different: 18:3, 22:0, 24:0, and 26:0 were not found in the adult insects whereas they were present in both groups of larvae. A similar change in composition was also found during development of the *G. mellonella* larvae. The fatty acid profile in the VIIth larval instar of *G. mellonella* from 0–2 h to 8 days after molting is different [6]. In this case, the concentrations of 16:0, 18:0, 18:1, and 18:2 in the extracts of this larvae were found to increase significantly during this period. Evidently, the lipid composition is determined by sex, developmental stage, and age [43]. Moreover, the lipid composition depends on the living conditions, i.e., temperature, dryness, and available food [46, 47]. In this study, the number of FFA identified by GC–MS analysis of cuticular extracts of *C. vicina* larvae is higher than that reported in our previous work on this fly species. Besides changes in the composition of cuticular lipids during development, this observation may be consistent with the fact that in the present study we used more a sensitive mass spectrometer with lower limits of

detection and quantification. Both results (present and earlier) showed the similar qualitative fatty composition, although data were obtained using different extraction methods and GC–MS equipments.

Free fatty acids present in the cuticular surface of insect larvae and pupae could be inhibitory to germination and growth of conidia and penetration of the integument by entomopathogenic fungi. In our previous work [37] fungistatic effects of 16:0, 16:1, 18:0, 18:1, 18:2, 18:3, 20:0, and 20:1 were shown. The cuticular lipids of larvae and pupae *C. vicina* contained FFA in this range, with the exception of 18:3. Also medium- and short-chain fatty acids which are present in cuticular lipids of larvae and pupae of *C. vicina* were demonstrated to present toxicity to filamentous fungi, including some that had been isolated specifically from insect cuticle [48, 49]. FFA might be engaged in protecting larvae from fungal pathogens, whereas the presence of, for example, 15:0 stimulated *C. coronatus* growth [37]. The determination of the cuticular fatty acid profiles and information on which particular fatty acids support the fungal assault and which contribute to insect resistance to entomopathogenic fungi is of great importance and requires a better understanding of the physiological aspects of fungal growth and virulence factors.

In conclusion, the conducted analyses exposed qualitative and quantitative differences in FFA chemical composition of the examined developmental stages. The major differences are cuticular lipids of pupae contained 6:0, 7:0, 19:1n-10, 20:3n-6, 20:2n-6, 22:1n-9, 26:1n-9, and 26:0, which were not found in larvae; In the cuticular lipids of larvae, the relative content of 16:1n-9 was higher than the relative content of 16:0. On other hand, in cuticular lipids of pupae, the relative content of 16:1n-9 was lower than that of 16:0.

Differences in FFA chemical composition of larvae and pupae may be responsible for susceptibility or resistance to fungal infection. Experiments which are currently ongoing in our laboratories will show which of the identified compounds possess antimicrobial activity. Hopefully the results described here revealing the chemical composition of fatty acids of *C. vicina* will be an important contribution to further studies of the taxonomy and physiology of insects.

Acknowledgments I would like to thank Prof. Mieczysława I. Boguś for providing the insects to analyze. I would like to express my gratitude to Anna Grubba for her assistance. Financial support was provided by the Polish Ministry of Research and Higher Education for 2010–2013 (grant N N303 504238) and the University of Gdansk (grant DS 8110-4-0085-1).

Abstract Our understanding of HDL metabolism would be enhanced by the measurement of the kinetics of pre β HDL, the nascent form of HDL, since elevated levels have been reported in patients with coronary artery disease. Stable isotope methodology is an established technique that has enabled the determination of the kinetics (production and catabolism) of total HDL apoA-I in vivo. The development of separation procedures to obtain a pre β HDL fraction, the isotopic enrichment of which could then be measured, would enable further understanding of the pathways in vivo for determining the fate of pre β HDL and the formation of α HDL. A method was developed and optimised to separate and measure pre β HDL and α HDL apoA-I enrichment. Agarose gel electrophoresis was first used to separate lipoprotein subclasses, and then a 4–10 % discontinuous SDS-PAGE used to isolate apoA-I. Measures of pre β HDL enrichment in six healthy subjects were undertaken following an infusion of L-[1- 13 C-leucine]. After isolation of pre β and α HDL, the isotopic enrichment of apoA-I for each fraction was measured by gas chromatography–mass spectrometry. Pre β HDL apoA-I enrichment

was measured with a CV of 0.51 % and α HDL apoA-I with a CV of 0.34 %. The fractional catabolic rate (FCR) of pre β HDL apoA-I was significantly higher than the FCR of α HDL apoA-I ($p < 0.005$). This methodology can be used to selectively isolate pre β and α HDL apoA-I for the measurement of apoA-I isotopic enrichment for kinetics studies of HDL subclass metabolism in a research setting.

Introduction

High-density lipoproteins (HDL) are heterogeneous particles, varying in shape, size, density and composition [1]. The main apolipoproteins of human HDL are apoA-I and apoA-II, which comprise 70 and 20 % of total HDL proteins, respectively. The mature forms of HDL are spherical, while nascent HDL, which is a minor component of total HDL, is discoidal [2]. Discoidal HDL is converted into the spherical form by lecithin-cholesterol acyltransferase (LCAT).

The heterogeneity of HDL extends to variations in surface charge resulting in differences in electrophoretic mobility. When separated by agarose gel electrophoresis, HDL has either prealpha (pre α), alpha (α), prebeta (pre β) or gamma (γ) migration [3]. The α -migrating HDL particles comprise the major proportion of HDL in plasma and exist as mature, spherical forms which include the HDL₂ and HDL₃ subfractions [1]. Pre β HDL comprises of one or two molecules of apoA-I combined with phospholipids and unesterified cholesterol and includes not only nascent HDL but also recycled lipid-poor apoA-I from the remnants of large HDL particles [2, 4].

Increasing the total level of HDL is regarded as a potential therapeutic target to prevent coronary artery disease (CAD). However, the failed trial of the cholesterol ester transfer protein (CETP) inhibitor torcetrapib challenged the concept that higher HDL cholesterol (HDL-C) would necessarily result in low heart disease risk [5]. Therefore, being able to understand the kinetics of HDL subclasses is essential to understanding their metabolism, as the biological functionality of individual HDL subclasses may be the key determinant of their cardiovascular protective properties. The heterogeneous characteristics of HDL and the bidirectional inter-conversion between HDL subclasses make its metabolism complicated. There is, therefore, an increased interest in measuring the kinetics of individual HDL subfractions. There is evidence that HDL subclass distribution changes in pathological conditions such as type 2 diabetes, dyslipidemia and CAD [6–8]. Previous studies indicate that pre β HDL increases dramatically in patients with CAD, hypertriglyceridemia and hypercholesterolemia [6, 9, 10]. Cheung et al. [7] have shown that the abnormal distribution of HDL subclasses is more strongly associated with the risk of CAD than a low level of HDL-C.

Stable isotope methodology is an established technique that enables determination of the kinetics of HDL apoA-I in vivo [11]. Our understanding of HDL metabolism would be considerably enhanced by the measurement of the discrete HDL subclass kinetics and in particular the kinetics of pre β HDL. Ultracentrifugation is a robust and effective

method for the separation of lipoproteins and has been used to determine the kinetics of HDL apoA-I [12]. However, a combination of high salt concentrations and high centrifugal forces may damage the integrity of certain HDL subpopulations and lead to the dissociation of apoA-I from HDL [13, 14]. Pre β HDL, therefore, cannot be recovered in the density range of $1.063 < d < 1.21$ g/ml, but is present in the density range of $d > 1.21$ g/ml [15]. Furthermore, apoA-I at a density higher than 1.21 g/ml may not only originate from pre β HDL in the plasma but may also include that disassociated from mature α HDL during ultracentrifugation, causing inaccuracies in the interpretation of kinetic data if all apoA-I at this density is assumed to be pre β HDL. Ultracentrifugation cannot, therefore, be used to isolate pre β HDL. Thus, it is necessary to develop an alternative method that avoids disturbing HDL subpopulation integrity and also avoids contamination of the pre β HDL subclass so that an accurate determination of pre β HDL apoA-I kinetics can be obtained. Therefore, in this article, we have described a procedure which can be used to isolate individual HDL subclasses and thereby improve specificity for the determination of HDL apoA-I kinetics. Our methodology utilises an initial agarose separation followed by SDS-PAGE to enable the isolation of apoA-I from the separated pre β HDL and α HDL particles. This process enables the measurement of individual enrichment levels of apoA-I in each of the subpopulations. This is likely to be an important area of research given the progress in clinical studies on HDL-based interventions, where manipulating HDL levels are seen as a target for reducing the risk of atherosclerosis.

Materials and Methods

Materials were from Sigma-Aldrich, Gillingham, Dorset, UK, Fisher Scientific UK, Loughborough, Leicestershire, UK, and Bio-Rad Laboratories, Richmond, CA, USA, unless otherwise stated.

Clinical Protocol

The study protocol was approved by the West Kent Local Research Ethics Committee and the University of Surrey Ethics Committee. All the subjects gave written informed consent. Six healthy subjects (4 females and 2 males) were recruited for this study. Following an overnight fast, a primed (1 mg/kg) constant (1 mg/kg/h) infusion of L-[1-¹³C] leucine (15 mg/ml, ¹³C enrichment 99 %; Cambridge Isotopes, MA, USA) was administered intravenously for 9 h using an IVAC 560 pump (IVAC, Hampshire, UK). Blood samples were taken at baseline and

every hour for 9 h. Samples for α -ketoisocaproate (α -KIC) were taken at 0, 4, 6, 7, 8 and 9 h.

Blood for pre β HDL and α HDL separation and plasma apoA-I concentration was collected in tubes containing EDTA at a final concentration of 0.1 %. Blood samples for α -KIC enrichment were collected in tubes containing lithium heparin. Plasma was separated from red blood cells at 2,500 rpm for 10 min at 4 °C by centrifugation (Sorvall legend RT centrifuge; Thermo Fisher Scientific, Waltham, MA, USA). Plasma samples for α HDL and pre β HDL separation, lipid profiles, apoA-I concentration and α -KIC enrichment were stored at -80 °C. It has previously been shown that there is no significant difference in the percent distribution of pre β HDL and α HDL between fresh plasma and plasma stored at -80 °C for up to 1 year [5]. In the current study, the separation of α HDL and pre β HDL by agarose gel electrophoresis was completed within 2 weeks of each metabolic study.

Isolation of pre β HDL and α HDL by Agarose Gel Electrophoresis

To separate α HDL and pre β HDL, 160 μ l plasma diluted with sample buffer (4:1 v:v, 50 % glycerol, 125 mM Tris, 125 mM tricine, 0.005 % bromophenol blue, pH 8.6) was loaded onto a 0.6 % agarose gel (low electroendosmosis agarose with a high gelling temperature; Fluka, Buchs, Switzerland) prepared with 25 mM, pH 8.6 Tris-tricine buffer (Tricine from Acros Organics, Geel, Belgium). Agarose gel electrophoresis used a flat-bed gel cassette with water cooling system placed on ice, (CHU20 max-cooled horizontal gel unit; Sie-plas, Southam, Warwickshire, UK), run at 25 mM, pH 8.6 Tris-tricine buffer at 170 V for 3 h. Samples were loaded on alternate lanes to avoid contamination between samples.

The agarose gel was stained with 0.05 % coomassie blue R250 (BDH, Corston, Bath, UK) prepared in methanol acetic acid solution (methanol:H₂O:acetic acid, 9:9:1, by vol) and stained for 3–4 h or until the bands were well developed. Excess dye was then removed by destaining with the same methanol acetic acid solution.

Extraction and Delipidation of Proteins from pre β HDL and α HDL

After destaining the agarose gel, individual α HDL and pre β HDL bands were excised and freeze-dried (ModulyoD Freeze Dryer; Thermo Fisher Scientific) overnight. Proteins were extracted from α HDL and pre β HDL bands with 3 ml of 1 % SDS solution for four and three times, respectively, at room temperature and then concentrated by freeze-drying. To precipitate and purify the HDL proteins from SDS, coomassie blue R250 and lipid, 4 ml ice-cold ethanol was

added to precipitate proteins on ice for 1 h. The samples were then centrifuged at 4,000 rpm for 1 h at 1 °C and the supernatant discarded. The remaining lipid in the samples was removed by adding 4 ml ice-cold diethyl ether and the samples again centrifuged as described above.

Isolation of apoA-I from pre β HDL and α HDL by SDS-PAGE

After delipidation, α HDL and pre β HDL samples were dissolved in 70 μ l sample buffer (0.15 M sodium phosphate, 12.5 % glycerol, 2 % SDS, 5 % β -mercaptoethanol, 0.001 % bromophenol blue, pH 6.8). ApoA-I was isolated by 4–10 % discontinuous SDS-PAGE (40 % polyacrylamide/Bis, 37.5:1) run with Tris–glycine buffer (0.25 M glycine, 25 mM Tris-base, 0.1 % SDS, w/v, pH 8.5) in a PROTEAN II gel Cell (Bio-Rad Laboratories) at 80 V for 16 h. Samples were loaded on alternate lanes to avoid contamination between samples. A low pH tris base-SDS buffer system (0.25 M Tris base, 0.2 % SDS, w/v, pH 6.8) was used for the 4 % stacking gel and a high pH tris base-SDS buffer system (0.75 M Tris base, 0.2 % SDS, w/v, pH 8.8) for the 10 % resolving gel. SDS-PAGE was stained using a silver staining kit following the manufacturer's protocol. The apoA-I bands were then excised from the gel and hydrolysed in 1 ml 6 M HCl at 120 °C for 24 h. The hydrolysed samples were purified by ion exchange chromatography (Polypropylene columns from Evergreen Scientific, CA, USA; AG50W-X8 cation exchange resin 100–200 mesh; BioRad Laboratories). Pre β HDL apoA-I has a low concentration in plasma. This makes background noise significant when isotopic enrichment is determined by a sensitive GC–MS method. A previous study has indicated that contamination can originate from reagents, gels and glassware [16]. All methodological steps— isolation by SDS-PAGE, hydrolysis, amino acid purification with ion exchange chromatography and derivatisation for GC–MS—have the potential to introduce contamination and their contribution to this effect was investigated. The largest source of contamination was found to be associated with the PAGE gel itself. The process of silver staining did not introduce any leucine contaminants. Pilot studies had shown that leucine contamination from fragments of gel was proportional to the extracted gel size. The samples processed in this study were all obtained from a single 1 cm² gel sample which was excised using a plastic corer thereby ensuring consistency in gel size extraction. Contamination experiments showed that reducing gel areas to 1 cm² areas and maximising sample volume by using 160 μ l plasma for each sample accounted for contamination levels of no more 1.6 % of the peak responses for pre β HDL. In each study, enrichment at each time point was

corrected for baseline enrichment which would correct for any contamination from the gel.

Derivatization of Amino Acids for GC–MS

After purification by ion exchange chromatography, apoA-I hydrolysed samples were freeze-dried and then derivatised with 100 μ l TFA/TFAA (1:1, by vol; Fluka) at 110 °C for 5 min. Toluene (0.5 ml) and H₂O (1 ml) were added and after vortexing, samples were centrifuged briefly and the top layer containing the derivatised amino acids in toluene transferred into GC vials. Isotopic enrichment of ¹³C leucine was analysed by GC–MS (7890A GC system, Agilent 5975 inert XL MSD; Agilent Technologies, Wokingham, Berkshire, UK) in negative chemical ionisation mode with methane as the reagent gas, monitoring ions m/z 209 (m) and 210 ($m + 1$). The GC was equipped with a Rtx-5, 30 m, 0.25 mm inner diameter (ID), 0.25 μ m film capillary column (Thames Restek, Bucks, UK) using helium as the carrier gas at a flow rate of 1 ml/min.

Determination of Plasma α -KIC Isotopic Enrichment

Isotopic enrichment of α -KIC was determined by a modified method of Ford et al. [17] with selected ion monitoring of fragments at m/z 259 (m) and 260 ($m + 1$) in electron ionisation mode by GC–MS equipped with same column as described above.

Measurement of apoA-I Concentration

Plasma apoA-I concentration was measured by an immunoturbidimetric method using an ABX Mira Plus (Horiba ABX, Northampton, UK). ApoA-I concentration from pre β HDL and α HDL was measured by western blotting. After agarose gel electrophoresis, the pre β HDL and α HDL bands were transferred to a 0.2- μ m nitrocellulose membrane (Amersham Pharmacia Biotech, Bucks, UK) and run overnight at 30 V in a glycine-tris (25 mM tris-base, 200 mM glycine pH 8.3) running buffer [18]. The membrane was incubated with a specific primary antibody (1:10,000, goat polyclonal to human apoA-I; Abcam, Cambridge, UK) and then incubated with secondary antibody [1:2,500, donkey polyclonal to goat IgG-H&L; Abcam] linked with the enzyme alkaline phosphatase (AP). ApoA-I was immuno-localised by staining the membrane with AP Conjugate Substrate Kit. The relative apoA-I ratio of pre β HDL and α HDL was calculated after scanning the western blotting membrane by a densitometer (GS800; Bio-Rad Laboratories). The concentrations of pre β HDL and α HDL apoA-I were then calculated from the total plasma apoA-I concentration. The CV for pre β HDL apoA-I

α HDL apoA-I concentration measured with this method was 2.3 and 0.27 %, respectively ($n = 3$).

Measurement of Lipid Concentration

Plasma and HDL TAG and cholesterol were measured using an ABX Mira Plus analyser using TAG and cholesterol assay kits (Horiba ABX).

Data Analysis

The atom percent excess (APE) of ¹³C-leucine and ¹³C α -KIC was calculated from the peak area ratio corrected for the baseline. It has recently been shown that APE rather than the tracer:tracee ratio is the correct method for expressing enrichment when calculating lipoprotein fluxes [19].

$$\text{APE (\%)} = [(R_t - R_0)/(R_t - R_0 + 1)] \times 100$$

where R_t and R_0 are the isotopic area ratios of ($m + 1$)/ m (210/209 for leucine, 260/259 for α -KIC) for the sample at time t and baseline sample at time zero, respectively. The fractional secretion rate (FSR) of HDL apoA-I in each subclass was calculated using linear regression as used previously for the measurement of total HDL apoA-I kinetics [20].

$$\text{FSR (pools/day)} = (\text{Slope of the apoA-I APE time curve} / \text{KIC}_{\text{APE}}) \times 24$$

where plasma α -ketoisocaproate enrichment (KIC_{APE}) is a measure of hepatic intracellular leucine enrichment [17]. In a steady state, the FSR is equal to fractional catabolic rate (FCR). The production rate (PR) was calculated from the product of the FSR and the pool size. ApoA-I pool size was calculated by the concentration of apoA-I of each subclass multiplied by plasma volume. Plasma volume was calculated as described by Pearson et al. [21].

Statistical Analysis

Results are presented as mean \pm SEM. Statistical differences in HDL subclass variables were analysed by paired two-tailed t test using the software SPSS 16.0 (SPSS, USA). In all the comparisons, $P < 0.05$ was considered statistically significant.

Results and Discussion

Development of Electrophoresis Methodology

A modified 2-dimensional electrophoresis (2-DE) method was used to separate α HDL and pre β HDL apoA-I directly

Fig. 1 **a** Plasma separation on agarose gel with coomassie blue staining. **b** ApoA-I separated by 4–10 % discontinuous SDS-PAGE with silver staining. **c** Western blot of SDS-PAGE

from plasma. This method of separation is based on both surface charge and molecular weight. The method avoided the use of ultracentrifugation to prevent possible structural and compositional changes of HDL. The protocol combines a non-denatured first-dimensional agarose gel step which separates lipoprotein particles on the basis of surface charge with a denatured second-dimensional SDS-PAGE separation. This separates proteins based on molecular weight. With this method, a relatively large plasma sample (160 μ l) was loaded onto an agarose gel (Fig. 1a). Purified apoA-I has pre β -migrating mobility and was used to identify the position of pre β HDL [22]. Albumin has α -migrating mobility and was used to identify the position of α -migrating HDL. After separation of pre β HDL and α HDL by agarose gel electrophoresis, individual bands of pre β HDL and α HDL were excised. The effects of high plasma TAG on agarose gel electrophoresis and potential contamination from non-HDL apoA-I containing particles such as from VLDL pre β apoAI were not investigated in this study. However, precipitation of apoB containing lipoproteins by magnesium chloride/heparin [23] as a process to avoid any confounding effects could be developed. This could prevent plasma samples with broad β -mobility from interfering with the pre β band and could also eliminate any potential contamination from VLDL pre β apoA-I.

Efficient extraction of the proteins in these bands was necessary before loading onto SDS-PAGE. A 1 % SDS solution was found to be an effective method for the extraction of proteins from the agarose gel bands. The effectiveness of a freeze-drying step prior to the SDS extraction procedure was also investigated. Results indicated that freeze-drying the bands improved the SDS extraction procedure. The sample volumes used for the extraction of apo A-I were approximately 10 and 12 ml for pre β HDL and α HDL, respectively. It was necessary to reduce these sample volumes and remove the SDS as well as any lipids and Coomassie blue before reconstitution in sample buffer. This was achieved by an ethanol precipitation to remove the SDS and Coomassie blue, followed by a diethyl ether extraction to remove any remaining lipids. This process allowed the isolation of apoA-I from both α HDL and pre β HDL for SDS-PAGE (Fig. 1b). When developing the method, the migrating position of apoA-I was confirmed by western blotting (Fig. 1c).

Optimising pre β HDL Concentration for GC–MS

The average peak area of α HDL was 28 times higher than that of pre β HDL. The relatively smaller peak areas of pre β HDL made it difficult to measure the ^{13}C -leucine isotopic enrichment accurately. To overcome this issue, the

derivatised samples of pre β HDL were adjusted to provide similar areas for both fractions.

To test the precision of the measurement of the isotopic enrichment of pre β HDL and α HDL apoA-I by GC-MS, pre β HDL and α HDL were isolated from six identical plasma samples (taken 9 h after the ^{13}C leucine infusion) using 2-DE. Pre β HDL and α HDL apoA-I isotopic enrichment had a CV of 0.51 and 0.34 %, respectively.

Pre β HDL and α HDL apoA-I Concentration Measured by Western Blotting

It is technically difficult to independently measure pre β HDL and α HDL apoA-I concentration directly from plasma, and, therefore, concentrations were estimated using the relative ratio of pre β HDL and α HDL apoA-I as detected by western blotting. Pre β HDL apoA-I, as a percentage of total apoA-I was 10.1 ± 0.35 % while α HDL was 89.9 ± 0.35 %. This is similar to a previous study which reported that pre β HDL and α HDL were 10.6 and 89.7 %, respectively, of total apoA-I in healthy subjects [8]. Pre β HDL apoA-I concentration was significantly lower than α HDL apoA-I concentration (0.15 ± 0.13 and 1.18 ± 0.083 mg/ml, respectively, $p = 0.005$).

Pre β HDL and α HDL apoA-I Kinetics

The possibility of using this two-dimensional electrophoresis method to measure the kinetics of apoA-I in α HDL and pre β HDL following isotopic labelling with ^{13}C leucine was explored in six healthy volunteers. The subject characteristics are shown in Table 1. All subjects with the exception of one had normal lipid levels. Pre β HDL apoA-I enrichment increased more rapidly than α HDL apoA-I enrichment and the FCR of pre β HDL apoA-I (0.20 ± 0.017 pools/day) was significantly higher than the FCR of α HDL apoA-I

Fig. 2 Enrichment (APE) of pre β HDL apoA-I (open circle) and α HDL apoA-I (open triangle). Results are presented as mean \pm SEM ($n = 6$)

(0.17 ± 0.016 pools/day, $p < 0.005$) (Fig. 2). Pre β HDL and α HDL kinetics have only been previously measured by one research group after separation by gel filtration fast protein liquid chromatography (FPLC) [24]. Both studies utilised a continuous infusion of stable isotopically labelled leucine to determine kinetics of pre β and α HDL in six healthy individuals. Individuals from both studies had similar plasma α HDL apoA-I and pre β -HDL concentrations and were fairly well matched, although the previous study infused [$5,5,5\text{-}^3\text{H}_3$] labelled leucine over a longer period of 14 h in males only. The current study infused 1- ^{13}C leucine for 9 h and also included two women. Pre-menopausal women generally have higher levels of HDL-C than age-matched men [25]. Pre β HDL apoA-I FCR in the current study ($0.124\text{--}0.237$ pools/day) was slightly lower than that measured by FPLC ($0.142\text{--}0.367$ pools/day), while α HDL apoA-I FCR in the current study ($0.107\text{--}0.209$ pools/day) was slightly higher than that measured by FPLC ($0.076\text{--}0.148$ pools/day) [24]. Differences in these results may have also been due to the type of kinetic analysis used; the previous study utilised a multicompartmental analysis,

Table 1 Subject characteristics ($n = 6$)

| | 1 | 2 | 3 | 4 | 5 | 6 | Mean \pm SEM |
|--------------------------------|-------|--------|-------|-------|-------|--------|-------------------|

and also had a longer clinical protocol. However, of importance is that the current study avoids the possibility of any overlap between subclasses which could occur when separating whole plasma α and pre β HDL with FPLC. Even though the previous study demonstrated the purity of apoA-I in pre β and α HDL populations as isolated by FPLC, the authors acknowledged that, in order to analyse pure subclasses, 10 FPLC fractions containing both pre β and α HDL had to be omitted [24].

The PR of pre β HDL apoA I (1.03 ± 0.06 mg/kg/day) was lower than the PR of α HDL (6.73 ± 0.4 mg/kg/day, $P < 0.001$). This was unexpected since pre β HDL is considered to be the precursor pool for α HDL. However, pre β HDL is a mixture of nascent HDL, recycled lipid-poor apoA-I and remnants of large HDL particles [2, 4]. Thus, the nascent HDL apoA-I enrichment, the precursor of α HDL, could be diluted by the recycling of apoA-I. An explanation for recycling of apoA-I possibly leading to a lower production rate could be related to the activity of plasma factors such as enzymes and receptors associated with the dissociation of apoA-I from more mature HDL. Pre β HDL can be subdivided into pre β 1 and pre β 2 fractions. These particles have been shown to have different sizes and may represent particles which are metabolised differently. In this context, the metabolism of pre β 1 has been more extensively investigated [26]. The isolation of pre β HDL fractions using two-dimensional separation techniques, also utilising sequential agarose and PAGE techniques, has been previously described [27]. These authors utilised pulse chase labelling techniques to show the preferential incorporation of labelled cholesterol from cultured fibroblasts into different pre β HDL particles which had been isolated from human blood. These particles (Pre β 1 and pre β 2) also showed differences in the rate of accumulation of enriched cholesterol. A similar approach could be incorporated with the kinetic study described here, measuring both labelled apoA-I and cholesterol fluxes to further elucidate the kinetics of the different HDL subpopulations, providing a more complete description of particles kinetics in relation to providing an explanation for the lower production rate of pre β HDL particles.

This protocol was adopted since it could be conducted in 1 day, and the primary aim was to generate samples for the development of a robust working method for the separation of apoA-I whose enrichment could be measured. ApoA-I has a relatively slow turnover rate with a mean residence time of approximately 5 days [28], so a much longer study needs to be undertaken with blood sampling over 1–2 weeks in order to develop a suitable model of HDL subclass kinetics [29]. This would only be possible using an intravenous bolus of isotopically labelled leucine rather than an infusion and would provide more information about the inter-conversion between HDL subclasses. Future

studies could also involve the separation of distinct pre β subclasses and could describe the kinetics of these particles utilising multicompartmental analysis. Multi-compartmental analysis is the most appropriate form of modelling to use, as it can provide data related to the recycling of the tracer which cannot be obtained by linear regression [30]. The use of multicompartmental techniques would enable the determination of the contribution of the recycling of unlabelled apoA-I from larger particles in addition to the production rate of nascent pre β HDL. The paper describes the use of a two-dimensional electrophoresis method for the complete separation of pre β HDL and α HDL apoA-I, which can be used to measure pre β HDL and α HDL apoA-I enrichment after isotopic labelling of apoA-I in human kinetic studies. Further studies need to be undertaken to develop a suitable clinical protocol which, when combined with this preparative methodology, can provide a robust measure of HDL subclass kinetics in a research setting.

Abstract Docosahexanoic acid (DHA) and eicosapentaenoic acid (EPA) have been shown to possess anti-carcinogenic properties in mammary cancers, both in vitro and in vivo. The objective of this study was to investigate the effect of treating three different breast cancer cell lines with DHA or EPA on cellular growth, chemotherapy efficacy, and CD95 expression and localization in the cell. MDA-MB-231, MCF-7 and SKBr-3 cells were incubated with EPA or DHA with or without chemotherapy agents [doxorubicin (dox), Herceptin]. Cell growth was assessed by WST-1 assay and CD95 expression was investigated using flow cytometry, Western blotting and confocal microscopy. DHA and EPA inhibited the growth of all three breast cancer cell lines in a dose-dependent fashion ($P < 0.05$). DHA, and to a lesser extent EPA, induced the movement and raft clustering of CD95 in the cell membrane (via confocal microscopy) and the surface expression (via flow cytometry) in MDA-MB-231 cells. Neither fatty acid altered the growth/metabolic activity of the non-transformed MCF-12A breast cell line. Pre-treatment with DHA, but not EPA, improved the efficacy of dox in estrogen receptor negative MDA-MB-231 cells ($P < 0.05$), but not in the other two cell lines. Pre-treating cells with DHA increased CD95 surface expression (threefold) and the plasma membrane raft content of CD95 (2fold) and FADD (>4-fold) after dox treatment, compared to dox treatment alone ($P < 0.05$). This study demonstrated that pre-treatment of estrogen receptor negative MDA-MB-231 cells with DHA increased the anti-cancer effects of dox and

presents evidence to suggest that this may be mediated in part by CD95-induced apoptosis.

Introduction

The long chain polyunsaturated fatty acids (PUFA) n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA) have been shown to exert a number of beneficial biological properties, including anti-cancer effects [1–4]. Our group and others have demonstrated that DHA and EPA decrease the in vitro growth of breast cancer cells, including estrogen receptor (ER)-negative [4–9] and ER-positive [10–14] cell lines. Considerable research exists demonstrating that oral intake of EPA and DHA inhibits the growth of mammary tumors in animal models [3, 9]. While it is recognized that n-3 PUFA alter tumor growth in cell and animal models, current

understanding of the cellular mechanisms is incomplete. Several candidate mechanisms have been proposed for the action of n-3 PUFA on breast cancer cells, including alterations in membrane structure and composition, as well as changes in membrane-mediated functions and signals (e.g., lipid rafts, lipid second messengers, signaling proteins, downstream transcription factors, and lipid peroxides) [9]. The cell membrane is a dynamic, asymmetric, heterogeneous structure containing lipid rafts. These microdomains are enriched in saturated fatty acids, sphingolipids, cholesterol and glycosylphosphatidylinositol-linked proteins [15, 16]. Rafts also contain an abundance of signaling proteins [17], suggesting a role in signal transduction, possibly by facilitating the interaction of signaling molecules with their corresponding receptors [18]. EPA and DHA are known to be readily incorporated into tumor cell membranes when provided in the diet or in cell culture media [2, 19–21] and to alter lipid raft organization [22]. Studies from our laboratory show that EPA and DHA are also incorporated into lipid rafts of MDA-MB-231 [5] and MCF-7 (unpublished data) breast cancer cells in vitro, and this is associated with reduced raft epidermal growth factor receptor expression in MDA-MB-231 cells [5].

There is evidence that suggests that long chain n-3 PUFA may also augment chemotherapy treatment of breast cancer. For example, breast cancer patients with a higher concentration of DHA in breast adipose tissue respond more favorably to chemotherapy than those with lower adipose DHA [23]. A recent open-label, single-arm, phase II study demonstrated that a daily intake of 1.8 g of DHA during anthracycline-based chemotherapy in breast cancer patients resulted in the longest overall survival for patients with the highest plasma DHA [24]. Correspondingly, there are in vitro and rodent-model studies indicating that n-3 PUFA sensitize breast cancer cells to the effects of chemotherapy (reviewed in [9, 25]).

A detailed understanding of the cellular processes responsible for the effects of DHA and EPA, not only on cell growth, but also on the action of chemotherapy drugs is lacking. We previously demonstrated that n-3 PUFA induced cell death through an apoptotic mechanism, the initiation of which is unknown [4]. The transmembrane death receptor CD95 (APO-1/Fas) is the best characterized member of the death receptors that activate the extrinsic apoptosis pathway [26]. Activation results in CD95 aggregation in the plasma membrane, followed closely by recruitment of Fas-associated death domain-containing protein (FADD) and caspase-8 to the CD95 receptor, forming the death-inducing signaling complex (DISC) [27]. Treatment of tumor cells with doxorubicin (dox), a widely used antineoplastic drug therapy, has been shown to induce apoptosis and the movement of DISC to membrane rafts [28, 29]. Given the ability of DHA and EPA to alter

lipid raft structure and function, we hypothesized that EPA and/or DHA may initiate cell-death by altering lipid raft-CD95 co-localization.

To increase the understanding of the mechanisms of action of n-3 PUFA on breast cancer cells, this study aimed to determine the impact on cell growth of treating three human cancer cell lines in vitro with DHA or EPA with and without dox and to identify the impact on the cellular content and location of the CD95 death receptor.

Materials and Methods

Cell Culture

Cell lines were obtained from the American Type Culture Collection (Rockville, MD). MDA-MB-231 cells were maintained in Iscove's modified Dulbecco's medium, MCF-7 cells in minimum essential medium, MCF-12A in Dulbecco's modified Eagle medium with 20 ng/ml epidermal growth factor, 100 ng/ml 1 cholera toxin, 10 µg/ml insulin and 500 ng/ml hydrocortisone, and SKBr-3 cells in McCoy's 5A medium. All media were supplemented with penicillin and streptomycin, and 5 % v/v fetal calf serum (all media components from Gibco Invitrogen Corporation, Burlington, ON, Canada). Cells were grown at 37 °C in 5 % CO₂ at 98 % relative humidity. Cells were seeded at 1×10^6 cells per flask (75 cm²) in 15 ml of medium and allowed 48 h to adhere prior to the application of experimental conditions. For WST-1 viability experiments cells were seeded in 96-well plates, and for immunofluorescence experiments cells were grown on coverslips in 12-well plates. All experiments were initiated at 75–80 % confluence of cells.

Conjugated Fatty Acids

Fatty acids were purchased from NuChek Prep Inc. (Elysian, MN). Fatty acids were conjugated to bovine serum albumin (BSA, Sigma Aldrich) as follows: fatty acids were solubilized in ethanol, dried under nitrogen gas and resuspended in 1 ml potassium hydroxide (0.1 M and incubated and 50 °C for 10 min). BSA was added drop-wise (9 ml, 7.5 %) and incubated overnight at 4 °C. Solutions were filtered through a 0.22 µm syringe filter and stored at –20 °C.

Control Conditions and Experimental Design

A series of preliminary experiments comparing the fatty acid profiles of human breast tissue to that of cultured cell lines indicated that the fatty acids supplied in the culture media described above were not sufficient to optimize cell growth and the supply of n-6 fatty acids (data not shown). To ameliorate this deficiency we supplemented all

conditions with 40 μM oleic acid (OLA) and 40 μM linoleic acid (LNA); this was considered the control condition (rather than plain culture media). Neither of these fatty acids exerts cytotoxic effects at those concentrations or even tenfold higher concentrations (data not shown). After 48 h of incubation in fatty acid-free medium, the culture medium was replaced with 15 ml of fresh medium containing the experimental fatty acids (on a background of 40 μM OLA/40 μM LNA) and the cells were further incubated for 48 h (treatments were reapplied after 24 h). For chemotherapy and other subsequent experiments, EPA and DHA concentrations were selected to yield approximately equivalent effects on cell death among differing cell lines. For chemotherapy experiments, after this initial 48 h fatty-acid pre-treatment, the fatty acids were removed and chemotherapy agents, specific for the cell lines, were added for 24 h. To choose concentrations of chemotherapy agents, preliminary experiments were conducted to yield equivalent cell death (approximately 20 %) in each of the studied cell lines in response to chemotherapy at 24 h (data not shown; 1.5×10^{-6} M dox for MCF-7, 4.1×10^{-7} M for MDA-MB-231, and 11 $\mu\text{g}/\text{ml}$ of HerceptinTM for the dox-resistant HER2/c-erb-2 over-expressing SKBr-3 cell line). Cells were then harvested using trypsin-ethylenetriaminetetraacetic acid (Gibco Invitrogen Corporation, Burlington, ON).

Assessment of Cell Growth via Cellular Viability

Cellular viability was assessed using the cell proliferation reagent, WST-1 (Roche Applied Science, Laval, PQ), according to manufacturer's instructions. Previous studies with the MTT assay confirmed that incubation with DHA and EPA reduced cell numbers [5]. Preliminary studies were conducted to confirm that reduction in WST-1 activity after incubation with DHA or EPA was consistent with a reduced number of MCF-7 or MDA-MB-231 cells. To confirm that viability was due to a decrease in cell numbers, cell counts were performed ($n = 3$) for EPA at 100 μM and DHA at 60 μM for 48 h and compared to 100 μM OLA for both the MCF-7 and MDA-MB-231 cells.

Immunofluorescence and Confocal Microscopy

Cells were seeded (5×10^5 cells/well) onto sterile coverslips in 12-well culture plates and incubated until 80 % confluence was reached. Fatty acid and chemotherapy treatment was carried out as described above. Cells were fixed in 4 % paraformaldehyde, and after 1 h of blocking with 1 % BSA in PBS, were incubated with the monoclonal antibodies anti-CD95 (Abcam, San Francisco, CA, USA) and Alexafluor 555-conjugated cholera toxin subunit

B (CTxB) (Invitrogen, Burlington, ON, Canada) for 1 h at room temperature. After washing with PBS, Alexafluor 488-conjugated goat anti-mouse secondary antibody was added. Nuclei were stained with 4',6'-diamidino-2-phenylindole (DAPI). Coverslips were inverted onto microscope slides, in mounting medium Fluorsave. Slides were examined with a Zeiss Axiovert 100 M confocal microscope coupled with a Zeiss LSM510 laser scanning system (Germany). Images were taken with a $63\times$ Plan-apochromat n.a. 1.4 with a zoom factor of 2. Alexafluor 488 was scanned with an argon laser (excitation wavelength, 488 nm; emission wavelength, 505 nm), and Alexafluor 555-labeled CTxB with a HeNe laser (excitation wavelength 543 nm, emission wavelength 560 nm). For DAPI staining, a Coherent Mira 2-Photon laser tuned at 780 nm was used, and emission was collected with a BP 390–465 IR. Confocal reflectance images were obtained by reflecting excitation wavelengths to a confocal detector.

Lipid Raft Isolation

Lipid rafts were isolated as previously described [5]. The sucrose gradient(s) containing rafts were identified by measuring raft markers Gzi (using anti-Gzi antibody, Oncogene Research Products, CedarLane Laboratories) by Western blotting, as previously described [5].

Western Blotting

Whole cell and lipid raft protein lysates were prepared from cells as previously described [4]. Protein content was determined by bicinchoninic acid protein assay (Sigma). Equal amounts of protein (60 μg) from each treatment were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis as previously described [4, 5]. Precision Plus ProteinTM All blue (BioRad Laboratories Ltd., Mississauga, ON, Canada) molecular weight standards were used to monitor protein separation. Ponceau S staining was used to confirm transfer and even protein loading. Anti-Gz (i) (Cell Signaling Technology, New England Biolabs, ON, Canada) was used to identify rafts. Membranes were blocked for 1 h at room temperature in Tris-buffered saline plus Tween-20 (TBST: 0.01 M Tris-HCl pH 6.8, 0.15 M NaCl, 0.1 % v/v Tween-20) and 5 % w/v powdered milk. After rinsing with TBST, membranes were incubated overnight at 4 °C with anti-CD95 or anti-FADD (Abcam) or anti-glyceraldehyde-3-phosphate dehydrogenase (Cell Signaling Technology, Danvers MA) as a loading control, diluted 1:10,000 in TBST containing 5 % BSA. A 1:2,500 dilution of the secondary antibody, horseradish peroxidase-conjugated donkey anti-rabbit IgG (Jackson ImmunoResearch Labs, Cedarlane Laboratories), or goat anti-mouse IgG (Invitrogen, Burlington, ON, Canada) in TBST and 5 %

w/v powdered milk was incubated with the membranes for 1 h at room temperature. Membranes were developed using enhanced chemiluminescence (ECL Plus™) western blotting detection reagents (Amersham Biosciences, GE Healthcare, Baie d'Urfe, QC, Canada) and read on a Typhoon™ Trio+ variable mode imager (Amersham Biosciences). The intensity of target bands was quantified using ImageQuant™ TL software (Amersham Biosciences).

Flow Cytometry

Cells were treated as indicated, harvested with 0.5 % trypsin and suspended in 4 % FCS-PBS. After 30 min of incubation with anti-CD95 or isotype controls at 4 °C, cells were washed twice and resuspended in phosphate buffered saline containing paraformaldehyde (10 g/l plus Na azide) and analyzed on a FACScan (Becton–Dickinson, Sunnyvale, CA, USA) according to the relative fluorescence intensity using CellQuest software. Resulting percentages were corrected for background fluorescence (0–5 %) determined by incubating the cells with appropriate isotype placebos (IgG1).

Statistical Analyses

All statistical analyses were carried out using SAS, version 9.1 (SAS Institute, Cary, NC, USA). For cell culture experiments, a minimum of three separate experiments were conducted. Data were tested for normal distribution and, once confirmed, analyzed by one-way or one-way repeated measures ANOVA, followed by post hoc analysis using Tukey's test to identify significant ($P < 0.05$) differences among fatty acid and chemotherapy treatments.

Results

Cell Viability

Treatment with DHA (Fig. 1a), and to a lesser extent, EPA (Fig. 1b), significantly ($P < 0.05$) reduced cellular viability (assessed by using the WST-1 assay) of all cancer cell lines tested compared to either incubation with no fatty acids or a control fatty acid treatment of similar concentration (data not shown). The cell viability of non-transformed breast epithelial cell line MCF-12A was not significantly affected by either fatty acid (Fig. 1a, b). In additional experiments it was confirmed that the decrease in the WST-1 assay was consistent with a decrease in cell number. Incubation of MCF-7 cells with EPA (100 μ M) or DHA (60 μ M), compared to cells incubated with a control fatty acid mixture (OLA/ALA) for 48 h resulted in reduced cell numbers by 52 ± 4 and 42 ± 4 %, respectively). For

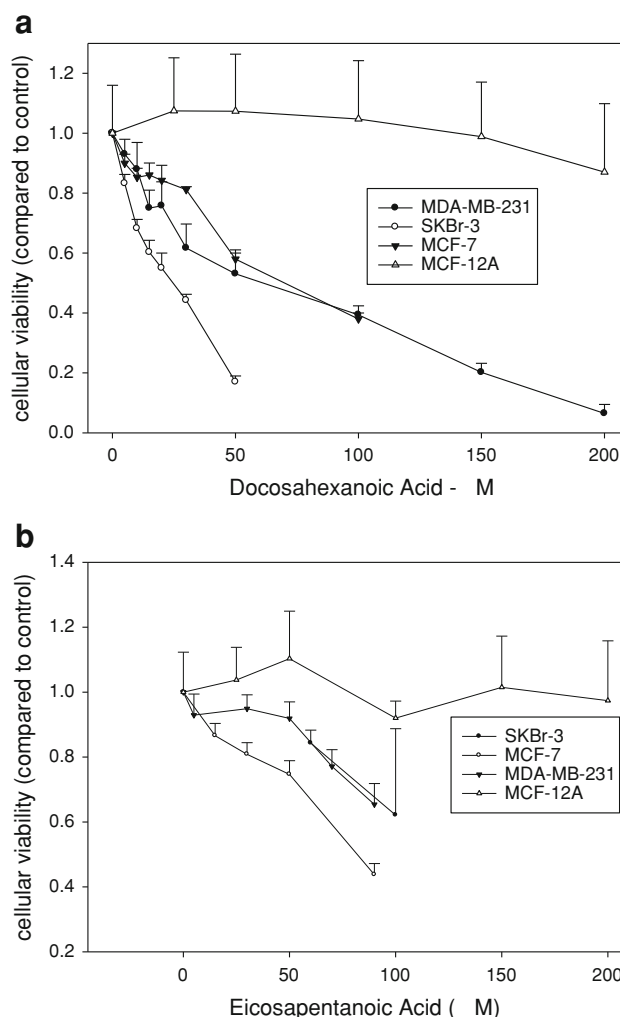

Fig. 1 Cellular viability in response to n-3 polyunsaturated fatty acid treatment in normal and transformed human breast cell lines. Viability was assessed in response to increasing concentrations of **a** DHA and **b** EPA. MDA-MB-231, MCF-7, SKBr-3 breast cancer cells and non-transformed MCF-12A cells were incubated for 72 h in the presence of varying concentrations of albumin-conjugated DHA or EPA. Viability was assessed using the WST-1 assay. Viability of transformed cells was significantly decreased with increasing concentrations of DHA and EPA ($P < 0.05$). The growth of non-malignant breast cells (MCF-12A) was not affected until concentrations ≥ 200 μ M for DHA and 300 μ M for EPA. For transformed cells, $n = 6$ –8 cell passages, for MCF-12A, $n = 3$

MDA-MB-231 cells, the same EPA and DHA concentration resulted in reduced cell counts by 59 ± 3 and 59 ± 4 %.

Interaction with Chemotherapeutic Agents

Pre-treatment with EPA at 100 μ M and DHA at all concentrations tested (25, 50 and 100 μ M) significantly reduced the growth of SKBr-3 cells but neither fatty acid increased the effect of Herceptin on tumor cell viability (Table 1). At 25 and 50 μ M, EPA significantly reduced the

Cells were incubated with the fatty acid treatment for 48 h. This was followed by a 24 h incubation without (–dox) or with (+dox). Values are means \pm SEM ($n = 4$ independent replications/treatment). Within a column, means that do not share a common superscript are significantly different ($P < 0.05$). The comparison of the cells treated with and without dox is indicated in the column labeled comparison. All dead indicates that there were no cells left to measure

viability of Herceptin-treated SKBr-3 cells compared with EPA treatment alone ($P = 0.03$) Incubation with EPA at 100 μM and DHA at all concentrations tested (25, 50 and 100 μM) significantly reduced the growth of MCF-7 cells but pre-incubation with either fatty acid did not

significantly change the effect of dox treatment on cell viability (Table 2). Incubation with EPA at 100 μM and DHA at all concentrations tested (30, 60, and 100 μM) significantly reduced the cell viability of MDA-MB-231 cells. Preincubation with EPA at 100 μM and DHA at

>60 μM increased the effect of dox on reducing the metabolic activity of MDA-MB-231 cells (Table 3). Based on the results in Table 3, EPA incubation for 48 h at 100 μM and DHA at 60 μM was used in all subsequent experiments. Cell counting experiments ($n = 3$) were also performed in the MDA-MB-231 cell line to confirm that the decrease seen in the WST-1 assay was consistent with a decrease in the number of cells. Compared to pre-incubation with OLA/LNA (control), 48 h of treatment with DHA reduced cell numbers by $66 \pm 1\%$ ($P < 0.05$). Pre-treating MDA-MB-231 cells with control fatty acids for 48 h before dox (0.22 $\mu\text{g/ml}$ for 24 h) resulted in reduced cell numbers ($76 \pm 6\%$), while pre-treatment with DHA (50 μM) resulted in a significantly greater cell loss ($45 \pm 1\%$, $P < 0.05$).

CD95 Localization in Tumor Cells

Localization of CD95 was determined in MDA-MB-231 cells (Fig. 2a) and MCF-7 cells (Fig. 2b) by examining the overlay (D panels; yellow regions indicate areas of colocalization) of CD95 (A panels, green) with the lipid raft marker cholera toxin subunit B (B panels, red). Blue nuclei (C panels) are included to indicate the location of nuclei. Under control conditions (Box 1) and with dox treatment (Box 2), no colocalization of CD95 and cholera toxin subunit B was observed, indicating that CD95 is intracellular under these conditions. Membrane organization was disrupted in dox treated cells (Boxes 2B, 4B, 6B). There was also a suggestion of lipid raft clustering after incubation with DHA or EPA (panels 3D/5D and 4D/6D with and without dox in MDA-MB-231 cells. When DHA (Box 3) and DHA+dox (Box 4) were applied, CD95 co-localized with the lipid raft marker in both cell lines (panels 3D, 4D) after DHA treatment. This appeared more dramatic in MDA-MB-231 (Fig. 2a) cells than in MCF-7 cells (Fig. 2b). EPA (Box 5) and EPA+dox (Box 6) did not appear to induce CD95 translocation to the cell membrane.

n-3 PUFA and Dox Effects on CD95 in MDA-MB-231 Cells

The surface expression (mean fluorescence) of CD95 increased with EPA, DHA or dox treatment (control treatment not shown in Fig. 3a). Treatment with DHA or dox increased CD95 surface expression significantly more than EPA (Fig. 3a, b). However, pre-treatment with DHA (Fig. 3a, b), but not EPA (Fig. 3a) before treatment with dox, resulted in a significantly greater (threefold increase) CD95 surface expression on MDA-MB-231 cells. The total amount of CD95 (Fig. 3c) or FADD (data not shown) in cells did not change with any of these treatments. However, both DHA and dox treatment increased the relative amount

Fig. 2 Immunolocalization of CD95 in MDA-MB-231 (Fig. 3a) and MCF-7 cells (Fig. 3b). Cells were pretreated for 48 h with either no n-3 PUFA (box 1, 2) 60 μM DHA (box 3, 4) or 100 μM EPA (box 5, 6), followed by a 24 h treatment with dox (boxes 2, 4 and 6). CD95 was labeled with Alexafluor-488 conjugated antibody (green) and was intracellular under control conditions and upon treatment with dox. Membrane organization was disrupted in dox-treated cells, as indicated by the Alexa-fluor 555-conjugated lipid raft marker, cholera toxin subunit B (red). When DHA and DHA + dox were applied, CD95 appeared to co-localize with lipid rafts, observed in the yellow portions of the overlay. To a lesser extent, EPA also induced CD95 translocation to lipid rafts. Scale size: $73 \times 73 \mu\text{m}$. Images are representative of the results of three separate experiments

of CD95 (Fig. 3d), but not FADD (Fig. 3e) in membrane rafts compared to the control fatty acid treatment (statistics not illustrated on Fig. 3). Pre-treating cells with DHA resulted in significantly more CD95 (Fig. 3d) and FADD (Fig. 3e) in lipid rafts after dox treatment, compared to all the other treatments.

Discussion

Consistent with previous studies [9, 30, 31], in the present study we demonstrated the growth-inhibitory effects of DHA and EPA on human breast cell cancers. Our studies demonstrate that DHA and EPA, even at high concentrations, do not affect the growth and metabolic activity of the non-transformed breast cell line MCF-12A. In the conditions in this study, DHA induced cell death at lower concentrations than EPA in all transformed cell lines. We also showed that DHA and EPA (albeit at higher concentrations) enhanced the efficacy of the chemotherapy drug, dox, in MDA-MB-231 cells. Lastly, we determined that at least a portion of the cytotoxic effect of DHA and its beneficial effects on the action of dox may be due to the movement of the CD95 (Fas) and FADD, two key proteins in DISC, into the lipid raft portion of the membrane in MDA-MB-231 cells.

Effect of EPA and DHA on the Selective Effect on the Growth of Human Breast Cancer Cells

Long-chain n-3 PUFA have been shown to reduce the viability of breast cancer cells, both in vitro and in animal models [3, 12, 23, 32, 33]. Consistent with these observations, the current study demonstrates the dose-responsive cytotoxic properties of DHA and EPA on transformed breast cells, and is the first, to our knowledge, to confirm the lack of effect of these PUFA, even at high concentrations, on the growth/metabolism of non-transformed breast cells. This observation has the potential to be of clinical importance as most of the current therapies for malignant cells have negative effects on healthy cells. The

concentration of DHA or EPA needed to induce anti-cancer effects *in vivo* is unknown, but our previous work has demonstrated that the concentrations selected in the current study for the drug experiments result in a fatty acid composition of n-3 and n-6 fatty acids [5] similar to concentrations reached in mammary tumor phospholipids when rodents are fed a high fish oil diet (EPA and DHA) [21].

A number of mechanisms have been proposed to explain the effects of n-3 PUFA on the growth and death of breast cancer cells [4, 34, 35]. Most hypothesized mechanisms involve the fatty acids being incorporated into the cell membrane. Previous work by our group [4] has demonstrated that DHA/EPA treatment of human breast cancer cells increases apoptosis and alters the composition of lipid rafts [5]. The FAS receptor, also known as CD95, is a receptor on the surface of cells that regulates apoptosis in cancer cells [36]. Upon activation, CD95 moves to lipid rafts in the plasma membrane [37]. Cancer cells have been demonstrated to under-express CD95 [29] and inducing expression is a mechanism by which many anticancer drugs work [27]. Incorporation of n-3 fatty acids alters other receptors in breast cancer cells [5] and DHA has been shown to induce caspase-8 activation [32], which is an early step in the CD95 pathway.

Using the immunofluorescent overlay of CD95 with cholera toxin subunit B; used to identify lipid rafts [38, 39], our data suggests that the anti-growth effects of DHA, and to a much lesser extent EPA, may in part be due to movement of CD95 to the raft. With fluorescent microscopy there was an indication of raft clustering after treatment with DHA in the MDA-MB-231 cells but not the MCF-7 which may have contributed to the effects on growth. Modified clustering of lipid rafts, and an increase in their size has been shown in response to DHA, but not EPA, in EL4 cells [40]. Further studies using the MDA-MB-231 cell line demonstrated that incubation with DHA resulted in increased surface expression of CD95 and increased CD95 in the membrane rafts; further supporting that DHA may mediate some of its cytotoxic effect on highly metastatic ER⁻ tumor cells via activation of the death receptor complex on the cell surface. A recent nutrigenomic study investigating the effects of EPA on breast cancers differing in ER status concluded that the ER status of breast cancer cells may play a role in breast cancer cell response to treatments with n-3 and n-6 fatty acids [41]. In the present study, the similar rate of cytotoxicity (reduced metabolic activity) after treatment with DHA and EPA between the MDA-MB-231 cells (ER⁻) and the MCF-7 cells (ER⁺), suggest that ER status may not be the major mechanism by which n-3 PUFA act, at least *in vitro*. SKBr-3 cells over-express Her2, a growth receptor that is part of the epidermal growth receptor family. We have previously demonstrated that treatment with a mixture of

DHA and EPA reduced the movement of the epidermal growth receptor into lipid rafts in MDA-MB-231 cells [5] suggesting a mechanism by which EPA and DHA inhibit the growth of SKBr-3 cells in the current study. This may also be the mechanism responsible for the increased cell death we observed in response to low concentrations of EPA (25 and 50 μ M) and Herceptin. It is unclear why higher concentrations of EPA do not induce the same effects; further investigation of growth receptor expression and localization in response to EPA and Herceptin treatment is warranted.

To our knowledge, this is the first report of CD95 membrane co-localization in response to n-3 PUFA in breast cancer cells; but is consistent with what has been reported to occur in T-cells from fish oil-fed mice [42]. Conversely, a study of migration and metastasis in MDA-MB-231 cells reported that DHA treatment (at concentrations similar to those used in the current study) also alter the structure of lipid rafts, but described this disruption in a manner similar to what occurs after treatment with methyl-beta-cyclodextrin [43]. In the current study, we demonstrate that treatment with DHA (and to a lesser extent EPA) resulted in the movement of a key signaling molecules, CD95, to the membrane in two human breast cancer cell lines.

Effect of Pre-treatment with EPA or DHA on Dox Sensitivity

Pre-treatment with either EPA or DHA did not significantly increase the cytotoxic effect of Herceptin or dox in SKBr-3 cells and MCF-7 (except perhaps when pre-treated with 100 μ M DHA). However, for MDA-MB-231 cells there was a higher toxicity of dox when cells had been pre-treated with EPA (100 μ M) or DHA (>50 μ M), suggesting a potential therapeutic benefit of providing this fatty acid prior to treatment with chemotherapy drugs. Vibet et al. [44] also observed that treating MCF-7 cells with DHA did not increase the sensitization to dox [44], which suggests that activity of the drug is not influenced by changes in membrane composition in this ER⁺ cell line. Our study is the first report, to our knowledge, examining the potential effect of n-3 fatty acids on the action of Herceptin, a mAb that blocks the binding to the Her2 receptor.

Pre-treatment with DHA and EPA (albeit at higher concentrations), significantly improved the anti-growth/metabolic effect of dox treatment on MDA-MB-231 cells. This was accompanied by a higher surface expression of CD95 (threefold) and content of CD95 (twofold) in the lipid raft fraction (twofold) over DHA or dox treatments alone. As we were unable to detect changes in total cellular CD95 protein, our results suggest that the combination of DHA and dox causes intracellular CD95 to move into the

lipid rafts in the cell membrane. CD95 aggregation is known to result in the recruitment of FADD to the CD95 receptor in membrane rafts, forming the CD95-DISC, which activates the apoptotic cascade initiated by caspase-8 [27]. Consistent with the literature [28, 29], in the present study, dox treatment increases FADD content in the rafts. Our data extends this by demonstrating that pre-treatment with DHA increases (fourfold) the amount of FADD that moves into the raft.

Although identifying the mechanism to explain how pre-treatment with DHA increases the co-localization of CD95/FADD in the raft, it is logical to predict that this may occur via an increase in the DHA content of the rafts. We have previously reported that providing DHA (with EPA) significantly increases the content of DHA in plasma membrane rafts in MDA-MB-231 cells [5]. Similarly, we have fed DHA to rodents and produced changes in the DHA content of the rafts in immune cells that were similar to what would have occurred in the tumor cells in the current study. JCR:LA-cp rats fed a diet containing 28 g fish oil/kg diet enriched the lipid raft DHA concentration to approximately 1.0 ± 0.1 % of total fatty acids [45]. Treating MDA-MB-231 cells with $40 \mu\text{M}$ DHA yielded a raft DHA concentration of 2.6 ± 0.4 % ($n = 6$) for total fatty acids (unpublished results).

A change in ceramide content in the cells could also contribute to the anti-cancer properties of DHA as DHA treatment results in a decreased sphingomyelin content and increased ceramide content in rafts from MDA-MB-231 cells [5]. A change in the cellular content of ceramide in tumors increases the content of CD95 and DISC in the membrane [46] and has been demonstrated to induce apoptosis [47]. Additionally, dox treatment has been reported to increase ceramide synthesis in tumor cells [48]. DHA treatment has also been demonstrated to facilitate the ability of dox to induce oxidative stress in tumor cells [44], supporting another membrane associated mechanism for improved sensitization.

Our findings are of potential clinical relevance as treatment with the anthracycline-based antibiotic, dox, is one of the drugs of choice for treatment of highly invasive metabolically active breast tumors, which are modeled by the MDA-MB-231 cell line [29, 49]. There is clinical evidence to support our findings. Breast cancer patients with higher concentrations of DHA in breast adipose tissue at the time of diagnosis were reported to respond more favorably to chemotherapy (i.e., had greater tumor regression) [23]. There is also preliminary evidence suggesting that treatment/feeding DHA might improve/prevent some of the side effects (both clinical and the development of drug resistance) of several chemotherapy drugs (reviewed by [9, 25]). In support of this, a phase II study examining effects of DHA supplementation on epirubicin (optical isomer of dox) efficacy in patients with highly

metastatic breast cancer found DHA treatment was associated with improved survival [24].

In summary, our study provides evidence that pre-treatment with DHA prior to treatment with a commonly used breast cancer drug, can increase the anti-cancer effects of the drug in an ER⁺, highly invasive human breast tumor. Our data suggests that increased membrane raft localization and aggregation of CD95 and formation of DISC, an important signal of apoptosis, may be one of the mechanisms to explain this increased sensitivity. Future studies aimed at linking changes in the cell mediated by DHA pre-treatment will assist in understanding the potential role that DHA supplementation could have as adjuvant treatment for breast cancer.

Abstract The objective of the present work was to study the renal function of healthy and tumor-bearing rats chronically supplemented with fish oil (FO), a source of n-3 polyunsaturated fatty acids. Weanling male rats were divided in two groups, one control (C) and another orally supplemented for 70 days with FO (1 g/kg body weight). After this time, half the animals of each group were injected in the right flank with a suspension of Walker 256 tumor cells (W and WFO). The W group had less proteinemia reflecting cachectic proteolysis, FO reversed this fact. Tumor weight gain was also reduced in WFO. Glomerular filtration rate (GFR) was not different in FO or W compared to C, but was higher in WFO. Renal plasma flow (RPF) was higher in the FO supplemented groups. The W group had lower plasma osmolality than the C group, but FO supplementation resulted in normalization of this parameter. Fractional sodium excretion (FE_{Na+}) of FO rats was similar to C. Proximal Na^+ reabsorption, evaluated by lithium clearance, was similar among the groups. Urinary thromboxane B_2 (TXB_2) excretion was lower in the supplemented groups.

The number of macrophages in renal tissue was higher in W compared to C rats, but was lower in WFO rats compared to W rats. In conclusion, FO supplementation resulted in less tumor growth and cachexia, and appeared to be renoprotective, as suggested by higher RPF and GFR.

Introduction

The n-3 and n-6 polyunsaturated fatty acid (PUFA) families are derived from the desaturation and elongation of the α -linolenic and linoleic acids that are ingested as components of food. While the principal members of the n-3 PUFA family are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), arachidonic acid (ARA) is the main derivate in the n-6 PUFA family [8]. Over the past 150 years, human beings have significantly increased their consumption of saturated and n-6 PUFA, while reducing the intake of n-3 PUFA. Consumption of a high n-6:n-3 PUFA ratio promotes elevated concentrations of potential proinflammatory, thrombotic and vasoconstrictor mediators that are associated with high incidence of chronic diseases such as hypertension, diabetes, and cancer [46, 50]. Diet supplementation with fish oil (FO), which is rich in n-3 PUFA, has reduced the incidence of these diseases [32, 46, 50]. In particular, epidemiologic and experimental studies have shown that long-chain n-3 PUFA (n-3 PUFA) have the ability to chemoprevent and chemosuppress the growth of tumors as well as the tumor-associated syndrome cachexia [22, 40]. Cachexia is characterized by anorexia, weight loss, early satiety, changes in taste perception, weakness, anemia and edema, depletion of carbohydrates, protein and lipid stores, and skeletal muscle wasting [36, 54]. Impaired salt-water excretion is a well-known systemic effect of cancer cachexia that has been studied in several animal models, including Walker 256 tumor-bearing rats [5, 28, 45]. In addition to alterations in hydro-electrolyte metabolism, some forms of carcinomas show a glomerular disease, which is mainly manifested as heavy proteinuria or progressive renal failure [57]. In a previous study, we investigated the effect of lifelong consumption of FO on hydroelectrolyte metabolism and renal function in cachectic rats; the animals' diet was supplemented with FO throughout gestation and lactation and into adulthood. A renoprotective effect was observed, but glomerular hemodynamics and tubular functions were not analyzed [24].

In the kidney, the cyclooxygenase enzyme system is the major pathway for ARA metabolism, leading to the formation of prostaglandins (PG) and thromboxanes [43]. These products modulate the actions of the other hormones or autacoids, in particular, physiological actions on renal vascular tone, mesangial and glomerular functions, and handling of salt and water [31, 43]. Inhibition of cyclooxygenase activity in the absence of exogenous administration or endogenous release of hormones such as angiotensin II (AII) or arginine-vasopressin (AVP) has little effect on renal functional parameters [33, 39]. On the other hand, the products of cyclo-oxygenase metabolism have been implicated as mediators of renal functional changes observed in several disorders: glomerular injury

(IgA nephropathy, lupus nephritis, etc.), various forms of acute and chronic renal failure, allograft rejection, cyclosporine nephrotoxicity, hepatorenal syndrome, diabetic nephropathy, and renal hypertension [30, 49]. FO-supplemented diets lead to competition among the substrates involved in ARA oxygenation pathways, leading to the formation of biologically less active end products [12, 43]. This mechanism explains the preventive effects of FO-supplemented diets on the various pathologies cited above [4, 7, 9, 17, 26]. The effect of a diet supplemented with FO on renal functional parameters in healthy subjects has been less studied, and available reports are contradictory [16, 19, 43].

Therefore, the objective of this study was to investigate the renal function of healthy and tumor-bearing rats chronically supplemented with FO.

Materials and Methods

Animals and Study Design

All experimental procedures were carried out in accordance with the ethical principles established by the Experimental Brazilian Council (COBEA), and with the requirements of the "Guide for the care and use of experimental animals (Canadian Council on Animal Care)". The local Animal Ethics Committee approved the experimental protocols used in this study (protocol no. 243). Weanling male Wistar rats (aged 21 days) were maintained under controlled temperature ($22 \pm 3^\circ\text{C}$) and humidity, in a 12 h/12 h light/dark cycle and divided into two groups. One group received a standard commercial chow [carbohydrate 63,4 %kcal, protein 25,6 %kcal and lipid 11 %kcal, where the fatty acid composition represented (% of fatty acid): palmitic acid (16:0) 20.7, stearic acid (18:0) 2.3, oleic acid (18:1n-9) 19.5, linoleic acid (18:2n-6) 51.3, α -linolenic (18:3n-3) 5.0 and arachidonic acid (20:4n-6) 0.1] (Nurilab CR1, Nuvital Nutrients Ltda., Curitiba, PR, Brazil) diet ad libitum and the other was fed the same chow diet but were also orally supplemented with FO (kindly donated by the Herbarium Foundation for Health and Research, Curitiba, PR, Brazil). The FO used was a mixed marine triacylglycerol preparation containing 180 g eicosapentaenoic acid (EPA) and 120 g docosahexaenoic acid (DHA) per kg. EPA and DHA were not detectable in regular chow. The oil supplement was administered at a dose of 1 g/kg body weight per day and was given orally as a single bolus using a precision microliter pipette. This dose represents approximately 1.25 % (w/w) of the diet. At 90 days of age half the animals of each group were injected into the right flank with a sterile suspension of 2×10^7 Walker 256 tumor cells

obtained from an ascitic tumor-bearing rat, and the other animals were injected with 1.0 mL 0.9 % (w/v) NaCl without anesthesia, as previously described [23]. The amount injected ensured that the tumor mass was 5–8 % of the carcass weight at the time of the measurements (the 14th day after inoculation). The following groups were set up: control and supplemented with FO (C and FO, respectively), and group tumor-bearing and tumor-bearing supplemented with FO (W and WFO, respectively). Body weight was determined every two days during the experimental time.

As the animals to be supplemented with FO were handled every day this could induce certain level of stress. To rule out this effect a pilot study was performed with a control oil supplement, coconut fat (rich in saturated fatty acids), at a dose of 1 g/kg body weight per day. In healthy rats supplemented with coconut fat the body weight gain was similar to that observed in C and FO groups, but in tumor-bearing rats they present similar weight loss and tumor mass weight than W group, the opposite to that observed in WFO (see Electronic supplementary material).

Kidney Function

The rats were prepared for kidney function measurements as follows. Half of animals were housed individually in metabolic cages (EB 309 Insight®, Riberão Preto, SP, Brazil) for 2 days prior to killing (day 14th after tumor inoculation). The cages facilitated accurate collection of urine not contaminated with feces or food. Fourteen hours before the renal test, 1 mL LiCl (60 mmol LiCl/100 g body wt) was given by means of gavage. The rats had free access to tap water but no food. Spontaneously voided urine was collected under oil into a graduated centrifuge tube, and urinary volume was determined gravimetrically. Next day the animals were injected with pentobarbital sodium 150 mg/kg for blood collection by cardiac puncture and after were killed with an overdose of pentobarbital. The tumor and kidney were removed, weighed and frozen at -80°C for analysis. Plasma was collected by blood centrifugation at 2,000g. Plasma and urine were used for the determination of creatinine, urea, electrolyte (Na^+ , K^+ and Li^+), total protein content, and osmolality.

Clearance Studies

The glomerular filtration rate (GFR) was determined by inulin clearance and renal plasma flow (RPF) by *p*-aminohippuric acid (PAH) clearance. The animals were anesthetized with 65 mg/kg and 10 mg/kg body weight (wt) of sodium pentobarbital and ketamine, respectively, administered intraperitoneally. After anesthesia the rats were

prepared for clearance experiments. In brief, a tracheotomy was performed and the left jugular vein was also cannulated with another catheter for infusion of inulin, PAH and fluids. To collect urine samples, the urinary bladder was cannulated by a suprapubic incision with a double catheter allowing air injection to expedite emptying. The urine was collected under oil, and the volume determined gravimetrically. Following the surgical procedure, an initial dose of inulin (30 mg/100 g body wt diluted in 0.9 % NaCl) and PAH (0.02 mg/mL of extracellular fluid, assuming extracellular fluid at 20 % of body wt) were administered through the jugular vein. Subsequently, a constant infusion of inulin, PAH and 3 % mannitol in saline was infused at a rate of 0.1 mL/min throughout the experiment. After 40 min of stabilization urine and blood samples (by cardiac puncture) were collected twice with approximately 30 min of interval. The values for renal clearance were derived from the average of the two collection periods. The results are reported as means \pm SEM per kg body wt. At the end of the experiment, the right kidney was removed and frozen at -80°C .

Plasma and Urine Analysis

Plasma and urine creatinine and urea were measured by a colorimetric method (picric acid) and the Bergmeyer method, respectively (Labtest Diagnostica, Lagoa Santa, MG, Brazil). Total plasma and urine protein content was determined by the biuret method (Labtest Diagnostica, Lagoa Santa, MG, Brazil). Inulin in plasma and urine was measured by the anthrone method [27]. PAH in plasma and urine was determined by a modification of Smith's method [51]. Sodium, potassium and lithium concentrations were measured by flame photometry (CELM, FC180, São Paulo, Brazil). Osmolality of plasma and urine was measured by a vapor pressure osmometer (MicroOsmometer–Vapro5520®, WESCOR-USA).

Calculations

Renal clearances and fractional excretions were calculated by standard techniques. Fractional electrolyte (Na^+ , K^+ and lithium) excretion (FE_{ion^+}) (%) was calculated as $C_{\text{ion}^+}/C_{\text{Cr}}$, where C_{ion^+} is Na^+ , K^+ or lithium clearance and C_{Cr} is creatinine clearance. Lithium clearance (C_{Li^+}) was used to assess proximal tubule output [53]. It should be noted that lithium is assumed to be reabsorbed in the proximal tubules in parallel with sodium and water, and that it is neither secreted nor reabsorbed beyond the proximal tubule [6]. Proximal Fractional Reabsorption of Na^+ (PFR_{Na^+}) and Post-Proximal Fractional Excretion of Na^+ ($\text{PPFR}_{\text{Na}^+}$) were calculated as $(\text{CF}_{\text{Na}^+} - \text{DD}_{\text{Na}^+})/\text{CF}_{\text{Na}^+}$ % and $(C_{\text{Na}^+}/C_{\text{Li}^+}) \times 100$, respectively. Where, DD_{Na^+} is Distal

Delivery of sodium ($C_{Li+} \times P_{Na+}$, $\mu\text{equiv/min}$); C_{Li+} , C_{Na+} and C_{Cr} are lithium, sodium and creatinine clearance (mL/min), respectively; and P_{Na+} is plasma sodium concentration (mequiv/L). Osmolality measurements were used to determine osmolar clearance (C_{osm}) (mL/min) and free water clearance (C_{H_2O}) (mL/min), which C_{H_2O} as $C_{osm} - V_u$, where V_u is urinary flow (mL/min).

Immunohistochemical Studies

At the end of RBF and GFR experiments, the animals were killed by an intravenous injection of thiopental (100 mg/kg body wt). Renal tissue samples were fixed in 9 % formalin NaCl, stocked at 70 °C ethanol, and then embedded in paraffin. For renal histology evaluation, longitudinal sections of 5 μm of thickness were stained with trichrome. For immunostaining of macrophages, a monoclonal mouse anti-rat ED-1 antibody that only reacts against antigens present in the cytoplasm of macrophages and monocytes (anti-ED1, 1:1,000; Serotec, Oxford, United Kingdom) was used. Desmin staining was performed with a monoclonal mouse anti-rat antibody (anti-desmin 1:100; Dako, Glostrup, Denmark). These sections were incubated for 60 min at room temperature. After washing, the sections were incubated with rabbit anti-mouse immunoglobulin with low affinity for rat IgG (1:200; Dako, Glostrup, Denmark). The reaction product was detected with avidin–biotin–peroxidase complex (Vector Laboratories, CA). The color reaction was developed with 3,3'-diaminobenzidine (Sigma Chemical Co.) supplemented with hydrogen peroxide, and the material was then counterstained with methyl green, dehydrated, and mounted. Negative controls were created by replacing the primary monoclonal antibody with equivalent concentrations of normal mouse IgG. The extent of ED1-positive cell infiltration in glomerulus and tubular cells was evaluated in 30 microscopic fields (measuring 0.245 mm^2 each), and mean values per kidney were calculated. In the evaluation of immunoperoxidase staining for desmin, each glomerulus or field of renal cortex (each measuring 0.245 mm^2) was graded semiquantitatively under light microscopy (40 \times), and the mean score per kidney (ranging from 0 to 4) was calculated. Each score primarily reflected changes in the extent, rather than the intensity, of staining and depended on the percentage of the grid field showing positive staining: absence of staining or less than 5 % = 0; 5 to 25 % = 1; 25 to 50 % = 2; 50 to 75 % = 3; and more than 75 % = 4. This semiquantitative scoring system has been reported to be reproducible among different observers, and highly correlated with those obtained by computerized morphometry and evaluated using light microscopy (40 \times).

Determination of PGE₂ and TXB₂ Concentration in Urine

Urine PGE₂ and TXB₂ concentrations were determined by an enzyme immunoassay kit according to the manufacturer's instructions (Cayman Chemical Co, Ann Arbor, MI, USA). Standard curves were constructed by serially diluting PGE₂ and TXB₂ in buffer at concentrations between 7.8 and 1,000 pg/mL. Data were expressed in pg/min, where the concentrations were normalized by urinary flow.

Statistical Analysis

Data are reported as means \pm SEM. All data were initially tested for normality by the Kolmogorov–Smirnov test. Statistical comparisons were made by analysis of variance (ANOVA) followed by Tukey's multiple comparison test, using the statistical software GraphPad Prism version 5.00 for Windows (GraphPad Inc, San Diego, CA, USA), and the level of significance was set at $p < 0.05$.

Results

The body and tumor weight of the different groups are shown in Table 1. In healthy rats the body weight gain in the FO group was similar to the control group (C), but for the Walker 256 tumor-bearing rats (W) it was significantly lower than control ($p < 0.05$). FO supplementation was able to modify weight loss of tumor-bearing animals, where the FO tumor-bearing group (WFO) presented body weight gain when compared to the W group. FO supplementation also reduced tumor mass weight by 60 % compared to the W group ($p < 0.05$) (Table 1). Kidney weight of the W group was significantly lower than control, however when kidney weight was normalized by animal weight this difference was not observed (Table 1). The FO supplementation did not modify this parameter significantly.

The tumor-bearing group showed a clear signal of cancer cachexia, i.e., a depletion of protein stores. Proteinemia was significantly lower in the W group compared to the C and FO groups. On the other hand, the FO tumor-bearing group (WFO) was similar to the C and FO groups (see Table 2). Urinary excretion of proteins was not modified by FO supplementation or tumor presence.

Glomerular filtration was determined by inulin clearance. This parameter did not present significant changes in the FO group or in the W group if compared to control group (see Table 2). At the same time, FO supplementation in tumor presence (WFO group) increased the GFR significantly compared with W ($p < 0.05$). Despite the differences observed in GFR, plasma creatinine concentration was similar among the groups (see Table 2). In the same

Table 1 Effect of FO supplementation on animal body weight before and after tumor inoculation

| | C (<i>n</i> = 14) | FO (<i>n</i> = 12) | W (<i>n</i> = 12) | WFO (<i>n</i> = 11) |

way, plasma urea concentration was similar among the groups (Table 2).

The values of *p*-aminohippuric acid clearance represent RPF. FO supplementation increased the blood flow significantly in the control and tumor-bearing groups (*p* < 0.05), where FO promoted a rise of 54 % compared with C and WFO a rise of 91 % in relation to W (see Table 2). These results indicate that FO supplementation was able to modify renal hemodynamic, inducing vasodilatation. Despite the changes observed in RPF, the filtration fraction data were not changed significantly by FO supplementation or tumor presence (Table 2).

The tumor-bearing group (W) had less plasma osmolality compared to control rats (C) (see Table 3). This alteration in plasma osmolality was reverted in supplemented animals (WFO). Despite these differences, urine osmolality and osmolar clearance were similar among the different groups. Moreover, the free water clearance presents negative values in all groups, indicating that the distal segments keep the ability of water reabsorption (Table 3).

Table 4 shows renal handling of sodium and potassium. Na⁺ and K⁺ urinary excretion were not significantly modified by FO supplementation or tumor presence. The FE_{Na+} of control rats supplemented with FO was similar to control. FE_{Na+} in W group was nominally lower than control groups but not statistically significant (see Table 4). Plasma sodium concentration of supplemented and tumor-bearing groups was similar to the control group. The lithium clearance method was used to calculate the amounts of water and sodium delivered from the end of the proximal straight tubule. Table 4 shows the values of fractional lithium excretion (FE_{Li}), Na⁺ Distal Delivery (DD_{Na+}), Proximal Fractional Reabsorption of Na⁺ (PFR_{Na+}) and C_{Na+}/C_{Li} ratio (expressing the post-proximal fractional excretion of Na⁺). FE_{Li} and PFR_{Na+} were not modified by FO supplementation or tumor presence, indicating that proximal Na⁺ reabsorption was similar among the groups. C_{Na+}/C_{Li} ratio represents post-proximal fractional excretion of sodium, and this parameter is utilized to estimate the distal sodium reabsorption. So, an increase in

Data are presented as means ± SEM

^a $p < 0.05$ vs C group

post-proximal fractional excretion of sodium, an increase in C_{Na+}/C_{Li} ratio, indicates that the distal sodium reabsorption was reduced. C_{Na+}/C_{Li} ratio was not modified by FO supplementation in control rats, indicating that fractional sodium reabsorption beyond the proximal tubule was equivalent between these groups. However, FO supplementation significantly reversed the tendency to increase in fractional distal sodium reabsorption observed in tumor-bearing rats (W), as indicated by the increased value for C_{Na+}/C_{Li} ratio in the WFO group (see Table 4).

Urinary excretion of TXB₂ in control animals averaged 30 ± 4 ng/min and decreased by 40 % to 18 ± 1 ng/min ($p < 0.05$), $n = 9$, after FO supplementation. FO supplementation in tumor-bearing rats was also able to reduce urinary excretion of TXB₂ (see Table 2). Despite the differences observed in TXB₂ excretion, urinary excretion of PGE₂ was similar among groups (Table 2).

Immunohistochemical Studies

In kidneys that underwent histological studies, no significant differences in appearance were found in glomerular or tubulointerstitium morphology among the different groups (data not shown). The number of macrophages/monocytes in renal tissue was evaluated by immunolocalization of

ED1 positive cells. In glomerulus, the number of ED1 (macrophages/monocytes)-positive cells were similar in C and FO groups: 0.79 ± 0.16 and 1.17 ± 0.07 , respectively, $p > 0.05$ (see Fig. 1). However, for tumor-bearing rats it was significantly higher: 5.57 ± 1.82 positive cells number, a value that was reduced to control levels by FO supplementation (WFO): 2.32 ± 0.56 positive cells number/field, $p < 0.05$ (Fig. 1). A similar profile was observed in tubulointerstitium cortical area (see Fig. 2).

The expression of desmin at glomerular edge was not significantly modified by FO supplementation or tumor presence (Fig. 3). The group mean score was 0.078 ± 0.078 in C, 0.024 ± 0.017 in FO, 0.65 ± 0.41 in W, and 0.30 ± 0.10 in WFO. In most rat strains, glomerular expression of desmin is confined to mesangial cells, and podocytes only express it following injury. Therefore, higher desmin expression at glomerular edge can be considered as a marker of podocyte damage.

Discussion

This study shows that dietary supplementation with FO of only 1.25 % w/w resulted in a slight modification in renal function of healthy rats (an increase in renal blood flow).

However, in tumor-bearing rats, the same diet led to a decrease in tumor growth and a renoprotective effect accompanied by a rise in RPF and the preservation of glomerular filtration.

Over the past 20 years, several studies have suggested the efficacy and potential clinical utility of n-3 fatty acid dietary supplementation in human renal diseases such as idiopathic immunoglobulin A nephropathy, lupus nephritis,

cyclosporine A toxicity, vascular access thrombosis of end-stage renal disease, and idiopathic calcium urolithiasis [3, 13, 18, 21]. The most accepted hypothesis explaining the multifaceted actions of n-3 fatty acids on kidney diseases relates to the activities of the metabolites derived from EPA as opposed to those derived from ARA. The n-3 fatty acids compete with ARA in the cellular membrane, ultimately reducing inflammatory, thrombotic, and aggregation

Fig. 3 Score for desmin at glomerular edge in the renal cortex of rats from C, FO, W and WFO groups. Immunolocalization of desmin at glomerular edge: **a** Groups C ($n = 2$), **b** FO ($n = 4$), **c** W ($n = 3$) and **d** WFO ($n = 4$) (40 \times)

mediators such as PGE₂ and TXB₂, and increasing mediators such as PGE₃ and TXB₃, which attenuate these processes [2, 34].

Despite numerous studies devoted to several different kinds of renal diseases, few investigations have examined the effects of n-3 fatty acid dietary supplementation on renal function in healthy animals or humans [19, 35, 48]. In the present work, we observed that chronic dietary supplementation with n-3 fatty acids in rats did not significantly alter the GFR, but did promote a rise of 91 % in renal blood flow, suggesting preferential vasodilatation of efferent arteriole. However, Schmitz et al. [48] observed a significant increase in the single-nephron glomerular filtration rate (SNGFR) when glomerular hemodynamics was evaluated in rats by using micropuncture. The elevated SNGFR was primarily due to a marked increase in single-nephron plasma flow, which was associated with a significant reduction in efferent arteriolar resistance. The increase in RPF observed in the groups fed with supplemented diet could be explained by competition between n-3 fatty acid metabolism and the production of ARA-derived prostanoids in the kidney [2]. FO, which is rich in EPA, generates series 3 prostanoids (PGI₃, PGE₃, and TBX₃) and series 5 leukotrienes, with vasodilating characteristics. In contrast, arachidonic acid derivatives such as thromboxanes (TBX₂) have vasoconstrictive actions [1, 31]. Potent renal vasodilators include PGI₃ and PGE₃, whereas TBX₃ has little effect on vascular smooth muscle tone. In the present work, we observed a significant reduction in the urinary excretion of TBX₂ in n-3 fatty acid-supplemented animals, suggesting a fatty acid-mediated decrease in TBX₂ synthesis. Despite the reduction

observed in TBX₂ excretion, urinary excretion of PGE₂ was similar among the groups. The EIA methodology utilized in this study has a limitation resulting from cross reactivity between TXB₂ and TXB₃, and between PGE₂ and PGE₃. The lack of effect on urinary excretion of PGE₂ can be explained by this limitation. On the other hand, Logan et al. [35] observed that feeding FO for 1 month to rats had no effect on the mean GFR (as determined using inulin clearance) or RPF. In a similar manner, we reported in a previous study that FO supplementation in the diet fed to female rats throughout pregnancy and lactation, and then in their offspring post-weaning diet for 10 weeks, also did not modify glomerular filtration [24].

The discrepancies observed between our study and others could be attributed to the differences in experimental design, such as duration of supplementation period and amount of FO added to the experimental diets. The study by Schmitz et al. [48] was performed after 4–6 weeks of n-3 fatty acid dietary supplementation, whereas the present study was conducted after 10–12 weeks. Furthermore, the animals described in the Schmitz publication were fed standard laboratory chow supplemented with 18 % (w/w) of FO, whereas the chow used in our study was supplemented with approximately 1.25 % (w/w) FO. Despite the observed changes in renal hemodynamics in the FO group, other parameters like renal handling of sodium and potassium were not modified by the supplementation. Previous studies with healthy humans have also reported that inhibition of COX-derived prostanoids have minimal effects on renal hemodynamics and tubular function [15, 52].

Cachexia-anorexia syndrome (a devastating state of malnutrition) is a common manifestation of cancer and

non-malignant chronic diseases such as AIDS, advanced congestive heart failure, chronic obstructive pulmonary disease, and rheumatoid arthritis, among others [20, 29]. Epidemiological studies have shown a link between fat-rich diets and incidence of cancer [10, 40]. Tumor growth demands energy, which must be provided by the host. As a consequence, depletion of energy stores (glycogen in the liver and muscles; protein in the muscles; triacylglycerol in the adipose tissue) of the host ensues. In the current study, tumor growth was associated with reduced animal growth and reduced total serum protein concentration. Thus, this model induced cancer cachexia. Supplementation with FO significantly reversed the reduction in weight gain observed in the Walker 256 tumor-bearing rats, reduced tumor growth, and increased total serum protein concentrations. In previous studies by our group, we observed that several “cachectic” serum parameters such as glucose, lactate, cholesterol, and HDL-C returned to normal levels in Walker 256 tumor-bearing rats supplemented with FO [38, 56]. The mechanisms used by n-3 PUFA to combat neoplastic cells are yet to be elucidated. Modifications in prostaglandin biosynthesis, cyclooxygenase-2 activity, and angiogenesis, and modulation of the immune function and lipid peroxidation have all been suggested to play a significant role [32]. There is an alternative hypothesis of reducing weight loss in cachexia from an increase in lipid in the diet. An increase in total caloric intake leads to a rise in fat stores or reduced depletion of energy stores potentially relieving the reliance on protein catabolism. FO supplementation increases total caloric intake in only 3.3 %, an amount unlikely to explain the effect observed in weight loss.

The progression of renal injury depends on many factors such as immune cell recruitment, inflammatory mediators, and cellular proliferation [44, 59]. Monocyte/macrophage recruitment in the renal tissue is the initial stage of the injury process, and this recruitment is mainly initiated by a chemokine monocyte chemoattractant protein 1 (MCP-1) [14, 47]. In the present study, we observed an increase in macrophage recruitment by the renal tissue (glomerular and interstitial) of tumor-bearing rats (W group), indicating renal disease in its initial stages. Despite these inflammatory signals, renal hemodynamical parameters were preserved in these rats. Macrophage recruitment was reversed in the WFO group, suggesting an increase in the production of anti-inflammatory mediators or inhibition of pathways involved in renal injury. An et al. [2] demonstrated that anti-inflammatory effects of FO in the kidney may be explained by decreased MCP-1 expression; this is suggested in a 5/6 nephrectomy model, where FO reduced renal injury, as well as the activation of ERK and NF- κ B, and MCP-1 expression, which are pathway participants in the progression of fibrosis. Similar results were also observed by Peake et al. [41] in a model of obstructive

renal injury in rats. As discussed above, FO supplementation decreased the production of ARA-derived prostanoids with vasoconstrictive actions, like TBX₂. This explains the significant reduction observed in urinary excretion of TBX₂ in this group. Another factor that could contribute to the increase in GFR induced by FO supplementation is reduction in whole blood viscosity due to reduced serum lipid levels. In a previous study, we observed that Walker 256 tumor-bearing rats given a FO-supplemented diet displayed reduced serum triacylglycerol (TAG) levels in contrast to the W group, but similar to the control rats [42]. Therefore, FO dietary supplementation may have caused a reduction in plasma and/or whole blood viscosity, which likely contributed to the observed decrease in renal vascular resistance. On the other hand, control rats on the same diet had serum TAG and cholesterol levels similar to the non-treated control animals [56]. Thus, the small effects of this supplementation on the GFR in control animals that were observed in the present work could be explained in part by the constancy of plasma lipid levels, and in part, by the slight effect of inhibition of cyclooxygenase products on the renal parameters of normal rats and humans [39, 58].

Injury of foot process and the glomerular barrier can be detected by desmin immunostaining [11]. We observed that desmin expression was not significantly modified by FO supplementation or tumor presence. In animal models of renal damage, an increase in desmin expression in the glomerulus is usually indicative of glomerular sclerosis and loss of glomerular selectivity to macromolecules such as proteins [25]. These lesions could result in marked and persistent proteinuria; however, proteinuria was not observed in the present study.

As Walker 256 carcinoma progresses in control rats (W), their water intake is sustained despite their progressive decline in food consumption [24]. This apparent excessive water intake has been attributed to retention of water associated with the known retention of sodium ions due to increased secretion of aldosterone, and/or inappropriate antidiuretic hormone secretion [5, 37]. The reduced plasma osmolality observed in the tumor-bearing rats in the present study corroborates this tendency to retain water. Another factor to be considered is the decrease in total serum protein concentration, which caused a reduction in the blood colloid oncotic pressure, favoring the movement of water from the vascular to the interstitial space, resulting in hypovolemia and renal preservation of salt and water [55]. Other authors have reported a decrease in urinary Na⁺ excretion by W rats, as observed in the present study [24, 45, 55]. Supplementation with FO reversed the alterations caused by tumor growth on renal fractional excretion of sodium. The tumor-bearing animals that were fed FO also had a plasma osmolality similar to the control group, indicating a reversal in the tendency to retain water that accompanies cancer cachexia.

In summary, dietary supplementation with FO (1,25 % w/w) induced only slight modifications in renal hemodynamics in control animals. Interestingly, in tumor-bearing rats, this change in n-3 PUFA intake caused a remarkable reduction in tumor growth and cachexia, and had a reno-protective function as well.

Acknowledgments Authors thank Dr. Carolina A. Freire for the osmolality readings and useful suggestions. Research supported by Fundação Araucária, Paraná, Brasil. Luiz C. Fernandes and Terezila M. Coimbra were supported by grants of the Conselho Nacional de Pesquisas (CNPq), Brasil.

Abstract The weight loss supplement conjugated linoleic acid (CLA) consists of an equal mixture of *trans*-10,*cis*-12 (10,12) and *cis*-9,*trans*-11 (9,11) isomers. However, high levels of mixed CLA isomers, or the 10,12 isomer, causes chronic inflammation, lipodystrophy, or insulin resistance. We previously demonstrated that 10,12 CLA decreases de novo lipid synthesis along with the abundance and activity of stearoyl-CoA desaturase (SCD)-1, a δ -9 desaturase essential for the synthesis of monounsaturated fatty acids (MUFA). Thus, we hypothesized that the 10,12 CLA-mediated decrease in SCD-1, with the subsequent decrease in MUFA, was responsible for the observed effects. To test this hypothesis, 10,12 CLA-treated human adipocytes were supplemented with oleic acid for 12 h to 7 days, and inflammatory gene expression, insulin-stimulated glucose uptake, and lipid content were measured. Oleic acid reduced inflammatory gene expression in a dose-dependent manner, and restored the lipid content of 10,12 CLA-

treated adipocytes without improving insulin-stimulated glucose uptake. In contrast, supplementation with stearic acid, a substrate for SCD-1, or 9,11 CLA did not prevent inflammatory gene expression by 10,12 CLA. Notably, 10,12 CLA impacted the expression of several G-protein coupled receptors that was attenuated by oleic acid. Collectively, these data show that oleic acid attenuates 10,12 CLA-induced inflammatory gene expression and lipid content, possibly by alleviating cell stress caused by the inhibition of MUFA needed for phospholipid and neutral lipid synthesis.

Introduction

Losing body fat without reducing food intake or increasing physical activity is attractive to many who want to lose weight. One approach is consumption of conjugated linoleic acid (CLA), a fatty acid found in dairy products and ruminant meats and in supplements and fortified foods marketed worldwide for weight loss. Indeed, a meta-analysis of 18 clinical studies revealed that adults that consumed daily an average of 3.2 g of an equal mixture of two CLA isomers, *cis*-9,*trans*-11 (9,11) and *trans*-10,*cis*-12 (10,12) lost approximately 0.2 lb of body fat per week without changing food intake [1]. Intriguingly, mice consuming higher amounts of CLA than humans lose body fat more rapidly, but may concurrently develop side effects including chronic inflammation, insulin resistance, or lipodystrophy [2].

Only the 10,12 isomer reduces adiposity or delipidated adipocytes. However, at high doses 10,12 CLA alone and an equal mixture of 10,12 and 9,11 CLA has been reported to cause inflammation, lipodystrophy, or insulin resistance in mice [2] and human subjects [3, 4]. In contrast, the 9,11 isomer alone has anti-inflammatory and adipogenic properties, and improves insulin sensitivity in mice [5, 6]. Proposed anti-obesity mechanisms of 10,12 CLA include regulation of (1) energy metabolism, (2) adipogenesis, (3) lipid metabolism, (4) inflammation, and (5) adipocyte apoptosis (reviewed in [7]). However, direct linkages of these potential mechanisms to body fat loss, especially inflammation, are unclear.

One potential mechanism by which CLA decreases adiposity is by repressing the expression or activity of lipogenic enzymes such as stearoyl-CoA desaturase-1 (SCD-1), the rate-limiting enzyme required for the synthesis of monounsaturated fatty acids (MUFA), thereby reducing the synthesis of phospholipids and neutral lipids. Such reductions in these lipids could cause cell stress given their important role in regulating membrane function and eicosanoid synthesis. Consistent with this hypothesis, 10,12 CLA alone or a mixture of 10,12 and 9,11 CLA decreases the levels of MUFA in rodents [8, 9], 3T3L1 adipocytes [10], and primary human

adipocytes [11, 12]. We also recently found in primary human adipocytes that (1) 10,12 CLA decreased the expression of SCD-1 and of two transcription factors that regulate SCD-1 transcription, sterol regulatory element binding protein (SREBP)-1C and liver X receptor (LXR) α , within 5–7 h of treatment, and (2) 10,12, but not 9,11 CLA completely ablated the protein levels of SCD-1 after 12 h of treatment [12]. However, 10,12 CLA supplementation reduced body weight in SCD-1 knockout mice, simultaneously increasing the ratio of C16:0/16:1 fatty acids and decreasing the ratio of C18:0/18:1 fatty acids [13], suggesting CLA's reduction in adiposity is independent of SCD-1.

Consequences of inhibiting SCD-1 activity include increasing the ratio of saturated fatty acids to MUFA, which is known to cause inflammation and insulin resistance (reviewed in [14]). Thus, we hypothesized that supplementing 10,12 CLA-treated cultures with the MUFA oleic acid (C18:1) would overcome this anticipated blockade of MUFA synthesis, thereby mitigating cell stress associated with deficiencies in phospholipids and neutral lipids. To test this hypothesis, we supplemented 10,12 CLA-treated primary human adipocytes with micromolar levels oleic acid for 12 h to 7 days, and measured inflammatory gene and protein expression, insulin-stimulated glucose uptake, lipid content, and the expression of several G protein receptors (GPR). To show the specificity of MUFA, we also pretreated cultures with stearic acid, a substrate for SCD-1, and 9,11 CLA. Consistent with our hypothesis, oleic acid reduced inflammatory gene expression in a dose-dependent manner, and restored the lipid content of 10,12 CLA-treated adipocytes without improving insulin-stimulated glucose uptake. In contrast, supplementation with stearic acid, a substrate for SCD-1, or 9,11 CLA did not prevent increased inflammatory gene expression by 10,12 CLA. Lastly, 10,12 CLA affected the expression of several GPR, cell surface receptors that respond to extracellular stimuli including free fatty acids (FFA), which was attenuated by oleic acid. Collectively, these data show that oleic acid supplementation attenuates 10,12 CLA-induced inflammatory gene expression and lipid content, possibly by alleviating cell stress caused by the inhibition of MUFA needed for phospholipid and neutral lipid synthesis.

Materials and Methods

Materials

All cell-culture wares and Hyclone fetal bovine serum were purchased from Fisher Scientific. Adipocyte medium (AM-1) was purchased from Zen-Bio. Isomers of CLA (+98 % pure) were purchased from Matreya (Pleasant Gap, PA). Gene expression assays for interleukin-1 β (IL-1 β), IL-6, IL-8, cyclooxygenase-2 (COX-2), monocyte chemoattractant

protein-1 (MCP-1), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were purchased from Applied Biosystems Inc. (Foster City, CA). The polyclonal antibody for anti-GAPDH and activating transcription factor (ATF)3 were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Anti-total or anti-phospho (P) JNK, ERK, I κ B α , and P-cJun antibodies were purchased from Cell Signaling Technologies (Beverly, MA). GW9508 was purchased from Tocris Bioscience (Ellisville, MO). All other chemicals and reagents were purchased from Sigma unless otherwise stated.

Cell Culture Model

Abdominal adipose tissue was obtained from non-diabetic Caucasian and African–American females between the ages of 20 and 50 years old with a body mass index ≤ 32.0 who had undergone elective surgery as previously described [15]. These selection criteria allow for reduced variation in gender, age, and obesity status. Institutional Review Board approval was granted through the University of North Carolina at Greensboro and the Moses H. Cone Memorial Hospital. Stromal vascular (SV) cells from human adipose tissue were isolated via collagenase digestion and subsequently grown as described previously [15]. Cells were differentiated in differentiation media [i.e., AM-1 supplemented with 250 μ M isobutylmethylxanthine and 1 μ M rosiglitazone (BRL49653; a PPAR γ agonist generously provided by Dr. Per Sauerberg at Novo Nordisk A/S, Copenhagen, Denmark)] for 3 days. Subsequently, differentiated cultures were maintained in AM-1 only for 7–14 days. These cultures contain approximately 50 % adipocytes and 50 % preadipocytes by day 7. CLA isomers were given at physiological levels [16, 17]. Oleic acid was given at micromolar levels given its abundance in human blood [18] and adipocytes [11]. Fatty acids were complexed to fatty acid-free (>98 %) bovine serum albumin (BSA; Sigma A7030, lot #040M1649) at a 4:1 molar ratio. This BSA was chosen based on its decreased capacity to increase inflammatory gene expression compared to other BSA samples tested (unpublished data). BSA levels were normalized to the highest fatty acid treatment so that all cultures contained the same amount of BSA vehicle. Fatty acids treatments were added at the same time. Each experiment was repeated in triplicate using a mixture of cells from at least two different subjects unless otherwise indicated.

RNA Isolation and Real-Time Quantitative PCR (qPCR)

Primary human SV cells were seeded in 35-mm dishes at 0.4×10^6 cells per dish and differentiated for 3 days. The media was changed on days 3 and 6. Cells were treated on

day 7 with fatty acids or BSA vehicle control. After 18 h RNA was isolated from cell cultures using the RNeasy mini kit (Qiagen, Valencia, CA) following the manufacturer's protocol for human adipocytes. For real time qPCR, 2 μ g of total RNA was used to generate first strand cDNA using the Applied Biosystems high capacity cDNA archive kit. qPCR was performed using a 7500 fast real-time PCR system (Applied Biosystems) using Taqman[®] universal PCR master mix and Taqman gene expression assays. To account for possible variation related to cDNA input amounts or the presence of PCR inhibitors, the endogenous reference gene GAPDH was quantified simultaneously for each sample in separate wells of the same 96-well plate.

Lipid Content Determination

Primary human SV cells were seeded in 12-well plates at 2×10^6 cells per plate and differentiated for 3 days. The media was changed to AM-1 on days 3 and 6. Cells were treated on days 7 and 11 with fatty acids or BSA control. On day 14, the media was removed and cell cultures were washed with Hank's balanced salt solution (HBSS). The presence of intracellular lipid was visualized by staining the cultures with oil red O, and lipid content was quantified based on absorbance levels at 540 nm as we previously described [11].

Immunoblotting

Immunoblotting using 20 μ g of protein per lane was conducted using 4–12 % NuPage Pre-Cast Gels (Invitrogen) as previously described [19]. Briefly, PVDF membranes were blocked with 5 % milk in TBST for 1 h and washed 3 \times in TBST for 5 min. Blots were incubated overnight at 4 °C with primary antibodies targeting I κ B α , P-cJun, P-JNK, P-ERK, total cJun, total ERK, and ATF3 at a dilution of 1:1,000, and subsequently incubated in the respective horseradish peroxidase-conjugated secondary antibody at a dilution of 1:5,000 at room temperature for 1 h. Primary and secondary antibodies targeting GAPDH were used at a 1:5,000 dilution. After washing, blots were treated with chemiluminescence reagent for 1 min and film was exposed using a SRX-101A Konica Minolta film developer. Densitometry was performed using a Kodak image station 440 CF by Perkin Elmer and Kodak molecular imaging software version 4.0.

Insulin-Stimulated 2-[³H]Deoxy-glucose (2-DOG) Uptake

Primary human SV cells were seeded in 12-well plates at 1.6×10^5 per well and differentiated for 12 days. On day 12, media were changed to serum free low glucose

(5 mmol/L) media. Twenty-four hours later, cultures were pretreated with fatty acids or BSA control. The culture media was removed and replaced with 0.5 mL of HBSS without or with 100 nmol/L human insulin for 10 min. After insulin preincubation, 4 nM 2-DOG (0.5 μ Ci per well) was added to each well and incubated at 37 °C for 90 min. Basal and insulin-stimulated 2-DOG uptake were measured as described previously [11].

Statistical Analysis

Data are expressed as means \pm SEM. Data were analyzed using one-way analysis of variance followed by Student's *t* tests for each pair for multiple comparisons. Differences were considered significant if $p < 0.05$. All analyses were performed using JMP IN version 9.0 software (SAS Institute, Cary, NC).

Results

Oleic Acid Attenuates 10,12 CLA-Mediated Inflammatory Gene Expression and Delipidation

In order to determine the extent to which 10,12 CLA-induced inflammatory gene expression was caused by inhibition of SCD-1-mediated MUFA synthesis [11, 12], we co-supplemented 10,12 CLA-treated primary human adipocytes with oleic acid. Oleic acid and 9,11 CLA alone had no effect on inflammatory gene expression (Fig. 1). Consistent with our hypothesis, 10,12 CLA-mediated increases in the expression of IL-6, IL-8, COX-2, and IL-1 β were decreased in a dose-dependent manner by co-supplementation with oleic acid (Fig. 1). However, oleic acid did not prevent 10,12 CLA-mediated activation of ERK, JNK, cJun, or I κ B α or increased abundance of ATF3 (data not shown). Given the decrease in the inflammatory response by oleic acid, we speculated that oleic acid would also attenuate 10,12 CLA-induced delipidation. Indeed, 10,12 CLA-mediated delipidation was a blocked by co-supplementation with oleic acid (Fig. 2). However, oleic acid did not prevent 10,12 CLA-mediated insulin resistance (data not shown).

Stearic Acid or 9,11 CLA Supplementation do not Attenuate 10,12 CLA-Mediated Inflammatory Gene Expression or Delipidation

In order to determine the specificity of oleic acid inhibition of inflammatory gene expression in 10,12 CLA-treated cultures, primary human adipocytes were co-supplemented with stearic acid, a substrate for SCD-1 and a precursor to oleic acid. Unlike oleic acid, stearic acid alone increased

the expression of IL-6, IL-8, and COX-2 (Fig. 3), consistent with the reported effects of saturated fatty acids on markers of inflammation (reviewed in [14]). Furthermore, stearic acid co-supplementation did not attenuate 10,12-mediated inflammatory gene expression (Fig. 3). In fact, the two highest levels of stearic acid exacerbated 10,12 CLA-mediated induction of inflammatory genes.

Because of the reported anti-inflammatory and anti-diabetic properties of 9,11 CLA [5], we co-supplemented 10,12 CLA-containing cultures with 9,11 CLA. Although 9,11 CLA alone did not increase inflammatory gene expression, its inclusion in the 10,12 CLA-treated cultures did not prevent 10,12 CLA-mediated inflammatory gene expression (Fig. 4) or delipidation (data not shown). These data demonstrate that the 9,11 CLA isomer does not directly prevent 10,12 CLA-mediated inflammatory gene expression or delipidation in vitro. Collectively, these data suggest that CLA-mediated inflammatory gene expression is due, in part, to lack of oleic acid, an abundant MUFA [11, 18] required by mammalian cells for the synthesis of phospholipids and neutral lipids.

Oleic Acid Influences the Effects of 10,12 CLA on GPR Expression

Free fatty acids activate FFA receptors, including G-protein-coupled receptors (GPCR) and GPR, that impact inflammatory signaling and metabolism (reviewed in [20]). Notably, activation of GPR120 has anti-inflammatory properties. Therefore, we examined the effects of 10,12 CLA in the absence and presence of oleic acid on the expression of several GPR expressed in adipocytes. Interestingly, 10,12 CLA decreased the expression of GPR120, but increased the expression of GPR56 and GPRC5A (Fig. 5a). Furthermore, the GPR40/120 agonist GW9508 attenuated 10,12 CLA-mediated increase of inflammatory gene expression and suppression of lipogenic gene expression (Fig. 5b). Intriguingly, oleic acid supplementation attenuated 10,12 CLA-mediated suppression of GPR120, and induction of GPRC5A (Fig. 5c), but not GPR56 (data not shown). Taken together, these data suggest that 10,12 CLA influences specific GPR that impact signaling pathways involved in inflammation and lipogenesis.

Discussion

Consistent with our hypothesis, oleic acid supplementation attenuated 10,12 CLA-induced inflammatory gene expression (Fig. 1) and delipidation (Fig. 2) in primary human adipocytes. In contrast, stearic acid, a substrate for SCD-1, or 9,11 CLA did not prevent 10,12 CLA-mediated increase

Fig. 1 Cultures of primary human adipocytes were treated without or with 30–300 μ M oleic acid (OA), 50 μ M 9,11 CLA, or 50 μ M 10,12 CLA for 12 h. Subsequently, mRNA levels of IL-8, IL-6, IL-1 β , COX-2, and GAPDH (load control) were measured using qPCR. Data were normalized to BSA vehicle controls (OA, 0, -CLA). Means \pm SE ($n = 3$ –4) not sharing a common superscript (a–e) are significantly different ($p < 0.05$). Data are representative of three independent experiments

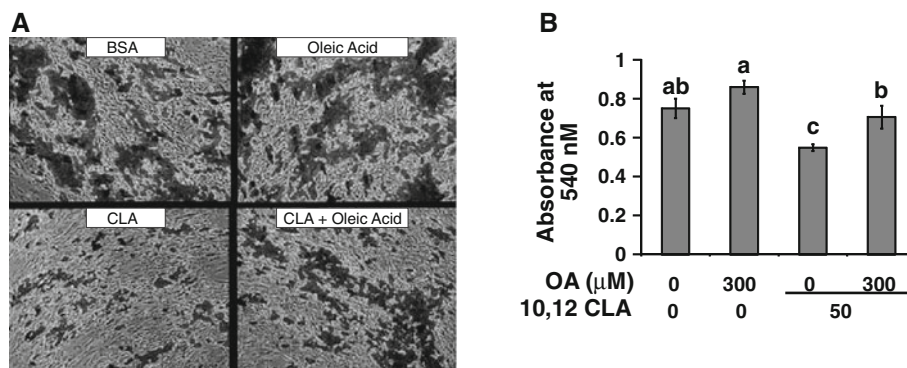

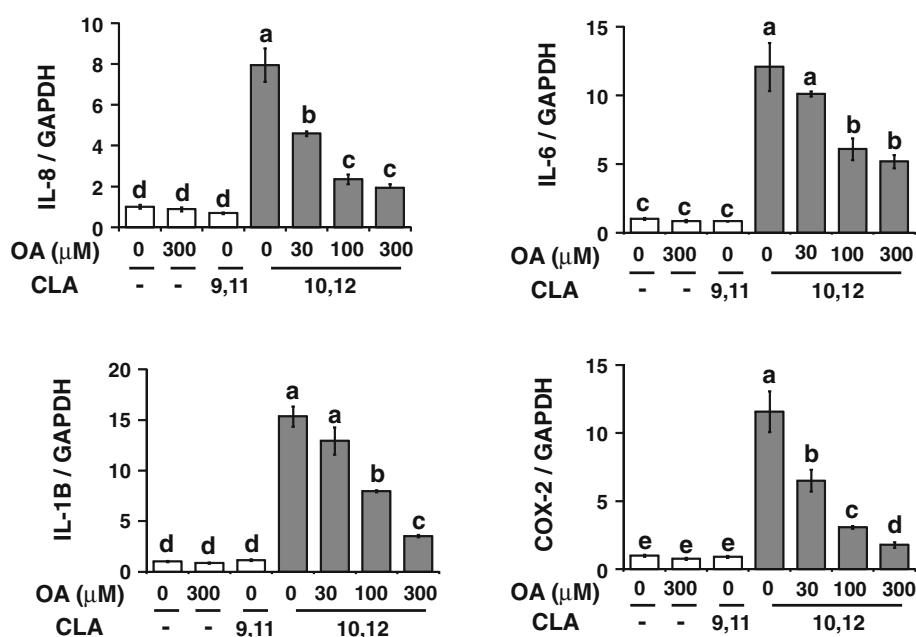

Fig. 2 Cultures of primary human adipocytes were treated without or with 300 μ M oleic acid (OA), 50 μ M 10,12 CLA, or BSA vehicle (0 OA, 0 CLA) for 7 days. Subsequently, **a** cultures were stained with oil red O and photographed using an Olympus inverted microscope

with a 20 \times objective and **b** the stain concentration was quantified. **b** Means \pm SE ($n = 3$) not sharing a common superscript (a–c) are significantly different ($p < 0.05$). Data are representative of two independent experiments

in inflammatory gene expression (Figs. 3, 4) or delipidation (data not shown). These data are consistent with our previous findings in primary human adipocytes showing that 10,12 CLA decreased (1) de novo lipid synthesis within 24–72 h, (2) the MUFA/saturated fatty acid ratio within 24 h, (3) the mRNA and protein levels of SCD-1 within 7 h in an isomer-specific fashion, and (4) the expression of LXR α and SREBP-1c within 5 h [12]. They are also consistent with data obtained from mice [8, 9], and murine [10, 21–23] or porcine [24] (pre)adipocytes, suggesting that 10,12 CLA rapidly reduces the abundance or activity of SCD-1. Collectively, these data suggest that by reducing the abundance or levels of lipogenic transcription factors that control SCD-1 (i.e., LXR α , SREBP-1c, PPAR γ), 10,12 CLA suppresses the synthesis of MUFA needed for phospholipid and neutral lipid synthesis, storage, or

metabolism. Such a scenario could conceivably cause cell stress that impairs the adipocyte's capacity to sequester, synthesize, and store lipids. Consistent with this hypothesis, we previously demonstrated that 10,12 CLA, but not 9,11 CLA, decreased de novo lipid synthesis of triglycerides (TG), FFA, diacylglycerol, cholesterol esters, cardiolipin, phospholipids, and ceramides in human adipocytes within 3–24 h [12].

Ntambi first proposed that 10,12 CLA-mediated inhibition of SCD-1 in mice [10, 21, 22] and in humans [23] is important for its anti-lipogenic effects. SCD-1 and diacylglycerol transferase-2 (DGAT2) have been shown to co-localize in the ER and be important for TG synthesis [25]. Dietary and endogenous palmitate (C16:0) and stearate (C18:0) are desaturated by SCD-1 and channeled to DGAT2 for the final step in TG synthesis in the ER. This

Fig. 3 Cultures of primary human adipocytes were treated without or with 10–100 μ M stearic acid (SA), 50 μ M 9,11 CLA, or 50 μ M 10,12 CLA for 12 h. Subsequently, mRNA levels of IL-8, IL-6, IL-1 β , COX-2, and GAPDH (load control) were measured using qPCR. Data were normalized to BSA vehicle controls (SA, 0, -CLA). Mean \pm SE ($n = 3$ –4) not sharing a common superscript (a–e) are significantly different ($p < 0.05$). Data are representative of two independent experiments

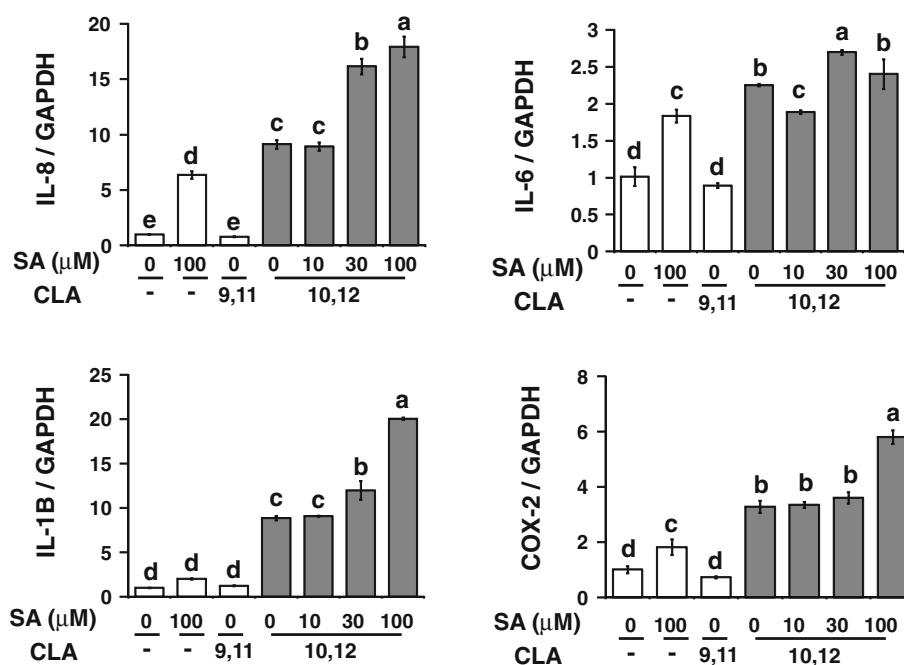

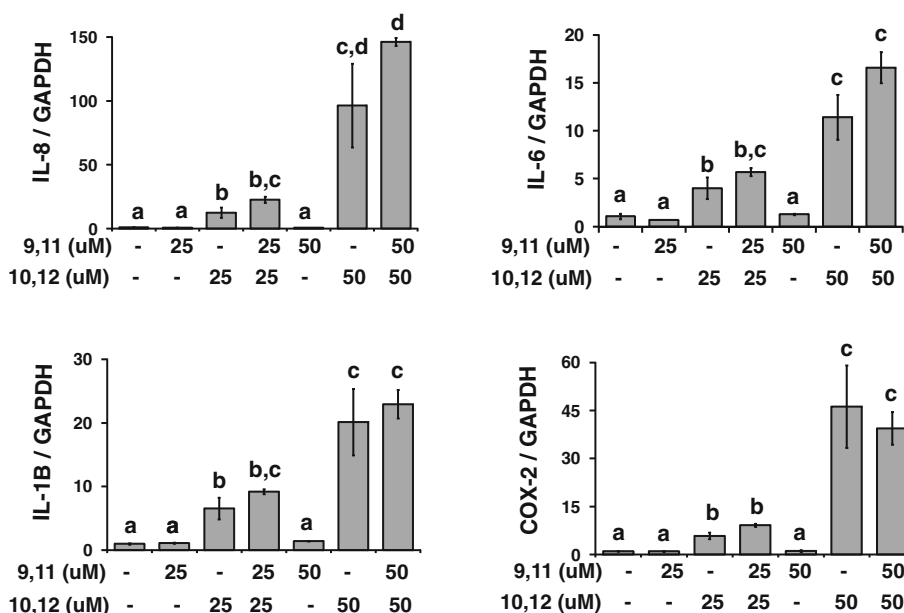

Fig. 4 Cultures of primary human adipocytes were treated without or with 25–50 μ M 9,11 CLA, or 10,12 CLA for 18 h. Subsequently, mRNA levels of IL-8, IL-6, IL-1 β , COX-2, and GAPDH (load control) were measured using qPCR. Data were normalized to BSA vehicle controls (–9,11, –10,12 CLA). close association between SCD-1 and DGAT2 enhances the efficiency of TG synthesis [25]. However, 10,12 CLA-mediated reduction in body fat mass was similar in SCD-1 knockout and wild type mice, suggesting that the reduction in adiposity by 10,12 CLA is independent of SCD-1 in mice [13]. Indeed, SCD-1 is not the only lipogenic gene suppressed by 10,12 CLA, given its antagonism of the key lipogenic transcription factors LXR α , SREBP-1c, and PPAR γ (reviewed in [7]).

We anticipated that, because oleic acid supplementation attenuated inflammatory gene expression, it would also

decrease the activation of upstream transcription factors and mitogen-activated protein kinases (MAPK) controlling the expression of these genes. However, 10,12 CLA-mediated activation of ERK, JNK, cJun, ATF3, and NF- κ B was not inhibited by oleic acid supplementation (data not shown). Reasons for this lack of inhibition of inflammatory transcription factors and MAPK are unclear, as we have previously shown that inhibiting 10,12 CLA-mediated activation of NF- κ B [26], cJun [27], ERK [15], and JNK [19] attenuates 10,12 CLA-mediated inflammatory gene expression. Perhaps 10,12 CLA's reported increase in the

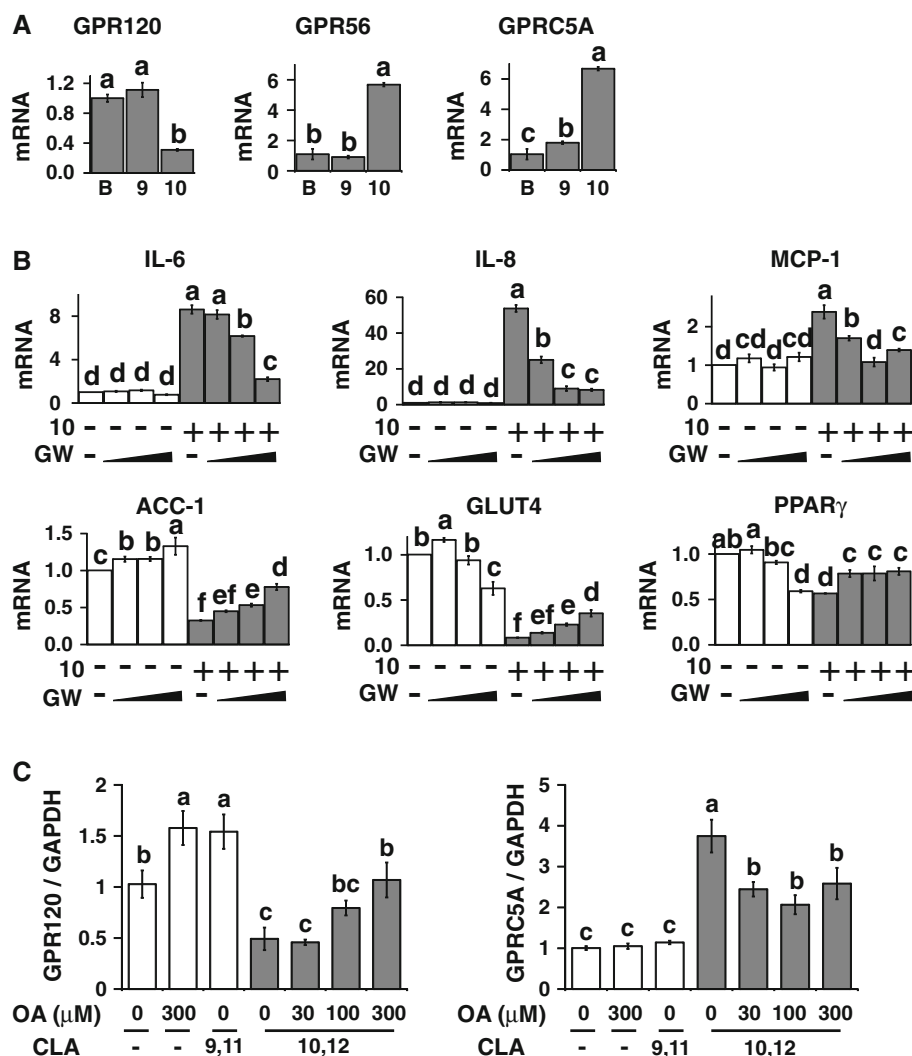

Fig. 5 Cultures of primary human adipocytes were treated without or with: **a** 50 μ M 9,11 CLA, 10,12 CLA, or BSA vehicle for 12 h; **b** 50 μ M 10,12 CLA or 1, 10, or 100 μ M GW9508 for 18 h; or **c** 30–300 μ M oleic acid (OA), 50 μ M 9,11 CLA, or 50 μ M 10,12 CLA for 12 h. Subsequently, mRNA levels of candidate genes were measured using

qPCR. Data were normalized to BSA vehicle controls. Means \pm SE ($n = 3$ –4) not sharing a common superscript (**a**–**f**) are significantly different ($p < 0.05$). Data are representative of at least two independent experiments

typical integrated stress response [28] or atypical ER stress response [29] contributes to the induction of inflammatory gene expression independent of NF- κ B, AP-1, or MAPK.

Alternatively, oleic acid may attenuate 10,12 CLA-mediated inflammatory gene expression by impacting specific GPCR or GPR that regulate inflammatory signaling and delipidation. GPR40, 84, 119, and 120 are classically activated by long chain FFA, and GPR41 and 43 by short chain FFA. Importantly, (1) cell surface, FFA receptors [30–32] and putative GPCR [33–35] activated by FFA impact on cell signaling, (2) CLA reduces FFA transport in tumors and white adipose tissue by activating specific GPCR [36, 37], (3) CLA increased pancreatic insulin release via islet GPR40 [38], and (4) we found that impairing coupling between GPCR and Gi/o with pertussis

toxin blocked 10,12 CLA's suppression of PPAR γ target gene expression and lipid metabolism in adipocytes [15].

Notably, long chain unsaturated FFA such as docosahexanoic acid activate GPR120, which is highly expressed in adipose tissue and contributes to their anti-inflammatory properties [30]. GPR120 also binds other mono- and polyunsaturated fatty acids including oleic acid [39]. Consistent with these data, we found that (1) oleic acid increased GPR120 expression (Fig. 5c), (2) 10,12 CLA decreased the expression of GPR120 (Fig. 5a,c), which was attenuated by supplementation with oleic acid (Fig. 5c), (3) the GPR40/120 agonist GW9508 attenuated 10,12 CLA-mediated inflammatory gene expression and suppression of lipogenic gene expression (Fig. 5b), (4) oleic acid supplementation inhibited 10,12 CLA-mediated suppression of

GPR120 (Fig. 5c), and (5) 10,12 CLA had no effect on the expression of GPR40 (data not shown), which had very low levels of expression in primary human adipocytes. These data suggest that 10,12 CLA's pro-inflammatory effects may be linked upstream to its inhibition of GPR120. Studies on the activity of GPR120 in cells treated with 10,12 CLA are needed to test this hypothesis.

We also measured the expression of GPR56 and GPRC5A, members of the non-classical adhesion [40] and tumor suppressor [41] families reported to be expressed in inflamed tissues [42], respectively, that we identified as CLA-induced candidates in a microarray assay (unpublished data). Indeed, 10,12 CLA increased the expression of GPRC5A and GPR56 (Fig. 5a), and oleic acid supplementation decrease this response for GPRC5A (Fig. 5c). Aside from the fact that these GPR are expressed in inflamed tissues, the physiological significance of these GPR findings in primary human adipocytes is unclear at this time.

Taken together, these data demonstrate that oleic acid supplementation attenuates 10,12 CLA-induced inflammatory gene expression and delipidation in primary human adipocytes, possibly by alleviating cell stress [28, 29] caused by the inhibition of SCD-1 [11, 12]. Our previous findings showed that 10,12 CLA rapidly reduces de novo lipid synthesis proceeded by inhibition of transcriptional regulators of lipogenesis and their downstream targets, including SCD-1 [12]. Therefore, we hypothesize that these changes impair MUFA synthesis needed for phospholipid and neutral lipid accumulation, thereby delipidating human adipocytes.

Of those with chronic infection, 20–30 % develop cirrhosis and hepatocellular carcinoma (HCC) [1]. Interferon (IFN)-based treatment regimens have been widely used, but these treatment regimens have side effects, require long-term therapy, and are expensive. Estimation of the effectiveness of IFN-based therapy prior to treatment would be beneficial.

The velocity of decrease in viral load during IFN-based therapy is a good indicator for the prediction of sustained virological response (SVR). High SVR rates are predicted by rapid virological response (RVR) and early virological response (EVR) [2, 3]. Although mechanisms of treatment failure are poorly understood, previous reports have proposed IFN-stimulated genes and the inability to develop effective anti-HCV immunity as possible explanations [4].

Recently, fatty acids have been implicated in the pathogenesis of several diseases associated with metabolic disorders (such as obesity, diabetes and cardiovascular disease) [5, 6] and in immunological response [7]. In liver diseases, especially in non-alcoholic steatohepatitis, the effect of impaired peroxisomal polyunsaturated fatty acid metabolism and nonenzymatic oxidation on fatty acid constitution is associated with disease progression [8]. It has been reported that HCV core protein has effects on fatty acid synthesis, and that fatty droplets in the liver are related to development of disease [9, 10]. Although there have been reports about the role of fatty acids in liver in patients with HCV [9, 10], the relationship between serum fatty acids and efficacy of IFN-based antiviral therapy against HCV remains controversial.

The aims of the present study were to evaluate whether the composition of serum fatty acids could predict RVR, EVR, or SVR from IFN-based therapy in patients with HCV. Data from HCV patients were collected and in-vitro assays were performed using HCV-replication cell culture systems.

Patients and Methods

Patients

Consecutive patients with HCV treated with IFN-based therapy at Ehime University Hospital were enrolled prospectively from December 2008 to December 2010. Moreover, 10 healthy volunteers (age range 26–70 years) were enrolled in this study as healthy subjects. This study was carried out in accordance with the Declaration of Helsinki, and the institutional review board of Ehime University Hospital approved this study (Approval # 0710004). Written informed consent was provided by study participants.

Patients with chronic HCV infection, with creatinine clearance >50 mL/min, and who had not been previously

treated with antiviral or immunosuppressive agents within the 3 months preceding enrollment were included. Patients with other liver disease such as autoimmune hepatitis, primary biliary cirrhosis, hepatitis B virus (HBV) infection, or HCC; co-infection with human immunodeficiency virus; poorly controlled cardiovascular, hematologic or pulmonary disease; pregnancy; autoimmune disease; severe depression or other psychiatric disorders; and/or active substance abuse were excluded. To exclude HBV infection, hepatitis B surface antigen (HBs-Ag) and anti-hepatitis B core (HBc) antibody were checked. Patients with positive HBs-Ag or a high titer of anti-HBc antibody were excluded.

Interferon and Ribavirin Combination Therapy

Patients received one of four treatment regimens: [1] pegylated interferon (PEG-IFN) α -2b 1.0 μ g/kg/week or 1.5 μ g/kg/week subcutaneously in combination with oral ribavirin (RBV) dosed by body weight (40–65 kg, 800 mg/day; >65–85 kg, 1,000 mg/day; >85–105 kg, 1,200 mg/day; >105–125 kg, 1,400 mg/day), [2] PEG-IFN α -2a 180 μ g/week subcutaneously plus oral RBV dosed as above, [3] PEG-IFN α -2a 180 μ g/week subcutaneously, or [4] IFN- β 600 million IU/day intravenously plus oral RBV dosed as above. In order to identify the levels of fatty acids that could have an important role in the response to treatment with IFN, all patients who had been treated with IFN were enrolled. After informing potential subjects about the costs, estimated adverse events, and effects of each treatment protocol according the Japanese guidelines for anti-HCV treatment [11], the required treatment regimen was chosen and treatment was started.

Laboratory Assessment

Patients' serum samples were collected around 6 a.m. after fasting on day 2 of the study before IFN-based treatment. Additionally, fasting serum was collected at the end of IFN-based treatment. Serum samples were frozen and stored at -80°C within 4 h of collection and then thawed at the time of measurement. Fatty acid concentrations in total serum lipids was measured with liquid chromatography (SRL Co. Ltd., Tokyo, Japan). Subjects were diagnosed as having dyslipidemia if they had TC ≥ 220 mg/dL, and/or HDL-c ≤ 40 mg/dL, and/or TG ≥ 150 mg/dL [12], and/or taking lipid-lowering agents.

The HCV genotype was determined by the polymerase chain reaction (PCR) using a mixed primer set derived from nucleotide sequences from the nonstructural-5 (NS5) region (SRL Co. Ltd.) [13]. HCV RNA was measured quantitatively before and during therapy using PCR (Cobas Amplicor HCV monitor v 2.0 using the tenfold dilution method, Roche Diagnostics, Mannheim, Germany). The

lower level of detection for this assay was less than 1.2 log₁₀ IU/mL. Undetectable serum HCV RNA on testing was considered a negative test. RVR was defined as undetectable serum HCV RNA within 4 weeks from the start of the treatment. EVR was defined as undetectable serum HCV RNA within 12 weeks from the start of the treatment. SVR was defined as undetectable serum HCV RNA within 24 weeks after the end of treatment.

The HCV genotype recovered from patients was determined using the Illumina Human610-quadrant BeadChip (Illumina, San Diego, CA, USA) as previously described [14, 15]. Amino acid substitutions of aa70 or aa91 in the core region of HCV genotype 1b were evaluated by agarose gel electrophoresis using mutation-specific primers for wild-type (aa70: arginine, aa91: leucine) and mutant (aa70: glutamine/histidine, aa91: methionine) viruses (SRL Co. Ltd.) [16]. In this study, the pattern of arginine (wild-type) at aa70 and leucine (wild-type) at aa91 was evaluated as double wild-type, while the other patterns were non-double wild-type. The nucleotide sequence of the interferon sensitivity-determining region (ISDR) in the HCV NS5A region was determined by direct sequencing through PCR-amplified materials [17]. Wild-type ISDR was defined as having no amino acid substitutions based on the HCV-J strain of genotype 1b.

Assay for Detecting Single Nucleotide Polymorphisms of Interleukin-28B (IL-28B)

Two single nucleotide polymorphisms of interleukin-28B (rs8099917 [14] and rs12979860 [15]) were examined using the TaqMan assay. The sequence of the probe and primers for the TaqMan assay for detecting rs8099917 was provided by Dr. Yasuhito Tanaka (Department of Virology and Liver Unit, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan), and rs12979860 was provided by Dr. David B. Goldstein (Center for Human Genome Variation, Duke University, Durham, NC, USA). Patient DNA was isolated from blood samples. For rs8099917 [14], homozygotes (T/T) were defined as having the IL-28B major allele, and heterozygotes (T/G) or homozygotes (G/G) were defined as having the minor allele. For rs12979860 [25], homozygotes (C/C) were defined as having the major allele, and heterozygotes (T/C) or homozygotes (T/T) were defined as having the minor allele.

Preparation of the In-Vitro Replication System

The human hepatoma cell lines Huh7 (Japanese Collection of Research Bioresources, Osaka, Japan) and Huh7.5.1 (provided by Dr. Francis V. Chisari; Department of Immunology and Microbial Science, The Scripps Research

Institute, La Jolla, CA, USA) were cultured with Dulbecco's modified Eagle's medium (DMEM) (Sigma Chemical, St. Louis, MO, USA) containing 10 % fetal bovine serum (Filtron PTY LTD, Brooklyn, Australia).

For the in-vitro assay of HCV genotype 1, the plasmid-based binary HCV replication system was used [18, 19], in which the plasmid contained the infectious full-length genotype 1a cDNA sequence corresponding to the H77 prototype strain with the T7 promoter sequence (pT7-flHCV-Rz, provided by Dr. Raymond T. Chung (Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA, USA)). pT7-flHCV-Rz cells were transfected to Huh7 cells by using Lipofectamine (Invitrogen, Carlsbad, CA, USA). Subsequently, the T7 polymerase was delivered by using a replication-defective adenovirus vector (Ad-T7pol) at a multiplicity of infection of 10.

For the in-vitro assay of HCV genotype 2, the HCV replication system pJFH1-full that encodes HCV genotype 2a JFH1 sequence was used, which was provided by Dr. Takaji Wakita (Department of Virology II, National Institute of Infectious Diseases, Tokyo, Japan) [20]. HCV RNA was synthesized using the Megascript T7 kit (Ambion, Austin, TX, USA), with the linearized pJFH1-full as template. After DNase I (Ambion) treatment, the transcribed HCV RNA was purified using ISOGEN-LS (Nippon Gene, Tokyo, Japan). For RNA transfection, Huh 7.5.1 cells were resuspended in Opti-MEM I (Invitrogen) containing 10 µg of HCV RNA and subjected to an electric pulse (960 µF and 260 V) using the Gene Pulser II apparatus (Bio-Rad, Richmond, CA, USA). After electroporation, the cell suspension was cultured under normal conditions with DMEM.

Evaluation of Effect of Palmitic Acid In Vitro

For the in-vitro assay, palmitic acid (Sigma Chemical), myristic acid (Sigma Chemical), stearic acid (Sigma Chemical), and oleic acid (Sigma Chemical), were solubilized in ethanol with albumin as a stock solution of 20 mM and stored at −20 °C, as described previously [21, 22]. These fatty acid-albumin complex solutions were freshly prepared before each experiment. Subsequently, preliminary experiments were performed using 10–500 µM solutions of fatty acids in order to assess the concentrations of fatty acids that would not compromise cell viability. Cell viability was not compromised when 10–100 µM fatty acids were used in the MTS assay (cytotoxicity assay using 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, CellTiter 96 Aqueous One Solution cell proliferation assay[®], Promega, Madison, WI) [18]; thus, 100 µM fatty acids were used for culture experiments. Fatty acids were added after the preparation of H77 and JFH1 HCV replication cells, and then IFN-α2b

(100 IU/mL) and RBV (50 μ M) were added to the culture medium of those cells. In the control samples, solubilized solutions were added without fatty acids.

Quantitative Real-Time Reverse-Transcription PCR

Cellular mRNA was extracted by TRIzol (Invitrogen), and levels of HCV replication were quantified by real-time reverse transcription-PCR with SYBR green I dye (Roche Diagnostics) and primers encoded for the 5'UTR of HCV using LightCycler technology (Roche Diagnostics) as described previously [18, 19]. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Roche Diagnostics) was detected using primer sets under the recommended conditions. Data are expressed as copy numbers of HCV RNA or cellular mRNA per molecule of GAPDH mRNA.

Statistical Analysis

Data are expressed as means \pm standard deviations or as means \pm standard errors of mean. The Wilcoxon test was used to analyze continuous variables. The Chi-square test was used for analysis of categorical data. Group comparisons involving more than two independent groups were performed using the Kruskal–Wallis test. Multivariate analysis was performed using a logistic regression model with stepwise method. The relationships between palmitic acid and the other parameters were analyzed with the Pearson product-moment correlation coefficient. Each cutoff point for continuous variables was decided by receiver operating characteristics (ROC) curve analysis. The RVR, EVR, and SVR rates of patients with low levels of palmitic acid were defined as positive predictive value (PPV) in the prediction of RVR, EVR, and SVR. Non-RVR, non-EVR, and non-SVR rates in patients with high levels of palmitic acid were defined as the negative predictive value (NPV) for prediction of non-RVR, non-EVR, and non-SVR. A *P* value of less than 0.05 was considered statistically significant. Statistical analyses were performed using JMP version 9 software (SAS Institute Japan, Tokyo, Japan).

Results

Patient Characteristics

A total of 55 patients with HCV were included. There were 27 men and 28 women. The mean age was 53.59 ± 11.15 years (range 22–69 years). The baseline characteristics of the study population are shown in Supplemental Table 1. Thirty-seven patients were infected with genotype 1 (all genotype 1b) and 18 patients with genotype 2

(14 with genotype 2a and four with genotype 2b). There was no significant difference between two groups in serum lipid composition (Table 1).

Response to Treatment

Among patients with genotype 1, 22 % (8/37) of patients received PEG-IFN α -2a plus RBV, 16 % (6/37) received PEG-IFN α -2a, 51 % (19/37) received PEG-IFN α -2b plus RBV, and 11 % (4/37) received IFN- β plus RBV. Among patients with genotype 2, 6 % (1/18) of patients received PEG-IFN α -2a plus RBV, 22 % (4/18) received PEG-IFN α -2a, 67 % (12/18) received PEG-IFN α -2b plus RBV, and 6 % (1/18) received IFN- β plus RBV.

RVR was achieved in 35 % (19/55) of patients overall. Twenty-seven percent (10/37) of patients with HCV genotype 1, and 50 % (9/18) with genotype 2 achieved RVR. EVR occurred in 64 % (35/55) of patients. EVR was achieved in 51 % (19/37) of patients with HCV genotype 1, and in 89 % (16/18) of patients with genotype 2.

For assessment of SVR, four patients dropped out of the treatment because of depression (2/4), general fatigue (3/4), and retinopathy (1/4). SVR was achieved in 69 % (35/51) of patients overall, in 56 % (19/34) of patients with HCV genotype 1, and in 94 % (16/17) of patients with genotype 2 evaluated by the above described protocol.

Predictors of Virological Response

Univariate analysis was performed for factors associated with RVR, EVR, and SVR (Supplemental Table 2). For RVR, a low serum triglyceride level was identified as a contributing factor. For EVR, low body mass index (BMI) and HCV genotype 2 were identified as contributing factors. For SVR, low BMI, total cholesterol, and HCV genotype 2 were identified as contributing factors. Further analysis was performed to examine the relationship of fatty acid levels to RVR, EVR, and SVR (Table 2). Table 2 shows the fatty acids significantly associated with virological response to IFN-based therapy by univariate analysis (*P* < 0.05). Other than the listed fatty acids, lauric acid, arachidic acid, behenic acid, lignoceric acid, myristoleic acid, eicosenoic acid, erucic acid, linoleic acid, γ -linolenic acid, arachidonic acid, and eicosapentaenoic acid were evaluated; however, those fatty acids were not significantly associated with any treatment response (RVR, EVR, or SVR). For RVR, low levels of myristic acid, palmitic acid, stearic acid, oleic acid, α -linolenic acid, eicosadienoic acid, adrenic acid, docosapentaenoic acid, and docosahexaenoic acid were identified as significant contributing factors. For EVR, palmitic acid and nervonic acid were identified as significant contributing factors. For SVR, myristic acid, palmitic acid, palmitoleic acid,

Table 1 Total serum lipid composition ($\mu\text{g/mL}$) in 55 patients infected with HCV

| Genotype | All ($n = 55$) | 1b ($n = 37$) | 2a or b ($n = 18$) | <i>P</i> value (1b vs. 2a, b) |

Values are expressed as means \pm standard deviation

P values were determined by the Wilcoxon test

nervonic acid, mead acid, dihomogamma-linoleic acid, and adrenic acid were identified as significant contributing factors. Only a low level of palmitic acid was found to contribute significantly to all of RVR, EVR, and SVR. In Table 2, the odds ratio for each fatty acid was near 1.0, because the range of palmitic acid was wide (from 370.8 to 955.9) compared to the value of the treatment effect of RVR, EVR, and SVR (from 0 to 1).

Multivariate logistic regression analysis was conducted in order to determine independent predictive variables associated with virological response. With regard to fatty acids, palmitic acid was selected for multivariate analysis because it was a significant factor for RVR, EVR, and SVR by univariate analysis. Palmitic acid concentration was found to be significantly correlated with total cholesterol, triglycerides, and 12 fatty acids by the Pearson product-moment correlation in patients with HCV (Supplemental Table 3). Moreover, the serum levels of palmitic acid were not different statistically by the regimen of IFN based

treatment ($554.2 \pm 96.4 \mu\text{g/mL}$ in PEG-IFN α -2a + RBV, $556.4 \pm 95.8 \mu\text{g/mL}$ in PEG-IFN α -2a, $643.6 \pm 140.7 \mu\text{g/mL}$ in PEG-IFN α -2b + RBV, and $658.3 \pm 209.4 \mu\text{g/mL}$ in IFN β + RBV).

For additional factors for multivariate analysis, seven factors were selected that had been identified in previous reports: age, gender, BMI, serum alanine aminotransferase, genotype, viral load, and a history of IFN therapy [23–26]. As a result of stepwise multivariate analysis, only low levels of palmitic acid and HCV genotype 2 were found to be significant contributing factors for RVR, EVR, and SVR (Table 3).

Evaluation of Palmitic Acid Level as a Predictor of Virological Response

ROC curves were constructed and areas under curves (AUC) were calculated (Table 4). A graph of the AUC for RVR, EVR, and SVR is shown in Supplemental Fig. 1. As

is seen in Table 4, AUC, cutoff value, sensitivity, specificity, PPV, NPV, and diagnostic accuracy of prediction in RVR were 0.79, 569.1 $\mu\text{g/mL}$, 73.68, 77.78, 63.64, 84.85, and 76.36 %, respectively; in EVR were 0.7, 586.7 $\mu\text{g/mL}$, 60, 80, 84, 53.33, and 67.27 %, respectively; and in SVR were 0.7, 587.7 $\mu\text{g/mL}$, 63.64, 77.78, 84, 53.84, and 68.63 %, respectively. Low levels of palmitic acid in RVR were associated with high specificity and NPV, while low levels of palmitic acid in EVR and SVR were associated high specificity and PPV.

Serum levels of palmitic acid in patients with HCV were significantly higher than those in healthy subjects (614.44 ± 138.03 vs. 480.67 ± 117.53 $\mu\text{g/mL}$, respectively, $P = 0.01$). Ninety-one percent (50/55) of patients with HCV had higher levels of palmitic acid compared to the mean level of palmitic acid in healthy subjects. Additionally, serum levels of palmitic acid were evaluated between patients with SVR and patients without SVR. The levels of palmitic acid were

significantly lower in patients with SVR compared to patients without SVR (554.3 ± 138.6 vs. 668.5 ± 183 $\mu\text{g/mL}$, respectively, $P = 0.01$).

Genetic Analysis

The relationship between palmitic acid and IL-28B polymorphism was investigated in the 37 patients with genotype 1 HCV infection. The level of palmitic acid was compared between major and minor polymorphisms. There were no significant differences between the two groups (Table 5). Amino acid substitution in the core region of HCV and mutated nucleotide sequence of ISDR were not associated with serum levels of palmitic acid (Table 5).

In patients with HCV genotype 1 infection, further analysis was performed in order to evaluate whether the level of palmitic acid could be a predictive factor of the efficacy of anti-HCV treatment. Univariate logistic

Data are given as means ± standard deviations

HCV hepatitis C virus, IL-28B interleukin-28B, ISDR interferon sensitivity-determining region, PCR polymerase chain reaction

P value was determined by the Wilcoxon test

^a For IL-28B, the major allele of rs8099917 was defined as TT, and the minor allele was defined as T/G or G/G. The major allele of rs12979860 was defined as C/C, and the minor allele was defined as T/C or T/T

^b Amino acid substitutions were evaluated in pretreatment serum by PCR with mutation-specific primers. Wild-type at aa 70 and wild-type at aa 91 were evaluated as double-wild-type, while the other patterns were considered non-double-wild-type

^c In ISDR, 0–1 was defined as having no amino acid substitutions or one substitution, ≥2 was defined as containing two or more amino acid substitutions

regression analysis was performed for IL-28B polymorphisms (rs8099917 and rs12979860), amino acid substitution in HCV core 70 and 91, mutated nucleotide sequence of ISDR, and palmitic acid level (Supplementary Table 4). Analysis revealed that palmitic acid level and the ISDR mutation could be significant predictive factors for RVR ($P = 0.03$ and $P = 0.02$, respectively). For EVR and SVR,

only the palmitic acid level was identified as a significant predictive factor ($P = 0.01$ for both EVR and SVR). Moreover, multivariate logistic regression analysis revealed that the level of palmitic acid was the only significant contributing factor for EVR (odds ratio = 0.988, 95 % confidence interval 0.979–0.996; $P = 0.01$); however, it was not a significant factor for RVR or SVR (Table 6).

Effect of Fatty Acids In Vitro

The effect of palmitic acid on HCV replication was assessed in vitro using transfected cultured cells expressing H77 (Fig. 1a) or JFH1 (Fig. 1b) HCV clones. In both cell lines, levels of HCV RNA were not altered with the addition of palmitic acid alone. However, anti-HCV effects of IFN and RBV were diminished by addition of palmitic acid ($P = 0.028$ and $P = 0.038$ for H77 and JFH1, respectively, by Wilcoxon test). Moreover, other saturated fatty acids (such as myristic acid and stearic acid) and unsaturated fatty acids (such as oleic acid) were assessed. Myristic acid, stearic acid, and oleic acid did not affect HCV replication, and did not alter the treatment effect of IFN and RBV (Supplementary Fig. 2A, 2B).

Discussion

The present study suggests that low serum levels of palmitic acid could be a predictive factor for virological response to IFN-based therapy in both HCV genotype 1 and 2 infections. In addition, it was also suggested that palmitic acid impairs the anti-HCV effects of IFN and RBV in vitro.

Several studies have shown that HCV core protein disrupts fatty acid homeostasis [9, 26]. HCV core protein has been shown to significantly increase the proportion of C18:1 fatty acids (such as oleic and vaccenic acids), but not palmitic acid, in the livers of patients with HCV infection [9, 10]. Irmisch et al. [27] compared fatty acids in serum of patients with untreated chronic HCV infection with those in treated patients and healthy controls. They showed that

Table 6 Factors associated with virological response to interferon-based therapy in patients with genotype 1 identified by multivariate analysis

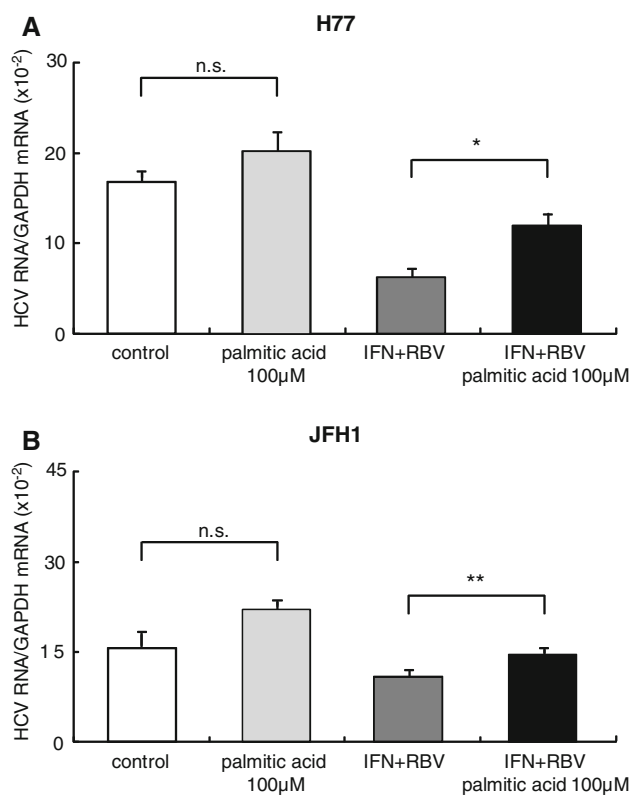

Fig. 1 Effects of palmitic acid on in-vitro viral replication and activity of interferon- α plus ribavirin. Levels of HCV RNA were measured after adding interferon- α (IFN- α) and ribavirin (RBV) with or without 100 μ M palmitic acid. H77 plasmid-based replication (HCV genotype 1a) (a). JFH1 HCV replication system (HCV genotype 2a) (b). * $P = 0.028$. ** $P = 0.038$. Data are mean \pm standard error of the mean (SEM) of six independent experiments. The Wilcoxon test was used to analyze the data. $P < 0.05$ was considered statistically significant. ns not significant

women who responded to treatment and healthy controls had significantly higher levels of eicosapentaenoic and arachidonic acid than did untreated HCV patients. There was no significant difference in palmitic acid among the three groups [27]. However, the study did not use

pretreatment serum of treated HCV patients and was not a comparison between treated HCV patients who responded to anti-HCV therapy and those who did not. The study compared patients who responded to anti-HCV treatment and untreated patients (including patients who would have responded to anti-HCV treatment if they had received it).

Kapadia et al. and Leu et al. [21, 22] found that both an increase in saturated fatty acids, including palmitic acid, and an increase in monounsaturated fatty acids enhanced HCV replication, whereas increases in polyunsaturated fatty acids such as arachidonic acid suppressed HCV replication in vitro. Huang et al. [28] showed that arachidonic acid inhibited HCV replication by increasing lipid peroxidation, resulting in a decrease in the amount of HCV RNA. In addition, Leu et al. [22] showed that when arachidonic acid was added to IFN- α , a strong synergistic anti-HCV effect was observed in vitro; however, the mechanism of this effect is not well understood.

In the present study, it was found that the concentration of arachidonic acid in the serum of patients infected with HCV was not associated with a change in the effect of IFN-based therapy (data not shown). In fact, the quantity of HCV RNA did not correlate significantly with concentrations of any fatty acids, including palmitic acid, in the serum of HCV patients (data not shown). The present in-vitro data obtained with HCV cell culture systems also indicated that there is no association between saturated fatty acids (including palmitic acid and unsaturated acids such as oleic acid) and HCV replication. However, in this in-vitro system, palmitic acid had an inhibitory effect on IFN-based therapy against HCV. These clinical and in vivo results indicate that inhibitory effects of palmitic acid against IFN-based therapy may be direct effects on hepatocytes.

Another potential explanation for the decreased effect of IFN-based therapy associated with palmitic acid would be the inability of patients to develop effective anti-HCV immunity [29]. It was previously been reported that

palmitic acid can induce inflammation and impair the antigen-specific function of dendritic cells (DC) in humans and mice [7]. These conditions might be comparable to chronic HCV infection. Function of DC is impaired in HCV infection [30, 31]. High levels of palmitic acid might further impair the function of DC, reducing anti-HCV immunity. Further studies are needed to identify the mechanisms underlying the effects of palmitic acid, including immunomodulatory effects.

Multiple factors have been reported to be associated with a poor response to IFN-based treatment. Viral factors [including HCV genotype, quantity of HCV RNA, nucleotide sequence of ISDR, and amino acid substitutions in the core region (core aa70 and aa91)] have been shown to affect response to IFN-based therapy [17, 23, 24, 32–34]. On the host side, older age, male gender, obesity, insulin resistance or metabolic syndrome, low density lipoprotein, race, and either steatosis or advanced fibrosis on liver biopsy have all been reported as factors associated with poor response to IFN-based therapy [24–26, 33, 34]. Recently, IL-28B polymorphism has received attention as a potential factor affecting response to therapy [14].

Based on the present results, previously reported factors that have been shown to influence the effect of IFN therapy were not associated with the level of palmitic acid. Based on the results of univariate and multivariate analyses, the level of palmitic acid was a significant independent predictive factor of response to IFN-based therapy in patients with HCV genotypes 1 and 2. However, a validation study with a larger number of patients with HCV is needed.

In conclusion, this study is the first to report that the serum level of palmitic acid could be a pretreatment predictive factor of virological response with IFN-based therapy in patients with HCV infection. According to the present findings, pretreatment serum concentration of palmitic acid could be used to select patients more likely to respond to IFN-based therapy. It is possible that a special diet or drugs that lower levels of palmitic acid might improve response to IFN-based therapy in patients with HCV infection.

Acknowledgments This work was supported in part by a Grant-in-Aid for Scientific Research [JSPS KAKENHI 23700907 to T.M.; JSPS KAKENHI 21590848 to Y.H.] from the Japanese Ministry of Education, Culture, Sports, Science and Technology, and a Grant-in-Aid for Scientific Research and Development from the Japanese Ministry of Health, Labor and Welfare to Y.H. We thank Ms. Satomi Yamanaka, Ms. Chie Matsugi and Ms. Sakiko Inoh for excellent technical assistance. The sequence of the probe and primers for the TaqMan assay for detecting rs8099917 was kindly provided by Dr. Yasuhito Tanaka (Department of Virology and Liver Unit, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan), and rs12979860 was provided by Dr. David B. Goldstein (Center for Human Genome Variation, Duke University, Durham, NC, USA). The HCV replication system with pJFH1-full was kindly provided by Dr. Takaji Wakita (Department of Virology

II, National Institute of Infectious Diseases, Tokyo, Japan), and that with pT7-flHCV-Rz was provided by Dr. Raymond T. Chung (Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA, USA). We also thank Dr. Francis V. Chisari (Department of Immunology and Microbial Science, The Scripps Research Institute, La Jolla, CA, USA) for providing the Huh7.5.1 human cancer cell lines.

concentrations compared to a diet high in polyunsaturated fatty acids (PUFA) [1–8]. As circulating levels of cholesterol are related to heart disease, including elevated levels of LDL, the ability to reduce plasma cholesterol levels with dietary intervention has been the focus of many studies over the past few decades.

Dietary cholesterol can play a role in modulating plasma cholesterol levels. An increase in dietary cholesterol often leads to an increase in plasma cholesterol levels [9, 10]. The impact of dietary cholesterol on plasma cholesterol levels begin with its uptake by enterocytes of the small intestine. Intraluminal cholesterol, dietary as well as biliary cholesterol, is solubilized into micelles containing fatty acids, phospholipids, and monoacylglycerols. The micelles cross the unstirred water layer where they are taken up by protein-mediated processes, i.e. NPC1L1, or passively diffuse into the enterocytes. These chylomicrons reach the systemic circulation where smaller chylomicron remnants are produced which are then taken up by the liver by way of the LDL receptor-related protein (LRP). As most chylomicron remnants are taken up by the liver, a majority of diet-derived cholesterol is taken up by the liver. The diet-derived hepatic cholesterol can then be stored as cholesteryl ester, utilized for cellular maintenance and regulatory processes, or be secreted back into the circulation as VLDL. Circulating VLDL is converted to LDL within the circulation after lipase hydrolysis of core triacylglycerols. The LDL particles are cleared primarily via the LDL receptor [11]. HDL is formed in the circulation as the result of apo AI-mediated efflux of cholesterol from cells with some HDL secreted from the intestine [12, 13]. HDL-cholesterol also can be obtained from VLDL after transfer of ester by way of cholesteryl ester transfer protein (CETP). HDL is taken up by a number of tissues, including the liver and steroidogenic tissues via SR-BI [14]. Various intraluminal factors influence cholesterol absorption, independent of genetic effects on cholesterol transporters. For example, a change in luminal bile acid concentrations and composition can affect cholesterol absorption by altering micellar formation [15–19]. Indeed, we showed that humans given a cholic acid supplement had increased intraluminal bile acid concentrations and consequently more cholesterol carried in non-vesicles, likely micelles [20]. We further showed that cholesterol is absorbed when carried in micelles and not vesicles [21]. A high fat diet also enhances cholesterol absorption, possibly by increasing substrates for micellar formation [22].

Though the relationship between the amount of dietary fat consumed and cholesterol absorption is well known, the effect of dietary fatty acid composition on cholesterol absorption in humans is uncertain. The impact of different fatty acids on cholesterol absorption can be several-fold. First, fatty acids could theoretically affect micellar

formation. Dietary SFA could remain relatively insoluble, making poor micelles, and/or cholesterol could partition into the undigested lipid. Either effect would result in reduced absorption or reduced plasma lipid levels with SFA, which seems unlikely. In addition, dietary fatty acids can affect expression of genes involved in processes of cholesterol absorption. The PPARs are known mediators of dietary PUFA, as they are activated by PUFA [23]. Recent studies have shown that PPAR α can enhance cholesterol absorption by way of NPC1L1 [24].

Though some studies using human subjects have shown a decrease in absorption of cholesterol with diets enriched in PUFA versus SFA [9, 10, 22], the studies have either used indirect measurements of cholesterol absorption (plant sterols), sterol balance measurements, or used non-physiological diets, i.e. liquid diets or diet that contain extremely large amounts of cholesterol. Thus, the purpose of the current study was to directly measure cholesterol absorption using stable isotopes in humans fed a solid diet. Cholesterol fractional synthetic rates were also measured as these will often be inversely affected by cholesterol absorption. As verification of results, plant sterol and cholesterol biosynthetic intermediate levels were measured as well, as was intraluminal levels of micelles and/or vesicles.

Subjects and Methods

Subjects

The study was a randomized cross over study and healthy adult males and females of any race ($n = 20$), ages 18–40 were recruited by advertisement at the University of Cincinnati, College of Medicine and the Cincinnati Children's Hospital Medical Center (CCHMC). The protocol was approved by the Institutional Review Board of CCHMC as well as the Scientific Advisory Committee of the General Clinical Research Center (GCRC) of CCHMC, Cincinnati, OH, USA (Protocol number #2008-0298). Subjects were screened for any evidence of cardiovascular, pulmonary, renal, gastrointestinal, hepatobiliary diseases or soy allergy and excluded if any conditions were found. Subjects with diabetes mellitus, chronic usage of any medication including oral contraceptives and plasma total and LDL cholesterol exceeding 200 and 120 mg/dl, respectively, were also excluded. Only subjects with Apo AIV 1/1 and Apo E 3/3 genotypes were enrolled in order to reduce the genotypic influence. Apo E and AIV gene expressions could affect cholesterol absorption and account for inter-individual variation in total serum cholesterol concentrations [10, 25, 26]. Females were non-pregnant and not planning pregnancy during the course of the study.

Experimental Design

After fulfillment of inclusion/exclusion criteria and a complete verbal explanation of the study, subjects signed the consent form. Subjects provided a 3-day diet diary. Based upon caloric intakes from the diet diary, total calories required to maintain steady body weight were estimated and diet menus were made on a 3 day rotating schedule. During the study, subjects consumed a diet consisting of P/S ratio of 2:1 or a similar diet with a P/S ratio of 0.5:1. The dietary compositions for the two experimental diets are shown in Table 1. Subjects were randomized to diet using a random number table and stratified by age (<30, ≥30) because of perceived differences in metabolic rates between these age groups. At baseline (day 0) physical examination was performed on the subjects and blood drawn for measuring plasma TAG, total, LDL and HDL cholesterol concentrations. Subjects visited the center daily or every third day to pick up prepared diets which were frozen after preparation. Diets were prepared by the research dietitian on the GCRC at the CCHMC. During each week of the study period, subjects' body weights were obtained to ensure maintenance of basal weight. Subjects were advised not to eat anything other

than the foods provided. Subjects were also instructed to follow the dietary instructions such as eating all the meals on time and to maintain their physical activity to be same throughout the study. No alcohol was permitted during the whole study period. During and at the end (day 14 and 19, respectively) of each phase, fasting blood samples were collected for analysis and urine for pregnancy testing for females.

After 2 weeks on the diet (day 14), fasting blood samples were collected from study subjects for analysis. Plasma was separated for measuring TAG, as well as total, LDL and HDL cholesterol concentration measurements. 2 days later (day 16) subjects were provided with an intravenous injection of 15 mg [25,26,26,26,27,27,27-D₇] cholesterol and a 75-mg oral dose of [3,4-¹³C] cholesterol for cholesterol absorption analysis according to the method of Bosner et al. [27], as originally proposed by Zilversmit [28] and as described previously [29]. The ratio of ingested 3,4-¹³C cholesterol to injected 25,26,26,26,27,27,27-D₇ cholesterol enrichment in red blood cells (RBC) cholesterol after 48, and 72 h was taken as an indicator of the cholesterol fractional absorption rate. Cholesterol synthesis rates were also measured using the deuterium incorporation approach. On day 19, after an overnight fast, baseline blood was drawn for RBC cholesterol isotope measurement. Subjects were given oral deuterated water, and the next day (day 20) blood was obtained at the same time as the isotope administration on day 19. On completion of first dietary period, subjects participated in the alternative arm of the study after a washout period of at least 4 weeks. Thereafter, the same sequence of events was performed as described for the first phase of the study.

Table 1 Composition of the experimental diets

| Composition | Low P/S | High P/S |
|------------------------------|---------|----------|
| Proteins (g/100 kcal) | 5.04 | 4.94 |
| Carbohydrates (g/100 kcal) | 12.56 | 12.59 |
| Fats (g/100 kcal) | 3.28 | 3.32 |
| Cholesterol (mg/100 kcal) | 15.05 | 12.05 |
| Fatty acids (g/100 g of fat) | | |
| 6:0 | 0.07 | 0.10 |
| 8:0 | 0.11 | 0.10 |
| 10:0 | 0.21 | 0.15 |
| 12:0 | 0.21 | 0.30 |
| 14:0 | 1.82 | 0.94 |
| 16:0 | 22.15 | 19.77 |
| 18:0 | 10.43 | 8.48 |
| 20:0 | 0.04 | 0.05 |
| 16:1 | 2.85 | 1.82 |

| PUFA (g/100 kcal) | 0.56 | 1.14 |
| MUFA (g/100 kcal) | 1.37 | 1.29 |

P/S polyunsaturated/saturated fatty acids, SFA saturated fatty acids, PUFA polyunsaturated fatty acids, MUFA monounsaturated fatty acids

Plasma Lipid Concentrations

Blood samples after collection were centrifuged at 1,500 rpm for 15 min to separate RBC and plasma. Separated aliquots were immediately stored at −80 °C until analysis. Plasma total and HDL cholesterol and TAG concentrations were measured enzymatically by Quest Diagnostics Nichols Institute, a certified Center for Disease Control (CDC) Lipid Research Clinic.

Desmosterol and lathosterol levels were measured in plasma as markers for cholesterol synthesis and campesterol and β-sitosterol levels were measured as cholesterol absorption markers [30]. Sterol concentrations were determined by gas liquid chromatography (GLC), as described by Ntanios and Jones [31], using 5α-cholestane (Sigma-Aldrich Canada Ltd, Oakville, ON, Canada) as an internal standard. Briefly, after saponification, non-saponified materials were extracted and derivatized with TMSi reagent [pyridine-hexamethyl disilazantrimethyl chlorosilane (9:3:1,

vol:vol)] [32]. Sterols were identified using known standards (Sigma-Aldrich Canada Ltd, Oakville, ON, Canada).

Cholesterol Absorption

Free cholesterol was extracted from RBC according to established methods [33]. ^{13}C cholesterol enrichments in RBC lipid extracts were determined using on-line gas chromatography/combustion/isotope ratio mass spectrometry approach (Agilent 6890N chromatograph interfaced with a Finnigan Delta V Pulse isotope ratio mass spectrometer (Bremen, Germany)). Isotope abundance, expressed in delta (d) per mil (‰), was calculated using CO_2 as a reference gas and further corrected against the international reference standard, Pee Dee Belemnite limestone. The measurement of free-cholesterol deuterium enrichment was performed using online gas chromatography/pyrolysis/isotope ratio mass spectrometry and expressed relative to standard mean ocean water and a series of standards of known enrichment. Isotope abundance, expressed in d ‰, was calculated using H_2 as reference gas. The average ^{13}C and D_7 enrichments of 48 and 72 h RBC free cholesterol relative to baseline samples were used to calculate the cholesterol absorption coefficient using the ratio of orally ingested ^{13}C cholesterol to intravenously administered D_7 cholesterol as described by Bosner et al. [27] and by us [29].

Cholesterol Fractional Synthetic Rate

Cholesterol synthesis rates were assessed after 24 h of deuterium water administration using the deuterium incorporation approach [34] as described before [29]. This method measures cholesterol synthesis as the rate of deuterium incorporation from body water into RBC membrane free cholesterol over a 24 h period. Deuterium enrichment was measured in both RBC free cholesterol and plasma water as described above. Enrichments were expressed relative to standard mean ocean water using a calibration curve of working standards. FSR is taken to represent RBC free-cholesterol deuterium enrichment values relative to the corresponding mean plasma water sample enrichment after correcting for the free-cholesterol pool. FSR represents that fraction of the cholesterol pool that is synthesized in 24 h and is calculated as per the equation [34].

Intraluminal Cholesterol Solubilization

After blood collection on day 14, duodenal aspirates were collected and treated as described [29]. Topical anesthesia was applied to the nose and throat, and sedation was used with intravenous midazolam if subjects wished. A nasoduodenal tube was placed with fluoroscopic guidance with

the tube tip placed at the ligament of Trietz, and 12–20 ml of duodenal drainage was collected by siphonage for 15 min (–15 to 0 time). Subjects then ingested a meal consisting of olive oil, egg and egg white, sucrose, vanilla extract and 0.15 M NaCl in 240 ml water [29]. Duodenal drainage was collected in 15 min intervals for 90 min and then one 30 min interval. Anti-microbial and anti-bacterial compounds were added as samples were collected. After completion of collection periods, 0.5 ml aliquots were saved to measure lipids in luminal contents and remaining 12–15 ml separated into the subphase. The subphase was separated into vesicles and non-vesicles by size-exclusion column chromatography as described [35]. Cholesterol was measured directly in the total and subphase intraluminal contents by GLC; the ratio of subphase to total cholesterol was considered solubilized cholesterol. Cholesterol was also measured in the fractions from the size exclusion columns mostly by GLC. Vesicular cholesterol was that which came off the column in the void volume and non-vesicular cholesterol, including micellar cholesterol, was that which was eluted from the column after the initial vesicular fraction.

Apolipoprotein Genotypes

DNA from peripheral blood was isolated according to instructions provided in the High Pure PCR Template Preparation Kit (Boehringer Mannheim, Indianapolis, IN, USA). ApoE and ApoA-IV genotypes were determined as described by earlier [36, 37].

Statistical Analysis

Results were expressed as means \pm SEM obtained from ANOVA using the root mean square error to estimate the pooled standard error. End point variables were tested for statistical significance by student's t test and repeated measures ANOVA with $p < 0.05$. The correlations among plasma lipid profile, cholesterol absorption and synthesis, cholesterol precursors, sterols and their ratios were analyzed using Pearson correlations. All statistical measures were analyzed using Statistical Package for the Social Sciences (SPSS) version 10.0.

Results

Seventeen subjects (8 males and 9 females) with an average of 26.5 ± 3.6 years of age, 70.9 ± 16.6 kg and BMI of 24.3 ± 3.3 kg/m² (Table 2) started the study of which 16 completed both phases of study. Fifteen Caucasians and one African subject participated. One subject withdrew from the study after completing first phase which was a

Table 2 Baseline characteristics of subjects

| Variables | Subjects (<i>n</i> = 17) |
|--------------------------------------|---------------------------|
| Age (years) | 26.47 ± 3.57 |
| Body weight (kg) | 70.89 ± 16.65 |
| Height (cm) | 169.63 ± 13.01 |
| Body mass index (kg/m ²) | 24.3 ± 3.27 |
| Total cholesterol (mg/dl) | 163.4 ± 26.5 |
| LDL (mg/dl) | 95.1 ± 21.9 |
| HDL (mg/dl) | 51.0 ± 19.47 |
| Triglycerides (mg/dl) | 89.0 ± 34.6 |

high ratio P/S diet due to personal reasons and not related to the study. No adverse events were recorded during the study due to the diet.

No significant changes were observed in body weights when comparing both between the phases and between the baseline and end points of each phase. Plasma total cholesterol ($P = 0.015$) and LDL-cholesterol ($P = 0.014$) concentrations were reduced as early as 14 days of consumption of a diet with a high P/S ratio (Table 3). By day 19 of the study, a further reduction in total ($P = 0.011$) and LDL-cholesterol concentrations ($P = 0.003$) occurred such that total cholesterol was reduced $\approx 8\%$ and LDL-cholesterol was reduced $\approx 12\%$ (Table 3). No impact of diet on HDL-cholesterol or TAG concentrations was observed at either time point after diet consumption.

No significant difference was found in fractional cholesterol absorption determined by dual stable isotope kinetics measurement (Fig. 1). Cholesterol absorption markers including β -sitosterol and campesterol showed no significant changes in their concentrations as well their ratios with cholesterol in plasma between high and low P/S ratio diet phases (Table 4). In parallel with results, there was no difference in the solubilized cholesterol in the

Values are expressed as means ± SEM (*n* = 10)

lumen of the subjects containing either diet (Fig. 2a). As might be expected, the percentage of non-vesicular cholesterol also remained similar between all subjects (Fig. 2b).

No apparent change was seen in cholesterol absorption, or fractional synthetic rate of cholesterol with different dietary fatty acid composition (Fig. 3). Indirect measures of cholesterol synthesis, plasma cholesterol precursor levels, i.e. desmosterol and lathosterol, failed to significantly differ between groups (Table 5).

Discussion

Our results confirm that diets consisting of greater P/S ratios had reduced plasma cholesterol concentrations, specifically LDL-cholesterol [3, 5, 38–40]. Importantly, our results specifically show that the decrease in LDL-cholesterol levels was not due to an effect of dietary fatty acid composition on cholesterol absorption or synthetic rate. Support for these results was confirmed by indirect

Table 3 Lipid profile of subjects during and after consuming a high or low P/S ratio diet

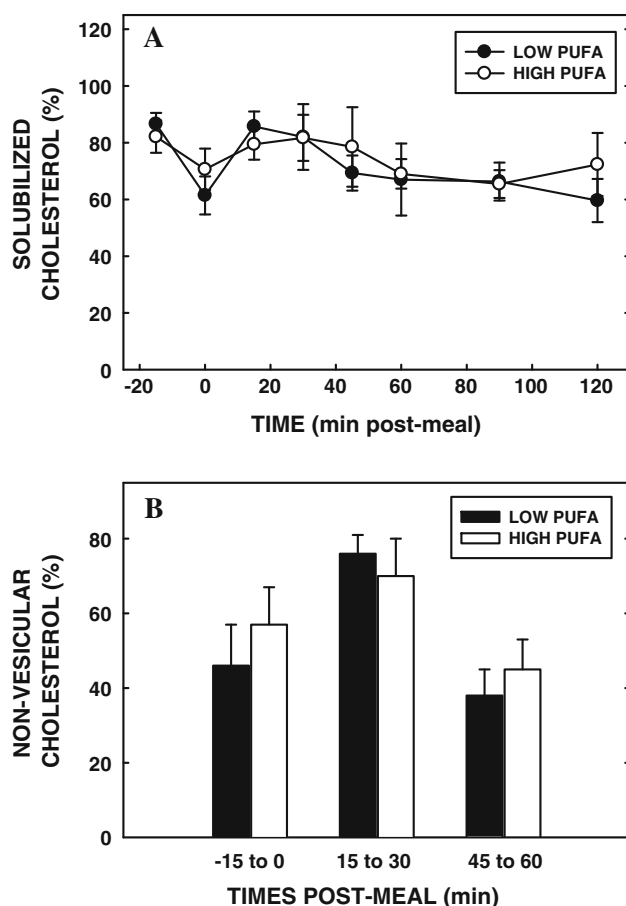

Fig. 2 The amount of cholesterol solubilized in the aqueous fraction (subphase) of the luminal samples of subjects fed low or high PUFA diets. After an overnight fast, a naso-duodenal tube was placed at the ligament of Trietz and 15–20 ml of luminal sample collected. Subjects consumed a liquid meal as described in the study design section of the Research Plan, and samples collected from the lumen every 15 min for 2 h and then for 30 min. Samples were spun to separate the subphase from total contents. The amount of cholesterol in the total and subphase was measured by GLC and amount solubilized shown (a). The percentages of total cholesterol present as non-vesicular cholesterol in the subphase at –15 to 0, 15 to 30, and 45 to 60 min post-meal are shown (b). Data are presented as means \pm SEM ($n = 16$)

measurements of cholesterol trafficking. Specifically, the extent of non-vesicular cholesterol, likely present as micelles, was the same in lumens of subjects on either diet. As cholesterol needs to be packaged into micelles prior to absorption [21], it is not surprising that cholesterol absorption was not different. Likewise, circulating plant sterol concentrations were similar, an indication of similar cholesterol absorption [30]. For cholesterol synthesis, cholesterol biosynthetic precursors in the circulation were similar as well [30].

Until now, the relationship between dietary fat composition and cholesterol absorption in humans has remained unclear since methods used included different indirect

absorption measurements, variably controlled subject populations, and variations in dietary cholesterol. Unlike our study, in which dietary cholesterol was rigorously controlled, subjects were normolipemic, subjects from specific apo E genotypes, and cholesterol absorption measured by the dual isotope method; most previous studies were much less carefully controlled using state-of-the-art methods at the time of publication. McNamara et al. [9] evaluated the effect of a dietary cholesterol challenge within diets containing either saturated or polyunsaturated fat. Fractional cholesterol absorption was not affected by the P/S ratio, regardless of amount of cholesterol fed. Grundy and Ahrens directly compared cholesterol absorption in subjects given SFA versus high P/S diets containing relatively high levels of dietary cholesterol and observed no differences in fractional cholesterol absorption and marked variability [41]. Using a cross over design, Wood et al. [22] studied the effect of liquid formula containing dietary fat as predominantly saturated or unsaturated fat plus high levels of cholesterol in five normolipidemic adults and found decreased cholesterol absorption when subjects received diets containing predominantly unsaturated fat. Finally, Miettinen et al. discovered that cholesterol absorption decreased when changing from a diet relatively high in cholesterol and fat (38 % calories) with mostly saturated fat ($P/S = 0.28$) to one with half as much cholesterol and less fat (24 % calories) with a higher P/S

ratio (0.72). Even though there was less amount of fat and cholesterol in the diet, impact of changes with dietary fat composition on cholesterol was very large [10].

A number of additional studies have been completed in which sterol synthesis was measured. As reduced cholesterol absorption will lead to increased sterol synthesis, these studies could also help delineate the effect of dietary fatty acid on cholesterol absorption. Interestingly, a number of studies found that the fractional synthetic rate for cholesterol was higher in subjects fed PUFA-containing diets compared to baseline diets or diets containing high SFA [40, 42–45]. If PUFA only affected absorption, these studies would suggest that PUFA affected cholesterol absorption in subjects of these other studies. However, other variables exist that can lead to a separation of the two processes. For example, different fatty acids can have direct impact upon metabolism. Likewise, some of these studies used hypercholesterolemic or obese subjects. In support of our absorption data, we detected no differences in cholesterol synthesis by stable isotope or by cholesterol biosynthetic intermediate concentrations.

Cholesterol absorption measurements have also been carried out in various animal models. Studies in rats and rabbits have shown that dietary PUFA either increased or decreased cholesterol absorption [46–48]. Mott et al. showed cholesterol absorption to be similar in baboons fed diets containing either saturated or unsaturated fat independent of cholesterol content [49, 50], whereas Tanaka and Portman [51] showed that PUFA versus SFA-enriched diets lead to increased cholesterol absorption in squirrel monkeys. Part of the differences in the various models are likely due to variations in cholesterol metabolism [50], making the current studies important and relevant as they were completed in humans.

Even though there was no effect on cholesterol absorption in the current studies, plasma cholesterol concentrations were still reduced in subjects consuming a greater P/S ratio. Over the years, several different processes have been shown to be affected by dietary PUFA. Daumerie et al. [52] demonstrated a reduction in hepatic LDL receptor activity and elevated LDL cholesterol production rate in hamsters fed with a SFA-enriched diet compared to one enriched in PUFA or MUFA, ultimately leading to increased plasma LDL-cholesterol concentrations [52–54]. Perhaps SFA have a greater effect on increasing plasma cholesterol versus the impact of PUFA on decreasing plasma cholesterol levels, depending on the baseline or comparison. This is actually supported by equations devised by Keys et al. [55] and Hegsted et al. [2] and more recently by Etherton and colleagues [56] that gives a relative change in plasma cholesterol based on the nature of the fat fed. Other effects of lipids on metabolism might also occur. In addition, high PUFA containing diets

lead to reduced activities of lipogenic enzymes such as phosphatidase, phosphohydrolase and diacylglycerol acyl-transferase compared with low PUFA containing olive oil and thereby decrease serum lipid concentrations [57]. Consumption of a diet with high P/S ratio also increases postprandial fat oxidation [42, 58]. Thus, some of these non-absorptive effects of PUFA must have played a role in the reduction of plasma cholesterol when higher P/S diets are fed to normocholesterolemic subjects.

In conclusion, consumption of a high P/S ratio diet did not affect cholesterol absorption or synthesis in normolipidemic subjects, despite a decrease in total and LDL cholesterol concentrations. Results indicate that high P/S diets alter lipids through mechanisms other than cholesterol absorption and synthesis in normolipidemic subjects.

Acknowledgments We thank YenMing Chan, Richardson Centre for Functional Foods and Nutraceuticals, and Dr. Scot Harding, adjunct professor, Department of Human Nutritional Sciences, University of Manitoba for their help with the analytical part of the study. We also thank Suzanne Summer and the staff of the Body Composition Core of the General Clinical Research Center for their help with dietary management for the study. We were also supported by the National Institute of Health RR 08084 and DK 068463.

Conflict of interest No authors have any conflict of interest with the current study.

of them related to cardiac or cerebral ischemia [1]. In most cases, atherosclerosis is the pathology behind cardiovascular complications. Atherosclerosis is a complex systemic disorder with a progressive development involving various cell types [2]. Among them, vascular smooth muscle cells (VSMC) play important roles throughout the slow progression of the pathology. Indeed, VSMC migration and proliferation from the media toward the intima of the vessel wall contribute to stable plaque development. They also synthesize extracellular matrix proteins, part of building blocks of a thick fibrous cap. In advanced lesions, VSMC apoptosis favors plaque instability by thinning the fibrous cap, increasing thereby risks of plaque rupture and thrombosis [3, 4].

Among risk factors of CVD, type 2 diabetes (T2D) has become a widespread concern. The American Centers for Disease Control and Prevention have approximated in the 2011 National Diabetes Fact Sheet that 25.8-million people, 8.3 % of the population in USA, were affected by diabetes in 2010 [5]. A major cardiovascular complication of T2D is an accelerated process of atherosclerosis pathogenesis, associated with metabolic syndrome and insulin resistance [6]. Hyperinsulinemia and a high plasma level of free fatty acids (FFA) are well known characteristics of these conditions. While hyperinsulinemia affects the proliferation, migration and contractility of VSMC [7–9], it is recognized that FFA at high concentration, and according to their nature, can play various roles on VSMC functions.

Saturated fatty acids (SFA) are present in high proportion in the Western diet, associated with increased risk of developing CVD [10, 11]. Many studies have demonstrated that SFA have a negative impact on different cell types, principally by inducing apoptosis. Indeed, it has been reported that SFA such as palmitic or stearic acids cause higher level of apoptosis in VSMC [12, 13], but also in endothelial cells [14, 15], hepatocytes [16], β -cells [17, 18] and cardiomyocytes [19, 20]. On the other hand, monounsaturated fatty acids (MUFA), which are more abundant in the Mediterranean diet, are recognized for their protective impact against CVD [21–23]. MUFA such as palmitoleic or oleic acids can reduce the impact of SFA on apoptosis [13, 15, 16]. It has also been demonstrated in different studies that oleic acid (OLA) promotes VSMC proliferation and migration [24–26]. Thus, OLA seems to have an important protective role in late stages of atherosclerosis, by preventing plaque thinning.

Most of these studies were performed with individual FFA or with a combination of two, but rarely with complex mixes, although dietary fatty acids are composed of a group of FFA rather than being limited to one or two of them. Therefore, the role of FFA on VSMC apoptosis when they are combined in groups of various proportions is still unclear. In one of our previous studies, we found that

VSMC apoptosis level was higher when cells were treated with adipocyte supernatants isolated from male mice fed with a high-fat diet from animal origin richer in SFA (named AD, for animal diet) than when treated with adipocyte supernatants from male mice fed with a high-fat diet from vegetal origin richer in MUFA (named VD, for vegetal diet) [27]. This level was further increased when adipocytes were stimulated with a high dose of insulin (unpublished data). With these results in mind, we hypothesized that in a hyperinsulinemic state, a combination of synthetic FFA with a higher proportion of SFA (hSFA) would induce more elevated VSMC apoptosis rates than a combination of FFA with a higher proportion of MUFA (hMUFA).

Thus, this work aims to assess the impact of these two FFA combinations, derived from both diets in our previous studies, on the proliferation and apoptosis of VSMC in the presence or not of a high insulin dose. The two combinations tested contain the same FFA but in different proportions. Our results show that the FFA combinations have a pro-apoptotic impact on VSMC, principally due to SFA. The presence of OLA in these combinations reduces VSMC apoptosis rates induced by SFA, even more than when OLA was alone. Such an effect was modulated by the FFA ratios and the presence or not of a high insulin dose. In the presence of a competition between pro- and anti-apoptotic mechanisms, these results suggest that the relative concentration of each FFA in a combination (SFA vs. MUFA) is as important as their total concentrations to determine their impact on VSMC functions.

Materials and Methods

Cell Isolation and Culture

VSMC were isolated from the aortas of 10-week old male mice C57BL/6 (Charles River, Montreal, Canada) using a method modified from Ray et al. [28]. Briefly, mice were euthanized by a ketamine/xylazine mix and full length aortas, from aortic arch to kidneys, were extracted. Freshly isolated aortas were dissected into 2–3 mm pieces and digested with type II collagenase (Invitrogen, Carlsbad, CA, USA) for 5 h at 37 °C, 5 % CO₂. The digested aortas were then washed twice by centrifugation for 5 min at 300×g to remove all traces of collagenase. The obtained VSMC were put in culture to be amplified in Dulbecco's Modified Eagle Medium (DMEM) low glucose (Invitrogen), 1 % penicillin–streptomycin (Invitrogen), 10 % fetal bovine serum (FBS) (PAA Laboratories, Pasching, Austria), 0.5 ng/ml EGF and 2 ng/ml FGF-basic (Pepro-Tech, Rocky Hill, NJ, USA), at 37 °C, 5 % CO₂. The smooth muscle cell phenotype was confirmed by a positive

staining for alpha smooth muscle actin (rabbit monoclonal antibody, ab32575, 1:400) and for SM-22 α (rabbit polyclonal antibody, ab14106, 1:100) (Abcam, Cambridge, MA, USA), both specific markers of smooth muscle cells. Positive stains were visualized by immunofluorescence with a confocal microscope (LSM510) and analysed with a Zeiss LSM Image Browser System (Zeiss, Toronto, Canada). Cells at passage 4 or 5 were used throughout this study. All animal procedures in this protocol (#2010-59-1) were approved by the Animal Ethics Committee of the Montreal Heart Institute.

Fatty Acid Preparation and VSMC Stimulations

Palmitic [C16:0, PAM], palmitoleic [C16:1n-7, PAL], stearic [C18:0, STA], oleic [C18:1n-9, OLA], linolenic [C18:3n-3, ALA] and arachidonic [C20:4n-6, ARA] acids (Sigma-Aldrich, St. Louis, MO, USA) were dissolved at 50 mM in 80 °C water containing a 10 % excess of NaOH 1 N (55 mM). After dissolution, each free fatty acid (FFA) was immediately added to a 20 % fatty acid-free bovine serum albumin (FA-free BSA) (PAA Laboratories) solution that has been pre-heated at 45 °C to obtain 10 mM FFA stock solutions with a molar ratio of 3.3:1 FFA/BSA. The FFA-BSA complexes were stirred at 45 °C until complete dissolution, filter sterilized and stored in aliquots at –20 °C until usage. For VSMC stimulations, cells were treated whether with a combination of FFA at a final concentration of 900 μ M or with individual FFA at the concentration found in each combination. The two combinations used contained the same mix of fatty acids but at different ratios and were derived from diets with fat of animal origin (AD, D12492, Research Diets, New Brunswick, NJ, USA) and vegetal origin (VD, D06061202, Research Diets) used in our previous studies [27]. The concentrations of each FFA present in both combinations are shown in Table 1. For the control condition, cells were treated with a BSA solution without FFA. The VSMC stimulations were done for 24 or 72 h, depending on the measured parameter, in the presence or not of 1 nM insulin (Sigma) in 1 % FBS DMEM medium.

Proliferation Assays by Manual Counts

The effects of fatty acid combinations and insulin on proliferation were evaluated by manual cell counts. VSMC were plated into 24-well culture plates at a seeding density of 1×10^4 cells/well and allowed to grow for 24 h. After an overnight starvation in a 0.1 % FBS DMEM medium and 72 h of stimulation with the fatty acid combinations, with or without insulin, cells in each well were trypsinized and re-suspended in 100 μ l of 20 % FBS DMEM medium for cell count. Live and dead cells were counted by Trypan

Table 1 Molar ratios of the two fatty acid combinations

| Fatty acid (μ M/900 μ M) | hSFA combination | hMUFA combination |
|-----------------------------------|------------------|-------------------|
| C16:0 PAM | 244 | 135 |
| C16:1n-7 PAL | 39 | 1.8 |
| C18:0 STA | 139 | 106 |
| C18:1n-9 OLA | 443 | 650 |
| C18:3n-3 ALA | 18 | 8.1 |
| C20:4n-6 ARA | 17.1 | 0 |
| Total SFA | 383 | 241 |
| Total MUFA <i>cis</i> | 482 | 652 |
| Total PUFA <i>cis</i> | 35.1 | 8.1 |

PAM palmitic acid, PAL palmitoleic acid, STA stearic acid, OLA oleic acid, ALA alpha-linolenic acid, ARA arachidonic acid, SFA saturated fatty acids, MUFA monounsaturated fatty acids, PUFA polyunsaturated fatty acids

blue stain (Invitrogen) exclusion with a hemocytometer under a phase-contrast microscope.

Apoptosis Induction as Measured by Caspase-3 Assays

To determine the level of apoptotic VSMC, cells were seeded in a black 96-well plate with a clear flat bottom (Corning Inc., Corning, NY, USA) at 2.6×10^4 cells/well and stimulated for 24 h with the fatty acid combinations or with individual FFA, with or without insulin. Caspase-3 activity was evaluated with the Apo-ONE Homogeneous Caspase 3/7 Assay Kit (Promega, Madison, WI, USA), according to the manufacturer's instructions. After 2 to 4 h of incubation, the activity was measured on a microplate reader (Synergy 2 Multi-Mode, Biotek, Winooski, VT, USA) at 520 nm, the fluorescent emission wavelength of the substrate cleaved by caspase-3.

Cell Cycle Analysis by Flow Cytometry

To determine the impact of fatty acid combinations and insulin on cell cycle phase modulation, VSMC were plated into 6-well plates at a seeding density of 4×10^4 cells/well and stimulated for 24 h as mentioned above. After trypsinization and washing in PBS-BSA 0.5 %, cells were permeabilized with 0.1 % saponin in PBS for 10 min and then fixed in a 1:1 acetone/methanol mix at –20 °C for another 10 min. For DNA staining, after 3 washing steps, 50 μ g/ml propidium iodide (Sigma) in PBS-BSA 0.5 % containing 5 μ g/ml of ribonuclease A (Sigma) was added to cells for 30 min. Following 2 washing steps, cell cycle phases were evaluated on a flow cytometer with a 488-nm wavelength argon laser (Coulter EPICS XL, Beckman Coulter, Brea, CA, USA) and analyzed with the Weasel software (Walter and Eliza Hall Institute of Medical

Research, Parkville, Australia). Data are presented as the percentage of cells in each phase of cell cycle.

Statistical Analysis

In all experiments, data are expressed as means \pm SEM and each group of data was compared using one-way ANOVA with Tukey–Kramer or Dunnett multiple comparison tests. The Tukey–Kramer comparison test was used to compare groups of data between themselves, while the Dunnett comparison test was used to compare each testing group to the control group. Data from Figs. 1 (hSFA vs. hMUFA), 2 (hSFA vs. hMUFA), 3 (hSFA vs. hMUFA), 4 (vs. PAM or STA) and 5 (vs. PAM + 0 μ M OLA or STA + 0 μ M OLA) were analyzed with Tukey–Kramer test whereas data from Figs. 1 (vs. BSA controls), 2 (vs. BSA controls), 3 (vs. BSA controls), 4 (vs. hSFA or hMUFA combinations) and 5 (vs. OLA alone) were evaluated with the Dunnett test. A $P < 0.05$ was considered statistically significant.

Results

Fatty Acid Combinations Inhibit VSMC Proliferation

A 72-h treatment with either hSFA or hMUFA FFA combination at 900 μ M decreased by 35–40 % the number of cells when compared to BSA alone (Fig. 1). This decrease was significant for hSFA and hMUFA when combined with a 1 nM insulin stimulation (hSFA: $18,587 \pm 1,575$ cells/well and hMUFA: $17,810 \pm 720$ cells/well vs. BSA: $30,175 \pm 2,200$ cells/well, $P < 0.0001$) whereas in absence

Fig. 1 Effect of fatty acid combinations on VSMC proliferation. Cells were stimulated for 72 h with either hSFA or hMUFA fatty acid combinations at 900 μ M, in the presence or not of 1 nM insulin. Cell proliferation was evaluated by manual counts. Data are means \pm SEM and represent the number of cells per well of a culture plate ($n = 7$). * $P < 0.05$ versus BSA. ††† $P < 0.001$ versus BSA I

of insulin, it was significant only for hMUFA (hMUFA: $16,413 \pm 1,446$ cells/well vs. BSA: $25,143 \pm 3,024$ cells/well, $P = 0.0285$).

Both hSFA and hMUFA FFA combinations cause the induction of apoptosis of VSMC. The observed inhibition of proliferation was related to an enhanced apoptosis rate. Indeed, a 24-h treatment with both FFA combinations at 900 μ M significantly increased caspase-3 activity compared to BSA control condition (hSFA: 2.90 ± 0.21 -fold, hMUFA: 3.00 ± 0.24 -fold vs. BSA without insulin, $P < 0.0001$; Fig. 2a and hSFA: 2.73 ± 0.25 -fold, hMUFA: 3.65 ± 0.17 -fold vs. BSA with insulin, $P < 0.0001$; Fig. 2b). While caspase-3 activity was the same between

Cells were treated for 24 h with either hSFA or hMUFA fatty acid combinations at 900 μ M in the absence (a) or presence (b) of a co-treatment with 1 nM insulin. The induction of apoptosis was measured by caspase-3 activity. Data are means \pm SEM and represent the relative caspase-3 activity (fold-increase) compared to BSA controls ($n = 4$). *** $P < 0.001$ versus BSA, ††† $P < 0.001$ versus BSA I, ‡ $P < 0.05$ hSFA I versus hMUFA I

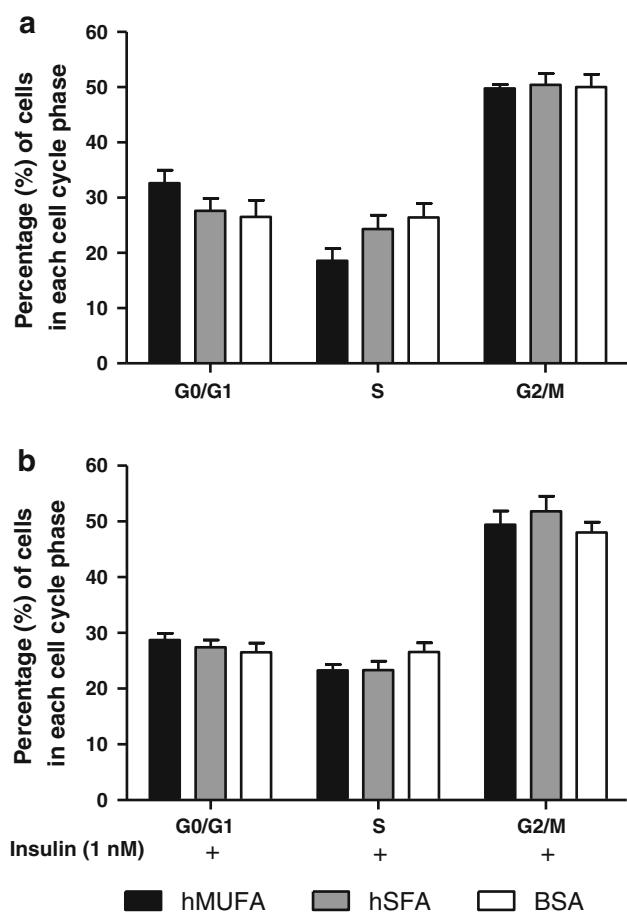

Fig. 3 Influence of fatty acid combinations on the modulation of VSMC cell cycle phases. Cells were treated for 24 h with either hSFA or hMUFA fatty acid combinations at 900 μ M in the absence (a) or presence (b) of a co-treatment with 1 nM insulin. Cell cycle modulation was evaluated by flow cytometry with a PI staining. Data are means \pm SEM and are expressed as the percentage of cells in each cell cycle phase ($n = 4$). The black bars represent the hMUFA combination, the gray bars are for the hSFA combination and the white bars for BSA

hSFA and hMUFA stimulations in absence of insulin, a co-treatment with 1 nM insulin increased it for hMUFA compared to hSFA ($P = 0.0220$; Fig. 2b). Since this difference between the two FFA combinations was not observed in the inhibition of proliferation (Fig. 1), the increased level of apoptotic VSMC with hMUFA stimulation combined with insulin may be due to a blockage in a cell cycle phase. However, analysis of PI stained cells by flow cytometry revealed no significant difference in the cell cycle phases between stimulations with hSFA and hMUFA FFA combinations in absence or presence of insulin (Fig. 3a and b). Therefore, enhanced apoptosis following VSMC stimulation with the hMUFA FFA combination in the presence of insulin was not related to a cell cycle blockage.

Saturated Fatty Acids are the Main Inducers of Apoptosis in hSFA and hMUFA Combinations

To investigate the contribution to apoptosis induction of the different FFA, VSMC were also stimulated with each single fatty acid for 24 h at the same concentration as the one found either in hSFA or in hMUFA combinations (Table 1). Caspase-3 activity was mainly induced by palmitic (PAM) and stearic (STA) acids, both SFA, at the concentrations found in hSFA (PAM: 75 ± 5 RFU, $P < 0.01$ vs. PAL and ARA, $P < 0.001$ vs. ALA), (STA: 86 ± 5 RFU, $P < 0.05$ vs. OLA, $P < 0.001$ vs. PAL, ALA and ARA) when compared with caspase-3 activity caused by MUFA and polyunsaturated fatty acids (PUFA) (OLA: 52 ± 8 RFU, PAL: 27 ± 7 RFU, ALA: 2 ± 10 RFU, ARA: 20 ± 8 RFU) (Fig. 4a). Similar results were demonstrated at the concentrations found in hMUFA (PAM: 116 ± 15 RFU, $P < 0.001$ vs. OLA: 29 ± 2 RFU, PAL: 0 ± 10 RFU and ALA: -4 ± 6 RFU), (STA: 168 ± 2 RFU, $P < 0.001$ vs. OLA, PAL and ALA) (Fig. 4b). When stimulations with individual FFA were combined with 1 nM insulin, a similar pattern was obtained for concentrations present in hSFA (PAM: 120 ± 3 RFU, $P < 0.01$ vs. PAL: 60 ± 13 RFU, $P < 0.001$ vs. OLA: 33 ± 4 RFU, ALA: 26 ± 2 RFU and ARA: 25 ± 14 RFU), (STA: 141 ± 6 RFU, $P < 0.001$ vs. OLA, PAL, ALA and ARA) (Fig. 4c) and hMUFA (PAM: 131 ± 5 RFU, $P < 0.001$ vs. OLA: 20 ± 2 RFU, PAL: 0.33 ± 1.20 RFU and ALA: 29 ± 7 RFU), (STA: 145 ± 5 RFU, $P < 0.001$ vs. OLA, PAL and ALA) (Fig. 4d).

Saturated Fatty Acids Alone Induce Higher Caspase-3 Activity than When Combined in hSFA and hMUFA

SFA induced much higher apoptosis at concentrations found in both hSFA and hMUFA when added alone to the culture media than when mixed in the combinations. PAM induced a 6.8-fold-increase (75 ± 5 RFU), STA a 7.9-fold-increase (86 ± 5 RFU) and, interestingly, the MUFA OLA a 4.8-fold-increase (52 ± 8 RFU) in caspase-3 activity compared to the hSFA combination (11 ± 2 RFU, $P < 0.001$ vs. PAM and STA, $P < 0.05$ vs. OLA; Fig. 4a). In contrast, apoptosis was increased by 16-fold with PAM (116 ± 15 RFU) and by 23-fold with STA (168 ± 2 RFU) compared to the hMUFA combination (7.3 ± 0.3 RFU, $P < 0.001$; Fig. 4b). In presence of 1 nM insulin, similar results were obtained at hSFA concentrations for PAM (7.1-fold-increase, 120 ± 3 RFU) and for STA (8.3-fold-increase, 141 ± 6 RFU) compared to the hSFA combination (17 ± 0.6 RFU, $P < 0.01$), but not significant with OLA stimulation (1.9-fold-increase, 33 ± 4 RFU vs. hSFA combination) (Fig. 4c). A similar pattern was induced with single FFA at hMUFA concentrations (PAM: 20-fold-increase,

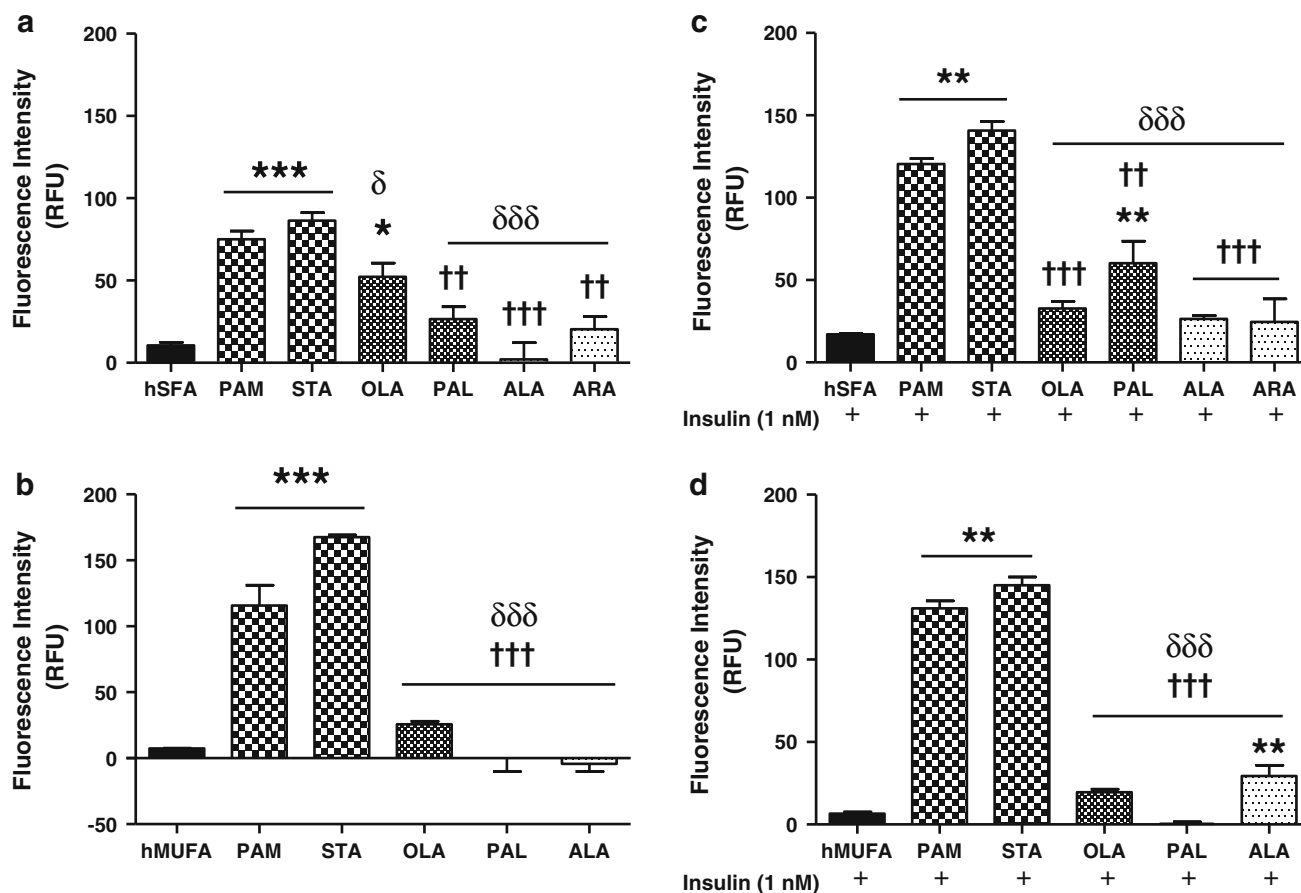

Fig. 4 PAM and STA are the main inducers of VSMC apoptosis in the fatty acid combinations. Cells were stimulated for 24 h with individual fatty acids present in the combinations found in hSFA combination (**a, c**) or hMUFA combination (**b, d**) in the absence (**a, b**) or presence (**c, d**) of a co-treatment with 1 nM insulin. The induction of apoptosis was measured by caspase-3 activity. Data are means \pm SEM (BSA control values for each fatty acid were subtracted) and represent the relative fluorescence intensity

(RFU) of the product of Z-DEVD-R110 substrate, cleaved by the active caspase-3 into its R110 fluorescent form ($n = 3$). The black bars represent hSFA or hMUFA combination, the bars with a large grid are for SFA, those with a small grid for MUFA and the dotted bars are for PUFA. * $P < 0.05$, ** $P < 0.01$ and *** $P < 0.001$ versus hSFA or hMUFA combination. †† $P < 0.01$ and ††† $P < 0.001$ versus PAM, $\delta P < 0.05$ and $\delta\delta\delta P < 0.001$ versus STA

131 \pm 5 RFU and STA: 22-fold-increase, 145 \pm 5 RFU) compared to the hMUFA combination (6.7 \pm 0.9 RFU, $P < 0.01$; Fig. 4d).

OLA Attenuates the Impact of Saturated Fatty Acids on the Apoptosis Level in a Dose-Dependent Manner

VSMC were stimulated for 24 h with PAM or STA at the same concentrations as those in hSFA and hMUFA combinations. These stimulations were made alone or combined with increasing doses of OLA until reaching the concentration of this fatty acid in hSFA (443 μ M) or hMUFA (650 μ M). OLA reduces the impact of SFA on caspase-3 activity in a dose-dependent manner at both hSFA and hMUFA concentrations. At hSFA concentrations of SFA, OLA, at the two highest doses tested, significantly attenuated the effect of PAM (PAM 244 μ M + OLA

225 μ M: 49 \pm 9 RFU, +OLA 443 μ M: 35 \pm 1 RFU vs. PAM 244 μ M: 106 \pm 5 RFU, $P < 0.05$; Fig. 5a) and at all doses tested for STA (STA 139 μ M + OLA 50 μ M: 79 \pm 3 RFU, +OLA 100 μ M: 77 \pm 12 RFU, +OLA 225 μ M: 62 \pm 12 RFU, +OLA 443 μ M: 44 \pm 10 RFU vs. STA 139 μ M: 137 \pm 5 RFU, $P < 0.01$; Fig. 5a). When combined with SFA at hMUFA concentrations, all doses of OLA significantly attenuated the level of apoptosis for both PAM and STA (PAM 135 μ M + OLA 50 μ M: 45 \pm 9 RFU, +OLA 100 μ M: 40 \pm 4 RFU, +OLA 225 μ M: 34 \pm 1 RFU, +OLA 443 μ M: 30 \pm 1 RFU, +OLA 650 μ M: 27 \pm 2 RFU vs. PAM 135 μ M: 152 \pm 15 RFU, $P < 0.001$) (STA 106 μ M + OLA 50 μ M: 65 \pm 1 RFU, +OLA 100 μ M: 49 \pm 6 RFU, +OLA 225 μ M: 38 \pm 1 RFU, +OLA 443 μ M: 31 \pm 2 RFU, +OLA 650 μ M: 32 \pm 0.3 RFU vs. STA 106 μ M: 207 \pm 2 RFU, $P < 0.001$) (Fig. 5b).

With a 1 nM insulin co-treatment, the reducing effect of OLA on PAM at hSFA concentration was significant for all doses (PAM 244 μ M + OLA 50 μ M: 48 ± 7 RFU, +OLA 100 μ M: 32 ± 2 RFU, +OLA 225 μ M: 30 ± 1 RFU, +OLA 443 μ M: 24 ± 2 RFU vs. PAM 244 μ M: 150 ± 3 RFU, $P < 0.01$; Fig. 5c) and, as already observed without insulin, on STA too (STA 139 μ M + OLA 50 μ M: 68 ± 9 RFU, +OLA 100 μ M: 41 ± 4 RFU, +OLA 225 μ M: 33 ± 1 RFU, +OLA 443 μ M: 31 ± 2 vs. STA 139 μ M: 178 ± 6 RFU, $P < 0.01$; Fig. 5c). At hMUFA concentrations in presence of insulin, OLA maintained its capacity to reduce SFA-induced caspase-3 activity (PAM 135 μ M + OLA 50 μ M: 53 ± 4 RFU, +OLA 100 μ M: 43 ± 2 RFU, +OLA 225 μ M: 40 ± 0.3 RFU, +OLA 443 μ M: 34 ± 1 RFU, +OLA 650 μ M:

32 ± 1 RFU vs. PAM 135 μ M: 174 ± 5 RFU, $P < 0.01$) (STA 106 μ M + OLA 50 μ M: 48 ± 1 RFU, +OLA 100 μ M: 42 ± 1 RFU, +OLA 225 μ M: 40 ± 2 RFU, +OLA 443 μ M: 37 ± 2 RFU, +OLA 650 μ M: 34 ± 2 RFU vs. STA 106 μ M: 199 ± 5 RFU, $P < 0.01$) (Fig. 5d).

The Combination of OLA with SFA has a Higher Reducing Effect than OLA Alone on the Apoptosis Level at hSFA Concentrations

When PAM and OLA were combined at concentrations present in hSFA, the caspase-3 activity was significantly lower than with OLA alone (PAM 244 μ M + OLA 443 μ M: 35 ± 1 RFU vs. OLA 443 μ M: 74 ± 8 RFU, $P < 0.05$; Fig. 5a). In presence of 1 nM insulin, this

Fig. 5 Protective effect of OLA on VSMC apoptosis induced by SFA. Cells were stimulated for 24 h with PAM or STA alone or combined with increasing doses of OLA in the absence (a, b) or presence (c, d) of 1 nM insulin. Concentrations used for PAM, STA and for maximal doses of OLA were those found in hSFA (a, c) or hMUFA (b, d) combinations. The induction of apoptosis was measured by caspase-3 activity. Data are means \pm SEM and represent the relative fluorescence intensity (RFU) formed by active caspase-3 ($n = 3$). $^{\dagger}P < 0.05$, $^{\dagger\dagger}P < 0.01$, $^{\dagger\dagger\dagger}P < 0.001$ versus PAM. $^{\delta\delta}P < 0.01$, $^{\delta\delta\delta}P < 0.001$ versus STA. $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus OLA alone (black bars)

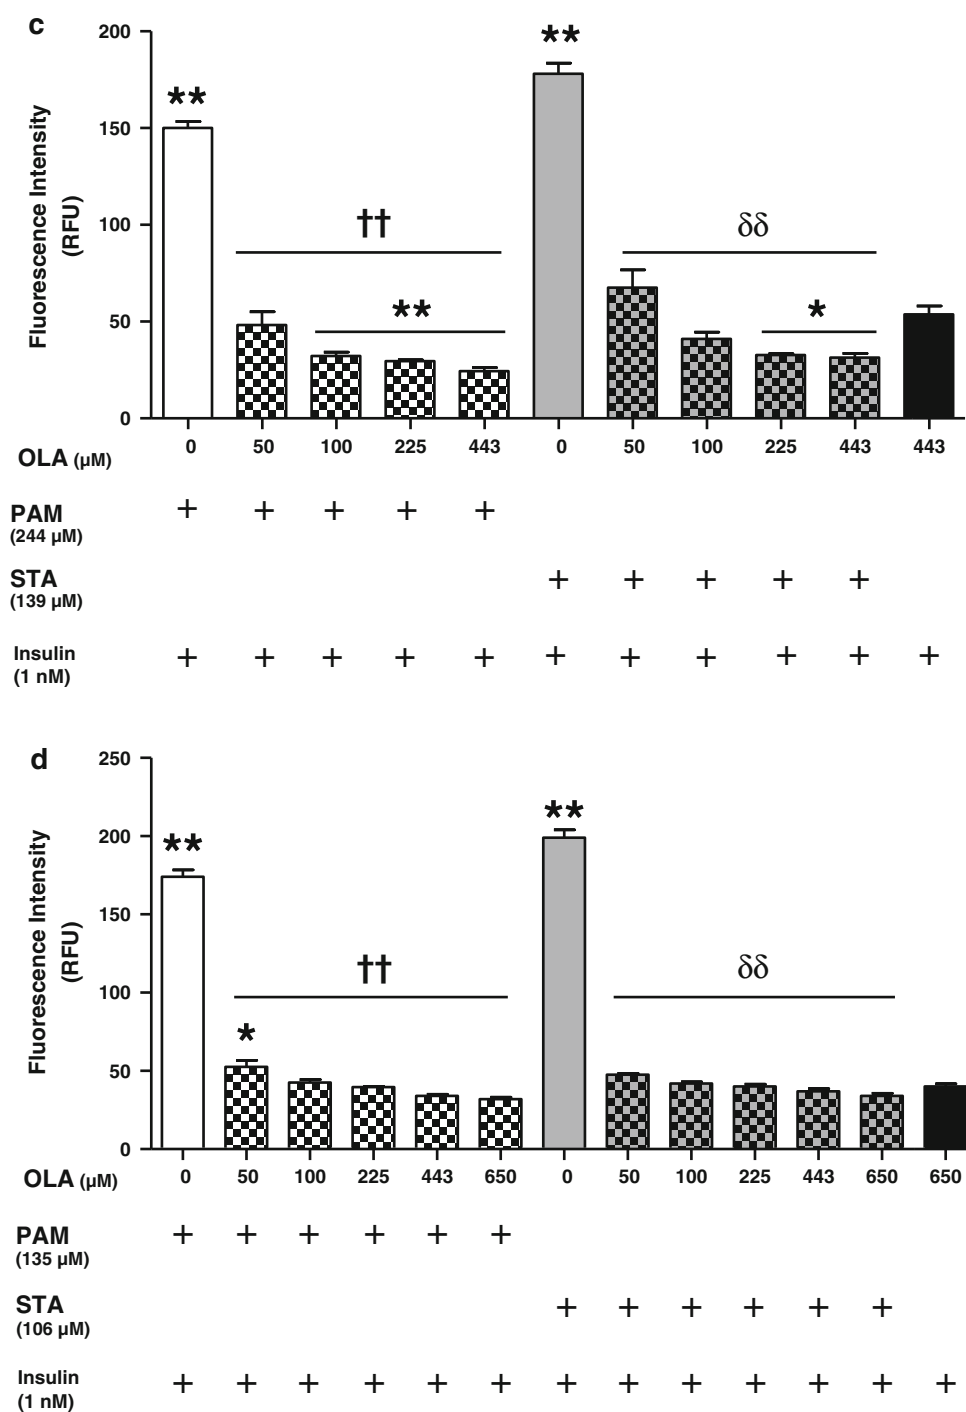

Fig. 5 continued

phenomenon was observed starting from 100 μM OLA when combined with PAM (PAM 244 μM + OLA 100 μM : 32 ± 2 RFU, +OLA 225 μM : 30 ± 1 RFU, +OLA 443 μM : 24 ± 2 RFU vs. OLA 443 μM : 54 ± 4 RFU, $P < 0.01$; Fig. 5c) and from 225 μM OLA when combined with STA (STA 139 μM + OLA 225 μM : 33 ± 1 RFU, +OLA 443 μM : 31 ± 2 RFU vs. OLA 443 μM , $P < 0.05$; Fig. 5c). This observation was not

made at hMUFA concentrations, either with or without insulin.

Discussion

A high plasma concentration of FFA is a common feature in patients suffering atherosclerosis in combination with

T2D. It is generally accepted that SFA, known to induce apoptosis in many cell types, have a pro-atherogenic role on vascular cells [17, 20]. In contrast, MUFA have a protective impact with an anti-apoptotic effect [13, 15]. Since most studies are conducted with only one or two FFA at a time, little is known about the impact of relevant complex groups of FFA on vascular cells. In this study, we assessed the impact of two FFA combinations, containing the same FFA but in different proportions, on VSMC viability. The hSFA combination was richer in SFA than the hMUFA combination, which contained a higher proportion of MUFA. The hSFA combination was inspired by the Western diet composition, while the hMUFA combination was rather modeled on the Mediterranean diet. The hyperinsulinemia found in diabetic and atherosclerotic patients was reproduced by the addition of insulin to FFA combinations in the cellular assays.

The first parameter evaluated was VSMC proliferation. Since BSA, used for FFA solubility, and insulin are individually known to be pro-proliferative [29, 30], an enhanced mitogenic action was expected with those mixed proteins. However, the detectable FFA effects *in vitro* exceed the BSA effects, as published studies have demonstrated pro-proliferative impacts of FFA such as oleic acid [25] and anti-proliferative impacts of FFA such as stearic acid [15] compared to BSA controls. When using FFA combinations, we rather observed an inhibition of VSMC proliferation, significant with hMUFA combination in absence of insulin. The anti-mitotic effect of hSFA combination became apparent in the hyperinsulinemic condition. This observation suggests that insulin cannot counteract the impact of FFA combinations on VSMC proliferation. Indeed, the pro-proliferative effect of insulin alone on VSMC is relatively low, with around 20 % increase in proliferation for cells treated 72 h with insulin doses from 0.5 to 5 nM compared to untreated cells (data not shown).

Since a large proportion of FFA in the combinations used for this study was composed of pro-apoptotic SFA, we hypothesized that the observed inhibition of VSMC proliferation could be due to an induction of apoptosis. With individual FFA, at concentrations found in hSFA and hMUFA combinations, the highest caspase-3 activity was associated to SFA. Also, the apoptosis rate of VSMC was much lower with mixed FFA than with the majority of individual FFA, except for the PUFA. This important observation suggests the presence in the combinations of one or more FFA with a protective impact on cell viability. Because oleic acid is the most abundant FFA in the combinations and is well known for its anti-apoptotic activity, we postulated that it may be primarily responsible for the protective effect. We confirmed the anti-apoptotic dose-dependent properties of oleic acid on VSMC stimulated

with palmitic or stearic acids at concentrations found in both combinations. This effect could be due to an enhanced SFA internalization into triacylglycerol (TAG) vesicles by oleic acid. It was reported that internalized oleic acid is preferentially integrated into cellular TAG vesicles. In contrast, SFA are rather metabolized in their active form involved in lipotoxicity effects. However, the combination of SFA with oleic acid favors the integration of SFA into TAG vesicles, with an inverse correlation between FFA lipotoxicity and storage levels into TAG [15, 31, 32].

Furthermore, oleic acid attenuated VSMC apoptosis levels more strongly when combined with a SFA than when used alone, but only at hSFA concentrations. This observation suggests a competition between pro- and anti-apoptotic mechanisms that relies on given relative concentrations of SFA and MUFA. At hSFA concentrations, the phenomenon was significant only when oleic acid was almost two times more abundant (1.82-fold) than palmitic acid. With stearic acid, a similar ratio was reached with 225 μ M oleic acid (1.62-fold). In this case, significant inhibition of caspase-3 activity was not reached most probably because of the higher pro-apoptotic potential of stearic acid compared to palmitic acid. A better protective effect was obtained at a 3:1 ratio (oleic acid/stearic acid), without being significant, although very close. At hMUFA concentrations, oleic acid combined with a SFA tends to have the same effect. However, since the apoptosis level with the hMUFA concentration of oleic acid (650 μ M) alone was initially lower than at hSFA concentration, it became difficult to further reduce it when added with SFA. This could explain why the effect seems to be more important at hSFA concentrations. It also highlights the importance of MUFA in the hSFA combination, which is rich in harmful SFA.

In the presence of insulin, the basal apoptosis rate observed with oleic acid was lower than without insulin. This combined protective effect was transposed in a further reduction of VSMC apoptosis when single SFA was added at hSFA concentration. This effect was observed this time with both palmitic and stearic acids even with lower oleic acid doses. It is known that insulin increases fatty acid transporter CD36 translocation on cell surface, increasing therefore FFA uptake [33]. Since it has been demonstrated that there is no specific preference for FFA binding to CD36 [34], this probably did not have an impact on oleic acid uptake compared to SFA uptake. However, as an anabolic hormone, insulin is known to reduce palmitic acid β -oxidation and to increase its esterification into TAG in skeletal muscles [35]. Thus, oleic acid could be more effective in presence of insulin in VSMC due to a combined promotion of SFA integration into TAG vesicles rather than to a preferential cellular uptake.

Besides oleic acid and SFA, hSFA and hMUFA combinations contained other FFA such as palmitoleic, linolenic and arachidonic acids. These three FFA were in much lower proportions, but still could have affected VSMC viability. Indeed, palmitoleic and linolenic acids are recognized to reduce the pro-apoptotic impact of SFA in different cell types by inhibiting endoplasmic reticulum stress [16, 36–38]. In our previous studies, palmitoleic acid was present in the diets used for our experiments and we added this fatty acid to our present combinations to reproduce the same composition [27]. It was added since it is the only other MUFA apart from oleic acid in our combinations. More importantly, the ratio of this FFA between the two diets used previously was very different (approximately 20 times more in hSFA). It is possible though, that the concentration of palmitoleic acid in hMUFA combination was too low to have a detectable impact on cell viability. We have focused our study on oleic acid, as it is present in a much higher proportion in the combinations and as many studies have demonstrated its protective roles. However, it would be of great interest to repeat the experiments with palmitoleic acid combined with a SFA in our future works, to see if it has the same impact as oleic acid on reducing VSMC apoptosis rates.

When testing for linolenic acid, we observed an apoptosis level similar to the one obtained with its respective BSA control at the hSFA concentration. At hMUFA concentration, the apoptosis level was even lower with linolenic acid than with its BSA control, hence corroborating the anti-apoptotic effect described above. In the presence of insulin however, apoptosis rates were slightly higher. Since PUFA are particularly sensitive to oxidation, they could potentially be oxidized more easily in a hyperinsulinemic condition, thus increasing apoptosis rates. This is although a hypothesis since, to our knowledge, no study has ever been published concerning possible links between insulin and PUFA oxidation levels. For arachidonic acid, it has been demonstrated in turn that its oxidation-derived products have a pro-apoptotic impact on VSMC [39]. As it is only part of the hSFA mix, we were expecting a higher apoptosis rate for this combination than for hMUFA. Nevertheless, in the previously mentioned study, the investigators noticed decreasing cell viability from a minimal concentration of 20 μM for this FFA [39]. Since arachidonic acid concentration in the hSFA combination was 17.1 μM , it was likely too low to create an impact on VSMC apoptosis.

Taken together, the results from this investigation suggest that the hSFA combination was not more harmful for VSMC than the hMUFA combination in a hyperinsulinemic condition. In our previous studies, VSMC apoptosis rates were higher when cells were stimulated with insulin-treated adipocyte supernatants derived from mice fed with

the hSFA diet (AD) rather than with the hMUFA diet (VD). The adipose tissue of mice was conditioned *in vivo* by each high-fat diet for 20 weeks, resulting in metabolic alterations leading to T2D development [27]. Adipocytes were then isolated, stimulated or not with insulin and supernatants were collected to obtain conditioned media for VSMC stimulations. In that case, stimulation media contained components other than FFA, including adipokines, which influenced VSMC functionality and viability. Adiponectin, one of the most important hormones secreted by adipocytes, is associated with an anti-atherogenic impact. It impairs palmitic acid-induced apoptosis of endothelial cells by reducing ROS production. Adipocytes also secrete leptin, which has a pro-atherogenic impact [40] and a mitogenic effect on VSMC [41]. Adipocyte supernatants from hSFA (AD) and hMUFA (VD) groups, used to stimulate VSMC, had lower adiponectin levels but higher leptin levels compared to those from the control diet.

In addition, orally consumed sources of FFA go through a process of absorption and metabolization, which creates an impact on the nature and quantity of FFA released in the blood stream. Circulating FFA are transported and stored in adipocytes. Upon adipocyte isolation, the ratio of FFA released in supernatants could be quite different from the initial proportions found in the diets, due in part to metabolic alterations developed by mice fed on high-fat diets [27]. While some evidences suggest that FFA composition of TAG stored in adipocytes is similar to the FFA composition ingested, conflicting results propose that the ratio of secreted FFA is not always similar to the ratio of FFA into TAG [42–46]. FFA relative release, compared to its percentage into TAG, depends on FFA chain length and unsaturation degree. Accordingly, a higher release is reported for palmitoleic, linolenic and arachidonic acids. This selective mechanism might be altered according to the dysfunction degree in adipocytes, with hypertrophy found to be more extensive in cells from mice fed with the hSFA diet (AD) compared to those from mice fed with the hMUFA diet (VD), a pattern associated to increased lipolysis [47]. Therefore, even if the FFA ratios used in the actual combinations were selected from those found in the mice diets, results on VSMC viability are clearly different. We have observed a difference between: our *in-vitro* study using purified FFA and the *in-vivo* based works, where final FFA concentrations were influenced by the ingestion process and the mouse's metabolic status. Since, *in vivo*, the source of FFA interacting with VSMC does not only originate from the diet, but also in part from *de-novo* synthesis; this factor could have also contributed to this difference in results. Indeed, FFA coming from *de-novo* synthesis, which occurs principally in the liver, are transported throughout the blood flow by very low density lipoproteins (VLDL) and can hence interact with vascular

cells [48]. Of course, in the current in-vitro experimental setting, no adipokines, de-novo synthesis or metabolic alterations, that would have been present in an in-vivo study, were involved. Nevertheless, our in-vitro study allowed us to isolate FFA direct effects from all other components during VSMC stimulations, offering a better-defined environment.

In conclusion, these results demonstrate that complex groups of FFA, representative of what is found in modern diets, may have a negative impact on VSMC viability. They highlight the importance of MUFA in combinations containing high proportions of SFA to attenuate increased VSMC apoptosis rates. They also underline that the relative concentration of a given FFA in a combination is as important as its total concentration on the pro-and anti-apoptotic balance.

Acknowledgments We would like to thank Dr. Christine Des Rosiers's team for their advice on the preparation of fatty acid solutions. decreases the body fat mass and in parallel increases the lean muscle mass [9]. On the other hand, some publications describe negative effects of CLA. It was shown that CLA may induce non-alcoholic hepatic steatosis in mice as a consequence of delipidation of adipose tissue [10]. In addition, it was proposed that CLA contributes to a decrease in insulin sensitivity in humans [11] and an increase in proinflammatory cytokines in human adipocytes in vitro [12]. However, due to the reported positive effects of CLA on body mass composition and in spite of the observed negative effects, CLA are currently being discussed to be used as food additives in the future. CLA are classified as “novel foods” in Europe and a premarketing risk assessment of CLA is a mandatory part of the novel food approval.

For a reliable risk assessment of CLA it is necessary also to focus on furan fatty acids (furan-FA) which are oxidative products of CLA [13]. Furan-FA are fatty acids characterized by a furan ring flanked by altered alkyl and carboxyl side chains in the α -positions of the furan ring (Fig. 1). The presence of the aromatic furan ring system in furan-FA gives rise to the assumption that these compounds may have toxic potential since furan itself is classified by the International Agency for Research on Cancer (IARC) as group 2B, possibly carcinogenic to humans.

Conjugated linoleic acids preparations may contain significant amounts of furan-FA, and increased intake of CLA, e.g., via food additives might also result in an increased uptake of furan-FA. There are no data available concerning the furan-FA concentrations in CLA supplements or in CLA-containing foodstuffs, however, Yurawecz et al. have

shown that CLA can easily be oxidized in the presence of dioxygen. The authors showed that 3 % of the initial CLA amount of a given sample was converted to furan-FA upon simple stirring of the sample for 46 h at 40 °C [13]. Furan-FA have been poorly characterized so far, and toxicological data are almost not available.

In this study we present data on the toxicological characterization of four different furan-FA isomers by using human cells relevant after oral absorption of the compounds. The human hepatoma cell line HepG2 was chosen as an in-vitro model for the liver as the cells retain many properties of primary liver cells, including metabolic activation [14, 15]. The human colorectal adenocarcinoma cell line Caco-2, on the other hand, is a well-established in-vitro model for human intestinal enterocytes to evaluate nutrient absorption and metabolism. The cells express numerous CYPs including CYP2E1 and have the capacity to detoxify various compounds [16]. By using these cell lines, the four furan-FA isomers were assayed for cytotoxicity and for their effects on cellular proliferation and apoptosis. Moreover, a proteomic approach using two-dimensional gel electrophoresis and mass spectrometry was chosen to identify differentially expressed proteins in Caco-2 cells treated with furan-FA in order to get insights into the cellular effects of furan-FA on the molecular level.

Materials and Methods

Chemicals

All chemicals were purchased from Merck (Darmstadt, Germany) or Sigma Aldrich (Taufkirchen, Germany) in the highest available purity. All reagents and equipment for the two-dimensional gel electrophoresis were purchased from GE Healthcare (Chalfont St. Giles, UK). The furan fatty acid 9,12-epoxy-9,11-octadecadienoic acid (9,11-furan-FA) was obtained from Biotrend (Köln, Germany) and 10,13-epoxy-10,12-octadecadienoic acid (10,12-furan-FA) was obtained from Larodan (Malmö, Sweden). Two additional furan fatty acid isomers, 8,11-epoxy-8,10-octadecadienoic acid (8,10-furan-FA) and 11,14-epoxy-11,13-octadecadienoic acid (11,13-furan-FA), were a kind gift from Prof. Steinhardt (University of Hamburg, Germany). The abbreviations given in brackets are used throughout the manuscript. All fatty acids were dissolved in DMSO to give 0.1 M stock solutions.

Cell Culture

Culture media and supplements were obtained from PAA Laboratories GmbH (Pasching, Austria). The human

Fig. 1 Structures of furan fatty acids being oxidation products of conjugated linoleic acids [13]: **a** 8,11-epoxy-8,10-octadecadienoic acid (8,10-furan-FA); **b** 9,12-epoxy-9,11-octadecadienoic acid (9,11-furan-FA); **c** 10,13-epoxy-10,12-octadecadienoic acid (10,12-furan-FA); and **d** 11,14-epoxy-11,13-octadecadienoic acid (11,13-furan-FA)

adenocarcinoma cell line Caco-2 (European Collection of Cell Culture, ECACC No. 860 10 202) and V79-cells (ECACC No. 860 41 102) were cultured in Dulbecco's modified Eagle's medium (DMEM) and the human hepatoma cell line HepG2 (ECACC No. 850 11 430) was cultured in Roswell Park Memorial Institute Medium (RPMI), each supplemented with 10 % fetal calf serum, 100 U/mL penicillin and 100 µg/mL streptomycin in a humidified atmosphere of 5 % CO₂ at 37 °C. Cells were passaged every 2–4 days by treatment with 0.1 % trypsin and 0.04 % EDTA and then plated at a density of $1.3\text{--}2 \times 10^4$ cells/cm².

For incubation experiments the cell culture medium was replaced by a serum-free medium supplemented with 1 % insulin–transferrin–selenium (ITS, Invitrogen, Karlsruhe, Germany) and 0.1 mg/mL BSA with various concentrations of the respective fatty acid. Prior to this, furan fatty acids were complexed to fatty acid-free BSA (Sigma-Aldrich, Taufkirchen, Germany), with a molar ratio of fatty acid to BSA of 4:1.

Cytotoxicity Assay

Cells were plated in 96-well plates with 5,000 cells/well for Caco-2 cells and with 10,000 cells/well for HepG2 cells and treated with various concentrations of furan fatty acids for 3 days. Cytotoxicity was estimated by using the neutral red assay. Cells were incubated with 200 µL neutral red dye (0.005 % in DMEM) for 3 h and then washed twice with PBS. After addition of 200 µL of a solution of 50 % ethanol and 1 % acetic acid in water the plates were shaken for 15 min until complete dissolution of the dye. Absorbance at 540 nm was recorded using a Mithras Multimode Reader LB 940 (Berthold Technologies, Vienna, Austria). Values are expressed as percentages of the negative control which were cells exposed to medium containing 0.1 % DMSO. Control values were set as 100 % viable cells.

Cell Proliferation Assay

Caco-2 and HepG2 cells, respectively, were grown and treated with furan-FA as described above. After 48 h of incubation the cell proliferation rate was determined by using the cell proliferation reagent WST-1 (Roche Diagnostics GmbH, Mannheim, Germany) following the protocol described by the manufacturer.

Caspase Activity Assays

To measure the enzymatic activity of caspases as an indicator of apoptosis, Caco-2 cells were treated with furan-FA as described above. The level of apoptosis was determined with the fluorogenic caspase-3 tetrapeptide substrate

Ac-DEVD-AMC (Calbiochem, Darmstadt, Germany) as described by Wenzel et al. [17]. In the case of HepG2 cells, the activity of caspase-3 and caspase-7 was determined using a Caspase-Glo[®]3/7 Assay (Promega, Mannheim, Germany) following the protocol described by the manufacturer.

Ames Test

The bacterial reverse mutation assay (Ames test) was performed according to OECD guideline 471. For detection of the mutagenic potential of 9,11-furan-FA the *Salmonella typhimurium* strains TA98, TA100, TA1535, TA1537 and TA1538 (MoltaxTM) were assayed with various concentrations of the compound in the absence and in the presence of the exogenous metabolic activation system S9, respectively, with the plate incorporation method. The S9 fraction was prepared from livers of rats that had been treated with phenobarbitone and β-naphthoflavone before by a standard procedure according to the OECD guideline. In the absence of the S9 fraction, the following positive controls were used: 3.16 µg/plate 2-nitrofluoren for the strains TA98 and TA1538, 4 µg/plate sodium azide for the strains TA100 and TA1535, and 25 µg/plate 9-aminoacridin for strain TA1537. In the presence of the S9 fraction, 2 µg/plate 2-aminoanthracene was used as a positive control for all strains. The solvent DMSO (50 µL/plate) was used as a negative control. The number of revertants was counted for each plate after 48 h of incubation.

V79 Micronucleus Assay

The in-vitro mammalian cell micronucleus test was performed with V79-cells according to OECD Guideline 487. Cells were cultured on microscope slides and were exposed to 9,11-furan-FA for 3 h and cultured for another 21 h without furan-FA. In a parallel experiment, the S9 fraction was added to the cells during the incubation period of 3 h. Cells were fixed to the microscope slides and nuclei staining was conducted as described in the OECD guideline. Cells containing micronuclei and cells undergoing mitosis were identified via microscopic inspection. 1,000 cells were analysed for each microscope slide, and each experiment was done in duplicate.

Two-Dimensional Polyacrylamide Gel Electrophoresis (2-DE)

The 2-DE methodology is based on the techniques developed by Goerg et al. [18]. For protein extraction, Caco-2 cells were washed threefold with phosphate-buffered saline (PBS) and lysed in 500 µL lysis buffer (7 M urea, 2 M thiourea, 4 % w/v CHAPS, 2 % IPG-buffer (pH 3–10 NL),

1.2 % DeStreak Reagent, 20 mM spermine and 1 % Protease-Inhibitor Cocktail Set III (Merck KGaA, Darmstadt, Germany). After gentle sonication, the samples were centrifuged for 60 min at $100,000\times g$ at 15 °C to remove cellular debris. Protein content of supernatants was determined according to Bradford [19]. The extracts were stored in aliquots at -80°C .

Protein extracts were separated via 2-DE, in which four technical 2-DE gel replicates were performed for each of the three biological samples. Isoelectric focusing (IEF) was carried out using 24 cm IPG gel strips with a non-linear pH-gradient from pH 3 to pH 10. Rehydration of gel strips was performed in a volume of 450 μL rehydration buffer [7 M urea, 2 M thiourea, 4 % w/v CHAPS, 0.5 % IPG-buffer (pH3-10 NL) and 1.2 % DeStreak Reagent] containing 200 μg protein. IEF was performed on the Ettan IPGphor[®] 3 IEF System with a maximum current setting of 50 μA per strip and the following stepwise conditions: 30 V for 15 h (in-gel rehydration); 200 V for 1.5 h; 500 V for 1 h; gradient from 500 to 1,000 V within 13.5 h; gradient from 1,000 to 8,000 V within 3 h; 8,000 V for 6 h. After IEF separation, the gently washed gel strips were stored at -80°C until further use. The gel strips were equilibrated for 15 min in equilibration buffer containing 6 M urea, 75 mM Tris (pH 8.8), 30 % v/v glycerol, 2 % w/v SDS and 2 % w/v DTT. Subsequently, the gel strips were equilibrated in the same buffer containing 2.5 % w/v iodoacetamide instead of DTT for another 15 min. The equilibrated strips were then transferred onto the second-dimension SDS-PAGE gels and sealed in place with 0.5 % agarose. SDS-PAGE was performed on lab-made 12.5 % polyacrylamide gels using the ETTAN Dalt twelve[®] separation unit with a constant power of 3 W per gel for 30 min and 15 W per gel for approximately 4.5 h until the dye front reached the bottom of the gels. Gels were fixed in aqueous 10 % acetic acid/30 % ethanol and stained with fluorescent Ruthenium II Tris-complex (10 nM; according to Rabilloud [20]). The fluorescence-stained 2-DE gels were digitally scanned with a ProXPRESS[®] fluorescence imaging workstation (PerkinElmer Lifesciences, Waltham, MA, USA).

Gel Image Analysis

Gel image analysis was carried out using Delta2D software version 3.6 (DECODON, Greifswald, Germany). It includes matching, spot detection, quantification of spots and statistical analysis. Image analysis with Delta2D led to an artificial fusion gel image (union fusion), on which the spot detection was performed automatically (parameters: local background region = 120, average spot size = 15, weak spot sensitivity = 20.0, noise cutoff = 40.0).

The Delta2D software was used to detect and quantify the volume of all protein spots. For the calculation of

Fig. 2 Cytotoxic effect of furan-FA in Caco-2 cells. Cells were treated with **a** 8,10-furan-FA, **b** 9,11-furan-FA, **c** 10,12-furan-FA, and **d** 11,13-furan-FA, respectively, at the indicated concentrations for 72 h. Cell viability was determined by neutral red assay and expressed as percentages of the negative control which was exposed to medium containing 0.1 % DMSO (set as 100 %). Medium containing 0.005 % Triton-X 100 was used as positive control. Data are expressed as the mean \pm SD $n = 3$. * $p < 0.05$ compared with control cells; ** $p < 0.01$ compared with control cells

expression changes, normalized gel images were compared. For statistical analysis, all gels of one concentration were organized in one group which was compared to the group with the gels with the extracts from the untreated control cells. A protein spot was considered as up- or downregulated when the expression ratio changed more than 1.5-fold. Between-group comparisons were performed using the Student's *t* test for independent samples (two tailed), *p* values < 0.05 were considered significant. Spot picking was performed using the InvestigatorTM ProPicTM workstation (Genomic Solutions, Ann Arbor, MI, USA).

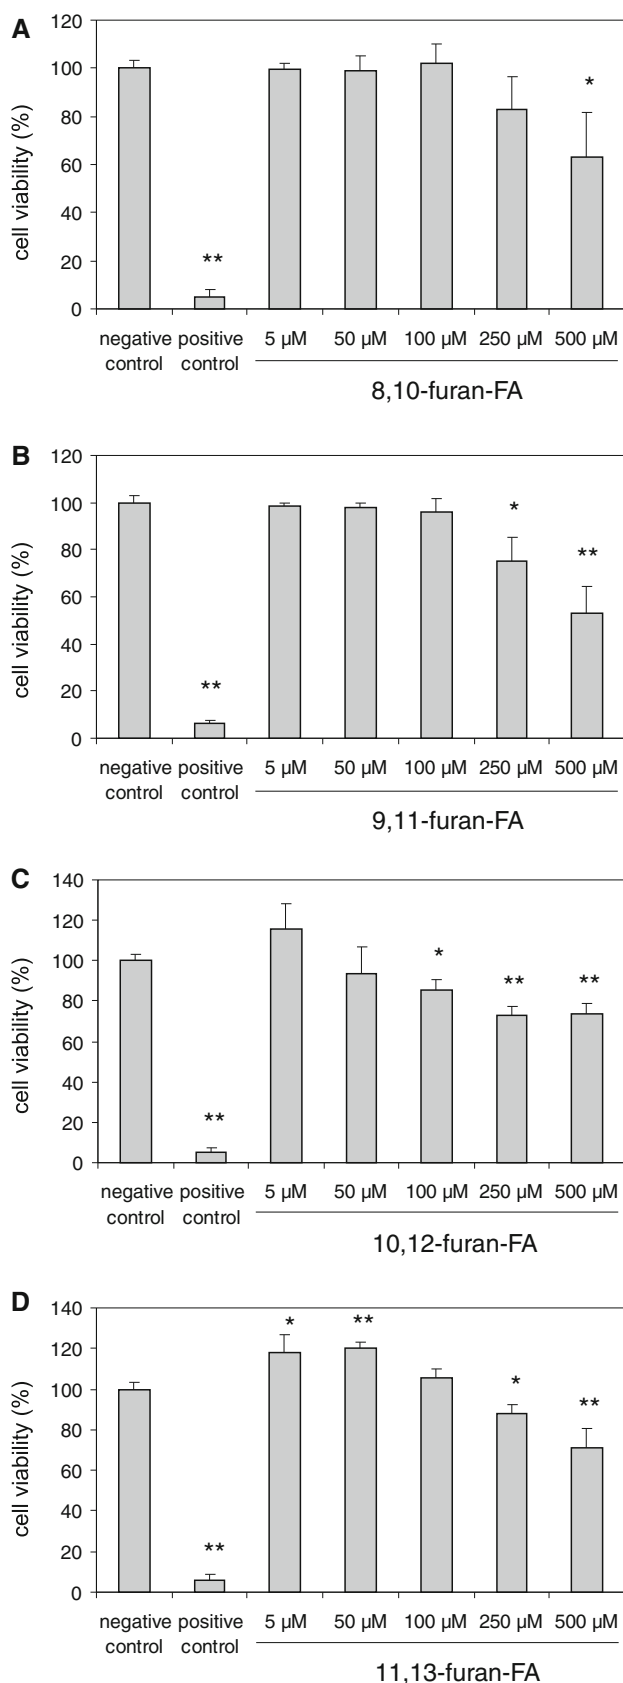

In-Gel Tryptic Digestion, Mass Spectrometry and Database Research

Tryptic in-gel digestion of proteins was carried out according to the protocol of Shevchenko et al. [21]. Extracted peptides were mixed with HCCA matrix, applied to a anchorTM 600 target (Bruker, Bremen, Germany) and subjected to MALDI-TOF analysis using an Ultraflex II mass spectrometer (Bruker, Bremen, Germany). Spectra were recorded in the deflection mode at 30 % laser intensity. Spectra were calibrated externally using a commercial peptide standard (Pepmix Standard 1000-4000; Care, Bremen, Germany). By using the Mascot platform, peptide mass lists were entered into searches against the *Homo sapiens* sequences of the SwissProt database. A maximum of one missed trypsin cleavage, complete modification of cysteine by carboxyamidation, partial methionine oxidation and 100 ppm mass tolerance were specified in the search settings. Results with a *p* value < 0.05 were considered significant.

Results

Cellular Effects of Furan-FA Isomers on Caco-2 Cells

To examine potential effects of furan-FA on cellular viability, cell proliferation and apoptosis rates, Caco-2 cells were treated with four different furan-FA isomers (8,10-furan-FA, 9,11-furan-FA, 10,12-furan-FA, and 11,13-furan-FA) as depicted in Fig. 1. Cellular viability was assayed by taking advantage of the neutral red cytotoxicity assay. No cytotoxic effects were observed for any tested

furan-FA isomer at concentrations lower than 100 μM (Fig. 2). However, 10,12-furan-FA caused a significant cytotoxic effect at a concentration of 100 μM and at higher concentrations. All furan-FA isomers displayed significant cytotoxic effects at a concentration of 500 μM , and except for 8,10-furan-FA also at 250 μM . Taken together, furan-FA displayed weak cytotoxicity in Caco-2 cells that was significant only at very high concentrations.

In a parallel experiment, a cell proliferation assay was conducted to estimate the potential of the furan-FA isomers to affect cellular proliferation. Incubation of the cells with furan-FA did not increase proliferation of the cells. In contrast, high furan-FA concentrations resulted in a decrease of cellular proliferation (data not shown). The results obtained with the WST-1 assay were comparable to those obtained with the neutral red cytotoxicity assay (see above). Thus, the results can not be interpreted as an antiproliferative effect of furan-FA but rather reflects the cytotoxic effects of the compounds at high concentrations.

Finally, we investigated the possible effect of furan-FA on the apoptosis rate of Caco-2 cells by using the caspase-3-substrate Ac-DEVD-AMC. In these experiments, camptothecin was used as a positive control and clearly induced apoptosis in Caco-2 cells at a concentration of 25 μM . Nevertheless, no increase of caspase-3-activity was determined in Caco-2 cells upon incubation of the cells with up to 500 μM of the respective furan-FA isomer (data not shown). Hence, furan-FA did not affect apoptosis in this cell line.

In sum, the data indicate, that the furan-FA isomers tested in this study did not affect general cellular parameters such as cytotoxicity, cell proliferation, or apoptosis, of Caco-2 cells up to a concentration of 500 μM .

Identification of Proteins in Caco-2 Cells that were Differentially Regulated upon Exposure to 10,12-Furan-FA

A proteomic approach was chosen to address the question whether furan-FA affect Caco-2 cells on the molecular level. The furan-FA isomer 10,12-furan-FA was chosen for these experiments since this compound is the oxidation product of the most potent CLA isomer t10,c12-CLA. Caco-2 cells were incubated for 48 h with 10, 100, and 1,000 μM of 10,12-furan-FA, respectively. Total protein extracts were separated by two dimensional gel electrophoresis (2-DE). To obtain statistically significant results, three biological replicates were used for analysis and each protein sample was run four times in the 2-DE to get a set of twelve gel images for each 10,12-furan-FA concentration. These gel images were analyzed with Delta2D

Fig. 3 Fusion gel image of the proteome of Caco-2 cells treated with 10,12-furan-FA: The Gene Names were used to designate identified proteins. Upregulated proteins are marked in **bold letters**. Proteins that were not identified are indicated in the figure by a *question mark*

software as described in the Materials and Methods section. Delta2D analysis resulted in the detection of 1,723 independent protein spots. Image-analysis revealed significant changes (fold change ≥ 1.5 , $p < 0.05$) in the intensities of 48 spots caused upon incubation of the cells with at least one of the tested furan-FA-concentrations. Among these protein spots, 44 were downregulated and only four were upregulated in the furan-FA-incubated cells in comparison to the untreated control cells.

Figure 3 shows the fusion gel image of Caco-2 proteome obtained from all gel images of this project. Regulated spots with a fold change ≥ 1.5 ($p < 0.05$) are indicated by spot shapes, and gene names are given for the proteins of those 30 spots that were identified by MALDI-TOF analysis. Table 1 summarizes the results of the identified proteins. Two proteins, namely NUDT5 (nudix (nucleoside diphosphate linked moiety X)-type motif 5) and PTGES3 (prostaglandin E synthase 3) were each represented by two different spots in the 2-DE gels. They had identical masses but showed slight differences in the pI value. Posttranslational modifications might explain the presence of one and the same protein in more than one spot.

Of the identified proteins, only three proteins were upregulated on incubation of Caco-2 cells with 10,12-furan-FA, and these proteins were associated with lipid droplet biogenesis. Those proteins that were downregulated

were associated with general cellular processes such as transcription, protein biosynthesis and further protein processing (see “Discussion” for details). In sum, there was no indication that any specific signal transduction pathway of toxicological relevance was affected by 10,12-furan-FA in Caco-2 cells.

Cellular Effects of Furan-FA Isomers on HepG2 Cells

Based on the assumption that the furan ring of furan-FA might be activated in the liver by cellular metabolic activity, the human hepatoma cell line HepG2 was included in this study. This cell line was shown to retain many properties of primary liver cells, including metabolic activation [14, 15] and might therefore have the potential to activate the furan ring system of furan-FA. Thus, the cytotoxic potential of the furan-FA isomers as well as the effects of furan-FA on HepG2 proliferation and apoptosis were examined.

The results of the cytotoxicity assay (Fig. 4) are comparable to those obtained with the Caco-2 cell line (Fig. 2). The furan-FA isomers tested in this study displayed cytotoxic effects to HepG2 cells only at high concentrations above 100 μM . Moreover, incubation of HepG2 cells with the furan-FA isomers did not result in any effect on cellular proliferation and on apoptosis (data not shown). Again,

these results are in line with those obtained for the Caco-2 cell line. Taken together, there was no indication that HepG2 cells were more sensitive to furan-FA treatment than Caco-2 cells.

The Genotoxic Potential of 9,11-Furan-FA

To further address the question as to whether the furan ring system of furan-FA can be activated enzymatically, the substance was incubated with rat liver homogenate (S9 fraction) that contains numerous enzymes of the CYP

family capable of activating various substances including compounds with aromatic moieties. Two genotoxicity assays, the Ames test and the micronucleus assay, were chosen to examine the effects of metabolic activation of furan-FA in vitro, because positive controls are available for both assays being carried out either with or without S9-mediated metabolic activation. 9,11-furan-FA was chosen for these experiments since we had to focus on one furan-FA isomer for these elaborate assays.

The Ames test was carried out with five different *S. typhimurium* strains according to OECD guideline 471.

These strains harbor either point mutations or frameshift mutations in genes essential for growth under the experimental conditions. Thus, the growth of bacterial colonies is due to the formation of revertants, and the number of revertants increases in the presence of mutagenic compounds. The *S. typhimurium* strains were cultured in the presence of various amounts of 9,11-furan-FA either in the presence or in the absence of the S9 fraction for enzymatic activation. As summarized in Table 2, the respective positive control clearly increased the number of revertants per plate whereas the presence of 9,11-furan-FA did not increase the number of revertants independent of the presence or absence of the S9 fraction. Interestingly, a cytotoxic effect of 9,11-furan-FA on the bacteria was observed. This effect was indicated by an abnormal background growth of the bacteria and by a decrease in the reversion rates in comparison to the negative control (Table 2; values given in brackets). The cytotoxic effect of 9,11-furan-FA was primarily observed when the cells were cultured in the absence of the S9 fraction and was only detected for strain TA1537 for the highest concentration of 9,11-furan-FA in the presence of S9 fraction. Thus, cytotoxic effects induced by the furan-FA isomer seem to be decreased by the S9 fraction.

In the micronucleus assay, the presence of a mutagenic compound results in the formation of micronuclei due to imbalances in cell division and in parallel in a decrease of mitotic activity. The in-vitro micronucleus assay was carried out with V79 cells according to OECD guideline 487. The furan-FA isomer was given to the cells either in the presence or in the absence of the S9 fraction for enzymatic activation. The results of the assay are summarized in Table 3. Again, incubation of the cells with the positive controls clearly increased the number of micronuclei and decreased the number of mitotic events whereas the presence of 9,11-furan-FA had no effect on these two parameters. Incubation of the cells with 9,11-furan-FA in the presence of the S9 fraction yielded similar results (Table 3). Concentrations of 9,11-furan-FA above 100 μM were cytotoxic to V79 cells (data not shown). Thus, 9,11-furan-FA did not display clastogenic potential up to a concentration of 100 μM independent of the presence or absence of the S9 fraction.

Discussion

Due to some properties that are proposed to be beneficial for human health CLA are currently being discussed for use as food additives in the future [22]. CLA preparations might contain significant amounts of furan-FA which are oxidative products of CLA. In particular the presence of a furan ring system in furan-FA raised some concerns on

potential toxic properties of these compounds. Therefore, for a reliable risk assessment of CLA formulas additional data concerning furan-FA toxicity are required. In this study we present first in-vitro data on the toxicological properties of furan-FA on the cellular as well as on the molecular level. By using two cell lines as models for the human intestine (Caco-2) and the human liver (HepG2) general cellular parameters such as cytotoxicity, cell proliferation and apoptosis were examined. Moreover, rat liver homogenate (S9 fraction) was employed for enzymatic activation of the aromatic furan ring in order to generate potential toxic furan-FA derivatives. In case of furan, this compound was shown to be activated by CYP2E1 to form an epoxide which further reacts to the dialdehyde *cis*-2-butene-1,4-dial [23–25]. Epoxides as well as dialdehydes are electrophiles which can covalently bind to proteins, lipids and DNA. Mutations might be induced upon DNA-adduct formation which may be the initial step of cancerogenesis [26, 27]. Indeed, furan has been shown to be cancerogenic in rodents probably due to a genotoxic mechanism (reviewed in Heppner and Schlatter [28]). Several in-vitro genotoxicity assays conducted either with furan or with its metabolite *cis*-2-butene-1,4-dial gave inconsistent results. In some studies, these compounds were shown to be genotoxic in the respective in-vitro assay [26, 29, 30] whereas other studies did not confirm these results [31, 32]. In this study, the Ames test as well as the in-vitro micronucleus assay yielded negative results with 9,11-furan-FA independent of the presence or absence of the S9 fraction for enzymatic activation of the compound. Thus, based on these two in-vitro assays, 9,11-furan-FA seems to have no genotoxic potential. Assuming a similar mechanism of activation one would expect the formation of an epoxide at the furan ring of 9,11-furan-FA as it was observed for furan [23–25]. The high reactivity of epoxides always gives rise for genotoxic potential of an epoxide-containing substance. However, further oxidation of the furan ring system of 9,11-furan-FA would yield a diketone due to the presence of the alkyl and the carboxyl side chain, respectively, at the α position of the furan ring. A diketone is much less reactive than the dialdehyde that is formed upon activation of furan. This might explain that 9,11-furan-FA was negative in the genotoxicity assays also in the presence of S9 fraction for enzymatic activation.

In addition to the direct genotoxic mechanism there are further indirect mechanisms being discussed for cancerogenic activity of furan. As an example, it was shown that furan irreversibly inhibits oxidative phosphorylation in the mitochondria of rat primary hepatocytes [33]. The authors concluded that the resulting lack of ATP might be responsible for inaccurate function of, e.g., DNA-repairing enzymes. In this scenario, furan would not have a direct mutagenic effect on DNA but would more likely prevent

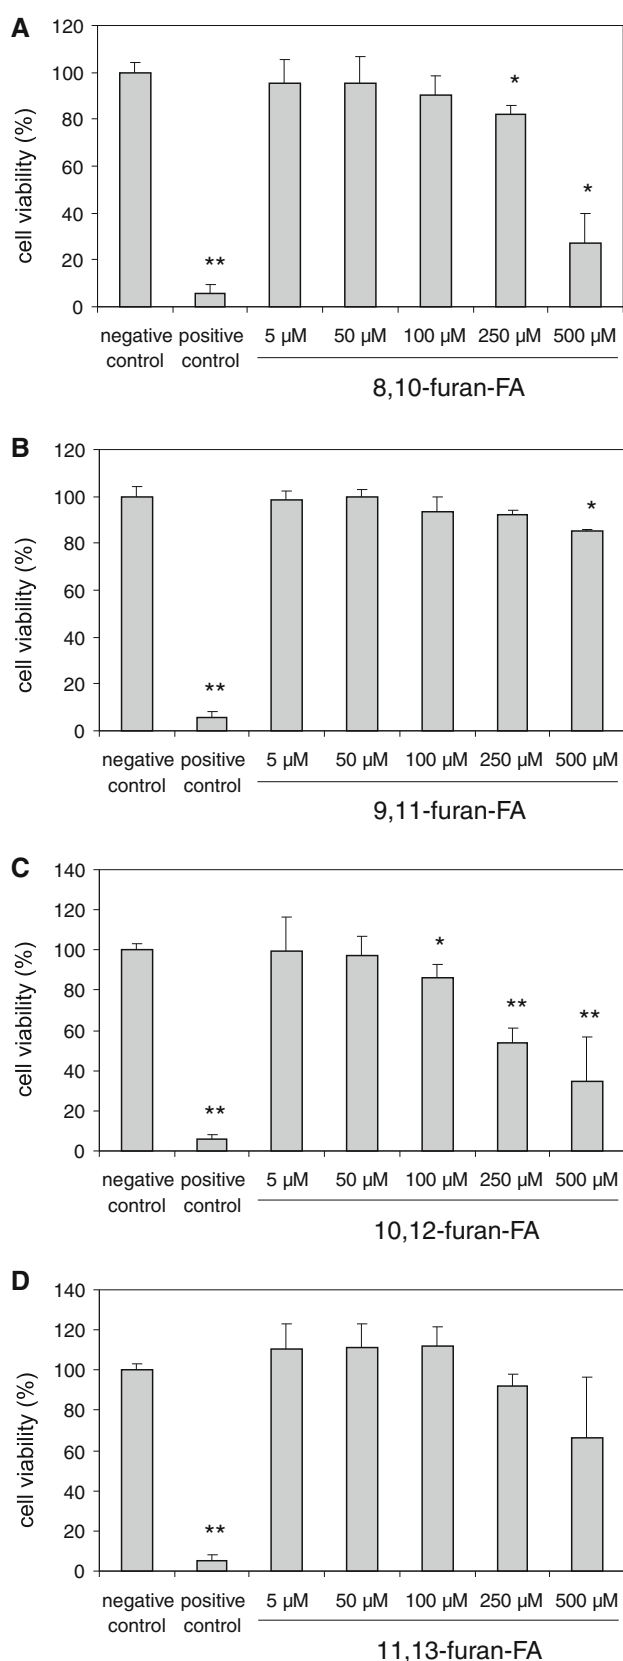

Fig. 4 Cytotoxic effect of furan-FA in HepG2 cells. Cells were treated with **a** 8,10-furan-FA, **b** 9,11-furan-FA, **c** 10,12-furan-FA, and **d** 11,13-furan-FA, respectively, at the indicated concentrations for 72 h. Cell viability was determined by neutral red assay and expressed as percentages of the negative control which was exposed to medium containing 0.1 % DMSO (set as 100 %). Medium containing 0.005 % Triton-X 100 was used as positive control. Data are expressed as means \pm SD $n = 3$. * $p < 0.05$ compared with control cells; ** $p < 0.01$ compared with control cells

efficient DNA repair. In another study it was shown that the strong hepatotoxic effect of furan is partially compensated for by increased proliferation of hepatocytes in mouse livers [34]. Moreover, furan was shown to induce expression of some apoptosis-associated genes in mouse and rat hepatocytes [35, 36]. In general, an imbalance between proliferation and apoptosis plays an important role in cancerogenesis, and furan-induced tumor development might also be due to some indirect mechanism.

In spite of the presence of a furan ring, furan-FA can also simply be regarded as fatty acids. In contrast to furan which is clearly a toxic compound, CLA which are the precursor of furan-FA are being discussed as having properties which might be beneficial for human health. Some studies with a focus on colon cancer indicate that CLA may have anticancerogenic effects. It was shown that the 9,11-furan-FA precursor *cis*-9,*trans*-11-CLA inhibits proliferation of colon cancer cell lines such as Caco-2 or HT-29 [37]. In addition, CLA was shown to induce apoptosis in HT-29 cells [38] whereas there were only minor effects on apoptosis observed in Caco-2 cells [39]. In vivo, chemically induced colon tumors in rat were inhibited by CLA due to an increased apoptosis rate of the tumor cells [40].

In this study, furan-FA being a chimera with structural characteristics of aromatics and of fatty acids have been examined for their effects on proliferation and apoptosis of two different cell lines. The four furan-FA isomers tested in this study neither induced nor inhibited proliferation in the Caco-2 cell line or in the HepG2 cell line. Moreover, there was no indication that apoptosis was affected by the four furan-FA isomers in these two cell lines. The four compounds displayed only weak cytotoxic effects at concentrations above 100 μ M, however, these high concentrations are not of physiological relevance. Although there are no data available for furan-FA concentrations in human blood serum, total CLA has been determined to be in a range around 20 μ M in human serum [41], and the furan-FA serum concentrations should be clearly below this value. Thus, the in-vitro data of this study do not support the hypothesis that furan-FA might be as toxic as furan or as

furan derivatives such as furfural. The general cellular parameters tested in this study gave no evidence for any furan-FA property being of toxicological relevance.

In a previous study it was shown that 9,11-furan-FA was absorbed by Caco-2 cells and incorporated into triglycerides for storage in lipid droplets [42]. Therefore, assuming that furan-FA must have some effect on Caco-2 cells after absorption, a non-targeted proteomic approach was chosen to examine the furan-FA-dependent effects on the molecular level. The 2-DE analysis of furan-FA-treated Caco-2 cells uncovered a set of 48 protein spots with altered expression levels. The proteins of 30 of these spots could be identified by MALDI-TOF analysis (Table 1). Only three of these proteins (PLIN2, TPD52L2 and SEC13) were upregulated upon exposure of the cells to 10,12-furan-FA, and these proteins are associated with lipid droplet biogenesis. PLIN2 is a member of the PAT protein family (perilipin, adipophilin, TIP47) which regulate the coordination of lipid droplet formation and which are associated to the surface of lipid droplets [43]. TPD52L2 is a member of the tumor protein D52 protein family. TPD52, the main member of this family, is a binding partner of

perilipin [44] and of TIP47, which is another lipid droplet-associated protein of the PAT family. Hence, it would be possible, that TPD52L2 is involved in lipid droplet biogenesis via its interaction with members of the PAT-family. SEC13 is the third protein that was found to be upregulated after treatment of Caco-2 with 10,12-furan-FA. In HeLa cells, siRNA knockdown of SEC13 inhibited the transport of PLIN2 to lipid droplets [45]. Thus, the observed increase in SEC13 protein in our study might be associated with the increased PLIN2 requirement for lipid droplet formation.

In summary the three upregulated proteins give some indication on the molecular level for the formation of lipid droplets in Caco-2 cells upon incubation of the cells with 10,12-furan-FA. Lipid droplet biosynthesis is accompanied by reorganization of the cytoskeleton which is indicated by the downregulation of four cytoskeleton-associated proteins (ACTBL, KRT8, CKAP4, MEMO1). Moreover, downregulation of all the other proteins that have been identified in the course of this proteomic study indicate downregulation of general cellular processes such as DNA-replication and transcription (PCNA, UBE2C, NUDT5),

translation and protein biosynthesis (MRPS2, RPLP0, RPL5, ENOPH1 and ADI1) as well as protein processing (CALU, CALR, ANXA3, ANXA7, FBXO2 and CTSD; see Table 1). PCNA acts as a cofactor of DNA polymerase delta and is therefore involved in DNA replication and DNA repair [46]. UBE2C is required for the destruction of mitotic cyclins and for cell cycle progression [47]. Hence, downregulation of UBE2C decreases proliferation of the cells. The protein NUDT5 is a nudix hydrolase which is part of nucleotide metabolism [48] and is able to eliminate toxic nucleotide derivatives from the cells [49] and is also downregulated through treatment with furan-FA.

Regarding protein biosynthesis, three different proteins were identified which are structural constituent of ribosomes (MRPS2, RPLP0, RPL5). ENOPH1 and ADI1 are proteins involved in amino acid metabolism and in particular in the methionine salvage pathway [50, 51]. CALU and CALR are calcium-binding proteins located in the ER which have various functions including chaperone activity, protein folding and trafficking [52]. Furthermore, the proteomic approach identified two different annexins to be downregulated upon furan-FA treatment, ANXA3 and ANXA7. Annexins are proposed to be involved in vesicle trafficking, membrane repair, membrane fusion and ion channel formation [53]. Two of the downregulated proteins, FBXO2 and CTSD, are proteolytic enzymes which are involved in protein degradation [54, 55].

With respect to lipid metabolism and energy expenditure, the proteins identified in this study (PTGES3, IDI1, UROD, CYB5B and NDUFS8) which are involved in these general metabolic processes were also downregulated upon incubation of Caco-2 cells with 10,12-furan-FA. Finally, downregulation of GPX1 which is one of the most important anti-oxidant enzymes in humans [56] indicates that 10,12-furan-FA does not induce oxidative stress in Caco-2 cells.

Taken together, downregulation of the numerous proteins identified in this study indicates that general cellular processes such as DNA replication and transcription, protein biosynthesis, protein processing and transport, lipid and energy metabolism is diminished in Caco-2 cells after exposure to 10,12-furan-FA. This may lead to the interpretation that metabolic activity in general is decreased in the cells which appear to have entered a state of rest. The results of the proteomic study, however, have to be considered as preliminary results and have to be confirmed, e.g., by Western blot experiments in future studies.

The furan-FA isomers examined in this study showed no mutagenic and no cytotoxic effects at concentrations that could be relevant for humans. Moreover, the substances had no effect on cell proliferation and on the apoptosis rate of Caco-2 cells or of HepG2 cells. This suggests that furan-FA have no cancerogenic potential. Furthermore, treatment

of furan-FA with liver enzyme extracts gave similar results indicating that no toxic metabolite was formed from furan-FA by the action of the liver metabolic enzymes. On the molecular level, the proteomic approach gave no indication that any signal transduction pathway of toxicological relevance was affected by 10,12-furan-FA in Caco-2 cells. The proteomic data indicate that the cells store furan-FA in lipid droplets and go into a metabolic state of rest. As neither the cell assays and the genotoxicity tests nor the proteomic study revealed any significant toxic effects after treatment of the cells with furan-FA, our results support the notion that the furan-FA isomers examined in this study have no obvious property of toxicological relevance.

suitable host can be a potential alternative source of some valuable PUFA besides traditional fermentation techniques. Among them, progress has been made in the accumulation of specific PUFA by using genetic engineering strains of *Saccharomyces cerevisiae* [4] and *Pichia pastoris* [5]. However, its application is also extremely limited due to low and unstable productivity of PUFA. It seems difficult to solve this problem because the regulatory mechanisms of PUFA biosynthesis and the control of desaturase gene expression in these two strains and other organisms are not clearly understood.

In the last few years, more interest has mostly been focused on the regulation of desaturases from different organisms. In *Bacillus subtilis*, two-component procaryotic modulator-effector pairs DesK/DesR senses a changes in membrane fluidity caused by a temperature downshift or exogenous fatty acids and then regulates the expression of its only desaturase gene ($\Delta 5$, called *des*) [6]. In *S. cerevisiae*, its only desaturase gene ($\Delta 9$, called *OLE1*) is transcriptionally regulated in response to various different environmental stimuli including carbon sources [7, 8], growth temperature [9], fatty acids [10, 11], metal ions [12, 13] and oxygen levels [12, 14]. Two related homologous proteins Spt23p and Mga2p located in endoplasmic reticulum initially can maintain the basal level of transcription after being transported into the nucleus to promote *OLE1* transcription [15, 16]. The Mga2p/Spt23p pathway is also probably involved in the regulation of *OLE1* in response to exogenous unsaturated fatty acids (UFA), low temperature and hypoxic conditions [17–19]. But in these examples, the information about the regulatory mechanism of desaturase genes is still fragmentary, so there have been no complete signaling pathways obtained in the light of our present knowledge and perhaps other new transcription factors, new cellular sensors and new signaling pathways remain to be identified.

Unlike the yeast *S. cerevisiae*, which has only one $\Delta 9$ -desaturase encoded by the *OLE1* gene, *P. pastoris* possesses a relatively complete system of UFA biosynthesis including the formation of two PUFA species linoleic acid (LNA, C18:2n-6) and α -linolenic acid (ALA, C18:3n-3) from the conversion of oleic acid (OLA, C18:1n-9) which requires two other desaturases ($\Delta 12$ and $\Delta 15$) in addition to $\Delta 9$ -desaturase. The methylotrophic yeast *P. pastoris* has also been proved to be an excellent system for high-level expression of heterologous proteins because of many advantages [20, 21]. For the reasons above, *P. pastoris* is a better choice for constructing a transgenic strain for the production of specific fatty acids and a good eukaryotic model organism for studies on the regulation mechanism of fatty acid biosynthesis.

Therefore, in this study, we investigated the effects of different external conditions such as low temperature and exogenous fatty acids on desaturase gene expression, desaturase gene promoter activity and fatty acid production of *P. pastoris* GS115. Moreover, our findings demonstrate

Fig. 1 Time-course expression study of *P. pastoris* GS115 desaturase genes in response to low temperature. The graphs show the relative quantitation results of four desaturase gene expressions (a *Fad9A* gene, b *Fad9B* gene, c *Fad12* gene, d *Fad15* gene) by real-time PCR. Relative gene expression measured relative to β -actin and normalized to controls was calculated as $2^{-\Delta\Delta C_T}$. Error bars represent the average SD of three separate experiments with three parallels

that Spt23p plays a role in the regulation of two $\Delta 9$ -desaturase genes and the synthesis of OLA. However, to understand the actual function of Spt23p in the regulation of desaturase gene expression and fatty acid metabolism, further experimental work is needed.

Materials and Methods

Strains and Media

The methylotrophic yeast *P. pastoris* GS115 strain (*his⁻ Mut⁺*) commercially available from Invitrogen (San Diego,

CA, USA) was used for the whole work. It was grown under normal conditions at 30 °C in a yeast extract–peptone–dextrose (YPD) medium consisting of 1 % yeast extract, 2 % peptone, and 2 % dextrose. Minimal dextrose plates (MD) containing 1.34 % yeast nitrogen base without amino acid, 4×10^{-5} % biotin, 2 % dextrose, 2 % agar were used for the selection of His⁺ transformants. In experiments employing fatty acid supplements, the growth medium was supplemented with 1 % Nonidet P-40 (Sigma, USA) and appropriate fatty acids (Cayman Chemicals, USA) at a concentration of 1 or 2 mM.

Real-Time PCR Analysis of Desaturase Gene Expression

The *P. pastoris* cells were grown until the late exponential growth phase ($OD_{600} = 2.5$) and then shifted quickly to the low-temperature (15 °C), or added high concentration of exogenous fatty acids (at a concentration of 1 mM) to the cultures. Cells were harvested after a further incubation period of 1, 4 and 8 h by centrifugation and washed twice in cold RNase-free water. Total RNA was extracted using TRNzol reagent according to the manufacturer's protocol (TianGen, China). Residual genomic DNA contamination was removed by digestion with 10 units of DNase I (Takara, China) at 37 °C for 30 min followed by inactivation at 80 °C for 10 min. Reverse transcription PCR was

performed using M-MLV reverse transcriptase (Promega, USA) to synthesize the first cDNA. Five pairs of specific primers for real-time PCR (Table 1) were designed according to the previously published gene sequences in the *P. pastoris* GS115 genome database (<http://www.pichiagenome.org/>) [22]. The mRNA levels were measured by the SYBR Green I fluorescence method. Realtime PCR was performed in 96-well optical plates on an iCycler iQ5 multicolor real-time PCR detection system (Bio-Rad). Each reaction was performed according to the manufacturer's protocol (TianGen, China). Relative expression of target gene products was normalized to the housekeeping gene β -actin and calculated using the comparative C_T method, and all the data obtained were treated by the iQ5 optical system software version 2.0.

Fatty Acid Extraction and Analysis

The cultured cells were harvested at different time points by centrifugation and washed three times in distilled water. Subsequently, cellular fatty acids were extracted by incubating 100 mg dry yeast powder in 5 mL 5 % (w/v) KOH/methanol for saponification at 70 °C for 5 h. After the pH was adjusted to 2.0 with HCl, total fatty acids were subjected to methyl esterification with 4 mL 14 % (w/v) boron trifluoride in methanol at 70 °C for 1.5 h. Then, fatty acid methyl esters (FAME) were extracted with *n*-hexane after

addition of saturated sodium chloride solution. The total FAME were analyzed by gas chromatography (GC) using a GC-6890N machine (Agilent, USA) equipped with a flame ionization detector and a HP-INNOWAX capillary column (25.0 m × 0.53 mm × 0.20 μm). The temperatures of the injector and detector were 280 °C, respectively. The oven temperature was programmed starting at 160 °C, and then increased to 210 °C at a rate of 10 °C/min, held for 5 min, and then increased gradually to 240 °C at a rate of 2 °C/min, held for 15 min. Ultra-high purity N₂ was used as the carrier gas at a constant flow rate of 1.0 mL/min. The split ratio was 4:1, and the injection volume was 5 μL. Relevant FAME were identified by comparison of their peaks with those of standards (Cayman Chemicals, USA).

Generation of pFAD15 Promoter–Reporter Gene Construct and β-Galactosidase Assay

The *lacZ* gene was amplified by PCR using YEp356 [23] as the template and then cloned into the promoterless *P. pastoris* integrative pIB1 vector [24] (*SpeI/PstI*) to create pIB1lacZ. The promoter region of *P. pastoris* Δ15-desaturase gene (pFAD15) was obtained from genomic DNA and the PCR product was digested with *Bam*HI and *Spe*I and then inserted into pIB1lacZ which had been digested with the same enzymes. The primers used for the PCR are listed in Table 1. All constructs were sequenced to confirm correct orientation of insertion and no PCR-induced mutations. The *Stu*I-linearized and dephosphorylated promoter–reporter gene construct was directly electrotransformed into strain GS115. The recombinant colonies of His⁺ phenotype were selected on MD plates and evaluated by PCR with primers pIB1-F and pIB1-R (Table 1) and the resulting PCR fragments were subsequently confirmed by DNA sequencing. Positive transformants were grown to late exponential phase in YPD media. After treatments of low temperature and exogenous fatty acids, pFAD15 activities were determined via β-galactosidase assay. β-Galactosidase assay was measured in triplicate with *o*-nitrophenyl-β-D-galactopyranoside (ONPG) as a substrate on permeabilized cells treated with SDS and chloroform according to previously established method [25, 26].

Construction of *P. pastoris* *Spt23*Δ Mutant Strain

The *Spt23* ORF was amplified from genomic DNA by PCR using primer pair PPSpt23FA and PPSpt23RA (Table 1). The amplified fragment was then subcloned into pMD19-T simple vector (TA-cloning vector, Takara, Japan), generating pMD19T-Spt23. The *His4* gene cassette was obtained from the plasmid pPIC3.5K (purchased from Invitrogen) by using specific primers containing *Bam*HI flanking restriction sites (Table 1). The resulting fragments were

purified and treated with *Bam*HI, and then ligated into the *Bam*HI site of the plasmid pMD19T-Spt23 within *Spt23* gene to produce pMD19T-Spt23/His. The disruption cassette *Spt23*/His4/*Spt23* was amplified using the corresponding primer pair in Table 1 from pMD19T-Spt23/His and transformed into *P. pastoris* GS115 by electroporation. After a double crossover-mediated gene replacement, His⁺ transformants were selected on MD plates lacking histidine at 30 °C. The His⁺ transformants of *Spt23*Δ were further evaluated on genomic DNA by PCR to determine if disruption does occur with primer pair PPSpt23FA and PPSpt23RA, and PHis4TT-F23 and PHis4TT-R23, respectively. All the resulting PCR fragments were subsequently confirmed by DNA sequencing.

Statistical Analysis

Differences in mRNA and β-galactosidase expression between control and other samples, and growth rates between wild type and mutants were evaluated using one-way analysis of variance (SPSS for Windows Version 13.0), which were considered statistically significant when the *P* value was <0.05.

Results

Effects of Low Temperature and Exogenous Fatty Acids on mRNA Expression of Desaturase Genes

Because it has been reported that the desaturase genes are regulated by low temperature and exogenous UFA in *B. subtilis* [6, 27], *S. cerevisiae* [9, 10] and also other fungi [28, 29], the effects of the two factors on expression of desaturase genes in *P. pastoris* were investigated by real-time PCR analysis using the β-actin gene as an internal control. As shown in (Fig. 1), the mRNA expression of four genes reached a maximum at the time point of 1 h, and the increase was followed by a decrease in the mRNA expression at later time-points of 4 and 8 h after the quick shift from 30 to 15 °C. The upregulation of mRNA expression by low temperature was greater for two Δ9-desaturase genes (*Fad9A* and *Fad9B*) compared with the Δ12-desaturase gene (*Fad12*) and Δ15-desaturase gene (*Fad15*) after 1 h incubation at 15 °C and there was little increase in the mRNA level of *Fad12* (1.3-fold) 1 h after the shift. There was almost no change in the gene expression of the control which was cultured at normal growth temperatures during the 8 h period. As shown in Fig. 2, after 1 h of the treatment with 1 mM OLA, mRNA expression of all genes was downregulated rapidly, with *Fad9A* and *Fad9B* being more potent, and no further decrease in the levels of these transcripts was observed at 4

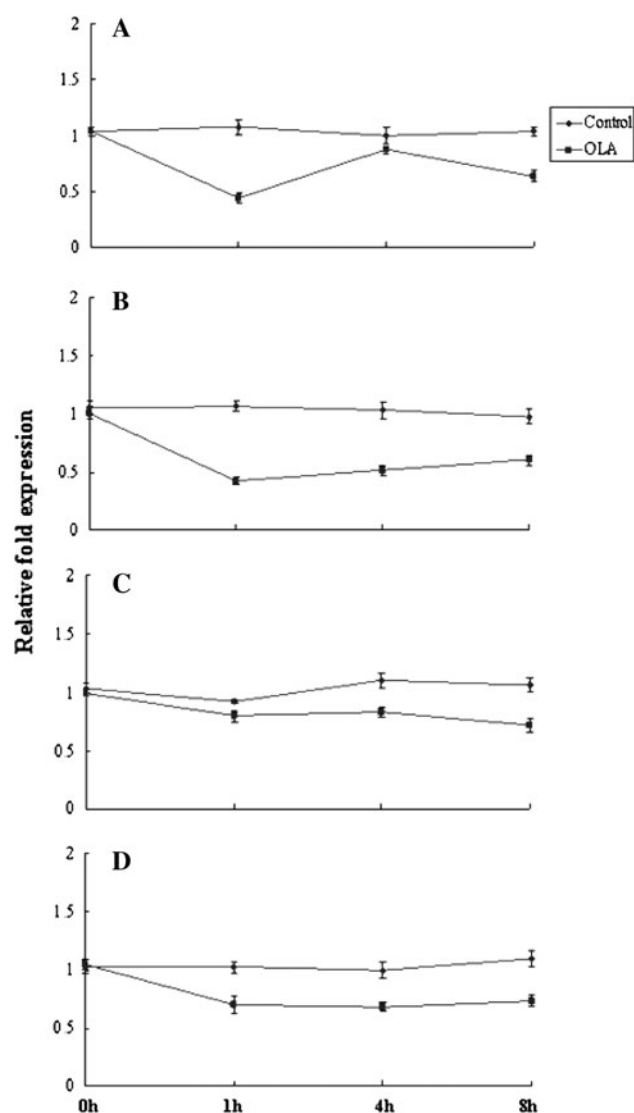

Fig. 2 Time-course expression study of *P. pastoris* GS115 desaturase genes in response to exogenous OLA. The graphs show the relative quantitation results of four desaturase gene expression (a *Fad9A* gene, b *Fad9B* gene, c *Fad12* gene, d *Fad15* gene) by real-time PCR. Relative gene expression measured relative to β -actin and normalized to controls was calculated as $2^{-\Delta\Delta C_T}$. Error bars represent the average SD of three separate experiments with three parallels

and 8 h. However, unlike monounsaturated OLA, saturated STA did not lower mRNA abundance of four genes and even mRNA levels of *Fad9A* and *Fad9B* were slightly increased at 1 h after the addition of STA (Fig. 3).

Changes in Fatty Acid Compositions in Response to Low Temperature and Exogenous Fatty Acids

In order to characterize the relationship between desaturase gene expression and fatty acid production, we measured the relative abundance of the corresponding fatty acid products using GC at the product level. As shown in Table 2, there was

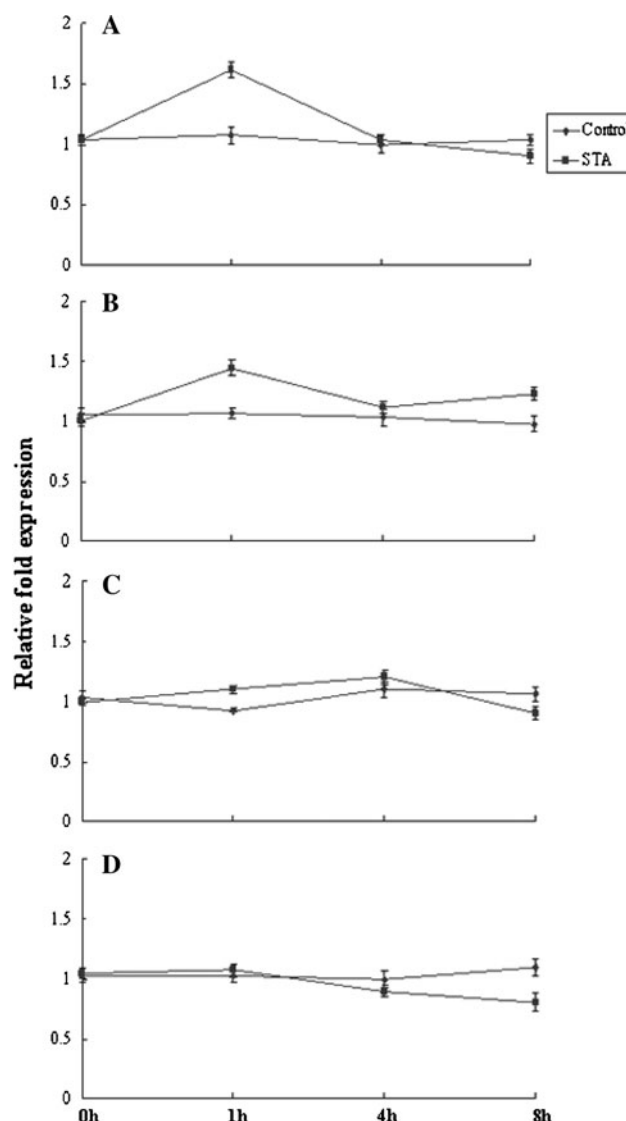

Fig. 3 Time-course expression study of *P. pastoris* GS115 desaturase genes in response to exogenous STA. The graphs show the relative quantitation results of four desaturase gene expression (a *Fad9A* gene, b *Fad9B* gene, c *Fad12* gene, d *Fad15* gene) by real-time PCR. Relative gene expression measured relative to β -actin and normalized to controls was calculated as $2^{-\Delta\Delta C_T}$. Error bars represent the average SD of three separate experiments with three parallels

no obvious increase in the content of corresponding desaturation products OLA + LNA + ALA, LNA + ALA and ALA at the time point of 1 h after the low-temperature shift even though the mRNA expression of Δ^9 -desaturase gene, Δ^{12} -desaturase gene and Δ^{15} -desaturase gene were all increased at the same time point. Surprisingly, a substantial increase of OLA amount and decrease of ALA content compared with control was observed ($P < 0.05$). As shown in Table 2, the percentage of OLA increased from 60.54 to 69.51 % after 8 h of low temperature treatment, whereas the ALA content decreased from 7.99 % to a minimum value of

2.31 % at 4 h of low temperature treatment, and to 4.09 % after low temperature treatment for 8 h. However, the interesting mechanisms of why low temperature treatment increased the production of OLA but repressed the production of ALA during a short time period remain to be determined at the molecular level in the future. Likewise, changes in desaturase gene expression caused by the addition of STA and OLA did not correspond to the changes observed in fatty acid composition (Table 3). As shown in Table 3, a nearly continuous increase in STA or OLA proportion was observed after feeding STA or OLA. This might be a result of their entering cells and being incorporated into cellular lipids with the passage of time. In contrast, the levels of other fatty acids were reduced on the whole but the LNA and ALA content increased transiently at 1 h after feeding OLA as shown in Table 3. These results indicated that the correlation between changes in mRNA transcript abundance and fatty acid products profiles was varied and there may be post-transcriptional control and other modes of regulation of UFA synthesis in *P. pastoris* when facing different stimuli.

Effects of Low Temperature and Exogenous Fatty Acids on pFAD15 Promoter Activities

There was no direct relationship between mRNA levels of desaturase genes and the relative amount of UFAs. We therefore measured the activity of desaturase gene promoter and we first selected a 1,000-bp 5' flanking fragment of *Fad15* (pFAD15) as the research object and studied the effects of low temperature and exogenous fatty acids on pFAD15 promoter activity. The pFAD15 promoter construct was transformed into GS115 to measure the β -galactosidase activity with wild-type GS115, pIB1 and pIB1lacZ constructs as the control. As shown in Fig. 4, after temperature downshift, β -galactosidase expression was increased approximately 1.2-fold at 1 h, approximately 1.4-fold at 4 h, and increases gradually to a level that is approximately threefold ($P < 0.05$) at 8 h. As shown in Fig. 5, when incubating cells with different fatty acids, neither PAM nor STA had a significant effect on reporter activity, whereas UFA resulted in a continuous, time-

Fig. 4 Analysis of pFAD15 promoter activity under low temperature by β -galactosidase assays. The results were obtained after 1 h (a), 4 h (b), 8 h (c) incubation. All values are mean of three replicates \pm SD

dependent and dose-dependent reduction ($P < 0.05$) in promoter activity, and ALA containing three double bonds appeared to have a more effective inhibition than LNA and OLA. The β -galactosidase activities of control were nearly undetectable.

Possible Function of Spt23p in Transcriptional Regulation of Desaturase Gene Expression

Previous studies have revealed that the transcription of the *S. cerevisiae* *OLE1* gene appears to be mediated by two homologous proteins Spt23p and Mga2p, and Mga2p was the first identified sensor for low temperature and UFA in the regulation of the *S. cerevisiae* *OLE1* gene [30]. A homologues of the *S. cerevisiae* *Spt23/Mga2* genes was found in the published *P. pastoris* GS115 genome using Basic Local Alignment Search Tool (BLAST) searches. To test whether the Spt23p protein of *P. pastoris* GS115 has similar functions in the regulation of its desaturase genes, we constructed the *Spt23* disruption mutant by homologous recombination as described in the “Materials and

Fig. 5 Effects of different exogenous fatty acids on pFAD15 promoter activity by β -galactosidase assays. The results were obtained after 1 h (a), 4 h (b), 8 h (c) incubation. All values are the means of three replicates \pm SD

Methods” section. After initial selection of *P. pastoris* integrants on MD plates, successful gene disruption was confirmed by PCR amplification using sequence-specific primers and genomic DNA template. The oligonucleotides are shown in Table 1. Wild type GS115 generated a fragment of about 3.3 kb with the primers PPSpt23FA and PPSpt23RA, while *Spt23Δ* generated a fragment of about 7.0 kb because a *His4* gene cassette of about 3.7 kb was inserted into the *Bam*HI site within *Spt23*. Wild type GS115 yielded a 3.7 kb fragment using primers PHis4TT-F23 and PHis4TT-R23, but the wild type could not (Fig. 6). The results confirmed that *Spt23* was deleted via double-crossover homologous recombination. Real-time analysis was performed to determine the effects of disruption of *Spt23* on the transcript levels of desaturase genes. Resulting data showed that the mRNA levels of *Fad9A* and *Fad9B* in the stationary phase cells of Δ *Spt23* mutant were markedly reduced at the levels $<25\%$ of

Fig. 6 Identification of *Spt23* mutation by PCR. *M* NI DNA marker III, 1 PCR product with PPSpt23FA and PPSpt23RA (*Spt23*Δ as template), 2 PCR product with PPSpt23FA and PPSpt23RA (wild type as template), 3 PCR product with PHis4TT-F23 and PHis4TT-R23 (*Spt23*Δ as template), 4 PCR product with PHis4TT-F23 and PHis4TT-R23 (wild type as template)

wild-type ($P < 0.05$). By contrast, the mRNA levels of *Fad12* and *Fad15* changed much less in comparison with the changes in the mRNA levels of *Fad9A* and *Fad9B* (Table 4). We further analyzed the changes in fatty acid composition, a decrease in the relative abundance of OLA and an increase in the relative content of LNA and ALA were observed ($P < 0.05$) (Table 5).

The time-course expression study showed that there were no clear changes in the expression for *Fad9A* and *Fad9B* of *Spt23*Δ strain in response to low temperature and exogenous OLA during the test period which was not

consistent with the results obtained with the wild type strain (Fig. 7). While there were no clear differences in the gene expression profiles of *Fad12* and *Fad15* in response to low temperature and exogenous OLA between the wild-type strain and *Spt23*Δ strains (data not shown). These data indicated that *Spt23p* are probably necessary for the control over the transcription of *Fad9A* and *Fad9B*, but not *Fad12* and *Fad15*. In addition, we also proved that the *Spt23*Δ strain grew much more slowly than wild-type cells under normal growth conditions by monitoring OD₆₀₀ of the cultures at 2-h intervals for 36 h (Fig. 8).

Discussion

In many organisms, multiple types of environmental stress could affect the productivity of PUFA. But a major hindrance preventing thorough investigation into the regulation mechanism of different desaturase when facing external stimuli or internal stimuli has been the lack of an effective way to quantify the amount and activity of desaturase. Thus, one of the aims of this study was to investigate the transcriptional changes of *P. pastoris* desaturase genes in response to various environmental factors such as low temperature and exogenous fatty acids. Both of two conditions can lead to changes in membrane fluidity with resultant subnormal functioning of cellular activities [31]. Our results demonstrate that the transient increase in the mRNA abundance for all desaturase genes occurred in response to low temperature and the repression of desaturase gene transcription by exogenous UFA was also transient which presumably reflects that the transcription of desaturase genes is only regulated by the external signal at the initial stage. It is perhaps noteworthy that expression of *Fad9A* and *Fad9B*, both of which encode Δ⁹-desaturase converting STA into OLA in the first step of *P. pastoris* PUFA synthesis, were strongly regulated compared with the other two desaturase genes. It is also quite interesting for us to investigate the possible reasons in the future.

Further analysis revealed that the fatty acid compositions change irregularly and did not correspond to changes of levels of mRNA expression over a period of hours when cells are shifted to low temperature or exogenous fatty acids. These results demonstrate that UFA synthesis in

P. pastoris appear to be controlled predominantly by post-transcriptional regulation of desaturase genes. Similar mechanisms were also found in *S. cerevisiae* [10], *Mucor rouxii* [28, 29] and *Synechococcus* sp. [32].

Functional analysis of the pFAD15 promoter indicated that low temperature functions as a transcriptional activator and UFA act as negative regulators of desaturase gene transcription. SFA failed to downregulate the promoter activity. The responses of promoter activities to low temperature and exogenous fatty acids appeared to be different with gene expression profile changes which were basically rapid and transient during the test period. This observation suggested that there may be an unknown end-product (changes in fatty acid compositions) feedback regulation in the transcription of desaturase genes to maintain cellular UFA homeostasis.

P. pastoris Spt23p shared a high degree of sequence identity in the conserved domains with *S. cerevisiae* Spt23p/Mga2p, so we hypothesized that *P. pastoris* Spt23p exerts a similar function with *S. cerevisiae* Spt23p/Mga2p. In this study, we observed that *P. pastoris* Spt23p may control the expression of Δ9-desaturase genes and the production of OLA. Unlike *S. cerevisiae*, in which the simultaneous disruption of Spt23p/Mga2p results in synthetic auxotrophy for UFA due to loss of *OLE1* mRNA [15], in *P. pastoris*, disruption of *Spt23* resulted in substantial inhibition in expression of *Fad9A* and *Fad9B*, production of OLA and strain growth, but these were not completely inhibited as in *S. cerevisiae*. It is not surprising that the regulation of desaturase gene expression in *P. pastoris* is more complex than *S. cerevisiae* and involves multiple signal transduction systems that act at several levels of modulating gene expression.

In conclusion, our study suggests that low temperature and exogenous UFA can regulate the expression of *P. pastoris* desaturase genes at the transcriptional level and the primary function of Spt23p is to serve as a probable transcription regulator of the Δ9-desaturase gene, although perhaps other regulatory proteins and sensing mechanisms remain to be identified in the regulation of Δ9-, Δ12- and Δ15-desaturase genes under a wide range of physiological conditions. Further studies are in progress to address this point which is not clear at the moment.

Acknowledgments This study was supported by the National Natural Science Foundation of China (No. 30771355, 31270096).

biology materials has greatly facilitated the throughput of a fatty acid assay in a simple, rapid, and high throughput way [10–12]. However, the entire procedure for total lipids is time-consuming, requiring 60 min at 100 °C [10] or 2 h at 80 °C [13] with conductive heating for a complete transesterification of fatty acids, and increases the potential for oxidation.

Following the application of microwave irradiation in lipids extraction from foods [14], Lie Ken Jie and Yan-Kit initially applied microwave irradiation to the transformation of fatty acids in 1988 [15], including the esterification of free fatty acids within 5 min using a domestic microwave oven. Ever since, the application of the microwave as an energy source has been further developed in transesterification of phospholipid fatty acids from sheep brain serotonin receptor preparation [15, 16], human blood [17], vegetable and fish oil [18], and glycosphingolipids [19], with a reaction time as short as 20 s [16]. The fatty acid structures of products are identical either from microwave irradiation or the heatblock heating assay [18].

Nevertheless, compared to conductive heating, the transesterification of fatty acids by microwave irradiation using a household microwave oven are incomplete with a recovery of 78 % for total fatty acids in blood [17]. Clearly, the use of a domestic microwave oven in chemical synthesis presents significant safety issues. Thus, the application of microwave radiation in a fatty acid assay has not been further developed or optimally established. Tomas et al. [20] first applied a chemically safe, single-mode microwave oven to quantify meat acylglycerides with methanol and chlorotrimethylsilane. In this study, we sought to optimize the conditions of transesterification in microwave reaction systems for the fatty acids in human serum total lipids using methanol:hexane with acetyl chloride as the catalyst. It proved that the microwave irradiation could significantly reduce the reaction time with complete transesterification of fatty acids under optimal conditions.

Materials and Methods

Chemicals

Methanol was purchased from Burdick & Jackson (Muskegon, MI); hexane from EMD Chemicals Inc (Gibbstown, NJ); acetyl chloride from Sigma–Aldrich (St. Louis, MO); 2,6-Di-*tert*-butyl-4-methylphenol (BHT) from Acros (Geel, Belgium); sodium carbonate (anhydrous powder) from Mallinckrodt Baker, Inc. (Paris, KY). Standard docosatrienoic ethyl ester (22:3n-3) and GC reference standards GLC-462 were purchased from Nu–Chek Prep (Elysian, MN). The latter contains 28 fatty acid methyl esters

(FAME). All chemicals were of analytical grade, commercially purchased, and used without further purification.

Human Serum

All serum samples analyzed in this report were from one research blood donor, with an omnivore diet, in the Clinical Center of the National Institutes of Health. A bulk of blood was collected by venipuncture, and left at room temperature for 1 h prior to being centrifuged at 1,700g for 15 min at 4 °C to collect the serum. The serum was aliquoted, frozen, and stored at –80 °C until analysis.

Instrumentation

Analog Drybath Incubator

An analog heatblock from VWR International, LLC (West Chester, PA) was the conductive heating source as utilized in the reference method for fatty acid determination.

Microwave Reaction Systems

Two microwave reaction systems from CEM Corporation (Matthews, NC) were employed in microwave irradiation fatty acid analysis (microwave assay). Both systems provided constant temperatures at a pre-set number of degrees during transesterification of human serum lipids.

System S is a single-mode microwave reaction system (DISCOVER BenchMate), briefly referred to as Single-mode. Samples were processed one at a time in a pressurized 10-mL Pyrex glass reaction vessel with “snap-on” Teflon cap, which automatically vented when internal pressure reached 300 psi (2,068 pKa). The reaction temperature of 100 or 125 °C was pre-set and directly measured inside the glass vessel with a fiber optic temperature probe. Microwave power was initially set at no greater than 50 or 300 W, and automatically adjusted to maintain the reaction temperature through temperature and pressure feedback in the cavity. The reaction duration was examined at 1–5 min.

System M is a multimode microwave accelerate reaction system (MARS), briefly referred to as Multimode. It can process multiple reactions simultaneously, up to 24 20-mL Pyrex glass vessels or up to 40 10-mL Teflon reaction vessels. The accessory for glass vessels, GlassChem20, included one turntable with a shield containing 24 receptacles. One set of reaction vessels was composed of a glass vessel, a vessel top, a vent plug, and a composite sleeve. Reaction temperatures of 100 or 125 °C was pre-set, measured, and controlled through a single reference vessel using a fiber optic probe inserted into a thermowell that was in direct contact with the sample in the reagent

mixture. For the Teflon vessels, pressurized “snap-on” Teflon caps were employed, and an onboard infrared sensor was used to measure and control the temperature. After having reached the reaction temperature, 100 or 125 °C, the initial microwave power of 400 W ($n \leq 4$) was automatically adjusted to hold the temperature until the end of the reaction. Compressed air was applied to cool down the sample. Reaction duration was examined at a range of 1–10 min.

Gas Chromatography

An Agilent 6890 (Plus LAN) fast gas chromatograph, coupled with a flame ionization detector and a 7683 series injector (Agilent Technologies, Inc., Santa Clara, CA), was employed to acquire the signal of the FAME. A fused-silica, narrow-bore, high-efficiency DB-FFAP capillary column (15 m length \times 0.1 mm ID \times 0.1 μ m film thickness) was used for chromatographic separation of FAME with hydrogen as the carrier gas at a constant pressure of 51.5 psi (355 kPa). The make-up nitrogen gas was set at a constant flow of 10 mL/min. The inlet and detector temperature were set-up at 250 °C. A split ratio of 50:1 was applied. The oven temperature program was initially set at 150 °C with a 0.25 min hold, ramped at 35 °C/min to 200 °C, a further 8 °C/min ramp to 225 °C with a 3.2 min hold, and then 80 °C/min ramp to 245 °C with a 9 min hold to bake off the column. A total of 28 FAME in GLC-462 were eluted in about 8 min with a total run of about 17 min [21]. GC ChemStation Rev. B.01.01 (164) SR1 was employed for data acquisition and peak integration.

Fatty Acid Direct Transesterification Method

The one-step direct transesterification in the Lepage & Roy fatty acid assay [10, 13] was applied as the reference method. Compared to the conventional technique, the quantification of fatty acids in the Lepage & Roy assay was carried out in methanol:hexane (4:1, by vol) with acetyl chloride without prior extraction of lipids. It is rapid and reliable; in particular, capable of maintaining short chain fatty acids, which are essential in dietary studies but easily underestimated in the conventional method during lipid extraction and subsequent evaporation. Briefly, 100 μ L of serum or 0.9 % sodium chloride as the solvent blank was added to a 16 \times 100 mm disposable borosilicate glass test tube placed in ice containing 1.6 mL of methanol, 0.4 mL of hexane, and 200 μ L of acetyl chloride. Standard 22:3n-3 ethyl ester (27.6 nmol per sample) was used as the internal standard (ISTD). The test tubes were then tightly closed under nitrogen with Teflon-lined caps, and heated in an analog heating block at 100 °C for 60 min. Afterwards, the samples were chilled in ice and then neutralized by the

addition of 5 mL of 6 % Na₂CO₃ solution followed by centrifugation at 1,700g for 4 min. The hexane, served as the upper phase containing fatty acid methyl ester, was collected and the volume was reduced to \sim 30 μ L prior to being placed in a GC autosampler tray. In general, 1 μ L of aliquot was injected into GC inlet for data acquisition.

The microwave accelerated fatty acid assay was modified from the above Lepage & Roy procedures with only modification in the heating conditions, including energy source, temperature, duration, and reaction vessels. A set of experiments ($n = 11$) was designed to optimize the reaction duration at 100 or 125 °C with complete transesterification of the fatty acids in the solvent system of methanol, hexane, and acetyl chloride. As presented in Table 1, all procedures across eleven microwave groups (series S and M) were the same except for the varied reaction temperatures (100 or 125 °C), duration (1, 2.5, 5, or 10 min), the initial power of microwave irradiation (50, 300, or 400 W), and materials of reaction vessels (disposal glass, pressurized glass or Teflon). Multispeed magnetic stirring and compressed air cooling were also employed. All of the microwave assays were carried out in triplicate except group M1 (duplicate).

Calculation and Statistics

Data were expressed as means \pm SD in concentrations, μ mol of fatty acid per L serum (μ M), or the proportion of each fatty acid in total amount of the identified fatty acids in each sample (mol%). The concentrations were calculated by comparing the integrated areas of each fatty acid peak in the gas chromatograms with that of the known amount of ISTD added in the sample. Automated data processing through macro programming with Microsoft VBA 6.3 (Microsoft Corp; Seattle, WA) was performed during calculation of fatty acid values. Details were reported in the previous study [13]. Recovery of each fatty acid was defined as the percentage of fatty acid values determined by the microwave assay to those by the reference method. The 20- and 22-carbon fatty acids with three or more carbon-carbon double bonds were categorized as highly unsaturated fatty acids (HUFA), which included 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6 in n-6 PUFA; 20:5n-3, 22:5n-3, and 22:6n-3 in n-3 PUFA; and 20:3n-9. The proportion of n-6 or n-3 HUFA, that is n-6 % or n-3 % HUFA, was computed by dividing the sum of n-6 or n-3 HUFA by the total HUFA in each sample and multiplying by 100.

Results of each fatty acid determined by multiple methods were compared by One-way ANOVA followed by a Post Hoc Tamhane's T2 test using SPSS 17.0 (SPSS Inc.; Chicago, IL). Statistic significance for a particular experimental condition was presented in comparison with the reference method at $P < 0.01$.

Table 1 Conditions of transesterification by either conductive heating or microwave irradiation

| Groups | Reaction conditions for human serum total lipids | | | | | | |
|---------|--|------------------|----------------|----------------|------------------|--------------|----------|
| | Heaters | Temperature (°C) | Duration (min) | Energy sources | Reaction vessels | Abbreviation | |
| Control | Analog heatblock | 100 | 60 | conductive | glass 1, 7 mL | C-100x60 | |
| S1 | Single-mode | 100 | 5 | MW ≤ 50 W | glass 2, 10 mL | S1-100x5 | |
| S2 | Single-mode | 100 | 2.5 | ↓ | ↓ | S2-100x2.5 | |
| S3 | Single-mode | 100 | 1 | | | ≤ 50 W | S3-100x1 |
| S4 | Single-mode | 100 | 1 | | | 300 W | S4-100x1 |
| S5 | Single-mode | 125 | 1 | | | 300 W | S5-125x1 |
| M1 | Multimode | 100 | 1 | 400 W | glass 2, 20 mL | M1-100x1 | |
| M2 | Multimode | 100 | 2.5 | 400 W | ↓ | M2-100x2.5 | |
| M3 | Multimode | 100 | 5 | 400 W | | M3-100x5 | |

Results and Discussion

This study focused on microwave irradiation as an alternative energy source for one-step direct transesterification of fatty acid components of total lipids in human serum. The fatty acid concentrations (μmol/L) determined by microwave assays in methanol:hexane:acetyl chloride (4:1:0.2, by vol) were compared in Fig. 1, including total fatty acids (A), low abundance fatty acids (<50 μM; B), intermediate abundance (50–250 μM; C), and high abundance (>250 μM; D). The Lepage & Roy assay was employed as the reference method, which applied the same solvent system but transesterified in a heating block. The corresponding fatty acid profiles (mol%) are presented in Table 2.

Complete Transesterification

It was apparent that the concentrations of various fatty acids in microwave groups S4-100 × 1 and M5-125 × 5 in Fig. 1a–d were consistently close to those in the control group (C-100 × 60). As presented in Table 2, the total amount of fatty acids (μmol/L) was 7,562 (S4-100 × 1) and 7,304 (M5-125 × 5) in microwave groups compared to 7,304 in control group, which represented recoveries of 103 and 100 %, respectively. Similarly, the recoveries of the categorized fatty acids, including saturates, monounsaturates, n-6 PUFA, and n-3 PUFA, were in the ranges of 96–106 % (S4-100 × 1) and 97–102 % (M5-125 × 5). Compared to the control group, it was observed that the recoveries of individual fatty acids ($n = 23$) in both groups were 94 % or greater for all except some minor fatty acids—20:0, 22:0, 24:0, and 24:1n-9, which were lower as 84 %

(range 79–91). These minor ones accounted less than 2.5 % of moles of total fatty acids. In particular, the recoveries of individual PUFA in both groups were in range of 95–105 % except for 18:3n-6 (109 %) and 20:2n-6 (113 %) in S4-100 × 1, and 20:3n-6 (109 %) and 20:5n-3 (109 %) in M5-125 × 5. Marginal greater recoveries for 20:5n-3 could be explained by the reduced potential oxidation in microwave assay, as observed by Khan and William [22]. It was likely similar to 20:3n-6. Furthermore, 100.0 % of ISTD 22:3n-3 ethyl esters added in samples were transmethyated to 22:3n-3 methyl esters in M5-125 × 5, and 99.5 % in S4-100 × 1. Thus, taking the above conditions as optimal, the fatty acids of interest in human serum were completely transesterified for all major ones and most minor ones with microwave irradiation heating at 100 °C for 1 min in Single-mode with an initial power of 300 W (S4-100 × 1) or 125 °C for 5 min in Multimode with 400 W (M5-125 × 5).

Additionally, the recoveries for the categorized fatty acids in group S1-100 × 5, 100 °C for 5 min in Single-mode, were in the range of 96–103 % which indicated a complete transesterification of those in groups S4-100 × 1 and M5-125 × 5. However, upon inspection of panels B and C in Fig. 1, the minor fatty acids—20:0, 22:0, 24:0, and 24:1n-9, reached only 60–69 %. Thus, this was not considered as optimal transesterification.

Given the varied features of the two microwave reaction systems, the difference between the two optimal conditions were expected and could be mainly derived from the different temperature control systems and the varied number of sample processed in each system. The actual temperature in Multimode was measured and controlled by an internal fiber optic probe inserted in the reference vessel,

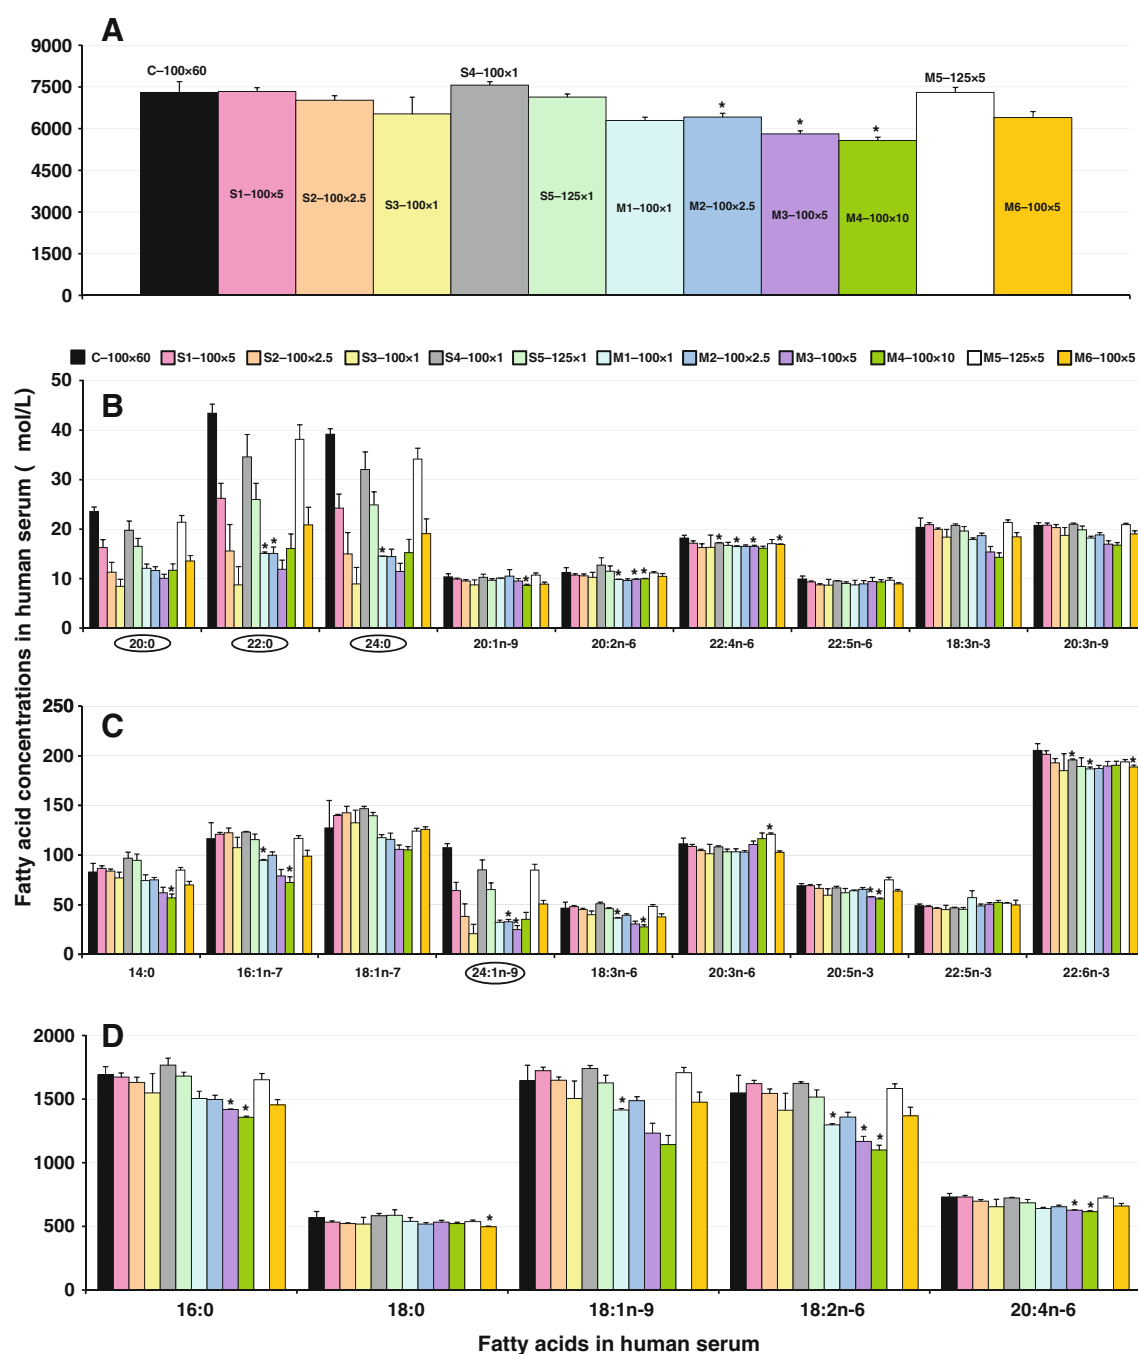

Fig. 1 Comparison of the concentrations of fatty acids (μmol/L) in human serum determined by microwave accelerated assay for eleven conditions (S and M series) with those by Lepage & Roy assay, the reference method (control group C-100 × 60). Values are presented as means ± SD, $n = 3$ except M1-100 × 5 ($n = 2$) and C-100 × 60 ($n = 16$). **a** Total fatty acids; **b** Low abundance fatty acids, <50 μM;

c Intermediate abundance fatty acids, 50–250 μM; **d** High abundance fatty acids, >250 μM. Further details regarding the reaction conditions are presented in Table 1. One-way ANOVA followed by Tamhane's T2 was applied to multiple comparison; asterisks indicate statistically differences in comparison with the control group at $P < 0.01$. Unit conversion: 1 μmol/L of fatty acid ≈ 0.36 μg/mL

but in Single-mode by the cavity outside the reaction vessel. In addition, it would be expected in Multimode that a much higher initial microwave power setting would be needed to maintain the optimal transesterification conditions when the number of samples in each batch increased.

The recent report by Tomas et al. [20] shows similar results ranging between 103 and 117 % for recoveries of 16:0, 18:0, 18:2n-6, and 20:4n-6 in meat acylglycerides using a single-mode microwave reaction system. However, the catalyst (chlorotrimethylsilane) applied in microwave

irradiation to accelerate transesterification is different from that in the reference method (boron trifluoride). This might cause some variation.

Partial Transesterification

In the remaining nine microwave conditions tested, including groups S1–S3, S5, M1–M4, and M6, only

86–99 % of 22:3n-3 ethyl esters were converted to methyl esters. Similarly, the recoveries (%) for total fatty acids, saturates, monounsaturates, and n-6 and n-3 PUFA, were within lower and wider ranges as 76–100, 81–96, 68–103, and 90–99, respectively. It was observable that fatty acids were partially transesterified under these conditions, which were thus considered as sub-optimal. However, after having been calibrated with ISTD, the concentrations of

^c Mono–monounsaturates; HUFA: highly unsaturated fatty acids; see footnote to Table 1 for further abbreviations

^d Unit conversion: 1 μmol/L of fatty acid ≈ 0.36 μg/mL

HUFA in these nine groups showed results close to those from the optimal conditions, groups S4–100 × 1 and M5–125 × 5, as summarized in Table 2. The average

concentration of total HUFA in eleven microwave groups was $1,146 \pm 53$ μmol/L serum with coefficients of variance as low as 4.6 %. It reflected about 94 % (range

89–100 %) of that in the Lepage & Roy control group ($C-100 \times 60$).

In addition, n-6 % HUFA exhibited a very narrow range as 71–72 %, while its counterpart, n-3 % HUFA, as 26–28 %, across the eleven microwave groups presented in Table 2. The ratio of n-6 to n-3 HUFA was 2.6–2.7. Compared to the reference method, their recoveries were 99–101, 98–104, and 95–103 %, respectively. Apparently, these indices were very consistent with those in the control group. A similarity can be observed in Armstrong's study [17] where n-3 % HUFA in human whole blood measured by microwave assay (53.6 %) was close to that by conventional assay (54.4 %) despite low recovery for the concentration of n-3 HUFA (74 %). Thus, if only n-3 % or n-6 % HUFA was of interest in human serum total lipids, transesterification under both optimal and sub-optimal conditions in either single-mode or multimode microwave systems would be sufficient.

Low Efficiency Transesterification

The recoveries of fatty acids 20:0, 22:0, 24:0, and 24:1n-9 in the microwave assay under sub-optimal reaction conditions were significantly lower than under optimal conditions; only 20–70 %, as observable in the bar graph presented in Fig. 1 panels B and C. These low recoveries could not be calibrated by ISTD added prior to chemical analysis. The extension of the reaction time up to 10 min ($M4-100 \times 10$) did not increase the efficiency of transesterification. This is in agreement with a reported study of microwave-assisted extraction of active ingredients of plants [23], in which longer times do not yield higher extraction recovery. It could possibly be explained as some lipids, such as sphingolipids, being more difficult to transesterify than other lipids regarding the microwave irradiation power, duration, and temperature, as suggested by Armstrong et al. [17].

Previously, the low recoveries of transesterification by microwave irradiation using a domestic microwave oven were extensively observed for all fatty acids, such as 78 % for total fatty acids, 61–87 % for PUFA, and 20–30 % for 22:0, 24:0, and 24:1n-9 [17]. In addition to the non-professional microwave irradiation applied, this low efficiency derivatization is probably in part due to a contribution of the applied boron fluoride, which is a better catalyst for methanol methylation of non-esterified fatty acids [24] or transesterification of isolated lipids than the lipid complexes in the biological samples.

Application and Limitation

Compared to the extreme explosive conditions utilized in domestic microwave ovens in previous reports [16, 17],

these innovative microwave reaction systems in this study were designed to be explosion proof for pressurized organic reactions. The transesterification of fatty acids in these systems was not only chemically safe, but also well controlled over the reaction temperature with automated, continuous adjustment of the microwave power. This made it possible to achieve complete transesterification of the fatty acids in human serum total lipids at the conventional reaction temperatures as those in heatblock heating, but greatly reduced the reaction duration. Because of the disparity differences in the capacities, such as pressure control, temperature control, and reaction efficiency, no reaction conditions applied in domestic microwave oven would be examined in these microwave reaction systems.

However, this microwave fatty acid assay was validated only with transesterification of total lipids in one particular solvent system (methanol, hexane, and acetyl chloride) at small sampling size. Further studies are needed to define conditions for fatty acid determination in individual lipid classes or for various tissues. Based on the present work it is expected that such applications could be validated with replacement of the heating block by microwave irradiation and with similar chemical procedures. Future work would also be needed to determine if even faster times are possible.

Summary

Under optimal conditions ($S4-100 \times 1$ and $M5-125 \times 5$) utilizing either a single-mode or a multimode innovative microwave reaction system, microwave irradiation energy could replace the conductive heating to transesterify fatty acids in human serum lipids by methanol, hexane, and acetyl chloride. Microwave irradiation heating provided fatty acid quantifications, which were comparable to the reference method but with greatly reduced reaction duration, from 60 min to 5 min or less. This microwave accelerated fatty acid assay could be useful in small- or large-scale clinical studies and laboratory research as a rapid, reliable, safe, and efficient method.

Acknowledgments The authors wish to acknowledge Drs. Norman Salem Jr., Charlie Serhan, and William E.M. Lands for the valuable advice and encouragement on the method development. Thanks to Ms. Keller Barnhardt for set-up of the microwave reaction systems and to Ms. Cindy Clark from the NIH Library Writing Center for assistance with manuscript editing. This project was funded by the Intramural Research Program of the National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health.

the American Institute of Nutrition (AIN) [1]. One rationale for developing this diet was to provide researchers with a nutritionally adequate diet that would allow for standardizing studies between laboratories. Not long after this diet was developed several groups reported undesirable physiological effects linked to the diet, such as hemorrhagic deaths [2], nephrocalcinosis [3], and fatty liver [4]. An amended formulation of the diet (AIN-76A) was developed in 1980 with an increased vitamin K content to address the hemorrhagic effect [5]. In 1993 two revised diets were formulated to replace the AIN-76A, a version for growing animals (AIN-93G) and a maintenance formula for mature animals (AIN-93M). These revised diets contained a higher calcium to phosphorus ratio (from 0.75 to 1.3) to prevent the nephrocalcinosis found in female rats consuming the AIN-76A diet [1]. In addition, the carbohydrate composition was changed from 50 % sucrose and 15 % cornstarch in the AIN-76A formula to ~40 % cornstarch, 15 % dextrinized cornstarch, and 10 % sucrose in the AIN-93G diet. This change represents a fivefold decrease in the fructose content of the diet and is not associated with the accumulation of hepatic lipids caused by long-term feeding of the high sucrose levels [6]. Despite the availability of the improved rodent diets, the AIN-76A still remains popular in specific research fields, such as in studies investigating the effects of diet on colon cancer using the aberrant crypt foci model (ACF). In fact, in a database maintained to compare the efficacy of diet modulation on the incidence of ACF, the overwhelming majority of studies have utilized the AIN-76A [7].

The propensity of the AIN-76A diet to result in accumulation of hepatic lipids is potentially of interest to human nutrition, as it is estimated that between 20 and 30 % of adults in Western countries have nonalcoholic fatty liver disease (NAFLD) and this level rises to between 70 and 90 % in obese individuals and those with diabetes [8]. To test the hypothesis that high levels of dietary fructose are responsible for the accumulation of hepatic lipids, Bacon et al. [9] tested the effects of modifying the sucrose content of the AIN-76A diet in a 3-week feeding study in rats. According to the results, diets containing greater than 25 % sucrose resulted in significantly higher hepatic triacylglycerols (TAG) than ones with less than 20 % sucrose or chow.

We recently conducted an ACF study utilizing the AIN-76A diet to investigate the potential chemopreventive effects of a complex milk fat fraction [10]. In the study we used three diets with different fat compositions: (1) corn oil (CO), (2) anhydrous milk fat (AMF), and (3) anhydrous milk fat supplemented with milk fat globule membrane (AMF-MFGM). CO diet is the standard fat source for the AIN-76A diet, and for the AMF diet, the 5 % mass of fat was replaced with AMF. Formulation of the AMF-MFGM

diet was achieved by utilizing an isolate of MFGM (providing 10 % phospholipids of total fat) that was isolated from cream, and which also contained protein, carbohydrate, and minerals in addition to the fat. The details of the diet formulation have been reported previously [10].

MFGM is derived from the apical surface of mammary epithelial cells and surrounds the fat droplets in milk [11]. It is composed primarily of TAG, proteins, and phospholipids (PL) [12]. The composition of the polar lipids of MFGM can vary according to the method of isolation, but the major constituents are phosphatidylcholine (~32 %), phosphatidylethanolamine (32 %), sphingomyelin (~24 %), phosphatidylinositol (~4 %), phosphatidylserine (~3 %), and gangliosides (~3 %) [13]. A large amount of this material is produced in the USA each year as a byproduct of butter production, and is available as a food ingredient. Owing to its unique lipid profile and membrane protein profile, MFGM has been suggested as a potentially bioactive food ingredient with novel nutritional functionalities [14]. Despite this supposition, few studies have been conducted in vivo with either animal models or humans to evaluate the potential of this material as a bioactive ingredient.

The goal of this study was to investigate lipid metabolism in rats fed a diet known to induce hepatic stress. Our approach involved subjecting lipid-metabolizing tissues to two different, yet comprehensive analytical techniques (lipid and gene expression profiling) to understand how the dietary fats affected the lipid metabolism.

Materials and Methods

Animals and Diets

Eleven animals used in this study were among a group of 63 male, weanling Fischer-344 rats (Charles River Laboratories) used in another study [10]. They were randomly assigned to one of three isocaloric dietary treatments that differed only in the fat source [10]. After a 7-day acclimation period on standard chow diets, the rats were individually housed in a room controlled for temperature, humidity, and light cycle and were given free access to experimental diets and deionized water. Food intake and weight were measured weekly. All experimental protocols involving animals were approved by the Utah State University Institutional Animal Care and Use Committee.

Animals were fed experimental diets for 12 weeks. After MRI analysis of body composition (EchoMRI-900TM), rats were killed by cardiac puncture following ketamine/xylazine anesthesia. Liver, adipose, and skeletal muscle tissues and blood samples were collected, flash frozen in liquid nitrogen, and stored at –80 °C for until the time of analysis.

Lipid Extraction

Tissue samples were removed from the freezer and a sample of tissue was cut into small pieces with a razor and placed in a mortar with liquid nitrogen and ground to obtain a fine homogenous powder. About 200 mg of the tissue powder or plasma from each sample was weighed and put into a screw-capped glass tube. Surrogate standards, including sphingomyelin, phosphatidylcholine, phosphatidylserine, phosphatidylethanolamine, diacylglycerol (DG), unesterified fatty acids (FFA), TAG, and cholesteryl esters (CE), were prepared in chloroform. Surrogate standards (100 μ l) for different lipid classes were added to each sample and weights were recorded. Lipids were extracted by the method of Folch et al. [15] with slight modifications. Samples were mixed with 5 ml chloroform/methanol (2:1 with butylated hydroxytoluene, BHT). The whole mixture was sonicated and then agitated for 15–20 min in an orbital shaker at room temperature. The mixture was washed with 0.2 volumes (1 ml for 5 ml solvent mixture) of 0.9 % NaCl solution and vortexed for 20 s. Subsequently, the mixture was centrifuged at $1,500\times g$ for 10 min to separate the two phases. The lower (chloroform) phase containing lipids was collected and evaporated under a nitrogen stream and then reconstituted in a small volume of hexane with BHT in a 4-ml amber vial and stored at -80°C until further analysis.

Separation and Recovery of Different Lipid Classes

Individual lipid classes of the extracted lipid were separated using thin-layer chromatography (TLC). Extracted lipid from each tissue was diluted by hexane with BHT such that 20 μ l of solution contained around 2.5 mg of lipid. Aliquots of 20 μ l were spotted on a 20×20 cm silica gel 60 Å analytical plate (500 μ m layer) (Whatman Inc., Florham Park, NJ). Lipid class standards were also spotted for detecting target bands. Total lipid classes were separated by developing the plate in a solvent system containing hexane, diethyl ether, and formic acid in the ratio of 80:20:2 (v/v/v). The TLC plate was then sprayed with 0.05 % primulin in acetone/water (8:2 v/v). Individual lipid bands on the TLC plate were detected under a hand-held UV lamp and the margins were marked with a pencil. Target lipid classes bands were scraped from the TLC plate using a small razor blade and collected into screw-capped glass tubes. Recovered lipid classes from total lipid TLC plate were PL, DG, FFA, TAG, and CE.

Fatty Acid Methyl Esters

Recovered lipid classes were transesterified into fatty acid methyl esters (FAME) using the method of Curtis et al.

[16] with slight modifications. In each tube, 0.8 ml hexane and 1.2 ml 10 % (v/v) acetyl chloride in methanol were added. Tubes were capped, vortexed for 20 s, and placed in an oven at 100°C for 40 min. Upon completion of the incubation period, samples were removed and allowed to cool to room temperature. Then 2 ml of a 6 % sodium carbonate solution and 0.4 ml hexane were added into each tube. On subsequent vortexing and centrifuging of tubes two distinct phases were obtained. The top organic layer was removed and transferred to gas chromatography (GC) vials. Solvent was evaporated under a nitrogen stream and FAME were collected in 100 μ l of hexane with BHT and transferred to GC vial inserts. The samples were subsequently analyzed by GC using a GC2010 (Shimadzu Scientific Instruments, Columbia, MD).

GC Data Analysis

For each GC run, standard curves were generated using commercially available FAME standards (Nu-Chek Prep, Elysian, MN). To establish the linearity of the detector response, a three-point calibration was generated with every sample set. The calibration standard, GLC-463, contained 42 fatty acids representing most of the common species found in mammalian tissues and dairy products. Chromatograms of sample FAME were compared with those of FAME standards to identify target fatty acids. The peak area for each fatty acid was then normalized to the peak area and concentration of the corresponding surrogate standard. Next, the molar concentration of the analytes was calculated and then converted to moles of the corresponding lipid classes through molecular weight calculations. The molar concentration of lipid classes was normalized to tissue sample weights to obtain concentrations ($\mu\text{mol/g}$ tissue) in each tissue. Lastly, the mole percentage of each fatty acid species was calculated.

Gene Expression Analysis

Total RNA was extracted from liver, muscle, and adipose tissue and prepared as previously described [10]. Microarray data were generated by Genome Quebec using the Illumina platform (Illumina, Inc., San Diego, CA). Data were analyzed using FlexArray 1.6, a custom statistical software program developed by Genome Quebec [17]. The expression data were filtered to remove feature ids that have not been detected. Next, a background adjustment and normalization were carried out using the Lumi algorithm (based on lumi Bioconductor package) in FlexArray 1.6. Background correction was carried out by using negative controls. Variance was stabilized by the variance-stabilizing transformation (VST) method and subsequently a robust spline normalization was conducted. Analysis of

variance (ANOVA) was conducted to evaluate significant diet effects on gene expression across treatment groups. The Cyber-T algorithm was employed to identify differentially regulated genes (CT gene lists) among tissues between treatment groups from ANOVA gene lists [18] followed by the Benjamini–Hochberg false discovery rate multiple testing correction [19]. The CT gene lists were then subjected to Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis using ArrayTrack v.3.5.0 (NCTR/FDA) [20].

Real-Time PCR

Total RNA was extracted from liver samples using the RNAeasy Mini-Kit (Qiagen, Valencia, CA). RNA quality was checked and the concentration measured by NanoDrop 1000 (Thermo Fisher, Waltham, MA). RNA (1 µg) was converted to cDNA using high-capacity cDNA reverse transcription kit (Life Technologies, Carlsbad, CA). Validated and predesigned TaqMan primers and probes (Life Technologies) were used to quantify cytochrome P450, family 8, subfamily b, polypeptide 1 (Cyp8b1, ID: Rn00579921_s1), 1-acylglycerol-3-phosphate *O*-acyltransferase 2 (Agpat2, ID: Rn01438505_m1), and angiopoietin-like 4 (Angptl4, ID: Rn01528817_m1). Beta-actin (Actb, ID: ID Rn00667869_m1) was used as an endogenous control. Real-time PCR amplifications were carried out in a DNA Engine Opticon® 2 two-color real-time PCR detection system (Biorad, Hercules, CA). PCR results were analyzed with the Opticon Monitor 3 software (Biorad). The comparative C_t method was used to quantify gene expression. ΔC_t was obtained by normalizing to beta-actin. $\Delta\Delta C_t$ was determined by the arithmetic formula described by López-Parra et al. [21]. Symmetrical raw fold change was obtained by comparing $\Delta\Delta C_t$ values of two groups compared.

Liver Fat Analysis by Histology

Cryostat sections in 6 µm thickness were made from liver samples taken out of −80 °C freezer. The tissue sections were brought to room temperature on glass slides. The slides were dipped a few times in 60 % triethyl phosphate and then stained in 0.5 % Oil Red O (in 60 % triethyl phosphate) for 15 min. After being rinsed in water for 2 min, the slides were counterstained in Harris modified method hematoxylin stain (Thermo Fisher, Waltham, MA) for 2 min. The slides were placed in saturated lithium carbonate solution for 10 s, rinsed in water for 5 min, and held in water. The slides were mounted with warm glycerin jelly and observed with light microscopy. Color images were captured with a digital camera attached to the microscope. Lipids in randomly sampled areas from each

slide were quantified by ImageJ [22]. The fat content of each sample was expressed by quantification of Oil Red O-stained areas as a percentage of whole area.

Liver Diacylglycerol Acyltransferase (DGAT) Enzyme Assay

The microsomal fraction was obtained by the methods of Ko et al. [23] and Coleman [24]. Rat liver (approximately 1.5 g) was minced and then homogenized in 15 ml of STE buffer (0.25 M sucrose, 10 mM Tris–HCl, pH 7.4, 1.0 mM EDTA) with a Teflon-glass homogenizer at medium speed. The homogenate was centrifuged at 14,000×*g* for 20 min at 4 °C. The supernatant was centrifuged at 100,000×*g* for 1 h at 4 °C to obtain a microsomal pellet. The pellet was suspended in STE buffer without EDTA and centrifuged at 100,000×*g* for 1 h at 4 °C. The final pellet was resuspended in STE buffer without EDTA. Total protein in final solution was quantified by the Bradford assay. The microsomal fractions were stored in aliquots at −80 °C.

A fluorescent DGAT assay was carried out as described by McFie and Stone [25]. Briefly, a master mix was prepared in a test tube containing 20 µl of 1 M Tris–HCl (pH 7.6), 4 µl of 1 M MgCl₂, 10 µl of 4 mM dioleoyl-*sn*-glycerol, 10 µl of 12.5 mg/ml bovine serum albumin, 10 µl of 500 µM NBD-palmitoyl CoA, and 96 µl of water per reaction. Tubes were pre-incubated in a 37 °C water bath for 2 min and 50 µl of protein sample was added to start the reaction, which was held at 37 °C for 10 min with occasional shaking. The reaction was terminated by addition of 4 ml CHCl₃/MeOH (2:1, v/v). Samples were added to 800 µl of water and allowed to sit at room temperature for 1 h. Tubes were centrifuged at 3,000×*g* for 5 min to separate aqueous and organic phases. The organic phase was removed via pipette and dried under a stream of nitrogen. Lipids were resuspended in 50 µl CHCl₃/MeOH (2:1) and spotted on a 20 × 20 cm TLC plate. TLC plates were developed in the solvent system, hexane/diethyl ether/acetic acid (80:20:1, v/v/v). The plates were air-dried for 1 h and scanned by Typhoon Trio + Laser Imager 7 (GE Healthcare, Waukesha, WI). The following settings were used: excitation, blue (488 nm) LED laser light source; emission, 520 nm BP emission filter. Fluorescence was quantified by ImageJ [22]. The newly synthesized NBD-TAG was quantified as units (fluorescence intensity) of NBD-TAG formed per minute per milligram of protein.

Statistical Analysis

A one-way ANOVA was performed using SAS software version 9.2 (SAS Institute Inc.) to perform comparisons among groups or using FlexArray 1.6 for gene expression among groups and tissues. Group means were compared

using Cyber-T algorithm for gene expression data and Ryan–Einot–Gabriel–Welsch multiple range test for other data. Data were reported as mean \pm standard deviation.

Results

Fatty Acid Profile of Diets

The most abundant fatty acids of the test diets are shown in Fig. 1. Both the milk-fat-based diets have similar fatty acid profiles, and are very different from the CO diet. The milk fat diets both have significant contributions of saturated fatty acids ($\sim 65\%$), whereas in the CO diet the percentage is much lower ($\sim 17.5\%$). All diets have similar levels of monounsaturates, with oleic acid contributing approximately 25%. The other notable difference is in the polyunsaturated fatty acid content (PUFA) content (CO 54%, AMF 4.5%, and AMF-MFGM 6%) and n-6/n-3 ratio (CO 54:1, AMF 6:1, AMF-MFGM 7:1).

Food Intake, Body Weight, Growth Rate, and Body Fat Composition

There were no significant differences in terms of food intake, final body weight, growth rate, or body fat composition (MRI analysis) among groups [10].

Fatty Acids Profile of Red Blood Cells

The red blood cell (RBC) fatty acid profile was measured to compare the CO diet to the milk-fat-based diets, and to determine if the higher polar lipid content of the AMF-MFGM had an effect compared with the AMF diet. RBC fatty acids that were significantly affected by the diets and present at $>1\%$ of total fatty acids are shown in Fig. 2. Not surprisingly,

Fig. 1 Fatty acid profile of experimental diets. Only fatty acids significantly different across groups and present at $>1\%$ of total fatty acids are shown. Means in a row with different superscripts are significantly different ($p < 0.05$)

Fig. 2 Red blood cell (RBC) fatty acids from rats fed CO (corn oil), AMF (anhydrous milk fat), and AMF-MFGM (anhydrous milk fat-milk fat globule membrane). Only fatty acids significantly different across diet groups and present at $>1\%$ of total fatty acids are shown. Means in a row with different superscripts are significantly different ($p < 0.05$)

the CO cohort had a higher percentage of 18:2n-6, 20:4n-6, and 22:4n-6, all n-6 fatty acids, presumably because of the high linoleic acid content of the diet. In addition, these animals had lower percentages of 16:1n-7, 18:1n-9, 18:1n-7, 20:3n-9, 20:5n-3, 22:5n-3, and 22:6n-3 compared to the animals fed the milk fat diets. The RBC from animals fed the two milk-fat-based diets had remarkably similar fatty acid profiles with two statistically relevant differences. Namely, the AMF-MFGM-fed animals had a higher percentage of 18:1n-7 and a lower percentage of 20:3n-9.

Fatty Acids Profile of Skeletal Muscle Tissue and Visceral Adipose Tissue

As with the RBC, there were large differences between the fatty acid profile in skeletal muscle and visceral adipose tissue of the rats fed the CO diet versus the milk fat diets which were virtually identical. In skeletal muscle, the CO-fed animals had significantly less 16:1n-7, 18:1n-9, and 20:3n-9, and more 18:2n-6, 20:4n-6, and 22:4n-6 (Fig. 3). Unlike skeletal muscle, the contribution of long chain fatty acids to the adipose lipids was low (Fig. 4). However, among the major fatty acids ($>1\%$ total), the CO animals had less 16:0, 16:1n-7, 18:0, and 18:1n-9 and more 18:2n-6. The only fatty acid that differed among the animals fed the milk fat diets was 20:3n-9, which in both tissues was slightly lower in the AMF-MFGM group.

Fatty Acids Profile of Liver Tissue

Fatty acids in liver tissue which were significantly affected by the CO, AMF, and AMF-MFGM diets and which contribute $>1\%$ of fatty acids in one tissue are presented in Fig. 5. Animals from the CO group had less 16:1n-7, 18:1n-9, 20:3n-9, and 22:6n-3 and more 18:2n-6 and 20:4n-6. Unlike the

Fig. 3 Fatty acid profile of skeletal muscle from rats fed CO (corn oil), AMF (anhydrous milk fat), and AMF-MFGM (anhydrous milk fat–milk fat globule membrane). Only fatty acids significantly different across diet groups and present at >1 % of total fatty acids are shown. Means in a row with different superscripts are significantly different ($p < 0.05$)

Fig. 4 Fatty acid profile of visceral adipose tissue from rats fed CO (corn oil), AMF (anhydrous milk fat), and AMF-MFGM (anhydrous milk fat–milk fat globule membrane). Only fatty acids significantly different across diet groups and present at >1 % of total fatty acids are shown. Means in a row with different superscripts are significantly different ($p < 0.05$)

RBC, skeletal muscle, and adipose tissues, supplementation of the AMF diet with MFGM results in several differences in the fatty acid profile of the liver. For example, of the six fatty acids which are significantly affected across the diets and present at >1 %, five are significantly different in livers of the animals fed the AMF and AMF-MFGM diets. Thus, the increased polar lipid concentration of the AMF-MFGM diet appears to have significant effects on liver lipid metabolism and partitioning. The largest differences are in 18:1n-9, which is higher in the AMF animals, and 20:4n-6 and 22:6n-3 which are higher in the AMF-MFGM cohort.

Plasma, Visceral Adipose, and Liver Lipid Classes

To better understand the differences in lipid partitioning as affected by the CO, AMF, and AMF-MFGM diets, plasma

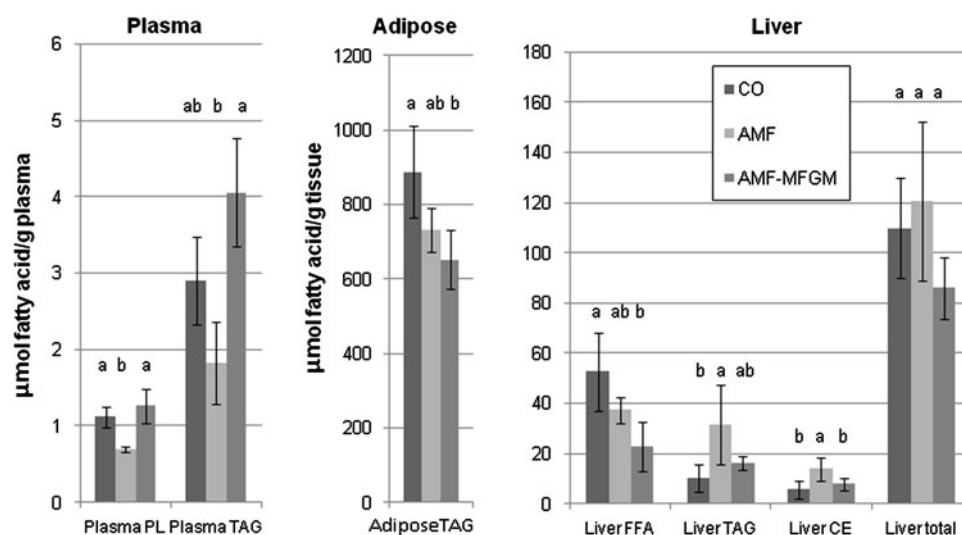

Fig. 5 Fatty acid profile of liver tissue from rats fed CO (corn oil), AMF (anhydrous milk fat), and AMF-MFGM (anhydrous milk fat–milk fat globule membrane). Only fatty acids significantly different across diet groups and present at >1 % of total fatty acids are shown. Means in a row with different superscripts are significantly different ($p < 0.05$)

adipose and liver lipid classes were analyzed and classes with significant differences are shown in Fig. 6. Interestingly, the animals consuming AMF as the fat source had less total PL in plasma than animals fed the CO and AMF-MFGM diets. Additionally, there was less TAG than the animals fed the AMF-MFGM diet. In the visceral adipose, there was more TAG in the animals fed CO than those fed the AMF-MFGM. In the liver, there was more FFA in the animals fed the CO diet than in those fed the AMF-MFGM diet, and a similar trend for the AMF animals, although this was not significant. On the other hand, the CO diet resulted in less accumulated TAG than the AMF diet, with the AMF-MFGM diet in between. Lastly, both the CO and the AMF-MFGM diets resulted in lower hepatic CE than did the AMF diet.

Tissue Gene Expression

In total, 293, 1,124, and 831 genes were found to be differentially expressed respectively in skeletal muscle, adipose, and liver at $p < 0.05$. To identify metabolic pathways that were affected across the three diets all the genes that were differentially regulated according to the ANOVA were analyzed with the program ArrayTrack, a free software tool developed by the National Center for Toxicological Research (NCTR) and the US Food and Drug Administration (FDA). All three diets were compared and the data generated from this analysis are summarized in Table 1. On a diet comparison basis, the fewest number of pathways affected across the three tissues were between the two milk-fat-fed animal groups (22 pathways) and the most pathways were affected between the CO and AMF-MFGM groups (40). In specific tissues, there were 18 pathways differentially affected in skeletal muscle, 31 in adipose, and

Fig. 6 Quantitative analysis of lipid classes from plasma, visceral adipose, and liver. *PL* phospholipids, *TAG* triacylglycerols, *FFA* free fatty acids, *CE* cholesteryl esters. Means in a row with different superscripts are significantly different ($p < 0.05$)

40 in the liver. In specific diet/tissue comparisons, the fewest number of pathways were affected in skeletal muscle between the CO and the AMF diets (2). There were 16 pathways affected between the AMF and CO diets in the liver and 16 pathways between the AMF-MFGM and CO diets in adipose. In the lower half of Table 1 the pathways that were significantly affected across at least two diet combinations are shown. For example, in the muscle tissue, the circadian rhythm pathway (KEGG rno 04710) was significantly affected between all three diets, whereas adipocytokine signaling (rno00020) was only affected in the diet combinations in which AMF was compared. Similar to the fatty acid data of the selected tissues, there were fewer pathways affected in the muscle and adipose tissue compared to the liver. A striking feature of the pathway analysis shown in the bottom half of Table 1 is that only three pathways were different in the liver between the two milk fat diets, whereas >10 were affected when these diets were compared to the CO diet.

Although the two milk fat diets were nearly identical at the fatty acid level, there were several differences in the liver and plasma lipid profiles of the rats fed the AMF and AMF-MFGM diets. Therefore, the expression of several genes of interest was determined using RT-PCR and the results are shown in Table 2. The three genes selected were chosen from the KEGG pathways differentially affected by the milk fat diets in Table 1. The results of the RT-PCR in Table 2 are expressed relative to β -actin, and thus a smaller number indicates a higher expression level. Comparing the two milk fat groups, all three genes are more highly expressed in the livers of the AMF-MFGM rats compared to the AMF group.

Liver Fat Analysis by Histology and DGAT Assay

In general, both the lipid analysis and the gene expression profiling indicated that the diets had the greatest effect on the liver. Although there was not a quantitative difference in the fatty acid content of the livers, there were significant differences in distributions across lipid classes (Fig. 6). For example, there is more triacylglycerol in the livers of rats fed AMF compared to the CO, yet the total fatty acid was not different. Interestingly, expression of diacylglycerol *O*-acyltransferase 2 (DGAT2), was lower in the CO-fed animals than in the other two groups. Consequently, the livers were stained with Oil Red O and DGAT activity was measured via enzymatic assay of the microsomal fraction, and the results are shown in Fig. 7. There was significantly less staining of the hepatic tissue of the CO-fed rat (Fig. 7a), and this corresponded with lower DGAT activity (Fig. 7b).

Discussion

The main focus of this work was to utilize tissue fatty acid profiling and transcriptomics to determine the effects of changing the lipid source of the AIN-76A diet on lipid metabolism. This work was conducted on key tissues involved in lipid metabolism, storage, and processing (skeletal muscle, visceral adipose, and liver) as well as plasma. The fat sources used in formulating the diets (corn oil, anhydrous milk fat, and anhydrous milk fat supplemented with milk fat globule membrane) were originally selected for an ACF study previously reported [10]. In that study, as in most ACF studies, the CO diet was selected as a control, whereas the AMF-MFGM diet was included to

determine potential cancer protective effects of specific lipids associated with this material, such as sphingomyelin and plasmalogens. The AMF diet was included to control

for the potential for other lipids in milk fat to affect the development of ACF, such as butyrate and conjugated linoleic acid.

Fig. 7 Hepatic Oil Red staining (a) and hepatic DGAT activity (b) in liver tissue from rats fed CO (corn oil), AMF (anhydrous milk fat), and AMF-MFGM (anhydrous milk fat–milk fat globule membrane). Means with different superscripts are significantly different ($p < 0.05$)

The membrane composition of RBC reflects dietary fat sources, and several groups have investigated the correlation of RBC fatty acid profiles with disease susceptibility in humans. For example, Harris and Von Schacky [26] showed that the omega-3 index, the combined percentage of EPA (20:5n-3) and DHA (22:6n-3) in RBC, correlates with the risk of coronary heart disease (CHD) in humans with values above 8 % being associated with the most protection and values below 4 % with the least. A similar metric, the percent contribution of omega-6 fatty acids to highly unsaturated fatty acids (% n-6 HUFA), was shown by Lands [27] to correlate with CHD mortality in several human populations with levels below 40 % being protective. The omega-3 indices were 0.9 for the CO diet, 2.5 for the AMF diet, and 2.0 for the AMF-MFGM diet, whereas the % n-6 HUFA levels were 96, 79, and 83 %, respectively. Although these metrics may not be applicable in rodents, it is interesting nonetheless that all three diets result in very low levels of n-3 long chain PUFA in RBC which likely affect many physiological processes.

One interesting fatty acid which is present at significant levels in the RBC, muscle, adipose, and liver of the milk-fat-fed animals, but not those consuming CO, is 20:3n-9. This fatty acid is an elongation product of oleic acid and has been shown to be a sensitive marker of PUFA intake. According to Lands [27], 20:3n-9 correlates with low PUFA intakes and a value of approximately 10 % in the HUFA indicates PUFA insufficiency. To our knowledge, no studies have provided data on the percentage contribution of 20:3n-9 to tissue HUFA for RBC, muscle, adipose, and liver which are shown in Table 3. Animals fed the AMF diet have the highest levels of this fatty acid across all tissues measured, whereas those consuming the AMF-MFGM diets also had high levels. Interestingly, the HUFA percentage of 20:3n-9 in adipose was high for the CO-fed animals, albeit not as high as the other groups. This may be a result of the very low concentration of HUFA in adipose, as the lipids in this tissue are primarily less than 18 carbons in length.

The lipid profiles of the RBC, muscle, adipose, and liver reflect the fat sources of the three diets, and there were few differences between those fed the AMF and AMF-MFGM.

However, there were quantitative differences across lipid classes in both plasma and the liver. Pathway analysis of the gene expression data indicated that the fewest pathways were affected in skeletal muscle and the most in liver. There were no differences in total liver fatty acids between treatments, but there was in the distribution of fatty acid across lipid classes (Fig. 6). One striking feature is the high FFA and low TAG in the livers of the CO-fed rats compared to those fed the AMF-MFGM diet. To further investigate this finding we compared Oil Red O staining in livers across the three treatments, and the results are shown in Fig. 7a. In the rats fed the CO diets there is less Oil Red O staining. According to O'Rourke et al. [28] Oil Red O staining of tissues is well correlated with triglyceride content. The inverse relationship between the hepatic TAG and FFA suggests that the differences may be due to triglyceride synthesis activity. According to the gene expression profiling, DGAT2, the enzyme responsible for the final step in TAG synthesis from diacylglycerols and FFA was 1.25-fold lower in the CO-fed rats compared to those fed AMF and 1.46-fold lower compared to those fed AMF-MFGM. These differences are modest, and it was not clear if their expression would translate into physiological differences. Thus, the triacylglycerol synthetic activity in liver microsomal fractions was measured using a functional assay and the results are shown in Fig. 7b. In agreement with the Oil Red O staining, the DAG activity measure suggests that the differences in FFA, DAG, and TAG levels in the liver may be partially explained by the conversion of FFA and DAG into TAG.

Although excess hepatic TAG storage has typically been viewed as a negative physiological response, it may be protective under some metabolic situations. For example, in a mouse model of nonalcoholic steatohepatitis (NASH), Yamaguchi et al. [29] evaluated the effects of hepatic DGAT2 expression on disease development using an antisense nucleotide treatment. Although reducing expression of DGAT2 did prevent hepatic steatosis, the increase in FFA was associated with markers of lipid peroxidation/oxidant stress and fibrosis. From this study the authors concluded that accumulation of hepatic TAG is actually protective against progressive liver damage in NAFLD. It

is unclear why the CO diet resulted in lower DGAT expression and activity in the CO-fed rats. However, one distinguishing feature of this diet is the PUFA content primarily in the form of linoleic acid. Interestingly, reviewing the fatty acid composition of diets used to study NASH, Romestaing et al. [30] drew the conclusion that dietary PUFA with a high omega-6 to omega-3 ratio may be a causative factor via effects on lipid peroxidation and proinflammatory cytokine production.

There are several differences in the plasma and hepatic lipid profiles of the animals fed the two milk fat diets which is surprising considering the similarity of these diets at the fatty acid level. According to the KEGG pathway analysis conducted on the hepatic gene expression and shown in Table 1, the two milk fat diets affected PPAR signaling (rno03320), C21 steroid hormone metabolism (rno00140), and glycerophospholipid metabolism (rno00564). The affected PPAR signaling in both the liver and skeletal muscle was mediated through PPAR α receptors. The involved genes were associated with lipogenesis, cholesterol metabolism, and fatty acid transport in the liver and with lipogenesis in skeletal muscle. Consequently, the expression of three genes from these pathways was validated using RT-PCR. The genes *Cyp8b1*, *Agpat2*, and *Angptl4* were selected from the differentially expressed genes in the pathways determined by the gene expression profiling. They were chosen owing to their physiological function and potential to affect tissue lipid partitioning, and the results are shown in Table 2. The function of these genes is discussed below including their potential roles in affecting lipid metabolism across the two milk fat groups. Of course these findings are only correlations and positive confirmation of their roles will need to be tested explicitly for confirmation.

Cyp8b1 is a cytochrome P450 enzyme which is a component of the primary bile acid biosynthesis and PPAR α signaling pathways in the liver. *Cyp8b1* is involved in the synthesis of cholic acid [31]. *Cyp8b1* controls the ratio of cholic acid to chenodeoxycholic acid in bile salts, and as cholic acid is less effective in solubilizing cholesterol it may affect its absorption [32]. The AMF-MFGM diet was associated with a lower hepatic cholesteryl ester content (Fig. 6). Milk polar lipids affect both the absorption and fecal excretion of cholesterol when fed both acutely and chronically. For example, Noh and Koo [33] found that infusion of milk sphingomyelin via a duodenal catheter resulted in decreased cholesterol, fat, and vitamin E absorption. In a chronic feeding study, Kamili et al. [34] fed mice high-fat diets for 5 weeks; the diets were supplemented with two different formulations of milk phospholipids at 1.2 % by weight. Both milk polar lipid preparations resulted in significant decreases in liver cholesterol and triglyceride which was accompanied by an

increase in fecal cholesterol excretion. Data from the present study indicate that the decreased cholesterol absorption and increased fecal excretion resulting from luminal milk polar lipids in those previous studies may be mediated, at least in part, by the ratio of bile acids.

Agpat2 is an enzyme responsible for the conversion of lysophosphatidic acid to phosphatidic acid, a step in PL synthesis, and is a component of KEGG pathway glycerophospholipid metabolism. The expression of *Agpat2* was higher in the AMF-MFGM group than the AMF group (Table 2) but there was not a significant difference in hepatic PL. There was, on the other hand, a significant increase in plasma PL in the AMF-MFGM group. The increased plasma PL may result from increased hepatic synthesis and secretion. Previous studies with milk polar lipids have also shown the ability of these constituents to increase both plasma PL and TAG. For example, Wat et al. [35] fed mice both a low-fat, non-purified diet and a high-fat diet formulated with and without a 2.5 % PL-rich milk fat extract. In the mice fed the low-fat, non-purified diet, the milk PL increased the plasma TAG by 20 % and the plasma PL by 5 % compared with values in the control mice fed the low-fat diet. However, in the mice fed the high-fat diets, the PL-rich extract actually reduced both the plasma TAG and PL to levels similar to the low-fat control. The increased plasma lipid concentration in the rats fed the AMF-MFGM diet, compared to those fed the AMF diet, may be a result of either more lipid exported from the liver, or from reduced clearance via peripheral tissues.

Expression of *Angptl4* was also verified by RT-PCR. *Angptl4* is a component of the PPAR α signaling pathway. It is an angiopoietin-like protein which increases plasma TAG via suppression of lipoprotein lipase [36]. Interestingly, there were significant differences in plasma TAG between the two milk-fat-fed groups (Fig. 6). Also known as fasting-induced adipocyte factor (Fiaf), *Angptl4* is highly expressed in the gut epithelium in germ-free mice and prevents accumulation of fat into adipocytes, whereas conventionalization with a microflora suppresses this effect [37]. Although it is not clear if hepatic expression of *Angptl4* in the AMF-MFGM-fed rats contributed to the increase in plasma TAG, this finding indicates a potential mechanism via which this effect was mediated.

Despite the fact that it is still commonly used in ACF studies with rodents [7], the high sucrose content of the AIN-76A diet has been long known to cause fatty liver in animals fed the diet for long periods of time [9]. Therefore, when reviewing the different effects of the fat sources on tissue lipid composition and gene expression it is necessary to keep in mind that these changes are in the context of an overall metabolically stressful diet. From the data presented here, a few hypotheses may be drawn that can be tested in studies designed specifically for their evaluation.

For example, compared to the milk fat diets, the CO diet caused a significant increase in hepatic free fatty acids, a potential trigger for the development of NASH from NAFLD. Conversely, compared to the CO and AMF-MFGM diets, the AMF diet resulted in more hepatic TAG storage which in itself may be undesirable. Supplementing the AMF diet with polar lipids from milk appears to reduce the accumulation of hepatic TAG yet appears to achieve this effect via promotion of lipid export into plasma. The long-term physiological significance of this is unknown. In conclusion, the fat source of the AIN-76A diet affects the tissue profile of key tissues involved in lipid trafficking and storage as well as gene expression networks within these tissues.

Acknowledgments This study was supported by both a seed grant from the Center for Integrated Biosystems at Utah State University and by the Utah Agricultural Experiment Station and was approved as journal paper number 8290. We are grateful to Dallin Snow for preparing RNA samples for Microarray analysis and Dr. Aaron Olsen and Kent Udy for assistance with animal studies.

diseases and cancer. The molecular changes in adipose tissue that promote these disorders are not completely understood. For a long time, fat tissue was perceived as storage of free fatty acids (FFA) in the form of triacylglycerols (TAG). Over the last years, this perception of adipose tissue has been replaced by the notion that adipose tissue has a central role in lipid and glucose metabolism: expressing and secreting factors that play important endocrine functions. These factors include leptin, adiponectin, tumor necrosis factor- α (TNF- α), monocyte chemoattractant protein-1 (MCP-1), interleukin-6 (IL-6) and plasminogen activator inhibitor-1 (PAI-1) [1–3]. Over the years, studies have strengthened the notion that obesity is not a homogeneous condition and that the regional fat distribution is an important indicator for metabolic and cardiovascular alterations [4, 5].

The obesity epidemic has drawn attention to visceral adipose tissue (VAT) as a risk factor for type 2 diabetes and cardiovascular diseases. VAT has been shown to be very important source of circulating FFA. The FFA are much more easily liberated from visceral fat than from subcutaneous fat. Excess of plasma FFA leads to increased FFA uptake by tissues e.g. skeletal muscle and in the result, to intramuscular lipid accumulation. Several lines of evidence suggest that visceral adiposity rather than general adiposity might play an important role in the development of insulin resistance and cardiovascular diseases [6–8]. Epicardial adipose tissue (EAT) is a type of visceral fat that has not been studied as thoroughly as VAT and subcutaneous abdominal adipose tissue (SAT) [9]. EAT as a fat depot might function as a lipid-storing tissue—source of FFA, and as an endocrine organ secreting hormones and other biologically active molecules, which affect glucose homeostasis, energy metabolism, body weight regulation and insulin sensitivity [10–15]. It must be underlined that lipolytic activity in EAT is even higher than in other visceral fat tissues [16]. Data from several studies suggest that accumulation of intramuscular lipids is responsible for induction of insulin resistance in the tissue [17, 18]. Among these lipids are: ceramides (Cer)—central molecules in sphingolipid metabolism, diacylglycerols (DAG) and long chain acyl-CoA (LCACoA). These lipids are probably implicated not only in obesity-associated skeletal muscle but also fat tissue insulin resistance. Recent evidence suggests that adipose tissue inflammation and abnormalities in sphingolipid metabolism may contribute to the metabolic disorders associated with obesity [19]. It has been shown, that ceramide is implicated in the pathogenesis of obesity, insulin resistance [20, 21] and cardiovascular disease [22–24]. Although there is some evidence that ceramide affects insulin stimulated glucose uptake in adipose tissue in the same way as in skeletal muscle, there is very little information about biologically active lipids in SAT. We found only three reports on the ceramide content

in human SAT [25–27]. Ceramide content was higher in SAT of obese men and women compared to lean non-diabetic subjects when the content of Cer was expressed per adipocyte [27]. Moreover, the ceramide level was more highly elevated in the SAT of obese woman with fatty liver than in body mass index (BMI)-matched obese individuals with no hepatic steatosis [25]. However, another report indicated that total adipose tissue ceramide content was lower in the adipose tissue from obese non-diabetic (OND) and obese diabetic (OD) subjects compared to lean non-diabetic (LND) people in spite of greater mRNA levels of SMases, SPT and CDases [26]. Another, *in vitro*, study demonstrated that ceramide plays an important role in the induction of insulin resistance in the adipocytes [28], but the contribution of adipose tissue to the disorder is still unclear. Nothing is known about DAG and LCACoA in adipose tissue and its implication in adipocytes as well as whole body insulin resistance. Recently, it has been found that DAG activates PKC ϵ that results in inhibition of insulin stimulated insulin receptor kinase activity and in the result causes hepatic insulin resistance [29]. However, there is no information about the content of biologically active lipids in visceral fat. Therefore the aim of the present study was to examine the effect of obesity and type 2 diabetes on sphingolipid, DAG, and LCACoA content in human subcutaneous fat and epicardial fat tissue (as visceral fat tissue) and to understand whether relationships exist between the content of these particular lipids and insulin sensitivity.

Materials and Methods

The study included 41 patients undergoing elective coronary bypass graft surgery. The subjects were divided into three groups: (1) lean (BMI \leq 26.0, n = 14) without a history of diabetes and with normal fasting blood glucose (\leq 100 mg/dl) and glycated hemoglobin (\leq 6.5 %) level, (2) obese (BMI \geq 30.0) without a history of diabetes and with normal fasting glycemia and glycated hemoglobin level (n = 12) and (3) obese with type 2 diabetes (n = 15). In the obese diabetic group only patients who were diagnosed as type 2 diabetic of 5–7 years duration were included in the study. All participants according to NYHA (New York Heart Association) were classified to second class that is characterized as mild symptoms and slight limitation during ordinary activity. Six of the volunteers with type 2 diabetes received insulin, two of them received metformin, one received metformin and sulfonylurea, one received insulin together with metformin, and two of the patients were on a diet. All patients were around 60 years old. We used a homeostasis model assessment for calculating insulin resistance (HOMA-IR). Blood samples were taken in a fasting state from the antecubital vein into heparinized

tubes at the day of the surgery. At the beginning of the surgical intervention, a sample of epicardial adipose tissue was taken from the anterior wall of the left ventricle. Subcutaneous adipose tissue was taken from the subcutaneous fat on the sternum. Dissected tissues were promptly frozen in liquid nitrogen and then stored at -80°C until further processing. During the surgery, blood glucose levels were kept within the physiologic range in all patients. The investigation conforms to the principles outlined in the Declaration of Helsinki and was approved by the Ethical Committee for Human Studies of the Medical University of Białystok. All patients gave their informed consent prior to their inclusion in the study.

Blood Samples

We measured plasma FFA concentration using UPLC/MS according to Persson et al. [30]. Briefly, the concentrations of FFA were measured against a six point standard curve constructed by taking 250 μl of the 400- μM stock solution and making dilutions with 10 mM phosphate buffer to yield 400, 200, 100, 50, 25 and 0 μM standards. Aliquots of 100 μl of plasma were taken for extraction. A quantity of 50 μl of the heptadecanoate internal standard solution was spiked to each concentration standard and each plasma sample. The standards and plasma samples were extracted with freshly prepared Dole solution composed of isopropanol:heptanes:1 M H_2SO_4 (40:10:1; v/v/v). The extracts were allowed to dry under nitrogen. The dried samples were resuspended in 100 μl of buffer A prior to injecting 10 μl onto the LC/MS (Agilent 6460 triple quadrupole) coupled with a Agilent 1290 Infinity UPLC system. Fatty acids were separated on the LC using a reverse-phase Zorbax SB-C18 column 2.1×150 mm, 1.8 μm , using two buffers. Buffer A was 80 % acetonitrile, 0.5 mM ammonium acetate; buffer B was 99 % acetonitrile, 1 % 0.5 mM ammonium acetate. The flow rate was 0.4 ml/min, and the gradient conditions were as follows: 0–3 min isocratic at 55 % B, 3–3.2 min 55–95 % B, 3.2–5 min isocratic at 95 % B, 5–5.5 min 55–95 % B, and 5.5–7 min isocratic at 55 % B.

Moreover, we measured plasma triacylglycerols, total cholesterol, HDL-cholesterol and LDL-cholesterol concentration. The plasma samples were stored at -80°C before analysis. We also measured the fasting plasma insulin and glucose concentration for calculation HOMA-IR (homeostasis model assessment) to estimate insulin resistance.

Adipose Tissue Bioactive Lipids

Sphingolipids

The content of sphingolipids was measured using a UPLC/MS/MS approach according to Blachnio-Zabielska et al.

[31]. Briefly, the adipose tissue samples (40 mg) were homogenized in a solution composed of 0.25 M sucrose, 25 mM KCl, 50 mM Tris and 0.5 mM EDTA, pH 7.4. Immediately afterwards, 50 μl of the internal standard solution (17C-sphingosine and 17C-S1P, and C17-Cer Avanti polar lipids) as well as 1.5 ml of an extraction mixture (isopropanol:water:ethyl acetate, 30:10:60; v:v:v) were added to each homogenate. The mixture was vortexed, sonicated and then centrifuged for 10 min at 4,000 rpm (Sorvall Legend RT). The supernatant was transferred to a new tube and pellet was re-extracted. After centrifugation supernatants were combined and evaporated under nitrogen. The dried sample was reconstituted in 100 μl of LC Solvent A (2 mM ammonium formate, 0.15 % formic acid in methanol) for UPLC/MS/MS analysis. Sphingolipids were analyzed by means of an Agilent 6460 triple quadrupole mass spectrometer using positive ion electrospray ionization (ESI) source with multiple reaction monitoring (MRM). The chromatographic separation was performed using an Agilent 1290 infinity ultra performance liquid chromatography (UPLC). The analytical column was a reverse-phase Zorbax SB-C8 column 2.1×150 mm, 1.8 μm . Chromatographic separation was conducted in binary gradient using 2 mM ammonium formate, 0.15 % formic acid in methanol as solvent A and 1.5 mM ammonium formate, 0.1 % formic acid in water as solvent B at the flow rate of 0.4 ml/min.

Diacylglycerols

Diacylglycerols were extracted together with sphingolipids. A known amounts (50 ng) of internal standard (1,3 dipentadecanoyl-*sn*-glycerol) was added to each sample. Next, samples were extracted as described above. The following DAG were quantified: C18:1/18:2, C16:0/18:2, C16:0/16:0, C16:0/18:1, C18:0/20:0, C18:0/18:1, C18:1/18:1, C18:0/18:2 and C16:0/18:0 using UPLC/MS/MS. The chromatographic separation was performed using an Agilent 1290 infinity ultra performance liquid chromatography (UPLC). The analytical column was a reverse-phase Zorbax SB-C8 column 2.1×150 mm, 1.8 μm . Chromatographic separation was conducted in a binary gradient using 2 mM ammonium formate, 0.15 % formic acid in methanol as solvent A and 1.5 mM ammonium formate, 0.1 % formic acid in water as solvent B at the flow rate of 0.4 ml/min.

Long-Chain AcylCoA

LCACoA was measured according to Blachnio-Zabielska et al. [32]. Briefly, LCACoA was extracted with the use of ACN:2-propanol:methanol (3:1:1; v:v:v). A known amount of heptadecanoyl-CoA was added as an internal standard. The molecules (C14:0-CoA, C16:0-CoA, C16:1-CoA,

C18:2-CoA, C18:1-CoA, C18:0-CoA, C20:0-CoA) were separated on a reverse-phase Zorbax SB-C18 column 2.1 × 150 mm using a binary gradient with ammonium hydroxide (NH₄OH) in water and NH₄OH in ACN. The LCACoA were quantified using multiple reaction monitoring (MRM) on a Triple quadrupole mass spectrometer in positive electrospray ionization (ESI) mode.

Statistical Analysis

All data are presented as means ± SD. Data were analyzed by one-way analysis of variance (ANOVA), followed by the Newman–Keuls post hoc test. p values <0.05 were taken to indicate statistical significance.

Results

Clinical Characteristics

Clinical characteristics of the studied groups are given in Table 1. In the obese non-diabetic group and in the obese diabetic group the BMI was 37 % ($p < 0.01$) and 53 % ($p < 0.001$) higher as compared to lean non-diabetic participants. The blood glucose concentration in the obese diabetic group was about 54 % ($p < 0.001$) and 58 % ($p < 0.001$) higher compared to the lean non-diabetic and obese non-diabetic subjects respectively. The plasma insulin concentration was 62 % ($p < 0.001$) and 31 % ($p < 0.01$) higher in obese diabetic participants as compared to the lean non-diabetic and obese non-diabetic subjects respectively. There were no significant differences in the content of glucose and insulin concentration between lean non-diabetic and obese non-diabetic subjects. There were also no significant differences in total plasma cholesterol concentration between the three groups. Plasma HDL-cholesterol concentration was almost 40 % ($p < 0.01$) lower in obese diabetic group as compared to the lean individuals. Plasma concentration of the LDL-cholesterol fraction was 49 % ($p < 0.05$) and 72 % ($p < 0.001$) higher in the obese non-diabetic and the obese diabetic groups respectively as compared to the lean group. Plasma triglycerides concentration was 63 % ($p < 0.01$) and 82 % ($p < 0.01$) higher in the obese non-diabetic and obese diabetic groups, respectively compared to the lean participants. The value of glycated hemoglobin (HbA1c) was almost 29 % ($p < 0.01$) higher in the obese diabetic group as compared to the lean control group. HOMA-IR significantly increased only in the obese diabetic group ($p < 0.001$).

Plasma FFA Concentration (Table 2)

All the fatty acid species measured were elevated in the plasma of both obese groups. The greatest increase in both obese groups was observed in palmitate (C16:0) (~2.5 times, for both $p < 0.001$) and in stearic acid (C18:0) concentrations (by 100 %, for both $p < 0.001$) comparing to the lean non-diabetic group. The concentration of oleic acid (C18:1) increased by 63–70 % (for both $p < 0.001$) in the obese non-diabetic and obese diabetic groups respectively. The concentration of arachidonic acid (C20:4) increased by around 30 % in the obese non-diabetic group and by 48 % ($p < 0.001$) in the obese diabetic group.

The linoleic acid (C18:2) concentration increased by around 54–43 % in the obese non-diabetic and obese diabetic groups, respectively (for both $p < 0.01$). The smallest, but still significant changes were noticed in myristic acid (C14:0) and palmitoleic acid (C16:1). The

Table 2 Plasma FFA concentration in lean non-diabetic, obese non-diabetic, and obese diabetic groups

Values are expressed in nmol/ml (mean ± SD)

LND lean non-diabetic, OND obese non-diabetic, OD obese diabetic

^a $p < 0.05$, ^b $p < 0.01$, ^c $p < 0.001$ versus lean non-diabetic

concentration of the fatty acids increased in both obese groups by around 20 % (for all $p < 0.05$). Total plasma FFA concentration increased by 80–87 % (for both $p < 0.001$) in the obese non-diabetic and obese diabetic groups, respectively as compared to lean non-diabetic participants.

Fat Tissue Sphingolipids Content (Table 3)

Subcutaneous Adipose Tissue

The contents of SPA, S1P, C14-Cer, C16-Cer, C18:1-Cer, C18-Cer and C24:1-Cer in the subcutaneous adipose tissue were greater in obese diabetic subjects as compared to their lean non-diabetic counterparts (for all $p < 0.001$). In the obese non-diabetic group the content of SPA, C14-Cer, C24:1-Cer (for all $p < 0.001$), C18:1-Cer and C24-Cer (for both $p < 0.05$) was greater than in the lean non-diabetic group. Moreover, content of S1P, C16-Cer, C18:1-Cer and C18-Cer was markedly higher in the obese diabetic group compared to the obese non-diabetic group (for both $p < 0.001$).

As expected, total ceramide content was higher in both obese groups as compared to lean non-diabetic subjects ($p < 0.001$). There were also significant differences between total ceramide content in obese non-diabetic and obese diabetic group ($p < 0.001$).

Epicardial Adipose Tissue

In epicardial adipose tissue, the content of Sph, SPA, S1P, C14-Cer, C16-Cer, C18:1-Cer, C18-Cer and C24:1-Cer was higher in the obese diabetic group comparing to the lean non-diabetic counterpart (for all $p < 0.001$). Moreover, the content of Sph, SPA, S1P, C14-Cer, C16-Cer (for all $p < 0.001$) and C18:1-Cer ($p < 0.05$) was greater in the obese non-diabetic group than in the lean non-diabetic group. There were also differences in sphingolipid content between both obese groups. The content of Sph, C14-Cer (for both $p < 0.05$), S1P, C18:1-Cer, C18-Cer and C24:1-Cer (for all $p < 0.001$) was higher in the obese diabetic group as compared to the obese non-diabetic group. Total ceramide content was higher in both obese groups comparing to the lean non-diabetic group (for both $p < 0.001$).

and was significant higher in the obese diabetic group as compare to the obese non-diabetic group ($p < 0.01$).

Fat Tissue DAG Content (Table 4)

Subcutaneous Adipose Tissue

In subcutaneous fat tissue, the content of C18:1/C18:2, C16:0/18:2, C16:0/16:0, C18:0/18:1 (for all $p < 0.001$), C16:0/18:1 ($p < 0.01$) and C18:1/18:1 ($p < 0.05$) increased in the obese diabetic group as compared to lean subjects. The level of C16:0/18:2, C18:1/18:0 (for both $p < 0.001$), C16:0/18:1 ($p < 0.01$) and C18:1/18:1 ($p < 0.05$) was higher in the obese non-diabetic group as compared to the lean non-diabetic group. There were also differences in C16:0/16:0 ($p < 0.001$) and C18:1/18:2 ($p < 0.05$) content between both obese groups. The higher content of the compounds was noticed in the obese diabetic group. As expected, total DAG content increased in both obese groups as compared to the lean control group (for both $p < 0.001$).

Epicardial Adipose Tissue

All measured DAG species increased in the obese diabetic group (for all $p < 0.001$, except C18:0/18:2 where $p < 0.01$) as compared to the lean non-diabetic group. Elevated content of all measured DAG (for all $p < 0.001$ except C16:0/18:2 and C18:0/18:2 where $p < 0.01$) was also noticed in the obese non-diabetic group as compared to the lean control group. Moreover, increased content of C16:0/16:0 ($p < 0.05$) and C18:0/18:1 ($p < 0.01$) was observed in the obese diabetic group comparing to the obese non-diabetic group. As expected, total DAG content in that tissue was also greater in both obese groups as compared to the lean control group (for both $p < 0.001$).

Fat Tissue LCACoA Content (Table 5)

Subcutaneous Adipose Tissue

In both obese groups, the content of C16:1-CoA, C18-CoA (for both $p < 0.05$), C16-CoA and C18:1-CoA (for both $p < 0.01$), was greater as compared to the lean non-diabetic

group. The total LCACoA content was also greater in both obese groups ($p < 0.001$) comparing to the lean control group. There were no statistical differences between both obese groups.

Epicardial Adipose Tissue

In the epicardial fat tissue, the content of C14-CoA, C16:1-CoA (for both $p < 0.05$), C16-CoA, C18:1-CoA and C18-CoA (for all $p < 0.001$) was greater in the obese diabetic group comparing to the lean control group. In the obese non-diabetic group, content of C14-CoA, C18-CoA (for both $p < 0.01$), C16-CoA and C18:1-CoA ($p < 0.001$) was higher comparing to the lean non-diabetic group. There was a difference in C16-CoA content between both obese groups. The content of C16-CoA was greater in the obese diabetic group as compared to the obese non-diabetic group ($p < 0.001$). The total LCACoA content was also higher in the both obese groups (for both $p < 0.001$) comparing to the lean non-diabetic group. There were no differences in total LCACoA content between both obese groups.

Associations Between Bioactive Lipids and HOMA-IR (Fig. 1)

We found a strong positive correlation between the total content of ceramide in subcutaneous fat and HOMA-IR ($r = 0.78$, $p < 0.001$). The strongest correlation was noticed with C16-Cer ($r = 0.79$, $p < 0.001$). We did not find such a correlation in epicardial fat tissue. There was also a positive correlation between total DAG content in subcutaneous fat tissue and HOMA-IR ($r = 0.64$, $p < 0.001$) and between HOMA-IR and 16/18:2 DAG ($r = 0.56$, $p < 0.001$). No such associations were detected in epicardial fat tissue. In epicardial fat tissue we found a strong correlation between C16:0-CoA content and HOMA-IR ($r = 0.73$, $p < 0.001$).

Associations Between Bioactive Lipids and Cardiac Structure Alterations

We found highly significant ($p < 0.001$ in all cases) correlations between the content of some lipid species determined in adipose tissue samples and the left ventricular end-diastolic diameter (LVEDd) of the heart. Namely, there was a positive relationship between LVEDd and the level of sphinganine, C18:1-CoA, total acyl-CoA and 18:1/18:1-DAG in the subcutaneous adipose tissue ($r = 0.64$, 0.59, 0.61 and 0.63, respectively). Moreover, a similar correlation was observed for 16:0/18:2-DAG content in the epicardial adipose tissue ($r = 0.59$). These findings suggest the existence of a link between adipose tissue lipid metabolism and alterations in cardiac structure related to the development of cardiomyopathy. However, further studies are required to reveal the nature of this relationship.

Discussion

Obesity is a major global health concern that increases the risk of metabolic and cardiovascular disease. Most of the work in the field of lipid accumulation, obesity and insulin resistance has focused on lipid metabolism in skeletal muscle [20, 33–39]. Although fat tissue is not the main tissue responsible for insulin stimulated glucose uptake, it seems to be the major tissue responsible for induction of the whole body insulin resistance. Our goal was to understand whether adipose tissues lipid content is altered in different fat tissue depots in obese non-diabetic and obese diabetic humans and, if so, whether there was any association between adipose tissue lipids and insulin resistance. In most works about obesity, fat tissue and insulin resistance, only triacylglycerols and adipokines have been taken into consideration. Ours is the first study to provide a comprehensive profile of the distinct molecular species not

only of ceramides but also of DAG (TIC of DAG in SAT is presented in Fig. 2) and LCACoA within two fat depots (visceral and subcutaneous) of lean non-diabetic, obese non-diabetic and obese diabetic subjects. We have found that the lipid content is elevated in both fat tissue depots. As mentioned above, intramuscular accumulation of the lipids impairs insulin action in skeletal muscle and liver.

In-vitro studies revealed that in 3T3-L1 adipocytes and in brown adipocytes, ceramide impairs insulin stimulated GLUT4 expression and glucose uptake [28]. It has also been shown that ceramide mediates the effect of TNF- α on GLUT4 mRNA content in these cells [40, 41]. Data from brown adipocytes suggest that the de novo ceramide biosynthesis plays a main role in mediating the effect of TNF- α on insulin action in these cells. There are few data from in vitro studies, showing, that pharmacological reduction of glycosphingolipids in cultured adipocytes strikingly improves glycemic control [42]. Such data prove that sphingolipids play an important role not only in regulating skeletal muscle but also adipocyte insulin sensitivity. There is some, but limited information about ceramides in human subcutaneous tissue [27]. Our previous work [26] provided information that ceramide metabolism in human subcutaneous tissue from lean healthy subjects differs from that in both obese non-diabetic and obese diabetic participants. We have demonstrated that total ceramide content decreased in subcutaneous fat tissue in both obese non-diabetic and obese diabetic patients compared to lean non-diabetic subjects. In the present work we have found, that total ceramide content as well as other measured lipids were greater in the both obese groups comparing to the lean non-diabetic group. It should be underlined, that although in both studies we used subcutaneous fat tissue, the tissue was taken from different places. In the previous study [26], the fat was taken from the abdominal region and in the present study the tissue was taken from the subcutaneous fat on the sternum. It appears that the differences in metabolic activity between fat tissues relates not only to subcutaneous and visceral but also to subcutaneous fat tissue from different regions [43, 44]. Obesity is associated with a state of chronic, low-grade inflammation and with increased plasma FFA concentrations which likely contributes to ceramide accumulation. Ceramide synthesis is activated by a variety of mediators, including proinflammatory cytokines, and an increased level of free fatty acids [45, 46]. In our work, we measured plasma FFA concentration and we found, that the concentration of plasma FFA is greater in both obese groups than in the lean group. The highest increase was found in saturated fatty acids concentrations (stearic acid and palmitic acid). There is some data showing that palmitate is responsible for lower adiponectin expression in fat tissue [47]. It is possible, that the mentioned effect of palmitate on adiponectin expression could occur through the increased level of bioactive lipids that contain palmitate.

Another key finding of our study was the positive correlation between total ceramide content in SAT and HOMA-IR ($r = 0.78$) and between C16-Cer content in subcutaneous fat tissue and HOMA-IR ($r = 0.79$) (Fig. 1a). Moreover, other positive correlations were found

Fig. 2 TIC total ion current of DAG in human subcutaneous adipose tissue (**a**). Peaks of particular DAG species (**b**)

between HOMA-IR and total DAG content in SAT and between HOMA-IR and C16:0/18:2 ($r = 0.56$ and $r = 0.64$, respectively, Fig. 1b). We did not observe such a relation in epicardial fat tissue. However, we found a correlation between C16-CoA content in epicardial fat tissue and HOMA-IR ($r = 0.73$), (Fig. 1c). In the all cases (ceramide, DAG in subcutaneous fat tissue and LCACoA in epicardial fat tissue), the strongest correlation was found with the molecule containing palmitate. A strong positive correlation between hepatic DAG content in lipid droplets and HOMA-IR values had previously been found and that hepatic DAG content in lipid droplets is the best predictor of insulin resistance [48]. Moreover it has been postulated that increases in intracellular diacylglycerol content lead to activation of new protein kinase C (PKC) isoforms that inhibit insulin action in the liver and skeletal muscle [49].

Our data demonstrated that the biologically active lipids increase in fat tissue of obese and obese diabetic patients and correlate with insulin resistance which suggests that they might play some special role in the induction of whole body insulin resistance. However, there is still an open question as to what is the mechanism by which increased lipids content in adipose tissue affects the whole body insulin sensitivity.

In conclusion, this is the first report on bioactive lipid content in human subcutaneous and epicardial adipose tissue of lean non-diabetic, obese non-diabetic, and obese diabetic subjects. The study has shown that in obese and obese diabetic patients, bioactive lipids content is greater in subcutaneous and epicardial fat tissue and the particular lipids content correlates with insulin resistance (HOMA-IR).

palmitoleic acid is positively correlated with obesity in adults and children [5, 6]. Whether a component of human or livestock diets, palmitoleic acid may act to regulate lipid metabolism.

Previous results from our laboratory showed palmitoleic acid functions to reduce de novo fatty acid synthesis and reduce lipogenic gene expression in cultured bovine adipocytes [7]. Concurrent with 16:1 increasing in palmitoleic acid-treated cells, *cis*-vaccenic (18:1 *cis*-11) and eicosenoic (20:1 *cis*-13) acids also increase. The physiologic consequence, however, of these long-chain MUFA are largely unknown. We hypothesize that 18:1 *cis*-11 and 20:1 *cis*-13 are products of palmitoleic acid elongation that are jointly responsible for the lipogenic effects seen with palmitoleic acid supplementation in bovine adipocytes. Therefore, the objectives of this study were to: (1) confirm elongation products of palmitoleic acid (16:1 *cis*-9) elongation in vitro using stable isotopes and (2) evaluate if exogenous supplementation of palmitoleic acid, elongation products, or both are responsible for decreased desaturation and lipogenesis rates observed with palmitoleic acid supplementation in bovine adipocytes.

Materials and Methods

Cell Culture

Primary bovine stromal vascular cultures were harvested from intermuscular adipose tissue obtained at the lateral edge of longissimus muscle between the longissimus costarum and posterior serratus dorsalis at the 12th rib of two beef carcasses as described by Hirai et al. [8] using slight modifications as described by Pratt et al. [9]. Cells were plated at 1×10^4 cells/cm² and passaged every 2–4 days when 60 % confluent. Cells were incubated at 37 °C under 5 % CO₂ humidified atmosphere with media [Dulbecco's modified Eagles medium (DMEM) containing 10 % fetal calf serum (FCS), and 2× antibiotic/antimycotic (AB/AM; containing 10,000 U/mL penicillin G, 10,000 µg/mL streptomycin, and 25 µg/mL amphotericin B)] replacement every 2 days. After four passages, cell lines were stored in liquid nitrogen at 1×10^6 cells/mL in freezing media (DMEM, 20 % FCS, and 10 % dimethyl sulfoxide) for later use.

Treatments

Individual cultures from two beef carcasses were used in duplicate for each of these two experiments ($n = 4$). Cells were thawed, passaged three times, and seeded in plates at 1×10^5 cells/cm². Cells were allowed to reach confluence, held for 2 days, and differentiated on day 0 with DMEM

containing 5 % FCS, 2× AB/AM, 2.5 µg/mL insulin, 0.5 mM 2-isobutyl-1-methylxanthine (IBMX), 0.25 µM dexamethasone (DEX), 5 µM troglitazone (TRO), and 10 mM acetate [8, 9]. Secondary differentiation media (DMEM, 5 % FCS, 2× AB/AM, 2.5 µg/mL insulin, 5 µM TRO, and 10 mM acetate) was applied for 4 (day 6) along with 0 µM additional fatty acids (control) or 150 µM fatty acids. Fatty acids were bound to fatty acid-free bovine serum albumin (2:1, w/w) as described by Van Harken et al. [10] prior to media addition. Control media contained an equal amount of fatty acid-free bovine serum albumin as used in fatty acid treatment media. According to the objectives of the experiment, cells were either harvested on day 6 for fatty acid composition and lipogenic gene expression or treated with stable isotopes on day 6 for enzymatic activity assays. Previously, our stromal vascular cultures displayed characteristic changes in morphology, lipid-filling, and adipogenic gene expression upon hormonal treatment, consistent with adipocyte differentiation by day 6 [7, 9].

Experiment 1

Previously, our palmitoleic acid-treated cultures showed a dramatic increase in 18:1 *cis*-11 and 20:1 *cis*-13 [7]. It has been proposed that palmitoleic acid can be elongated into 18:1 *cis*-11 and potentially elongated further into a 20C fatty acid [11]. To confirm 18:1 *cis*-11 and 20:1 *cis*-13 as elongation products and to measure elongation in vitro, we added stable isotope labeled palmitoleic acid [150 µM (U-¹³C)16:1] on day 6 for 0, 6, 12, 24, and 36 h to adipocytes cultures. At harvest, cells were washed three times with PBS, removed with trypsin, and placed directly into 2:1 chloroform/methanol (vol/vol) to terminate all enzymatic activity. Cellular fatty acids were extracted using Folch et al. [12] and transmethylated according to Park and Goins [13]. Fatty acid methyl esters (FAME) were analyzed using an Agilent 6890N gas chromatograph (GC; Agilent Technologies, Inc., Santa Clara, CA, USA) equipped with an Agilent 5973 mass spectrometer (MS) using a 100m Varian CP7489 (Varian Instruments Inc., Walnut Creek, CA, USA) capillary column (0.25 mm i.d. and 0.20 µm film thickness). Samples were run in the chemical ionization mode with He as the carrier gas and CH₄ as the reagent gas.

Ions of mass-to-charge ratio (m/z) 268 (m) and 284 ($m + 16$) were selectively measured to calculate the isotopic enrichments of 16:1. Similarly, ion abundance of 298 (m) and 312 ($m + 16$) were measured for 18:1 *cis*-11. We calculated the relative abundance (RA) of labeled ($m + 16$) to unlabeled (m) isotopomers of 16:1 and 18:1 *cis*-11. Fatty acid enrichment was calculated as tracer-to-tracee ratio (TTR), according to Wolfe and Chinkes [14].

$$\text{TTR}_{\text{sample}} = (\text{RA}_{\text{sample}} - \text{RA}_{\text{blank}}).$$

Samples that were not exposed to the labeled isotope served as ‘blanks’. Molar percent excess (MPE) of 16:1 was calculated by $\text{TTR}/(\text{TTR} + 1)$ and fractional synthetic rate (FSR) of elongation was calculated from $\text{TTR}_{18:1 \text{ cis-11}}$ and $\text{MPE}_{16:1}$.

$$\text{FSR}_{\text{elongation}} = \frac{\text{TTR}_{18:1 \text{ cis-11, time1}} - \text{TTR}_{18:1 \text{ cis-11, time0}}}{\text{MPE}_{16:1} \times (\text{time1} - \text{time0})}.$$

Experiment 2

The objective of this experiment was to determine if palmitoleic acid or an elongation product was responsible for changes in lipogenesis. Therefore, we treated adipocytes cultures with 0 μM fatty acids (control) or 150 μM palmitic (16:0), 150 μM palmitoleic, or 150 μM *cis*-vaccenic acids on day 2–6. FAME were prepared from cultures on day 6 as stated above for analysis with an Agilent 6850 GC equipped with an Agilent 7673A automatic sampler. Separations were accomplished using a 100m Supelco SP-2560 (Supelco, Inc., Bellefonte, PA, USA) capillary column (0.25 mm i.d. and 0.20 μm film thickness) according to Duckett et al. [15]. Individual fatty acids were identified by comparison of retention times with standards (Sigma, St. Louis, MO, USA; Matreya, Pleasant Gap, PA, USA). Fatty acids were quantified by incorporating an internal standard, methyl tricosanoic (23:0) acid, into each sample during methylation and expressed as a weight percentage of total fatty acids per well.

Lipogenesis

To measure lipogenesis in vitro, we substituted unlabeled acetate in the culture media on day 6 with stable isotope labeled acetate [10 mM ($1\text{-}^{13}\text{C}$)₂] to cultures treated with 0 μM fatty acids (control), 150 μM palmitoleic, or 150 μM *cis*-vaccenic acid for 0, 12, 24, and 36 h. Cells were harvested and FAME prepared as described above. Ions of mass-to-charge ratio (m/z) 270 (m), 271 ($m + 1$), and 272 ($m + 2$) were selectively measured to calculate the isotopic enrichments of 16:0, the primary product of de novo lipogenesis.

The formation of a fatty acid polymer, 16:0, from repeating units of acetate is an ideal application of mass isotopomer distribution analysis (MIDA) [14]. Therefore, we used this approach to estimate enrichment in our precursor pool and calculate FSR of lipogenesis. First, we calculated RA of singly ($m + 1$) and doubly ($m + 2$) labeled 16:0 to unlabeled (m) 16:0 isotopomers. To account for background noise and natural abundance of ^{13}C isotope when using a singly-labeled tracer, the enrichment of 16:0 was calculated as $\text{TTR}_{16:0} = (\text{RA}_{\text{sample}} - \text{RA}_{\text{blank}}) \times (1 - A)^N$, where

A was the natural abundance of ^{13}C , $A = 0.011$, and N was the number of C in the fatty acid molecule, $N = 16$ [14]. Samples that were not exposed to labeled isotope served as ‘blanks’. Precursor enrichment in MPE was estimated by:

$$\text{MPE}_{\text{precursor}} = \frac{2 \times (\text{TTR}_{(m+2)}/\text{TTR}_{(m+1)})}{(p - 1) + (2 \times (\text{TTR}_{(m+2)}/\text{TTR}_{(m+1)}))}$$

where, p is the number of precursor monomers present in the polymer, $p = 8$. Finally, our estimate of lipogenesis could be derived by calculating FSR [14].

$$\text{FSR}_{\text{lipogenesis}} = \frac{\text{TTR}_{16:0, \text{time1}} - \text{TTR}_{16:0, \text{time0}}}{(p \times \text{MPE}_{\text{precursor}})(1 - \text{MPE}_{\text{precursor}})^{p-1}(\text{time1} - \text{time0})}.$$

Desaturation

Stearoyl-CoA desaturase 1 (SCD1) is the enzyme responsible for creating a double bond at the Δ^9 position of several fatty-acyl CoA and its preferred substrates are 16:0 and 18:0 [16]. Its transcription and activity can be regulated by certain fatty acids [17], including palmitoleic acid [7]. In order to measure desaturation rates in vitro, we added 100 μM [$\text{U-}^{13}\text{C}$]18:0 to cultures treated with 0 μM fatty acid (control) or 150 μM palmitic, palmitoleic, or *cis*-vaccenic acid on day 6 for 0, 12, and 24 h. Samples were prepared and analyzed as described above for analysis with GC–MS. Ions of mass-to-charge ratio (m/z) 298 (m) and 316 ($m + 18$) were selectively measured to calculate the isotopic enrichments of 18:0. Similarly, isotope abundance of 296 (m) and 314 ($m + 18$) was measured for 18:1 *cis*-9. Since tracer enrichment can be measured in this case and the product of the SCD reaction is not a polymer of the tracer, it was not necessary to use MIDA. The FSR was calculated for rate of desaturation using the precursor enrichment, $\text{MPE}_{18:0}$.

$$\text{FSR}_{\text{desaturation}} = \frac{\text{TTR}_{18:1 \text{ cis-9, time1}} - \text{TTR}_{18:1 \text{ cis-9, time0}}}{\text{MPE}_{18:0} \times (\text{time1} - \text{time0})}.$$

Gene Expression

Total cellular RNA was isolated from cells using the *mir*-Vana microRNA Isolation kit (Ambion, Austin, TX, USA) according to the manufacturer’s instructions and RNA quality as described by Duckett et al. [18]. Quality was assessed using a Nanodrop 2000 Spectrophotometer (Thermo Fisher Scientific, Inc., Waltham, MA, USA) and Agilent Bioanalyzer 2100. All tRNA samples used in real-time PCR had a 260:280 absorbance ratio >1.9 on the Nanodrop and RNA integrity number >9.0 (1.0–10.0 scale) using Agilent RNA 6000 Nano kit. Superscript III reverse transcriptase (Invitrogen Corp., Carlsbad, CA, USA) was used to synthesize first strand cDNA. Real-time PCR was

conducted using an Eppendorf MasterCycler ep realplex (Westbury, NY, USA) with the QuantiTect SYBR Green RT-PCR Two Step Kit (Qiagen, Valencia, CA, USA) according to the manufacturer's directions. Two genes, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and β -actin, were evaluated as housekeeping genes for data normalization [18]. To determine the appropriate housekeeping gene to be used to normalize the data, the cycle threshold values (C_T) for GAPDH, β -actin, and all target genes per sample were entered into the BESTKEEPER program (<http://www.gene-quantification.info>). The program determines the most stable housekeeping gene to be used for normalization by repeated pair-wise correlation and regression analysis [19]. Both GAPDH and β -actin exhibited a correlation coefficient of 0.99 ($P < 0.001$) in the analysis and were suitable for data normalization. Primers for bovine mRNA were designed using Primer 3 software (<http://www.frodo.wi.mit.edu/primer3/>). Genes of interest for this study were those involved in fatty acid biosynthesis including acetyl-CoA carboxylase (ACC), fatty acid synthase (FASN), fatty acid elongase (ELOVL) -5 and -6, SCD1, sterol regulatory element binding protein-1c (SREBP), and carnitine palmitoyl-transferase 1A (CPT1A). Primer sets were first evaluated according to Duckett et al. [18], with the exceptions of ELOVL5 (forward: 5'-gtcatctggccgtgtacatt-3'; reverse: 5'-gggaagaaaagctgtgatg-3'), ELOVL6 (forward: 5'-ggaagcaacgaagctgac-3'; reverse: 5'-tggtgtgtgtgtgtgtcat-3'), and CPT1A (forward: 5'-gtgatgtcgaccatgtacgc-3'; reverse: 5'-agcagcaccttcaggagta-3').

Statistical Analysis

The data were analyzed using Proc GLM procedure of SAS 9.2 (SAS Institute Inc., Cary, NC, USA) for treatment comparisons over time. For Experiment 1, an analysis of variance (ANOVA) was performed as a completely randomized design with factor time (0, 6, 12, 24, and 36 h). For Experiment 2, a two-way ANOVA was performed as a completely randomized design with factors fatty acid (control, palmitic, palmitoleic, and *cis*-vaccenic), time (0, 12, 24, and 36 h), and two-way interaction. Least squares means were computed and separated statistically using Fisher's protected LSD test. For the analysis of relative gene expression, all C_T values for each sample/primer pair combination and the respective primer efficiency were analyzed using the REST-2009 program (<http://www.gene-quantification.de/rest-2009.html>; [19]) and the data were normalized using GAPDH. This software calculates relative gene expression using Pair-wise Fixed Reallocation Randomization Test and relative expression determined at the 95 % confidence interval.

Results

Experiment 1

Incubating bovine adipocytes with [U - ^{13}C] 16:1 resulted in enrichment ($P < 0.001$) of 16:1 and 18:1 *cis*-11 fatty acids over time. TTR of 16:1 was greater than 0 ($P < 0.01$) 6 h after [U - ^{13}C] 16:1 addition to the media and remained elevated ($P < 0.01$) to 36 h (Fig. 1). Enrichment of 18:1 *cis*-11 as TTR was also greater than 0 ($P < 0.05$) by 6 h and continued to increase ($P < 0.01$) above 6 h levels at 24 and 36 h. The $FSR_{elongation}$ increased ($P < 0.05$) over the 36 h period (Fig. 1).

In addition to label appearing in 16:1 and 18:1 *cis*-11 fatty acids following incubation with [U - ^{13}C] 16:1, enrichment was also seen in 20:1 *cis*-13 and *cis*-9, *cis*-11 CLA after concentrating the samples. These 20:1 *cis*-13 and *cis*-9, *cis*-11 CLA were present at very low levels in our samples ($<1.0/100$ g total fatty acids). Fatty acid peaks contained masses consistent with $m + 16$ enrichment from [U - ^{13}C] 16:1. Enrichment of 20:1 *cis*-13 was present at 24 and 36 h with TTR of 0.15 and 0.20, respectively. Enrichment of *cis*-9, *cis*-11 CLA was present at 24 and 36 h with TTR of 0.42 and 0.55 respectively.

Experiment 2

Comparing fatty acid data between control, palmitic, palmitoleic, and *cis*-vaccenic acid-treated cells, there was a main effect of fatty acid treatment ($P < 0.01$) for total fatty acids (Table 1). Micrograms of total fatty acids were greatest ($P < 0.001$) in palmitoleic and *cis*-vaccenic acid-treated cells at about $2\times$ greater than control cells (Table 1). Palmitic acid-treated cells also had higher ($P < 0.05$) levels of total fatty acids compared with controls, but lower ($P < 0.05$) than palmitoleic and *cis*-vaccenic acid-treated cells, despite being supplemented at the same level.

Palmitic acid-treated cells had increased ($P < 0.05$) levels of 16:0, 18:0, 18:1 *cis*-9, and 18:2n-6 compared with all other treatment groups (Table 1). Palmitoleic acid-treated cells had increased ($P < 0.05$) levels of 16:1 compared with all other treatment groups. In addition, palmitoleic acid cells had increased ($P < 0.05$) levels of 18:1 *cis*-11 and 20:1 *cis*-13 compared with controls, consistent with results from our previous work [7]. *cis*-Vaccenic acid-supplemented cells had slightly elevated ($P < 0.05$) 16:1 compared with controls, but were not different ($P > 0.05$) than palmitic acid-treated cells. Also, *cis*-vaccenic acid-supplemented cells had the greatest ($P < 0.05$) amount of 18:1 *cis*-11 and 20:1 *cis*-13 compared with all other treatment groups. Palmitoleic and *cis*-

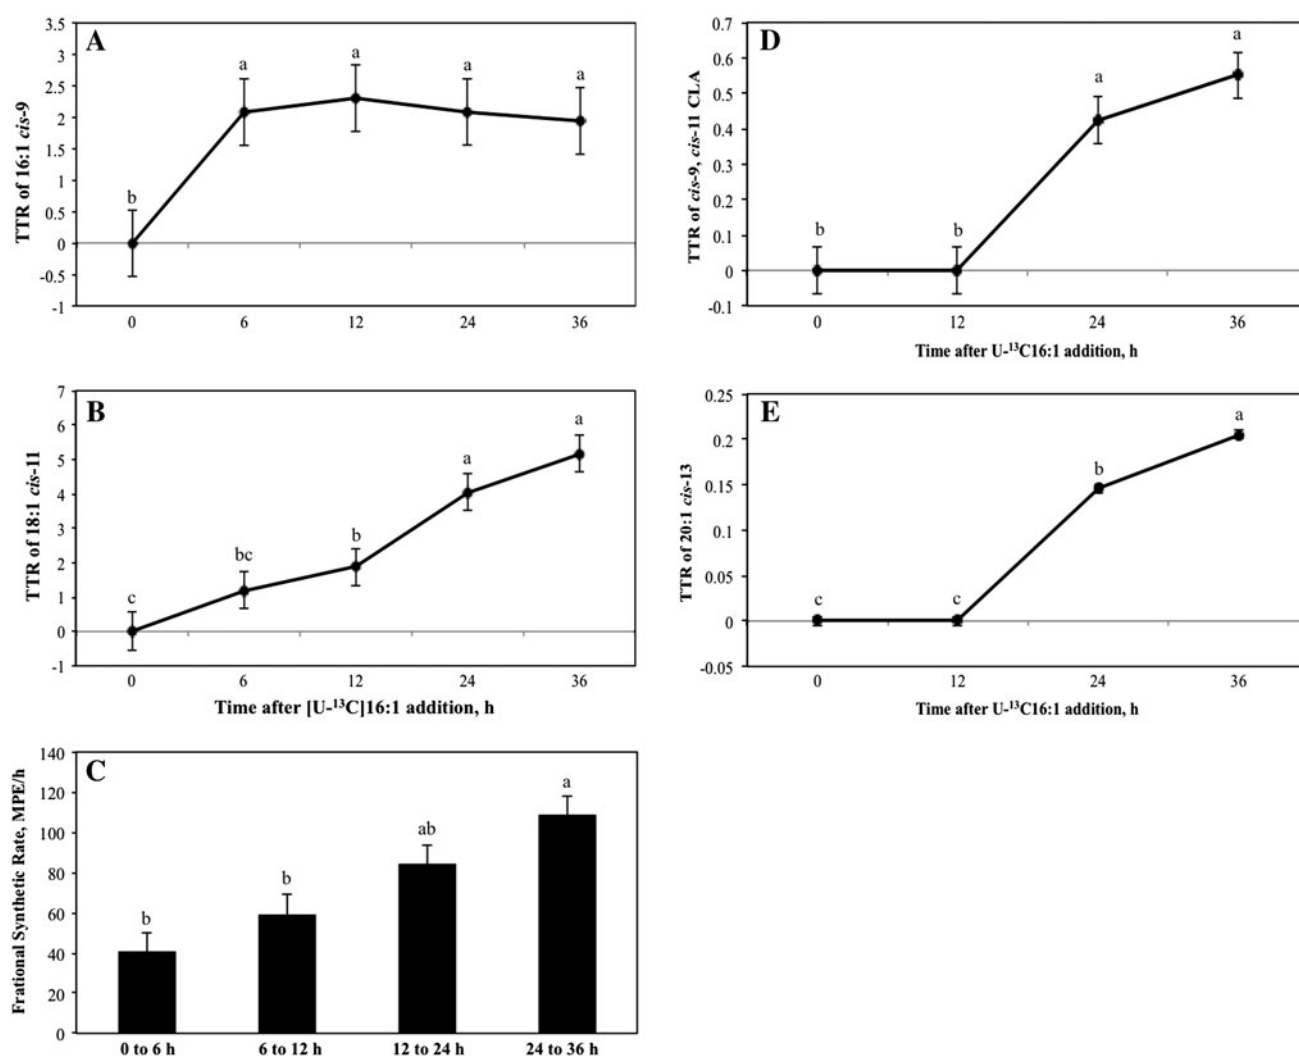

Fig. 1 Elongation of 16:1 to 18:1 *cis*-11 in bovine adipocyte cultures. **a** Main effect of time on tracer-to-tracee ratio (TTR) of 16:1 following 150 μ M [U-¹³C]16:1 addition to the media at 0 h. **b** Enrichment of 18:1 *cis*-11 displayed as TTR over time in cells. **c** Fractional synthetic rate of [¹³C]18:1 *cis*-11 from [¹³C]16:1 displayed as molar percent excess (MPE) per h and was calculated

over a 36 h period following stable isotope administration. **d** Enrichment of [¹³C] 18:2 *cis*-9, *cis*-11 displayed as TTR over time in cells. **e** Enrichment of [¹³C] 20:1 *cis*-13 displayed as TTR over time in cells. ($n = 4$, mean \pm SEM). ^{a-c}Time points without a common letter differed ($P < 0.01$)

vaccenic acid-treated cells had the lowest ($P < 0.05$) levels of 18:1 *cis*-9 and 18:2n-6 fatty acids. In addition, C20:4n-6 tended ($P = 0.07$) to be lower in both MUFA-treatment groups compared with controls.

Despite low levels of 18:1 *cis*-9 in both MUFA-treated groups, the desaturation index of 18:1 *cis*-9/18:0 was reduced ($P < 0.05$) in palmitoleic acid treated cells only compared with all other treatment groups (Table 1). The desaturation index of 18:1 *cis*-9/18:0 indicates desaturase activity was only impacted by palmitoleic acid supplementation, not *cis*-vaccenic acid.

Lipogenesis: precursor enrichment, MPE_{acetate}, did not change ($P > 0.05$) over time or due to treatment in our cultures using MIDA, nor was there a time by treatment

interaction (Fig. 2), suggesting we had isotopic steady state in our cultures [20]. There was an interaction ($P < 0.01$) between fatty acid treatment and length of [¹³C] 2 incubation on 16:0 enrichment. The TTR_{16:0} did not differ ($P > 0.05$) between treatment groups at 0 or 12 h and increased ($P < 0.05$) in all groups over time. At 24 and 36 h time points, TTR_{16:0} was decreased ($P < 0.05$) in palmitic, palmitoleic, and *cis*-vaccenic acid-treated cells compared with controls. The FSR_{lipogenesis}, calculated from MPE_{precursor} and TTR_{16:0}, also shows a reduction in lipogenesis in palmitic, palmitoleic, and *cis*-vaccenic acid-treated cells. The FSR_{lipogenesis} was decreased ($P < 0.05$) in palmitoleic acid-treated cells between 0 and 12 h and decreased ($P < 0.01$) in all fatty acid-treated cells

Table 1 Fatty acid composition of bovine adipocyte cultures treated with 0 μM fatty acids (control), 150 μM palmitic, palmitoleic, or *cis*-vaccenic acid ($n = 4$)

| Fatty acid ($\mu\text{g}/\text{well}$) | Control | 150 μM | | | SEM | <i>P</i> value |

ND fatty acid not detectable

^{a–d} Within a row, means without a common superscript differ ($P < 0.05$)

compared with controls between the 12–24 and 24–36 h time points (Fig. 2).

Desaturation: because the desaturation index of 18:1 *cis*-9/18:0 is not always representative of SCD1 activity [21], we supplemented a labeled substrate of the SCD1 reaction [$U-^{13}\text{C}$]18:0 to our bovine adipocyte cultures to serve as a measurement of desaturase activity. There was a treatment by length of incubation interaction for precursor enrichment, $\text{TTR}_{18:0}$. Enrichment of 18:0 was not different ($P > 0.05$) than 0 at 0 h, but $\text{TTR}_{18:0}$ increased ($P < 0.05$) over time for each sample. However, there was a differential incorporation of labeled [$U-^{13}\text{C}$] 18:0 into the different treatment groups. Cells treated with palmitoleic and *cis*-vaccenic acids had increased ($P < 0.01$) $\text{TTR}_{18:0}$ compared with control and palmitic acid-treated cells (Fig. 3). There was also a treatment by incubation time interaction ($P < 0.01$) for $\text{TTR}_{18:1\text{cis-9}}$. At 0 h, there was no enrichment ($P > 0.05$) of 18:1 *cis*-9 in any treatment group; by 12 h, $\text{TTR}_{18:1\text{cis-9}}$ of palmitoleic acid-treated cells was lower ($P < 0.01$) than all other treatment groups and was not different ($P > 0.05$) than 0. Control, palmitic, and *cis*-vaccenic acid-treated cells did not differ ($P > 0.05$) from each other and were enriched ($P < 0.05$) with 18:1 *cis*-9 at 12 h. By 24 h, all treatment groups had enrichment ($P < 0.05$) of 18:1 *cis*-9 and differed ($P < 0.05$) from each other. Palmitoleic acid-treated cells had reduced ($P < 0.01$) $\text{TTR}_{18:1\text{cis-9}}$ compared to controls, palmitic, and *cis*-vaccenic acid treated cells at 12 and 24 h. Palmitic and *cis*-vaccenic acid-treated cells had higher ($P < 0.05$) $\text{TTR}_{18:1\text{cis-9}}$ at 24 h than controls, which were also higher ($P < 0.05$) than palmitoleic acid-treated cells. Despite increased $\text{TTR}_{18:0}$ in both palmitoleic and *cis*-vaccenic acid-treated cells, only palmitoleic acid-treated cells

showed less ($P < 0.05$) formation of the desaturase product, as $\text{TTR}_{18:1\text{cis-9}}$, than control cells.

The $\text{FSR}_{\text{desaturation}}$ over 0–12 h was decreased ($P < 0.01$) in palmitoleic acid-treated cells compared with all other treatment groups, which did not differ ($P > 0.05$) from each other (Fig. 3). *cis*-Vaccenic acid-treated cells tended ($P = 0.052$) to have a reduced $\text{FSR}_{\text{desaturation}}$ from 0 to 12 h compared with controls. From 12 to 24 h, however, all treatment groups had a different $\text{FSR}_{\text{desaturation}}$. Palmitic acid-treated cells had the highest ($P < 0.01$) rate of desaturation and palmitoleic acid-treated cells had the lowest ($P < 0.01$) $\text{FSR}_{\text{desaturation}}$ from 12 to 24 h (Fig. 3).

Gene expression: palmitic acid supplementation down-regulated ($P < 0.05$) expression of SREBP and up-regulated ($P < 0.05$) CPT-1a mRNA expression (Fig. 4). Palmitoleic acid supplementation down-regulated ($P < 0.05$) FASN, SCD-1, and ELOVL6 mRNA expression and up-regulated ($P < 0.05$) ACC and CPT-1a mRNA expression compared with controls. *cis*-vaccenic acid supplementation up-regulated ($P < 0.05$) ACC and CPT-1a mRNA expression and down-regulated ($P < 0.05$) FASN and ELOVL6 mRNA expression compare to controls.

Discussion

Our previous work with palmitoleic acid supplementation in bovine adipocyte cultures resulted in a large increase in 18:1 *cis*-11 concentration within the cells [7]. Enrichment of 16:1 shortly after [$U-^{13}\text{C}$] 16:1 addition to the media shows that there was rapid incorporation of palmitoleic acid into the adipocytes on day 6. In addition, the enrichment of 18:1 *cis*-11, as shown by $\text{TTR}_{18:1\text{cis-11}}$, confirmed

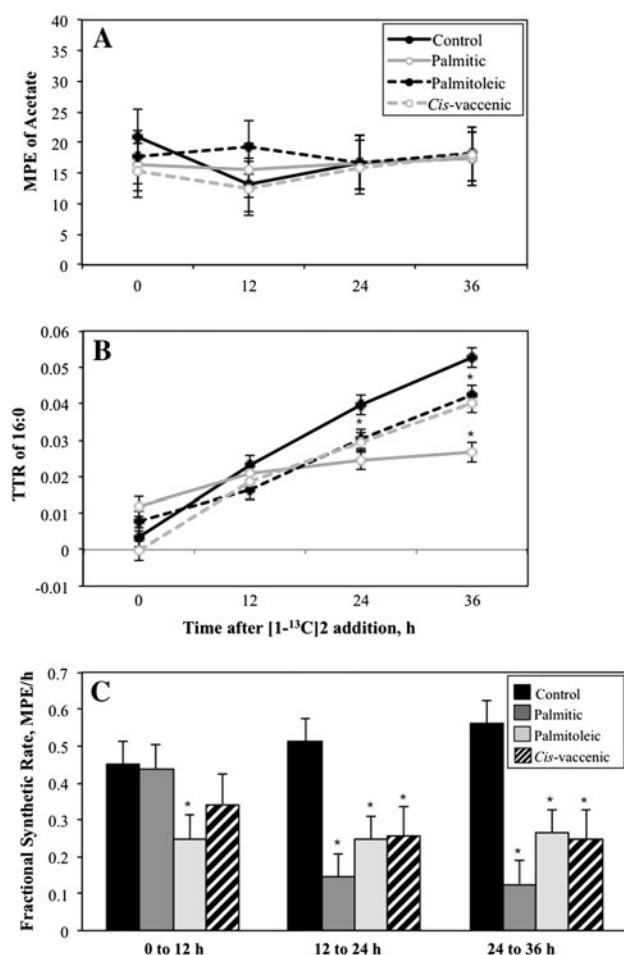

Fig. 2 Lipogenesis in bovine adipocyte cultures treated with 0 μ M fatty acid (control), 150 μ M palmitoleic, or 150 μ M *cis*-vaccenic acid. **a** Estimation of molar percent excess (MPE) of acetate after [13 C] 2 addition to the media. **b** Enrichment of 16:0 displayed as tracer-to-tracee ratio of 16:0 over time. **c** Fractional synthetic rate of [13 C] 16:0 from [13 C] 2 displayed as molar percent excess (MPE) per h calculated over a 36 h period following stable isotope administration. ($n = 4$, mean \pm SEM). Asterisk indicates within a time point, fatty acid-treated cells differed ($P < 0.05$) from controls

18:1 *cis*-11 as a direct elongation product of 16:1. Presence of [13 C] tracer in 18:1 *cis*-11 fatty acids definitively shows that palmitoleic acid is taken in by bovine adipocytes and elongated to 18:1 *cis*-11 in vitro. Originally isolated from horse brain [22] and later in intestinal bacteria [23] and a host of mammalian tissues [24], *cis*-vaccenic acid is a MUFA. It can be derived from the diet or biosynthetic pathways, but its role in metabolism is largely unknown. Elongase enzymes generally have chain-length and saturated bond specificity for their fatty acids substrates [25]. The conversion of 16:1 to 18:1 *cis*-11 is generally attributed to the ELOVL6 isoform of the mammalian elongase enzyme, which adds an acetate molecule to the carboxylic acid end of the fatty acyl chain. Mice deficient in ELOVL6 show increased levels of 16:0 and 16:1 *cis*-9 and reduced

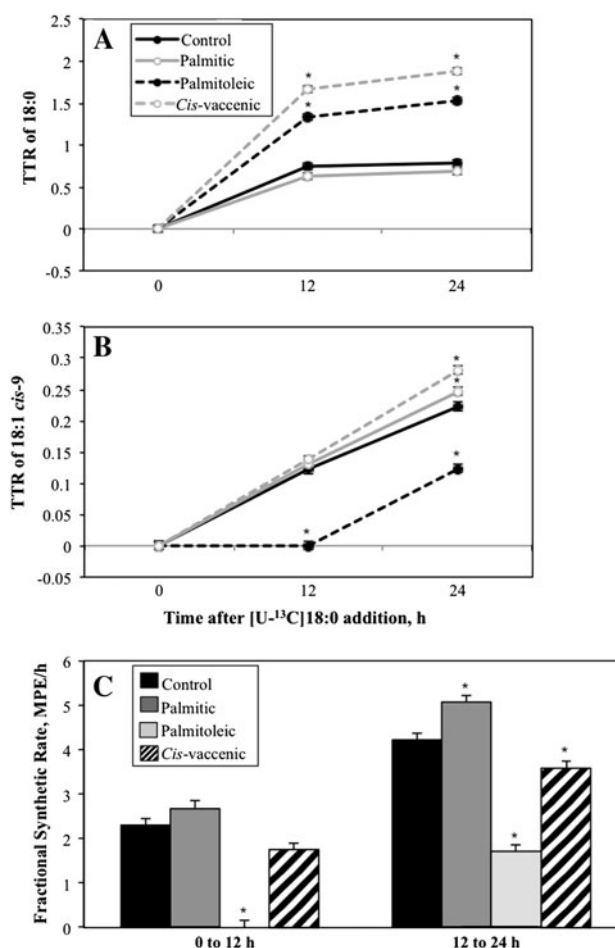

Fig. 3 Desaturation of 18:0 to 18:1 *cis*-9 in bovine adipocyte cultures treated with 0 μ M fatty acids (control), 150 μ M palmitic, 150 μ M palmitoleic, or 150 μ M *cis*-vaccenic acid. **a** Tracer-to-tracee ratio (TTR) of 18:0 and **b** 18:1 *cis*-9 displayed over time following 100 μ M [13 C] 18:0 addition to the media. **c** Fractional synthetic rate of [13 C] 18:1 *cis*-9 from [13 C] 18:0 displayed as molar percent excess (MPE) per h calculated over a 24 h period following stable isotope administration. ($n = 4$, mean \pm SEM). Asterisk indicates within a time point, fatty acid-treated cells differed ($P < 0.05$) from controls

18:0, 18:1 *cis*-9, 18:1 *cis*-11, and other long chain fatty acids [11]. However, previous work in our lab suggests that ELOVL6 mRNA is down-regulated in response to palmitoleic acid supplementation despite an obvious increase in the ELOVL6 reaction product 18:1 *cis*-11 [7]. This is the first conclusive study in bovine adipocytes that provides proof of 18:1 *cis*-11 elongation from 16:1 *cis*-9. In addition, 18:1 *cis*-11 subsequent elongation to 20:1 *cis*-13 and desaturation to *cis*-9, *cis*-11 CLA have not been reported to date.

We successfully incorporated our fatty acid supplements into bovine adipocyte cultures based on detection of increased levels ($P < 0.01$) of treatment fatty acids in cells after all media had been removed. Reduced total fatty acids in palmitic acid-treated cells compared with MUFA-treated

Fig. 4 Relative gene expression of bovine adipocytes supplemented with 0 μ M fatty acids (control), 150 μ M palmitic, 150 μ M palmitoleic or 150 μ M *cis*-vaccenic acid. **a** Expression of sterol response element binding protein-1c (SREBP), fatty acid synthase (FASN), stearoyl-CoA desaturase 1 (SCD1), and **b** Acetyl-CoA carboxylase (ACC), fatty acid elongase (ELOVL) 5 and 6, and carnitine-palmitoyl

transferase 1A (CPT1A), genes associated with fatty acid biosynthesis and metabolism pathways. All C_T values were normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) ($n = 4$). Asterisk indicates gene expression for this treatment differed ($P < 0.05$) from controls

cells may be due to an apoptotic effect of palmitic acid supplementation. In murine adipocytes, palmitic acid induces endoplasmic reticulum stress and apoptosis at 100, 250, and 500 μ M treatment levels [26]. Similarly, we suspected that palmitic acid-supplementation in our bovine adipocyte cultures induced apoptosis, resulting in reduced total lipid accumulation and treatment fatty acid inclusion compared with MUFA-supplemented cells. To test this hypothesis, we treated differentiated adipocytes with palmitic and palmitoleic acid to day 6 and assayed cell viability using the Cell Counting Kit-8 (Dojindo Molecular Technologies, Inc., Rockville, MD, USA) according to manufacturer's instructions. Relative cell viability was greater ($P < 0.05$) for palmitoleic acid-treated cells and controls compared with palmitic acid-treated cells (data not shown). Despite a reduction in cell viability, palmitic acid-treated cells had the greatest levels of 18:0 and 18:1 *cis*-9, which may indicate increased conversion of 16:0 into products with less lipotoxic properties.

Reduced lipogenesis in palmitoleic acid-treated cultures is consistent with our previous results when we supplemented 150 μ M palmitoleic acid, which resulted in approximately 45 % reduction in lipogenesis between 0 and 24 h [7]. In the current study, both MUFA induced a repressive effect on lipogenesis of the same magnitude from 12 to 24 h at approximately 50 %. Therefore, this effect of palmitoleic acid supplementation on lipogenesis cannot be solely attributed to palmitoleic acid as its elongated form, *cis*-vaccenic acid, also displayed anti-lipogenic effects. Palmitic acid-treated cultures also showed a reduction in lipogenesis, but this effect is most likely related to cell viability in palmitic acid-treated cultures discussed previously. The genes that primarily involved in de novo lipogenesis are ACC and FASN. The gene

expression results from these two genes are seemingly contradictory as MUFA treatments increase ACC mRNA and decrease FASN mRNA. However, ACC activity can also be regulated allosterically and through phosphorylation. Regulated by the transcription factor SREBP, FASN gene expression was reduced by approximately 40 % in MUFA treatments, similar to FSR_{lipogenesis} results.

The isotopic measure of SCD1 activity, FSR_{desaturation}, showed a more dramatic effect of fatty acid supplementation on desaturase activity than the 18:1 *cis*-9/18:0 desaturation index results. The reduction in desaturase activity due to palmitoleic acid was approximately 100 % from 0 to 12 h and approximately 60 % from 12 to 24 h. By contrast, palmitoleic acid reduced the desaturation index by less than 25 % compared with controls (Table 1). The FSR_{desaturation} also showed a reduction in SCD1 activity by approximately 15 % from 12 to 24 h due to *cis*-vaccenic acid (Fig. 3), whereas the desaturation index for *cis*-vaccenic acid-treated cells was not different from controls. Therefore, the FSR_{desaturation} is a more sensitive measurement of SCD1 activity than the 18:1 *cis*-9/18:0 desaturation index when fatty acids are supplemented to adipocyte cultures.

Transcription of SCD1 mRNA is controlled primarily by SREBP, which binds to the sterol response element in the promoter region of the SCD1 gene [27, 28]. The promoter region of the bovine SCD1 gene contains a fat specific element, PUFA response element, and SREBP-response region [29]. In addition to PUFA, expression of SCD1 is also regulated by its products and not by the availability of its substrates [29]. For instance, the addition of 18:1 *cis*-9 and *cis*-9, *trans*-11 CLA reduced SCD promoter activity, but 18:1 *trans*-11 did not [29]. In this study, palmitoleic acid impacts SCD1 activity based on both the FSR_{desaturase} and desaturase index in addition to

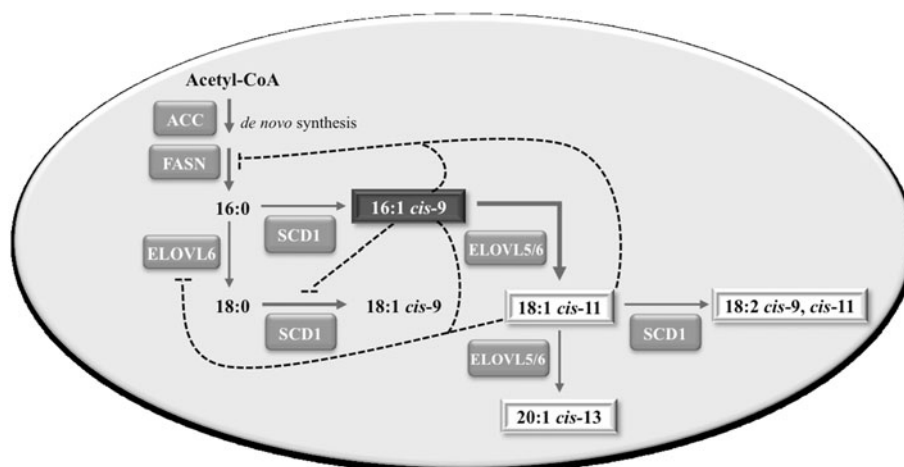

gene expression; whereas, *cis*-vaccenic acid induces a minimal response in rate of desaturation with no effect on the desaturation index or gene expression. In addition, palmitic acid increases the rate of desaturation with no effect on the desaturation index.

Several elongase enzymes are present in mammalian cells and are responsible for adding acetyl-CoA molecules to the carboxylic acid end of a fatty acid hydrocarbon skeleton. Seven elongases have been identified and given the designation of ELOVL for elongation of very long fatty acids (ELOVL 1–7; 30). Elongases can be divided into two groups based on substrate preference: (a) elongation of saturated and monounsaturated fatty acids (ELOVL1, 3, and 6) and (b) elongation of polyunsaturated fatty acids (ELOVL2, 4, 5, and 7; 30, 31). ELOVL1 appears to play a role in elongation of very long chain saturated fatty acids (up to 26C) for sphingolipid formation and maintenance of membrane integrity [30]. ELOVL1 is expressed in lung, brain, kidney and heart but barely detectable in live, brown adipose tissue, and skin [32]. ELOVL2 has been shown to elongate arachidonic acid and long-chain (20C or greater) omega-3 fatty acids in transfected yeast and mammalian cells but no activity was demonstrated for saturated or monounsaturated fatty acids [31]. Expression of ELOVL3 was only detected in skin [32]; however, others have reported strong correlations with ELOVL3 and brown adipose tissues [31]. ELOVL4 is specifically expressed in human retina where it is believed to have a role in elongation of docosahexaenoic (C22:6) acid [31, 32]. ELOVL5 is involved in the elongation of PUFA 18–20C but cannot elongate beyond 22C [31]. ELOVL5 expression is detected in all tissues [32]. ELOVL6 is responsible for the elongation of saturated fatty acids 12–16C to 18C and cannot elongate beyond 18C. ELOVL6 is ubiquitously expressed, especially in tissues with high lipid levels like adipose tissue, liver and brain [31, 32]. ELOVL7 exhibits activity for

acyl-CoAs of 16–20C with highest activity for 18:3n-3 and 18:3n-6 [33].

In this study, supplementation of palmitoleic acid to adipocyte cultures resulted in increased levels of 18:1 *cis*-11 and also 20:1 *cis*-13 to a more limited extent. Likewise, supplementation of C18:1 *cis*-11 to adipocyte cultures increased levels of C20:1 *cis*-13. As FASN is not capable of synthesizing fatty acids greater than 16C in length, acetate molecules were most likely added to 16:1 *cis*-9 by an elongase. Others [11] have proposed that 16:1 *cis*-9 can be elongated into 18:1 *cis*-11 and potentially elongated further into a 20C fatty acid, 20:1 *cis*-13, but this study is the first to confirm this pathway through the use of stable isotope technology. Elongation of MUFA is reportedly carried out by ELOVL6 but ELOVL5 has been reported to also have some activity for this reaction as well, especially in the absence of ELOVL6 [34]. Green et al. [34] proposed that ELOVL6 preferentially elongates C16 to C18, which then can be further desaturated to C18:1 *cis*-9, and that ELOVL5 preferentially elongates C16:1 *cis*-9 to C18:1 *cis*-11 based on knockdown and overexpression studies in rat insulinoma cell lines (INS-1). These authors propose a coordinated regulation of the elongases in order to balance the levels of C16:1 *cis*-9, C18:1 *cis*-11 and C18:1 *cis*-9 in the cell. Due to increased fatty acid elongation products (18:1 *cis*-11 and 20:1 *cis*-13) observed in our study, we know elongation occurs in palmitoleic and *cis*-vaccenic acid-treated cultures. However, mRNA expression of ELOVL6 was reduced in both palmitoleic and *cis*-11 vaccenic acid supplemented cells compared to controls; whereas ELOVL5 mRNA expression was not altered with MUFA supplementation. Transcription factors that regulate elongases include SREBP-1c for ELOVL6 [35] and peroxisome proliferator-activated receptor- α (PPAR α) for both ELOVL5 and 6 [36]. Our results would indicate that transcription levels may not be directly related to enzyme

Fig. 5 Proposed fatty acid metabolism and biosynthesis pathways in bovine adipocytes supplemented with palmitoleic acid (16:1 *cis*-9). Dotted lines depict inhibitory effects

activity and that further research is needed to examine regulation of elongases in adipocytes.

Carnitine palmitoyl-transferase 1A is responsible for transporting long chain fatty acids through the outer mitochondrial membrane for the purpose of β -oxidation in the mitochondrial matrix. In ruminants, CPT1A is expressed in numerous tissues including adipose tissue in contrast to a more restricted tissue abundance in monogastrics [37]. Inhibition of CPT1A is primarily attributed to malonyl-CoA, the product of the ACC reaction, in monogastric species [38]. Price et al. [37] found N-terminal sequence differences in ovine CPT1 that alter enzyme kinetics for certain substrates, which differs from that of the rat. All fatty acid treatments in this study resulted in increased CPT1A mRNA, which may lead to increase β -oxidation and ATP production.

In this study, we confirmed 18:1 *cis*-11 and 20:1 *cis*-13 as products of palmitoleic acid elongation in vitro and that *cis*-9, *cis*-11 CLA can also be produced through elongation and desaturation of palmitoleic acid. Supplementation of palmitoleic and *cis*-vaccenic acids reduces lipogenesis and FASN gene expression. However, palmitoleic acid is largely responsible for reducing SCD1 gene expression and desaturation activity with *cis*-vaccenic acid contributing a slight reduction in SCD1 activity. A schematic representation of fatty acid biosynthesis and regulation is depicted in Fig. 5. Overall, palmitoleic acid supplementation is directly responsible for decreased desaturation and jointly responsible, with its elongation products, for reduced lipogenesis. However, more research is still needed to determine the mode of action and potential application of these fatty acids to modulate lipogenesis in vivo.

Many studies have shown that conversion of ALA to DHA in vivo is minimal. The conversion of ALA to EPA and DHA in vivo is <2 % [1, 2]. Few studies have, however, shown that ALA can be converted to DHA in reasonable amounts if provided at higher levels in the diet. Ramaprasad et al. [3] have shown that EPA + DHA levels in serum and liver is increased when incremental amounts of ALA are given in the diet. Therefore, innovative approaches are needed to increase long chain omega-3 PUFA levels in serum and tissues, if it has to be derived solely from ALA.

Recent developments in the field of microemulsions are exploited by many investigators for the delivery of biologically important molecules. Studies have shown that EPA levels in the plasma are enhanced tenfold when given in encapsulated form as compared to those given without encapsulation [4]. The bioavailability of EPA and EPA + DHA in rats was enhanced by 45 and 43 %, respectively when provided in a gelled emulsion as compared to those given in the free form [5]. An increase in lipid bioavailability was observed with higher assimilation of DHA when given as liposomes [6]. Liposomes also help in enhancing the bioavailability. A twofold increase in plasma concentration of curcumin was observed in rats when given as a curcumin–phospholipid complex. Curcumin nanoparticles have shown a ninefold increase in bioavailability [7]. Therefore, microemulsions may provide a means of enhancing the bioavailability of lipophilic molecules such as omega-3 fatty acid enriched oils.

The primary objective of this investigation was to explore the possibility of increasing the uptake and conversion of ALA to EPA and DHA using microemulsions. Microemulsions were prepared with different binding materials such as whey protein, gum acacia and lipid. Protein-based emulsifiers such as whey protein increase the viscosity of the interfacial layer and the surrounding water phase, and restrict the penetration and mobility of prooxidants into the oil [8]. Whey protein is a film-forming material with good emulsifying properties. Whey protein is used as hydrogels and a nanoparticulate system for encapsulation and controlled delivery of bioactive compounds [9, 10]. Gum Arabic (gum *Acacia*) is a hydrocolloid produced by the natural exudation of acacia trees and is an effective encapsulation material with high water solubility, low viscosity and acts as an oil-in-water emulsifier [11].

Commercially available phospholipid-based materials are also used as binding materials [12]. Liposomes are used as oral route vectors for delivering fatty acid supplements. Studies have shown that fatty acid absorption including that of omega-3 PUFA is enhanced when given through liposome administration. The high amount of phospholipids in liposomes facilitates the transport of the products to

the unstirred water layer of enterocytes. The bioavailability of omega-3 PUFA is increased when bound to phospholipid (PL) when compared with that delivered through triacylglycerol (TAG) [6, 13, 14]. A study performed on preterm infants showed that the absorption of long chain omega-3 PUFA, especially DHA was greater with formulations of phospholipid as compared to the formulas supplemented with TAG [15]. Studies have also shown that microemulsions protect PUFA from oxidation and they can also be used to increase the uptake of omega-3 PUFA in serum [4, 5].

The aim of the present study was therefore to explore the possibility of delivering omega-3 PUFA-rich oils using different types of microemulsion. The conversion of ALA to long chain omega-3 PUFA when given in microemulsion form was also investigated in this study.

Materials and Methods

Materials

Linseed oil (LSO) was provided by Kamani Flax Omega Industries, Mumbai, India. Sunflower oil (SNO) was purchased from a local market. Lipoid S75-3 (Soy lecithin at 69 % phosphatidylcholine and 10 % phosphatidylethanolamine) was a gift from Lipoid (Ludwigshafen, Germany). Sodium chloride was purchased from Sisco Research Laboratories, Mumbai, India. Whey protein concentrate (WPC) was obtained from Mahaan Foods (Mumbai, India). Gum acacia, maltodextrin, α -tocopherol and sodium azide were procured from Himedia, Mumbai, India. Polyethylene glycol, eicosapentaenoic acid, docosahexaenoic acid and alpha linolenic acid were procured from the Sigma Chemical Company, St. Louis, MO, USA. All the solvents were of analytical grade and distilled before use.

Preparation of LSO/SNO Emulsions

LSO/SNO was encapsulated in microemulsions using one of the three different binding materials. Carbohydrate (gum acacia), protein (whey protein) and phospholipid (lipoid) based materials were used for encapsulating the oil.

1. Carbohydrate based emulsions of LSO/SNO:

The carbohydrate-based emulsion of LSO or SNO was prepared by using gum acacia [16]. The gum acacia (0.5 %) and maltodextrin (20 %) were dissolved in distilled water. The gum acacia solution was heated at 45 °C with constant stirring for 30 min and then allowed to cool. Emulsions with LSO were prepared by adding dropwise and dispersing the oil (10 %) into the aqueous gum acacia solution. Two drops of Tween 80 was added to aid

emulsification. α -Tocopherol (0.065 %) was added as an antioxidant. Sodium azide (0.02 wt%) was added to the emulsions as an antimicrobial agent. The emulsions were homogenized for 5 min at 6,000 rpm using a laboratory mixer (Silverson L4RT, Silverson Machines Ltd., Chesham, Bucks, England). These emulsions were then further homogenized at 800 bar with ten cycles at 4 °C using a high pressure homogenizer (Panda, GEA Niro Soavi, Italy). The emulsions were collected and stored at –20 °C till further use.

2. Protein based emulsions of LSO/SNO:

The protein based emulsions of LSO or SNO were prepared by using Whey protein concentrate (WPC) [17]. The WPC solutions were prepared by dispersing the powder (10 wt%) in buffer solution (5 mM phosphate buffer, pH 7). The pH of WPC solution was adjusted to 7.0. The final concentration of dissolved solid was 30 % (w/w) which comprised 20 wt% maltodextrin and 10 wt% whey protein. Two drops of Tween 80 was added to aid emulsification. α -Tocopherol (0.065 %) and sodium azide (0.02 wt%) were added to the emulsions. The oil-in-water emulsions were prepared in two stages: (a) The core material [LSO or SNO in the ratio of 1:3 (core: wall)] was progressively added to the aqueous phase during pre-emulsion preparation and homogenized for 5 min at 6,000 rpm using a laboratory mixer (Silverson L4RT, Silverson Machines Ltd., Chesham, Bucks., England). (b) These coarse emulsions were then further homogenized at 800 bar with ten cycles at 4 °C using a high pressure homogenizer (Panda, GEA Niro Soavi, Italy). These emulsions were collected and stored at –20 °C till further use.

3. Phospholipid based emulsions of LSO/SNO:

The phospholipid based emulsions of LSO or SNO were prepared using Lipoid S75-3 [12]. The components used to prepare the emulsions were Lipoid (0.075 %), polyethylene glycol (3 %) and NaCl (0.9 %) dissolved in distilled water. LSO or SNO (10 wt%) was added to this lipid solution. The emulsions were homogenized for 5 min at 6,000 rpm using a laboratory mixer (Silverson L4RT, Silverson Machines Ltd., Chesham, Bucks, England). These emulsions were then further homogenized at 800 bar with ten cycles at 4 °C using a high pressure homogenizer (Panda, GEA Niro Soavi, Italy). The emulsions were collected and stored at –20 °C till further use.

Measurement of Encapsulation Efficiency

The encapsulation efficiency of the binding materials was determined as described by Danviriyakul et al. [18]. The total oil in the encapsulated material was extracted in hexane by Soxhlet extraction. The weight of oil extracted

was taken as the amount of oil associated with microcapsules. Adsorbed oil on the surface of microcapsule was extracted by gently shaking the microcapsules in petroleum ether (b.p. 60–80 °C) for 10 min without damaging the microcapsules. The solvent was decanted and the residue was dried in a rotavapor and weighed until constant weight was obtained. Encapsulation efficiency of the binding material calculated as follows.

$$\text{Encapsulation efficiency (\%)} = \frac{[(\text{total oil} - \text{adsorbed oil}) \times 100]}{\text{total oil}} \quad (1)$$

Scanning Electron Microscopy (SEM) of Encapsulated Oil

Scanning electron microscopy was used to study the surface and internal structures of the encapsulated materials as described by Rosenberg et al. [19]. Powder particles were attached to a sample stub with double-sided sticky tape. The specimens were sputter coated with gold using a Polaron sputter coater and examined using a LEO 435 VP (LEO Electron Microscopy Ltd., Cambridge)) at an accelerating voltage.

Analysis of Emulsion Particle Size

The particle size distributions of the emulsified lipid droplets were determined using a Mastersizer fitted with small volume sample presentation unit and integration software (Malvern Instruments Ltd., Worcestershire, UK). The particle size distributions were calculated based on a relative particle refractive index of 1.350 [20]. Distilled water was used as the dispersant for the determination of the emulsion lipid globule size distribution. The mean droplet diameter was expressed as the volume mean diameter. Each sample was analyzed in triplicate and the data were reported as averages.

Fatty Acid (FA) Composition

Fatty acid composition of encapsulated oils, dietary lipids, serum, and tissues were analyzed as methyl esters using gas liquid chromatography (Fisons, fitted with a flame ionization detector [FID]) fitted with a fused silica capillary column 25 m \times 0.25 mm (Parma bond FFAP-DF-0.25, Machery-Negal GmbH co., Duren, Germany). The methyl esters of fatty acids were prepared using 14 % BF_3/MeOH as described by Morrison and Smith [21]. The operating conditions of gas liquid chromatography were: column temperature 220 °C, injection temperature 230 °C, and detector temperature 240 °C. Nitrogen was used as the carrier gas. Individual fatty acids were identified by

comparison with the retention times of standards (Nu-Check-Prep, Inc, Elysian MN) and were quantified by an online Shimadzu Chromatopack CR6A integrator. Penta-decanoic acid was used as the internal standard for the quantification of specific fatty acids.

Intestinal Absorption of Encapsulated Oil—Intestinal Everted Sac Model

Male Wistar rats (OUTB-Wistar, IND-cft (2c) weighing 140–150 g were kept for 1 week on standard rodent pellets (Christie Foods, Bangalore, India) with free access to food and water. Rats were sacrificed by anesthetizing with diethyl ether. The abdomen was opened by midline incision. The small intestine was removed by cutting each end. The intestine was washed with 0.9 % saline. After thoroughly cleaning both inside and outside of the small intestine with saline, it was everted and cut into sacs of 8 cm length. Each sac was filled with Krebs–Ringer phosphate buffer containing 10 mM glucose. Absorption of the oil was determined by incubating the everted rat intestinal segments in the Krebs–Ringer phosphate buffer—10 mM glucose medium (10 ml) placed in a series of 25 ml conical flask containing varying concentrations of the oil (1.25–80 mg). The oil was added to this medium containing 0.04 % Tween 20. The flasks were aerated with a 95 % oxygen and 5 % carbon dioxide mixture and maintained at 37 °C in a Julabo shaking water bath for 3 h [22]. The lipids from mucosal medium, serosal fluid and the intestinal tissue were extracted by the Folch procedure (1957) [23].

Absorption of Encapsulated Oil—In Vivo Studies

Male Wistar rats [OUBT-Wistar, IND-cft (2c)] weighing 40 ± 4 g were grouped (six rats in each group) by random distribution and housed in individual cages, under a 12 h light/dark cycle, in an approved animal house facility at the Central Food Technological Research Institute in Mysore, India. The rats were fed standard rodent pellets for 30 days. Growth of the rats was monitored by weighing at regular intervals. The rats had free access to food and water throughout the study. The rats were administered 1 mL of emulsion of SNO or LSO by gavage once a day at 10AM for 30 days. The major fatty acid present in 1 mL of SNO emulsion was 46 mg of LA where as 1 ml of LSO contained 41 mg of ALA. After 30 days of feeding emulsified fats, rats were fasted overnight and sacrificed under ether anesthesia. Blood was drawn by cardiac puncture and serum was separated by centrifugation at 1,100 g for 30 min. The liver was removed, rinsed with ice-cold saline, blotted, weighed and stored at -20 °C until analyzed. The experimental protocol for these studies was approved by the Institutional Animal Ethics Committee recognized by the Government of India.

Statistical Analysis

Fisher's least significant differences (LSD) test was used to differentiate the treatment means and the significant level was reported at $P < 0.05$. Statistical analysis was performed by using Statistica Version 5.5 (Statsoft Inc., OK, USA) software.

Results

Encapsulation Efficiency of Gum Acacia, Whey Protein and Lipoid

Encapsulation efficiency of the binding material indicates the amount of oil that was successfully encapsulated and calculated from total oil in microcapsules and extractable oil from surface. Lipoid showed greater encapsulation efficiency in entrapping oils (83–85 %) followed by Whey protein (74–75 %) and gum acacia (67–68 %). There were no significant differences in the amount of SNO or LSO encapsulated in these binding materials (Table 1).

Particle Size of Microemulsions Containing Oils

The particle size was measured using a particle size analyzer (Malvern Instruments Ltd., Worcestershire, UK). The average particle size of microemulsion containing oil in gum acacia was in the range of 1,092–1,093 nm, whereas the particle size of microemulsions containing oil in whey protein was found to be 700–704 nm. The particle size of microemulsions containing oil in lipoid was found to be 246–249 nm (Table 2). Results showed that high pressure homogenization for ten cycles was optimal for making microencapsulation of selected oils. Beyond ten cycles, no further changes in the particle size were observed. No significant differences in the particle size were observed when LSO or SNO was used as the core material.

Scanning Electron Microscopy of Encapsulated Oils

Scanning electron microscopy (SEM) is an important tool for studying microencapsulation, and helps in the selection

Table 1 Encapsulation efficiency of various binding materials

| Oils | Encapsulation efficiency (%) | | |
|------|------------------------------|-------------------|------------------|
| | With gum acacia | With whey protein | With lipoid |
| SNO | 67.2 ± 1.1^a | 74.2 ± 3.0^b | 83.8 ± 1.8^c |
| LSO | 68.4 ± 2.2^a | 75.2 ± 2.9^b | 84.7 ± 3.1^c |

Values are mean \pm SD, $n = 4$; mean in a row with different superscripts differ significantly at $P < 0.05$

SNO sunflower oil, LSO linseed oil

Table 2 Particle size of microencapsulated oils

| Groups | | Emulsion size (d_{43} , nm) | | |
|--------|-----|--------------------------------|--------------------------|--------------------------|
| | | With gum acacia | With whey protein | With lipid |
| 1 | SNO | 1,092 \pm 4 ^c | 704 \pm 5 ^b | 249 \pm 4 ^a |
| 2 | LSO | 1,093 \pm 3 ^c | 700 \pm 4 ^b | 246 \pm 3 ^a |

Values are mean \pm SD, $n = 4$; mean in a row with different superscripts differ significantly at $P < 0.05$

SNO sunflower oil, LSO linseed oil

of wall materials, to view the distribution of core material in microcapsules, and for elucidating the mechanisms of capsule formation. The gum acacia which encapsulated oil showed a rounded external surface with concavities and teeth. The surface had no apparent cracks or porosity. Microencapsules with whey protein showed a spherical shape. No vacuoles were present indicating good microcapsules formation without any breakage. No oil droplets were observed in the outer structure of the capsules. The oil encapsulated with lipid showed a spheroid shape. The oil was walled and protected by the lipid and evenly distributed in the capsules (Fig. 1). Thus, differences in the shape of the microencapsules were observed when different binding materials were used.

Fatty Acid Composition of Encapsulated Oils

The fatty acid composition of native and encapsulated oil with different binding materials used in this study is shown in Tables 3 and 4. The major fatty acid of sunflower oil encapsulated with these three binding materials was 58 % linoleic acid, 28 % oleic acid, and 9 % palmitic acid (Table 3). The major fatty acid of linseed oil encapsulated in gum acacia, whey protein and lipid was 51 % alpha linolenic acid, 21 % oleic acid, and 14 % linoleic acid (Table 4). There was no significant difference in the fatty acid composition of oil encapsulated with three different binding materials as compared to that found in native oil.

Intestinal Absorption of Encapsulated Oils—In Vitro Model Using Intestinal Everted Sacs

The amount of oil absorbed through intestinal everted sacs when given at different concentrations is shown in Tables 5 and 6. Eight-centimeter long intestinal everted sacs were incubated with different amounts (1.25–80 mg) of oil in 10 ml incubation medium. The absorption of oil by the everted intestinal sacs increased proportionately up to 10 mg. No further increase in oil absorption was observed beyond this amount of oil in the incubation medium. No significant difference in the absorption of oil was observed when it was given in encapsulated form in

gum acacia or as non encapsulated form. However, when SNO was given as microemulsions with lipid there was an increase in the uptake of oil by 50, 33, 28, and 11 % as compared to oil given in native form at 1.25, 2.5, 5 and 10 mg levels. Even though there was no further increase in the absorption of oil given beyond 10 mg levels in the incubation medium, there was a 10 % higher level of absorption of oil given in lipid at all the concentrations tested (Table 5). Similarly when LSO was given in microemulsions with lipid, there was an increase in the uptake of oil by 51, 42, 28 and 12 % as compared to those given in native form at 1.25, 2.5, 5 and 10 mg levels, respectively. Thus, at different levels of SNO or LSO, intestinal everted sacs absorbed significantly higher levels of oil in microemulsion form with whey protein or lipid as compared to oils given in the native form. However, no significant differences in the extent of absorption were observed when SNO or LSO was given at similar concentrations (Table 6).

Effect of Encapsulation on Intestinal Absorption of Omega-6 and Omega-3 Fatty acids—In Vitro Studies

The amount of LA absorbed from the oil is shown in Tables 7, 8. When everted sacs of rat intestine were incubated with SNO containing 5.8 mg LA, 5.1 mg of LA was found in the absorbed lipids. When SNO was encapsulated in whey protein or gum acacia or lipid and incubated with intestinal everted sacs, the amount of LA observed in oil that was absorbed was 5.1, 5.2 and 5.2 mg, respectively (Table 7). Arachidonic acid was not observed in SNO that was absorbed from the intestinal everted sacs. There was no significant difference in LA content of SNO that was absorbed when given in encapsulated form or when it was given as oil without encapsulation.

When LSO was given without encapsulation or after encapsulation in gum acacia, whey protein or lipid, the ALA that was present in the oil that was absorbed intestine was found to be 3.6, 3.8, 4.2 and 4.6 mg, respectively (Table 8). The amount of ALA present in LSO used in this study was 5.1 mg. Thus the increase in the amount of ALA found in oil after absorption when given as microemulsions with gum acacia, whey protein and lipid were 6, 17 and 28 %, respectively as compared to that observed in oil that was absorbed when LSO was provided without encapsulation. Interestingly, when 10 mg of LSO was given as microemulsion with lipid, 0.48 mg of EPA + DHA was observed in the oil that was absorbed. Thus, a small but a significant amount of ingested ALA was converted to longer chain EPA + DHA when given as microemulsions with lipid. EPA and DHA were not detected when LSO was given as microemulsions with gum acacia and whey protein.

Fig. 1 SEM photograph of **a** oil encapsulated with gum acacia, **b** single particle of gum acacia containing oil, **c** oil encapsulated with whey protein, **d** single particle of whey protein encapsulating oil, **e** oil encapsulated with lipid, **f** single particle of lipid containing oil

Since no advantages in terms of ALA uptake or its conversion to longer chain omega-3 fatty acids were observed when LSO was given as a microemulsion with gum acacia, all further studies were carried out with whey protein and lipid as encapsulating materials.

Serum Fatty Acid Composition of Rat Given Native and Encapsulated Oils

Rats were given native oils or oils after encapsulating in whey protein or lipid daily for a period of 30 days as

Table 3 Fatty acid composition (%) of native oil and microencapsulated oil-SNO

described in the Methods section. The serum lipids of rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid contained LA to an extent of 30.4, 31.5 and 30.3 % of the total fatty acids. The arachidonic acid content in the serum lipids of rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid were 13.2, 12.9 and 12.7 % of the total fatty acids. Significant differences were not observed in LA and ARA present in serum lipids of rats given SNO encapsulated in whey protein and SNO encapsulated in lipid as compared to those given SNO without encapsulation (Table 9).

Serum lipids contained omega-3 fatty acids in rats given LSO, LSO encapsulated in whey protein or LSO in lipid. The rats given LSO, LSO encapsulated in whey protein and LSO encapsulated in lipid showed ALA to an extent of 1.8, 2.4 and 3.8 %, respectively of total fatty acids in the serum lipids (Table 10). The EPA content in rats given LSO, LSO encapsulated in whey protein and LSO encapsulated in lipid were found to be 0.6, 0.8 and 4.8 %, respectively. The rats given LSO, LSO encapsulated in whey protein and LSO encapsulated in lipid contained DHA in serum lipids to an extent of 0.4, 0.8 and 3.9 % of total fatty acids (Table 10). This indicated that ALA from LSO, LSO encapsulated in whey protein and LSO encapsulated in lipid were converted to EPA and DHA with a higher degree of conversion being

Values are mean ± SD, *n* = 6; mean in a row with different superscripts differ significantly at *P* < 0.05

LSO linseed oil, nd not detected

observed when given as emulsions in lipid. The omega-6 to omega-3 fatty acid ratio in serum lipids given LSO, LSO in whey protein and LSO in lipid were 10.03, 6.72 and 1.62, respectively indicating higher efficacy of microemulsified oils in increasing omega-3 fatty acid levels by replacing omega-6 fatty acids in serum lipids (Table 10).

Liver Fatty Acid Composition of Rat Given Native and Encapsulated Oils

The fatty acid composition of liver lipids in rats given native oil and oils encapsulated with different binding

Table 11 Fatty acid composition (%) of liver lipids in rats given SNO

| | SNO | | With lipid encapsulation |
|----------------|-------------------------|---------------------------------|--------------------------|
| | Native oil | With whey protein encapsulation | |
| 16:0 | 26.2 ± 1.6 ^a | 26.7 ± 1.4 ^a | 26.6 ± 1.3 ^a |
| 16:1(n-7) | 2.5 ± 0.3 ^a | 2.4 ± 0.3 ^a | 2.3 ± 0.2 ^a |
| 18:0 | 7.8 ± 0.4 ^a | 7.8 ± 0.2 ^a | 8.1 ± 0.6 ^a |
| 18:1(n-9) | 20.1 ± 0.5 ^a | 19.4 ± 0.7 ^a | 19.2 ± 0.4 ^a |
| 18:2(n-6) | 28.8 ± 1.2 ^a | 29.6 ± 1.2 ^b | 29.4 ± 1.1 ^b |
| 20:4(n-6) | 14.6 ± 1.3 ^a | 14.1 ± 0.75 ^a | 14.4 ± 0.91 ^a |

Values are mean ± SD, *n* = 6; Mean in a row with different superscripts differ significantly at *P* < 0.05

SNO sunflower oil, *nd* not detected

materials is given in Tables 11, 12. The rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid contained LA to an extent of 28.8, 29.6 and 29.4 % of the total fatty acids in liver. The arachidonic acid content in the liver of rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid were 14.6, 14.1 and 14.4 % of the total fatty acids. Thus, no significant difference in LA or ARA content was observed in rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid as compared to rats given SNO without encapsulation (Table 11).

The ALA levels of liver lipids in rats given LSO, LSO encapsulated in whey protein, and LSO encapsulated in lipid were found to be 2.7, 3.0 and 3.8 %, respectively. The EPA levels in liver lipids of rats given LSO, LSO encapsulated in whey protein and encapsulated in lipid were found to be 1, 2.3 and 6.1 % of the total fatty acids, respectively. The rats given LSO, LSO encapsulated in whey protein and LSO encapsulated in lipid contained DHA to an extent of 0.6, 1 and 4.8 % of total fatty acids in the liver. This indicated that ALA from LSO and LSO encapsulated with whey protein and LSO encapsulated with lipid was converted to EPA and DHA to different extents. The ratio of omega-6 to omega-3 fatty acids in liver lipids of rats given LSO, LSO in whey protein and LSO in lipid were found to be 7.17, 4.56 and 1.51, respectively indicating greater efficiency in conversion of ALA to long chain omega-3 PUFA when LSO was given as a microemulsion in lipid (Table 12).

Discussion

The primary objective of this investigation was to increase the bioavailability of ALA and possibly enhance its conversion

Table 12 Fatty acid composition (%) of liver lipids in rats given LSO

LSO linseed oil, *nd* not detected

to long chain omega-3 PUFA in experimental animals such as rats. ALA is a precursor to DHA which is essential for normal growth and development of infants. Sufficient quantities of DHA need to be provided to pregnant women and to children during the pre- and postnatal period. DHA is a predominant structural fatty acid in the central nervous system and retina, and its availability is crucial for the functioning of the central nervous system. The World Association of Prenatal Medicine, the Early Nutrition Academy, and the Child Health Foundation recommended that pregnant and lactating women should get an average daily intake of least 200 mg of DHA [24]. The majority of the Indian population are vegetarians. They have to obtain DHA by converting ALA present in vegetable oils which they consume from dietary sources. Several studies have shown that conversion of ALA to DHA is very minimal in mammals [25]. However, studies have also shown that when ALA is provided in the diet at higher levels it can drive the system towards formation of DHA [3, 25].

To build enhanced concentration of ALA and its subsequent conversion to DHA innovative approaches are needed. Several studies have shown that the bioavailability of lipophilic molecules can be enhanced significantly when given as microemulsion, nanoemulsion form. Microemulsions have smaller particle size and hence may cross the intestinal barriers more efficiently. Emulsification is an important step in the digestion and absorption of fats. Therefore, emulsification and encapsulation technology can be adopted to enhance bioavailability of lipid and lipid soluble molecules [26, 27].

Our study showed that there was a significant increase in ALA in rats when LSO was given in encapsulated form. When LSO was encapsulated in whey protein or in lipid and incubated with intestinal everted sacs the content of ALA that was absorbed was found to be higher by 17 and 28 % when compared to those given the oil without encapsulation. Interestingly, we also observed a small but significant presence of EPA + DHA in the absorbed lipids when LSO was given after encapsulation with lipid. However, no significant changes were observed in absorption of LA from SNO when it was provided in free or encapsulated form. These observations were made when the intestinal everted sac model was used to study the absorption of oil. The studies were extended *in vivo* by giving rats the encapsulated oils through intubation. The amount of ALA in the serum of rats given without encapsulation of LSO or after encapsulation with whey protein or lipid was found to be 32.1 ± 2.1 , 41.4 ± 5.3 and 48.8 ± 2.2 $\mu\text{g/ml}$ (mean \pm SD), respectively. Thus, the amount of ALA found in serum of rats given LSO encapsulated in whey protein or lipid was higher by 29 and 52 %, respectively as compared to that found in rats given LSO without encapsulation. The amount of EPA in serum was found to be 17 ± 0.9 and 41 ± 1.8 $\mu\text{g/ml}$ (mean \pm SD) in rats given LSO encapsulated in whey protein or lipid, respectively. When the same oil was given without encapsulation, the EPA level in serum was found to be 9.1 ± 1.4 $\mu\text{g/ml}$. Thus, the EPA level in serum was enhanced by 86 and 350 % when LSO was given in the form of encapsulated materials. DHA level in serum lipid was found to be 13 ± 1.9 and 34 ± 2.2 $\mu\text{g/ml}$ when given as emulsions with whey protein and lipid, respectively. The DHA levels in serum were found to be 8.8 ± 1.6 $\mu\text{g/ml}$ when LSO was given without emulsion formation. Thus, the DHA level in serum lipid was increased by 50 and 288 % in rats given LSO emulsion form with whey protein and with lipid, respectively when compared to those given native oil. In liver lipids, the EPA levels was increased by 130 and 510 % in rats given LSO encapsulated with whey protein or with lipid compared to those given native oil. The DHA level in liver was increased by 100 and 875 % in rats given LSO encapsulated in whey protein and in lipid compared to rats given native oil. These studies indicated that ALA was taken up and further metabolized to long chain omega-3 PUFA in a more efficient manner when given in encapsulated form with whey protein or with lipid. However, such a conversion of ALA to EPA or DHA was not observed when LSO encapsulated in gum acacia was given.

The pharmacokinetics of ALA absorption in rats fed flaxseed oil was recently studied by Coudelo et al. [28]. They quantitated the *in-vivo* absorption of ALA in thoracic lymph duct cannulated rats which were fed flaxseed oil in emulsified or non emulsified form. The maximum ALA

concentration in lymph of rats given non emulsified flaxseed oil was found to be 9 mg/ml in 5 h and the area under the curve kinetics was found to be 26 mg/h/ml. However, when flaxseed oil was given after emulsification with lecithin and sodium deoxycholate the maximum ALA concentration in lymph of rats was increased to 14 mg/ml at 3 h and the area under curve kinetics was increased to 48 mg/h/ml. Thus, a 55 % increase in ALA absorption and 85 % increase in ALA in lymph were observed when flaxseed oil was given in emulsion form. Further, the maximum levels of ALA were observed in chylomicrons within 3 h when given in emulsified form as compared to 5 h in control rats given native oil. This indicated a faster and higher rate of ALA absorption from emulsified oil. Earlier studies have also shown that egg phosphatidylcholine and soy phosphatidylcholine significantly enhances the intestinal absorption of triglyceride in rats [29]. Dietary gamma linolenic acid and EPA also showed a significant enhancement in the bioavailability when given as phospholipid emulsions [30, 31]. Marine phospholipids have also been used for making liposomes to deliver triacylglycerols containing EPA and DHA from fish oil. In this system it was observed that the lipid absorption in thoracic lymph duct-cannulated rats was 97 % when given in the liposome form but only 73 % absorption was observed when the oil was given in nonencapsulated form. DHA was assimilated to an extent of 91 % in the liposome group as against 65 % assimilation of DHA in the rats given fish oil without encapsulation [13, 32]. Higher levels of DHA was observed in the plasma TAG when fish oil was given in liposome form as compared to those given fish oil without encapsulation.

Earlier studies focused on the encapsulation of linseed oil to preserve its qualities and prevent oxidation of highly unsaturated ALA. [33, 34]. Recent studies have shown that the bioavailability of EPA and EPA + DHA was enhanced by 45 and 43 % in rats when provided in gelled emulsions (2–5 μm of particle size) as compared to those given without encapsulation [5]. Ammar et al. [4] have shown that the bioavailability of EPA was enhanced tenfold in encapsulated form as compared to those given without encapsulation. Raatz et al. [35] observed that emulsified fish oil had a higher absorption rate and showed enhanced levels of EPA and DHA in the serum of rats as compared to rats given fish oil in capsule form. The ratio of total omega-6 to omega-3 fatty acids in rats given emulsified fish oil was reduced significantly as compared to rats given fish oil in capsule form. Our results are in agreement with these findings where emulsified omega-3 rich oils showed higher bioavailability and resulted in the accumulation of long chain omega-3 fatty acids.

In addition to omega-3 rich oils, the absorption of lipophilic molecules such as curcumin and many drugs are also significantly enhanced when encapsulated in

phospholipid emulsions [36]. The bioavailability of anti-inflammatory compound such as curcumin was enhanced by 69 fold in rats when provided in phospholipid formulation [37, 38]. The antiarthritic drug piroxicam was also absorbed at a faster rate and reached a maximum of 53 $\mu\text{g/ml}$ when given as phospholipid dispersions, but reached a maximum level of 39 $\mu\text{g/ml}$ in plasma when given without phospholipids. The cyclosporin an immunosuppressant drug was absorbed better when given in vesicular lecithin system. Soy lecithin based nanoparticles enhanced the absorption of vinpocetine [39]. The maximum concentration of the drug observed in plasma was 3 $\mu\text{g/ml}$ when given with soy lecithin as compared a value of 0.75 $\mu\text{g/ml}$ when given without lecithin. The microemulsions of lecithin containing lipid as a surfactant enhanced the in-situ permeability of the drug Paclitaxel by threefold through the rat small intestine [40]. Drugs encapsulated in lipid showed higher anti-tumor activity against human breast cancer and multiple myeloma cell lines [41]. The Saquinavir drug loaded in flax seed oil containing lipid emulsion crossed the blood brain barrier [42].

All these studies clearly indicate that phospholipid based liposomes/emulsions could enhance the bioavailability of TAG, omega-3 fatty acids as well as drug molecules which are poorly soluble in aqueous media. We have used lipid to deliver ALA from LSO with greater efficiency. Lipid is made up of soy lecithin and phosphatidylethanolamine which again support the earlier observations that phospholipid based formulation can serve as effective delivery system for lipophilic molecules.

The conversion of linoleic acid however to longer chain ARA was not increased when rats were given SNO in microemulsion form. The rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid contained LA at similar levels in serum (490 ± 17 , 492 ± 18 , and 488 ± 14 $\mu\text{g/ml}$, respectively). The arachidonic acid content in the serum of rats given SNO, SNO encapsulated in whey protein and SNO encapsulated in lipid were also similar (212 ± 17 , 208 ± 11 , and 209 ± 8 $\mu\text{g/ml}$, respectively). Similar trends were observed in liver lipids. Earlier Gariova et al. [30] showed that the pre emulsification of edible oil mixture prior to ingestion increases the absorption of omega-3 fatty acids EPA and DHA but not that of saturated fatty acids and LA. Therefore, though the omega-3 fatty acid pathway appears to be activated when given as microemulsions with lipid, the same trend was not observed with the omega-6 pathway. This may also reflect on the higher levels of omega-6 fatty acids normally found in serum and liver and further requirement for its enhancement may not be warranted. However, since omega-3 fatty acids are limiting this pathway may have been activated. This requires activation of desaturase and elongase enzymes. The phospholipid based emulsions such

as lipid could achieve this as has been observed by increased levels of EPA and DHA in rats given ALA rich oil with lipid. The reason for this needs further investigation.

The ratio of omega-6 to omega-3 fatty acids is often considered to be crucial for the conversion of ALA to long chain omega-3 PUFA as omega-6 fatty acid (LA) can compete with delta-6 desaturase which acts on both omega-6 and omega-3 fatty acids. In our studies, the ratio of total omega-6 to omega-3 fatty acids in serum lipids was reduced by 80 and by 32 % when LSO encapsulated in lipid or with whey protein were given as compared to rats given LSO without emulsification. A similar trend were observed in the liver.

In addition to the nature of the encapsulated material, the particle size may also influence the bioavailability of entrapped materials. The nanoparticles have the ability to cross the gastrointestinal barrier either by passive diffusion or by active processes mediated by membrane-bound carriers or membrane-derived vesicles. Solid lipid nanoparticles (SLN) were used to enhance the bioavailability of γ -tocotrienol by tenfold as compared to the controls which were given as mixed micelles. The pharmacokinetics showed that the plasma concentration of γ -tocotrienol was significantly higher (938 ng/ml) in rats receiving SLN formulation compared to control (212 ng/ml). It is primarily caused by enhanced passive permeability (Abuasal et al.) [43]. The high adhesion of microemulsions to the gastrointestinal tract cause the emulsion droplets to remain closely in contact with intestinal cells for a long period promoting transmembrane transport of encapsulated material. The reduction in particle size increases the surface area of the particles. It has been reported that the delivery of drugs is enhanced when they are emulsified to increase the surface area of the delivery systems. The high dispersibility of emulsions enhances the steady absorption of encapsulated materials.

In conclusion, our study showed that ALA absorption from LSO was enhanced when given in the encapsulated form in lipid. Further ALA was also converted to EPA and DHA when ALA-rich oil such as LSO was given to rats as a microemulsion in lipid. This also caused the omega-6/omega-3 fatty acid ratio in the serum and liver to be lower. Thus, lipid may be a useful phospholipid based emulsifying material for enhancing the uptake of ALA and its conversion to long chain omega-3 fatty acids. However, the exact mechanism in terms of stability, surface area of the emulsion which may influence absorption mechanisms, hydrolysis of TAG in emulsions, chylomicron formation, protecting ALA from β -oxidation pathway to increase its availability to TAG synthesis and influence on desaturase pathway need to be addressed.

that are responsible for off-flavors in fish oils. Thus, it is possible to have oils with very low PV that taste very rancid. Secondary oxidation products are primarily assessed through the use of anisidine value (AV) for which GOED specifies a limit of 20 [1]. AV reflects the level of aldehydes with α - and β -unsaturation. There is very little evidence that AV and sensory properties are correlated; it may be that the sensitivity of this method is not high enough to detect minute changes in aldehyde concentrations that could affect sensory properties [2]. The poor relationship between PV, AV and sensory properties highlights the need for new methods to assess oil quality that correlate well with sensory parameters.

Sensory panels are the most accurate method for assessing fish oil quality as humans are capable of tasting certain compounds at concentrations much lower than chemical techniques are able to detect [2]. Unfortunately, sensory panels can be cost prohibitive due to the expenses associated with their set up and maintenance. An alternative to sensory panels is the use of solid phase microextraction (SPME), coupled with gas chromatography-mass spectrometry (GCMS), which can be used to monitor the presence of volatile secondary oxidation products in the headspace of fish oil. Volatile compounds are responsible for the off flavors and odors caused by oxidation.

The aim of this study is to compare the results of sensory panel assessment of three fish oils with different concentrations of EPA and DHA with PV, AV and proportions of volatile oxidation products. The goal is to create a robust method that can be used to predict sensory quality of fish oil and to identify key oxidative volatiles associated with those sensory properties.

Materials and Methods

Materials

SPME fibers (divinylbenzene/Carboxen/polydimethylsiloxane, 50/30 μm coating), a SPME fiber holder for manual sampling, 22-ml glass vials, polytetrafluoroethylene/silicone rubber septa and screw caps were purchased from Supelco (Oakville, ON). A custom-made heating block designed to accommodate 22-ml glass vials was used to control the temperature. Optima chloroform was obtained from VWR (Mississauga, ON). An Isotemp 100 Series Model 126G oven was used to incubate samples and was obtained from Fisher Scientific (Ottawa, ON) along with all other glassware. Methyl tricosanoate, methyl eicosapentaenoate, methyl docosahexaenoate and 1,2-dipalmitin were purchased from Nu-Chek Prep (Elysian, MN). 1,3-dipalmitin was purchased from Doosan Serdary Research Laboratories (Etobicoke, ON). Tripalmitin was purchased from

Sigma Aldrich (Oakville, ON), along with all other chemicals. Two fish oils containing a blend of mixed natural tocopherols were obtained from Ocean Nutrition Canada Ltd. (Dartmouth, NS) and a third oil was obtained from EPAX (Oslo, Norway). Oil 1 contained approximately 30 % EPA and DHA, while Oil 2 contained roughly 50 %. Oil 3 contained approximately 65 % EPA and DHA. All oils were marketed as triacylglycerols and all were blends of anchovy and sardine oil sourced from Peru.

Experimental Design

Amber bottles (250 ml) were each filled with 200 ml of fish oil and placed, uncapped, in an oven held at 40 °C. Oils were removed from the oven at varying time intervals, ranging from 2 to 15 h, over the course of 10–14 days, with a new bottle being used at each sampling point. From each bottle, aliquots of 14.0 ml were placed in 22-ml glass vials and then capped with phenolic screw caps with PTFE/silicone septa and analyzed with SPME-GCMS. Approximately 15 ml of each sample was used for PV and AV testing, and the remainder of each 200-ml sample was either stored at -80 °C under nitrogen or evaluated by a sensory panel. One sample per 24 h time period underwent PV and AV analysis and was tasted by a sensory panel. All samples were analyzed by SPME-GCMS. The experiment was conducted in triplicate for each of the three oil types.

Measures of Oil Quality

The fatty acid profile of the fish oil was analyzed using the method described by Sullivan Ritter et al. [3]. The PV and AV of each sample was measured in triplicate following American Oil Chemists' Society (AOCS) Official Method Cd 8-53 [4] and AOCS Official Method Cd-18-90 [5], respectively.

Lipid Class Analysis

Lipid classes were analyzed using HPLC. Aliquots of each oil were diluted with $\text{CHCl}_3/\text{MeOH}$ (2:1 by vol) to achieve a final concentration of 0.25 mg/ml. Samples were filtered using 0.45- μm filters and transferred to autosampler vials. Analysis was done in triplicate using a Thermo Finnigan Surveyor HPLC with an autosampler (Thermo Fisher Scientific, Mississauga, ON) coupled to a Sedex 80 low temperature evaporative light scattering detector (Sedere, North York, ON) set to 30 °C with a gain of 8. The injection volume for each sample was 10 μl . The mobile phase was made up of hexane and *tert*-butyl methyl ether (TBME) (Table 1) at a flow rate of 2 ml/min and the total run time was 10 min. Samples were first analyzed on a YMC-Pack PVA-Sil column (5- μm particles,

Table 1 Composition of mobile phase for gradient elution with HPLC analysis

| Time (min) | Hexane (%) | TBME (%) |
|------------|------------|----------|
| 1 | 98 | 2 |
| 5 | 100 | 0 |
| 7 | 100 | 0 |
| 8 | 98 | 2 |
| 10 | 98 | 2 |

100 × 30 mm I.D.) with matching guard cartridge (2.0 × 20 mm I.D.) to confirm that samples did not contain any monoglycerol (MAG). Because of inconsistent retention times when the YMC-Pack PVA-Sil column was used, a silica column (Waters Spherisorb, 5-μm particles, 250 mm × 4.6 mm) with matching guard column was used to quantify diacylglycerol (DAG) and triacylglycerol (TAG). The column was held at 20 ± 1 °C. Standard curves were prepared using tripalmitin, 1,2-dipalmitin and 1,3-dipalmitin with concentration ranges between 0.63 and 6.25 mg/ml depending on the standard.

SPME Analysis

The SPME method is described by Sullivan Ritter and Budge [6]. SPME samples were placed in a heating block held at 80 °C and allowed to equilibrate for exactly 15.0 min while the SPME fiber was placed in the injector port of the GC at 250 °C to desorb any volatiles that had accumulated during storage. The SPME fiber was then inserted into the vial at a depth of 2 cm and exposed to the sample headspace for exactly 45.0 min. Extracted volatiles were analyzed by ion trap GCMS in electron ionization mode (200 °C). The fiber was inserted into the injector of the GC to a depth of 5 cm (splitless mode, 250 °C; 1 mm liner) and left for 5 min. Volatile analytes were separated on a free fatty acid phase column (Nitroterephthalic acid modified polyethylene glycol 30 m × 0.25 mm ID × 0.25 μm film thickness, Agilent, Mississauga, Canada). Helium was used as the carrier gas (1.0 ml/min). The oven temperature was initially held at 40 °C for 5 min and increased at a rate of 10 °C/min to 250 °C and held for 5 min (total run time 29 min). Data were acquired as area counts and converted to area percentages. Retention indexes were calculated by comparing retention times of oxidative volatiles to those of the two closest eluting *n*-alkanes in a C8–C20 retention index (RI) standard. Volatile oxidation products were identified by comparison to pure external standards. When standards were not available, compounds were tentatively identified by matching them with mass spectral data in the NIST/EPA/NIH Mass Spectral Library (National Institute of Standards and Technology), through matching of fragmentation patterns generated by

HighChem Mass Frontier 4.0 (HighChem Ltd., Bratislava, Slovakia) and through comparison to RI and fragmentation patterns available in the literature.

Sensory Assessment of Oil Quality

Between ten and twelve samples from each oil trial were assessed for quality using an untrained, descriptive sensory panel [7]. To assess tasting abilities of potential panelists, volunteers were screened to eliminate those who could not distinguish fishy flavors. This was accomplished by challenging them with a triangle test, consisting of acceptable, fresh fish oil with a low volatile content and fish oil that had been incubated in an open container at 40 °C for 7 days to force the formation of fishy volatiles. Those who could not distinguish between the fishy sample and the fresh sample were removed from the panel. The final panel consisted of 10 volunteers. Each panelist was asked to rank samples on a scale of 1–10, with 10 being “excellent” and 1 being “terrible”, using a fresh vegetable oil sample as a reference. These classifications were then used to assign a scalar value to each tasted sample. Samples with sensory panel scores ≤7 were considered unacceptable, based on the descriptions of the scalar values. Each sample evaluated by the final panel was tasted by a minimum of three people. The design and screening of the sensory panel as well as the score sheets used to evaluate the samples were adapted from guidelines provided by the AOCS [7]. Of the 184 samples analyzed with SPME-GCMS, 93 were evaluated for sensory characteristics, leaving approximately half untasted.

Statistical Analysis

Because SPME-GCMS data was expressed as area percentages, data was transformed using a geometric mean function [8], following Eq. 1.

$$x_n = Ln \frac{a_n}{\sqrt[n]{a_1 a_2 \dots a_n}} \quad (1)$$

where a_n is the amount, in area percent, of each peak quantified in the sample. This was necessary because proportional data are constrained between zero and one, thereby violating the assumption of independence of observations inherent in most statistical techniques [9]. These data were then combined with sensory panel results. The next step in data analysis was to remove outliers, as multivariate techniques are highly influenced by outliers. Mahalanobis distances are commonly employed to identify outliers in multivariate data sets and were used here. This measure takes into account the variance of each variable and the covariance between variables. These were

calculated for all samples as described by Filzmoser and Hron [10] and those with χ^2 statistic greater than the critical value for $p \leq 0.001$ were eliminated. Following this elimination, 10 % of remaining tasted samples were removed from the dataset to be used for method validation.

Because variables were highly correlated with each other, principal component analysis (PCA) was then used to reduce the number of variables in the dataset into a smaller number of uncorrelated variables. The new variables, called principal components (PC), were linear combinations of the original variables and maximized the variability they represented. Each PC had a value, or score, which corresponded to a specific data point (e.g. Fig. 1). Since each PC represented a linear equation of the original variables, loadings were simply the coefficients associated with each original variable in the equation. For instance, if a variable was particularly important in calculating a PC score, its loading might be 10, while a less important variable might have a loading of 0.1. Each replicate of each of the three oils underwent PCA of the covariance matrices. In the present study, the original data set contained 106 volatile oxidation products that were highly correlated and PCA was used to reduce the number of variables into separate PC.

PC scores were then treated as the independent variables in multiple linear regression analysis in order to generate an equation that could be used to predict the sensory quality of fish oil. Multiple linear regression is analogous to simple linear regression, but rather than one explanatory variables, there are multiple ones. This technique also requires that independent variables are uncorrelated. In this case, backwards linear regression was used, which begins by entering all predictor variables, in this case PC, into a regression model. The weakest predictor is then removed and the regression is recalculated. If the removal of a variable significantly weakens the model to the point where it is no longer significant, then that variable is added back

in. This is repeated until only significant variables remain in the model. Often, more than one significant model ($p < 0.05$) was generated. In these cases, the model that had the highest R^2 and adjusted R^2 , and lowest standard error of the estimate was selected. To validate the function, a sensory score was calculated for the samples that were tasted but not used to create the regression by calculating the PCA scores for each sample that was not used in the original PCA and regression function and inputting them into the regression equation. The calculated sensory score was then compared to the actual sensory score assigned by the sensory panel. The final step in this analysis was to test in the same way the omitted samples in other trials of the same oil to check for robustness. SPSS 11.0 [11] statistical software was used for all statistical analysis.

Results

Fatty Acid Analysis

All three oils met suppliers' specifications for EPA and DHA (Table 2) and all three had different levels of these fatty acids.

Peroxide and Anisidine Values

As expected, PV and AV increased over time for all three oils. Initial PV was low (2.0 ± 1.3 mequiv/kg) for all samples, indicating that samples were only slightly oxidized at the beginning of the experiment. As the study progressed, the PV increased for all oils, far exceeding the 5 mequiv/kg limit specified by GOED (Fig. 2). Initial AV were also below the GOED limit of 20, with an average starting value of 9.4 ± 1.4 . These values increased over time, but only one sample exceeded this limit at the end of the experiment (Fig. 3). Although the rate of increase of PV and AV differs from oil to oil, the sensory ratings for each oil are consistent within oils of the same type. The average PV at which samples were deemed unacceptable by a sensory panel was 14.9 ± 6.5 mequiv/kg which is almost 3 times the PV limit of 5 mequiv/kg specified by

GOED. The average AV at the sensory rejection point was 14.2 ± 3.7 , almost 6 units below the GOED limit.

Lipid Class Analysis

TAG produced a linear standard curve while polynomial curves were the best fit for 1,2-DAG and 1,3-DAG. Oil 1 had higher TAG and lower DAG levels than specified by the manufacturer (Table 3), but Oil 2 and Oil 3 agreed with the manufacturers' specifications. In the case of Oil 1, the TAG value was likely higher because the oil did not

undergo a concentration step during processing. The FA profile of Oil 1 with EPA and DHA levels of 16.6 and 12.5 %, respectively, was what one would expect to find naturally in a sardine-anchovy oil blend that has not undergone concentration during refining [12].

SPME and Sensory Analysis

A total of 106 oxidation products were detected using SPME-GCMS (Fig. 4). The most common structures were aldehydes and ketones, though alcohols, acids and

hydrocarbons were also detected. Typical compounds associated with oxidation were detected, including 3-hexen-1-ol, heptenal and multiple isomers of 2,4-heptadienal. Sensory scores for the samples ranged from 10 (excellent) to 4 (very poor). The scores of the test samples used to validate the regression models fell within the range of the scores used to build the models. There were no correlations between any of the oxidation products mentioned above and sensory scores.

Statistical Analysis

PCA of SPME-GCMS data generated from five to nine PC for each of the nine oil trials. When these PC were used to develop regression models, from two to five PC were needed to create a significant regression function, depending on the oil type and replicate (Table 4). Although

the percent variance explained by the PC used in the regression models appear low, it was possible to achieve a high R^2 value (e.g. Oil 1 Trial 1). The reverse was also true (e.g. Oil 1 Trial 2). Regression of principal components gave well-fitting, significant ($p < 0.05$) models with for all but one oil replicate for Oil 3 (Table 4). Further statistical analyses on this trial were not carried out.

All samples that had not been used to create the regression functions were assigned sensory ratings using the appropriate regression function (Table 5). The calculated sensory scores for all three replicates of Oil 1 were quite close to the scores given by the sensory panel. All three samples had PV and AV levels below the average rejection values. The regression functions for two of the three replicates of Oil 2 also produced sensory scores that were very close to those given by the sensory panel. The sample with the poor result had a PV of 11.8 ± 0.0 mequiv/kg and an AV of 14.6 ± 0.1 . The AV of the sample was very close to the average AV score at the sensory rejection point, while the PV was approaching the rejection point. The other two replicates of Oil 2 had PV and AV values well below the rejection thresholds. For Oil 3, the regression equation for the first replicate gave scores that were different from those assigned by the sensory panel. This replicate had a PV (23.0 ± 0.0 mequiv/kg) much higher than the average PV at the rejection point. The AV (14.4 ± 0.1) of this sample was also close to the rejection value for AV. In contrast, the regression equations for the second replicate of Oil 3 gave

very accurate scores when compared to those given by a sensory panel. This samples had PV (5.0 ± 0.0 mequiv/kg) and AV (8.44 ± 0.1) that were well below the average rejection values. Finally, when regression equations were tested with other replicates of the same oil type, the calculated sensory scores agreed with the actual scores for all but Oil 3 Replicate 2 (Table 5). When the sensory score for the omitted sample from Oil 3 Replicate 2 was calculated using the regression function for Oil 3 Replicate 1 a score of -1 was obtained, a value that is not valid. All other samples were within three sensory units of their taste panel score and most were within one unit.

Discussion

PCA and multiple linear regression were used instead of other multivariate techniques because of the characteristics of the SPME-GCMS data. The high number of volatile oxidation products (>100) resulted in a situation where there were many more variables than tasted samples, which eliminated the use of many common statistical methods such as multivariate analysis of variance (MANOVA). The levels of volatile oxidation products were highly correlated as most compounds were either increasing or decreasing over time making regression on raw data impossible. The

changes in volatile levels occurred gradually so there was no clear divide between acceptable and unacceptable samples, instead there seemed to be an indistinct area where samples were neither good nor bad, making it difficult to obtain valid results using other classification techniques such as discriminant function analysis [6]. This was evident when scores of PC1 versus PC2 were plotted for each oil trial separately; samples showed a clear transition with time, with samples taken early in the time course in one quadrant and late samples in another quadrant (Fig. 3). Samples in the middle of the time course grouped near the center of the plot, emphasizing the lack of a distinct separation between new and old, or acceptable and unacceptable, indicating that the transition from acceptable to unacceptable happened gradually rather than suddenly. This gradual transition made it difficult to pinpoint the exact time when fish oil quality was considered unacceptable.

As an alternative, linear regression was considered. This is a useful technique for characterizing samples, but only if variables are uncorrelated. The volatile oxidation products studied here were highly correlated, so PCA was used to generate uncorrelated variables. PCA also greatly reduced the number of variables to <10. Linear regression of these variables generated a simple equation to assign sensory scores to fish oil samples. One tasted sample, selected at random, was left out of each trial with removal occurring before PCA analysis. Removal at this early point in data analysis allowed the samples to truly serve as a validation of the regression functions. One sample per oil trial corresponded to roughly 10 % of tasted samples being omitted during construction of the regression methods.

The combination of PCA and regression employed in this study allowed all data to be capitalized on as PCA transforms highly correlated variables, in this case volatile oxidation products, into uncorrelated linear combinations of the original variables, while still capturing all variability in the original data set. Initially, SPME-GCMS results of all replicates of all oils were combined and PCA was applied. When PC scores were examined, oils were clearly separated by oil type rather than state of oxidation as was expected due to differences in fatty acid and lipid class profiles between oils. It is well documented that PUFA, including EPA and DHA, oxidize more rapidly than other fatty acids [2, 13] so Oil 2 and Oil 3 which contained higher levels of these fatty acids were expected to oxidize at a different rate than Oil 1, with lower PUFA content. There is some evidence that DAG and MAG oxidize more rapidly than TAG [14, 15], so different levels of these structures in the oils may also be responsible for their clear separation based on volatile secondary oxidation products. Additionally, Oil 1 and Oil 2 were produced by the same manufacturer, while Oil 3 came from another, so slight

differences in oil refining processes could affect the oxidation patterns and stability of the oils. For example, differences in the winterization process may result in oils having higher levels of shorter chain saturated fatty acids, which are more resistant to oxidation. Because PCA results were not useful when applied to all trials of all oils combined in a single group, data were separated by oil type and PCA was applied to Oil 1, 2, and 3 separately. PCA then detected the variance between oil replicates, rather than changes occurring in the same oil due to oxidation, resulting in three distinct groupings of samples according to replicate within a time course. Slight differences between replicates of the same oil were expected, as all trials were done sequentially rather than concurrently. This was done intentionally in order to develop a more robust method but unfortunately prevented all time courses of the same oil from being analyzed as one unit. These results demonstrate the sensitivity of PCA to small changes in volatile composition among replicates of the same oil. Thus, it was necessary to treat each replicate of each oil as an individual experiment.

When regression equations were tested with samples from other replicates of the same oil type, Oils 1 and 2, along with the first replicate of Oil 3 gave results consistent with the sensory panel. The results of the second replicate of Oil 3 were poor, giving an impossible score of -1 . It is unclear what caused this odd result as no inconsistencies in the data were noted. With the exception of Oil 3 Trial 2, the consistency of the calculated scores compared to the sensory panel scores suggests that this classification method is robust and will hold true for oils of the same type, despite the need to develop separate regressions for each time replicate.

When PC and sensory panel scores were used to build regression equations, it became clear that the first PC (PC1) had a large affect on the reliability of the equation as all equations incorporated PC1. This is logical as PC1 is the component that describes the most variability in a given dataset. Because PC are linear combinations of the original variables, each PC is comprised of many oxidation products. For all trials, the compounds that had the highest correlations ($R \geq 0.80$) with each PC used in the regression equations were examined and compared. Since PC1 described such a large proportion of the change that occurred in the dataset and was incorporated into each regression equation, the replicates of the same oil type had many peaks in common, that were also highly correlated with PC1. When all replicates of all three oil types were compared there were eight peaks with high correlations with the PC used in the regression common to all trials (Table 6). These consisted of four aldehydes, one ketone, one benzene derivative and one hydrocarbon all of which had previously been identified in oxidized fish or fish oil. It

is interesting to note that not all of these compounds increased in proportion over time; three actually decreased.

It is well known that aldehydes play a role in the sensory properties of fish oil, and all four aldehydes identified here increase over time. (*E,Z*)-2,4-octadienal has been identified previously as a fish oil oxidation product and is associated with green odors [6, 16]. The second aldehyde, 3,6-nonadienal, is a degradation product of EPA and is associated with a green odor [2]. It has also been identified by MacFarlane et al. [17] as an oxidative volatile associated with sensory properties, and is a key component in the Fatty Acid Smell and Taste (FAST) method of predicting oil quality. The third aldehyde identified was (*E,E*)-2,4-decadienal, a compound with a deep-fried odor that is often identified in oxidized fish oil [17–19]. Jacobsen et al. [18] found that an increase in this oxidation product was correlated with an increase in rancid, fishy flavors in fish oil enriched mayonnaise. The final aldehyde associated with sensory properties of fish oil, (*E,E,Z*)-2,4,7-decatrinal, has been identified in oils and emulsions containing omega-3 fatty acids and is believed to have green, plant-like odors [16, 19, 20].

Only one ketone, 3,5-octadien-2-one, which increased over time, was shown to be strongly related to sensory parameters of all three oil types. The configuration of the double bonds could not be determined. Both the (*E,Z*) and (*E,E*) isomers of this compound have been identified in fish oil-enriched mayonnaise by Jacobsen et al. [18] and Hartvigsen et al. [16], who found that both isomers were strongly correlated with oxidation. Venkateshwarlu et al. [19] identified this ketone in fish oil-enriched milk. The (*E,Z*) isomer has been linked to green, fruity and fatty

odors as well as plastic and synthetic odors, while the (*Z,Z*) isomer is associated with fresh, green and fruity odors [16, 19].

The ether 2-ethylfuran was also identified as being a significant indicator of sensory characteristics, and decreased as oxidation progressed. This is a common oxidation product of omega-3 fatty acids and can be formed from the 12-hydroperoxide of EPA and the 16-hydroperoxide of DHA [21]. Venkateshwarlu et al. [19] identified this compound as having a sweet odor. Since sweet odors are commonly associated with positive sensory properties, a reduction in this compound could mean that positive sensory attributes are being eliminated as oxidation progresses, allowing negative attributes to become more noticeable.

An unknown isomer of decene had a strong relationship to sensory properties of oils and decreased over time. 1-decene can be formed during oxidation of oleic acid which is present in small amounts in fish oil [22]. Chung et al. [23] identified both 1-decene and 3-decene in mackerel although no relationship with sensory properties was mentioned. Although hydrocarbons are generally thought to be flavorless, the importance of this oxidative volatile to predicting sensory quality suggests that it plays a role in the flavor of fish oil.

Benzaldehyde was strongly associated with sensory properties of fish oil and decreased with time. This compound has a sweet odor and has been detected in fish oil-enriched mayonnaise [16], tuna oil [24] and cod liver oil [25]. It is unlikely that benzaldehyde is a direct product of fish oil oxidation, but it could be an oxidation product of a larger benzene derivative that was initially present in the oil. Giogios et al. [26] hypothesized that benzene compounds could be decomposition products of amino acid or sugars, explaining their low levels in fish oils.

PV and AV are convenient ways to monitor the formation of oxidation products in fish oil, but this work supports the well-known issue with these measures: limits, including those specified by GOED do not correlate with sensory properties of the oil. Hydroperoxides are primary oxidation products, which then degrade into volatile secondary oxidation products that are responsible for off-flavors and odors in oils. Frankel [2] has said that sensory panels can detect off-flavors in oils with PV < 1 mequiv/kg. This is supported by results collected by MacFarlane et al. [16] that showed freshly refined fish oil samples with PV of <1 mequiv/kg had strong fishy tastes. In some cases this might be because the hydroperoxides increased to their maximum and had now begun to degrade into secondary oxidation products. In that situation elevated AV would be expected. Conversely, the results of this study suggests that oils with high PV do not necessarily have poor sensory properties, likely because hydroperoxides have not yet

Table 6 Volatile oxidation products correlated with sensory characteristics of all 3 oils

| Retention index | Compound | Direction of proportion change | Method of identification |
|-----------------|-----------------------------------|--------------------------------|--------------------------|
| 963 | 2-Ethyl furan | Decrease | b, c |
| 996 | Octene | Decrease | b, c, d |
| 1385 | 3,6-Nonadienal | Increase | b, c |

degraded to sufficient extent to form detectable levels of secondary oxidation products.

A number of samples in this study had PV >10 mequiv/kg and were classified as acceptable by the sensory panel and the PV at the point of rejection was 14.5 ± 6.5 mequiv/kg, suggesting that the commonly used limit of 5 mequiv/kg is not appropriate. Although there is little evidence that AV is related to sensory properties of fish oils [2], a value of 20 is commonly used as the rejection value when assessing fish oil quality. Because the regression model was created using data produced by monitoring proportions of volatile oxidation products produced over time, these results suggest that AV may be of more importance to sensory quality than was previously thought, with an average AV of 14.2 ± 3.7 at the sensory panel rejection point being lower than the limit of 20 specified by GOED. Interestingly, MacFarlane et al. [17] found that fish oil samples that had poor sensory properties with PV <1 mequiv/kg also had AV <20 indicating that hydroperoxides had likely not yet reached their maximum and begun to degrade. The regression models created from SPME-GCMS data classified samples with AV >14 as unacceptable, with predicted sensory scores ≤ 7 , despite sometimes positive ratings given by the sensory panel. This also suggests that the current limit of 20 is too high. At least one study [27] found that AV was strongly correlated with sensory evaluation and headspace volatiles in partially hydrogenated soybean oil used for frying. The results of this study suggest that PV and AV may both be accurate and reliable methods to assess sensory quality but the limits that are currently used are not ideal, with the PV limit too low and the AV limit too high.

Sensory panels have long been recognized as the best way to monitor fish oil quality; however, the expenses associated with them often prevent them from being implemented. It is costly to train and maintain panels. Often people do not want to participate in a panel that involves tasting foods with poor sensory characteristics, so compensation is essential. A proper sensory panel requires specially designed tasting booths, lighting and air flow systems. Despite the best training, sensory assessment is still highly subjective and even trained panelists can give inaccurate results on occasion. Our results offer support for this. When our regression model was used to assign a sensory score to samples, the majority of the results were within one unit of the score given by the sensory panel. There were three samples that were assigned a high score (8 or 9) by the sensory panel, but when classified using the regression model, received scores of 5 suggesting that the sample was of poor quality. On closer examination, it was found that all three were samples that were taken late in the time course, and all had AV above 14.2, the average AV at the point of sensory panel rejection. Two of the three

samples also had PV >20 mequiv/kg indicating that oxidation had progressed considerably. The combination of these factors suggest that the regression models may actually be more accurate than the sensory panel in predicting the quality of highly oxidized oil samples; however, for the regression model to be accurate the sensory panel must also provide accurate initial assessments as this is the source of the data for the regression equations. Because of the cyclic relationship, it may be more logical to use PV and AV to evaluate the quality of very oxidized samples, or to present the taste panel with more samples to evaluate so that more data is available to build the regression model. This study was very small and limited samples were tasted by the sensory panel. Future research will focus on expanding the sensory panel and the number of oil samples evaluated to improve the robustness of this method.

The method presented here can be used by fish oil refiners and dietary supplement manufacturers to determine if fish oil has acceptable sensory parameters without the need to maintain an expensive sensory panel. Although a panel is required to develop the method, after the initial set up there should be no further need to maintain the sensory panel. Because the PV and AV limits currently used to determine oil quality seem to be of little use in predicting sensory quality, this method will provide more accurate results; however, in a commercial setting it should be possible to determine PV and AV limits that correlate with sensory parameters and then use these as an additional measure of quality. Based on results in this study, a maximum PV limit of 15 mequiv/kg and a maximum AV of 14 would appear to be appropriate for the oils used here.

In conclusion, PCA and linear regression can be used in conjunction with SPME-GCMS of oxidative volatiles to predict the sensory quality of fish oil. The method presented here suggests that the PV and AV values typically used to indicate fish oil quality have little relationship with sensory properties.

local topography, wind, cloud cover, aerosols, ozone, green house gases, variable solar radiation fluxes and season [1]. The latest Intergovernmental Panel on Climate Change [2] report predicts, for non-mitigation global warming scenarios, increases in average surface air temperature of between 0.64 and 0.69 °C for 2011–2030 and, depending upon the modeling scenario, increases of as much as 1.8 °C by mid-century (2046–2065). In addition, the IPCC report predicts an increase in the number of extreme heat days for northern temperate ecosystems [2]. Sustained and extreme increases in surface air temperatures have an immediate effect on shallow systems (i.e. streams, ponds) as their water temperatures are directly influenced by air temperatures [3, 4]. Global warming is also contributing to polar stratospheric ozone loss, delaying the recovery of the ozone layer [5] which helps to protect life on the surface of the planet from damaging UVB radiation. Thus, temperature and UVB radiation are inextricably linked to global climate change where they function as key drivers of the proximate physical environment experienced by animals.

Temperature induces strong effects on the physiology of poikilotherms, including fishes. At the cellular level, temperature can be regarded as a stressor to which fish must respond in order to establish a new equilibrium between their environment and the physico-chemical properties of their membranous structures; a phenomena called “homeoviscous adaptation” by Sinensky [6]. Thus, biochemical and physiological adaptations in response to temperature, at the membrane level, provide the most sustained and specific response to fluctuating temperatures experienced by fish. These biochemical responses are principally mediated by changes in the composition and concentrations of individual fatty acids (FA) and sterols in cell membranes [7].

UV radiation also exerts strong effects on the physiology of fishes and other aquatic organisms [8]. In an earlier study, we demonstrated that juvenile Atlantic Salmon (*Salmo salar*, Linnaeus, 1758) exposed to enhanced levels of UVB radiation had higher mass fractions of 18:2n-6 and 18:3n-3, total n-6 FA and saturated fatty acids (SFA) in their tissues compared with fish in reduced UV treatments, suggesting that salmon exposed to UV radiation were more quiescent than fish in the reduced UV treatments resulting in a buildup of catabolic substrates [9]. This finding is broadly consistent with observations of depressed feeding behavior and reduced agonistic interactions in juvenile salmon exposed to UVR in artificial flumes [10]. In addition, exposure to enhanced UVB radiation retarded growth, decreased hematocrit value and plasma protein concentration, in Atlantic Salmon parr [11]. Such effects may, in general, decrease resistance to pathogens in salmonids [12]. Finally, exposure to UVB, regardless of water temperature, had a negative effect on immune function

parameters, growth and physiological condition of Atlantic Salmon parr, although interactive effects between temperature and UVB were also observed [13].

It is important to consider the effects of both UVB and temperature because these two physical forcing variables may act additively or synergistically on specific aspects of fish biochemistry, physiology, and behavior. Thus, we exposed Atlantic Salmon parr to three environmentally realistic [9, 11, 13] spectral treatments differing in the intensity of UVB radiation at two different temperatures (12 and 19 °C). We assayed FA mass fractions in Atlantic Salmon, held in outdoor rearing tanks subjected to different UV and temperature treatments, because lipids are key molecules involved in many cellular and physiological processes and because they are known to be sensitive to stress, including UVR. We tested the null hypotheses that juvenile (parr) Atlantic Salmon exposed to different temperature or UVB regimens demonstrated no direct and/or interactive effects on FA profiles in their dorsal skin, ventral skin, dorsal muscle, or ocular tissue.

Materials and Methods

Experimental Setup

The experiment was conducted at the Institute of Marine Research's (IMR) Austevoll Research Station (60°5'42"N, 5°13'8"E). At the beginning of the experiment 100 juvenile Atlantic Salmon (*Salmo salar*; Norsk LakseAvl strain; mean weight at start = 8.3 g) were placed in tanks (3 m wide × 1 m deep) which were filled with ~4,500 L of sand-filtered freshwater from a nearby lake. Incoming water was routinely aerated, the turnover rate was high, and the fish biomass to water volume ratio was very low, so oxygen was considered to be saturated. The fish were held in nylon net cages (50 × 60 × 60 cm; L × W × H) which were immersed in the water so that the distance from the surface to the bottom of the net cages was 30 cm.

The fish were randomly divided into the cages to achieve an even size distribution, and were fed with a specially prepared salmon feed (see below). The duration of the experiment was 54 days (July 17–September 8, 2003). At the end of the experiment all fish were euthanized using tricaine methanesulfonate (MS-222, Sigma Chemical Co). There were 6 tanks (experimental units) corresponding to the six possible spectral × temperature combinations (see below). Additional details of the experimental setup and conditions can be found elsewhere [9, 11, 13]. Fish were handled, and sacrificed, following standard procedures accepted by the Institutional Animal Care Committee of the Institute of Marine Research, Austevoll Aquaculture Research Station, Storebø, Norway.

Spectral Treatments

The three spectral treatments were: (1) natural sunlight filtered through Rohm Plexiglas® GS-231 (hereafter referred to as -UVR) which has a sharp cutoff below 400 nm (i.e. no UVB or UVA radiation), (2) UVB-depleted solar radiation (hereafter, -UVB) i.e. sunlight screened through polyester plastic film (0.2 mm thick Mylar-D®, DuPont Teijin Films, Delaware, USA, 50 % transmittance at 318 nm), and (3) solar radiation supplemented with UVB radiation (hereafter +UVB) from an overhead fluorescent tube lamp (TL40/12 RS, Philips Lighting, Rosendal, NL, emission maximum at 315 nm) placed 100 cm above the water surface. To remove UVC radiation the lamp was wrapped in cellulose triacetate film (95 mm, Clarifoil Co., UK), and the film was changed every 18 h. The lamp was turned on at noon for 4 h. For the spectral output of the TL40/12 RS lamp, see [14]. For details concerning the average daily irradiances in the +UVB and -UVB treatments see [13] Table 1).

These three spectral treatments were carried out simultaneously at two temperatures; at the normal rearing temperature of salmon in the area of the experimental site (~12 °C) and at ~7 °C above the normal rearing temperature (increased to ~19 °C by a thermostatic heater) to explore potential additive or synergistic effects of different combinations of the two environmental stressors. The temperature of the warm water treatment was consistently higher than the cold water treatment (repeated measures ANOVA on ranks, Tukey multiple comparison *p* value ≤ 0.0001; Fig. 1).

Salmon Diet

The feed was manufactured by Nofima (<http://www.nofima.com/>; formerly SSF, Norway), in spring 2002 and was utilized in another experiment conducted in 2002 [9].

Table 1 Degrees of freedom (d.f.) for three-way and two-way ANOVA tests conducted to assess the effects of temperature and exposure to ultraviolet radiation on fatty acids of Atlantic Salmon parr

Fig. 1 Mean (±SD) water temperature of the experimental tanks used to test for the effects of temperature and UV exposure on juvenile Atlantic Salmon tissues (*n* = 3). The average water temperatures of the warm and cold-rearing tanks were 19 and 12 °C, respectively. Note: the average temperature of the cold rearing tanks was incorrectly reported as 14 °C in Jokinen et al. [13]

Peruvian Anchovy (*Engraulis ringens*) oil was added to the base feed formulation to provide the salmon with key dietary essential n-3 FA. This feed is hereafter referred to as the anchovy feed. The detailed ingredients, gross chemical composition, and energy content of the anchovy feed is provided elsewhere [9]. The feed was processed into 1.0, 1.5 and 2.0 mm diameter pellets so that juvenile salmon could be fed appropriately-sized particles as they grew. The feed was stored in the dark in a -50 °C chest freezer from the time it was manufactured until the end of the 2003 experiment. Salmon were hand-fed ad libitum.

Tissue Collections and Processing

At the end of the experiment, four different tissues were collected from six randomly selected Atlantic Salmon juveniles from each of the spectral and temperature combinations. The tissues sampled included dorsal and ventral skin, dorsal muscle) and ocular tissue. Dorsal skin, adjacent to the dorsal fin, was sampled by gripping it with a pair of surgical pliers and peeling it off the underlying muscle tissue. A surgical razor blade was then used to trim excess fat and/or muscle that remained attached to the skin. Ventral skin was obtained from the region between the pectoral fins and anus. Because we could not efficiently separate the retina from surrounding tissues we here refer to samples consisting of the entire posterior portion of the inner regions of the eye as ocular tissues. Ocular tissue was chosen because dietary supply of docosahexaenoic acid (DHA; 22:6n-3) is known to affect retinal DHA concentrations in fish [17, 18] and visual acuity in vertebrates [19–21]. Finally, UVR negatively affects several aspects of

vision in vertebrates (e.g. major cytoskeletal structures such as microtubules and actin) leading to cataract formation [22, 23]. We chose skinless dorsal muscle (land-marked to either side of the dorsal fin) because it is the largest tissue in these fish and because of its economic importance (i.e. filets). Dorsal skin was chosen because it should be a major target site for UVR damage [15, 16]. Ventral skin is relatively less pigmented (protected) than dorsal skin and, therefore, should be more vulnerable to the effects of UV radiation when/if exposed.

Fatty Acid Analyses

The tissue samples were placed in cryovials, frozen in liquid nitrogen and immediately transferred to a cryogenic freezer (-85°C) where they remained until FA analyses. All tissues were freeze-dried for 48 h prior to analyses. A total of 144 individual tissue samples were analyzed for FA (3 light treatments \times 2 temperatures \times 4 tissues \times 6 fish per treatment cell). Lipids and FAME of the freeze-dried salmon feed and salmon tissues were obtained in a three-step process: extraction [24], derivatization using the boron trifluoride method [25] and quantification on a HP6890 gas chromatograph (as in [26]). Each freeze-dried sample was weighed to the nearest microgram (Sartorius ME5 microbalance), and homogenized to extract the lipids in 2 mL of 2:1 (v/v) chloroform:methanol (modified from Folch et al. [24] in that dry tissues were extracted). This was repeated three times. The resulting supernatants (after centrifugation to remove non-lipid containing material) were combined in a 15-mL centrifuge tube. The lipid extract was then accurately adjusted to 8 mL with 2:1 (v/v) chloroform:methanol, and 1.6 mL of a 0.9 % NaCl in water solution was added. The two phases were then thoroughly mixed and centrifuged (2,000 rpm at 4°C). The upper aqueous layer was removed and discarded. The FA were dissolved in 2 mL hexane prior to derivatization. Two milliliters of BF₃-methanol (10 % w/w) was added and vials were heated (70°C) for 2 h after which 1 mL of water was added. The FAME-containing hexane-layer was carefully removed and put into a 2-mL Kuderna-Danish receiving vial (Sigma #6-4689U). One milliliter of hexane was then added to the original Shimadzu vial to extract the remaining FAME. This step was repeated once more to get the best extraction efficiency (90–95 %). The FAME-hexane solution was evaporated to 2.0 mL using nitrogen gas and transferred to a 2 mL glass GC vial and stored in a -80°C cryogenic freezer prior to GC analysis. FAME were quantified using a Hewlett Packard 6890 GC (splitless injection; column = Supelco SP-2560, 100 m \times 0.25 mm ID \times 0.20 μm thick film) by comparing peak retention times and areas between the samples and standard curves created using a 37-component FAME standard (Supelco

#47885-U). FA results are reported as mass fractions (i.e. μg FAME/mg dry weight tissue).

Statistical Analyses

The effect of water temperature and UV exposure on the FA composition of juvenile Atlantic Salmon tissues was examined using a series of analysis of variance (ANOVA) tests. FA mass fractions were log-transformed prior to analysis to satisfy normality and homogeneity of variance assumptions of parametric analysis. Three-way ANOVAs were used to compare FA composition among the four tissue types (dorsal muscle, dorsal skin, ventral skin and ocular) at two water temperatures (cold and warm) and three UV exposures (+UVB, –UVB and –UVR). Since multiple 3-way ANOVA testing was employed, the false discovery rate correction, which controls the proportion of errors among the rejected hypotheses, was applied to reduce the risk of Type I errors [27]. Two-way ANOVA and Tukey multiple comparison tests were used to compare FA responses to water temperature and UV exposure within each tissue type. Tukey multiple comparison tests control the Type I error rate for multiple pairwise comparisons [28]. Results are presented as untransformed means \pm SD. Differences were considered significant at $p < 0.05$. Statistical analyses were performed using SigmaStat for Windows software (version 3.11; Systat Software Inc., San Jose, CA, USA).

Results

Fatty Acids Profiles of Salmon Tissues

Juvenile Atlantic Salmon tissues had high mass fractions of 22:6n-3, 16:0 and 18:1n-9 (Fig. 2). The mean mass fraction of all other FA was $<5 \mu\text{g}/\text{mg}$ dry tissue. Mass fractions of total FA across all tissue types averaged $43.3 \pm 15.1 \mu\text{g}/\text{mg}$ dry tissue. FA composition differed among tissue type (three-way ANOVA; Tables 1, 2). In general, mass fractions of FA were greater in ocular tissue as compared to dorsal muscle and dorsal and ventral skin (Fig. 2). Differences among tissues were temperature dependent (Table 2). Temperature also interacted with UV exposure although UV exposure main effects were not significant.

Effect of Temperature and UV Exposure on Individual Tissues

The FA composition of dorsal muscle and dorsal and ventral skin tissues were not significantly affected by UV exposure (two-way ANOVA, UV exposure main effect $F_{2,30} \leq 3.1$, p values ≥ 0.06), but were often significantly

| Total FA | $35.77 \pm 3.04^{a,A}$ | 31.20 ± 2.93^b | 33.51 ± 3.86^a | 40.22 ± 5.49^b | 31.64 ± 3.99^a | 42.59 ± 4.10^b |

Values are expressed as means \pm SD. Values in the same row with different letters indicate significant differences between water temperature treatments within each tissue type (two-way analysis of variance temperature effect $p < 0.05$). Interaction terms were not significant ($p \geq 0.05$) with two exceptions

SFA saturated fatty acids, MUFA monounsaturated fatty acids, PUFA polyunsaturated fatty acids, FA fatty acids

^A Total FA was greater in the +UVB treatment as compared to the –UVB treatment at cold water temperature

^B 22:6n-3 was greater at cold water temperature as compared to warm water temperature within the –UVB treatment

total n-6, total polyunsaturated fatty acids (PUFA), and total FA were greater in fish reared at cold water temperature (Table 3). For dorsal and ventral skin tissues, mean mass fractions of the individual FA were greater in fish reared at the warm water temperature with the exception of 22:6n-3 in dorsal skin. The mean mass fractions of the summary FA indices were also greater in fish reared at warm water temperatures although differences in total n-3 and total PUFA were not significant in dorsal skin tissue (Table 3).

For ocular tissue, the mean mass fraction of most FA was greater in fish reared at warm water temperature (two-way ANOVA, temperature main effect p values < 0.05 ; Table 4). The effect of water temperature on FA composition in ocular tissue differed among UV exposure level (interaction effect $F_{2,30} \geq 3.3$, p values < 0.05 ; Table 4). At the colder temperature, juvenile salmon exposed to +UVB had higher mass fractions of 20:2, 20:4n-6, 22:6n-3, total n-3, total n-6, total PUFA and total FA in their ocular tissues

compared to fish exposed to –UVR (Tukey multiple comparisons, p values < 0.05). At warm water temperature, fish exposed to –UVR had higher mass fractions of 14:0, 16:0, 16:1n-7, 20:5n-3, 22:5n-3, total n-3, total n-6, total SFA, total PUFA and total FA in their ocular tissues compared to fish exposed to +UVB (Table 4). At both cold and warm water temperatures, FA mass fractions in ocular tissues of fish exposed to –UVB were intermediate to mass fractions in fish exposed to +UVB and –UVR (Table 4).

Discussion

Water temperatures in native streams and rivers inhabited by Atlantic Salmon can increase in response to the removal of riparian cover and/or because of climate warming. Removal of riparian cover (e.g., due to logging operations) can increase water temperature in streams by as much as 4 to 6 °C [29–31]. Climate model scenarios predict an

increase in the number of extreme heat days as well as globally-averaged increases in surface air temperatures of between +0.64 and +0.69 °C for 2011–2030 and as much as +1.8 °C by mid-century (2046–2065) [2]. Past climate warming (e.g. the period between 1985 and 2009) has already increased mean night-time surface water temperatures of inland water bodies by an average rate of 0.045 ± 0.011 °C year^{−1} (and as high as 0.10 ± 0.01 °C year^{−1}) with the greatest warming in the mid- and high latitude ranges of the northern hemisphere [32] inhabited by Atlantic Salmon.

Atlantic Salmon grow optimally at ~ 16 °C [33]. Here, we demonstrate that increasing the water temperature by ~ 7 °C (from 12 to 19 °C) had pronounced effects on mass fractions of individual FA and on summary FA measures for all four tissues of Atlantic Salmon (Tables 3, 4). This suggests that anthropogenically-induced (climate change and/or removal of riparian cover) increases in the water temperature of boreal freshwater streams and rivers could affect the nutritional status of juvenile (parr) Atlantic Salmon. This interpretation must be tempered by the reality that Atlantic Salmon will encounter much larger changes in

temperature than the relatively constant conditions to which they were exposed during our experiment. Further, the temperature increase in our experiment should be viewed as a worst-case scenario. Nevertheless, our experimental design isolated the specific effects of temperature on FA profiles, which is difficult to impossible to do in the complex environments of natural streams and rivers. With these caveats in mind, our results can be viewed as indicative of how increasing water temperature in streams and rivers may affect wild juvenile Atlantic Salmon at biochemical and physiological levels during the period prior to and during smoltification. Further, the observed changes in mass fractions of specific FA in dorsal muscle are broadly consistent with what has been observed with respect to membrane adaptations (average membrane lipid order, i.e. fluidity) in response to changing temperature [7]. In agreement with these previous findings we also observed generally higher mass fractions of total and individual SFA (16:0, 18:0) and lower mass fractions of total and individual PUFA (e.g. 18:3n-3, 22:5n-3, 22:6n-3, and 20:4n-6) in dorsal muscle (Table 3) as temperatures increased. Finally, others [34] have commented on the potential of

climate change to affect the health of Atlantic Salmon in native streams/rivers. These authors point out that climate change models for the Maritime Provinces of eastern Canada (where natural reproduction of Atlantic Salmon still occurs) indicate an expected increase in air temperature of between 2 and 6 °C and they highlight how fork lengths (a gross index of fish condition) of Atlantic Salmon are negatively correlated with water temperatures.

Muscle is a good long-term integrator of the effects of changing temperatures and/or diet on a fish's nutritional status [35]. Juvenile salmon remain in freshwater streams and rivers for periods ranging from a year to several years and then transform from parr to smolts during their migration to the ocean. During this period they eat a diet mainly consisting of freshwater invertebrates [36, 37] which contain high levels of C₁₈ PUFA, intermediate levels of C₂₀ PUFA and generally lower levels of C₂₂ PUFA [38–40]. It has been suggested that lipid metabolism in salmon may influence the process of parr-smolt transformation, ultimately affecting successful seawater adaptation [41]. For example, hepatocyte fatty acyl desaturation/elongation activities in juvenile Atlantic Salmon are primarily controlled by environmental factors such as temperature and photoperiod but diet also plays a role [42]. Thus, prior to smoltification the FA composition of parr salmon is influenced by, (1) diet, (2) their ability to modify that dietary FA input via catabolism and by desaturation and elongation pathways and, (3) the influence of water temperature and photoperiod (and possibly also the levels of UV to which they are exposed) on the latter processes. During the period leading up to smoltification, tissue FA composition changes from a typical freshwater pattern, which is relatively low in long-chain polyunsaturated fatty acids (LC-PUFA), to a more typical marine pattern which is relatively rich in LC-PUFA such as 20:5n-3 and 22:6n-3 [42]. Thus, the elevation of n-3 LC-PUFA in salmonids is considered a key pre-adaptive response to seawater entry [43, 44]. Our finding that n-3 LC-PUFA in muscle tissue was reduced at warmer water temperatures—even while diet remained constant—suggests climatic warming and/or removal of riparian cover may affect the physiological competency of Atlantic Salmon with respect to their ability to transition from freshwater to seawater.

The fish feed used in our experiment deviated from the natural, mostly insect-based, food of wild parr salmon in that aquatic insects have relatively higher amounts (both as proportions and mass fractions) of 18:3n-3 and 18:2n-6 and lower amounts of 20:5n-3 and especially 22:6n-3 than the anchovy-based feed. When diets more closely mimic the FA composition of aquatic insects, desaturation of 18:3n-3 and 18:2n-6 to LC-PUFA such as 20:5n-3, 22:6n-3 and 20:4n-6 occurs at a higher rate than when predominantly fish oil diets are fed to Atlantic Salmon parr [41]. Thus,

desaturation rates are expected to be more conservative in our experiment. Nevertheless, we observed significantly lower concentrations of 18:3n-3, 20:4n-6, 22:6n-3, total n-3, total n-6 and PUFA in dorsal muscle of fish raised at the warmer temperature (Table 3). This occurred despite the fact that mass fractions of other FA did not change significantly (e.g. 14:0, 16:1n-7, 18:2n-6, 20:1n-9, 20:5n-3) or else increased (16:0). In our experiments, diet quality (anchovy-based feed) and quantity (all fish were fed ad libitum) was the same in all treatments so any changes in the mass fractions of FA in the four tissues examined here, in response to increasing temperature, are not attributable to differences in the underlying diet. It is also important to note that, in natural situations, the essential FA composition of lower trophic level organisms in aquatic food webs (e.g. algae, seston, zooplankton, and aquatic insects) inhabited by, and ultimately consumed by, higher trophic level consumers like salmon may also be negatively affected by water temperature (e.g. [45, 46]). In addition, all of the salmon used in this experiment came from the same broodstock and were randomly allocated to the different treatments, therefore, it is unlikely that there would have been gross systematic differences among the individual fish (for genetic reasons) with respect to their ability to desaturate and elongate shorter-chain FA. Taken together, these results suggest that desaturase and elongase activities were higher in salmon raised in colder water resulting in generally higher tissue PUFA mass fractions, although we cannot rule out the possibility that dietary PUFA were merely retained at a higher rate in the cold water treatment.

We also observed that mean mass fractions of most of the individual FA in dorsal and ventral skin tissues were greater in fish reared at the warm water temperature with the exception of 22:6n-3 in dorsal skin (Table 3). Although a review of the literature did not reveal previous studies relating water temperature to fish skin FA composition, other researchers have provided evidence that subjecting fish to water temperatures that are substantially different than their optimal growth temperature may increase the risk of parasite infection [47, 48]. For example, sea lice (*Lepeophtheirus salmonis*) infections of cultured Atlantic Salmon are highest in summer and/or in shallow bays when temperatures are warmest [49]. The barrier functions of the skin are primarily a consequence of the lipid composition of the stratum corneum [50], therefore, we suggest that the increases in specific individual FA that we observed as a function of increasing temperature may represent a generalized defense response to the increased risk of parasite infection when salmon are raised in water temperatures that are above their optimal growth temperatures.

UV-induced damage including, for example, sunburn [51, 52] and reduced numbers of mucous secreting goblet cells [15] have been observed in some fish species, whereas

other species appear to benefit from protective substances in their skin [53, 54]. Lipids in the outermost layer of skin (*stratum corneum*) are affected by UV exposure in three ways; (1) β scission (fragmentation of the carbon chain), (2) hydrogenation of the double bond of unsaturated compounds and (3) formation of oxygenated entities from unsaturated lipids [50]. In our experiments, the FA composition of dorsal and ventral skin tissues were largely unaffected by UV exposure. Similarly, Arts et al. [9] did not observe significant changes in mass fractions of individual FA of dorsal skin in Atlantic Salmon exposed to enhanced UVB radiation.

Although the main effects of UV exposure on FA profiles were not significant across tissues in our experiment there were, nonetheless, significant interactive effects between temperature and UV exposure for certain FA and FA summary indices (Table 2). These interactive effects were mostly driven by changes in mass fractions of several FA in ocular tissue (Table 4). Enhanced UVB had different effects on individual FA mass fractions when fish were raised in cold versus warm water conditions. Specifically, ocular tissues of fish raised in cold water demonstrated higher mass fractions of 22:6n-3 and 20:4n-6 in response to enhanced UVB stress, whereas this effect was not observed in ocular tissue of fish raised in warm water. We suggest, for the reasons below, that this may be an adaptive metabolic response of ocular tissues to enhanced UVB stress. We further suggest that future studies examine free radical production, vitamin status and histology in skin and ocular tissues as a function of UV exposure and that fatty acid analyses be conducted on specific phospholipid classes (e.g. phosphatidylcholine, phosphatidylethanolamine) so that the overall response to UV radiation can be better understood.

Compromised vision occurs in fishes exposed to UV radiation under controlled experimental conditions. For example, cataract formation increased in Rainbow Trout (*Onchorynchus mykiss*) that received chronic UV exposure [23] while corneal tissue transmission decreased in UV-exposed Hawaiian Saddleback Wrasse (*Thalassoma duperrey*) [54]. Similarly, damage from ambient solar UVR was concluded to be a contributing factor explaining the formation of anterior lens cataracts in cage-reared Atlantic Halibut (*Hippoglossus hippoglossus*) [55]. Finally, wild Atlantic Salmon postsmolts taken from trawl hauls in the Norwegian Sea demonstrated effects ranging from hazy opacity in the anterior part of their lenses to cataracts affecting the whole lens [56]. These authors concluded that the primary cause of these cataracts was defective osmoregulation but they did not rule out oxidative stress caused by exposure to UV radiation as a contributing factor to osmotic cataract development.

Vertebrate retinal tissue is known to contain high concentrations of 22:6n-3 mostly located in membrane

phospholipids [57] and retinal 22:6n-3 concentration in fish is known to be responsive to dietary 22:6n-3 manipulations [18]. The 22:6n-3 contained in the vertebrate retina plays a crucial role in visual acuity [21], in part by promoting the survival and differentiation of photoreceptors [20]. Thus, 22:6n-3 is critical for both visual acuity (especially at low light intensities, [17]) and schooling behavior in fish [58].

Desaturases and elongases appear to be up-regulated in Atlantic Salmon raised in cold water compared to warm water, as evidenced by significantly higher concentrations of 22:6n-3 in dorsal muscle (Table 3). Up-regulation of enzymatic activity related to the production of higher amounts of n-3 LC-PUFA is consistent with what other researchers have found when teleosts are exposed to colder water temperatures [59]. Although we did not measure cataract formation or lens opacity, the studies summarized above suggest that compromised vision possibly occurred in the Atlantic Salmon parr exposed to enhanced UVB radiation in our experiment. We further suggest that the increased rate of 22:6n-3 synthesis in cold-water-raised salmon likely provided them with a compensatory mechanism to deal with compromised vision as a result of exposure to enhanced UVB radiation. Thus, we hypothesize that, as visual acuity was compromised following exposure to enhanced UVB radiation, salmon in the cold water treatment were able to compensate for reduced light transmission to the retina by increasing the mass fraction of 22:6n-3 (Table 4). We found a similar pattern when comparing the response of ocular tissue FA between two feeds that differed in mass fraction of LC-PUFA [9]. In that study, ocular tissues of fish in the enhanced UVB treatment had higher 22:6n-3 and 20:4n-6 mass fractions when they were fed a LC-PUFA-rich food source as compared to when they were fed a relatively less rich LC-PUFA food source, again suggesting that when higher amounts of LC-PUFA are available (either through diet or through temperature-induced up-regulation of desaturases and elongases) ocular tissues compensate for reduced function (e.g. cataracts, opacity) by increasing 22:6n-3 concentrations.

Conclusions

Raising the water temperature by $\sim 7^\circ\text{C}$ had pronounced effects on FA profiles of dorsal muscle, and dorsal and ventral skin of juvenile (parr) Atlantic Salmon raised in outdoor tanks. We observed higher mass fractions of total and individual SFA (16:0, 18:0) at the higher temperature and lower mass fractions of total and individual PUFA (e.g. 18:3n-3, 22:5n-3, 22:6n-3, and 20:4n-6) in dorsal muscle and higher mean mass fractions of most of the individual FA in dorsal and ventral skin tissues in fish reared at the warmer water temperature. Since biochemically-important

essential FA were negatively affected by temperature, these changes probably forecast a host of ensuing physiological and ecological responses of juvenile Atlantic Salmon to increasing temperatures in native streams and rivers where these salmon mature before smolting and returning to the sea [34, 60]. We further suggest that exposure to enhanced UVB radiation as a result of ozone thinning may add another stress factor to juvenile salmon (with respect to vision) especially when protective riparian cover is removed and/or water temperatures increase.

Changes in nutritional status in early life stages can have unforeseen but significant fitness consequences to animals later in life [61, 62]. Thus, we propose that future studies be designed to assess the effects of temperature and/or exposure to UVR early in life on fitness consequences to later life-history stages of Atlantic Salmon. Finally, we hypothesize that, because some of the LC-PUFA produced in aquatic ecosystems is transferred to adjacent terrestrial systems [63], the reduced nutritional quality (from an essential FA perspective) of juvenile Atlantic Salmon maturing in warmer water may also have long-term health consequences for their mammalian and avian fish predators.

Acknowledgments We thank Penny Kuhn (CONFORTE) for her assistance with the UV measurements and dose estimates. We are grateful to Bjørn Johnson (the Norwegian Radiation Protection Authority), Arne Dahlback (the University of Oslo) and Kåre Edvardsen (the Norwegian Institute for Air Research) for access to the Bergen irradiance data. We also thank Stig Ove Utskot (Institute of Marine Research, Norway) for maintaining tanks and taking care of the fish and Reidun Bjelland for helping with the tissue dissections. Tyler Spencer (Environment Canada) helped with the FA analyses. The project was supported by grants from the Research Council of Norway (140472/130), the Norwegian Institute of Marine Research (Sensory Biology and Behavior Project) and Environment Canada.

last 20 years [1–4], especially in relation to eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) [1, 5–7]. The structure of DHA provides this fatty acid with many important functions in fish metabolism [4], and has been demonstrated to be superior to EPA in promoting growth and conferring vitality to larvae [1, 8], being preferentially incorporated into biomembranes [6, 9]. It has been reported that marine fish larvae DHA content rapidly decreases during the first 10 days after hatching, therefore high contents of DHA must be supplied to larvae in order to maintain adequate levels of DHA in growing larvae [1]. Due to their limited capacity to synthesize DHA and EPA from their precursors, fish require diets rich in these fatty acids [10]. Today, live prey substitution by compound diets containing high levels of DHA is crucial for lowering costs and increasing production quality, mainly by reducing the incidence of skeletal deformities and increasing welfare in fingerlings [10]. However, DHA is very susceptible to attack by reactive oxygen species (ROS) due to its high degree of unsaturation [11].

ROS are produced during normal cellular function [12], being beneficial or even indispensable at low concentrations in processes such as defense against microorganisms by contributing to phagocytic bactericidal activity. Fish possess enzyme systems and low-molecular-weight molecules with antioxidant functions capable of neutralizing ROS and protecting against their adverse effects [13]. However, ROS generation can exceed its removal rates and oxidative stress can occur [14] with ROS attacking diverse cellular components. One of the consequences of oxidative stress is the oxidative peroxidation of PUFA. The high unsaturation content of these fatty acids renders them very susceptible to lipid oxidation. Thus, the high requirements of marine fish larvae for long-chain PUFA (LC-PUFA), mainly DHA and EPA, makes them more prone to suffering peroxidative attack than adults [15]. Therefore, the importance of nutrition in the pro-oxidant–anti-oxidant balance process may be highly critical for fish larvae, as their high LC-PUFA contents disposes larval tissues vulnerable to oxidative stress, and an increase in the content of antioxidant nutrients is essential. Among the antioxidant nutrients, vitamin E (tocopherols and tocotrienols) is the major membrane-bound lipid-soluble antioxidant [13], whereas vitamin C (ascorbic acid, vitC) is an important water-soluble antioxidant which protects low density lipoproteins from oxidation and is required for the correct formation of cartilage [16]. The presence of sparing mechanisms between both vitamins was first hypothesized by Tappel [17]. This hypothesis proposes that the oxidized α -tocopherol (α -TOH) is reduced by ascorbate, thereby regenerating α -TOH. In some fish species, the presence of a vitamin C/E sparing mechanism has been suggested [18–22], and reported to influence growth, tissue

composition or immune responses. For instance, supplementation with 100 mg/kg of ascorbyl-2-polyphosphate to an α -TOH-deficient diet in juvenile channel catfish (*Ictalurus punctatus*) decreased vertebral deformities and improved weight gain, feed intake and feed efficiency rate [22]. High supplementation of ascorbate might also spare α -TOH in diets for hybrid tilapia (*Oreochromis niloticus* \times *O. aureus*) as shown by the increased weight gain, feed efficiency and α -TOH concentrations. However, little is known about the effect of both vitamins in preventing oxidative stress in fish larvae, when high levels of LC-PUFA are administered. Similarly, insufficient information exists regarding exact larval requirements for DHA, α -TOH or vitC, with levels ranging from 0.5 to 4 % for DHA [23, 24], 120 to 3,000 mg/kg for α -TOH [25, 26] or 30 to 2,500 mg/kg for vitC [27, 28].

The potentially deleterious effects of ROS are counteracted by a suite of antioxidant enzymes (AOE), including radical-scavenging enzymes such as catalase (CAT; EC 1.15.1.1) and superoxide dismutase (SOD; EC 1.11.1.19) or peroxidases such as glutathione peroxidase (GPX; EC 1.11.1.6). In Manchurian trout larvae (*Brachymystax lenok*), high lipid content microdiets stimulated the activity of AOE, generally accompanied by an increase in thio-barbituric acid reactive substances (TBARS) content [29]. In contrast, Mourente et al. [30] did not find a direct relationship between the activity of AOE and the level of dietary n-3 LC-PUFA in *Dentex dentex* larvae, but decreased α -TOH and increased TBARS contents were found in larvae fed high n-3 LC-PUFA-enriched *Artemia*. Furthermore, it seems that the level of antioxidant enzymes rises with larval development, whereas the level of antioxidant molecules falls [31].

In mammals, ROS can induce changes in gene expression during normal development [32], causing defective embryo development and retardation of embryo growth [33]. Similarly, oxidative stress causes embryonic mortality and developmental arrest in sea urchins (*Paracentrotus lividus* and *Sphaerechinus granularis*) larvae [34]. Oxygen stress during early larval stages of fish may also alter development. Somatic growth in fish is regulated by insulin-like growth factors I and II (IGF-I and IGF-II), two single chain polypeptides that also have a function as myogenic regulatory factors which increase satellite cell proliferation and differentiation [35, 36]. In addition, IGFs stimulate cartilage growth by the incorporation of sulphate into cartilage and also affect cell differentiation, growth and proliferation [37, 38]. Differences in myogenesis regulation, such as myosin isoform expression, have also been observed in the earliest stages and during temperature acclimation [39–41]. However, no information is available about the effect of different dietary components on the regulation of the various components of the IGF signaling

pathways, as well as their role on muscle growth in fish [42].

In previous studies, we have shown the alteration of sea bass (*Dicentrarchus labrax*) larvae oxidative status when they were fed high levels of DHA (5 %), and α -TOH (3,000 mg/kg) having a limited effect in preventing alterations such as muscular dystrophy or hepatic ceroidosis [43, 44]. Therefore, the aim of the present study was to evaluate the combined effect of α -TOH and vitC in preventing oxidative stress in sea bass larvae fed high levels of DHA in relation to larval performance or antioxidant status as well as the incidence of morphological alterations, including the expression of selected related genes.

Materials and Methods

Fish

The experiment was carried out at the Grupo de Investigación en Acuicultura facilities (Telde, Canary Islands, Spain). Sea bass larvae were obtained from a natural spawning from the Instituto de Acuicultura de Torre de la Sal (CSIC, Castellón, Spain). Prior to starting the feeding experiment, larvae were fed enriched yeast-fed rotifers (DHA Protein Selco®; INVE, Belgium) until they reached 14 days post-hatching (dph). Then, larvae (total length 8.58 ± 0.64 mm, dry body weight 0.36 ± 0.00 mg) were randomly distributed in experimental tanks ($n = 9$) at a density of 1,000 larvae/tank and were fed one of the experimental diets for 21 days, at a water temperature of 19.5–21.0 °C. All tanks (170 L, light gray color, cylindrical fiberglass tanks) were supplied with filtered sea water (34 ‰ or ppm salinity) at an increasing rate of 1.0–1.5 L/min during the feeding trial. Sea water entered the tank from bottom to top; water quality was tested daily and no deterioration was observed. Water was continuously aerated (125 mL/min), attaining 5–8 g/L dissolved O₂ and 60–80 % saturation.

Diets

Three isonitrogenous and isolipidic experimental microdiets (pellet size <250 μ m) were prepared containing two levels of DHA, vitC and α -TOH (Table 1). The levels of DHA and vitamin E were selected based on previous trial data [43, 44]. In those studies, larvae fed diets containing 1 % DHA and 1,500 mg/kg of α -TOH exhibited low incidence of muscular lesions and TBARS content, whereas larvae fed diets containing 5 % DHA and 3,000 mg/kg of α -TOH showed altered oxidative status with an increase in both parameters. A low oxidation risk diet (1/1,500) contained low DHA (1 % DW) and α -TOH

Table 1 Formulation (in % DW) of experimental diets containing two levels of DHA, vitamin E and ascorbic acid and fed to sea bass (*Dicentrarchus labrax*) larvae for 21 days

(1,500 mg/kg); a high oxidation risk diet contained the highest DHA (5 % DW) and α -TOH (3,000 mg/kg) levels; and a third diet contained high DHA (5 % DW) and α -TOH (3,000 mg/kg) together with double the quantity of vitamin C than the former two diets (3,600 mg/kg). The protein source used was squid meal defatted 3 consecutive times with a chloroform:squid meal ratio of 3:1 to allow a better control of the fatty acid profile of the microdiet. EPA, DHA, α -TOH, and vitC sources used in the experimental diets were EPA50 and DHA50 (CRODA, East Yorkshire, UK), DL- α -Tocopheryl Acetate (Sigma-Aldrich, Madrid,

Spain) and Rovimix Stay-C 35 (Roche, Paris, France), respectively. Oleic acid (Merck, Darmstadt, Germany) was added to equalize the lipid content in all diets. Microdiets were prepared according to Liu et al. [45] by first mixing the squid powder and water-soluble components, followed by lipid- and fat-soluble vitamins and, finally, warm water-dissolved gelatin. The paste was pelleted and oven-dried at 38 °C for 24 h. Pellets were ground and sieved to obtain particle sizes below 250 µm. Diets were analyzed for proximate and fatty acid composition of dry matter and kept in plastic bags under nitrogen atmosphere at −20 °C until the beginning of the experimental trial. Diets were manually supplied 14 times per day every 45 min from 0900 to 1900 hours. Daily feed supplied was 2, 2.5, and 3 g/tank during the first, second, and third weeks of feeding, respectively. Each diet was tested in triplicate.

Growth and Survival

Final survival was calculated by individually counting live larvae at the beginning and end of the experiment. Growth was determined by measuring dry body weight (105 °C for 24 h) and total length (Profile Projector V-12A; Nikon, Tokyo) of 30 larvae/tank at the beginning, middle, and end of the trial.

Biochemical Analysis

All remaining larvae in each tank were washed with distilled water, sampled, and kept at −80 °C for biochemical composition and TBARS analyses after 12 h of starvation at the end of the trial. Moisture, protein [46], and lipid [47] contents of the larvae and diets were analyzed.

Total Lipid Fatty Acid Analysis

Fatty acid methyl esters (FAMES) were obtained by transmethylation of total lipids as described by Christie [48]. FAMES were separated by GLC, quantified by FID (GC-14A; Shimadzu, Tokyo, Japan) under the conditions described in Izquierdo et al. [49] and identified by comparison with previously characterized standards and GLC-MS.

Determination of α -TOH Content

α -TOH concentrations were determined in diets and larvae samples using high-pressure liquid chromatography (HPLC) with UV detection. Samples were weighed, homogenized in pyrogallol, and saponified as described by McMurray et al. [50] for diets or according to Cowey et al. [51] for larvae. HPLC analysis was performed using a 150 × 4.60 mm, reverse-phase Luna 5 µm C18 column

(Phenomenex, CA, USA). The mobile phase was 98 % methanol pumped at 1.0 mL/min. The effluent from the column was monitored at a wavelength of 293 nm and quantification achieved by comparison with (+)- α -tocopherol (Sigma-Aldrich) as external standard.

Determination of Vitamin C Content

Ascorbil-2-monophosphate concentrations were determined in diets using a HPLC procedure with UV detection. The HPLC system comprised of a 150 × 4.6 mm, 5-µm particle size, Gemini C18 column fitted with a Gemini pre-column of the same material. The mobile phase consisting of phosphate buffer was delivered at a flow rate of 0.8 mL/min. Samples were dissolved with 0.4 M phosphate buffer (pH 3.0) and centrifuged at 1,610g for 5 min at room temperature. The supernatants were kept at 4 °C until assayed. vitC concentrations were determined at a wavelength of 293 nm and quantification achieved by comparison with tris(cyclohexylammonium) ascorbic acid-2-phosphate (Sigma-Aldrich), used as a reference substance.

Measurement of Thiobarbituric Acid Reactive Substances (TBARS)

TBARS were measured in triplicate samples using a method adapted from that used by Burk et al. [52]. Approximately 20–30 mg of larval tissues per sample were homogenized in 1.5 mL of 20 % trichloroacetic acid (w/v) containing 0.05 mL of 1 % BHT in methanol. To this, 2.95 mL of freshly prepared 50 mM thiobarbituric acid solution was added before mixing and heating for 10 min at 100 °C. After cooling, protein precipitates were removed by centrifugation (Sigma 4K15; Osterode am Harz, Germany) at 2,000g, the supernatant was read in a spectrophotometer (Evolution 300; Thermo Scientific, Cheshire, UK) at 532 nm. The absorbance was recorded against a blank at the same wavelength. The concentration of TBA-malondialdehyde (TBARS) expressed as nmol per g of tissue was calculated using the extinction coefficient 0.156 µM^{−1} cm^{−1}.

Histopathological Sampling

Thirty larvae from each tank were collected every 7th day from the beginning of the feeding trial, and fixed in 10 % buffered formalin for 1 or 2 days, dehydrated through graded alcohols then xylene, and finally embedded in paraffin wax. Six paraffin blocks containing five larvae per tank were sectioned at 3 µm and stained with Hematoxylin and Eosin (H&E) for histopathologic evaluation [53].

Ten larvae per tank were fixed for 24 h at 4 °C in 2.5 % glutaraldehyde in 0.2 M phosphate buffer (pH 7.2).

Samples were then rinsed in phosphate buffer and post-fixed for 1 h in 2 % osmium tetroxide in 0.2 M potassium ferrocyanide. Each larva was then embedded in an Epon/Araldite resin block. Serial transverse and longitudinal larvae thick sections were cut at 1 μ m, stained with toluidine blue and examined under light microscopy [54]. Thin sections were cut at 50 nm and stained with lead citrate before observing with a ZEISS EM 910 transmission electron microscope (Germany) at the Electron Microscope Service of University of Las Palmas de Gran Canaria.

In addition, 100 larvae from each tank at 35 dph were fixed in 10 % buffered formalin in order to perform deformity analyses. Prior to staining, larvae were measured under a Profile Projector (PJ 3000; Mitutoyo, Japan), divided into three size classes (<10.0 mm, 10.0–12.0 mm, and >12.0 mm) and stained with Alizarin red [55] to determine bone mineralization. Larvae from the different experimental groups were stained simultaneously in order to prevent any technical variability. Deformities were classified into different groups according to their localization. Firstly, cranial deformities or axial skeleton deformities, which were subdivided into four categories: (1) lordosis, (2) kyphosis, (3) neural process alterations, and (4) others, e.g., vertebral compression or scoliosis. Cranial deformities included those found in the jaws, such as pugheadness or crossbite and opercular deformities. And secondly, axial skeleton deformities included spine curvatures such as lordosis (ventral curvature), kyphosis (dorsal curvature) or scoliosis (lateral curvature); neural processes alterations such as wrong direction or twisting, and vertebral compression that comprises two alterations, the flattening of vertebral end plates and vertebral fusion. The surface corresponding to bone in whole colored larvae was visualized and quantified using a computerized image analysis package (Image-Pro Plus[®]; Media Cybernetics, MD, USA). By selecting ranges of pixel values in color images the pixels associated with red could be distinguished. The number of selected pixels was then quantified using a particle analysis operation and by counting the area of all bright objects (in pixels). Larval size was estimated by calculating the surface areas (in pixels) covered by whole stained larvae.

RNA Extraction and Quantitative RT-PCR

Molecular biology analyses were carried out at the University of Insubria (Varese, Italy). Total RNA was extracted from sea bass larvae (\approx 200 mg; pool per tank), using PureYield RNA Midiprep System (Promega, Italy). The quantity and purity of RNA was assessed by spectrophotometer. Visualization on 1 % agarose gel stained with ethidium bromide showed that RNA was not degraded. Three micrograms of total RNA was reverse transcribed into complementary DNA (cDNA) in a volume of 12 μ l,

including 1 μ l of oligo dT16 primer (50 pmol) and 1 μ l of 10 mM deoxynucleotide triphosphates (dNTPS). This mix was heated at 65 °C for 5 min, chilled on ice, and then 4 μ l of 5X reverse transcription buffer, 2 μ l 0.1 M DTT, 1 μ l RNase out and 1 μ l of Moloney murine leukemia virus (M-MLVRT) were added. After incubation at 37 °C for 50 min, the reaction was stopped by heating at 75 °C for 15 min.

PCR primers sequences used for the PCR amplification of the cDNAs of target genes were CAT, SOD, GPX, IGF-I, IGF-II, and MyHC. To perform PCR, an aliquot of 4 μ l of cDNA was amplified using 25 μ l GoTaq Green Master Mix (Promega, Italy) in 50 μ l of final volume and 50 pmol of each designed primer.

A total of 31 PCR amplification cycles (eight touch-down) were performed for all primer sets, using an automated Thermal Cycler (MyCycler; BioRad, Italy). An aliquot of each sample was then subject to electrophoresis on a 1 % agarose gel in 1X TAE buffer (Bio-Rad) and bands were detected by ethidium bromide. Samples were run together with a 100 bp \pm 1.5 kb DNA ladder to control molecular weight of the DNA. The negative control (a reaction mixture without cDNA), confirmed the absence of genomic contamination. The PCR products from each primer set amplification were then cloned using pGEM[®]-T easy vector (Promega) and subsequently sequenced in both directions (T7 and SP6).

TaqMan[®] real-time reverse transcription PCR was performed on a StepOne Real-Time PCR System (Applied Biosystems, Italy) using Assays-by-DesignSM PCR primers (Applied Biosystems) and gene-specific fluorogenic probes. Primer sequences and TaqMan[®] probes of target genes were the following:

Target gene: Sea bass CAT.

Forward primer: 5'-ATGGTGTGGGACTTCTGGAG-3'

Reverse primer: 5'-GCTGAACAAGAAAGACACCTGATG-3'

TaqMan[®] probe: 5'-CAGACACTCAGGCCTCA-3'

Target gene: Sea bass SOD.

Forward primer: 5'-TGGAGACCTGGGAGATGTAAC TG-3'

Reverse primer: 5'-TCTTGTCCGTGATGTCGATCTTG-3'

TaqMan[®] probe: 5'-CAGGAGGAGATAACATTG-3'

Target gene: Sea bass GPX.

Forward primer: 5'-AGTTAATCCGGAATTCGTGAG-3'

Reverse primer: 5'-AGCTTAGCTGTCAGGTCGTAAAC-3'

TaqMan[®] probe: 5'-AATGGCTGGAAACGTG-3'

Target gene: Sea bass IGF-I.

Forward primer: 5'-GCAGTTTGTGTGTGGAGAGA GA-3'
 Reverse primer: 5'-GACCGCCGTGCATTGG-3'
 TaqMan[®] probe: 5'-CTGTAGGTTTACTGAAATAAA A-3'

Target gene: Sea bass IGF-II.

Forward primer: 5'-TGCAGAGACGCTGTGTGG-3'
 Reverse primer: 5'-GCCTA CTGAAATAGAAGCCTC TGT-3'
 TaqMan[®] probe: 5'-CAAACCTGCAGCGCATCC-3'

Target gene: Sea bass MyHC.

Forward primer: 5'-TGGAGAAGATGTGCCGTACTC T-3'
 Reverse primer: 5'-CGTGTCATTGATTTGACGGACA TTT-3'
 TaqMan[®] probe: 5'-AACTGAGTGAAGTGAAGACC-3'

Data from TaqMan[®] PCR runs were collected with ABI's Sequence Detector Program. Cycle threshold (Ct) values corresponded to the number of cycles at which the fluorescence emission monitored in real time exceeded the threshold limit. The Ct values were used to create standard curves to serve as a basis for calculating the absolute amounts of mRNA in total RNA. To reduce pipetting errors, master mixes were prepared to set up duplicate reactions (2 × 30 µl) for each sample.

Statistical Analysis

Results are given as mean ± SD. Survival, growth, fatty acid, ossification degree and molecular biology data were tested for normality and homogeneity of variances with Levene's test, not requiring any transformation. Chi-squared test was employed for incidence of muscular lesions, deformities and TBARS content. Survival, growth, fatty acid, ossification degree and molecular biology data were treated by one-way ANOVA. Means were compared by Duncan's test ($P < 0.05$) using SPSS for Windows 14.0 (SPSS, Chicago, IL, USA, 2005). For analysis of one-way ANOVA, the following general linear model was used:

$$Y_{ij} = m + D_i + e_{ij}$$

where Y_{ij} is the mean value of the tank, m is the mean population, D_i is the fixed effect of the diet and e_{ij} is the residual error.

Results

The diet containing about 1 % DHA (diet 1/1,500) showed higher amounts of monoenoic fatty acids than diets containing 5 % DHA (5/3,000 and 5/3,000 + vitC) due to the

higher oleic acid content in the former diet (Table 2). DHA contents in the diets varied from 4.58 % of total fatty acids in the 1/1,500 diet, 24.55 % in the 5/3,000 diet and 27.54 % in the 5/300 + vitC diet. Elevation of dietary DHA (5/3,000 diets or 5/3,000 and 5/3,000 + vitC diets) increased n-3 PUFA and n-3 LC-PUFA fatty acids contents, as well as n-3/n-6 PUFA ratio. α -TOH levels were more than 2 times higher in diets containing 3,000 mg/kg compared to the control diet (1/1,500) (Table 3). vitC contents were also higher in the diet supplemented with vitC than in the others.

All experimental diets were well accepted by larvae. The highest total length was found in the 1/1,500 diet larvae. Increasing DHA from 1 to 5 % in the 5/3,000 diet larvae, significantly reduced larvae total length, despite the α -TOH increase. However, vitC levels in the 5/3,000 + vitC diet enhanced larval total length compared to the 5/3,000 diet larvae ($P = 0.005$). Sea bass larvae survival or dry weight was not significantly different among the treatments (Table 4).

The level of lipid peroxidation-derived aldehydes, as indicated by TBARS content (nmol/g larval tissues) was lowest in larvae fed diet 1/1,500 and was significantly higher in larvae fed the higher DHA content (5/3,000 and 5/3,000 + vitC) diets. However, the inclusion of vitC prevented the formation of hydroperoxides, observed by a decrease in TBARS levels. The lowest α -TOH content was found in larvae fed 5/3,000 diet. However, an increase in dietary vitC contents increased α -TOH levels in larvae fed 5/3,000 + vitC diet. Regarding larval α -TOH contents, the elevation of dietary vitamin E in diet 5/3,000, together with the increase in DHA, in comparison to diet 1/1,500, did not significantly affect the α -TOH contents in the larvae (Table 4).

Fatty acid composition of the larvae (Table 5) generally reflected the fatty acid composition of the diet. Accordingly, a higher content of 18:1n-9 was observed in 1/1,500 larvae. However, its retention rate regarding dietary levels was much lower in 1/1,500 larvae (47.30 %) than in 5/3,000 (67.22 %) or 5/3,000 + vitC larvae (67.82 %), balancing the monoenoic acids content among larvae fed the different dietary treatments. Equally, EPA retention was low in all larvae, especially in those fed 5/3,000 (43.93 %) and 5/3,000 + vitC (43.96 %) diets. The highest content of total n-3 LC-PUFA ($P = 0.006$) was observed in larvae fed the diet supplemented with vitC probably due to a higher dietary content. However, regarding 22:6n-3 content, the highest retention rate was observed in 1/1,500 larvae. Similarly 20:4n-6 was highly retained in larvae fed the 1/1,500 diet, although higher contents were found in larvae fed diets 5/3,000. In contrast to the differences in the n-3/n-6 ratio observed in diets, no differences were observed in larvae among the different treatments.

Histopathological examinations revealed the presence of lesions affecting larvae axial musculature, showing the typical features of necrotic degeneration of muscle.

1/1,500 1 % DHA and 1,500 mg/kg vitamin E diet; 5/3,000 5 % DHA and 3,000 mg/kg vitamin E diet; 5/3,000 + vitC 5 % DHA and 3,000 mg/kg vitamin E diet with increased ascorbic acid content

The incidence of muscular lesions increased with DHA dietary content (5/3,000 diet; Table 4). However, inclusion of vitC (5/3,000 + vitC diet) proved to be effective in reducing incidences to less than half of those in 5/3,000 larvae. More detailed features of muscular lesions could be observed on semithin and TEM sections, where muscle degeneration with the presence of hydropic vacuoles and organelles swelling within some of the affected fibers was found in larvae fed the 5/3,000 diet. Some fibers presented disarrangement of the myofilaments just like myelin figures, denoting intracellular lipid oxidation (Fig. 1).

Regarding skeletal morphology, among larvae measuring 10–12 mm, 28.33 ± 1.30 % of the larvae fed the 1/1,500 diet showed skeletal deformities, and similar values were found in those fed the 5/3,000 + vitC diet (29.67 ± 6.51 % of the larvae analyzed). Larvae fed the 5/3,000 diet presented 33.11 ± 5.11 % deformities, but no statistical differences were detected between groups ($P = 0.10$; Table 4). The ossification degree of 35 dph sea bass larvae was determined in terms of surface of mineralized bones per larval surface (Table 4). High dietary levels of DHA decreased the formation of mineralized bone in larvae, whereas increased vitC did not affect mineralization.

Different types of deformities were observed at the end of the experimental period, depending on the level of dietary DHA. All of the experimental groups exhibited a statistically similar percentage of kyphosis, however, no lordosis was observed in larvae fed the 1/1,500 diet (Fig. 2). Skull deformities were especially high in fish fed high DHA levels, although vitC increase reduced the incidence of this deformity ($P = 0.013$).

The general pattern of gene expression, excepting IGF-II, in all groups of sea bass larvae was characterized by a rapid increase between 14 and 26 dph (Figs. 3, 4). CAT gene expression was elevated in larvae fed diets containing a high content of DHA, the highest number of mRNA copies being found in larvae fed diet 5/3,000 + vitC

($P = 0.027$; Fig. 3a). The SOD mRNA expression was also highest in 5/3,000 groups ($P = 0.048$; Fig. 3b). Accordingly, GPX gene expression was quite strong in larvae fed diets containing a high level of DHA compared to larvae fed low levels ($P = 0.039$; Fig. 3c).

The IGF-I gene expression increased from 14 to 26 dph in all treatments, at day 35 showing a decrease in the 1/1,500 and 5/3,000 + vitC fed larvae and a continuous increase in the 5/3,000 fed larvae (Fig. 4a). Regarding IGF-II, gene expression was higher in larvae fed 5/3,000 and 5/3,000 + vitC diets than in those fed diet 1/150 throughout the trial (Fig. 4b).

Table 3 Proximate composition, α -tocopherol and ascorbic acid content (mean \pm SD) in experimental diets fed to sea bass larvae for 3 weeks

| | Diets | | |
|---------------------------------|----------------------|----------------------|----------------------|

MyHC gene expression was low in larvae fed diet 1/1,500 and significantly increased by the elevation of both α -TOH and DHA in diet 5/3,000 (Fig. 4c). However, the increase in vitC in diet 5/3,000 + vitC significantly reduced MyHC expression to levels similar to those of the 1/1,500 diet.

Discussion

Marine fish larvae are subjected to high levels of oxidative stress when using inert diets due to the high content of LC-PUFA, particularly DHA, and pro-oxidants such as minerals as well as the high surface to volume ratio of these feed particles [56]. Therefore, inclusion of high dietary levels of LC-PUFA to match the high requirements of marine fish larvae may call for increased dietary supplementation with antioxidants such as α -TOH to prevent oxidative damage. For instance, increasing DHA by up to 5 % in diets for sea bass markedly reduced larval survival and growth and increased the incidence of muscular lesions [43]. Even if no differences were observed among treatments in terms of final survival, survival rate ranged from 48 % in larvae fed 5 % DHA diets to 60 % in those fed 1 %. This survival rate may seem low if compared to results obtained from other larval experiments [57], but it is worth mentioning that low larval performance has been related to the use of inert microdiets [58], being improved by cofeeding with rotifers or artemia [58]. Nonetheless, our survival rates were similar to or even higher than those

Table 4 Sea bass larvae performance and levels of lipid peroxidation products (TBARS) and vitamin E (α -tocopherol) content in sea bass larvae at the beginning and after eating the experimental diets with two levels of DHA (1 and 5 %) and α -tocopherol (1,500 or 3,000 mg/kg) and supplemented or not with ascorbic acid (1,800 mg/kg) for 3 weeks

obtained in other nutritional experiments in sea bass larvae employing both live prey (3.6 %, [59]) or inert microdiets (41 %, [60]; 33.5 %, [61]), indicating that our results are within normal range. The same applies for growth and deformities rates as around 30 % of marine fish larvae reared in commercial hatcheries exhibit morphological and skeletal deformities [62].

In the present study, high levels of α -TOH (3,000 mg/kg) together with high DHA (5 %) were not able to counteract the adverse effects of lipid oxidation on the incidence of muscular lesions. Accordingly, these larvae showed very high levels of TBARS indicating that their oxidative status is altered when they are fed high DHA levels even at such high dietary α -TOH levels. Moreover, AOE expression was higher in those larvae, denoting a high antioxidant response. A compensatory induction of these endogenous antioxidants is found in animals exposed to dietary oxidative stress [63]. Indeed, α -TOH contents in these larvae were not increased by the elevation of dietary α -TOH levels, suggesting, on the one hand, a prooxidant effect of this vitamin due to the high levels included in the diet or, on the other hand, a depletion of this vitamin to neutralize ROS. Similarly, increased n-3 LC-PUFA did cause depletion of α -TOH contents when this vitamin was supplemented in the diet in previous studies [56, 64, 65].

In contrast, the increase in vitC dietary supplementation from 1,800 to 3,600 mg/kg markedly improved the protection against peroxidation, decreasing TBARS contents to less than one-third, sparing vitamin E that was significantly increased in larval tissues, and effectively reducing the incidence of muscular lesions. vitC supplementation has also been found to reduce TBARS formation in hybrid striped bass (*Morone chrysops* ♀ × *M. saxatilis* ♂) fed diets deficient in α -TOH [26]. The increased α -TOH content found in the present study when larvae were fed high levels of vitC is in agreement with studies in other fish species [19, 21, 56] and denotes the sparing effect of vitC

Fig. 1 Longitudinal semithin (a) and transversal electron micrographs (b) of sea bass (*Dicentrarchus labrax*) larvae fed the 5/300 diet. **a** Damaged muscle fibers showing breakage (arrow) as well as darkening due to protein coagulation (asterisk). **b** Affected fiber showing disarrangement of the myofilaments (arrows), swollen sarcoplasmic reticulum (SR) and myelin figures (asterisk)

on α -TOH in sea bass larvae, the first vitamin recycling the second one. Thus, under dietary conditions of high LC-PUFA and α -TOH, vitC dietary contents of 1,800 mg/kg may not be sufficient to recycle α -TOH and prevent the high rate of ROS formation and, therefore, vitC requirements may be higher than under low oxidation risk dietary situations.

vitC is known to be a powerful antioxidant by efficiently trapping peroxy radicals in the aqueous phase before they can initiate lipid peroxidation, thereby protecting the biomembranes [66]. Thus, the decrease in the incidence of muscular lesions observed in the present study, when high levels of vitC were employed, could be due to the

Fig. 2 Skeletal deformities found in 35 dph larvae at the end of the experimental period

protective effect of this antioxidant nutrient, quenching free radicals before they can attack muscular membranes, in addition to recycling α -TOH. Moreover, the species formed after the loss of one electron are relatively stable and fairly unreactive compared to tocopheroxyl radical [67], thus preventing a pro-oxidant action. The reduced incidence of muscular lesions was also accompanied by a decrease in IGF-I expression, the highest IGF mRNA copies occurring in larvae fed the highest DHA and α -TOH levels, which also showed the lowest growth and the highest incidence of muscular lesions. These results are in line with the higher expression of IGF-I found in sea bream larvae fed high DHA levels [68]. In contrast to the present study, in sea bream, high IGF-I expression was correlated with high growth [68], suggesting the negative effect of high DHA contents in sea bass growth in relation to the altered oxidative status. A feasible explanation for the overexpression of IGF-I in larval groups with higher TBARS values could be a compensatory mechanism in fish larvae to try to counteract the adverse effects of ROS, since IGF-I interferes with activation of apoptosis in several cells and organ systems in mammals [69]. For instance, an increase in IGF-I has been found to suppress oxidative stress in atherosclerotic Apo-E-deficient mice [70]. Furthermore, the IGF system can promote muscle growth and differentiation in fish, by activating cell proliferation and DNA synthesis. Thus, the increase in mRNA copies of IGF-I observed in larvae fed 5 % DHA and 3,000 mg/kg α -TOH could also be due to the compensatory regeneration process carried out by satellite cells, and which was not directly reflected on a growth improvement. This is supported by the results of MyHC expression, as a high expression of myosin has been associated with regeneration processes in sea bream after mechanical injury [71]. In addition, in the present study, IGF-I and MyHC expression follows a similar pattern, indicating that their biological functions may be interrelated. In this sense, it is known that

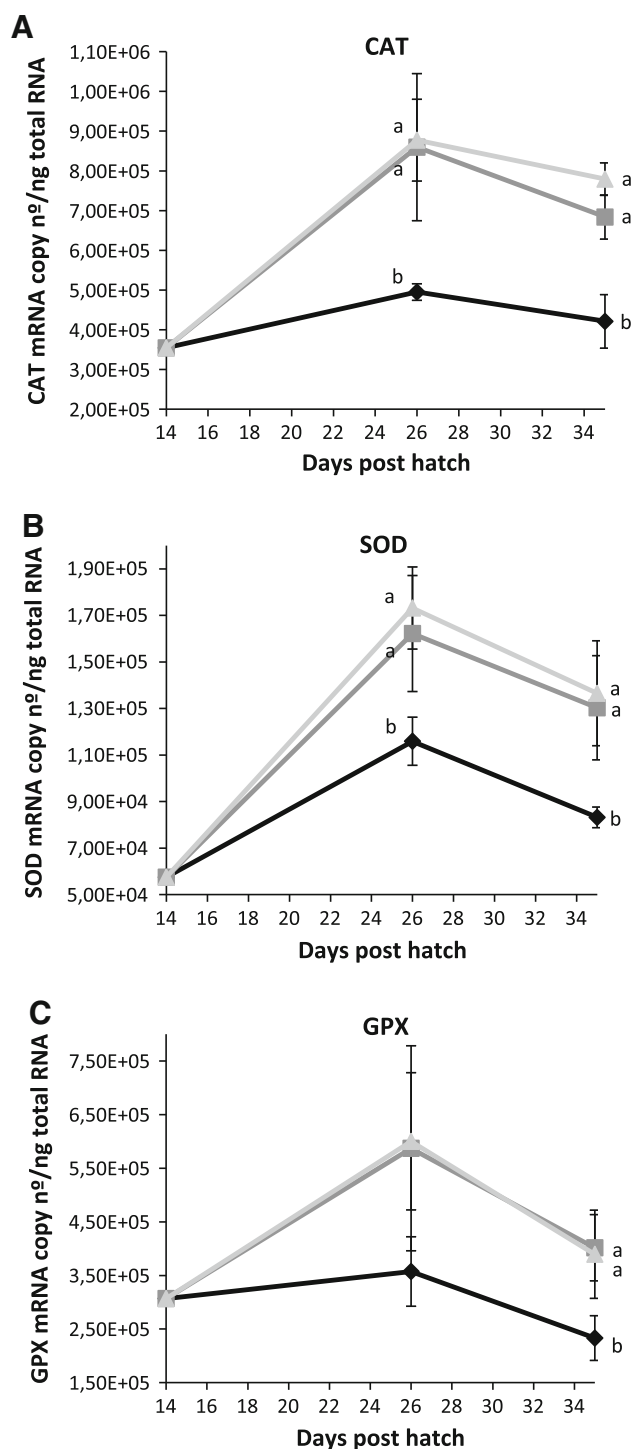

Fig. 3 Catalase (CAT), superoxide dismutase (SOD) and glutathione peroxidase (GPX) expression levels measured by real-time PCR in *Dicentrarchus labrax* larvae fed diets 1/150 (filled diamond), 5/300 (filled square) or 5/300 + vitC (filled triangle). mRNA copy number of each gene was normalized as a ratio to 100 ng total RNA. Values are means, with standard deviations represented by vertical bars. Mean values with different letters were significantly different in gene expression among the treatments at a given sampling points

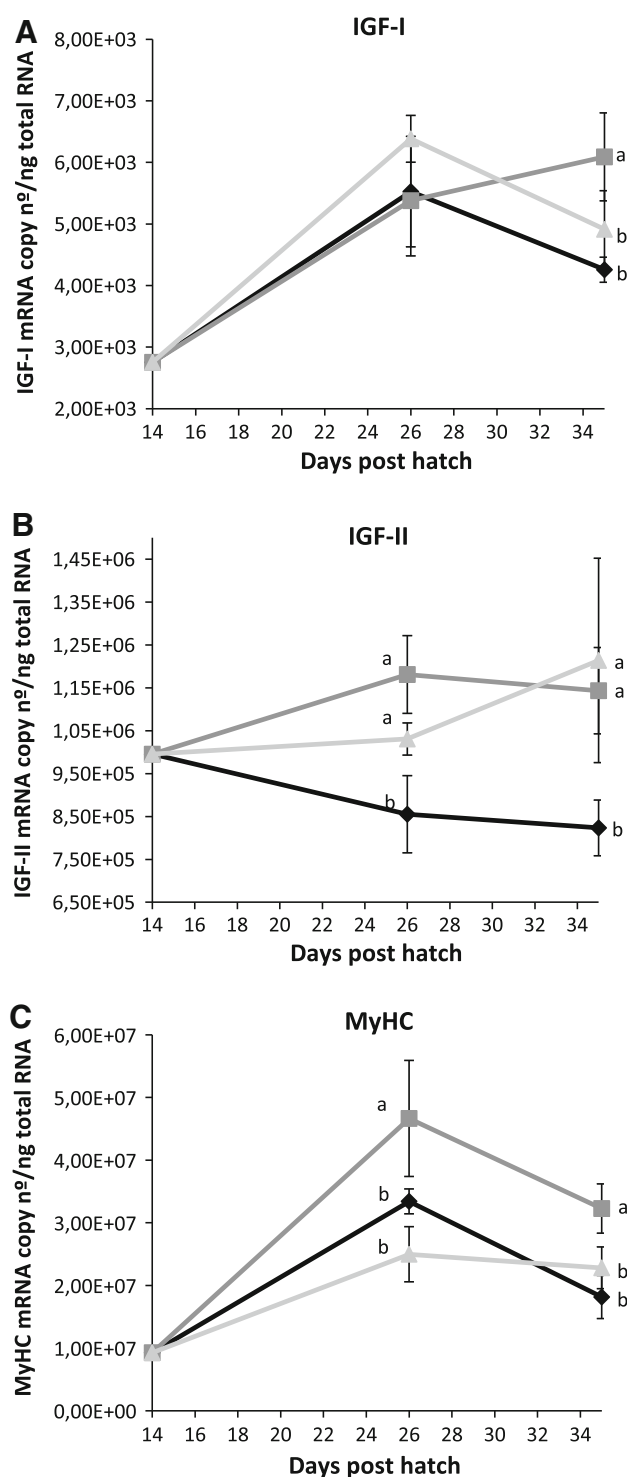

Fig. 4 Insulin-like growth factors I and II (IGF-I and II) and myosin heavy chain (MyHC) expression levels measured by real-time PCR in *Dicentrarchus labrax* larvae fed diets 1/150 (filled diamond), 5/300 (filled square) or 5/300 + AA (filled triangle). mRNA copy number of each gene was normalized as a ratio to 100 ng total RNA. Values are means, with standard deviations represented by vertical bars. Mean values with different letters were significantly different in gene expression among the treatments at a given sampling points

IGF-I overexpression results in greater skeletal muscle mass in fine flounder (*Paralichthys adspersus*, [72]) and in mice, in which IGF-I can activate MyHC as well as other transcriptional factors [73]. Thus, the parallel increase in IGF-I and MyHC expression observed in the present study confirms that, when sea bass larvae are subjected to oxidative stress, a compensatory overexpression of genes related to cell/muscle proliferation occurs.

In the present study, vitC elevation did not reduce the expression of AOE genes, suggesting an antioxidant effect independently of these enzymes, but acting in parallel with them to quench ROS. vitC acts as a cofactor for at least eight enzymes involved in the biosynthesis of collagen and carnitine, conversion of the neurotransmitter dopamine to noradrenaline, metabolism of tyrosine, and amidation of peptide hormones. In this sense, vitC acts with peptidyl-glycine α -amidating monooxygenase (PAM), an enzyme that adds amide groups to peptide hormones, greatly increasing their stability [74, 75]. Thus, the antioxidant role of vitC in fish might not only be reduced to trapping peroxy radicals from the aqueous phase or recycling α -TOH but also to support the formation of molecules with sound antioxidant potential. More studies are required to clarify the interrelationships between the different components of antioxidant defenses in marine fish, as well as to corroborate if the AOE activity really reflects their gene expression.

In terms of skeletal deformities, it can be observed that a DHA increase up to 5 % raised the incidence of alterations in chondroid bone, such as that of the cranium, whereas no differences were found in other deformities attaining intramembranous bone, such as kyphosis. These results match with previous studies on sea bream larvae fed high DHA rotifers (5.2 % DW; [68]), as ROS are known to actively destroy cartilage tissue [76], therefore affecting chondroid bones with characteristics of cartilage rather than directly affecting intramembranous bones. However, in the same study, in contrast to the present one, the incidence of cranial deformities was reduced when high contents of α -TOH were included in the rotifer enrichment media, in relation to the reduced TBARS and AOE expression. In another study from our research group [77], inclusion of organic selenium to diets containing high DHA and α -TOH was enough to decrease the TBARS values, but not to reduce cranial deformities, suggesting that the appearance of these kinds of deformity could not only be related directly to the DHA oxidation but also to the deficit of vitC due to the pro-oxidant environment originated by the high levels of α -TOH and LC-PUFA. Similarly, in the present study, an extra dosage of vitC proved to be efficient in reducing the incidence of cranial deformities when high levels of DHA are included in the diets. Apart from being a potent antioxidant, vitC acts with

three enzymes that participate in collagen hydroxylation by adding hydroxyl groups to the aminoacids proline or lysine in the collagen molecules, greatly increasing stability of the collagen [68]. Thus, the protective effect of vitC on chondroid bones could be due both to its antioxidant activity and to a higher stability in the cartilage formation. Recent work on sea bass larvae also showed a reduction in the incidence of cranial deformities when enhanced levels of vitC were included in the diet (50 mg/kg; [27]). However, in the same study, elevated levels of this nutrient (400 mg/kg) caused a similar percentage of deformities to diets with a deficiency in vitC. In the present work, the levels of vitC employed are much more elevated (1,800 mg/kg), but it also has to be noted that levels of vitC higher than those required for growth are necessary to satisfy the demands of other nutrients, in this case, to counteract the depletion in α -TOH caused by ROS.

The appearance of lordosis in fish fed high DHA and α -TOH content could be related to the high IGF-I expression observed in these larvae caused by an imbalance in the development of the musculoskeletal system, in agreement with previous studies [78]. On the one hand, the high incidence of muscular lesions occurring in these larvae may also contribute to increase the lordosis rate, as a result of the increased muscular tensions created during tissue regeneration. In this sense, Madsen and Dalsgaard [79] showed that the rainbow trout fry syndrome, characterized by muscular dystrophy among other pathologies, was associated with an increased incidence of vertebral deformities. On the other hand, IGF-II expression follows a different tendency within each dietary treatment and also as compared to IGF-I expression. These differences may support the idea that different hormonal signals and mechanisms of gene transcription control the regulation of expression of both IGF forms [80, 81].

In conclusion, an increased dosage of vitC in microdiets for sea bass larvae containing a 5 % of DHA and 3,000 mg/kg of α -TOH was shown to be successful in compensating, to some extent, the effect of lipid oxidation, thereby preventing the appearance of muscular lesions and reducing cranial deformities and TBARS values, a major indicator of oxidative stress. However, no counteracting effect was found on AOE expression, suggesting that other nutrients could be involved in enhancing the antioxidant defenses at such levels. Moreover, a sparing effect between vitC and α -TOH seems to occur in sea bass larvae. The implication of vitC in regulating other antioxidant components requires further investigation.

Acknowledgments Mónica B. Betancor was supported by a grant given by the Cabildo Insular de Gran Canaria. The present study was funded by the Spanish Ministry of Sciences and Education (AGL2009-14661). The experiments were designed according to the Animal Welfare Ethics Committee guidelines of Las Palmas

University. Acknowledgments are due to Instituto de Acuicultura de Torre la Sal that kindly provided the sea bass eggs and to Croda Company that provided DHA and EPA 50.

Introduction

Long chain omega-3 (or n-3) fatty acids and alpha-linolenic acid (ALA), are essential for growth and early development, and may play important roles in prevention and treatment of coronary artery disease, hypertension, arthritis, diabetes, and cancer, as well as other inflammatory disorders [1, 2].

Flaxseed (FS) is an oilseed that contains substantial ALA; based on work in our laboratory, as well as that of others, its inclusion in cattle diets increases ALA concentrations in blood plasma, fat and muscle tissues [3–6]. Compared to FS, high oleic acid sunflower seed (SS) contains similar concentrations of linoleic acid (LA), and low concentrations of ALA, but is rich in oleic acid (OA). Consequently, these two oilseed sources may differ in their effects on fatty acid profiles in plasma and subcutaneous fat (SQ) and perhaps growth performance of feedlot cattle. Wheat dried distillers' grains with solubles (DDGS) are a by-product of bioethanol production that can substitute for barley grain and barley silage in feedlot cattle diets [7–9]. Distillers' grains derived from triticale, a cross between wheat and rye, can also be a dietary ingredient for feedlot cattle and may have advantages over wheat as a substrate for ethanol production [10]. In previous studies, replacement of barley grain with wheat DDGS did not alter total *trans* fatty acids, however, it decreased 18:1-*n*-7 and increased vaccenic acid (VA), rumenic acid (RA or CLA-*c*9,*t*11) [11] and ALA in beef fat [12]. Replacement of barley silage with wheat DDGS in the diet of finishing steers also increased ALA concentrations of the pars costalis diaphragmatic muscle [13]. However, little information is available on the effects of a combination of oilseeds and DDGS in feedlot diets on fatty acid profiles in plasma and SQ fat of beef cattle during the finishing period. We hypothesized that inclusion of mixtures of FS or SS with DDGS in finishing feedlot diets, compared to addition of these ingredients alone, will result in more favorable changes in plasma and adipose tissue fatty acid profiles of beef cattle.

Materials and Methods

Animal and Feeding Experiment

The study was conducted at the Lethbridge Research Centre, Agriculture and Agri-Food Canada and was approved by the centre's Animal Care Committee, under the auspices of the Canadian Council of Animal Care [14]. British-continental steers (90) were stratified by body weight and randomly assigned to one of six finishing diets ($n = 15$ per treatment): (1) control (CON) diet, 90 %

barley grain concentrate + 10 % barley silage on a dry matter (DM) basis; and the following diets in which barley grain was substituted with: (2) 30 % DDGS; (3) 10 % FS; (4) 30 % DDGS + 8.5 % FS (FS + DDGS); (5) 10 % SS; and (6) 30 % DDGS + 8.5 % SS (SS + DDGS) (Table 1). Oilseeds in the combination diets were reduced to maintain total dietary lipid levels below 9 % of DM [15] and to determine if favorable changes in the fatty acid profile of adipose tissue could be maintained or enhanced at this reduced level. This approach reduced the likelihood of a fat-mediated reduction in DM digestion while maximizing the likelihood that the addition of oilseeds to the diet would alter the fatty acid profile of fat. With the addition of a vitamin and mineral supplement, all diets fully met or exceeded nutrient requirements of finishing cattle, as recommended by NRC [16] whereas the calculated net energy (NEm, NEg) levels were similar among the diets (Table 1). Steers were housed in individual pens and fed a total-mixed ration *ad libitum* at 0800 h daily. Orts were collected weekly to estimate daily feed intake of each individual. Barley silage DM was monitored weekly and did not vary sufficiently (<2 %) to merit reformulation of the diet. Steers were weighed at the start of the study and after 6 and 12 weeks to estimate average daily gain and the Gain:Feed ratio over the experimental period. At all three weighings, backfat thickness and rib eye area were estimated with ultrasonography [5], and amounts of trimmable fat and retail product in the carcass estimated [17].

Blood and Subcutaneous Fat Sampling

Blood samples were collected from the jugular vein using evacuated tubes (Becton–Dickinson, Franklin Lakes, NJ, USA) containing Na₂-EDTA at the start of the experiment and after 6 and 12 weeks, as previously described [4, 5]. An initial, subcutaneous fat biopsy (0.2–0.5 g) was recovered 15 cm to the left of the last thoracic vertebrae of each steer as previously outlined [5]. After 6 and 12 weeks, the second and the third biopsies were collected on the same side within the same region but 4 and 8 cm left of the scar from the first biopsy.

Lipid Extraction, Methylation and Gas Chromatograph Determination of Fatty Acids

Lipids in the samples were extracted using published procedures for plasma [4], feed samples and backfat [5]. Unless otherwise designated, all chemicals were purchased from Sigma-Aldrich Inc. (Oakville, ON, Canada). Nonadecanoic acid (C19:0) methyl ester (100 µL, 5.96 mg/mL hexane Nu-Chek Prep, Inc., MN, USA) was added to the lipids as an internal standard. A combined base/acid methylation procedure was used [5, 18]. A gas chromatograph

^a The supplement provided 1 kg diet (in DM) with additional: 14.67 mg copper, 58.32 mg zinc, 26.73 mg manganese, 0.66 mg iodine, 0.23 mg cobalt, 0.29 mg selenium, 4825 IU vitamin A, 478 IU vitamin D and 32 IU vitamin E

(Hewlett Packard GC System 6890, Mississauga, ON, Canada), equipped with a flame ionization detector and SP-2560 fused silica capillary column (75 m × 0.18 mm × 0.14 μm, Supelco Inc., Oakville, ON, Canada), was used for separation of fatty acid methyl esters (FAME) [5]. Peaks in chromatograms were identified and quantified using pure methyl ester standards and internal standard obtained from Sigma-Aldrich Inc. when available. Published information on retention time and elution order from previous reports was also used to tentatively identify 18:1-*n*10 and C18:2-*n*11,*c*15 isomers for which no commercial standards were available [19–21].

Statistical Analyses

Data for growth performance, backfat thickness, predicted productivity, and fatty acid composition of plasma and SQ fat were analyzed using the MIXED procedure of SAS [22]. The statistical model included DDGS, OS including FS and SS and the DDGS by OS interaction (DDGS × OS) as fixed effects. The MIXED procedure

with a REPEATED statement was conducted to compare changes of major fatty acids in plasma and backfat within the same treatment over the experimental period or to compare dietary effects within the same period. Turkey's test was used to perform a multiple comparison among treatment means [22].

Results

Dietary Nutrient and Fatty Acid Profiles

Inclusion of DDGS in diets increased dietary crude protein but decreased degradable carbohydrate levels on %DM basis (Table 1). Inclusion of FS or SS raised the dietary crude fat to a level >7 or 8 % respectively, whereas inclusion of DDGS increased dietary total unsaturated fatty acids (USFA) (Table 1). The FS diet had the highest ALA, whereas SS had the highest oleic acid (18:1-*c*9). Inclusion of DDGS in FS- and SS- diets slightly lowered USFA, while increasing LA in diets that contained oilseeds.

| 12 weeks | 0.18 | 0.15 | 0.18 | 0.15 | 0.17 | 0.14 | 0.01 | <0.01 | 0.02 [‡] | 0.73 |

[#] No difference ($P > 0.05$) between Non-OS-diets and FS-diets, and both $> SS$ -diets ($P < 0.05$)

[‡] FS-diets $> SS$ -diets ($P < 0.05$) whereas Non-OS-diets was in between ($P > 0.05$)

Growth Performance

Inclusion of DDGS reduced ($P < 0.01$) body weight although it tended to increase ($P = 0.08$) DM intake after the cattle had been fed diets for 6 and 12 weeks (Table 2). Inclusion of OS in the diet did not affect ($P > 0.05$) final body weight. Inclusion of DDGS in the diets decreased ($P < 0.05$) average daily gain during the first 6 weeks and over the entire 12 weeks experiment. The Gain:Feed ratio was also reduced ($P < 0.01$) as a result of inclusion of DDGS in the diets. Inclusion of SS reduced ($P = 0.02$) the Gain:Feed ratio during the first 6 weeks compared to CON and FS as well as during the overall 12 weeks compared to FS.

Backfat Thickness, Rib Eye Area and Predicted Productivity

After 12 weeks, average backfat thickness and rib eye area approximately doubled from the start of the experiment (Table 3). Inclusion of DDGS reduced ($P = 0.04$) backfat after 12 weeks. There was no significant difference in rib eye area among treatments. Compared to diets that did not contain DDGS, DDGS reduced ($P < 0.02$) trimmable fat and retail product as predicted by body weight, backfat thickness and rib eye area measured after 6 and 12 weeks.

Plasma Fatty Acid Profile

Inclusion of DDGS or OS in the diet increased ($P < 0.05$) plasma total FAME at 12 weeks (Table 4). When comparing mol%, the effect of two main factors (DDGS and

OS) on PUFA and MUFA were different ($P < 0.01$). Inclusion of DDGS increased ($P < 0.05$) PUFA concentrations, but decreased ($P < 0.05$) MUFA. Inclusion of FS resulted in higher ($P < 0.05$) PUFA compared to SS. There was a DDGS by OS interaction ($P < 0.05$) for total n-3 FA, *trans* 18:1, non-conjugated non-methylene interrupted dienes (NCD), *trans* FA, *trans* FA excluding CLA&VA. The FS group had the highest n-3 FA and ALA ($P < 0.05$) among the groups, whereas the FS and DDGS + FS groups were higher ($P < 0.05$) in total n-3 FA and ALA compared to CON and SS groups (Table 4).

Inclusion of DDGS increased ($P < 0.05$) LA which was the most abundant fatty acid in plasma, whereas FS resulted in less ARA ($P < 0.05$) compared to SS- and Non-OS-diets (Table 4). Dietary treatment had no effect on the major CLA e.g., 18:2-*c9,t11* or RA. The plasma lipids contained very small amounts of NCD, including 18:2-*t11,c15* with these concentrations being increased ($P < 0.05$) only in the FS group.

Inclusion of DDGS in CON and FS-diets decreased ($P < 0.05$) total *trans* FA and *trans* FA excluding CLA&VA, whereas SS did not (Table 4). The DDGS, FS and FS + DDGS groups were lower ($P < 0.05$) in total *trans* 18:1 compared to CON. Feeding DDGS decreased ($P = 0.03$) 18:1-*t10* without affecting ($P > 0.05$) 18:1-*t11*. Inclusion of DDGS decreased ($P < 0.01$) plasma concentrations of both palmitic acid (16:0) and palmitoleic acid (16:1). FS-diets resulted in less ($P < 0.05$) 16:0 compared to SS-diets and Non-OS-diets. There was a DDGS by OS interaction ($P < 0.01$) for stearic acid (18:0); the combination of SS and DDGS resulted in the highest ($P < 0.05$)

levels of plasma 18:0 among groups. Inclusion of DDGS decreased ($P < 0.01$) *cis* 18:1, including *c9* and *c15*. Inclusion of SS increased ($P < 0.05$) 18:1-*c9*, whereas FS increased ($P < 0.05$) 18:1-*c15*.

Temporal Changes in Plasma FA

The effect of oilseed inclusion in combination with DDGS on plasma 18:1-*c9*, CLA&VA, total n-3 FA, NCD and *trans* FA's excluding CLA&VA at 6- and 12-week is shown in Fig. 1. The mol% of plasma 18:1-*c9* was lower ($P < 0.05$) in FS + DDGS after 6 and 12 weeks whereas that in the CON and SS groups was higher ($P < 0.05$) after 12 weeks. Inclusion of DDGS to FS-diet resulted in lower plasma 18:1-*c9* after 6 and 12 weeks compared to levels at the start of the experiment. After 6 and 12 weeks, the mol% of plasma CLA&VA in DDGS, DDGS + FS and SS treatments were lower ($P < 0.05$) than at the start of the experiment. Total n-3 FA concentrations in cattle fed FS increased ($P < 0.05$) over the 12 weeks study, whereas these concentrations decreased ($P < 0.05$) in cattle fed CON, DDGS and SS-diets. Compared to the start of the experiment, plasma NCD did not change ($P > 0.05$) after 6 weeks, with the exception of an increase ($P < 0.05$) in cattle fed FS. However, by 12 weeks, plasma NCD concentrations declined ($P < 0.05$) in all treatments compared to either start or 6 weeks. The plasma total *trans* FA excluding CLA&VA decreased ($P < 0.05$) in cattle fed DDGS, but did not change ($P > 0.05$) in the CON over the experiment. Reductions in

plasma *trans* FA in DDGS, FS + DDGS, SS and SS + DDGS groups were lower ($P < 0.05$) than at the start of the experiment after 12 weeks.

Fatty Acid Profiles of Backfat

The mol% of PUFA in backfat was increased ($P < 0.05$) with inclusion of DDGS. It was also increased with inclusion of FS in the diet as compared to Non-OS or SS-diets, whereas concentrations of total SFA, USFA, MUFA and total CLA + VA were not affected ($P > 0.05$) by treatment (Table 5). Inclusion of FS increased ($P < 0.05$) n-3 FA and ALA with further increases ($P < 0.05$) occurring in these fatty acids as well as in LA when DDGS was included in the diet. Treatments had no effect on the major CLA i.e., 18:2-*c9,t11* or RA. There was a DDGS by OS interaction ($P = 0.03$) for NCD and 18:2-*t11,c15* concentrations in backfat, with FS having the highest ($P < 0.05$) concentrations of NCD and 18:2-*t11,c15* among treatments. Inclusion of DDGS with FS decreased ($P < 0.05$) NCD concentrations they were still higher ($P < 0.05$) than CON, SS and SS + DDGS (Table 5).

Inclusion of FS increased ($P < 0.05$) total *trans* FA and the *trans* FA excluding CLA&VA whereas SS increased ($P < 0.05$) total *trans* 18:1 (Table 5). Inclusion of DDGS decreased ($P < 0.05$) these fatty acids and 18:1-*t10*. Major SFA e.g., 16:0 and 18:0 and major *cis* MUFA e.g., 18:1-*c9* were not affected ($P > 0.05$) by treatments (Table 5; Fig. 2). Inclusion of FS increased ($P < 0.05$) 18:1-*c15* compared to

Table 4 Comparison on fatty acid profile of plasma samples at 12 weeks

the SS- and Non-OS-diets, whereas inclusion of FS or SS decreased ($P < 0.05$) 16:1-*c*9 compared to Non-OS.

Temporal Changes in Backfat FA

The effect of oilseeds inclusion in combination with DDGS on fat 18:1-*c*9, CLA&VA, total n-3 FA, NCD and *trans* FA excluding CLA&VA at 6- and 12-week is shown in Fig. 2. The mol% of 18:1-*c*9 in backfat increased ($P < 0.05$) over

the 12 weeks period in CON, DDGS and SS + DDGS and exhibited a trend in this direction in all the other treatment groups, whereas total CLA&VA decreased ($P < 0.05$) in CON and exhibited a trend in this direction in all the others. Total n-3 FA in FS and FS + DDGS groups consistently increased ($P < 0.05$) after 6 and 12 weeks, whereas these concentrations decreased ($P < 0.05$) in CON and SS-diets, but did not change ($P < 0.05$) in DDGS or DDGS + SS diets. Levels of n-3 FA were clearly enhanced ($P < 0.05$) in

In the present study, inclusion of flaxseed did not affect growth performance during the 12 weeks feeding period, which was generally consistent with a previous study on cull cows when 15 % flaxseed was added to a basal diet composed of 47.5 % barley silage DM [5].

Collection of three biopsy fat samples over the feeding period in the present study clearly documented how the fatty acid composition of adipose was altered by diets containing DDGS, FS and SS (alone or in combination). Inclusion of flaxseed in the diet consistently increased ALA and its biohydrogenation NCD intermediates in backfat, a finding consistent with our studies using cull beef cows fed diets containing 15 % flaxseed and 55 %

silage or hay [5]. Others have also found similar results with flaxseed in terms of an increase in the ALA content of meat from finishing steers [3, 26]. Furthermore, the present study is apparently the first report that inclusion of triticale DDGS along with flaxseed in the finishing diet resulted in an additional increase in ALA levels in backfat without a further increase in NCD. These results support our hypothesis that inclusion of a combination of DDGS and FS in a finishing diet further improves the fatty acid profile of beef through an additional increase in ALA concentrations in adipose tissue.

In several studies, DDGS has been assessed as a replacement for barley grain and silage in diets for feedlot

Fig. 2 Comparison of selected fatty acid composition in backfat over a 12 weeks feeding period. *Within a period, means differ from the initial ($P < 0.05$). #Within a period, means differ between 6 and 12 weeks and from the initial ($P < 0.05$). a–c Within a period, means without a common letter differ ($P < 0.05$)

cattle where their inclusion has primarily been from the perspective of as an energy source as opposed to a protein source [7–10]. Although DDGS was not rich in ALA content, it was recently found in our lab that substitution of wheat DDGS for barley and silage in a barley-based finishing diet increased ALA in total FAME by 28 % in the beef *pars costalis diaphragmatis* [13]. Furthermore, ALA in backfat linearly increased when wheat DDGS replaced barley grain in finishing diets of beef cattle [12]. The mechanism whereby increasing levels of DDGS elevate ALA in adipose tissue remains unclear. Inclusion of DDGS resulted in a 30–40 % increase in the ALA content of DDGS and SS + DDGS diets, a factor that maybe responsible the increased levels of ALA in backfat of steers fed these diets. However, the

inclusion of DDGS in the FS-diet reduced ALA intake by ~10 %, but increased the ALA in backfat of steers fed this diet by almost 20 % as compared to FS alone. The increase of ALA in backfat with inclusion of DDGS in the FS-diet may arise as a result of a number of factors including altered rumen microbial biohydrogenation, or changes in ALA absorption or metabolism in adipocytes [27]. The dienes, including 18:2-*t*11, *c*15, originate from the biohydrogenation of ALA and were found to increase concurrently with ALA in backfat from cull cows fed a 15 % FS-diet [5, 6]. In the present study, inclusion of DDGS with flaxseed resulted in substantial increase in ALA in backfat, but without a corresponding increase in the concentrations of less desirable end products of ALA metabolism such as 18:2-*t*11, *c*15.

The ALA in beef fat is primarily derived from the diet, although compared to monogastric animals, ruminants are far less efficient at incorporating dietary ALA into adipose tissue. Incorporation of ALA into adipose tissue of fattening horses was 10-fold higher than that observed in Japanese Black or Holstein steers fed similar diets [28]. In ruminants, a substantial portion of the dietary ALA in flaxseed is biohydrogenated by rumen bacteria, with concentrations reduced by approximately half after 24 h of rumen exposure [29]. Strategies to reduce the biohydrogenation of alpha-linolenic acid such as inclusion of tannins in the diets of cattle have only been marginally successful [29]. Vitamin E supplementation in beef cattle diets containing flaxseed increased n-3 fatty acids in beef intramuscular fat by approximately 18 % (from 2.0 to 2.4 % of total FAME [30]). Concomitantly, the dienes including 18:2-*n*-7, 11, 15 were also significantly increased by inclusion of vitamin E in a FS-diet [30], which differs from the observed reduction in dienes observed in the present study as a result of the inclusion of DDGS with FS.

In addition to rumen biohydrogenation, differences between ruminants and monogastric animals in de novo fatty acid synthesis may also affect the fatty acid profile in adipose tissue. Lipogenesis in bovine adipocytes largely depends on synthesis of fatty acids from volatile fatty acids (VFA) arising from rumen fermentation, with acetate and propionate predominating [31]. In a previous study, replacing barley grain and barley silage with triticale DDGS linearly decreased acetate without affecting average daily gain, but increased propionate in rumen of steers [10]. Similar results were also observed in cattle fed diets where wheat DDGS was substituted for these feedstuffs [32]. Such dramatic changes in the amount of acetate and propionate may affect de novo synthesis of SFA and MUFA. Acetate is more extensively used than propionate in fatty acids synthesis in bovine tissues [31] as it is mainly used for gluconeogenesis in the liver [33]. Promotion of high PUFA levels in plasma by inclusion of oilseed or DDGS in the diets may inhibit de novo synthesis of non-essential fatty acids [34], resulting in a proportional increase in ALA concentrations in adipose tissue.

Plasma ALA concentrations have been highly correlated with dietary intake of flaxseed in Holstein cows [4] and beef cows [5]. In the present study, there was a similar elevation in plasma ALA by inclusion of flaxseed in the diet, even though the levels of flaxseed (10 vs. 15 % diet DM) included in the diet were lower than those provided to cull beef cows [4, 5]. After 12 weeks of feeding, plasma ALA was higher in steers fed FS than in those fed DDGS + FS, presumably due to the higher level of flaxseed in the FS-diet compared to DDGS + FS.

Plasma NCD concentrations were reduced with DDGS, suggesting that addition of this by-product might alter ALA

biohydrogenation in the rumen, but the impact of DDGS on the flow of n-3 FA to the duodenum was not examined in this study. It has been suggested that low rumen pH may inhibit ruminal lipolysis and biohydrogenation [27, 35], conditions that are common in cattle fed high grain diets. This relationship was supported by a study where addition of pH neutralizing sodium sesquicarbonate to the rumen of cattle fed a barley grain diet temporarily resulted in a lower 18:1-*n*-7/*n*-11 ratio in beef [36]. Thus, replacement of barley grain with DDGS lowered starch and increased fiber content of the diet and may have increased ruminal pH. We infer that optimization of omega-3 concentrations in beef depends not only on the nature of the fatty acid profile delivered in the diet, but also on how ruminal biohydrogenation can be manipulated in a manner that favors the flow of omega-3 fatty acids to the lower intestinal tract.

Among the other biohydrogenation intermediates, percentage of CLA plus VA in plasma or adipose tissue was not affected by inclusion of DDGS or oilseeds. However, weight% of C18:1-*n*-7 in both plasma and adipose tissue was reduced by inclusion of DDGS. Inclusion of wheat DDGS in a barley grain-based finishing diet increased the ratio of 18:1 *n*-7/*n*-10 in fat of steers [11, 12], but no similar increase was reported in tail adipose tissue when triticale DDGS was included in a lamb finishing diet [23]. The effect of inclusion of DDGS on major *trans* 18:1 in plasma and fat tissues may also be attributable to alterations in ruminal biohydrogenation.

The high oleic SS that we used in the study contained 63 % OA and 29 % LA, which was opposite to that of high linoleic SS used in previous beef cattle studies with 14–17 % OA and 66–73 % LA [37–39]. However, it was relatively high in LA compared to the high oleic SS used by Gibb et al. [37] with 87 % OA and only 2 % LA. Inclusion of high linoleic SS in beef diets resulted in higher CLA in subcutaneous fat, whereas in the present study inclusion of high oleic SS did not affect CLA plus VA in fat. Furthermore, inclusion of high oleic SS did not affect growth performance, ultrasound backfat thickness or REA, consistent with a previous report [37]. In the present study there was no significant difference in most growth performance parameters, with the exception of the Gain:Feed ratio was lower for high oleic SS than FS.

Trimable fat is a major fat source for ground beef products and increasing the n-3 FA or ALA of this tissue may be the easiest avenue to produce ground beef products that reach the level required for a source omega-3 claim, which is a minimum 130 mg of ALA per 114 g serving in the USA [40] and as high as 300 mg total omega-3 per 100 g serving in Canada [41]. Although inclusion of DDGS in the FS affected performance and reduced predicted trimmable fat and the amount of predicted retail product as compared to FS alone, it did reduce the cost per kg feed and increased ALA

concentration in SQ fat. The total costs for flaxseed, barley and DDGS (average prices were 0.519, 0.211 and \$0.216 per kg respectively [42]) was \$165 per steer for both FS and FS + DDGS treatments (based on 12 weeks feed intake and diet composition) when performance differences were considered. The estimated trimmable fat at 12 weeks in the FS and FS + DDGS treatments could provide 556 and 640 g ALA per steer respectively. With the same feed cost after 12 weeks of feeding, the FS + DDGS treatment could provide 15 % more ALA in trimmable fat compared to FS treatment. In the present study, we were not able to compare complete retail products as the fatty acid compositions were estimated strictly from backfat biopsies. However, there were very close correlations on profiles of major fatty acids including ALA and total n-3 FA between backfat and muscle from beef cows fed with or without inclusion of flaxseed in previous studies [5, 6] and in other studies conducted in our laboratory [43].

In summary, inclusion of 30 % DDGS in a barley grain-based finishing diet with or without FS or high oleic acid SS reduced growth performance of finishing steers. However, inclusion of FS consistently increased ALA in beef cattle during the finishing period. Inclusion of a combination of DDGS and FS further increased ALA accumulation, but lowered levels of *trans* fatty acids and NCD concentrations in backfat. Mixtures of DDGS with FS could reduce the dietary costs associated with promoting favorable changes in the fatty acid profile of beef.

structurally to three types of analogs: (1) 4-saturated dihydroxy analogs comprising sphinganine (dihydrosphingosine), *trans*-8-sphingenine, and *cis*-8-sphingenine; (2) *trans*-4-unsaturated dihydroxy analogs comprising *trans*-4-sphingenine (sphingosine), *trans*-4,*trans*-8-sphingadienine [d18:2(t4,t8)], and *trans*-4,*cis*-8-sphingadienine [d18:2(t4,c8)]; and (3) 4-hydroxy analogs comprising 4-hydroxysphinganine (phytosphingosine), 4-hydroxy-*trans*-8-sphingenine [t18:1(t8)], and 4-hydroxy-*cis*-8-sphingenine [t18:1(c8)]. Among these analogs, the 8-unsaturated sphingoid bases are exclusively major components in plant glucosylceramides; *trans*-8-sphingenine and *cis*-8-sphingenine are found in limited members of plants such as Brassicaceae and Fabaceae as major components [8, 9]. In contrast, sphinganine, *trans*-4-sphingenine, and 4-hydroxysphinganine are minor or undetectable components in plants.

LC–MS/MS approaches have recently been applied for characterizing glucosylceramide molecular species in plants [10–14]. Despite this, molecular species profiles of the glucosylceramides that differentiate between *cis*-8 and *trans*-8 sphingoid bases are not yet clear in the previous approaches. It is important to develop appropriate techniques for determining the levels of the *cis*-8 and *trans*-8 isomers of sphingoid bases in individual glucosylceramide species, because glucosylceramide species have distinctive physicochemical properties depending on their *cis*-8 and *trans*-8 isomerism [15]. The application of octadecylsilyl (ODS) reversed-phase HPLC to analysis of plant glucosylceramides provides separation of peaks for individual species by acyl chain length and grade of desaturation of the fatty acid moiety. In addition, the peaks for individual species are also separated on the basis of the grade of desaturation and hydroxylation and the *cis*-8 and *trans*-8 isomerism of the sphingoid base moiety [15, 16]. Mobile phases described in the previous reports on LC–MS/MS analysis were rather expensive and complex in preparation [10–13]. We present here the first detailed molecular species analysis by reversed-phase HPLC coupled to ESI–MS/MS with a cost-effective and simple binary gradient for characterizing the *cis*-8 and *trans*-8 isomers of sphingoid bases, and glucosylceramides from rice callus and orchardgrass leaves were analyzed as a typical example of plant samples.

Materials and Methods

Chemicals and Plant Materials

Except where noted, all chemicals were of HPLC grade or highest grade available from Wako Pure Chemical (Osaka, Japan). Glucosylceramides from rice and soybean were purchased from Nagara Science (Gifu, Japan).

The seeds of rice (*Oryza sativa* L. cv. Koshihikari) were dehusked and washed with tap water to remove dust and

other surfactants. These seeds were then surface-sterilized with sodium hypochlorite solution (1 % active chlorine) containing 0.1 % Tween for 20 min, followed by rinsing with 70 % (v/v) ethanol for 30 s. The sterilized seeds were rinsed three times with sterile distilled water. These seeds were cultured for callus induction on modified Murashige and Skoog (MS) medium [17] with the nitrogen components replaced by those of N6 medium [18], supplemented with 30 g/L sucrose, 2 mg/L 2,4-dichlorophenoxyacetic acid, and 8 g/L agar (pH 5.8). The cultures were incubated at 28 °C in the dark. About 100 mg of callus obtained after 30 days of culture was harvested and used for lipid extraction. The seeds of orchardgrass (*Dactylis glomerata* L.) were germinated in a HYPONeX soil mixture (HyponeX Japan, Osaka, Japan) and grown at 28 °C for 3 weeks under a light/dark cycle of 16/8 h. About 1 g of medium-sized and not yet fully expanded leaves was harvested and used for lipid extraction.

Separation and Purification of Glucosylceramides

Total lipids from rice callus and orchardgrass leaves were extracted according to the method of Bligh and Dyer [19]. Then, the total lipids were subjected to mild alkaline hydrolysis with 0.4 M KOH for 2 h at 37 °C. The sample was separated in a Sep-Pak Plus silica cartridge (Waters, Milford, MA, USA) by eluting with chloroform/acetic acid

(100/1, v/v) and chloroform/methanol (2/1, v/v). The chloroform/methanol fraction was applied to liquid chromatography–tandem mass spectrometry (LC–MS/MS). For GC analysis, the chloroform/methanol fraction was separated by silica gel thin-layer chromatography (TLC) (Merck TLC plates, Sigma-Aldrich Japan, Tokyo), using chloroform/methanol/water (65/29/4, by volume) as the solvent system, and the spots of glucosylceramides were scraped off the TLC plates [20].

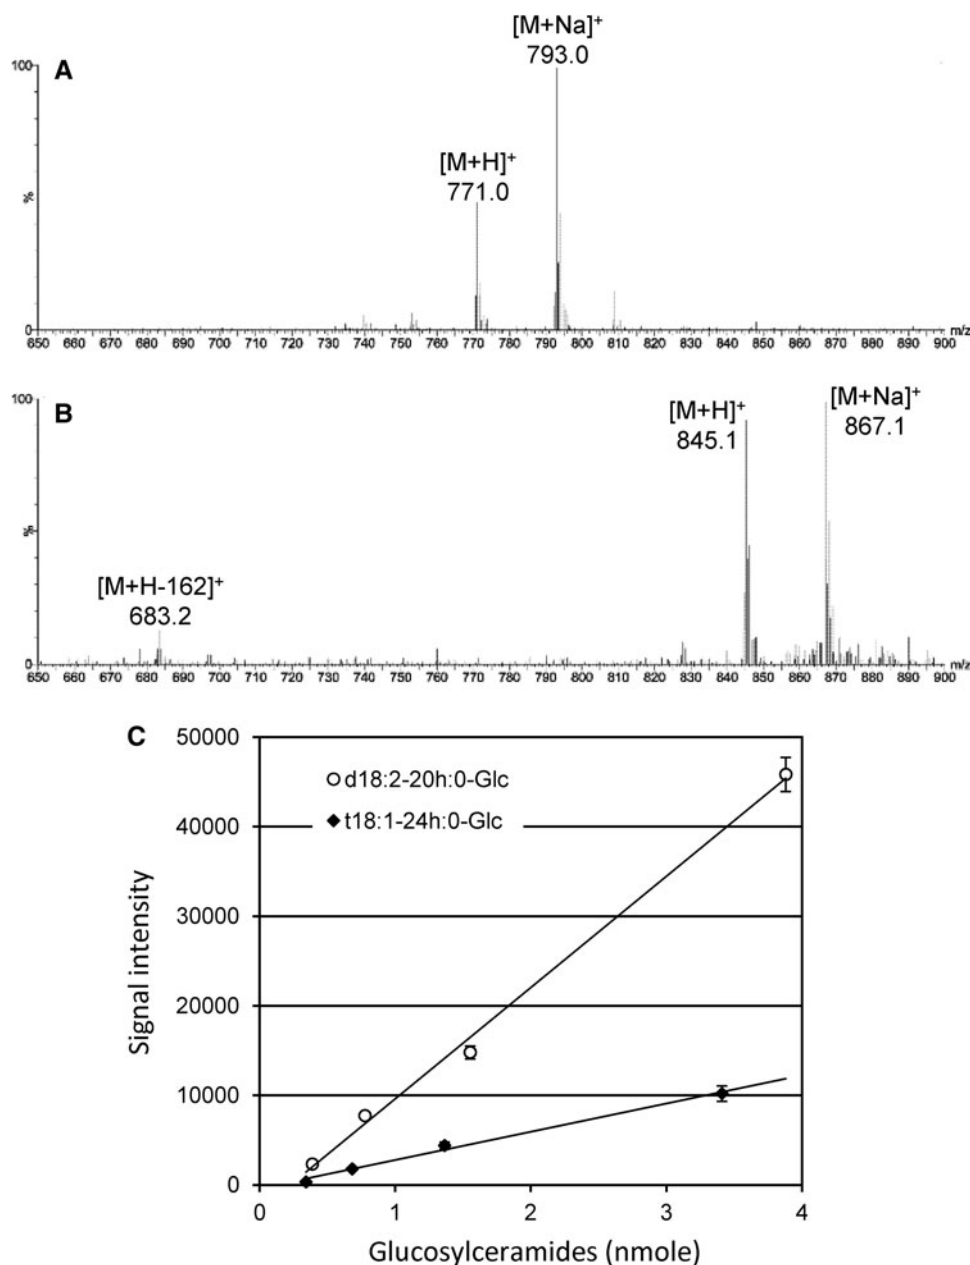

LC–MS/MS Analysis

The LC–MS/MS analysis was performed with NANO-SPACE SI-2 HPLC instruments (Shiseido, Tokyo, Japan)

coupled to an ACQUITY TQD tandem quadrupole mass spectrometer (Waters). Chromatographic separation was performed in two tandemly connected SUPERIOREX ODS columns [(250 × 2.0 mm i.d.) × 2, Shiseido] held at 40 °C. A binary elution gradient consisting of methanol/formic acid (1,000/1, v/v) as solvent A and water/formic acid (1,000/1, v/v) as solvent B was used. The flow rate was 200 µL/min with the following conditions: 95 % solvent A/5 % solvent B initially, then proceed to 100 % solvent A in a linear fashion after 60 min, and then maintained with 100 % solvent A for an additional 30 min. For each run, 1–5 µL of each sample was injected.

The transitions of the precursor ions $[M + H]^+$ to the main product ions of the sphingoid bases were used as

precursor/product ion pairs in the positive ionization multiple reaction monitoring (MRM) mode for quantification of the molecular species of the glucosylceramides. For glucosylceramides consisting of 4-hydroxy-8-sphingenine and 4,8-sphingadienine, the transitions of $[M+H]^+$ to 262 and for those with 8-sphingenine, the transitions of $[M+H]^+$ to 264, were used as precursor/product ion pairs; 30 channels of precursor/product ion pairs were selected based on the 2-hydroxy fatty acid composition of

glucosylceramides determined by GC [14]. The following conditions were used: capillary voltage, 3 kV; desolvation gas flow, 600 L/h; nebulizer gas flow, 50 L/h; source temperature, 120 °C; collision gas flow, 0.3 mL/min (4–5 mbar). Molecular species were identified by comparing their retention times with those authentic standards of glucosylceramides from rice, soybean (Nagara Science), and *Rumex obtusifolius* [14] when several peaks were detected.

HPLC and GC Analyses

Glucosylceramide molecular species with 4,8-sphingadienines and 2-hydroxy arachidic acid [i.e., d18:2(t4,c8)-20h:0-Glc and d18:2(t4,t8)-20h:0-Glc] and their species with 4-hydroxy-8-sphingenines and 2-hydroxytetracosanoic acid [i.e., t18:1(c8)-24h:0-Glc and t18:1(t8)-24h:0-Glc] were fractionated from commercially obtained rice and soybean glucosylceramides (Nagara Science) using an ODS column (SUPERIOREX ODS, 250 × 6.0 mm i.d., Shiseido). The glucosylceramide samples were analyzed with a NANOSPACE SI-2 HPLC system equipped with a 3002 UV-VIS detector (Shiseido). Chromatographic separation was performed in two tandemly connected SUPERIOREX ODS columns [(250 × 2.0 mm i.d.) × 2, Shiseido] held at 40 °C. Elution was carried out at 200 μL/min by isocratic flow with methanol/water (30/1, v/v). Glucosylceramide molecular species were detected by absorbance at 210 nm [15, 16, 21].

The glucosylceramides from rice callus and orchardgrass leaves, which were purified by TLC, were hydrolyzed with 3 % (w/v) HCl (gaseous) in dry methanol at 100 °C for 3 h to analyze the 2-hydroxy fatty acids. After adding water, the resulting fatty acid methyl esters were extracted with *n*-hexane. The 2-hydroxy fatty acid methyl esters were analyzed by a GC-18A gas chromatograph (Shimadzu Scientific) equipped with a TC-1 capillary column coated with dimethyl polysiloxane of 0.25 μm thickness (0.25 mm i.d. × 15 m; GL Science, Tokyo, Japan) and a hydrogen flame ionization detector (FID). The column temperature was programmed from 180 °C to 240 °C at 3 °C/min, and the injector and detector temperatures were maintained at 250 °C. 2-Hydroxy fatty acid methyl esters were identified by comparing their retention times with those of authentic standards that had been prepared from the 2-hydroxy fatty acids of glucosylceramides from rice, soybean (Nagara Science), and *Rumex obtusifolius*.

Four samples of the glucosylceramide molecular species fractionated by HPLC were hydrolyzed with 1 N HCl in

methanol at 80 °C for 18 h to analyze the sphingoid bases. The reaction mixture was washed twice with *n*-hexane and adjusted to pH 9.6 with 6 M KOH. The sphingoid bases were extracted with diethyl ether and converted to fatty aldehydes by the method of NaIO₄ oxidation [7]. The resulting fatty aldehydes were analyzed by GC (GC-18A; Shimadzu Scientific) equipped with a TC-70 capillary column coated with 70 % cyanopropyl polysilphenylene-siloxane of 0.25 µm thickness (0.25 mm i.d. × 60 m; GL Science) and a hydrogen flame ionization detector. The column temperature was maintained at 200 °C. The injector and detector temperature were maintained at 250 °C. Fatty aldehydes were identified by comparing their retention times with those of authentic standards that had been prepared from the sphingoid bases of glucosylceramides from *Lotus japonicus* [9].

Results and Discussion

The transition of precursor ions $[M + H]^+$ to the product ions of sphingoid base moieties was used for identifying and quantifying the glucosylceramide molecular species in plants (Table 1). Because of the variety of individual glucosylceramide species in plant samples, it is difficult to obtain authentic standards with identical chemistry to the glucosylceramides of interest, and commercially available standards are not chemically identical to glucosylceramide species found in plants. Glucosylceramide species such as d18:2(4,8)-20h:0-Glc and t18:1(8)-24h:0-Glc are generally found to be major constituents in plants belonging to the grass family [12, 15, 16, 22]. Thus, to determine the response of the mass-spectral signals, these molecular species purified from commercially obtained rice and soybean glucosylceramides were used as a panel of ideal standards that represent each type of glucosylceramide to be analyzed. In the positive full-scan mode, $[M + H]^+$ and $[M + Na]^+$ were the predominant signals (Fig. 1A, B). In t18:1(8)-24h:0-Glc, the loss of glucose $[M + H - 162]^+$ was detected. The calibration curves were almost linear within the examined range (Fig. 1C), suggesting that the linearity of the mass-spectral responses is good over the range in which the type 2 and 3 analogs are compared. However, the signal intensities were significantly different between d18:2(4,8)-20h:0-Glc and t18:1(8)-24h:0-Glc; d18:2(4,8)-20h:0-Glc showed about 3- to 4-fold greater intensities than did t18:1(8)-24h:0-Glc. From these data, signal intensity/mole factors for the type 2 and 3 analogs could be estimated as 3 and 1, respectively, and these factors were used for the calculation of the relative amount of the glucosylceramide molecular species in this study.

Although ESI-MS/MS approaches have enabled high selectivity and sensitivity for the identification and

Fig. 4 Comparison of relative peak areas (%) of molecular species containing the corresponding fatty acids as determined by LC-MS/MS and mol % of the major fatty acids determined by GC. In LC-MS/MS data, signal intensity/mole factors for glucosylceramides containing 4,8-sphingadienine [d18:2(4,8)] and 4-hydroxy-8-sphingenine [t18:1(8)] were set as 1 and 3, respectively. Methyl esters of the 2-hydroxy fatty acids formed by the methanolysis of glucosylceramides were analyzed by GC equipped with flame ionization detector. **A** Glucosylceramides from callus of rice; **B** glucosylceramides from leaves of orchardgrass. quantification of glucosylceramide molecular species in plants, it is essential to develop applicable methods for differentiation between *cis*-8 and *trans*-8 isomers of sphingoid bases in glucosylceramide species. It has been reported that binary or ternary solvent mixtures containing acetonitrile–water or methanol–tetrahydrofuran–water are applied to LC-MS/MS analysis of plant glucosylceramides as the mobile phase [10–12]. It is clear that the use of acetonitrile reduces instrumental pressure in comparison with methanol. On the other hand, acetonitrile and tetrahydrofuran are currently much more expensive than methanol. In addition, it has recently been required to develop

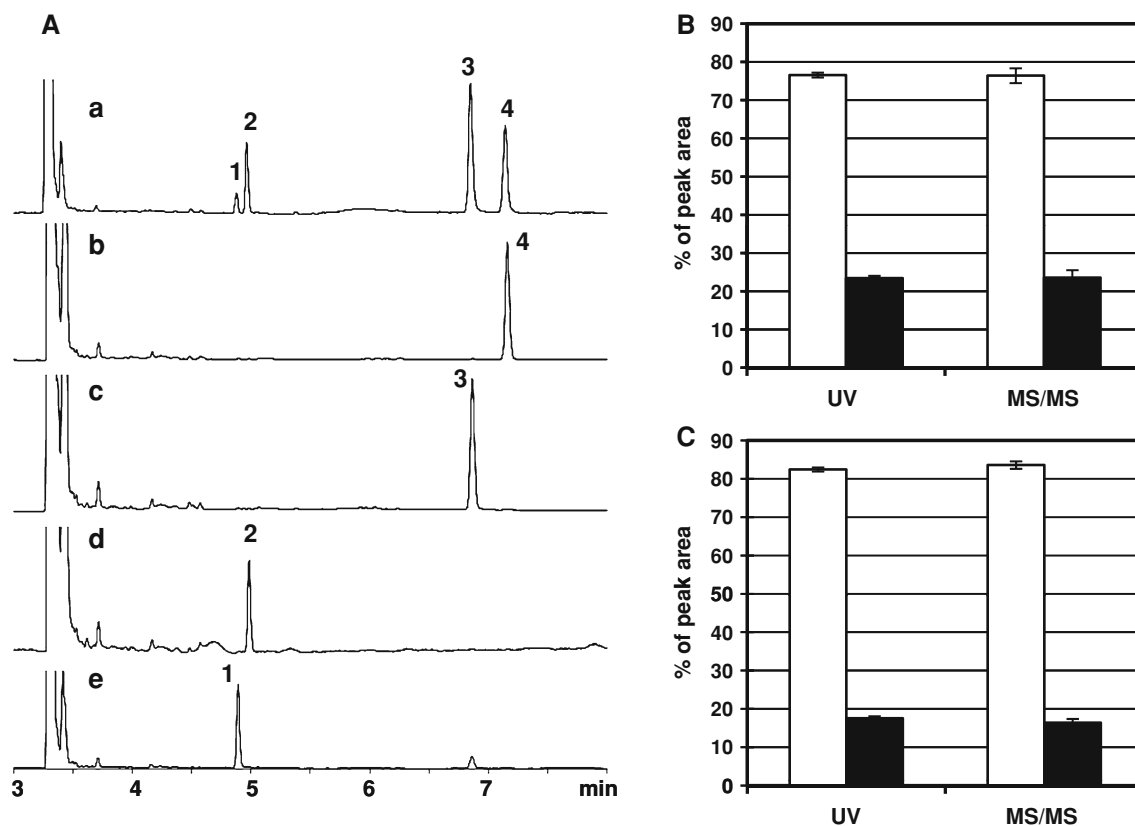

Fig. 5 Analyses of glucosylceramide molecular species having the *cis*-8 and *trans*-8 isomers of sphingoid bases. **A** GC profiles of fatty aldehydes converted from the corresponding component sphingoid bases of glucosylceramide molecular species: *a* an authentic standard prepared from the sphingoid bases of glucosylceramides from *Lotus japonicus* [9], *b* d18:2(t4,c8)-20h:0-Glc, *c* d18:2(t4,t8)-20h:0-Glc, *d* t18:1(c8)-24h:0-Glc, and *e* t18:1(t8)-24h:0-Glc. Peak numbers: 1 t18:1(t8), 2 t18:1(c8), 3 d18:2(t4,t8), and 4 d18:2(t4,c8). **B**, **C** Comparison of the relative peak areas (%) of major glucosylceramide species determined by spectrophotometry and ESI-MS/MS.

alternative methods to reduce or eliminate the use of acetonitrile because acetonitrile prices are unstable and will continue to rise prohibitively. For these reasons, an LC method with a cost-effective and simple binary gradient that enables sufficient separation of individual glucosylceramide species was optimized using methanol–water as a standard system of the mobile phase.

The total ion and selected chromatograms of glucosylceramides from callus of rice are shown in Fig. 2. Using two tandemly connected SUPERIOREX ODS columns, the column backpressure was about 11 MPa in 95 % solvent A/5 % solvent B. Molecular species containing 4,8-sphingadienine attached to 2-hydroxy fatty acids with 18–24 carbon chain length were substantially detected at complete baseline separations with two peaks (Fig. 2A, b–e). In contrast, molecular species containing 4-hydroxy-8-sphingenine attached to 2-hydroxy fatty acids with 20–26 carbon chain length were found in several peaks (Fig. 2A, h–k),

Spectrophotometry was performed under absorbance at 210 nm. **B** The level of the *cis*-8 and *trans*-8 isomers of glucosylceramide species containing d18:2(t4,c8)-20h:0 (open bars) and d18:2(t4,t8)-20h:0 (solid bars). Data represent mean \pm SD ($n = 3$). **C** The level of the *cis*-8 and *trans*-8 isomers of glucosylceramide species containing t18:1(c8)-24h:0 (open bars) and t18:1(t8)-24h:0 (solid bars). suggesting that the precursor ion selectivity for glucosylceramide species containing 4-hydroxy-8-sphingenine was little specific. For example, peak signals from Fig. 2A–c gave rise to false signal in Fig. 2A–h at 52.88 and 54.04 min. Thus, during the initial stages of this study, the transition of precursor ions $[M + H]^+$ to the product ion of m/z 298.3 was used for the identification and quantification of glucosylceramide molecular species having 4-hydroxy-8-sphingenine [11]; however, the signal intensity of the product ion was very low. For these reasons, the product ion of m/z 262.3 was used for 4-hydroxy-8-sphingenines [10]. Using a glucosylceramide standard purified from soybean glucosylceramides by HPLC, we confirmed that the peaks of t18:1(8)-24h:0-Glc were eluted at 68.47 and 69.64 min. The total ion and selected chromatograms of glucosylceramides from leaves of orchardgrass are shown in Fig. 3A. Molecular species containing monounsaturated 2-hydroxy fatty acids with 22 and 24 carbon chain length were detected. Despite

Fig. 6 Composition of the glucosylceramide molecular species from rice and orchardgrass: **A** callus of rice, and **B** leaves of orchardgrass. the retention times of the molecular species containing t18:1(c8)-22h:0 and t18:1(c8)-24h:1 being very close to each other (Fig. 3B, e, f), these species could be differentiated by their product ion spectra in the multiple reaction monitoring mode. Collectively, from these data and the evidence that the former and latter peaks are molecular species having the *cis*-8 and *trans*-8 isomers of sphingoid bases, respectively [15, 16], retention time plots were applied to identify glucosylceramide molecular species (Fig. 2B and 3B). A good fit was found in each of the four types of molecular species containing saturated hydroxy fatty acids, where the coefficients of determination r^2 were >0.998 .

The result of 2-hydroxy fatty acid composition achieved by HPLC-ESI-MS/MS was compared with that achieved by gas chromatography with flame ionization detection (GC-FID) (Fig. 4A), indicating that the two methods yield similar molar compositions. Analysis of glucosylceramides

in orchardgrass leaves by LC-MS/MS and GC-FID showed a tendency of the mass spectrometer to be more sensitive to 22h:1-containing glucosylceramide species than to other 2-hydroxy fatty acid-containing glucosylceramide species, suggesting that this is likely due to the enhancement of the analyte signal in the presence of matrix components. Nevertheless, the 2-hydroxy fatty acid compositions of the orchardgrass glucosylceramides determined by the two methods were similar overall (Fig. 4B).

The *cis*-8 and *trans*-8 configuration of sphingoid bases in four samples of the glucosylceramide molecular species [d18:2(t4,c8)-20h:0-Glc, d18:2(t4,t8)-20h:0-Glc, t18:1(c8)-24h:0-Glc, and t18:1(t8)-24h:0-Glc] fractionated by HPLC were confirmed by GC (Fig. 5A). The relative levels of the *cis*-8 and *trans*-8 isomers of sphingoid bases in these samples were determined by ultraviolet (UV) spectrophotometry and ESI-MS/MS. As shown in Fig. 5B, C, the *cis*-8 and *trans*-8 levels determined by ESI-MS/MS of both species were strikingly similar to those determined by UV spectrophotometry, indicating that both isomers have similar mass-spectral responses.

Molecular species containing d18:2(t4,c8)-20h:0 was the most abundant component, accounting for about 35 % of the total species in glucosylceramide samples from rice callus (Fig. 6A). Among molecular species containing 4-hydroxy-8-sphingenine, t18:1(c8)-24h:0-Glc was the predominant species, accounting for about 12 % of the total. In orchardgrass leaves, molecular species containing t18:1(c8) accounted for about 82 % of the total glucosylceramide species; the primary species was t18:1(c8)-24h:1-Glc, which accounted for about 43 % of the total (Fig. 6B).

In the present study, the composition of the glucosylceramide species was determined by LC-MS/MS from the chloroform/methanol fraction of Sep-Pak Plus silica cartridges. This fraction mainly contained glucosylceramides and steryl glucosides as determined by TLC (data not shown). Although we confirmed that glucosylceramide species were sufficiently detected in the current LC-MS/MS system using the crude lipid extract (data not shown), it may be appropriate to perform mild-base hydrolysis of the total lipid extract and subsequent solid-phase extraction, especially for plant samples with green organs to reduce interference with ionization efficiency by other compounds. The current method should be applicable to seeking the active components of glucosylceramide molecular species from vegetative, tuberous or cereal products in response to biological challenges.

Acknowledgments We thank Ayae Wada for technical and experimental assistance. We also thank Dr. Kouhei Yamamoto, Osaka Prefecture University, for his valuable advice.
