Abstract In 1937 Butler and Marrian found large amounts of the steroid pregnanetriol in urine from a patient with the adrenogenital syndrome, a virilizing condition known to be caused by compromised adrenal secretion even in this pre-cortisol era. This introduced the concept of the study of altered excretion of metabolites as an *in vivo* tool for understanding sterol and steroid biosynthesis. This approach is still viable and has experienced renewed significance as the field of metabolomics. From the first cyclized sterol lanosterol to the most downstream product estradiol, there are probably greater than 30 steps. Based on a distinctive metabolome clinical disorders have now been attributed to about seven post-squalene cholesterol (C) biosynthetic steps and around 15 en-route to steroid hormones or needed for further metabolism of such hormones. Forty years ago it was widely perceived that the principal steroid biosynthetic defects were known but interest rekindled as novel metabolomes were documented. In his career this investigator has been involved in the study of many steroid disorders, the two most recent being P450 oxidoreductase deficiency and apparent cortisone reductase deficiency. These are of interest as they are due not to mutations in the primary catalytic enzymes of steroidogenesis but in ancillary enzymes needed for co-factor oxido-reduction. A third focus of this researcher is Smith-Lemli-Opitz syndrome (SLOS), a cholesterol synthesis disorder caused by 7-dehydrocholesterol reductase

mutations. The late George Schroepfer, in whose honor this article has been written, contributed greatly to defining the sterol metabolome of this condition. Defining the cause of clinically severe disorders can lead to improved treatment options. We are now involved in murine gene therapy studies for SLOS which, if successful could in the future offer an alternative therapy for this severe condition.

Introduction

The class of natural lipids we call steroids all have in common the perhydrocyclopentanophenanthrene structure, the core ring unit produced by the cyclization of oxidosqualene. This structure is used as a backbone of a remarkable suite of essential biochemicals with very diverse tasks, from cholesterol with its global responsibilities (membrane and neuron structure, steroid precursor, etc.), to bile acids with their cell signaling and detergent qualities, to skeletally essential vitamin D, to the gonadal steroids, and to the adrenal hormones that regulate our intermediary metabolism and salt and water balance. While all these vital components are derived from acetate, the first intermediate with the fused ring-structure is the C-30 sterol lanosterol and from that precursor there are likely more than 30 steps leading to the most distal steroid products such as estradiol and the terminal metabolites of cortisol.

Following the confirmation of the structure of cholesterol in 1932, defining the enzymes and other factors that are needed to progress from acetate to the most distal metabolites has taken more than 70 years and remains a work in progress. The study of the hormonal biosynthetic

process started in the 1940s with the characterization of individual compounds within glandular tissues, mostly obtained from domestic animals. Radioactively labeled versions of these compounds (and their possible precursors) were synthesized and utilized in tissue perfusion studies or incubated with cellular fractions. Step by step a hypothetical biosynthetic scheme for cortisol evolved but its veracity proved difficult to confirm without *in vivo* experimentation.

The field that we now term metabolomics has been key to verifying the biosynthetic pathway leading to cholesterol, the hormonal steroids, and their metabolites. Metabolomics is the systematic study of the unique chemical fingerprints that specific cellular and bodily processes leave behind—specifically the study of small-molecule metabolite profiles. In reality, relatively little information can be obtained solely by studying the blood or excretory metabolic profile of healthy individuals, it is those with biosynthetic disorders (inborn errors) that provide the necessary keys to understanding synthetic sequences as well as defining the biological role and importance of the biosynthetic end product.

In describing the elucidation of the steroid biosynthetic pathway through metabolomics it is useful to focus on cholesterol as the mid-point and discuss the pre-cholesterol (upstream) and post-cholesterol (downstream) processes separately. This author has been involved in research interpreting metabolic profiles of each process and three personal examples will be highlighted, two “Downstream” and one “Upstream”.

Downstream from Cholesterol

Cortisone was the first major adrenal steroid hormone to be identified and as soon as sufficient was synthesized for pharmacological testing it was found to ameliorate the symptoms of arthritis [1]. It was designated the “wonder-drug” of 1949 and for this discovery Kendall, Hench and Reichstein received the 1950 Nobel prize. A little later it was realized that a cortisone precursor, hydrocortisone (or cortisol) was in fact the true adrenally synthesized glucocorticoid. Following the identification of the major glucocorticoids there was a dramatic acceleration of studies of the biosynthesis of these hormones mostly carried out by groups in New York and the Worcester foundation in Massachusetts.

The initial breakthroughs in understanding adrenal steroid biosynthesis were uncovered independently of metabolomics. These studies were conducted *in vitro*, and generally consisted of isolating steroids from bovine adrenal tissues obtained from abattoirs, perfusions of such glands with individual labeled steroids, and finally

metabolism studies utilizing sub-cellular fractions. By the mid 1950s there was already evidence that the likely synthetic route was pregnenolone oxidation to progesterone, sequential 17-hydroxylation, 21-hydroxylation and 11 β -hydroxylation, finally producing cortisol. It was postulated at the time that cholesterol was the precursor of pregnenolone but there was no direct evidence to prove it. Proposing this biosynthetic pathway was a remarkable achievement based on the methodologies available at that time, and the story is well documented in the 1954 review by Hechter and Pincus [2].

The synthetic scheme, while attractive, still represented a series of deductions based primarily upon the ability of substrates to be converted. What was lacking was information derived from *in vivo* metabolism, and that was soon supplied by what we now refer to as metabolomics. It was the study of the steroidal products produced by patients with inborn errors of steroid biosynthesis that finally verified the postulated biosynthetic sequence. What follows is a brief history of these discoveries which are readily followed by viewing Fig. 1. For the benefit of readers less familiar with the numbering system of steroids, this is detailed in the structure of cholesterol illustrated.

Interestingly, the first metabolomic discovery pre-dated the actual discovery of the primary glucocorticoids (cortisol/cortisone) by a decade. This was the 1937 characterization of pregnanetriol in the urine of patients with the adrenogenital syndrome by Butler and Marrian [3]. The adrenogenital syndrome is a condition in which adrenal insufficiency is associated with masculinization of female fetuses. In their early paper they do not (and cannot) speculate on the reason for this overproduction as the terminal product of the adrenal steroidogenic pathway had yet to be identified. By today's standards the achievement of metabolite characterization was challenging. A great volume of urine was processed and in these pre-chromatography days identification comprised of nothing more than differential extraction, targeted chemical reactions and crystallization to constant melting point.

It took many more years before a clearer understanding of the significance of the pregnanetriol discovery was obtained. Eberlein and Bongiovanni in 1955 re-identified pregnanetriol as the major urinary metabolite in the adrenogenital syndrome (now referred to as congenital adrenal hyperplasia, CAH), but by then it was possible to connect this to cortisol deficiency [4]. Having deduced that pregnanetriol was a metabolite of 17-hydroxyprogesterone (17OHP) these investigators proposed a block between 17OHP and cortisol and suggested that 21-hydroxylase was deficient. It should be emphasized that in this era only urine analysis was practical, widespread use of sensitive immunoassay procedures that allowed serum hormone measurement were still two decades away.

Fig. 1 Cortisol biosynthesis and the first reported forms of Congenital Adrenal Hyperplasia (CAH). Identifying urinary metabolites and defining these conditions confirmed the postulated adrenal biosynthetic pathway determined by in vitro experimentation. The first form of CAH investigated was 21-hydroxylase deficiency [1], followed by 11 β -hydroxylase deficiency [2] and 3 β -hydroxysteroid dehydrogenase deficiency [3]. LAH patients [4] essentially had absence of urinary metabolites, with adrenal cholesterol build-up. 17-Hydroxylase deficiency [5] was the final form defined during the classical era. The major urinary metabolites are shown in italics, steroid hormones and their precursors in conventional script

Following this report on 21-hydroxylase deficiency the same investigators described a hypertensive form of CAH and the metabolic profile was defined by a high excretion of tetrahydro-11-deoxycortisol, pointing to a deficiency of 11 β -hydroxylase [5]. Step by step these metabolite identifications were verifying the biosynthetic pathways proposed by the in vitro experimenters. In 1962 Bongoivanni described CAH due to 3 β -hydroxysteroid dehydrogenase deficiency (3 β HSD) hallmarked by high excretion of Δ^5 steroids such as pregnenetriol and DHEA [6]. In 1955, Prader and Gurtner [7] reported on neonates with a fatal condition marked not by the production and excretion of distinctive metabolites, but by the apparent absence of steroid hormone metabolites. At post-mortem examination the adrenal glands of these infants were found to be filled with cholesterol and its esters suggesting a deficiency in the conversion of cholesterol to the first C21 steroid, pregnenolone. This was attributed at the time to cholesterol side-chain cleavage (desmolase) deficiency, but now it is known to be due to a cholesterol transport protein deficiency. This condition was termed lipoid adrenal hyperplasia (LAH). The final example of disorders causing cortisol insufficiency was the description in 1966 of a second hypertensive form of CAH, 17-hydroxylase deficiency by Biglieri and co-workers [8]. The metabolome of patients with this disorder was based on the overproduction of 17-deoxycorticoids such as deoxycorticosterone (DOC) and corticosterone.

By the mid 1960s a basic understanding of the biosynthesis of adrenal steroids had pretty much been established, at least from the aspect of defining the primary

transformations and the order in which they occur. These achievements have been summarized in Fig. 1.

Analyzing the Metabolome: The Author's Introduction

In metabolomic studies of urinary steroids the compounds quantified are not secreted hormones or precursors, but rather end products produced by renal or hepatic metabolism. For example, the 3-oxo-4-ene structure of a typical hormone or precursor is reduced to form a 3 α -hydroxysteroid with either a 5 α or 5 β hydrogen. These metabolites are referred to as “tetrahydro-metabolites”, for example *tetrahydrocortisol* (Fig. 1). A carbonyl group at position 20 may be converted to a hydroxyl and commonly hydroxyl groups at positions 17 β and 11 β are converted to carbonyls. Thus, it seems that whatever functional moiety an active hormone has is to a great extent oxidized or reduced to its “opposite” prior to excretion. Finally, essentially all metabolites with a 3 α -hydroxyl are excreted as glucuronide conjugates and those with 3 β -hydroxy-5-ene groups are excreted as sulfates.

While the earliest characterizations within the urinary steroid metabolome were made without the benefit of chromatography, by the 1950s paper chromatography came into own thanks to the painstaking developments by Ian Bush [9] and Zaffaroni [10]. The former in particular standardized methodologies to the extent that steroid metabolic profiles as we know them could be used clinically [11]. All of the first batch of steroidogenic disorder discoveries were documented by this technique.

My first introduction to the field was my undergraduate thesis entitled “cholesterol and cholesterol esters in the bovine corpus luteum during formation and regression”, a study completed in 1964. My supervisor was the noted cholesterol researcher Robert Cook who published one of the first monographs on the subject [12]. My perseverance in the field was tested severely as I had to spend untold distressing hours at the slaughterhouse in Dundee, Scotland, collecting tissue samples. I started work on steroid metabolomics at the end of the golden age for steroid biochemists when the fundamental biosynthetic route to cortisol had largely been confirmed and primary defects described. I was employed in 1964 in the Dept of Clinical Chemistry, the University of Edinburgh to study the steroid metabolome of newborn infants and determine how it differed qualitatively and quantitatively from later life. My earliest experiments were conducted using paper chromatography for the identification and measurement of the steroids excreted by human newborns but soon realized that the rapidly developing TLC methodologies were much more effective and sensitive. By using this technique with three color reactions we could separate and quantify all the major excreted steroids of humans [13]. Although the methodology was effective it was soon overtaken by gas chromatography and the combined GC/MS technique. In 1966 I was privileged to use the first commercial GC/MS instrument purchased in the UK to identify some of the novel newborn steroids isolated by TLC [14]. This instrument belonged to Professor Charles Brooks of Glasgow University, a seminal steroid researcher of this era.

For post-doc training I went to the Karolinska institute in Stockholm to work with Professor Jan Sjövall, a previous recipient of the Schroepfer medal, to get a thorough education in this new field. Jan was a co-developer with Ragner Ryhage of the first practical GC/MS instrument which was marketed as the LKB 9000. By 1968, GC/MS was truly a metabolomic tool in the steroid field. By use of the combination of methyloxime protection of carbonyl groups and trimethylsilylation of hydroxyls, all neutral human steroids, whatever their origin and complexity could be analyzed in a single chromatogram. In 1970, I returned to the MRC in London and continued my studies on steroid biosynthetic disorders using GC/MS. Our group was at the forefront in introducing capillary column methodology in producing steroid profiles [15], in the use of GC/MS in athletic doping control [16] and in improving steroid recovery techniques by the first use of SPE (solid phase extraction) with cartridges [17].

In 1979 I moved to Berkeley, California to assist Dr Al Burlingame establish a national resource for biomedical mass spectrometry. While there we made the first utilization of the new Fast Atom Bombardment technique to the analysis of steroid of clinical relevance. With my colleague

Ken Straub we showed that single spectrum profiles of urinary steroid conjugates could be used to diagnose five disorders of steroid biosynthesis [18, 19]. This was the first practical analysis of intact conjugates because in previous studies by paper, TLC and GC/MS steroid conjugates had first to be hydrolyzed prior to analysis. This technique was overtaken by development of HPLC/MS, first using the thermospray interface [20] soon followed by electrospray ionization. However, close to 50 years after the introduction of GC/MS for analyzing the steroid metabolome, this technique is still preferred for this role [21]. HPLC/tandem MS now has extreme sensitivity and is ideally suited to the measurement of circulating hormones and precursors but finds challenging the separation and quantitation of the characteristic steroids found in a urinary extracts.

Discovery of the 6th Form of Congenital Adrenal Hyperplasia (CAH)

The description of the five classical forms of CAH seemed to signal an end to the first chapter in the story of steroid biochemistry. As they covered the needed transformations in the ACTH-regulated pathway from cholesterol to cortisol and served to validate the pathway deduced from the original *ex vivo* investigations. In the late 1970s one more unique urinary steroid metabolome was documented by the late Dr Meta Nielsen and myself. Meta from the Glostrup hospital in Copenhagen was second-to-none in her ability to accurately diagnose steroid disorders by TLC of urinary steroids but she still needed a collaborator to confirm steroid identities by GC and GC/MS. A distinctive metabolome was seen in two sisters with masculinized genitalia, one who had been brought up as a boy. The unique feature was that there was elevated excretion of the metabolites of 17 α -hydroxyprogesterone (pregnanetriol and pregnanetriolone, indicative of 21-hydroxylase deficiency) as well as elevated excretion of corticosterone metabolites (tetrahydrocorticosterone and others), a feature suggesting 17-hydroxylase deficiency. We termed the condition “combined 17- and 21-hydroxylase deficiency” but unwisely we did not pursue this to publication.

It was several years before another example of this metabolome was seen and then it was a patient of Dr Ralph Peterson and Julianne Imperato-McGinley at Cornell Medical School in New York. These investigators had an active program studying isolated kindreds in the Dominican Republic with high incidence of ambiguous genitalia and I had a role in diagnosing these individuals by GC/MS analysis. Almost all DSD (Disorders of Sexual Development) individuals had a disorder not directly related to cortisol synthesis called 5 α -reductase deficiency, but one young virilized girl had a steroid profile of combined

17- and 21-hydroxylase deficiency. This patient was studied in detail and a resulting publication became the index case of the disorder [22]. Many years were to pass before the true cause of the disorder was determined but during that period there were isolated reports of other cases where patients were described with features of 17- or 21-hydroxylase deficiency. With my colleague Ewa Malunowicz of Warsaw we reviewed several of these papers and questioned the authors original interpretations as they all seemed to have a metabolome suggesting combined 17- and 21-hydroxylase deficiency [23]. Interestingly, several patients of this type described in the 1990s were not initially investigated because of DSD but because their dominant phenotype was consistent with Antley-Bixler syndrome, a skeletal disorder with features including skull, limb and finger abnormalities.

Enough was known of the genetics of steroidogenesis to render simultaneous errors in both 17- and 21-hydroxylase genes unlikely, so the focus was directed to ancillary factors that are required for the function of both enzymes. The most important co-factor for both 17-hydroxylase and 21-hydroxylase is cytochrome P450 oxidoreductase (OR), the enzyme responsible for regenerating the NADPH required for hydroxylase enzyme function. In 2003 my colleague Prof. Wiebke Arlt at Birmingham started to sequence this enzyme in a few patients (from various clinicians) which we had identified by metabolic profile and a year later several mutations had been found and we published a paper describing the “sixth” form of CAH, a condition caused by deficiency of P450 oxidoreductase [24]. Simultaneous studies on Antley-Bixler syndrome and P450 oxido-reductase deficiency were carried out by Professor Walter Miller’s group in San Francisco and Dr Hisao Hidachi in Japan; these were published the same year [25, 26].

There was one aspect of “combined 17-hydroxylase/21-hydroxylase deficiency” patients which confounded endocrinologists since the first description of the condition. The original forms of CAH (21- and 11 β -hydroxylase deficiencies) were always associated with hyperandrogenism causing masculinization of female fetuses, a hyperandrogenism which persists for life in untreated patients. In this new form caused by oxidoreductase deficiency (ORD) (P450 oxidoreductase deficiency), females were virilized but males had ambiguous genitalia. While it was obvious that females were virilized we found that post-natal androgen levels were low, as one would expect due to the attenuation of 17 α -hydroxylase and 17,20-lyase activity caused by the deficient OR. Hydroxylation of C17 and subsequent lyase activity are carried out by a single enzyme encoded by single mRNA. The OR enzyme is required to facilitate the transfer of electrons from NADPH to CYP17 allowing oxidation. In the presence of co-factor cytochrome b5 the lyase function oxidatively removes the

Fig. 2 Oxido-reductase and 17,20-lyase activity. 17-Hydroxylase and C17,20-lyase activities reside in a single protein encoded by a single gene. This enzyme only works effectively in concert with P450 oxido-reductase which is necessary for providing the electrons required for oxidation. The lyase function of the hydroxylase enzyme also needs cytochrome b5

side-chain, the rate-limiting step in the process (Fig. 2). Inactivity of OR attenuates the process and androgen formation is inhibited.

Clearly, the virilization of female fetuses was transient but how could this be explained? We formulated a hypothesis for the transient fetal hyperandrogenism by study of the pregnancy metabolic profile from a mother carrying an OR deficient fetus [27]. We had proof of the presence of ORD in this pregnancy because estriol (a primary product of pregnancy) excretion was almost negligible being replaced in urine by a pregnenolone metabolite. The conversion of pregnenolone to estriol requires active C17,20 lyase activity. In sequential maternal urine steroid assays carried out throughout an affected pregnancy a disproportionate increase in two 5 α -reduced steroids androsterone and 3 α ,17 α -dihydroxy-5 α -pregnan-20-one compared to their 5 β -reduced epimers was also noted [27]. We suggest that the ORD fetus uses a novel pathway where 3 α ,17 α -dihydroxy-5 α -pregnan-20-one is converted to androsterone which in turn is oxidized to the potent androgen 5 α -dehydrotestosterone (DHT). The oxidation of a 3 α -hydroxyl group has always been considered unlikely in human metabolism although this pathway has been shown to be important in the tammar wallaby [28]. The viability of our hypothesis rests on the finding that 3 α ,17 α -dihydroxy-5 α -pregnan-20-one is a much better substrate for residual 17,20-lyase activity than the conventional substrates 17-hydroxypregnenolone or 17-hydroxyprogesterone [29]. We have termed this “the alternative pathway” for fetal androgen synthesis (Fig. 3) and current studies are directed to proving this theory. This is an excellent example of a hypothesis developed by detailed metabolomic studies of urine; it would have been almost impossible to achieve by any form of conventional hormone analysis. The unique metabolic profile of ORD allows for GC/MS to be routinely used for diagnosing this condition both pre-and postnatally [27, 30].

While I have focused on the disorders of cortisol biosynthesis, investigations over the last 30 years have

Fig. 3 Proposed alternative pathway of fetal-placental androgen synthesis from 17-hydroxypregnenolone. The *lower-left corner* represents the conventional pathway of androgen synthesis requiring sequential side-chain removal, oxidation by 3 β HSD, 17-keto reduction by 17 β HSD and finally 5 α -reduction terminating in DHT. The

alternative pathway (*upper right corner*) starts with the formation of 17-hydroxyprogesterone and its reduction to 5 α -pregnane-3 α ,17 α -diol-20-one. In spite of attenuated 17,20-lyase activity due to POR deficiency this steroid can be converted to androsterone and likely on to DHT

uncovered the causes of many other steroid endocrinopathies. In terms of intersex conditions there have been the description of 5 α -reductase [31] and 17 β HSD deficiencies [32] causes of incomplete male development and aldosterone (the mineralocorticoid hormone) biosynthetic defects such as aldosterone synthase deficiency and glucocorticoid repressible hyperaldosteronism. The urinary steroid metabolomes of these disorders were first described by the late Dr Stanley Ulick [33, 34].

Studies of the Cortisol-Cortisone Interconversion

Oxidation

Cortisol, with its 11 β hydroxy group is the primary glucocorticoid product of the adrenal glands. It can be interconverted with cortisone (which has a carbonyl at position 11) by means of 11 β hydroxysteroid dehydrogenase (11 β HSD). In the normal human metabolome there are virtually equivalent amounts of metabolites with 11-carbonyl and 11 β -hydroxyl functions. The principal cortisone metabolites are tetrahydrocortisone (THE) and the cortolones (20 α and 20 β); while the principal metabolites of cortisol are tetrahydrocortisols (THF and its 5 α -epimer, 5 α THF) and the cortols (20 α and 20 β).

In the late 1970s, GC/MS was used by us and Drs Stanley Ulick and Maria New to study the excretion of

steroids by young patients with an unusual form of hypertension. These patients retained salt which suggested high production of a mineralocorticoid but atypically low aldosterone and low renin, the opposite of what was expected. It was found that the urinary cortisol metabolites essentially only had the 11 β -hydroxyl group, the steroids with 11-carbonyl were virtually absent [35, 36]. Further studies showed that the deficient enzyme was a novel renal 11 β HSD which was named 11 β HSD 2. This enzyme operates exclusively in an oxidative direction and has the function of protecting the renal tubules against cortisol which competes with aldosterone for the mineralocorticoid receptor. In individuals with the deficiency cortisol acts as a potent mineralocorticoid giving rise to sodium retention and hypertension. We termed this interconversion the “cortisol-cortisone” shuttle and demonstrated its importance in blood pressure regulation. In the years following multiple patients with this disorder have been studied and many loss-of-function mutations genetic found. These studies were carried out with my colleagues Chris Edwards, Paul Stewart, Maria New, among others [37].

Reduction

It had long been known that there could be active regeneration of cortisol from cortisone. In fact, for the first years of adrenal hormone discovery it was assumed that cortisone was the glucocorticoid hormone. Kendall and

colleagues received the Nobel prize for their clinical studies with this steroid, as it was successfully used for treatment of rheumatoid arthritis. In the beginning of the 1950s it was finally recognized that cortisol was the true hormone and that the therapeutic efficacy of cortisone was due to its reduction to cortisol. Studies in recent years have shown that regeneration of cortisol is conducted by a long-known liver 11β -hydroxysteroid dehydrogenase, now called 11β HSD 1 after discovery of the kidney enzyme termed 11β HSD 2. It is the concerted action of 11β HSD1 and 11β HSD 2 which gives rise to the quantitative equivalence between the tetrahydrometabolites of cortisol and cortisone in human urine.

In 1996, we did a detailed study of two sisters, patients of Dr George Phillipov in Australia, who had a unique metabolome where essentially only the metabolites of cortisone were present (11-carbonyl containing steroids), i.e., THE and the cortolones. Thus, the metabolome appeared to be exactly the opposite of the aforementioned AME syndrome [38]. Interestingly, these individuals clearly had huge cortisol production but showed no symptoms of hypercortisolism (Cushing's syndrome). This was attributed to the rapid and irreversible metabolism to cortisone, almost certainly catalyzed by hepatic 11β HSD 1. The disorder has been termed Cortisone Reductase Deficiency (CRD) and several more patients with the condition have been described in recent years [39]. The apparent inability of these patients to regenerate cortisol from cortisone causes ACTH-mediated hyperandrogenism which manifests in early pseudopuberty in males and midlife hirsutism and infertility in women.

My colleagues at Birmingham under the direction of Professor Paul Stewart spearheaded studies of the genetics of this disorder. Interestingly, no mutations were found in 11β HSD 1 in affected patients, so analogous to the ORD studies described above, attention was paid to the generation of NADPH, which in the endoplasmic reticulum lumen is carried out by hexose-6-phosphate-dehydrogenase (H6PD). Drs Gareth Lavery and Elizabeth Walker of our department have conducted these studies and have demonstrated loss-of-function mutations in H6PD in four patients with the disorder [39]. The disorder and its affect on the metabolome are summarized in Fig. 4. These studies led to the development of a mouse model for the disorder and study of their steroid metabolome. In contrast to humans the mouse glucocorticoid is the 17 -deoxysteroid corticosterone and the metabolic profile was composed of reduced metabolites of this steroid. H6PD knockouts have a high percentage of 11 -dehydrocorticosterone metabolites proving the importance of this enzyme co-factor for corticosterone regeneration, strong evidence for the importance of this enzyme in cortisone to cortisol conversion in man.

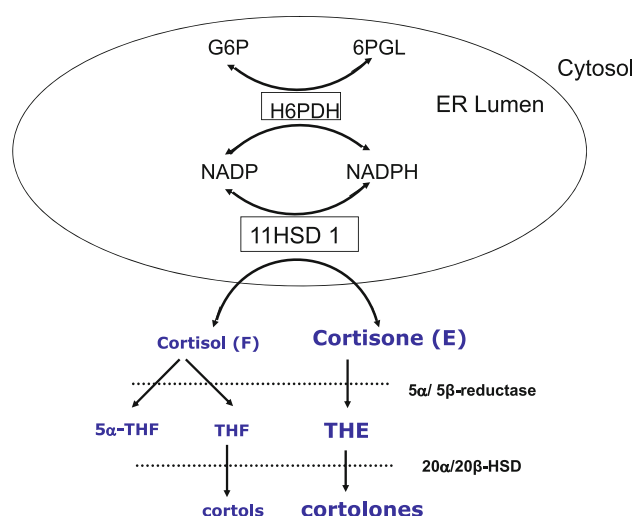

Fig. 4 Cortisone reductase deficiency. This disorder was discovered in affected patients through the domination in urine of THE and the cortolones, corticosteroids with 11-carbonyl function. The analogous steroids with 11β -hydroxyl function, the epimeric tetrahydrocortisols (THFs) and cortols were severely diminished. This reduction was attributed to attenuated 11β HSD1 activity preventing hepatic regeneration of cortisol from cortisone. Reduced activity was shown to be caused by mutations in H6PDH responsible for NADP oxidation

Upstream of Cholesterol

The first product of squalene cyclization is the C-30 sterol lanosterol and conversion of this to the C-27 cholesterol is a multistep process. Disorders of post-squalene cholesterol biosynthesis were unknown prior to 1993 but since then a few have been described in humans, all bar one extremely rare. These disorders can be considered more severe than those downstream of cholesterol as they are invariably associated with dysmorphology, mental retardation and are frequently fatal. The original descriptions of the conditions were usually based on increased concentrations of the precursors for enzyme conversion in serum or cellular preparations. Verification of the deficiency has been obtained by detecting mutations in genes for individual proteins and development of transgenic mouse models [40].

In descending order as the disorders appear in the Kandutsch-Russell cholesterol biosynthetic pathway [41] the first is Antley-Bixler syndrome a skeletal dysmorphology syndrome. It was initially proposed that it was caused by lanosterol demethylase (Cyp 51) inactivity although the enzyme itself has been shown to have no mutations in affected individuals [42]. The most likely cause of attenuated Cyp 51 activity is the previously discussed P450 oxidoreductase deficiency since the latter enzyme is required for NADPH regeneration. The second condition is HEM dysplasia initially considered to be

thought due to Δ^{14} reductase deficiency although more likely now a laminopathy [40, 43] and the third desmosterolosis due to inactive Δ^{24} reductase [44]. The fourth condition, is CHILD syndrome probably caused by NHSDDL (4,4-demethylase) deficiency [45] and the fifth, CDPX2 due to deficiency in Δ^7 – Δ^8 isomerase [46]. The sixth post-lanosterol disorder is lathosterolosis caused by deficient 5-desaturase [47] and the seventh and final is Smith-Lemli-Opitz syndrome (SLOS) caused by deficient 3β -hydroxysterol- Δ^7 -reductase (7-dehydrocholesterol reductase DHCR7, EC 1.3.1.21) [48].

SLOS was the first of the cholesterol deficiency syndromes to be reported [48] and has by far the highest incidence. Biochemically, SLOS patients have reduced cholesterol synthesis and elevated levels of 7-dehydrocholesterol (7DHC) and its isomer 8-dehydrocholesterol (8DHC). Phenotypically SLOS presents with a variety of problems such as multiple malformations, delayed development and growth, cognitive deficiency, and autistic-like behavior. Affected individuals have a compromised quality of life and present a lifelong challenge to their families and the medical community. There is no cure for SLOS.

George Schroepfer in whose honor the AOCS medal is awarded, and to whom this paper is dedicated, played a significant role in defining the sterol metabolome of the condition. His studies gave the most comprehensive analysis of circulating steroids as a result of the enzyme deficiency [49]. For the last decade our laboratory in Oakland has focused on the study of this disorder concentrating on three questions: (1) How does the cholesterol deficiency and build-up of 7- and 8-dehydrocholesterol impact the production of hormonal steroids and their metabolites? (2) Does the unique steroid metabolome of the condition offer new diagnostic options, particularly in the form of prenatal diagnosis? and (3) could gene therapy be a treatment option for increasing the deficient cholesterol synthesis?

In studying the steroid metabolome of the disorder, we were indebted to Drs Richard Kelley and Lisa Kratz at the Kennedy Krieger institute for their collaboration, particularly in supplying needed samples from affected individuals they had diagnosed. The other participants were two synthetic chemists Dr William Wilson and Liwei Guo who painstakingly synthesized and authenticated important Δ^7 and Δ^8 reference compounds. These investigators were part of Dr Schroepfer's department at Rice University, which emphasizes how, even after his untimely death, his legacy in SLOS research was cemented through his group's continuing studies on this serious disorder.

In the urine of affected adults and children, we identified multiple steroids with additional 7- or 8-unsaturation indicating that many biosynthetic transformations could take place using the excess 7- and 8-dehydrocholesterol substrates. However, we found little or no formation of

dehydro versions of cortisol metabolites hinting that 21- and 11 β -hydroxylation may not utilize such precursors [50]. We found normal excretions of adrenal hormone metabolites in urine from affected individuals indicating surviving SLOS patients were unlikely to suffer from adrenal insufficiency.

An immediate consideration when we were studying the steroid metabolome in SLOS was the possibility that maternal steroids excreted could include novel components originating in the affected fetuses. Such compounds could provide the basis for developing a non-invasive prenatal test for the disorder. It was predicted that 7- or 8-dehydro versions of estriol (1,3,5(10)-estratrien-3,16 α ,17 β -triol, Fig. 5) in particular would be present since this steroid is almost exclusively of fetal origin. We did indeed find such compounds in urine, also interesting in that they have structures appropriate for the long-known "equine" estrogens, derivatives of equilin and equilinenin, prominent estrogens produced by mares [51, 52]. The Rice University researchers chemically synthesized 7- and 8-dehydroestriol and we were able to confirm that the major metabolite in the urine of mothers carrying SLOS fetuses was 8-dehydroestriol (53, Fig. 5). Measurement of this steroid together with a dehydro steroid of the pregnane series has formed the basis of a non-invasive test for this serious disorder. Its efficacy has been evaluated in a large study including a million participants [54]. Not only were we able to validate the test but we were able to provide updated information of the incidence of the disorder in the North American population [54, 55].

At the final analysis, studying the metabolome of specific disorders should lead to new therapeutic options, and we are pursuing this aspect. Current treatment for SLOS is dietary cholesterol supplementation and anecdotal reports show positive, albeit limited, effects of exogenous cholesterol on somatic growth and behavior, but development outcome does not appear to be altered. However, an effect of dietary cholesterol on behavior would be somewhat surprising as the brain is believed to be impervious to external cholesterol, and a recent clinical trial showed no behavioral differences between short-term cholesterol supplementation and placebo. Because both cholesterol deficiency and excess 7-DHC likely contribute to the pathogenesis of SLOS, the therapeutic goal of treatment has been to enhance cholesterol accretion while decreasing accumulation of potentially toxic cholesterol precursors such as 7-DHC. Some studies report a positive effect of combining a high cholesterol diet with administration of a statin inhibitor of sterol biosynthesis.

My institutional colleague Gordon Watson and I considered that the "single enzyme deficiency" nature of SLOS made it an attractive experimental model for gene therapy. We have been conducting experiments on a mouse

Fig. 5 Structures of Estriol and Dehydroestriol. Estriol together with pregnanediol are the two dominant steroids excreted during pregnancy, products of feto-placental steroid synthesis. Women with a

SLOS affected steroids excrete dehydroestriols, predominantly Δ^8 . Measurement of 8-dehydroestriol can be used for prenatal diagnosis of the condition

Fig. 6 Sterol and steroid synthesis and metabolism. Simplified scheme showing reported deficiencies in steroid synthesis and metabolism. A list of disorders and the causes attributed are given in Table 1

model of the disorder and have introduced a recombinant adeno-associated virus (AAV) vector containing the human gene to young affected animals and controls. These studies were moderately successful, as we have shown in the presence of human DHCR7 DNA and mRNA in liver for several weeks after administration. In addition it was shown that the introduction of a functional gene does increase the amount of cholesterol while simultaneously

decreasing the amount of accumulated 7DHC, i.e., the C/DHC ratio was increased in both liver and serum [56]. While promising, the potential impact of gene therapy must be kept in perspective. Cholesterol synthesis may be stimulated, and potentially toxic precursors limited but the major dysmorphological and developmental outcomes of the disorder cannot be reversed as they result from fetal cholesterol deficiency in the earliest days of pregnancy.

Table 1 Disorders of sterol and steroid synthesis and metabolism

| # | Disorder | Attributed to |
|----|---|---|
| 1 | Desmosterolosis | Sterol Δ^{24} reductase (DHCR24) deficiency |
| 2 | Antley-Bixler syndrome | CYP51 (sterol C14 demethylase) probably attenuated. Suggested cause P450 oxidoreductase deficiency (#11) |
| 3 | Greenberg skeletal dysplasia | Sterol Δ^{14} reductase deficiency |
| 4 | CHILD syndrome | 4-demethylase (NSDHL) deficiency |
| 5 | CDPX2 syndrome | Δ^7 – Δ^8 isomerase (aka. epamomil binding protein, EBP) deficiency |
| 6 | Lathosterolosis | Sterol 5-desaturase (Sc5D) deficiency |
| 7 | Smith-Lemli-Opitz syndrome (SLOS) | 7-dehydrosterol reductase. (DHCR7) deficiency |
| 8 | CAH, Lipoid adrenal Hyperplasia (LAH) | Steroid acute regulatory (StAR) protein deficiency |
| 9 | CAH, LAH | Cholesterol side-chain cleavage. CYP11A1 |
| 10 | CAH, 17-hydroxylase deficiency | CYP17A1 |
| 11 | CAH, oxido-reductase deficiency | P450 Oxidoreductase, POR |
| 13 | CAH 3β -hydroxysteroid dehydrogenase deficiency | HSD3B2 |
| 14 | CAH, 21-hydroxylase deficiency | CYP21A1 |
| 15 | CAH, 11β -hydroxylase deficiency | CYP11B1 |
| 16 | Hypoaldosteronism Aldosterone synthase | CYP11B2 |
| 17 | Cortisone reductase deficiency (CRD) | Hexose-6-phosphate-dehydrogenase (H6PD) |
| 18 | Apparent mineralocorticoid excess (AME) syndrome | 11β -Hydroxysteroid dehydrogenase, HSD11B2 |
| 19 | 17β -hydroxy-steroid dehydrogenase deficiency | HSD17B3 |
| 20 | Aromatase deficiency | CYP19A1 |
| 21 | 5α -Reductase deficiency | SRD5A2 |
| 22 | 5β -Reductase deficiency | Aldoketoreductase. AKRD1 |
| 23 | Sulfokinase “deficiency” | SULT2A1 attenuated. Caused by PAPSS2 mutations |
| 24 | Steroid Sulfatase deficiency | STS |

In Summary

I sense we are closing in on the end of a long and remarkable era in the study of the formation and disposition of cholesterol in mammals. On the basis of study of the circulating and excreted steroid metabolome, as well as tissue conversion experiments, we have now a good understanding of the biosynthesis and further metabolism of cholesterol, the steroid hormones and the genetic errors that cause disease. While the original studies were on the primary enzymes (typically hydroxylases and dehydrogenases) involved in structurally altering a molecule, recent exciting developments have stressed the importance of partner enzymes and other factors that are essential for effecting the transformation. Examples are our own studies on ORD and H6PD without which steroid hydroxylases and 11β HSD would not function, and the studies by others of StAR transport protein which is essential for enabling cholesterol side-chain cleavage in most steroidogenic tissue, deficiency of which causes LAH [58]. Steroid metabolomics has been a key player in these discoveries.

Table 1 lists most of the known disorders and their proven or putative causes. These are illustrated in the

simplified biosynthetic and metabolic scheme shown in Fig. 6. This scheme pays no attention to the tissue specificity of the many transformations. The known (and in a couple of cases, postulated) errors of transformative proteins (mostly enzymes) are listed in Table 1. Even this scheme is not comprehensive as major pathways have not been included, primarily of those leading to the formation of oxysterols and bile acids. These topics have been discussed by previous recipients of the Schroeder medal such as Professors Björkhem and Sjövall. Unexpected outcomes from detailed study of these metabolic products suggest that not only are they involved in cholesterol disposition but can be important signaling molecules interacting with receptor proteins.

Acknowledgments Firstly, I thank the AOCS for the honor of awarding me the 2010 Schroeder medal. I am most grateful to my Birmingham and Oakland colleagues who made all the recent studies possible, particularly Professors Wiebke Arlt and Paul Stewart and Doctors Nils Krone, Gareth Lavery, Gordon Watson, Josep Marcos, Montserrat Serra and Xavier Matabosch. Ms Beverly Hughes has provided us with an excellent mass spectrometric analytical service. SLOS studies would not have been possible without the collaboration of Drs Lisa Kratz, Richard Kelly, Denny Porter and William Wilson. Final thanks are to Professor Jan Sjövall of the Karolinska Institute

who was fundamental to the early development of GC/MS and steroid metabolomics. My education in this field and continued interest was due to him. Recent grant support comes from the NIH (NICHD 5R01HD053036) and The Wellcome Trust (Grant 082809/Z/07/Z; PI, Prof Paul Stewart).

Abstract Niemann-Pick C2 protein (NPC2) is a lysosomal soluble protein that is highly expressed in the liver; it binds to cholesterol and is involved in intracellular cholesterol trafficking, allowing the exit of lysosomal cholesterol obtained via the lipoprotein endocytic pathway. Thus, this protein may play an important role in controlling hepatic cholesterol transport and metabolism. The aim of this work was to study the relevance of NPC2 protein expression in hepatic cholesterol metabolism, biliary lipid secretion and gallstone formation by comparing NPC2 hypomorph [NPC2 (h/h)] and wild-type mice fed control, 2% cholesterol, and lithogenic diets. NPC2 (h/h) mice exhibited resistance to a diet-induced increase in plasma cholesterol levels. When consuming the chow diet, we observed increased biliary cholesterol and phospholipid secretions in NPC2 (h/h) mice. When fed the 2% cholesterol diet, NPC2 (h/h) mice exhibited low and high

gallbladder bile cholesterol and phospholipid concentrations, respectively. NPC2 (h/h) mice fed with the lithogenic diet showed reduced biliary cholesterol secretion, gallbladder bile cholesterol saturation, and cholesterol crystal and gallstone formation. This work indicates that hepatic NPC2 expression is an important factor in the regulation of diet-derived cholesterol metabolism and disposal as well as in diet-induced cholesterol gallstone formation in mice.

Keywords Niemann-Pick type C2 protein · Cholesterol · Liver · Biliary lipid secretion · Gallstone disease · Gallbladder

Introduction

Niemann-Pick type C (NPC) disease is a fatal hereditary disorder characterized by the accumulation of cholesterol and other lipids in endosomes and lysosomes [1]. There is mounting evidence that the primary cause of this disease is

failure of low-density-lipoprotein (LDL)-derived cholesterol to exit from the lysosomes, which secondarily causes the build-up of other lipids in different tissues [2]. Genetic mutations in either *Npc1* or *Npc2* are responsible for NPC disease. The major disease locus, *Npc1*, is responsible for 95% of NPC cases. *Npc1* encodes a transmembrane protein localized in lysosomes/late endosomes [1, 3]. *Npc2*, the minor disease locus, is responsible for 5% of cases, and encodes a small cholesterol-binding lysosomal soluble protein [1, 4]. Homozygous mutations in either gene in mice essentially produce indistinguishable cellular and biochemical characteristics as well as the same clinical phenotype, providing strong genetic evidence that the two gene products, Niemann-Pick C1 protein (NPC1) and Niemann-Pick C2 protein (NPC2), function in a coordinated manner [5].

NPC2 was previously identified as HE1, one of the major secretion proteins of the human epididymis [6]. NPC2 binds cholesterol specifically with a stoichiometry of 1:1 [6]; its three-dimensional structure is well known [7] with a pocket structure in which cholesterol is bound [8]. Recent studies have shown that NPC2 recognizes the aliphatic cholesterol chain, while NPC1 binds to the cholesterol 3- β hydroxyl group in its soluble amino terminal domain (NTD) [8–11]. On the other hand, it has been demonstrated that NPC2 or the NPC1 NTD can transfer cholesterol to vesicles in vitro and that the speed of cholesterol transfer to membranes by the NPC1 NTD radically increases in the presence of NPC2 [8, 10, 11]. Together, the data suggest a working model in which NPC2 binds the free cholesterol that is generated after hydrolysis of the cholesterol esters that come to the lysosome from LDL-receptor-mediated endocytosis, and delivers it to NPC1, which mediates transfer through the lysosomal membrane [11].

NPC2 expression has been detected in several cellular types, including fibroblasts, hepatocytes, neurons, and astrocytes [4, 12–14]. We have previously reported that NPC2 is expressed in the liver and is secreted into the plasma and bile, suggesting that NPC2 may have a global function in cholesterol homeostasis [15].

In mammals, the liver plays a critical role in lipoprotein cholesterol metabolism and is a key organ for body cholesterol removal into the bile [16–18]. The receptor-mediated endocytic pathway in which the NPC proteins participate is one of the major uptake mechanisms of lipoprotein cholesterol into the liver, including lipoprotein remnant metabolism [17]. Hepatocytes efficiently eliminate sterols through the bile as unesterified cholesterol and bile acids [18]. Biliary cholesterol disposal is critical not only for normal body cholesterol homeostasis, but also for the pathogenesis of cholesterol gallstone, which is a highly prevalent and costly disease condition in Western countries [19, 20].

We have previously shown that NPC1 plays a critical role in controlling the biliary secretion of plasma lipoprotein-derived cholesterol in mice [21, 22]. Hepatic NPC1 overexpression by adenovirus-mediated gene transfer increases biliary cholesterol secretion in wild-type mice and cholesterol-fed NPC1 (–/–) mice [21]. NPC1 (–/–) mice fed a high-cholesterol diet cannot normally process dietary cholesterol, leading to its accumulation in the liver without increasing biliary cholesterol secretion [21, 22]. Furthermore, NPC1-deficient mice are highly resistant to diet-induced cholesterol gallstones due to impaired secretion of excess cholesterol into the bile [22]. In contrast, no information is available on plasma, hepatic, and biliary lipid physiology and pathophysiology in NPC2-deficient mice fed normal chow and high-cholesterol diets.

The present study was undertaken to analyze the physiological relevance of hepatic NPC2-mediated lipoprotein cholesterol trafficking by comparing cholesterol plasma lipoprotein profiles, hepatic cholesterol metabolism, and biliary lipid secretion between NPC2-deficient hypomorph [NPC2 (h/h)] mice expressing 0–4% residual protein in different tissues and wild-type mice. We also analyzed the role of NPC2 in diet-induced cholesterol gallstone formation by studying biliary lipid secretion, gallbladder bile lipid composition, and gallstone formation in NPC2 (h/h) mice fed a lithogenic diet.

The main findings of this study are that reduced NPC2 expression in NPC2 hypomorph mice leads to increased hepatic cholesterol content and reduced biliary cholesterol and bile acid secretion in mice fed with a lithogenic diet (1.5% cholesterol, 0.5% cholic acid). Moreover, NPC2 (h/h) mice fed with this lithogenic diet are protected against cholesterol gallstone formation. Minor effects were observed when NPC2 (h/h) mice were fed a cholesterol alone-enriched diet. The major conclusion of this work is that hepatic NPC2 expression is an important factor in the regulation of diet-derived cholesterol metabolism and disposal as well as in diet-induced cholesterol gallstone formation in mice.

Materials and Methods

Animals and Diet

BALB/c mice carrying a heterozygous genetic mutation in *Npc2* were generously provided by Dr. Peter Lobel (University of Medicine and Dentistry of New Jersey-Robert Wood Johnson Medical School, Piscataway, NJ, USA). As described by Sleat et al. [5], the homozygous mutant animals are hypomorphs (i.e., they express 0–4% of NPC2 protein depending on the tissue analyzed). The heterozygous mice were bred to produce wild-type controls and homozygous

mutant [NPC2 (h/h)] mice, and the offspring was genotyped as described previously [5]. All mice had free access to water and a chow diet (<0.02% cholesterol; Prolab RMH 3000, PMI Feeds, St. Louis, MO, USA) until they were used for the studies. Most measurements were performed on 7 week-old NPC2 (h/h) mice, thus avoiding the detrimental effects observed in older animals with neurodegenerative disease [5]. For the experiments, 5 week-old NPC2 (h/h) and control male mice were fed the chow diet, or either a 2% cholesterol or bile-acid/low-fat lithogenic diet (chow diet supplemented with 1.5% cholesterol and 0.5% cholic acid) for 10 days or 2 weeks. In some experiments, 7 week-old NPC2 (h/h) and control male mice were fed with the lithogenic diet for 14 days. All animals were fasted for 2 h before bile, blood, and liver sampling.

All protocols were approved by our institution's review board for animal studies and were in agreement with the US Public Health Service Policy on Humane Care and Use of Laboratory Animals recommended by the Institute for Laboratory Animal Research in its Guide for Care and Use of Laboratory Animals.

Hepatic and Gallbladder Bile, Blood and Liver Sampling

Mice were anesthetized by intraperitoneal injection of ketamine and xylazine at 80–100 and 5–10 mg/kg, respectively. The abdomen was opened, the cystic duct was ligated, and a common bile duct fistula was performed with a polyethylene catheter. Hepatic bile was collected for 30 min, while mice remained hydrated, warm, and stable [22], and then blood, liver, and gallbladder were removed. The liver was immediately frozen at -80°C . The gallbladder was opened and bile was removed. When present, gallstones were separated from the bile by low-speed centrifugation. Some fresh samples were subjected to biochemical analyses, and the remaining bile was frozen at -20°C until required.

Alanine Aminotransferase Analysis

Serum alanine aminotransferase (ALT) was measured by ALAT kit (Kovalent, Rio de Janeiro, Brazil) following manufacturer's instructions.

Plasma, Hepatic, and Biliary Lipid Analyses

Plasma lipoprotein separation was performed by fast protein liquid chromatography gel filtration using a Superose 6 column [23]. Total plasma and lipoprotein cholesterol were measured as described previously [23]. Hepatic cholesterol content was analyzed after lipid extraction [22]. Hepatic bile and gallbladder bile cholesterol were measured by an

enzymatic method [24], phospholipids were assessed by a colorimetric method [25], and bile acids were determined by an enzymatic method [26]. Hepatic triglyceride content was determined using commercial kits (Sigma Chemicals Co, St. Louis, USA) according to the manufacturer's instructions. Gallbladder bile cholesterol saturation was calculated based on critical tables [27] using biliary lipid measurements performed at 10 days of feeding with the lithogenic diet and before mice developed cholesterol gallstones.

Quantitative Real-Time Reverse Transcriptase-Polymerase Chain Reaction Assay

Total RNA was extracted from liver, pretreated with DNase I (Invitrogen, Carlsbad, CA, USA), and then reverse-transcribed to cDNA using random primers (Invitrogen). The real-time polymerase chain reaction (PCR) was performed by SYBR Green I chemistry (SYBR Green PCR Master Mix, Applied Biosystems, Naerum, Denmark) with 25 ng of template cDNA and each gene-specific primer present at 5 μM using the ABI 7500 sequence detection system (Applied Biosystems). The PCR conditions and gene-specific primer sequences are listed in Table 1. The mRNA levels were quantified using the mathematical model described by Pfaffl et al. [28]. The mRNA levels of different genes were normalized to those of 18S rRNA.

Gallstone Formation

After 2 weeks of consuming the lithogenic diet, fresh gallbladder bile was taken from mice and evaluated for the presence of microscopic and macroscopic features of gallstone formation, according to criteria described by Wang et al. [29].

Statistics

The statistical significance of differences between the means of the experimental groups was evaluated with Student's *t* test and a 95% confidence interval using Prism 5.00 (GraphPad, La Jolla, CA, USA). A difference was considered to be statistically significant at $p < 0.05$.

Results

Analyses of Plasma Lipoprotein Cholesterol, Hepatic Cholesterol and Triglyceride Levels in Wild-Type and NPC2 (h/h) Mice Fed Control, 2% Cholesterol, and Lithogenic Diets

Lipid measurements were performed in 7 week-old NPC2 (h/h) mice since they are at steady state during the first

Thermal cycling involved 35 cycles at 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 30 s. The melting curves were performed according to the manufacturer's procedure

7 weeks of life and before detrimental effects were observed in older animals due to the neurodegenerative disease [5]. The total plasma cholesterol levels in wild-type and NPC2 (h/h) mice in response to these diets are listed in Table 2. The concentrations of total plasma cholesterol were slightly higher in NPC2 (h/h) mice fed the control diet than in wild-type animals. Feeding the mice for 2 weeks with the 2% cholesterol and the lithogenic diets increased the plasma cholesterol concentration in wild-type mice by 14 and 37%, respectively, relative to those fed the control diet. In contrast, no increase in plasma cholesterol was detected in NPC2 (h/h) mice fed with the 2% cholesterol or lithogenic diets (Table 2). We also measured plasma cholesterol levels after 3, 7 and 10 days of feeding with the lithogenic diet (Table 1, Supplementary material). Consistent with our previous results, wild-type mice increased their plasma cholesterol in response to lithogenic diet and days of diet-feeding, whereas this response was not observed in NPC2 (h/h) mice.

The lipoprotein cholesterol profiles of wild-type and NPC2 (h/h) animals fed control, 2% cholesterol, and lithogenic diets are shown in Fig. 1. When consuming the control diet, the amount of cholesterol in the intermediate-density lipoprotein and LDL fractions was slightly increased in NPC2 (h/h) mice compared to wild-type animals (Fig. 1a). Wild-type mice responded as expected to the cholesterol-rich diets [21], exhibiting a greater amount of cholesterol transported in large lipoproteins, presumably in the VLDL fraction, and a slight decrease in cholesterol associated with HDL fractions, which is seen more clearly

after using the lithogenic diet. When consuming the 2% cholesterol diet, the amount of cholesterol present in the VLDL fraction (Fig. 1b) was lower in NPC2 (h/h) mice than in wild-type mice. When consuming the lithogenic diet, NPC2 (h/h) mice exhibited a significant decrease in the amount of cholesterol transported in VLDL and HDL fractions (Fig. 1c).

Hepatic cholesterol concentrations in wild-type and NPC2 (h/h) animals fed the control, 2% cholesterol, and lithogenic diets are listed in Table 2. As expected, when consuming the control diet, the amount of hepatic cholesterol was significantly higher in NPC2 (h/h) mice than in wild-type mice. The difference between the NPC2 (h/h) mice and wild-type mice became even more pronounced when consuming the cholesterol-rich (2% cholesterol and lithogenic) diets. Unlike the wild-type animals, which maintained the liver size within the normal range, NPC2 (h/h) animals developed significant hepatomegaly when fed cholesterol-rich diets (Table 2). Hepatic triglyceride levels showed a decrease under all diets in NPC2 (h/h) mice compared with wild-type mice (Table 2), indicating that NPC2 (h/h) mice specifically accumulate cholesterol rather than triglycerides in the liver.

As expected, liver samples from NPC2 (h/h) animals showed signs of hepatic inflammation and damage as indicated by histological analysis and increased serum ALT levels (Fig. 2; Table 3). Normal portal and lobular architecture was observed in livers of wild-type mice fed the chow-diet, whereas mild lobular inflammatory activity

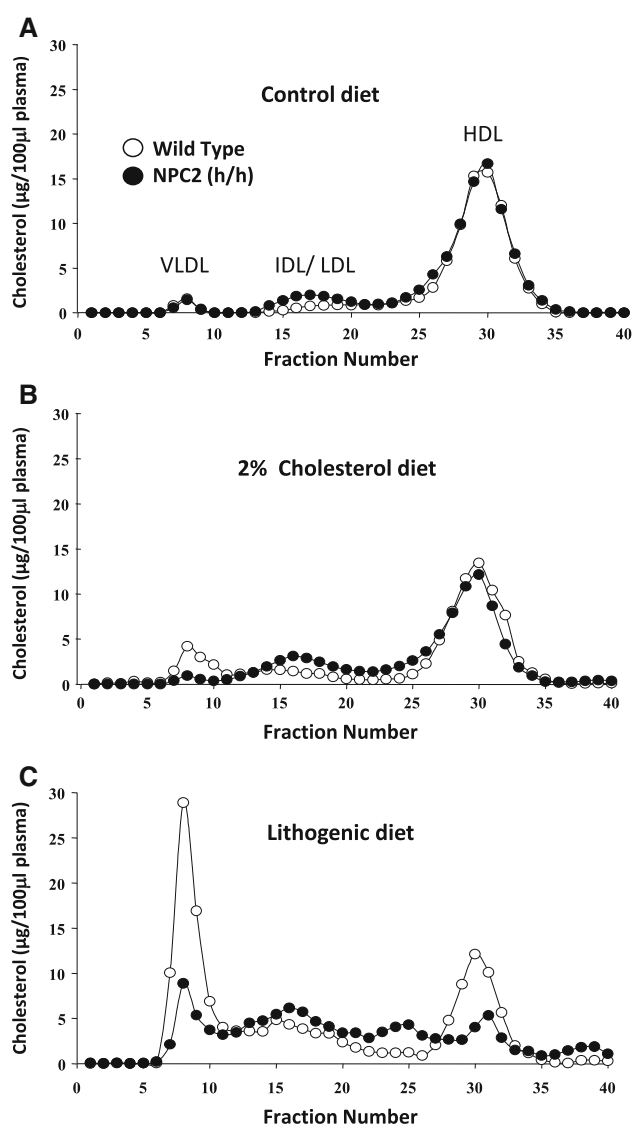

Fig. 1 Plasma lipoprotein cholesterol profile in wild-type and NPC2 (h/h) mice. Plasma lipoproteins were separated by fast protein liquid chromatography and then cholesterol content of each fraction was determined. The lipoprotein profile was analyzed for the following three dietary conditions: control (a), 2% cholesterol (b), and lithogenic (c) in wild-type mice (open circles) and NPC2 (h/h) mice (filled circles)

was observed when they were fed the high-cholesterol diets (Fig. 2, arrowheads). As expected, numerous foamy cells, presumably macrophages, were observed in sinusoids of livers from NPC2 (h/h) mice (arrows in Fig. 2). In addition, an increase of the liver damage-related marker ALT was detected in serum of lithogenic-diet fed-NPC2 (h/h) mice, being more dramatically elevated in older animals (Table 3). Interestingly, 14 days of diet are required to significantly increase ALT levels in both NPC2 (h/h) and wild-type mice, without effect at earlier time points (Table 3).

Biliary Lipid Secretion and Gallbladder Bile Lipid Composition in Wild-Type and NPC2 (h/h) Mice Fed the Control, 2% Cholesterol, and Lithogenic Diets

The results for lipid secretion from the liver into bile in wild-type and NPC2 (h/h) mice are shown in Table 2. When consuming the control diet, cholesterol and phospholipid, but not bile salt, secretions were slightly but

significantly higher in NPC2 (h/h) animals than in wild-type animals. No differences in biliary cholesterol and bile salt secretion were found between NPC2 (h/h) and wild-type mice consuming the 2% cholesterol diet; both exhibited similar increases compared to animals fed the control diet. However, NPC2 (h/h) mice exhibited a greater increase in phospholipid secretion. Wild-type animals fed the lithogenic diet exhibited 20-, 10-, and 5-fold increases

in cholesterol, phospholipid, and bile-salt secretion, respectively (Table 2). However, the NPC2 (h/h) mice responded more moderately to the lithogenic diet than did their wild-type counterparts, increasing their cholesterol and phospholipid secretions by six- and seven-folds, respectively, and their bile salt secretion by threefold.

We subsequently analyzed lipid concentrations in the gallbladder bile in wild-type and NPC2 (h/h) mice fed control, 2% cholesterol, and lithogenic diets (Table 4). Cholesterol, phospholipid, and bile salt concentrations in the gallbladder bile did not differ between wild-type and NPC2 (h/h) mice fed the control diet. When consuming the 2% cholesterol diet, the cholesterol concentration was lower and the phospholipid concentration was higher in NPC2 (h/h) mice than in wild-type mice (Table 4). When fed the lithogenic diet, the cholesterol, bile salt, and phospholipid concentrations were 37, 39, and 16%, respectively, lower in NPC2 (h/h) mice than in wild-type mice (Table 4).

Hepatic Gene Expression in Wild-Type and NPC2 (h/h) Mice Fed the Control, 2% Cholesterol and Lithogenic Diets

The differences observed in lipoprotein profiles, biliary lipid secretion, and lipid concentrations in the gallbladder bile of the NPC2 (h/h) mice may be related to changes in the expression of key genes that participate in the hepatic transport and metabolism of lipids. Therefore, we measured the expression of several lipid-related genes in the liver.

The expressions of *Ldlr* and *Srbi* did not differ significantly between wild-type and NPC2 (h/h) mice under any of the dietary conditions (Fig. 3). *Abca1* mRNA levels increased significantly only in NPC2 (h/h) mice fed the lithogenic diet. The hepatic expression of *Npc1* was lower in NPC2 (h/h) mice fed the lithogenic diet compared to their wild-type counterparts (Fig. 3). *Mttp* mRNA levels were not significantly different between wild-type and NPC2 (h/h) mice fed the control and cholesterol-enriched diets. Interestingly, however, the hepatic expression of *Pctp* was dramatically increased in NPC2 (h/h) mice fed the 2% cholesterol and lithogenic diets.

As expected from Lee et al. [30], the expression of *Cyp7a1* was significantly lower in both wild-type and NPC2 (h/h) mice fed the lithogenic diet than in mice fed the control diet (Fig. 3). On the other hand, *Hmgcr* expression decreased under the lithogenic diet condition in both wild-type and NPC2 (h/h) mice, with this change being smaller in the NPC2 (h/h) mice (Fig. 3). *Cyp27* and *Acat2* expression did not vary significantly with the animals' genetic background or dietary manipulation (Fig. 3).

Biliary lipid secretion is mediated by different members of the ABC transporter superfamily. Given that bile salt secretion increases in animals fed the lithogenic diet, it was expected that the expression of the bile-salt transporter *Abcb11* (*Bsep*) would also increase [30]. A small such response was observed in wild-type mice, but was absent in the NPC2 (h/h) mice (Fig. 3). Furthermore, the level of *Abcb11* expression was significantly lower in NPC2 (h/h) animals fed the 2% cholesterol and lithogenic diets than in their wild-type counterparts. An increase in the expression

Table 4 Effect of 2% cholesterol and lithogenic diet feeding on gallbladder bile lipid composition and cholesterol saturation index in wild-type and NPC2 (h/h) mice

| Strain and age | Diet | Gallbladder bile lipid composition (mmol/L) | | | Saturation index ^a (%) |
|-----------------------------|----------------|---|---------------------------|---------------------------|-----------------------------------|

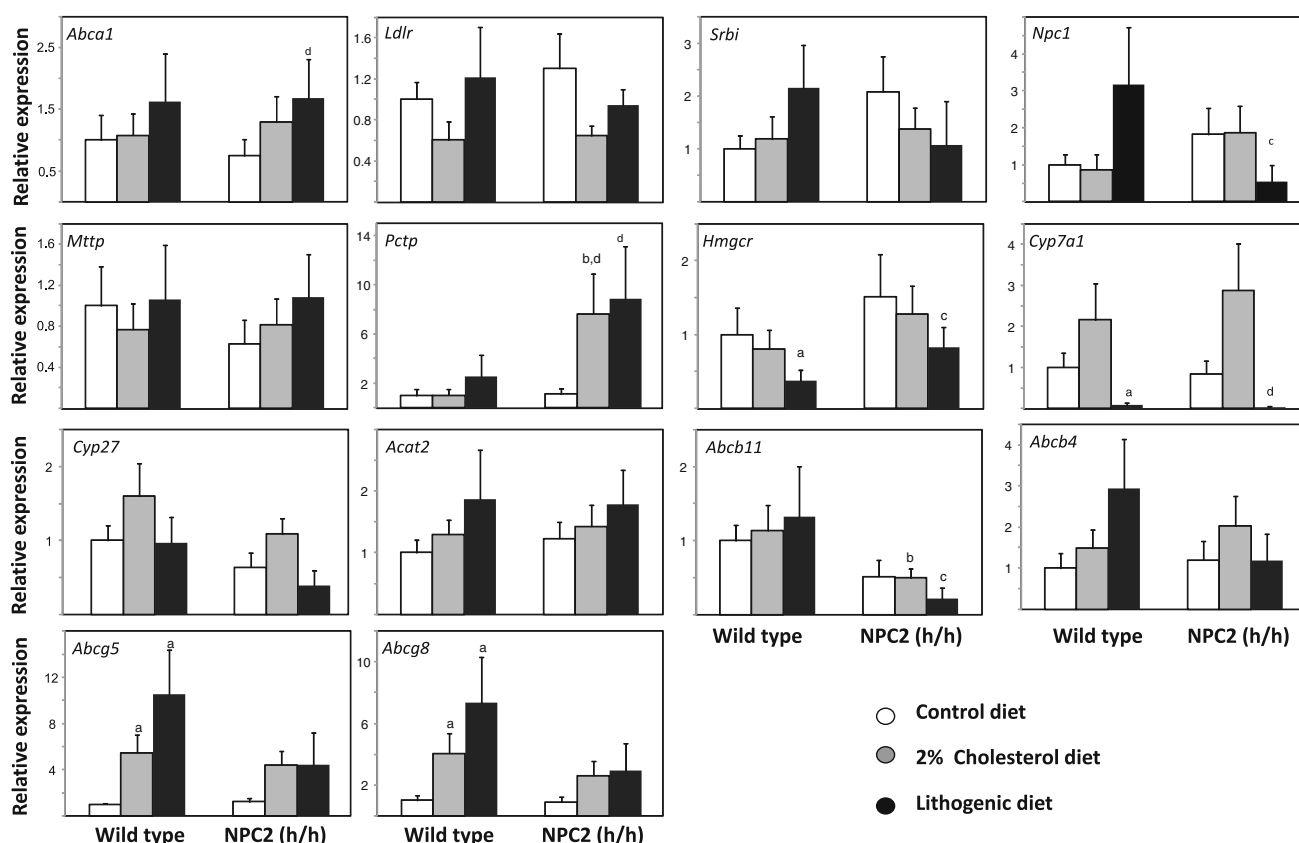

Fig. 3 Hepatic gene expression in wild-type and NPC2 (h/h) mice fed with cholesterol-rich diets. Five wild-type and five NPC2 (h/h) mice were included in each diet group. mRNA levels were normalized to 18S rRNA and expressed as increases relative to the wild-type animals fed with the control diet. The following genes were analyzed: lipoprotein transporters and receptors *Abca1*, *Ldlr*, and *Srbi*; lysosomal cholesterol transport protein *Npc1*; VLDL packing *Mttp* and phospholipid transfer *Pctp* proteins; cholesterol metabolism-related hepatic enzymes *Hmgcr*, *Cyp7a1*, *Cyp27*, *Acat2*, and;

canalicular transporters, *Abcb11*, *Abcb4*, *Abcg5* and *Abcg8*. The statistical analysis of relative expression results in real-time PCR was evaluated using the relative expression software tool (REST, described by Pfaffl et al. [28]). ^aSignificantly different from wild-type mice fed with the control diet; ^bSignificantly different from wild-type mice fed with the 2% cholesterol diet; ^cSignificantly different from wild-type mice fed with the lithogenic diet; ^dSignificantly different from NPC2 (h/h) mice fed with the control diet

of *Abcb4*, which encodes a protein that transports phospholipids into bile, was observed in wild-type mice, but this increase was not significant. Finally, ABCG5/G8 is a heterodimer that transports cholesterol into bile; its expression is expected to be higher when consuming cholesterol-rich diets [31]. This response was observed for the 2% cholesterol and lithogenic diets in wild-type mice but not in NPC2 (h/h) mice (Fig. 3).

Effect of the Lithogenic Diet on the Formation of Cholesterol Crystals and Gallstones in Wild-Type and NPC2 (h/h) Type Mice

BALB/c mice are gallstone-susceptible when they are subjected to a high-cholesterol and bile acid diet and nearly 100% of them develop cholesterol gallstones after 2 weeks of feeding this diet [22, 32]. We decided to measure gallbladder bile saturation index after 10 days of feeding with

the lithogenic diet before cholesterol crystal or gallstone formation to avoid difficulties in obtaining reliable biliary lipid measurements due to the presence of an excess of cholesterol crystals, which increase at longer dietary intervention (Table 4). The NPC2 (h/h) and wild-type mice exhibited a mean saturation index of 51.2 and 91.1%, respectively (Table 4), indicating that the gallbladder bile of wild-type mice was very close to saturation with cholesterol, while that of the NPC2 (h/h) mice remained unsaturated. When consuming the lithogenic diet, gallbladder bile from NPC2 (h/h) mice after a thaw/freezing cycle was notably translucent, while that from wild-type mice was opalescent (Fig. 4a).

After 14 days on the lithogenic diet, 100 and 90% of wild-type mice exhibited cholesterol crystals and gallstones, respectively (Fig. 4a, b). Furthermore, wild-type animals showed a time-dependent increase in both cholesterol crystals and gallstones between 3 and 14 days of

Fig. 4 Biliary cholesterol crystallization and gallstone formation in wild-type and NPC2 (h/h) mice fed with a lithogenic diet. **a** Macroscopic appearance of gallbladder bile in wild-type and NPC2 (h/h) mice fed the lithogenic diet. The photograph of 0.6 ml tubes containing bile from a single mouse in each group was taken after one freeze/thaw cycle. **b** Polarizing-light microscopy of gallbladder bile from lithogenic diet-fed wild-type and NPC2 (h/h) mice (magnification 20 \times). **c** Prevalence of gallbladder bile cholesterol crystals and gallstones in wild-type and NPC2 (h/h) mice that were fed with the lithogenic diet for 3, 7, 10, and 14 days ($n = 8$ –10 mice in each experimental group)

feeding with this diet (Fig. 4c). On the other hand, NPC2 (h/h) mice did not have either cholesterol crystals or gallstones in the gallbladder after consuming the lithogenic diet (Fig. 4c). This indicates that the NPC2 (h/h) mice were highly resistant to cholesterol cholelithiasis.

Although we decided to perform most of the lipid measurements in 7 week-old NPC2 (h/h) mice before detrimental effects were observed in older animals due to the neurodegenerative disease, we also included a group of older animals (fed for 14 days with the lithogenic diet starting at 7 weeks of age) to analyze gallbladder bile lipid concentrations and gallstone formation. We found that bile in the NPC2 (h/h) mice remained unsaturated (Table 4). Unfortunately, gallbladders of wild-type mice were filled with cholesterol stones, thus we were unable to obtain enough bile for measuring biliary lipid levels. Notably, older NPC2 (h/h) mice showed a higher increase in ALT levels compared to younger animals fed with the same diet (Table 3). Moreover, older NPC2 (h/h) mice did not have cholesterol crystals or gallstones in the gallbladder after consuming the lithogenic diet, whereas all wild-type mice formed cholesterol crystals and gallstones. Our results show that age is not a relevant factor for gallstone formation in these mice and confirm that older NPC2 h/h mice fed with this lithogenic diet remain protected against cholesterol gallstone formation.

Discussion

This study demonstrates that hepatic NPC2 plays important roles in regulating dietary cholesterol transport and biliary lipid secretion. In addition, NPC2 is critical in the pathogenesis of diet-induced gallstone formation in mice, suggesting its potential role during gallstone formation in humans.

Total plasma cholesterol was not different between control and Npc2 (h/h) mice except on the chow diet. Under this latter condition, plasma cholesterol levels were slightly higher in NPC2 (h/h) mice than in wild-type animals, which was not related to changes in the expression of genes associated with lipoprotein cholesterol metabolism, such as *Ldlr*, *Srbi*, or *ApoA1*. Interestingly, NPC2 is found in plasma [15] and may be involved in the transport or metabolism of plasma cholesterol. However, it is not known whether NPC2 present in plasma is functional at neutral pH or whether it is found free or as a component of a plasma lipoprotein complex. Studies in primary astrocytes have shown that most sterols are secreted separately from NPC2 into the surrounding medium, suggesting that secreted NPC2 is not primarily associated with cholesterol-containing particles [13]. Further studies are required to determine how NPC2 deficiency affects cholesterol levels in plasma.

The lower plasma cholesterol detected in NPC2 (h/h) mice fed the 2% cholesterol and lithogenic diets compared to wild-type mice is not attributable to intestinal cholesterol absorption deficiency. Indeed, cholesterol-enriched diets induced a dramatic increase in hepatic cholesterol content in NPC2 (h/h) mice relative to wild-type mice. In accordance with our results, recent studies have established that NPC2 expression is not required for cholesterol absorption in the intestine under a chow diet [33]. The inability of the NPC2 (h/h) mice to increase VLDL cholesterol levels upon receiving a cholesterol-enriched diet suggests that dietary cholesterol is not available for hepatic VLDL packaging and subsequent secretion into the plasma in the NPC2 (h/h) mice. No alterations were found in *Mttp* expression in the NPC2 (h/h) mouse liver, suggesting that a deficiency in cholesterol availability, rather than a global VLDL production defect, is actually limiting cholesterol incorporation in VLDL particles. In addition, our results show that NPC2 (h/h) mice accumulate less triglyceride in livers under all diets, which may also impair VLDL particle assembly. In agreement with our results, it has recently been shown decreased hepatic and serum triglyceride levels in NPC1-deficient mice [34].

The dramatic increase in hepatic unesterified cholesterol content observed in NPC2 (h/h) mice under the 2% cholesterol and lithogenic diets is consistent with the proposed role for NPC2 in cholesterol trafficking from the endosomal endocytic pathway [11]. Although the hepatic cholesterol of wild-type mice also increased with a dietary challenge of cholesterol, changes in free cholesterol were small and a larger contribution was due to the accumulation of hepatic cholesteryl esters.

Biliary lipid concentration and secretion were mainly unaffected under physiological conditions in NPC2 (h/h) mice when compared to wild-type mice. Similar results were obtained with NPC1 (–/–) mice [21]. Additional sources of cholesterol, such as hepatic neosynthesis and uptake from HDL, may be compensating for the impaired contribution of lipoprotein endocytosis to the pool of metabolically active cholesterol in livers of NPC2 (h/h) mice. Indeed, rates of cholesterol synthesis are increased in the liver of NPC1 (–/–) mice [35]. Our results show a trend to higher *Hmgcr* mRNA levels in NPC2 (h/h) mice, which suggests that hepatic cholesterol neosynthesis is somewhat increased.

Surprisingly, even though unesterified cholesterol was retained in lysosomes in NPC2 (h/h) mice, no impairments in biliary cholesterol and bile salt secretions were found in NPC2 (h/h) mice after feeding the 2% cholesterol diet. This normal biliary lipid phenotype may be due to the hypomorphic feature of the NPC2-deficient model used in this study, and thus residual NPC2 may be able to export some of the lysosomal cholesterol

obtained from the diet to be secreted into the bile. Support for this hypothesis comes from our observation that NPC2 (h/h) mice are able to convert a fraction of dietary cholesterol into hepatic cholesteryl esters. In contrast, NPC1 (–/–) mice fed a 2% cholesterol diet exhibited a more marked phenotype, with less cholesterol esterification as well as impaired biliary cholesterol and bile salt secretion [21]. Another possibility that cannot be totally excluded is that NPC1 and NPC2 do not have exactly the same function in cholesterol transport from the endocytic pathway, as recently suggested for other lysosomal cargo [36].

Interestingly, we found that biliary phospholipid secretion was greater in NPC2 (h/h) mice fed with normal chow and high-cholesterol diets than in similarly fed wild-type mice. In addition, gallbladder bile phospholipid concentration was increased in NPC2 (h/h) mice fed the 2% cholesterol diet compared to wild-type mice on the same diet. The reasons for these differences are unclear, but it could be related with the increased mRNA levels of the *Pctp* phospholipid transporter observed in livers of NPC2 (h/h) mice that were fed the 2% cholesterol-rich and lithogenic diets, suggesting a facilitated phospholipid delivery to the canalicular pole. However, studies of mice with homozygous disruption of the *Pctp* gene have shown normal phospholipid secretion into bile [37]. Although disruption of the *Pctp* gene did not affect the output of phospholipid, bile salts and cholesterol into bile of *Pctp* lacking mice fed a chow diet, the secretion of these biliary lipids was impaired when these mice were fed a high-fat, high-cholesterol lithogenic diet [38]. This may indicate that under conditions of a dietary challenge phosphatidylcholine transfer protein (PCTP) is critical in the trafficking of the biliary components to the canalicular membrane. PCTP plays a variety of regulatory effects on lipid and glucose metabolism [39–41]. Indeed, its expression is up-regulated by peroxisome proliferator-activated receptor (PPAR) α , a key transcription factor for global metabolism regulation [41]. Further studies are required to determine the consequences of *Pctp* up-regulation in the liver of NPC2 (h/h) mice. No significant difference was found in the mRNA expression levels of *Abcb4* in the livers of NPC2 (h/h) mice.

The decrease detected in cholesterol in the gallbladder bile of NPC2 (h/h) mice consuming the 2% cholesterol diet was not correlated with a decrease in biliary cholesterol secretion from the liver. We cannot rule out that this phenotype is related to a direct function of NPC2 in bile, perhaps as a solubilizing factor or an inhibitor of cholesterol transport from the bile into the gallbladder epithelium. In fact, it is known that active cholesterol transport into the epithelium occurs in the gallbladder by a process that is probably regulated by proteins [42].

The use of a lithogenic diet in mice produces an overload of dietary cholesterol as well as bile salts in the liver. Wild-type animals respond to this diet with an increase in biliary secretion and concentration of cholesterol, bile salts, and phospholipids. These changes are correlated with increased expression of *Abcg5/8* cholesterol transporters and a tendency toward an increase in the expression of *Abcb11* bile salt and *Abcb4* phospholipid transporters (Fig. 3). This response is strongly diminished in NPC2 (h/h) mice, as clearly indicated by the decrease in biliary cholesterol secretion and concentration in NPC2 (h/h) compared with wild-type mice fed the lithogenic diet as well as the lack of regulation in the mRNA levels of *Abcg5/8*. In accordance with our results, it has been shown that NPC1 and NPC2 cells synthesize less oxysterols, the endogenous LXR ligands that induce cholesterol efflux and the expression of cholesterol transporters such as ABCG5/G8 [43, 44].

The expression levels of several additional lipid-related genes were analyzed in the livers of NPC2 (h/h) mice. The mRNA levels of *Acat2*, which encodes an enzyme that converts free cholesterol into cholesterol esters, did not change under any condition. In fact, this gene does not seem to be transcriptionally regulated in the liver of either wild-type or NPC1 mice faced with a dietary cholesterol overload [22]. As expected, *Cyp7A1* mRNA levels decreased in wild-type and NPC2 (h/h) mice fed the bile acid-rich lithogenic diet. *Npc1* levels were decreased in the liver of NPC2 (h/h) mice fed a lithogenic diet. Interestingly, a reciprocal regulation in the levels of NPC1 in the NPC2 (h/h) mice was not found, whereas in various models NPC2 increases in the absence of NPC1 [13, 15]. Further studies are required to elucidate the molecular mechanisms involved in this regulation. Hepatic *Abca1* mRNA levels were increased in NPC2 (h/h) mice fed the lithogenic diet; however, ABCA1 protein regulation in murine liver seems to occur mainly via posttranscriptional mechanisms and has been shown to be increased in NPC1 deficiency [45]. Further studies are required to determine whether hepatic ABCA1 protein levels are regulated in NPC2 (h/h) mice.

Since lithogenic diet-fed NPC2 (h/h) mice exhibited signs of hepatotoxicity as indicated by increased serum alanine aminotransferase and abundance of foamy hepatic cells, it cannot be completely rule out the influence of liver damage in some of the lipid metabolism abnormalities observed in these mice. However, bile flow (data not shown) as well as phospholipid secretion were normal, indicating that some biliary secretory pathways remained functional. Our results differ with those recently published by Yamanashi et al. [46]. They found a decrease in biliary cholesterol secretion in mice fed a control diet with decreased expression of NPC2 mediated by recombinant adenovirus containing a shRNA against NPC2. This discrepancy may be due to differences in the model (transient

decrease in NPC2 expression with adenovirus versus stable manipulation in KO mice) or the mouse strain used.

The dramatic reduction in biliary cholesterol crystallization found in BALB/c NPC2 (h/h) mice fed with a lithogenic diet was correlated with reduced biliary cholesterol secretion in these animals. Our results further show that NPC2 expression regulates cholesterol concentration and saturation index in the gallbladder bile, which are critical factors in initiating the formation of cholesterol crystals. A remarkably finding was that the NPC2 (h/h) mice exhibited a complete resistance to gallstone formation during the 2 week period that they consumed the lithogenic diet, with no cholesterol sludge, crystals, or gallstone formation being observed. Our results suggest a role for the NPC2-dependent endocytic pathway in gallstone formation induced by a lithogenic diet. Consistent with this conclusion, we have shown previously that apolipoprotein E and NPC1, which are cholesterol transport proteins also involved in the hepatic lipoprotein endocytic pathway, play a critical role in regulating biliary secretion of dietary cholesterol and diet-induced cholesterol gallstone formation in mice [22, 23]. Moreover, the findings of this study are very similar with those obtained when studying hepatic cholesterol transport in NPC1 mice, which is not surprising due to the tight functional cooperation of NPC1 and NPC2 [47] allowing cholesterol exit from lysosomes [5]. Our results strongly suggest that NPC1 is incapable of compensating the lack of NPC2 and they agree with previous data showing that NPC gene products participate in the same cholesterol trafficking pathway performing different but complementary functions [5, 11].

On the other hand, it has been demonstrated that NPC2 is found in bile in a pronucleating fraction of glycoproteins that bind to concanavalin A [15]. Therefore, NPC2 may function as a pronucleating factor, favoring cholesterol crystal and gallstone formation in the gallbladder. If so, the deficiency of NPC2 may have protected these mice from gallstone formation. It remains to be determined whether NPC2 has a function in biliary cholesterol solubilization, and further studies such as assays of cholesterol crystallization in vitro in the presence of purified NPC2 are required.

In conclusion, the present study has provided data supporting a role for NPC2 in the regulation of the hepatic availability of lipoprotein cholesterol and its utilization for bile secretion as well as in diet-induced cholesterol gallstone formation in mice. Additional work is required to establish the implications of these findings for human gallstone disease.

Acknowledgments The authors thank Dr. Juan Francisco Miquel for helpful discussions. We also acknowledge the Humboldt Foundation (Germany) for donating the ABI 7500 sequence detection system used for gene expression analysis. Finally, Dr. David Sleat and Dr. Peter Lobel generously provided NPC2 (h/h) mice used in this

study. This work was supported by the Fondo Nacional de Desarrollo Científico y Tecnológico (FONDECYT Grant # 1070622), FONDAPE 15090007 and Dirección de Investigación, Facultad de Medicina, UC (Programa Inmersión de Verano, Grant to PA).

Abstract Amyloid- β (A β) is secreted from lipogenic organs such as intestine and liver as an apolipoprotein of nascent triacylglycerol rich lipoproteins. Chronically elevated plasma A β may compromise cerebrovascular integrity and exacerbate amyloidosis—a hallmark feature of Alzheimer's disease (AD). Probucol is a hypocholesterolemic agent that reduces amyloid burden in transgenic amyloid mice, but the mechanisms for this effect are presently unclear. In this study, the effect of Probucol on intestinal lipoprotein-A β homeostasis was explored. Wild-type mice were fed a control low-fat diet and enterocytic A β was stimulated by high-fat (HF) diet enriched in 10% (w/w) saturated fat and 1% (w/w) cholesterol for the duration of 1 month. Mice treated with Probucol had the drug incorporated into the chow at 1% (w/w). Quantitative immunofluorescence was utilised to determine intestinal apolipoprotein B (apo B) and A β abundance. We found apo B in both the perinuclear region of the enterocytes and the lacteals in all groups. However, HF feeding and Probucol treatment increased secretion of apo B into the lacteals without any change in net villi abundance. On the other hand, HF-induced enterocytic perinuclear A β was

significantly attenuated by Probucol. No significant changes in A β were observed within the lacteals. The findings of this study support the notion that Probucol suppresses dietary fat induced stimulation of A β biosynthesis and attenuate availability of apo B lipoprotein-A β for secretion.

Introduction

Alzheimer's disease (AD) is the most common cause of dementia, characterized by neuronal cell loss and amyloid-beta (A β) deposition on extracellular matrices and within the cerebrovasculature [1]. Amyloid- β is present at sub-nanomolar levels in most biological fluids, such as cerebrospinal fluid and plasma [2] and, at physiological levels, regulates cell growth [3–5]. A hydrophobic protein, A β may undergo oligomerisation when it becomes disassociated from chaperone proteins that ordinarily facilitate kinetics and metabolism. It is the fibrillar form of A β that is thought to trigger pro-inflammatory pathways that compromise neuronal integrity [6, 7].

The origin of cerebrovascular A β deposits in AD is presently unclear. Amyloid- β may be generated as a

consequence of proteolytic processing of the amyloid-precursor-protein, which is expressed in significant quantities on the plasma membrane of neuronal cells [8]. However, biogenesis of A β is not increased in sporadic and late onset AD—the most common phenotype of AD [9, 10]. Rather, accumulating evidence suggests that enhanced blood-to-brain delivery relative to efflux, or via A β degradative pathways within the choroid plexus results in extracellular retention of A β and thereafter, inflammatory sequelae [11, 12].

Significant A β in blood is associated with apolipoprotein B (apo B) lipoproteins, particularly those enriched in triacylglycerol (TAG). Subjects with AD have greater apo B lipoprotein-A β relative to age-matched controls [13], and in transgenic amyloid mice, onset and progression of cerebral amyloidosis is associated strongly with the secretion into and concentration of plasma apo B lipoprotein-A β [14]. Apolipoprotein B immunoreactivity is evident in parenchymal amyloid plaque from human cadaver specimens [15]; and in A β -transgenic mice, cerebral apo B distribution and abundance strongly colocalise with extracellular deposits of A β [16]—observations consistent with a vascular contribution to disease aetiology.

A range of lipoprotein (lipid)-lowering agents are commonly used in clinical practice for the prevention and treatment of cardiovascular disease and may reduce AD risk by reducing cerebrovascular exposure to apo B lipoprotein-A β . The hydroxy-methyl-glutaryl coenzyme A reductase inhibitors lower plasma cholesterol by enhancing apo B lipoprotein clearance via high affinity receptor pathways and inhibiting apo B lipoprotein biogenesis [17–19]. Similarly, fibrates reduce plasma TAG by suppressing lipogenesis, a driver for the secretion of apo B lipoproteins [20]. Population and clinical studies generally support a risk reduction for all forms of dementia in subjects taking lipid-lowering agents [21, 22], although the mechanisms for this association are not clear.

Probucol is an older generation cholesterol-lowering agent that reduces plasma cholesterol by enhancing uptake via receptor pathways [23, 24]. However, other properties of Probucol make this a particularly interesting lipid-lowering agent relative to the plasma kinetics and metabolism of apo B-lipoprotein-A β . Probucol is hydrophobic and secreted into blood incorporated within the nascent TAG-rich apo B lipoproteins, a phenomenon that may influence A β association with, and secretion of, these macromolecules [23, 25]. In addition, lipoproteins that contain Probucol are cleared from circulation almost exclusively by the liver and consequently vascular retention is substantially reduced [23]. A small clinical study suggested that Probucol reduced cognitive decline in subjects with mild cognitive impairment [26, 27] and, consistent with the human findings, studies in transgenic amyloid mice showed that Probucol reduced the

severity of amyloidosis [26]. In the latter, enhanced A β -efflux was put forward as one possible mechanism for the Probucol-induced effects.

The putative effects of Probucol on A β biogenesis and lipoprotein synthesis in lipogenic organs have not been reported. This study utilised an *in vivo* high-fat (HF) feeding model previously shown to stimulate enterocytic abundance of A β , to determine if Probucol modulates the secretion of apo B lipoprotein-A β from absorptive epithelial cells of the small intestine—a major site of A β biosynthesis [28–30].

Methods and Materials

Animals and Diet Conditions

The Curtin University Animal Experimentation and Ethics Committee approved the animal housing, handling and experimental procedures described. Seven-week-old female wild-type mice (C57BL/6J) were housed in groups and randomised into the diet or drug treatment groups ($n = 8$ mice per group). All mice were maintained on a 12-h light and dark cycle room, at 22°C and with free access to water and food. The low-fat control diet was standard AIN93M rodent chow containing <4% (w/w) fat as polyunsaturates, with <1% total digestible energy as lipids and was free of cholesterol (Glen Forrest Stockfeeders, Perth, Western Australia). To stimulate enterocytic A β production, the control feed was replaced with a HF diet enriched in saturated fats 10% (w/w) and 1% (w/w) cholesterol (Glen Forrest Stockfeeders). The principal fatty acid types in the HF treatment group were palmitic (16:0) and stearic (18:0) (total of 13% w/w) and oleic acid (18:1n-9, 6% w/w). Mice treated with Probucol (Sanofi-Aventis, Paris, France) had the drug incorporated into the chow at 1% (w/w) at the time of feed manufacture in order to achieve an estimated dose rate of 30 mg/day [23].

Tissue Collection and Sample Preparation

Mice were maintained for 32 days on the diets indicated and weighed weekly. Thereafter, mice were anaesthetised with pentobarbitone (45 mg/kg *i.p.*) and exsanguinated by cardiac puncture. Blood was collected into heparin tubes and stored in ice. Plasma was separated by short-speed centrifugation at 4°C and stored at –80°C.

A 2 cm segment of the small intestine duodenum at the proximal end was isolated, flushed with chilled phosphate buffer saline (PBS, pH 7.4) and fixed in 10% buffered formal saline for a minimum of 24 h. The tissues were then processed and longitudinal segments embedded in paraffin

wax. Serial sections of 5 μm thick were cut and mounted on silanised slides for histology and immunofluorescence.

Amyloid- β and Apolipoprotein B Immunofluorescence

Intestinal A β and apo B were detected by an immunofluorescent amplification method as previously described [31]. Intestinal tissue sections (5 μm) were deparaffinised, rehydrated and antigen-retrieval was carried out in boiling deionised water for 15 min. Briefly, all sections were permeabilised in PBS and incubated in blocking serum (20% goat serum).

For A β staining, polyclonal rabbit anti-human A $\beta_{1-40/42}$ antiserum (AB5076, Chemicon Temecula, CA), diluted to 1:2,000 in PBS was incubated overnight at 4°C. The specificity of the antibodies was previously established [28]. Sections were washed in PBS and incubated with biotinylated goat anti-rabbit secondary antibody (1:2,000 dilution) (E0432, DAKO, Carpinteria, CA) at room temperature for 1 h, followed by incubation with Streptavidin-Alexa Fluor® 546 (1:300 dilution) (S11225, Invitrogen, Victoria, Australia) for another hour in the dark for amplification. The nuclei were counterstained with DAPI (1:1,000 dilution) (Invitrogen, Victoria, Australia) for 5 min. The sections were then mounted with antifade mounting medium.

Enterocytic apo B was determined essentially as described for A β detection. Polyclonal rabbit anti-mouse apo B (ab20737, Abcam, Cambridge, UK) as primary and the biotinylated goat anti-rabbit secondary antibody was used at 1:2,250 dilutions.

Imaging

Digital images for photo microscopy were acquired through AxioCam HRm camera (Zeiss, Jena, Germany) with an AxioVert 200 M inverted microscope by Zeiss at 200 \times magnification (Plan Neofluar \times 20 objective, 1.3 numerical aperture). Excitation and emission were achieved by using filters 43 (Ex BP545/25, beam splitter FT570 and Em BP605/70) and filter 49 (Ex G365, beam splitter FT395 and Em BP445/50) to determine fluorescence of Alexa Fluor® 546 and DAPI, respectively. Individual channels are free from fluorescence from other emission sources and are therefore clear of overlap. Each image was captured under identical exposure times utilising AxioVision software (version 4.7.1) to avoid artificial modification in pixel intensity.

Quantitative Immunofluorescent Imaging and Analysis

Images were collected at 200 \times magnification and approximately 30–50 images were captured per group showing at

least four villi in each image (1,388 \times 1,040 pixels per image). Pixel intensity for each fluorescent dye was obtained by calculating the densitometric sum by Automatic Measurement Program in AxioVision (Software version 4.7.1). Densitometric sum was calculated for each image staining intensity of A β , apo B and DAPI (nuclei).

For each image, either apo B or A β pixel intensities were standardised with total DAPI pixel intensity to normalise for cell number in the image, and expressed as per DAPI. Staining intensity in the perinuclear region within the enterocytes was calculated and expressed as perinuclear intensity per total DAPI for the image (perinuclear apo B/total DAPI, perinuclear A β /total DAPI). Lacteal staining intensity was obtained by subtracting perinuclear staining intensity from the whole villi intensity (lacteal apo B/total DAPI, lacteal A β /total DAPI). The data were then collated and final results are expressed as mean intensity \pm standard error of mean per area unit.

Plasma Cholesterol and Triacylglycerol Analysis

Plasma Cholesterol and TAG were determined in duplicate by enzymatic assays (Randox Laboratories, Crumlin, UK) according to the manufacturers' instructions.

Statistical Analysis

All data was analysed by either parametric or non-parametric one-way analysis of variance (ANOVA) to assess the main effects of dietary fat and Probuco treatment and their two-way interactions. Post-hoc comparison of means was done if the associated main effect or interaction was statistically significant within the ANOVA procedure. *P* values < 0.05 were considered to be statistically significant.

Results

The distribution and abundance of immunoreactive apo B, an exclusive marker for nascent chylomicrons, was determined by quantitative immunofluorescent microscopy as previously described. Perinuclear enterocytic and lacteal abundance were utilized as surrogate markers of production and secretion, respectively. In all groups, the majority of immunoreactive apo B (\approx 80%) was located within the lacteals (Fig. 1, 2a), indicative of the efficient packaging and secretory pathway of dietary lipids with chylomicrons. Provision of an HF diet for 32 days resulted in a 60% increase of secreted apo B commensurate with decreased perinuclear apo B (Fig. 1, 2a), but there was no significant change in net villi apo B abundance (perinuclear + lacteal). Incorporation of Probuco in the LF diet, like the HF

Fig. 1 Images showing apo B (red) and A β (yellow) in the intestinal villi. The nuclei are stained blue. The villi are lined with a single layer of absorptive epithelial cells. Amyloid- β staining is concentrated at the perinuclear region of the enterocytes (*P* arrow) with very little

staining in the lacteals (*L* arrow). In contrast, a high concentration of the apo B is found within the lacteals of all the groups. Bar 30 μ m, LF low-fat, HF high-fat, P probucol

diet, stimulated secretion of apo B. However, there did not appear to be a synergistic effect of HF + P. The findings of similar net villi abundance of apo B between treatment groups and a strong negative association between the perinuclear- versus lacteal-apo B distribution (Fig. 2c), is consistent with studies suggesting that enterocytic apo B is synthesized constitutively, whereas the secretion of the nascent lipoproteins is modifiable in response to the availability of dietary lipids [32].

The perinuclear and lacteal distribution of A β was qualitatively identical to that of apo B. Indeed, co-localisation analysis confirms that A β secreted from enterocytes was associated with chylomicrons. However, there were substantial differences in the relative villi abundance of A β and apo B and in the pattern of secretion between the two proteins. In contrast to apo B, approximately 70–80% of total intestinal villi A β was observed within the baso-lacteal nuclear region of the absorptive epithelial cells, suggesting that only small quantities of the total enterocytic A β pool were being secreted (Fig. 1, 2b). The HF-enriched diet doubled intestinal villi A β abundance but, in contrast to apo B, this was reflected predominantly in increased enterocytic abundance with virtually no change in the secreted component (Fig. 2b). Incorporation of Probucol in the HF diet normalized enterocytic A β to levels that were comparable to the LF control, in the absence of a reduction in lacteal A β . The latter suggests that Probucol reduced enterocytic A β primarily as a consequence of lower rates of biosynthesis. However, correlation analysis of perinuclear versus lacteal

A β identified a relatively weak but nonetheless positive association (Fig. 2d), suggesting that increased rates of A β production also lead to modest increases in apo B lipoprotein-A β secretion.

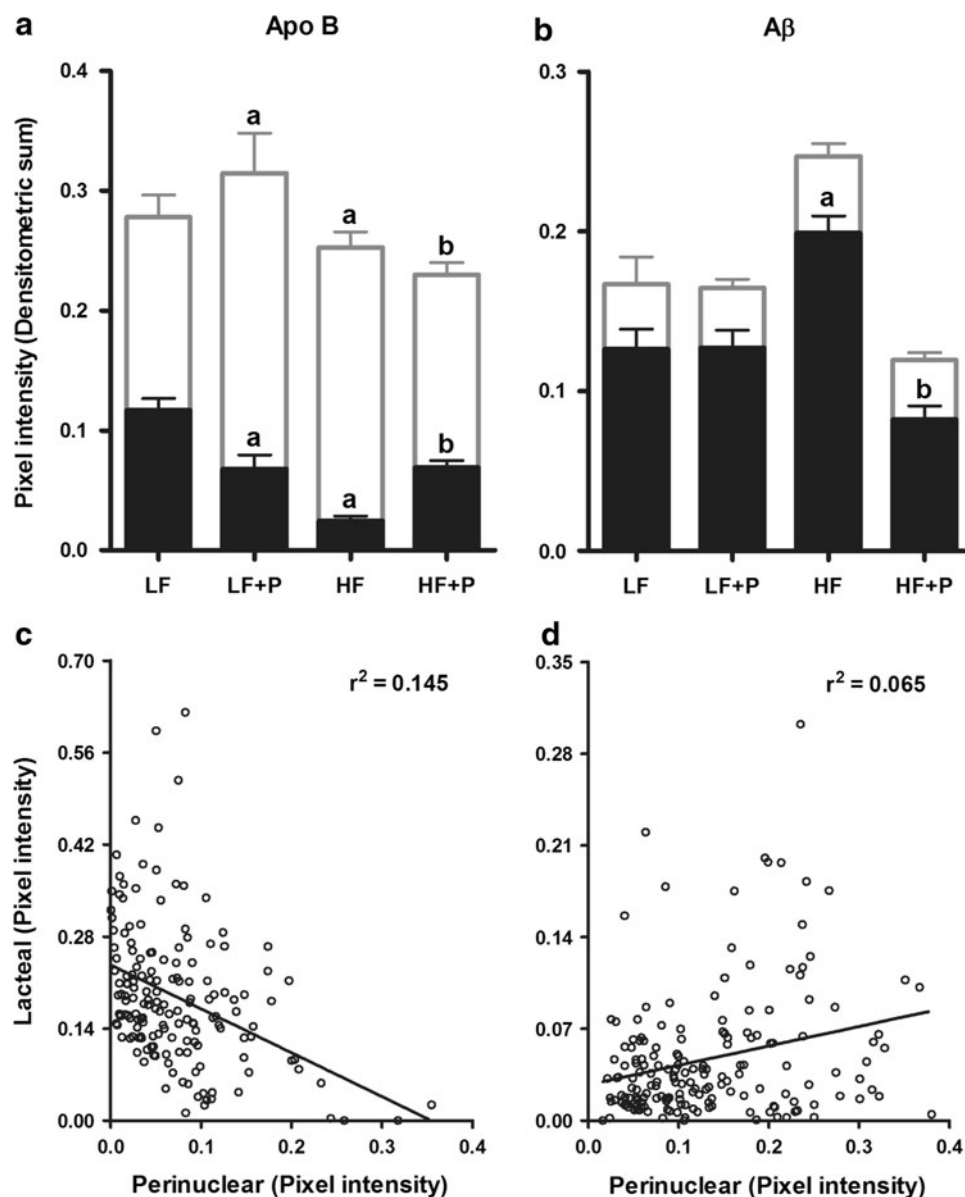

The effects of HF- or Probucol-supplemented diets on plasma cholesterol, plasma TAG and body weight gain for each group of mice is given in Table 1. The mice fed the HF enriched diet had an increase in plasma cholesterol of more than two-fold compared to the LF control; however, the incorporation of Probucol completely abolished this effect. Indeed, the HF + P group had comparable plasma cholesterol to the LF + P treated mice. Probucol also significantly reduced plasma cholesterol in LF mice. In contrast, there was no appreciable effect of HF feeding, or Probucol, on plasma TAG in any treatment group.

Mice maintained on the HF diet were found to have a greater rate of body weight gain compared to mice maintained on the LF diet. Probucol had a synergistic stimulatory effect on body weight gain. Mice on LF + P were similar in weight to mice maintained on the HF diet, and mice on the HF + P were significantly heavier in weight than mice on HF alone.

Discussion

In absorptive epithelial cells of the small intestine, dietary fats regulate enterocytic abundance of A β profoundly, reflecting either changes in A β biogenesis, or in the

Fig. 2 **a, b** Bar graphs showing quantitative analysis of perinuclear (filled squares) and lacteal (open squares) apo B and A β staining intensities. Pixel intensity is expressed as densitometric sum as a ratio of nuclei intensity to normalise for nuclei number. **c, d** Scatter plots showing the distribution of apo B and A β between the perinuclear and lacteal regions of all groups. Pearson's correlation analysis (r^2 values) for apo B and A β was 0.145 ($P < 0.0001$) and 0.065 ($P = 0.0006$), respectively. **a** Statistically significant in comparison to the LF group ($P < 0.05$). **b** Statistically significant in comparison to the HF group ($P < 0.05$). secretion of lipoproteins containing A β [28, 29]. Several lipid-lowering agents, including statins and fibrates, have been shown to suppress apo B secretion [17, 18, 20]; however, Probucol may have pleiotropic benefits post-secretion, including enhanced hepatic clearance apo B lipoprotein-A β and anti-oxidant activity.

In this study, an established *in vivo* murine model was used to investigate if Probucol modulates the effects of a HF diet on enterocytic A β and its secretion thereafter, with apo B lipoproteins. The study confirms that a HF diet substantially increases enterocytic perinuclear abundance of A β . Apolipoprotein B lipoprotein secretion is enhanced by HF feeding, but without evidence of a concomitant increase in lacteal A β staining. Therefore, the HF-mediated effect on enterocytic A β abundance is likely to be a consequence of greater rates of A β synthesis, rather than

diminished rates of secretion. Previous studies reported that a HF-induced accumulation of enterocytic A β is progressively depleted in the post-absorptive state, or once food is withdrawn [28]. Hence, a dietary fat induced stimulation in A β biogenesis with constitutive rates of secretion as suggested in this study, would result in extended post-prandial amyloidemia. Clinical studies in normal healthy subjects consuming a mixed lipid meal are consistent with a transient single meal effect [34]. A phenomenon of extended exposure may be important in modulation vascular function. Co-administration of Probucol with the HF diet completely abolished the HF-induced effect on enterocytic A β abundance in the absence of a significant stimulatory effect on apo B lipoprotein-A β secretion. The findings are consistent with Probucol normalising enterocytic A β biogenesis, rather than promoting enterocytic secretion of A β .

Table 1 Effect of various feedings regimes on the average weight and plasma lipids in wild-type mice (C57BL/6J)

| Feeding regime ^c | Body weight (g) ^d | | Plasma lipids (mM) ^e | |
|-------------------------------|------------------------------|--------------------------|---------------------------------|-------------|
| | Final | Weight gain | TC | TAG |
| LF (<i>n</i> = 8) | 20.56 ± 0.27 | 2.00 ± 0.16 | 1.86 ± 0.06 | 0.55 ± 0.05 |
| LF + <i>P</i> (<i>n</i> = 8) | 22.23 ± 0.36 ^a | 4.55 ± 0.16 ^a | 0.83 ± 0.04 ^a | 0.65 ± 0.06 |
| HF (<i>n</i> = 8) | 22.48 ± 0.33 ^a | 4.36 ± 0.19 ^a | 2.88 ± 0.17 ^a | 0.63 ± 0.10 |
| HF + <i>P</i> (<i>n</i> = 8) | 23.58 ± 0.32 | 5.82 ± 0.19 ^b | 0.67 ± 0.05 ^b | 0.39 ± 0.04 |

Data represented as mean ± standard error of the mean (SEM), numbers (*n*) indicate total number of samples used

LF low-fat, HF high-fat, *P* probucol, TC total serum cholesterol, TAG serum triglyceride

Values with lower case ^a and ^b indicate statistical significance in comparison with LF and HF groups, respectively, where *P* < 0.05

^c Wild-type mice (C57BL/6J) were randomised to four different feeding regimens (*n* = 8 mice per group) and were fed their respective diets for 32 days. Weights, total serum cholesterol and triglyceride levels at the end of the experiment were compared between the groups with Post-hoc comparison of means within the ANOVA procedure and *P* < 0.05 was considered significant

^d The average final body weights (per mouse) for LF + *P* and HF groups were significantly greater in comparison to the LF group; however, HF + *P* group final body weight was similar to that of the HF group. There was significant weight gain by all groups (vs LF) and there was also weight gain by the HF + *P* treated mice in comparison to the HF group

^e Total plasma cholesterol level was significantly reduced by probucol treatment alone (vs LF), also by the HF + *P* treated group in comparison to the HF group. Fat feeding significantly have increased the circulating cholesterol level. On the other hand, neither the probucol treatment nor fat feeding did not affect the triglyceride concentration

Indeed, whilst Probucol was found to stimulate apo B lipoprotein secretion in LF-fed mice, there was no evidence that this translated into significantly increased enterocytic release of Aβ.

The HF diet utilized in this study contained both SFA and cholesterol, provided together in a context that it is physiologically relevant in comparison to commonly consumed atherogenic diets. The effects of Probucol on Aβ synthesis and secretion reported in this study must therefore be considered in the context of a mixed dietary lipid setting. Regulation by Probucol may change depending on the interactive effects of dose and duration of dietary lipids.

Several studies have shown synergistic stimulatory effects of fatty acids and cholesterol on apo B lipoprotein secretion [35, 36]. Therefore, the finding of increased apo B lipoprotein secretion shown in this study in HF-fed mice is to be expected. However, previous studies in the same strain of mice fed SFA, or cholesterol, found stimulatory and suppressive effects, respectively, on enterocytic abundance of Aβ [29, 33]. Saturated fatty acids were shown to have a profound stimulatory effect on enterocytic Aβ abundance, whereas dietary cholesterol was inhibitory. The reasons for the paradoxical differences between SFA and cholesterol have not been determined but may include differential regulation of Aβ biogenesis, transfer and association of Aβ with apo B lipoproteins and/or changes in intracellular degradation of Aβ or apo B lipoproteins.

In this study, saturated fats presented at 20% of digestible energy combined with 1% (w/w) cholesterol increased enterocytic abundance by approximately 75% above control mice given the LF diet alone. Hence, it would appear that the effects of SFA on enterocytic Aβ

homeostasis were substantially greater than that of dietary cholesterol. How SFA influence Aβ biogenesis and association with apo B lipoproteins is not known. One possibility is increased lipidation of Aβ, a process found to protect other lipophilic apoproteins from proteolytic degradation.

Several studies suggest that the intracellular distribution between free cholesterol may be important in modulating Aβ homeostasis and intracellular kinetics. Inhibition of cholesterol trafficking in neuronal cells decreased β-secretase but enhanced γ-secretase processing of Aβ precursor protein [37]. The substantial increase in γ-secretase resulted in an increased intracellular concentration of Aβ [37]. Whilst in enterocytes Aβ biogenesis does not appear to occur at the plasma membrane, the subcellular distribution of cholesterol might nonetheless induce critical changes in the cell membranes of intracellular compartments such as within the endoplasmic reticulum and Golgi or re-localise enzymes responsible for Aβ synthesis, or its association with primordial lipoproteins. The notion that Probucol regulates enterocytic biogenesis of Aβ or association with apo B lipoproteins via modulation of intracellular pools of cholesterol is supported by the findings of Tawara et al. [38], who reported that Probucol stimulates cholesterol biosynthesis in absorptive epithelial cells of the small intestine, a process that would suppress Aβ biogenesis.

The HF diet resulted in greater body weight gain compared to LF-fed mice, presumably as a consequence of increased caloric intake and, somewhat surprisingly, Probucol also enhanced body weight gain in LF-fed mice. However, there was no evidence that body weight was associated with perinuclear or lacteal abundance of Aβ, or

of apo B lipoprotein-A β , so it is unlikely there is a causal association.

Clinical and animal studies suggest that Probucol may reduce AD risk and attenuate amyloidosis [26, 27, 39]. Suggested mechanisms include enhanced cerebrovascular efflux of soluble A β and neuro-protection as a consequence of suppression of oxidative pathways. Other indirect lines of evidence suggest that Probucol could confer AD protection by reducing vascular exposure to cytotoxic compounds including exaggerated plasma cholesterol, fatty acids or a reduction in inflammatory proteins including A β . The findings of this study support the latter notion and show that Probucol appears to suppress dietary fat induced stimulation of A β biosynthesis.

The 1 month dietary intervention study described in this study did not identify any significant increase in secretion of apo B lipoprotein-A β per se, and hence may reflect a localised phenomenon that is not particularly relevant to AD risk. Clearly, longer term feeding studies with an emphasis on the effects of Probucol on blood–brain barrier integrity and plasma A β homeostasis are warranted.

Serum 2-Methoxyestradiol, an Estrogen Metabolite, is Positively Associated with Serum HDL-C in a Population-Based Sample

Abstract Serum HDL cholesterol (HDL-C) is inversely associated with coronary artery disease, ischemic stroke, and atherosclerosis in men and women. Among postmenopausal women, oral conjugated equine estrogen (CEE) increases serum HDL-C. This is due to activation of hepatic nuclear estrogen receptors, resulting in increased HDL-C expression, as well as modulation of proteins which metabolize HDL-C. 2-methoxyestradiol (2-MeOE2), an estrogen metabolite, has several vasculoprotective effects and may play a role in HDL-C production. 2-MeOE2 inhibits HMG-CoA reductase in vitro but no study has examined the relationship between serum 2-MeOE2 and serum HDL-C. A population-based sample provided information regarding demographic characteristics and use of antihyperlipidemic medications. Serum was analyzed for 17β -estradiol (E2), estrogen metabolites (EMs), and lipoproteins. Results included serum EM data from 51 men and 47 postmenopausal women. Preliminary analysis revealed no correlation between 2-MeOE2 and serum HDL-C in men so the current analysis includes only women ($N = 40$) with no missing demographic, medication, EM, or lipoprotein data. Linear regression revealed that serum 2-MeOE2 and antihyperlipidemic medications were positively associated with serum HDL-C ($\beta = 0.276$, $P = 0.043$, and $\beta = 0.307$, $P = 0.047$, respectively) when age, race/ethnicity, and body mass index were held constant. Prospective studies are needed to

determine if 2-MeOE2 is causally related to HDL-C in women.

Introduction

Serum HDL-C is inversely associated with coronary artery disease [1], ischemic stroke [2], and atherosclerosis in men and women [3]. HDL-C provides atheroprotection by promoting cholesterol efflux from peripheral tissues, transporting cholesterol to the liver for excretion as free

cholesterol or bile acids, serving as an anti-oxidant, and suppressing inflammation [3, 4]. Serum HDL-C levels are higher [5] and cardiovascular disease rates are lower among pre-menopausal women compared to similarly aged men [6]. Recent analysis of WHI data indicate that women in the 50–59 year age group with prior hysterectomy who took CEE without progesterone had a significantly lower risk of MI (HR = 0.54, 95% CI, 0.34–0.86) compared to controls [7]. This effect may have been due to atheroprotection from HDL-C, which is known to increase with oral estrogen supplementation [8].

But how does oral CEE increase serum HDL-C levels? A hepatic first pass effect may be important [9] because transdermal estrogen does not lead to increased serum HDL-C [10]. CEE contains E2 [11] and in the liver, E2 activates nuclear estrogen receptors (ERs) and increases the expression of HDL-C and apo A-I, the major protein component of HDL-C [9, 12]. E2 also modulates the expression of proteins involved in the metabolism of HDL-C, such as HL and SR-BI [13, 14]. Human studies demonstrate a correlation between HL activity and HDL catabolism [15]. Estrogen reduces HL mRNA levels in rats, suggesting transcriptional inhibition of this enzyme [16]. In vitro, E2 increases SR-BI promoter activity via nuclear ERs [13]. SR-BI has several effects, including enhanced HDL cholesterol uptake by the liver (reverse cholesterol transport) [17] and increased efflux to lipoproteins from atheromatous arteries [18].

Increasing evidence suggests that 2-MeOE2, a major endogenous metabolite of E2, also has beneficial effects on serum cholesterol and vascular integrity [19]. In ovariectomized rats, oral administration of 2-MeOE2 reduced total cholesterol levels by 34% compared to controls [20]. Subcutaneous infusion over 24 weeks of 2-hydroxyestradiol, the precursor of 2-MeOE2, into obese ZSF1 rats, a genetic model of obesity and the metabolic syndrome, led to significant reductions in total cholesterol, body weight, fasting plasma glucose, and glycated hemoglobin compared to controls [21]. More recently, subcutaneous infusion of 2-MeOE2 into apolipoprotein E-deficient mice reduced both total serum cholesterol and aortic atherosclerotic plaque size compared to controls [22]. However, the mechanism of these effects is not known [20–22].

A recent study found that 2-MeOE2 inhibits HMG-CoA reductase in vitro [23]. Because HMG-CoA reductase inhibitors reduce LDL-C and raise HDL-C in vivo [24], a mechanism exists by which endogenous 2-MeOE2 may influence circulating cholesterol levels. In addition, the ability of oral CEE to increase serum HDL-C may be augmented by the conversion of E2 in CEE to 2-MeOE2 by hepatic estrogen metabolizing enzymes, such as CYP3A4 [25]. Given its inhibition of HMG-CoA reductase, we hypothesized that serum 2-MeOE2 would be positively

associated with serum HDL-C in a population-based sample of adults.

Materials and Methods

Data for this study were gathered in the fifth year of the Chicago Health, Aging, and Social Relations Study (CHASRS), which is a population-based longitudinal study designed to examine the relationships between psychosocial characteristics and health outcomes among middle-aged and older adults. Written, informed consent was obtained from the subjects prior to their participation in this study (protocol # 11143B), which was approved by the University of Chicago's Institutional Review Board.

Subjects completed surveys regarding their demographic, dietary, and exercise characteristics, as well as their medication usage. Body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared. The following medications were classified as anti-hyperlipidemic agents: HMG-CoA reductase inhibitors (statins), niacin, bile acid sequestrants, and cholesterol absorption inhibitors. Serum was analyzed for E2 and 14 EMs using LC-MS/MS [26]. Mean values for all EMs are reported separately for men and women in Masi et al. [27]. EM values exhibited a positively skewed distribution and were therefore subjected to natural log (ln) transformation. Non-fasting HDL-C, total cholesterol, and triglycerides were measured using the Cholestech LDX kit (Cholestech Corporation, USA), a system that meets CDC reference standards for accuracy and reproducibility. LDL-C was calculated using the Friedewald equation. In year 5, we had serum EM data from 51 men and 51 women; all of the women were postmenopausal. Four women were excluded because they were taking hormone replacement therapy. Preliminary analysis revealed no correlation between 2-MeOE2 and serum HDL-C in men so the current analysis includes only women who had no missing demographic, medication, EM, or cholesterol data ($N = 40$).

Ordinary linear regression analysis was used to evaluate the relationship between serum HDL-C and predictor variables, including age, race/ethnicity, BMI, use of anti-hyperlipidemic medications, and serum 2-MeOE2. Given the directional nature of the hypothesis, a one-tailed t test of the significance of the regression coefficient for 2-MeOE2 was used to evaluate our hypothesis that 2-MeOE2 would be positively associated with HDL-C.

Results and Discussion

Table 1 provides descriptive statistics of the sample of post-menopausal women in the Chicago Health, Aging, and

Table 1 Demographic characteristics, mean 2-MeOE2 concentration, and mean serum lipid profile of study participants

| Variable | Women not on HRT (<i>N</i> = 47) |
|---|-----------------------------------|
| Age (years) | 57.3 (3.9) ^a |
| White (%) | 48.9 |
| Black (%) | 23.4 |
| Latino (%) | 27.7 |
| Body mass index | 32.0 (7.3) |
| Use of antihyperlipidemic medications (%) | 32.6 |
| 2-Methoxyestradiol (2-MeOE2, pg/ml) | 19.0 (17.6) |
| Serum cholesterol & triglycerides (mg/dl) | |
| Total cholesterol | 205.6 (38.2) |
| HDL-C | 56.2 (18.4) |
| LDL-C | 117.8 (36.9) |
| Triglycerides | 163.0 (84.3) |

Social Relations Study. Correlational analysis revealed a sizeable positive relationship between serum ln 2-MeOE2 and serum HDL-C ($r = 0.31$; $P = 0.05$). Neither serum ln E2 ($r = 0.08$; $P = 0.59$) nor any other serum ln EM was significantly associated with serum HDL-C. Multivariate regression analysis showed that 2-MeOE2 retained a positive association ($\beta = 0.28$, $P < 0.05$) with serum HDL-C when age, BMI, race/ethnicity, and antihyperlipidemic medications were held constant (see Table 2). In the same model, use of antihyperlipidemic medications was also positively associated with serum HDL-C. To test whether the positive relationship between serum ln 2-MeOE2 and serum HDL-C reflected an effect of E2, we added serum ln E2 to the model shown in Table 2. In this ancillary analysis, serum ln E2 was not associated serum HDL-C. In addition, the positive association between serum ln 2-MeOE2 and HDL-C remained unchanged.

Consistent with our hypothesis, we found a positive association between serum 2-MeOE2 and serum HDL-C. This was true among postmenopausal women but not among similarly aged men. Animal studies indicate that 2-MeOE2 lowers serum total cholesterol [20–22] and shrinks atherosclerotic plaque size [22]. A key factor in cholesterol efflux from peripheral tissues, including atherosclerotic plaques, is HDL-C [3]. It is possible, therefore, that the reduction of atherosclerotic plaque size among mice receiving subcutaneous 2-MeOE2 is due to induction of HDL-C by 2-MeOE2. This is plausible given the demonstrated inhibition of HMG-CoA reductase by 2-MeOE2 [23] and that HMG-CoA reductase inhibition increases serum HDL-C in humans [24].

ER-dependent mechanisms of oral E2-induced HDL-C production include increased hepatic expression of HDL-C

Table 2 Model predicting serum HDL-C in postmenopausal women (*N* = 40)

| Predictor | Standardized coefficient (β) | <i>P</i> value |
|---------------------------------------|--------------------------------------|----------------|
| Constant | | 0.309 |
| Age | 0.098 | 0.289 |
| Black | −0.119 | 0.250 |
| Latino | −0.258 | 0.080 |
| Body mass index | −0.121 | 0.253 |
| Use of antihyperlipidemic medications | 0.307 | 0.047 |
| ln 2-MeOE2 | 0.276 | 0.043 |

and apo A-I [9, 12], as well as modulation of proteins involved in the metabolism of HDL-C [14, 15]. Although the ability of oral E2 to raise serum HDL-C in postmenopausal women is well-recognized [8, 28], research has not established a relationship between endogenous E2 and HDL-C, at least in premenopausal women [8, 29]. The lack of correlation we found between serum E2 and HDL-C is therefore consistent with previous studies. In addition, because E2 was not correlated with HDL-C in univariate or multivariate analysis, we are confident that the association between 2-MeOE2 and HDL-C does not reflect an association between E2 and HDL-C.

The validity of our results is supported by our finding of an expected positive association between use of antihyperlipidemic medications and serum HDL-C. The effect size of these medications ($\beta = 0.31$) is only slightly larger than the effect size of 2-MeOE2 ($\beta = 0.28$), suggesting that 2-MeOE2 may be a potent inducer of HDL-C. However, given the cross-sectional nature of the study design, causal inferences cannot be made. For example, our results are also consistent with induction of 2-MeOE2 by HDL-C or with induction of both by a third variable. Prospective studies are therefore needed to determine the causal direction of this association.

Whereas EMs were once thought to be biologically insignificant, an increasing number of studies have demonstrated the metabolic importance of these molecules [25], particularly with respect to breast cancer risk [30]. We previously demonstrated an inverse relationship between serum 16 α -hydroxyestrone and systolic blood pressure among postmenopausal women [27]. In addition, Dubey et al. have documented several vasculoprotective effects of 2-MeOE2, including inhibition of abnormal growth of vascular smooth muscle cells, cardiac fibroblasts, and glomerular mesangial cells, as well as suppression of inflammation, and enhanced endothelium-dependent arterial relaxation (reviewed in [31]). Despite progress in this area, ours is the first study to document a positive association between serum 2-MeOE2 and serum HDL-C, an

essential component of athero- and cardioprotection. Further studies are needed to determine whether 2-MeOE2 can indeed increase HDL-C and what behavioral and genetic factors lead to higher levels of this EM. If 2-MeOE2 is causally related to HDL-C, this association may point to new strategies for reducing cardiovascular disease risk among postmenopausal women.

Abstract The current study examined the efficacy of graded doses of *c9,t11* and *t10,c12* CLA isomers on body composition, energy expenditure, hepatic and serum lipid liver biomarkers in hamsters. Animals ($n = 105$) were randomized to seven treatments (control, 1, 2, 3% of *c9,t11*; 1, 2, 3% of *t10,c12*) for 28 days. After 28 days treatment, 1–3% of *t10,c12* lowered ($p < 0.05$) body fat mass compared to the control group. The 1–3% *t10,c12* and 3% *c9,t11* fed groups showed higher ($p < 0.05$) lean mass compared to other groups. We observed unfavorable changes in plasma total cholesterol and non-HDL cholesterol levels in animals fed with 3% *t10,c12* CLA isomers. The 2%, 3% *t10,c12* groups presented elevated ($p < 0.05$) ALT levels. The present data suggest that a diet enriched with more than 2% *t10,c12* led to liver malfunction and poses unfavorable changes on plasma lipid profiles. The 1% *t10,c12* CLA lowered ($p < 0.05$) body fat mass and

increased ($p < 0.05$) lean body mass. The *c9,t11* CLA has less potent actions than *t10,c12* CLA. We conclude that the actions of CLA on energy and lipid metabolism are form and dose dependent in the hamster model.

Introduction

Major isomers of CLA include *cis*-9,*trans*-11 (*c9,t11*) CLA and *trans*-10,*cis*-12 (*t10,c12*) CLA [1]. Over the last decade, health benefits of CLA have received a great deal of attention in various animal models and humans. Results have shown that *c9,t11* and *t10,c12* CLA mixtures possess anticancer effects both in vitro and in vivo [2–5]. Other effects including body composition modulation, atherosclerosis prevention, as well as immune system enhancement, have also been suggested in animal models [6–9]. CLA isomer enriched diets also effectively reduce body fat and increase lean body mass in several species [7, 10, 11]. However, previous studies have mainly focused on the effect of *c9,t11* and *t10,c12* CLA mixtures and conflicting results have been reported in many studies (Supplemental Table 1). Such sizable variation in results may due to the variability in animal model, duration of feeding as well as form, and the dosage of each isomer used. Indeed, the two

CLA isomers may play different roles in body composition changes as well as lipid metabolism. The favorable modulation of body composition is mainly ascribed to the *t*10,*c*12 CLA isomer [12], while a less potent effect has been reported for the *c*9,*t*11 CLA isomer. Lack of effect on *c*9,*t*11 CLA consumption on body composition modulation may due to the use of mixture of isomers, where the effect of one isomer may overshadow another, or to the relative low dosage used in different trials.

In terms of lipid metabolism and safety, previous investigations have shown that CLA lowers total cholesterol and triglyceride levels in plasma [13, 14]; nevertheless, these appear to be highly species dependent. Less consistent results have been observed in hamster and human studies [13, 15]. Moreover, safety issues have been raised over CLA supplementation since increased spleen and liver weights have been observed in some animal studies [16, 17]. Indeed, a systematic comparison of the two major isomers at graded dosages has not been previously conducted. Very few studies have investigated the effect of highly enriched *c*9,*t*11 and *t*10,*c*12 CLA isomer effect solely (Supplement Table 1). Therefore, the current investigation was aimed to examine both isomer and dosage effect of *c*9, *t*11 and *t*10, *c*12 CLA on body composition changes and serum lipid content modulation in Golden Syrian hamsters. Hamsters are considered to be a suitable model for studying lipid changes due to their similar lipoprotein profile and metabolism compared to humans [18]. Additionally, safety evaluation was also assessed in the present study.

Materials and Methods

Animals and Study Design

One hundred and five male Golden Syrian hamsters (Charles River Laboratories, Montreal, Quebec) weighing between 90 and 100 g were housed individually in plastic cages and subjected to a 12 h light/dark cycle at constant room temperature 25 °C. Upon arrival, the hamsters were provided with free access to rodent chow diet (Nestle, Purina, USA) and water for 3 weeks, and then switched to a semi-purified hypercholesterolemic diet containing 5% fat and 0.25% cholesterol for 3 more weeks. The study used a completely randomized design. Hamsters were randomized into 7 groups of 15 animals. Seven experimental diets were tested, including a control diet with no CLA and treatment diets enriched with 1, 2, 3% of *c*9, *t*11 CLA as well as 1, 2, 3% of *t*10,*c*12 CLA, each provided for 4 weeks. CLA isomers were provided in free fatty acid form and prepared by low temperature crystallization. Both CLA isomers were supplied by Lipid Nutrition

(Wormerveer, Netherlands). Table 1 presents the macronutrient and fatty acid composition of experimental diets. Dietary ingredients were purchased from Harland Laboratories Inc. (Indiana, USA) except cornstarch and sucrose which were purchased locally. Butylated hydroxytoluene (Sigma-Aldrich, Inc. ON, Canada) was added as an antioxidant. Food intake was measured every 2 days and body weight was measured weekly. On day 28, hamsters were anesthetized by isoflurane inhalation. Blood samples were taken by cardiac puncture then transferred into pre-coated heparin tubes. Hamsters were sacrificed followed by evisceration. Organ samples were wrapped and snap frozen by liquid nitrogen then stored at −80 °C until further analysis. The study was approved by the University of Manitoba Animal Care Protocol Review Committee, and carried out in accordance with the guidelines of the Canadian Council on Animal Care [19].

Body Composition Measurement

Body composition was measured by DEXA from Lunar Prodigy Advance. Tissue analyses were conducted by software Encore version 9.30.044. Percentage body fat, body fat mass and lean body mass were assessed using this software.

Lipid Profile and Hepatic Biomarker Measurement

Blood samples were thawed at room temperature then centrifuged at 3,500 rpm for 20 min. Red blood cells (RBC), plasma and serum samples were collected separately. Serum samples were used for lipid profile and liver enzyme assessment. Analyses were conducted by the Vitro Chemistry System 350 (Ortho-Clinical Diagnostics, Inc. Rochester, NY, USA). Triglyceride, total cholesterol and HDL-cholesterol levels were measured directly, whereas non-HDL cholesterol levels were calculated by subtracting HDL-cholesterol from total cholesterol content. Serum concentrations of liver enzymes AST, ALT and GGT were also measured.

Cholesterol Synthesis Measurement

Hamsters received 0.5 ml of deuterium oxide (D₂O, 99.9%, Cambridge Isotope Laboratories, Inc MA, USA) by intraperitoneal injection 2 h prior to sacrifice to assess cholesterol synthesis rate. Deuterium-enriched cholesterol was used as an indication of cholesterol synthesis [20]. Isotope ratios of DH/H₂ of plasma cholesterol were expressed in δ per mil, relative to Vienna Standard Mean Ocean Water. Enrichment of deuterium in both plasma water and RBC cholesterol were measured. Cholesterol samples extracted from RBCs were analyzed by online GC/pyrolysis/isotope

ratio mass spectrometry (IRMS) equipped with an Agilent 6890N GC and Finnigan Delta V Plus IRMS (Bremen, Germany) through a Finnigan combustion interface (Combustion Interface III, Bremen, Germany). Cholesterol fractional synthesis rates were measured and calculated as previously described [20].

Energy Expenditure Assessment

On day 25, energy expenditure was assessed by the MM100-metabolic monitor system (CWE, Inc Ardmore, USA). Animals were kept in individual air chambers. Oxygen consumption was measured indirectly by monitoring oxygen and carbon dioxide concentrations in the chamber for 2 h per animal.

Hepatic Lipid Content Analysis

Liver lipids were extracted according to the Folch method [21] by chloroform and methanol in a ratio of 2:1 (v/v). Analysis of hepatic triglyceride and cholesterol concentrations was conducted by commercial available enzymatic kits (Roche Diagnostics, QC, Canada).

Statistics Analysis

All statistical analyses were performed by Statistical Analysis System (version 8.1; SAS Institute Inc Cary, NC). Data from different diet groups were analyzed by one-way ANOVA for overall significance then followed by Tukey's

post-hoc tests to identify the significant difference between treatment groups. Results were expressed as means \pm SEM (standard error mean). Regression analysis was also performed. Treatment effects and differences between means were considered significant when $p < 0.05$.

Results

Effects of CLA Consumption on Food Intake, Body Composition and Energy Expenditure

Hamsters fed with *t10,c12* CLA enriched diets showed a lower ($p < 0.05$) food intake in comparison to control and other groups (Table 2). No differences were noted in average daily food intake between the control animals and *c9,t11* treatment groups. Energy expenditure data suggested a strong tendency towards animals on three dosages of *t10,c12* CLA supplementation having greater oxygen consumption rate compared to control group and others ($p = 0.0657$). At the end of the 28-day experimental period, hamsters in all seven treatment groups exhibited similar body weights. Body composition results are presented in Table 2. DEXA analyses data indicate that hamsters fed with 1, 2, and 3% *t10,c12* CLA enriched diets showed 27, 30 and 23% less ($p < 0.0001$) body fat mass compared to control animals, respectively. Additional, higher lean body mass was found in groups fed with all three dosages of *t10,c12* CLA supplemented diets. Such effects were also observed in animals fed with 3% *c9,t11*

CLA compared to control ($p = 0.0002$). Both 1 and 3% $\iota 10, c12$ CLA fed animals had a lower body weight gain over 4 weeks, whereas opposite effects were observed in animals on 3% $c9, \iota 11$ CLA enriched diet (Fig. 1).

Effect of CLA Consumption on Lipid Profiles

Serum lipid content was affected by $\iota 10, c12$ CLA isomer in hamsters (Table 3). Neither the serum HDL-cholesterol concentration nor the triglyceride concentration differed among treatment groups. However, animals consuming 3% $\iota 10, c12$ CLA enriched diets displayed the highest total cholesterol and non-HDL cholesterol levels, in contrast to the rest of the treatment groups after 28 days of dietary intervention ($p < 0.05$).

Effect of CLA Consumption on Liver Weight and Hepatic Lipid Content

Data on effects of CLA consumption on liver weight and hepatic lipid content are presented in Table 4. Hamsters in the 2 and 3% $\iota 10, c12$ CLA diet groups exhibited higher liver weight ($p = 0.001$). With regard to hepatic lipid content, neither liver cholesterol nor the triglyceride concentration differed between groups after 28 days of consumption of CLA enriched diets. No differences were observed between dosages. Moreover, there was no difference in serum total protein level across the treatment groups (data not shown).

Effect of CLA Consumption on Hamster Liver Enzyme Level

After the 4-week experimental period, elevated ALT levels were observed in hamsters fed 2 and 3% $\iota 10, c12$ CLA diets ($p < 0.0001$), however, such results were not noted in any of the other treatment groups. Additionally, ALT levels in animals on 3% $\iota 10, c12$ CLA enriched diet were higher ($p = 0.0155$) than those in animals fed with 2% $\iota 10, c12$ CLA enriched diet. No differences were noticed in hepatic

Fig. 1 Body weight changes in hamsters fed diets enriched with 1, 2, 3% $c9, \iota 11$ CLA or 1, 2, 3% $\iota 10, c12$ CLA for 28 days $n = 15$

AST or GGT levels across the seven experimental diets (Table 5).

Effect of CLA Consumption on Cholesterol Synthesis

Hamsters displayed similar cholesterol synthesis rates regardless of CLA intervention after 28 days (Fig. 2). Regression analysis suggested that the elevated serum cholesterol level of 2 and 3% $\iota 10, c12$ CLA treatment groups occurred independently of the individual rates of cholesterol synthesis across animals.

Discussion

The primary finding of the present study was that 1% $\iota 10, c12$ CLA effectively altered body composition without exhibiting potential adverse effects on the lipid profile and liver health. Similar body composition changes were also observed at 2 and 3% of $\iota 10, c12$ CLA. However, data from both serum lipid profiles and hepatic biomarkers suggest that 3% $\iota 10, c12$ CLA led to unfavorable increases in total as well as non-HDL cholesterol levels. Moreover, both 2 and 3% $\iota 10, c12$ CLA treatment induced elevated ALT

levels. Such changes may suggest health concerns associated with consuming high dosages of *t10,c12* CLA.

As a secondary effect of CLA, data from the current study suggest that *t10,c12* CLA decreases energy intake in hamsters. These data are in line with results reported by others [12, 22, 23]. Data from the present study show that animals on the *t10,c12* CLA treatment had a lower fat body

**Fig. 2** Cholesterol synthesis rate in hamsters fed diets enriched with 1, 2, 3% *c9,t11* CLA or 1, 2, 3% *t10,c12* CLA for 28 days $n = 15$

mass which was in accordance with previous observations [10, 22, 24, 25]. In earlier studies, *t10,c12* CLA isomers were identified as being responsible for biological effects on body composition [13]. Results from the current study also provide evidence supporting a physiological effect of CLA on fat mass in a manner that is isomer dependent. Several possible mechanisms may explain body fat reduction effects in response to CLA supplementation. Much evidence suggests that *t10,c12* CLA may induce fat mass reduction by decreasing energy intake, inhibiting adipogenesis or lipogenesis by suppressing gene expression of sterol regulatory element binding protein (SREBP), liver X-receptor (LXR) α , PPAR- α and PPAR- γ target genes [26–29]. Additional evidence supports a *t10,c12* CLA-induced down regulation of the hypothalamic appetite regulating gene expression which suppresses appetite, leading to reduced energy intakes [30, 31]. Data from current study indicate that reductions in fat mass following the three doses of *t10,c12* CLA were associated with decreased energy intake as well as a tendency towards increased energy expenditure.

Notably, animals fed with 3% *c9,t11* CLA displayed increased lean body mass. The same observation was also noticed in animals fed all three dosages of *t10,c12* CLA. To our knowledge, the current study is the first evidence supporting an effect on hamster body composition by consumption of the *c9,t11* CLA isomer solely. Other work

suggests that a CLA mixture including 25% *c9,t11* CLA induced increased carcass lean tissue in growing pigs [32]. Previous works reported that CLA consumption increases lean body mass in several species (reviewed in [33]). However, the lack of evidence of such an effect on *c9,t11* CLA isomer may be explained by the relative low dose of *c9,t11* CLA isomer or *c9,t11* containing mixture used in previous studies. Recently, Nall et al. [34] demonstrated that CLA and arginine increased lean body mass, due possibly to a depression in muscle protein turnover, however, the mechanism of CLA supplementation increasing lean body mass remains to be fully understood and requires further investigation.

The effects of *c9,t11* and *t10,c12* CLA on serum lipid profiles vary between animals and humans [14, 35]. In the present study, animals fed 3% *t10,c12* enriched diet exhibited the highest total as well as non-HDL cholesterol levels, in comparison with the rest of the groups. These results are in accordance with some studies published by other authors when animals were fed diets with either a CLA mixture or the *t10,c12* CLA isomer. Bissonauth et al. [36] reported an increase in LDL-cholesterol levels induced by 2% highly enriched *t10,c12* CLA. Kritchevsky et al. [9] demonstrated elevated total cholesterol levels induced by CLA mixtures (43:44%, *c9,t11*:*t10,c12*) in rabbits. In contrast, evidence supports either a positive action or no effects on total cholesterol and non-HDL cholesterol levels by either pure or mixed CLA consumption [37–39]. Current data fail to provide any further positive indication of CLA improving serum lipid profile. Most human studies report no effect of supplementation with CLA mixtures on lipid profiles [35]. Tricon et al. [40] reported that serum concentration of total cholesterol, LDL cholesterol, TG and the ratio of total to HDL cholesterol were elevated after consumption of CLA capsules containing 80% *t10, c12* in healthy subjects. Moloney et al. [41] also demonstrated an increased LDL to HDL ratio in subjects with type II diabetes. Moreover, a recent review has suggested that all fatty acids with a double bond in the *trans*-configuration raise the LDL to HDL ratio [15]. Data from the present work partially reflects this adverse effect of high dose *t10,c12* CLA isomer on serum lipid content. The isotope work indicates that increased total serum cholesterol is not the result of augmented endogenous cholesterol synthesis. Navarro et al. [42] found that *t10,c12* CLA significantly reduced the LDL-receptor number when expressed as an arbitrary value of per mg of protein in hamster liver. One possible theory offered was that *t10,c12* CLA induced an increase in free cholesterol pool size, perhaps related to down regulation of the LDL receptor. In comparison with the aforementioned study, the high dosage of *t10,c12* CLA provided in the current study significantly increased serum total and non-HDL cholesterol levels, with

a lack of change in hepatic lipid content. Taken together, growing evidence suggests that *t10,c12* CLA does not favorably change serum lipid levels.

Recently, the safety of CLA consumption has become a concern. In the present study, the high dosages of *t10,c12* CLA (2 and 3%) increased hamster liver weights compared with control and *c9,t11* CLA treatments. This finding is consistent with those of a number of other studies [13, 21, 43]. Along with this observation, our study has shown that CLA supplementation did not affect lipogenesis in liver since the triglyceride concentrations failed to differ across treatment groups. The increased liver weight in animals fed with *t10,c12* isomer are not necessarily due to liver lipid accumulation but rather from a greater number of hepatocytes [13, 44]. Future histological analysis may provide a better understanding of the underlying cause of elevated liver weight.

It is well known that serum liver enzyme activity exists as an indicator of liver function. In our study, elevated ALT concentrations in liver were observed in animals fed 2 and 3% *t10,c12* CLA. Such results suggest that high doses of *t10,c12* may lead to liver malfunction since ALT serves as a biomarker for hepatocellular necrosis [45]. Elevated ALT level may also indicate increased inflammation and oxidation subsequent to *t10,c12* CLA consumption. In contrast, animal studies conducted by Macarulla et al. [44] reported no changes in hepatic ALT concentration after 6-week consumption of *t10,c12* CLA. The discrepancy could be attributed to the dosage variances between studies (0.5 vs. 2% and higher).

In a recent investigation on the safety of dietary CLA consumption, Iwata et al. [46] reported slight increases in ALT activities in the high dose CLA (6.8/d) group after 12-week intervention in healthy overweight Japanese subjects. Taken together, *c9,t11* CLA and 1% *t10,c12* CLA did not exert any adverse effect on liver health in the hamster model. Present data show clearly that the degree of impact of CLA supplementation on liver health is isomer dependent. Recently, the European Food Safety Authority has issued positive safety opinions about two CLA products as a safe ingredient for food and beverage [47]. In the present study, 1, 2 and 3% CLA-enriched diet correspond to human diet equivalents (2,500 kcal intake daily) of 2, 4 and 6 g/d. These levels of intakes are very similar to what EFSA has recommended. The 3% CLA treatment represented the higher dosages than what has been recommended by EFSA (6 g at 3% vs. 3.5–4.5 g) which provided a better idea for safety evaluation for CLA consumption. Iwata et al. [46] reported mild to moderate adverse effects in overweight male Japanese subjects supplemented with either 3.4 or 6.8 g/d CLA (50:50, *c9,t11*:*t10,c12*), where slight increases in AST and ALT activity levels were observed at 12 weeks. The author indicated that such elevations were

small and within the normal range. Moreover, one of the most recent reviews conducted by Katan and colleagues [15] has suggested that CLA exerts a negative effect on the circulation lipid profile.

In summary, the present study provided a systematic comparison of two CLA isomers at three different dosages. The most important finding is that low dose intakes of *t10,c12* CLA effectively lower body fat mass and increase lean body mass without posing unfavorable changes in serum lipid profile. Higher dosages (2 and 3%) of *t10,c12* CLA supplementation produce adverse effects in liver function and 3% *t10,c12* CLA has negative effects on serum lipid content. 3% *c9,t11* CLA also increased lean body mass; however, no body fat lowering effects of the *c9,t11* CLA isomers were seen at any of the three dosages. Additionally, *c9,t11* CLA did not have any adverse effect in liver function in the hamster model. Data from the present study suggests that 1% *t10,c12* CLA, which was close to the EFSA recommended level, effectively modulates body composition whereas 2 and 3% cause unfavorable physiological changes.

Abstract The effect of dietary conjugated linoleic acid (CLA) supplementation in combination with fat from vegetable versus animal origin on the fatty acid deposition, including that of individual 18:1 and 18:2 (conjugated and non-conjugated) isomers, in the liver and muscle of obese rats was investigated. For this purpose, 32 male Zucker rats were randomly assigned to one of four diets containing palm oil or ovine fat, supplemented or not with 1% of 1:1 *cis(c)9,trans(t)11* and *t10,c12* CLA isomers mixture. Total fatty acid content decreased in the liver and muscle of CLA-fed rats. In the liver, CLA increased saturated fatty acids (SFA) in 11.9% and decreased monounsaturated fatty acids (MUFA) in 6.5%. n-3 Polyunsaturated fatty acids (PUFA) relative proportions were increased in 30.6% by CLA when supplemented to the ovine fat diet. In the

muscle, CLA did not affect SFA but decreased MUFA and PUFA percentages. The estimation of $\Delta 9$ -indices 16 and 18 suggested that CLA inhibited the stearoyl-CoA desaturase activity in the liver (a decrease of 13–38%), in particular when supplemented to the ovine fat diet. Concerning CLA supplementation, the *t10,c12* isomer percentage was 60–80% higher in the muscle than in the liver. It is of relevance that rats fed ovine fat, containing bio-formed CLA, had more *c9,t11* CLA isomer deposited in both tissues than rats fed palm oil plus synthetic CLA. These results highlight the importance to further clarify the biological effects of consuming foods naturally enriched in CLA, alternatively to CLA dietary supplementation.

Introduction

A huge focus has been attributed to the beneficial properties of conjugated linoleic acid (CLA), which is a group of linoleic acid (*c*9,*c*12-18:2) isomers with conjugated double bonds in *trans*(*t*) or *cis*(*c*) configuration. In particular, the *c*9,*t*11 CLA isomer (*c*9,*t*11-18:2) has been shown to inhibit carcinogenesis in cell cultures and animal experiments, although studies in humans have revealed inconclusive results [1]. The *t*10,*c*12 CLA isomer has been described as more efficient on lipid metabolism modulation, reducing body fat mass on several models [2].

Ruminant food products are good sources of CLA, predominantly of the *c*9,*t*11 CLA isomer, called rumenic acid, that is produced by bacterial isomerization and hydrogenation of linoleic acid in the rumen. Alternatively, in tissues, the vaccenic acid (*t*11-18:1), also produced in the rumen, is converted to rumenic acid via Δ 9-desaturation by the action of stearoyl-CoA desaturase (SCD) enzyme [3]. This endogenous synthesis through vaccenic acid is also observed in other animal species, as rodents [4]. Although the majority of dietary CLA isomers in foodstuff is rumenic acid, commercial supplements with synthetic CLA often include the *t*10,*c*12 CLA isomer in equivalent proportions.

Today's unhealthy diet and lifestyles promote excessive intake of saturated fats [5]. High fat diets, which are usually unbalanced in fatty acids, may directly increase the prevalence of obesity worldwide [6]. Concerning different types of dietary fat, Kloss et al. [7] observed that CLA was more beneficial in controlling blood lipids and adiposity when supplemented to a diet rich in saturated (coconut oil) versus unsaturated (corn oil) fat. Butter naturally enriched in CLA had increased serum concentrations of alpha-linolenic acid (18:3n-3), and decreased myristic (14:0) and palmitic (16:0) acids in growing pigs, comparing to animals fed regular butter [8]. This implies a potential benefit of CLA on the serum fatty acid composition [8]. CLA may compete for elongation and desaturation pathways with other unsaturated fatty acids [9], thus modifying the fatty acid profile of different tissues [10]. However, research performed so far has not adequately compared the effects of CLA supplementation on the tissue fatty acid composition facing dietary fats from distinct origins, vegetable and animal. Moreover, the influence of synthetic and bio-formed *c*9,*t*11 CLA isomer on tissues fatty acid profile is not well explored.

Ruminant edible fats are a major contributor to saturated fat intake in human nutrition [11]. Yet, these fats also contain variable amounts of *trans* and *cis* isomers of oleic (*c*9-18:1) and linoleic acids originating from the incomplete biohydrogenation of these fatty acids in the rumen. The production of ruminant edible fats (milk and meat) enriched

in rumenic and vaccenic acids has been extensively exploited [12], as it can be an effective approach to increase human dietary intake of these fatty acids with potential health benefits [13]. The ovine fat used in the present experiment was naturally enriched in rumenic and vaccenic acids, as well as other PUFA and *trans* fatty acids (TFA). The vegetable fat chosen was palm oil as it is the second most consumed edible oil [14], rich in saturated fatty acids (SFA) but having a distinct fatty acid profile comparing to ruminant edible fats. Detailed data on the fatty acid deposition in tissues derived from rumen biohydrogenation intermediates (18:1 and 18:2 fatty acids) ingestion, and possible interactions between them and CLA, are scarce.

In this study, it was hypothesized that *c*9,*t*11 and *t*10,*c*12 CLA isomers supplementation would influence the tissue fatty acid composition of obese Zucker rats according to the type of dietary fat (vegetable vs. animal). In addition, we intended to clarify if *c*9,*t*11 CLA isomer deposition in tissues is dependent on its origin, synthetic (industrially produced) or bio-formed (ruminant fat naturally enriched in CLA).

Materials and Methods

CLA Oil and Experimental Diets

The CLA oil used, from PharmaNutrients Inc. (Gurnee, IL, USA), contained similar proportions of *c*9,*t*11 and *t*10,*c*12 isomers with 80% purity. The remaining ingredients, apart from the ovine fat, were purchased from Provimi Kliba SA (Kaiseraugst, Switzerland) to manufacture the experimental diets. Peritoneal ovine fat was collected from lambs raised with forage enriched in seed oils, as described by Jerónimo et al. [15], thus having high contents of total CLA, other PUFA and TFA. The raw ovine fat was melted, and then filtered to subsequent mixture with the remaining ingredients. Diets were prepared and pelleted by Provimi Kliba following the AIN-93G formulation, with some modifications to obtain high fat diets. The ingredients composition (% feed) was: casein (20.0), dextrose (13.2), sucrose (11.9), corn starch (29.3), cellulose (5.0), vitamin-mixture (0.5), mineral-mixture (2.4), L-cysteine (0.3), cholesterol (2.0), cholic acid sodium salt (0.5) and BHT (0.01). Diets had a dry matter (DM) concentration of 928 g/kg feed and the following crude composition (g/100 g DM): protein (20.0), fat (16.6), ash (3.9), fiber (3.9) and carbohydrate (55.6). The four experimental diets differed in their fat composition. Two groups received fat from vegetable origin: group P—11.25% of palm oil plus 3.75% of sunflower oil; group PCLA—11.25% of palm oil plus 2.53% of sunflower oil and 1.22% of CLA oil. The other two groups (O and OCLA) received ovine fat instead

of palm oil. The fatty acid characterization of the experimental diets is presented in Table 1.

Animals

Thirty-two obese male Zucker rats (*falfa*), a widely used experimental model that develops morbid obesity due to a mutation (*fa*) on the leptin receptor [16], were obtained from Harlan Interfauna Iberia (Barcelona, Spain) at 5 weeks old. Animals were housed individually upon arrival and maintained on a 12 h light:dark cycle at 22 ± 2 °C. After an adaptation period of 1 week, animals were divided into four groups with eight rats each ($n = 8$) and fed the aforementioned semi-purified diets for 13–14 weeks. Animals had free access to water and food. Body weight and feed intake were monitored twice a week. At the end of the animal experiment, rats were killed by decapitation, under light isoflurane anesthesia. Liver and longissimus dorsi muscle were dissected, weighed and stored at -80 °C for further analysis. The experimental protocol of this study was reviewed by the Ethics Commission of CIISA/FMV and approved by the Animal Care Committee of the National Veterinary Authority (Direcção Geral de Veterinária, Portugal), following the appropriated European Union guidelines (N. 86/609/EEC).

Analysis of Fatty Acids

Liver and longissimus dorsi muscle samples were lyophilized (-60 °C and 2.0 hPa) and maintained desiccated at room temperature. Lipids were extracted using the method of Christie et al. [17], slightly modified by Raes et al. [18]. Fatty acids were directly converted to methyl esters by a combined procedure of methylation, base-catalysis followed by acid-catalysis. Briefly, 1 mL of dry toluene was added to 0.25 g of lyophilized samples and fatty acids were methylated, at 50 °C, with sodium methoxide in anhydrous methanol (0.5 mol/L), for 30 min, followed by hydrogen chloride in methanol (1:1 vol/vol), for 10 min. Fatty acid methyl esters (FAME) were extracted twice with 3 mL of *n*-hexane and pooled extracts were evaporated at 35 °C, under a stream of nitrogen, until a final volume of 2 mL was reached. The resulting FAME, including 18:1 and 18:2 non-conjugated, were then analyzed by gas–liquid chromatography (GC) using a fused-silica capillary column (CP-Sil 88; 100 m \times 0.25 mm i.d., 0.20 mm film thickness; Chrompack, Varian Inc., Walnut Creek, CA, USA), equipped with a flame-ionization detector (FID), as described by Bessa et al. [19].

In order to obtain a detailed profile of individual CLA isomers, FAME were injected into a high performance liquid chromatography (HPLC) system (Agilent 1100 Series, Agilent Technologies Inc., Palo Alto, CA, USA), equipped with triple silver-ion columns in series (ChromSpher 5 Lipids,

250 mm \times 4.6 mm i.d., 5 μ m particle size; Chrompack, Bridgewater, NJ, USA), an autosampler and a diode array detector (DAD) adjusted to 233 nm, according to a procedure previously reported [20]. The identification of individual CLA isomers was achieved by comparison of their retention times with commercial and prepared standards, as well as with values published in the literature.

The fatty acid composition was expressed as a percentage, i.e. g/100 g of total fatty acids. The contents of CLA isomers were calculated from their Ag^+ -HPLC peak areas relative to the GC peak area of the main *c9,t11* CLA isomer, which also included *t7,c9* and *t8,c10* CLA isomers, as described by Rego et al. [20]. Diets followed the same analytical procedure described for fatty acid profile in muscle and liver.

Estimation of *c9,t11* CLA Isomer Deposition

An estimate of *c9,t11* CLA isomer deposition in tissues depending on its origin, synthetic or bio-formed, was calculated by comparing two experimental groups PCLA and O. Additionally to the amount of *c9,t11* CLA isomer ingested, the evaluation was also based on its endogenous synthesis. For this purpose, we used the average of 20% for the *t11-18:1* conversion to *c9,t11*, reported for male Wistar rats by Kraft et al. [4]. The deposition values were calculated by dividing the total amount of *c9,t11* quantified in the tissue by the total amount of *c9,t11* ingested (the exogenous contribution) plus 20% of *t11-18:1* derived (the endogenous contribution).

Statistical Analysis

The statistical analysis for fatty acid profiles was performed with the general linear model (GLM) procedure of Statistical Analysis System, version 9.1 (SAS Institute, Cary, NC, USA). Data were reported as means with their standard errors of the mean (SEM). The effects of CLA (with or without 1% of CLA) and dietary fat type (palm oil or ovine fat) were analyzed as a 2×2 factorial arrangement. The model contained the main effects, CLA and fat type, and their interaction (CLA \times fat type). When the interaction effect was significant, differences between experimental groups were analyzed by the Tukey's post hoc test. To test differences on *c9,t11* CLA isomer deposition for each tissue between PCLA and O groups, the ANOVA test was applied. Statistical significance was set up at $P < 0.05$.

Results

Hepatic Fatty Acid Composition

Livers from rats fed CLA had lower total FAME (14.2–14.9 g/100 g organ) than those from rats fed no CLA

Table 1 Fatty acid content (g/100 g diet) and composition (g/100 g total fatty acids) of experimental diets

Experimental diets: *P* palm oil, *PCLA* palm oil plus 1% CLA, *O* ovine fat, *OCLA* ovine fat plus 1% CLA, *n.d.* not detected

(16.7–18.1 g/100 g organ) (Table 2). The major fatty acids in the hepatic lipids were 16:0, *c*9-16:1, *c*9-18:1 and 18:2n-6 for all experimental groups. CLA and fat type affected six and 11 of the 20 individual fatty acids depicted in Table 2, respectively. As ovine fat diet contributed with many intermediates of rumen biohydrogenation, the Σ i-18:1, Σ nc-18:2 and Σ CLA are discriminated below. As expected, the different origins of dietary fat affected all fatty acids identified, excluding the 20:5n-3, according to the fatty acid profile of the diets (Table 1). The percentage (g/100 g total fatty acids) of SFA in hepatic lipids was significantly increased in rats fed CLA. Monounsaturated fatty acids (MUFA) percentage decreased in both PCLA and OCLA groups, although more effectively in the ovine fat group, being the *c*9-16:1, *c*9-18:1 and Σ i-18:1 the main fatty acids responsible for these differences. The sum of PUFA was not affected by CLA supplementation in the diet, in contrast to some individual PUFA. The percentages of 18:2n-6, 18:3n-6, 20:5n-3 fatty acids decreased in the liver, whereas 20:4n-6 increased, due to the presence of CLA in the diet. CLA supplementation increased the sum of n-3 PUFA in the liver of animals fed ovine fat, mainly due to the 18:3n-3, 22:5n-3 and 22:6n-3 fatty acids. Contrarily, in the palm oil diets, the percentage of n-3 PUFA did not change. CLA did not affect the sum of n-6 PUFA but palm oil groups were richer in n-6 PUFA than ovine fat groups, mainly due to the linoleic acid. The sum of *trans* fatty acids (TFA; fatty acids with a *trans* double bound, except CLA isomers) was enhanced by CLA supplementation. CLA did not affect the following six fatty acids: 14:0, 15:0, *c*7-16:1, 20:0, 20:3n-6 and 22:5n-6. PUFA/SFA and n-6/n-3 ratios in the liver were decreased by CLA supplementation.

Regarding CLA and fat type interaction, eight of 20 fatty acids were differentially affected by CLA supplementation, depending on the dietary fat origin (Table 2). The *c*9-16:1, 18:3n-3, 20:2n-6, 22:5n-6 and 22:6n-3 fatty acids did not show differences between P and PCLA groups, but were increased in OCLA comparing to O group. The *c*9-17:1 had a decrease in the OCLA group relatively to the O group. CLA increased the 18:0 fatty acid in both fat types but more extensively in the OCLA group. CLA decreased the 22:4n-6 percentage when supplemented

Table 2 Effect of dietary CLA supplementation and fat type on total fatty acid content (g/100 g organ) and composition (g/100 g total fatty acids) in the liver of obese Zucker rats

Data are means ± standard error of mean (SEM) for eight rats per group

Experimental diets: *P* palm oil, *PCLA* palm oil plus 1% CLA, *O* ovine fat, *OCLA* ovine fat plus 1% CLA. Significance level: *ns* not significant, *n.d.* not detected

[†] These fatty acids co-eluted

P > 0.05; * *P* < 0.05; ** *P* < 0.01; *** *P* < 0.001; means in the same row with different superscripts are significantly different (*P* < 0.05)

to palm oil diets. The Δ9-index16 was higher in the OCLA than in the O group. In addition, CLA increased the Δ9-index18 in both fat types, although more markedly in the OCLA group.

The detailed composition of oleic acid and linoleic acid isomers in the liver, which partial sums were depicted in Table 2 (Σ i-18:1, Σ nc-18:2 and Σ CLA), are presented in

Table 3. CLA and fat type affected 7 and 15 of the 28 fatty acids analyzed, respectively. CLA supplementation increased the percentages of *t*10- and *t*12-, but decreased *c*11-18:1 levels. The *t*11- and *c*15-18:1 isomers only increased in the OCLA group. Among non-conjugated 18:2 isomers, CLA diminished the *t*8,*c*12/*c*9,*t*12-, *t*11,*c*15- and *c*9,*c*15-18:2 isomers. Most of the conjugated 18:2 isomers

increased with CLA supplementation, although *c/t*11,13- and *t*7,*c*9-18:2 levels were not affected. The major CLA isomer found in the liver for all dietary groups, the *c*9,*t*11 isomer, increased ~1 g/100 g total fatty acids in the PCLA and OCLA groups. The hepatic level of accumulation was lower for the *t*10,*c*12 than for the *c*9,*t*11 CLA isomer.

Muscle Fatty Acid Composition

Total FAME content in the muscle, which varied from 7.23 to 10.7 g/100 g organ, was significantly lower in CLA-supplemented rats, as well as in the ovine fat, comparing to palm oil fed rats (Table 4). The main fatty acids in the muscle lipids from all dietary groups were 16:0, *c*9-16:1, *c*9-18:1 and 18:2n-6. CLA and fat type individually affected nine and 14 of the 20 fatty acids presented in Table 4, respectively. The results of Σ i-18:1, Σ nc-18:2 and Σ CLA are depicted below in further detail. All fatty acids were affected by the type of dietary fat, except for 20:2n-6 and 20:4n-6. Once more, these differences are firstly explained by the dietary fatty acid composition (Table 1). CLA affected the majority of fatty acids, except for 16:0, *c*9-16:1, 18:0, 18:3n-6, 18:3n-3, 20:4n-6, 22:5n-3 and 22:6n-3. The percentage of total SFA in muscle lipids was not affected by CLA, which could be due to the absence of effects on two major SFA, 16:0 and 18:0. CLA decreased the relative proportions of MUFA. Palm oil groups had higher MUFA levels than ovine fat groups. This trend was observed for *c*9-18:1, the main MUFA. PUFA percentages were diminished by dietary CLA. CLA supplementation increased the total CLA level in 1.7 and 1.8 g/100 g of total fatty acids in palm oil and ovine fat diets, respectively. The n-3 PUFA sum was increased in the ovine fat groups and CLA effect was undetected. CLA decreased the n-6 PUFA sum, in particular, 18:2n-6, 20:3n-6, and 22:4n-6 fatty acids. The sum of TFA only increased with CLA supplementation in the palm oil diet. Dietary treatments with CLA decreased PUFA/SFA and n-6/n-3 ratios. The Δ 9-indices 16 and 18 were not affected by CLA supplementation, while palm oil groups had higher values of Δ 9-index16, but lower values of Δ 9-index18, comparing to ovine fat groups.

Some fatty acids displayed significant effects for CLA \times fat interaction (eight of 20 fatty acids). CLA did not change *c*9-17:1 and 22:5n-6 fatty acids in the palm oil group but increased their percentages in the ovine fat groups. On the contrary, the 20:2n-6 fatty acid was decreased in the PCLA group. In both dietary fat types, the 15:0 percentage increased but this change was higher in the ovine fat than in the palm oil group. CLA diminished the 22:4n-6 percentage in a higher extent in the palm oil than in the ovine fat group.

Table 5 shows the profile of oleic acid and linoleic acid isomers in the muscle, intermediates of ruminal biohydrogenation of C18 PUFA, for which the partial sums were depicted in Table 4 (Σ i-18:1, Σ nc-18:2 and Σ CLA). CLA and fat type individually affected nine and 15 of the 28 fatty acids presented in the Table 5, respectively. Results showed that *t*11- and *c*11-18:1 were the major oleic isomers in muscle lipids. CLA supplemented groups had lower *t*9- and *c*11-18:1 percentages but higher *t*12-18:1. The *t*10-, *c*12- and *c*15-18:1 were increased by CLA supplementation only in the palm oil groups. Regarding non-conjugated 18:2 isomers, CLA increased the levels of *t*8,*c*13/*c*9,*t*13-18:2 but decreased the *t*9,*c*12-18:2. The *t*8,*c*12/*c*9,*t*12-, *c*9,*c*15- and *c*12,*c*15-18:2 were not changed. The conjugated 18:2 isomers profile reflected the proportions of the various CLA isomers in the diets. CLA supplementation promoted an increase in most of the isomers percentages, excluding *t*12,*t*14-, *t*11,*t*13- and *t*7,*c*9-18:2 isomers. Similarly to the liver, the most prevalent CLA isomer in the muscle from all experimental groups was the *c*9,*t*11 isomer. In contrast, the percentage of the *t*10,*c*12 CLA isomer was much lower, but, nevertheless, the second most prevalent isomer found in diets supplemented with CLA.

Deposition of *c*9,*t*11 CLA Isomer in the Liver and Muscle

The total intake of *c*9,*t*11 CLA isomer during the experiment was 5.57 and 2.88 g, for PCLA and O groups, respectively. Regarding the *t*11-18:1 ingestion, values of 0.03 and 4.83 g of *c*9,*t*11 endogenous synthesis were estimated for PCLA and O groups, respectively.

In the liver, the total *c*9,*t*11 CLA isomer deposition was significantly lower ($P < 0.001$) in the PCLA (1.51 g) than in the O group (3.99 g) of *c*9,*t*11/100 g of exogenous plus endogenous *c*9,*t*11 isomer. In the muscle, the depositions were also significantly different ($P < 0.05$), 0.16 versus 0.25 g of *c*9,*t*11/100 g of exogenous plus endogenous *c*9,*t*11 CLA isomer for PCLA and O groups, respectively.

Discussion

As expected, obese Zucker rats, a commonly used genetic model for human obesity [16], had relatively high values of total fatty acids in the liver and muscle. This experimental model was selected in order to achieve a better understanding of CLA effects facing an obesity scenario, as this fatty acid has been recognized as an anti-adipogenic agent. Ovine fat contrasts with palm oil because it contains a large number of fatty acids derived from rumen metabolism, which includes *trans* and *cis* isomers of oleic acid and

Data are means ± standard error of mean (SEM) for eight rats per group

Experimental diets: *P* palm oil, *PCLA* palm oil plus 1% CLA, *O* ovine fat, *OCLA* ovine fat plus 1% CLA. Significance level: *ns* not significant, *n.d.* not detected

[†] These fatty acids co-eluted

P > 0.05; * *P* < 0.05; ** *P* < 0.01; *** *P* < 0.001; means in the same row with different superscripts are significantly different (*P* < 0.05)

conjugated and non-conjugated isomers of linoleic acid [19]. Additionally, the ovine fat used in this study derived from animals fed with forage supplemented with seed oils. As a result, this ruminant fat had a more complete fatty acid profile, richer in TFA, PUFA and CLA isomers, than those from animals fed conventional diets [19, 21]. The fatty acid profile of liver and muscle indicates that these isomeric fatty acids were widely deposited in both tissues. Moreover, the high content of palmitic acid provided by

the palm oil diet might constitute an additional factor affecting the results, as well as non-fatty acid components of both fat sources, which were not addressed in this study.

The percentages of SFA and MUFA in the liver and muscle were modulated by the dietary intake of CLA, in particular for 16:0, 18:0, *c*9-16:1 and *c*9-18:1 fatty acids, as seen by others [22, 23]. Therefore, the Δ9-indices were calculated in order to predict the SCD activity. The discussion of these results is limited as SCD activities and

mRNA expression levels were not determined. Nevertheless, the results herein suggest that CLA may have inhibited SCD activity in the liver when supplemented to the ovine fat diet, while in the muscle, CLA had no effect. This tissue discrepancy may derive from the liver's higher sensitivity because it is the key organ in lipid metabolism in rodents [24].

CLA may be incorporated into membrane phospholipids [25] and compete with other PUFA for enzymes that metabolize the conjugated diene metabolites [26]. In particular, dietary CLA may be deposited in the liver at the expenses of linoleic [27] and arachidonic [28] acids. However, in the present study, sunflower oil replaced CLA oil in the experimental diets without CLA supplementation, and a reduction in linoleic acid in CLA supplemented groups was expected. For all dietary groups, similar arachidonic acid percentages were observed in the muscle but, surprisingly, CLA increased the hepatic relative proportions of this fatty acid. The long chain n-3 PUFA, 22:5n-3 and 22:6n-3, prevalent in membrane phospholipids, were higher in the OCLA than in the O livers. This may result from the fact that ovine fat possesses more alpha-linolenic acid, which is the precursor of these fatty acids.

The *trans* and *cis* isomers of oleic acid and conjugated and non-conjugated *trans* isomers of linoleic acid are typical fatty acids of ruminant tissues. Ovine fat diets promoted a deposition of these minor isomers, whose biological effects are not completely understood. In human diets, the most common TFA is the *t*11-18:1 [4], and due to its bioconversion into *c*9,*t*11 CLA isomer by SCD, the *t*11-18:1 has been considered a neutral or beneficial *trans* isomer [13]. Butter naturally enriched in *t*11-18:1 and *c*9,*t*11 CLA isomer reduced lipid deposition in rabbits aorta [29]. As stated in a companion work [30], our rats did not present any morphological alteration in transversal segments of the aorta. CLA supplementation did not change *t*11-18:1 percentages in muscle from animals fed both fat types, but in the liver, CLA supplementation increased its percentages in animals fed the ovine fat. As the OCLA diet provided a higher amount of CLA than any other tested diet, the eventual inhibition of SCD activity could result in a decrease of desaturation *t*11-18:1 leading to higher *t*11-18:1 percentage in tissues. Also in the liver, it was observed an unexpected increase of *t*10-18:1 percentage with CLA supplementation. In the muscle, this augmentation was confined to the PCLA diet. We hypothesized that partial biohydrogenation of dietary *t*10,*c*12 CLA isomer might occur in the rat's intestine and, then, the isomers formed might be absorbed via coprophagy.

The CLA isomeric profile in both tissues reflect, partially, the CLA isomers composition of the diets. However, a differential deposition was observed for some CLA isomers. Interestingly, there was a preferential accumulation

of *t*11,*t*13- and *c*/*t*11,13-18:2 isomers in the muscle comparing to the liver. Concerning the *c*11,*t*13-18:2, Kramer et al. [25] reported a higher percentage of this fatty acid in heart than in liver lipids. Also, the *t*10,*c*12 CLA isomer was higher in the muscle than in the liver. Despite equal amounts of *c*9,*t*11 and *t*10,*c*12 CLA isomers in CLA supplemented animals, their respective depositions in the liver and muscle were quite different. In both tissues, the *c*9,*t*11 CLA isomer was more efficiently deposited than the *t*10,*c*12, as reported by others [23, 30, 31]. Li et al. [32] found more *c*9,*t*11- than *t*10,*c*12-18:2 in the liver, serum, bone and marrow. In contrast, other organs, like spleen, muscle and heart contained more *t*10,*c*12 than *c*9,*t*11 CLA isomer. Tsuzuki and Ikeda [33] observed a similar extent of lymphatic recovery of these two isomers in rats, suggesting that geometrical and positional isomerism of conjugated double bounds had no influence on the absorption by the small intestine. The *t*10,*c*12 CLA isomer has been reported to activate the β -oxidation system more strongly [34, 35] and to be more susceptible to oxidation [36] than the *c*9,*t*11 isomer, which could explain the lower percentage of the *t*10,*c*12 isomer in tissues.

The present experiment allowed the estimation of *c*9,*t*11 CLA isomer deposition from synthetic and bio-formed origins in the liver and muscle from rats fed PCLA and O diets. This estimation had to take into account both exogenous and endogenous sources of CLA. To the best of our knowledge, the conversion of vaccenic to rumenic acid has not been described, yet, for obese Zucker rats. Therefore, calculations were based on a conversion of 20% of vaccenic to rumenic acid described for male Wistar rats [4]. In the liver, the intake of bio-formed *c*9,*t*11 CLA isomer promoted a deposition of this fatty acid two-times higher than the intake of synthetic *c*9,*t*11 CLA. Also in the muscle, the *c*9,*t*11 CLA isomer deposition was higher due to the intake of O diet rather than PCLA diet. Relatively low levels of CLA intake from natural rich sources, as dairy products, can decrease the incidence of cancer [37]. Additionally, other authors reported that dietary beef tallow, itself with negligible contents of CLA, may increase the efficacy of CLA supplementation in reducing mammary and colon carcinogenesis [38, 39].

We report here the fatty acid composition, including the individual 18:1 and 18:2 (conjugated and non-conjugated) isomers in the liver and muscle of obese Zucker rats, as affected by CLA supplementation and type of dietary fat (palm oil or ovine fat). It is a fact that the total CLA contents were different among the various diets. In a future study, this can be easily overcome by equalizing its amount, through the supplementation of a palm oil based diet with the exact CLA content available in the ovine fat. Nevertheless, our data indicate that the effect of dietary CLA supplementation on the fatty acid deposition of liver

and muscle from obese Zucker rats is strongly influenced by the dietary fatty acid composition. The fatty acid profile in both tissues of obese rats fed palm oil and ovine fat displayed many interactions between CLA and fat type. Rats fed diets containing ovine fat and CLA supplementation had increased hepatic percentages of 18:3n-3 and 22:6n-3, although palm oil diets did not change n-3 PUFA. Regarding CLA isomers deposition, muscle had at least 60% higher amounts of ι 10,c12 CLA isomer than the liver, contrary to the c9, ι 11 isomer that displayed similar values. This finding suggests a differential degree of metabolization of these isomers in both tissues. Furthermore, the high efficiency of the c9, ι 11 CLA isomer deposition as a component of the ruminant fat warrants further research. In particular, its aim should focus on the promising health benefits of foods naturally enriched in CLA, such as ovine fat, in comparison to CLA dietary supplements.

Acknowledgments The CLA oil was a generous gift from PharmaNutrients Inc. (Gurnee, IL, USA). Abstract Lipoprotein lipase (LPL) is the crucial enzyme for intravascular catabolism of triglyceride-rich lipoproteins. Fatty acid synthase (FAS) is a key anabolic enzyme that catalyzes the terminal steps in the *novo* biosynthesis of 18:2n-6. The involvement of both LPL and FAS in tumor biology has been widely demonstrated in different studies and to verify whether there are regional differences in the expression of these enzymes in visceral adipose tissue from patients with colorectal cancer might be representative of events which sustain tumor growth. The objective of this study was to evaluate LPL and FAS activity and expression of their genes in adipose tissue adjacent to neoplasia and distant from it from patients operated for colorectal cancer. LPL enzymatic activity was evaluated by a fluorescent method and FAS activity by a radiometer assay. Reverse-transcription and real-time PCR were used to detect mRNA levels of two enzymes. Our findings show a significant reduction in both LPL and FAS gene expression and activity levels in adipose tissue adjacent to tumor lesion compared to those detected in paired tissue distant from neoplasia. These results underline the influence of tumor microenvironment on lipid metabolism in adipose tissue, demonstrating a tumor-induced impairment in the formation and lipid storing capacity of adipose tissue in patients with colorectal cancer.

Introduction

Adipose tissue is no longer considered to be solely used for energy storage, but exerts important endocrine functions, which are mediated by a complex network of various soluble factors, called adipocytokines [1, 2]. Visceral adipose tissue, in comparison to the subcutaneous depot, is generally accepted to be metabolically more active [3] and it has intrinsic characteristics possibly involved in the pathogenesis of obesity and inflammatory diseases [4, 5].

Adipose tissue synthesizes lipoprotein lipase (LPL), the crucial enzyme for intravascular catabolism of triglyceride-rich lipoproteins [6]. Adipose tissue LPL plays a pivotal role in lipid metabolism and changes in LPL expression could affect both the rate of fat accumulation and the metabolism of triglyceride-rich lipoproteins [3]. In patients with resectable non-small cell lung cancer, higher levels of LPL activity have been detected in cancer tissue than in adjacent non-cancer lung tissue [7]. Moreover, increased LPL activity in non-small cell lung cancer tissue predicts

shorter patient survival, independent of standard prognostic factors [6].

Fatty acid synthase (FAS) is a key anabolic enzyme that catalyzes the terminal steps in the *novo* biosynthesis of 18:2n-6 [8]. Altered expression of FAS appears to be an important process required by many transformed cells for growth and survival in different types of tumor [9–11]. FAS expression appears also to play an important role in the growth and pathogenesis of colon carcinoma [11, 12]. Previously, we demonstrated that FAS activity levels, as well as the expression of its mRNA are up-regulated in colorectal cancer tissues [13].

The involvement of both LPL and FAS in tumor biology has been widely demonstrated in different studies and to find regional differences in the expression of these enzymes in visceral adipose tissue collected from patients with colorectal cancer might be representative of events which sustain tumor growth. Therefore, the aim of this study was to evaluate LPL and FAS activity and expression of their genes in adipose tissue adjacent to neoplasia and distant from it from colorectal cancer patients.

Materials and Methods

Patients

Thirty-two consecutive CRC patients (20 females and 12 males, mean age 65 ± 5.8 years) undergoing surgery of the colon were enrolled in the study. Adipose tissue adjacent to a neoplastic lesion and distant from it (about 10 cm) was obtained from each of them according to a standardized procedure. Specimens were taken within 1 h after the surgical procedure and stored at -80°C until assayed. All analyses were performed within 3 months.

Anthropometric measurements were obtained by the participants and body mass index (BMI) was calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). The study had institutional approval and all patients gave informed consent to participate in the study.

Adipose Tissue Homogenization

Paired samples of adipose tissue (approximately 50 mg of peritumoral adipose tissue and distant from neoplasia) were homogenized in 20 mM Tris-HCl pH 7.5, 1 mM DTT, 1 mM MgCl_2 , 1 mM EDTA, and centrifuged at $10,000 \times g$ for 10 min at 4°C . Aliquots of supernatant were used to determine total protein content, LPL and FAS activity.

LPL Activity Assay

LPL enzymatic activity was evaluated on specimens of adipose tissue adjacent to a neoplastic lesion and distant from it by a fluorescent method (LPL activity Kit, Roar Biomedical, New York, NY). An aliquot of supernatant (100 μl) was incubated with 100 μl of pre-diluted substrate emulsion at 37°C for 1 h, according to the manufacturer's recommendations. The hydrolyzed triglycerides formed were measured at 370 nm excitation and 450 nm emission. The fluorescence intensity values of samples were compared with the fluorescence intensity values of a standard curve applied on the same plate together with samples in each run. LPL activity was expressed as picomoles of hydrolyzed substrate per minute per milligram of total proteins, evaluated using the Lowry method (pmol/min/mg prot). All measurements were made in duplicate and paired samples of the same patient were analyzed in the same batch.

FAS Activity Assay

FAS activity was determined on samples of adipose tissue adjacent to a neoplastic lesion and distant from it. After tissue homogenization and centrifugation, an aliquot of supernatant (50 μl) was pre-incubated with 100 mM potassium phosphate buffer, pH 7 for 15 min at 37°C . Subsequently, 20 μl of reaction mix (2.5 mM NADPH, 1.25 mM acetyl-CoA, 1.25 mM malonyl-CoA and 0.02 mM 2- ^{14}C -malonyl-CoA (52 mCi/mmol, Amersham Biosciences, UK)) were added and samples were incubated for 10 min at 37°C . Reactions were stopped by the addition of 500 μl 1N HCl/methanol (6:4, v:v); 18:2n-6 were extracted with 1 ml of petroleum ether and incorporation of 2- ^{14}C -malonyl-CoA was analyzed by scintillation counting. FAS activity was expressed as picomoles of incorporated 2- ^{14}C -malonyl-CoA per minute per milligram of total proteins (pmol/min/mg prot). All measurements were made in duplicate and paired samples of the same patient were analyzed in the same batch.

LPL and FAS Gene Expression Analysis

Total RNA from samples of adipose tissue was isolated with TRI-Reagent (Mol. Res. Center Inc., Cincinnati, OH, USA), following the manufacturer's instruction. Briefly, the tissue was homogenized in 0.25 ml of cold 0.9% NaCl; then, 0.75 ml of TRI-Reagent and 0.2 ml of chloroform were added to the homogenate. The samples were vigorously shaken and centrifuged and the RNA present in the aqueous phase was precipitated with 0.5 ml of isopropanol. The RNA pellet was washed once with 1 ml of 75% eth-

anol, dried, resuspended in sterile water and quantified by UV absorbance. Then 2 µg of total RNA was used for the reverse transcription reaction performed in 20 µl of the final volume at 41 °C for 60 min, using 30 pmol of antisense primer (Table 1) for analyses of the LPL, FAS and the β -actin gene. Human β -actin gene was utilized as the reference gene, selected according to the literature data [14]. Real-time PCRs were performed in 25 µl of the final volume containing 2 µl of cDNA, master mix with SYBR Green (iQ SYBR Green Supermix Bio-Rad, Milan, Italy) and sense and antisense primers for the LPL, FAS and β -actin gene (Table 1).

Real-time PCR was carried out in an iCycler Thermal Cycler System apparatus (Bio-Rad) using the following parameters: one cycle of 95 °C for 1 min and 30 s, followed by 45 cycles at 94 °C for 10 s, 55 °C for 10 s and 72 °C for 30 s and a further melting curve step at 55–95 °C with a heating rate of 0.5 °C per cycle for 80 cycles. The PCR products were quantified by external calibration curves, one for each tested gene, obtained with serial dilutions of known copy number of molecules (10^2 – 10^7 molecules). All expression data were normalized by dividing the target amount by the amount of β -actin used as the internal control for each sample. The specificity of the PCR product was confirmed by gel electrophoresis.

Statistical Analysis

The differences in LPL and FAS activity and their mRNA levels between adipose tissue adjacent to a tumor lesion and distant from it were analysed by the Wilcoxon signed-rank test. Differences were considered significant at a 5% probability level.

Results

The clinical and histopathological features of all patients are shown in Table 2. Considering their histology, all tumors were shown to be adenocarcinomas. They were classified according to their grade of histological differentiation and tumor stage.

There was a significant reduction in both LPL and FAS activity levels in adipose tissue adjacent to a tumor lesion compared to those detected in paired tissue distant from neoplasia (Fig. 1a, b). Median values of LPL and FAS activity between two regions considered were statistically different (63 vs. 115 and 1.45 vs. 3.25 pmol/min/mg prot, $P = 0.031$ and $P = 0.028$, respectively).

According to the findings of enzymatic activity, low levels of LPL and FAS mRNA were observed in peritumoral adipose tissue with respect to mRNA levels detected

in adipose tissue distant from neoplasia (Fig. 2). Median values of LPL and FAS mRNA between two regions considered were statistically different (0.18 vs. 0.78 and 0.04 vs. 0.30 no. molecules of LPL or FAS gene/no. molecules of β -actin, $P = 0.020$ and $P = 0.045$, respectively).

No difference was detected in LPL and FAS activity levels, as well as in mRNA expression in relation to sex, tumor site, stage and histological grading (data not shown).

Discussion

Tumor growth and abnormal cell proliferation are shown to be associated with a number of cellular metabolic alterations [15]. The present findings seem to indicate changes of metabolic pathways in presence of neoplastic lesion. In contrast to “normal” adipose tissue, adipose cells adjacent to tumor lose the ability to express lipogenic enzymes. In our samples, the significant reduction in both LPL and FAS gene expression and activity levels in adipose tissue adjacent to a tumor lesion compared to those detected in paired tissue distant from neoplasia underlines the influence of tumor microenvironment on lipid metabolism in adipose tissue.

Adipose and colon tissue could interact affecting enzymatic expression of protein involved in cell proliferation.

Fig. 2 Levels of FAS and LPL mRNA in adipose tissue distant from neoplasia and adjacent to tumor lesion from 32 colorectal cancer patients. The bars and whiskers represent the mean value and standard error, respectively. The mRNA levels are expressed as no. molecules mRNA FAS or LPL/no. molecules mRNA β -actin. * $P < 0.05$, Wilcoxon signed rank test

The increased demand of long-chain 18:2n-6 by the tumor lead, probably, to adipose atrophy resulting in alterations of lipid metabolism. Adipose atrophy is a hallmark of cancer cachexia, considered a metabolic disorder characterized by progressive loss of body weight with depletion of adipose tissue [16]. Moreover, pronounced morphologic and molecular alterations of adipose tissue have been observed in tumor-bearing mice [17]. The tumor burden seems to alter adipose tissue mass and function by affecting the expression of genes that control lipogenesis and lipid utilization. Several studies have demonstrated a clear association between obesity and the risk of colorectal cancer [18–20]. Mature adipocytes seem to influence colon cancer cell proliferation [21]. This trophic effect of adipose tissue is overall mediated via leptin [21, 22]. Recent experimental studies have shown that leptin stimulates the proliferation and invasiveness of human colon cancer cells [21–23].

The tumor microenvironment is a dynamic network that includes the cancer cells and their neighboring cells. The mechanisms whereby the LPL and FAS expression/activity are decreased in adipose tissue surrounding the tumor are not yet clear. However, it is likely that the tumor secretes humoral factors affecting directly adipose tissue of the host [24]. Moreover, the decreases in the activities of adipose tissue LPL and the lipogenic enzymes during tumor growth in rats are associated with a consistent drop in serum insulin levels, as demonstrated by other authors [25].

There is already evidence suggesting FAS and LPL involvement in tumor progression [7, 9–13]. Our previous study demonstrated that FAS activity levels were significantly higher in cancer than in the corresponding normal

colorectal mucosa [13], demonstrating that FAS is a functionally active enzyme and that the entire fatty acid synthesis pathway is up-regulated in colorectal carcinoma. Moreover, LPL activity has been shown to be highest in areas containing actively proliferating cells in a variety of human sarcomas and carcinomas [16].

The findings of this study demonstrate that a tumor-induced impairment in the formation and lipid storing capacity of adipose tissue occurs in patients with colorectal cancer, underling the influence of tumor microenvironment on lipid metabolism in adipose tissue. Further studies, with a larger number of cases, will be necessary to understand and demonstrate the mechanism underlying malignancy-related lipotrophy and if tumor-associated factors or pro-inflammatory mediators, such as cytokines, can influence lipid metabolism in peritumoral adipose tissue.

Conflict of interest The authors declare that they have no conflict of interest.

Abstract Jasmonic acid (JA) is synthesized from linolenic acid (18:3n-3) by sequential action of 13-lipoxygenase, allene oxide synthase (AOS), and allene oxide cyclase. The fungus *Lasiodiplodia theobromae* can produce large amounts of JA and was recently reported to form the JA precursor 12-oxophytodienoic acid. The objective of our study was to characterize the fatty acid dioxygenase activities of this fungus. Two strains of *L. theobromae* with low JA secretion (~0.2 mg/L medium) oxygenated 18:3n-3 to 5,8-dihydroxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid as well as 9*R*-hydroperoxy-10*E*,12*Z*,15*Z*-octadecatrienoic acid, which was metabolized by an AOS activity into 9-hydroxy-10-oxo-12*Z*,15*Z*-octadecadienoic acid. Analogous conversions were observed with linoleic acid (18:2n-6). Studies using [11*S*-²H]18:2n-6 revealed that the putative 9*R*-dioxygenase catalyzed stereospecific removal of the 11*R* hydrogen followed by suprafacial attack of dioxygen at C-9. Mycelia from these strains of *L. theobromae* contained 18:2n-6 as the major polyunsaturated acid but lacked 18:3n-3. A third strain with a high secretion of JA (~200 mg/L) contained 18:3n-3 as a major fatty acid and produced 5,8-dihydroxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid

from added 18:3n-3. This strain also lacked the JA biosynthetic enzymes present in higher plants.

Introduction

Jasmonic acid (JA), an important signal molecule in plant defense and development, is present throughout the plant kingdom as the free acid, the methyl ester, the hydroxyl

derivatives, or amino acid conjugates [1–3]. The tropical and subtropical plant pathogen *Lasiodiplodia theobromae* (synonym *Botryodiplodia theobromae*) secretes JA [4, 5] and some strains could even be used for commercial JA production [5, 6].

JA is formed in plants sequentially from α -linolenic acid (18:3n-3) or hexadecatrienoic acid (16:3n-3) by 13S-lipoxygenase (13S-LOX), allene oxide synthase (AOS), allene oxide cyclase, 12-oxophytodienoate reductase, and three steps of β -oxidation [1–3, 7]. Key intermediates are 12-oxophytodienoic acid (12-OPDA) and dinor-12-OPDA from 18:3n-3 to 16:3n-3, respectively. JAs have a wide array of biological activities in plants (plant defense, stress adaptation and development) and can inhibit aflatoxin production and delay spore germination of *Aspergillus flavus* [8]. A recent report also suggests that JA could be of medical value as a growth suppressor of human cancer cells [9].

A biosynthetic pathway from 18:3 to 16:3 to JAs, essentially as described in plants, seems likely in fungi [6, 10], and plants and fungi form JAs with identical absolute configuration [5, 11]. JAs and the methyl ester of a key intermediate, 12-OPDA, were identified as a metabolite of 18:3n-3 in the culture medium of *L. theobromae* [10]. However, whether JA and 12-OPDA are formed by the same enzymes as in plants is unknown. LOXs are ubiquitous in plants, but only few LOXs of fungi have been identified and characterized. Unfortunately, the genome of *L. theobromae* has not yet been sequenced. Hydroperoxy fatty acids can be formed in fungi also by heme containing dioxygenases, e.g., linoleate diol synthases (LDS) and other oxygenases of the dioxygenase-cytochrome P450 (DOX-CYP) family of fusion proteins [12–16]. For comparison, *Aspergillus terreus* was recently found to express linoleic acid 9R-dioxygenase (9R-DOX) and AOS activities [17]. This 9R-DOX activity could be due to a heme containing dioxygenase, as LOX genes have not been identified in the genome of *A. terreus* [17].

The aim of the present study was to investigate the oxidation and further transformation of polyunsaturated fatty acids by *L. theobromae*. This fungus is a devastating plant pathogen, and its access from many fungal collection centers is restricted for environmental safety reasons. The few strains, which produce JA in large amounts [18], are also guarded by commercial interests. In this study, we used two strains of *L. theobromae* from the CBS Fungal Biodiversity Center, and a non-commercial strain with prominent JA biosynthetic capacity [19].

Materials and Methods

Materials

16:3n-3 (99%), oleic acid (18:1n-9; 99%), 12Z-octadecenoic acid (18:1n-6; 99%), linoleic acid (18:2n-6; 99%),

U[^{13}C]18:2n-6 (98%), 18:3n-3 (99%), γ -linolenic acid (18:3n-6; 99%), and 9Z,12Z-eicosadienoic acid (20:2n-6; 99%) were from Lipidox, Sigma and Larodan, and stored as stock solutions (50–100 mM) in ethanol at -20°C . HPLC solvents were from VWR. [11S- ^2H]18:2n-6 (>95% ^2H) was prepared as described [20, 21]. 9-Hydroxy-10-oxo-10,12Z-octadecadienoic acid was from Lipidox (Stockholm, Sweden). 11S- and 11R-hydroperoxy-7Z,9E,13Z-hexadecatrienoic acids (11-HPHDTRE), 9S-hydroperoxy-10E,12Z-octadecadienoic acid (9S-HPODE), 13R-hydroperoxy-9Z,11E-octadecadienoic acid (13R-HPODE), 13R-hydroperoxy-9Z,11E,15Z-octadecatrienoic acid (13R-HPOTRE), and 13S-HPODE were prepared with LOXs (tomato fruit [22], recombinant manganese LOX (Mn-LOX) [23], and soybean LOX-1 (Lipoxidase, Sigma)). 11S- and 11R-HOME(12Z) were prepared with PGH synthase-1 and Mn-LOX [24, 25]. A racemic mixture of HPODE was obtained by photo oxidation with methylene blue [26]. The O-methyloxime (MO) derivative of [5,5,7- $^2\text{H}_3$](–)-JA used as an internal standard during quantification of JA was synthesized by treatment of (–)-JA with Na_2CO_3 in D_2O followed by preparation and isolation of the MO derivative. Solvents for HPLC and other chemicals were of analytical grade and obtained from VWR and Sigma-Aldrich. *L. theobromae* (CBS 117454; CBS 122127) were from CBS Fungal Biodiversity Center (Baarn, Delft, The Netherlands). The *B. theobromae* strain 2334 was isolated in Cuba, characterized and grown as described [19], and it will be referred to as *L. theobromae* strain 2334.

Fungal Growth

The two CBS strains were grown on agar slants (15 g agar/2 g malt extract/0.75 g NaNO_3 /0.35 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ /5 g sucrose) at 27°C for 3–4 days and then stored at $+4^\circ\text{C}$. For analysis, a piece of the agar slants of *L. theobromae* were grown in a modified Czapek-Dox medium (per liter: 2 g KH_2PO_4 , 0.6 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.3 g KCl, 7.5 g NaNO_3 , 50 g sucrose, 1 ml trace metals ([27])); pH was adjusted to 5.5 with KOH) at 27°C without shaking for 10–12 days. The *L. theobromae* strain 2334 was grown in malt extract agar slant at 30°C for 3 days and then stored at 4°C ; for analysis, a piece of the agar slants of this fungus was grown in a medium previously described [19]. The mycelia of the strains were harvested by filtration. The filtrate was assayed for JAs, whereas the mycelia were washed with saline, blotted dry, weighed, grinded in liquid nitrogen and stored at -80°C until analysis.

Assay of Enzyme Activity

The nitrogen powder was homogenized (glass-Teflon, 10 passes; $+4^\circ\text{C}$) in 10–20 vols. (w/v) of 0.1 mM KH_2PO_4

buffer (pH 7.4)/2 mM EDTA/0.04% Tween-20, and centrifuged at $15,000\times g$ (10 min, $+4\text{ }^{\circ}\text{C}$). The supernatant was used immediately for studies of enzyme activities. Typically, an aliquot (0.25–0.5 ml) was incubated with 80–100 μM of fatty acids or fatty acid hydroperoxides for 30–40 min on ice. The incubation was terminated with ethanol (4 vols.) and centrifuged. The supernatant was diluted with water and extracted (SepPak/C₁₈; Waters), as described [21, 28]. Triphenylphosphine was used to reduce hydroperoxy fatty acids to alcohols. The subcellular distributions of enzyme activities were determined by differential centrifugations ($15,000\times g$, 10 min; $+4\text{ }^{\circ}\text{C}$; $100,000\times g$; $+4\text{ }^{\circ}\text{C}$; 60 min) and assay of enzyme activities in the high speed supernatant and the microsomal fractions.

LC–MS/MS

Reversed phase-HPLC (RP-HPLC) with MS/MS analysis was performed with a Surveyor MS pump (ThermoFisher), a manual or an automatic injector (Surveyor; ThermoFisher), and with an octadecyl silica column (5 μm ; $150\times 2.1\text{ mm}$; Phenomenex), which was eluted at 0.3 ml/min with methanol/water/acetic acid, 750/250/0.05 or 800/200/0.05. The effluent was subjected to electrospray ionization (ESI) in a linear ion trap mass spectrometer (LTQ, ThermoFisher) with analysis of negative ions. In some experiments, we also analyzed the effluent by UV absorption (photodiode array detector, path length 5 cm; Surveyor PDA plus, ThermoFisher). The heated transfer capillary was set at $315\text{ }^{\circ}\text{C}$ and the ion isolation width usually at 1.5 (and at 5 in the first selection for MS³ analysis of hydroperoxides [26]). The collision energy was set at 35 (arbitrary scale) and the tube lens at 90–120 V. For analysis of products formed from [²H₁₁]18:2n-6, we used an isolation width of 6 for the carboxylate anion.

Normal phase HPLC (NP-HPLC) and chiral phase-HPLC (CP-HPLC) were performed as described in [17, 28]. Steric analysis of 10-HODE was performed with a Reprosil Chiral-NR column (8 μm ; $250\times 2\text{ mm}$; eluted with isopropanol/hexane/acetic acid, 3/97/0.01). The enantiomers of 9- and 13-HODE, 9-HOTRE, HOME, HHDTRE and α -ketols were resolved with Reprosil Chiral AM (5 μm ; $250\times 2\text{ mm}$; eluted with methanol/hexane/acetic acid or ethanol/hexane/acetic acid, 5/95/0.01, at 0.15–0.2 ml/min) [28]. The effluent was mixed with isopropanol/water, 60/40, from a second pump (Surveyor MS) [28] and subjected to ESI with MS/MS analysis of carboxylate anions.

Quantitative Determination of (–)-JA and (+)-7-iso-JA and Fatty Acid Analysis

The medium (0.05–2 mL) of the growing cultures of *L. theobromae* was diluted with water to make a total volume

of 2 mL and treated with 8 mL of a methanolic solution of 30 mM methoxyamine hydrochloride. The mixture was vortexed and kept at room temperature for 15 h. The *O*-methyloxime (MO) derivative of [5,5,7-²H₃](–)-JA (3 μg) was added as an internal standard, and the material obtained following extraction with diethyl ether was dissolved in chloroform/2-propanol (2:1, v/v) and applied to a Supelclean LC-NH₂ solid phase extraction cartridge (Supelco, Bellefonte, PA). Elution with diethyl ether/acetic acid (98:2, v/v) afforded the JA-MO derivative, which was methyl-esterified by treatment with diazomethane and subjected to GC–MS analysis. For this purpose, a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas-chromatograph was used. The instrument was operated in the selected ion monitoring mode using the ions *m/z* 253 (unlabeled JA-MO methyl ester) and 256 (deuterium-labeled JA-MO methyl ester). Amounts of (–)-JA and (+)-7-iso-JA were calculated from areas of the *m/z* 253 peaks due to these compounds and from the area of the *m/z* 256 peak due to the deuterated standard.

The fatty acid composition of *L. theobromae* was determined by GC–MS analysis after hydrolysis as described [29]. The fatty acid methyl esters were separated on a Supelcowax-10 Capillary GC Column (30 m, film thickness 0.25 μm , carrier gas helium), and the column temperature was raised from $150\text{ }^{\circ}\text{C}$ at $5\text{ }^{\circ}\text{C}/\text{min}$.

Results

Fatty Acid Composition

We analyzed the fatty acid composition of *L. theobromae* strains CBS 122127 and 2334.

The four main fatty acids in the mycelium of CBS 122127 were 16:0 (37%), 18:2 (25%), 18:1 (24%), and 18:0 (14%). Traces of 20:0 were detected, but not the two expected precursor fatty acids of JA biosynthesis, 18:3n-3 and 16:3n-3. In contrast, the mycelium of *L. theobromae* strain 2334 contained 18:3n-3 as a major fatty acid, as illustrated in Fig. 1 along with the major fatty acids also found in CBS122127. 16:3n-3 was not detected.

Jasmonic Acid Production

Both commercial strains produced JAs, but (–)-JA and (+)-JA could only be detected in the growth medium in low concentrations [$<0.2\text{ }\mu\text{g}/\text{mL}$; e.g., $57\text{ ng}/\text{mL}$ (–)-JA, $109\text{ ng}/\text{mL}$ (+)-7-iso-JA (3*R*,7*S*-JA)]. In contrast, *L. theobromae* strain 2334 formed JAs in large amounts, about $200\text{ }\mu\text{g}/\text{mL}$ (e.g., $196\text{ }\mu\text{g}/\text{mL}$ (–)-JA and $13\text{ }\mu\text{g}/\text{mL}$ (+)-7-iso-JA) in agreement with previous reports [18]. In

Fig. 1 GC–MS analysis of the fatty acid composition of *L. theobromae* strain 2334 with prominent JA biosynthesis. The fatty acids were analyzed as methyl ester derivatives. The commercial strain CBS 122127 lacked 18:3n-3, contained the other fatty acids of strain 2334, and formed only relatively small amounts of JA (0.2 vs 200 mg/L)

another experiment, media collected after growth of strain 2234 for 10 and 12 days were found to contain 216 µg/mL and 178 µg/mL, respectively, of (–)-JA plus (+)-7-*iso*-JA.

Oxylipin Biosynthesis by Subcellular Fractions

Subcellular fractions (10,000×*g*) of all three strains contained 5,8-LDS activity as judged from 8-hydro(per)oxy metabolites and 5,8-diols formed from 18:2n-6, [U-¹³C] 18:2n-6, and 18:3n-3. Unexpectedly, subcellular fractions of the strain 2334 with prominent secretion of JA did not produce significant amounts of other oxylipins than 8-hydro(per)oxy metabolites and 5,8-diols, whereas the two commercial strains appeared to oxygenate fatty acids to these and to additional metabolites.

18:3n-3 and 16:3n-3 18:3n-3 was oxidized by nitrogen powder of the two *L. theobromae* CBS strains to 5,8-DiHOTrE and to an α -ketol, 9-hydroxy-10-keto-12Z,15Z-octadecadienoic acid, as shown in Fig. 2a. The ESI–MS/MS spectrum of the α -ketol (*m/z* 309 → full scan) is shown in Fig. 2b. A characteristic ion with mass of even number was noted at *m/z* 200, likely a radical ion, which is also present in the corresponding spectrum of 9-hydroxy-10-oxo-12Z-octadecenoic acid [17]. Significant amounts of the corresponding γ -ketol could neither be detected by RP-HPLC nor NP-HPLC. The α -ketol was likely formed from an allene oxide, 9,10-epoxy-10,12Z,15Z-octadecatrienoic acid. Hydrolysis of this allene oxide was expected to mainly form the *S* stereoisomer, and this was confirmed (insert in Fig. 2a).

The MS/MS spectrum of 5,8-DiHOTrE was as reported [30]. The less polar metabolites were identified as a mixture of 8-H(P)OTrE, 10-H(P)OTrE, and 9-H(P)OTrE (mainly 9*R*). Although 13-HPOTrE was not detected, we investigated whether 13*S*- or 13*R*-HpOTrE were substrates of the AOS activity, but this was not the case.

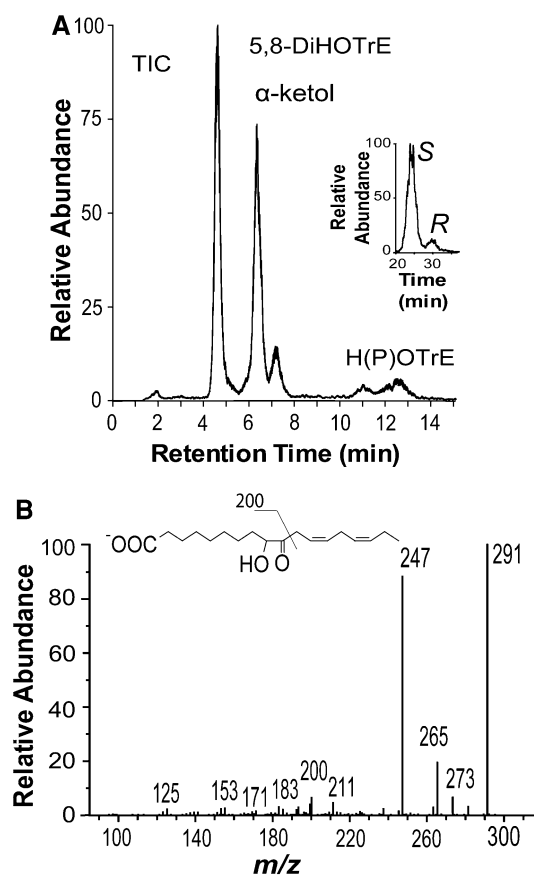

Fig. 2 LC–MS/MS analysis of oxidation of 18:3n-3 by subcellular fractions of *L. theobromae*. **a** RP-HPLC–MS analysis of metabolites formed by CBS 117454. TIC from MS/MS analysis of *m/z* 309 and 293. The two major peaks contained 5,8-DiHOTrE and an α -ketol, as indicated. Small amounts of H(p)OTrE were also detected. Strain CBS 122127 yielded a similar pattern. The inset chromatogram shows that the *S* and *R* stereoisomers of α -ketols were formed from hydrolysis of the allene oxide in a ~10:1 ratio (CP-HPLC–MS/MS). **b** MS/MS spectrum (*m/z* 309 → full scan) of the α -ketol derived from hydrolysis of an allene oxide. The insert shows formation of the even numbered signal at *m/z* 200, which presumably is due to a radical anion [17]

16:3n-3 was oxidized to approximately equal amounts of 10-HHDTTrE and 11-HHDTTrE (Fig. 3). A steric analysis by CP-HPLC showed that 10*R*-HHDTTrE and 11*S*-HHDTTrE were mainly formed (Fig. 3b, c). It seems likely that the 10*R*- and 11*S*-DOX activities are due to the linolenate 9*R*-DOX activity. Chain shortening of 18:3n-3 by two carbons thus changed the oxygenation from C-9 to C-10, and led to biosynthesis 11*S*-HPHDTTrE after hydrogen abstraction at C-9. 11*S*-HPHDTTrE is a precursor of JA in plants [2], but it was not transformed by AOS of *L. theobromae*.

18:2n-6, 18:3n-6, and 20:2n-6 18:2n-6 was transformed to a major polar metabolite, which eluted after 7 min during LC–MS/MS analysis (Fig. 4a). [U-¹³C]Linoleic acid was oxidized in the same way. The mass spectrum of the main metabolite was identical with that of an α -ketol, 9-hydroxy-10-oxo-12Z-octadecenoic acid [17]. Small

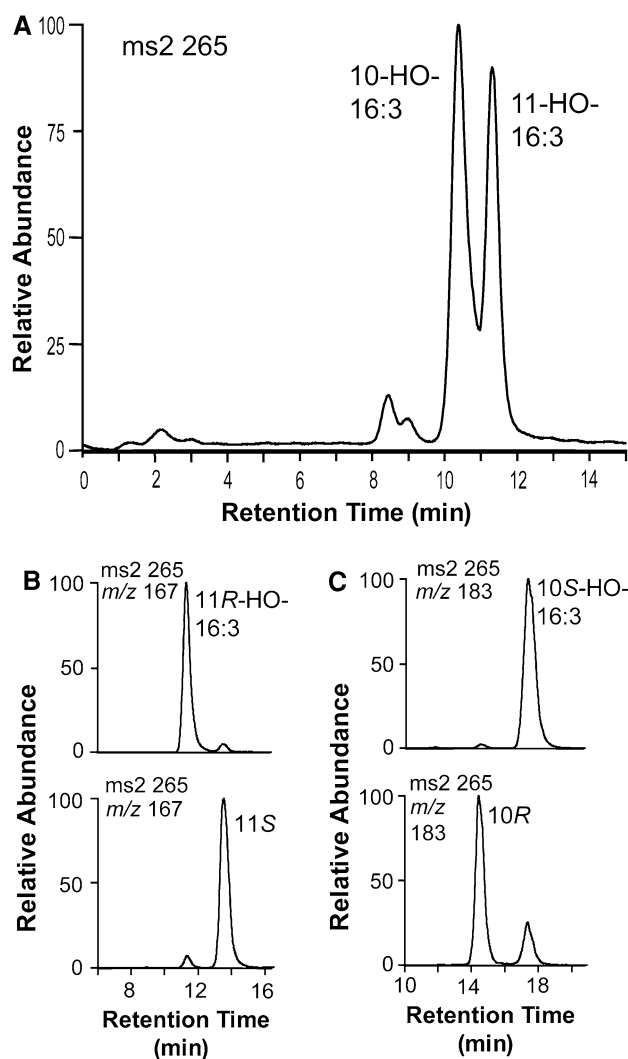

Fig. 3 Analysis of oxidation of 16:3n-3 by subcellular fractions of *L. theobromae*. The products formed by strain CBS 122127 were analyzed by RP- and CP-HPLC with ESI-MS/MS after reduction to alcohols with triphenylphosphine. **a** RP-HPLC. The first eluting major peak contained 10-HHDTRE (marked 10-HO-16:3) and the second peak II 11-HHDTRE (marked 11-HO-16:3). **b** CP-HPLC-MS analysis of 11-HHDTRE (bottom chromatogram) with aid of an 11R-HHDTRE standard (top chromatogram; the 11R stereoisomer was produced with Mn-LOX [32]). **c** CP-HPLC-MS analysis of 10-HHDTRE (bottom chromatogram) with aid of the 10S stereoisomer (prepared with Mn-LOX [32])

amounts of the γ -ketol, 13-hydroxy-10-oxo-11*E*-octadecenoic acid, was detected after 5 min (Fig. 4a); MS/MS and MS/MS/MS spectra as reported [17]. The two ketols were apparently formed from 9*R*-HPODE via hydrolysis of an unstable allene oxide, 9,10-epoxy-10,12*Z*-octadecadienoic acid [17]. Steric analysis of the α -ketol supported this mechanism of biosynthesis from 9*R*-HPODE, as CP-HPLC showed that it consisted mainly of the 9*S* stereoisomer (cf. insert in Fig. 2a). The 9*R*-DOX activity was present in the soluble fraction and the AOS activity in the microsomal

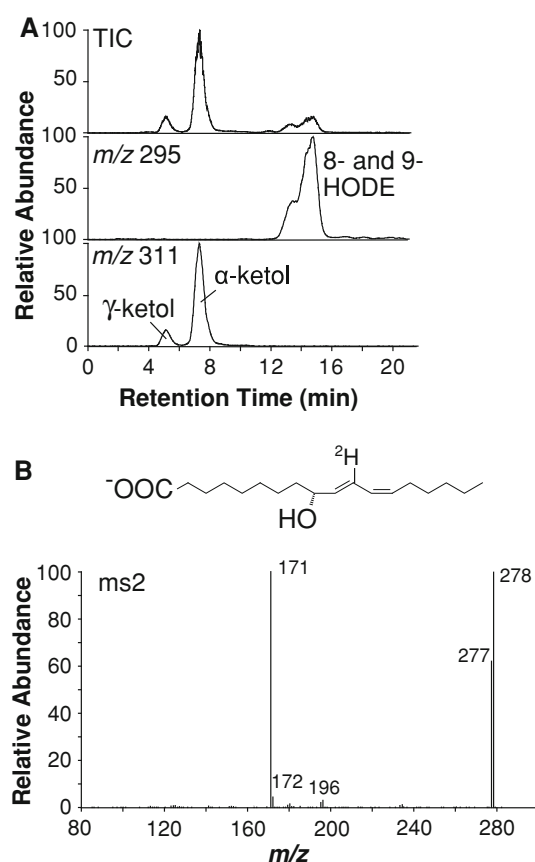

Fig. 4 LC-MS/MS analysis of oxidation of 18:2n-6 by subcellular fractions of *L. theobromae* (CBS 117454). **a** RP-HPLC-MS analysis showed that the major products were α - and γ -ketols and 8- and 9-HODE. **b** MS/MS analysis (m/z 292–298) \rightarrow full scan of 9-HODE from an incubation with [11*S*- 2H]18:2n-6 (95% 2H). The latter was diluted with endogenous 18:2n-6 in the incubation. The signals at m/z 277 and 278 of this mass spectrum, mainly due to loss of water from the carboxyl group, showing that the deuterium label was retained, as m/z 277 and 278 were present in the same relative intensities as in 8-HODE of this experiment

fraction, which are in agreement with the distribution of plant LOX and AOS (CYP74) [2].

Other metabolites were 5,8-DiHODE, 8-H(P)ODE, and small amounts of 10-H(P)ODE and 13-H(P)ODE ($\sim 5\%$ of 9-H(P)ODE). Steric analyses showed that 10-HODE was almost racemic ($\sim 60\%$ *S*), whereas 13-HODE was mainly formed with *S* configuration (data not shown).

The oxidation of 18:2n-6 was investigated with [11*S*- 2H]18:2n-6 (95% 2H). RP-HPLC with MS and MS/MS analysis of 9*R*-HODE showed that this deuterium label was retained (Fig. 4b), suggesting that the 9*R*-DOX of *L. theobromae* catalyzes suprafacial hydrogen abstraction at C-11 relative to the oxygenation at C-9. The apparent deuterium content, as judged from the ion intensities at m/z 277 and 288 of both 8- and 9-HODE, was 60%, due to dilution with endogenous 18:2n-6. The deuterium label was also retained in 13*S*-HODE, a minor metabolite in comparison with 9-HODE.

The 9R-DOX activity also transformed 18:3n-6 to 9-HPOTrE(n-6) as the main metabolite, but further transformation to an α -ketol could not be detected. This fatty acid was not oxygenated by 5,8-LDS in agreement with previous reports [31]. Significant formation of 13-HO-TrE(n-6) was also detected, as judged from the signal intensities of characteristic ions [m/z 169 (80%; 9-HO-TrE(n-6)) and m/z 193 (20%, 13-HOTrE(n-6))].

20:2n-6 was oxidized at C-11 and C-15, but these hydroperoxides were not further converted to α -ketols.

18:1n-9 and 18:1n-6 Oleic acid was exclusively oxidized by *L. theobromae* to 5,8-DiHOME and 8-H(P)OME, as shown in Fig. 5a. We could not detect signs of hydrogen abstraction at C-11, as judged from insignificant formation of 9-HOME(10E) and 11-HOME(9Z). This suggested that 18:1n-9 was not oxidized by the 9R-DOX activity.

The 9R-DOX activity might conceivably abstract the hydrogen at C-11 of 18:1n-6 with formation of 11S-HOME(12Z) or 13S-HOME(11E), whereas LDS enzymes mainly oxidize 18:1 with formation of stereoisomers with *R* configuration [25]. 13S-HOME(11E) was not detected. As shown in Fig. 5b, the formation of 11S-HOME(12Z) was only 10–15% of the biosynthesis of 11R-HOME(12Z) and could be attributed to oxidation by 5,8-LDS [24, 25].

In conclusion, 18:1n-9 and 18:1n-6 did not appear to be oxidized to a significant extent by the 9R-DOX activity.

13S-HPHTrE and 11S-HPHDTTrE—these hydroperoxides were not transformed by the AOS activity.

Discussion

Tsukada et al. [10] demonstrated that JA is formed in *L. theobromae* from 18:3n-3 [10]. In these experiments, the fungus was grown for 10 days with ^{13}C -labeled sodium acetate or with $[\text{H}_6]\text{18:3n-3}$, and found to secrete significant amounts of $[\text{C}^{13}]\text{JA}$, $[\text{H}_5]\text{JA}$, and $[\text{H}_5]\text{-iso-JA}$, respectively. These authors also isolated 12-OPDA (methyl ester), a key intermediate in the biosynthesis of JA in higher plants. Interestingly, NMR analysis of the deuterated 12-OPDA indicated a stereochemical difference between the fungal and plant cyclopentenone reductase reactions. This result suggested that fungal JA biosynthesis could have evolved independently from plant biosynthesis with both similarities and differences.

We did not find evidence for the presence in *L. theobromae* of the JA biosynthetic enzymes present in higher plants. Instead, we report that mycelia of two commercial strains of *L. theobromae* express prominent linolenate 9R-DOX and AOS activities after growth for about 10 days. These strains only secreted small amounts of JA, and we therefore also investigated the strain 2334 with large

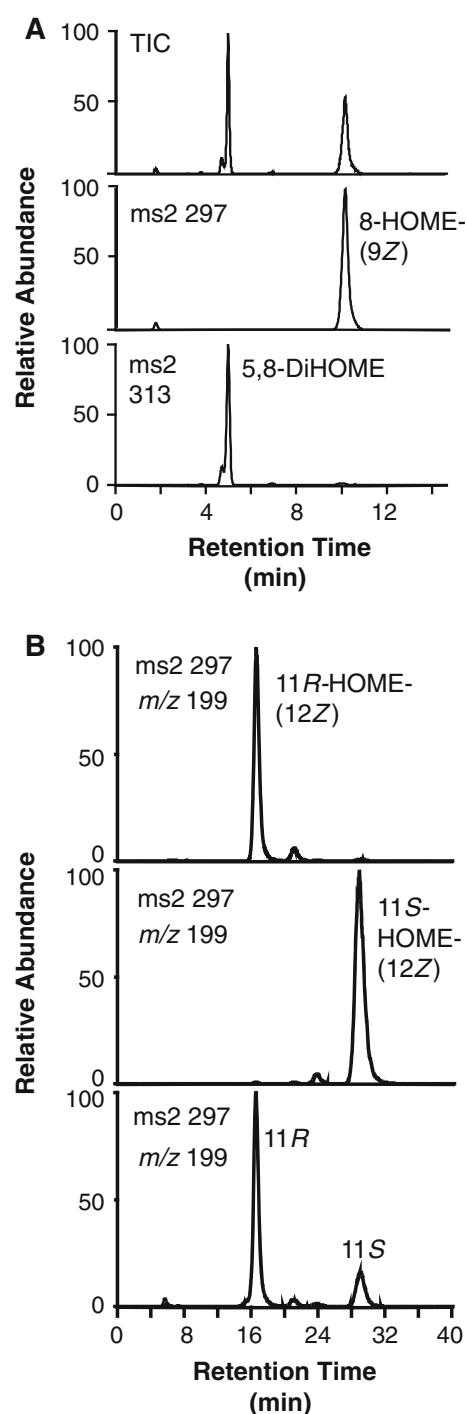

Fig. 5 LC-MS analysis of products formed during oxygenation of 18:1n-9 and 18:1n-6 by subcellular fractions of *L. theobromae*. **a** RP-HPLC analysis of oxidation of 18:1n-9 by strain CBS 122127. The two main products were 5,8-DiHOME and 8-HOME. **b** CP-HPLC analysis of oxidation of 18:1n-6–11-HOME(12Z) with aid of standards; the *top chromatogram* showing elution of 11R-HOME (prepared with Mn-LOX), the *middle chromatogram* elution of 11S-HOME (prepared with COX-1). The *bottom chromatogram* showing separation of products formed by *L. theobromae*. The latter thus mainly formed the 11R stereoisomer, and this metabolite can be attributed to the 5,8-LDS activity [25]

Fig. 6 Overview of the transformation of 18:3n-3 and 16:3n-3 to *cis-trans* conjugated hydroperoxides and an allene oxide by *L. theobromae*. **a** Oxidation of 18:3n-3. The soluble 9*R*-DOX activities are likely due to a lipoxygenase and the microsomal AOS activities to P450. **b** Oxidation of 16:3n-3. These metabolites are also formed by Mn-LOX but with the opposite chirality, and presumably formed by the same enzyme with oxidizes 18:2n-6 and 18:3n-3 to 9*R*-hydroperoxy metabolites

capacity to secrete JA. This strain contained 18:3n-3 and secreted large amounts of JA at time points (10 and 12 days).

We found that 18:3n-3 and 18:2n-6 were both oxygenated to 9*R*-hydroperoxides, which were further transformed to allene oxides. The oxidation of 18:3n-3 by this pathway is summarized in Fig. 6a. The 9*R*-DOX activity showed broad substrate specificity, and also oxidized 16:3n-3, 18:3n-6, and 20:2n-6.

16:3n-3 can be converted to JA in plants, and the first step is biosynthesis of 11*S*-HPHDT*rE* [3]. This metabolite was formed by *L. theobromae*. 16:3n-3 was oxidized to approximately equal amounts of 10*R*-HHDTrE and 11*S*-HHDTrE (Fig. 6b), however, since we could not detect formation of α-ketols it is apparent that these hydroperoxides were not substrates of AOS. The oxidation of 16:3n-3 is summarized in Fig. 6b.

9*R*-DOX and AOS activities have also been reported in *A. terreus* [17]. The genome of *A. terreus* appears to lack LOXs, whereas there is no information of the genome of *L. theobromae*. At first, it seemed likely that these two fungi could form 9*R*-HPODE and allene oxides by homologous enzymes. The 9*R*-DOX activity was present in the soluble fraction, whereas the AOS activity was mainly

Fig. 7 A schematic presentation of the hydrogen abstraction mechanisms of 9*R*-DOX and Mn-LOX. **a** Mechanism of hydrogen abstraction of 18:2n-6 and direction of oxygenation by the 9*R*-DOX activity. **b** Mechanism of hydrogen abstraction of 18:2n-6 and direction of oxygenation by Mn-LOX. If the substrate could be oxidized by Mn-LOX in the reverse orientation, the products and the oxygenation mechanism would be similar to that of the 9*R*-DOX activity

present in microsomal fraction. Both fungi therefore likely express microsomal AOS of the cytochrome P450 family, but the 9*R*-DOX activities of *L. theobromae* and *A. terreus* could be due to different classes of dioxygenases, i.e., a heme-containing dioxygenase in case of *A. terreus* and a lipoxygenase in case of *L. theobromae*. The latter hypothesis is based on the following observations.

First, γ-linolenic acid (18:3n-6) was oxidized to 9-HPOT*rE*(n-6) as a prominent metabolite by *L. theobromae*. This fatty acid is readily oxidized by many plant LOXs, but it is not oxidized by a series of fungal DOX-CYP fusion proteins, e.g., 5,8-LDS, 7,8-LDS, and 10*R*-DOX, and not by the 9*R*-DOX of *A. terreus* [17]. Second, LOXs oxygenate 18:1 only slowly [24], and we could not attribute the oxidation of 18:1n-6 or 18:1n-9 to the 9*R*-DOX activity of *L. theobromae*. Thirdly, we were struck by the similarities of Mn-LOX and 9*R*-DOX.

Both enzymes oxidize 16:3n-3 at the n-7 (C-10) and the n-6 carbons (C-11), albeit with different chirality [32]. The oxidation at the n-7 position is not a common feature of LOXs, but was recently reported by the LOX domain of a fusion protein of a cyanobacterium [33]. Oxygenation by 9*R*-DOX and Mn-LOX differ with regard to regiochemical and stereochemical specificity, but both enzymes catalyze suprafacial hydrogen abstraction and oxygenation [34], as outlined in Fig. 7. It is tempting to speculate that 9*R*-DOX activity of *L. theobromae* could be due to a LOX homologue of Mn-LOX with reverse substrate orientation in the active site (cf. Fig. 7). DOX-CYP fusion proteins and PGH synthases catalyze antarafacial hydrogen abstraction [24], whereas the 9*R*-DOX activity of *A. terreus* also is suprafacial [17]. The main difference between the two fungal 9*R*-DOX activities resides in the oxidation of 18:3n-3.

The AOS activity of *L. theobromae* appeared to be specific for 9R-HPODE and 9R-HPOTrE, since we could not detect significant formation of α -ketols from 16:3n-3, 18:3n-6, 20:2n-6, 13S- or 13R-HPOTrE. The substrate specificity of AOS of *A. terreus* is restricted to 9R-HPODE. In contrast, AOS (CYP74A) of plants are specific for 9S- or 13S-hydroperoxides [35, 36].

In summary, we report that *L. theobromae* efficiently oxidized 18:2n-6 and 18:3n-3 sequentially to 9R-hydroperoxides and to unstable allene oxides. The AOS activity is microsomal and probably catalyzed by a homologue of CYP74, whereas the soluble 9R-DOX activity might be due to a LOX. It appears that the genome sequence of *L. theobromae* will be needed to elucidate the detailed mechanism of JA formation in this fungus.

Abstract The lipid and fatty acid compositions of the total lipids of three cultured populations (migratory between fresh and salt water, Lake Biwa landlocked, and Setogawa River forms) of ayu, *Plecoglossus altivelis*, were investigated to clarify the difference in lipid characteristics and temperature adaptability among the three groups. Triacylglycerols were the dominant depot lipids of the three populations, while phospholipids, such as phosphatidylcholine and phosphatidylethanolamine, were found to be the major components of the polar lipids, and their lipid classes are similar to each other. The major fatty acids in the triacylglycerols of all specimens were 16:0, 18:0, 16:1n-7, 18:1n-7, 18:1n-9, 18:2n-6 (linoleic acid), 20:5n-3 (EPA, icosapentaenoic acid), and 22:6n-3 (DHA, docosahexaenoic acid), similar to the tissue phospholipids of the three populations, 16:0, 18:0, 16:1n-7, 18:1n-7, 18:1n-9, 18:2n-6, 20:4n-6, EPA, and DHA. All classes had high levels of 18:2n-6, which originates from their dietary lipids. Compared with the lower DHA levels of the triacylglycerols, the higher levels in the phospholipids suggest their selective accumulation or a biosynthetic pathway to DHA as in freshwater fish. Two populations (the migratory

and Setogawa River forms) adapted to lower temperatures with comparatively high levels of polyunsaturated fatty acids (PUFA) for their membrane fluidities. With significantly higher levels of n-3 PUFA and total PUFA, the mean DHA content in the lipids of the Setogawa River form (the population that adapted to lower temperatures) was significantly higher than that of the migratory form. From these results, we concluded that the Setogawa River population actively concentrates long-chain PUFA in its polar lipids and has high adaptability to low temperature.

Introduction

It is generally known that all marine animals, not only marine fishes but also invertebrates, characteristically

accumulate various types of n-3 long-chain polyunsaturated fatty acids (PUFA) in their lipids, in particular docosahexaenoic acid (DHA, 22:6n-3) and icosapentaenoic acid (EPA, 20:5n-3), while n-6 PUFA with n-3 PUFA are always observed as major PUFA in terrestrial animal lipids [1–3]. For example, linoleic (18:2n-6) and arachidonic acids (20:4n-6) are simply accumulated in freshwater animals, which take terrestrial prey, while n-3 long-chain PUFA are considered to originate from phytoplankton and to accumulate in marine animals in higher trophic levels through the food web [4–6]. There are many reports about the chemical components of pelagic sea water fish, in particular, on the fatty acids of fish, with growing recognition of the beneficial uses of dietary fish oils for humans [7–9]. As for a detailed determination of the fatty acid in freshwater species, little information has been available except for salmonids, such as rainbow trout *Oncorhynchus mykiss* [10–12].

Ayu, *Plecoglossus altivelis* Temminck et Schlegel (Plecoglossidae, Salmonidae, Salmoniformes), is an osmerid fish with an annual life cycle [13, 14]. The species ranges over the Japanese archipelago and is also found on the Korean Peninsula and some parts of the Chinese continent, migrating amphidromously between rivers and the sea. Commercially, it is the most important and expensive freshwater fish species in Japan because it possesses a characteristic watermelon-like aroma on its skin surface, making it a favorite seafood throughout Japan and Korea. The aroma is due to the dietary freshwater algae by its adult's herbivorous feeding [15, 16]. In general, animals in cold water require low-melting-point membrane lipids to maintain their fluidity [17–19]. Therefore, fishes in cold environments contain high levels of PUFA in their lipids [20–22]. Despite considerable attention paid to the biological and ecological aspects of *P. altivelis* (ecology: 23–25, phylogeny: 26–28), only a few reports on determination of the chemical components have been published [16, 29]. In particular, there has been no report of a detailed analysis of the fatty acid composition of *P. altivelis* [30–32] in different environments.

There are two primary populations of *P. altivelis* in Japan, the migratory and the Lake Biwa landlocked forms. The Lake Biwa is an ancient lake, which was closed 4 million years ago, where more than 50 species live indigenously. The Lake Biwa landlocked form is often cultured in many Japanese farms.

The migratory form ranges over all the rivers in the Japanese archipelago and the Lake Biwa landlocked form spans only the rivers that flow into Lake Biwa (Fig. 1). In 1975, the Sameura dam was built on the Yoshino River in Shikoku Island. The Setogawa River, which is a branch of the Yoshino River, flows into the artificial lake

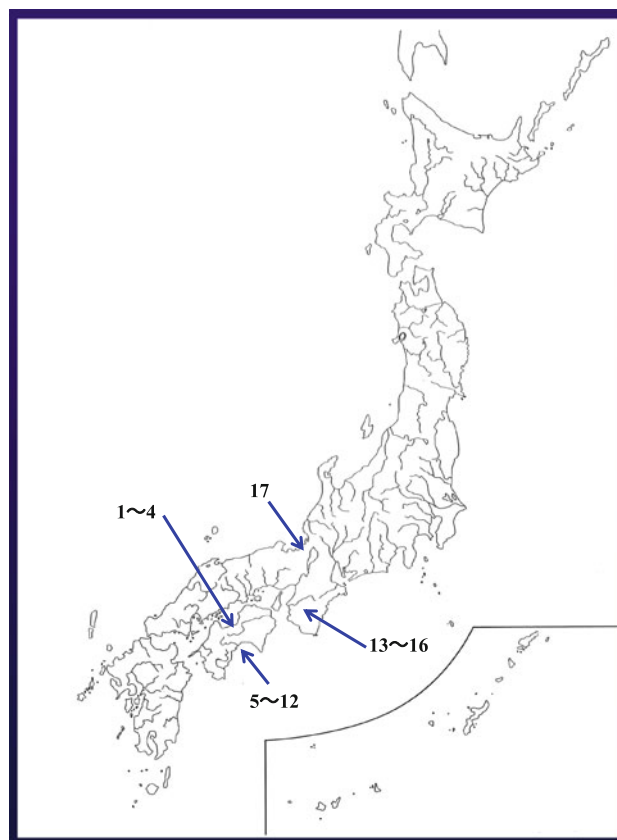

Fig. 1 The sampling site of *P. altivelis*. Parents of the Setogawa River artificially landlocked form (sample no. 1–4) were collected from the Setogawa River on Shikoku Island in spring 1995. Parents of the migratory form (sample no. 5–8) were collected in Tosa Bay in the Pacific Ocean in spring 1996. In 1997, other parents of the migratory form (sample no. 9–12) were collected from Monobe River flowing into Tosa Bay. Clone samples of the migratory form (sample no. 13–16) were continuously produced at Wakayama Prefectural Freshwater Fisheries Center in 1987. Parents of the Lake Biwa landlocked form (sample no. 17) were collected from Lake Biwa in 1996

formed by the Sameura dam, closing the Setogawa River system. The Setogawa River is at a high altitude in Shikoku with severely cold weather in winter. In the 1980s, the migratory form of *P. altivelis* was stocked in the Setogawa River. The form adapted to the low temperature, naturally reproduced, and became known as the Setogawa River form, which is considered tolerant of low temperatures.

In the present study, the lipid class and fatty acid compositions of the three cultured populations of *P. altivelis* (migratory, Setogawa River, and Lake Biwa landlocked forms) were investigated to determine the differences in their lipid characteristics and their lipid physiology. In particular, the differences of their PUFA levels under different water temperatures is discussed to assess the influence of environmental conditions.

Table 1 Biological data of the three populations of *Plecoglossus altivelis*

| Sample no. | Population | Date | Temperature (°C) | Length (cm) | Weight (g) |

Results are expressed as means ± standard error (*n* = 4–6) for each sample

Materials and Methods

Materials

The biological data of *P. altivelis* are listed in Table 1. In spring 1995, parents of the Setogawa River artificially landlocked form were collected from the Setogawa River (40°50'N and 133°35'E) on Japan's Shikoku Island (samples 1–4; Fig. 2). In the autumns of 1995 and 1996, hundreds of F1 and F2 larvae of the landlocked form were hatched. In autumn 1997, hundreds of F3 (samples 1–4) larvae from the landlocked F2 were obtained and then tested in June 1998. In spring 1996, parents of the migratory form were collected in Tosa Bay in the Pacific Ocean (samples 5–12; Fig. 2). In autumn 1996, hundreds of F1 larvae of the migratory form were also hatched. F2 larvae (samples 5–8) were obtained in autumn 1997 and then tested in June 1998. In 1997, other parents of the migratory form were collected from the Monobe River (33°33'N and 133°43'E) flowing into Tosa Bay. In autumn 1997, hundreds of F1 larvae (samples 9–12) of the migratory form were hatched, cultured, and then tested in August 1998. Clone samples of the migratory form were continuously produced at Wakayama Prefectural

Freshwater Fisheries Center in 1987. In autumn 1997, hundreds of F1 larvae (samples 13–16) of the clone sample were hatched, cultured, and then tested in August 1998 [33]. Parents of the Lake Biwa landlocked form were collected from Lake Biwa (35°19'N and 136°05'E) in 1996. In autumn 1996, hundreds of F1 larvae of the Lake Biwa landlocked form were hatched, and F2 larvae (sample 17) were obtained in autumn 1997 and then tested in August 1998.

All samples were cultured at the Kochi Freshwater Fisheries Center for nine months (from November 1997 to August 1998). The samples were cultured with the same artificial feedstuff (samples 18–19 in Tables 2, 3) in 2-ton FRP aquariums indoors at 19 °C. Before acclimation to different water temperatures (15.0, 18.0, 20.0, and 23.0 °C), all populations were cultured for about 200 days under the same conditions. Samples 1–16 of *P. altivelis* were cultured at four different temperatures for 2 weeks (Table 1). Before starting the experiments, fish were acclimated and starved 2 days. Feed was offered by hand as restricted feeding for 2 weeks; the fish in all groups were fed at 3.0% of their body weight per day (two times daily at 10:00 and 16:00 h). In June 1998, the samples 1–8 were fed by the same feed stuff (sample 18), and the samples

1. The Setogawa River Form

2. The amphidromous Form F2

3. The amphidromous Form F1

4. The amphidromous clone sample

5. The Lake Biwa landlocked Form

Fig. 2 In spring 1995, parents of the Setogawa River form were collected. In the autumns 1995 and 1996, F1 and F2 larvae of the landlocked form were hatched. In autumn 1997, F3 (samples 1–4) larvae from the landlocked F2 were obtained, cultured, and then tested in June 1998. In spring 1996, parents of the migratory form were collected in Tosa Bay. In autumn 1996, F1 larvae of the migratory form were hatched. F2 larvae (samples 5–8) were obtained in autumn 1997, cultured, and then tested in June 1998. In 1997, other

parents of the migratory form were collected from Monobe River. In autumn 1997, F1 larvae (samples 9–12) of the migratory form were hatched, cultured, and then tested in August 1998. In autumn 1997, F1 larvae (samples 13–16) of the clone sample were hatched, cultured, and then tested in August 1998. Parents of the Lake Biwa landlocked form were collected in 1996. In autumn 1996, F1 larvae of the Lake Biwa landlocked form were hatched, and F2 larvae (sample 17) were obtained in autumn 1997, cultured, and then tested in August 1998

9–17 in August 1998, were fed with another feedstuff (sample 19), respectively. A total of 2,000 individual *P. altivelis* were cultured in an aquarium, from which 10 randomly selected specimens were chosen for lipid analysis. After their biological data were measured, the specimens were immediately frozen at -40°C .

Lipid Extraction and Analysis of Lipid Classes

After 2 months storage in the laboratory at -40°C , each individual *P. altivelis* was dissected into ordinary muscle and other organs, which contained skin, dark muscle, and viscera. Each sample was homogenized in a mixture of chloroform and methanol (2:1, v/v), and a portion of each homogenized sample was extracted according to the Folch procedure [34]. Each crude total lipid was separated into

classes on silicic acid columns (Merck and Co. Ltd., Kieselgel 60, 70–230 mesh). Quantitative analysis of the lipid constituents was performed using gravimetric analysis of fractions collected from column chromatography. The first eluate (dichloromethane/*n*-hexane, 2:3, v/v) was collected as steryl ester, wax ester, and diacylglycerol ether fractions. This was followed by eluting the triacylglycerols (TAG) with dichloromethane and eluting the sterols with dichloromethane/ether (35:1, v/v); eluting the diacylglycerols with dichloromethane/ether (9:1, v/v); eluting the free fatty acids with dichloromethane/methanol (9:1, v/v); eluting the phosphatidylethanolamine (PtdEtn) with dichloromethane/methanol (1:5, v/v); eluting other minor phospholipids with dichloromethane/methanol (1:20, v/v); and eluting phosphatidylcholine (PtdCho) with dichloromethane/methanol (1:50, v/v) [35].

Results are expressed as mol% of the total fatty acids. Data are means ± standard error ($n = 5-6$)

In Tables 3, 4, 5, 6, 7, the major fatty acids are selected if at least one mean datum was detected at a level of 0.4% or more of total fatty acids

Individual lipids from each lipid class, such as the phospholipid class, were qualitatively identified with standards by comparing the R_f values using thin-layer chromatography (Merck & Co. Ltd., Kieselgel 60, thickness of 0.25 mm for analysis). All the sample lipids were dried under argon at room temperature and stored at $-40\text{ }^{\circ}\text{C}$ under argon.

Preparation of Methyl Esters and Gas–Liquid Chromatography (GLC) of Esters

Individual components of TAG, PtdEtn, and PtdCho fractions were converted to fatty acid methyl esters by direct trans-esterification with methanol containing 1% concentrated hydrochloric acid under reflux for 1.5 h, as previously reported [35]. The methyl esters were purified using silica gel column chromatography by elution with dichloromethane/*n*-hexane (2/1, v/v).

Composition of the fatty acid methyl esters was determined by gas–liquid chromatography. Analysis was performed using Shimadzu GC-8A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and HP-5890 (Hewlett Packard Co. Ltd., Yokogawa Electric Corporation, Tokyo, Japan) gas chromatographs equipped with an Omegawax 250 fused silica capillary column (30 m \times 0.25 mm i.d.; 0.25 μm film, Supelco Japan Co. Ltd., Tokyo, Japan). The temperatures of the injector and the column were held at 230 and 215 $^{\circ}\text{C}$, respectively, and the split ratio was 1:76. Helium was used as the carrier gas at a constant flow rate of 0.7 mL/min. Quantitation of individual components was performed by means of Shimadzu Model C-R3A (Shimadzu Seisakusho Co. Ltd.) and HP ChemStation System (A. 06 revision, Yokogawa HP Co. Ltd., Tokyo, Japan) electronic integrators.

Preparation of 4,4-Dimethyloxazoline Derivatives (DMOX) and Analysis of DMOX by Gas Chromatography—Mass Spectrometry (GC/MS)

The DMOX derivatives were prepared by adding an excess amount of 2-amino-2-methyl propanol to a small amount of fatty acid methyl esters in a test tube under an argon atmosphere. The mixture was heated for 18 h at 180 $^{\circ}\text{C}$ [35, 36].

Analysis of the DMOX derivatives was performed using a HP G1800C GCD Series II (Hewlett Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) GC/MS equipped with the same capillary used for determining the respective fatty acids with the HP WS (HP Kayak XA, G1701BA version, PC workstations). The temperatures of the injector and the column were held at 230 and 215 $^{\circ}\text{C}$, respectively. The split ratio was 1:76; the ionization voltage was 70 eV. Helium was used as the carrier gas at a

constant flow rate of 0.7 mL/min. The fatty acid methyl esters were identified by comparing the methyl ester and DMOX derivative mass spectral data obtained by GC/MS. The DMOX derivatives were identified by comparing them with the mass spectral data obtained from authentic samples collected by Christie [37].

Statistical Analyses

The mean DHA, total n-3 PUFA, total PUFA levels in the PtdEtn and PtdCho of sample **1** were compared with those in samples **5** and **9**. Significant mean differences were determined using a one-way analysis of variance (ANOVA) to test the influence of the water temperature. Tukey's multiple procedure was used to compare the differences among mean values. Differences were regarded as significance level of $P < 0.05$.

Results

Lipid Content of the Three Populations of *P. altivelis* Under the Four Different Temperatures

The biological data of *P. altivelis* samples are listed in Table 1 with relevant data. The size and weight of the clone (No. **13–16**) and Lake Biwa landlocked (No. **17**) samples were slightly larger than were those of the other samples (No. **1–12**). The total lipid content of the *P. altivelis* samples is listed in Table 2 with the lipid classes. Lipid levels of the normal samples (Setogawa samples **1–4** and migratory samples **5–8**) collected in June 1998 were similar to each other. For example, the growth and lipid content at the lowest temperature condition (15 $^{\circ}\text{C}$; Setogawa sample **1** and migratory sample **5**) were similar to those at higher temperatures (18–23 $^{\circ}\text{C}$; Setogawa samples **2–4** and migratory samples **6–8**). As shown in Table 2, TAG (64.4–92.8% of TL) was the major component in all sample lipids, with small levels of sterols, PtdEtn, and PtdCho.

Fatty Acid Composition in TAG Deposit Lipids of *P. altivelis*: Relationship with Dietary Lipids

The fatty acids in TAG of the feedstuff and all samples under different conditions are listed in Tables 3, 4. Both the diets (samples **18** and **19**) have high levels of fat contents (5.7–10.4% in Table 2); therefore, their TAG mainly influence the fatty acid composition of the ayu depot lipids. Nine dominant fatty acids (more than 3% of total fatty acids: TFA) in the dietary lipids (Table 3) were found: 14:0, 16:0, and 18:0 as saturated fatty acids; 16:1n-7, 18:1n-9, and 18:1n-7 as monounsaturated fatty acids (MUFA); 18:2n-6 as n-6 dienoic fatty acid; EPA and DHA

Results are expressed as mol% of the total fatty acids. Data are means ± standard error ($n = 4-6$)

In Tables 3, 4, 5, 6, 7, the major fatty acids are selected if at least one mean datum was detected at a level of 0.4% or more of total fatty acids

as n-3 PUFA. In particular, the fatty acid compositions were similar to each other and medium levels (more than about 10% of TFA) of 18:2n-6 (10.3–12.5% of TFA) were found in both the feedstuff lipids.

Similar to the fatty acid compositions of the dietary lipids, the same nine dominant fatty acids in the tissue TAG were also found in all the different areas and conditions: 14:0, 16:0, and 18:0; 16:1n-7, 18:1n-9, and 18:1n-7; 18:2n-6 as n-6 dienoic fatty acid; EPA and DHA as n-3 PUFA, with noticeable levels (more than about 1% of TFA) of five fatty acids: 20:1n-11, 20:1n-9, 22:1n-11, 18:3n-3, and 22:5n-3 (docosapentaenoic acid). This suggests that the depot lipids in all samples (Table 4) are directly influenced by the fatty acid composition of the feedstuff TAG lipids (Table 3).

Fatty Acid Composition in Tissue Phospholipids in *P. altivelis*

Similar to the fatty acid compositions of TAG in the three populations, which were acclimated to different conditions with various temperatures, the major fatty acids of the

phospholipids (PtdEtn and PtdCho) are listed in Tables 5, 6, 7. In the fatty acid composition of PtdEtn (Tables 5, 6), nine similar major fatty acids were consistently found in all samples. The major fatty acids were 16:0 and 18:0; 16:1n-7, 18:1n-9, and 18:1n-7; 18:2n-6 and 20:4n-6; EPA and DHA, with noticeable levels of three fatty acids, 14:0, 24:1n-9, and 22:5n-3. Similarly, in the fatty acid compositions of PtdCho (Tables 5, 7), the same major fatty acids were consistently found in all samples. These were 16:0 and 18:0; 16:1n-7, 18:1n-9, and 18:1n-7; 18:2n-6; EPA and DHA, with noticeable levels of four fatty acids, 14:0, 24:1n-9, 20:4n-6, and 22:5n-3.

Discussion

Lipid Content of the Three Populations of *P. altivelis* Under the Four Different Temperatures

In Table 2, the lipid content of all the samples was higher than that of the wild fish species [32], because they were

Results are expressed as mol% of the total fatty acids. Data are means ± standard error ($n = 6$)

In Tables 3, 4, 5, 6, 7, the major fatty acids are selected if at least one mean datum was detected at a level of 0.4% or more of total fatty acids

cultured under better nutritional conditions. Although the lengths and weights of clone samples **13–16** were larger than were those of Setogawa and migratory samples **1–12** (Table 1), their lipid content was markedly lower than the normal sexually reproduced samples. This finding suggests that the activity of lipid accumulation in the clone samples may be weaker than those in normal samples. Moreover, lipid levels of the normal samples (Setogawa samples **1–4** and migratory samples **5–8**) collected in June 1998 were similar to each other. Therefore, the nutrient intakes of the samples were similar to each other in spite of various water temperatures and different populations.

Fatty Acid Composition in TAG Deposit Lipids of *P. altivelis*: Relationship with Dietary Lipids

Medium levels of 18:2n-6 were found in the feedstuff lipids, and this finding is characteristic of dietary lipids, which are added with plant lipids.

Although the fatty acid compositions of TAG of the migratory, Lake Biwa and Setogawa River forms varied slightly among the samples (Setogawa and migratory samples **1–12**, Lake-Biwa landlocked sample **17**) under four different conditions (water temperature: 15.0, 18.0, 20.0, and 23.0 °C; Table 4), the major fatty acids in tissue TAG were almost the same in all samples. The levels of the major fatty acids were also similar to each other under all conditions among the different populations. Similarly, the same fatty acids were found as major acids in the TAG of the clone samples, as shown in Table 5.

The depot lipids of *P. altivelis* were probably influenced by dietary lipids, which originated from the same feedstuff [38]. The three populations of *P. altivelis* presumably accumulated intact dietary lipids as their depot lipids. Interestingly, high levels of 18:2n-6 (8.2–11.0% in Table 4 and 11.2–12.1% in Table 5) in the TAG of all populations were observed, suggesting that TAG was influenced by that in the dietary lipids (18.5–19.8%; Table 3), because it is

Results are expressed as mol% of the total fatty acids. Data are means ± standard error ($n = 4-6$)

In Tables 3, 4, 5, 6, 7, the major fatty acids are selected if at least one mean datum was detected at a level of 0.4% or more of total fatty acids
Values in a column with different superscripts (*) are significantly different at the 5% level

known that artificial feedstuff contains plant seed oils, which have high levels of 18:2n-6 [30–32].

Fatty Acid Composition in Tissue Phospholipids in *P. altivelis*

Although the kinds of fatty acids between the TAG and phospholipids of *P. altivelis* were the same, their levels in the phospholipids of *P. altivelis* significantly differed from

those in TAG. For example, high levels of total n-3 PUFA (21.4–46.7% for PtdEtn and 30.4–50.8% for PtdCho) were found in the polar phospholipids, different from those in TAG (13.2–16.4%). This indicates that n-3 PUFA is specifically transferred from depot lipids to tissue polar lipids in the ayu, similar to the circumstances in other aquatic animals such as fishes [4, 6, 38] and mollusks [39]. In particular, high DHA levels were found in both PtdEtn (38.3–46.76% for samples Setogawa-15 °C sample 1,

Results are expressed as mol% of the total fatty acids. Data are means ± standard error ($n = 3-6$)

In Tables 3, 4, 5, 6, 7, the major fatty acids are selected if at least one mean datum was detected at a level of 0.4% or more of total fatty acids. Values in a column with different superscripts (*, **, ***) are significantly different at the 5% level, respectively

migratory-15 °C sample 5, and migratory-15 °C sample 9 in Table 6) and PtdCho (44.4–50.8% for samples 1, 5, and 9 in Table 7) under low temperature conditions, markedly different from that in TAG. The high n-3 PUFA levels that accumulated in the phospholipids suggest the importance of long-chain n-3 PUFA for *P. altivelis* plasma membrane lipids as a fish species [6]. *P. altivelis* might biosynthesize or actively accumulate n-3 PUFA at the tissue level because of the biosynthetic ability of freshwater fishes to long-chain n-3 PUFA [40, 41].

Accumulation and Biosynthesis of 20:4n-6 at the Tissue Levels of *P. altivelis*

Both TAG and PtdEtn contained similar levels of total n-6 PUFA (11.0–13.0% for TAG and 10.2–13.3% for PtdEtn of normal samples 1–12 and 17), as shown in Tables 4 and 6. With medium levels of 18:2n-6 and trace levels of 20:4n-6 in *P. altivelis* TAG, noticeable 20:4n-6 levels in the polar lipids (PtdEtn and PtdCho in Tables 6, 7) suggest the biosynthesis of long-chain n-6 PUFA in *P. altivelis* PtdEtn.

18:2n-6 is modified to 18:3n-6 by 6-desaturase, and 20:4n-6 is derived from 18:3n-6 by C₂-elongation and Δ 5-desaturation [8, 42–44]. 18:2n-6 in all polar lipids (4.9–8.8% for PtdEtn and 2.2–5.2% for PtdCho) is thought to be transferred from TAG 18:2n-6 (9.3–11.0%), which is directly influenced by dietary lipids. In particular, the lower levels of PtdCho 18:2n-6 also suggest enzymatic modification to 20:4n-6.

Furthermore, there were tendencies in regard to the variations of n-6 PUFA in PtdEtn influenced by temperature differences. For example, the slightly higher levels of 20:4n-6 (3.6, 3.5, and 3.3% for samples **1**, **5**, and **9** at 15 °C; 3.5, 3.4, and 3.4% for samples **2**, **6**, and **10** at 18 °C; 2.2, 3.3, and 3.2% for samples **3**, **7**, and **11** at 20 °C; 2.5, 2.3, and 2.8% for samples **4**, **8**, and **12** at 23 °C) under lower temperature conditions were found with lower levels of 18:2n-6 (5.5, 4.5, and 4.9% for samples **1**, **5**, and **9** at 15 °C; 6.2, 7.4, and 5.3% for samples **2**, **6**, and **10** at 18 °C; 6.7, 7.6, and 5.6% for samples **3**, **7**, and **11** at 20 °C; 8.8, 7.8, and 5.3% for samples **4**, **8**, and **12** at 23 °C) under all other conditions of higher temperature.

Accumulation and Biosynthesis of DHA in the *P. altivelis*

The high levels of total n-3 PUFA in the phospholipids, markedly different from those in TAG as mentioned above, suggest biosynthesis of long-chain n-3 PUFA in *P. altivelis* tissue lipids, and that freshwater fishes are able to synthesize DHA [40–42]. With low levels of DHA in *P. altivelis* TAG, the high DHA levels in the polar lipids (PtdEtn and PtdCho) of *P. altivelis* suggest the biosynthesis and accumulation of DHA in the *P. altivelis* polar lipids. The levels of 22:5n-3 in the polar lipids were slightly higher than were those in TAG. 22:5n-3, which is an intermediate to DHA, was probably derived from EPA by C₂-elongation [8, 42–44]. Although we did not find 24:5n-3 and 24:6n-3 in the *P. altivelis* phospholipids, DHA can be speculatively considered to be derived from 22:5n-3, similar to biosynthesis in mammal (Sprecher's shunt: 45, 46).

Influence of Different Temperatures on *P. altivelis* Tissue Lipids: Adaptation to Low Temperature by Increase of DHA

Although the fatty acid compositions in the TAG of *P. altivelis* were similar to each other in all specimens (Table 4), and there were no such tendencies of the fatty acids in TAG among the four different-temperature samples, those in PtdEtn and PtdCho show a clear trend (Tables 6, 7). For example, in all samples (Setogawa River form samples: **1–2**, migratory type samples: **5–6** and **9–10**) in PtdEtn (Table 6) and PtdCho (Table 7) under lower

temperature conditions, significantly higher levels of total PUFA, total n-3 PUFA, and DHA were found, compared with those in other samples (**3–4**, **7–8**, and **11–12**) under higher temperature conditions. In particular, under the lowest temperature (15 °C, for samples **1**, **5**, and **9**), the highest levels of these long-chain n-3 PUFA were found. Especially, only DHA varied markedly according to temperature changes. Therefore, DHA is certainly the most important acid for acclimation of the fish plasma membrane to low temperatures. These findings suggest a mechanism for increasing unsaturation to DHA for membrane fluidity under low temperatures [17–19, 47]. A similar trend was found in the clone samples (**13–16** in Table 5). However, the concentration of DHA in the clone samples under low temperatures is not so clear, and this implies the weakness of enzyme activity in the clone samples compared with that in the normal sexually reproduced samples.

Difference of Temperature Adaptability Among Populations of *P. altivelis*

In two populations (Setogawa River and migratory forms), which are acclimatized to various temperature conditions, the major fatty acids of the phospholipids (PtdEtn and PtdCho) are listed in Tables 6, 7. Higher DHA levels in accordance with lower temperature acclimatization were found in both populations. Compared with the levels of the key fatty acids (total PUFA, total n-3 PUFA, and DHA) in the polar lipids at 15 °C in the two populations, many data in PtdEtn and PtdCho show them to have significant differences (Tables 6 and 7) and some data show to have tendencies, which mean higher levels of these PUFA in the Setogawa River form. For example, in PtdCho, the level of DHA in Setogawa samples **1** ($41.8 \pm 1.2\%$) was significantly (ANOVA with a Tukey's test) higher than were those in migratory samples **5** and **9** (36.9 ± 1.2 and $35.4 \pm 1.8\%$). The biosynthetic and accumulative abilities of the Setogawa River form in regard to DHA are probably higher than are those in the migratory form. Although we investigated only one temperature condition (18 °C) in the case of the Lake Biwa landlocked form (sample: **17**), the levels of n-3 PUFA, such as DHA in PtdEtn and PtdCho (Tables 6, 7), were similar to those in the migratory form (samples **6** and **10**).

The increase of DHA in the tissue levels of freshwater fishes is important for supplying a healthful diet [8, 9]. As for the level of DHA, which was accumulated or biosynthesized in *P. altivelis* tissues, the Setogawa River form is superior among the three populations, and are thus a useful food source rich in long-chain n-3 PUFA. The Setogawa River form has adaptability to high temperature and is a novel and valuable ayu population as a healthful food rich in DHA.

Acknowledgments The authors thank Ms. Mikiko Tanaka and Mr. Kojiro Ogomori for their skilled technical assistance. H. Saito performed all aspects of the study including the designing the experiments, analyzing the data, and writing the manuscript. C. Xue assisted in data collection and analysis. M. Okabe assisted in culturing the fish and collecting samples.

Separation of Lipid Classes by HPLC on a Cyanopropyl Column

Petter Olsson · Jan Holmbäck · Bengt Herslöf

Received: 1 September 2011 / Accepted: 20 October 2011 / Published online: 20 November 2011
© AOCS 2011

Abstract A new method for the separation and identification of lipid classes by normal-phase HPLC on a cyanopropyl column is described. The use of a simple binary gradient, with toluene as a component, provided a rapid separation of non-polar as well as phospholipid classes. The inherent small differences in performances between possible non-polar eluent components of the gradient, such as hexane, heptane, and iso-octane, had a pronounced impact on retention times for individual phospholipid classes. Separation of molecular species within a lipid class could also be observed.

Introduction

For more than three decades HPLC has been the method of choice for the separation and quantification of lipid classes. During this period of time, several technical advancements have been introduced, such as new detection systems (evaporative light scattering detectors) [1] and various types of interfaces to the mass spectrometer [2, pp. 279–303]. However, none of the numerous methods that have been reported has become widely adopted or found to be generally useful for the many applications and lipid sources that need to be analyzed. In contrast to the analysis of fatty acid methyl esters by gas chromatography, which is more or less a standard procedure, it seems that most laboratories have to work out their own procedures for the analysis of lipid class composition. There are several reasons for this, the most important being that lipid classes are, with respect to their respective structures, a very heterogeneous group of compounds which require a broad composition of the eluent system ranging from very unpolar to strong polar conditions. Another important factor is related to the many different applications that require lipid class analysis, where the specific case can vary very much in terms of number and proportions of the classes involved. It is very unusual that all types of lipid classes are represented in one sample, which means that methods are often optimized for a certain source or type of application which might be less useful in the analysis of other types of lipid samples.

Since the advent of HPLC, silica has been the most favored stationary phase for the separation of lipid classes [3]. The introduction of the evaporative light scattering detectors (ELSD) in the 1980s made gradient elution of lipids possible and the first lipid class separation was performed on a silica column in 1985 [4]. The wide differences in polarities between the classes often led to that the

silica columns slowly changed performances due to their actual water content, which resulted in poor reproducibilities and variabilities between column manufacturers and laboratories. The use of bonded phases was a possible way to avoid such problems. Lipid class separations had earlier been performed with UV-detection on amino [5, 6], cyanopropyl [7, 8], and diol [9] columns. The ELSD gave the possibility to use complex gradient systems which greatly increased the separation opportunities. This area has been extensively described and reviewed by Christie [2, pp. 73–76, 103–116].

Christie et al. [10] published excellent separations of plant lipids on cyanopropyl and polymerized vinyl alcohol (PVA) columns in 1995. Some difficulties were observed with phosphatidylserine on the cyanopropyl column in the rather complex elution system, which was a combination of a solvent gradient and a flow rate gradient. The PVA column performed slightly better, and the separation is described in detail by Christie [2, pp. 113–115] also in 2010. In the last few years, PVA columns [11, 12], diol columns [13, 14], and amino columns [15, 16] have been used by other groups in the separation of polar lipid classes. Cyanopropyl columns have been employed in the separation of non-polar lipid classes, mainly in applications related to transesterification reaction products [17–19].

After Christie's work on plant lipids [10] there have not been any reports in the literature related to the separation of phospholipids or polar lipid classes on the cyanopropyl column. This work was undertaken because we the authors believe that there is an undisclosed potential for lipid separations on the cyanopropyl phase. The aim of this initial study was to reinvestigate the use of cyanopropyl columns for the simultaneous separation of non-polar as well as polar lipid classes, primarily phospholipids. Alkanes such as hexane, heptane, or iso-octane were used as the non-polar eluent component and a toluene/methanol mixture was used as the polar eluent component. It was found that the choice of alkane had a pronounced impact on the retention pattern of phospholipid classes, and that separation of molecular species within a class could also be observed.

Experimental

Materials

All solvents were HPLC grades (Rathburn Chemicals Ltd, Walkerburn, Scotland. Lipid class standards 1,3-dioleoylglycerol 99% (DAG), 1-monooleoylglycerol 99% (MAG), phosphatidylserine from bovine spinal cord >98% (PS), phosphatidylinositol from soybean >98% (PI), and sphingomyelin from chicken egg yolk >98% (SM) were purchased

from Larodan Fine Chemicals AB (Malmö, Sweden). 1,2-dioleoyl-*sn*-glycero-3-phosphatidylcholine >98% (dioleoyl-PC) and 1,2-dimyristoyl-*sn*-glycero-3-phosphatidylcholine >99% (dimyristoyl-PC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol >98.5% (dipalmitoyl-PG) and 1,2-dioleoyl-*sn*-glycero-3-phosphatidylethanolamine >98% (dioleoyl-PE), was obtained from Lipoid GmbH (Ludwigshafen, Germany). Samples of palm oil triglycerides (TAG), sunflower lecithin, and egg-PC were kindly donated by Lipid Systems Sweden AB (Norberg, Sweden). A mixture of the lipids in chloroform/methanol 1:2 was prepared containing TAG 0.142 mg/ml, DAG 0.142 mg/ml, MAG 0.163 mg/ml, PE 0.142 mg/ml, PG 0.060 mg/ml, PC 0.142 mg/ml, PS 0.177 mg/ml, SM 0.071 mg/ml and PI 0.177 mg/ml (Standard mixture).

HPLC

Chromatography was performed on a Reprosil-Pur 120 CN column 250 × 4.6 mm i.d. with 5 µm particles with a 10 × 4.6 mm guard column of the same material (Dr. Maisch GmbH, Ammerbuch, Germany). The gradient system shown in Table 1 was used at a flow rate of 1.0 ml/min and a column temperature of 22 °C. A YL9110 pump was used connected to a YL9181 evaporative light scattering detector (Young Lin Instruments Co. Ltd, Korea) with the spray chamber at 40 °C, the drift tube at 80 °C, and the exhaust tube at 70 °C. The gas pressure was 49.7 psi (nitrogen). The samples were dissolved in chloroform/methanol 1:2 and the injection volume was 5 µl.

Results and Discussion

Several solvents were investigated to constitute the strong eluent, i.e. solvent B in the binary gradient system. In order to avoid chloroform (safety regulations) a number of solvents were tested, including 2-propanol, tetrahydrofuran, acetone, methanol, acetonitrile, ethyl acetate, methyl *tert*-butyl ether, dichloromethane, and toluene. Although rarely

Solvent A was a hydrocarbon (specified in each case) and solvent B was a mixture of toluene/methanol with the addition of acetic acid and triethylamine (60:40:0.2:0.1 by wt). A linear gradient was applied at a flow rate of 1.0 ml/min

used in the chromatography of lipids, toluene proved to be an effective component due to its compatibility with non-polar hydrocarbon components as well as polar solvents, such as methanol. By applying a fractional factorial design, the effect of different parameters was studied. For example, an increase in the toluene concentration affects

Fig. 1 Separation of standard lipid classes with *n*-hexane (a), iso-octane (b), and heptane (c) as solvent A respectively. An asterisk denotes an unidentified compound

phosphatidylglycerol to a higher extent than phosphatidylcholine and accordingly the elution order can be reversed for these two components. The gradient profile was also studied in order to find a good compromise between peak shape, resolution and analysis time. A mixture of toluene and methanol 60:40 modified with small amounts of acetic acid and triethylamine turned out to be an excellent solvent B capable of separating and eluting all the investigated lipid classes with acceptable peak shapes in a linear gradient in less than 20 min.

A range of hydrocarbon solvents was investigated for the weak eluent, i.e. solvent A. Pentane, *n*-hexane, isohexane, cyclohexane, heptane, and iso-octane were evaluated. Surprisingly it was found that the elution pattern of the polar lipid classes could vary quite dramatically due to the hydrocarbon composition of solvent A which is shown in Table 2.

n-Hexane as solvent A gave the best overall resolution of the standard compounds (Fig. 1). All phospholipid classes were clearly separated including PG, PS and PI. Pentane gave also a reasonably good resolution, with shorter retention times and PS appeared before PC in contrast to the order in *n*-hexane. Iso-hexane gave a somewhat poorer resolution with PC and PS co-eluting.

Cyclohexane gave a poor resolution with the co-elution of PE/PG and PC/PS/SM respectively. Iso-Octane co-eluted PG/PC and PS/SM. However the most pronounced differences was observed with heptane, in which solvent all phospholipid classes except PI eluted in one peak. These observations indicate the subtle and delicate interactions between the analyte and the mobile and stationary phases.

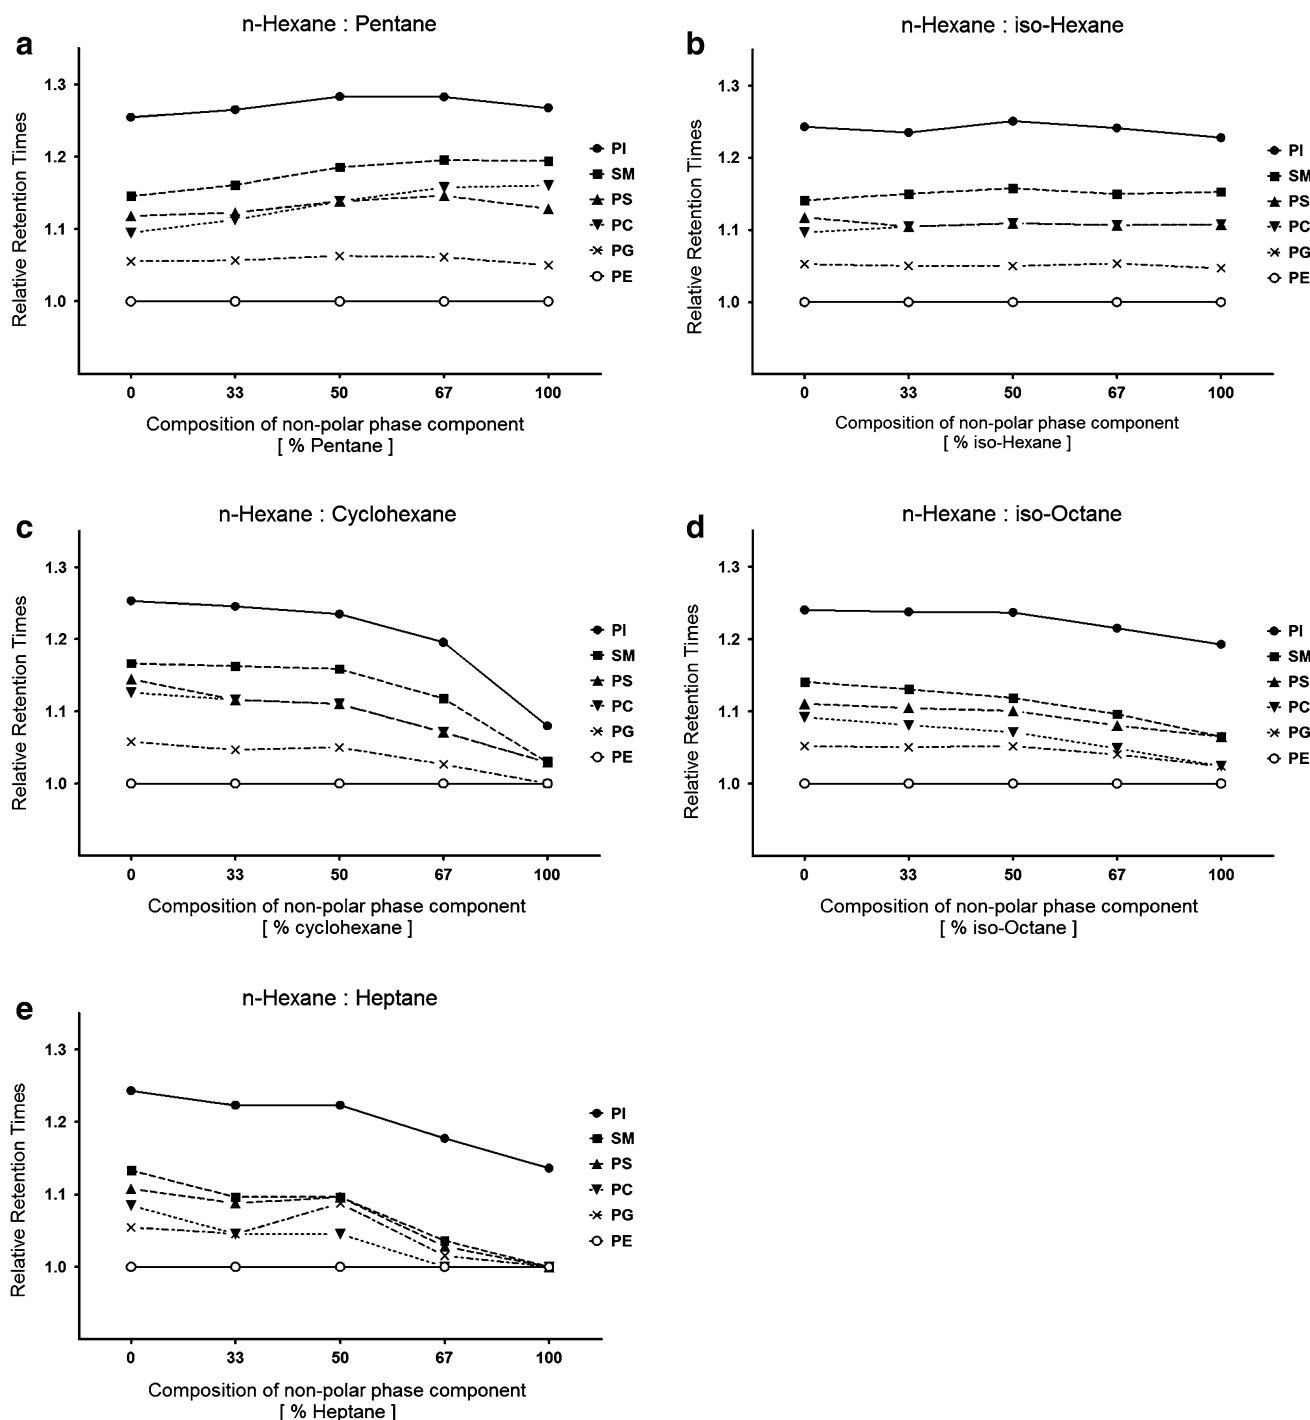

Fig. 2 Changes in relative retention times (PE = 1) of phospholipid classes in *n*-hexane/pentane mixtures (a) *n*-hexane/iso-hexane mixtures (b), *n*-hexane/cyclohexane mixtures (c), *n*-hexane/iso-octane mixtures (d), and in *n*-hexane/heptane mixtures (e) respectively

To verify these observations solvent mixtures from *n*-hexane with increasing proportions of the five other investigated hydrocarbon solvents were prepared and used as solvent A. The observed retention times of the investigated lipid classes in each of the five solvent pairs are shown in Fig. 2.

The separation behavior of the cyanopropyl column used was confirmed by testing two columns from other suppliers: Nucleosil CN column 250×4.6 mm i.d. with 5- μ m particles and Hypersil GOLD CN column 150×4.6 mm i.d. with 3- μ m particles.

The observed differences in retention behavior were obvious in the analysis of a sunflower lecithin sample. Figure 3 shows two separate runs of sunflower lecithin with *n*-hexane and heptane as solvent A respectively. The observed patterns indicate the presence of a fair amount of PI in the sample.

The sunflower lecithin was further fractionated by a semi-preparative cyanopropyl column (250×10 mm version of the analytical cyanopropyl column used; to be published). The collected fractions were investigated by NMR which indicated that two peaks (1 and 2 in Fig. 3) relate to PE and three peaks (3, 4, and 5 in Fig. 3) relate to PC. These indications mean that the separation capabilities of the cyanopropyl phase also could distinguish between certain molecular species within a class. Standard PC-species were analyzed in order to find out if this type of separation is possible. Figure 4 shows the baseline

separation of dioleoyl-PC from dimyristoyl-PC. Further evidence was found in the separation of PC from egg yolk (Fig. 4) which gave four peaks, which tentatively correspond well to the molecular species distribution reported by Holub and Kuksis [20], who report the four most abundant species (>60%) to be 16:0,18:1-PC, 18:0,18:1-PC, 18:0,18:2-PC, and 18:0,20:4-PC.

The separation of molecular species is a complicating factor since late eluting peaks from one class might overlap with early eluting peaks from another class. This phenomenon needs to be taken into account in the interpretation of the lipid class chromatograms in general since it is probably not limited to the elution system used in this work.

Hydrocarbons have previously been used as non-polar components in the analysis of lipids by LC–MS and LC–MS/MS [21], but according to the authors' judgment this field has not been sufficiently investigated, and the use of the cyanopropyl column as described in this article may be a useful tool in further development of such applications.

Conclusions

From the present work it can be concluded that the cyanopropyl phase has the potential to be used in advanced separations of lipid classes. As could be expected, the composition of the mobile phase is crucial and minor changes can have a great impact on the separations.

Fig. 3 Sunflower lecithin with *n*-hexane (a) and with heptane (b) as solvent A respectively. NMR assigned peaks 1 and 2 as PE species and peaks 3–5 as PC species (a)

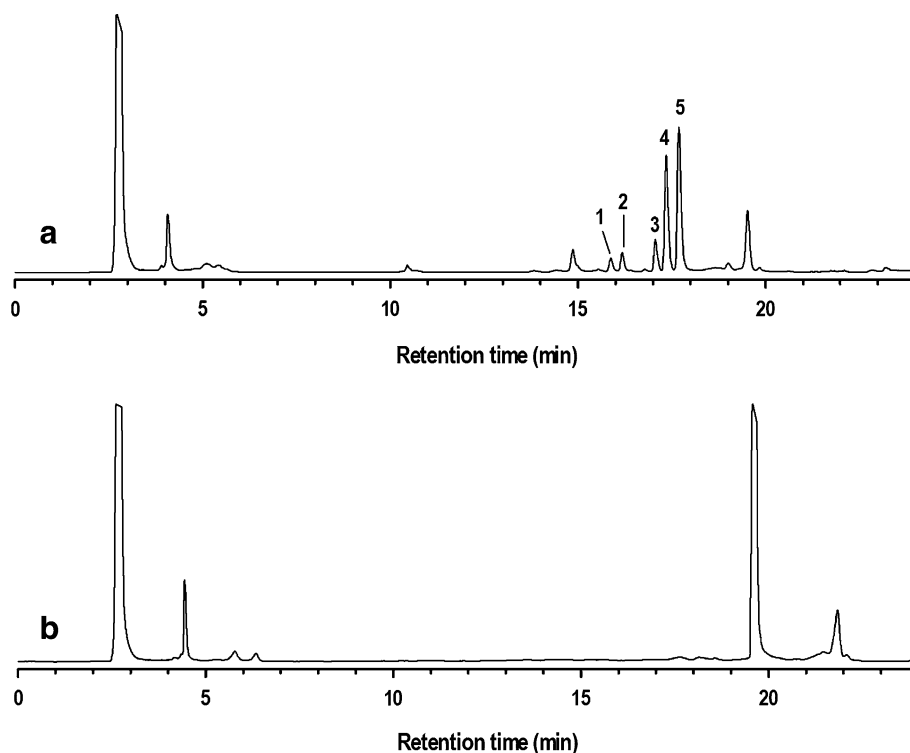

Fig. 4 Separation of molecular species in standard PC samples (dioleoyl-PC/dimyristoyl-PC; **a**) and egg-PC (**b**). Hexane was used as solvent A and toluene/methanol/acetic acid/triethylamine 60:40:0.2:0.1 by wt as solvent B

Toluene as a component seems to be a good alternative to chloroform. However, the importance of the hydrocarbon component which was clearly demonstrated in this work, has to the authors' knowledge not been reported before, and adds to the tools which can be utilized to tailor make a method for the analysis of specific lipid samples, for example in LC–MS or LC–MS/MS applications

Applications of Stereospecifically-Labeled Fatty Acids in Oxygenase and Desaturase Biochemistry

Alan R. Brash · Claus Schneider · Mats Hamberg

Received: 6 June 2011 / Accepted: 30 August 2011 / Published online: 5 October 2011
© AOCs 2011

Abstract Oxygenation and desaturation reactions are inherently associated with the abstraction of a hydrogen from the fatty acid substrate. Since the first published application in 1965, stereospecific placement of a labeled hydrogen isotope (deuterium or tritium) at the reacting carbons has proven a highly effective strategy for investigating the chemical mechanisms catalyzed by lipoxygenases, hemoprotein fatty acid dioxygenases including cyclooxygenases, cytochromes P450, and also the desaturases and isomerases. This review presents a synopsis of all published studies through 2010 on the synthesis and use of stereospecifically labeled fatty acids (71 references), and highlights some of the mechanistic insights gained by application of stereospecifically labeled fatty acids.

Keywords Lipid biochemistry · Lipoxygenase · Cyclooxygenase · Cytochrome P450 · Desaturase · Eicosanoids · Oxylipins

Introduction

In 1965, Schroepfer and Bloch reported the preparation of four different stearic acids containing a single stereospecific D or L tritium label on either the 9- or 10-carbon and

their use in analyzing the mechanism of desaturation to oleic acid [1]. Other applications in unraveling mechanisms of fatty acid transformation soon followed, and many of the fundamental concepts in fatty acid, eicosanoid or oxylipin biosynthesis rest squarely on the results of this type of experiment. The heart of this review is a chronological list of all the primary literature we could find that used stereospecifically labeled substrates to study mechanisms of fatty acid oxygenation, desaturation, or double bond isomerization (Refs. 1–71, Tables 1, 2). The approach was recognized as a powerful tool back in the 1960s and it continues to be fruitfully applied, with about one third of our list of citations being published from the year 2000 onwards. Although there are numerous additional applications in which stereoselective hydrogen abstraction is measured from other types of substrate, for example in the cytochrome P450 field, this review is limited to fatty acid-related biochemistry. We also do not include purely regiospecific labeling experiments (e.g. using [11,11-²H₂] linoleic acid).

Mechanistic Insights in Oxygenase and Desaturase Reactions: General “Rules”

Insights gained from an understanding of the stereoselectivity of hydrogen abstraction are a spatial understanding of the biochemical transformation, and from isotope effects, the order of events. Among the fundamental mechanisms established using this methodology is the almost universal “rule” in cyclooxygenase and lipoxygenase catalysis that reaction is initiated by a stereospecific hydrogen removal from the CH₂ between two *cis* double bonds, and that molecular oxygen is covalently coupled on the opposite face of the reacting fatty acid—the so-called antarafacial

relationship of hydrogen abstraction and oxygen insertion (Fig. 1a) [2, 3, 9, 72].

The antarafacial relationship in dioxygenase reactions contrasts with the predominantly suprafacial character of cytochrome P450 monooxygenation first observed already in the late 1950s ([73]; for review, see Ref. [74, 75]) (Fig. 1b). In the case of cytochrome P450, the oxygen rebound mechanism is sufficiently fast to secure hydroxylation of the substrate mainly on the face suprafacial to the initial hydrogen abstraction. There is, however, sufficient time-lapse (on the order of picoseconds) to allow some rotation of substrate prior to oxygen rebound, thus giving partial racemization to the process, observed as less than “pure” suprafacial oxygenation (e.g. Refs. [30, 76, 77]).

The fundamentals of desaturase mechanism were also revealed using stereospecifically labeled substrates (included in the following reviews, Refs. [78–81]). Invariably the initial and rate-limiting hydrogen abstraction occurs on the carbon nearest the fatty acid carboxyl (or polar head-group, e.g. in ceramides, the amide linkage to sphingosine), followed by the second hydrogen removal, and depending on the conformation of the carbon chain, forming either a *cis* or *trans* double bond (Fig. 1c).

Applications related to desaturases are summarized in Table 2 and the order of the stereospecific hydrogen abstractions in Fig. 1c, and otherwise desaturase biochemistry is not discussed further in our review. For insightful analysis of the mechanism of desaturases as it relates to stereospecific hydrogen abstractions, we particularly recommend the excellent review by Buist [81], also Shanklin and Cahoon’s review of desaturase biochemistry

[82], and the earlier classic on stereospecific hydrogen abstractions by Morris [78].

Insights from Kinetic Isotope Effects

Experiments with stereospecifically-labeled substrates provide not only an understanding of the reaction stereochemistry but also further insights into the enzymatic mechanism. As outlined by Fersht [83], it is easier to break a C–H bond compared to a C–D bond by a factor of 7 at 25 °C. Because of the greater mass of tritium, C–T bonds are broken even more slowly (by a factor of ~ 16.5 over C–H). These differences translate into kinetic isotope effects (KIE) in enzymatic reactions involving abstraction of a deuterium or tritium label. If abstraction is the rate-limiting step, as commonly occurs, then the heavy atom-labeled molecules will react at a slower rate, giving one measure of the KIE. Furthermore, in competitive reactions involving both labeled and unlabeled substrate molecules, during the course of the reaction there will be a gradual enrichment of the heavy atom-labeled molecules in the pool of unreacted substrate, providing a second parameter for quantitative analysis. Alternatively, if the H-abstraction is stereo-random and occurs after the commitment to reaction, the isotope effect can result in an enrichment of heavy atom label in the product: with the option of losing a hydrogen or deuterium/tritium from the same carbon, the KIE will lead to selective retention of the heavy atom (e.g. Ref. [18]).

Quantitative differences in reaction rate reflect the enzymatic mechanism involved in bond breaking. Purely

based on bond energies, one might expect a relative rate for k_H/k_D of ~ 7 , yet distinctly different numbers are observed with specific enzymes. The exceedingly high deuterium KIE of ~ 80 associated with hydrogen abstraction in LOX catalysis is used to infer a lower energy transition pathway available only for the H-labeled species, a phenomenon known as hydrogen tunneling [38]. By contrast, a recent

estimate for the deuterium KIE in COX catalysis is only 1.6–2.3 [84], clear evidence for the different mechanisms employed by LOX and COX for hydrogen removal. Those mechanisms center around a proton-coupled electron transfer to non-heme iron in LOX enzymes [85, 86], compared to abstraction of a hydrogen atom by a tyrosyl radical in COX [87, 88]. Further distinctions are observed

Fig. 1 Stereospecific hydrogen abstractions in fatty acid biochemistry. **a** The antarafacial relationship of the initial hydrogen abstraction and oxygen insertion, a characteristic feature of cyclooxygenase and lipoxygenase catalysis, here illustrated on linoleic acid in either of two head-to-tail orientations in the active site. **b** Suprafacial hydrogen abstraction and oxygenation as typified in cytochrome P450 catalysis, and illustrated here on linoleic acid in one of the two possible head-to-tail orientations. **c** Stereospecific hydrogen abstractions associated with desaturation to produce a *cis* double bond (*left side*), or *trans* (*right side*)

in association with hydrogen abstraction by cytochromes P450, which exhibit deuterium KIE values more reflective of relative bond energies, ~ 9 in aliphatic hydroxylations [89]; these P450 data are interpreted as consistent with the abstraction–recombination mechanism for aliphatic hydroxylation [90].

C18:3 ω 6, yet pro-*R* in C18:3 ω 3. For the same reason, the pro-*R* and pro-*S* hydrogens at C-10 in arachidonate (designated using both systems as D_R and L_S, respectively), remain as D or L in 15-hydroperoxy-eicosatetraenoic acid (15-HPETE), but the pro-*R*, pro-*S* designations reverse. To get around this potentially confusing issue with the *R/S* system, sometimes there is a cautionary note to the

Stereochemistry of the Hydrogens in Fatty Acids

Many of the older papers assign chirality and prochiral hydrogens using the Fischer (D/L) system, which is less commonly used nowadays, although it does have an advantage in some situations. Because the Fischer system is based solely on the left or right orientation of the hydrogen in space, changing the nearby substituents has no effect on the D/L designation, whereas it might or might not change the *R/S* assignment based on Cahn-Ingold-Prelog. For substituents on fatty acids, making the D or L assignment is easy. Imagine the molecule hanging down with the carboxyl group on top. The chiral or prochiral carbon is then pointed towards the viewer (as in Fig. 2) and from there the hydrogen, hydroxyl, or other substituent on the chain is either on the right side (D), or the left (L).

A couple of specific examples illustrate the useful features of the Fischer nomenclature. The prochiral 11L-hydrogen in linoleic acid is also 11L in γ -linolenate or α -linolenic acid because it occupies the same position in space (on the left, when observed as in Fig. 2). However, adding the 15,16 double bond in α -linolenate changes the priority order at C-11 such that 11L is pro-*S* in C18:2 ω 6 or

Fig. 2 Prochiral hydrogens in fatty acids, D/L assignment. With the fatty acid carboxyl on top and the carbon bearing the substituent aligned towards the viewer, the assignment is D (on the *right*) or L (*left*). The figure is a slight modification of an earlier version, reproduced with permission from Academic Press [137]

effect that chirality assignments throughout a report refer to the assignment in the parent fatty acid.

Synthesis of Stereospecifically Labeled Fatty Acids

Numerous fatty acids stereospecifically labeled with deuterium or tritium have been prepared by total organic synthesis, starting either with chiral natural products or by sequences involving chemical or enzymatic resolution of intermediates [17, 37, 42, 62, 64–67, 69, 70]. For example, a potentially general approach involving resolution of terminal epoxides was reported for synthesis of both enantiomers of palmitic acid stereospecifically deuterated at C-4 or C-5 [70]; the method offers flexibility and generality for synthesis of various saturated deuterated acyl chains simply by selection of the desired chain lengths of the building blocks. An interesting extension of such syntheses is to generate an isotopically labeled non-chiral compound into which chiral center(s) are introduced by an enzymatic method. Thus, [2R,3R-²H₂]heptanoic acid was generated by exposing [2,3-²H₂]2E-heptenoic acid to the enoate reductase of *Clostridium tyrobutyricum* [56, 60]. Alternatively, the unlabeled 2E-heptenoic acid was incubated with the reductase in ²H₂O to afford [2S,3S-²H₂]heptanoic acid. In another study, soybean lipoxygenase-1 was used to prepare [11S-²H]linoleic acid from synthetically prepared [11RS-²H₁]linoleic acid (i.e. singly deuterated linoleate, racemic at C-11), a process which is based upon the strong kinetic deuterium isotope effect accompanying the lipoxygenase-catalyzed conversion. As a consequence of this isotope effect, molecules containing a C-11 pro-S deuterium are almost unreactive and accumulate as [11S-²H₁]linoleic acid, while the molecules unlabeled in the pro-S position (which are deuterated at pro-R) are removed by enzymatic transformation to hydroperoxide [38, 52].

A common strategy for stereospecific introduction of isotope into acyl chains, used already in the first study in this area [1], is based on the availability of enantiomerically pure long-chain hydroxy derivatives, most often hydroxystearates, as starting materials. These are converted into the corresponding *p*-toluenesulfonate derivatives which are treated with lithium aluminum deuteride/tritide for introduction of isotope. It has been clearly shown that substitution of the *p*-toluenesulfonyloxy group by deuteride takes place as an S_N2 reaction resulting in inversion of the absolute configuration of the carbon attacked [91]. The required chiral hydroxy fatty acids can in many cases be isolated in optically pure form from natural sources; examples are ricinoleic acid, β-dimorphelic acid and 2R-hydroxylinolenic acid (for review, see Ref. [92]). Furthermore, certain optically active

hydroxy acids such as 9R- and 13S-hydroxyoctadecanoates can easily be prepared by catalytic hydrogenation of lipoxygenase-generated fatty acid hydroperoxides. Stereospecifically labeled steirates may also be prepared by chemical synthesis [4, 14, 18, 45]. This may involve an optically active short-chain hydroxy acid as starting material, obtained from commercial sources, as a natural product or prepared by resolution of an alkaloid salt of the racemic compound. Additionally, enantiomerically pure 3R-hydroxy acids can be obtained from polyhydroxyalkanoates [93] or prepared by enzymatic reduction of the corresponding β-keto acid using baker's yeast [46]. Subsequent elongation to the required chain-length can conveniently be performed using anodic coupling (the so-called Kolbe synthesis; see Ref. [94]). Chiral HPLC separation of racemic *p*-toluenesulfonate derivatives of hydroxystearates labeled with tritium at the chiral carbon followed by elimination of the tosylate by LiAlH₄ reduction offers an additional possibility to generate stereospecifically labeled steirates [40].

In the vast majority of papers given in Table 1, the above-mentioned procedures end up with stereospecifically labeled stearic acids. For studies of dioxygenases, which most often operate on mono- or polyunsaturated fatty acids of 18 or 20 carbon chain lengths, the labeled steirates have to be desaturated. Four organisms have found use for such conversions, i.e. *Tetrahymena pyriformis*, *Saprolegnia parasitica*, *Chlorella vulgaris*, and a readily available mutant of *Saccharomyces cerevisiae*. *Tetrahymena* is a ciliated protozoan which efficiently takes up exogenous stearate converting it mainly to γ-linolenate without noticeable scrambling of the isotope label [4]. Also labeled oleate and linoleate can be prepared using this organism. The proportion of unsaturated fatty acids in *Tetrahymena* is temperature-dependent; lower temperatures (20–25 °C) favor formation of γ-linolenate. *Saprolegnia parasitica* converts added stearate mainly to linoleate, arachidonate, and 5,8,11,14,17-eicosapentaenoate [95]; a reversed-phase HPLC chromatogram of the profile of fatty acids is illustrated in Schneider et al. [40]. The green alga *Chlorella vulgaris* has been used to prepare linoleate from stearate [10]. A practical disadvantage associated with these bio-desaturations is dilution of the specific activity of the labeled material with endogenous unlabeled fatty acid. The extent of dilution can be severe, perhaps in the order of ten- to 100-fold, and particularly confounds the analysis of protium/deuterium ratios by mass spectrometry. A mutant of *S. cerevisiae* constructed by Reed et al. [96] converts labeled steirates to oleates and linoleates with very little isotopic dilution. This methodology, which was used by the original authors to prepare [12-²H]-, [13-²H]- and [18,18,18-²H₃]-linoleic acids, is readily adaptable for production of stereospecifically labeled oleates and linoleates.

Scheme 1

pathway. The discovery that the LTA synthase is none other than the lipoxygenase that produces the HPETE substrate was quite unexpected at the time. It was surprising because there was no such precedent from analysis of the soybean lipoxygenase, upon which almost all LOX biochemistry was founded. Initially, one of the main lines of evidence making the connection between LOX and LTA synthase—even before purification of the enzyme—was the demonstration that LTA epoxide synthesis proceeds with an initial stereospecific hydrogen abstraction, the well-established feature of lipoxygenase catalysis [13–17]. Taking leukocyte 5-LOX as the prototypical example, in forming 5S-HPETE the enzyme catalyzes a stereospecific hydrogen abstraction from C-7, then in a simple “frame-shift” along the carbon chain to the next available pentadiene, hydrogen abstraction from C-10 initiates the synthesis of LTA₄ (Scheme 1). As suggested in Scheme 1, to form LTA₄ as the correct *trans* epoxide requires positioning of the hydroperoxide such that it is suprafacial to the C-10 hydrogen abstraction, as the lipoxygenase iron participates in both the H-abstraction and cleavage of the hydroperoxide (cf. Refs. [106–108]). Ultimately several lipoxygenases were purified and shown to catalyze the conversion of HPETE to an LTA-type epoxide [21, 104, 109, 110].

The apparent occurrence of exclusively *S* lipoxygenases in Nature was first contradicted by the report of Gordon Bundy and colleagues of the Upjohn Company that arachidonic acid is converted to its 8*R*-hydroperoxide (8*R*-HPETE) by extracts of the Caribbean coral *Plexaura porosa* [111]. It was soon found that other corals and marine invertebrates also produce 8*R*-HPETE or other *R*-configuration hydroperoxides (e.g. Refs. [23, 112–117]), although at first there was no indication whether this new type of enzyme was structurally related to the

lipoxygenases of plants and higher animals. That 12*R*-HPETE is produced in sea urchin eggs via an antarafacial relationship of H-abstraction and oxygenation was reported by Hawkins and Brash [118], and later the same relationship was shown for 8*R*-HPETE in coral extracts by Hughes and Brash [26]. A decade later, a search for the enzyme responsible for biosynthesis of 12*R*-HETE in human skin led to the cloning and expression of mammalian 12*R*-lipoxygenase; the report demonstrated the now universally observed antarafacial relationship of H-abstraction and oxygenation in lipoxygenase catalysis, in this case the formation of 12*R*-H(P)ETE by recombinant human 12*R*-LOX and in samples of human skin containing the enzyme activity [34].

Purification and molecular cloning of an enzyme producing 8*R*-HPETE from the coral *Plexaura homomalla* proved that the 8*R*-lipoxygenase belongs to the same enzyme superfamily as the *S*-LOX already characterized [119]. More recent X-ray crystallographic analysis of a *P. homomalla* 8*R*-LOX [120] demonstrated that the coral 8*R*-LOX protein has a very similar overall topology to the plant and mammalian *S*-specific LOX [121–123]. Meanwhile, a search for active site residues that might influence *R* or *S* oxygenation specificity in lipoxygenases resulted in the discovery of a critical residue, conserved as Gly in *R*-LOX and Ala in *S*-LOX [124]. This provided evidence that rationalized the difference between *R* and *S* LOX enzymes. Oxygenation can occur at either end of the reacting pentadiene, at one end giving the *S* configuration, at the other *R* (Fig. 1a). Switching the Ala-to-Gly residue or vice versa by site directed mutagenesis induces this transformation between *R* and *S* oxygenation. Following up on this finding, it was shown using stereospecifically 11-³H-labeled linoleic acids and soybean lipoxygenase with mutated active site Ala-to-Gly that, as had been predicted, 9*R* and 13*S* oxygenation of linoleic acid involve the same initial hydrogen abstraction with oxygenation occurring at opposite ends of the same face of the reacting pentadiene (Fig. 1a) [44]. Similarly, the equivalent Ala-to-Gly mutation in 9*S*-LOX induces the formation of 13*R*-product [125].

The effects of this Ala-to-Gly interconversion are now substantiated with several other LOX enzymes [126]. Occasionally there is a twist to the “rule” such as the natural occurrence of the larger Ala in association with *R*-LOX activity, with site-directed mutagenesis to Val or Ile inducing formation of *S*-configuration products [127, 128]. Interestingly, there is a naturally occurring Ala-to-Gly “mutant” lipoxygenase in the olive plant (GenBank accession no. EU678670) encoding Gly568 rather than the expected Ala. In accord with the above concepts, the enzyme produces 13*R*-HPODE in addition to 9*S*-HPODE [129], as predicted from the results of site-directed mutagenesis experiments with recombinant LOX enzymes.

Cyclooxygenase Mechanism, Stereospecific Hydrogen Abstraction, in Historical Context

Fundamental insights into the cyclooxygenase reaction of prostaglandin biosynthesis were reported by Hamberg and Samuelsson in two papers published side-by-side with their soybean lipoxygenase studies [2, 4]. At the time (1967) it was recognized that prostaglandins are formed from a linear C20 polyunsaturated fatty acid via a putative endoperoxide intermediate in which a cyclopentane ring is comprised of carbons 8–12, with the two atoms of a molecule of molecular oxygen bridging C-9 and C-11, and another oxygen molecule reacting at C-15. Using two labeled eicosatrienoic acids (20:3 ω 6) with stereospecific tritium at the 13-carbon, the authors demonstrated that the 13L_S hydrogen is selectively removed in the transformation of 20:3 ω 6 to prostaglandin E₁ [4]. A strong associated kinetic isotope effect, which resulted in the gradual enrichment of the specific activity of the unreacted substrate during the course of the transformation, indicated that 13L_S hydrogen abstraction is, or coincides with, the initial and rate-limiting step of prostaglandin biosynthesis. This alone provided circumstantial evidence that the initial oxygenation of the fatty acid occurs at C-11 and that the resulting 11-peroxyl radical goes on to form the peroxide bridge spanning C-11 to C-9 in the endoperoxide intermediate.

Additional studies on the formation of cyclooxygenase side products also made use of the labeled [13-³H]20:3 ω 6 substrates [2]. The 12-hydroxy-C_{17:2} fatty acid side-product (the 20:3 equivalent of 12-hydroxyheptadecatrienoic acid (HHT) from arachidonic acid) was shown to exhibit a similar stereospecific loss of the 13L_S hydrogen and retention of the 13D_R hydrogen as occurs in biosynthesis of PGE₁. Use of other 20:3 ω 6 substrates with tritium labels at either C-9, C-10, C-11 or C-15, provided the proof that this 12-hydroxy-C_{17:2} side product is formed with loss of three carbons from the cyclopentane ring. Furthermore it was noted that cyclooxygenase substrates that gave rise to the C₁₇-OH by-product also formed significant thiobarbituric acid reactive substances (indicative of an aldehyde), and indeed, the radioactive 3-carbon fragment formed from [11-³H]20:3 ω 6 was isolated and identified as malondialdehyde [2]. This line of evidence provided additional support for the formation of a cyclic endoperoxide as an intermediate in the formation of the stable prostaglandins.

In these early papers it was noted that C₁₈ polyunsaturated fatty acids are also metabolized by the preparation of COX-1 (sheep seminal vesicle microsomes) and the products from linoleic acid were identified as the 9- and 13-hydroxy derivatives [3]. In 1980, Hamberg and Samuelsson reported on the stereochemistry associated with transformation of [11-³H]linoleic acid [11]. The 9-hydroxy

product was mainly of the 9L_R configuration (equivalent to the 11R-HETE by-product from arachidonic acid) and the other was mainly 13L_S-hydroxy. These were each formed with ~80% removal of the 11L (pro-*S*) hydrogen from the substrate. The stereo fidelity was not so high as found using the 20:3 ω 6 substrate, apparently reflecting less than perfect control of oxygenation of linoleic acid by COX-1. Later studies by Hamberg gave similar results using COX-2 [35]. The subsequent description of COX-1 crystal structures with bound substrate indicated that, similar to 20:3 ω 6 and arachidonic acid, linoleic acid lies in the cyclooxygenase active site with the appropriate bis-allylic hydrogen (the 13L_S of the C20 substrates and 11L_S of linoleic acid) poised for reaction with an incipient radical on Tyr-385 [130, 131]. By contrast to the better COX substrates, oxygenation of linoleic acid (and EPA) were much more severely compromised by active site mutations that modified the positioning of the α or ω ends of the fatty acid carbon chain [131]. Linoleic acid in particular has to assume a more stretched out α chain in order for the carboxyl to make contact and be stabilized by interaction with the Arg-120 and Tyr-355 at the entrance to the oxygenase substrate-binding channel, making the interactions more easily disturbed by mutagenesis within the COX active site.

In the early 1990s an interesting and unexpected arachidonic acid metabolite was detected upon reaction with aspirin-acetylated COX-2. Whereas aspirin inhibition completely blocks all oxygenase activity in COX-1, aspirin treatment of COX-2 blocks prostaglandin biosynthesis, but switches the oxygenation specificity to produce 15R-HETE as the only enzymatic product [132–134]. This 15R specificity is opposite to the usual 15S oxygenation associated with the final steps of prostaglandin endoperoxide biosynthesis. Accordingly, Schneider and Brash questioned the specificity of the hydrogen abstraction associated with this 15R-HETE production. The result that might have been anticipated, based on parallels to *R* and *S* oxygenation in lipoxygenase catalysis, is that the substrate would assume a reversed orientation and that the H-abstraction would also be the reverse of normal. Using 13R-³H and 13S-³H arachidonic acids, however, it was found that the specificity matches that in normal prostaglandin production, i.e. specifically the pro-*S* hydrogen at C-13 is removed in formation of PG endoperoxide with normal COX-2 and in 15R-HETE synthesis in the aspirin-treated enzyme. This formation of 15R-HETE appears, therefore, to be the one known example in which the relationship of stereospecific hydrogen abstraction to oxygenation is suprafacial, rather than antarafacial. The authors rationalized this result by proposing that the main body of the substrate (including the 13-carbon) lies in the usual orientation, but the tail carbons are twisted over to expose the 15R position to attack by O₂ (Fig. 4). In discussion, it was further proposed that the

Fig. 4 Synthesis of 15R-HETE by aspirin-acetylated COX-2. Unlike all specific oxygenations by COX and LOX enzymes, this reaction exhibits suprafacial relationship of hydrogen abstraction and the 15R oxygenation. The figure is reproduced from Ref. [39] with permission

terms suprafacial and antarafacial begin to lose their utility under these circumstances [39].

Fatty Acid Monooxygenation and Stereospecific Hydrogen Abstraction

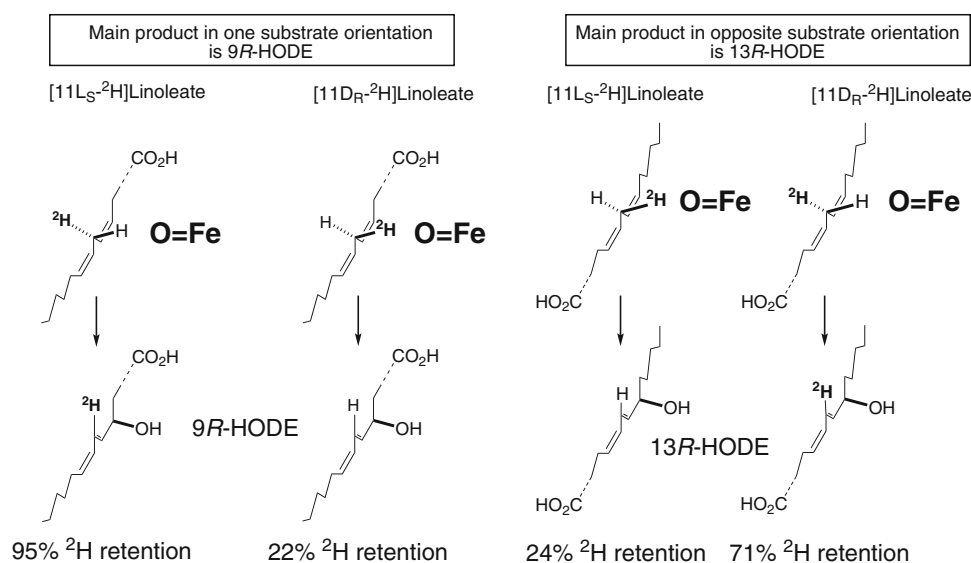

Cytochrome P450 is the prototypical fatty acid monooxygenase (hydroxylase and epoxigenase). The principles related to hydrogen abstraction in P450 reactions were mainly worked out using other substrates, and the “rules” subsequently shown to apply to fatty acid monooxygenation (reviewed in Refs. [74, 75] and in earlier editions of the book). Typically, the relationship of the hydrogen abstraction and oxygenation (“oxygen rebound”) in P450 catalysis is suprafacial (Figs. 1b, 5). Unlike in LOX and COX reactions the activated oxygen in P450s is covalently bound to the reactive heme iron. Also, it is this very same ferryl species which catalyzes the H-abstraction.

Depending on the substrate, there may be sufficient mobility within the active site so that it can spin around prior to oxygen rebound, in which case the relationship between H-abstraction and oxygenation appears to be antarafacial.

Therefore for the reasons cited, with many substrates there is an element of apparently stereorandom oxygenation following hydrogen abstraction in P450 catalysis. There may be some evidence of this in the results of linoleic acid oxygenation as reported by Oliw and co-workers in rat liver microsomes [30], yet mainly the results hold to the suprafacial relationship of H-abstraction and oxygenation. The major products detected were 9R-HODE (formed with 95% retention of deuterium from [11L_S-²H]linoleic acid and 22% retention from [11D_R-²H]linoleic acid), and 13R-HODE (24% retention from [11L_S-²H]linoleic acid and 71% retention from the 11D_R-²H). What may not have been discussed before is the concept that formation of these two products and their associated hydrogen abstractions can be accounted for by a change in the head-to-tail orientation of the substrate in the P450 active site (Fig. 5). This is akin to the concepts of reversal of substrate binding orientation that is well established in the lipoxygenase literature.

Formation of the minor hydroxy products in the same study (9S-HODE and 13S-HODE) can be rationalized similarly. The 9S position on linoleate is on the same face of the substrate as 13R, and by-and-large the results of Oliw et al show qualitatively similar deuterium retentions in the 9S-HODE and 13R-HODE products [30]. Based on these results, it can be inferred that the substrate is mainly in the same head-to-tail orientation in forming 9S- and 13R-HODE. A similar match applies for the major 9R-HODE and the minor 13S-HODE, which assume the

Fig. 5 Suprafacial H-abstraction and oxygenation in cytochrome P450 mediated oxidation of linoleic acid in rat liver microsomes [30]. The reported retentions of deuterium in the major products from [11D_R-²H]- and [11L_S-²H]linoleic acids are rationalized here in terms of two possible head-to-tail orientations of the substrate, thus accounting for formation of 9R-HODE and 13R-HODE with predominantly suprafacial hydrogen abstraction and oxygenation. A similar analysis can rationalize formation of the two minor products reported, 9S-HODE and 13S-HODE (not shown)

opposite orientation. It also follows from this line of thinking that each major product is formed by oxygenation at the “top” end of the pentadiene as cartooned in Fig. 5, while the minor products are each formed at the lower end.

Finally, the other significant mono-hydroxylated product in this study is 11-HODE, which showed 38% retention of the $11D_R$ - 2H label and 69% retention of the $11L_S$ - 2H . Because the $11D_R$ deuterium label is largely retained, and assuming a suprafacial relationship of H-abstraction and oxygenation, these data suggest that 11-HODE is mainly formed in the head-to-tail orientation on the right side of Fig. 5.

Future Prospects/Open Issues

The fundamentals of the catalytic mechanisms of lipoxygenases, cyclooxygenases, cytochromes P450, desaturases, and isomerases have long been established, yet new enzymes and reactions continue to arise. Quite recently, stereospecifically labeled fatty acids were applied in exploring the reaction mechanism of novel dioxygenases in fungal pathogens of the *Aspergillus* species and a similar type of enzyme in the bacterium *Pseudomonas aeruginosa* [48–51]; these enzymes have both dioxygenases and peroxidase (P450-related) domains which this mechanistic approach can help unravel. The discovery of a catalase-related hemoprotein from *Anabaena* PCC 7120 that converts 9*R*-hydroperoxylinolenic acid into a leukotriene A-type epoxide together with a highly unusual bicyclobutane fatty acid presents another opportunity to glean insights using this methodology [135]; the proposed intermediates in the transformation are carbocations, and an enzyme-catalyzed hydrogen abstraction is required in the course of the transformation. Equivalent reactions initiated on linoleic acid produce a conjugated diene analog of LTA [136]. Among other issues, comparison with the mechanism of the lipoxygenase-catalyzed route to LTA epoxides should be of interest.

Abstract Dihydroceramide $\Delta 4$ -desaturase 1 (DES1) catalyzes the last step of the de novo ceramide biosynthesis, which consists of the introduction of a *trans* $\Delta 4$ -double bond in the carbon chain of the dihydroceramide. It was previously observed that myristic acid binds DES1 through N-myristoylation. This N-terminal modification significantly increased the activity of the recombinant DES1 in COS-7 cells and targeted part of the enzyme initially present in the endoplasmic reticulum to the mitochondrial outer membrane, leading to an increase in ceramide levels. Since these results were obtained in a recombinant COS-7 cell model with high expression of rat DES1, the purpose of the present study was to investigate if the native DES1 enzyme was really upregulated by its N-myristoylation in cultured rat hepatocytes. We first showed that DES1 was the main dihydroceramide desaturase isoform expressed in rat hepatocytes. In this model, the wild-type myristoylable recombinant form of rat DES1 was found in both the endoplasmic reticulum and the mitochondria whereas the mutated non-myristoylable recombinant form (N-terminal glycine replaced by an alanine) was almost exclusively localized in the endoplasmic reticulum, which evidenced the importance of the myristoylation. Then, we showed that compared to other fatty acids, myristic acid was the only one to increase native DES1 activity, in both total cell

lysates and mitochondrial fractions. The myristic acid-associated increase in DES1 activity was not linked to elevated mRNA or protein expression but more likely to its N-terminal myristoylation. Finally, the myristic acid-associated increase in DES1 activity slightly enhanced the number of apoptotic cells.

Keywords Myristic acid · N-myristoylation · Rat · Sphingolipid · Dihydroceramide desaturase · Lipoapoptosis

Abbreviations

| | |
|------|---|
| ALA | α -Linolenic acid |
| DES | Dihydroceramide $\Delta 4$ -desaturase |
| LAU | Lauric acid |
| LNA | Linoleic acid |
| MYR | Myristic acid |
| NMT | Myristoyl-CoA: protein N-myristoyltransferase |
| OLA | Oleic acid |
| PAM | Palmitic acid |
| SFA | Saturated fatty acid(s) |
| VDAC | Voltage dependant anion channel |

Introduction

Saturated fatty acids (SFA) are usually associated with negative consequences for human health, but recent evidence highlighted that they also carry out important and specific biological roles at the molecular level in the cells [1]. Among the SFA, myristic acid (14:0) displays a unique function in the cells, through its ability to acylate proteins [2]. This reaction is called N-terminal myristoylation and consists of the linkage, via an irreversible amide bond, between myristoyl-CoA and the NH_2 -terminal glycine

residue of eukaryotic and viral proteins, as described in increasing numbers of reports regarding myristoylated proteins [3]. Myristoylation is catalyzed by the Myristoyl-CoA: protein *N*-myristoyltransferases (NMT) and has been shown to mediate protein subcellular localization, protein–protein interaction or protein–membrane interaction of the myristoylated proteins [2, 3]. Therefore, through this covalent modification of proteins, myristic acid exhibits a specific and important role in modulating protein functions [4].

The family of myristoylated proteins includes not only key components in intracellular signaling pathways [5], oncogenes [6], structural viral proteins [7], caspase-cleaved proteins which are post-translationally myristoylated [8], but also common constitutive eukaryotic proteins [2, 9]. Among this last group, the dihydroceramide $\Delta 4$ -desaturases type 1 (DES1) and 2 (DES2) have recently been identified as new members of the myristoylated protein family [10]. These enzymes are involved in the *de novo* ceramide biosynthesis pathway, which requires four successive steps starting with the condensation of palmitoyl-CoA with serine and ending with the introduction of a *trans* $\Delta 4$ -double bond in the carbon chain of the dihydroceramide leading to the production of ceramide [11, 12]. This last step is specifically catalyzed by DES1, whereas the DES2 isoform has been shown to possess a bifunctional $\Delta 4$ -desaturase/C4-hydroxylase activity in the intestine [13]. The introduction of the *trans* $\Delta 4$ -double bond in the sphingoid base is necessary for the acquisition of the biological activities of ceramide. Indeed ceramide but not dihydroceramide [14, 15] is involved in cell growth [16], stress response and apoptosis [17, 18]. DES activity depends on the tissue considered [19], on the chain length of the sphingoid base and on the length of the *N*-acyl chain [12], but its regulation is still poorly understood. Recently, we showed that myristoylation increases recombinant DES1 activity when expressed in COS-7 cells [10]. We also showed that the myristoylation of recombinant DES1 can target part of the enzyme pool from the endoplasmic reticulum to the mitochondrial outer membrane, leading to an increase in ceramide levels which in turn leads to increased apoptosis in the COS-7 cell model [20].

The purpose of the present study was therefore to increase our knowledge of the regulation of DES1 by different fatty acids. We first demonstrated that cultured rat hepatocytes are a suitable model to study native DES1 regulation, because this DES isoform is highly expressed and active. As already shown in COS-7 cells, the subcellular localization of the recombinant DES1 is governed by its myristoylated status in cultured rat hepatocytes. Then, we compared the effect of myristic acid with other saturated and unsaturated fatty acids on native DES1 enzymatic activity, protein expression and mRNA level, and showed that myristic acid only increased DES1 activity. Finally,

we evaluated the effect of each saturated fatty acid on apoptosis induction.

Materials and Methods

Chemicals

[9,10- ^3H]-Myristic acid was purchased from American Radiolabeled Chemicals (Isobio, Fleurus, Belgium). [1- ^{14}C]-*N*-octanoyldihydroceramide was chemically synthesized in our laboratory, as previously described [21]. Reagents for electrophoretic application were from GE Healthcare (Orsay, France) and BioRad (Marnes-la-Coquette, France). Solvents (HPLC grade) came from Thermo Scientific (Elancourt, France). Other chemicals were obtained from VWR (Fontenay-sous-Bois, France) or from Sigma (Saint-Quentin-Fallavier, France).

Animals and Cultured Rat Hepatocytes

The experimental procedure was in compliance with recommendations of the 2003/65/CEE European directive for animal experimentation. The agreement reference to carry out experiments with living vertebrate animals is #A35-238-38 and the experimental authorization number is #35-83. Hepatocytes were obtained from rats after *in situ* collagenase perfusion of liver, as previously described [22]. The culture medium (Williams' E) was supplemented with 26 mmol L $^{-1}$ NaHCO $_3$, 12.5 mmol L $^{-1}$ HEPES, 15 $\mu\text{mol L}^{-1}$ BSA, antibiotic mixture (50,000 IU L $^{-1}$ penicillin, 50 mg L $^{-1}$ streptomycin, 10 mg L $^{-1}$ gentamycin), 1 $\mu\text{mol L}^{-1}$ insulin, 1 $\mu\text{mol L}^{-1}$ dexamethasone and 7% (vol/vol) FBS for plating only (1.6×10^6 cells/dish of 60 mm diameter and 4.8×10^6 cells/dish of 100 mm diameter). After plating, the cells were maintained in a humidified incubator at 37 °C under 5% CO $_2$ in air. The plating medium was changed after 4 h with a serum-free culture medium.

Incubation with Fatty Acid Albuminic Complexes

The incubation media containing the fatty acid albuminic complexes were prepared as previously described [22]. Briefly, each fatty acid (lauric acid 12:0, LAU; myristic acid 14:0, MYR; palmitic acid 16:0, PAM; oleic acid 18:1n-9, OLA; linolenic acid 18:2n-6, LNA; α -linolenic acid 18:3n-3, ALA) was incubated for 30 min at 70 °C with 1 mL NaOH 0.5 mol L $^{-1}$ in methanol. The fatty acid salts obtained were dissolved at a molar concentration of 0.5 mM at pH 10 in Williams' E medium containing 0.15 mmol/L BSA. The fatty acid:albumin molar ratio was 3.3:1. After 24 h of shaking, the incubation media were

obtained by adjusting pH to 7.35 and adding antibiotic mixture (50,000 IU L⁻¹ penicillin, 50 mg L⁻¹ streptomycin, 10 mg L⁻¹ gentamycin), 1 µmol L⁻¹ insulin, and 1 µmol L⁻¹ dexamethasone. At 4 h of culture, incubation was initiated by replacing the culture medium with 2 mL of the medium with each fatty acid albuminic complex. The medium was renewed at 26 h of culture. Incubation with fatty acids was carried out for 40 h at 37 °C in 5% CO₂ atmosphere. At the end of the incubation, the medium was taken-off and cells were washed and harvested in PBS (phosphate buffer saline: NaH₂PO₄ 4 mM, Na₂HPO₄ 0.94 mM, NaCl 150 mM, pH 7.4). The protein content of the cell lysates was determined by a modified Lowry procedure [23].

Transfection and Purification of Recombinant DES1

The plasmids coding for the wild-type myristoylable form of rat DES1 (referred to as pcDNA3.1/V5/His/DES1-Gly) and its mutant non-myristoylable form (pcDNA3.1/V5/His/DES1-Ala) have already been described [10]. At 24 h of culture, cultured rat hepatocytes were transfected with 10 µg of plasmid/1.6 × 10⁶ cells by using the jetPEITM-Hepatocyte kit (Polyplus-transfection, France). Histidine-tagged recombinant wild-type and mutated DES1 were then immunopurified using HisTrap column (GE Healthcare).

Subcellular Fractionation

After having been washed in ice-cold PBS (phosphate buffer saline: NaH₂PO₄ 4 mM, Na₂HPO₄ 0.94 mM, NaCl 150 mM, pH 7.4), rat hepatocytes were incubated on ice for 10 min in a lysis buffer (Nuclei EZ prep nuclei isolation kit, Sigma). The suspension was homogenized using a Dounce homogenizer (40 strokes) and the mixture was centrifuged for 5 min at 500g to remove unbroken cells and nuclei. The supernatant was centrifuged at 11,000g for 30 min to isolate the mitochondria. The mitochondrial pellet was washed by PBS and resuspended in a sucrose buffer (0.25 M). The supernatant containing the microsomes and the cytosol was conserved.

Immunoblot and Characterization of Subcellular Fractions

Reduced protein samples were separated by SDS-PAGE and blotted onto nitrocellulose. To detect the native DES, membranes were probed with an anti-DES polyclonal antibody raised against the peptide 153-CTTLRKLWVVI LQPL-167 and purified on HiTrap NHS-activated HP column (GE Healthcare). Recombinant DES1 expressed in hepatocytes was detected using an anti-V5 antibody

(Invitrogen, France). Antibodies against VDAC (voltage dependent anion channel), calreticulin and GAPDH were used to characterize the mitochondria, endoplasmic reticulum and cytosol, respectively. Primary antibodies were then coupled to HRP conjugated anti-IgG antibodies and peroxidase activity was determined by chemiluminescent detection using Immobilon reagents (Millipore, Guyancourt, France). The protein level was estimated using anti-actin antibody for total cell lysates and anti-VDAC antibody for mitochondrial fractions.

Dihydroceramide Δ4-Desaturase Activity Assay

Dihydroceramide desaturase assay was performed as previously described [10]. After incubation of the cells with each fatty acid (0.5 mM), 50 µL of hepatocyte homogenate or mitochondrial fraction were incubated in a reaction mixture containing 110 µL of 150 mM phosphate buffer (pH 7.2), NADH and NADPH 2 mM and 40 µL of radio-labeled [1-¹⁴C]-*N*-octanoyldihydroceramide (30 µM in octylglucoside 1.5%; 5 mCi/mmol) as the starter of the reaction. After 2 h of incubation at 37 °C, the reaction was stopped by adding 1,520 µL of chloroform, 1,520 µL of methanol and 800 µL of water. Sphingolipids were extracted twice in chloroform and separated by HPLC (Alliance Integrated System, Waters, France) [10]. *N*-octanoylceramide was separated from *N*-octanoyldihydroceramide by elution (1 mL/min) with a mixture of methanol/H₂O (90:10) during 10 min increasing to 100% methanol in 15 min, and quantified by liquid scintillation counting (Perkin Elmer Life Science, France).

Quantification of the *des1* and *des2* mRNA Level by Real-Time PCR

RNA was isolated from the hepatocytes by Extract-All[®] reagent (Eurobio, France). Retrotranscription was performed from 2 µg of total RNA in duplicates using SuperScriptTM II reverse transcriptase (Invitrogen, France) according to the supplier's instructions. Real-time PCR was performed in duplicate with the TaqMan Universal PCR Master Mix (Applied Biosystems, France) containing 40 ng of retrotranscribed RNA, 0.5 µM of forward and reverse primers, and 0.25 µM of TaqMan probe (Table 1) in a total volume of 40 µL. PCR was run using ABI Prism 7000 sequence detection system (Applied Biosystems, France) as follow: 2 min at 50 °C, 5 min at 95 °C, 40 cycles of 10 s at 95 °C and 1 min at 60 °C. Normalization was realized using the Yakima Yellow[®]-Eclipse[®] Dark Quentcher 18S rRNA control kit (Eurogentec, France). The relative expression was evaluated as: $2^{(-\Delta Ct \text{ } des1) / 2^{(-\Delta Ct \text{ } 18S)}}$.

Table 1 Primers and TaqMan probes designed for quantitative RT-PCR analysis of rat DES genes

Apoptosis Assays

Microscopic detection of apoptosis was carried out with adherent cells after treatment using nuclear chromatin staining with 10 µg/mL Hoechst 33342 in 1 mL of culture medium for 30 min at 37 °C. Cells with apoptotic nuclei (condensed or fragmented) were directly counted in dishes in comparison with total population ($n \geq 200$ cells) using a fluorescence Olympus BX60 microscope. Caspase activity assays were realized as previously described [24]. Briefly, both floating and adherent hepatocytes were lysed in the caspase activity buffer (20 mM PIPES, 100 mM NaCl, 1 mM EDTA, 0.1% CHAPS, 10% sucrose and 10 mM DTT, pH 7.2) and 40 µg of crude cell lysates were incubated with 80 µM DEVD-AMC (Asp-Glu-Val-Asp-7-amido-4-methylcoumarin) for 2 h at 37 °C. Caspase-mediated cleavage of DEVD-AMC was measured by spectrofluorimetry (Spectramax Gemini, Molecular Devices) at an excitation/emission wavelength pair of 380/440 nm at different times ($t = 0, 60$ and 120 min). The caspase activity was expressed as the % of fluorescence arbitrary units compared with control.

Statistical Analysis

Results are expressed as the mean \pm SD or SEM. Data were analyzed by analysis of variance with the R statistical software, followed by Student *t* test for two-group comparison. The level of significance was $P < 0.05$.

Results

DES1 is the Main Native DES Isoform in Cultured Rat Hepatocytes

In the first part of this study, we wanted to investigate if cultured rat hepatocytes are a suitable model to study the regulation of DES1. In order to discriminate between the *des1* and *des2* genes, the levels of *des1* and *des2* mRNAs were measured by real-time quantitative PCR in cultured rat hepatocytes. Figure 1 shows that the expression of *des1* mRNA was five times higher than that of *des2* mRNA. Therefore, these results show that DES1 is the main DES isoform expressed in cultured rat hepatocytes.

Fig. 1 Comparison of mRNA expression of the two isoforms of dihydroceramide $\Delta 4$ -desaturase in rat hepatocytes. Expression of *des1* and *des2* mRNA measured by real-time quantitative PCR in rat hepatocytes. Values are means \pm SD, $n = 7$ (** $P < 0.001$)

Cultured rat hepatocytes exhibited functional DES1 activity (Fig. 2). Radiolabeled dihydroceramide incubated with hepatocyte homogenate was converted into ceramide and no C4-hydroxylation activity (corresponding to the bifunctional DES2) was detected (data not shown). When measured in vitro, the activity was linear up to 2 h of incubation time (Fig. 2a). DES1 activity increased linearly with protein amount (Fig. 2b) in the 0–700 µg range. The activity showed a plateau with dihydroceramide concentrations higher than 20 µM (Fig. 2c). By using Lineweaver–Burk representation, the obtained apparent K_m value was 1.48 µM and the maximal velocity (V_{max}) was 12.5 pmol/min/mg protein. In addition, hepatocytes exhibited dihydroceramide $\Delta 4$ -desaturase activity at up to 72 h of culture (Fig. 2d).

The Subcellular Localization of the Recombinant DES1 is Governed by its Myristoylated Status

We have already shown in the recombinant COS-7 cell model that DES1 myristoylation can modify its subcellular localization [20]. We therefore wanted to know if myristoylation of DES1 also occurs in cultured rat hepatocytes. Hepatocytes were transiently transfected with plasmids encoding the wild-type myristoylable form of rat DES1 and its mutated non-myristoylable form (N-terminal glycine

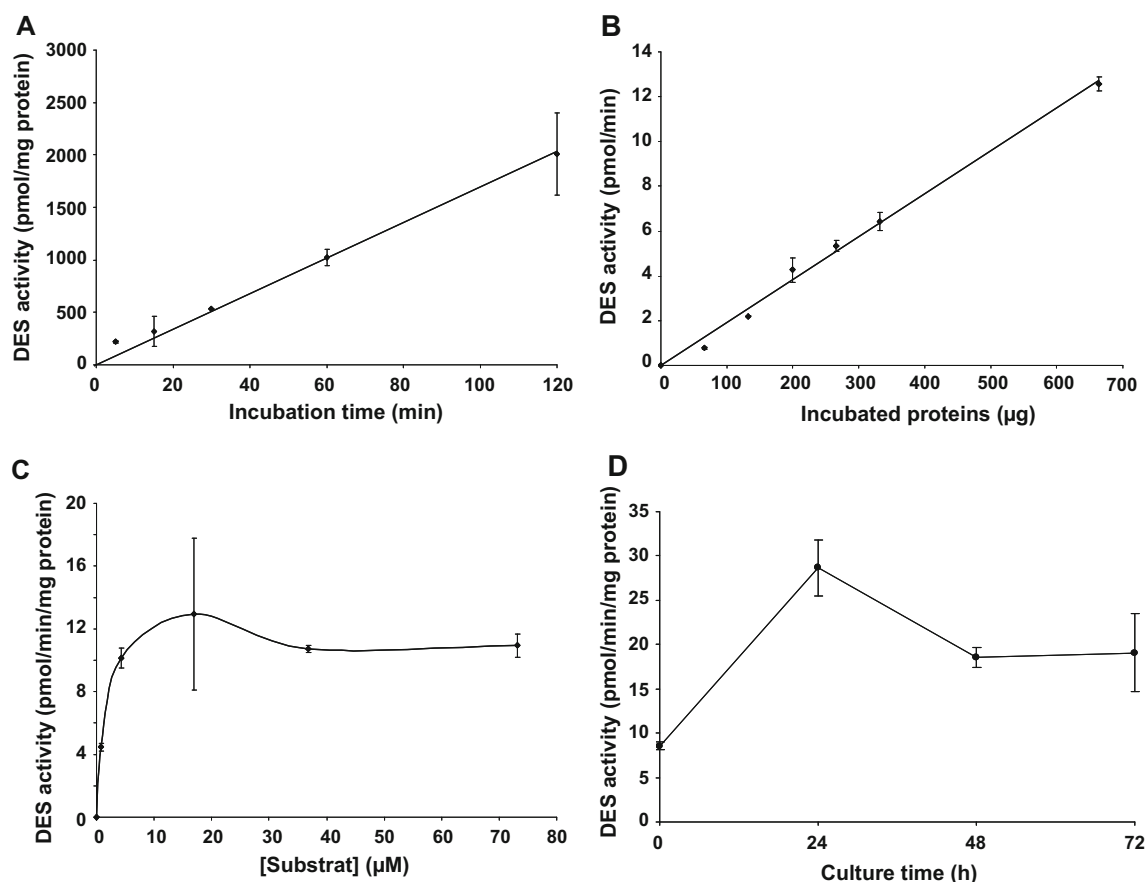

Fig. 2 Dihydroceramide Δ^4 -desaturase 1 (DES1) activity in the cell homogenates of rat hepatocytes. DES1 activities are expressed as a function of incubation time (**a**), incubated proteins (**b**), substrate

concentration (**c**) and culture time of hepatocytes (**d**). Results were calculated from the amount of radiolabeled ceramide produced. Values are means \pm SD ($n = 3$)

replaced by an alanine), followed by subcellular fractionation. In this model, the wild-type myristoylable rat DES1 was found in both the endoplasmic reticulum and the mitochondria (Fig. 3) whereas the mutated non-myristoylable recombinant form was almost exclusively localized in the endoplasmic reticulum. This result evidenced the importance of the myristoylation of DES1 in this cellular model.

Myristic Acid Increases DES1 Activity in Cultured Rat Hepatocytes

The above results suggested that cultured rat hepatocytes are a suitable model to further study the regulation of native DES1 activity, especially through its N-terminal myristoylation. Therefore, we subsequently measured the effect of several fatty acids on DES1 activity in this model. We were especially interested in studying the effect of myristic acid on DES1 activity. Lauric and palmitic acids were also used because they flanked myristic acid by their carbon chain length. As shown in Fig. 4a, myristic acid added at 0.5 mM in the culture medium for 40 h

significantly increased DES1 activity compared to control cells incubated without fatty acids. On the contrary, palmitic acid induced a significant decrease in DES1 activity, compared with both myristic acid-treated cells and control cells. Lauric acid had no effect on DES1 activity.

We also investigated the effects of several unsaturated fatty acids on DES1 activity by incubating cultured rat hepatocytes with 0.5 mM oleic, linoleic and α -linolenic acids. Figure 5 shows that oleic acid did not modify DES1 activity compared to control cells whereas the 2 polyunsaturated fatty acids inhibited DES1 activity significantly.

Myristic Acid also Significantly Increases DES1 Activity in the Mitochondria of Cultured Rat Hepatocytes

Having previously shown that myristoylation can target recombinant DES1 from the endoplasmic reticulum to the mitochondria (Fig. 3), we also measured native DES1 activity in the mitochondrial fraction of rat hepatocytes, after incubation with the saturated fatty acids. Figure 6a once more shows a significant activation of DES1 activity

Fig. 3 Effect of recombinant dihydroceramide $\Delta 4$ -desaturase 1 (DES1) expression and myristic incubation on the subcellular distribution of the protein in rat hepatocytes. Immunoblot was performed to control the protein expression in the different fractions of hepatocytes after immunopurification of recombinant DES1. V5 epitope was detected to analyze the expression of recombinant DES1 Gly (*wild-type*) or DES1 Ala (*mutant*) proteins fused to V5 epitope. The fractions were characterized with actin, VDAC and calreticulin which are the markers of total cells, mitochondria and endoplasmic reticulum, respectively

Fig. 4 Effect of saturated fatty acids on dihydroceramide $\Delta 4$ -desaturase 1 (DES1) activity and expression in rat hepatocytes. **a** DES1 activity measured in rat hepatocytes after an incubation of 40 h with 0.5 mM of lauric (LAU), myristic (MYR) or palmitic acids (PAM). Control cells (CTRL) were incubated without fatty acids. The results are expressed as a percentage of the activity obtained with control cells. Values are mean \pm SD ($n = 7$; $*P < 0.05$). **b** DES1 was detected by immunoblot with the anti-DES antibody. Actin is a control of similar protein loading

after incubation with myristic acid (increase of 60% compared to control cells) and a significant inhibition after incubation with palmitic acid. A smaller but significant increase of DES1 activity was also observed after incubation with lauric acid.

Fig. 5 Effect of unsaturated fatty acids on dihydroceramide $\Delta 4$ -desaturase 1 (DES1) activity in rat hepatocytes. **a** DES1 activity measured in rat hepatocytes after an incubation of 40 h with 0.5 mM of oleic (OLA), linoleic (LNA) and α -linolenic acids (ALA). Control cells (CTRL) were incubated without fatty acids. The results are expressed as a percentage of the activity obtained with control cells. Values are means \pm SD ($n = 5$; $*P < 0.05$). **b** DES1 was detected by immunoblot with the anti-DES antibody. Actin is a control of similar protein loading

The Myristic Acid-Associated Increase of DES1 Activity is not Linked to mRNA or Protein Expression

In order to determine why myristic acid is the single fatty acid that increases DES1 activity, we measured *des1* mRNA transcript levels after incubation of the cells with the same fatty acids. As shown in Fig. 7, saturated and unsaturated fatty acids did not significantly modify the *des1* mRNA level in rat hepatocytes. Moreover, when analyzing the DES1 protein expression, we showed that saturated fatty acids did not modify the DES1 protein level in the whole or mitochondrial fractions of rat hepatocytes (data not shown).

The Increase in Native DES1 Activity Has Small Effects on Apoptosis

To go further, we wanted to know whether the myristic acid-associated increase in DES1 activity could induce apoptosis in the cells, via the production of ceramide. Therefore, we measured the effect of myristic acid and other SFA on apoptosis in cultured rat hepatocytes. The potential pro-apoptotic effect of these fatty acids was measured by counting apoptotic cells (Fig. 8a) and measuring caspase 3 activity (Fig. 8b). Figure 8a showed that the three SFA, and especially palmitic acid, increased slightly but significantly the number of apoptotic cells,

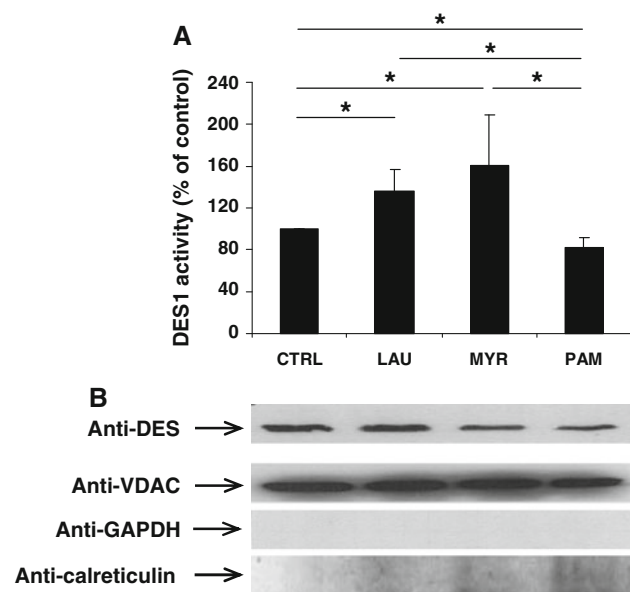

Fig. 6 Effect of saturated fatty acids on dihydroceramide $\Delta 4$ -desaturase 1 (DES1) activity and expression in the mitochondrial fraction of rat hepatocytes. **a** DES1 activity measured in the mitochondrial fraction of rat hepatocytes after an incubation of 40 h with 0.5 mM of lauric (LAU), myristic (MYR) or palmitic acids (PAM). Control cells (CTRL) were incubated without fatty acids. The results are expressed as a percentage of the activity obtained with control cells. Values are means \pm SD ($n = 5$; $*P < 0.05$). **b** DES1 was detected by immunoblot with the anti-DES antibody; anti-VDAC, anti-GAPDH and anti-calreticulin level assessed by immunoblot are the markers of mitochondrial fraction purity

compared to control cells. However, none of these SFA increased caspase 3 activity (Fig. 8b).

Discussion

Dihydroceramide $\Delta 4$ -desaturase (DES) is responsible for introducing a *trans* 4,5-double bond in the sphingoid

backbone of dihydroceramide, leading to the biosynthesis of ceramide [11]. Because this double bond is critical for the acquisition of the biological activities of ceramide, and because the enzyme modulates the dihydroceramide/ceramide ratio in the cells, the regulation of DES isoforms has become a focus of interest [12, 19, 25–27]. It has been shown for instance that dihydroceramide $\Delta 4$ -desaturase activity is modulated by oxidative stress in several cell lines [26]. In C2C12 myotubes, with a view to study the sphingolipid-mediated insulin resistance, physiologically relevant concentrations of palmitate increased *des1* mRNA and DES1 activity and this effect was attenuated by oleate co-treatment [28]. We have also contributed to decrypt the mechanistic insights as to how DES1 is regulated. Recently, we showed that both rat DES isoforms are myristoylated and that N-myristoylation increased the recombinant DES1 activity in COS-7 cells [10]. We also showed that the myristoylation of recombinant DES1 can target part of the enzyme from the endoplasmic reticulum to the mitochondrial outer membrane, leading to an increase in ceramide levels which in turn leads to apoptosis in the COS-7 cell model [20]. Therefore, we then focused our attention on studying the effect of myristic acid and other saturated or unsaturated fatty acids on the native DES1 in cultured rat hepatocytes.

Rat hepatocytes were chosen as a useful physiological model of cultured cells because, in the rat, a tissue distribution study has shown that the liver contains the highest DES activity [19]. Ceramide de novo biosynthesis was also shown to occur in cultured rat hepatocytes incubated with radiolabeled serine [12, 29]. In addition, DES activity was detected in permeabilized rat hepatocytes incubated with radiolabeled dihydroceramide [11] and in microsomes from rat liver [19]. However, all these studies were carried out before the identification of the two mammalian *des1* and *des2* genes encoding for the two protein isoforms of

Fig. 7 Effect of saturated and unsaturated fatty acids on dihydroceramide $\Delta 4$ -desaturase 1 (*des1*) mRNA expression in rat hepatocytes. *des1* mRNA expression in rat hepatocytes after an incubation of 40 h with 0.5 mM of saturated fatty acids **a** lauric (LAU), myristic (MYR) or

DES [13, 25]. Although it has been suggested that the bifunctional $\Delta 4$ -desaturase/C4-hydroxylase DES2 is mainly expressed in the small intestine in mice, with preferential phytoceramide production [13], we first characterized the relative expression level of DES1 and DES2 isoforms in cultured rat hepatocytes. By analyzing mRNA levels (Fig. 1), our results demonstrated that DES1 is the main dihydroceramide desaturase isoform expressed in hepatocytes.

The present study also shows that rat hepatocytes in culture exhibited DES1 activity at up to 72 h of culture (Fig. 2d). In order to measure the dihydroceramide desaturase activity in vitro, we used N -[1- 14 C]octanoyldihydroceramide as substrate. We chose this substrate with a short 14 C-labeled fatty acyl chain engaged in the amide bond because Michel et al. [12] have shown that optimal in vitro activity of the desaturase is obtained with substrates with N -acyl chain length of 8 carbon atoms compared to 12 or 18 carbons. In another study by Causeret et al. [19], the chain length of the N -linked fatty acid hardly affected the activity of the desaturase from rat liver microsomes. However, little is known about the chain length that is actually optimal in cells and it is very difficult to determine if this substrate is a good one for all DES isoforms, which could explain why no hydroxylase activity corresponding to the potential DES2 isoform was detected. Other studies have been carried out by using an in situ dihydroceramide desaturase assay (C12-dhCCPS converted to C12-CCPS) [26, 27]. DES1 activity presented a typical Michaelis–Menten kinetic (Fig. 2c). The level of activity reported here was between 10 and 25 pmol/min/mg protein when considering the whole cell homogenate, which is consistent with the values reported in the tissues (2–3 pmol/min/mg protein in fresh rat liver) [19]. The kinetic parameters (K_m , V_{max}) that we obtained are also consistent with the

values very recently described in rat liver microsomes [30]. Altogether, the optimization of the conditions for the DES1 activity assay (Fig. 2) provides a reliable tool for investigating the effect of individual parameters on its regulation.

Since we had previously demonstrated that myristoylation can target part of the DES1 from the endoplasmic reticulum to the mitochondria in the COS-7 cell model [20], we wanted to know if myristoylation of DES1 also occurs in cultured rat hepatocytes. Hepatocytes were transfected with plasmids coding for the wild-type myristoylable (DES1 Gly) or mutant unmyristoylable (DES1 Ala) forms of DES1, followed by incubation with myristic acid. We showed that the wild-type of DES1 was present in the microsomes and mitochondria, whereas the mutant was mainly in the microsomes (Fig. 3). This result provides indirect proof that myristoylation of native DES1 occurs in rat hepatocytes, consistent with previous results showing that native dihydroceramide $\Delta 4$ -desaturase activity was found in both the endoplasmic reticulum and the mitochondria in isolated hepatocytes [20]. This result is also consistent with a previous study showing that Myristoyl-CoA: protein N -myristoyltransferase (NMT) is active in cultured rat hepatocytes and can use exogenous myristic acid added to the culture medium to acylate proteins [31]. Altogether, these results suggest that cultured rat hepatocytes are a suitable model to study further the regulation of DES1 activity, especially through its N -terminal myristoylation.

Cultured rat hepatocytes were then incubated with different saturated and unsaturated fatty acids, solubilized in the culture medium at the physiological range of 0.5 mM. Fatty acids were supplied to the cells after complexation with albumin, with a fatty acid:albumin molar ratio equal to 3.3:1. Among these fatty acids (Figs. 4a, 5a), myristic acid was the single one able to upregulate DES1 activity compared to control cells. Lauric and oleic acids had no

effect on the activity whereas palmitic, linoleic and α -linolenic acids inhibited DES1 activity measured in the whole cell homogenate. The activation of DES1 by myristic acid was slight (about 10%) but significant and reproducible compared not only to control cells but also to palmitic acid-treated cells (Fig. 4a). This myristic acid-associated increase in DES1 activity was more significant in the mitochondrial fraction compared to both control cells (about 60%) and palmitic acid-incubated cells (Fig. 6a). No significant effect was shown upon incubation with the different fatty acids on *des1* mRNA (Fig. 7) and DES1 protein levels (data not shown). Although the mechanism is not fully demonstrated, all these results argue for a regulation of DES1 through its N-terminal myristoylation. First, the specific effect of myristic acid on native DES1 activity (Fig. 4a), with no effect at the transcriptional and translational levels, is in accordance with the increased activity shown in COS-7 cells expressing the recombinant wild-type DES1-Gly and incubated with myristic acid, compared to cells expressing the myristoylation-site-deficient mutant DES1-Ala [10]. In cultured rat hepatocytes, the effect on native DES1 is not that high, probably because myristic acid is not the rate-limiting molecule for myristoylating DES1, as it becomes in transfected cells expressing high level of recombinant DES1 protein [10]. We had previously carried out extensive studies on the metabolic fate of lauric, myristic and palmitic acids in cultured rat hepatocytes [22, 31, 32]. Based on these previous studies, we placed emphasis on several major differences between saturated fatty acid utilization by liver cells in terms of both lipid metabolism (including incorporation into cellular and secreted lipids, β -oxidation, conversion to other fatty acids by elongation and desaturation) and fatty acid acylation of proteins (N-terminal myristoylation and lateral acylation). In addition, depending on the fatty acid used, it is also possible that some fatty acids were not bound to albumin but rather present in free form. In a previous work [22], we measured the level of unbound myristate and palmitate at different fatty acid:albumin molar ratios in the incubation medium and shown that albumin binding capacity for myristic acid was always smaller than for palmitic acid. Consequently, myristic acid was more rapidly taken up by the cells than was palmitic acid. However, this higher uptake rate of myristic acid did not exceed the esterification ability of the cells, and we did not find any differences when we measured the incorporation of myristic acid and palmitic acid into the cellular non-esterified fatty acids in this previous work. Secondly, the effect of myristic acid on native DES1 activity was significantly higher in the mitochondrial fraction than in the whole cell homogenate (Fig. 4). This last result can be related to the subcellular targeting of part of DES1 from the endoplasmic reticulum to the

mitochondrial outer membrane when the protein is myristoylated, as already shown with the recombinant protein in the COS-7 cell model [20], and in rat hepatocytes in the present study (Fig. 3). This result also suggests a decrease in the cellular pool of native non-myristoylated DES1 proteins and a concomitant increase in the level of myristoylated DES1 upon incubation with myristic acid for 40 h. Another interesting result of the present study was that, although lauric acid had no effect on DES1 activity in the whole cell homogenate, a significant positive effect appeared in the mitochondria (Fig. 6a). This result can be explained by the elongation of lauric acid to myristic acid, as previously described in rat hepatocytes [33], which therefore supplies a higher amount of endogenous myristic acid available for the myristoylation of DES1. The presence of myristoyl-CoA in the cells is indeed required for myristoylating DES1.

Therefore, the myristic acid-associated increase in DES1 activity shown in the present study was possibly the consequence of its N-terminal myristoylation. In addition, DES proteins are believed, like other mammalian desaturases and especially fatty acid desaturases, to cooperate with NADH-cytochrome b5 reductase (NCb5R) in the endoplasmic reticulum [34]. Since NCb5R is also known to be myristoylated [35–37], both the myristoylation of DES and NCb5R could account for the increased activity of the whole complex of desaturation, as recently suggested for the $\Delta 6$ -desaturase (FADS2) involved in polyunsaturated fatty acid biosynthesis [38].

Now, we can also put forward several hypotheses concerning the negative effect of palmitic acid on DES1 activity. Palmitic acid is the preferred substrate of the first step of ceramide biosynthesis (condensation with a serine). Incubation with palmitic acid, but not with stearic or oleic acid, has been shown to increase sphingolipid de novo synthesis in rat liver cells [29, 39]. In our study, the high concentration of palmitic acid brought by the medium could therefore stimulate the whole metabolic pathway leading to ceramide biosynthesis. The higher level of cellular ceramide could inhibit the last step catalyzed by DES1, as a negative feed-back. In addition, although NMT displays a high affinity for myristoyl-CoA [40], the high level of cellular palmitoyl-CoA could compete with myristoyl-CoA for the N-myristoylation of DES1 [41], leading to a decrease of its myristoylated status and a subsequent decrease of its enzymatic activity. In C2C12 mouse myotubes, palmitate markedly increased *des1* mRNA and DES1 activity, suggesting that the effect of individual saturated fatty acid on DES1 could vary with the tissue considered [28].

Because ceramide is involved in apoptosis [18], we finally wanted to measure the effect of the myristic acid-associated increase in DES1 activity on apoptosis induction

in cultured rat hepatocytes incubated with myristic acid and other saturated fatty acids. Moreover, it is well known that ceramide induces apoptosis via mitochondrial dysfunction [42, 43]. Indeed, chemically-modified ceramide analogs that target mitochondria promote autophagy, retard cell growth and induce apoptosis [44]. We hypothesized that the level of synthesized ceramides could increase in cells incubated with myristic acid, due to the higher rate of conversion of dihydroceramide to ceramide by DES1. Indeed, our results demonstrate that apoptosis measured by counting apoptotic cells was weakly, but significantly, increased in cultured rat hepatocytes incubated with myristic acid, compared to control cells (Fig. 8a). Lauric acid and especially palmitic acid also increased the number of apoptotic cells. In COS-7 cells expressing recombinant DES1, we showed that myristic acid highly increased both the number of apoptotic cells and caspase 3 activity [20]. Interestingly, the modest increase of DES1 activity when cultured hepatocytes were incubated with myristic acid (Fig. 4a) is correlated with the weak effect on apoptosis (Fig. 8a). In contrast, the induction of apoptosis by palmitic acid is higher than that induced by myristic acid (Fig. 8a), whereas palmitic acid inhibited DES1 activity (Fig. 4a). It is actually well known that a high concentration of free saturated fatty acids (C16:0 and C18:0) incubated with various type of cells induce apoptosis, a mechanism that has therefore been called lipoapoptosis. Two complementary type of mediation have been explored to explain this lipotoxicity, involving or not ceramide. First, palmitic and stearic acids are also both able to induce partial mitochondria uncoupling [47], endoplasmic reticulum stress [48] and to generate reactive oxygen species [49] and nitric oxide [50]. Second, apoptosis induced by these saturated free fatty acids is correlated with de novo synthesis of ceramide. In the present study, we focused on the pathway leading to the de novo synthesis of ceramide and especially on the last step catalyzed by DES1. As discussed above, since palmitic acid is the preferred substrate of the first step of ceramide biosynthesis, we suggest that incubation with palmitic acid could therefore stimulate the whole metabolic pathway leading to ceramide biosynthesis (and therefore to apoptosis induction), even if the last desaturation step catalyzed by DES1 is less active compared to control cells or to cells incubated with myristic acid. In addition it is possible that the higher effect shown on the induction of apoptosis with palmitic acid could be the consequence of the other pathway (mitochondria uncoupling, endoplasmic reticulum stress and generation of reactive oxygen species and nitric oxide) since myristic acid has not been described as having these effects.

However, none of the 3 saturated fatty acids significantly increased caspase 3 activity, which is an important

marker of apoptosis (Fig. 8b). Therefore, although cultured rat hepatocytes are a suitable model for studying DES1 regulation, they would not be a good model to study apoptosis induction under these conditions because primary cells are more resistant to apoptosis induced by free fatty acids than other cellular models [45] and because insulin added to the culture medium is known to protect liver cells from saturated fatty acid-induced apoptosis [46].

In summary, our data demonstrate that myristic acid is the single fatty acid able to increase enzymatic DES1 activity, possibly through its myristoylation, in the suitable physiological model of cultured rat hepatocytes.

Acknowledgments We are indebted to the Centre National Interprofessionnel de l'Economie Laitière (CNIEL, France) for its financial support and constructive discussions. We thank N. Montheau, F. Boissel and R. Marion for able technical assistance and animal care. We thank Béatrice Dendele and Fatiha Djoudi for technical assistance concerning apoptosis assays. We thank Jane Wilson-Giron for her English revision of the manuscript.

Abstract The aim of this study was to evaluate tissue distribution of vitamin E isoforms such as α - and γ -tocotrienol and γ -tocopherol and interference with their tissue accumulation by α -tocopherol. Rats were fed a diet containing a tocotrienol mixture or γ -tocopherol with or without α -tocopherol, or were administered by gavage an emulsion containing tocotrienol mixture or γ -tocopherol with or without α -tocopherol. There were high levels of α -tocotrienol in the adipose tissue and adrenal gland, γ -tocotrienol in the adipose tissue, and γ -tocopherol in the adrenal gland of rats fed tocotrienol mixture or γ -tocopherol for 7 weeks. Dietary α -tocopherol decreased the α -tocotrienol and γ -tocopherol but not γ -tocotrienol concentrations in tissues. In the oral administration study, both tocopherol and tocotrienol quickly accumulated in the adrenal gland; however, their accumulation in adipose tissue was slow. In contrast to the dietary intake, α -tocopherol, which has the highest affinity for α -tocopherol transfer protein (α TTP), inhibited uptake of γ -tocotrienol to tissues including adipose tissue after oral administration, suggesting that the affinities of tocopherol and tocotrienol for α TTP in the liver were the critical determinants of their uptake to peripheral tissues. Vitamin E deficiency for 4 weeks depleted tocopherol and tocotrienol stores in the

liver but not in adipose tissue. These results indicate that dietary vitamin E slowly accumulates in adipose tissue but the levels are kept without degradation. The property of adipose tissue as vitamin E store causes adipose tissue-specific accumulation of dietary tocotrienol.

Introduction

Vitamin E is a fat-soluble antioxidant that inhibits lipid peroxidation in biological membranes. In nature, compounds with vitamin E activity are α -, β -, γ -, and δ -tocopherol and α -, β -, γ -, and δ -tocotrienol. α - and γ -tocopherol are abundant in dietary vitamin E whereas tocotrienol is only present in some plant sources such as palm oil and rice bran; dairy foods contain low levels of tocotrienol. Although tocotrienol has been suggested to have some beneficial biological effects including antioxidative [1, 2], anticancer [3, 4], antiatherosclerotic [5, 6], and neuroprotective [7, 8] effects, its concentration in various tissues is extremely low compared with α -tocopherol.

Dietary tocopherol and tocotrienol are absorbed in the small intestine and secreted with triacylglycerol-rich chylomicrons into the lymph and blood [9, 10]. After lipolysis of the triacylglycerol-rich chylomicrons in the circulation, the dietary tocopherol and tocotrienol are transported to the liver [11]. α -Tocopherol is preferentially incorporated into VLDL and transported to various tissues by lipoprotein [12, 13] because of its high affinity for α -tocopherol transfer protein (α TTP) [14]. In contrast, the other vitamin E isoforms, γ -tocopherol and tocotrienol, are catabolized and excreted. Therefore, α -tocopherol has the highest biological activity among vitamin E isoforms. Levels of α - and γ -tocotrienol fell below measurable limits in plasma and major tissues of rats fed a diet containing α -tocopherol and α - and γ -tocotrienol for 8 weeks, in contrast to the high levels of α -tocopherol [15].

Some reports showed peripheral tissue-specific accumulation of tocotrienol in animals. Hayes et al. [16] observed significant amounts of α - and γ -tocotrienol in adipose tissue of hamsters fed a diet containing α - and γ -tocotrienol. Podda et al. [17] showed that α - and γ -tocotrienol were present in the skin of hairless mice fed a commercial diet containing small amounts of tocotrienol with a high amount of α -tocopherol. We also observed α - and γ -tocotrienol accumulation in adipose tissue and skin of rats fed a diet containing α -tocopherol and α - and γ -tocotrienol [15, 18]. Thus, tocotrienol accumulates in some peripheral tissues including adipose tissue and skin of rats fed not only tocotrienol but also tocotrienol with α -tocopherol as vitamin E. The tocotrienol accumulation in the peripheral tissues is not explained by its low affinity for α TTP.

We previously found that dietary α -tocopherol decreases α -tocotrienol but not γ -tocotrienol concentration in some tissues including adipose tissue and skin of rats fed tocotrienol for 8 weeks [19]. To obtain more information on tocotrienol metabolism we examined in this study the effect of α -tocopherol supplementation on α - and γ -tocotrienol and γ -tocopherol concentrations in various tissues of rats by both dietary intake and oral administration by gavage of vitamin E isoforms. To detect γ -tocotrienol, which is quickly catabolized, the rats used for the dietary study had free access to food until killed in contrast to food deprivation for 24 h until killed in our previous reports [15, 19]. We also determined the effect of vitamin E on tocopherol and tocotrienol stores in adipose tissue.

Materials and Methods

Materials and Animals

RRR- α -tocopherol, *RRR*- γ -tocopherol, and a tocotrienol mixture extracted from palm oil and purified by HPLC

were used for experimental diets and emulsified solutions for gavage administration. The tocotrienol mixture comprised α -tocotrienol (339 mg/g), β -tocotrienol (40 mg/g), γ -tocotrienol (471 mg/g), δ -tocotrienol (110 mg/g), and *RRR*- δ -tocopherol (1 mg/g); α -, β - and γ -tocopherol were undetectable in the mixture. *RRR*- α -tocopherol, *RRR*- γ -tocopherol, and the tocotrienol mixture were generously donated by Eisai Food and Chemical (Tokyo, Japan).

Male Wistar rats aged 6 weeks were purchased from Japan SLC (Shizuoka, Japan) and maintained at 24 °C with a 12 h light cycle (lights on from 0800 to 2000 hours). This study was approved by the Laboratory Animal Care Committee of Nagoya University of Arts and Sciences; all procedures were performed in accordance with the Animal Experimentation Guidelines of Nagoya University of Arts and Sciences.

Experiment 1

Rats were fed a diet containing 147.5 mg tocotrienol mixture/kg (T3 group), 147.5 mg tocotrienol mixture/kg with 50 mg α -tocopherol/kg (T3 + α T group), 50 mg γ -tocopherol/kg (gT group) or 50 mg γ -tocopherol/kg with 50 mg α -tocopherol/kg (gT + α T group) for 7 weeks. The tocotrienol mixture (147.5 mg) contained 50 mg of α -tocotrienol and 69 mg of γ -tocotrienol. The composition of the diets is shown in Table 1. The diets were freshly prepared, stored at −30 °C, and used within 1 week. The rats had free access to food until sacrifice and were killed by decapitation. The perirenal adipose tissue, epididymal fat, skin, serum, liver, lung, thymus, heart, testis, kidney, adrenal gland, spleen, muscle, and aorta were taken and stored at −30 °C until use for the determination of vitamin E concentration.

Experiment 2

Rats were fed a vitamin E-free diet (Table 1) for 1 month to deplete tissue stores of α -tocopherol. Then, they were administered by gavage 1 mL of an emulsion containing 10 mg of α -tocopherol, 10 mg of γ -tocopherol, or 29.5 mg of tocotrienol mixture. All three emulsions contained 200 mg of sodium taurocholate, 200 mg of triolein, and 50 mg of albumin. The tocotrienol mixture (29.5 mg) contained 10 mg of α -tocotrienol and 14 mg of γ -tocotrienol. The rats had free access to food until vitamin E administration and were deprived of food thereafter. Eight or 24 h after administration, the rats were killed by decapitation and the perirenal adipose tissue, epididymal fat, skin, serum, liver, lung, heart, kidney, adrenal gland, muscle, aorta, and brain were taken and stored at −30 °C until use for the determination of vitamin E concentration. Rats without vitamin E administration were used as the group at 0 h.

Experiment 3

Rats were fed a vitamin E-free diet (Table 1) for 1 month to deplete tissue stores of α -tocopherol. Then, they were administered by gavage 1 mL of an emulsion containing 29.5 mg of tocotrienol mixture (T3 group), 29.5 mg of tocotrienol mixture with 1 mg of α -tocopherol (T3 + aT1 group), 29.5 mg of tocotrienol mixture with 10 mg of α -tocopherol (T3 + aT10 group), 10 mg of γ -tocopherol (gT group), 10 mg of γ -tocopherol with 1 mg of α -tocopherol (gT + aT1 group), or 10 mg of γ -tocopherol with 10 mg of α -tocopherol (gT + aT10 group). All six emulsions contained 200 mg of sodium taurocholate, 200 mg of triolein, and 50 mg of albumin. The tocotrienol mixture (29.5 mg) contained 10 mg of α -tocotrienol and 14 mg of γ -tocotrienol. The rats had free access to food until vitamin E administration and were deprived of food thereafter. Eight hours after administration, the rats were killed by decapitation and the perirenal adipose tissue, epididymal fat, skin, serum, liver, lung, heart, kidney, adrenal gland, muscle, aorta, and brain were taken and stored at -30°C until use for the determination of vitamin E concentration.

Experiment 4

Rats were fed a diet containing 40 mg α -tocopherol/kg and 147.5 mg tocotrienol mixture/kg for 6 weeks. The tocotrienol mixture (147.5 mg) contained 50 mg of

α -tocotrienol and 69 mg of γ -tocotrienol. Then, the rats were fed a vitamin E-free diet for 0, 1, 2, 3, or 4 weeks. The composition of the diets is shown in Table 1. The diets were freshly prepared, stored at -30°C , and used within 1 week. After food deprivation overnight, the rats were killed by decapitation and the liver and perirenal adipose tissue taken and stored at -30°C until use for the determination of vitamin E concentration.

Measurement of vitamin E and lipid concentrations

Vitamin E concentration was determined by HPLC with a fluorescence detector, as described previously [11]. Serum cholesterol and triacylglycerol concentrations were measured by commercial kits (Wako Pure Chemical Industries, Osaka, Japan).

Statistical analysis

Data are presented as means \pm SEM for six (experiment 1), five (experiments 2 and 3), or eight rats (experiment 4) per group. Data were analyzed by 1-way ANOVA followed by Tukey's post hoc test. In experiment 1, vitamin E concentration (Figs. 1, 2) were analyzed by Student's *t* test for parameters with equal variance or by Welch's test for parameters with unequal variance. Differences were regarded as significant at $P < 0.05$. All data were analyzed using GraphPad Prism 5 for Windows (GraphPad Software, La Jolla, CA, USA).

Results

Experiment 1

The dietary vitamin E isoforms did not affect growth, organ weights, and serum lipid concentrations (data not shown). Both α - and γ -tocotrienol were present in the perirenal adipose tissue, epididymal fat, skin, serum, liver, lung, thymus, heart, testis, kidney, adrenal gland, spleen, muscle, and aorta in the rats fed the diet containing the tocotrienol mixture (Fig. 1). In the T3 group the α -tocotrienol concentration in adrenal gland was highest among those in all tissues and serum, and the α -tocotrienol concentration in the tissues and serum was lower in the T3 + aT group than in the T3 group. In contrast, the γ -tocotrienol concentration was higher in the adipose tissues than in the other tissues and serum in the T3 group whereas the γ -tocotrienol concentration in almost all tissues of the T3 and T3 + aT groups was similar.

γ -Tocopherol was also present in all tissues and serum of the gT group, and the γ -tocopherol concentration in the

adrenal gland was higher than those that in the other tissues (Fig. 2). The γ -tocopherol concentration in all tissues except for liver and aorta was lower in the gT + aT group than in the gT group. In the T3 + aT (Fig. 1) and gT + aT (Fig. 2) groups fed a diet containing α -tocopherol, α -tocopherol concentration in the adrenal gland was extremely high ($>1 \mu\text{mol/g}$) compared with in other tissues and serum.

Experiment 2

The α -tocopherol concentration in serum, liver, kidney, adrenal gland, heart, lung, and skin was higher at 8 and 24 h than that at 0 h, however, the concentrations in the aorta, perirenal adipose tissue, epididymal fat, and brain at 24 h were not different from that at 0 h (Fig. 3). At 8 and 24 h, the α -tocopherol concentration was highest among four isomers in serum, liver, kidney, adrenal gland, aorta, muscle, perirenal adipose tissue, epididymal fat, and brain. γ -Tocopherol and α - and γ -tocotrienol were present in serum and tissues except for epididymal fat and brain at 8 and 24 h, although they were undetectable at 0 h. The γ -tocotrienol concentration was lower than those of γ -tocopherol and α -tocotrienol in serum, liver, kidney, adrenal gland, and lung at 8 h.

Experiment 3

The α -tocopherol in serum, liver, kidney, and adrenal gland was higher in the T3 + aT1 group than in the T3 group, and

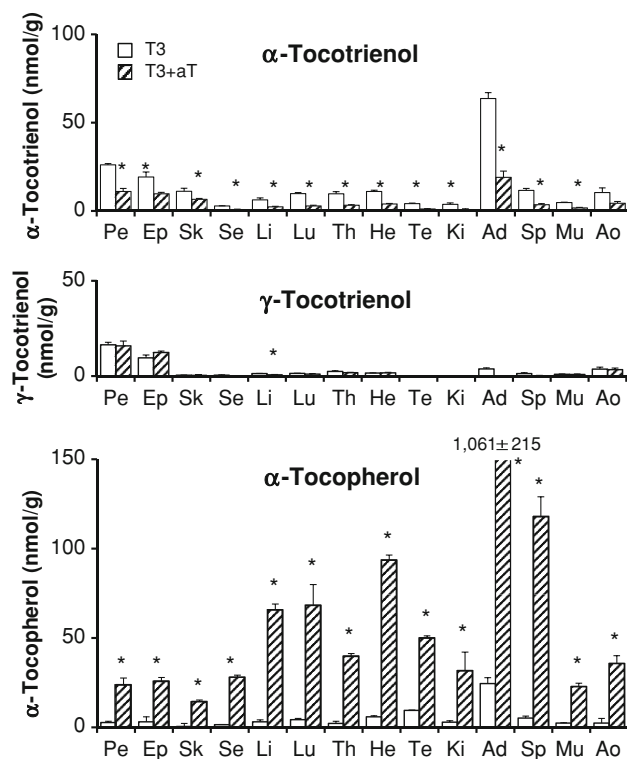

Fig. 1 Tissue distribution of α - and γ -tocotrienol and α -tocopherol in rats fed a diet containing a tocotrienol mixture (T3) or a tocotrienol mixture with α -tocopherol (T3 + aT) in experiment 1. γ -Tocotrienol was undetectable in adrenal gland of the T3 + aT group. Values are means \pm SEM; $n = 6$. * $P < 0.05$ vs. T3 group. Fig. 2 Tissue distribution of γ - and α -tocopherol in rats fed a diet containing γ -tocopherol (gT) or γ -tocopherol with α -tocopherol (gT + aT) in experiment 1. Values are means \pm SEM; $n = 6$. * $P < 0.05$ vs. gT group. Pe perirenal adipose tissue, Ep epididymal fat, Sk skin, Se serum, Li liver, Lu lung, Th thymus, He heart, Te testis, Ki kidney, Ad adrenal gland, Sp spleen, Mu muscle, Ao aorta

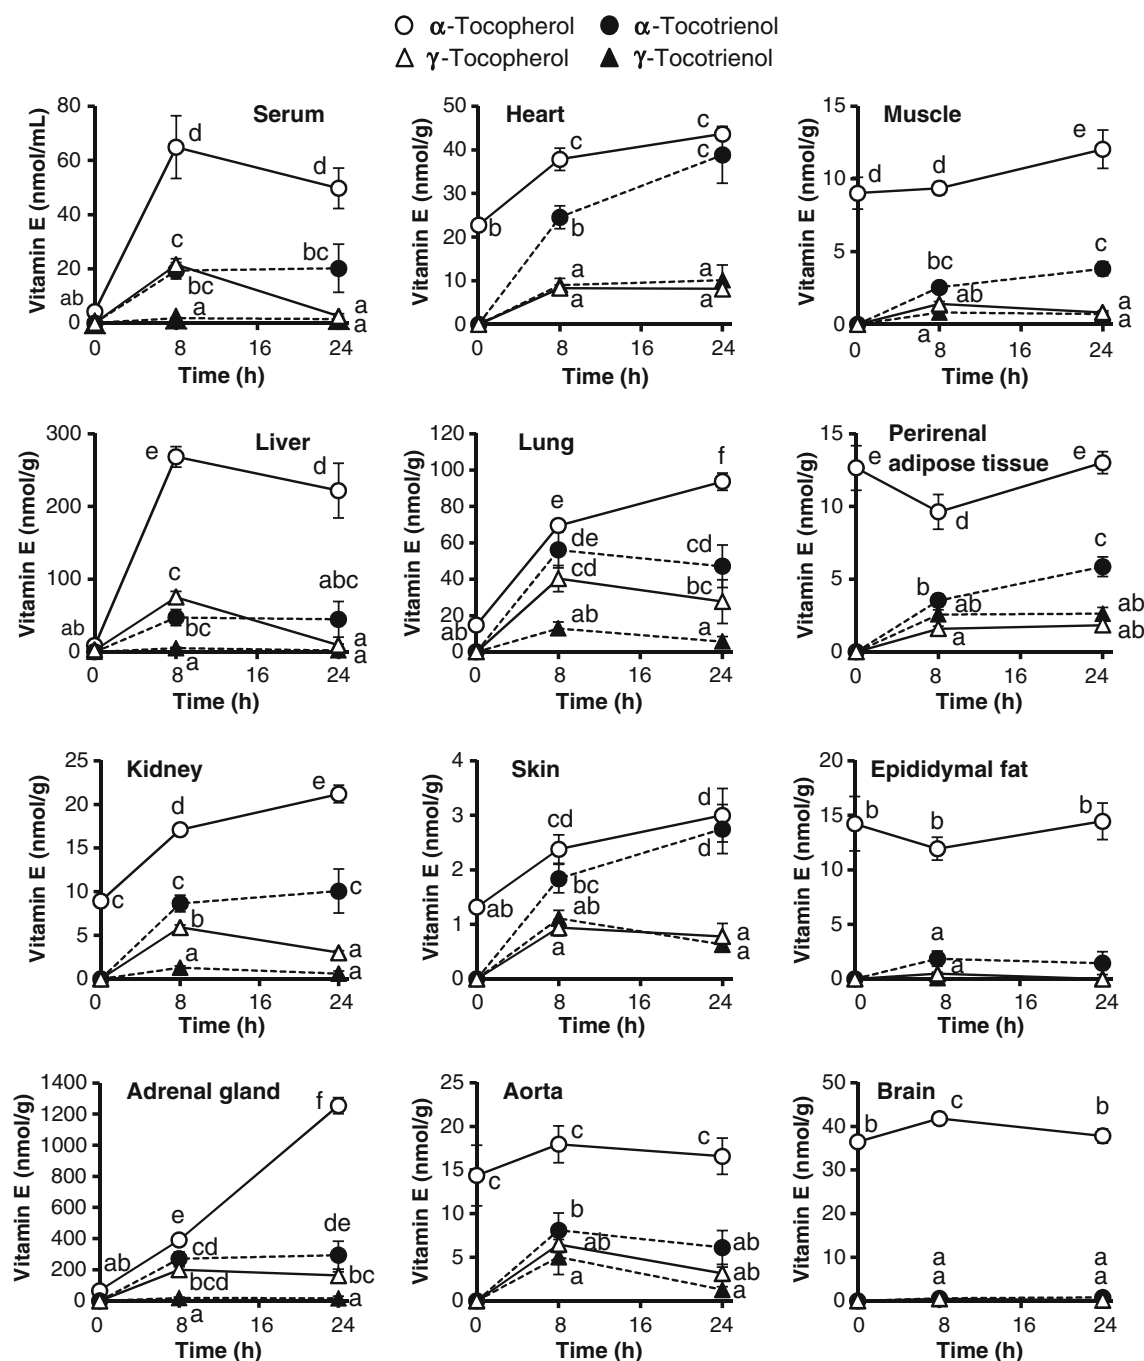

Fig. 3 Time-course changes of α - and γ -tocopherol and α - and γ -tocotrienol concentrations in tissues and serum after oral administration of α - or γ -tocopherol or a tocotrienol mixture in experiment 2. Values are means \pm SEM; $n = 5$. Means not sharing a letter differ at

a significance of $P < 0.05$; symbols without letters are below the detection limits. Only α -tocopherol was detected in serum and tissues at 0 h. γ -Tocopherol was undetectable in epididymal fat and γ -tocotrienol was undetectable in epididymal fat and brain at 24 h

the concentrations in serum, liver, kidney, adrenal gland, heart, lung, skin, and aorta were higher in the T3 + aT10 group than in the T3 group (Fig. 4). In contrast, α -tocotrienol concentrations in serum, kidney, adrenal gland, heart, lung, skin, aorta, muscle, and perirenal adipose tissue were lower in the T3 + aT1 and T3 + aT10 groups than in the T3 group. In heart, skin, aorta, and perirenal adipose tissues the

γ -tocotrienol concentrations were also lower in the T3 + aT1 and T3 + aT10 groups than in the T3 group.

In addition, the α -tocopherol concentration in the kidney was higher in the gT + aT1 group than in the gT group, and α -tocopherol concentrations in serum, liver, kidney, adrenal gland, heart, lung, skin, and aorta were higher in the gT + aT10 group than in the gT group (Fig. 5). In

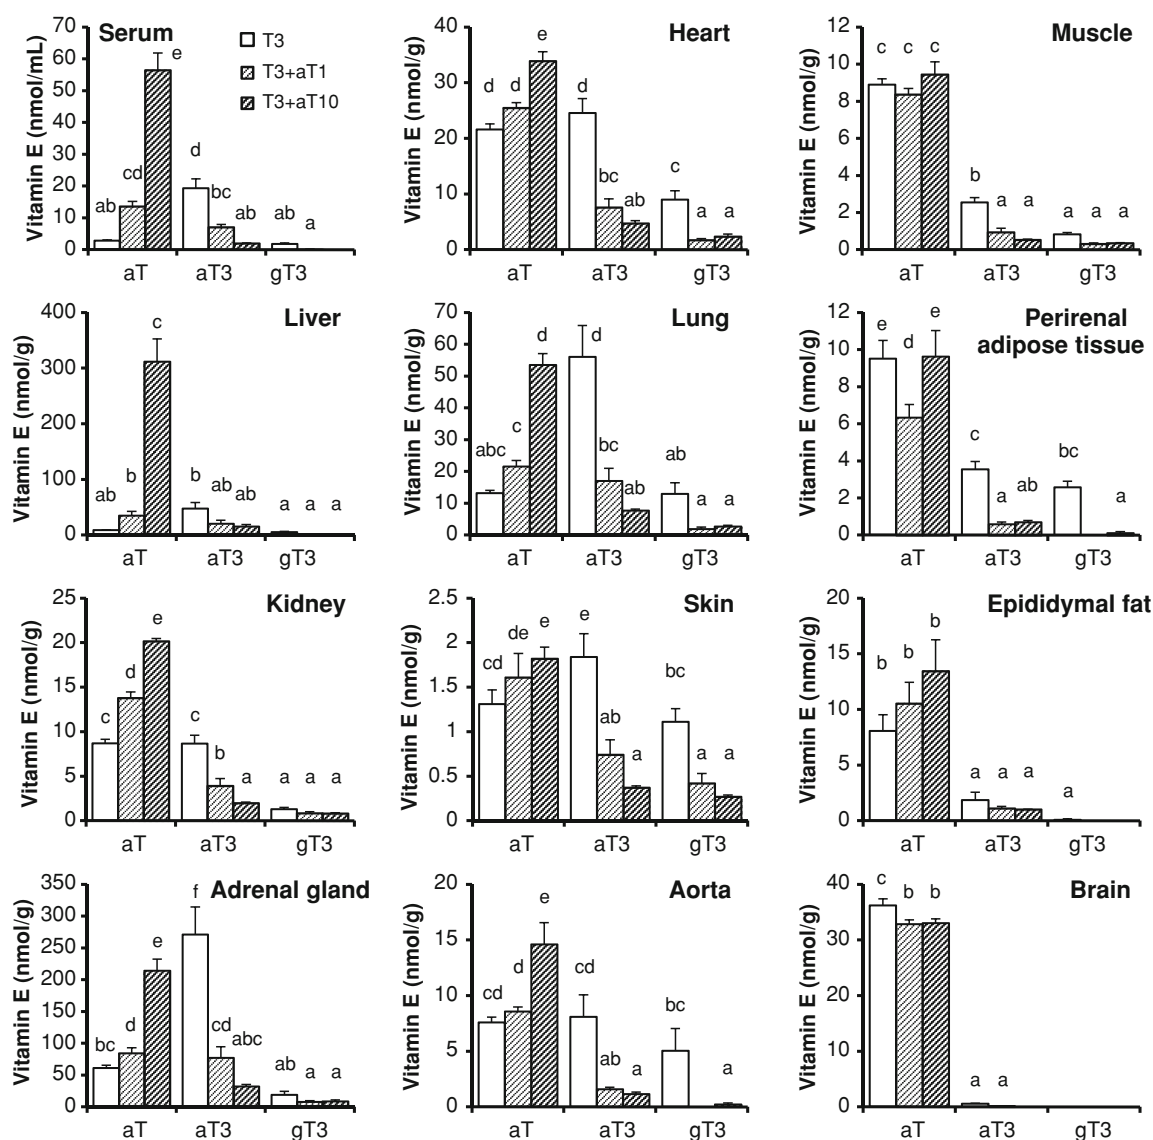

Fig. 4 Concentrations of α -tocopherol (aT), α -tocotrienol (aT3), and γ -tocotrienol (gT3) in tissues and serum 8 h after oral administration of 29.5 mg of tocotrienol mixture (T3), 29.5 mg of tocotrienol mixture with 1 mg of α -tocopherol (T3 + aT1), or 29.5 mg of

tocotrienol mixture with 10 mg of α -tocopherol (T3 + aT10), in experiment 3. The tocotrienol mixture (29.5 mg) contained 10 mg of α -tocotrienol and 14 mg of γ -tocotrienol. Values are mean \pm SEM; $n = 5$. Means not sharing a letter differ at $P < 0.05$

contrast, γ -tocopherol concentration in adrenal gland, lung, and aorta was lower in the gT + aT1 group than in the gT group, and γ -tocopherol concentrations in serum, kidney, adrenal gland, heart, lung, and skin were lower in the gT + aT10 group than in the gT group.

Experiment 4

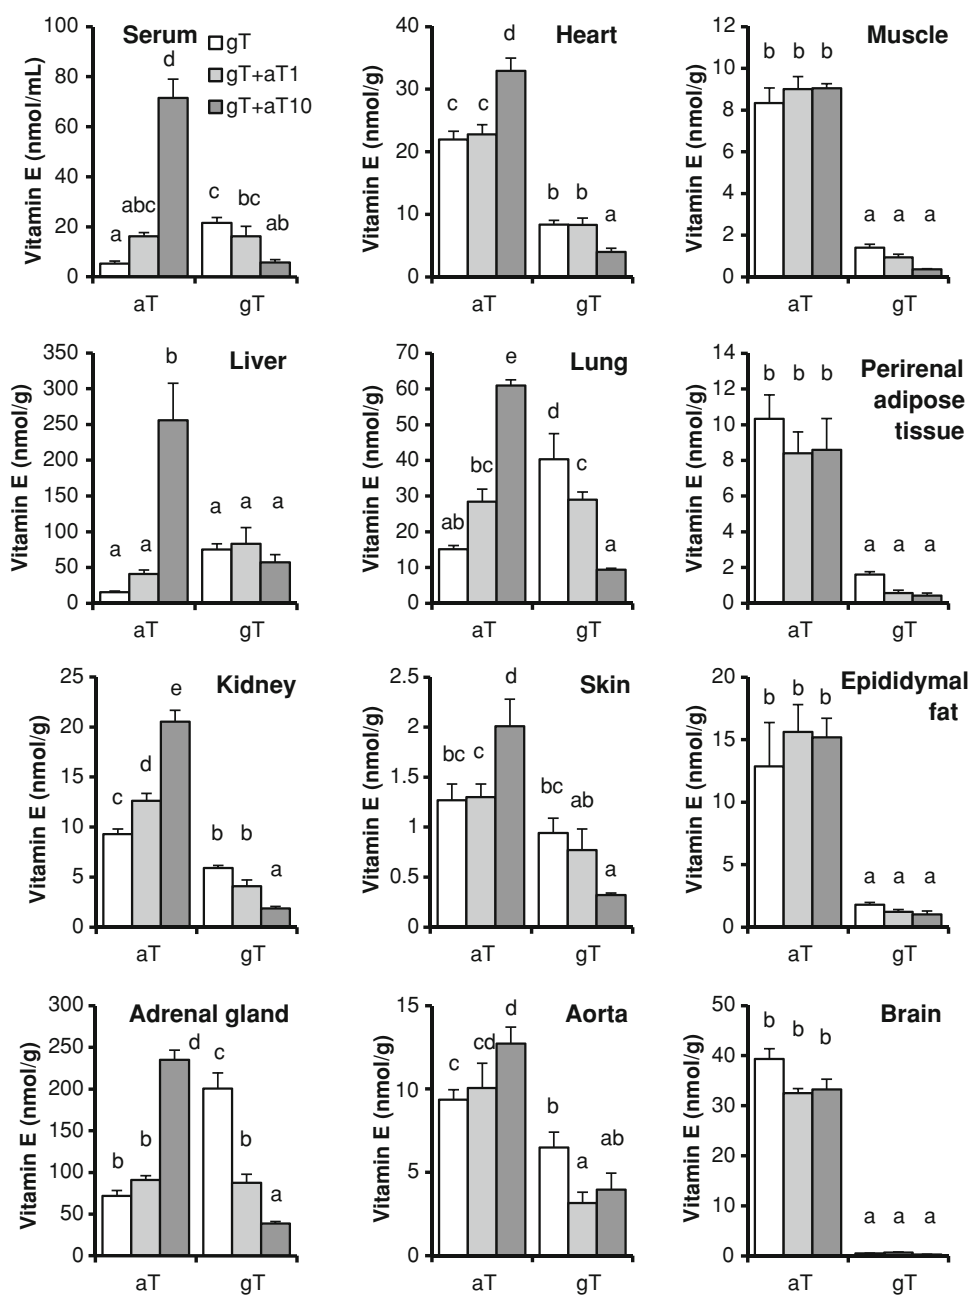

The body weight of rats after feeding on a diet containing α -tocopherol and α - and γ -tocotrienol for 6 weeks was 234.6 ± 4.6 g, and those at 0, 1, 2, 3, and 4 weeks after intake of vitamin E-free diet were 221.9 ± 4.7 , 242.8 ± 4.8 , 256.8 ± 4.6 , 272.5 ± 7.1 , and 291.2 ± 3.5 g, respectively.

The vitamin E-deficient periods did not affect liver and spleen weights (data not shown). α -Tocopherol and α - and γ -tocotrienol concentrations in perirenal adipose tissue were unchanged for 4 weeks, although α -tocopherol and α -tocotrienol concentrations in liver decreased over a period of 1–4 weeks (Fig. 6). γ -Tocotrienol was undetectable in liver at 4 weeks.

Discussion

We had previously found that dietary intake of tocotrienol for 8 weeks caused accumulation of a significant amount of

Fig. 5 Concentrations of α -tocopherol (aT) and γ -tocopherol (gT) in tissues and serum at 8 h after oral administration of 10 mg of γ -tocopherol (gT), 10 mg of γ -tocopherol with 1 mg of α -tocopherol (gT + aT1), or 10 mg of γ -tocopherol with 10 mg of α -tocopherol (gT + aT10), in experiment 3. Values are means \pm SEM; $n = 5$. Means not sharing a letter differ at $P < 0.05$

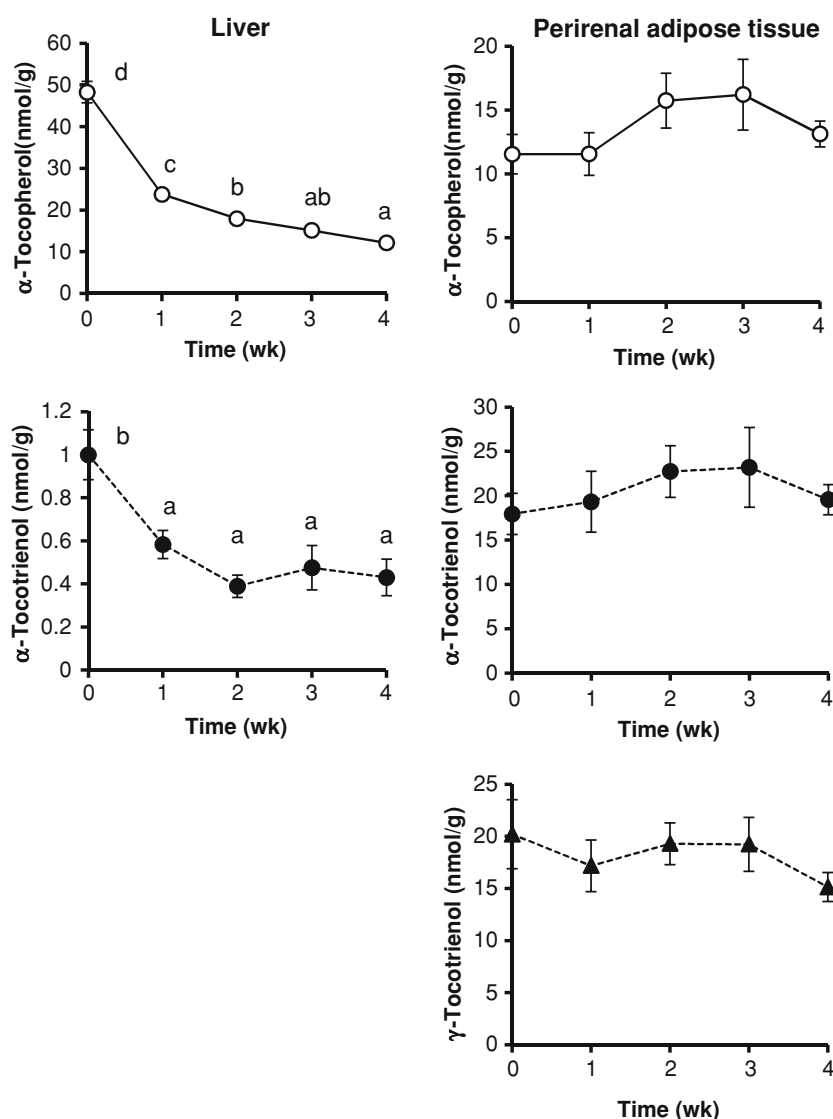

tocotrienol in adipose tissue [15, 19]. Dietary α -tocopherol decreased α -tocotrienol but not γ -tocotrienol concentration in liver, kidney, heart, lung, brain, muscle, perirenal adipose tissue, epididymal fat, skin, and plasma [19]. In the present study, we examined the effect of dietary α -tocopherol on α - and γ -tocotrienol and γ -tocopherol concentrations in the same tissues along with the thymus, testis, adrenal gland, spleen, and aorta of rats killed without food deprivation.

A considerable amount of α - and γ -tocotrienol accumulated in the perirenal adipose tissues and epididymal fat of rats fed a tocotrienol mixture (Fig. 1), as seen in the

previous study [19], whereas the γ -tocopherol concentrations were lower in the adipose tissues than in some tissues including adrenal gland, liver, and spleen of rats fed γ -tocopherol (Fig. 2). The α -tocopherol concentration was also lower in adipose tissue than those in the adrenal gland, liver, and spleen of rats fed α -tocopherol (Figs. 1, 2). The tissue-specific accumulation of tocotrienol is not explained by its affinity for α TTP because the affinity of α -tocotrienol for α TTP is nearly identical to that of γ -tocopherol—12.4 and 8.9% of the affinity of α -tocopherol, respectively [14]. Moreover, the α - and γ -tocotrienol concentrations were 9.4- and 36.4-fold higher, respectively, in the perirenal adipose

Fig. 6 Time-course changes of α -tocopherol and α - and γ -tocotrienol concentrations in liver and perirenal adipose tissue of rats fed vitamin E-free diet for 4 weeks in experiment 4. Rats were fed diet containing α -tocopherol and tocotrienol mixture for 6 weeks before intake of a vitamin E-free diet. γ -Tocotrienol was undetectable in the liver at 4 weeks. Values are means \pm SEM; $n = 8$. Means not sharing a letter differ at $P < 0.05$

tissue than in serum whereas the α - and γ -tocopherol concentrations were 0.9- and 1.7-fold higher. The data suggest that adipose tissue preferentially uptakes or stores tocotrienol compared with tocopherol.

To confirm the preferential uptake of tocotrienol into adipose tissue, the time-course change of the tocotrienol concentration for 24 h after tocotrienol administration by gavage was determined in experiment 2 (Fig. 3). Both tocopherol and tocotrienol quickly accumulated in the adrenal gland. However, tocopherol and tocotrienol slowly accumulated in skin, muscle, adipose tissues, and brain. α -Tocotrienol concentrations in these tissues at 8 h were <5 nmol/g. Moreover, γ -tocotrienol was undetectable in epididymal fat at 24 h after administration of the tocotrienol mixture. This suggests that tocotrienol accumulation in the adrenal gland in experiment 1 was caused by preferential uptake of tocotrienol, but that in adipose tissue was not.

Dietary α -tocopherol lowered α -tocotrienol and γ -tocopherol concentrations in the tissues of rats fed the tocotrienol mixture or γ -tocopherol (Figs. 1, 2). However, dietary α -tocopherol did not lower γ -tocotrienol concentrations in the tissues of rats fed the tocotrienol mixture (Fig. 1). Since the affinities of tocopherol and tocotrienol for α TTP in the liver are critical for their discrimination [14], the data indicate a possibility of liver-independent transport of dietary γ -tocotrienol into the various tissues. In experiment 3, the effect of α -tocopherol supplementation on the other tocopherol and tocotrienol concentrations at 8 h after oral administration of the isoforms to vitamin E-deficient rats were determined. α -Tocopherol supplementation inhibited α -tocotrienol and γ -tocopherol uptake to the various tissues (Figs. 4, 5). Both α -tocotrienol and γ -tocopherol concentrations in the adrenal gland and α -tocotrienol concentration in the perirenal adipose tissue were clearly lowered by simultaneous administration of

α -tocopherol. Surprisingly, α -tocopherol supplementation also inhibited γ -tocotrienol uptake to some peripheral tissues such as heart, skin, aorta, and perirenal adipose tissue, although those concentrations were low. Thus α -tocopherol inhibits uptake of not only α -tocotrienol and γ -tocopherol but also γ -tocotrienol to the peripheral tissues after their oral administration. The interference with the tissue accumulation of the other isoforms by α -tocopherol does not suggest a liver-independent transport of dietary γ -tocotrienol to the tissues but a similar transport mechanism to that of α -tocotrienol. It is likely that both α - and γ -tocotrienol along with tocopherol are transported to the tissues by liver-dependent transport mechanism.

Tissue accumulation of vitamin E results from flux, balance of its uptake, and efflux. We compared vitamin E decreases in liver and adipose tissue by vitamin E deficiency in experiment 4. Machlin et al. [21] reported that α -tocopherol depletion from adipose tissue was extremely slow in vitamin E-deficient guinea pigs, whereas α -tocopherol concentration in the liver decreased within 1 week. In the present study, α -tocopherol and α - and γ -tocotrienol concentrations in adipose tissue were unchanged at 4 weeks after the change from diet containing α -tocopherol and α - and γ -tocotrienol to vitamin E-free diet. In contrast, both α -tocopherol and α -tocotrienol concentrations in the liver decreased after 1 week. Therefore, adipose tissue is a unique site for body storage of not only tocopherol but also tocotrienol. These data indicate that vitamin E uptake to adipose tissue is slow (Fig. 3) but the vitamin E levels in adipose tissue are maintained without degradation for several weeks. We believe that maintenance of the vitamin E level without degradation causes adipose tissue-specific accumulation of dietary tocotrienol (Fig. 1). However, the reason for γ -tocotrienol accumulation without interference by α -tocopherol (Fig. 1), unlike in the study of oral administration of γ -tocotrienol (Fig. 4), remains unclear.

It was revealed that a significant amount of α -tocopherol accumulated in the adrenal gland. The adrenal α -tocopherol concentration was $>1 \mu\text{mol/g}$ in rats fed a diet containing 50 mg/kg of α -tocopherol for 7 weeks (Figs. 1, 2). Moreover, α -tocopherol quickly accumulated in the adrenal gland, and the concentration reached $>1 \mu\text{mol/g}$ at 24 h after α -tocopherol administration by gavage (Fig. 3). The adrenal gland has high steroidogenic activity, and the steroidogenesis involves cytochrome P450 (CYP)-dependent reactions, which are major sources of free radical formation. The tissue has high levels of not only α -tocopherol but also other antioxidants, ascorbic acid, and reduced glutathione and is resistant to prooxidant-induced damage [22]. Additionally, vitamin E deficiency reduces synthesis and secretion of corticosterone in rats [23]. These data suggest that antioxidants protect the adrenal gland from oxidative stress associated with steroidogenesis.

Rats have high levels of HDL, a major lipoprotein associated with α -tocopherol in the circulation. Recent studies suggest that the scavenger receptor class B type I (SR-BI), which mediates cellular uptake of cholesteryl ester from HDL, is also involved in α -tocopherol uptake in the brain [24, 25], lung [26], and its intestinal absorption [27]. In SR-BI-deficient mice, the α -tocopherol concentrations in some tissues including ovary, testis, lung, and brain decrease in contrast to increasing in plasma [28]. SR-BI might be involved in the preferential uptake of α -tocopherol in adipose tissue because SR-BI is highly expressed in the adrenal gland [29] and contributes to steroidogenesis.

Vitamin E catabolism is another important factor for its bioavailability. Tocopherol and tocotrienol undergo catabolism to phytyl short-chain carboxyethyl-hydroxychromans (CEHCs) such as 2,5,7,8-tetramethyl-2-(2'-carboxyethyl)-6-hydroxychroman (α -CEHC), a metabolite of α -tocopherol and α -tocotrienol, and 2,7,8-trimethyl-2-(2'-carboxyethyl)-6-hydroxychroman (γ -CEHC), a metabolite of γ -tocopherol and γ -tocotrienol [30–32]. The catabolic pathway involves ω -hydroxylation of the phytyl chain and subsequent β -oxidation [33]. The rate-limiting step is ω -hydroxylation of tocopherol and tocotrienol by CYP4F2 in humans [34, 35]. CEHC is then conjugated with glucuronate in humans or with sulfate in rats and subsequently excreted in the urine. Vitamin E metabolites are found in the liver, kidneys, small intestine, and serum of rats after oral administration of tocopherol or tocotrienol [36].

After oral administration of α - and γ -tocopherol, γ -tocopherol is rapidly catabolized to γ -CEHC whereas α -tocopherol is maintained in the plasma and little is metabolized to α -CEHC in humans [37]. In addition, tocotrienol is rapidly catabolized compared with tocopherol in human liver microsomes [35]. We found that ketoconazole, a potent CYP inhibitor, decreased urinary excretion of α - and γ -CEHC, and increased α - and γ -tocotrienol concentrations in various tissues of rats after oral administration of α - and γ -tocotrienol [38]. Ketoconazole also increased γ -tocopherol concentrations in rat tissues by inhibiting its catabolism to γ -CEHC, suggesting that CYP-dependent catabolism of vitamin E is a critical determinant of its bioavailability. Some reports indicate that α -tocopherol enhances γ -tocopherol catabolism to γ -CEHC [35, 36, 39]. In contrast, dietary α -tocopherol does not affect urinary excretion of γ -CEHC in rats fed a diet containing γ -tocotrienol for 8 weeks [19]. The minor effect of α -tocopherol on γ -tocotrienol catabolism might contribute towards γ -tocotrienol accumulation without interference by α -tocopherol (Fig. 1).

In the present study, we found high levels of α -tocotrienol in adipose tissue and adrenal gland, γ -tocotrienol in adipose tissue but not in the adrenal gland, and

γ -tocopherol not in adipose tissue but in adrenal gland of rats fed diet containing α - and γ -tocotrienol and γ -tocopherol. After oral administration, tocotrienol slowly accumulated in adipose tissue compared with in other tissues including adrenal gland. The α - and γ -tocotrienol uptake to some peripheral tissues including adipose tissue was clearly inhibited by α -tocopherol. Moreover, adipose tissue kept high vitamin E levels without degradation for several weeks in vitamin E-free rats, suggesting that the property of the adipose tissue as a vitamin E store causes adipose tissue-specific accumulation of dietary tocotrienol.

Acknowledgments This work was supported by KAKENHI (21700771, 22500782). We acknowledge generous donation of vitamin E isoforms and CEHC from Eisai Food & Chemical.

Abstract A sucrose-rich diet (SRD) induces insulin resistance and dyslipidemia with impaired hepatic glucose production and gluconeogenesis, accompanied by altered post-receptor insulin signaling steps. The aim of this study was to examine the effectiveness of fish oil (FO) to reverse or improve the impaired hepatic glucose metabolism once installed in rats fed 8 months a SRD. In the liver of rats fed SRD in which FO replaced corn-oil during the last 2 months, as dietary fat, several key enzyme activities and metabolites involved in glucose metabolisms (phosphorylation, glycolysis, gluconeogenesis and oxidative and non oxidative glucose pathway) were measured. The protein mass levels of IRS-1 and α p85 PI-3K at basal conditions were also analyzed. FO improved the altered activities of some enzymes involved in the glycolytic and oxidative pathways observed in the liver of SRD fed rats but was unable to restore the impaired capacity of glucose phosphorylation. Moreover, FO reversed the increase in PEPCK and G-6-Pase and reduced the G-6-Pase/GK ratio. Glycogen concentration and GSa activity returned to levels similar to those observed in the liver of the control-fed rats. Besides, FO did not modify the altered protein mass levels of IRS-1 and α p85 PI-3K. Finally, dietary FO was effective in reversing or improving the impaired activities of several key enzymes of hepatic carbohydrate metabolism contributing, at least in part, to the normalization of plasma glucose levels in the SRD-fed rats. However, these positive effects of FO were not observed under basal conditions in the early steps of insulin signaling transduction.

Introduction

The liver plays a central role in the regulation of glucose metabolism and maintenance of blood glucose homeostasis by regulating glycogen storage and breakdown and gluconeogenesis. It is well known that alterations in the composition of dietary macronutrients (e.g. carbohydrates, lipids, etc.) could deeply and rapidly modify the hepatic glucose metabolism in rats and humans [1–4]. In this regard, several studies have observed reduced insulin suppression of glucose production and hepatic gluconeogenesis, increased capacity for gluconeogenesis, reduced protein mass levels of Glut2 (isolated hepatocytes) and high TAG contents in the liver of rats fed a high sucrose/fructose diet for 1–8 weeks [1, 5–7]. Moreover, sucrose induced the impairment of hepatic insulin action involving multiple post-receptor insulin signaling steps such as tyrosine phosphorylation of insulin receptor substrate proteins-1 and 2 (IRS-1, IRS-2), interaction of phosphoinositide kinase (PI-3K) with IRS protein and phosphorylation of Akt [8]. Recent studies have suggested that the c-jun N terminal kinase (JNK) may also contribute to fructose induced antagonist of insulin signaling in liver [9].

On the other hand, animal studies have demonstrated that the quality of dietary fat is as important as its quantity to induce or prevent insulin resistance [10]. There is accumulated evidence of the beneficial role of n-3 long chain fatty acids (20:5 n-3, 22:6 n-3 PUFA) contained in dietary fish oil on animal and human health, especially concerning their protecting role against the adverse symptoms of the metabolic syndrome [11–13]. It has been shown that dietary fish oil prevents the onset of insulin resistance and dyslipidemia, hepatic steatosis as well as impaired glucose tolerance in rats fed a high-fat or high-sucrose diet [13–15]. However, few studies have analyzed the capacity of dietary fish oil to reverse insulin resistance once installed in rats after a long-term (6 months) feeding of a sucrose-rich diet (SRD). Using this experimental model we have previously demonstrated that partial changes in the dietary fat composition—from corn oil (18% total energy) to fish oil (cod liver oil 16% plus corn oil 2% of total energy)—lead to a normalization of the preexisting state of dyslipidemia, altered glucose homeostasis, whole body peripheral insulin insensitivity and visceral adiposity without detectable changes in plasma insulin levels [11, 16, 17]. However, a study by Podolin et al. [18] found that when the sucrose-rich diet containing a lower amount of menhaden oil (6% total energy) was given to insulin-resistant rats, the insulin action on the glucose metabolism remained impaired. The amount, duration and fatty acid composition of supplemented n-3 PUFA could also contribute to this discrepancy.

N-3 PUFA regulate the expression of a number of genes involved in lipid and carbohydrate metabolism by modulating the activity or expression of several transcription factors [19]. In the liver of rats fed a SRD during 8 months, Hein et al. [20] have recently demonstrated a decrease in the protein mass expression of liver X receptor α (LXR α) while enhancing peroxisome proliferators activated receptor α (PPAR α) after shifting the source of dietary fat from corn oil to fish oil during the last 2 months of the experimental period. This was accompanied by a decrease in the activities of hepatic enzymes involved in “de novo” lipogenesis, stimulating fatty acid oxidation and therefore decreasing liver steatosis, hyperlipidemia and normalizing the whole body peripheral insulin resistance produced by the SRD. Among the effects of n-3 PUFA on liver carbohydrate metabolism, Liimatta et al. [21] demonstrated that n-3 PUFA decrease liver pyruvate kinase activity while Jump et al. [22] showed that they suppress mRNA encoding glucokinase. Recently, it was shown that a carbohydrate response element binding protein (ChREBP) is a pivotal transcription factor implicated in the reciprocal regulation of lipogenesis and glycolysis by glucose and n-3 PUFA [23].

To our knowledge, no studies have been reported focusing on the possible beneficial effect of dietary n-3 PUFA to improve/reverse the impaired hepatic glucose metabolism and insulin insensitivity in rats fed a SRD for a long time in which a well-established dyslipidemia and insulin resistance was present at 6 months of diet before the source of dietary fat was partially replaced by fish oil during the following 2 months (6–8 months). Therefore, the aim of this study was to analyze the effect of fish oil on: (i) the enzyme activities and metabolites involved in glucose metabolisms (phosphorylation, glycolysis, gluconeogenesis and oxidative and non oxidative glucose disposal pathways); and (ii) the protein mass levels on the early proximal insulin signaling steps: insulin receptor substrate-1 (IRS-1) and the subunit α p85 of phosphoinositol-3 kinase (PI-3K) in the liver of rats chronically fed a SRD under the experimental conditions described above.

Materials and Methods

Animals and Diets

Male Wistar rats initially weighing 180–190 g and purchased from the National Institute of Pharmacology (Buenos Aires, Argentina) were maintained under controlled environmental conditions (temperature 22 ± 1 °C; humidity and air flow condition; 12-h light/dark cycle, light-on 0700 to 1900). After 1-week period of acclimation, the rats were randomly divided into two groups (control

and experimental). The sucrose-rich diet (SRD) group ($n = 72$) received a purified high-sucrose diet containing by weight, 62.5% sucrose, and 8% corn oil (CO). The control group ($n = 36$) received the same semisynthetic diet, but sucrose was replaced by cornstarch (62.5%) [high starch diet (CD)]. The SRD group was fed the diet for 6 months, after which the rats were randomly subdivided into two subgroups. The rats of the first subgroup continued on the SRD up to month 8 of feeding. The second subgroup (SRD + FO) received the SRD in which the source of fat (CO 8 g/100 g) had been replaced by FO (7 g/100 g of cod liver oil, ICN Biomedical, Costa Mesa, CA, plus 1 g/100 g of CO) from month 6 to 8 (Table 1). The control group received the CD during 8 months. The SRD without the addition of FO used for the 2 last months and the CD were balanced for cholesterol and vitamins D and A, present in the FO. Dietary fats were analyzed by capillary GC as previously described [24]. The fatty acid composition of the different fat sources is shown in Table 2. Diets were isoenergetic, providing approximately 16.3 kJ/g of food and were available ad libitum as previously described [20]. The weight of each rat was recorded twice each week over 8 months. In a separate experiment, the individual energy intakes and weight gains of eight rats in each group and subgroup were assessed twice each week. At the end of the 8-month dietary period, experiments were performed before 10:00 h. Rats were anesthetized with intraperitoneal pentobarbital sodium (60 mg/kg of body weight). Blood and liver samples were obtained as previously described [20]. The experimental protocol was approved by the

Human and Animal Research Committee of the School of Biochemistry, University of Litoral, Santa Fe, Argentina.

Analytical Methods

Plasma triacylglycerols (TAG), cholesterol (C) free fatty acids (FFA) and glucose levels were measured by spectrophotometric methods as previously described [25, 26]. The immunoreactive insulin assays were calibrated against a rat insulin standard (Novo Nordisk, Copenhagen, Denmark) as previously described [25, 26]. Homogenates of frozen liver powder were used for the determination of TAG, glycogen, glucose-6-P and fructose-2,6-bisphosphate by standard spectrophotometric methods as previously described [25]. Fructose-1-P was assayed by the method of Eggleston L [27].

Enzymes Activity Assays

Hepatic glucokinase (GK) (EC 2.7.1.2) and hexokinase (HK) (EC 2.7.1.1) activities were assayed in homogenates of frozen liver by the spectrophotometric method described by Barzilai and Rossetti [28]. Glucose-6-Phosphate phosphatase (G-6-Pase) (EC 3.1.3.9) activity was assayed by the method described by Harper [29]. The rate of reaction was measured by the increase in inorganic phosphate with time according to the method of Fiske and Subbarow [30]. The extraction of phosphoenolpyruvate carboxykinase (PEPCK) (EC 4.1.1.32) was performed according to Blakely et al. [31], and the determination of PEPCK

activity according to Petrescu et al. [32]. Pyruvate kinase (PK) (EC 2.7.1.40) activity was assayed in homogenates of fresh liver according to Osterman et al. [33]. Glycogen synthase (GSa) (EC 2.4.1.11) activity was determined and the fractional velocity of GSa was calculated as previously described in detail [9]. The extraction and determination of pyruvate dehydrogenase (PDHc) (EC 1.2.4.1) activity from liver tissue has been previously described in detail [34].

Western Blot Analysis of Liver Protein Mass Levels of Insulin Receptor Substrate-1 (IRS-1), α p85 Subunit of Phosphoinositide-3 kinase (PI-3K), Glucokinase (GK) and Hexokinase (HK)

Animals were killed before 10:00 h. To minimize differences in time being euthanized between treatments, three rats were chosen randomly in the three different dietary groups and were killed simultaneously. Frozen liver powder (100 mg) was homogenized and centrifuged at 16,000g for 20 min to remove insoluble materials [2] for IRS-1 and α p85

PI-3K. Liver homogenates were prepared as described by Zhang et al. [35] for GK and HK protein mass levels analysis. Total protein samples were resolved on SDS-PAGE and transferred to PVDF membranes. For immunoblotting, the membranes were probed with specified antibodies (rabbit polyclonal antibody anti-IRS-1, anti- α p85, anti-GK or polyclonal goat antibody anti-HK, from Santa Cruz Biotechnology, Inc., Santa Cruz, CA). The blots were then incubated with horseradish peroxidase-linked secondary antibody followed by chemiluminescence detection according to the manufacturer's instructions (Super Signal West Pico chemiluminescence detection, Pierce Biotechnology, Rockford, IL). The protein levels were normalized to β actin. The intensity of the bands was quantified by NIH imaging software. The relationship between the amount of sample subjected to immunoblotting and the signal intensity observed was linear under the conditions described above.

Statistical Analysis

Sample sizes were calculated on the basis of measurements previously made in our laboratory with rats fed either a CD or a SRD [16, 20, 34], considering an 80% power. Results were expressed as means \pm SEM. Statistical comparisons were done transversely between different dietary groups. The statistical significance between groups was determined by one-way ANOVA, with one factor (diet) followed by the inspection of all differences between pairs of means by the Newman–Keuls test [36]. Differences having *p* values lower than 0.05 were considered to be statistically significant. In all cases the interclass correlation coefficients were at least 0.73.

Results

Body-Weight Gain, Energy Intake, Plasma Metabolites and Insulin Levels

Energy intake and body weight were carefully monitored in all groups of rats throughout the experimental period. As we have previously shown [17, 20] a significant increase (*p* < 0.05) in body weight and energy intake occurred in rats fed a SRD for 6 months compared with rats fed a CD (Table 3). These differences in body weight and energy intake were still present in the SRD group when the diet was extended till month 8 of feeding. The presence of FO did not modify the body weight of the SRD-fed rats. However, in spite of a similar energy intake between the SRD and SRD + FO fed rats at month 8, the weight gain was moderately decreased in the latter group (Table 3). The daily individual intake of fatty acids in the three dietary groups was as follows (mean \pm SEM, *n* = 8): monounsaturated: CD:

0.455 ± 0.016 g; SRD: 0.565 ± 0.028 g and SRD + FO: 0.743 ± 0.024 g; polyunsaturated: CD: 0.700 ± 0.024 g (0.77% of n-3); SRD: 0.869 ± 0.043 g (0.77% of n-3) and SRD + FO: 0.0466 ± 0.150 g (69.6% of n-3).

In agreement with previous publications [17, 20] plasma levels of TAG, FFA, C and glucose were higher in rats fed the SRD for 8 months compared with the age-matched controls fed a CD (Table 3). Similar values were obtained in rats fed a SRD for 6 months (data not shown). All the variables returned to control values in the SRD-fed rats in which FO replaced corn oil for the last 2 months of feeding. No statistically significant differences in plasma insulin levels were observed at the end of the experimental period among the three dietary groups. Under these experimental conditions, plasma insulin/glucose ratio showed a significant decrease $p < 0.05$ in the SRD fed group compared with both CD and SRD + FO (Table 3). Furthermore, the enhanced liver TAG

content in the SRD-fed rats decreased when the diet was switched to SRD + FO (Table 3).

Liver Enzymes Activities and Metabolites Concentration

Table 4 depicts the activities of GK and HK (enzymes involved in glucose phosphorylation); PK (glycolytic pathway); the active form of PDHc (PDHa)—as an estimation of glucose oxidation—the protein mass levels of GK and HK and the concentration of fructose-1-P and fructose-2,6-bisphosphate in the liver of the three dietary groups at the end of the experimental period.

SRD-fed rats showed a significant decrease ($p < 0.05$) of GK without changes in HK activities and their protein mass levels compared to the CD-fed rats. However, PK and the PDHa activities increased approximately 4 and

1.4-fold, respectively compared to those fed a CD. Besides, a twofold increase in fructose-1-P without changes in fructose-2,6-bisphosphate concentration was recorded in the SRD fed rats. Dietary fish oil did not modify the behavior of both HK and GK activities. The latter stayed similarly lower than those observed in the SRD fed rats. Interestingly, no statistically significant differences in the protein mass levels of GK and HK were observed in the liver of SRD + FO rats (Table 4).

On the other hand, under FO administration, the PK activity significantly decreased ($p < 0.05$) while both the activity of PDHa and fructose-1-P contents reached values similar to those recorded in the CD group. FO did not induce changes in fructose-2,6-bisphosphate levels.

Table 5 shows the activities of key enzymes related to glycogen synthesis, gluconeogenesis and glucose homeostasis and the concentration of glycogen and glucose-6-P in the liver of the three dietary groups. Glycogen synthase (GSa)—expressed as a percentage of the fractional activity—as well as glycogen levels were significantly increased in the SRD-fed rats. A reduction in both GSa activity and glycogen content was observed when the source of fat in the SRD (corn oil) was partially replaced by FO. However, while the glycogen content returned to values similar to those recorded in the CD group, the GSa activity was still significantly higher than that in the CD-fed rats. No changes in liver glucose-6-P concentration were observed among all dietary groups.

In addition, Table 5 depicts that the liver of the SRD-fed rats showed a significant increase in the activities of two enzymes involved in the gluconeogenesis pathway: PEPCK and G-6-Pase. Both enzyme activities reached values similar to those observed in the CD-fed rats in the group of rats fed a SRD + FO.

On the other hand, the terminal step of glucose release from the liver is a function of the activities of G-6-Pase and GK. The addition of FO that normalizes G-6-Pase activity was able to significantly decrease G-6-Pase/GK ratio. Values were as follows (means \pm SEM, $n = 6$) 13.45 ± 2.1 for CD, 27.24 ± 3.2 for SRD and 19.81 ± 2.3 for

SRD + FO; $p < 0.05$ CD vs SRD and SRD + FO; $p < 0.05$ SRD vs SRD + FO.

Protein Mass Levels of IRS-1 and α p85 PI-3K

The immunoblotting of liver tissue revealed a single 175 kDa band consistent with IRS-1 and 85 kDa bands for α p85 PI-3K. Each gel contained an equal number of samples from the CD, SRD and SRD + FO groups (Fig. 1a). After densitometry of immunoblots, both the IRS-1 and α p85 PI-3K of the CD group were normalized to 100% and the levels of IRS-1 and α p85 PI-3K from SRD and SRD + FO were expressed relative to this. The qualitative and quantitative analysis of the Western blot showed that the relative abundance of IRS-1 and α p85 PI-3K were significantly decreased ($p < 0.05$) in the liver of the SRD group when compared with rats fed a CD (Fig. 1b). The addition of FO to the diet of the SRD-fed rats did not induce any changes in either IRS-1 or α p85 PI-3K; values were similar to those recorded in the SRD-fed rats.

Discussion

The main purpose of this work was to explore whether dietary FO can improve or reverse the altered hepatic glucose metabolism and insulin resistance induced in rats by the chronic administration of a sucrose-rich diet, to investigate the key enzymatic steps and early proximal insulin signaling responsible for these changes. The new major findings in the present study are as follows: (i) The significant increase in PK and PDHa activities, key enzymes of the glycolytic and oxidative glucose pathways, as well as fructose-1-P level observed in the liver of the SRD-fed rats were significantly improved or normalized, reaching values similar to those of the CD-fed group in which FO replaced corn oil as a dietary fat during the last 2 months of the experimental period (8 months). However, FO was unable to restore the altered capacity of glucose phosphorylation (decreased GK activity) present in the

liver of the SRD-fed rats. (ii) FO was able to reverse the increased activities of PEPCK and G-6-Pase, enzymes involved in the gluconeogenesis pathway. FO significantly reduced the G-6-Pase/GK ratio, which led to decreased hepatic glucose output. In addition, increased glycogen concentration and GSa activity returned to levels similar to those recorded in the CD-fed rats. (iii) Dietary FO did not modify the altered protein mass levels of IRS-1 and the subunit of α p85 PI-3K.

Glucose release from hepatocytes is a function of the enzymatic activities of GK and G-6-Pase. The present work shows a decrease in GK and conversely, an increase in G-6-Pase activities in the SRD-fed rats. This could in part contribute to losing control of the hepatic glucose output. Interestingly, at that time, the reduction in the hepatic GK activity was not accompanied by changes in their protein mass level. Although we did not evaluate the GK translocation in the present study, Shin et al. [37] in ZDF-rats recently demonstrated a lack of GK translocation from the nucleus to the cytoplasm altered expression of the enzyme leading to an inadequate endogenous glucose production and glucose uptake. When FO replaced corn oil as a source of fat in the SRD, no further changes in the already decreased GK activity and protein mass level were observed. However, in mice fed 2–5% of n-3 PUFA in vivo and in vitro Dentin et al. [23] showed that hepatic GK gene expression is inhibited decreasing the amount of total GK protein content and activity. They observed that the suppressive effect of n-3 PUFA on the gene expression of GK and liver PK is caused by an alteration of ChREBP nuclear translocation. On the other hand, FO decreases the activity

and mRNA of G-6-Pase in rats fed a high-fat diet [38]. The present data shows that the increase in G-6-Pase activity in the liver of rats fed a SRD was significantly decreased when FO replaced corn oil in this diet. Therefore, although glucose phosphorylation is still impaired in the SRD + FO group, an inhibiting effect of FO on the G-6-Pase activity leading to a decreased G-6-Pase/GK ratio could improve the altered hepatic glucose homeostasis present in the SRD-fed rats.

Several studies showed that the hepatic disposal of a large amount of fructose increased the liver PK and PEPCK activities and expression as well as the PDHc activity [31, 39–41]. The current study in which rats were fed a SRD for an extended period (8 months) shows a substantial increase in PK, PEPCK and G-6-Pase activities that leads to an elevated hepatic glucose production. Moreover, the glucose oxidation estimated by PDHc activity as well as fructose-1-P concentration was also increased without changes in the fructose-2,6-bisphosphate level. No change in the latter metabolite was observed in sucrose-fed rats by Sommercorn et al. [42]. The present data shows that FO oil was able to normalize the hepatic fructose-1-P level, and decrease the PK activity thus decreasing the flux through pyruvate and in turn diminishing the PDHc activity that reached values similar to those of the CD-fed group. A decrease in both hepatic PK activity and gene expression was observed by Higuchi et al. [43] in mice fed dietary fish oil compared to those fed a lard diet. Dietary fish oil significantly decreased the PEPCK activity reaching values similar to those recorded in the CD fed group. Neschen et al. [44] showed that FO decreased PEPCK mRNA when

compared with safflower oil. On the other hand, FO significantly reduced the high plasma FFA levels measured in the SRD-fed rats, since fatty acids provide fuel for gluconeogenesis, thus a reduction in the hepatic availability of these metabolites could contribute, at least in part, to the normalization of this metabolic pathway.

On the other hand, we recently demonstrated [20] that under the same experimental conditions, FO was able to inhibit hepatic lipogenesis through the up regulation of PPAR α and down regulation of LXR α and normalized liver TAG content.

Gergely et al. [45] showed that fructose-1-P stimulates glycogen synthesis in normal rats intravenously injected with fructose. Moreover, fructose-1-P concentration inhibited glycogen phosphorylase and regulated glycogen accumulation when fructose delivery was increased [5]. Similarly, our results show an increase in glycogen synthase activity, and both glycogen and fructose-1-P contents in the liver of the SRD-fed rats. Dietary FO decreased all

these parameters which reached values similar to those of the CD group.

Hepatic changes in the early steps of insulin signaling transduction may play a role in the insulin resistance induced by high sucrose or fructose diet. Under basal conditions Bezerra et al. [2] reported no differences in IR and IRS-1 protein levels in both liver and muscle of rats fed a high fructose diet for a short time (4 weeks). However, after insulin stimulation, they demonstrated a significant reduction in tyrosine phosphorylation of IR and IRS-1 phosphorylation levels in both tissues. A reduction in IRS-1/PI-3kinase association was also observed in liver and muscle. Besides, in rats fed a high sucrose diet for 5 weeks, Wei et al. [9] showed that hepatic insulin resistance was mediated in part via activation of the JNK activity through changes in serine phosphorylation of IRS-1. Our present results extend those described by Bezerra et al. [2] since when the SRD was administered for 8 months instead of 4 weeks, a reduction in liver protein mass levels of IRS-1

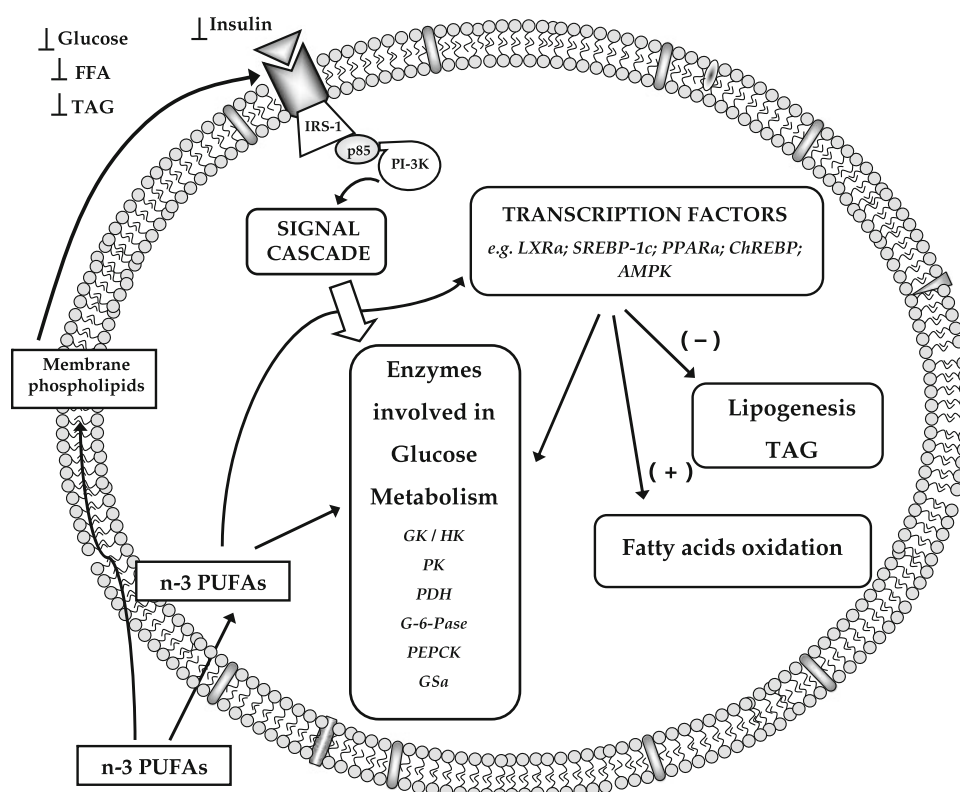

Fig. 2 Integrated effect of fish oil (FO) on liver glucose and lipid metabolism in the SRD-fed rats. FO regulates glucose and lipid metabolism through changes in the activity or abundance of different transcription factors families (e.g. PPARs, SREBPs, LXRs, ChREBP). In the SRD-fed rats FO enhanced hepatic fatty acid oxidation and decreased lipogenesis, leading to normalization of liver and plasma TAG levels, thus contributing to its hypolipemic effects. Several liver key enzymes activities and metabolites involved in

hepatic glucose metabolism were improved. FO reversed the increased activities of PEPCK and G-6-Pase and reduced the G-6-Pase/GK ratio which leads to reduce hepatic glucose output but was unable to restore the impaired capacity of glucose phosphorylation. FO restored glucose oxidation and GSa activity. Besides, FO did not modify protein mass levels of IRS-1 and α p85 PI-3K involved on the early steps of insulin signaling transduction. FO normalized glucose homeostasis without changes in circulating insulin levels

and α p85 PI-3K was observed just under basal conditions, without the stimulus of insulin. The replacement of corn oil by FO did not improve the decreased protein mass levels of IRS-1 and α p85 PI-3K. This was a particularly unexpected result, since FO normalizes both the altered plasma basal insulin/glucose ratio and hyperglycemia without changes in insulinemia. Moreover, as previously demonstrated [11], it reverts the low plasma adiponectin levels and insulin resistance (euglycemic–hyperinsulinemic clamp), thus normalizing whole body peripheral insulin sensitivity. Klimes et al. [46] showed no changes in insulin binding and autophosphorylation of the insulin receptor beta subunit under basal conditions and/or after insulin stimulation from the liver of rats fed a SRD or SRD plus FO diet for 3 weeks. However, FO improved insulin-stimulated tyrosine kinase activity and insulin action. On the other hand, a decrease in PI-3K activity in the liver and muscle with an increase in adipose tissue was observed by Corporeau et al. [47] in rats fed a low amount of FO into a normolipidic diet. Taouis et al. [14] showed that a high fat diet enriched in n-3 PUFA in rats maintained IR, IRS-1 tyrosine phosphorylation, PI-3K activity and total Glut4 in muscle but not in liver. Figure 2 depicts the effect of n-3 PUFA on liver glucose metabolism in the SRD fed rats.

Finally, dietary FO was effective in reversing or improving the impaired activities of several key enzymes of hepatic carbohydrate metabolism contributing at least in part to the normalization of plasma glucose levels in the experimental model of dyslipidemia and insulin resistance. FO reversed liver steatosis and dyslipidemia. However, these positive effects of FO were not observed under basal conditions in the early steps of insulin signaling transduction. Further studies are needed in order to clarify this matter.

Abstract Intake of fish and omega-3 (n-3) fatty acids is associated with a reduced concentration of plasma triacylglycerols (TAG) but the mechanisms are not fully clarified. Stearoyl-CoA desaturase-1 (SCD1) activity, governing TAG synthesis, is affected by n-3 fatty acids. Peripheral blood mononuclear cells (PBMC) display expression of genes involved in lipid metabolism. The aim of the present study was to estimate whether intake of lean

and fatty fish would influence n-3 fatty acids composition in plasma phospholipids (PL), serum TAG, 18:1n-9/18:0 ratio in plasma PL, as well as PBMC gene expression of SCD1 and fatty acid synthase (FAS). Healthy males and females ($n = 30$), aged 20–40, consumed either 150 g of cod, salmon, or potato (control) daily for 15 days. During intervention docosahexaenoic acid (DHA, 22:6n-3) increased in the cod group ($P < 0.05$), while TAG concentration decreased ($P < 0.05$). In the salmon group both eicosapentaenoic acid (EPA, 20:5n-3) and DHA increased ($P < 0.05$) whereas TAG concentration and the 18:1n-9/18:0 ratio decreased ($P < 0.05$). Reduction of the 18:1n-9/18:0 ratio was associated with a corresponding lowering of TAG ($P < 0.05$) and an increase in EPA and DHA ($P < 0.05$). The mRNA levels of SCD1 and FAS in PBMC were not significantly altered after intake of cod or salmon when compared with the control group. In conclusion, both lean and fatty fish may lower TAG, possibly by reducing the 18:1n-9/18:0 ratio related to allosteric inhibition of SCD1 activity, rather than by influencing the synthesis of enzyme protein.

Introduction

Numerous epidemiological studies have demonstrated a reduced risk of cardiovascular diseases (CVD) in response to an increased intake of fish or fish oils [1–3]. Especially fatty fish is a major source of long chain omega-3 polyunsaturated fatty acids (n-3 PUFA), such as eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). Many of the beneficial health effects of fish and fish oils have been linked to intake of these fatty acids [4–10]. Serum triacylglycerols (TAG) is recognized as an independent risk factor of CVD [11] and marine n-3 fatty acids in high doses (>3 g/day) have been shown to reduce serum TAG by 25–30% [12–15]. The magnitude of the TAG reducing effect seems to be dependent on n-3 fatty acid dose and baseline TAG concentrations [14, 16]. The American heart association (AHA) recommend the consumption of a variety of fish (preferably fatty fish) at least twice a week as guidance for healthy people [17]. However, intake of lean fish is also known to provide health benefits [18–20] in which one effect is reduced serum TAG [20]. Whether the health beneficial effects of lean fish are related to the n-3 fatty acids content, or to other bioactive components, is not known.

The molecular mechanisms involved in the hypotriglyceridemic effect of marine n-3 fatty acids have not been clarified. In general, the effects could be due to reduced production, and/or to increased elimination of TAG [2]. In the present work we have focused upon some aspects of the synthesis of TAG. In the fasted state serum TAG is mainly carried in very low density lipoproteins (VLDL), which are synthesized and secreted in the liver. TAG, cholesterol esters (CE) and phospholipids (PL) in VLDL preferably contain monounsaturated fatty acids, i.e., palmitoleic (16:1n-7) and oleic (18:1n-9) acid. The rate limiting enzyme for the synthesis of these fatty acids is stearoyl-CoA desaturase-1 (SCD1 or $\Delta 9$ desaturase). Mice lacking SCD1 have reduced hepatic lipogenesis and lower plasma TAG concentration [21, 22]. Accordingly, one mechanism

by which fish intake decreases serum TAG could be inhibition of desaturase activities in the liver, caused directly or indirectly by some of the constituents in fish. In general, the rate of an enzyme catalyzed reaction may be influenced by the amount of enzyme protein, by phosphorylation and dephosphorylation of the enzyme, or by allosteric regulation [23]. Oleic acid is a major constituent of TAG produced by de novo lipogenesis, and therefore the 18:1n-9/18:0 ratio, i.e., a product/precursor ratio, in plasma may be used to estimate SCD1 activity [22, 24–26]. Animal studies have demonstrated that marine n-3 fatty acids can suppress hepatic lipogenesis [4], and one regulatory mechanism may be inhibition of SCD1 activity [27] or by transcriptional regulation of sterol regulatory element-binding protein 1 (SREBP1) [28]. SREBP1 is regulating the expression of lipogenic genes such as SCD1 and fatty acid synthase (FAS) [28], and an inhibition of SREBP1 by n-3 fatty acids will cause a down-regulation of these genes [29]. To study whether n-3 fatty acids might influence human hepatic gene expression in vivo is challenging. However, since human PBMC can display the expression of genes involved in lipid metabolism [30–35] we have chosen PBMC as a test system.

The aim of the present exploratory study was accordingly to investigate whether daily intake of lean and fatty fish for 2 weeks would influence n-3 fatty acids composition in plasma PL, serum TAG levels, 18:1n-9/18:0 ratio in plasma PL (an estimated indication of SCD1 activity), and to assess SCD1 and FAS by their mRNA levels in PBMC, in healthy subjects.

Subjects and Methods

This study is an extension of a previous study involving 38 healthy subjects randomized to four different intervention groups consuming either salmon ($n = 11$), cod ($n = 9$), blue mussel ($n = 8$) or potato (control) ($n = 10$) in order to study arsenic metabolism (Molin et al., manuscript in preparation). The opportunity was taken to investigate lean versus fatty fish in this exploratory study ($n = 30$).

Subjects

Thirty subjects (7 men and 23 women) aged 20–40 were recruited from Akershus University College, Lillestrøm, Norway. Healthy subjects with C-reactive protein (CRP) <10 mg/L using no medication, except for oral contraceptives (female subjects ($n = 11$)), all subjects maintained the use throughout the study, except for one subject in the control group, were included in this study. Smoking, pregnancy and lactation were exclusion criteria. Additionally, subjects who had a habitual seafood consumption

of more than three servings per week were excluded. All subjects were compliant with the protocol throughout the study. Compliance was assessed based on observations of the participants during the test meals, served at the University College and the amount of leftovers after the experimental period. Compliance was estimated to be 95–100% in all three groups. The study protocol was approved by Regional Committee of Medical Ethics in Norway. Written informed consent for participation was obtained from each subject and it complied with the Declaration of Helsinki.

Study Design

A 15 days randomized controlled parallel-group study was conducted. The participants were randomized but not stratified by gender, and therefore by chance all the subjects in the salmon group were females. The subjects received a daily test meal of 150 g of either farmed salmon (*Salmo salar*) ($n = 11$), cod (*Gadus morhua*) ($n = 9$) or potato (control) ($n = 10$) for 15 consecutive days. The subjects were carefully instructed not to eat any seafood except the seafood provided in the study, and not to take any dietary supplements during the intervention period. Marine n-3 supplements (including cod liver oil) were prohibited 5 weeks prior to and during the study. Each subject was requested not to change dietary and exercise habits during the study.

Test Meals

A homogenous mixture of cod or salmon fillets was prepared as fish puddings and cut into cubes. Potatoes were cooked and cut into cubes. The test meal menu was a 7-day menu which was served hot and repeated twice and all the dishes were similar for all intervention groups except for the fish/potato. The test meal was served at Akershus University College Monday–Friday, and lunch boxes to bring home were provided for the weekend.

Blood Sampling and Biochemical Analysis

Blood samples were collected from fasting subjects (minimum 12 h) at the same time (between 8 a.m. and 10 a.m.) at baseline and at the end of the study. PBMC were isolated using cell preparation tubes (CPT) according to the manufacturer's instructions (Becton, Dickinson and Company, NJ 07417, USA). Determination of serum total cholesterol (total-C), HDL cholesterol (HDL-C), LDL cholesterol (LDL-C), TAG and CRP was performed using routine laboratory methods (Først Medical laboratory, Norway). Plasma was obtained from EDTA tubes and kept frozen (-70°C) until analysis.

Fatty Acid Composition in Fish

Homogenous mixture of cod or salmon fillets were kept frozen (-20°C) until analysis and total lipids were extracted by adding chloroform/methanol (2:1, vol/vol), and non-adeylic acid (19:0) was added as internal standard. The samples were filtered, saponified, and methylated using 12% BF_3 in methanol. Fatty acid composition of total lipids was analyzed using methods as described earlier [36, 37].

Fatty Acid Composition in Plasma PL

Fatty acid composition in plasma PL was determined as previously reported [38]. The 18:1n-9/18:0 ratio was calculated from the fatty acid composition in plasma PL and used as an estimate of desaturase activity.

RNA Isolation and Quantitative Real-Time Polymerase Chain Reaction (Q-RT-PCR)

Total RNA was extracted from PBMC using a combination of TRIzol Reagent (Invitrogen, Carlsbad, CA, USA) and RNeasy mini kit (Qiagen, Hilden, Germany) purified with RNase-free DNase (Invitrogen). Subsequently the samples were stored in RNase-free water at -80°C . RNA quality was measured on an Agilent Bioanalyser 2100 system (Agilent Technologies, Santa Clara, CA, USA) and showed RNA integrity numbers (RIN) between 8.7 and 9.8. Total RNA yield was measured on a Nanodrop ND-1000 Spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). For cDNA synthesis, 500 ng RNA of each total RNA sample was reverse-transcribed by Super Script (Invitrogen) according to the manufacturer's protocol, using oligo dT as primers. The Taqman real-time polymerase chain reaction (RT-PCR) technique was used to quantify the mRNA expression of each gene. cDNA corresponding to 15 ng RNA was applied to each well and each sample was run in triplets. Quantification was performed using the relative standard curve method. A combination of aliquots from all cDNA samples was made and diluted in order to make a dilution curve that was included on each plate. The points on the standard curve corresponded to 50, 25, 12.5 and 6.25 ng RNA. The average of the three values measured per gene per sample were divided by the average of the corresponding combined Glucuronidase-beta ($\text{GUS}\beta$) and TATA binding protein (TBP) values, generating a normalized value used to compare the relative amount for each gene in the different samples. $\text{GUS}\beta$ and TBP were chosen as endogenous genes due to the results from running a TaqMan Human Endogenous Control Plate-test from Applied Biosystems (data not shown). The primers and probes for $\text{GUS}\beta$ and TBP were initially designed as three assays per gene, and validated for efficiency and specificity. The best of the three was then

chosen. The primers and probe for the GUS β assay were: forward primer: 5'-GAAAATATGTGGTTGGAGAGCTC ATT-3', probe: 5'-CCAGCACTCTCGTCCGTGACTGTT CA-3' and reverse primer: 5'-CCGAGTGAAGATCCCC TTTT-3'. TBP forward primer: 5'-CTGGAAAAGTTG TATTAACAGGTGC-3', probe: 5'-AGCAGAAATTTATG AAGCATTGAAAACATCTACCCTATT-3' and reverse primer: 5'-CATTACGTCGTCTTCCTGAATC-3'. All other genes were measured by "single tube" assays, which are a premade combination of primers and probe, specific for the gene to be determined (Applied Biosystems, Foster City, CA) and utilized according to the manufacturer's protocol. SCD1 (Δ -9 desaturase): no. Hs01682761_m1 and FAS: no. Hs00188012_m1. RT-PCR was carried out on a 7900HT real time PCR machine from Applied Biosystems (Applied Biosystems, Foster City, CA, USA).

Statistical Analysis

Probability values (asymptotic) were considered statistically significant at a value of $P \leq 0.05$. Non-parametric tests were used due to the small sample size and values are given as median (25–75 percentile). Percent change is calculated from median values. Differences between the randomization groups were analysed at end of study (baseline adjusted values). Delta values refer to values at end of study minus baseline values for the plasma parameters, while gene expression delta values refer to values at end of study divided with baseline values (fold change). The present study is considered an exploratory study and therefore no adjustment for multiple testing was performed. Mann–Whitney U test and Wilcoxon matched-pair signed-rank test were used to either compare changes between groups or within-groups, respectively. Coefficients of correlation were calculated by the Spearman's rho test. The SPSS for Windows (version 18.0) was used for all statistical analyses.

Results

Baseline Characteristics

There were no significant differences in baseline characteristics between the study groups (Table 1).

Intake of n-3 Fatty Acids from the Intervention Meals

Daily intake of EPA and DHA provided from the seafood lunch meal were 1.4 and 1.7 g/day in the salmon group while the total daily n-3 fatty acids intake was 5.4 g (Table 2). Corresponding intake were 0.048 and 0.086 g/day in the cod group with a total n-3 intake of 0.15 g/day. The potatoes did not contain any marine n-3 fatty acids, but

total intake of n-3 fatty acids (α -linolenic acid, 18:3n-3) was 0.14 g/day (Table 2).

Fatty Acid Profile in Plasma PL

Daily intake of 150 g fish for 15 days significantly increased the amount of total n-3 fatty acids (EPA and DHA) in plasma PL in both the cod ($P = 0.008$) and the salmon ($P < 0.001$) groups, compared to the control group (Table 3). DHA increased in the cod group ($P = 0.003$) while both EPA and DHA increased in the salmon group ($P < 0.001$ and $P = 0.001$, respectively), compared to the control group. The baseline values of EPA and DHA were not different between the groups, nor were any of the other fatty acids in the plasma PL.

Serum Concentration of TAG, Total-C, HDL-C and LDL-C

As shown in Table 4, the serum concentration of TAG was significantly decreased both in the cod group ($P = 0.02$) and in the salmon group ($P = 0.003$) as compared with the control group. The reduction was significant within the cod ($P = 0.05$) and the salmon ($P = 0.008$) groups, corresponding to a reduction of 11 and 22%, respectively. No significant alteration in the TAG concentration was seen within the control group. Serum HDL-C was significantly increased after intake of salmon compared with the control group ($P = 0.009$), and the within-group increase was 5% ($P = 0.02$). Serum total-C and serum LDL-C was not changed between or within any of the groups (Table 4).

The change in both EPA and DHA in plasma PL correlated negatively with the change in TAG ($n = 30$) ($r = -0.5$, $P = 0.007$ and $r = -0.4$, $P = 0.04$, respectively) (Data not shown).

Effects on the 18:1n-9/18:0 Ratio in Plasma PL

As shown in Fig. 1, there was a significant reduction in the 18:1n-9/18:0 ratio in plasma PL in the salmon group compared with the control group ($P = 0.004$), and a significant within-group reduction after intake of cod ($P = 0.04$) and salmon ($P = 0.003$) for 2 weeks. In contrast, there was no significant within-group change in the control group during the experiment (Fig. 1).

Relationship Between Serum TAG, Marine n-3 Fatty Acids and the 18:1n-9/18:0 Ratio in Plasma PL

As illustrated in Fig. 2, there was a positive correlation ($r = 0.5$, $P = 0.01$) between change in the 18:1n-9/18:0 ratio and change in serum TAG ($n = 30$) (Fig. 2). Since previous studies suggest that SCD1 might be regulated by

EPA and DHA, we investigated whether the 18:1n-9/18:0 ratio was related to n-3 fatty acids in plasma PL. Indeed, as shown in Fig. 3, there was a highly significant negative correlation between the increase in marine n-3 fatty acids in plasma PL and reduction in the 18:1n-9/18:0 ratio (*n* = 30) (*r* = −0.7, *P* < 0.001).

Effects on mRNA Expression in PBMC

There was no significant change in mRNA level of the two selected lipogenesis related genes in the two intervention groups when compared to the control group (Fig. 4). However, mRNA level of FAS was significantly increased within the salmon group (*P* = 0.008) (Fig. 4).

Discussion

In this exploratory study in healthy subjects we found that a short term intake of both lean and fatty fish decreased serum TAG levels (Table 4) and the 18:1n-9/18:0 ratio in plasma PL (an estimated indication of SCD1 activity) (Fig. 1). The marine n-3 fatty acid DHA in plasma PL

increased significantly after intake of lean and fatty fish, while EPA increased only after fatty fish intake (Table 3).

Most studies have investigated health effects after intake of relatively high doses of n-3 fatty acids, often administered as supplements. In the present study n-3 fatty acids were provided as regular fish meals. The hypotriglyceridemic effect of fatty fish has been largely attributed to n-3 fatty acids, and our finding of a decrease in serum TAG in the salmon group is consistent with previous reports [12]. However, as shown in the present study also cod significantly reduced serum TAG. The main carriers of TAG in fasting plasma are VLDL, and in general the hypotriglyceridemic effect of fish could be related to reduced production, and/or to increased elimination of these lipoproteins. The present work focused only upon some aspects of TAG synthesis. TAG, CE and PL in VLDL preferably contain monounsaturated fatty acids, i.e., palmitoleic and oleic acid. Since SCD1 is the rate limiting enzyme for the synthesis of these fatty acids, one mechanism by which fish intake decreases serum TAG could be a reduced hepatic desaturase activity, caused directly or indirectly by some of the constituents in fish. Fish intake might influence the amount of SCD1 enzyme protein and

during the past decade, several human intervention studies have focused on diet-induced gene interactions using PBMC as a model system [33, 34, 39, 40]. From the present work it would appear that fish intake might not affect the amount of enzyme protein in PBMC, since there was no alteration in mRNA levels of SCD1 in response to fish intake. Even so, this observation does not rule out the possibility that fish/n-3 fatty acids intake affect the hepatic SCD1 mRNA levels, which have been reported by others [25, 41–45]. Human PBMC display the expression of genes involved in lipid metabolism [30–35, 46, 47] and recently we showed that n-3 fatty acids regulate lipid gene expression in ex vivo PBMC [48]. Human research has limitations in tissue availability except for blood samples which is readily and easily obtained. It has been shown that the expression of genes involved in lipid metabolism are

regulated in PBMC in a similar pattern as in liver upon fasting [33] and several dietary intervention studies have shown that expression of genes involved in lipid metabolism is altered in PBMC after intervention [34, 35, 46, 47]. This indicates that PBMC is a potentially good model system in dietary intervention studies to study genes related to lipid metabolism. However, liver cells and PBMC do have different biochemical properties and the use of PBMC as a model system of hepatic activity is at its very beginning and weaknesses with this model system may exist. It is also likely that due to the small sample size in the present study, type 2 errors are liable to occur and a false effect on gene expression cannot be ruled out. The increase in FAS mRNA in PBMC after intake of salmon in the present work (Fig. 4) is in contrast to previous observations from in vitro and mice studies where it has been shown that PUFA

suppress the hepatic expression of FAS [25, 28, 29, 49–51]. Even though the present mRNA level of FAS in the salmon group has two outliers, the within-group change is still significant (*P* = 0.02) when these are removed from the analysis. However, Knight et al. [52] showed that the gene expression of FAS and SCD1 was increased in mice liver injected with a synthetic activator of β -oxidation (a peroxisome-proliferator activated receptor alpha (PPAR α) agonist). Thus, discrepancy exists regarding the effect of PUFA in the hepatic regulation of lipogenesis.

Even though fish intake did not influence mRNA levels involved in synthesis of SCD1, the data seem to fit the hypothesis that n-3 fatty acids can reduce the activity of SCD1, indirectly estimated in the present study by the 18:1n-9/18:0 ratio, as has been previously reported by others [27]. However, this “desaturase index” approach is an indirect method to assess whether desaturases are inhibited, in lack of a more direct biochemical measure which is required to demonstrate an inhibiting effect.

Nevertheless, we suggest that fatty acids like EPA and DHA might serve as allosteric inhibitors. In support of this suggestion are the lowered 18:1n-9/18:0 ratio after intake of fatty fish (Fig. 1), the positive correlation between the 18:1n-9/18:0 ratio and serum TAG (Fig. 2), as well as the inverse relationship between the 18:1n-9/18:0 ratio and EPA and DHA (Fig. 3). It would appear that various fatty acids compete for being incorporated into PL. Although monounsaturated fatty acids seem to be the preferred ones for PL formation [53], both EPA and DHA can be incorporated into the same position in plasma PL. By mass action it is assumed that the level of plasma PL 18:1n-9 should decrease as the levels of EPA and DHA increase. Hence, other unsaturated fatty acids in plasma PL, in addition to EPA and DHA, should be inversely associated with the 18:1n-9/18:0 ratio. This is not the case in the present study. The change in linoleic acid (18:2n-6) is in fact positively associated with the change in the 18:1n-9/18:0 ratio ($r = 0.5$, $P = 0.003$), while the change in arachidonic acid (20:4n-6) shows no association at all. It is however hard to appreciate the magnitude of this possible mass effect, as compared with the other suggested explanations for obtaining reduced desaturase indexes after fish intake. Even though the intake of cod contributed to only 0.13 g of marine n-3 fatty acids per day, the level of DHA (but not EPA) in plasma PL in this group increased significantly compared to the control group (Table 3), and both the level of DHA and EPA in plasma PL correlated positively with the treatment effect on TAG ($n = 30$) (data not shown). The n-3 fatty acids in cod are largely incorporated into PL, in contrast to fatty fish which mainly have the fatty acids incorporated in TAG in adipose tissue. We recently demonstrated that the bioavailability of n-3 fatty acids from krill oil (also mainly incorporated into PL [54]) is more efficient than n-3 fatty acids from fish oil (TAG) [55]. This may partly be the reason why we find positive health effects (reduced TAG

concentration) also after cod intake, despite low levels of n-3 in cod. Previously, DHA has been demonstrated to have similar TAG-lowering effects as EPA [56–58] and the increase in DHA observed in the cod group in the present study may at least partly explain the reduction in serum TAG.

Also other bioactive molecules in fish, like taurine, have been suggested to have TAG reducing effects [59]. Yanagita et al. [59] found that when HepG2 cells were stimulated with taurine, there was a reduction in TAG in both cells and medium. They also found that taurine reduced the incorporation of [^{14}C]-labelled oleic acid into cellular TAG, suggesting the inhibition of TAG synthesis. Or there may be a synergistic effect of taurine and marine n-3 fatty acids which have the reducing effect on TAG [18]. Since our data suggest that also lean fish may reduce serum TAG, it would appear that the TAG lowering effect of lean fish is relevant to reduce CVD risk, thus supporting a previous study by Leaf and Hatcher [20]. In addition to increased TAG levels being a risk factor of CVD, HDL-C levels correlate inversely with cardiovascular risk [60]. In the present study HDL-C levels are increased after intervention with fatty fish (Table 4), which is in line with a previous report [61]. There is a well-known inverse relationship between plasma TAG levels and HDL-C [62], and this may be the reason why salmon intake might increase HDL-C. However, there is a discrepancy in the n-3 fatty acids effect on HDL-C as reviewed by Harris [13].

In conclusion, both lean and fatty fish can increase the level of marine n-3 fatty acids in plasma PL, and reduce the serum TAG levels in healthy subjects after short term intervention. The hypotriglyceridemic action of dietary marine n-3 fatty acids can be related to a reduced 18:1n-9/18:0 ratio in plasma PL, but whether gene expression in PBMC is influenced is not clarified. Our results would seem to fit the hypothesis that components in both lean and

fatty fish may lower serum TAG possibly by reducing the 18:1n-9/18:0 ratio related to allosteric inhibition of SCD1 activity, rather than by influencing the synthesis of enzyme protein.

Acknowledgments We are grateful to all the participants who made this work possible. We are also grateful to researcher Mari C.W. Myhrstad for critically reading the manuscript. The study was supported by Akershus University College, Norwegian Research Council (grant number 176619/V00 and grant number 142468/140), The Norwegian Cancer Society (grant number 88309/010) and Eastern Norway Regional Health Authority RHF (grant number 2006094 and grant number 2007021). Abstract This study explores the potential use of stable carbon isotope ratios ($\delta^{13}\text{C}$) of single fatty acids (FA) as tracers for the transformation of FA from diet to milk, with focus on the metabolic origin of *c9,t11*-18:2. For this purpose, dairy cows were fed diets based exclusively on C_3 and C_4 plants. The FA in milk and feed were fractionated by silver-ion thin-layer chromatography and analyzed for their $\delta^{13}\text{C}$ values. Mean $\delta^{13}\text{C}$ values of FA from C_3 milk were lower compared to those from C_4 milk (-30.1‰ vs. -24.9‰ , respectively). In both groups the most negative $\delta^{13}\text{C}$ values of all FA analyzed were measured for *c9,t11*-18:2 (C_3 milk = $-37.0 \pm 2.7\text{‰}$; C_4 milk $-31.4 \pm 1.4\text{‰}$). Compared to the dietary precursors 18:2n-6 and 18:3n-3, no significant ^{13}C -depletion was measured in *t11*-18:1. This suggests that the $\delta^{13}\text{C}$ -change in *c9,t11*-18:2 did not originate from the microbial biohydrogenation in the rumen, but most probably from endogenous desaturation of *t11*-18:1. It appears that the natural $\delta^{13}\text{C}$ differences in some dietary FA are at least partly preserved in milk FA. Therefore, carbon isotope analyses of individual FA could

be useful for studying metabolic transformation processes in ruminants.

Introduction

Diet formulation for dairy cows is the most efficient tool to enhance milk quality strategically in terms of lipid composition. However, a substantial amount of FA not present in the diet is formed by microbial activity in the rumen during passage of the lipids through the digestive tract. Maintaining the delicate balance of intact transfer of desired FA to the milk and its enrichment with favorable primary or secondary products of ruminal biohydrogenation is an important issue of research in ruminant nutrition [1]. For humans ruminant-derived foods are the major source of conjugated linoleic acids (CLA) [2, 3], a group of

positional and geometric isomers of octadecadienoic acid with conjugated double bonds [4]. *Cis*-9, *trans*-11 octadecadienoic acid (*c9,t11*-18:2; ruminic acid) is the main isomer in ruminants and represents up to 90% of total CLA in cow's milk [5] but its concentration depends on the diet. Especially this isomer is supposed to have anti-carcinogenic [6, 7], anti-atherogenic [8, 9], and anti-diabetic effects [10]. It therefore gained attention both in human [11] and animal nutrition research [12, 13].

The concentration of *c9,t11*-18:2 depends on the dietary proportions of linoleic acid (18:2n-6) and α -linolenic acid (18:3n-3) [14] as it occurs as an intermediate in the rumen during microbial biohydrogenation of these polyunsaturated FA (PUFA). During this process 18:2n-6 originating from the diet is first isomerized at the *cis*-12 double bond, producing *c9,t11*-18:2, which is then converted to vaccenic acid (*t11*-18:1) [4, 15]. Similarly, 18:3n-3 first undergoes an isomerization step to *c9,t11,c15*-18:3, which is followed by a hydrogenation of the *cis*-double bonds to *t11*-18:1 [4]. This intermediate of 18:3n-3 and 18:2n-6 biohydrogenation can endogenously be desaturated to *c9,t11*-18:2 by Δ^9 -desaturase in the tissue. It has been estimated that >60% of *c9,t11*-18:2 in milk fat originate from desaturation and the remaining <40% directly from microbial isomerization [4, 16]. Thus, the metabolic availability of *c9,t11*-18:2 in ruminants depends on (i) the extent of ruminal production of *c9,t11*-18:2 and *t11*-18:1, determined by nutritional factors and ruminal biohydrogenation processes [12, 14, 17], and (ii) the extent of endogenous desaturation of *t11*-18:1 to *c9,t11*-18:2 [16].

To be able to influence concentrations of *c9,t11*-18:2 strategically in ruminant-source foods it is necessary to know the proportions of this FA which originate from 18:2n-6 or 18:3n-3. This can be accomplished by using specifically labeled FA as metabolic tracers. DeNiro and Epstein [18] showed that the isotopic composition ($\delta^{13}\text{C}$ values in ‰ vs. Vienna Pee Dee Belemnite standard, VPDB) of the body of animals is determined by their diet, with a ^{13}C enrichment (trophic shift) of about 1‰. Therefore, stable isotope ratios of FA have been used before in animals when dealing with ecological [19–21], traceability [21–23], and metabolic research questions [24–26]. Using specifically labeled FA for oral administration in large animals is a very expensive approach, and artificial diet components may have to be used. Alternatively, the natural difference between feeds from C_3 and C_4 plants, differing in their stable carbon isotope composition might be utilized. This approach has been successfully applied in transfer studies in ruminants [27]. Molkentin et al. [27] reported ^{13}C -depleted organic milk as compared to conventional milk as a consequence of a wide exclusion of maize as a forage plant in this production system. The metabolism of C_4 plants like maize using the Hatch-Slack

cycle discriminates less against ^{13}C during photosynthetic fixation of atmospheric CO_2 ($\delta^{13}\text{C}$ of -16 to -9‰), while C_3 plants such as temperate climate grasses and cereals follow the Calvin-Benson cycle ($\delta^{13}\text{C}$ of -34 to -22‰) [28]. Since various feeds from C_3 and C_4 plants are available, a less expensive approach to evaluate the metabolic origin of FA in ruminant products could be developed on this basis. Indeed, differences in $\delta^{13}\text{C}$ values have been found between individual FA of various plant species [29–36]. For methyl branched FA, de novo synthesized by microorganisms, clear differences in the $\delta^{13}\text{C}$ values from those of straight-chain FA have been shown [26]. However, the rumen microbial influence on the isotopic composition of FA, which are only hydrogenated and isomerized in the rumen, is not yet documented.

In the present study we explore the possible use of naturally occurring differences in the C isotope composition of individual long-chain FA between C_3 and C_4 plant species to trace the digestive and metabolic fate of these FA in ruminants. This would offer an approach to quantify the relative contribution of diet components to the pools of long-chain FA used for tissue (meat) and milk synthesis. In particular, this study aims at evaluating changes in the $\delta^{13}\text{C}$ values between dietary 18:2n-6 or 18:3n-3 and *c9,t11*-18:2 in milk fat, which may originate from endogenous desaturation in the tissues and/or from microbial isomerization in the rumen. This should elucidate whether such an approach can give useful information for the description of *c9,t11*-18:2 synthesis pathways. The separation of FA groups by silver-ion thin-layer chromatography (Ag^+ -TLC) prior to compound-specific isotope analysis (CSIA) of individual FA with gas chromatography-combustion-stable isotope ratio mass spectrometry (GC/C/IRMS) could be a useful approach to trace transformations of dietary FA in ruminants digestion (biohydrogenation of PUFA) and endogenous processes (chain-elongation of dietary PUFA). Here we compare the stable C isotope composition of individual FA from two experimental diets based on C_3 and C_4 plants with those extracted from the milk of cows consuming these diets.

Materials and Methods

Animals and Diets

Two isoenergetic and isonitrogenous diets were designed and fed to dairy cows that were in mid to end of lactation and having a limited milk yield of on average 15 kg/day. In this stage of lactation cows were assumed to be in a steady or anabolic phase and to be not mobilizing body lipids. Six cows received a diet composed of feeds obtained only from C_3 plants. These included [g/kg dry matter (DM)] barley

straw (459 g/kg dry matter, DM), barley grain (266 g/kg DM), soybean meal (238 g/kg DM) and sugar beet molasses (21 g/kg DM). Another five animals received a diet composed exclusively of C₄ plant feeds, namely maize straw (444 g/kg DM), maize pellets (368 g/kg DM), maize gluten (151 g/kg DM) and sugar cane molasses (22 g/kg DM). Both diets were supplemented by minerals, vitamins and some urea. The C₃ and C₄ diets contained 18.6 and 36.0 g/kg DM total fat and were balanced in net energy for lactation (5.46 MJ/kg DM) and protein (217 and 211 g/kg DM, respectively). At the start of the experiment, the diet was changed stepwise within 6 days from hay ad libitum and 3 kg/day of barley grain to the experimental diets. Data and sample collection did not start before a further 14 days had passed, thus minimizing carry-over effects in C-isotope composition from the previous diet. Then feed intake and milk yield were measured daily, and milk samples were collected every morning and evening for another 8 days. These samples were pooled per cow. Feed samples were collected two times. The feed samples were homogenized and pulverized and stored in 150 mL PET flasks at room temperature until analysis. Milk fat was obtained by centrifugation of milk samples and stored in the dark at –20 °C. For analysis, milk fat samples were thawed at room temperature. The governmental veterinary authority for animal welfare approved the animal experiment. Further information about diets and other experimental details are given elsewhere [14, 24].

Lipid Extraction from Feed Samples

Aliquots of 2–3 g of each compound of the powdered feed samples (except molasses), were weighed in metallic extraction thimbles (Dionex Corporation, Sunnyvale, CA, USA). Lipids were extracted with hexane/isopropanol (3:2, v/v) over night by accelerated solvent extraction (ASE 200, Dionex Corporation, Sunnyvale, CA, USA) [37]. The solvent was then evaporated under a N₂ stream and residues were dissolved in dichloromethane. Evaporation under N₂-atmosphere was repeated and the lipid extract was saponified as described below.

Saponification of Lipid Extracts and Milk Fat, and FA Derivatization

The lipids in the samples were saponified with methanolic sodium hydroxide. For FA conversion, methanolic boron trifluoride was used according to IUPAC method 2.301 [38]. After boiling, approximately 100 mg of pure fat with 2 mL NaOH (0.5 M) for 3 min, 3 mL methanolic boron trifluoride (1.3 M) was added and the mixture was heated again for 4 min. The reaction was stopped by adding 7 mL NaCl (0.34 M) and 2 mL hexane. Subsequently, tubes were

shaken for 30 s and centrifuged at 1,100×g for 1 min. A 1 mL aliquot of the upper layer, containing the FA methyl esters (FAME), was cleaned (e.g., removal of dyes) in a solid phase extraction column filled with silica gel (Isolute, Biotage, Cardiff, UK). The FAME were eluted with 6 mL dichloromethane and stored in three 2-mL vials with a final total FA concentration of approximately 20 mg/mL.

Silver-Ion Thin-Layer Chromatography

The Ag⁺-TLC was used to separate saturated from mono- and from polyunsaturated FAME. This step was necessary to improve C18 FA (e.g., *cis*-18:1 and *trans*-18:1) separation in compound-specific C-isotope analysis. The Ag⁺-TLC was applied for all samples as described by Richter et al. [39]. The TLC silica gel glass plates (60F-254 glass plates, 20 × 20 cm, MERCK, Darmstadt Germany) were first conditioned in TLC tanks filled with chloroform/methanol (1:1, v/v). After impregnation with 10% AgNO₃ in acetonitrile, plates were dried at 110 °C and 500 µg FAME were applied as a narrow linear band in the lower part of the plate. The mobile phase contained toluene/hexane (1:1, v/v). After the mobile phase reached the area between the borders of silver-ion and stationary phase, plates were dried at room temperature for 1 h. Four FAME bands, representing PUFA, monounsaturated FA (MUFA), *trans* FA (TFA) and saturated FA (SFA) were visualized by spraying with 2,7-dichlorofluorescein in ethanol. Each band was detached by scraping and washed with 4 mL chloroform/methanol (9:1, v/v) into filtration tubes filled with sodium sulfate and fiberglass. Eluents were dried under nitrogen and residues were dissolved in 200 µL hexane and stored at +4 °C for further analyses.

FA Analysis by GC/MS and GC/FID

In advance of CSIA, GC/MS and GC/FID analyses were performed in order to identify and quantify the individual FA. The analysis of FA in feed and milk fat was performed in duplicate on a gas chromatograph (GC; Agilent 6890 Series GC-Systems, Wilmington, DE, USA) equipped with a 30 m × 320 µm × 0.25 µm Supelcowax-10 column (Sigma Aldrich, Bellefonte, PA, USA) and a flame ionization detector. Helium was used as carrier gas with a constant flow of 1.1 mL/min. Samples were injected at a temperature of 200 °C and a split of 10:1. The oven temperature program was 2 min at 150 °C, +5 °C/min up to 160 °C for 5 min, +10 °C/min up to 190 °C for 5 min and +3 °C/min up to 250 °C for 5 min and the total time was 42 min. Individual FAME were identified by comparison of retention times with those of a standard FAME mixture (Supelco 37 component FAME Mix, Inc., Bellefonte, PA,

USA), after characterization of the single FA by gas chromatograph–mass spectrometry (Thermo Fisher, Argenteuil, France) equipped with a Supelcowax-10 column (see above). Chromatograms were evaluated by using the HP ChemStation software (Hewlett Packard, Palo Alto, CA, USA).

Carbon Isotope Analyses of FA Using a Gas Chromatography-Combustion-Isotope Ratio Mass Spectrometer

The $\delta^{13}\text{C}$ values of individual FA were obtained by using an Agilent 6890 GC coupled to a Thermo Fisher (Bremen, Germany) Delta V isotope ratio mass spectrometer (IRMS) by a combustion (C) interface III (GC/C/IRMS) under a constant helium flow of 1.1 mL/min. The combustion interface consists of two ceramic furnaces: an oxidation reactor with CuO/NiO/Pt wires at 940 °C and a reduction reactor with Cu wires at 600 °C. Water was removed from the effluent gas by passing it through a Nafion tube (Perma Pure, Toms River, NJ, USA) with an annular back-flow of helium. The GC was operated with the same type of column (Supelco-Wax 10 column) and temperature program used for GC/FID analyses. The background subtraction and $\delta^{13}\text{C}$ values calculation were performed using the Thermo Fisher ISODAT 2.5 software. The standard deviations for repeatability ranged between 0.03 and 1.0‰ for the main FAME. The accuracy of the GC/C/IRMS analyses was checked every 10 analyses by injection of a 20:0 methyl ester isotope standard prepared by A. Schimmelman from the Biogeochemical Laboratories at Indiana University, USA. The isotopic shift due to the carbon introduced in the FA methylation was corrected by a mass balance equation [33]: $\delta^{13}\text{C}_{\text{FAME}} = f_{\text{FA}}\delta^{13}\text{C}_{\text{FA}} + f_{\text{MeOH}}\delta^{13}\text{C}_{\text{MeOH}}$ where $\delta^{13}\text{C}_{\text{FAME}}$, $\delta^{13}\text{C}_{\text{FA}}$ and $\delta^{13}\text{C}_{\text{MeOH}}$ are the C-isotope compositions of the FAME, the FA, and the methanol used for methylation of the FA, respectively, and f_{FA} and f_{MeOH} are the C-fractions in the FAME due to the alkanolic chain and methanol, respectively. Since *trans* 18:1 isomers elute close to each other, the $\delta^{13}\text{C}$ value reported as $\tau 11\text{-}18:1^*$ include isomers $\tau 9$, $\tau 10$, $\tau 11$ with $\tau 11$ being by far the most abundant (e.g., in the milk from C_3 fed cows $\tau 11\text{-}18:1 \sim 71.3\%$; in the milk from C_4 fed cows $\tau 11\text{-}18:1 \sim 81.2\%$) [14].

Statistical Evaluation

Isotopic values for total diets were calculated based on proportionate intakes of individual FA from the individual feeds [14]. To compare the stable C isotope composition of the diets at two different sample collection dates, a *t*-test was carried out on the individual FA of the diet components, but no significant differences (data not shown) between the sampling dates were found. The isotopic

values of the individual FA in the three C_3 feeds and the three C_4 feeds, as well as of the six and five milk samples were subjected to analysis of variance using the general linear model (GLM procedure; SAS software, version 9.1, SAS Institute Inc., Cary NC, USA), considering as effects individual FA and diet type and the interaction. Multiple comparisons among FA means in the feeds were performed using Tukey's method. Mean values of individual milk FA within one diet group were compared by the least significant difference test ($p < 0.05$).

Results

Carbon Isotopic Composition of the FA in the C_3 and C_4 Feeds

The carbon isotope composition measured in the FA of individual feeds and calculated for the total C_3 and C_4 diets are given in Table 1. All the FA $\delta^{13}\text{C}$ values in C_3 feeds (mean value: -32.3‰) were more negative ($p < 0.001$) than those in C_4 feeds (mean value: -23.4‰). In both diet types, the lower $\delta^{13}\text{C}$ values were measured in 18:0 and FA with <18 C-atoms compared to the unsaturated C18 fatty acids (Table 1). Within the groups of isotopically light FA, there was a further differentiation for 18:0, which had a more negative $\delta^{13}\text{C}$ than 16:0 and 16:1. No significant interaction between feed type and FA occurred for $\delta^{13}\text{C}$ values.

Carbon Isotopic Composition of FA in Cow's Milk

The mean $\delta^{13}\text{C}$ values of the main FA of milk samples from animals fed with C_3 or C_4 diets were lower compared to those of C_4 milk ($-30.1 \pm 4.4\text{‰}$ and $-24.9 \pm 3.8\text{‰}$, respectively; Table 2). Significant differences in $\delta^{13}\text{C}$ of most FA (except 14:1, 16:1, 17:1 and 18:3n-3) were observed between milk samples from C_3 and C_4 diets. Within a diet group, differences ($p < 0.001$) in $\delta^{13}\text{C}$ values between the main FA were found. In both groups the lowest $\delta^{13}\text{C}$ values were measured for $c9,\tau 11\text{-}18:2$ (C_3 milk = $-37.0 \pm 2.7\text{‰}$; C_4 milk = $-31.4 \pm 2.6\text{‰}$; Table 2). A trend was identified in the $\delta^{13}\text{C}$ values of C18 FA in C_3 milk. They were enriched in ^{13}C with increasing degree of desaturation ($18:0 < 18:1\text{n-}9$ and $\tau 11\text{-}18:1 < 18:2\text{n-}6 < 18:3\text{n-}3$), with the exception of $c9,\tau 11\text{-}18:2$ (Table 1). In C_4 milk, such enrichment was only observed for $\tau 11\text{-}18:1$ and 18:2n-6. The $\delta^{13}\text{C}$ values of 18:1n-9 and $\tau 11\text{-}18:1$ were not significantly different in both groups (C_3 milk: -31.8 ± 1.4 and $-30.6 \pm 2.6\text{‰}$, C_4 milk: -26.5 ± 2.1 and $-23.4 \pm 1.4\text{‰}$). Different results between groups were observed for 18:3n-3, which had lower $\delta^{13}\text{C}$ values than $\tau 11\text{-}18:1$ in C_4 milk but higher $\delta^{13}\text{C}$

Table 1 Means for stable carbon isotope composition in individual fatty acids from the diet ($\delta^{13}\text{C}$, ‰ VPDB)

* Proportions of the *trans* 18:1 isomers in %: milk from the C₃ diet: *t*9 = 14.9%, *t*10 = 13.8%, *t*11 = 71.3%; milk from the C₄ diet: *t*9 = 10.2%, *t*10 = 8.5%, *t*11 = 81.2% [14]

values in C₃ milk. There was an interaction between milk samples from different diet types and individual FA in $\delta^{13}\text{C}$ ($p = 0.002$).

Relationships of $\delta^{13}\text{C}$ Values of Individual FA Between Feed and Milk

The 16:0 was ^{13}C enriched in milk fat by 4.4‰ when fed the C₃ diet and by 1.6‰ with the C₄ diet relative to the plant 16:0 (Tables 1, 2; Fig. 1). Mean $\delta^{13}\text{C}$ values of milk 16:1 were similar to those of the C₄ diet, and 6‰ higher for the C₃ diet. The $\delta^{13}\text{C}$ values of 18:3n-3 and 18:0 in milk from C₃ fed cows were higher (-26.5 ± 1.5 and -34.6 ± 1.4 ‰, respectively) than for the FA of the calculated total C₃ diet (-30.5 and -36.8 ‰ respectively; Fig. 1). The $\delta^{13}\text{C}$ value of 18:2n-6 from C₃ diet and milk

samples were similar (-29.3 ± 3.7 ‰ and -29.4 ‰, respectively). For *c*9,*t*11-18:2 the value was much lower (-37.0 ± 2.7 ‰) than for its precursors 18:2n-6 (-29.4 ‰) and 18:3n-3 (-30.5 ‰) in the C₃ diet.

The $\delta^{13}\text{C}$ values for 18:3n-3 in the C₄ milk samples were up to 9‰ lower than those calculated by mass balance from the total C₄ diet (milk = -26.0 ± 5.5 ‰, diet = -17.2 ‰; Fig. 1). The isotopic composition of 18:0 in the milk (-26.6 ± 3.7 ‰) was similar to the calculated total C₄ diet (-26.3 ‰, Fig. 1), and for 18:2n-6 the $\delta^{13}\text{C}$ values of the milk samples (-22.4 ± 2.2 ‰) were always lower. The highest intake of 18:3n-3 and 18:2n-6 was from maize pellets, due to the comparatively higher total fat content. The isotopic value of *c*9,*t*11-18:2 (-31.4 ± 2.6 ‰) was much lower than for its precursors 18:2n-6 (-19.9 ‰) and 18:3n-3 (-17.2 ‰) in the C₄ diet.

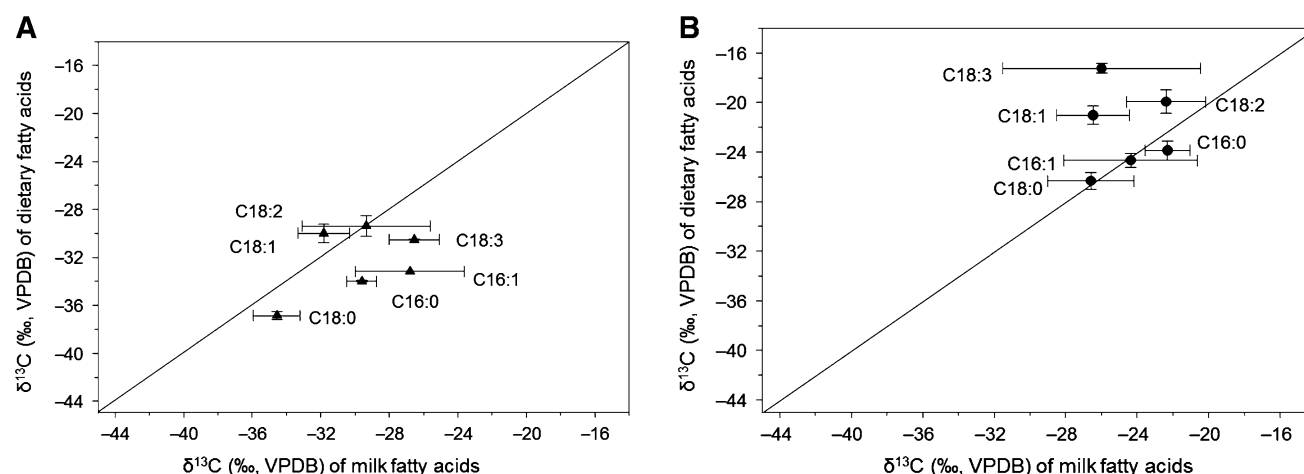

Fig. 1 Mean and standard deviation of $\delta^{13}\text{C}$ values (‰, VPDB) of individual fatty acids in the milk samples as opposed to those of the C_3 (a) and the C_4 diet (b). The isotopic composition of the total C_3 and C_4 diets were determined by mass balance calculations

Discussion

$\delta^{13}\text{C}$ Values of Individual FA in Feeds and Diets Derived from C_3 and C_4 Plants

Significant isotopic differences between (1) a specific FA in different plant species (e.g., C_3 versus C_4 plants), or (2) between FA of the same plant or (3) both are required to be able to trace transformations of FA in digestion and metabolism through natural stable C isotope compositions. A C isotope discrimination between C_3 and C_4 plants is well documented for total biomass [28] and for individual FA [29–31, 33–36, 40]. The $\delta^{13}\text{C}$ values measured in the experimental feeds for individual FA were in good agreement with these published values. The isotopic difference between 16:0 and 18:0 in the C_3 and C_4 feeds was 3.4 and 2.2‰, respectively. In both C_3 and C_4 feeds the unsaturated C18 fatty acids were depleted in ^{13}C on average by about 8‰ compared to 18:0. These differences are higher than those reported for pure vegetable oils [29–36].

Differentiation was not significant between 18:3n-3 and its precursor FA 18:1n-9 and 18:2n-6 with feeds from both C_3 and C_4 plants. In plants, 18:0 is used for the production of 18:1n-9, which is synthesized by Δ^9 -desaturase. The 18:1n-9 can then be desaturated to 18:2n-6 (via Δ^{12} -desaturase) at a different site of the plant cell and a further desaturation step produces 18:3n-3 (via Δ^{15} -desaturase). These biosynthetic pathways may explain the small variations found in the $\delta^{13}\text{C}$ values. However, the highest $\delta^{13}\text{C}$ values compared to the other C18 FA were observed in the 18:3n-3 extracted from maize gluten and pellets (made from maize grains), but not in the maize straw composed mainly of leaves and stem. This ^{13}C enrichment might have resulted from the preferential cleavage of ^{12}C – ^{12}C bonds over ^{12}C – ^{13}C bonds during oxidation [33] of 18:3n-3

triggered by the separation of gluten from corn, pellet preparation, and their storage. Such ^{13}C enrichment of 18:3n-3 compared to 18:0, 18:1n-9 and 18:2n-6 was recently reported for poppy oil [31].

$\delta^{13}\text{C}$ Values of Individual FA in Milk from Cows Fed C_3 and C_4 Diets

In the present study, the mobilization of adipose lipids for milk synthesis was considered to be negligible. Cows were in a stage of lactation and had a milk yield where energy intake can be easily covered by intake and cows typically even deposit FA in their adipose tissues. The differences measured in the isotopic composition between individual milk FA within diet groups therefore reflect initial differences in the diets, the isotopic fractionation during biosynthesis, and differences in rates of their metabolic turnover. FA in milk from ruminants originate either directly from the diet (plant FA such as 18:2n-6 or 18:3n-3), from microbial modification in the rumen (such as *trans* 18:1 isomers), from microbial synthesis in the rumen (odd- and branched-chain FA) or from de novo synthesis within the mammary gland (short-chain and medium-chain FA with 4–14 C atoms). The C16 FA can originate from both sources [41, 42], where the endogenous synthesis of 16:0 uses acetate from ruminal fermentation of carbohydrates as precursor. Even though the fat content of the C_3 total diet was lower than of the C_4 diet, in both groups of cows the 16:0 intake was similar [14]. However, the 16:0 concentration in the C_3 milk was higher [14], which suggests a higher endogenous synthesis. This is additionally supported by the ^{13}C enrichment, found in the C_3 milk fat for 16:0 and 16:1 relative to the dietary C16, which most probably reflects the isotopic composition of acetate, originating from ruminal degradation of the heavier

carbohydrates and being the endogenous precursor of C16. The bulk feed samples mainly consisted of carbohydrates and were isotopically heavier [24] than the individual fatty acids. Lipids are ^{13}C depleted relative to carbohydrates as a result of isotopic fractionation during biosynthesis [43]. The difference between the $\delta^{13}\text{C}$ values of 16:0 and 18:0 for C₃ and C₄ milk was $+5.0 \pm 1.4$ and $+4.3 \pm 1.6\text{‰}$, respectively. Apart from dietary origin, 18:0 may be produced by microbial biohydrogenation of unsaturated C18 FA being the terminal product of ruminal biohydrogenation [41]. The $\delta^{13}\text{C}$ values of 18:0 in milk from C₃- and C₄-fed cows were different by $+2.2$ and -0.3‰ , respectively, compared with those of the dietary 18:0. This may be explained by the trophic enrichment of ^{13}C and probably microbial activity. The 18:1n-9 in milk is derived to a large proportion from desaturation of 18:0 in the mammary gland. However, 18:1n-9 in milk of cows fed the C₃ diet was enriched in ^{13}C relative to 18:0 in the milk, as it was also observed in the diets, whereas no effect was found with the C₄ diet. With the C₃ diet, the isotopic difference between 18:0 and 18:1n-9 in milk was -2.7‰ compared to -6.8‰ in the diet. These observations suggest that feeding the C₃ diet (20% 18:1n-9) [14] either caused quantitatively more 18:1n-9 to be transferred directly from the feed or that an isotopic fractionation during the endogenous synthesis of 18:1n-9 with 18:0 as a precursor took place or both. Since no such fractionation took place with the C₄ diet (15% 18:1n-9) [14], the latter seems less likely.

Dietary polyunsaturated C18 FA undergo intensive modification during ruminal digestion [12, 15]. Important intermediates and end products of these processes are *c9,t11-18:2*, *t11-18:1* and 18:0 [4, 16]. Being essential, 18:2n-6 and 18:3n-3 may occur in the endogenous metabolism only as primary dietary FA. However, their $\delta^{13}\text{C}$ was not the same in feed and milk. In C₃ milk, 18:3n-3 was 4‰ enriched in ^{13}C compared to the total diet. This suggests a preferential biohydrogenation of the isotopically light 18:3n-3 molecules in the rumen followed by a transfer of the residual 18:3n-3, which is more enriched in ^{13}C to the milk. By contrast, the $\delta^{13}\text{C}$ value of 18:3n-3 in C₄-plant derived milk was much lower (about -9‰) compared to the corresponding diet. Further work is in progress to confirm these results and explain these apparently opposite isotopic trends of 18:3n-3 in milk from animals feed with C₃ or C₄ diets.

The *c9,t11-18:2* was depleted in ^{13}C in milk from both diet types, compared to all other milk FA. This would suggest an isotope fractionation occurring during the isomerization step in ruminal biohydrogenation. Microbial C isotope fractionation has been observed previously for the conversion of *cis-16:1* to *trans-16:1* by the bacterium *Pseudomonas putida*, with the *trans*-molecule being

depleted in ^{13}C by up to 2.1‰ [44]. However, in the milk of the present study, *t11-18:1* (with minor proportions of other 18:1 *trans* isomers) did not show a comparably large deviation in $\delta^{13}\text{C}$ values from the precursors 18:2n-6 and 18:3n-3 as that found with *c9,t11-18:2*. Since *t11-18:1* occurs after *c9,t11-18:2* in the biohydrogenation pathway, it seems unlikely that the isotopic difference measured for *c9,t11-18:2* was a consequence of the rumen microbial activity. Therefore, as *c9,t11-18:2* can also be produced in the body tissue from *t11-18:1* by Δ^9 -desaturase [4, 16], the enzyme catalyzing the endogenous desaturation might discriminate against ^{13}C . This could be explained by stronger chemical bonds of the heavier isotopologues ($^{12}\text{C}-^{13}\text{C}$, $^{13}\text{C}-^{13}\text{C}$) compared to $^{12}\text{C}-^{12}\text{C}$ followed by lower enzymatic rate constants [33]. Accordingly, Gilmore et al. [45] suggested that the variations in $\delta^{13}\text{C}$ values of individual FA in Arctic foxes could be attributed to isotopically distinct dietary sources and isotopic fractionation during desaturation and chain elongation. Also Fang et al. [46] assumed that a kinetic isotope effect, resulting in intermolecular isotope fractionation during desaturation and chain elongation, could be responsible for $\delta^{13}\text{C}$ differences in FA in seep organisms.

The significant interaction found between diet type and FA suggests that the differentiation in $\delta^{13}\text{C}$ values of individual FA in milk might depend on both, the diet type and the precursor FA. That implies that measurements of stable C-isotope ratios may be a useful approach to differentiate metabolic pathways of FA in ruminants if the dietary conditions are controlled.

Conclusion

By using GC/C/IRMS combined with Ag⁺-TLC we were able to demonstrate natural differences between $\delta^{13}\text{C}$ values of dietary FA and milk FA. The differences in the C₃ and C₄ diets were partly preserved in the cows' milk. In particular, *c9,t11-18:2* was depleted in ^{13}C compared to its dietary precursors. The study provided evidence that this was a result of the endogenous desaturation of *t11-18:1* to *c9,t11-18:2* in the body tissue rather than from rumen microbial biohydrogenation. These findings could be the basis for initiating more detailed stable isotope-based research in ruminant FA metabolism. Especially studies on various ruminant species and with different diet types are required to quantify by observing such fractionations the relative importance (species specificity, frequency, persistence) of precursors of milk FA.

Abstract In vitro batch incubations were used to study the rumen biohydrogenation of unsaturated fatty acids. An earlier study using increasing supplementation levels of stearidonic acid (18:4n-3), revealed that the rumen microbial population extensively biohydrogenates 18:4n-3 after 72 h of in vitro incubation, though several intermediates formed were not completely characterized. Therefore, in the present study, samples were reanalyzed in order to identify the 18:2, 18:3 and 18:4 biohydrogenation intermediates of 18:4n-3. Gas–liquid chromatography coupled to mass spectrometry was used to characterize these intermediates. The acetonitrile chemical ionization mass spectrometry of the fatty acid methyl esters derivatives enabled the discrimination of fatty acids as non-conjugated or conjugated biohydrogenation intermediates. In addition, the acetonitrile covalent adduct chemical ionization

tandem mass spectrometry yielded prominent ions indicative of the double bond position of the major 18:3 isomers, i.e. $\Delta 5,11,15$ 18:3. Furthermore, the 4,4-dimethyloxazoline derivatives prepared from the fatty acid methyl esters enabled the structure of novel 18:2, 18:3 and 18:4 biohydrogenation intermediates to be elucidated. The intermediates accumulated in the fermentation media after 72 h of incubation of 18:4n-3 suggest that similar to the biohydrogenation pathways of linoleic (18:2n-6) and α -linolenic (18:3n-3) acids, the pathway of the 18:4n-3 also proceeds with the formation of conjugated fatty acids followed by hydrogenation, although no conjugated dienes were found. The formation of the novel biohydrogenation intermediates of 18:4n-3 seems to follow an uncommon isomerization pattern with distinct double bond migrations.

Introduction

Stearidonic acid (SDA; 18:4n-3) is a polyunsaturated fatty acid (PUFA) that constitutes the first metabolite of α -linolenic acid (18:3n-3) in the metabolic pathway leading to the endogenous production of eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) [1]. An increased interest has emerged in the last few years on these long chain n-3 PUFA due to their benefits to human health [2, 3]. Recently it was suggested that 18:4n-3 itself may be a surrogate for 20:5n-3 for health promotion and disease prevention [4]. In dairy products, the potential of 18:4n-3 enriched soybean oil to increase the n-3 fatty acid content was demonstrated by Bernal-Santos et al. in rumen fistulated cows [5].

In ruminants, PUFA are biohydrogenated in the rumen, often resulting in the formation of *cis* and *trans* isomers, including conjugated isomers, *trans* monoenes or others intermediates. The biohydrogenation of PUFA by the rumen microbial population has been widely studied in vitro, mostly by using linoleic acid (18:2n-6), 18:3n-3, 20:5n-3, and 22:6n-3 as fatty acids or oil sources [6–11]. Recently, in vitro batch incubations were conducted to evaluate the biohydrogenation of 18:4n-3 by the rumen microbial population with increasing supplementation levels [12]. These in vitro incubations showed an extensive biohydrogenation of 18:4n-3. However, at high 18:4n-3 supplementation levels several 18:2, 18:3 and 18:4 biohydrogenation intermediates accumulated after 72 h of incubation. As far as we know, there are no reports on the characterization of the intermediates formed during the biohydrogenation of 18:4n-3. A more complete characterization of these intermediates is important to understand the overall biohydrogenation process and underlying mechanisms for their formation. The importance of disclosure all the detailed information on isomeric profile is linked to the current knowledge that slight structural differences can profoundly modify the biological action of these fatty acids [13].

Gas–liquid chromatography coupled to mass spectrometry (GLC–MS) has been widely used for the characterization of fatty acids, despite the location of the double bonds being particularly difficult. For this, several methods have been used, including covalent adduct chemical ionization tandem mass spectrometry (CACIMS/MS) of fatty acid methyl esters (FAME) derivatives [14, 15], and the

mass spectrometry analysis of others derivatives, such as 4,4-dimethyloxazoline (DMOX), picolinyl, and pyrrolidides [16–20]. The objective of this study was to determine the structure and composition of the novel biohydrogenation intermediates formed during in vitro incubations with 18:4n-3, and the effect of increasing supplementation levels on the pattern of biohydrogenation intermediates formed.

Materials and Methods

Chemicals

All reagents and solvents were analytical and chromatographic grade, and were obtained from Sigma-Aldrich (St. Louis, MO, USA). Ag⁺-ion SPE cartridges (750 mg/6 mL) and a mixture of FAME standards were purchased from Supelco Inc. (Bellefonte, PA, USA). A bacterial acid methyl esters mix was purchased from Matreya LLC (Pleasant Gap, PA, USA).

In Vitro Incubations

Samples from batch incubations were obtained from an experiment described elsewhere [12]. Briefly, Hungate tubes containing 4.5 mL buffered ruminal fluid, obtained from 3 adult cows, were supplemented with increasing levels of 18:4n-3 (pure free fatty acid from Sigma-Aldrich, St. Louis, MO, USA) and incubated at 39 °C for 72 h. Stearidonic acid was supplemented at 0 (control), 0.25, 0.50, 0.75, 1.00, 1.25, and 1.50 mg per 33 mg total mixed ration (TMR, dry matter (DM) basis). Each treatment was replicated in triplicate within the incubation. Reactions were stopped after 72 h by cooling in an ice-slurry, and tubes stored at –20 °C until analysis.

Preparation of Fatty Acid Methyl Esters

Lipids from in vitro incubations were extracted from freeze-dried whole fermentation media using a mixture of dichloromethane and methanol (2:1, by vol.) and FAME were prepared by a combined transesterification method, as described by Maia et al. [12]. In order to detect FAME co-elutions during GLC analysis, selected samples were fractionated into saturated, *trans*-18:1, *cis*-18:1, 18:2, 18:3 and 18:4 isomers by Ag⁺-SPE using hexane with increasing amounts of acetone, according to Kramer et al. [21].

Preparation of 4,4-Dimethyloxazoline Derivatives

4,4-Dimethyloxazoline derivatives were prepared from FAME by adding 0.5 μ L of 2-amino-2-methyl-1-propanol,

and left at 170 °C for 16 h under nitrogen. Once cooled, DMOX derivatives were extracted twice with a mixture of diethyl ether and hexane (1:1, by vol.) and rinsed with water. After drying over anhydrous sodium sulphate the solvent was evaporated under nitrogen at 34 °C and the residue dissolved in 1 mL of hexane (GC-grade).

Instrumentation

Quantification of FAME was determined using a gas chromatograph HP6890A (Hewlett-Packard, Avondale, PA, USA), equipped with a flame-ionization detector (GLC-FID) and a CP-Sil 88 capillary column (100 m; 0.25 mm i.d.; 0.20 µm film thickness; Chrompack, Varian Inc., Walnut Creek, CA, USA). The injector and detector temperatures were 250 and 280 °C, respectively. Initial oven temperature of 100 °C was held for 1 min, increased at 50 °C/min to 150 °C and held for 20 min, increased at 1 °C/min to 190 °C and held for 5 min, and then increased at 1 °C/min to 200 °C and held for 35 min. Helium was used as carrier gas at a flow rate of 1 mL/min, the split ratio was 1:10 and 1 µL of sample was injected.

Identification of C18 biohydrogenation intermediates of FAME and DMOX derivatives was achieved by GLC–MS analysis using an ion trap Varian Saturn 2200 system (Varian Inc., Walnut Creek, CA, USA) and the same capillary column and oven temperatures used in GLC-FID analysis. The ion trap parameters used in the present analyses are similar to those described in Alves and Bessa [22]. Identification of fatty acids was achieved by electron impact (EI) and chemical ionization (CI) mass

spectrometry, using acetonitrile as the reagent of CI. Additionally, the acetonitrile CACIMS/MS technique was used for location of the double bond position in some biohydrogenation intermediates.

Statistical Analysis

The effect of increasing 18:4n-3 supplementation levels on the concentration of the novel biohydrogenation intermediates after 72 h of incubation was analyzed by a single effect model using the GLM procedure of SAS (SAS Inst. Inc., 2002, Cary, NC). When a significant effect was observed the means were compared using the least square difference method.

Results

Identification of C18 FAME Derivatives by EI and CI Mass Spectrometry

Two partial GLC chromatograms of the C18 FAME region from ruminal in vitro incubations supplemented with 0 and 1.5 mg of 18:4n-3 per 33 mg of TMR DM are presented in Figs. 1 and 2. Both figures show that several 18:2, 18:3 and 18:4 fatty acids were produced during the incubation of 1.5 mg of 18:4n-3. The mass spectrometry analysis under EI or CI, of the C18 FAME intermediates allowed the recognition of the carbon chain length and number of double bonds in incubation samples. Electron impact mass spectra of homoallylic (methylene-interrupted) 18:3n-3,

18:4n-3 and of two novel biohydrogenation intermediates formed are presented in Fig. 3. There are small differences between 18:3 mass spectra, however no diagnostic ions were produced to clarify the position of the double bonds.

Similarly, there are no diagnostic ions in the EI mass spectrum of the novel 18:4 isomer (peak 34), although its mass spectrum is quite different from the mass spectrum of 18:4n-3. The ion at m/z 91 is presumably formed from the

Fig. 4 CACIMS spectrum of 18:3 and 18:4 isomers showing the base peak $[M + 54]^+$ and the common ions $[MH]^+$, $[MH - 32]^+$ and $[M + 54 - 32]^+$. Peak numbers correspond to peaks in Figs. 1 and 2

tropylium ion. The homologous series m/z 105, 119, 133, 147 are also probably tropylium ions with alkyl substituent [23].

The acetonitrile CI mass spectra also allowed the identification of the number of double bonds in C18 fatty acid intermediates. The product of acetonitrile self-reaction, generated under CACIMS conditions, reacts with the fatty acid double bond to yield molecular ions with 54 atomic mass units above the parent analyte. The $[M + 54]^+$ ions at m/z 346 and 344 for the 18:3 and 18:4 isomers, respectively, are shown in Fig. 4. The CACIMS also produce other ions, corresponding to the protonated molecule ($[MH]^+$), and losses of methanol from the protonated molecule ($[MH - 32]^+$) and from adduct ($[M + 54 - 32]^+$), at m/z 293, 261 and 314 for the 18:3 isomers and at m/z 291, 259 and 312 for the 18:4 isomers. The intensity ratios of $[M + 54]^+ / [M + 54 - 32]^+$ have previously been shown to be related to double bond geometry [14, 24, 25]. Table 1 shows the

CACIMS $[M + 54]^+ / [M + 54 - 32]^+$ ratios for the 18:2, 18:3 and 18:4 isomers. The non-conjugated 18:2 isomers showed ratios around 4.33 whereas the conjugated linoleic acid isomer (CLA) *cis*-9,*trans*-11 18:2 showed a ratio of 0.35. Similarly, the 18:3n-3 and others four isomers eluting before the 18:3n-3 showed ratios between 22.1 and 61.3, and other two 18:3 isomers eluting after 18:3n-3 showed ratios lower than 3. The 18:4n-3 showed a ratio of 61, whereas its isomers showed ratios between 3.25 and 4.79.

Identification of C18 DMOX Derivatives by EI Mass Spectrometry

The DMOX derivatives were prepared from FAME incubation samples in order to characterize the novel C18 biohydrogenation intermediates formed. Table 2 presents the characteristic ion fragments of DMOX derivatives of C18 biohydrogenation intermediates. The base peak in all

^a Peak numbers correspond to peaks in Figs. 1 and 2

* Unidentified 18:3 isomers

fatty acids was observed at m/z 126 formed by cyclization-displacement reaction. The abundant ion at m/z 113 is also a characteristic ion in DMOX derivatives and is produced by a McLafferty rearrangement.

Two of the five 18:2 biohydrogenation intermediates identified in incubation samples at high supplementation levels are novel intermediates and their EI mass spectra of DMOX derivatives (Fig. 5) showed the molecular ion at m/z 333. The even mass homologous series at m/z 126 + 14 amu is interrupted in the region of the double bond, with a gap of 12 amu. Although the mass spectra of both 18:2 peaks, showed a gap of 13 amu at m/z 140/153 and a gap of 12 amu at m/z 208/220 and 222/234, for peaks 9 and 11, respectively. The presence of odd-numbered ion at m/z 153 accompanied by the m/z 152, are diagnostic ions in the mass spectra of DMOX derivatives of fatty acids with their first double bond at carbon-5 [26, 27]. The published rules

for unsaturated fatty acids reveal the presence of intense peaks containing $n - 2$ and $n + 2$ carbon atoms, therefore the presence of the intense ion at m/z 208 in spectrum of peak 9 presumed a double bond at carbon-11. However, the 12 amu gap was observed between m/z 208 and 220, locating the double bond at carbon-10. The order of elution of either peaks 9 and 11 in GLC-FID presumed a *trans*,*-trans* configuration system.

Four novel 18:3 non-conjugated fatty acids were putatively identified by their DMOX mass spectra, showing all the molecular ion at m/z 331 (Fig. 6). Peaks 20 and 24 showed identical mass spectra, both having a prominent ion at m/z 262 (Fig. 6), which is characteristic of a *bis*-methylene interrupted double bond system, resulting in the formation of stabilized allylic radical fragments, and confirming the location of double bonds at carbons-11, 15 in either peaks 20 and 24. The third double bond was putatively identified at carbon-5 because a gap of 12 amu was observed between m/z 140 and 152. However, this does not match with the published rules for the presence of a double bond at carbon-5 and what was observed for the Δ 5,10 and Δ 5,11 dienes. The published rules for the DMOX derivatives with double bonds at C-4, C-5 and C-6, presume that the ions (i.e., m/z 138, 152 and 166, respectively) derived from cleavage at the double bond are accompanied by intense odd-numbered ions (i.e., m/z 139, 153 and 167, respectively). Nevertheless, as none of these intense odd ions were observed, peaks 20 and 24 were putatively characterized as Δ 5,11,15 18:3 having different *cis/trans* configurations. Seeing that peak 20 elutes before peak 24 in the CP-Sil88 capillary column, and taking in account the order of elution of geometric 18:3 isomers [28, 29], we assume that peak 20 might contain three *trans* double bonds and peak 24 might contain at least one *trans* double bond.

The mass spectrum of the DMOX derivatives of peaks 21 and 22 (Fig. 6) showed a gap of 12 amu between ions at m/z 140 and 152, similarly to what was observed for the Δ 5,11,15 18:3 isomers, suggesting that both peaks might have a double bond at carbon-5. Moreover, peak 21 contained ion fragments with mass interval of 12 amu at m/z 222/234 and 262/274 that were separated by gaps of 14 amu, which enabled the characterization of peak 21 as Δ 5,11,14 18:3. Additionally, the mass spectrum of peak 22 showed ion fragments with gaps of 12 amu at m/z 220/234 and 276/288, allowing the Δ 5,10,15 18:3 structure to be elucidated. On the other hand, the geometry of the double bonds of both Δ 5,11,14 and Δ 5,10,15 18:3 isomers could not be determined.

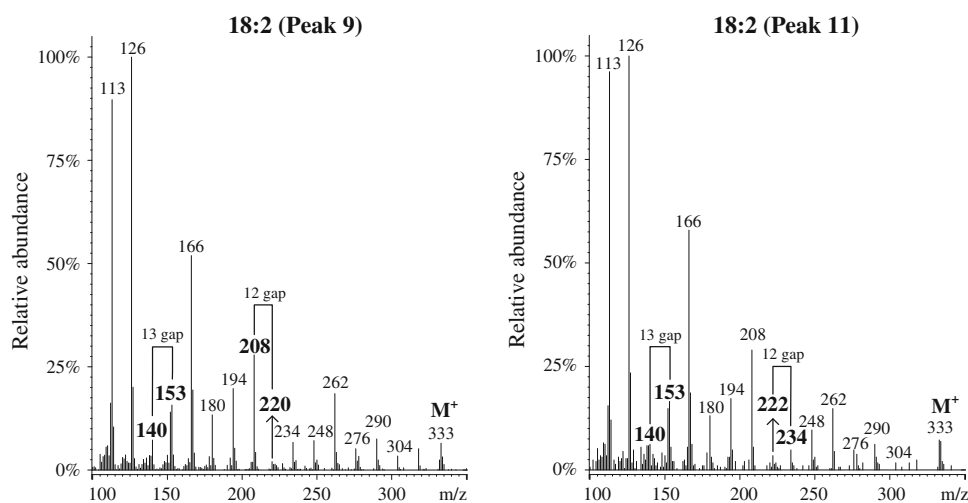

Four partially conjugated 18:4 isomers were identified in incubation samples at high supplementation levels of 18:4n-3. The mass spectra of DMOX derivatives of 18:4n-3 and peaks 28, 31 and 34 are presented in Fig. 6. The mass

Fig. 5 GLC–MS mass spectra of DMOX derivatives of 18:2 isomers

spectra of 18:4n-3 (peak 28) clearly shows the 12 amu gaps at *m/z* 194/206, 234/246 and 274/286 enabling the three end double bonds to be located at carbons-9, 12, 15. The first double bond was identified at carbon-6 by the presence of an intense odd ion at *m/z* 167 and the even ion at *m/z* 166, confirming the presence of the Δ 6,9,12,15 18:4 (18:4n-3).

In the mass spectrum of peak 31, an intense peak at *m/z* 260 characteristic of an ethylene interrupted double bond system together with gaps of 12 amu at *m/z* 220/232 and 274/286 enabled the location of two double bonds at

carbons-11, 15. The conjugated double bond was putatively identified at carbons-5, 7 by the gap of 12 amu at *m/z* 140/152 and 166/178. Thus, peak 31 was tentatively identified as Δ 5,7,11,15 18:4.

Three 18:4 peaks (33, 34 and 36) showing identical DMOX mass spectra were identified in the incubation samples, their mass spectra containing ion fragments with a mass interval of 12 amu at *m/z* 180/192, 206/218 and 274/286, which enabled the conjugated double bond to be located at carbons-8, 10 and a terminal double bond at carbon-15. The first double bond was putatively identified

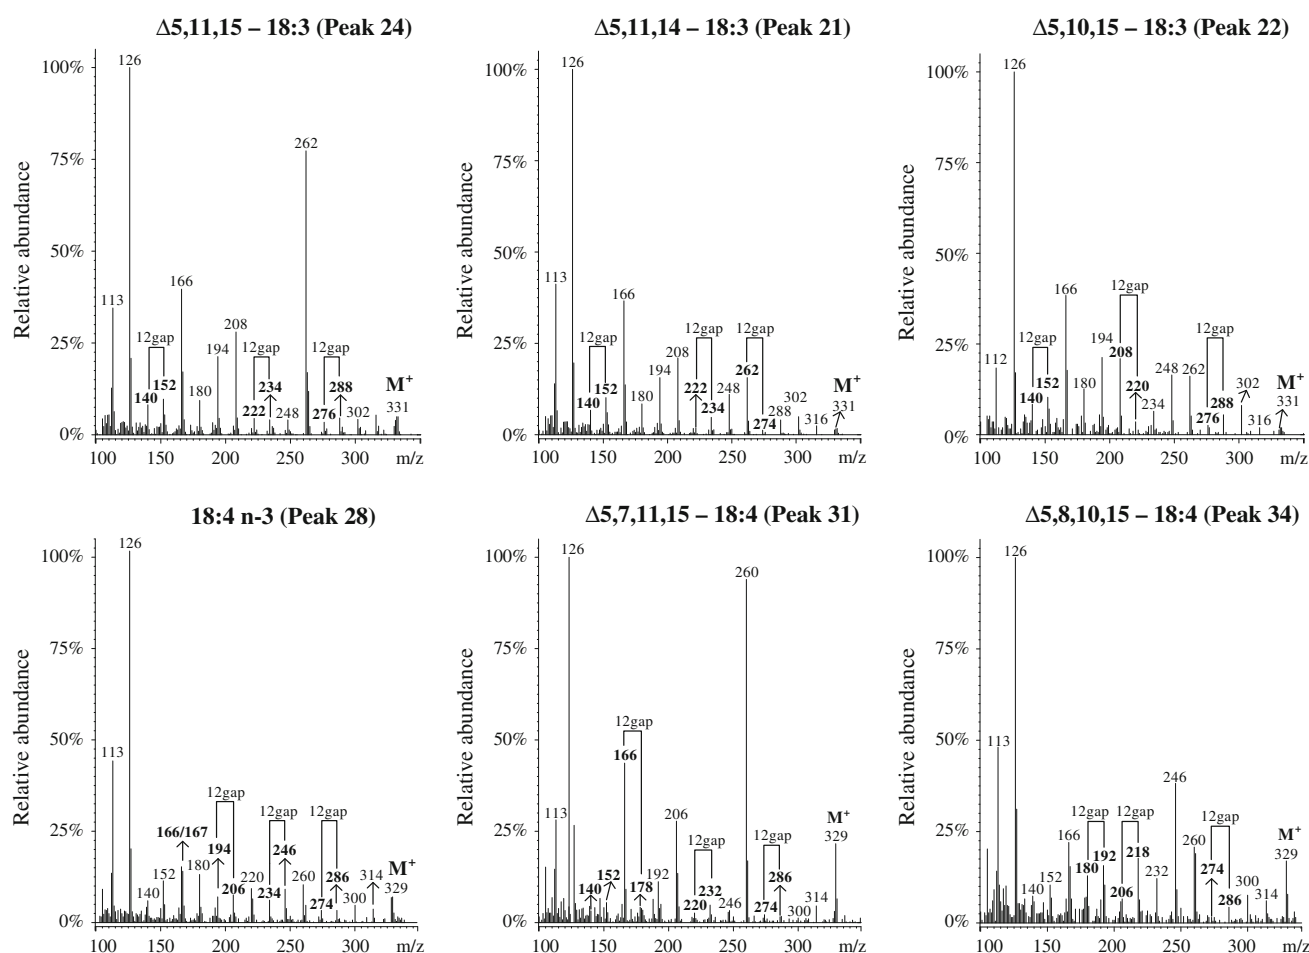

Fig. 6 GLC-MS mass spectra of DMOX derivatives of 18:3 and 18:4 isomers

at carbon-5 (Fig. 6) by the gap of 12 amu between ion fragments at m/z 140 and 152. Once more, no intense odd ions were observed accompanying the even ion at m/z 152 and 166.

Identification C18 FAME Derivatives by CACIMS/MS Mass Spectrometry

The CACIMS/MS technique was applied for the identification of the major 18:3 biohydrogenation intermediates. Peaks 20 and 24 showed identical CACIMS/MS mass spectra, peak 24 being obtained by collisionally activated dissociation of the $[M + 54]^+$ ion at m/z 346 (Fig. 7). The ion at m/z 318 corresponds to a cleavage between C16 and C17, indicating a double bond at carbon-15. The series of ions containing the carboxyl group at m/z 264, 276 and 290, and the end of the molecule at m/z 162, 176 and 190, indicates a double bond at carbon-11. Finally, the fragment at m/z 246 corresponds to a cleavage vinylic to the double bond between C4 and C5. These fragmentations allowed to establish the structures as $\Delta 5,11,15$ 18:3, however the

geometry could not be determined. The identification of the others minor 18:3 and 18:4 intermediates by CACIMS/MS was not successfully achieved, due to the low amount of these intermediates in samples or because mass spectra did not show prominent ions useful to establish the double bond.

Effect of 18:4n-3 Supplementation on C18 Biohydrogenation Intermediates

Table 3 shows the effect of increasing 18:4n-3 supplementation levels on 18:2, 18:3 and 18:4 biohydrogenation intermediates accumulated after 72 h of ruminal incubations. Supplementations at 0 and 0.25 mg of 18:4n-3 per 33 mg of TMR DM were not included because almost no novel biohydrogenation intermediates were detected at these levels. Increasing the 18:4n-3 supplementation level, increased the number of novel biohydrogenation intermediates formed. Indeed, the *trans*-5,*trans*-10 18:2, $\Delta 5,11,15$ 18:3, $\Delta 5,11,14$ 18:3, $\Delta 5,12,15$ 18:3 and $\Delta 5,7,11,15$ 18:4 accumulate from supplementation level of 1.0 mg onwards.

Fig. 7 CACIMS/MS spectra obtained upon collisionally deactivated dissociation of $[M + 54]^+$ ion for $\Delta 5,11,15$ 18:3 isomer

The 18:3 and 18:4 biohydrogenation intermediates that occurred at greater percentages were the $\Delta 5,11,15$ 18:3 (peak 24) and the $\Delta 5,8,10,15$ 18:4 (peak 34), reaching 64.4 and 66.9% of the total 18:3 and 18:4 fatty acids identified in 1.50 mg supplementation level, respectively.

Discussion

Recently, we reported that the supplementation of 18:4n-3 by the rumen microbial population *in vitro* promoted an accumulation of several unknown octadecapolyenoic biohydrogenation intermediates, though not completely characterized [12]. The present work reports the characterization of those C18 biohydrogenation intermediates.

The octadecapolyenoic intermediates comprised five 18:2, four 18:3, and four 18:4 fatty acids, which were almost undetected at supplementation level of 0.25 mg of 18:4n-3 per 33 mg of TMR DM. The electron impact and chemical ionization GLC–MS analysis of FAME were used for the identification of carbon chain length and number of double bonds. According to the literature, the location and geometry of double bonds in EI mass spectra of FAME cannot be accurately determined because positional and geometrical isomers show almost identical mass spectra.

Indeed, the double bond becomes mobile and moves up and down the chain under EI ionization, hence its original position cannot be reliably determined. This is mainly due to the high sensitivity of the carboxyl group to fragmentation and to double bond migration [30, 31]. Isomerization of double bonds during DMOX preparation was reported by some authors [32], therefore the identification of double bond position using DMOX derivatives should be used carefully. Thus, complementary methods that do not use chemical treatment of the sample such as CACIMS are preferred.

The acetonitrile CI mass spectra of FAME derivatives, apart from the recognition of carbon chain length and number of double bonds, allows a rapid recognition of the non-conjugated, partially conjugated and fully conjugated structure. The CACIMS $[M + 54]^+/[M + 54 - 32]^+$ ratios of non-conjugated fatty acids are substantially higher than the partially conjugated and fully conjugated ratios [14, 24, 25]. Lawrence and Brenna [24] reported that partially conjugated 18:3 isomers showed ratios around 2 whereas fully conjugated 18:2 and 18:3 isomers showed ratios lower than 1. Based on these rules, we could discriminate the novel 18:3 and 18:4 fatty acids as non-conjugated or partially conjugated structures. The GLC retention time in the cyanopropylpolysiloxane stationary phase can also be used to predict the conjugated structure seeing that FAME with conjugate double bonds have higher retention times compared with homologous non-conjugated FAME [33]. Indeed, the partially conjugated 18:4 isomers showed higher retention times than the homoallylic 18:4n-3. Conversely, the novel non-conjugated 18:3 isomers identified in incubated samples showed much lower retention times compared with the 18:3n-3.

The single stage MS analysis of FAME does not give information about the location of the double bond position. Although the MS/MS using acetonitrile, i.e., CACIMS/MS, has been successfully used for the identification of double bond position in a variety of fatty acids including methylene-interrupted [15, 34], conjugated and partially conjugated [14, 24], and long chain non-methylene interrupted highly unsaturated FAME [25]. Therefore, the CACIMS/MS technique was used to clarify the position of the double bonds of 18:3 and 18:4 isomers. However, only the major 18:3 biohydrogenation intermediates were successfully identified by CACIMS/MS. Nitrogen containing derivatives, like DMOX derivatives, have also been used for the location of double bond in a variety of fatty acids [16, 20, 35], these derivatives being only slightly less volatile than FAME and with comparable resolution. Indeed, during EI mass spectrometry the amide moiety carries the charge when the molecule is ionized preventing the double bond to become mobile and move up and down through the chain [23]. In the mass spectra of DMOX derivatives, a saturated

chain is indicated by regular gaps of 14 amu between ions, in unsaturated derivatives an interval of 12 amu between ions, corresponding to fragments containing $n - 1$ and n , identifies a double bond positioned between carbons n and $n + 1$ [27]. In addition, some exceptions can be found for double bonds closer to the carbonyl group. Several authors reported that odd numbered fragments at m/z 139, 153 and 167 accompanied by even mass ions at m/z 138, 152, and 166 are used to locate double bonds at C-4, C-5 and C-6, respectively [26, 27]. This rule was used for the identification of peaks 9 and 11 (Δ 5,10 and Δ 5,11, showing intense ions at m/z 152 and 153) and 18:4n-3 peak (*cis*-6,9,12,15, showing intense ions at m/z 166 and 167). However, it could not be applied for the identification of the others 18:3 and 18:4 biohydrogenation intermediates. The intense ion at m/z 180 in the DMOX mass spectra of peaks 20, 21, 22, 24, 31, 33, 34 and 36, suggests that a double bond exists at carbon-4, -5 or -6. However, a double bond at carbon-4 implies a reduction in the intensity of the ion at m/z 126, which was not observed. Therefore, as no odd ions at m/z 153 and 167 were observed, the gap of 12 amu rule was used to infer the double bond position at carbon-5 for the 18:3 isomers (Δ 5,11,15, Δ 5,11,14 and Δ 5,10,15) and 18:4 isomers (Δ 5,7,11,15 and Δ 5,8,10,15).

Although geometry of the double bonds could not be determined, at least one *trans* double bond should be present in the novel biohydrogenation intermediates, as two Δ 5,11,15-18:3 isomers and three Δ 5,8,10,15-18:4 isomers were identified from 1.00 mg 18:4n-3 level onwards. Considering the order of elution in the cyanopropylpolysiloxane stationary phase, we can expect that the two Δ 5,11,15-18:3 isomers might be the *trans*-5,*trans*-11,*trans*-15 and the *trans*-5,*trans*-11,*cis*-15. The tentative allocation of *cis* double bond position at carbon-15 was achieved by biological plausibility given that this isomer was the highest biohydrogenation intermediate accumulated in samples and because the *trans*-11,*cis*-15 double bond system is commonly found in ruminal C18 intermediates.

The biohydrogenation intermediates formed in 1.00, 1.25, and 1.50 mg supplementation levels, suggest that different patterns of isomerizations and hydrogenations had occurred. The 18:4n-3 biohydrogenation pathway in the rumen is still unknown, however, taking into account the recognized biohydrogenation pathways of 18:2n-6 and 18:3n-3 [36, 37], the results herein obtained suggest that the 18:4n-3 pathway also involves the formation of conjugated fatty acids and hydrogenation of double bonds. The

Fig. 8 Schematic representation of the double bonds migration from 18:3n-3 and 18:4n-3 into conjugated dienoic derivatives. The arrows do not imply proven biochemical conversions

main biohydrogenation pathway of 18:2n-6 in the rumen involves the formation of the conjugated diene *cis*-9,*trans*-11, followed by reductions to *trans*-11 18:1 and to 18:0. However, others pathways have been hypothesized because new intermediates have been reported to be formed during the 18:2n-6 metabolism in the rumen, like the CLA isomers $\Delta^{10,12}$, $\Delta^{11,13}$ and others $\Delta^{9,12}$ isomers with different *cis/trans* configurations [38, 39]. The main biohydrogenation pathway of 18:3n-3 in the rumen involves the formation of the partially conjugated *cis*-9,*trans*-11,*cis*-15 18:3, which is subsequently hydrogenated to the non-conjugated *trans*-11,*cis*-15 18:2 and further hydrogenated to 18:1 isomers and 18:0 [36]. However, several new 18:3 biohydrogenation intermediates have been identified [37, 40–43]. Very recently, rumen incubation of ^{13}C labelled 18:3n-3 was described to produce fourteen 18:3 isomers, 5 non-conjugated 18:2 isomers and 8 CLA isomers, indicating that 18:3n-3 biohydrogenation pathways are more complex than those previously reported [42]. Similarly, rumen biohydrogenation of 18:4n-3 might also produce 18:4 conjugated isomers, which is supported by the tentatively identification of several partially conjugated 18:4 isomers after 72 h of rumen incubations.

The formation of the partially conjugated 18:4 isomers may involve multiple *cis/trans* and carbon–carbon isomerizations, including shifts of the double bonds two-carbons away, and isomerizations close to the carboxyl group. Indeed, three double bonds in the novel 18:4 isomers moved position, despite not being clear if these multiple migrations occurred sequentially or simultaneously. A sequential migration of the double bonds implies the formation of intermediate isomers between 18:4n-3 and the conjugated 18:4 isomers identified. We could not detect these intermediates, but it is not clear if they were not formed, which would exclude the sequential double bond

migration, or if they were transient and were not present after the 72 h of incubation.

The 18:4 biohydrogenation intermediates identified showed isomerizations of double bonds to two-carbons away from the initial position, i.e., the double bonds at carbons-9 and -12 in 18:4n-3 were converted into double bonds at carbons -7 and -10 in the conjugated $\Delta^{5,7,11,15}$ and $\Delta^{5,8,10,15}$, respectively (Fig. 8). A migration of double bonds two-carbons away might also occur during the biohydrogenation of 18:3n-3 because *trans*-11,*cis*-13 and *trans*-11,*trans*-13 have been proposed as intermediates of 18:3n-3 [42, 44–46], suggesting a shift of double bonds at carbons-12, 15. A polyenoic fatty acid isomerase (PFI) found in *Ptilota filicina* marine algae was described to perform a single enzymatic isomerization of two double bonds, one allylically and one homoallylically [47, 48]. These authors reported the conversion of *cis*-6,9,12 18:3 (γ -linolenic) into a conjugated triene by the PFI, in which double isomerization in that the double bond at carbon-9 is transferred to the carbon-8 and the double bond at carbon-12 migrates two-carbons away to form the double bond at carbon-10, producing the conjugated triene *cis*-6,*trans*-8,*trans*-10. Although not yet described in the rumen ecosystem, a similar unusual enzymatic mechanism might occur in microbial isomerases. However, further work is necessary to evaluate the occurrence of this feature in the rumen microbial ecosystem. Hypothetical migrations of the double bonds from both 18:3n-3 and 18:4n-3 into conjugated derivatives are presented in Fig. 8.

Although isomerization from carbon-6 to carbon-5 have not been reported, Kairenus et al. [16] recently suggested that hydrogenation of long chain polyenoic fatty acids in the rumen may proceed via two distinct mechanisms that involve sequential reduction and/or isomerization of *cis* double bonds closest to the carboxyl group.

The three 18:3 non-conjugated isomers putatively identified are probably formed by hydrogenation of the second double bond (closest to the carbonyl group) in the partially conjugated 18:4 isomers. The double bond at carbon-15 may be further hydrogenated to produce the novel 18:2 biohydrogenation intermediates identified in samples. However, the double bond at carbon-15 is considered less likely to be hydrogenated in the first steps of biohydrogenation as demonstrated through the known pathways of 18:3n-3, in which its biohydrogenation leads to the formation of the triene *cis*-9,*trans*-11,*cis*-15 and the dienes *trans*-11,*cis*-15 [36]. Nevertheless, recent results showed that the biohydrogenation of 18:3n-3 can produce the conjugated diene *cis*-9,*trans*-11. Lee and Jenkins [42] found an enrichment of about 40% of *cis*-9,*trans*-11 with labeled ^{13}C from 18:3n-3, implying a reduction of the double bond at carbon-15. The same authors also detected enrichments in others CLA isomers, including *trans*-9,*cis*-11, *cis*-9,*cis*-11, *trans*-11,*trans*-13, *trans*-8,*trans*-10 and *cis*-10,*cis*-12 at 3–48 h of incubation. In the present study, no increase of conjugated dienes was found during the biohydrogenation of 18:4n-3. This suggests that either the 18:4n-3 biohydrogenation pathway does not involve the formation of CLA isomers or that after 72 h of incubation they could have been reduced to monoenoic acids.

A putative metabolic pathway for the formation of the novel 18:2, 18:3 and 18:4 biohydrogenation intermediates identified in incubation samples at the 1.00 mg supplementation level and greater is presented in Fig. 9. The intermediates accumulated after 72 h of incubation are probably the main intermediates formed in the 18:4n-3 biohydrogenation pathway and are not end products

Fig. 9 Putative metabolic pathway for the formation of the novel 18:2, 18:3 and 18:4 biohydrogenation intermediates from 18:4n-3 by rumen microbes. Dotted arrows represent suggested carbon–carbon isomerization and solid arrows represent proposed hydrogenations, based on the identified biohydrogenation intermediates

because in the incubations at lower supplementation levels of 18:4n-3, none of these novel intermediates were found.

In vitro incubation of rumen fluid with increasing supplementation levels of 18:4n-3 produced several novel biohydrogenation intermediates comprising non-conjugated 18:2 and 18:3, and partially conjugated 18:4 isomers, particularly at greater levels (1.0–1.5 mg 18:4n-3 per 33 mg TMR DM). The identification of these intermediates was achieved by gas–liquid chromatography coupled to mass spectrometry analysis of fatty acid methyl esters and DMOX derivatives. However, the *cis* and *trans* geometry of the novel intermediates was not determined.

Abstract Establishment of sensitive methods for the detection of cellular sterols and their derivatives is a critical step in developing comprehensive lipidomics technology. We demonstrate that electrospray ionization tandem (triple quadrupole) mass spectrometry (ESI-MS/MS) is an efficient method for monitoring steryl glucosides (SG) and acyl steryl glucosides (ASG). Comparison of analysis of SG and ASG by ESI-MS/MS with analysis by gas chromatography with flame ionization detection (GC–FID) shows that the two methods yield similar molar compositions. These data demonstrate that ESI-MS/MS response per molar amount of sterol conjugate is similar among various molecular species of SG and ASG. Application of ESI-MS/MS to seed samples from wild-type *Arabidopsis* and a mutant deficient in two UDP-glucose:sterol glucosyltransferases, UGT80A2 and UGT80B1, revealed new details on the composition of sitosteryl, campesteryl and stigmasteryl glucosides and ASG. SG were decreased by 86% in the *ugt80A2,B1* double mutant, compared to the wild-type, while ASG were reduced 96%. The results indicate that these glucosyltransferases account for much of the accumulation of the sterol conjugates in wild-type *Arabidopsis* seeds.

Introduction

Sterols are ubiquitous constituents of eukaryotic cells. In contrast to animals and fungi, which contain primarily cholesterol and ergosterol, respectively, plants synthesize a complex mixture of sterols comprised of sitosterol, campesterol, stigmasterol and additional minor sterols that include cholesterol [1]. While sitosterol and stigmasterol are implicated in membrane functions [2, 3], campesterol is the precursor to the brassinosteroids, which are plant steroid hormones required for cell division and cell expansion [4, 5]. In plants, steryl glycosides (SG) and acyl steryl glycosides (ASG) are major derivatives of sterols [6–9]. Variation in SG originates from differences in the type of sterol, the sugar, the configuration of the linkage, number of sugar groups, and acylation of the sugar(s). In the most common form of SG, a sugar monomer, usually the pyranose form of D-glucose, is attached to the 3 β -hydroxy group on the C3 of the sterol (Fig. 1a). Acylation may occur at the C6 of the sugar moiety with fatty acids (Fig. 1b), palmitic (16:0) being most common.

Fig. 1 Molecular structures for SG and ASG. **a** SG structures are shown for sitosteryl, campesteryl, and stigmasteryl glucosides. The pyranose form of D-glucose is covalently attached to the 3 β -hydroxy group on C3 of the A ring of the sterol. **b** ASG structures are shown

for sitosteryl glucosides with various acyl chain modifications: 16:1 (palmitoleic), 16:0 (palmitic), 18:3 (linolenic), 18:2 (linoleic), 18:1 (oleic) and 18:0 (stearic) acids. The acyl modification occurs on C6 of the D-glucose monomer that is attached to the sterol

As sterol conjugates, SG and ASG, which are biosynthetically interconvertible, serve as membrane components, storage forms of sterols, transporters, and/or signaling molecules in plants [6], and one report has suggested the role of SG as primers in the synthesis of cellulose [10]. SG are synthesized by UDP-glucose:sterol glucosyltransferases (UGTs) which catalyze the glucosylation of the 3 β -hydroxy group of sterols to produce 3- β -D-glucosides [11, 12]. *Arabidopsis ugt80A2,B1*, double mutant for *UGT80A2* and *UGT80B1*, was shown to have a significant reduction in SG and ASG levels in several plant tissues [13]. These mutants display an array of phenotypes in the seed, including small embryo size, transparent testa, defects in flavonoid deposition, loss of the cuticle layer, and a decrease in aliphatic suberin and cutin-like polymers.

Characterization of the *ugt80A2,B1* mutants has indicated a role for SG and ASG in trafficking of lipid polyester precursors in seeds [13].

After isolation of SG and ASG from tissues, gas chromatography (GC) can be used to quantify these lipids. To perform the analysis, the SG and ASG are each hydrolyzed to yield sterols and trans-esterified to yield fatty acid methyl esters. Gas chromatography with flame ionization (GC-FID) is quantitative, but the classes need to be isolated and hydrolyzed/transesterified. In this report we demonstrate the detection of underivatized SG and ASG conjugates of sitosterol, campesterol, and stigmasterol from seed samples using electrospray ionization tandem (triple quadrupole) mass spectrometry (ESI-MS/MS). Mass spectrometry methods, exemplified by ESI-MS/MS, have

enabled high sensitivity and high mass resolution specificity for the identification and quantification of lipids from diverse biological samples [14]. Previously it was shown that ESI-MS/MS can be utilized to efficiently quantify phospholipids and polar glycerolipids from *Arabidopsis* [15, 16].

In the present study we show that ESI-MS/MS is a simple and rapid detection method that is advantageous over GC methods for the analysis of steryl glycolipids, since there is no need for derivatization, and quantitative information about the specific SG and ASG molecular species is readily obtained. Using seed samples from *ugt80A2, B1* mutants and wild-type, ESI-MS/MS analysis has revealed new details about SG and ASG molecular species, adding to our understanding of the roles of the UGT80 glucosyltransferases in *Arabidopsis* seeds.

Experimental Procedure

Plant Materials and Growth Conditions

Wild-type and mutant *Arabidopsis thaliana* lines were in the Wassilewskija (WS)-O background. *ugt80A2, B1*, double mutant for *UGT80A2* (At3g07020) and *UGT80B1* (At1g43620), was previously described [13]. Plants were grown on soil comprised of 7:3:4 Metro-Mix 380:Vermiculite (Therm-O-Rock #10-2200):Perlite (Therm-O-Rock #10-1123) (Hummert International, Topeka, KS, USA) under continuous light at 23 °C and 70% humidity in a standard growth chamber. Dry seeds were harvested at 8 weeks. For the comparison of ESI-MS/MS to GC-FID analysis, mixtures of isolated soybean-derived SG (catalog #1117: 54% sitosteryl glucoside, 27% campesteryl glucoside, 17% stigmasteryl glucoside, 1% Δ^5 -avenasteryl glucoside) and ASG (catalog #1118: esterified steryl glucosides, fatty acid composition: 34% 16:0, 8% 18:0, 8% 18:1, 36% 18:2, 4% 18:3, 1% 20:0, 4% 22:0, 2% 23:0, 2% 24:0 and 1% others; According to the Matreya LLC 2011–2012 catalog, “actual composition may vary according to dietary history and condition of the source”) were purchased from Matreya LLC, Pleasant Gap, PA, USA.

Lipid Extraction from Seeds

Seeds were extracted by a modification of the method of Bligh and Dyer [17]. 100 *Arabidopsis* seeds were added to 2.0 ml isopropanol with 0.01% butylated hydroxytoluene at 75 °C; the heating at 75 °C was continued for 15 min, before cooling to room temperature. To the seed–solvent mixture precise amounts of internal standards: 10 nmol of di12:0 PtdGro and 10 nmol of di20:0 (diphytanoyl) PtdGro

(Avanti Polar Lipids, Alabaster, AL) were added. The mixture was then transferred to a Dounce homogenizer, homogenized to allow for complete and consistent extraction of lipids, and transferred to a glass tube. The homogenizer was rinsed with 2.0 ml each of chloroform and methanol to recover the sample fully, and the rinse was combined with the isopropanol–seed mixture. 1.6 ml water was added and the one-phase mixture was shaken. An additional 1.0 ml each of chloroform and water were added, followed by shaking and centrifugation to form two phases. The lower layer was removed. 2.0 ml of chloroform were added, the tube was shaken and centrifuged, and the lower layer was removed. This was repeated and the three lower layers were combined. 1.0 ml of 1 M KCl was added, the mixture shaken and centrifuged for 10 min, and the upper layer was removed and discarded. A second wash was performed with 1.0 ml water, followed by evaporation of the solvent. Samples were dissolved in 1 ml chloroform and 5–15 μ l of each of these samples were added to 1.2 ml chloroform/methanol/300 mM ammonium acetate in water (300/665/35) for ESI-MS/MS analysis.

Gas Chromatography

The SG mixture (#1117, Matreya LLC, Pleasant Gap, PA, USA) and the ASG mixture (#1118, Matreya LLC, Pleasant Gap, PA, USA), both isolated from soybean by the commercial provider, were prepared for sterol analysis according to Rintoul et al. [18]. SG (40–100 μ g) were hydrolyzed by heating at 70 °C for 1 h in 2.5 ml 2 M sodium hydroxide in methanol/water (5:1). 2.0 ml water was added and the sample was extracted twice with pentane. Combined pentane extracts were dried with sodium sulfate. The pentane was evaporated, and the samples were redissolved in 100 μ l pentane, of which 1 μ l was analyzed. Sterols were analyzed on a Hewlett Packard 5890A gas chromatograph on a 15-m, 0.25 mm inner diameter, Rtx-65TG column (#17005 Restek; distributed by Alltech, State College, PA). Injection was in the splitless mode, with helium as the carrier gas with a head pressure of 125 kPa and a flow of 54 ml/min. The oven temperature was maintained isothermally at 240 °C and the injector and detector temperatures were at 300 °C. Total analysis time was 12 min with the major plant sterols eluting between 8 and 11 min. Detection was by flame ionization. Peak areas were integrated with a Beckmann 427 integrator. The areas were divided by the molecular weights before determining the mole percentage of each sterol.

The ASG mixture (#1118, Matreya LLC, Pleasant Gap, PA, USA) was prepared for analysis of fatty acid composition by converting the acyl groups to fatty acid methyl esters. ASG (~200 μ g) in 1.0 ml 3 M methanolic HCl was heated under nitrogen at 78 °C for 1 h. Then 2.0 ml water

was added, followed by two extractions with pentane. Water was removed from the combined extracts with sodium sulfate, pentane was evaporated, and the sample was dissolved in ~30 µl of carbon disulfide, of which 1 µl was analyzed. Fatty acid methyl esters were analyzed on a Hewlett Packard 5890A gas chromatograph, on a 30-m SP2380 column with a 0.32 mm inner diameter (#2-4115, Supelco, Bellefonte, PA, USA). Injection was in the splitless mode with helium as the carrier gas with a head pressure of 50 kPa and a flow of 52 ml/min. The oven temperature was maintained isothermally at 160 °C, and the injector and detector temperatures were 220 °C. Detection was by flame ionization. Total analysis time was 25 min with the fatty acid methyl esters of interest eluting between 13 and 21 min. Peak areas were integrated with a Beckmann 427 integrator. The areas were divided by the molecular weights before determining the mole percentage of each fatty acid methyl ester. To calculate the mol% of SG and ASG for the spike-in experiment, the signals (in weight %) were adjusted for the molecular weights of the free sterols and fatty acid methyl esters, and a random distribution of fatty acids on the various sterols in ASG was assumed.

Electrospray Ionization Tandem Mass Spectrometry

Purified SG or ASG (Matreya LLC, Pleasant Gap, PA, USA) or unfractionated lipid extracts were introduced by continuous infusion into the ESI source on a triple quadrupole MS/MS (4000 QTrap, Applied Biosystems, Foster City, CA, USA). Subsequently, 5–15 µl of *Arabidopsis* extracts or 1–20 nmol of purified SG or ASG in 1.2 ml of chloroform/methanol/300 mM ammonium acetate in water (300/665/35) were introduced by an autosampler (LC Mini PAL, CTC Analytics AG, Zwingen, Switzerland) fitted with the required injection loop for the acquisition time and presented to the ESI needle at 30 µl/min. Targeted methods for analysis of internal standards, SG and ASG lipid species were employed. In the *Arabidopsis* samples, the internal standards (di12:0 PtdGro and di20:0 PtdGro) were detected with a scan for neutral loss of the head group moiety, NL 189.04 ($C_3H_9O_6P + NH_3$) in positive mode. In all samples, SG were revealed with a scan for neutral loss of the hexose moiety, NL 197.09 ($C_6H_{12}O_6 + NH_3$) in the positive mode, and ASG lipid species were detected with the following neutral loss scans for the hexose moiety acylated with a particular fatty acid: 16:1, NL 433.30 ($C_{22}H_{40}O_7 + NH_3$); 16:0, NL 435.32 ($C_{22}H_{42}O_7 + NH_3$); 18:3, NL 457.30 ($C_{24}H_{40}O_7 + NH_3$); 18:2, NL 459.32 ($C_{24}H_{42}O_7 + NH_3$); 18:1, NL 461.34 ($C_{24}H_{44}O_7 + NH_3$); and 18:0, NL 463.35 ($C_{24}H_{46}O_7 + NH_3$). While adducts other than the $[M + NH_4]^+$ can be formed by ESI, the addition of ammonium acetate to the lipid mixture

enhances the formation of $[M + NH_4]^+$, and scanning for NL of the ammonia-containing hexose or acylated hexose fragments is critical to assure that $[M + NH_4]^+$ adducts are the detected precursors.

The collision gas pressure was set at 2 (arbitrary units). Collision energies, with nitrogen in the collision cell, were +21 V for SG and +30 V for ASG. Declustering potentials were +65 V for SG and +100 V for ASG. Entrance potentials were +10 V for SG and +14 V for ASG. Exit potentials were +10 V for SG and +14 V for ASG. The mass analyzers were adjusted to a resolution of 0.7 u full width at half height. For each spectrum, 400 continuum scans were averaged in multiple channel analyzer (MCA) mode. The source temperature (heated nebulizer) was 100 °C, the interface heater was on, +5.5 kV was applied to the electrospray capillary, the curtain gas was set at 20 (arbitrary units), and the ion source gases were set at 45 (GS1) and 45 (GS2) (arbitrary units). Mass spectra were detected by fragment ion counting.

For each spectrum, background subtraction, data smoothing and peak area integration were performed using a custom script and Applied Biosystems Analyst software. Within each spectra, the data were isotopically deconvoluted based on the sterol portion of SG and ASG. For purified SG and ASG samples, the signals for containing each indicated sterol or fatty acid group were summed and divided by the total signal to obtain mol fractions. For *Arabidopsis* samples, the sterol derivatives in each class were quantified in comparison to the two internal standards (di12:0 PtdGro and di20:0 PtdGro) using LipidomeDB Data Calculation Environment at the website <http://lipidome.bcf.ku.edu:9000/Lipidomics/> [19]. The SG and ASG signals were normalized such that a signal of 1.0 represents a signal equal to the average signal of 1.0 nmol of di12:0 PtdGro and di20:0 PtdGro, and were additionally corrected for isotopic overlap between head groups (NL fragments).

Total phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn) of the wild-type and *ugt80A2,B1* seed extracts were analyzed using 10 µl of extract and the mass spectral conditions described in Devaiah et al. [16], considering the amounts for all the PtdCho species in that publication except minor species PtdCho(36:1) and all the PtdEtns, except minor species PtdEtn(34:1), PtdEtn(36:1), PtdEtn(38:6), and PtdEtn(42:4). The PtdCho and PtdEtn mass spectral signals were quantified in relation to the same PtdGro internal standards used for the SG and ASG analysis.

Spike-in Experiment

Varying quantities of soybean SG containing various known amounts of each glucoside (as determined by GC

analysis of derived sterols) in varying quantities were spiked into 5 μ l from 1 ml of extract from 100 wild-type seeds and into 5 μ l of 1 ml of extract from 100 mutant seeds (each containing 50 pmol di12:0 and di20:0 PtdGro internal standards). ASG containing known concentrations of 18:2 and 16:0 ASG (as determined by GC analysis of fatty acids and sterols and assuming random combinations into ASG) in varying quantities were spiked into 15 μ l of 1 ml of extract from 100 wild-type seeds and 15 μ l of 1 ml extract from 100 mutant seeds (each containing 150 pmol di12:0 and di20:0 PtdGro internal standards). The samples were analyzed by ESI-MS/MS and the data processed as described above, except 939–1,000 continuum scans for each analysis were averaged in multiple channel analyzer (MCA) mode. Five biological replicate analyses were performed for SG and each ASG. Signals for SG and ASG analytes, normalized to the average signal for the internal standards in the analyzed sample, are shown.

Results

A direct infusion ESI-MS/MS approach was used to detect and quantify SG and ASG containing sitosterol, campesterol

and stigmasterol (Fig. 1). A major advantage of this approach is that it is not necessary to separate SG and ASG from other compounds prior to analysis. Both SG and ASG can be analyzed as $[M + NH_4]^+$ ions, and detected in positive mode by a series of neutral loss scans specific for the hexose or acyl hexose moieties. SG and ASG with greater than one sugar are very rare [7] and we did not target these compounds in our analysis. Table 1 shows the mass spectral scan values that were used to detect SG and ASG molecules. A previous report on analysis of cholesteryl esters using ESI-MS/MS indicated that mass spectral response varied considerably among sterol esters with different acyl groups [20]. To determine whether various SG and ASG molecular species have variable mass spectral responses, isolated soybean-derived SG and ASG mixtures from a commercial source were separately analyzed by GC–FID and the results were compared with those obtained by ESI-MS/MS. The data indicate that, although there was a slight tendency of the mass spectrometer to be more sensitive to SG and ASG containing campesterol relative to those containing the sitosterol and stigmasterol, the mole fractions of each sterol in the SG and ASG mixtures detected by the two methods were very similar (Fig. 2). Sitosterol was the most prominent sterol found in both commercially-obtained

Table 1 Mass spectral scan values for sterol glucosides and acyl sterol glucosides

| Class | Formula [M] | Scan mode | Mass of intact ion analyzed $[M + NH_4]^+ (m/z)$ |
|-----------------------------|--|------------|--|
| Sterol glucoside (SG) | | | |
| Campesterol | C ₃₄ H ₅₈ O ₆ | +NL 197.09 | 580.46 |

Fig. 2 Sterols from purified soybean SG and ASG as a mole fraction of the total detected sterol compounds. After hydrolysis of the SG or ASG, sterols were determined by GC-FID, or the SG and ASG were analyzed intact by ESI-MS/MS. In the ESI-MS/MS data, the signals for various ASG molecular species with each sterol component were summed. **a** SG. **b** ASG. Error bars represent standard deviations (SD) for GC ($n = 3$ for the number of independent samples) and ESI-MS/MS ($n = 12$ for the number of independent samples)

Fig. 3 Fatty acids of purified soybean ASG as a mole fraction of the total detected fatty acids. Fatty acids were determined by GC-FID after formation of methyl esters, or the ASG were analyzed intact by ESI-MS/MS. In the ESI-MS/MS data, the signals for various ASG molecular species with each fatty acid component were summed. Error bars represent standard deviations (SD) for GC ($n = 3$ for the number of independent samples) and ESI-MS/MS ($n = 12$ for the number of independent samples)

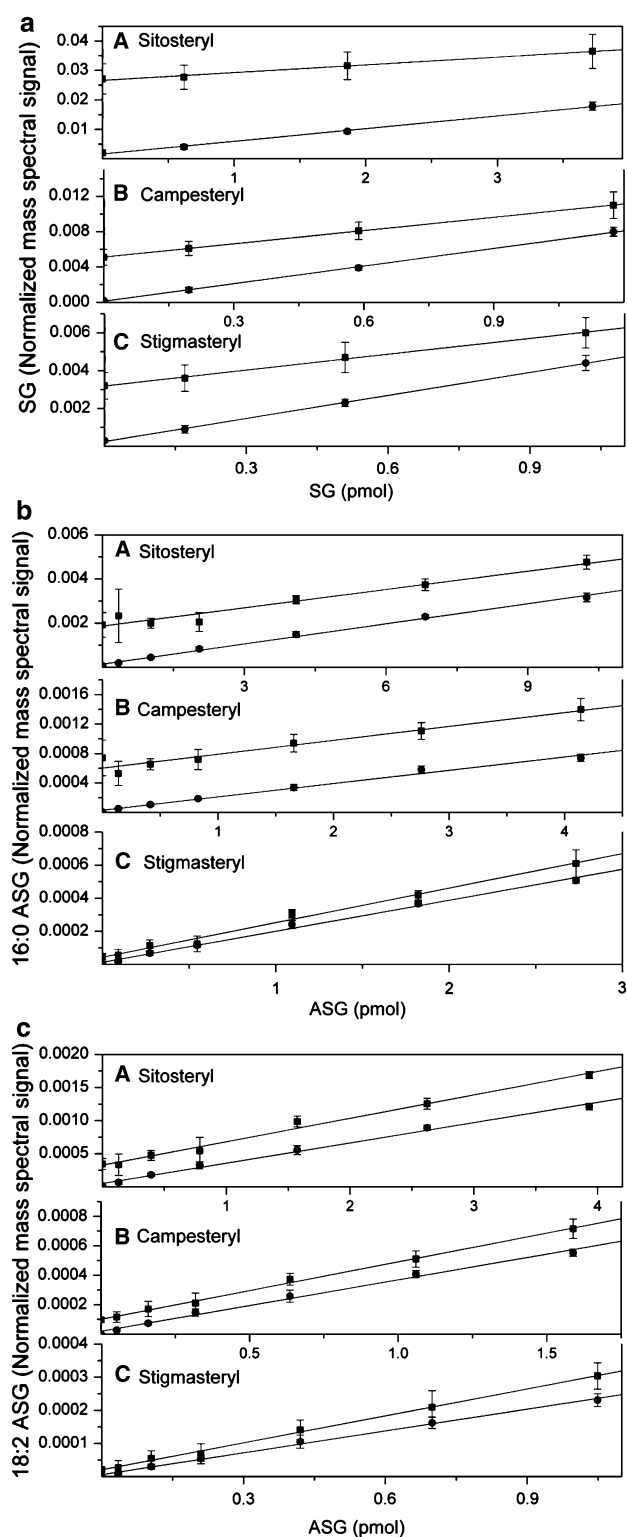

soybean SG and ASG. Campesterol and stigmasterol were the other major sterols, while minor sterols comprised $\sim 2\%$ or less.

Analysis of the purified ASG mixture by GC-FID and ESI-MS/MS showed a tendency of the mass spectrometer to be less sensitive to 18:2 (linoleic acid)-containing ASG than to other fatty-acyl SG, but the fatty acid compositions of the purified ASG determined by the two methods were similar overall (Fig. 3). The major fatty acid found in purified commercially-obtained soybean ASG was 16:0 (palmitic acid), comprising greater than 50% of the total, followed by 18:2 (linoleic), 18:0 (stearic), 18:1 (oleic), 18:3 (linolenic) and 16:1 (palmitoleic) acids. Taken together, the data indicate that the composition of SG and ASG determined by ESI-MS/MS of the isolated compounds is very close to that determined by GC-FID, indicating that various SG and ASG molecular species have similar molar mass spectral responses. In addition, our data are comparable to the percentile compositions provided by Matreya LLC, the commercial source of the SG and ASG mixtures (see “Experimental Procedure”).

We next applied ESI-MS/MS to seed samples from wild-type *Arabidopsis* and the *ugt80A2,B1* mutant using a spike-in experiment to verify linearity of response of the normalized mass spectral signals. SG and ASG were analyzed by direct infusion of unseparated seed extracts, and known amounts of soybean SG and ASG were spiked-in to wild-type and mutant samples to determine the linearity of their ESI-MS/MS response in the presence of other seed lipids. The linearity of SG and ASG response was good

over the range in which the mutant and wild-type are compared, and the mutant and wild-type spike-in data form parallel lines (Fig. 4). The data show that wild-type values fall within the linear range of the spike-in to the mutant samples, indicating that the amounts of SG and ASG in the wild-type samples are linearly related to the amounts in the mutant samples. These data indicate that the ESI-MS/MS method is useful for comparison of biological samples.

Levels of SG and ASG in *Arabidopsis* seeds of *ugt80A2,B1* mutants and wild-type are shown in Fig. 5 (Table S1) with individual molecular species of SG and ASG indicated. The masses detected were consistent with identification of sitosterol, campesterol, and stigmasterol as the three major sterols in *Arabidopsis* seed SG and ASG. Minor sterols, with masses consistent with identifications of cholesterol and brassicasterol, were also detected by ESI-MS/MS as $\sim 2\%$ or less of the total SG (data not shown). The data show that sitosteryl, campesteryl, and stigmasteryl glucosides were significantly reduced by 85, 92, and 82% (7-, 13- and 6-fold), respectively, in *ugt80A2,B1* in comparison to wild-type seeds, and total SG were reduced by 86% (sevenfold) (Fig. 5; Table S1). Although SG levels were reduced in *ugt80A2,B1*, the relative proportions of SG that contained sitosterol, campesterol and stigmasterol were similar to those in wild-type. In addition, we observed that the levels of phospholipids PtdCho and PtdEtn were very similar in the mutant and wild-type (Table S2), indicating that the *ugt80A2,B1* mutant is specifically deficient in SG and ASG.

The major ASG molecular species, 16:0 (palmitic), 18:1 (oleic), 18:2 (linoleic), and 18:3 (linolenic) acids were reduced to a slightly greater extent than SG in *ugt80A2,B1* compared to wild-type seeds. Total ASG levels were reduced 96% (23-fold) in the double mutant (Fig. 5; Table

Fig. 4 Spike-in experiments indicate linear responses in mass spectral signals from ESI-MS/MS analysis of SG and ASG. Normalized mass spectral signals are shown for compounds from *Arabidopsis* seeds of wild-type (squares) and the *ugt80A2,B1* mutant (circles) for **a** SG, **b** 16:0 ASG, and **c** 18:2 ASG in three panels from top to bottom. Each panel is further sub-divided to indicate quantification of (A) sitosteryl, (B) campesteryl, and (C) stigmasteryl SG, 16:0 ASG or 18:2 ASG, respectively. A normalized signal of 1.0 for SG and ASG is the same amount of signal as the average signal produced by 1.0 nmol of the internal standards, di12:0 and di20:0 PtdGro. Error bars represent standard deviations (SD) for $n = 5$ biological replicates

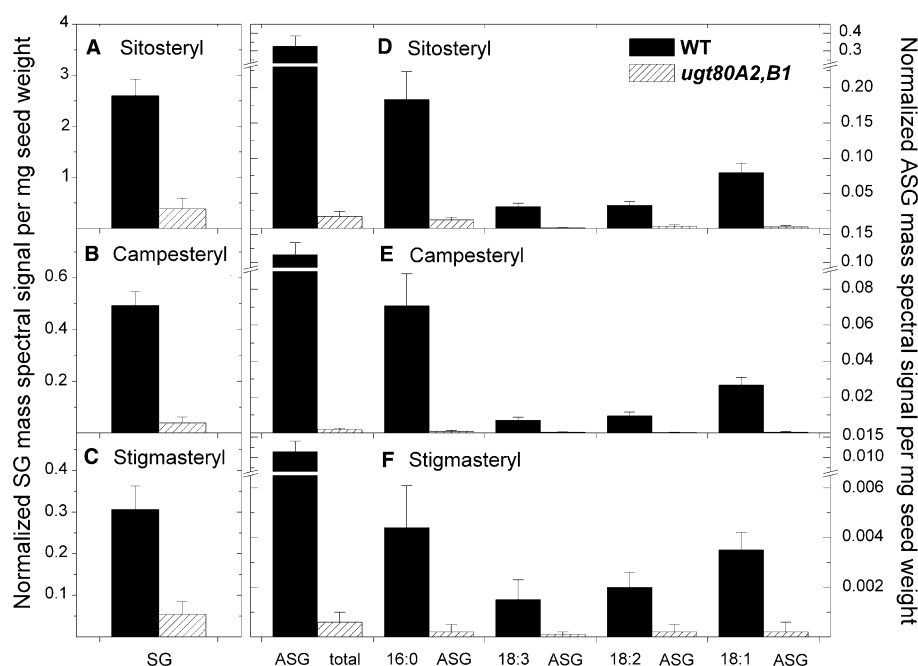

S1). Among the ASG detected in seeds, 16:0 (palmitic acid) was the predominant acyl group accounting for 57 and 66% of the total ASG signal in wild-type and mutant, respectively. Strikingly, campesterol-containing ASG were reduced 98% (61-fold), while decreases in sitosterol- and stigmasterol-containing ASG were reduced to a lesser extent. Campesterol-containing ASG accounted for only 10% of the ASG in *ugt80A2,B1* in comparison to 25% in wild-type. In wild-type, the signal from SG accounted for 88% of the total glucosylated sterol signal (SG + ASG), and in the *ugt80A2,B1* mutant the signal from SG accounted for 96% of the total glucosylated sterols. Overall, there was a reduction of 87% (eightfold) in SG + ASG content in the mutant in comparison to wild-type.

Discussion

The development of a high throughput platform for the detection of sterol conjugates will enhance our ability to characterize mutations that affect the levels of these compounds. Here we present a first step towards including SG and ASG analysis in a comprehensive lipidomics platform. We show that ESI-MS/MS, with a direct injection non-chromatographic approach, allows us to analyze seed extracts directly without purification of the SG and ASG classes from the lipid extract. This approach is simple compared to the traditional GC-FID method since derivatization and chromatographic separation of products is not required. Our spike-in data reveal the mass spectral signals behave linearly to spiked-in standards for a given matrix (Fig. 4). The levels of SG and ASG were comparable to those reported for tobacco seeds [21] and various *Arabidopsis* tissues [13, 22].

While this article was in review and revision, another article describing the mass spectral analysis of SG and ASG was published [22]. Wewer et al. analyzed SG and ASG by direct infusion, but used quadrupole time-of-flight mass spectrometry in contrast to the triple quadrupole method that was applied in our work. In agreement with our data, these authors determined that naturally-occurring

Fig. 5 SG and ASG levels are reduced in seeds from *ugt80A2,B1* mutants of *Arabidopsis*. ESI-MS/MS was applied to analyze SG and ASG from seeds of wild-type (WT) (solid bars) and *ugt80A2,B1* (stippled bars). Normalized mass spectral signals per mg seed weight are indicated for each compound: **a–c** SG and **d–f** 16:0, 18:3, 18:2, and 18:1 ASG. **a** SG and **d** ASG containing sitosteryl. **b** SG and **e** ASG containing campesteryl. **c** SG and **f** ASG containing stigmasteryl. The total ASG amount was calculated by adding the normalized mass spectral signal of molecular lipid species of that group. Error bars represent standard deviations (SD) for $n = 5$ biological replicates

sterol derivatives had similar response factors in ESI-MS/MS analysis. Sample preparation by Wewer et al. [22] included a solid phase extraction step followed by direct infusion of samples to the mass spectrometer. Addition of this step yielded increased sensitivity and reduced matrix effects during ionization, which the authors deemed critical for the development of a comprehensive lipidomics platform encompassing linear responses of mass spectral signals from multiple lipid classes. In the current work, care was taken to keep the matrix relatively constant during analysis. Our results, like those of Wewer et al. [22], indicate that ESI mass spectrometry methods are very sensitive for SG and ASG from biological samples. In particular, the use of the triple quadrupole mass spectrometer in our work allowed detection of changes in SG and ASG at sub-picomole levels.

Application of ESI-MS/MS to seed samples from wild-type *Arabidopsis* and a mutant in two UGT enzymes (UGT80A2 and UGT80B1) has revealed new details on the composition of SG and ASG in the *ugt80A2,B1* mutant. A previous study, using GC-FID analysis, showed that combined SG + ASG content was decreased 5-, 21-, and 22-fold in leaf, stem, and inflorescence + silique tissues of *ugt80A2,B1* mutants in comparison to wild-type [13]. In our work, analyses of dry seeds from *ugt80A2,B1* and wild-type indicate that total SG + ASG levels were reduced similarly, 87% or about 8-fold, in *ugt80A2,B1* seeds. The ESI-MS/MS analysis revealed that the reduction is slightly greater in ASG than in SG levels. In addition, the lower levels of acyl campesteryl glucosides in the mutant, compared to other ASG, may reflect a preference of the

acylating enzymes for sitosteryl and stigmasteryl glucosides, or possibly a different subcellular localization of the various SG and/or acylating enzymes. Our results demonstrate that mass spectrometry methods such as ESI-MS/MS are poised to accelerate research in the detection of SG and ASG lipids whose biological roles are just beginning to be uncovered.

Suitability of Soxhlet Extraction to Quantify Microalgal Fatty Acids as Determined by Comparison with In Situ Transesterification

Abstract To assess Soxhlet extraction as a method for quantifying fatty acids (FA) of microalgae, crude lipid, FA content from Soxhlet extracts and FA content from in situ transesterification (ISTE) were compared. In most cases, gravimetric lipid content was considerably greater (up to sevenfold) than the FA content of the crude lipid extract. FA content from Soxhlet lipid extraction and ISTE were similar in 12/18 samples, whereas in 6/18 samples, total FA content from Soxhlet extraction was less than the ISTE procedure. Re-extraction of residual biomass from Soxhlet extraction with ISTE liberated a quantity of FA equivalent to this discrepancy. Employing acid hydrolysis before Soxhlet extraction yielded FA content roughly equivalent to ISTE, indicating that acidic conditions of ISTE are responsible for this observed greater recovery of FA. While crude lipid derived from Soxhlet extraction was not a useful proxy for FA content for the species tested, it is effective in most strains at extracting total saponifiable lipid. Lipid class analysis showed the source of FA was primarily polar lipids in most samples (12/18 lipid extracts contained <5% TAG), even in cases where total FA content was high (>15%). This investigation confirms the usefulness of ISTE, reveals limitations of gravimetric methods for projecting biodiesel potential of microalgae,

and reinforces the need for intelligent screening using both FA and lipid class analysis.

Introduction

Microalgae have been suggested as a sustainable source of biodiesel based on a number of perceived advantages. Many species grow quickly, have the ability to accumulate a large proportion of triacylglycerols (TAG) as biomass under certain conditions, and can use waste sources of CO₂ and nutrients such as flue gas and municipal wastewater to support growth. The application of microalgae to economical production of biodiesel requires that a high percentage of microalgal biomass be composed of fatty acid containing compounds that can be converted to fatty acid

methyl esters (FAME). This fraction, otherwise known as ‘saponifiable lipid’ includes neutral lipid such as TAG, but may also derive from other cellular components such as membrane lipids.

Considerable uncertainty remains as to whether it is possible to satisfy this requirement with scaled-up cultivation efforts. One of the challenges in resolving this question is the unclear meaning of various lipid content values reported in the scientific literature [19], generally referred to as ‘oil content’ or ‘lipid content’, with wide-ranging [25], and even unreferenced estimates commonly cited to make the case for microalgal biofuels [7]. In addition, there are researchers growing microbial heterotrophs [4] or algae heterotrophically [30], who consistently report higher lipid content values that may be included when modeling phototrophic biodiesel production as a sustainable fuel source. For example, the heterotrophic thraustochytrid *Schizochytrium* sp. and heterotrophic microalgae *Cryptothecodinium cohnii* were both included in a table that was labeled “Oil content of some microalgae” in a well-cited paper on microalgal biodiesel [7].

Contributing to this uncertainty, a number of different techniques are currently in use to evaluate crude lipid content, many based on the classic methods of Folch [14] and Bligh and Dyer [3]. Other examples include spectrofluorometric determinations where lipid bodies are directly stained and quantified [6], supercritical CO₂ extraction [13] and Soxhlet extraction [30, 17, 22]. It is clear that whichever method is chosen, careful attention is required to optimize the extraction conditions—pre-processing is in some cases essential [27], as is reaction time and reagent concentration [12, 40].

Even assuming optimized pre-treatment and extraction conditions, a key limitation of the above techniques is that they are unable to resolve lipid classes, as in liquid chromatography or thin layer chromatography. Although it is apparent to experienced lipid chemists that lipid extracts may contain polar lipids, sterols, pigments, waxes, and oxidatively-altered fats in addition to TAG [37], many biofuel studies still rely on simple gravimetric estimations (hereafter referred to as ‘crude lipid’) to assess biodiesel yields [31, 39], despite the fact that including non-saponifiable lipid overestimates the suitability of a feedstock for biodiesel fuel. In contrast, other publications report crude lipid and FAME profiles [18], while others studies rigorously combine crude lipid, FAME profiles and quantification of FAME/TAG [42]. Also confounding simple comparison between studies is the polarity of the solvent used, which has a significant impact on the yield and composition of extracts from microalgae [22].

The use of gas-chromatography (GC) techniques, which yield accurate quantification and identification of FAME, is a simple procedure to resolve this uncertainty. FAME

quantification gives information on the amount of biomass that is potentially convertible to biodiesel and also indirectly quantifies the amount of additional material extracted as crude lipid which has no value as a fuel.

The most commonly applied procedure for preparing FAME is an initial solvent extraction followed by transesterification (TE) of the resulting lipid with an alcohol, typically methanol [9]. To reduce the time required for this process, other authors [21] have suggested a single-step method where biomass is simultaneously extracted and transesterified, known variously as *in situ* transesterification (ISTE), direct transesterification, or one-step transesterification. Omitting the initial extraction step offers a significant savings in time and energy, results in increased precision [28], and a more complete extraction of fatty acids compared to conventional extraction (i.e. Folch, Bligh and Dyer) followed by transesterification [21, 29]. The various applications of ISTE have been thoroughly reviewed by Carrapiso and García [5].

In addition to requiring less time and potentially resulting in more complete extraction of fatty acids [21, 29], a key advantage of ISTE is that since the entire extraction/transesterification is carried out in a single vessel and quantified by GC, this procedure can be easily applied to small quantities (<10 mg) of biomass without concerns for either loss of sample or analytical precision that would be expected using traditional extraction methods [5]. With these advantages in mind, a standardized ISTE protocol was developed in this laboratory, which was based on previously published standard transesterification procedures [8] as well as information from several recent investigations into ISTE of microalgal lipids [12, 40].

The goal of this investigation was to use ISTE to assess the relevance of gravimetric lipid data from Soxhlet solvent extraction to making projections about biodiesel productivity from microalgae. By comparing these two methods, it was also possible to investigate the factors responsible for the increased efficiency of ISTE procedures versus solvent extraction that have been previously reported [21]. Across 18 samples representing 16 species of microalgae, gravimetric lipid data was found to be an inconsistent metric for measuring total fatty acid content when compared with ISTE. This result confirms the effectiveness of ISTE for measuring total fatty acids in microalgae, and argues for caution in interpreting gravimetric lipid data from microalgae.

Experimental Procedure

Microalgal Culture

A list of the microalgae species cultivated to provide biomass for this study is listed in Table 1. All cultures were

Table 1 Microalgae species used in the study, their taxonomic grouping and media requirements

| Species | Taxonomy | Media |
|---|------------------------|---|
| <i>Scenedesmus dimorphus</i> | Freshwater chlorophyte | Freshwater with F/2 [24] |
| <i>Porphyridium aerugineum</i> UTEX 755 | Brackish rhodophyte | 10% v/v seawater/ freshwater with F/2 media |
| <i>Nannochloropsis granulata</i> CCMP 529 | Marine eustigmatophyte | Seawater with F/2 |
| <i>Nannochloropsis granulata</i> CCMP 535 | Marine eustigmatophyte | Seawater with F/2 |
| <i>Phaeodactylum tricornutum</i> CCMP 1327 | Marine bacillariophyte | Seawater with F/2 |
| <i>Neochloris oleoabundans</i> UTEX 1185 | Freshwater chlorophyte | Bold's 3 N [38] |
| <i>Botryococcus braunii</i> Race B UTEX 572 | Freshwater chlorophyte | Freshwater with F/2 |
| <i>Emiliania huxleyi</i> CCMP 1324 | Marine pyrmnesiophyte | Seawater with F/2 |
| <i>Tetraselmis chuii</i> PLY429 | Marine chlorophyte | Seawater with F/2 |
| <i>Glossomastix chrysoplasta</i> CCMP 1537 | Marine pinguiophyte | Seawater with F/2 |

| CCMP 2327 | Marine bacillariophyte | Seawater with F/2 |
| <i>Eutreptiella pomquetensis</i> CCMP 1491 | Marine euglenophyte | L1 Medium [23] |

grown under continuous illumination, and all diatom cultures were supplemented with 100 μ M silicate. Cultures were harvested by centrifugation with the exception of CCMP 1142, which was harvested by sieving. Photosynthetic batch cultivation was conducted in either enclosed 'Brite-Box' photobioreactors ranging in capacity from 200–1,000 L [10] or in 18-L plastic carboys. All batch cultures were harvested at a stationary phase of growth. One strain, *Isochrysis galbana*, was cultivated in an N-limited chemostat and harvested at steady-state at a dilution rate of 0.5 day⁻¹. All cultures were lyophilized after harvest and stored at -20 °C prior to analysis. Three separate biomass samples of *Botryococcus braunii* Race B were analyzed, indicated by the numbers 1, 2 and 3.

Soxhlet Lipid Extraction

Freeze-dried biomass (0.5 g) was homogenized with a mortar and pestle and extracted using the Soxtec 2050 automated solvent extraction system (FOSS North America, Eden Prairie MN) with the following program: boiling 25 min, rinsing 40 min, solvent recovery 15 min and pre-drying 2 min. Extraction temperatures for different solvents were as follows: chloroform/methanol (2:1)—150 °C, acetone—150 °C, hexane—155 °C, ethanol—250 °C.

The solvents used in all Soxhlet extractions for two-step FAME analyses (TE) were chloroform/methanol (2:1). All solvents were HPLC grade or better (Fisher Optima). After extraction with the Soxtec 2050, lipids were dried at

105 °C for 1 h, placed in a desiccator for 1 h, and weighed to determine gravimetric lipid yield. All values were standardized to ash-free dry weight of algal biomass unless otherwise indicated. Ash-free dry weights were determined by baking biomass overnight at 550 °C and reweighing the combusted residue [43].

Lipids were resolubilized in chloroform/methanol (2:1) and stored under nitrogen at -20 °C until further analysis. Some extractions were done on residual 'defatted' biomass previously extracted in the Soxhlet apparatus (Fig. 1). Defatted biomass was kept in a fume hood to evaporate solvent, and stored at -20 °C before re-analysis.

For acid hydrolysis pre-treatment, samples were processed with the Soxcap 2047 acid hydrolysis kit, according to application note 3907 (FOSS North America, Eden Prairie, MN). Briefly, the samples were boiled for 1 h in 3 M HCl, rinsed with tap water until neutralized, dried at 60 °C overnight and extracted in the Soxtec 2050 as previously described above.

Lipid Derivatization and In Situ Derivatization

Standard transesterification procedures [8] and recent investigations into ISTE of microalgal biomass [12, 40] were used to develop lipid derivatization protocols. For two-step lipid derivatization (TE), a maximum of 20 mg of lipids extracted with the Soxtec apparatus were dried under nitrogen at room temperature to constant weight in pre-weighed Pyrex tubes (previously baked at 450 °C overnight to minimize lipid contamination). For in situ

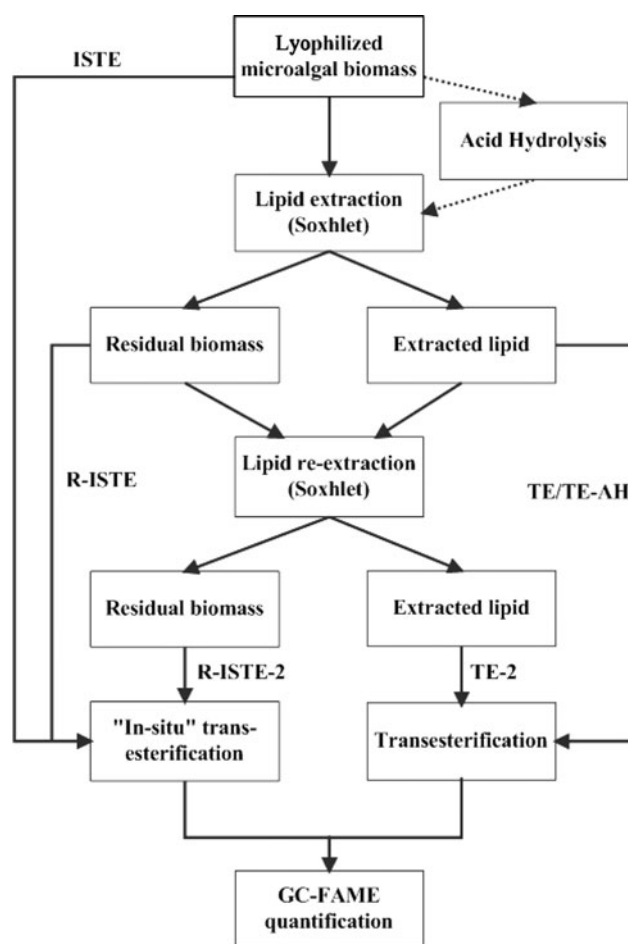

Fig. 1 Flow chart describing lipid analysis as presented in Table 1, as well as Figs. 2, 3, 4 and 5. The lipid re-extraction steps designated TE-2 and R-ISTE-2 are presented solely in Fig. 5. Acid hydrolysis pre-treatment followed by transesterification (TE-AH) was performed only for data presented in Fig. 6

derivatization, a maximum of 20 mg of biomass was weighed directly into clean Pyrex tubes. For both treatments, 1 mL of anhydrous toluene (Sigma-Aldrich) was added, followed by 2 mL of 5% acetyl chloride (Fluka)/anhydrous methanol (99.8% Sigma-Aldrich), prepared fresh for each reaction. Tubes were purged with nitrogen, capped, mixed gently, and kept at 105 °C in a heating block for 1 h. Derivatized lipids were cooled to room temperature, washed with 5 mL of 18.2 MΩ H₂O with 5% NaCl (w/v), 4 mL of 18.2 MΩ H₂O with 2% NaHCO₃ (w/v), dried over anhydrous sodium sulfate and filtered through glass wool to exclude residual sodium sulfate.

Total derivatized lipid was then dried under nitrogen, weighed, diluted to 5 mg/mL with hexane and analyzed using gas chromatography. All reactions included a reagent blank to confirm clean solvents and glassware. Lipid and FAME yields were standardized to the ash-free dry weight of the biomass, with the FAME yield from the re-extracted

defatted biomass represented as a percentage of the original biomass. Readers may refer to Fig. 1 for a schematic description of these steps.

GC Quantification and Identification

All samples were analyzed on an Omegawax 250 column with an Agilent 7890 gas chromatograph equipped with a FID. Samples were run in constant flow mode (3 mL/min) and temperature programmed as follows: 110 °C for 1 min, then 5 °C/min to 250 °C where the program was held for 20 min (total run time 49 min). Inlet temperature was set at 250 °C, and detector temperature to 300 °C. The carrier gas was helium. Peaks were automatically integrated by Chemstation software (Agilent).

A known quantity of internal standard (nonadecanoic acid, Sigma-Aldrich) was added to each tube before adding sample. The concentration of all other integrated peaks was calculated by calibrating to the area of the internal standard peak as per Tran et al. [40] and Griffiths et al. [21]. Individual fatty acids were provisionally identified by comparing retention times to two standard mixtures (Supelco 37 and PUFA No. 3, Sigma-Aldrich). Long-chain fatty acids (C28:1 and C28:2) in *B. braunii* were provisionally identified from previous LC-MS analysis of Soxhlet lipid extracts (data not shown). For the comparison of individual FA, only components that comprised >2% of the total fatty acid pool by area % in the ISTE extracts were considered.

TAG Quantification by HPLC-CAD

Lipid profiling of the Soxhlet extracts of 18 different algal strains was carried out using HPLC with Charged Aerosol Detection (CAD). An Agilent 1100 HPLC binary pump was used with a Halo C8 50 × 3.0 mm column held at 40 °C. The detector was an ESA Biosciences Corona-Plus CAD detector operated with a N₂ gas pressure of 37 psi and the range was set to 100 pA. The mobile phase was delivered at 0.4 mL/min and consisted of (A) 20% water/80% methanol and (B) 70% isopropanol/30% methanol. The gradient was held at 50% B from 0 to 5 min, then increased from 50 to 100% B from 5 to 8 min, and held at 100% B from 8 to 15 min. The column was then equilibrated back to starting conditions for an 8 min period. Liquid chromatography solvents methanol and isopropanol were HPLC-grade and purchased from Caledon (Georgetown, ON, Canada). Samples were diluted to 0.1 mg/mL in methanol and filtered in 0.22 μm centrifugal tubes before analysis. Triolein (18:1/18:1/18:1) was purchased from Nu-Chek Prep (Elysian, MN, USA) and calibration standards ranged from 0.1 to 100 μg/mL. The injection volume in all cases was 10 μL.

Results

Figure 1 shows a flow diagram of the analyses that were performed for this investigation and the acronyms used to refer to them in the text. All microalgal biomass samples were initially extracted by both one-step ISTE and Soxhlet methods as described in “Experimental Procedure”. For the Soxhlet extractions, lipid extracts were subsequently transesterified to FAME in a second step (TE). A number of additional processing reactions were then carried out on some of the ‘defatted’ biomass residues recovered from the Soxhlet apparatus to assess its effectiveness for determining saponifiable fatty acid content. Several residual biomass samples were subjected to re-extraction by the ISTE method (designated R-ISTE) in addition to back extraction by Soxhlet and transesterification (TE-2) in identical fashion to TE extractions. The residues from the TE-2 analysis were again subjected to ISTE analysis (designated R-ISTE-2). In other experiments, biomass samples were pre-treated with acid hydrolysis, subjected to Soxhlet extraction and transesterification (designated TE-AH).

The Effect of Extraction Solvent on Gravimetric Lipid Content

Initial experiments on Soxhlet extraction for three microalgal species (Fig. 2) demonstrated a clear effect of solvent polarity on crude lipid yield. Polar solvents (chloroform/methanol (2:1), ethanol and acetone) yielded higher lipid content, while the non-polar solvent hexane gave a lower yield. With the exception of *B. braunii*, which is known to contain a high proportion of neutral lipids such as TAG [2], hexane extracted little lipid (~4%) relative to more polar

Fig. 2 Lipid content using different solvent matrices for three microalgal species, as determined by Soxhlet extraction. Bars indicate standard deviation of the mean ($n = 6$). Values are not standardized for ash or dry weight content of individual samples

solvents such as ethanol or chloroform/methanol (2:1). Ethanol showed a higher variability in lipid content relative to the other solvent matrices.

Comparison of Fatty Acid Content from Soxhlet and In Situ Transesterification (ISTE) Methods

Figure 3a shows that for 12 samples, TE and ISTE methods yielded a similar amount of FAME, with little or no FAME detected in R-ISTE extracts. In contrast, Fig. 3b shows that six samples yielded additional FAME with re-extraction of residual biomass from Soxhlet extraction (R-ISTE), indicating an incomplete extraction of fatty acids with the Soxhlet procedure. For *B. braunii*, the marine chlorophyte designated CCMP 1142 and *Tetraselmis chuii*, FAME yield derived from Soxhlet extraction-TE was not similar to ISTE. In two cases (CCMP 1142 and *B. braunii*-3), >50% of the total FAME extracted with the ISTE method was not detected with the TE method, but subsequently recovered with R-ISTE treatment.

Gravimetric Lipid Yield Compared with Total Fatty Acid Content

In 16 of 18 samples (Fig. 3a, b), gravimetric lipid content as determined by solvent extraction was, as expected, greater than the weight of fatty acids determined by quantification of FAME using both methods (TE, ISTE). In *Emiliania huxleyi* extracts, the lipid content was ~7× greater than the fatty acid content as determined by TE or ISTE, but for most species the lipid content was between 2 and 3× greater than the total FAME content. In two cases where Soxhlet extraction was not effective at liberating all extractable fatty acids (Fig. 3b: CCMP 1142, *B. braunii*-3), gravimetric lipid content was less than the fatty acid content of the biomass as determined by ISTE.

Intact Lipid Analysis by High Performance Liquid Chromatography

To gain an understanding of these apparent discrepancies between the gravimetric lipid content and the lipid content determined by GC-FAME analysis, 18 algal strains were also analyzed by HPLC-CAD to obtain profiles of intact lipids. CAD was chosen over the more commonly used evaporative light scattering detector (ELSD), as it offers higher sensitivity, wider dynamic range, and more consistent response factors [41]. The HPLC method was developed to rapidly resolve TAGs from other major lipid classes to allow for total TAG quantification, as shown in Fig. 4a. Moderately polar lipids, such as free fatty acids, phospholipids, and chlorophylls eluted early in the chromatogram between 1 and 5 min, while TAGs eluted

Fig. 3 Comparison of gravimetric crude lipid content to FAME yield for microalgal biomass. Methods to determine yield of FAME include Soxhlet extraction followed by transesterification (TE), in situ transesterification (ISTE) and in situ transesterification of residual biomass from Soxhlet extraction (R-ISTE). Bars represent mean values with error plotted as range ($n = 2$) except where otherwise indicated. Single asterisks (*) represent triplicates, and double asterisks (**) indicate $n = 4$. In these cases, the error is plotted as the standard deviation of the mean. Values are standardized to AFDW

between 8 and 12 min. TAGs were eluted over a narrow region of the chromatogram to minimize variation in response caused by the gradient [32]. Quantification of TAGs was achieved by summing the total peak area of the TAG region of the chromatogram and calibrating with triolein (C18:1), previously demonstrated as an effective calibrant for a wide range of TAGs [32]. Shown in Fig. 4b are the TAG levels measured across

the 18 algal strains, calculated as the percentage of the total lipid content measured gravimetrically. As anticipated, TAG content varied between species, ranging from roughly 1% of lipid content for CCMP 2321 and *E. huxleyi* to as high as 64% for the Antarctic marine bacillariophyte CCMP 2327. Furthermore, the strains with low TAG content exhibited high levels of the moderately polar lipids in the chromatograms, while those with high

Fig. 4 a HPLC-CAD chromatogram of the Antarctic marine bacillariophyte CCMP 2337 and **b** comparison of TAG content across the 18 algal strains, calculated as the percentage of the total lipid content measured gravimetrically using HPLC-CAD with triolein (C18:1) for calibration

TAG levels yielded proportionally lower levels of the polar lipid classes.

Effect of Extractions on Recovery of Individual Fatty Acids

Table 2 shows that for all species tested, the sum of FAME from re-extraction of the residual biomass (R-ISTE) and Soxhlet extraction (TE) closely approximated the values for the initial in situ procedure (ISTE), indicating that individual fatty acids were recovered effectively from residual biomass by the R-ISTE procedure. Table 2 also compares the amount of major fatty acids (>2% by weight) extracted with different procedures, standardized to original ash-free dry weight. For *B. braunii*-3 (Table 2), Soxhlet

solvent extraction was selective in its effect, with C16:0/C18:3n3 being preferentially extracted with respect to other fatty acids. The marine chlorophyte CCMP 1142 showed a slight extraction bias for some fatty acids (e.g. C16:0 vs. C17:1), but *T. chuii* did not follow a similar trend—all fatty acids were extracted with similar effectiveness.

Effect of Soxhlet Re-Extraction of Residual Biomass on the Extraction of Fatty Acids

In order to test whether or not the lower yield of fatty acids with Soxhlet extraction was due to non-optimized extraction conditions, pre-extracted ('defatted') biomass was subjected to an additional Soxhlet extraction step. Figure 5

Values given as averages with ranges* ($n = 2$) or averages with standard deviation† ($n = 3$). Only individual FA comprising >2% of the area of total integrated peaks were used for this comparison. The values in column four are derived as indicated by the title. The percentages in column five are calculated as follows: $[R-ISTE / (R-ISTE + TE)] \times 100\%$. TE 2-step transesterification (solvent extraction followed by acidic transesterification), R-ISTE 1-step transesterification of residual biomass from Soxhlet solvent extraction, ISTE 1-step extraction-transesterification, FA fatty acid, AFDW ash-free dry weight

shows that while additional extractions increased the FAME recovery in all species (TE-2), residual biomass from the second extraction still contained FAME recoverable by the ISTE method (R-ISTE-2). These results indicated that low fatty acid yields obtained in the initial Soxhlet extractions (TE) could not have been significantly improved by doubling the extraction time.

The Effect of Acid Hydrolysis on Soxhlet Extraction of Fatty Acids

A major difference between Soxhlet extraction and the ISTE procedure is the absence of an acidic catalyst with Soxhlet extraction. To test the importance of an acidic reagent for complete extraction of fatty acids, biomass was

treated with an acid hydrolysis step prior to Soxhlet extraction and the results for four biomass samples are shown in Fig. 6. Acid treatment increased FAME yields in all strains tested, and in the case of *B. braunii*, fatty acid content with acid hydrolysis pre-treatment (TE-AH) closely matched ISTE values, in contrast to untreated biomass where there was a large discrepancy (Fig. 3b).

Discussion

This paper investigated the effectiveness of using automated Soxhlet extraction to assess biodiesel potential of microalgal biomass. Soxhlet solvent extraction is a commonly used lipid extraction technique, and has the potential

Fig. 5 The effect of increased extraction steps on FAME yield for three species. Values obtained from in situ transesterification (ISTE) are plotted against the sum of transesterification of solvent-extracted lipid (TE), the subsequent re-extraction of ‘defatted’ biomass and transesterification (TE-2), and the in situ transesterification of the resultant biomass (ISTE-2). Bars represent mean values with error plotted as range ($n = 2$) except where otherwise indicated. Single asterisks (*) represent triplicates, and in these cases, error is plotted as standard deviation of the mean. Values are standardized to AFDW

Fig. 6 The effect of acid hydrolysis on FAME content of biomass. Solvent-extracted and transesterified lipid (TE) was compared to an identical extraction with acid hydrolysis pre-treatment (TE-AH) and in situ transesterification (ISTE). Bars represent mean values with error plotted as range ($n = 2$) except where otherwise indicated. Single asterisks (*) represent triplicates, and in these cases, error is plotted as standard deviation of the mean. Values are standardized to AFDW

to be automated for high sample throughput. However, initial data generated in this lab from Soxhlet extraction of microalgal biomass showed that the choice of solvent had a large effect on gravimetric lipid content (Fig. 2), which

was anticipated and agrees with data from previous investigations [22]. For example, in the case of biomass from *Nannochloropsis granulata* (Fig. 2, CCMP 529) hexane extracted ~3% lipid, while ethanol and chloroform/methanol (2:1) extracted >25% lipid on a dry weight basis.

Based on these higher yields with polar solvents, and observation of significant pigmentation in polar solvent extracts, it was hypothesized that polar solvents are able to extract additional polar lipids, as well as a significant quantity of non-esterifiable matter [37]. Any non-saponifiable lipid co-extracted with fatty acid-containing lipid will invalidate the use of gravimetric determinations from Soxhlet systems to estimate total fatty acid content.

In order to assess whether or not this was the case for several species, 18 samples of microalgal biomass were processed by Soxhlet extraction with chloroform/methanol (2:1), and subsequently transesterified with methanol to quantify FAME (Fig. 3). In the “Results” section, the terms “FAME yield/FAME content” are used interchangeably as a proxy for total fatty acid content of biomass as determined by transesterification. Chloroform/methanol (2:1) was chosen for all analyses because of its ability to liberate polar and non-polar lipids, as well as its wide application as a standard lipid extraction solvent in methods such as Folch and Bligh and Dyer.

In situ transesterification was used as a comparative method to assess the efficacy of Soxhlet extraction based on previous reports indicating that ISTE is more effective than standard solvent extraction methods at liberating fatty acids from biomass [21], as well as experiments in our lab that revealed the identical phenomenon. Initial experiments with *B. braunii* biomass showed a discrepancy in the yield of FAMES between the TE and ISTE methods, with TE giving considerably lower yields. Based on this data, residual biomass from Soxhlet extractions was analyzed with the ISTE method (R-ISTE) to attempt to explain this difference. These data, summarized in Fig. 3, show that ISTE yielded comparable or higher values than extraction–transesterification in all but one case (*C. vulgaris*). While it appears that Soxhlet extraction was effective at liberating all fatty acid-containing lipid for the majority of species tested (Fig. 3a), ISTE was reliable even in cases where the Soxhlet system did not extract all saponifiable lipid, showing a similar result to a recent investigation [21] which compared ISTE to the lipid extraction techniques of Folch, Bligh and Dyer, and Smedes and Askland.

A key finding of this study is that gravimetric yields were not a reliable estimate of total fatty acid content. While this result is not unexpected, we were able to show that the magnitude of this difference was highly variable between samples. Data presented in Fig. 3a, b shows that in most cases gravimetric lipid content does not correlate well

with total fatty acid content, with gravimetric lipid content being several-fold greater in many cases (Fig. 3a, b), and in certain samples (Fig. 3b) actually underestimating total fatty acid content of the biomass due to incomplete Soxhlet extractions. Thus, Soxhlet methods used alone can significantly overestimate or underestimate the potential of specific microalgal strains for biodiesel production, resulting in projected values several times larger than those determined by quantification of FAME. In addition, variations in the percent of FAME in gravimetric extracts between samples (Fig. 3a, b), precludes the use of gravimetric values as an estimate of fatty acid content across diverse strains.

The technique of ISTE proved to be a useful tool that did not share this weakness, and data on individual fatty acids extracted (Table 2) show that re-extraction of residual biomass (R-ISTE) accounted for the balance of individual fatty acids. This confirms that the ISTE procedure is extracting the balance of FAME that were not liberated by Soxhlet extraction rather than extracting additional lipid. Interestingly, values for polyunsaturated fatty acids corresponded well between the two treatments, indicating minimal oxidative damage from Soxhlet extraction, despite exposing extracted lipids to a drying step at 105 °C for 1 h without protection from oxygen.

By comparing the ratio of fatty acids extracted in the TE and R-ISTE treatments to the total for these two treatments, it could be determined that for *B. braunii* (Table 2), Soxhlet extraction was selective in its effect, with C16:0/C18:3n3 being preferentially extracted with respect to other fatty acids, indicating that certain FAME-convertible lipids are more ‘recalcitrant’, notably C28:1, C28:2 and C18:1n9. Data from CCMP 1142 and *T. chuii* did not follow a similar trend (Table 2)—all fatty acids were extracted with identical effectiveness. It should be noted that the results obtained from the *B. braunii* analysis indicate that either technique used in isolation (TE, ISTE) will produce a different FA profile. This argues for caution when interpreting fatty acid data for microalgae, as the extraction technique chosen may bias the profile obtained [22].

In order to test the possibility that the lower FAME yields from TE were due to inadequate and therefore incomplete Soxhlet extractions, residual biomass from ‘recalcitrant’ strains was subjected to an additional, identical solvent extraction treatment, followed by TE of the lipid generated (TE-2) and ISTE of the resulting residual biomass (R-ISTE-2). The results (Fig. 5) show that this additional treatment did not extract all of the remaining fatty acids, indicating that manipulating Soxhlet extraction conditions will not likely result in the maximum yield of fatty acids in this case. It should be noted that these ‘recalcitrant’ fatty acids in *B. braunii* have been shown to

be present at high abundance as C28:1/C18:1/C18:1 and C28:2/C18:1/C18:1 TAGs by previous liquid chromatography-mass spectrometry (LC-MS) studies [33]. These TAG may be difficult to extract due to their large molecular weight, though further analysis of intact TAG would be required to confirm this. Alternatively, *B. braunii* is known to produce degradation-resistant biopolymers that include the identified C28:1/C28:2 fatty acids [26], which may also explain this phenomenon.

In order to understand why ISTE was able to extract total fatty acids more effectively, several experiments were conducted. The use of an identical solvent matrix as the ISTE procedure with the Soxhlet system did not result in an increase in total FA content (data not shown), so it was hypothesized that the acidic nature of the transesterification catalyst was responsible for this pattern. Acidic treatments have been demonstrated to increase the extraction of fatty acids from microalgae [11], presumably due to the hydrolytic release of lipid from other macromolecules as in conventional acid extraction [5].

To demonstrate that acidic treatment was necessary for maximal FAME yields in certain samples, an acid-hydrolysis pre-treatment step was employed for four species (Fig. 6). There was a clear effect of acid hydrolysis, with total fatty acid yield being increased in all cases, although TE-AH approximated the ISTE procedure only in the case of *B. braunii*. This is likely due to the cumbersome nature of this procedure—the extracted lipid from this procedure is not easily re-solubilized in the extraction solvent, and sample loss during boiling steps is possible. In addition, a disadvantage of this procedure is that it yields a gravimetric lipid percentage that is in some cases up to twice that from non-hydrolyzed biomass (data not shown). In the case of *Botryococcus braunii*, this resulted in yields of >70% lipid, which is unlikely to accurately reflect ‘oil’ or biofuel potential, unless other hydrocarbons known to accumulate in *B. braunii* under certain conditions [35, 36] are present in large quantities (not measured in this study).

In addition to offering more rigorous extraction conditions, acidic catalysts have the additional advantage of being able to transesterify all classes of saponifiable lipids [8], which will undoubtedly include compounds other than neutral lipids, such as phospholipids and sphingolipids. In this manner, this technique will likely give an upper limit for the maximum amount of biodiesel that can be produced from microalgal biomass, neither underestimating (Fig. 3b) nor overestimating in the case of crude lipid determinations (Fig. 3a, [13, 34]).

While ISTE analysis is a useful tool, it gives no information on lipid class, a critical consideration for biodiesel where TAG is the preferred feedstock. Thus, while ISTE can give information about esterifiable lipid content, one cannot determine the original source of the FAME. We

therefore decided to use HPLC-CAD to quantify TAG and polar lipids as a percentage of the gravimetric extract. For several samples, the overestimations of fatty acid content by gravimetric yields inversely correlate with TAG levels as measured by HPLC. For instance, *E. huxleyi* exhibited the largest discrepancy between gravimetric lipid content and FAME content (Fig. 3a), while TAG levels were measured at just greater than 1% of overall lipid content (Fig. 4b). In contrast, the Antarctic marine bacillariophyte CCMP 2337, *Scenedesmus dimorphus* and *B. braunii* Race B-2, which showed the smallest discrepancies between gravimetric lipid content and FAME content by ISTE, yielded the highest relative TAG contents of the lipid extract at 64, 45, and 35%, respectively (Fig. 4b). On the other hand, the samples CCMP 2321 and *T. chuii* which also showed a low discrepancy between ISTE and gravimetric yield, had very low TAG content (<5%, Fig. 4b), showing that while the extract had a high fraction of esterifiable matter, TAG was not the main source of the FAME detected. For samples CCMP 1142 and *B. braunii* Race B-3, Soxhlet extraction did not effectively extract total esterifiable lipid, so comparisons could not be confidently made.

Most of the remaining extracts examined that showed larger discrepancies between gravimetric lipid yield and FAME yield by ISTE had correspondingly lower TAG content, with the exception of *N. granulata* CCMP 529 which showed 20% TAG content of the lipid extract. Therefore, the presence of various moderately polar lipid classes and other co-extracted compounds that do not generate FAME upon esterification contribute significantly to the overestimations of gravimetric yields for total fatty acid content. Also, these data show that higher FAME content derived from ISTE does not necessarily suggest TAG accumulation (e.g. CCMP 2321, Figs. 3a, 4b).

In this investigation, the majority of microalgal strains analyzed do not contain greater than ~15% esterifiable lipid with low TAG content, a yield that is likely to decline in an industrial-scale extraction scenario. It is important to point out however, that with the exception of the single N-limited *Botryococcus braunii* culture (Fig. 3b, *B. braunii* Race B-2), and the *I. galbana* chemostat culture (Fig. 3a), none of the microalgae used in this study were cultivated under conditions designed to induce lipid accumulation. Under conditions of nutrient stress, many species of microalgae respond by accumulating lipid, particularly TAG, in storage bodies, presumably as a mechanism to dissipate excess energy capture and/or as a readily available source of energy to mobilize when favorable conditions return [19, 25]. The comparatively low FAME yields presented here may be due to the cultivation conditions employed, which were designed to maximize growth rate and biomass productivity, rather than lipid content.

This investigation has confirmed the potential of strains such as *B. braunii* for biodiesel production, but has also shown that under conditions of fast growth, other purportedly oleaginous strains have low FAME yields, suggesting minimal triacylglycerol accumulation. Lipid content values obtained from hexane extractions strongly suggested minimum neutral lipid content, a conclusion supported by LC-MS analysis [33]. In the future, our lab will be following the lead of other investigators [15, 42] to directly quantify TAG accumulation to support these analyses.

This study confirms the main advantages for using ISTE which include increased precision and accuracy, reduced time and labor costs, elimination of time-consuming pretreatment [27] and easy applicability for routine screening of new microbial isolates [4]. In this lab, replicable FAME data from small scale algal physiological experiments is routinely generated from biomass samples of ~1 mg, something not easily achievable to the authors' knowledge with two-step extraction–transesterification procedures. In addition, the previously mentioned strategies for increasing algal lipid productivity are poorly understood from a physiological perspective [25], and ISTE will be useful in determining whether or not increases in neutral lipid content represent an increase of the total cellular lipid content, rather than a reallocation of FA from one pool to another [16].

Results obtained here argue for caution in projecting oil productivities of microalgal culture using solely gravimetric analyses. The crude lipid values obtained in this study correspond well with the values cited by Chisti [7] for the 'oil content' of selected species of microalgae, including many of the species studied in this paper. Such gravimetric data might lead an inexperienced analyst to conclude a strain has a high potential for biodiesel production, despite the fact that gravimetric data alone cannot give an accurate measure of biodiesel potential.

While Soxhlet extraction of microalgae does not yield crude lipid values useful for judging biodiesel potential, it appears that it is an effective method for extracting total lipids for class analysis, based on the similar FAME yields between TE and ISTE procedures for 12/18 samples investigated here. Based on this data, we suggest the use of quick and accurate GC-FAME analyses such as ISTE, combined with lipid class analysis by GC-TAG or HPLC-CAD to generate an accurate value for 'biodiesel potential' of microalgae. When standardized to daily productivity [20], this offers a robust technique to evaluate microalgal strains for the production of biodiesel.

Abstract Sphingolipids are an important class of compounds that regulate signal transduction and other vital cellular processes. Herein, we report sensitive normal and reversed phase LC–MS/MS methods for quantitation of multiple sphingolipid classes. In the normal-phase ESI/MS/MS method, a high content of organic solvents was utilized, which, although it included hexane, ethyl acetate, acetonitrile containing 2% methanol, 1–2% acetic acid, and 5 mM ammonium acetate, resulted in a very efficient electrospray ionization of the ceramides (Cers) and hexosylceramides (MHCers). Three normal-phase LC–MS/MS methods using segmented phases were developed to specifically target Cers, MHCers, or sphingomyelins (SMs). This segmentation scheme increases the number of data points acquired for a given analyte and enhances the sensitivity and specificity of the measurements. Nine separate reversed phase chromatography methods were developed for the three classes of compounds. These assays were used for comparing the levels of Cers, SMs, and MHCers from mouse embryonic fibroblast (pMEF) and human embryonic kidney (HEK293) cells. These findings were then compared with the reported data from RAW264.7 mouse macrophage cells, BHK21 hamster cells, and human plasma and serum samples. The analysis of cell lines, using both normal and reversed phase chromatography, revealed discrimination based on the type of

chromatography chosen, while sphingolipid assays of samples containing different amounts of protein showed different results, even after normalizing for protein content. Also, LC/MS/MS profiles were provided for the classes and individual compounds so that they could be used as “molecular profiles” for class or individual sample analysis.

Introduction

Sphingolipids, such as ceramides (Cers), hexosylceramides (MHCers), and sphingomyelins (SMs), are an important class of compounds that play vital roles in cell architecture and function [1, 2]. They are highly conserved and are involved in a number of metabolic functions and signal transduction cascades [3–9]. Abnormalities in these compounds are associated with a variety of human diseases, including inborn errors of metabolism, diabetes, atherosclerosis, arrhythmias, myocardial infarction, Alzheimer's, and other neurodegenerative diseases [4, 10–24]. Importantly, certain types of human malignancies, including breast, prostate, colon, ovary, and endometrium cancers, exhibit high levels of fatty acid synthase expression and activity, implicating a role for these compounds in the biology of cancer [25–29]. Considering their role in diseases, these Cers, MHCers, and SMs may represent reasonable biomarkers for providing diagnostic or prognostic information [17, 21, 30–33]. For example, sphingolipids can be potentially used as biomarkers for Alzheimer's disease or other neurodegenerative disorders, disease progression, and therapeutic intervention [30].

Owing to their chemical diversity, no single analytical method is sufficient for studying all the analytes of each of the sub-classes/classes of the lipids. Liquid chromatography–tandem mass spectrometry (LC–MS/MS) methods for sphingolipid analysis, utilizing both electrospray (ESI) and atmospheric pressure chemical ionization (APCI) [34–44], have been reported. It is well established that each class of sphingolipids (i.e., Cers, SMs, and MHCers; the representative compounds with their product ions are shown in Fig. 1), does not separate into individual components by normal-phase chromatography. Instead, all components from a distinct class (e.g., Cers) will move as a single head-group when normal phase chromatography is used. In reversed-phase chromatography, however, each group of compounds (e.g., Cers) tends to separate into individual components [34–39].

Herein we report specific normal-phase and reversed-phase LC–MS/MS methods, where the individual component of analytes from each class of sphingolipids is found to exhibit high sensitivity and good individual peak separations. The sensitivity and specificity of these assays were enhanced because in each method only a few analyte transitions were incorporated that allowed sufficient time to collect more data points on each analyte, and all individual components of analytes exhibited good selectivity. For analysis of analytes by normal-phase ESI/MS utilizing non-polar solvents such as hexane, the organic phase is mixed with 5% isopropanol and ≥ 50 mM buffer salt [43, 44]. In the present context of normal phase chromatography, a high content of organic solvents that includes hexane, ethyl acetate, acetonitrile containing 2%

methanol, 1% acetic acid, and 5 mM ammonium acetate was utilized, yet this method resulted in a very efficient electrospray ionization of the ceramides and hexosylceramides. For normal phase assay, three MS/MS methods were developed, and each of these methods was segmented to include only specifically targeted analytes from each sphingolipid class according to their chromatographic retention times. These three methods were sufficient to incorporate the entire range of analytes from the Cers, SMs, and MHCers. Due to the wider chromatographic selectivity of reversed-phase chromatography, a total of nine methods, three for each individual class of compounds, was developed. Subsequently, these optimized analytical methods were applied to quantitate and compare cellular sphingolipid contents from mouse embryonic fibroblasts (pMEF) and human embryonic kidney (HEK293) cells. We also show the evidence of quantitative discrimination related to the type of chromatography used, and the amount of protein present in compared samples.

Experimental Section

Materials

The following were purchased from Avanti Polar Lipids, Inc., Alabaster, AL. *N*-arachidonoyl-D-erythrosphingosine (Cer d18:1 Δ^4 c20:0); *N*-nervonoyl-D-erythrosphingosine (Cer d18:1 Δ^4 c24:1), *N*-palmitoyl-D-erythro-sphingosylphosphorylcholine (SM d18:1 Δ^4 c16:0); *N*-stearoyl-D-erythro-sphingosylphosphorylcholine (SM d18:1 Δ^4 c18:0); and LM 6002 internal standard, which is a 25- μ M mixture of 10 different sphingolipids; Sphingosine (C17:1 base); Sphinganine (C17:0 base); Sphingosine-1-PO₄ (C17:1 base); Sphinganine-1-PO₄ (C17:0 base); Lactosyl(β) C12 Ceramide; 12:0 Sphingomyelin; Glucosyl(β) C12 Ceramide; 12:0 Ceramide; 12:0 Ceramide-1-PO₄; and 25:0 Ceramide. Reagents and all HPLC-grade solvents were purchased from either Fisher Scientific (Pittsburgh, PA) or Sigma-Aldrich (St. Louis, MO). The HEK293 cell line was obtained from the American Type Culture Collection (ATCC; [#CRL-10892]), designation 293 C18.

HEK293 Cell Growth and Lysis

HEK293 cells were grown in suspension, using serum-free medium. After harvesting, the cells were washed three times in PBS buffer and the cell pellets were stored at -80 °C. To obtain the lysate, cells were resuspended in 50 mM NH₄HCO₃ (pH 7.9), placed in a Dounce homogenizer, and homogenized by 10 gentle strokes. The supernatant was collected after centrifugation at low speed (500 \times g) for 15 min, and assayed for protein content using a BCA assay.

Fig. 1 Structures for some of the representative ceramides, hexosylceramides, and sphingomyelins and their associated specific product ions that were monitored. A core chain for a sphingoid base can be saturated or unsaturated and contains a 2-amino-1,3-dihydroxy moiety, and a notation d18:1^{Δ4}; for example, a dihydroxy 18 carbon core chain with a double bond on the fourth carbon atom starting from

the hydroxyl terminus of the core chain. The notation c18:0 is for the number of carbon atoms on the *N*-acyl side chain. All d18:1^{Δ4} and d18:0 ceramides, hexosylceramides, and sphingomyelins can form specific carbocation product ion fragments of *m/z* 264 and 266, respectively. Sphingomyelins will form a highly sensitive product ion choline phosphate of *m/z* 184

Isolation of Primary Mouse Embryonic Fibroblasts (pMEF)

The cells were isolated from pregnant mice as follows. E 10.5 dpc (day post-coitum) embryos were separated from the yolk sac, washed twice with PBS buffer (pH 7.2), and trypsinized for 10 min. The cells were disaggregated by pipetting several times and suspended in 1 mL of pre-warmed (37 °C) DMEM supplemented with 10% FBS. The suspension was allowed to stand for 2–3 min at room temperature, and the visible clumps were removed. The suspension was centrifuged at 500×*g* for 3 min, and the

cell pellet was collected, resuspended in MEF media (DMEM + 10% FBS), and plated on a 6-well plate. The plates were incubated at 37 °C with 3% O₂ and 5% CO₂ [45]. The medium was replaced the next day, and the cells cultured for 4–5 days. Forty-eight hours before extracting the lipids, the cells were shifted to serum-free DMEM medium. Total cell lysate was prepared by homogenizing the cells by applying 20 strokes using a Dounce homogenizer and homogenization buffer (50 mM tris, pH 7.4, 1 mM EDTA, 50 mM NaCl). Cell debris was removed using low-speed centrifugation (500×*g* for 15 min) and the sample assayed for protein content using BCA assay.

Preparation of Sphingolipid Extracts

Lipid extracts were prepared according to the method described by Merrill et al. [37–39]. In brief, to 50 μL of pMEF cell extract containing $\sim 250 \mu\text{g}$ of protein, or 1×10^7 of HEK293 cell lysate taken in a 4-mL Teflon-capped glass vial (Fisher scientific, cat # W 224582) were added 0.5 mL of methanol (CH_3OH), 0.250 mL of chloroform (CHCl_3), 50 μL of water (H_2O), and 30 μL of 25 μM solution of LM-6002, providing 750 pmol of each of its individual constituent internal standards. The lipid aggregates were dispersed by sonicating 6 times, using a Branson tip sonicator at an amplitude setting of 21% for 10 s each, with a resting interval of 5 s between pulses. The samples were further sonicated for 1 h, using a bench top sonicator, and incubated overnight at 48 $^\circ\text{C}$ with shaking. After cooling the sample to ambient temperature, 75 μL of 1 M methanolic potassium hydroxide (KOH) was added, followed by incubation at 37 $^\circ\text{C}$ for 2 h with shaking to hydrolyze glycerophospholipids. The sample solution was divided into two equal aliquots. One aliquot was neutralized by the addition of 7 μL of glacial acetic acid (CH_3COOH) and 2 mL of water. The mixture was extracted twice, using two 1.2-mL volumes of CHCl_3 . The lower organic portions were collected, combined, and evaporated to dryness using a Savant Speed Vac Concentrator (GMI, Ramsey, MN). The dried sample was re-suspended in 300–400 μL of 1:3 (v/v) CHCl_3 and normal-phase A (5 mM $\text{CH}_3\text{COONH}_4$ dissolved in 20 mL CH_3OH , 15 mL CH_3COOH , 270 mL CH_3CN , 300 mL $\text{CH}_3\text{COOCH}_2\text{CH}_3$, and 400 mL hexanes). The other half of the sample was evaporated to approximately 25 μL , using a Speed Vac Concentrator, and reconstituted by adding 300–400 μL of 1:1 (v/v) reversed mobile phase A (74/25/1 [v/v/v] $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{HCOOH}$ containing a final concentration of 5 mM HCOONH_4) and reversed mobile phase B (99:1 [v/v] $\text{CH}_3\text{OH}:\text{HCOOH}$ containing a final concentration of 5 mM HCOONH_4). The sample was vortexed for 1 min, followed by centrifugation at $13,200\times g$ (Eppendorf Centrifuge 5415 D) for 2 min, and the supernatant was transferred to a fresh Eppendorf tube.

Liquid Chromatography–Tandem Mass Spectrometry

Liquid chromatography–tandem mass spectrometry (LC–MS/MS) analysis was performed using a TSQ Discovery triple quadrupole mass spectrometer (Thermo Electron Corp., San Jose, CA, USA) equipped with an electrospray ionization (ESI) source. The mass spectrometer was coupled to an Agilent 1100 series HPLC system fitted with a 100- μL /min max flow controller and a 40- μL sample injection loop.

Normal-phase chromatography was performed using a binary system and a 7.5 cm \times 3.0 mm \times 3 μm Supelcosil

LC- NH_2 column operating at a flow rate of 100 $\mu\text{L}/\text{min}$ and maintained at 37 $^\circ\text{C}$. Initially, a high flow rate method was tried using this column; however, at the slow flow rate of 100 $\mu\text{L}/\text{min}$, good optimal results were observed. The mobile phase buffer A consisted of 5 mM $\text{CH}_3\text{COONH}_4$ dissolved in 20 mL CH_3OH , 10 mL CH_3COOH , 270 mL CH_3CN , 300 mL $\text{CH}_3\text{COOCH}_2\text{CH}_3$, and 400 mL hexanes. Mobile phase buffer B consisted of 5 mM $\text{CH}_3\text{COONH}_4$ in 99:1 (v/v) $\text{CH}_3\text{OH}:\text{CH}_3\text{COOH}$. Approximately 10 μL of sample was injected onto the column and the following gradient conditions were applied: 0% B was held for 5 min, increased to 18% mobile phase B over 1.5 min and held there for 2.5 min; increased to 65% B over 0.5 min and held there for 3.5 min; increased to 98% B over 5 min and held there for 3.5 min; and decreased to 0% B over 0.5 min. The column was re-equilibrated for 8 min prior to the next injection.

Reversed-phase chromatography was performed using a 5 cm \times 1 mm i. d. \times 5 μm Discovery C18 column (Supelco, Bellefonte, PA), operating at a flow rate of 100 $\mu\text{L}/\text{min}$ and maintained at 37 $^\circ\text{C}$. Mobile phase A consisted of 5 mM HCOONH_4 in 74/25/1 (v/v/v) $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{HCOOH}$, while mobile phase B consisted of 5 mM HCOONH_4 in 99:1 (v/v) $\text{CH}_3\text{OH}:\text{HCOOH}$. For each LC–MS/MS experiment, ca. 10 μL of sample was injected onto the column and was fractionated using the following gradient conditions: 10% B was held for 4 min; increased to 95% B over 3 min and held there for 4 min; increased to 99% B buffer over 6 min and held there for 6 min; decreased to 10% B over 0.5 min. The column was re-equilibrated for 6.5 min prior to the next injection. Both normal-phase and reversed-phase chromatography were performed in main-pass flow in a normal mode on a 40- μL injection volume and without any post-time column flow.

The ESI source conditions were optimized at a LC flow rate of 100 $\mu\text{L}/\text{min}$, using a mixture of LM 6002, brain porcine, and other Cer and SMs, including Cer d18:1 $^{\Delta 4}$ c12:0, Cer d18:1 $^{\Delta 4}$ c18:1, Cer d18:1 $^{\Delta 4}$ c18:0, Cer d18:1 $^{\Delta 4}$ c20:0, Cer d18:1 $^{\Delta 4}$ c24:1, Cer d18:1 $^{\Delta 4}$ c24:0, SM d18:1 $^{\Delta 4}$ c12:0, SM d18:1 $^{\Delta 4}$ c16:0, and SM d18:1 $^{\Delta 4}$ c18:0. The optimized source parameters were as follows: ionization mode, positive; sheath gas pressure, 7 psi; auxiliary gas pressure, 3 (arbitrary units); electrospray needle voltage, 4,500 V; capillary temperature, 300 $^\circ\text{C}$; skimmer offset, -5 V . No in-source fragmentation was observed when the reference compounds were analyzed using direct infusion with skimmer offset values of -7 and less. However, at higher skimmer offset values of 15, ceramides seemed to undergo some water loss to form $[\text{M}+\text{H}-\text{H}_2\text{O}]^+$ ions.

Collision energies between 23 and 31 V provided optimal fragmentation of $[\text{M}+\text{H}]^+$ ions to product ions at m/z 264.2 and 266.2, corresponding to doubly dehydrated product ion fragments for unsaturated and saturated d18:1 $^{\Delta 4}$ or d18:0 sphingoid base backbones, respectively, from Cer

and MHCer, and m/z 184.1, corresponding to the choline phosphate moiety of sphingomyelin. Collision-induced dissociation was performed using nitrogen gas within Q2, which was offset from Q1 by 10 V. Prior to running SRM experiments, precursor ion scans were performed for m/z 184, 264, and 266 to detect choline containing analytes or sphingolipid constituents with d18:1 or d18:0 sphingolipid base backbone. For experiments conducted using normal-phase chromatography, a total of three single-reaction monitoring (SRM) methods were constructed, each partitioned into 5 segments. Between six and eight analyte transitions from a specific sphingolipid class, along with the corresponding internal standard, were included in each segment to maximize the number of data points and attain maximum sensitivity. The first (3 min) and fifth segments (6 min) of each method contain fictional analyte transitions. In the second segment (3 min), transitions targeting Cer were included, while the third (10.5 min) and fourth segments (7.5 min) contain transitions to measure MHCers and

SMs, respectively. Because no analytes were monitored in the fifth segment, a dummy transition was incorporated in this segment. For reversed-phase chromatography experiments, three individual SRM methods comprised of three segments were constructed for each class of compounds; therefore, for three classes of compounds Cers, MHCers, and SMs, nine individual methods were constructed as analytes from each sub-class, spanning a much wider zone. The first and the last segments, spanning 6 and 3 min, respectively, contain the fictional transition, as no analytes were eluted during these time spans, while the second segment (21 min) contains 6–7 analytes and their internal standard transitions.

The acquisition parameters common to all analytes were: scan width (m/z) 0.10; scan time, 0.20 s for each transition; peak width (FWHM) 0.70 for both Q1 and Q3; collision pressure 1.5 mTorr; and skimmer offset at -5 V. Other acquisition parameters and chromatographic retention times are listed in Tables 1, 2, and 3. Data acquisition

Table 1 Retention times and compound-specific SRM parameters for ceramides (Cer), hexosylceramides (MHCer), and sphingomyelins (SM) transitions that are included in the 2nd, 3rd, and 4th segments of the five-segmented normal-phase HPLC–ESI–MS/MS method 1

and analysis were accomplished using Xcalibur software v.2.0.5 (Thermo Electron Corp.). Quantitation data was not corrected for the double bond differences since the degree of unsaturation is limited, due to the existence of up to only two double bonds. However data was corrected for the carbon number difference between a given molecular species and the selected internal standard (i.e., to include the difference in degrees of freedom due to varying carbon chain lengths, which results in different ionization efficiencies) according to the following formula: $z_1 = (1 + 0.011n + 0.011^2 n(n-1)/2)/(1 + 0.011s + 0.011^2 s(s-1)/2)$ [42].

The internal standard LM 6002 was added to each sample at the beginning of sample preparation, and the ratio of peak areas of an analyte versus internal standard was calculated. An advantage of this quantitative technique is that ionization suppression effects of the matrix, and the variation in ionization efficiency between standards and analytes are compensated.

Results and Discussion

Normal-Phase Liquid Chromatography–Tandem Mass Spectrometry

Ceramides, SMs, and MHCers can be resolved and quantitated using normal-phase liquid chromatography, since the separation is based on head group characteristics rather than on the presence of different lengths of fatty-*N*-acyl side chains [46, 47]. Therefore, the components of an individual sphingolipid class elute together when separated by normal-phase liquid chromatography, and a single peak, primarily due to lipophilic (hydrophobic) interaction, is displayed. Thus, all Cers elute with similar retention times, as do MHCers and SMs, etc., which are displayed as single peaks but at different retention times. Accordingly, the quantitative analysis of the head group classes by normal-phase chromatography is not capable of distinguishing the isotopic ¹³C contributions from [M+H+1]⁺ and

NP Normal phase; RP reversed phase; NO not observed; NI not identified; V Volts; min minutes; m/z mass to charge ratio

$[M+H+2]^+$ and other isomeric species, since it does not provide a distinction between the compounds containing an unsaturated (sphingosine) and/or saturated (sphinganine) base structures, as all the components are displayed at a single retention time. The MS/MS mass filters that are used to identify these analytes cannot differentiate between co-eluting compounds with overlapping m/z values, unless the transition ions used for SRM are widely different for each analyte that was monitored. Therefore, normal-phase chromatography is typically employed to quantitate total Cers or SMs inclusive of all low- and high-abundant species, rather than individual components of Cers and SMs. In normal-phase chromatography, although all lipid classes are separated, components of the same lipid class elute together; thus, there exists the possibility of inter-molecular interactions from individual components within the lipid class that may lead to some ion suppression. In comparative analysis, when performed, for example, between wild and mutant species, such effects during analysis do cancel each other out.

In the present non-polar LC–MS/MS method presented here, many of the components from each class of compounds (e.g., MHCer d18:1 Δ^4 c16:0 [retention time, 9.96 min, Fig. 2, panel j], MHCer d18:1 Δ^4 c18:0 [rt: 9.41 min, Fig. 2, panel l], MHCer d18:1 Δ^4 c20:0 [rt: 8.91 min, Fig. 2, panel n] or between cer d18:1 Δ^4 c16:0 [rt: 4.33 min, Fig. 2, panel c] and cer d18:1 Δ^4 c18:0 [rt: 4.30, Fig. 2, panel f]) were well resolved. This method is also capable of differentiating between saturated (sphinganine-containing) and unsaturated (sphingosine-containing) isomorphous components that differ only by two hydrogen atoms (e.g., SM d18:1 Δ^4 c18:0 [rt: 17.52 min, Fig. 2, panel t], and SM d18:0 c18:0 [rt: 17.16 min, Fig. 2, panel u]). The present method exhibits picogram-level sensitivity for each lipid class.

Three SRM–MS assays that rely on normal-phase separation to analyze Cers, SMs, and MHCers from mammalian cells, as described in the Experimental Section, were developed. Using these methods, as shown in Figs. 2, 3, and 4 and Tables 1, 2, and 3, Cers appear at retention times between 4.1 and 4.5 min, while MHCers and SMs

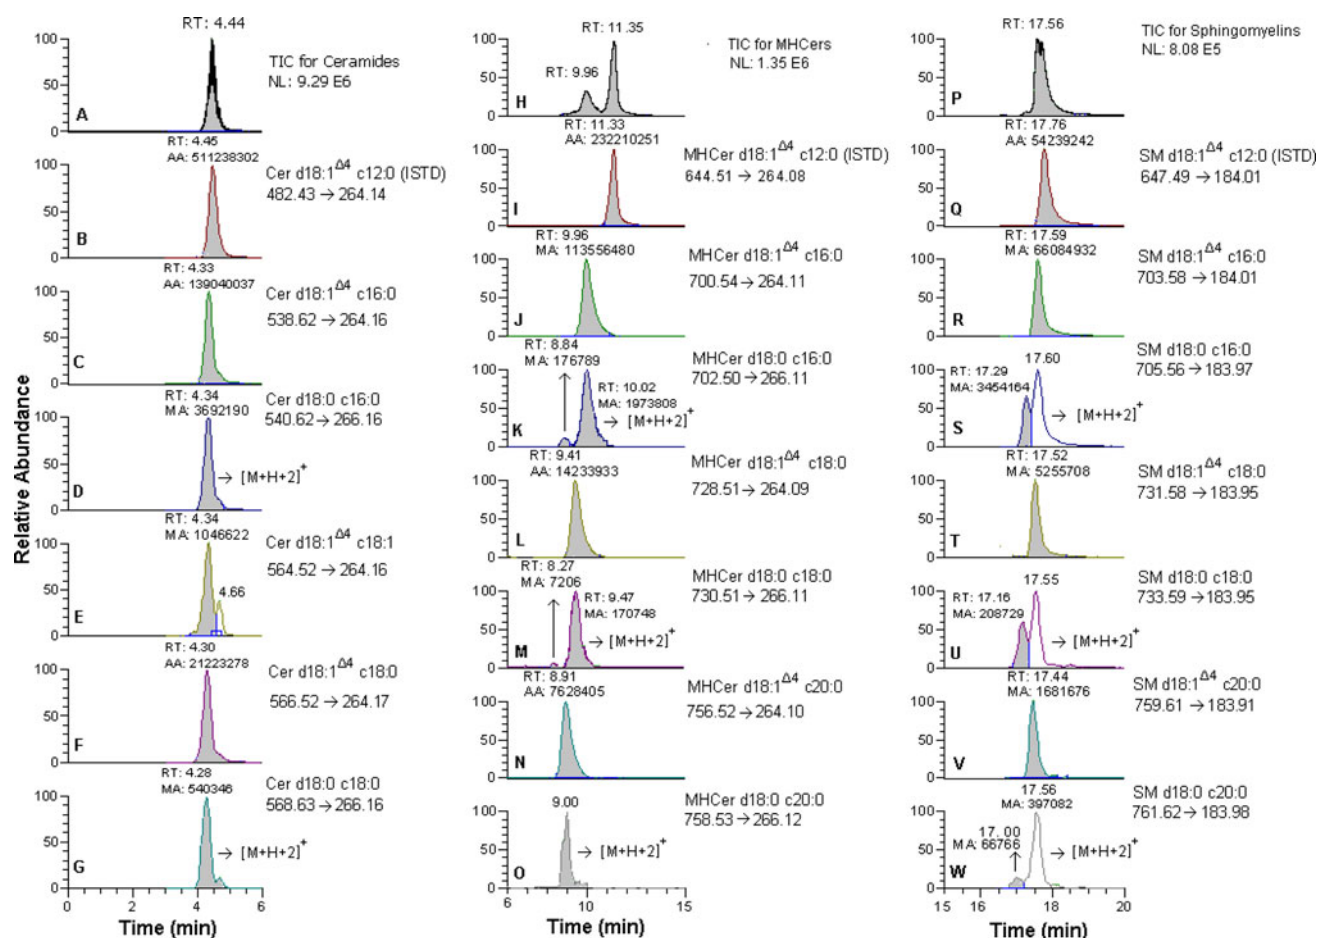

Fig. 2 Extracted ion chromatogram from SRM scans of precursor \rightarrow double-dehydrated carbocation product fragment for the ceramides (transitions from molecular ions of 482–568), hexosylceramides (transitions from molecular ions of 644–758), and sphingomyelins

(transitions from molecular ions of 644–758), including the respective internal standards by method 1 of the normal-phase liquid chromatography–tandem mass spectrometry

elute over wider retention time ranges, (7.7–11.5 and 16.2–17.8 min, respectively). Compounds containing the sphingoid base backbone that differ by two hydrogen atoms, but contain equivalent numbers of all other atoms, are fully resolved for MHCers and reasonably well to partially resolved for SMs by using this method. A few trends are clearly discernable within the data. As the number of methylene groups within the Cers, MHCers, and SMs increase, the retention times decrease. For example, Cer d18:1 Δ^4 c16:0 appears at a retention time of 4.33 min (Fig. 2, panel C), while Cer d18:1 Δ^4 c18:0 appears at a retention time of 4.30 min (Fig. 2, panel f). Compounds with unsaturated sphingoid base backbones and their saturated counterparts containing the same number of non-hydrogen atoms but differing by only two hydrogen atoms, always appear as pairs, with the saturated compound eluting first. For example, SM d18:1 Δ^4 c22:0 (Fig. 3, panel Q) and SM d18:0 c22:0 (Fig. 3, panel r) appears at a retention time of 17.38 and 16.85 min, respectively. For compounds with an equivalent number of non-hydrogen

atoms, the saturated compound elutes fastest, followed by the one in which the double bond is present on the sphingoid base backbone. When double bonds are present both on the sphingoid base and the fatty-*N*-acyl moiety, then such a compound elutes last. This is illustrated in the example for the following series of compounds with 18 carbon atoms on the sphingoid chain and 24 carbon atoms in the *N*-acyl fatty acid side chain, where the order of elution is: d18:0 c24:0 < d18:1 Δ^4 c24:0 < d18:0 c24:1 < d18:1 Δ^4 c24:1. Finally, the retention times shown for compounds possessing an unsaturation in both their sphingoid base backbone and side chain are similar to the compound that contains the same sphingoid base backbone but with two fewer methylene groups and does not possess any unsaturation in its *N*-acyl side chain. For example, the retention time exhibited for MHCer d18:1 Δ^4 c24:1 (Rt: 8.45 min, Fig. 3, panel l) is similar to that of MHCer d18:1 Δ^4 c22:0 (Rt: 8.49 min, Fig. 3, panel j), or SM d18:1 Δ^4 c24:1 (Rt: 17.34 min, Fig. 3, panel t) is similar to that of SM d18:1 Δ^4 c22:0 (Rt: 17.38 min, Fig. 3, panel q).

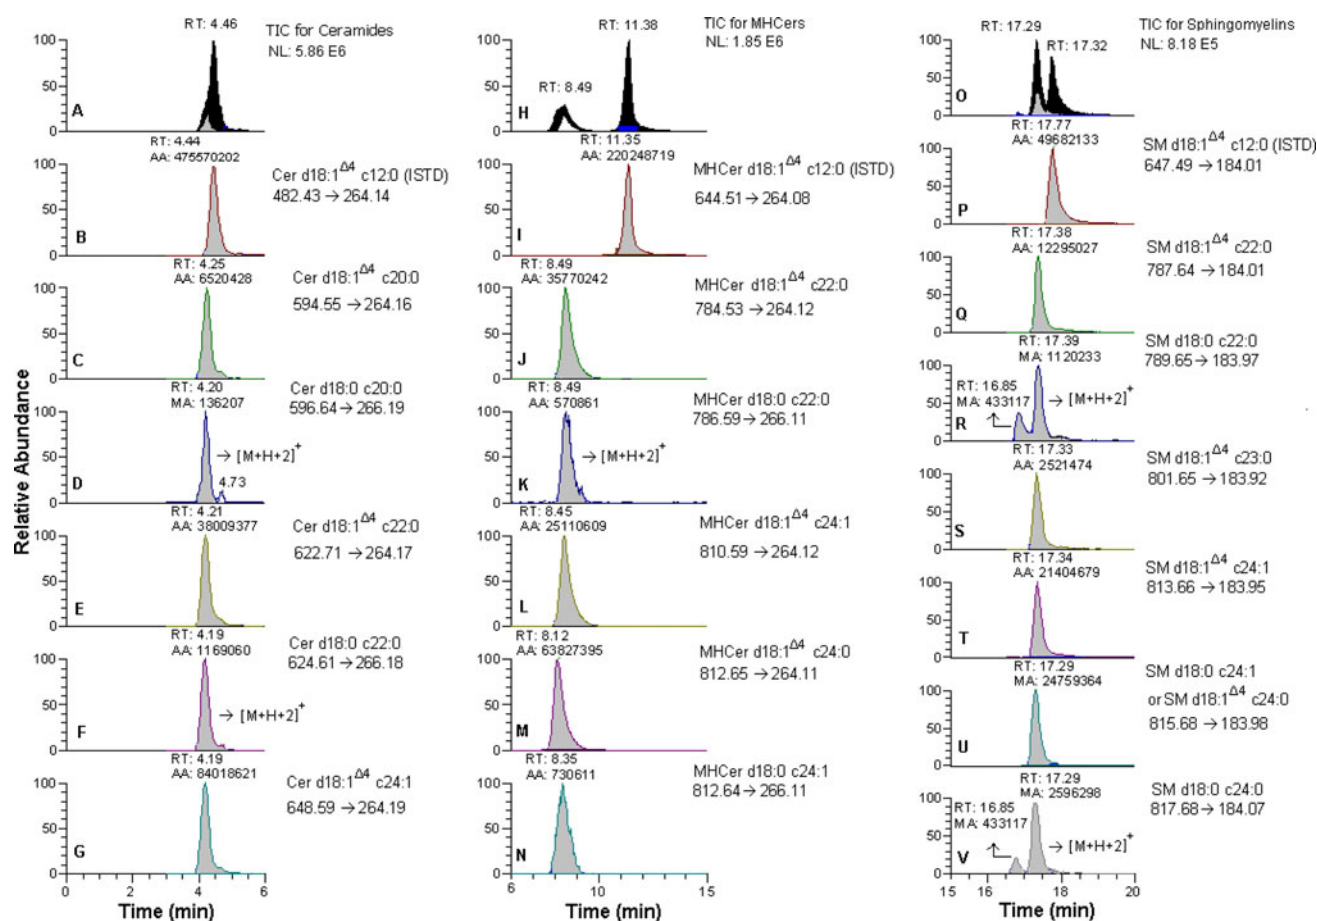

Fig. 3 Extracted ion chromatogram from SRM scans of precursor \rightarrow double-dehydrated carbocation product fragment for the ceramides (transitions from molecular ions of 594–648), hexosylceramides (transitions from molecular weight of 784–812), and sphingomyelins

(transitions from molecular ions of 787–817), including the respective internal standards by method 2 of the normal-phase liquid chromatography–tandem mass spectrometry

Sphingolipid analysis of RAW264.7 cells using normal-phase LC–MS/MS has been reported previously by Shaner et al. [35]; however, individual analytes from each sphingolipid class were not chromatographically resolved. In their study, ceramides and hexosylceramides eluted as single peaks, as did SMs and lactosylceramides. If the components from each class of analytes are not resolved, there will be considerable overlap of not only the compounds with the same nominal masses such as isomeric and isobaric species, but also, due to the $[M+H+1]^+$ and $[M+H+2]^+$ carbon ^{13}C isotopic contributions from 2 Da lower sphingoid core unsaturated compounds to a 2 Da higher sphingoid base saturated molecular species. This problem is compounded when the unsaturated analogue is more abundant than its corresponding saturated sphingoid base analogue. Theoretically, the isotopic contribution from $[M+H+1]^+$ and $[M+H+2]^+$ can be calculated based on the number and kind of atoms present or the intensity of the peak observed, and for the $[M+H+2]^+$, should be in the theoretical range ca. 6–10%, depending upon the number of

atoms present; in addition, the double ^{13}C isotope must be contained in both the precursor and product ion. In the present experiments, the isotopic contributions to the saturated sphingoid base dihydro species due to $[M+H+2]^+$ from the corresponding sphingoid base dehydro species (e.g., un-saturated d-18 sphingoid base with product ion of m/z 264.2), are found to be 6–10% of the amount of the unsaturated species, even if for example m/z 266.2 of the saturated d-18 sphingoid base product ion transition is monitored by SRM. Thus, the dehydro species almost always seems to exhibit a lingering (residual) small d-saturated product ion transition coming from the sphingoid base skeleton, similar to that arising from the dihydro species, or could as well be due to some isobaric contribution. Hence, unless the d-unsaturated and d-saturated analogues are chromatographically resolved, or if the retention times for both species are the same, the existence of the dihydro-saturated species can only be considered if the peak area of the saturated dihydro compound is more than 5–10% of the corresponding dehydro-unsaturated species.

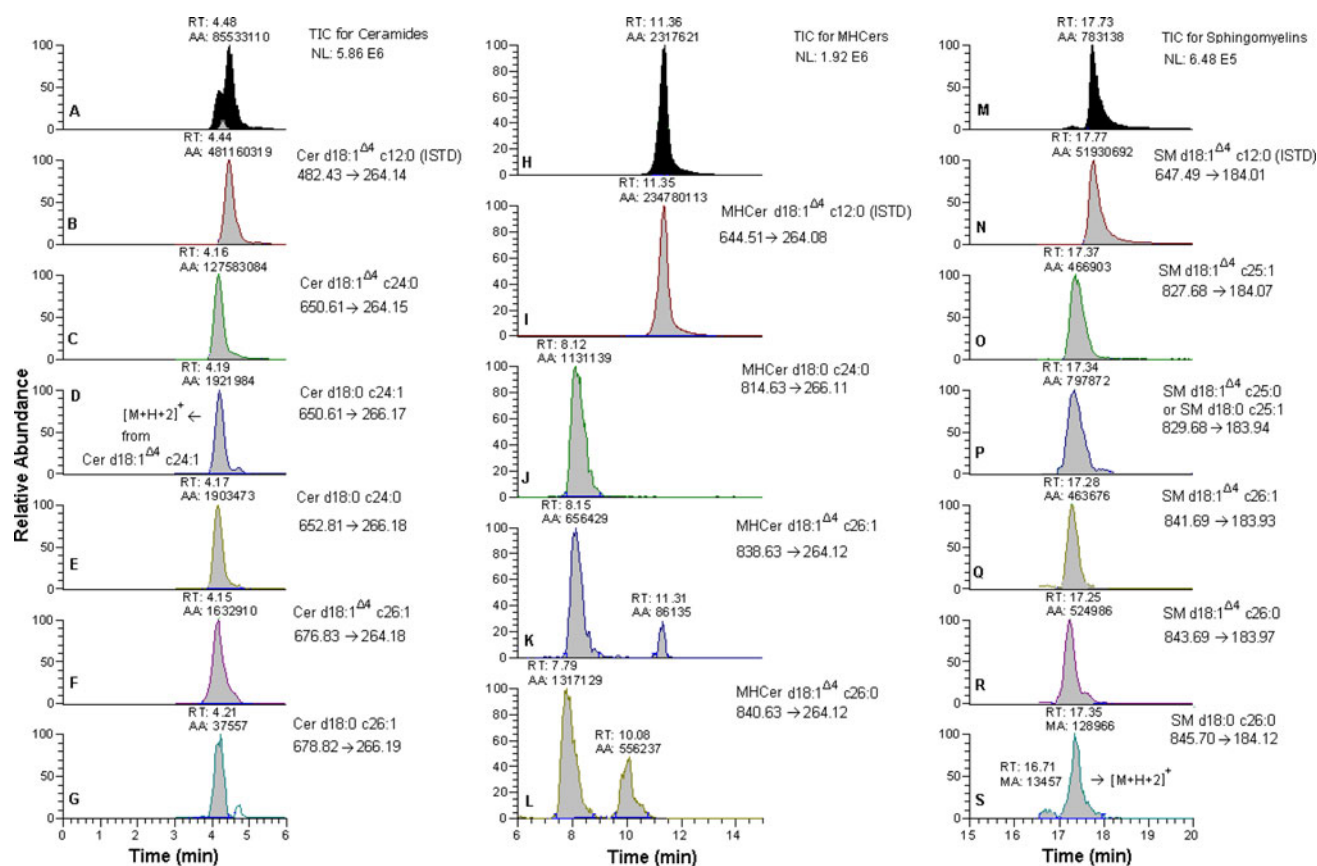

Fig. 4 Extracted ion chromatogram from SRM scans of precursor → double-dehydrated carbocation product fragment for the ceramides (transitions from molecular ions of 650–679), hexosylceramides (transitions from molecular weight of 814–840), and sphingomyelins

(transitions from molecular ions of 827–845), including the respective internal standards by method 3 of the normal-phase liquid chromatography–tandem mass spectrometry

The LC–MS/MS data for sphingolipids obtained from the analysis of HEK293 and MEF cells are presented in Tables 4 and 5, respectively. Table 4 presents the data obtained using normal-phase chromatography to analyze the HEK293E cells, while Table 5 provides comparative data obtained by both normal-phase and reversed-phase chromatography to analyze MEF cells. The quantitative data indicates that the ceramide levels in HEK293E cell present are ca. 10 nmol, while the levels for MHCers and SMs are <50 nmol each. Therefore, the fatty acid contribution from these sphingolipid classes is <200 nmol in this cell analysis.

Comparative Sphingolipid Measurements

Normal-phase LC–MS/MS methods were developed to quantify and compare the levels of SMs, Cers, and M in HEK293 and MEF cells (Tables 4, 5). In both cell types, d18:1 Δ^4 c16:0 represents ~45–55% of the total amount of SM, followed by d18:1 Δ^4 c24:1 (~20%) and d18:1 Δ^4 c24:0 (~17.5 and 10% in HEK293 and MEF cells, respectively). The major Cer present in HEK293 cells is d18:1 Δ^4 c24:0

(~32% of total), followed by d18:1 Δ^4 c16:0 (25%), d18:1 Δ^4 c24:1 (25%), and d18:1 Δ^4 c22:0 (17%). In MEF cells, a similar pattern was observed with d18:1 Δ^4 c16:0, d18:1 Δ^4 c24:1, d18:1 Δ^4 c24:0, and d18:1 Δ^4 c22:0 constituting about 80–90% of the total Cer content.

The measurement of monohexosylceramide, i.e., hexosylceramide (MHCer), levels in HEK293 cells using normal-phase chromatography, shows d18:1 c24:0 as the dominant MHCer (~50% of total), followed by d18:1 Δ^4 c22:0 (~21%), d18:1 Δ^4 c24:1 (~14%), and d18:1 Δ^4 c16:0 (~10%), respectively. In MEFs, d18:1 Δ^4 c16:0 (30%) and d18:1 Δ^4 c24:0 (30%) are the dominant MHCers, followed by d18:1 Δ^4 c24:1 (20%) and d18:1 Δ^4 c22:0 (11%). Overall, the Cer, MHCer, and SM profiles of the two cell types are similar, with the predominant species being the d18:1 Δ^4 c16:0, d18:1 Δ^4 c24:0, d18:1 Δ^4 c24:1, and d18:1 Δ^4 c22:0 molecules. Importantly, the sphingolipids mixture of internal standard containing C17 or C12 bases (LM6002) are unnatural synthetic lipids, and consequently, no endogenous signals of these categories were observed from the cell lines.

In the study by Shaner et al. [35], the most abundant SM in RAW264.7 mouse macrophage cells was d18:1 Δ^4 c16:0,

CV is based on triplicate run of samples. *NO* not observed; *NI* not identified

followed by d18:0 c16:0 and d18:1 Δ^4 c24:1. These results are similar to what we observed for HEK293 and MEF cells, except that we found much lower levels of d18:0 c16:0. The levels of Cer d18:1 Δ^4 c24:0, d18:1 Δ^4 c16:0, and d18:1 Δ^4 c24:1 found using our method, are also similar to those reported by Merrill et al. While we and Merrill et al. found that MHCer d18:1 Δ^4 c16:0 was the most abundant MHCer in MEF cells, this lipid was the third most abundant species in HEK293 cells. Previously Koivusalo et al. [47] found only three SMs in the BHK21 hamster cells, SM, d18:1 Δ^4 c16:0 (65% of total sphingolipid content), SM d18:1 Δ^4 c24:1 (20%), and SM d18:1 Δ^4 c24:0 (15%), similar to the top three SMs observed in HEK293 and MEF cells. Other SMs in their studies might not have been observed, perhaps due to the lack of the sensitivity of their assay. Hammad et al. [48] performed the sphingolipidomic analysis of the serum and plasma samples of both healthy human males and females, and these authors reported d18:1 Δ^4 c16:0, and d18:1 Δ^4 c24:1 as the two most abundant sphingomyelins and monohexosylceramides, and d18:1 Δ^4 c24:0, d18:1 Δ^4 c24:1 as the two most abundant ceramide species. Thus, from all these quantitative analyses of different cells and tissues, we can say with some confidence that d18:1 Δ^4 c16:0 and d18:1 Δ^4 c24:1 might be the top sphingomyelin candidates, and Cer d18:1 Δ^4 c24:0, d18:1 Δ^4 c16:0, and d18:1 Δ^4 c24:1 might be the top three ceramide

species present in many types of mammalian cells; and therefore, comparison of these dominant top sphingolipids in healthy and disease cells might provide some insights into the prognosis of health and disease. It should be noted that nerve tissues that are not studied here might have some other Cers and SMs, such as those that contain hydroxyl fatty acids in their chains as the dominating species.

Impact of the Sample Protein Amount on Sphingolipids Quantitation

When different batches of MEF cell samples containing different amounts of protein were collected and processed for NP-LC/MS/MS, the quantitative data was irreproducible, even after normalization based on protein concentration. Initially, it was thought that this discrepancy in data might be due to a subtle variation in the cell preparation and collection technique, and consequently in the sample handling; hence, the samples might have varying matrix type of effects. However, this discrepancy might also be due to the different protein levels that were present in the samples when different amount of samples were taken; and if this is true, then at what range of protein content in the sample will the sample give consistent quantitative estimation of analytes. To test these hypotheses, aliquots of MEF cells containing different amount of proteins

(i.e., 400, 250, 100, 50, and 25 μ g of total protein levels) were processed for LC–MS analysis. The sphingolipid data for SMs and Cers along with their percentages are presented in Table 6. These samples were prepared identically and then processed at the same time. It is very clear from

Table 6 that as the absolute amount of protein in the samples decreases, the total amount of Cer measured increases. At moderately high protein content (400 μ g), the Cer levels measured were only half as great compared to those found in the sample containing the lowest amount of

Table 6 Comparative liquid chromatography selected reaction monitoring data obtained for the evaluation of sphingomyelin (SM), and ceramides (CER) from mouse embryonic fibroblast cells that contain

different amount of absolute protein. Data is normalized to the 1-mg protein level

protein (25 µg). However, it is apparent that the overall percentages of the individual Cer components remain similar. Ceramide levels in the samples containing 50–250 µg of protein exhibited minimal differences. To measure Cer in cells, the absolute range of protein levels should be between 50 and 300 µg; otherwise, the data will lose quantitative integrity in terms of absolute amounts.

For SM, the data shows consistency between 50 and 400 µg of protein, whereas at 25 µg of protein, the total SM levels appear to be relatively high; however, some of the signals were of low intensity and showed poor peak shape. Therefore, if sphingolipids such as Cers, MHCers, and SMs are being measured in comparative samples, it is important to begin with samples containing similar amounts of total protein. The recommended protein level is between 50 and 300 µg.

It is known that analyzing lipids by direct infusion into the mass spectrometer at high concentrations (i.e.,

10 pmol/µL or ca. 150 pmol/µL of total lipids), the relative response decreases strongly to increasing acyl chain length [47]. At lower concentrations (i.e., 5 or 60 pmol/µL of total lipids), however, the response is essentially linear with the chain length as lipid–lipid interactions and lipids-to-solution droplets crowding at the ESI inter-phase are minimized [42, 47]. It should, however, be noted that use of chromatography will essentially dilute this process because of the separation of analytes, and at a given duration of time not many analytes co-elute. This is particularly true for RP chromatography, where individual analytes from each class are well separated. Even with NP chromatography, all the sphingolipid classes viz. ceramides, hexosylceramides, and sphingomyelins are well separated into bands appearing at vastly different retention times, with many individual analytes from each class partially to fully resolved. Further, the volume of sample solution injected on to a column in this study is ca. 10–20 µL from a total

sample volume of ca. 700–800 μL divided between the NP and RP chromatography; therefore, given the amount of protein assayed in these samples, the lipid contents in this injected volume might not be too high at all.

Sphingolipid Analysis Using Reversed-Phase Liquid Chromatography–Tandem Mass Spectrometry

We also developed reversed-phase LC–MS/MS methods to quantitate Cers, MHCers, and SMs. The SRM profiles are shown in Figs. 5, 6, and 7, respectively. Reversed-phase chromatography has higher selectivity and specificity for these compounds than normal phase chromatography, owing to its superior resolution of these molecules. The separation in reversed-phase chromatography is based on the hydrophobicity of the fatty-*N*-acyl side chains, rather than on head group separation of these molecules. For each class of analytes, three SRM methods were constructed, each employing between 5 and 7 analyte transitions, enabling the analysis of 18–20 molecules within each class. Excellent signals were observed for all SMs (Fig. 7); however, signals for MHCer were very poor for samples

containing low and moderate levels of these compounds (Fig. 6). Some of the elution trends observed when separating the compounds using normal-phase chromatography were reversed in reversed-phase chromatography, e.g., as the number of methylene groups increased in each class of sphingolipids, their retention times increased, while the d-unsaturated and d-saturated still appeared as pair, the dihydro species appearing at a higher retention time, compared to the corresponding dehydro compound.

Obtaining the necessary sensitivity for some of the low-abundant species, particularly for hexosylceramides in reversed-phase chromatography, may require injecting larger amounts of material onto the column. This need can be a limiting factor when little biological sample is available. Furthermore, the interaction of Cers, MHCers, and SMs with the solvents used in reversed- and normal-phase chromatography differ. Owing to their choline head group, SMs have stronger dipole–dipole and H-bonding type of interactions with reversed-phase solvents, compared to weaker van der Waals, London–London and other dispersion forces with normal-phase solvents. Consequently, SMs resolve better under reversed-phase conditions.

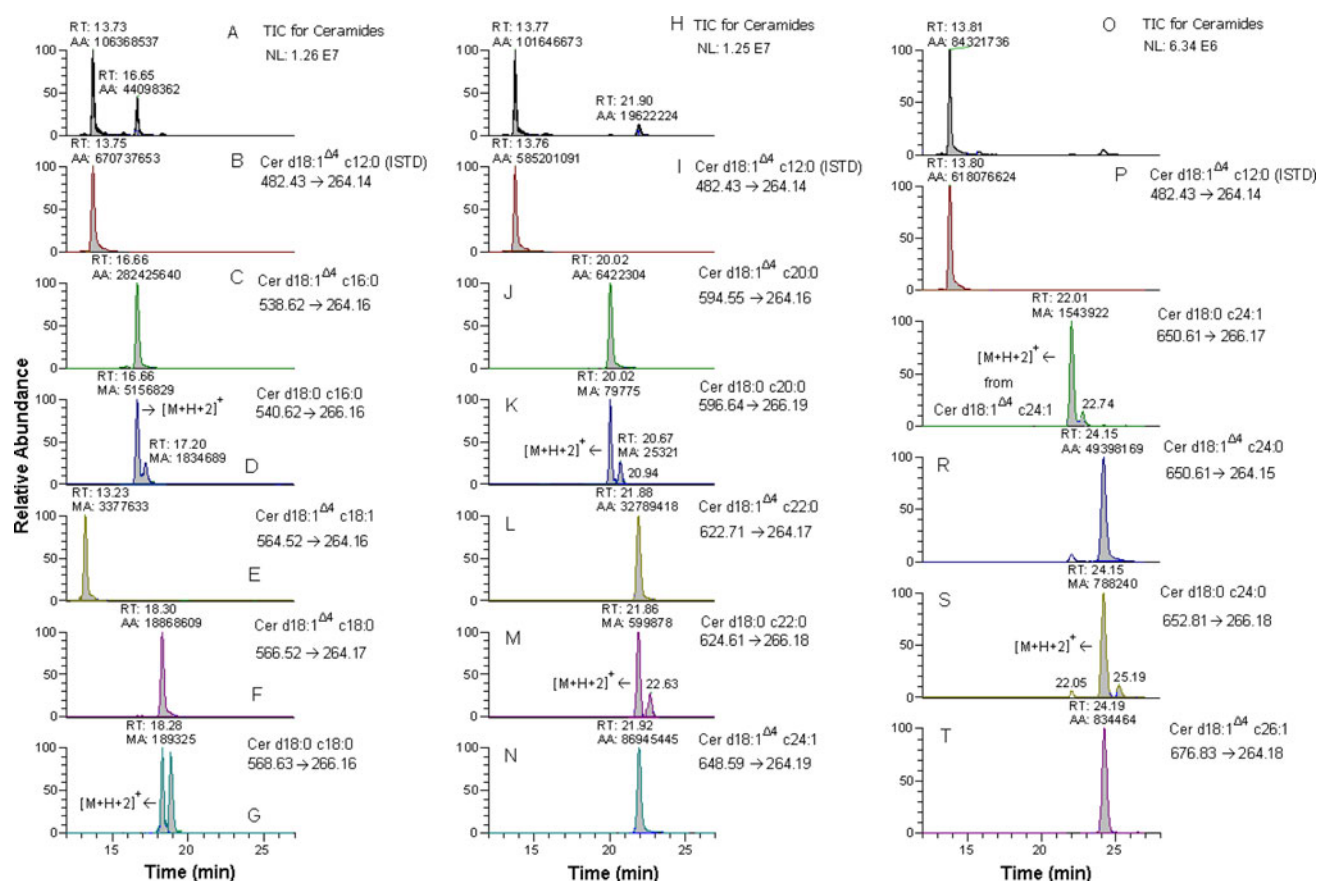

Fig. 5 Extracted ion chromatogram from SRM scans of precursor \rightarrow double-dehydrated carbocation product fragment for all the ceramides, as observed by three reversed-phase methods. All three

reversed-phase methods contain only transitions from ceramides. Each method also comprises a transition from the ceramide internal standard

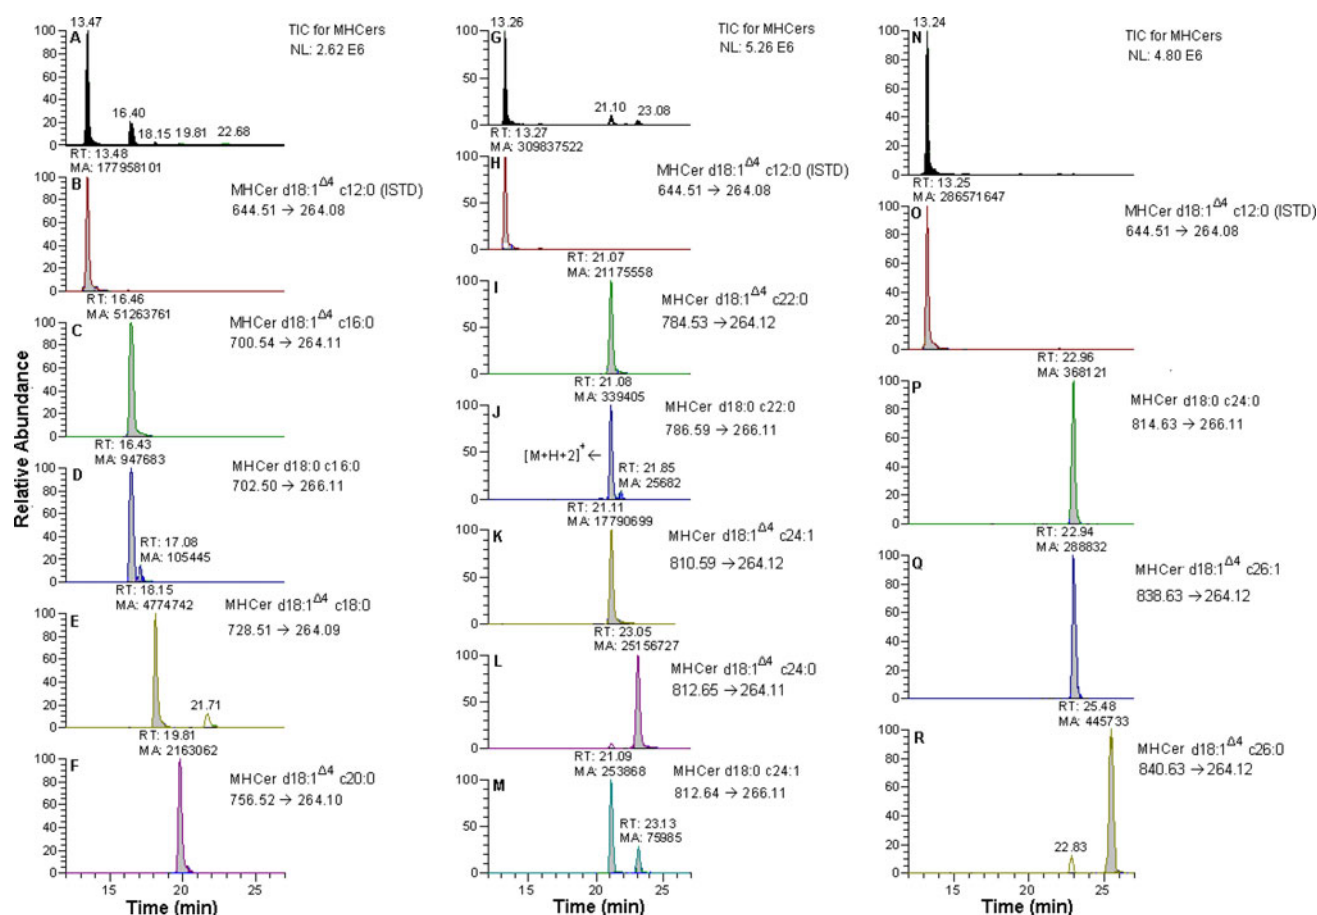

Fig. 6 Extracted ion chromatogram from SRM scans of precursor \rightarrow double-dehydrated carbocation product fragment for all the hexosylceramides (MHCer), as observed using three reversed-phase methods.

Although ESI normally does not ionize efficiently under the high content of non-polar organic solvents, such as hexane, CHCl_3 , ethyl acetate or ether, but in the presence of 5 mM $\text{CH}_3\text{COONH}_4$ dissolved in 20 mL CH_3OH and containing 1–2% CH_3COOH , the ceramides and MHCers seem to exhibit good ionization efficiency and good sensitivity, in comparison to their ionization efficiency with reversed-phase solvents. It should be noted that the run times in both normal- and reversed-phase chromatography are almost identical (ca. 22 min); however, in normal-phase chromatography, each of the three classes of sphingolipids is displayed within a narrow elution time window of its own: Cers elute between 3.7 and 4.5 min, MHCers between 8 and 12 min, and SMs between 16 and 19 min, thus making it possible to combine analytes from each sub-class together into different segments to run them concurrently in each method. The individual MRM pair that uniquely identifies each species can then be summed to yield the total class species. In reversed-phase chromatography compounds from each class of sphingolipids are well resolved, with retention time ranging widely between

All three reversed-phase methods contain only transitions from MHCer. Each method also comprises a transition from the MHCer internal standard

12 and 27 min. Further, because of a large elution window between the internal standard that was used and the respective analytes of that class, each sub-class of sphingolipids was run separately, instead of juxtaposing the peaks over each other chromatographically. Because of this larger elution window, as, for example, there is more than 10 min difference between the elution time of Cer d18:1 Δ^4 c12:0 internal standard and the analyte Cer d18:1 Δ^4 c24:1, there remains a strong possibility for ionization differences between earlier and later eluting analytes, in comparison to the use of only one either earlier or later eluting internal standard, which might result in a disparity of data between the normal- and reversed-phase chromatography. However, data from Table 5 shows the calculated amounts of individual Cers, MHCers, and SMs obtained by both reversed- and normal-phase chromatography, indicating the overall bias is less for SMs. For Cers and MHCers, the earlier eluting analytes exhibit higher amounts in comparison to the use of only one earlier eluting internal standard for each. Thus, it seems prudent to use more than two internal standards that span the entire elution window for each class

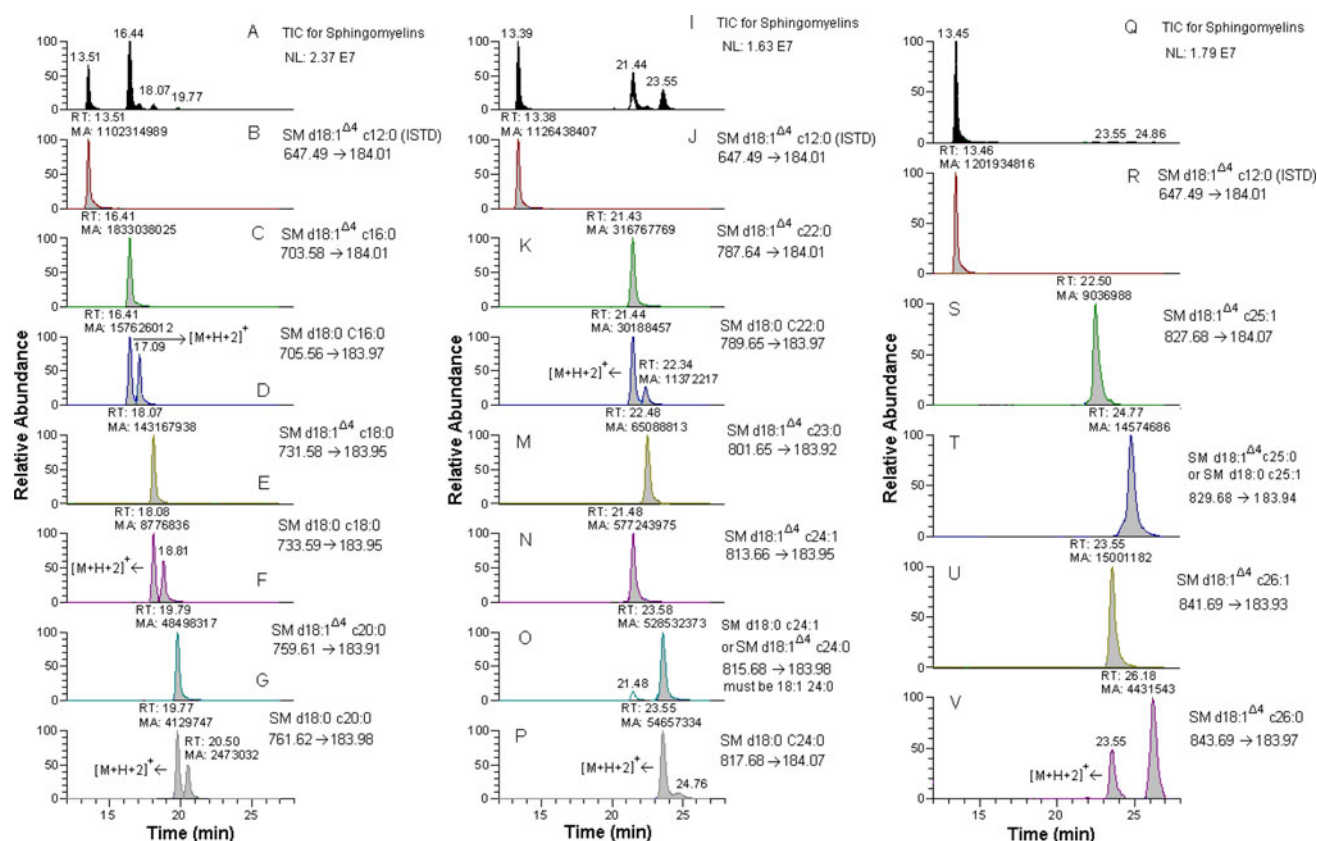

Fig. 7 Extracted ion chromatogram from SRM scans of precursor → double-dehydrated carbocation product fragment for all the sphingomyelins (SM), as observed by three reversed-phase methods. All three

reversed-phase methods contain only transitions from SM. Each method also comprises a transition from the SM internal standard

of analytes when reversed-phase chromatography is performed.

As the NP and RP-LC/MS/MS quantitation results were inconsistent between the two, a solution containing four reference standards, two each of ceramides and sphingomyelins, viz. Cer d18:1^{Δ4} c20:0, Cer d18:1^{Δ4} c24:1, SM d18:1^{Δ4} c16:0, and SM d18:1^{Δ4} c18:0, were prepared at the 1-μg/mL level and then spiked in equal amounts and studied by both NP and RP-LC/MS/MS. The peak areas obtained by NP chromatography for these reference standards were 2.85×10^7 , 3.19×10^8 , 4.64×10^8 , and 2.41×10^8 , while under reversed-phase conditions, the respective peak areas were 9.63×10^7 , 1.17×10^7 , 2.01×10^9 , 1.04×10^9 ; these results also suggest different ionization efficiencies in NP and RP chromatography. Thus, data obtained with these spiked reference standards also suggested the similar discriminatory results between the NP and RP chromatography. Recovery between 70–80% and 90–95% were observed for samples processed by normal-phase and reversed-phase, respectively, using the comparative calculations of the peak areas of individual components from neat and LM6002 prespiked sample.

A series of reliable, efficient, and highly sensitive LC-MS (SRM) methods using normal-phase and reversed-phase liquid chromatography was developed to quantitate mammalian Cers, MHCers, and SMs containing saturated and unsaturated sphingoid base cores. In the context of normal phase chromatography a high content of organic solvents still provided efficient electrospray ionization of the ceramides and hexosylceramides. Using non-polar solvents in normal phase chromatography, even low abundant Cers having similar retention times were implicitly resolved, while reversed-phase chromatography was used to resolve the Cer compounds explicitly. SMs could be resolved using either type of chromatography, however, reversed-phase chromatography provided better specificity, selectivity, and sensitivity. Hexosylceramides were best resolved and quantitated using normal phase chromatography. Because the interaction of Cers, MHCers, and SMs differs between normal-phase and reversed-phase solvents and there is a possibility of some ion suppression effects, it is essential to link the quantitative results to the type of chromatography utilized. An absolute total amount of protein amounts between 100 and 300 μg is essential to

get consistent quantitative results for all the sphingolipids. Overall, the quantitative results show that for MEF and HEK293 cells, more than 75% of the Cers, MHCers, and SMs exist as d18:1^{Δ4} c16:0, d18:1^{Δ4} c24:1, and d18:1^{Δ4} c24:0.

Abstract Very long chain polyunsaturated fatty acids such as arachidonic acid (ARA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), docosapentaenoic acid (DPA, 22:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) are essential components of cell membranes, and are precursors for a group of hormone-like bioactive compounds (eicosanoids and docosanoids) involved in regulation of various physiological activities in animals and humans. The biosynthesis of these fatty acids involves an alternating process of fatty acid desaturation and elongation. The desaturation is catalyzed by a unique class of oxygenases called front-end desaturases that introduce double bonds between the pre-existing double bond and the carboxyl end of polyunsaturated fatty acids. The first gene encoding a front-end desaturase was cloned in 1993 from cyanobacteria. Since then, front-end desaturases have been identified and characterized from a wide range of eukaryotic species including algae, protozoa, fungi, plants and animals including humans. Unlike front-end desaturases from bacteria, those from eukaryotes are structurally characterized by the presence of an N-terminal cytochrome *b₅*-like domain fused to the main desaturation domain. Understanding the structure, function and evolution of front-end desaturases, as well as their roles in the biosynthesis of very long chain polyunsaturated fatty acids offers the opportunity to

engineer production of these fatty acids in transgenic oil-seed plants for nutraceutical markets.

Keywords Desaturases · n-3 fatty acids · n-6 fatty acids · Polyunsaturated fatty acids (PUFA) · Biotechnology · Lipid biochemistry · General area

Introduction

A desaturase is a special type of oxygenase that can remove two hydrogens from a hydrocarbon chain, especially from a fatty acyl chain, catalyzing the formation of a double bond in the substrate [1, 2]. Unlike normal oxygenases which directly transfer molecular oxygen to a substrate; a desaturase uses activated molecular oxygen to abstract hydrogens from the substrate creating a carbon/carbon double bond in a fatty acid and a molecule of water [1, 3].

According to their regioselectivity, desaturases are typically categorized as Δx desaturase that introduces a double bond at position *x* referred to from the carboxyl end of a fatty acid; or ωy desaturase that introduces a double bond at position *y* referred to from the methyl end [4–6]. In addition, desaturases can additionally be labelled as *v*+*z* or *v*–*z* desaturases. The *v*+*z* desaturase introduces a double bond at *z* carbons after the pre-existing double bond *v*, [7] i.e. towards the methyl end, while the *v*–*z* desaturase can introduce a double bond at *z* carbons before the pre-existing double bond *v*, i.e. towards the carboxyl end. An example of a Δx desaturase is the acyl-ACP $\Delta 9$ desaturase from plants, a soluble enzyme introducing a first $\Delta 9$ double bond into saturated palmitoyl-ACP or stearoyl-ACP [8, 9]. The membrane-bound $\omega 3$ desaturase from nematode *Caenorhabditis elegans* is an example of a ωy desaturase that inserts an $\omega 3$ double bond into a polyunsaturated fatty acid

[10, 11]. An example of $\nu+3$ desaturase is the *Claviceps purpurea* “ $\Delta 12$ ” desaturase that has a preference for introducing double bonds at the $\Delta 12$ position, three carbons after the pre-existing double bond at the ninth position [7], while the $\Delta 4$ desaturase from *Thraustochytrium* is catalytically a $\nu-3$ desaturase and can only introduce a double bond at position 4 which is three carbons before the pre-existing double bond at the seventh position [12].

Based on the position of the double bond insertion relative to a pre-existing double bond in a fatty acyl chain, desaturases can also be referred to as front-end desaturases or methyl-end desaturases [13]. Unsaturated fatty acids are essential for all living species in which the initial de novo fatty acid synthesis generally results in production of saturated fatty acids with 18 carbons or 16 carbons in length. The first double bond is often inserted at approximately the middle position of a fatty acid chain. Fatty acids with different chain length and double bond position are generated later by various fatty acid modifying enzymes, such as elongases and desaturases. A methyl-end desaturase introduces a double bond between the pre-existing double bond and the methyl-end, while a front-end desaturase inserts a double bond between the pre-existing double bond and the carboxyl end of a fatty acid [14]. Commonly-found membrane-bound ωy and $\nu+z$ desaturases such as “ $\Delta 12$ ”, “ $\Delta 15$ ” and $\omega 3$ desaturases in plants are examples of methyl-end desaturases, while widely spread $\nu-z$ desaturases in microorganisms such as $\Delta 4$, $\Delta 5$, $\Delta 6$ and $\Delta 8$ desaturases belong to front-end desaturases.

Although both methyl-end desaturase and front-end desaturase are involved in the biosynthesis of very long chain polyunsaturated fatty acids, their occurrence in living species is not identical. The former is widely present in plants and microorganisms, while the latter mostly occur in animals and microorganisms, although certain types of front-end desaturases have been identified in a small number of higher plants, such as borage [15], echium [16] and conifers [17]. Higher animals including humans lack the methyl-end desaturase such as “ $\Delta 12$ ”, “ $\Delta 15$ ” and $\omega 3$ desaturase [18]. Consequently, they cannot synthesize linoleic acid (LA, 18:2-9,12) and linolenic acid (ALA, 18:3-9,12,15) from oleic acid (OA, 18:1-9), the two essential fatty acids that have to be acquired from the diet. LA and ALA are precursors for the biosynthesis of very long chain polyunsaturated fatty acids such as arachidonic acid (20:4n-6, ARA), eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA). As shown in Fig. 1, to synthesize these fatty acids, LA and ALA are desaturated by a first front-end desaturase—the $\Delta 6$ desaturase, introducing a $\Delta 6$ double bond into the substrates giving gamma-linolenic acid (GLA, 18:3-6,9,12) in the $\omega 6$ pathway, and stearidonic acid (SDA, 18:4-6,9,12,15) in the $\omega 3$ pathway, respectively. GLA and SDA are elongated by a $\Delta 6$ elongase

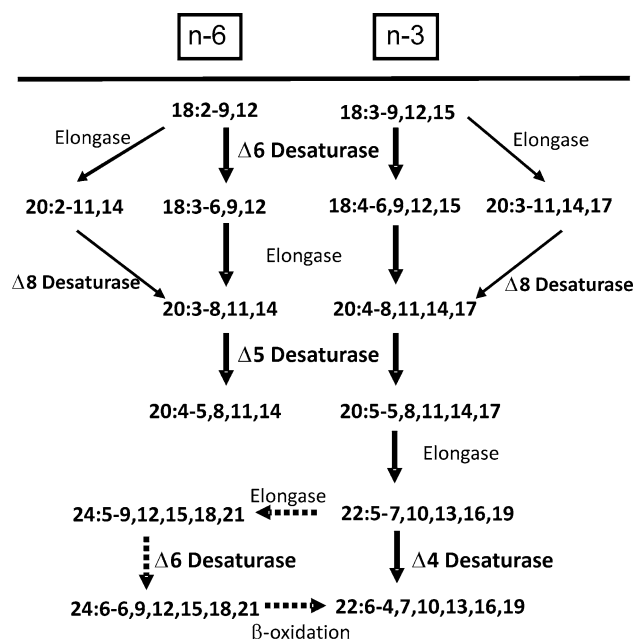

Fig. 1 Front-end desaturases involved in the biosynthesis of very long chain polyunsaturated fatty acids. The dotted arrow indicates Sprecher's pathway for DHA biosynthesis

to dihomogamma-linolenic acid (DGLA, 20:3-8,11,14) and eicosatetraenoic acid (ETA, 20:4-8,11,14,17), which are then desaturated by a second front-end desaturase—the $\Delta 5$ desaturase giving rise to arachidonic acid (ARA, 20:4-5,8,11,14) and eicosapentaenoic acid (EPA, 20:5-5,8,11,14,17), respectively. EPA is elongated to docosapentaenoic acid (DPA, 22:5-7,10,13,16,19) which is then desaturated by a third front-end desaturase—the $\Delta 4$ desaturase, giving docosahexaenoic acid (DHA, 22:6-4,7,10,13,16,19) in the $\omega 3$ pathway. However, mammals including humans lack the $\Delta 4$ desaturase. Biosynthesis of DHA in mammals takes “the retro-conversion pathway” [19] which involves two rounds of chain elongation of EPA and another $\Delta 6$ desaturation on the elongated product, followed by a single 2-carbon chain shortening of the $\Delta 6$ desaturated product in the peroxisome, giving DHA. The $\Delta 8$ desaturase is another front-end desaturase involved in the biosynthesis of very long chain polyunsaturated fatty acids [20–22]. This desaturase works on a branching pathway of the biosynthesis, introducing a $\Delta 8$ double bond into elongated products LA or ALA, i.e. 20:2-11,14 or 20:3-11,14,17, giving rise to DGLA and ETA, respectively, which can then be desaturated by a $\Delta 5$ desaturase, giving ARA and EPA as described above (Fig. 1). The individual front-end desaturases are described below.

$\Delta 6$ Desaturase

The first $\Delta 6$ desaturase gene was cloned in 1993 from the cyanobacterium *Synechocystis* using a gain-of-function

expression approach [23]. The protein sequence of this first front-end desaturase shows a similarity to other acyl-lipid desaturases with different regioselectivity from cyanobacteria [23]. Like its homologous sequences, the $\Delta 6$ desaturase from *Synechocystis* does not contain a cytochrome b_5 -like domain as was later found in eukaryotic $\Delta 6$ desaturases. A similar $\Delta 6$ desaturase was later cloned from another cyanobacterium *Spirulina platensis* [24]. In 1997, the first eukaryotic $\Delta 6$ desaturase gene was cloned from borage plant by two independent groups [15, 25]. Unlike bacterial $\Delta 6$ desaturases, the $\Delta 6$ desaturase encoded by this gene is a modular protein that has a cytochrome b_5 -like domain fused to the N-terminus of the main desaturation domain. This modular structure was later observed to be a feature of all the $\Delta 6$ desaturases isolated from eukaryotes including algae [26–28], moss [29], plants [15, 16], fungi [30–32], animals [33, 34] and humans [35]. The existence of an N-terminal cytochrome b_5 -like domain is not exclusive to this front-end desaturase, a similar motif has been also observed in other front-end desaturases such as $\Delta 5$, $\Delta 8$ and $\Delta 4$ desaturases and some sphingolipid desaturases from eukaryotes [36]. Beside the cytochrome b_5 -like domain at the N-terminus, the rest of the $\Delta 6$ desaturase sequences have sequence similarity to methyl-end desaturases with characteristics of three highly conserved histidine-rich motifs, i.e. H-X₃₋₄-H, H-X₂₋₃-H-H and H/Q-X₂₋₃-H-H. However, the first histidine of the third motif in the front-end desaturase is usually replaced by glutamine [15]. Conversion of this residue back to histidine resulted in loss of the activity, implying this residue might be very important for the structural configuration of this modular type of desaturases for front-end desaturation [37].

The function of $\Delta 6$ desaturases isolated from prokaryotes and eukaryotes was mostly established by their expression either in yeast (*Saccharomyces cerevisiae* or *Pichia pastoris*) or in plants. Functional enzymatic studies have showed that most of $\Delta 6$ desaturases isolated from eukaryotes can use both LA and ALA as substrates effectively at the similar level. However, some $\Delta 6$ desaturases showing a preference for ALA have also been reported [38]. A bifunctional $\Delta 6$ desaturase was identified in *Ceratodon purpureus* that can convert the $\Delta 6$ double bond it creates to a triple bond [39]. A human $\Delta 6$ desaturase was found to have the capability of introducing a $\Delta 6$ double bond into two distinct substrates with different chain lengths, i.e. 18:2-9,12 and 24:5-9,12,15,18,21 [40]. The observation of the $\Delta 6$ desaturation of the latter substrate provides the important evidence supporting the retro-conversion pathway that requires the desaturation step for DHA biosynthesis in humans.

The first published transgenic production of GLA, a $\Delta 6$ desaturated fatty acid in the $\omega 6$ pathway, in plants using a $\Delta 6$ desaturase was reported by Reddy and Thomas (1996)

who expressed the *Synechocystis* $\Delta 6$ desaturase under the control of a constitutive CaMV 35S promoter in tobacco. Transgenic tobacco carrying the gene produced very small amounts of GLA and SDA in leaves, but not in seeds [15, 41]. That the prokaryotic $\Delta 6$ desaturase did not work well in plants might be due to incompatible cofactors required for the desaturation (see below). Production of high levels of GLA and SDA, two $\Delta 6$ desaturated fatty acids, in transgenic oilseeds has since been achieved by several other groups using eukaryotic $\Delta 6$ desaturases [42]. The seed-specific expression of a fungal $\Delta 6$ desaturase and $\Delta 12$ desaturase from *Mortierella alpina* produced up to 43% GLA in seeds of *Brassica napus* [43]. A similar level of GLA was produced in *B. juncea* seeds by expressing a single $\Delta 6$ desaturase from fungus *Pythium irregulare* [32]. Seed expression of a *B. napus* $\Delta 15$ desaturase gene with *M. alpina* $\Delta 6$ and $\Delta 12$ desaturases resulted in production of SDA accounting for 16–23% of the total fatty acids [44]. Co-expression of a borage $\Delta 6$ desaturase and an *Arabidopsis* $\Delta 15$ desaturase in soybean produced up to 30% of SDA [45]. Very recently, a very high level of GLA (more than 60%) in transgenic safflower oilseeds was achieved using a $\Delta 6$ desaturase from *Saprolegnia diclina* [46].

$\Delta 5$ Desaturase

The first $\Delta 5$ desaturase gene was cloned in 1998 from the fungus *M. alpina* by two independent groups almost simultaneously using sequence information of the front-end $\Delta 6$ desaturases from borage for degenerate RT-PCR [47, 48]. Since then, many $\Delta 5$ desaturases have been cloned from diverse species including lower plants [49, 50], animals [51] including human [52], fungi [48, 53], moss [54], protozoa [55] and algae [28, 56]. Like $\Delta 6$ desaturases from eukaryotes, the $\Delta 5$ desaturase comprises a cytochrome b_5 -like domain fused at the N-terminus of the sequence.

The function of the $\Delta 5$ desaturases was mostly established by expressing the genes in yeast. Like the $\Delta 6$ desaturase, $\Delta 5$ desaturase can use two substrates, both $\omega 3$ (ETA) and $\omega 6$ (DGLA) are desaturated almost equally effectively, producing EPA and ARA, respectively. However, besides the two major substrates, some $\Delta 5$ desaturases are active on LA and ALA, producing polymethylene-interrupted $\Delta 5$ desaturated fatty acids such as pinolenic acid (18:3-5,9,12), which was found naturally in seeds of some conifer trees [53]. A $\Delta 5$ desaturase from zebrafish also carries $\Delta 6$ desaturase activity at the similar level, i.e. it is bifunctional [57].

Various $\Delta 5$ desaturase have been used to transform plants for transgenic production of $\Delta 5$ desaturated polyunsaturated fatty acids. Abbadi et al. [58] (2004) introduced a $\Delta 5$ desaturase from *M. alpina* along with a $\Delta 6$ desaturase and $\Delta 6$ elongase from *Physcomitrella patens*

into tobacco and flax, which led to the accumulation of small amounts of ARA and EPA in transgenic seeds. An acyl-CoA $\Delta 5$ desaturase from an alga, along with other genes, was also used to transform *Arabidopsis* resulting in production a small amount of $\Delta 5$ desaturated fatty acids in seeds [27]. Recently a high level of EPA in transgenic *Brassica carinata* was reported using a *Thraustochytrium* $\Delta 5$ desaturase along with a $\Delta 6$ desaturase from *Pythium irregulare* and an elongase from *Thraustochytrium* [59]. It appears that $\Delta 5$ desaturase from fungal species works very effectively when expressed in plants.

$\Delta 4$ Desaturase

The $\Delta 4$ desaturase gene was first cloned in 2001 using the degenerate RT-PCR approach from *Thraustochytrium*, a single cellular Thraustochytrid that can accumulate a high level of DHA [12]. In 1991, 10 years previously, Sprecher and co-workers published their systematic work on the biosynthesis of DHA which suggested that DHA biosynthesis in mammals occurs independently of a $\Delta 4$ desaturase and involves retro-conversion of a 24-carbon $\Delta 6$ fatty acid through a controlled β -oxidation [60]. According to this pathway, the intermediate C24 polyunsaturated fatty acid required for DHA synthesis would be expected to be observed in *Thraustochytrium*. However, when the fatty acid profile of *Thraustochytrium* was examined, no polyunsaturated fatty acids more than 22 carbons in length were found. Therefore, DHA biosynthesis in *Thraustochytrium* was suggested not to follow the Sprecher's pathway, but instead to involve a $\Delta 4$ desaturase that might have a primary structure similar to other eukaryotic front-end desaturases such as the $\Delta 6$ desaturase in borage and the $\Delta 5$ desaturase in *M. alpina*. The $\Delta 4$ desaturase gene was thus isolated from *Thraustochytrium* using the degenerate RT-PCR strategy and it indeed encodes a fusion protein with $\Delta 4$ desaturation activity introducing a Δ -4 double bond in docosapentaenoic acid (22:5n-3) and docosatetraenoic acid (22:4n-6), respectively. Since then, a few other $\Delta 4$ desaturases have been isolated from protists [61, 62] and microalgae [63, 64] using the sequence information of this desaturase. It is noteworthy that the first $\Delta 4$ desaturase of vertebrate animals involved in the DHA biosynthesis was recently identified in teleost fish (*Signus canaliculatus*) [65].

The discovery of the first $\Delta 4$ desaturase in microorganisms provides a simple pathway for DHA biosynthesis and suggests the possibility of producing this important fatty acid in heterologous systems, especially in plants, in a cost-effective way. Indeed, several laboratories worldwide have since actively pursued reconstitution of this simple pathway to produce DHA in plants, such as in soybean [66], *Brassica juncea* [67] and *Arabidopsis thaliana* [68]. However, so far, these efforts to produce DHA in oilseeds

have met with only limited success; a level of DHA in transgenic oilseeds that is commercially viable has not been achieved.

$\Delta 8$ Desaturase

The first Δ -8 desaturase gene was cloned in 1999 using degenerate RT-PCR amplification from the protist *Euglena gracilis* [20]. The deduced protein sequence is highly similar to the $\Delta 6$ desaturase from *Caenorhabditis elegans* with a cytochrome b_5 -like domain at the N-terminus. Functional analysis of this gene in yeast shows the desaturase introduces a $\Delta 8$ double bond in 20:2-11,14 and 20:3-11,14,17 which could be produced by the elongation of LA and ALA [69], giving 20:3-8,11,14 and 20:4-8,11,14,17, respectively. Since the discovery of the $\Delta 8$ desaturases, this branching pathway has drawn much attention because it provides an alternative to the traditional $\Delta 6$ desaturation pathway for the biosynthesis of very long chain polyunsaturated fatty acids. Homologous $\Delta 8$ desaturases have now been isolated from protozoan [20–22], mammals [70] and marine algae [71].

Use of the $\Delta 8$ desaturase was first attempted, along with a $\Delta 9$ elongase from *Isochrysis galbana*, and a $\Delta 5$ desaturase from *M. alpina* for production of $\Delta 5$ desaturated fatty acids in vegetative tissues of *Arabidopsis* [72]. The branching pathway via this front-end desaturase was perceived to be advantageous over the traditional $\Delta 6$ desaturase pathway in overcoming the elongation bottleneck. However, the $\Delta 8$ desaturase from *Euglena* appeared to have low activity in plants. As such, only a very low amount of ARA and EPA was produced in oilseed crops when this desaturase along with other elongases and desaturases was co-expressed (Qiu et al. unpublished data). Recently, a new $\Delta 8$ desaturase from *Pavlova salina*, a $\Delta 9$ elongase from *I. galbana* and a $\Delta 5$ desaturase from *P. salina* were co-expressed in transgenic *Arabidopsis thaliana* and *Brassica napus*, respectively, resulting in production of a relatively high level of ARA (20%) in *Arabidopsis* seeds and a low level of EPA (approximately 3%) in *B. napus* seeds [73].

Acyl Carrier Substrate Specificity of Front-end Desaturases

Desaturases can be classified as acyl-CoA desaturases, acyl-ACP desaturases and acyl-lipid desaturases based on the acyl-carrier they use as substrate. Acyl-ACP desaturases have only been found in the lumen of plastids in plants where de novo biosynthesis of fatty acids occurs. Saturated fatty acids freshly synthesized in the plastids which are still linked to acyl carrier protein are the

substrate for this type of desaturase [74]. Acyl-CoA desaturases are usually membrane-bound and located in the endoplasmic reticulum of eukaryotes using fatty acid linked to Coenzyme A as substrate, while acyl-lipid desaturases introduce double bonds into fatty acids linked to complex lipid molecules such as glycolipid, phosphoglycerolipid and sphingolipids [2]. Depending on the origin, front-end desaturases can be either acyl-CoA desaturases or acyl-lipid desaturases. All known mammalian desaturases are believed to be acyl-CoA desaturases [14], thus front-end desaturases from higher animals would be predicted to use acyl-CoA as substrates. In plants, evidence on the substrate specificity of front-end desaturase was provided by Stymne and colleagues using borage $\Delta 6$ desaturation as an example where [^{14}C]-linoleoyl phosphatidylcholine was desaturated to radioactive γ -linolenoyl phosphatidylcholine in developing seeds, indicating that the substrate for the linoleate $\Delta 6$ -desaturase was phosphatidylcholine. In addition, they also showed that the $\Delta 6$ desaturase was positionally specific to linoleate at the *sn*-2 position of phosphatidylcholine [75, 76]. Recently, the acyl carrier substrate specificity of front-end desaturases was systematically examined in a yeast system using a variety of $\Delta 6$ and $\Delta 5$ desaturases by Heinz and colleagues. Detailed analysis of desaturated products in acyl-CoA, phospholipid and neutral lipid pools during a time course showed that front-end desaturases from lower plants, fungi, worms and algae belong to acyl-lipid desaturases where the desaturation occurs predominately at the *sn*-2 position of phosphatidylcholine. On the other hand, a human $\Delta 6$ desaturase tested uses linoleoyl-CoA as the substrate [26, 77]. Since then, a few acyl-CoA front-end desaturases have been identified from microalgae using the same approach [27, 78]. However, it is worthwhile to point out that all these assignments for acyl carrier specificity are solely based on the *in vivo* experiment where the yeast strain expressing a heterologous front-end desaturase was supplied with substrates and presence of desaturated products in different lipid classes in a time course was used to assign the substrate form. Although this *in vivo* approach can provide useful information on the likely acyl carriers used by front-end desaturases, direct evidence such as that obtained from *in vitro* assays is needed for conclusive determination of the substrate form of the desaturases.

Electron Donors of Front-end Desaturases

The front-end desaturation reaction, like other oxygenation reactions, is an aerobic process requiring molecular oxygen and an electron donor for the oxidation. Like acyl-ACP desaturase and glycolipid desaturases from plastids of plants, front-end desaturases in cyanobacteria are the prokaryotic type of acyl-lipid desaturases that use ferredoxin,

ferredoxin reductase and NADPH as the electron transport system [2]. The front-end desaturases located in endoplasmic reticulum of eukaryotes such as acyl-CoA desaturases from animals and phospholipid desaturases from plants and fungi are the eukaryotic type that utilizes cytochrome b_5 , cytochrome b_5 reductase and NADH as the electron transport system [79]. As mentioned above, most of front-end desaturases, except for the ones from cyanobacteria [23, 24] are fusion proteins with a cytochrome b_5 -like domain at the N-terminus. This structure suggests that all these front-end desaturase would use cytochrome b_5 as electron donor for the desaturation. It is noteworthy that the existence of a cytochrome b_5 fusion is also observed in a yeast $\Delta 9$ desaturase where the cytochrome b_5 -like domain is fused at the C-terminus [80]. Deletion of the C-terminal cytochrome b_5 domain of the yeast $\Delta 9$ desaturase resulted in complete loss of enzymatic activity [81]. Similarly, when expressed in the endogenous cytochrome b_5 -disrupted strain or the wild type yeast strain, the borage $\Delta 6$ desaturase is able to functionally introduce a $\Delta 6$ double bond into the substrate, whereas, deletion of the N-terminal cytochrome b_5 -like domain of the desaturase resulted in the loss of the function [82], indicating that cytochrome b_5 -like domain is an essential part of the enzyme such that the free cytochrome b_5 could not substitute the electron transport function. *Spirulina platensis* $\Delta 6$ desaturase is a smaller polypeptide which does not contain the cytochrome b_5 -like domain. When expressed in *Escherichia coli* with supplementation of ferredoxin, the transformant produced GLA from exogenous LA. However, when expressed in yeast, *Spirulina* $\Delta 6$ desaturase N-fused or co-expressed with the cytochrome b_5 from *Mucor rouxii* produced GLA from LA [83]. This result indicates that the prokaryotic front-end desaturases may not have a strict requirement for a particular electron transport system. The ferredoxin requirement of the prokaryotic $\Delta 6$ desaturase can be complemented by the corresponding eukaryotic electron donor, cytochrome b_5 . However, for eukaryotic front-end desaturases, the requirement for electron donor appears to be more stringent that deletion of cytochrome b_5 domain or mutation of the heme-binding motif in the cytochrome b_5 domain of front-end desaturases totally eliminates the activity [82, 84].

Structural Determinants for Regioselectivity of Front-end Desaturases

The regioselectivity of a desaturase refers to the specific positioning of a double bond in a fatty acyl chain. Generally, front-end desaturases, regardless of their origin, have high regioselectivity and substrate specificity which are determined by the structure of the desaturase proteins. However, due to lack of information of three-dimensional structures of front-end desaturases, there is little

information available on the exact relationship between the structure and function of these enzymes. Nevertheless, a model previously proposed [11] for the methyl-end desaturases can shed some light on the structure–function relationship of the front-end desaturase. In this model, structural determinants for substrate specificity and regioselectivity include a head group binding domain or a methyl group-binding domain, a pre-existing double bond binding domain, and the active site. From this model, we would presume that the substrate specificity and regioselectivity of front-end desaturases might be controlled by more than one domain. Targeted mutagenesis of amino acid residues that are present in close proximity to the histidine boxes of *Mucor rouxii* $\Delta 6$ desaturase revealed that some of these residues are involved in substrate binding [85]. Using domain swapping, Napier and colleagues showed that the regions of first two membrane-spanning helices and carboxyl terminus of borage front-end desaturases are important for the substrate binding and regioselectivity [86]. Despite these studies, our understanding of the individual functional domains of front-end desaturases still remains very limited.

The Catalytic Mechanism of Front-end Desaturases

Like other desaturases, the front-end desaturases belong to a group of metalloenzymes that activate the molecular oxygen using non-heme di-iron active sites to abstract two hydrogens from fatty acids resulting in the introduction of a front-end double bond [87]. Non-heme iron-containing oxygenases have been widely found in nature. They catalyze not only fatty acid desaturation, but also a wide range of other oxygenation reactions [87, 88]. For instance, non-heme iron-containing alkane monooxygenase catalyzes hydroxylation of alkane producing alcohol, which has been the focus of recent research on petroleum contamination remediation [89]. Non-heme iron-containing lipoxygenase that catalyzes the insertion of a molecular oxygen into the (1Z,4Z)-pentadiene of a polyunsaturated fatty acid producing hydroxyperoxide, a key precursor for a variety of oxylipins involved in the response to biotic and abiotic stresses [90]. Catechol dioxygenase is another non-heme iron-containing enzyme that converts 3,4-dihydroxybenzoate to β -carboxy-*cis,cis*-muconate [91]. Although these oxygenases have distinct primary structure in protein sequences, and catalyze different enzymatic reactions, the catalytic mechanism is found to be similar by using the oxo-ferric intermediate in the catalytic reaction [1, 88]. The di-iron catalytic center is believed to be coordinated by three conserved histidine-rich motifs [92]. Abstraction of two hydrogens by front-end desaturases usually takes place in a stepwise manner as *syn*-elimination with the initial oxidation site close to the carbon at the carboxyl end

according to deuterium kinetic isotope effects associated with the C–H bond cleavages [93]. Actual stereospecific *syn*-dehydrogenation might be controlled by the geometry of the hydrophobic pocket that is in the proximity of the di-iron center of the desaturase [79, 94]. However, the detailed mechanism underlying the front-end desaturation remains to be elucidated.

Evolution of Front-end Desaturases

The evolution of desaturases as a whole has been thoroughly reviewed by Heinz and colleagues [79]. According to the solubility in an aqueous environment, desaturases can be classified into two major groups, soluble desaturases and membrane-bound desaturases. Each group of desaturases possesses characteristic features in their primary structure and is believed to have evolved independently [79]. Front-end desaturases are membrane-bound enzymes with a wide range of substrate selectivity and high regioselectivity and/or stereospecificity. This type of desaturases is recalcitrant to biochemical purification, thus no information is available on the three dimensional structure of the desaturases. In the past decade, the number of front-end desaturase sequences that have been functionally characterized has grown rapidly with the advance of molecular cloning and genome sequencing technologies. This has provided opportunities for an evolutionary analysis of the front-end desaturases to elucidate their phylogenetic origin and catalytic diversity based on amino acid sequence information. As shown in Fig. 2, front-end desaturases in microorganisms, plants and animals are evolutionarily distinct from methyl-end desaturases from cyanobacteria and plants. In another words, the evolution of front-end desaturases has undertaken a path different from that of the methyl-end desaturases. Front-end desaturases selected from a wide range of organisms including cyanobacteria, algae, protozoa, moss, fish, plants and mammals can be phylogenetically grouped into three main clades. The first clade consists of animal front-end desaturases including those from fish and humans. The second clade comprises front-end desaturases mainly from plants, worms and fungi. The third clade contains front-end desaturase mainly from algae, fungi and cyanobacteria. The cyanobacterial front-end desaturases grouped with those of algae and fungi, but not with the methyl end (“ $\Delta 12$ ”) desaturases from their own species, reaffirms that front-end desaturases might take an evolutionary path different from the methyl-end desaturases. The prototype of prokaryotic $\Delta 6$ desaturase might be the progenitor of all the front-end desaturases in eukaryotes, even though their primary structures are quite different. In addition, it could also be seen from the phylogenetic tree that front-end desaturases are not always clustered according to their

Fig. 2 Phylogenetic analysis of front-end desaturases. Amino acid sequences retrieved from NCBI by their accession number were aligned using ClustalW using default parameters. The resulting

alignment was used to generate a rooted phylogenetic tree using the neighbor joining method and visualized by Treeview

regioselectivity and origin. For instance, $\Delta 5$ and $\Delta 6$ desaturases from *C. elegans* which are tightly grouped together belong to the clade of front-end desaturases including $\Delta 8$ desaturases from protist, $\Delta 6$ desaturases from fungi and plants. On the other hand, the *Mortierella* $\Delta 6$ desaturase forms a clade with other $\Delta 6$ desaturases from algae and plants, while the *Mortierella* $\Delta 5$ desaturase belongs to the clade of front-end desaturases with $\Delta 4$, $\Delta 5$, $\Delta 6$ and $\Delta 8$ regioselectivity from algae and fungi. From an

evolutionary point of view, front-end desaturases with $\Delta 5$, $\Delta 8$ and $\Delta 4$ regioselectivity in eukaryotes might have evolved independently from the progenitor $\Delta 6$ desaturase through multiple independent gene duplication events and diversification. It is noteworthy that we should not rule out the other possibility that eukaryotic front-end desaturases might have evolved from their sphingolipid desaturases as the latter occur more widely and are very closely related to the front-end desaturases. Since sphingolipid desaturases

do not belong to front-end desaturase, they are not described here.

Concluding Remarks

Front end desaturases are remarkable for their structural similarity and functional diversity. Almost all the front-end desaturases except for cyanobacterial ones are modular proteins containing a cytochrome *b₅*-like domain at the N-terminus and a desaturation domain at the C-terminus. Three conserved histidine-rich motifs which are believed to be responsible for di-iron binding at the catalytic center are located at the C-terminal domain. All of front-end desaturases from eukaryotes share a similar hydrophobicity profile, which indicates a common membrane topology [86]. Phylogenetic analysis of front-end desaturases provides very interesting insights into the structure–evolution relationships of these desaturases. Substrate specificity and regioselectivity and catalytic mechanisms of eukaryotic front-end desaturases involve not only the structure feature of the desaturase, but also substrate features such as fatty acid chain length, existing double bonds and acyl carrier [11, 95].

Very long chain polyunsaturated fatty acids are synthesized by a series of front-end desaturases and elongases which play important roles in the integrity and function of biological membranes in eukaryotes. Perceivably, their biosynthesis in the cells should be subjected to the tight control through expression regulation of these enzymes. However, so far, there has been no information available on how the expression of these desaturases and elongases is regulated. There is evidence that the biosynthesis of unsaturated fatty acids in bacteria and human is achieved by the feedback control of transcriptional regulation of fatty acid desaturase genes, mediated through signalling pathways activated by sensors embedded in cellular membranes, in response to environmental factors [96]. The regulation of front-end desaturases is likely to adopt the similar strategy. If so, how is the transcriptional regulatory control achieved for front-end desaturase genes? Answering this question will be an attractive target for the future research of front-end desaturases.

Very long chain ω 3 polyunsaturated fatty acids are essential for human health and well-being. Numerous randomized, placebo-controlled and double blind trials have shown that dietary supplementation of these fatty acids can provide protection against many common chronic diseases such as cardiovascular diseases, diabetics and inflammatory disorders. Moreover, they also play important roles in maintaining the function or enhancing performance of the eyes and brain. Unfortunately, the current dietary source for these fatty acids is limited to oils from

wild fish and oleaginous fungi. Oils from marine fish for these fatty acids are already over-exploited, which results in dramatic reductions of fish populations in ocean. In addition, possible contamination in fish oil with heavy metals and toxins is increasingly becoming a concern. Oil from oleaginous fungi is expensive due to the high cost of fungal culture and oil extraction. Therefore, the scientific community and commercial entities are currently under intensive pressure to explore alternatives to these fatty acids. Transgenic production of very long chain polyunsaturated fatty acids in plants using genes encoding the front-end desaturases and elongases cloned from microalgae and fungi have been viewed as an attractive alternative source for these fatty acids. The biosynthetic pathways of these fatty acids have been successfully reconstituted in plants independently by several groups worldwide [97, 98]. A high level of EPA and ARA has already been achieved in transgenic oilseed crops, which provide great opportunity for nutraceutical markets for these fatty acids as dietary supplements. However, an economically viable level of DHA in transgenic plants has not been realized due to the metabolic bottleneck of acyl trafficking in the complex pathways involving too many genes [58, 67] comprising three to four of those for front-end desaturases. Our further understanding of the mechanism underlying the structure, function and evolution of front-end desaturases is vital for us to reach the goal—production of a high level of very long chain ω 3 fatty acids in transgenic oilseed crops for nutraceutical and functional food markets [99–102].

Acknowledgments We thank Drs. Mark Smith and Patrick Covello for their critical reading of this manuscript. We also wish to thank the authors for their wonderful works referred here. As there are a large number of publications in this field, we apologize to those authors whose works are relevant but might have been overlooked and thus not included in this review.

7-Ketocholesterol is Not Cytotoxic to U937 Cells When Incorporated into Acetylated Low Density Lipoprotein

Abstract The growth of the necrotic core region within advanced atherosclerotic plaque is thought to be driven by oxidised low density lipoprotein (oxLDL)-induced death of macrophage cells. OxLDL and atherosclerotic plaque are rich in oxysterols, especially 7-ketocholesterol (7KC). As 7KC triggers cell death at physiological concentrations when added directly to the cell culture media, 7KC and other oxysterols have been suggested to be the main cytotoxic agent of oxLDL. We investigated this hypothesis by examining the toxicity of 7KC to monocyte-like U937 cells when incorporated into high-uptake non-toxic acetylated LDL (acLDL). Incorporation of 7KC into acLDL greatly reduced the oxysterol toxicity when compared with an equivalent amount of 7KC added directly to U937 cells. Enrichment of oxLDL with 7KC did not significantly enhance lipoprotein toxicity. OxLDL was highly cytotoxic yet generated only low levels of intracellular 7KC. In comparison, 7KC-acLDL generated high intracellular 7KC concentrations with little loss in cell viability. The data show that when incorporated into lipoprotein, 7KC cytotoxicity is greatly reduced, even though intracellular levels exceed those measured when cells are incubated with oxLDL, which suggests 7KC is not the significant toxic agent within oxLDL.

Introduction

The formation of oxidised low density lipoprotein (oxLDL) and the resulting cytotoxicity of oxLDL to macrophage cells is a key driver in the development of the necrotic core of advanced atherosclerotic plaque [1, 2]. OxLDL contains numerous oxidised components that could potentially be cytotoxic. Copper ion-, peroxy radical- and macrophage-oxidised LDL all contain high levels of lipid and protein hydroperoxides, as well as oxidation products of the various antioxidants [3, 4]. The decay of lipid peroxides is a dominant reaction in the later stages of LDL oxidation, resulting in the formation of oxysterols, isoprostanes and reactive short chain aldehydes [5]. The short chain aldehydes, 4-hydroxynonenal (HNE) and malondialdehyde (MDA), derivatise the lysine residues of apolipoprotein B100, destroying the binding site for the LDL receptor but rendering the particle a ligand for the scavenger receptors [6, 7].

Oxysterols, aside from being implicated in the formation of foam cells, have also been cited as a key agent in oxLDL-induced cell death [8–10]. Oxysterols are known to be abundant in atherosclerotic lesions [5, 11] and are produced in significant quantities by various methods of *in vitro* LDL

oxidation [12, 13]. Several of these oxysterols, including 7-ketocholesterol (7KC), 7-hydroxycholesterol, 7 β -hydroxycholesterol and 25-, 26- and 27-hydroxycholesterol have been shown to have potent cytotoxic effects on cell viability when delivered directly to cultures of endothelial cells [14], macrophages [8], monocytes [10] and smooth muscle cells [14]. The suggested mechanisms of 7KC-induced cytotoxicity arise from its disruption of lipid raft micro-domains in the plasma membrane, which allows calcium ion influx and the associated calcium-dependent activation of pro-apoptotic pathways [15]. 7KC incorporation into unoxidised acetylated LDL (acLDL) has also been reported to inhibit sterol export from macrophages, leading to the formation of lipid-laden foam cells [16].

Though these studies have been very informative they assume that free oxysterols, suspended in a tissue culture media, will interact with and be handled by cells in the same way as the oxysterols within oxLDL. Being hydrophobic, oxysterols are normally trapped within the LDL particle and become available to the cell only when the oxLDL particle is taken up by scavenger receptors and degraded in the lysosomes [16]. In vivo, it is highly unlikely that oxysterols could leach from oxLDL particles to become free in the media (as micelles or liposomes), as used in the cited cytotoxicity experiments. Our study examined whether the oxysterol 7KC is still cytotoxic when packaged into unoxidised lipoprotein particles. To achieve the high uptake of particles seen with oxLDL, we used acLDL which has no cytotoxic effect on cells [16] and contains no oxidised components. The 7KC added to the acLDL is therefore the only “oxidised” component of the acLDL particle.

7KC is the major oxysterol present in oxLDL [12], in oxLDL-loaded human monocyte-derived macrophages [17] and advanced atherosclerotic plaque [18]. In human monocyte-like U937 cells, 7KC triggers cell death with oxidative stress and caspase activation [19]. U937 cells are an excellent model system, as oxLDL triggers the same cytotoxic events in U937 cells as those observed in actual human monocyte-derived macrophages (prepared from human blood) [2, 20, 21]. In this study we treated U937 cells with increasing levels of 7KC loaded acLDL and compared the cytotoxicity to oxLDL and 7KC added directly to the cells. We have also examined the effect of adding additional 7KC to already oxidised LDL. The experiments described here directly test the hypothesis that 7KC is the main cytotoxic agent in oxLDL.

Methods

Chemicals

All chemicals and reagents were of analytical grade or better and obtained from the Sigma Chemical Company

(USA), BDH Chemicals New Zealand Ltd., or Merck (Germany). All solutions were prepared using ion-exchanged ultra-filtered water, which was produced using a NANOpure ultrapure water system from Barnstead/Thermolyne (IA/USA). Cell culture plasticware was supplied by Greiner Bio-one through Raylab Ltd. 7KC was obtained from the Sigma-Aldrich Chemical Co. (USA) and 7,8-dihydroneopterin from Schircks Laboratories (Switzerland). Phosphate buffered saline (PBS) consisted of 150 mM sodium chloride and 10 mM sodium phosphate, pH 7.4.

Lipoprotein Isolation

Human plasma (anti-coagulated with EDTA) was isolated by venipuncture from healthy male and female donors following an overnight fast (ethics approval from Upper South A Ethics Committee, CTY/01/04/036). LDL was isolated from human plasma by buoyant density gradient ultracentrifugation using an NVTi 60 rotor (Beckman Coulter, USA) [22]. The LDL concentration was determined by enzymatic cholesterol assay using a CHOL kit (Roche Diagnostic, USA) assuming an LDL molecular weight of 2.5 MDa and a cholesterol content of 31.6% [22]. The KBr and EDTA were removed and the LDL concentrated by ultrafiltration using Amicon® Ultra-15 filter tubes (Millipore, USA). LDL preparations were filter-sterilised (0.22 μ m, Membrane Solutions, USA) and stored in the dark at 4 °C under argon gas.

Incorporation of 7KC into LDL

Human plasma was combined with 7KC dissolved in ethanol, to give a final concentration in plasma of 2.4 mM 7KC with an ethanol concentration less than 2.6% (v/v) and incubated at 37 °C with gentle shaking for 6 h [16]. The 7KC-enriched LDL was isolated by buoyant density gradient ultracentrifugation, then ultra-filtered and concentrated as described for native LDL.

Lipoprotein Modifications

Copper-oxidised LDL was prepared using a method adapted from Gerry et al. [13]. LDL at 10 mg/ml total mass (2 mg/ml apoB protein) was placed in a dialysis bag (12–14 kDa, Medicell International, UK) with the addition of CuCl₂ to give a final concentration of 0.5 mM. The dialysis bag was placed in a solution of PBS (100 ml buffer per 5 mg of LDL total mass) containing 0.5 mM CuCl₂ and incubated at 37 °C for 24 h. Oxidised lipoprotein was dialysed against three changes of Chelex-containing PBS at 4 °C for 24 h.

7KC-oxLDL was prepared by first loading the LDL with 7KC before oxidising 7KC-LDL with copper ions, as described above.

AcLDL and 7KC-acLDL were prepared using an adaptation of the method described by Kritharides et al. [23]. Specifically, the lipoprotein solution (10 mg/ml) was combined, on ice with very gentle stirring, with an equal volume of saturated sodium acetate solution. Acetic anhydride was added to lipoprotein, in 2- μ l aliquots, at 10-min intervals to a final concentration of 6 μ l acetic anhydride per mg LDL protein. The acetylated lipoprotein solution was buffer-exchanged and concentrated by ultra-filtration before filter-sterilisation.

Gel Electrophoresis

Modification of the lipoprotein was confirmed by non-denaturing gel electrophoresis using a Beckman Paragon® native gel electrophoresis kit and apparatus in B-2 barbital buffer at 100 V for 30 min. The relative electrophoretic mobility (REM) was calculated as the distance travelled by the oxidised or acetylated LDL relative to the reference native LDL.

Cell Culture

U937 human monocyte-like cells were grown in suspension in culture medium consisting of RPMI-1640 containing penicillin G (100 U/ml) and streptomycin (100 μ g/ml) (Gibco Invitrogen, NZ) supplemented with 5% heat-inactivated foetal bovine serum (Invitrogen, USA). Cells were incubated at 37 °C in a humidified atmosphere containing 5% CO₂ (Sanyo CO₂ Incubator). Cells in serum-free RPMI-1640 at 5×10^5 cells/ml were transferred to non-adherent suspension plates coated with 8 μ l of 50 mg/ml bovine serum albumin per well containing a total of 1 ml of medium, to prevent cells sticking to plastic. Serum is known to inhibit oxLDL toxicity to cell lines, so serum was removed from the cell medium by centrifugation and washing in PBS immediately prior to use in experiments and the serum-free medium was used in all experiments.

A 10 mM 7KC stock solution was prepared in absolute ethanol (Merck, Germany) and diluted to a concentration of 100 μ M with RPMI-1640 before addition to wells, so that the final concentration of ethanol in the culture medium was below 0.5% (v/v). A 2 mM 7,8-dihydroneopterin stock solution was prepared immediately before use in experiments, before dilution with further RPMI-1640 to working concentrations. When cells were treated simultaneously with 7,8-dihydroneopterin and 7KC, the 7,8-dihydroneopterin was introduced into the culture medium 10 min prior to treatment with 7KC.

Cell Viability

Cell viability was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) reduction assay using the method of Mosmann [24] but using 10% (w/v) sodium dodecyl sulphate to lyse cells and solubilise the insoluble MTT-formazan salt.

Measurement of 7KC

Measurement of unesterified 7KC was performed by solvent extraction followed by high performance liquid chromatography (HPLC) analysis [25]. Following treatments, cells were washed twice with warm PBS and lysed with 0.2 M NaOH for 15 min before extraction into hexane. Hexane extracts were evaporated under nitrogen gas and re-dissolved in acetonitrile:isopropanol (4:5) before being quantified by isocratic reverse phase HPLC using a Phenosphere C-18 column (4.6 \times 250 mm, 5 μ m particle size, Phenomenex, Auckland, NZ) developed with a mobile phase of acetonitrile/isopropanol/water in a ratio of 44:54:2. The 7KC was detected by absorbance at 234 nm and quantification was by comparison to pure standards.

Cellular GSH

Glutathione (GSH) levels were measured by derivatisation with monobromobimane and reverse phase C-18 HPLC analysis of the fluorescent derivative using monobromobimane-derivatised GSH as a standard [26].

Statistical Analysis

Data shown are the result of single experiments and representative of three separate experiments. The mean and standard error of the mean (SEM) shown within each experiment were calculated from triplicate samples in every case. Data were analysed using the Prism software package (version 4.0, GraphPad Software Inc., USA). Significance was confirmed via one way analysis of variance (ANOVA) followed by Tukey's multiple comparison test. Asterisks indicate significance from the control or initial value (unless otherwise indicated) when * $p \leq 0.05$, ** $p \leq 0.01$ and *** $p \leq 0.001$.

Results

OxLDL-Induced U937 GSH Loss, Cell Viability Loss and 7KC Uptake

OxLDL induced a dramatic loss of U937 cell viability, as measured by the cells' ability to metabolically reduce MTT

(Fig. 1a). With 0.2 mg/ml oxLDL, cell viability after 24 h was only 32% of the control, with the viability loss occurring predominantly between 1.5 and 6 h of incubation (Fig. 1c). Loss of metabolic activity was consistent with changes in cellular morphology (data not shown) such as blebbing, cell swelling and lysis and appearance of cellular debris, consistent with the caspase-independent necrosis previously described in U937 cells [20].

OxLDL triggers reactive oxygen species formation in U937 cells as shown by the rapid and early loss of cellular glutathione [20, 27]. The decrease in cellular glutathione levels closely followed the loss of cell viability (Fig. 1d), showing that the oxidative stress was intense and developed rapidly in response to oxLDL exposure [20]. Increasing concentrations of oxLDL resulted in a concentration-dependent increase in cellular 7KC content, indicating the internalisation of the oxysterol (Fig. 1b).

7KC-Induced U937 GSH Loss, Cell Viability Loss and 7KC Uptake

Treatment of U937 cells with 7KC, added to the culture medium dissolved in ethanol, induced a dramatic and

concentration-dependent loss of cell viability with an estimated LD₅₀ of 18 μ M (Fig. 2a). The concentration of 7KC is reported to be approximately 25 μ M in advanced lesions so this concentration is similar to physiological levels within plaques [11]. The viability loss was not due to the ethanol, as the maximum concentration used caused no significant loss of cell viability (as in the 0 μ M 7KC control). In contrast to oxLDL, the 7KC-induced viability loss occurred only after a 9-h lag period (Fig. 2c). Cell viability loss occurred predominantly between 12 and 28 h, which was also much slower than that observed with oxLDL. This lag phase kinetic followed by a slow decline in viability was mirrored by the loss of cellular glutathione (Fig. 2d) which is consistent with other published reports using U937 cells [28] and suggests a much lower level of reactive oxygen species production with 7KC compared to oxLDL. Examination of cells at 24 h showed that 7KC was absorbed into the cell to a maximum intracellular concentration of 19 nmol 7KC/10⁶ cells (Fig. 2b). As many of the cells were undergoing necrosis above 20 μ M added 7KC, this resulted in an apparent saturation effect in the uptake kinetics and impairment of the cellular uptake mechanisms, due to the cell death process. We have

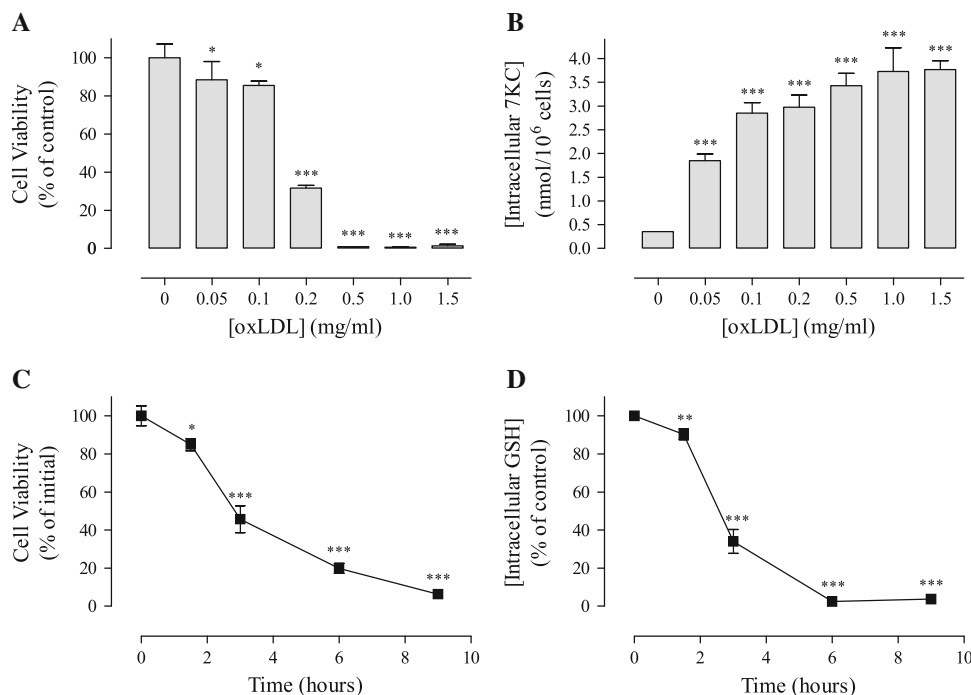

Fig. 1 OxLDL causes U937 cell viability loss, GSH loss and increased 7KC content. U937 cells were incubated with increasing concentrations of oxLDL in RPMI-1640 for 24 h before **a** cell viability was determined by MTT reduction assay and **b** cellular 7KC content was measured by HPLC analysis. Cell viability is expressed as a percentage of the 0 mg/ml oxLDL treatment. U937 cells were incubated with 0.25 mg/ml oxLDL in RPMI-1640 and cell samples

were taken at various time points for measurement of **c** cell viability by MTT reduction assay and **d** intracellular GSH content by HPLC analysis. Cell viability is expressed as a percentage of the initial viability and intracellular GSH is expressed as a percentage of the GSH content at corresponding time points. Untreated U937 cell GSH concentration is 11 nmol/mg protein of cell protein

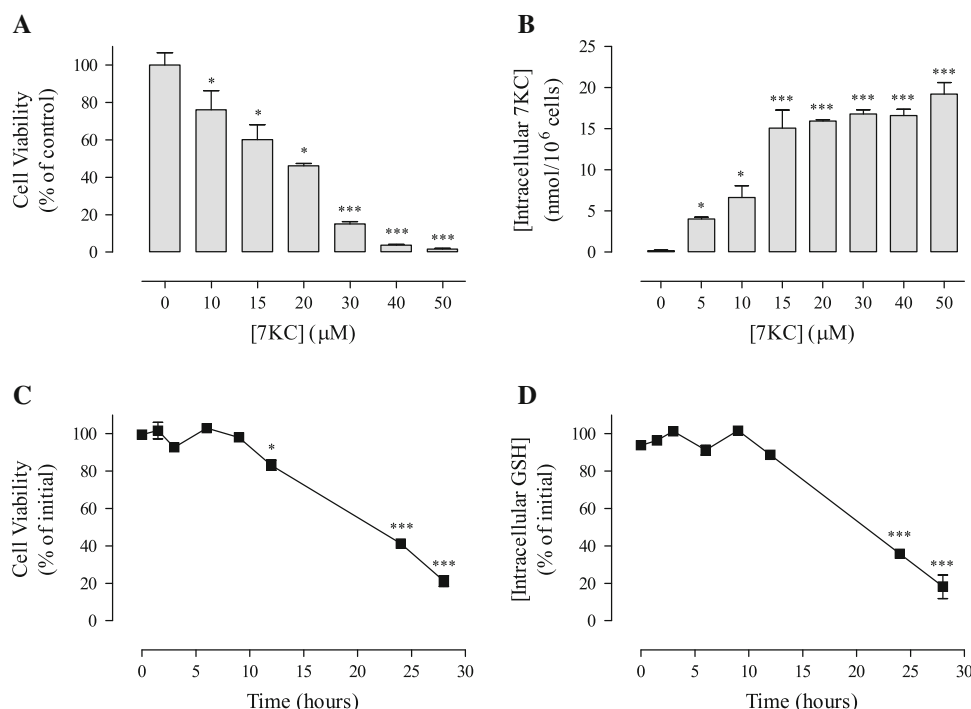

Fig. 2 7KC causes U937 cell viability loss, GSH loss and increased 7KC content. U937 cells were incubated with increasing concentrations of 7KC in RPMI-1640 for 24 h before **a** cell viability was determined by MTT reduction assay and **b** cellular 7KC content was measured by HPLC analysis. Cell viability is expressed as a percentage of the 0 μM 7KC treatment. The 0 μM 7KC control contained 0.5% (v/v) ethanol which was the maximum concentration

of ethanol used as a vehicle for 7KC. U937 cells were incubated with 30 μM 7KC in RPMI-1640 and cell samples were taken at various time points for measurement of **c** cell viability by MTT reduction assay and **d** intracellular GSH content by HPLC analysis. Cell viability and GSH content are each expressed as a percentage of the initial level. Untreated U937 cell GSH concentration is 11 nmol/mg protein of cell protein

measured only unesterified intracellular 7KC levels as esterification has been shown to prevent 7KC cytotoxicity in U937 cells [29].

7,8-Dihydroneopterin Does Not Protect Against 7KC-Induced U937 Cell Viability Loss

We had previously shown that the water soluble antioxidant, 7,8-dihydroneopterin, inhibits oxLDL toxicity by scavenging intracellular oxidants. 7,8-Dihydroneopterin inhibits oxLDL toxicity by scavenging intracellular oxidants independently of other antioxidants such as glutathione or α -tocopherol [30, 31]. Using 7,8-dihydroneopterin as a probe of the toxicity mechanism, we found that it did not protect U937 cells from the cytotoxic effect of 7KC, indicating that oxidative stress was not a key factor in driving the 7KC-induced cell death (Fig. 3). This is in direct contrast to that observed with oxLDL-treated U937 cells [20, 27].

7KC-acLDL Displays High 7KC Uptake and Low Toxicity to U937 Cells

To examine the effect of 7KC on lipoprotein toxicity, LDL was purified from human plasma, which had been enriched

Fig. 3 7,8-Dihydroneopterin (7,8-NP) does not protect against 7KC-induced U937 cell viability loss. U937 cells were treated with increasing concentrations of 7,8-dihydroneopterin for 10 min before incubation with or without (control and 7,8-dihydroneopterin control containing 200 μM 7,8-dihydroneopterin) 15 μM 7KC in RPMI-1640 for 24 h at which point, cell viability was determined by MTT reduction assay. Results are expressed as a percentage of the viability of the control treatment and significance is indicated from the control

with 7KC. The purified lipoprotein was converted to the high-uptake form by acetylation. As expected, acetylation increased the electrophoretic mobility of the LDL 4-fold

over native LDL, while extensive copper oxidation increased the lipoprotein mobility 4.4-fold (Fig. 4a). Importantly, the incorporation of 7KC did not alter the electrophoretic mobility of the acLDL, showing that there were no major changes to the LDL charge/mass ratio. Analysis of the 7KC-acLDL showed a 7KC content of 228 mol/mol LDL while the copper-oxidised LDL used for comparison had a 7KC content of 131 mol/mol LDL (Fig. 4b). Zero or minute quantities of 7KC were measured in native and acLDL, respectively.

The U937 cells rapidly internalised 7KC-acLDL, with the intracellular 7KC concentration reaching 80% of maximum within 6 h (Fig. 5a). The intracellular concentration of 20 nmol 7KC/ 10^6 cells achieved with 1.5 mg/ml 7KC-acLDL after 24 h incubation (Fig. 5b), was 5-fold higher than that measured with oxLDL (Fig. 1b). The increase in intracellular 7KC concentration achieved with 7KC-acLDL did not translate into increased cytotoxicity. Using 0.2 mg/ml 7KC-acLDL, which contains 18 μ M 7KC, there was no viability loss (Fig. 5c), while a similar concentration of

7KC (20 μ M) added as an ethanol solution caused 55% loss in viability (Fig. 2a). If we compare just the intracellular levels of 7KC, there was a 17% loss of viability with 15 nmol 7KC/ 10^6 cells (0.5 mg/ml of 7KC-acLDL, Fig. 5) while with 7KC added in ethanol, an intracellular concentration of 16 nmol 7KC/ 10^6 cells resulted in a 54% decrease in cell viability (Fig. 2). The 7KC toxicity was greatly reduced when incorporated into acLDL. The overall levels of intracellular 7KC achieved with 7KC-acLDL were up to five times higher than that achieved with oxLDL, yet oxLDL was far more cytotoxic.

7KC-oxLDL and OxLDL Display Similar Toxicity to U937 Cells

The higher toxicity of oxLDL compared to 7KC-acLDL is possibly due to different processing of the lipoprotein particle. If 7KC is the toxic agent within oxLDL, the selective enrichment of oxLDL with 7KC should therefore make it more toxic. The 7KC content of oxLDL was increased more than 5-fold (Fig. 5e) yet this did not affect the toxicity with U937 cells, except at concentrations of 1 mg/ml 7KC-oxLDL or above (Fig. 5e). With 0.3 mg/ml of either oxLDL (10 μ M 7KC) or 7KC-oxLDL (60 μ M 7KC) there was only a small viability loss of 10% for each. At 0.5 mg/ml lipoprotein, the 7KC loading appeared to decrease the toxicity by 10%, though this was well beyond the LD₅₀. It was only at extremely toxic concentrations of oxLDL (80% viability loss) and above, that the corresponding 7KC-oxLDL induced further loss of viability. This shows that raising oxLDL 7KC levels without causing further oxidative damage does not increase cytotoxicity.

Fig. 4 Relative electrophoretic mobility and 7KC content of native and modified LDL. Native and modified LDL were prepared as described at “Lipoprotein Isolation”, “Incorporation of 7KC into LDL” and “Lipoprotein Modifications”, and **a** relative electrophoretic mobility was examined on a non-denaturing Paragon® LIPO gel. Lanes 1 and 5 were loaded with native LDL, lanes 2 and 6 with oxLDL, lanes 3 and 7 with acLDL and lanes 4 and 8 with 7KC-acLDL, at 2.0 mg/ml LDL protein. **b** The non-esterified 7KC content of individual lipoprotein preparations was measured by HPLC analysis and is representative of at least three separate preparations

Discussion

Oxysterol cytotoxicity has been measured in numerous *in vitro* studies by direct addition to the cell culture medium. As oxysterols are normally located within lipoproteins *in vivo*, the findings presented here have been generated using a more physiologically relevant model system where 7KC was incorporated into LDL.

The U937 cell line we used was found to be very sensitive to oxLDL and 7KC toxicity (Figs. 1, 2). Yet when U937 cells were incubated with 7KC incorporated into high-uptake acLDL (7KC-acLDL) the toxicity was greatly reduced (Fig. 5). Across the different methods of 7KC exposure to U937 cells, there was no correlation between intracellular 7KC concentration and cytotoxicity. While relatively low intracellular concentrations of 7KC correlated with very high oxLDL toxicity, comparatively large intracellular 7KC concentrations from the uptake of 7KC-acLDL caused only a small viability loss. Furthermore, the

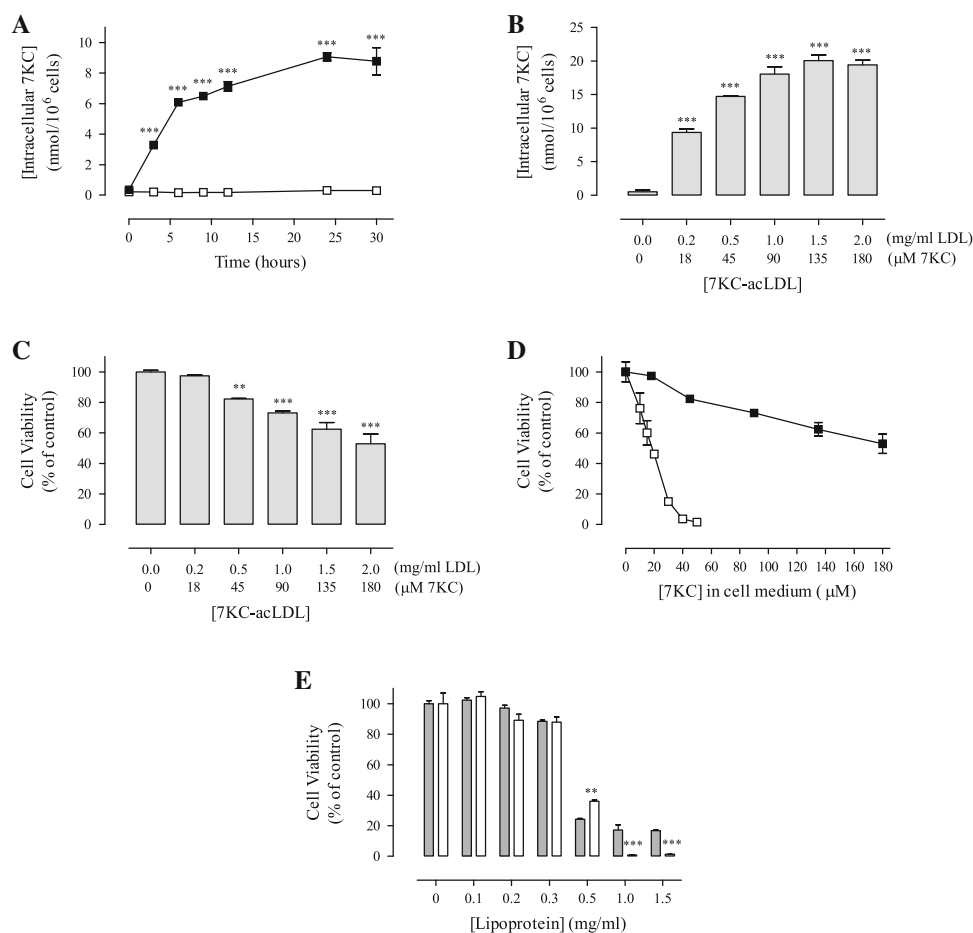

Fig. 5 7KC-acLDL displays high uptake and low toxicity to U937 cells. **a** Intracellular 7KC content was measured at various time points during incubation of U937 cells with (black squares) or without (white squares) 0.2 mg/ml 7KC-acLDL (equivalent to 18 μM 7KC) in RPMI-1640 over 30 h. Significance is indicated from the control data for each time point. U937 cells were incubated with increasing concentrations of 7KC-acLDL in RPMI-1640 for 24 h before **b** measurement of cellular non-esterified 7KC content by HPLC analysis and **c** determination of cell viability by MTT reduction assay. The X axis values give both the 7KC and total lipoprotein

concentration in the media for each treatment. Cell viability is expressed as a percentage of the 0 mg/ml 7KC-acLDL treatment. **d** Data from Figs. 2a and 5c are represented together, showing the comparison of U937 cell viability with 7KC (white square) and 7KC-acLDL (black squares). **e** U937 cell viability was measured following a 24 h incubation with oxLDL (grey bars) and 7KC-oxLDL (white bars). The oxLDL preparation contained 87 mol 7KC/mol LDL and the 7KC-oxLDL preparation contained 501 mol 7KC/mol LDL. Significance is indicated from the respective oxLDL data for each concentration

treatment of cells with 7KC-oxLDL, which contained 6-fold more 7KC than normal oxLDL, did not show an increased level of cell viability loss, except at the very highest 7KC-oxLDL concentrations. Collectively, these findings do not support the hypothesis that 7KC is the main cytotoxic agent in oxLDL.

OxLDL toxicity to U937 cells and human monocyte-derived macrophages is driven by the induction of reactive oxygen species generation, which can be inhibited by antioxidants such as 7,8-dihydroneopterin [2, 21, 27]. Though 7KC cytotoxicity is reportedly inhibited by glutathione in U937 cells [28] and NADPH-oxidase inhibitors in mouse J774A.1 cells [32], 7,8-dihydroneopterin was unable to prevent cell viability loss when 7KC was added directly to cells (Fig. 3). We have previously demonstrated that

7,8-dihydroneopterin is taken up by cells [21] suggesting that in the case of oxLDL, the inhibition of the oxidative stress is most likely to occur intracellularly whereas much of the cytotoxic effect of 7KC may occur on the plasma membrane [33]. This indicates that oxLDL and 7KC exert toxicity via different mechanisms and that oxLDL toxicity is unlikely to be dependent on 7KC toxicity. This is also mirrored in the rate of GSH loss; which was rapid with oxLDL and much slower with the direct addition of 7KC.

The key difference in cytotoxicity between 7KC added directly to the cell media and 7KC in a lipoprotein appears to be how the cell handles the oxysterol. When given directly to cells, 7KC collects on the plasma lipid membrane within the lipid rafts, disrupting calcium control [15]. In contrast, when 7KC enters the cells via a lipoprotein, it

is rapidly rendered non-toxic through esterification after release from the lipoprotein in the lysosomes [29]. The esterified 7KC appears to be unable to concentrate in the plasma membrane and disrupt the lipid rafts.

7KC is not the only oxysterol found within heavily oxidised LDL. 25-Hydroxycholesterol and 7-beta-hydroperoxycholesterol-5-en-3-beta-ol, to name a few have been shown to be cytotoxic when added directly to the cells [10, 34]. The toxic effects described for this class of compounds appear similar, suggesting that like 7KC they may also have reduced cytotoxicity when incorporated into a lipoprotein. If this is the case, the question remains, what is the main cytotoxic component in copper-oxidised LDL? Lipid oxidation and oxLDL cytotoxicity are strongly linked [8], as are protein oxidation and oxLDL cytotoxicity, where the lipid peroxyl radical attacks the apoB100 protein moiety [4]. HOCl treatment of LDL oxidises predominately the protein moiety with very little oxysterol formation, yet is just as toxic as copper ion-oxidised LDL to U937 cells [35]. This suggests that the toxicity of oxLDL is via advanced protein oxidation products rather than oxysterols. This does not mean that oxLDL oxysterols are irrelevant, since 7KC in 7KC-acLDL has been shown to impair sterol efflux to ApoA-I from mouse peritoneal macrophages [16], implicating oxysterols in actual foam cell formation and fatty streak formation.

Although our results indicate that the toxicity of 7KC (and possibly other oxysterols) is massively diminished when incorporated into high-uptake LDL, they do not preclude the possibility that 7KC is a significant toxin within atherosclerotic plaques. Although we are not aware of any possible mechanism, our research does not rule out the possibility that within the environment of the plaque 7KC and other oxysterols may be removed from the lipoprotein particles and concentrated onto the surface of the macrophage foam cells, so inducing cell death.

Acknowledgments This work was partly funded through a project grant from the National Heart Foundation of New Zealand and Student Research Support from the School of Biological Sciences, University of Canterbury. We would like to thank our blood donors for our source of blood and the Nurses from The Health Centre for carrying out the blood collection.

Abstract The liver X receptor alpha (LXR α), a member of the nuclear receptor superfamily, has been shown to regulate the expression of the fatty acid synthase (FAS) gene through direct interaction with the *FAS* promoter. However, its regulation of gene expression is not completely understood. Histone modifications and chromatin remodeling are closely linked to transcriptional activation of genes. In the present study, we examined the effect of LXR α activation or silencing on histone modifications (i.e., acetylation, methylation, and phosphorylation) across the *FAS* gene, with the aim to investigate whether LXR α could regulate its target gene expression at the epigenetic level.

The addition of LXR agonist T0901317 or ectopic expression of LXR α stimulated the *FAS* transcription, which was coupled with increased levels of histones H3 and H4 acetylation and H3 phosphorylation and methylation at the LXR response element (LXRE). LXR ligation or overexpression induced distinct histone modification patterns at the distal region 2,272 bp upstream from the transcription start site (TSS) and TSS of the *FAS* gene. Moreover, RNA interference-mediated downregulation of LXR α impaired the histone acetylation and methylation but not phosphorylation on the *FAS* gene. In conclusion, we provide evidence that LXR α ligation-mediated transcriptional activation of the *FAS* gene is associated with LXR α -dependent histone acetylation and methylation rather than phosphorylation on this target gene.

Introduction

Liver X receptors (LXRs) belong to a class of ligand-dependent nuclear receptors that play an important role in

hepatic bile and fatty acid synthesis, glucose metabolism, as well as sterol efflux [1, 2]. They are known to be activated by oxysterols [3]. Ligand-activated LXRs form obligate heterodimers with retinoid X receptors (RXRs) and regulate the transcription of their target genes by binding to specific LXR response elements (LXREs) [4]. There have been two subtypes of LXRs identified: LXR α and LXR β . The inducible LXR α is abundantly expressed in liver, spleen, kidney, adipose, and small intestine, whereas LXR β is ubiquitously expressed [5]. LXR α plays a critical role in maintaining the homeostasis of cholesterol, which is supported by the finding that LXR α knockout mice, when fed a high-cholesterol diet, develop massive hepatic accumulation of cholesterol [6]. Apart from affecting cholesterol metabolism, LXR α is also involved in the control of lipogenesis. Genetic ablation of LXR α impairs the expression of several lipogenic genes including fatty acid synthase (FAS), acetyl coenzyme A, steroyl-coenzyme A desaturase, and sterol regulatory element binding protein 1 (SREBP-1) [6]. The biosynthetic enzyme FAS is a central enzyme required for the anabolic conversion of dietary carbohydrates to fatty acids [7]. The expression of FAS is controlled primarily at the level of transcription and is tightly regulated by both hormonal and nutritional signals [7, 8]. Previous work has demonstrated that LXRs regulate FAS expression through direct interaction with the *FAS* promoter [1]. Demeure et al. [9] also reported that there is a functional LXRE in the promoter of chicken *FAS* gene, which is responsible for the induction of FAS expression by a pharmacological LXR agonist, T0901317.

Eukaryotic chromatin is the complex of DNA and histone proteins that form nucleosomes. It is well known that chromatin remodeling plays a crucial role in gene transcription. The structure of chromatin is altered to allow greater accessibility by transcription factors when a gene is to be activated [10]. Nuclear receptors are involved in the change to a more accessible state by recruiting two classes of chromatin remodelers, histone modifying enzymes and ATP-dependent chromatin remodeling factors [11]. These remodelers modify chromatin structure at target gene promoters by posttranslational modification of histones and by disrupting DNA-histone interactions, respectively. Progesterone and glucocorticoid receptors have been found to recruit different coactivator complexes and promote distinct patterns of histone modification [12]. Ananthanarayanan et al. [13] reported that the nuclear hormone receptor, farnesoid X-receptor (FXR), facilitates arginine methylation of histone H3 by co-activator-associated arginine methyltransferase 1. Considering that LXRs and FXR are structurally and closely related nuclear receptors that play critical roles in lipid metabolism [14], we speculated that LXRs might also have an influence on chromatin modification, providing a novel mechanism for its

regulation of gene transcription. To test this hypothesis, we examined herein the histone modification status of different regions of the *FAS* gene upon the stimulation with LXR agonist T0901317 for varying durations (30–120 min), and investigated the role of the LXR α isoform in the modification of histones using RNA interference (RNAi) and overexpression approaches.

Materials and Methods

Cell Culture and Reagents

Samples of the human hepatocellular carcinoma cell line HepG2 were purchased from the Chinese Academy of Sciences (Shanghai, China) and cultured in Dulbecco's modified Eagle's medium (Hyclone, Logan, UT, USA) with 10% heat-inactivated fetal bovine serum (Hyclone), 100 U/ml penicillin, and 100 μ g/ml streptomycin in a 5% CO₂ incubator at 37 °C. T0901317 was obtained from Cayman Chemical (Ann Arbor, MI, USA) and dissolved in dimethyl sulfoxide (DMSO; Sigma, St. Louis, MO, USA). If not stated otherwise, 1 μ M T0901317 [15] was used to treat cells.

Plasmids, Small Interfering RNA (siRNA), and Transient Transfection

Constructs expressing LXR α -specific siRNA (siLXR α) or nonspecific scrambled siRNA as negative control were purchased from Wuhan GeneSil Biotechnology Co. Ltd. (Wuhan, China). The sense sequence of the siLXR α and control siRNA was 5'-GCAACTCAATGATGCCGAGTT-3' and 5'-GACTTCATAAGGCGCATGC-3', respectively. HepG2 cells at 85–90% confluence were transfected with either siLXR α or control siRNA using PolyJet in vitro DNA transfection reagent (SignaGen Laboratory, Gaithersburg, MD, USA) according to the manufacturer's instructions. To monitor the transfection efficiency, cells were in parallel co-transfected with a plasmid expressing enhanced green fluorescent protein (EGFP). The transfection efficiency, measured by counting EGFP-positive cells using a fluorescence microscope, was about 72%. The siRNA-mediated silencing of LXR α was determined by polymerase chain reaction (PCR) and Western blot analysis as described below.

For overexpression studies, a plasmid expressing human wild-type LXR α (GenBank accession number: NM_001130101) was purchased from Shanghai Genechem (Shanghai, China). HepG2 cells at 85–90% confluence were transfected with the LXR α -expressing plasmid or GV142 empty vector, using PolyJet in vitro DNA transfection reagent. At 0, 12, 24, and 36 h after transfection, cells were

harvested and subjected to chromatin immunoprecipitation (ChIP) assays.

RNA Isolation, PCR, and Quantitative Real-Time PCR (qRT-PCR)

Total RNA was extracted from HepG2 cells using Trizol reagent (Invitrogen, Carlsbad, CA, USA) and was reverse-transcribed with RevertAid First Strand cDNA Synthesis kit (Fermentas, Ontario, Canada) according to the manufacturer's recommendations. PCR amplification of cDNA was conducted using primers specific for LXR α : 5'-TGGGAACA CGATGGGAGAAC-3' (forward) and 5'-CTGCCGTGCC ACCTTG-3' (reverse); and β -actin 5'-TGACGGTCAGG TCATCACTATCGGCAATGA-3' (forward) and 5'-TTG ATCTTCATGGTGATAGGAGCGAGGGCA-3' (reverse). Amplification of β -actin cDNA served as an internal control. Quantitative PCR experiments were carried out on an ABI 7300 real-time PCR system (Applied Biosystems, Foster City, CA, USA) using commercial primers for human FAS and β -actin (Applied Biosystems). All samples were run in triplicate. Gene expression was normalized to β -actin transcripts, and the relative mRNA expression was calculated using the $2^{-\Delta\Delta C_t}$ method (where C_t is the cycle threshold number) [16].

ChIP Coupled to Detection by qRT-PCR

The ChIP assay was performed using the Chromatin Immunoprecipitation Assay Kit (Upstate Biotechnology, Lake Placid, NJ, USA) according to the manufacturer's protocol with minor modifications [17]. Unstimulated or T0901317-treated HepG2 cells ($\sim 2 \times 10^6$) were cross-linked for 10 min at 37 °C using 1% formaldehyde. Cells were resuspended in 400 μ l of ChIP lysis buffer [10 mM EDTA, 50 mM Tris-HCl (pH 8.0), 1% sodium dodecyl sulfate (SDS), and protease inhibitors] on ice for 10 min. The chromatin was sheared by sonication using an ultrasonic processor (VC130P; Sonics & Materials, Newtown, CT, USA) in an ice bath to produce DNA fragments ranging from 200 to 1,000 bp, as determined by agarose gel electrophoresis. After removal of debris by centrifugation, the chromatin solution was diluted 10-fold with ChIP dilution buffer [2 mM EDTA, 16.7 mM Tris-HCl (pH 8.1), 0.01% SDS, 16.7 mM NaCl, and 1.1% Triton X-100] and precleared with Protein A Agarose/Salmon Sperm DNA at 4 °C for 30 min. For immunoprecipitation, the following antibodies were used: anti-histone H3, anti-histone H4, anti-acetyl-histone H3, anti-acetyl-histone H4, anti-phospho-histone H3 (ser10), and anti-trimethyl-histone H3 lysine 4 (H3K4; Upstate Biotechnology). The antibody-chromatin complexes were precipitated by incubation with Protein A Agarose/Salmon Sperm DNA. DNA-protein crosslinks were reversed by incubation at

65 °C for 4 h followed by proteinase K treatment. DNA was recovered by purification with the Qiaquick PCR purification column (Qiagen, Hilden, Germany). Quantification of immunoprecipitated DNA was determined using qRT-PCR with primers listed in Supplementary Table S1. Each assay was performed in triplicate. The relative amount of immunoprecipitated DNA to input DNA was calculated.

Western Blot Analysis

Samples of protein extracts from cells were resolved by sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred to polyvinylidene fluoride membranes. After blocking with 5% bovine serum albumin (Sigma) for 1 h, the membranes were incubated overnight at 4 °C with mouse anti-human LXR α monoclonal antibodies (ab41902, abcam, Cambridge, UK; 1:1,500 dilution) or β -actin (Sigma), followed by incubation with horseradish peroxidase-linked secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA). Bound antibodies were visualized by an enhanced chemiluminescence detection kit (Amersham Biosciences, Piscataway, NJ, USA).

Statistical Analysis

Data are expressed as means \pm standard deviation. All experiments were performed in triplicate. Differences among groups were determined by the Student–Newman–Keuls test. $P < 0.05$ was considered statistically significant.

Results

LXR Activation Affects the Histone Modification Pattern on the *FAS* Gene

qRT-PCR analysis revealed that HepG2 cells exposed to LXR agonist T0901317 had a rapid increase in the abundance of FAS mRNA (Fig. 1a). The increase began approximately 2 h after the T0901317 treatment and peaked at 16 h, suggesting transcriptional upregulation of FAS by LXR activation. Western blot analysis demonstrated that the LXR α protein level was profoundly elevated 16 h after the T0901317 treatment, and remained elevated for up to 48 h (Fig. 1b).

To get more insight into the mechanism(s) regulating the FAS expression, we used ChIP to measure the effect of LXR activation on histone modifications at different regions of the *FAS* gene (Fig. 1c), i.e., the distal site 2,272 bp upstream from the transcription start site (TSS; referred to as the distal site), LXRE (−756/−718), TSS (+1), and exon 3 (+2,818/+2,905) used as a negative

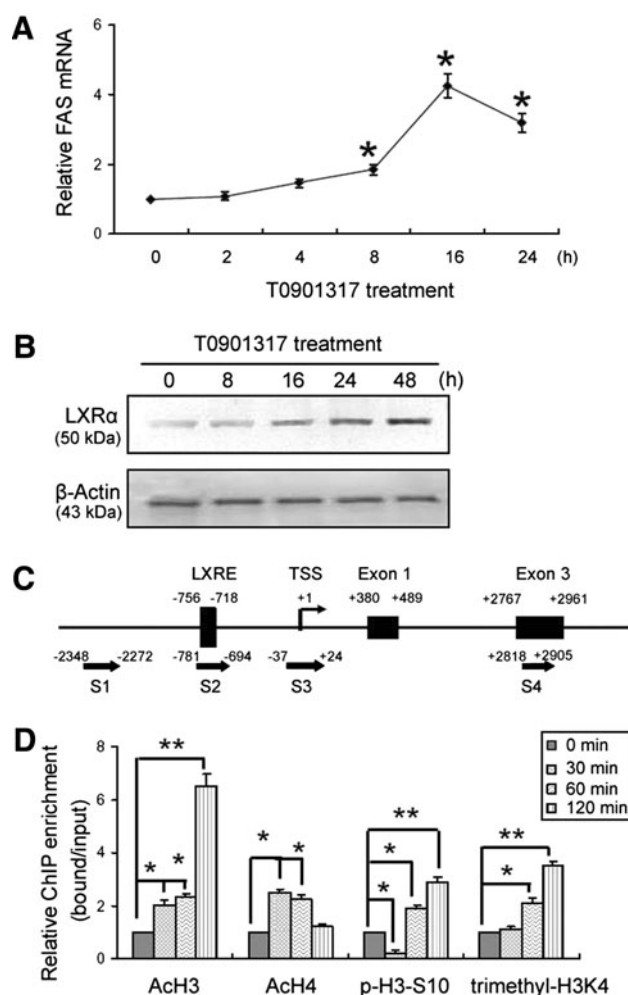

Fig. 1 LXR ligation induces *FAS* expression and histone modifications at the LXRE of the *FAS* gene. **a** Relative expression of *FAS* mRNA analyzed by qRT-PCR. HepG2 cells were treated for indicated time with 1 μ M T0901317 and were subjected to real-time PCR assays. The *FAS* levels were determined relative to that at time 0 and normalized to β -actin levels. * P < 0.05 compared to that at time 0; n = 3. **b** Western blot analysis for LXR α expression in HepG2 cells treated with 1 μ M T0901317 for indicated durations. Representative blots of three independent experiments with similar results are shown. β -Actin was used as loading control. **c** Schematic illustration of the human *FAS* gene. The primers (named S1, S2, S3, and S4) used for quantitative ChIP analysis of histone modifications are indicated by arrows. Numbers represent the nucleotide position relative to the transcription start site (TSS). **d** Histone modifications at the LXRE of the *FAS* gene induced by LXR agonist. HepG2 cells were exposed to T0901317 (1 μ M) for 0, 30, 60, or 120 min, and ChIP assays were conducted with antibodies against acetylated H3 (AcH3), acetylated H4 (AcH4), phosphorylated H3-S10 (p-H3-S10), trimethylated H3K4 (trimethyl-H3K4), as well as H3 and H4. Immunoprecipitated DNA was analyzed by real-time PCR using the S2 primer set indicated in Fig. 1c. The ratio of immunoprecipitated DNA to total input DNA was determined for each antibody. The value for the level of acetylation, phosphorylation, and trimethylation of H3 was divided by H3 occupancy respectively, and that for the level of acetylation of H4 was divided by H4 occupancy. Values at time 0 were set to be 1. * P < 0.05, ** P < 0.01 for indicated comparisons; n = 3

control site. Antibodies specific for acetylated H3 and H4 revealed a prompt acetylation at the LXRE (Fig. 1d). Both revealed a strong increase in histone acetylation at the 30-min time point. H4 acetylation was transient, peaking at 30 min, whereas acetylated H3 remained elevated up to 120 min. The level of H3-S10 phosphorylation increased after a transient reduction, reaching a maximum at 120 min. Additionally, T0901317-treated cells showed a >3-fold increase in the level of trimethylated H3K4 120 min post stimulation.

Notably, there was a divergent pattern of histone modifications on the other regions examined. Acetylation of H4 at both the distal site and the TSS, and H3 phosphorylation at the distal site were potentiated by T0901317 (Fig. 2b, c). However, there was a marked reduction in the acetylation, phosphorylation, and methylation of H3 at the TSS (Fig. 2a, c, d). No evident changes in histone modifications were found at the exon 3 (Fig. 2).

LXR α is Required for Histone Acetylation and Methylation but not Phosphorylation on the *FAS* Gene

Next, we attempted to determine whether LXR α was required for the modifications of histone on the *FAS* gene. We specially knocked down the endogenous expression of LXR α in HepG2 cells using siRNA. Both semiquantitative PCR and Western blotting analysis confirmed the down-regulation of LXR α in siLXR α -transfected cells (Fig. 3a). Targeted inhibition of LXR α abrogated the induction of *FAS* by T0901317 (Fig. 3b).

Of note, the histone modifications on the *FAS* gene were markedly affected by siRNA-mediated targeting of LXR α . As illustrated in Fig. 4, LXR α knockdown impaired T0901317-induced H3 acetylation at the LXRE, H4 acetylation at the distal site, the LXRE, and the TSS, as well as H3 methylation at the LXRE. Conversely, T0901317-mediated reduction of H3 acetylation and methylation at the TSS were reversed by LXR α downregulation (Fig. 4a, d). However, knockdown of LXR α had little influence on H3 phosphorylation (Fig. 4c).

Overexpression of LXR α Modulates Histone Modifications on the *FAS* Gene

We also examined the effects of LXR α overexpression on histone modifications on the *FAS* gene. Western blot analysis revealed an overexpression of LXR α in the cells transfected with LXR α relative to mock transfectants (data not shown). Ectopic expression of LXR α significantly facilitated H3 and H4 acetylation, H3-S10 phosphorylation,

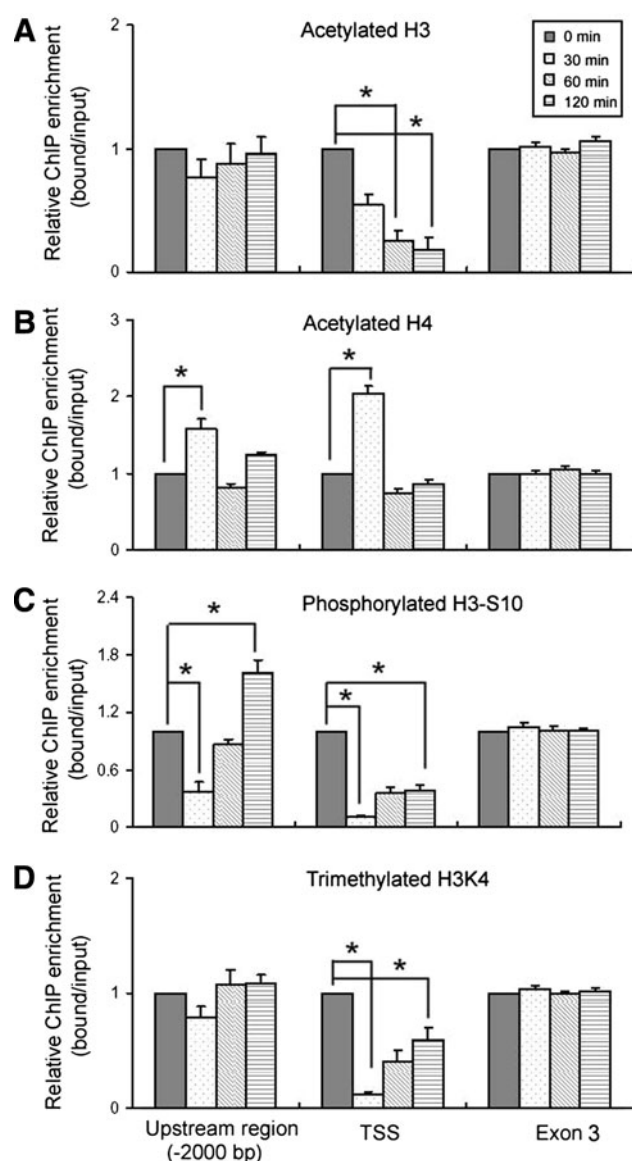

Fig. 2 Histone modifications at the upstream region, TSS, and exon 3 of the *FAS* gene in response to LXR activation. HepG2 cells were exposed to T0901317 (1 μ M) for indicated durations, and ChIP assays were conducted with antibodies against acetylated H3, acetylated H4, phosphorylated H3-S10, trimethylated H3K4, as well as H3 and H4. Immunoprecipitated DNA was analyzed by real-time PCR using S1, S3, or S4 primer sets as indicated in Fig. 1c. The ratio of immunoprecipitated DNA to total input DNA was determined for each antibody. The value for the level of acetylation, phosphorylation, and trimethylation of H3 was divided by H3 occupancy respectively, and that for the level of acetylation of H4 was divided by H4 occupancy. Values at time 0 were set to be 1. * P < 0.05, ** P < 0.01 for indicated comparisons; n = 3

and H3K4 methylation at the LXRE in comparison with mock transfection (P < 0.01; Fig. 5a–d). There were lower levels of H3 acetylation, phosphorylation, and methylation and higher levels of H4 acetylation at the TSS in LXR α -overexpressing cells than in mock-transfected cells

Fig. 3 siRNA-mediated knockdown of LXR α abrogates the induction of FAS by LXR agonist. **a** Downregulation of endogenous LXR α by siRNA delivery. Untransfected HepG2 cells (lane 1) and those transfected with negative control siRNA (lane 2) or specific LXR α siRNA (lane 3) were assessed for the LXR α mRNA (left) and protein (right) expression. Shown are representative images of three independent experiments with similar results. β -Actin was used as loading control. **b** Relative expression of FAS mRNA analyzed by qRT-PCR. HepG2 cells transfected with negative control siRNA or specific LXR α siRNA were treated for indicated time with 1 μ M T0901317 and were subjected to real-time PCR assays. The FAS levels were determined relative to that at time 0 and normalized to β -actin levels. * P < 0.05, ** P < 0.01 compared to control cells; n = 3

(Fig. 5a–d). LXR α overexpression resulted in a transient reduction in H3-S10 phosphorylation at the distal site (Fig. 5c), but did not markedly affect H3 and H4 acetylation or H3K4 methylation at the same site (Fig. 5a, b, d).

Discussion

The present study was undertaken to characterize more definitively the mechanism involved in the regulation of FAS expression by LXR α . We examined the effects of LXR α on histone modifications at 4 different regions of the *FAS* gene. LXRE and the region surrounding the TSS play important roles in the control of gene transcription. In addition to the proximal promoter elements, FAS expression may be regulated by distal transcriptional regulatory elements. The distal site about 2,000 bp upstream of the TSS was used to study epigenetic changes in the distal promoter of *FAS* gene. The exon 3 region was used as a negative control for histone modifications; no apparent epigenetic changes were observed at this region under the experimental conditions of this study. We showed that LXR ligation-mediated transcriptional activation of FAS is associated with the modifications of histones on this gene. The LXR α isoform is implicated in the induction of FAS by LXR agonist T0901317, probably through alteration of histone acetylation and methylation rather than

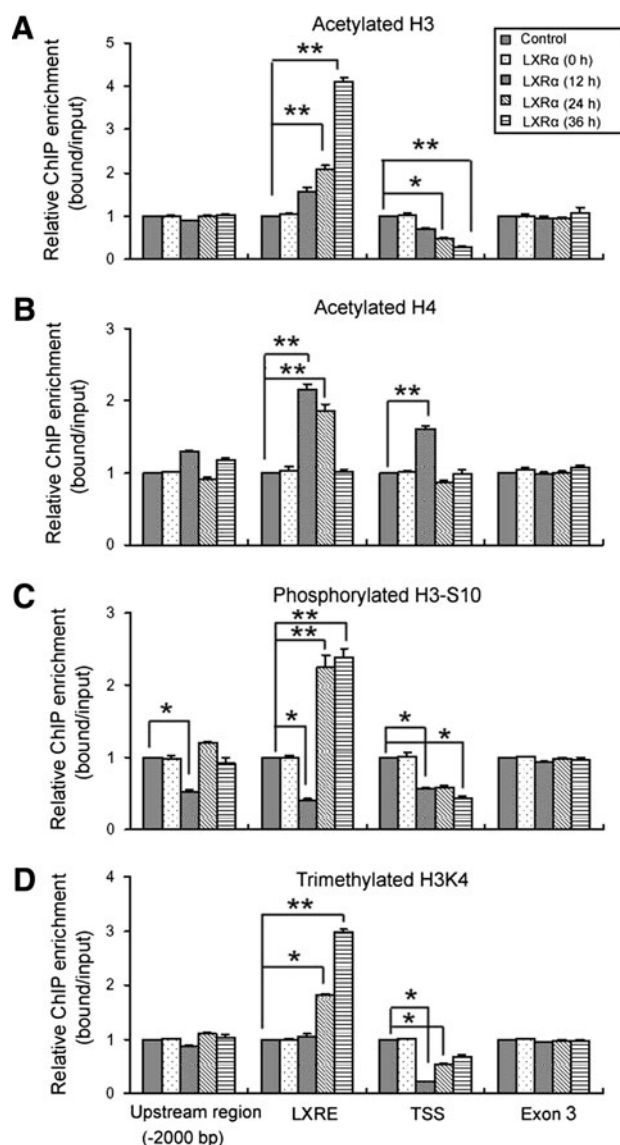

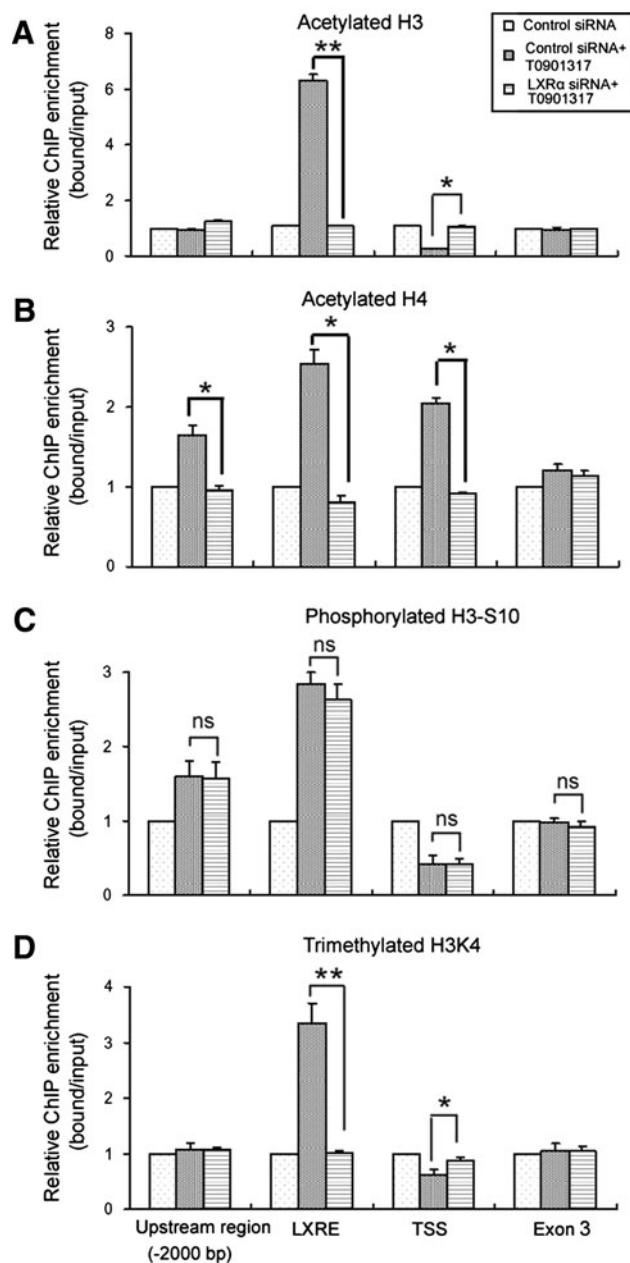

Fig. 5 Ectopic expression of LXR α modulates histone modifications on the *FAS* gene. HepG2 cells were transfected with the LXR α -expressing plasmid or GV142 empty vector. At 0, 12, 24, and 36 h after transfection, LXR α -transfected cells were collected and subjected to ChIP assays that were performed with antibodies against acetylated H3, acetylated H4, phosphorylated H3-S10, trimethylated H3K4, as well as H3 and H4. Empty vector-transfected cells were used as control. Immunoprecipitated DNA was analyzed by real-time PCR using primer sets indicated in Fig. 1c. The ratio of immunoprecipitated DNA to total input DNA was determined for each antibody. The value for the level of acetylation, phosphorylation, and trimethylation of H3 was divided by H3 occupancy respectively, and that for the level of acetylation of H4 was divided by H4 occupancy. The results are expressed relative to the corresponding values for control cells (set to be 1). * P < 0.05, ** P < 0.01 for indicated comparisons; n = 3

phosphorylation. Our data highlight an important role for LXR α in chromatin modification, providing more insight into their regulation of gene expression.

Chromatin structure has been tightly linked to the control of gene expression. Many factors, including histone variants, histone modifications, DNA methylation, and the binding of non-histone architectural proteins regulate the structure of chromatin [18]. LXRs act as ligand-dependent transcription factors to bind to specific DNA elements in the promoters of target genes. Besides of a set of basic transcriptional factors, a number of transcriptional co-regulators are required for ligand-dependent transcriptional controls by nuclear receptors [19, 20]. Histone modifying enzymes and chromatin remodelers are these potential co-regulators that modulate chromatin organization and thereby support transcriptional regulation by nuclear receptors. Kim et al. [21] have revealed that activating signal cointegrator-2 (ASC-2), a coactivator of multiple nuclear receptors and transcription factors, controls FXR transactivation through its associated histone H3K4 methyltransferase activity. Similarly, ASC-2 plays a key role in the transactivation by LXRs by recruiting H3K4 methyltransferases to LXRs [22]. Here, we demonstrate that manipulation of LXR α expression has a profound influence on the histone modifications of the *FAS* gene. Overexpression of LXR α was found to induce acetylation, methylation, and phosphorylation of histones at the LXRE of the *FAS* promoter. Targeted depletion of LXR α using siRNA reversed these histone modifications except phosphorylation. Accumulating evidence indicates that co-regulator complexes that associated with nuclear receptors contribute to histone acetylation and methylation [23–26]. Chen et al. [26] reported that the histone acetyltransferase activity of CREB-binding protein/p300 is responsible for hormone-mediated dramatic hyperacetylation at endogenous target genes. DiRenzo et al. [24] showed that the co-regulator Brahma-related gene one is recruited to estrogen-responsive promoters by estrogen receptor and cooperates with other factors to promote histone acetylation. In light of these findings, we propose that LXR α ligation might recruit several co-regulators and target them to the regulatory regions of *FAS*, facilitating histone modifications and chromatin remodeling. Further studies are needed to define the assumed LXR α -associated co-regulators.

Histone acetylation is believed to increase the accessibility of transcription factors to nucleosomal DNA and correlates with transcriptional activity [27, 28]. The addition of LXR agonist has been found to promote H3 and H4 acetylation at the promoter of the target gene ATP-binding cassette transporter A1 in macrophages from LXR^{+/+} mice, leading to relief of transcriptional repression [29]. Consistent with this study, our data demonstrated that H3 and H4 acetylation was significantly enriched at the LXRE within 30 min of ligand addition. This increased state of H3 acetylation remained for up to 120 min, while H4 acetylation was slowly reduced to the basal level after

120 min. Similarly, LXR α overexpression enhanced H3 and H4 acetylation at the LXRE. In the presence of T0901317, there were increased levels of H4 acetylation at the distal site and the TSS, whereas levels of H3 acetylation were reduced at the TSS and remained unaffected at the distal site. Likewise, elevated H4 acetylation levels and reduced H3 acetylation levels were observed at the TSS region in LXR α -overexpressing cells. These results collectively indicate that LXR α induces a dispersed pattern of histone acetylation on the *FAS* gene. LXR α ligation-mediated transcriptional activation of the *FAS* gene may be linked to enrichment of acetylated histones at the upstream and proximal promoter regions.

The consequences of histone methylation on transcription are dependent on the specific residue and degree of methylation. Trimethylation of H3K4 is associated with active transcription, whereas H3K9 methylation has been shown to correlate with transcriptional repression [30, 31]. H3K4 trimethylation is often enriched near the TSS of actively transcribed genes [32, 33]. However, we found that T0901317 treatment resulted in reduced trimethylation of H3K4 at the TSS region. Conversely, levels of H3K4 trimethylation at the LXRE were significantly increased by T0901317. The unique pattern of histone methylation may reflect the important role of the LXRE in the LXR α -mediated transcriptional activity. Indeed, gain- and loss-of function studies revealed that the levels of H3K4 trimethylation at the LXRE were positively associated with LXR α -mediated transcriptional activation of the *FAS* gene.

In addition to acetylation and methylation, histone phosphorylation has been shown to regulate gene transcription. The location of the serine 10 residue in close proximity to other modifiable amino acids in the histone H3 tail enables the possibility of an interaction between phosphorylation of serine 10 and methylation and/or acetylation of lysine 9 and lysine 14 [34]. H3-S10 phosphorylation has been reported to be functionally linked to Gcn5-mediated acetylation at lysine 14 [35]. However, we did not observe a parallel increase between H3 acetylation and phosphorylation in T0901317-treated HepG2 cells. Indeed, the level of H3-S10 phosphorylation at the LXRE was unexpectedly decreased within the first 30 min and afterwards increased stably. This finding, combined with the independence of LXR α on H3-S10 phosphorylation on the *FAS* gene, likely reflects the existence of LXR-independent co-receptor complex that were responsible for H3 phosphorylation. H3-S10 phosphorylation was also enriched at the distal region upon LXR α ligation, suggesting a possible transcriptional regulatory element in this region. Unexpectedly, LXR α ligation or overexpression resulted in decreased levels of H3-S10 phosphorylation at the TSS, which coincided with a reduction in H3 methylation and acetylation at this region. It still remains to be determined whether and how, if any, the

inactive histone modifications at the TSS contribute to the LXR α -mediated transcriptional activation of the *FAS* gene.

Gene knockout mouse studies reveal that LXR β does not have a role comparable to that of LXR α in hepatic cholesterol metabolism and exhibits subtle effects on the expression of lipid metabolism-related genes such as *FAS* and *SREBP-1* [36]. Therefore, in this study, we did not examine the role of LXR β in epigenetic regulation of the *FAS* gene. However, we cannot exclude the possibility that LXR β might contribute to the T0901317-induced epigenetic changes across the *FAS* gene in the hum context. Indeed, in the setting of LXR α deficiency, there was still a marked increase in H3 phosphorylation in T0901317-treated HepG2 cells.

In summary, our data demonstrate that histone acetylation and methylation near the promoter of the *FAS* gene are dependent on the expression of LXR α and correlate with active transcription of this gene. However, T0901317-induced H3 phosphorylation across the *FAS* gene is LXR α -independent. Additional studies are required to address to what extent these histone modifications are involved in the liganded LXR α -mediated transcriptional activation of target genes.

Abstract Paraoxonase 1 (PON 1) has antioxidant and cardioprotective properties and is abnormally low in type 2 diabetic serum. This study aimed to determine the effect of type 2 diabetes and meals rich in saturated fat and oleic acid on PON1 activity in chylomicrons and very low density lipoproteins (VLDL). PON1 arylesterase activity was measured in chylomicrons and VLDL that were isolated in serum from 20 patients with type 2 diabetes and 20 age- and gender-matched, overweight controls 3 h after meals rich in cream or olive oil in a randomized, cross-over study. Chylomicron–PON1 activity (45%, $P = 0.02$), ratio chylomicron–PON1/chylomicron–triacylglycerides (TAG) (42%, $P = 0.03$) and chylomicron–protein content (46%, $P < 0.001$) were significantly lower in patients with type 2 diabetes compared with controls after the olive oil meal with comparable findings after the meal rich in cream. After ingestion of olive oil, chylomicron–PON1 activity was significantly higher in controls ($P = 0.01$) and marginally higher ($P = 0.06$) in diabetic patients and chylomicron–TAG were significantly ($P < 0.05$) higher in both groups of subjects, compared with values after ingestion of cream. VLDL–PON1 increased (two-fold) significantly ($P < 0.003$) during both meals. Chylomicron–PON1 activity was correlated significantly with chylomicron–protein ($P < 0.001$, $n = 40$) and with postprandial serum PON1 activity ($P \leq 0.001$, $n = 40$). Our data suggest that type 2 diabetes is associated with abnormally low chylomicron–PON1 activity after fatty meals and this may be linked to lower chylomicron–protein content and serum PON1

activity. Switching from saturated fat to olive oil in the meal increases PON1 activity in the chylomicron fraction largely due to increased numbers of chylomicron particles.

HDL High density lipoproteins
PON1 Paraoxonase 1
TAG Triacylglycerides
VLDL Very low density lipoproteins

Introduction

Human serum paraoxonase 1 (PON1) is an enzyme with esterase and lactonase activities [1, 2]. In vitro, PON1 inhibits the oxidative modification of low density lipoproteins (LDL) [3] that is believed to be a crucial step in the development of atherosclerotic lesions. In animal models of atherosclerosis, genetic deletion of PON1 increases atherosclerotic lesion formation [4, 5] while overexpression of human PON1 transgene attenuates lesion formation [6]. Serum PON1 arylesterase activity is abnormally low in individuals with angiographic evidence of coronary artery disease compared with those who do not have coronary artery disease [7]. Furthermore, low systemic levels of PON1 arylesterase activity is associated with the presence of angiographically determined coronary artery disease and prospectively with increased numbers of major cardiovascular events in subjects with or without pre-existing coronary artery disease [7]. In patients with type 2 diabetes, serum PON1 mass and

arylesterase activity are abnormally low [8–10] and risk of coronary artery disease is high. In addition, increasing expression of PON1 attenuates the development of streptozotocin-induced diabetes in mice [11].

In fasted serum, PON1 is almost entirely associated with high density lipoproteins (HDL) and is thought to contribute to their antioxidative, antiatherogenic properties [12]. Small quantities of PON1 are also present on triacylglyceride (TAG)-rich lipoproteins including chylomicrons and very low density lipoproteins (VLDL) in human serum [13, 14]. There is evidence that this PON1 in chylomicrons and VLDL is partly derived by transfer of PON1 from HDL to these TAG rich lipoproteins [13, 14]. In the postprandial state after a fatty meal, levels of PON1 increase in the serum VLDL fraction [13]. In patients with type 2 diabetes, plasma concentrations of TAG-rich lipoproteins are often abnormally high after an overnight fast and in the postprandial state following a fatty meal [15]. The effect of type 2 diabetes on PON1 activity in fasted and postprandial triglyceride-rich lipoproteins is uncertain.

Lipids play an important role in the maintenance of PON1 in serum. PON1 binds to HDL phospholipids through its N-terminal hydrophobic region [16]. Lipids containing oleic acid, the predominant fatty acid in olive oil, stabilizes PON1 and protect it from oxidative deactivation in vitro [17]. Furthermore, intake of oleate elevates serum PON1 activity in rats [18]. Diets rich in saturated fat increase risk of coronary artery disease while adherence to a Mediterranean type of diet that includes olive oil as the major fat component, is thought to attenuate risk of developing coronary artery disease [19, 20]. There is little information on the effect of the type of fat in the meal and the presence of type 2 diabetes on activity of PON1 in serum chylomicron and VLDL fractions. The aim of the present study was to test the effect of type 2 diabetes and meals rich in saturated fat in the form of cream, and olive oil on PON1 activity in chylomicrons and VLDL. These lipoprotein fractions were isolated from serum by ultracentrifugation and their PON1 arylesterase activity was measured. Our study showed that PON1 arylesterase activity was abnormally low in patients with type 2 diabetes and changing from saturated fat to monounsaturated fat rich meals increases PON1 activity in both chylomicrons and VLDL fractions mainly due to increased postprandial levels of these lipoproteins after ingestion of monounsaturated fat.

Subjects and Methods

Subjects

Twenty patients with type 2 diabetes (10 men and 10 women) and 20 healthy controls who were matched with

the diabetic patients for gender and age within 5 years, were recruited. The diabetic patients were recruited from the Diabetes Clinic at Dunedin hospital and were aged >18 years. Diabetic patients who had a glycated hemoglobin >10% indicating poor diabetic control, were excluded. Seven diabetic patients were receiving diet treatment for their diabetes, five were receiving metformin, four metformin plus gliclazide, two gliclazide alone, one metformin plus gliclazide plus insulin and one metformin plus insulin. Seven patients were receiving statin therapy, five were receiving aspirin and three were treated with cilazapril. Controls were recruited from overweight subjects who had previously participated in a study in our laboratory and from respondents to a newspaper advertisement. Controls were excluded if they had a history of serious illness, smoked cigarettes, or took medications. Written and informed consent was obtained from the participants prior to the study. The study was approved by the Lower South Regional Ethics Committee (protocol number: LRS/07/06/022).

Study Design

The study had a randomized, cross-over design with a 1-week washout period. Participants were randomized to receive either a meal rich in olive oil or cream and then after at least a week, they received the alternate meal. The 1-week period between test meals during which time approximately 21 other free-choice meals would have been consumed, eliminates credible carry-over effects from one test meal to the next. Participants were advised to maintain their usual lifestyle during the study.

Meals

The cream meal contained dairy cream (105 g/m² body surface area, low fat milk (150 ml), tinned apricots without syrup and sugar (50 g), low fat yoghurt (10 g), egg yolk (12 g), egg white (30 g) and sugar-free chocolate flavoring (3 tsp). The olive oil meal contained olive oil (40 g/m² body surface area), low fat milk (200 ml), and the same amounts of the other ingredients that were in the cream meal. The meals were homogenized into a milkshake and contained 44 g fat/m² body surface area, 34 g carbohydrate and 12 g protein.

Methods

Blood was collected in a plain tube. Serum was prepared by low speed centrifugation at 4 °C of blood that had been allowed to clot during 30 min at room temperature. To isolate chylomicrons, 3 ml serum was added to a 6.5-ml ultraclear ultracentrifuge tube that was topped up with a

$d = 1.0063$ solution of sodium chloride containing 1 mmol/l calcium chloride and then spun for 30 min at 22,000 rpm and 4 °C in a 50.3 Ti rotor in a Beckman L8-70 ultracentrifuge. The chylomicrons were harvested from the top 1 ml of the tube and this was made up to 5 ml using the $d = 1.0063$ solution of sodium chloride. The chylomicron fraction was not washed or subjected to dialysis in order to prevent dissociation of PON1 from the lipoproteins. The chylomicron fraction was stored overnight at 4 °C and assayed for PON1 activity the next day. The VLDL fraction was isolated by adding 4 ml of fasted serum or chylomicron depleted postprandial serum to 6.5-ml Ultraclear® ultracentrifuge tubes, filling the tubes with $d = 1.0063$ sodium chloride solution containing 1 mmol/l calcium chloride and ultracentrifuging the tubes for 18 h at 40,000 rpm and 4 °C in a Beckman 50.3 Ti rotor. The upper fraction of the tube containing VLDL was isolated and diluted to 5 ml using the $d = 1.0063$ sodium chloride solution and assayed for PON1 activity. Arylesterase activity was determined in triplicate essentially as was described previously [13, 21]. Aliquots of 40-fold diluted serum (60 μ l), chylomicron fraction (300 μ l) or VLDL fraction (500 μ l) were incubated at 22 °C with 3 ml buffer containing phenyl acetate (1 mmol/l), calcium chloride (0.9 mmol/l) in 20 mmol/l Tris-HCl and pH 8 and absorbance at 270 nm was measured. After subtraction of appropriate blank values to allow for spontaneous hydrolysis of phenyl acetate, the initial rate of phenyl acetate hydrolysis as μ mol/ml/min was determined. Absorbance readings that were taken at minute intervals were linear during the 6-min incubation of the phenyl acetate reagent with chylomicron and VLDL fractions. The rate of phenylacetate hydrolysis during the 6-min period was calculated and arylesterase activity in the chylomicron fraction was calculated as change in absorbance during 6 min (ΔA_6) \times 2.33 μ mol/ml/min. The arylesterase activity in the fasted VLDL fraction was calculated as $\Delta A_6 \times 1.113$ μ mol/ml/min and in the postprandial VLDL fraction as $\Delta A_6 \times 1.854$ μ mol/ml/min. A molar extinction coefficient of 1,310 mol l⁻¹ cm⁻¹ for phenol was used in the calculation of arylesterase activities. The concentration of salt in the assay of PON1 arylesterase activity in chylomicron and VLDL fractions was at a level (≤ 0.02 M) that does not affect arylesterase activity [22]. Furthermore, we showed that serum PON1 arylesterase activity was comparable (113 versus 118 μ mol/ml/min) when 60 μ l of serum diluted 40-fold with saline plus 300 μ l saline or 60 μ l serum diluted 40-fold with 10 mM Tris buffer (pH 7) plus 300 μ l of this Tris buffer were added to the assay buffer (3 ml) containing phenyl acetate. Serum cholesterol, TAG, HDL cholesterol, chylomicron-TAG and VLDL-TAG were measured enzymatically using commercial kits (Roche Diagnostics). Protein in chylomicron and VLDL fractions was measured using a modified Lowry method [23].

Statistics

Values are median (interquartile range) unless stated otherwise. The nonparametric Wilcoxon's tests for paired data were used to test for differences in the postprandial response (3 h change) between the meals. Wilcoxon's test for unpaired data was used to compare values between diabetic patients and controls. Spearman's rank correlation coefficients were used to test for relationships between variables.

Results

The characteristics of the participants at baseline (first visit) are summarized in Table 1. The diabetic patients had significantly lower plasma cholesterol concentrations, serum PON1 activity, and ratio VLDL-protein/VLDL-TAG and significantly higher ratio VLDL-PON1 activity/VLDL protein compared with the age and gender matched controls. Fasted PON1 activity in the serum VLDL fraction

Table 1 Characteristics of the diabetic patients and controls at baseline (first visit)

| | Diabetic patients (n = 20) | Controls (n = 20) | P* |
|--|-------------------------------|----------------------|--------|

* Significance diabetic patients versus controls using Wilcoxon's rank test for unpaired values

was not significantly different between diabetic patients and controls.

Table 2 shows TAG, protein and PON1 activity in serum chylomicron fractions harvested 3 h after the meals in diabetic patients and controls. Serum chylomicron–TAG concentrations were not significantly different between diabetic patients and healthy controls and were significantly higher after the olive oil meal compared with the cream meal in both diabetic patients and controls. Chylomicron–PON1 activity and chylomicron–protein content were significantly lower in diabetic patients compared with controls after the meals. The ratio chylomicron PON1 activity/chylomicron TAG was significantly lower in diabetic patients compared with controls following the meal rich in olive oil and was lower but not significantly following the meal rich in cream. The ratio chylomicron–PON1 activity/chylomicron–protein was not significantly different between diabetic patients and controls. Chylomicron–PON1 activity was significantly ($P = 0.01$) higher after the olive oil meal compared with the cream meal in control subjects and was higher at a marginal level of

significance ($P = 0.06$) after the meal rich in olive oil compared with the cream meal in diabetic patients.

Table 3 shows baseline and 3 h changes in serum lipids, lipoprotein lipids and protein, PON1 and VLDL–PON1 activities in diabetic patients and controls during the fatty meals. VLDL–PON1 activity increased significantly ($P < 0.003$) by approximately two-fold after both meals in diabetic patients and by 88 and 44% during the olive oil and cream meals respectively in the controls. In control subjects, the 3 h increase in VLDL–PON1 activity was significantly ($P = 0.001$) larger following the olive oil meal compared with the meal rich in cream. The ratios VLDL–PON1/VLDL–TAG and VLDL–PON1/VLDL–protein also increased significantly during the meals in both diabetic patients and controls with significantly larger increases during the olive oil meal compared with the cream meal in controls. The increase in the ratio VLDL–PON1/VLDL–protein during the cream meal was significantly higher in diabetic patients compared with controls. As expected, serum TG, VLDL–TAG and VLDL–protein concentrations increased significantly ($P < 0.003$) 3 h after both meals in the diabetic patients and controls. In the control subjects, the increase in plasma TG ($P = 0.002$) was significantly larger following ingestion of the olive oil meal compared with the cream meal. Serum HDL cholesterol decreased significantly ($P = 0.01$) during the olive oil meal in diabetic patients and this decrease was significantly ($P = 0.004$) different compared with the corresponding change during the cream meal and was significantly ($P = 0.04$) different from the change in HDL cholesterol during the olive oil meal in controls. Serum PON1 activity did not change significantly during the meals.

Figure 1 shows the relationships between serum chylomicron–PON1 activity and serum concentrations of chylomicron–TAG and protein and serum PON1 activity 3 h after the meals in the total study population. Serum chylomicron–PON1 activity was correlated significantly with serum chylomicron–TAG concentrations after the meal rich in olive oil in the total study population. The corresponding correlation during the meal rich in cream did not quite attain statistical significance. This relationship was also marginally significant in diabetic patients after the olive oil meal ($r = 0.443$, $P = 0.05$) and highly significant in the control subjects after both meals (olive oil $r = 0.723$, $P < 0.001$; cream $r = 0.566$, $P = 0.009$). Serum chylomicron–PON1 activity was correlated significantly with serum chylomicron–protein concentrations after both the meals. This relationship was also significant in both diabetic patients (olive oil $r = 0.765$, $P < 0.001$; $r = 0.452$, $P = 0.05$) and controls (olive oil $r = 0.841$, $P < 0.001$; $r = 0.792$, $P < 0.001$) after both meals. During both the meals, chylomicron–PON1 activity was correlated significantly with postprandial PON1 activity in the total study population and

in diabetic individuals (olive oil $r = 0.460$, $P = 0.04$; cream 0.832 , $P < 0.001$). The corresponding correlations in the healthy controls did not achieve statistical significance (olive oil $r = 0.257$, $P = 0.27$; cream $r = 0.357$, $P = 0.12$). Chylomicron–PON1 activity was also correlated significantly with fasted serum PON1 activity (olive oil meal $r = 0.461$, $n = 40$, $P = 0.003$; cream meal $r = 0.638$, $n = 40$, $P < 0.001$). The ratio chylomicron–PON1 activity/chylomicron protein was correlated significantly with the 3 h postprandial serum PON1 activity after both meals (olive oil meal $r = 0.454$, $n = 40$, $P = 0.003$; cream meal $r = 0.614$, $n = 40$, $P < 0.001$) in the total study population.

Serum VLDL–PON1 activity was correlated significantly with serum VLDL–TAG and serum VLDL–protein

at first visit baseline and after the meals in the total study population (correlation coefficients between 0.714 and 0.930, all $P < 0.001$). Serum VLDL–PON1 activity was not correlated significantly with serum PON1 activity at first visit baseline ($r = -0.011$) and 3 h after the meals (olive oil $r = 0.168$; cream $r = 0.188$) in the total study population. The increases in serum VLDL–PON1 activity were correlated significantly with the corresponding increases in serum total TAG concentrations (olive oil $r = 0.853$, $P < 0.001$; cream $r = 0.803$, $P < 0.001$) and serum VLDL–TAG concentrations (olive oil $r = 0.782$, $P < 0.001$; cream $r = 0.809$, $P < 0.001$) during the meals in the total study population ($n = 40$) and in diabetic patients and controls separately (data not shown).

Fig. 1 Correlations between serum chylomicron paraoxonase 1 arylesterase activity (CHY-PON1) and serum chylomicron-triacylglyceride (CHY-TAG) concentration, chylomicron-protein (CHY-protein) concentration and PON1 arylesterase activity in patients with type 2 diabetes (*open diamonds*) and healthy controls (*open squares*) 3 h after meals rich in olive oil (**a, c, e**) and cream (**b, d, f**). Spearman's rank correlation coefficients are shown

Discussion

These data suggest that after a meal rich in fat, chylomicron-PON1 activity is lower in patients with type 2 diabetes compared with similarly overweight but otherwise healthy controls.

Chylomicron-PON1 arylesterase activities in ten healthy male controls in the present study (1.20 and 1.88 $\mu\text{mol/}$

ml/min) were comparable with reported values (1.20 $\mu\text{mol/}$ ml/min) in ten healthy men [13] when data were adjusted to levels of chylomicron-TAG (1.71 mmol/l) similar to those in the previous study [13]. This adjustment gives a comparison of chylomicron-PON1 arylesterase activity between the studies at similar numbers of chylomicron particles. A similar adjustment of fasting, first visit levels of VLDL-PON1 arylesterase activity, gave a mean

VLDL–PON1 activity of 0.18 $\mu\text{mol}/\text{ml}/\text{min}$ in healthy men that was 59% lower than the corresponding reported activity [13]. The factors responsible for the lower fasting VLDL–PON1 activity in the current study are unclear. We cannot exclude the possibility that PON1 was dissociated from or inactivated in VLDL during its isolation. On the other hand, time taken to isolate VLDL was under half the corresponding time in the previous study [13].

In the present study, total PON1 activity in the chylomicron fraction and chylomicron–PON1 arylesterase activity normalized to chylomicron–TAG, were abnormally low in patients with type 2 diabetes. The factors responsible for this low chylomicron–arylesterase activity in diabetic patients are unclear but may include abnormal composition of chylomicron particles, reduced transfer of PON1 from HDL to chylomicrons, inactivation of PON1 by glycation and glycooxidation, and incorporation of less PON1 into chylomicrons during their synthesis in the intestine. The composition of chylomicrons in the diabetic patients appeared to be abnormal including a low protein content as indicated by the abnormally low ratio chylomicron–PR/chylomicron–TAG. Low chylomicron protein content may include low levels of PON1 protein and may account for much of the difference in chylomicron–PON1 activity between diabetic patients and controls. Chylomicron–protein levels were closely correlated with PON1 activity and when chylomicron PON1 activity was expressed in relation to chylomicron–protein content values were no longer appreciably different between diabetic patients and controls. The factors responsible for the abnormally low protein content of diabetic chylomicrons are unclear. Few studies have reported on the total protein content of chylomicrons in patients with type 2 diabetes. A previous study has reported transfer of PON1 from HDL to chylomicrons *in vitro* [13]. It is possible therefore that this process also occurs *in vivo*. In diabetic patients, low levels of HDL and PON1 activity in serum and HDL [24] could potentially limit transfer of PON1 from HDL to chylomicrons during the postprandial period after a fatty meal resulting in lower chylomicron–PON1 content and activity. The correlation between chylomicron–PON1 and serum PON1 activities in the present study appears to be consistent with this mechanism. There is evidence that glycation and glycooxidation inhibit PON1 activity [25, 26]. In patients with type 2 diabetes, the activity and mass of PON1 are abnormally low and amounts of glycated PON1 in serum are high [25]. Lastly, animal studies have detected PON1 mRNA in several tissues including the intestine [27]. Further studies are needed to test the mechanisms we have postulated to account for lower PON1 activity in diabetic chylomicrons.

In this study, the presence of type 2 diabetes did not appear to influence PON1 activity in endogenous TAG-rich lipoproteins. The activity of PON1 in the total VLDL

fraction of fasted serum and PON 1 activity per VLDL particle as indicated by the ratio VLDL–PON1 activity/VLDL–TAG, were not appreciably different between diabetic patients and controls. The higher ratio VLDL–PON1 activity/VLDL–protein may reflect the abnormal composition of VLDL in the diabetic patients as was indicated by a low ratio protein/TAG. A previous study has reported abnormally low protein content of VLDL 2 in patients with type 2 diabetes [28]. We cannot exclude the possibility that treatment of diabetic patients with lipid lowering drugs and hypoglycemic medications may have attenuated the effect of diabetes on serum VLDL concentration and VLDL–PON1 activity. Serum VLDL–TAG concentrations were not clearly different between the diabetic patients and controls. By contrast, previous studies have reported abnormally high concentrations of serum VLDL–TAG in patients with type 2 diabetes [29].

The 25% higher PON 1 arylesterase activity in the serum chylomicron fraction of healthy subjects after a meal rich in olive oil compared with a meal rich in cream in the present study may be due to the formation of a greater number of chylomicrons and delayed clearance of chylomicron remnants after ingestion of olive oil. Chylomicron–TAG concentrations were higher after the meal rich in olive oil and were associated with chylomicron–PON1 activity. The higher levels of chylomicron–PON1 activity normalized to chylomicron–TAG and the higher protein content of chylomicrons after the meal rich in cream may reflect greater enrichment of chylomicrons with proteins including PON1. Enrichment of chylomicrons with PON1 activity appeared to be proportional to enrichment with protein. The ratio chylomicron–PON1 activity/chylomicron–protein was not altered appreciably during the meals. However, any enrichment of chylomicrons with PON 1 activity had minimal effect on PON1 activity in the serum chylomicron fraction after ingestion of cream, as this activity was lower than the corresponding activity after the meal rich in olive oil. Increased numbers of chylomicrons after ingestion of olive oil may have the predominant effect on serum chylomicron–PON1 activity. Previous studies have reported higher levels of postprandial lipemia, greater numbers of chylomicrons and large TAG-rich lipoproteins and higher levels of chylomicron remnants after meals rich in olive oil compared with meals rich in saturated fat [30–32]. Also, there is evidence that oleic acid may increase numbers of chylomicron particles by increasing the expression of apo B mRNA and may be more efficiently incorporated into lipoproteins by microsomal triacylglycerol transfer protein [33].

Meals rich in olive oil and saturated fat may also have differential effects on postprandial HDL–cholesterol levels including a decrease in levels after ingestion of saturated fat and unchanged levels after olive oil meals in healthy

subjects and patients with type 2 diabetes [34, 35]. In the present study, by contrast, there was a small (3%) decrease in HDL cholesterol following the olive oil meal in the patients with type 2 diabetes. However, the magnitude of this decrease was comparable with measurement error. Furthermore, this change in HDL-cholesterol was not accompanied by corresponding changes in PON1 activity in the serum chylomicron and VLDL fractions.

Fuhrman and coworkers reported a nearly two-fold increase in VLDL-PON1 arylesterase activity in healthy men 3 h after a fatty meal [13]. In the present study, there were increases in VLDL-PON1 activity of comparable proportions 3 h after the fatty meals in diabetic patients and controls. These postprandial increases in serum VLDL-PON1 activity were closely linked with the corresponding increases in serum total TAG and VLDL-TAG concentrations suggesting that increased production of VLDL particles contributed to the increase in VLDL-PON1 activity during the meals. However, increased numbers of VLDL particles did not appear to be solely responsible for the increases in VLDL-PON1 activity. The postprandial increases in VLDL-PON1 activity remained when serum VLDL-PON1 activity was normalized to VLDL-TAG and VLDL-protein content. This finding suggests that enrichment of VLDL particles with PON1 activity may also have occurred. PON1 may be incorporated into VLDL in the liver or may be transferred from HDL in the circulation. Both PON1 [36] and VLDL are synthesized in the liver and there is evidence that VLDL can support PON1 secretion from cells [14]. Furthermore, transfer of PON1 from VLDL to HDL occurs *in vitro* [14]. In the present study, the greater increase in serum VLDL PON1 activity may be due to the greater and closely related increase in serum TAG with a similar trend in serum VLDL-TAG, during the meal rich in olive oil compared with the meal rich in cream in the controls. This finding is reminiscent of the pattern for chylomicrons during the meals and may also be at least partly attributable to reported increase in numbers of large TAG-rich lipoproteins formed during meals rich in oleic acid [30–33].

This study has limitations. The PON1 protein content of chylomicrons and VLDL was not measured. Approximately two-thirds of the diabetic patients were receiving drugs including statins, sulphonylureas, and aspirin, which have been reported previously as increasing serum PON 1 activity in some studies [37]. On the other hand, treatment with statins does not appear to affect serum PON 1 activity in patients with type 2 diabetes [38]. Also, the effect of sulphonylurea hypoglycemic agents on serum PON 1 activity has only been tested in animals and the effects of aspirin therapy on serum PON 1 activity are controversial [37]. Furthermore, in the present study, serum PON 1 activity was markedly lower in diabetic patients compared

with controls suggesting that the effect of diabetes on this enzyme activity remained predominant over any effects of drug therapy. Treatment with statins may contribute to the lower plasma TC concentrations in the diabetic patients and may have attenuated the effect of diabetes on serum TG and HDL cholesterol concentrations.

Low PON1 activity in chylomicrons may be relevant to the high risk of coronary artery disease in patients with type 2 diabetes. There is evidence that chylomicron-PON1 activity may participate in the removal of potentially atherogenic, oxidized lipids. *In vitro*, chylomicrons inhibit copper ion-induced oxidation of LDL by a mechanism which relies on the initial hydrolysis of lipid peroxides that may be at least partly mediated by PON1 [13]. Thus, low chylomicron PON1 activity in diabetic patients may potentially attenuate metabolism of atherogenic, oxidized lipids.

In conclusion, our data suggest that the presence of type 2 diabetes is associated with lower PON1 arylesterase activity in chylomicrons. In overweight but otherwise healthy individuals, switching from saturated fat to olive oil in a meal increases PON1 activity in the chylomicron and VLDL fractions largely due to a concomitant increase in numbers of chylomicron and VLDL particles. Whether lower PON1 activity in chylomicrons contributes to the increased risk of coronary artery disease that is associated with type 2 diabetes, remains to be determined.

Acknowledgments This study was funded by a grant from the Otago Medical Research Foundation Laurensen Award. The authors are grateful to the participants in the study. We dedicate this paper to the memory of our colleague and friend Sylvia de Jong who died recently.

Abstract We investigated the influence of an egg-enriched diet on plasma, hepatic and fecal lipid levels and on gene expression levels of transporters, receptors and enzymes involved in cholesterol metabolism. Sprague–Dawley rats fed an egg-enriched diet had lower plasma triglycerides, total cholesterol, low density lipoprotein (LDL)-cholesterol, hepatic triglyceride, and cholesterol concentrations, and greater plasma high-density lipoprotein cholesterol concentration, fecal neutral sterol and bile acid concentrations than those fed a plain cholesterol diet. Chicken egg yolk had no effect on sterol 12 α -hydroxylase and sterol 27 α -hydroxylase; but upregulated mRNA levels of hepatic LDL-receptor, cholesterol 7 α -hydroxylase (CYP7A1) and lecithin cholesterol acyltransferase, and downregulated hepatic hydroxymethylglutaryl-(HMG)-CoA reductase and acyl-CoA:cholesterol acyltransferase (ACAT) after 90 days. Modification of the lipoprotein profile by an egg-enriched diet was mediated by reducing de novo cholesterol synthesis and enhancing the excretion of fecal cholesterol, via upregulation of CYP7A1 and the LDL receptor, and downregulation of HMG-CoA reductase and ACAT.

Introduction

Hypercholesterolemia is one of the most prevalent risk factors for arteriosclerosis, which can contribute to many forms of human disease, most notably cardiovascular disease (CVD). A multitude of epidemiological studies has shown a direct link between high plasma cholesterol,

particularly of low-density lipoprotein (LDL)-cholesterol and the risk of CVD [1]. Coronary dietary guidelines to prevent CVD emphasize the reduction in dietary cholesterol to <300 mg/day. Consequently, eggs, as a food high in dietary cholesterol, have been targeted as a food to limit when advising patients on a diet aimed at lowering serum cholesterol levels [2].

Even though it has been reported that dietary cholesterol increases the concentrations of both LDL-cholesterol and high-density lipoprotein (HDL)-cholesterol, an egg-rich diet is unlikely to have substantial overall impact on the risk of CVD among healthy men and women [3, 4]. Thus, it is thought that some components in the egg might help in controlling serum cholesterol concentrations. Animal experiments confirmed that the egg yolk intakes for *apoE*^{−/−} knockout mice had little effect on plasma cholesterol [5], probably because phosphatidylcholine (PC) and sphingomyelin (SM) present in egg can markedly inhibit the absorption of cholesterol, fat and other lipids. Phospholipids might slow the rate of luminal lipolysis, micellar solubilization and transfer of micellar lipids to the enterocytes [6, 7]. Another possible functional factor that can lower the cholesterol concentration in blood is egg white protein (EWP), which is digested in the stomach and intestines. Animal experiments also indicated that EWP intake for rats could reduce cholesterol concentrations in the blood. Thus, long-term consumption of egg white hydrolyzed with pepsin (hEW) on spontaneously hypertensive rats (SHR) exerted a beneficial effect on the lipid profile, lowering triglycerides and total cholesterol without changing HDL levels [8, 9]. Egg ovomucin (OV) experiments in vitro and in vivo suggested that the suppression of cholesterol absorption might occur by direct interaction between cholesterol mixed micelles, which could also inhibit the reabsorption of bile acids [10]. However, few experiments have been conducted to investigate the roles of egg yolk and whole egg intakes on cholesterol metabolism in healthy rats. Eggs are a central food in human diets that span all socioeconomic classes and come from a unique animal source providing high bioavailability [11]. Moreover, increases in one food type might lead to changes in the consumption of other foods that could modulate disease

risk. Therefore, we have focused on the overall effect of cholesterol in healthy rats fed with whole egg and egg yolk.

We evaluated the effect of the long-term consumption of an egg yolk diet or whole egg diet on plasma, hepatic and fecal lipid levels and on pathological changes in the liver of Sprague–Dawley (SD) rats, using real time quantitative polymerase chain reaction (RT-qPCR) amplification to measure the mRNA expression of enzymes associated with cholesterol metabolism. No association between egg supplementation and blood lipid profile in the rats was found. Moreover, we found an egg-enriched diet could mediate excretion and deposition of cholesterol, which might be indicative of some special functional factors in egg that need to be identified in the future.

Materials and Methods

Animals and Diet

Male SD rats ($n = 70$; aged 8 weeks with a body weight (BW) of 250 ± 15 g) were obtained from the Animal Center of Tongji Medical University, Wuhan, China. Rats were housed in cages each containing five animals in a temperature-controlled room (21 ± 2 °C $60 \pm 5\%$ relative humidity) with a 12/12-h light/dark cycle fed a commercial rodent chow and water ad libitum. After a 7-day wait, the rats were randomly divided into four groups which began to consume the experimental diets (Table 1) for 3 months. In the Common Control Group, CCG ($n = 18$), rats were given commercial chow according to the recommendation of the Chinese Association for Laboratory Animal Sciences [12]; in the Cholesterol Group, CLG ($n = 18$), rats were fed a supplemented cholesterol diet containing 0.75% cholesterol and 17.5% lard; in the Egg Yolk Group, EYG ($n = 18$), rats were fed a supplemented egg yolk diet containing 31.25% vacuum freeze-dried egg yolk powder containing 24 mg/g cholesterol; in the Whole Egg Group, WEG ($n = 16$), rats were fed a whole egg diet containing 55.56% vacuum-freeze-dried whole egg powder containing 13.5 mg/g cholesterol. Except for the CCG rats, the other groups' diets contained 0.75% cholesterol and similar fat. Egg yolk

Table 1 Composition of the diets

| Group | Crude protein (%) | Crude fat (%) | Carbohydrate (%) | Crude ash (%) | Moisture (%) | Cholesterol (%) |
|-------|-------------------|---------------|------------------|---------------|--------------|-----------------|
| CCG | 19.87 | 1.55 | 60.13 | 8.86 | 9.58 | 0.002 |
| CLG | 19.81 | 18.83 | 41.81 | 8.81 | 9.74 | 0.750 |
| EYG | 21.78 | 20.23 | 43.03 | 5.61 | 8.60 | 0.750 |
| WEG | 36.09 | 14.72 | 39.28 | 3.26 | 5.90 | 0.750 |

CCG ($n = 18$), rats were given standard chow; CLG ($n = 18$), rats were fed a cholesterol diet containing 0.75% cholesterol and 17.5% lard; EYG ($n = 18$), rats were fed a egg yolk diet containing 31.25% vacuum freeze-dried egg yolk powder with 24 mg/g cholesterol; WEG ($n = 16$), rats were fed a whole egg diet containing 55.56% vacuum freeze-dried whole egg powder with 13.5 mg/g cholesterol

powder and whole egg powder were made by vacuum-freeze-drying, then analyzed for cholesterol content [13]. In a previous experiment, we added different cholesterol contents in commercial chow to SD rats and found that a 0.75% cholesterol concentration could increase plasma lipids.

Sample Collection

After consuming the experimental diets for 60 and 90 days, the rats were weighed and deprived of food overnight (~14 h); then they were anesthetized with 1 g/L sodium pentobarbital in a 0.9% sodium chloride solution and killed by exsanguination from the abdominal aorta. Blood was centrifuged at 1,200g for 15 min at 4 °C and the plasma was collected. The livers of rats in all groups were removed. Liver fragments measuring $1 \times 0.5 \times (0.2\text{--}0.3)$ cm were placed into 4% paraformaldehyde fixative for routine histological examination. Fecal samples of the rats in each group were collected for 3 days at the end of the experimental period. All samples were frozen at -70 °C until analysis. The internal organs were weighed and recorded. The animal protocol was approved by the Institutional Animal Care and Use Committee of Tongji Medical University, Wuhan, People's Republic of China.

Biochemical Analyses

The plasma triglyceride, cholesterol, total bile acid (HBA), HDL-cholesterol, LDL-cholesterol, apolipoprotein-A-1 (apoA1) and apolipoprotein-B-100 (apoB) were determined spectrophotometrically using appropriate kits (Daiichi Pure Chemicals Co., Tokyo, Japan). Total lipids were extracted from the liver [14], and cholesterol and triglyceride contents were measured as above. Because the amount of the fecal sample for individual rats in the same group was insufficient to analyze neutral sterols and bile acids, fecal samples were pooled in the same group, then divided into five equal portions, freeze-dried and ground. Neutral sterols and bile acids were extracted [15] and determined using cholesterol and bile acids kits (Daiichi Pure Chemicals Co., Tokyo, Japan).

Histopathology

The remaining liver samples were fixed in 4% formaldehyde at room temperature and were processed by standard methods. Briefly, tissues were embedded in paraffin wax, sectioned at 5 μ m, stained with hematoxylin and eosin, and then picked up on glass slides for light microscopy. An experienced pathologist blinded to the experiment evaluated all samples. All fields in each section were examined for grading of steatosis and necroinflammation according to the criteria described by Brunt [16].

Quantitative RT-qPCR

Total RNA was isolated from rat liver by TRIZOL reagent (Life Technologies Co., Carlsbad, CA, USA) according to the manufacturer's protocol. The RNA concentration was estimated by measurement with a UV spectrophotometer at 260 and 280 nm. Samples of 300 ng of total RNA from eight rats were run in triplicate and subjected to RT-PCR amplification using the One-Step RT-PCR Quick Master Mix (Toyobo Co. Ltd., Tokyo, Japan). The messenger RNA (mRNA) expression of genes was measured by RT-qPCR using Real Time PCR Master Mix (SYBR Green; Toyobo Co. Ltd., Tokyo, Japan) and an iCycler (Bio-Rad, Hercules, CA, USA). For determining mRNA concentration, a threshold cycle was obtained from each amplification curve using iQ5 software (Bio-Rad, Bio-Rad, Hercules, CA, USA). Calculation of the relative mRNA concentration was made using the $2^{-\Delta\Delta C_t}$ threshold cycle method [17]. We used the housekeeping gene for glyceraldehyde-3-phosphate dehydrogenase (GAPDH; EC1.2.1.12) for normalization. The primer sequences used for RT-PCR are described in Table 2. The total reaction volume was adjusted to 25 μ l. Five microliters of a 1:100 dilution of each cDNA was used for reactions with primers, which were all used at a final concentration of 100 nM. The annealing temperature used was 60–62 °C and 40 amplification cycles were performed. Melting curves were done after each run and a single distinct peak was obtained for each primer set.

Statistical Analysis

All values are expressed as mean \pm SD. Data were analyzed using a one-way analysis of variance and all differences were inspected by Duncan's new multiple-range test using SPSS 18.0 statistical software (SPSS Inc., Chicago, IL, USA); $p < 0.05$ was considered statistically significant.

Results

Weight Gain and Organ Index

Weight gain in the four groups was similar during the first 40 days of the study (data not shown), indicating that all diets met the nutritional requirement of rats in their growing phase, but at the end of the experiment (60 and 90), the CLG rats gained more body and liver weight than rats fed other diets ($p < 0.05$; Table 3); however, the WEG rats gained less weight than those fed other diets ($p < 0.05$). The food intake and food titer during the experimental period did not differ among the groups. Compared with the liver index in the CCG rats, that in the CLG rats was higher than others ($p < 0.05$), while as time

increased, that in the EYG rats was lower than in other groups ($p < 0.01$). As to visceral fat index, the WEG rats were also significantly lower than others at the end of 90 days ($p < 0.01$) because of the low levels of epididymal fat and low mesenteric fat index.

Plasma Lipid Levels

After 60 and 90 days of treatment, the triglyceride and cholesterol levels in the plasma of CLG rats were significantly higher than in other groups ($p < 0.05$; Table 4). The triglyceride and total cholesterol levels among the EYG, WEG and CCG rats showed no significant differences, while the triglyceride level in WEG rats was the lowest. The LDL-cholesterol and apoB level in the plasma of CLG rats were significantly greater than others at the end of 90 days ($p < 0.01$) and there was no significant difference between the EYG, WEG and CCG rats. In contrast, the HDL-cholesterol and apoA1 in plasma of CLG were significantly lower than others ($p < 0.01$). The total bile acid (TBA) concentrations of the CLG, EYG and WEG rats were greater than in the CCG rats ($p < 0.05$), especially for WEG ($p < 0.01$). The TBA levels of the four groups were ranked WEG > EYG > CLG > CCG.

Hepatic Triglyceride and Cholesterol Levels

At the end of 60 and 90 days treatment, the total cholesterol level in the liver of EYG and WEG rats were greater than in the CCG rats ($p < 0.05$; Table 4) but the total cholesterol level in the liver of CLG rats was much higher ($p < 0.01$),

showing that dietary egg can partially increase hepatic cholesterol with little effect on overall mechanics. However, at the end of 90 days, triglyceride levels in the liver of CLG rats was significantly higher than in other groups ($p < 0.01$) and there were no significant differences between the CCG, EYG and WEG rats. Interestingly, the triglyceride level in the WEG rats was the lowest, similar to the triglyceride level in plasma.

Neutral Sterol and Bile Acid Levels in Feces

After 90 days of treatment, the dried fecal neutral sterol excretions by the CLG, EYG and WEG rats were 13.92, 23.52 and 27.48 $\mu\text{mol/g}$ greater than in the CCG rats (5.12 $\mu\text{mol/g}$; $p < 0.05$; Table 4), especially in the WEG rats ($p < 0.01$). Fecal bile acid levels excreted by the CCG, CLG, EYG and WEG rats were 17.64, 41.76, 91.73 and 123.66 $\mu\text{mol/g}$ dry feces, respectively.

Pathological Changes in Livers

Before obtaining the histopathology, the rats' livers were observed in each group. The CCG, EYG and WEG rats had normal liver appearance with moderate shape, red color and soft texture, while the CLG rat livers were a little different with larger shape, khaki color, moderate texture and greasy feeling of the cut surface (data not shown). Subsequently, liver sections from rats fed with the regular dry rat chow (CCG) and egg diet (EYG and WEG) had a normal morphological appearance. The hepatocytes were polygonal, clear, with abundant cytoplasm and morphologically

normal. In the CLG rats, hepatocytes were swollen with loose cytoplasm and many different sizes of fat vacuoles pushing the nucleus to one side (Fig. 1).

mRNA Expression Levels of Hepatic Enzymes Associated with Cholesterol Metabolism

HMG-CoA reductase catalyzes the conversion of HMG-CoA to mevalonic acid and is subject to both short-term and long-term effects on hepatic cholesterol de novo synthesis. Its mRNA expression levels in the CLG, EYG and WEG rats were 13-, 40- and 15-fold lower than in the CCG rats at the end of 90 days, respectively ($p < 0.01$; Fig. 2). LDL receptor is a mosaic protein found in clathrin-coated pits on the cell surface that mediates the endocytosis of LDL-cholesterol. Its mRNA expression levels in the EYG and WEG rats were 6.2- and 8.8-fold higher than in the CCG rats at the end of 90 days, respectively, while they were 1.8- and 2.6-fold higher than in the CLG rats ($p < 0.01$).

Cholesterol 7 α -hydroxylase (CYP7A1) is the rate-limiting enzyme in the synthesis of bile acid from cholesterol, catalyzing the formation of 7 α -hydroxycholesterol. Its mRNA expressions in the EYG and WEG rats were 4.7- and 5.5-fold higher than in the CCG rats at the end of 90 days, respectively, while they were 2.2- and 2.6-fold higher than in the CLG rats ($p < 0.01$; Fig. 2). CYP7A1 mRNA expression level in WEG rats was higher than in the EYG rats at the end of 90 days. Sterol 27 α -hydroxylase (CYP27A1) is the key regulatory enzyme in the alternative pathway and sterol 12 α -hydroxylase (CYP8B1) controls the ratio of cholic acid and chenodeoxycholic acid synthesis in both the neutral and acidic pathways; there were no significant differences in its mRNA expression levels in the four groups.

Acyl-CoA:cholesterol acyltransferase (ACAT) is responsible for esterification of cholesterol absorbed from the intestine, its mRNA expression in the CLG rats was significantly higher than in the other groups ($p < 0.01$; Fig. 2), while the other three groups had no significant difference between them (at the end of 90 days). The lecithin cholesterol acyltransferase (LCAT) mRNA expression in the EYG rats was 2.8-, 2.7- and 1.9-fold higher than in the CCG, CLG and WEG rats, while in the WEG rats it was 1.4-fold higher than in both the CCG and CLG rats ($p < 0.01$; Fig. 2).

Discussion

Because the plasma levels of LDL-cholesterol correlate strongly with the incidence of human coronary heart disease, much effort has been directed at developing and implementing therapies to lower plasma LDL-cholesterol levels. Excessive intake of cholesterol could explain a significant increase in plasma LDL-cholesterol level and decrease in HDL-cholesterol level. However, the same intake of cholesterol among the CLG, EYG and WEG rats in the present study caused different results. Though the fat content among these three groups was not exactly the same and high level of protein in WEG, we focus on the need for adding the whole egg yolk or egg to commercial chow and evaluating the effect of the long-term consumption of egg diet to parameters relative with cholesterol, while not to investigate the specific effect of one factor from egg. Total saturated fatty acids concentration in lard was remarkably higher than egg yolk which was consistent with our diet composition, being that high proportion of saturated fatty acids and cholesterol content in meat may easily result in

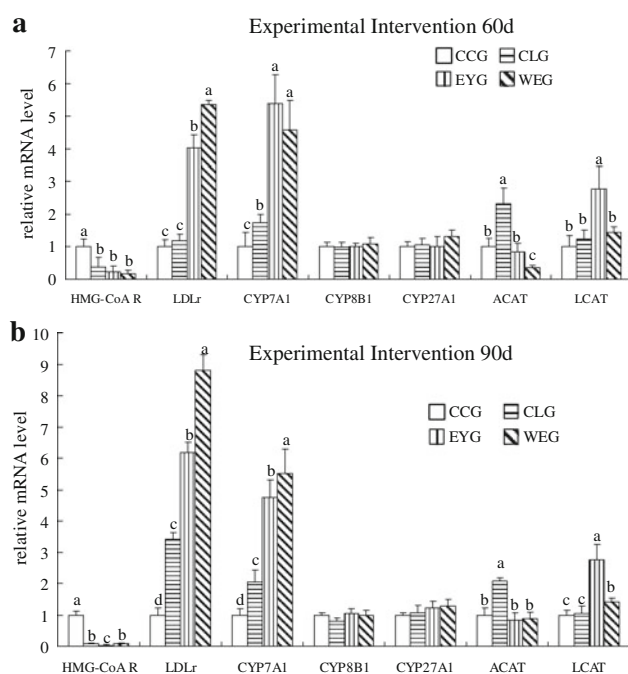

Fig. 2 Effects of diet consumption for 60 days (a) and 90 days (b) on cholesterol-related metabolic enzymes mRNA expressions. The graph represents the mRNA levels from quantitative RT-PCR relative to the control gene, GAPDH. Values are mean \pm SEM; $n = 9$ (except for the WEG rats; $n = 8$). Mean values in a row with different superscript letters differ significantly ($p < 0.05$)

atherosclerosis disease. Particularly as a substitute for dietary saturated fatty acids, the benefit of increasing unsaturated fatty acids intakes deserves considerable attention [18]. Possibly, the egg diet promoted the transformation and excretion of cholesterol by ways other than remaining in the blood and organs and some components repaired the damage to LDL-cholesterol, which was in agreement with previous studies. Bartov et al. studied the hypercholesterolemic effects in the female rats of egg yolk and crystalline cholesterol dissolved in lard. That study demonstrated that serum and liver cholesterol levels were significantly higher in the animals fed cholesterol dissolved in lard than those fed diets containing air-dried or lyophilized egg yolk, apparently from the significantly higher retention of neutral steroids [19]. Patricia et al. [5] investigated the protective effect of lutein and egg yolk supplementation on plasma lipid profile in apolipoprotein E-deficient (*apoE*^{-/-}) mice and showed that egg yolk significantly reduced plasma triglyceride levels without change in total cholesterol, decreased plasma lipid peroxidation and improved the lipid profile. These results are in disagreement with other studies, which seems mainly to arise from differences in the methodology. The earlier studies were carried out on human subjects, the amount of cholesterol fed was extremely high (3–10 g, equivalent to

12–40 eggs per day) and the composition of the experimental diets was not always equalized [20, 21]. Moreover, in the present study the diets contained a more realistic content of cholesterol.

Because of the same cholesterol content in the CLG, EYG and WEG diets, the abundance of cholesterol sources would inhibit rate-limiting enzyme HMG-CoA reductase activity of cholesterol synthesis, but the inhibitory effect of the egg diet seemed more obvious. Furthermore, the synthesis rate of the LDL receptor was negatively correlated with cellular cholesterol content. This is the main receptor on the hepatocyte surface acting to remove LDL from the circulation. The higher LDL receptor expression levels in the EYG and WEG rats were consistent with decreased LDL-cholesterol concentrations in plasma and increased fecal excretion of bile acids and neutral sterols. Spady et al. [22] demonstrated that overexpression of the exogenous CYP7A1 gene effectively reduced the plasma cholesterol level in hamsters fed a low- or high-fat diet. The higher CYP7A1 mRNA expression levels in the EYG and WEG rats showed that the egg diet promoted CYP7A1 enzyme activity and increased bile acid synthesis. This might have accelerated the exclusion of fecal bile acid because it was consistent with a high fecal bile acid level. Moreover, the plasma cholesterol level was negatively correlated with the CYP7A1 mRNA level. In the present study, the liver CYP7A1 mRNA level was upregulated by egg supplementation in the diet. This may be the mechanism by which dietary egg content could reduce plasma cholesterol levels. At the beginning, the EYG rats seemed to excrete more cholesterol through this channel, but after 2 months the WEG rats excreted more. This phenomenon needs further study. We speculate that the egg diet increased hepatic LDL receptor expression, which facilitated the lowering of LDL-cholesterol and increased CYP7A1 expression, which in turn facilitated cholesterol catabolism and upregulation.

The 3-OH group of cholesterol can become fatty-acylated to form cholesterol esters that can be stored in cytoplasmic lipid droplets, which enzyme responsible for this activity is ACAT. To transport excessive amount of cholesterol intake in rats—except to excrete with bile acids—the major route is to generate the conversion of cholesterol esters stored in lipid droplets. Egg yolk and whole egg intake significantly inhibited ACAT activity and decreased cholesterol stored in the body in the form of cholesterol esters. LCAT is responsible for the maturation of the HDL pool and promote the efflux of cholesterol from peripheral tissues. Evidence for this comes from studies of LCAT-deficiency syndromes in which only nascent type HDL accumulates in the plasma [23]. The high LCAT mRNA expressions in the EYG and WEG rats showed that the egg diet promoted LCAT activity and accelerated the removal of cholesterol from the body. This inference was consistent with the low cholesterol and

LDL-cholesterol levels of plasma in the EYG and WEG rats and the high HDL level of plasma in the EYG and WEG rats, compared with the CLG rats. Thus reverse cholesterol transport is one of several proposed mechanisms by which HDL provides protection from CVD. Previous studies have demonstrated that overexpression of LCAT results in an anti-atherogenic lipoprotein profile with reduced apolipoprotein-B-containing lipoproteins in addition to elevated plasma levels of HDL [24]. Currently, ACAT inhibition and overexpression of LCAT are promising avenues of intervention with the development of atherosclerosis and clinical trials in patients are underway [25].

Compare with CLG, egg yolk diet could mediate plasma lipids level in a good way with the similar composition of the diet, while whole egg diet could maintain the same plasma lipids level as CCG and attenuate the damage from excessive intake of cholesterol with higher protein content and lower fat content. Thus, some egg components including phospholipids, active proteins, fatty acids and other trace elements might have cholesterol-lowering activity, were suspected to play regulatory roles in the cholesterol absorption, transportation, metabolism and excretion. This finding agrees with previous *in vivo* studies [6, 7]. *In vitro* studies using intestinal segments [26] or intestinal cell lines [27] showed that egg phospholipids, whether in mixed micelles or in lipid emulsions, interfere with the intestinal uptake of cholesterol by altering the rates of micellar formation and diffusion and/or impeding the hydrolysis of TG and subsequent uptake of cholesterol. Asato et al. [28] have reported that the consumption of EWP reduced the serum total- and LDL-cholesterol concentrations in humans. Nagaoka et al. [10] reported that ovomucin, which is an EWP, inhibited the incorporation of cholesterol into Caco-2 cells by binding to bile acids. However, the ovomucin content of EWP is only 1.5–3.5% [29]. Therefore, it is unlikely that the cholesterol-lowering activity of EWP is due to ovomucin alone. Some have reported that cysteine supplementation or cysteine-enriched protein reduced the total serum cholesterol concentration in rats fed a high-cholesterol diet [30]. Mansoa et al. [8] indicated that hEW played an important role in the antioxidative defense in SHR and exerted a beneficial effect on the lipid profile, lowering triglycerides and total cholesterol without changing HDL levels. Possible regulating roles of these egg active components on cholesterol metabolism still need to be validated. Even though the differences on protein, fat and carbohydrates might be at in part responsible for the effects, this difference is the unity of relativity which might help us to find out which active constituents from egg do work.

The conventional approach to weight reduction is a high-carbohydrate, low-fat, energy-deficient diet that reduces total energy intake, increases satiation and is metabolized with less energetic efficiency compared with high-fat diets

[31]. In theory, the egg diet would be more likely to cause obesity. However, the conventional dietary approach has not proven to be very effective for many obese and overweight individuals, so they have turned to the use of other diets approaches to attain healthier weights, such as the Atkins' diet, a low-carbohydrate/high-fat/high-protein diet [32]. Low-carbohydrate diets appear to have beneficial lipoprotein effects in individuals with atherogenic dyslipidemia, which comprises a triad of increased blood concentrations of small, dense low-density lipoprotein particles, decreased high-density lipoprotein particles, and increased triglycerides [33]. The egg diet has its origins in the induction phase of the Atkins Diet, as eggs are one of the healthiest ways to consume a high-protein, low-carbohydrate diet that is also a significant source of vitamins without increasing saturated fats. The difference in weight gain and organ index might be attributed to the low-carbohydrate, high-protein and high-fat in the EYG and WEG diets in comparison with the CCG and CLG groups in the present study.

The present study has demonstrated that an egg-enriched diet could significantly reduce cholesterol absorption, restrain *de novo* cholesterol synthesis and deposits in the form of cholesterol esters, and activate bile acid synthesis and excretion in feces and deposition. However, the mechanisms by which an egg diet lowers plasma cholesterol need to be further characterized and the special functional factors in egg need to be identified.

Abstract A low-protein, high-carbohydrate (LPHC) diet for 15 days increased the lipid content in the carcass and adipose tissues of rats. The aim of this work was to investigate the mechanisms of this lipid increase in the retroperitoneal white adipose tissue (RWAT) of these animals. The LPHC diet induced an approximately two- and tenfold increase in serum corticosterone and TNF- α , respectively. The rate of de novo fatty acid (FA) synthesis in vivo was reduced (50%) in LPHC rats, and the lipoprotein lipase activity increased (100%). In addition, glycerokinase activity increased (60%), and the phosphoenolpyruvate carboxykinase content decreased (27%). Basal [U- 14 C]-glucose incorporation into glycerol-triacylglycerol did not differ between the groups; however, in the presence of insulin, [U- 14 C]-glucose incorporation increased by 124% in adipocytes from only control rats. The reductions in IRS1 and AKT content as well as AKT phosphorylation in the RWAT from LPHC rats and the absence of an insulin response suggest that these adipocytes have reduced insulin

sensitivity. The increase in NE turnover by 45% and the lack of a lipolytic response to NE in adipocytes from LPHC rats imply catecholamine resistance. The data reveal that the increase in fat storage in the RWAT of LPHC rats results from an increase in FA uptake from circulating lipoproteins and glycerol phosphorylation, which is accompanied by an impaired lipolysis that is activated by NE.

Introduction

The role of adipose tissue in energy balance was first recognized in energy storage in the form of TAG and its mobilization in energy-demanding situations. It was later demonstrated that white adipose tissue (WAT) also maintains body homeostasis by synthesizing and releasing adipokines [1]. Adipokines bind to receptors in several tissues, including adipocytes, and control many functions of these organs. Leptin, the first adipokine described, contributes to the central control of energy balance by regulating food intake and energy expenditure [1]. The discovery of other adipokines (TNF- α , adiponectin) has renewed interest in understanding both WAT physiology and the role of these adipokines in the control of energy storage in adipose tissue itself.

The TAG content in WAT depends on the balance of lipogenesis and lipolysis, two opposing processes that are controlled by a complex interaction of several factors. Accumulation of lipids within white adipocytes is generally associated with stimulation of lipogenesis by anabolic hormones, such as insulin, and the inhibition of the lipolytic activity of catabolic agents, such as norepinephrine (NE), epinephrine, glucocorticoids and others [1]. Adipokines, such as TNF- α and leptin, have an important lipolytic function in WAT in several metabolic situations, such as stress and obesity, in humans and rodents [1, 2].

Previous studies have shown that a low-protein diet correlates with an increase in absolute and/or relative body lipid content [3, 4]. Data reveal that when the amount of protein in the diet is near the protein requirement [5], the increase in body lipid content is accompanied by an increase in food intake [4, 6]. However, many studies have shown that even with a higher food intake, the amount of protein ingested is lower when compared with the requirement [7], and the increase in food intake can be stimulated by an increase in energy expenditure [3]. Aparecida de França et al. [8] confirmed this theory in rats fed a low-protein, high-carbohydrate diet (LPHC; 6% protein and 74% carbohydrate) for 15 days in the growth stage (when the animal's energy expenditure is high) and also demonstrated that these animals have an increase in lipid content in the whole carcass, epididymal adipose tissue (EAT) and retroperitoneal adipose tissue (RWAT).

Preliminary studies performed in the EAT of LPHC rats showed that glycerol-3-phosphate (G3P) generation (from glucose, by glyceroneogenesis and phosphorylation of glycerol) and de novo fatty acids (FA) in this tissue are not altered by the diet. Moreover, lipoprotein lipase (LPL) activity was reduced, which suggests a decreased utilization of FA from circulating lipoproteins [9]. Thus, available data indicate that lipogenesis is not increased in the EAT of LPHC rats and suggest a reduced sensitivity to the lipolytic action of NE in isolated adipocytes that could account for the higher TAG storage in this depot [9].

The alterations observed in the lipid metabolism of EAT in LPHC rats are not necessarily valid for other adipose tissues because different responses to the same stimulus are fundamental for maintaining body homeostasis in different metabolic situations. Pond et al. [10] showed that dietary manipulations, hormones and cytokines induce distinct metabolic responses at different fat depots. Regional differences in the sensitivity of WAT depots to dietary manipulations have also been described by Belzung et al. [11]. Gaíva et al. [12] observed some differences between retroperitoneal and epididymal WAT metabolic responses to dietary fat. The distinct responses of adipose tissue when submitted to the same stimulus can be attributed to the different roles of these depots in the energy metabolism of the body: while EAT seems to be involved in local metabolic control, RWAT seems to be the main adipose depot responsible for the maintenance of energy homeostasis of the organism as a whole [13, 14]. The RWAT that we studied is different from EAT, but there are no relations of these tissues with human visceral or subcutaneous adipose tissues.

Thus, the aim of this study was to identify the effect of the LPHC diet on lipogenesis, lipolysis and the insulin signaling pathway in RWAT to better understand the mechanisms of lipid accumulation in this tissue and also to understand the adaptive mechanisms of the organism to a diet containing low protein and high carbohydrate. In turn, understanding the mechanisms that lead to lipid accumulation in animals with hyperphagia can provide insights into diet-induced obesity in humans. Furthermore, the consumption of a low-protein diet with a higher intake of carbohydrates (similar to the LPHC diet) after weaning is particularly common in developing countries.

Materials and Methods

Animals and Treatment

Male Wistar rats (7–14 animals) with an initial body weight of approximately 100 g were randomly divided into two groups. The control rats were fed a diet composed of 17% protein, 63% carbohydrate and 7% lipid, whereas the

LPHC rats were fed a diet composed of 6% protein, 74% carbohydrate and 7% lipid for 15 days. The decrease in dietary protein was compensated with an increase in dietary carbohydrates to maintain isocaloric diets (16.3 kJ g⁻¹, Table 1). The rats were maintained in individual metabolic cages at 22 ± 1 °C with a 12-h light:dark cycle. The rats received water and food ad libitum. The body weight and food intake of each rat was recorded daily. All of the experiments were performed between 08:00 and 10:00 a.m., and all of the rats were killed on day 15 of treatment. The rats were housed according to the Brazilian College of Animal Experimentation Rules, and the experiments were approved by the Ethics Committee of the Federal University of Mato Grosso (protocol no. 23108.033936/08-3).

NE Turnover Rates and NE Content in RWAT

NE turnover rates in RWAT (found on the dorsal side of the peritoneum) were estimated from the decline in tissue NE levels after inhibition of catecholamine synthesis with the drug DL- α -methyl-p-tyrosine methyl ester (α -MT, Sigma). This procedure has previously been described in detail [15].

Briefly, tissues were homogenized in 0.2 N perchloric acid with EDTA and sodium metabisulfite as antioxidants. Dihydroxybenzylamine was used as internal standard. After protein removal by centrifugation, catecholamines were adsorbed in alumina, eluted with 0.1 N perchloric acid and isolated by HPLC (LC-7A, Shimadzu Instruments) with a Spherisorb ODS-2 (5 μ m) (Sigma-Aldrich) reversed-phase column. NE and an internal standard were quantitated with an electrochemical detector (LC-ECD-6A, Shimadzu).

Table 1 Compositions (g kg⁻¹) of the control and low-protein, high-carbohydrate diets

| Ingredient | Control diet (17%) | Low-protein, high-carbohydrate diet (6%) |

In Vivo Rates of Lipogenesis

In vivo rates of FA synthesis were evaluated by the incorporation of tritiated water into RWAT FA. ³H₂O (3 mCi in 0.5 mL saline) was injected intraperitoneally into fed and nonanesthetized animals. After 1 h, they were killed by decapitation, and blood samples were collected for plasma water-specific radioactivity determination. The RWAT was rapidly removed for measurement. The lipids were extracted, TAG-FAs were isolated, and FA radioactivity, as well as plasma water-specific activity, was determined by liquid scintillation counting as previously described [16].

Isolation of Adipocytes

After cervical dislocation, the RWAT from rats was removed and pooled (until ~5 g was collected). According to Rodbell's method [17], the RWAT was disaggregated with collagenase in Krebs-Henseleit buffer (27 mM HEPES, 137 mM NaCl, 4.2 mM NaHCO₃, 0.4 mM Mg SO₄·7H₂O, 0.5 mM MgCl₂·6H₂O, 0.4 mM KH₂PO₄, 5.4 mM KCl, 1.3 mM CaCl₂·2H₂O), pH 7.4, supplemented with 10 g L⁻¹ fatty acid-free albumin and 0.55 mM glucose. After continuous shaking for 40 min at 37°C, the adipocytes were filtered through a 300- μ m nylon mesh and washed three times with the same buffer in the absence of glucose. An aliquot of the isolated adipocytes suspension was diluted five times, and the number of cells was determined in four fields of the Neubauer's chamber in a microscope (Nikon eclipse E200, Melville, NY, USA), using a 10 \times objective. The isolated adipocytes were used in the [U-¹⁴C]-glucose incorporation into TAG-glycerol and lipolysis experiments.

Incorporation of [U-¹⁴C]-glucose into TAG-glycerol

Aliquots of the adipocytes suspension (1 mL) were incubated for 1 h at 37°C in Krebs-Henseleit buffer supplemented with 10 g L⁻¹ fatty acid-free albumin, 5.0 mM glucose and 0.5 μ Ci mL⁻¹ [U-¹⁴C]-glucose. The incorporation of [U-¹⁴C]-glucose into TAG-glycerol was evaluated in the absence or presence of 1 mU mL⁻¹ insulin. Lipids were extracted, saponified and the radioactivity of TAG-glycerol was determined by liquid scintillation counting as previously described [16].

Lipolysis

Aliquots of the adipocyte suspension (1 mL) were incubated for 1 h at 37°C in Krebs-Henseleit buffer supplemented with 10 g L⁻¹ fatty acid-free albumin and 5.0 mM glucose in the absence or presence of various

concentrations of NE (10^{-7} , 10^{-6} or 10^{-5} M). The lipolysis rate was estimated by measuring glycerol release into the buffer and was expressed as $\mu\text{mol} \times 10^6 \text{ cells}^{-1} \text{ h}^{-1}$. The concentration of glycerol was determined enzymatically using a commercial kit (Labtest).

Enzyme Activity Measurement

Following the recommendations of Newsholme et al. [18], glycerokinase (GyK) activity was measured in the supernatants obtained after RWAT homogenization using an Omni mixer in ice-cold 1% KCl with 1 mM EDTA and centrifugation at 2,000g. Aliquots of the 2,000 g supernatant were incubated for 30 min in an assay mixture containing: 0.1 M Tris, pH 7.5, 6 mM ATP, 4 mM MgCl_2 , 1 mM EDTA, 25 mM NaF, 20 mM 2- β -mercaptoethanol, 10 mM phosphocreatine, 26 U mL^{-1} creatine kinase, 1 mM glycerol, 10 $\mu\text{Ci mL}^{-1}$ [^{14}C -glycerol] and 1% albumin. After the incubation period, the reaction was stopped with EtOH. The synthesized [^{14}C]-glycerol p-phosphate was isolated by paper chromatography and quantified using liquid scintillation counting as previously described [16]. The protein concentration of the homogenate for assay was determined by the Lowry [21].

LPL activity was determined in the supernatants obtained after preincubation of RWAT in heparin-containing medium. The supernatant was incubated with tri- $[^{14}\text{C}]$ -oleoylglycerol, stabilized by lecithin and prepared in glycerol as previously described [19]. The ^{14}C -FA produced during incubation was isolated using a modification of the liquid-liquid partition system as previously described [20] and quantified by liquid scintillation counting. The enzyme activities were expressed by mg protein of homogenate used in the evaluation.

Western Blot for Protein Analysis

Rats were anesthetized by intramuscular administration of ketamine (0.1 mL) and xylazine (0.05 mL) for each 100 g of body weight. The abdominal cavity was opened, and 0.5 mL of insulin (4 U mL^{-1}) dissolved in saline was administered into the portal vein. RWAT fragments were collected 2 min before and after insulin administration and immediately homogenized in 100 mM Tris-HCl buffer, pH 7.4, containing 1% Triton X-100, 100 mM sodium pyrophosphate, 100 mM sodium fluoride, 10 mM EDTA, 10 mM sodium orthovanadate, 2.0 mM phenylmethylsulfonyl fluoride and 0.1 mg mL^{-1} aprotinin at 4°C. The total protein concentration was determined by the Bradford method [22]. RWAT proteins (100 μg for the detection of PEPCK and α -tubulin, and 125 μg for the detection of insulin signaling intermediates) were separated by 10% SDS-PAGE, transferred to nitrocellulose membranes and blotted with antibodies against PEPCK, IR, IRS-1, PI3-K_(p85), AKT1, α -tubulin and

phospho-AKT1/2/3 (Ser 473). Specific bands were detected with the SuperSignal West Pico chemiluminescent substrate, and the band intensity was quantified using the Scion Image Program (version 4.03, Frederick, MD, USA). The PEPCK band intensity was normalized to the α -tubulin band intensity. There was no difference between α -tubulin band intensities of the different groups. The band intensity of phosphorylated AKT was normalized to the total AKT band intensity. The results are expressed as the relative ratios.

Other Chemical Analyses

The serum concentrations of triiodothyronine (T3), thyroxine (T4), corticosterone, tumor necrosis factor- α (TNF- α) and free fatty acids (FFA) were determined using commercial kits. Only the FFA concentration was determined in rats that had been fasted for 14 h. Total tissue lipids were determined gravimetrically after extraction using the procedure from Folch et al. [23].

Chemicals

The radioisotopes [^{14}C]-glucose, $^3\text{H}_2\text{O}$, glycerol tri- $[^{14}\text{C}]$ -oleate and [^{14}C]-glycerol were purchased from PerkinElmer Life and Analytical Sciences (MA, USA). SX20-5 scintillation liquid was from Fisher Scientific (ON, Canada). The commercial kits for T3 and T4, TNF- α , corticosterone, FFA and glycerol determination were obtained from Interkit (CA, USA), Thermo Scientific (IL, USA), Assay Designs (MI, USA), Wako Chemicals (VA, USA) and Labtest (MG, Brazil), respectively. Collagenase (type I) and insulin (Humulin Regular human insulin for phosphorylated AKT and insulin from porcine pancreas for lipolysis experiments) were obtained from Worthington Biochemical (NJ, USA), Eli Lilly (SP, Brazil) and Sigma-Aldrich (MO, USA), respectively. Nitrocellulose membranes were purchased from Amersham Bioscience (NJ, USA). Anti-PEPCK, anti-IR β , anti-IRS-1, anti-PI3-K_(p85), anti-AKT1, anti-phospho-AKT1/2/3 (Ser273) and anti- α -tubulin antibodies (all recommended for the detection of rat proteins) were purchased from Santa Cruz Biotechnology (CA, USA), and anti-goat IgG was purchased from Invitrogen (CA, USA). Ketamine hydrochloride and xylazine hydrochloride were obtained from Agribands (SP, Brazil) and Bayer (ON, Canada), respectively. All other chemicals were of analytical grade and were purchased from Sigma-Aldrich (MO, USA).

Statistical Analysis

All data were expressed as the mean \pm standard error (SE) for the number of rats indicated in parentheses. Statistical analysis was performed using the Statistic Software package (Statsoft, Tulsa, OK, USA). Bartlett's test for the

homogeneity of variances was initially used to determine whether the data complied with the assumptions for parametric analysis of variance. When necessary, the data were log-transformed to correct for variance in heterogeneity or non-normality [24]. The incorporation of [U-¹⁴C]-glucose into TAG-glycerol, lipolysis and pSer-AKT levels were tested with two-way variance analysis (effects of diet and stimulus). When necessary, these analyses were complemented by the least significant difference test to determine the significance of individual differences (Tukey HSD test). Except for the calculated rates of turnover, which were compared using 95% confidence intervals as described by Taubin et al. [25], and the analyses cited above (incorporation of [U-¹⁴C]-glucose into TAG-glycerol, lipolysis and pSer-AKT), the statistical significance of all other experiments was analyzed using a Student's *t* test. The criterion of significance was $p < 0.05$.

Results

The total food intake of LPHC rats was approximately 14% higher than that of control rats during the experimental period. However, despite this increase in food intake, the final body weight in the LPHC group was 12% lower than in the control group at the end of the 15th day of treatment. Despite the reduction in body weight, the weight and lipid content of the RWAT increased 29 and 42%, respectively (Table 2), in LPHC rats. These data agree with previously published results by Aparecida de França et al. [8] and Buzelle et al. [9].

Serum corticosterone and TNF- α increased approximately two- and tenfold, respectively, in the LPHC animals as compared with the control group. There was no difference in serum T3, T4 and FFA levels.

The RWAT NE content was similar between the LPHC and control rats. However, the NE turnover rate, an indicator of sympathetic flux, was higher in the RWAT from LPHC rats ($t_{1/2} = 9.5$ h) than in the RWAT from control rats ($t_{1/2} = 14.9$ h, Table 3).

The de novo FA synthesis rate estimated in vivo via ³H₂O was markedly lower by approximately 50% in the RWAT from LPHC rats than in the RWAT from control rats (Fig. 1). This finding is consistent with the low level of postprandial plasma insulin, which had previously been observed [8]. In contrast, the LPHC diet induced an approximate 100% increase in the LPL activity of RWAT (Fig. 2), which suggests an increased uptake of FAs from circulating lipoproteins in this tissue.

Evaluation of the G3P pathways showed that LPHC rats had approximately 27% less PEPCK content (Fig. 3) and approximately 60% higher levels of GyK activity (Fig. 4). These results suggest that glyceroneogenesis is reduced,

Table 2 Final body weight, total food intake, and weight and lipid content of retroperitoneal adipose tissue and the serum concentrations of corticosterone, free fatty acid, thyroxine, triiodothyronine and tumor necrosis factor- α from LPHC and control rats after 15 days of treatment

and the generation of G3P by direct glycerol phosphorylation is increased in RWAT. G3P generation from glucose, which was evaluated by the incorporation of [U-¹⁴C]-glucose into TAG-glycerol in isolated adipocytes, was similar in the LPHC and control rats in the absence of insulin ($p < 0.10$, Fig. 5). The rate of [U-¹⁴C]-glucose incorporation into TAG-glycerol increased approximately 124% in isolated adipocytes from control rats when incubated with insulin (Fig. 5). However, insulin did not affect the [U-¹⁴C]-glucose incorporation into TAG-glycerol in adipocytes from LPHC rats (Fig. 5).

Fig. 5 The effect of the low-protein, high-carbohydrate diet on the rate of [U- 14 C]-glucose incorporation into TAG-glycerol in the absence and presence of insulin. Adipocytes were isolated from the retroperitoneal adipose tissue of LPHC and control rats. The data are represented as the mean \pm SE of six tubes per experimental condition of each diet group. Mean values with different letters are significantly different ($P < 0.05$; two-way ANOVA). C control diet, LPHC low-protein, high-carbohydrate diet

(Fig. 6b and 6d), but did not change IR_{β} and p85-PI3-K content (Fig. 6a and 6c). Basal AKT phosphorylation was also reduced by approximately 48% in the RWAT from LPHC rats when compared to control rats (Fig. 6e). In vivo insulin administration induced an increase in AKT phosphorylation by approximately 70% in the RWAT from control rats, but did not affect AKT phosphorylation in the RWAT from LPHC rats (Fig. 6e).

The rate of basal lipolysis, which was evaluated in isolated adipocytes by glycerol release into the incubation buffer, did not differ between the two groups. There was a significant increase in the lipolysis of adipocytes from control rats, which was proportional to the increase in NE concentration in the incubation buffer. However, the lipolytic response to adrenergic stimulus by noradrenaline was impaired in the LPHC rats when compared with basal lipolysis even under high NE concentrations (Fig. 7).

Discussion

The TAG content stored in adipose tissue is a balance between esterification of FA with G3P and its mobilization. Thus, we evaluated the biochemical parameters and pathways involved in these two metabolic processes to help clarify the factors responsible for TAG accumulation in the RWAT of rats fed by a LPHC diet for 15 days during the growth stage, as previously observed by Aparecida de França et al. [8].

LPHC rats represent the first physiological situation that decreases insulin plasma levels [8] and increases serum corticosterone, TNF- α (Table 2), norepinephrine [9] and leptin [8]. The increase in serum corticosterone in the LPHC group (100%) agrees with other published data that show hormonal and neuronal changes induced by consuming a protein-restricted diet are similar to those changes induced by chronic stress. This chronic increase in corticosterone is an important and characteristic alteration observed in this condition as a consequence of hypothalamic-pituitary-adrenal axis (HPA) dysfunction [26]. Rats fed a diet consisting of 8% protein for 30 days had higher levels of serum corticosterone as well as an increase in adrenal gland weight and the number of ACTH-secreting cells (63.8%) in the pituitary gland as compared to rats fed a normoproteic diet [27], suggesting activation of the HPA system. Other investigations have shown a direct correlation between malnutrition and elevated blood glucocorticoid levels [28]. There is evidence that TNF- α induces

Fig. 7 The effect of different concentrations of norepinephrine on the rate of lipolysis in adipocytes. Adipocytes were isolated from the retroperitoneal adipose tissue of LPHC and control rats. Each point represents the mean \pm SE of six tubes per experimental condition of each diet group. Mean values with different lowercase letters are significantly different ($P < 0.05$; two-way ANOVA). C control diet, LPHC low-protein, high-carbohydrate diet

activation of the HPA system in response to various threats to homeostasis [2]. Thus, it is possible that the high level of TNF- α in LPHC rats can be responsible for the corticosterone release in these animals. In turn, the TNF- α plasma level seems to be controlled by glucocorticoids; this control is exerted through the reduction of TNF- α secretion and half-life [29]. In opposition to glucocorticoid action,

adrenergic stimulation induces an increase in plasma TNF- α levels [30] simultaneously with stimulation of sympathetic activity by high levels of TNF- α and leptin [31]. The high levels of corticosterone may also be associated with the reduced plasma insulin levels of rats fed an LPHC diet [8], and studies have demonstrated that chronic exposure to elevated levels of glucocorticoids severely impairs glucose-stimulated insulin secretion from islets derived from normal rodents [32]. Therefore, the complex interrelation of factors determined by glucocorticoids, TNF- α , insulin, leptin and sympathetic activity in LPHC rats deserves further study. Increase in the sympathetic flux in the RWAT of these animals was also observed in brown adipose tissue [8] and EAT [9], which could simultaneously be related to the high-carbohydrate and low-protein content of the diet. NE turnover rates increased in the RWAT from rats fed on a cafeteria diet supplemented with 20% sucrose in the drinking water [33] and after supplementation of a standard rat diet with glucose or fructose [34]. It has previously been shown that the consumption of a low-protein diet (5% casein) increases the NE turnover in the EAT and brown adipose tissue of rats [35].

The increase in FA uptake from circulating lipoproteins in LPHC rats is essential for the increase in TAG content of the RWAT in these animals (Fig. 2). However, the LPHC diet induced a reduction in de novo FAs synthesis in this tissue (Fig. 1), which may be a consequence of impaired insulin signaling in the RWAT of LPHC rats as evidenced by the reduction in IRS-1 and AKT protein levels as well as AKT phosphorylation (Fig. 6). The reduction in insulin signaling can also impair glucose uptake by adipocytes in the RWAT of LPHC rats. The lack of an insulin response in the incorporation of [U- 14 C]-glucose into glycerol-TAG in vitro by adipocytes from LPHC rats corroborates this hypothesis. Studies have shown that TNF- α and glucocorticoids impair the response to insulin. In vitro, TNF- α reduces the expression and phosphorylation of IR and IRS-1 as well as the synthesis and translocation of GLUT-4 to the membrane of adipocytes, which in turn leads to a decreased glucose uptake mediated by insulin [36, 37]. The effect of TNF- α on insulin resistance correlates to a reduced PPAR γ expression at the pre- and post-translational levels through activation of serine kinases that inhibit transmission of the insulin signal [38]. Dexamethasone also decreases IRS-1 expression and phosphorylation in 3T3-L1 cells, which also diminishes PI3-K activation and GLUT-4 translocation without affecting GLUT-4 expression [39, 40]. In addition, glucocorticoids reduce glucose uptake mainly by completely inhibiting glucose transport, as the normalization of IRS-1 expression and PI3-K activity in adipocytes 3T3-L1 previously treated with dexamethasone did not affect the reduced glucose uptake [39]. Despite reduced plasma insulin levels and impaired insulin signaling, the

increase in LPL activity in the RWAT from LPHC rats can be explained by elevated glucocorticoid levels. Studies have shown that glucocorticoids increase LPL activity in the RWAT of rats [41]. Glucocorticoids increase the activity of LPL either through increases in transcription or posttranscriptional modifications such as increased activation or decreased degradation [42]. However, the effect of glucocorticoids in regulating LPL seems to be fat pad-specific [43] because the LPL activity in the EAT of LPHC rats is not altered when compared with the LPL activity from the EAT of control rats [9].

Regarding the generation of G3P, it seems clear that the route of direct phosphorylation of glycerol by GyK seems to guarantee the supply of G3P for FA esterification and increases the TAG content in the RWAT of the LPHC rats, since the generation of G3P by other means was not increased (low content of PEPCK and glucose incorporation of insulin-stimulated G3P is impaired).

Under normal conditions, GyK activity is relatively low in WAT; however, our data show that this activity is increased by 60% in LPHC rats (Fig. 4). The literature reports that in various experimental models, GyK activity is fundamental for obesity manifestation. Experiments performed in genetically obese animals and in knockout animals for GyK have demonstrated an increase in the activity of GyK and established a positive relationship of its activity and the accumulation of TAG [44–48].

We have previously shown that GyK expression/activity is directly controlled by the sympathetic nervous system in brown adipose tissue and WAT [16, 33, 49]. Other studies have demonstrated that the expression and content of PEPCK in WAT are strongly inhibited by insulin and glucocorticoids [50, 51]. The fact that the LPHC group presented a high level of corticosterone and an impairment of insulin signaling suggests that the effect of glucocorticoids on expression and content of PEPCK outweighs the effect of reduced insulin in the RWAT of these animals (Fig. 3).

Glucocorticoids repress transcription of the PEPCK gene in adipocytes by inhibiting the CCAAT/enhancer-binding protein (C/EBP)-mediated activation. Previous work has demonstrated that glucocorticoid treatment of 3T3-F442A adipocytes reduces nuclear C/EBP α concentration and markedly diminishes the binding of nuclear proteins to the C/EBP recognition sites (but not to the PPAR/RXR recognition sites) in the PEPCK gene promoter [52].

As mentioned earlier, the TAG content depends not only on lipogenesis, but also on lipolysis. The increases in the serum levels of glucocorticoids, TNF- α (Table 2), catecholamines [9] and leptin [8] and the increased NE turnover in RWAT of LPHC rats (Table 3) are associated with high levels of lipolysis. However, these animals did not show a difference in the levels of circulating FFA when

compared with the control animals. Catecholamines, mainly NE, released by sympathetic terminals, induce lipolysis by activating a cAMP-dependent classical signaling pathway that activates PKA, which phosphorylates perilipin A and simultaneously stimulates hormone-sensitive lipase (HSL) and adipose triglyceride lipase (ATGL) to promote FA mobilization from WAT [52, 53]. In addition, studies have recently demonstrated that dexamethasone directly stimulates lipolysis by remodeling the elements of the lipolytic cascade in isolated adipocytes [54]. Dexamethasone downregulates the mRNA and protein levels of PDE3B [51], and directly increases cAMP production by promoting basal and forskolin-stimulated activity of adenylyl cyclase in adipocytes [55]. Dexamethasone also induces the phosphorylation of perilipin and the downregulation of perilipin proteins [54]. In spite of the induction of ATGL and HSL mRNA by glucocorticoids in adipocytes, dexamethasone does not induce HSL translocation to the lipid droplet surface in differentiated adipocytes [55]. The increase in insulin resistance in response to glucocorticoids could also contribute to FA mobilization. Insulin inhibits lipolysis, stimulates cAMP degradation by PDE3B and reduces HSL and perilipin phosphorylation [56]. TNF- α -induced lipolysis also involves remodeling of the elements of the lipolytic cascade in isolated adipocytes by downregulating PDE3B and perilipin expression in adipocytes [57, 58]. However, other studies have shown that TNF- α reduces the HSL and ATGL content [59, 60], impairing the lipolytic activity of adipocytes. Lipolysis suppression in the presence of forskolin and dibutyryl-cAMP in adipocytes previously treated with TNF- α [61] reinforces this hypothesis. Our findings show that the adipocytes of the RWAT from LPHC rats are less responsive to NE in vitro (Fig. 7). The impaired response to catecholamines can be related to any of the points in the lipolytic cascade, such as reduction in the adrenoceptor number or in the signaling pathway responsible for lipolysis activation or even in the lipase content. Isolated adipocytes from the EAT of rats submitted to one daily foot-shock session on 3 consecutive days demonstrate elevated corticosterone levels accompanied by a reduction in glucocorticoid receptors and β_1 - and β_3 -adrenoceptors, and an increase in β_2 -adrenoceptors [62]. These in vitro experiments demonstrate that a high corticosterone concentration downregulates glucocorticoid receptors [62]. These effects can attenuate the lipolytic actions of catecholamines, glucocorticoids and TNF- α in LPHC rats.

Thus, the results of this study show that the increase in FA uptake from circulating lipoproteins, direct phosphorylation of glycerol by Gylk and a decreased response to catecholamine may contribute to the increase in weight and lipid content in the RWAT of LPHC rats. Moreover, it

seems that the source of glycerol for phosphorylation by Gylk is the diet (fed rats), and although the lipid content in both diets is the same, the animals of the LPHC group ingested more food (14%) than the animals of the control group during the 15 days of treatment. Given the low activity of Gylk in WAT (in spite of a 60% increase in LPHC rats) and because it is probably the only G3P-generating pathway activated in the RWAT of these animals, the impaired stimulation of the tissue by catecholamine may be the main mechanism that preserves the lipid content.

Acknowledgments We thank Air Francisco Costa, Marlene Mariano and Celso Roberto Afonso for their technical assistance. We also thank Renato Hélio Miglioni in memoriam for being an exemplary scientist and professor. Abstract The impact of a moderate Zn deficiency on growth and plasma and liver lipids was investigated in two 4-week experiments with male weanling rats fed fat-enriched diets. Semisynthetic, approximately isocaloric diets containing 3% soybean oil were supplemented with either 7 or 100 mg Zn/kg diet and with 22% beef tallow (BT) or sunflower oil (SF). In Experiment 1, which compared the dietary fat level and the fat source in a factorial design of treatments, all diets were fed ad libitum to 6×8 animals, whereas intake of the high-Zn BT and SF diets was restricted in Experiment 2 (5×6 rats) to the level of intake of the respective low-Zn diets. The low-Zn SF diet consistently depressed food intake and final live weights of the animals to a greater extent than the other low-Zn diets, while intake and growth were comparable among the animals fed the high-Zn diets. The marginal Zn deficit per se did not alter plasma triglyceride and cholesterol concentrations nor hepatic concentrations of triglyceride, cholesterol and phospholipids. The fatty acid pattern of liver phospholipids did not indicate that chain elongation and desaturation of fatty acids was impaired by a lack of zinc. It was concluded that dietary energy and fat intake, and fat source have a greater effect on plasma and liver lipids than a moderate Zn deficiency. Marginally Zn-deficient diets enriched with sunflower oil as a major energy source cause a greater growth retardation than diets rich in carbohydrates or beef tallow.

Introduction

In young animals, early signs of severe zinc (Zn) deficiency are growth retardation, depressed food intake and a cyclic feeding pattern [1–3]. The dietary fat source and fat level may alter the effects of dietary Zn depletion on growth rate and lipid metabolism. Bettger et al. [4] found that dietary substitution of 5% hydrogenated coconut oil for corn oil as a source of essential fatty acids improved the growth of young rats, suggesting an interaction between these nutrients. In

similar studies with chicks [5], the effects were the opposite. The addition of corn oil, soybean oil or a mixture of polyunsaturated fatty acids (PUFA) to Zn-deficient diets retarded growth of the animals to a greater extent as compared to hydrogenated coconut oil and exacerbated the symptoms of Zn deficiency. Huang et al. [6] reported that growth retardation of young rats was partially alleviated when the animals were given daily subcutaneous injections of primrose oil, but when safflower oil was injected the effect was minimal. In a recent study [7], fat source in fat-enriched diets markedly affected growth rates of weanling rats when the dietary Zn supply was marginal, i.e. about two-third of the minimum requirement for unlimited growth. Low-Zn diets supplemented with 18% sunflower oil or olive oil depressed final live weights of the animals to a greater extent than diets enriched with beef tallow, whereas no difference was evident among corresponding high-Zn diets.

The objective of the present study was to investigate the impact of highly fat-enriched diets on growth and lipid metabolism of weanling rats when dietary Zn supply is either marginal or adequate for unlimited growth. Semisynthetic diets were supplemented with 7 or 100 µg Zn/g and were enriched with 22% fat as beef tallow (BT) or as sunflower oil (SF) above a basal fat content of 3% soybean oil in all diets. In a first experiment, which included diets without supplemental fat, all diets were fed ad libitum for 4 weeks, whereas intake of the high-Zn diets was restricted in a second experiment according to the intake of the respective low-Zn BT and SF diets. The low-Zn SF diet consistently reduced food and energy intake and final live weights to a greater extent than the other low-Zn diets. Changes in plasma and liver lipids observed in response to dietary treatments were primarily attributable to differences in energy and fat intake and to fat source rather than to the moderate Zn deficiency. We conclude that dietary energy and fat intake, and fat source have a greater effect on plasma and liver lipids than a moderate Zn deficit, and that Zn-deficient diets enriched with sunflower oil as a major energy source cause a greater growth retardation than diets rich in carbohydrates or beef tallow.

Experimental Procedures

Animals and Diets

In Experiment 1, a total of 48 male weanling Wistar rats (Harlan Winkelmann, Borcheln, Germany) with an initial live weight of 48 ± 2.8 g (mean \pm SD) were randomly assigned to six treatment groups of eight animals each, following a 2×3 factorial design for dietary Zn and fat treatments. Semisynthetic diets for these groups differed in

Zn supplementation (7 vs. 100 µg/g, added as $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$), and in fat supplementation: 22% beef tallow (BT) or 22% sunflower oil (SF) versus a low-fat, carbohydrate-rich control diet (CT). All diets contained 3% soybean oil to offer sufficient amounts of essential fatty acids. The major components of the diets are summarized in Table 1. They contributed a basal Zn level of about 0.5 µg/g by analysis. In the high-fat diets parts of cornstarch were replaced by cellulose to compensate for differences in energy. The fatty acid composition of the low- and high-fat diets is shown in Table 2. Diets were stored at 4 °C. Ad libitum feeding was practiced, replacing remainders by fresh portions daily.

In Experiment 2, six male weanling rats each (50 ± 2.8 g initial live weight) were randomly allocated to five dietary treatments: (1) low-Zn BT diet fed ad libitum, (2) high-Zn BT diet fed in restricted amounts according to

Values are means of three independent determinations per diet

^a The concentration of additional fatty acids was less than 1.5 mol/100 mol across diets

average intake of group 1, (3) low-Zn SF diet fed ad libitum, (4) high-Zn SF diet fed in restricted amounts according to average intake of group 3, and (5) high-Zn SF diet fed ad libitum. Diet composition was the same as described in Tables 1 and 2 regarding ingredients, Zn and fat supplementation. Food consumption was determined daily to control intake of the rats in group 2 and 4.

Approval of the experimental protocols for use and care of laboratory animals in research was obtained by the regional Animal Protection Authority (Regierungspräsidium Giessen, II 25.3-19c20/15c GI 19/3). The rats were housed individually in stainless steel metabolic cages in an environmentally controlled room (22 °C, rel. humidity of 55%, 12 h light and dark cycle). They had free access to deionized water. In Experiment 1, feces were collected daily during week 2 and 3, freeze-dried and stored at 4 °C for determination of energy and fat content. After 4 weeks, the animals were fasted overnight and anesthetized with carbon dioxide followed by decapitation. Blood was collected in test tubes containing heparin and centrifuged (3,000g for 10 min at 4 °C), and the resulting plasma was stored at −80 °C. The liver and right femur were excised, weighed and frozen on dry ice for subsequent measurements.

Analytical Procedures

Diets were analyzed for dry matter, crude protein, fat and neutral detergent fiber by official methods [9]. Fecal samples were treated with 4 M HCl before fat extraction using *n*-hexane. Gross energy (GE) in diets and feces was determined by adiabatic bomb calorimetry. The metabolizable energy (ME) of the low- and high-fat diets was calculated as digestible energy (intake minus fecal excretion of GE during week 2 and 3 of Experiment 1) multiplied by 0.96 [10].

Zn concentration in the femur bone and diets was analyzed by ICP-AES (inductively coupled plasma atomic emission spectrometry) after dry-ashing (450 °C) and dissolving in 3 M HNO₃. Plasma Zn concentration was measured directly after dilution with 0.1 M hydrochloric acid by flame atomic absorption spectrometry. The activity of the alkaline phosphatase (AP; EC 3.1.3.1) in plasma was determined photometrically with a standard method [11]. The activity of the glucose-6-phosphate dehydrogenase (G6PD; EC 1.1.1.49) in liver homogenates was assayed with a commercial reagent kit (Boehringer Mannheim GmbH, Germany). The protein content in liver homogenates was determined by the Lowry method [12].

Liver total lipids were extracted with a mixture of hexane:isopropanol (3:2, by vol) according to the method of Hara and Radin [13] with minor modifications. Briefly, frozen liver was weighed and homogenized in 0.15 M NaCl solution. Hexane:isopropanol (3:2, by vol), containing 0.005% (wt/vol) butylhydroxytoluol, was added and the mixture centrifuged for 10 min at 3,000g and 10 °C. The upper organic phase was collected and the solvent evaporated under liquid nitrogen. The resulting residues were quantified gravimetrically as total lipids and resuspended in hexane:isopropanol (3:2, by vol). Aliquots of the liver lipid extracts and plasma samples were analyzed for their content of triglycerides and cholesterol using commercial test kits (Ecoline 25, Merck KGaA, Darmstadt, Germany). The phospholipid (PL) content was quantified by phosphate measurement in aliquots of the liver lipid extracts using a commercial test combination for phosphorus and phospholipids (Boehringer Mannheim GmbH, Germany).

Liver PL were separated from the total lipid extracts for subsequent fatty acid analysis by aminopropyl-bonded phase columns (Bond Elut, Agilent Technologies); this solid phase extraction method has been shown to be superior to other separation techniques [14]. Aliquots of liver lipid extracts were dissolved in chloroform and applied to hexane pre-conditioned columns. After treatment with several other solvents that released neutral lipids and free fatty acids from the column, methanol was added to provoke the elution of the PL fraction. These fractions, to which heptadecanoic acid (17:0) was added as internal standard, were subjected to transmethylation with *N*-trimethyl sulfonium hydroxide. Fatty acid methyl esters (FAME) were separated by gas chromatography. They were identified by comparing retention times of FAME in a standard mix (Supelco 37, Sigma-Aldrich, Inc) that was supplemented with docosapentaenoic acid (D5679, Sigma-Aldrich, Inc). Individual FA were quantified on the basis of area under the curve and internal standard response as molar percentage of the total amount of fatty acids.

Statistical Analyses

Statistical analyses were performed using IBM SPSS Statistics 19 for Windows (IBM Company, Chicago, IL, USA). Data were analyzed by two-way analysis of variance (ANOVA) according to the linear model for a completely randomized design to test for treatment effects of Zn, fat and Zn \times fat interaction (2×3 -factorial in Expt. 1 and 2×2 -factorial in Expt. 2). Since the factor “fat” included fat level (low vs. high) and fat source (BT vs. SF) in Experiment 1, bifactorial ANOVA was also applied to the high-fat treatments to test for effects of fat source. In addition, univariate analysis was applied to test for differences among groups within each dietary Zn level in Experiment 1 and among the three groups fed the SF diets in Experiment 2. The Tukey test was used as a post hoc test to compare treatment means or, alternatively, the Games–Howell test if homogeneity of variance (Levene test) could not be attained by logarithmic (\ln) or square root transformation of the data. The significance was set at $p < 0.05$ in post hoc tests.

Results

Experiment 1

Food and Energy Intake and Final Live Weight

In Experiment 1, in which all diets were offered ad libitum during the 28-days feeding period, the marginal Zn supplementation of the diets markedly ($p < 0.001$) reduced food and energy intake and final live weights (Table 3). ME intake and final live weights significantly differed among the rats fed the low-Zn diets, but not among the animals fed the high-Zn diets. Both level and source of dietary fat contributed to a significant Zn \times fat interaction, as the reductions in ME intake and final live weights due to the moderate Zn deficiency differed among the CT, BT and SF groups (about 14, 22 and 30% in ME intake and 12, 19 and 28% in final weights relative to the respective high-Zn groups). ME intake per gram of weight gain was significantly higher for the rats fed the low-Zn diets, but the difference was relatively small (less than 7%), and may be attributed primarily

Table 3 Effect of diets differing in Zn concentration and fat supplementation on food and energy (ME) intake, final live weight, fat and energy digestibility, plasma and femur Zn concentration,

plasma alkaline phosphatase activity, and liver glucose-6-phosphate dehydrogenase (G6PD) activity in weanling rats (Experiment 1)

^{a, b, c} Group means (*M*) with different superscript letters within rows and within the same zinc level significantly differ ($p < 0.05$; Tukey test; in the case of G6PD Games–Howell test)

^d ANOVA after \ln transformation of data

to a higher proportion of energy expended for maintenance in the animals fed the low-Zn diets.

Fat and Energy Digestibility

Fat digestibility in the BT groups was approximately 8–9% U lower than in the CT and SF groups independent of the dietary Zn level (Table 3). This difference may be attributed to the high content of saturated fatty acids in beef tallow. Gross energy (GE) digestibility of the BT and SF diets was markedly lower than that of the CT diets (about 20 and 15% U, respectively; $p < 0.001$), reflecting the pronounced difference in dietary cellulose content. GE digestibility also significantly ($p < 0.001$) differed between the BT and SF diets according to the difference in fat digestibility.

Zinc and Metabolic Status

Zn concentrations in plasma and femur and activity of the alkaline phosphatase (AP) in plasma, which were analyzed as indicators of Zn status, were substantially reduced ($p < 0.001$) by the marginal dietary Zn supply in Experiment 1 (Table 3). Dietary fat level and fat source also affected these parameters to different degrees. Plasma Zn concentrations were lower in the rats fed the high-fat diets as compared to those fed the CT diets. This difference was

most marked for the SF-fed animals. The plasma AP activity was enhanced by the high-fat diets.

The activity of glucose-6-phosphate dehydrogenase (G6PD), a member of the lipogenic enzyme family [15], was greatly reduced ($p < 0.001$) in the liver of the rats fed the high-fat diets as compared to those given the low-fat CT diet, regardless of the dietary Zn level (Table 3).

Plasma and Liver Lipids

Plasma concentrations of triglycerides (TAG), total cholesterol (TC) and HDL-C were not significantly altered by the dietary Zn level, but they were by the level and type of fat in the diets in Experiment 1 (Table 4). The SF diets consistently reduced plasma TAG concentrations regardless of the dietary Zn level. TC and HDL-C concentrations in the low-Zn CT group were significantly higher ($p < 0.05$) than in the low-Zn BT and SF groups, but not when the dietary Zn level was high. Fat source did not significantly affect plasma TC and HDL-C concentrations.

Liver concentrations of total lipids, TAG and cholesterol (Table 4) were significantly higher in the rats fed the high-Zn BT and SF diets than in those fed the respective low-Zn diets, while they did not differ between the two CT-fed groups. Concentrations of these lipids were substantially higher for the SF-fed than for the BT-fed animals

($p < 0.001$). In contrast, hepatic PL concentrations were not altered by any of the dietary treatments.

Fatty Acid Composition of Liver Phospholipids

Table 5 presents the fatty acid pattern in the PL extracted from the liver in Experiment 1. Total molar proportions of saturated fatty acids (SFA) were comparable across dietary treatments. However, the percentages of 16:0 and 18:0 significantly differed among groups ($p < 0.001$). Palmitic acid (16:0) was the major SFA in the CT groups, whereas 18:0

dominated in the BT and SF groups. Oleic acid (18:1) was the predominant monounsaturated fatty acid (MUFA) in all groups. The highest mean percentage of this fatty acid was recorded in the BT groups. As expected, the SF diets increased the total percentages of n-6 PUFA, especially those of 18:2, 20:4 and 22:4, and depressed the percentages of n-3 PUFA, leading to substantially higher ratios of n-6 PUFA to n-3 PUFA in the SF-fed groups. Significant Zn effects were noted in the case of linoleic (18:2), γ -linolenic (18:3n-6) and docosapentaenoic acid (22:5n-3), which were present in higher proportions when the rats were fed the low-Zn BT and

^f The sum of monounsaturated fatty acids (MUFA) includes small amounts of 16:1 (about 1.2 mol%), 20:1 (<0.1 mol%) and 22:1 (about 0.8 mol%) in the case of the CT groups, and 20:1 (0.2 mol%) and 22:1 (about 1.0 mol%) in the case of the SF groups

SF diets as compared to the respective high-Zn diets. The highly significant Zn \times fat interaction observed for 18:2 ($p = 0.001$) is basically due to the different direction and height of response to the dietary fat level among the corresponding low- and high-Zn groups. This diet effect on 18:2 is also reflected in a significant Zn \times fat interaction of the n-6 PUFA to n-3 PUFA ratio ($p < 0.05$).

Experiment 2

Energy Intake and Final Live Weight

In Experiment 2, in which food intake of the high-Zn BT and SF diets was restricted to amounts consumed by the animals offered the corresponding low-Zn diets, final live weights were not affected by the difference in Zn supply, whereas the animals allowed to consume the high-Zn SF diet ad libitum reached significantly higher final live weights (Table 6). ME intake and final live weights of the rats fed the low-Zn SF diet were lower (about 13%; $p < 0.01$) than those fed the low-Zn BT diet. As in Experiment 1, ME intake per gram weight gain was reduced by the high-Zn diets, presumably due to a slightly leaner tissue gain.

Zinc Status

Plasma and femur Zn concentrations and plasma activity of the alkaline phosphatase (AP) were markedly reduced

($p < 0.001$) by the marginal dietary Zn supply in Experiment 2 (Table 6). Fat source did not significantly ($p > 0.05$) affect these parameters.

Plasma and Liver Lipids

Plasma concentrations of TAG, TC and HDL-C were not significantly altered by the dietary Zn level in Experiment 2 (Table 7). TAG concentrations in the SF groups were lower than those in the BT groups. But plasma TC and HDL-C concentrations were not significantly affected by fat source. The livers of the rats consuming the corresponding low- and high-Zn BT and SF-diets in equivalent quantities had comparable concentrations of total lipids, cholesterol and PL (Table 7). However, the animals fed the high-Zn SF diet ad libitum showed a significantly ($p < 0.05$) increased hepatic TAG content. PL concentrations were about 10% higher in the SF-fed than in the BT-fed animals.

Discussion

The present experiments were designed to investigate the effect of a moderate Zn deficiency on growth and selected features of lipid metabolism in weanling rats fed diets that greatly differed in fat level and fat source. As expected, the low-Zn diets (7 $\mu\text{g/g}$ supplemental zinc) were associated with notable reductions in food and energy intake and final

live weights compared to animals fed the high-Zn diets (100 $\mu\text{g/g}$ supplemental zinc), but without the complications that would arise from feeding severely Zn-deficient diets, i.e. growth arrest, development of a cyclic feeding pattern, conspicuous inanition, and the manifestation of clinical deficiency symptoms [1–3]. The increase in dietary fat level implied a pronounced difference in energy intake as carbohydrate and fat in Experiment 1. Available carbohydrates (cornstarch and sucrose) and fat accounted for about 69 and 8% of ME intake of the rats fed the low-fat diets, respectively, whereas carbohydrates contributed no more than about 22% and fat at least 55% of ME intake in the case of the high-fat diets (Table 1). There was a small difference in ME content between the BT and SF diets due the fact that fat digestibility was significantly lower for the BT diets than for the SF and CT diets (Table 3).

In Experiment 1, in which all diets were fed ad libitum, mean daily ME intake and final live weights were comparable among the rats fed the three high-Zn diets regardless of dietary fat level and fat source. This, however, was not the case among the animals fed the corresponding low-Zn diets. The animals given the low-Zn SF diet displayed the greatest reductions in ME intake (about 30%) and final live weights (about 28%) relative to those consuming the corresponding high-Zn diet

(Table 3). Again in Experiment 2, daily ME intake and final live weights were significantly lower for the rats fed the low-Zn SF diet as compared to the low-Zn BT diet (Table 6). This observation supports a previous study in which marginally Zn-deficient diets enriched with sunflower or olive oil depressed food intake and weight gain of young rats to a greater extent than did low-Zn diets containing equivalent percentages of beef tallow, butterfat or coconut oil [7]. Although it is a common observation that both food intake and growth rate are depressed by dietary Zn deficiency, previous studies have clearly shown that growth retardation cannot be attributed to the lower food or energy intake. Chesters and Quartermann [1] observed that force-feeding Zn-deprived rats a Zn-deficient diet not only failed to alleviate the growth arrest but rapidly induced signs of severe ill-health and morbidity. This finding has been confirmed by later investigators reporting that young rats with an initially normal Zn status cease to tolerate force-feeding of Zn-deficient diets in amounts exceeding voluntary consumption after about 9–11 days [16–18]. These studies demonstrate that a deficit of zinc per se must be responsible for the growth retardation. It is well established that a lack of zinc impairs cell division, differentiation and growth in various species, including microorganisms, plants and vertebrates (see [19] for review).

Zn concentrations in plasma and femur and AP activity in plasma, known to be sensitive indicators of Zn status under experimental conditions, responded markedly to the difference in dietary Zn nutrition in both experiments (Tables 3, 6). In Experiment 1, the rats fed the SF diets had the lowest plasma Zn concentrations at either dietary Zn level. This finding may suggest a decreased intestinal Zn availability as a possible explanation for the lower final live weights of the rats consuming the low-Zn SF diet. In Experiment 2, mean plasma Zn concentration was again lower (12%) in the low-Zn SF than in the low-Zn BT group, but the difference failed to be statistically significant. In addition, femur Zn concentrations and plasma AP activities, which reflect Zn status over a longer period than plasma zinc, were comparable between the low-Zn BT and SF groups in either experiment, and thus argue against the idea that enriching the diets with sunflower oil may have lowered Zn availability and hence growth of the animals.

Regarding the effect of dietary Zn depletion on plasma or serum lipids, the literature data are not uniform. Some authors reported that Zn-deficient rats had decreased triglyceride (TAG) concentrations compared to pair-fed or ad libitum-fed control animals [20, 21], whereas others found that Zn depletion did not significantly alter TAG levels [22–24]. In a series of studies, in which young rats were force-fed Zn-deficient diets containing different fat levels and fat sources, TAG concentrations were increased or remained unaffected relative to values of control rats force-fed equal quantities of the same diets with adequate Zn supply [18, 24, 25]. In our experiments, the difference in dietary Zn supply did not significantly affect plasma TAG concentrations regardless of fat content and fat source (Tables 4, 7). Thus, it does not appear that a moderate Zn deficit plays a primary role in modulating TAG levels in circulating blood. In contrast, fat source significantly influenced plasma TAG concentrations. Proposed mechanisms explaining the lower plasma TAG levels in response to the ingestion of polyunsaturated relative to saturated fats include a decreased rate of lipoprotein secretion [26–29] and an increased lipoprotein clearance from circulation [30, 31]. Gene expression studies provide support for both of these mechanisms (see [32] for a recent review).

The effect of Zn deficiency on plasma or serum cholesterol concentrations has also been found to differ among previous studies. In several investigations, Zn depletion of young rats was associated with lower cholesterol levels [20, 21, 33–35], whereas in others cholesterol values of Zn-depleted rats did not differ from those of pair-fed or ad libitum-fed control animals [22, 23, 36–38]. Young rats force-fed Zn-deficient diets in quantities above those voluntarily consumed by Zn-deprived animals showed rather regularly elevated cholesterol levels compared to animals force-fed equivalent amounts of Zn-adequate diets [19, 25].

In Experiment 1 of our study, plasma total and HDL cholesterol concentrations were also higher in the rats consuming the low-Zn, low-fat diet as compared to the corresponding high-Zn CT diet. In both experiments, however, the rats fed the high-fat diets displayed comparable cholesterol levels regardless of dietary Zn level, fat source and energy intake. This finding agrees with a former study in which serum cholesterol concentrations were comparable among rats fed diets containing 20% fat as beef tallow or sunflower oil [39]. A possible explanation for the lower HDL-cholesterol levels in plasma of the animals given the high-fat diets may be the former observation that activation of the peroxisome proliferator-activated receptor alpha (PPAR α) decreases circulating HDL in rodents [40].

A few former investigations found that dietary Zn depletion did not alter TAG concentrations in the liver of young rats [33, 41], whereas others reported reduced contents compared to animals fed Zn-adequate diets either ad libitum [21, 38] or in restricted amounts [42]. Our experiments indicate that dietary fat content and level of energy intake have a greater impact on liver lipids than a moderate Zn deficit. In Experiment 1, the livers of the animals fed the high-Zn BT and SF diets had significantly higher TAG contents than those given the corresponding low-Zn diets (Table 4), but their energy intake was also significantly higher due to the ad libitum feeding protocol (Table 3). In Experiment 2, in which intake of the high-Zn diets was restricted to the intake of the respective low-Zn diet, the difference in dietary Zn intake did not alter hepatic TAG concentrations. But the rats offered the high-Zn SF diet for ad libitum intake had a markedly higher hepatic TAG content than those consuming the SF diet in lower amounts (about 27%). Data documented by Cunnane [41] also suggest that a difference in food intake of about 20% may be sufficient to affect TAG levels in the liver of growing rats fed diets supplemented with greatly different levels of zinc.

The fat source was a significant factor for hepatic lipid concentrations in both experiments of our study. The SF diet effected substantially higher TAG concentrations in the liver than the BT diet. This agrees with numerous former investigations reporting that diets containing oils rich in unsaturated fatty acids (including sunflower oil among other vegetable oils) increase hepatic TAG concentrations compared to saturated fats [21, 29, 43, 44] or to diets low in fat [45]. Various mechanisms have been proposed for the differences in hepatic TAG concentration. Monsma and Ney [45] reported that the intestinal absorption of the stearate-rich diets was reduced. A reduced fat digestibility was also evident in our study for the BT diet compared to the other diets (as discussed before). The lower digestibility of the beef tallow, however, must be considered insufficient to explain the lower hepatic TAG levels in our experiments for the following reasons. First,

TAG levels of the rats fed the BT diets were comparable to those observed for the rats given the low-fat control diets. Secondly, ME intake per unit weight gain was closely comparable among diets within the same dietary Zn level in both experiments. Finally, other workers demonstrated that PUFA-rich diets reduce the assembly and secretion of VLDL in the liver (see [32, 46] for reviews).

Previous studies, in which low-fat diets were fed to growing rats, showed that dietary Zn depletion of rats does not significantly alter hepatic cholesterol concentrations [21, 33, 47]. The livers of the rats fed the low-fat diets in Experiment 1 of our study also had comparable cholesterol concentrations regardless of the dietary Zn level. This was also true for the high-fat diets in Experiment 2, in which intake of the high-Zn diets was restricted. Therefore, the significant difference in liver cholesterol concentrations between the low-Zn and high-Zn BT and SF groups in Experiment 1 must be attributed to the difference in energy or fat intake. Higher cholesterol concentrations in the liver of young rats in response to an increased dietary fat supply have been observed previously [48, 49]. The rats consuming the SF diets had the highest cholesterol concentrations in both experiments of our study. This effect is consistent with numerous former studies showing higher hepatic cholesterol concentrations in rats fed diets enriched with (15% or more) unsaturated vegetable oils as compared to diets supplemented with saturated fats [44, 48–50]. Increased hepatic cholesterol levels in response to the feeding of diets rich in n-6 PUFA may result from a lower formation and secretion of VLDL as discussed before in the case of hepatic TAG concentrations.

Previous studies with young rats have found that phospholipid (PL) concentrations are barely affected by feeding Zn-deficient diets [18, 41, 47] or by different fat sources [45]. In agreement, the hepatic PL concentrations remained closely comparable in the present study despite substantial differences in zinc, fat and energy intake and dietary fat source. The fatty acid composition of the hepatic PL also reflects a remarkable resistance to the dietary variables, most notable in the similar total percentages of saturated (SFA) across diets. There is no evidence from our data that the conversion of linoleic and α -linolenic acid into longer-chain PUFA might have been impaired by the moderate Zn deficiency, even though linoleic, γ -linolenic (18:3n-6) and docosapentaenoic (20:5n-3) acid were present in significantly higher proportions in the PL of the rats fed the low-Zn diets than in those given the corresponding high-Zn diets. The percentages of arachidonic (20:4n-6) and docosahexaenoic (22:6n-3) acid, the main end products of linoleic and α -linolenic acid, respectively, were closely comparable between the corresponding low- and high-Zn groups. This supports those former studies showing that dietary Zn deficiency per se does not impair the chain

elongation/desaturation pathway of essential fatty acids (see [51] for review).

As expected, the diet enriched with sunflower oil, containing linoleic acid as dominant fatty acid, markedly promoted the incorporation of n-6 PUFA, especially arachidonic acid, into the PL, mostly at the expense of docosahexaenoic acid. A significant effect of the dietary fat level is evident among the SFA. The hepatic PL of the rats fed the low-fat diets contained higher proportions of palmitic than stearic acid. The proportions of these two SFA were reversed in the case of the animals consuming the high-fat diets. Two major reasons may explain this shift. First, hepatic de novo lipogenesis was evidently the major source of palmitic acid in the liver of the CT-fed rats, whereas SFA intake was low. In support, the activity of glucose-6-phosphate dehydrogenase, which belongs to the lipogenic enzyme family and closely correlates with the rate of fatty acid synthesis in the liver [15], was very much higher in the CT groups than in the high-fat groups (Table 3). Secondly, stearic acid was presumably desaturated to oleic acid in the liver of the CT-fed animals to a major extent, since its intake was also low, yet its proportions in the PL fraction approximately as high as those in the high-fat groups, for which oleic acid was available in appreciable amounts from dietary intake.

Conclusion

Taken together, the current study shows that diets highly enriched with either beef tallow or sunflower oil have a quantitatively greater impact on plasma and liver lipid composition than a moderate Zn deficiency. Yet, none of the lipid parameters seems to offer a possible explanation why the marginal Zn supply caused a greater growth retardation when the diet contained sunflower oil instead of beef tallow. Fatty acids certainly were the major energy source in either of these groups. However, in the SF diet over 85% of the fatty acids were unsaturated, mainly linoleic acid, whereas the BT diet contained less unsaturated fatty acids (about 52%). Considering the limited dietary supply of carbohydrates and SFA from the SF diet and the need of SFA in the synthesis of membrane and storage lipids, it is conceivable that the SF-fed rats may have largely relied on PUFA as energy source. Mitochondrial and peroxisomal β -oxidation of unsaturated fatty acids, including linoleic and oleic acid, requires Δ^3, Δ^2 enoyl-CoA isomerase (ECI, EC 5.3.3.8) as key auxiliary enzyme [52, 53]. In the liver of young rats force-fed Zn-deficient diets, mRNA profiling showed that the transcription of genes coding for enzymes of the β -oxidation scheme, including ECI, was markedly reduced compared to Zn-adequate control animals [54, 55]. Further research is needed to

investigate whether and to what extent a moderate Zn deficiency may lead to a reduced ECI activity as a possible explanation of the consistently attenuating effect of diets enriched with sunflower oil on weight gain of weanling rats in the present experiments and in a previous study [7].

Abstract A cDNA encoding protein with homology to plant secretory phospholipase A₂ (sPLA₂), denoted as Nt1 PLA₂, was isolated from tobacco (*Nicotiana tabacum*). The cDNA encodes a mature protein of 118 amino acid residues with a putative signal peptide of 29 residues. The mature form of Nt1 PLA₂ has 12 cysteines, Ca²⁺ binding loop and catalytic site domain that are commonly conserved in plant sPLA₂s. The recombinant Nt1 PLA₂ was expressed as a fusion protein with thioredoxin in *E. coli* BL21 cells and was purified by an ion exchange chromatography after digestion of the fusion proteins by Factor Xa protease to obtain the mature form. Interestingly, Nt1 PLA₂ could hydrolyze the ester bond at the *sn*-1 position of glycerophospholipids as well as at the *sn*-2 position, when the activities were determined using mixed-micellar phospholipids with sodium cholate. Both activities for the *sn*-1 and -2 positions of glycerophospholipids required Ca²⁺ essentially, and maximal activities were found in an alkaline region when phosphatidylcholine, phosphatidylglycerol or phosphatidylethanolamine was used as a substrate. The level of Nt1 PLA₂ mRNA was detected at a higher level in tobacco flowers than stem, leaves and roots, and was induced by salicylic acid.

Introduction

Phospholipase A₂ (phosphatide 2-acylhydrolase, EC 3.1.1.4, PLA₂) catalyzes the hydrolysis of the *sn*-2 fatty acyl ester bond of glycerophospholipids, liberating free fatty acids and lysophospholipids. PLA₂ comprises a large family with multiple isoforms exhibiting different structure and catalytic properties [1]. In plant, PLA₂s have been proposed to involve in seed germination [2], cell division and growth [3], wounding response [4] and auxin signal [5]. One of the plant PLA₂ groups is constituted of secretory enzyme (sPLA₂) with a low molecular mass. The sPLA₂s have been purified from elm (*Ulmus glabra*) [6] and partially purified from rice (*Oryza sativa*) [7]. The cDNA clones of sPLA₂s from rice [7], carnation (*Dianthus caryophyllus* L. cv. *Degio*) [8], *Arabidopsis* (*Arabidopsis thaliana*) [9–11], tobacco (*Nicotiana tabacum*) [12] and citrus (*Citrus sinensis*) [13] are also isolated. Plant sPLA₂s have been classified to two groups, group XIA and XIB,

based on their primary structures [14]. The gene expression analysis of the plant sPLA₂s has shown that the expression levels of carnation and citrus sPLA₂ mRNAs were induced during flower development [8] and by light [13], respectively. In *Arabidopsis*, four genes of sPLA₂ (AtsPLA₂) denoting AtsPLA₂- α , - β , - γ and - δ , exist in its genome and are found to be a functional enzyme [15]. AtsPLA₂- β and - γ transcripts were detected in flower at a higher level than the other tissues [10, 11], and the gene suppression of AtsPLA₂- β , - γ and - δ simultaneously is caused sterility with less pollen germination [16], indicating that AtsPLA₂s play a role in the process of reproduction. From the analysis of the transgenic plants suppressing and overexpressing AtsPLA₂s, AtsPLA₂- β was found to be involved in cell elongation by mediating auxin, shoot gravitropism [10], and stomatal movement [17]. On the other hand, AtsPLA₂- α is negatively regulated during the hypersensitive response of plants resistant to microbial pathogens [18] and is involved in PIN-FORMED protein trafficking [19]. Although the information concerning plant sPLA₂ has now been accumulated, the physiological functions of plant sPLA₂ remain to be elucidated.

In our previous study [12], we found high PLA₂ activities in tobacco flower and cloned a cDNA encoding a sPLA₂ with homology to plant group XIB sPLA₂, denoted Nt PLA₂ (renamed Nt2 PLA₂ in this study). Furthermore, we have reported that another sPLA₂ is expressed in tobacco flower. In this study, we newly isolated a cDNA encoding a sPLA₂ with homology to that of group XIA PLA₂ from tobacco flower, and investigated enzymatic characteristics of recombinant mature enzyme, using mixed-micellar phospholipid substrate with sodium cholate. We also investigated the mRNA expression pattern in tobacco tissues and the influence of plant hormones on the mRNA expression of tobacco sPLA₂s.

Materials and Methods

Materials

1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoglycerol (POPG) were purchased from Avanti Polar Lipids, Inc. (Birmingham, AL, USA). 9-Anthryldiazomethane and sodium cholate were obtained from Funakoshi Co., Ltd. (Tokyo, Japan). POROS HS/M cation-exchange column (4.6 \times 100 mm) and cosmosil 5C18 column were obtained from Perseptive Biosystems (Framingham, MA, USA) and Nacalai Tesque (Kyoto, Japan), respectively. The Silver Staining II Kit was purchased from Wako Pure Chemicals (Osaka, Japan), Factor Xa

proteinase was purchased from Promega (Madison WI, USA) and pET32a and *E. coli* BL21 (DE3) were obtained from Novagen (Madison, WI, USA). The DC Protein assay kit was obtained from Bio-Rad Laboratories (Hercules, CA).

Tobacco Culture

Tobacco BY-2 cells (*Nicotiana tabacum* cv. Bright Yellow 2) were cultured on Linsmaier and Skoog's medium containing 2.5 mM KH₂PO₄, 3 mM thiamin-HCl, 3%(w/v) sucrose and 1 μ M 2,4-dichlorophenoxyacetic acid (2,4-D) solidified with 0.8% (w/v) agar at 28 °C in the dark for 3 days. To test the effects of plant hormones on PLA activities (PLA₁ and PLA₂ activities) and mRNA expression levels of Nt1 and Nt2 PLA₂s, the BY-2 cells were cultured on the above medium excluding 2,4-D with or without 50 μ M salicylic acid, 20 μ M 3-indoleacetic acid or 1.8 μ M 2,4-D, at 28 °C in the dark for 24 h.

Tobacco Plant

Tobacco (*Nicotiana tabacum* L. cv. SR-1) plants were grown at 28 °C in light/dark (16/8 h) in the green house.

Preparation of Crude Extract from Tobacco Tissues or BY-2 Cells

Tobacco tissues and BY-2 cells were homogenized in the extraction buffer (20 mM Tris-HCl, pH 8.0, 1 M KCl, 2 mM EDTA, and 2 mM PMSF) and centrifuged at 10000 \times g for 10 min. The resulting supernatant was used as a crude extract for determination of PLA activities (PLA₁ and PLA₂ activities) and protein concentration.

Standard Assay for PLA Activity and Determination of Protein Concentration

PLA activities were assayed as described previously [12]. The standard incubation system (100 μ L) for the assay of PLA activities contains 2 mM POPC, 8 mM sodium cholate, 100 mM NaCl, 10 mM CaCl₂, and 50 mM Tris-HCl (pH 8.0). The reaction was carried out at 37 °C for 60 min. Palmitic acid released by PLA₁ and oleic acids released by PLA₂ action were labeled with 9-anthryldiazomethane, and the derivatized fatty acids were detected by a reverse-phase HPLC with a spectrofluoromonitor. One unit (U) was defined as the liberation of 1 μ mol free fatty acid (free palmitic acid released from the *sn*-1 position of glycerophospholipid for PLA₁ activity or free oleic acid released from the *sn*-2 position of glycerophospholipid for PLA₂ activity) per min. Each experiment was performed two times, and the results presented were the means.

Ca^{2+} -dependent PLA activities in the tissue and BY-2 extracts, were determined by subtracting the activities assayed with 20 mM EDTA showing Ca^{2+} -independent PLA activity, from those with 10 mM CaCl_2 including both Ca^{2+} -independent and -dependent PLA activities.

Protein concentration was measured with DC Protein assay kit using bovine serum albumin as a standard.

RT (Reverse-Transcription)-PCR

Total RNA was isolated from tobacco flowers with the acid guanidinium thiocyanate–phenol–chloroform (AGPC) method as described previously [12]. Total RNA (3 μg) was reverse-transcribed by using PowerScript Reverse Transcriptase (BD Biosciences Clontech, Tokyo, Japan) and oligo-dT primer. The primers used in this study are shown in Supplemental Table 1. Primers, T1a and T1b, were designed according to the partial amino acid sequences, Ile62–Gly68 and Gly73–Cys81 of the putative tomato sPLA₂ (GeneBank Accession No. BG127198), respectively. PCR was carried out for 40 cycles of 30 s at 95 °C for denaturation, 30 s at 58 °C for annealing and 60 s at 72 °C for polymerization, with ExTaq DNA polymerase (Takara Bio, Shiga, Japan) using T1a and P1 as forward and reverse primers, respectively. An aliquot of the primary PCR products was used in secondary PCR with T1b and P2 as forward and reverse primers, respectively. The secondary PCR was carried out under the same conditions to the primary PCR. The PCR product was subcloned into the pGEM-T Easy vector (Promega, Madison, WI) and used to transform into *E. coli* XL-1 Blue cells. After selecting positive clones according to the manufacturer's protocol, plasmid DNAs were purified from positive clones with the QIAprep Spin Miniprep Kit (Qiagen, Tokyo, Japan). The nucleotide sequence was determined by the ABI 373A sequencer (Applied Biosystems, USA) using the DYEnamic ET Terminator Cycle Sequencing Kit (Amersham Biosciences Corp, Piscataway, NJ), according to the manufacturer's protocol.

5'-RACE (Rapid Amplification of cDNA Ends)-PCR

5' Rapid amplification of the cDNA ends (5'-RACE) was performed essentially as described previously [12]. An adaptor-ligated double-stranded cDNA was synthesized using the Marathon cDNA Amplification Kit (BD Biosciences Clontech) according to the manufacturer's instruction. From the determined nucleotide sequence of the internal cDNA, new primers, 5T1a and 5T2b (complementary to nt 393–417 and nt 426–450 in GeneBank Accession No. AB190177, respectively), were designed for 5'-RACE. PCR was carried out for 40 cycles of 30 s at 94 °C, 30 s at 58 °C and 60 s at 72 °C with AP1 and 5T1a

as forward and reverse primers, respectively. An aliquot of the primary PCR product was used in secondary PCR with AP2 and 5T1b as forward and reverse primers, respectively. PCR was carried out for 40 cycles of 30 s at 95 °C, 30 s at 63 °C and 60 s at 72 °C. A unique band obtained by the RACE was subcloned into the pGEM-T Easy vector as described above.

Expression and Purification of Recombinant Nt1 PLA₂

A sense primer that contains restriction enzyme sites and nucleotide sequence for a factor Xa cleavage site (Ile-Glu-Gly-Arg) adjacent to the N-terminal residue of mature protein of Nt1 PLA₂, and antisense primer are shown in Supplemental Table 1. A PCR fragment encoding for a factor Xa cleavage site followed by mature Nt1 PLA₂ was prepared with ExTaq DNA polymerase, and subcloned into pGEM-T Easy vector as described above. The insert was subcloned into an expression vector pET32a encoded thioredoxin (Trx), and the resulting plasmid transformed *E. coli* BL21 (DE3). For recombinant protein preparation, 4 mL of overnight culture was inoculated at 30 °C in 400 mL of LB medium containing 1% tryptone peptone, 0.5% yeast extract, 0.5% NaCl and 50 $\mu\text{g}/\text{mL}$ ampicillin. When the absorbance at 600 nm of the cultures reached 0.5, the recombinant proteins were expressed by induction with 0.1 mM IPTG for 3 h at 30 °C. Cells were harvested at 3000 $\times g$ for 5 min and frozen at –20 °C. The cells were resuspended in 15 mL of 20 mM Tris–HCl (pH 8.0) containing 2 mM EDTA. The cells were lysed by adding 6 mL of 1 M NaOH and neutralized with 1 M HCl. The lysate was centrifuged at 8000 $\times g$ for 30 min at 4 °C, and the resulting cell extract was dialyzed against 2 L of 20 mM Tris–HCl (pH 7.0). The dialysate was digested with Factor Xa proteinase for 90 min at 37 °C (the ratio of Factor Xa to protein was 1:1,000, w/w), and loaded on POROS HS/M column at a flow rate of 2 mL/min, which had been equilibrated with 20 mM MES–NaOH (pH 6.0). The protein was eluted with a linear gradient of NaCl. The active fractions were pooled and stored at –40 °C.

SDS-PAGE

SDS-PAGE was carried out as described previously [12] by using a 16% polyacrylamide gel in the presence of 2-mercaptoethanol, and the proteins were visualized with the Coomassie brilliant blue staining.

RNA Extraction and Quantitative RT-PCR

Total RNA was isolated from the tobacco tissues such as flowers, leaves, stems and roots, and BY-2 cells by the AGPC method as described above and treated with DNase

I (Takara, Tokyo, Japan). 500 ng of total RNA was reverse-transcribed by using PowerScript Reverse Transcriptase and oligo-dT primer. Quantitation of mRNAs for Nt1 and Nt2 PLA₂s and actin as an internal reference gene (GeneBank Accession No. AB190177) was performed using Chromo4 System for Real-Time PCR Detection (Bio-Rad, Hercules, CA) according to the manufacturer's instructions. Forward and reverse primers are shown in Supplemental Table 1, Nt1 PLA₂ (identical to nt 50–67 and complementary to nt 148–160 in GeneBank Accession No. AB190177, respectively); Nt2 PLA₂ (identical to nt 78–95 and complementary to nt 180–190 in GeneBank Accession No. AB190178, respectively); Actin as an internal reference (identical to nt 933–952 and complementary to nt 1100–1119 in GeneBank Accession No. AB158612, respectively). PCR amplification was initiated by denaturation at 95 °C for 15 s and annealing at 55 °C for 30 s, and then by extension at 72 °C for 30 s. Fluorescence was acquired during extension using an excitation wavelength of 470 nm and emission detection at 530 nm. A melting-curve analysis was carried out by continuously monitoring fluorescence between 55 and 95 °C with 0.5 °C increments every 10 s. Threshold values (Ct) were set manually in each experiment to correspond to the early exponential phase of amplification, and Opticon monitor program provided with the system was used to determine the cycle at which the threshold was attained. The level of each transcript levels was determined from standard curves generated using each known concentration of PCR product amplified with each specific primer set. Normalization was done by dividing the transcript levels of Nt1 and Nt2 PLA₂s by those of the actin. The reaction products were electrophoresed on a 1% agarose gel for checking a single amplifying band. All reactions were performed triplicate.

Results

Isolation of cDNA Clone for Nt1 PLA₂

Primers for PCR were designed based on the amino acid sequence of the putative tomato sPLA₂. RT-PCR was performed with total RNA prepared from tobacco flowers. A partial cDNA fragment was isolated, and the nucleotide sequence of the cDNA showed a significant homology to that of tomato sPLA₂. Using a RACE method, the full-length cDNA sequence was determined. The cDNA clone has a 441 bp open reading frame that encodes 147 amino acids. The protein encoded in the cDNA was named Nt1 PLA₂. Therefore, another tobacco PLA₂ encoded in a cDNA isolated previously [12], was named Nt2 PLA₂ in this report. The nucleotide sequence of Nt1 PLA₂ cDNA was registered in GeneBank under an Accession Number

AB190177. The calculated molecular mass and pI value of Nt1 PLA₂ were 16,195 Da and 8.24, respectively. The hydropathy profile suggests that the N-terminal amino acid sequence of Nt1 PLA₂ includes a signal sequence as well as that of Nt2 PLA₂. From the analysis of the amino acid sequence by Signal P program [20], Nt1 PLA₂ contains 29 residue of a potential signal sequence preceding the mature enzyme. An alignment of the amino acid sequence of Nt1 PLA₂ with the sequences of various plant and animal sPLA₂s is shown in Fig. 1. The amino acid sequence of Nt1 PLA₂ showed 31% homology to that of Nt2 PLA₂ (showed in the lower far right of Fig. 1). The Ca²⁺ binding loop (Tyr84–Gly94) and the catalytic domain (Pro100–Asp112) were highly conserved in Nt1 PLA₂. In addition, Nt1 PLA₂ contains 12 Cys residues in the mature protein. The positions of Cys residues in the mature protein are well conserved among the plant sPLA₂s. Nt1 PLA₂ has the sequences, KLEEL, at the C-terminus, which is similar to the endoplasmic reticulum retention sequence (KDEL) [21]. A phylogenetic tree was derived from an alignment of the amino acid sequences between plant and animal sPLA₂s, using the CLUSTAL W program [22] and Tree view [23] (Supplemental Fig. 1). This tree shows that Nt1 and Nt2 PLA₂s are placed in the branch of the plant sPLA₂s, but are separated into two subgroups, XIA and XIB PLA₂s. The group XIA PLA₂ contains tobacco Nt1 PLA₂, three *Arabidopsis* PLA₂s (AtsPLA₂-β, -γ and -δ) and rice Rice-I PLA₂, while the group XIB PLA₂ contains tobacco Nt2 PLA₂, carnation PLA₂, elm PLA₂, *Arabidopsis* AtsPLA₂-α, and rice Rice-II PLA₂. Therefore, Nt1 PLA₂ was suggested to be group XIA PLA₂, which maybe localized in the endoplasmic reticulum.

Expression, Purification and Characterization of Recombinant Nt1 PLA₂

Nt1 PLA₂ was expressed by *E. coli* BL21 cells using pET32a as a fusion protein with thioredoxin having the factor Xa cleavage site adjacent to the N-terminal residue of mature Nt1 PLA₂. The fusion protein digested with Factor Xa protease was applied to a POROS HS/M column. As the PLA₂ activity was detected only in the peak indicated in supplemental Fig. 2a, the peak was pooled as the purified Nt1 PLA₂ to yield a final enzyme preparation. SDS-PAGE analysis showed that Nt1 PLA₂ could be purified as a single protein band (Supplemental Fig. 2b). The purified recombinant Nt1 PLA₂ was used for analyzing the enzymatic properties. Some studies for enzymatic properties of *Arabidopsis* AtsPLA₂s showed that the premature form containing the signal peptide had lower enzymatic activities than that of the mature form [9–11]. Therefore, the mature form of Nt1 PLA₂ was prepared for enzymatic assay. PLA activity was determined using

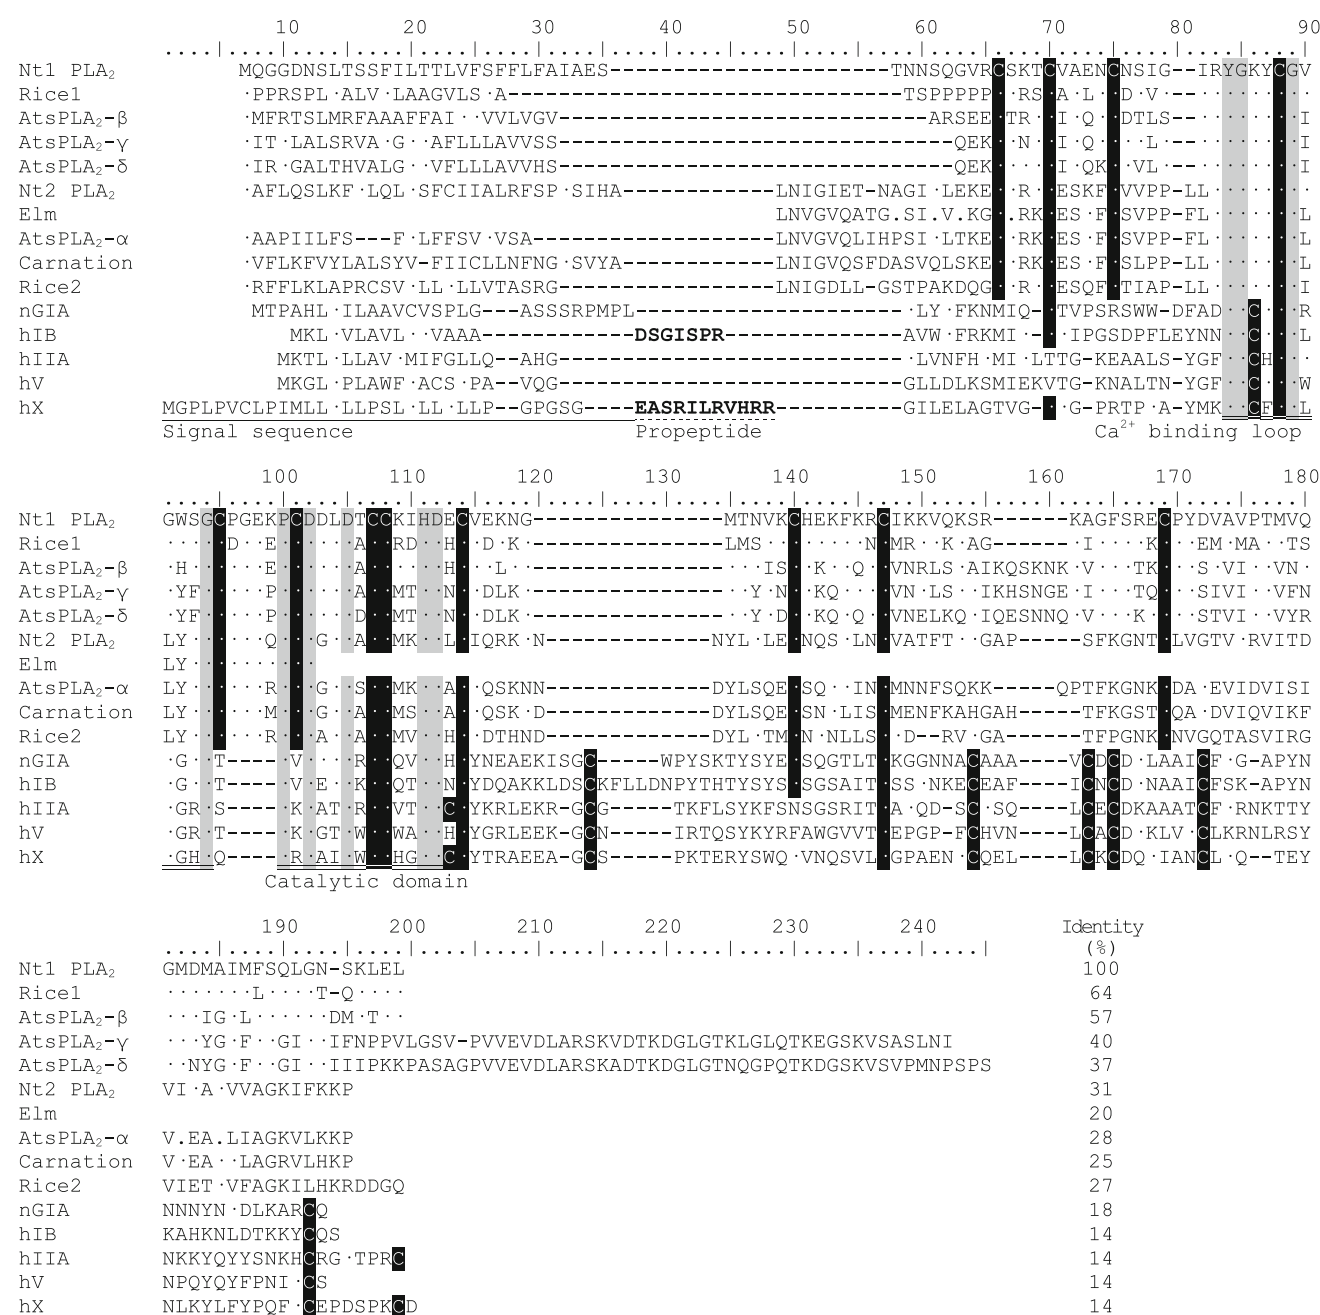

Fig. 1 Alignment of amino acid sequences of tobacco Nt1 PLA₂ with other plant and animal sPLA₂s. The N-terminal signal sequences were predicted by the SignalP program. Propeptide is shown in **bold**. Dots indicate the conserved amino acid residues identical to those of Nt1 PLA₂. Sequence identities (%) of plant and animal sPLA₂ with Nt1 PLA₂ are indicated in the lower far right of the table. Nt1 PLA₂, tobacco Nt1 PLA₂ (this study, Acc. mixed-micellar phospholipids with sodium cholate. Nt1 PLA₂ could hydrolyze both palmityl ester bonds at the *sn*-1 and oleoyl-ester bonds at *sn*-2 positions in phosphatidylcholine, respectively, while Nt2 PLA₂ was only at the *sn*-2

position (Fig. 2). Therefore, the PLA₁ activity of Nt1 PLA₂ was determined as the liberation of free palmitic acid, and PLA₂ activity was done as that of free oleic acid in this study. Effects of pH and concentrations of Ca²⁺ and

Fig. 2 Elution profile of the derivatized fatty acids on a reverse-phase HPLC. The reaction mixture with Nt1 PLA₂ (a) or Nt2 PLA₂ (b) using POPC as a substrate was applied a Cosmosil 5C18 column, which was pre-equilibrated with acetonitrile. The elution of the fatty acids derivatized with 9-anthryldiazomethane was followed by monitoring with a spectrofluorometer. C18:1; oleic acid, C16:0; palmitic acid, C17:0; *n*-heptadecanoic acid

sodium cholate on the activities of Nt1 PLA₂ toward phospholipids containing three head groups (POPC, POPG and POPE) are shown in Fig. 3. The activities of Nt1 PLA₂ for POPE were increased with increasing pH, while the maximal activities for POPC and POPG were found in pH 8–10 and in pH 8, respectively (Fig. 3a, b, c). The activities of Nt1 PLA₂ toward all three phospholipids were not detected in the presence of 1 mM EDTA (Fig. 3d, e, f). The activities of Nt1 PLA₂ toward the phospholipids were observed in the presence of Ca²⁺, and maximal activities were detected above 1 mM Ca²⁺ (Fig. 3d, e, f). Although the activities of Nt1 PLA₂s toward the phospholipids were not detected in the absence of sodium cholate, it was greatly increased by the addition of sodium cholate. The maximal activities of Nt1 PLA₂ were found at 20 mM sodium cholate (cholate/phospholipids molar ratio of 10) (Fig. 3g, h, i).

Distribution of PLA Activity, and Expression of Nt1 PLA₂ and Nt2PLA₂ mRNA in Tobacco Tissues

The crude extracts and total RNA were prepared from flowers, stems, leaves and roots of tobacco. PLA activities (PLA₁ and PLA₂ activities) in the extract were measured using the mixed-micellar POPC substrate with sodium cholate. As the Nt1 PLA₂ (Fig. 3) as well as Nt2 PLA₂ [12] required essentially millimolar concentration of Ca²⁺ for the optimal enzyme activities (Fig. 3), Ca²⁺ dependent PLA activities in the extract were determined as described in the materials and methods sections. As shown in Fig. 4a, both Ca²⁺ dependent PLA₁ and PLA₂ activities were extremely high in the flowers, followed by the root and

stem, but it was hardly detected in the leaf. To investigate the expression levels of Nt1 and Nt2 PLA₂ mRNAs in tobacco tissues, quantitative RT-PCR using the Chromo4 System (Bio-Rad) was performed with specific primers for Nt1 and Nt2 PLA₂s and actin. The each reaction product amplified with their specific primers was shown as a single band on an agarose gel electrophoresis (data not shown). In addition, each PCR product had a single melting temperature (data not shown). These results showed that all PCR reaction specifically amplified the cDNAs of Nt1 and Nt2 PLA₂s and actin in the PCR conditions. As shown in Fig. 4b, the expression level of Nt1 PLA₂ mRNA was higher in the flower than in the other tissues. Although the expression levels of Nt1 PLA₂ mRNA were 13- to 22-fold lower than those of Nt2 PLA₂ mRNA in tobacco tissues, the patterns of both mRNA expressions in tobacco tissues were similar with each other.

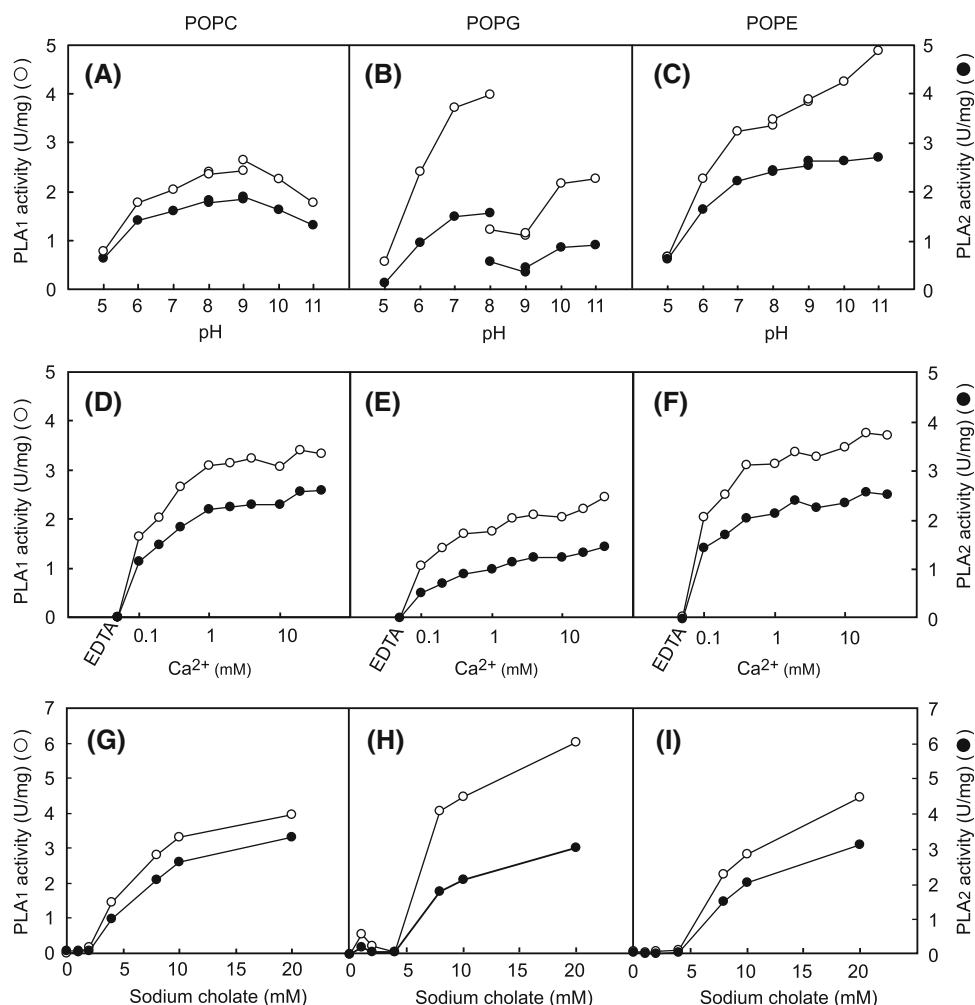

Effect of the Plant Hormones on the PLA Activities and Expression of Nt1 PLA₂ and Nt2 PLA₂ mRNA in Tobacco BY-2 Cells

As shown in Fig. 5a, both Ca²⁺ dependent PLA activities in tobacco BY-2 cells were increased by treatment by plant hormones, salicylic acid (SA), 3-indoleacetic acid (3-IAA) and 2,4-dichlorophenoxyacetic acid (2,4-D). In the meanwhile, the expression level of Nt1 PLA₂ mRNA was higher in BY-2 cells treated by SA, but not by 3-IAA and 2,4-D, than that in the mock-treated cells, whereas Nt2 PLA₂ mRNA levels were decreased in all hormone treated cells (Fig. 5b).

Discussion

We had previously cloned a cDNA for Nt2 PLA₂ named in this report, showing a high homology to plant group XIB sPLA₂s [12]. In this study, we isolated a cDNA encoding a novel sPLA₂, denoted as Nt1 PLA₂. The primary structure of Nt1 PLA₂ revealed that it belongs to group XIA PLA₂ including three *Arabidopsis* (AtsPLA₂-β, -γ, and -δ) and rice (Rice1) sPLA₂s. Similarly to the other plant sPLA₂s, the N-terminus of Nt1 PLA₂ was suggested to have a signal sequence. There are some reports about the subcellular localization of *Arabidopsis* sPLA₂s (AtsPLA₂) with the analysis of fluorescence protein fused to portion of AtsPLA₂s. The N-terminal regions of AtsPLA₂s appear to function as a signal sequence for the secretion of protein [10, 11]. Nt1 PLA₂ is presumably processed between Ser29 and Thr30 by a signal peptidase at the endoplasmic reticulum (ER). However, the existence of an ER retention signal had been predicted at the C-terminus of AtsPLA₂-β, and it was recently reported that AtsPLA₂-β may be

Fig. 3 Effects of pH (a–c), Ca^{2+} (d–f) and sodium cholate (g–i) on the activities of purified recombinant tobacco Nt1 PLA₂ for various phospholipids, POPC (a, d, g), POPG (b, e, h) and POPE (c, f, i). a–c The reaction mixtures containing purified Nt1 PLA₂, 2 mM phospholipid, 6 mM sodium cholate, 100 mM NaCl, and 5 mM CaCl_2 were incubated for 60 min at 37 °C in a total volume of 100 μL . The buffers used were 50 mM Tris-maleate buffer at pH 5, 6, 7 and 8, 50 mM Tris-HCl at pH 8 and 9, and 50 mM glycine-NaOH at pH 9, 10 and 11 d–f The reaction mixtures containing purified Nt1 PLA₂, 2 mM phospholipid, 6 mM sodium cholate, 100 mM NaCl, 50 mM Tris-HCl (pH 8.0), and 1 mM EDTA or 0–40 mM CaCl_2 were incubated. g–i The reaction mixtures containing purified Nt1 PLA₂, 2 mM phospholipid, 100 mM NaCl, 50 mM Tris-HCl (pH 8.0), and various concentrations of sodium cholate. PLA₁ (open circle) and PLA₂ (closed circle) activities were measured as described in “Materials and Methods”

localized to the ER of guard cells [17]. As Nt1 PLA₂ has an ER retention-like sequence (KLEL shown in Fig. 1) at the C-terminus as well as *Arabidopsis* sPLA₂(AtsPLA₂-β), Nt1 PLA₂ is assumed to retain in the ER after processing its signal sequence by signal peptidase at the ER membrane. On the other hand, Nt2 PLA₂ is suggested to secrete into the intercellular space, because it has no ER retention like-sequence at its C-terminus. Thus, it is possible that Nt1 and Nt2 PLA₂s are localized at different subcellular organelles in tobacco tissues. The mature form of Nt1 PLA₂ has structural characteristics similar to those of other plant sPLA₂s, such as 12 Cys residues, the Ca^{2+} binding loop, and the catalytic domain. The gene of Nt1 PLA₂ encodes a functional enzyme in tobacco, because recombinant Nt1 PLA₂ is able to hydrolyze mixed-micellar phospholipid substrates. Although Nt1 PLA₂ requires Ca^{2+} for the enzyme activity as well as the other plant sPLA₂s, it is very interesting to note that Nt1 PLA₂ can hydrolyze the ester bond at the *sn*-1 position of glycerophospholipids, as well as at the *sn*-2 position. The elm and *Arabidopsis* sPLA₂s can hydrolyze only at the *sn*-2 position of

glycerophospholipids. The enzymatic characteristics of rice sPLA₂ (Rice1), which showed the highest similarity (64%) to Nt1 PLA₂, have not been investigated. High molecular mass PLA₂, patatin-like PLA₂, has both PLA₁ and PLA₂ activities [24]. However, there is no report that low molecular mass sPLA₂s have both PLA₁ and PLA₂ activities. From the similarity of the primary structures of plant sPLA₂ in the region involved in catalytic reaction, His110 of Nt1 PLA₂ (Fig. 1) is suggested to be an active site in catalysis [25]. However, because there is little information on the enzymatic characteristics of plant sPLA₂ in contrast to that of animal sPLA₂, it is difficult to explain the detailed mechanism to hydrolyze the ester bonds at both *sn*-1 and *sn*-2 positions of glycerophospholipids by Nt1 PLA₂.

The gene expression analysis of tobacco sPLA₂ to speculate on its physiological functions revealed that both Nt1 and Nt2 PLA₂ mRNAs were highly expressed in the flowers, followed by stems, roots and leaves. In carnation and *Arabidopsis*, the gene expression of sPLA₂ was induced during flower development [8, 16], suggesting that

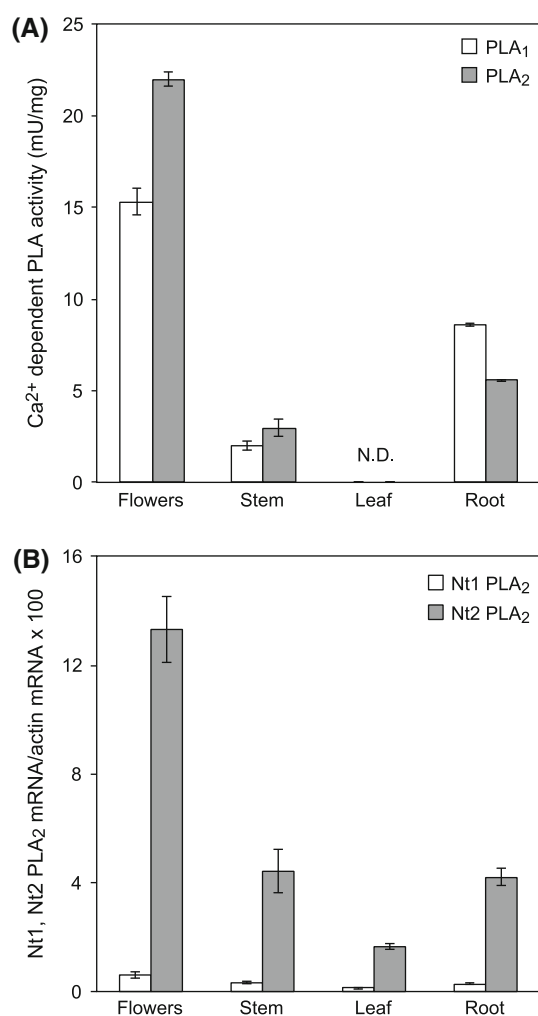

Fig. 4 Distribution of PLA activity (a), and expression (b) of Nt1 PLA₂ and Nt2 PLA₂ mRNA in the various tissues of tobacco. **a** The reaction mixture consisted of 50 mM Tris-HCl (pH 8.0), 2 mM 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine, 8 mM sodium cholate, 10 mM CaCl₂, 0.1 M NaCl in a final volume of 0.1 mL. Data were obtained in duplicate. Ca²⁺ dependent PLA₁ (open bar) and PLA₂ (closed bar) activities were determined as the activities subtracted from those of the activities from the activity assayed with 20 mM EDTA in place of 10 mM CaCl₂. ND not detected. **b** Quantitative RT-PCR analysis for expression of Nt1 PLA₂ (open bar) and Nt2 PLA₂ (closed bar) mRNA in the tobacco tissue was performed as described in “Materials and Methods”. Data were obtained in triplicate

plant sPLA₂s play important roles in flower tissues. Besides higher gene expression levels of Nt1 PLA₂ in flowers, Nt1 PLA₂ mRNA level in tobacco BY-2 cells was dramatically increased with treatment with salicylic acid (SA) [26] known as a defense signal factor by pathogen attack. Plant phospholipase is suggested to release fatty acid from membrane phospholipids for the biosynthesis of oxylipin in response to environmental stress [3, 27]. Recently, AtsPLA₂-α was demonstrated to interact with the *Arabidopsis* transcription factor, AtMYB-30, in the nucleus of the cells

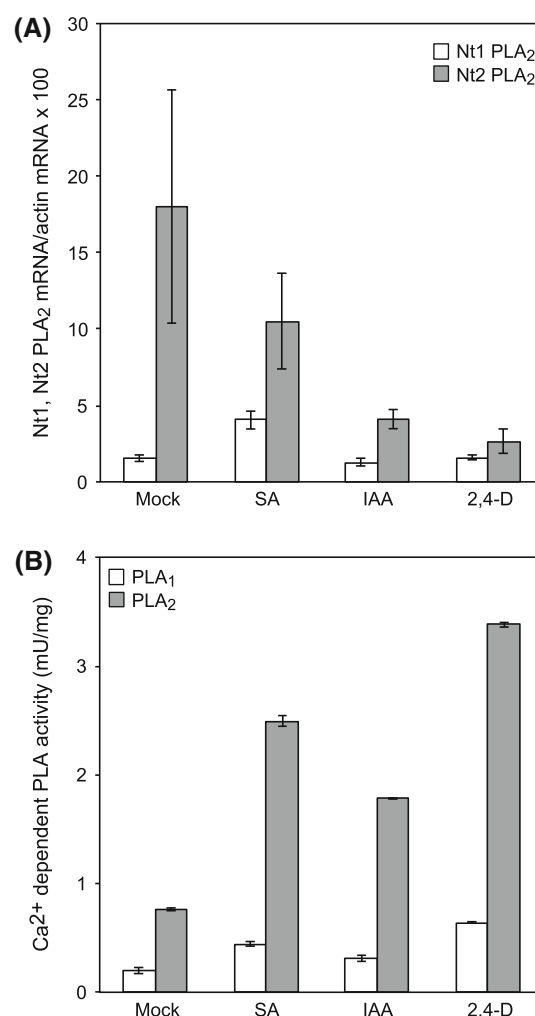

Fig. 5 Effect of various hormones, SA, IAA and 2,4-D, on PLA₁ and PLA₂ activities (a) and expression (b) of Nt1 PLA₂ and Nt2 PLA₂ mRNA in tobacco BY-2 cells. **a** PLA₁ (open bar) and PLA₂ (closed bar) activities in the crude extract were measured as described in the legend of Fig. 4. **b** Nt1 PLA₂ (open bar) and Nt2 PLA₂ (closed bar) mRNA in tobacco BY-2 cells were analyzed by quantitative RT-PCR as described in the “Materials and methods” section

adjacent to those infected by the pathogen. This indicates that AtsPLA₂-α inhibits the binding of AtMYB-30 to DNA to activate the transcription of the plant defense genes causing programmed cell death (hypersensitive response) [18]. Although the physiological function of plant sPLA₂ remains unclear at present, Nt1 PLA₂ has a possibility to be involved in the SA-related plant defense response. On the other hand, the mRNA expression levels of Nt1 PLA₂ and Nt2 PLA₂ in BY-2 cells were not increased by auxin, but Ca²⁺ dependent PLA₂ activities were increased by auxin. In *Arabidopsis*, gene expression of low molecular mass sPLA₂, AtsPLA₂-β and patatin-related high molecular mass PLA₂, AtPLA IIA, was induced by auxin [10, 28]. In the *Arabidopsis* genome, there are 4 and 10 members of low molecular mass and patatin-related high molecular

mass PLA₂s, respectively [15, 29]. So far, three PLA₂ isozymes with high molecular mass (about 46 kDa) in tobacco leaves have been reported [30]. Therefore, a marked increase in Ca²⁺-dependent PLA₂ activity should be due to the induction of the gene expression of other PLA₂ isozymes, except Nt1 and Nt2 PLA₂s, in auxin-treated tobacco cells.

In this study, a cDNA clone for a novel low molecular mass PLA₂ was isolated from tobacco flowers. The primary structures of Nt1 and Nt2 PLA₂s suggest that they are differentially localized in tobacco cells. Our results hypothesize that Nt1 and Nt2 PLA₂s play some role in flower tissues and multiple PLA₂ isozymes have some role in lipid signaling for SA and auxin responses in the tobacco plant. To resolve the above question, the gene expression in response to plant hormone treatment and pathogen attack will provide valuable information on the cellular function of Nt1 and Nt2 PLA₂s in tobacco tissues. Furthermore, transgenic plants over expressing or suppressing these PLA₂s will also provide powerful tools for investigating physiological roles of Nt1 and Nt2 PLA₂s in tobacco.

Abstract Conjugated fatty acids are regularly found in nature and have a history of biogenic activity in animals and humans. A number of these conjugated fatty acids are microbially produced and have been associated with potent anti-carcinogenic, anti-adipogenic, anti-atherosclerotic and anti-diabetogenic activities. Therefore, the identification of novel conjugated fatty acids is highly desirable. In this study, strains of bifidobacteria and propionibacteria previously shown by us and others to display linoleic acid isomerase activity were assessed for their ability to conjugate a range of other unsaturated fatty acids during fermentation. Only four, linoleic, α -linolenic, γ -linolenic and stearidonic acids, were converted to their respective conjugated isomers, conjugated linoleic acid (CLA), conjugated α -linolenic acid (CLNA), conjugated γ -linolenic acid (CGLA) and conjugated stearidonic acid (CSA), each of which contained a conjugated double bond at the 9,11 position. Of the strains assayed, *Bifidobacterium breve* DPC6330 proved the most effective conjugated fatty acid producer, bio-converting 70% of the linoleic acid to CLA, 90% of the α -linolenic acid to CLNA, 17% of the γ -linolenic acid to CGLA, and 28% of the stearidonic acid to CSA at a substrate concentration of 0.3 mg mL⁻¹. In conclusion, strains of bifidobacteria and propionibacteria can bio-convert linoleic, α -linolenic,

γ -linolenic and stearidonic acids to their conjugated isomers via the activity of the enzyme linoleic acid isomerase. These conjugated fatty acids may offer the combined health promoting properties of conjugated fatty acids such as CLA and CLNA, along with those of the unsaturated fatty acids from which they are formed.

one or more conjugated double bonds. These conjugated isomers are commonly found in nature, being detected in the milkfat and tallow of ruminant animals [1, 2], plant seed oils [3–6] and marine algae [7–10]. In addition, conjugated fatty acids may be formed chemically via the alkaline isomerisation of unsaturated fatty acids [11, 12]. Of these natural and synthetic fatty acids, the conjugated linoleic acid (CLA) isomers are the best characterised. These fatty acids have been demonstrated to exhibit a range of potentially health-promoting properties, including anti-atherosclerotic, anti-obesogenic and anti-diabetogenic activities; however, it is the anti-carcinogenic properties which are most extensively reported [13, 14]. In addition to CLA isomers, other conjugated fatty acids have been shown to exhibit biological activities with relevance to human health. Indeed, naturally occurring CLNA isomers traditionally found in plant seed oils and in ruminant fats have been reported to exhibit anti-carcinogenic and anti-obese activities [15–18]. Other synthetically produced conjugated isomers, such as conjugated eicosadienoic acids (C20:2) and conjugated eicosatrienoic acids (C20:3) have been associated with body fat reduction and increased lean mass [12]. Conjugated eicosapentaenoic acids (C20:5) have been reported to exhibit anti-carcinogenic activity, and conjugated docosahexaenoic acids (C22:6) to exert anti-carcinogenic and anti-adipogenic activity [11, 19–22]. The mechanisms of action of conjugated fatty acids are reported to be either via competitive inhibition during the metabolism of proinflammatory n-6 fatty acids to eicosanoids, via increased cellular lipid peroxidation, or at the genetic level via their impact on the expression of cell cycle arrest regulators, transcription factors, and key metabolic enzymes (for reviews see [13, 14, 17]). Given the extent and significance of the health promoting biological activities associated with conjugated fatty acids, economic strategies for their production are highly desirable.

The potency of conjugated fatty acids has prompted increased research into their identification and economic production [23, 24]. These investigations have highlighted in particular the ability of a range of microbes to produce CLA [25, 26]. Indeed, it has been reported that dairy propionibacteria and intestinally isolated bifidobacteria possess the ability to conjugate the *c*9,*c*12 double bond of linoleic acid (C18:2) yielding the *c*9,*t*11-C18:2 and *t*9,*t*11-C18:2 CLA isomers, via the action of the enzyme linoleic acid isomerase [27–29]. Furthermore, recent in vitro evidence has highlighted the ability of strains of bifidobacteria to produce the *c*9,*t*11,*c*15-C18:3 CLNA isomer from free α -linolenic acid, and of *Lactobacillus plantarum* AKU 1009a to produce conjugated γ -linolenic acid (CGLA) from free γ -linolenic acid [16, 30]. These observations demonstrate the potential of CLA producing bacteria to conjugate a range of PUFA. Similar to CLA, the ability of

propionibacteria and bifidobacteria to produce novel conjugated fatty acids may be used to enrich milk and yoghurt with conjugated fatty acids through fermentation, or the establishment of microbiota in the human gastrointestinal tract (GIT) capable of producing these fatty acids in situ. Indeed, further credence is given to this theory in light of the recent evidence pertaining to the ex vivo production of CLA by intestinally isolated strains of lactobacilli and bifidobacteria reported by Ewaschuk et al. [31] and our studies on in vivo production of CLA by bifidobacteria from dietary linoleic acid in mice [32].

The aims of this study were (1) to assess the ability of strains of bifidobacteria and propionibacteria previously shown by us to conjugate linoleic acid to CLA to bioconvert a range of PUFA during fermentation [27–29, 33], and (2) to identify and characterise any novel microbially produced conjugated fatty acids.

Materials and Methods

Bacterial Strains and Fatty Acid Substrates

The strains of *Bifidobacterium* and *Propionibacterium* used in this study are listed in Table 1, and were selected based on their ability to bioconvert linoleic acid (*c*9,*c*12-C18:2) to the *c*9,*t*11 CLA isomer [27–29]. All strains were grown in DeMan-Rogosa-Sharpe (MRS) medium (Difco, Detroit, MI, USA) containing 0.05 mg mL⁻¹ L-cysteine hydrochloride (Sigma Aldrich., St Louis, MO, USA) (cys-MRS) under anaerobic conditions (Anaerocult A Gas Packs (78% N₂, 18% CO₂, 4% Other), Merck, Darmstadt, Germany) at 37 °C for 18 h. Where solid media was required, 1.5% (wt/vol) bacteriological agar (Oxoid, Basingstoke, Hampshire, UK) was added to the cys-MRS medium. Cell counts were determined by serial dilutions and plating using cys-MRS agar.

All fatty acid substrates were of the highest purity (Table 2) and were delivered to the growth medium in the form of a 30 mg mL⁻¹ stock solution containing 2% (wt/vol) Tween 80 (Merck-Schuchardt, Hohenbrunn, Germany). To ensure sterility, all substrates were filter sterilized through a 0.45 μ m Ministart filter (Sartorius AG, Goettingen, Germany).

Microbial Conjugated Fatty Acid Production

A 4% (vol/vol) inoculum of the activated culture was added to 10 mL cys-MRS medium containing 0.45 mg mL⁻¹ [exceptions being 0.15 mg mL⁻¹ for eicosapentaenoic acid (EPA), and stearidonic acid] of the respective unsaturated fatty acid substrates and incubated anaerobically (Anaerocult A, Merck) at 37 °C (bifidobacteria) or 30 °C

(propionibacteria) for 72 h with regular spectrophotometric monitoring of conjugate production (6, 12, 24, 48, and 72 h) [29]. Fatty acids were extracted from 4 mL of the fermentation medium using 2 mL of 2-propanol (Fisher Scientific Ltd, Dublin, Ireland) and 4 mL of *n*-hexane (Fisher Scientific Ltd), as described by Coakley et al. [27]. Following extraction, the *n*-hexane was removed by heating under N₂, and the extracted fatty acids converted to fatty acid methyl esters (FAME) by acid catalyzed methylation with 12 mL of 4% (vol/vol) methanolic-HCl for 10 min under nitrogen at ambient temperature, followed by extraction with 4 mL *n*-hexane. Gas liquid chromatography (GLC) was used to separate FAME using a CP-SELECT CB column (100 m \times 0.25 mm id \times 0.25 μ m film thickness, Varian BV, Middelburgh, The Netherlands) and Varian 3400 Capillary GC (Varian, Walnut Creek, CA, USA) fitted with a flame ionization detector (FID) as described by Coakley

et al. [27]. The presence of a conjugated double bond was confirmed spectrophotometrically, using a modification of the method of Barrett et al. [29] using FAME rather than free fatty acids. Briefly, 200 μ L of the methylated sample, prepared as described above, was dispensed into a UV transparent 96 well plate (Costar, Corning NY) and the absorbance of UV light at a wavelength of 234 nm measured using a 96 well plate spectrophotometer (GENios Plus, Medford, MA). All experiments were performed in triplicate. Conjugated fatty acid production was expressed as mg mL⁻¹ and percentage bioconversion, the latter calculated by:

$$\text{Cc/Sc} \times 100 = \% \text{ bioconversion}$$

Sc = Substrate concentration prior to fermentation.

Cc = Conjugated fatty acid concentration following fermentation

Purification and Identification of Microbially Produced Conjugated Fatty Acids

Total fatty acids extracted using the method of Coakley et al. [27] were partially concentrated using a rotary evaporator (<50 °C) (Buchi Rotavapor R-210) and washed once with 0.88% (wt/vol) KCl and twice with water/methanol (1:1, vol/vol). The hexane was then evaporated by heating at 45 °C under a steady flow of nitrogen. The remaining lipid was resuspended at a concentration of 100 mg mL⁻¹ in acetonitrile/acetate (100:0.14, vol/vol), and stored at -20 °C under nitrogen until use. The conjugated fatty acids were isolated using RP-HPLC on a Luna 5 μ C18 (2) 100A preparative column (250 mm \times 21.20 mm) (Phenomenex, Macclesfield, Cheshire, UK) and the Varian Prostar HPLC system (Varian). The mobile phase used to obtain optimal separation was acetonitrile/water/acetate (70:30:0.12, vol/vol) at a flow rate of 10 mL min⁻¹. Conjugated fatty acids were detected using a diode array detector (DAD) at an absorbance of 234 nm. Fractions containing the conjugated fatty acids were collected and pooled. Following removal of the acetonitrile from the pooled fractions by rotary evaporation (<50 °C), the conjugated fatty acids were re-extracted as described above. Fatty acid compositions of the pure oils were confirmed by GLC as previously described [27]. Conjugated fatty acids were identified by Mylnefield Lipid Analysis (Dundee, Scotland) by the preparation and analysis of FAME, 4,4-dimethyloxazoline (DMOX), 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) and/or pyrrolidide derivatives by GLC-mass spectrometry (GLC-MS) [34].

Following, their identification by GC-MS, samples of the purified oils produced by *B. breve* DPC6330 were used as GLC standards to identify similar conjugated fatty acids produced by the additional strains of bifidobacteria and propionibacteria assayed. The methylation was conducted as described above, while the GLC conditions were as described by Coakley et al. [27].

CLNA, CGLA and CSA Production by *B. breve* DPC6330

During the initial assessment of the strains for conjugated fatty acid production *B. breve* DPC6330 proved most efficient in terms of the bio-production of conjugated fatty acids from linoleic, α -linolenic, γ -linolenic and stearidonic acid. Subsequently, to determine the impact of substrate fatty acid concentration on conjugated fatty acid production, *B. breve* DPC6330 was incubated anaerobically for 72 h at 37 °C in the presence of linoleic acid, α -linolenic acid (Sigma Aldrich), γ -linolenic acid (Nu-Chek Prep, Elysian, MN) or stearidonic acid (Cayman Europe, Akadeemia tee, Tallinn, Estonia) at concentrations of 0.15,

0.3 and 0.45 mg mL⁻¹ ($n = 3$). To determine the time course of CLNA, CGLA and conjugated stearidonic acid (CSA) production by *B. breve* DPC6330, 16 individual fermentations (10 mL volumes) were set up in triplicate for each fatty acid at a substrate fatty acid concentration of 0.3 mg mL⁻¹. At 16 different time points, over the 80-h fermentation period, triplicate aliquots were removed and assessed for bacterial cell numbers by serial dilution and plating using cys-MRS agar and for fatty acid composition by GLC following extraction and methylation of lipids.

Results

Conjugated Fatty Acid Production by Bifidobacteria and Propionibacteria

The performance of the intestinally isolated bifidobacteria and dairy propionibacteria when exposed to 0.45 mg mL⁻¹ of the respective PUFA (0.15 mg mL⁻¹ of EPA or stearidonic acid) was visually observed to be strong (Table 3). Using GLC and UV spectrophotometric analysis, it was determined that four of the PUFA substrates were microbially bioconverted to their respective conjugated fatty acid isomers (Table 4). These fatty acid substrates were linoleic, α -linolenic, γ -linolenic and stearidonic acids, all of which contained the *c*9,*c*12 double bond. The production of the *c*9,*t*11 and *t*9,*t*11 CLA isomers from linoleic acid by the strains of bifidobacteria and propionibacteria was confirmed using GLC and a range of commercial CLA standards (Matreya LLC, PA), while the conjugated fatty acids derived from α -linolenic, γ -linolenic and stearidonic acids were identified by GLC-MS.

Identification of Microbially Produced Conjugated Fatty Acids

The predominant conjugated fatty acid isomer produced by the strains of bifidobacteria and propionibacteria from free α -linolenic acid was identified as 9,11,15-C18:3 (CLNA1). The mass spectrum derived from the FAME confirmed the molecular weight as 278 (Fig. 1a), while the mass spectrum of its DMOX derivative identified the molecule as the 9,11,15-C18:3 isomer (Fig. 1b). Further confirmation of the structure was achieved by the comparison of the DMOX spectra of this fatty acid with that of CLNA1 identified by both Destailats et al. [18] and Winkler and Steinhart [35].

The predominant conjugated fatty acid isomer produced by the strains of bifidobacteria and propionibacteria from free γ -linolenic acid was identified as 6,9,11-C18:3 (CGLA1). The mass spectrum of the FAME confirmed the molecular weight as 278 (Fig. 2a). However, due to the

migration of the 9,11-double bond system to the 8,10-position during the DMOX derivatization process (Fig. 2b) MTAD and pyrrolidide derivatizations were also employed in the identification of the molecule. The mass spectrum of the MTAD derivative, with the ion at $m/z = 250$, confirmed that the fatty acid possessed a conjugated double bond in the 9,11-position, with the third double bond located on the carboxyl side of the conjugated double bond (Fig. 2c) [36]. Pyrrolidide derivatization with the fingerprint of ions at $m/z = 140$, $m/z = 154$ and $m/z = 166$ characterised the position of a double bond in position-6 of the carbon chain (Fig. 2d) [37].

The predominant conjugated fatty acid isomer produced by strains of bifidobacteria and propionibacteria from stearidonic acid was identified as 6,9,11,15-C18:4 (CSA1). The mass spectrum of the FAME confirmed the molecular weight as 276 (Fig. 3a). Once again, DMOX derivatization of the fatty acid resulted in the migration of the 9,11-double bond system to the 8,10-position (Fig. 3b). The spectrum produced for the MTAD derivative, with the base ion now at $m/z = 248$, confirmed the presence of a conjugated double bond in the 9,11-position, along with the presence of a double bond on either side of this (Fig. 3c). Although the use of DMOX derivatives did not allow the identification of

the position of the first three double bonds, a double bond at position-15 of the carbon backbone was confirmed by the presence of a gap of 12 amu between $m/z = 274$ and $m/z = 286$ (Fig. 3b). The mass spectrum observed with the pyrrolidide derivative of this fatty acid confirmed the presence of a double bond at position-6 (Fig. 3d).

Using GLC-MS analysis, it was not possible to determine the double bond conformation of CLNA1, CGLA1 and CSA1. However, given the specificity of the enzyme linoleic acid isomerase for the conjugation of c9,c12 double bond to the c9,t11 bond conformation, the most probable bond conformation for CLNA1 is c9,t11,c15-C18:3, while that of CGLA1 and CSA1 are likely to be c6,c9,t11-C18:3 and c6,c9,t11,c15-C18:4, respectively [27, 28]. This prediction is supported by the studies of Ogawa et al. [24] and Kishino et al. [38] who successfully identified the production of c9,t11,c15-C18:3 (CLNA1) and c6,c9,t11-C18:3 (CGLA1) from free α -linolenic acid and γ -linolenic acid, respectively, by strains of lactobacilli exhibiting linoleic acid isomerase activity.

In addition to the production of CLNA1, CGLA1 and CSA1 by the strains of bifidobacteria and propionibacteria, a second conjugated isomer was also produced from α -linolenic acid, γ -linolenic acid and stearidonic acid,

Production of Conjugated Fatty Acids by *B. breve* DPC6330

Of the strains assayed in the present study, *B. breve* DPC6330 was the most effective in terms of ability to

convert linoleic, α -linolenic, γ -linolenic and stearidonic acids to their respective conjugated isomers (Table 4). Consequently, this strain was selected for further studies to assess the impact of incrementally increasing the concentration of substrate fatty acids on the production of the

Fig. 4 GLC profiles of *B. breve* DPC6330 grown in cys-MRS containing 0.3 mg mL⁻¹ of the PUFA **a** α -linolenic acid, **b** γ -linolenic acid and **c** stearidonic acid, following 80 h anaerobic incubation. 1 Stearic acid, 2 Vaccenic acid, 3 Oleic acid, 4 α -linolenic acid, 5 CLNA1, 6 CLNA2, 7 γ -linolenic acid, 8 CGLA1, 9 CGLA2, 10 Stearidonic acid, 11 CSA1, 12 CSA2

conjugated fatty acid isomers CLNA, CGLA and CSA, as well as to assess the time-scale of conjugated fatty acid production.

Increasing the concentration of the substrate α -linolenic acid from 0.15 to 0.45 mg mL⁻¹ resulted in an increase in the concentration of CLNA1 and the putative CLNA2 isomers following 72 h incubation (Table 5). However, the effect of increasing substrate concentration on the percentage bioconversion of α -linolenic acid to CLNA was less profound (Table 5). In an attempt to elucidate the time-scale for the production of both CLNA1 and the putative CLNA2 isomers by *B. breve* DPC6330, growth and CLNA

production by the strain was monitored over 80 h in cys-MRS containing 0.3 mg mL⁻¹ α -linolenic acid ($n = 3$) (Fig. 5). Following the initial inoculation at 8.0 log cfu mL⁻¹, production of both the CLNA1 and putative CLNA2 isomers corresponded with a 16-h period of logarithmic growth by the strain (0–0.292 mg mL⁻¹ CLNA 1, and 0–0.016 mg mL⁻¹ CLNA 2, respectively) (Fig. 5).

Increasing the concentration of the substrate γ -linolenic acid from 0.15 to 0.45 mg mL⁻¹ resulted in subsequent increases in the total concentration of the CGLA1 isomer produced by *B. breve* DPC6330, but a decrease in the percentage bioconversion of γ -linolenic acid to CGLA1

Table 5 Effect of substrate concentration on the production of conjugated fatty acids CLNA, CGLA and CSA and the concentration of residual substrate following 72 h anaerobic fermentation

was obtained (Table 5). Increasing the concentration of the substrate γ -linolenic acid from 0.15 to 0.45 mg mL⁻¹ did not increase the concentration of γ -linolenic acid bioconverted to the putative CGLA2 isomer (Table 5). Growth and CGLA production by *B. breve* DPC6330 was monitored over 80 h in cys-MRS containing 0.3 mg mL⁻¹ γ -linolenic acid ($n = 3$) (Fig. 5). Conjugated fatty acid production occurred during a 16-h period of logarithmic growth by *B. breve* DPC6330 (Fig. 5). This resulted in CGLA1 concentrations increasing from 0 to 0.035 mg mL⁻¹ during this period.

When the concentration of substrate stearidonic acid was increased from 0.15 to 0.3 mg mL⁻¹, a subsequent increase in the concentration of CSA1 produced by *B. breve* DPC6330 was observed along with a small increase in the concentration of the putative CSA2 isomer (Table 5). Increasing the substrate concentration from 0.15 to 0.3 mg mL⁻¹ resulted in a 2.64% increase in the percentage bioconversion of stearidonic acid to CSA1, and a 0.55% decrease in the percentage bioconversion of stearidonic acid to the putative CSA2 isomer (Table 5). At a stearidonic acid concentration of 0.45 mg mL⁻¹, growth of *B. breve* DPC6330 was completely inhibited and neither CSA isomer was produced (Table 5). CSA production by *B. breve* DPC6330 from stearidonic acid was characterised over an 80 h-period in cys-MRS containing 0.3 mg mL⁻¹ of stearidonic acid ($n = 3$) (Fig. 5), and it was observed that following 3 h exposure to stearidonic acid the viability of the strain declined steadily (by 3.83 log cfu mL⁻¹

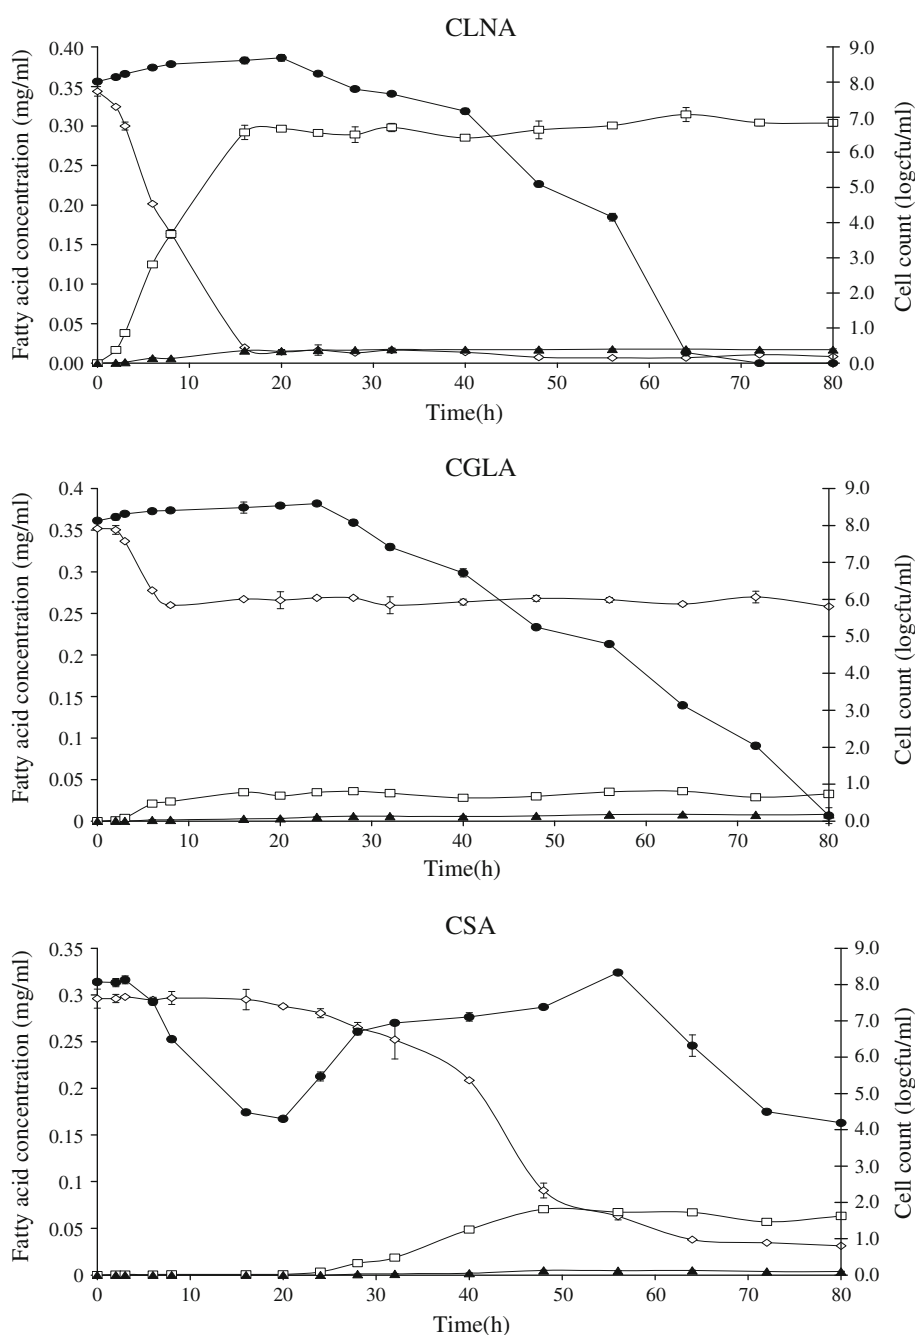

following 20 h) (Fig. 5). Subsequently, following this time an increase in cell numbers was observed from 4.30 to 6.70 log cfu mL⁻¹ during which time the production of both CSA1 and the putative CSA2 isomer was observed (Fig. 5).

We assessed the substrate preference of *B. breve* DPC6330 to isomerise the C18 unsaturated fatty acids linoleic acid, α -linolenic acid, γ -linolenic acid and stearidonic acid (0.3 mg mL⁻¹) to CLA, CLNA1, CGLA1 and CSA1 over an 80-h fermentation period, relative to the percentage bioconversion of linoleic acid to the *c*9,*t*11 CLA isomer which was set at 100% (Table 5). We found that *B. breve* DPC6330 has a preference for the conjugation of C18 fatty acid substrates in the order: α -linolenic acid (130%) > linoleic acid (100%) > stearidonic acid (27%) > γ -linolenic acid (14%).

Discussion

In this study, we report that certain strains of bifidobacteria and propionibacteria possess the ability to bioconvert substrate fatty acids containing a *c*9,*c*12 double bond to their conjugated isomers. Two conjugated fatty acids products were produced by most strains from each unconjugated fatty acid substrate, which were believed to share equivalence with the *c*9,*t*11 CLA and *t*9,*t*11 CLA isomers produced by certain bifidobacteria and propionibacteria from linoleic acid, although the latter isomer has

Fig. 5 Growth and CLNA/CGLA/CSA production by *B. breve* DPC6330 over 80 h in the presence of 0.3 mg mL^{-1} α -linolenic acid/ γ -linolenic acid/stearidonic acid. CLNA1/CGLA1/CSA1 (squares), CLNA2/CGLA/CSA2 (filled triangles), α -linolenic acid/ γ -linolenic acid/stearidonic acid (diamonds) and log cfu/ml (filled circles)

also been known to be produced from *c9,t11* CLA under methylation conditions [23, 27, 28]. GLC-MS confirmed that the strains used in the present study catalysed the bioconversion of the *c9,c12* double bond of the substrate fatty acids linoleic, α -linolenic, γ -linolenic and stearidonic acids, to the conjugated 9,11-double bond form via linoleic acid isomerase activity. These observations correspond with the findings of others who identified the production of CLNA1 and CGLA1 by *Lactobacillus* strains via the activity of the enzyme linoleic acid isomerase [24, 38]. In these studies, the bond conformation of CLNA1 was

identified as *c9,t11,c15*-C18:3, with that of CGLA1 determined to be *c6,c9,t11*-C18:3 [18, 24, 38].

The extent to which α -linolenic, γ -linolenic and stearidonic acids were bioconverted to their respective conjugated fatty acid isomers differed substantially between the strains and among the fatty acid substrates used in the present study. Differences in the extent to which bacterial strains conjugated linoleic acid to CLA have been reported with some regularity and attributed to variations in the toxicity of the substrate fatty acids to the strains [26–29], but may also be a result of the bond position of the substrate fatty acids [39].

Increasing the concentration of the substrate fatty acid resulted in increased conjugated fatty acid production by *B. breve* DPC6330, but also to increased residual substrate concentrations. These observations may be, respectively, attributed to the increased availability of substrate fatty acid, and to the substrate concentration exceeding the isomerising capacity of the growing culture [28, 40, 41].

Of the strains assayed, *B. breve* DPC6330 was most efficient in terms of the bio-production of conjugated fatty acids from linoleic, α -linolenic, γ -linolenic and stearidonic acid with results suggesting a higher affinity of the strain to conjugate α -linolenic acid than γ -linolenic acid. Although stearidonic acid substantially inhibited the growth of *B. breve* DPC6330, CSA production from stearidonic acid exceeded CGLA production from γ -linolenic acid at a substrate fatty acid concentration of 0.3 mg mL^{-1} . The inhibition of bacterial growth by stearidonic acid is likely related to the ability of certain fatty acids to disrupt cell membrane composition and cell energetics [42–44]. However, when the conjugation of linoleic, α -linolenic, γ -linolenic, and stearidonic acids by the strain were viewed together, it was apparent that the presence of an additional double bond towards the distal end of the fatty acid molecule (e.g. α -linolenic acid) encouraged conjugation by the strain, while the addition of a double bond between the carboxyl group and the *c*9,*c*12 double bond (e.g. γ -linolenic acid) discouraged conjugation of the double bond.

In this study, we found that in particular, when γ -linolenic acid and stearidonic acid were provided as fatty acid substrate to *B. breve* DPC6330 the sum of the concentration of conjugated fatty acids produced and residual substrate following fermentation was not equivalent to the quantity of substrate initially provided. Although it would require the use of labelled fatty acids to discern the exact fate of this missing substrate, it is likely that this difference is attributable to bifidobacterial metabolic activity [45–47].

Overall, this study has demonstrated the ability of strains of certain commensal bifidobacteria and dairy propionibacteria to produce a range of novel conjugated fatty acids from PUFA containing the *c*9,*c*12 double bond system. If bioactive in vivo, the production of such conjugated fatty acids by commensals and potential probiotics offers a valuable strategy for the production and delivery of these novel conjugated fatty acids to the GIT [25, 48–50]. Furthermore, the production of conjugated fatty acids such as CLNA1, CGLA1 and CSA1 by potentially probiotic bifidobacteria may present a valuable strategy for the in situ production of bioactive molecules in the human GIT. As the substrate fatty acids can be found in the human diet, it is not unreasonable to assume their in vivo production occurs [51–53]. Indeed, further credence is given to this theory in light of the evidence pertaining to the ex vivo and in vivo production of CLA from linoleic acid [31, 32].

Acknowledgments We would like to thank Seamus Aherne and Lina Cordeddu for their technical assistance. The assistance with GLC-MS by Mylnefield Lipid Analysis is gratefully acknowledged. A. A. Hennessy is in receipt of a Teagasc Walsh Fellowship. This research was funded by EU project QLK1-2001-02362 and by Alimentary Pharmabiotic Centre (APC).

Abstract Commercial fish oils and foods containing fish may contain *trans* and/or isomerized fatty acids (FA) produced during processing or as part of prepared foods. The current American Oil Chemists' Society (AOCS) official method for marine oils (method Ce 1i-07) is based on separation by use of poly(ethylene glycol) (PEG) columns, for example Supelcowax-10 or equivalent, which do not resolve most unsaturated FA geometric isomers. Highly polar 100-m cyanopropyl siloxane (CPS) columns, for example SP-2560 and CP Sil 88 are recommended for separation of geometric FA isomers. Complementary separations were achieved by use of two different elution temperature programs with the same CPS column. This study is the first direct comparison of the separations achieved by use of 30-m Supelcowax-10 and 100-m SP-2560 columns for fatty acid methyl esters (FAME) prepared from the same fish oil and fish muscle sample. To simplify the identification of the FA in these fish samples, FA were fractionated on the basis of the number and type of double bonds by silver-ion solid-phase extraction (Ag^+ -SPE) before GC analysis. The results showed that a

combination of the three GC separations was necessary to resolve and identify most of the unsaturated FA, FA isomers, and other components of fish products, for example phytanic and phytenic acids. Equivalent chain length (ECL) values of most FAME in fish were calculated from the separations achieved by use of both GC columns; the values obtained were shown to be consistent with previously reported values for the Supelcowax-10 column. ECL values were also calculated for the FA separated on the SP-2560 column. The calculated ECL values were equally valid under isothermal and temperature-programmed elution GC conditions, and were valuable for confirmation of the identity of several unsaturated FAME in the fish samples. When analyzing commercially prepared fish foods, deodorized marine oils, or foods fortified with marine oils it is strongly recommended that quantitative data acquired by use of PEG columns is complemented with data obtained from separations using highly polar CPS columns.

Introduction

The nutritional value of the long-chain n-3 polyunsaturated fatty acids (LC n-3 PUFA) in marine oils and products prepared from fish is well recognized [1], in large part because of humans' low capacity to bioconvert linolenic acid (18:3n-3) into the highly unsaturated n-3 metabolites [2]. For this reason increased consumption of LC n-3 PUFA is recommended to improve the health of infants, nursing mothers [3], and other adults [4]. The fatty acids (FA) in marine oils are usually determined by gas chromatography (GC) after their conversion to fatty acid methyl esters (FAME). The latest official method of analysis of saturated FA, *cis*-monounsaturated fatty acids (MUFA), and *cis*-PUFA in marine and other oils (method Ce 1i-07) was approved by the American Oil Chemists' Society (AOCS) in 2007 [5]. It recommended the use of 30-m fused silica capillary columns coated with poly(ethylene glycol) (PEG) phases [5]. These GC stationary phases separate FAME primarily on the basis of chain length, then on the basis of the number of double bonds and their position [6–9]. However, PEG-coated GC columns are not suitable for separation of the geometric isomers and unsaturated FA commonly occurring in natural products including fish oils [8, 10].

Formation of positional and *trans* isomers from naturally occurring all-*cis* unsaturated FA is difficult to avoid during most domestic or commercial preparation of fish [11, 12], deodorization of fish oils [13–17], preparation and storage of infant formulas supplemented with docosahexaenoic (DHA; 22:6n-3) and arachidonic (20:4n-6) acids [18], or commercial production of enriched n-3 PUFA supplements [19]. Separation and identification of the *trans* isomers of LC n-3 PUFA contained in marine oils or foods, or processed foods containing fish, requires the use of 100-m highly polar 100% cyanopropyl siloxane (CPS) columns [13–16]. Many of the unsaturated FA with one or more *trans* double bonds coelute with their all-*cis* isomers when separated on PEG-coated columns [10], which could lead to overestimation of the all-*cis* LC n-3 PUFA content of fish products. This observation was recently confirmed when Fourier transform near-infrared (FT-NIR) spectroscopy was evaluated as an alternative method for LC n-3

PUFA determination [20]. FT-NIR quantification based on calibrated data acquired with a PEG column overestimated the amount of the all-*cis* LC n-3 PUFA compared with FT-NIR quantification based on calibration data obtained by use of a 100-m highly polar CPS column. In addition, the 30-m PEG column was unable to separate, and enable quantification of, the *trans* 18:1 isomers contained in the fish oil supplements [20].

For this reason there seems to be a need to combine the results obtained by use of a PEG column, that makes identification of PUFA easier [7, 8], and by use of a highly polar CPS column, that is able to resolve, and enable identification of, geometric FA isomers [18, 21–24]. Comparison of the separation of the same fish oil and fish muscle samples on a 30-m PEG column and a 100-m CPS column has not been reported. Mjøs [25] compared separation of the geometric isomers of eicosapentaenoic acid (EPA) and DHA on a 50-m PEG column (BP-20; SGE, Ringwood, Australia) with that on a 60-m BPX-70 column that has only 70% the polarity of a CPS column [26], and he only compared the immediate EPA and DHA chromatographic regions.

Equivalent chain length (ECL) calculations have been used to describe the relative elution of FA on specific columns [7–9, 27, 28]. However, a summary of ECL values for the FA identified in fish oils using the GC columns recommended for marine oil analysis [5] and the CPS GC columns recommended for *trans* FA analysis [29] is not available. A summary of the ECL of many PUFA found in fish oil obtained by use of a BPX-70 column can be found at http://www.chrombox.org/data/class_fame/ECL-kart%20BPX-03.pdf. However, because the polarity of the BPX-70 column is only 70% that of CPS columns (for example SP-2560), this means that, even though the elution sequence within a group of FAME of similar structure will be comparable, because of the higher polarity, the relative elution pattern between the FAME groups will be different. For instance, on a BPX-70 column the saturated FAME 20:0 elutes just before the conjugated linoleic acid (CLA) isomers and most 20:1 isomers coelute among the CLA isomers (same web site); on a CPS column, however, all the 20:1 isomers elute before the CLA isomers [10].

In this study we compared separations of the FAME prepared from menhaden oil and from a fish muscle lipid extract on a 30-m Supelcowax-10 and a 100-m SP-2560 capillary column. Complementary silver-ion solid-phase extraction (Ag⁺-SPE) was conducted as described elsewhere [24] to confirm the identity of unsaturated FA on the basis of their chain length, double bond number and position, and geometric configuration in the fish products. To obtain further support for their identities the ECL values of all separated FAME on both GC columns were calculated from their retention times.

Materials and Methods

All chemicals and solvents (hexane, acetone, methanol, and acetonitrile) were of analytical grade, and all gases used in the GC operations were of the highest purity.

Standards

Pure FAME reference materials and reference mixtures were purchased from Nu-Chek Prep (Elysian, MN, USA). Commercial GC reference mixtures (#463 and #674) were spiked with a mixture of four positional CLA isomers (#UC-59M) and long-chain saturated FAME 21:0 and 23:0. Menhaden fish oil analytical standard (#47116), 0.5 N methanolic base (#33080), and Discovery Ag⁺-Ion SPE tubes (#54225-U, 750 mg/6 ml) were purchased from Supelco (Bellefonte, PA, USA). Several PUFA standards (16:2n-4, 16:3n-3, 18:4n-3, 20:4n-3, 21:5n-3, and 22:5n-6) were purchased from Larodan Fine Chemical (Malmö, Sweden). A sample of fresh gilthead sea bream (*Sparus aurata*) tissue was obtained from a local fish farm and stored frozen at −80 °C until analyzed. A sample of the diet fed was also analyzed.

Sample Preparation

The sample of fresh gilthead sea bream (*Sparus aurata*) tissue was divided into five portions of approximately 5 g each and freeze-dried (lyophilized). The lipids were extracted by use of a modification of the Bligh and Dyer procedure as described by Cruz-Hernandez et al. [23]. All extracts from fish samples were methylated by use of 0.5 N methanolic base (#33080; Supelco) as described elsewhere [23]. In addition, the total lipids extracted from fish muscle were fractionated by use of silver-ion solid-phase extraction (Ag⁺-SPE) cartridges as described elsewhere [24] (see below).

Ag⁺-SPE Fractionation

Ag⁺-SPE cartridges (750 mg/6 mL) were conditioned with 4 mL acetone, to remove any moisture, then with 4 mL hexane. One milliliter of total lipid FAME prepared from fish muscle was dissolved in hexane and loaded on to the Ag⁺-SPE tube. The FAME were eluted with consecutive 6 mL volumes of hexane containing increasing amounts of acetone [24]. One percent acetone in hexane eluted saturated FAME (Fraction 1; F1), 4% acetone eluted mono-*trans* FAME plus the *t/t*-CLA (F2), 10% acetone eluted mono-*cis* FAME plus the *c,t/t,c*-CLA (F3), and 100% acetone eluted dienoic FAME (F4). This was followed by 3% acetonitrile in acetone to elute trienoic FAME (F5), 6% acetonitrile in acetone to elute tetraenoic FAME (F6), and 100% methanol to elute most of the remaining unsaturated

FAME (F7). All fractions were evaporated to dryness in a stream of N₂ and reconstituted in appropriate volumes of hexane before GC analysis.

Gas Chromatography

Samples were analyzed by use of an Agilent 7890A gas chromatograph (Agilent Technologies, Wilmington, DE, USA) equipped with two FID detectors, two split/splitless injection ports, and an autosampler. The system was controlled by the Agilent ChemStation (Version B.04.02) chromatography manager. A Supelco SP-2560 GC column (100 m × 0.25 mm internal diameter × 0.20 μm film thickness) was installed on one injection port, and a Supelcowax-10 (30 m × 0.25 mm internal diameter × 0.25 μm film thickness) on the other. The carrier gas was H₂, the injection volume was 1 μL (equivalent to approximately 1–2 μg FAME). The split ratio was set to 100:1 for the GC standards and test samples, and to 20:1 for the Ag⁺-SPE fractions. Further details of the two GC columns and the chromatographic conditions are reported in Table 1. When utilizing the SP-2560 GC column, two different temperature programs denoted 175 and 150 °C (on the basis of their plateau temperatures) were used to separate co-eluting FAME [24, 26]. Monounsaturated FA and non-methylene interrupted (NMI) PUFA were designated by use of the Δ nomenclature, i.e., 9c-18:1. FA with two or more methylene-interrupted double bonds were designated by use of the n-notation, i.e., 18:2n-6.

Results

The GC separations of the FAME prepared from the menhaden oil analytical standard (#47116, Supelco) and from the fish muscle (gilthead sea bream, *Sparus aurata*) by use of the SP-2560 GC and Supelcowax-10 columns are shown in Figs. 1 to 4. In each figure the upper panel (a) shows the separation obtained by use of the SP-2560 column and the elution temperature with plateau at 175 °C, the middle panel (b) shows the separation obtained by use of the SP-2560 column and the plateau at 150 °C, and the lowest panel (c) shows the separation obtained by use of the Supelcowax-10 column. In each panel the chromatograms show separations of menhaden oil (MO) and/or of fish muscle (FM) FAME, followed by the FAME contained in selected Ag⁺-SPE fractions from fish muscle (F1–F7), and, at the bottom, GC reference mixture #463 or #674. The GC separations were divided into Figs. 1 to 4 on the basis of the elution principle of PEG columns in which all unsaturated FA of chain length *x* elute between the retention time of the saturated FAME C_{*x*}:0 and the saturated FAME (C_{*x+2*}):0. Figure 1 shows the separation segment of

^a Conditions were essentially the same as described elsewhere [24]

^b Conditions were essentially the same as recommended in the official AOCS method (Ce 1i-07) for marine oil analysis [5]

FAME from 16:0 to 18:0, Fig. 2 from 18:0 to 20:0, Fig. 3 from 20:0 to 22:0, and Fig. 4 from 22:0 to 22:6n-3. Identification of the *cis/trans*-16:1, *cis/trans*-18:1, and *cis/trans*-20:1 isomers was based on the principles of silver-ion separation, direct comparison with selected isomers contained in the GC reference standards, and comparison with previously synthesized compounds and published reports [5, 10, 23, 24, 30–32]. Selected fractions and total menhaden oil were also analyzed by use of a 100-m SLB-1L111 ionic-liquid column [33] to compare their elution times with those of synthetic FAME [32].

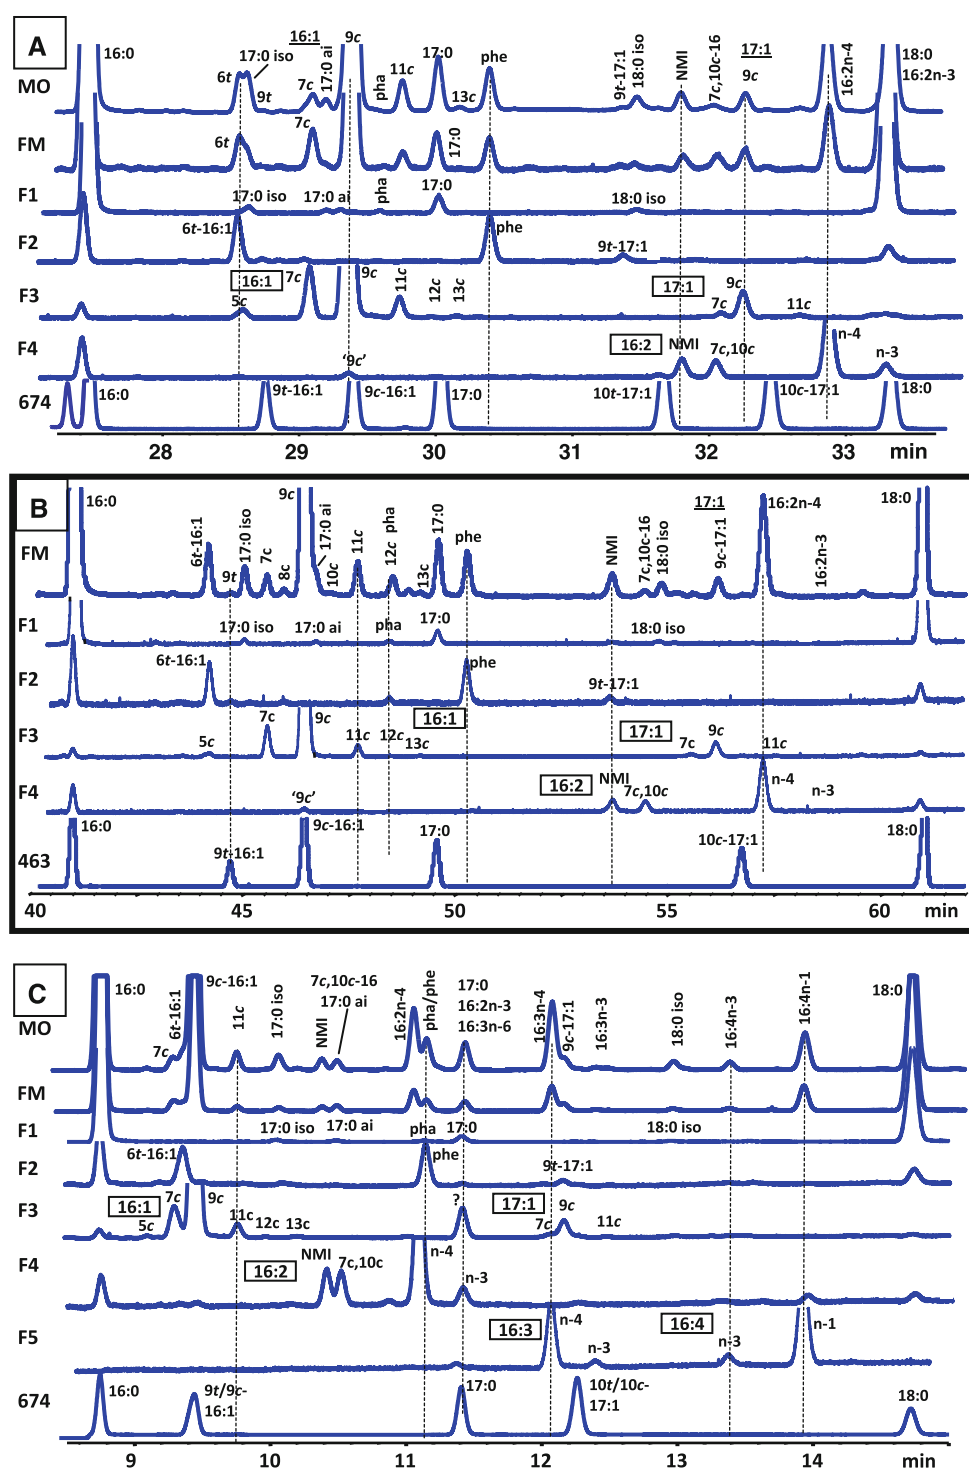

Each panel shows the separation of only the Ag⁺-SPE fractions that provide useful information for identification of the FAME eluting in that region. The GC separation of the Ag⁺-SPE fractions showed there was only minor carryover of the saturated (F1), *trans*-MUFA (F2), *cis*-MUFA (F3), and diunsaturated FA (F4) into subsequent fractions. However, partial overlap of the trienoic and tetraenoic unsaturated FAME was observed for fractions F5 to F7 (e.g. Figs. 3, 4), and some overlap of the tetraenoic and pentaenoic unsaturated FAME was observed for F6 and F7 (e.g. Figs. 3, 4). DHA, and FAME with six double bonds were not recovered even by use of 100% methanol as eluent.

Figure 1 shows the separation of the geometric and positional isomers of 16:1 by use of the SP-2560 column with both the 175 and 150 °C temperature programs (Fig. 1a, b), and by use of the Supelcowax-10 column (Fig. 1c). The Supelcowax-10 column enabled some resolution of the positional isomers of MUFA methyl esters, but it failed to resolve the geometric isomers of 9-16:1 and 10-17:1, which is present in GC #674, and to resolve 6*t*-16:1 from the 6-7/-8/-9-16:1 cluster (Fig. 1c). In contrast, the unsaturated C16 FA were well resolved from each other by use of this column (Fig. 1c), all eluting before the 18:0 FAME, including four 16:2 (F4; Fig. 1c), two 16:3 (F5;

Fig. 1c), and two 16:4 FAME isomers (F5; Fig. 1c). However, some C16 PUFA overlapped, for example 16:2*n*-4 with methyl phytanate and phytanate, 16:2*n*-3 with 17:0, and 16:3*n*-4 with 9*c*-17:1. The separation of the unsaturated C16 FA on the SP-2560 column was very different, because of the higher polarity of its stationary phase. Considering the C16 PUFA, only the four 16:2 isomers eluted before 18:0 (F4; Fig. 1a), and one of the isomers (16:2*n*-3) overlapped with 18:0 when the 175 °C temperature program was used (F4; Fig. 1a). However, the latter pair was resolved at 150 °C (F4; Fig. 1b). The more unsaturated FA of C16 eluted in the 18:1 FA region on the SP-2560 column, irrespective of the elution temperature plateau used. Branched-chain iso and anteiso-17:0 FA coeluted with other FA on both columns. These branched-chain FA were identified in the SP-2560 separations by comparing the separations obtained in the elution profiles with plateaus at 150 and 175 °C (Fig. 1a, b); 17:0 anteiso coeluted with 7*c*, 10*c*-16:2 on the Supelcowax -10 column (Fig. 1c). Of special interest was the identity of a *trans*-16:1 isomer that coeluted with 17:0 iso at 175 °C, but was resolved at 150 °C. Menhaden oil and fraction F2 were analyzed by use of a 100-m SLB-1L111 column that resolves the 6*t*-, 7*t*-, and 8*t*-16:1 isomers [33] that coelute on a SP-2560 column [32]. This result showed that this peak eluted at the same time as 6*t*-16:1.

Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) and phytenic acid (3,7,11,15-tetramethylhexadec-2-enoic acid) were generally present in fish muscle, but their identification required Ag⁺-SPE fractionation before GC analysis. As seen in the separations obtained by use of the SP-2560 (Fig. 1a, b) and Supelcowax -10 columns (Fig. 1c), methyl phytanate (pha) eluted in the SPE saturated FA fraction (F1), and methyl phytanate (phe) in the *trans*-MUFA SPE fraction (F2). These results showed that trace amounts of methyl phytanate were present in fish

Fig. 1 Partial GC separation of the FAME that eluted between 16:0 to 18:0 obtained from menhaden oil (MO), a fish muscle (FM) sample, fractions 1–5 from Ag⁺-SPE of FM, and GC standard mixtures #674 and/or #463. The separations presented in panel **a** were obtained by use of a 100-m SP-2560 column operated using a temperature program from 45 to 215 °C with a plateau at 175 °C; those in panel **b** were obtained by use of the same 100-m SP-2560 column operated using a temperature program from 45 to 215 °C with a plateau at 150 °C, and panel **c** was obtained by use of a Supelcowax-10 column operated using a temperature program from 170 to 225 °C. Complete details of the chromatographic conditions are reported in Table 1. Monounsaturated FA were designated by use of the “Δ” nomenclature whereas the more unsaturated FA were designated by use of the “n-x” nomenclature. *DMP* dimethyl phthalate, *NMI* non-methylene interrupted, *pha* methyl phytanate, *phe* methyl phytenate, *c* *cis*, *t* *trans*, *ai* anteiso. Fatty acids shown in quotation marks are residual fatty acids in the subsequent Ag⁺-SPE fractions; those with a question mark are tentative identifications

muscle and eluted in the tail of the 9c-16:1 peak on the SP-2560 column with the 175 °C plateau (Fig. 1a) and just ahead of 12c-16:1 with the 150 °C plateau (Fig. 1b). On the other hand, a significant amount of methyl phytenate was present in fish muscle and eluted after 17:0 FA on the SP-2560 column used with either temperature program (Fig. 1a, b). The elution of methyl phytenate and phytenate using the SP-2560 column and both temperature programs

has previously been established by use of authentic standards (Kramer et al., unpublished). Methyl phytenate and phytenate coeluted when using the Supelcowax-10 column, and these two compounds were only partially separated from 16:2n-4 FA (Fig. 1c).

Figure 2 shows the partial GC chromatogram from 18:0 to 20:0 FA using both GC columns. Separations using the SP-2560 column included mainly the 18:1 and 18:2

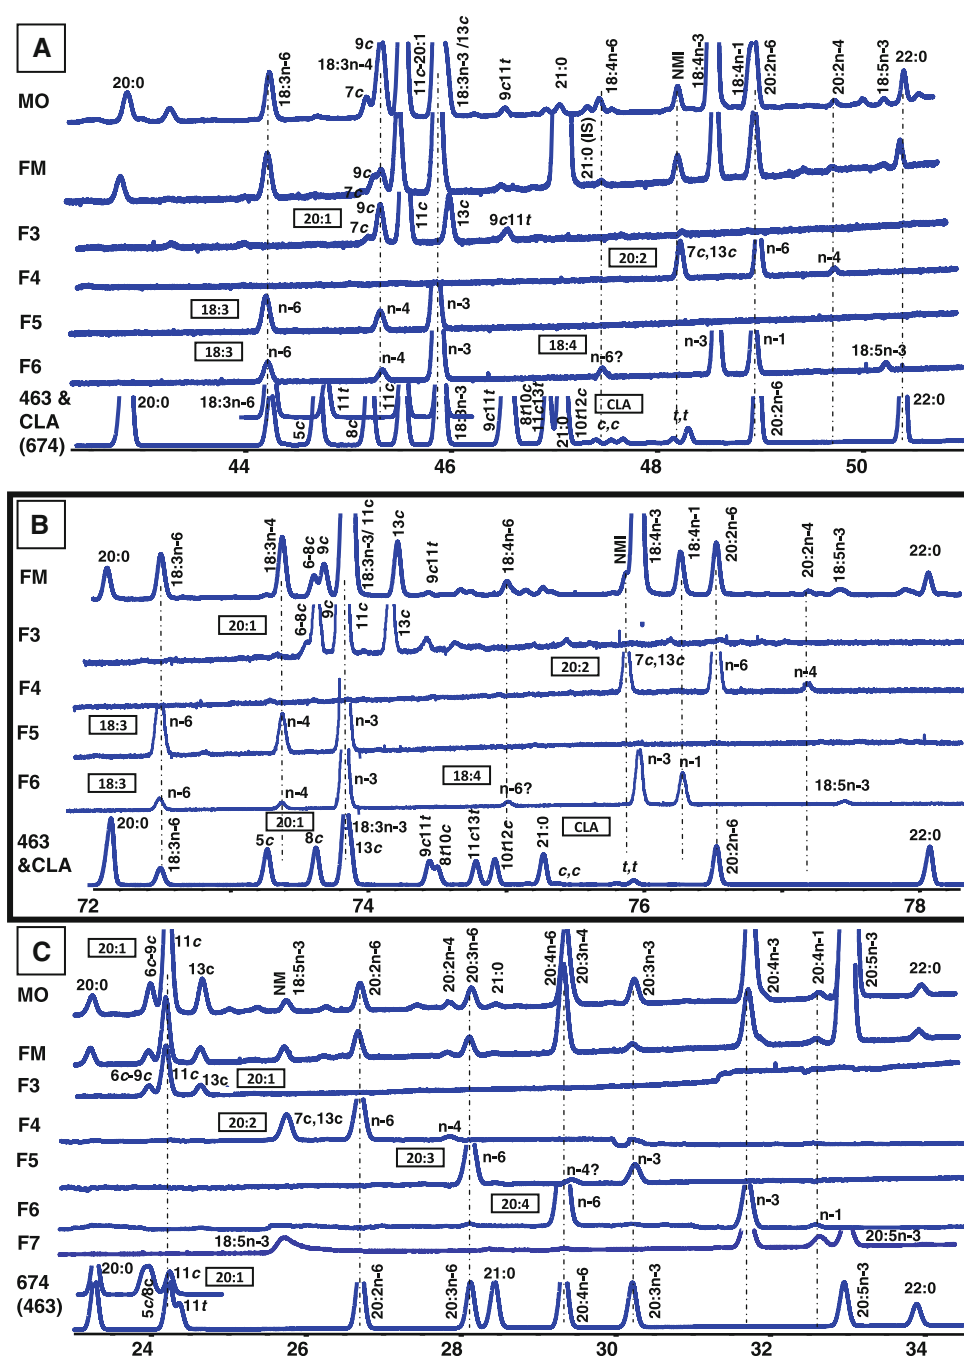

Fig. 2 Partial GC separation of the FAME that eluted between 18:0 to 20:0 obtained from menhaden oil (MO), a fish muscle (FM) sample, fractions 2–6 from Ag⁺-SPE of FM, and GC standard mixtures #674 (with a partial insert from #463). Other details are the same as for Fig. 1

isomers plus the highly unsaturated C16 FA (Fig. 2a, b), whereas this selected portion of the chromatogram using the Supelcowax-10 column included all the 18:1, 18:2, and 18:3 plus CLA isomers (Fig. 2c). Small amounts of several *trans*-18:1 isomers were identified in both the menhaden oil and fish muscle samples, as was evident from the separations achieved by use of the SP-2560 column (F2; Fig. 2a). To see whether the *trans*-18:1 isomers were derived from the diet, the feed was analyzed and found to contain 0.16% FAME; this amount was similar to that found in the fish muscle (0.14%) and the distribution of

trans-18:1 was also similar. In contrast, the commercial menhaden oil contained 0.20 and 0.13% *trans*-18:1 and CLA, respectively. By contrast, when the Supelcowax-10 column was used, these isomers all coeluted with the *cis*-18:1 isomers (Fig. 2c). The SP-2560 column also resulted in improved resolution of the positional isomers of *cis*-18:1 (Fig. 2a, b) compared with that obtained by use of the Supelcowax-10 column (Fig. 2c). GC separation of reference mixture #674 confirmed the lack of resolution of the geometric isomers of 6-18:1, 9-18:1, and 11-18:1, and the positional isomers of 6-18:1 and 9-18:1, and 7*t*-19:1 and

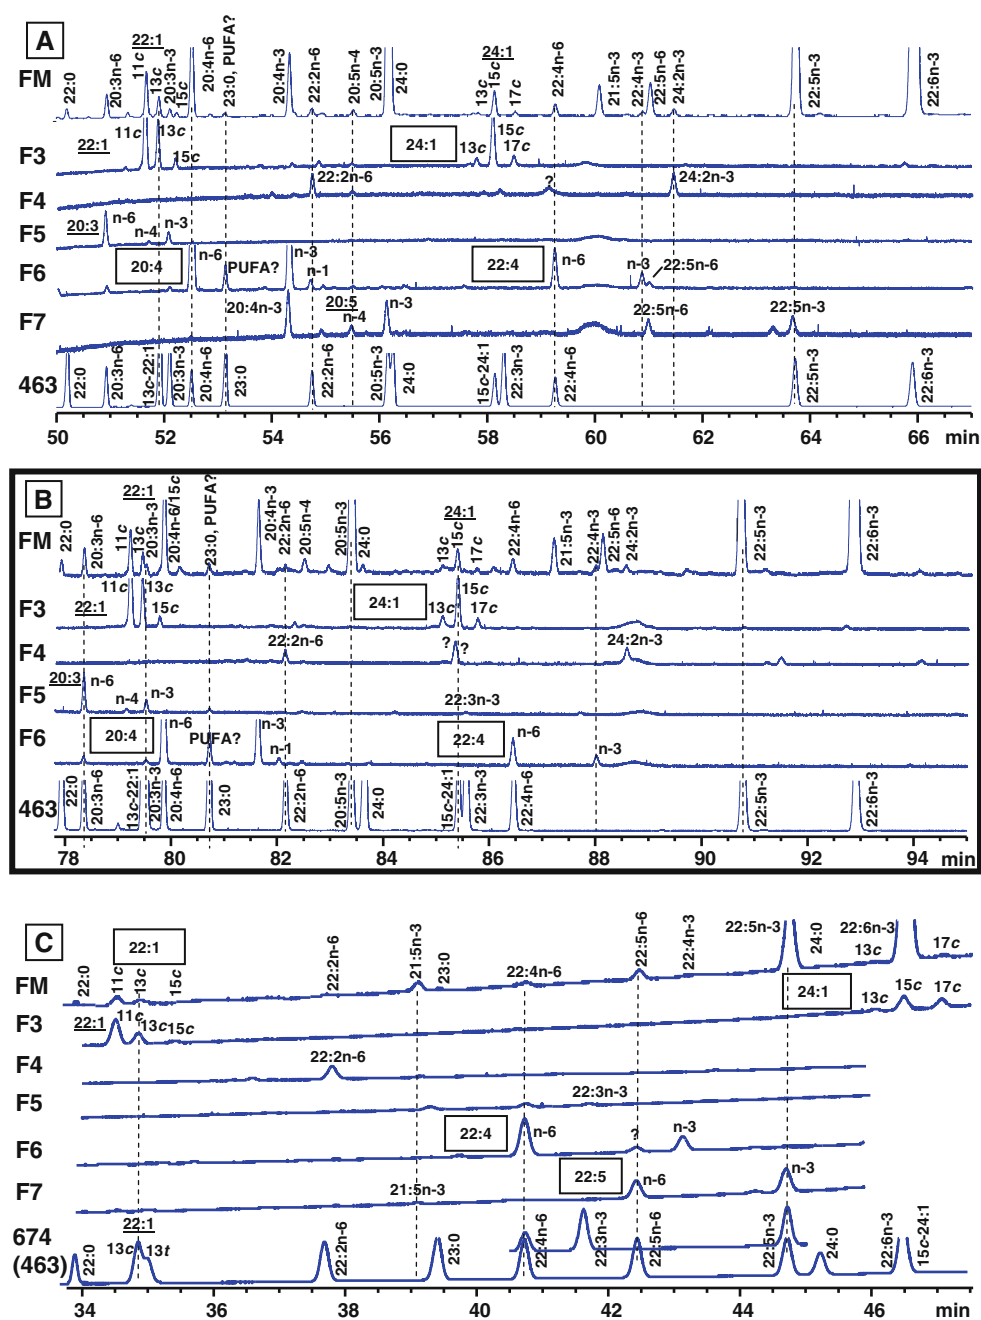

Fig. 3 Partial GC separation of the FAME that eluted between 20:0 to 22:0 obtained from menhaden oil (MO), a fish muscle (FM) sample, fractions 3–7 from Ag⁺-SPE of FM, and GC standard mixture #463 spiked with CLA mixture #UC-59M, and FAME 21:0. Other details are the same as for Fig. 1

10*t*-19:1 (Fig. 2c). However, the Supelcowax-10 column clearly resolved four 18:2 (F4; Fig. 2c), three 18:3 (F5 and F6; Fig. 2c), and possibly three 18:4 (F6; Fig. 2c) isomers with little interference from other FA, except for 18:3n-6 with 19:0, 18:3n-4 with several 19:1 isomers, and 18:4n-3 and 18:4n-1 with a number of *c/t* and *c/c* CLA isomers (Fig. 2c). Identification of two 16:3 and two 16:4 isomers in fish products was a challenge when using the SP-2560 column; 16:3n-4 and 16:3n-3 coeluted with 9*c*-18:1 and 11*c*-18:1, respectively, at 175 °C (Fig. 2a) whereas at 150 °C both of these FA pairs were separated (Fig. 2b).

Identification of 16:3n-3 was confirmed by use of an authentic standard. A similar situation occurred with the two 16:4 isomers—16:4n-3 was better separated at 175 °C (Fig. 2a) whereas 16:4n-1 was better resolved at 150 °C (Fig. 2b). The structure of the two NMI 18:2 isomers was established by comparison with similar peaks in GC chromatograms obtained by use of the official AOCS method (Ce li-07) for marine oils. The 18:0–20:0 region of the chromatogram obtained by use of the SP-2560 column also included the four 18:2 isomers (F4), which were resolved by use of either temperature program (Fig. 2a, b).

Fig. 4 Partial GC separation of the FAME that eluted between 22:0 to 22:6n-3/24:1 obtained from menhaden oil (MO), a fish muscle (FM) sample, fractions 3–7 from Ag^+ -SPE of FM, and GC standard mixtures #463 or #674 (with a partial insert from #463). Other details are the same as for Fig. 1

When the Supelcowax-10 column was used the *c,t,t,c*-LA isomers eluted among the 18:4 FA, and the *t,t*-CLA isomers eluted just before 20:0.

Figure 3 shows the partial GC chromatograms obtained from 20:0 to 22:0 FA. In this region, four *cis*-20:1 isomers isolated in Ag^+ -SPE fraction F3 are eluted from both GC columns. This region on the SP-2560 column also included three 20:2 (F4; Fig. 3a, b), three 18:3 (F5; Fig. 3a, b), three 18:4 (F6; Fig. 3a, b), and the CLA isomers (Fig. 3a, b). This region on the Supelcowax-10 column (Fig. 3c) included three 20:2 (F4), three 20:3 (F5), and three 20:4 (F6) isomers. Trace amounts of *trans*-20:1 isomers were

detected in fish muscle (F2 fraction not included in Fig. 3a). The Supelcowax-10 column only partially separated the *cis/trans* isomers of 11-20:1 FA contained in GC reference standard #674 (Fig. 3c). However, the C20, C21, and C22 unsaturated FA were all well separated, with the exception of 20:3n-4 and 20:4n-6 FA (Fig. 3c). The *cis* and *trans* 20:1 isomers were well resolved by use of the SP-2560 column, but they overlapped with several 18:3 isomers (Fig. 3a, b). Little separation of the geometric and positional isomers of 20:1 was achieved by use of the Supelcowax-10 column, but no other FA interfered with them (Fig. 3c). Use of the SP-2560 column with the 175 °C

temperature program resulted in the coelution of two 18:3 isomers with *cis*-20:1 isomers (18:3n-4 with 9*c*-20:1 and 18:3n-3 with 13*c*-20:1), and of 18:4n-1 with 20:2n-6 (Fig. 3a). Each of these three pairs of FA were separated, or coeluted with different FA, when the 150 °C program was used (Fig. 3b), thus enabling their resolution. The chromatogram obtained from the reference mixture shows that the CLA isomers eluted in a region free of other FA when the SP-2560 column was used, with the exception of 21:0 (Fig. 3a). When the 175 °C program was used 21:0 eluted close to 10*t*,12*c*-CLA (Fig. 3a) whereas at 150 °C 21:0 eluted among the *c,c*-CLA isomers (Fig. 3b). When the Supelcowax-10 column was used the CLA isomers eluted among the 18:4 FA isomers, and well before 20:0 (Fig. 2c). Minor peaks observed in both fish products that eluted in the CLA region were tentatively identified as *c,t*-CLA, *t,c*-CLA, and *t,t*-CLA isomers; the distribution of these CLA isomers seems to be random.

Figure 4 shows the partial GC chromatograms obtained from the remaining FA starting from 22:0 FA. This segment contained the long-chain MUFA (LC-MUFA) 22:1 and 24:1, plus the most unsaturated PUFA present in fish products. Three positional isomers of *cis*-22:1 and *cis*-24:1 were detected, and were well resolved by use of either GC column, as is evident in the separation of fraction F3 from Ag⁺-SPE. Cetoleic acid (11*c*-22:1) was the most abundant 22:1 isomer, and nervonic acid (15*c*-24:1) was the most abundant 24:1 isomer (Fig. 3). When the Supelcowax-10 column was used the two geometric isomers of 22:1 present in GC reference standard #674 were not resolved (Fig. 4c). No *trans* isomers of 22:1 and 24:1 were detected in fish muscle (data for F2 not shown). The SP-2560 column separated three isomers of 20:3 (F5; Fig. 4a, b), three isomers of 20:4 (F6; Fig. 4a, b), two isomers of 22:4 (F6; Fig. 4a, b), two isomers of 20:5 (F7; Fig. 4a), and two isomers of 22:5 (F7; Fig. 4a, b). Fraction F7 was not included in Fig. 3b (150 °C program) because of the weak detector response. The separation of 20:5n-3 and 24:0 by use of the SP-2560 column at 175 °C was partly obscured by the dominant 20:5n-3 peak in these fish products (Fig. 4a). However, these two FA were resolved by use of the 150 °C program (Fig. 4b). The Supelcowax-10 column separated most C22 and C24 unsaturated FA, which included two 22:4 isomers (F6; Fig. 4c), 21:5n-3, and two 22:5 isomers (F7; Fig. 4c), with the exception of 22:6n-3 from 15*c*-24:1 in the reference standard (Fig. 4c). On the other hand, when utilizing the SP-2560 column, two 20:3 isomers coeluted with *cis*-22:1 isomers (20:3n-4 with 11*c*-22:1 at 175 °C (Fig. 4a), and 20:3n-3 with 13*c*-22:1 at 150 °C (Fig. 4b)). Trace amounts of 23:0 were detected in Fraction 1 on both columns (data not shown in Fig. 4); in addition, when the SP-2560 column was used, an unknown PUFA eluted in Fraction 6 with the same retention time as

23:0 both at 175 °C (Fig. 4a) and at 150 °C (Fig. 4b). However, this additional PUFA peak was not clearly evident in Fraction 6 of Figs. 3c or 4c when the Supelcowax-10 column was used.

Discussion

The separations presented here, obtained by use of the 30-m Supelcowax-10 and the 100-m SP-2560 columns, provide complementary results in the analysis of FAME prepared from fish oils or fish tissues. The Supelcowax-10 column was very useful for identifying unsaturated FA by chain-length, and number and position of their double bonds. On the basis of this observation, Ackman [8] first suggested the use of PEG columns as reference in inter-laboratory studies for quantification of FA in marine oils by GC to minimize overlaps of unsaturated FA. Since then, PEG-coated GC columns have been used to confirm the presence of highly unsaturated FA in marine and other oils containing LC PUFA. This type of GC column is currently recommended in the most recent official AOCS method (Ce 1i-07) for quantification of FA in marine oils [5]. However, the limitations of separations achieved by use of PEG-coated columns are equally evident, particularly regarding the coelution of geometric isomers of unsaturated FA. For instance, the Supelcowax-10 column could not separate the geometric isomers of the 16:1, 18:1, 19:1, 20:1, and 22:1 FA contained in reference mixtures #674 and #463, but was able to resolve the positional isomers themselves except the ones with the double bond toward the methyl end of the molecule. On the other hand, the SP-2560 column separated the geometric isomers of all 16:1, 18:1, 19:1, 20:1, and 22:1 FA, and also enabled superior separation of the positional isomers themselves. Selecting a 60-m Supelcowax-10 column, instead of the 30-m version recommended in AOCS official method Ce 1i-07, would result in improved separation of some FAME and in a slight shift of the order of elution of others [10]. For instance, the 60-m Supelcowax-10 column resulted in separation of 22:6n-3 and 15*c*-24:1, but 22:0 and 20:5n-3 overlapped, and the *t,t*-CLA isomers coeluted with the 20:1 FA isomers. However, most importantly, increasing the length of the Supelcowax-10 column did not improve the separation of the geometric isomers of the unsaturated FAME. Mjøs [25] used a 50-m BP-20 (PEG type) column and achieved separation of several mono-*trans* and di-*trans* isomers of EPA and DHA, but did not comment whether this column could resolve other geometric isomers that might be present in fish products.

The lack of separation of geometric isomers of unsaturated FA using the PEG columns is a major concern that has serious implications for the analysis of fish oil and

fish-containing products whenever *trans* FA isomers are suspected to be present. Mjøs [13] isomerized pure EPA and DHA, by use of *p*-toluenesulfonic acid in dioxane, and was able to separate most of their mono and di-*trans* geometric isomers on a 100-m SP-2560 column, after isolating the compounds by silver-ion HPLC chromatography. In a similar study, Fournier et al. [15–17] investigated the geometric isomers of EPA and DHA produced during the deodorization of fish oil, and showed that separation of the geometric isomers required the use of a 100-m CP-Sil 88 column. Mjøs [25] further showed that the geometric isomers of EPA and DHA could be equally well resolved by use of a 50-m BP-20 (PEG) or a 60-m BPX-70 column; Fournier et al. [15–17] did not report the separation of these FA isomers by use of PEG-coated columns. These results are consistent with the observations of Sébédio et al. [11] who found only small quantities of geometric isomers of the LC highly unsaturated PUFA in deep fried mackerel by use of a 30-m Supelcowax-10 column. It would seem from these results that PEG columns, for example the 50-m BP-20 column, are able to resolve many of the geometric isomers of EPA and DHA.

On the basis of our results with the 30-m Supelcowax-10 column, isomers of EPA and DHA were not detected, but the geometric isomers 16:1–22:1 were not separated. This would explain why Sébédio et al. [11] found only geometric isomers of LC highly unsaturated PUFA in deep fried mackerel by use of a 30-m Supelcowax-10 column, the same GC column we used. We recently evaluated FT-NIR for quantification of FA in fish oil preparations enriched with EPA and DHA [20]. We observed that the amount of the all-*cis* highly unsaturated FA contained in these oils was significantly overestimated when a 30-m PEG FAMEWAX column was used for calibration of the FT-NIR spectrometer, rather than when a 100-m CP Sil 88 column was used. Similar results would be expected in analysis of the PUFA and *trans* FA content of foods containing fish or fish oil, infant formulas supplemented with marine or algal oils, or n-3-enriched capsules using any 30-m PEG-coated GC column. The observation of a *trans*-16:1 peak in fish muscle (Fig. 1) was of interest. This FA could not be identified by use of the Supelcowax-10 column, but on the CPS column it had the same elution time as the *6t/7t/8t*-16:1 peak [32]. On further investigation of the fish sample by use of an SLB-1L111 ionic-liquid column [33] it was shown that this isomer had the same elution time as *6t*-16:1 in the synthetic mixture of 16:1 isomers [33]. It is interesting to note that Ackman [34] reported the occurrence of *6t*-16:1 in a number of marine species. A single *trans*-16:1 isomer, *3t*-16:1, was also identified in spinach by use of similar CPS columns [35].

It was tempting to determine the presence of isomerized FA in fish products by using the recommended SP-2560

column for the analysis of *trans* FA [29] in addition to using the Supelcowax-10 column recommended for marine oil analysis [5]. However, such a detailed comparison of elution profiles provided by these two GC columns for the same fish samples is not currently available. Complete analysis of the unsaturated FA in fish muscle and fish oil by use of the highly polar SP-2560 capillary column proved to be a challenge, because of the extensive overlap of unsaturated FA with those of longer chain length, and the presence of *trans* isomers. To confirm the identity of several FA contained in menhaden oil and fish muscle samples, complementary silver-ion separation of the total fish muscle FAME was conducted by use of Ag⁺-SPE cartridges. These Ag⁺-SPE cartridges proved to enable rapid, economical, and effective fractionation of the total FAME of fish muscle on the basis of their number of double bonds and geometric configuration. The success of Ag⁺-SPE fractionation depends on loading the SPE tubes with a moderate amount of FAME; approximately 0.4–1 mg was generally sufficient. Each of the seven fractions obtained from Ag⁺-SPE was then compared with the original fish muscle FAME preparation, utilizing the results from both GC columns. The identities reported in Figs. 1 to 4 were established only when there was agreement between the FA separated using both GC columns, the results obtained by use of both temperature programs with the SP-2560 column, and the fractions obtained by use of the Ag⁺-SPE cartridges. Additional confirmation using GC–mass spectrometry was considered but suitable equipment was not available.

Every effort was made in this study to avoid conditions leading to isomerization of menhaden oil and lipids extracted from the fish muscle sample, and the results indicate no *trans* isomers of 22:6n-3, 22:5n-3, and 20:5n-3 were present. However, trace amounts of *trans* and CLA isomers were observed in the separations using the SP-2560 column. It was suspected that the diet might be the source of the minor *trans*-18:1, *trans*-20:1, and CLA isomers (Figs. 2, 3) as suggested by Ackman [36], because fish from the ocean do not contain these FA [34]. To confirm the presence of the CLA isomers, Fraction 3 could have been analyzed by Ag⁺-HPLC with UV detection at 233 nm [23]. Minor peaks observed in Figs. 3 and 4 were also tentatively identified as geometric and positional isomers of dienoic and trienoic FA. Identification of geometric isomers of PUFA in fish oil and fish muscle was made difficult by the unavailability of reference materials of isomerized C20 and C22 unsaturated FA. To locate the region in the chromatogram where the C18 to C22 unsaturated FA isomers would be expected to elute, separation of the FAME prepared here from the menhaden oil sample was compared with that of fractions obtained from a partially hydrogenated fish oil (PHFO) sample acquired during a previous study (Kraft and Kramer, unpublished data). The

PHFO sample had been fractionated by Ag^+ -SPE, by following the same procedure described here, yielding, among others, fraction F4 that contained non-conjugated dienoic FA and fraction F5 that contained trienoic FA. These fractions were analyzed by GC with an SP-2560 column operated under the same chromatographic conditions described here, and the temperature program with the elution plateau at 175 °C [24]. Figure 5 shows the stacked separations of menhaden oil FAME, fractions F4 and F5 from the PHFO sample, and of GC reference mixture #463 spiked with CLA. Direct comparison of the individual FAME isomers of menhaden oil and fractions F4 and F5 from PHFO is obviously not possible, or intended, because partial hydrogenation and thermal isomerization would produce different sets of FA isomers, but it does provide an indication of where these dienoic and trienoic FA might elute. Minor unidentified peaks were evident in the menhaden oil FAME separation at retention times corresponding to the clusters of *c,t/t,c* and *c,c-18:2*, *c,t/t,c* and *c,c-20:2*, *c,t/t,c* and *c,c-22:2* in F4, and *c,c,t*, *c,t,t*, and *c,c,c-18:3*, *c,c,t*, *c,t,t*, and *c,c,c-20:3*, and *c,c,t*, *c,t,t*, and *c,c,c-22:3* in F5 (Fig. 5), indicating the possible presence of FA with similar chemical structure. The total amounts of all the peaks that were not assigned in the GC chromatogram of menhaden oil and fish muscle were 0.91 and 0.60%, respectively. This value would be the sum of unknown natural PUFA in the fish and possible isomerized FA; the

latter could also originate from the feed that contained 0.71% unassigned peaks.

ECL values are often calculated for FAME separated on different GC columns to provide greater ease of comparison, because the logarithms of the retention times have a characteristic relationship with common FA structures [8, 9, 27, 28, 37]. MUFA and methylene-interrupted PUFA with the same number of double bonds, in the same geometric configuration, and in the same position relative to the terminal carbon have similar ECL values when separated with the same GC column, irrespective of their chain length. The ECL values reported in Table 2 for the FA identified in the separations achieved on both GC columns were calculated by use of the equations described by Bannon et al. [27] for uncorrected FA retention times. Only the ECL values obtained from the uncorrected retention times for most of the FAME of interest in fish oil are presented in Table 2, because differences between ECL values obtained by use of uncorrected and corrected retention time values were minimal. FAME with the same terminal double bond system using the “*n-x*” nomenclature gave similar ECL differences, or fractional chain lengths (FCL), relative to the corresponding saturated FA analogues. The average FCL values of unsaturated FA within each “*n-x*”-FA family is also presented. Although the ECL concept was primarily developed for isothermal GC operations [8], these results suggest the concept applies to ECL

Fig. 5 Partial GC separations of the FAME that eluted between 16:4n-3 and 22:6n-3 from the *top*: FAME prepared from menhaden oil (MO); Ag^+ -SPE fractions 4 (dienoic FA) and 5 (trienoic FA) obtained from separation of FAME prepared from partially hydrogenated fish oil using the same Ag^+ -SPE technique (Kramer et al. [24]);

GC standard mixtures #463 spiked with CLA mixture #UC-59M, and FAME 21:0 and 23:0. All separations were achieved by use of an SP-2560 capillary column operated using the temperature program with a plateau at 175 °C (Kraft and Kramer, unpublished data), as described in Table 1

Table 2 Equivalent chain length (ECL), determined as described by Bannion et al. [27], of unsaturated fatty acids found in fish products. Also included are differences between ECL values for each fatty acid and for the corresponding saturated fatty acid analogue, i.e., the fractional chain length (FCL), and the average (Avg) within each of the unsaturated “*n-x*”-fatty acid families

Fatty acids are presented as A:Bn-x, where A = chain length, B = number of double bonds, n-x = number of carbons (n) from the terminal methyl group (x). The positions of double bonds from the carboxyl end of the fatty acids (Δ values) are given in parentheses

nd not detected; ni not included in average; NM non-methylene interrupted

values of FA determined after use of temperature programs (Table 2). However, the ECL values did decrease somewhat for the very LC PUFA of C22 and C24 (Table 2). The ECL values calculated in this study from the separations achieved by use of the Supelcowax-10 column were consistent with previously published ECL values for the same FA using the same GC column [7, 27, 37, 38]. In this study we include the ECL values of all FA of interest from fish oil using both the Supelcowax-10 and SP-2560 columns (Table 2).

There were some differences in the FCL values within the “n-x”-FA families that were mainly attributed to how the retention times of the FAME were determined. In chromatography, peaks are expected to have a Gaussian shape, and the retention time is the elution time at which the tangent of the chromatographic signal turns from positive to negative. As noted by Delmonte and Rader [39], when separating FAME on a GC capillary column coated with a highly polar stationary phase, the retention time of the FAME is affected by the amount injected on to the

column. FAME, especially those with a long chain and few double bonds, are poorly soluble in the thin coating of the highly polar stationary phase covering the internal wall of the capillary tube. The longer the hydrophobic chain of these FAME, the lower is the solubility of the FAME in the liquid stationary phase. During elution, if the concentration of the FAME reaches the condition of saturation into the liquid stationary phase, it will no longer correctly repartition between the gas carrier and the liquid coating, causing the peak to lose symmetry and resulting in a triangular shape and a progressive increase in retention time. For FAME that will not reach the saturation point in the liquid stationary phase, the top of their chromatographic peak gives a good estimate of the retention time. However, when the peak loses symmetry and acquires the classic triangular shape the beginning of the peak provides a better estimate of the FAME retention time. The ECL values in Table 2 were calculated on the basis of the retention times at maximum peak height. When the beginning of the peak, rather than the maximum peak height, was used to estimate

the FAME retention times of some peaks the ECL values for those FAME proved more consistent.

In this study, ECL values in combination with Ag^+ -SPE fractions were used to assign several FA peaks in the separations achieved by use of the Supelcowax-10 column that were not labeled in the chromatograms presented in the AOCS official method (Ce 1i-07) for analysis of marine oils [5]. This included several FAME tentatively identified as 16:2n-3, 12c-18:1, 18:4n-6, 6c-9c-20:1, 9c-19:1, 20:2n-4, 20:3n-4, 20:4n-1, 11c-22:1(n-11), 15c-22:1(n-7), 22:4n-4, and 24:4n-3. In addition, several coeluting *trans* isomers of 16:1 and 18:1 FA were clearly observed, as well as a 20:2 isomer and 18:5n-3. The 20:2 isomer seems to be 7c,13c-20:2, a chain elongated metabolite of 5c,11c-18:2, because they have a similar ECL (Table 2). Furthermore, some FA in the commercial marine standard seem to be incorrectly labeled (10c-17:1 should be 9c-17:1, 13c-18:1 should be 12c-18:1, 9c-11c-22:1 should be 11c-22:1(n-11), and 13c,16c,19c-22:3(n-3) and 7c,10c,13c,16c-22:4(n-6) should be exchanged). Identification of methyl phytanate and methyl phytenate in fish muscle by use of the Supelcowax-10 column proved particularly difficult, because these two isoprenoid FA coeluted and partially overlapped with 16:2n-4 (Fig. 1c). The major isoprenoid FA in fish muscle seemed to be phytenic acid rather than phytanic acid. These two isoprenoid FA were well separated on the SP-2560 column, and their identity was assigned on the basis of similar retention times from the GC analysis, the Ag^+ -SPE fraction in which they eluted, and consistency in the three separations (Fig. 1a, b, c).

The complementary results obtained by use of these two GC columns suggest that there is a need to use more than the PEG column to evaluate the FA composition of fish products, particularly when fish products are combined with other fats, for example partially hydrogenated vegetable oils or dairy fats. It is becoming evident that even a 100-m CPS by itself is limited in its capacity to resolve these FAME mixtures in a single analysis. Mjøs and Haugsgjerd [40] recently reported extensive overlap of FA common in fish oils with 16:1, 18:1, 18:2, and 18:3 isomers present in other fats. FAME were identified on the basis of the distinct differences in their electron impact mass spectra, but identification of minor and overlapping peaks by mass spectrometry was not possible [40]. There are numerous instances of such limitations in GC separations, indicating that mass spectrometric analysis and silver-ion separations will both be necessary to resolve these mixtures. We have recently evaluated the separation of FAME mixtures achieved by use of new ionic liquid capillary GC columns that are more polar than CPS columns [33]. Compared with CPS columns, the SLB-1L111 ionic liquid capillary column had increased capacity in the separation of unsaturated FAME on the basis of double bond number, position, and

geometric configuration, but also generated a different set of co-elutions. The elution pattern of FAME from ionic-liquid columns is sufficiently different from patterns from CPS columns to become a valuable complementary GC separation for analysis of complex FA mixtures.

Conclusion

The current official capillary GC method for analysis of saturated, *cis*-MUFA, and *cis*-PUFA in marine and other oils containing LC PUFA (AOCS Ce 1i-07) recommends the use of 30-m PEG-coated GC columns, for example Supelcowax-10 [5]. This GC column proved valuable for identifying unsaturated FAME but was ineffective for separation of unsaturated geometric FA isomers that can be present in fish products when subjected to processing or thermal stress or when combined with other foods. Evaluation of the FA composition of the same fish products by use of a 100-m SP-2560 column, a GC column recommended for analysis of *trans* FA contained in other food matrices, enabled enhanced separation of several FA and led to identification of *trans* FA and other components, for example phytanic and phytenic acids, and 6t-16:1. When the Supelcowax-10 column was used, many of these compounds were not resolved. Fractionation of the FAME mixture from the original fish sample by Ag^+ -SPE before GC analysis proved valuable in establishing the identity of many unsaturated FA contained in fish products. GC separation of the Ag^+ -SPE fractions resulted in little overlap of unsaturated FA with different numbers of double bonds and geometric configuration, with the exception of very highly unsaturated FA (F5–F7). Several of the pentaenoic and hexaenoic FA were not completely eluted from Ag^+ -SPE cartridges, even by 100% methanol. Calculation ECL values provided valuable assistance in the identification of many unsaturated FA contained in fish products, and the results were in agreement with those obtained by use of Ag^+ -SPE fractionation. Thorough examination of the separations obtained from the Supelcowax-10 and SP-2560 columns (the latter used with two temperature programs), with analysis of the samples before and after Ag^+ -SPE fractionation, provided the information necessary to identify most of the FA in fish oil and fish muscle. The approach described here complements the chromatographic separation recommended by AOCS official method Ce 1i-07 for marine oil analysis [5] with separations on a 100-m CPS column. This will be needed for analysis of commercially prepared fish foods, deodorized marine oils, or foods fortified with marine oils.

Acknowledgments The authors thank Drs Roberto Anedda and Carlo Piga for their encouragement and for assistance with extraction

of lipids from the fish muscles, and the staff at Porto Conte Ricerche Srl for their assistance with these studies.

Abstract The fatty acid composition of the temperate calcareous marine sponge *Leuconia johnstoni* Carter 1871 (Calcaronea, Calcarea) was characterized for the first time in specimens collected off the Brittany coast of France over four years from October 2005 to September 2008. Forty-one fatty acids (FA) with chain lengths ranging from C₁₄ to C₂₂ were identified as fatty methyl esters (FAME) and *N*-acyl pyrrolidide (NAP) derivatives by gas chromatography–mass spectrometry (GC–MS). Twenty-two saturated fatty acids (SFA) were identified accounting for 52.1–59.0% of the total FA and dimethylacetals (DMA). In addition, among the SFA, we noticed the presence of numerous methyl-branched *iso* and *anteiso* FA, suggesting a large number of associated bacteria within *L. johnstoni*. Thirteen monounsaturated fatty acids (MUFA, 28.0–36.0% of total FA + DMA) were also identified as well as six polyunsaturated fatty acids (PUFA, 4.0–8.2%). A noticeable DMA was detected at a high level, particularly in September 2008 (11.8%), indicating the presence of plasmalogens in this sponge species. This calcareous sponge lacked the non-methylene-interrupted FA (NMI FA) with a $\Delta 5,9$ system typical of siliceous

Demosponges and Hexactinellids. The occurrence of the unusual 8,13-octadecadienoic acid was reported for the first time as a minor PUFA in a calcareous sponge. The major FA, representing 20–25% of this sponge FA, was identified as the new 2-methyl-13-icosenoic acid from mass spectra of its methyl ester and its corresponding *N*-acyl pyrrolidide derivatives as well as a dimethyl disulfide adduct.

Introduction

Sponges are very ancient metazoans, with fossils dating back to the Early Cambrian period about 530 million years

ago. Interestingly these sessile marine invertebrates have the ability to biosynthesize a wide variety of structurally unique secondary metabolites, with no equivalent in terrestrial natural products. Because many of these metabolites display biological and pharmacological activities with potential applications in human health and biotechnological industry, they have become excellent candidates for the discovery of new bioactive natural products [1, 2]. While the siliceous Demospongia and Hexactinellida sponge classes, which represent about 90% of the species in the Porifera phylum, have been extensively studied, the chemistry of the Calcarea sponges was barely investigated. Chemical investigations on Calcispongiae have mostly concerned sponges of the Calcinea subclass and very few studies included representatives of the Calcaronea subclass [3–5].

Marine sponges have also proved to be a major source of unusual fatty acids (FA) including very long-chain (up to 34) non-methylene-interrupted fatty acids (NMI FA) with the particular unsaturation pattern $\Delta 5,9$ [6]. Although numerous usual and original FA have been identified from marine Demosponges [7] and some Hexactinellids [5], to the best of our knowledge, only five studies report on the phospholipid FA composition of a few calcareous sponge species [8–12], two of them revealing antimicrobial activity or protein kinase C inhibition activity [11, 12].

The widespread association of marine sponges with a great variety of microorganisms has generated much recent interest, as in numerous chemical studies associated microorganisms proved to be the true producers of sponge metabolites. Our investigations on the role of sponge associated bacterial communities led us to detect bacterial markers in their calcareous sponge hosts through cellular localization, chemical and microbial approaches [13, 14]. The temperate calcareous sponge *Leuconia johnstoni* Carter 1871 (class Calcispongiae, subclass Calcaronea, order Baerida, family Baeriidae) was selected for investigation of its FA composition which can be linked to the abundance of its resident bacteria. Indeed, previous studies have reported that significant levels of *i/ai* SFA can be assigned to bacterial sponge symbionts [15]. However, due to the low available biomass of this small encrusting calcareous species and the observation by thin layer chromatography (TLC) that phospholipids constituted the major class of this sponge lipids, the study was focused on the characterization of its FA composition. These FA were identified through gas chromatography coupled to mass spectrometry (GC–MS) on their methyl esters (FAME) and *N*-acyl pyrrolidide (NAP) derivatives to determine the chain length, degree and position of unsaturations.

Materials and Methods

Sponge Material

Leuconia johnstoni Carter 1871 [16] is a small-sized calcareous sponge species with an encrusting growth form (compressed lobes fused at the base, with a maximum size of 50 mm in diameter and 15 mm thick) living on sub-vertical rock surfaces in wave exposed sites with a distribution ranging from the British Isles to the French Brittany coasts [17]. Specimens of the intertidal calcareous sponge *L. johnstoni* were collected off the Brittany coast (North-East Atlantic, Finistère, France) near Concarneau (Plage des Dames, 47°52'N and 3°55'W). Four successive collections of specimens pooled from several rock-encrusting colonies were realized on the same site on October 2005, September 2007, March 2008 and September 2008 (through a permit granted to S. Derrien, MNHN-Concarneau). Samples were frozen immediately after collection and stored at -80°C until further investigations. Four voucher specimens are available from the Muséum National d'Histoire Naturelle in Paris as collection number MNHN n°C2009-3, n°C2009-10, n°C2009-15 and n°C2009-12, respectively.

Extraction of Total Lipids and Preparation of Fatty Acid Methyl Esters

The extraction was based on the Bligh and Dyer method [18] as amended by Meziane and Tsuchiya [19] and included four successive steps: extraction of total lipids, saponification, methylation and purification of FA by TLC.

Briefly, frozen sponge samples were lyophilized and extracted twice with water/chloroform/methanol (1:1:2, v/v/v) mixture. The combined chloroform extracts yielded the crude total lipids.

The mixture was heated with 2 mL of methanol and 1 mL of sodium hydroxide (2 M). The saponification reaction was stopped by adding an aliquot of hydrochloric acid (35%). After two successive washes with chloroform, followed by centrifugation at 2,000 rpm for 5 min, the lipid fraction was evaporated under a nitrogen stream.

Methylation of FA was obtained by adding 1 mL of a solution of 10% of boron trifluoride (BF_3) in methanol. After 10 min at 90°C , all FA of the total lipids were converted into the fatty methyl esters (FAME). Samples were then extracted twice by a water/chloroform (1:1, v/v) mixture and centrifuged at 2,000 rpm during 5 min. The chloroform was evaporated under nitrogen and FAME were dissolved in a chloroform/methanol (2:1, v/v) mixture, suitable for their preservation.

The lipids extracts were evaporated to dryness and recovered with three washings of 500 μL of a chloroform/methanol (98:2, v/v) mixture. Neutral and polar lipids were separated by column chromatography on silica gel micro-columns (30 \times 5 mm I.D. Kieselgel 70-230 mesh, Merck) using a chloroform/methanol (98:2, v/v) mixture to elute the neutral lipids, followed by neat methanol to elute the polar lipids. Each fraction was then treated in the same way as the bulk sample.

Preparation of *N*-Acyl Pyrrolidides

N-acyl pyrrolidide derivatives (NAP) were prepared by direct treatment of the FAME with a pyrrolidine/acetic acid (10:1, v/v) mixture under reflux for 2 h [20].

Preparation of the Dimethyl Disulfide Adduct

The dimethyl disulfide (DMDS) adduct was obtained from a FAME mixture (2 mg) in dimethyl disulfide (0.48 mL) by adding a solution (0.1 mL) of iodine in diethyl ether (60 mg mL⁻¹) under agitation for 24 h at room temperature [21]. The reaction was stopped by adding hexane (6 mL), washed with a dilute solution of sodium thiosulfate (1.2 mL of a 7 mg/100 mL solution) and dried over anhydrous sodium sulfate and evaporated to dryness. The product was taken up in fresh hexane for injection onto the GC–MS.

Gas Chromatography–Mass Spectrometry Analyses

Gas chromatography coupled with mass spectrometry (GC–MS) experiments were performed on a Hewlett-Packard HP-6890 chromatograph (Agilent Technologies, Massy, France) linked to a HP-5989 spectrometer (70 eV) equipped with a HP-9000-345 integrator and using a SLBTM 5-ms 60 mm \times 0.25 mm \times 0.25 μm fused silica capillary column (splitless) (Supelco, Bellefonte, PA, USA). The carrier gas was helium (flow rate 1 mL/min). Injector and detector temperatures were used at 250 and 280 °C, respectively. The oven temperature was maintained at 170 °C for 4 min and then programmed from 170 to 310 °C at a rate of 3 °C/min and at 200 °C for 4 min and then programmed from 200 to 310 °C at a rate of 3 °C/min for FAME and NAP derivatives, respectively.

Mass spectral data for the two novel FA structures in the calcareous sponge *L. johnstoni*, identified as their FAME and NAP derivatives or DMDS adduct, are presented below.

2-Methyl-13-icosenoic acid methyl ester MS *m/z* (rel. intensity %) [M^+] 338 (1.3), 307 (4.0), 306 (6.1), 291 (0.7), 278 (1.2), 263 (0.5), 250 (1.2), 242 (0.4), 235 (0.4), 222 (0.3), 208 (1.4), 194 (0.7), 181 (0.5), 167 (0.8), 166 (1.0), 165 (1.1), 157 (2.2), 151 (1.2), 143 (2.3), 125 (3.8), 101

Results

The fatty acid (FA) composition of *L. johnstoni* was identified for four samples corresponding to four successive collections on the same geographical site, in the period 2005 to 2008 including autumn (3 replicates) and spring (1 replicate) as reported in Table 1. FA were characterized as their methyl esters (FAME) and *N*-acyl pyrrolidide (NAP) derivatives using gas chromatography-mass spectrometry (GC–MS). Identification of FA was confirmed by comparing their equivalent chain length values (ECL) and their mass spectra (MS) with those of known standards.

Forty-one FA with chain lengths between C₁₄ and C₂₂ were identified in the different samples, as illustrated in Table 1.

Saturated Fatty Acids

In all three samples collected in autumn from October 2005 to September 2008, similar SFA were determined whereas in the sample collected in early spring, March 2008,

FA identified as traces: *SFA* (ECL) 16-Methylheptadecanoic (17.64), 19-Methylcosanoic (20.66), 16-Methyloctadecanoic (18.79), Docosanoic (22.00); *MUFA* 13-Methyl-4-tetradecenoic (14.32), 10-Hexadecenoic (15.90), 15-Methyl-5-hexadecenoic (16.40), 6-Octadecenoic (17.54), 14-Octadecenoic (17.94), 9-Icosenoic (19.30); *DUFA* 13, x-Docosadienoic (21.80)(not previously characterized in a calcareous sponge)

^a Not previously reported in nature

^b Undetermined unsaturations

^c Not previously characterized in a calcareous sponge

ai-16:0, 19:0 and 21:0 were lacking. The linear SFA hexadecanoic acid (16:0) and octadecanoic acid (18:0) were always determined as dominant. They represented between 16.0 and 23.5% and between 9.6 and 14.9% of the total FA + DMA, respectively. The minor linear SFA (20:0) was observed at similar levels (between 1.1 and 1.8%) in the four samples. In contrast, the shortest length SFA (14:0) was identified between 0.2 and 1.9% depending on sample. Additional linear SFA were also observed at noticeable levels of the total FA and DMA in all samples (less than 0.5% for 15:0 and less than 1% for 17:0).

Furthermore, *L. johnstoni* also contained a high proportion of branched SFA including *iso* (*i*) and *anteiso* (*ai*) FA. The diversity of *iso* FA was similar to those of *anteiso* FA (*i/ai* -15:0 to *i/ai*-19:0) excepted for *i*-18:0, *ai*-19:0 and *i*-20:0, only identified as traces. The isoprenoid-type 4,8,12-tridecanoic acid (*br*-13:0) was also identified from 0.5 to 3.1% of the FA + DMA (ECL value of the FAME = 14.50).

Monounsaturated Fatty Acids

Monounsaturated FA (MUFA) represented from 28.0 to 36.0% of the total FA + DMA in the sponge. Surprisingly, an unusual MUFA was present in all samples with an aliphatic chain of 20 carbons (ECL value of 20.18). The mass spectrum (MS) of its methyl ester (FAME) revealed a molecular ion $[M]^+$ at m/z 338 corresponding to a $C_{20:1}$ FA structure (Fig. 1).

In the MS of its FAME, the fragment ion at m/z 88 (C_3 fragment + H) as the base peak and the major ion at m/z 101 could remind a McLafferty rearrangement of a FA ethyl ester. But, the presence in the MS of the relatively intense fragment ion at m/z 306 ($[M-31]^+$) indicated that the

compound was obviously a FAME. These key observations allowed to identify this compound as a MUFA with a methyl group at C-2, which was also supported by the MS of its NAP derivative, showing the molecular ion at m/z 377 (Fig. 2).

The MS of its pyrrolidide derivative displayed the expected McLafferty ion at m/z 113, while the base peak was present at m/z 127, confirming the 2-methyl branching nature of this MUFA. This observation was in accordance with the occurrence of an elevated peak at m/z 140, as depicted in the Lipid Library, for a 3-methyl branched NAP. In addition, the gap of 12 amu between fragment ions at m/z 278 and m/z 266 suggested localization of the double bond between carbons C-13 and C-14 of the aliphatic chain. In order to confirm this hypothesis, the dimethyl disulfide (DMDS) adduct of this 2-methyl MUFA was prepared as previously described by Imbs et al. [21]. Analysis of the MS of the corresponding DMDS adduct showed the presence of characteristic fragments at m/z 145, 213, 241 and 273 (Fig. 3), confirming unambiguously the localization of the unsaturation between C-13 and C-14. However its configuration could not be determined.

This MUFA was unequivocally identified as 2-methyl-13-icosenoic acid (2-Me-13-20:1). Its occurrence in all samples of *L. johnstoni* collected at the same geographical site at different seasons is noteworthy. Indeed, this unusual 2-methyl FA represented 22.4% and 24.3% in autumn (September 2007 and October 2005 respectively) and 20.8% of the total FA + DMA of specimens collected in spring (March 2008). However in winter (February 2006 and 2007) the sponge lipid profile was dominated by SFA and the abundance of this unusual 2-Me-13-20:1 dropped to respectively 7.8 and 9.8% of FA + DMA, although it still dominated the sponge MUFA (data not shown, publication in preparation).

Fig. 1 Mass spectrum of 2-methyl-13-icosenoic acid methyl ester from *L. johnstoni*

Fig. 2 Mass spectrum of 2-methyl-13-icosenoic acid pyrrolidine derivative from *L. johnstoni*

Fig. 3 Mass spectrum of 2-methyl-13-icosenoic acid dimethyl disulfide derivative from *L. johnstoni*

It appeared to us that the peak representing the new 2-methyl-13-icosenoic acid was highly represented in the polar phospholipid fraction.

Two additional hexadecenoic-type MUFA, 5-hexadecenoic and 9-hexadecenoic, were also identified in low amounts (0.3–1.4 and 0.7–1.8%, respectively) as well as two octadecenoic-type MUFA: 9-octadecenoic (0.8–2.0%) and 11-octadecenoic (0.7–4.1%). 13-icosenoic (1.5–2.5%) and heneicosenoic acid (1.1–1.5%) were only identified in three specimens out of four.

In addition, six MUFA were identified as traces: 13-methyl-4-tetradecenoic, 10-hexadecenoic, 15-methyl-5-hexadecenoic, 6-octadecenoic, 14-octadecenoic, 9-icosenoic (Table 1).

The two monomethyl branched MUFA, 13-methyl-4-tetradecenoic and 15-methyl-5-hexadecenoic, were readily identified from their GC mobilities (ECL of 14.32 and 16.40, respectively) and from their corresponding NAP derivatives MS spectra. The MS of the NAP of 13-methyl-4-tetradecenoic displayed the molecular ion at m/z 293

(15:1 FA structure), as well as fragment ions at m/z 139 and 152, and an intense fragment ion at m/z 166 (53%) indicating a double bond between C-4 and C-5, as shown in the Lipid Library [22]. Furthermore, a very weak ion at m/z 264 indicated an *iso*-branched FA. Similarly, the MS of the NAP of 15-methyl-5-hexadecenoic displayed the molecular ion at m/z 321 (17:1 FA structure), and fragment ions at m/z 140 and 153, indicating a double bond between C-5 and C-6. In this case, the *iso*-branched was indicated by a weak peak at m/z 292.

Polyunsaturated Fatty Acids

Four DUFA were observed, in low amounts (<2%).

The DUFA, eluted just before the 9,12-octadecadienoic (0.8–1.1%), had an ECL value of 17.82 as methyl ester and showed in its MS a molecular ion at m/z 294, indicating a 18:2 acid structure. The MS of its NAP showed a molecular ion at m/z 333 (18:2). The two double bonds were located by the 12 amu gaps between the peaks at m/z 182 (C-7) and

Fig. 4 Mass spectrum of 8,13-octadecadienoic acid pyrrolidide derivative from *L. johnstoni*

m/z 194 (C-8) and between the peaks at m/z 250 (C-12) and m/z 262 (C-13), indicating $\Delta 8$ - $\Delta 13$ unsaturations. Major diagnostic fragmentations of FAME and NAP of 8,13-octadecadienoic acid under electron impact are given in the “Materials and Methods” section. This DUFA 8,13-octadecadienoic acid occurred in low abundance in all samples with values ranging from 0.6 to 0.9% of total FA + DMA (Fig. 4).

The two other detected DUFA are 11,15-icosadienoic acid (0.8–3.1%) and 13,x-docosadienoic acid (traces). Complete identification of the latter failed due to its very small amount.

Two other PUFA 5,8,11,14-icosatetraenoic acid (0.8–1.9%) and 5,8,11,14,17-icosapentaenoic acid (0.7–1.8%) were also observed.

Dimethylacetals

Several DMA were detected at trace levels in the lipid fraction of *L. johnstoni*. However, one of them was detected at a significant amount in all samples, accounting for 11.8% of total FA + DMA in September 2008. MS of this dominant DMA (ECL = 20.75), showed characteristic fragment ions at m/z 75 ($[(CH_3O)_2-CH]^+$) [23] and m/z 322 corresponding to $[M-31]^+$, indicating a C_{21} saturated fatty aldehyde with two unsaturations.

Discussion

By contrast with siliceous Demosponges and Hexactinellids, only a few reports have characterized the lipid composition of Calcsponges [8–10]. To obtain further insight into the FA content of Calcsponges, we selected *Leuconia johnstoni* as a calcareous sponge model belonging to the chemically poorly studied Calcaronea subclass. We investigated its FA

composition comparing four specimens collected at the same site in a time series over 4 years.

Out of the forty-one identified FA, twenty-two were saturated FA (SFA), including eighteen major SFA represented between 52.1 and 59.0% of the total FA + DMA. In addition to the known linear SFA, *ilai* C_{14} – C_{22} , typical FA of bacteria, were observed in all *L. johnstoni* specimens at significant levels ranging from 9 to 16% of total FA + DMA. Previous studies had reported that *ilai* FA were found as minor compounds or traces in terrestrial eukaryotes but in high amounts in some marine eukaryotes such as sponges, nudibranch molluscs, asteroidea and tunicates [9, 24, 25]. These mid-chain-branched *ilai* FA, which are considered as membrane constituent especially in Gram-positive bacteria, have often been assigned to bacterial sponge symbionts [15, 26, 27]. Recently, methyl-branched fatty acids were proposed to be synthesized by Poribacteria [28]. Nevertheless, 16-methyl-octadecanoic acid (*ai*-19:0) which is reported as a major FA in several Calcareous sponge species mostly of the Calceinea subclass [9] was found in low amounts in *L. johnstoni*. Furthermore, although 17-methyl-nonadecanoic acid (*ai*-20:0) was previously reported as a major compound of presumably sponge cell origin in Calcspongiae [9], this FA was lacking in our samples even as traces.

Other branched FA have also been considered as bacterial markers, especially some monounsaturated FA (MUFA). In this study, thirteen MUFA were observed, among which seven had major relative abundance (28.0–36.0%). However, *iso*-15:1 and *iso*-17:1 MUFA with various positions of the double bond, which were previously reported as characteristic of sulfate-reducing bacteria of the genus *Desulfovibrio* [29, 30], were both lacking in all samples of *L. johnstoni*.

As a major result, our study led to the identification for the first time in a calcareous sponge of a new natural

MUFA identified as 2-methyl-13-icosenoic acid as the dominant MUFA. Its high relative abundance, ranging from 20.8 to 25.8% of the total FA + DMA in all four samples of *L. johnstoni*, suggests that it might play a significant role in the biology of this sponge, potentially in the function of its cellular membranes. Unfortunately, despite of its high relative abundance, the purification of this 2-methyl FA remained difficult due to the low available sponge biomass of *L. johnstoni*.

Previously, some 2-methyl branched unsaturated FA have already been isolated but only from siliceous marine sponges. In 1990, the first 2-methyl branched FA, 2-methyloctadecanoic acid was identified from the Demosponge *Plakortis halichondroides* [31]. Later, two additional 2-methyl branched MUFA, 2-Me-24:1n-7 and 2-Me-26:1n-9 were isolated in small amounts (7.1% of sponge total FA) from the Demosponge *Halichondria panicea* [21].

Further chemotaxonomic studies would be necessary to demonstrate the specificity of this new 2-methyl-13-icosenoic acid as potential biomarker for sponges of the genus *Leuconia*.

Six polyunsaturated FA (PUFA) accounting between 4.0 and 8.2% of the total FA + DMA, including the two non-methylene-interrupted FA (NMA) 8,13-18:2 and 11,15-20:2 and one additional diunsaturated FA (DUFA) 9,12-18:2, were also detected. This is the first time that the unusual 8,13-octadecadienoic acid was characterized in a calcareous sponge. Numerous NMI FA, such as 5,11-20:2, 5,13-20:2, 7,13-22:2 and 7,15-22:2 have already been identified from marine sponges [6, 7, 32]. The 11,15-icosadienoic acid NMI observed in this study was previously identified from the Caribbean Demosponge *Amphimedon complanata* and the Axinellida sponge *Pseudaxinella* cf. *lunaecharita* [7, 33, 34]. The origin of the two PUFA 5,8,11,14-icosatetraenoic acid and 5,8,11,14,17-icosapentaenoic acid, which were detected in all samples of *L. johnstoni*, remains unknown [35]. They were observed at a very low level, representing less than 2% of the total FA and DMA content. No other PUFA with 3 or more double bonds were identified.

Furthermore, we noticed that demospongiac acids, defined by Christie for the database Lipid Library as long-chain FA with a $\Delta^{5,9}$ unsaturation system and recently revisited as NMI FA, were totally absent in *L. johnstoni*. These NMI FA, observed in various marine sources with a large range of chain-lengths (C₁₆–C₃₂) [36] were previously reported in specimens of calcareous sponges in the genera *Clathrina* (Calcinea subclass) and *Sycon* (Calcareo-nea subclass) [8].

Finally, some DMA were observed, of which one was abundant, identified as 21:2 and accounting for 2.9–11.8% of the total FA + DMA.

The finding of DMA among FAME in *L. johnstoni* points to the presence of plasmalogens (1-*O*-1'-enyl-2-acyl-glycerophospholipids) in the sponge. The DMA are produced from aldehydes, released from plasmalogens, concomitantly with the FAME during the esterification step [23]. These plasmalogens are widely distributed in the animal kingdom and also occur in some anaerobic microorganisms and marine invertebrates [37]. In mammals, they could have a role in physical properties of cell membranes, storage of arachidonic acid, activation of phospholipase A₂ and cellular signalization. They are also involved in protection against oxidative stress [38]. The presence of plasmalogens was previously reported in the Demosponge *Polymastia penicillus* but their structures could not be determined due to both low amounts and co-elution with other lipids during purification [7]. However, to date, the biological role of plasmalogens in sponges is not clearly determined. We speculate that they may have similar functions as in more complex metazoan organisms including protection against oxidative stress or against attack by microorganisms.

Surprisingly, by contrast with all other FA, which were in constant relative abundance in the four specimens collected during two seasons over 4 years, detection of this DMA was variable and fluctuated between 2.9 and 11.8% without any seasonal corroboration.

In conclusion, this first investigation of the fatty acid composition of the Calcareo-nea species *Leuconia johnstoni* Carter 1871 identified the new 2-methyl-13-icosenoic FA in a calcareous sponge. It also revealed the occurrence at low levels of the unexpected PUFA 20:4 and 20:5 and of the DMA 21:2 although in fluctuating ratios. The nearly constant high relative abundance of the new 2-methyl-13-icosenoic FA in *L. johnstoni* suggests that this MUFA might be further explored as a potential biomarker. Further investigations on lipids and FA composition of *Leuconia* species remain to be carried out to substantiate this hypothesis.

Acknowledgments This work is part of Elodie Quévrain's Ph.D. thesis, supported by a grant from the French Ministère de l'Enseignement Supérieur et de la Recherche. The authors also thank the director and staff of the Laboratoire de Biologie Marine du Muséum National d'Histoire Naturelle, Station Marine de Concarneau, France, for providing access to facilities for regular sponge collections.

Abstract Endocannabinoids have been implicated in cancer development and cause heterogenous effects in tumor cells, by inducing apoptosis, reducing migration, causing anti-angiogenic activity and alterations in the cell cycle resulting in growth arrest. Recently, several novel amides of fatty acids that are structurally related to endocannabinoids have been isolated from mammalian sources, although the functions of these fatty amides are not well studied. One group of these novel fatty acid amides are the *N*-acyl taurines (fatty acids conjugated to the amino acid taurine). This study examined if *N*-acyl taurines, specifically *N*-arachidonoyl taurine and *N*-oleoyl taurine could function in a similar way to endocannabinoids and result in cell cycle alterations or growth arrest in the human prostate adenocarcinoma cell line PC-3. PC-3 cells were treated with various concentrations of *N*-arachidonoyl taurine and *N*-oleoyl taurine and cell proliferation and viability was measured using resazurin and colony formation assays. Effects of *N*-acyl taurines on the cell cycle was measured using FACS analysis. Treatment with *N*-arachidonoyl taurine and *N*-oleoyl taurine resulted in a significant reduction in proliferation of PC-3 cells, even at concentrations as low

as 1 μ M. Treatment with *N*-oleoyl taurine resulted in an increased number of cells in the subG1 population, suggesting apoptosis, and a lower number of cells in S-phase of the cell cycle. In summary, our results show that novel biologically active lipids, the *N*-acyl taurines, result in reduced proliferation in PC-3 cells.

Introduction

The endocannabinoid system is an endogenous signaling system that has pleiotropic effects on metabolism, cell proliferation, appetite, pain sensation and neuromodulatory effects (for review see [1]). Currently, several amides of fatty acids have been isolated from mammalian sources, which are structurally related to endocannabinoids, however, details of how these molecules are synthesized and degraded in vivo are only emerging. One group of these fatty acid amides is the *N*-acyl amino acids present in mammalian species, which have generated renewed research interest in part because of their structural relationship to the endocannabinoids [2, 3]. *N*-Acyl amino acids are fatty acids conjugated to amino acids such as glycine, taurine, alanine, serine etc. and fatty acid conjugates with the common 20 amino acids have now been

identified in mammalian tissues [2]. However, *N*-acyl amino acids are not considered endocannabinoids as they do not activate the cannabinoid receptors. The functions of *N*-acyl amino acids are still not clear but it is emerging that they function as putative signaling molecules with a wide range of biological activities (for review see [4]). The first *N*-acyl amino acid detected in mammalian systems was *N*-arachidonoyl glycine (NAGly-arachidonic acid conjugated to glycine) which was found in rat brain and other tissues [5]. NAGly is synthesized by several pathways, including an enzymatic conjugation of arachidonoyl-CoA with glycine [6], synthesis by cytochrome c in the presence of arachidonoyl-CoA and hydrogen peroxide [7], and finally by oxidation of anandamide (an endocannabinoid) by alcohol and aldehyde dehydrogenases [8].

A further group of *N*-acyl amino acids identified in 2005 are the *N*-acyl taurines (fatty acids conjugated to taurine). *N*-Acyl taurines were first detected by global metabolic profiling in the fatty acid amide hydrolase (FAAH) knockout mouse model in brain, spinal cord, testes and liver [9, 10]. Saturated, monounsaturated and polyunsaturated *N*-acyl taurines of various fatty acid chain-lengths have been identified in vivo in mouse, with the liver and kidney containing higher levels of polyunsaturated *N*-acyl taurines than saturated *N*-acyl taurines, while the brain contains higher levels of saturated rather than polyunsaturated *N*-acyl taurines [11]. It was also shown recently that *N*-arachidonoyl taurine can be oxidized by lipoxygenase enzymes, resulting in oxidative metabolites of *N*-arachidonoyl taurine which may have their own biological function [12]. Interestingly, *N*-arachidonoyl taurine was shown to activate transient receptor potential (TRP) vanilloid type channels, TRPV1 ($EC_{50} \sim 28 \mu\text{M}$) and TRPV4 ($EC_{50} 21 \mu\text{M}$), suggesting a role for taurine conjugated fatty acids in cell signaling via cell surface receptors [11]. The TRPV1 and TRPV4 are cation channels, activated by a number of endogenous substances, resulting in an influx of calcium into cells. They play roles in pain regulation, regulation of blood pressure, osmotic sensation and in respiratory diseases (for review see [13]). Increased expression of TRPV1 has been found to be associated with human prostate carcinoma and cancers associated with colon, pancreas and bladder [14].

It is known that endocannabinoids (e.g. anandamide and 2-arachidonoylglycerol) exert anti-proliferative actions on a wide spectrum of tumor cells in culture [15, 16]. Endocannabinoids cause heterogeneous effects in tumor cells, by inducing apoptosis, reducing migration, causing anti-angiogenic activity and cause alterations in the cell cycle resulting in growth arrest. The anti-proliferative effects of endocannabinoids occurs mainly by binding and activating their specific cannabinoid receptors and inhibiting adenylyl cyclase/cyclic AMP resulting in altered downstream

pathways such as mitogen-activated protein kinases, survival pathways and forkhead transcription factors [15, 16]. As endocannabinoids have been shown to have anti-proliferative effects in cancer models, and the *N*-acyl taurines are structurally related to endocannabinoids, we were interested to investigate the anti-proliferative effects of *N*-acyl taurines in two cancer cell lines, PC-3 (human prostate adenocarcinoma cell line) and MCF-7 (human breast adenocarcinoma cell line). Our results show that *N*-arachidonoyl taurine (C20:4 taurine) and *N*-oleoyl taurine (C18:1 taurine) significantly inhibit cell proliferation in PC-3 cells, and were more effective in PC-3 cells than in MCF-7 cells.

Materials and Methods

Chemicals and Reagents

N-Arachidonoyl taurine and *N*-oleoyl taurine were purchased from Cayman Chemical Company (Ann Arbor, MI, USA). A 10 mM stock was prepared in 100% DMSO (Sigma-Aldrich, St. Louis, MO, USA) and stored at -20°C . Propidium iodide (PI) was purchased from Invitrogen (Eugene, OR, USA) and RNase A was purchased from Fermentas (Burlington, Canada). Cell culture medium and supplements were purchased from Gibco (Carlsbad, CA, USA).

Cell Culture

PC-3 human prostate adenocarcinoma cell and MCF-7 human breast adenocarcinoma cell lines were kindly provided by Professor Thomas Helleday. Both cell lines were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% foetal bovine serum, penicillin 100 U/ml and streptomycin 100 $\mu\text{g/ml}$ at 37°C in an atmosphere containing 5% CO_2 .

Cell Viability Assay (Proliferation Assay)

20,000 cells/well were plated in six-well plates in 2 ml of complete DMEM medium. The next day the cells were treated with *N*-acyl amino acids or vehicle (DMSO) in delipidated foetal bovine serum in DMEM at concentrations of 10 and 40 μM for 24, 48 and 72 h. Viable cells were collected by trypsinization and counted in Coulter Counter (Coulter Electronics, Bedfordshire, England). Resazurin assay (Sigma-Aldrich, St. Louis, MO, USA) was used to estimate cell numbers in accordance with the manufacturer's instructions. The dehydrogenase activity was fluorometrically determined by measuring the reduction of resazurin (blue, non-fluorescent) to resorufin (pink,

highly fluorescent). Cells were plated in 96-well plates at 5,000 cells/well in 200 μ l of complete DMEM medium. The next day the cells were treated with *N*-acyl amino acids or vehicle in delipidated serum in DMEM at a range of concentrations for 24, 48 and 72 h. After treatment cells were washed with PBS and incubated with 10 μ g/ml resazurin for 1 h at 37 °C in an atmosphere containing 5% CO₂. The cell viability was determined by measuring the fluorescence at 535/590 nm (excitation/emission) using Polar Star Omega multi-plate reader (BMG Labtech, Offenburg, Germany).

Colony Formation Assay (Cytotoxicity Assay)

Cells were plated in 100-mm dishes at a density of 500 cells/dish in complete DMEM medium. The next day the cells were treated with *N*-acyl amino acids or vehicle in delipidated serum in DMEM at concentrations of 10 and 40 μ M and after 48 h the medium was replaced with fresh complete DMEM. After 2 weeks incubation (at 37 °C/5% CO₂), when colonies could be observed, the colonies were fixed and stained with methylene blue in methanol (4 g/l) and counted.

Propidium Iodide Staining and FACS Analysis

0.5 \times 10⁶ cells in 75-cm² flasks (Sarstedt, Nümbrecht, Germany) were treated with *N*-acyl amino acids (10 and 40 μ M) or vehicle in delipidated serum in DMEM and collected after 48 h by trypsinization. Cells were fixed in ice-cold 70% ethanol overnight at –20 °C for FACS analysis. The cells were then rehydrated in PBS and stained with 50 μ g/ml propidium iodide (PI) and 10 μ g/ml RNase A in PBS for 30 min at room temperature (in the dark). Samples were further analyzed on a BD Biosciences FACScan. The data was analyzed using the WinMDI software version 2.9.

Statistical Analysis

All data are presented as means \pm SEM. Statistical analysis was performed using two-way ANOVA, except for the resazurin assay which was analyzed using one-way ANOVA.

Results

N-Arachidonoyl Taurine and *N*-Oleoyl Taurine Significantly Reduce Proliferation of PC-3 Cells

Two different human adenocarcinoma cell lines were used as model systems to study the effect of *N*-arachidonoyl taurine and *N*-oleoyl taurine on proliferation of PC-3

cells (prostate) and MCF-7 (breast). The effect of *N*-arachidonoyl taurine and *N*-oleoyl taurine on cell proliferation was analyzed using three different assays. In the first assay, PC-3 and MCF-7 cells were treated with 10 or 40 μ M of either lipid and cells were counted following treatment for 24, 48 and 72 h. These concentrations of 10 or 40 μ M were chosen as previous studies showed that *N*-arachidonoyl taurine activates the TRPV1 and TRPV4 channels; EC₅₀ \sim 28 μ M (11–70 μ M, 95% confidence limits) and EC₅₀ \sim 21 μ M (3–130 μ M, 95% confidence limits) respectively [11]. The number of PC-3 cells treated with vehicle increased over the period of treatment, while treatment with *N*-arachidonoyl taurine had no effect on the cell number after 24 h treatment at 10 and 40 μ M concentrations, but 40 μ M *N*-arachidonoyl taurine resulted in a slower rate of cellular proliferation after 48 and 72 h of treatment (Fig. 1a). However, this effect was not statistically significant.

Treatment with *N*-oleoyl taurine resulted in a slower rate of cellular proliferation than control cells following treatment with 10 and 40 μ M *N*-oleoyl taurine and a significant

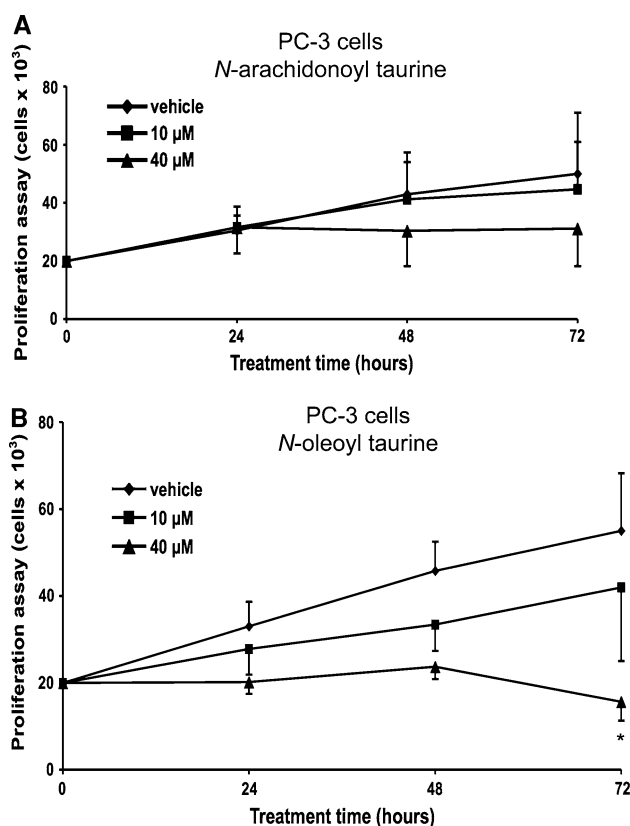

Fig. 1 *N*-Oleoyl taurine inhibits proliferation of PC-3 cells. Cells were seeded in six-well plates with 20,000 cells/well and treated with **a** *N*-arachidonoyl taurine **b** *N*-oleoyl taurine, or vehicle (DMSO) at concentrations of 10 and 40 μ M for 24–72 h. Cell viability was determined by cell counting. Data are presented as means \pm SEM ($n = 3$). *Significantly different from control treatment, $p < 0.05$

decrease in proliferation seen after 72 h of treatment with 40 μ M *N*-oleoyl taurine ($p < 0.05$) (Fig. 1b).

A second assay using a resazurin labeling method, which is a more sensitive method to measure cell viability and proliferation, was used. PC-3 cells were treated with 10, 20 and 40 μ M *N*-arachidonoyl taurine and *N*-oleoyl taurine and cell viability was examined. *N*-Arachidonoyl taurine resulted in a reduced proliferation of PC-3 cells after 48 and 72 h (after 48 h ($p < 0.001$) and 72 h ($p < 0.001$)) (Fig. 2a). *N*-Oleoyl taurine was particularly potent in reducing cell proliferation even at 10 μ M ($p < 0.001$) (Fig. 2b), and therefore similar experiments were carried out with lower concentrations of *N*-oleoyl taurine, using 1 and 5 μ M. Following 48 h treatment, a significantly reduced cellular proliferation was evident (Fig. 2c). Interestingly, *N*-oleoyl taurine decreased cellular proliferation significantly after 24 h with 10 μ M to 80% ($p < 0.0126$) and to 70% with concentrations as low as 1 μ M after 48 and 72 h ($p < 0.0010$ and $p < 0.0001$) (Fig. 2c).

To identify whether the effects of *N*-acyl taurines were specific for PC-3 cells, MCF-7 cells were also treated with *N*-acyl taurines. Treatment with both *N*-arachidonoyl taurine and *N*-oleoyl taurine resulted in a reduced cell proliferation of MCF-7 cells, showing that anti-proliferative effects of *N*-acyl taurines were not specific for prostate cell lines. *N*-Arachidonoyl taurine had a significant effect on cell proliferation of MCF-7 cells at 20 μ M after 24/48 h of treatment (Fig. 3a), whereas significant effects were evident in PC-3 cells after 48/72 h treatment (Figs. 2a and 3a). *N*-Oleoyl taurine was more potent at reducing proliferation of MCF-7 cells than *N*-arachidonoyl taurine, with significant effects evident after 24 h and especially after 72 h treatment (Fig. 3b), although *N*-oleoyl taurine was more potent in PC-3 cells than MCF-7 cells (compare Figs. 2b and 3b).

PC-3 cell survival was further investigated following treatment with *N*-arachidonoyl taurine and *N*-oleoyl taurine, using the colony formation assay. Cells were treated for 48 h with *N*-arachidonoyl taurine and *N*-oleoyl taurine (10 or 40 μ M) in delipidated serum and allowed to proliferate for 2 weeks in complete medium (medium changed every other day). In this assay treatment of PC-3 cells with 40 μ M of *N*-arachidonoyl taurine and *N*-oleoyl taurine reduced the colony number significantly ($p < 0.01$) to 56 and 62% respectively (Fig. 4).

N-Oleoyl Taurine Treatment Increases the Number of Cells in SubG1 Phase in PC-3 Cells

As *N*-arachidonoyl taurine and *N*-oleoyl taurine resulted in reduced cellular proliferation of PC-3 cells, the effect of treatment with these lipids at different stages of the cell cycle was examined by flow-cytometry. No significant effects were seen after treatment with *N*-arachidonoyl

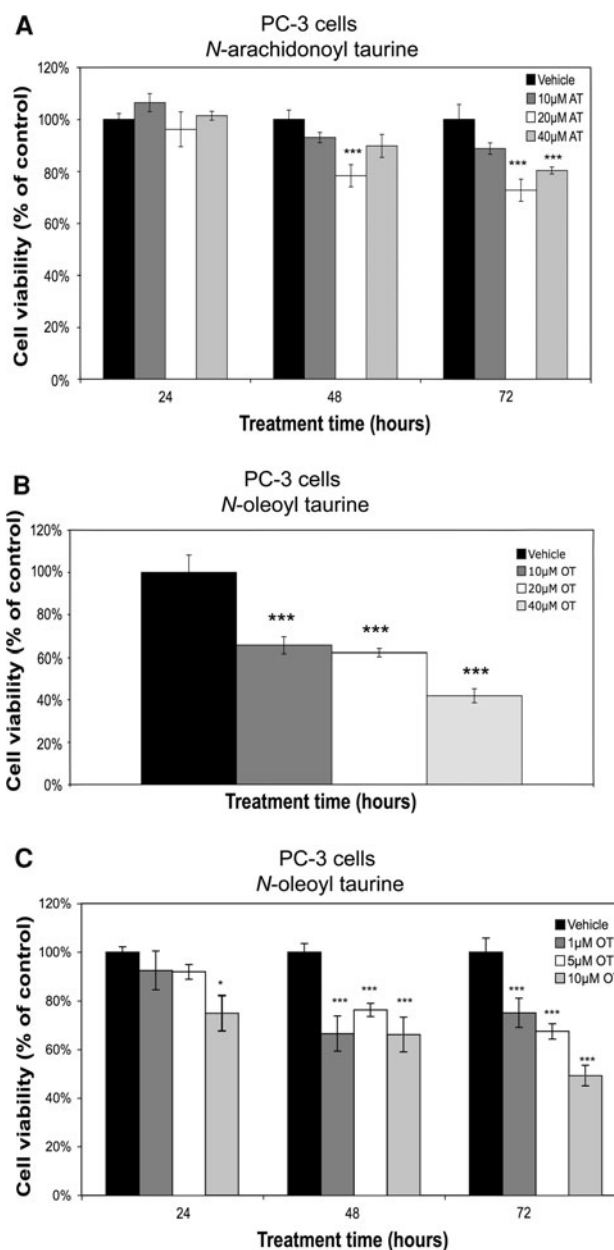

Fig. 2 *N*-Arachidonoyl taurine and *N*-oleoyl taurine inhibit proliferation of PC-3 cells. Cells were seeded in 96-well plates in the amount of 5,000 cells/well and cell viability was determined by a resazurin-based method following 24–72 h treatment with different concentrations of *N*-acyl taurines or vehicle (DMSO). **a** PC-3 cells treated with 10, 20 and 40 μ M of *N*-arachidonoyl taurine (AT) after 24, 48 and 72 h. **b** PC-3 cells treated with 10, 20 and 40 μ M of *N*-oleoyl taurine (OT) after 72 h. **c** PC-3 cells treated with 1, 5 and 10 μ M of *N*-oleoyl taurine after 24, 48 and 72 h. Data are presented as means \pm SEM. * $p < 0.05$, *** $p < 0.001$

taurine in any phases of the cell cycle (Fig. 5a, c). Interestingly, *N*-oleoyl taurine treatment resulted in an increase in the number of cells in the subG1 phase (40 μ M *N*-oleoyl taurine ($p < 0.001$)), with a reduction of cell numbers in the S and G2/M phases (Fig. 5b, c).

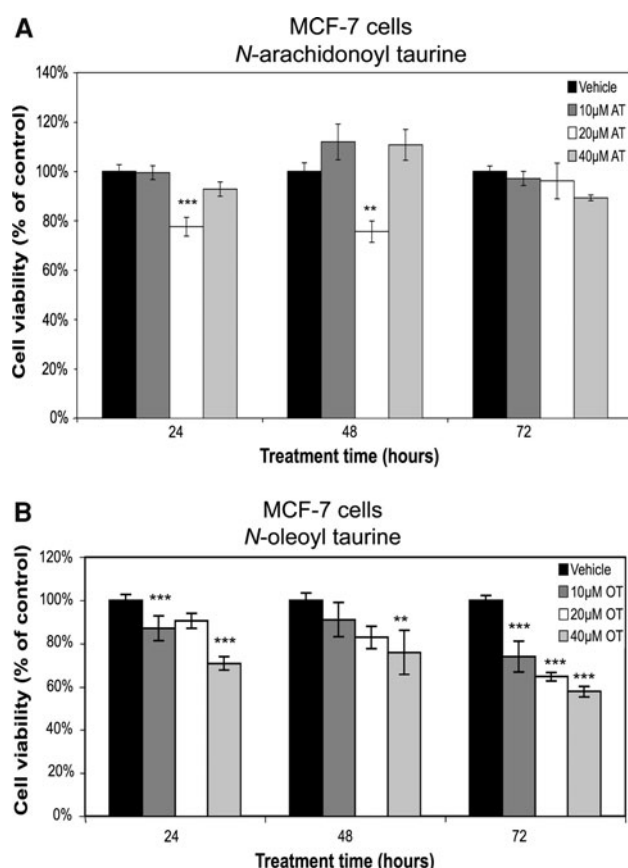

Fig. 3 *N*-Arachidonoyl taurine and *N*-oleoyl taurine inhibit proliferation of MCF-7 cells. Cells were seeded in 96-well plates in the amount of 5,000 cells/well and cell viability was determined by a resazurin-based method following 24–72 h treatment with different concentrations of *N*-acyl taurines or vehicle (DMSO). **a** MCF7 cells treated with 10, 20 and 40 μ M of *N*-arachidonoyl taurine (AT) after 24, 48 and 72 h. **b** MCF7 cells treated with 10, 20 and 40 μ M of *N*-oleoyl taurine (OT) after 24, 48 and 72 h. Data are presented as means \pm SEM. ** p < 0.01, *** p < 0.001

Discussion

The discovery of novel lipids which are structurally related to endocannabinoids indicates the existence of novel signaling pathways in mammals. Endocannabinoids have been implicated in cancers and cause heterogeneous effects in tumor cells by inducing apoptosis, reducing migration, by possessing anti-angiogenic activity and cause alterations in the cell cycle resulting in growth arrest [15–17]. This study aimed to elucidate if *N*-acyl taurines, a recently identified family of novel lipids [10], may have similar effects on pathways controlling cell growth and proliferation.

In this study, the major anti-proliferative effects on PC-3 cells were identified with *N*-oleoyl taurine (C18:1 taurine), even at concentrations as low as 1 μ M. The effects on PC-3 cells were also significant with *N*-arachidonoyl taurine (C20:4 taurine) at various concentrations. Various endogenous lipids act as ligands for multiple types of receptors

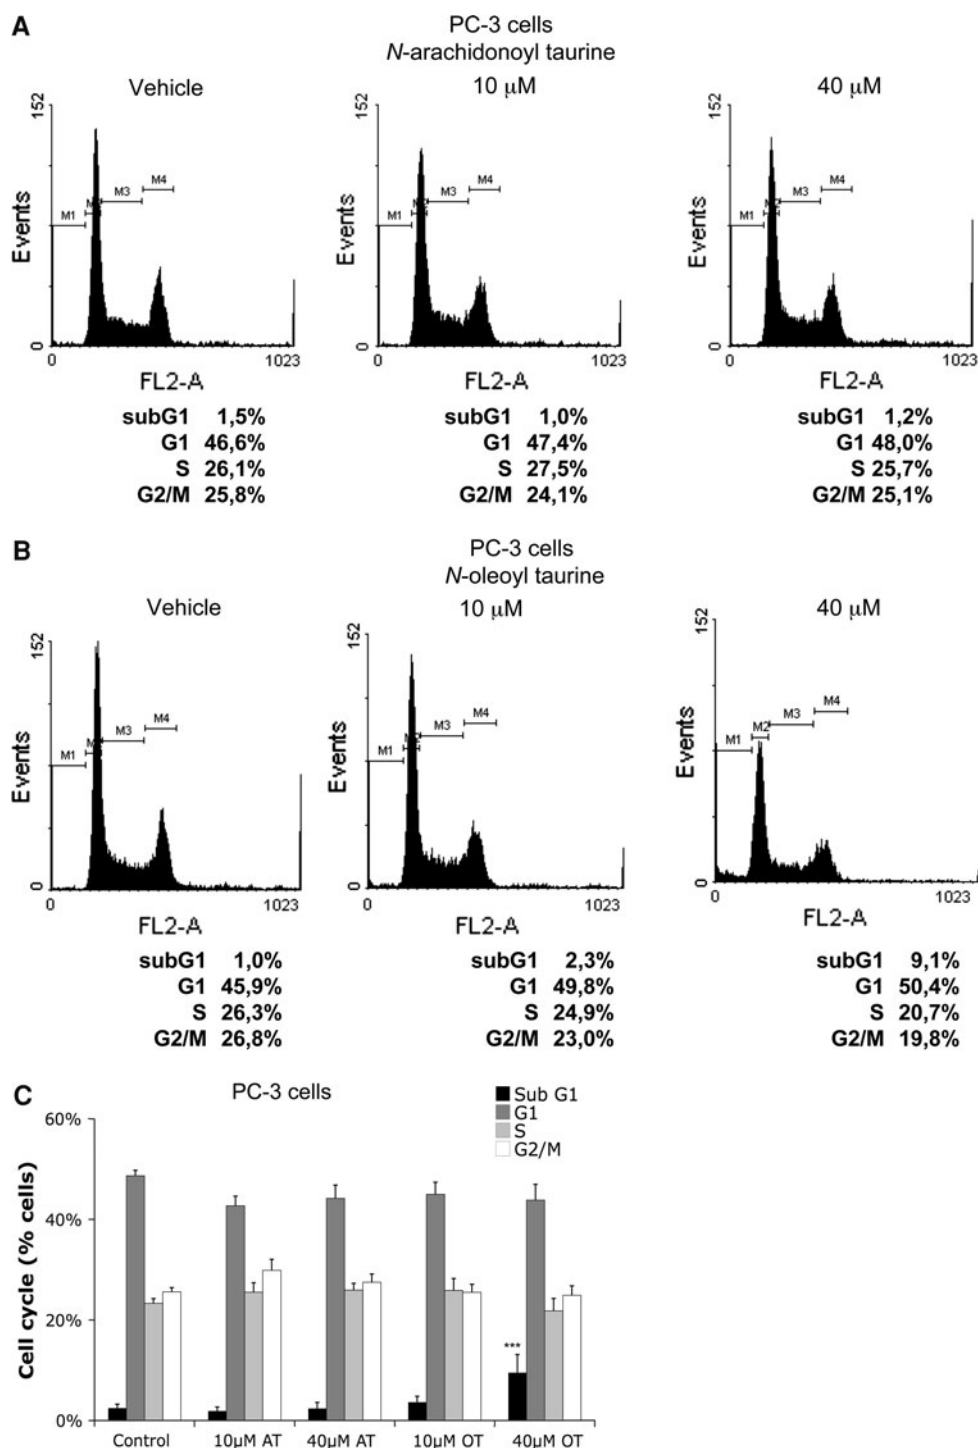

Fig. 4 *N*-Oleoyl taurine and *N*-arachidonoyl taurine reduces the colony-forming abilities of PC-3 cells. Cells were seeded in 100 mm dishes at a density of 500 cells/dish in DMEM with delipidated serum and treated with *N*-arachidonoyl taurine, *N*-oleoyl taurine or vehicle at concentrations of 10 and 40 μ M for 48 h. After 48 h, medium was replaced with DMEM + foetal bovine serum (complete medium). Colonies formed were counted after 2 weeks in culture. Data are presented as means \pm SEM (n = 3). ** p < 0.01

and *N*-arachidonoyl taurine activates the TRPV1 and TRPV4 channels; EC_{50} \sim 28 μ M (11–70 μ M, 95% confidence limits) and EC_{50} \sim 21 μ M (3–130 μ M, 95% confidence limits) respectively, whereas no activity with *N*-arachidonoyl taurine was identified with the cannabinoid receptors CB1 and CB2 or nuclear receptors such as peroxisome proliferator-activated receptors [11]. In our study concentrations of *N*-acyl taurines in the region of those required to activate the TRPV1 and TRPV4 channels were used, although significant effects on cell proliferation with 1 μ M *N*-oleoyl taurine were identified. The anti-proliferative effects of *N*-oleoyl taurine in carcinoma cells were comparable to other fatty acid amides. Anandamide (*N*-arachidonylethanolamide) inhibits the proliferation of MCF-7 and EFM-19 cells at concentrations of between 0.5 and 1.5 μ M [17] and also inhibits the proliferation of PC-3 cells at concentrations of 1–10 μ M [18].

There are potentially two pathways to regulate the intracellular levels of *N*-acyl taurines: a) hydrolysis by the FAAH (which hydrolyzes *N*-acyl taurines to the free fatty acid and taurine) or b) oxidative metabolism of *N*-acyl taurines, resulting in generation or termination of novel signaling molecules [12]. The FAAH has been shown to hydrolyze both *N*-arachidonoyl taurine and *N*-oleoyl taurine [19]. Inhibition of the FAAH in mice resulted in accumulation of micromolar levels of *N*-acyl taurines in liver, kidney and the CNS, suggesting that micromolar levels can be reached in vivo [11]. An enzymatic pathway for the synthesis of saturated *N*-acyl taurines has been identified in peroxisomes [20], but as yet a pathway for synthesis of unsaturated *N*-acyl taurines is not known.

Fig. 5 *N*-Oleoyl taurine treatment increases the subG1 population of PC-3 cells. Cell cycle analysis was performed on PC-3 cells treated with *N*-acyl taurines or vehicle for 48 h. Cells were stained with propidium iodide and analyzed by FACS and data analyzed using the WinMDI software version 2.9. Representative histograms are shown in **a** *N*-arachidonoyl taurine (AT) and **b** *N*-oleoyl taurine (OT). **c** Data are presented as means \pm SEM
*** $p < 0.001$ = significantly different from SubG1 phase in control cells treated with vehicle ($n = 4$)

Interestingly, the FAAH is not expressed in PC-3 cells [21] and therefore *N*-oleoyl taurine and *N*-arachidonoyl taurine should remain 'active' for a longer period of time as a bioactive lipid signaling molecule as they will not be hydrolyzed by FAAH. It would be of interest to test these bioactive lipids in DU-145 and LNCaP prostate carcinoma cell lines, as LNCaP express high levels of FAAH, whereas DU-145 cells express low levels of FAAH [21], which may

result in different effects on cellular proliferation in different prostate carcinoma cell models. Interestingly, our results identified significant differences in how the two *N*-acyl taurines studied affected the cell cycle with a significant increase in the number of cells in subG1 phase following treatment with *N*-oleoyl taurine, suggesting apoptosis. The different effects may be due to acyl chain composition [*N*-arachidonoyl taurine (polyunsaturated) vs.

N-oleoyl taurine (monounsaturated) and chain length (C20:4 vs. C18:1 respectively)].

The second pathway regulating intracellular levels of *N*-acyl taurines was identified following a study by Turman et al. on the ability of cyclooxygenases (COXs) and lipoxygenases (LOXs) to oxygenate *N*-arachidonoyl taurine [12]. Although *N*-arachidonoyl taurine was a poor substrate for COXs, mammalian 12 S and 15 S-LOXs oxygenated *N*-arachidonoyl taurine very efficiently, generating 12 and 15-hydroxyeicosatetraenoyltaurines (HETE-Ts) and dihydroxyeicosatetraenoyltaurines (diHETE-Ts). *N*-Arachidonoyl taurine was rapidly taken up and converted primarily to 12-HETE-T in murine resident peritoneal macrophages [12]. Therefore, the oxidative metabolism of polyunsaturated *N*-acyl taurines may represent a pathway for the generation or termination of novel signaling molecules. At present, it is not known if *N*-arachidonoyl taurine or *N*-oleoyl taurine are further oxidized to HETE-Ts in PC-3 cells, but this is likely as LOX is expressed in prostate cancer and PC-3 cells [22].

Conclusions

In summary, our results show that novel biologically active lipids, the *N*-acyl taurines, result in reduced cell proliferation in PC-3 cells, due to an increased number of cells in the subG1 population and fewer cells in the S-phase. Therefore, an increase in intracellular levels of *N*-acyl taurines in vivo may result in effects on cell proliferation and lead to apoptosis in various cells and tissues such as the prostate gland.

Abstract Abnormalities in lipid metabolism have been frequently observed in cancer and are associated with a poor prognosis. However, a detailed, longitudinal characterization of fatty acid status is lacking. This study aimed to assess plasma phospholipid fatty acids before chemotherapy, immediately after and 1 month following chemotherapy in a group of 50 patients newly diagnosed with lung cancer and explore factors which may contribute to aberrations in fatty acids. Their mean \pm SD characteristics: age 64 ± 8.5 years, 75% advanced stage disease, body mass index 27.0 ± 5.4 kg/m², 6 month weight loss $-4.6 \pm 6.1\%$. Compared to patients with early stage disease, patients with advanced disease had

abnormal fatty acid profiles including significantly lower ($P < 0.05$) amounts of total phospholipid fatty acids, saturated, and polyunsaturated fatty acids (linoleic, arachidonic, eicosapentaenoic and docosahexaenoic). Longitudinal analysis revealed that patients with advanced disease who completed chemotherapy had stable fatty acid levels and continued to maintain levels 1 month following completion of chemotherapy. Comparatively, patients who did not complete chemotherapy due to toxicity or disease progression had progressive loss of total phospholipid fatty acids, stearic, linoleic and n-6 fatty acids and a trend towards lower docosahexaenoic, arachidonic, palmitic, n-3 and saturated fatty acids. These results suggest that loss of fatty acids is prevalent, progressive and potentially influenced by advanced disease and chemotherapy treatment.

Introduction

In advanced cancer, metabolism of nutrients may differ from healthy individuals. Abnormalities in lipid metabolism, including increased lipolysis [1] and oxidation of free fatty acids [2] have been observed in advanced cancer. Plasma phospholipids (PL) reflect the metabolism of endogenous and dietary fatty acids and contain the majority of n-6 and n-3 polyunsaturated fatty acids (PUFA) in blood. Thus, the fatty acid composition of plasma PL has been used as a measure of dietary intake and fatty acid status in a variety of conditions [3–5].

Several studies have reported alterations in PL fatty acids in patients with advanced cancer compared to healthy individuals [6–9]. In particular, striking differences in n-6 and n-3 fatty acids have been observed including decreased arachidonic acid (ARA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) in patients with cancer. These differences were independent of changes in caloric and fat intake [9]. Total PL and phosphatidylcholine which is the main constituent of membrane PL, were also found to be low [10, 11], likely due to elevated phosphatidylcholine turnover by tumor cells [12].

The causes of the aberrations in PL fatty acids are unclear. One study suggested that chemotherapy may contribute to depletion of n-6 and n-3 fatty acids [9], but low n-3 and n-6 fatty acids have also been observed in the absence of chemotherapy [6, 10]. Cvetković et al. [10] showed an association between aggressive and advanced stage non-Hodgkin lymphoma and lower PL EPA and DHA. However, this is the only study to explore the relationship between cancer stage and the composition of PL.

Deficits in plasma fatty acids could be expected to affect the availability of fatty acids to peripheral tissues for tissue repair and other physiological processes. In support of this notion, loss of plasma PL has been observed to occur concurrently with weight loss [11], loss of skeletal muscle and adipose tissue in advanced cancer patients [13]. Thus, identification of potential causes or the point in time during the course of the disease trajectory and treatment that this evolves is important for planning effective and timely intervention. However, a detailed, longitudinal characterization of fatty acid status in patients with cancer is lacking. The objectives of this study were to assess fatty acids before, immediately after chemotherapy and 1 month post chemotherapy in patients with lung cancer and determine factors which may influence amounts of fatty acids.

Methods

Patient Population

This study was approved by the Alberta Cancer Research Ethics board as a minimal risk study (chart review, no intervention). All patients were recruited from the lung cancer new patient clinic at the Cross Cancer Institute (Edmonton, Alberta, Canada) between August 2007 and November 2009 and were followed for >1.5 years. The Cross Cancer Institute is the major cancer center for all of Northern Alberta (population 1.8 million) and sees >95% of referrals for consideration of treatment with chemotherapy or radiation therapy. All newly referred patients with lung cancer attend a medical oncology clinic. At clinic, patients are given a handout that briefly describes available nutritional studies and patients are asked to indicate interest. Patient response informs investigators who to approach regarding participation in research studies. Patients in this study were accrued with the purpose of detailing changes in fatty acids during chemotherapy and the potential impact this has on clinical outcomes. A portion of these patients served as a control group (standard of care, no intervention) for a study which examined the effect of fish oil supplementation on body composition [14] and chemotherapy efficacy [15].

Study Design

Patients with a histologically confirmed diagnosis of non-small cell lung cancer (NSCLC) were included. This patient population was chosen because a high proportion of patients with lung cancer experience malnutrition [16]. Additional inclusion criteria were: >18 years of age, no gastrointestinal tumors, able to maintain oral intake, naive to chemotherapy and able to provide written, informed consent. Since this study was focused on change in fatty acids during chemotherapy, patients were only approached for study participation if they were referred for either adjuvant chemotherapy or first-line palliative chemotherapy for advanced/metastatic disease based on standard practice specifically agreed upon as Clinical Practice Guidelines by the Alberta Provincial Lung Tumor Group.

Stage of disease was based on the American Joint Committee on Cancer stage groupings, I, II, III, and IV [17]. Height was measured by a stadiometer and weight was measured using a medical balance beam scale at baseline and at each time point. Height and weight were used to compute body mass index (BMI) (kg/m^2). World Health Organization [18] categories were used to classify patients as: underweight, BMI <18.5; normal, BMI 18.5–24.9;

overweight BMI 25.0–29.9; or obese BMI ≥ 30.0 . Self-reported weight loss history in the 6 months preceding referral was obtained from medical records or the Patient Generated Subjective Global Assessment [19] which is completed by patients at their first clinic visit.

Chemotherapy Treatment

All patients were seen in consultation for treatment with standard chemotherapy. At our cancer center, chemotherapy for NSCLC consists of platinum-based doublet chemotherapy. Typically, cisplatin and vinorelbine are used for adjuvant chemotherapy and carboplatin in combination with vinorelbine or gemcitabine is used to treat patients with advanced disease. This chemotherapy regimen is typically administered on a 3-week cycle for 2 cycles, after which response to chemotherapy for those with advanced lung cancer is assessed by imaging. If there is disease response (stable disease or decreased disease burden) chemotherapy is continued for 4 cycles, otherwise chemotherapy is stopped. The end of the study was considered to be akin to completion/the end of chemotherapy as this coincided with the last study blood draw. As per chemotherapy protocol, all patients had an Eastern Cooperative Performance Status [20] between 0 (fully active, no limitations) and 2 (up and about more than 50% of waking hours).

Lipid Extraction and Phospholipid Separation

Blood (12 mL) was drawn into a heparinized tube by a Registered Nurse prior to starting chemotherapy (baseline), prior to each 3 week cycle of chemotherapy and 1 month following chemotherapy if patients continued to be followed at our cancer institute. To minimize patient burden, blood draws were arranged to coincide with routine blood work that was ordered as part of routine clinical protocol. Serum aspartate aminotransferase (AST) levels recorded from complete blood count tests were recorded as an indication of liver dysfunction.

Blood was centrifuged, plasma was isolated and immediately frozen at -80°C until analysis. Fatty acids were extracted from plasma using a modified Folch method [4] and the PL fraction was isolated using thin layer chromatography. The PL band was visualized, scraped and C17:0 (10.1 mg/100 mL; Supelco, Bellefonte, PA, USA; Sigma Chemical, St. Louis, MO, USA) was added as an internal standard followed by methylation at 110°C for 1 h. Plasma PL fatty acid composition was determined using gas liquid chromatography (Varian 3900CX Gas Chromatograph) equipped with a flame ionization detector, autosampler and a 30-meter BP-20 fused capillary column (SGE Instruments Australia). Peaks of saturated (SFA),

monounsaturated (MUFA) and PUFA fatty acids between 6 and 24 carbon chain lengths were identified by comparison with a commercially available standard of known fatty acid composition and quantified using the C17:0 standard peak. Fatty acid content of PL was calculated using the area peak of the internal standard and expressed as $\mu\text{g/mL}$. Mean fatty acid amounts were calculated from duplicates. An acceptable level of variation between duplicates was set at 5%. A random selection of 20 samples were run twice on the gas chromatograph on separate days. The co-efficient of variation between fatty acids amounts from the two runs was $<5\%$.

Statistical Analysis

Data are reported as means \pm standard deviation. Two sample *t* tests or Fischer's exact test were used to compare groups as appropriate. Pearson correlation was used to identify a potential relationship between serum AST and total amounts of PL fatty acids. All tests were two-sided. Repeated measures analysis of variance with Bonferroni post hoc comparisons was used to compare changes in fatty acids from baseline to end of study. Significance was reported at levels of $P < 0.05$ and trends were identified at $P < 0.10$. Statistical analysis was completed using SPSS for Windows (version 18.0, SPSS, Chicago, IL, USA).

Results

Patient Demographics

Overall, 60 patients were accrued, 50 received at least a baseline blood draw and 42 completed the study. The number of patients who consented but were subsequently withdrawn is a reflection of the patient population. The majority of patients had advanced stage disease and many had disease related symptoms which impacted upon performance status and their ability to tolerate chemotherapy. Patients who received at least a baseline blood draw were included in this analysis.

Of the 50 patients with a baseline blood draw, three did not receive any chemotherapy due to rapid decline in performance status, and four patients had baseline blood draws only. Thus, these 7 patients were only included in baseline analyses. Baseline patient demographics and anthropometrics are shown in Table 1. Despite generally advanced disease, patients had heavy body weights and only one patient was underweight (BMI $<18.5\text{ kg/m}^2$). Similar to the general lung cancer population [21], comorbid conditions were common. The most frequently reported conditions were hypertension (44%), chronic obstructive pulmonary disease (20%) and hyperlipidemia/

hypercholesterolemia (16%). Median survival was not determined due to the inclusion of patients with early stage disease and insufficient power for survival analyses on the subset of patients with advanced disease.

Plasma Phospholipid Fatty Acids at Baseline

At baseline, total plasma PL ranged widely from a minimum of 94.6 µg/mL to a maximum of 1,284 µg/mL. To examine potential sources of this variation, patients were divided into groups based upon stage of disease (advanced stage; III and IV, *n* = 38 or early stage; I and II, *n* = 12). The patients with advanced stage cancer were further divided into two groups based upon the presence or absence of liver metastases.

Mean ± standard deviation, two sample *t* test

SFA saturated fatty acids, MUFA monounsaturated fatty acids, PUFA polyunsaturated fatty acids

Patients with advanced stage lung cancer were not different for age, gender, or BMI compared to patients with early stage lung cancer. The presence of hyperlipidemia and hypertension also did not differ between groups (*P* = 0.35). However, compared to early stage patients, patients with advanced disease had lower total PL and alterations in most fatty acids (Table 2). The amount of EPA was particularly disparate between disease stages, and was nearly 50% lower in patients with advanced cancer.

Liver function and liver metastases did not appear to influence fatty acid amounts. There was no relationship between total PL amounts and serum AST levels (Pearson correlation *r* = 0.04; *P* = 0.79). Individual fatty acids, classes of fatty acids and total fatty acid amounts in patients with liver metastases (*n* = 13) were not different from patients without liver metastases (*n* = 25) (Supplementary data).

Plasma Phospholipid Fatty Acids During Chemotherapy

During the course of the study, two clear groups emerged: patients who completed a full course of chemotherapy (≥4 cycles; completers, *n* = 27) and patients who stopped chemotherapy due to either disease progression or toxicity (<4 cycles; non-completers, *n* = 16). The mean duration of chemotherapy was 11.4 ± 2.4 weeks in the completers group and 7.2 ± 2.9 weeks in the non-completers group. The groups were similar in age, gender and BMI, but the proportion of patients with early and advanced stage differed. Only 3 patients (19%) in the non-completers group had early stage disease compared to 9 patients (33%) in the completers group. Patients with early stage disease generally tolerate chemotherapy better, with fewer and milder side effects than patients with advanced disease. In addition, total and individual amounts of fatty acids were influenced by stage of disease (Table 2), and thus the comparison between completers and non-completers was limited to patients with advanced disease (13 in the non-completers group and 18 in the completers group). A comparison between early stage completers and non-completers was not undertaken as there were only 3 patients in the non-completers group with early stage disease.

There were no changes in fatty acids from baseline to end of chemotherapy in advanced stage patients who completed chemotherapy (Table 3). Conversely, advanced stage patients who did not complete chemotherapy had lower linoleic, stearic acid, n-6 fatty acids, PUFA and total PL fatty acids at the end of chemotherapy compared to baseline and a trend towards lower palmitic, ARA, DHA, n-3 and SFA at the end of chemotherapy (Table 3). Comparison of fatty acids at the end of chemotherapy between

Table 3 Change in plasma PL fatty acids from baseline to end of study in advanced stage patients who did not complete chemotherapy due to intolerance or disease progress (<4 cycles) and patients who completed a full course of chemotherapy (≥4 cycles)

| Fatty acid (μg/mL) | Non-completers (n = 13) | | | Completers (n = 18) | | |
|--------------------|-------------------------|--------------|------|---------------------|--------------|------|
| | Baseline | End of study | P | Baseline | End of study | P |

completers and non-completers revealed no differences except for a trend towards lower EPA in the non-completers group (4.0 ± 2.8 vs. 6.3 ± 4.1 μg/mL; $P = 0.09$).

Plasma Phospholipid Fatty Acids Following Chemotherapy

Of the patients who completed chemotherapy, 17 had a follow-up blood draw approximately 1 month following study and chemotherapy completion (mean 38.1 ± 20.2 days). All fatty acid amounts were stable between chemotherapy completion and follow-up (mean increase of total PL fatty acids by 19.9 μg/mL, equivalent to approximately a 3% increase). There were also no significant differences in any fatty acid amounts between baseline and follow-up.

Discussion

The fatty acid profile of patients with cancer is not well characterized due to a limited number of studies in patients with heterogeneous tumor types. Here we provide a comprehensive assessment of plasma PL fatty acids in a major tumor group prior to, immediately after chemotherapy and 1 month following the end of chemotherapy. Using this approach, we report that patients with advanced stage lung cancer have alterations in PL fatty acid composition at diagnosis which may be further exacerbated during chemotherapy.

Patients with advanced disease had lower amounts of most fatty acids compared to patients with early stage disease. This is similar to what has been reported in serum PL in non-Hodgkin lymphoma [10]. The significance of

these differences is unclear, but we have previously reported that low PL fatty acids indicate poor prognosis [22] and now suggest that low PL fatty acids may relate to the ability to complete all planned chemotherapy. The differences in PL fatty acids between disease stages may be the culmination of several factors. During periods of tumor growth, there is increased demand for PL by the tumor for cell replication and altered PL membrane metabolism [23, 24]. Proximity to death may have also contributed to the difference in fatty acids between early and advanced stage patients. Although survival was not assessed, it is expected that advanced stage patients have shorter survival compared to patients with early stage disease and declines in fatty acids have been reported near death in advanced cancer patients [13]. Medications such as statins, fibrates and beta blockers for treatment of hypertension and hyperlipidemia may affect lipids levels. Although we were not privy to medication details (brand, dose and frequency), the presence of hypertension and hyperlipidemia was similar between groups. It is also unlikely that differences in PL fatty acids between early and advanced stage patients resulted from differences in diet as fat intake would be expected to alter the composition but not the amount of PL fatty acids. Fatty acid amounts also appeared to be unaffected by the presence of liver metastases.

Loss of fatty acids is progressive, with further decreases from baseline in patients who did not complete chemotherapy. Of interest, change in n-3 fatty acids during chemotherapy appears to be minimal, with only a trend towards lower n-3 fatty acids and DHA and no change in EPA. To provide a frame of reference, PL fatty acids in the non-completers group were compared to the fatty acid profile of advanced cancer patients from the same cancer center that has been previously published [13] (Table 4).

Table 4 Plasma PL fatty acids at the end of study in advanced stage patients receiving <4 cycles of chemotherapy and in a group of advanced cancer patients <8 or >8 months from death

| Fatty acid ($\mu\text{g/mL}$) | Non-completers End of study ($n = 13$) | <8 months to death ($n = 36$) | >8 months to death ($n = 36$) |

Mean \pm standard deviation. Data from a previous study of advanced cancer patients [13] is shown for reference and were not statistically compared to patients in this study

SFA saturated fatty acids, MUFA monounsaturated fatty acids, PUFA polyunsaturated fatty acids

Patients who were <8 months from death had similar levels of EPA and DHA as the non-completers at the end of their treatment whereas the amount of all other fatty acids were in the range of or appeared greater than fatty acids reported in patients >8 months from death. This may suggest that loss of n-3 fatty acids precedes depletion of other classes of fatty acids and may serve as a predictive marker for survival and response to chemotherapy, especially in the palliative setting. However, this hypothesis needs to be tested in larger populations.

It seems possible that depletion of fatty acids is related to either indirect or direct effects of chemotherapy treatment. Disturbances in the gastrointestinal tract resulting from chemotherapy may affect the availability, absorption or metabolism of fatty acids [25]. This may explain the decline in fatty acids in the non-completers group which included a number of patients with severe chemotherapy toxicity. Low levels of n-6 and n-3 fatty acids in plasma PL have been observed in advanced breast cancer following induction chemotherapy, with further declines following high dose chemotherapy [9]. However, here we report little variation in amounts of fatty acids throughout chemotherapy in over half of our patients (patients that completed chemotherapy). It appears that change in fatty acids during chemotherapy may be related to disease control as patients with progressive disease (non-completers group) lost fatty

acids. Conversely, patients experiencing a benefit from treatment (reduced tumor burden or stable disease) exhibited stable fatty acids which showed no change even one month following the end of chemotherapy. Given the short disease trajectory of advanced lung cancer, this hypothesis could be tested by following patients with stable disease until the point of disease progression and quantifying fatty acids throughout this time period.

Conclusion

This research shows that loss of fatty acids is prevalent, progressive and possibly influenced by the stage of the disease, chemotherapy treatment and disease control. Larger studies which account for these variables and follow patients over a longer period of time would help to define these relationships further.

Abstract Multifunctional acyltransferases are able to catalyze the esterification of various acyl-acceptors with activated fatty acids. Here we describe the identification of four proteins from *Tetrahymena thermophila* that share certain properties with mammalian acyltransferases regarding their predicted transmembrane structure, their molecular mass and the typical acyltransferase motif. Expression of the *Tetrahymena* sequences results in production of triacylglycerols and wax esters in recombinant yeast when appropriate substrates are provided. The in vitro characterization shows, that these enzymes are capable of esterifying different acyl-acceptors including fatty alcohols, diols, diacylglycerols and isoprenols with acyl-CoA thioesters. Based on these catalytic activities and the sequence similarities of the *Tetrahymena* proteins with acyl-CoA:diacylglycerol acyltransferase 2 (DGAT2) family members, we conclude that we identified a new group of DGAT2-related multifunctional acyltransferases from protozoan organisms.

Keywords Multifunctional acyltransferase · *Tetrahymena* · Wax ester · DGAT · Prenyl ester · Diester

Abbreviations

ASAT Acyl-CoA:sterol acyltransferase, steryl ester synthase

| TAG | Triacylglycerol(s) |
| WE | Wax ester(s) |
| WS | Wax synthase |

Introduction

Acyltransferases belong to the large group of enzymes, transferring groups other than amino-acyl groups (EC 2.3.1) onto acyl-acceptors like fatty alcohols (EC 2.3.1.75) or diacylglycerols (EC 2.3.1.20). Genes encoding multifunctional acyltransferases catalyzing the esterification of a variety of acyl-acceptor moieties with acyl-CoA thioesters have been characterized from prokaryotic and eukaryotic organisms [1–5].

More recently, genes essential for wax ester synthesis became important tools for developing renewable resources for the technical industry [6–8]. The increasing prices of fossil material make up the market for tailor-made wax esters (WE). These lipids in general are excellent lubricants with good stability under high temperature and pressure and they are very resistant to hydrolysis [6], which makes them attractive as lubricants. While saturated long-chain monoesters have good lubricity but poor low temperature fluidity, unsaturated monoesters or diesters overcome this lack and combine it with good thermal and oxidative stability and high viscosity indices [9]. To achieve the renewable production of WE, experiments are in progress to identify new enzymes catalyzing respective esterification

reactions [10–13]. Production of high levels of WE in oil crops [6, 7] or microorganisms [8, 12] might be able to replace fossil materials in future.

Tetrahymena is a unicellular protozoan and belongs to the phylum of Ciliophora [14]. It is common in temperate freshwater [15] and can be cultivated in the laboratory. *Tetrahymena* is a model system for eukaryotic cells that provides features of higher eukaryotic organisms which cannot be found in other unicellular model systems like *Saccharomyces cerevisiae* [16]. Studies on lipid components in *Tetrahymena thermophila* (before 1976 *T. thermophila* was referred to as *T. pyriformis* variety or syngen 1 [17]) showed that the cells are able to accumulate large amounts of lipids. During the logarithmic phase, 24% of the cell dry weight is made up by lipids [18], 28% of which are neutral lipids located in lipid droplets [19], mainly triacylglycerols (TAG) esterified with saturated fatty acids of 14–18 carbon atoms [20]. The WE make up a small portion of the total lipid content of only about 0.15% [21]. Unlike TAG they contain branched-chain acyl-groups of 17–21 carbon atoms (76%) and branched-chain alcohols of 17–19 carbon atoms (45%) [21]. In addition to long-chain WE, fatty acid methyl and ethyl esters have also been found in *Tetrahymena*, of which methyl linoleate, ethyl myristate and ethyl linoleate are the most abundant [22]. The physiological function of these esters and WE is not clear because the low amount excludes storage functions [21]. They might be communication scents or simply a way to control the level of free alcohols to prevent toxic effects for the cells [22].

Like other ciliates, *Tetrahymena* has two specialized nuclei: the micronucleus (MIC) is the diploid germline while the haploid macronucleus (MAC), which differentiates from the MIC, is the somatic gene expression machine [15, 23]. The recent whole genome shotgun sequencing and assembly of the *Tetrahymena* MAC genome by the Institute for Genomic Research (TIGR) in 2006 revealed that the genome contains 104 Mb which cluster on 250–300 chromosomes [16, 24]. Computational analyses revealed about 25,000 protein coding reading frames, about 17,000 of which have strong matches to genes in other organisms [16]. Similarity based analyses of the *Tetrahymena* genome database (TGD) [24] with known mammalian wax synthase sequences [1, 3, 13] revealed several proteins, some of which were analyzed in this work.

In this study we identified four sequences related to DGAT2 family members. Heterologous expression studies in a suitable yeast mutant and enzyme assays with transgenic yeast membranes revealed that these sequences encode multifunctional acyltransferases which accept various acyl-acceptors.

Materials and Methods

Identification and Cloning of Putative Wax Synthases

BLASTp [25] studies were undertaken to investigate the predicted *Tetrahymena thermophila* proteome for putative wax synthases using the NCBI server (<http://blast.ncbi.nlm.nih.gov/>). Human wax synthase sequences AWAT1 (NCBI: NP_001013597) and AWAT2 (NCBI: NP_001002254) were used as query sequences. The derived protein sequences (for NCBI accession numbers and nomenclature see below) were used to generate nucleotide sequences adapted to expression in *Brassica* and synthesized by GeneArt. The respective sequences were cloned from GATEWAY® entry vectors (pDONR221) into pYES-DEST52 expression vectors (Invitrogen) and expressed in *S. cerevisiae* BY4741 Δ lro1 Δ dgal [26], a yeast mutant lacking TAG synthesis (MAT α his3 Δ 1 leu2 Δ 0 met15 Δ 0 ura3 Δ 0 lro1- Δ ::kanMX4 dgal- Δ ::natMX4). In the following the *Tetrahymena* proteins are termed as follows: XP_001027910: TtWS1; XP_001026090: TtWS2; XP_001008104: TtWS3; XP_001017939: TtWS4.

Functional Analysis in Yeast

Transgenic yeast strains expressing a *Tetrahymena* sequence in pYES-DEST52 vectors (Invitrogen) were cultivated in SD minimal medium containing 0.17% (w/v) yeast nitrogen base (MP Biomedicals), 0.068% (w/v) complete supplement medium without uracil and leucine (MP Biomedicals), 0.5% NH₄SO₄ (w/v), 0.01% (w/v) leucine and 2% glucose (Roth) for 24 h at 28 °C. The cells of 50 ml cultures were induced with 2% galactose for 48 h and were supplemented with 125 μ M decanol, dodecanol, tetradecanol, hexadecanol and octadecanol (Roth). Cells were harvested, washed and stored at –20 °C until extraction.

Extraction of yeast cells was performed according to the protocol of Bligh and Dyer [27]. The lipid extracts were separated by TLC on preparative TLC plates (Silica Gel 60 plates 0.5 mm thickness, Merck) in heptane/diethyl ether/acetic acid (90/30/1, v/v/v) and visualized under UV light after spraying with dichlorofluorescein (0.3% (w/v) dissolved in isopropanol) [28]. Myristoyl-dodecanoate (Sigma Aldrich) and TAG isolated from sunflower oil were used as standards.

GC Analysis of WE and TAG

Bands co-chromatographing with the WE and TAG standards were transmethyalted in 0.5 M sulfuric acid and 3% dimethoxypropane in methanol for 1 h at 80 °C. 250 nmol docosanoic acid was added as an internal standard before

transmethylation. Fatty acid methyl esters (FAME) and fatty alcohols were extracted with heptane, concentrated and analyzed via gas chromatography (GC) with flame ionization detection (FID). For quantification of WE the total amount of fatty alcohols in the fractions was summarized, for quantification of TAG the sum of FAME was divided by 3.

GC-FID analysis was carried out using the HP6890 gas chromatograph equipped with an OPTIMA225 column (Macherey & Nagel) (25 m length, 0.25 mm diameter, 0.25 μ m film thickness). 1 μ l of the extract was analyzed in splitless injection with N₂ as carrier gas (constant flow, 0.9 bar pressure, total column flow 1 ml/min) and inlet and detector temperatures of 260 °C. A temperature program was carried out starting at 120 °C, 8 °C/min to 144 °C, 4 °C/min to 240 °C. Peaks were identified via comparison of the respective retention times with standard substances of different fatty alcohols and FAME (Sigma Aldrich).

Phylogenetic Analysis and Structure Prediction

Sequence analyses were carried out using ClustalX2 [29] and GeneDoc [30] software. Phylograms were computed with MEGA5 [31] and neighbor-joining method [32] with 1,000 bootstrap replicates using *p*-distance method. All gaps were deleted for computation of evolutionary distances.

Molecular mass and isoelectric points were calculated using ProtParam [33] on the ExPASy Server (<http://web.expasy.org/protparam/>). Transmembrane structures of *Tetrahymena* proteins and mammalian wax synthases were predicted using TMHMM software (<http://www.cbs.dtu.dk/services/TMHMM/>) [34–36]. Predictions were compared to Kyte Doolittle plots [37] with window parameters of 19, which revealed similar results. Acyltransferase superfamily motifs and putative acyl-acceptor binding pockets were discovered by NCBI conserved domain search (<http://www.ncbi.nlm.nih.gov/Structure/cdd/>) [38].

Preparation of Yeast Membranes and In Vitro Wax Synthase Assay

Transgenic yeast cells of 200-ml cultures were harvested after 16 h of induction, washed in Tris–H₂SO₄ (50 mM, pH 7.4), frozen for 15 min at –20 °C and disrupted using glass beads (0.75–1 mm diameter, Roth) by vortexing for 5 min in 2 ml Tris–H₂SO₄ buffer. Cell disruption was repeated three times and the supernatants were collected by centrifugation and combined. After sonication (two times for 30 s) the cell debris was sedimented (2,500 \times g, 15 min and 4 °C) and the membranes were isolated from the supernatant by high speed centrifugation (1 h, 140,000 \times g, 4 °C). The sedimented membranes were resuspended in an

appropriate volume of Tris–H₂SO₄ buffer and stored in aliquots at –80 °C. The protein concentration was determined [39].

WS activity was measured in 10 mM BIS–Tris-propane pH 9, 13 μ M [1-¹⁴C]-labeled acyl-CoA ([1-¹⁴C]-myristoyl-CoA and [1-¹⁴C]-stearoyl-CoA purchased from Biotrend, specific activity 2.03 Bq/pmol, [1-¹⁴C]-palmitoyl-CoA purchased from Perkin Elmer, specific activity 2.22 Bq/pmol, [1-¹⁴C]-oleyl-CoA purchased from Perkin Elmer, specific activity 2.03 Bq/pmol, [1-¹⁴C]-decanoyl-CoA specific activity 0.09 Bq/pmol and [1-¹⁴C]-dodecanoyl-CoA, specific activity 0.7 Bq/pmol and 2-methyl-acyl-CoA (14:0, 16:0 and 18:0) specific activity 0.62 Bq/pmol were prepared by Prof. Sten Stymne and members of his laboratory, SLU Alnarp, Sweden) and 300 μ M acyl-acceptors (Sigma Aldrich) using 1–2 μ g protein from total membrane fractions. Acyl-acceptors were dissolved in heptane and evaporated to dryness in the reaction tubes before addition of further assay components, DGAT activity was measured under standard WS assay conditions with endogenous DAG present in the yeast membranes. Incubation was carried out at 35 °C for 20 min. Lipids were extracted with 250 μ l chloroform:methanol (1:1) and 100 μ l 0.45% NaCl-solution. 80 μ l of chloroform phase was applied to TLC silica gel plates (Merck) and chromatographed in heptane/diethyl ether/acetic acid (90/20/1 v/v/v). The bands were visualized with the FLA-3000 bioimager system (Fujifilm). For quantification, single bands were analyzed in a liquid scintillation counter LS 6500 (Beckman Coulter).

Results

Identification of Putative Wax Synthases from *Tetrahymena thermophila*

Sequence similarity based searches conducted with human AWAT1 and AWAT2 wax synthase sequences as query against the annotated *Tetrahymena thermophila* proteome resulted in several protein sequences with similarities to the human wax synthases. Four sequences (for NCBI accession number see experimental procedures) with the highest identities to human sequences (15–21%) were analyzed. Sequence identity between the *Tetrahymena* proteins varied between 34 and 44%. No sequence similarities could be detected with jojoba type wax synthases from plants [11, 40] or *Euglena* [10] or the bifunctional proteins from petunia [41] or *Acinetobacter* [4, 42]. The *Tetrahymena* sequences share certain identities with DGAT2 related proteins from plants and fungi (13–20%) [43–47]. As shown in Fig. 1, the *Tetrahymena* proteins build a new branch of proteins related to the DGAT2 protein family.

The relation to the mammalian DGAT2 family is supported by some distinct features that can be found in both families. All proteins contain 306–333 amino acids and have a predicted molecular mass between 35 and 38 kDa. The isoelectric point lies between 9.3 and 9.4, which is a typical feature of DGAT2 family members [48]. In addition TtWS1, TtWS2 and TtWS4 contain a predicted transmembrane helix at the N-terminus like AWAT1 (Fig. 2a), while the C-terminal part of the protein is predicted to be exposed to the cytoplasmic phase. TtWS3, like AWAT2, shows a slightly different topology in the models with two to three transmembrane domains at the N-terminal part of the protein, but the C-terminus is also reaching out into the cytosol. Conserved sequence search displayed an acyltransferase superfamily motif (NCBI database cl00357) in all sequences in which several conserved amino acids can be found that are predicted to belong to an acyl-acceptor binding pocket (cd07986) (Fig. 2a).

Sequence alignments with human AWAT showed the highest variety in the N-terminal part of the protein, where the transmembrane domains are located. Furthermore the HPHG (amino acids 103–106 in HsAWAT1) motif which

is characteristic for DGAT2 family members [48–50] was found in TtWS1 and TtWS4, while TtWS2 and TtWS3 showed a modified version in which glycine is substituted with asparagine or tyrosine, respectively (Fig. 2b, Supplemental data 1).

Functional Expression in Yeast

To determine the identities of the four *Tetrahymena* proteins, lipid extracts of transgenic yeasts expressing a *Tetrahymena* sequence were analyzed. Thin layer chromatography suggested that TtWS2, TtWS3 and TtWS4 were able to restore triacylglycerol synthesis in yeast, while TtWS1, TtWS2 and TtWS4 appear to cause wax production as well, if they are provided with appropriate alcohols. The identities of the products were verified and the amounts were quantified by GC analysis after transmethylation of the WE and TAG bands scraped off from the TLC plates (Fig. 3).

By GC analysis decanol (10:0-OH), dodecanol (12:0-OH), tetradecanol (14:0-OH) and hexadecanol (16:0-OH) and the FAME corresponding to palmitic (16:0),

Fig. 2 Predicted domains and motifs of *Tetrahymena* WS proteins. The putative transmembrane domain (TMD) and the acyltransferase superfamily motif (ATSF) are shown by squares, amino acids of the putative acyl-acceptor binding pocket are labeled with pins (**a**). The

conserved HPHG motif of DGAT2 family members and the substitutions of the glycine residues in TtWS2 and TtWS3 are depicted (**b**). Figure **a** was created using ExPASy Prosite Mydomains and the alignment (**b**) was created with ClustalX2 and GeneDoc

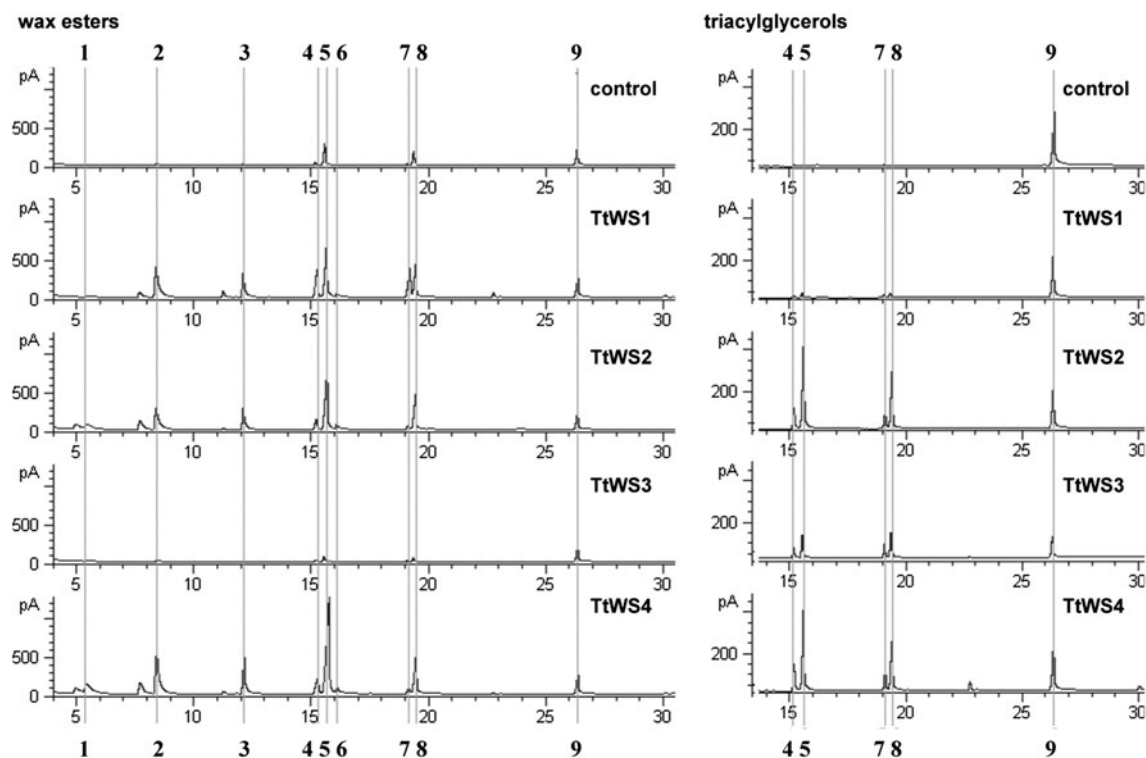

Fig. 3 Functional expression of TtWS sequences in yeast cells. Lipids were extracted from the yeast cells after 48 h cultivation in medium supplemented with 125 μ M 10:0-, 12:0-, 14:0-, 16:- and 18:0-OH, separated by TLC and wax esters and triacylglycerols were quantified by GC using 250 nmol methyl docosanoate as internal

standard. The respective GC chromatograms of transmethylated WE and TAG are depicted, the *x*-axis displays the retention time [min] and the *y*-axis corresponds to the FID signal strength [pA]. 1 10:0-OH, 2 12:0-OH, 3 14:0-OH, 4 methyl-16:0, 5 methyl-16:1, 6 16:0-OH, 7 methyl-18:0, 8 methyl-18:1, 9 methyl-22:0 (internal standard)

palmitoleic (16:1), stearic (18:0) and oleic acid (18:1) were identified. The empty vector control and TtWS3 expressing cells showed very small amounts of alcohols in the WE fractions only, while TtWS1, TtWS2 and TtWS4 expressing cells contained distinctly higher amounts (Fig. 4). 12:0-OH was the most abundant alcohol (50% of alcohol in WE) followed by 14:0-OH (5–30%) then 10:0-OH (10–15%) and 16:0-OH (<10%). Regarding the fatty acids in the WE fraction the biggest portion was made up by mono-unsaturated fatty acids with 16 or 18 carbon atoms (Fig. 3). The fatty acid pattern of the TAG fractions (Fig. 3) of TtWS2, TtWS3 and TtWS4 expressing cells resembled the one

found in the WE fractions, where the 16:1 and 18:1 were most abundant and comprised 80% of the total fatty acid mixture of WE and TAG. GC-analysis of WS and TAG of TtWS3 expressing cells showed almost equal amounts of C₁₆ and C₁₈ fatty acids.

Quantification of the WE and TAG content showed that TtWS4 expressing cells had the highest content of waxes of about 5 μ mol WE per gram cell fresh weight; the TAG production was about 1 μ mol/g. TtWS2 expressing yeasts produced about 4 μ mol/g WE and 1 μ mol/g TAG. In TtWS1 expressing yeast cells, about 2 μ mol/g WE could be detected but no significant amounts of TAG. TtWS3

Fig. 4 Production of wax esters (WE) and triacylglycerols (TAG) in transgenic yeast cultures expressing the empty vector (control) or one of the *Tetrahymena* sequences (TtWS1–4). The amount of wax esters and TAG was quantified by GC as shown in Fig. 3. Mean values and standard deviations of three preparations are given

showed low amounts of both WE and TAG, but merely the TAG level was significantly above the background level (Fig. 4).

In summary it can be concluded that all four proteins were functionally expressed in yeast and caused wax ester or TAG production.

Optimizing an In Vitro WS Assay

To analyze the properties of the four *Tetrahymena* enzymes, an in vitro wax synthase assay was optimized, using membranes of TtWS1 expressing yeast cells as the enzyme source. Enzymatic activity was only detectable in the membrane fraction and not in the soluble fraction indicating that the protein is associated with membranes. These results are in line with the predicted protein structure. The highest wax synthase activities were obtained using approximately 13 μM palmitoyl-CoA (Supplemental data 2a), 300 μM decanol (Supplemental data 2b) and 10 mM BIS-Tris-propane buffer at pH 9.0 (Supplemental data 2c). Under these conditions the WS activities were linear with at least 2 μg membrane protein and an incubation time of 20 min at 35 °C.

Substrate Specificities

As wax synthesis was already observed in yeast when cultures were provided with straight-chain alcohols, they were tested as acyl-acceptors in the optimized enzyme assay first. It could be shown that all enzymes had the highest wax synthase activities with medium-chained saturated alcohols of 10–12 carbon atoms (Fig. 5), while all except TtWS3 were inactive with alcohols of <9 carbon atoms. In contrast to TtWS1, which showed a narrow chain-length preference between 10:0-OH and 12:0-OH, TtWS2 and TtWS4 also accepted alcohols with chain-

lengths of 14 or 16 carbon atoms and TtWS3 esterified 16:0-CoA with 8:0-OH (Fig. 5).

In addition to WE, one further product was detected on TLC that co-migrated with TAG. It was clearly detected in all WS assays using membranes from yeasts expressing TtWS2, TtWS3 and TtWS4, but it was barely detected in assays with TtWS1 expressing membranes. These results were in line with the TAG level determined in the yeast cells expressing one of the *Tetrahymena* sequences (Fig. 4). The amount of TAG produced inversely depended on the amount of WE synthesized. When less attractive alcohols were used as acyl-acceptors, more TAG were produced and vice versa, which led to the assumption, that there was a competition reaction for the acyl-acceptor binding site of the enzyme. Since these *Tetrahymena* proteins were at least bifunctional and the fact that several acyltransferases show quite broad substrate acceptances [1, 2, 5], we had a closer look at further substrates.

In addition to saturated 1-alcohols, we ran assays with decan-2-ol and mono-unsaturated fatty alcohols. All enzymes had distinctly lower activities with 2-alcohols than with 1-alcohols of the same chain length. With the mono-unsaturated fatty alcohols 16:1-OH and 18:1-OH, TtWS2, TtWS3 and TtWS4 performed higher activities than with the corresponding saturated alcohols, while TtWS1 was inactive with unsaturated alcohols (Fig. 5).

As branched-chain WE are of high interest for the chemical industry, we assayed different kinds of branched-chain alcohols. TtWS4 was found to be active with 3,7-dimethyl-octanol (3,7-diMe-8:0-OH), but transferred the branched alcohols to palmitoyl-CoA at nearly the same rate as 10:0-OH. As some *Tetrahymena* species contain 2-methyl-branched alcohols in their waxes [21], it was interesting to see whether the *Tetrahymena* enzymes were active with a mixture of 2-methyl-branched alcohols of 16–20 carbon atoms. As given in Fig. 5, TtWS2 and TtWS4 performed WS activities with iso-alcohols, while TtWS1 and TtWS3 did not.

Another class of branched alcohols are isoprenols which can be esterified with acyl-CoAs to form prenol esters. We investigated phytol, farnesol and geranylgeraniol as substrates for prenol ester synthase (PES) activity. Especially TtWS4 displayed high activities with farnesol and geranylgeraniol, but a lower one with phytol. Unlike TtWS4, TtWS2 and TtWS3 were active with geranylgeraniol (Fig. 5) only.

As *Tetrahymena* also contains sterol esters, we investigated whether these acyltransferases possess sterol ester synthase (ASAT) activity. *Tetrahymena* species contain a special sterol termed tetrahymanol [51], but they are able to utilize both exogenously added cholesterol and ergosterol for ester synthesis [52]. WS assays with those sterols revealed that none of the *Tetrahymena* enzymes was active

Fig. 5 Acyl-acceptor specificities of TtWS enzymes expressed in yeast. Relative formation rates of WE by yeast membranes harboring a TtWS enzyme from 16:0-CoA and the given acyl-acceptors under otherwise standard assay conditions are depicted as mean values of at least four enzyme assays. Before calculating the mean values, the activities of the control membranes (empty vector) of about $18 \text{ pmol mg}^{-1} \text{ min}^{-1}$ were subtracted from the activity of the yeast membranes with the *Tetrahymena* enzymes. 100% correspond to the activity of the respective TtWS enzyme with 10:0-OH and 16:0-CoA, namely TtWS1: $330 \text{ pmol mg}^{-1} \text{ min}^{-1}$, TtWS2: $270 \text{ pmol mg}^{-1} \text{ min}^{-1}$, TtWS3: $114 \text{ pmol mg}^{-1} \text{ min}^{-1}$, TtWS4: $558 \text{ pmol mg}^{-1} \text{ min}^{-1}$

with cholesterol and ergosterol, suggesting that they possess no ASAT activity (Fig. 5).

A last group of interesting alcohols are diols. These can be esterified with two acyl-CoAs to form wax diesters, or they are esterified at only one hydroxyl-group to form a hydroxyl-wax monoester. Diester synthase (DES) activity was obtained with TtWS2 and 1,2-dodecanediol (1,2-12:0-diol) and the respective 1,12-isomer (1,12-12:0-diol), while the other enzymes were hardly active with these substrates (Fig. 5).

Analyses of the acyl-CoA specificities of the TtWS enzymes gave the following results (Fig. 6): the highest WE formation rates were obtained with saturated long-chain acyl-CoA thioesters of 14–18 carbon atoms, while activities with 18:1-CoA were detectable with TtWS3 only. Acyl-CoAs with chain-lengths of 10–12 carbon atoms were hardly incorporated into WE or TAG. The thioester specificity of TtWS3 and TtWS4 differed between WS and

acyl-CoA:diacylglycerol acyltransferase (DGAT) activities. While TtWS3 produced high levels of WE with 18:1-CoA, TAG were hardly detectable. TtWS4 performed the highest WS activity with 18:0-CoA and the highest DGAT activity with 14:0-CoA (Fig. 6). In addition to straight-chain acyl-CoAs, we also investigated 2-methyl-branched acyl-CoAs with chain-lengths of 14–18 carbon atoms. The activities with these substrates were distinctly lower than with the non-branched acyl-CoAs and could only be detected when incubation time and protein amount were increased (data not shown).

In summary, we were able to characterize four new acyltransferases with different properties (Fig. 7). TtWS1 synthesized WE as the main product especially with 10:0-OH and 14:0-CoA. DGAT and PES activities of TtWS1 were distinctly lower than WS activities, while DES and ASAT activity were hardly detectable. TtWS2 displayed high WS and DGAT activities with a broad range of

Fig. 6 Acyl-CoA specificities of TtWS enzymes expressed in yeast. Relative formation rates of WE and TAG by yeast membranes harboring a TtWS enzyme from 10:0-OH and the given acyl-CoA thioester under otherwise standard assay conditions are depicted as mean values of at least four enzyme assays. 100% correspond to the activity of the respective TtWS enzyme with 10:0-OH and 16:0-CoA as given in Fig. 5

saturated and mono-unsaturated alcohols ranging from 10 to 18 carbon atoms and saturated acyl-CoAs of 14–18 carbon atoms. In addition, it readily accepted diols as substrates. TtWS3 performed similar DGAT and WS activity, while PES activity was twofold lower. It had the highest activities not only with 10:0-OH and 14:0-CoA, but also with 10:0-OH and 18:1-CoA. In comparison to

TtWS2, TtWS4 had a broad but different substrate specificity. WS activity of TtWS4 was high with straight-chain alcohols from 9 to 14 carbon atoms as well as with methyl-branched alcohols or isoprenols. TtWS4 formed more TAG than WE, but the proportion of the two products varied depending on the acyl-group of the thioester as observed with TtWS3 (Fig. 6).

Fig. 7 Comparison of the maximal acyltransferase activities of yeast membranes harboring *Tetrahymena* enzymes with various acyl-acceptors. Data of the highest activities with different substrate groups were taken from Figs. 5 and 6. (DGAT: diacylglycerol acyltransferase activity determined with 10:0-OH and 14:0-CoA, WS:

wax synthase activity with 10:0 or 11:0-OH and 16:0-CoA, DES: diester synthase activity with 12:0-diol and 16:0-CoA, PES: prenyl-ester synthase activity with geranylgeraniol and 16:0-CoA, ASAT: sterol-ester synthase activity with ergosterol and 16:0-CoA)

Discussion

In this study we identified four proteins from *Tetrahymena thermophila* which possess distinct properties of DGAT2 family members including the HPHG motif [49]. This motif is found in vertebrate DGAT2 acyltransferases [48–50] and the histidine and proline residues have been shown to be essential for acyltransferase activity [49]. Mutagenesis experiments will show whether these amino acids conserved in the four *Tetrahymena* proteins are critical for the enzymatic activities as well and whether the glycine group in the motif, which is substituted by arginine or tyrosine in two of the four *Tetrahymena* proteins (Fig. 2b), affects the activity or the properties of the enzymes. Sequence analyses suggest that these TtWS proteins build up a new branch of DGAT2 related multifunctional acyltransferases (Fig. 1), which are perhaps typical for protozoal organisms, as protein sequences similar to those of *Tetrahymena* were identified in other protozoa like *Paramecium tetraurelia* (NCBI: XP_001425482, XP_001451326, XP_001433749).

The identity of the TtWS proteins was further supported by functional expression studies in yeast in combination with in vitro enzyme assays. These experiments clearly demonstrated that the four *Tetrahymena* proteins possess acyltransferase activities but differ in their acyl-acceptor and -donor specificities, as they caused the formation of different patterns of lipophilic reaction products when provided with the respective substrates. TtWS1 was found to have the most pronounced and TtWS2 and TtWS4 the most relaxed acyl-acceptor specificity (Fig. 5). Unlike TtWS1, which largely produces WE when expressed in yeast membranes, expression of the other TtWS proteins caused biosynthesis of TAG, WE, prenol esters and diesters but in different proportions (Fig. 6).

Multifunctional acyltransferases like the ones described here have been identified in human. AWAT2, for instance, shows equal WS and diacylglycerol synthase activities and lower DGAT and retinyl ester synthase activities [1, 3]. DGAT1, which belongs to a protein family different from that of AWAT2 (Fig. 1) efficiently catalyzes the production of TAG, while production of WE, diesters and retinyl esters was eightfold lower [2]. Hence both mammalian enzymes utilize an acyl-acceptor spectrum different from that of the *Tetrahymena* enzymes. An acyltransferase from *Acinetobacter*, which does not possess sequence similarity to the enzymes from *Tetrahymena* or mammals, was found to be a multifunctional acyltransferase as well [5]. Unlike *Tetrahymena* enzymes it performs not only WS, DGAT and diester, but also steryl ester synthase activity.

The broad acyl-acceptor specificities of most *Tetrahymena* acyltransferases and the observation that the amount of TAG production depended inversely on that of WE, suggests that *Tetrahymena* acyltransferases have flexible hydrophobic binding pockets in which various acyl-acceptors compete for binding. However, we cannot exclude other protein models like different interacting binding sites. Protein structure analyses will show in which way the acyltransferases mediate and regulate the esterification of acyl-acceptors.

In contrast to the broad acyl-acceptor specificities of the *Tetrahymena* proteins, the acyl-donor specificities were more pronounced and higher activities were obtained with saturated than with unsaturated acyl-CoA thioesters (Fig. 6). In that way, the *Tetrahymena* enzymes differ from that of *Acinetobacter*, which was shown to readily accept acyl-CoA thioesters of 8–20 carbon atoms [42]. They also have an acyl-donor specificity different from that of AWAT2, that was highly active with unsaturated long-chain acyl-CoA thioesters [3]. Interestingly, yeast cells expressing a *Tetrahymena* sequence formed WE and TAG mainly esterified with unsaturated acyl-groups (Fig. 3). These results are likely caused by the high level of unsaturated acyl groups in yeast cells [53] so that the introduced acyltransferases are predominantly provided with 16:1- and 18:1-CoA. Such a substrate channeling might allow incorporation of branched-chain acyl-moieties into WE as well.

The application of heterologous expression of genes encoding wax synthesizing enzymes in host systems is well under way. For instance, expression of genes from jojoba in transgenic *Arabidopsis thaliana* seeds led to the accumulation of WE [11, 40]. The protozoan enzymes described here were found to differ not only in their acyl-CoA but also in their acyl-acceptor specificities. Expression of sequences like TtWS2 or TtWS4 in plant systems in combination with suitable fatty acyl-CoA reductases will reveal their suitability for field application and industrial uses.

Acknowledgments We are grateful to Professor Sten Stymne (SLU Alnarp, Sweden) for the coordination of the ICON project and his research group (especially Dr. Jenny Lindberg Yilmaz and Dr. Ida Lager) for providing us with the labeled acyl-CoA thioesters and teaching us acyl-CoA synthesis. Furthermore we would like to thank Professor Mats Hamberg (Karolinska Institute Stockholm, Sweden) for providing us with labeled and unlabeled 2-methyl-branched fatty acids. This work was funded in part by the European Commission through the FP7 ICON project.

Abstract Cancer chemotherapy is associated with neutropenia and impaired neutrophil function. This study aimed to investigate whether supplementation with low dose fish oil (FO), providing n-3 polyunsaturated fatty acids, in cancer patients receiving chemotherapy after surgical tumor (mainly gastrointestinal) removal is able to improve the function of blood neutrophils. Patients ($n = 38$) receiving chemotherapy (5-fluorouracil and leucovorin) were randomized into two groups; one group (control) did not receive a supplement, while the other group (FO) received 2 g FO/day for 8 weeks; the FO provided 0.3 g eicosapentaenoic acid plus 0.4 g docosahexaenoic acid per day. Patients in the control group lost an average of 2.5 kg of weight over the 8 weeks of the study. The number of blood polymorphonuclear cells (PMNC), mainly neutrophils, and their functions (phagocytosis and

hydrogen peroxide production) decreased in the control group (average decreases of approximately 30, 45 and 17%, respectively). FO prevented these decreases and actually increased body weight (average of 1.7 kg weight gain; $p < 0.002$ vs. control group), PMNC number (average 29% increase), phagocytosis (average 14% increase) and superoxide production (average 28% increase). FO may be useful in preventing chemotherapy-induced decline in neutrophil number and function.

Introduction

Dietary fat may influence a variety of physiological events and cellular functions in the human body and thereby could impact on the pathogenesis of several diseases [1–3]. Changes in dietary fatty acid profile can modify the fatty acid composition of many cell types, including those involved in the development of inflammatory and immunologic diseases [4–6]. There has been a great interest in the immunomodulatory effects of n-3 polyunsaturated fatty

acids (PUFA), particularly those found in fish oil (FO) [7]. These are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Dietary supplementation with the n-3 PUFA (from FO capsules or FO-supplemented enteral formulas) has been reported to attenuate weight loss in cancer patients [8–12], and improvement in body weight over 14 days in cancer patients receiving oral FO supplements was linearly related to increased EPA content of plasma phospholipids [13]. Neutrophils play a crucial role in the first-line defense against invading microorganisms through phagocytosis, generation of reactive oxygen metabolites and release of microbiocidal substances [14]. Cancer chemotherapy induces neutropenia and impairment of neutrophil function [15–17]. Thus, chemotherapy induces effects that increase the risk of infection, so predisposing to poor patient outcome. Therefore, strategies that maintain neutrophil number and function may be of clinical benefit. Because FO has been shown to influence aspects of human immune cell function [7], including neutrophil responses [18–28], we considered that FO might have a role in improving neutrophil function in patients receiving cancer chemotherapy. Therefore, we have investigated the effect of FO in patients receiving chemotherapy following surgery for removal of a tumor.

Materials and Methods

Materials

Unless otherwise indicated chemicals were purchased from the Sigma Chemical Company (USA). Trypan blue and Ficoll Paque Plus were from GE Healthcare Bio-sciences, Sweden. FO capsules were kindly donated by Herbarium[®], Colombo, PR, Brazil.

Subjects

Procedures involving human subjects were approved by the Angelina Caron Hospital and Local Research Ethics Committee. Patients who had recently undergone surgery for removal of tumors at various sites, predominantly gastrointestinal, and who were about to begin chemotherapy were recruited. All 38 patients recruited gave written informed consent. Patients were randomly allocated to two groups. The control group received standard chemotherapy [5-fluorouracil (425 mg/m²) and leucovorin (20 mg/m²) intravenously] three times a week, and the other group (FO) received 2 g/day FO in addition to the standard chemotherapy. All patients received the same dose of FO which provided approximately 0.3 g EPA plus 0.4 g DHA per day. This dose was determined pragmatically; it was thought to be tolerable by the patients (previous studies of

FO supplements in cancer patients have noted a lack of tolerability [29–31] and a resulting high drop-out rate of patients from the study [29, 30]), it represents a significant increase in anticipated intake of EPA and DHA, and is in line with recommended intakes for the general population and for various patient groups [32]. The study lasted for 8 weeks. At study entry and 8 weeks later patients were weighed and a blood sample taken; the initial blood sample was taken immediately prior to initiating chemotherapy and the 8 week blood sample was taken prior to administration of that day's dose of chemotherapy. Characteristics of patients in the two groups are shown in Table 1.

Isolation of Plasma and Polymorphonuclear Cells

Venous blood samples were collected into tubes containing the calcium chelator EDTA as anti-coagulant. Polymorphonuclear cells (PMNC), mainly neutrophils, were isolated by centrifugation on a Ficoll Paque gradient [33]. PMNC isolation was initiated within 15 min of collecting blood samples. PMNC were collected and washed twice with phosphate-buffered saline (PBS). They were placed in RPMI 1640 culture medium and cell viability and number were determined by Trypan Blue dye exclusion (greater than 98% for all samples) in a Neubauer chamber. PMNC purity was typically 90%. A portion of the cells was pelleted and frozen immediately at –80 °C for fatty acid composition analysis. The rest of the cells were used for functional assays. PMNC functions were assessed and cultures initiated within 2 hours of cell isolation.

Fatty Acid Composition of Polymorphonuclear Cells

Total lipids were extracted from PMNC using chloroform–methanol (2:1 vol/vol). The crude lipid extracts were suspended in methanol and the pH adjusted to ≥ 12 with 5 mol/L NaOH. The aqueous solution was acidified

(pH \leq 2.0) with concentrated hydrochloric acid, followed by solvent extraction of fatty acids with hexane. The extracts were evaporated until dry under a gentle stream of nitrogen (40 °C). Fatty acids were derivatized with 4-bromomethyl-7-coumarin and then separated on a Varian pro-Star high performance liquid chromatograph using an octadecylsilica column (25 cm \times 4.6 mm i.d.; particle size 5 μ m). Fatty acid derivatives were resolved isocratically using a mobile phase of acetonitrile–water (gradient from 77:23 to 90:10 vol/vol) at a flow rate of 1 mL/min. Fatty acid derivatives were detected by fluorescence (325-nm excitation; 395-nm emission) and integration data was acquired by Pro-Star LC 6.0 workstation.

Phagocytosis of Zymosan by Polymorphonuclear Cells

PMNC were seeded in 96-well flat-bottomed tissue culture plates (2×10^5 cells in 0.1 mL). Neutral red stained zymosan (10 μ L containing 10^6 particles) was added and the plates incubated for 30 min. Then, cells were fixed with Baker's formol-calcium solution (4% formaldehyde, 2% sodium chloride, 1% calcium acetate) for 30 min and centrifuged at 453 g for 5 min. The neutral red stain was extracted by 0.1 mL of acidified alcohol (10% acetic acid, 40% ethanol in distilled water) for 30 min. The absorbance was read on a microplate reader at 550 nm. Phagocytosis was calculated from a standard curve of stained zymosan and results expressed as absorbance (Abs)/ 10^6 PMNC/mL.

Polymorphonuclear Cell Lysosomal Volume

The volume of the lysosomal system of PMNC was assessed as described previously [34]. Briefly, 2×10^5 cells (in 0.1 mL) were incubated for 30 min in 20 μ L of neutral red (3% in PBS) and then washed twice with PBS by centrifugation (453 g for 5 min). Neutral red was solubilized in 0.1 mL of ethanol-acetic acid (40:10%, v:v). The absorbance was read at 550 nm and lysosomal volume was expressed as absorbance (Abs)/ 10^6 PMNC/mL.

Superoxide Anion Production by Polymorphonuclear Cells

Superoxide anion production by PMNC was measured by the reduction of nitroblue tetrazolium [35]. PMNC (10^5 in 0.1 mL) suspended in PBS were incubated for 1 h at 37 °C in the presence of 10 μ L of phorbol myristyl acetate (4 μ M final concentration) and 0.1% (wt/v) nitroblue tetrazolium. Then the mixture was centrifuged for 5 min at 453 g and the cells were fixed with 50% methanol for 10 min and then air-dried and centrifuged as before. Reduction of

nitroblue tetrazolium results in the formation of blue formazan which was solubilized by 30 min incubation with 120 μ L of 2 M potassium hydroxide and 140 μ L of dimethyl sulfoxide per well. The absorbance was read at 550 nm. The results are expressed as absorbance (Abs)/ 10^6 PMNC/mL.

H₂O₂ Production by Polymorphonuclear Cells

Hydrogen peroxide production by PMNC was measured as described previously [35]. This assay is based on the horseradish peroxidase (HRPO)-dependent conversion of phenol red into a colored compound by H₂O₂. PMNC (10^5 in 0.1 mL) were incubated in the presence of glucose (5 mM), phenol red solution (0.56 mM), and HRPO (8.5 U/mL) in the dark for 1 h at 37 °C. After this period, the absorbance was measured at 620 nm on a plate reader. The concentration of H₂O₂ was determined from a standard curve prepared in parallel. The results are expressed as μ mol/ 10^6 PMNC/mL.

Statistical Analysis

Data were normally distributed and are presented as means \pm SEM. Statistical analyses using data for both groups and time points were performed by ANOVA followed by a post hoc Tukey test. Changes over time were compared between the groups using independent Student's *t* tests. In all cases differences were considered statistically significant when $p < 0.05$.

Results

Subjects

The two groups did not differ significantly in age or body weight at study entry (Table 1). Body weight did not differ significantly between groups after chemotherapy. However, the patients in the control group lost an average of 2.5 kg while subjects in the FO group gained an average of 1.7 kg. The change in weight over the 8 week period was significantly different ($p < 0.002$) between groups (Table 1).

Fatty Acid Composition of Polymorphonuclear Cells

Fatty acid composition of PMNC did not change significantly over 8 weeks in the control group (Table 2). EPA and DHA in PMNC increased significantly and arachidonic acid (AA) decreased significantly after 8 weeks of FO (Table 2). The ratio of AA to EPA was significantly decreased by FO (Table 2).

Polymorphonuclear Cell Number and Function

PMNC number tended to decline in the control group ($p = 0.06$) but not in the FO group, such that after 8 weeks the number of PMNC was higher (by about 30% on average) in the FO group than in the control group (Table 3). The change in PMNC number over the 8 week study period was significantly different between the control and FO groups. Phagocytosis of zymosan by PMNC declined significantly in the control group (Table 3); the average decrease was about 45%. In contrast, in the FO group PMNC phagocytosis did not decline, but increased on average by 15% (Table 3). At the end of the 8 week treatment period phagocytosis by PMNC was greater in the

FO group than in the control group. Uptake of neutral red by PMNC decreased by an average of about 40% in the control group (Table 3). This did not occur in the FO group (Table 3). FO significantly increased superoxide production by PMNC (Table 3). Hydrogen peroxide production by PBMC decreased significantly in the control group (Table 3). This did not occur in the FO group.

Discussion

This was a randomized trial examining the effect of FO, rich in n-3 PUFA, on PMNC number and function in patients receiving chemotherapy post-surgical resection,

mainly of gastrointestinal tumors; neutrophils make up the bulk of PMNC. The dose of FO and of n-3 PUFA used here was lower than that used in a number of previous studies of neutrophil function in healthy humans [18–27] and in previous studies in weight losing cancer patients [8–13, 29–31, 36]. However, it was important to use a tolerable dose of FO in these patients who would be sensitive to possible adverse effects of higher FO doses, such as off flavors. Indeed, previous studies of FO supplements in cancer patients have noted a lack of tolerability, expressed as fishy aftertaste and belching, nausea, and fish smelling breath and perspiration [29–31] and a resulting high drop-out rate of patients from the study [29, 30]. In the control group receiving chemotherapy alone PMNC number declined and PMNC function became impaired. This is entirely consistent with reports in the literature [15–17]. The reduction in PMNC number observed in the current study is consistent with reductions seen previously [15–17] and is considered to be clinically relevant. The combination of reduced PMNC and impaired PMNC function would most likely result in an inability to provide vigorous host defense against pathogens, so increasing the risk of infection.

In contrast to the effects seen in the control group, oral FO supplementation prevented the decline in PMNC number and function, and in some cases improved these measures. As far as we are aware this is the first study to report that oral FO can prevent some of the deleterious effects of chemotherapy on PMNC numbers and function. However, a recent study reported that oral FO improved the response rate to chemotherapy in patients with advanced non-small cell lung cancer and had a clinical benefit [36]. How n-3 PUFA might prevent the loss of neutrophils that accompanies chemotherapy is not clear. However, these fatty acids might affect the concentrations of hematopoietic cytokines active on cells of the leukocyte lineages. The mechanism involved needs further investigation. If the reduction in PMNC numbers and function induced by chemotherapy is of clinical relevance, then preventing those reductions would be of great clinical importance, perhaps lowering the risk of infections. Unfortunately, in the current study we did not evaluate clinical outcomes such as infections and antibiotic use.

The findings of the current study suggest that there may be a role for n-3 PUFA in maintaining innate immune function in patients receiving chemotherapy and this maintenance of function could be important in preventing infections during this sensitive time and may also contribute to prevention of tumor regrowth. PMNC became enriched in EPA and DHA over the 8 week period of supplementation with FO. The level of enrichment in these bioactive n-3 PUFA is likely strongly related to the dose provided [6]. In order to explore this further, data for EPA

enrichment from the current study was compared with data for EPA enrichment in neutrophils reported in other studies in humans [13, 18, 27, 28, 37], irrespective of their duration. Such interrogation showed the findings to be extremely varied. Thus, two studies using high doses of EPA [37] or EPA + DHA [27] for 4 weeks in healthy humans report marked neutrophil enrichment in EPA. In contrast, a third study using high dose EPA + DHA for 6 weeks reported much more modest EPA enrichment in neutrophils of healthy volunteers [18], while high dose EPA + DHA for 2 weeks in advanced cancer patients did not alter neutrophil phosphatidylcholine fatty acid composition [13]. These studies suggest that there may be many exogenous factors that influence the changes in neutrophil fatty acids induced by n-3 PUFA. Healy et al. [28] reported on the dose-dependent incorporation of n-3 PUFA into neutrophils over 12 weeks in healthy humans; the range of doses included the dose used in the current study. Figure 1 shows the mean neutrophil enrichment in EPA as a function of oral EPA dose reported by Healy et al. [28] with the findings of the current study superimposed. It is evident that the incorporation observed in the current study accords well with that reported by Healy et al. [28].

Patients in the control group lost weight during the 8 weeks of the study period. Patients in the FO group did not lose weight and, in fact, on average they gained weight. This observation is surprising given the low dose of n-3 PUFA used. However, it is consistent with some other studies, especially those in pancreatic cancer [8–12]; these

Fig. 1 Comparison of blood neutrophil enrichment with EPA in the current study and in the dose-response study of Healy et al. [28]. Mean enrichment of neutrophil phospholipids with EPA in healthy volunteers consuming one of four doses of fish oil for 12 weeks taken from Healy et al. [28] is shown in the black circles (average of $n = 8$ for each dose); the line of best fit (forced to go through zero) is shown. Mean enrichment of neutrophil lipids with EPA in the current study is shown in the grey squares, with the bars indicating + SEM

studies used higher doses of n-3 PUFA than used here. It is not clear how this benefit on body weight occurs. It may relate to maintained or improved appetite in the FO group, as has been reported in some studies of weight losing cancer patients [11, 31] and in patients with Alzheimer's disease [38]. We did not measure appetite or food intake in the current study, but it will be useful for these to be assessed in follow-up studies.

Many studies show that n-3 PUFA can modify aspects of neutrophil function in healthy humans [18–28]. Neutrophils constitute the first line of host defense against bacterial infection. Three processes are important for the role of neutrophils in host defense: phagocytosis, degranulation, and release of reactive oxygen species (ROS) derived from the superoxide-generating NADPH oxidase. Phagocytosis is the process of recognition and engulfment of microorganisms and tissue debris that accumulate during infection, inflammation and wound repair. Phagocytosis declined over 8 weeks in the group receiving chemotherapy only. Eight weeks of FO prevented this decline and the resulting activity was higher at 8 weeks than in the control group at this time. The mechanism by which FO promotes neutrophil phagocytosis (or prevents its decline) is not clear. Many membrane proteins and lipids are involved in the phagocytic process, as is the formation of membrane microdomains termed rafts [39]. It is known that n-3 PUFA influence the fatty acid composition of neutrophil phospholipids [18, 27, 28, 37]. Thereby they might alter membrane fluidity or the formation of raft regions [4–6]. In a cross-sectional study the content of n-3 PUFA was positively correlated with the ability of human blood neutrophils to phagocytosis *E. coli* [40], suggesting that a higher membrane content of these fatty acids improves phagocytosis.

Lysosomal volume, indicated here by neutral red uptake, indicates the extent of lysosomal swelling as a result of post-phagocytosis processing of engulfed material. Lysosomal volume declined over 8 weeks in the group receiving chemotherapy only. Eight weeks of FO prevented this decline and the resulting volume was higher at 8 weeks than in the control group at this time. This is consistent with the changes seen for phagocytosis according to chemotherapy and FO exposure.

Generation of superoxide anions by the NADPH oxidase complex follows from phagocytosis and is an indispensable component of the host defense response, since it is essential for the killing of invading microorganisms. FO was shown to better maintain or to improve production of superoxide radicals and hydrogen peroxide. Superoxide generation was initiated by exposure to PMA bypassing the need for phagocytosis and early membrane-mediated processes. Thus, n-3 PUFA must have an enhancing effect on protein kinase C activity and/or the events that follow it. In a cross-

sectional study the content of n-3 PUFA was positively correlated with the ability of human blood neutrophils to produce superoxide in response to PMA [40], suggesting that a higher membrane content of these fatty acids improves phagocytosis.

Thus n-3 PUFA in the form of FO improve neutrophil numbers and function in cancer surgery patients undergoing chemotherapy. These data suggest that a higher content of n-3 PUFA improves the functioning of the cells.

In summary FO supplementation (2 g/day) for 8 weeks in chemotherapy patients altered the fatty acid composition and function of blood PMNC, mainly neutrophils. This may represent an improvement in host defense in these patients which would increase the likelihood of a positive clinical outcome.

Acknowledgments The authors would like to thanks the nurses and physicians of the Oncology Department of the Angelina Caron Hospital.

Abstract The current low consumption of n-3 long chain polyunsaturated fatty acids (n-3 LCPUFA) led scientists to wonder about the possible enrichment of human food, including meats such as beef, with n-3 LCPUFA. However, their biosynthesis from dietary n-3 PUFA seems limited in mammalian tissues implying that a better understanding of the molecular mechanisms responsible for this down regulation is needed. This study aimed at identifying and comparing the limiting steps of n-3 LCPUFA synthesis in liver, intermuscular adipose tissue (IM-AT) and semitendinosus muscle (ST) from six Limousin bulls. Tissue FA composition was analysed by GLC and mRNA abundance of enzymes and transcription factors involved in n-3 LCPUFA synthesis was assessed by RT-qPCR. In liver, mRNA encoding proteins involved in n-3 LCPUFA synthesis were present in agreement with the significant high content of n-3 LCPUFA (8.4 mol% of total FA, 257 mg/100 g of fresh tissue) in this organ. In IM-AT, these mRNA were all present, but at a tenfold lower intensity than in liver in agreement with the low contents of n-3 LCPUFA in this tissue. In ST muscle, these mRNA were all present except elongase 5 mRNA which was only present as trace, the corresponding protein being undetectable, probably inducing a break of n-3 LCPUFA synthesis from 18:4n-3. In conclusion, Limousin bull ST muscle seemed unable to synthesize n-3 LCPUFA. However, the presence of 20:5n-3 (EPA) and 22:5n-3 (DPAn-3) in muscle raised the question of the origin of these n-3 LCPUFA.

Introduction

The long chain polyunsaturated fatty acids of the n-3 family (n-3 LCPUFA), particularly EPA, DPAn-3 and DHA (22:6n-3), have been shown to have many beneficial biological effects [1]. Thus, DHA was shown to be essential for the development and the functioning of retina and brain [2] and in the prevention of various chronic diseases such as cardiovascular and inflammatory disorders, depression, Parkinson's and Alzheimer's diseases and some cancers [1]. Similarly, EPA and DPAn-3 were also recognized to participate to the prevention of cardiovascular diseases [3, 4] and in cell membrane functions via eicosanoid production [5].

Currently, seafood products, notably oily fishes and fish oils, are among the most important dietary sources of n-3 LCPUFA for humans. However, their consumption in most western populations is sub-optimal since it corresponds to only 54% of the minimal amount recommended by the European Food Safety Authority [6]. Therefore, the current challenge to ensure an optimal n-3 LCPUFA intake for human is to diversify food sources for humans. An attractive strategy would be the enrichment in n-3 LCPUFA of terrestrial animal products such as beef, as they are largely consumed in industrialized countries.

Several nutritional strategies are proposed to directly increase n-3 LCPUFA content in meat or to increase tissue deposition of linolenic acid (ALA), as a precursor of n-3 LCPUFA in cells of vertebrates. Thus, the addition of fish oil or of marine algae in diets of ruminants significantly increases n-3 LCPUFA content of phospholipids in bovine [7] and lamb [8] muscles. However, the addition of fish oil in terrestrial animal ration is currently excluded in some Western countries, in particular for ruminants because of the animal origin. On the other hand, the use of micro-algae was not recommended because they modify ruminal bacteria, thus altering dietary PUFA biohydrogenation and favoring accumulation of *trans* 18:1 in the rumen contents [9]. Feeding of rations rich or enriched with ALA represents an alternative strategy. Thus, for grazing ruminants [10], ALA content of muscles significantly increases with non negligible increase in n-3 LCPUFA contents. In contrast, although the addition of linseed or rapeseed in diets of ruminant [11, 12] also significantly increase the ALA content of muscles, n-3 LCPUFA levels stay unchanged or increase only modestly. These results suggest a low conversion of ALA to DHA in ruminant as reported in humans [13]. Consequently, the abundance of n-3 LCPUFA in bovine muscles appears to depend not only on dietary n-3 PUFA but also on their endogenous biosynthesis via elongation and desaturation of dietary n-3 PUFA.

Metabolic studies in rodents had identified the various steps involved in the conversion of ALA to DHA. This biosynthesis is performed through alternating steps of desaturation and elongation followed by a final step of peroxisomal β -oxidation. This mainly involves activities of two desaturases ($\Delta 5$ and $\Delta 6$ desaturases), two elongases (elongases 2 and 5) and of enzymes of the peroxisomal β -oxidation [14–16] (Scheme 1). The activity of these enzymes is currently regarded as potential limiting steps in this biosynthesis probably in a tissue and/or species dependent manner. Indeed, $\Delta 6$ desaturase is considered to be the main rate limiting step for the conversion of ALA to DHA in dog liver [17] and in fish muscle [18] whereas elongase 2 is missing in rat heart [19, 20]. Additionally, the low expression of some peroxisomal β oxidation enzymes (L-PBE and ACOX1) could cause a bottle neck in n-3

LCPUFA synthesis for neuroblastoma cells [21]. Moreover, several studies have recently shown in rodents that the main regulators of these enzymes are transcription factors such as SREBP-1c, RXR, LXRs and PPARs [14, 15].

In this context, we hypothesized that one or several enzymes and/or transcription factors were very low in abundance in the bovine muscles leading to the reduced level of n-3 LCPUFA reported in these tissues. To answer this hypothesis, we focused on identifying accurately the possible limiting steps of this synthesis by quantifying the mRNA abundance of known enzymes and transcription factors involved in this pathway in bovine liver that plays a central role of lipid metabolism [22], the inter-muscular adipose tissue that is the major site of lipogenesis in ruminant [23] and the ST muscle as an edible tissue.

Materials and Methods

Animals, Diet and Tissue Sampling

The experiment was conducted according to the national legislation on animal care (Certificate of Authorization for Experimentation on Living Animals n° 7740, Ministry of Agriculture and Fish Products). Six young Limousin bulls (15–18 month old) were given a concentrate/straw based diet (75:25) (representative of a standard diet) for the 100-day finishing period. Fatty acid composition of the diet is given Table 1. Animals were slaughtered at an average body weight of 627 ± 16.3 kg in the INRA experimental abattoir (Saint-Genès Champanelle, France). Representative samples (~ 50 g) of the liver, the inter-muscular adipose tissue (IM-AT, between the thoracic portion of the trapezius muscle and the rhomboideus thoracis muscle) and the semitendinosus muscle (ST) were collected within 30 min and immediately frozen in liquid nitrogen and stored at -80°C until analysis.

Lipid Analysis

Tissue samples of liver, IM-AT and ST (~ 50 g) were ground into a fine and homogeneous powder in liquid nitrogen with a mixer mill (Retch MM 301, Germany). Total lipids were extracted according to the method of Folch [24] by mixing tissue powder with a mixture chloroform–methanol 2/1 (vol/vol) and determined by gravimetry. Transmethylation into fatty acid methyl esters (FAME) was performed as previously described [11]. FAME analysis was achieved by gas–liquid chromatography (GLC) using the Peri 2100-model chromatograph (Perichrom Society, Saulx-les-Chartreux, France) fitted with the CP-Sil 88 glass capillary column (Varian, USA) (length: 100 m; \varnothing : 0.25 mm) with H_2 as the carrier gas,

Scheme 1 Metabolic pathway of biosynthesis of n-3 LCPUFA in mammals. The conversion of ALA (18:3n-3) occurs in the endoplasmic reticulum to successively produce EPA, DPAn-3 and 24:6n-3. Then, 24:6n-3 is transferred to the peroxisomes to be β -oxidized in DHA involving several specific enzymes

RNA Isolation and cDNA Synthesis

Total RNA was extracted from the powder of liver (300 mg), IM-AT (1,000 mg) and ST muscle (500 mg) by using Trizol reagent (Invitrogen, Life Technologies, CA, USA) according to the manufacturer's recommendations. Total RNA was then treated with DNase to remove genomic DNA using NucleoSpin® mini kit columns (Machery-Nagel, PA, USA) according to the manufacturer's protocol, except for samples of adipose tissue for which were used RNA mini kit columns (Invitrogen, Life Technologies, CA, USA) as previously described [26]. Tissue RNA was quantified with the Nanodrop ND-1000 Spectrophotometer (Nanodrop Technologies, Wilmington, DE, USA) given RNA concentrations of about 2.19, 0.04 and 0.22 mg/g of fresh tissue for liver, IM-AT- and ST muscle, respectively. The quality and integrity of RNA were examined by the RNA Integrity Number (RIN) determined by using the kit RNA 6000 Nano Assay on the 2100 bio-analyzer (Agilent technologies, Palo Alto, CA, USA). Only samples displaying a RIN ≥ 8.0 and an $A_{260/280} > 1.8$ were considered. The corresponding cDNA (about $0.38 \pm 0.01 \mu\text{g}/\mu\text{l}$ for all tissues) was synthesized by reverse transcription from 2.5 μg of total RNA using 100 U of Superscript II reverse transcriptase (Invitrogen,

under temperature conditions described by Scislowski et al. [25]. Total FA were quantified by using C19:0 as the internal standard. Identification and calculation of the response coefficient of each individual FAME was obtained by using the quantitative mix C4–C24 FAME (Supelco, Bellafonte, USA).

Life Technologies, CA, USA) and 0.5 µg of oligodT in a final volume of 50 µl. RNA and cDNA samples were stored at −80 °C until analysis.

Quantitative Real Time PCR

The qPCR was performed by using a StepOne Plus (Applied Biosystems, Foster City, CA, USA) from a dilution of cDNA of 1/50 for the liver and 1/25 for the IM-AT and the ST muscle. A total of 17 genes involved in n-3 LCPUFA biosynthesis were studied and 3 genes were used as reference genes (Table 2). The primers were designed by using The ProbeFinder Software from Roche Applied Science and ordered from Sigma Aldrich. The PCR reaction was performed by using Power Sybergreen PCR master mix (Applied Biosystems, Foster City, CA, USA) in a reaction buffer (cDNA + each of forward and reverse primers + DNase/RNase free water + Sybergreen PCR master mix) in a MicroAmp Optical 96-well reaction plate (Applied Biosystems, Foster City, CA, USA). qPCR conditions were as follows: 95 °C/10 min, 40 cycles of 95 °C/15 s (denaturation), 60 °C/45 min (annealing), 95 °C/15 s (extension). The melting cycle consisted in 60 °C/1 min, increased by 0.6 °C up to 95 °C and held 15 s. The specificity of primers was confirmed by melting curve analysis and by electrophoresis of PCR products on 2% agarose gel stained with ethidium bromide. Samples were run in triplicate and concentration of each mRNA was determined from a calibration curve prepared from a cDNA pool from the three bovine tissues. The qPCR data were expressed in arbitrary units taking into account differences in cDNA dilutions between tissues. Data were normalized using the geometric mean of the three reference genes TOP2B, TBP, RPLPO as previously described by Bonnet et al. (Unpublished data), Goossens et al. [27] and Wang et al. [28].

Protein Extraction and Expression

Liver samples (3 g) were homogenized in 10 ml of Tris–sucrose buffer (250 mM sucrose, 50 mM Tris-base, pH 7.4) supplemented with a mixture of inhibitors of proteolytic enzymes (PMSF 1 mM, benzamidine 1 mM, leupeptine 5 µg/ml). After centrifugation at 10,000g for 30 min at 4 °C, the supernatant was collected. For ST muscle and IM-AT, total protein extraction was performed as previously described by Bouley et al. [29] and Taga et al. [30], respectively. Tissue protein concentrations were determined using the Lowry's method [31] with bovine serum albumin as the standard by using the RCDC protein assay kit (Biorad, Marnes-la-Coquette, France).

Elongase 5 protein contents in the liver, the IM-AT and the ST muscle were determined by Western Blot analysis

on 12% polyacrylamide gel slabs in denaturing conditions according to Laemmli [32] from 50 µg of total proteins. Immunoblot analysis was performed by using purified rabbit polyclonal antibody raised against amino acids 211–299 mapping at the C-terminus of ELOVL5 of human origin (1:200 dilution, Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA). Control of loading was assayed by using purified mouse monoclonal Actin α antibody (1:10,000 dilution, IgG2a, Clone AC-40, Sigma-Aldrich, St. Louis, MO, USA) and purified mouse monoclonal Actin β antibody (1:4,000 dilution of IgG1a, Clone AC-74, Sigma-Aldrich, St. Louis, MO, USA). The secondary fluorescent-conjugated IRDye 800CW antibodies (anti-rabbit or anti-mouse IgG) were supplied by LICOR Biosciences (Lincoln, Nebraska, USA). Protein bands were visualized by infrared fluorescence detection using a scanner Odyssey (LI-COR Biosciences) (800 nm laser, 169 µm spatial resolution and fixed gain = 5).

Statistical Analysis

Values are expressed as means \pm SEM of six animals. Comparison of data between the liver, the IM-AT and the ST muscle were analysed according to a split-plot design using the MIXED procedure of SAS (Cary, NC, USA) in which tissues were accepted as constant factors and animals as a random factor. Statistical significance was set at $p < 0.01$.

Results

Fatty Acid Composition

Total PUFA accounted for about 42.9 mol% of total FA in the liver (Table 3), but only for 4.4 and 23.8 mol% of total FA in IM-AT and ST muscle, respectively, the predominate FA in these tissues being SFA (53.3 mol% and 40.2 mol% in IM-AT and ST, respectively) and MUFA (41.8 mol% and 35.6 mol% in IM-AT and ST, respectively) (Table 3). Among PUFA and in all tissues, n-6 PUFA relative amounts were 3- to 8-fold higher than those of n-3 PUFA. However, the part of n-3 PUFA was able to reach 9.4 mol% in the liver while it represented only 0.5 and 4.0 mol% of total FA in IM-AT and ST muscle, respectively. The two predominant n-3 PUFA in the liver were 22:5n-3 and 22:6n-3 that corresponded to about 5.14 and 1.55 mol% of the total FA, respectively. In contrast, the predominant n-3 PUFA in the IM-AT was 18:3n-3 (0.53 mol% of total FA). In the ST muscle, equivalent levels of 18:3n-3 and 22:5n-3 were observed. In the IM-AT and the ST muscle, 22:6n-3 were present as only traces (Table 3).

mRNA Expression

In the liver, mRNA encoding for proteins involved in the biosynthesis of n-3 LCPUFA were all present at a

significant level (Fig. 1). In the same way, mRNA of transcription factors involved in the regulation of n-3 LCPUFA biosynthesis were all present (Fig. 2) excepted for the mRNA of PPAR γ_2 that was undetectable.

^a, ^b, ^c Significant differences between anatomic sites (*p* < 0.01)

In the IM-AT, mRNA encoding for proteins involved in n-3 LCPUFA biosynthesis (Fig. 1) were also all present, but their abundance was 10-fold lower than that in the liver (*p* < 0.02). In the same manner, abundance of mRNA of all transcription factors involved in the regulation of n-3 LCPUFA biosynthesis were 6-fold lower in the IM-AT than in the liver (*p* < 0.003) (Fig. 2).

In the ST muscle, the level of mRNA encoding for proteins known to be involved in n-3 LCPUFA biosynthesis was about 1.8- to 5.1- fold lower than in the liver excepted for elongase 5, elongase 2 and GNPAT (Fig. 1). The expression of GNPAT gene was similar between ST muscle and liver. The main differences affected the genes of elongases 5 and 2, their mRNA abundance being 100- and 25-fold lower in ST muscle than in liver, respectively

(*p* < 0.0015). For transcription factors (Fig. 2), expressions of SREBP-1c, RXR α and LXRs genes were 1.4- to 2.3-fold lower in the ST muscle than in liver (*p* ≤ 0.0001) whereas PPAR γ 2 mRNA was undetectable in the both tissues.

Protein Expression

Protein level of elongase 5 in the liver, the IM-AT and the ST muscle were determined by Western blot analysis (Fig. 3). This method revealed a single and intense band with a molecular mass of approximately 35 kDa corresponding to the elongase 5 molecular weight reported in the liver of bulls. In the IM-AT and the ST muscle, this band was undetectable.

Discussion

To our knowledge, the present study has reported for the first time the identification of the possible limiting steps of the endogenous synthesis of n-3 LCPUFA by using both biochemical (FA composition) and molecular biology (expression of the seventeen proteins and the six nuclear transcriptional factors regulating the transcription of these genes) techniques in various tissues of Limousin bulls such

as the liver, the inter-muscular adipose tissue and the ST muscle.

Several studies had clearly shown that the conversion of ALA to n-3 LCPUFA in mammalian cells involved serial steps of desaturation and elongation reactions with a final peroxisomal chain shortening [13, 33]. Our present study demonstrated that the bovine liver expressed all genes encoding proteins and transcription factors involved in n-3 LCPUFA biosynthesis. This suggests that the bovine liver

Fig. 3 Representative Western blot analysis of elongase 5 from the liver, the intermuscular adipose tissue (IMAT) and the semitendinosus (ST) muscle of Limousin bulls fed a concentrate-based diet. Loading control proteins were β actin for the liver and the IM-AT and α actin for the ST muscle

could efficiently convert dietary ALA to n-3 LCPUFA in agreement with the significant amount of DHA present in this organ (around 47 mg/100 g tissue). Various studies, using radiotracer or heavy isotope labelled ALA infusion, had already suggested the ability of the liver to such metabolic conversion both on models for human research such as the rat liver [34] or the HepG2 cells [35], and on animals of agronomic interest such as swine [36], poultry [37] and fish [38]. However, the study of gene expression of enzymes known to be involved in this biosynthesis has never been reported until now. Moreover, in the current study, bovine liver expressed mRNA of all transcription factors involved in the regulation of n-3 LCPUFA biosynthesis except the peroxisome proliferator activated receptor gene $PPAR\gamma_2$. Distribution of $PPAR$ isoforms is tissue specific [39]. $PPAR\gamma$ was mainly expressed in the adipose tissue [40] to stimulate FA uptake and adipogenesis [41] whereas $PPAR\alpha$ is markedly expressed in the liver [39] where it generally induces expression of FA β -oxidation genes [42] but also of $\Delta 5$ and $\Delta 6$ desaturase genes [43]. Consequently, our results first demonstrate the implication of genes necessary for n-3 LCPUFA biosynthesis in the bovine liver. Thereby, the liver represents an appropriate model to study n-3 LCPUFA biosynthesis in bovine tissues and therefore can be considered as an appropriate positive control.

In the inter-muscular adipose tissue, mRNA encoding the various proteins involved in ALA conversion to n-3 LCPUFA were present but with a 10-fold lower abundance than in the liver, suggesting that IM-AT is less oriented towards the n-3 LCPUFA than liver. These results are in agreement with the very low content of n-3 LCPUFA determined in lipids of IM-AT. The low proportion of phospholipids compared to triacylglycerols in the adipose tissue and the preferential incorporation of n-3 LCPUFA in this polar fraction in ruminant animals could explain this result [44]. Moreover, a recent study using the *in vitro* method of incubated bovine adipose tissue slices in presence of radiolabeled fatty acids showed that only 1.3% of ALA taken up by adipose tissues are converted to 20:5n-3 without any detectable synthesis of DHA [45]. In the same

way, mRNA of all transcription factors were poorly represented in IM-AT. It is well known that the mRNA abundance of these factors is not necessary representative of the activity of their corresponding protein (which could be stimulated by ligand binding, alterations in protein–protein interaction and transcription factor phosphorylation) [46]. However, it can be hypothesized that the low gene expression of these transcription factors would be related to the low mRNA abundance of enzymes involved in n-3 LCPUFA biosynthesis in IM-AT of bovine.

In the ST muscle, mRNA encoding proteins involved in n-3 LCPUFA biosynthesis were less abundant than in liver, particularly for the elongases 5 and 2. The concomitant undetectable elongase 5 protein in ST muscle strongly argued for a lack in elongase activity. This enzyme is predominately involved in the elongation of C_{18} and C_{20} PUFA [47] and is expressed in most human [48] and rat [19] tissues. Little is known about the regulation of elongase family members, both regarding mRNA and protein expression, as well as enzymatic activity. However, available data in the literature would indicate a controlled elongase activity by transcriptional regulation [15]. Two studies suggested a regulatory role of LXR, SREBP-1c and $PPAR$ through transcriptional activation of elongase 5 in human hepatoblastoma Huh7 cells [49] and on mice [50]. In the bovine muscle, SREBP-1c, $PPAR\alpha$ and LXR mRNAs were present but, as discussed above, their mRNA abundance is not necessary representative of their activity. Elongases are condensing enzymes that interact with the 3-keto acyl-CoA reductase, a dehydratase, and *trans*-2, 3 enoyl-CoA reductase to elongate FA [51]. The rate of FA elongation is generally regulated by the activity of the elongase (condensing enzyme) and not by reductase or dehydratase. However, the low elongase 5 gene expression noted in the bovine muscle might be the result of deficient expression of reductase and dehydratase as well as of elongase. Additional studies will be required to examine the expression of these enzymes in bovine muscle. Although elongase 5 mRNA and protein was undetectable in bovine muscle suggesting a limitation of n-3 LCPUFA synthesis from 18:4n-3, this did not explain the low but

significant amount of n-3 LCPUFA determined in muscle lipids, especially EPA and DPAn-3. This result is corroborated by numerous studies on fatty acid composition of bovine muscles [12, 52, 53]. The presence of these FA in muscle could be explained by their essential role in cell function, especially through the regulation of membrane fluidity and eicosanoid production [5]. Two hypotheses can be proposed: (i) ST muscle could take up circulating EPA and DPAn-3 coming from the diet. However, EPA and DPAn-3 contents in the concentrate-based diet were not detected (ii) ST muscle could take up n-3 LCPUFA synthesized in the liver from dietary ALA and subsequently release them into the blood as part of the VLDL particles. Indeed, numerous studies using an isotope tracer technique on rodents reported that the liver plays a major role in supplying n-3 LCPUFA to various organs and tissues especially the brain, retina, heart and kidney [54–57]. Uptake of long chain FA across cell membranes is known to involve two main mechanisms: (i) a passive diffusion through the membrane bilayer [58] and (ii) a protein facilitated transfer [59]. Nowadays, it is generally recognized that membrane-associated FA-binding proteins not only facilitate but also regulate cellular FA uptake through their inducible rapid translocation from intracellular storage pools to the plasma membrane [60, 61]. A number of FA transporters has been identified (CD36/FAT, FABPpm, FATP1-6, etc) and it has been recently reported that CD36 downregulation in 3T3-L1 adipocytes decrease n-3 LCPUFA uptake by cells [62]. Consequently, the intensity of gene expression of FA transporters in bovine muscle could explain the presence of n-3 LCPUFA in this tissue. Despite the presence of DHA precursors (namely EPA and DPAn-3) in the bovine ST muscle, DHA deposition was very low and the involved metabolic mechanisms were not elucidated. This could not result from a higher intensity of β -oxidation of DHA than of EPA and DPAn-3 since EPA was reported to be more readily β -oxidized than DHA [63, 64]. One hypothesis is that circulating DHA could be preferentially taken up by tissues other than muscles (e.g. brain, retina) linked to (i) a higher abundance of FA transporters on membranes of these tissues, (ii) an easier diffusion of DHA through the membranes of these tissues. Another hypothesis is that muscle DHA has a greater sensitivity to lipoperoxidation than muscle EPA and DPA. Indeed, it is well known that n-3 PUFA are particularly susceptible to peroxidation due to their high degree of unsaturation. Recently, the sensibility to peroxidation of three n-3 PUFA (ALA, EPA and DHA) was compared in rats [65]. The serum lipid peroxidation index, assessed by the level of TBA-reactive substances, becomes higher and the α -tocopherol levels are inversely lower with an increasing number of double bonds in PUFA. Therefore, further investigations are needed to test this hypothesis.

In conclusion, our present study shows for the first time that the Limousin bull ST muscle may be unable to convert ALA to n-3 LCPUFA because of the undetectable elongase 5 protein and corresponding mRNA. However, additional studies are required to validate these results such as the measurement of elongase 5 activity and the enlargement of experimental conditions (number of animals, other muscles, breed, type of animals). The presence of EPA and DPAn-3 in the ST muscle suggested that these FA, probably synthesized by the liver, could be efficiently taken up by this tissue. In contrast, the low level of DHA in the ST muscle could be the consequence of its preferential peroxidation or of its preferential uptake by other tissues/organs. A better understanding of peroxidation phenomena of n-3 LCPUFA as well as the regulation of DHA uptake by extra-hepatic tissues should provide further insights for future efforts to improve beef nutritional quality taking into accounts the risks that such manipulations could lead to animal health.

Acknowledgments This work was conducted within the framework of European ProSafeBeef Program (Project N° FOOD-CT-2006-36241). We are grateful to the experimental installations and the abattoir of INRA (Clermont-Ferrand/Theix) for animal rearing and slaughtering. We thank Dr. Brigitte Picard for her scientific advice on protein analysis. We also thank Françoise Duboisset and Christiane Legay for her excellent technical support, Geneviève Gentes, Sébastien Bes and Nicole Dunoyer for their technical advice.

Abstract Recent evidence suggests that HER2 (ErbB2; Her-2/neu) and the related PI3K/Akt signaling pathway substantially affect the malignant phenotype of colorectal cancer cells. Moreover, fatty acid synthase (FASN), which mediates de-novo fatty acid synthesis, is crucially important in the carcinogenesis process of a variety of cancers, including colorectal cancer. The purpose of this study was to investigate the malignant phenotype regulation of colorectal cancer cells via the “HER2–PI3K/Akt–FASN axis”. Caco-2 cells with high expression of HER2 and FASN and high transfection efficiency were selected for functional characterization. The cells were transfected with either HER2-specific RNAi plasmid or negative control RNAi plasmid, followed by Q-RT-PCR and western blot assays to examine expression of HER2, PI3K, Akt, and FASN. MTT and colony-formation assays were used to assess proliferation. Migration was investigated by use of the transwell assay, and apoptosis and cell cycle were assayed by use of flow cytometry. Expression of HER2,

PI3K, Akt, and FASN were downregulated when HER2 was silenced. Proliferation decreased after downregulation of HER2, which was consistent with increased apoptosis. Migration of HER2-silenced cells was also impaired. Loss of HER2 inhibits the activity of the “HER2–PI3K/Akt–FASN axis” of Caco-2 cells, and reduced activity of this axis alters the malignant behavior of Caco-2 cells.

Introduction

Colorectal cancer is the third most common cause of cancer-related mortality in the world, and the most frequent malignancy of the gastrointestinal tract. Approximately 150,000 new cases are diagnosed annually [1]. HER2 (ErbB2; Her-2/neu) is a member of the epidermal growth factor receptor (EGFR) family of receptor tyrosine kinases (RTKs) that regulates biological functions such as cellular proliferation, transformation, differentiation, motility, and apoptosis [2, 3]. Modulation of HER2 is also tightly regulated in normal cellular function. In-vitro and animal studies have revealed that deregulated HER2 expression/activity is pivotal in oncogenic transformation,

tumorigenesis, and metastasis [4, 5]. Recent studies have provided evidence that HER2 and its family members are overexpressed by colorectal cancer cells, implying it is important in mediating malignant progression [6, 7].

A high-fat diet has been related to the development of many human solid tumors, including colon, breast, and ovarian carcinoma [8]. Fatty acid synthase (FASN) is a multifunctional enzyme that performs seven sequential reactions to convert acetyl-CoA and malonyl-CoA to palmitate and is of central importance in the anabolic conversion of dietary calories into a storage form of energy in mammals [9, 10]. Numerous clinical and basic studies indicate that increased expression of FASN is a common event in breast cancer and in varieties of human solid tumors, particularly those with poor prognosis [11]. Our previous study and recent studies have demonstrated that inhibition of FASN by use of pharmacological inhibitors is selectively cytotoxic to human cancer cells and leads to a significant antitumor effect [12, 13], suggesting that activation of fatty acid synthesis is required for carcinogenesis. Collectively, overexpression of FASN occurs in a wide variety of human cancers and is associated with poor prognosis, suggesting that fatty acid synthesis is an advantage in tumor growth and could be a feature of many human solid tumors and a promising target for chemoprevention or chemotherapy.

It is worthy of note that HER2 has been shown to regulate FASN transcriptional expression by altering the activity of the PI3K/Akt signaling pathway, revealing a molecular connection between HER2 and FASN in breast cancer cells [14]. Inhibition of FASN preferentially induced apoptosis of HER2-overexpressing breast cancer cells [15], suggesting that downregulation of FASN expression might be involved in HER2-mediated cell survival and tumorigenesis. Although lipogenesis has proved to be important for the survival and proliferation of colorectal cancer cells, it remains largely unknown how HER2 regulates lipogenic enzymes (for example FASN), and the factors and mechanisms determining the malignant phenotype of colorectal cancer cells are not yet completely understood. Thus, in this study, we hypothesized that HER2 can regulate FASN expression and change malignant behavior via the PI3K/Akt signaling pathway in colorectal cancer cells.

Materials and Methods

Cell Culture and Target Cell Selection

Four human colorectal cancer cells, Caco-2, HT-29, LoVo, and LS174T, were used in this study. All cells were purchased from the Shanghai Cell Biology Institute of the Chinese Academy of Sciences (Shanghai, China). HT-29,

LoVo, and LS174T cells were cultured in RPMI-1640 medium supplemented with 10% fetal bovine serum (Invitrogen, USA). Caco-2 cells were cultured in minimum essential medium (MEM) supplemented with 10% fetal bovine serum (Invitrogen). All cells were incubated at 37 °C in a humidified atmosphere supplemented with 5% CO₂. HER2 and FASN mRNA expression by the four types of cell were detected by Q-RT-PCR. A negative control RNAi plasmid with scrambled sequences (denoted MR-Neg) (Table 1) was synthesized according to the manufacturer's instructions (Invitrogen), and the four types of cell were transiently transfected with MR-Neg to determine transfection efficiency. HER2 and FASN mRNA expression and transfection efficiency for the four types of cell were integrated for selection of target cells.

HER2-specific RNAi Plasmid Construction and Stable Transfection

Knockdown of HER2 (NCBI reference sequence: NM_001005862.1) was achieved by an RNA interference approach, using pcDNATM 6.2-GW/EmGFP-miR (Invitrogen) to obtain stable clones. Four pairs of HER2-specific RNAi oligos were designed by Block-iTTM RNAi Designer and synthesized (Table 1). After being annealed, connected, and transformed, four different HER2-specific RNAi plasmids (denoted MR-HER2-1 to MR-HER2-4) were synthesized according to the manufacturer's instructions (Invitrogen), and Caco-2 cells were transiently transfected with them. HER2 mRNA expression was detected by Q-RT-PCR to validate the knockdown effect and to choose the most effective HER2-specific RNAi plasmid. Caco-2 cells were then transfected with the most effective HER2-specific RNAi plasmid (MR-HER2-4) and the negative control RNAi plasmid (MR-Neg) by use of Lipofectamine 2000, in accordance with the Invitrogen technical bulletin. Blastisidin (7 µg/ml) was used to select for stable clones.

Experimental Groups

All further experiments were divided into three groups. The experimental group (denoted Caco-2 + MR-HER2): Caco-2 cells were stably transfected with the MR-HER2-4 and collected. Blank control group (denoted Caco-2): Caco-2 cells were cultured normally and collected. Negative control group (denoted Caco-2 + MR-Neg): Caco-2 cells were stably transfected with the MR-Neg and collected.

Quantitative Real-Time Polymerase Chain Reaction

Total RNA was isolated by the TRIzol method (Invitrogen). cDNA was synthesized by use of a reverse

transcription kit (Invitrogen) in accordance with the manufacturer's instruction. Gene mRNA expression was verified by use of a fluorescence quantitative PCR system (BioRad, USA). Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as internal standard. The gene primer sequences are listed in Table 2. The cycling conditions were: initial denaturation at 95 °C for 2 min, followed by 40 amplification cycles of 95 °C for 10 s, 60 °C for 30 s, and 70 °C for 45 s. Every real-time PCR assay contained 1.2 µl cDNA template, 0.5 µl SYBR green, and 0.5 µl of every forward and reverse primer in 25 µl reaction mixture. Relative gene mRNA expression was analyzed by use of the $2^{-\Delta\Delta CT}$ method [16]. Every experiment was repeated three times.

Western Blot Analysis

Equal amounts of protein (100 µg per lane) were applied to 4–12% NuPAGE Novex Bis-Tris Mini Gels (Invitrogen) and the separated proteins were transferred on to an Immobilon P PVDF membrane (Invitrogen). The membranes were blotted using primary antibodies directed against human HER2, PI3K, Akt (1:300, 1:400, 1:500;

Signalway Antibody, USA), Phospho-Akt, and FASN (1:500; Cell Signaling Technology, USA). After incubation with the appropriate antirabbit or antimouse horseradish peroxidase-conjugated secondary antibody (1:10,000, Santa Cruz, CA, USA), immunoreactive bands were visualized by chemiluminescence, dissolved, and exposed to X-ray film. GAPDH (1:10,000, Santa Cruz) protein expression was used as a normalization control for protein loading.

Cell Proliferation Assay

Cells (6×10^3 /200 µl/well) were seeded in 96-well plates. Viable proliferating cells were detected by use of the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay at different times (24, 48, 72, 96, and 120 h), using six wells per time. Cell viability was expressed as optical density (OD), which was detected by use of an enzyme-linked immunoabsorbent assay reader (MK3; Thermo, USA) at 492 nm. Every experiment was repeated three times.

Colony-Formation Assay

Cells (6×10^2 /2 ml/well) were seeded in 6-well plates, and cultured for 2 weeks to form colonies. The colonies formed were stained with Giemsa, and the colonies containing more than 50 cells were counted under an inverted microscope. Every experiment was repeated three times.

Cell-Migration Assay

Cell migration was measured in 24-well plates by the transwell assay using a chamber containing a poly(ethylene terephthalate) filter membrane with 8-µm pores (Corning, USA). Cells (6×10^4 /200 µl/chamber) were seeded in the upper chamber with MEM, and 500 µl MEM supplemented with 10% fetal bovine serum was placed in the

lower well as a chemoattractant. After incubation for 24 h, the chambers were stained with hematoxylin–eosin (HE). Migrated cells were counted from five randomly selected fields under an inverted microscope. Every experiment was repeated three times.

Cell-Apoptosis Analysis

Cells (5×10^5) were harvested, washed with PBS, and resuspended in binding buffer (Kaijibio, China), followed by mixing with Annexin V-FITC and propidium iodide (Kaijibio). Cells were analyzed by use of a Becton–Dickinson FACSCalibur flow-cytometer provided with CellQuest software (Brentford, MA, USA). Every experiment was repeated three times.

Cell-Cycle Analysis

Cells (1×10^6) were harvested, washed with PBS, and fixed in 70% ethanol. The fixed cells were washed with PBS and resuspended in RNase A (Kaijibio), followed by incubation at 37 °C for 30 min. Cells were stained with PI solution (Kaijibio) and analyzed by use of a Becton–Dickinson FACSCalibur flow-cytometer provided with CellQuest software (Brentford, MA, USA). Every experiment was repeated three times.

Statistical Analysis

Statistical comparisons were performed by use of SAS software, version 9.1 (SAS Institute, Cary, NC, USA). Values are presented as mean \pm standard error of mean (SEM). The statistical significance of differences was determined by one-way ANOVA with a post-hoc test (Student–Newman–Keuls test). Values of $P < 0.05$ were considered to be statistically significant.

Results

Target Cell Selection

HER2, FASN mRNA expression of Caco-2 cells were respectively 138.46 ± 77.6 and 70.52 ± 11.53 . Compared with HT-29, LoVo and LS174T cells, they were both higher (Fig. 1a). After transient transfection with MR-Neg for 24 h (Fig. 1b), transfection efficiency for the four types of cell were observed by use of an inverted fluorescence microscope. Compared with HT-29, LoVo, and LS174T cells, transfection efficiency for Caco-2 cells was, again, higher (Fig. 1c). Hence, Caco-2 cells were selected as the target cells for further experiments.

The Most Effective HER2-specific RNAi Plasmid Selection and Stable Transfection

After transient transfection with four different HER2-specific RNAi plasmids and MR-Neg for 24 h (Figs. 1b, 2a), HER2 mRNA expression of Caco-2 cells was 0.53 ± 0.2 , 0.52 ± 0.07 , 0.31 ± 0.09 , 0.29 ± 0.13 , 1.00. Compared with other groups, HER2 mRNA expression of Caco-2 cells transfected with MR-HER2-4 was the lowest ($P < 0.05$) (Fig. 2b). Therefore, Caco-2 cells were transfected with the most effective HER2-specific RNAi plasmid (MR-HER2-4) and the negative control RNAi plasmid (MR-Neg), and blasticidin (7 $\mu\text{g/ml}$) was used to select for stable clones. The fluorescein signal of stable clones was detected as a granular pattern in the cytoplasm surrounding the nuclei (Fig. 3).

Inhibition of HER2 Expression by RNA Interference-Suppressed FASN Expression of Caco-2 Cells via the PI3K/Akt Signaling Pathway

HER2 mRNA expression by the experimental group was 0.3 ± 0.08 , significantly lower than by the control groups ($P < 0.05$) (Fig. 4a). HER2 protein expression was also reduced compared with the two control groups (Fig. 4b). Interestingly, after inhibiting HER2 expression, PI3K, Akt, and FASN mRNA expression of the HER2–RNAi group were 0.14 ± 0.02 , 0.02, and 0.37 ± 0.03 , all significantly lower than the control groups ($P < 0.05$) (Fig. 4a). Correspondingly, PI3K, Akt, and FASN protein expression also declined dramatically (Fig. 4b). Western blot analysis also revealed a significant decrease in Phospho-Akt (Fig. 4b).

Inhibition of the “HER2–PI3K/Akt–FASN Axis” Blocked the Proliferation and Migration of Caco-2 Cells

To examine possible involvement of the “HER2–PI3K/Akt–FASN axis” in cancer progression, the proliferation and migration of Caco-2 cells after silencing of HER2 were assessed by use of the MTT, colony-formation, and transwell assays. As shown in Fig. 5a, the OD values measured after 5 days showed that proliferation for the experimental group was significantly lower than for the two control groups ($P < 0.05$). Colony-formation by the HER2-silenced group was $4.72 \pm 0.01\%$, and had obviously declined, compared with the blank control group ($11.33\% \pm 0.02$) and the negative control group ($11.78\% \pm 0.02$) ($P < 0.05$) (Fig. 5b). In the transwell assay, HER2-silenced cells migrated less efficiently than control cells ($P < 0.05$) (Fig. 5c). The number of migrating HER2-silenced Caco-2 cells was 158.67 ± 6.51 , compared with 295.33 ± 4.04 for the blank

control group and 327 ± 14.53 for the negative control group.

RNA Interference-Induced Apoptosis of Caco-2 Cells

HER2 silencing led to a greater early apoptosis ($71.13 \pm 0.04\%$) of Caco-2 cells ($P < 0.05$) (Fig. 6a). There was no difference between late apoptosis of HER2-silenced and control cells ($P > 0.05$) (Fig. 6a) and no significant changes in cell cycle were observed upon HER2 silencing ($P > 0.05$) (Fig. 6b).

Discussion

Historically, HER2 was identified as an oncogene because of its ability to induce the malignant transformation of cultured fibroblasts. HER2 oncogene is highly expressed in different types of human cancer and is linked with poor prognosis of clinical outcome. Therefore, HER2 has become an important therapeutic target in a variety of human tumors for two reasons:

1. HER2 expression closely correlates with the pathogenesis and aggressive behavior of some human tumors; and

Fig. 3 Fluorescence photograph of Caco-2 cells stably transfected with the most effective HER2-specific RNAi plasmid and the negative control RNAi plasmid ($\times 200$ magnification)

Fig. 4 HER2, PI3K, Akt, and FASN expression of Caco-2 cells by RNA interference. **a** HER2, PI3K, Akt, and FASN mRNA expression. *Compared with the two control groups, $P < 0.05$. **b** HER2, PI3K, Akt, Phospho-Akt, and FASN protein expression

- the expression level of HER2 in human cancer cells with HER2 amplification is higher than in normal tissue, so targeted therapy may reduce its toxicity toward normal tissue.

In this study, we observed that inhibition of HER2 blocked the proliferation and migration of Caco-2 cells and increased apoptosis. This implies that an HER2-mediated pathway essentially controls the malignant behavior of Caco-2 cells, and HER2 overexpression may be a malignant characteristic of colorectal cancer.

Endogenous fatty acid synthesis catalyzed by lipogenic enzymes such as FASN has emerged as an oncogenic stimulus that drives many epithelial malignancies [17, 18]. Intriguingly, recent experimental evidence supports the notion that the oncogenic nature of FASN-mediated lipogenesis largely depends on the activity and/or expression of important cancer-related oncogenes, for example HER2 [19]. HER2 overexpression leads to constitutive upregulation and maintenance of exacerbated FASN-catalyzed endogenous fatty acid synthesis [20, 21];

this “lipogenic benefit” enhances the proliferation, survival, chemoresistance, and metastasis of human cancer cells [22–24], and activation of endogenous fatty acid synthesis in non-cancerous epithelial cells, only, is sufficient to induce a cancer-like phenotype functionally dependent on HER2 activity [17]. Taken together, these findings suggest that HER2 increases the expression of FASN, thereby ensuring hyperactive de-novo fatty acid synthesis which potentiates its oncogenic effect. In this study, we demonstrated that inhibition of HER2 significantly suppressed FASN expression of Caco-2 cells; it further blocked the cell proliferation and cell migration. This implies that HER2 may affect the FASN-mediated lipogenic process and change malignant phenotypes in colorectal cancer cells.

It is well known that aberrant expression of HER2 can trigger the activation of multiple downstream signaling pathways, including the PI3K/Akt signaling pathway and the MAPK signaling pathway, which mediates different aspects of malignancy [25, 26]. PI3K is activated as a result of ligand-dependent activation of HER2, and Akt has

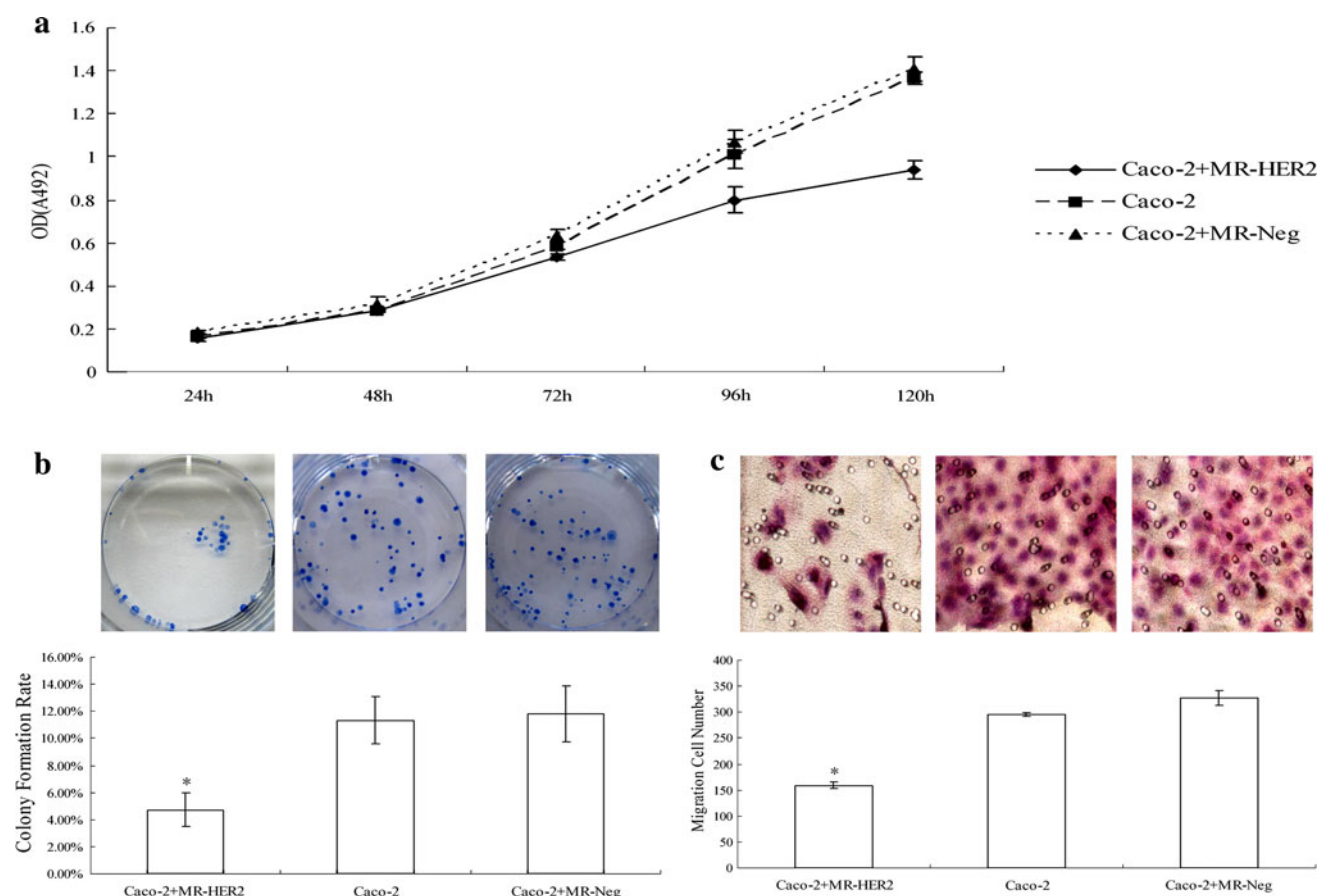

Fig. 5 Proliferation and migration of Caco-2 cells after RNA interference. **a** The proliferation curve. Compared with the two control groups, $P < 0.05$. **b** Colony formation rate. *Compared with the two control

emerged as an important regulator of widely divergent cellular processes, including proliferation, apoptosis, differentiation, and metabolism [27]. However, it remains

largely unknown whether specific “effectors” regulated by HER2 ultimately contribute to its tumorigenic effects. There is substantial evidence that the PI3K/Akt signaling

pathway is important in oncogenic transformation and cancer progression, and it has been linked with FASN expression in cancer cells [17, 28]. Kumar-Sinha et al. [14] used a DNA microarray to compare and identify genes induced by HER2 in a mammary epithelial cell line with ectopic HER2 overexpression and in breast cancer cell lines derived from patients with different levels of HER2 expression. They found that HER2 overexpression activated FASN promotion and transcription and increased protein production and activity, whereas inhibitors of HER2, e.g. herceptin and CI-1003, attenuated the effect of HER2 on FASN expression. PI3K activity was thought to be the mediator of HER2 control of FASN expression, because LY294002, a known PI3K inhibitor, abrogated HER2-induced FASN protein production in HER2 overexpressing normal mammary epithelial and breast cancer cells. Thus, transcription of the FASN gene may be induced by HER2 via the PI3K/Akt pathway. Similarly, in our study, we confirmed that inhibition of HER2 expression by RNA interference suppressed FASN expression by Caco-2 cells via the PI3K/Akt signaling pathway, and further blocked the proliferation and migration of Caco-2 cells. This indicates that the “HER2–PI3K/Akt–FASN axis” previously described in breast cancer cells might also exist in colorectal cancer cells, and the axis could be crucially important in the carcinogenesis process of colorectal cancer.

In summary, our results are indicative of the presence of an axis among HER2, the PI3K/Akt signaling pathway, and FASN, and that this “HER2–PI3K/Akt–FASN axis” is crucially importance in the carcinogenesis process of colorectal cancer. Elucidating the molecular link between the “HER2–PI3K/Akt–FASN axis” and malignant phenotype of colorectal cancer cells may be important to the development of molecularly targeted therapy against human colorectal cancer.

Abstract Cats have limited $\Delta 6$ desaturase activity. However, γ -linolenate (GLA) feeding may by-pass the $\Delta 6$ desaturase step allowing arachidonate (ARA) accumulation via $\Delta 5$ -desaturation. Alternatively, high dietary linoleate (LNA) may induce limited $\Delta 6$ desaturase also resulting in ARA accumulation. Fatty acid profiles were determined after feeding high LNA, high GLA, or adequate LNA diets. Adult female cats ($n = 29$) were assigned to one of three groups and fed for 8 weeks. Plasma samples were collected at weeks 0, 2, 4 and 8 for plasma triacylglycerol (TAG), total cholesterol (TC), lipoprotein (LP), and plasma and red blood cell membrane phospholipid fatty acid determinations. Time, but no diet, effects were observed for TAG, TC, and LP fractions at weeks 2 and 4 with significant increases likely due to increased dietary fat. However, all values were within feline normal limits. The GLA diet resulted in increased dihomo- γ -linolenic acid (DGLA) and ARA as early as week

2, supporting a $\Delta 5$ desaturase. Further evidence of $\Delta 5$ desaturase was found at high dietary LNA with the appearance of a novel fatty acid, 20:3 $\Delta 7, 11, 14$, apparently formed via $\Delta 5$ desaturation and chain elongation of LNA. However, $\Delta 6$ desaturase induction at high dietary LNA concentration was not observed. Cats are able to maintain plasma and red blood cell ARA when fed a practical diet containing GLA using what appears to be an active $\Delta 5$ desaturase enzyme.

Introduction

Most mammalian species readily convert linoleic acid (LNA) to arachidonic acid (ARA) utilizing enzyme steps

including $\Delta 6$ desaturation, chain elongation, and $\Delta 5$ desaturation [1]. By contrast, early evidence in cats showed that this species lacked sufficient $\Delta 6$ desaturase activity for this purpose concluding that a dietary source of ARA was necessary for this species [2–5]. Cats fed diets adequate in LNA but deprived of ARA, showed dry, lusterless hair coats, dandruff, behavioral infertility, and hepatic lipid infiltration [2]. A series of studies [2, 3, 6–8] ultimately demonstrated essential fatty acid (EFA) deficiency pointing to the absence of $\Delta 6$ desaturase even though cats had been fed the requisite LNA and α -linolenic acid (ALA) [9].

Further studies involving EFA metabolism of cats were conducted by Sinclair et al. [10] in which an EFA deficient diet was fed using hydrogenated beef tallow. These workers found evidence of Mead acid (i.e. 20:3 $\Delta 5$, 8, 11) even though earlier work had not detected it [3, 4]. It was also noted that, although EFA-deficient rats accumulated Mead acid as a result of $\Delta 6$ and $\Delta 5$ desaturase activities [11], this would likely not occur in feline species because of the limited activity of the $\Delta 6$ desaturase enzyme. Instead, it was hypothesized that the accumulation of Mead acid would more likely be the result of chain elongation of oleic acid followed by $\Delta 8$ and $\Delta 5$ desaturation. However, Frankel and Rivers did not find any evidence of $\Delta 5$ desaturase and no ARA accumulation after feeding a GLA enriched diet [7]. In a following study, however, Sinclair et al. supplemented cats with GLA and reported an increase in ARA as well as the presence of an unknown non-methylene interrupted eicosatrienoic acid that they identified as 20:3 $\Delta 5$, 11, 14. Thus it was concluded that the $\Delta 5$ desaturase was operable in cats [1].

More recently, studies using GC/MS and stable isotope techniques have provided support for the presence of detectable amounts of both $\Delta 6$ and $\Delta 5$ desaturase products in feline liver [12]. In view of the above findings, given the likelihood of a feline $\Delta 5$ desaturase, it was hypothesized, that feeding cats a diet enriched in γ -linolenic acid (GLA) may be a practical way to provide precursors for ARA synthesis via by-passing the limited $\Delta 6$ desaturase step.

Because of the presence of small amounts of $\Delta 6$ desaturase in cats, an additional hypothesis in the present work was that high dietary amounts of LNA with minimal ARA would induce a constitutively low $\Delta 6$ desaturase activity in feline species and thus allow for ARA accumulation as a possible alternative. This question was based on the finding that Pawlosky et al. observed more labeled ARA in cats fed a diet enriched in LNA that was nearly devoid of ARA compared to a commercial dry, extruded diet that contained increased ARA (LNA/ARA ratios of approximately 580 vs. 43 respectively [12]). They attributed their finding to demonstrable $\Delta 6$ desaturation and we therefore wished to test whether it could be induced using a high LNA, low ARA diet.

Materials and Methods

Animals and Diets

Twenty-nine adult, sexually intact female cats ranging in age between 1.5 and 2 years with body weights (BW) between 2.4 and 6.0 kg were used. Cats were individually maintained in kennels according to the American Physiological Society Guidelines for Animal Research, and the protocols were approved by Texas A & M University Animal Care and Use Committee. The cats were assessed to be clinically normal prior to entering the study as indicated by complete blood counts, serum biochemistry profiles, and physical examination. The animals were randomly assigned to one of three groups according to diet fed; high linoleic acid (HL, $n = 9$), formulated with LNA-rich safflower oil; low linoleic acid (LL, $n = 10$), in which safflower oil was replaced by coconut oil to reduce LNA to only adequate levels, and high γ -linolenic acid (GLA, $n = 10$), formulated to contain adequate LNA plus an enriched borage oil containing 70% GLA. The diets were similar in all respects except for fatty acid composition (Table 1). The expected nutrient compositions of the diets were: 35% protein, 18% fat, 7.5% ash, 8% moisture, and 2% crude fiber. The experimental diets were formulated to be complete and balanced in order to meet or exceed minimal nutrient requirements established for adult cats [13, 14] and manufactured by Nestlé Purina PetCare (Saint Louis, MO). Analyses of the diets were performed by Nestlé Purina Laboratories and results were within expected analytical variance for the above targets (Table 2).

Cats were fed according to their individual metabolic body weights ($100 \text{ kcal ME} \times (\text{BW}_{\text{kg}}^{0.67}/\text{day})$) and to maintain a body condition score (BCS) of 5 out of 9 [18]. The cats consumed a pre-experimental diet (PED, Kit N Kaboodle®, Nestle-Purina Pet Care, minimums, 30% protein and 8% fat; and maximums, 12% moisture and 4.5% crude fiber) for 4 weeks prior to the start of the trial then fed the experimental diets for 8 weeks (see Table 1 for the fatty acid profile of the PED).

Prior to the experimental period, daily food consumption of the PED was measured and determined to be generally sufficient to maintain the animal's body weight at BCS 5. Cat BW and BCS were determined weekly during this time and the cats were allowed to play with paper bags to provide physical activity. The controlled dietary amounts fed and the stimuli to play helped them maintain BCS of 5 and with minimal changes in body weights. In a few cases cats with BCS >5 were provided a reduced calorie allowance to ($80 \text{ kcal ME} \times (\text{BW}_{\text{kg}}^{0.67}/\text{day})$). These animals were maintained in this fashion during the PED period until reaching the desired BCS 5. The animals were fed once daily and food consumption and BMR (Body Maintenance Energy

The diets are designated as described in the text. The dry, extruded-type diets were manufactured by Nestlé-Purina Petcare. Diet ingredients (by weight): Brewers milled rice, 35.9%; Soybean protein isolated, 23.3%; Chicken whole carcass and parts, 21.6%; Soybean hulls, 3.67%; Dicalcium phosphate, 2.93%; Coconut oil, 2.80%; Flavor coating, 1.5%; Beef tallow, 0.7%; Potassium chloride, 0.65%; Mineral premix, 0.34%; Choline chloride, 0.32%; Calcium carbonate, 0.29%; Sodium chloride, 0.22%; DL-methionine, 0.18%; Taurine, 0.1%; Vitamin premix, 0.07%; Vitamin E (50%), 0.03%. Vitamin premix contents: 146.32 g/kg nicotinic acid, 10.35 g/kg vitamin A acetate, 90 g/kg DL-α-tocopherol acetate, 84 mg/kg cholecalciferol, 52 g/kg thiamine mononitrate, 51.06 g/kg calcium D-pantothenate, 24.4 g/kg riboflavin, 14.52 g/kg pyridoxine hydrochloride, 6 g/kg folic acid, 508 mg/kg menadione sodium bisulfite, 93 mg/kg vitamin B-12, and 36.8 mg/kg biotin. Mineral mix contents: 65 g/kg zinc as zinc sulfate, 39 g/kg iron as ferrous sulfate, 18.25 g/kg manganese as manganese sulfate, 3.2 g/kg copper as copper sulfate, 651 mg/kg iodine as calcium iodate, and 50 mg/kg selenium as selenium selenite. The remaining percent of each diet were consisted of three dietary oils: Coconut oil, 5.58% in LL diet and Safflower oil, 5.24% in HL diet, which provided the desired fatty acid profiles, Coconut oil 4.85% and Borage oil at 70% GLA, 0.5%. Values are the means of duplicate determinations

calculated for each animal. Individual allometric factors were used to calculate the amount to feed each cat during the subsequent experimental period to maintain a BCS of 5. This allowed each animal to be fed to maintain its ideal body weight and condition. Because of individual variation in caloric needs among outbred cat colonies, individualized feeding was necessary.

Blood Sample Collection and Analyses

Blood samples were obtained from each cat by venipuncture at weeks 0, 2, 4 and 8 during the experimental period. Food had been withheld for 12 h and 7 ml of blood were drawn from a saphenous vein into EDTA-containing tubes. At week 0, complete blood counts and plasma biochemistry profiles were evaluated. Blood samples were centrifuged at 1,800×g for 15 min and plasma was separated from red blood cells (RBC) and frozen at −80 °C in small aliquots

for subsequent analysis. Packed RBC were kept on ice for immediate RBC membrane ghost preparation. The cells were washed with isotonic saline and lysed with deionized water, followed by a sequence of slow speed centrifugation and deionized water washes to isolate membranes. The membranes were suspended in 10 mM phosphate buffer, pH 7.2, and stored at -80°C . Total lipids were then extracted from both plasma and RBC membranes [15]. Total plasma phospholipid fractions were separated by thin layer chromatography, scraped from the plates, and trans-methylated to yield fatty acid methyl esters for analysis via gas chromatography [15]. Although some minor fatty acid components in the chromatograms remained unidentified, most of these occurred in samples obtained at week 0 at the start of the feeding study. Nonetheless, identification of all fatty acids including any unique fatty acids eluting in the region between GLA and ARA on the chromatograms were specifically identified using authentic standards and confirmed, when necessary, using covalent adduct chemical ionization gas chromatography/mass spectrometry (CAGC/MS) [16].

Fatty acid data are presented in mol%. Earlier studies in numerous species including cats have found that RBC membrane phospholipid content is unaffected by dietary fat type [17–21]. Also, plasma phospholipid and RBC membrane fatty acids represent similar pools because transfer and exchanges between plasma and RBC membranes are likely the major source of fatty acid enrichment between these two pools in the circulation. Thus it was anticipated that should similar findings between plasma PL and RBC membrane fatty acid profiles occur, they could be readily compared and thus better address the proposed hypotheses in this investigation.

Plasma triacylglycerol (TAG) and total cholesterol (TC) concentrations were determined using enzymatic methods [22]. Lipoprotein cholesterol distributions (LP-C) were determined using freshly isolated plasma via 1% agarose gel electrophoresis and quantified by scanning densitometry [22].

Digestibility Assays

All cats were used for apparent digestibility determinations during week 6 of the feeding period. Complete fecal samples were individually collected twice a day for 5 consecutive days, pooled for each cat, and frozen at -40°C . All samples and diets, were sent to the Nestlé Purina Petcare Laboratory, Saint Louis, for analysis. The parameters evaluated were coefficients of apparent digestibility of crude protein, total fat, crude fiber, ash, and gross energy. The coefficient for digestible energy (DE) and metabolizable energy (ME) were calculated based on DE and urinary loss [13].

Data Analysis

Values presented are means \pm SEM. All data except for the normative BCS data were found to be normally distributed by the Shapiro–Wilks test. The BCS data were analyzed by the nonparametric Kruskal–Wallis one-way ANOVA (SAS 9). Digestibility coefficients were analyzed for main diet and time effects, and diet \times time interactions using Proc GLM ANOVA by SAS ($P < 0.05$). For the other data, statistical significance was determined using repeated measures ANOVA for diet, time, and diet \times time interactions for the following plasma parameters including plasma TAG, TC, LP-C, total phospholipid fatty acid profile, RBC membrane fatty acid profile, food consumption, body weight, and allometric metabolizable energy factor using Proc Mixed by SAS ($P < 0.05$). For all parameters Tukey's multiple comparison of means was performed where appropriate, with the P value set at <0.05 .

Results

Food and Metabolic Energy Consumption

All cats readily consumed the diets when offered and all food was consumed within 4 h. No diet refusals were observed. Diet effects were not observed for either the average weekly energy consumption or amounts of food (g) consumed ($P = 0.77$). A significant time effect for average weekly energy consumption was seen between week 0 and week 5 ($P = 0.05$) (Fig. 1). It should be noted, however, that although the energy densities of the experimental diets were similar, the PED contained less energy per kg (3,200 kcal/kg). Thus, the amount of PED food consumed was higher at week 0 when compared to week 8 ($P = 0.005$) after the experimental diets had been fed.

Body Weights and Body Condition Scores

The cats showed a modest but statistically significant weight loss from week 1 to 8 (overall time effect ($P = 0.0001$)) (Fig. 1) but no changes in BCS were observed (data not shown). The animals' body maintenance requirement (i.e. allometric energy factor) remained stable ($P = 0.14$) except for some minor variation when comparing week 0 to the other time periods ($P < 0.0003$) (Fig. 1).

Plasma TAG, TC, and Lipoprotein Cholesterol Distributions

Time effects but no diet effects were seen for all plasma lipid concentrations. All lipid values were increased at week 4 yet remained within the normal range for adult cats.

Fig. 1 Average weekly food consumption (left axis, bars) and body weights (right axis, lines) of cats fed the experimental diets. Open bars and symbols GLA diet; closed bars and symbols HL diet; Cross-hatched bars and symbols LL diet. *a* indicates a significant difference in average weekly consumption at week 0 compared to the other weeks by repeated measures ANOVA, $P < 0.05$. *b* indicates a significant difference between week 0 and 5 overall by repeated measures ANOVA, $P < 0.05$

Plasma TC was maximally elevated at week 4 as was the α -LP-C (α -LP-cholesterol) fraction. This fraction was responsible for most of the total plasma cholesterol elevation although the other LP fractions also contributed to a lesser extent to this increase over time (Table 3). The pre- β -LP-C followed a similar pattern with a maximal value achieved at week 2 remaining at week 4 and decreasing thereafter to its initial level at week 8. The β -LP-C fraction also increased but, in this case, remained elevated at week 8 unlike the other LP-C fractions. No diet effect was observed for plasma TAG ($P = 0.25$), but concentrations were significantly different over time ($P = 0.04$) (Table 3). Feeding the experimental diets resulted in statistically significant higher TAG concentrations over baseline values at week 4 which decreased to baseline at week 8 but these elevations were of small magnitude.

Plasma Phospholipid Fatty Acids

Numerous time effects were observed reflecting the fatty acid contents of the experimental diets versus baseline.

However, where diet \times time interactions occurred, additional ANOVA were performed to identify reasons for the differences (Table 4). Compared to the HL diet, both GLA and LL diets resulted in a statistically significant accumulation of 14:0 at weeks 2 and 4 and this increase was maintained at week 8 with the LL diet. Increases in 16:1n-7 were seen with time for all diets and the LL group was higher than GLA and HL groups at all sample times. Increased LNA was found with the HL and LL diets at week 2 which remained elevated throughout the study compared to the GLA diet which showed no change in this fatty acid.

The GLA diet measurably affected 18:3n-6 concentrations. At week 2, this fatty acid increased from 0.26 to 0.82 mol% then slowly decreased but remained significantly higher compared to baseline values. These values were also statistically different compared to the HL and LL diets at all subsequent times. Furthermore, amounts of dihomo- γ -linolenic (DGLA, 20:3 Δ 8, 11, 14) were also significantly elevated with the GLA diet compared to the other groups increasing by more than 5 times at week 2 (i.e. from 1.43 to 7.43 mol%) and continuing to increase to nearly 7 times basal values (9.80 mol%) at week 8. By contrast, amounts of DGLA in the other two groups remained at approximately 1 mol% at all times. It is noteworthy that after week 2, relative amounts of 18:3n-6 decreased at the same time as DGLA increased.

Differences in ARA contents with diet were also observed even though all dietary concentrations were identical. When the GLA diet was fed, ARA was maintained at baseline values while amounts seen in the other two groups were decreased. As such, statistically significant differences were seen at weeks 2, 4 and 8 when the GLA group was compared to the HL group with LL diet fed cats showing intermediate values. The HL diet resulted in decreased plasma PL ARA at all sample times compared with baseline values (approximately 4 vs. 6.8 mol% at baseline). The LL diet also resulted in decreased ARA at week 2 but values recovered somewhat thereafter yet trended downward. It is especially noteworthy that the HL

Table 3 Plasma lipid and lipoprotein-cholesterol concentrations in adult cats during the experimental period

Mean values and overall SEM

GLA diet ($n = 9$), HL diet ($n = 10$) and LL diet ($n = 9$); superscript letters not in common in a row within a diet group indicate a significant difference between weeks by ANOVA, $P < 0.05$ and superscript numbers not in common in a row within a week indicate a significant difference between diets by ANOVA, $P < 0.05$

Fig. 2 Summary of the pathway involving $\Delta 5$ desaturase for the production of 20:3 $\Delta 7, 11, 14$ eicosatrienoic acid from linoleic acid in feline species

diet also showed statistically significant increases of 20:2 $\Delta 11, 14$ at weeks 2, 4 and 8 and of 20:3 $\Delta 7, 11, 14$ at week 8 compared to the GLA diet at all sample times. The presence of this latter fatty acid was verified by analysis of 8 separate samples from cats in the HL group by CACI-GC-MS/MS. Thus the identity of the peak corresponding to this fatty acid was 20:3 $\Delta 7, 11, 14$. One possible pathway for its production from LNA may be $\Delta 5$ desaturation followed by elongation (Fig. 2). No 18:3 $\Delta 5, 9, 12$ was observed.

Other differences observed were increased amounts of plasma PL LNA in the LL group compared to the GLA group even though both groups contained similar amounts of LNA. Also, depletion of EPA and DHA was observed in all groups during the feeding period; none of the diets contained any appreciable amounts of these fatty acids.

Red Blood Cell Membrane Fatty Acids

As with the plasma PL fatty acid profiles, RBC membrane fatty acids were similarly affected (Table 5). Small, statistically insignificant amounts of 12:0 were found in cats fed the GLA and LL diets both of which contained medium chain fatty acids from coconut oil. Linoleic acid increased in the HL group, achieved maximal values at weeks 2 and 4, then returned to baseline thereafter. Even though ARA concentrations of all experimental diets were identical, differences in this fatty acid were again observed with both the HL and LL diets compared to baseline while ARA values of cats fed the GLA diet were maintained. As expected, the GLA-enriched diet promoted a measurable increase of GLA in the RBC membranes as early as week 2 and also thereafter. In addition, dramatic increases of DGLA were also seen with this diet. Furthermore the GLA diet resulted in increased membrane ARA at week 2 and thereafter compared with the other two diets where decrements were observed. The HL diet again resulted in

significantly higher amounts of 20:3 $\Delta 7, 11, 14$ at weeks 4 and 8 compared to the GLA diet group. A significant increase of RBC membrane 20:2 $\Delta 11, 14$ was also found with the HL diet at week 4 but not at the other times.

Diet Digestibilities

For all parameters tested, only total fat digestibilities were different among diets ($P = 004$). The HL (92.2%) was significantly different than GLA (94.3%) and LL diets (93.2%).

Discussion

All experimental diets resulted in similar amounts of food consumed, BW, allometric energy factor, and BCS. Food intake during week 0 was somewhat different from the subsequent values because the first week of feeding was used for adaptation to the experimental diets which, for cats, generally requires 4–5 days [13]. After eliminating week 0 values in the analysis, neither time nor diet effects were observed except for a modest decrease in body weight. This latter finding was expected because all cats had been fed to achieve a BCS of 5 out of 9 and began the study at a moderately higher score. The allometric energy factor found for all cats under these maintenance conditions was approximately the same as has been described for adult, intact females in other studies at 104.1 ± 2.8 kcal/(kg body weight)^{0.75} [14].

Plasma TAG, TC and lipoprotein fractions similarly showed no diet effects. However, time effects were observed which were likely due to the increased amount of crude fat present in the experimental diets compared to the PED (i.e. approximately 190 g/kg crude fat in the experimental diets vs. about 130 g/kg crude fat in PED on a dry matter basis). Because cats and dogs primarily transport lipids in circulation via high density lipoprotein fractions [23, 24] the increase in the α -LP-C fraction (i.e. high density lipoprotein cholesterol) observed was consistent with that previously seen in dogs fed higher fat diets. Such partitioning of cholesterol is considered to be protective against atherosclerotic diseases in feline and canine species [23, 24].

Diet effects were clearly observed in the plasma PL and RBC membrane fatty acid fractions. Although two of the diets contained medium chain triacylglycerols, accumulation of shorter chain fatty acids in these fractions was not expected. The reason for this is that long chain fatty acids are generally more readily incorporated due to acyl specificity of the fatty acid synthetase for long chain fatty acids during triacylglycerol esterification [25]. Thus, only small amounts of the shorter chain components were seen.

Mean values and overall SEM

GLA diet ($n = 9$), HL diet ($n = 10$) and LL diet ($n = 9$); superscript letters not in common in a row within a diet group indicate a significant difference between weeks by ANOVA, a $P < 0.05$ and superscript numbers not in common in a row within a week indicate a significant difference between diets by ANOVA, $P < 0.05$

Increased amounts of LNA in plasma PL and RBC membranes were found with the HL diet but accumulation of GLA was not observed. Although this latter fatty acid is generally presumed to be a short lived metabolite due to rapid chain elongation, its absence in the samples is also consistent with low $\Delta 6$ -desaturase in feline species. In addition, the increase in plasma PL and RBC membrane LNA suggests that dietary amounts of this fatty acid may have saturated the chain elongation step (yielding 20:2 $\Delta 11$, 14) resulting in a modest, yet significant, accumulation of LNA. Competition among substrates for chain elongation may explain, in part, why 20:2 $\Delta 11$, 14, a chain elongation product of LNA, was increased in cats fed the HL and LL diets but not when GLA was fed.

Although the GLA and LL diets contained similar amounts of LNA, plasma PL LNA was increased in the LL group compared to the GLA group. It should be noted that, in general, the P/S ratio of fatty acid profiles will often be nearly constant unless diets are dramatically different (e.g. total EFA deficiency). In the present study, calculated P/S ratios of the plasma PL fractions of the GLA and LL groups were 0.94 and 0.93 respectively. Furthermore, because the GLA group accumulated DGLA, LNA appears to have been substituted by this longer chain derivative and the total amounts of these two plasma PL fatty acids are approximately equivalent among all of the diet groups. It is unknown, however, whether there may have been any increased utilization of LNA when GLA was fed as this was not determined in this study.

The present work confirms the existence of an active $\Delta 5$ desaturase in cats as originally demonstrated by Sinclair et al. [1]. Sinclair et al. [10] also identified 20:3 $\Delta 5$, 11, 14 in feline RBCs and hypothesized that it was formed via chain elongation of 18:1 $\Delta 9$ and $\Delta 8$ desaturation to 20:2 $\Delta 11$, 14 with subsequent $\Delta 5$ desaturation. As such, they hypothesized that ARA might also be formed from LNA using both $\Delta 5$ and $\Delta 8$ desaturase systems. By contrast, in the current study, although 20:2 $\Delta 11$, 14 was observed, we identified the 20:3 isomer as 20:3 $\Delta 7$, 11, 14 and confirmed it by CACI-GC–MS/MS. Our result is consistent with $\Delta 5$ desaturation of LNA followed by chain elongation (Fig. 2) rather than elongation followed by two desaturation steps as proposed by Sinclair et al. [10]. It is also a methylene-interrupted fatty acid species unlike that reported by Sinclair et al.

It is of interest, however, that the $\Delta 5$ desaturase product of LNA, 18:3 $\Delta 5$, 9, 12, was not observed in the present study. This finding is similar to the recent study of Stroud et al. [16] who also observed 20:3 $\Delta 7$, 11, 14, but no 18:3 $\Delta 5$, 9, 12, using $\Delta 6$ desaturase-null mice (–/–) fed a high LNA diet similar to the HL diet reported here. In that study, the authors described the pathway noted in Fig. 2 and concluded that $\Delta 5$ desaturation of LNA is likely due to loss

of competition from the absence of $\Delta 6$ desaturation as well as for fatty acid incorporation into phospholipids [16]. The observation of Stroud et al. is consistent with that found here in feline species, a naturally occurring model of absent $\Delta 6$ desaturase. Findings from both models are consistent with $\Delta 5$ desaturation, although the level of activity may be different in cats compared to $\Delta 6$ desaturase-null mice (–/–). Nonetheless, taken together, decreases of plasma PL ARA with the HL and LL diets and of RBC membranes with the HL diet along with the maintenance of ARA in the GLA group supports the presence of $\Delta 5$ desaturase activity.

It is possible that both eicosatrienoic acid isomers, 20:3 $\Delta 7$, 11, 14, found in the present study and 20:3 $\Delta 5$, 11, 14, reported by Sinclair et al. [10] may occur depending upon experimental conditions employed. The studies of Sinclair et al. [10] used a combination of GC, silver nitrate thin layer chromatography, ozonolysis with triphenyl phosphine, and separation of aldehyde and aldehyde esters by GC in order to identify their 20 carbon fatty acid. In contrast, the present study employed covalent adduct chemical ionization gas chromatography/mass spectroscopy [14]. Although a tracer study is needed to verify the actual pathway involved, the present findings support the possibility that DGLA, formed when GLA is fed, may be followed by its $\Delta 5$ desaturation thereby providing a functional alternative for maintaining ARA levels using a practical diet in cats. It is of interest that an earlier study of Frankel and Rivers found no ARA accumulation in cats fed 0.73% dietary GLA versus controls [7] and concluded that a $\Delta 5$ desaturase was absent. The present study contained 0.35% dietary GLA but was fed for a longer period which may explain this discrepancy. Also, by comparison, the study of Sinclair et al. [1] fed 6 doses (250 mg each) of GLA for 13 days followed by 6 doses (500 mg each) for the following 13 days and observed marked RBC ARA enrichment in 2 cats. These amounts are roughly equivalent to 160 mg GLA/day per cat overall versus 210 mg GLA/day per cat in the present study.

Cats fed the GLA-enriched diet were thus able to maintain plasma PL and RBC membrane ARA and this difference was statistically significant compared to the HL diet. It should also be noted that ARA trended upward during the feeding period in the GLA group and a longer feeding period may have resulted in further increases. Nonetheless, this difference was statistically significant compared to the HL diet even at week 4. Cats fed the LL diet also appeared not to maintain ARA levels and this result continued trending downward after 8 weeks of feeding. These differences were observed at low, yet identical dietary ARA intake overall. One limitation of this study, however, is that the FA changes observed were relative and not absolute because total FA concentrations were not determined. While unlikely, the possibility exists

that fatty acid pool sizes may have changed given the uniqueness of the cat model and because other plasma lipid alterations were observed over time in this investigation.

Reasons for the downward trend of ARA levels with both the HL and LL diets are unclear given that all diets were formulated to contain minimal, yet adequate, amounts of this fatty acid. The possibility exists that decreased ARA may be related to an effect of LNA on ARA incorporation into PL fractions. For example, Spector et al. [26], using human umbilical vein endothelial cells in culture that also lack $\Delta 6$ desaturase, observed that high concentrations of LNA interfered with the ability of these endothelial cells to maintain adequate ARA. They additionally found that ARA incorporation into PL fractions is reduced as the availability of LA increases [26]. Should these phenomena also occur in $\Delta 6$ desaturase deficient cats, then the 3.5-fold higher LNA concentration of the HL diet would, in part, explain the more marked decrease of ARA in cats fed this highest LNA concentration. Furthermore, plasma PL LNA levels were significantly greater with both the HL and LL diets consistent with the possibility of LNA interference with ARA incorporation as observed by Spector et al. [26]. Finally, although not dramatic, the minimal drop of body weight observed overall by repeated measures ANOVA may have limited actual ARA intake to some extent. If so, cats fed GLA as an alternative precursor for ARA synthesis would maintain ARA levels while animals fed the other two diets may have either consumed less than the minimal ARA requirement or increased its utilization leading to its subsequent depletion.

While a physiologic role for 20:3 $\Delta 7$, 11, 14 is presently unknown, murine macrophage cells have been shown to readily take up pinolenic acid (PNA, 18:3 $\Delta 5$, 9, 12) and elongate it to its respective eicosatrienoic acid. In addition PGE₁ from DGLA and PGE₂ from ARA were both suppressed in that study, presumably due to substrate competition [27]. These authors also suggested that the inhibitory effect of PNA on eicosanoid production may have been the result of competitive incorporation of PNA and 20:3 $\Delta 7$, 11, 14 into phospholipids which reduced the levels of DGLA and ARA available for eicosanoid formation. This possibility may also explain, in part, why ARA was lowest in the HL diet fed cats compared with the GLA and LL groups.

Induction of feline $\Delta 6$ desaturase via increased dietary LNA could not be confirmed in the present study given the decrement of ARA observed in the HL group. Thus, we found no support for the hypothesis that the limited $\Delta 6$ desaturase activity of felines might be induced by high dietary LNA. In rats, feeding high dietary LNA at constant ALA to dams caused reductions in brain and retina ARA in pups as it was transmitted through milk lipid [28]. No effects in plasma and other pools were found, however.

Consequently, feeding high LNA to rats may induce substitution for ARA thereby explaining a drop in ARA. Previous studies in our lab using dogs found no additional accumulation of ARA in either plasma PL or neutrophils when high LNA safflower oil was fed compared to low LNA beef tallow [29]. In addition, a recent review has concluded that increasing dietary LNA content does not increase tissue ARA content in humans consuming a Western-type diet [30]. Such a phenomenon may also be the case in feline species.

As a final point, it was noted that some depletion of EPA and DHA was observed in all groups during the feeding period. This result was not unexpected because the diets did not contain any appreciable amounts of these fatty acids. The 2006 Nutrient Requirements publication for cats has concluded that there are no published studies on an absolute requirement for EPA [14]. However, it does recommend that approximately 0.2% EPA be present. The commercial diet fed to the cats for several months prior to the PED diet contained about 0.2% EPA as determined in our laboratory. However EPA in the commercially available PED (fed for 4 weeks) was not detected and only trace amounts were present in our experimental diets fed for 8 additional weeks. It is unknown whether this would lead to a deficiency over time as optimal amounts of this fatty acid in the diet or concentrations in tissues are not defined in this species.

In summary, the present study demonstrates that GLA-enriched diets are readily consumed by cats without major alteration of BW and BCS or plasma lipid indices. The findings also support the presence of an active $\Delta 5$ desaturase enzyme in feline species. Thus, provision of a dietary vegetable oil source of GLA provides substrate for ARA synthesis in cats most likely via by-passing the $\Delta 6$ desaturation step. The accumulation of DGLA when GLA is fed may also serve as an important precursor for modulation of eicosanoid synthesis in cats. In addition, the $\Delta 6$ desaturase enzyme does not appear to be inducible at high dietary LNA content. Cats are thus a suitable naturally occurring animal model for $\Delta 6$ desaturase deficiency to which experiments involving the null mice (–/–) can be compared. Finally, based on these findings, studies employing dietary stearidonic acid to address questions involving longer chain n-3 fatty acid synthesis such as EPA and DPA (n-3) but also including DHA which requires $\Delta 6$ desaturase in a final step, will provide intriguing future investigations.

Abstract The effect of diets containing either 18-carbon n-3 fatty acids (FA) or 20/22-carbon n-3 FA on canine plasma and neutrophil membrane fatty acid composition, superoxide and leukotriene B₄ and B₅ production when fed at the same n-6:n-3 fatty acid ratio was investigated. Four groups of ten dogs each were fed a low fat basal diet supplemented with safflower oil (SFO), beef tallow (BTO), linseed oil (LSO), or Menhaden fish oil (MHO) for 28 days. Dietary fat provided 40.8% of energy and the n-6:n-3 of the diets were ~100:1, 9.7:1, 0.38:1, and 0.34:1 for the SFO, BTO, LSO and MHO groups, respectively. The MHO and LSO groups had increased incorporation of EPA and DPA in both the plasma and neutrophil membranes compared to the BTO and SFO groups. DHA was observed in the MHO but not in the LSO group. Neutrophils from the MHO diet fed dogs had less LTB₄ and greater LTB₅ than the other three groups. The LSO group

also showed a reduction in LTB₄ and greater LTB₅ production compared to the SFO and BTO groups. Both LSO and MHO groups had lower superoxide production compared to the SFO and BTO groups. Diets containing 18 or 20/22 carbon n-3 FA fed at the same n-6:n-3 resulted in differential incorporation of long chain n-3 FA into neutrophil membranes. Thus, fatty acid type and chain length individually affect neutrophil membrane structure and function and these effects exist independent of dietary total n-6:total n-3 FA ratios.

Introduction

Neutrophils are highly specialized white blood cells essential to the host immune response. When activated, neutrophils adhere to endothelial cells, migrate into tissues (chemotaxis), phagocytose opsonized microbes, and produce toxic compounds [1–3]. Although essential to host defense, neutrophil damage to host tissues is associated with the pathology and progression of specific diseases such as inflammatory bowel diseases, rheumatoid arthritis, coronary heart disease, psoriasis, and ischemic reperfusion injury [1, 2, 4]. The pathophysiology of these diseases is due, in part, to extracellular release of toxic compounds as well as eicosanoid synthesis, including leukotriene B₄ (LTB₄) in the inflammatory response [1–3]. Diets rich in long chain n-3 FA, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), prominent in fish oil, have been shown to have beneficial effects in cardiovascular disease, rheumatoid arthritis, hypertension, renal diseases, and the inflammatory response [5–9] and affect the immune response in mice [10, 11]. These benefits have been attributed, in part, to a reduction in pro-inflammatory leukotrienes produced by neutrophils as well as serving as a substrate for the potent anti-inflammatory compounds known as resolvins [12].

Dietary long chain n-3 FA supplementation results in their incorporation into plasma lipids and phospholipid fractions of circulating immune cells [1, 2, 13–16]. The incorporation of EPA and DHA into neutrophil lipids occurs at the expense of the more pro-inflammatory arachidonic acid (ARA) [17–19]. Furthermore, replacement of ARA with EPA and DHA results in a decrease in neutrophil superoxide production without involvement of the cyclooxygenase pathway and without altering neutrophil lysosomal enzyme release [20]; inhibition of chemotaxis-mediated phosphoinositide formation and chemotaxis [21]; and a decrease of stimulated neutrophil chemiluminescence as an index of production of free oxygen radicals [22]. Membrane fatty acid modifications via diet FA also alter neutrophil leukotriene production. For example, incorporation of EPA and DHA into neutrophil membranes is associated with a reduction in the powerful chemotactic agent, LTB₄, and a corresponding increase in LTB₅, which is 30–100 times less stimulatory than LTB₄ [2, 20, 23–26]. Because polyunsaturated n-3 and n-6 FA compete for insertion into cellular lipids and for enzymes involved in their metabolism [15, 26] the dietary total n-6:total n-3 (tot(n-6):tot(n-3)) ratio rather than absolute amounts of n-6 and n-3 FA have typically been used in studies investigating altered ARA metabolism and eicosanoid synthesis [27–29]. However, it is unlikely that diets rich in plant derived 18-carbon n-3 FA, compared to 20/22-carbon n-3 FA derived from marine

sources, elicit the same anti-inflammatory effects when fed at the same tot(n-6):tot(n-3) ratio. The reason for this is the known limited conversion of 18-carbon n-3 FA precursors to the longer chain derivatives [30, 31, reviewed in 32].

Several studies have examined the effects of fish oil, linseed oil, or fish oil/linseed oil combinations on neutrophil composition and cell functions in laboratory animals and humans [22, 23, 31–36]. Some studies have reported such effects in canine species [37–39]. In addition, one recent work reported the effect of diets containing fish oil on lymphocyte proliferation [40] while another study found that the amount of dietary n-3 fatty acid affected plasma fatty acid profiles of normal dogs independent of the n-6:n-3 FA ratio [41]. However, no investigations to date have examined the separate effects of 18- versus 20/22-carbon dietary n-3 FA on plasma phospholipids, neutrophil fatty acid composition, and cellular functions in canine species when fed at the same n-6:n-3 FA ratios. The present study is the first to address this question.

Materials and Methods

Materials

All chemicals were reagent grade or better and purchased from Sigma Chemical Industries unless otherwise noted.

Experimental Diets

A basal diet was produced by Ralston-Purina Co. (Table 1) and designed to be supplemented with one of the following oils; safflower oil (SFO), beef tallow (BTO), linseed oil (LSO), or menhaden fish oil (MHO) (Table 2). The safflower oil and beef tallow were provided by Ralston-Purina Co (now Nestlé Purina). Cargill Inc. and Zapata Protein (now Omega-Protein, Inc.) supplied the linseed oil and Menhaden fish oil, respectively. Using each of these oil sources, four supplemented diets were prepared daily at the time of feeding containing varying n-6:n-3 FA ratios: The SFO and the BTO supplemented diets had n-6:n-3 of ~100:1 and 9.7:1, respectively and the LSO and MHO diets, had nearly identical n-6:n-3 of 0.38:1 and 0.34:1, respectively. Fatty acid composition of the oil supplemented diets, n-6:n-3, and percentage energy from n-6 and n-3 FA, are summarized (Tables 3 and 4). In addition, total cholesterol contents of the single lot oils were determined and cholesterol concentrations of each oil were equilibrated to that present in the menhaden oil. To inhibit oxidation of the oils the α - and γ -tocopherol contents of the oils were also determined and α - and γ -tocopherols and TBHQ were added to all oils to achieve final concentrations of 1, 1,

Table 1 Composition of the basal diet

| Component | Amount (g/kg) |
|--------------------------------------|---------------|
| Rice, #4 | 420.0 |
| SUPRO (Protein Intl., St. Louis, MO) | 54.6 |
| Soybean meal | 391.2 |
| Meat and bone meal | 79.9 |
| NaCl | 10.4 |
| Palatability coating | 22.6 |
| Vitamin premix | 9.32 |
| Phosphorus dicalcium | 3.87 |
| L-Lysine | 3.00 |
| Mineral mix | 3.46 |
| Choline chloride (70%) | 1.39 |
| Flavor premix | 0.12 |
| Vitamin E (50%) | 0.15 |

The basal diet was a reduced-fat, complete and balanced formula designed to be supplemented with dietary oils at a rate of 18 g/100 g diet. It was prepared by Ralston Purina Co. (presently Nestle-Purina PetCare), St. Louis, MO, USA. The diet ingredients, by weight, included #4 rice, 42.0%; dehulled soybean meal, 39.1%; meat and bone meal, 8.0%; Supro 620[®] protein, 5.5%; flavor coating, 2.3%; sodium chloride, 1.0%; vitamin premix, 0.9%; dicalcium phosphate, 0.4%; choline chloride (70%), 0.15%; vitamin E (50%), 0.02%; and flavor premix, 0.01%. The vitamin premix, contained 146.32 g/kg nicotinic acid, 10.35 g/kg vitamin A acetate, 90 g/kg DL- α -tocopherol acetate, 84 mg/kg cholecalciferol, 52 g/kg thiamine mononitrate, 51.06 g/kg calcium D-pantothenate, 24.4 g/kg riboflavin, 14.52 g/kg pyridoxine hydrochloride, 6 g/kg folic acid, 508 mg/kg menadione sodium bisulfite, 93 mg/kg vitamin B-12, and 36.8 mg/kg biotin. The mineral mix contained 65 g/kg zinc as zinc sulfate, 39 g/kg iron as ferrous sulfate, 18.25 g/kg manganese as manganese sulfate, 3.2 g/kg copper as copper sulfate 655 mg/kg iodine as calcium iodate, and 50 mg/kg selenium as selenium selenite. The remaining 13.3% was provided by various dietary oils which provided the desired fatty acid profiles. Finally, 18 g of beef tallow, safflower oil, linseed oil, or Menhaden fish oil were supplemented/100 g of basal diet at the time of feeding to produce the desired final total fat and n6:n3 fatty acid ratios as described in the text and Table 4

Table 2 Experimental diet nutrient profiles

| Nutrient | Basal diet g/kg (as-is basis) | Basal diet + supplement ^a (as-is basis) |
|-----------------------|-------------------------------|--|
| Crude protein | 364 | 309 |
| Crude fat | 74 | 215 |
| Nitrogen-free extract | 548 | 465 |
| Ash | 14 | 11 |
| Energy (kJ/g) | 16 | 19 |

Values are means of duplicate determinations. Energy is calculated based on macronutrient analyses and modified Atwater factors of 14.6, 14.6, 35.6 kJ/g for protein, nitrogen-free extract, and fat respectively

^a 18 g of either beef tallow, safflower oil, linseed oil, or Menhaden fish oil was supplemented/100 g of basal diet at the time of feeding to produce the desired final total fat and n6:n3 fatty acid ratio as described in the text and Table 4

Table 3 Fatty acid content of basal diets plus oil supplements

en% percent energy provided in the diet

and 0.2 g, respectively, per kg oil. Tocopherols and TBHQ were provided by Eastman Chemicals, Kingsport, Tennessee.

Experimental Design

Dogs were individually maintained in kennels according to the American Physiological Society Guidelines for Animal Research and protocols were approved by the Texas A&M University Animal Care and Use Committee. They ranged in bodyweight from 9 to 25.8 kg and in age from 1.5 to 7 years. The study population consisted of 12 hounds, 8 Beagles, and 20 mixed-breed dogs. Because gender effects on canine lipid metabolism are unknown, hounds and Beagles were blocked by breed and gender and randomly assigned to one of four treatment groups. The remaining 20 mixed-breed dogs were blocked by gender and randomly assigned to one of four treatment groups. The feeding trial consisted of four groups of ten dogs each in which the basal diet was supplemented with BTO, LSO, SFO, or MHO at 18 g oil per 100 g of diet and fed for 28 days. Amounts of diets fed were determined based on metabolic body weight of individual dogs. Dogs were weighed weekly and the amount of feed offered adjusted if needed to ensure that weight was maintained. All dogs were healthy and clinically normal based on complete blood counts, serum biochemistry profiles, and serum concentrations of T₃ and T₄ prior to entering the study.

Blood Collection, Plasma Preparation and Neutrophil Isolation

Venous blood samples (30 mL) were collected prior to daily feeding at 9 a.m into tubes containing heparinized saline. Plasma was separated by low speed centrifugation at 150×*g* for 5 min. Neutrophil isolation was performed according to Markert et al. [42]. Purity of neutrophils was >95% and cell viability, as determined by trypan blue exclusion, was >95%. Cell concentrations were determined microscopically using a hemocytometer.

Lipid Extraction and Fatty Acid Analysis

Plasma and neutrophil total lipids were extracted using chloroform:methanol (2:1, v/v) via a modified Folch procedure [43, 46]. Total plasma phospholipids (PL) were separated via thin layer chromatography, fatty acid methyl esters prepared using the plasma PL and neutrophil lipid extracts, and fatty acid profiles were determined via capillary gas chromatography [45, 47].

Superoxide Production

The determination of superoxide production was performed according to Markert et al. [42]. The release of the superoxide anion (O₂^{•−}) was measured by the SOD inhibited reduction of ferricytochrome c.

Leukotriene Extraction and Quantitation

Stimulation of neutrophil leukotriene production and fractionation were performed according to Ziboh and Fletcher [33]. Leukotrienes B₄ and B₅ were separated based on retention times of authentic standards (Cayman Chemicals, Ann Arbor, MI, USA) and collected. Samples were stored under N₂ gas at −80 °C until further analysis.

Quantitation of LTB₄ and LTB₅ was performed using an ELISA kit (Amersham Life Science Inc., Arlington Hts., IL, USA) and microplate reader and according to the manufacturer's instructions.

Statistics

Data were analyzed using statistix[®] for windows (Tallahassee, FL, USA). Data are expressed as means ± SD. Data were subjected to one way ANOVA with differences considered significant at *P* < 0.05 or as otherwise noted. Where appropriate, multiple comparisons were conducted by Scheffe's tests. An experiment-wide type I error of 0.05 was maintained. All data were found to follow a normal distribution at *P* < 0.05 using the Shapiro–Wilk test. If variances were non-homogeneous log₁₀ transformed data were analyzed.

Results

Dogs and Diets

The diets were palatable and readily consumed. All dogs remained healthy and body weights were maintained without significant weight gain or loss throughout the study (data not shown).

Plasma Phospholipid FA

Plasma phospholipid FA in the LSO and MHO groups were significantly enriched in EPA with mean values of 4.42 and 10.17 mol% respectively and DPA n-3 at 2.62 and 4.19 mol% respectively. By comparison, neither the BTO nor SFO groups exceeded mean values of 1.44 mol% for these two long chain n-3 FA (*P* < 0.05) (Table 5). The MHO group was also significantly enriched in DHA (6.71 mol%) compared with ≤0.38 mol% in any of the other groups (*P* < 0.05). It is noteworthy that no accumulation of DHA occurred with the LSO diet. For that matter, LSO group mean DHA values were similar to the SFO and BTO groups with no group exceeding 0.38 mol%. The LSO group was the only group to have increased amounts of ALA (2.44 vs. <0.12 g/100 in each of the other groups (*P* < 0.05). Significantly less ARA was observed in the MHO group (i.e. mean value of 10.26 mol% compared

to the other three groups ($P < 0.05$). The SFO and BTO groups had higher, yet similar, amounts of ARA with mean values of 18.10 and 18.61 mol% respectively while the LSO group mean was found to be 14.57 mol%. Dogs fed the SFO diet had the highest amount of LNA at 21.72 mol%; the BTO and LSO groups had intermediate and similar values of 15.92 and 16.90 mol% respectively; while the MHO group was found to have the least LNA with only 5.84 mol% of this FA (all $P < 0.05$). Palmitic acid in the LSO group was significantly lower than the other three groups (9.39 vs. ≥ 14.04 mol%) and stearic acid was statistically lower in the BTO group, especially compared with the LSO and MHO diets even though the BTO diet was relatively enriched in this fatty acid compared with the other diets ($P < 0.05$). Oleic acid was significantly increased by approximately 2-fold in the BTO group compared with the other three groups ($P < 0.05$).

Neutrophil Total Lipid Fatty Acid Composition

Significant enrichment of long chain n-3 FA was found in both LSO and MHO groups compared to the BTO and SFO groups (Table 6). The neutrophils of dogs in the MHO group were markedly higher in both EPA and DHA with mean values of 4.21 and 1.79 mol% respectively compared with the BTO and SFO groups where both of these fatty acids were undetected. In the LSO group, a significantly lower mean value of 1.14 mol% for EPA was observed compared to 4.21 mol% in the MHO group ($P < 0.05$). Only small amounts of ALA (mean value, 0.86 mol%) were

seen compared to the other three groups where ALA was undetected. However, no DHA was detected in the LSO group and this was also the case with both the BTO and SFO groups (Table 6). With regard to the n-6 FA, ARA was lower in the LSO group (mean value of 11.96 mol%) compared with 15.00 and 15.64 mol% in the BTO and SFO groups respectively ($P < 0.05$). However, this effect was more pronounced in the MHO group at 9.24 g ARA/100 g ($P < 0.05$). Membrane lipids from SFO were significantly enriched in n-6 fatty acids as follows: an approximate 2-fold increase in 18:2n-6 and 20:3n-6 and a ≥ 5 -fold increase in 20:2n-6. Amounts of 22:4n-6 were also highest with the SFO diet at 3.47 mol% compared with 2.27 with the BTO diet and < 0.5 mol% in both the LSO and MHO groups. Modest, but statistically significant, increases in saturated fatty acids were observed in the BTO group including 15:0, 17:0, and 24:0 compared to all other groups. All groups were also found to have considerable amounts of 24:1n-9 with the MHO group showing the largest increase in this FA (8.21 vs. 5.62, 5.73, and 6.63 mol% in BTO, SFO, and LSO groups respectively ($P < 0.05$)).

Superoxide Production

Supplementation with n-3 FA resulted in significantly less ex vivo superoxide production, presented as $\text{nmol} \times (10 \text{ min})^{-1} \times (10^6 \text{ cells})^{-1} \pm \text{SD}$, in MHO and LSO groups (21.0 ± 2.1 and 21.1 ± 1.2 SD respectively) compared to the BTO and SFO groups (24.4 ± 3.6 and 23.5 ± 4.8 SD respectively) ($P < 0.05$) (Fig. 1).

Table 6 Neutrophil phospholipid fatty acid profiles of dogs fed the diets

Values given as means ± SD; nd not detected; detection limit 1 ng; n = 10 dogs/group. Values within rows with different superscripts are significantly different, $P < 0.05$

Fig. 1 Superoxide production of phorbol myristic acetate stimulated neutrophils isolated from dogs fed the experimental diets for 28 days, $n = 10$ dogs/group. The release of the superoxide anion (O_2^-) was measured by the SOD inhibited reduction of ferricytochrome c according to the method as described by Markret et al. [42]. Values are means ± SD. Means without a common letter differ, $P < 0.05$

Leukotriene Production

Neutrophil LTB_4 production, after ex vivo stimulation, expressed as $ng \times (5 \times 10^6 \text{ cells})^{-1} \pm SD$, was lowest in the MHO group at 16.6 ± 3.9 compared to the other groups with the SFO group producing the highest amount,

30.3 ± 7.2 , followed by 26.3 ± 7.2 for BTO and 20.8 ± 7.0 for LSO groups ($P < 0.001$) (Fig. 2a and 2b). By contrast, production of LTB_5 was markedly increased in the MHO and LSO groups at 7.52 ± 2.44 SD and 3.52 ± 2.48 respectively compared to 0.88 ± 0.44 with the BTO diet and 0.69 ± 0.17 in the SFO group ($P < 0.001$). It should be noted that the MHO group LTB_5 increase was more than that observed for the LSO group ($P < 0.001$).

Discussion

Significant differences due to diet were observed in this study for plasma phospholipid and neutrophil total lipid fatty acid compositions, superoxide production, and leukotriene production. Dietary supplementation with linseed or Menhaden fish oil resulted in the enrichment of long chain n-3 FA, consistent with reports in other species [4, 15, 32, 44, 45]. ALA was converted to EPA and further elongated to DPA n-3 but was not converted to DHA. This confirms earlier reports of limited metabolism of n-3 PUFA in dogs [32, 46, 47] and may reflect the inability of adult canine liver to convert DPA to DHA [47]. The modest

Fig. 2 Leukotriene production of calcium ionophore A23187 stimulated neutrophils isolated from dogs fed the experimental diets for 28 days, $n = 10$ dogs/group. Values are means \pm SD. Stimulation of neutrophil leukotriene production and fractionation were performed according to Ziboh and Fletcher [33]. LTB₄ and LTB₅ were separated by HPLC based on retention times of authentic standards (Cayman Chemicals, Ann Arbor, MI) and collected. Samples were stored under N₂ gas at -80°C until analysis. Quantitation of LTB₄ and LTB₅ was performed via ELISA (Amersham Life Science Inc., Arlington Hts., IL, USA) and microplate reader. **a** Leukotriene B₅; **b** Leukotriene B₄. Means without a common letter differ, $P < 0.05$

amounts of ALA seen in plasma PL and neutrophil lipids when linseed oil was fed may be the result of either low acyl specificity for esterification or increased utilization. Nonetheless, this finding suggests that only limited amounts of ALA would be available as substrate for further desaturation and elongation. Preferential oxidation of this particular fatty acid exists which may be due to differences in substrate specificity of carnitine palmitoyltransferase I and increased amounts of mRNA for hepatic fatty acyl oxidative enzymes [48]. Such findings have been previously reported in rats and humans where overall conversion of ALA to DHA is limited (reviewed in [32]).

As expected, no enrichment of n-3 FA was observed in the BTO and SFO groups. Incorporation of long chain n-3 FA into both plasma PL and neutrophils was significantly greater in the MHO group compared to the LSO group. This effect was seen even though both groups contained

nearly identical n-6:n-3 FA ratios (0.34 vs. 0.38, respectively). Given this observation, it is noteworthy that the LSO diet provided twice as much total n-3 FA. Thus, when diets containing similar (n6):(n3) FA ratios are fed, those containing menhaden fish oil as n-3 FA source more efficiently result in increased long chain n-3 fatty acid accumulation into both plasma and neutrophils. An earlier study by Hall et al. [41] investigated a dietary fish oil dosage effect at constant tot(n-6):tot(n-3) ratio of 1:1 and similar ALA content, but with increasing amounts of fish oil EPA + DHA to geriatric, female Beagles for 12 week. It was found that the dose (and likely type) of n-3 FA was more important than the ratio to achieve maximal EPA and DHA enrichment. The dosage of EPA + DHA in the MHO group of the present study was approximately four times higher than that of the highest n-3 concentration used by Hall et al. and utilized younger dogs of mixed breed and gender. Also, although Hall et al. [41] fed for 12 weeks, we have previously shown that a plasma fatty acid metabolic steady state can be achieved after 4 weeks and remaining so for 12 weeks. An important difference, however, is that the present study compared 18-carbon n-3 FA (i.e. ALA) with 20/22-carbon n-3 FA at the same tot(n-6):tot(n-3) ratio whereas that of Hall et al. fed increasing amounts of 20/22-carbon n-3 at relatively constant ALA. In any case, the present findings are consistent with the earlier study regarding the lack of a contribution of dietary FA ratio to tissue enrichment compared to FA type and dose. It is of interest that relative amounts of 22 carbon highly unsaturated FA, whether n-3 or n-6 FA, were modestly increased and nearly constant among neutrophils of all dietary groups. Both SFO and BTO groups accumulated 22:4n-6 (2.27 and 3.47 mol%, respectively) while the MHO and LSO group had more DPA n-3 (2.09 and 2.55 mol%, respectively). In view of the high dietary polyunsaturated fatty acid concentrations fed each group, resultant chain elongation of the 20 carbon FA (ARA and EPA) appears to have occurred. The possibility exists that these 22 carbon acids may subsequently serve as potential reservoirs of 20 carbon eicosanoid precursors via retroconversion during periods of neutrophil membrane active remodeling. This hypothesis is supported by MacDonald et al. [49] who reported that neutrophil phospholipids undergo extensive turnover with respect to the fatty acyl moiety in their *sn*-2 position. Retroconversion of DHA to EPA at high doses is well documented [50, 51]. The accumulation of DPA found in plasma when n-3 FA are fed may thus represent a central fatty acyl metabolite that may be either retroconverted to EPA in cells such as leukocytes or forward converted to DHA when taken up by neurologic tissues [46, 52].

It is noteworthy that nearly identical incorporation of ARA in plasma PL and neutrophil total lipids occurred when either SFO or BTO diets were fed even though the

SFO diet contained nine times more LNA than the BTO diet. To some extent, increased ARA synthesis and tissue enrichment would be expected as more LNA is fed. However, such an effect was not observed suggesting that other mechanisms may exist that define threshold saturation for AA accumulation even at relatively modest amounts of dietary LNA. Indeed studies by Lands et al. and Bauer et al. [53, 54] have observed such tissue and plasma saturation of ARA as a function of dietary LNA in rats, humans, and dogs. While the physiological significance of this finding is presently unknown, limiting the cellular enrichment of ARA in the presence of high dietary LNA may help prevent the accumulation of deleterious amounts of substrate for eicosanoid synthesis. By contrast, when dietary n-3 FA especially from fish oil are added, the ARA content of neutrophils and plasma was attenuated below this putative saturation level.

It is also of interest that increased amounts of 24:1n-9 were found in neutrophils in all groups and especially in dogs fed the MHO diet. A likely explanation for this observation is active sequential chain elongation of 18:1n-9 occurring in this cell type. By contrast, while 18:1n-9 was increased in plasma PL in the BTO group, 24:1n-9 was not. Thus, this finding appeared to be unique to neutrophils in this study. It should be noted that dietary 18:1n-9 was highest in the BTO diet yet it also contained increased amounts of 16:0 and 18:0 compared to the other diets fed. Because dietary beef tallow has previously been shown in pigs to increase steroyl-CoA desaturase activities [55], a similar effect may have occurred in the BTO diet-fed dogs in the present study leading to desaturation of 18:0.

Enrichment of neutrophil membranes with long chain n-3 FA resulted in a reduction of pro-inflammatory mediators, superoxide anion, and LTB₄. The LSO and MHO groups had approximately a 20% reduction in superoxide production compared to the BTO and SFO groups. This observation is consistent with other reports of the effects of n-3 polyunsaturated fatty acid supplementation on neutrophil superoxide production [56, 57]. This reduction can be attributed to decreased AA because this fatty acid is required for the activation of NADPH oxidase [58]. Abramson et al. reported that ARA, in part, regulates superoxide production by increasing binding of GTP to its regulatory G-protein [59]. Furthermore, these authors concluded that ARA, through its capacity to activate protein kinase C, stimulates NADPH oxidase and activates plasma membrane G-proteins [59].

Because leukotrienes synthesized by neutrophils have a prominent role in the inflammatory response, altering their production by diet is one way in which to modulate the inflammatory response. In the present study it was found that leukotriene production was significantly affected by dietary fat type. Supplementation with linseed oil or

Menhaden fish oil resulted in decreased LTB₄ and increased LTB₅ compared to the SFO and BTO groups. As with long chain n-3 fatty acid enrichment, the decrease in LTB₄ and increase in LTB₅ was significantly greater in the MHO group compared to all other groups. The quantities of leukotrienes produced from isolated canine neutrophils in our study [$\text{ng} \times (5 \times 10^6 \text{ cells})^{-1}$] are consistent with those reported in rats, humans, and one report in dogs [36–38]. By contrast another study investigating the effects of n-3 diets on canine neutrophil leukotriene production reported only 30–100 pg of LTB₄ per 5×10^6 cells [39]. Differences in methodologies used may explain these differences.

The formulation of a low fat basal diet supplemented with either Menhaden fish oil or linseed oil allowed for the creation of diets with nearly identical n-6:n-3 FA ratios. However, these diets differed considerably in their 18-carbon versus 20/22-carbon n-3 FA content. The diets were formulated using ingredients and oils that are commonly used in the manufacture of pet food and could be used for the therapeutic treatment of chronic inflammatory diseases. Given the results of the present study, long chain n-3 FA from marine sources are more efficiently incorporated into neutrophil membranes than diets containing ALA when fed at the same n-6:n-3 ratio. The beneficial effects of n-3 FA due to their competition with n-6 polyunsaturated FA for cellular membrane incorporation has lead to the suggestion that the dietary n-6:n-3 ratio be used as a dietary index to modulate cell composition and cellular function [39, 60]. The findings reported here do not support the use of the n-6:n-3 ratio for this purpose. Several workshops have reviewed the health aspects of n-3 PUFA and have concluded that the use of an overall n-6:n-3 ratio is inappropriate [61–65]. Our findings are consistent with this recommendation. Thus, both the type and amount of n-3 FA, but not the n-6:n-3 ratio of diets contribute to alterations in membrane n-3 highly unsaturated fatty acid composition and subsequent changes in cell function.

Abstract Furan fatty acids (furan-FA) can be formed by auto-oxidation of conjugated linoleic acids (CLA) and may therefore be ingested when CLA-containing foodstuff is consumed. Due to the presence of a furan ring structure, furan-FA may have toxic properties, however, these substances are toxicologically not well characterized so far. Here we show that 9,11-furan-FA, the oxidation product of the major CLA isomer *cis*-9,*trans*-11-CLA (c9,t11-CLA), is not toxic to human intestinal Caco-2 cells up to a level of 100 μ M. Oil-Red-O staining indicated that 9,11-furan-FA as well as c9,t11-CLA and linoleic acid are taken up by the cells and stored in the form of triglycerides in lipid droplets. Chemical analysis of total cellular lipids revealed that 9,11-furan-FA is partially elongated probably by the enzymatic activity of cellular fatty acid elongases whereas c9,t11-CLA is partially converted to other isomers such as c9,c11-CLA or t9,t11-CLA. In the case of 9,11-furan-FA, there is no indication for any modification or activation of the furan ring system. From these results, we conclude that 9,11-furan-FA has no properties of toxicological relevance at least for Caco-2 cells which serve as a model for enterocytes of the human small intestine.

LNA Linoleic acid

Introduction

Conjugated linoleic acids (CLA) are polyunsaturated fatty acids that are present in many natural food sources. The term CLA describes a group of positional and geometric isomers of linoleic acid (LNA) derivatives having conjugated double bonds. The conversion from LNA to CLA occurs in the rumen of ruminants by bacterial metabolic activity [1]. Therefore, the main source for CLA taken up by humans is foodstuff derived from ruminants such as milk or meat.

Over the last decade the interest in CLA has arisen because various publications suggested that CLA may have many different positive physiological effects. In vitro, CLA inhibited the growth of various human cancer cells such as colon [2], mammary [3] and prostate [4] cancer cell lines. This anticarcinogenic effect was also determined in vivo where supplementation with CLA resulted in a decreased size of chemically or genetically induced tumors in experimental animals (reviewed in [5]). In addition, CLA seem to prevent atherosclerosis [6, 7, 8] and may improve the immune system [9, 10]. On the other hand, some publications describe negative effects of CLA supplementation, i.e. the induction of non-alcoholic hepatic steatosis in mice [11], the decrease of insulin sensitivity in human subgroups [12], or the increase in proinflammatory cytokines in human adipocytes in vitro [13]. In the past decade,

attention has predominantly been drawn on a potential anti-adipogenic role of CLA as these substances are proposed to have a positive effect on body composition by decreasing body fat mass and increasing lean muscle mass (reviewed in [14]). In the case of body composition, the CLA isomer *trans*-10, *cis*-12-CLA (t10,c12-CLA) seems to be responsible for reduction of body fat [15]. On the other hand, it was proposed that the isomer *cis*-9,*trans*-11-CLA (c9,t11-CLA) was more effective concerning the inhibition of tumor development [16]. Milk and meat of ruminant animals contain 28 different CLA isomers, and the most abundant isomer in food is the c9,t11-CLA isomer, which represents up to 80% of total CLA.

Due to the reported positive effects of CLA on body mass composition and despite controversial data and some observed negative effects of CLA, these compounds are already available in numerous formulas of food supplements and are currently being discussed for their use as food additives. CLA are classified as “novel foods” in Europe and a premarketing risk assessment of CLA is a mandatory part of the novel food approval. For a reliable risk assessment of CLA it is necessary to focus additionally on the oxidation products of CLA, the furan fatty acids (furan-FA).

Furan-FA are comprised of a furan ring flanked by one alkyl and one carboxyl side chain in the α -positions of the furan ring. It has been shown that in the presence of air CLA can react with dioxygen to form furan-FA [17] (Fig. 1). Therefore, if CLA-containing food supplements are consumed, significant amounts of furan-FA may be taken up by the consumer in parallel. Up to now, hardly anything is known about the toxicological potential of furan-FA. The presence of the aromatic furan ring system in furan-FA gives rise to the assumption that these compounds may have hazard potential since furan itself and numerous furan derivatives have shown themselves to have properties of toxicological relevance (reviewed in [18]). The aim of our study was to investigate the absorption and the metabolism of furan-FA by human intestinal cells. The well-established Caco-2 system was employed for this

study as it is a widely used in vitro model for the intestinal barrier. Differentiated Caco-2 cells are known to form a tight cellular monolayer with morphological and biochemical properties very similar to those of enterocytes of the small intestine [19, 20]. In addition, the Caco-2 system is a well-established model for intestinal lipid metabolism [21].

Experimental Materials and Methods

Chemicals and Fatty Acids

All chemicals were purchased from Merck (Darmstadt, Germany) or Sigma-Aldrich (Taufkirchen, Germany) in the highest available purity. The CLA isomers *cis*-9,*trans*-11-octadecadienoic acid (c9,t11-CLA) and the furan fatty acid 9,12-epoxy-9,11-octadecadienoic acid (9,11-furan-FA) were obtained from Biotrend (Köln, Germany). LNA was purchased from Sigma-Aldrich (Taufkirchen, Germany). All fatty acids were dissolved in DMSO to get 0.1 M stock solutions.

Cell Culture and Treatment with Fatty Acids

Cells were obtained from the European Collection of Cell Culture (ECACC). Culture media and supplements were obtained from PAA Laboratories GmbH (Pasching, Austria). The human adenocarcinoma cell line Caco-2 (ECACC No. 860 10 202) was cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum, 100 U/ml penicillin and 100 μ g/ml streptomycin in a humidified atmosphere of 5% CO₂ at 37 °C. Cells were passaged every 3–4 days by treatment with 0.1% trypsin and 0.04% EDTA and then plated at a density of $1.3\text{--}2 \times 10^4$ cells/cm².

For experimentally treatment with fatty acids, cells were allowed to attach by cultivating overnight in medium containing 10% FCS and were then incubated in serum-free medium supplemented with 1% insulin–transferrin–selenium

Fig. 1 Structures of LNA, c9,t11-CLA and 9,11-furan-FA

(ITS, Invitrogen, Karlsruhe, Germany) and 0.1 mg/ml fatty acid-free BSA (Sigma-Aldrich, Taufkirchen, Germany) with various concentrations of the respective fatty acid with a molar ratio of fatty acid to BSA of 4:1.

Oil-Red-O Staining

Caco-2 cells were cultivated on cover slips in 24-well plates with 40,000 cells/well. After 48 h of treatment with fatty acids staining with Oil-Red-O (Sigma-Aldrich, Taufkirchen, Germany) was performed. Cells were washed with Phosphate Buffered Saline (PBS) and fixed with 3.7% formaldehyde for 1 h. 0.3% Oil-Red-O in isopropanol was then added directly to the fixed cells and incubated for 1 h. The microscopy studies were performed with a Axio Observer microscope equipped with a digital camera (Zeiss, Jena, Germany).

Cell Viability Assay

Cells were plated in 96-well plates with 7,500 cells/well for Caco-2 cells in 100 μ l medium. After 2 days of treatment with fatty acids cell viability was estimated by the Cell-Titer-Blue[®] Cell Viability Assay (CTB Assay) (Promega, Madison, WI). Assays were performed by adding 20 μ l of a 1:4 dilution of the CTB reagent in phosphate-buffered saline (PBS) directly to the cells cultured in 100 μ l medium, incubating for 1 h at 37 °C and then measuring fluorescence at 540/590 nm with a Mithras Multimode Reader LB 940 (Berthold Technologies, Vienna, Austria). Values are expressed as percentages of the negative control which was exposed to medium containing 0.1% DMSO and which was taken as 100%. As a positive control for cytotoxicity: cells were exposed to medium containing 0.05% Triton X-100.

Extraction of Total Cellular Lipids and Fatty Acid Derivatization

Caco-2 cells were incubated with 100 μ M of LNA, c9,t11-CLA or 9,11-furan-FA for 48 h. Cells were washed twice with PBS, and after treatment with trypsin/EDTA cells were transferred to reaction tubes. 20 μ l of a 10 mM solution of butylated hydroxytoluene (BHT) in acetonitrile was applied to the cell suspensions to protect the lipids from oxidative damage. Subsequently, cells were lyophilized to completely remove the water and total lipids were extracted twice from the dried cell pellet with 0.7 ml of a 2:1 (v/v) chloroform:methanol mixture. 150 μ l of a 20% solution of BF₃ in methanol was applied to the lipid extracts, and transmethylation was conducted for 10 min at 70 °C. Methylated fatty acids were extracted with 1 ml of hexane, dried over anhydrous sodium sulfate, concentrated in vacuo and finally dissolved in 200 μ l hexane.

GC/MS Analysis

GC/MS analysis was conducted with an Agilent 7890A gas chromatograph coupled to an Agilent MSD 5975C mass spectrometer. Methylated fatty acids were separated with an Rt-2560 column (100 m \times 0.25 mm \times 0.2 μ m; Restek, Bad Homburg, Germany) by using helium as the carrier gas at a flow rate of 1 ml/min. 2 μ l of each samples was applied to the cold injection system (splitless mode, 15 °C) by taking advantage of an MP5 autosampler (Gerstel, Mülheim, Germany). The oven program was as follows: 6 min at 35 °C, ramp to 165 °C at 65 °C/min, 2 min at 165 °C, 1 min at 180 °C, 0.5 min at 190 °C, 1 min at 210 °C. Methylated fatty acids were identified by comparison of retention times with authentic standards and by the fragmentation pattern in the mass spectra. The artificial methylated fatty acid C19:0 was used as the internal standard. Mass spectra were recorded both in the SCAN modus and in the SIM modus to increase sensitivity. The quantitation limit of the method was 0.25 ng/ μ l for each individual fatty acid.

Results

Viability of Caco-2 Cells

In this study we focused on c9,t11-CLA, the major CLA isomer in foodstuff, and on its oxidation product 9,11-furan-FA. Moreover, the metabolic precursor of c9,t11-CLA, LNA, was included in the study.

To analyse potential cytotoxic effects of LNA, c9,t11-CLA and 9,11-furan-FA, Caco-2 cells were incubated with various concentrations of these substances. Subsequently, cellular viability was tested by using the CTB assay. As shown in Fig. 2, incubation of the cells with up to 100 μ M of the respective substance did not affect cellular viability whereas cellular viability was decreased to a level of about 3% upon incubation of the cells with medium containing 0.05% Triton X-100 which was used as positive control. Thus, none of the substances tested in this study displayed cytotoxic potential to Caco-2 cells up to a level of 100 μ M.

Fatty Acid Absorption by Caco-2 Cells

Caco-2 cells have the capacity to absorb free fatty acids and to incorporate them into triglycerides for storage in lipid droplets [22]. To analyze whether the enzymatic machinery of Caco-2 accepts furan-FA as a fatty acid-type substrate at all, lipid droplet staining was conducted with LNA-, CLA- and furan-FA-treated cells in order to visualize cellular absorption of the respective fatty acid. Caco-2 cells were incubated either with LNA, c9,t11-CLA, or

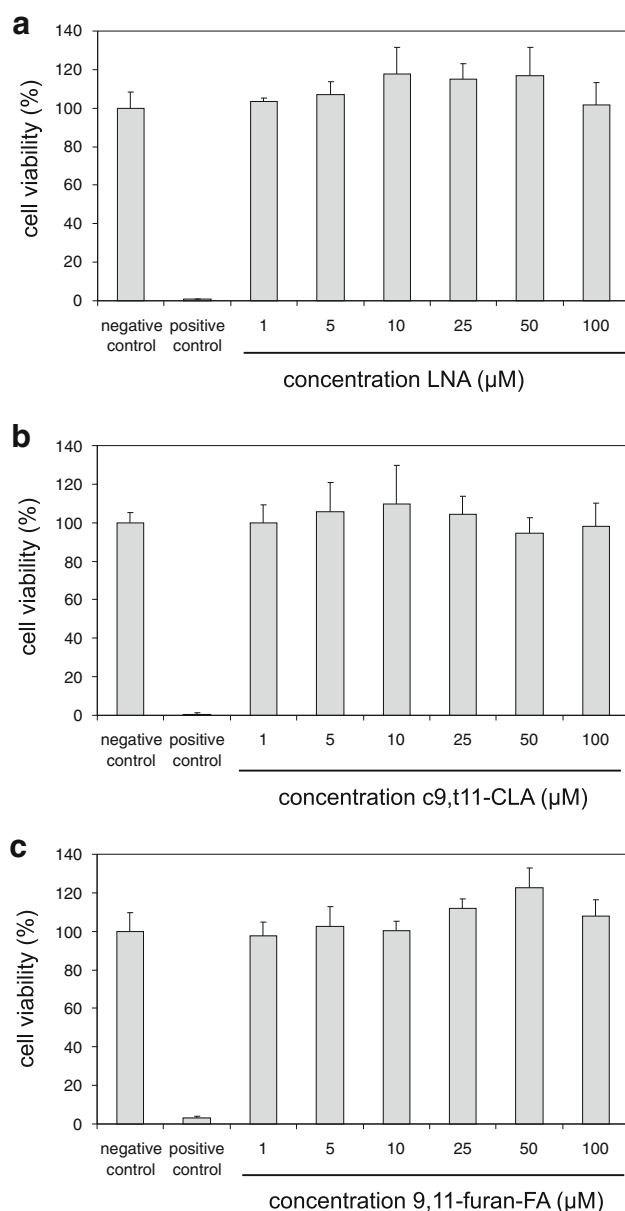

Fig. 2 Viability of Caco-2 cells. Cells were treated with various concentrations of (a) LNA, (b) c9,t11-CLA, and (c) 9,11-furan-FA for 48 h. Cellular viability was determined using the CTB assay and expressed as percentages of negative control which was exposed to medium containing 0.1% DMSO (set as 100%). Data are expressed as the means \pm SD; $n = 5$

9,11-furan-FA, and Oil-Red-O-staining of the cells was conducted after 48 h of incubation in order to visualize the formation of intracellular lipid droplets. In control cells, intracellular red stain was rarely visible, whereas numerous small lipid droplets were stained in cells that had been incubated with 10 μ M LNA, c9,t11-CLA or 9,11-furan-FA (Fig. 3). Incubation of the cells with 100 μ M of the respective free fatty acid yielded cells full of large lipid droplets (Fig. 3). Therefore, Fig. 3 clearly illustrates that

lipid droplet formation in Caco-2 cells increased with increasing concentrations of free fatty acid offered to the cells, independent of the type of fatty acid. Moreover, microscopic inspection of numerous cells indicated that Caco-2 cells treated with 100 μ M of the respective fatty acid tend to be enlarged in size due to lipid droplet formation. In these experiments there was no observation of specific alterations in cell morphology such as shrinking of the cells that might point to toxic effects induced by fatty acid treatment. Thus, in sum, Caco-2 cells seem to absorb 9,11-furan-FA and to store it as triglycerides in lipid droplets as they do with LNA and c9,t11-CLA.

Analysis of Fatty Acid Composition

To follow the fate of the fatty acids taken up by the cells, a GC/MS method was employed to analyze cellular fatty acid composition in more detail. For this purpose, total cellular lipids were extracted from Caco-2 cells that had been incubated with 100 μ M of LNA, c9,t11-CLA, or 9,11-furan-FA, respectively. After lipid hydrolysis and fatty acid derivatization, the resulting mixture of fatty acid methyl esters was separated by gas chromatography. Fatty acid identification was achieved by subsequent MS analysis of individual peaks. The relative amount of the respective fatty acid was calculated from the peak area in relation to the peak area of the internal standard. The results of this analysis are summarized in Table 1.

Incubation of the cells with LNA resulted in an approximately four-fold increase in the relative intracellular content of LNA and in a concomitant relative decrease of the amount of the other fatty acids with two exceptions. Compared to the control cells, the relative amount of the well-known LNA-metabolite 20:4n-6 increased upon incubation of the cells with LNA. In addition, a small amount of t9,t11-CLA was detectable in the samples obtained from LNA-incubated cells.

In the case of c9,t11-CLA, an approx. 20-fold increase in the relative intracellular amount of this substance was observed. In addition, the relative amount of the CLA isomers c9,c11-CLA and t9,t11-CLA increased whereas the relative content of the remaining fatty acids decreased.

Incubation of the cells with 9,11-furan-FA yielded an approx. 20-fold increase in the relative intracellular amount of this compound and a simultaneous decrease of the relative content of all other fatty acids. There was, however, an additional peak in the gas chromatogram that was neither present in the chromatogram of the control cells nor in the chromatograms of the cells incubated with LNA or c9,t11-CLA. The peak area of the additional peak was at a level of about 10% compared to the area of the 9,11-furan-FA peak (data not shown). Comparison of the mass spectra of 9,11-furan-FA and of the unknown substance from the

Fig. 3 Oil-Red-O staining. Caco-2 cells were incubated with LNA, c9,t11-CLA, or 9,11-furan-FA for 48 h. Oil-Red-O staining was conducted as described in the methods section. Red staining is indicative of lipid droplets (color figure online)

Table 1 Incorporation of LNA, c9,t11-CLA, and 9,11-furan-FA, respectively, into the total cellular lipids of Caco-2 cells after 48 h of incubation

| Fatty acid (wt. %) | Control | LNA | c9,t11-CLA | 9,11-furan-FA |
|--------------------|--------------|--------------|--------------|---------------|
| 16:0 | 6.10 ± 2.72 | 2.56 ± 1.22 | 0.92 ± 0.30 | 0.22 ± 0.06 |

nd not detected

additional peak revealed that this substance must be a metabolite of 9,11-furan-FA (Fig. 4). Two major peaks with m/z 165 and m/z 179 in the mass spectrum of 9,11-furan-FA (Fig. 4a) can be explained by the cleavage of the compound between carbon atoms C7 and C8, and between C6 and C7, respectively. Additional β -cleavage of these products between C13 and C14 results in masses of m/z 95 and m/z 107, respectively, additional major peaks in spectrum of Fig. 4a. Since these four masses are also present in the mass spectrum of the unknown metabolite (Fig. 4b), it can be concluded that this metabolite is a derivative of 9,11-furan-FA. Moreover, preservation of

these four masses indicates that the furan ring is still intact in the metabolite and that it was not altered upon cellular metabolic activity.

Since the molecule peak of 9,11-furan-FA with m/z 308 (Fig. 4a) was shifted to a mass of m/z 336 (Fig. 4b), the mass of the metabolite has increased by 28 atomic units (a.u.). In addition, the series of m/z 237, m/z 251, m/z 265 and m/z 277 of Fig. 4a has shifted by 28 a.u. to m/z 265, m/z 279, m/z 293 and m/z 305, respectively, in Fig. 4b. The increase of 28 a.u. can be explained by the addition of two methylene groups to 9,11-furan-FA, resulting in the C20-derivative as depicted in the insert of Fig. 4b.

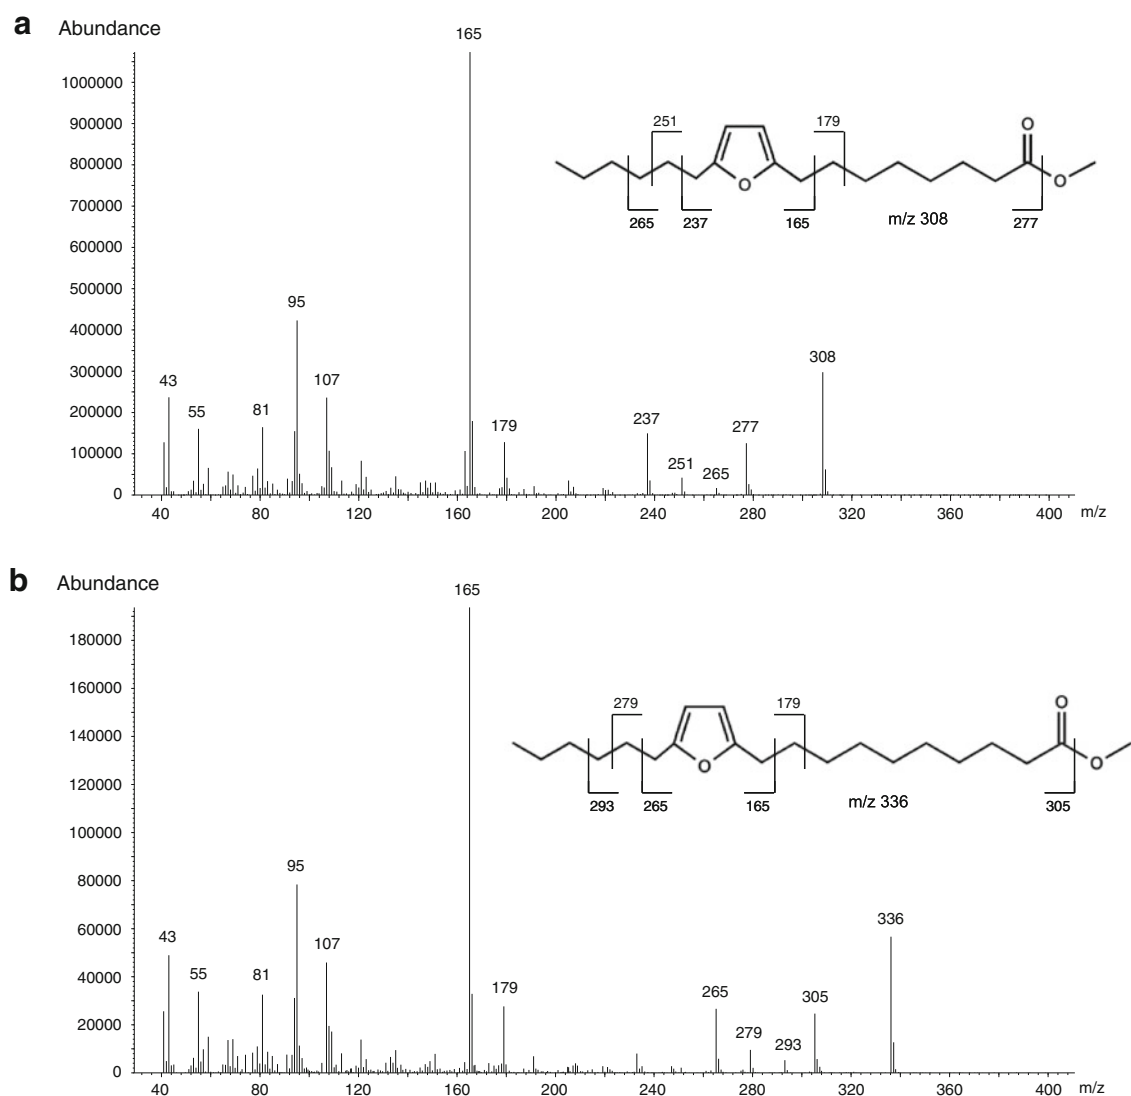

Fig. 4 Mass spectra of **(a)** 9,11-furan-FA and of **(b)** the metabolite that was formed upon incubation of Caco-2 cells with 9,11-furan-FA. The masses of the major cleavage products are assigned to the structures of the respective molecule

Discussion

In the past decades, CLA have been intensively investigated in numerous *in vivo* and *in vitro* studies. These substances are supposed to have various positive effects on human health. Therefore, CLA are already available as food supplements, and the risks and benefits of supplementation of foodstuff with CLA are currently under discussion. Surprisingly, the putative presence of furan-FA in CLA preparations plays no role in these discussions so far, although it was shown that furan-FA might arise from auto-oxidation of CLA in the presence of molecular oxygen [17]. From a toxicological point of view, furan-FA are of particular interest because furan-FA harbor a furan ring system, and furan and furan derivatives have been shown to

be toxic compounds (reviewed in [18, 23, 24]). In the liver, furan and furan derivatives are activated by CYP2E1 to form epoxides, and subsequently these epoxides are further converted to yield aldehydes in some cases [25–27]. Epoxides as well as aldehydes can directly react with lipids, proteins or DNA and are therefore toxic to cellular systems. Due to their reactivity to DNA, they are potent mutagens. Therefore, the toxicological characterization of furan-FA has to be conducted in parallel to the current risk and benefit assessment of CLA supplementation.

It is well-known that plants produce furan-FA as secondary metabolites. These furan-FA of plant origin carry methyl groups at one or both β -positions of the furan ring. If these compounds are ingested with food, the methyl groups are converted by liver metabolic activity to carboxylic acid

groups and the resulting urofuran acids are then excreted via the kidney (reviewed in [28]). In contrast to the plant furan-FA, the furan-FA analyzed in this study is an oxidation product of c9,t11-CLA and does not carry substituents at the β -positions of the furan ring. There are only few examples for non-substituted furan-FA in nature. A few non-substituted furan-FA have been isolated only from marine sponges so far, and preliminary in vitro studies revealed considerable cytotoxic potential of these isolates [29, 30]. The furan-FA analyzed in this study, however, showed no cytotoxic effect up to a concentration of 100 μ M.

The Caco-2 cell line used in this study serves as a model for human intestinal enterocytes. Caco-2 cells have been shown to be capable of lipid metabolism including triglyceride synthesis and lipid droplet formation. Moreover, these cells express numerous P450 enzymes and have the capacity to detoxify various compounds. Among others, the CYP2E1 enzyme has shown itself to be expressed by Caco-2 cells [31]. Therefore, the Caco-2 system was the ideal model to study uptake and metabolism of furan-FA by human intestinal cells, because triglyceride formation as well as β -oxidation and CYP-mediated activation of the furan ring could be examined by using this cell line. Our results indicate that furan-FA are taken up by the cells, esterified to triglycerides and stored in lipid droplets. At first glance, there seems to be no difference in the uptake and conversion of LNA, CLA and the corresponding furan-FA by Caco-2 cells. Hydrolysis of total cellular lipids and subsequent fatty acid quantification revealed that LNA and CLA were partly converted to related fatty acids by the cells (Table 1).

In the case of LNA, a relative increase in arachidonic acid (20:4n-6) was observed. It is well-known that mammalian cells have the capacity to use LNA as a precursor for the formation of 20:4n-6. Fatty acid elongation is facilitated by the activity of ELOVL5, a member of the ELOVL (elongation of very long chain fatty acid) protein family [32, 33] followed by the subsequent insertion of two additional double bonds. Thus, based on our lipid analysis, there is some indication that Caco-2 cells do not only take up fatty acid and store them as triglycerides in lipid droplets, but the cells also seem to elongate fatty acids prior to triglyceride formation.

Incubation of the cells with c9,t11-CLA resulted in a relative increase in the CLA isomers c9,c11-CLA and t9,t11-CLA (Table 1). It has recently been shown that the human colon cell line HT-29 can convert t11,t13-CLA into its isomer c9,t11-CLA probably by an enzymatic two-step saturation/desaturation reaction [34]. This might explain the appearance of the c9,c11-CLA isomer in our experiment but can not explain the presence of the t9,t11-CLA isomer as mammalian cells do not introduce *trans* double bonds into fatty acids. We can not exclude that *cis-trans* isomerization

might have occurred chemically during sample preparation or derivatization. By using a solution of c9,t11-CLA in control experiments, however, there was no indication of *cis-trans* isomerization under the given experimental conditions (data not shown). Finally, the unexpectedly high amounts of the different CLA isomers and of 9,11-furan-FA already in the control cells might have been due to the fact that the cells had been incubated in a medium containing 10% fetal calf serum (FCS) that may contain significant amounts of bovine-specific fatty acids.

Lipid extracts from cells incubated with 9,11-furan-FA yielded an additional peak in the gas chromatogram that was not detected with extracts from cells that had been treated with LNA or c9,t11-CLA. Based on the corresponding mass spectrum, we propose a structure for the furan-FA-derived metabolite as presented in Fig. 4b. From a biological point of view, the presence of this compound can simply be explained by the elongation of 9,11-furan-FA probably again by the action of a member of the ELOVL protein family and the subsequent reduction of the condensation product as described for LNA above.

Finally, GC/MS analysis of fatty acid extracts derived from furan-FA-treated Caco-2 cells gave no indication for any modification at the furan ring system. There were no metabolites detected that might have been formed upon epoxide formation or any other modification of the furan ring. Therefore, furan-FA might be either not accepted as a substrate for the cellular CYP machinery, or esterification of furan-FA to form triglycerides and subsequent storage in lipid droplets might be favoured in comparison to the postulated oxidative conversion of the furan ring. In conclusion, furan-FA taken up by human intestinal cells seem to end up preferentially in lipid metabolic pathways such as fatty acid elongation and triglyceride formation, whereas the furan ring present in furan-FA does not seem to be attacked by detoxifying enzymes. In vivo, intestinal cells pack triglycerides into chylomicrons which are VLDL-like particles and secrete them into the blood stream. These chylomicrons are then taken up by liver cells where they are further metabolized. Since our results indicate that the furan ring system of furan-FA was not affected by the metabolic activity of intestinal cells, we will address the question in future studies as to whether the furan ring might be attacked by liver metabolic activity.

Acknowledgments We thank Dr. Lukrecia Benesch-Girke for giving helpful advice in the GC/MS measurements. Linda Brandenburger and Anja Köllner are acknowledged for their technical assistance. This project was funded by the Deutsche Forschungsgemeinschaft (DFG project LA 1177/5-4). There are no conflicts of interest.

Abstract We investigated the role of aminoguanidine and benfotiamine on the inhibition of reactive oxygen species (ROS) generation in macrophages induced by advanced glycated albumin (AGE-albumin) and its relationship with cell cholesterol homeostasis, emphasizing the expression of the ATP binding cassette transporter A-1 (ABCA-1). AGE-albumin was made by incubating fatty acid-free albumin with 10 mM glycolaldehyde. ROS production and ABCA-1 protein level were determined by flow cytometry in J774 macrophages treated along time with control (C) or AGE-albumin alone or in the presence of aminoguanidine or benfotiamine. Mitochondrial function was evaluated by oxygraphy. Compared to C-albumin, AGE-albumin increased ROS production in macrophages, which was ascribed to the activities of NADPH oxidase and of the mitochondrial system. Mitochondrial respiratory chain activity was reduced in cells incubated with AGE-albumin. ROS generation along time was associated with the reduction in macrophage ABCA-1 protein level. Aminoguanidine prevented ROS elevation and restored the ABCA-1 content in macrophages; on the other hand, benfotiamine that promoted a lesser reduction in ROS generation was not able to restore ABCA-1 levels. Inhibition of oxidative stress

induced by AGE-albumin prevents disturbances in reverse cholesterol transport by curbing the reduction of ABCA-1 elicited by advanced glycation in macrophages and therefore may contribute to the prevention of atherosclerosis in diabetes mellitus.

Introduction

Advanced glycation end products (AGE) are prevalent in hyperglycemia, and together with the enhanced glucose

metabolism along the hexosamine, polyol and diacylglycerol-PKC pathways, set up a link between oxidative stress and the development of long-term complications in diabetes mellitus (DM) [1, 2]. By reacting with oxoaldehydes, lipoproteins and albumin can be modified by AGE especially in the postprandial phase in DM as well as in inflammation and in renal chronic disease [3–5]. Atherosclerosis that prevails in DM is associated with serum levels of AGE [6].

Advanced glycated albumin (AGE-albumin) impairs the ATP binding cassette transporter A-1 (ABCA-1) and ATP binding cassette transporter G-1 (ABCG-1) expressions and consequently also the apo A-I and HDL-mediated cholesterol efflux [7–9]. ABCA-1 plays a major role in the first step of the reverse cholesterol transport system by exporting the excess of cell cholesterol to lipid poor apo A-I which ultimately is converted into mature HDL that delivers cholesterol to the liver for bile excretion and to steroidogenic organs [10]. Methylglyoxal, glyoxal and 3-deoxyglucosone can mediate the generation of AGE, although previous reports have demonstrated that glycolaldehyde plays a major role in protein derivatization and in cell lipid efflux damage [7, 8].

Intracellular production of ROS elicited by AGE has mainly been ascribed to NADPH oxidase and to the mitochondrial respiratory chain, leading to the production of vascular adhesion molecules and inflammatory mediators, as well as to the expression of the advanced glycation end products receptor (RAGE) [11–13]. Together, these events are related to endothelial, retinal, renal and neuronal injury in DM [1, 11, 14–16].

To date, there are no data linking intracellular redox imbalance with changes in cholesterol homeostasis elicited by alterations in the expression of ABCA-1. We then investigated whether the AGE-induced ROS generation in macrophages relates to the reduction in ABCA-1 transporter level as well as the role played by anti-AGE and antioxidant compounds, such as aminoguanidine and benfotiamine.

Materials and Methods

This study was approved by The Ethical Committee of the Hospital das Clínicas of the Faculty of Medical Sciences of the University of São Paulo, Brazil (#0807/07). All protocols with humans conformed to the Declaration of Helsinki and animal experiments were done according to the US National Institutes of Health guidelines.

Preparation of AGE-Albumin

AGE-albumin was prepared by incubating bovine fatty acid free albumin (FAFA, 40 mg/mL) with 10 mM

glycolaldehyde (Sigma Chem. Com. St. Louis, MO) for 4 days, at 37 °C, under sterile conditions and a nitrogen atmosphere in a water bath shaker in the dark. Control albumin (C-albumin) was incubated with PBS only. After extensive dialysis, samples were sterilized. Samples contained <50 pg endotoxin/mL as determined by the chromogenic *Limulus amoebocyte* assay (Cape Cod, Falmouth, MA).

Cell Culture

J774 macrophages were cultured in RPMI 1640 containing 10% fetal calf serum (FCS), 1% penicillin–streptomycin and 4 mM L-glutamine and maintained in a 5% CO₂ incubator at 37 °C.

After reaching confluence, cells were treated for different intervals of time with C or AGE-albumin alone (2 mg/mL DMEM) or in the presence of aminoguanidine (AMG) or benfotiamine (BF) to evaluate ABCA-1 protein content, ROS generation and mitochondrial respiration. In all cell culture experiments, cell viability controlled by exclusion with trypan blue was superior to 98%. Apoptosis, assessed by the number of annexin V-FITC positive cells, did not change after exposure to AGE-albumin (data not shown).

Assessment of Carbonyl Content in Macrophages

Lysates from C or AGE-albumin-treated cells were incubated with 10 mM of dinitrophenylhydrazine in 2.5 M HCl for 1 h at room temperature. The reaction was blocked by the addition of 20% trichloroacetic acid (TCA). The pellets were washed twice with absolute ethanol/ethyl acetate (1:1) and once with 10% TCA. The protein pellets were dissolved in 6 M guanidine hydrochloride and the absorption at 370 nm was determined. Carbonyl content was calculated using the molar absorption coefficient of aliphatic hydrazones of 22,000 M⁻¹ cm⁻¹ and expressed as nanomoles carbonyl per milligram of protein.

Immunoblot

J774 macrophages were scraped into Tris buffer saline containing protease inhibitors. Equal amounts of cell protein were applied to a polyacrylamide gel (SDS-PAGE) and CD-36 and RAGE expressions determined using anti-RAGE and anti-CD-36 antibodies (Fitzgerald Industries International, Inc., Concord, MA). The difference between the bands was analyzed in pixels, using the JX-330 Color Image Scanner (Sharp®) and ImageMaster software (Pharmacia Biotech). The results are expressed as arbitrary units, analyzing AGE-albumin versus C-albumin. Ponceau staining was utilized to assure equal protein loading.

Assessment of Carboxymethyllysine Adducts in Control and AGE-Albumin

Equal amounts of C and AGE-albumin were loaded into 10% SDS-PAGE and the content of carboxymethyllysine was determined with an anti-CML antibody (Novus Biologicals, Inc., Littleton, CO). Ponceau staining was also utilized to assure equal protein loading.

Agarose Gel Electrophoresis

Ten micrograms of C and AGE-albumin were subjected to 1% agarose gel electrophoresis and the samples' mobility was determined after 1 h run and staining with Coomassie blue.

Determination of ABCA-1 Protein Level by Flow Cytometry

ABCA-1 content by flow cytometry was analyzed due to the difficulty in attaining a good signal in SDS-PAGE. For this experiment, J774 macrophages previously treated for 24 h with 8-Br cyclic AMP (0.5 mM), were incubated for different intervals of time with C or AGE-albumin in the presence or absence of AMG (5 and 10 mM) or BF (350 μ M). After that, a 10^6 cells concentration was fixed in paraformaldehyde (PFA—4%), incubated with anti-ABCA-1 antibody (Novus Biologicals, Inc., Littleton, CO – 1:250 dilution) for 1 h at room temperature and incubated afterwards with 4 μ g/mL Alexa Fluor 488 antibody (Invitrogen, USA). Cellular fluorescence intensity was evaluated by flow cytometry using a FACS Calibur and the Cellquest software (B. D., San Jose, CA). Under all of the conditions, we corrected for basal cellular fluorescence (without Alexa Fluor 488 antibody).

Reactive Oxygen Species Production

After treatment with C or AGE-albumin, J774 macrophages (1×10^6) were incubated with 5 μ M dihydroethidium (DHE) probe (Molecular Probes, OR) for 45 min. ROS production was evaluated by flow cytometry using a FACS Calibur and the Cellquest software (B.D., San Jose, CA). In order to evaluate the contribution of the NADPH oxidase system to the AGE-induced oxidative stress, cells were incubated for 50 min with DHE in the absence or in the presence of the 10 μ M NADPH oxidase inhibitor, diphenylene iodonium (DPI) (Sigma) and the ROS production was determined.

High-Resolution Respirometry

Respiration rates were recorded with the high-resolution OROBOROS oxygraph (Paar, Innsbruck, Austria) in C and

AGE-albumin-treated macrophages (24 h treatment). The culture medium was maintained in an open chamber at 37 °C (temperature controlled by Pelletier effect), homogenized with a magnetic stirrer (600 rpm), and left to equilibrate with the atmosphere before signal calibration. Oxygen concentration was computed from the partial pressure measured by the electrode. During respiration measurements, each chamber (2-mL working volume) was closed by a piston to prevent oxygen exchange with the atmosphere. Data were recorded at 0.4 s intervals and analyzed by the Datlab Acquisition and Analysis software (Paar). As indicated, 2 μ g/mL of an ATPase inhibitor (oligomycin) was added.

14 C- Acetate Incorporation into Cholesterol and Cholesterol Esterification Rates

After 4 h of treatment of the J774 macrophages with 0.25 mM glycolaldehyde (GAD), the cells were washed twice with PBS containing 1 mg/mL FAFA and incubated for 5 h with 8 μ Ci/mL (2- 14 C) sodium acetate (GE-Amersham Biosciences, USA) in DMEM containing 1 mg/mL of FAFA. Cell lipids were extracted with a hexane/isopropanol (3:2, v:v) mixture. The solvent was evaporated under N₂ flow and, after dilution in chloroform, samples were spotted on silica G plates by an automated system (Analtech Inc., USA) for thin layer chromatography development. Lipid standards (Sigma) were utilized and the unesterified and esterified cholesterol bands were isolated in order to measure the associated radioactivity. Cholesterol biosynthesis was expressed as total counts per microgram of cell protein.

Statistical Analysis

Statistical analysis was performed using GraphPad Prism 4.0 software (GraphPad Prism, Inc., San Diego, CA). One-way analysis of variance (ANOVA) and the Newman Keuls post test were utilized to compare differences among groups. Summary data are reported as mean values \pm standard error. A *p*-value <0.05 was considered statistically significant.

Results

Glycolaldehyde-modified albumin was characterized by the determination of CML content. As shown in Fig. 1a CML was greatly superior in AGE-albumin as compared to C-albumin. In addition, the mobility of AGE-albumin was faster than that of C-albumin on agarose gel electrophoresis (Fig. 1b).

Fig. 1 Carboxymethyllysine content and electrophoretic mobility is increased in AGE-albumin. **a** CML content in albumin modified by 10 mM glycolaldehyde (AGE-albumin) and control albumin (C-albumin) was determined by immunoblot using an anti-CML antibody, **b** electrophoresis mobility was determined in 1% agarose gel and staining with Coomassie blue. *C-albumin* control albumin, *AGE-albumin* advanced glycated albumin

Further, we addressed ROS generation in AGE-albumin-treated cells and its association with the reduction in the ABCA-1 protein level. In macrophages, AGE-albumin induced a higher content of carbonyl derivatives in comparison to C-albumin (Fig. 2a). ROS generation was increased by 24% in J774 macrophages treated with AGE-albumin in comparison to C-albumin and was prevented by incubating cells with a flavoprotein inhibitor, DPI, which is consistent with the role of NADPH oxidase in ROS production in these cells (Fig. 2b).

In an attempt to investigate the oxygen flow along the mitochondrial respiratory chain, C- and AGE-albumin-treated macrophages were evaluated under two different conditions: basal and following the addition of oligomycin. In comparison to C-albumin-treated cells, oxygen flow (pmol/s/mL) was significantly reduced (46%) in cells treated with AGE-albumin (Fig. 2c). In comparison to the basal condition, in the presence of oligomycin, oxygen

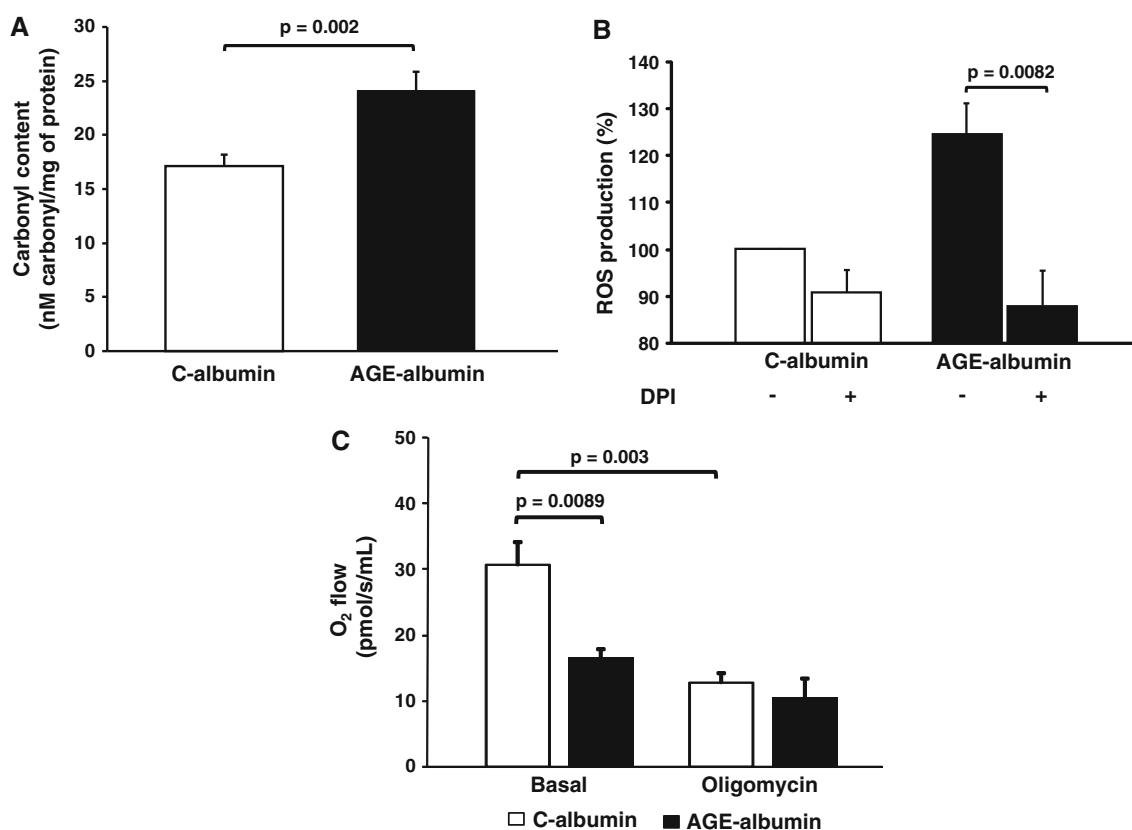

Fig. 2 AGE-albumin enhances carbonyl content and induces ROS production in macrophages: contribution of NADPH oxidase and mitochondria. **a** Carbonyl content was determined in macrophages treated for 24 h with C or AGE-albumin by spectrophotometry, **b** ROS production (mean \pm SE) was determined by flow cytometry in J774 cells treated for 24 h with C or AGE-albumin with the NADPH oxidase inhibitor, DPI ($n = 8$), **c** oxygen consumption rates

(mean \pm SE) were determined in J774 cells after treatment with C or AGE-albumin under basal conditions and after addition of oligomycin (inhibitor of ATP synthase) as indicated ($n = 4$). Results are representative of at least four independent experiments. *C-albumin* control albumin, *AGE-albumin* advanced glycated albumin, *DPI* diphenylene iodonium

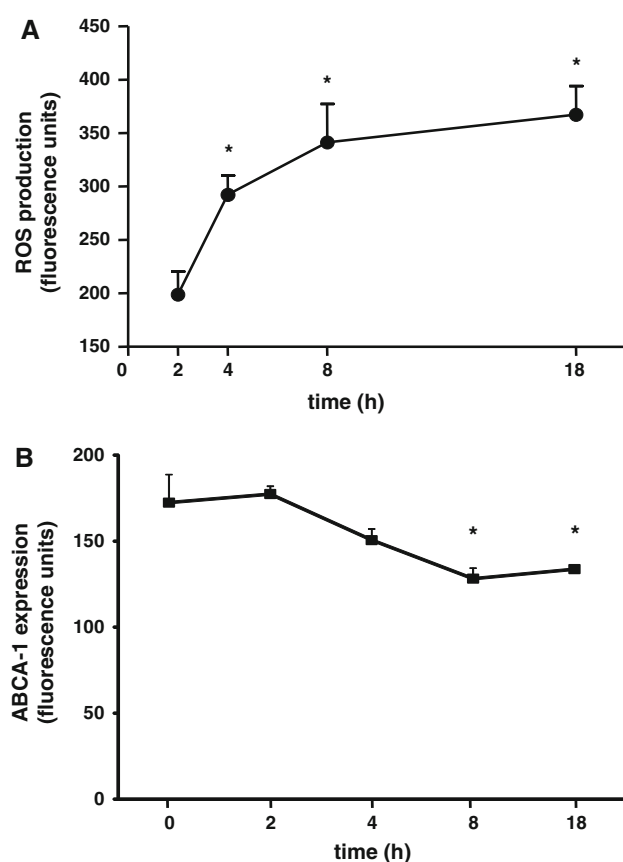

Fig. 3 AGE-albumin increases ROS and decreases ABCA-1 in a time dependent manner. J774 macrophages were treated for different periods of time with C or AGE-albumin. **a** ROS production (mean \pm SE) was determined by flow cytometry (* p < 0.05 compared to 2 h incubation; n = 6, two independent experiments), **b** ABCA-1 protein level was determined by flow cytometry (* p < 0.05 compared to time 0)

flow decreased in C-albumin-treated cells only, with no changes in the cells treated with AGE-albumin.

ROS production was significantly increased along time in AGE-albumin treated macrophages and approached to plateau at the 18th hour (Fig. 3a). ROS generation was accompanied by significant reductions in ABCA-1 protein level after 8 h and 18 h of treatment (Fig. 3b). The association between ROS generation and ABCA-1 reduction was further confirmed by incubating cells with AMG or BF, compounds that function as antioxidants and AGE inhibitors. ROS generation observed in macrophages treated with AGE-albumin alone was reduced 45% by cell incubation with AGE-albumin plus 10 mM AMG (Fig. 4a, inner panel). At this concentration AMG was able to restore the ABCA-1 protein level in macrophages treated with AGE-albumin (Fig. 4a). ROS generation was less inhibited by BF (26%) in cells treated with AGE-albumin (Fig. 4b, inner panel) and, accordingly, BF was not able to restore the ABCA-1 level (Fig. 4b).

It is well-known that reactive oxoaldehydes can be directly formed in the arterial wall. We then measured cholesterol biosynthesis and esterification as well as ROS generation in macrophages directly exposed to glycolaldehyde. Cells subjected to glycoxidation showed a 42% reduction in cholesterol biosynthesis (dpm/ng of cell protein \pm SD) in comparison to control cells (Fig. 5a). In contrast, the cholesterol esterification rate was increased 2.3 fold in macrophages incubated with GAD as compared to control cells (Fig. 5b). In addition, ROS generation was 28% higher in GAD-treated macrophages in comparison to control cells (Fig. 5b, inner panel). These results are in agreement with the observed impairment in the cholesterol efflux elicited by intracellular glycoxidation that subsequently leads to reductions in ABCA-1 protein and intracellular lipid accumulation [8].

Compared to C-albumin, the expression of RAGE and CD-36 were increased by 60 and 35%, respectively, after treatment with AGE-albumin (data not shown).

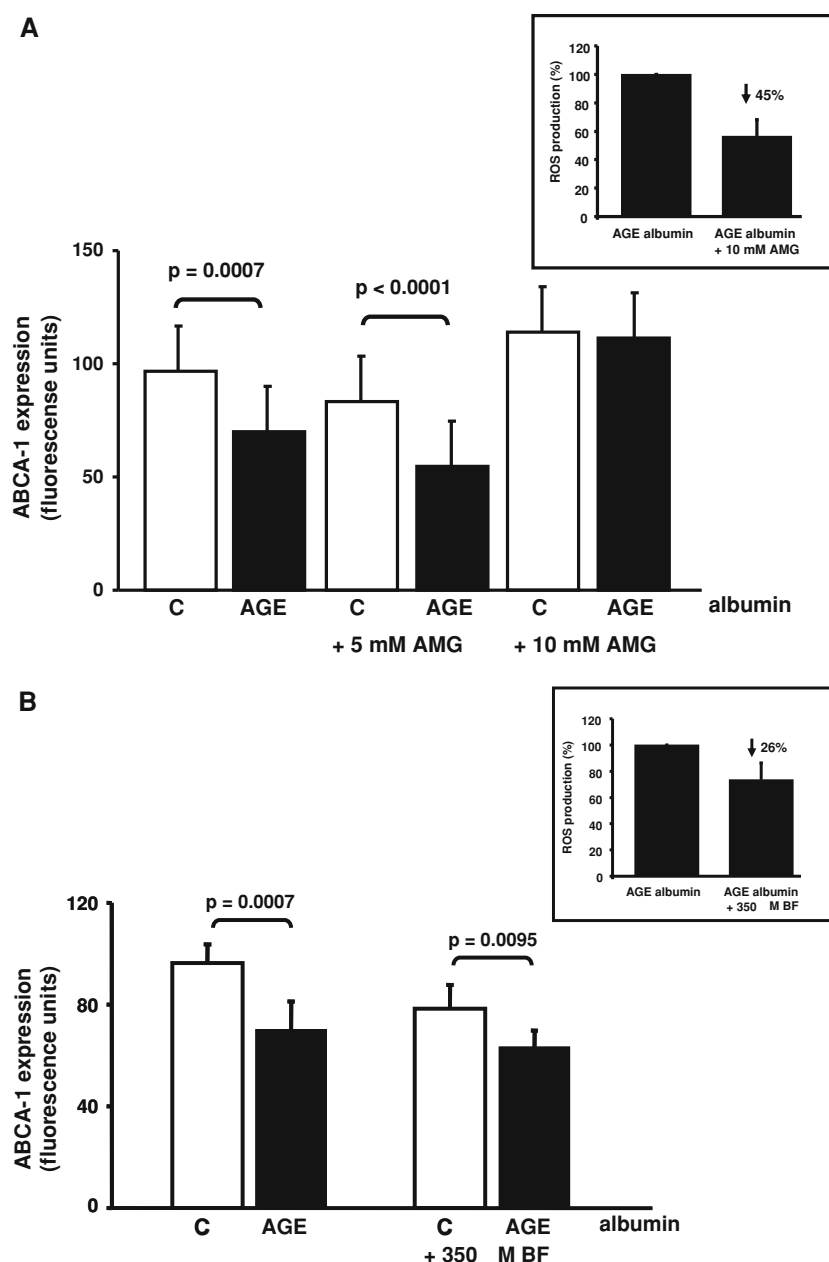

Discussion

Glycated albumin constitutes the overwhelming majority of circulating glycated proteins. AGE-modified albumin is prevalent in DM and disturbs macrophage cholesterol efflux [7]. In the present study, we analyzed the role of control and AGE-albumin on macrophage oxidative stress and its relationship to disturbances in cell cholesterol homeostasis.

Reactive oxygen species were significantly increased in cells treated with AGE-albumin. Our results indicate a combined role of the NADPH oxidase and the mitochondrial respiratory chain in the oxidative stress, although a lower magnitude of ROS levels was detected in our study when compared to data from other authors dealing with different cell types [11, 17].

A diminished mitochondrial respiration contributes to the generation of ROS by mitochondria in consequence of the high reduction state of respiratory chain components [18]. The bulk of mitochondrial ROS generation occurs at the electron transport chain, as a byproduct of respiration. Enhanced electron transport that reflects increased mitochondrial respiratory rates may prevent ROS formation by decreasing oxygen tension in the mitochondrial microenvironment. On the other hand, conditions that lead to lower respiratory rates are frequently accompanied by enhanced ROS release [19]. Then, the contribution of mitochondria to ROS generation and oxidative stress in macrophages exposed to AGE-albumin can be confirmed by the reduction in mitochondrial oxygen flux, increasing both cellular oxygen tension and the reduced state of monoelectronic donors of the respiratory chain. Oligomycin did not show

Fig. 4 Aminoguanidine but not benfotiamine greatly diminishes ROS production in AGE-albumin-treated macrophages and restores ABCA-1 protein level. J774 macrophages were treated with AGE-albumin for 8 h in the presence or absence of **a** 5 and 10 mM aminoguanidine (AMG) or **b** 350 μ M of benfotiamine (BF). ROS production (*inner panels*) and ABCA-1 protein levels were determined by flow cytometry (mean \pm SE; $n = 4$)

an effect in AGE-albumin-treated cells likely because of the already low oxygen consumption rate observed under basal conditions.

The increase in ROS production in macrophages treated with AGE-albumin was accompanied by a severe reduction in ABCA-1 expression. Moreover, the ABCA-1 protein level reduction was consistently observed in several independent experiments. Elevations in ROS were prevented by 10 mM of AMG, a substance that has been shown in identical concentrations to prevent disturbances in cholesterol efflux elicited by AGE by diminishing CML formation [7]. Since no changes in ABCA-1 mRNA levels have been ascribed to cell glycoxidation [8], it is

reasonable to consider that post-transcriptional degradation of ABCA-1 could contribute to its reduction in the AGE-albumin-treated macrophages [20]. In fact, ABCA-1 gene transcription is unaltered by glycoxidative stress [8, 9].

Lipid accumulation can also be worsened in the presence of AGE-albumin due to the enhanced expression of scavenger receptors, LOX-1, CD-36 and RAGE [21, 22] and also by the increased rate of cholesterol esterification by ACAT shown by us. In other words, increased cholesterol flow into cells aggravates atherosclerosis ascribed to an AGE-mediated impairment in the reverse cholesterol transport.

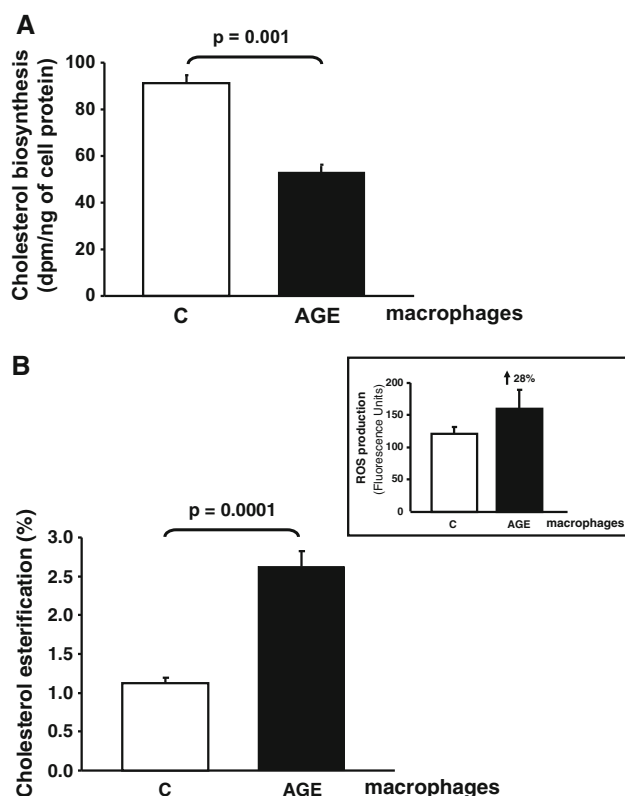

Fig. 5 Glycoxidation reduces cholesterol biosynthesis and enhances cholesterol esterification in macrophages. J774 macrophages were treated with 0.25 mM glycolaldehyde. Control (C) cells were incubated with DMEM only. Cells were treated for 5 h with 8 μ Ci/mL ($2\text{-}^{14}\text{C}$) sodium acetate in order to determine **a** the cholesterol biosynthesis and **b** the percentage of cholesterol esterification (mean \pm SD; $n = 6$). ROS production (*inner panel*) was determined by flow cytometry (mean \pm SE; $n = 5$)

AGE-albumin interacts with RAGE and as consequence of intracellular signal transduction ROS is produced leading to activation of NF- κ B that ultimately leads to RAGE expression [22, 23]. Therefore, AGE-albumin is able to generate and propagate oxidative stress in cells, which was also reflected by the increase in cellular carbonyl content.

Our findings are strengthened by the demonstration that serum albumin isolated from uncontrolled type 1 and 2 DM patients reduces the apo A-I and HDL-mediated cholesterol efflux, inducing macrophage lipid accumulation in a similar pattern to that observed in macrophages treated with AGE-albumin (the same in-vitro modified albumin utilized in the present study) [24]. In addition, albumin isolated from DM patients presented a higher amount of CML as compared to albumin isolated from healthy individuals [24]. AGE-albumin utilized in the present study also showed a large amount of CML in comparison to C albumin, although we cannot exclude that other AGE adducts may be present. Besides, taking into account that oxoaldehydes can be generated in the arterial wall, produced in

non-hyperglycemic conditions and are also acquired from food sources, the contribution of AGE-albumin to disturbances in cholesterol homeostasis may be important in a broad spectrum of metabolic conditions. From this point of view, cell lipid accumulation can be minimized by drugs that reduce ROS generation induced by AGE, which should be addressed in future experiments.

Conclusion

AGE-albumin disturbs macrophage lipid homeostasis by increasing the expression of scavenger receptors and diminishing ABCA-1. The reduction in the ABCA-1 protein level elicited by AGE-albumin in macrophages is associated with the oxidative stress via NADPH oxidase system and mitochondria. Anti-AGE and antioxidant compounds known to mitigate greatly the ROS production might hinder the disturbances in the reverse cholesterol transport thus contributing to the prevention of atherosclerosis in DM and other conditions of carbonyl stress such as inflammation and chronic kidney disease.

Phospholipid Peroxidation: Lack of Effect of Fatty Acid Pairing

Sarah E. Norris · Todd W. Mitchell ·

Abstract Phospholipids where both fatty acids are polyunsaturated are very rare. Most organisms prefer to couple their polyunsaturated fatty acids (PUFA) with either a saturated (SAT) or a monounsaturated (MUFA) fatty acid. This study examined if these natural couplings are there to protect PUFA from themselves. Specifically, does the coupling of PUFA to SAT or MUFA reduce the potential for increased rates of peroxidation by shrouding these highly peroxidisable fatty acids with less peroxidisable fatty acids? The influence of head group was examined by using the two most common phospholipids found in vertebrate membranes i.e. phosphatidylcholine and phosphatidylethanolamine species. Fatty acid pairings included 16:0/18:2 versus 18:2/18:2 and 16:0/22:6 versus 22:6/22:6. All phospholipids were incorporated into liposomes that were matched for their total PUFA content i.e. 25% PUFA/PUFA or 50% SAT/PUFA with phosphatidylcholine 16:0/16:0 used as the background phospholipid. An iron initiator ($\text{Fe}^{2+}/\text{H}_2\text{O}_2$) was used to induce peroxidation and lipid hydroperoxide production was used to measure peroxidation. The results show that coupling of PUFA together on the same molecule does not increase peroxidation rates and therefore does not support the proposed hypothesis. The lower than expected levels of

peroxidation measured for some phospholipid species (e.g. PtdEtn 22:6/22:6) is possibly due to the partitioning of these molecular species into the inner leaflet of the bilayer.

Introduction

Hundreds of different phospholipid molecular species constitute the major lipid component of membranes [7]. The breadth of variation in phospholipids is due primarily to the different combinations of fatty acids associated with the major phospholipid classes. For example, in a recent study analysing six major phospholipid classes (PtdCho, PtdEtn, PtdSer, PtdOH, PtdGro and PtdIns), in kidney and brain of three different sized mammals, up to 120 different phospholipid molecular species were found in kidney and up to 66 in the brain [16]. Analysis of the original data used to produce this study shows that virtually no phospholipids (<1%) possess two polyunsaturated fatty acids together on the same molecule, i.e. at both the sn1 and sn2 positions on their glycerol backbones. This presents a rather interesting question, why do organisms tend to avoid the use of PUFA/PUFA phospholipids in their membranes?

Double PUFA phospholipids certainly exist, examples include phospholipids in various microorganisms [25], cephalopod tissues, [21], mitochondrial membranes of oxidative muscle in trout [12] and rod outer segment membrane in higher vertebrates [3]. In these cases docosahexaenoic acid (DHA; 22:6n-3) combines with itself or other PUFA. Macroalgae also possess PUFA/PUFA phospholipids [17] with green algae using 16:3n-3 (hexadecatrienoic acid) and 18:3n-3 (α -linolenic acid, ALA) while brown algae combine 20:4n-6 (arachidonic acid) and 20:5n-3 (eicosapentaenoic acid). These examples of PUFA/PUFA phospholipids are however uncommon. The only commonly known phospholipid that possesses multiple PUFA is cardiolipin (Ptd₂Gro). Cardiolipin is a novel phospholipid found almost exclusively in mitochondria where it binds proteins and is involved, via its oxidation, in initiating apoptosis [20]. Cardiolipin is a diphosphatidylglycerol (a double phospholipid) with four fatty acid tails, and the best-known form of cardiolipin is a tetra linoleic acid (i.e. $4 \times 18:2n-6$) species that predominates ($\sim 85\%$ of cardiolipin) in the heart of mammals [18]. Interestingly in some bivalve molluscs a tetra DHA molecular species is common [11].

One possible explanation for the general lack of PUFA/PUFA phospholipids in membranes is that it presents a peroxidation hazard to the cell. This is because like other molecules within the body, phospholipids are prone to the effects of reactive oxygen species (ROS). But unlike many other molecules, lipid oxidation (or peroxidation) once initiated is self-propagating due to the formation of lipid oxyl (LO^\bullet) and peroxy (LOO^\bullet) radical products that can perpetuate the peroxidative process. Another ‘problem’ lipids face is that they also possess very high O_2 solubilities, ~ 20 – 30 times more than aqueous media [2] so oxygen is readily available to fuel these reactions in a lipid environment. Most at risk of peroxidation are PUFA because they possess bis-allylic hydrogen’s (hydrogen’s on methylene groups between double bonds) that have lower bond energies meaning that they are more readily removed (or abstracted) by ROS. Therefore, the more double bonds or the greater the level of polyunsaturation (not unsaturation as monounsaturates have no bisallylic hydrogens) the greater the potential for lipid peroxidation. This relationship between the level of polyunsaturation and capacity to peroxidise is expressed in the peroxidation index (see [5]). The peroxidation index is an empirically derived value showing that the oxidizabilities of polyunsaturation fatty acids are dependent upon the number of bis-allylic methylene groups present.

Therefore the coupling of PUFA together on the same phospholipids, and the possibility that these phospholipids might form micro-domains within the membrane has

the potential to fuel rapid, and potentially uncontrollable rates of lipid peroxidation. This could occur as lipid radicals move rapidly from PUFA to PUFA on double PUFA phospholipid molecules forming a peroxidative cascade. Alternatively by coupling PUFA on phospholipids to either a saturated or a monounsaturated fatty acid, peroxidation is likely to be hindered and therefore slower. This could result from ‘steric’ hindrance provided by the presence of far less peroxidisable fatty acids that may act to slow the diffusion of lipid radicals within the lipid environment of the membrane [19], providing time for the normal membrane antioxidant systems to operate.

The aim of this research was to test if phospholipids with PUFA/PUFA combinations of fatty acids display faster rates of peroxidation than phospholipids with the same number and types of PUFA coupled to SAT rather than PUFA. To test this idea liposomes of identical peroxidative capacity were produced using the two most common phospholipid classes found in higher vertebrates i.e. phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn). Fatty acid pairings included 16:0/18:2 versus 18:2/18:2 and 16:0/22:6 versus 22:6/22:6. These liposomes were then subject to the same peroxidative stress and the level of peroxidation measured as the amount of lipid hydroperoxide formed.

Materials

All synthetic phospholipids were purchased without any added BHT from Avanti Polar Lipids Inc (Alabama, USA). These included; 1,2-dilinoleyl-sn-glycero-3-phosphatidylcholine (PtdCho 18:2/18:2), 1,2-dilinoleyl-sn-glycero-3-phosphatidylethanolamine (PtdEtn 18:2/18:2), 1,2-didocosaheptaenoyl-sn-glycero-3-phosphatidylcholine (PtdCho 22:6/22:6), 1,2-didocosaheptaenoyl-sn-glycero-3-phosphatidylethanolamine (PtdEtn 22:6/22:6), 1-palmitoyl-2-linoleoyl-sn-glycero-3-phosphatidylcholine (PtdCho 16:0/18:2), 1-palmitoyl-2-linoleoyl-sn-glycero-3-phosphatidylethanolamine (PtdEtn 16:0/18:2), 1-palmitoyl-2-docosaheptaenoyl-sn-glycero-3-phosphatidylcholine (PtdCho 16:0/22:6) and 1-palmitoyl-2-docosaheptaenoyl-sn-glycero-3-phosphatidylethanolamine (PtdEtn 16:0/22:6), 1,2 dipalmitoyl-sn-glycero-3-phosphatidylcholine (PtdCho 16:0/16:0) and a mixed phospholipid soy lecithin. All phospholipids were kept in their sealed containers at -20°C until required. Ammonium ferrous sulphate and xylenol orange were purchased from Sigma-Aldrich (USA). Methanol and chloroform (HPLC grade) were purchased from Crown Scientific (Australia) and sulphuric acid from AJAX Chemicals (Australia). All chemicals used were of analytical grade.

Methods

Liposome Preparation

Liposomes were prepared by mixing various combinations of phospholipids (from stock solutions made-up at 10 mg/mL in 2:1 chloroform:methanol stored at -20°C). Phospholipid mixtures were dried down under N_2 at 37°C for 45 min. These were then immediately rehydrated at 45°C (being above the highest phase transition temperature of 41.5°C for 1,2 dipalmitoyl-sn-glycero-3-phosphatidylcholine (PtdCho16:0/16:0) that was used to form the liposomes) in 140 mM NaCl solution at pH 7.3. This was followed by vigorous vortexing for 10 min. The final concentration of the liposomal suspensions was 0.4 mg of phospholipid/mL. The resuspended phospholipid solutions were subsequently sonicated 3×45 s at an amplitude of 10 μm using a probe-type-sonicator (Sanyo Soniprep 150). Sonication, and the subsequent formation of liposomes, was marked by the opaque phospholipid solutions partially clarifying.

The aim of this investigation was to produce stable liposomes with an identical number of polyunsaturated and saturated fatty acids derived from phospholipids with different ‘geometries’ (i.e. PUFA/PUFA or SAT/PUFA). Liposomes consisted of 75 or 50% PtdCho 16:0/16:0 with either 25% of a phospholipid with a PUFA/PUFA pairings, or 50% of a phospholipid with a PUFA paired with a saturated fatty acid (16:0), respectively. A series of both 18:2 and 22:6 containing phospholipids (both PtdCho and PtdEtn) were compared (in theory the peroxidative capacity of the 22:6 series is five times that of the 18:2 series with the same numbers of fatty acids present [5]). The PUFA/PUFA phospholipids used included: PtdCho 18:2/18:2, PtdEtn 18:2/18:2, PtdCho 22:6/22:6 and PtdEtn 22:6/22:6. The SAT/PUFA phospholipids used included: PtdCho 16:0/18:2, PtdEtn 16:0/18:2, PtdCho 16:0/22:6 and PtdEtn 16:0/22:6. In order to form stable liposomes these peroxidizable phospholipids were combined with the relatively non-oxidisable ‘carrier’ phospholipid PtdCho16:0/16:0 (i.e. 75% for PUFA/PUFA phospholipids and 50% for SAT/PUFA phospholipids).

Liposomes therefore consisted of either 25% of a PUFA/PUFA phospholipid combined with 75% of PtdCho16:0/16:0 or 50% of a SAT/PUFA phospholipid (with the SAT being 16:0) together with 50% PtdCho16:0/16:0. The net result was that all liposomes consisted of 25% PUFA (either 18:2 or 22:6) and 75% SAT (16:0 only). Liposomes were freshly prepared and used immediately following preparation.

Peroxidation

Liposome peroxidation was initiated by using ferrous iron (Fe^{2+}) together with hydrogen peroxide to produce final

reaction concentrations for both products of 10 μM Fe^{2+} / H_2O_2 (hereto referred to as the iron initiator). The final pH of the peroxidation system was 4.4. Ferrous iron (Fe^{2+}) was derived from ammonium ferrous sulphate $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2$ as it was found to be more effective at initiating peroxidation than Fe^{2+} from FeSO_4 . The lower pH of ammonium ferrous sulphate helped to maintain the presence of Fe^{2+} [1] whereas Fe^{2+} from FeSO_4 tended to produce a brown precipitate (assumed due to the conversion of Fe^{2+} to Fe^{3+} and the formation of insoluble Fe^{3+} compounds). Autoperoxidation of the phospholipids was measured by running parallel incubations without the addition of the iron initiator. All peroxidation experiments involved six separate experiments run at 45°C (above 41.7°C being the highest phase transition temperature of PtdCho16:0/16:0) ensuring that all phospholipids in the liposomes were in a liquid state when measured.

Peroxidation was determined by measuring the production of lipid hydroperoxides (i.e. LOOH) using the xylenol orange based method employed in the FOX2 assay. The method used was as previously described by Deiana et al. [6] and reviewed by Bou et al. [4]. The final concentration of the assay medium consisted of 0.25 mM $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2$, 0.25 mM H_2SO_4 , 100 μM xylenol orange and 1 mM of butylated hydroxytoluene (added as an antioxidant) in methanol. LOOH production was measured over 3 h with the first measurement made after 10 min. Preliminary measurements at earlier times (2 and 4 min) indicated an essentially linear rate of LOOH for the first 10 min of the experiment. Standard curves were constructed using tert-butyl hydroperoxide (linear range between 0 and 20 nmol; $r^2 = 0.9991$).

Preliminary experiments were conducted on a mixed PtdCho phospholipid i.e. soy lecithin (fatty acid composition: 14.9% 16:0, 3.7% 18:0, 11.4% 18:1, 63% 18:2 and 5.7% 18:3) using the TBARS method (a butylated hydroxytoluene/thiobarbituric acid based assay with tetramethoxypropane used as a standard). Soy lecithin when used with the FOX2 and the TBARS methods produced excellent correlation $r^2 = 0.91$ ($n = 20$) between the methods. However when employed in the current experiment the level of malondialdehyde produced from the phospholipids that contained 18:2 as their only PUFA was very small (as previously found; [10]). This made the use of the TBARS method far less sensitive when liposomes contained linoleic acid as their only PUFA. The formation of dienes during peroxidation was also explored as a means of measuring peroxidation but was found to be too variable whereas the FOX2 method was reliable, highly repeatable and sensitive. Subsequently, the FOX2 method was used to measure peroxidation of the liposomes made from the pure phospholipids. The molecular composition of all PtdCho lipids was confirmed using a QTrap5500 triple quadrupole

linear ion trap mass spectrometer (AB Sciex, Tronto, Canada) equipped with a TriVersa NanoMate automated nanospray source (Advion, Ithica, USA).

Statistical Analysis

Differences in overall peroxidation of liposome with the same head group but different fatty acid couplings were subject to repeated measure ANOVA with one-way ANOVA's at individual time points. A student *t* test was used to compare LOOH present in phospholipids at baseline, those produced during sonication, peroxide present due to the addition of the iron initiator and total peroxides present at initiation of peroxidation. All statistical analysis was performed using SPSS Statistics (v17.0).

Results

Prior to determining the 'peroxidisabilities' of the various liposomes the preexisting level of peroxide present at the various stages of liposome preparation was determined. Figure 1 shows the level of lipid hydroperoxides (LOOH) present at baseline (A), produced during sonication (B), present as a result of the addition of the iron initiator (C), and total levels (D). The baseline values ranged from essentially zero up to 53 nmol LOOH/mg of phospholipid with the PUFA/PUFA phospholipids (i.e. PtdCho 18:2/18:2 PtdEtn 18:2/18:2 and 22:6/22:6) generally displaying significantly higher levels of LOOH than the SAT/PUFA coupled phospholipids (PtdCho and PtdEtn 16:0/18:2 and 16:0/22:6) with the notable exception of PtdCho 22:6/22:6 that had virtually no LOOH present at baseline.

Although preliminary experiments were conducted to minimize LOOH production during sonication the probe sonicator still produced between 22 and 95 nmol of LOOH/mg of PL. PtdEtn 16:0/18:2 and PtdCho 18:2/18:2 generally produced more LOOH than the other phospholipids during sonication. The addition of the iron initiator to the liposomes produced a small and similar (not significant different) rise in peroxide levels across all liposome preparations. This rise in peroxide level was assumed to be due to the presence of H₂O₂ in the iron initiator. The cumulative total of peroxide present in the liposomes varied from 85 to 168 nmol/mg of PL with both PtdCho and PtdEtn 18:2/18:2 having significantly ($p < 0.002$) more peroxide than most of the other phospholipids (e.g. PtdCho 16:0/18:2 and 22:6/22:6 and PtdEtn 16:0/22:6; PtdCho 18:2/18:2 also had higher total levels of peroxide than PtdEtn 22:6/22:6) at the start of the reaction. Subsequently all preparations were normalized by subtracting preexisting total levels of peroxides present for each preparation (with all

preparations except PtdCho and PtdEtn 18:2/18:2 having similar preexisting levels of peroxide) prior to determining the effect of the iron initiator on phospholipid peroxidation.

The subsequent total level of peroxidation for the four different phospholipid pairings (PtdCho and PtdEtn as either 16:0/18:2 versus 18:2/18:2 or 16:0/22:6 versus 22:6/22:6) is shown in Fig. 2. In all cases there was an initial burst of LOOH production followed by either a plateauing or decrease in LOOH production towards the end of the 3 h incubation period. There was no apparent lag phase involved in these experiments presumably due to the pre-existing presence of peroxides that allowed the iron initiator to induce peroxidation immediately upon addition. The phospholipid that produced the greatest total level of LOOH was PtdCho 16:0/22:6. All other lipids produced similar levels of LOOH except for PtdEtn 18:2/18:2 that produced significantly lower total levels of LOOH. It should be noted that both PtdCho and PtdEtn 18:2/18:2 that both had significantly more peroxide at the start of the experiment did not produce more peroxide compared to the other phospholipids following the addition of the iron initiator (especially PtdCho and PtdEtn 16:0/18:2). Since total lipid peroxidation included both an autoperoxidation and an iron initiator component liposome peroxidation was measured either with or without iron initiator to distinguish between the two components.

The profile of autoperoxidation (shown in Fig. 3) was quite different from that found for total peroxidation (shown in Fig. 2). Autoperoxidation displayed an essentially linear profile of peroxide production for all phospholipids over the 3 h of measurement. Interestingly, the fastest rate of peroxidation was found in liposomes that contained 16:0/18:2 followed by phospholipids with 18:2/18:2 then either 16:0/22:6 or 22:6/22:6, irrespective of head group.

To determine the rate and overall level of liposome peroxidation induced by the iron initiator, autoperoxidation was subtracted from total peroxidation. The level of iron-induced peroxidation (shown in Fig. 4) shows increasing levels of LOOH production during the initial 1–2 h of incubation followed by a definite decline in production in the third hour. It was interesting that in preliminary experiments liposomes made using a liposome-maker (from Avanti Polar) tended not to peroxidise as readily as those produced by sonication suggesting that some initial peroxidation (i.e. peroxide production) was required to 'set-off' a continuous peroxidation process. The phospholipid with the highest rate of iron induced peroxidation was PtdCho 16:0/22:6. This phospholipid had significantly higher levels of peroxidation than for the other phospholipids measured. All other phospholipids displayed similar rates and levels of peroxidation (based on LOOH production) except for PtdEtn 18:2/18:2 that had a significantly

Fig. 1 Level of peroxide present at the various stages of liposome production. These include; **a** levels prior to sonication (i.e. at baseline), **b** levels produced during sonication, **c** levels present due to the addition of the iron initiator, and **d** total levels. *Non-identical letters indicate where preparations were different from one another at a significance level of $p < 0.05$. lower level of peroxidation, and after 3 h of incubation was displaying virtually no peroxidation as a result of the addition of the iron initiator (Fig. 4).

Discussion

There is no clear explanation as to why phospholipids of natural membranes have their PUFA normally coupled to either a SAT or a monounsaturated fatty acid with the pairing of PUFA on the same phospholipid, standing out as something unique and special [22]. This study examined the idea that these natural couplings are there to protect polyunsaturated fatty acids from themselves. That by coupling PUFA to SAT or MUFA the rate of peroxidation of the prone PUFA will be reduced by shrouding them in less peroxidisable fatty acids. In other words, SAT and MUFA hinder the ability of ($LO\cdot$) and ($LOO\cdot$) radicals formed from PUFA, from being able to come in contact with other PUFA and continue their peroxidative cascade. Some support for this idea is found in triglycerides where the peroxidisability of docosahexaenoic acid (22:6n-3) is less likely to occur when in the middle of the molecule (at the sn-2 position) and shrouded by saturates on both sides [24].

The results of the present study however did not support this idea that SAT/PUFA and PUFA/PUFA phospholipids (incorporated into liposomes at the same concentration) peroxidise at different rates. The results show that the peroxidation of phospholipids when matched for PUFA content but derived from different phospholipids with either single or double PUFA pairings overall peroxidise at similar rates and levels. This is at odds with the only other study that has measured peroxidation of phospholipids with SAT/PUFA and PUFA/PUFA pairings [26]. In this study Zerouga and colleagues found PtdCho's composed of 18:0/18:3, 18:0/22:6 and 22:6/22:6 incorporated into liposomes made primarily of PtdCho 18:0/18:1 had quite different levels of peroxidation. They [26] found PtdCho 18:0/22:6 peroxidised at twice the rate of PtdCho 22:6/22:6 and four times more than PtdCho 18:0/18:3, the opposite of that hypothesized and but similar to the present study in that the double PUFA phospholipids did not show increased levels of peroxidation compare to the SAT/PUFA phospholipids.

The Zerouga study [26] used a copper initiator (Cu_2SO_4/H_2O_2) similar to the iron initiator used in the present study. In their study peroxidation was determined by the formation of conjugated dienes in a Tris buffered solution. In our study we found the measurement of conjugated dienes to

Fig. 3 Autoperoxidation (incubated without the iron initiator) of liposomes composed of phosphatidylcholine and phosphatidylethanolamine lipid matched for total PUFA and SAT content but organised either as PUFA/PUFA or as SAT/PUFA pairs. *Non-identical letters indicate preparations different from one another at a significance level of $p < 0.05$. be less precise and that the addition of buffers (HEPES and phosphate) reduced overall peroxidation. This effect of buffers on reducing peroxidation has previously been noted [8, 9] and is why we avoided the use of buffers in the current experiments, alternatively allowing the system to settle at a final pH of ~ 4.4 with the added benefit of helping to maintain iron in its ferrous state.

Prior to performing these experiments we expected that the docosahexaenoic acid containing phospholipids would demonstrate a much higher level of peroxidation than those containing linoleic acid. This was based on the assumption that the level of peroxidation is related to the level of unsaturation, or more specifically to the peroxidation index. The 18:2 containing liposomes in theory have one-fifth of the peroxidative capacity of the 22:6 containing liposomes [5]. Yet peroxidation measured by the production of LOOH showed no major difference between the liposomes. For example, using a linear estimate for LOOH production rate (for the iron initiator component of lipid production) using the time point closest to time zero (i.e. at 10 min), the rate of LOOH production can be estimated as 4.27 ± 0.53 nmol LOOH/mg of PL per minute for the four 18:2 containing phospholipids and 4.81 ± 0.41 nmol

LOOH/mg of PL per minute for the 22:6 containing phospholipids (a non-significant difference).

These estimates for LOOH generation can be used to predict how much of the original PUFA may have been peroxidised over the 3 h of incubation. Using average molecular weights of 738 for 18:2 and 762 for 22:6 containing phospholipids it can be calculated that if these maximal rates continued over the entire 3 h of incubation then 0.774 and 0.864 μmol of LOOH would be produced from the 18:2 and 22:6 containing phospholipids, respectively. If one assumes that one LOOH is produced per PUFA fatty acid (which is theoretically accurate for 18:2 but less than that theoretically capable of being produced by 22:6) then 0.678 and 0.656 μmol of LOOH could be produced from the incubations containing the 18:2 and 22:6 phospholipids, respectively. So in theory most of the 18:2 is likely peroxidised over the 3 h of iron induced peroxidation whereas the 22:6 containing phospholipids would still have a reserve peroxidation capacity. This might account for some of the difference in the peroxidation profiles of the 18:2 and 22:6 containing phospholipids induced by the iron initiator (Fig. 4).

Fig. 4 Peroxidation due to the presence of the iron initiator ($10 \mu\text{M Fe}^{2+}/\text{H}_2\text{O}_2$) derived from total peroxidation minus autoperoxidation of liposomes composed of phosphatidylcholine and phosphatidylethanolamine lipid matched for total PUFA and SAT content but organised either as PUFA/PUFA or as SAT/PUFA pairs. *Non-identical letters indicate preparations different from one another at a significance level of $p < 0.05$. Error bars are SEM, $n = 6$*

The results of the present study imply that both 18:2 and 22:6 form similar amounts of LOOH product per fatty acid molecule rather than that predicted from their peroxidation indices. This is not a new observation. Visioli and colleagues [23] found the yield of peroxidation product from different fatty acids (over 3 h of peroxidation using AAPH—[2,2'-azo-bis(2-amidinopropane)dihydrochloride]) can vary. Visioli et al. found 18:2 produced more LOOH and more conjugated dienes than more highly polyunsaturated fatty acids such as 20:5, 20:4 and 22:6. Whereas they also found that the production of thiobarbituric acid-reacting substances was several fold greater for 22:6, 20:4 and 20:5 than for 18:2 (in our preliminary experiments we also found 18:2 did not produce appreciable amounts of malondialdehyde as measured using TBARS). The conclusion being that different fatty acids differentially contribute to the formation of peroxidation products and that this formation is not necessarily related to their peroxidation capacity. This conclusion may have important physiological implications based on the different roles of these products in organisms. Other studies have also found similar noncompliance [15] between peroxidation products from fatty acids in relationship to their peroxidation capacity.

One reason why 22:6 and 18:2 containing phospholipids might produce similar amounts of LOOH in the present study is that LOOH formed from the 22:6 containing phospholipids decompose at a faster rate than those formed from 18:2. It is interesting to note that the autoperoxidation of the 22:6 containing phospholipids was much lower than those containing 18:2 indicating the possibility of rapid disappearance (or alternatively low production). In fact the low activity of some of the phospholipids, notably PtdCho 22:6/22:6, promoted us to question if these phospholipids may have already peroxidised in storage (i.e. there was no PtdCho 22:6/22:6 left to peroxidise). To test this we analyzed all PtdCho phospholipids (PtdCho 16:0/18:2, PtdCho 18:2/18:2, PtdCho 16:0/22:6, PtdCho 22:6/22:6) using mass spectrometry and found each to contain a single product at the exact mass-to-charge ratio expected of the purified phospholipid. This suggested that the phospholipids had not peroxidised in storage and that the lower than expected rates of peroxidation were real. In the Visioli study [23] the high capacity of 18:2 to produce LOOH was matched by a rapid disappearance of 18:2 as measured using gas chromatography, with only 31% of original fatty acid remaining after 3 h versus 72% of 22:6 remaining

after the same period of peroxidation. Again this tends to support the idea that 18:2 has the capacity to produce high levels of LOOH relative to 22:6.

One of the interesting and unexpected results of the present study was the seemingly lower than expected peroxidation of the phosphatidylethanolamine lipids that contained double PUFA and also PtdCho 22:6/22:6. These phospholipids tended to have lower levels of peroxidation and lost their ability to continue to peroxidise over the 3 h. There are a number of possible explanations for this result. One possibility is that the phosphatidylethanolamines did not solubilize in the aqueous medium and therefore were simply less available in the liposomes (although the more soluble PtdCho 22:6/22:6 also showed a lower than expected peroxidation). Another possibility is that the 'smaller' head group of PtdEtn when combined with two large surface area occupying PUFA fatty acids (18:2/18:2 and 22:6/22:6) might produce molecules with a cone-shape that would tend to partition better into the increased curvature of the inner versus the outer leaflet of the liposome bilayer. This would make these molecules less available for peroxidation and lower their LOOH product formation. Similarly, the increased surface area of two 22:6 PUFA in PtdCho 22:6/22:6, even with its larger headgroup, might also favor its partitioning into the inner leaflet. It is well known that the charge on polar head groups, volume of the phospholipid, curvature of liposomes and molar ratios of phospholipids are all factors that can influence phospholipid distribution in liposomes [13, 14].

In conclusion, this study did not show the hypothesised increased peroxidation of PUFA/PUFA compare to SAT/PUFA phospholipids. The study found that 18:2 and 22:6 containing phospholipids do not produce LOOH in proportion to their peroxidation index. The study also showed that many of the PUFA/PUFA phospholipids seemed to have lower than expected rates of iron-induced peroxidation measured over 3 h, and it was hypothesized that one possible reason for this might be the partitioning of these molecules into the inner leaflet of the liposome bilayer.

Acknowledgments We would like to thank Prof Tony (A. J.) Hulbert and Assoc Prof Steven Blanksby for comments on the original manuscript, also Mr Colin Cortie for helping with some of the experimentation.

Abstract γ -Tocotrienol (γ -T3), a member of the vitamin E family, has been reported to possess an anticancer activity. γ -T3 is a lipophilic compound with low oral bioavailability. Previous studies showed that γ -T3 has low intestinal permeability. Thus, we have hypothesized that enhancing γ -T3 intestinal permeability will increase its oral bioavailability. Solid lipid nanoparticles (SLN) were tested as a model formulation to enhance γ -T3 permeability and bioavailability. γ -T3 intestinal permeability was compared using in situ rat intestinal perfusion, followed by in vivo relative oral bioavailability studies. In addition, in vitro cellular uptake of γ -T3 from SLN was compared to mixed micelles (MM) in a time and concentration-dependent studies. To elucidate the uptake mechanism(s) of γ -T3 from SLN and MM the contribution of NPC1L1 carrier-mediated uptake, endocytosis and passive permeability were investigated. In situ studies demonstrated SLN has tenfold higher permeability than MM. Subsequent in vivo studies showed γ -T3 relative oral bioavailability from SLN is threefold higher. Consistent with in situ results, in vitro concentration dependent studies revealed γ -T3 uptake from SLN was twofold higher than MM. In vitro mechanistic characterization showed that while endocytosis contributes to γ -T3 uptake from both formulations, the reduced contribution of NPC1L1 to the transport of γ -T3, and passive diffusion enhancement of γ -T3 are primary explanations for its enhanced uptake from SLN. In conclusion, SLN

successfully enhanced γ -T3 oral bioavailability subsequent to enhanced passive permeability.

Introduction

γ -Tocotrienol (γ -T3) is a natural form of vitamin E with potential anticancer activity in breast cancer [1–3]. Unfortunately the oral bioavailability of γ -T3 is low [4, 5]. In humans, the absolute bioavailability has not been determined, however in rats γ -T3 oral bioavailability has been found to be as low as 9% [5]. γ -T3 is an oily liquid that is poorly soluble in aqueous solutions [6]. Due to poor aqueous solubility and miscibility, its oral bioavailability can be poor and erratic. As a result, many formulation approaches have been used to enhance its bioavailability by increasing its dissolution including lipid-based formulations, self-emulsifying drug delivery systems (SEDDS), emulsions, and oil solutions [5–8]. However, recent in situ permeability studies in our laboratory have revealed that in addition to the low solubility, γ -T3 intestinal permeability is also low [9]. The results of these studies have demonstrated the intestinal absorption of γ -T3 is a concentration-dependent and saturable process, that is mediated by the

transporter Niemann-Pick C1-like 1 (NPC1L1) [9]. Thus, when therapeutic γ -T3 is administered at doses that saturate its own uptake by NPC1L1, γ -T3 oral bioavailability is expected to decrease. To overcome such limitation, it is anticipated that increasing the permeability of γ -T3 using new formulation approaches or structural modifications will enhance its permeability, thus its oral bioavailability.

One of the most promising strategies to increase the absorption is the encapsulation of the drug in a nano-scale delivery system which will facilitate the drug permeability across the intestinal barrier [10, 11]. In this case, bioavailability is not dependent on the physicochemical properties of the drug, but on the properties of the nano-carrier [12–14]. Solid lipid nanoparticles (SLN), a type of submicron particulate drug delivery system, are regarded as an alternative carrier to traditional colloidal systems such as emulsions, liposomes, polymeric microparticles and nanoparticles [15–17]. The natural or artificial synthetic solid lipids are used as carriers with the drug enveloped or dispersed inside the particles to obtain the solid colloidal particles. The particle diameters are in the range of approximately 10–1,000 nm [18]. The advantages of the system include high biocompatibility, high bioavailability, and no problems with multiple routes of administration such as oral, intravenous, pulmonary and transdermal routes [17, 19–22]. Sufficient data implicate the bioavailability of poorly hydrophilic and lipophilic drugs can be improved when these drugs are encapsulated in SLN [10, 19, 23–25]. For example, Nitrendipine, an antihypertensive drug, is a lipophilic drug with poor oral bioavailability ranging from 10 to 20%. When this compound was loaded into SLN and given to rats by intraduodenal administration, the bioavailability of Nitrendipine increased by three- to fourfold compared to that of a Nitrendipine suspension [26]. Following oral administration, nanoparticles have to cross the gastrointestinal barrier either by passive diffusion or by active processes mediated by membrane-bound carriers or membrane-derived vesicles [27].

Recently, SLN has been used in the formulation of γ -T3 [28, 29], however the effect of γ -T3 encapsulation in SLN on its oral bioavailability have not been investigated. γ -T3 is usually administered as an oily solution or in micelle systems [5, 8]. After administration, it will be subjected to digestion and dissolution to form mixed micelles. Mixed micelles (MM) are the end product of intestinal digestion that is most readily available for absorption [30]. In this article the potential of SLN as oral delivery system for γ -T3 will first be illustrated by comparing its intestinal permeability to that from MM utilizing in situ rat intestinal perfusion studies, and relative oral bioavailability of γ -T3; MM preparation was used in the comparative bioavailability and permeability studies to rule out the effect of dissolution rate on γ -T3 absorption process. Then, the

mechanisms of uptake of γ -T3 from both formulations will be demonstrated by elucidating the contribution of carrier-mediated transport by NPC1L1, endocytosis, and passive diffusion to the enhanced uptake of SLN. To address the mechanism of cellular uptake and monitor experimental parameters, in vitro studies utilizing HepG2 cells as a model cell line was chosen. HepG2 cells are human derived hepatocytes with remarkable endogenous expression of NPC1L1 transporter [31].

Materials and Methods

Materials

γ -T3 was provided by First Tech International Co., Ltd. (Hong Kong). Ezetimibe was kindly donated by Schering-Plough Corporation (NJ, USA). Cholesterol and γ -tocopherol were obtained from Sigma (St. Louis, MO). Sodium taurocholate and phosphatidylcholine were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). [1,2- 14 C]-PEG4000 (polyethylene glycol 4000, Specific activity 0.75 mCi g $^{-1}$) was purchased from American Radiolabeled Chemicals, Inc. (St. Louis, MO). Unlabeled PEG4000 was purchased from Spectrum Chemical (Gardena, CA). Supplies for cell culture were obtained from American Type Cell Culture Collection (ATCC; Manassas, VA). Chlorpromazine was purchased from Sigma. Lutrol $^{\circledR}$ F62 (poloxamar 188) and compritol ATO were obtained from BASF (Floham Park, NJ). Other chemicals and reagents were obtained from VWR Scientific (West Chester, PA).

Animals

Male Sprague–Dawley rats weighing 260–320 g were acquired from Harlan Laboratories (Houston, TX). All animal experiments were approved by the Institutional Animal Care and Use Committee of the University of Louisiana at Monroe and all surgical and treatment procedures were consistent with the IACUC policies and procedures. Rats were maintained on a 12 h light/dark cycle before the study and were fasted 12–16 h with water ad libitum prior to each experiment.

Formulation of SLN and MM

γ -T3-loaded SLN were prepared as previously described [29]. SLN were manufactured by hot oil/water micro-emulsion using a high shear homogenization technique. In brief, γ -T3, lutrol, and compritol ATO (w/w of the final aqueous dispersion) lipid phase was first prepared by melting compritol ATO at 80 °C to which 0.2% (w/w) γ -T3 was added to form the homogeneous oil phase. In a

separate vial, a 0.2% (w/w) lutrol solution was prepared by dissolving the surfactant in deionized water. The solution was heated to the same temperature as the oil phase. The hot aqueous surfactant solution was then added to the molten lipid phase to form the premix that was further homogenized at 20,000 rpm for 5 min using IKA® Ultra-Turrax T8 mixer (IKA® Work inc., NC, USA). The formed hot pre-emulsion was then ultrasonicated at 60% pulsar rate for 10 min using an ultra sonic probe homogenizer (Biologics, Inc., VA). Nanoparticles were subsequently formed by cooling the sonicated nano-emulsion overnight at 4 °C. Intensity-weighted mean particle size and population distribution (polydispersity index, PI) of the emulsion were measured by photon correlation spectroscopy (PCS) at 23 °C and a fixed angle of 90° using Nicomp™ 380 ZLS submicron particle size analyzer (PSS Inc, Santa Barbara, CA). SLN average particle size was 105 nm ($n = 3$ preparations), with polydispersity index (PI) value of 0.134 ± 0.007 .

Mixed micelles were prepared as previously described [32]. γ -T3 diluted in methanol, phosphatidylcholine diluted in methanol, taurocholate diluted in 96% ethanol, and mono- and diglycerides (oleic acid and Capmul dissolved in methanol) were mixed, then evaporated to dryness with mild heating under nitrogen gas. A transport buffer (141 mM NaCl, 4 mM KCl, 1 mM MgSO₄, 10 mM HEPES, 10 mM glucose, and 2.8 mM CaCl₂ adjusted to pH 7.4) was then added to prepare the medium for transport experiments. Final concentrations were: taurocholate 5 μ M, phosphatidylcholine 10 μ M, oleic acid 100 μ M, mono- and diglycerides 300 μ M, and the required γ -T3 concentration in each experiment. The micellar solution was thoroughly vortexed and stirred at 37 °C for 30 min.

In Vitro Studies

Cell Culture

HepG2 cells were cultured in RPMI-1640 supplemented with 10% fetal bovine serum (FBS) and 2.5% antibiotics (penicillin and streptomycin) in a humidified incubator with 5% CO₂ at 37 °C. Cells were plated on 75 cm² flask at a density of 1×10^6 cells/flask and were then harvested at 80% confluence with trypsin–EDTA. Cells were seeded onto a 48-well plate at a density of 50,000 cells/well. When confluent, uptake studies were performed as described below. All experiments were conducted in triplicate.

Time Dependent Studies

On the day of the experiment, SLN and MM were diluted in transport buffer to prepare 2 μ M final concentration of

γ -T3. The media in the incubated plates was discarded, and cells were washed once with warm transport buffer before addition of SLN or MM for 0, 5, 10, 20, 30, 40, 60, 120 min. At the end of the incubation time cells were washed two times with ice cold PBS and lysed with 200 μ l lysis buffer for 2 h before analysis by LC–MS.

Concentration Dependent Studies

Solid lipid nanoparticles and MM were diluted in transport buffer to prepare different concentrations ranging from 1 to 200 μ M. Two hundred microliters from each concentration of SLN and MM were incubated for 60 min. At the end of the experiment, cells were washed twice with ice cold PBS and lysed with 200 μ l lysis buffer for 2 h before analysis by LC–MS.

NPC1L1 Inhibition Studies

To compare the effect of formulation on the carrier-mediated uptake of γ -T3 by NPC1L1, inhibition studies of NPC1L1 by ezetimibe (selective inhibitor of NPC1L1) were performed [9, 33–36]. After washing the cells with warm transport buffer, cells were pre-incubated with rising concentration of ezetimibe at 0, 1, 5, 10, 25, and 50 μ M for 30 min. Cells were then incubated with 4 μ M of γ -T3 prepared as SLN or MM for 60 min with increasing concentration of ezetimibe. After washing with ice cold PBS, cells were lysed with 200 μ l lysis buffer before analysis by LC–MS.

Endocytosis Inhibition Studies

To investigate the contribution of endocytosis to the uptake of SLN and MM, cellular uptake experiment were conducted with and without chlorpromazine (endocytosis inhibitor) [37]. γ -T3, at 5 and 10 μ M, as MM and SLN were prepared. The cells were pre-incubated for 30 min with 0, 25, 50, and 100 μ M of chlorpromazine dissolved in transport buffer, then γ -T3 prepared as SLN or MM was added for 60 min. At the end of the experiments cells were washed and lysed as mentioned above before analysis by LC–MS.

Cellular Uptake Study at 4 °C

At 4 °C, active transport including pinocytic/endocytic uptake of drugs is usually not functioning [38, 39]. Thus, 4 °C experiments will account for passive uptake of SLN and MM. On the day of the experiment, confluent cells were washed and incubated with rising γ -T3 concentrations prepared as SLN or MM as described above in the concentration dependent study; however incubations were conducted at 4 °C. After 60 min incubation, cells were washed, lysed and analyzed by LC–MS.

LC–MS Analysis of γ -T3 in Cellular Uptake Studies

Cell lysates (75 μ l) were mixed with similar volume of acetonitrile in eppendorf tubes and vortex mixed for 30 s. Samples were then centrifuged for 10 min at 10,000g. From the collected supernatant 10 μ l were injected onto the LC–MS system. The chromatographic separation was performed on a 250 \times 4.6 mm Luna 5 μ PFP column (Phenomenex, Torrance, CA) using an Agilent 1100 series LC system (Santa Clara, CA), and 3200 Qtrap LC/MS/MS system (Applied Biosystems, Foster City, CA). The mobile phase consisted of methanol, ethanol and acetonitrile (40:30:30, v/v/v) delivered at 1.0 ml min⁻¹ flow rate with the addition of 0.05% acetic acid. γ -T3 was detected by MS using electrospray ionization (ESI) interface operated in positive mode. γ -T3 was then detected and quantified by MS/MS using multiple-reaction monitoring (MRM) method. The transition (precursor > product) used for quantification was 411 > 151. Protein concentration of the lysate was determined by a BCA kit (Thermo scientific, Rockford, IL). Final samples concentrations were expressed as μ g mg⁻¹ protein.

In Situ Perfusion Studies

In situ rat intestinal perfusion studies were conducted to investigate the difference in the intestinal permeability of γ -T3 loaded in SLN or MM. This experiment was conducted as previously described [9, 40]. In brief, following overnight fasting, rats were anesthetized. The small intestine was then exposed by midline incision and approximately 15 cm of upper jejunum (proximal to the duodenum) was externalized. The isolated segment was flushed with warm normal saline to remove intestinal contents and cannulated with glass cannulas inserted at the inlet and the outlet of the segment. The inlet tubing was connected to a syringe that was placed in an infusion pump. The perfusate was pumped through the lumen at 0.05 ml min⁻¹ flow rate. The perfusate solution consisted of 1 μ M γ -T3 prepared as SLN or MM. [¹⁴C]-PEG4000 (0.02 μ Ci ml⁻¹) with 0.1% cold PEG4000 was added to the perfusate solution as a marker for water secretion or absorption. The perfusate was collected in vials at 20 min intervals for 100 min after 40 min stabilization period. Samples were kept at 4 °C till analysis by HPLC. Effective permeability of γ -T3 from SLN and MM preparations was calculated based on γ -T3 loss from the perfusate according to the equation:

$$P_{\text{eff}} = \frac{-Q \times \ln(C_i/C_0)}{2\pi rL}$$

where Q is the perfusate flow rate through the segment (0.05 ml min⁻¹), r is the radius of the intestinal lumen (0.2 cm), L is the length of the perfused segment (15 cm), C_0 is γ -T3 concentration at the start of perfusion (from the

entry tubing), and C_i is the steady state of γ -T3 concentration exiting the perfused intestinal segment.

In Vivo Relative Bioavailability Experiments

After 12 h fasting, rats were orally gavaged with 10 mg kg⁻¹ γ -T3 prepared as SLN or MM. Rats were anesthetized with intraperitoneal injection of 1.0 g kg⁻¹ urethane dissolved in normal saline. Blood samples were withdrawn from the femoral vein at 1, 2, 3, 4, 5, 6, 8, 10, 12 h. Blood samples were collected in heparinized eppendorf tubes. Samples were then centrifuged at 10,000 rpm for 10 min to separate the plasma. Plasma samples were kept at -20 °C until analysis with HPLC. Following analysis, plasma levels versus time profiles were plotted and fitted using PK-Plus module in GastroplusTM (Simulation Plus, Inc CA). Pharmacokinetic parameters were calculated using non-compartmental analysis.

HPLC Analysis of Intestinal Perfusate and Plasma Samples

Quantification of γ -T3, in the intestinal perfusate was achieved by an isocratic Prominence Shimadzu HPLC system (Columbia, MD) as previously described with some modifications [9, 41]. In brief, perfusate samples were diluted with acetonitrile (1:10 v/v) before injection of 20 μ l into the HPLC. For the extraction of γ -T3 from plasma, 50 μ l plasma and 50 μ l ethanol containing 1% ascorbic acid and 1 μ g ml⁻¹ δ -tocopherol (internal standard) were added in a glass tube and vortex mixed, followed by the addition 1 ml hexane. The mixture was vortex-mixed for 90 s before centrifugation for 10 min at 5,000g. Eight hundred microliters of the supernatant were then transferred to another glass tube and evaporated to dryness by a centrifugal evaporator (Centrivap concentrator, Kansas City, MO, USA) followed by reconstitution with 100 μ l mobile phase before 20 μ l injection onto the HPLC column. The system consisted of SIL 20-AHT autosampler, and LC-20AB pump connected to a DGU-20A3 degasser. Data acquisition was achieved by Shimadzu LC Solution software version 1.22 SP1. The separation was performed at room temperature on an Agilent eclipse XDB-C18 column (5 μ m, 150 \times 4.6 mm id; Agilent Technologies Inc., CA, USA). The mobile phase used for the separation of γ -T3 in perfusate and plasma samples consisted of methanol, ethanol and acetonitrile (85:7.5:7.5, v/v/v) delivered at 1.0 ml min⁻¹ flow rate. UV detection of γ -T3 in perfusate samples was carried out at a wavelength of 210 nm (Shimadzu SPD-20A UV/VIS), while γ -T3 in plasma was detected by fluorescence detection (Shimadzu, RF10A XL) set at 298 nm excitation and 325 nm emission.

Statistical Analysis

Results were expressed as means \pm SEM. Jump[®] software was used to conduct the statistical analysis. A Student's *t* test for the in situ studies, or ANOVA and a *t* test for the endocytosis and NPC1L1 inhibition studies were used for statistical comparison. $p < 0.05$ was considered statistically significant. All animal studies were performed at $n = 3$ per experiment per formulation.

Results

In Situ Perfusion Studies

Results from the in situ perfusion studies revealed that the permeability of γ -T3 prepared as SLN was significantly higher than that from MM. The permeability of γ -T3 delivered as SLN was $9.42 \times 10^{-5} \pm 2.3 \times 10^{-5} \text{ cm s}^{-1}$ while its permeability from MM was $0.9 \times 10^{-5} \pm 0.29 \times 10^{-5} \text{ cm s}^{-1}$ which is approximately tenfold lower than SLN formulation. Results of the in situ perfusion experiments are presented in Fig. 1.

Relative Oral Bioavailability Studies

Following oral administration of a single 10 mg kg^{-1} γ -T3 dose as SLN or MM to fasted rats, γ -T3 plasma concentrations were calculated and plotted versus time (Fig. 2). Peak concentration (C_{max}) and time of peak concentration (T_{max}) were obtained directly from individual plasma concentration–time profile of each rat. The area under the concentration–time curve from time zero to time *t* (AUC_{0-t}) was calculated using the trapezoidal method. The relative bioavailability (F_{rel}) of γ -T3 from SLN compared to MM was calculated using the following equation: $F_{\text{rel}} = (\text{AUC}_{0-t}(\text{SLN})/\text{AUC}_{0-t}(\text{MM})) \times 100\%$.

Fig. 1 Effective permeability (P_{eff}) of γ -T3 delivered as SLN or MM using in situ intestinal perfusion ($n = 3$ each). Each value represents the mean \pm SEM ($p < 0.05$)

The AUC of γ -T3 following SLN administration was $12.1 \pm 5.7 \mu\text{g-h ml}^{-1}$ compared to its AUC from MM $3.9 \pm 0.7 \mu\text{g-h ml}^{-1}$ which is approximately threefold lower than SLN ($F_{\text{rel}} = 310\%$). The oral pharmacokinetic parameters of γ -T3 following both formulations are listed in Table 1. As illustrated in Fig. 2 plasma concentration of γ -T3 at all time points are significantly higher for rats administered with SLN formulation compared to MM ($p < 0.05$). The C_{max} value for γ -T3 from SLN was $938 \pm 63 \text{ ng ml}^{-1}$ compared to $212 \pm 111 \text{ ng ml}^{-1}$ from MM. These results demonstrate that incorporation of γ -T3 into SLN significantly increased its absorption thus bioavailability following oral administration.

In Vitro Uptake Studies

Comparative effects of incubation time (5–120 min) on cellular uptake of γ -T3 presented as SLN or MM is shown in Fig. 3a. Results showed significantly preferential and higher uptake of γ -T3 from SLN compared to MM at all examined time points. Comparison of the effect of

Fig. 2 Plasma concentrations (ng ml^{-1}) versus time (h) profiles of γ -T3 following oral administration of 10 mg kg^{-1} dose of γ -T3 loaded in SLN or MM. Each value represents the mean \pm SEM ($n = 3$)

Table 1 Comparative pharmacokinetic parameters of γ -T3 oral absorption when delivered in SLN or MM following 10 mg kg^{-1} oral administration to rats

| Parameter | SLN | MM |
|--|----------------|-----------------|
| AUC ($\mu\text{g ml}^{-1} \text{ h}$) | 12.1 ± 5.7 | 3.9 ± 0.7 |

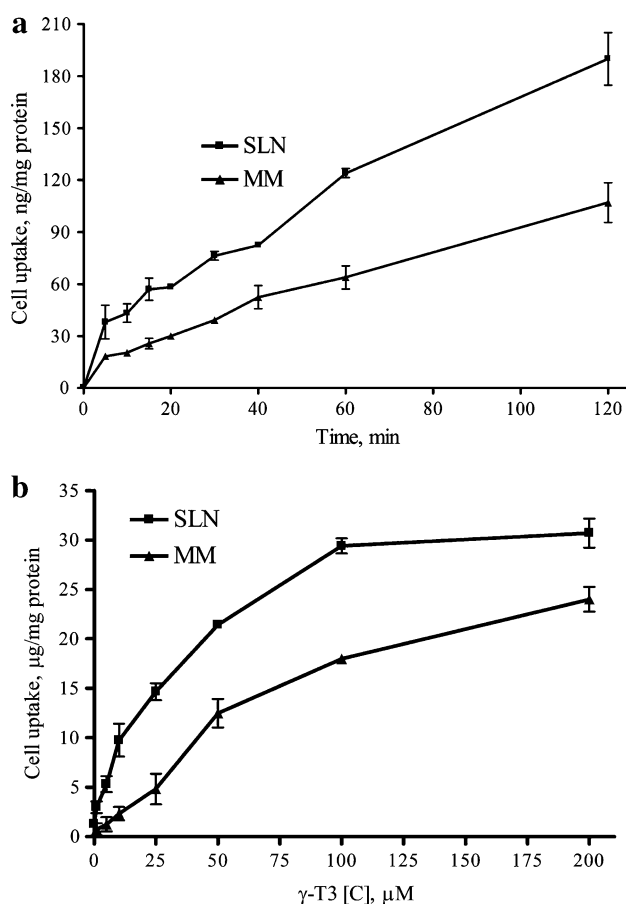

Fig. 3 Comparative effects of **a** incubation time on cellular uptake of 2 μM γ-T3 delivered as SLN or MM, and **b** various concentrations of γ-T3-loaded SLN or MM on γ-T3 cellular uptake following treatment for 60 min. Each value represents the mean ± SD from three independent experiments

incubated concentrations of γ-T3-loaded SLN or MM on the cellular uptake following 60 min of treatment is presented in Fig. 3b. For practicality reasons, including sensitivity and less variability, incubation with γ-T3 delivered as SLN or MM for 60 min was selected. Results of this experiment revealed a significantly higher concentration dependent uptake of SLN in comparison to MM after 60 min incubation at 37 °C. The results from ezetimibe inhibition studies of γ-T3 uptake mediated by NPC1L1 are shown in Fig. 4 and demonstrated a dose-dependent decrease in the uptake of γ-T3 after incubation with different ezetimibe concentrations for both SLN and MM. However, while the uptake of γ-T3 prepared as SLN is higher than that from MM, the percent decrease in the uptake of γ-T3 prepared as MM is more than that from SLN ($p < 0.05$). Maximum inhibition of γ-T3 uptake was achieved at ezetimibe concentrations ≥ 10 μM for both preparations.

The effect of endocytosis inhibition by chlorpromazine on γ-T3 uptake prepared as SLN and MM was also

Fig. 4 Effects of NPC1L1 inhibition by ezetimibe on carrier-mediated uptake of 4 μM γ-T3 delivered as SLN or MM. Results of this experiment are presented as relative uptake to control (absence of ezetimibe) from three independent experiments. Each value represents the mean ± SD. Asterisk indicates significantly different from control (absence of ezetimibe), and hash symbol indicates significantly different from SLN, $p < 0.05$

investigated and the results are illustrated in Fig. 5. The results of this experiment revealed that at the two concentrations examined for γ-T3 (5 and 10 μM) both SLN and MM were responding to endocytosis inhibition; however the decrease in the uptake of γ-T3 from both preparations was similar and low (approximately 25% reduction), but statistically significant (Fig. 5).

It is assumed that at the temperature 4 °C, active carrier-mediated transport and pinocytotic/endocytic uptake of molecules are usually hampered [38, 39]. Thus, studies conducted at 4 °C account for passive uptake of γ-T3

Fig. 5 The effect of endocytosis inhibition by chlorpromazine on the uptake of γ-T3 delivered as SLN or MM at 10 μM concentration following treatment for 60 min. Results of this experiment are presented as relative uptake to control (absence of chlorpromazine) from three independent experiments. Each value represents the mean ± SD. * Significantly different from control (absence of chlorpromazine), $p < 0.05$

Fig. 6 Concentration dependent uptake studies of γ -T3 delivered as SLN or MM at 37 and 4 °C following treatment for 60 min. Each value represents the mean \pm SD from three independent experiments

loaded in SLN and MM. Comparison of the concentration dependent uptake of γ -T3 at 4 °C and at 37 °C from SLN and MM is presented in Fig. 6. At 4 °C the uptake of γ -T3 delivered as SLN while reduced remains significantly higher than that for MM ($p < 0.05$). In addition, cellular uptake of γ -T3 loaded in SLN and MM at 4 °C was significantly lower than its cellular uptake at 37 °C.

Discussion

The results of this study demonstrated that intestinal permeability and oral absorption of γ -T3 are significantly enhanced when packaged in SLN delivery system compared to MM.

The in situ rat intestinal perfusion model represents an excellent technique to investigate drugs intestinal absorption because it is the closest system to the in vivo physiological conditions. Furthermore, the presence of intact mucosa and drug transporters (e.g. NPC1L1) would accurately predict the in vivo intestinal absorption process. In a previous in situ rat intestinal perfusion study we have demonstrated that the intestinal absorption of γ -T3 is a saturable, dose dependent process and mediated by NPC1L1 [9]. In addition to γ -T3 low solubility, this saturable absorption process by NPC1L1 is believed to contributing to γ -T3 low intestinal permeability thus bioavailability when given in amounts that are higher than NPC1L1 transport capacity.

In the current study, the intestinal permeability and bioavailability of γ -T3 packaged in SLN delivery system were compared to MM preparation. Results from the in situ perfusion studies of γ -T3 demonstrated higher uptake of γ -T3 delivered as SLN compared to MM. This tenfold difference in the permeability of SLN ($9.4 \times 10^{-5} \pm 2.3 \times 10^{-5} \text{ cm s}^{-1}$)

compared to MM ($0.9 \times 10^{-5} \pm 0.29 \times 10^{-5} \text{ cm s}^{-1}$) enhanced the oral bioavailability of γ -T3 administered as SLN by threefold. The above findings confirmed that enhancing γ -T3 intestinal permeability improves its oral bioavailability.

Consistent with in situ studies findings, in vitro HepG2 cellular uptake studies showed significantly higher uptake of γ -T3 delivered as SLN in comparison to MM. HepG2 cell line, derived from hepatocellular liver carcinoma cells, is a pharmacologically validated system for NPC1L1-mediated cholesterol uptake due to its significant endogenous expression of NPC1L1 compared to Caco-2 (derived from human epithelial colorectal adenocarcinoma cells) cell line [42]. Thus, in the current study HepG2 cells were utilized to further investigate the mechanism of enhanced γ -T3 uptake and the contribution of NPC1L1 to γ -T3 carrier-mediated uptake from SLN and MM preparations. The time-dependent studies of 2 μM γ -T3 delivered as SLN or MM showed a time-dependent preferential cellular uptake of γ -T3 from SLN (Fig. 3a). In addition, concentration dependent studies for 60 min with SLN or MM containing γ -T3 in the range of 1–200 μM demonstrated a significantly higher cellular uptake of γ -T3 from SLN compared to MM (Fig. 3b). These findings confirm that γ -T3 administered as SLN would have greater intestinal absorption following oral administration.

To explain the enhanced intestinal permeability and cellular uptake of γ -T3 delivered as SLN compared to MM, in vitro mechanistic studies were performed including NPC1L1 carrier-mediated uptake, endocytosis, and passive uptake. Contribution of the carrier-mediated uptake of γ -T3 by NPC1L1 was investigated by treating cells with γ -T3 loaded as SLN or MM with rising concentrations of ezetimibe. Results were expressed as relative uptake of γ -T3 in reference to control (absence of ezetimibe). The results revealed the uptake of γ -T3 loaded in MM was more sensitive to NPC1L1 inhibition by ezetimibe compared to SLN. This was attributed to the fact that γ -T3 delivered as SLN did not efficiently expose γ -T3 to NPC1L1 as it will be impeded inside the SLN matrix (Fig. 4) [29]. As a result, only γ -T3 available on the surface of SLN or released in the media will be exposed to transport by NPC1L1. These findings, thus, demonstrate that the enhanced intracellular uptake of γ -T3 was not attributed to NPC1L1 mediated uptake. On the other hand, the results indicate the important role of NPC1L1 to the cellular uptake of γ -T3 where NPC1L1 inhibition by ezetimibe reduced γ -T3 intracellular levels approximately by 80% for MM and 40% for SLN.

Endocytosis is another proposed mechanism of the uptake of SLN and similar colloidal systems. To investigate the role of endocytosis in the enhanced uptake of SLN, endocytosis inhibition studies with chlorpromazine were conducted. Chlorpromazine is an inhibitor of the clathrin

dependent endocytosis (CDE) pathway. It works by inhibiting clathrin-coated pit formation by a reversible translocation of clathrin and its adapter proteins from the plasma membrane to intracellular vesicles [43]. CDE is the best-characterized endocytic pathway and is believed to be the preferred pathway for microspheres up to 200 nm in size [44]. Thus, in this work it has been considered for evaluation. The inhibition of endocytosis resulted in approximately 25% reduction in γ -T3 uptake from both SLN and MM (Fig. 5). This data revealed that the contribution of endocytosis of both formulations was the same and does not explain the higher uptake of γ -T3 delivered as SLN. While γ -T3 uptake reduction by chlorpromazine does not completely rule out enhanced endocytosis of SLN, for example by clathrin independent pathway, consequent experiments at 4 °C demonstrated an alternative mechanism for the enhanced uptake. Several reports demonstrated cell membrane penetration at 4 °C is related to passive processes [38]. When cells were treated with different concentrations of γ -T3 loaded as SLN or MM and incubated at 4 °C for 60 min, the uptake of γ -T3 from both formulations was reduced. However, the uptake of γ -T3 delivered as SLN remained to be significantly higher than that from MM (Fig. 6), most probably because of the enhanced passive diffusion. SLN surfactants and excipients possibly caused an increase in γ -T3 passive permeability. This assumption was supported by a separate experiment where cells were treated with γ -T3-free SLN (empty vehicle) and γ -T3. The results showed that the cellular uptake of γ -T3 in the presence of SLN vehicle was significantly higher than γ -T3 alone. For example, the addition of SLN vehicle to different concentrations of γ -T3 at 5 and 10 μ M, γ -T3 intracellular level increased from 1.1 ± 0.6 and $1.4 \pm 0.7 \mu\text{g mg}^{-1}$ protein for cells treated with γ -T3 alone, respectively, to 3.4 ± 0.08 and $5.7 \pm 0.04 \mu\text{g mg}^{-1}$ protein for cells treated with γ -T3 and SLN vehicle, respectively. Thus, such data demonstrate that presence of SLN excipients enhanced γ -T3 cellular uptake by approximately fourfold. Furthermore, the data obtained from γ -T3 in the presence of SLN vehicle were comparable to those obtained from γ -T3-loaded SLN at 5 and 10 μ M concentrations and were 3.5 ± 0.03 and $5.3 \pm 0.14 \mu\text{g mg}^{-1}$ protein, respectively.

Collectively, the above results suggest that γ -T3 packaged in SLN delivery system enhanced γ -T3 intestinal permeability and bioavailability by enhancing the passive permeability of γ -T3, and by reducing the contribution of NPC1L1 to the carrier-mediated transport of γ -T3 compared to MM, thus NPC1L1 saturation will occur at higher load of γ -T3 delivered as SLN compared to MM.

In conclusion, at 10 mg kg⁻¹ dose SLN successfully enhanced the oral bioavailability of γ -T3 in comparison to MM. In vitro and in situ studies revealed that the enhanced

bioavailability is mostly related to the enhancement of absorption and permeation across the intestine. Subsequent in vitro uptake studies suggested that enhanced bioavailability of γ -T3 from SLN is primarily a result of its enhanced passive permeability and the reduced contribution of NPC1L1 to the transport of γ -T3.

Abstract Tocotrienol (T3) is an important phytonutrient found in rice bran and palm oil. T3 has gained much interest for lipid lowering effects, especially for cholesterol (Cho) by inhibiting 3-hydroxy-3-methylglutaryl-coenzyme A reductase. Also, usefulness of T3 in improving triglyceride (TG) profiles has been suggested, but its efficacy and mechanism have been unclear. We investigated how T3 decreases TG concentration in cultured cells and animals. In a cell culture study, human hepatoma cells (HepG2) were incubated in a control or a fat (1 mM oleic acid)-loaded medium containing γ -T3 for 24 h. We found that 10–15 μ M γ -T3 inhibited cellular TG accumulation significantly, especially in the fat-loaded medium. This manifestation was supported by mRNA and protein expressions of fatty acid synthase, carnitine palmitoyltransferase 1, and cytochrome P450 3A4. In concordance with these results, rice bran T3 supplementation to F344 rats (5 or 10 mg T3/day/rat) receiving a high fat diet for 3 weeks significantly reduced TG and the oxidative stress marker (phospholipid hydroperoxides, PLOOH) in the liver and blood plasma. T3 supplementation did not show changes in the Cho level. These results provided new information and the mechanism of the TG-lowering effect of T3. The lipid lowering effects of dietary T3 might be mediated by the reduction of TG synthesis.

Introduction

In 1922, tocopherol (Toc) was discovered in green leafy vegetables as a micronutrient essential for reproduction [1]. More than 40 years later, tocotrienol (T3) was isolated from latex [2]. Structurally, vitamin E substances differ only in their side chains (Fig. 1). Toc has saturated phytol

side chain, while T3 contains unsaturated isoprenoid tail. To date, eight substances have been found in nature as vitamin E: α -, β -, γ -, and δ -Toc and α -, β -, γ -, and δ -T3. Vitamin E is synthesized in the plastids of plants, and Toc is widely present in a variety of foods such as vegetable oils and nuts. But, T3-containing foods are limited. Rice bran, palm oil, and annatto seed are rich in T3 [3].

Tocopherol and T3 are classified based on their ability (vitamin E activity) to prevent the resorption of rat fetuses. α -Toc displays the highest efficacy among the eight vitamin E substances, whereas α -T3 has about one-third of the activity of α -Toc. Regardless, all forms of vitamin E are able to induce antioxidative effects and to act as protective agents against lipid peroxidation in biological membranes. In some model membrane studies, T3 has been reported to be a more potent antioxidant than Toc [4]. Moreover, T3 has recently gained increasing interest due to its several health-promoting properties that differ somewhat from those of Toc. For example, T3 protects neuronal cells against oxidative damage [5], and suppresses pathological angiogenesis [6, 7] and cancer [8]. These unique effects of T3 could be partly explained by its abilities to induce cell cycle arrest [9], to activate p53 and caspase [10, 11], to suppress adhesion molecules [12], to inhibit nuclear factor- κ B [13], and to down-regulate c-Myc and telomerase [14].

Besides the above activities [5–14], T3 has also gained much attention for its lipid-lowering properties, especially the reduction of cholesterol (Cho). The Cho-lowering effects have been observed in cell culture [15–17], animal [18–21], and human studies [22], and the mechanism may involve a repression of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A reductase through a post-transcriptional process [15, 16]. However, it should be noted that several research groups failed to observe significant changes in serum Cho profiles after supplementation of T3 to hypercholesterolemic patients [23–25] and hyperlipidemic patients with carotid atherosclerosis [26]. Therefore, the effect of T3 on Cho is still controversial and needs further studies.

On the other hand, although little attention has been paid to whether T3 affects other lipids apart from Cho, some earlier studies have suggested a usefulness of T3 in improving triglyceride (TG) profiles. For instance, T3 supplementation has been reported to decrease serum TG levels in healthy human [27] and hypercholesterolemic patients [28]. In support of these results, Zaiden et al. [29] recently reported the ability of T3 to reduce TG biosynthesis in human hepatoma cells (HepG2). Therefore, these studies [27–29] raise a novel possibility that reduction of TG may be a primary role for the lipid-lowering properties of T3. However, because there are few reports in the literature that have evaluated the impact of T3 on TG at gene expression levels, further biological studies are needed to elucidate the mechanism(s) how T3 decreases TG.

In this study, we aimed to investigate how γ -T3 (most abundant isomer of rice bran T3, RBT3) suppresses TG levels by affecting TG-related gene expressions in a control (normal) and a fat (oleic acid) loaded HepG2. In rats fed a high fat diet, the TG-lowering properties of RBT3 was further evaluated, and compared with the Cho-lowering activity. We confirmed that T3 attenuates TG accumulation by regulating fatty acid synthase (FASN), carnitine palmitoyltransferase 1 (CPT1A), and cytochrome P450 3A4 (CYP3A4) genes and protein expression.

Materials and Methods

Reagents and Cells

α -T3 and γ -T3 were purchased from Chromadex (Santa Ana, CA, USA). α -Toc was obtained from Sigma (St. Louis, MO, USA) and WST-1 reagent from Dojindo Laboratories (Kumamoto, Japan). All other reagents were of analytical grade. RBT3 was kindly provided by Sanwa Yushi Co. Ltd. (Tendo, Yamagata, Japan). RBT3 was composed of 82.3% T3 (31.4% α -T3, 50.5% γ -T3, and

Fig. 1 Chemical structures of T3 and Toc

0.4% δ -T3) and 6.0% Toc (1.9% α -Toc, 2.1% γ -Toc, and 2.0% δ -Toc) (w/w). Vitamin E-stripped corn oil was purchased from Acros Organics (Fairlawn, NJ, USA).

Human hepatoma cells were obtained from the RIKEN cell bank (Tsukuba, Japan). The cells were cultured in RPMI-1640 medium (containing 0.3 g/L L-glutamine and 2.0 g/L sodium bicarbonate, Sigma) supplemented with 10% fetal bovine serum (FBS; Biowest, Paris, France), 100 kU/L penicillin, and streptomycin (100 mg/L) (Gibco BRL, Rockville, MD, USA) at 37 °C in a 5% CO₂/95% air atmosphere in a humidified incubator.

Preparation of Experimental Medium for Cell Culture Study

γ -T3 was dissolved in ethanol at a concentration of 50 μ M. The stock solution was diluted with either 1% bovine serum albumin (BSA; Sigma)/RPMI-1640 (control test medium) or 1% BSA/RPMI-1640 containing 1 mM oleic acid as the fat-loaded medium [30] to achieve the desired final concentration of γ -T3 (0–50 μ M). The final concentration of ethanol in the experimental medium was less than 0.1% (v/v), which did not affect cell viability. A medium with ethanol alone was similarly prepared and used as control medium.

Cell Viability Assay

For cell viability assays, HepG2 (1×10^5) were pre-incubated with 10% FBS/RPMI-1640 in 96 well culture plates. Twenty-four hours later, the cells were washed with PBS and the medium was replaced with the experimental medium. As for the control condition, HepG2 were incubated in the experimental medium without oleic acid together with 0–50 μ M γ -T3. In fat-loaded condition, HepG2 were cultured with experimental medium containing 1 mM oleic acid (as the fat-loaded medium) and γ -T3. After incubation for 24 h, the number of viable cells was determined using WST-1 reagent according to the manufacturer's instructions. In brief, WST-1 reagent (10 μ L) was added to the medium, and incubated at 37 °C for 3 h. Absorbance (450/655 nm) of the medium was measured with a microplate reader (Model 550, Bio-Rad Laboratories, Inc., Hercules, CA, USA). WST-1 is a tetrazolium salt that is converted into the soluble formazan salt by succinate-tetrazolium reductase of the respiratory chain of active mitochondria of viable cells [31].

TG Analysis

Cellular TG concentrations were evaluated using Folch method [32]. Briefly, HepG2 (1×10^5) were pre-incubated with 10% FBS/RPMI-1640 in a 35 mm cell culture

plate for 24 h, and were cultured under control and fat-loaded conditions as described above. After 24 h incubation, cells were washed with PBS and scraped using rubber policeman, transferred into an Eppendorf tube (1.5 mL) and were centrifuged at 1,000g for 3 min. Cell pellets were transferred to a micro smashing tube with the addition of 500 μ L PBS buffer for homogenization. After homogenization, the contents of the cellular protein were determined using the Bradford protein assay (Bio-Rad Laboratories) [33]. Cellular TG was extracted using the Folch method and was measured using a commercial TG kit (Wako).

Isolation of Total RNA and Analysis of mRNA Expression

After 24 h of treatment of HepG2 (1×10^5) with the experimental medium, cells were lysed, scraped with a rubber police man, and transferred into a micro smashing tube. Total RNA was isolated with an RNeasy Plus Mini kit (Qiagen, Valencia, CA, USA) for real-time quantitative reverse transcription-PCR (RT-PCR). cDNA was synthesized using a Ready-To-Go T-Primed First-Strand kit (GE Healthcare, Piscataway, NJ, USA), and PCR amplification was performed with a CFX96 Real-Time PCR Detection System (Bio-Rad Laboratories, NSW, Australia) using SYBR Premix Ex Taq (Takara Bio Inc., Shiga, Japan) and gene-specific primers for FASN, CPT1A, CYP3A4, and β -actin (Table 1). PCR conditions were 95 °C for 60 s, 95 °C for 5 s, and 65 °C for 30 s for 40 cycles.

Western Blotting Analysis

After HepG2 (1×10^5) both in control and fat-loaded conditions were incubated with test medium for 24 h, proteins were separated by SDS-PAGE (4–20% e-PAGE; Atto, Tokyo, Japan). The protein bands were transferred to polyvinylidene fluoride membranes (Invitrogen, Carlsbad, CA, USA). After blocking for 1 h, the membranes were incubated with primary antibodies for FASN, CPT1A, CYP3A4, and β -actin (Cell Signaling Technology, Beverly, MA, USA), followed by horseradish peroxidase-conjugated secondary antibody (Cell Signaling Technology). ECL Plus (GE healthcare) was used for detection. Band intensities were measured using Image Lab software version 3.0 (BioRad, Hercules, CA, USA).

Animal Experiments

Male F344 rats (6 weeks of age) were obtained from CLEA (Tokyo, Japan), and housed in cages kept at 23 °C with a 12 h light:dark cycle. The rats were acclimated with MF rodent chow (5% of calories from fat; Oriental Yeast,

Tokyo, Japan) and water for 1 week. After acclimatization, rats received ad libitum either MF or high fat diet [35% of calories from fat (powdered beef tallow 15%/100 g and high oleic acid safflower oil 20%/100 g), High Fat Diet HFD32, CLEA]. The high fat treated rats were fed with 5 mg of RBT3 (1.57 mg α -T3, 2.52 mg γ -T3, 0.02 mg δ -T3, 0.10 mg α -Toc, 0.11 mg γ -Toc, and 0.10 mg δ -Toc), 10 mg of RBT3 (3.14 mg α -T3, 5.04 mg γ -T3, 0.04 mg δ -T3, 0.19 mg α -Toc, 0.21 mg γ -Toc, and 0.20 mg δ -Toc), or 10 mg α -Toc once a day for 3 weeks by oral gavage using 200 μ L vitamin E-stripped corn oil as a vehicle. Positive (high fat diet treated) and negative (MF rodent chow treated) control rats received only the vehicle (vitamin E-stripped corn oil). During the feeding period, the weight of rats and food intake were recorded. At the end of the 3-week period, the rats were fasted for 12 h, weighed, and blood samples were collected after decapitation. Blood was treated with EDTA, and plasma was isolated by centrifugation at 1,000g for 15 min at 4 °C. Liver, heart, lung, spleen, kidney, and adipose tissues were removed and weighed. These protocols were reviewed by the Committee on the Ethics of Animal Experiments and carried out in accordance with the Animal Experiment Guidelines of Tohoku University.

Hepatic and Plasma Parameters

Livers were homogenized in an aqueous solution containing 1 mM EDTA and 0.09% NaCl. The liver homogenates were then subjected to lipid extraction by the Folch method [32]. Total lipid extracts were subjected to TG, total Cho (T-Cho), and phospholipid (PL) analyses using commercial kits (Wako).

For plasma samples, TG, T-Cho, and PL were measured by the Mitsubishi Chemical Medicine Corporation (Tokyo, Japan).

Plasma and Liver Phospholipid Hydroperoxides

To examine oxidative stress, phospholipid hydroperoxides (PLOOH) in total lipid extracts from plasma and liver were measured by HPLC with chemiluminescence (CL) detection [34, 35]. PLOOH is a collective term for phospholipid hydroperoxides such as phosphatidylcholine hydroperoxide (PCOOH) and phosphatidylethanolamine hydroperoxide (PEOOH). The column was a Finapak SIL NH2-5 (4.6 \times 250 mm; Japan Spectroscopic Co., Tokyo, Japan), the eluent was 2-propanol–methanol–water (135:45:20, v/v/v), and the flow rate was 1 mL/min. Post-column CL detection was carried out using a CLD-100 detector (Tohoku Electronic Industries Co., Sendai, Japan). A mixture of luminol and cytochrome *c* in 50 mM borate buffer (pH 10.0) was used as a hydroperoxide-specific post-column CL reagent. Calibration was carried out using standard PLOOH.

Statistical Analysis

The data were expressed as means \pm standard deviations (SD). One-way ANOVA was performed, followed by the Bonferroni/Dunn test for multiple comparisons. Differences were considered significant at $P < 0.05$.

Results

Effect of γ -T3 on HepG2 Proliferation

In order to investigate whether T3 affects TG concentrations, an increasing amount of γ -T3 was administered to HepG2 cells for 24 h in both control as well as fat-loaded conditions. Before investigating the effect on TG, cytotoxic activity of γ -T3 was first evaluated. As for the control condition, HepG2 proliferation was somewhat increased by

γ -T3 treatment (1–5 μ M), while 10–15 μ M γ -T3 did not affect on the proliferation (Fig. 2a). As some papers have already reported [36], higher doses (over 15 μ M) of γ -T3 showed a cytotoxic effect (data not shown). A similar effect of γ -T3 was observed under fat-loaded conditions, although under this conditions a more increased proliferation was shown than under the control condition (Fig. 2a). Because 1–15 μ M γ -T3 showed no cytotoxicity except for 15 μ M γ -T3 under the fat-loaded condition showing little decrease in proliferation, we utilized these γ -T3 concentrations in the next experiments for evaluating their effects on TG.

TG Accumulation is Attenuated with γ -T3 by Affecting Fatty Acid Synthase and β -Oxidation Genes and Proteins Expressions in HepG2

TG accumulation in HepG2 was evaluated by the Folch method. For the control condition, 1–5 μ M γ -T3 showed a little effect on TG concentrations (Fig. 2b), probably due to an increase in the proliferation. However, it was found that 10–15 μ M γ -T3 revealed a marked decrease in TG concentration. For the fat-loaded condition, 1–10 μ M γ -T3 treated cells showed an increase in TG concentrations, whereas a significant decrease in TG was observed at 15 μ M. The reason why 1–10 μ M γ -T3 supplementation increases TG concentration may be due increased cell proliferation. These data clearly suggested the TG-lowering effect of T3, and we therefore investigated the effect of γ -T3 on TG-synthesis related gene (FASN) and β -oxidation

genes (CPT1A and CYP3A4). Significant down-regulation of FASN as well as up-regulation of CPT1A and CYP3A4 genes were observed by γ -T3 treatment (over about 10 μ M) in both control and fat-loaded conditions (Fig. 3). Similarly, γ -T3 attenuated the expression of FASN protein and at the same time induced the expression of CPT1A and CYP3A4 proteins (Fig. 4). Therefore, a possible mechanism of the TG-lowering effect of γ -T3 is mediated by down-regulation of FASN and up-regulation of CPT1A and CYP3A4 genes.

Dietary T3 Reduces TG and PLOOH Accumulations in Liver and Plasma of Rats

To verify the TG-lowering effect of T3 in vivo, a rat study was conducted. Rats received either control MF or high fat diet with or without RBT3 for 3 weeks. The high fat diet caused a significant increase in the weight of rats, and the weight tended to decrease ($P = 0.34$) in the 10-mg RBT3 group (Table 2). RBT3 supplementation did not affect the weight of organs, but adipose tissues, especially epididymal and mesenteric fats, showed a reduction in the weight in the 10-mg RBT3 group (Table 2). No differences were observed for food intake (data not shown). For liver parameters, the high fat diet caused significant accumulation of TG and tended to induce PL ($P = 0.11$) accumulation, and also showed a significant accumulation of PLOOH (oxidative stress marker) (Fig. 5). It was found that these accumulations, especially TG and PLOOH, were significantly attenuated in the 10-mg RBT3 supplemented group (Fig. 5).

Fig. 2 Effect of increasing concentrations of γ -T3 on cell proliferation (a) and TG accumulation (b) of HepG2 in control and fat overloaded conditions. Experimental procedures are shown in the “Materials and Methods” section. Data are expressed as means \pm SD ($n = 6$ for cell proliferation and $n = 3$ for TG accumulation). Means without a common letter differ, $P < 0.05$. The “% of control for control condition” represents the fold-increase in cell proliferation under the fat overloaded condition as compared to under the control condition

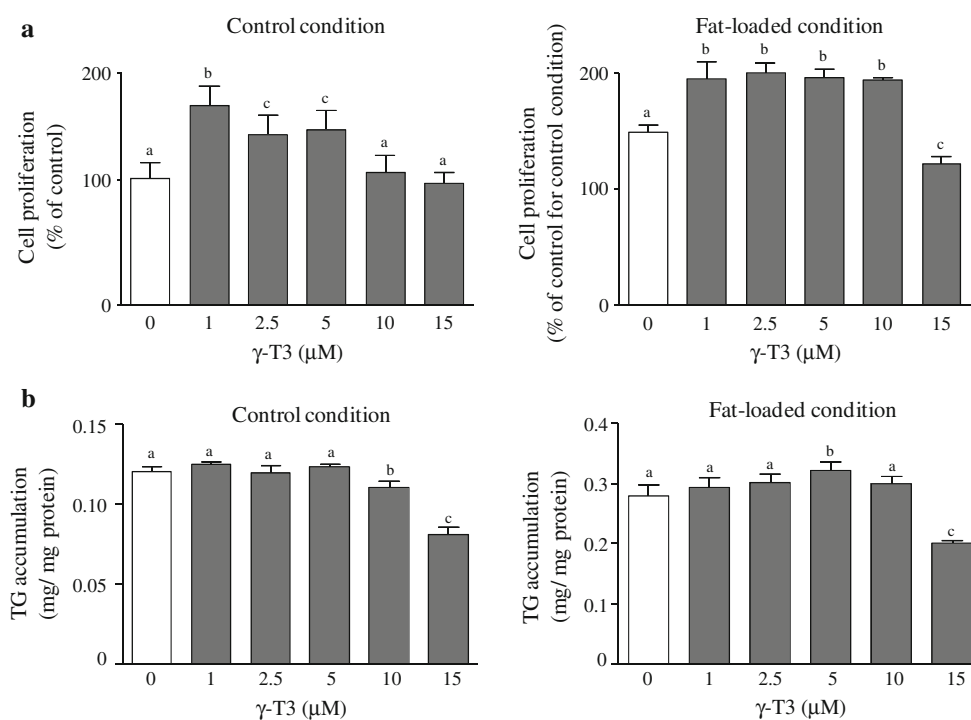

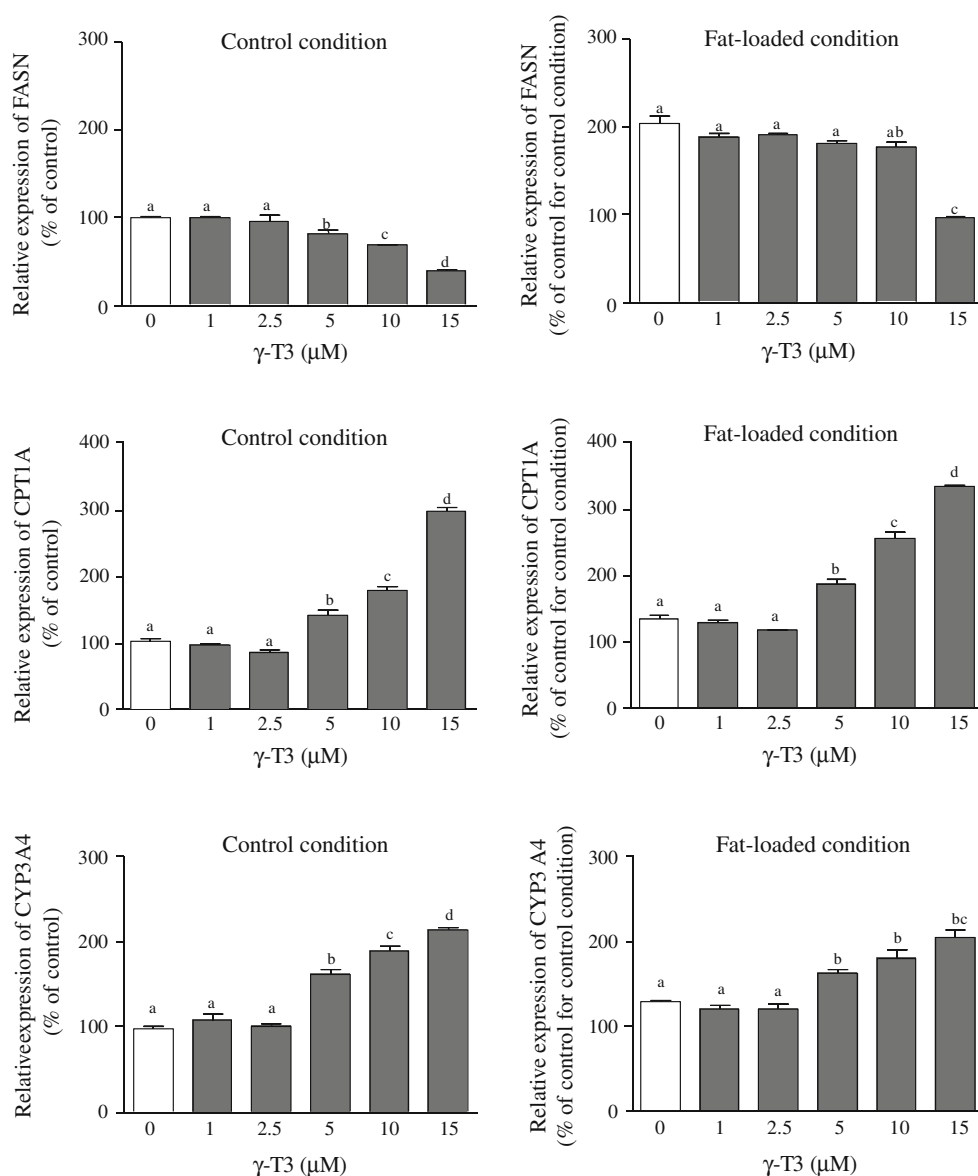

Fig. 3 Effect of increasing concentrations of γ -T3 on mRNA expression of FASN, CPT1A, and CYP3A4 genes in HepG2 in control and fat overloaded conditions. Experimental procedures are shown in the “Materials and Methods” section. Data are expressed as means \pm SD ($n = 6$). Means without a common letter differ, $P < 0.05$. The “% of control for control condition” represents the fold-increase in mRNA expression under fat overloaded conditions as compared to control condition

Similar results were observed for plasma (Fig. 6). In contrast, no significant differences were observed for liver and plasma T-Cho. For the α -Toc supplemented group, no differences were found for lipids and PLOOH parameters in the liver and plasma. These results indicated that the main lipid lowering effects of dietary T3 might be mediated by the reduction of TG, thereby possibly attenuating the TG-induced PLOOH accumulation [37].

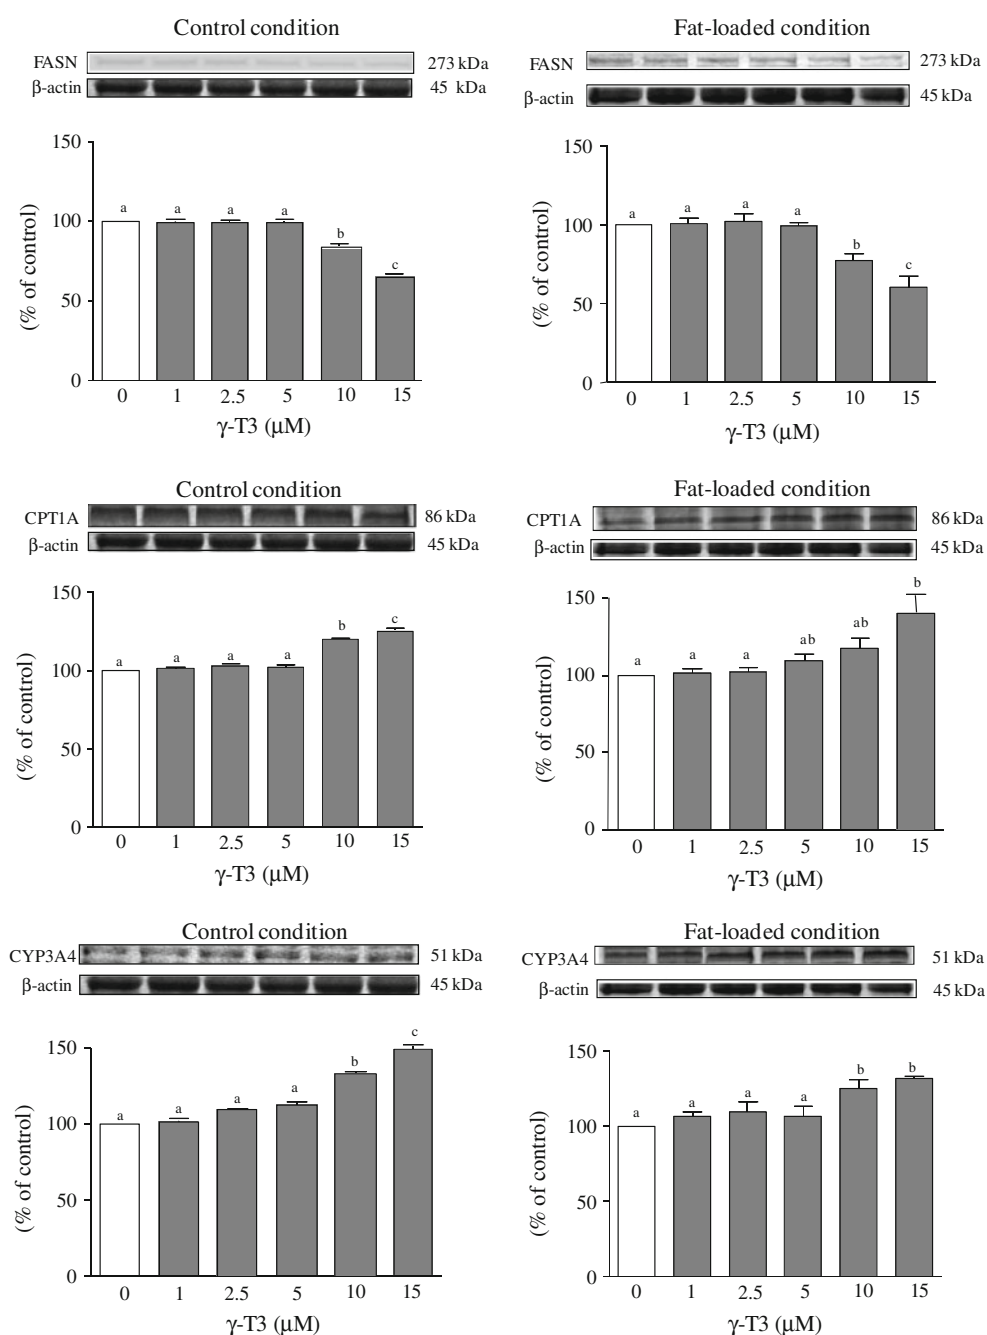

Discussion

TG accumulation has been linked to an increased risk of different afflictions such as coronary artery diseases. In addition, the involvement of oxidative stress (i.e., PCOOH formation) probably due to high TG concentration in vivo has been reported [37]. On the other hand, a novel

possibility pertaining to the attenuating effect of T3 on TG accumulation has been published in some (but not many) studies [27–29]. Since the specific target of T3 in the lipogenic pathway is still vague, further biological studies are needed to elucidate the mechanism(s) on how T3 decreases TG. In the present study, we confirmed the TG-lowering effect of T3 in both in vivo and in vitro studies, and the effect of T3 could be partly explained by its ability to down-regulate the hepatic fatty acid synthase gene and up-regulate β -oxidation genes. These results support a hypothesis that reduction in TG may be the primary benefit caused by dietary T3 [29].

In this study, similar to previous papers [36], a higher dosage of γ -T3 (over 15 μ M) caused cytotoxicity to HepG2 possibly due to apoptosis induction (Fig. 2a). However, low doses of γ -T3 (1–5 μ M) somewhat increased HepG2 proliferation (Fig. 2a). The reasons of the induced cellular

Fig. 4 Effect of increasing concentrations of γ -T3 on expression of FASN, CPT1A, and CYP3A4 proteins in HepG2 under control and fat overloaded conditions. Experimental procedures are shown in the “Materials and Methods” section. Means without a common letter differ, $P < 0.05$. Each Western blot is a representative example of data from three replicate experiments

proliferation still remain unknown, but such increased proliferation was found when cells were incubated with certain antioxidants such as catechin [38]. Consequently, because 1–15 μ M γ -T3 showed no obvious cytotoxicity, we utilized these γ -T3 concentrations in the next experiments for evaluating their effects on TG.

For TG concentration, addition of oleic acid as a fat inducer showed an approximately 1.5 fold increase in TG in HepG2 as compared to the control (Fig. 2b). Such an increase was markedly attenuated by 15 μ M γ -T3. An effect similar to its control condition counterpart was

observed. To date, to the best of our knowledge, there has been one report focusing on the effect of T3 on TG in a cell culture study. Zaiden et al. [29] reported that treatment of γ -T3 and δ -T3 (each 20 μ M) reduces TG synthesis and VLDL secretion in HepG2, however, this study did not measure the actual TG content of the cells. The present study provides quantitative TG results in the cells after administration of γ -T3, and significant attenuation of TG was observed at lower concentrations of γ -T3 (15 μ M).

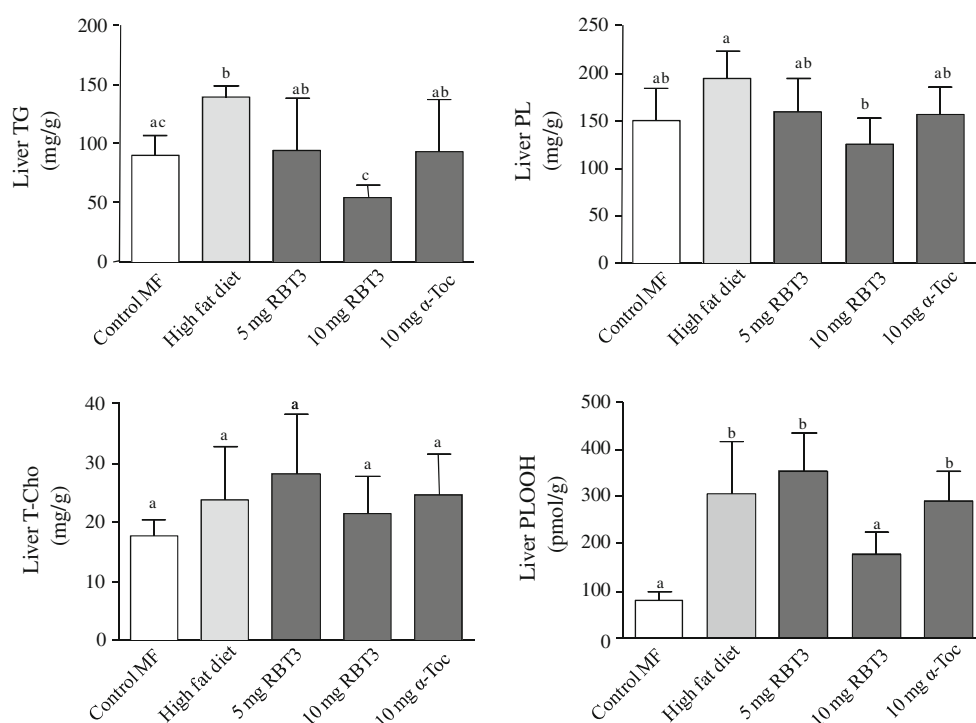

In the present study, we provided new information regarding the possible mechanism of the action of γ -T3 for

Table 2 Body and tissue weights of rats (g)

| | Body weight | Liver | Heart | Lung | Spleen | Kidney | Perinephric fat | Mesenteric fat | Epididymal fat |

Means without a common letter differ, $P < 0.05$

Fig. 5 Effect of RBT3 supplementation on liver lipids (TG, PL, and T-Cho) and oxidative parameter (PLOOH) of rats receiving control MF or high fat diet for 3 weeks. Experimental procedures are shown in the “Materials and Methods” section. Because phosphatidylcholine hydroperoxide (PCOOH) and phosphatidylethanolamine hydroperoxide (PEOOH) are major forms of PLOOH in liver [34, 35], PLOOH is calculated as sum of PCOOH and PEOOH. Data are expressed as means \pm SD ($n = 7$). Means without a common letter differ, $P < 0.05$

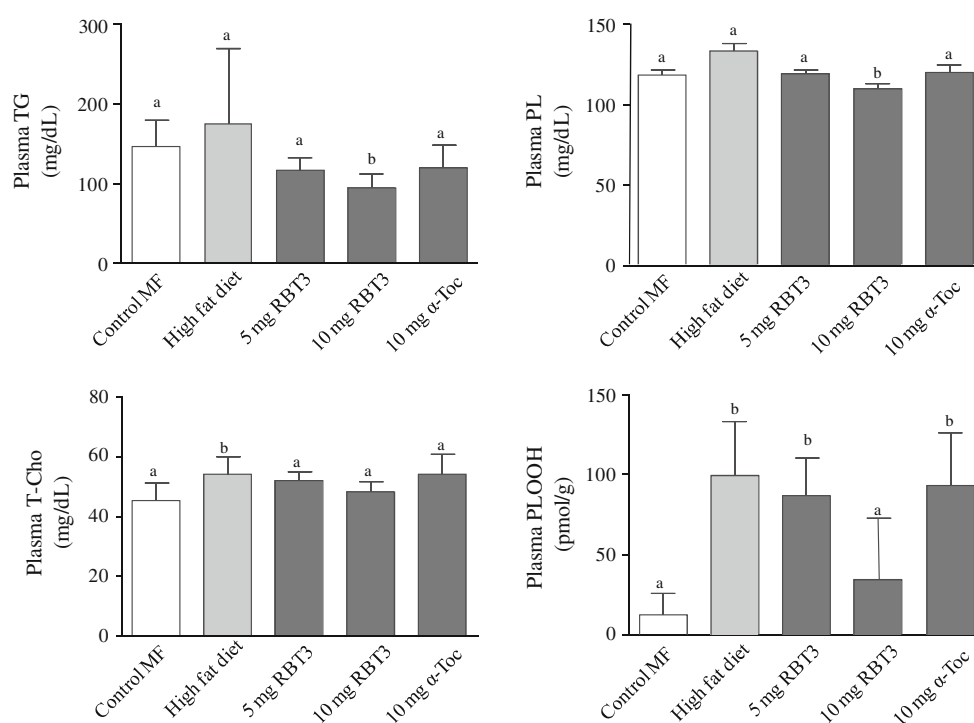

its TG lowering property by down regulation of FASN and up regulation of CPT1A and CYP3A4 in both mRNA and protein levels (Figs. 3, 4). Way et al. [39] showed that by down regulation of FASN, key enzymes for lipogenesis by Pu-erh tea supplementation can attenuate lipid accumulation such as TG in HepG2 cells. On the other hand, β -oxidation genes such as CPT1A and CYP3A4 have different interplaying roles in lipid metabolism. For instance, CPT1A, rate-limiting enzyme for fatty acid oxidation in all tissues was up-regulated in HepG2 upon consumption of polyunsaturated fatty acids, polyphenol and L-carnitine which led to reduced plasma lipid concentrations in a human study [40]. Moreover, CYP3A4, one of the most important enzymes involved in the metabolism of

xenobiotics in the body, has been reported to participate in lipid metabolism by regulation of 25-hydroxycholesterol in mouse liver cells derived cell line [41]. In support to these reports [39–41], administration of γ -T3 in HepG2 significantly down regulated FASN and up-regulated CPT1A and CYP3A4 genes thereby attenuating TG accumulations (Figs. 2b, 3). In addition, similar effects were observed in the protein expression of these genes (Fig. 4).

In support of the cell culture study, the 10-mg RBT3 diet significantly attenuated the accumulation of TG in both liver and plasma of rats (Figs. 5, 6). T3 has been reported to have a potent antioxidative effect [4]. A high fat diet has been reported to increase oxidative stress and resulted in increase in plasma and liver PLOOH [37]. It is therefore

Fig. 6 Effect of RBT3 supplementation on plasma lipids (TG and PL) and oxidative parameter (PLOOH) of rats receiving control MF or high fat diet for 3 weeks. Experimental procedures are shown in the “Materials and Methods” section. Because PCOOH is a major form of PLOOH in plasma [34, 35], PCOOH content is presented as PLOOH. Data are expressed as means \pm SD ($n = 7$). Means without a common letter differ, $P < 0.05$

conceivable that T3 can markedly reduce high fat diet-induced PLOOH accumulation in vivo (Figs. 5, 6). In contrast, dietary RBT3 failed to affect T-Cho concentrations (Figs. 5, 6). Concerning the reported Cho-lowering effect of T3, Quereschi et al. [42] actually demonstrated that the effect of T3 was attenuated by α -Toc. Therefore, the unchanged Cho levels may be due to the presence of α -Toc in the RBT3 (around 0.6 mg for 10 mg RBT3) used in this study. On the other hand, α -Toc did not show any attenuation of TG (Figs. 5, 6). In support of this peculiarity, a study published by Punithavathi et al. [43] showed no effect of α -Toc supplementation alone on TG in an isoproterenol-induced myocardial infarcted Wistar rats. Moreover, our study [44] reported that α -Toc attenuated the cytotoxic effect of δ -T3 in human colorectal adenocarcinoma cells. The present study suggests that among all vitamin E family isomers, a more detailed research between the interactions of these isomers is of great interest. In addition, since the amount of α -T3 present in RBT3 is considerably high, α -T3 was then subjected to proliferation and TG assays to remove any doubt that this T3 isomer might contribute to the TG attenuating effect of T3 (γ -T3). It was found that α -T3 did not show any cytotoxicity nor attenuated the TG accumulations in HepG2 cells (Supplementary Fig. 1). Interestingly, supplementation of RBT3 (10 mg/day) as well as α -Toc showed a significant reduction in the weight of both the perinephric and epididymal fats of rats (Table 2), and therefore we are now investigating the possible mechanism behind this interesting attenuating effect of α -Toc on adipose tissue deposition.

Lipid biosynthesis has a broad array of interplaying genes in its pathway therefore a thorough testing of any possible genes that regulates lipid synthesis and nailing down these genes would provide a more adequate knowledge about the right target for the discovery of medicines for lipid-related diseases. The TG attenuating effect of T3 in both in vivo and in vitro in this study provides novel data about the new TG lowering function of T3.

Abstract This study explores the pharmacokinetics of 22-S-hydroxycholesterol (22SHC) in vivo in rats. We also carried out a metabolic study to explore whether the beneficial effects observed of 22SHC on glucose and lipid metabolism in vitro could be seen in vivo in rats. In the pharmacokinetic study, rats were given 50 mg/kg of [^3H]22-S-hydroxycholesterol before absorption, distribution and excretion were monitored. In the metabolic study, the effect of 22SHC (30 mg/kg/day for 3 weeks) in rats on body weight gain [chow and high-fat diet (HFD)], serum lipids triacylglycerol (TAG) content and gene expression in liver and skeletal muscle were examined. Results showed that 22SHC was well absorbed after oral administration and distributed to most organs and mainly excreted in feces. Rats receiving 22SHC gained less body weight than their controls regardless whether the animals received chow diet or HFD. Moreover, we observed that animals receiving HFD had elevated levels of serum TAG while this was not observed for animals on HFD supplemented with 22SHC. The amount of TAG in liver was reduced after 22SHC treatment in animals receiving either chow diet or HFD. Gene expression analysis revealed that two genes (carnitine palmitoyltransferase 2 and

uncoupling protein 3) involved in fatty acid oxidation and energy dissipation were increased in liver. Ucp3 expression (both protein and mRNA level) was increased in skeletal muscle, but insulin-stimulated glucose uptake and TAG content were unchanged. In conclusion, 22SHC seems to be an interesting model substance in the search of treatments for disorders involving aberrations in lipid metabolism.

Introduction

Liver X receptors (LXRalpha and LXRbeta) are involved in both cholesterol homeostasis, lipid and glucose

metabolism and have been regarded as possible new drug targets both in the fields of type 2 diabetes (T2D), obesity and atherosclerosis [1]. However, many studies have shown that LXR ligands exert both beneficial effects such as increased reverse cholesterol transport and increased insulin-sensitivity/glucose transport, and undesirable effects such as ectopic lipid accumulation in liver and skeletal muscle [2, 3]. We have previously shown in vitro that the LXR modulator 22-*S*-hydroxycholesterol (22SHC) selectively reduced fatty acid accumulation and lipogenesis in human myotubes [4, 5]. Lipogenesis was also decreased in liver (HepG2) cells, while it was increased in adipocytes (SGBS cells) [6]. Glucose utilization was also increased by 22SHC in human myotubes [4, 5, 14]. Thus, 22SHC have properties that make the substance interesting for drug development.

Transcriptional activation of LXR is dependent of the entry of specific ligands, like certain cholesterol metabolites [7–9]. Oxysterols that activate LXR have a strong hydrogen acceptor at either carbon 22, 24 or 27, illustrated by the fact that 24(*S*), 25-epoxy cholesterol is a potent LXR activator while cholesterol does not affect the receptor [10]. The most abundant cholesterol metabolite in vivo is 27-hydroxycholesterol, which is present in plasma, liver and macrophages [11]. Naturally occurring agonists for LXRs include 24(*S*), 25-epoxycholesterol (liver), 25-hydroxycholesterol, 24(*S*)-hydroxycholesterol (brain) and 22-*R*-hydroxycholesterol (adrenal gland) [8, 12]. Recently, glucose was also suggested to be an endogenous LXR ligand [13] while the synthetic compound 22SHC can best be described as an LXR modulator [4, 9]. It binds to the LXR receptors, abolish agonist (T0901317) effects on certain genes important for fatty acid metabolism, but not other typical LXR target genes such as ABCA1 and GLUT4 [4, 5].

Previously, we examined the role of LXR on crucial regulatory steps in glucose- and lipid-metabolism both at genetic and functional levels [2, 4–6]. Results from experiments performed with myotubes established from matched lean, obese and obese T2D subjects showed that treatment with T0901317 increased lipogenesis more in myotubes established from T2D subjects than in myotubes from lean subjects, and that these effects could be efficiently counteracted by 22SHC [2]. Further studies in human myotubes showed that 22SHC reduced de novo diacylglycerol (DAG) production below basal level, reduced fatty acid uptake and oxidation at the same time as glucose uptake and oxidation were increased [4, 5]. Importantly, 22SHC also decreased the expression of genes involved in cholesterol biosynthesis without altering the expression of the reverse cholesterol transporter ABCA1 [5]. We also showed that de novo lipogenesis was differently affected by 22SHC in vitro depending on the cell type [6].

The previous studies [4–6] showed that 22SHC has the potential to affect lipid and glucose metabolism in vitro. Therefore, this study was conducted to elucidate whether 22SHC can be a model substance in the search of treatments for disorders involving lipid aberrations by exploring the pharmacokinetics of 22SHC and effects of 22SHC on glucose and lipid metabolism in vivo in rats.

Materials and Methods

Bioavailability Study-Pilot

Male Wistar rats (Norwegian Institute of Public Health), 304–316 g, were acclimatized for 1 week and housed in standard stainless-steel cages before two fasted rats were used for oral administration and two fasted rats for intravenous doses of 10 mg (~30 mg/kg) 22-*S*-hydroxycholesterol (22SHC). The 22SHC was dissolved in 45 % water solution of 2-hydroxypropyl- β -cyclodextrin. Blood samples (0.5 ml) were taken before dosing and at 0.3, 1, 3, 7 and 24 h after oral dosing (by gastric tube) and at 5, 30 min and 1.5, 5 and 24 h after i.v. administration.

Determination of 22-*S*-Hydroxycholesterol in Plasma with HPLC–APCI–MS

Plasma (100 μ L) was diluted with 300 μ L 2-propanol. After thorough mixing (15 min) and centrifugation (10 min, 4,000g at 10 °C), an aliquot of 5 μ L was injected from the supernatant into the HPLC system. HPLC was performed with a HP 1100 liquid chromatograph (Agilent Technologies, Palo Alto, CA, USA) interfaced by APCI to a HP mass spectrometric detector (MS) operated in single ion monitoring mode (SIM). 22SHC was separated on a C18, 4.6 mm \times 50 mm reversed phase column at 60 °C. For the pilot study, a three-point analytical curve was made from analysis of albumin solution enriched with known 22SHC concentration. The method was linear from 0.01 to 30 μ g/ml at least and the limit of detection was 5 ng/ml.

Animals for the Pharmacokinetic Study

Male Sprague–Dawley rats (Charles River UK Ltd, Margate, UK), age 6–9 weeks (180–240 g) were used (32). During the acclimatization period, rats were housed in standard stainless-steel cages of up to six rats per group. After dosing, rats were returned to their cages. All rats were weighed before dose administration and again at the time of termination. Diet (VRF1) and drinking water were available to the animals ad libitum. [3 H]22-*S*-hydroxycholesterol ([3 H]22SHC) were administered at doses of

50 mg/kg as single bolus intravenous doses into a caudal vein or as single oral doses. [^3H]22SHC was dissolved in 45 % water solution of 2-hydroxypropyl- β -cyclodextrin. Serial blood samples were collected by venipuncture of a caudal vein and terminal samples were taken by cardiac puncture under isoflurane/oxygen anesthesia. The extent of tritium exchange from [^3H]22SHC following oral administration to two rats was small after 24 h (~ 1.5 %) which means that radio labelled [^3H]22SHC should reflect 22SHC levels in vivo.

Absorption

After single oral and intravenous doses of [^3H]22SHC to three or four subgroups of three male rats, two serial blood samples and one terminal blood sample were taken from each subgroup. Blood samples were taken at 0.25, 0.5, 1, 2, 3, 4, 6, 8 and 24 h after oral dosing and at 5, 10, 15, 30, 45 min and 1, 2, 3, 4, 6, 8 and 24 h after i.v. administration.

Distribution

After administration of single oral doses of [^3H]22SHC to five male rats, one animal was exsanguinated and killed (cervical dislocation) at each of the following time points: 1, 3, 6, 24 and 168 h post-administration. Each terminal blood sample was transferred to a heparinized tube and a portion retained as whole-blood for measurement of radioactivity concentrations. The remainder was immediately centrifuged and the separated plasma transferred into a clean plastic tube; blood cells were retained for analysis. After sacrifice, a selection of tissues and organs were removed or sampled from each carcass.

Excretion

After a single intravenous or oral dose of [^3H]22SHC two groups of three male rats were housed singly in glass metabowls designed to permit the separate collection of urine and feces. Total excreta were collected during 0–168 h post-dose for radioactivity analysis. Urine was collected at 0–6, 6–24 h and subsequently at 24 h intervals up to 168 h post-dose. Feces were collected separately at 24 h intervals during 0–168 h. Expired air (oral dose group) was trapped in purified water and radioactivity monitored. Expired air traps were changed at 24 h intervals and collection continued until <0.1 % of the dose was recovered in two consecutive daily air traps (or until 168 h post-dose). The interiors of the metabolism cages were washed with purified water at 24 h intervals. At 168 h post-dose, the cages were also washed with methanol and all washings were retained for radioactivity measurement.

Animals for the 22-*S*-Hydroxycholesterol-Effect Study

Male Wistar rats were purchased from Scanbur AS, Norway. The rats were fed ad libitum a regular maintenance diet (Special Diets Services (SDS), Witham, Essex, UK) for 5 days after arrival to our animal facilities. Then a feeding regimen was adopted using chow and a high-fat diet (HFD, see “Diets”) for 21 days. The rats were about 9-week-old at the start of the experimental feeding. Wistar rats were randomly divided into four groups with six animals each, receiving either chow \pm 22SHC (30 mg/kg/day) or HFD \pm 22SHC. There were three animals in each cage and they had free access to tap water. The experimental protocol (Id 823) was approved by the National Animal Research Authority.

Diets

The animals were given either chow or HFD. In total, HFD consisted of 1.9 % gelatin, 5.7 % wheat bran, 7.7 % vitamin and mineral mix, 25.1 % cornstarch, 25.7 % casein, 26.8 % beef tallow and 7.1 % sunflower oil. The HFD provided approximately 60 % of the energy from fat.

Experimental Protocol

The rats ($n = 24$) were fed ad libitum on the experimental diets, and the total feed intake of HFD for each group ($n = 6$) was recorded at the end of the experiment. Rats were given 22SHC in 45 % water solution of 2-hydroxypropyl- β -cyclodextrin by gavage. They received 30 mg/kg/day of 22SHC calculated at the beginning of the feeding period. Body weight was registered twice a week. Controls and treated rats were weighed at the same day during the experimental feeding. Blood samples were collected from a vein in the leg in the morning between 08:30 and 09:00 a.m. once a week. Immediately after termination, blood samples (cardiac puncture) and tissues (snap frozen in liquid nitrogen) were collected between 10:00 a.m. and 14:00 p.m. Time-curves of serum analysis are presented only for 0, 1 and 2 weeks since the 3-week samples were collected differently.

Serum Analysis

After anaesthetizing the rats with 20 mg pentobarbital (i.p. 50 mg/ml), blood was collected from all 24 animals by aortic puncture and left in room temperature to coagulate. Serum was prepared and stored at -20 °C prior to analysis. Serum lipids and glucose were measured on the MaxMatPL system (ILS Laboratories Scandinavia AS, Oslo, Norway) using the following kits: glucose, triacylglycerol (TAG), total cholesterol and non-esterified fatty acids (NEFA) (all from ILS Laboratories Scandinavia AS). Serum levels of

insulin were measured by a commercially available ELISA kit (Linco Research, MO, USA).

Determination of Triacylglycerol Content

Frozen tissue samples from all 24 animals were weighed and homogenized in 1 ml ice cold 1 mmol/l EDTA buffer (liver) or 0.2 mmol/l EGTA buffer (gastrocnemius) with Precellys®24 bead beater (5,800 beats, 30 s, <http://www.precellys.com>) and spun down for 10 min, 1,000g at 4 °C. The supernatant was transferred to new tubes. Triacylglycerol content was measured with a TG PAP 150-kit (BioMerieux, Marcy l'Etoile, France) according to the supplier's protocol.

Measurement of Glucose Uptake

Epitrochlearis and soleus muscle strips were dissected out from six animals from the HFD control group and six animals for the HFD 22SHC treated group and suspended on holders at their approximate resting length [14]. For in vitro studies, the holders with muscles were placed in test tubes containing Krebs–Henseleit solution (with 5.5 mM glucose, 2 mM sodium pyruvate, 5 mM HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid) and 0.1 % bovine serum albumin (BSA, fraction V, Sigma), pH 7.4). All incubations were performed at 30 °C and gas (95 % O₂/5 % CO₂) was continuously bubbled through the buffer. After 30–50 min of preincubation, glucose uptake was determined with [³H]-deoxy-D-glucose [15]. Briefly, 0.25 µCi/ml 2-[1,2-³H(*N*)]-deoxy-D-glucose (20.0 Ci/mmol; DuPont, Perkin-Elmer) and 0.1 µCi/ml [1-¹⁴C]-D-mannitol (51.5 mCi/mmol; PerkinElmer) were added to the buffer (containing 5.5 mM glucose) and glucose uptake was calculated from the intracellular accumulation of [³H]-2-deoxy-D-glucose as previously described [15]. After incubations, the muscles were blotted on filter paper and frozen in liquid N₂. For measurement of glucose uptake, the muscles were freeze dried, weighed and dissolved in 600 µl 1 M KOH for 20 min at 70 °C. Of the digest, 400 µl was added to 3 ml scintillation solution (Hionic–Fluor, Packard), mixed and counted for radioactivity (TRI-CARB 460C, Packard, USA).

Gene Expression Analysis

Liver and muscle samples (soleus and gastrocnemius) were collected from each rat and snap-frozen in liquid N₂ before storage at –70 °C. The tissues were homogenized in 1 ml lysis buffer with a Precellys®24 bead beater (5,800 beats, 30 s) and total RNA was isolated by Agilent Total RNA isolation kit (Agilent Technologies, Santa Clara, CA, USA) or TRIzol® (muscle tissue) according to the supplier's total

RNA isolation protocol. RNA samples isolated from TRIzol® (Invitrogen, Paisley, Scotland) were treated with TURBO DNA-free™ (Ambion, Austin, TX, USA) as an additional step after the RNA isolation procedure. Each sample of total RNA was reversely transcribed using Applied Biosystem's High Capacity cDNA Reverse Transcription Kit with RNase inhibitor according to the manufacturer's descriptions. Real time qPCR was performed using an ABI PRISM® 7000 Detection System. DNA expression was determined by SYBR® Green (Applied Biosystems, Warrington, UK), and primers [36B4 (NM_022402), Gapdh (NM_017008), Lpl (NM_012598), Cd36 (NM_031561), Scd1 (NM_139192), Cpt1a (NM_031559), Cpt1b (NM_013200), Cpt2 (NM_012930), Ndubf3 (NM_001106912), Ndubf1 (NM_001005550), Mte-1 (NM_138907), Ucp3 (NM_013167)] were designed using Primer Express® (Applied Biosystems) and purchased from Invitrogen Corp. (<http://www.invitrogen.com>). Each target gene were quantified in triplicates and carried out in a 25 µl reaction volume according to the supplier's protocol. All assays were run for 40 cycles (95 °C for 12 s followed by 60 °C for 60 s). The transcription levels were normalized to the housekeeping control genes 36B4 and GAPDH.

Carnitine Palmitoyltransferase 2 (CPT2) Activity

Frozen tissue samples were homogenized as described above (“[Determination of Triacylglycerol Content](#)”) for six animals from the HFD control group and six animals for the HFD 22SHC treated group. CPT2-activity was measured in total homogenate from liver. The assay contained 25 mM HEPES, 75 mM KCl, 1 M HCl, 6 mM palmitoyl-CoA, 0.4 % Triton X-100 and pH was adjusted to 7.4. The reaction was started by adding 6 mM [methyl-¹⁴C]-L-carnitine (0.1 mCi/ml) (PerkinElmer). The enzymatic activities were analyzed using two identical parallels with 0.5 mg protein for each sample. The samples were extracted twice with water-saturated butanol to separate the substrate from the CPT2 product. The radioactivity was determined by liquid scintillation.

Western Blot Analysis

Tissue samples were homogenized as described above (Determination of triacylglycerol content) for six animals from the HFD control group and six animals for the HFD 22SHC treated group. Total cell lysates prepared in Laemmli buffer were electrophoretically separated on 12 % (w/v) polyacrylamide gels (acrylamide/*N,N'*-bis-methylene acrylamide = 37.5:1) followed by blotting to nitrocellulose membrane and incubation with antibodies recognizing human UCP3 [16]. Immunoreactive bands were visualized with enhanced chemiluminescence and

quantified with Gel-Pro Analyzer (version 2.0) software. Antibody against α -tubulin was used to normalize the UCP3 signal versus the amount of protein loading.

Statistical Methods

Significant difference between the two diet groups was analyzed by Mann–Whitney nonparametric test using a significance level of $p < 0.05$. Statistical comparison between different treatments and days of feeding was performed by linear mixed model (LMM) using SPSS. Correlations are presented with Spearman's correlation coefficient (r).

Results

Pharmacokinetics of 22SHC in Rats

The bioavailability of 22SHC was measured with labeled [^3H]22SHC and non-labeled substance. The bioavailability of 50 mg/kg [^3H]22SHC was found to be $\sim 50\%$ (Fig. 1a; Table 1), and the bioavailability of 30 mg/kg non-labeled 22SHC was $\sim 40\%$ (data not shown). $T_{1/2}$ for [^3H]22SHC was 8.1 and 6.4 h after i.v. and oral administration, respectively. The highest concentration of 22SHC obtained in plasma (C_{max}) after i.v. administration was 22.4 ng/ml after 8 min, while after oral dosing the peak concentration was 7.5 ng/ml after 4 h.

Radiolabeled 22SHC was found in almost all tissues examined and the highest concentrations in most tissues were found after 6 h. The concentration of 22SHC after oral administration was very high through the whole

gastrointestinal tractus throughout the experimental period and highest after 1 h (Table 2). The organs with the highest concentrations of 22SHC were liver (65 $\mu\text{g/g}$ tissue/6 h), mesenteric lymph nodes (58 $\mu\text{g/g}$ tissue/3 h) and adrenal glands (33 $\mu\text{g/g}$ tissue/6 h). 22SHC levels were also quite high in heart, kidney, lungs, pancreas, bone marrow, and subcutaneous and perirenal fat depots. One week after the oral dose, the highest levels of 22SHC were found in adrenal glands (2.4 $\mu\text{g/g}$ tissue/168 h), subcutaneous fat (1.1 $\mu\text{g/g}$ tissue/168 h) and liver (0.9 $\mu\text{g/g}$ tissue/168 h).

The main part of 22SHC was excreted through feces regardless of oral (89 %) or i.v. (77 %) administration, although a higher fraction was excreted through urine after i.v. administration (Fig. 1b). Also, most of urine excretion was found within 48 h while 22SHC was found in feces also at 96 h (data not shown).

Effects of 22SHC on Body Weight

All animals receiving 22SHC, regardless of diets, gained less body weight than the control animals during the 3-week feeding period (Fig. 2a, b, $p < 0.05$ overall effect). Rats on chow diet receiving 22SHC showed a lower body weight gain compared to control rats during the last week of the experiment (Fig. 2a), while in rats on HFD the 22SHC-induced reduction of body weight gain was apparent already after 1 week (Fig. 2b).

Effects of 22SHC on Serum Lipids, Glucose and Insulin

Treatment with 22SHC did not influence the level of serum triacylglycerol (TAG) in rats on chow diet (Fig. 3a). Serum

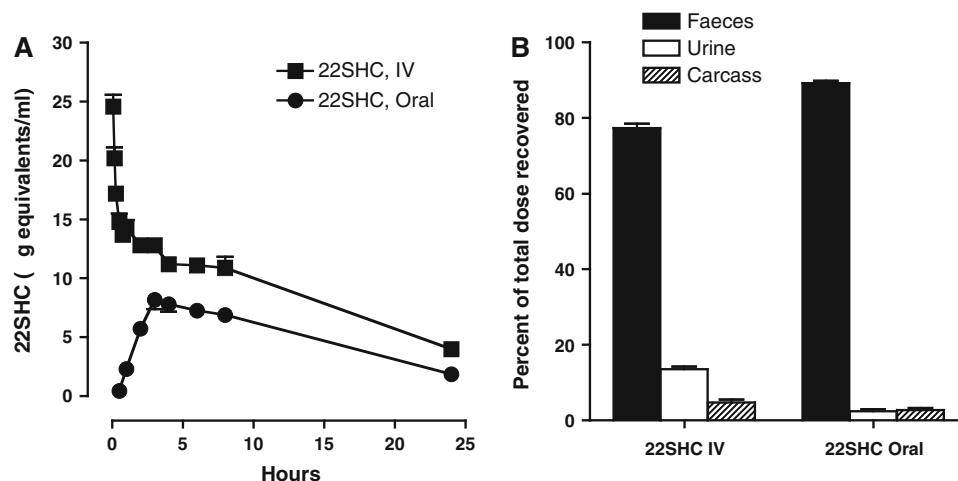

Fig. 1 Absorption (a) and excretion (b) of 22SHC after intravenous and oral administration. Single oral and intravenous (i.v.) doses (50 mg/kg) of [^3H]22SHC were administered to male Sprague–Dawley rats. In a, two serial blood samples and one terminal blood sample were taken from each subgroup. Blood samples were taken at

0.25, 0.5, 1, 2, 3, 4, 6, 8 and 24 h after oral dosing and at 5 min, 10 min, 0.25, 0.5, 0.75, 1, 2, 3, 4, 6, 8 and 24 h after i.v. administration. b Cumulative rates of excretion of radioactivity during 168 h for feces, urine and the remaining carcass. Data in a and b are presented as means \pm SEM ($n = 3$)

Table 1 Pharmacokinetic parameters of non-volatile radioactivity in plasma following single intravenous or single oral doses of [³H]22-S-hydroxycholesterol (50 mg/kg) to male rats

| Parameter | Intravenous dose (phase A) | Oral dose (phase B) |
|--------------------------------|----------------------------|---------------------|
| C_{\max} (ng/ml) | 22.4 | 7.5 |
| T_{\max} (h) | 0.08 | 4 |
| AUC_t (ng h/ml) | 174 | 95.2 |
| AUC (ng h/ml) | 195 | 104 |
| $T_{1/2}$ (h) | 8.1 | 6.4 |
| Extent of tritium exchange (%) | 2.8 | 1.2 |

C_{\max} highest concentration measured, T_{\max} when C_{\max} is measured, AUC area under curve, $T_{1/2}$ half life

Table 2 Distribution of [³H]22-S-hydroxycholesterol in rats

| Tissue/organ | μg Equivalents [³ H]22-S-hydroxycholesterol/g tissue | | | | |

levels of TAG were increased by HFD in rats and treatment with 22SHC seemed to completely counteract this elevation of TAG (Fig. 3b, $p < 0.05$ overall effect). Treatment with

22SHC for 3 weeks did not influence serum concentrations of total cholesterol, non-esterified fatty acids (NEFA), glucose or insulin in any of the animal groups (Table 3).

Effects of 22SHC on Levels of Triacylglycerol in Liver and Skeletal Muscle

The concentration of TAG was higher in livers from rats fed HFD than chow diet, and treatment with 22SHC for 3 weeks reduced TAG levels in liver in both treatment groups (Fig. 4a). There were no significant differences in the amount of TAG in gastrocnemius muscle after different diets and treatments (Fig. 4b), however, TAG was correlated negatively with protein levels of UCP3 after 22SHC treatment ($r = -0.822$, $p < 0.05$).

22SHC Did Not Influence Glucose Uptake in Skeletal Muscle Strips

To see if HFD induced insulin-resistance, soleus muscles strips from HFD-fed rats were incubated. Insulin dose-dependently (0, 0.2 and 10 mU/ml insulin) increased glucose uptake (Fig. 5). Furthermore, the insulin-stimulated glucose uptake was not altered after 22SHC treatment compared to control animals.

RNA Expression, UCP3 Protein Level and CPT2-Activity

We wanted to investigate whether the reduced body weight gain (Fig. 2) and reduced concentration of serum and liver TAG (Fig. 4) in the rats receiving the HFD together with 22SHC could be correlated with an increase in mRNA levels of genes involved in fatty acid uptake and oxidation (Fig. 6 Lpl, Cd36, Scd1, Cpt1a (liver), Cpt1b (muscle), Cpt2 (liver), Ndufb3, Ndufs1, Mte-1 (muscle), Ucp3).

In liver we found that the uncoupling protein 3 (Ucp3) mRNA level had increased nearly tenfold (Fig. 6a) by 22SHC, but this was not reflected by increased protein levels of Ucp3 (Fig. 7a). Ucp3 mRNA levels had also increased 2.5-fold in both gastrocnemius (Fig. 6b) and soleus (Fig. 6c) muscles from animals given 22SHC, and protein level of Ucp3 in gastrocnemius had increased 12-fold (Fig. 7a). Hepatic carnitine palmitoyltransferase 2 (Cpt2) mRNA level had increased two-fold (Fig. 6a) while the CPT2-activity only tended to increase (Fig. 7b).

Discussion

Pharmacokinetic studies of 22SHC showed that 22SHC was well absorbed and distributed to different organs after oral administration with a half-life of 6.4 h. Further, administration of 30 mg/kg 22SHC once daily reduced

Fig. 2 Body weight gain in Wistar rats during 3 weeks feeding with chow (a) or high-fat diet (b). Rats were randomly divided into four groups with six animals each, receiving either chow (maintenance diet, SDS) \pm 22SHC (30 mg/kg/day) or high-fat diet (HFD) \pm 22SHC (30 mg/kg/day) for 21 days. The rats were given free access

to tap water and were weighed in the morning on day 0, 3, 7, 10, 14, 17 and 21. Data are presented as means \pm SEM ($n = 6$). 22SHC treatment significantly decreased overall body weight gain ($p < 0.05$), linear mixed model, SPSS

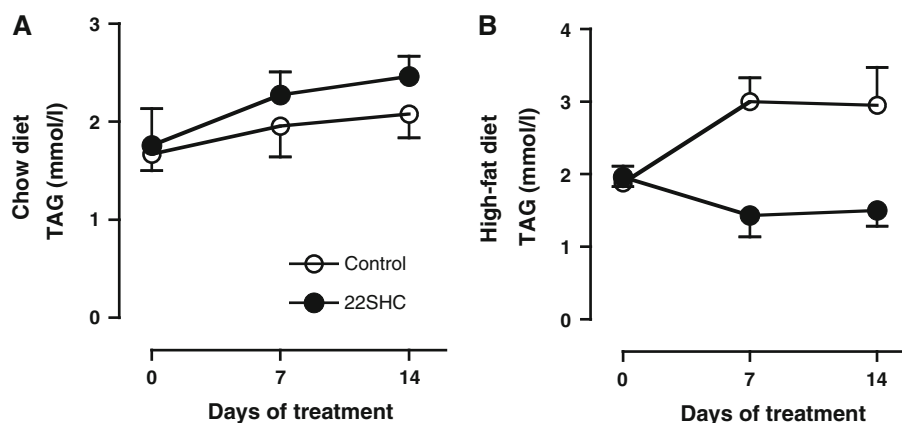

Fig. 3 The concentration of triacylglycerol in serum during feeding chow (a) or high-fat diet (b). Rats were randomly divided into four groups with six animals each, receiving either chow \pm 22SHC or high-fat diet (HFD) \pm 22SHC for 21 days. The rats were given free access to tap water. Blood samples were collected in the morning between 08:30 and 09:00 am once a week at day 0, 7 and 14. Serum

was prepared and stored at -20°C prior to analysis. Serum triacylglycerol (TAG) was measured using the MaxMatPL system as described in “Materials and methods”. Data are presented as means \pm SEM ($n = 6$). 22SHC treatment significantly decreased overall increase of TAG in serum after high-fat diet ($p < 0.05$), linear mixed model, SPSS

body weight gain, and abolished high-fat diet-induced increase of triacylglycerol (TAG) levels in serum. In liver, expression of Cpt2 and Ucp3 was increased and accumulation of TAG was reduced after HFD. In skeletal muscles, Cpt2 and Ucp3 were increased, but 22SHC did not improve insulin-stimulated glucose uptake.

One of the main findings in this study was that rats receiving 22SHC gained less body weight than their controls, regardless of whether the animals received a chow diet or a high-fat diet (HFD). To study the mechanisms

behind these observations, we analyzed mRNA expression of several genes involved in fatty acid transport and oxidation (Lpl, Cd36, Scd1, Cpt, Ndufs, Mte-1, Ucp) in liver and skeletal muscle. 22SHC treatment increased the expression of Cpt2 (liver) and Ucp3. The 22SHC-induced increase of Ucp3 mRNA level was about 10- and 2.5-fold in liver and skeletal muscle, respectively. This response to 22SHC treatment was confirmed by a markedly elevated protein level of Ucp3 in gastrocnemius muscle. Ucp3 is a mitochondrial anion carrier protein with a highly selective

Table 3 Characteristics of the study population

| Parameters | Wistar rats (male) | | | |
|---|--------------------|----------------------|------------------------|------------------------|
| | Chow | +22SHC | High-fat | +22SHC |
| Number of animals (<i>n</i>) | 6 | 6 | 6 | 6 |
| Start body weight (g) | 188 ± 4 | 187 ± 2 | 185 ± 3 | 182 ± 2 |
