SOLITON QUENCHING IN THE ONE-DIMENSIONAL ISING SYSTEM

Ludwik KOMOROWSKI

Institute of Organic and Physical Chemistry,
 Technical University of Wrocław,
 Wyb. Wyspiańskiego 27, 50-370 WROCŁAW, Poland.

Abstract Local excitations of the soliton- and exciton-type in a uniform one-dimensional Ising chain have been indicated. The response of that system to the temperature decrease has been analysed.

Quasi one-dimensional organic materials have been known to show peculiar magnetic property: at low temperature a "Curie tail" is frequently observed in the magnetic susceptibility $\chi(T)$.¹ Numerous arguments have been found that contradict a common belief that this phenomenon might be caused by mere impurity.²⁻⁴ This study aims to provide arguments that similar behaviour can be predicted even for a simple 1-D Ising chain under a suitable cooling regime. In contrast to the profound statistical analysis by Glauber,⁵ and Reiss,⁶ the local excitations will only be considered here. Two lowest one-site excitations are:

the first being simply a domain wall or a kink. They will be called, somewhat arbitrarily, "soliton" and "exciton", respectively, throughout this work, to manifest a fundamental difference between both. In contrast to the exciton (E), annihilation of a soliton (S) cannot occur unless by collision with another partner, i. e.: $S + S \rightarrow E \rightarrow$ ground state. consequently, the annihilation rate for solitons can be approximated as :

$$\frac{d x}{d t} = - N \nu_0 \exp(-J/kT) x^2 P_S ; \quad P_S = (\frac{1}{2})^{1/x}$$

P_S denotes probability of collision of two solitons by stochastic hopping with frequency $\nu = \nu_0 \exp(-J/kT)$. Temperature is changed hyperbolically in time: $1/T = 1/T_0 + \beta t$.⁶

FIGURE 1
Mole fraction of solitons as a function of the spin exchange energy; x_0 - at 300 K; x_1 - at low temperature limit.

FIGURE 2
Mole fraction of solitons vs. temperature for various parameters of the system.

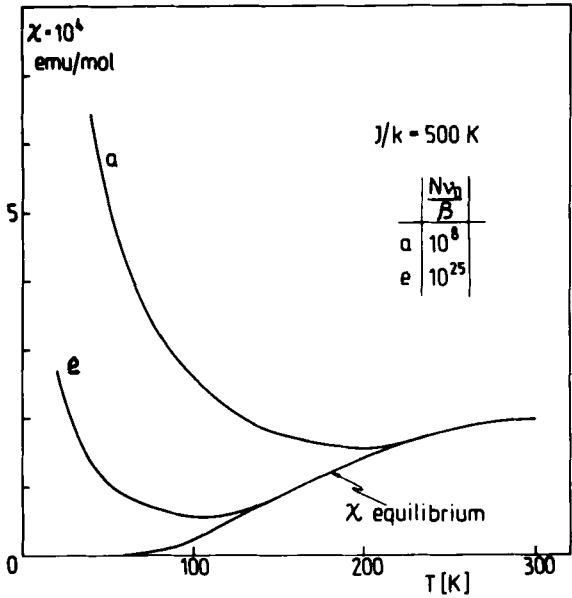

FIGURE 3a, b
Temperature dependence of the magnetic susceptibility;
 $T_0 = 300 \text{ K}$.

Solution of that kinetic equation leads to results depicted in Figs. 1, 2. Starting from an equilibrium concentration of solitons, x_0 at $T_0 = 300$ K, temperature decrease inevitably produces some non-zero limiting concentration x_1 at low temperature. This must be regarded as freezing of solitons due to undercooling the system; the equilibrium situation would simply be $x \rightarrow 0$ for $T \rightarrow 0$. Fig. 2 shows the transition from an equilibrium decay of x to the freezing region (flat), where concentration of solitons remains constant. Figs. 3a, b demonstrate appropriate variation of magnetic susceptibility: the "Curie tail" behaviour is readily recognized. Strangely enough, large variation of parameters ($N \chi_0 / \beta$) causes relatively minor change in $\chi(T)$ relationship. This tends to suggest that for a given system, where only β can be varied (and usually by no more than $2 + 3$ orders of magnitude), changing β will not have much effect on $\chi(T)$ function observed experimentally. The Curie-type behaviour would then appear as an intrinsic property of the system (1). On the other hand, one may expect the experimental curve $\chi(T)$ to be sample dependent, as the chain length parameter N may have some relation to the crystal perfection.

The way to experimental verification of the hypothesis described above remains open; recent reports on quenching phenomena in organic superconductors claim for paying more attention to kinetic effects on experimental data at low temperatures, in particular for the quasi one-dimensional systems.
