We have shown that the combination of the contributions to the specific contact resistance determined by the GBTM model and the Poole-Frenkel/Schottky model can provide a model of the dependence of the contact resistance on the gate bias V_G. Because of the link of the gate bias V_G to the gate capacitance C_i the contact resistance is strictly related to the charge induced by the gate electrode in the accumulation layer as well as on the overlap area of the gate electrode with the electrodes contacts. As a consequence the contact resistance is strictly related to the gate capacitance of the OTFT. Given the validity of our model, we inferred on the possibility to scale-down the contact resistance by implementing the parameters which are involved in the model.

Fig. 1. Schematic diagram of cruciform and coplanar molecular structures.

fluorescence is strongly quenched [6]. In order to obtain high solid-state fluorescence efficiency OPV derivatives, much work has been done to prevent the aggregation of DSB derivatives. Involving the stereo-linkages into the phenylenevinylene chromophores was mostly considered [4]. Remarkable practices should be referred here are the cruciform oligo(phenylenevinylene)s constructed by Ma's group [5,14b]. Through the cruciform chemical structure, (see Fig. 1) the morphology of the materials can be adjusted to facilitate the fluorescence radiation.

It is undoubted that, compounds with large π-conjugate scale and rigid coplanar configurations usually have high fluorescence quantum yield in dilute solutions. It is the intermolecular interactions, but not the coplanar conjugated molecules themselves that depress their solid-state fluorescence.

Till now, nearly all the reported hyper-branched molecules were supposed to be non-coplanar [2,7–9]. In this study, we reported that multi-branched conjugated compound with a coplanar configuration that inclined to form amorphous film, and the aggregation-induced fluorescence quenching effect was weakened due to the steric hindrance of the multi-branched structure. The topology of the chemical structure, with four arm-branches attached to a linear bone, looks like the letter "H" (As shown in Scheme 1).
Scheme 1. Chemical structure of the H-shaped molecules.

With facile synthesis routes, the purpose of establishing coplanar and rigid conjugate conformation while with less aggregated stacking mode is realized.

2. Experimental

2.1. Chemicals and instruments

All reagents and starting materials in the synthetic procedures are commercial available and used as received. The TG and DSC were measured on a Diamond Differential Scanning Calorimeter under nitrogen atmosphere. ^{1}H NMR and ^{13}C NMR spectra were recorded at 25 °C using Bruker Avance 400 spectrometer. Microanalyses (C, H, N) were performed using a German Vario EL III elemental analyzer. Electro-spray mass spectrum (ES-MS) was recorded on a Finnigan LCQ mass spectrograph, and the concentration of the samples was about 1.0 mmol/mL. Absorption measurements were carried out on a TU-1800 spectrophotometer. Photoluminescence (PL) measurements were recorded using a Hitachi F-4500 fluorescence spectrophotometer with a 150 W Xe lamp. The fluorescence lifetime measurement was performed on the Edinburgh FLS920 spectrofluorometer with hydrogen flash lamp (pulse duration 1 ns) as the excitation source on the same spectrofluorometer. XRD investigations were carried out on a Bruker D8 advanced diffractometer equipped with Cu Kα radiation (λ = 1.5405 Å). The data were collected using a Ni-filtered Cu-target tube at room temperature. Single-crystal structural analysis was performed on a Bruker APEX [2] CCD area-detector diffractometer. By SHELXL-97 program, the structures were resolved with direct method and refined by Full-matrix least-squares method on F2. The AFM images were obtained by using a Digital Instruments (DI) Dimension 3100 AFM operating in contact mode. PL efficiencies were determined using a solution of quinine sulfate as a standard (ca. 1×10^{-6} M in 0.1 M H$_2$SO$_4$, having a quantum yield of 55%). Solvents were purified and dried according to standard procedures.

The thermal properties of the two H-shaped compounds were investigated by using differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). Both of them exhibit high TG and high thermal stability with the decomposition temperatures upto ∼400 °C. (Details are shown in Table 1).

2.2. Synthesis

The synthetic route to the two H-shaped molecules is shown in Scheme 2.

TBD. This compound was synthesized by the Suzuki coupling method. Under argon atmosphere, to a stirred mixture of 1.32 g (5 mmol) of 2,5-dibromobenzaldehyde and 2.72 g (20 mmol) of 4-methylphenylboronic acid in

Table 1

Route 1

Route 2

Scheme 2. The synthetic route of the H-shaped molecules.

10 ml THF and 5 ml 2 M Na₂CO₃, 0.05 g of Pd(PPh₃)₄ was added. The mixture was heated to 85 °C for 10 h. After cooling, the mixture was poured into water and then extracted with CH₂Cl₂ for three times, washed with water and dried with Na₂SO₄, filtrated and evaporated the solvent. The residue was purified by column chromatography (silica gel, petrol ether/ethyl acetate = 5:1) to give white solids of 1.32 g (Yield 92%). ^{1}H NMR (400 MHz, CDCl₃, ppm) δ: 2.432 (d, 6H), 7.258 (s, 1H), 7.307 (m, 5H), 7.511 (d, 1H, J = 8.0), 7.582 (dd, 2H, J = 6.6, J = 1.6), 7.857 (dd, 1H, J = 8, J = 2.1), 8.241 (d, 1H, J = 2.0), 10.048 (s, 1H). ^{13}C NMR (CDCl₃, 100.57 MHz, ppm) δ: 20.699, 20.764, 125.188, 126.444, 128.760, 129.240, 129.577, 130.847, 131.356, 133.479, 134.067, 136.177, 137.352, 137.630, 139.905, 144.073, 192.235.

4Br1B. This compound was synthesized by the solventless Wittig–Horner method. About 1.32 g (5 mmol) of 2,5-dibromobenzaldehyde, 0.537 g (1.67 mmol) of tetraethyl 1,4-xylene diphosphonate and 2.8 g (25 mmol) fresh t-BuOK were placed in a dry mortar. The mixture was milled vigorously for about 15 min. Then the mixture was dispersed in 80 mL methanol, filtrated and the solids were washed with methanol for two times. The product was light yellow powders, 0.75 g (Yield 75%). ^{1}H NMR (400 MHz, CDCl₃, ppm) δ: 7.045 (d, 2H, J = 16), 7.237 (dd, 2H, J_1 = 8.6, J_2 = 2), 7.400 (d, 2H, J = 16), 7.450 (d, 2H, J = 8.4), 7.566 (s, 4H), 7.800 (d, 2H, J = 2). ^{13}C NMR (CDCl₃, 100.57 MHz, ppm) δ: 121.057, 122.135, 126.040, 126.937, 128.969, 131.121, 131.598, 133.900, 136.258, 138.493.

4Br2B. 4Br2B was synthesized according to the same procedure of 4Br1B using 1.32 g (5 mmol) of 2,5-dibromobenzaldehyde, 0.757 g (1.67 mmol) of tetraethyl

4,4′-dimethylenebiphenyl diphosphonate and 2.8 g (25 mmol) fresh t-BuOK. The product was light yellow powders, 0.92 g (Yield 82%). ^{1}H NMR (400 MHz, CDCl₃, ppm) δ: 7.083 (d, 2H, J = 16), 7.243 (dd, 2H, J_1 = 8.8, J_2 = 2.4), 7.417 (d, 2H, J = 16), 7.454 (d, 2H, J = 8.4), 7.649 (m, 8H), 7.815 (d, 2H, J = 2.4). ^{13}C NMR (CDCl₃, 100.57 MHz, ppm) δ: 121.065, 122.131, 125.816, 126.792, 127.046, 128.953, 131.092, 131.642, 133.915, 135.335, 138.522, 139.938.

3B1B. (Route 1) The synthesis of 3B1B in route 1 was by a solventless Wittig–Horner method. 0.573 g (2 mmol) of TBD, 0.214 g (0.664 mmol) of tetraethyl 1,4-xylene diphosphonate and 1 g (9 mmol) fresh t-BuOK were placed in a dry mortar. The mixture was milled vigorously for about 15 min. Then the mixture was dispersed in 80 mL methanol, filtrated and the solids were washed with methanol for two times. The pure product was obtained by recrystallization from CH₂Cl₂–ethanol (10–1), 0.31 g (Yield 73%). (Route 2) The synthesis of 3B1B in route 2 was by a Suzuki coupling method. Under argon atmosphere, to a stirred mixture of 0.299 g (0.5 mmol) of 4Br1B and 0.544 g (4 mmol) of 4-methylphenylboronic acid in 12 ml THF and 5 ml 2 M Na₂CO₃, 0.05 g of Pd(PPh₃)₄ was added. The mixture was heated to 85 °C for 30 h. After cooling, the organic solvent was evaporated; the residue was filtrated and washed by water, and then dissolved in CH₂Cl₂, filtrated through a silica gel funnel to remove the Pd (0) catalyst residue. The pure product was obtained by recrystallization from CH₂Cl₂–ethanol (10-1), as light yellow crystallites, 0.18 g (Yield 57%). ^{1}H NMR (400 MHz, CDCl₃, ppm) δ: 2.431 (d, 6H), 7.138 (m, 6H), 7.295 (m, 20H), 7.394 (d, 2H, J = 7.9), 7.541 (dd, 2H, J = 7.9, J = 1.8),

7.590 (d, 4H, *J* = 8.1), 7.929 (d, 2H, *J* = 1.7). ^{13}C NMR (CDCl$_3$, 100.57 MHz, ppm) δ: 20.675, 20.754, 123.901, 125.760, 126.397, 126.541, 127.493, 128.435, 128.613, 129.070, 129.312, 130.273, 135.226, 136.386, 136.434, 136.739, 137.106, 137.546, 139.377, 139.791. Anal. Cal. For C50H42: C, 93.41; H, 6.59. Found: C, 93.09; H, 6.37. Crystal data for 3B1B (C50H42): Mr = 642.87, Triclinic, space group $P\bar{1}$, a = 10.0165(2) Å, α = 74.649(2)°, b = 12.2636(3) Å, β = 75.141(2)°, c = 17.0433(4) Å, γ = 68.5490(10)°, V = 1849.07(7) Å^3, Z = 2, ρ_{calcd} = 1.155 Mg/m^3, T = 293(2) K, Crystal size 0.43 × 0.13 × 0.03 mm, R_1 = 0.0579, wR_2 = 0.1221, [$I > 2\sigma(I)$].

3B2B. (Route 1) The synthesis of 3B2B in route 1 was according to the same procedure of 3B1B (Route 1) using 0.573 g (2 mmol) of TBD, 0.302 g (0.664 mmol) of tetra-ethyl 4,4′-dimethylenebiphenyl diphosphonate and 1 g (9 mmol) fresh t-BuOK. The product was bright yellow crystallites, 0.37 g (Yield 77%). (Route 2) The synthesis of 3B2B in route 2 was according to the same procedure of 3B1B (Route 2) using 0.337 g (0.5 mmol) of 4Br2B and 0.544 g (4 mmol) of 4-methylphenylboronic acid in 14 ml THF and 6 ml 2 M Na$_2$CO$_3$, 0.05 g of Pd(PPh$_3$)$_4$, the product was 0.237 g (Yield 66%). ^{1}H NMR (400 MHz, CDCl$_3$, ppm) δ: 2.438 (d, 6H), 7.195 (m, 6H), 7.314 (m, 16H), 7.412 (d, 2H, *J* = 7.9), 7.476 (d, 4H, *J* = 8.3), 7.580 (m, 10H), 7.955 (d, 2H, *J* = 1.6). ^{13}C NMR (CDCl$_3$, 100.57 MHz, ppm) δ: 20.690, 20.772, 123.989, 125.815, 126.556, 126.582, 127.717, 128.459, 128.528, 129.085, 129.334, 130.297, 135.230, 136.260, 136.417, 136.761, 137.105, 137.538, 139.151, 139.375, 139.807. Anal. Cal. For C56H46: C, 93.55; H, 6.45. Found: C, 93.29; H, 6.29. Crystal data for 3B2B (C56H46): Mr = 718.93, Triclinic, space group $P\bar{1}$, a = 6.332(5) Å, α = 92.416(5)°, b = 13.359(5) Å, β = 96.844(5)°, c = 24.105(5) Å, γ = 102.027(5)°, V = 1975.3 (18) Å^3, Z = 2, ρ_{calcd} = 1.209 Mg/m^3, T = 293(2) K, Crystal size 0.37 × 0.11 × 0.05 mm, R_1 = 0.0701, wR_2 = 0.1733, [$I > 2\sigma(I)$].

2.3. Device fabrication and characterization

OLED devices were fabricated by thermal vacuum-deposition under 1.33×10^{-4} Pa. Patterned indium tin oxide (ITO) were cleaned with detergent, de-ionized water, acetone and then de-ionized water in an ultrasonic bath (30 min each cycle), and finally treated in an ultraviolet-ozone chamber. Deposition rates were monitored with a quartz oscillation crystal and controlled at about 0.1 nm/s for organic layers and about 0.5 nm/s for metal layers. The active area of the device was about 4 mm^2. The thickness of films was measured by a Dektak surface profi-lometer. The EL spectra and current–voltage–luminance (*J–L–V*) characteristics were measured with a Spectrascan PR 650 photometer and a computer-controlled DC power supply. All the measurements of the devices were carried out under ambient conditions.

3. Results and discussion

3.1. Synthesis and characterization

Scheme 2 shows the synthesis of the two H-shaped molecules. Two synthetic routes are employed. Two kinds of classic organic reactions are adopted, Suzuki and Wittig–Horner [10]. In route 1, 2BD reacted with the boro-nic acid through the Suzuki coupling reactions to give an aldehyde-containing intermediates TBD with the yield of 92%. Then, the two H-shaped molecules were obtained by solid-state Wittig–Horner reactions between the interme-diate and two diphosphonate compounds (yields 73% and 77%, respectively). Route 2 is, actually, a reversed proce-dure of route 1. 2BD firstly took a solid-state Wittig–Horn-er reaction with the two diphosphonates to form another two mediate products 4Br1B and 4Br2B (yields 75% and 82%, respectively). Then the Suzuki reactions between 4Br1B, 4Br2B and the boronic acid produced the two H-shaped products with the yields of 57% and 75%, respec-tively. The structure of the molecules were verified by ^{1}H NMR, ^{13}C NMR and elemental analysis and confirmed by X-ray crystallographic analysis.

3.2. Crystal structure analysis: coplanar configuration of the H-shaped molecules

For organic semiconductors, many physical properties (e.g., optoelectronics and charge transport) are highly
Fig. 2. The X-ray structures and crystal packings of 3B1B and 3B2B, two crystallographically independent conformations appear in both of them.

dependent on their molecular configuration and the stacking mode. Thus, information of the crystal structures plays an important role in the exploration of structure–property relationship. Nevertheless, crystal structures of hyper-branched molecules are difficult to obtain due to their large molecular size and the multi-branched structures. Here, after many experimental attempts, single crystals of the two H-shaped molecules have been obtained by a very slow growing process, and their crystallographic structures were determined by X-ray diffraction. (See Fig. 2) In the crystals of the two H-shaped compounds, each molecule shows a quasi-coplanar "H" shape; the supposed twisted configurations through the central phenylenevinylene chain do not appear. The two phenyl rings as the crunodes on the two sides of "H" are parallel exactly to each other, even for the biphenyl linked 3B2B, and the two phenyl rings of the central biphenyl in 3B2B are coplanarized exactly, too (See Fig. 3). There are moderate twist angles between the single bonds linked phenyl rings along each side of the terphenyl dipoles. Anyhow, just as what we can see from the side view of these H-shaped molecules, the two side dipoles of "H" are parallel to each other, and the whole molecule is located in a plane just with little deviations. So, we call them quasi-coplanar molecules. This special factor can ensure the unbroken conjugation of the whole H-shaped molecule. And they should be totally different from those twisted or cruciform ones in terms of morphology (aggregation mode) and aggregated optical properties. To gain insight as to why these molecules adopt coplanar configurations, the quantum chemical calculation using a DFT/B3 LYP/6-31G (d) method [3a,5a] was performed on 3B2B, the result showed a non-coplanar H-shape, with a twist angle of ∼40° between the two sides terphenyl dipoles of the molecule. It shows that, the theoretical calculations may not always reflect the information of the actual situation. We consider that, maybe it is the comparative long distance between the side
dipoles and the intrinsic property of the central phenylene-vinylene chain, cooperatively make this H-shaped topology a coplanar one. Although the topology of H-shape is not a new concept [11], the construction we proposed here bears an exact non-twisted "H" shape. This coplanar configuration can endow molecules with an integrative two-dimensional conjugations, thus, the enlarged delocalized π electrons would enhance their fluorescence yield. And intriguingly, there are two crystallographically independent conformations in both of the two H-shaped molecules, they make alternate stackings, which may enhance their solid-state fluorescence [12]. Now, we have seen the novel coplanar configuration of the H-shaped molecules, in the following researches, by testing their optical properties in solutions, thin films and crystallites, and their EL performances, the effects of different morphologies are shown.

3.3. Morphology and optical properties of the H-shaped molecules

For the photophysics properties of the H-shaped molecules, firstly, the UV–vis absorption and photoluminescence spectra of the two compounds in several solutions were recorded. They exhibit very weak solvent polarity dependence due to the absence of any electron donor or acceptor groups. Fig. 4 shows the spectra in THF (1 μM) (Detailed data are tabulated in Table 1). Due to the two-dimensional conjugations of the H-shaped molecules, their absorption profiles show two-peaks spectra. The short wavelength absorption band (299 nm) may be related to the side terphenyl dipoles; while the long wavelength absorption band (∼360 nm) may be related to the central DSB or distyrylbiphenyl portion. Their PL emissions present shoulder peaks for each compound. Thanks to the large π-conjugate scale and rigid planar configurations, both of the H-shaped molecules are with quite high fluorescence quantum yields, bright blue light can even be observed under solar irradiation.

In order to understand well how the two-dimensional conjugation affects the electronic structure, the shapes of HOMO-1, HOMO, LUMO, LUMO+1 of 3B2B are shown in Fig. 5. As shown in Fig. 5, the majority of the electron

Fig. 3. Molecular configuration of the H-shaped molecules. In each molecule, the blackened phenyl rings on each side of "H" are parallel to each other. Blow: side view of the two molecules.
Fig. 4. UV–vis absorption and PL spectra of the H-shaped molecules in THF.
Fig. 5. Frontier HOMOs and LUMOs of 3B2B. (Calculations were based on DFT/B3LYP/6-31G (d).)

distribution of the HOMO and LUMO were found to be located over the distyrylbiphenyl entity, while the electron distribution of the HOMO-1 and LUMO+1 were found to be located mainly over the two side terphenyl dipoles. The energy levels of the orbitals from HOMO-1 to LUMO+1 are −5.53, −5.14, −1.47 and −0.93 eV, respectively.

The most that we want to show here are the solid-state optical properties of these coplanar H-shaped molecules, and their dependence on different morphologies. When the compounds are vacuum sublimated on substrate to form films, what is easy to imagine is, considering the short deposition time for several tens of nanometers' organic compounds, it is hard for the multi-branched molecules to adopt close packing in just a few minutes, even though they bear coplanar structures. Amorphous films should be formed.

To verify this speculation, X-ray diffraction (XRD) analysis was taken on 3B2B powders and film. As shown in Fig. 6, for the powders of 3B2B, there are sharp diffraction peaks in the XRD patterns, indicating that they are apparently crystalline. While for the sublimated films, only inconspicuous broad peak appears on their XRD patterns, meaning that they are determinately amorphous. The XRD measurement of the same film sample after storage for two months under ambient conditions shows no trend of crystallization, indicating that this amorphous film of coplanar hyper-branched molecules is morphological stable. The morphology of the thin film is a key factor related to the performance of thin film devices of organic materials. As shown in Fig. 7, the atomic force microscopy (AFM) topography of the sublimated films demonstrate that the 3B2B film is continues, neat and smooth.
Fig. 6. Comparison of XRD patterns of 3B2B powders (black), thin film-1 (as prepared, blue) and thin film-2 (after two months, red). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 10. PL spectra of 3B2B in solution, thin film and powders and the EL spectrum of device based on 3B2B.

Table 2
Fluorescence properties of 3B2B in different morphologies.

3B2B	Λ_{max}^{em} (nm)	τ (ns)
In THF	411	1.65
Thin film	445	1.37
Powder (crystalline)	500	3.86
EL device	443	–

The essence of the difference is proposed in Fig. 8. The coplanar H-shaped molecules adopt a close packing mode in crystallites, they stack layer by layer, and the π–π distance between two adjacent molecular planes is about 3.64 Å. While in the amorphous films, thanks to the molecules' intrinsic characteristics of multi-branches, they can not stay close to each other owing to the intermolecular steric hindrance, just like two hedgehogs can not keep close to each other. In the sublimation process, they would make random, disorder and unconsolidated packing (As shown in Fig. 8, left). Thus, the π–π interactions should be very weak in such environment. Different morphology results in different optical properties. As shown in Fig. 9, in solution (THF), 3B2B shows blue–purple light; in the sublimated films, it has a blue fluorescence; while in crystalline powders, it luminescent obviously green (The details see the spectrum in Fig. 10 and data in Table 2).

Taken the morphology (aggregation mode) and the fluorescence property of the coplanar hyper-branched molecules together, we can see that they are consistent with each other. In the amorphous thin films, they make a disorder and unconsolidated packing, there are less intermolecular π–π actions, the circumstance of the interactions is some what like that in solutions. Thus, the spectra of the film shows relative small red-shift to that of in the solutions (blue emitting); while in crystallites, the layer

by layer close packing of the coplanar molecules leads to the intensive intermolecular π–π interactions, and subsequently result in largely red-shift (green emitting). These arguments can also be verified by the time-resolved photoluminescence spectra of the solution, film and crystallites of 3B2B. The time-resolved fluorescence can provide valuable information about the interaction of molecule in the excited state with its environment [13]. Just as illustrated

Fig. 8. Molecular packings of coplanar H-shaped molecules (3B2B) in amorphous films (proposed) and in crystallites.
Fig. 11. PL lifetime spectra of 3B2B in solution (yellow), thin film (pink) and powders (deep pink). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

by the emission decay lifetime spectra in Fig. 11 and the lifetime data in Table 2, the fluorescence decay curves of 3B2B in solution and in the thin film nearly resemble to each other; while that of in the crystallites is much more longer than the two formers. The lifetime in crystallites is 2–3 times longer than that of in solution and in the thin film. The thin film and powders, although both of them are in solid state, with different morphology and different aggregation mode, there are intrinsic changes in the molecules' environment, and have distinct optical behaviors.

3.4. Electroluminescence properties of the H-shaped molecules

Considering the effective inhibition of intermolecular π–π interactions in the thin films of the two coplanar

conjugated molecules, enhanced electroluminescence performances can be expected. Employing the two H-shaped molecules as emitting materials, typical OLEDs were fabricated. The device configuration was: ITO/NPB (40 nm)/H-shapeds (40 nm)/AlQ (30 nm)/LiF (1 nm)/ Al (80 nm) (NPB = 4,4′-bis(1-naphthyl-N-phenylamino)- biphenyl, acted as hole transport layer; AlQ = tris(8- hydroxyquinoline)aluminum, acted as electron-transport layer). Both of the devices had rather low turn on voltages of 3.6 and 3.3 V. The devices exhibited bright blue light, with the Commission Internationale de l'Eclairage (CIE) coordinates of (0.17, 0.19) (3B1B) and (0.16, 0.14) (3B2B), and showed hardly no variations with the change of applied voltage. The naked devices were found to be with good stability during the measuring process, just as their nice morphological stability of the sublimated films. Fig. 12 gives their EL spectra. The device luminance efficiencies (η_c) are 2.4 (3B1B) and 2.3 (3B2B) cd A^{-1}, and their power efficiencies (η_p) are 1.6 (3B1B) and 2.2 (3B2B) lm W^{-1} (All details are summarized in Table 3). At an operating voltage of 10 V, the brightness of these coplanar H-shaped molecules based devices approached or even exceeded 10000 cd m^{-2} (See Fig. 13). It should be noted that the values are quite high, there is no evidence indicating that the aggregation-induced fluorescence quenching. And as shown in Fig. 10, the EL spectrum of 3B2B nearly overlaps with its PL spectrum in thin film, indicating that the blue emission comes from just the 3B2B layer. Maybe thanks to the larger π-conjugation and a more planar configuration of 3B2B than that of 3B1B, the PL and EL performances of 3B2B are better than those of 3B1B. To

3B1B/**B**	3.7	18667	2.6	2.2	(0.16, 0.18)	446
3B2B/**A**	3.3	18964	2.3	2.2	(0.16, 0.14)	443
3B2B/**B**	3.7	20490	2.8	2.6	(0.16, 0.14)	443

[a] Configuration **A**: ITO/NPB (40 nm)/H-shaped molecules(30 nm)/AlQ (30 nm)/LiF (1 nm)/Al (80 nm); Configuration **B**: ITO/NPB (40 nm)/H-shaped molecules(30 nm)/BCP (10 nm)/AlQ (30 nm)/LiF (1 nm)/Al (80 nm).

Fig. 14. Current efficiency vs. current density characteristics of devices based on the two H-shaped molecules. (Configuration B.)

optimize the device efficiency, BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) was chosen as a hole-blocking layer (10 nm) to insert between the H-shaped emitters and the electron-transport layer AlQ. As shown in Fig. 13 and Fig. 14, the resultant devices were found to be promoted in terms of both efficiency and brightness, the turn on voltages were slightly elevated to 3.7 V for a higher charge injection barrier. Their luminance efficiencies reached 2.6 and 2.8 cd A^{-1}, and the power efficiencies reached 2.2 and 2.6 lm W^{-1}, respectively. For the 3B2B based devices, an Lmax of 20490 cd m^{-2} was obtained. In summary, these results are comparable with those of the non-coplanar or spiro-configurations compounds [4,5a,6,10], and are higher than the performances of the tetrahedral OPVs or the cruciform dimeric OPVs with cross arrangement dipoles which have similar constructing blocks to our H-shaped molecules and with the same EL device configuration [5a,14]. This demonstrate that, if we choose an appropriate topology of chemical structure, such as this H-shaped multi-branched construction, the conjugated compounds based on coplanar configurations likewise can be with reduced aggregation-induced fluorescence quenching effect, and show high EL performances as the non-coplanar ones.

4. Conclusion

In conclusion, with facile synthesis routes, a new series of H-shaped molecules have been synthesized. X-ray crystal structures of them showed that every molecule possesses a coplanar "H" shape, without twist between the two side dipoles. The sublimated thin films with amorphous morphologies show significant blue-shifted and enhanced photoluminescence than those of the crystalline powders. Employing these coplanar H-shaped molecules as non-doped emitters, high brightness blue OLEDs were fabricated. The devices showed a maximum luminance of 20490 cd m^{-2} and a luminescence efficiency of 2.8 cd A^{-1} (2.6 lm W^{-1}) with the CIE coordinate of (0.16, 0.14). These results are comparable with or even better than those of the devices based on the non-coplanar or spiro-configuration compounds. The results indicate that the multi-branched conjugated molecules with coplanar configurations are appropriate for high performance EL applications. Works to explore new coplanar multi-branched conjugated compounds may be a new way for high efficient OLEDs. Moreover, the chemical structure of the H-shaped molecules can be easily rendered variously, which will attract more attentions in other electronic and optical related fields, such as TPA (two-photon absorption) and fluorescent sensors.

blend on transparent indium tin oxide (ITO) glass. Such a polymer–organic blend system can be easily applied by simple spin coating or printing techniques. In order to achieve the maximum power conversion efficiency for a given material system, organic photovoltaic devices require low series resistance and high shunt resistance. It is also required to have two ohmic contacts in order that bulk series resistance is minimized; first is that between the positive electrode and the active layer, and second is that between the active layer and the metallic electrode. Sandwiching the active layer made of poly(3-hexylthiophene)/[6,6]-phenyl-C61-butyric acid methyl ester (P3HT/PCBM) blend is the hole extraction layer (poly(3,4-ethylenedioxy-thiophene):poly(4-styrene sulfonate) [PEDOT:PSS] coated ITO) and a negative electrode, metallic conductor such as

Al. Because of a relatively low conversion efficiency of single OPV devices, they need to be fabricated with large scale connectivity. On the other hand, resistivity at large area hole extraction and active layer will induce an increase of series resistance which results in a reduction of current flow, thus affecting the conversion efficiency. A close relationship between the device area and the conversion efficiency is now well established [6].

In this study, we focus on our efforts to partition the hole extraction layer into smaller areas by means of the insulating walls so as to minimize the lateral contribution on the series resistance, thus to prevent lowering of the efficiency by increasing the overall active area. We demonstrate that this method is universally applicable to all organic materials used in OPV. Also, our method will provide a distinct advantage of implementing by simple printing such as inkjet, gravure, offset and screen, lithography, and soft contact transfer. We should note here that our method differs from the conventional module fabrication technique that inserts low resistance metal lines between active areas.

2. Material and methods

2.1. Fabrication of devices

PEDOT:PSS (poly(3,4-ethylene dioxythiophene): poly(styrene sulfonate)) aqueous dispersions (Baytron® AI4083, P and PH-500) were used as the hole extraction layer, spin coated on top of 300–400 nm thick ITO coated

Fig. 1. (a) Schematics and actual picture of insulation layer coating on etched ITO and (b) cross-sectional schematics of fully processed device.
Fig. 2. FIB-TEM images; bottom left: partitioned cell, top images: cross-sectional images from insulating wall edge to center of wall.

glass. In the case of DMSO blended PH-500, the ratios of PH-500: methanol: DMSO were 1: 2: 5%, respectively. The PEDOT:PSS stock solution was spin coated at 2000 rpm for 40 seconds to form about 35 nm thick film, then was baked at 200 °C for 10 min in a high purity nitrogen environment glove box. ITO glass was cleaned by boiling in chloroform, isopropyl alcohol and acetone for 30 min in each solvent, sonification for 15 min in 50:50 isopropyl alcohol and acetone solution, and finally rinsed with deionized water. A typical example of the next step of sample preparation is as follows: 2.4 wt% of P3HT and PCBM blend with 1:0.6 ratio by weight was dissolved in anhydrous chlorobenzene and was spin coated on prepared PEDOT:PSS coated ITO glass at 2500 rpm for 40 s. The thickness of resulting active layer was 220 nm and pre-annealed at 150 °C for 10 min 0.8 nm thick LiF, which served as a buffer layer, was deposited on top of the active layer and 150 nm thick aluminum was evaporated by thermal vapor deposition at 10^{-6}–10^{-7} Torr, and prepared device was post annealed at 120 °C for 10 min. All of the processing was performed in the glove box with high purity nitrogen environment. Photocrosslinkable positive photoresist resin of acrylate derivates (Nippon Zeon Corp.) was used to form partitioning wall of height of 500 μm. Standard partitioned subcell area was 300×300 μm, and the partitioning wall was 200 μm in width and 500 μm in height. After finishing the series of the preparation processes, the device was encapsulated with glass plate using an UV curable resin in a high purity nitrogen environment glove box.

2.2. Characterization

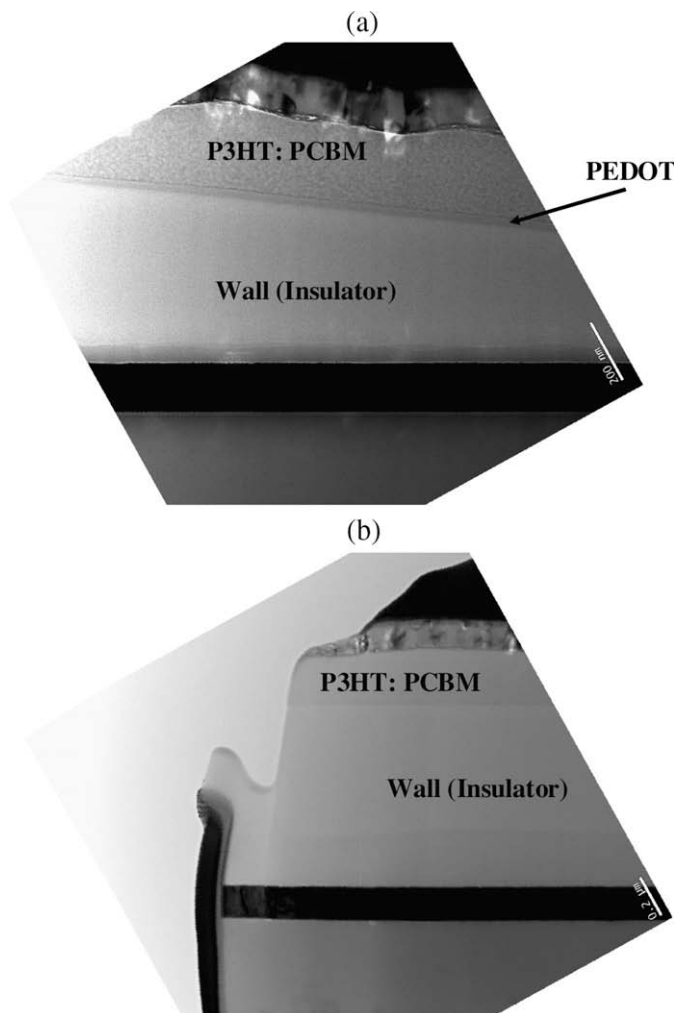
For cross-sectional transmission electron microscope (TEM) (FEI TECNAI F20) observation of device, a thin flake in situ lift-out sample was prepared using focused ionbeam (FIB) machine (FEI Nova600) with a Ga ion focused beam. Thickness of coated film was measured with surface profiler (TENCOR®, P-10 α-step). Oriel Class A type solar simulator (IEC 904) with Oriel Reference Cell (calibrated data taken by NREL) was used as a light source and all measurement was performed under 1 sun condition (100 mW/cm²). The measurements were not corrected for reflection


Fig. 3. FIB-TEM images; (a) interface area of partitioning wall and (b) center position of partitioning wall.

losses and light absorption in the ITO electrode. Current–voltage characteristics were determined with Keithley 2400 source–measure unit.

3. Results and discussion

In Fig. 1 is displayed our fabrication design of photovoltaic cells consisting of smaller sized subcells to the conventional cell size, i.e. 0.04 cm². Eventually we have increased the total cell size to 1 cm², to which we will return at the end. Parenthetically, the size of 1 cm² is quite a large cell for OPV. Our test coupon is made of three single cells of 0.04 cm², one partitioned cell with actual active area of 0.027 cm² which consisting of 25 subcells of the same size (300 μm × 300 μm), and 200 μm space between them. These are so formed by an insulator on top of one inch by one inch ITO coated glass as shown in Fig. 1. The partitioned subcells form a single cell upon covering its top with an Al electrode.

It is quite simple to build the insulating walls to disconnect the hole extraction layer by means of a curable resin via a lithographic method. With TEM micrographs in Fig. 2 and Fig. 3, we show that the hole extraction layer (PEDOT:PSS) is discontinued at few tens of micrometer away from the edge of insulating walls so that the series resistance is reduced through a smaller active area. Each divided active area acts like an isolated small cell so that the series resistance is reduced. In order to elucidate the effect of partitioning the active areas, a cell without partitioning wall is used as the reference.

Fig. 4 shows the profiles of current density vs. bias voltage (J–V) between single and partition cells for three different formulations of hole extraction layer. The results are

Fig. 5. Transmittance of ITO and insulating walls, and absorption characteristics of P3HT/PCBM blend.

summarized in Table 1. When Baytron 4083 is used as the hole extraction layer having a low conductivity (~10–3 S/cm), there was no detectable difference between the single and partitioned cells. However, when the conductivities were higher (Baytron P: ~1 S/cm and Baytron PH-500 blended with dimethyl sulfoxide: ~100 S/cm), there were significant differences in the efficiency between the two, and the degree of this difference was in the order of conductivity of the hole extraction layer formulations. Henceforth, we refer Baytron PH-500 blended with dimethyl sulfoxide (DMSO) as simply PH-500. Clearly, the observed enhancements of the current density and efficiency are closely correlated to the conductivity of the hole extraction layer. Thus, we infer that there exist lateral contributions of the series resistance from the rest of active area to a subcell for the bulk resistance. As is shown in

Fig. 4. J–V characteristics for three different hole extraction layers; (a) single cell and (b) partition cells.

Table 1
Influence of conductivity of hole extraction layer on performance of OPV device (s: single area cell; p: partitioned cell).

Conductive layer	Area	Open circuit voltage (V)	Current density (mA/cm²)	Fill factor	Series resistance (Ω cm²)	Efficiency

	p	0.591	12.39	0.626	1.81	4.58

Table 2
Influence of wall to active area ratio (active area was 300 μm × 300 μm).

Conductive layer	Wall width (μm)	Open circuit voltage (V)	Current density (mA/cm²)	Fill factor	Series resistance (Ω cm²)	Efficiency
Baytron Al 4083	None	0.590	8.53	0.460	22.68	2.35
(10^{-3} S/cm)	20	0.595	8.23	0.460	25.62	2.27
	50	0.593	8.27	0.480	23.25	2.39
	100	0.595	8.47	0.490	15.49	2.46
	200	0.595	8.27	0.500	10.78	2.49
Baytron PH-500	None	0.596	8.09	0.570	8.09	2.75
(100 S/cm)	20	0.602	7.75	0.564	8.51	2.63
	50	0.592	9.23	0.586	6.21	3.20
	100	0.586	10.26	0.517	6.27	3.11
	200	0.596	12.93	0.561	4.63	4.32

Fig. 5, the lowering of series resistance can be observed clearly by the increasing slope of the current density vs. bias voltage profile above the open circuit voltage; the inverse of slope in the figure represents the bulk series resistance. Despite the enhanced conductivity of the hole extraction layer, it still has a relatively high resistance compared to that of the electrode. Such a high resistance of the hole extraction layer is attributed to the contributions from far away areas, whereas such is not the case with a low conductive hole extraction layer. In short, for highly conductive hole extraction layers, the deleterious effect of the lateral contributions of the series resistance from the rest of active areas to the bulk resistance is rather significant. Therefore, the enhancement of the efficiency will be substantial over that of a cell made with low conductivity formulations if the hole extraction layer is disconnected from each other by partitioning into smaller area subcells.

We have also investigated the influence of wall to active area ratio using different partitioned cells and the results are summarized in Table 2. The power conversion efficiency was increased with increasing partitioning wall width. When Baytron Al 4083 was used as the hole extraction layer, there was no detectable difference in the power conversion efficiency among the different wall widths. However, when Baytron PH-500 was used, there were significant differences in the efficiency and the series resistance among wall widths, and the degree of this difference was in the order of wall widths. This result is quite reasonable since lateral contributions of the series resistance from the rest of active area to the subcell should be decreased with increasing wall width.

We now turn to the uncertainty with respect to the estimate of active cell area. As was shown in Fig. 2 with the cross-sectional TEM micrographs by focused ion-beam (FIB), we estimate that the boundary of PEDOT:PSS coating is about 30 μm from the edge of insulating wall. Since PEDOT:PSS has to be coated over rather tall insulating walls, having a height of 500 μm at the center position, our cell coating process is different from the coating on flat ITO surface. Unlike the reported edge effect (effective areas are 300–400 μm from the edge) [7] when PEDOT:PSS is coated on a flat surface, the actual active area in our device starts about 30 μm away from the edge since the PEDOT:PSS does not extend flush to the edge. This issue is being raised because the size of active area is critical to the efficiency, particularly when the active area is small
Fig. 6. Transmittance of ITO and insulating walls, and absorption characteristics of P3HT/PCBM blend.
Fig. 7. *J-V* characteristics of a partitioned device with and without mask.

[7]. In addition, the insulating wall materials with the 500 μm height at the center, as referred to in the above, absorb visible light and the transmittance at the P3HT/PCBM blend absorption region is less than 50% as shown in Fig. 6. Therefore, the actual exciton formation in the area between the insulting wall to the PEDOT:PSS coating edge may be small but still needs to be accounted for in the estimate of the efficiency. Thus, the actual active area in the partitioned cell is subject to a certain range of uncertainty. Nevertheless, we emphasize that the trend of increasing current extraction with a high conductivity of the hole extraction layer by partitioning is firmly established.

Table 3
Characteristics of large area cell.

Conductive layer	Area	Open circuit voltage (V)	Current density (mA/cm^2)	Fill factor	Series resistance (Ω cm^2)	Efficiency
Baytron Al 4083 (10^{-3} S/cm)	s	0.590	8.53	0.460	22.68	2.35
	p	0.595	8.27	0.500	10.78	2.49
Baytron PH-500 (100 S/cm)	s	0.596	8.09	0.570	8.09	2.75
	p	0.596	12.93	0.561	4.63	4.32

It is well known that artifacts caused by the edge effect are to be taken into account with care [7,8]. In fact, it is a point of a recent controversy with the solar cell efficiency [9]. According to the report by Cravino et al. [7] a small area cell like ours is significantly affected by the edge effect as expected. We thus examine the edge effect by masking the device area. Fig. 7 shows J–V characteristics of the partitioned device with and without mask. When the entire fabricated device was exposed to incident light without masking, the power conversion efficiency was about 6.5; the current density was ~20.9 mA/cm^2 and the fill factor was 0.523. On the other hand, when the mask was placed so as to expose only active area to the incident light, the power conversion efficiency was reduced to 4.6; the current density was ~12.4 mA/cm^2 and the fill factor was 0.626. Thus, we conclude that the edge effect is indeed significant relative to the actual power conversion efficiency. It can be readily understood that the current density decrease and fill factor increase are caused by the charges formed only in the active area.

Finally, we come to the issue of a large area size cell of 1 cm^2. Despite difficulty in quantifying the power conversion efficiency arising from the uncertainty of actual active area within the partitioned walls, the key point of this study is clear: One can fabricate a large area OPV device without sacrificing the power conversion efficiency, if not enhancing, when hole extraction layer is partitioned into smaller subcells. A large area cell (~1 cm^2) was prepared by the same manner as described in the above. To elucidate the partitioning effect, a single area cell with the comparable active area was also prepared. The results are summarized in Table 3. As was seen in Table 3, the partitioned cell performance with Baytron Al 4083 showed no distinct difference from that of single cell (efficiency change from 2.35 to 2.49). On the other hand, the partitioned cell performance with Baytron PH-500 showed about 40% improvement in the efficiency over that of single cell (efficiency change from 2.75 to 4.32). Notwithstanding any uncertainty relative to the absolute estimate of the power conversion efficiency arising from the active area uncertainty, the results in Table 3 make it compelling that the partitioning works when compare to a device with the same overall active area.

Major factor causing this difference is the series resistance, noted by the slope of J–V curve beyond open circuit voltage (Fig. 5). As discussed previously, the partitioning of hole extraction layer caused the series resistance decrease. This is entirely consistent with a report by Yoo et al. [10] that the series resistance increased with the number of cells upon connecting them in series. Since the areas of these two cells were same, it was clear that a partitioned

cell with a high conductivity hole extraction layer would have a lower series resistance resulting in enhanced current extraction leading to improved power conversion efficiency.

4. Conclusion

We conclude with these results that the partitioning of the active area into smaller areas can improve the power conversion efficiency of organic photovoltaic devices. The lateral serial contributions to the series bulk resistance of the hole extraction layer with a high conductivity profoundly affect the power conversion efficiency. Our method reported here is to be differentiated from the conventional metal line insertion for the purposes of increasing the current output as used in photovoltaic industry.

applications. The main reason is attributed to random-oriented behavior of phthalocyanine crystals. Many grain boundary and defections were found in films that bring lots of charge traps that degrade the efficiency of charge transportation. More recently, Yan's group proposed an effective method to improve the mobility of phthalocyanine by weak epitaxy growth technology [11]. They prepared phthalocyanine films on the top of rod-like molecules (para-sexiphenyl and 2, 2′; 7′, 2″-terphenanthrenyl) and realized high field-effect mobilities [11–13].

In this paper, two typical phthalocyanine compounds, titanyl-phthalocyanine (TiOPc) and CuPc, were selected as material pair to realize high-performance OFET. Both of them possess excellent chemical and thermal tolerances,

especially attractive low-cost. In air phthalocyanines undergo no noticeable degradation up to 400–500 °C, and even strong acids and bases cannot affect them [14]. TiOPc is a nonplanar molecule with significant molecular overlaps and short intermolecular distances [15]. It often exhibits quasi-intrinsic semiconductor state, p-type in air doping by oxygen and n-type in high vacuum conditions [16]. Comparing with another family member, metal phthalocyanine such as CuPc, TiOPc has lower mobility possibly due to poor film quality [15]. However, it exhibits disk-like crystal shape that is clearly distinguished from CuPc with needle-like shape at high-temperature substrate [17]. This unique characteristic makes it to be an excellent template molecule to prepare high-quality CuPc film. In this study, CuPc grown on the top of TiOPc exhibited domain-oriented, closely stacked film morphology. The corresponding OFET revealed a high field-effect mobility of 0.12 cm^2/V s, and 10^5 on/off current ratio.

2. Experiment

OFET devices with top contact (Fig. 1a) were fabricated according to the following procedure. Heavily doped n-type silicon wafers (0.01–0.15 Ω Cm) were acted as gate electrode and substrate. A layer of oxide (SiO$_2$) with unit capacitance of 8 nF/cm^2 covered on the substrate was served as gate insulator by thermal growth. The wafers were ultrasonically cleaned with acetone, isopropyl alcohol, and ultra purified water, respectively. Then these wafers were inserted to octadecyltrichlorosilane (OTS) solution (chloroform as solvent, 2 mM) for 24 h to form a self-assembly monolayer in order to optimize the surface properties of SiO$_2$ [15]. TiOPc and CuPc with various thicknesses were deposited in succession at a base pressure of (4–5) × 10^{-4} Pa at a rate of 1 Å/s, while the substrates were held at 200 °C. The thickness values were recorded by quartz crystal. Subsequently to prepare the source/drain electrodes, gold film with 30 nm was evaporated through shadow mask defining channel width of 3800 μm and length of 180 μm, respectively. For comparison, OFETs based on TiOPc or CuPc single-layer with 25 nm were fabricated and held with the same condition described above. All organic source samples were purchased from Sigma–Aldrich without further purification. Electrical characteristics of OFETs were performed in ambient by a semiconductor parameter analyzer (Agilent technology 4155C). The atomic force microscopy (AFM) images were performed by SPI 4000 with tapping mode. X-ray diffraction (XRD) was measured in D/Max-2550 with Cu Kα source (λ = 1.541 Å).

3. Results and discussion

Fig. 1b displays the morphology of the TiOPc thin-film with 5 nm covered on the substrate of OTS/SiO$_2$ recorded by AFM images. It exhibited typical discontinuous island crystals with disk-like shape consisting of several monodomains analogous to conventional phenyl-derives that were distinguished from CuPc film with needle-like shape

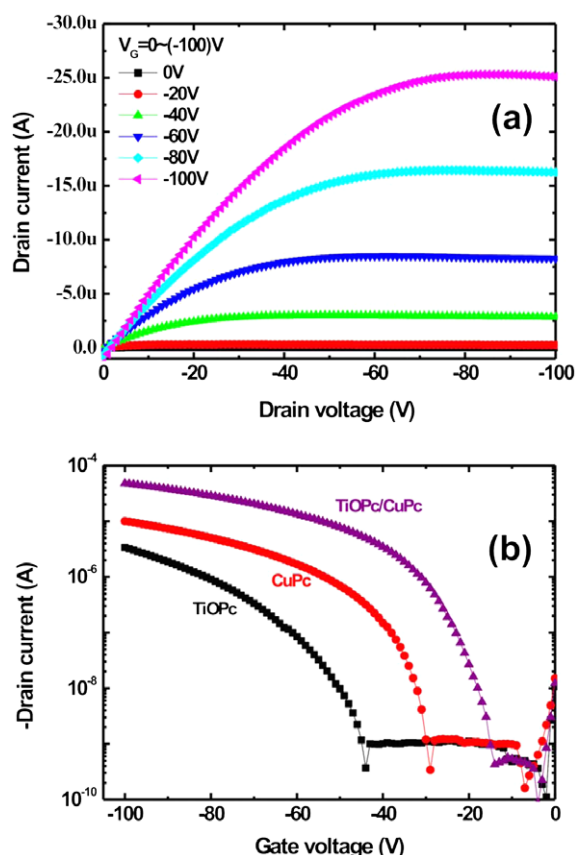
(Fig. 1c). This result is due to the titanyl atom perpendicular to phthalocyanine ring and then forming out-plane structure that resulted in layer-by-layer growth manner with "edge-on" molecular orientation, similar report may be found elsewhere [18]. Moreover, the domain height is ∼10 nm, which is attributed to strong diffusion behavior of TiOPc molecules at a high substrate temperature. The mean domain size of TiOPc is ∼250 nm and ratio of grain area is 68% by SPI 4000 analysis. Thus a molecular template was ready for the growth of CuPc. Fig. 1d shows the morphologies of 20 nm CuPc film based on 5 nm TiOPc template. It can be found that CuPc firstly grown on the top of TiOPc monodomain and then connected with each other. In each domain area, CuPc grains oriented along a constant direction and formed well-ordered arrangement marked by dark circles in Fig. 1d. AFM analysis showed that a root mean square roughness of CuPc/TiOPc is 6.8 nm which is lower than that of CuPc/OTS/SiO$_2$ with 9.1 nm. In contrast to CuPc on OTS/SiO$_2$ (Fig. 1b), a morphological transform from random orientation to domain-order orientation may be clearly observed by utilizing TiOPc template at a high substrate temperature by comparing Fig. 1c and d. XRD results (Fig. 1e) indicated that the CuPc film on TiOPc exhibited high crystallization and typical β crystal phase, in which 6.8° and 7.0° correspond to (2 0 0) and (0 0 1)


Fig. 2. (a) The output characteristics of CuPc (20 nm)-based OFET utilizing TiOPc (5 nm) molecular template. (b) Three transfer characteristics for TiOPc/OTS/SiO$_2$, CuPc/OTS/SiO$_2$, and CuPc/TiOPc/OTS/SiO$_2$ OFETs. All active layers of devices were controlled at 25 nm.

planes of the β form, respectively [18]. This result implied that CuPc molecules grown adopting a herringbone structure that stand up on TiOPc stacking along *b*-axis are in the P21/a space group [18]. The growth mode of CuPc on TiOPc template is illustrated in Fig. 1. For comparison, the XRD patterns of CuPc growth on OTS/SiO$_2$ were also presented. A single sharp diffraction peak was found at 2α of ca. 6.8° (7.0° is not exhibited that distinguished the CuPc on TiOPc template), which corresponds to the (2 0 0) lattice planes. It revealed that the crystalline structure is parallel to substrate defined as a metastable herringbone-like α phase [19]. The appearance of new diffraction peak in CuPc/TiOPc implied a new crystal phase and improved film order.

The electrical characteristics of OFET devices with 20 nm CuPc on 5 nm TiOPc are presented in Fig. 2a and b, which displayed typical hole-accumulation mode under various gate and drain biases. Field-effect mobility and on/off current ratio extracted from saturation region were 0.12 cm^2/V s and beyond 10^5, respectively. Threshold voltage of −19 V was obtained from transfer curves. Here it should be figured out that high threshold voltage must come from low capacitance of gate insulator (8 nF/cm^2). However, it does not obstruct us to obtain clear results in this work. For comparison, the transfer characteristics of single-layer CuPc and TiOPc devices are also shown in Fig. 2b, from which a mobility of 0.018 cm^2/V s for TiOPc and that of 0.019 cm^2/V s for CuPc have been obtained which indicated that an improvement has been achieved (0.12 cm^2/V s for TiOPc/CuPc devices). The domain-oriented

film and closely stacked between domains resulted in low trap concentration and reduced hopping distance of carriers, which may be responsible for the improvements. The threshold voltages of these devices were extracted, −58 V for TiOPc and −32 V for CuPc, which revealed that threshold voltage was simultaneously reduced by applying TiOPc template (−19 V). TiOPc is a typical quasi-intrinsic semiconductor. It operates in n-type operation mode in inert ambient, and the majority carriers are electrons in film possibly originating from residual impurities working as n-type dopants [20]. In our devices, holes are induced by these electrons in TiOPc and pre-accumulated at the side of CuPc due to the difference of Femi energy level when put them together. This provides an enhanced hole-accumulation effect under given gate bias that results in the decrease of threshold voltage. The amount of threshold voltage shift may be described by $\Delta V_{th} = \Delta Q_{deep}/C_i$ [21], where ΔV_{th} is the shift of threshold voltage, ΔQ_{deep} is the trap charges that could be filled by the gate voltage, and C_i is the unit capacitance of gate insulator. So ΔQ_{deep} may be established to be 1.04×10^{11} cm^{-2} that represented the difference of trap charge concentration between conventional CuPc-based devices and herein CuPc/TiOPc-based devices. Furthermore, we note that the off-state current of CuPc/TiOPc OFET has a slight decrease that is different from those heterojunction devices in the previous reports [12,13]. It is possibly attributed to the energy level of CuPc and TiOPc that are similar which induces the amount of accumulated charges at the interface decrease and then result in a low bulk conductivity [22]. As a result, the whole device performances were
Fig. 3. AFM images (a) 20 nm CuPc on 2.5 nm TiOPc. (b) 20 nm CuPc on 5 nm TiOPc. (d) 20 nm CuPc on 7.5 nm TiOPc. The insets are TiOPc films (2.5, 5, and 7.5 nm) grown on OTS/SiO$_2$ substrate. (c) The TiOPc thickness dependence on device performances of OFETs. The thickness of CuPc was kept at 20 nm.

improved due to the optimization of film properties by templating effects, as well as heterojunction functions.

For further clarifying the TiOPc template effects, the thickness dependence of device performances was investigated. The 20 nm CuPc film morphologies growth on TiOPc with different thicknesses have been shown in Fig. 3. The insets in Fig. 3a–c are the AFM images of TiOPc with different thicknesses (2.5, 5, and 7.5 nm), in which the film continuity was gradually improved with the increase of thickness that resulted. According to 2.5 nm TiOPc substrate, CuPc grains are similar with CuPc/OTS due to many vacancy areas of TiOPc film (see inset Fig. 3a). However, the grains exhibited domain-oriented arrangement when the TiOPc thickness is 5 nm. Further increasing the thickness to 7.5 nm, CuPc grains formed closer contact and domain orientation seemed to be slightly lowered that is attributed to the improvement of TiOPc continuity. As a result, the TiOPc thickness played a crucial role for the growth of CuPc. 5 nm is a critical thickness for the form of high-ordered, domain-oriented CuPc film. Fig. 3d shows mobility and threshold voltage as a function of TiOPc thickness. It can be found that the highest mobility and the lowest threshold voltage were obtained from the devices with 5 nm TiOPc template. The decrease of TiOPc thickness induces the reduction of the domain-oriented area of CuPc, which results in the drop of device performances. On the other hand, when further increasing TiOPc thickness (7.5 nm) to form continuity film, it probably exhibits TiOPc charge transportation behavior that leads to low mobility. In this case, the electrical characteristics of OFET are comparable with those of single-layer TiOPc device when the TiOPc thickness is successively increased to 20 nm. Thereby, a peak value of device performance appears with the change of TiOPc thicknesses.

Both the morphology of organic heterojunction films and its corresponding electrical structure have strong influences on OFET performances, simultaneously, they have an intimate correlation. Generally, this system is very complicated, involving many factors such as energy level, polycrystalline film morphology, and interface properties of two components. According to this topic, relative studies are just beginning. TiOPc/CuPc pair will provide a distinguished example to detect some unique characteristics that occurred in organic semiconductors, which are expected to push the study of new organic electrical devices.

4. Conclusion

In summary, CuPc film with domain-oriented crystal structure has been prepared by employing titanyl-phthalocyanine (TiOPc) as molecular template deposited at a high substrate temperature. CuPc molecules stand up on the top of TiOPc domains, at the same time closely stacking among domains and high-order arrangement were observed. The corresponding OFETs devices were fabricated that exhibited an improved device performance, a 0.12 cm^2/V s of mobility and a 10^5 of on/off ratio. Threshold voltage also revealed a decrease of 13 V compared with that of conventional devices. All results were attributed to the controlling of film morphology and heterojunction functions realized by the TiOPc template. These indicated that molecular template is an effective method for the preparation of high-quality thin-film applied in organic optoelectronics.

removal. Additionally, most of the recent researches typically have used organic/polymer substance for the depositing materials [16].

In this report, we demonstrate high-resolution patterned inorganic Ag nanoparticulate electrodes and organic semiconductors using non-relief-lithography pattering technology for all printed organic thin film transistors (OTFTs). Using surface patterning of self-assembled monolayer (SAM) by direct deep-ultraviolet (DUV) light exposure, photoresist processing can be avoided and barrier-like structure for defining electrodes were fabricated from non-relief-lithography process [8]. Additionally, for fast and cost effective processing, dip-casting process was carried out by controlling withdrawal speed of the surface-patterned substrates. In particular, our emphasis is on identifying the physical conditions that ensure ideal processes for all printed OTFTs and electronics using the novel surface patterning process and dip-casting.

2. Experimental

Fig. 1 shows the experimental procedure which was used to obtain Ag nanoparticulate electrodes and all printed TFTs. A hydrophobic octadecyltrichlorosilane (OTS) SAM was formed by immersing the substrate into a 30 mM solution of OTS in hexane. Subsequently, ultrasonication process was performed and another OTS formation process was carried out for building dense and stable SAM. Spatial patterning of OTS covered substrates was achieved using DUV exposure through a quartz mask [17,18]. The DUV radiation was obtained from a low pressure mercury lamp with primary output wavelengths of 254 nm (90%) and 185 nm (10%). The 185 nm exposure results in rapid removal of the OTS SAM layer. Our preliminary measurement of contact angles from water droplet has shown 100° and 20° before and after OTS removal, respectively on SiO$_2$ surface. Deep ultraviolet light exposure was conducted by UV ozone cleaner (UV253H, Filgen, Japan).

Ag nanoparticulate solution including an average nanoparticle diameter of 10–20 nm was purchased from InkTec (www.inktec.com) Company. For controlling Ag ink viscosity, ethanol was added into the original solution and stirred at the temperature 60 °C for 2 h. The ink viscosity was measured by SV-10 (Sine-Wave vibro viscometer, A&D Company, Japan). Dip-casting process was performed to fabricate Ag electrodes using home-made dip-casting system with a stepping motor in air ambient at room temperature. Surface patterned substrates (patterned hydrophilic area on SiO$_2$/Si) were fully immersed into the Ag nanoparticulate solution and withdrawn with a controlled speed. After waiting for 30 min, the patterned Ag electrodes were annealed with a temperature of 180 °C for 30 min on a hot plate in air ambient. The resistivity of Ag electrodes were averaged by measuring at least four point in a sample.

The bottom gate and bottom contact *all printed* OTFTs were fabricated on heavily doped p-type Si wafers with a 200 nm thermally grown SiO$_2$ layer. The Si wafer was used as both substrate and common gate electrode, while the SiO$_2$ layer acted as a gate dielectric layer. Using the non-relief patterned surface patterning, source/drain Ag electrodes for TFTs were fabricated on thermally oxidized silicon wafer by controlling various dip-casting parameters. For the organic and inorganic active layer deposition, two deposition methods such as an ink-jetting and a dip-casting were used, respectively. The solution-processed organic semiconductors, 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene) [19], was prepared from 2 wt% chlorobenzene solution. After second surface patterning process on the pre-patterned Ag electrodes, active organic semiconductor layer deposition was performed by using piezoelectric ink-jet printing system (UniJet UJ2100). The piezoelectric ink-jet nozzle had a diameter of 50 μm (orifice size of 50 μm). The frequency of the jetting was 150 Hz and the diameter of the ink drop was approximately 30–50 μm. All the electrical measurements were performed using Keithley 4200-SCS in a dark and air ambient at room temperature.
Fig. 1. Process flow of non-relief-lithography process for patterning solution-processed organic semiconductors.

3. Results and discussion

3.1. Non-relief lithographic patterning of nanoparticulate Ag electrodes

To fabricate the barrier-like structure, a functional SAM (see experimental section) was patterned onto the substrate using deep ultra-violet (DUV) light exposure. The deposited nanoparticulate Ag solution can be steered into the desired hydrophilic areas by low surface energy SAMs and the barrier-like structure. Because this approach does not require photoresist coating, development, and removal processes, the non-relief patterning of a SAM can easily result in a fine-patterned barrier-like structure, making it cost effective. Direct DUV exposure of a SAM also offers great flexibility for two dimensional patterning. Patterning is not limited to surface energy effects and chemical reactivity or other surface properties can be used to meet the needs of specific applications [18]. DUV irradiation of silane SAMs typically induces a photochemical reaction which involves cleavage of Si–O or O–C bonds to form a reactive oxygen radical, which can react with atmospheric oxygen and moisture to form silanol or hydroxyl groups and produce a hydrophilic surface [20]. Thus, for a hydrophobic SAM, DUV irradiation can result in a hydrophobic to hydrophilic transformation.

Firstly, we investigated the influence of withdrawal speed of substrates which may be effective to control ink volume deposited on hydrophilic area. In dip-casting process, a patterned OTS substrate is immersed into Ag nanoparticulate solution for a certain time (around 1 min), and then withdrawn at a well-defined speed under controlled temperature and atmospheric conditions. Ethanol was mixed into original nanoparticulate Ag solution with a var-ious volume ratio to control the ink viscosity. Fig. 2a shows optical micrographs of patterned Ag nanoparticulate electrode arrays from various withdrawal speeds. As shown in Fig. 2b, thinner thickness (thus smaller amount of ink in a hydrophilic area) was obtained from slower withdrawal speed because of stronger liquid–liquid interaction than liquid–solid (substrate) interaction [7,21]. The electrodes from lower withdrawal speed from 1–10 mm/min. typically have shown some aggregation of Ag nanoparticulates with no fine-patterning structures (less than 40 μm), which is possibly due to fast solidification of Ag nanoparticulates from small amount of solvent in thinner film. Additionally, a significant aggregation of the ink was also observed at faster withdrawal speed (Fig. 2a). Typically smaller volume of ink has led to thinner film and thus higher convective and Marangoni flow enhanced by the increased surface tension may induce faster evaporation of solvents in the films [22]. In our experiments, the thinner films from withdrawal speed from 1–10 mm/min. result in fast solvent evaporation before the splitting of ink, inducing incomplete dewetting or splitting. Fig. 2c indicates the averaged line width and pitch as a function of withdrawal speed from 10 times repeated experiments. The thicker films from the faster withdrawal speed are also problematic for fine-patterning process.

The influence of Ag ink viscosity was also studied while maintaining withdrawal speed of 50 mm/min. Ink viscosity was controlled by the addition of ethanol into original nanoparticulate Ag solution. High ink viscosity (>2 mPa s) typically has led to too thick film which is beyond the critical thickness H_c for fine-pattern splitting. In contrast, lower viscosity ink induced too thin film and thus fast evaporation of solvent occurred before the splitting of ink, resulting in incomplete dewetting. Similar to the
Fig. 2. (a) Optical micrographs of patterned Ag nanoparticulate electrodes from surface patterning and dip-casting process, (b) an averaged thickness of patterned electrodes as a function of withdrawal speed, and (c) an averaged line width and pitch of electrodes as a function of withdrawal speed.

influence of withdrawal speed, ink viscosity also appears to be closely related to the ink volume or liquid thickness on the pre-patterned area [23,24]. Fig. 3a and b demonstrates the optical and confocal micrographs which show relatively uniform distribution of dip-cast Ag electrode from the surface patterning and dip-casting process. These images may provide additional information regarding thickness uniformity of the self-formed Ag electrodes. The dip-casted Ag dots or line arrays from optimal conditions typically have shown an average thickness 120 nm with ±15 nm variations and more than 80% uniformity. Fig. 3c shows an average limit of electrode resolution and pitch as a function of ink viscosity. Fig. 3d shows the resistivity of Ag electrodes as a function of electrode thickness and viscosity. For the application of printed electronics, the conductivity of electrodes is also critical for large area electronics and device performance. Typically, the direct printed Ag electrodes including thickness >50 nm shows resistivity of low 10^{-5} Ω cm ranges through annealing at 180 °C for 30 min, which is a little bit higher or similar to that of vacuum deposited metal thin films.

From our experiments, the differential wettability from solution process seems to be mainly defined by contact angles and geometry of surface. Incomplete splitting of ink was typically observed in samples which had too fast/slow withdrawal speed and higher ink viscosity which are likely to related with volume of the ink solution on hydrophilic area. According fluid-dynamic model [25], in a homogeneous solid substrate, the contact angle θ satisfies the Young equation [26].

$$\cos(\theta) = (\sigma_{VS} - \sigma_{LS})/\sigma_{LV}$$

where σ_{VS}, σ_{LS}, and σ_{LV} are the vapor–solid, liquid–solid, and liquid–vapor interfacial tensions, respectively. In our preliminary experiments, the contact angles of 100° (θ_δ:

contact angle on hydrophobic area) and 20° (θ_γ: contact angle on hydrophobic area) were measured on hydrophobic area (OTS SAM) and patterned hydrophilic area, respectively. During the dip-casting process, the hydrophilic stripes are completely covered by Ag ink, and the contact lines of this channel are located at the surface domain boundaries. As more Ag ink adds onto the hydrophilic stripes, the thickness of ink increases but they still have the shape of cylindrical or spherical caps and their contact lines are still pinned at the domain boundaries, resulting in increased contact angles, which no longer satisfies the Young equation. With appropriate ink volume (from withdrawal speed/ink viscosity), the contact angle of Ag ink at the boundaries are well consistent with differential wettability condition [27] such as

$$\theta_\delta < \theta < \delta_\gamma$$

If the ink volume on the hydrophilic stripes is more than a critical value (or thickness H_c), the contact angle exceeds θ_δ, developing a bulge as soon as the contact angle $\theta > \theta_\delta$. If the two neighboring bulges are enough close to merge or bridge, the patterned Ag electrodes typically have shown instable patterning properties. This is well consistent with our observation which indicates narrow process-window in fine-pitch electrode arrays as well as instable Ag ink patterns from too fast withdrawal speed and high ink viscosity.

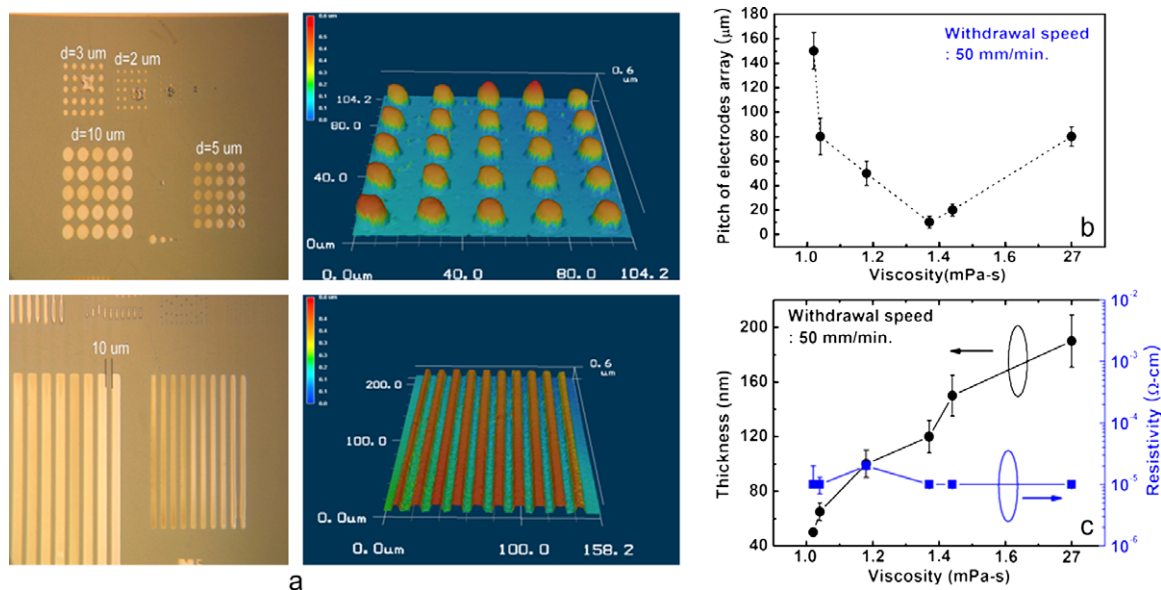
As well as the effect of contact angle change, the patterning resolution during dip-casting process seems to be also affected by polarity and vapor pressure of solvents. Typically, a polar solvent is affected more by a hydrophobic surface, resulting in higher resolution patterning possible [14]. The flowing speed of the Ag nanoparticulate solution on the heterogeneous surface should be faster than that of solvent evaporation speed, which can steer the liquid into


Fig. 3. (a) Optical micrographs (left) and confocal 3D micrographs (right) of patterned Ag nanoparticulate electrodes, (b) an averaged pitch of patterned electrodes as a function of ink viscosity, and (c) an averaged thickness and resistivity of patterned electrode as a function of ink viscosity.

desired area before solidification of the ink solution on hydrophobic area. In our experiments, ethanol is continuously evaporated during the dip-cast process, inducing change of interface/surface energy of the liquid on the hydrophilic stripes. Therefore, if the solidification exceeds a critical value before splitting occurred, the interaction energy for repelling between the liquid and hydrophobic solid is critically diminished, resulting in poor dewetting properties. Therefore, solvents including lower vapor pressure may limit the resolution of electrode arrays due to their faster evaporation speed. For the results described here, it is likely that patterning geometry, withdrawal speed, ink viscosity, solvent polarity, and vapor pressure are some of the key factors for the simple and high-resolution Ag nanoparticulate patterning process.

Fig. 4 shows simple comparison between direct printed Ag nanoparticulate electrodes by well-controlled ink-jet printing including ink drop size of around 35 µm on non-surface treated substrate and dip-cast Ag nanoparticulate electrodes on differentially patterned substrate using the non-relief-lithography patterning technology. As shown in this figure, while it may be difficult to obtain high resolution and fine-pitch electrodes on untreated surface even using a well-controlled direct ink-jet printing due to the larger ink-droplet and the difficulty of controlling ink spread, the dip-cast electrodes with non-relief patterned lithography patterning have shown high-resolution and fine-pitch, implying simple and high-resolution patterning possible.

3.2. All printed organic thin film transistors

The bottom gate and bottom contact *all printed OTFTs* were fabricated on heavily doped p-type Si wafers with a 200 nm thermally grown SiO_2 layer. The Si wafer used as both substrate and common gate electrode, while the SiO_2 layer acted as a gate dielectric layer. Using the non-relief patterned surface patterning, source/drain Ag electrodes for TFTs were built on thermally oxidized silicon wafer. Fig. 5a shows the optical micrograph of fabricated source and drain electrodes on SiO_2 layer. The channel length of 5–10 µm were easily achieved using the non-relief-patterned surface pattering and dip-casting process. To achieve fine patterning of organic and inorganic semiconductors, *second* non-relief-patterned surface patterning

was performed with the identical process of first surface patterning, resulting in a new barrier structure for confining semiconductor solutions.

Firstly, TIPS-pentacene from 2 wt% chlorobenzene solution was ink-jetted over the pre-patterned barrier-like structure. The schematic diagram of fabricated bottom contact and bottom gate TIPS-pentacene OTFTs was demonstrated (bottom of Fig. 5b). As shown in Fig. 5b, dropped TIPS-pentacene ink was automatically confined within the patterned OTS area. The diameter of dropped ink was around 30 µm with a volume of 30 pl. Fig. 5c shows $\sqrt{I_D}$ and $\log(I_D)$ versus V_{GS} characteristics for V_{DS} = −40 V, and I_D versus V_{DS} characteristics for the TIPS-pentacene OTFT with a surface energy patterned source–drain electrode and active layer deposited from a 2 wt% chlorobenzene solution. All electrical measurements were performed in an air ambient at room temperature. The device had a gate length of 10 µm, a gate width of 100 µm, and a 200 nm-thick silicon dioxide gate dielectric. The electrical characteristics such as field-effect mobility of about 0.03–0.06 cm^2/V s, on/off current ratios > 106, and subthreshold slope < 0.7 V/decade were obtained from more than 20 devices measurements. The typical performance of all printed OTFTs fabricated from the surface patterning and dip-casting process was similar to that of same configuration OTFTs (0.02–0.06 cm^2/V s) from ink-jet printed semiconductors and photolithographically patterned bottom contact electrodes [14,28,29].

Although we demonstrate non-relief-lithography-patterned Ag nanoparticulate source/drain electrodes based OTFTs, adopting the novel patterning technology to polymer substrate or organic dielectric is still problematic due to the difficulty of chemical reaction between OTS and polymer substance. Recently, a successful non-relief-lithography patterning of organic semiconductors on polymer gate dielectric materials was reported using a composite silane SAM layers [30]. The composite SAM layer was used as a base layer to promote dense and uniform formation of phenyl groups, which cannot be achieved by direct reaction between the SAMs and the polymer surface. The composite layer also contains alkyl groups which lead a hydrophobic state. Additionally, in our recent experiments, differential surface states were successfully obtained on polymer substrates and dielectric materials using the same non-relief-lithography patterning

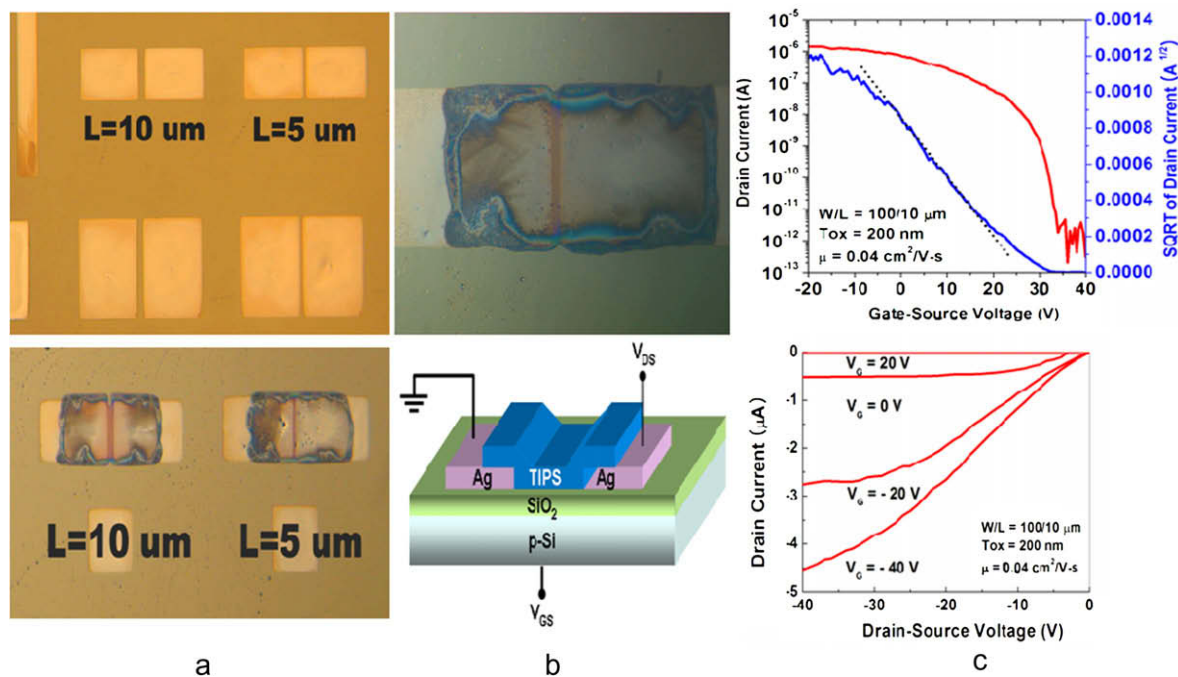

Fig. 5. (a) Optical micrograph of patterned Ag nanoparticulate source/drain electrodes for unit TFT and simple circuit from surface pattering and dip-casting process, (b) optical micrographs of ink-jet printed TIPS-pentacene on the patterned electrodes, and (c) electrical characteristics of all printed TIPS-pentacene OTFT ($\sqrt{I_{DS}} - V_{GS}$ and $\log(I_{DS}) - V_{GS}$ ($V_{DS} = -40$ V), $I_{DS} - V_{DS}$) from surface patterning and dip-casting.

process and a specially developed surface surfactant. Based on the recently developed technologies and materials, we believe that forming multi-stacking layers will be possible from the non-relief patterning technology and dip-casting for all printed high-resolution flexible OTFTs and electronics.

4. Conclusions

In summary, using a surface patterning, photoresist-free process and simple dip-casting, we have fabricated reproducible all solution-processed transistors with patterned active layers and source/drain electrodes. The influences of ink viscosity, deposition speed, solvent polarity, and boiling point were systematically investigated to obtain high-resolution and fine-pitch printed Ag nanoparticulate electrodes. Based on the patterned electrodes, we have demonstrated all printed high-resolution and short channel OTFTs. This simple patterning technology for solution-processed inorganic and organic materials can provide not only high resolution but also reproducible and high performance flexible printed electronics. This work demonstrates that surface energy patterning technology may provide a path to low-cost and high performance all printed electronics.

Until now, PCE up to 5% has been achieved from the BHJ of poly(3-hexylthiophene) (P3HT) blended with PCBM [1]. Although the transport properties have been dramatically improved by vertical phase separation of both donor and acceptor due to the self-organization effect [2–5], they still lack the absorption in the red and infrared regions. Therefore, great deal efforts have been undertaken to enhance the J_{SC} of solar cells by enhancing the absorption spectra of active layers. Recently, much work has been focused on synthesis the conjugated polymers [6–13]. Among several types of organics materials, polymer with electron donor–acceptor architectures is one of the most efficient ways to synthesize the narrow bandgap polymers. The effect of intramolecular charge transfer between the electron donor and acceptor units has been found in the polymers with donor–acceptor architectures leading to a narrow bandgap [14–21].

Recently, much BHJ polymer solar cells using polyfluorene based alternating copolymers as donor have been reported due to their high charge carrier mobility [22,17]. However, polyfluorene copolymers in general have high bandgaps giving blue-shift optical absorption and hence have limited the photocurrent generation. For example, poly[9,9'-dioctyl-fluorene-co-bithiophene] (F8T2) only absorbs light at wavelengths less than 500 nm [23]. Even though F8T2 exhibits excellent thermo tropic liquid crystallinity allowing better chain packing via self-assembly [24], the poor absorption still depresses the extraction of photocurrent dramatically. In this article, the BHJ device performance of a low-bandgap polyfluorene copolymer which comprises the phenothiazine units is reported. The copolymer used for here is referred to as PF-PThCVPTZ. With the incorporation of phenothiazine units into PF, the absorption can be stretched due to the donor–acceptor structure.

2. Experimental

2.1. Synthetic procedures

2.1.1. Synthesis

Monomer was synthesized according to a reported procedure [25], and the characterization is described as follows. The copolymer PF-PThCVPTZ is shown in Scheme 1, and this synthetic procedure is described as follows.

2.1.2. Monomer

Yield: 53%. ^{1}H NMR (CDCl$_3$, ppm), δ: 7.72 (dd, J = 8.7, 1.8 Hz, 1H), 7.45–7.36 (m, 3H), 7.29–7.18 (m, 3H), 7.07–7.01 (m, 5H), 6.79 (d, J = 8.7 Hz, 2H), 3.80 (t, J = 7.2 Hz, 2H), 1.80 (m, 2H), 1.45–1.14 (m, 6H), 0.89 (m, 3H). ^{13}C NMR (CDCl$_3$, ppm), δ: 148.11, 146.00, 143.66, 140.67, 140.14, 138.08, 135.80, 134.54, 132.05, 131.00, 130.89, 130.67, 128.54, 128.11, 127.49, 126.56, 125.31, 124.32, 123.88, 123.53, 122.87, 116.56, 116.49, 115.43, 114.99, 112.64, 112.62, 102.51, 100.94, 48.00, 31.35, 29.67, 26.49, 22.59, 13.98. 2.1.3. General procedure for the synthesis of PF-PThCVPTZ

The synthetic route of polymers is shown in Scheme 1. The polymerizations was carried out through the palladium(0)-catalyzed Suzuki coupling reactions. Into 50 mL of two-neck flask, 1 equiv of monomer and 1 equiv of 2,7-bis-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-
Scheme 1. Synthetic routes of PF-PThCVPTZ.

dihexylfluorene (1) were added in 10 mL of anhydrous toluene. The Pd(0) complex, Pd{P(p-tolyl)$_3$}$_3$ (1 mol%), was transferred into the mixture in a dry environment. Then, 2 M aqueous potassium carbonate and the phase transfer catalyst, i.e., aliquat 336 (several drops), were subsequently transferred via cannula into the previous mixture under nitrogen. The reaction mixture was stirred at 90 °C for 2 days, and then the excess amount of iodobenzene and phenylboronic acid, the end-capper, dissolved in 1 mL of anhydrous toluene was added and stirring for 4 h, respectively. The reaction mixture was cooled to 50 °C and added slowly into a vigorously stirred mixture of 300 mL of methanol. The polymers were collected by filtration and reprecipitation from methanol. The crude polymers were further purified by washing with acetone for 3 days in a Soxhlet apparatus to remove oligomers and catalyst residues. The resulting polymers were soluble in common organic solvents.

2.2. Fabrication of photovoltaic devices

The PV devices in this study consists of a layer of PF-PThCVPTZ:PCBM blend thin film sandwiched between transparent anode indium tin oxide (ITO) and metal cathode. Before device fabrication, the ITO glasses (1.5 × 1.5 cm^2) were ultrasonically cleaned in detergent, de-ionized water, acetone and isopropyl alcohol before the deposition. After routine solvent cleaning, the substrates were treated with UV ozone for 15 min. Then, a modified ITO surface was obtained by spin-coating a layer of poly(ethylene dioxythiophene): polystyrenesulfonate (PEDOT:PSS) (~30 nm). After baking at 130 °C for 1 h, the substrates were then transferred into a nitrogen-filled glove box. The polymer PV devices were fabricated by spin-coating blend of PF-PThCVPTZ:PCBM on the PEDOT:PSS modified ITO surface. Subsequently, a 30 and 100 nm thick of calcium and aluminum was thermally evaporated under vacuum at a pressure below 6 × 10^{-6} Torr through a shadow mask. The active area of the device was 0.12 cm^2. In the hole-only devices, the MoO$_3$ was used to replace Ca with higher work function (Φ = 5.3 eV), which is a good hole injection contact for PF-PThCVPTZ:PCBM [26]. The MoO$_3$ was thermally evaporated with a thickness of 20 nm and then capped with 50 nm of Al. For the electron-only devices, PEDOT:PSS layer was replaced with CsCO$_3$ (Φ = 2.9 eV) which has been used as an efficient electron injection layer [27]. The Cs$_2$CO$_3$ was thermally evaporated with a thickness of 2 nm. The active layers were annealed at 130 °C for 20 min before the hole and electron-only devices were fabricated.

2.3. Characterization of polymer films and PV devices

Cyclic voltammetry (CV) studies were performed with a three-electrode cell with 0.1 M LiClO$_4$/ACN using ITO as the working electrode, a platinum sheet as the counter electrode, and nonaqueous Ag/Ag$^+$ (containing 0.01 M AgNO$_3$ and 0.1 M TBAClO$_4$ in ACN) as the reference electrode. For measuring absorption and photoluminescence (PL) emission properties of polymer films, samples were fabricated on a glass substrate. The UV–visible absorption spec-

tra were measured using a Jasco-V-670 UV–visible spectrophotometer. PL spectra were obtained using a Hitachi F-4500 photoluminescence. Surface morphologies were observed by an atomic force microscopy (AFM, Digital instrument NS 3a controller with D3100 stage). The thickness of all polymer films was measured using a surface profiler (Alpha-step IQ, KLA Tencor). Current–voltage (J–V) characteristics were measured in the glove box under nitrogen atmosphere with simulated AM 1.5 G irradiation at 100 mW/cm^2 using a xenon lamp based solar simulator (Thermal Oriel 1000 W). The light intensity was calibrated by a mono-silicon photodiode with KG-5 color filter (Hamamatsu, Inc.). The external quantum efficiency (EQE) action spectrum was obtained at short-circuit condition. The light source was a 450 W Xe lamp (Oriel Instrument, model 6266) equipped with a water-based IR filter (Oriel Instrument, model 6123NS). The light output from the monochromator (Oriel Instrument, model 74100) was focused onto the photovoltaic cell under test.

3. Results and discussion

The CV was performed to investigate the electronic state of the PF-PThCVPTZ. As shown in Fig. 1a, the CV of PF-PThCVPTZ presents an oxidation process ($E_{ox}^{1/2}$ = 0.89 V vs. Ag/Ag$^+$) and a reduction process ($E_{red}^{1/2}$ = −1.08 V). Furthermore, the E_{ox}^{onset} and E_{red}^{onset} are 0.78 and −0.81 V, respectively, which allows us to calculate the highest molecular orbital (HOMO) and lowest molecular orbital (LUMO) according to following equation [28]: $E_{HOMO/LUMO}$ = $[-(E_{onset} - 0.45) - 4.8]$ eV. The factor of 0.45 and 4.8 are derived from the formal potential for ferrocene vs. Ag/Ag$^+$ and the energy level of ferrocene below the vaccum. On the basis of these electrochemical data, the HOMO and LUMO levels can be defined as −5.13 and −3.54 eV. Therefore, the bandgap offset between the LUMOs of PF-PThCVPTZ and PCBM is enough for electrons to be driven forward. Moreover, the polymer also reveals a multiply
Fig. 1. Cyclic voltammogram of PF-PThCVPTZ film cast on a platinum wire in 0.1 M LiClO$_4$/acetonitrile at 50 mV/s. (Inset: picture of the polymer film on the ITO electrode at different coloration states.)

colored electrochromic property. Fig. 1a shows the photographs of PF-PThCVPTZ films in uncharged (neutral, red), half (Re-1, green) and full (Re-2, blue) reduction states. The film colors are homogenerously distributed across the electrode surface and the color changes are easily detected by the naked eye.

The normalized optical absorption spectra of the PF-PThCVPTZ in solution and solid film and PL emission spectra of pristine polymer and their blend films with PCBM are depicted in Fig. 2. The solid film shows similar absorption pattern compared with the one of solution. However, slight red-shift still can be observed due to the interchain association and aggregation in the solid state. The PF-PThCVPTZ

film reveals a spectral absorption with a peak at 510 nm and an absorption onset at 645 nm. Furthermore, the corresponding PL emission maxima λ_{em} of PF-PThCVPTZ is centered at 660 nm. The PL emission is significantly quenched by the addition of 50 wt% PCBM. This highly efficient photoluminescence quenching is the consequence of ultrafast photoinduced charge transfer from the polymer to PCBM. Based on these characterizations, the copolymer is an excellent candidate to fabricate the photovoltaic devices.

The current density for the devices with varying active layer thickness are plotted in Fig. 3. The devices were fabricated by spin coating a solution of PF-PThCVPTZ/PCBM (1:1 in weight, 4 mg/mL) dissolved in 1,2-dichlorobenzene (DCB). The V_{OC} remains unchanged at about 0.8 V on changing the active layer thickness as shown in the inset. However, the J_{SC} and the PCE of the devices vary significantly with thickness. The J_{SC} varies from as low as 1.20 mA/cm² (for the device with active layer thickness,

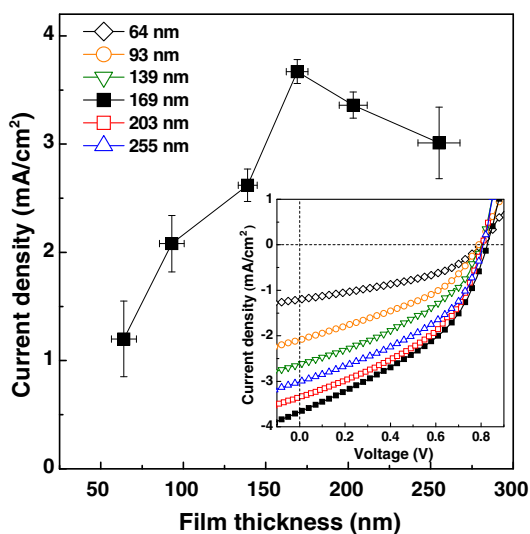
Fig. 2. UV–vis spectrum in DCB (dash line) and in the solid state (solid line), photoluminescence in solid state (□) and photoluminescence quenching for PF-PThCVPTZ:PCBM (1:1) (○).


Fig. 3. J_{SC} plotted as a function of the thickness of active layer for the PF-PThCVPTZ:PCBM solar cells. (Inset: corresponding J–V characteristics.)
Fig. 4. J_{SC}, V_{OC}, FF and PCE plotted as a function of the composition for the PF-PThCVPTZ:PCBM solar cells.

t = 64 nm) to as high as 3.67 mA/cm^2 (t = 170 nm) and back to 3.0 mA/cm^2 (t = 255 nm). The increased J_{SC} is contributed from the larger absorbance with thicker active layer. However, the J_{SC} decreases with a thickness larger than 169 nm due to the large series resistance and poor charge transport leading to a serious recombination [29]. An efficiency of 1.23% is achieved for the device with t = 170 nm.

Fig. 4 shows the performance parameters of the measured devices, namely J_{SC}, V_{OC}, FF and PCE as a function of PCBM weight ratios. First, the J_{SC} increases from 2.98 for the device with containing 33 wt% PCBM to 3.87, and 4.93 mA/cm^2 for those containing 50 and 66 wt% PCBM. However, the J_{SC} decreases with a larger PCBM weight ratio as shown in Fig. 3a which means that a higher PCBM weight ratio leads to an imbalanced mobility between donor and acceptor, thus impeding the charge transport. Second, the V_{OC} and the FF strongly decrease with PCBM loading, resulting in a doubling of the calculated PCE when increasing the PCBM concentration from 33 to 80 wt%. According to our previous work [30], we have found that the values for V_{OC} and FF based on polyfluorene copolymer

decrease monotonically with increasing fullerene content in the BHJ films. This can be rationalized by the incomplete charge generation and transport resulted from the aggregation of the large amount of fullerenes [31]. The best cell has an active layer thickness of about 180 nm, containing 66 wt% of PCBM with a J_{SC} of 4.93 mA/cm^2, a V_{OC} of 0.77 V, a FF of 40%, and a PCE of 1.51%.

In order to control the morphology of the blending films, we investigated the effect of solvents with different boiling points. Fig. 5 compares the morphology of the films cast from chloroform (CF), chlorobenzene (CB), DCB and 1,2,4-trichlorobenzene (TCB) with the boiling points of 60, 132, 180 and 218 °C, respectively. The images are obtained in tapping mode for a 2 × 2 μm^2 surface area. It can be found the films spin-cast from CB, DCB and TCB show a coarse chainlike feature stretching across the surfaces. With higher boiling point, the chainlike feature is more obvious and the root mean square roughness (RMS) also increases from 4.3 (for the film cast from CB) to 7.8 (TCB). These chainlike features are originated from the strong π–π stacking of the polymer chains which is believed to enhance the charge transport [32,33]. This feature
Fig. 5. AFM images of the blended films cast from (a) CF, (b) CB, (c) DCB and (d) TCB.

is well known and easily reproducible for the P3HT:PCBM blends using slow growth with high boiling point solvent such as TCB or DCB. In contrast, the film prepared from CF solution appears a very smooth surface without apparent nanostructure. Although CF is a good solvent for PF-PThCVPTZ, however, its low boiling point and rapid evaporation limit the time for crystallization during the spin-coating process.

To further understand the dependence of charge transfer properties on morphologies that were introduced by varying the solvents, we have performed dark current measurements on hole-only and electron-only devices based on the blend films. The charge mobilities were calculated by space-charge limited current (SCLC) [34]. The dark current is given by $J = 9\varepsilon_0\varepsilon_r\mu V2/8L^3$, where $\varepsilon_0\varepsilon_r$ is the permittivity of the polymer, μ is the carrier mobility, and L is the device thickness. The hole and electron mobilities of the blend films preapard from different solvents are summarized in Table 1. For the device made by CF have the lowest hole and electron mobility. Overall, the largest mobility can be found in the devices fabricated from TCB. The hole and electron mobility up to 1.93×10^{-8} and $2.41 \times 10^{-8}\,\mathrm{m^2\,V^{-1}\,s^{-1}}$ is observed. Furthermore, we observed more balanced charge mobility ($\mu_h/\mu_e = 0.8$) in the film cast from TCB which can enhance the photocurrent.[35,36] For both DCB and TCB (which has a higher boiling point) it takes 10–15 min for the film to dry, while films cast from CF would dry within a few seconds of spinning. Therefore, the molecules in TCB can self-organization over a long time to form a thermodynamically favored structure leading to higher charge mobility [37,38].

Fig. 6 shows the J–V curves and EQE of the PV devices fabricated from various solvents. The J_{SC} values of the devices fabricated from CF, CB, DCB and TCB are 2.45, 3.58, 4.73 and 5.37 mA/cm^{-2}, and the FF values are 45.4, 41.4, 38.3 and 43.0%, respectively. The V_{OC} values of all cases are almost the same (0.80 V). As a result, the PCE of 1.84% is the highest among these devices which is obtained from TCB. The highest J_{SC} of device fabricated from TCB can be realized by the slow growth effect which provides a charge transport channel formed from self-organization leading to a higher photocurrent. This is supported by EQE characterization. After measuring the J–V curves, the devices were encapsulated in a nitrogen-filled glove box, and the EQE of the devices were measured in air. As shown in the inset, the devices exhibit a photoresponse covering from 350 to 650 nm. It can be seen that the EQE values increase by using solvents with higher boiling points. These results are in good agreement with the values of J_{SC}. The EQE for the device fabricated from CF shows a maximum

Fig. 6. J–V curves of the PF-PThCVPTZ:PCBM solar cells fabricated from different solvents. (Inset: corresponding EQE characteristics.)

of 20.7% at a wavelength of 370 nm. On the other hand, for the device fabricated from TCB, the EQE maximum increases to 39.8 at 450 nm leading to a larger J_{SC}.

4. Conclusion

An alternating PF copolymer, PF-PThCVPTZ, containing a low-bandgap donor–acceptor segment has been designed and synthesized for use in PV devices. A broad absorption spectrum in PF-PThCVPTZ film covers the visible solar spectrum, resulting in an extended photocurrent response. Under AM 1.5 G 100 mA/cm^2 illumination, the devices fabricated from TCB with 67 wt% PCBM reveal a PCE of 1.84%. Based on these findings, PF-PThCVPTZ is a potential candidate for application in polymer solar cells.

In this article, we study how the electric polarization or dipole moment of a ferroelectric polymer can induce NDR effect in organic devices. As a ferroelectric polymer, we have chosen poly(vinylidene fluoride) (PVDF), which is particularly important as non-volatile memory elements with high stability and excellent solubility. We show how the electric polarization of PVDF induces NDR in an organic molecule that otherwise does not exhibit any NDR effect.

2. Experimental

The molecule of interest in this work is fluorescein, which is a molecule in the xanthene class known for organic memories [9]. Fluorescein has exhibited electrical bistability through carrier-transporting channels [24]. Molecular structure of fluorescein is shown in the inset of Fig. 1. It can be mixed well with PVDF in a common solvent to form spun-cast films. Powder form of PVDF (M_W = 534,000), obtained from Aldrich Chemical Company, was sonicated to dissolve in THF. In this work, we have varied the concentration of fluorescein in PVDF matrix between 5% and 50%. Apart from PVDF:fluorescein films, thin-films were obtained from only PVDF and fluorescein. All the films were spun from 20 mg/ml solution in tetrahydrofuran (THF) to keep the thickness the same (around 150 nm). The films were annealed at 60 °C for 4 h. Indium tin oxide (ITO) coated glass substrates acted as the base electrode; aluminum (Al), thermally evaporated under 10^{-6} Torr, was the top electrode. PVDF thin-films had an electroactive β-phase due to residual stresses between the films and the substrates. Formation of β-phase of PVDF films was also supported by X-ray diffraction (XRD) spectrum that has showed a peak at 21°; the spectrum has matched well with the reported result [25].

To record I–V characteristics, bias was applied to the ITO electrode with respect to the Al one. Capacitance–voltage (C–V) plots were recorded in a parallel mode by a Solartron 1260 Impedance Analyzer. While the test voltage was 100 mV rms, frequency of test signal was kept at a fixed value (50, 500, 1k and 10k Hz). Open- and short-circuit compensations were performed with standard normalization procedure in order to minimize the effect of any stray and wire capacitances. The instruments were controlled with a personal computer via a general-purpose interface bus (GPIB). The measurements were carried out with SMART software.

3. Results and discussion

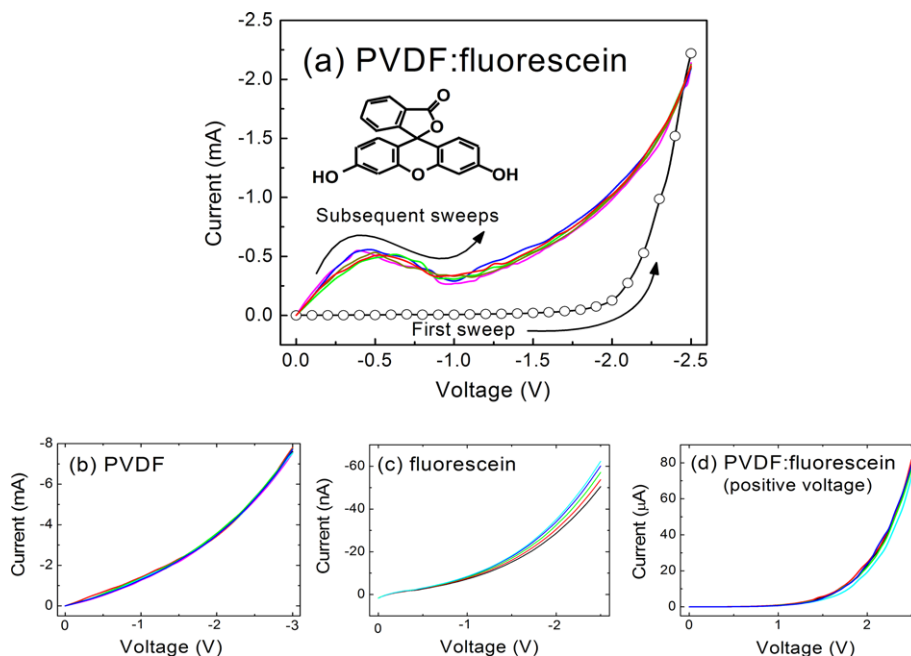
We have recorded I–V characteristics of different devices with varied concentration of fluorescein in PVDF. Films, which are initially unpolarized, have been characterized; after application of a suitable voltage, the ferroelectric polymer becomes polarized; then the films were again characterized for many times. To record the effect of polarization, we scanned voltage from zero to a negative value (or a positive value) in succession. Results from a typical device, with 20% fluorescein in PVDF, in the negative bias region are shown in Fig. 1a. The unpolarized film shows non-ohmic current–voltage characteristics. Once the films are poled by the application of a bias (V_{Max}, the value up to which voltage was scanned), I–V of the devices becomes NDR in nature. The NDR effect repeated in subsequent sweeps and cycles without any decrease in the ef-


Fig. 1. Current–voltage characteristics of (a) PVDF:fluorescein (20 wt.%) (b) PVDF, and (c) fluorescein under multiple voltage sweeps to a negative bias. Characteristics for the PVDF:fluorescein system under multiple voltage sweeps to a positive bias is shown in (d). Different sweeps are shown by lines of different colors except in (a), where the first sweep is represented by open symbols. Molecular structure of fluorescein is shown in the inset of (a).

fect. There was no role of scan-speed in the 20–200 mV/s range on the observation. The NDR effect can only be erased by an application of an opposite voltage (positive voltage, in this case).

The role of a ferroelectric polymer in the observed NDR has been tested by several control experiments. The NDR effect could not be observed in devices based only on PVDF or fluorescein. Both the devices returned non-ohmic *I–V* characteristics, which have not changed in successive voltage-scans. The plots are shown in Fig. 1b and c, respectively. Similar sweeps towards a positive voltage did not yield any NDR in PVDF:fluorescein films or its components. Absence of NDR in PVDF:fluorescein films under successive scans to a positive voltage is shown in Fig. 1d. In the positive voltage direction, NDR did not appear even during sweeps to a higher value. The results in Fig. 1a, in conjunction with that in Fig. 1b–d show that the ferroelectric polymer induces NDR in fluorescein in the negative voltage region. This could be due to the induced polarization in PVDF; fluorescein in an inert polymer, such as poly (methyl methacrylate) does not exhibit any NDR.

Upon application of a suitable negative bias at the ITO electrode (with Al being the ground) nearing the coercive voltage during the first voltage sweep, polarization occurs in the ferroelectric film. The electric polarization of PDVF now leads to band-bending with the ITO electrode at the interface [21]. The band-bending expectedly facilitates electron-injection in the device. Fluorescein, being electron-transporting in nature, now receives more electrons (from ITO electrode) than the pre-polarization situation and becomes reduced. The reduced fluorescein molecules have a higher conductivity than the neutral one as evidenced by energy minimization calculation on xanthene molecules [26]. In the second and subsequent voltage sweeps towards the same direction, the (magnitude) current at a particular voltage hence become higher than that in the first voltage sweep. Now, with an increase in the (the magnitude of) voltage with more electron-injection, the molecules undergo a second reduction; the doubly reduced molecules have a lower conductivity than the singly reduced ones. The (magnitude of) current hence decreases with an increase in (magnitude of) voltage in the *I–V* characteristics. With further increase in voltage, the current shows usual increase due to non-ohmic contact with the electrodes. The *I–V* characteristics hence become NDR in nature.

When bias was swept towards a positive voltage in a PVDF:fluorescein device, polarization of the ferroelectric polymer occurs in the opposite direction. Due to band-bending, hole injection from the ITO electrode becomes possible. Carrier injection from the Al electrode is hindered possibly due to an oxide layer formed during thermal evaporation of the top electrode. Since fluorescein is electron-acceptor in nature, the injected holes cannot reduce the molecules to a higher-conducting state. The injected holes may further tend to decrease the conductivity of fluorescein, as shown by lower current in Fig. 1d as compared to that in Fig. 1a. Since there was no possibility of reduction or double-reduction of the molecules, NDR effect was hence not observed in the positive bias direction of the *I–V* characteristics.

To substantiate polarization-assisted double-reduction in fluorescein molecules, we have recorded *I–V* characteristics after application of voltage pulse of different amplitudes (Fig. 2). With an increase in the amplitude of voltage pulse that induces polarization in the ferroelectric polymer, the degree of electric polarization is expected to increase till saturation is reached. The Fig. 2 however shows that the NDR effect did not increase with an increase in the degree of polarization. With an increase in the amplitude of voltage pulse, the NDR occurred at a lower bias in voltage-scans with the NDR peak shifting to a lower (amplitude of) voltage. The higher degree of polarization might have speeded up the second reduction of fluorescein molecules shifting the appearance of NDR to a lower (amplitude of) voltage. When the amplitude of preceding voltage pulse decreased below a threshold value (2.5 V), there was no polarization of the ferroelectric polymer; neither first nor second reduction was possible and consequently no NDR effect was observed.

Role of the ferroelectric polymer in inducing NDR effect in fluorescein can best be understood by varying the concentration of the organic molecule in PVDF matrix. Concentration of fluorescein in the thin-films has been varied between 5 and 50 wt.%. Thickness of the active layer of all the devices were however same. We have compared the NDR effect in these devices after application of a voltage pulse. All the devices show NDR effect; the effect was however small in the extreme systems. The peak-to-valley ratio is a measure of NDR effect; a plot of the ratio versus fluorescein concentration goes through a peak (Fig. 3). The results are in consistent with Fig. 1b and c evidencing absence of NDR in PVDF- and fluorescein-based devices, respectively. The systems in the extreme cases are not favorable to observe NDR. When concentration of fluorescein is low, the molecules do not form many percolative channels between the two electrodes resulting in low device current. As the other extreme, at a higher fluorescein concentration, the PVDF matrix is nearly discontinuous to polarize and hence to built a density of charge carriers. The fluorescein molecules, due to its high-bandgap and correspondingly fewer electron-injection, could not be electroreduced to exhibit NDR effect. At an intermediate
Fig. 2. Current–voltage characteristics of a PVDF:fluorescein (20 wt.%) film after application of voltage pulse (width = 5 s) of different amplitude (as shown in the legend).
Fig. 3. Peak-to-valley ratio of negative differential resistance for PVDF:fluorescein films with different concentration of fluorescein. The line is to guide the eye.

fluorescein concentration in PVDF, the molecules form percolative networks between the two electrodes in the device. Also, the ferroelectric polymer could become polarized and subsequently facilitate electroreduction in a large number of fluorescein molecules. Under application of external voltage, the reduced molecules may then undergo a second reduction to yield a large NDR in the devices.

To substantiate electric polarization of the polymer, we have measured capacitance of the devices. Measurements were carried out at fixed (test) frequencies under a dc voltage sweep. Results from a PVDF:fluorescein (20%) device at 10 kHz are shown in Fig. 4. Capacitance values for five consecutive sweeps (from 0 to −3.2 V) are shown in the figure. In the first sweep when the ferroelectric polymer was yet to be polarized, capacitance was initially high. With polarization of the polymer followed by first electroreduction of fluorescein molecules, conductance of the device increases. The capacitance of the device hence decreased. During the subsequent sweeps, a dip in the C–V plots might points to the sign change in differential resistance (peak in the I–V

characteristics) in the devices. Measurements carried out at different test frequencies yielded similar nature in the C–V characteristics; magnitude of capacitance however decreased with an increase in ac test frequency.

4. Conclusions

In summery, we have shown that NDR in fluorescein could be induced by the use of PVDF polymer. While neither the fluorescein nor the ferroelectric polymer exhibit NDR, devices based on fluorescein in PVDF matrix yield reproducible NDR effect. We have inferred that electric polarization of the ferroelectric polymer enhances carrier injection followed by reduction and then a double-reduction of fluorescein molecules in the device to result NDR nature in the I–V characteristics. We have substantiated our findings by varying the concentration of fluorescein in PVDF matrix and by varying the degree of polarization (by applying voltage pulse of different amplitudes).

Acknowledgements

Fig. 4. Capacitance–voltage plots of a PVDF:fluorescein (20 wt.%) film under multiple voltage sweeps to a negative bias. While the first sweep is represented by open symbols, results for other sweeps are shown by lines of different colors. Frequency of test ac signal was 10 kHz.

lead to a substantial progress in the field, with the best power conversion efficiencies achieved in the laboratory currently being in the 5–6% range [1–3].

For a given material system, the control of the blend structure at the nanoscale is, in fact, one of the most effective ways to significantly enhance the organic solar cell efficiency. In the case of the most extensively studied material systems (e.g. poly(3-hexylthiophene) (P3HT) and soluble fullerene derivative PCBM), 10-fold increases in the power conversion efficiency have been reported when comparing devices based on as-spun active layers, and active layers with a controlled structure [4]. Typical protocols include slow drying of the active layer, thermal and vapor annealing, as well as appropriate solvent (or solvent mixture) choices [4–8]. A comprehensive review on the effect that morphology has on bulk heterojunction solar cells has been recently published by Yang and Loos [9]. Interestingly, it has been found that for the case of P3HT:PCBM blends, all of these fabrication protocols result in a similar optimized morphology (see Ref. [8] and references therein). This consists of a bicontinuous blend of the electron donor (the polymer chains) and electron acceptor (the fullerene molecules), with crystalline domains on the nanometer-length scale, and a composition gradient normal to the device electrodes. The optimum size of the nanodomains represents a compromise between good charge transport (large interconnected domains that form percolating pathways) and efficient charge generation (i.e. large exciton dissociation rate, which requires domains around twice as big as the exciton diffusion length, ~ 10 s nm) [8,9]. The composition gradient improves the contact selectivity thus reducing the leakage current.

Moreover, the post-deposition treatments, and in particular thermal annealing, have also an additional positive effect: they – in principle – increase the OPV stability by means of the concomitant stabilization of the active layer blend compared to the frozen non-equilibrium morphology of the as cast films [9]. This is particularly important if one takes into account that the relatively low glass transition temperatures that most soluble conjugated polymers exhibit may cause a morphology change as the temperature significantly rises during device operation [9]. In the process of stabilizing the morphology, thermal annealing does, however, also yield large-scale phase separation [8,10–12]. For instance, annealing at 140 °C for one hour a 1:1 (in wt.%) regio regular P3HT:PCBM blend film leads to micron-sized PCBM clusters (see Fig. 1a) that are not beneficial to OPV performance. The fabrication of OPVs with appropriate control over the nanostructure is, therefore, a key challenge for which currently only a few general rules – regarding optimum composition – have been found [11].

In this paper we investigate the possibility of using ternary mixing in order to control the blend morphology. The rationale is that small amounts of an amorphous polymer may form a dilute matrix which would allow the formation of small crystallites but prevent the large-scale phase separation of the components. For devices based on blending PCBM with P3HT of two different molecular weights [13], it was observed that the advantages of both low molecular weight (efficient charge generation) and high molecular weight (enhanced transport) could be combined and thus this type of ternary mixing resulted in enhanced device performance. Here we have chosen ternary blends of PCBM with regio regular (RR-) P3HT and regio random (RRa-) P3HT. We will show that besides a very efficient control of the blend morphology, regio random P3HT also adds several other functionalities, such as energy transfer to the more crystalline RR-P3HT, enhanced charge generation and improved open circuit voltage, all with minimum cost in terms of charge carrier mobility. The final ternary-based devices, even without optimization procedure, are about 20% more efficient than the conventional annealed blends when excited with low intensity monochromatic light.

2. Experimental section

2.1. Materials and thin film fabrication

Regio regular (Aldrich #669067, regioregularity >95% head-to-tail regioregular (HNMR), Mn = 17,500) and regio random poly(3-hexylthiophene) P3HT (Aldrich #510823, regioregularity = 1:1 (head-to-head):(head-to-tail) linkages of regioisomers, no data available of Mn) were purchased from Aldrich and used as received. Herein, regio regular and regio random materials are denoted RR-P3HT and RRa-P3HT, respectively. [6,6]-Phenyl C_{61}-butyric acid methyl ester (PCBM) was obtained from Luminescence Technology and was also used as received.

Binary blends consisting of RR-P3HT and RRa-P3HT were prepared from different solution concentrations (from 15 to 50 g/l) in high grade chlorobenzene, and spin coated at varying spin speeds (2000–4000 rpm) so to produce different thicknesses. The relative concentration of regular and random (RR-P3HT:RRa-P3HT) polymers was varied in 0.25 steps: (1:0), (0.75:0.25), (0.5:0.5), (0.25:0.75) and (0:1). The mobility on binary systems was measured in devices containing around 150-nm-thick films deposited from a total 50 mg/ml solution.

For ternary blends, total 60 mg/ml solutions in chlorobenzene were prepared, from which 30 mg was PCBM, and the other 30 mg split between RR-P3HT and RRa-P3HT, so to finally produce constant (1:1) fullerene:(polymer) concentrations. The relative content of regular P3HT and random P3HT was varied leading to the following PCBM:RR-P3HT:RRa-P3HT concentrations (1:1:0), (1:0.9:0.1), (1:0.75:0.25), (1:0.5:0.5), (1:0.25:0.75) and (1:0:1). Herein, we denote conventional blend the films comprising the (1:1:0) ratio, i.e. (1:1) PCBM:RR-P3HT, and it will be used as reference. Moreover, a different set of devices was fabricated from solutions made by adding RRa-P3HT to a 1:1 PCBM:RR-P3HT (60 mg/ml) solutions, ending up in the following relative concentrations: (1:1:0.1) and (1:1:0.25). For the devices, a two-step process was identified during spin speed optimization: 1000 rpm for 3 s in order to produce a homogeneous distribution of the solution throughout the substrate, followed by 90 s at 2000 rpm. This protocol typically resulted in active layers with thickness in the 85–105 nm range.

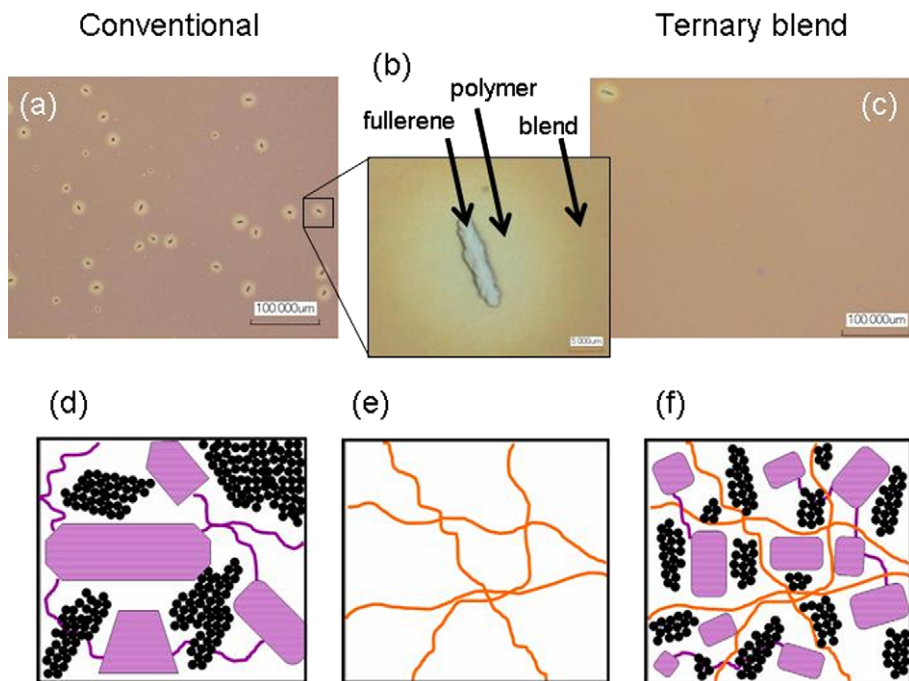
The solutions were spin coated on cleaned quartz substrates or on ITO-covered glass (150-nm-thick ITO layer


Fig. 1. Comparison of the microscale morphology of the conventional blend and the ternary systems. (a–c) UV laser microscope images of annealed ternaries with PCBM:regular P3HT:random P3HT concentrations of (a) 1:1:0; (b) 1:1:0 (zoom-in detail); and (c) 4:3:1; (d–f) schematics of (d) a conventional PCBM:regular P3HT blend; (e) dilute random matrix; and (f) ternary system comprising a dilute random P3HT matrix filled with crystallites of PCBM and regular P3HT.

with a sheet resistance of 10 Ω/sq, SLR grade, Sanyo Vacuum Industries Co. Ltd). For the solar cells, PEDOT:PSS (Baytron P VP Al 4083 (H.C. Starck)) was spin coated (3000 rpm for 90 s) onto the ITO-coated glass and annealed at 200 °C for 20 min. The ternary systems were thermally annealed at 140 °C for 1 h inside a nitrogen-filled Glovebox (O_2 and H_2O levels less than 2 ppm).

2.2. Thin film characterization

Film thicknesses were measured using a Dektak 3030 profilometer (and double checked with the thicknesses deduced from the absorption data using the optical constants from Ref. [8]). Scanning laser microscopy images were taken using a Keyence VK-9700 microscope. At least 10 images were employed for each sample in order to obtain average values of the density of large-scale (micron size) aggregates of PCBM. Atomic Force Microscopy (AFM) was carried out with an SPA 400 system by Seiko Instruments, Inc. Typically, at least three AFM images were taken for each sample and their surface roughness was analyzed using the Spisel 32 piece of software. X-ray diffraction (XRD) experiments were conducted using a Material Analysis and Characterization SRA system, model M18XHF, which employs a Cu Kα2 source (40 kV, 60 mA) with wavelength 0.1544390 nm. Upon background removal, the data were fitted with a Gaussian function in order to obtain the peak intensity, width and angular position at the maximum. These data were then used to deduce the average interplane distance within the crystallites (from Bragg's law), estimate crystallite size (from Scherrer's relationship)

and overall degree of crystallinity (integrating the area underneath the XRD peak).

The thin film absorption spectra were measured using a Perkin–Elmer Lambda750 UV/Vis spectrometer from 300 to 800 nm. Photoluminescence (PL) data were collected using a Perkin–Elmer LS55 Fluorescence Spectrometer. Unless otherwise stated, the PL excitation wavelength was set to 450 nm (around the absorption maximum for RRa-P3HT).

Pristine polymer films deposited onto pre-cleaned ITO/glass substrates were used to measure the HOMO levels of the polymers by means of a Riken Keiki AC-2 ultraviolet photoelectron spectrometer. The experimental set-up is similar to that of conventional UPS but it does not require vacuum. On the other hand, the precision of our apparatus is smaller than that of a conventional UPS in vacuum, with uncertainty values ∼0.03 eV. Using ultraviolet photoelectron spectroscopy we obtained a HOMO value of 4.61 ± 0.03 eV for regio regular P3HT, while that of regio random P3HT was found to be 4.73 ± 0.03 eV. The slightly smaller values obtained here for RR-P3HT (often around 5 eV) might be related to possible effects of the ITO surface on the measurement. We note that two samples with different thicknesses were measured for each polymer, and each sample was measured twice. The deviation between measurements and samples is smaller than the 0.03 eV uncertainty values.

2.3. Device fabrication and characterization

Single carrier devices were fabricated and the dark current–voltage characteristics measured and analyzed in the

space charge limited (SCL) regime following the references [4] and [14]. Hole only devices consisted of the active material (binary or ternary system) spin coated onto glass/ITO substrates, and capped with a 5-nm evaporated MoO_3 layer followed by a 100-nm-thick Al contact. The evaporation mask defined 4 pixels in each sample with a 4-mm^2 area for each pixel. For the electron only devices, the structure was glass/ITO/Al/blend/Ba/Al, where both Ba and Al were evaporated. High-purity MoO_3 (6 N grade, Mitsuwa Chemicals Co., Ltd), Ba (Aldrich), and Al (AL-011480, Nilaco Co.) source materials were employed as delivered. The standard deviation of the fit to the SCL equations for the electron only devices was slightly higher than that for the hole only devices, indicating a larger error on the extracted electron mobilities. The reported mobility data are average values over the four pixels of each sample at a given film composition.

For the solar cells, the active blend was spin coated on top of PEDOT:PSS coated glass/ITO substrates in a clean room, and then transferred into an interconnected Glovebox where the Al electrode was thermally evaporated. Thermal annealing of the devices was done inside the Glovebox before the deposition of the contacts. All of the devices were encapsulated with a glass cap using an ultraviolet curing epoxy resin. The 15-min exposure to the UV radiation was performed from the Al metal side to avoid photodegradation of the organic layers across the active region.

The current–voltage characteristics of the encapsulated devices were measured outside the Glovebox, using a semiconductor characterization system (SCS4200, Keithley Instruments Inc.) at room temperature. For light J–V and EQE measurements, the above instrument was coupled to a JASCO CT-25C grating monochromator which selects the wavelength coming from a USHIO Optical Modulex light source. The intensity of the monochromatic light was fixed at 20 µW after calibration against a standard Coherent Fieldmaster photodiode with circular detecting area of 8 mm in diameter (resulting in an illumination density of 400 mW/m^2). In order to explore the light intensity dependence of the solar cell parameters, the light intensity was varied using optical density filters between 0.3 and 45 µW. The encapsulated devices were kept in air and darkness for 10 months, when some of them were measured again to check the variation in performance with time.

3. Results and discussion

3.1. Characterization of binary and ternary systems

Fig. 1a shows a representative laser microscopy image of a conventional PCBM:RR-P3HT (1:1) blend film annealed at 140 °C for 1 h. To start with, annealing leads to the appearance of large size aggregates as clearly seen in the image. These aggregates, which are not present in the as-spun films, are rich in PCBM molecules [8,11] and are surrounded by a polymer-rich region, seen here as a halo-like structure. It has been shown that PCBM nucleates into these aggregates upon annealing [8], or, in other words,

once they are large enough to be seen using a microscope, they grow bigger in size, but their number remains constant. The average diameter of the region containing one PCBM aggregate and the associated P3HT halo is around 13 µm (see Fig. 1b), in good agreement with previous reports [8].

Such a large phase separation is, in principle, detrimental for solar cell performance since it is several orders of magnitude larger than the exciton diffusion length (∼tenths of nm's), and thus charge generation is strongly inhibited on these regions. By averaging over 10 microscope images across the sample, we estimate the density of PCBM micron-sized domains to be around 700 aggregates per square mm. If we consider the average size of the aggregates, this means that around 9% of the area is covered with these structures, and thus, 9% of the film is not acting positively as light-to-electricity converter. The introduction of the regio random polymer into the blend has a marked effect on the structure of the film. Substituting 25% of RR-P3HT by RRa-P3HT (1:0.75:0.25 sample Fig. 1c) already decreases in more than two orders of magnitude the density of these large aggregates, down to just 3 aggregates/mm^2. This represents less than 0.04% of the total film area. The density is further reduced for larger amounts of the RRa-P3HT polymer in the ternary system. The samples with compositions 1:0.5:0.5 and 1:0.25:0.75 have 1 aggregate/mm^2 and 0.15 aggregates/mm^2, respectively (not shown). It is clear that this approach is extremely efficient at controlling the microscopic morphology of the blend films.

An important question that needs to be answered is whether the introduction of the RRa-P3HT chains yields an overall amorphous structure, not only at the micron level, but also down to the nanoscale. If the resulting morphology is totally amorphous, the mobility would likely fall and the absorption would be blue shifted, and as a consequence, the overall solar cell performance would be poor. As we will see below, the RR-P3HT chains can still crystallize in the ternary blends and, in addition, the extent of the phase separation is now greatly controlled with microscopic scale phase separation being almost totally suppressed. We will come back to this point below. The eventual appearance of micron-sized aggregates also in ternary systems containing RRa-P3HT (<3 aggregates/mm^2) is, in most cases, associated with film defects, such as edges of the substrate, in which inhomogeneities in film composition might be present. An optimization of the film fabrication conditions may, therefore, lead to an even smaller number of large size aggregates in films based on ternary blends.

The advantages of controlling the large-scale phase separation by using RRa-P3HT rather than other amorphous conventional polymers, such as polystyrene or polymethylmethacrylate, is twofold. First, we expect high chemical affinity amongst the blended materials due to the common backbone between RRa- and RR-P3HT polymers. Other glassy polymers could promote an even larger phase separation if the interaction between chains overcomes the entropy increase granted by mixing (following Flory's theory of mixing). Optical and atomic force microscopy images show no evidence of large-scale phase separation in

RR-P3HT:RRa-P3HT binaries or in ternary blends (see details below). Second, perhaps even more importantly, RRa-P3HT can act as an active matrix, helping the proper functioning of the devices and even adding functionality. In the following, we demonstrate several examples of this added functionality of the multicomponent system.

Fig. 2 shows the normalized absorption (solid lines) and photoluminescence emission (dashed lines) of RRa-P3HT (blue) and RR-P3HT (red). The red shift spectra of the regular polymer compared to that of the random polymer is associated to different molecular packing morphologies. Regioregularity enables a better ordering of chains into lamella crystallites where the polymer adopts a planar conformation with longer conjugation lengths and fewer defects, such as twists and radicals on the chains [15,16]. Regio random chains form, on the other hand, glassy films whose optoelectronic properties are governed by individual chain processes [15,16]. The crystallization of P3HT results in the appearance of pronounced structures in the absorption and PL spectra – phonon replica – not present in the data for RRa-P3HT films. Interestingly, the long wavelength shoulder observed in the absorption of RR-P3HT has been assigned to two-dimensional excitations [17,18], and hence is a direct consequence of the good interchain interactions within the crystallites. The intensity of this shoulder has, in fact, been found to be directly proportional to the X-ray deduced overall degree of P3HT crystallinity in P3HT:PCBM blend films subjected to various annealing treatments [19]. Another indication of the degree of chain interaction is given by the PL quantum efficiency (η). Jiang et al. showed that RRa-P3HT has a much larger η ($\sim$8%) than RR-P3HT ($\sim$0.5%) [15] due to the isolation of chains in the random case. Here, we also found that RRa-films exhibit more than one order of magnitude higher PL than RR-P3HT films with comparable thicknesses (see Fig. 3b). It is thus apparent that regioregularity strongly determines the degree of interchain interaction [16].

From the electronic point of view, one important effect of the aforementioned interactions is that the band gap of RR-P3HT is about 0.3 eV smaller than that of RRa-P3HT, as estimated by extrapolating the absorption edge. This implies that RR-P3HT will be more appropriate for harvesting
light in the red and infrared parts of the sun's spectrum. Charge mobility will also depend on the interaction between neighboring chains [17] and, in fact, hole mobility in RRa- is several orders of magnitude lower than for RR-P3HT (we will come back to this point below). Therefore, in order to ensure good charge generation (and short circuit current) in OPVs based on ternary systems, the amount of RRa-P3HT should, in principle, be small compared to that of RR-P3HT.

Enhancing the interchain interactions typically leads to the splitting of the HOMO and LUMO levels (e.g. by means of Davydov splitting). Quantum chemical calculations have shown that bringing polymer chains closer together decreases (in absolute terms) the HOMO level [20]. The glassy morphology of the RRa-P3HT films can be associated to an effective isolation of the polymer chains, and thus, one may expect a larger (again in absolute terms) HOMO level [15,20]. Using air ultraviolet photoelectron spectroscopy we found a 0.12 eV shift comparing the two polymers, with higher HOMO for RRa-P3HT, as expected from the argument above. On the other hand, the open circuit voltage (V_{oc}) in OPVs is proportional to the difference between the HOMO of the electron donor (polymer) and the LUMO of the electron acceptor (fullerene) [21], and thus one may expect an enhancement in the V_{oc} values for OPVs based on ternary systems. This is, in fact, what is experimentally observed, as we will show.

Fig. 3a and b shows the absorption and emission spectra, respectively, of binaries consisting of a varying concentration of RR-P3HT:RRa-P3HT, as well as the pristine materials for reference. The spin coating conditions were controlled in order to have films with comparable thicknesses ($\sim$80 nm). The dotted lines in Fig. 3a correspond to a linear addition of the absorption of the pristine materials weighted by the composition fraction of each material. For instance, the absorption of the 0.75:0.25 binary is simulated (with no fitting parameters) by adding the absorption of RR-P3HT multiplied by 0.75 and the absorption of RRa-P3HT multiplied by 0.25. The surprisingly good agreement between the measured and simulated data suggests that, on the one hand, there is not strong interaction between the two polymers in terms of absorption (no new steady state species are created), and on the other side, the crystallization of RR-P3HT is not inhibited by the presence of the random chains. The latter is very important, especially after Chirvase and co-workers pointed out that PCBM molecules prevent the crystallization of RR-P3HT, which is only restored upon thermal annealing [10]. We note that the data shown in Fig. 3 correspond to non-annealed binary films.

The PL spectra for binaries cannot, however, be modeled using a linear combination of the PL spectra of the pristine materials. The addition of a small amount of RR-P3HT (25%) reduces the PL yield by sixfold, almost down to the level of RR-P3HT (see Fig. 3b). Given the good spectral overlap between the emission of RRa-P3HT films and the absorption of RR-P3HT (see Fig. 2), energy transfer from the random to the regular chains seems a plausible explanation for this. Comparison between the PL recorded using two different excitation wavelengths (450 nm and 550 nm, the latter being the maximum absorption for RR-P3HT, not

Fig. 2. Optical properties of the pristine polymer. Normalized absorption (solid line) and emission (dashed line) for regio random P3HT (blue) and regio regular P3HT (red). Fig. 3. Optical properties of binary systems. (a) Absorption and (b) emission of Regular:Random P3HT binary films.

shown) also points towards this explanation. Whether a real (re-absorption) or a virtual (energy transfer properly speaking) process of transferring the absorbed photon energy from regio random to regio regular, or even a combination of both, is not clear at this stage. In any case, the PL spectra strongly indicate that the transfer is actually happening and thus the absorption of light in the regio random chains is followed by a transfer of a substantial part of that energy to regio regular material where electrons are excited and through which the transport of carriers can be greatly facilitated. A detailed time-resolved study on the PL dynamics could bring useful information in this respect.

The efficient charge transfer (exciton dissociation) between the polymer chains and fullerene molecules, necessary step for charge generation, is often seen experimentally as a strong reduction in the PL quantum yield upon blending the polymer with the fullerene molecules. PCBM is an extremely efficient PL quencher in both cases RR- and RRa-P3HT (contrast for instance Figs. 3b and 4b). Comparing the PL exhibited by films containing the same amount of polymer with and without PCBM, it is possible to estimate the degree of PL quenching. It turns out that the PL quenching is much more pronounced (∼50 times more) in RRa-P3HT than in RR-P3HT. The most likely reason for this is the finer intermixing between components achieved in PCBM:RRa-P3HT films compared to the conventional blend, resulting from the glassy morphology of the random polymer with very little – or even none – tendency to crystallize. It has been shown that the crystallization of P3HT is, in fact, one of the main factors driving the

diffusion of PCBM molecules into phase-separated regions [8] and thus, a non-crystallizing polymer (such as RRa-P3HT) may accommodate more easily the fullerene molecules within polymer chain voids. This view is supported by the lack of micron-sized PCBM aggregates in the ternary systems: fullerene molecules are somehow anchored in the voids left by the dilute random matrix. AFM images of PCBM:RRa-P3HT films show no evidence of phase separation and the corresponding surface roughness remains extremely small (<0.6 nm) after mixing the random polymer with the fullerene molecules. Therefore, random P3HT might, interestingly, lead to an efficient charge generation due to the resulting morphologies of their films. Ternary systems show a gradual decrease in the PL intensity with increasing RRa-P3HT concentration, as shown in Fig. 4b, which suggests an increased capability for PL quenching, or exciton splitting with adding RRa-P3HT.

As for the case of the conventional PCBM:RR-P3HT blends, the incorporation of the fullerene molecules precludes the formation of P3HT crystallites in the as-spun films also in the ternary systems. Similarly, thermal annealing (at 140 °C for 1 h) enhances the crystallization also in the ternaries. Fig. 4a shows the absorption spectra for annealed ternary blends. Judging by the ratio of the intensities of the maximum and the shoulder centered at around 650 nm, one may risk to say that ternary blends are equally, or even slightly more, crystalline (in relative terms) than the conventional binary [22].

Surface roughness, as obtained from AFM images, has often revealed the degree of crystallinity in the films
Fig. 4. Optical properties of ternary systems. (a) Absorption and (b) emission of ternary films with constant solution concentration (60 mg/ml), and constant PCBM:polymer concentration (1:1), with varying relative concentrations of regular and random P3HT.

underneath (see e.g. Ref. [23]). We have taken AFM images of the ternary systems and confirm the increase in roughness (crystallinity) upon annealing suggested by the absorption spectra. Fig. 5a and b compare the morphology of a film based on the conventional blend before and after thermal annealing, respectively. The Ra surface roughness increases from 0.6 to 0.7 nm upon annealing. All of the as-spun ternary films are smoother than the conventional blend, but, interestingly, the surface roughness for the ternaries increase to larger values than that of the PCBM:RR-P3HT blend with annealing (see e.g. Fig. 4c and d and Table 1). This may again suggest that the degree of crystallization is larger in ternary systems than in the conventional blend. However, another possible explanation could be that the three components are phase separating and thus produce a rougher surface. For comparison, it might be noted that the Ra roughness of the pristine RR- and RRa-P3HT films is 6.6 nm and 0.3 nm, respectively. The AFM deduced roughness values for the ternary films are summarized in Table 1.

In order to get a better understanding of the aforementioned phenomena suggested by the absorption and AFM data, we have performed X-ray diffraction (XRD) measurements on annealed ternary films. The data for these experiments are shown in Fig. 5e, including those of the pristine RR-P3HT film used here as reference. The material parameters deduced from the analysis of the results are summarized in Table 1. We note that the sample containing only regio random P3HT does not show any diffraction peak, in accordance to the expected lack of crystallinity. Our deduced 1.72 nm interplane distance (following Bragg's law) agrees well with previous data for P3HT [19]. Moreover, it seems to slightly increase from 1.72 nm to 1.76 nm with increasing RRa-P3HT concentration from 0% to 75% in the total polymer content. Although we do not have a full explanation for this, it might be due to the fact that the regio regular crystallites are immerged in a soft matrix of the random material, which may shrink in order to accommodate the expanding (through annealing) regio regular crystallites; while in the case of the conventional blend, the crystallites cannot expand because they might be in contact with other, equally hard, crystallites. If this was the case, it might be interesting to see the effect that a semicrystallizing matrix that formed harder crystallites would have on the interplane distance (and even hole mobility) of P3HT:PCBM blends. Some support for this very initial hypothesis may come from the fact that when the effect of a rigid substrate interface is made apparent (by decreasing film thickness), P3HT chains pack into different type of crystallites [24].

The RR-P3HT crystallite size was estimated using Scherrer's relationship and the average sizes we find are larger than those reported by Zhokhavets et al. [19], as one could expect given the fact that our annealing times are much longer (1 h in our case, and 5 min in theirs). Importantly, as the content of regio random is increased, the crystallite size is greatly reduced from around 16 nm for the PCBM:RR-P3HT:RRaP3HT (1:1:0) film to ca. 10 nm for the (1:0.25:0.75) sample. This suggests that there might be an increase in polymer chain entanglement with increasing random concentration which prevents the formation of large crystallites. We note that we have employed only the optimum annealing temperature for the conventional blend, and thus there is room for optimizing the thermal annealing procedure for the ternary systems which may require longer annealing times, or higher annealing temperatures to create crystallites of the same size as the conventional blend.

By integrating the area of the XRD peak, one may obtain a measure of the degree of crystallinity of the film [19]. Interestingly, this evaluation again indicates that ternary systems are more crystalline than the conventional blend (see Table 1), in agreement with the absorption and AFM data, and thus rules out the hypothesis of the large-scale phase separation of the three materials as the main explanation of the increased roughness in annealed ternary films compared to the conventional binary.

Therefore, all of the evidences suggest that the structure of ternary films consists of crystallites of regular P3HT – of smaller size than those found in the conventional blend – embedded into a random polymer matrix, and where PCBM can only form small aggregates and not the micron-sized structures often observed in the conventional case. Fig. 1d and f schematically depict the nanomorphology of the conventional binary and the proposed ternary

systems, respectively. The study of the ternary system phase diagram would also be interesting to gain further insight into the phase separation capabilities of the materials as well as optimum temperatures and compositions [11].

Summarizing the main results up to now, from a structural point of view, the random P3HT chains define a dilute matrix, or soft scaffolding, within which crystallites of the regular P3HT chains and aggregates of PCBM molecules can be formed in a controlled fashion (using the available but limited free volume), preventing large-scale phase separation of the components.

3.2. Charge carrier mobilities

In order to understand the effect of ternary mixing in the carrier mobilities, devices have been fabricated in which the active blend film was sandwiched between two contacts that were selected in a way so to obtain hole only or electron only devices (see Section 2). By varying the film thickness we identified the range of thicknesses in which the current–voltage characteristics are governed by the space charge limited (SCL) regime. We then deduced the zero field hole and electron mobilities by fitting the current–voltage curves following Refs. [4] and [14]. Fig. 6a shows three representative cases. The experimental points (symbols) are very well fitted with the SCL equation for over three to four orders of magnitude in the values of the current density.

Fig. 6b shows the SCL deduced hole (circles) and electron (squares) mobilities for binary (solid symbols) and annealed ternary (open symbols) systems. Each data point is the average of the mobility values extracted from four devices. The hole mobility values obtained for the conventional blends agree well with those reported in the literature for annealed samples [4] ($\sim 1.2 \cdot 10^{-8}$ $m^2\,V^{-1}\,s^{-1}$). As for the electron mobility, our values are slightly smaller than those reported, perhaps due to a possible small partial oxidation of the evaporated Al electrode before the spin coating of the active blend, or to a small underestimation of the electron mobility values resulting from higher fitting standard deviations. Regio random P3HT shows a hole mobility of almost five orders of magnitude lower than that of regio regular P3HT. Interestingly, this value ($\sim 5 \cdot 10^{-13}$ $m^2\,V^{-1}\,s^{-1}$) is not very far from the hole

mobility values of $\sim 3 \cdot 10^{-12}$ $m^2\,V^{-1}\,s^{-1}$ exhibited by non-annealed (or low temperature annealed) regular P3HT blended with PCBM [4]. It seems clear, therefore, that the low mobility of RRa-P3HT is the result of lack of crystallinity and the associated weak interchain interactions (c.f. RR-P3HT).

Perhaps the most important result in this section is the finding that the carrier mobilities are only slightly affected by the introduction of this – very low mobility – polymer. Amazingly, substituting 75% of the regio regular chains by regio random chains in the ternary system only decreases the hole mobility from $\sim 1.2 \cdot 10^{-8}$ $m^2\,V^{-1}\,s^{-1}$ to $\sim 3.5 \cdot 10^{-9}$ $m^2\,V^{-1}\,s^{-1}$, i.e. less than one order of magnitude. For comparison, it is worth noting that thermal annealing has a much stronger effect on charge transport: the as-spun conventional blend has almost four orders of magnitude lower hole mobility than the thermally annealed (at 130–150 °C) case [4]. However, this interesting result may not be unexpected on the light of the morphology investigations reported above: absorption, photoluminescence, AFM and XRD data all indicate that the ternary systems are also highly crystalline. Goffri et al. have also found a similar behavior for the field effect transistor hole mobility of P3HT blended with semicrystalline commodity polymers [25], so perhaps this is a relatively general trait of semiconducting polymers independent of whether mobility is measured across the film thickness or in the perpendicular direction, and even at totally different carrier density values. There are two possible readings for this phenomenon. First, the material percolation threshold requires very little amount of the crystallizing component (less than 25% in our case), probably due to the extended length of the polymeric macromolecule. A second interpretation could be, however, that most of the film is, in practice, not contributing (at least positively) to the transport of charges. The second possibility opens one important question: how could one process a film so to employ 100% of the material to actively participate in the charge transport? This key question has, to our knowledge, not being answered yet.

The slight mobility decrease might be related to smaller crystallite sizes. We find a linear relationship between charge mobility and crystallite size, with the holes having a stronger dependence (in terms of the slope of the fitted
Fig. 6. Study of the carrier mobility in binary and ternary systems. (a) Typical current density versus voltage curves for a conventional blend (open squares), a ternary blend with composition 1:0.5:0.5 (open triangles) and regio random P3HT (open diamonds). The solid lines are the fits to the SCL equations; (b) Hole (circles) and electron (squares) mobilities deduced for single carrier devices based on regular:random binaries (solid symbols) and ternary (open symbols) systems.

straight line). On the other hand, the mobility values do not seem to be so clearly related to the overall degree of P3HT crystallinity, i.e. when plotted together, the experimental points scatter through the graph with no distinguishable trend. This apparent contradiction was also observed in pristine P3HT films with different molecular weights: lower molecular weight P3HT is much more crystalline but, nonetheless, its mobility is lower than that of higher molecular weight P3HT [26,27]. This can be explained in terms of poorer connectivity and more insulating grain boundaries for the more crystalline polymer [26]. This explanation could be perfectly applied here, since smaller crystallites (even at a constant total crystallinity) would exhibit many more grain boundaries than larger crystallites. It is important to emphasize that, compared to the almost four orders of magnitude changes in field effect mobility [26] (or 15 times in the SCL mobilities [27]) observed when increasing the number average molecular weight from 3.2 to ca. 40 kDa, in our case the effect is very mild, with a decrease in zero field mobility of less than one order of magnitude when substituting 75% of RR-P3HT by RRa-P3HT.

It is important to note that binary and ternary systems have very similar hole mobilities for RRa-P3HT concentrations smaller than 50% with respect to the concentration of RR-P3HT. However, it seems that the percolation threshold for the binary happens at higher random concentration than in the ternary system. The thermal annealing (only applied here to the ternaries) may help to enhance hole mobility in the ternary systems containing 75% of regio random, when compared to the values for non-annealed binary RR-P3HT:RRa-P3HT blends with also 75% or RRa-P3HT, even when the crystallinity of the binaries is expected to be high according to their absorption spectra (Fig. 3a). Alternatively, this difference between binary and ternary blends may support the report by Tuladhar and co-workers [28], who were able to demonstrate that PCBM not only helps to enhance the hole mobility of the polymer by a possible modification of the polymer chain packing, but they also found that the hole and electron mobilities deduced using the time of flight technique for a system consisting of PCBM embedded into an insulating polystyrene matrix have a similar value, independently of

the film thickness. This strongly indicates that PCBM actively contributes to the hole mobility (polystyrene is an insulator). In other words, comparison between the mobility values deduced for regular:random binaries and the ternary systems may indicate that PCBM is also actively enhancing the hole mobility in our case.

3.3. Solar cells based on ternary systems

Fig. 7 shows the performance of solar cells based on ternary blend films with different RR- to RRa-composition ratios, and keeping the overall polymer to fullerene weight ratio constant (1:(X:Y)) with X + Y = 1. The current density vs. voltage curves measured at monochromatic light (550 nm, 20 µW) show two clear trends with increasing regio random composition in the ternary: (i) decrease in the J_{sc}; and (ii) increase in the V_{oc}. Table 1 summarizes these values.

The case of the V_{oc} can be understood in terms of the increase in the relative importance of the regio random chains in the charge generation. As we discussed above, the non-interacting chains of RRa-P3HT yield a higher HOMO than the crystalline P3HT [15,20]. Since the V_{oc} is proportional to the difference between the energy levels of the donor HOMO and acceptor LUMO [21], an increase in the polymer HOMO may be responsible for the observed increase in V_{oc}. This conclusion is supported by a recent study made with polythiophenes with different alkyl chain lengths (P3AT). It was found that the V_{oc} of annealed devices made with different P3ATs increases from 500 to 600 mV with increasing alkyl length – and thus reducing interchain interactions – from butyl to dodecyl [29]. A very recent report [30] on solar cells based on the addition of higher-HOMO level MDMO-PPV chains to the conventional PCBM:P3HT blends also shows improved V_{oc}, and thus again supports our hypothesis.

It is important to note that the increase in V_{oc} is not linearly proportional to the amount of RRa-P3HT, but, instead, it has a strong effect already for low random concentrations and then saturates at about 50%. This can be understood in terms of the resulting ternary blend morphology, since the PCBM molecules might accommodate themselves more easily in the polymer voids left by the amorphous
Fig. 7. Solar cell characteristics for devices based on the ternary systems. *J–V* curves (a), *J–V* curves normalized by the absorption at 550 nm (b) and EQE (c) for devices based on ternaries with constant solution concentration (60 mg/ml), and constant PCBM:polymer concentration (1:1), with varying relative concentrations of regular and random P3HT.

RRa-P3HT matrix than to be embedded into the RR-P3HT crystallites. This interpretation is supported by the PL quenching data shown in Fig. 4b. The measured superlinear behavior in the enhancement of V_{oc} with increasing RRa-P3HT content relaxes the apparent compromise between the observed opposite trends of J_{sc} and V_{oc}.

With respect to the decrease in the J_{sc}, it may be associated to the combination of two main factors: (1) a decrease in the absorption of the ternary active layer at 550 nm; and (2) a decrease in carrier mobility with increasing RRa-content. To evaluate the relative importance of these two factors, we have plotted in Fig. 7b the *J–V* characteristics normalized by the absorption of the films at 550 nm. From this graph, it seems that there are two distinct regimes: up to concentrations containing 50% of RRa-, the effect of reduced mobility is only small; however, for larger amounts of the regio random polymer the polymer percolation threshold for good device operation is overpass and then the J_{sc} drastically falls.

We have recently demonstrated a similar compromise between J_{sc} and V_{oc} in organic solar cells using another approach but with a similar argument in terms of the energy levels of the active materials [31]. By inserting an ultrathin metal–phthalocyanine layer (CuPc or ZnPc, HOMO - 5.1 eV) at the bilayer interface between pentacene (HOMO $\sim$ 5.0 eV) and fullerene, a higher V_{oc} was observed. The V_{oc} increased with increasing CuPc or ZnPc layer thickness as a result of the higher-HOMO level; however, the J_{sc} decreased due to the lower mobility of the phthalocyanine than that of pentacene [31]. A compromise in phthalocyanine thickness was found between enhanced V_{oc} and

reduced J_{sc} so to finally obtain higher device efficiencies. Similarly, in the ternary blends case, increasing in excess the concentration of the low mobility random chains can lead to surpassing the threshold composition for percolation of the highly conductive regio regular P3HT chains and thus the photocurrent drops. However, the compromise between device parameters in the ternary blends is much more relaxed, as we will show below.

It is worth noticing that there could be an alternative explanation for the observed trends in photocurrent and open circuit voltage. This interpretation is based on the idea that the addition of the random chains may result in a different recombination constant. Assuming that the theory of Langevin recombination is valid in the ternary systems, a reduction in the mobility could cause a reduction of the recombination constant and therefore a lower photocurrent and a higher open circuit voltage, as it is sometimes observed in OPV systems based on polymers with low charge carrier mobilities [32]. As we will see, the fact that we can decouple the effect in J_{sc} and V_{oc} for low RRa-P3HT concentrations may suggest that this effect is significant only for large RRa-P3HT relative concentrations.

The different absorption spectra for varying compositions (Fig. 3 (a)) are also reflected in the external quantum efficiency (EQE), as shown in Fig. 7c. It is even possible to distinguish the RRa-P3HT absorption peak centered at around 450 nm in the EQE of the devices based on the 1:0.25:0.75 composition (top curve in bottom panel). This further indicates the active role that the random P3HT plays in the solar cell. We note that the relatively large inhomogeneity of the light intensity through the beam

spot leads to EQE uncertainties of the order of 5% in the deduced EQE values reported here.

Our results suggest that if the lower absorption is compensated for, small concentrations of RRa-P3HT could lead to overall better device performance by increasing V_{oc} while keeping J_{sc} constant. A straightforward way of doing this without the need for systematic optimization is to fabricate solar cells based on blends which keep the PCBM:RR-P3HT ratio (1:1) constant, and then adding small amounts of the RRa-P3HT into the solution. Fig. 8 shows the J–V characteristics under the same illumination conditions as above for devices based on ternary films with PCBM:RR-P3HT:RRa-P3HT compositions 1:1:0.1 and 1:1:0.25, as well as the 1:1:0 conventional blend for reference. As we have predicted, once the absorption of light at 550 nm is kept constant, the J_{sc} shows an almost constant value within the experimental uncertainty. In fact, the EQE spectra at 0 V for these three devices are almost identical (not shown). On the other hand, the V_{oc} for solar cells based on ternary systems is clearly enhanced by more than 100 mV with respect to the reference conventional blend, as shown in Fig. 8. This is fully consistent with the 0.12 eV increase in HOMO level for RRa-P3HT compared to RR-P3HT, as deduced here using ultraviolet photoelectron spectroscopy. Moreover, the fill factor also slightly improves by ternary mixing. Overall, there is a 20% increase in the maximum power obtained at 550 nm, $V_{max}J_{max}$ comparing the reference (1:1:0) and the sample with 25% added random polymer chains (1:1:0.25), which may indicate a 20% enhancement in efficiency in the current illumination conditions.

In order to check the evolution of device performance and morphology with time, these three samples (with four devices per sample) were measured again after a period of 10 months, through which they were kept in air and in darkness. These solar cells still work perfectly fine after this time span, which suggests that the glass encapsulation and darkness ambient conditions have prevented chemical oxidation of the active layers and interfaces. Nonetheless, there are some changes in the current/voltage curves after this time, which we preliminarily assign to morphologic relaxation of the films over time. These changes over time are much larger than the pin to pin differences amongst
Fig. 9. J–V curves in logarithmic scale for PCBM:Regular P3HT concentration (1:1:0), (open squares, left panel) and with added Regio Random P3HT 1:1:0.1 (filled triangles, right panel) as prepared (solid lines) and after 10 months (dashed lines).

the four pins in a given sample. The percentage change of the J–V curves (see Fig. 9) when comparing the samples as fabricated and after 10 months is much more pronounced (∼75% more) for the conventional binary than for the ternary-based samples. These data suggest that the natural entanglement of the glassy amorphous RRa-P3HT chains helps to stabilize the film morphology and thus positively contributes to increase the effective lifetime of the cells. These preliminary results are currently being systematically investigated in order to further test the hypothesis of improved morphological stability.

The OPV performance under varying light intensities shows that the V_{oc} of the conventional binary-based cells increases with light intensity towards the V_{oc} of the ternary system cells (see Fig. 10). This may suggest that the regular chains that do not form part of the crystallites, and thus are found in a more amorphous state, begin to participate on the photovoltaic action for higher light intensities, perhaps after the expected charge traps are filled. Our proposed ternary system-based devices exhibit a less strong intensity dependence of performance (and always higher V_{oc} regardless of the light intensity), as deduced from the slopes of

Fig. 8. Solar cell characteristics for devices based on the ternary systems with equivalent short circuit current. J–V curves for devices based on ternaries with constant PCBM:regular P3HT concentration (1:1), with added regio random P3HT 1:1:0 (open squares), 1:1:0.1 (filled triangles) and 1:1:0.25 (open down triangles).
Fig. 10. Solar cell characteristics as a function of the incident light intensity. Light intensity dependence of the open circuit voltage (top panel) and short circuit current (bottom panel) for a conventional blend (squares) and a 1:1:0.25 ternary blend (circles).

the linear fits in Fig. 10. This may be originated, as we have mentioned, by a reduced recombination constant arising from slightly lower mobilities in the ternary systems than the conventional blend [32]. This weaker dependence in light intensity could mean a significant advantage when this type of device is used in low light intensity applications such as highly sensitive photodiodes and solar cells placed indoors or at particular outdoor conditions (e.g. cloudy days or early and late hours of the day).

Although there are clearly a large number of parameters that could be further optimized, such as polymer molecular weights [26,27], ternary composition [11,25], thermal annealing treatment [4,33] and film thickness [34,35], it is patent that the presented strategy results in a more controlled blend structure and enhanced solar cell performance. The device optimization might be facilitated by the measurement of the phase diagram of the ternary system, which will aid to predict the optimum composition ratio and thermal annealing treatment [11]. Moreover, the natural entanglement of the glassy chains may also help to provide long-term morphological stability, as suggested by our preliminary results, which would help to keep a constant performance of the devices under operation at elevated temperatures. Some of these investigations are currently being carried out and will be published elsewhere.

Finally, we believe that the ternary mixing approach is very general, and could be used to control the morphology at the micro- and nano-scales for a large variety of semi-crystalline polymers with poor capability for quality film formation when blended with fullerenes and otherwise good optoelectronic properties. Examples of this include polythiophenes with different alkyl side chains, such as poly(3-butylthiophene) (P3BT) [29,36], Selene-substituted regio regular poly(3-hexyl)selenophene (P3HS) [37], and very low band gap regular poly(3-decyloxythiophene-2,5-diyl) (P3DOT) [38], to name but a few. Furthermore, other dilute polymer matrices might be used to add different functionalities, such as simultaneous optimization of charge generation and transport [13,30] or chemical and mechanical stability [25], which could permit an overall more efficient and stable organic solar cell and thus bring closer the market uptake turn point of this technology.

4. Conclusions

To summarize, in this contribution we have investigated ternary systems consisting in adding regio random P3HT into the conventional regular P3HT:PCBM blends. The rationale for this was to be able control the formation of microscale phase separation through the natural entanglement of random polymer chains, while allowing the formation of crystallites at the nanoscale in the voids left by the diluted polymer matrix. We successfully demonstrate that ternary mixing helps to control the morphology by reducing the area covered with unwanted micron-sized aggregates from 9% in the conventional blend, down to less than 0.04% for the ternaries. Moreover, the addition of random polymer chains does not prevent the crystallization of their regular counterparts and we found, in fact, that the overall degree of film crystallization is enhanced in the ter-

nary blends, at the expenses of smaller crystallite sizes. This results in the fact that concentrations of up to 50% of the random polymer in the total polymer content have a very small effect on charge carrier mobilities, compared, for instance, to the effects due to thermal annealing or molecular weight. Finally, we fabricated solar cells based on ternary systems and show that they exhibit a similar short circuit current but ca. 100 mV positively shifted open circuit voltage which results in enhanced device efficiency. The origin of this shift is associated to a higher polymer HOMO arising from the isolated – non-interacting – nature of the random chains.

Fig. 1. Schematics of a pentacene OFET along with the chemical structures of the materials used in the study.

Crosslinkable BCB can provide a high-quality hydroxyl-free interface [10] to organic semiconductors with a high dielectric breakdown strength exceeding 3 MV/cm [11]. With poly (α-methylstyrene) (PMS) as a surface modification layer on gate dielectrics, a record mobility of 7 cm²/V s in a thin-film pentacene transistor has been reported [12]. Here, polystyrene (PS) instead of PMS was used due to its lack of dipole moment (such as CH_3- in PMS). Both BCB and PS have already been demonstrated as stable gate dielectrics for n-channel C_{60} OFETs by our group [13].

2. Experimental details

Pentacene transistors were fabricated on heavily n-doped silicon substrates (n^{++}-Si, as the gate electrode) with a 100 nm-thick Al_2O_3 layer deposited by atomic layer deposition (ALD) as a gate dielectric insulator. The process details and dielectric characterization of Al_2O_3 by ALD are described elsewhere [14]. A top-contact OFET device geometry was used as shown in Fig. 1. To better control the interfacial properties at the dielectric and the pentacene layer, as well as enhance the device operation stability and reproducibility, the Al_2O_3 dielectric surface was passivated with different hydroxyl-free polymers (PS and BCB in this work) as thin buffer layers. The thin polymeric layers were formed and processed as follows. The BCB thin films from diluted Cyclotene™ 3022 were crosslinked at 250 °C on a hot plate for 1 h in a N_2-filled glovebox. PS

films were spin-coated from a 4 mg/ml solution in toluene and annealed at 130 °C on a hot plate for 1 h. The Al_2O_3 surface was also modified with a self-assembled monolayer (SAM) with octadecyl-trichlorosilane (OTS) molecules. OTS has been widely known as a good tunneling barrier to hydroxyl groups on oxide surfaces due to its long alkyl chain, and a good surface layer for controlling structural order of pentacene films. OTS layer was formed by soaking the substrates in a 5 mM toluene solution of OTS for 15 h in a dry N_2-filled glovebox. The capacitance density C_{OX} (nF/cm²) was measured from parallel-plate capacitors with 12 varying contact areas. The added buffer layer on Al_2O_3 reduced the capacitance density C_{OX} from 66.4 nF/cm² to 64.1 nF/cm², with OTS, to 46.8 nF/cm² with BCB, and to 42.7 nF/cm² with PS. The results on C_{OX} are listed in Table 1 and were used to calculate the OFET electrical parameters.

Pentacene (Aldrich), purified using gradient zone sublimation, was deposited at a rate of 1 Å/s to a thickness of 50 nm. 60 nm-thick Au as S/D electrodes were deposited at a rate 1 Å/s on top of pentacene through a shadow mask in the same chamber without breaking the vacuum. The substrates were held unheated during the deposition and the chamber vacuum was about 5×10^{-8} Torr. The samples were transferred in a vacuum tight vessel without being exposed to atmospheric conditions into a N_2-filled glovebox (O_2, H_2O < 1 ppm) for electrical testing. The electrical measurements were performed using an Agilent E5272A source/monitor unit in the dark.

Table 1
Summary of the electrical parameters for pentacene OFETs with different dielectric surfaces. rms, root–mean–square surface roughness; Θ, water contact angle on the dielectric surface; μ, field-effect mobility; V_{TO}, turn-on voltage; V_T, threshold voltage; S, subthreshold slope; $I_{on/off}$, on/off current ratio; τ, characteristic trapping time; β, dispersion parameters.

Pentacne OFETs with	rms (Å)	Θ (°)	C_{OX} (nF/cm²)	μ (cm²/Vs)	V_{TO} (volts)	V_T (volts)	S (V/dec)	$I_{on/off} \times 10^5$	τ (s)	β
PS/Al₂O₃	2.3	84	42.7	0.64	−1.6	−3.39	0.20	7.2	1.5×10^8	0.41
BCB/Al₂O₃	2.4	86	46.8	0.47	−1.6	−3.62	0.26	3.8	2.4×10^5	0.41
OTS/Al₂O₃	4.1	98	64.1	0.36	0.2	−0.86	0.30	1.7	2.1×10^6	0.42

The chemical and physical surface properties of the dielectrics, including surface wetting properties, surface roughness, and surface defect density are important parameters that affect the electrical performance of OFETs, through the morphology/structural ordering of organic semiconductor films and the charge transport at the dielectric/semiconductor interface. To characterize the surface properties, the surface morphology of Al_2O_3 with different surface modification layers was investigated by AFM (Digital Instruments NanoScope™ Scanning Probe Microscopes). The root-mean-square (rms) surface roughness of the dielectric surfaces with different surface treatment was estimated to be below 5 Å when measured over an area of 1 μm × 1 μm, as listed in Table 1. With polymeric surfaces, the dielectric surface roughness of 100 nm-thick Al_2O_3 was further decreased to below 3 Å after spin coating. The effect of surface roughness on the charge transport at the interface can be negligible for a rms value smaller than 5 Å [15,16]. The surface energy of the dielectric surface with different buffering layers was studied by contact angle measurement using DI water, with the results listed in Table 1. All the surfaces became highly hydrophobic with aqueous contact angles around 90°, indicating low surface energy with BCB, PS or OTS as passivation layers on the dielectric surface.

The morphology of pentacene films can be affected by the deposition conditions (substrate temperature, deposition rate and thickness) as well as the dielectric surface properties (surface roughness, surface energy, and etc). Here, the deposition conditions of pentacene were kept constant. AFM and X-ray diffraction (XRD) were used to characterize the film morphology and the structural ordering of pentacene molecules, as illustrated in Fig. 2. Pentacene films on all dielectric surfaces exhibited high structural order and displayed island formation. However, the grain size varied significantly for the substrates with different surface energy and surface roughness. The morphology of pentacene shows small grains on OTS-treated Al_2O_3, probably caused by the large surface roughness of the dielectrics. The pentacene growth on the smoother dielectric surfaces (PS and BCB in this case), on the other hand, was less disturbed and prone to form large grains and good connectivity. The slight difference on the grain size with PS and BCB can be attributed to the different surface energy. The diffraction spectrum of island films consisted of crystalline peaks with a first diffraction peak at $2\Theta = 5.74°$, corresponding to "thin film" spacing of 15.4 Å, and the presence of higher order peaks was observed. The lattice spacing corresponds to a tilt of the molecules of 17.1° to the surface normal, assuming a triclinic single crystal structure. The presence of a "bulk" phase of pentacene with a spacing of 14.4 Å was not observed since the substrate temperature was held at room temperature during deposition. The XRD peak intensity mirrored the grain size of the crystalline structure observed in the AFM images; films with larger grains showed higher intensity.
Fig. 2. AFM images and XRD patterns of pentacene films on the different dielectric surfaces.

3. Operational stability and electrical characterization

In order to accurately characterize the device performance, the devices need to be stable during measurement. Testing procedures like hysteresis scans and duty-cycle-like tests were used to test the stability and reproducibility of the devices. The fabrication and testing were carried-out in a N_2-filled glove box in the dark so that the device instabilities induced by light, water, and oxygen were avoided. The electrical instability/degradation is attributed to both trapping by shallow and deep states. For deeper trapping sites, longer trapping time/relaxation time is required. The trapping at the shallow sites is usually reversible sometimes even at room temperature. The ratio and distribution of shallow and deep traps are dependent on the materials, fabrication, and device operation. Electrical instability induced by the trapping on different time scales can manifest itself as a hysteresis, a current decay, or a threshold voltage shift. The devices showing hysteresis are less stable, and this property is highly undesirable when the devices are not used as memory devices.

The hysteretic transfer characteristics were measured with a resolution of 20 ms and duration of several seconds in the saturation regime with $V_{DS} = -10$ V. The representative transfer curves and normalized output curves (I_{DS} was normalized by the capacitance density C_{OX}) are compared in Fig. 3 for the devices with the same geometry (channel length L of 100 μm and channel width W of 1000 μm) and different dielectric surface treatments. On the time scale of this measurement, negligible hysteresis and threshold voltage shift were found in transistors with polymeric dielectric surfaces as well as OTS-treated dielectric surfaces. Next, all devices were repeatedly stressed by measuring transfer characteristics in the saturation regime 100 times with a 2 s waiting time between cycles. The superimposed measured transfer curves from the first 10 cycles and the last 10 cycles are shown in Fig. 4. Here again, no significant performance degradation could be observed in any of the transistors under investigation. The shape of the successive transfer curves remained unchanged during hysteresis scans and during 100 duty-cycle scans, indicating there exists no shallow states from structure defects within the semiconductor or the gate dielectric caused by the applied gate field [17]. In these two types of measurements, the rest time between successive stressing was varied between 20 ms to several seconds and no changes could be observed. We can speculate that either no fast trapping had occurred or that the trapped charges were de-trapped/released during the rest time. Negligible threshold voltage shift occurred on this time scale, indicating a good electrical stability and reproducibility for devices under normal operation using Al_2O_3 gate dielectrics with PS, BCB, and OTS passivation layers. This can be attributed to the low concentration of shallows traps at the dielectric surfaces. Trapping species expected at Al_2O_3 surfaces, such as highly polar $Al(OH)_3$, absorbed water molecules, or other impurities, are screened by the hydroxyl-free polymers used to passivate the surface.
Fig. 3. (a)–(c) Hysteretic transfer characteristics with $V_{DS} = -10$ V. (d) Comparison of output characteristics with $V_{GS} = -10$ V.
Fig. 4. Superimposed transfer curves from the first 10 scans (black) and the last scans (blue) during a duty-cycle-like test with 100 scans and 2 s rest time between cycles. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

With good stability under normal operating conditions, the device performance parameters can be extracted reliably from a forward gate bias scan as seen in Fig. 3. Field-effect mobilities μ and threshold voltages V_T were calculated in the saturation regime defined by standard MOSFET models by fitting the $\sqrt{I_{DS}}$ vs. V_{GS} data to the square law. Also extracted from the transfer characteristics are the turn-on voltage (V_{TO}) and the on/off current ratio ($I_{on/off}$). The extracted electrical parameters (μ, V_{TO}, V_T, S, and $I_{on/off}$) are summarized and compared in Table 1 along with rms and C_{OX} previously measured.

Devices with PS and BCB dielectric surfaces show similar electrical performance with high mobility, low subthreshold voltage, and high on/off current ratios. The higher mobility from pentacene transistors on PS can be correlated to the structural ordering of pentacene films: larger grains, higher XRD intensity and less trapping. Since OTS might not fully passivate the $Al(OH)_3$ groups on the surface, these electron-trapping residuals could give rise to an earlier turn-on voltage and lower threshold voltages in pentacene OFETs with OTS.

To investigate the dependence of mobility on the channel length L, field-effect mobilities of devices are statistically plotted over the inverse of channel length (L^{-1}) with a channel width $W = 1000\ \mu m$ in Fig. 5a. All the devices with different dielectric surfaces show a similar trend: the mobility remains nearly independent of channel

length larger than 25 μm. However, the device mobility with short channels of 25 μm increases instead of decreasing like in many organic transistors where the channel current is contact-limited due to the large Schottky barrier at the metal/organic interface. The higher mobilities at short-channel devices could be explained through the presence of fewer traps in the grain boundaries existing within a shorter length. It also implies a very low contact resistance and good ohmic contact between Au S/D electrode and pentacene films.

To gain a better understanding of the effect of the contacts on the mobility, the contact resistance of pentacene transistors with PS as a surface treatment layer was extracted using the transmission line method (TLM) based on the dependence of current–voltage characteristics on channel length. In the linear regime, the overall device resistance R_{on} can be considered as the sum of the channel resistance R_{ch} and a total contact resistance R_C according to Rolland [18]. A set of devices with channel lengths ranging from $L = 50$ to $200\ \mu m$ and a fixed channel width of $W = 1000\ \mu m$ was used to calculate the contact resistance at a low drain-source voltage (V_{DS}) of -0.1 V for V_{GS} values ranging from -3 to -10 V. The width-normalized contact resistance ($R_C W$) was estimated using the y intercept of the least squares when extrapolating $R_{on} W$ to $L = 0\ \mu m$, as plotted in Fig. 5b. The contact resistance drops drastically with V_{GS} since the resistance of pentacene film was
Fig. 5. (a) The dependence of mobility on the inverse of channel length. (b) The width-normalized contact resistance obtained from pentacene OFETs with PS dielectric interface.

reduced by the increasingly induced charge density in the accumulation regime with V_{GS}. A low R_CW of 500 Ω cm was achieved at $V_{GS} = -10$ V. This value is even lower than the best result reported by Klauk et al. [19]. Since the contact resistance between the Au S/D electrodes and pentacene films is quite low and the values are similar for the devices with different dielectric surfaces, its change during the operation can be negligible compared to that of the channel resistance with a long channel length such as $L = 100$ μm. Therefore, the effect of contact resistance on the electrical stability can be ignored in this study.

4. Bias stress effect

To further explore the effect of different dielectric interfaces on the stability of pentacene transistors, the time-dependent decay of I_{DS} was tested under dc bias stress with $V_{GS} = V_{DS} = -10$ V for 1 h, as plotted in Fig. 6a. The current decay in this experiment exhibited typical features of bias stress instability showing an exponential decay function. The trapping rate slows down with stressing time since the density of the vacant trapping sites decreases as more holes are trapped with time. Then, trapped charges screen the electrical field and in turn cause the negative shift of the threshold voltage.

The bias stress instability can be described by a stretched-exponential function based on threshold voltage shift (ΔV_T) or drain-source channel current decay. A stretched-exponential equation was proposed by Libsch and Kanicki based on ΔV_T [20]:

$$|\Delta V_T(t)| = |V_{GS} - V_{TO}| \left\{ 1 - \exp\left[-\left(\frac{t}{\tau}\right)^\beta\right] \right\}. \tag{1}$$

$V_{GS} - V_{TO}$ is the effective voltage drop across the gate insulator and V_{TO} is the initial threshold voltage at $t = 0$ s. The dispersion parameter β is the stretched-exponential factor, reflecting the width of the involved trap distribution. The constant τ represents the characteristic trapping time of the carriers. The trapping/detrapping process is assumed thermally activated.

The above model can be extended with the measurement of drain-source channel on-current decay with time under dc bias stress [21]. Using on-current degradation instead of threshold voltage shift to estimate stability can avoid the error and inaccuracy caused by the measurement and extraction of threshold voltages. The derivation of stretched-exponential function based on on-current degradation was carried-out as follows.

The current–voltage characteristics in the saturation regime can be described as:

$$I_{DS} = \frac{1}{2}\mu C_{OX} \frac{W}{L}(V_{GS} - V_{TO})^2 = K(V_{GS} - V_{TO})^2. \tag{2}$$

When the device has been operated for a long period of time t that resulted in a threshold voltage shift ΔV_T, the current–voltage characteristics after an elapsed time t can be expressed as:

$$I_{DS}(t) = K[V_{GS} - (V_{TO} + \Delta V_T(t))]^2. \tag{3}$$

Then, the current decay with time $\Delta I_{DS}(t)$ can be described as:

$$\Delta I_{DS}(t) = \frac{I_{DS}(t)}{I_{DS0}} = \frac{[V_{GS} - (V_{TO} + \Delta V_T(t))]^2}{(V_{GS} - V_{TO})^2}. \tag{4}$$

Combining a stretched-exponential function for ΔV_T from Eq. (1), a stretched-exponential function for $\Delta I_{DS}(t)$ can be reduced to:

$$\Delta I_{DS}(t) = \frac{I_{DS}(t)}{I_{DS0}} = \exp\left[-1\left(\frac{t}{\tau}\right)^\beta\right] \tag{5}$$

As shown in Fig. 6a, the solid points are the experimental data and the line is a fit according to Eq. (5). The simulated results indicate that the experimental data can be fitted with Eq. (5) where the on current in the channel was obtained in the saturation regime.

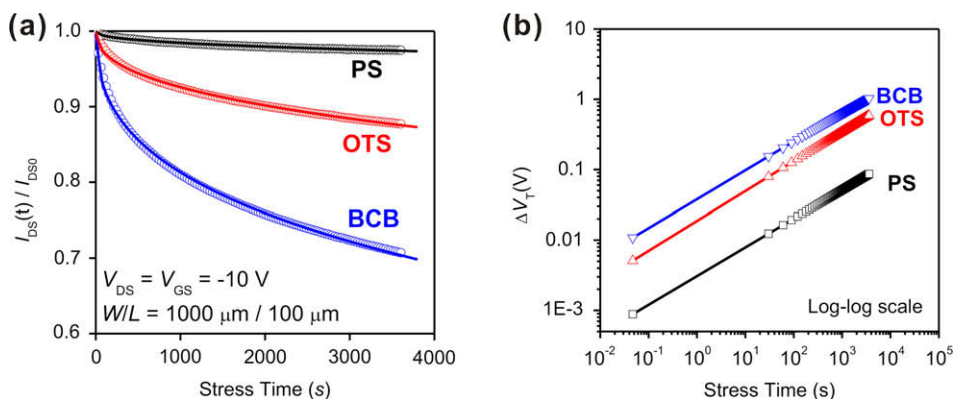
The threshold voltage shift under the same condition can be calculated from Eq. (1) using the fitting parameters listed in Table 1, as shown in Fig. 6b. The dispersion parameter β, reflecting the width of the involved trap distribution, is similar (0.41–0.42) in the devices with polymeric interfaces and SAM. The values are similar to the value obtained by Mathijssen [3,22] using hexamethyldisilazane (HMDS) SAM to passivate the dielectric surface. The β value was found to be lower with higher HMDS coverage


Fig. 6. (a) Drain-source current decay when stressed with $V_{GS} = V_{DS} = -10$ V for 1 h with a resolution of 20 ms. The points are experimental data and the dash lines are the fitting curves using Eq. (5). (b) Threshold voltage shift (ΔV_T) was simulated with the fitting parameters obtained from Fig. 6a.

[3]. The stability during dc bias stress can be quantitatively compared with the trapping time τ at room temperature. Longer times τ are desirable because they lead to transistors with smaller threshold voltage shifts and increased stability. Since polar Al(OH)$_3$ groups can acts as traps, the presence of a spatial barrier between the mobile charge carriers and the traps results in a much longer time scale for the threshold voltage shift dynamics. Therefore, the stability of the devices with treated dielectric surfaces (PS, BCB or OTS SAM) was improved with values for τ in the range of 10^5–10^8 s, with small ΔV_T below 1 V. Among them, pentacene OFETs with a PS-treated gate dielectric surface show the highest stability with the trapping time even longer than that of amorphous Si thin film transistors (TFTs) [23]. Pentacene transistors passivated with PS exhibit an outstanding stability with estimated ΔV_T of 0.2 V after 3600 s stressed under dc bias with $V_{GS} = V_{DS} = -10$ V based on the values of β and τ extracted by fitting the current decay. Devices with OTS-treated surfaces also show good stability with time constants in the range of 10^6–10^7 s, which agrees well with the results reported by Miyadera using β-phenethyltrichlorosilane SAM [24].

We notice that the stability with BCB-treated gate dielectrics in pentacene OFETs is poorer than that of devices with PS or OTS SAM. This observation is in contrast with the results obtained in n-channel C$_{60}$ OFETs where devices with BCB-treated gate dielectrics were found to be most stable [13]. Hence, there is a fundamental difference in the trapping mechanisms giving rise to the degradation of the electrical performance of C$_{60}$ and pentacene-based OFETs with BCB-treated gate dielectrics. The non-polar nature of BCB seems to rule out a dipolar origin to the trapping mechanisms occurring in pentacene OFETs, therefore further investigation is required to explore the origin of this slow trapping mechanism. It is worth pointing out that in C$_{60}$ OFETs, passivation of the gate dielectric with PS acted almost as effectively as BCB to stabilize the electrical performance. Therefore, the results presented in this paper also indicate that PS offers a good compromise to achieve stable operation both in C$_{60}$ and pentacene OFETs. Indeed, with PS as the gate dielectric passivation layer, organic complementary inverters with high noise margins and dc gains have been demonstrated recently [25].

The characteristic trapping time τ (10^5–10^8) is several orders of magnitude longer than the time duration for hysteresis and repeatability (10^{-3}–10 s) testing. In other words, when the devices experienced short-time stress, no bias stress effect was introduced. To further investigate the trap distribution and the activation energy of traps, the measurement of current decay at various thermal temperatures is required.

This model is able to predict the threshold shift behavior for any time duration. However, this model only addresses the electrical stress with dc bias. In AMLCD, a-Si:H TFTs are subjected to pulsed gate bias addressing with a typical frequency of 60 Hz [26]. The magnitude of threshold voltage shift caused by ac stress or pulsed gate bias is significantly lower. A logical explanation is that the trapped charges at the shallow states will be released if the rest time between the testing is longer than the trapping time.

5. Conclusion

We studied the device performance and operational stability of pentacene OFETs in which the gate dielectric was passivated by PS and BCB polymers or by OTS. The device performance was found to correlate with the structural ordering of pentacene films and the surface properties of gate dielectrics. Both PS and BCB passivation can yield devices with high charge mobility due to the formation of pentacene films with large grain size on the smooth surface with low surface energy. However, when measured under prolonged dc gate bias, the electrical performance of devices with BCB deteriorated. The stability of devices with OTS was found superior but the best overall performance was obtained in devices passivated with PS.

the Ag anode. P3HT was known to be a hole-transport material and has been frequently applied in the devices of organic field-effect transistor [12,13] and photovoltaic [14–16]. The hole-transport property of P3HT is supposed to be advantageous to the hole-injection from an Ag anode. Furthermore, it had been shown that P3HT molecules bond chemically to Ag or Cu substrates through the linkage of S atom in the thiophene ring [17]. Therefore, it is possible to prepare a P3HT thin layer on Ag surface using a facile self-assembly process. This strategy was first examined in this work.

In a previous research [18], it was found that a SAM containing a terminal group of high electronegativity (e.g. fluorine) triggers a high work function of the modified surface. Based on this result, an electron-withdrawing function group, 1-fluoro-2-nitro-4-azidobenzene (FNAB), was introduced into the terminal tail ($-C_6H_{13}$) of the P3HT thin layer. This modified anode, Ag/P3HT/FNAB, was proved to have a higher work function and is more efficient to enhance the hole-injection. The importance of P3HT in the present strategy was confirmed by comparing the result with another device using 3-methylthiophene (CH_3TP)-modified Ag anode.

2. Experimental

Two T-PLEDs (ITO/Ag/HY-PPV/Ca/Ag and ITO/modified Ag/HY-PPV/Ca/Ag) were prepared in this study. Ag film of 150 nm thickness is deposited on the cleaned ITO glass substrate by thermal evaporation under a base pressure 10^{-6} torr and a deposited rate of 0.1 Å/s. After formation of Ag film, Ag anode was immersed in a chloroform solution containing 0.1 wt% P3HT for 30 min. After rinsing with chloroform and dried in a nitrogen steam, the P3HT modified anode, Ag/P3HT, was prepared. For the Ag/P3HT/FNAB anode, appropriate amount of FNAB solution was spread on Ag/P3HT substrate and air-dried in dark. FNAB was prepared by diazotization reaction of 4-fluoro-3-nitroaniline (FNA) as the procedure reported in the literature [19–21]. The FNAB-covered substrate was then exposed to a UV lamp (365 nm) for 20 min to carry out the nitrene reaction between azide (N_3) group of FNAB and methyl group ($-CH_3$) of P3HT. The substrate was then washed in succession by chloroform, and acetone, and dried in a nitrogen steam. The substrate was delivered to a vacuum chamber at 10^{-2} torr for 1 h and then transferred to the nitrogen-filled glove-box. The proposed structures for the prepared P3HT and P3HT/FNAB thin layers were schematically shown in Fig. 1. "High-yellow" phenyl-substituted poly(-para-phenylenevinylene) copolymer (HY-PPV) was used as the light-emissive layer and was spin-coated onto the Ag anodes. Finally, a semi-transparent top cathode, Ca (12 nm)/Ag (17 nm), was vapor deposited under 10^{-6} torr. The active pixel area of the device was 6 mm^2. The current–voltage (*I–V*) and brightness–voltage (*L–V*) characteristics were measured using a current/voltage source measurement unit (Keithley 2400) and a calibrated silicon photodiode driven by a Keithley source. The EL spectra are measured by a CCD array spectrum meter (Ocean optics USB2000). All the measurements are performed in a nitrogen-filled glove-box. XPS spectra were measured by JEOL, JAMP-9500F auger electron spectroscopy with a Mg Kα source (1253.6 eV). The work function of the anode electrodes were measured by a Riken Keiki AC-2 photoelectron spectroscopy in air.

3. Results and discussion

Table 1 shows the contact angle of water on base and modified Ag substrates. The contact angle of water on base Ag surface is 77.0°, ascribed to the absorption of hydrocarbon and carbonaceous impurities from the atmosphere [22]. After modification by P3HT, the contact angle increases slightly to about 107.1°, a value consistent to the contact angle measured for alkyl-chain terminated surfaces (90–110°) [23,24]. Therefore, the hydrophobic property of the P3HT modified Ag surface is attributed to the exposing of alkyl chains ($-C_6H_{13}$) contained in P3HT molecules.

After incorporation of FNAB by nitrene reaction, the contact angle of water on the Ag/P3HT/FNAB substrate was measured to be 92.6°. The effect of UV light illumination (required for nitrene reaction) on the P3HT properties was also examined by exposing the Ag/P3HT under UV lamp (365 nm) for 20 min. The contact angle measured for the UV-treated Ag/P3HT substrate was 106.5°, which is nearly identical to the result of non-UV-treated Ag/P3HT. This result suggests that the UV light illumination does not make significant change to the surface wettability of Ag/P3HT and, therefore, after the nitrene reaction, any variation in the contact angle should be resorted to the incorporation of FNAB [20]. For the ideal molecular model proposed in Fig. 1, the terminated ($-CH_3$) group was replaced by a less hydrophobic group FNAB. Therefore, it is
Fig. 1. The process for the deposition of P3HT and FNAB.

Table 1
Contact angle of water on base and modified substrates.

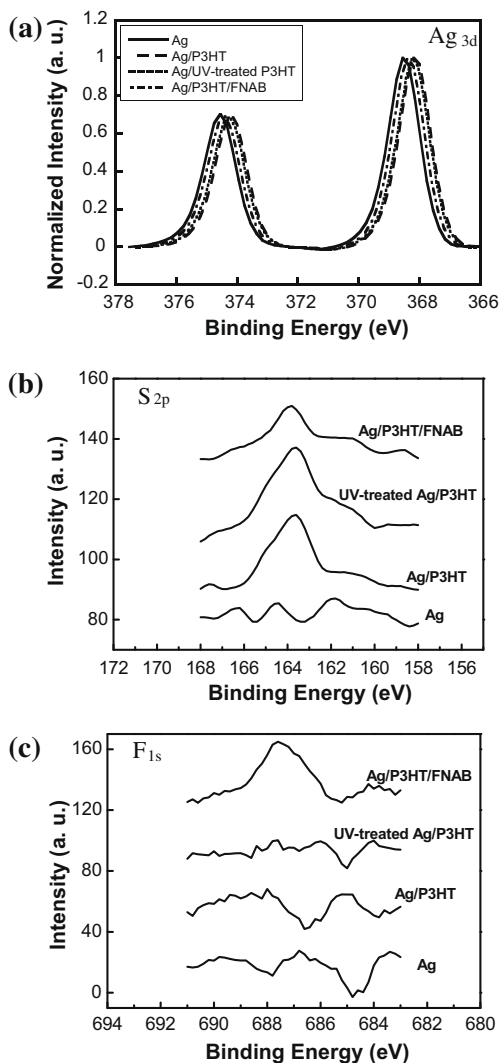
Substrates	Contact angle of water (°)
Ag	77.0
Ag/P3HT	107.1
Ag/UV-treated P3HT	106.5
Ag/P3HT/FNAB	92.6


Fig. 2. High resolution XPS scans of Ag$_{3d}$ (a), S$_{2p}$ (b), and F$_{1s}$ (c) regions for the base and modified Ag anodes.

reasonable that the contact angle will become smaller after the nitrene reaction.

The surface compositions of the substrates were measured by XPS. Fig. 2 shows the high resolution XPS spectra scanning over the binding energy range of Ag$_{3d}$, S$_{2p}$, and F$_{1s}$. In Fig. 2a, peaks corresponding to Ag$_{3d3/2}$ and Ag$_{3d5/2}$ were observed on all the substrates, including the modified and unmodified ones. In comparison with the base Ag substrate, the binding energy of Ag$_{3d}$ decreases slightly after

the modification of P3HT or P3HT/FNAB, attributable to the chemical bonding of silver to the sulfur atom in P3HT [26]. For the S$_{2p}$ peaks shown in Fig. 2b, the peaks appear only on Ag/P3HT, Ag/UV-treated P3HT, and Ag/P3HT/FNAB anodes, demonstrating the presence of P3HT molecules on the modified Ag surfaces. The feature peaks of S$_{2p}$ exhibit a doublet structure at 162.1/163.6 eV, corresponding to S$_{2p3/2}$ and S$_{2p1/2}$ peaks of silver-thiolate sulfur species (Ag–S–R) [25]. This result gives further evidence to the chemical linkage of sulfur to the silver substrate. In Fig. 2c, the peak at 687.6 eV observed on Ag/P3HT/FNAB surface is consistent with the binding energy of a fluorine atom bonded to an aromatic ring. It is reasonable that F$_{1s}$ peak does not appear on the other Ag anodes.

The effect of the P3HT and P3HT/FNAB modification on the hole-injection was studied first by using hole-dominated devices which using aluminum as cathodes. The *J–V* characteristics of these devices are shown in Fig. 3. It was found that the threshold voltage of charge injection decreases significantly due to the modification of Ag anode. Furthermore, the Ag/P3HT/FNAB anode demonstrates a superior effect, than Ag/P3HT, in enhancing the hole-injection.

The enhancement effect of these modified layers was studied by measuring the work function of the related anodes using AC2 and the result were shown in Table 2. It appears that the work functions of these anodes increase in the order: Ag (4.35 eV) < Ag/P3HT (4.42 eV) < Ag/UV-treated P3HT (4.47 eV) < Ag/P3HT/FNAB (4.65 eV). It is noteworthy that the highest occupied molecular orbital (HOMO) of P3HT measured by AC2 is 4.68 eV [26]. The work function measured for Ag/P3HT, 4.42 eV, indicates that the P3HT assembled on the Ag surface is not in a bulk state, but as an ultrathin-film. The HOMO level of HY-PPV was reported to be 5.2 eV [27]. Therefore, the barrier height for the hole-injection decreases with increasing work function of these electrodes. The deposition of P3HT layer on an Ag surface causes only a slightly increase of work function (0.07 eV), which is similar to the increment of work function (0.05 eV) caused by the following UV-treatment. Comparing between Ag/P3HT and Ag/UV-treated P3HT anode, the slightly decrease of threshold voltage of the Ag/UV-treated P3HT anode is attributed to the small increase of the work function after the UV-treatment.
Fig. 3. *J–V* characteristics for ITO/Ag/HY-PPV/Al and ITO/modified Ag/HY-PPV/Al devices.

Table 2

Work function measured by AC2 for the base and modified Ag anodes.

Substrates	Work function (eV)
Ag	4.35
Ag/P3HT	4.42
Ag/UV-treated P3HT	4.47
Ag/P3HT/FNAB	4.65

However, in comparison with the base Ag anode, the threshold voltage of Ag/P3HT anodes decreases significantly due to the presence of P3HT thin layer, which cannot be attributed completely to the small increment of work function. Therefore, the intrinsic property of the P3HT thin layer should play a role to enhance the hole-injection from the Ag anode to HY-PPV layer, probably associated with the hole-transport characteristic of P3HT.

For the Ag/P3HT/FNAB anode which has the best performance in hole-injection, the work function greatly increases from 4.42 to 4.65 eV due to the incorporation of FNAB, attributed to the presence of the fluorine and NO_2 group at the terminated group of the thin layer. The high electronegativity of fluorine atoms and NO_2 group triggers a polarization of electrons toward the end groups, inducing a dipole moment on the surface, shifting the vacuum energy to a higher level, and therefore, leading to a higher work function of the Ag/P3HT/FNAB anode [4]. The large increment of work function due to the incorporation of FNAB is reasonably responsible for significant decrease of threshold voltage of the Ag/P3HT/FNAB anode.

In order to identify the intrinsic property effect of P3HT on the hole-injection, 3-methylthiophene (CH_3TP), a molecule with similar structure as the repeated unit of P3HT, was also used to modify the Ag anode. The CH_3TP-modified Ag anode (Ag/CH_3TP), as well as the anode further modified by FNAB (Ag/CH_3TP/FNAB), was used to fabricate hole-dominated devices. The *J–V* curves measured for these devices were shown in Fig. 4. The result shows that the threshold voltage measured for the Ag/CH_3TP device is much higher than that for the bare Ag anode. That is, introduction of the CH_3TP layer triggers an additional resistance to the hole-injection, a result contrary to the effect of P3HT. However, for the following UV-treatment and FNAB modification, their enhancement effects are similar to that observed for P3HT. Since CH_3TP is not a semi-conducting material as P3HT, the presence of a CH_3TP layer forms a passivation layer on Ag surface which obstructs the transport of charges. On the other hand, insertion a thin layer with p-type semi-conducting characteristic (e.g. P3HT) between Ag anode and emitting layer is advantageous to the hole-injection. It is inferred that the presence of an ultra-thin hole-conducting layer triggers an easier injection of holes from Ag to HY-PPV layer. However, the real mechanism is presently not understood completely.
After confirming the effect of modified layers on the hole-injection, these modified anodes were applied to fabricate top-emitting devices. Fig. 5 shows the *J–V* and *L–V* characteristics of the top-emitting devices with the structures of ITO/Ag(150 nm)/HY-PPV/Ca(12 nm)/Ag(17 nm), ITO/Ag(150 nm)/P3HT/HY-PPV/Ca(12 nm)/Ag(17 nm), and ITO/Ag/P3HT/FNAB/HY-PPV/Ca(12 nm)/Ag(17 nm). The results show that the effects of P3HT and P3HT/FNAB layers on the threshold voltages of *J–V* (Fig. 5a) and *L–V* (Fig. 5b)

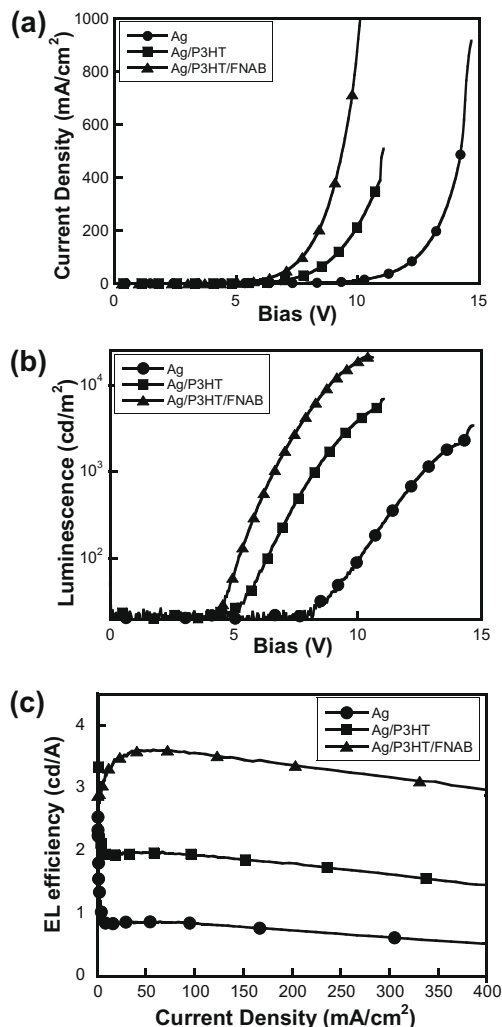
Fig. 4. *J–V* characteristics for ITO/Ag/HY-PPV/Al and ITO/modified Ag/HY-PPV/Al devices.


Fig. 5. *J–V* characteristics for ITO/Ag/HY-PPV/Ca/Ag and ITO/modified Ag/HY-PPV/Ca/Ag devices.

curves are similar to those on the hole-dominated devices shown in Fig. 3. The maximum brightness obtained from the base Ag, Ag/P3HT, and Ag/P3HT/FNAB anodes are 3432 cd/m^2 (at 14.67 V), 6960 cd/m^2 (at 11.06 V), and 21339 cd/m^2 (at 10.46 V), respectively. The luminous efficiencies (*LE*) shown in Fig. 5c demonstrate that the Ag/P3HT/FNAB anode has the highest efficiency, which is about four times higher than the efficiency of a base device. At a light intensity of 1000 cd/m^2, the *LE* of the base Ag, Ag/P3HT, and Ag/P3HT/FNAB device are 0.82, 1.97, and 3.51 cd/A, respectively. The highest performance of Ag/P3HT/FNAB anode is attributed both to the hole-transport characteristic of P3HT and the increase of work function induced by the incorporation of FNAB.

4. Conclusion

P3HT thin layer was proved to be an efficient modified layer of an Ag anode for enhancing the hole-injection of a T-PLED. The introduction of the P3HT causes little increase in the work function and, therefore, the enhancement effect of the P3HT thin layer is ascribed to its hole-conducting characteristic. By using a nitrene reaction, FNAB can be incorporate into the terminal group of the P3HT thin layer, which leads to a significant increase of work function and a further improvement in the hole-injection and device performance. By using the present strategy, the luminous efficiency of a T-PLED can be increased to a value four times higher than that of a base device.

In this paper, we report efficient red, green, and blue (RGB) single layer phosphorescent OLEDs with a configuration of ITO/dopant:TPBi/LiF/Al, in which TPBi is 1,3,5-tris(N-phenylbenzimidazole-2-yl)benzene for electron transport, while the dopant was varied among tris(1-phenylisoquinoline)iridium [Ir(piq)₃], tris(2-phenylpyridine)iridium [Ir(ppy)₃] and bis(3,5-difluoro-2-(2-pyridyl)phenyl-(2-carboxypyridyl)iridium [FIrpic] to realize different emission colors. Subsequently, the device structure was optimized by inserting a pure dopant buffer layer to ITO/dopant/dopant:host/LiF/Al for efficiency and stability improvement, as well as maintaining the simple material selection and fabrication. It was found that efficient simplified RGB phosphorescent OLEDs could be realized by utilizing the triplet dopant's charge transport properties to directly accept and transport holes from ITO anode to the emission zone.

2. Experimental

Ir(piq)₃, Ir(ppy)₃, and TPBi were purchased from LumTec, used as received. FIrpic was synthesized according to the literature [20], sublimated prior to use. To construct an appropriate device configuration for RGB devices, we first used green dopant Ir(ppy)₃ to optimize the overall device thickness, doping concentration, thickness of the buffer layer and so forth. We then applied these parameters to fabricate red and blue OLEDs. All devices were fabricated in a Kurt J. Lesker LUMINOS® cluster tool, using a method described previously [21]. Briefly, the commercially patterned anode with a sheet resistance of 15 Ohms/sq was ultrasonically cleaned with a standard regiment of Alconox®, acetone, and methanol followed by ultraviolet (UV) ozone treatment prior to loading into a deposition chamber. Iridium complexes, TPBi and LiF were deposited in a dedicated organic ultrahigh vacuum chamber with a base pressure of ~10^{-8} Torr. The Al cathode lines (2 mm wide) were deposited orthogonally to the ITO anode lines (1 mm wide) in a separate metallization chamber with a base pressure of ~10^{-7} Torr. A total of four different device structures were fabricated on a single substrate to eliminate possible run-to-run variability caused by potential variations in process conditions. The luminance–current density–voltage (L–I–V) was measured using HP4140B picoammeter and Minolta LS-110 luminance meter. The electroluminescent (EL) spectra were recorded using an USB2000-UV–vis Miniature Fiber Optic Spectrometer. The constant current density during lifetime testing was provided by a Keithley 2400 source. All measurements were carried out in ambient atmosphere and at room temperature.

3. Results and discussion

Fig. 1 shows a schematic device structure, chemical structure and energy level diagram of the molecules used in this work. The work function of ITO and HOMOs for Ir(piq)₃, Ir(ppy)₃, FIrpic and TPBi are ~5.0 [10], 5.1 [22], 5.4 [23], 5.8 [16] and 6.3 [24] eV, respectively. Based on the energy level alignment, the hole injection barrier from ITO to TPBi (~1.3 eV) is extremely high, while hole injection into Ir(piq)₃, Ir(ppy)₃, and FIrpic are energetically favorable with barriers of only ~0.1, 0.4, and 0.8 eV, respectively. This suggests that single layer phosphorescent OLEDs might be made possible by injecting holes directly into the iridium complex dopant rather than into the TPBi host.

It is known that the recombination zone in bilayer structure OLEDs is easily defined at the HTL and ETL interface [1,25]. However, for the single layer device, there is no heterointerface, the holes and electrons have to be recombined during transport or they will contribute to dark current. Furthermore, the hole-electron pair should be formed in a region away from both the anode and cathode; otherwise exciton quenching will occur and be responsible for lowering the device performance [26,27]. Hence the overall thickness of the single layer device has to be optimized in order to create an efficient zone for the recombination. We maintained the doping concentration at ~10 wt% (the typical doping concentration for phosphorescent OLEDs in literature) in the devices ITO/Ir(ppy)₃:TPBi (~10 wt%)/LiF (1 nm)/Al (100 nm), and varied the thickness between 60, 80, 100, and 120 nm. The characteristics of the four
Fig. 1. Chemical structure and energy level diagram of the investigated molecules.

devices are summarized in Fig. 2. Similar to previously reported single layer devices [17], the device has higher driving voltage when the thickness is increased. The turn-on voltage for the device with a 60 nm thickness is only 2.9 V, while this was increased gradually to 3.8 V as the overall thickness increased to 120 nm. However, the device has higher efficiencies as the thickness increased, for example, the maximum current efficiency increased from 4.2 to 14.8 cd/A, and the power efficiency increased from 2.5 to 6.8 lm/W when the overall thickness is increased from 60 to 120 nm. Based on the performances of both driving voltage and efficiency of the four devices, we choose 100 nm as the device thickness in the following experiments.

We noticed that the above four devices have maximum current efficiency at high luminance (over 1000 cd/m^2), which may be attributed to an inefficient hole injection from anode to dopant since there should be no problem for electron injection into and transport in TPBi. Considering that increasing the doping concentration may lead to enhanced injection and increased transporting channels, another three devices using the configuration of ITO/Ir(ppy)$_3$:TPBi (100 nm)/LiF/Al were fabricated with doping concentrations of 14, 18 and 37 wt%, respectively. Fig. 3 shows their performance, as well as that of the reference device with a doping concentration of 10 wt%. The driving voltage decreased remarkably as the doping concentration

increased from 10 to 14 wt% and 18 wt%. However, the difference between the devices with a doping concentration of 37 and 18 wt% is small. This indicates that 18 wt% of Ir(ppy)$_3$ doped TPBi is sufficient for hole injection and transport. With an optimized doping concentration, the device performed the best, the device yields 34.5 cd/A current and 44.1 lm/W power efficiencies at 1 cd/m^2, and 23.4 cd/A and 15.5 lm/W even when the luminance was increased to 1000 cd/m^2 under an applied voltage of 4.7 V. Moreover, the maximum efficiency obtained here is as high as, or even higher than, that of some multilayer phosphorescent OLEDs [28].

For the single layer device, though the holes can be injected into and transported on the Ir(ppy)$_3$ dopant, the recombination zone is expected to be close to the anode because TPBi is a good electron transporting molecule. Therefore, the efficiency could be further improved by inserting a buffer layer between the anode and the emission layer. To maintain the simple fabrication process, we used Ir(ppy)$_3$ as the buffer layer and fabricated another three devices with a configuration of ITO/Ir(ppy)$_3$/Ir(ppy)$_3$:TPBi (18 wt%, 100 nm)/LiF/Al, where the thickness of the Ir(ppy)$_3$ buffer layer is 1, 5, and 10 nm, respectively. Fig. 4 shows the EL spectra comparison of the devices with and without the Ir(ppy)$_3$ buffer layer. Both devices emitted a pure green light with an emission peaking around 520 nm, and international commission on illumination (CIE) chromaticity coordinate of (0.31, 0.63), which originates

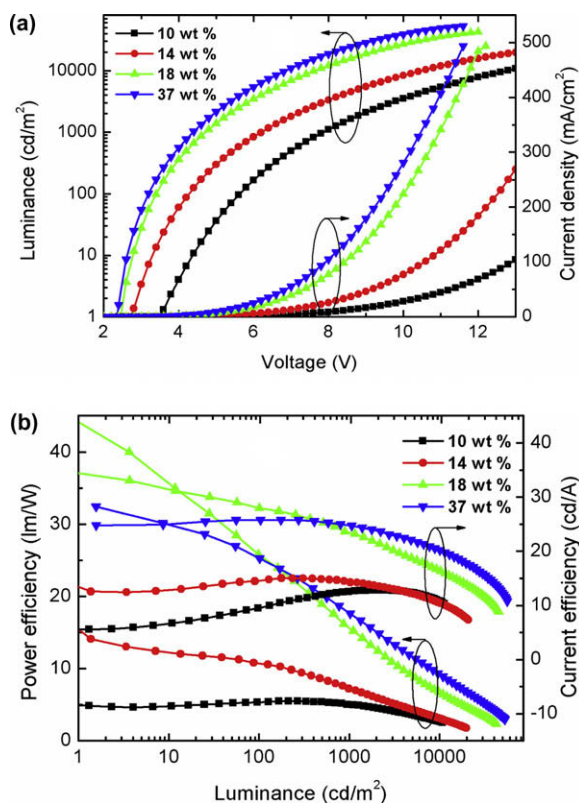

Fig. 3. (a) L–I–V and (b) current– and power efficiency–luminance characteristics of devices ITO/Ir(ppy)$_3$:TPBi (100 nm)/LiF/Al as a function of doping concentration.
Fig. 4. EL spectra comparison between the green devices with and without the Ir(ppy)₃ buffer layer.

from the Ir(ppy)$_3$ dopant. Moreover, the device with a Ir(ppy)$_3$ buffer layer has an identical EL spectrum to that of the device without the buffer layer, indicating that holes and electrons are recombined in the Ir(ppy)$_3$:TPBi layer rather than Ir(ppy)$_3$ layer, otherwise there will be a red-shifted emission because of heavy triplet–triplet quenching in pure Ir(ppy)$_3$ layer.

Fig. 5 shows the *L–I–V* and efficiency–luminance characteristics of the three devices, as well as that of the reference device without a Ir(ppy)$_3$ buffer layer. With the insertion of a 1 nm thick Ir(ppy)$_3$ buffer layer, the device performs with a much lower driving voltage and higher efficiency. In addition, further decreasing driving voltage and increasing efficiency are observed by increasing the Ir(ppy)$_3$ buffer layer thickness from 1 to 10 nm. As a result, the best performance was achieved in the device with an Ir(ppy)$_3$ thickness of 10 nm.. The maximum current and power efficiencies were 43.3 cd/A and 56.2 lm/W at 1 cd/m^2, respectively, and the efficiencies remain as high as 34.6 cd/A and 25.2 lm/W even when the luminance was increased to 1000 cd/m^2 at a low applied voltage of only 4.3 V.

It should be noted that the Ir(ppy)$_3$ buffer layer only improves device performance at low doping concentrations. Table 1 summarizes the characteristics comparison between devices with a configuration of ITO/Ir(ppy)$_3$/Ir (ppy)$_3$:TPBi (37 wt%, 100 nm)/ LiF/Al, in which the thickness of Ir(ppy)$_3$ varied between 0 and 1 nm. As can be seen from the table, the devices with and without a Ir(ppy)$_3$ buffer layer have identical performance. This can be easily understood since holes are easily injected into and transported on the Ir(ppy)$_3$ dopant at higher doping levels, leading to a recombination zone at sufficient distance away from the anode.

The Ir(ppy)$_3$ buffer layer not only improves driving voltage and efficiency, but also improves the device stability. Fig. 6 shows the accelerated lifetime trend of the two simplified devices with and without a Ir(ppy)$_3$ layer, as well as that of a three layer reference device ITO/α-NPD (40 nm)/Ir(ppy)$_3$:CBP (20 nm)/TPBi (60 nm)/LiF (1 nm)/Al (100 nm), where α-NPD and CBP are 4,4′-bis[N-(1-napthyl)-N-phenyl-amino] biphenyl and 4,4′-N,N′-dicarbazole-biphenyl, respectively. Since lifetime was measured

in air, the exact values are meaningless. Here, the lifetime trends of the three devices are compared for their relative stability. As can be seen from the figure, the device without an Ir(ppy)$_3$ buffer layer between the ITO and emission layer has a very short lifetime, which could be attributed to multiple factors such as ion diffusion from the anode into the emission layer. The device with an Ir(ppy)$_3$ buffer layer has a much improved stability, even better than that of a typical three layer OLED.

Encouraged by the results of the simplified green devices, we also test the concept "direct hole injection into and transport on triplet dopant" in red and blue OLEDs. With a similar device configuration deduced above, two
Fig. 6. Lifetime tends of two simplified devices with and without a 10 nm Ir(ppy)₃ layer, as well as that of a three layer device with a configuration of ITO/NPB (40 nm)/Ir(ppy)₃:CBP (20 nm)/TPBi (60 nm)/LiF/Al.

red-emitting devices with configurations of ITO/Ir(piq)₃ (0 or 10 nm)/Ir(piq)₃:TPBi (21 wt%, 100 nm)/LiF/Al and two blue-emitting devices with configurations of ITO/FIrpic (0 or 10 nm)/FIrpic:TPBi (18 wt%, 100 nm)/ LiF/Al were fabricated. It should be noted that the red and blue device configuration fabricated here has not been optimized. The parameters optimized in the green device, including device thickness, doping concentration, and thickness of the buffer layer, may not the best for red and blue devices because each dopant has different hole injection barrier and carrier mobility. Their EL spectra, as well as L–I–V and efficiency–luminance characteristics are shown in Figs. 7 and 8, respectively.

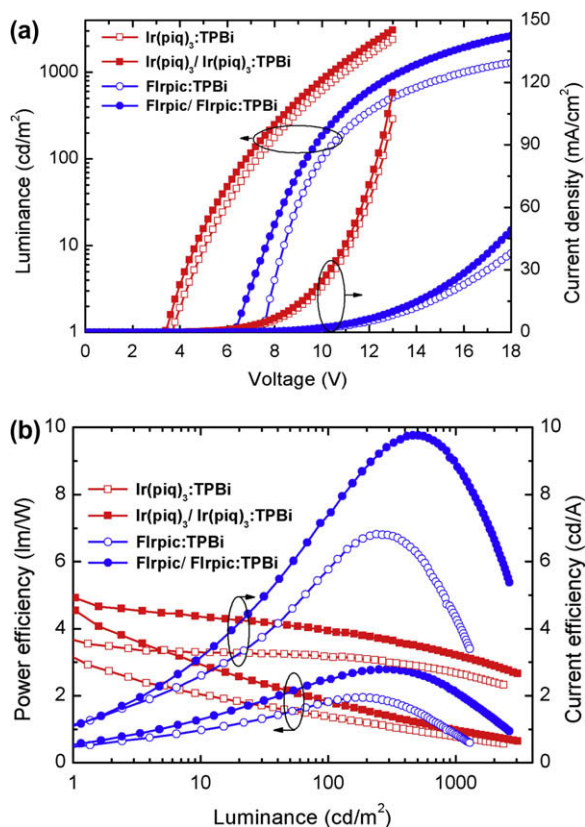
The red-emitting devices, either with or without a 10 nm thick Ir(piq)₃ buffer layer, had an identical emission with a maximum wavelength around 628 nm, CIE chromaticity coordinate of (0.69, 0.33), which is the same as those reported for other Ir(piq)₃ based devices [29]. The device without a Ir(piq)₃ buffer layer had current and power efficiencies around 3.7 cd/A and 3.2 lm/W at 1 cd/m², and 2.7 cd/A and 0.8 lm/W at 1000 cd/m² under 11.0 V applied bias, respectively. The performance was improved somewhat by inserting a 10 nm thick Ir(piq)₃ buffer layer, hav-
Fig. 7. EL spectra of devices ITO/Ir(piq)₃ (0 or 10 nm)/Ir(piq)₃:TPBi (21 wt%, 100 nm)/LiF/Al and ITO/FIrpic (0 or 10 nm)/ FIrpic:TPBi (18 wt%, 100 nm)/LiF/Al.


Fig. 8. (a) L–I–V, and (b) efficiency–luminance characteristics of ITO/ Ir(piq)₃ (0 or 10 nm)/Ir(piq)₃:TPBi (21 wt%, 100 nm)/LiF/Al and ITO/FIrpic (0 or 10 nm)/FIrpic:TPBi (18 wt%, 100 nm)/LiF/Al.

ing current and power efficiencies around 4.9 cd/A and 4.6 lm/W at 1 cd/m², and 3.2 cd/A and 1.0 lm/W at 1000 cd/m² under 10.4 V applied bias, respectively.

As for the blue-emitting devices, the devices with and without a 10 nm thick FIrpic buffer layer also have identical emission band around 500 nm with CIE chromaticity coordinate of (0.20, 0.49). The emission spectra observed here are different to those reported for FIrpic-based devices, having an emission peak around 470 nm with a sub-peak around 500 nm [30]. It is known that there are two emission bands associated with two different triplet states in FIrpic. Here the dominate 500 nm emission band may be explained by the fact that the triplet energy level of TPBi is low (2.67 eV, [31]) and consequently results in a favored energy transfer to the lower triplet state of FIrpic [32].

Similarly, the insertion of 10 nm thick FIrpic buffer layer improves device performance, having lower driving voltage and higher efficiencies. For example, the device without the FIrpic buffer layer has a turn-on voltage of 7.6 V, maximum current and power efficiencies around 6.8 cd/A (239 cd/m², 11.2 V) and 1.9 lm/W (187.6 cd/m², 10.8 V). The turn-on voltage decreased to 6.4 V, and the efficiencies increased to 9.8 cd/A (460.4 cd/m², 11.4 V) and 2.8 lm/W (287 cd/m², 10.6 V), respectively, by inserting a 10 nm FIrpic layer. Still, the blue-emitting devices have much higher

Table 2

[a] The anode and cathode are ITO and LiF (1 nm)/Al (100 nm), respectively. The thickness of the iridium complex buffer layer and doped emission layer are 10 and 100 nm, respectively. The doping concentration for green, red, and blue OLEDs are 18, 21, and 18 wt%, respectively.
[b] EL spectra were taken at a luminance higher than 1000 cd/m^2.

driving voltage than that of the red- and green-emitting devices, which is not surprising since the hole injection barrier from ITO to FIrpic is ∼0.8 eV; this is much higher than that to Ir(piq)$_3$ (0.1 eV) and Ir(ppy)$_3$ (0.4 eV). The efficiency for the blue-emitting device was obtained at high applied voltage, which is also indicative of inefficient hole injection. This might be improved by employing new anode materials with higher work function [33].

4. Conclusion

In summary, we have demonstrated single layer phosphorescent OLEDs with a configuration of ITO/dopant:TPBi/LiF/Al and ITO/dopant/dopant:TPBi/LiF/Al (Table 2). These simplified structures are applicable to red, green, and blue OLEDs with common phosphorescent dopants Ir(piq)$_3$, Ir(ppy)$_3$, and FIrpic, respectively. Efficient performance of the simplified single layer devices is attributed to direct hole injection into, and transport on the triplet dopants. This concept indicates a new way to fabricate simplified OLEDs with competitive performance by utilizing charge injection and transport properties of the dopants. Moreover, the concept also shows a possible new direction for developing future OLEDs is to synthesize phosphorescent dopants with better carrier injection and transporting ability.

[28] To understand the reliability of our results, we fabricated a standard phosphorescent device with a configuration of ITO/α-NPD (40 nm)/Ir(ppy)$_3$:CBP (∼9 wt%, 20 nm)/BCP (6 nm)/AlQ (20 nm)/LiF/Al, where BCP and AlQ are 2,9-dimethyl-4,7-diphenyl-phenanthroline and tris-(8-hydroxy-quinoline)aluminum, respectively. The power efficiency at 100 cd/m^2 of the standard device was 23 lm/W, which was comparable to the value of 19 lm/W reported by Forrest et al. with an Mg:Ag cathode.

fluorescence detection system for a disposable lab-on-a-chip device.

For many OPD applications, spectral selectivity is critical. An OPD used for biological imaging must discriminate between strong excitation and weak fluorescent emission signals that have narrow spectral separation (and often must furthermore distinguish the emission of multiple fluorescent dyes). To this end, Pais et al. [6] incorporated two cross-aligned polarizer films to separate the fluorescence signal from the excitation light source. Addressing spectral selectivity requirements for colorimetry applications, Antognazza et al. [11] used three distinct organic materials in the active layers of their OPDs, demonstrating photoresponse curves that mirrored the standard color matching function. Seo et al. [12] demonstrated a color sensor by vertically stacking three photodetectors that were individually sensitive to only blue, green, or red light. However, the color separation characteristics in the stacked sensor were sub-optimal, primarily due to the broad absorption spectra of the active organic layers. Achieving wavelength selectivity by simply using organic dyes with different absorption spectra often presents additional practical challenges, particularly in optimizing the electrical characteristics of the detector.

Optical microcavity effects provide an alternative approach to tune the wavelength selectivity of a photodetector. These effects arise due to the interference of electromagnetic waves in dielectric cavities sandwiched by reflective layers, in which the optical path length is on the order of a wavelength. As with a Fabry–Perot interferometer, the microcavity structure exhibits spectral selectivity due to resonant optical modes in the cavity. Lupton et al. [13] utilized this effect in an OPD by replacing the cavity layer with photoactive materials, fabricating a Bragg reflector below the indium tin oxide (ITO) substrate and depositing a semi-transparent silver top electrode to form the top mirror. The spectral selectivity of the device was shown to depend on the bilayer cavity thickness, although the sensitivity and spectral selectivity remained relatively low due to a relatively low cavity quality (Q) factor caused by parasitic absorption in the thick photoactive layers. Furthermore, the maxima of the standing wave of the resonant field were positioned far from the donor–acceptor interface where exciton dissociation takes place, lowering the quantum efficiency of the detector.

In this work, we demonstrate a microcavity organic photodetector that incorporates a conductive, transparent optical spacer inside the cavity and places the organic heterojunction near a peak intensity of the resonant field. This results in a stronger optical microcavity (an enhanced Q factor) and hence increases the sharpness of the spectral response. Detector sensitivity is enhanced by two orders of magnitude over prior work [13], and the peak wavelength can be tuned across a much wider range. We also study the effects of metal mirror roughness on the external quantum efficiency (EQE) spectrum, accounting for roughness explicitly in our optical model and demonstrating excellent agreement between predicted and measured EQE when topographical data obtained via atomic force microscopy (AFM) is incorporated. Finally, we study the angular dependence and frequency response of our devices.

Appropriate optical spacer materials should exhibit low electrical and optical losses, as well as a properly matched work function to reduce contact resistance. Optical spacers such as TiO_x [14], bathocuproine (BCP), and C_{60} [1] have previously been used in organic solar cells. Archetypal organic solar cells, however, are weak microcavities since they are most often deposited onto ITO electrodes, resulting in a low cavity Q factor. Instead, we use thin metal films for both anode and cathode [15], and employ a considerably thicker optical spacer to substantially increase the strength of the electric field near the organic heterojunction, thereby enhancing the narrow-band quantum efficiency of the device. We use vacuum-deposited molybdenum trioxide (MoO_3) as the optical spacer, facilitating the fabrication of the photodetector by conventional vacuum thermal evaporation. As shown in Fig. 1, MoO_3 has good transparency over a broad range of the visible spectrum (where the EQE peaks of our OPDs are located). Current–voltage measurements of a 40 nm Ag/140 nm MoO_3/50 nm Al structure yielded Ohmic characteristics with a resistivity of 5×10^5 Ω cm, which is several orders of magnitude lower than that of most organic materials. The work function of MoO_3 is known to be 5.8 eV [16], enabling efficient hole collection.

To precisely identify OPD structures with desired external quantum efficiency (EQE) spectra, we employed optical models based on the transfer matrix approach, which predicts the optical field distribution within the multilayer structure. These models were coupled to exciton transport equations that account for exciton generation, extinction, and diffusion [1,17,18]. We assumed literature values for exciton diffusion length (100 Å for CuPc and 300 Å for C_{60}) [1], and assumed 100% charge dissociation and extraction efficiency. The simulated device layer structure has a 50 nm Al anode, variable thickness MoO_3 spacer, 20 nm copper phthalocyanine (CuPc) donor, 40 nm C_{60} acceptor, 7 nm BCP exciton blocking layer, and 40 nm semi-transparent silver cathode. Wavelength-dependent optical constants for these layers were taken from literature [18–21]. A cross-sectional diagram of the photodetector structure is illustrated in the inset of Fig. 1. Calculated electric field profiles within the device for the visible range of incident wavelengths are shown in Fig. 2a, assuming a 150 nm thick
Fig. 1. A comparison of the absorption coefficients of MoO_3, CuPc, and C_{60}, indicating that a MoO_3 film remains transparent across the visible spectrum. (inset) A cross-sectional illustration of the photodetector structure.
Fig. 2. (a) Calculated electric field intensity $|E|^2$ distribution throughout the photodetector for a range of incident wavelengths. The thickness axis denotes the distance from the air–cathode interface, on which light is incident. The external quantum efficiency (EQE) is plotted also along the back plane of the graph to represent the strong correlation between $|E|^2$ and EQE. (b) A plot comparing $|E|^2$ profiles inside the OPD for 430 nm and 520 nm incident light. A strong second mode can be seen for 520 nm illumination. The device structure used in the simulation for both (a) and (b) is: 50 nm Al / 150 nm MoO_3 / 20 nm CuPc / 40 nm C_{60} / 7 nm BCP / 40 nm Ag.

MoO_3 optical spacer. The engineered spectral responsivity is apparent in Fig. 2b, which compares the electric field profile for the 430 nm non-resonant wavelength to that of the 520 nm wavelength, which is near the second resonant mode of the microcavity. The left peak for the resonant mode is very close to the organic heterojunction, leading to increased optical absorption in this region and hence larger photocurrent. Even though the light couples in through a 40 nm thick semi-transparent silver film, the peak light intensity near the donor–acceptor junction is comparable to that of a conventional ITO based solar cell [17,18]. Below the wavelength of the second resonant mode, there exist third and fourth resonant modes in the electric field contour, indicating possible absorption in the ultra-violet range. Thicker spacers make the peaks narrower, and push the higher resonant mode into the visible range, similar to the Fabry–Perot interferometer. The calculated EQE spectrum, plotted in Fig. 2a, shows a strong correlation with the resonant electric field. Note that the EQE spectrum of a microcavity device can be largely decoupled from the absorption spectra of the active photosensitive materials (Fig. 1), a consequence of the strong resonant effects.

Following our optical analysis, we fabricated device structures having layer sequences and thicknesses identical to those modeled (within experimental error), deposited onto 1 mm thick glass substrates using vacuum thermal evaporation (VTE) at 10^{-6} Torr and 1–2 Å/s evaporation rate. The nominal layer sequence was as follows: thick aluminum that serves as the bottom mirror and an-

ode, MoO_3 optical spacer varied from 110 nm to 220 nm thick, CuPc electron donor, C_{60} electron acceptor, BCP hole and exciton blocking layer, and semi-transparent silver serving as the top mirror and cathode. Cathodes were defined by depositing through a shadow-mask, which was mounted in atmosphere immediately after depositing the C_{60} layer. Device photocurrent was measured in atmosphere using a transimpedance amplifier at zero bias, with the photodetector illuminated by monochromated light from a halogen lamp; a lock-in amplifier (at 89 Hz chopping frequency) was used to enhance the signal-to-noise ratio in determining the EQE. Incident light power was measured using a calibrated silicon photodetector (Newport 818-SL).

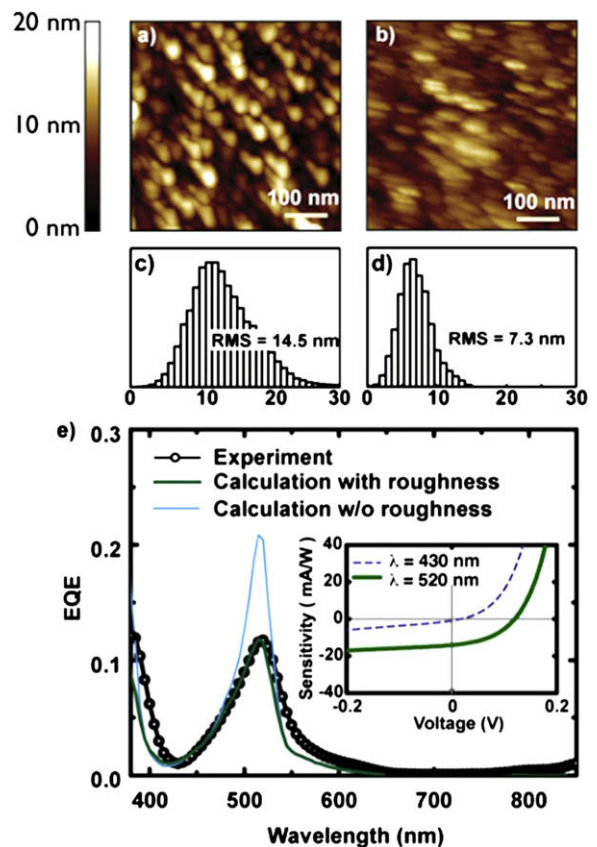
For a device having a target resonant mode at 520 nm, our calculation suggested a 150 nm thick optical spacer. This resonant peak was confirmed by EQE measurements on a fabricated device with 150 nm optical spacer thickness, as shown in Fig. 3e. Despite the accuracy of the pre-


Fig. 3. Atomic force microscopy (AFM) scans of (a) aluminum thin films deposited onto glass substrates, and (b) silver thin films deposited onto the organic layers of BCP, C_{60} and CuPc on the aluminum, along with histograms (c–d) of the measured surface height values, which exhibit a Gaussian distribution. The root-mean-square (RMS) roughness measures 14.5 nm for aluminum and 7.3 nm for silver. (e) A plot superimposing the measured and calculated external quantum efficiency spectra. Two calculated spectra are shown – one that does not take electrode roughness into account, and one that does. (inset) A plot of photodetector sensitivity for illumination wavelengths of 430 nm and 520 nm, showing clear spectral selectivity.

dicted peak position, there is a mismatch in the peak height. This is due to a lowering of the cavity Q factor, most likely a result of the roughness of the evaporated metal mirrors. To include the scattering caused by mirror roughness in our optical model, we used Filinski's theory [22] of modified reflection coefficients, which accounts for phase variations resulting from small height differences by a Gaussian distribution characterized by the root-mean-square (RMS) of the film topography. Atomic force micros-

copy (AFM) was used to quantify the roughness of the aluminum and silver films, as shown in Figs. 3a–d. We found RMS roughness values of 14.5 nm for aluminum deposited onto glass substrates, and 7.3 nm for silver films deposited onto the organic layers. Incorporating Filinski's correction into our optical model and using these RMS values explicitly resulted in excellent agreement with experiment, as shown in Fig. 3e. In the inset of Fig. 3e we compare the sensitivity of the detector to monochromatic light at wavelengths of 430 nm and 520 nm, corresponding respectively to the valley and peak of the EQE spectrum of the heterostructure. The sensitivity ratio for these two wavelengths was 15 at zero applied bias. Further measurements of the EQE spectra under a reverse bias of 2 V showed no changes in the wavelength peak or spectral width, although the magnitude of the peak increased slightly, as the sensitivity curve (inset of Fig. 3e) indicates.

To further demonstrate the spectral selectivity of the microcavity-based organic photodetector, we calculated (again accounting for roughness) the position of the resonance peak for a range of spacer thicknesses between 130 nm and 210 nm, predicting that the resonance peak would span wavelength ranges from 490 nm to 620 nm (Fig. 4a). These predictions were confirmed experimentally, as shown in Fig. 4b. By varying only the optical spacer thickness in the fabricated device structures, we are able to span a 450 nm to 630 nm range with the EQE spectrum. Some discrepancy between simulation and experiment is present for longer wavelengths, attributable to two effects. Firstly, the extinction coefficients used in our model for this wavelength range are based on literature values [20]; however, these coefficients can vary in practice for deposited films due to differences in film morphology. We separately performed optical absorption measurements on Ag thin films deposited in our thermal evaporation system and found that they had a slightly higher extinction coefficient for longer wavelengths than predicted in [20]. Secondly, we note that the two experimental

Fig. 4. (a) Calculated and (b) measured external quantum efficiency spectra versus incident wavelength for optical spacer layers of different thickness. The calculated response predicts that the resonance peak can be shifted from 490 nm to 620 nm (corresponding to optical spacer thicknesses of 130–210 nm). The observed peak in the response shifts from 450 nm to 630 nm for spacer thickness ranging from 110 nm to 220 nm, while other elements of the OPD structure remain unchanged. (c) A further comparison between theory and experiment, plotting the peak position versus spacer layer thickness; two sets of calculated peaks are shown for calculations that either do or do not account for electrode roughness. Note that the dotted lines in (b) and the last two experimental data points in (c) were obtained from heterostructures that use α-NPD instead of CuPc for the electron donor layer, to demonstrate control of the width of the spectrum via absorber layer composition.

Fig. 5. A plot of the EQE spectra for several incident angles (0° = normal incidence), including both p- and s-polarized light, calculated for a microcavity photodetector employing a 150 nm thick optical spacer. The peak blue-shifts with increasing angle, while the absolute magnitude of the EQE reduces at shallower incidence, regardless of polarization, due to a combination of increased reflectivity and increased absorption of light in the top silver mirror. The inset shows similar changes in peak wavelength measured experimentally.
Fig. 6. A plot of the −3 dB bandwidths of OPDs employing a thick MoO_3 spacer layer (50 nm Al / 150 nm MoO_3 / 20 nm CuPc / 40 nm C_{60} / 7 nm BCP / 40 nm Ag) and thin MoO_3 spacer (50 nm Al / 20 nm MoO_3 / 20 nm CuPc / 40 nm C_{60} / 7 nm BCP / 40 nm Ag) as measured at several input impedances by a 300 MHz bandwidth oscilloscope. A green LED (λ = 530 nm) with intensity of 1.3 mW/cm^2 was modulated in a square wave pattern, illuminating a circular device 1 mm in diameter through a focusing objective. The bandwidth extrapolated at 50 Ω input impedance is ~15 MHz, and decreases only negligibly upon the addition of the MoO_3 optical spacer, indicating that the small resistance of the optical spacer contributes very little to the RC time constant.

EQE spectra for photodetectors with optical spacer thicknesses of 200 nm and 220 nm (dashed lines in Fig. 4b) were obtained from a heterostructure that used N,N′-di-[(1-naphthalenyl)-N,N′-diphenyl]-(1,1′-biphenyl)-4,4′-diamine (α-NPD) instead of CuPc for the donor layer. While substituting a different absorber demonstrates the ability to further control the spectral response, it also leads to reduced detector sensitivity, in this case due to the low intrinsic optical absorption of C_{60} and α-NPD near the second resonant peak of the microcavity mode (590 nm and 620 nm for the two dashed spectra). Fig. 4c plots the peak position versus spacer layer thickness as a more direct comparison between theory and experiment. The two experimental data points with the largest spacer thicknesses correspond to the C_{60}/α-NPD heterostructure and demonstrate the ability to significantly reduce the photodetector response peak width with proper choice of absorber. The agreement observed between model and experiment suggest that our model can serve as a viable design tool.

Optical microcavities tend to be sensitive to the angle and polarization of incident light. We calculated EQE spectra at several incident angles for a microcavity photodetector employing a 150 nm thick optical spacer. The inclined incident (and polarized) light (0° = normal incidence) blue-shifted the peak wavelength of the photodetector, as shown in Fig. 5, attributable to the decreased optical phase difference of reflection at higher angles, as predicted by Fabry–Perot theory. Similar peak wavelength changes were measured experimentally, as shown in the inset of Fig. 5. The absolute magnitude of the EQE was progressively smaller at oblique incidence, regardless of polarization, attributed to a combination of increased reflectivity and increased attenuation of light in the top silver electrode. As a result, variation of the EQE spectrum with incident angle is minimal. We note that, while small, this manifestation of microcavity effects at varying incidence

angles could constrain some applications. It also potentially could be used as a means to actively tune the spectral response of a given OPD.

The frequency response of a photodetector is another important design consideration; one might suspect that inserting additional transport layers in a heterostructure could significantly reduce the response time. However, we find that the insertion of MoO_3 introduces negligible delays in the response time of the detector. We measured the bandwidth of two device structures with different MoO_3 thicknesses: 50 nm Al / 150 nm MoO_3 / 20 nm CuPc / 40 nm C_{60} / 7 nm BCP / 40 nm Ag and 50 nm Al / 20 nm MoO_3 / 20 nm CuPc / 40 nm C_{60} / 7 nm BCP / 40 nm Ag. These OPDs were defined by 1 mm diameter circular cathodes and were illuminated by a green LED (λ = 530 nm) with 1.3 mW/cm^2 intensity that was modulated by a function generator (Agilent 33120A). The transient OPD response for a range of load resistances was measured using a 300 MHz bandwidth oscilloscope (Tektronix TDS 3032B) as shown in Fig. 6. The bandwidth extrapolated at 50 Ω input impedance is approximately 15 MHz. This bandwidth is significantly lower than that measured in [1] for certain devices (430 MHz), most likely due to the fact that the devices in [1] were thinner, contained multiple junctions, and were measured in reverse bias and at higher illumination intensity. Importantly, the bandwidth of our device was measured to decrease only negligibly upon the addition of the MoO_3 optical spacer (see Fig. 6), indicating that the small resistance of the optical spacer contributes very little to the RC time constant.

In summary, we developed a means for tuning the spectral response of an organic photodetector across the visible spectrum by engineering its optical microcavity through the insertion of an electrically conducting and optically transparent spacer layer. We tested this concept using a spacer layer of thermally evaporated MoO_3, which exhibits good transparency and hole transport properties that do not limit the OPD's spectral or temporal response. Our calculations of the detector's photoresponse match well with experiments, particularly when the measured roughness of the electrodes (mirrors) is taken into account explicitly. We anticipate applications of this type of tunable organic photodetector design in colorimetry, fluorescence detection, and large-area flexible imagers, and photovoltaic cells.

driving voltage of ~5 V can be achieved by using diphosphine oxide derivatives as host [17–19]. The low driving voltage can be rationalized by the following two reasons. One is the *intrinsic* good electron-transporting ability of diphosphine oxide derivatives, which can be helpful to the transport of electrons in the bulky organic layer. The other contribution comes from the reduction of the energy barrier between diphoshpine oxide derivatives and LiF/Al cathode since these materials have a low LUMO level of 2.9 eV. However, the diphosphine oxide derivatives have a low-lying HOMO level of 6.6 eV, which causes a large energy barrier for the transport of holes from nearby HTL into the host. Consequently, the quantum efficiency of blue PHOLEDs based on diphosphine dioxide derivatives as host was significantly below 100%.

To summarize the development of host material in the previous studies, an appropriate blue phosphorescent host material should not only have a high triplet excited state as well as bipolar transport property, but also a minimum energy barrier between the host and adjacent carrier-transporting material. Unfortunately, up to now, it is not an easy task to find a host material that will satisfy all the above-mentioned requirements. In this paper, we will introduce a composite emitter incorporating a carrier-transporting material into the emitter composed of diphosphine oxide derivatives host and organometallic iridium dopant. The problematic transport of holes from the HTL into diphosphine oxide derivatives host can be alleviated through the adoption of carrier-transporting material, thus the probability of carrier recombination can be increased and the driving voltage can be decreased. Consequently, a blue PHOLED with a power efficiency of 20 lm/W and low driving voltage of 4.2 V at practical brightness of 1000 cd/m^2 is achieved.

2. Experimental

The composite emitter comprises a wide-band-gap host, 2,8-bis(diphenylphosphoryl)dibenzothiophen (PPT) [18], which has a triplet excited state of 3.0 eV, a blue phosphorescent dopant, iridium(III)bis((4,6-difluoro-phenyl)-pyridinate-N,C$^{2'}$)picolinate (FIrpic), which possessed a triplet excited state of 2.62 eV [2], and a carrier-transporting material, 4,4',4''-tri(N-carbazolyl)triphenyl-amine (TCTA), which possessed a triplet excited state of 2.76 eV [2] as well as a good hole-transporting ability (1.6×10^{-4} cm^2/Vs at 10^5 V/cm) [The data was measured by time-of-flight method, the detailed results will be reported in elsewhere]. In addition, a electron-blocking layer (EBL), bis[4-(p,p'-ditolylamino)phenyl]diphenylsilane (DTASi) [20], with high triplet excited state of 2.95 eV and a high-lying LUMO level of 2.2 eV was used to confine all generated exciton in emitter. A high electron mobility material (10^{-4} cm^2/Vs at 10^5 V/cm), 4,7-diphenyl-1,10-phenanthroline (Bphen) [21], and 20% (vol%) cesium carbonation (Cs$_2$CO$_3$) doped with Bphen [22] were used as ETL and n-ETL, respectively, to achieve low driving voltage. The device architecture used is ITO (150 nm)/NPB (45 nm)/DTASi (15 nm)/composite emitter (15 nm)/Bphen (25 nm)/n-ETL (20 nm)/Al (100 nm), where 4,4'-bis[N-(1-naphthyl)-N-phenyl-amino]biphenyl (NPB) is HTL. In order to investigate the effect of doping carrier-transporting material in FIrpic/PPT emitter, the doping concentration of blue dopant was fixed at 15% and the doping concentration of 0%, 10%, and 20% for the carrier-transporting material were tested.

Fig. 1 shows the detailed molecular structures of materials and architecture of device used in this study. All the materials were deposited by thermal evaporation in an UL-

VAC Solciet OLED coater at a base vacuum of 10^{-7} Torr. The device performance of luminance yield and EL spectra, $CIE_{x,y}$ color coordinates were measured by a Minolta luminance meter and a Photo Research PR-650 spectrophotometer driven by a programmable dc source, respectively.

3. Results and discussion

Fig. 2 shows the dependence of current density–voltage (J–V) characteristics of the blue PHOLEDs on the doping concentration of carrier-transporting material in emitter. Lower driving voltage was observed in the device with doping carrier-transporting material in emitter as compared with that of undoped device. For instance, the driving voltage at current density of 20 mA/cm^2 is 5.0 V for doping 20% carrier-transporting material in the emitter and 5.6 V for the undoped device. The decreased driving voltage can be attributed to the transport of holes from EBL (DTASi) into host (PPT) which was promoted through doping carrier-transporting material (TCTA) in emitter, since TCTA possesses a good hole-transporting ability and
Fig. 3. Current efficiency–current density (cd/A–J) characteristics of blue PHOLEDs.

a HOMO level (5.7 eV) lying between that of DTASi (5.6 eV) and PPT (6.6 eV). The device energy diagram is shown in the inset of Fig. 2.

Fig. 3 shows the dependence of current efficiency–current density (cd/A–J) characteristics of the blue PHOLEDs on the doping concentration of carrier-transporting material in the emitter. When doping 10% carrier-transporting material in the emitter, the device exhibited a current efficiency of 26.8 cd/A with low driving voltage of 4.2 V (J ∼4 mA/cm^2), which is 2 times higher than that of the undoped device with 12.3 cd/A and 5.0 V (J ∼8.2 mA/cm^2) at a practical brightness of 1000 cd/m^2. The current efficiency sustains as high as 25 cd/A when the doping concentration of carrier-transporting material is increased to 20% in the emitter. We believe the dramatic enhancement in current efficiency when doping carrier-transporting material in the emitter is resulted from the "hole-facilitating" character of carrier-transporting material, which can increase the concentration of holes in the emitter as opposed to that of undoped device. Therefore, the probability of carrier recombination can be increased.

In addition, at current density of 20 mA/cm^2, the device with 10% carrier-transporting material doped in emitter exhibited a current efficiency of 22.6 cd/A, which is 2.5 times higher than that of undoped device with only 9.2 cd/A. This result demonstrates that the problematic efficiency roll-off in blue PHOLEDs can also be suppressed by doping carrier-transporting material in the emitter. For instance, the efficiency roll-off from low (1 mA/cm^2) to high current density (40 mA/cm^2) is 29% and 23% for 10% and 20% carrier-transporting material in the emitter, respectively, while it is nearly 60% for the undoped device. The suppression of efficiency roll-off in blue PHOLEDs when doping carrier-transporting material in the emitter can be attributed to the "hole-facilitating" character of carrier-transporting material, which can reduce the accumulated holes at the EBL (DTASi) and FIrpic/PPT emitter interface to inhibit triplet-polaron quenching. Triplet-polaron quenching has been reported to be one of the major reasons for efficiency roll-off in PHOLEDs [23]. The detailed device performances of these blue PHOLEDs are summarized in Tables 1 and 2.

In order to prove that the transport of holes from EBL (DTASi) into FIrpic/PPT emitter was promoted by doping carrier-transporting material, two additional device architectures were fabricated; one has a pure PPT layer inserted in-between the EBL and emitter while the other has a TCTA:PPT (10:90) composite layer. The detailed device architectures and energy diagram are depicted in Fig. 4. When inserted a pure PPT layer in-between the EBL and FIrpic/PPT emitter, the device exhibited a very low current efficiency (<1 cd/A) and its EL spectrum displayed three dominant peak emissions at 420, 472, and 580 nm as shown in Fig. 5, which were originated from NPB, FIrpic, and the exciplex emission of DTASi/PPT, respectively. This phenomenon can be rationalized by the following mechanism. Firstly, according to the energy diagram, the holes and electrons were accumulated at the EBL/pure PPT interface. Secondly, a portion of the carriers recombined and the others formed the DTASi/PPT exciplex. Thirdly, the excitons diffused to either anode or cathode side across the

interfacial barriers of DTASi and PPT both of which have high excited state. Finally, the low excited energy of NPB and FIrpic captured the excitons to give the light emission.

On the contrary, when inserted a TCTA:PPT (10:90) composite layer in-between the EBL and FIrpic/PPT emitter, the device with a current efficiency of 11.5 cd/A at a brightness of 1000 cd/m^2 was closed to that of device with whole FIrpic/PPT emitter shown in Fig. 3. And also, the EL spectrum displayed only one dominant peak emission at 472 nm without detecting the emission from the exciplex of DTASi/PPT. This phenomenon further supports the spec-

ulation that the transport of holes from the EBL into PPT is promoted by doping carrier-transporting material. Therefore, the holes and electrons can no longer accumulate at EBL/PPT interface and the recombination zone is shifted toward the FIrpic/PPT emitter.

4. Summary

For solid-state lighting application, the low efficiency and the problematic efficiency roll-off are critical issues to be overcome in blue PHOLEDs. Here, we have proposed
Fig. 5. EL spectra of device with a pure PPT or TCTA:PPT layer inserted in-between EBL and FIrpic/PPT emitter as well as current efficiency–current density (*cd/A–J*) characteristics (inset).

a composite emitter concept and shown that doping a carrier-transporting material in the conventional blue phosphorescent emitter composed of wide-band-gap host and dopant can efficiently facilitate the transport of carriers into the emitter, as well as increase the carrier recombination and reduce carrier accumulation at interface. We showed that this composite blue phosphorescent emitter not only can decrease the driving voltage of device, but also increase the current efficiency as well as suppress the efficiency roll-off problem often encountered at high current density.

transparency using an interference effect [7]. DMD-transparent electrodes based on ZnS/Ag/ZnS (ZAZ) and WO_3/Ag/WO_3 (WAW) had previously been studied as anodes and cathodes, respectively, for OLEDs [7,8]. Transmission larger than 80% and sheet resistance smaller than 10–20 Ω/sq. were reported in those systems. However, OLED devices based on those electrodes turned out inefficient mainly due to poor hole (electron) injection properties of Ag/ZnS (Ag/WO_3) systems. Moreover, all those devices were fabricated on conventional glass substrates, and thus the potential of DMD electrodes for flexible OLEDs was not known. In this work, we introduce the optimal ZnS/Ag/WO_3 (ZAW) electrode structure that leads to OLED devices that not only exhibit a performance and operational stability comparable to or better than ITO-based devices but also show the flexibility far superior to that of ITO-based devices. Mechanical flexibility of ZAW electrodes and OLEDs based on them is carefully evaluated as a function of radius of curvature for bending and as a function of the number of bending cycles. Mechanisms/interfaces limiting the flexibility of OLED devices are also discussed.

2. Experimental

Before deposition of electrode materials, polyethylene terephthalate (PET) substrates (PANAC co., 250 μm) were cleaned using soapy water, deionized (DI) water, acetone, and isopropyl alcohol (IPA) successively in an ultrasonic bath, and were treated by air plasma (PDC-32G, Harrick plasma) for 5 min. Right after the plasma treatment, PET films were spun-coated with transparent photoresist (SU-8, Kayaku Microchem) at 3000 rpm (30 s) for planarization of their surfaces. Those planarized PET films were dried in the oven at 120 °C for 1 h and then loaded into a deposition chamber in which ZnS (Alfa Aesar, 99.99%), Ag (Alfa Aesar, 99.999%) and WO_3 (Alfa Aesar, 99.99%) were deposited sequentially on the PET film by vacuum thermal evaporation. Sample holders and evaporation source were approximately 0.6 m apart, and no damage or deformation was observed in PET substrates without active cooling for substrates.

OLED devices under study were based on N,N′-Bis(naphthalen-1-yl)-N,N′-bis(phenyl)-benzidine (NPB) as a HTL, tris(8-hydroxy-quinolinato) aluminium (Alq$_3$) as an emitting and electron transporting layer [9], and LiF/Al as a cathode with transparent DMD anodes in a structure of ZnS/Ag/WO_3 as shown in Fig. 1a. (Also refer to Fig. 1b for energy-level diagram. The highest occupied molecular orbital (HOMO) of WO_3 is given as the range of values considering the values reported in the literature [10,11].) Control samples on conventional ITO on polyethylene naphthalate (PEN) substrates (Peccell Technology Inc., 250 μm) were also fabricated in the same batch for comparison.

All the measurement was carried out in an N$_2$-filled glove box that is directly connected to the deposition chamber. Current density–voltage (J–V) and luminance–voltage (L–V) characteristics were recorded using a source-measure unit (Model 2400, Keithley), a photodiode (FDS100-CAL, Thorlab) with the calibrated spectral re-

sponse, and a pre-calibrated fiber–optic spectrometer (EPP-2000-UV–VIS–NIR, StellarNet). For a bending cycle test, we used a custom-made bending tester which can modulate both the number of bending cycles and the radius of curvature.

3. Results and discussion

3.1. The properties of ZAW multilayer electrodes

In DMD electrodes, both outer and inner dielectric layers, or D_o and D_i layers as shown in Fig. 1a, respectively, are used to enhance the optical transparency. It is known that a dielectric layer with a higher refractive index n has an advantage in that it can fulfill the optimum 'zero-reflection' condition with a thicker metal film, making it easier to realize a low sheet resistance without sacrificing the transmission [12]. A good example illustrating the advantage of using high-n dielectric layers is presented in Fig. 2 which clearly shows the calculated maximum achievable transmission T in both D_iMD_o/glass geometry (air-to-air T) and organic layers/D_iMD_o/glass geometry (organic-to-air T) increases monotonically as n of D_o layer increases. (Calculation is based on the transfer-matrix formalism of multilayer thin films [12,13].) In such respect, ZnS ($n = 2.35 \pm 0.05$ at $\lambda = 550$ nm) [7] has been chosen as D_o layer rather than WO_3 ($n = 1.95 \pm 0.05$ at $\lambda = 550$ nm) [14]. For D_i layer, however, we chose WO_3 because it is known to have a good hole injecting property to common organic HTLs [10]. ZnS was previously tried by Pang et al. for D_i layer in OLED devices based on ZAZ anodes, but there was a significant increase in turn-on voltage with respect to ITO-based devices [7], indicating that the hole injection of ZAZ electrodes is fairly limited when compared to that of ITO electrodes. In our own trial, devices based on ZAZ electrode indeed showed the turn-on voltage as large as 10.7 V, which is approximately four times larger than that of typical ITO-based NPB/Alq$_3$ devices.

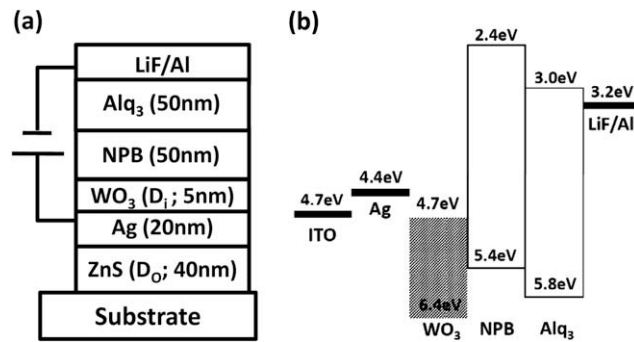
In addition to the selection of dielectric layers and optimization of their optical structure, our study indicates that one of the key factors in achieving both high transmission and low sheet resistance in these DMD electrodes is in fact to obtain uniform and continuous metal thin films, as their thickness is typically in the range of 5–20 nm. Making the metal films thicker could ease the continuity issue but would result in a rapid decrease in optical transmission. Fig. 3 shows the two distinctive cases for scanning electron microscopy (SEM) images of Ag films with a nominal thickness of 10 nm that were deposited at the same batch. The Ag films grown on a bare microscope slide glass (Fig. 3a) exhibited a morphology characterized with numerous small clusters of silvers that are essentially separated from one another, resulting in the sheet resistance R_{SH} that is too high to be measured. On the other hand, the Ag films grown on a microscope slide glass planarized by SU-8 films (Fig. 3b) exhibited continuous and uniform film morphologies. In such case, R_{SH} values of Ag films having the thickness of 12 and 20 nm were 14.5 and 6.0 Ω/sq., respectively, which are comparable to the results reported by O'Connor et al. [15].


Fig. 1. (a) Schematic device structure of the OLED device with ZnS/Ag/WO$_3$ (ZAW) anodes under study and (b) its energy-level diagram. D_i layer refers to the inner dielectric layer which interfaces with organic semiconductors and D_o layer refers to the outer dielectric layer which is closer to a substrate. The HOMO of WO$_3$ layer is given as a range of values considering the values reported in the literature.
Fig. 2. Maximum achievable transmission (T) at $\lambda = 550$ nm in both D_i(WO$_3$, x nm)/M(Ag, 18 nm)/D_o(y nm)/glass geometry (air-to-air T; dashed line) and Alq$_3$(50 nm)/NPB(50 nm)/D_i(WO$_3$, 5 nm)/M(Ag, 18 nm)/D_o(y nm)/glass geometry (Alq$_3$-to-air T; solid line) as a function of refractive index (n) of D_o layer. x and y refer to the thickness of a dielectric layer that is allowed to vary to find optimum condition. Calculation is based on the transfer-matrix formalism of multilayer thin films [12,13].

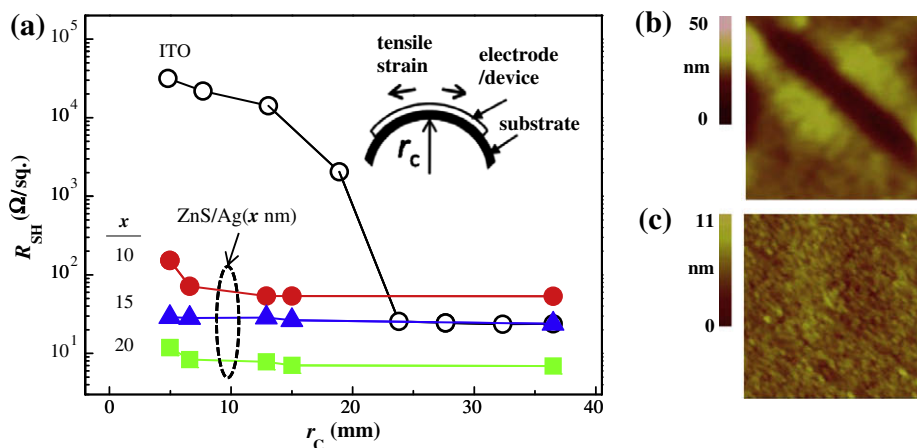
In a DMD electrode prepared on a glass substrate, ZnS layer with a thickness of a few tens of nanometer was able to provide a smoothening effect by itself, and therefore, high quality Ag films could be achieved on its top without an additional planarization layer. However, in case of PET substrates, successful DMD electrodes could not be realized without the planarization layer. This is regarded due to the typical high roughness of their surfaces and accidental occurrence of peaks even higher than 50–100 nm [16]. Fig. 4a compares R_{SH} of ITO on PEN substrates with ZnS (40 nm)/Ag (x nm, x = 10, 15, 20) layers deposited on PET substrates planarized by the SU-8 layer as a function of the radius of curvature r_C after repeated bending. The experiment was done by bending a substrate 50 times against a cylindrical object with the substrate-side facing the object, resulting in a tensile stress on electrode layers (see the inset of Fig. 4a). First of all, one can note that the R_{SH} values of ZnS/Ag electrodes on PET substrates are comparable to the values observed in glass-based samples, indicating the effectiveness of SU8-based planarization in achieving low R_{SH} values on plastic substrates. Moreover, the observed tendency of R_{SH} with respect to r_C demonstrates the superiority of these multilayer electrodes in terms of mechanical flexibility over conventional ITO electrodes on PEN substrates. As one can easily note in the atomic force microscopy (AFM) images presented in Fig. 4b, formation of deep cracks was observed in the ITO films on PEN substrates after the repeated bending at r_C
Fig. 3. Scanning electron microscopy (SEM) images of Ag films with a nominal thickness of 10 nm grown on (a) a bare glass substrate, and (b) a glass substrate planarized by SU-8 polymer films.


Fig. 4. (a) Sheet resistance (R_{SH}) of ITO on PEN substrates (open circles) and ZnS(40 nm)/Ag (x nm, x = 10, 15, 20) layers grown on PET substrates (closed shapes) planarized by an SU-8 layer, as a function of a radius of curvature (r_C) after being bent 50 times against cylindrical objects with the radius of r_C. Atomic force microscopy (AFM) images for surface morphology of (b) ITO (top, 3×3 μm^2) on PEN and (c) ZnS (40 nm)/Ag on planarized PET (Ag on top) (bottom, 1×1 μm^2) after the bending test at r_C of 5 mm. Inset in (a): schematic diagram showing the bending test geometry.

of 5 mm [4]. On the other hand, the ZnS/Ag multilayer films exhibited only the hint of slight bending-induced line defects after the same bending experiment (see Fig. 4c), accounting for the fact that its R_{SH} value remained almost unchanged down to r_C of ~5 mm. Such low level of degradation in R_{SH} under the harsh bending condition is considered to result from the fact that sheet conduction in these multilayer electrodes occurs mostly within the metal films, which inherently have a good ductility [17].

3.2. The device performance and flexibility of OLEDs with ZAW anodes

Fig. 5a and b compare the performance of the OLED devices based on the proposed ZAW structure on PET substrates with the ITO-based control devices. The ZAW-based devices exhibit desirable OLED characteristics such as a turn-on voltage (V_{TO}) as small as 2.4 V and a luminous efficacy (η_L) of 6.2 cd/A at 1000 cd/m^2 with the maximum external quantum efficiency (EQE) of 2.0%. (See also the inset of Fig. 5a for the ZAW-based device under operation while it is bent.) This level of performance is well compared with those of ITO-based control samples which exhibited V_{TO} of 2.4 V, η_L of 5.0 cd/A at 1000 cd/m^2, and the maximum EQE of 1.7%. Also in the independent study using glass substrates (see the inset of Fig. 5b), devices based on the same ZAW structure was shown to exhibit a better performance than devices based on ITO electrodes, and moreover, they outperformed devices based on ZAW electrodes with a thicker WO$_3$ layer, although the current geometry had a lower air-to-air transparency (~60% at λ = 550 nm) than those with a thicker WO$_3$ layer [8]. It is not necessarily unusual because optimization of any OLED structure should carefully consider both optical and electrical aspects, and moreover, because optical optimization should consider a situation pertaining to the whole OLED configuration rather than simple air-to-air transmission of electrodes. Detailed description for optimization of

ZAW-based OLED device structure will be reported elsewhere [18].

Fig. 6a presents the luminance (L) of the flexible OLEDs as a function of r_C under the same bending test (=50-time bending; tensile stress as shown in the inset of Fig. 4a) used for the results in Fig. 4. Test was done by monitoring L at the bias V of 5.25 and 4.85 V for ITO-based and ZAW-based devices, respectively, which initially resulted in L of 510 ± 10 cd/m^2. One can easily note that ITO-based devices started to exhibit a rapid bending-induced degradation as r_C became smaller than 15 mm, and then lost all the luminescent output at r_C of 5 mm. Comparison between J–V characteristics (the inset of Fig. 6a) for r_C of 42 and 7 mm shows a significant change in their forward slopes, indicating that the degradation comes partly from the increase in R_{SH} of ITO electrodes. On the other hand, the ZAW-based devices exhibited no degradation down to r_C of 7 mm and started to lose about 30% of the initial L at r_C of 5 mm. Below r_C of 5 mm, however, the ZAW-based devices also lost all the luminescent output.

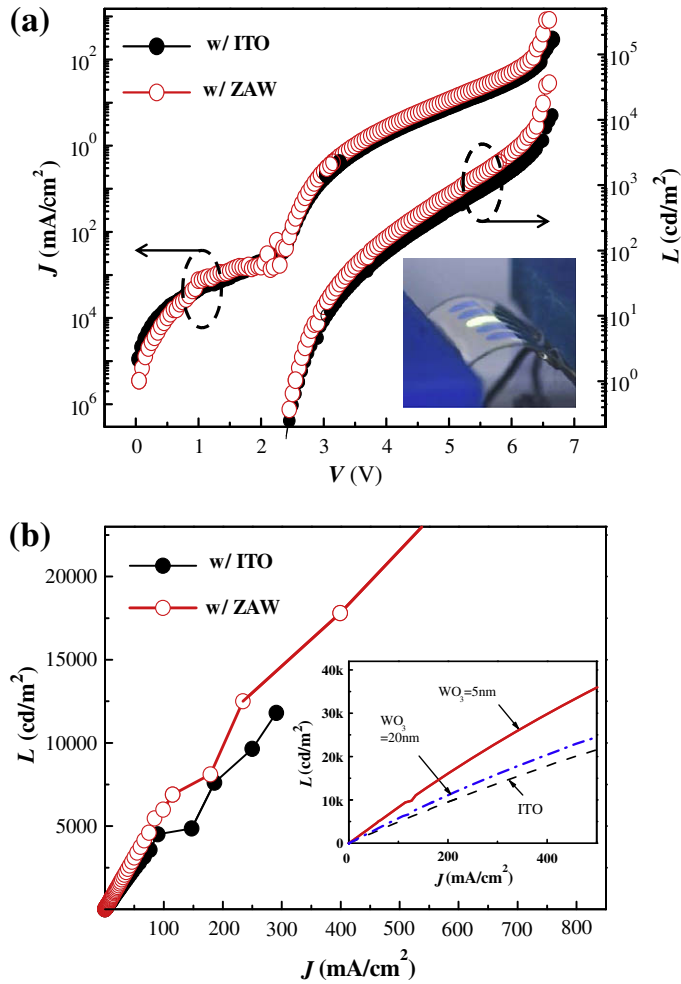
As can be seen in Fig. 6b, ZAW-based devices exhibited a significantly better performance than ITO-based devices also in a dynamic test in which their L values are recorded as a function of bending cycles N after bending the devices N times (tensile stress) at r_C of 18 and 25 mm, respectively. Both types of devices maintained the initial luminance (500 ± 10 cd/m^2) up to N of 5×10^3 at r_C of 25 mm. However, the ITO-based devices showed a rapid degradation after N of 10^2 and eventually became non-operable after N of approximately 10^3 at r_C of 18 mm, although r_C of 18 mm was the radius of curvature at which the ITO-based devices began to show only a glimpse of degradation at the 50-time-bending quick test described in Fig. 6a. On the other hand, the ZAW-based devices maintained the proper OLED characteristics without any degradation up to the maximum N we tried (=5×10^3) at both r_C values, demonstrating their excellent reliability under repeated tensile stress.


Fig. 5. (a) Current density–voltage (J–V), luminance–voltage (L–V), and (b) L–J characteristics of OLED devices with ITO (closed circles) or with ZAW (open circles). Inset in (a): a photograph of an OLED with ZAW electrodes under operation while it is bent (compressive stress applied in this picture). [Tensile stress applied, as shown in Fig. 4a.] Inset in (a): J–V characteristics of ITO-based devices near observation point for r_C of 42 mm (solid) and 7 mm (dashed). (b) Change in L as a function of bending cycles (N) measured at r_C of 18 and 25 mm. L values are normalized to the respective initial values L_0 in (a) and (b).

Fig. 7 presents the optical microscope images of OLED device active layers taken after the bending test corresponding to Fig. 6a at r_C of 15, 7, and 5 mm. In case of ITO-based devices (Fig. 7a), rather macroscopic line defects were observed in a direction parallel to the bending axis for small r_C values. The image of the ITO-based devices taken after deposition of Al over the whole sample area on the device side (the inset of Fig. 7a) shows that such line defects extends into the non-active area having ITO or ITO/organic layers only, indicating that the degradation observed in that range of r_C is mainly due to the formation of the cracks within the ITO layer that were observed also in Fig. 4b.

On the other hand, ZAW-based devices virtually show no change down to r_C of 7 mm and start to exhibit multiple of short line defects in the active area at r_C of ~5 mm (see Fig. 7b). These line defects were only visible when those samples were seen from the emission side through the substrate, suggesting that bending-induced strain resulted in local defects *internally* within the device active layers. In order to pinpoint the interfaces or layers that originate defects in these devices, thin Al layer was deposited on the device side of the whole samples as in the ITO case. Images taken after the blanket deposition of Al (the inset of Fig. 7b) reveal that those line defects observed in ZAW devices exist only in the location where cathode metal and organic layer both exist, indicating that either of the cathode metal or organic layers, or interface between them is the one most subject to creation of defects upon severe bending-induced tensile strain. Considering that both metal and organic layers typically have a good ductility and that areas only with anode and organic layers do not show defects, one can conclude that it is mainly the delamination occurring at the cathode metal–organic interface that induced the short line defects in the ZAW-based devices. This reminds us that one has to carefully consider the effect of bending-induced strain on some critical interfaces [19] while continuing to develop highly flexible electrodes, in order to realize ultra-flexible OLED devices or similar systems.

In addition to the device performance and mechanical flexibility, the operational stability cannot be overemphasized for any electrode technology to be practically meaningful. Fig. 8 shows the change in luminance L and voltage V of ZAW-based and ITO-based flexible OLEDs as a function of time under a supply of constant current I_0 of 1 mA. In this condition, the initial luminance values L_0 were 1600 and 610 cd/m^2 for the ZAW-based and the ITO-based devices, respectively. Both devices maintain the initial luminance quite well throughout the testing time-span of 60,000 s (≈16.7 h), as shown in Fig. 8a. The voltage required to support the current of 1 mA for the ITO-based device exhibited a gradual increase as time passed. Overall ~10% increase in the voltage was observed after operation for 60,000 s in the ITO-based device. Such behavior can be attributed to appearance of localized inactive areas which effectively decrease the device area and thus increase current density for a given current. Different from the case of ITO-based devices, the voltage for the ZAW-based devices remained almost constant except for a small fluctuation at an early stage. It is not yet clear whether ITO-based flexible devices are inherently poor in operational stability or it is rather specific to the batch of devices we tested. Nevertheless, the above results clearly demonstrate the competence of ZAW electrodes for flexible OLEDs with a high operational stability.

Another important aspect to consider for device stability particularly in flexible OLEDs is to protect a device from permeation of water vapor and oxygen, because most plastic substrates do not provide a sufficient protection by themselves due to their porous nature [20]. It is known that some dielectrics and metal layers can improve the barrier properties of plastic substrates [20]. DMD electrodes may then play an additional role as a gas barrier to some degree, as TiO$_x$ buffer layers used in organic solar cells were shown to work also as a barrier layer that reduced the air-sensitiv-
Fig. 7. Images of the device active area (appears as dark finger-like shapes) for (a) ITO-based devices and (b) ZAW-based devices taken from the emission side through substrates after 50-time-bending test in Fig. 6a at r_C = 15, 7, and 5 mm. Inset: images taken after deposition of Al layer over the whole sample area to tell whether cracks exist also in non-active area. Note that the ITO-based devices have cracks also in non-active layers, indicating the major portion of cracks comes from ITO itself.
Fig. 8. Luminance *L* and voltage *V* of ZAW-based (—) and ITO-based (– – –) flexible OLEDs monitored as a function of time under a supply of constant current of 1 mA. Values are normalized to their respective initial values L_0 and V_0.

ity of the cells [21]. A further study is needed to analyze the operational and environmental stability of these flexible OLEDs under various conditions and to develop a proper barrier structure that considers both optical and flexible properties of the overall device structure.

4. Conclusions

In summary, we have successfully demonstrated highly flexible OLEDs by replacing ITO electrodes with ZnS/Ag/WO₃ (ZAW) multilayer transparent electrodes showing an ideal balance among sufficiently low sheet resistance, mechanical flexibility, and carrier-injection compatibility with OLEDs. Performance as well as operational stability of the OLED devices with the proposed electrode geometry was shown to be comparable to or even better than that of ITO-based control devices. Readers are cautioned that ZAW electrodes presented in this work may not be the only DMD electrodes suitable for flexible organic devices. Because all DMD electrodes rely on ultra-thin metals for efficient conduction, one may in general expect that they can potentially be used as highly flexible transparent electrodes in many demanding applications, with the following guidelines met: (i) outer dielectrics to have a high refractive index and a low (possibly zero) extinction coefficient at visible wavelength; (ii) metal to have a high conductivity with a low extinction coefficient at visible wavelength, and to have a tendency to form a uniform, continuous thin film; and (iii) inner dielectric to have a relevant carrier-injection (collection) property to (from) adjacent semiconductors to be used in OLEDs and transparent thin-film transistors (organic solar cells).

Flexibility of the current OLED devices was only limited by the rather abrupt formation of delamination that occurred at interfaces between cathode metals and adjacent organic layers at a radius of curvature of ∼5 mm. This limit may be further reduced by the careful engineering of a multilayer structure so that device layers may be located

near neutral mechanical plane [22]. Since the minimum radius of curvature allowing for a consistent operation of flexible devices is highly important in making roll-type devices more compact and reliable, the work reported here is likely to bring the promise of OLEDs and other similar organic devices for future ultraportable displays and electronic appliances much closer.

To create such a detector clearly requires the use of an inherently flexible electronic device that can be fabricated over a large area and that is sensitive to the passage of X-rays. This combination of properties can be achieved by using an inorganic phosphor that is placed in contact with an organic photovoltaic device (OPV), with the OPV detecting luminescence emitted by the phosphor following the passage of the X-rays. Here, the use of an OPV is particularly beneficial as such devices can in principle be fabricated over relatively large areas onto a fully-flexible plastic substrate [11]. Indeed, an organic-semiconductor based system has recently been used to detect 70 kV X-rays used in medical imaging applications, with the device having sufficient level of radiation stability [12] and low dark-current [13] to make it suitable for practical imaging applications. Other recent reports on the sensitivity of organic materials such as polyfluorenes and poly(triarylamines) [14] and pentacene [15] to X-rays having an energy of 10's of kV also suggest such materials are often characterised by very promising levels radiation hardness, suggesting applications as electronic materials suitable for use in space-environments [15].

In this work, we focus on the detection of X-rays having higher energy (6 MV) using an OPV-based detector. Such X-rays are more highly penetrating (less well stopped) than those used in imaging (e.g. the total mass attenuation coefficient of 70 kV X-rays in SiO_2 is around 10 times greater than that of 6 MV X-rays [16]). Furthermore, the MV X-rays used in radiotherapy are typically delivered at dose-rates that are much larger than that used in imaging applications ($\sim$100 mGy s^{-1} compared to <1 mGy s^{-1} [17]). A practical detector for such MV X-rays must therefore have a linear response over a wide exposure range, and be able to withstand the passage of a significant radiation flux through its active layer without its functionality being compromised by radiation-induced damage. Concerns arise however as to the ability of organic-semiconductors to withstand the passage of a significant dose of MV X-rays without the generation of charge traps resulting from local ionisation. Whilst kV X-rays have been shown to generate a sufficient quantity of luminescence within a thin scintillator film that is detectable by an OPV [12,13], it is not clear whether significantly more penetrating X-rays of interest here would generate a detectable optical signal. As we report however, the devices that we have created have a sensitivity that is an order of magnitude better than that of a conventional (small-area) silicon p–n junction based device. Furthermore, we show that the organic X-ray detector prototyped is remarkably radiation tolerant, with only a small loss (2%) in sensitivity measured over the course of a relatively large (360 Gy) radiation exposure.

2. Experimental

The OPVs that we have used are based on a thin-film blend of the conjugated polymer poly(3-hexylthiophene) [P3HT] and the fullerene derivative PCBM. This material system currently represents the state of the art for organic photovoltaic devices, with the highest external quantum efficiencies (EQE) recorded being around 80% at 500 nm
Fig. 1. Schematic of the detector operation. The incident X-rays (red) produce a forward-scattered primary electron (blue) which then produces secondary ionisation electrons (yellow). This secondary ionisation excites the phosphor, whose luminescence (green) is detected by the organic photovoltaic device. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

[18,19]. A schematic of the devices is shown in Fig. 1. Briefly, devices are fabricated by spin-casting a layer of PEDOT:PSS onto an ITO anode which is then baked in N_2 for 10 min at 100 °C to remove adsorbed water. The substrates are then transferred to an overpressure nitrogen glovebox, where an 1:0.8 (by mass) blend solution of P3HT:PCBM in chlorobenzene is spin-cast onto the ITO/PEDOT:PSS anode. A cathode consisting 100 nm of aluminium is then evaporated onto the organic thin-film at a base pressure of <10^{-6} mBar. The devices are encapsulated by bonding a 0.5 mm glass sheet onto their surface using a UV curable glue. Finally, the devices are annealed at 150 °C for 60 min. Measurements using a calibrated solar-simulator operating at 100 mW cm^{-2} (Oriel Instruments AM1.5 solar-simulator calibrated with an NREL 4 cm^2 silicon reference cell) indicate that the devices have a typical power conversion efficiency (PCE) of 3.7% immediately following fabrication. However, since OPVs undergo a period of degradation when initially illuminated, the devices were aged for 30 min under 1 sun (AM 1.5) illumination to improve their stability. This process resulted in devices with a typical PCE of 3%. The measured EQE of the OPV devices is shown in Fig. 1. Here, it can be seen that our devices have a peak EQE of 57% at 504 nm (post aging). Each device has an active area of 4.5 mm^2, which is defined by the overlap of the anode and cathode strips.

As a phosphor we have used the material Gd_2O_2S:Tb. This was purchased from Applied Scintillation Technologies in the form of a flexible substrate that was coated with the phosphor at an area density of 279 mg/cm^2. In the experiments described, the substrate was placed in contact with the OPV such that luminescence emitted was directly incident upon the transparent anode. To evaluate the efficiency of the composite detector, we have used the linear accelerator facility at St. James's University Hospital in Leeds. The machine forms part of a dedicated research facility, however the linac is typical of machines used to

deliver megavoltage radiotherapy treatments around the world. This machine provides 6 MV X-rays up to a maximum dose rate of $\sim$100 mGy s^{-1} (approximately equivalent to 10^{14} photons s^{-1} m^2).

3. Results and discussion

The MV X-rays studied here can interact with matter in one of two ways; by Compton scattering and via pair-production. In both processes, a high-energy electron (or positron) is forward-scattered (by a distance of $\sim$1.5 cm in water), producing a shower of secondary ionisation. In radiation therapy these low-energy (<100 keV) secondary electrons are used to deliver the energy that destroys malignant tissue. In our detector, the secondary electrons created excite the Gd^{3+} (which is contained within a ceramic host-matrix) that then transfers its energy to the rare-earth Tb^{3+} dopant [20,21]. The luminescence from the Tb^{3+} is then detected by the OPV. The emission spectra of the phosphor recorded under X-ray illumination is shown in Fig. 2. It can be seen that the peak emission wavelength (540 nm) coincides well with the peak sensitivity of the OPV (504 nm), ensuring efficient detection. Indeed, from the overlap integral of the two spectra, we calculate that in an idealised device (i.e. having no optical loss), the luminescent photons should be detected with an efficiency of 44%.

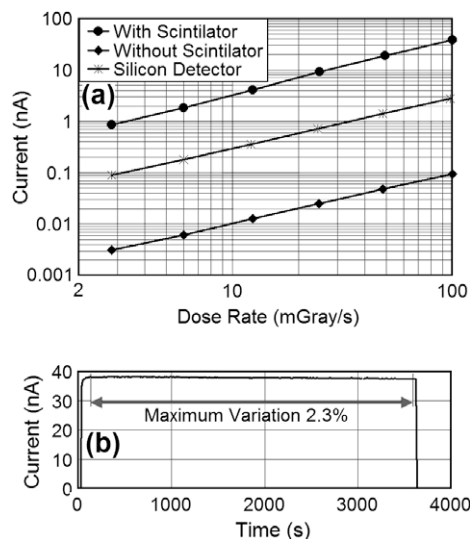
Fig. 3a plots the photocurrent from the device as a function of X-ray dose rate. We find that the X-rays are detected with a sensitivity of 0.086 C m^{-2} Gy^{-1} over the entire range of dose-rates explored, confirming the applicability of the device as a dosimeter. Control experiments in which no phosphor layer was used show that X-rays can be detected directly by the OPV itself but that the sensitivity is over two orders of magnitude lower. This relative insensitivity of the OPV to direct exposure to X-rays results from the fact that the active semiconductor is relatively thin ($\sim$150 nm in total), and thus the rate of charge generation within the OPV semiconductor layers is very low. We can also estimate the quantum efficiency (η) of the device (photoelectrons per X-ray absorbed in the phosphor) using $\eta = k/\gamma$ where k is the rate at which electrons are produced at the terminals (calculated directly from the current) and γ is the rate at which X-rays are absorbed. The rate at which X-rays are absorbed is calculated using $\gamma = \rho DA/E$
Fig. 2. The external quantum efficiency of the organic photovoltaic device shown together with X-ray excited luminescence spectra of the phosphor.


Fig. 3. Part (a) shows a log–log plot of output current versus X-ray dose rate for the OPV both with and without the phosphor present as well as for the reference silicon detector. Part (b) shows the current recorded from the device as a function of time whilst exposed to a constant X-ray dose rate of $\sim$100 mGy s^{-1}.

where ρ is the sheet density of the phosphor, D is the dose rate, A is the pixel area and E is the average energy of an X-ray (which is a third of the acceleration voltage). This leads to an overall efficiency of $\sim$62,000 electrons per absorbed X-ray photon. By dividing this figure by the OPV luminescent photon detection efficiency and assuming an optical loss of a half, we estimate the phosphor yield to be 47,000 photons per MeV. This value compares favourably with similar scintillators in the literature [22].

For comparison, we have also recorded the current generated by a commercial (Scanditronix EDP-10) silicon p–n junction based X-ray detector under identical conditions to that described above. This device is based on a silicon detector that is encapsulated within a stainless-steel/epoxy block (6.5 mm thick $\times$ 12 mm diameter), and works by directly collecting the ionised charge produced within the detector (rather than via the detection of luminescence). Encouragingly, we find that the photocurrent produced by the OPV/phosphor detector was $\sim$14 times larger than that recorded from the silicon-based devices when exposed to the same radiation flux. We note that a similar combination of OPV and an Gd_2O_2S:Pr phosphor have been used [12] to detect 70 kV X-rays. In such previous work, the lower energy X-rays were detected with a sensitivity of 1.28 C m^{-2} Gy^{-1} (when the OPV was run in short-circuit mode); a factor of $\sim$15 times higher than that demonstrated here. We believe that the 10 times higher penetration depth of the 6 MV X-rays used here most likely accounts for this difference in sensitivity.

It is clear that our device works as a radiation detector, however it is important to assess its relative stability under continuous exposure to X-rays. Devices were therefore subjected to prolonged operation (with phosphor present) and the output current monitored. This is plotted in Fig. 3b in which it can be seen that over the course of the exposure

(which lasts a period of 60 min and corresponds to a total radiation dose of 360 Gy) (the detected photocurrent drops) by around 2%. Measurements of the OPV PCE after such exposure failed to identify any significant degradation in device efficiency, demonstrating a relatively promising level of stability. Indeed, the typical dose received by a device during an individual radiation therapy treatment would be ~2 Gy, indicating that our un-optimized detector could survive many individual radiation exposures. We believe the relative radiation stability of an OPV results from the fact that the organic-semiconductor layer used in the OPV is very thin (conjugated polymers are direct-gap semiconductors and thus have very high extinction coefficients). For this application, this relative thinness is a distinct advantage as the rate of damage that occurs to the organic-semiconductor via direct interaction with the highly penetrating (and thus weakly interacting) MV X-rays is low. This observation is commensurate with the fact that the directly-generated photocurrent within the OPV is also low.

Finally, transparency is an important feature of any thin-film device that is to be used in real-time dosimetry during radiation therapy. We have therefore used the commercial silicon detector described above to determine the attenuation in X-ray flux passing through either the OPV, or the phosphor, or the stacked OPV and phosphor. We find that the intensity X-ray beam is attenuated by a 1.3% when passing through the phosphor, by 1.7% when passing through the OPV and thus by 3% when passing through the entire stacked device. This is a relatively low rate of attenuation, and would not compromise the efficacy of a typical radiation treatment.

4. Conclusions

We have prototyped a MV X-ray detector consisting of a flexible phosphor layer in contact with an organic photovoltaic fabricated from P3HT:PCBM. X-rays incident on the phosphor generate luminescence that is then detected by the organic photovoltaic. In order to increase the stability of the detectors, the organic photovoltaics were aged for 30 min under AM 1.5 simulated sunlight in order to remove any initial degradation in performance, however, even after this process the external quantum efficiency was greater than 55% at the peak wavelength emitted by the phosphor. This well matched spectral response between the phosphor and the organic photovoltaic resulted in a device having a sensitivity higher than a commercial silicon detector. The system also had excellent radiation hardness with less than 2% variance in output recorded over 360 Grays of radiation dose. Our measurements therefore suggest that organic detectors may find application as real-time, patient-specific dosimeters used in the imaging of X-rays for radiotherapy treatment.

[14–16]. In these tandem cells, the subcells were connected by external circuits to realize parallel connection. In this letter, we demonstrate a tandem polymer PV cell with the two stacked subcells having complementary absorption in parallel connection without using external circuit connection. A semitransparent metal layer combined with inorganic semiconductor compounds is utilized as the intermediate electrode of the two subcells to create the required built-in potential for collecting photo-generated charges. The advantage of this kind of tandem polymer solar cells is that each subcell can be optimized individually to achieve a highest J_{SC} since the overall J_{SC} of the stacked cell is the sum of the two subcells.

2. Experimental details

Fig. 1a shows the structure of the tandem polymer PV cells and the chemical structures of the active materials used in this study. The conjugated polymers of poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b′]dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT) and poly(3-hexylthiophene) (P3HT) are synthesized by our group with the number-average molecular weight (M_n) of 21,000 g/mol and a polydispersity index (PDI) of 3.15 for PCPDTBT, and a M_n of 24,000 g/mol, a PDI of 1.59 and a regioregularity higher than 97% for P3HT, respectively. The P3HT and PCPDTBT with different band-gaps are used as electron donors, which are blended with electron acceptor of [6,6]-phenyl C61-butyric acid methyl ester (PCBM) (purchased from Solenne Co. with a purity higher than 99%, used as received) to serve as the active layers in different subcells, respectively. As shown in Fig. 1a, the device was fabricated on a patterned indium tin oxide (ITO)-coated glass substrate with 10 Ω/square sheet resistance. An electron transport layer of titanium oxide (TiO_x) was prepared by means of sol–gel chemistry. Tetrabutyl titanate ($Ti[OC_4H_9]_4$, 10 mL) was as a precursor and mixed with ethanol (100 mL) and de-ionized water (2 mL) together. The mixture solution was heated to 80 °C and stirred for 2 h to form a TiO_x precursor sol–gel solution. The precursor sol–gel solution was diluted in ethanol and spin-coated onto the ITO glass substrate in air with a 0.45 μm filter at 3000 r.p.m. for 60 s. The film is subjected to hydrolysis to form a 10-nm-thick TiO_x layer (the ratio of Ti to O is 1:1.74). Then the substrate was transferred into a nitro-

gen-filled glove box and annealed at 150 °C for 10 min on a hot plate. A PCPDTBT:PCBM (1:3 in weight ratio) layer was spin-coated from chlorobenzene solution with a 0.45 μm filter on the TiO_x layer at 900 r.p.m. for 60 s to serve as the active layer of the front subcell. The connecting layers of molybdenum oxide (MoO_3, purchased from Alfa Aesar with a purity higher than 99.99%) (10 nm)/Al (2 nm)/Ag (15 nm)/MoO_3 (10 nm) were deposited successively via thermal evaporation in vacuo at a base pressure of about 4×10^{-4} Pa. The evaporation rates for all layers were 0.2 nm/s. Then the P3HT: PCBM (1:0.8 in weight ratio) active layer of the back subcell was spin-coated from chlorobenzene solution with a 0.45 μm filter at 700 r.p.m. for 60 s. Finally, a 100-nm-thick Al was deposited to serve as the top cathode. The finished PV cells were thermally annealed at 110 °C for 5 min on a hot plate inside the glove box and encapsulated for measurement. The active area of the tandem polymer PV cells is ca. 0.14 cm².

In order to measure in situ the device performance of the subcells and tandem cell, respectively, the ITO and top Al electrodes of the tandem polymer PV cells were patterned as shown in Fig. 1b that gives the top view of the patterned device configuration. It can be seen that there are four tandem PV cells on one substrate. From this kind of patterned device configuration, the device performance of the front and back subcells can be measured from right top and right bottom devices, respectively. The device performance of the tandem PV cell can be measured from the left two devices.

Current density–voltage ($J–V$) characteristics of the PV cells were measured using a computer-controlled Keithley 236 source meter in the dark and under AM1.5G illumination from a calibrated solar simulator with irradiation intensity of 100 mW/cm². The incident photon-to-current collection efficiency (IPCE) was measured with a lock-in amplifier at a chopping frequency of 280 Hz during illumination with the monochromatic light from a Xenon lamp. The absorption and transmittance spectra were measured using Shimadzu UV-3600 spectrophotometer.

3. Results and discussion

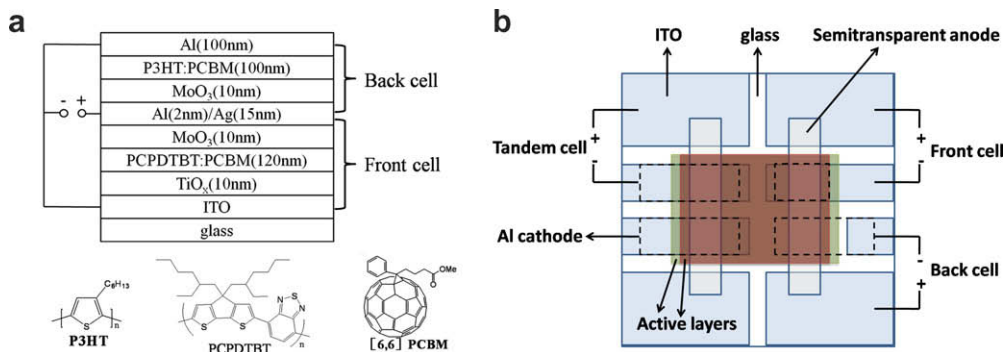
Fig. 2 shows the energy level diagram of the tandem polymer PV cells. Since the two subcells are stacked in parallel connection, the front subcell is designed with an in-


Fig. 1. (a) The device configuration of the tandem polymer PV cell and the chemical structures of the used materials. (b) The top view of the patterned device configuration in which the subcells' performance can be measured in situ.
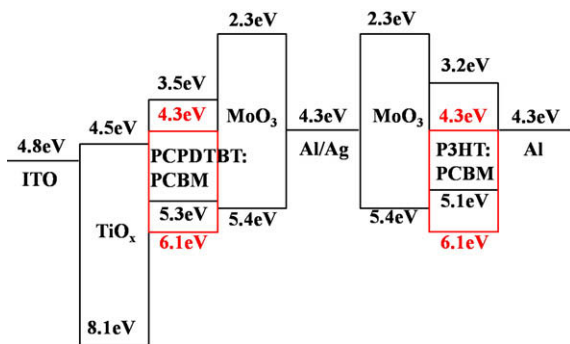

Fig. 2. Energy level diagram of the tandem polymer PV cell.

verted configuration. In the front subcell, TiO_x is used as an electron transport layer between the ITO electrode and the active layer. The lowest unoccupied molecular orbital (LUMO) level of TiO_x (4.5 eV) provides an ohmic contact with the LUMO level of PCBM (4.3 eV) for the electrons generated in the front cell [10,17]. The TiO_x layer also acts as a hole-blocking layer since its highest occupied molecular orbital (HOMO) level is ca. 8.1 eV [10,17,18]. A thin MoO_3 layer with a HOMO level of 5.4 eV is inserted between the semitransparent metal anode and the active layer to serve as the hole transport layer [19–23]. Therefore, the insertion of the TiO_x and MoO_3 layers makes the front subcell to form an inverted structure. In the back subcell, a thin layer of MoO_3 is also introduced between the semitransparent metal anode and the active layer to extract holes. The top Al cathode provides ohmic contacts with the LUMO level of PCBM to realize efficient electron extraction. The energy level alignment of the materials involved in the tandem polymer PV cell shows that the two subcells are in parallel connection.

Fig. 3 shows the absorption spectra of PCPDTBT:PCBM (1:3) and P3HT:PCBM (1:0.8) composite films used as the active layers in the tandem polymer PV cells. The absorption of the PCPDTBT:PCBM (1:3) composite film covers from 400 to 900 nm with strong absorption located at the range of 650–800 nm. The absorption of the
P3HT:PCBM film covers the visible spectral range from 400 to 650 nm, just falling in the valley of the PCPDTBT:PCBM absorption spectrum. The complementary absorption of the PCPDTBT:PCBM (1:3) and P3HT:PCBM (1:0.8) composites in the tandem polymer cells may effectively enhance the solar light harvesting. Transmittance of the multilayer structure of the MoO_3 (10 nm)/Al (2 nm)/Ag (15 nm)/MoO_3 (10 nm) connecting the two active layers is also shown in Fig. 3. It can be seen that the transmittance of the middle connecting layers decreases with the wavelength increasing. The transmittance is higher than 40% below 550 nm. When the wavelength is above 600 nm, the transmittance is less than 30%. In order to ensure more photons passing through the middle connecting layers and efficient light absorption in the back subcell, the P3HT:PCBM composite film is used as the active layer of the back subcell.

J–V characteristics of the tandem polymer PV cell together with the front and back subcells under AM1.5G illumination with an intensity of 100 mW/cm^2 are shown in Fig. 4 and the detailed parameters of these PV cells are summarized in Table 1. The J–V characteristics of the two subcells are measured in the stacked structure, and the J–V characteristic of the tandem polymer PV cell is measured with the ITO and top Al cathode being connected as shown in Fig. 1b. The front PCPDTBT:PCBM PV cell has a V_{OC} of 0.65 V, a J_{SC} of 6.49 mA/cm^2 and a calculated FF of 0.34. Therefore, the overall PCE for this cell is ca. 1.45%. For the back P3HT:PCBM PV subcell, the V_{OC}, J_{SC} and FF is 0.60 V, 4.25 mA/cm^2 and 0.49, respectively, leading to a PCE of 1.24%. The V_{OC} of the tandem polymer PV cell is 0.65 V, similar to each of the two subcells and the FF is 0.42. The J_{SC} of the tandem cell reaches 11.32 mA/cm^2, close to the sum of the J_{SC}'s of the two subcells indicating that the two subcells are in parallel connection. The overall efficiency of the tandem polymer PV cell is ca. 3.10%. Interestingly, this value is even higher than the sum of those of the two subcells. This may be attributed to the reduced overall series resistance (R_S) when the two subcells are stacked in parallel connection. The R_S of the front subcell, back subcell and the tandem cell are 35, 15 and 11 Ω cm^2, respectively, deduced from the illuminated J–V

Fig. 3. Absorption spectra of the PCPDTBT:PCBM (1:3) and P3HT:PCBM (1:0.8) bulk heterojunction composite films and transmittance of the middle connecting unit of MoO_3 (10 nm)/Al (2 nm)/Ag (15 nm)/MoO_3 (10 nm).

Table 1
Photovoltaic parameters for the front cell, back cell and tandem cell.

Device	V_{oc} (V)	J_{sc} (mA/cm^2)	FF	PCE (%)	R_s (Ω cm^2)
Front cell	0.65	6.49	0.34	1.45	35
Back cell	0.60	4.25	0.49	1.24	15
Tandem cell	0.65	11.32	0.42	3.10	11
Fig. 5. IPCE spectra of the front PCPDTBT:PCBM PV cell, the back P3HT:PCBM PV cell and the tandem polymer solar cell.

curves of these PV cells at a voltage above 1 V. The low R_S of the tandem polymer PV cell leads to improved J_{SC} and PCE.

Fig. 5 shows the IPCE spectra of the two subcells and the tandem PV cell. It can be seen that each subcell shows the known spectral response of its bulk heterojunction composite, which is in good agreement with the absorption spectra of the two composites as shown in Fig. 3. The front PCPDTBT:PCBM cell covers from 350 to 800 nm showing two dominant IPCE peaks with ca.17% at 430 nm and 26% at 750 nm. The back P3HT:PCBM cell exhibits a IPCE of 30% at a range of 450–620 nm. The tandem PV cell shows an improved IPCE which is sum of the two subcells.

4. Conclusion

In summary, we fabricated a parallel-connected tandem polymer solar cell with two different conjugated polymer/fullerene derivative blends as the active layers in the two subcells to improve the spectral coverage. The required built-in potential in the subcells is created by using inorganic semiconductor compounds as the charge transport layers and parallel-connected tandem PV cell is realized. Although the achieved efficiency of ca. 3.10% is not very high, the proposed structure of the stacked polymer solar cell possesses great potential to realize high PCE if the two subcells are well optimized and the middle connecting semitransparent metal layer is replaced by highly transparent ITO.

The double heterostructure OPV cells were fabricated on pre-cleaned glass substrates pre-coated with an ITO anode. ITO glass is pre-cleaned following an oxygen plasma treatment for 3 min prior to use for device fabrication. Films were grown at room temperature with a base pressure of 2×10^{-5} Torr in the following sequence: thermal evaporation of PTFE layer varied between 0.3, 0.5 and 1.0 nm; 20 nm thick film of the donor-like copper phthalocyanine(CuPc); followed by a 40 nm thick film of the acceptor-like buckyball C_{60}. A 12 nm thick large band-gap material, bathocuproine(BCP) was deposited as an exciton-blocking layer(EBL) because a previous report has found that BCP can be used to transport electrons to the cathode from the adjoining acceptor layer through the cathode-induced defect states in EBL energy gap, at the same time as effectively blocking excitons in the lower-energy-gap acceptor layer from recombining at the cathode [4]. Subsequently, an 100 nm thick Al cathode was deposited by thermal evaporation through a shadow mask. A Honle UV America Inc. UV light source SOL 500 I was used, with a stabilization period of at least 10 min prior to UV exposure on PTFE films. The work function of ITO/PTFE layers before and after UV exposure were determined by examining the contact potential difference(CDP) of the sample using a Kelvin probe arrangement (SKP5050, KP Technologies). All the current–voltage (I–V) measurements were made with a Keithley 2400 source meter in air ambient, in dark and under 82 mW/cm² solar irradiance (Oriel light source). The active area for all the devices was in excess of 0.1 cm² for this study. The consistency of the device performance was obtained by measuring a minimum of 5 samples for each individual devices structure.

In Fig. 1, the J_{sc} of the devices are plotted as a function of the PTFE thicknesses. It is clear that the device with 0.5 nm of PTFE as the buffer layer has better performances in term of J_{sc}, V_{oc} and FF compare to reference device with and without PEDOT:PSS. By inserting a 0.3 nm of PTFE, the J_{sc} increase 75% from 1.6 to 2.8 mA/cm², while the V_{oc} remained constant at 0.41 V (Table 1). The V_{oc} are significantly increased from 0.41 to 0.49 V when the PTFE layer thickness increased to 1.0 nm. However, the J_{sc} is de-
Table 1
List of device performance of OPV devices without PTFE, with PTFE and with UV treated PTFE.

Device structure	Teflon thickness (nm)	J_{sc} (mA/cm²)	V_{oc} (V)	FF (%)	η (%)
ITO/CuPc/C_{60}/BCP/Al	–	1.6	0.41	54.9	0.44
ITO/PEDOT:PSS/CuPc/ C_{60}/BCP/Al	–	2.5	0.44	52.4	0.70
ITO/PTFE/CuPc/C_{60}/ BCP/Al	0.3	2.8	0.4	60.9	0.83
	0.5	2.5	0.45	59.1	0.81
	1.0	2.1	0.47	27.9	0.34
After ultraviolet-illuminated fluoropolymer ITO buffer layers					
ITO/PTFE/CuPc/C_{60}/ BCP/Al	0.3	3.1	0.41	58.5	0.91
	0.5	4.8	0.48	56.3	1.58
	1.0	4.3	0.49	42.5	1.09

creased when the PTFE thickness increase. Since PTFE is an insulating material, with an extremely high resistivity of 10^{18} Ω/cm for its bulk properties, and a large value for its ionization potential of 9.8 eV [11], it is reasonable to expect that the short-circuit current densities of OPVs decrease with increasing thickness of the PTFE layer.

To study the effect UV treatment on the ITO/PTFE layers, Kelvin probe measurements were conducted on ITO, ITO/PTFE(0.5 nm) and ITO/PTFE(0.5 nm) with different UV exposure times with the resultant the work functions listed in Table 2. The work function of the anode was shown increase to from 4.83 eV (bare ITO) to 5.00 eV after a 0.5 nm PTFE layer was deposited on the ITO. For the UV-illuminated ITO/PTFE samples, the work function increased approximately to ~5.17 eV after 5 min of UV-illumination. However, further increase of the UV exposure time decreased the work function of ITO/UV-illuminated PTFE layer as shown in Table 2.

A similar treatment on the ITO buffer layer was used to make organic photovoltaic devices. The I–V characteristics of these OPV devices under solar simulator illumination are shown in Fig. 3. The J_{sc} and V_{oc} of the devices improved in parallel with the increased UV-illumination time for the initial 5 min. However, further increase of the UV-illumination time beyond 5 min saw a decrease in the J_{sc} and the V_{oc}. This observation is in agreement with the results from work function measurements where the work function increased for the first 5 min, with further increase in the illumination time reducing the work function of the ITO/PTFE anode.

Fig. 1. I–V characteristics of OPV devices with and without PEDOT:PSS and with the different PTFE thicknesses.

Table 2
Work function of ITO, ITO/PTFE and ITO/PTFE with different UV exposure time measured by Kelvin probe.

Sample	UV exposure time	Work function eV (±0.01)
Oxygen plasma cleaned ITO	–	4.84
ITO/PTFE(0.5 nm)	–	5.00
	1 min	5.13
	4 min	5.15
	5 min	5.17
	7 min	5.17
	10 min	5.02

The high J_{sc} in OPV devices with PTFE layer are mainly due to the reduction in the barrier height between ITO and organic matrix [11] and subsequently improved hole extraction processes. The improvement in current extraction from CuPc layer to anode is mainly due to the smaller barrier of charge extraction and, hence, an increased photo-generated current under forward bias was observed with the increment in J_{sc}. As shown in Fig. 1, the V_{oc} of the devices are strongly dependent on the PTFE thicknesses. For the reference devices, with the structure of ITO/CuPc/C_{60}/BCP/Al and ITO/PEDOT:PSS/CuPc/C_{60}/BCP/Al, the typical V_{oc} were found to be 0.41 V and 0.44 V, respectively (Table 1). However, the V_{oc} is found to be improved up to 0.55 V for the device with 1 nm of UV treated PTFE buffer layer (Fig. 2). The work function of the ITO surface typically varies from 3.90 to 4.80 eV depending on the surface treatment [12,13]. After inserting the untreated PTFE layer and the UV treated PTFE layer, the V_{oc} is improved from 0.41 to 0.49 V, because of the strong dipole layer created by the negatively charged fluorine rich untreated PTFE layer and UV treated PTFE layer that has modified the surface and further increased the effective work function of the ITO. As show in Table 1, the devices with UV treated PTFE buffer
Fig. 2. *I–V* characteristic of OPV devices consist of ITO/PTFE with different thicknesses exposed to 5 min UV treatment.
Fig. 3. The *I–V* characteristics of OPV devices consisting of PTFE (0.5 nm) as a buffer layer on ITO, which is exposed to different UV exposure times.

layer exhibited at least a factor of 2 increases in term of power conversion efficiency, compared to the devices with untreated PTFE buffer layer. Among the device with PTFE, a device with a 0.5 nm UV treated PTFE buffer layer exhibited the best performance with the PCE of 1.58%, which is attributed to the good coverage of 0.5 nm UV treated PTFE on the ITO to modify the ITO surface without increase in the surface resistance of ITO/UV treated PTFE anode. It can be seen from Fig. 2 that J_{sc} of the structure ITO/UV treated PTFE(0.5 nm)/CuPc/C60/BCP/Al is the highest because of the smallest hole extraction barrier. Interestingly, UV treatment of PTFE buffer layer can significantly change the contact properties [11]. Our results show that while the pristine PTFE layer is useful for reducing the contact barrier, its effect is considerably enhanced by UV-illumination.

Modification of polymers by exposure to UV irradiation has been reported previously [14,15]. Radiation energy can be absorbed via ionization, phonon excitation and atomic displacement. This causes bond breaking, followed by scissoring and subsequent release of volatile fragments, which may result in the cross-linking through C-C bonding. In our case, clusters of sp^2 bonding may also be formed, leading to an increased in conductivity [8]. At present, there is no clear explanation with regard to the interaction of UV light with PTFE properties and PTFE is found to be highly resistant to UV exposure [16]. However, UV-illumination on a few atomic layers of PTFE may have a very different interactions compared to UV radiation and impact on bulk properties of PTFE. In 2004, Tong and his co-workers have shown that UV-illumination on fluorocarbon coatings CF_x (the basic structure of PTFE), created the graphitic regions identified by X-ray photoelectron spectroscopy results. This leads to the higher conductivity of the CF_x layer and further improved OLED performance [8]. The same explanation may apply to the UV-illuminated PTFE layer where the J_{sc} of the OPV is improved due to the relatively higher conductivity of PTFE after UV-illumination.

In summary, insertion of UV treated PTFE buffer layer at the anode of ITO/organic interface can significantly improve the J_{sc}, V_{oc} and PCE of bulk-heterojunction OPV. The improved performance in the UV treated PTFE-coated ITO contact are consistent with its small hole extraction barrier. This fluoro-material also offers a significant advantage in that the film can be simply prepared by thermal evaporation.

behavior within a bulk HJ polymer cell, but have not considered the potential differences in alternative device structures [15].

The OPV cells studied in this work were based on copper phthalocyanine (CuPc) donor molecules and C_{60} acceptor molecules. Devices with three different HJ structures were fabricated: planar (or bilayer) [16,17], mixed [18–20], and planar-mixed [21,22]. The photoactive region in the planar devices consisted of 20 nm thick CuPc followed by 40 nm thick C_{60}; the photoactive region in the mixed HJ devices was a CuPc:C_{60} mixed layer with varying thickness and mixing ratio. The planar-mixed HJ structure consisted of a 20 nm thick CuPc:C_{60} mixed layer (with a 1:2 weight ratio) sandwiched between a 10 nm thick CuPc layer and a 30 nm thick C_{60} layer. These structures were chosen specifically to provide different situations for carrier generation and transport, thereby influencing the behaviors of the drift and diffusion photocurrents. For example, the diffusion current in a mixed HJ device is expected to be minimal as charges are generated across the entire active layer and there are no obvious potential barriers for charge transport in either direction; in a planar HJ device the diffusion current should be significant as charges are only generated at the HJ interface and the energy level offsets at the donor–acceptor interface (~1 eV) [16,23] prevent electrons and holes from diffusing into the donor and acceptor layer, respectively, giving rise to a concentration gradient.

The OPV cells were fabricated on glass substrates precoated with patterned indium–tin oxide (ITO) (~15 Ω/□ sheet resistance) anode stripes using a high vacuum thermal evaporator with a base pressure of approximately 10^{-7} Torr. Prior to use, the glass substrates were successively sonicated in a solution of Liquinox (by Alconox), deionized water, acetone, and isopropanol, and were exposed to a UV–ozone environment for 15 min immediately prior to loading into the deposition chamber. During deposition, quartz crystal microbalances were used to monitor the mixing ratio and total film thickness. An 8 nm thick exciton blocking layer [13] of bathocuproine (BCP) was deposited on the organic active region prior to the deposition of a 100 nm thick aluminum cathode. CuPc (Sigma–Aldrich) was purified by gradient zone sublimation [24] prior to use; high purity C_{60} (MER Corp.) and BCP (Lumtech) were used as purchased.

The photocurrent voltage and wavelength dependencies of the OPV cells were measured using a Stanford Research Systems 830DSP lock-in amplifier and Keithley 428 current amplifier. White light from a Xe-arc lamp was shined through an Oriel monochromator to provide a monochromatic light; this light was chopped at 800 Hz using a mechanical chopper prior to incidence on the devices. The monochromatic light intensity, P_0, was measured using a calibrated Newport Si detector and was on the order of 1–10 μW/cm². A white light bias from a halogen lamp with an intensity of approximately one sun (or 100 mW/cm²) was also used to illuminate the devices to set up the electric field and charge carrier distribution within the device as specified by the ASTM E1021 standard [25]. In this configuration, the total current of the device consists of the dark current, the photocurrent due to the

constant white light bias, and the photocurrent due to the periodically varying monochromatic light; the results obtained by the lock-in amplifier only correspond to the last component.

Based on the measured photocurrent density, J_{ph}, the external quantum efficiency η_{EQE} is determined as $\eta_{EQE}(V, \lambda) = \frac{hc}{q\lambda}\frac{J_{ph}(V,\lambda)}{P_0(\lambda)}$, where V is the applied voltage bias, λ is the incident monochromatic wavelength, and h, c, and q are Planck's constant, the speed of light, and the elementary charge, respectively. Under forward bias, the ITO anode and Al cathode were connected to positive and negative potentials, respectively. The current (both dark and photo) is defined as positive when it flows from anode to cathode. Fig. 1 shows the dependencies of η_{EQE} at λ = 650 nm for the three different CuPc:C_{60} HJ structures. For both the planar and planar-mixed devices, η_{EQE} monotonically decreases with the increase of the applied voltage, V, from η_{EQE} > 10% at the short-circuit ($V = 0$ V) to <0.05% at V = 1 V. Data at V > 1 V were unreliable due to overloading in the current amplifier. The voltage-dependence of the photocurrent for each of these two devices does not show significant changes as the wavelength of the incident monochromatic light is varied.

For the mixed HJ device, which has a 90 nm thick 1:1 (by weight) CuPc:C_{60} active layer, η_{EQE} reaches a minimum value at $V \approx 0.55$ V and is restored to ~10% at $V \approx 0.70$ V. For comparison, the open-circuit voltage under one sun illumination is approximately $V_{OC} \approx 0.5$ V for these devices [22]. Shown in the inset is the phase change of the photocurrent recorded from the lock-in amplifier. While the phase does not change significantly in either the planar or planar-mixed devices, it is shifted by 180° for the mixed HJ devices at the same voltage where the minimum of η_{EQE} is observed. This suggests that in the planar and planar-mixed devices, the photocurrent remains negative, i.e. flowing from cathode to anode, at any voltage. However, in the mixed HJ device, the photocurrent exhibits a reversal of direction as the voltage is increased from 0 to 1 V, with $\eta_{EQE} = 0$ occurring at $V_0 \approx 0.55$ V (V_0 defined as the voltage
Fig. 1. External quantum efficiency, η_{EQE}, at λ = 650 nm of three different organic photovoltaic heterojunction structures as a function of the applied bias, V. Inset shows the phase change for the photocurrent, $\Delta\Phi$, as obtained from the lock-in amplifier.
Fig. 2. Dependence of the zero-photocurrent bias V_0 on the wavelength of the incident monochromatic light, λ, for mixed HJ photovoltaic cells with 60, 90, or 120 nm thick CuPc:C_{60} (1:1) mixed active layers.

at which the photocurrent vanishes). At $V > V_0$, the photocurrent is positive, i.e. flowing from anode to cathode.

The zero-photocurrent bias, V_0, of the mixed HJ devices is shown to be dependent on the wavelength of the incident monochromatic light and the mixed layer thickness, exhibited in Fig. 2. For a device with a 90 nm (1:1) CuPc:C_{60} mixed layer, V_0 has a maximum of 0.58 V at $\lambda \leqslant 380$ nm and reaches a minimum of 0.51 V at $\lambda \approx 440$ nm. When $\lambda > 600$ nm, V_0 is relatively independent of λ, with $V_0 \approx 0.55$ V. When the mixed layer thickness is reduced to 60 nm, the V_0 minimum wavelength is blue-shifted, to $\lambda \approx 390$ nm. Conversely, by increasing the mixed layer thickness to 120 nm, the global minimum for V_0 is red-shifted to $\lambda \approx 500$ nm, with a local minimum emerging at $\lambda \approx 380$ nm.
Fig. 3. Schematic energy level diagrams of the donor–acceptor heterojunctions illustrating the behaviors of the drift and diffusion photocarrier motions at high and low positive biases. The net photocurrent direction is also indicated. Here, HOMO and LUMO stand for the highest occupied and lowest unoccupied molecular orbitals, respectively.

To explain the different observed photocurrent behaviors in each HJ device structure, we have considered the drift and diffusion motions of the photocarriers. As shown in Fig. 3, in planar HJ devices excitons dissociate at a distinct interface between the two planar layers, giving rise to a strong carrier concentration gradient within the device. The energy level offsets at the interface, ~1 eV for the CuPc/C_{60} interface [16,23], will also confine holes within the donor layer and electrons in the acceptor layer. The internal electric field points from the cathode to the anode when the applied bias V is low (or negative). As a result, both the drift and diffusion motions drive carriers away from the HJ interface, with holes moving toward the anode, and electrons the cathode. However, at sufficiently high applied biases, so that the internal electric field points from the anode to the cathode, the drift current tends to move carriers towards the HJ interface, resulting in an increased carrier concentration gradient that in turn increases the driving force for diffusion. Hence, as the applied bias is increased the negative diffusion current increases accordingly. As we did not observe a change in the overall photocurrent direction in the planar and planar-mixed HJ devices, this suggests that at high applied biases, the negative diffusion current is more than enough to overcome the positive drift current. The steady decrease in the photocurrent with bias at $V > 0.5$ V can be understood by considering the heterojunction interface as a "leaky capacitor". With holes confined in the donor side and electrons in the acceptor side, the interface is effectively a capacitor. Hence, when the photocarriers corresponding to the monochromatic light are generated at the two sides of the capacitor, it is understandable that an overall negative photocurrent will be produced with the discharging of the capacitor through the external circuit. There are, however, two main carrier leakage mechanisms within the capacitor, which become increasingly significant with the increase of the applied bias. As the bias is increased and more charge carriers accumulate at the interface, interface recombination of electrons and holes becomes more significant. In addition, the charge carriers will increasingly be able to overcome the potential barrier height at the interface by thermally assisted tunneling with an increased positive electric field. Both mechanisms lead to a reduced magnitude of the negative photocurrent at high biases.

In mixed HJ devices, charge carrier generation is distributed throughout the active layer, leading to no significant contiguous concentration gradient. In addition, there are no potential barriers within the active region to limit the transport of charge carriers in either direction. Diffusion is therefore a minor component compared to the drift current, except when the applied bias is such that the drift current vanishes as the internal electric field approaches zero. Note that CuPc and C_{60} molecules are homogeneously mixed at the ratios considered here [26]; hence we do not expect any significant variation in the local electric field distribution. Consequently, with the reversal of the electric field direction at sufficiently high biases, the direction of the drift current is reversed as well, leading to the total photocurrent changing from negative to positive.

The above explanation suggests that V_0 must occur at a bias when the internal electric field is negligible in mixed
Fig. 4. (a) Calculated carrier generation field within a 90 nm thick CuPc:C$_{60}$ (1:1) mixed layer as a function of the distance from the anode/organic interface, x, and the wavelength of incident light, λ. Indicated in white dots are the weighted average centers of charge generation at each wavelength, x_c. (b) Calculated wavelength dependence of x_c in CuPc:C$_{60}$ mixed HJ devices with a 60, 90, or 120 nm thick active layer.

HJ devices. To explain the wavelength dependence of V_0 in these devices, one has to consider the details of carrier generation within the mixed layers. Fig. 4a shows the calculated carrier generation field $G(x, \lambda)$ within a 90 nm thick CuPc:C$_{60}$ (1:1) active layer. Also indicated on the plot in white dots are the weighted average centers of charge generation at each wavelength, denoted as x_c. Here, $G(x, \lambda) = \alpha(\lambda) \cdot I(x, \lambda)$, where x is the distance from the anode/organic interface, $\alpha(\lambda)$ is the absorption coefficient of CuPc:C$_{60}$ (1:1), and $I(x, \lambda)$ is the optical intensity field, which is calculated using a transfer-matrix method [13]. The interference of the incident light and the portion of light reflected off the metal cathode leads to a standing optical wave whose peak intensity is located approximately at a distance of $(2m + 1)\lambda/4n$ away from the metal cathode, where n is the refraction index of the organic materials and $m = 0, 1, 2, \ldots$ is an integer indicating the order of interference. Hence, at $\lambda \geqslant 450$ nm, with the increase of λ, the peak optical intensity position shifts away from the cathode, causing a similar shift in x_c. However, at $\lambda \leqslant 400$ nm, the emergence of the second-order ($m = 1$) intensity peak draws x_c much closer to the anode. At $\lambda \approx 430$ to 440 nm, x_c is closest to the cathode. Fig. 4b shows a comparison of the wavelength dependence of the average center of charge generation in mixed HJ devices with different CuPc:C$_{60}$ active layer thicknesses. Compared with the experimental V_0 data shown in Fig. 2, we see a strong resemblance between the wavelength dependencies of V_0 and x_c, especially in the wavelengths of V_0 minima.

While a comprehensive device model may be needed to fully explain the correlation between V_0 and x_c, we hypothesize that it is related to the details of the diffusion current. In a CuPc:C$_{60}$ (1:1) mixture, the hole mobility is approximately three orders of magnitude lower than the electron mobility, $\sim 10^{-5}$ cm^2/V s vs. $\sim 10^{-2}$ cm^2/V s [26]. Logically, the charge extraction from the active region is limited by hole transport. When most holes are generated closer to the cathode, the corresponding hole diffusion current becomes lower due to the longer distance holes need to travel

to reach the anode. Thus, it requires a smaller positive drift current to cancel the negative diffusion current, and therefore a lower forward bias, leading to a lower V_0.

To summarize, we have found that the molecular heterojunction structure has significant effects on the photocarrier behavior in organic photovoltaic cells. The interplay between carrier diffusion and drift leads to an always negative photocurrent in planar and planar-mixed HJ cells where distinct interfaces for charge generation and barrier heights preventing charge transport in certain directions exist. The drift current generally dominates in a mixed HJ cell, leading to a reversal of photocurrent direction at high biases compared to that at the short-circuit condition; however, when the internal electric field is negligible the diffusion current becomes dominant and the detailed distribution of charge carriers throughout the mixed layer results in a wavelength dependence of the diffusion current and, consequently, a varying zero-photocurrent voltage.

affinity [9]. In the present study, we investigate the behaviour of the charge carrier mobility of OTFTs constructed using N,N′-Bis(n-pentyl)terrylene-3,4:11,12-tetracarboxylic diimide (TTCDI-5C, cf. Fig. 1a) with different metal electrodes to assess carrier transport in these OTFTs.

2. Experiments

TTCDI-5 thin films were deposited on SiO_2/Si substrate in vacuum with a base pressure below 5×10^{-9} Torr. A deposition rate of about $0.06 \, ml \, min^{-1}$ was used for all films prepared in this work. The thin films thickness is 15 ml. A detailed description of experimental procedure was given in previous work [9]. Fig. 1b presents an AFM image of a TTCDI film deposited at an optimized substrate temperature of 140 °C. Film morphology consists of compact rectangular grains with an average area of $0.06 \, \mu m^2$/grain. Roughness of the surface is 2 nm. From XRD spectra (not shown here), we found the molecules were highly ordered and oriented with the (0 0 1) axis normal to the surface substrate.

For the thin film transistors (OTFT), all experiments including molecular deposition, electrode contact as well as electrical measurement were carried out in vacuum. First, the TTDCI films were deposited on thermally grown SiO_2 (200 nm)/p-Si (0 0 1) substrates. Metals of electrodes

with a thickness of 50 nm were deposited using an e-beam evaporator for aluminium and a heated crucible for gold. The channel length was 50 μm and the width 400 μm. An illustration and photograph of the top-contact OTFT structure are shown in Fig. 2 (top). OTFTs thus prepared were transferred into the electrical measurement chamber for transistor analysis by means of a vacuum transfer system to avoid exposure to air. Electrical measurements were performed in vacuum of 10^{-5} Torr at a variable temperature from 50 to 310 K.

3. Results and discussion

3.1. Thermal behaviour of carriers mobilities

Fig. 2 (bottom) presents typical I_D–V_D curves of the TTCDI-5C transistors at room temperature (gold electrode). A clear difference in the threshold voltages (V_t) was observed depending on electrode metals. The V_t for Au and Al electrodes were 20 and 16 V, respectively. The main reason for the lower V_t in the Al electrode device originate from its lower work function (4.3 eV for Al and 5.1 eV for Au).

We calculated the mobilities of the TTCDI-5C OTFTs in the temperature range from 50 to 310 K in both devices prepared using gold or aluminium electrodes using the following equation [10,11]:

$$I_{D,sat} = \frac{W}{2L} C_{ox} \mu_{sat} (V_G - V_T)^2$$

where C_{ox}, μ_{sat} and V_T are the gate dielectric capacitance per unit area, field effect mobility at saturation regime and the threshold voltage, respectively. Then we prepared the Arrhenius plots of the carrier mobilities of the OTFTs which are shown in Fig. 3. These plots can be divided into two ranges: less temperature dependent range from 50 to 150 K and thermal activation temperature range from 150 to 310 K. Below 150 K, it can be regarded that the carriers are trapped at the defects and temperature is not high enough to activate these trapped carriers to conduction. This is a property of the TTCDI film and is not related to the metal used to prepare the electrodes.
A clear difference depending on the electrode material was observed in the temperature range above 170 K. To interpret this observation, we referred to the multiple trapping and release model (MTR). It supposes that charge transport in the semiconductor is ruled by charges trapping into localized states in the forbidden gap followed by thermal release [8,12] Thus we fitted the Arrhenius plots using next equation:

$$\mu = \mu_0 \exp\left(\frac{-E_a}{k_B T}\right)$$

where μ, k_B and E_a are carrier mobility, the Boltzmann constant and the activation energy, respectively. The activation energies were determined to be 130 and 85 meV for Au and Al contacts, respectively.

3.2. Discussion

Two distinct factors –trapping at the interface and energy mismatch between work function and LUMO– are probably contributing to the difference in the activation energy. In the following sections, we discuss respective factors.

3.2.1. Trapped carriers

To explain the difference between the values of the activation energies, we first evaluated carrier traps. In Fig. 4, both OTFTs exhibited positive threshold voltage shifts with decreasing temperature. Indeed at lower temperature there is less thermal energy available to activate trapped carriers into delocalized states. Thus more carriers remain trapped and screen the gate field. Therefore, OTFTs required a greater gate voltage to enable conduction [7,13]. The shifts in the threshold voltage ΔV were 23 V for the Au contacts and 15 V for the Al contacts. The number of trapped carriers can be estimated using the following equation with the elementary charge e [7,13]:

$$N_t = \frac{\Delta V C_{ox}}{e}$$

In the case of gold electrodes, N_t is about 2.4×10^{12} carriers/cm^2 while the corresponding value for the aluminium electrodes is 1.9×10^{12} carriers/cm^2. These values seem to

Fig. 3. Arrhenius plot of the carrier mobilities of the TTCDI-5C OFETs with gold and aluminium contacts.
Fig. 4. Evolution of the threshold voltage versus the temperature.
Fig. 5. Energy diagram of HOMO/LUMO levels of TTCDI-5C molecules and work function of god and aluminium.

be quite high when compared with the molecular density of TTCDI thin films which is typically in the range of 10^{14} molecules/cm^2. However N_t is a total summation of carriers including those trapped at the insulator/organic and the metal/organic interfaces, as well as those fixed in the insulator and organic films. Among these trapped carriers, the observed difference in N_t for the respective electrode metals can be ascribed to the carriers trapped at the metal/organic interfaces. This means that the activation energies should be determined by taking into account the carrier transfer at the metal/TTCDI interface. Here we note that the threshold voltage of the OTFT with Al electrodes remained lower than that with gold electrodes. This gap is linked to the defects at the metal/organic layer interface in addition to the relative work function of the metals. Regarding the defects, it should be mentioned that Al was deposited using a cooled e-beam evaporator while gold was deposited using a heated crucible so that the substrate temperature for the case during gold deposition was slighty higher possibly generating defects and increasing the numbers of trapped carriers at the Au/TTCDI interface.

3.2.2. HOMO/LUMO levels and metals work functions

With respect to the work functions of the electrode metals, we examined the energy-level diagram involving HOMO/LUMO levels and work functions of the electrode metals as shown in Fig. 5. In passing from gold to aluminium, the difference in energy between work function and the LUMO level of TTCDI-5C molecules is reduced. Consequently injection of electrons into the LUMO, as well as into the defects states, becomes easier causing a decrease in the energy for activating the charges into the organic layer. This explains the difference between the activation energies (E_a) of the different metal electrodes. Also, the mismatch between the Al work function and the LUMO is still around 0.78 eV according to our diagram so that this

barrier should affect the charges injection. This point has been raised previously and it has been proposed that the presence of an interfacial electric dipole layer lowers the barrier to electron injection and the apparent metal work function can vary by up to 1 eV [14–16].

4. Conclusion

In summary we have designed OTFTs based on TTCDI-5C which operated as n-channel transistors. Two kinds of transistors were prepared containing gold or aluminium electrodes. Dependences of the carriers mobility and threshold voltage on temperature were investigated. Two different behaviours were observed for carrier transport: a temperature independent behaviour below 170 K and a thermally activated one at higher temperature. Activation energies were calculated from the temperature dependence of the carrier mobility. Those were 85 meV for aluminium contacts and 130 meV for gold contacts. The difference in activation energies can be explained by the energy matching mainly between work function of electrodes metals and the LUMO level of the TTCDI-5C molecules. Additionally, defects and dipoles produced at the metal/molecule interface also influence carrier transport. These experimental results emphasize the importance of optimizing the energy levels of molecules with work functions of the metal electrodes, as well as the interface formation techniques.

Au memory device. The nonpolar switching is different from the previous reported WORM characteristics [12,13] and the bipolar switching characteristics [16,17]. Au electrodes are used in order to avoid oxidization [18] and the disputation about the use of Al electrode. It is found that no "forming" process is required to induce the resistive switching. The device area dependence, reproducibility, data retention, and nondestructive readout properties are also investigated.

2. Experiment

Fig. 1a and b show the schematic structure of PEDOT: PSS, which serves as an active layer in our memory devices. It has a tunable high electrical conductivity and high stability in air. The memory devices are fabricated using the following procedures. After a standard clean using sulfuric acid, hydrofluoric acid, and acetone sequentially, 10 nm Cr and 50 nm Au are deposited successively by an electron beam evaporator on a silicon substrate as the bottom electrode. Then a layer of PEDOT: PSS (1.3 wt% dispersion in H_2O) is spun on the bottom electrode initially at 500 rpm for 6 s, then at 3000 rpm for 60 s. After spin coating, the film is baked on a hot plate at 95 °C for 5 min in air. The film thickness is about 90 nm measured by a Veeco Dektak150. The top electrode is 80 nm Au deposited directly on the top of the PEDOT: PSS film with a shadow mask by the same electron beam evaporator. Then the sample is etched in oxygen plasma for 5 minutes to remove excess PEDOT: PSS using the gold electrode as an etching mask. Fig. 1c shows the schematic diagram of the memory device with a Au/PEDOT: PSS/Au sandwiched structure. All electrical measurements are performed at room temperature in darkness. The current–voltage characteristics are measured by a Keithley 4200 semiconductor characterization system.

3. Results and discussion

Fig. 2 shows the typical I–V characteristics of the Au/PEDOT: PSS/Au memory devices, in which the bias polarity is defined with reference to the bottom Au electrode. Different from the previous results on ITO/PEDOT: PSS/Al
Fig. 2. Typical nonpolar *I–V* switching characteristics of Au/PEDOT: PSS/Au memory devices, the sweep sequence and direction are indicated by the alphabets and arrows, respectively. The upper inset is the *I–V* fitting of ON-state in log–log scale, demonstrating a linear correlation, and the bottom inset is the reproducibility of the resistive switching characteristics under dc sweeping mode.

[16], no "forming" process is required to induce the resistive switching in our devices. The fresh devices are usually in the ON-state with a resistance of hundred ohms. When the bias voltage is increased to about 1 V in either polarity, the device enters the OFF-state (curve *a* or *c*). This bias voltage is referred to as the reset voltage (V_{reset}). In order to turn the device back to the ON-state, a current-limited set voltage (V_{set}) in either polarity should be added to the device (curve *b* or *d*). This limited current is called the compliance current. The typical resistances of the ON- and OFF-state at 100 mV are on the order of $10^2 \, \Omega$ (R_{on}) and $10^5 \, \Omega$ (R_{off}), respectively. From the top inset of Fig. 2, the ratio between the ON- and OFF-state is determined to be about 10^3. It is found that the devices exhibit a nonpolar switching behavior, i.e., the back and forth switching between the ON- and OFF-state could be realized in either positive bias or negative bias. There are other two kinds of resistance switching memory devices: unipolar and bipolar switching. In a unipolar resistance switching memory device, the operation is restricted to a special bias polarity; in a bipolar device, write and erase must be performed in the opposite bias polarity. Although the nonpolar switching behavior is widely reported in inorganic memory devices, such as V-doped $SrZrO_3$ [19], Cu doped SiO_2 [20] and Cu doped ZrO_2 [21], it is seldom reported in organic memory devices. The nonpolar device can be write, erase, and read in only one bias, while the bi-polar device must be write and erase in different polarity of bias. This operating bias flexibility makes it easy to achieve memory application for the nonpolar switching characteristic compared to the bipolar one.

The bottom inset of Fig. 2 shows the reproducibility of the resistive switching characteristics under a dc sweeping mode. Although V_{set} and V_{reset} show some variations, V_{set} is always higher than V_{reset}. No overlap between them is observed. Beginning from either resistance state (ON or OFF), the Au/PEDOT: PSS/Au memory devices can be switched to

Fig. 1. The structure of (a) PEDOT which has the properties of tunable high electrical conductivity and high stability in air, (b) PSS which is used as aqueous polyelectrolyte in the polymerization of 3,4-ethylene-dioxy-thiophene to form a dark blue, aqueous PEDOT/PSS dispersion, and (c) the schematic diagram of the device with Au/PEDOT: PSS/Au structure.

the other one by choosing a proper voltage value irrespective of bias polarity.

The compliance current (I_{comp}) during set process is necessary to prevent a permanent breakdown in memory devices. Shown in Fig. 3a is the change of reset current (I_{reset}, defined as the peak current during the reset process) and ON-state resistance (R_{on}) when I_{comp} varies from 100 μA to 10 mA. The I_{reset} increases and R_{on} decreases with the increasing of compliance current.

To further evaluate the performance of PEDOT: PSS memory devices, the scalability and resistance uniformity are studied on devices with different areas. The active area dependence of both ON and OFF resistance is shown in Fig. 3b. Each point represents an average value of ten different devices. Although the OFF-state resistance exhibits a clear dependence on the device area, the ON-state resistance shows a little dependence on device area. The resistance of the OFF-state increases about 4×10^3 times when the area of the devices shrinks 4×10^3 times, while the resistance of ON-state increases only 30 times at the same device area decreasing. This result also shows the ratio of R_{on} and R_{off} increases with device area decreasing, and provides promising scaling down prospect of Au/PEDOT: PSS/ Au devices. As shown in Fig. 3b, the error bars indicate standard deviation, according to which the resistance uniformity of each size devices is concentrated enough to distinguish the ON- and OFF-state.

Besides scalability and resistance uniformity, the retention time is also an important parameter for memory devices. Fig. 4 shows the retention ability at room temperature in darkness. By applying a continuous readout voltage (@ 100 mV), the device resistance is sampled every 60 s. The resistances of both ON- and OFF-state are stable and show no significant degradation over 10^4 s continuous stress test. This could provide low misreading rate, indicate nonvolatile nature and nondestructive readout property of the devices. The nonpolar nonvolatile characteristics of the devices can be observed after the retention testing.

To understand the mechanism of nonpolar switching behavior of PEDOT: PSS based devices, the I–V curve of
Fig. 4. Retention test upon continuous readout voltage (@ 100 mV). The devices are tested at room temperature in darkness.

ON-state is fitted with linear fitting in log–log scale. As shown in the upper inset of Fig. 2, the ON-state fitting curve demonstrates that the I–V characteristics follows a linear ohmic conduction (slope is close to 1). One of the probable models for the linear conducting behavior is the forming of conductive paths in insulating film. The conductive path mechanism is further confirmed by the dependence of the ON- and OFF-state resistance on the device area. The high conductive current in the ON-state is determined by a set of conductive paths [15], whose total effective cross-section area is much smaller than the device area and not sensitive to device area. In contrast, the low conductive current in the OFF-state is decided by the leakage current of the PEDOT: PSS film, which is proportional to the area of the device in principle.

Based on the analysis above, it is concluded that the forming and rupture of conductive paths is probably related with the oxidation and reduction of the PEDOT: PSS film. As shown in Fig. 5, hole hopping transport through PEDOT involves extraction and injection at each PEDOT site, which corresponds to transient reduction–oxidation cycles [22]. Initially, the device stays at the ON-state and the current transmits through the PEDOT$^+$ conductive paths, which exist in the oxide state of PEDOT: PSS film. As a reset voltage adds to the device, the holes, referred to h$^+$, are extracted from the PEDOT$^+$ and transported to the cathode where the holes are neutralized. The PEDOT$^+$ conductive paths change to low conductive PEDOT chains and the device changes to OFF-state. When a much higher current-limited voltage is added to the device at OFF-state, the holes are injected into the PEDOT again at the strong electric field and presence of Au. The low conductive PEDOT chains return to PEDOT$^+$ conductive paths and the device is set back to ON-state correspondingly. However, it is not sure that the oxidation and reduction of PEDOT: PSS is the only mechanism. Au atoms penetrating into the film during metal deposition and other defects may also influence the formation of conductive paths. Further studies are required to understand the detailed process of conductive paths formation.
Fig. 3. (a) Dependence of ON-state resistance (R_{on}) and reset current (I_{reset}) on the set compliance current (I_{comp}), and (b) the device area dependence of ON- and OFF-state resistance. Each point of the plots represents averaged values of ten different devices, and the error bars indicate the standard deviations of the devices.

4. Conclusion

The Au/PEDOT: PSS/Au sandwiched structure is fabricated and investigated for nonvolatile memory applications. It shows a nonpolar resistance switching characteristics, which is different from both the WORM characteristics and the bipolar switching characteristics reported before. No "forming" process is required to induce the resistive switching of the devices. This memory device shows reproducible resistive switching, a large ratio ($>10^3$) of R_{off} and R_{on}, a long retention time (10^4 s), and nondestructive readout. The area dependence of ON- and OFF-state guarantees the sufficient sensing margin when the device is scaling down. According to the experiment results, the nonpolar switching behavior is due to the forming and rupture of the conductive paths in the PEDOT: PSS film. The oxidation and reduction of the PEDOT is considered to be the probable mechanism to explain the forming and rupture of conductive paths in Au/PEDOT: PSS/Au devices.

conventional dielectrics typically operate at low voltages (<2 V) only for ultra-thin gate insulating layers (<50 nm); hence making printing impossible. Recent reports indicate that electrolytes constitute a promising electronic insulating layer to separate the gate electrode and the semiconductor [13–20]. This class of OFETs has a unique feature suitable for reel-to-reel manufacturing: the operating potential, of few volts, does not strictly depend on the electrolyte thickness [15]. One class of electrolytes used is proton conducting polyanionic membranes [15,19], such as polystyrenesulfonic acid (PSSH) [19] (Fig. 1b). The formation of the electric double layer capacitors (EDLCs) at the semiconductor/electrolyte and electrolyte/gate interfaces occurs at low voltages. The high capacitance and the quick response of the EDLC enable fast enhancement mode switching ($\sim$50 μs) and low-voltage operation (<1 V) of the EDLC–OFETs.

In this letter, we demonstrate the monolithic integration of an EDLC–OFET, including regio-regular poly(3-hexylthiophene) (P3HT) (Fig. 1c) as the semiconductor, and a PEDOT:PSS-based electrochromic display cell. The compatibility of the two devices is ensured by the common patterned PSSH layer acting both as the gate insulator in the OFET structure and as the proton transporting layer in the electrochromic display (Fig. 1d).

In this work, no attempts were made to achieve a fully printed OFET, rather our major goal was to demonstrate operational compatibility between the electrolyte-gated OFET and the electrochemical (EC) display device. To construct the OFET sketched in Fig. 1d, gold electrodes are patterned on a silicon wafer with thermally grown oxide by using photolithography and wet-etching. First, a 20 nm thick layer of P3HT is spin-coated from chloroform and then covered with a thin layer (85 nm) of PSSH. A titanium top gate contact is vacuum deposited through a shadow mask to complete the transistor. The output characteristics of this EDLC–OFET, with a channel length and width of 7 and 2000 μm, respectively, shows current modulation already below 1 V (Fig. 1e) and a maximum current throughput of around 5 μA. Upon negative gate bias, mobile protons migrate towards the gate electrode and the immobile polyanionic chains PSS$^-$ remain at the vicinity of the P3HT layer, which allows for the formation of a positively charged conducting channel between the source and the drain electrodes (p-channel). It should be noted that polyanions are immobile and, hence, cannot penetrate the organic semiconductor. Thus, electrochemical doping of the semiconductor bulk is entirely prevented, in contrast to EC transistors where current modulation is governed by bulk electrochemistry. The calculated carrier mobility for

the EDLC–OFET at saturation is in order of $3.67 \cdot 10^{-3}$ cm^2 V^{-1} s^{-1}.

The electrochromic display cell consists of a PSSH (AGFA PSSH 5% in water) layer sandwiched between two PEDOT:PSS (AGFA ICP-1010) electrodes, see Fig. 1b. The top polymer electrode serves as the electrochromic display element, while the counter electrode is hidden below the PSSH electrolyte. A white titanium dioxide nanopowder is added to the electrolyte to increase the color contrast. In its pristine transparent state, PEDOT:PSS is composed of positively doped PEDOT chains neutralized by sulfonate anions attached to the polystyrene chains (PSS). When a potential difference is applied between the two electrodes, the PEDOT of the negatively biased top electrode is re-duced (undoped) and turns blue. During this electro-reduction, protons migrate from the PSSH electrolyte into the top PEDOT:PSS electrode to neutralize the sulfonate anions (previously the doping counter-charge for PEDOT). The oxidation takes place at the bottom electrode. This electrochemical reaction is characterized by a current peak of around 33 μA (for 1 mm^2 sized display cell) during the first second (Fig. 1f). At 16 s, the potential is then set to zero and the top PEDOT:PSS electrode is re-oxidized to its transparent state. This electrochemical process is reversible such as that the display cell can be repeatedly cycled many times. Beside its low operating voltage, the electrochromic display pixel shows a high degree of bi-sta-bility; i.e. the pixel electrode remains reduced while the electrodes are disconnected. Many combined factors are dictating the switch time of an electrochromic pixel, such as the ionic resistance of the PSS layer which depends on geometrical parameters and water content (proton mobil-ity and concentration). For low ionic resistance, the reac-tion can be limited by the electron transport rates, which depends on the applied voltage.

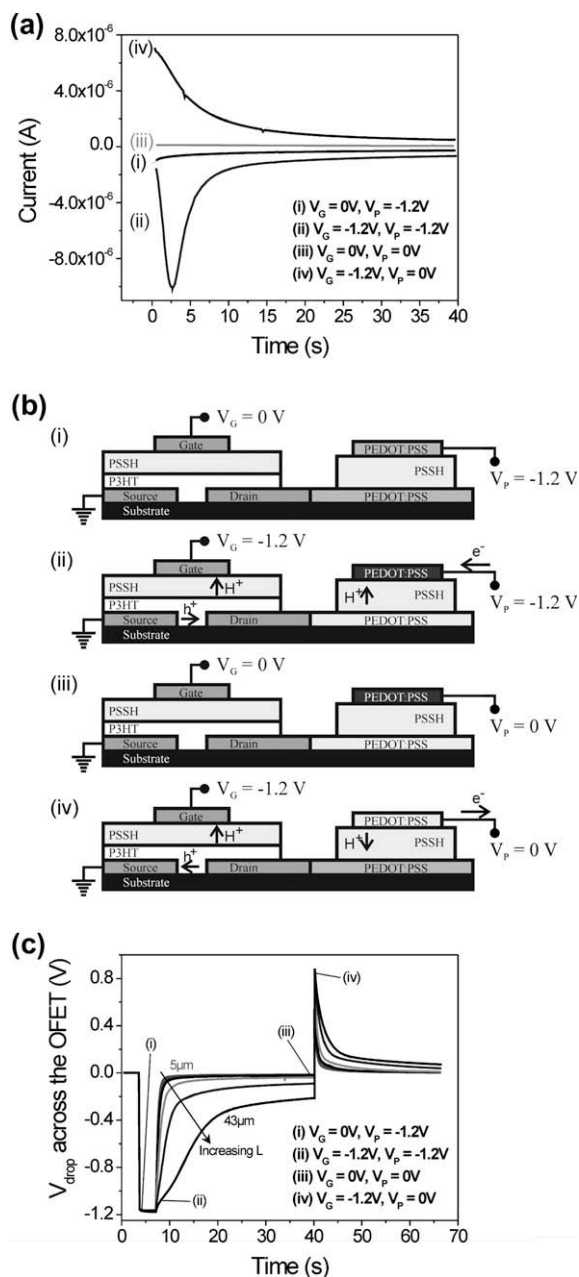
The EDLC–OFET and the electrochromic display pixel are assembled into a smart pixel circuit by coating partially the gold drain electrode of the transistor with the PED-OT:PSS bottom electrode of the pixel. The characteristics of the individual components and the smart pixels are measured using a Keithley 4200-SCS Semiconductor Char-acterization System in ambient atmosphere (40% relative humidity, room temperature). The smart pixel is updated in four steps: (i) $V_G = 0$ V, $V_P = -1.2$ V; (ii) $V_G = -1.2$ V, $V_P = -1.2$ V; (iii) $V_G = 0$ V, $V_P = 0$ V; (iv) $V_G = -1.2$ V, $V_P = 0$ V. During the entire updating cascade, the current is monitored (Fig. 2a) and the direction of the electron, the hole and the proton currents are illustrated in Fig. 2b. The potential drop (V_{drop}) across the transistor channel is continuously measured during the entire updating scheme in Fig. 2c. Firstly, despite the applied voltage across the dis-play cell ($V_P = -1.2$ V), the pixel remains in its off-state (PEDOT:PSS transparent) as indicated by the negligible current (curve (i) in Fig. 2a) that passes through the smart pixel. The transistor suppress updating of the display cell since it is in its high impedance state ($V_G = 0$ V) as indi-cated by the large potential drop across the transistor (step (i) in Fig. 2c). Secondly, as V_G is set to -1.2 V, the transistor channel opened and the potential across the OFET drops (step (ii) in Fig. 2c). Since V_P equals -1.2 V, the major part of the potential drop is across the display pixel. Holes flow


Fig. 2. The updating scheme of the smart pixel is realized in four combinations of electrical biases: (i) $V_G = 0$ V, $V_P = -1.2$ V; (ii) $V_G = -1.2$ V, $V_P = -1.2$ V, (iii) $V_G = 0$ V, $V_P = 0$ V, (iv) $V_G = -1.2$ V, $V_P = 0$ V. (a) Time evolution of the current crossing the smart pixel after each of the four steps. The two devices are integrated on a silicon substrate and the OFET has $W/L = 154$. (b) The sketch of the smart pixel illustrates the direction of charge carriers (electron, hole and proton) involved in the four steps. (c) Evolution of the potential drop across the transistors for various channel lengths (5, 7, 9, 13, 23 and 43 μm) during the updating scheme from step (i) to step (iv).

through the OFET (curve (ii) in Fig. 2a), which leads to oxi-dation of the bottom PEDOT:PSS electrode while PEDOT of the top electrode is reduced and turns blue. Thirdly, for $V_G = 0$ V and $V_P = 0$ V, charges cannot leak through the OFET (curve (iii) in Fig. 2a) and the pixel remains blue. In step

(iii) in Fig. 2c the pixel acts as a loaded battery such that the potential across the OFET is opposite as compared to the first updating step shown in step (ii) in Fig. 2c. Finally, the pixel is discharged to its transparent off-state by opening the transistor channel ($V_G = -1.2$ V) and keeping V_P at 0 V (curve (iv) in Fig. 2a). The efficiency of the smart pixel relates to the amount of charges that can be stored over long period of times. After a full cycle, we found a charge mismatch of about 9% between charging and discharging steps, which we attribute to the spontaneous re-doping of the reduced PEDOT by dioxygen. Note that this side reaction does not damage the electroactivity of the conducting polymer or the reversibility of the process.

The dynamic switch characteristics of the display pixels can be quantified with the time evolution of the charging/discharging current (Fig. 3a and b) and the associated color changes (Fig. 3c and d). The electrochromism is followed by irradiating a pixel of 1 mm^2 with a red laser (peaking at 650 nm to match the absorptions peak for a neutral blue-colored PEDOT:PSS) at an incident angle of 45° and detecting the diffused light with a Si-photodiode placed in the normal direction vs. the pixel surface (inset in Fig. 3c). A low photocurrent corresponds to a high degree of absorption of the red light, i.e. the PEDOT of the display cell is reduced and is deep blue. The response of the smart pixel is recorded for different OFET dimension; $W = 2000$ μm and L equals 43, 23, 13, 9, 7 and 5 μm. The response time of the display pixel depends significantly

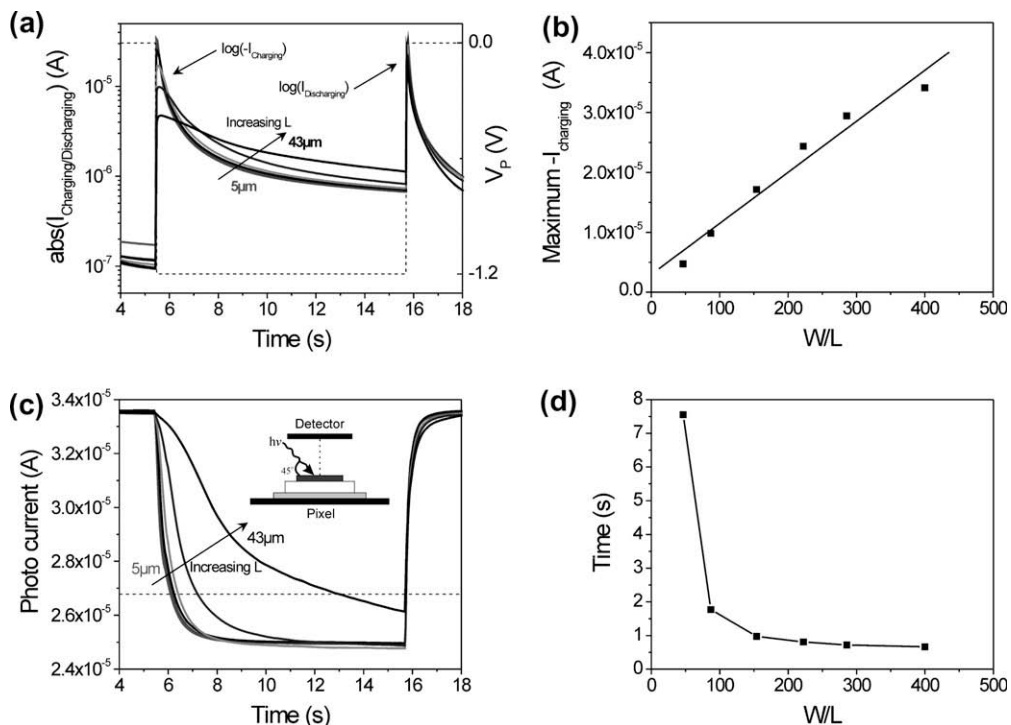
on the channel length; which indicates that the rate of the PEDOT:PSS electrochemical reaction of the display pixel is not the limiting updating mechanism for the specific PSS thickness and V_P chosen. The response time of the electrochromic display pixel is correlated to the current delivered by the OFET; which is proportional to W/L. Shorter channel lengths result in a larger current levels (Fig. 3b) and a pixel that correspondingly switches on and off relatively faster (<1 s) (Fig. 3d). The reduction process of the pristinely doped top electrode is not limiting the updating rate because of its high electrical conductivity (~10 S/cm). Interestingly, the off-switching is fast and only weakly dependent on the transistor channel length. In this case, the limiting factor for updating is not the current through the OFET but instead the high impedance of the reduced (colored) PEDOT of the top display electrode. The bottom PEDOT:PSS electrode is not limiting since in its highly doped state. Noteworthy, for long transistor channels (>15 μm), the electrochromic display pixel is unable to reach its fully reduced blue-colored state within the chosen time scale. Because the full reduction of the top PEDOT electrode cannot be reached for long transistor channels, there are fewer charges stored in the display pixel and the resistance of the pixel top electrode remains low. These two factors contribute together to fast discharging of the cell for long channels. The maximum charging current varies between 34 μA for $L = 5$ μm and 5 μA for $L = 43$ μm (Fig. 3b). This corresponds to a switch-


Fig. 3. (a) Charging/discharging currents (solid line) vs. time supplied by transistors with different channel lengths ($L = 5, 7, 9, 13, 23$ and 43 μm, and width $W = 2000$ μm) at $V_G = -1.2$ V and $V_P = -1.2$ V or 0 V (dashed line). (b) Maximum charging current vs. W/L (filled squares), recorded as the top of the charging current in (a). The solid line is the linear fit of the measured maximum charging currents. (c) Photo-currents reflect the kinetic of the color change in the pixel for various transistor channel lengths. The setup of this measurement is shown as an inset. (d) Time of the 20% of the maximum photo-currents (dashed line in c) vs. W/L.

ing time of 0.66 and 7.6 s for channel lengths of 5 and 43 μm (Fig. 3d).

In summary, we have presented a monolithic integration of an EDLC–OFET and an organic electrochromic pixel, i.e. a combination of a solid state device operating in a field-effect mode and a display cell operating in an electrochemical mode. Electrolyte gated-OFETs are more compatible with electrochemical displays than OFETs with traditional dielectrics for the following reasons: (i) low operating voltage (<1 V) independent of the electrolyte thicknesses, (ii) the large current throughput (5 μA for $W/L = 285$) because of the large capacitance of the EDLCs ($20\,\mu F/cm^2$); and (iii) acceptance to humid environments. Even though this type of transistor delivers less charge as compared to the electrochemical transistor equivalence, it is still capable of switching $1\,mm^2$-sized display cells. Such electrolyte-gated smart pixels possess relatively faster updating speeds, lower power consumption (thanks to the enhancement mode operation of the OFET) and no parasitic propagation of a reduction front, as compared to smart pixels built with EC transistors. The versatility of electrolyte-gating provided by the PSS layer, as it serves as both the gate insulator in the transistor and as the electrolyte in the display pixel, implies manufacturing with less materials and processing steps. This, in turn, promises for easy manufacturing of low-voltage operating and matrix-addressed displays using standard printing techniques.

dopant has resulted in improved efficiency, retaining the color co-ordinates [12].

External quantum efficiency (EQE) of OLED depends heavily on the efficiency of carrier injection and recombination as well as on the electron–hole balancing. Therefore, in order to achieve the maximal efficiency, a balanced carrier recombination in the emissive layer (EML) is a must for the device. Especially in the blue OLED, the recombination region should be confined within the EML closer to the anode side to avoid the recombination at the EML/electron transport layer (ETL) interface to ensure color purity [13]. However, the commonly used configuration of OLEDs does not provide the required conditions for a balanced carrier injection/transport that leads to efficient recombination. One of the reasons is that the injected hole is more mobile than the injected electron under the same applied electric field. Therefore, establishing an electron–hole balance by reducing the number of holes or increasing the number of electrons reaching the EML is considered one of the most direct and viable solutions to improve device efficiency. Hole Blocking Layers (HBLs) are generally used for this purpose but they in turn increase the operating voltages [14–16]. These HBLs most commonly are placed after EML, closer to cathode. Another approach has been to place HBL between HTL and EML. Divayana et al. [15] incorporated a HBL between Hole Injection Layer (HIL) and HTL, with a view that it would cause minimal increase in operating voltage, but this would clearly depend more on the choice of materials.

Another alternative is to use graded layers as in green OLED obtained from graded HTL and ETL [17]. But arguably the most effective approach providing a balance between loss of process ease and increased efficiency would be to use multiple quantum wells (MQW) structures [18–20] which are of two types. In one, the energy levels of the material having wider energy gap sandwich the energy levels of the material with the narrow energy gap, thus confining both electrons and holes in the latter. In the other, both highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of both the materials involved in the quantum well structure are offset in the same direction.

Among the MQW structures, Divayana and Sun [9] fabricated blue OLED by sequentially incorporating multiple layers of host and dopant for better control of process compared to co-evaporated host and dopant. Qiu et al. [18], in a green OLED, incorporated multiple layers of NPB (N,N'-diphenyl-N,N'-bis (1,1'-biphenyl)-4,4'-diamine)/rubrene adjacent to anode such that electrons and holes can be trapped in the rubrene layer. Therefore, as more and more multiples of these layers are incorporated, the emission changes from green to that of rubrene, allowing color tuning. While more common are MQWs with HOMO and LUMO levels in one well material offset with respect to the adjacent material in opposite direction, Wang et al. [20] demonstrated increased efficiency of a blue OLED by employing NPB/TMADN (2,3,6,7-tetramethyl-9,10-dinaphthyl-anthracene) MQW with staggered energy levels. This has resulted in improved performance of blue OLEDs marked by an increase in current efficiency to 4.1 cd/A

for the MQW device from 3.4 cd/A for the standard hetero-junction structure.

In this paper, we describe a facile method of fabricating a blue OLED with improved efficiency by stepwise insertion of HTL into EML thereby achieving multiple HTL/EML interfaces in the EML and the performance of such a modified device is compared with that of a conventional one with the same materials. The experimental observations are qualitatively explained by simulation.

2. Experimental

Device area of 16 mm^2 was photolithographically defined on Indium Tin Oxide (ITO) (sheet resistance<10 Ω/□) coated glass, which was used as substrate. Prior to organic layer evaporation, the substrates were thoroughly cleaned with the routine cleaning procedure and subjected to oxygen plasma treatment. Evaporation of organic materials and metal was carried out under high vacuum (~10^{-7} Torr). The structure of the conventional device and the corresponding energy level diagram are shown in Fig. 1. A HIL (DS205 from Doosan Electromaterials) of thickness 100 nm was deposited first. Then sequentially multiple steps of NPB (as HTL) and EML (consisting of a blue host, BH2 from Kodak, with 1% blue dopant BD3 from Kodak, deposited by co-evaporation from two crucibles placed symmetrically below the substrate) were deposited keeping the total thickness of HTL to be 20 nm and that of EML 30 nm. A 25 nm thick layer of Alq$_3$ (Tris-(8-hydroxyquinoline) aluminum) was deposited as the ETL. Finally a

(a)

(b)
Fig. 1. (a) The conventional device structure and (b) the energy level diagram of the device depicted in (a).

1 nm thick LiF layer and 150 nm thick Al layer were deposited as the cathode. All devices were encapsulated with UV-curable resin and glass cover under inert conditions. The electro-optical characteristics of the fabricated devices were measured using a CS-1000 Minolta spectroradiometer and a Keithley 2400 SMU. All measurements were carried out on encapsulated devices.

3. Results and discussion

For comparing the performance of multiple HTL/EML layers based devices, the standard devices were made consisting of ITO(150 nm) /HIL(100 nm) /HTL(20 or 30 nm) / EML(30 nm) /ETL(25 nm) /LiF(1 nm) /Al(150 nm). These devices are labeled Device 1 and Device 2 based on thickness of HTL as 20 or 30 nm, respectively. While a significant effort in this work is on investigating multiple HTL layers in a device, these two devices are used to examine if thickness of HTL itself has a dominant effect in the device performance.

Fig. 1b shows the energy level diagram of these standard devices. There is an energy offset of 0.3 eV between the HOMO of the EML host and HOMO of the HTL. This creates a barrier for hole injection from HTL to EML. Hence holes could pile up at this interface and their probability of radiative recombination with the electrons reaching this interface is high. But it is commonly believed that holes have much higher mobility in HIL and HTL than electrons in ETL and, in addition, electrons suffer from injection difficulty at the cathode. This leads to charge imbalance, leading to many holes escaping to cathode without recombining. Accordingly, a poor current efficiency of such devices is explained.

In the standard device, as Fig. 1b indicates, we note an energy barrier to hole transport between HTL and EML, but no barrier for electrons. Conventional methods incorporate a separate hole blocking layer to increase luminance. But, since the HTL/EML interface naturally offers a barrier to hole transport, in the present work, it is possible to divide up the total HTL and EML thicknesses in many parts and include them as repeated structures forcing holes to encounter this barrier as many times; this arrangement, in turn, could increase the efficiency of blue OLED by slowing down the holes. Dividing the HTL thickness of Device 1 in two parts, in our improved Device 3, we have inserted two repeating structures of HTL and EML, keeping their total thickness the same as in Device 1. Accordingly, the device structure is ITO(150 nm) /HIL(100 nm) /HTL(10 nm) / EML(15 nm) /HTL(10 nm) /EML(15 nm) /ETL(25 nm) / LiF(1 nm) /Al(150 nm). Similarly, in Device 4, the HTL/ EML units are repeated three times according to the scheme ITO(150 nm) /HIL(100 nm) /HTL(10 nm) / EML(10 nm) /HTL(6 nm) /EML (10 nm) /HTL(4 nm) / EML(10 nm) / ETL(25 nm) /LiF(1 nm) /Al(150 nm). Here we have selected the thickness of different HTL segments such that its thickness decreases towards the cathode, because of an expectation that concentration of holes will reduce further away from anode. The materials are so selected that the LUMO levels of HTL and EML host are similar, implying little energy barrier to electron transport.

Thus, while additional barrier is provided to hole transport by repeating the HTL/EML unit, electron transport remains unaffected.

3.1. Current–voltage–luminance characteristics

Fig. 2 shows the current density versus voltage (J–V) characteristics of all the devices (symbols only). Typical data from 16 identical devices is plotted for each stack. Devices 1 and 2, which differ only in the HTL thickness, have similar J–V characteristics, indicating hole mobility in HTL does not limit the carrier transport. But, the current density in the standard devices is much higher than those with the multiple layers (Devices 3 and 4), consistent with the additional hole barriers introduced at HTL/EML interface. Among these two also, the Device 4 with three such interfaces has lower currents than Device 3 with two interfaces.

A small increase in voltage for same current, in principle, is acceptable as long as luminance also increases, resulting in increased current and power efficiency. These situations will imply lower non-radiative recombination of holes in the device or at cathode, the very reason for which multiple HTL/EML interfaces were introduced. Clearly, as demonstrated in Fig. 3, for a current density, luminance in Device 3 is greater than that in the standard devices. In principle, the luminance should increase with further increase in number of such interfaces. However, the luminance in Device 4 remains the same, possibly because either most electrons are already recombining within two units of HTL/EML, or increasing the number of interfaces (for same total thickness) forces thinner layers, which may result is poor control on film deposition. Additional consequences of increased number of interfaces and thinner films may be adverse effect of interface states, diffusion of excitons out of EML and emission quenching by NPB cation. All these are discussed in a greater detail later.

Two important figures of merit that define the performance of a device are the current and power efficiency, apart from reliability issues, such as life-time. The current efficiency of our devices with multiple HTL/EML interfaces is compared in Fig. 4, in which a current efficiency of
Fig. 2. Current density–voltage characteristics of the devices. Dots are experimental data and solid lines are simulated curves for devices 1, 3 and 4.
Fig. 3. Current density–luminance characteristics of the devices studied.

approximately 3 cd/A is shown for both the standard Devices 1 and 2. The Device 3 with two HTL/EML interfaces exhibits the maximum current efficiency of 5.8 cd/A, and the Device 4 with three HTL/EML interfaces 5 cd/A, at a current density of 10 mA/cm². This indicates that the multilayer HTL/EML structure significantly improves the device efficiency, approximately 1.9 times at low current densities and 1.5 times at its higher values. The luminance at any current density from Device 3 and 4 appear similar (see Fig. 3). But at low current densities, slightly higher luminance in device 3 tends to amplify the current efficiency; note that this result is repeatable. But at higher current densities, this difference seems to reduce, with current efficiencies both for Device 3 and 4 becoming similar. It may also be noted that the HTL thickness (compare Device 1 and 2) variation does not impact luminance, just like the current density, and hence current efficiency.

The second figure of merit is power efficiency, which is compared in Table 1. Using voltage required for 1 cd/m² emission as the basis, the luminance threshold voltage increases from 3.6 V in standard devices to 4–5 V in multilayer structure. But, correspondingly, the current
Fig. 4. Current density–current efficiency characteristics of the four devices.

efficiencies increase from 3 cd/A to between 5 and 6 cd/A. However, although the voltage of operation would increase by including the multi-layers, the power efficiency still increases to 2.2 lm/W for Device 3 and, in Device 4, remains similar (1.5 lm/W) to those of standard devices (1.4 lm/W). Therefore, the gain in current efficiency combined with either an increase or similar power efficiency by including multilayer structure can possibly justify the increased voltage of operation.

3.1.1. The CIE color co-ordinates

A typical electroluminescence (EL) spectrum of emission from these devices is depicted in Fig. 5a. Along with it, also shown are the photoluminescence(PL) spectra of 500 nm thick blue host and dopant films (excitation at 370 nm). The PL of host with 1% dopant is also included in the same figure. The PL of host with dopant closely follows the dopant emissions, indicating substantial energy transfer to it. Further, the electroluminescent (EL) emission is in accordance with the corresponding PL for host with 1% dopant, except an additional peak beyond 500 nm (see the encircled portion). Since this peak is entirely missing in the PL spectrum and is reasonably broad and located where we expect Alq_3 to emit, this additional peak in EL is from the ETL. The color co-ordinates of device emission are, therefore, negatively affected by this emission.

Full color displays would require blue emission which is as saturated as possible. Typically, more important is the CIE y-co-ordinate, which should be closer to 0.15. The CIE (x, y) co-ordinates for all four devices are shown in Fig. 5b. The CIE x-co-ordinate remains relatively unchanged from device to device, although the devices with multiple HTL/EML interface yield a better color co-ordinate, especially at higher voltages. The CIE y-co-ordinate, however, shows much more significant improvement towards deeper blue in multiple interface devices. The improved emission by including multiple interfaces would accompany lower recombination in ETL (Alq_3), which also therefore shifts the emission to deeper blue in comparison to the standard devices.

Furthermore, in the practical voltage range, above 6 V, the color co-ordinates in Device 3 and 4 do not change with voltage. Thus, these devices may be suitable for display applications.

3.2. Device simulation

In order to gain insight into the role of multilayer structures in modifying charge transport and recombination zone, we developed a simulator. A set of partial differential equations governing underlying physics of the device is based on drift-diffusion approximation [21,22]. The injection/extraction of carriers is modeled with thermionic emission along with the field dependent barrier lowering and its time reversed back flowing process according to the approach of Malliaras and Scott [23,24]. The organic–organic interface discontinuity has been modeled according to the approach of Crone et al. [25], assuming no dipoles/sheet charges at the interface, but distributed pile-up of charges being allowed. The recombination in the device is bimolecular with Langevin coefficient. The density

Table 1
Electroluminescent characteristics of the devices studied. The distribution of the HTL thickness of each device is also given. Threshold voltages are for a luminance of 1 cd/m^2. Current efficiency and power efficiency are measured at 10 mA/cm^2.

	Threshold voltage (V)	Current efficiency (cd/A)	Power efficiency (lm/W)
Device 1 HTL:EML (20 nm:30 nm)	3.6	2.9	1.4
Device 2 HTL:EML(30 nm:30 nm)	3.6	3.0	1.4
Device 3 HTL:EML(10 nm:10 nm/10 nm:10 nm)	4.0	5.8	2.2
Device 4 HTL:EML(10 nm:10 nm/6 nm:10 nm/4 nm:10 nm)	4.8	5.0	1.5

of states in organic materials in the simulator is fixed to its molecular density and dielectric constant of all layers is taken as 3. Finally, before using the simulator here, it has been validated with previously published simulation results of other groups [24–26].
(a)
(b)

Fig. 5. (a) Typical photoluminescence (PL) spectra of host, dopant and host with 1% dopant and electroluminescence (EL) spectrum of the standard device. The peak encircled in the EL spectrum is the green emission due to the recombination in the ETL, Alq$_3$ (b) CIE color coordinates of the devices.

The simulated $J–V$ characteristics are compared with the experimental data in Fig. 2 (solid lines) for Devices 1, 3 and 4. The mobility of both electrons and holes are assumed to be of the type, $\mu = \mu_o e^{\sqrt{E/E_o}}$ where E is the electric field. Accordingly, the other mobility parameters (μ_o and E_o) listed in Table 2 are so selected that best match of $J–V$ characteristics are obtained for all three devices for the same set of mobility parameters. The simulation suffers from limitations that it does not include exciton diffusion or trap distribution in the organic materials and the only transport levels are discrete LUMO and HOMO levels. As a result, the match of $J–V$ characteristics with experimental data is not perfect, but a similar trend allows us to approximately probe the differences between Devices 1, 3 and 4.

In order to evaluate the effect of introducing multiple HTL/EML layers, based on Fig. 2, we select two current levels, 15 mA/cm^2 (low) and 80 mA/cm^2 (high), to examine the spatial distribution of electron and hole currents and recombination. In both cases, as shown in Fig. 6, holes injected from anode in Device 1 encounter the first barrier at HTL/EML interface (at 120 nm) causing a pile-up of holes (p, thin solid line); correspondingly, there is little or no voltage drop in HIL and HTL. Also, a large number of holes are seen to reach cathode. On the other hand, in Device 1, the electrons (n, thin solid line) injected at cathode also pile-up at ETL/EML (at 150 nm) interface. Beyond that, the electron concentration drops rapidly, with few electrons reaching the anode. As a consequence, the electron current (J_n) in ETL is large, dropping off to nearly zero beyond ETL towards the anode. Nonetheless, significant hole current (J_p) is seen reaching the cathode. Furthermore, since ETL has significant population of both electrons and holes, a large amount of recombination (R), defined as rate of holes or electrons recombining per unit volume, takes place in ETL. The radiative part of this recombination leads to Alq$_3$ green emission, which is to be avoided. That, our devices are primarily blue, and such large recombination in ETL is suggested by simulations indicates either vicinity of ETL to the cathode leads to substantial non-radiative recombination or this large recombination in ETL may be a consequence of our selection of simulation parameters (carrier mobilities and transport levels). However, in the latter case also, qualitative differences arising from different device structures (Devices 1, 3 and 4) can still be meaningfully predicted.

Apart from the recombination in EML, primary recombination leading to blue emission occurs at HTL/EML inter-

Table 2
Simulation parameters.

	HIL	HTL	EML	ETL
μ_o for holes (zero field hole mobility) (m^2/Vs)	$6 \times 10\text{-}8^*$	$6.1 \times 10^{-9*}$	1.8×10^{-9}	1.8×10^{-12}
μ_o for electrons (zero field electron mobility) (m^2/Vs)	$6 \times 10^{-10*}$	$6.1 \times 10^{-11*}$	$1.8 \times 10^{-8*}$	1.8×10^{-11}
E_0 for holes (V/m)	2×10^6	4.44×10^7	1.11×10^7	1.04×10^7
E_0 for electrons (V/m)	2×10^6	4.44×10^7	1.11×10^7	1.04×10^7

[*] These mobility values even if increased by 10 times make only a minor difference in calculations.

face (120 nm for Device 1) where the holes pile-up, as do electrons due to a small barrier. This small barrier for electrons leads to only a small increase in electron concentration compared to that of holes. The corresponding recombination is also shown in Fig. 6 for both current densities. We estimate the recombination current that leads to blue emission by integrating the recombination rate between 1 nm on either side of HTL/EML interface (119–121 nm for Device 1) and multiplying it by electron charge. Accordingly, for Device 1, this current is estimated as 0.06 and 0.56 mA/m^2 at a total current density of 15 and 80 mA/cm^2, respectively.

Upon introducing the multiple junctions of HTL and EML, such as in Device 3, the electrons and holes now

pile-up wherever the same interfaces as in Device 1 are available. Accordingly, the hole current reaching cathode decreases with a corresponding increase in electron current at the same location (see Fig. 6). As a consequence, the green recombination in ETL reduces (compare Device 1 with Device 3; due to log scale in Fig. 6, the change appears small), consistent with color co-ordinate improvement observed experimentally.

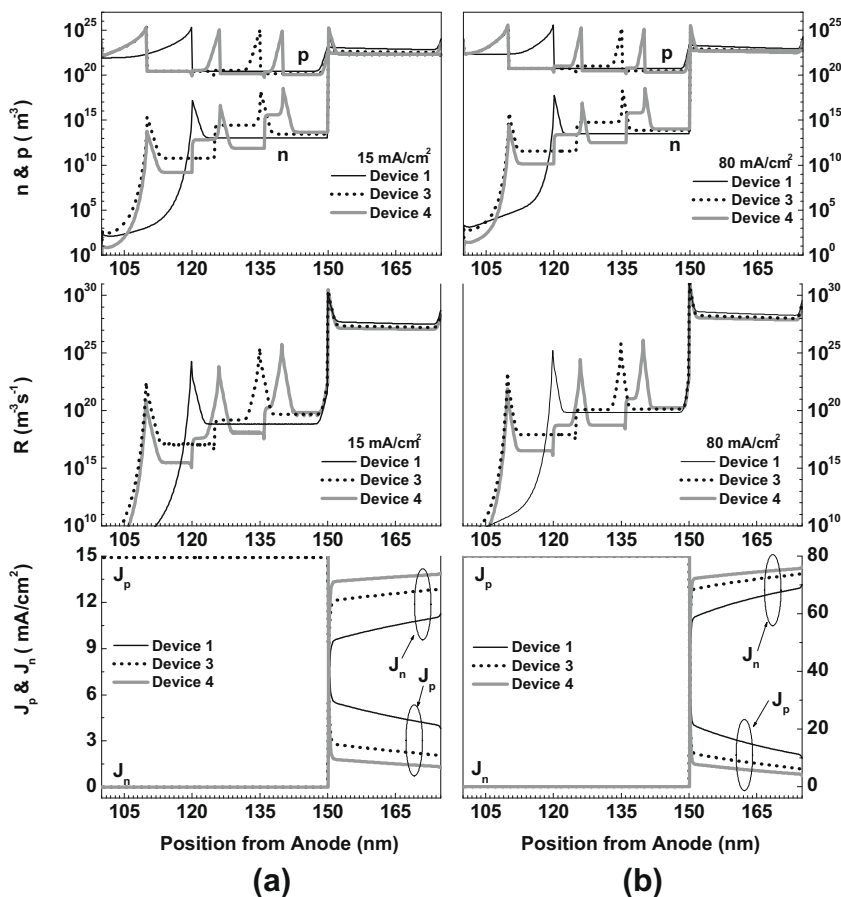
In Device 3, multiple HTL/EML interfaces which block holes lead to added blue emission at each of these interfaces. The recombination current near HTL/EML interface is estimated as 0.95 mA/m^2 (from Fig. 6a) and 2.10 mA/m^2 (from Fig. 6b). Thus, in this device the recombination current at low total current density increases to 0.95 mA/


Fig. 6. (a) Spatial distribution of electron density (n) and current (J_n), hole density (p) and current (J_p) and electron and hole recombination rates (R) at 15 mA/cm^2 total current density and (b) the same at 80 mA/cm^2.

m^2 from 0.06 mA/m^2 in Device 1, which experimentally is observed as an increase in current efficiency. At a higher total current density, this increase in calculated recombination current is from 0.56 mA/m^2 in Device 1 to 2.10 mA/m^2 in Device 3, representing a smaller increase than that at lower total current density. The same has been observed experimentally, where the improvement in current efficiency at lower current density is much more significant than that at higher current density (see Fig. 4)

Since there is still a substantial number of holes recombining at cathode, adding one more HTL/EML interface in Device 4 leads to predicting still higher electron current and lower hole current at cathode, lower recombination in ETL and increased recombination current to 2.15 (from Fig. 6a 4.21 mA/m^2 (from Fig. 6b) at HTL/EML interface. Experimentally, however, we observe lower current efficiency in Device 4 in comparison to Device 3.

This observation is similar to the result of inserting multiple layers of rubrene confined between NPB, where four layers resulted in maximum current efficiency [18]. The same group also reports a Alq$_3$ OLED with multiple layers of NPB and CuPc together constituting the HTL [27]. In this device, four such layers yield best efficiency, presumably, according to the authors, due to poor film quality of thinner layers and negative impact of surface states. In another MQW structure with phosphorescent materials, the cause of decline in EL efficiency beyond a number of multiple layers is ascribed to exciton diffusing out of the emissive region [28]. Therefore, in case of Device 4, a fall in current efficiency could be due to poor control in depositing thinner films, increased impact of interface states or exciton diffusion away from EML into HTL which has lower efficiency of radiative recombination; none of these effects are included in the simulation models.

Apart from these reasons, more recently, Young et al. [29] reported absorption spectrum of NPB cation to be at similar energies as a blue OLED emission. With this spectral overlap and a large Förster radius in a blue OLED, they ascribed quenching of emission at the HTL (NPB)/EML interface. Our simulation of the devices also indicates accumulation of holes (and thus NPB cation) at this interface. Hence, blue emission from the OLED in which the number of HTL/EML interfaces is increased is a balance of two opposing phenomena, the increased emission due to reasons as simulated here and its decrease due to quenching by NPB cation. This clearly explains why the EL efficiency decreases in Device 4, after an increase in Device 3.

4. Conclusions

In conclusion, we have fabricated a standard blue OLED (Devices 1 and 2), in which we have an energy barrier to hole transport between HTL and EML, but no barrier for electrons. Therefore, instead of a conventional method in which a separate hole blocking layer is introduced to increase luminance, we have exploited this hole blocking feature in a standard device by inserting multiple layers of HTL and EML of a blue OLED and achieved excellent improvement in device current and power efficiency. This

can be attributed to the increased recombination probability at the HTL/EML interfaces with only a marginal increase in operating voltage. Selecting materials that exhibit HOMO level offset between HTL and EML, but not in the LUMO levels, helps develop an increased carrier concentration and consequent recombination rate near the interface. The same HOMO level mismatch between HTL and EML reduces the hole current in the device. Together these factors lead to an improved current efficiency. These observations were then explained using device simulation. The simulated results qualitatively agree with the experimental observations and corroborate the assumption that multiple HTL/EML interfaces increase the recombination rate if the HOMO level mismatch can help pile up holes at such interfaces and this leads to improved efficiency. In the present case the color co-ordinates are also improved upon introducing more than one HTL/EML interfaces because this reduces chances of radiative recombination at the ETL. It appears that this technique could be applied to red and green emitters as well.

its excellent electrical characteristics. However, it has been reported that the processing condition of C-PVP requires very high temperature (higher than 175 °C) rendering C-PVP unsuitable to fabricate electronic devices on various flexible substrate [22–31]. It has been reported that cross-linking reaction between PVP and cross-linker (CLA) occurs at high temperature and it enhances the mechanical, thermal and electrical properties of C-PVP. However, we believe there is high possibility that the processing temperature of C-PVP can be reduced much below 100 °C.

In this paper, we report low-temperature processability of poly(4-vinylphenol) based gate dielectric by investigating the effect of composition and processing temperature on the thermal, mechanical and electrical characteristics of the gate dielectric. We also report the fabrication of flexible OTFT and complementary inverter with the low-temperature processable C-PVP. In order to investigate the effect of composition and processing conditions on mechanical, thermal and electrical properties of gate dielectrics, we have prepared six gate dielectrics based on PVP (G1–G6). The results and discussion section begins with the preparation of the gate dielectrics and their physical properties according to the composition and processing condition using pencil hardness test, thermogravimetry analysis, contact angle measurement and electrical analysis. It is followed by a discussion for the fabrication and performance of OTFTs with the six gate dielectrics and complementary inverter on a flexible substrate.

2. Experimental

2.1. Materials

Pentacene and Copper hexafluorophthalocyanine (F16CuPc) for the active layer formation were purchased from Aldrich Company and used without further purification. G1 and G2 Gate dielectric solutions were prepared from 10 wt.% poly(4-vinylphenol) (PVP) (M_w = 20,000 g/mol) in n-butanol and n-propanol, respectively, and followed by curing at 60 °C/10 min and 125 °C/60 min for G1 and at 40 °C/10 min and 70 °C/60 min under vacuum (10^{-2} Torr) for G2. G3, G4 and G5 gate dielectric solutions was prepared from 10 wt.% PVP and 5 wt.% cross-linking

agent (CLA), poly(melamine-co-formaldehyde) methylated (M_n = 511 g/mol) in PGMEA, n-butanol and n-propanol, respectively. The spin-coated films were cured at 80 °C/10 min and 175 °C/60 min under vacuum (10^{-2} Torr) for G3, at 60 °C/10 min and 125 °C/60 min under vacuum (10^{-2} Torr) for G4 and at 40 °C/10 min and 70 °C/60 min under vacuum (10^{-2} Torr) for G5. G6 gate dielectric solution was prepared from 6 wt.% PVP and 3 wt.% CLA in n-propanol and cured at 40 °C/10 min and 70 °C/60 min under vacuum (10^{-2} Torr).

2.2. Device fabrication

Top-contact pentacene OTFTs were fabricated on a glass substrate on which a 200 nm indium tin oxide (ITO) layer was patterned as the gate electrode by a conventional photolithographic method. The ITO/glass substrate was cleaned using the general cleaning process for electronic application: sonication in detergent, deionized water, acetone, and isopropanol in that order for 15 min at room temperature. The gate dielectrics solution was spin-coated on top of the ITO gate electrode as a gate insulator and then cured under the preparation conditions summarized in Table 1. A 50 nm thick pentacene layer was deposited on top of the gate dielectric through a shadow mask by a thermal evaporation at a pressure of 5×10^{-6} Torr. The evaporation rate of pentacene and substrate temperature were 0.3 Å/s and 90 °C, respectively. OTFTs were then completed by thermally evaporating a 50 nm thick source and drain gold electrode on top of the pentacene layer through a shadow mask (channel length (L) = 50 μm and width (W) = 1000 μm). Metal–insulator–metal (MIM) device were prepared for capacitance and leakage current measurements of the gate dielectrics. The MIM devices were completed by evaporating the top gold electrode. The final thickness of gate dielectric films were controlled to 500 nm. The active area of MIM device was 1.75mm². Flexible complementary inverters were fabricated on an ITO coated polyethersulfone (PES) substrate. The gate dielectrics solution was spin-coated on top of the ITO gate electrode and then cured under the preparation conditions summarized in Table 1. Then, a 50 nm thick pentacene and copper hexafluorophthalocyanine (F16CuPc) were deposited by a vacuum thermal evaporation for a p-type and n-type active layer, respectively. The deposition rate and substrate temperature were 0.3 Å/s and 90 °C, respec-

Table 1
Solution composition, curing condition and physical and electrical properties of the gate dielectrics.

	Composition (PVP wt%/CLA wt%)	Curing temp/time (°C/min)[a]		Thickness (nm)	Solvent (bp/°C)	Contact angle (°)	Capacitance (pF/mm²)
G1	10/0	60/10	125/60	350	n-Butanol (117.2)	79	70–75
G2	10/0	40/10	70/60	700	n-Propanol (97)	71	35–40
G3	10/5	80/10	175/60	600	PGMEA[b] (146)	80	40–45
G4	10/5	60/10	125/60	400	n-Butanol	80	70–75
G5	10/5	40/10	70/60	700	n-Propanol	72	35–40
G6	6/3	40/10	70/60	300	n-Propanol	71	75–80

[b] Propylene glycol monomethyl ether acetate.

tively. The complementary inverter was completed by forming a 50 nm thick gold electrode on top of the active semiconductor layer. The channel length and width for p-type OTFT were 250 and 200 μm, respectively. The channel length and width for n-type OTFT were 50 and 4000 μm, respectively.

2.3. Characterizations

The thickness of gate dielectrics was determined using an AMBIOS XP-100 surface profiler. All atomic force microscopy (AFM) images (512 pixels wide) of the surface of gate dielectrics were taken with a Digital Instrument Nanoscope IV operating in tapping mode in air using a low-force imaging technique (a small tip-sample contact area), which is beneficial for high-resolution imaging of polymers. Water contact angle on the gate dielectrics was measured using DSA100 drop shape analyzer. The electrical characterization of OTFT and complementary inverter were carried out using a HP4145B semiconductor parameter analyzer controlled by LabView program. Capacitance of the gate dielectrics was measured with a HP 4294A LCR meter. All electrical measurements of the devices were carried out in air without any encapsulation. Thermogravimetry analysis was carried out using PERKIN ELMER thermogravimetry analyzer TGA 7. Pencil hardness test of gate dielectrics was measured with WA-008 pencil hardness tester.

3. Results and discussion

Fig. 1 shows the chemical structure of PVP and C-PVP gate dielectric along with the chemical structure of CLA used for the fabrication of OTFT and complementary inverter. For this study six gate dielectrics (labeled as from G1 to G6) were prepared by spin coating the gate dielectric solutions in organic solvents with a different boiling temperature. The spin-coated films were further cured under different processing conditions for the preparation of the gate dielectrics. Organic solvents used for the preparation of the gate dielectrics were PGMEA (b.p. 146 °C), n-butanol (b.p. 117 °C) and n-propanol (b.p. 97 °C).

G1 and G2 gate dielectrics were prepared by spin coating a solution composed of only PVP (M_w = 20,000 g/mol) in n-butanol (G1) and n-propanol (G2), followed by curing at 125 °C (G1) and 70 °C (G2). Other gate dielectrics (G3–G6) were prepared by spin coating a solution composed of PVP and cross-linking agent, poly(melamine-co-formaldehyde) methylated (M_n = 511 g/mol, CLA) in different organic solvents, followed by curing at different temperature; G3: PGMEA and 175 °C, G4: n-butanol and 125 °C, G5: n-propanol and 70 °C and G6: n-propanol and 70 °C. G5 and G6 were prepared under the same process condition except that the concentration of the two solutions is different for the thickness control. The composition of the gate dielectrics, processing condition, thickness and physical and electrical properties of G1~G6 were summarized in Table 1.

It is well-known that cross-linked polymer thin-film usually shows stronger mechanical properties than non-cross-linked one due to the network structure formation between polymer chains by a cross-linking reaction. We expect that G3–G6 with CLA have the network structure and thus their mechanical and thermal properties are stronger than G1 and G2. In order to investigate mechanical properties of the gate dielectrics, we carried out pencil hardness test for G1, G3, G4 and G5 gate dielectric deposited on ITO/glass substrate and the results were shown in Fig. 2a. Gate dielectric G1 (PVP only) was completely removed by 4H pencil. Gate dielectric G3, which was prepared by the method reported previously by other groups (cured at higher than at 175 °C) [22–31], showed improved mechanical properties, little scratch by 4H pencil. This is because the linear structured main chain of PVP was changed to network structured one through a cross-linking process by the CLA at that high temperature. Gate dielectric G4 and G5 cured at 125 °C and 70 °C, respectively, showed comparable mechanical properties to that of G3 and much better than G1. From the pencil hardness test results, it can be inferred that the cross-linking reaction can be occurred at as low as 70 °C so that the curing temperature of gate dielectrics based on PVP can be reduced to 70 °C by simply changing the solvent from PGMEA to n-propanol with a lower boiling temperature.

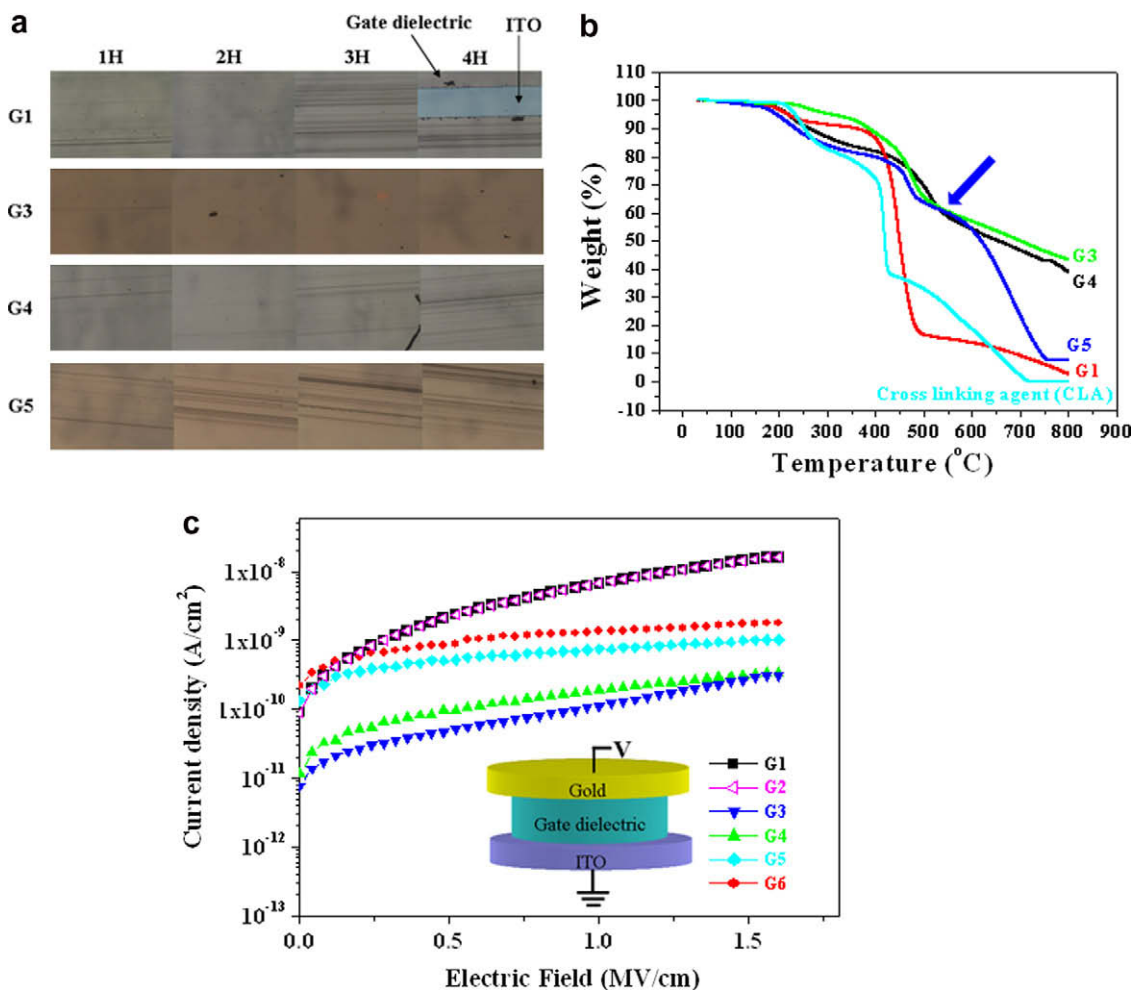
In order to further support the possibility of cross-linking reaction at that low-temperature, we carried out thermogravimetry analysis (TGA) for the G1, G3, G4 and G5 gate dielectrics as shown in Fig. 2b. For the TGA measurement all the gate dielectric solutions were spin-cast on a glass substrate and pre-cured according to the preparation
Fig. 1. Chemical structure of poly(4-vinylphenol) (PVP), poly(melamin-co-formaldehyde) methylated (cross-linking agent, CLA) and cross-linked PVP (C-PVP).


Fig. 2. (a) Pencil hardness test, (b) thermogravimetry analysis (TGA) thermograms for the G1, G3, G4 and G5 gate dielectrics and CLA and (c) leakage current density as a function of applied electric field (J–E) for all gate dielectrics.

method for each gate dielectric. Then the films were peeled out from the substrate and used for the TGA measurement. An abrupt weight loss was observed at 410 °C for G1 and the residual weight around 600 °C is almost zero. It indicates that the linear structured main chain of G1 is thermally weak and starts to decompose around 410 °C and decomposed almost completely around 600 °C.

On the other hand, for G3 prepared from PVP and CLA solution in PGMEA, no abrupt weight loss was observed in the entire range of temperature and residual weight was about 45% even at 800 °C indicating that linear structured main chain of PVP was changed to network structured one through a cross-linking reaction by the CLA at 175 °C. For G4 prepared from PVP/CLA solution in n-butanol by a curing at 125 °C, it showed almost identical thermal behavior to G3 indicating that the cross-linking reaction has been fully occurred even at 125 °C. G5 prepared from PVP/CLA solution in n-propanol by a curing at 70 °C showed similar thermal behavior to G3 and G4 up to 600 °C (indicated by an arrow), but when further heated, weight loss was observed. Please note that the first weight

loss was observed in the temperature range of 200–300 °C. The different behavior is caused by the different pre-curing condition for TGA samples (See Table 1). In order to make sure that the different thermal behavior of G3, G4 and G5 from that of G1 and G2 is not caused by CLA itself, we recorded TGA thermogram of CLA. The thermogram of CLA shows very different thermal behavior from the gate dielectrics. That is, the CLA starts to decompose before PVP does and is thermally very weak. It indicates that the better thermal behavior of G3, G4 and G5 than G1 is caused not by the added CLA but by a cross-linking reaction. In separate experiments we measured FT–IR spectra of G3 and G5. It was found that the two spectra were almost identical with each other. It gives us another indirect evidence for the cross-linking reaction between PVP and CLA at the low temperature.

The leakage current of gate dielectrics is one of the important concerns regarding high performance OTFTs. To determine the leakage current of the gate dielectrics, we prepared metal–insulator–metal (MIM) devices on the pre-cleaned ITO/glass substrates by sandwiching the gate

dielectric between bottom ITO and top gold electrode as shown in the inset of Fig. 2c. The active area was 1.75 mm². The plots of current density and an applied electric field (J–E) for the gate dielectrics are shown in Fig. 2c. It showed non-linear J–E behavior, which is typical for MIM devices based on polymeric gate dielectric. Although the leakage current (1.0×10^{-9} A/cm² at 1.5 MV/cm) of G5 and G6 is higher than that (1.0×10^{-10} A/cm² at 1.5 MV/cm) of G3 and G4 cured at 175 °C and 125 °C, respectively, it is much lower than that (2.0×10^{-8} A/cm² at 1.5 MV/cm) of G1 and G2, which is PVP only gate dielectric cured at 125 °C and 70 °C, respectively. The breakdown voltage of the gate dielectrics was more than 1.5 MV/cm. Capacitance of the gate dielectrics was measured using the same MIM devices and the values was summarized in Table 1.

From the results of pencil hardness, TGA analysis and leakage current density measurement, it can be inferred again that the curing temperature of PVP based gate dielectrics can be reduced up to 70 °C by choosing an appropriate solvent without any significant change in electrical, thermal and mechanical properties of the gate dielectrics.

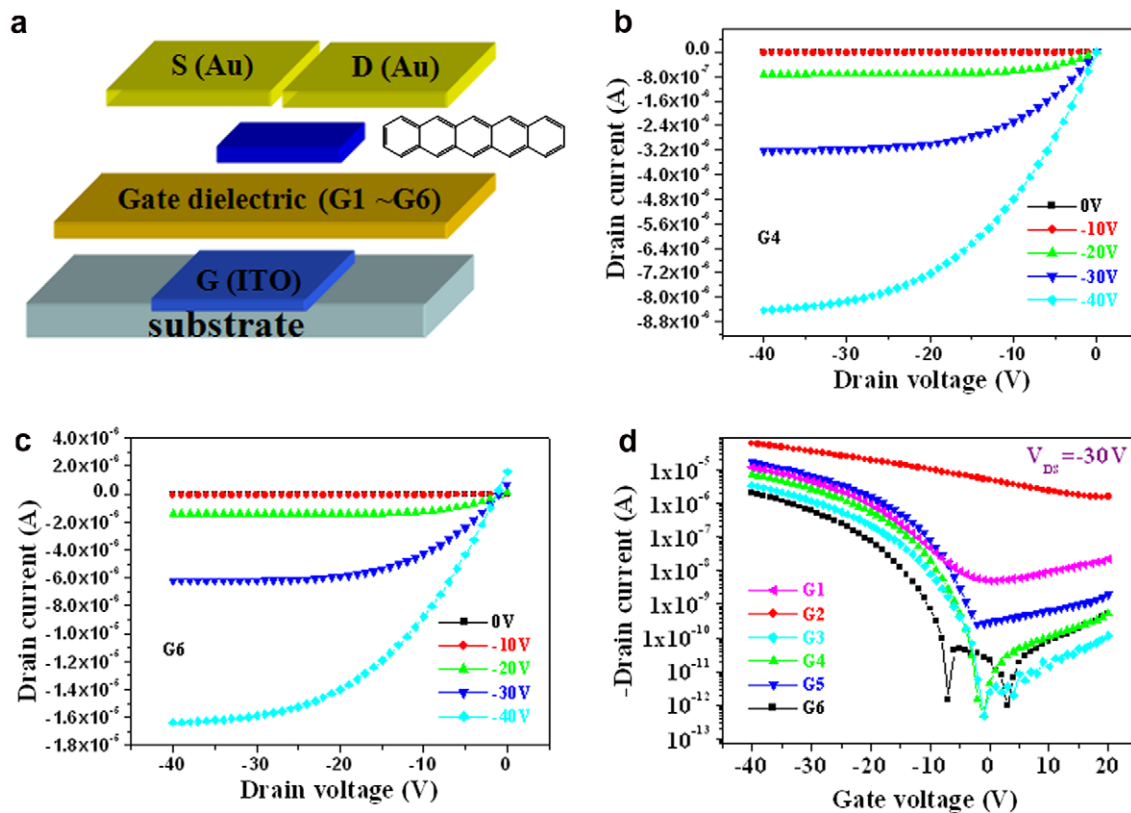
The water contact angle on the gate dielectrics were measured and found to be in the range of 71–80° (see Table 1) indicating that the composition and processing condition does not significantly influence surface properties of the gate dielectric. Fig. 3 shows the AFM images of pentacene deposited on gate dielectrics (G3, G4 and G6). Although the composition and curing conditions of the gate dielectrics are different from each other, the AFM images of pentacene are almost identical with each other having 2–3 μm
Fig. 3. AFM image of 50 nm thick pentacene film on (a) gate dielectrics G3, (b) gate dielectrics G4 and (c) gate dielectrics G6.


Fig. 4. (a) Schematic diagram of pentacene OTFTs. Output characteirstic curves at various V_{gs} (from 0 V to −40 V with a step of −10 V) for pentacene OTFTs with G4 (b) and G6 (c). Transfer characteristic curves (d) for pentacene OTFTs with all gate dielectrics (G1–G6). While V_{gs} was swept from +20 to −40 V and V_{ds} was set at −30 V. The OTFT has a channel length of 50 μm and a channel width of = 1000 μm.

Table 2
Performance parameters of pentacene OTFTs with the gate dielectrics. All parameters were extracted in the saturation region.

	V_{th} (V)	I_{on}/I_{off}	μ (cm^2/V s)	ss (V/dec)
G1	−6 to −14	7×10^2–2×10^3	0.13–0.25	7–11
G2	–	30	–	–
G3	−15 to −17	7×10^5–2×10^6	0.1–0.13	0.7–0.9
G4	−13 to −15	8×10^5–2×10^6	0.08–0.12	0.7–0.9
G5	−15 to −21	1×10^4–1×10^5	0.07–0.11	0.8–2.8
G6	−8 to −13	1×10^4–5×10^4	0.2–0.5	2.5–3.0

big leaf-like crystals. It tells us again that the composition and processing condition does not affect the surface property of gate dielectrics and growth of pentacene on them.

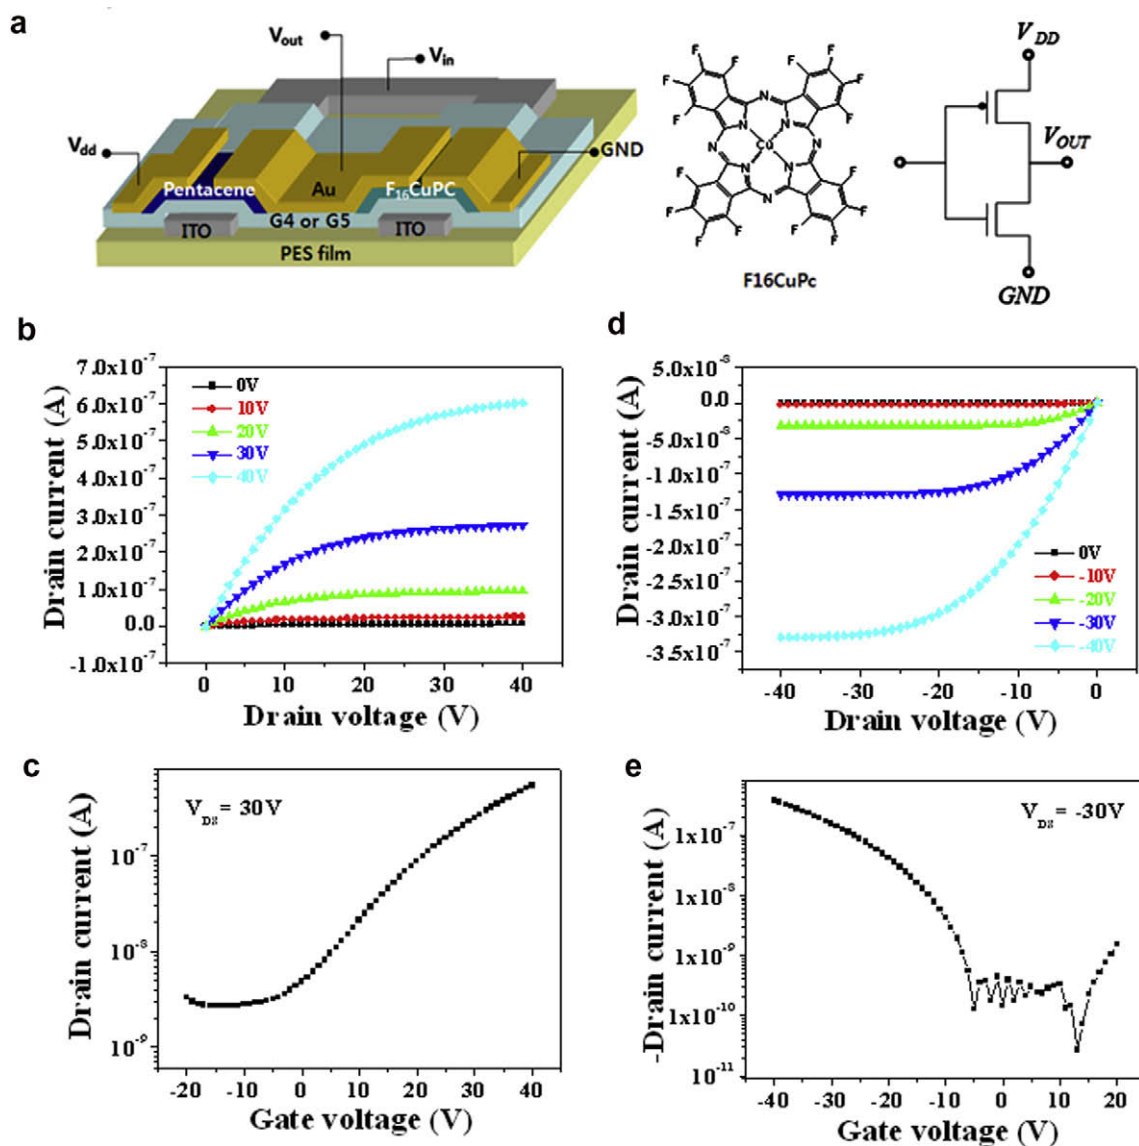
Based on the finding for low-temperature processability of PVP based gate dielectrics, we have fabricated OTFTs and flexible complementary inverter. A top-contact geometry was used for analyzing the electrical characteristics of pentacene OTFTs. The device fabrication procedures are depicted in Fig. 4a. The output (drain current vs. drain voltage, I_{ds} vs. V_{ds}) and transfer (drain current vs gate voltage, I_{ds} vs. V_{gs}) characteristic curves of the pentacene OTFTs with G1–G6 gate dielectrics are measured and are shown in Fig. 4b–d. The output curves of the OTFTs with G4 and G6 cured at 125 °C and 70 °C, respectively, at various V_{gs} (from 0 V to −40 V with a step of −10 V) are shown in Fig. 4b and c. It showed typical p-type characteristics with a clear transition from linear to saturation behavior. At a given V_{gs}, I_{ds} initially increased linearly with small negative V_{ds} and then saturates at high voltage. Fig. 4d shows transfer characteristic curves of OTFTs with G1–G6, where V_{gs}


Fig. 5. (a) Schematic structure of the complementary inverter along with the chemical structure of F16CuPc as a n-type semiconductor, output (b) and transfer (c) characteristic curves of n-type OTFT (L = 50 μm, W = 4000 μm), and output (d) and transfer (e) characteristic curves of p-type OTFT (L = 250 μm, W = 200 μm) built in complementary inverter with G5 gate dielectric (cured at 70 °C) on a PES substrate.

was swept from +20 to –40 V and V_{ds} was set at –30 V. The field-effect mobility (μ) was extracted from the plot of $\sqrt{I_{ds}}$ vs. V_{gs} in a saturation regime based on the following equation:

$$I_{ds} = \frac{WC_i}{2L}\mu(V_{gs} - V_{Th})^2 \qquad (1)$$

where W, L, V_{Th} and C_i are channel width, channel length, threshold voltage and capacitance per unit area, respectively. V_{Th} was determined from the plot of the square root of the I_{ds} and V_{gs} by extrapolating the measured data to I_{ds} = 0. The inverse subthreshold swing (ss), which is a measure of how sharply the device transits from the OFF to the ON state, is given by

$$ss = \left[\frac{d\log(I_{ds})}{dV_{gs}}\right]^{-1}.$$

The performance parameters of the OTFTs with G1–G6 were summarized in Table 2.

The OTFTs with G1 and G2, which are PVP only gate dielectric cured at 125 °C and 70 °C, respectively, showed high leakage current caused by poor electrical characteristics of G1 and G2 (see Fig. 2c). The performance of OTFTs with G4 (cured at 125 °C) is almost identical to that of reference OTFT with G3 prepared by the curing condition reported previously (175 °C/1 h). Furthermore, the OTFTs with G5 and G6 (cured at 70 °C) showed much better performance than OTFTs with G1 and G2, and it showed comparable performance to the reference OTFT with G3 except for a little decrease of I_{ON}/I_{OFF} and increase of ss. This indicates that C-PVP can be prepared by curing at 70 °C using n-propanol with a lower boiling temperature instead of PGMEA and act as a good gate dielectric.

Based on the results of OTFTs, we prepared the flexible complementary inverter by integrating p- and n-type OTFTs on a single PES substrate through a thermal vacuum evaporation and spin coating process. Fig. 5a shows the schematic structure of the complementary inverter along with the chemical structure of F16CuPc. Pentacene and F16CuPc were used as p- and n-type semiconductor,

respectively, and G4 and G5 were used as a gate dielectric. The electrical characteristics of each p- and n-type OTFTs of the complementary inverter with G4 (cured at 125 °C) were measured right after fabrication. The calculated μ, V_{Th}, I_{ON}/I_{OFF} and ss of the F16CuPc OTFT with a channel length and width of 50 μm and 4000 μm were 0.24×10^{-2} cm^2/Vs, 14 V, 3×10^2 and 10 V/dec, respectively. These device performance parameters are all similar to those of F16CuPc with silicon dioxide and polyimide gate dielectric indicating that the G4 is also suitable for a gate dielectric of n-type OTFT [32]. The calculated μ, V_{Th}, I_{ON}/I_{OFF} and ss of the pentacene OTFT with a channel length and width of 250 μm and 200 μm were 0.12 cm^2/Vs, –12 V, 3×10^4 and 1.8 V/dec, respectively.

Compared with the performance parameters of single pentacene OTFT with G4 (see Fig. 4), the pentacene OTFT of the complementary inverter shows a little worse performance. This may be due to the additional processes to fabricate the n-type OTFT and/or the longer channel length to match the I_{ds} of p- and n-type OTFTs for symmetric noise margin of the organic complementary inverter. We also have fabricated flexible complementary inverter with G5 gate dielectric, which is cured at 70 °C on a PES substrate. Fig. 5b and c show the output and transfer characteristic curves of the F16CuPc OTFT, respectively, and Fig. 5d and e shows the output and transfer characteristic curves of the pentacene OTFT, respectively. The calculated μ, V_{Th}, I_{ON}/I_{OFF} and ss of the F16CuPc OTFT were 0.3×10^{-2} cm^2/Vs, 7 V, 1×10^2 and 20 V/dec, respectively. The calculated μ, V_{Th}, I_{ON}/I_{OFF} and ss of the pentacene OTFT were 0.18 cm^2/Vs, –12 V, 3×10^3 and 2.6 V/dec, respectively.

The performance of the inverter is almost similar to that of inverter with G4. Fig. 6 shows the voltage transfer ($V_{out} - V_{in}$) characteristic curve of the complementary inverter with G4 and G5. The supply voltage (V_{DD}) is 40 V. The swing range of V_{out} for both inverters is the same as V_{DD}, which ensures "zero" static power consumption in digital circuits. Fig. 6 also shows almost symmetric noise margin as intended. For the inverter with G4, the noise margins for low and high voltage are 17 V and 14 V,
Fig. 6. The voltage transfer (V_{out}–V_{in}) characteristic curve of the complementary inverter based on F16CuPc (n-type) and pentacene (p-type) OTFTs. Inset: the signal gain and the photograph of the inverter.

respectively. The logic threshold, i.e. V_{in} where V_{in} is equal to V_{out}, is 22.5 V and the maximum voltage gain ($\partial V_{out}/\partial V_{in}$) of 7.8 is obtained at V_{in} = 22.5 V. The inverter with G5 showed almost identical characteristics to that of the inverter with G4 as shown in Fig. 6. The logic threshold is 21 V and the maximum voltage gain ($\partial V_{out}/\partial V_{in}$) of 8.1 is obtained at V_{in} = 21.0 V. The photograph of the flexible complementary inverter is shown in the inset of Fig. 6.

4. Conclusions

We have investigated the effect of composition and processing conditions on the thermal, mechanical and electrical properties of the PVP based gate dielectric using pencil hardness test, thermogravimetry analysis and electrical analysis. Unlike the reports telling that high processing temperature is required to prepare C-PVP gate dielectric, we found that the processing temperature can be reduced to up to 70 °C which allows most polymeric materials to be suitable to flexible substrate. Using the prepared low-temperature processable C-PVP gate dielectric we have successfully fabricated high performance pentacene and F16CuPc OTFTs, and flexible complementary inverter on a plastic substrate.

amorphous Si (a-Si:H) TFTs [11–15]. Low temperature a-Si:H thin-film transistors are generally n-channel [11,12,16] while organic semiconductors such as pentacene are generally p-channel [9,17,18]. Recently, pentacene-based thin-film transistors have had significant improvement, and are now comparable to a-Si:H TFTs [7,9,19]. Also, organic semiconductors showing n-type behavior with mobilities in the order of those of a-Si:H have been achieved; although this has been achieved in relatively simple devices [20,21].

In this work we demonstrate a novel CMOS integration approach that incorporates inorganic a-Si:H as the n-channel element and pentacene as the p-channel element using photolithography-based processing. Furthermore, the devices are fabricated on flexible substrates (PEN) and the maximum processing temperature is kept below the glass transition temperature of the substrate (<180 °C). Although CMOS devices have recently been demonstrated [5,7,9,20,22–24], our integration approach demonstrates an all-photolithography-based integration to fabricate several logic components integrated in the same substrate and compatible with current backplane manufacturing technology.

2. Results and discussion

The integration of a-Si:H and pentacene has been demonstrated in rigid substrates and by interconnecting the discrete devices [5,7]. As opposite to those initial reports, the CMOS integration scheme presented in this work involves fabricating the CMOS devices in a flexible substrate and using standard interconnection technology. The process starts by fabricating the a-Si:H nMOS devices first, followed by the pentacene pMOS devices. The resulting CMOS circuits are then encapsulated using parylene as passivation and vias are opened for further testing. A schematic cross-section and optical photograph of the CMOS devices on PEN are shown in Fig. 1a and b, respectively.

The detailed process is as follows. After planarization of the flexible substrate (PEN) the nMOS TFTs (a-Si:H) are fabricated using an inverted staggered architecture with the gate underneath and the semiconductor and source/drain on top (Fig. 1a). The components of the a-Si:H TFTs are: molybdenum as gate metal, Si_3N_4 gate dielectric, and aluminum as the source-drain metallization. Data lines and contacts are formed by deposition and patterning the n+ doped a-Si:H via PECVD and Al metal by DC sputtering. The maximum process temperature for nMOS fabrication was 180 °C. This process is completed at the Flexible Display Center at Arizona State University.

Typical current voltage characteristics for the resulting n-channel a-Si:H TFTs are shown in Fig. 2. From Fig. 2a we extracted a saturation mobility of 0.75 cm^2/V s with an I_{on}/I_{off} current ratio >10^8. Subthreshold slope is approximately 0.35 V/decade and threshold voltage of ~1.14 V. Fig. 2b shows a typical I_{DS}–V_{DS} family of curves for the n-channel a-Si:H process described above. Well behaved transistors characteristics are observed.

After nMOs fabrication, pentacene-based pMOS TFTs are fabricated at UT-Dallas. pMOS TFTs are fabricated using a bottom gate approach. In our process, the gate insulator (parylene) is deposited after the inter-level dielectric (ILD) [12,25,26]. This fabrication process includes aluminum as gate metal, parylene as ILD (500 nm), parylene (100 nm) as gate dielectric and gold as source-drain contacts and interconnect metallization. The pMOS fabrication process starts with the ILD (0.5 µm of parylene) deposition over Al gate metal formed during nMOS fabrication. The ILD is deposited at room temperature and patterned to define the metal gate vias and channel region (Fig. 1a). Next, gold (100 nm) is deposited by e-beam evaporation and patterned to form source-drain contacts and interconnects. Pentacene (150 nm) is then deposited at room temperature to create the active channel [27]. Finally, the devices are capped using a parylene encapsulation process and vias are opened for device testing. As we reported, this approach provides a pristine and hydrophobic surface, which provides a favorable surface for pentacene growth [25,26]. If the gate dielectric layer is patterned before patterning the ILD layer the gate dielectric surface becomes hydrophilic due to exposure to the RIE oxygen resulting in degraded pentacene performance [25].

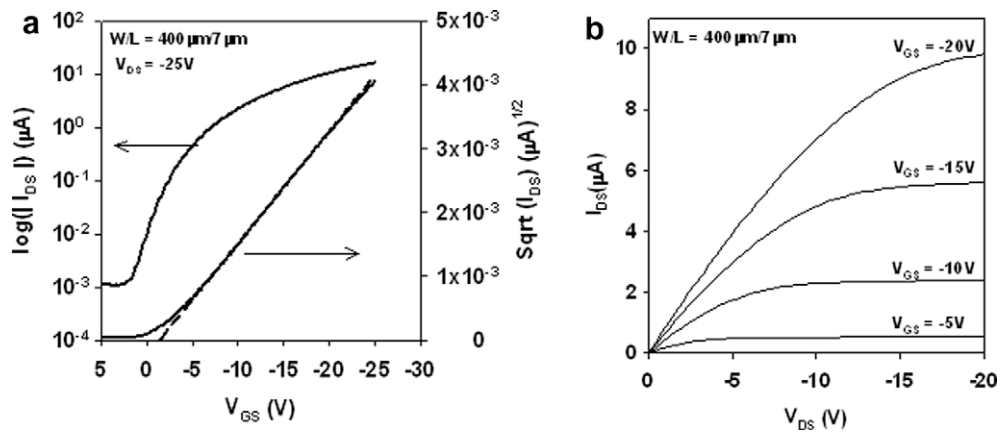

Fig. 3. (a) I_{DS}–V_{GS} for pentacene pMOS TFTs. (b) I_{DS}–V_{DS} for pentacene pMOS TFTs. Excellent transistor behavior is observed.

Fig. 3b shows typical I_{DS}–V_{DS} for the pMOs transistors obtained using the process described above. From these results we extracted a hole mobility of (0.05 cm^2/V s) and threshold voltage of −1.4 V. Fig. 3b shows the I_{DS}–V_{DS} curve-family, where drain-source voltage (V_{DS}) is swept from 0 V to −25 V for different gate voltages (V_{GS}). Excellent transistor characteristics are observed. The resulting circuits fabricated with the integration approach described above are discussed next.

Fig. 4a shows an optical image of a CMOS inverter, fabricated with the process described above. A typical voltage transfer curve for inverters is shown in Fig. 4b. The CMOS inverter has W/L for pMOS and nMOS of 500/5 and 100/11 µm, respectively. The inverter transition point is at $V_{DD}/2$, as expected from our circuit simulations, and shows a maximum DC gain of ~16. Figs. 5a and b show optical images and input–output characteristics for 2-input NAND and NOR gates, respectively. In both cases, for input A, a square wave with a 20 ms period and 50% duty cycle is used; for input B, a square wave with a 40 ms period and 50% duty cycle is used. As expected for a NAND gate, the output stays high except when both A and B are logic high.

On the other hand, for NOR gates the output stays low except when both A and B are logic low, as expected. These results demonstrate that with our integration approach we can achieve working CMOS devices on flexible substrates.

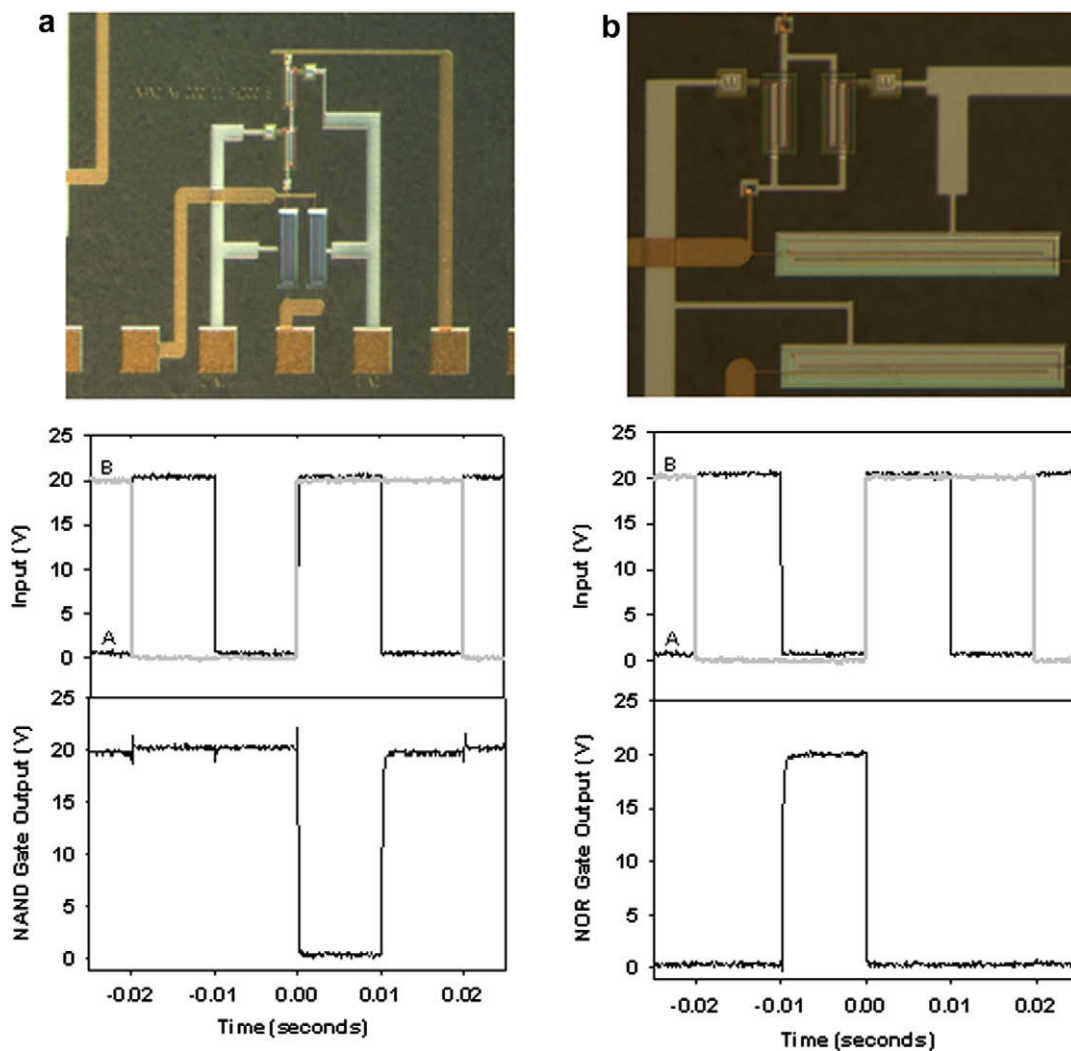
It is well known that many types of TFTs are electrically unstable, and their performance degrades with electrical usage and/or ambient conditions [28]. We have performed initial electrical stress testing of the integrated devices and the results are shown in Fig. 6. Fig. 6a (top) shows an optical image of a pMOS device from an inverter before stress; no noticeable defects observed. However, after stress, defects in the dielectric appear and are likely due to weak spots present in the parylene dielectric. Recently, we reported detailed time dependent dielectric breakdown (TDDB) studies of parylene [29]. We demonstrated that TDDB has a power law distribution and that the parylene breakdown is mainly driven by defects in the dielectric. This is likely the cause of the parylene gate dielectric breakdown observed in the pMOS devices used to fabricate our CMOS circuits (Fig. 6b). Nevertheless, the devices functioned for approximately 8 h before failure (50% duty cycle).
Fig. 4. (a) Optical image of the resulting CMOS inverter. (b) Voltage transfer curve and gain of the hybrid CMOS inverter.


Fig. 5. (a) Optical image of the resulting NAND (top) and logic verification (bottom). (b) Optical image of the resulting NOR (top) and logic verification (bottom).
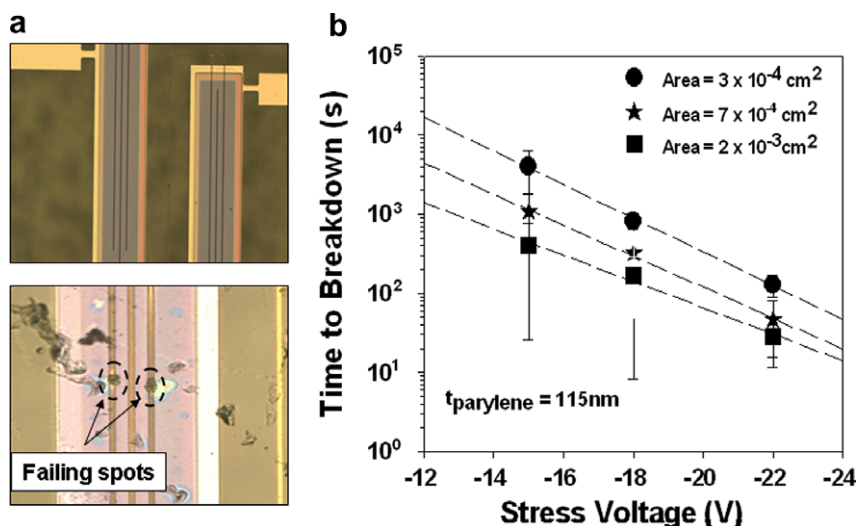

Fig. 6. (a) Optical image showing as fabricated (top) and stressed devices (bottom). (b) Area and voltage dependence for parylene TDDB. For a given stress voltage the larger the area the lower the time to breakdown. This indicates the presence of defects in the parylene dielectric.

3. Conclusions

We have demonstrated a novel integration approach for pentacene pMOS and a-Si:H nMOS. These TFTs were integrated on a flexible PEN substrate to fabricate CMOS circuits including inverters, NAND and NOR gates. The maximum processing temperatures are 180 °C for nMOS and 120 °C for the pMOS. Inverters with a gain of 16 were demonstrated and 2-input NAND and NOR gates with excellent logic behavior were demonstrated. Initial reliability of these devices indicates that the parylene gate dielectric in the pMOS limits device lifetime due to electrical stress. We are currently evaluating alternate gate dielectrics to improve CMOS device reliability.

Scheme 1. (a) Schematic depiction of P3HT/C_{60} BHJ solar cell using novel approach with retro Diels–Alder reaction, (b) structure of soluble fullerene derivatives.

solubilizing group [13]. But more dramatically, polyacetylene was processed from a soluble precursor and converted to insoluble polyacetylene via a retro Diels–Alder reaction by Feast et al. [14] and a phthalocyanine was generated *in situ* via a retro Diels–Alder reaction by Aramaki et al. [15].

We thus have attempted a novel approach for high-efficiency BHJ solar cells utilizing a BHJ active layer consisting of poly(3-hexylthiophene) (P3HT) as a donor and buckminsterfullerene, C_{60} as an acceptor. Recently, we synthesized the modified fullerene derivatives [16], hexyl 5,6-C_{60}-bicyclo[2.2.1]hept-2-ene-2-carboxylate (**C_{60}–CpCO$_2$Hex**), octyl 5,6-C_{60}-bicyclo[2.2.1]hept-2-ene-2-carboxylate (**C_{60}–Cp CO$_2$Oct**), and 2-ethylhexyl 5,6-C_{60}-bicyclo[2.2.1]hept-2-ene-2-carboxylate (**C_{60}–CpCO$_2$EHex**) to provide better solubility in organic solvents. Interestingly, the addends with their solubilizing side chain, in these derivatives, are easily dissociated into pure C_{60} and side chain by retro Diels–Alder (DA) reaction over 100 °C. A BHJ film of P3HT and one of the above mentioned modified fullerene derivatives spun-cast from solution converts efficiently into one consisting of P3HT and pure C_{60} after heat-treatment above 100 °C (Scheme 1).

2. Results and discussion

The soluble fullerene derivatives, **C_{60}–CpCO$_2$Hex**, **C_{60}–CpCO$_2$Oct**, and **C_{60}–CpCO$_2$EHex** used in this study were synthesized from Diels–Alder reaction of C_{60} and Thiele's esters that are made by DCC coupling reaction of Thiele's

acid (dicyclopentadiene dicarboxylic acid) and hexanol, octanol, and 2-ethlyhexanol, respectively. The retro DA reaction of these derivatives occurs by simple annealing above 100 °C, and the dissociated side chains are evaporated below 200 °C, as shown by thermogravimetric analysis (TGA).

All **C_{60}–CpCO$_2$Hex**, **C_{60}–CpCO$_2$Oct**, and **C_{60}–CpCO$_2$EHex** films by solution processing reveal typical behavior of ideal n-type OFETs as shown in Fig. 1. A non-negligible big difference between **C_{60}–CpCO$_2$Hex**, **C_{60}–CpCO$_2$Oct**, and **C_{60}–CpCO$_2$EHex** in the I_{ds} vs. V_{gs} is not clearly observed. The linear plot of $I_{ds}^{1/2}$ vs. V_{gs} derived from the measurements of I_{ds} vs. V_{gs} yields electron mobilities of $\mu_1 = 1.4 \times 10^{-3}$ cm^2/V s, $\mu_2 = 1.5 \times 10^{-3}$ cm^2/V s, and $\mu_3 = 3.1 \times 10^{-3}$ cm^2/V s for **C_{60}–CpCO$_2$Hex** (μ_1), **C_{60}–CpCO$_2$Oct** (μ_2), and **C_{60}–CpCO$_2$EHex** (μ_3), respectively.

BHJ films were prepared under optimized conditions according to the following procedure reported previously [7]. In the course of studying the characteristics of over 500 solar cells, we have determined the optimum component ratio for the BHJ consisting of P3HT/**C_{60}–CpCO$_2$R**. The characteristics of device performance were compared with a P3HT/C_{60} BHJ solar cell as reference device. To clarify the new approach for P3HT/C_{60} BHJ solar cells, we investigated the change of infrared (IR) absorption for P3HT/**C_{60}–CpCO$_2$-Hex** BHJ films. Fig. 2 shows the FTIR spectra of as-prepared P3HT/**C_{60}–CpCO$_2$Hex** BHJ film (red line),[1] after annealing at

Fig. 2. Infrared (IR) spectra of as-prepared P3HT/**C₆₀–CpCO₂Hex** BHJ film (red line) after annealing at 120 °C (black line) followed by vacuum drying (blue line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

120 °C (black line), followed by vacuum drying (blue line). The carbonyl stretching peak of at 1700 cm^{-1} from **C₆₀–CpCO₂Hex** ester group appears clearly in the as-prepared film and decreases in intensity after annealing at 120 °C,

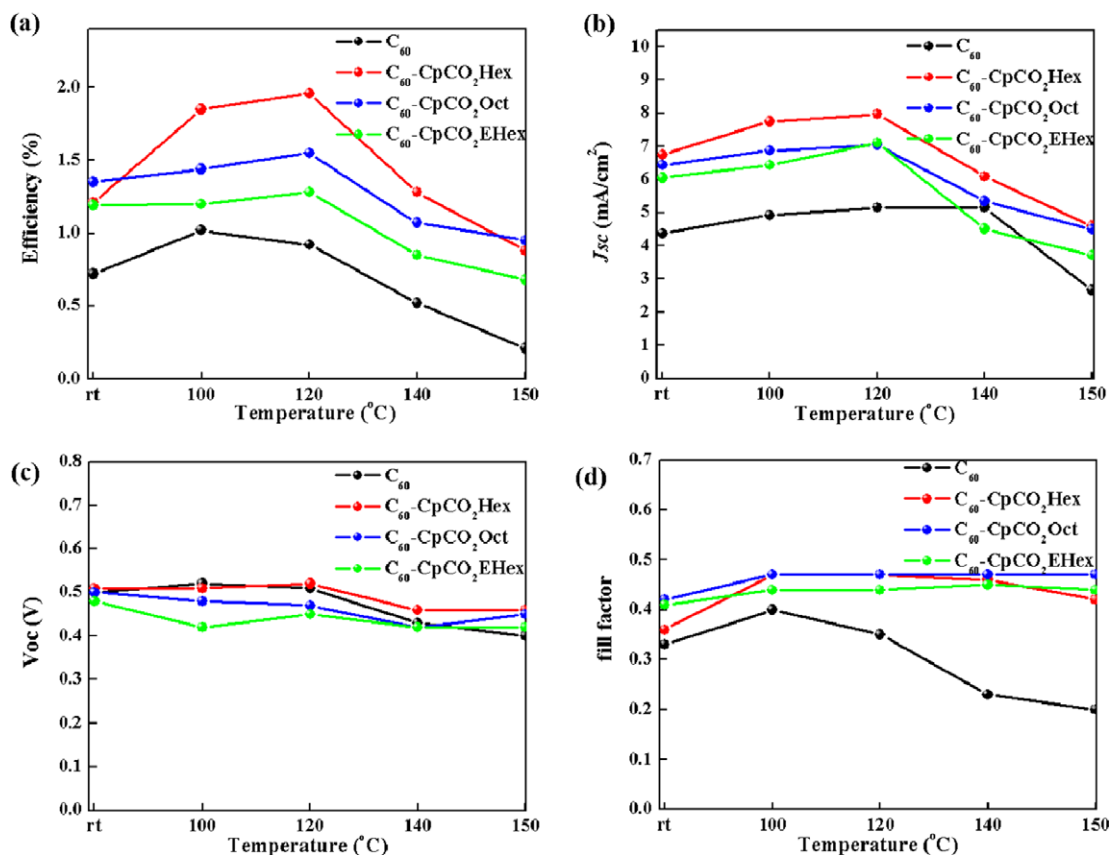
indicating the dissociation into pure C$_{60}$ and volatile side chain. The peak almost disappeared after vacuum drying below <10^{-6} torr of the annealed P3HT/**C₆₀–CpCO₂Hex**


Fig. 3. Photovoltaic device characteristics (efficiency (a), Jsc (b), Voc (c), and FF (d)) of ref. P3HT/C$_{60}$ (black) and P3HT/C$_{60}$ induced from P3HT/**C₆₀–CpCO₂R** (**R** = **Hex (red), Oct (blue), and EHex (green)**) film. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

BHJ film at 120 °C. Similar results were also observed with the other addends, **C_60–CpCO_2Oct** and **C_60–CpCO_2EHex**. From these results, it is clear that the retro DA reaction approach applied to P3HT/**C_60–CpCO_2R** (**R = Hex, Oct, and EHex**) BHJ films, produces a P3HT/C_60 BHJ film and the dissociated side chain could be removed under the high vacuum conditions required for the aluminum electrode deposition.

Fig. 3 shows the photovoltaic device characteristics (e.g. *Jsc, Voc, FF*, and power-conversion efficiency) of refs. P3HT/C_60 and P3HT/C_60 resulting from P3HT/**C_60–CpCO_2R** (**R = Hex, Oct, and EHex**) films. The P3HT/C_60 BHJ film from P3HT/**C_60–CpCO_2R** exhibits better performance than the ref. P3HT/C_60. The optimum efficiencies of these thermally generated P3HT/C_60 BHJ devices, from all P3HT/**C_60– CpCO_2R**, are observed after post-annealing at 120 °C and that are significantly degraded beyond this temperature

The ref. P3HT/C_60 BHJ device exhibits a decreased efficiency above 100 °C. As shown in Fig. 2, the **C_60–CpCO_2Hex** yields the highest performance among these **C_60–CpCO_2R** (**R = Hex, Oct, and EHex**) fullerene derivatives. The efficiency is two times higher than that obtained with C_60, likely derived from high *Jsc* and *fill factor*. The values obtained from all devices are similar. Besides, interestingly, the decrease in efficiency of P3HT/C_60 BHJ devices derived from P3HT/**C_60–CpCO_2R** by annealing above 120 °C are mainly governed by the decrease in their *Jsc* but the decrease in efficiency of ref. P3HT/C_60 BHJ device above 100 °C is caused by the decrease in their fill factor. These results indicate that the morphology of P3HT/C_60 BHJ film based on P3HT/**C_60–CpCO_2R** BHJ film could be better than as-prepared P3HT/C_60 BHJ film and the use of **C_60–CpCO_2. Hex** gives the best P3HT/C_60 BHJ film, compared to the others.
Fig. 4. Tapping mode AFM images of ref. P3HT/C_60 BHJ film after annealing at 120 °C (a) and 140 °C (b) and P3HT/C_60 BHJ film induced from P3HT/**C_60– CpCO_2Hex** BHJ film after annealing at 120 °C (c) and 140 °C.

Fig. 4 shows the tapping mode AFM images of ref. P3HT/C_{60} BHJ film after annealing at 120 °C (a) and 140 °C (b) and the images of P3HT/C_{60} BHJ film produced from the P3HT/**C_{60}–CpCO$_2$Hex** BHJ film after annealing at 120 °C (c) and 140 °C (d). As shown in Fig. 3, the ref. P3HT/C_{60} BHJ film at 120 °C exhibits large aggregated domains of C_{60} due to its strong Van der Waals interaction but even though the P3HT/**C_{60}–CpCO$_2$Hex** BHJ film at 120 °C, had converted into a P3HT/C_{60} BHJ film, it exhibited much better morphology compared with the reference P3HT/C_{60} BHJ film. Although more and larger aggregate domains of C_{60} are observed in the reference film at 140 °C, the film based on P3HT/**C_{60}–CpCO$_2$Hex** BHJ at 140 °C shows relatively less aggregated morphology. These results indicate that the P3HT/C_{60} BHJ film converted from well-defined P3HT/**C_{60}–CpCO$_2$Hex** BHJ film by retro DA reaction produces better morphology than that of the ref. P3HT/C_{60}. Note that the polymer in a well-blended former film can slow down the aggregation of C_{60} with increasing temperature, resulting in a better bicontinuous network.

3. Conclusions

In conclusion, we have demonstrated a new approach for high-efficiency BHJ solar cells utilizing a BHJ active layer consisting of P3HT as a donor and buckminsterfullerene, C_{60} as acceptor. P3HT/C_{60} BHJ films generated by facile separation of C_{60} from its soluble adduct, **C_{60}–CpCO$_2$R** (**R = Hex, Oct, and EHex**) by retro Diels–Alder reaction above 100 °C exhibit enhanced performances and showing better morphologies, compared to an as-prepared P3HT/C_{60} BHJ film. In addition, the polymer in the former film reduces the aggregation of C_{60} with increasing temperature, an effect that is absent in the latter films with concomitant decrease in efficiency of P3HT/C_{60} BHJ solar cells.

4. Experimental

Poly(3,4-ethylene-dioxythiophene):poly(styrensulfonate) PEDOT:PSS (Baytron PH) was spun-cast on an indium tin oxide (ITO)-coated glass substrate from aqueous solution to form a film of thickness around 40 nm. The substrate was dried for 10 min at 140 °C in air, then transferred into a glove-box to spin-cast the active layer. A solution containing a mixture of P3HT/ **C_{60}–CpCO$_2$R (R = Hex, Oct, and EHex**) (1:0.7) in chlorobenzene was then spun-cast on top of the PEDOT:PSS layer. Subsequently, after the film was dried at 80 °C for 10 min, followed by

retro DA reaction at 120 °C in N_2 atmosphere, the device was pumped down in vacuum (<10^{-6} torr; 1 torr – 133 Pa), and a ~100 nm thick Al electrode was deposited on top. For calibration of the solar simulator, we first carefully minimized the mismatch of the spectrum (the simulating spectrum) obtained from the Xenon lamp (300 W Oriel) and the solar spectrum using an AM1.5G filter. We then calibrated the light intensity using calibrated standard silicon solar cells with a proactive window made from KG5 filter glass traced to the National Renewable Energy Laboratory (NREL). Measurements were done with the solar cells inside the glove-box using an optical fiber to guide the light from the solar simulator outside the glove-box. Current density–voltage curves were measured with a Keithley 236 source measurement unit. The AFM images were obtained with a Dimension 3100 atomic force microscope.

of molecules due to their ability to self-assemble into microscopic elongated crystalline aggregates, or 'nanofibers' [6]. In addition to their polarized and highly anisotropic photoluminescence output [7] and their wave guiding [8] and lasing [9] properties, chemical functionalization of these molecular building blocks opens the way for the specific tailoring of nanofiber properties at the molecular level [10]. Electrical interfacing to individual nanofibers allows the electrical properties to be studied [11] and could enable the fabrication of nanoscale LEDs (as electroluminescence has been observed from oligophenylene thin films [12]) with configurable properties.

We have previously conducted experimental investigations of charge transport in a large number of individual nanofibers made from para-hexaphenylene (p6P) molecules and have found their hole mobility to be above 0.3 cm^2 V^{-1} s^{-1} [13]. In this work, we present a similar investigation of two other types of nanofibers made from 5,5′-di-4-biphenylyl-2,2′-bithiophene (PPTTPP) [14,15] and 4–4′-di-2,2′-dithienyl-biphenyl (TTPPTT) [15], respectively, and compare the results here with those from the p6P nanofibers. The molecular structures, crystal lattice geometries, and fluorescence microscopy images of all three materials are shown in Fig. 1.

To complement the experimental studies, we have also used quantum–mechanical calculations to study the charge transport properties. There are two main régimes of charge transport in organic molecular crystals, the band-like régime, similar to 'conventional' charge transport in inorganic single crystals, or the hopping régime, where the carrier is localized on one molecule through the formation of a self-trapped state (a polaron) and transport occurs through a thermally activated hopping mechanism [19]. The band-like régime is generally observed only at low temperatures in highly ordered samples [20], so that the hopping mechanism is usually in effect at temperatures relevant for practical technological applications. In the hopping régime, the carrier mobility is proportional to the intersite electron transfer rate k_{ij}, which, in the semi-classical approximation, can be evaluated by the Marcus equation [19,21],

$$k_{ij} = t_{ij}^2 \sqrt{\frac{\pi}{\hbar^2 k_B T \lambda_{ij}}} \exp\left(-\frac{(\Delta E_{ij} - \lambda_{ij})^2}{4\lambda_{ij} k_B T}\right), \tag{1}$$

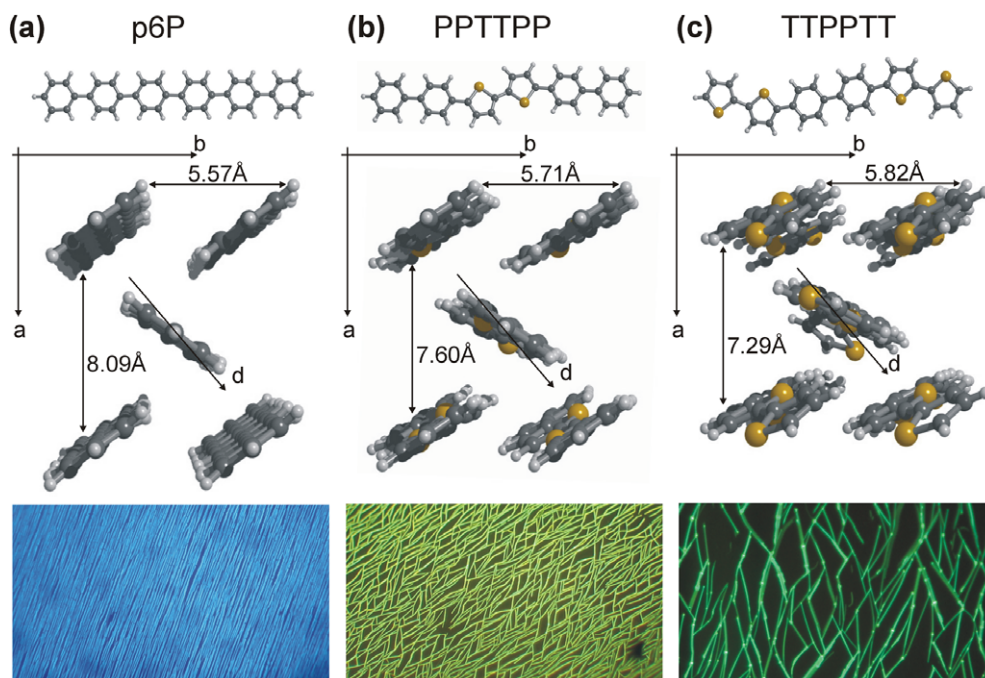
where t_{ij} is the transfer integral, λ_{ij} is the reorganization energy, ΔE_{ij} is the energy difference between the initial and final states, T is the temperature, and k_B and $\hbar$ are the Boltzmann and Planck constants, respectively. Since the energy difference between initial and final states in a crystal is often vanishingly small [22], the two parameters governing the transfer rate at a particular temperature are the reorganization energy and transfer integral. Here, we have used density functional theory (DFT) to evaluate differences in reorganization energies and transfer integrals of the three types of molecular crystals and have related these calculated charge transfer parameters to experimentally determined charge carrier mobilities.


Fig. 1. Molecular and crystal structures of (a) p6P, (b) PPTTPP, and (c) TTPPTT. The geometric data of the crystal structures are from Refs. [16–18], respectively. The arrows indicate the crystal lattice directions used in the density functional theory calculations. The bottom part shows fluorescence microscopy images of nanofibers made from the above molecules (p6P nanofibers, 112 μm × 63 μm; PPTTPP nanofibers, 223 μm × 125 μm; TTPPTT, 130 μm × 74 μm).

2. Methods

2.1. Experimental details

The nanofibers are fabricated by physical vapor deposition of the molecules from a Knudsen cell onto a heated muscovite mica substrate under high vacuum conditions [6]. Through interaction with the electrical surface dipoles of the mica substrate, the molecules align and self-assemble into nanofiber aggregates with typical cross-sectional dimensions of a few hundred nanometers (width) by tens of nanometers (height) and a length of tens of micrometers. The fluorescence micrographs in Fig. 1 show the three types of as-grown nanofibers on mica substrates. Upon growth, a few nanofibers are transferred from the mica substrate to a prefabricated device substrate consisting of an elevated silicon dioxide platform on a silicon chip. The nanofiber transfer is accomplished by gently pressing the mica substrate against the device substrate under conditions of high humidity, which releases the nanofibers from the mica substrate. By inspection with a fluorescence microscope, a suitable nanofiber is identified and a set of electrodes is made using a silicon nanowire as a local shadow mask during metal deposition to form the two gold top contacts on the nanofiber [11]. Gold has a relatively high work function and, consequently, the use of gold contacts leads to hole conduction [13]. After metal deposition, the nanowire shadow mask is removed by mechanical manipulation, and the sample is wire bonded for electrical characterization. The electrical measurements are carried out using a home built setup consisting of a Labview-controlled NI PCI-6229 DAQ device and Stanford Research SR570 current pre-amplifier. The transport properties are studied by two-point measurements in which current is measured as the applied voltage is increased from 0 V. The sample dimensions, in particular the uncoated length of the nanofiber (distance between electrodes) and its cross-sectional dimensions, have been determined from SEM and AFM (tapping mode) measurements.

2.2. Theoretical details

To determine the charge transfer rate, k_{ij}, using Eq. (1), the transfer integral and the reorganization energy must be calculated. The transfer integral is determined mainly by the intermolecular overlap of the frontier molecular orbitals of the involved molecules – HOMO (highest occupied molecular orbital) for hole transfer and LUMO (lowest unoccupied molecular orbital) for electron transfer. Therefore, its value depends on molecular packing structure. Recently, Valeev et al. [22] described a transfer integral calculation method that includes the influence from site energy differences that can arise from geometric differences and polarization effects between inequivalent molecules in the crystal unit cell. By defining one-electron dimer states from localized monomer orbitals (ψ_i) and assuming that the dimer HOMO and HOMO−1 (LUMO+1 and LUMO) originate only from the interaction of the monomer HOMOs (LUMOs), the site energies e_i and transfer integrals t_{ij} are obtained from

$$e_i = \langle \psi_i | \hat{H} | \psi_i \rangle \tag{2}$$

$$t_{ij} = \langle \psi_i | \hat{H} | \psi_j \rangle, \tag{3}$$

where $\hat{H}$ is the Hamiltonian. Since Eq. (1) assumes an orthogonal basis and the monomer orbitals are, in fact, not strictly orthogonal, the transfer integral as determined by Eq. (3) cannot be applied directly. First, an orthonormal basis set is required and is obtained using Löwdin's symmetric transformation [22] to give

$$t_{12}^{eff} = \frac{t_{12} - \frac{1}{2}(e_1 - e_2)S_{12}}{1 - s_{12}^2}, \tag{4}$$

where S_{12} is the overlap integral. Here, density functional theory (DFT) is used together with Eqs. (2)–(4) for calculation of transfer integrals.

The reorganization energy comprises both inter- and intramolecular contributions [1]. The intermolecular part is due to the polarization and relaxation of the surrounding medium. The intramolecular part is due to the changes in equilibrium geometries of both the donor and acceptor molecules upon charge transfer and, therefore, consists of two terms related to each of the molecules involved: (1) the relaxation of the donor molecule upon going from the charged-state geometry to the neutral-state geometry (λ_0) and (2) the relaxation of the acceptor molecule upon going from the neutral-state geometry to the charged-state geometry (λ_1), respectively. The intramolecular reorganization energy is determined from the adiabatic potential surfaces as

$$\lambda_0 = E_{0/1} - E_{0/0} \tag{5}$$

$$\lambda_1 = E_{1/0} - E_{1/1}, \tag{6}$$

where $E_{0/0}$ and $E_{1/1}$ are the ground state energies of the neutral and charged molecule, respectively, $E_{1/0}$ is the energy of the charged state at the optimal geometry of the neutral state, and $E_{0/1}$ is the energy of the neutral state at the geometry of the charged molecule. The intramolecular reorganization energy is determined by calculating the energies at the various optimized geometries of a single molecule in the gas phase. In the gas phase, all three molecules considered here will exhibit significant inter-ring torsional angles that are not observed in the solid-state geometry where the molecules exhibit more coplanar geometries. To be consistent with the geometries observed in the crystal structure, intramolecular reorganization energies have been obtained by constraining the molecules to planar geometries during the optimization process.

The transfer integral calculations have been performed using the Amsterdam Density Functional [23] and Gaussian 98 [24] software packages, while the calculation of the intramolecular reorganization energies was done using Gaussian 98 [24]. For the transfer integral calculations, the PW91 functional was used with a DZP basis set. This functional was found by Huang and Kertesz to provide results in closest agreement with experimental values [25]. In the calculation of reorganization energies, hybrid functionals that include a fraction of Hartree–Fock exchange provide higher estimates of reorganization energies than pure DFT methods. By comparison with experimental re-

sults from photoelectron spectroscopy studies on oligoacenes [26] and oligothiophenes [27], recent reports found the B3LYP functional to yield values closest to experiments. Therefore, the B3LYP functional is used in the calculations of intramolecular reorganization energies.

3. Results and discussion

3.1. Experiment

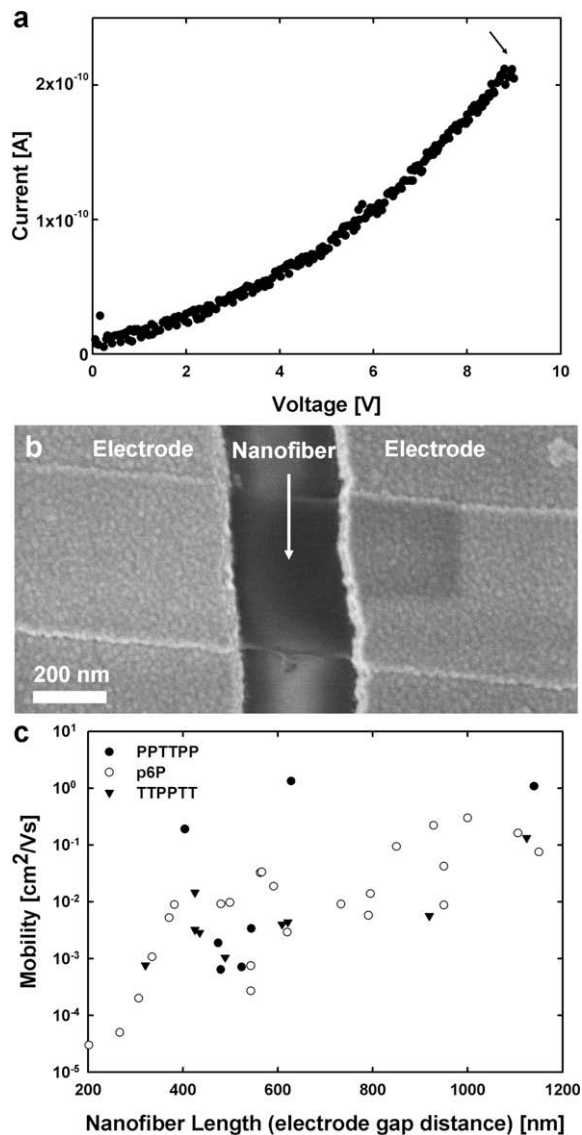
Fig. 2a shows a typical current–voltage data set from an individual nanofiber (a TTPPTT oligomer type) contacted


Fig. 2. (a) Typical result of a current versus voltage measurement on a single nanofiber (here made from TTPPTT molecules) contacted with two gold electrodes. The arrow indicates the point used in the calculation of the mobility as described in the text. (b) Scanning electron microscopy image of a nanofiber supported on silicon dioxide and contacted with two gold electrodes. (c) Charge carrier mobility estimates from individual p6P, PPTTPP and TTPPTT nanofibers based on the Mott–Gurney formalism as described in the text.

with gold electrodes. We use the Mott–Gurney formalism to analyze the data, as has been done in previous studies [13]. This allows the charge carrier mobility μ to be estimated from

$$\mu_{\min} = \frac{8IL^3}{9\varepsilon_r\varepsilon_0 AV^2},\tag{7}$$

where I is the current, L is the device length, $\varepsilon_r\varepsilon_0$ is the dielectric permittivity, A is the cross-sectional area, and V is the applied voltage. The use of Eq. (7) implicitly assumes charge transport in the space-charge limited (SCL) regime and does not account for additional current-limiting factors such as interface barriers or charge traps. These factors effectively reduce the current from its theoretical maximum. The resulting mobility estimated from Eq. (7) should, therefore, be interpreted as a lower bound to the accurate value of the mobility.

A TTPPTT nanofiber with gold electrodes is seen in the SEM image in Fig. 2b, from which the uncoated length (321 nm) and width (428 nm) are obtained. The height (35 nm) is determined from AFM data (not shown), and A is found as the product of the width and height. We estimate the uncertainty on the length and width data to be ±5% and on the height data to be ±10%. The uncertainty on the mobility is considered to be affected primarily by the uncertainty on the SEM and AFM data. This leads to a worst-case uncertainty on $\mu_{\min}$ of +35%/−26%. Ten samples were prepared for each of the PPTTPP and TTPPTT nanofibers. From those samples, seven PPTTPP and nine TTPPTT samples exhibited current–voltage characteristics that indicate current flow through the nanofibers. The remaining samples displayed much lower resistances, which upon closer inspection were found to originate from short circuits caused by metal residues from the contacting process. Fig. 2c shows these 16 mobility values versus nanofiber length together with the data from 24 p6P nanofiber samples from Ref. [13].

Since charge carrier mobility is an intrinsic material parameter, no length dependence is expected. The mobility data presented in Fig. 2c seems to indicate that the longer the nanofiber, the higher the estimated mobility. This implies that for the shorter nanofibers, the estimate provided by Eq. (7) is significantly below the true mobility, most likely due to contact effects that reduce the current. This is not unexpected, as contact effects are more severe for short samples where the bulk nanofiber resistance is comparably small. For longer nanofibers, however, the contribution from the nanofiber bulk to the resistance is higher, and Eq. (7) is expected to provide a better estimate. Therefore, we expect that the long nanofibers provide the best estimate of the true mobility. The largest estimated carrier mobility is found for PPTTPP and is 1 cm² V⁻¹ s⁻¹. Both p6P and TTPPTT exhibit carrier mobilities approximately an order of magnitude below that.

3.2. Theory

The transport properties and hence charge mobility in molecular crystals exhibit a directional anisotropy. By selecting different combinations of molecules, the effective

transfer integrals along various crystal directions indicated in Fig. 1 can be found and are listed in Table 1. Pentacene is often regarded as a benchmark for evaluating electronic coupling strengths and hole mobilities, with typical mobility values of more than 1 cm^2 V^{-1} s^{-1} at room temperature [28] and with values up to 35 cm^2 V^{-1} s^{-1} having been reported [29]. For comparison, the transfer integrals for pentacene are larger than those calculated for the systems that are investigated here. In pentacene, the effective hole transfer integral (along the d1 diagonal direction) is 85 meV [30]. The intramolecular reorganization energies relevant for both hole and electron transfer in p6P, PPTTPP, and TTPPTT molecules were calculated and are listed in Table 2. Reorganization energies for pentacene and hexathiophene (α-6T) are provided for comparison.

In order to obtain an estimate of the charge transfer rate, the charge transfer parameters we have calculated can be injected into Eq. (1). The contribution of the intermolecular part to the total reorganization energy is usually assumed to be smaller than or of same order of magnitude as the intramolecular contribution [1,32]; exact values are difficult to estimate since they require to take account of the lattice phonons. Here, since we are mainly interested in trends, we have chosen to take into account the potential contributions of the intermolecular reorganization energy to the entire reorganization energy in an effective way: we have simply calculated the hole and electron transfer rates along the diagonal direction in the p6P crystal for different amounts of external reorganization energy, shown in Fig. 3. If an intermolecular reorganization energy of 0.1 eV is used, transfer rates of 3×10^{12} s^{-1} and 3×10^{10} s^{-1} for electron and hole transfer are obtained, respectively. Fig. 3 illustrates that when similar values for the external reorganization energies are used for both electron and hole transfer, the hopping rate for electrons is $\sim 10^2$ larger than for holes in this crystal direction.

The intermolecular contribution to the reorganization energy is generally less dependent on the chemical structure than the intramolecular part [1]. Thus, as a first step, we assumed that the external contributions were similar in all the systems considered here and evaluated the charge carrier transfer rates relative to that in pentacene. Due to its superior transport properties, the latter can be considered as a benchmark system and its transfer rate has been found by inserting the previously quoted transfer integral and reorganization energy into Eq. (1). The charge transport parameters for oligophenylene and oligophenylene–thiophene crystals have been calculated to describe charge transport in nanofiber structures. In order to make

Table 2

this correlation, we consider the transfer integrals corresponding to charge transfer along the long direction of the nanofiber, which approximately corresponds to the direction of the applied electric field in the experimental geometry shown in Fig. 2. For p6P, this would correspond to the charge transfer occurring in the d direction of the crystal (see Fig. 1). Since the contact face between the growth substrate and the PPTTPP or TTPPTT crystals is currently not known experimentally, the direction of the applied electric field relative to the crystal structure is also unknown. Therefore, a charge hopping direction similar to that observed in p6P is assumed, i.e. along the diagonal. For hole transfer, we find that the transfer rates in p6P and PPTTPP are similar and approximately three orders of magnitude smaller than in pentacene. The large hole transfer integral along the d direction in TTPPTT (see Table 1) re-

Table 1

sults in a hopping rate (using a planar geometry to calculated the intramolecular reorganization energy) $\sim 10^{-2}$ times that of pentacene.

3.3. Discussion

The experimentally found carrier mobilities are up to $1\,cm^2\,V^{-1}\,s^{-1}$ for PPTTPP and roughly an order of magnitude smaller for both p6P and TTPPTT. The value of $1\,cm^2\,V^{-1}\,s^{-1}$ for PPTTPP is one of the largest observed mobilities for such nanoscale organic crystals. These results can be compared with the mobility found in pentacene of up to $35\,cm^2\,V^{-1}\,s^{-1}$. However, it should be noted that pentacene molecules cannot to our knowledge self-assemble into nanofibers and are, therefore, less suited for applications that require structuring at the nanoscale. Based on the transfer rate calculations, crude estimates of the mobility can be made from the Einstein relation $\mu = eD/k_BT$, in which e is the electronic charge and D the diffusion coefficient [33]. D can be estimated from $D = L^2 k_{ij}/2$, where L is the effective length of charge transfer that can be approximated by the center of mass distance [33]. By neglecting the intermolecular reorganization energy, this leads to mobility estimates of $10^{-2}\,cm^2\,V^{-1}\,s^{-1}$ for p6P and PPTTPP, while TTPPTT is predicted to have a mobility of $10^{-1}\,cm^2\,V^{-1}\,s^{-1}$. For comparison, this type of calculation provides an estimate of the mobility in pentacene of $10^1\,cm^2\,V^{-1}\,s^{-1}$. We again emphasize that the approximations made here render these mobility estimates rather crude.

The theoretical evaluations of the transfer rates (and thus mobilities) for all three systems considered here result in values that are two to three orders of magnitude lower than that found in pentacene, in reasonable agreement with the experimental findings. However, while PPTTPP is found experimentally to exhibit the highest mobility, theory estimates TTPPTT to be the better conductor. The likely explanation resides in the assumption we made of equal intermolecular contributions to the reorganization energy of all systems; we come back to this point below.

In general, the LUMO transfer integral is larger than the corresponding HOMO transfer integral. The magnitude of the transfer integrals along different directions can be rationalized by considering the molecular structures in Fig. 1. The distance between molecules in a pair has a strong influence on the degree of electronic interaction [19]. As seen in Table 1, the electronic coupling strength is large in the cofacial geometry. Since the dimers taken out of the crystal structure in the a and b directions are essentially displaced cofacial dimers, and since the molecules oriented along the b direction are significantly closer to one another than the molecules along the a direction, the transfer integrals are found to be larger along the b direction.

The reorganization energies in the oligophenylene and oligophenylene–thiophene molecules are larger than the corresponding values determined for pentacene. This is consistent with the observed lower charge mobilities. The molecular backbone of these structures is less rigid than in pentacene, which has very low reorganization en-

ergy on the order of 0.1 eV [34]. The reorganization energy for hexathiophene is also included in Table 2, since hexathiophene would be the next molecular structure in the sequence of p6P, PPTTPP, and TTPPTT. An increase in reorganization energy is observed upon the presence of thiophene rings with TTPPTT having a lower reorganization energy than PPTTPP. We recall that the reorganization energies have been calculated while constraining the molecules to planar geometries, which is reasonable in the case of p6P and PPTTPP for which on average approximately coplanar geometries are observed in the crystal structure [17,35]. In contrast, TTPPTT exhibits a wavy oscillation in the geometry along the long axis of the molecule [18] (seen clearly looking down the long axis of the molecule shown in Fig. 1). We speculate that the wavy structure in the crystal phase could give rise to more significant intermolecular contributions to the reorganization energy; this might be the origin of the discrepancy in the trends between the calculated transfer rates and the measured carrier mobilities in our series of compounds.

4. Conclusions and outlook

The charge transport properties for three molecular systems: p6P, PPTTPP, and TTPPTT, all of which can self-assemble into nanofiber structures, have been investigated both experimentally and theoretically. The experimental study was made by electrical two-point measurements on individual nanofibers. The analysis of the electrical measurements is based on the Mott–Gurney formalism, which describes charge transport in the space-charge limited régime. Therefore, it provides estimates of the lower bound of the carrier mobility. Experimentally, all three types of nanofibers were found to exhibit carrier mobility ranging from 0.1 to $1\,cm^2\,V^{-1}\,s^{-1}$ with PPTTPP nanofibers having the highest mobility.

In such molecular crystals, charge transport occurs via incoherent hopping between neighboring molecules. We analyzed the transport parameters on the basis of the semi-classical Marcus theory, which relates the rate of charge transfer to the transfer integral between the two molecules involved in the transfer process and to the reorganization energies accompanying the charge relocation. The transfer integrals in various crystal directions and the intramolecular reorganization energies were estimated for the three systems by density functional theory calculations. In the crystal direction corresponding to the charge transport direction in the experimentally realized geometry, the theoretical estimates of the magnitude of the carrier mobilities in p6P, PPTTPP, and TTPPTT with respect to that for pentacene were found to be in good agreement with experiment.

Further experimental effort is now focused on investigating the charge transport properties in a field-effect transistor configuration to enable the determination of the field-effect mobility. Furthermore, other types of nanofibers can be formed from other phenylene-based molecules, which could exhibit improved electrical characteristics. The next step will be to include theoretical

modeling of these systems to determine the most promising candidates for experiments.

represents a monodentate phosphine ligand] (as shown in Fig. 1) were employed in the preparation and studies of WOLEDs. The widely used blue phosphorescent emitter, FIrpic, exhibits very high photoluminescence (PL) quantum efficiency (>90%) in wide-gap hosts [6–8]. On the other hand, the Os complex Os(bpftz)$_2$(PPh$_2$Me)$_2$ with high steric hindrance shows orange–red emission around 603 nm, short excited-state lifetime (0.97 μs) and high PL quantum yield of ~90% in solution [9–11]. The present and related Os complexes had been used to fabricate highly efficient orange to red phosphorescent OLEDs with external quantum efficiencies approaching 20% [9–11]. Thus both iridium and osmium triplet emitters are intrinsically very efficient.

Selected spectral data of Os(bpftz)$_2$(PPh$_2$Me)$_2$: MS (FAB, ^{192}Os): m/z 1130 (M$^+$), 930 (M$^+$–PPh$_2$Me), 730 (M$^+$– 2PPh$_2$Me). ^{1}H NMR (400 MHz, d$_6$-acetone): δ 10.04 (d, 2H, J_{HH} = 6.8 Hz), 7.26–7.24 (m, 4H), 7.15–7.09 (m, 4H), 7.00 (t, 4H, J_{HH} = 7.6 Hz), 6.93–6.86 (m, 8H), 6.65–6.60 (m, 4H), 1.29 (s, 18H, ^{t}Bu), 1.22 (d, 6H, J_{HP} = 3.2 Hz, Me). UV/Vis λ_{max} (CH$_2$Cl$_2$): 401 (16,000), 448 (2500), 520 (1400) nm (ε, M^{-1}cm^{-1}); EL λ_{max} (degassed CH$_2$Cl$_2$, RT): 603 nm; ϕ = 0.91; τ_{obs} = 972 ns. EL λ_{max} (as thin film): 613 nm; τ_{obs} = 136 ns. Anal. Calcd. for C$_{50}$H$_{50}$F$_6$N$_8$OsP$_2$: C, 53.18; N, 9.92; H, 4.46. Found: C, 53.30; N, 10.06; H, 4.62.

2.2. OLED fabrication

All compounds used were subject to temperature-gradient sublimation under high vacuum before use. OLEDs were fabricated on the ITO-coated glass substrates with multiple organic layers sandwiched between the transparent bottom indium–tin-oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by vacuum evaporation in a vacuum chamber with a base pressure of <10^{-6} torr. The deposition system permits the fabrication of the complete device structure in a single vacuum pump-down without breaking vacuum. The deposition rate of organic layers was kept at ~0.2 nm/s. The active area of the device is 2×2 mm^2, as defined by the shadow mask for cathode deposition.

2.3. Device characterizations

Current–voltage–luminance (I–V–L) characterization of the devices was measured using an Agilent 4155B semiconductor parameter analyzer and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. Total photon output from the device (either from the viewing direction or from all surfaces of the device) was measured in an integrating sphere containing a calibrated photodetector.

3. Results and discussion

The first type of WOLEDs using these two complexes (i.e. Device A in Fig. 2) involved co-doping both emitters into the wide-gap host 1,3-bis(9-carbazolyl)benzene (mCP) as the emitting layer (EML) [12,13]. The structure of Device A was: ITO/α-NPD (30 nm)/TCTA (30 nm)/mCP: Firpic 8 wt.%: Os(bpftz)$_2$(PPh$_2$Me)$_2$ 0.5 wt.% (15 nm)/TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm), where 4,4′-bis[N-(1-naphthyl)-N-phenyl-amino] biphenyl (α-NPD) and 4,4′,4″-tris(carbazol-9-yl)-triphenylamine (TCTA) were used as the hole-transport layers (HTLs) [14,15], 3-(4-biphenylyl)-4-phenyl-5-(tert-butylphenyl)-1,2,4-triazole (TAZ) as the electron-transport layer (ETL) [16], and LiF as the electron-injection layer [17].

Fig. 3a shows the electroluminescence (EL) spectra of Device A (normalized at the emission peak of the Os complex) at different brightness levels, and Fig. 3b shows the corresponding 1931 CIE coordinates. The EL shows contributions from both blue emission of FIrpic and red emission of the Os complex, giving a white emission. The efficiency characteristics and the current–voltage–luminance (I–V–L)

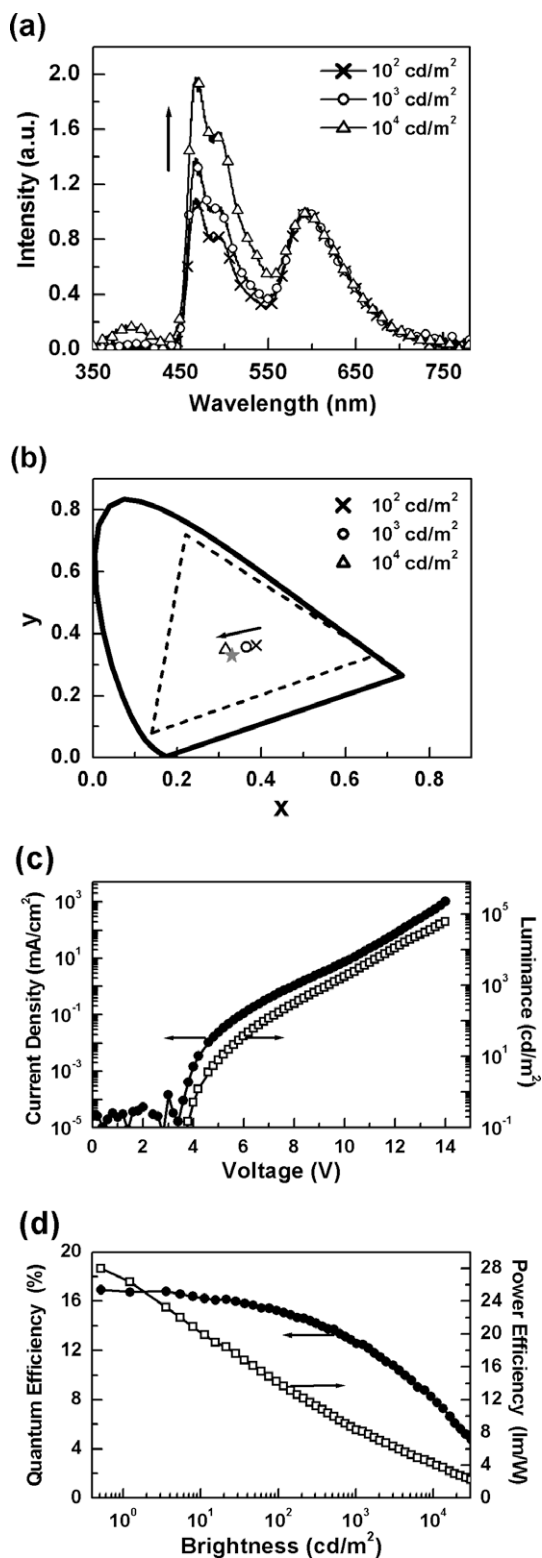
Fig. 2. Schematic structures of various devices.


Fig. 3. (a) The normalized EL spectra of Device A at different brightness levels; (b) CIE coordinates of different brightness levels. (c) Current–voltage–luminescence (I–V–L) characteristics. (d) External quantum efficiency/power efficiency (in the forward viewing direction) versus brightness.

characteristics of Device A are shown in Fig. 3c and d, respectively, and are summarized in Table 1. Impressively, with a simple single-emitting-layer configuration, the Device A shows rather high peak efficiencies of 17% photon/electron, 35.6 cd/A, and 28 lm/W for the forward viewing directions. Such high quantum efficiency implies a high internal quantum efficiency of nearly 85% in the device (assuming ~20% optical out-coupling efficiency from the device). At the practical brightness of 100 cd/m^2, the forward viewing efficiencies remained high at around 15.1%, 30.4 cd/A, and 13.6 lm/W. For lighting applications, the light emitted from all surfaces of the substrate can in principle be redirected to the forward direction by some lighting fixtures; hence the total efficiencies of the device were also characterized using an integrating sphere setup [18,19]. The total quantum and power efficiencies measured in the sphere were about 1.7 times larger than the forward viewing efficiencies, consistent with previous reports [2]. As such, Device A gave a peak total external quantum efficiency and a total power efficiency of 28.8% and 47.5 lm/W, respectively.

The high quantum efficiencies of the WOLED A were indeed surprising, since the control blue-emitting device with a structure similar to A exhibited substantially lower efficiencies. This control blue-emitting OLED (Device B, Fig. 2) had the structure of: ITO/α-NPD (30 nm)/TCTA (30 nm)/mCP: Firpic 8 wt.%/TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm), which was nearly the same as that of Device A except for no Os complex co-doped into the mCP host. Such a blue-emitting device gave a substantially lower peak external quantum efficiency of ~4.8% (in the forward viewing directions, Fig. 4c and Table 1). With co-doping a smaller amount of the Os complex in the emitting layer (i.e. Device A), the quantum efficiency of the whole system was more than tripled, indicating that the Os complex had additional and critical functionalities other than just serving as an energy acceptor for the blue emitter FIrpic.

To investigate the role of the Os complex, a third testing device structure (Device C, Fig. 2) with the Os complex doped into a portion (25 nm) of the hole-transport layer, TCTA, was then fabricated and characterized. This device had the structure of: ITO/α-NPD (30 nm)/TCTA: Os(bpftz)$_2$(PPh$_2$Me)$_2$ 3.0 wt.% (25 nm)/TCTA (5 nm)/mCP: Firpic 8 wt.% (15 nm)/TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm). The EL spectra and corresponding CIE coordinates of Devices B and C are shown in Fig. 4a and b, respectively. The external quantum efficiency versus luminance of Devices B and C are shown in Fig. 4c. As shown in Fig. 4a, EL from Device C shows dominant blue emission of FIrpic, yet the peak quantum efficiency is now largely raised to 11.7% (25.7 cd/A) as compared to 4.8% observed for Device B (Fig. 4c and Table 1). It is also worth mentioning that by replacing the 5-nm non-doped TCTA buffer in Device C with the higher-energy-gap mCP (Device C1, Fig. 2), the efficiency of the blue OLED can be further increased to 14% due to better confinement of high-energy triplet excitons (Table 1).

Comparing device results of Devices A, B, and C clearly suggests that doping the Os complex into either the hole-transport layer TCTA or the mCP host layer had improved the balance between hole and electron injection/transport

Table 1
Summary of devices characteristics.

Device	Efficiency (max.) [%, cd/A, lm/W]	Efficiency (at 10^2 cd/m^2) [%, cd/A, lm/W]	Total efficiency [%, lm/W]	CIE coordinates (at 10^2, 10^4 cd/m^2)
A	17.0, 35.6, 28.0	15.1, 30.4, 13.6	28.8, 47.5	(0.388, 0.363), (0.315, 0.348)
B	4.8, 10.2, 6.1	4.4, 9.3, 4.9	–	(0.170, 0.356), (0.172, 0.355)
C	11.7, 25.7, 12.6	11.7, 25.6, 11.8	–	(0.178, 0.359), (0.208, 0.366)
C1	14.0, 28.7, 16.8	13.6, 27.9, 12.2	–	(0.205, 0.344), (0.220, 0.344)
D	14.9, 29.3, 17.8	13.1, 25.9, 8.9	25.4, 35.3	(0.334, 0.362), (0.311, 0.356)

into the emitting layer mCP:FIrpic, thus greatly enhanced the EL efficiency. Electrochemical characterizations of related Os complexes show that they in general possessed low oxidation potentials (and thus low ionization poten-

tial). The ionization potential of the present Os complex estimated from the oxidation potential is about 4.8 eV [9], which is substantially lower than those of TCTA, mCP and FIrpic (all of 5.5–6.0 eV) [6,12–15]. In view of such an energy-level relationship, it is well expected that the Os complex functioned as an effective hole traps in both Devices A and C, retarding hole-transport and reducing excessive hole-injection into the emitting region [20–23]. Indeed, the lower voltage of Device B compared to those of Devices A and C (as compared in Fig. 5) clearly supports this hole-trapping picture. This hole trapping also reduces excessive hole-injection into the electron-transport layer since the UV emission from the electron-transport layer TAZ was generally reduced by doping the Os complex [24]. The accumulation of trapped holes might also help establish a stronger electric field for enhancing electron injection into the emitting layer. Overall, all these factors contributed to better balance of the carrier transport for both carriers and the efficiency enhancement.

The efficiencies of Device A are impressive, yet one notices that it showed a significant color shift when the bias/brightness was increased (Fig. 3a and b). Blue emission from FIrpic grows relatively to Os(bpftz)$_2$(PPh$_2$Me)$_2$ emission at higher current densities, causing the 1931 CIE coordinates to blue-shift from (0.388 0.363) to (0.315, 0.348) at the brightness of 10^2–10^4 cd/m^2. Color variation with increased bias is commonly seen in WOLEDs [25–27]. This issue may be mitigated by creating another channel in the device for the high-energy excitons to remain appropriately relaxed or be transferred to the lower-energy excited states of Os complexes even at high excitation densities. The bias- and brightness-dependent EL spectra of Device C (Fig. 4a and b) indeed provided a good hint to the design of such a device. In Device C, the contribution of the Os emission (although smaller) increased with the brightness, contrary

to the case of Device A. Such characteristic suggests that in Device C, at higher bias/brightness, either the carrier recombination zone shifted closer to the TCTA:Os(bpftz)$_2$ (PPh$_2$Me)$_2$ layer or a portion of the high-energy excitons in the mCP:FIrpic layer migrated to the TCTA:Os(bpftz)$_2$ (PPh$_2$Me)$_2$ layer (which is possible because the triplet energy of the 5-nm buffer TCTA was lower than that of FIrpic), increasing the emission from the Os complex.

Making use of such phenomena, the second type of WOLEDs in this work, Device D (Fig. 2), was fabricated using the structure of: ITO/α-NPD (30 nm)/TCTA: Os(bpftz)$_2$(PPh$_2$Me)$_2$ 3.0 wt.% (25 nm)/TCTA (5 nm)/ mCP:Firpic 8 wt.%: Os(bpftz)$_2$(PPh$_2$Me)$_2$ 0.3 wt.% (15 nm)/ TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm). Device D simultaneously incorporated a red EML and a white EML. On one hand, the concentration of the Os complex in the white EML was decreased to suppress the red emission from the white EML and to achieve a more balanced white at lower biases. On the other hand, the Os complex in the TCTA layer enhanced the red emission at higher biases. The resulting EL spectra and CIE coordinates of Device D at different brightnesses are shown in Fig. 6a and b. Compared to Device A, the variation of EL spectra with biases in Device D was greatly reduced, substantially improving the color stability. As shown in Fig. 6b, for the brightness of 10^2–10^4 cd/m^2, only a small shift of CIE coordinates from (0.334, 0.362) to (0.311, 0.356) was observed, giving ($\Delta x = -0.023$, $\Delta y = -0.006$). Fig. 6c and d show the I–V–L characteristics and efficiency of Device D. Device D gives peak efficiencies of 14.9%, 29.3 cd/A, and 17.8 lm/W in the forward viewing direction, corresponding to total peak efficiencies of 25.4% and 30.3 lm/W measured by the integrating sphere. At the practical brightness of 100 cd/m^2, this device exhibits efficiencies of 8.9 lm/W, 13.1%, and 25.9 cd/A in the forward viewing direction. The EL characteristics of devices are summarized in Table 1.

4. Conclusions

In summary, we have shown that the unique multifunctional capabilities of the orange–red phosphorescent Os complex are highly useful for achieving excellent internal and external efficiencies of WOLEDs. This is not only due to the high emission efficiency of the Os complex, but also due to its effective hole trapping capability, which is beneficial and useful for balancing hole/electron transport when doped at appropriate locations of the device. Furthermore, by placing an emitting/trapping layer incorporating the Os complex in the proximity of a white-emitting layer also incorporating the Os complex, we also report an efficient phosphorescent WOLED structure that would provide improved color stability versus biases/ brightnesses. Overall, we conclude that the multi-functionality of the phosphorescent Os complex may be of use for designs of highly efficient white phosphorescent OLEDs.

OFETs using the "macroscopic-sized" semiconductor single crystals. Here the macroscopic-sized crystals are roughly a 0.1-mm-square (or more) in size and the semiconductor devices can readily be made on them. Such crystals were hard to make by conventional vacuum deposition methods [8,9,15–17] including hot wall epitaxy (HWE) [18–23].

Our method resembles the physical vapor transport (PVT) [2–4,7,24–26] in that the crystal growth is carried out at an ordinary pressure. However, our method is more suitable for making the thin crystals directly onto the substrate; the PVT methods are mostly used for the fabrication of free-standing single crystals. Moreover, we need only a small size apparatus. The apparatus can be accommodated in a ∼10-cm cube (excluding a space of an inert atmosphere).

To achieve highest possible performance the crystals must have the smallest possible number of defects. Although in our initial attempt the crystals involved many cracks as in the case of the previous paper [13], we have been successful in removing them by inserting self-assembled monolayers (SAMs) between the semiconductor crystal and the device substrate. At the same time, the SAMs play a role in constructing a uniform interface between the organic semiconductor layer and the gate insulator [27].

Fig. 1a shows a schematic geometry of the apparatus. It is characterized by a couple of plates (one of which acts as the FET device substrate) put in close proximity such that their distance is kept less than 1 mm (typically 0.7 mm) by spacers placed at either side. Two heaters are vertically set in close contact with these plates. The source organic material is placed to be sublimed on the lower plate. The temperatures of the two heaters are regulated so that the bottom heater temperature can be held by 5–10 °C higher than that of the upper heater, allowing the crystals to grow directly on the upper substrate. In virtue of the narrow space surrounded with the two plates the crystal growth proceeds nearly at the thermodynamic equilibrium. This

enables us to produce high-quality single crystals with macroscopic size. The resulting crystals are well-defined polygons with individual sides clearly appearing. Moreover, these crystals are of the thickness of a hundred to several hundreds of nanometers and perfectly suited to forming the devices.

2. Experimental

2.1. Substrate preparation

We used for the substrates quarried Si wafers (∼1 cm × 1 cm) with a thermally grown SiO_2 layer (300 nm in thickness). The substrates were cleansed in a hot aqueous solution of sulfuric acid and hydrogen peroxide for 1 h and subsequently rinsed with distilled water in an ultrasonic cleaner for 10 min. These substrates were treated with three different species of SAMs. For the **1,1,1,3,3,3**-hexamethyldisilazane (HMDS) treatment, the substrates were exposed to HMDS vapor at 80–85 °C for 2 h and further immersed with toluene, acetone and isopropyl alcohol in the ultrasonic cleaner for 3–5 min each to remove the excess HMDS. In the case of phenyltrichlorosilane (PTS) the substrates were immersed into its 0.86 M toluene solution for 6 h and subsequently rinsed with toluene, acetone, and isopropyl alcohol in the ultrasonic cleaner for 10 min each. With the octadecyltrichlorosilane (OTS) treatment the substrates were immersed for 16 h in its 12.5 mM solution of a hexane/toluene mixture (hexane:toluene = 2:8) and rinsed similarly. All these substrates were further cleansed with ethanol vapor before use.

2.2. Crystal growth

Of the organic semiconductors, we chose from among thiophene/phenylene co-oligomers (TPCOs) 1,4-bis(5-phenylthiophen-2-yl)benzene (AC5) [28] and 5,5''''-diphenyl-2,2':5',2'':5'',2''':5''',2''''-quinquethiophene (P5T) [29]. Their structural formulae are depicted in Fig. 1b (AC5) and c (P5T). Their synthesis and purification methods are described in the literature [28,29].

The source organic material placed on the lower plate faced the oxide layer of the quarried Si wafer substrate attached to the upper heater (Fig. 1a). The bottom heater (to sublime the source material) is 5, 3 and 10 cm in width, height and length, respectively. The corresponding sizes of the upper heater (for the substrate) are 5, 3 and 5 cm. These are composed of a copper block equipped with a sheath heater. This configuration permits us to grow the crystal in firm contact with the oxide layer of the Si substrate and subsequently to shape the device. The crystal growth is routinely performed in a nitrogen atmosphere with the gas flow rate of 40 ml/min to prevent the organic material from degrading. In the case of the AC5 (P5T) growth the temperature of the upper heater was kept steadily at 223 °C (265 °C) for 5.5 h (8.5 h). The temperature of the bottom heater was kept at 230 °C (270 °C) for the first 1 h and then lowered monotonically to 223 °C (265 °C) taking another 4.5 h (7.5 h) in the case of the AC5 (P5T) growth.
Fig. 1. (a) Schematic diagram of the crystal growth apparatus. The distance of a couple of plates (the upper one of which acts as a substrate) is kept less than 1 mm (typically 0.7 mm) by glass spacers placed at either side. Two heaters are vertically set in close contact with these plates. (b and c) Structural formulae of the organic semiconductor materials. (b) AC5 and (c) P5T.

2.3. Structural characterization and electrical measurements

The nonpolarizing and polarizing micrographs of the grown crystals and fabricated devices were taken with a NIKON ELIPSE LV100POL microscope equipped with an Hg lamp. The X-ray diffraction of the AC5 crystals (placed on the substrates) was measured on a Rigaku RINT 2500 X-ray diffractometer with Cu Kα radiation. The thickness of the crystals was measured with an ULVAC DEKTAK-3ST surface profiler. The surface feature of the AC5 crystal grown on the HMDS-treated substrate was precisely observed using a Veeco Instruments Di Multimode IIIa atomic force microscope (AFM) operated in a tapping mode. The electrical measurements were carried out for the crystal devices using an Advantest R6245 two-channel voltage current source/monitor under an ambient environment and under vacuum ($\sim 10^{-3}$ Pa).

3. Results and discussion

3.1. Crystal growth and characterization

Fig. 2 shows a micrograph of an AC5 crystal (grown on the SiO$_2$/Si substrate without surface treatment). The crystal is a hexagon with each side ranging from 172 to 251 μm. Many cracks were present on its surface. These cracks were likely to be generated during the crystal growth process because of the difference in thermal expansion coefficients between the AC5 crystal and the substrate. The orientation of the cracks is parallel to the crystal axes. Fig. 3 shows polarizing micrographs of a crystal grown on the substrate treated with HMDS. The micrographs were taken under the diagonal position (Fig. 3a) and the extinction position (Fig. 3b) of the crossed Nicols. The hexagon crystal is free from the cracks. The size of the crystal sides ranged from 199 to 222 μm. An entirely vanishing view of the crystal at the extinction position (Fig. 3b) demonstrates the formation of a single crystal.

Fig. 3c shows the X-ray diffraction pattern of AC5 crystals grown on the HMDS-treated substrate. Only the first-

and higher-order peaks (up to 14th at 59.9°) of the same diffraction plane are observed. The plane distance is evaluated from these peaks to be $d = 21.74$ Å, in good agreement with the half distance of the *ab*-plane (21.63 Å) [30]. We determined the crystal axes as in Fig. 3a by comparing the characteristic angles of the crystal with the crystallographic data [30]. Fig. 3d shows the surface profile of the AC5 crystal scanned along the crystal *b*-axis. The crystal has a uniform thickness of 820 nm within an error of $\sim$3 nm. Fig. 3e shows the three-dimensional AFM picture of the AC5 crystal scanned over an area of 2 μm × 2 μm. Fig. 3f shows its depth profile as a function of the position. The observed step height is estimated to be $\sim$0.27 nm, indicating that the surface of the AC5 crystal is exceedingly flat with its roughness of at most the molecular length.

With a PVT method Liu et al. [13] fabricated micrometer-sized patterns of organic semiconductor single crystals with controlled sizes and shapes. Recently, we have demonstrated in the solution process that the crystals are selectively grown on the friction-transferred poly(tetrafluoroethylene) with the crystal axes preferentially oriented parallel to the drawing direction [31]. Our present method can consistently be combined on demand with such an epitaxial method to produce the micrometer-sized patterns.

3.2. Field-effect transistors made of the grown crystals

The crystals obtained by our method can immediately be applied to the OFET devices. Fig. 4a shows a micrograph of the device made of an AC5 crystal grown on the HMDS-treated substrate (top-contact configuration). The thickness of this particular crystal was 624 nm. Fig. 4b schematically shows the device structure. For the device to perform the normal action, it will be indispensable to secure the ohmic contact between the semiconductor layer and (source and drain) electrodes. This is done with the AC5 device by improving the deposition of metal; the substrate surface was tilted $\sim$30° to the deposition source to completely cover the crystal edges with gold (see the inset of Fig. 4b) [32]. The gold electrodes (70 nm in thickness) were formed in vacuum (less than 3×10^{-3} Pa) so as to be the drain and source contacts. The resulting parallel electrodes define the channel length as 20.4 μm and the width as 131.0 μm. The silicon wafer and the silicon dioxide layer were used as a gate contact and a gate insulator, respectively. Fig. 4c represents the output characteristics of the AC5 device in air. The device shows the typical p-type performance. Compared to our previous top-contact AC5 crystal devices [14,33], the convex-downward behavior of the drain current near the origin is drastically suppressed. The estimated mobility and threshold voltage at the saturation region were 0.040 cm^2/V s and −0.72 V, respectively. Those measured in vacuum were 0.037 cm^2/V s and −2.0 V. The mobility is significantly larger than those of our previous studies [14,33,34].

P5T crystal devices exhibit even better device performances. Fig. 5a shows a micrograph of the device made of a P5T crystal on the HMDS-treated substrate. The thickness of this particular crystal was 100 nm. Deposited gold electrodes define the channel length as 10.4 μm and the

Fig. 3. (a and b) Polarizing micrographs of an AC5 crystal on the SiO$_2$/Si substrate treated with HMDS before the crystal growth. These were taken under (a) the diagonal position and (b) the extinction position (i.e. rotated by 45° relative to the diagonal position) of the crossed Nicols. An entirely vanishing view of the crystal at the extinction position demonstrates the formation of a single crystal. (c) X-ray diffraction pattern of AC5 crystals on the HMDS-treated substrate. (d) Surface profile of the AC5 crystal. (e) Three-dimensional AFM picture of the AC5 crystal and (f) its depth profile.

channel width as 46.3 μm. The width was the average of w_1 and w_2 (Fig. 5a). The P5T device exhibits an excellent performance and sustains it both in air and in vacuum. To demonstrate this, we have repeatedly carried out the electrical measurements both in air and in vacuum (total 15 measurements in air and 10 measurements in vacuum) during fifteen days after the device fabrication. The device was stored in a vacuum desiccator after the measurements. Fig. 5b represents the output characteristics of the said P5T device measured in air at the last day. The p-type FET performance is characterized as follows: (i) the saturation in the drain current is clearly noted at higher drain–source voltages. (ii) the drain currents increase linearly with drain–source voltage around the origin (see Fig. 5c as the enlarged diagram); even a hint of a convex-downward behavior is unnoticeable.

The device sustains the aforementioned characteristics throughout the whole courses of data acquisition both in air and in vacuum. During these courses the device steadily keeps the mobility and threshold voltage. Taking into

account all these data (obtained both in air and vacuum), the mobilities ranged 0.09–0.13 cm^2/V s and the threshold voltages ranged −11.6 to −0.27 V. Notice that the varying range of the threshold voltages (∼11 V) is by far smaller than the corresponding number ∼100 V which was observed by Kumaki et al. [35] for the pentacene-based OFET in air. They attributed this shift to the deprotonation of SiOH on the gate insulator surface caused by the adsorption of H$_2$O and O$_2$ [35]. This contrast is due probably to that in the present studies the crystals are in close contact with the gate insulator assisted by the SAMs. This prevents air and moisture from infiltrating into that interface and, hence, ensures the steady device performance.

Similar device performances were attained in the P5T crystal devices fabricated on the substrates treated with the other SAMs. Fig. 6a shows the output characteristics of the P5T crystal device on the PTS-treated substrate. The characteristics of the OTS-treated device are indicated in Fig. 6b. The channel length and width of the PTS device

Fig. 5. (a) Micrograph of the top-contact OFET device made of a P5T thin crystal. The substrate was treated with HMDS. (b) The output characteristics of the P5T device. The measurements were repeatedly carried out both in air and in vacuum during fifteen days after the device fabrication. The particular characteristics were obtained in air at the last day. The carrier mobility and threshold voltage were estimated to be 0.10 cm^2/V s and −0.27 V in the saturation region, respectively. (c) Enlarged characteristics of (b) around the origin.

are 9.7 μm and 20.7 μm, respectively. Those of the OTS device are 10.0 μm and 70.8 μm. These SAM-treated devices exhibited the steady device performances as well. We examined the device performance during eleven (a hundred) days after the PTS (OTS) device fabrication. For the PTS device, the mobility and threshold voltage measured in air (in vacuum) at the last day were 0.13 cm^2/V s (0.13 cm^2/V s) and −5.4 V (−9.4 V) in the saturation region, respectively; those for the OTS device were 0.051 cm^2/V s (0.056 cm^2/V s) and 3.2 V (−2.2 V). For this device the mobility tended to increase with time during the course of the storage; the threshold voltage varied ∼20 V across the 0 V.

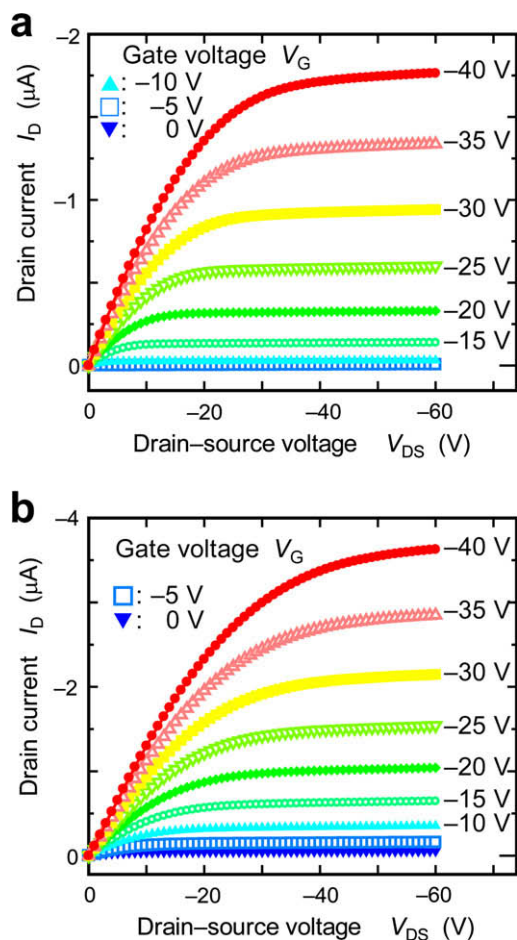
The mobilities we have recorded for the AC5 devices are two times as high as those obtained previously [14,33,34]. The highest mobility achieved in the present studies was


Fig. 6. Output characteristics of the P5T crystal OFET devices on the substrate treated with (a) PTS and (b) OTS. The PTS-treated device was measured both in air and in vacuum during eleven days. OTS-treated one was similarly measured during a hundred days. Both the characteristics were obtained in air at the last day.

0.13 cm^2/V s for the P5T device, comparable to that of a related TPCO material, 5,5″-bis(4-biphenylyl)-2,2′:5′,2″-terthiophene (BP3T) [14]. Nonetheless, the mobility level was two orders of magnitude lower than that of e.g. a rubrene-based device [7]. Two major issues are present in the OFET studies. One is related to the electrical contact between the organic layer and the electrodes and the other is pertinent to the choice of the gate insulator materials. The former issue was improved appreciably (see Figs. 5 and 6 for the complete suppression of the convex-downward behavior). With the other issue, however, we were not able to fully optimize the gate insulator materials. Recently Bisri et al. [36] recorded a mobility 1.6 cm^2/V s for the BP3T-based device, an order of magnitude higher than that obtained for the same material [14]. The point was that Bisri et al. [36] used poly(methyl methacrylate) for the gate insulator, whereas Yamao et al. [14] used SiO$_2$ for it. On the basis of this illustration the gate insulator materials will have to be further explored including the SAM species [7,37,38].

4. Conclusions

We have developed the method of making the high-quality thin single crystals directly onto the SiO$_2$/Si substrates in a vapor phase. The growth apparatus requires only a small space ($\sim$10-cm cube). The crystal growth is carried out within the narrow space surrounded with the two plates that are in close contact with heaters. In virtue of this configuration, the crystal growth proceeds nearly at the thermodynamic equilibrium, producing well-defined thin single polygon TPCO crystals of several hundreds of micrometers in size. In particular, we have succeeded in growing the exceedingly flat crack-free single crystals on the substrates treated with HMDS, PTS, and OTS as SAMs.

We have fabricated the top-contact OFETs using the TPCO crystals. The devices show the excellent performance and keep it steadily both in air and in vacuum more than ten days (maximum a hundred days). The pivotal points are summarized as follows: (i) the ohmic contact is fully secured between the organic semiconductor layer and the (source and drain) electrodes. (ii) The firm and uniform interface is formed between the organic layer and the gate insulator. The good ohmic contact is achieved by using the thin crystals (the P5T devices) or by the oblique metal deposition on the crystal (the AC5 device). The SAM is inserted as a part of the gate insulator between the semiconductor crystal and the device substrate to produce the ideal organic layer/gate insulator interface. The present method of the crystal growth can thus be suitably applied to other optical and electronic devices as well as the OFETs.

[9,10]. In this paper we can rule out this influence. Also fiber isolation is not needed and the use of solvent mixtures is avoided, which may allow for easier recycling of processing solvent. We found an optimal efficiency at a 42% fiber content of the casting solution and show that it can be linked to the morphology of the active layer.

2. Experimental

2.1. Preparation of P3HT fibers

P3HT was prepared via the Rieke method [11]. The regioregularity was determined at >94.5% and it had a M_n of 23.7 kg mol^{-1} (polydispersity index of 1.80) as determined by Analytical Size Exclusion Chromatography (SEC). The SEC was performed using a Spectra series P100 (Spectra Physics) pump equipped with two mixed-B columns (10 μm, 2 × 30 cm, Polymer Labs) and a Refractive Index detector (Shodex) at 60 °C. Chlorobenzene was used as the eluent at a flow rate of 1.0 mL/min. Molecular weight distributions are given relative to polystyrene standards. P3HT fibers were prepared by slow cooling of an orange coloured 0.7 wt% P3HT solution in *p*-xylene, as described elsewhere [11].

2.2. Solar cell fabrication

After the preparation of the P3HT fibers in the *p*-xylene solution, PCBM ([6-6]-phenyl C$_{61}$-butyric acid methyl ester (Solenne)) was added to the solution in a 1:1 weight ratio with P3HT to act as acceptor material. The casting solution was stirred for ~48 h at room temperature. The solar cells were prepared starting from indium tin oxide (ITO, 100 nm) coated glass plates that were successively cleaned in a soap solution, demineralised water and acetone, each for 10 min in an ultrasonic bath. This was followed by cleaning in boiling isopropanol for 10 min. A 25 nm thick poly(3,4-ethylenedioxythiophene–polystyrenesulfonate (PEDOT–PSS (Bayer)) layer was spin-coated on the clean glass/ITO substrates. The substrates were dried for 20 min on a hot plate at 120 °C. The active layer (P3HT:PCBM 1:1), was spin-coated at 750 rpm on top of the PEDOT–PSS layer. The solution from which the active layer was spin-coated, was heated gradually to several temperatures (between 37 and 50 °C). At each temperature used for the experiment, the solution was left to stabilize for at least 30 min before the active layer was spin-coated on top of the PEDOT–PSS layer. After deposition of the active layer, the devices were left in vacuum (10^{-6} mbar) to get rid of the remaining solvent. Finally, a calcium layer (~25 nm) and an aluminium layer (~70 nm) were evaporated to form the top contact of the solar cell. Each photovoltaic device had an active area of 25 mm^2. The *I–V*-characteristics were measured with an Oriel solar simulator equipped with a Xenon Short Arc lamp with a power of 150 W.

2.3. Morphology of the active layer studied with TEM

For each solution temperature, the morphology of the active layer was studied. A thin film, identical to the active layer of the solar cell, was deposited on a cleaned glass substrate, using the same procedure as for preparing the complete solar cell. This film was isolated by etching with 40% hydrofluoric acid (HF) to remove the glass substrate and then put on a copper TEM-grid. TEM-measurements were performed with a Philips CM12-STEM. The SAED patterns, recorded through TEM, originally suffered from a large background that resembled inelastic scattering. To improve the signal-to-noise ratio, integration across the complete diffraction ring was done, from which a fitted background due to inelastic scattering was subtracted (under the assumption that the blend in between the fibers is quasi-amorphous [12]).

2.4. Determination of the fiber content in the solution

At each solution temperature used for preparing a photovoltaic device, a small amount (<50 μL) of the casting solution was isolated just after spin-coating and diluted in ~3 mL of *p*-xylene of the same temperature. UV–Vis measurements (with a Varian Cary 500 Scan UV–Vis–NIR spectrophotometer) were performed on this highly diluted solution after cooling to room temperature. The obtained UV–Vis spectra were fitted as a sum of previously recorded spectra of PCBM, well-dissolved P3HT and fully fibrillar P3HT, all in *p*-xylene. The known relation between the latter two spectra allowed for the determination of the fiber content [11].

3. Results and discussion

Fig. 1 shows the photovoltaic (PV) parameters of solar cells with a nanofiber-P3HT:PCBM 1:1 active layer as a function of casting solution temperature together with the fiber content of the solution at each temperature. The graph shows that the fiber content of the solution is very sensitive to temperature. When raising the temperature from 37 to 50 °C, the fiber content of the solution decreases from 60% to 14%. The solar cell efficiency displays a quadratic dependence on temperature. An optimal efficiency of ~3.2% is found for a solution temperature of 45 °C. At this temperature, the fiber content was 42%. When comparing the different PV-parameters, it seems that the behavior of the efficiency is strongly related to the behavior of the short circuit current J_{sc}. The open circuit voltage V_{oc} of the solar cells has an increasing trend. The fill factor follows a rather rough course.

The origin of the dependence of the photovoltaic performance on the temperature of the casting solution can be found in the active layer morphology. Fig. 2 shows Bright Field Transmission Electron Microscopy (BFTEM) images of the active layers. The active layer spin-coated from a solution at a relatively low temperature (37 °C) shows large (up to 50 μm) needles (Fig. 2(a, left)). Spots in the Selected Area Electron Diffraction (SAED) patterns of the needles confirm that they are groups of PCBM single crystals [13]. In between the needles, fibers of P3HT are visible (Fig. 2(a, right)). They appear dark against a light background. SAED also gives information about this part of the active layer. In Fig. 3, the residual intensities of the
Fig. 1. Fiber content of the casting solution, efficiency η, short circuit current J_{sc}, open circuit voltage V_{oc} and fill factor of nanofiber-P3HT:PCBM (1:1) solar cells as a function of solution temperature.

Fig. 2. Bright Field TEM images of P3HT:PCBM 1:1 spin-coated from a solution at 37.1 °C (a), 40.5 °C (b), 41.9 °C (c), 44.9 °C (d) and 49.9 °C (e), at low temperatures PCBM assembles in needle-like structures, P3HT fibers appear as dark or light areas depending on the presence of PCBM within the polymer matrix. The insets show the SAED patterns of either the PCBM needles (left) or the homogeneous P3HT:PCBM regions (right).

SAED patterns of the homogeneous areas of the active layers are shown (the area in between the PCBM crystals). These curves were obtained after integration across the diffraction ring followed by subtraction of a fitted background due to inelastic scattering (*cf.* Experimental). For the film spin-coated at 37 °C, the residual intensity SAED pattern shows a clear peak at 0.38 nm (Fig. 3). This peak can be attributed to the superposition of the (0 0 2) and (0 2 0) reflections from the crystal planes of semi-crystalline P3HT [14]. The remainder of the SAED pattern appears featureless and no peaks corresponding to PCBM can be distinguished. This indicates that the major part of PCBM is assembled in the needles. By slightly increasing the solution temperature to ∼40 °C, a change in morphology is immediately observed. The PCBM needles have grown larger (Fig. 2b). We believe that the PCBM needles were formed in the casting solution during the long (>48 h) stirring at room temperature and elevated temperatures and not during spin-coating of the active layer. The spin-coating takes <120 s, which does not leave much time for the formation of such large needles. The long time available during stirring together with the perfect crystal shape and dependence of the crystal size on the temperature of the casting solution, all indicate that the crystals were formed during stirring of the casting solution by an Ost-

Fig. 3. Residual intensities of the SAED patterns of the polymer:PCBM matrix for several solution temperatures.

wald ripening process [15]. Higher temperatures accelerate the Ostwald ripening; therefore less but larger PCBM needles are visible at the solution temperature of ∼40 °C. These needles have grown at the expense of the needles

that were present in solution at $\sim$37 °C. For the solution temperature of $\sim$40 °C, a small increase in the diffraction intensity at 0.46 nm can be seen in the SAED pattern of the area in between the needles (Fig. 3). This small peak indicates that some amount of nano-crystalline PCBM [16] is now present in between the fibers. Apparently a small part of the PCBM has dissolved in the p-xylene at this temperature; the PCBM is no longer completely grouped in the needles. This gives a higher yield of exciton dissociation at the polymer:PCBM interface and thus a higher J_{sc} and better solar cell performance (*cf.* Fig. 1). As opposed to the film made from a solution at 37 °C, the P3HT fibers are now visible as light areas in the BFTEM image (Fig. 2). This is caused by the presence of PCBM with a higher density in between the polymer matrix [2]. A further increase of the solution temperature leads to the disappearance of the PCBM needles (Fig. 2). For solution temperatures of $\sim$42 °C, $\sim$45 °C (Fig. 3) and $\sim$48 °C (not shown) strong peaks corresponding to both P3HT (at 0.38 nm) and PCBM (at 0.2, 0.31 and 0.46 nm [16]) are present. These temperatures also correspond to the best photovoltaic performances (Fig. 1). Good charge transport due to crystalline P3HT, in combination with a large interfacial area between polymer and PCBM render good solar cells. At a solution temperature of $\sim$50 °C, there is a slight drop in solar cell efficiency. At this point the fiber content has decreased strongly, which will likely result in less efficient hole transport.

4. Conclusion

We have demonstrated that the fiber content of the P3HT-fiber:PCBM casting solution can be easily controlled by temperature. Meanwhile, the dissolution of PCBM varies with temperature. The combined effect can be used to control the active layer morphology in photovoltaic devices and thus also their performance. An optimal solar cell efficiency was found at a solution temperature of $\sim$45 °C when the fiber content was 42%. BFTEM images of the active layer morphology combined with SAED patterns revealed that this optimal photovoltaic efficiency occurred when the PCBM was dissolved completely at the highest possible fiber content. The initial increase in efficiency with temperature of the casting solution could be attributed to an increased solubility of PCBM in the casting solu-

tion. At temperatures lower than 41 °C, PCBM formed large (>50 μm) needles in the casting solution by Ostwald ripening, resulting in poorly mixed active layers and low solar cell efficiencies. At temperatures of 45 °C and higher, the PCBM was dissolved well and, after reaching its maximum, the solar cell efficiency started to decrease again with decreasing fiber content (due to the increasing solution temperature).

in combination with its technological compatibility in terms of materials (e.g. dielectrics including SiO_2 and polymers) and device architecture with standard bottom-contact transistors used in circuits.

In this work, we study the injection of electrons and holes in bilayer gate dielectric memory transistors, and demonstrate a reprogrammable ambipolar memory transistor in which trapping of electrons and holes from the transistor channel into the gate dielectric allows to program and erase the memory device at low voltages. The ambipolar nature of carrier injection in our device is illustrated by comparing the behavior of the ambipolar memory transistor with that of a unipolar p-type (a pentacene device measured in air) and a unipolar n-type device (based an a perylene derivative).

2. Experimental

2.1. Organic memory transistor fabrication

The transistors in this study have a bottom gate structure with top source and drain contacts as depicted in Fig. 1. All devices were fabricated on a highly n-doped Si wafer, which serves as the gate electrode, with 20 nm of thermally grown SiO_2 on top. On this substrate, a thin layer of poly(alpha-methyl styrene) (PαMS) was deposited by spin-coating a 0.1 wt.% PαMS (Fluka, Mw ~700,000) solution in toluene at 4000 rpm, followed by drying at 120 °C for 1 min on a hot plate. The thickness of the PαMS layer was measured by ellipsometry to be 3–5 nm. The SiO_2 and the PαMS layers form together the gate dielectric of the memory transistor. Subsequently, a 40-nm thick layer of pentacene or N,N'-ditridecyl-3,4,9,10-perylenetetracarboxylic diimide (PTCDI-$C_{13}H_{27}$) was deposited by thermal vacuum evaporation ($p \sim 10^{-8}$ Torr). The deposition rate and the substrate temperature during pentacene deposition were 0.25 Å/s and 68 °C, respectively. PTCDI-$C_{13}H_{27}$

was evaporated at room temperature at a rate of 0.40 Å/s. Finally, Au (on the pentacene devices) or LiF/Al (on the PTCDI-$C_{13}H_{27}$ devices) source and drain contacts were evaporated through a shadow mask.

The transistors had channel lengths, L, ranging from 50 μm to 210 μm. The channel width, W, was 2000 μm. For the pentacene devices, the initial hole mobility, extracted from the linear regime, $\mu_{h,init}$ and the initial threshold voltage $V_{T,init}$ were typically ~0.8 cm^2/(V s) and ~−1 V. For the devices with PTCDI-$C_{13}H_{27}$ the initial electron mobility $\mu_{e,init}$ was ~0.1 cm^2/(V s) and $V_{T,init}$ ~1 V.

2.2. Measurement method

Electrical data was obtained using two computer controlled Keithley 2602 units in a darkened nitrogen glovebox. Samples were not subjected to air, unless differently stated.

The typical measurement protocol was as follows. First, the initial characteristics were measured. The initial turn-on voltage of the device was determined. We defined the turn-on voltage, V_{on}, as the gate-source voltage V_{GS} at which the drain current I_D reaches 100 pA. Then, the device is subjected to a series of programming pulses, with intermediate gate voltage sweeps. The drain-source voltage during programming $V_{DS,prog}$ is always kept at 0 V.

The exact measurement procedure is illustrated in Fig. 2. We apply two subsequent pulses with the same duration, t_{prog}, and equal but opposite gate voltage, $V_{GS,prog}$. The pulse with negative $V_{GS,prog}$ shifts the transfer characteristics towards negative V_{GS}, while the positive $V_{GS,prog}$ shifts them towards positive V_{GS}. This is done twice to have a stable result. After each of the last two pulses, a small part of the transfer characteristics is measured to determine the V_{on}. V_{on-} denotes the turn-on voltage after the negative pulse, and V_{on+} denotes the value after the positive pulse. ΔV_{on} is defined as the difference between V_{on+} and V_{on-}. This last value is the memory window between the two different memory states. These measurement steps can then be repeated for different t_{prog} or $|V_{GS,prog}|$.

3. Results and discussion

3.1. Charge carrier trapping as a function of programming voltage

In Fig. 3a, we plotted the transfer characteristics of pentacene transistors, obtained with the measurement procedure described above and with a series of programming pulses of +/−17 V and +/−20 V. In this case, t_{prog} was kept constant at 1.5 ms. A shift of the turn-on voltage with the same polarity as the gate voltage is observed. This is attributed to the trapping of electronic charges in the vicinity of the semiconductor/insulator interface [6]. When pentacene is deposited directly on SiO_2, the change in turn-on voltage was less than 1 V (data not shown). This indicates that the presence of the PαMS is key to achieve the desired charge trapping and that these charge carriers are probably trapped in the polymer dielectric and/or at the interface between the polymer dielectric and SiO_2.

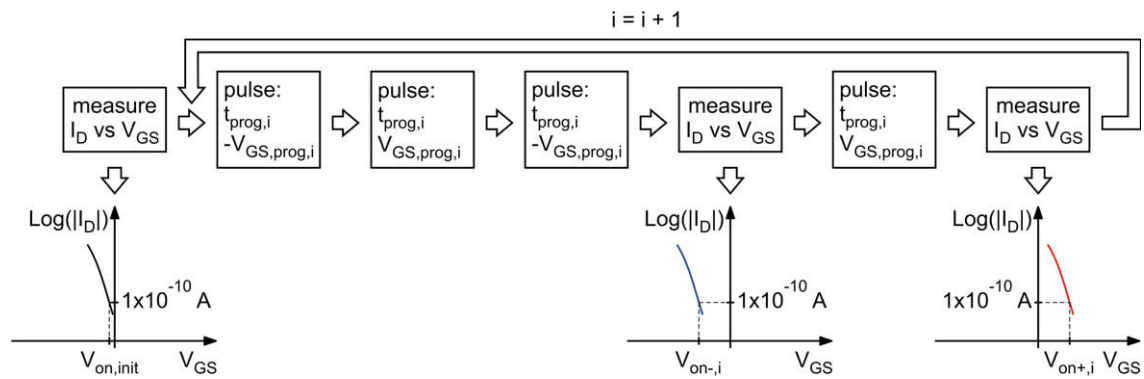

Fig. 2. Measurement flow diagram used to measure V_{on-} and V_{on+} in function of t_{prog} and $|V_{GS,prog}|$.
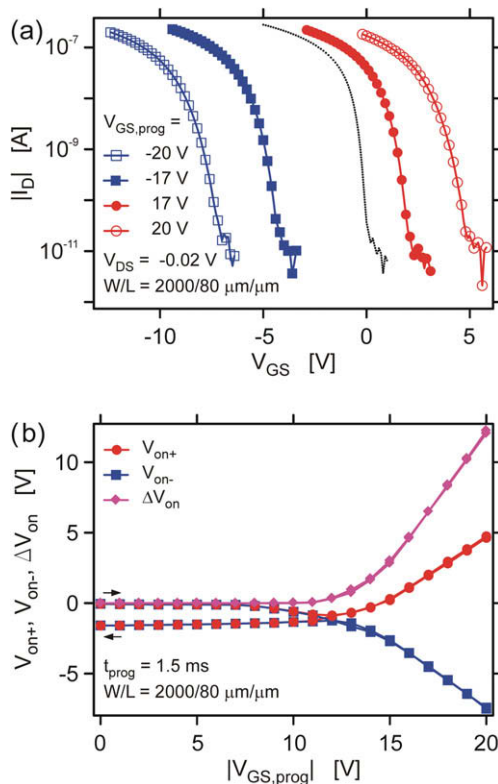

Fig. 3. For a pentacene device: (a) I_D vs. V_{GS} in the initial state (dotted line) and after programming pulses with t_{prog} = 1.5 ms and $V_{GS,prog}$ = −17 V (filled squares)/17 V (filled circles)/−20 V (open squares)/20 V (open circles). (b) V_{on-}, V_{on+} and ΔV_{on} as a function of $|V_{GS,prog}|$ for t_{prog} = 1.5 ms. The measured device is the same as in (a).

Fig. 4. For a pentacene device: V_{on-}, V_{on+} and ΔV_{on} as a function of t_{prog} for $|V_{GS,prog}|$ = 15 V.

obtained in the forward series (i.e. with increasing $|V_{GS,prog}|$). When the final V_{on-} and V_{on+} are compared to $V_{on,init}$, a small, overall shift is observed.

The data in Fig. 3 illustrates a number of important attributes that makes this effect promising to utilize as memory cells. Most notably is the negligible threshold voltage shifts at low programming voltages which allows non-destructive read-out. Furthermore, the large value of ΔV_{on} allows easy read-out as this is translated into a large difference in source-drain current for the different programmed states. Finally, this large memory window can be reached at low voltages thanks to the thin gate dielectric (both SiO$_2$ and PαMS layers). Interestingly, V_{on} can be shifted towards both positive and negative voltages by a sufficiently large respectively positive and negative pulse to the gate. This indicates that both electrons and holes are trapped in the gate dielectric.

3.2. Charge trapping as a function of programming time

The trapping mechanism of the charge carriers is further characterized by investigating the dependence of V_{on-}, V_{on+} and ΔV_{on} on t_{prog}. To do so, the measurement procedure described above is repeated with an increasing t_{prog} while $|V_{GS,prog}|$ is kept constant. In Fig. 4 can be seen that both V_{on-} and V_{on+} increase logarithmically with t_{prog}. The logarithmic time dependence of the amount of trapped

In Fig. 3b, V_{on-}, V_{on+} and ΔV_{on} are shown in function of $|V_{GS,prog}|$. For small values of $|V_{GS,prog}|$, the transfer characteristics are hardly changed. ΔV_{on} is much smaller than 1 V. However, when $|V_{GS,prog}|$ increases, the effect becomes significant above a critical value of $|V_{GS,prog}|$ ∼10 V. ΔV_{on} reaches a maximum value of 12 V for the highest value of $|V_{GS,prog}|$ being 20 V. When the device is subsequently subjected to a series of decreasing programming pulses, ΔV_{on} as obtained in the backward series is identical to the values

charge on the programming time is well-known in charge trapping devices: $Q_{tr}(t) = r_d \log (1 + t/t_0)$ with Q_{tr} the amount of trapped charges. This relation can be predicted for charge injection where the injection current depends exponentially on the density of the previously injected charge and points to tunneling from the semiconductor into the dielectric as the trapping mechanism [12,13].

3.3. Retention

In Fig. 5, the retention of the trapped charge after a programming pulse of −20 and 20 V is shown. In between the different measurement points, the sample was kept in the dark in the glovebox, without applying any voltages. Each data point is the average of a measurement on four different devices. V_{on+} decreases to 0 V within 3 h. This indicates that the electrons are trapped in shallow traps and that the positive part of the memory window cannot be used for practical applications. V_{on-} on the other hand, is only reduced to −3 V after 3 months. The holes are deeply trapped in a more complex distribution, making it possible to use the negative part of the memory window. In Ref. [11], the positive part of the memory window is used (program and erase electrons). In those devices, the thicker polymer dielectric blocks the electrons from tunneling back to the channel, improving the retention but also increasing the programming voltage. In our device we combine low programming voltages with a large retention for the negative part of the memory window (program and erase holes).

3.4. Supply of charge carriers in the channel

A condition for the tunneling of the charge carriers into the gate dielectric is the presence of these charge carriers in the channel. Fig. 6 illustrates that both holes and electrons can be accumulated in our pentacene device. The initial transfer characteristics, measured from −3 V to 14.5 V show both a hole current and an electron current with mobilities ($\mu_h \sim 0.8$ cm^2/(V s), $\mu_e \sim 0.01$ cm^2/(V s)) of the same order of magnitude as the values reported in literature [14]. This proves that our memory device is ambipolar. A second transfer sweep, measured from 14.5 V to
Fig. 6. The initial transfer characteristics of a pentacene device measured from −3 V to 14.5 V (filled triangles), followed by a sweep from 14.5 V to −15 V and back (open circles).

−15 V and back to 14.5 V shows how the memory transistor is programmed during the sweep: the V_{on} of the first part of this sweep is shifted towards a more positive V_{GS} with respect to $V_{on,init}$, by the accumulation of electrons in the transistor channel and subsequent tunneling in the gate dielectric, around 14.5 V. In the second part of the sweep, V_{on} is shifted to a V_{GS} more negative than $V_{on,init}$ by the accumulation and the tunneling of holes, around −15 V. Although t_{prog} and $V_{GS,prog}$ are not accurately defined during this kind of sweeps, such measurement confirms that $V_{on,init}$ can be moved both towards more positive and more negative biases by the accumulation and the tunneling of electrons and holes, respectively.

Fig. 7 shows the temperature dependence of V_{on-} and V_{on+}. V_{on-} is the result of the accumulation and tunneling of holes and shows to be temperature-independent. V_{on+}, on the other hand, decreases at lower temperatures. As the tunneling process itself is temperature-independent, the temperature dependence of V_{on+} might result from the temperature dependent supply of electrons in the channel [15,16]. In Fig. 8 we plot the electron mobility and V_{on+} on an Arrhenius plot. The fact that both can be fitted with the same activation energy $E_{A,e} = 53$ meV, indicates that the supply of electrons is indeed limiting the tunneling of the electrons [15,16]. For the holes, with a

Fig. 7. For a pentacene device: V_{on-} and V_{on+} as a function of the temperature for $t_{prog} = 1.5$ ms and $|V_{GS,prog}| = 20$ V.
Fig. 8. The electron mobility (open circles) and V_{on+} (filled circles) of a pentacene device, in function of $1000/T$. V_{on+} was measured with t_{prog} = 1.5 ms and $V_{GS,prog}$ = 20 V. The symbols are measurement points, the dotted lines fits with an Arrhenius equation (activation energy = 53 meV).

mobility of almost two orders of magnitude higher, the supply in the channel is not the limiting factor and V_{on-} is temperature-independent. The activation energy for the hole mobility, $E_{A,h}$ is 22 meV, which is similar to values reported in literature for pentacene on OTS-treated SiO_2 [17].

The finding that a lack of electrons reduces the memory window in this type of memory transistors should be kept in mind during the interpretation of results reported in literature. In the study of Baeg et al. [18], the memory window was shown to be smaller for a polar polymer dielectric like PVP (poly(4-vinyl phenol)) or PVA (poly vinyl alcohol) than for PαMS. Such polar dielectrics contain OH-groups which are known to decrease the electron mobility [19]. According to our findings, the smaller memory window in these devices could be partly explained by the poorer electron supply. Similarly, Katz et al., showed that hydrophobic dielectrics lead to larger shifts in V_T than hydrophilic ones [6], which we can directly relate to the corresponding electron mobilities expected to be larger on hydrophobic dielectrics compared to on hydrophilic dielectrics. Furthermore, illuminating the devices during programming improves the trapping of electrons but not that of holes [20]. We suggest that the effect of illumination is to supply extra electrons which can be trapped, analogous to how illumination accelerates bias stress [21]. Supplying more holes by illumination has no effect, as holes are already omnipresent in the channel.

3.5. Hole trapping only

Exposure of pentacene transistors to humid air leads to electron traps in the pentacene [22,23], which hampers the accumulation of electrons [24], leading to near-zero electron mobility. In Fig. 9a, we show the characteristics of a pentacene device which was left in air for 1 day and then measured in air: no electron current can be measured in the initial sweep from −3 V to 14.5 V. Consequently, V_{on} cannot be shifted towards more positive V_{GS} during the next sweep from 14.5 V to −15 V and back. On the other
Fig. 9. (a) The initial transfer characteristics for a pentacene device, brought in air for 1 day and measured in air from −3 V to 14.5 V (filled triangles), followed by a first sweep from 14.5 V to −15 V and back (open circles) and a second sweep from 14.5 V to −15 V and back (open squares). (b) The initial transfer characteristics for a PTCDI-$C_{13}H_{27}$ device measured in the glovebox from 3 V to −14.5 V (filled triangles), followed by a first sweep from −14.5 V to 15 V and back (open circles) and a second sweep from −14.5 V to 15 V and back (open squares).
Fig. 10. V_{on-} and V_{on+} as a function of $|V_{GS,prog}|$ for t_{prog} = 1.5 ms for a pentacene device, brought in air for 1 day and measured in air (open symbols and full line) and for a PTCDI-$C_{13}H_{27}$ device measured in the glovebox (open symbols and dotted line).

hand, holes can still be accumulated and V_{on} can still shift towards more negative V_{GS}. We note that the mobility of the holes decreased somewhat, to $\mu_h \sim 0.6$ cm^2/(V s), by the exposure to air, probably caused by moisture-related traps [25]. Remarkably, if the sweep from 14.5 V to −15 V and back is measured a second time, no difference in V_{on} for the first and the second part of the sweep can

be noticed. This means that even at 14.5 V trapped holes cannot be removed from the dielectric and as a result the memory window is actually decreased to zero. When Fig. 9a is compared with Fig. 6, it becomes clear that the electrons are needed to overwrite the tunneled holes which can otherwise not be removed from the dielectric at these gate fields. A similar observation can be made in Fig. 10 for the same pentacene sample measured in air. At $|V_{GS,prog}|$ = 15 V, holes can be trapped but not be removed, while in Fig. 3b, for a pentacene sample in the glovebox, the holes could be trapped and removed at $|V_{GS,prog}|$ = 15 V. If in Fig. 10, $|V_{GS,prog}|$ is increased to 20 V, the trapped holes can be removed from the dielectric, but still no electrons can be trapped. We draw from this experiment the important conclusion that in this type of memory devices ambipolarity in the transistor channel, i.e. the possibility to accumulate both types of charge carriers in the device channel, is a requirement for achieving reprogrammability at low gate fields.

3.6. Electron trapping only

To verify the more general validity of the statement that ambipolarity is required for erasing a programmed memory state at relatively low gate fields, we carried out experiments using the perylene derivative PTCDI-$C_{13}H_{27}$ as the organic semiconductor. PTCDI-$C_{13}H_{27}$ is a good electron conductor; hole conduction has not been reported for this material. In Fig. 9b, a PTCDI-$C_{13}H_{27}$ device measured in the glovebox only shows electron current and no hole current. In a memory device with bilayer oxide/PαMS dielectric, V_{on} can only be shifted towards more positive V_{GS} by tunneling of abundantly present electrons, but not towards more negative V_{GS}. When scanning to 15 V, the memory can be programmed only once, and trapped electrons cannot be removed from the dielectric. Similar results in Fig. 10 for the same PTCDI-$C_{13}H_{27}$ sample: electrons can be trapped from $|V_{GS,prog}|$ = 10 V on, but cannot be removed. Even if $|V_{GS,prog}|$ is increased to 20 V, the electrons stay trapped in

the dielectric. This is the pendant case of the pentacene device in air, and corroborates the statement that in order to erase trapped charges at relatively low gate fields, it is required to overwrite them with charges of the opposite sign, rather than to remove them by detrapping.

3.7. Model

From the figures in 3.4–3.6, it is obvious that to maximize the memory window of organic charge carrier trapping memory transistors, the accumulation of both holes and electrons needs to be possible. In this case, both charge carriers can be supplied in the channel, and one type of charge carrier can be used to overwrite the other, trapped, one.

A possible explanation for this behavior is schematically drawn in the band diagram in Fig. 11, taken along a vertical line in Fig. 1. In Fig. 11a, a charge carrier, a hole in this case, is accumulated in the channel and subsequently tunnels into the dielectric upon the application of an appropriate V_{GS}. The vertical electric field drops mainly over the two gate insulators and the driving force to tunnel into the dielectric is large. In a first approximation:

$$E_{PαMS} = V_{GS} \frac{\varepsilon_{SiO_2}}{t_{PαMS}\varepsilon_{SiO_2} + \varepsilon_{PαMS}t_{SiO_2}} \tag{1}$$

In our device for $V_{GS,prog}$ = 15 V, $E_{PαMS}$ = 9 MV/cm. We assume that the trap in the gate dielectric that stores the injected charge carrier is deep. In Fig. 11b, in an ambipolar device, electrons can be accumulated in the channel and tunnel into the dielectric. The positively charged hole traps are likely to attract such electrons, such that injected electrons can erase the initially positively trapped charge, before a net negative charge of trapped electrons is stored in the gate dielectric. Also for electron injection, the electric field drops mainly over the two insulators. In Fig. 11c, we sketch the situation when an equal gate voltage is applied in a unipolar device, pentacene measured in air for example. No electrons are accumulated, such that
Fig. 11. Schematic band diagram of a pentacene memory transistor during programming, taken along the line AB in Fig. 1. (a) A hole can tunnel from the channel into the dielectric upon the application of a negative V_{GS} (−15 V for example). (b) Measured in the glovebox: an electron can tunnel from the channel into the dielectric and overwrite the trapped hole upon the application of a low positive V_{GS} (15 V for example). (c) Measured in air: a trapped hole cannot be pushed back to the channel upon the application of a low positive V_{GS} (15 V for example).

part of the electric field drops over the organic semiconductor, reducing the electric field over the gate insulators. The remaining field, to first approximation:

$$E_{P\alpha MS} = V_{GS} \frac{\varepsilon_{SiO_2}\varepsilon_{pentacene}}{t_{P\alpha MS}\varepsilon_{SiO_2}\varepsilon_{pentacene} + \varepsilon_{P\alpha MS}t_{SiO_2}\varepsilon_{pentacene} + \varepsilon_{P\alpha MS}\varepsilon_{SiO_2}t_{pentacene}}$$

(2)

is insufficient to detrap the trapped hole from its deep hole trap ($E_{P\alpha MS}$ is only 3 MV/cm for $V_{GS,prog}$ = 15 V).

4. Conclusions

We fabricated an ambipolar bilayer organic transistor device, in which both holes and electrons can be accumulated in the channel and subsequently trapped into the gate dielectric. As both charge carriers can be trapped, a large memory window, extending on both sides of the initial turn-on voltage can be realized. Only the negative part of this memory window can be used (trapped holes) as the retention of the positive part (trapped electrons) is too low. The trapping mechanism for both charge carriers showed to be tunneling from the channel into the dielectric.

Our measurements indicate that the supply of the charge carriers in the channel can be a limiting factor for the memory behavior. This is for example the case for the low mobility electrons in the pentacene devices: further lowering their mobility results in a decreased memory window. This has its consequences for the chosen polymer insulator as this material will not only be part of the charge storage medium but also needs to be carefully chosen to not hinder the electron transport in the organic semiconductor.

Finally, we also show that the optimal method to erase a trapped charge carrier from the dielectric is overwriting it with a charge carrier of opposite polarity. Although the retention of the electrons is low, these electrons are necessary to lower the voltage to erase the trapped holes.

The combination of H_{16}CuPc and F_{16}CuPc was used before in bilayered field-effect transistors (FET) [11–13] to obtain ambipolar transport. For both materials a threshold voltage shift was observed if the respective other material is deposited on top of the transport material in the FET. For thicker layers the second deposited material opens an additional channel for the opposite charge carrier type to give ambipolar transport. The threshold voltage shift was related to a charge transfer with holes accumulating in H_{16}CuPc and electrons in F_{16}CuPc. Therefore the bilayer structure can be used to engineer the threshold voltage in FETs.

Mixed crystals of strong DA systems like TTF-TCNQ are well-known since the 1970s [14]. However, the growth of crystalline thin films of two organic semiconductors by vacuum deposition is a relatively new aspect for organic electronics. It has been demonstrated that charge transfer salts, such as TTF-TCNQ and its many derivatives, can be deposited as crystalline films by thermal evaporation of the bulk material [15]. The formation of mixed crystalline films by co-evaporation of molecules has only recently been observed for rod-like molecules [16], such as sexithiophene (6T), sexiphenyl (6P) and dihexylsexithiophene (DH6T). Thereby the structure of the films is predominantly determined by the size of the conjugated system. It was also shown that pentacene and perfluoro-pentacene can be grown as intercalated mixed crystalline layers on top of SiO_2; thereby the ionization energy can be continuously varied by the layer composition [17].

Here we present a study of blends using hydrogenated copper-phthalocyanine H_{16}CuPc in combination with its per-fluorinated version F_{16}CuPc. In addition to studying the fundamental structural, optical, and electrical properties centering around the question of the formation of mixed crystals we investigate the usability of these materials for photovoltaic cells as planar and bulk-heterojunction devices.

2. Experimental

The materials used in this study were purchased from Sigma Aldrich as sublimation grade and additionally purified by temperature gradient sublimation; for F_{16}CuPc the sublimation procedure was repeated once. The structural formulae are given in Fig. 1. The organic semiconductor films were deposited by thermal evaporation from two independent low-temperature effusion cells in a vacuum better than 10^{-7} mbar. The thickness of the films was controlled via deposition monitors using quartz microbalances. For mixed films two independent monitors were used. The layer sequence for the bilayer structure consists of H_{16}CuPc deposited on the hole injecting layer followed by F_{16}CuPc. The deposition rates were 0.35 Å/s for neat films and up to 1.4 Å/s for the material with the higher volume fraction in the mixtures. As substrates glass slides covered with 130 nm of indium-tin oxide (ITO) and 30 nm of the conducting polymer polyethylenedioxythiophene–polystyrenesulfonate (PEDOT:PSS, purchased from H.C. Starck as BAYTRON P) were used. For the optical absorption measurements the films were deposited on quartz glass slides. During the deposition of the phthalocyanine molecules the substrate was held either at room temperature (about 300 K) or at an elevated temperature (about 375 K).

The charge transport properties were analyzed in both unipolar and ambipolar diodes. For hole-only diodes the active organic layer was deposited on an ITO/PEDOT:PSS anode and a 100 nm thick Au film with a thin interlayer of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyano-quinodimethane (F_4TCNQ) was used as hole injecting layer [18]. The electron-only diodes contained a 100 nm thick Al bottom electrode and a 100 nm thick Al electrode on the top of the organic film with a 0.5 nm thick interface doping layer of LiF for the latter one. Using an ITO/PEDOT:PSS bottom contact together with a LiF/Al top electrode ambipolar injection and charge transport were obtained. The active organic layer in all investigated devices consisted of an 80 nm thick film of neat or blended materials (volume mixing ratio of 1:1). The active area was about $2 \times 2 \text{mm}^2$. Electrical characterization was performed without air-exposure under vacuum or in a nitrogen filled glove box.

To analyze the current–voltage characteristics the measured curves were fitted by the model of trap-free space charge limited currents (SCLC, Eq. (1)) [19] combined with a Poole–Frenkel type field-dependent mobility [20], which gives the current density as
Fig. 1. Structural formulae of hydrogen-terminated copper phthalocyanine H_{16}CuPc and fluorine-terminated copper phthalocyanine F_{16}CuPc.

$$j_{SCLC} = \frac{9}{8} \cdot \mu_0 \cdot \varepsilon_0 \varepsilon_r \frac{V_{eff}^2}{d^3} \exp\left[\gamma \sqrt{\frac{V_{eff}}{d}}\right]. \tag{1}$$

This equation contains a zero-field mobility μ_0 and a field activation parameter γ. d is the film thickness and V_{eff} the effective applied voltage $V - V_{Bi}$, with V_{Bi} being the built-in voltage, i.e. the difference of the work functions at both electrodes. The parameters μ_0, γ and V_{Bi} are determined by fitting the measured data in the higher voltage range above V_{Bi}.

Devices showing ambipolar injection and transport, i.e. devices comprising ITO/PEDOT:PSS and LiF/Al electrodes were additionally investigated as solar cells. In this case the active organic film consisted either of an 80 nm thick 1:1 blend or two neat layers with 40 nm thickness for each material. Current–voltage characteristics of the solar cells were measured in darkness and under illumination. The intensity of the solar simulator (AM1.5 filters) was varied up to 100 mW/cm², i.e. one sun.

In addition to the electrical measurements, the neat and blended organic films were analyzed by scanning force microscopy (SFM) and specular X-ray reflectometry. The SFM measurements were performed using a Thermo Microscopes Autoprobe CP-Research in non-contact mode. The X-ray scattering measurements were conducted on a GE/Seifert X-ray diffractometer (Cu Kα1 radiation, multi-layer mirror, and double bounce compressor monochromator). The optical absorption spectra were recorded for films deposited on quartz glass substrates using a Perkin Elmer Lambda 950 with a spectral range from 0.5 to 5.0 eV. X-ray scattering, SFM, and optical absorption measurements were performed under ambient conditions.

3. Results and discussion

3.1. Structural properties

The morphology of phthalocyanine films deposited on PEDOT:PSS/ITO was determined by non-contact scanning force microscopy. The results are shown in Fig. 2. Neat films evaporated at room temperature have a granular structure with a typical grain size of about 50 nm. Phthalocyanine films deposited at elevated temperature display a needle-like structure with a typical length of about 300 nm. The higher temperature during evaporation allows a faster diffusion of the molecules and thereby a better ordering resulting in these needle-like crystals. Blended phthalocyanine films show a similar morphology and roughness as the neat films at the same deposition conditions. This similarity in morphology is a first indication for the formation of mixed crystalline films. To confirm this, the films were further analyzed by X-ray scattering.

Fig. 3 shows the out-of-plane first order diffraction peak for the neat films as well as for the 1:1 blend deposited at room temperature. Importantly, the blended $H_{16}CuPc/F_{16}CuPc$ film shows only one diffraction peak located between the diffraction peaks of the neat materials. The peak width is similar to that of the neat films and the lattice spacing lies between those of the neat materials, consistent with a truly mixed crystalline film, which was already observed for 1:1 mixtures of different hydrogen terminated planar phthalocyanines [21]. The dependence of the lattice spacing on the concentration is summarized in Fig. 3(right). Additional blend ratios are included (3:1 and 1:3) which were not presented in Fig. 3(left) for clarity reasons. The lattice parameter for the mixed crystal system $H_{16}CuPc/F_{16}CuPc$ changes linearly with the concentration between the lattice parameters of the neat materials. This linear change is related to the gradual change of the content of the two planar molecular species with different diameter in the blends. The more crystalline films deposited at higher substrate temperature show basically the same lattice spacing with a slightly reduced peak width related to larger crystallites with coherent diffraction in agreement with the SFM analysis.

At this point it is useful to compare the results with other structural data. Identified by the Bragg-reflection at $q_z = 0.48$ Å⁻¹, neat thin films of $H_{16}CuPc$ on PEDOT:PSS crystallize in the α-phase, which is common for $H_{16}CuPc$ thin film growth [22]. This structure was earlier determined to be isostructural with other phthalocyanine α-phases, which show a herringbone structure with two molecules per unit cell [23]. However a later reexamination has shown that the $H_{16}CuPc$ α-phase has a triclinic structure with only one molecule per unit cell [24]. According to this structural data the peak at $q_z = 0.48$ Å⁻¹ corresponds to the (100) reflection, which means that the $H_{16}CuPc$ molecules are standing nearly upright and stack in the direction parallel to the substrate. For growth on SiO_2 $F_{16}CuPc$ thin films exhibit two polymorphs coined β-phase and $\beta_{bilayer}$-phase [25,26]. The two polymorphs exhibit different in-plane-stacking behaviour, in particular the β-phase has a herringbone arrangement, where as the $\beta_{bilayer}$-phase has a single molecule per unit cell and forms stacks parallel to the substrate similar to the $H_{16}CuPc$ α-phase. Since both $F_{16}CuPc$ polymorphs have an identical out-of-plane spacing, it cannot be determined by the data of Fig. 3 whether a herringbone arrangement is present in the neat film or not.

Due to the different size of the terminating atoms the size of the molecule varies and thereby also the lattice spacing a perpendicular to the substrate (see Fig. 4) [24,26]. The values are about 1.24 nm for the α-phase of $H_{16}CuPc$ and about 1.43 nm for $F_{16}CuPc$ films, respectively. Several other molecular arrangements have been observed. E.g. $H_{16}CuPc$ crystallizes in a β-phase when heated higher than 480 K [27]. For the present study the key point is not the subtle differences between different polymorphs, but rather the fact that the ordering motifs for both compounds are similar, thus facilitating the formation of mixed crystalline films. Fig. 4 shows schematic film structures for the neat phthalocyanines and a 1:1 mixture. A gradual change of the layer spacing can be rationalized by a varying content of the two molecular species with different size and a change of the tilt angle.

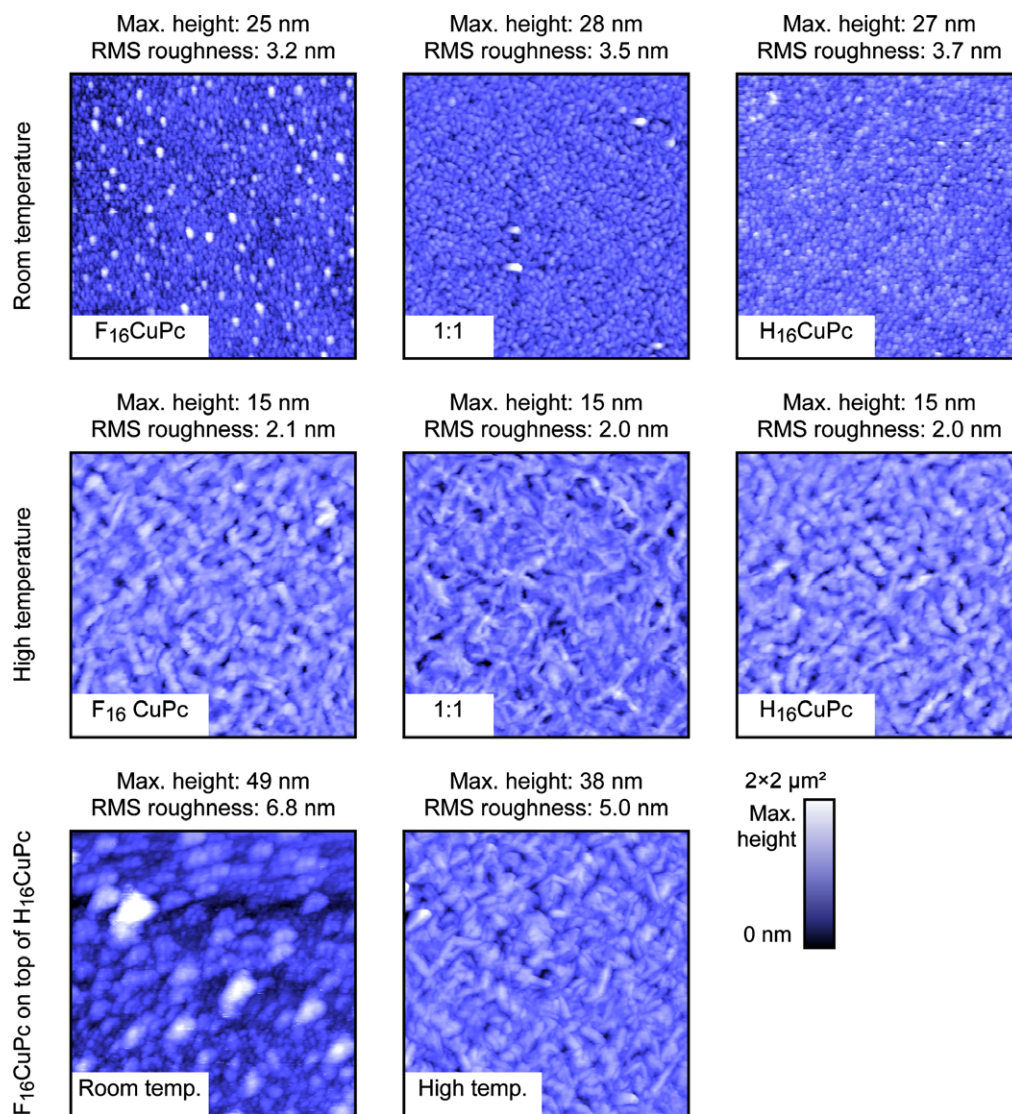
We note that the observation of a single diffraction peak in the blends does not automatically imply the formation of an *ordered* mixed crystalline film with an in-plane superstructure (as Fig. 4 would suggest). It merely indicates that both constituents are homogenously mixed on a molecular length scale without detectable phase separation or precipitation.


Fig. 2. Scanning force microscopy images taken in non-contact mode for neat $F_{16}CuPc$ and $H_{16}CuPc$ films as well as for a 1:1 blended film grown at 300 K (upper row) and 375 K (middle row) on PEDOT:PSS films. In the lower row the surface morphology of $F_{16}CuPc$ films deposited on top of a $H_{16}CuPc$ film is shown for deposition at room and high temperature, respectively. The total image size is $2 \times 2 \ \mu m^2$. The max height is given as the difference between the lowest value (dark blue) and the highest value (white) in each of the images. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The bilayer system containing a neat $H_{16}CuPc$ and a neat $F_{16}CuPc$ film was analyzed, too. The SFM images are shown in Fig. 2 (third row). The $F_{16}CuPc$ film on top of the $H_{16}CuPc$ film evaporated at room temperature is full of fissures. When the evaporation is performed at elevated temperature the film is closed and displays needle-like crystals. The room temperature grown film already shows XRD peaks (see Fig. 3), but only films evaporated at elevated temperatures have closed layers and can be used for bilayer devices.

3.2. Optical properties

Fig. 5 shows the optical absorption under normal incidence for neat phthalocyanine films as well as a blended

and a bilayer film. Both materials are almost transparent in the range of 2.5 eV to 3.0 eV. The absorption of $H_{16}CuPc$ films between 1.4 and 2.3 eV is related to the Q-band and the absorption in the UV-range (between 3.1 and 4.0 eV) to the B-band [28]. The Q-band absorption of $H_{16}CuPc$ shows one strong peak at about 1.81 eV in solution and displays two strong peaks in the solid state (peaks at 1.80 eV and 1.97 eV). As mentioned before $F_{16}CuPc$ films crystallize in two different crystal structures [25,26] with different absorption behaviour. In the visible range one structure is related to the peaks at 1.89 eV and 1.77 eV and the other structure has a large crystal shift resulting in a peak around 1.56 eV [29].

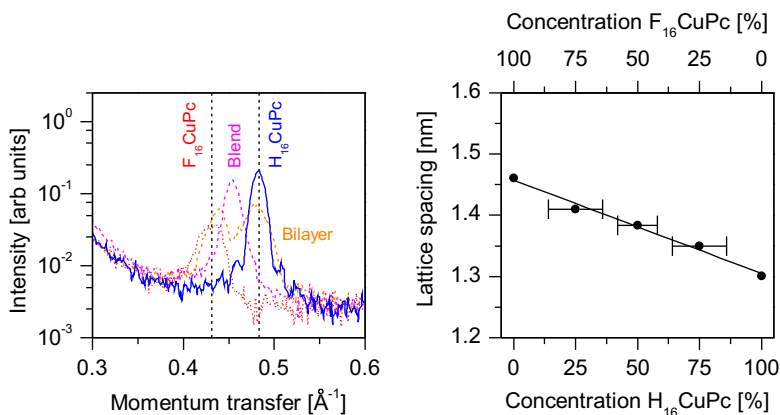
The measured spectrum of the blend (Fig. 5, left) shows one strong peak at 1.97 eV and a shoulder at about 1.80 eV.


Fig. 3. (left) X-ray diffraction spectra of neat films, a 1:1 blend and a bilayer structure evaporated onto PEDOT:PSS at room temperature. (right) Analysis of the lattice spacing determined from X-ray scattering spectra of films with different mixing ratios. The straight line is the linear fit of the measurement points.
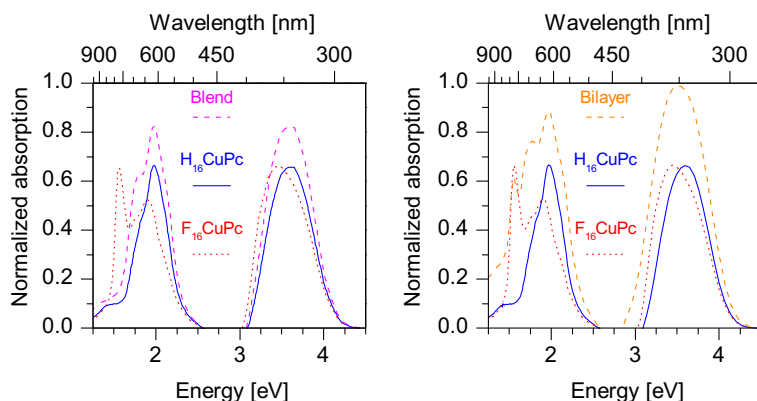
Fig. 4. Schematic molecular arrangement for neat and mixed phthalocyanine films. The interlayer spacing changes gradually from $H_{16}CuPc$ to the blend and further to $F_{16}CuPc$. For easier visualization an ordered structure of the blend is assumed. The lattice parameter a is about 1.3 nm related to the α-phase in $H_{16}CuPc$ and about 1.45 nm for $F_{16}CuPc$ [24,26].


Fig. 5. Absorption spectra of neat as well as blended (left) and bilayered (right) films using $H_{16}CuPc$ and $F_{16}CuPc$ deposited on quartz glass substrates at room temperature. The bilayer structure consists of an $H_{16}CuPc$ film on top of an $F_{16}CuPc$ film which shows the similar behaviour as the opposite film sequence. Additionally a higher on-set at the low energy side of the spectrum is observed for the bilayer structure as for the other samples which is related to differences in the interference effect due to the larger film thickness.

These features are located in the spectral range where both molecules show absorption. In addition, the far red-shifted peak at 1.56 eV in $F_{16}CuPc$ disappears indicating that the related packing motif is no longer present in the blend. This is another demonstration of the formation of mixed crystalline films by co-evaporation of the two different phthalocyanine molecules.

The absorption of a bilayered film ($F_{16}CuPc$ on top of a $H_{16}CuPc$ film) is shown in Fig. 5(right). There all peaks of the neat films are present and scale with the doubled film thickness in the bilayered system (40 nm $H_{16}CuPc$ + 40 nm $F_{16}CuPc$) as compared to the neat films (40 nm).

3.3. Electrical properties

The current–voltage characteristics were measured using various electrodes to realize hole-only, electron-only and ambipolar transport [30] and are shown in Fig. 6. In all samples unipolar electron currents are higher than unipolar hole currents. For the ambipolar transport, however, there is a huge difference between neat materials and the 1:1 blend. While for the former the ambipolar current is close to the current in the electron-only devices, indicating that the current is carried mostly by electrons, the latter system shows a reduction of the current by about four orders of magnitude in comparison to the ambipolar currents of the neat films and both unipolar currents in the blend. The resulting mobilities using the before described SCLC model are also shown in Fig. 6.

The unipolar mobilities of the blend are located between the unipolar mobilities of the neat materials. This alignment of the unipolar mobilities shows similar π-π-overlap in the mixed crystalline films as in the neat films. However, the ambipolar mobility in the blended film is orders of magnitude lower than both unipolar mobilities and the ambipolar mobilities of the neat materials. The same trend is observed for films grown on room temperature substrates, though, the reduction of the ambipolar mobility is more pronounced in the heated films. As the unipolar mobilities in the 1:1 mixture are just in between the values for neat films, the ambipolar transport cannot be limited by the absence of percolation pathways. The strongly reduced ambipolar mobility should rather be related to the simultaneous presence of both charge carrier types in the mixture. A possible explanation is the formation of charge transfer (CT) excitons by the injected charge carriers. These CT states will then limit the transport by blocking the occupied molecules for further injected charge carriers; they would be self-trapped. The idea of generation of charge transfer excitons is supported by the high EA of $F_{16}CuPc$. As mentioned in the introduction, the IP is 5.0 eV for $H_{16}CuPc$ and 6.1 eV for $F_{16}CuPc$, respectively. Taking identical transport gaps of 2.3 eV for both materials [31], results in a LUMO level of $F_{16}CuPc$ being only 1.2 eV above the HOMO of $H_{16}CuPc$. Thus, an intermolecular low-lying CT state could be possible in $H_{16}CuPc/F_{16}CuPc$ blends. However, as we do not see a signature in the optical absorption measured down to 0.6 eV (not shown here),
Fig. 6. Current–voltage characteristics of electron-only, hole-only and ambipolar diodes with neat $H_{16}CuPc$ and $F_{16}CuPc$ as well as a 1:1 blend as active layer. All films were deposited using high substrate temperatures. The lower right diagram shows the zero-field mobilities determined using an SCLC model for all nine diodes.

a direct electronic transition into and from this CT state seems to be not allowed, thus stabilizing the charge separated state. Consistently, due to the ambipolar nature of CT excitons the unipolar mobilities would not be affected.

The possibility of self-trapped CT excitons was suggested before for molecular crystals consisting of stacked alternating donor–acceptor molecules, such as anthracene-PMDA [32]. Materials of this type are insulating and CT excitons created by optical excitation are not mobile. We suggest that this could also happen in the system presented here for simultaneous injection of electrons and holes into a 1:1 blend.

We note that, strictly speaking, differences between electron-only and ambipolar devices could also be caused by different film growth modes, because in the former case Al is used as substrate whereas the latter films are grown on PEDOT:PSS. However, as there is also a large difference of the mobility in the blend between unipolar hole-only and ambipolar devices, which have the same PEDOT:PSS layer as anode, we do not consider the substrate as the decisive parameter for the significant drop of the ambipolar mobility in the 1:1 blend.

3.4. Photovoltaic cells

Organic donor and acceptor materials are promising candidates for photovoltaic cells [34]. In these cells the generated excitons dissociate into free charge carriers at the donor/acceptor interface by an ultra-fast photo-induced charge transfer [35,36]. To create this donor/acceptor interface bilayered (planar heterojunction) [4] and blended (bulk-heterojunction) [5,37] photovoltaic cells are employed. In bilayered systems the dissociation is localized at the interface between the two layers, while in bulk-heterojunction cells it occurs within the whole volume of the blended film. Due to this mixture of donor and acceptor materials the photon-to-current conversion efficiency and the power conversion efficiency were found to increase [5,37,38]. An obvious choice for donor–acceptor blends are organic semiconducting materials in their hydrogenated and fluorinated form, since they combine potentially suitable electronic properties with potential structural compatibility of the two constituents.

Fig. 7 shows the I–V characteristics for a solar cell containing a blended $H_{16}CuPc/F_{16}CuPc$ film as active layer deposited at elevated temperature. The measurement includes the dark current and the current under various illumination intensities up to one sun. The compensation voltage is about 0.36 eV [33] and slightly higher than the open circuit voltage at the highest intensity. The short circuit currents are orders of magnitude lower than comparable cells made from $CuPc/C_{60}$ blends [39,40]. Regarding the low ambipolar mobility in the $H_{16}CuPc/F_{16}CuPc$ blends the very low photocurrents are probably related to the above mentioned self-trapping process. However, the charge transfer excitons are not formed by a direct optical transition but rather by a photo-induced charge transfer after light absorption by one of the two molecular species. The fill factor of about 25% and a power conversion efficiency of only 0.002% shows the ill performance and the limited usability of this system in photovoltaic cells. Comparable solar cells deposited at room temperature show an even smaller open circuit voltage and similar short circuit currents as the heated ones. The power conversion efficiency is reduced to 0.001%.

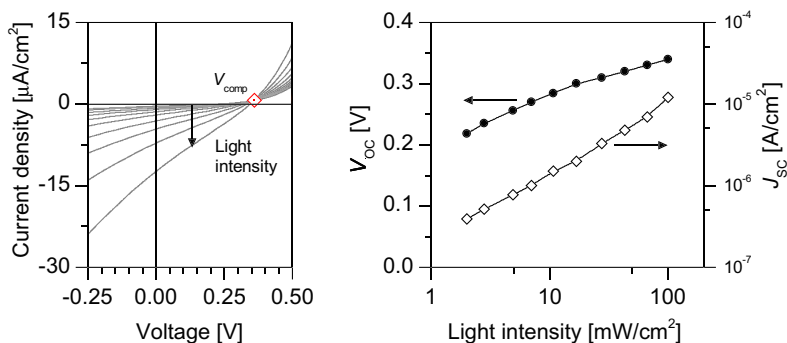
Fig. 8 (left) shows the I–V characteristics of the planar $H_{16}CuPc/F_{16}CuPc$ heterojunction in the dark and under white light illumination at one sun. Comparing to Fig. 6 one immediately notices a remarkable difference: the dark current at 2 V is about 6 orders of magnitude higher than in the blend, however, there is almost no effect of illumination. Even more remarkable is the fact that the reverse current at −1 V is about one order of magnitude higher than the forward current at +1 V. Forward biasing allows for the injection of electrons into $F_{16}CuPc$ and holes into $H_{16}CuPc$. Both carrier species are transported to the interface between both materials where they recombine. The formation of CT excitons is not an issue in this case due to the applied electric field across the interface. Under reverse bias conditions the injection of charge carriers should be blocked by large energy barriers at the electrodes. However, if the energy offset between the HOMO of $H_{16}CuPc$ and the LUMO of $F_{16}CuPc$ is small enough, tunneling of electrons from the further into the latter should be possible as shown in Fig. 8(right). This effect of creating an electron-hole pair under reverse bias conditions at an interface between a


Fig. 7. (left) Current–voltage characteristics for the blended $H_{16}CuPc/F_{16}CuPc$ solar cell with an active layer deposited at high temperature. The curves are shown for different white light intensities (simulated AM1.5 illumination). The compensation voltage V_{Comp} is determined as the crossing point of all curves [33]. (right) Open circuit voltage (V_{OC}) and short circuit current density (J_{SC}) determined from the left diagram as function of the light intensity.
Fig. 8. (left) Current–voltage characteristic for an ambipolar H_{16}CuPc/F_{16}CuPc bilayer diode in the dark and under one sun illumination. (right) Energy level diagram for an H_{16}CuPc/F_{16}CuPc bilayer diode to explain the charge generation layer under reverse bias conditions. The energy levels for H_{16}CuPc are taken from our own measurements and the energy levels for F_{16}CuPc from the literature [41].

p- and an n-type material is known as charge generation layer and has been employed in multilayer stacked organic LEDs and tandem solar cells [42,43]. We also investigated the influence of light for the planar heterojunction. As visible in Fig. 8 the forward current is only weakly increased by photo-generated charge carriers. In backward direction, however, this photo-induced change is obscured by the higher current due to the charge generation layer. Due to the absence of an open circuit voltage and the weak influence of light, this planar heterojunction can not be used as photoactive interface in organic photovoltaic cells.

4. Summary

In conclusion, we have shown that molecularly mixed crystalline films can be grown by co-evaporation of H_{16}CuPc and F_{16}CuPc on device-relevant ITO/PEDOT:PSS substrates. These blends show the usual X-ray spectrum and needle-like film morphology known from neat films of phthalocyanines. Due to different size of the molecules, a continuous change of the lattice spacing is observed by changing the mixing ratio. Optical absorption measurements confirm this scenario: they are not just a superposition of the spectra of neat materials, as would be expected for phase-separated blends, but show distinct new features. In particular the disappearance of the characteristic band at 1.56 eV in F_{16}CuPc is a clear indication of molecular mixing of both species.

A CT exciton could serve as an explanation for the unexpectedly low charge carrier mobility in ambipolar blends, which is found to be orders of magnitude lower than the ambipolar mobility in neat materials and the electron and hole mobilities in unipolar devices. The reduced mobility is also the origin of the poor performance of photovoltaic cells containing H_{16}CuPc/F_{16}CuPc blends. The charge collection efficiency is drastically reduced by the suggested formation of bound CT excitons. In contrast, a bilayered H_{16}CuPc/F_{16}CuPc device works as a charge generation layer which could be of interest in tandem solar cells.

(BL), can an adequate solution to both issues at the same time be achieved?

2. Theory

To understand the mechanism of bending a device comprising more than one layer, one can imagine a 175 μm thick polyethylene terephthalate (PET) substrate covered with a 100 nm ITO thin-film to have a structure somewhat analogous to a leaf spring, with 1750 soft leaves and one hard leaf, each 100 nm thick and connected in parallel. In contrast to the leaf spring, however, here the adjacent surfaces of neighbouring leaves are firmly bound to one another. When the structure is bent so that the uppermost surface of the thin layer is concave, it is reasonable to assume that there will be one "leaf" out of the 1751, which maintains its original length, and all others laid above it are stretched whilst those below it are compressed. The one with its original length is called the neutral layer (NL). The position of this layer is crucial because the strain in any of these springs is proportional to the distance from itself to the neutral layer. This will be deduced later.

To determine the position of NL in a multi-layer structure, others such as Kim and co-workers [7] and Hsueh [8] have put forward analytical solutions. In these studies, both the position of the NL and the stress in the layers are considered to be unknown parameters, and are solved with equations of equilibrium of static force and torque in the cross section. In the work presented here, the method introduced enables us to consider the multi-layer bending situation, visually. It is not a new concept since engineers have used routinely it to deal with the stress problems that arise when building with multi-material composite beams [9]. However, it is equally applicable to the realm of plastic electronics, where the nanoarchitectures involved comprise multiple thin layers on a much thicker flexible support, a particular example of which would be a flexible OLED device.

For the longitudinal stress in a plain film being bent, the stress is given by:

$$\sigma = E'\varepsilon$$
$$E' = \frac{E}{1-v^2} \tag{1}$$

where the Young's modulus of the film material is E, v is the Poisson's ratio, E' is the reduced elastic modulus and the strain of the film is ε. This strain is defined by:

$$\varepsilon = \frac{\Delta l}{l} \tag{2}$$

where l is the original unbent length, and Δl is the change of length after bending. Although these thin-films are not real springs, the strain caused by bending is only about 0.01 even when the radius is 10 mm. This means the higher order terms are negligible and Hooke's Law is still valid. When an arbitrary segment of a homogeneous film with a symmetric cross section is analysed, the NL should be right at the centre of the film. Assume the layer denoted by $\overline{ab}$ in Fig. 1a is the NL, and by definition its length remains unchanged on bending to an extent where R defines the radius of curvature experienced by the NL. Set the
Fig. 1. One segment of a single-material beam before (a) and after (b) bending. Layer ab is the Neutral Layer; Layer cd, c'd' is the same layer before and after bending with radius R.

length of $\overline{ab}$ to be l. Now consider the strain of another layer in the film, $\overline{cd}$, say, when the radius of curvature at the NL ($\overline{ab}$) is R. Before bending (Fig. 1a):

$$\overline{cd} = \overline{ab} = l \tag{3}$$

whilst after bending (Fig. 1b) the new length of $\overline{cd}$ becomes $\overline{c'd'}$, so that

$$\overline{ab} = l = R\theta \tag{4}$$
$$\overline{c'd'} = l + \Delta l = (R + y) \cdot \theta \tag{5}$$

where y is the distance from the layer to NL. The strain in the cd element at this distance from the NL thus becomes:

$$\varepsilon(y) = \Delta l/l = y/R \tag{6}$$

Therefore, the stress in any layer in a film with its distance from the NL being y is

$$\sigma(y) = \frac{E'y}{R} \tag{7}$$

The total bending moment M at one end of the segment is

$$M = \int_{-C}^{h-C} \sigma wy \, dy = \frac{E'}{R} \int_{-C}^{h-C} wy^2 \, dy = \frac{E'}{R}I_x \tag{8}$$

where h is the thickness of the film, C is the displacement from the bottom of the film to the NL, w is the width of the cross section and I_x is the second moment of area of the cross section. So we have the following equation to describe the stress developed in the layer as a result of bending completely:

$$\frac{\sigma}{y} = \frac{E'}{R} = \frac{M}{I_x} \tag{9}$$

From the above, the most critical property is the position of the NL. In a single-material, the position of NL is easy to determine. It is just at the centroidal axis of the cross section, so the distance from the layer of interest to the NL, y, will be known. When the architecture comprises two or more layers of different materials, for example ITO on a PET substrate, slightly more effort is required.
Fig. 2. Cross-section (a) and effective cross-section according to the top layer (b) of a two-material composite beam. The thickness of each layers are h_i and h_s.

Fig. 2a shows the cross section of the typical ITO coated PET substrate where h_s is the thickness of the substrate, and h_i is the thickness of ITO. Assume both layers are with the same width w and different Young's modulus: E_s and E_i. The total bending moment is

$$M = \int \sigma wy dy = \frac{E'_s}{R}\int_{-C}^{h_s-C} wy^2 dy + \frac{E'_i}{R}\int_{h_s-C}^{h_s-C+h_i} wy^2 dy$$
$$= \frac{E'_s}{R}I_x^s + \frac{E'_i}{R}I_x^i = \frac{E'_i}{R}\left(\frac{E'_s}{E'_i}I_x^s + I_x^i\right) \equiv \frac{E'_i}{R}I_x^{effective}$$
$$(10)$$

C is the position of NL from the bottom of substrate. The position of C is chosen at the $y = 0$ axis in the integration to determine the second moment of area instead of the conventional choice of the centroidal axis of the individual cross section. Formally, it is determined by equating the net force acting on the cross section under bending, to zero as follows:

$$0 = \frac{E'_s}{R}\int_{-C}^{h_s-C} wy dy + \frac{E'_i}{R}\int_{h_s-C}^{h_s-C+h_i} wy dy \qquad (11)$$

Eq. (10) shows that the total bending moment M of an ITO/PET composite film is the same as the pure ITO film with the effective cross section $I_x^{effective}$. Compared with Eq. (8), it can be seen that the effective cross section is really the original cross section of ITO plus the cross section of PET with the new width w' given by:

$$w' = \frac{E'_s}{E'_i}w \qquad (12)$$

Therefore, in the case of longitudinal stress, an ITO/PET composite film (as shown in Fig. 2a) is identical to the pure ITO film (as shown in Fig. 2b). This greatly reduces the effort of solving the position of NL from Eq. (11) to simply determining the centroidal axis of the effective cross section as if it were made from a single-material. When dealing with structures of more than two layers, with each layer having a different Young's modulus, the task of determining the position of NL using the Eq. (11) becomes even more complicated. However, the method we used here requires only the calculation of the effective cross section by

determining w' of each layer, using the reduced elastic modulus of the layer of interest as the denominator in Eq. (12). Once the equivalent cross section is determined, with the assumption that all the layers are now made from an identical material to the layer of interest, the NL is targeted at the position of centroidal axis of this effective cross section, and the stress in the layer of interest is just a factor times its distance from the NL in the effective cross section: the calculation has transformed the multi-material composite film into a single-material film made solely from the layer under investigation.

3. Results and discussion

Due to the poor performance of plastic substrates with respect to permeation of water and oxygen, mentioned earlier, one or more extra barrier layers would usually be inserted between the ITO layer and the PET substrate. The question is: is it possible that a single additional layer could both reduce the stress in the ITO to give it an extra relief when bending and provide an adequate oxygen/water barrier at the same time?

Glass, for example, has a permeation rate of oxygen and water vapour lower than the detection limit [10] and is therefore a good candidate for the protecting layer. Typically, an oxygen permeation rate for soda lime float glass is given as $<10^{-15}$ (cm^3 STP) cm^{-2} mm^{-1} s^{-1} (mm Hg)$^{-1}$. Applying the conventional assumption that permeability is inversely proportional to the layer thickness, and proportional to pressure difference across the layer, the permeability for a 1 mil (25 μm) film thickness, and a 1 atm pressure difference, is estimated to be $<2.6 \times 10^{-2}$ cm^3 m^{-2} day^{-1}, in the conventionally adopted units for discussing OLED device performance. By comparison, both oxygen and water permeation rates in 25 μm thick films of SiO$_x$ produced by plasma-enhanced chemical vapour deposition (PECVD) have been measured, and are 8×10^{-2} cm^3 m^{-2} day^{-1} at 1 atm pressure difference and 0.5 g m^{-2} day^{-1} at >90% relative humidity, respectively [11]. The upper limits for adequate OLED device performance are currently thought to be on the order of 10^{-3} cm^3 m^{-2} day^{-1} (oxygen) and 10^{-5} g m^{-2} day^{-1} (water), where material composition, layer thickness, and pressure difference are variables to achieve these values.

The reduced elastic modulus of ITO, glass, and PET film are assumed to be 120 GPa [12], 74 GPa, and 5 GPa, respectively, as in Table 2. If the total thickness of glass plus PET composite substrate is kept constant at 175 μm, with a typical ITO thickness of 100 nm, and the whole composite subjected to a bend radius of 10 cm, then from Eq. (7) the thicknesses of glass and PET optimized by simulation are 35 μm and 140 μm, respectively, as shown in Fig. 3. This structure would reduce the stress in ITO from the plain PET substrate – and, indeed, also a plain glass substrate – by a factor of 2.5.

To further understand how the overlaid OLED and cathode layers would affect the ITO stress, a knowledge of the Young's modulus of these organic layers is required. The lack of such information is partly because the PET substrate is softer than the organic layer which leads to the

Table 1
The list of samples tested by nano-indentation technology.

	Substrate material	Substrate thickness (mm)	Coating material	Coating thickness (nm)
Sample 1	PET	0.1	Alq$_3$	100
Sample 2	PET	0.1	Alq$_3$	200
Sample 3	PET	0.1	NPD	200

Table 2
The value of Young's modulus and reduced elastic modulus used in the simulation.

	Young's modulus (GPa)	Reduced elastic modulus (GPa)
Al	70	78
OLED	N/A	12
ITO	120	120
BL	N/A	6–70
PET	4	5
Glass	70	74

difficulty for the elasticity measurement. However, with the aid of triboindenter technology, the surface of the sample can be probed on the scale of several nanometers, thus allowing the effect of the soft base to be filtered out. Three samples are prepared, as listed in Table 1, in order to gauge the elastic property of N,N'-bis(naphthalen-1-yl)-N,N'-bis(phenyl)benzidine (NPD) and tris-(8-hydroxyquinoline)aluminum (Alq$_3$). The PET substrate was cleaned first with acetone, and then with isopropanol in an ultrasonic bath for 5 min each. Three separate samples were prepared by evaporating 100 nm of Alq$_3$, 200 nm of Alq$_3$ and 200 nm of NPD, respectively, on the PET substrate separately using the Kurt J. Lesker thermal evaporator under the vacuum of 5×10^{-7} mbar.

The Young's moduli of the samples were measured by standard nano-indentation techniques. For each material nano-indentation tests were performed under displace-ment control with maximum displacements from 10 nm to 1000 nm using a Hysitron Triboindenter fitted with a sharp Berkovich diamond indenter (tip end radius ∼50 nm). The diamond tip shape was carefully calibrated with a fused silica test sample (using the standard Oliver and Pharr method [13]) before and after testing with no change in shape recorded.

The indenter displacement is made up of two compo-nents, the plastic depth of the indent (contact depth) and the elastic deflection of the surface at the edge of the con-tact. The contact depth is typically <0.67 of the maximum displacement. Nano-indentation load–displacement curves were recorded for each indent and only those where evi-dence of plastic deformation was observed (i.e. the loading and unloading curves are different) were used in the anal-ysis of Young's modulus by the Oliver and Pharr method [13]. In this approach, the initial slope of the unloading curve can be used to determine the contact depth and the elastic modulus of the sample (effectively from the recovery of the elastic deflection of the surface) based upon the Sneddon flat punch solution. This requires the contact area to be calculated from the contact depth based upon an accurate knowledge of the tip end shape and defines the need for careful tip calibration as mentioned previously.

The result is shown in Fig. 4. The reduced elastic modu-lus in the y-axis direction only differs from the real Young's modulus by a factor of $(1 - v^2)^{-1}$. Because the thickness of the organic layers are 100 nm and 200 nm, the readings of the reduced elastic modulus at the contact depth deeper than a third of the coating thickness are greatly dominated
Fig. 4. Reduced elastic modulus of 100 nm Alq$_3$ (solid square), 200 nm Alq$_3$ (open square), and 200 nm NPD (open triangle) against the probing depth in the triboindenter measuring. All samples are deposited on 100 nm thick PET films.
Fig. 5. The stress in ITO against the thickness of buffer layer with different buffer layer Young's modulus in the five-layers structure: PET(100 μm)/Buffer(0–100 μm)/ITO(100 nm)/OLED(100 nm)/Aluminium (100 nm). The bending radius is 15 mm.

by the PET substrate. The Young's modulus commonly used for PET film is 4 GPa, and the Poisson's ratio lies between 0 and 0.5. However, the reduced elastic modulus in this regime is measured to be lower than 4 GPa, rather than larger values in the range 4–5 GPa as the common values above suggest. We believe this might be due to the thin planarization layer (smoothing layer) coated by the supplier (DuPont Teijin Films), which could be softer than PET.

When the contact depth is within a third of the coating thickness, the measured reduced elastic modulus contains an increasing contribution from the thin coating itself. So the value of the reduced modulus when the contact depth is extrapolated to zero can approximate the Young's modulus of the coating layer deposited. From Fig. 4, all the three samples have about same value of 12 GPa when the

contact depth approaches zero regardless of the difference in their thickness. For such a thin coating on a compliant substrate it is difficult to completely filter out the effect of the substrate and there may be considerable scatter in the extrapolated modulus due to the quality of the data available for extrapolation. Fracture in the coating can lead to discontinuities in observed behaviour and, at low indenter penetrations where most data is needed for accurate extrapolation, plastic deformation is limited. Thus, although this extrapolation process has been adopted in ISO 14577-4 (2007) for the assessment of the reduced modulus of thin coatings there remain some questions about its validity; for instance for a substrate harder or softer than the coated layer, the modulus determined by nano-indentation can be different [14]. The way the small molecules grow on different materials could alter the elastic response of the coating as well, therefore, we measured the samples on a PET substrate in order to keep everything the same as a working FOLED device. A full study of the Young's modulus of Alq$_3$ and NPD on different substrates to assess the reliability of the data is the subject of further work.

For OLED operation in a flexible regime, the value of 12 GPa suggests that the materials in small molecule based OLEDs are not remarkably different in their elastic moduli relative to either the long chain polymer materials in PLEDs (typ. 2–6 GPa) or, say, a PET support (4 GPa). Only the ITO (120 GPa) and metal cathode layers such as aluminum (70 GPa) require more careful attention.

The five-layers structure: PET (100 μm)/Buffer (x)/ITO (100 nm)/OLED (100 nm)/Aluminium (100 nm) is simulated with different values of reduced elastic modulus of the buffer layer (BL) and different thicknesses, x. The extension to accommodate the multiple thin layers in this case is particularly straightforward. The combined thickness of the thin layer stack is nearly three orders of magnitude less than that of the support, so the position of the neutral layer is determined almost exclusively by the composition of the thicker support. The stress in each of the

(a)

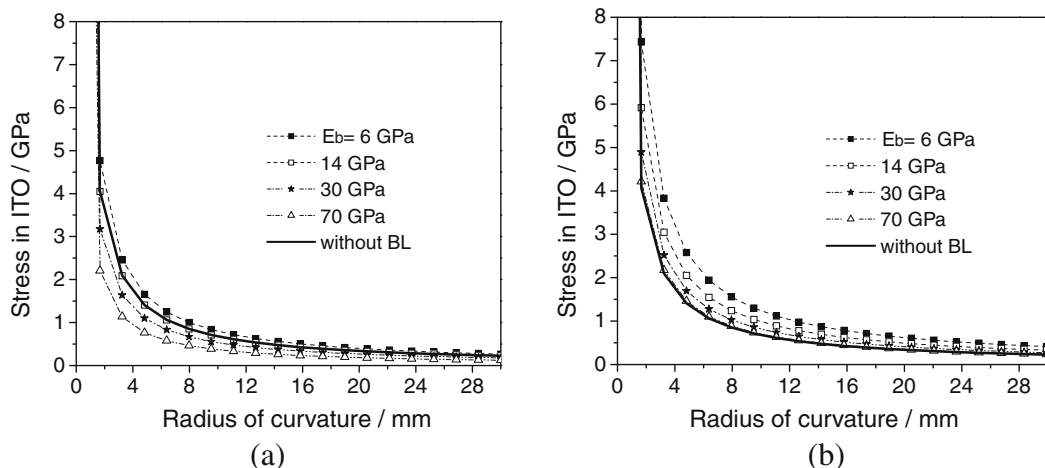
(b)


Fig. 6. The stress in ITO against the device bending radius with different buffer layer Young's modulus in the five-layers structure: (a) PET(100 μm)/Buffer(20 μm)/ITO(100 nm)/OLED(100 nm)/Aluminium(100 nm). (b) PET(100 μm)/Buffer(100 μm)/ITO(100 nm)/OLED(100 nm)/Aluminium(100 nm).

thin layers is then determined by the reduced elastic modulus of the thin layer, the distance from the neutral plane to the surface on which the thin layer is coated and the bend radius, just as for the single thin layer case. The reduced elastic modulus of the PET substrate is set to be 5 GPa. Assuming the bending radius is 15 mm, the stress in ITO against the thickness of BL is shown in Fig. 5. This shows a series of different buffer layer moduli, in the whole device structure. In contrast to Fig. 4, the PET layer now has a constant thickness and the buffer thickness is increased from zero. As the buffer material modulus increases, values in the range 14–70 GPa exhibit minima in ITO stress at a thicknesses of 15–20% of the PET layer. When the reduced elastic modulus of BL is smaller than 14 GPa, the ITO stress is increased. For a BL modulus of 70 GPa, the stress has the maximum reduction – about 50% – for a thickness of 20 μm. However, a larger stress occurs when it is thicker than 70 μm. This is the result of the competition between the changing of the NL position and the distance of ITO layer from NL as mentioned before. The stress in ITO against the bending radius with BL thickness of 20 μm and 100 μm is shown in Fig. 6a and b. This simulation presents a very interesting result. For the former thickness, it seems that the larger the Young's modulus, the better. But the effect will saturate eventually. However, the latter suggests that when BL is as thick as the PET layer (100 μm), the stress in ITO will never be reduced no matter what material is chosen. The value of Young's modulus and reduced elastic modulus used in the simulation is in Table 2.

4. Conclusion

An alternative approach to calculate the stress developed in a thin-film multi-layer has been adopted. With this method, the position of the NL can be determined and a concept of visualising changes in stress as the structural architecture is fine-tuned has emerged. A plastic/glass composite substrate with the thickness of 140 μm and 35 μm respectively, acting to provide a flexible barrier to oxygen and water vapour, has been predicted to reduce the stress in ITO deposited on the glass surface by a factor of 2.5, compared with 175 μm of either glass or PET on its own. The yield strength of ITO (the limit beyond which material deformation is irreversible) corresponding to a failure strain of *ca.* 1%, is 1.2 GPa [15]. The support composition above can be shown to adequately protect a thin ITO layer to bend radii significantly less than 1 cm; indeed, the stress in the ITO layer is predicted to reach its yield strength value at a bend radius as low as 3.3 mm. This prediction is particularly interesting, since currently, flexible glass as thin as 50 μm has been achieved, and the prospect of 30 μm is reported to be within reach [16]. The discussion of break stress in the flexible glass itself is beyond the scope of this report, and will be disclosed in the forthcoming patent literature [17]. As a guide, flexible glass with a thickness in the region of 30 μm exhibits a break stress of *ca.* 0.15 GPa. It is estimated that a composite glass/PET support of 175 μm total thickness could withstand a bend radius of 1.2 cm for a range of 10–40 μm glass thickness without breakage.

Finally, a practical five-layer OLED device structure has been simulated using the reduced elastic modulus values for NPD and Alq$_3$ measured here. It shows that the choice of the BL material's modulus, and its thickness relative to that of the underlying PET, are crucial in reducing the stress in ITO. For BL thicknesses equal to that of the PET, the BL is unable to decrease the ITO stress, regardless of its modulus. One has to bear in mind that all the materials in this simulation are assumed to be elastic. The mechanism of creep (changing of strain under fixed applied stress) and stress relaxation (changing of stress under fixed applied strain) is omitted. The mechanism of cracking is also not considered. There would be some cracks generated initially on each film during their fabrication, and the initial pattern of these cracks would not be expected to be the same for every sample. Nevertheless, reducing the stress in the most brittle layer should still slow down or prevent cracks from migrating further, thereby extending the device lifetime.

Practically, for commercial FOLED devices, it is generally necessary to cover the device with an extra encapsulation layer. With a careful choice of the thickness and elastic property of this encapsulating layer, it is possible to further reduce the distance between NL and the brittle anode layer thus diminish the stress even to zero. However, the problem of deformation or delamination between layers, either due to thermal stress or bending, may become the dominant concern in the FOLED device degradation.

open-circuit voltages of around 1 V. Moreover, in contrast to many other conjugated polymers, the lowest unoccupied molecular orbital (LUMO) energy level at 3.4 eV is close in energy to that of PCBM. Therefore, less voltage is lost during electron transfer at the D–A interface [7]. However, the photovoltaic performance of PF10TBT cells is strongly dependent on the molecular weight (MW) of the polymer [8]. Low MW devices show significantly lower short-circuit currents and fill factors, resulting in a reduction of the maximum output power by a factor of 2 compared to the best high MW devices.

For the further design of new donor polymers understanding of the dependence of solar cell performance on their chemical and structural properties is crucial. Low fill factors are commonly attributed to unbalanced charge carrier transport in the polymer and fullerene phase [9]. Molecular weight dependent hole mobilities have been observed in regioregular poly(3-hexylthiophene) (P3HT), using field-effect transistor measurements [10–12], space-charge limited currents [13] and the time-of-flight technique [14]. Most studies revealed an increase of the hole mobility with increasing molecular weight. Suggested causes include differences in chain packing, interconnectivity of the polymer network, backbone conformation and interchain hopping. It has been pointed out by Goodman and Rose that in a solar cell with a significant difference in the hole- and electron mean free path, accumulation of the slowest charge carriers will lead to a nonuniform electric field in the device [15]. When the slowest carrier has a very low mobility the photocurrent can even reach a maximum electrostatically allowed limit at high light intensity [9]. This space-charge limited (SCL) photocurrent has a three quarter power dependence on light intensity and a square root dependence on voltage, which limits the fill factor to 0.42.

A different cause of a low fill factor was recently identified in solar cells from a narrow band gap polymer and PCBM [16]. The low fill factor again results from a square root dependence of the photocurrent on voltage, albeit for entirely different physical reasons than in the space-charge limited case. Here, the photocurrent is limited by a small product of mobility and lifetime of free charge carriers due to recombination or trapping and is described by [15]:

$$J_{ph} = qG(\mu_{h(e)}\tau_{h(e)})^{1/2}V^{1/2} \qquad (1)$$

where G is the generation rate of free charge carriers and $\mu_{h(e)}$ and $\tau_{h(e)}$ are the mobility and lifetime of free holes (electrons), respectively. Experimentally, this recombination limited photocurrent can be discriminated from the SCL case since it depends linearly on light intensity. Furthermore, the saturation voltage V_{sat}, at which the photocurrent loses its half power dependence on voltage, is independent of light intensity for the recombination limited case, whereas for the SCL photocurrent it scales with the square root of light intensity. In this study we investigate the origin of the low fill factor and photocurrent in low molecular weight PF10TBT:PCBM solar cells. A half power dependence of the photocurrent on voltage is observed and its origin is revealed by a combination of optical and electrical measurements and device simulations.

2. Experimental

PF10TBT was synthesized at the Netherlands Organisation for Applied Scientific Research (TNO) and used as received. In this study two batches were used, which will be identified by their weight average molecular weight (M_w) in the remainder of this paper. The low MW polymer had $M_w \sim 5.1 \times 10^3$ g/mol and polydispersity index PDI ~ 1.7, the high MW batch had $M_w \sim 1.9 \times 10^5$ g/mol and PDI ~ 3.5. The electron acceptor, PCBM, was obtained from Solenne. Polymer and fullerene were mixed in a 1:4 weight ratio and dissolved in chlorobenzene. Since the solubility of high MW PF10TBT in chlorobenzene at room temperature is low, solutions were stirred and processed at 90 °C. ITO-patterned glass substrates were cleaned, treated in a UV-ozone reactor and coated with a 40–60 nm thin hole-transporting buffer layer of PEDOT:PSS (H.C. Starck GmbH). The photoactive layer was spin coated in air with typically 80–100 nm thickness. Solar cells were finalized with evaporation of a 1 nm LiF/100 nm Al cathode to ensure an ohmic electron contact with the PCBM phase. To study hole transport properties of the blend, an electron-blocking 20 nm Pd/80 nm Au top contact was applied instead of the LiF/Al cathode.

Current–voltage characteristics were recorded using a Keithley 2400 SourceMeter. Measurements were performed in the dark and under illumination from an uncalibrated Steuernagel SolarConstant 1200 metal halide lamp with an estimated intensity equivalent to ca. 1.3 suns, as determined by comparison of measured and calculated short-circuit current densities (see below).

Spectral responsivity (SR) measurements were carried out with a lock-in amplifier, a transimpedance amplifier and a focused, chopped monochromatic beam from a quartz tungsten halogen lamp and several narrow band pass filters. An estimation of the short-circuit current density (J_{sc}) under standard test conditions was calculated by convolving the SR spectrum with the AM1.5G reference spectrum, using the verified premise of a linear dependence of J_{sc} on light intensity. The estimated illumination intensity for the material under study was taken as the ratio of the measured and calculated J_{sc}.

The refractive index n and extinction coefficient k of thin films of PF10TBT:PCBM were determined with variable-angle spectroscopic ellipsometry (VASE), using a VASE ellipsometer from J.A. Woollam Co., Inc. The VASE measurements were combined with transmission and reflection measurements to enable accurate fits of the experimental ellipsometric data in the employed wavelength range from 300 to 1500 nm. The optical constants of glass, ITO, quartz, silicon and PEDOT:PSS were determined first. For ITO and PEDOT:PSS, anisotropic optical constants were found. Since illumination during current–voltage measurements takes place at normal incidence, the components in the direction perpendicular to the plane of the substrate were used in the transfer-matrix calculations. The optical properties of LiF and aluminum were taken from literature. Next, the n and k of composite layers of PF10TBT and PCBM on various substrates were determined by fitting the data with several Gaussian oscillators. No

indications of anisotropy in the active layers were found and the data were interpreted with a uniform dielectric function throughout the layer.

3. Results and discussion

Fig. 1 shows the photovoltaic performance of equally thick PF10TBT:PCBM solar cells that were made using low (squares) and high (circles) molecular weight PF10TBT. The differences in fill factor and short-circuit current density are striking. Although both cells are 95 nm thick, the high MW cell produces a 30% higher J_{sc} compared to its low MW counterpart. The fill factor increases significantly with molecular weight as well: it improves from 0.45 to 0.63. In the remainder of this article, we will systematically address the importance of the various effects of a change in molecular weight on device performance.

First, considering the marked difference in J_{sc}, one might anticipate a change in absorption due to variations in, for example, interchain interactions [12,17]. Usually low MW polymers exhibit a blue-shift in solid-state absorption. In a photovoltaic cell this may alter the number of photogenerated excitons and therefore the magnitude of the photocurrent, depending on the overlap of the absorption profile with the irradiance spectrum. When the absorption maximum changes in magnitude as well, the effect of changing MW on J_{sc} may be intensified. Fig. 2 shows the refractive index n and extinction coefficient k of composite layers of PF10TBT and PCBM, as determined with variable-angle spectroscopic ellipsometry. In the region where PF10TBT contributes most to the absorption of the blend layer, i.e., between 450 and 650 nm, the extinction coefficient of the low MW sample (black solid line) is indeed blue-shifted. In addition, the magnitude of k in this region is much lower. Due to optical interference effects, which play an important role in thin films capped with a highly reflective aluminum cathode [18], it is expected that the extent to which a change in optical constants influences the absorption in the active layer varies with the thickness of
Fig. 2. Index of refraction n and extinction coefficient k of PF10TBT:PCBM layers on glass. The heterojunction from the low MW polymer (solid line) shows reduced absorption compared to the one containing high MW PF10TBT (dotted line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the layer. The consequences of reduced absorption in low MW solar cells can be quantified by modeling of the optical electric field inside the device [18–20]. Using the transfer-matrix approach described by Pettersson et al. in Ref. [18], provided with the optical constants of Fig. 2 and the AM1.5G solar irradiance spectrum, we calculated the amount of photons that are absorbed each second in the bulk of the active layer as a function of position in the device, for both MW cases. The results are shown in Fig. 3. The active layer in the low MW device clearly absorbs less photons due to its lower extinction coefficient, yet the difference between the profiles is not as large as one might expect from consideration of the optical constants. Integration of the photon absorption rates over the position gives total photon absorption rates of $4.8 \times 10^{20}\ \mathrm{m^{-2}\ s^{-1}}$ and $5.1 \times 10^{20}\ \mathrm{m^{-2}\ s^{-1}}$ for low and high MW, respectively. Since these cells show a linear dependence of J_{sc} on light intensity, the observed difference of 30% in short-circuit current density cannot be explained by this increase of
Fig. 1. Current density under illumination (J_L) versus voltage characteristics of PF10TBT:PCBM solar cells made from low (squares) and high (circles) molecular weight PF10TBT. Both active layers were approximately 95 nm thick. The inset shows the chemical structure of PF10TBT.
Fig. 3. Photon absorption profiles calculated for the devices of Fig. 1, using the optical constants presented in Fig. 2. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

6% in absorption only. Furthermore, no significant influence on the fill factor would be expected. We therefore conclude that optics only account for a minor part of the variation in photovoltaic performance.

Other than optical effects, a change of molecular weight might cause electronic differences. As stated in the introduction, space-charge effects can limit the fill factor of an organic solar cell to 0.42. Such a limitation can only occur if charge transport in the solar cell is strongly unbalanced. A significant effect of polymer molecular weight on the electron mobility in the PCBM phase is highly unlikely, since the acceptor constitutes the largest part (80 wt.%) of the active layer. The electron mobility μ_e can be probed by consideration of the current through the solar cells in the dark. In fullerene-based solar cells, the dark current under forward bias is usually dominated by electrons due to their high mobility in the PCBM phase. As shown in Fig. 4, the dark current of the PF10TBT:PCBM solar cells under study is well described by the single carrier space-charge limited current (SCLC) [21],

$$J = \frac{9}{8}\varepsilon_0\varepsilon_r\mu_e\frac{V^2}{L^3} \qquad (2)$$

with L the layer thickness, $\mu_e = 8 \times 10^{-8}$ m²/Vs for low MW PF10TBT and $\mu_e = 1 \times 10^{-7}$ m²/Vs for the high MW case. The applied voltage was corrected for the built-in voltage (V_{bi}) and resistive losses in the ITO/PEDOT anode (V_{Rs}). The relative dielectric constant ε_r was taken as the spatial average of PF10TBT and PCBM. As expected, the electron mobility is hardly affected by the molecular weight of the polymer and its value is close to what has been found previously for PCBM in fullerene-based solar cells [22–24]. Limitations to the photocurrent, if any, should therefore be caused by a low hole mobility in the low MW polymer. To elucidate the influence of molecular weight on hole transport in PF10TBT based solar cells, we prepared hole-only

diodes from PF10TBT:PCBM bulk heterojunctions in a 1:4 weight ratio. The current density versus effective voltage characteristics presented in Fig. 5 were measured at room temperature for two such devices using low MW (squares) and high MW (circles) PF10TBT. The single carrier space-charge limited currents were modeled using exactly the same low-field hole mobility of 6×10^{-9} m²/Vs (solid lines). Hence, no effect of molecular weight on the mobility in the PF10TBT phase was found. Measurements on pristine polymer layers revealed similar mobility values in both MW cases, showing that the hole transport in the PF10TBT:PCBM blend is also not affected by PCBM loading. This behavior contrasts to the case of MDMO-PPV:PCBM heterojunctions [23,25] and to what has been reported for a similar polyfluorene copolymer [26]. From temperature-dependent measurements, the thermal activation energy of hole transport in the blend was found to be 0.33 eV in both cases. This exactly equals the theoretically predicted value, obtained from the relation between the universal mobility prefactor $\mu_0 = 3 \times 10^{-3}$ m²/Vs and the above-mentioned low-field mobility at room temperature [27]. Since the hole mobility in the blend is constant with molecular weight, and differs only an order of magnitude with the electron mobility in PCBM, a space-charge limitation of the photocurrent in these relatively thin solar cells is highly unlikely [28].

Fig. 6 presents a comparison of the photocurrent of two cells based on low (squares) and high (circles) molecular weight PF10TBT, plotted versus effective voltage. Here, the experimental photocurrent is defined as the difference between the current density under illumination J_L and in the dark J_D, thus $J_{ph} = J_L - J_D$. Since the photocurrent is zero at $V = V_0$, the horizontal axis represents the effective voltage available for charge extraction from the device. In both cases the photocurrent nicely saturates at high effective voltage, indicating that at sufficiently large reverse bias all photogenerated bound pairs are dissociated and

Fig. 4. Determination of the electron mobility from the dark current of PF10TBT:PCBM solar cells (symbols) using the single carrier SCLC (solid lines). The fits reveal an electron mobility in PCBM of $\mu_e = 8 \times 10^{-8}$ m²/Vs for low MW PF10TBT and $\mu_e = 1 \times 10^{-7}$ m²/Vs for the high MW case. The applied voltage was corrected for the built-in voltage (V_{bi}) and the voltage loss over the ITO/PEDOT anode (V_{Rs}). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 5. Current–voltage data of hole-only diodes of bulk heterojunctions containing low (squares) and high (circles) MW PF10TBT. The solid lines represent numerical simulations, both using a low-field hole mobility of $\mu_h = 6 \times 10^{-9}$ m²/Vs. The applied voltage was corrected for the built-in voltage (V_{bi}) and the voltage loss over the ITO/PEDOT anode (V_{Rs}). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 6. Experimental photocurrents in solar cells from low (squares) and high (circles) molecular weight PF10TBT. The lines denote calculations of $J_{ph} = qGL$, using a field and temperature-dependent generation rate $G(T,E) = G_{max}P(T,E)$ as given by Braun's model of dissociation of charge transfer states [30]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

extracted from the device. The occurrence of saturation was verified with temperature-dependent measurements (not shown). At lower voltages, however, the photocurrent of the low MW cell clearly depends stronger on the electric field as compared to the high MW cell. In this voltage regime, a square root dependence is observed. This is indicated by the tilted dotted lines with slope ½ in Fig. 7, which shows intensity dependence measurements of the photocurrent in the low MW solar cell. The experimental photocurrent depends linearly on light intensity and the saturation voltage V_{sat} is intensity independent. This combination of voltage and intensity dependence of the photocurrent is a clear fingerprint of a recombination limited photocurrent.
Fig. 7. Intensity dependent photocurrent of the same low MW device as shown in Fig. 6. The tilted dotted lines denote slope ½, indicating $J_{ph} \propto V^{0.5}$, whereas the horizontal dotted lines mark the saturated photocurrent at each intensity. The solid lines represent numerical device simulations. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Application of Eq. (1) in the square root regime reveals a free carrier lifetime of approximately 0.5 μs. However, as was mentioned before, illumination of organic solar cells does not directly result in free charge carriers: instead, after charge transfer a bound electron–hole pair is created. Due to the high Coulomb binding energy in organic solar cells, only a certain fraction of all photogenerated bound electron–hole pairs G_{max} is dissociated into free charge carriers, depending on field and temperature, and therefore contributes to the photocurrent $J_{ph} = qGL$. Consequently, the generation rate G of free charge carriers can be described by:

$$G(T,E) = G_{max}P(T,E) \qquad (3)$$

where $P(T,E)$ is the probability for charge separation at the donor/acceptor interface. The photogeneration of free charge carriers in low-mobility materials can be explained by the geminate recombination theory of Onsager [29]. An important addition to the theory has been made by Braun [30], who stressed the importance of the fact that the bound electron–hole pair (or charge transfer state) has a finite lifetime. In Braun's model, the probability that a bound polaron pair dissociates into free charge carries at a given electric field E and temperature T is given by:

$$P(T,E) = \frac{k_{diss}(E)}{k_{diss}(E) + k_f} \qquad (4)$$

with k_f the rate constant with which the bound electron–hole pair decays to its ground state, and $k_{diss}(E)$ the rate constant for separation into free carriers, which is given by [30]:

$$k_{diss}(E) = \frac{3k_R}{4\pi a^3} e^{-E_B/k_BT} \left[1 + b + \frac{b^2}{3} + \frac{b^3}{18} + \frac{b^4}{180} + \cdots \right] \qquad (5)$$

with a the initial separation distance of the bound electron–hole pair at the interface, $b = e^3E/8\pi\varepsilon_0\varepsilon_r k_B^2 T^2$, and E_B the binding energy of the electron–hole pair.

Once separated, the charge carriers can again form a bound pair with rate constant k_R. The dissociation model uses Onsager theory for field-dependent dissociation rate constants for weak electrolytes [29] for $k_{diss}(E)$, Langevin recombination of free electrons and holes [31] and a Gaussian distribution of donor–acceptor distances. Then, the generation rate of free electrons and holes depends on the charge carrier mobilities μ_e and μ_h of the electrons and holes respectively, the relative dielectric constant ε_r, the initial separation of e–h pairs a, and the ground state recombination rate k_f.

As expressed in Eq. (4), the relative magnitudes of dissociation and decay rates determine a field and temperature-dependent dissociation probability of bound pairs $P(T,E)$. Consequently, when the photocurrent of an organic solar cell is interpreted using Eq. (1), the obtained lifetime is in fact an *effective* lifetime, equal to $P(T,E)\tau$, where τ is now the true lifetime of free charge carriers [16]. Using device modeling, we can determine whether a low effective lifetime originates from short lifetimes of bound pairs (low P) or free carriers (low τ).

We continue the investigation of the molecular weight dependent photocurrents in Fig. 6 by modeling the field-
Fig. 8. Experimental (symbols) and simulated (lines) current–voltage characteristics of the solar cells of Fig. 1 under illumination. The lines show numerical fits that only differ in the used values of G_{max} (representing enhanced absorption in high MW PF10TBT) and k_f (obtained from Fig. 6). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Parameters used to fit the current–voltage characteristics presented in Fig. 8.

Parameter	Symbol	Value	
		Low MW	High MW
Band gap	E_{gap}	1.47 eV	1.38 eV
Electron mobility	μ_e	8×10^{-8} m^2/Vs	1×10^{-7} m^2/Vs
Hole mobility	μ_h	6×10^{-9} m^2/Vs	6×10^{-9} m^2/Vs
Eff. density of states	N_c	2.5×10^{25} m^{-3}	2.5×10^{25} m^{-3}
Generation rate	G_{max}	6.0×10^{27} m^{-3} s^{-1}	6.6×10^{27} m^{-3} s^{-1}
Rel. dielectric constant	ε_r	3.6	3.6
Initial e/h pair distance	a	2.2 nm	2.2 nm
e/h Pair decay rate	k_f	2.1×10^6 s^{-1}	2.3×10^5 s^{-1}

dependent generation. The solid lines represent calculations of the photocurrent according to $J_{ph} = qGL$, using a field and temperature-dependent generation rate of free carriers as given by Braun's model [30,32]. The dissociation probability $P(T,E)$ is parameterized by the initial separation distance of the bound electron–hole pair a and the decay rate k_f, which are now the only fit parameters since L is measured separately and G_{max} can be calculated directly from $J_{ph} = qG_{max}L$ in the saturation regime. The fits reveal a value of $a = 2.2$ nm, irrespective of molecular weight. However, the decay rate k_f in the low MW cell is at 2.1×10^6 s^{-1} an order of magnitude higher than k_f of the high MW cell. This value of k_f is in very good agreement with the effective lifetime of free carriers as determined from Eq. (1), since $(0.5~\mu s)^{-1} = 2 \times 10^6$ s^{-1}.

To model the photocurrent over the entire effective voltage range, we utilized our numerical device model [33]. Since diffusion of charge carriers is now also taken into account, the photocurrent can be simulated at low effective voltage as well. In the simulations, shown in Fig. 7, the experimentally determined values of the charge carrier mobilities, layer thickness, dissociation parameters a and k_f, and generation rate of bound pairs G_{max} were used. The calculations excellently fit the measured data at various light intensities. This clearly shows that the photocurrent of low molecular weight PF10TBT:PCBM cells is limited by recombination of short-lived bound electron–hole pairs. We speculate that the limitation arises from insufficient phase separation, resulting in localization of bound pairs in isolated donor–acceptor regions, which prohibits efficient dissociation. Indeed, transmission electron microscopy (TEM) measurements on blends of varying molecular weight have revealed little contrast in blends of low MW PF10TBT with PCBM, whereas pronounced PCBM and polymer rich regions were observed in high MW films [8].

Fig. 8 presents a direct comparison of the simulated current–voltage characteristics under illumination of the cells

of Fig. 1. The model parameters that were used to fit the current–voltage curves are summarized in Table 1. Compared with the simulation of the curve of the low MW cell, only three input parameters were changed to fit that of the high MW cell: the slightly higher, experimentally determined electron mobility was used, G_{max} was increased by 10% and the previously determined lower decay rate $k_f = 2.3 \times 10^5$ s^{-1} was used. The increase in G_{max} closely agrees with the small (6%) enhancement in the calculated absorption for high MW cells as presented in Fig. 3. For these relatively thin active layers, using a constant generation rate G_{max} throughout the active layer does not change the simulation results compared to the use of the calculated optical profile as input [34]. The slightly higher V_{oc} of the low MW cell originates from the inversely proportional relationship between the polymer band gap and the average number of repeating units in each chain [35]. At short-circuit conditions, the average dissociation probability of bound electron–hole pairs in the high MW cell is 19% higher (relative) than in the low MW device, due to the reduction in k_f. Thus, the concomitant effects of enhanced absorption (10%) and more efficient dissociation (19%) add up to the observed increase of short-circuit current (30%) and fill factor.

4. Conclusions

Using optical and electronic device modeling, we have unraveled the molecular weight dependence of the short-circuit current density and fill factor of PF10TBT:PCBM solar cells. The use of high molecular weight PF10TBT causes an enhancement of the extinction coefficient of the blend layer, resulting in a slight increase in the amount of photons that are absorbed. Charge transport in both phases was found to be virtually unaffected by a change in molecular weight. The electron mobility in the blend is only slightly higher for high MW PF10TBT and a reasonably high, molecular weight independent hole mobility was measured in blend layers as well as pristine polymer layers, which renders the influence of space-charge on the photocurrent insignificant. Intensity dependence measurements confirmed that the photocurrent of low molecular weight cells is recombination limited. From numerical device simulations, we conclude that a low dissociation prob-

ability of short-lived bound electron–hole pairs is the main cause of the poor performance. The limitation is most likely caused by insufficient phase separation, which leads to localization of charges on isolated parts of the donor and acceptor phases.

planarity, high symmetry, electron delocalization property and high conductivity and have been studied widely for a long time [10,11]. The highest mobility reported so far in Pc based OFET was a single crystal CuPc-FET, where the mobility reaches as high as $1.0 \, cm^2 \, V^{-1} \, s^{-1}$ [12]. The solution-processed OFETs fabricated from amphiphilic tris(phthalocyaninato) rare earth triple-decker complexes have been revealed to display excellent FET performance with the carrier mobility as high as $0.60 \, cm^2 \, V^{-1} \, s^{-1}$ and current modulation of 10^5 [13].

The present work explores the potential of a nonperipherally octahexyl substituted lead phthalocyanine (PbPc), the chemical structure of which is shown in Fig. 1a, as an active material for OFET devices. The compound was chosen because of its low band gap (1.2 eV) energy [14] and for its solubility in common organic solvents, enabling its ready formulation as thin forms by the conventional spin-coating technique and capability of demonstrating nonvolatile memory phenomena [15]. The synthesis of the material was reported earlier by Burnham et al. [16]. As yet only one report in the literature has addressed the potentiality of PbPc as an active material for OFET [14], but memory functionality of the material was not investigated. In this study, we have shown that OFET based on PbPc can efficiently be used as a nonvolatile organic memory device with continuous write–read–erase–read switching performance.

2. Experimental section

The OFETs were fabricated on patterned indium tin oxide (ITO) coated glass substrate which acted as a gate electrode. Before using, ITO substrates were cleaned successively with detergent, de-ionized water, acetone and isopropyl alcohol in ultrasonic bath. Polyvinyl alcohol (PVA, Mol. Weight: 100,000), purchased from Fluka Chemicals, was dissolved in distilled water (15 wt%) and after filtering with 0.2 µm syringe filters, was spin coated on ITO substrate at 2000 rpm. The thickness of the dielectric layer was measured by a Dektak (3030) surface profilometer to be around 450 nm. After drying the film at 110 °C for 1 h in vacuum, a solution of PbPc in tetrahydrofuran, with a

concentration of $4 \, mg \, ml^{-1}$, was spun on top of PVA film rotating at 2000 rpm. The deposited films (60 nm) were then dried in a vacuum oven (10^{-3} Torr) at 90 °C for 3 h to allow complete evaporation of solvent and surface moisture. On top of the PbPc layer, gold (Au) was vacuum evaporated (below 10^{-5} Torr) at 0.3 Å/s through a patterned interdigitated shadow mask to make source/drain (50 nm) contact. The channel length and width of the OFETs were 60 µm and 6.4 mm, respectively. The schematic diagram of the OFET device is shown in Fig. 1c. The electrical characteristics of the OFETs were obtained at room temperature under ambient condition using Hewlett–Packard (HP) 4140B semiconductor parameter analyzer. We have characterized as many as 10 devices, out of which eight devices worked excellently and two devices did not show any FET properties.

3. Results and discussions

Fig. 2 presents the tapping mode atomic force microscope (AFM) images of the PVA surface on ITO substrate (Fig. 2a) and the annealed PbPc film on top of the dielectric layer (Fig. 2b). The images in both the cases show almost smooth surfaces with very low roughness (less than 2 nm). The surface analysis of the dielectric layer indicate that there is lack of pinholes throughout the film with an rms surface roughness of 0.75 nm enabling effective carrier transport throughout the film.

The output characteristics of PbPc FETs with gold drain–source electrodes are shown in Fig. 3; displaying the drain–source current I_{DS} versus the applied drain–source voltage V_{DS} for different gate voltages V_G applied to the ITO substrate, which acted as a gate. The device exhibits a field effect with operation in a p-type accumulation mode. The linear and saturation regions can be observed clearly with the increase of drain voltage (V_{DS}). The matching of HOMO energy level of PbPc (5.2 eV) with the work function of gold (5.1 eV) can ensure efficient hole injection into the semiconductor channel which further ensured high device performance in OFETs based on PbPc.

We observed a difference in V_{GS}–I_{DS} plots when different biases are applied to the gate electrode. Fig. 4 shows the evolution of the hysteresis in the transfer characteristics of PbPc FET, displaying memory windows of the devices as swept to the various gate voltage ranges. Three different gate voltages (V_G = 30, 40 and 50 V) have been plotted in the figure. The gate bias was swept in a loop, i.e., from 0 to $+V_{Max}$, $+V_{Max}$ to $-V_{Max}$, and finally from $-V_{Max}$ to $+V_{Max}$, keeping the source–drain voltage as constant (V_{DS} = −50 V). The clockwise hysteresis direction indicates that when a negative gate bias is applied, holes are injected into the PbPc channel, corresponding to the programming (writing) process, and when a positive gate bias is applied, holes are injected from the PbPc channel, corresponding to the erasing process. The injection or ejection of holes in the gate dielectric will lead to a threshold voltage (V_t) shift, which is the so called memory window. When the gate voltage cycling range is enlarged, the shift of the threshold voltage (ΔV_t) of the forward and backward sweeps becomes wider. This memory window forms the basis for

The variation in ΔV_t from device to device has been indicated by error bars.

PbPc FETs working as memory devices. The shifts in V_t by 5.63 and 9.59 V are observed when the gate voltages are scanned, respectively, to $V_{Max} = 40$ and $V_{Max} = 50$ V with respect to the initial cycle of $V_{Max} = 10$ V, where the memory window of only 1.7 V can be observed (not shown). Different gate voltages have been applied to the device for the evolution of the hysteresis. The dependence of the memory window, i.e., the shift in threshold voltage (ΔV_t) with the maximum gate voltage applied ($V_{G,Max}$) is shown in the inset of Fig. 4. We have measured eight different devices and the results are summarized in the figure. The figure shows that with increase in amplitude of gate voltage ($V_{G,Max}$), the memory window increases nonlinearly. This means that higher the value of $V_{G,Max}$, larger is the rate of increment of ΔV_t. In other words, the increase in ΔV_t is more pronounced at higher V_G. The similar trends have been observed from all the devices with a slight fluctuation in the value of ΔV_t (indicated by error bars).

The hysteresis and memory behaviors in OFETs are normally proposed to be due to the charge storage [17], slow polarization of the gate dielectric [7] and electron trapping in the semiconductor [18]. The observation of hysteresis in the present OFET device is proposed to be due to locally trapped charges that induce shifts in V_t [9]. When a large negative gate bias is applied, the injected holes are trapped in the interface, leading to the built in electric field along the direction opposite to the applied field. This built in electric field screens the external field, resulting in more negative gate bias needed to turn the transistors on, and thus a negative directional V_t shift occurs (Fig. 4). Once the charges are trapped in the interface, they remain trapped leading to on state of the device, until at large positive bias the charges become detrapped and the device goes to the off state. The charging and discharging of PVA films has been known for quite a long time and was also reported by other groups [19,20]. We also have measured the gate leakage current (I_G) of the OFET as V_G is scanned in a loop with fixed

drain–source voltage ($V_{DS} = -50$ V). It can be seen from Fig. 5 that the maximum leakage current of the device is as low as 40 nA which is 25-folds lower than the corresponding drain current. With regard to the large threshold voltage shifts in the "forward" and "reverse" sweeps of the gate voltage, we applied different drain voltages, V_{DS}, to observe sizable differences in I_{DS} values. The memory effect is pronounced even at low V_{DS} (e.g., $V_{DS} = -30$ V) as shown in Fig. 5. The drain current and memory window, however, decrease with decrease in magnitude of drain voltage.

Fig. 6 presents a representative result of write–read–erase–read (WRER) cycle tests conducted on the devices for hours. Only a section of the results is depicted in the figure. In the write–read–erase–read cycle, the "write" (i.e., on state) is made by applying a negative voltage pulse (-40 V) and the "erase" (off state) is achieved through erasing the on state by applying a positive voltage pulse with an amplitude of 40 V. A small probe voltage (-20 V) pulse is employed to read the on state (write) and off state (erase) of the device. The drain voltage, during the measurement, was kept constant at $V_{DS} = -30$ V. The probe current in the on state is clearly higher than that in the off state. The ratio between the read currents in the on and off states (on/off ratio) of the PbPc FET was maintained to be more than five. The device has been operated under more than 60 WRER cycles and no current degradation is observed for either of the states. Also, during the test, it produces good rewritable characteristics.

One of the important parameters of any storage device is its memory retention time, which is defined as the time for which the memory can be read out unequivocally to be in the on or in the off state. We investigated the charge retention properties of the PbPc FET, i.e., the relaxation dynamics of trapped charge carriers after writing or erasing of the device, the results of which are summarized in Fig. 7. A voltage pulse of ±40 V was chosen to write (on)
Fig. 5. Transfer characteristics of the OFET for different drain (V_{DS}) voltages. Gate leakage current (I_G) is plotted on the right axis. Arrows indicate the sweep directions of V_G.
Fig. 6. Memory operation (write-read-erase-read) cycle with writing at $V_G = -40$ V, erasing at $V_G = 40$ V, and reading at $V_G = -20$ V. V_{DS} was kept at -30 V throughout the measurement.

or erase (off) the states of the device, followed by a read out of the states of the device by a -20 V read pulse (width = 2 s). The drain voltage was kept constant at $V_{DS} = -30$ V throughout the measurement. Fig. 7 shows current as a function of time for each of the two cases. To reduce the additive effect of the "probe" or "read" voltage on the existing state, we applied the "read" voltage in a pulse mode with a duty cycle of only 12%. It can be found from the figure that the device remains stable for more than 5 h in either of the states with no noticeable degradation. However, after 5.5 h, the device degraded a little with slight decrease in current. Here, we have calculated the time dependence of on/off ratio for different devices from their retention time measurements. The results are depicted in the inset of Fig. 7. Though there is a little variation in on/off ratio from device to device (as indicated by error bars), an average value of seven is maintained for all the devices for prolonged period of time.
Fig. 7. Data retention measurement of the On- (write) and off state (Erase) drain current (I_{DS}) of the OFET device measured at $V_G = -20$ V. V_{DS} was kept at -30 V throughout the experiment. Inset shows the plot of on/off ratio with time for different devices.

4. Conclusions

In summary, a programmable field-effect transistor with organic electret (PVA) as the gate insulator and lead phthalocyanine as the active semiconductor has been fabricated through solution processing. The device exhibited hysteresis and memory upon sweeping of the gate bias in the forward and reverse scan. Trapping and detrapping of charge carriers in the dielectric/semiconductor interface is proposed to be the mechanism behind the memory phenomena. The memory window increased with increase in magnitude of gate voltage or source–drain voltage. The device showed reproducible write–read–erase–read switching cycles and data retention of more than 5 h. The device fabrication by cheap solution processing makes it suitable for large area and low cost electronics. The memory performance of the device, though very promising, can further be improved by optimizing the device geometry, fabrication method and operating conditions.

photocurrent of ~9% at the maximum power voltage of 0.35 V and at B = 100 mT. They explained the enhancement of photocurrent as the result of an increase in the concentration of T excitons due to the enlarged intersystem crossing (ISC) rate of excitons from S state to T state. The different explanations on the above various MFEs observed in similar systems show that the mechanism of the MC effect in organic semiconductors remains obscure and more investigation is required.

In this work, we studied the MC of P3HT:PCBM based bulk heterojunction solar cells (BHJSCs) in dark and under illumination. The dark current always decreases with the applied magnetic field (−MC). However, when light illumination is turned on, the photocurrent is enhanced by the applied magnetic field (+MC). Because the photocurrent is in the opposite direction of the injection current, the MC trace of current under illumination exhibits a sign change around the open circuit voltage V_{oc}. We suggest that the +MC in photocurrent is due to the field-suppressed ISC of e–h pairs from S state to T state and −MC under illumination is mainly contributed by the dominating −MC in dark current because $I_{photo} \approx I_{dark}$ at those voltages. While the −MC in dark current is associated with the space charge limited current (SCLC). Other possible mechanisms for ±MC effects are also discussed.

2. Experimental

Our BHJSCs consist of a blended P3HT:PCB M (1:1 in weight) thin film sandwiched between poly(3,4-ethylene-dioxythiophene)/poly(styrenesulfonate) (PEDOT:PSS) coated indium tin oxide (ITO) and a modified metallic cathode. After the traditional cleaning process and UV/O₃ treatment, a PEDOT: PSS layer of ~50 nm thick was spin coated onto the ITO covered glass substrate and then annealed for an hour at 100 °C in vacuum. Then ~100 nm thick P3HT:PCBM photovoltaic layer (solved in dichlorobenzene) was spin coated onto the PEDOT:PSS layer and dried in vacuum at 90 °C for an hour. A 1 nm thick lithium fluoride (LiF) and a 100 nm thick aluminum cathode were thermally evaporated onto the organic layers through a shadow mask (active areas: 1×3 mm^2) in high vacuum (~10^{-5} Pa). During the measurement process, the samples were mounted on the cold finger of a close-cycle cryostat (Janis CCS-350s) which was located between the pole pieces of an electromagnet (Lakeshore EM647). The magnetic field with the maximum strength of 200 mT was applied parallel to the device surface and measured by Hall probe GaussMeter (Lakeshore 421) placed close to the sample. The J–V characteristics in dark or under illumination were measured by a Keithley 2400 SourceMeter and a halogen lamp with light intensity ~50 mW/cm^2 was used as the light source.

3. Results and discussion

Fig. 1 shows the MCs at two typical biases in the dark and under illumination as a function of the applied magnetic field. The open circuit voltage V_{oc} is 0.55 V in this device. The MC is defined as $[I(B) - I(0)]/I(0)$, where $I(B)$ and
Fig. 1. (a) MC vs. magnetic field in the P3HT:PCBM based BHJ solar cell device in dark and under illumination at the bias voltages of (a) 0.516 V, below the V_{oc} of the studied device; (b) 0.691 V, above the V_{oc}. The red solid lines are guides to the eyes. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

$I(0)$ are the currents in the presence and absence of a magnetic field B. As shown in Fig. 1a, −MC in dark current with value of ~0.7% is observed at 0.516 V below V_{oc}. When light illumination is turned on, the MC response shows a sign change and produces positive trace in photocurrent as shown in Fig. 1a. The same phenomenon is observed at other bias below V_{oc}. The red lines in this figure are added just as guides to the eyes. However, both the MCs in the dark and under illumination are negative at bias above V_{oc}. Typical traces at 0.691 V are selected and displayed in Fig. 1b.

Fig. 2 illustrates the current variation $\Delta I = I(B) - I(0)$ under an external magnetic field (~50 mT) as a function of
Fig. 2. Current variations $\Delta I = I(B) - I(0)$ under magnetic field of 50 mT as a function of J for the device in the dark and under illumination. The inset is the photocurrent under field (50 mT) and with no field as a function of the applied voltage. The olive solid lines are guides to the eyes.
Fig. 3. (a) Dark J–V characteristics (black solid square) and illuminated J–V characteristics (blue solid circle) of the device. The red solid line represents a power law fit to the log(J) vs. log(V) in the bias region (0.4–1.0 V). (b) MC of current in the dark (black open square) and under illumination (blue open circle) vs. log (V). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the current density J in the dark as well as under illumination. The photocurrents in the presence and absence of a B field $\sim$50 mT are compared in the inset (only show the currents around V_{oc}). Nearly constant enhancement of photocurrent is observed for all bias below V_{oc} due to the action of the magnetic field. When increasing the voltage, the photocurrent become positive and its variations are linear with J. Similar linear change is also observed in dark current. The observed phenomena suggest that the distinct J dependences of ΔI in negative and positive J region must be related with two different mechanisms of MC.

To investigate the correlations between the MC effect and the current character in our devices, we measured J–V characteristics in a small voltage range (0.15–1.0 V) in dark and under illumination, respectively. As shown in Fig. 3a, at low voltages the J–V characteristics in dark are linear. At higher voltages (0.4–1.0 V), power law behavior of $J \propto V^m$ with $m \sim 6$ (red solid line)[1] are observed. The J–V characteristics under illumination also contain two different regimes: (i) when $V < V_{oc}$, the current is dominated by the diffusion of photo-generated charges under the built-in electric field, (ii) when $V > V_{oc}$, the current under illumination is slightly larger than the dark current, i.e. $I_{photo} \approx I_{dark}$. The MC-voltage curves are displayed in Fig. 3b. In dark condition, the MC response is always negative and shows a weak dependence on the applied voltages. However, under illumination, +MC at bias below V_{oc} and $-$MC at bias above V_{oc} are observed. The inversion and large values of MC occur at voltages close to V_{oc}. In fact, this feature of MC response in current under light is not intriguing and has been reported by Desai et al. [18]. It can be easily understood that though the applied magnetic field only slightly enhances the negative photocurrent, a

drastic MC response is yielded at bias voltages around V_{oc} due to the denominator $I(0)$ is nearly zero when the bias voltage approaches V_{oc}.

At the voltages below V_{oc}, the measured augment of photocurrent with an applied B field is very similar with the result reported by Shakya et al. [17]. Instead of thinking that the external magnetic field can increase the ISC rate of excitons from S state to T state, we consider the magnetic field affected hyperfine modulation on the conversion of e–h pairs from S to T. Kalinowski et al. [1,2] suggested that the hyperfine interactions of electrons or holes with surrounding nuclei could partially convert the S e–h pairs into T pairs with a rate constant K_{ST}. In the absence of an external magnetic field, the S and T (T_0 and $T_{\pm}$) pair states nearly degenerate because of the negligible exchange interactions, resulting in an effective S $\rightarrow$ T conversion due to the hyperfine mixing. When a magnetic field is applied, the triplet degeneracy is removed and the hyperfine mixing can only occur between S and the T_0 state, leading to a decrease in K_{ST} and an increase in the concentration of S pairs. Under light illumination, the S excitons are generated in the blend by absorbing the photons. They can diffuse to the P3HT/PCBM interface and form the correlated S e–h pairs through a charge transfer process. Because the S e–h pairs have a stronger ionic character than T pairs, they have higher probability for dissociation or charge separation [1,19]. Under the light illumination with constant density, the applied B field boosts the population of S e–h pairs and therefore enlarges the photocurrent. In addition, a slight high field ($B > 50$ mT) decrease can be identified in the MC response of photocurrent when $V < V_{oc}$. Similar phenomenon has also been observed by Kalinowski et al. in the photoconductance of Alq$_3$ film [1]. Their pioneer interpretation based on the electronic Zeeman effect attributed this MFE to a non-negligible exchange interaction between S and T e–h pairs. Increasing the magnetic field pushes the T_+ state toward S state, and a sudden increase in the ISC rate from S to T_+ pair states and a minimum in the concentration of the S pairs can be expected at a level crossing field. A weak decreasing trend in the MFE on the photocurrent or photoconductance can be expected if considering a Gaussian distribution of the e–h pairs' distance instead of a constant charge separation distance for all e–h pairs.

In addition to the dissociation of S e–h pairs and S excitons, the reactions between the electrode and T excitons constitute another channel for the generation of photocurrent. T excitons can diffuse to the electrode interface owing to their long diffusion lengths for charge reaction, T + electrode $\rightarrow$ e + h, giving the so-called excitonic injection contribution to the total current [1,2,20]. But such a process in the blends should be much weaker than in the polymer films because the phase separation of donor and acceptor can greatly facilitate the interfacial dissociation of excitons and consequently increase the exciton dissociation efficiency. It was estimated that almost all the T excitons are highly probable to reach the donor/acceptor interface and dissociate into free charge carriers [17]. Hence we do not suggest that the T excitons induced excitonic injection of current is an important channel in the magnetic field effect on the photocurrent.

---

[1] For interpretation of color in Fig. 3, the reader is referred to the web version of this article.

According to the above discussed mechanism of MFE on photocurrent, the nearly constant ΔI in photocurrent at bias below V_{oc} as shown in Fig. 2 is due to the constant density of light illumination. When the applied voltage is larger than V_{oc}, the variations of current under illumination are linear with J and show a small difference in slope with the variations of dark current. This small difference could be caused by the photo-generated charges which fill the traps or drift in the blend.

As frequently been observed, the bulk transport in organic semiconductors is often dominated by the space charge limited current with an exponential traps distribution which leads to the relationship between J and V as $J \propto V^m$. Referring to Fig. 3a, the J–V characteristics of our BHJSC device exhibit similar behavior as $J \propto V^6$ (red solid line), which is likely a signature of trap filling [21]. Therefore we suggest that the $-$MC effect in dark current might be associated with the case of SCLC. This can be also confirmed by the case of current under illumination. At bias larger than $\sim$0.6 V, the current under illumination is also governed by the SCLC. The MC effects at this current regime under illumination are negative and have only a small difference in their values compared to the $-$MC effect of dark current. Similar effect has also been found in OLED by Bloom et al. who measured the magnetoresistance (MR) effect of the devices (device was current biased and the voltage drop was measured) [12,13]. Their findings show that when the $I(V)$ exhibits power law behavior ($I \propto V^6$), the MR is positive ($-$MC effect), and with the deviation from the power law the MR starts to decrease and even becomes negative ($+$MC effect). Currently the microscopic origin of the correlation between the SCLC and $-$MC is still unclear. More dedicated experiments are required to solve this issue and further development of theoretical model will also be a great challenge. At large bias, the current under illumination of our device is actually dominated by the dark current, for instant, at $V = 0.691$ V, $I_{photo} \approx I_{dark}$. Therefore in this voltage regime, the MC response is mainly due to the MFE on dark current. We ascribe the small difference between the $-$MC$_{photo}$ and $-$MC$_{dark}$ to the influence of the MFE on the photo-generated charge carriers which would decrease the injection current.

Recently, several groups have used bipolaron model to explain the MR effect of the organic devices [4,5,12–14]. This model relies on the spin dependent formation of doubly occupied sites during the hopping transport of charge carriers through the organic film [22]. As indicated in J–V, the SCLC with an exponential traps distribution would probably favor the formation of bipolarons. Since the donor and acceptor phases are separated in P3HT:PCBM blend, positive polaron pairs (P^+P^+) and negative polaron pairs (P^-P^-) should be formed in the P3HT polymer phase and fullerene phase, respectively. However, as seen in Fig. 3b, the $-$MC response in dark current seems to be voltage independent. Such a phenomenon is inconsistent with the bipolaron mechanism because the large concentration of bipolarons should be able to result in the increase of the magnitude of MC. Within the bias range of 0.5–0.8 V, the current density increases nearly two orders as shown in Fig. 3a. A stronger MC response should be anticipated but it is not observed in the experiment. Therefore the bipolaron model is not suitable to explain our observations.

4. Conclusion

We have investigated the MC effects in P3HT:PCBM based BHJSCs in the dark and under illumination. We observed a sign change in MC response under illumination occurred at the bias close to V_{oc}. At bias below V_{oc}, the $+$MC in photocurrent can be explained by the field dependent hyperfine mixing between the S and T e–h pairs, leading to an enhancement in S pair dominated charge dissociation and photocurrent. At bias larger than V_{oc}, both current under light and in the dark show similar $-$MC effect. Because the current under illumination at bias above V_{oc} is mainly due to the injection current (dark current), the $-$MC can be attributed to the MFE on dark current which displays the clear character of space charge limited current with an exponential traps distribution. Our study leads to the insight into the fundamental magnetic field dependent properties of the excitonic states formed in organic optoelectronic devices.

channel through ambipolar transport. In fabricating efficient ambipolar OLEFETs, balanced carrier conduction and controlled positioning of the recombination region are crucial. So far, either utilizing single ambipolar materials or combining two unipolar materials through co-evaporated or bilayered structures have been applied to realize ambipolar carrier conduction [15–23]. In most cases of single component- and co-evaporated blend-based OLEFETs, however, efficient light emission has not been observed due to the difficulties in achieving a balanced injection and carrier transport. While there is a physical separation between hole and electron transports, bilayer heterojunction-based OLEFETs have demonstrated well-balanced ambipolarity with high carrier mobilities and have consequently improved luminescence by tuning the gate voltage.

Another critical factor in fabricating high-performance OLEFETs is the preparation of good thin films. Unlike traditional vapor deposition and/or solution-processing methods, the neutral cluster beam deposition (NCBD) method employed in this study is a less popular, but promising deposition approach [24]. Neutral cluster beams of weakly bound organic molecules are generated at the throat of the nozzle when the vapor-phase molecules evaporated by resistive heating undergo adiabatic supersonic expansion in a high-vacuum. The unique characteristics of a neutral cluster beam are its high translational kinetic energy and directionality. The collision of such directional, energetic neutral clusters with a substrate of interest induces their facile decomposition into individual molecules, where their subsequent migration leads to the formation of smooth, uniform thin films. The novel scheme allows for significant improvement in surface morphology, crystallinity, packing density, and room temperature substrate deposition, whose unique advantages cannot be easily achieved through traditional vapor deposition techniques. In recent years a series of optoelectronic devices have been successfully prepared and characterized utilizing the NCBD method [25–33].

In this article, we describe our application of the NCBD method to fabricate bilayer heterojunction-based OLEFETs by successively superimposing two layers of α,ω-dihexyl-sexithiophene (DH6T) and N,N'-ditridecylperylene-3,4,9,10-tetracarboxylic diimide (P13). DH6T and P13 are hole- and electron-transporting materials with high mobilities and the relative positions of their highest occupied and lowest unoccupied molecular orbitals (HOMOs and LUMOs) are well-matched to form singlet excitons for high luminescence; the (HOMO, LUMO) levels of DH6T and P13 are estimated to be (-5.2 and -2.9 eV) and (-5.4 and -3.4 eV), respectively (Fig. 1). For the first time, our air-stable, heterojunction-based OLEFETs successfully

demonstrated good field-effect characteristics, stress-free operational stability, and electroluminescence based on well-balanced ambipolarity under ambient conditions.

2. Experiment

A homemade NCBD apparatus was employed to prepare the P13 and DH6T active layers [24]. The apparatus consisted of a pair of evaporation crucibles, a drift region, and the substrate. The as-received samples were placed inside the enclosed cylindrical crucibles (1.0 mm diameter, a 1.0 mm-long nozzle) and sequentially sublimated by separate resistive heating between 530 and 570 K for P13 and

480 and 510 K for DH6T. Each sample vapor then underwent adiabatic supersonic expansion into the high-vacuum drift region at a working pressure of approximately 6×10^{-6} Torr. Highly directional, weakly bound neutral cluster beams were formed at the throat of the nozzle and directly deposited onto the substrates. The optimum thickness and deposition rate were 300 Å at 1.0–2.0 Å/s for P13 and 150 Å at 0.5–1.0 Å/s for DH6T, respectively.

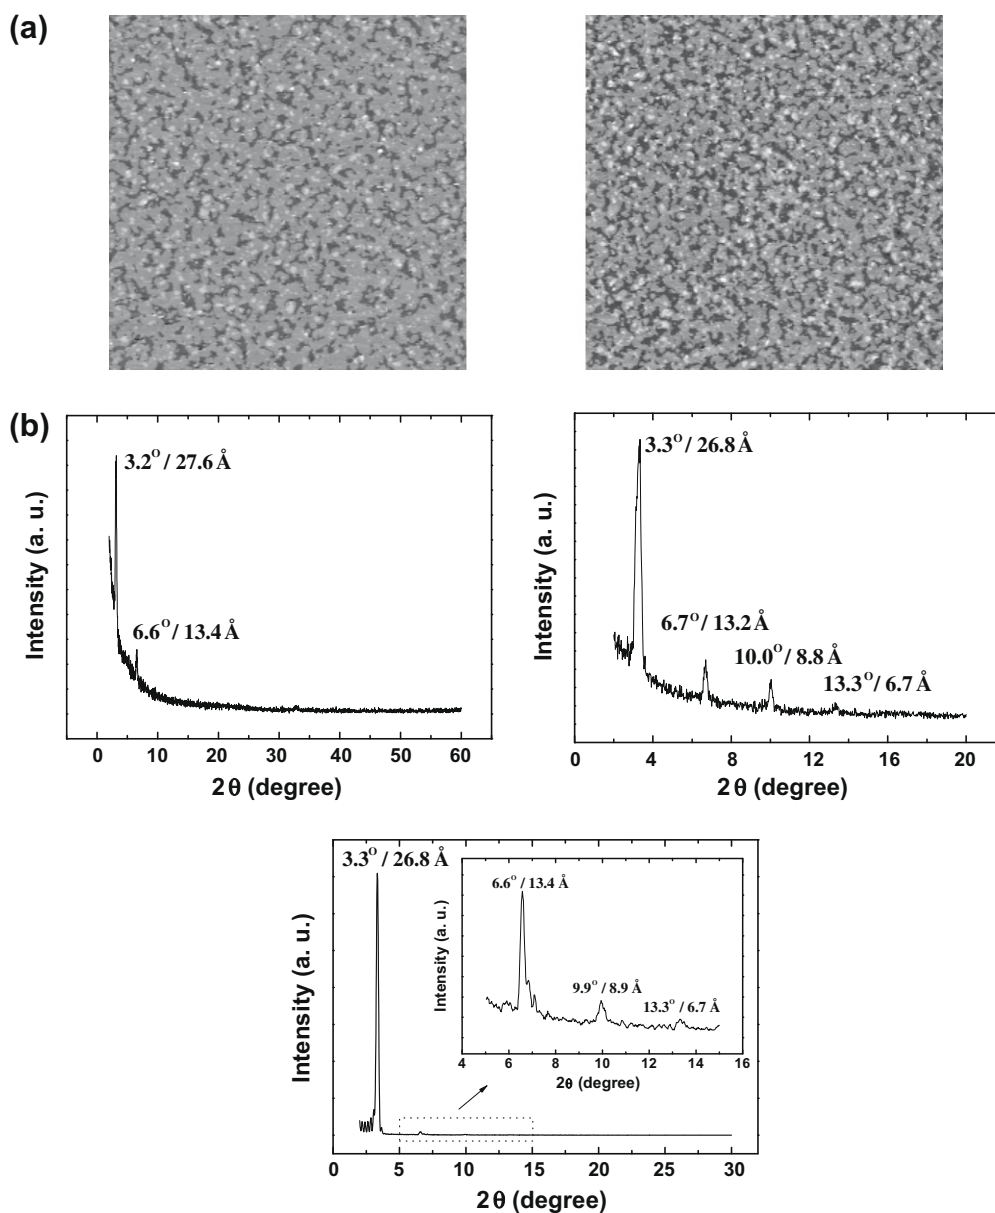
The OLEFET devices with a multi-digitated, long channel-width geometry were fabricated in the top-contact configuration as shown in Fig. 1. The substrates consisted of a highly doped, n-type Si wafer coated with an Al layer as the gate electrode and thermally grown 2000 Å-thick


Fig. 2. (a) Comparison of two-dimensional AFM micrographs ($10 \times 10 \ \mu m^2$ area) for the DH6T and P13/DH6T thin films. (b) Comparison of X-ray diffractograms for the DH6T, P13, and P13/DH6T thin films deposited on the SiO₂ substrates at room temperature.

SiO$_2$ layers as the gate dielectric. A rigorous cleaning procedure and UV treatment were necessary to improve OLEFET performance, involving a series of sequential ultrasonic treatments in acetone, hot trichloroethylene, acetone, HNO$_3$, methanol, deionized water, and blown dry with dry N$_2$. The substrates were finally exposed to UV (254 nm) for 15 min [34,35]. The multi-digitated transistors had a significantly longer channel-width (W) of 180.95 mm at a channel length (L) of 150 μm. Electron-beam evaporation using a properly shaped shadow mask was utilized to produce 500 Å-thick Au source and drain electrodes at a deposition rate of 6–8 Å/s. The current–voltage characteristics of OLEFETs and their light emission intensities were measured simultaneously in air, using an optical probe attached to an HP4140B pA meter-dc voltage source unit and an 818-UV Si photodiode with an 1830-C power meter (Newport Co.).

3. Results and discussion

Surface analysis using an AFM apparatus was carried out to perform the comparative characterization of surface morphologies for the DH6T and P13/DH6T films deposited on SiO$_2$ substrates at room temperatures. The root-mean-square (R_{rms}) values for the DH6T and P13/DH6T films were also measured as about 11 and 12 Å, respectively. Both films exhibited complete coverage with the highly packed grain crystallites, suggesting that the P13 bottom layer did not disturb the deposition conditions at the early stages and subsequent grain growth. The effect of the P13 bottom layer on the sequential deposition of DH6T active layer was also examined by the X-ray diffraction measurements using Cu Kα radiation in a symmetric reflection, coupled $θ$–$2θ$ scanning mode. Fig. 2b shows the XRD diffractograms for three different kinds of DH6T (300 Å), P13 (500 Å), and P13 (300 Å)/DH6T (150 Å) films. All thin films show a highly ordered structure. The sharp first-order peaks, as well as distinctive higher-order multiple peaks can be fitted to a series of (0 0 l) reflection lines with multiple d spacing. The XRD peaks of DH6T films located at $2θ = 3.2°$ and $6.6°$ correspond to d-spacings of 27.6 and 13.4 Å. The four reflection peaks of P13 films located at $2θ = 3.3°$, $6.7°$, $10.0°$, and $13.3°$ were assigned to be the d-spacings of 26.8, 13.2, 8.8, and 6.7 Å, respectively. In the case of the P13/DH6T bilayer films, strong and narrow first-order peaks were observed. Although the higher-order multiple peaks were much weaker compared to those in the DH6T films, the reflection peaks clearly showed the feature of the DH6T layer, indicating that the P13 layer placed at the bottom supports the crystalline growth of the DH6T top layer without causing the structural mismatch at the interface.

Fig. 3 displays the typical output characteristics of P13 (bottom)/DH6T (top)-based OLEFETs obtained under ambient conditions. The plot clearly exhibits the characteristic $I_{DS} = I_{DS} (V_{DS}, V_{DS})$ dependence expected for ambipolar devices, where I_{DS} is the drain-source current, V_{DS} the drain-source voltage, and V_{GS} the gate-source voltage. In the case of the reverse drain mode ($V_{DS} < 0$), there is a crossover point from electron-dominated current to hole-

dominated current. At low V_{GS} = 0 to −20 V, the drain current due to electron injection at the drain electrode decreases quadratically with decreasing V_{DS} (increasing $|V_{DS}|$). In the region of $V_{GS} \leqslant −30$ V, the drain current induced by hole injection from the grounded source electrode appeared to contribute substantially and showed a typical p-type transistor working in the accumulation mode. At a fixed $−V_{GS}$, I_{DS} initially decreased linearly with decreasing V_{DS} with I_{DS} tending to saturate due to a pinch
Fig. 3. Typical output characteristics of P13/DH6T-based OLEFETs obtained under ambient conditions.
Fig. 4. Typical transfer curves of P13/DH6T-based OLEFETs in the saturation regime together with the gate-dependence of the electroluminescence characteristics. Each transfer scan was run at a constant V_{DS}.

off in the accumulation layer. On the contrary, in the forward drain mode ($V_{DS} > 0$), a totally inverse phenomenon occurs. There is a crossover from the hole-dominated current to the electron-dominated current. At $V_{GS} = 0$–20 V, the drain current due to the hole injection at the drain electrode increased quadratically with increasing V_{DS}. In the region of $V_{GS} \geqslant 30$ V, the drain current induced by electron injection from the grounded source electrode appeared to contribute substantially and showed a typical n-type transistor working in the accumulation mode.

The extent of transport balance between the hole and electron carriers can be directly examined in the transfer characteristics. Fig. 4 shows the typical transfer curves in the saturation regime. Each transfer scan was run with a constant V_{DS}. In principle, for well-balanced ambipolar transistors, a symmetric form of the transfer curve centered near the I_{DS} minimum is expected. A good balance, especially in the positive V_{GS} region, is demonstrated in Fig. 4. Using standard FET analysis, quantitative carrier mobilities (μ_{eff}) can be calculated in the saturation regime by the following relationship:

$$I_{DS} = \frac{WC_i\mu_{eff}}{2L}(V_{GS} - V_T)^2$$

where C_i is the capacitance per unit area of the SiO_2 gate dielectric and V_T is the threshold voltage. For thermally grown, 2000 Å-thick SiO_2, the value for C_i is known to be 17.25 nF cm^{-2}. A hole mobility (μ_{eff}^h) of 2.22×10^{-2} cm^2/Vs at $V_{DS} = -60$ V is estimated to be nearly equal to an electron mobility (μ_{eff}^n) of 2.78×10^{-2} cm^2/Vs at $V_{DS} = 60$ V, implying that a well-balanced ambipolar carrier transport is clearly achieved in our OLEFETs. Several other device parameters can be also derived from the fits of the observed I–V characteristics for more than 10 OLEFETs and are listed in Table 1. The maximum hole and electron mobilities are also listed with the corresponding average mobilities (μ_{eff}^{avg}) with the standard deviation (σ). The μ_{eff} values at room temperature are comparable to or somewhat less than those obtained from the NCBD-based single-layer OFET devices, which are among the best to date for polycrystalline DH6T- and P13-based transistors using SiO_2 dielectric layers without any thermal post-treatment.

Herein, it should be noted that our measurements were carried out under ambient conditions, unlike most of the previous OLEFET investigations conducted either under inert atmosphere or vacuum conditions. In addition, due to

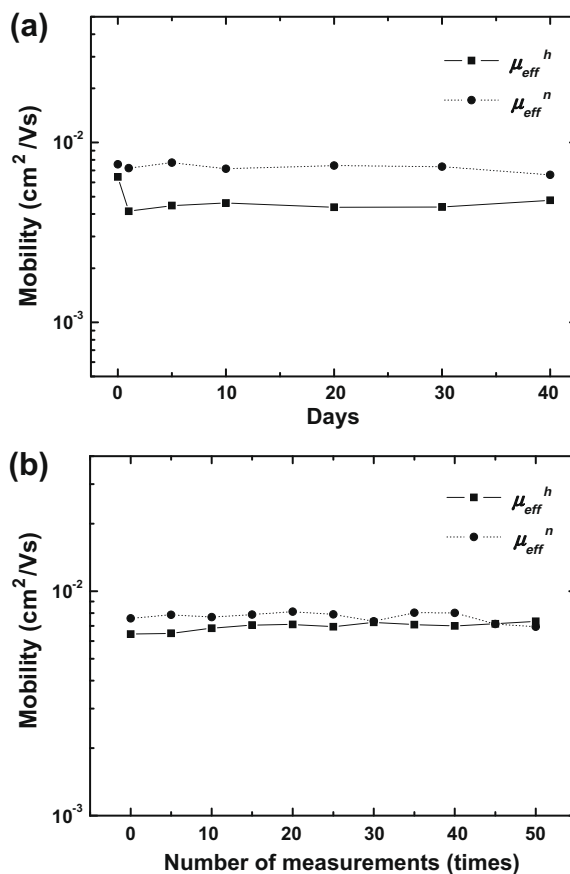
environmental effects, the deposition sequence of two active layers has been found to be critical in the fabrication process of stable bilayer heterojunction-based OLEFETs. In this study, by inverting the deposition sequence, the transistors with the bilayered structure of P13 superimposed on top of DH6T were also fabricated and characterized. However, since most n-type organic-based devices, including P13 devices, are sensitive to environmental contaminants such as moisture and oxygen that penetrate the channel region, device parameters such as mobilities deteriorate with time and therefore the OLEFETs do not


Fig. 5. Hole and electron mobilities of P13/DH6T-based OLEFETs monitored as a function of (a) time (days) and (b) number of measurements.

show reproducible device characteristics and operational stability. Similar deterioration phenomena were also reported in the P13-based organic devices [19,36]. On the other hand, as described in the previous section, when DH6T was deposited on top of the P13 layer, the DH6T layer appeared to act as a protective passivation layer and significantly improved operational stability. As displayed in Fig. 5a, the hole and electron mobilities monitored as a function of time did not change substantially, *even after 40 days*. Furthermore, the alleged stress phenomenon in our OLEFETs was not observed. The degradation process is known to occur when the devices are repeatedly operated. Fig. 5b shows the hole and electron mobilities as a function of the number of measurements. Transistor characteristics were consistently reproducible during repetitive operations up to 50, clearly manifesting that the operational stabilities of our OLEFETs were well maintained without degradation. Therefore, the bilayer structure with an air-stable organic compound deposited atop

as a protective passivation layer presented a reliable scheme in producing air-stable, stress-free ambipolar OLEFETs.

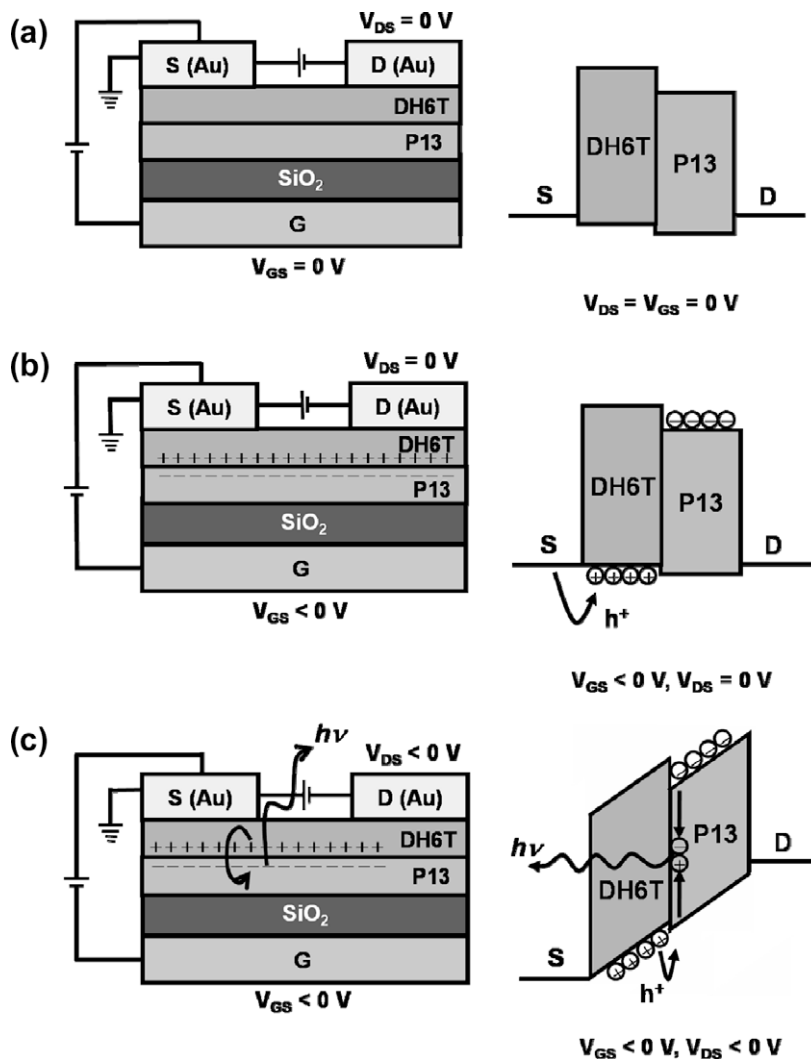
The gate-dependence of the electroluminescence characteristics corresponding to the transfer curves is also shown in Fig. 4. The light emission was observed in the region of $V_{GS} \leqslant -25$ V. In cases of single-layer OLEFETs, the maximum emission is generally expected to occur at $V_{GS} = 0.5 \ V_{DS}$, where an equal voltage drop for hole and electron carriers exists. To the contrary, emission in bilayer heterojunction-based OLEFETs are not required to satisfy the relationship. Instead, as revealed in Fig. 3, the position of the emission maximum shifts slightly with decreasing V_{GS} (increasing $|V_{GS}|$) and the intensity increases with decreasing V_{DS} (increasing $|V_{DS}|$). On the basis of the energy level diagram and the device structure in Figs. 1 and 6a, the operating mechanism to account for the observed light emission can be described as follows. When the gate electrode is negatively biased, the large electric field causes the


Fig. 6. Device operation and energy level diagram. (a) $V_{GS} = V_{DS} = 0$ V. (b) $V_{GS} < 0$ V, $V_{DS} = 0$ V. When the gate is negatively biased, the HOMO and LUMO levels shift up with respect to the Fermi levels of the Au metal electrodes and formation of the P13/DH6T dipole layer occurs. (c) $V_{GS} < 0$ V, $V_{DS} < 0$ V. At the proper negative V_{DS}, some carrier recombination takes place in the P13 layer to form the exciton leading to the electroluminescence.

HOMO and LUMO levels in both semiconductors to shift up with respect to the Fermi levels of the Au electrodes, inducing formation of a positively charged accumulation layer in the bottom of the DH6T layer (Fig. 6b); the holes injected from the Au electrodes are transferred into the DH6T layer with high hole mobility (Table 1) to form the active channel placed near the organic interface. Since P13 is an electron-transporting material with negligible hole mobility, the formation of such an active channel does not take place in the P13 layer. Instead, due to the positive charges placed at the interface, the favorable electrostatic interaction induces the attraction of the negative charges in the P13 layer with high electron mobility, leading to formation of the DH6T/P13 dipole layer. Afterwards, upon application of the proper negative drain voltage, the mobile holes can flow into the P13 layer and some carrier recombination takes place to form the exciton leading to the observed electroluminescence (Fig. 6c). Here, since P13 has a smaller energy gap and the higher energy barrier for hole transport from DH6T to P13 exists compared to that for the electron transport from P13 to DH6T, most light emission is highly likely to occur in the P13 layer. Our observation of the luminescence process stands in contrast with the measurements for the α,ω-dihexylquarterthiophene (DH4T)/P13-based ambipolar OLEFETs conducted under vacuum conditions by Dinelli et al. [19]. While the V_{GS} dependence of the emission intensity examined under vacuum conditions was similar to that in this study, the light emission due to the balanced transport was reported to occur only when the DH4T layer was placed at the bottom, in direct contact with the dielectric, irrespective of the deposition sequence of the two layers. Further experimental and theoretical investigations related to the conduction mechanisms of bilayer heterojunction-based OLEFETs are required.

4. Summary

The air-stable, heterojunction-based OLEFETs with well-balanced ambipolarity were fabricated for the first time, and good field-effect characteristics, stress-free operational stability, and electroluminescence were demonstrated under ambient conditions. Fabrication and characterization of several OLEFETs using various π-conjugated molecules through the NCBD method are underway. We hope these studies to provide further insights into the operating mechanisms and the structure-performance relationships at the molecular level.

promising technique for eliminating the need for alternating organic/inorganic stacks in the encapsulation of organic electronics, because of its unique capability of forming defect-free inorganic films at low temperatures [20–22]. Thin-film encapsulation of organic light-emitting diodes and small-molecule organic PVs using a single-layer ALD Al_2O_3 film, either with or without an organic capping layer, has been attempted with promising results [23–25], but has not been reported for polymer bulk-heterojunction PVs.

In this study, ALD was employed to deposit inorganic metal oxide thin films to encapsulate polymer bulk-heterojunction PVs, where blended poly-3-hexothiophene (P3HT) and [6,6]-phenyl C61 butyric acid methylester (PCBM) comprised the active layer. The objectives were: (1) eliminating O_2/H_2O-caused degradations to the PVs' characteristics and (2) achieving high efficiency in the encapsulated PVs. The effects of the temperature and duration of the ALD process on the efficiency of the encapsulated PVs were determined to select the optimal settings. The intrinsic degradation rate of the PVs, i.e., the degradation rate under O_2/H_2O-free environment, was determined as a baseline, against which the encapsulated PVs were evaluated. Two types of ALD films, Al_2O_3 and an $Al_2O_3/$ HfO_2 nanolaminate, were tested, and their gas permeation rate and microstructure were determined to improve their effectiveness as encapsulating films.

2. Experimental

2.1. Device fabrication and characterization

The cross-sectional structure of the PV devices used in this study from anode to cathode was: indium tin oxide (ITO)/poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS)/P3HT:PCBM/Al/encapsulation, as illustrated in Fig. 1a. The PEDOT:PSS layer (thickness = 50 nm) was spin-coated from Baytron PH500 (Bayer AG) followed by baking at 180 °C for 60 min in a glove box. The P3HT:PCBM layer (thickness = 110 nm) was spin-coated from a mixed solution of 1 wt.% P3HT (Mn = 50000 $gmol^{-1}$, regioregularity = 98.5%, purchased from Rieke Metals and used as received) and 0.8 wt.% PCBM (purchased from Nano-C and used as received) in anhydrous chlorobenzene. The Al layer (thickness = 250 nm) was formed by thermal evaporation through a shadow mask under high vacuum (10^{-6} torr). The control devices were annealed at 140 °C for 60 min in the glove box followed by encapsulation with a glass lid sealed with UV-curable epoxy resin (A1438, Addison Clear Wave; used after degassing under vacuum for 2 h). The current density–voltage (J–V) characteristics of the devices were measured with a Keithley 2400 source meter under simulated AM1.5G illumination (ThermoOriel and ScienceTech solar simulators with integrated intensity = 100 mW cm^{-2}), which was calibrated with a Hamamatsu silicon photodiode with KG-5 filter against an NREL-calibrated solar simulator. The lifetime of the devices, defined as the time required for the power conversion efficiency (PCE) to drop to 50% of the initial value, was measured by monitoring the change in their IV characteristics with the storage time either in air or in the glove box. All air storage tests reported in this work were conducted in ambient light at 28 °C and 60% relative humidity unless noted otherwise.

2.2. Atomic layer deposition

Savannah 100 ALD system by Cambridge Nanotech Inc. was used to deposit ALD Al_2O_3 and HfO_2 films. The $Al_2O_3/$ HfO_2 nanolaminated films were composed of 52 pairs of alternating 2 Å Al_2O_3 and 3 Å HfO_2 layers. The precursors used for Al_2O_3 and HfO_2 were trimethylaluminum (TMA)/ H_2O and tetrakis(dimethylamido)hafnium (TDMAHf)/H_2O, respectively. The deposition temperature was 140 or 150 °C and the chamber pressure was 0.1 Torr. High-purity N_2 (flow rate = 20 sccm) was used as carrier gas for the precursors. The ALD cycle for Al_2O_3 consisted of the following steps: a 0.03 s pulse of TMA, a 5 s purge with N_2, a 0.02 s pulse of H_2O, and a 5 s purge with N_2; the ALD cycle for HfO_2 was the same except for the first step, which was a 0.1 s pulse of TDMAHf. It should be noted that the TMA and TDMAHf pulses were placed before the H_2O pulse to prevent incursion of H_2O into the devices, as the adsorbed TMA or TDMAHf molecules would rapidly consume the incoming H_2O molecules before they could entered the devices [22]. A cycle produced 1 Å and 1.2 Å for Al_2O_3 and HfO_2, respectively, as determined by ellipsometry (EP3, Nanofilm Tech.). For the ALD process with a soak period for each of the precursors (during which the reactor contained a precursor without being pumped or purged), the steps in the cycle were a 0.1 s pulse of TMA, a 25 s soak, a 25 s purge with N_2, a 0.1 s pulse of H_2O, a 25 s soak, and a 25 s purge with N_2.

2.3. Surface characterization

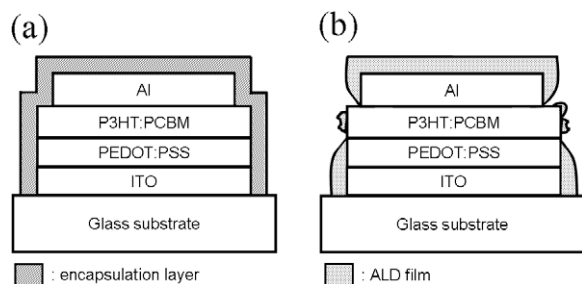
Scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX) analyses were conducted with a field-emission SEM (JSM-6700F, JEOL) operated at an accelerating voltage 10 kV, and the samples were coated a thin layer of platinum (~3 nm) before analysis. Water contact angles were measured using a Ramé-Hart contact angle goniometer (Model 100), where the sessile drop of 2–3 μl in volume was dispensed with a microsyringe and the contact angle was measured within 30 s after its formation.


Fig. 1. Schematics of the cross-section of the PV devices: (a) encapsulated by a barrier film with complete coverage over all device surface and (b) encapsulated by a barrier film that has poor surface coverage over the P3HT/PCBM layer.

2.4. Helium permeation measurement

The helium transmission rate (HeTR) of the ALD films was measured at room temperature with ALD films deposited on polyimide substrates (thickness = 50 μm; area = 5 cm^2). The samples were sealed with a rubber gasket between two isolated volumes, one of which contained He at constant 0.5 atm and the other of which was connected to a helium leak detector (ASM142, Alcatel). He molar flow rates through the samples were recorded with the leak detector, which divided by the sample area followed by subtracting the substrate contribution were the HeTR values. Detailed measurement setup and procedures can be found elsewhere [26].

3. Results and discussion

As the ALD encapsulation process was operated at elevated temperatures, it inevitably annealed the active layer and changed its morphology. Given that the performance of bulk-heterojunction polymer photovoltaics is crucially dependent upon the morphology of the active layer [27], it was important to determine the temperature and total time of the ALD process that would produce the optimal morphology. The effects of ALD time on the PCE of encapsulated cells are shown in Fig. 2 for two ALD temperatures, 140 °C and 150 °C. With both of the ALD temperatures, the PCE increased initially with increasing time, but the trend reversed after the PCE reaching an maximum at 30 and 60 min for 150 and 140 °C, respectively. This is similar to the effects of thermal annealing reported elsewhere [28,29]. Thermal annealing increases the PCE by inducing aggregation of the P3HT and the PCBM domains, which facilitates transport of charge carriers through the domains, but prolonged thermal annealing reduces the PCE by causing over-aggregation of the domains, which excessively reduces the bulk-heterojunction area that is critical for charge generation. We verified that the heating action of the ALD process was the sole cause of the observed encapsulation-induced changes in the PCE, as devices that
were thermally annealed (without the ALD process) under the same temperature/time condition as those of the ALD process showed almost identical after-annealing characteristics to those of the ALD-encapsulated devices (Fig. 3 and Table 1). This also indicates that the ALD precursors, although highly reactive, did not cause damage to the devices during the encapsulation process. Of the two ALD temperatures tested, 140 °C was used in the rest of this study because its optimal time in terms of the PCE of encapsulated devices, 60 min, allowed greater flexibility in fine-tuning the conditions of the ALD process.

To accurately evaluate the effectiveness of our encapsulation methods, i.e., their capability of blocking O_2 and H_2O from air, we first determined the degradation profile of control devices in an O_2- and H_2O-free environment, as shown in Fig. 4, against which we compared the degradation profiles of encapsulated devices stored in air. The control devices (annealed at 140 °C for 60 min without undergoing ALD) were encapsulated with adhesive-sealed glass plates and then stored in a glove box with below 0.5 ppm O_2 and H_2O concentrations to minimize any possible O_2 or H_2O incursion. As can be seen in Fig. 4, the control devices degraded slowly but significantly even in the nominally O_2/H_2O-free environment. This degradation behavior agrees with those reported elsewhere for P3HT/PCBM bulk-heterojunction PVs whose morphology were optimized with thermal annealing or controlled drying and whose initial PCE were >2.4% [30]. We attribute the inherent instability of the cells to two known mechanisms: (1) reaction of the aluminum cathode with P3HT/PCBM under sun light [30,31], and (2) gradual shift in the P3HT/PCBM morphology from the optimum that was initially achieved by thermal annealing [32]. It should be noted that the PCE stabilized after reaching ~1.6% (45% of initial PCE) and remained above 1.4% (40% of initial PCE) for over 3000 h, which was consistent with the reported stability of P3HT/PCBM bulk-heterojunction PVs whose initial PCE was low (<1%) [33]. The degradation profile of the glass-encapsulated control devices stored in air was also determined

Fig. 3. *J–V* characteristics of a device encapsulated with the ALD Al_2O_3 process at 140 °C for 60 min and another device annealed at 140 °C for 60 min without undergoing ALD.

Table 1
Characteristics of the devices plotted in Fig. 3.

Condition	V_{oc} (volt)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)
With ALD encapsulation	0.58	9.85	63.4	3.62
With annealing, but without ALD	0.58	9.98	63.2	3.66

V_{oc}: open-circuit voltage.
J_{sc}: short-circuit current density.
FF: fill factor.
Fig. 4. Degradation profiles of the devices with various encapsulations. All profiles except for that of the control were measured over storage in air at 28 °C with 60% relative humidity. The initial PCE of the devices ranged from 3.1% to 3.7%. The Al$_2$O$_3$/HfO$_2$ nanolaminated films were made with the with-soak process.

(also shown in Fig. 4): They degraded much more quickly than stored in the glove box, indicating that degradation caused by O$_2$ and H$_2$O permeating through the adhesive at the device perimeter was significant. It was this O$_2$- and H$_2$O-caused degradation that this study aimed to eliminate, and the issue of inherent instability is the topic of our ongoing work and will not be discussed here.

In encapsulating the PVs with ALD films, we observed three issues: (1) poor nucleation of ALD films on the surface of the P3HT/PCBM active layer that was exposed at the edges of the devices, which led to incomplete coverage of the ALD films (and therefore incomplete encapsulation) at the device edges (see Fig. 1b for a schematic illustration); (2) rapid hydrolysis of the ALD films in air, which caused the encapsulating films to disintegrate as the devices aged; (3) susceptibility of the ALD films to mechanical damages during device characterization and handling. As can be seen in Fig. 1, the device surfaces to be encapsulated by the ALD film included the Al cathode, the PCBM/P3HT active layer, the PEDOT:PSS layer and the ITO anode. Among the surfaces, the PCBM/P3HT layer was hydrophobic and therefore difficult for the ALD film to nucleate [34], while the other layers contained hydroxyl groups at their surfaces as chemisorption sites for facile ALD nucleation [35] and were therefore well-nucleated (see Supplementary materials). The poor nucleation of ALD films on P3HT/PCBM was observable with SEM and EDS. The surface of a P3HT/PCBM film coated with a 5 nm ALD Al$_2$O$_3$ layer appeared highly inhomogeneous under SEM (Fig. 5a), and EDS analyses (Fig. 5c and d) confirmed that the surface contained both Al$_2$O$_3$-coated (bright patches in SEM) and uncoated or little-coated areas (dark patches); on the other
Fig. 5. SEM images of the ALD Al$_2$O$_3$ films deposited on a P3HT/PCBM film (a) without-soak, and (b) with-soak. The scale bars are 1 μm. (c) EDS spectrum taken at the bright patches in (a); (d) EDS spectrum taken at the dark patches in (a).

hand, the ALD-coated Al, ITO and PEDOT:PSS surfaces were homogeneous (featureless) under SEM and were not shown. The poor nucleation was due to the lack of chemisorption sites (e.g. –OH groups) on the P3HT/PCBM surface. Nucleation of the ALD films was improved by employing a 25 s soak period for each of the ALD precursors in the first 5 cycles of the ALD process. The soak periods improved nucleation by allowing more precursor molecules to adhere to the P3HT/PCBM surface through physisorption/absorption, thereby improving surface coverage and uniformity of the ALD films. The improvement can be seen in the SEM image in Fig. 5b, where the P3HT/PCBM surface was free of heterogeneous features after being coated with the with-soak ALD process. In terms of the degradation rate of encapsulated devices, the with-soak ALD process also showed significant improvement over the without-soak process, as shown in Fig. 4: with a 26 nm ALD Al_2O_3 film as encapsulation, the devices encapsulated using the with-soak process had ~2.5-fold longer in-air lifetime than the devices encapsulated using the without-soak process. However, even with the nucleation issue addressed, the ALD-encapsulated devices still showed significant air-induced degradation, as determined by comparing the degradation profile with that of the control. This was attributed to hydrolysis of the Al_2O_3 films upon exposure to humidity in air, which created defects in the Al_2O_3 films.

The degradation of the ALD Al_2O_3 films during storage in air was evident under SEM (Fig. 6b), which shows severe delamination of a Al_2O_3 film from the device surface after 200 h. Meanwhile, the water contact angle of the film's surface (insets of Fig. 6b) also greatly reduced, from 68° to 23°. Conversely, films stored in lower humidity (30% relative humidity instead of 60%) were able to withstand longer storage before delaminating. In terms of barrier performance, the helium transmission rate (HeTR) through the Al_2O_3 films increased by a factor of ~7 after 50 h of storage in air, which was due to defects created by the delamination. The fact that degradation was faster at higher humidity and that the Al_2O_3 surface became more hydrophilic upon air exposure indicated that hydrolysis was the cause of the degradation, given the strong tendency of Al_2O_3 to hydrolyze into $Al(OH)_x$ [36]. Because of the low thickness of the ALD films, the effects of hydrolysis, including volume expansion and micro-structural changes, can occur not only at the surface but also throughout the bulk of the films, and therefore the degradation was much more pronounced than with thicker films. The resistance to hydrolysis was greatly increased in the Al_2O_3/HfO_2
Fig. 6. SEM images and water contact angles (inset) of ALD films deposited on the solar cells, before and after storage in air at 28 °C with 60% relative humidity: (a) as-deposited Al_2O_3, (b) Al_2O_3 after storage, (c) as-deposited Al_2O_3/HfO_2 nanolaminate, (d) Al_2O_3/HfO_2 nanolaminate after storage, (e) as-deposited two-layer Al_2O_3/HfO_2 and (f) two-layer Al_2O_3/HfO_2 after storage. The scale bars in the SEM images are 1 μm.

nanolaminated films, where the HfO$_2$ layers, being more hydrophobic than Al$_2$O$_3$ (water contact angle = 89° for HfO$_2$ versus 68° for Al$_2$O$_3$, see insets of Fig. 6), served as moisture barriers that prevented humidity from building up in the Al$_2$O$_3$ layers. The increased resistance to humidity can be seen in the SEM images and water contact angle measurements shown in Fig. 6c and d. Upon being stored for 200 h in air, the surface of the Al$_2$O$_3$/HfO$_2$ nanolaminated films remained free of defects under SEM; moreover, the water contact angle remained constant at 89°, which is the characteristic value of HfO$_2$ surface [37]. The absence of hydrolysis-induced damage in the nanolaminates was also confirmed by their constant HeTR over >400 h of storage in air, as shown in Fig. 7. With good hydrolysis-resistance, the Al$_2$O$_3$/HfO$_2$ nanolaminated films were significantly more effective encapsulation for the devices than Al$_2$O$_3$, slowing the degradation rate by ~2 folds (Fig. 4). It should be noted that a two-layer Al$_2$O$_3$/HfO$_2$ laminate (a 12 nm Al$_2$O$_3$ layer capped with a 14 nm HfO$_2$ layer) was also tested and found less effective than the multilayer nanolaminate, as shown in Fig. 6e and f, where the two-layer laminate still showed hydrolysis-induced delamination. This may be due to the crystalline nature of ALD HfO$_2$ films, which yields ample grain boundaries as rapid gas-diffusion pathways and therefore were not effective H$_2$O barriers for the underlying Al$_2$O$_3$ layer [38,39]. The hydrolysis-resistance of the multilayer nanolaminate, on the other hand, is attributed to the interspersed Al$_2$O$_3$ layers, which amended defects in the underlying HfO$_2$ layers and enhanced nucleation of the overcoated HfO$_2$ layers.

The Al$_2$O$_3$/HfO$_2$-encapsulated devices, however, required a UV-curable epoxy resin film as a capping layer to approach the degradation profile of the control, as shown in Fig. 4. The requirement of the capping layer may be attributed to following two reasons. Firstly, the Al$_2$O$_3$/HfO$_2$ film was susceptible to accidental damages during device characterization and handling due to its small thickness, and the resin layer provided mechanical protection. Notably, the role of the resin layer as an additional permeation barrier was minimal because of its much higher permeability than the oxide layer (by several orders of magnitude [18]). Secondly, the hydrophobicity of the PCBM/P3HT surface may still have caused small defects in the ALD film even with the with-soak process employed. This would suggest that the PCBM/P3HT surface may be more difficult for ALD nucleation than the C60/pentacene surface studied elsewhere, where a 200 nm ALD Al$_2$O$_3$ film was found adequate as an encapsulating film for C60/pentacene bulk-heterojunction solar cells [25]. It should be noted that in addition to the 26 nm ALD encapsulating films, we also tested thicker films (100–200 nm) and found that they yielded poorer results (see Supplementary materials). This may be accounted for with the two following mechanisms: (1) the barrier performance of ALD films plateaus in the 10–30 nm thickness range, above which little improvement is gained [20,21]; (2) the processing time for depositing the thicker films was longer than what was optimal (60 min at 140 °C) in terms of the annealing effect, and therefore the resulted devices were over-annealed and more prone to degradation.

4. Conclusion

A two-layer thin-film encapsulation structure, which consisted of an 26 nm ALD Al$_2$O$_3$/HfO$_2$ nanolaminated film and a UV-curable epoxy resin film, effectively protected P3HT/PCBM bulk-heterojunction photovoltaic cells from degradations caused by ambient gases, allowing the cells to show in-air degradation profile that was nearly identical to that of the control devices stored in a nominally O$_2$/H$_2$O-free environment. The ALD process also served as a thermal annealing step, which upon optimization in terms of temperature and processing time resulted in a 3.66% initial PCE. The surface coverage of the ALD films over the P3HT/PCBM surface was improved by employing a precursor soaking step, which enhanced nucleation. The nanolaminated structure prevented the Al$_2$O$_3$ layers from hydrolysis-induced disintegration in the presence of humidity, as the HfO$_2$ layers served as hydrophobic barriers against moisture while the Al$_2$O$_3$ layers amending
Fig. 7. HeTR of the ALD Al$_2$O$_3$ film and Al$_2$O$_3$/HfO$_2$ nanolaminate versus storage time in air at 28 °C with 60% relative humidity.

defects in and enhancing nucleation of the HfO_2 layers, thereby enabling the nanolaminated films to maintain constant barrier performance over time in air. The significant inherent degradation of the devices, i.e., degradation unrelated to ambient gases, were attributed to reaction of the cathode with the active layer and change in the morphology of the active layer, and it will be addressed through non-encapsulation means that is the subject of our ongoing work.

molecular systems. For example, charge separation by internal photoemission and exciton dissociation were distinguished by surface photovoltage spectroscopy in porphyrin layers deposited on gold [11].

A possible strategy to engineer surface work functions is related to the deposition of oriented molecules with donor–acceptor pairs (D–A), in which the A and D units are strong electron-withdrawing and electron-donating moieties, respectively. The appropriate choices of the molecular geometry and the A and D units characteristics allows the control of the dipole direction and magnitude. Furthermore, it is possible to tune the metal work function using molecular structures that hold D–A moieties with the capacity to form electropolymerized films over the metal surface. The electrochemical polymerization permits fine control over thickness and polymer properties; allowing to obtain stable and reproducible organic films over metal electrode. In this way, Shi et al. recently showed the capability of electrochemical deposited poly(3,4-ethylenedioxythiophene) (PEDOT) derivatives in the tuning of gold and ITO work functions [12].

In this work, we report the changes on gold surface work function by electropolymeric spirobifluorene-based bipolar films obtained from the monomers shown in Fig. 1. Recently, has been reported the electro-optical properties of polymer thin films on conducting substrate obtained by electropolymerization of pendant electroactive triphenylamine (TPA) units in spirofluorene derivatives [13–18]. Also, endcapping polyflourenes with hole-transporting moieties showed the improvement of the performance of OLEDs [19–22]. The spiro linkage improves the morphological stability of the materials while retaining their electrical properties [23]. Moreover, the perpendicular arrangement of the two molecular halves leads to a high steric demand of the resulting rigid structure, efficiently suppressing molecular interactions between the π-systems [23]. In the present case, the spiro configuration
that bonds perpendicularly the two D–A moieties with a tetrahedral carbon impedes the π-orbital interaction between the different D–A substituents in the two molecular branches (Fig. 1). The electron-donating (D) moieties are TPA groups and the electron-withdrawing (A) are the cyano ones. In particular, **CN1** molecules showed the capability to form stable electrogenerated polymeric films. Meanwhile **CN2** is structurally related to **CN1**, but with higher electron acceptor capacity due to the presence of four cyano acceptor groups, and **CN2** does not form an electropolymer due to the stability of its radical cation [18]. Here, the electrodeposited layers of **CN1** were coated with **CN2** by dipping in solution to investigate the role of the presence of an acceptor surface layer on the polymeric film. Changes of the surface work function and charge separation were studied by measurements of the contact potential difference (CPD) and surface photovoltage spectra (SPV) [24] in Kelvin-probe arrangement [25,26] in order to distinguish charge separation mechanisms for different electronic transitions. It will be shown that spirobifluorene compounds with donor–acceptor pairs are suitable for engineering of the surface work function and open new opportunities in design and study of molecular architectures with applications in organic electronics.

2. Experimental

2.1. General

All the chemicals used where provided by Sigma–Aldrich in spectroscopic or electrochemical grade and used without purification. The synthesis and characterization of **CN1** and **CN2** molecules have been described elsewhere [18,27]. The **CN1** polymer was obtained both, as film by electropolymerization over Au electrode, and in solution by chemical oxidation reaction [28].

2.2. Sample preparation

Layers of **CN1** molecules were electro deposited on Au electrodes from 0.55 mM in acetonitrile (MeCN) solution containing 0.1 M tetra n-butylammonium perchlorate (TBAP) as supporting electrolyte [18]. The Au electrodes were evaporated on glass coated with Cr as adhesion layer. The electro deposition was performed by cyclic voltammetry (CV) at the scan rate of 0.1 V/s. A platinum coil was uses as counter electrode and a silver wire as a pseudo-reference electrode. Ferrocene was added to the cell as an internal standard. Fig. 2a shows 32 voltammograms of successive electro deposition of **CN1** on a gold electrode. Upon oxidation, the TPA undergoes radical cation dimerization to produce tetraphenylbenzidine (TPB). The two TPA substituents act independently, in the two molecular branches, rendering the electropolymerization processes feasible [17,18]. The successive increase of the current indicates the formation of an electroactive film over the gold surface.

After rinsing in MeCN and exchanging the electrolyte to 0.1 M TBAP in MeCN, the electrodeposited layers of **CN1** show the typical redox responses whereas the current density increases with the number of electro deposition cycles

Fig. 1. Molecular structures of the spirobifluorene donor–acceptor bipolar systems.
Fig. 2. (a) Successive cyclic voltammograms of **CN1** electro deposition on Au electrode (0.55 mM in MeCN, 0.1 M TBAP). (b) Cyclic voltammograms of electrodeposited **CN1** grown at different potential cycle numbers (MeCN, 0.1 M TBAP).

(Fig. 2b). This behavior demonstrated the formation of stable layers of **CN1** with different thickness. Each polymer sample was investigated before and after dipping in **CN2** solution, in order to investigate the role of a surface layer with preferentially acceptor like character.

2.3. Kelvin-probe and surface photovoltage spectroscop

The contact potential difference was measured with a Kelvin-probe (Delta Phi Besocke) in a home-made vacuum chamber (pressure 2×10^{-5} mbar). The same Kelvin-probe was used for investigations with surface photovoltage spectroscopy. The sample was illuminated through the vibrating gold mesh. A quartz prism monochromator (SPM2) with a halogen lamp was used for illumination in the photon energy range from 0.6 to 4 eV. The samples were stabilized in the dark before starting the surface photovoltage measurements. The scan rate of the surface photovoltage measurements was identical for all measurements. The accuracy of the absolute CPD signal is unknown due to the presence of uncontrolled adsorbates. We assumed that the relative influence of the adsorbates is the same for all samples. The measurement accuracies of the CPD and SPV signals were less than 1 mV. Transition energies were obtained with accuracies of the order of 10 meV.

3. Results and discussion

3.1. Analysis of the contact potential difference

Fig. 3 shows the dependence of the contact potential difference of Au electrodes coated with **CN1** film on the number of electrochemical deposition cycles. The behavior of the contact potential difference describes the change of
Fig. 3. Dependence of the contact potential difference of Au electrodes coated with **CN1** film on the number of electrochemical deposition cycles.

the surface work function after layer deposition, i.e. the change of the surface dipole. The contact potential difference (CPD) of gold was set to 0 V. The measurements of the CPD were performed in the dark after relaxation of the signal to a constant value. The CPD was about −0.24 V after one electrochemical deposition cycle of **CN1** molecules (**CN1**-1, Fig. 3). The value of CPD increased to about 0.2 V after two electrochemical deposition cycles (**CN1**-2) and remained nearly constant for more deposition cycles. The insets in Fig. 3 depict the idealized scheme of the orientation of **CN1** molecules after one, two and more cycles of electro deposition. The lowest CPD was measured after one cycle which can be interpreted as a preferential orientation of –CN groups towards the gold surface. It is

know the strong surface binding ability of the cyano nitrogen. Surface-enhanced Raman spectroscopy of a series of nitrile compounds [29–31] adsorbed on gold indicated the formation of σ-bonding of the nitrile nitrogen to the metal surface. Thus, it is not unlikely that **CN1** monomer acquire a preferential orientation over electrode surface in the electropolymerization mechanism. We suggest that the cyano groups pick up electrons and link to the gold surface. On the other hand, the CPD jumped to its maximum after two deposition cycles of **CN1**. This can be explained in terms of preferential orientation of –CN groups towards the external surface. In this case, the –NPh$_2$ groups of the first and second layer would bond each other during electropolymerization [18], so that the surface dipole changes the sign. For thick layers, CPD decreases to an average value. Obviously preferential orientation of surface dipoles is lost.

However, a layer of **CN2** (which does not have electropolymerization capability) over naked gold surface obtained by dipping procedure shows small positive ΔCPD effect (Fig. 4). The observed behaviors could be due to different molecular structural organization in the deposited layers. In the case of **CN1** films, the polymerized structure can holds a preferential dipole orientation over gold surface, which is not present in the case of **CN2** layer over naked gold. This shows the importance of electropolymerization procedure in the control of electrode work function. On the other hand, the value of CPD did not change after depositing **CN2** molecules on the Au/**CN1**-1 sample (see Fig. 4). Therefore, the deposition of **CN2** molecules on **CN1** film by dipping does not change the preferential surface dipole orientation.

3.2. Analysis of the surface photovoltage spectra

The contact potential difference changed under illumination due to separation of photo-generated charge carriers. Contact potential difference spectra are shown in

Fig. 4 for the Au/**CN2**, Au/**CN1**-1, and Au/**CN1**-1/**CN2** samples. A photoinduced increase of the contact potential difference means a preferential separation of photo-generated electrons (holes) towards the external (internal) surface whereas a photoinduced decrease of the contact potential difference means a preferential separation of photo-generated holes (electrons) towards the external (internal) surface. For the Au/**CN2** and Au/**CN1**-1 samples the contact potential difference increases under illumination, i.e. electrons are separated preferentially towards the external surface. It should be noted, as is shown in Fig. 4, that the light induced change of the contact potential difference was quite small after electro deposition of layers of **CN1** only, and clearly increased after dipping in **CN2** solution. Remarkably **CN2** over the naked gold surface shows only a small SPV effect.

Fig. 5 shows the (negative) surface photovoltage spectra of the Au/**CN2**, Au/**CN1**-1, and Au/**CN1**-1/**CN2** samples together with the shapes of the optical density spectra of the **CN1** polymer and **CN2** molecules in diluted solution. For the Au/**CN2** sample the SPV signal sets on at photon energy of 1.95 eV (onset of the T1 transition). For comparison, the electronic transition sets on at a photon energy of 2.23 eV for the optical density spectrum. Therefore, the electronic transitions of the SPV spectrum are red-shifted

Fig. 4. Contact potential difference spectra under illumination of an Au electrode dipped in **CN2** molecule solution (Au/**CN2**) red triangles), an Au electrode with electrodeposited **CN1** film after one electrochemical deposition cycle (Au/**CN1**-1, blue circles) and dipped in **CN2** molecule solution (Au/**CN1**-1/**CN2**, black squares). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 5. Negative surface photovoltage spectra of Au/**CN2** (a), Au/**CN1**-1 (b) and Au/ **CN1**-1/ **CN2** (c). The red and blue solid lines in (a) and (b) show the shapes of the optical density spectra of **CN2** (a) and **CN1** (b) molecules in solution. T1, T2 and T3 denote the onset of optical transitions. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

by 0.28 eV in comparison to the optical density spectrum. The SPV signal remains nearly constant at photon energies higher than about 2.4 eV.

For the Au/**CN1**-1 sample two transitions (T2 and T3) can be distinguished in the SPV spectrum. The T2 and T3 transitions set on at a photon energies of 1.45 and 2.71 eV, respectively. For comparison, the electronic transition sets on at 2.71 eV in the optical density spectrum. Therefore, the T3 and T2 transitions of the SPV spectrum correspond to the un-shifted and red-shifted by 1.26 eV electronic transition of the optical density spectrum, respectively. The separations of photo-generated charge carriers lead always to the increase of the contact potential difference of the Au/**CN1**-1 sample.

All three transitions appear also in the SPV spectrum of the Au/**CN1**-1/**CN2** sample as demonstrated in Fig. 4c. The SPV signals related to the T1 and T2 transitions have the same sign as for the Au/**CN1**-1 and Au/**CN2** samples. At photon energies larger than 2.45 eV the separation of photo-generated charge carriers lead to a decrease of the contact potential difference of the Au/**CN1**-1/**CN2** sample. The reason for this decrease is a change of the direction of separation of photo-generated charge carriers for the T3 transition.

The analysis of the SPV spectrum of the Au/**CN1**-1/**CN2** sample shows that the T2 and T3 transitions are "broadened" towards lower photon energies, i.e. charge separation begins even at photon energies less than the onsets of the T2 and T3 transitions taken from the SPV spectrum of the Au/ Au/**CN1**-1 sample.

3.3. Dependence of the T1, T2 and T3 transitions on the CN1 layer thickness

The SPV spectra did not change qualitatively if the thickness of the **CN1** layer was increased by increasing the number of electrochemical deposition cycles. The detailed deconvolution of the SPV spectra is rather complicated since the spectra contain integrated and non-integrated components. For the discussion of the charge separation mechanisms a qualitative analysis will be sufficient. Therefore, here we describe the general tendencies of the thickness dependent SPV signals for the T1, T2 and T3 transitions.

For the Au/**CN1** samples the thickness dependencies of the SPV signals related to the T2 and T3 transitions can be distinguished if comparing the values of the SPV signals at 2.4 and 3.4 eV (Fig. 5a). The (negative) SPV signal related to the T2 transition (value at 2.4 eV) increases with increasing number of electrodeposition cycles from 7 mV (Au/**CN1**-1) to 17 (Au/**CN1**-2) and 33 (Au/**CN1**-4) mV. For very large numbers of electrodeposition cycles the SPV signal related to the T2 transition decreases to 20 (Au/**CN1**-32) and 3 (Au/**CN1**-50) mV.

Contributions of the different transitions to the SPV signal can be estimated if considering differences of the SPV at characteristic energies where one or two transitions dominated the SPV spectrum. For the analysis we assume that the SPV signals of the various transitions are independent of each other and that the SPV signal related to the T2 transition tends to saturation at higher photon energies.

The (negative) SPV signal related to the T3 transition of the Au/**CN1** samples can be described as the difference between the SPV signal obtained at 2.4 and 3.4 eV (see also Fig. 6a). The SPV signals related to the T3 transition are 15, 16, 21 mV for the Au/**CN1**-1, Au/**CN1**-2 and Au/**CN1**-4 samples, respectively what is nearly constant if comparing with the T2 transition. The SPV signal of the T3 transition decreases very strongly to 3 and 1 mV for the Au/**CN1**-32 and Au/**CN1**-50 samples, respectively.

The (negative) SPV signal of the T1 transition can be estimated from the SPV spectra of the Au/**CN1**/**CN2** samples in comparison to the Au/**CN1** samples if assuming a linear superposition. Fig. 6b shows the values of the SPV signals measured at 2.4 eV for the Au/**CN1**/**CN2** samples together with the difference between these values and those values measured at 2.4 eV for the Au/**CN1** samples. It can be seen that the SPV signal related to the T1 transition decreases continuously with increasing number of electrodeposition cycles from 96 (Au/**CN1**-1/**CN2**), 64 (Au/**CN1**-2/**CN2**), 54 (Au/**CN1**-4/**CN2**), 35 (Au/**CN1**-32/**CN2**), 23 (Au/**CN1**-50/**CN2**) mV.

3.4. (d) Mechanisms of charge separation

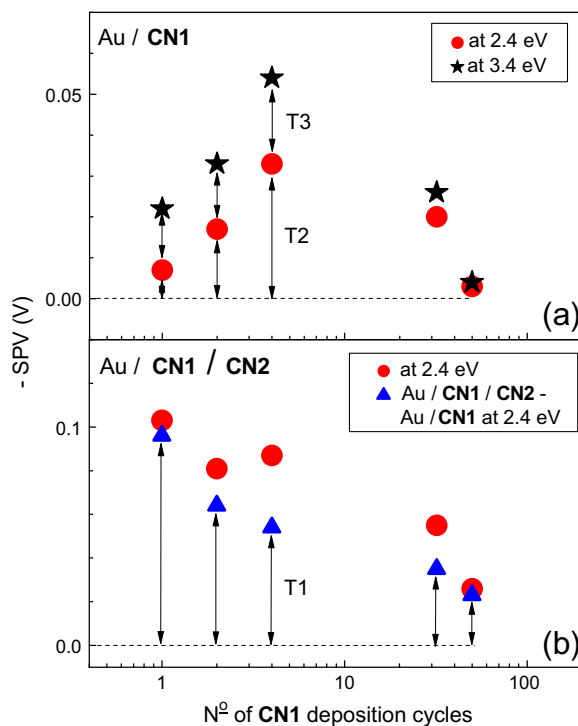
The T1 and T2 transitions should be related to internal photoemission of photo-generated electrons from Au into


Fig. 6. Dependence of the negative values of the surface photovoltage on the number of electrochemical deposition cycles of **CN1** molecules for Au/**CN1** samples: (a) at 2.4 (red circles) and 3.4 (black stars) eV and of Au/**CN1**/**CN2** samples (b) at 2.4 eV (red circles) and of the difference of the surface photovoltages of the Au/**CN1**/**CN2** and Au/**CN1** samples at 2.4 eV. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

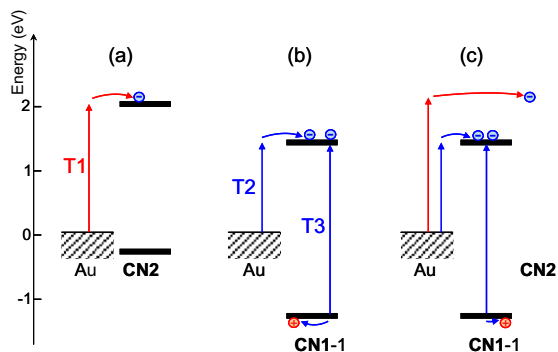
the LUMO levels of the molecules (Fig. 7). In such case the red-shifted onsets of the transitions spectra in comparison to the optical density spectra correspond to the difference between the Fermi-level of the Au and the energy of the HOMO level of the respective molecule.

The SPV signal of the T1 transition decreased with increasing number of **CN1** electrodeposition cycles. This can be understood with respect to Eq. (1).

$$SPV = \frac{\Delta d}{\varepsilon \cdot \varepsilon_0} \cdot \Delta Q \qquad (1)$$

A surface photovoltage signal contains information about the amount of charge separated in space (ΔQ) and about the distance over which the centres of positive and negative charges are separated (Δd, charge separation length) where $\varepsilon_0 = 8.85 \times 10^{-12}$ As/(Vm) and ε is the relative dielectric constant. Both parameters ΔQ and Δd can be varied by changing the thickness of ultra-thin layers in charge selective layer systems. Thus, the charge separation length increases linearly with increasing number of **CN1** electrodeposition cycles. However, the probability of internal photoemission of electrons from Au into the **CN2** layer decreases exponentially with increasing distance. Therefore the overall SPV signal of the T1 transition decreases with increasing number of **CN1** electrodeposition cycles (Fig. 6b).

Regarding to an exponential decrease of the charge transfer rate for internal photoemission with increasing distance, it is really surprising that the SPV signal of the T1 transition remains relatively large even for Au/**CN1**-32/**CN2** and Au/**CN1**-50/**CN2** samples. We believe that prolonged electrodeposition of **CN1** leads to the formation of porous or dendrite like structures giving space for quite inhomogeneous penetration of **CN2** molecules during dipping. In order to investigate the film permeability, we performed CV with a model redox couple in solution (ferrocene), both over bare Au and Au/**CN1** films. The ferrocene redox potential lies within the potential window where the **CN1** film does not show an electrochemical response and, therefore, behaves solely as a blocking layer


on the Au electrode. If the polymer film forms an ideal compact layer, without defects or pinholes, not Faradaic current should be observed in the CV. However, in our case we obtained typical s-shape ultramicroelectrode voltammogram in the ferrocene oxidation over Au/**CN1** film. As it is know, this kind of behavior is evidence of a high coverage of the Au bare electrode by a film with pores spaced far apart in relation to the radius of the pores [32]. This fact supports our assumption about **CN2** molecules penetration during dipping process.

On the other hand, the SPV signal of the T2 transition increased with increasing number of **CN1** electrodeposition cycles for **CN1**-1 to **CN1**-4 (Fig. 6a). This is not surprising since the amount of electrons emitted from Au to longer distances in the **CN1** film increases with increasing number of **CN1** electrodeposition cycles. However, the SPV signal of the T2 transition decreased for **CN1**-32 and **CN1**-50 layers. The origin of this effect is unclear, but could be due to morphological changes in the film with thickness increasing.

The SPV signal of the T3 transition has to be related to light absorption in the **CN1** film. The (negative) SPV signal of the T3 transition of the Au/**CN1** samples is practically constant for **CN1**-1, **CN1**-2 and **CN1**-4 since the charge separation length and the amount of photons absorbed in the first monolayer of **CN1** molecules are practically unchanged. It means also that the ordering of the first **CN1** monolayer at the Au surface is preserved during the following polymerization process. For **CN1**-32 and **CN1**-50 the amount of **CN1** molecules in front of the first **CN1** monolayer acts as an optical filter limiting strongly photon absorption in the **CN1** monolayer at the Au surface leading to a strong decrease of the SPV signal. The (positive) SPV signal of the T3 transition in Au/**CN1**/**CN2** samples at energies values higher that 2.35 eV is probably due to hole injection from **CN1** excited state into **CN2** molecules.

4. Conclusions

It has been shown that the work function of conducting surfaces can be engineered by electrodeposition of spirobifluorene compounds with donor–acceptor pairs. It should be mentioned that a modification of the work function of organic polymers is also possible due to electrochemically driven oxidation/reduction (for example, in PEDOT:PSS [33]). Related effects may disturb changes of the work function and charge separation caused by changes of preferential orientation of electrodeposited molecules. Some advantages of the used spirobifluorene derivatives are their synthetic versatility, stability and charge transport capability. The results showed that the formation of electrosynthetic films is a versatile tool for surface work function tuning. Surface dipole of a gold layer can be changed over more than 0.4 V by electrodeposition of **CN1** molecules, and the surface dipole can be modified by internal photoemission. The highest SPV was reached after the combination of **CN1** electrodeposited film and coated with **CN2** molecule layer. This might become interesting for molecular electronics.

Fig. 7. Energy diagram of the T1, T2 and T3 transitions in Au/**CN2** (a), Au/**CN1**-1 (b) and Au/ **CN1**-1/**CN2** (c) samples. The transitions T1 and T2 are related to internal photoemission of electrons from the Au electrode into LUMO levels of the **CN1** and **CN2** molecules, the transitions T3 is related to light absorption in the **CN1**-1 film.

it is commonly observed that the more the absorption of an organic compound is shifted towards low energies, the less the compound is able to stand long term exposition to ambient atmosphere [12], especially for a device under operating conditions (applied bias, illumination, temperature). To overcome this issue it is often necessary to develop encapsulation techniques for the efficient isolation of the device active layer from oxygen and moisture [13], thus increasing complexity and costs, and reducing the mentioned advantages of the organic technology.

Employing squaraine dyes, thanks to their good absorption properties in the red-NIR region, as the active absorbing material in bulk-heterojunction configuration with Phenyl-C61-Butyric-Acid-Methyl-Ester (PCBM), we explored the possibility to develop fast and efficient NIR detectors capable of operating in air without need for an encapsulation.

Since the charge transport properties are crucial in determining the optoelectronic behavior of devices, we realized detectors in parallel with transistors, from which we could easily extract charge carrier mobilities. In order to provide a fair comparison of the two devices, we developed photodetectors with a planar architecture, so to have the same current flow with respect to the substrate as in transistors [14].

2. Experimental

2.1. Synthesis and characterization of the materials employed

Squaraines AlkSQ and GlySQ were prepared according to the literature procedure [15,16].

PCBM was purchased from Aldrich Chemicals and used without further purification.

HOMO and LUMO energies were estimated by Cyclic Voltammetry (CV) considering the redox peak and the optical band gap [17].

2.2. Devices preparation

Both the pristine and the bulk-heterojunction devices were obtained by a two steps spin-coating (60s at 100 rpm followed by 60s at 1000 rpm) of a 10 mg ml^{-1} chloroform solution. For bulk-heterojunction films, the 1:1 and 1:3 by weight blend solutions of squaraine and PCBM were stirred overnight prior deposition, in order to promote the mixing of the two components.

UV–vis absorption spectra (transmission mode) of films were measured on 500 μm thick fused silica substrates with a Fourier Transform Infrared Spectrometer Nicolet MAGNA 560.

Photodetectors were obtained by depositing the active material on a 500 μm thick fused silica substrate, patterned by lithography with 40 nm thick interdigitated gold contacts with channel length of 6 μm and width of 15 mm or 5 mm. The photodetectors, biased with a voltage of 60 V, were irradiated by means of a set of light emitting diodes (LEDs) providing 500 μs long light pulses. The resulting photocurrent was read by connecting the device to a low-noise transimpedance amplifier. The external quantum efficiency (EQE) was calculated as the ratio of the number of collected charges, determined by integrating the transient output photocurrent during the radiation pulse, and the number of incident photons, obtained by calibrating the LEDs (giving a light intensity of about 30 mW cm^{-2}) by means of a silicon photodetector. Electrical cross-talk between the detector circuit and the driving LEDs has been avoided by carefully aluminum shielding each component of the set-up with the only exception of the coupling window between the emitting LED and the photodetector active area, and by suitably choosing the detector-LED distance (about 13 mm). Trains of light pulses were recorded at the output of a band-pass filter connected to the transimpedance amplifier in order to improve the signal to noise ratio.

Transistors were realized with the same deposition technique onto a 500 μm thick p$^+$-doped silicon wafer acting as the gate and provided with a 130 nm thick SiO$_2$ dielectric. Gold source and drain contacts were defined by lithography directly onto the oxide in a bottom contact configuration, yielding devices with 15 mm channel width and 6 μm channel length. Field-effect mobility was extracted from the transfer characteristic curves in the saturation region ($|V_{DS}| = 30$ V and $|V_{GS}|$ ranging from 0 V to 30 V). Contact resistances were extracted in the linear regime ($|V_{DS}| = 1$ V and $|V_{GS}|$ ranging from 0 V to 30 V), according to the procedure outlined in Ref. [18].

All the electrical characterizations were performed both in vacuum (at 10^{-6} mbar) and in air.

AFM analyses were performed in non-contact mode through a *Nanosurf EasyScan 2* system.

3. Results and discussion

Squaraines are the condensation product of electron rich molecules, usually activated arenes, π-excessive heterocycles, and heteroaromatic anhydrobases, with squaric acid [19]. Thanks to their peculiar sharp and intense absorption mainly localized in the red-NIR region [20], along with remarkable stability and wide molecular structure diversity, squaraines have been exploited in a number of technologically relevant applications including photoconductivity [19,21], data storage [22], light emitting field-effect transistors [23], solar cells [24,15], nonlinear optics [25], highly stable fluorescent NIR dyes [26] and fluorescence patterning [27].
Fig. 1. Chemical structure of **AlkSQ** and **GlySQ**, differing one from the other by the presence of either alkyl side chains (**AlkSQ**) or glycolic side chains (**GlySQ**).
Fig. 2. Solid state absorption spectra of films based on pristine and blended squaraines **AlkSQ** and **GlySQ**. In the passage from a pristine squaraine film to a bulk-heterojunction film, the absorbance tail in the UV region is enhanced due to the presence of PCBM.

Among the various possible substitution patterns around the squarylium core that have been described in the literature [28], we exploited hydrazone end-capped symmetric squaraines in order to achieve at the same time an efficient absorption in the red and NIR regions (Figs. 1 and 2) and a reversible redox behavior. As non-functionalized squaraines are known to be particularly insoluble and high-melting point derivatives, on the pyrrolic nitrogen we introduced a long functionalization chain in order to provide solubility in chlorinated solvents, where the PCBM is also particularly soluble.

3.1. Alkyl functionalized squaraine

We started with a pristine squaraine functionalized with an *alkyl* chain, named in the following **AlkSQ** (see Fig. 1): this functionalization enabled us to prepare films by spin-coating of a 10 mM chloroform solution of the dye. The obtained films were rough (25 nm rms) and
showed the formation of globular, micron sized structures clearly distinguishable in the AFM height images (Fig. 3). We attributed this behavior to a natural tendency of **AlkSQ** towards self-assembling, possibly enhanced by its hydrophobic character leading to a repulsive interaction with the polar substrate (silica).

When characterized in vacuum, the resulting device showed an External Quantum Efficiency (EQE) under pulsed illumination of 4.9% in the NIR, with the peak of the EQE located at 670 nm, as shown in Fig. 4 (see Section 2 for details on EQE measurement). Despite this interesting efficiency, the device was unsuitable for signal detection since its response time was unsatisfactory: the transient response to 500 μs long light pulses showed a 90–10% decay time as long as 3 ms (see Figs. 5 and 6). To better investigate this aspect, we performed the electrical characterization of the corresponding thin-film transistor, extracting a hole mobility μ_h of 6×10^{-5} cm^2 V^{-1} s^{-1} whereas no electron mobility μ_n was detected (see Fig. 6). If holes were dominating the transients, the hole transit time (calculated as $L^2/\mu_h V$, with L interelectrode spacing and V applied bias voltage) should be an estimate
Fig. 4. External Quantum Efficiency of planar photodetectors based on pristine **AlkSQ** (-▲-), **AlkSQ**/PCBM blend with 1:1 by weight ratio (-★-), pristine **GlySQ** (-◇-), **GlySQ**/PCBM blend with 1:1 by weight ratio (-□-) and **GlySQ**/PCBM blend with 1:3 by weight ratio (-○-) upon light irradiation with 500 μs long light pulses. Lines are only a guide to the eye.

Fig. 3. (a) AFM image of the pristine **AlkSQ** spin-coated film showing the presence of micron sized structures – (b) Rms value of the film roughness for devices based on the pristine squaraines and the bulk-heterojunctions, extracted by the AFM analysis.
Fig. 5. Transient response of the detectors based on pristine **AlkSQ** (green), **AlkSQ**/PCBM 1:1 blend (orange), **GlySQ**/PCBM 1:1 blend (red) and **GlySQ**/PCBM 1:3 blend (black) to a 500 μs long light pulse at a wavelength of 670 nm. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 6. Trend of the decay time and of the mobility for both holes and electrons in devices based on pristine and blended squaraines. In devices based on the bulk-heterojunction of **GlySQ** and PCBM in 1:3 ratio, electrons mobility and response speed are improved at the same time with respect to the other samples. In such detectors, the optimal balance between holes mobility and electrons mobility is achieved.

by excess of transients themselves. In our case the hole transit time turned out to be in the range of 400 μs, which was about an order of magnitude lower than the 90–10% photodetector decay time. As a consequence, transients were dominated by electrons, slowly drifting and, likely, trapped at the grain boundaries [29–31]. To address this point, the EQE was measured under CW illumination. In this case, the measured EQE was as high as 200% in the NIR (the difference with 4.9% under pulsed light arising because the steady state was not reached within the pulse duration). This means that pristine **AlkSQ**-based devices were affected by a photoconductive gain [32], due to easy injection and circulation of holes while photogenerated electrons were trapped [33].

In addition, the device could not be operated in ambient air because the dark currents, which were in the range of tens of nA in vacuum, reached the value of tens of μA in air and were characterized by an erratic and noisy behavior. This was due to p-doping of the dye: in fact **AlkSQ**-based transistors showed an on/off ratio as high as 10^4 in vacuum, but as low as few units in air. It is likely that doping was highly facilitated by the surface roughness, leading to deep penetration of oxygen/moisture into the film [34,35].

Given the morphology as the source of the ambient instability, and the unbalanced mobilities hampering the response speed, we turned to the deposition of a blend of **AlkSQ** with a suitable molecule. We chose PCBM, because: (i) it belongs to the same solubility class of **AlkSQ**, therefore it is expected to favorably and effectively mix with **AlkSQ** acting as a disturbing agent against the **AlkSQ** self-aggregation; (ii) it is electronically active being a very good electron conductor; (iii) it has a LUMO level which is located at about 4.0 eV below the vacuum level, 0.2 eV lower than the LUMO of **AlkSQ** (3.8 eV), thus it is poten-

tially able to act as electron acceptor material in the bulk-heterojunction [36].

The obtained 1:1 by weight ratio blend films indeed possessed a roughness of about 1 nm, in contrast to the 25 nm rms of the pristine film (Fig. 3), and were essentially featureless. Air stability was also achieved as no difference could be observed in the dark currents (about 100 pA) and in the EQE measured in vacuum or in ambient conditions. In addition the response time decreased by one order of magnitude, reaching a 90–10% decay time of 400 μs (Figs. 5 and 6), thanks to PCBM which hampered **AlkSQ** crystallization, suppressed the electron trapping process and created percolation paths for electrons. In fact, from transistor measurements we extracted an electron mobility of 2×10^{-8} cm^2 V^{-1} s^{-1} (see Fig. 6).

Despite this goods, the pulsed EQE of the detector strongly reduced from 4.9% to 0.2%, as shown in Fig. 4: this means that no photoconductive gain mechanism was occurring, even though a relatively large (100 fold) mobility unbalance was still present (given $\mu_h = 4.4 \times 10^{-6}$ cm^2 V^{-1} s^{-1}). Since photoconductive gain requires, in addition to unbalanced mobilities, an ohmic contact for the injection of the more mobile carrier, we conclude that PCBM blending also had an impact on the contacts injecting properties. To investigate this, we extracted the contact resistances from transistor measurements [18]: from pristine to blended **AlkSQ**, contact resistances for holes grew larger by a factor of 10 (from 12 MΩ/cm to 106 MΩ/cm). This can be explained by considering that the hole mobility diminished by a factor of about 10 from pristine to blended **AlkSQ**, likely due to the less ordered nature of the latter film, and recalling that semiconductor charge transport properties are known to strongly affect current injection in organic semiconductors [37]. In addition, a lower ionization potential due to aggregation and hence a more facile injection cannot be excluded in pristine **AlkSQ**. This worsening of hole injecting properties from pristine to blended **AlkSQ** is confirmed by the drop of the dark currents of a factor 10^2 (from about 30 nA to 100 pA at 60 V), which is not merely justifiable as the consequence of a ten-times smaller hole mobility and suggests ohmic injection in the pristine **AlkSQ** and injection limited conduction regime in the blend. In conclusion, hole injection efficiency is high (ohmic) in pristine **AlkSQ** whereas is poor in the blend, thus preventing the gain mechanism to occur despite the unbalanced mobilities.

Since holes were not effectively injected to maintain electrical neutrality, space charge build-up was expected, limiting the EQE to the unsatisfactory value of 0.2%[2] [38,39] by collapsing the active device area to a small region close to the contact biased to collect the slow carrier (electrons). The ultimate cause of the bad transport properties of the device can be traced back to the fact that, belonging to the same solubility class, PCBM and **AlkSQ** can probably mix even too efficiently, affording almost no phase segregation and yielding poor percolation pathways for electrons [40–42].

---

[2] In addition, effects on the exciton binding energy due to the expected different molecular packing from pristine **AlkSQ** to blended **AlkSQ** cannot be excluded.

3.2. Glycolic functionalized squaraine

To solve this problem, we chemically tailored the squaraine exploiting a glycolic functionalization pattern (named **GlySQ**, see Fig. 1) instead of the alkyl one. The glycol functionalization provided the dye with a higher hydrophilic character, thus reducing its mixing capabilities with PCBM, while preserving the favorable dye solution processability.

Firstly, we discuss pristine **GlySQ** and compare it to pristine **AlkSQ**, because the comparison strengthens our previous observations. In fact, at the molecular level the two **GlySQ** and **AlkSQ** do not differ in their optoelectronic properties (as the kind of functionalization on the pyrrolic nitrogen does not affect in a relevant way the squaraine spectroelectrochemical properties – Fig. 2), therefore any differences in devices performances can be traced back to differences at the film level, in terms of degree of order, molecular packing and morphology. We found that, thanks to the good wetting capabilities towards polar surfaces provided by the glycol chain, pristine **GlySQ** yielded smooth films (the rms roughness was 1.2 nm – Fig. 3), and the related devices[3] turned out to be air stable: this confirms the key role of morphology in yielding air stable devices. On the other hand, the hole mobility was relatively low ($5 \times 10^{-6} cm^2 V^{-1} s^{-1}$), due to the amorphous nature of the film. In addition, pristine **GlySQ** photodetectors showed an EQE of only 0.11% when measured under CW illumination, ruling out gain mechanisms. The lack of gain, despite a probable large mobility unbalance (the electron mobility was undetected), suggests non-ohmic contacts: this is in agreement with contact resistances being as large as 150 MΩ/cm in this case, which is the same order of magnitude classified to yield poor injecting contacts in case of **AlkSQ**/PCBM. This comparison confirms the role of aggregation and hence of mobility in determining the degree of charge injection from the contacts and, ultimately, the occurrence of photoconductive gain.

Turning now to the **GlySQ**/PCBM 1:1 blend, we measured in transistors a practically unchanged mobility for holes ($\mu_h = 2.5 \times 10^{-6} cm^2 V^{-1} s^{-1}$) compared to **AlkSQ**:PCBM, but a mobility for electrons of $1.5 \times 10^{-7} cm^2 V^{-1} s^{-1}$ (Fig. 6), which was one order of magnitude higher. This is the evidence that by tailoring the squaraine solubility class it is possible to control the degree of phase separation. As a consequence of the improved electron transport, the device optoelectronic properties were enhanced: the EQE reached the value of 1.3% (at 670 nm), while the 90–10% decay time in response to a 500 μs light pulse turned out to be of about 200 μs (see Figs. 4–6). The AFM image showed a featureless and smooth morphology (similar to **AlkSQ**:PCBM blends – see Supporting information) which conferred air stability to the device. In addition, the device had a striking shelf-life: measurements carried out in air on a device stored for 1 year under ambient atmosphere with no precaution whatsoever regarding oxygen and moisture contamination, demonstrated an

overall decrease in the EQE lower than 25% (see Supporting information), and no detectable aging related degradation was observed in the response time.

Finally, with the aim of further enhancing the device performance, we started an optimization study of the **GlySQ**:PCBM blend. Since in the 1:1 blend electrons still had a mobility one order of magnitude lower than holes, we increased the PCBM content obtaining a **GlySQ**:PCBM 1:3 by weight ratio blend, in order to get better efficiency [39] and transit time. Transistor measurements showed that this latter blend succeeded into balancing the mobility of the charge carriers giving $\mu_h = 1.27 \times 10^{-6} cm^2 V^{-1} s^{-1}$ and $\mu_n = 6.25 \times 10^{-6} cm^2 V^{-1} s^{-1}$ (Fig. 6). As a consequence, EQE in the NIR improved, reaching the remarkable value of about 3.5%, and the 90–10% fall time (upon 500 μs light pulse) diminished by one order of magnitude reaching a value below 10 μs (Fig. 5). Detector speed was further investigated by testing with light pulses as short as 100 ns (at 670 nm), obtaining a 90–10% fall time of about 240 ns, as shown in Fig. 7a. The dependence of the fall time on the pulse duration is currently not understood and will be the subject of further investigation, but nevertheless this suggests that detection of fast light pulses is indeed feasible with this technology. In fact, by suitably amplifying the device photocurrent (see Section 2), we were able to detect a
Fig. 7. (a) Photocurrent response of the photodetector based on **GlySQ**/PCBM 1:3 blend to a 100 ns light pulse stimulation at a wavelength of 670 nm. (b) Time response of the same detector to a train of light pulses at a wavelength of 670 nm and with a 10 MHz repetition frequency. The photo-response of the device is recorded at the output of a band-pass filter connected to the transimpedance amplifier (see Section 2), which introduces a group delay that is responsible for the occurrence of the peaks of the output voltage in a shifted position (delayed) with respect to the corresponding light pulse.

---

[3] I_{on}/I_{off} ratio in FETs in the order of 10^3 both in vacuum and under air exposure.

train of light pulses with a repetition frequency as high as 10 MHz, as the single shot acquisition of Fig. 7b shows. In addition, the ratio between the photogenerated and the dark current (with the device biased at 60 V), which is particularly important for applications [43,44], exceeded 10^4, with dark currents values settling around 10 pA. All these characteristics, thanks to a smooth morphology, were maintained even in ambient air operation.

4. Conclusions

We have studied planar photodetectors operating in the red-NIR range of the spectrum and based on the bulk-heterojunction of squaraine dyes and PCBM as active materials. Guided by the comparison of pulsed and CW illumination tests on the photodetectors, as well as by the transport properties extracted from FET structures, we have addressed the efficiency, speed, and stability issues working both at the chemical level, by tailoring the squaraine substitution pattern, and at the device level, by tuning the blend composition, thus achieving: (i) a smooth morphology, which enables long term air stability with no need for encapsulation (over one year lifetime in the 1:1) (ii) a good balance between holes and electrons mobility, which leads to high EQE (3.5% at 670 nm in 3:1 blend) and fast response speed in the range of few hundreds of nanoseconds.

donor/acceptor couple is limited to ∼5% due to the incomplete match with the solar spectrum and the large offset of the LUMO energy levels of the donor and acceptor [3,12,13].

The maximum photon flux of the solar spectrum (at 1.6–1.8 eV) lies slightly beyond the reach of most organic conjugated polymers, which have band gaps >1.8 eV. Despite of significant progress in the synthesis and processing of low band gap polymers, which are capable of absorbing a broad range of solar photons, only a few polymeric systems have achieved power conversion efficiency comparable with P3HT [14,15]. A possible route to overcome the low performance often observed with low band gap polymer might be the use of low band gap small molecule as donor.

Solution processable small molecules have attractive features such as low band gap and high charge carrier mobility than conjugated polymers. These small molecule donors can be more easily synthesized in many variant and purify (e.g. of trace metal catalysis employed in the synthesis) are intrinsically more mono-dispersive, and are often environmentally more stable [16–18]. There are several families of solution processable small molecules that have been used as donor materials in BHJ solar cells [19–22].

Triphenylamine (TPA) seems to be a promising candidate as the electron-rich moieties and polymers containing TPA unit have presented high photoluminescence efficiency, good hole-transporting ability, outstanding photoconductivity, three-dimensional steric, and good light-harvesting properties. Due to the non-coplanarity of the three phenyl ring, TPA and related derivatives can be viewed as 3D systems and the amorphous character of these materials offers possibilities to develop active materials for optoelectronic devices with optical and charge-transport properties. Moreover their amorphous behavior, electronic and redox properties are also important and might be influenced by the type of structures. Dendritic or hyperbranched structures with TPA derivatives, which show interesting properties like energy transfer, and light-harvesting antenna, have received significant attentions. The three-dimensional structure of a branched polymer or monomer might improve carrier transport to offer favourable electrical properties. Certain BHJ solar cells based on materials containing TPA have been reported very recently [23,24].

Benzothiadiazole (BTD) is a commonly used electron acceptor, which can conjugatively link with an electron-rich molecule to form low band gap functional polymers or small molecules, and materials prepared in this manner showed usefulness in light emitting diodes, solar cells, light-harvesting and other optical or electronic functional devices [25,26].

Cyano groups could be used as the electron-withdrawing units. Materials with high electron affinities played a crucial role in the development of high-performance conjugated polymer optoelectronic devices [27]. The introduction of cyano groups onto a poly(p-phenylenevinylene) backbone has been proved an effective way of lowering the LUMO level of the polymer [28]. Furthermore, the electrochemical stability of the polymers could be enhanced by

introducing cyano groups [29], which is also desirable for optoelectronic devices.

In this investigation we report the synthesis and characterization of two new vinylene compounds, **TPA-TNP** and **BTD-TNP**, which contain triphenylamine and benzothiadiazole segments, respectively. The first compound is a star-shaped molecule, while the second is a linear molecule. Their chromophore was extended by incorporating thiophene and then vinylene moieties to the central TPA and BTD unit. Moreover, a cyano and a nitro substituent were inserted into the vinylene bond and the terminal phenyls, respectively. The chemical structure of the compounds was designed so as to broadening their absorption. The thermal, photophysical, electrochemical and photovoltaic properties of these compounds were systematically investigated.

2. Experimental

2.1. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^{1}H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–vis spectra were recorded on a Beckman DU-640 spectrometer with spectrograde THF. The PL spectra were obtained with a Perkin Elmer LS45 luminescence spectrometer. The PL spectra were recorded with the corresponding excitation maximum as the excitation wavelength. TGA was performed on a DuPont 990 thermal analyzer system. Ground samples of about 10 mg each were examined by TGA and the weight loss comparisons were made between comparable specimens. Dynamic TGA measurements were made at a heating rate of 20 °C/min in atmospheres of N_2 at a flow rate of 60 cm^3/min. Thermomechanical analysis (TMA) was recorded on a DuPont 943 TMA using a loaded penetration probe at a scan rate of 20 °C/min in N_2 with a flow rate of 60 cm^3/min. The TMA experiments were conducted at least in duplicate to ensure the accuracy of the results. The TMA specimens were pellets of 10 mm diameter and ∼1 mm thickness prepared by pressing powder of sample for 3 min under 8 kp/cm^2 at ambient temperature. The T_g is assigned by the first inflection point in the TMA curve and it was obtained from the onset temperature of this transition during the second heating. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

2.2. Reagents and solvents

Tributyl-2-thienyl-stannane was prepared from the reaction of thiophene with n-BuLi in hexane and subsequently with tributylchlorostannane according to the literature [30]. 4-Nitrobenzyl cyanide was synthesized from the nitration of benzyl cyanide with concentrated nitric and sulfuric acid [31]. N,N-Dimethylformamide (DMF) and tetrahydrofuran (THF) were dried by distillation over CaH$_2$. Toluene was dried by distillation over sodium. All

other reagents and solvents were commercially purchased and were used as supplied.

2.3. Preparation of compound **TPA-TNP**

A flask was charged with a solution of **3** (0.48 g, 0.83 mmol) and 4-nitrobenzyl cyanide (0.41 g, 2.52 mmol) in anhydrous ethanol (20 mL). Sodium hydroxide (0.33 g, 8.25 mmol) dissolved in anhydrous ethanol (10 mL) was added portion-wise to the stirred solution. The mixture was stirred for 1 h at room temperature under N_2 and then was concentrated under reduced pressure. Compound **TPA-TNP** precipitated as a dark green solid by cooling into a refrigerator. It was filtered off, washed thoroughly with water and dried (0.44 g, 53%).

FT-IR (KBr, cm^{-1}) (Fig. 1a): 3044, 2924, 2158, 1654, 1584, 1522, 1490, 1440, 1346, 1320, 1290, 1186, 1108, 1014, 854.

^{1}H NMR (CDCl$_3$, ppm) (Fig. 1b): 8.19 (m, 6H, phenylene "f"); 7.67 (broad, 3H, vinylene "d"); 7.48 (m, 6H, phenylene "e"); 7.32–7.31 (m, 6H, thiophene "c"); 7.23 (m, 6H, phenylene "b"); 7.09 (m, 6H, phenylene "a").

Anal. Calc. for $C_{57}H_{33}N_7O_6S_3$: C, 67.91; H, 3.30; N, 9.72. Found: C, 67.23; H, 3.36; N, 9.68%.

2.4. Preparation of compound **BTD-TNP**

A flask was charged with a solution of **7** (0.14 g, 0.39 mmol) and 4-nitrobenzyl cyanide (0.13 g, 0.80 mmol) in anhydrous ethanol (15 mL). Sodium hydroxide (0.10 g, 2.50 mmol) dissolved in anhydrous ethanol (8 mL) was added portion-wise to the stirred solution. The mixture was stirred for 1 h at room temperature under N_2 and then was concentrated under reduced pressure. Compound **BTD-TNP** precipitated as a dark green solid by cooling into a refrigerator. It was filtered off, washed thoroughly with water and dried (0.16 g, 64%).

FT-IR (KBr, cm^{-1}): 3078, 3044, 2952, 2922, 2150, 1654, 1586, 1522, 1476, 1344, 1292, 1184, 1108, 1016, 936, 876, 830.

^{1}H NMR (CDCl$_3$, ppm): 8.13 (m, 4H, phenylene ortho to nitro); 7.83 (m, 2H, benzothiadiazole); 7.69 (s, 2H, vinylene); 7.47 (m, 4H, phenylene meta to nitro); 7.21 (m, 4H, thiophene).

Anal. Calc. for $C_{32}H_{16}N_6O_4S_3$: C, 59.62; H, 2.50; N, 13.04. Found: C, 59.37; H, 2.43; N, 12.95%.

2.5. Fabrication of photovoltaic cells

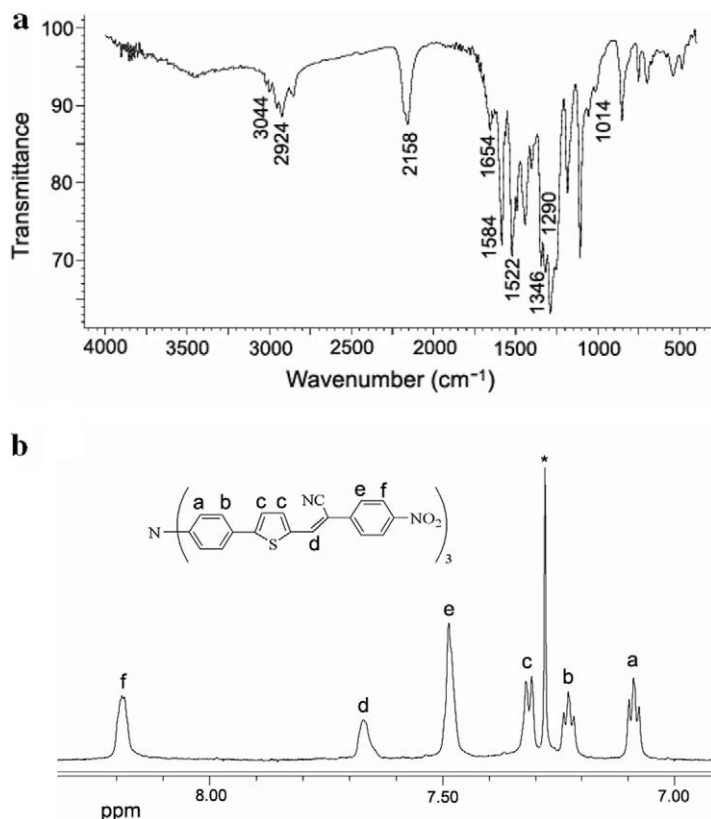
The photovoltaic performance of the devices was performed with the structures ITO/**TPA-TNP**:PCBM/Al (device A) and ITO/**BTD-TNP**:PCBM/Al (device B). The small molecules **TPA-TNP** and **BTD-TNP** were used as donor and PCBM as acceptor, which were defined as devices A and B. Both the devices were prepared in air, on the pre-cleaned indium tin oxide coated glass substrates. The active layer of blend was prepared by spin coating on ITO glass using a solution of **TPA-TNP**:PCBM or **BTD-TNP**:PCBM (1:1 ratio by wt) in


Fig. 1. FT-IR spectrum (a) and ^{1}H NMR spectrum in CDCl$_3$ solution (b) of compound **TPA-TNP**.

1,2-dichlorobenzene. The thermal annealing was carried out at 100 °C for 10 min in a glove box. The thickness of the active layer in all devices is around 100 ± 5 nm. Finally, to complete the devices, the Al electrode was deposited onto the blend film by thermal evaporation at the vacuum around 10^{-5} Torr. The effective area of all devices is about 25 mm². All of the current–voltage characteristics of the devices were measured in air using a Keithley electrometer having built in power supply. A 100 W tungsten–halogen lamp was used as light source. For the photovoltaic measurements, the devices were illuminated through the ITO side with an illumination intensity of 100 mW/cm².

3. Results and discussion

3.1. Synthesis and characterization

Schemes 1 and 2 outline the synthesis of the target compounds **TPA-TNP** and **BTD-TNP** which are derivatives of the triphenylamine and benzothiadiazole, respectively. The intermediate compounds **1** [32], **2** [33], **3** [33], **4**, [34], **5** [34], **6** [6a] and **7** [33,35] were synthesized according to the literature. Compounds **TPA-TNP** and **BTD-TNP** were prepared by reacting 4-nitrobenzyl cyanide with **3** and **7**, respectively, in anhydrous ethanol in the presence of NaOH. This reaction could be catalyzed with *tert*-BuOK instead of NaOH. **TPA-TNP** and **BTD-TNP** were soluble in common organic solvents such as THF, chloroform and dichloromethane even though they lacked of aliphatic chains. **TPA-TNP** displayed higher solubility in these sol-

vents than **BTD-TNP** due to the dendronized nature of the former and the non-coplanar conformation of the triphenylamine core.

The chemical structures of the compounds were confirmed by FT-IR and ¹H NMR spectroscopy. Fig. 1 depicts the IR and ¹H NMR spectra of compound **TPA-TNP**. The IR spectrum (Fig. 1a) showed characteristic absorption bands at 3044 (aromatic C–H stretching); 1584, 1490, 1440 (C=C aromatic ring stretching band); 2158 (cyano group); 1654 (C=C olefinic stretching vibration); 1522, 1346 (nitro group) and 1014 cm⁻¹ (trans olefinic bond). Furthermore, **TPA-TNP** displayed characteristic absorption at 2924, 1320 and 1290 cm⁻¹ assigned to the triphenylamine. Finally, compound **BTD-TNP** displayed absorptions at 2952, 2922, 1476, 1292, 1108, 876 and 830 cm⁻¹ associated with the benzothiadiazole unit.

The ¹H NMR spectrum of **TPA-TNP** (Fig. 1b) exhibited an upfield peak at 8.19 ppm assigned to the phenylene protons labeled "f" which was deshielded by the electron-withdrawing nitro group. The vinylene proton "d" resonated at a relatively higher shift (7.67 ppm) than that of the usual vinylene protons owing to the cyano substituent on the vinylene bond. The aromatic protons "e", "c", "b" and "a" gave signals at 7.48, 7.32–7.31, 7.23 and 7.09 ppm, respectively. Likewise, the ¹H NMR spectrum of **BTD-TNP** showed upfield resonances at 8.13 (phenylene ortho to nitro) and 7.83 ppm (benzothiadiazole). Finally, the vinylene protons, the aromatic protons meta to nitro and the thiophene gave peaks at 7.69, 7.47 and 7.21 ppm, respectively.
Scheme 1. Synthesis of compound **TPA-TNP**.
Scheme 2. Synthesis of compound **BTD-TNP**.
Fig. 2. TGA thermograms of compounds **TPA-TNP** and **BTD-TNP** in N_2. The inset shows the TMA traces of these compounds. Conditions: N_2 flow, 60 cm^3/ min; heating rate, 20 °C/min.

Table 1
Thermal and optical properties of compounds **TPA-TNP** and **BTD-TNP**.

Compound	TPA-TNP	BTD-TNP
$T_d{}^a$ (°C)	456	521
$Y_c{}^b$ (%)	65	82
$T_g{}^c$	50	62
$\lambda_{a,max}{}^d$ in solution (nm)	357, 469, *638*	348, 469, *650*
$\lambda_{a,max}{}^d$ in thin film (nm)	359, 473, *640*	359, 452, *640*
$E_g^{opt\,e}$	1.67 eV (744 nm)^f	1.65 eV (751 nm)^f

Numbers in italic indicate the long wavelength absorption maximum.
  [a] Decomposition temperature corresponding to 5% weight loss in N_2 determined by TGA.
  [b] Char yield at 800 °C in N_2 determined by TGA.
  [c] Glass transition temperature determined by TMA.
  [d] $\lambda_{a,max}$: the absorption maxima from the UV–vis spectra in THF solution or in thin film.
  [e] E_g: The optical band gap calculated from the onset of the thin film absorption.
  [f] Numbers in parentheses indicate the onset of the thin film absorption.

Thermal characterization of compounds was accomplished by TGA and TMA (Fig. 2). The decomposition temperature (T_d), the char yield (Y_c) at 800 °C in N_2 by TGA as well as the glass transition temperature (T_g) by TMA are listed in Table 1. Both compounds displayed good thermal stability since were stable up to ~350 °C, decomposed above 450 °C and afforded Y_c of 65–82%. This feature is attributable to the absence of aliphatic chains in the molecules. **BTD-TNP** was more thermally stable than **TPA-TNP** and exhibited higher T_d and Y_c values. However, the T_g's were relatively low (50–62 °C) due to the monomeric character of the compounds.

3.2. Photophysical properties

Fig. 3 depicts the UV–vis absorption spectra in both THF solution (10^{-5} M) and thin film of the compounds. All the spectroscopic features are summarized in Table 1.

The absorption spectra (Fig. 3) of the compounds had the same pattern in both solution and thin film with three maxima ($\lambda_{a,max}$) around 360, 460 and 650 nm. It should be emphasized that the absorption spectra of the compounds were broad and covered a wide range of the UV–vis and near-infrared spectrum up to about 800 nm. This feature is desirable for the photovoltaic properties of the compounds. The presence of the nitro groups at the terminal phenyls of the molecules contributed to the broadening of their absorption as has been well established in the literature [36]. Even though the long wavelength $\lambda_{a,max}$ in thin film was identical for both compounds (650 nm), **BTD-TNP** showed an absorption onset at slightly higher wavelength and consequently lower optical band gap (E_g^{opt}) than **TPA-TNP**. Specifically, the thin film absorption onset was located at 744 and 751 nm which correspond to E_g^{opt} of 1.65 and 1.67 eV for **TPA-TNP** and **BTD-TNP**, respectively (Table 1). These E_g^{opt} values are significantly lower as compared to related materials. Particularly, a series of related triphenylamine–thienylenevinylene star-shaped molecules[57] have shown E_g^{opt} of 2.38–1.78 eV. In addition, E_g^{opt} of 2.14 eV has been reported for star-shaped molecule with triphenylamine as core and benzo[1,2,5]thiadiazole vinylene as arms [37]. Finally, a conjugated copolymer [38] based on 4,7-dithien-2-yl-2,1,3-benzothiadiazole and 2,7-dibenzosilole had E_g^{opt} of 1.90 eV.

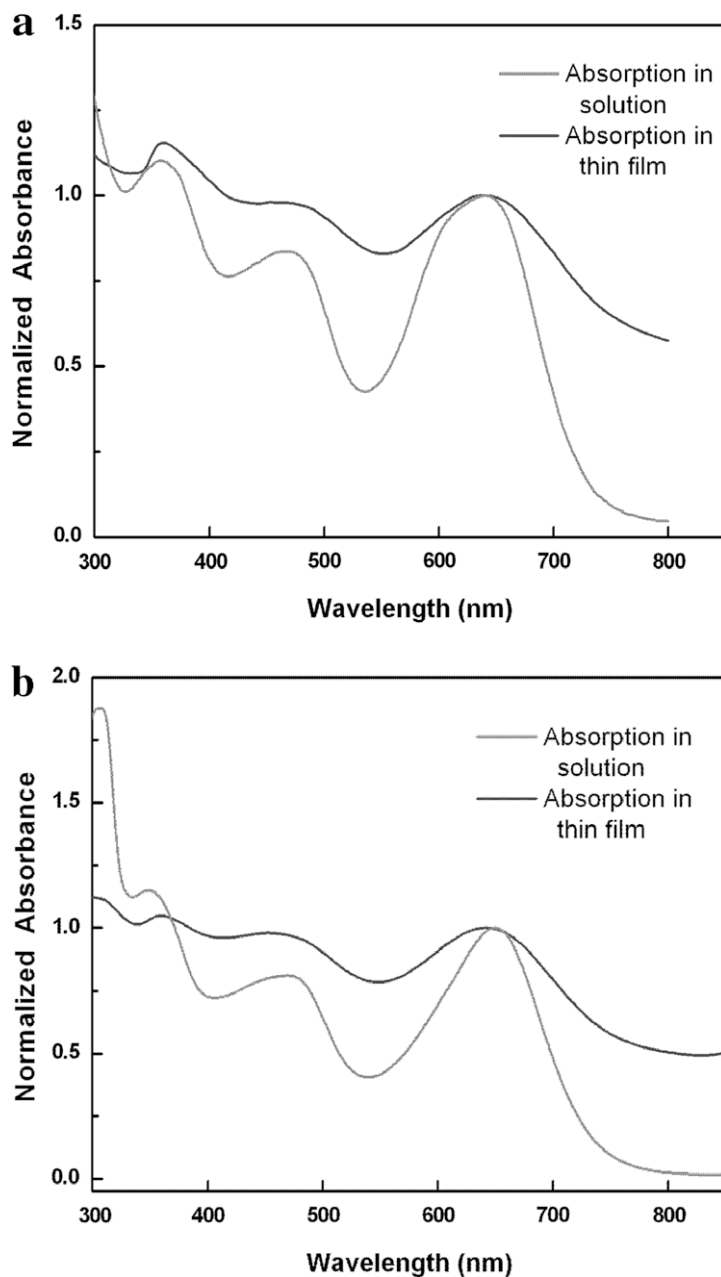
For the photoinduced efficient charge transfer in bulk heterojunction photovoltaic devices, the relative position of the lowest unoccupied molecular orbital (LUMO) of the donor (D) and acceptor (A) components used in photoactive layer is crucial. For the initiation of photoinduced charge transfer process, the difference between the LUMO level of D and A should be larger than the binding energy of excitons [39,40]. The magnitude of exciton binding energy in most of the organic semiconductor is about 0.5 eV [41]. The highest occupied molecular orbital (HOMO) and the LUMO energy levels of the compounds estimated from cyclic voltammetry measurement are −4.9 and −3.2 eV for


Fig. 3. Normalized UV–vis absorption spectra in THF solution and thin film of compounds **TPA-TNP** (a) and **BTD-TNP** (b).

TPA-TNP, −4.9 and −3.25 eV for **BTD-TNP** and −6.6 eV for PCBM. The difference between the LUMO levels of these small molecules and PCBM is comparatively larger than the binding energy of the exciton. Therefore, the relevant energy level positions and the absorption in long wavelength region suggest that these new small molecules should be effective donors in BHJ with PCBM as acceptor in photovoltaic devices.

3.3. Electrical properties of **BTD-TNP** and **TPA-TNP** films

The J–V characteristics of the ITO/**BTD-TNP**/Al and ITO/**TPA-TNP**/Al devices in the dark are shown in Fig. 4. The J–V

characteristics of the devices show asymmetrical and exhibit rectification. This behavior can be explained by the small work function of the Al electrode and the p-type semi-conductivity of both organic layers. The rectification effect observed in this device is due to the formation of a Schottky barrier at the Al–organic layer and Ohmic contact with the ITO electrode. In the present device, the Fermi level of the ITO (−4.7 eV) matches closely to the HOMO level of both compounds **BTD-TNP** and **TPA-TNP** and indicates the formation of Ohmic contact for hole injection from ITO electrode, whereas the Al forms the Schottky barrier with both organic compounds, which is responsible for the rectification effect.
Fig. 4. Current–voltage characteristics of the devices based on **TPA-TNP** and **BTD-TNP** in the dark.

In order to get information about the position of Fermi level and charge carrier mobility for the present organic compounds, we have measured the current–voltage characteristics of the devices in the dark at different temperatures ranging from 300 to 380 K. It was found that the J–V characteristics in low voltage region (0–0.3 V), the slope of $\log(J)$–$\log(V)$ curves at different temperature range is about unity, indicating the Ohmic conduction in this region as observed for phthalocyanines [42] and other small molecules [43]. The J–V characteristics in this region are described by the following expression

$$J = N_v q \mu (V/d) \exp[-E_F/kT] \tag{1}$$

where N_v is the density of the state in HOMO level taken as 10^{27} m^{-3}, q is the electronic charge, E_F is the position of Fermi level above the HOMO level, V is the applied voltage, d is the thickness of organic film, k is the Boltzmann's constant and T is the temperature. By plotting the $\log(J)$ against $1000/T$ at voltage of 0.2 V (as shown in Fig. 5), and fitting the data in accordance to Eq. (1), the values of E_F and μ are being estimated as 0.45 eV and 2.2×10^{-5} cm^2/V s, respectively for **TPA-TNP**. Similarly, the values of E_F and μ for **BTD-TNP** are 0.41 eV and 4.4×10^{-5} cm^2/V s, respectively.

In order to get information about the formation of Schottky barrier, we measured the incident photon to the current efficiency (IPCE) of the devices. The values of IPCE have been estimated using the following expression:

$$IPCE = 1240 J_{sc}/\lambda P_{in} \tag{2}$$

where J_{sc} (mA/cm^2) is the short circuit photocurrent density for monochromatic irradiation and λ (nm) and P_{in} (W/m^2) are the wavelength and the intensity of the monochromatic light, respectively. The IPCE spectra of the ITO/**BTD-TNP**/Al

device, illuminating through the ITO and Al side are shown in Fig. 6. Similar results were also obtained for the device based on **TPA-TNP**. It can be seen from Fig. 6 that the IPCE spectra of the device, illuminating through the Al side follow the absorption spectra of **BTD-TNP** (see Fig. 3). Since the binding energy of the exciton in the organic semiconductor is about 0.3 eV, the photocurrent in devices based on these materials is only due to the dissociation of excitons into free carriers at the Schottky barrier or p–n junction present in the devices. When the device is illuminated through the Al side, photons corresponding to the absorption peak of **BTD-TNP** are absorbed near the Al/**BTD-TNP** interfaces, generate excitons in this region and subsequently dissociate into free carrier, resulting higher photocurrent. However, the photons corresponding to the low and long wavelength regions (low absorption), penetrate more into the bulk of organic layer and are absorbed far from the Al/**BTD-TNP** interface and generate the excitons there. Only few excitons are able to reach the Al/BDT-TNP interface resulting low photocurrent because of short exciton diffusion length (10–15 nm) in organic semiconductors. The IPCE spectra of the device illuminating through ITO do not follow the absorption spectra of **BTD-TNP**. When the device is illuminated through the ITO side, the incident light penetrate more into the Al/**BTD-TNP** interface, at the wavelengths, where the absorption is low and generate excitons near this interface and subsequently dissociated into free carriers, resulting high photocurrent. However, when the absorption coefficient of organic layer is high, the excitons are generated near the ITO/**BTD-TNP** interface and only few excitons reach the Al/**BTD-TNP** interface resulting low photocurrent.

From the above results, we conclude that these materials behave as p-type organic semiconductors with average
Fig. 5. Variation of log(J) with 1000/T in Ohmic region for ITO/**BTD-TNP**/Al device.
Fig. 6. IPCE spectra of the ITO/**BTD-TNP**/Al device illuminating through ITO and Al side.

hole mobility of the order of 10^{-5} cm^{-2}/V s which form an Ohmic contact and Schottky barrier with high work function ITO electrode and low work function Al electrode, respectively. The generation of photocarrier in this device is due to the dissociation of excitons into free charge carriers due to the built in field at the Al–organic layer interface. These materials can be used as electron donors for bulk heterojunction photoactive devices.

3.4. Photovoltaic properties of blend **TPA-TNP** and **BTD-TNP** with PCBM

The IPCE spectra of the devices based on **TPA-TNP**:PCBM and **BTD-TNP**:PCBM having same structure, illuminating through the ITO side, are shown in the Fig. 7. It seems from this figure that the IPCE spectra of the device match closely to the absorption spectra of the
Fig. 7. IPCE spectra of the devices using **BTD-TNP**:PCBM and **TPA-TNP**:PCBM layers, illuminating through the ITO side.

active layer. This suggests the formation of donor and acceptor interfaces throughout the bulk of the active layer. The peak around 370 nm corresponds to the absorption of the PCBM. The IPCE value for these devices which corresponds to the absorption peak of donor (**TPA-TNP** or **BTD-TNP**) is higher than that for the device using only **TPA-TNP** or **BTD-TNP** due to the formation of large D–A interfacial area, resulting effective dissociation of exciton into free charge carriers.

The current–voltage characteristics (J–V) of the photovoltaic devices based on **TPA-TNP**:PCBM and **BTD-TNP**:PCBM blends were measured using an illumination intensity of 100 mW/cm^2, and are shown in Figs. 8a and 8b, respectively, along with the J–V characteristics for the devices using only **TPA-TNP** or **BTD-TNP**. Under illumination, the device based on **TPA-TNP** and **BTD-TNP** gives a power conversion efficiency (η) of 0.08%, and 0.09%, respectively, while the device with **TPA-TNP**:PCBM and **BTD-TNP**:PCBM gives η of about 1.13% and 1.32%, respectively. The overall photovoltaic performance of the devices using the blend active layers is much higher than that of **TPA-TNP** or **BTD-TNP**. The improvement in the overall photovoltaic performance can be attributed to the formation of bulk D/A heterojunction through the volume of
Fig. 8a. Current–voltage characteristics of the devices based on **TPA-TNP** and **TPA-TNP**:PCBM under illumination of 100 mW/cm^2.
Fig. 8b. Current–voltage characteristics of the devices based on **BTD-TNP** and **BTD-TNP**:PCBM under illumination intensity of 100 mW/cm^2.

active layer that leads to an efficient dissociation of photo-generated exciton into free charge carriers and subsequent charge transfer from donor to acceptor. The slightly higher power conversion efficiency for the device with **BTD:PCBM** than device with **TPA-TNP** has been attributed to the more efficient photoinduced charge transfer in former device.

We have investigated the effect of thermal annealing on the photovoltaic properties of the **BTD-TNP**:PCBM (1:1 ratio) based device (Fig. 9) and the photovoltaic parameters are listed in Table 2. It can be seen from this table that significant improvement in the photovoltaic performance was

achieved upon thermal annealing (the power conversion efficiency increases from 1.32% to 2.42%). The open circuit voltage is slightly lower than that for the un-annealed one. The short circuit photocurrent increases by almost one order of magnitude and the fill factor also increases. Therefore, it is concluded that the annealing process plays an important role in the improvement of the device performance.

Different models have been proposed for the origin of V_{oc} [44,45]. In a single layered organic photovoltaic device, in which the active layer is composed of one type organic
Fig. 9. Current–voltage characteristics of the devices based on as cast and thermally annealed **BTD-TNP**:PCBM blends under illumination intensity of 100 mW/cm^2.

Table 2
Photovoltaic parameters of the devices.

Device	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor	Power conversion efficiency (η) (%)
ITO/**TPA-TNP**/Al	0.36	0.54	0.42	0.08
ITO/**BTD-TNP**/Al	0.42	0.53	0.44	0.09
ITO/**TPA-TNP**:PCBM/Al	2.9	0.76	0.49	1.13
ITO/**BTD-TNP**:PCBM/Al	3.37	0.78	0.50	1.32
ITO/**BTD-TNP**:PCBM (annealed)/Al	6.42	0.70	0.54	2.42

semiconductor, donor or acceptor, the open circuit voltage, V_{oc} is principally determined by the difference in the work functions between the two metal electrodes: the metal–insulator–metal (MIM) model [45]. In this model the organic layer is assumed to have a negligible amount of intrinsic charge carriers and can therefore be considered as an insulator. Hence, the upper limit of the V_{oc} can be calculated from the estimation of the difference between the work function of the two electrodes. The V_{oc} of the ITO/**TPA-TNP**/Al device is 0.54 V, which closely matches the work function difference (0.6 eV) between the ITO (4.8 eV) and the cathode Al (4.2 eV). However, the MIM model cannot be applied to solar cells with a BHJ structure. It has been found that the V_{oc} is highly dependent on the LUMO level of the acceptors, suggesting that a Fermi level pining between the negative electrode and acceptor could be the origin of the Ohmic like behavior of the acceptor-negative electrode contact [44].

The large values for J_{sc} and FF, upon thermal annealing imply lower series resistance and higher carrier mobility. Thus, the increased efficiency upon thermal annealing results from higher nanoscale crystallinity due to the de-mixing between the two components in the bulk hetero-junction film after thermal annealing.

Fig. 10 shows the experimental J_{ph} of the devices using as cast and annealed **BTD-TNP**:PCBM blends in a double logarithmic plot as a function of the effective voltage ($V_o - V$). As can be seen in this figure, the photocurrent shows a strong enhancement, when the thermally annealed blend is used as active layer for the device. The short circuit current (J_{sc}) increases by a factor of 1.9, the FF increases by a factor of 1.08 and the overall enhancement of η by about a factor of 1.82, when compared to the device with the cast blend. The effect of the thermal annealing on the solar cells performance in terms of physical parameters such as charge carrier mobility and photocurrent generation efficiency in these devices will be discussed in a following section of the paper.

In present device, after the photoinduced electron transfer at the donor/acceptor interfaces present in bulk photoactive layer and subsequent dissociation, the electrons are localized in the PCBM phases, whereas the holes remain in the **BTD-TNP**. Subsequently, the free electrons and holes must be transported via PCBM and **BTD-TNP** pathways towards the electrodes to produce the photocurrent. Therefore, the electron transport in PCBM and hole transport in **BTD-TNP** are crucial for understanding the photocurrent generation in the **BTD-TNP**:PCBM blend film. For pure PCBM the electron mobility was about 2.0×10^{-3} cm^2/V s [46], which is about 100 times higher than the hole mobility in pure **BTD-TNP** as discussed earlier. An important question is whether these mobilities
Fig. 10. Variation of photocurrent (J_{ph}) with effective applied voltage ($V_o - V$) of ITO/**BTD-TNP**:PCBM/Al device employing (a) as cast and (b) annealed photoactive layers.

are modified or not, when the materials are blended as in the active layer of the photovoltaic device. We have measured the hole and electron mobility in the blend using the space charge limited current (SCLC) method.

In order to measure the SCLC for only one type of charge carrier in the blend, the other charge carrier must be suppressed by a large injection barrier, resulting in an electron or hole only device. This approach has been successfully used to measure the hole and electron mobility in the conjugated polymer:PCBM blend [47,48], polymer:polymer blend [46], conjugated polymer: inorganic metal oxide nanoparticles blends [49,50] and CuPc:C$_{60}$ blend [51]. Since the HOMO and LUMO offsets between the compound **BTD-TNP** and PCBM are approximately 1.7 and 0.8 eV, respectively (HOMO and LUMO levels have been estimated from cyclic voltammetry measurements as discussed earlier), the transport of charge carriers in the mixed blend layer should occur along the paths consisting of only a single molecular species, i.e. compound **BTD-TNP** for holes and PCBM for electrons. Therefore, we model the *J–V* characteristics for electron and hole only devices using the SCLC theory [52].

$$J = \frac{9}{8}\varepsilon\varepsilon_{\mathrm{o}}\mu(E)\theta\frac{V^2}{d^3} \qquad (3)$$

where $\varepsilon = 3.2$ is the relative dielectric constant of the organic film, ε_{o} is the vacuum dielectric constant, $\theta \leqslant 1$ is the shallow trapping factor (where $\theta = 1$ in the trap free limit), d is the film thickness and $\mu(E)$ is the electric field (E) dependent charge carrier mobility, given by Poole Frenkel law [53]

$$\mu(E) = \mu_o \exp[\gamma(E)^{1/2}] \qquad (4)$$

where μ_{o} is the mobility at $E = 0$ and γ denotes the field activation parameter. The field dependence arises from the interaction between the charge carriers and randomly oriented permanent dipoles in a molecular film, where charge carriers are transported by thermally assisted hopping [53].

Fig. 11a shows the *J–V* characteristics of the **BTD-TNP**:PCBM blend film (as cast and annealed) sandwiched between ITO and Au electrodes (hole only device). In this configuration, holes are injected from ITO (work function of $\varphi_{\mathrm{ITO}} = 4.8$ eV) into HOMO of compound **BTD-TNP**, whereas electron injection from Au into LUMO of PCBM is suppressed due to its high work function of 5.1 eV. The experimental curves are fitted to the above equations and the zero field hole mobility in the blend (as cast) is about 6.5×10^{-5} cm^2/V s, which is lower than the value for **BTD-TNP**. However, when the annealed blend film is used in the device, the zero field mobility is increased by one order of magnitude (from 6.5×10^{-5} to 3.4×10^{-4} cm^2/V s).

The *J–V* characteristics of the **BTD-TNP**:PCBM blend (as cast and annealed film) sandwiched between two Al electrodes, to allow the efficient injection of electron from Al into the LUMO of PCBM are shown in Fig. 11b. In this device, the high injection barrier between Al and HOMO of **BTD-TNP** suppress the injection of holes and the device behaves as electron only device. The electron mobilities which were estimated using these curves are about 1.86×10^{-3} and 3.4×10^{-3} cm^2/V s, for the as cast and annealed film, respectively. From these results, we conclude that the electron and hole mobilities are more balanced for the device in which the annealed blend is used, resulting efficient charge transportation and collection that enhance the power conversion efficiency.
Fig. 11a. Current density–voltage characteristics in the dark for hole only device using **BTD-TNP**: PCBM films.
Fig. 11b. Current density–voltage characteristics in the dark for electron only device using **BTD-TNP**:PCBM films.

The LUMO level of compound **BTD-TNP** is at considerably higher energy level than that of PCBM and provides the sufficient energy to the excitons to dissociate into the free holes and electrons. The holes and electrons are collected at the respective electrodes by their transportation through the percolating paths of **BTD-TNP** and PCBM, respectively. The large difference between the electron and hole mobilities in the device with as cast film, results unbalanced charge transport due to the accumulation of space charge near the electrode. In this case the space charge limits the photocurrent. However, when the annealed film is used for the device, the difference between the electron and hole mobilities is reduced and the space charge no longer limits the charge transportation due to the more balanced charge transportation in device based on the annealed film.

4. Conclusions

Starting from triphenylamine and benzothiadiazole two new vinylene compounds **TPA-TNP** and **BTD-TNP** were synthesized. These compounds were soluble in common organic solvents like THF, chloroform and dichloromethane. They showed relatively low glass transition temperature and high thermal stability. Both compounds displayed broad absorption with longer wavelength absorption maximum at 638–650 nm and optical band gap of 1.65–1.67 eV. The photovoltaic properties of the bulk heterojunction devices based on **TPA-TNP** and **BTD-TNP** as electron donor and PCBM as electron acceptor were investigated through analyzing their current–voltage characteristics. The power conversion efficiency of the device **BTD-TNP**:PCBM (annealed) blend is about 2.42%, which is attributed to the balanced charge transport in the device.

performance [19], more research has been done to better control morphology via this facile solvent or solvent mixture method [17,20–24]. By far, it has been developed into one of the most powerful approaches to modify the morphology of photoactive layer and thus improve device performance. Peet et al. have demonstrated that longer charge carrier life time can be achieved by adding alkanethiol to the P3HT:PCBM composites in toluene due to an improved morphology with the formation of ordered structure in the untreated film [25]. Also by using this solvent additive method, Peet et al. have obtained the highest efficiency device to date in low-band gap polymers [26,27]. Though the solvents used and systems or materials investigated are different, one of the key tasks for all these works is to substantially improve the crystallinity of components in the composite film while maintaining large interfacial area.

Generally, for any semi-crystalline polymers, besides the molecular configuration, their crystallinity is frequently influenced by the crystallization conditions which could be classified into thermodynamic and kinetic determinations. Traditional polymer physics has revealed that crystallization temperature, time and the environments, e.g. external force, spatial confinement, surface and so on, play significant role in determining the crystallization behaviors of semi-crystalline polymers. Previously, most efforts have been diverted to the investigations on how to directly increase the crystallinity or tune the morphology of component itself in the composite. However, less attention has been paid to study how the crystallization behaviors of a specific component are affected by the other components involved in the composite, which has been shown that it plays a key role in determining the morphology of the thin composite film served as the photoactive layer of bulk-heterojunction polymer solar cells [28].

C60, as the first discovered fullerene molecule, is much cheaper than the widely used PCBM or other novel fullerene derivates in organic Photovoltaic (PV) devices [29–33]. Therefore, C60 is a worthy candidate for lower production cost devices. Whereas, the performance of device based on P3HT:C60 composite film is usually lower than that based on P3HT:PCBM composite at present. To reveal the hindrances towards efficient polymer PV devices based on the low cost C60, we carry out comparative studies by choosing two composites consisting of the same electron donor material P3HT but different acceptors C60 and PCBM. In this work, we show that though the difference between C60 and PCBM is small in terms of molecular structure, the crystallization of P3HT is severely affected by C60 when compared with PCBM, resulting in distinct crystallinity variation of P3HT in untreated P3HT:C60 and P3HT:PCBM composite films spin coated from solution in the widely used ODCB solvent. The reason for the extremely low crystallinity of P3HT in P3HT:C60 composite has been analyzed and the solution to solve this problem has been proposed.

2. Experimental details

2.1. Materials

P3HT with M_w = 100,000 g/mol, regioregularity greater than 98.5%, was purchased from Rieke Metals Inc. C60,

PCBM and ODCB (anhydrous, 99%) were purchased from Sigma–Aldrich Co. Ltd. Chlorobenzene (CB), 1,2,4-trichlorobenzen (TCB), tetralin, 1-Methylnaphthalene (M-naph) and 1-Chloronaphthalene (Cl-naph) were purchased from Beijing Chemical Reagent Co. Ltd., China. All these materials were used as received without further treatment.

2.2. Sample preparation

For C60 and PCBM solubility measurements, first, certain amount of C60 or PCBM was added into 1 ml solvent under intensive stirring for more than 24 h at room temperature. Second, the solutions were placed in quiet condition for at least 12 h to check if there was solid precipitating from the solution. Third, if no solid or precipitate was found, more C60 or PCBM was added to further dissolve in the solution until very little amount saturating crystallites are observed by optical microscopy. And for the solubility of P3HT, the solution was heated to 50 °C to completely dissolve P3HT by stirring for overnight and then cooled down to room temperature. Thus obtained solution was placed in quiet condition for 2 days to achieve thermodynamic equilibrium state. It is well known that if P3HT forms ordered aggregates, an absorption peak centered at ca. 610 nm will appear in its UV–vis absorption spectrum [34–36]. Therefore, UV–vis absorption measurements were performed on the solution. The approximate solubility of P3HT could be obtained by determining the concentration at which the peak at around 610 nm (see Fig. 1) just appears.

With respect to the preparation of composites, given amount of C60 or PCBM was firstly dissolved in solvents or solvent mixtures by intensive stirring. Afterwards, the designated amount of P3HT was added into the solution to get a mixture with P3HT:C60 = 5:4 or P3HT:PCBM = 1:1 by weight. These mixtures were continuously stirred in the dark for more than 12 h so that solutions with a concentration of 8.0 mg/ml for P3HT were obtained.

The thin films were obtained via spin coating (Laurell Spin Processor WS-400B 6NPP Lite) the as prepared solutions onto pre-cleaned glass cover slides. The spin coating speed of 500–1500 rpm was selected so as to eventually achieve homogeneous thin films having dimensions in order of one square centimeter and thickness of ca. 80 nm.

PV cells were fabricated according to standard device fabrication procedures. i.e. the photoactive layer was first fabricated by depositing the prepared solution on well-cleaned glass substrates covered with 100 nm thick layers of indium tin oxide (ITO) and a spin coated layer of poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS). The thickness of the photoactive layer is around 80 nm for all the devices. The devices were completed by evaporation of 1 nm LiF layer and subsequently 100 nm Al layer as cathode.

2.3. Characterization: transmission electron microscopy (TEM)

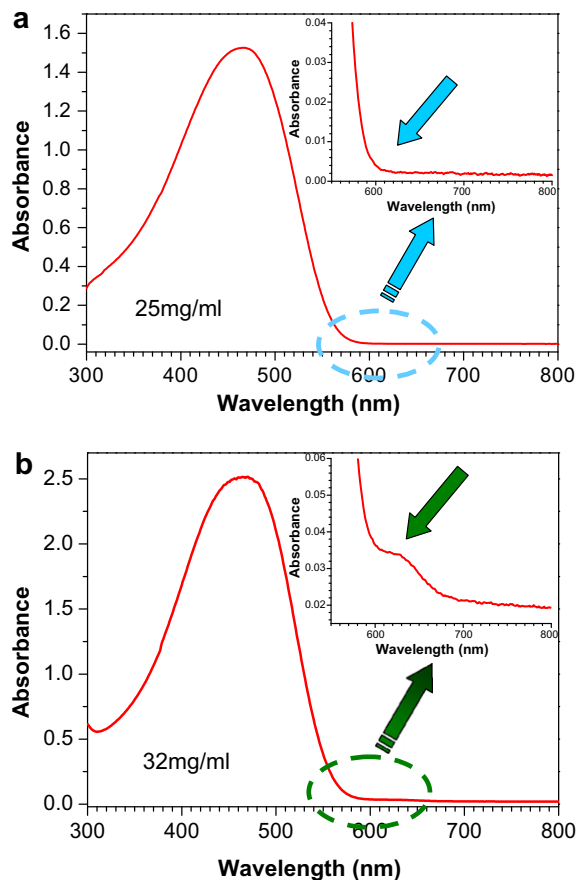
The spin coated films were floated on distilled water, then transferred to 400-mesh copper grids and dried in


Fig. 1. UV–vis absorbance spectra of P3HT with a concentration of (a) 25 mg/ml (b) 32 mg/ml in ODCB solution.

vacuum overnight. TEM was performed on a JEOL JEM-1011 transmission electron microscope operated at an acceleration voltage of 100 kV. To quantitatively relate the diffraction intensity in selected area electron diffraction (SAED) patterns to the crystallinity of the specimen investigated, all these SAED patterns were performed by using a standard recording mode. i.e. fixed magnification, filed-limiting aperture of 100 μm, current density of 0.6 pA cm^{-2} and exposure time of 11.0 s for SAED acquisition. Identical settings were used for film development and digitalization.

2.4. Film thickness measurements

Film thickness measurements were performed with a Veeco DekTak 6 M stylus profiler via measuring the height step between sample surface and the scrape.

2.5. Wide angle X-ray diffraction (WAXD)

WAXD profiles were obtained by using a Bruker D8 Discover Reflector with fixed X-ray wavelength of 1.542 Å. The diffraction was recorded at θ–2θ symmetry scanning mode with scan angle from 2θ 3°–18°.

2.6. Atomic force microscope

Surface topography was observed by atomic force microscopy (AFM) operating in tapping mode on Agilent 5500 at room temperature.

2.7. UV–vis absorption spectroscopy

The obtained mixed solutions and films were directly used in UV–vis absorption spectroscopy investigations. The UV–vis absorption spectra were acquired on a Lambda 750 spectrometer (Perkin-Elmer, Wellesley, MA).

2.8. Infrared spectroscopy

Infrared spectra were obtained using a Bruker Vertex 70 FTIR spectrometer. Samples were prepared by drop casting solution onto potassium bromide substrates and placed in dark ambient condition for solvent evaporation. Afterwards, the obtained films on potassium bromide substrates were dried in vacuum to exclude the remaining solvents. Thermal annealing was performed directly on potassium bromide substrates in inert atmosphere at 180 °C for 20 min.

2.9. Device characterization

Spectral response data were determined in air with a Keithley-2400 source meter, using monochromatic light from a xenon lamp in combination with a monochromator. A calibrated Si cell was used as reference. The performance characterization for the PV cells was also carried out with a Keithley-2400 source meter. The cells are illuminated by a tungsten-halogen lamp (filtered by a Schott KG1 and GG385 filter resulting in a spectral range of 400–900 nm with a maximum at 650 nm) at an intensity of 100 mW/cm^2.

3. Results and discussion

3.1. The substantial crystallization suppression of P3HT in its composite with C60

Both the untreated thin films of P3HT:C60 and P3HT:PCBM composites basically give similar morphology, as shown by bright-field TEM images in Fig. 2, however, there are quite a few short and bright rods observed in the P3HT:PCBM composite. These nanorods are attributed to the P3HT crystals as dispersed in smooth thin film with relatively high density of the matrix. However, SAED patterns (The inset in each figure) which are in situ obtained disclose obviously different crystalline order in between the two composite films. For P3HT:C60 composite film, except for one diffused diffraction ring can be well resolved from the SAED pattern (Inset of Fig. 2a), which is associated to the diffraction from C60 nanocrystallites [7,37], only an indistinct diffraction ring (indicated by the arrow in Fig. 2a) with d-spacing of 0.39 nm is observed outside. However, the SAED pattern for the untreated P3HT:PCBM composite film gives much clearer diffraction ring (indi-
Fig. 2. BF-TEM images and corresponding SAED patterns (up-left inset) of the untreated composite films spin coated from ODCB solution. (A) P3HT:C60 (5:4, w/w), (B) P3HT:PCBM (1:1, w/w).

cated by the arrow in Fig. 2b) with *d*-spacing of 0.39 nm outside the broad diffractions which is ascribed to PCBM nanocrystallites [38,39]. As is known, the diffraction ring with *d*-spacing of 0.39 nm is associated to the reflections from crystallographic (0 2 0) planes of typical whisker-like P3HT crystals [40]. Since SAED pattern has been well established for semi-quantitative crystallinity analysis and proven to be a feasible and powerful tool in this field [7,8,28], we are able to draw a preliminary conclusion that the crystallization of P3HT in the composite with C60 has been substantially suppressed compared to that in P3HT:PCBM composite, as proven by the low electron diffraction intensity of crystallographic (0 2 0) planes of P3HT in the inset of Fig. 2a.

The crystallinity variation in these two untreated composites was further verified by WAXD measurements. As shown in Fig. 3a, the diffraction profile associated to untreated P3HT:C60 composite shows a broad and hardly to be resolved diffraction peak at $2\theta = 5°$, which is assigned to the reflections of crystallographic (1 0 0) planes of P3HT crystals [41,42]. The very low diffraction intensity in combination with its broad peak reveals very low crystallinity and quite small crystalline aggregates of P3HT in this specimen. In contrast, for the P3HT:PCBM composite a well resolved diffraction peak is observed at the same position. Particularly, the diffraction intensity of this peak is even comparable with that of thermally annealed P3HT:C60 composite film at 150 °C for 20 min. It should be noted that the position and the width of the crystallographic (1 0 0) peaks in P3HT:C60 annealed film and untreated P3HT:PCBM film are slightly different. The relatively small d-spacing of P3HT crystallographic (1 0 0) planes in untreated P3HT:PCBM film is mainly resulted from the side-chain interdigitation which is usually observed in untreated films prepared by solution deposition method. Though the P3HT crystallite size calculated by using the Scherrer equation is smaller in the untreated

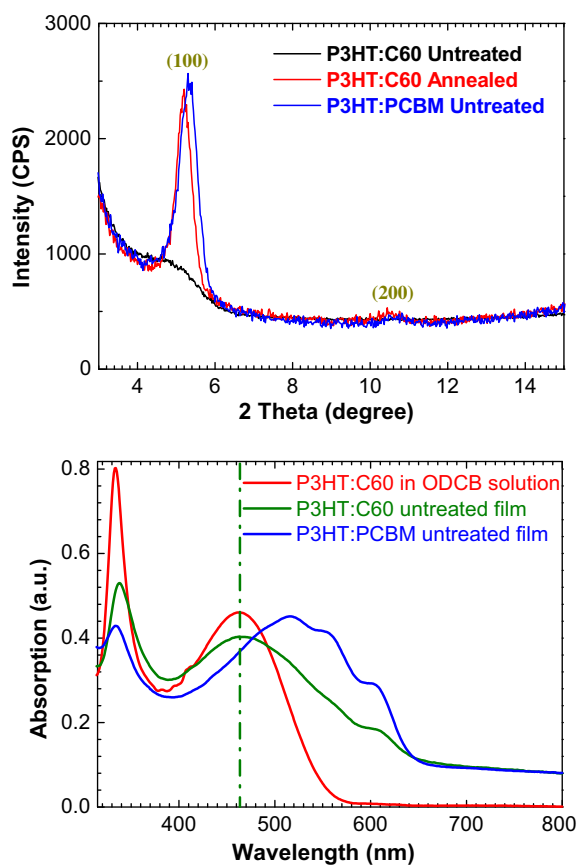
P3HT:PCBM film when compared to that in thermally annealed P3HT:C60 film, the WAXD results clearly indicate


Fig. 3. WAXD profiles (a) and UV–vis absorption spectra (b) of P3HT composites.

that the crystallinity of P3HT in untreated P3HT:C60 film is much lower than that in untreated P3HT:PCBM film.

For crystallizable conjugated polymers, the crystallinity in solid film can also be qualitatively determined by UV–vis absorption at specific wavelengths. The UV–vis absorption spectra of thin films of P3HT composites with C60 or PCBM are shown in Fig. 3b. The spectrum of P3HT:C60 mixture in ODCB is also included for comparison. Two peaks at 334 and 461 nm, respectively, are observed for P3HT:C60 composites in ODCB solution. This spectrum is actually the simple superposition of individual absorption from C60 molecules and the intra-chain π–π^* transition of P3HT single chain in the solution. For the P3HT:C60 solid composite film spin coated from above mentioned ODCB solution, a weak absorption peak additionally appeared at ca. 607 nm, which is associated to the inter-chain π–π^* transition of P3HT, and the intensity of this peak is correlated to the degree of inter-chain packing order [35,43,44]. Therefore, the weak intensity at 607 nm again confirms low crystallinity of P3HT in its untreated composite film with C60. However, with respect to the untreated P3HT:PCBM composite film, three peaks associated to the optical absorption of P3HT can be well resolved in Fig. 3b. Besides, the absorbance peak related to π–π ordered inter-chain packing at ca. 607 nm becomes more prominent and its intensity is increased when compared to that in untreated P3HT:C60 composite film, revealing the crystallinity of P3HT in P3HT:PCBM composite film is much higher than that in P3HT:C60 composite.

Based on the above observations, we have shown that the crystallization of P3HT in untreated P3HT:C60 composite has been substantially suppressed and its crystallinity is much lower than that in untreated P3HT:PCBM composite. Generally, decreased crystallinity of a crystallizable polymer in the composite compared to its pure bulk sample is usually ascribed to the result of "dilution effect" [45–47], which hinders the ordered packing of adjacent polymer chains by mechanical or spatial separation of other components in the composite. However, both composites (P3HT:C60 and P3HT:PCBM) employed in this study are prepared with identical conditions, i.e. the identical molar ratio between the two components, the same solvent, concentration and conditions used for solution preparation and thin film deposition. The only difference is the one component used in the composites, in which PCBM is decorated with a substitute on C60 cage. However, the crystallization of P3HT in the untreated P3HT:PCBM composite film is not extremely suppressed. Thereby, the low crystallinity of P3HT in the untreated P3HT:C60 composite could not be explained by the conventional "dilution effect". Recently, McGehee et al. [48] have shown that some fullerene derivates will intercalate between the side chains of conjugated polymers to form bimolecular crystals and thus influence the phase separation and photovoltaic performance of the composite films. However, they found that PCBM could not form such bimolecular crystals with P3HT due to the reason that there is insufficient room between hexyl-side chains for intercalation to occur. Based on their experimental results and simulation [48], the molecules with diameter smaller than 0.6 nm can intercalate between the adjacent hexyl-side chains of P3HT whose dis-

tance is 0.78 nm [49,50]. However, the diameter of C60 molecule is 0.71 nm which is much larger than 0.6 nm and comparable to the distance between adjacent hexyl-side chains, thus there is not enough free volume between the hexyl-side chains to accommodate the C60 molecules. Therefore, the different crystallization behaviors of P3HT in between the composite of P3HT:C60 and P3HT:PCBM can not be interpreted by the bimolecular crystals yet.

3.2. The mechanism for substantially suppressed crystallization of P3HT in P3HT:C60 composites

As shown in Fig. 3b, the obvious red shift of main absorption of P3HT in the untreated P3HT:PCBM composite film compared to that of P3HT in the solution reveals that longer effective conjugation length could be obtained in solid state even when "diluted" by PCBM. However, the main absorption peak of P3HT in untreated P3HT:C60 composite film nearly maintains the same as that in ODCB solution. Based on the origin of the UV–vis absorption at this position for P3HT, we can conclude that the effective conjugation length of P3HT in the untreated P3HT:C60 composite film is hardly increased upon solidification from ODCB solution.

To get deeper insight into the conformation of P3HT chains, we resort to FT-IR spectroscopy investigations. As shown in Fig. 4a, only one main absorption peak at 821 cm^{-1}, which is assigned to the absorption of out of plane CH deformation of the thiophene ring [51], is observed in pure P3HT film. For pure C60 film, all the absorption peaks locate in the region with wave number less than 800 cm^{-1} for the range of 500–1000 cm^{-1}. However, the intensity of the peak at 821 cm^{-1} decreases and a new absorption additionally appears at ca. 836 cm^{-1} for P3HT in the untreated P3HT:C60 composite, resulting in a very broad absorption within the region in between the wave number of 821 and 836 cm^{-1}. Whereas upon thermal annealing at 180 °C for 20 min, the broadened absorption at 821–836 cm^{-1} will restore to the same shape and intensity as that observed in pure P3HT, with disappearance of the newly emerged peak at 836 cm^{-1}. As a reference, we have also performed FT-IR measurements on the MDMO-PPV system. However, untreated MDMO-PPV:C60 composite shows the simple superposed spectrum of C60 and MDMO-PPV (Fig. 4c) in the whole region. Therefore, the peak at 836 cm^{-1} is ascribed to the split of 821 cm^{-1}. Both the decreased absorption at the band of 821 cm^{-1} and the appearance of the split peak at 836 cm^{-1} suggest that the chain conformations of P3HT in pure P3HT and P3HT:C60 composite are different. It has been reported that C60 is "wrapped" by the alkyl-side chain of P3HT in the untreated film of P3HT:C60 [52]. However, as is proven, fullerenes will form homogenous nanoscale crystallites instead of molecularly distributing in solid film when spin coated from solution [38]. Therefore, the hexyl-side chains of P3HT will actually wrap the C60 nanoaggregates. The inclusion of C60 nanocrystallites onto P3HT chains will greatly influence on their conformations. It is known that the peak at 821 cm^{-1} is assigned to out of plane CH deformation of 3-alkylthiophene on the backbone, the appearance of split at 836 cm^{-1} indicates that the backbone has

Fig. 4. FT-IR spectra of (a) pure P3HT and C60, respectively, and both their untreated and thermally annealed composite films; (b) pure P3HT and PCBM, respectively, and both their untreated and thermally annealed composite films; (c) pure MDMO-PPV and C60, respectively, and their untreated composite film. Some curves have been shifted along Y-axis for clarity.

Due to the high similarity between C60 and PCBM, comparable phenomenon could also be observed in P3HT:PCBM composite, as shown in Fig. 3b. However, for P3HT in the untreated P3HT:PCBM composite, the intensity of the original absorption at 821 cm^{-1} does not drop down that much compared to pure P3HT, and the newly emerged absorption at 836 cm^{-1} appears like a shoulder peak due to its low intensity. This behavior is obviously different from that of P3HT in the P3HT:C60 composite, which reveals that the distortion of P3HT between thiophene rings in P3HT:PCBM untreated film is much weaker than that in P3HT:C60 untreated film.

As a derivative of C60, PCBM has higher solubility in the most organic solvents upon chemical decoration on its C60 cage, while its physical properties are expected to be preserved. Upon a series of solubility determinations on fullerenes and P3HT in ODCB, we find that C60 shows comparable solubility to P3HT (see Table 1), whereas, PCBM has much higher solubility than P3HT. Based on these results, we can conclude that when using ODCB as solvent, C60 and P3HT will nearly simultaneously crystallize from the solution during spin coating. However, due to high symmetry of C60 molecules, they will form large number of nanoscale crystallites in the concentrated and viscous solution in a very short time. Since the crystallization of P3HT is a relatively slow process, the presented large number of nanoscale crystallites in the viscous solution will severely hinder the ordered packing of crystallizable P3HT chains, which results in severe crystallization suppression of P3HT. Therefore, the P3HT chains in the untreated P3HT:C60 film spin coated from ODCB solution will nearly maintain their original chain conformation in the solution, in contrast to the observation in most cases that the effective conjugation length in a solid film is longer than that in the solution. This difference is in consistence with the results of FT-IR and UV–vis measurements (Figs. 4a and 3b). However, in the P3HT:PCBM composite, P3HT becomes saturated first and it will crystallize from the ODCB solution before PCBM starts to form tiny crystallites. In this case, the crystallization of P3HT is less influenced by the "dilution effect", leading to higher crystallinity which conforms to the observations by TEM, XRD, UV–vis and FT-IR as shown in Figs. 2, 3a and 4b, respectively. Therefore, we propose that the tremendous difference of P3HT crystallinity in between C60:P3HT and PCBM:P3HT untreated composite films spin coated from ODCB solution

Table 1
The solubility of P3HT and fullerenes in different solvents at room temperature (The temperature in the lab varies in between 18 and 22 °C).

Solvent	b.p. (°C)	C_{60} (mg/ml)	P3HT (mg/ml)	PCBM (mg/ml)
ODCB	180	28	30	>50
TCB	214	8	30	>50
CB	130	7	30	>50
Tetralin	207	16	0.5	>50
M-Naph	244	35	20	>50
Cl-Naph	259	56	12	>50
Tetralin/CB (1:1, v/v)		8	17	>50
M-Naph/CB (1:20, v/v)		8	18	>50
Cl-Naph/CB (1:33, v/v)		9	18	>50

been influenced by the trapped C60 nanoscale crystallites, which makes the thiophene-thiophene plane distort to each other. Subsequently, the crystallization of P3HT during spin coating process may be severely hindered by the inclusion of C60 nanoscale crystallites onto its chains.

may correlate to the different solubility of the components in ODCB.

To verify this assumption, we first choose TCB as solvent for thin film deposition due to its comparable boiling point with ODCB but lower solubility of C60 (Table 1). Upon choosing a speed as high as 3000 rpm for TCB solution but only 600 rpm for ODCB solution, a comparable drying time during spin coating process could be achieved for both solutions. However, the crystallinity of P3HT in the P3HT:C60 untreated film from TCB is higher than that from ODCB as proven by red shift and three obvious electron vibration bands in the UV–vis absorbance spectrum (Fig. 5a). Second, if CB is used to prepare the film, C60 will also crystallize from the solution before P3HT due to rather low solubility of C60 in it. As is shown in Fig. 5a, although the volatility of CB is higher than ODCB, we are still able to observe that P3HT shows longer conjugation length in the P3HT:C60 film as is indicated by ca.10 nm red shift in the UV–vis absorbance spectrum when compared to the film prepared from ODCB solution. This result is more obvious in the films prepared by drop casting (inset in Fig. 5a), with the appearance of prominent absorption at 607 nm associated to increased crystallinity of P3HT. Finally, we use mixed solvent CB/tetralin (1:1, v/v) to further check our assumption. Tetralin is a very poor solvent for P3HT but

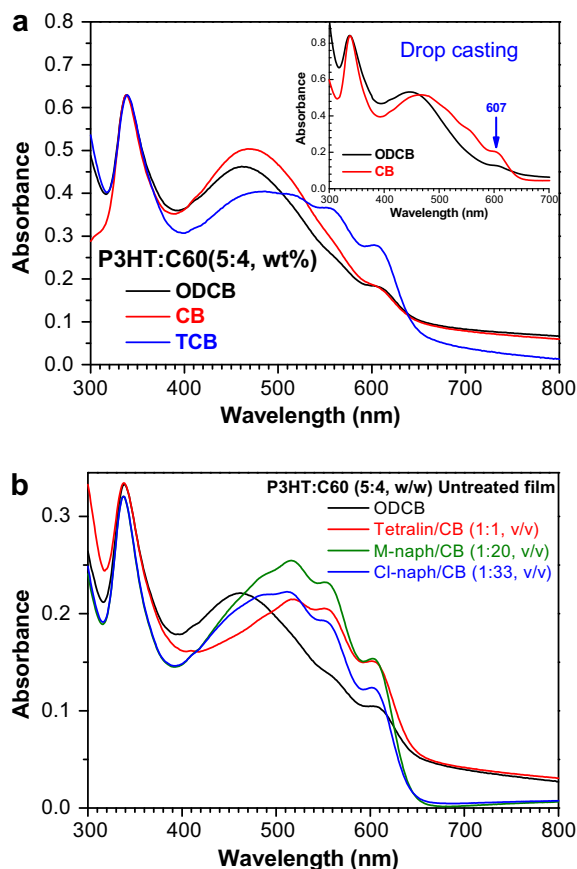
shows modest solubility for C60. It is anticipated that C60 will precipitate from the solution later than P3HT due to the lower volatility of tetralin comparing with CB. As is shown in Fig. 5b, the addition of tetralin into the CB solution does not cause any ordered precursors of P3HT in the solution [17], but the optical absorption spectrum of the untreated P3HT:C60 film shows obvious red shift and very prominent three electronic vibration bands, indicating that the crystallinity of P3HT in such composite is substantially increased. Similar results can also be obtained by replacing tetralin with less amount of M-naph or Cl-naph which show even higher solubility of C60 than tetralin. It should be noted that both M-naph and Cl-naph are low volatile solvents due to their high boiling points, thus longer crystallization time is obtained when P3HT is spin coated from M-naph or Cl-naph comparing with CB, and higher crystalline P3HT is anticipated. However, only little amount of M-naph or Cl-naph is added into the CB solvent (M-naph/CB, 1:20; Cl-naph/CB, 1:33, by volume), the increased crystallinity of P3HT contributed by the high boiling point is negligible. Moreover, we find that in the case that C60 forming crystallites before P3HT, the crystallinity of P3HT is not as high as in that C60 forming crystallites from the solution after P3HT, as is confirmed by the UV–vis absorbance measurements (Fig. 5). This finding is different from the results obtained by Yao et al. in P3HT/PCBM system [23], in which the formation of PCBM "clusters" benefit the crystallization of P3HT and improvement of morphology. Such difference could be originated from the different crystallization ability between C60 and PCBM. As is known, lower symmetry of PCBM makes it more difficult to nucleate, which eventually results in less in quantity but larger in size for PCBM "clusters" during crystallization from the solution. In the cases of C60 forming crystallites before P3HT, the higher crystallizability of C60 results in larger number of C60 nanocrystallites, as confirmed by the homogenously distributed C60 nanocrystallites obtained in P3HT:C60 composite [7], in contrast to only a few PCBM crystals observed in P3HT:PCBM system. With the presence of these homogeneously dispersed crystallites in the concentrated and viscous solution, the subsequent crystallization of P3HT will be hindered, leading to low crystallinity. Whereas, in the cases that low volatile solvent with high solubility of C60 such as tetralin, M-naph or Cl-naph is added into the main solvent CB, some part of C60 molecules will preferentially dissolve in it. Therefore, during spin coating, the C60 molecules dissolved in the low volatile solvent is still molecularly dispersed, while P3HT starts to crystallize from its good solvent CB which is relatively volatile. Therefore, during spin coating, less C60 nanocrystallites appear in the concentrated solution, which facilitates the formation of more highly crystalline P3HT fibers in the final composite film. It should be pointed out that other factors such as interaction parameters, surface energy, and interfacial tension may also contribute to the formation of crystalline P3HT to some extent [53]. However, the solubility may play an important role in determining the crystallinity of P3HT because only by using the low volatile solvent with higher solubility of fullerene, higher crystallinity of P3HT or larger ordered aggregates of conjugated polymers can


Fig. 5. UV–vis absorbance spectra of the P3HT:C60 untreated films prepared from different solvents and solvent mixtures via spin coating.

be obtained as is shown above and reported by Lee et al. [26], respectively. Therefore, our observations have proven that the comparable solubility of C60 and P3HT in ODCB is mainly responsible for the extremely low crystallinity of P3HT in P3HT:C60 untreated film prepared from ODCB solution, thus the low performance of device. Recently, Troshin et al. have shown that the solubility of PCBM in organic solvents will also severely influence the phase separation scale via forming different sizes of PCBM domains in the composite film with P3HT and thus it plays an important role in determining the final device performance [33]. Therefore, the influence of component solubility on the final device performance is universal and it should be taken into account while designing new materials for more efficient photovoltaic devices.

3.3. Solutions for constructing high performance P3HT:C60 polymer solar cells

With only two short substitute side groups on the fullerene cage, the difference between PCBM and C60 should be very small in terms of optoelectronic physics, however, up to now the solar cells based on P3HT:C60 composite usually show lower power conversion efficiency than its counterpart system P3HT:PCBM composite. As shown in Fig. 6a, current density–voltage (J–V) curves reveal significantly different performance of the untreated devices by using these two composites. Except for the slight difference in open-circuit voltage (V_{oc}), quite low $J_{sc} = 1.74$ mA/cm^2 and $FF = 0.34$ are obtained in devices based on P3HT:C60 composite, in contrast to the device based on P3HT:PCBM composite which shows $J_{sc} = 5.20$ mA/cm^2 and $FF = 0.40$, respectively, as illuminated by a halogen lamp with an intensity of 100 mW/cm^2. In Fig. 6b, for both untreated devices, the device based on P3HT:C60 composite shows a very narrow photocurrent spectral response and quite low IPCE values compared to that of the untreated P3HT:PCBM device. These differences eventually result in more than triple folds variation in power conversion efficiency of 0.34% for P3HT:C60 and 1.23% for P3HT:PCBM composite, respectively. The unsatisfactory performance of the devices based on untreated P3HT:C60 composite is mainly attributed to the very low crystallinity of P3HT within the photoactive layer, which results in two negative influences on the device performance. On one hand, low crystallinity will cause mismatch between the optical absorption of photoactive layer and solar spectrum. On the other hand, it will lead to low hole mobility, which results in inefficient hole transport to the anode. Consequently, the probability of charge recombination increases. Thereby, higher crystallinity is required for P3HT:C60 solar cells to further improve device performance.

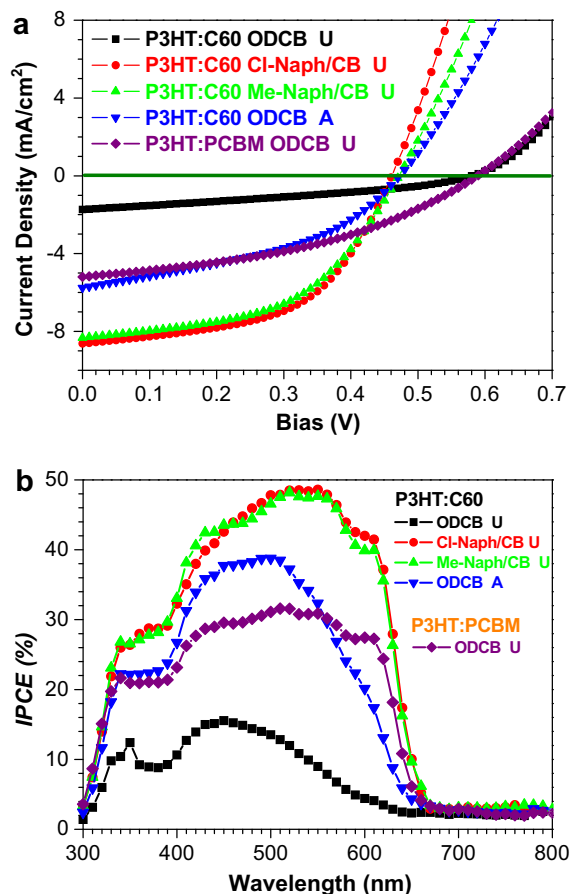
The above mentioned mixed solvent method has shown its feasibility to increase the crystallinity of P3HT in P3HT:C60 composite, therefore it has shown the potential application in constructing more efficient photovoltaic devices. As we known, besides the crystallinity of P3HT, the morphology of photoactive layer also plays an important role in determining the device performance. In Fig. 7a, for the P3HT:C60 composite film spin coated from ODCB, the phase separation scale is very small and the whole surface


Fig. 6. Current density–voltage characteristics of P3HT:C60 (5:4 by weight) and P3HT:PCBM(1:1 by weight) polymer solar cells and their corresponding IPCE properties. (U: untreated; A: annealed).

is quite smooth, indicating that P3HT is nearly molecularly mixing with C60 nanocrystallites without constructing interpenetrating networks. However, for the P3HT:C60 untreated film prepared from Cl-naph/CB (Fig. 7b), homogeneously distributed aggregates ascribing to C60 crystallites are observed over the film. The average domain size increases greatly and the surface roughness is an order of magnitude higher than that observed in Fig. 7a, implying that the phase separation scale between C60 and P3HT has been increased. The formation of larger C60 crystallites is mainly contributed by the longer drying time obtained for "selectively extracted "C60 molecules to crystallize when low volatile solvent with higher solubility of C60 is added into the main solvent CB. Moreover, from the inset SAED patterns we can find that the diffraction intensity of P3HT crystallographic (0 2 0) plane as is indicated by the arrow in Fig. 7b is higher than that in Fig. 7a, implying that the crystallinity of P3HT in P3HT:C60 film prepared by using Cl-naph/CB solvent mixture has really been enhanced when compared with that prepared by using ODCB. The formation of larger C60 crystallites in combination with long P3HT fibers contributes to an improved morphology in which not only large interface area for exciton dissociation is preserved but also bi-continuous pathways
Fig. 7. AFM images showing the topography of the P3HT:C60 untreated films prepared from (a) ODCB and (b) Cl-naph/CB (1:33, v/v) via spin coating. Inset in each figure is its corresponding SAED. Scale bar: 500 nm. RMS in (a) and (b) is 1.0 nm and 11.2 nm, respectively.

are constructed for more efficient charge transport through the film. Therefore, better device performance can be anticipated. As shown in Fig. 6a, current density–voltage (J–V) measurements reveal that, for the untreated device based on a thin P3HT:C60 composite film spin coated from M-naph/CB solution, short circuit current density (J_{SC}) has been increased from 1.74 to 8.33 mA/cm^2, and also an increased filling factor (FF) from 0.34 to 0.52 has been achieved in contrast to the untreated device prepared from pure ODCB solution. Generally, a large serial resistance and too small parallel resistance (shunt) tend to result in reduced FF [1]. Therefore, quite large serial resistance exists in the untreated P3HT:C60 photoactive layer prepared from pure ODCB while substantially decreased serial resistance is achieved in the photoactive layer prepared by using the M-naph/CB mixed solvents. Besides, a somewhat decreased open-circuit voltage (V_{OC}) from 0.58 to 0.47 V is observed, which is most probably attributed to the enhanced electric conductivity of the composite film contributed from substantially increased crystallinity of P3HT included [17,20]. However, these parameters eventually could result in power conversion efficiency (PCE) up to 2.04%, which is higher than that via thermal annealing in our investigations. Furthermore, the device with comparable efficiency of 2.1% is obtained by using Cl-naph/CB (1:33, v/v) mixture (Fig. 6a), which is the highest efficiency to date for bulk-heterojunction devices achieved in untreated P3HT:C60 composite. This remarkably increased device performance by using Cl-naph is mainly attributed to the substantially increased crystallinity of P3HT and thus improved morphology in the composite, and the contribution from its inherent high boiling point is very limited [54].

The increased device performance is further proven by IPCE measurements. In Fig. 6b, comparing with the untreated device prepared from pure ODCB, the device prepared from M-naph/CB and Cl-naph/CB solution show not only much broader response range but also higher IPCE

values covering from 350 nm to 650 nm, with a maximum ~48% at ca.550 nm. We find that there is ~13% variation between the J_{sc} calculated from IPCE and that observed in J–V measurements for the untreated device prepared from M-naph/CB and Cl-naph/CB. This might be attributed to degradation of photoactive layer caused by the diffusion of humidity and oxygen for performing IPCE measurements on devices in air without encapsulation. As a reference, the device prepared from ODCB solution shows modest increase of IPCE after thermal annealing, which is consistent with the device performances obtained above.

Therefore, the crystallinity of P3HT in the untreated P3HT:C60 composite film could be substantially enhanced by choosing an appropriate low volatile solvent to form solvent mixtures with the main solvent, which should satisfy these two criterions. Firstly, both P3HT and C60 could be dissolved in this solvent mixture to achieve a solution with required concentration. Second, C60 should have much higher solubility than P3HT in the low volatile solvent. In such a case, P3HT will on one hand saturate from the solution before C60, achieving both longer effective conjugation length and higher crystallinity in the untreated composite film. On the other hand, the preferentially dissolved C60 molecules have more time to form larger crystallites, which ensures more continuous path ways for electron transport. It should be noted that the efficiency of the PV device fabricated from the solvents mixture in which C60 has higher solubility than that of P3HT is comparable to those devices prepared via post-treatment (thermal annealing or solvent vapor treatment), although the compositions still needs to be further optimized to realize more efficient PV devices [55]. However, the short circuit current has already reached a considerable high value and it is comparable to those obtained in P3HT:PCBM devices upon post-treatments, implying an improved morphology has been achieved in the composite film (Fig. 7b). The improved morphology not only increases the optical absorption of the photoactive layer in red re-

gion due to the enhanced crystallinity of P3HT, but also provides continuous pathways for faster charge carrier transportation towards anode. Therefore, we have identified the influence of specific component solubility on the crystallization of other components involved in the composite, and also successfully demonstrated an approach to achieve more efficient devices based on P3HT:C60 composite. Furthermore, our results provide additional rules for designing new materials for optoelectronic application, i.e. not only the importance of its optoelectronic property, but also its other properties, e.g. solubility in the solvent and its influence on the crystallization and morphology of counterpart component involved in the composite should be taken into account.

4. Conclusion

We have demonstrated substantial crystallization suppression of P3HT in the untreated P3HT:C60 composite film prepared from ODCB solution and its hardly increased conjugation length compared to that in solution. This has been confirmed to be mainly associated to the comparable solubility of C60 and P3HT in ODCB, which leads to formation of numerous C60 nano-crystallites in the solution and suppresses the subsequent crystallization of P3HT. Based on this finding, we propose the solutions to improve both the crystallinity and effective conjugation length of P3HT in the untreated P3HT:C60 composite via adding small amount of low volatile solvent with much higher solubility of C60 than P3HT into the main solvent. In such a case, C60 will become saturated in the solution later than P3HT, which lessens the dilution effect of C60 aggregates on the crystallization of P3HT. As a consequence, both crystallinity and effective conjugation length of P3HT could be increased in the composite, contributing to an improved morphology for the photoactive layer and thus better device performance. These results not only demonstrate the feasibility of constructing high performance photovoltaic devices based on the composites of P3HT and low cost C60, but also provide additional rules for designing new materials for polymer optoelectronic devices.

few differences between the organic salt-doped devices and the frozen-junction LECs. The differences include the fact that the forward- and reverse-biased current–voltage (*I–V*) and luminance–voltage (*L–V*) curves of the typical LECs are almost symmetric in contrast to the diode-like behavior of the organic salt-doped devices even at an elevated temperature. The fact that the organic salt-doped devices strongly depend on the thickness of active layer in contrast to the LECs is another claimed difference. Unlike the dynamic-junction LECs, however, the frozen-junction LECs show the unipolar light emission which means the light emission can only be detected if the applied voltage polarity is the same as during the precharging process, i.e., positive [14,15]. Since the ions are rendered immobile in the frozen-junction LECs, the *I–V* and *L–V* characteristics should be asymmetric and similar to those of the conventional organic LEDs. Moreover, in that the frozen-junction LECs retains all the advantages of LECs operating in the dynamic-junction LECs including the insensitiveness of cathode material and balanced carrier injection [2,15], the frozen-junction LECs have clear advantages. Nevertheless, since the state of ions present in the organic salt-doped devices has not yet been known clearly as such that the few previous reports [11–13] had claimed that the ions should exist as being separated with the active organics near electrodes, we think that it should be clarified by examining the operating characteristics of the organic salt-doped devices. In this study, we show that the organic salt-doped devices behave similarly with the frozen-junction LECs in that the devices exhibit much improved carrier balance, which is one of the characteristics of LECs.

2. Experimental details

We used poly(*N*-vinyl carbazole) (PVK; Mw = 1,100,000) as a host polymer for the devices, which was supplied from Aldrich and used without further purification. For a single emissive layer, a hole transporting *N,N'*-diphenyl-*N,N'*-bis(3-methylphenyl)-[1,1-biphenyl]-4,4'-diamine (TPD, Aldrich), an electron transporting 2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD, American Dye Source), and a phosphorescent green emitter *fac*-tris(2-phenylpyridine)iridium (Ir(ppy)$_3$, Gracel) were added in the PVK host polymer with an appropriate composition. A mixture of the active organics was dissolved in a mixed solvent of dichloroethane (C$_2$H$_4$Cl$_2$) and chloroform (CHCl$_3$). As an organic salt, an appropriate amount of tetra-*n*-butyl-ammonium tetrafluoroborate (Bu$_4$NBF$_4$, Aldrich) was added in the solution mixture for the single emissive layer. A hole injection material, poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS) (Baytron P, AI 4083), was used for the devices.

For this study, PLEDs with ITO/PEDOT:PSS/PVK + TPD + PBD + Ir(ppy)$_3$ + Bu$_4$NBF$_4$/Al structure were fabricated. For the devices, a hole injecting PEDOT:PSS was first spin coated on pre-cleaned ITO substrates for 30 s at 1500 rpm to have the thickness of 40 nm and then baked at 110 °C for 5 min. For all the devices, the weight ratio of active organic materials used was set to PVK:PBD:TPD:Ir(ppy)$_3$ = 0.61:0.24:0.09:0.06. These materials were dissolved in a

mixed solvent of dichloroethane and chloroform with a ratio of 3:1. The active layer was spin coated for 30 s at 1000 rpm to have the thickness of 70 nm and then baked for 30 s at 80 °C. In order to investigate the effect of organic salt on the device performance, the devices was doped with the organic salt Bu$_4$NBF$_4$ at a concentration of 0.6 wt.%. For some samples, 1 nm thick LiF layer was thermally evaporated on top of the active layer at a pressure of 5×10^{-7} torr. An Al cathode layer (120 nm) was formed on top of the devices via thermal deposition at a pressure of 5×10^{-7} torr. After the devices were fabricated, they were treated thermally and electrically for the activation of organic salt. For the activation, the devices were brought on the surface of hot plate maintained at an elevated temperature of 65 °C, and then a preset voltage was applied to the devices for a period of time.

All electrical measurements were performed under ambient condition. The current–voltage–luminance (*I–V–L*) characteristics were measured using a source measure unit (Keithley 2400) and using a luminance meter (Minolta CS100). The electroluminescence (EL) spectra and device efficiencies of the devices were recorded by using Minolta CS1000.

3. Results and discussion

When PVK-based single emissive layer has been doped with the organic salt Bu$_4$NBF$_4$, the anions NBF$_4^-$ and cations Bu$_4$N$^+$ should be separated and forced to move toward the corresponding electrodes under an applied bias. For this purpose the fabricated devices were subject to the simultaneous thermal and electrical annealing, which we call this process with the activation of organic salt. Due to the rigid and non-electrolytic nature of PVK host polymer, the layer has been heated to an elevated temperature in order to help the ions to move through the polymer more easily. In this study the layer was heated to 65 °C for increasing the mobility of ions. The temperature was selected well below the glass transition temperature (*T*$_g$) of PVK which is known to range from 162 to 225 °C depending on its molecular weight. An external voltage was applied for a certain time period while the temperature of the layer was maintained (at 65 °C). Even though the higher voltage is quite beneficial in increasing the velocity of the ion movement, there is also the disadvantage that the devices could be degraded by intense light emission and current flow at the high voltage during the process. In this study, an applied voltage of 13 V was selected and the activation time was varied for the salt activation.

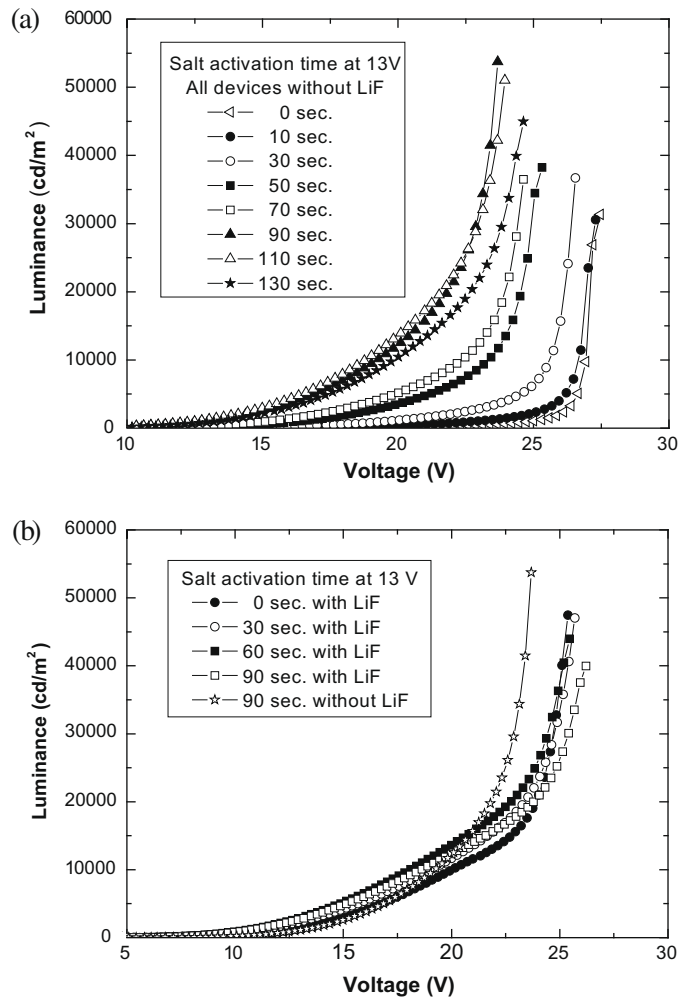
In case of the salt-doped but un-activated devices (without LiF layer), the *L–V* curve exhibited the abrupt increase in luminance up to 30,000 cd/m^2 around 27 V as shown in Fig. 1a. Normally, polymer LED devices without the electron-injecting LiF layer are known to show the gradual increase in luminance with a high turn-on voltage. This unique feature in the light emission from the salt-doped un-activated devices has been reported in the literature [10]. The activation for a short 10 s at 13 V affected little the *L–V* curve. The longer the time for the activation


Fig. 1. (a) The luminance–voltage curves for the salt-doped devices (without LiF layer) measured after the salt activation at 13 V and 65 °C for various time durations. (b) The comparison between the luminance–voltage curves for the salt-doped devices with and without LiF layer after the salt activation at 13 V and 65 °C.

process was, the lower the turn-on voltage became and the higher the maximum luminance reached. Beyond a certain time of activation, the process started not to affect the L–V curve advantageously. The highest luminance was obtained with the devices activated for around 90–110 s at the temperature and applied voltage of 65 °C and 13 V, respectively. It is obvious from the figure that the salt doping helps to inject carriers more efficiently to result in lower turn-on voltage and enhanced luminance after an appropriate salt activation.

As shown in Fig. 1b, the L–V curves of the salt-doped devices with conventional LiF layer were found to show different behavior. First thing to note is that the salt activation process does not affect appreciably the L–V curve of the devices with LiF layer. We think that it is because the electron injection occurs dominantly with the help of the LiF layer rather than the doped organic salt. Also due to the LiF layer, the devices are turned on at lower operating voltages compared with those without LiF layer. At voltages from 15 to 23 V, however, the increase in luminance with increasing

voltage tends to slow down before the luminance rises sharply around 25 V. On the contrary, the luminance of the salt-activated devices (90 s.) without LiF layer increases steadily with increasing voltage and finally reaches a higher luminance at a lower applied voltage. We consider that it is responsible for the fact that the salt doping helps to have the holes and electrons balanced in the devices while the LiF layer helps the injection of electrons only.

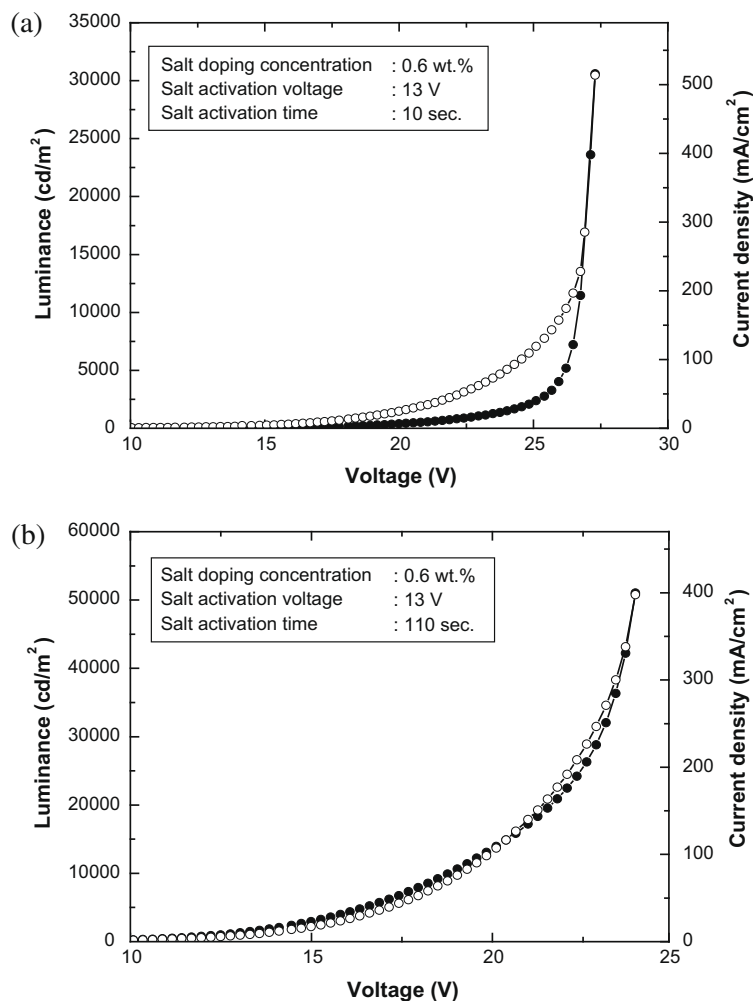
Even though we do not know how the organic salt exists in the devices at this stage of research, it is obvious that the incorporated ions provide the positive effect on the device performance from Fig. 1. In order to correlate the increase in luminance with the electrical current flowed through the devices, we showed the I–V and L–V curves together for two devices (without LiF layer) after the activation for 10 and 110 s in Fig. 2. In the figures the scales in luminance and current density were adjusted so as for the maximum point of luminance and current density to be overlapped. In this way, the relative behavior in luminance and current density with respect to the


Fig. 2. The current density–voltage (open symbol) and luminance–voltage (solid symbols) curves for the salt-doped devices after the activation for (a) 10 s and (b) 110 s. The scales of luminance and current density were adjusted so as to have the maxima of luminance and current density coincide in the graph.

applied voltage can be easily investigated. For the device activated for 10 s, it was observed that the luminance was measured relatively low throughout the operating voltage while the current flowed in a considerable amount through the device. The discrepancy between luminance and current density curves was reduced as the activation time increases (not shown here). Finally, when the salt activation is completed after the simultaneous thermal and electrical annealing (salt activation) for 110 s, the L–V and I–V curves became closely matched up to the highest luminance above 50,000 cd/m². From this observation, we can deduce a couple of view-points for the operational characteristic of the devices. The first thing to note is the fact that the current should have been consumed somewhere, not being utilized for the emission during the activation when the activation of organic salt is not enough. We think that the current could have been consumed for the electrochemical doping processes near electrodes. Even though it is not clear yet at this moment, it is likely that the n-doping occurs in electron transporting PBD with Bu_4N^+ while the p-doping oc-

curs in hole transporting PVK [9,10,16,18] or TPD [17,19] with BF_4^-. Another important thing to note from Fig. 2b is that in whole luminance level the electrons and holes are balanced to form excitons for the light emission. Since the balance of electrons and holes is a characteristic of LECs, we think that the organic salt-doped devices in this study are similar to the frozen LECs formed by the electrochemical doping of the organic salt into the functional organics in the active layer. Even though the organic salt-doped devices behave similarly to the frozen LECs, however, there is also a distinct difference between the two kinds of devices, in that the I–V characteristics of the salt-doped devices were influenced by the addition of LiF layer as shown in Fig. 1 while those of the frozen LECs should be insensitive to the electrode structures.

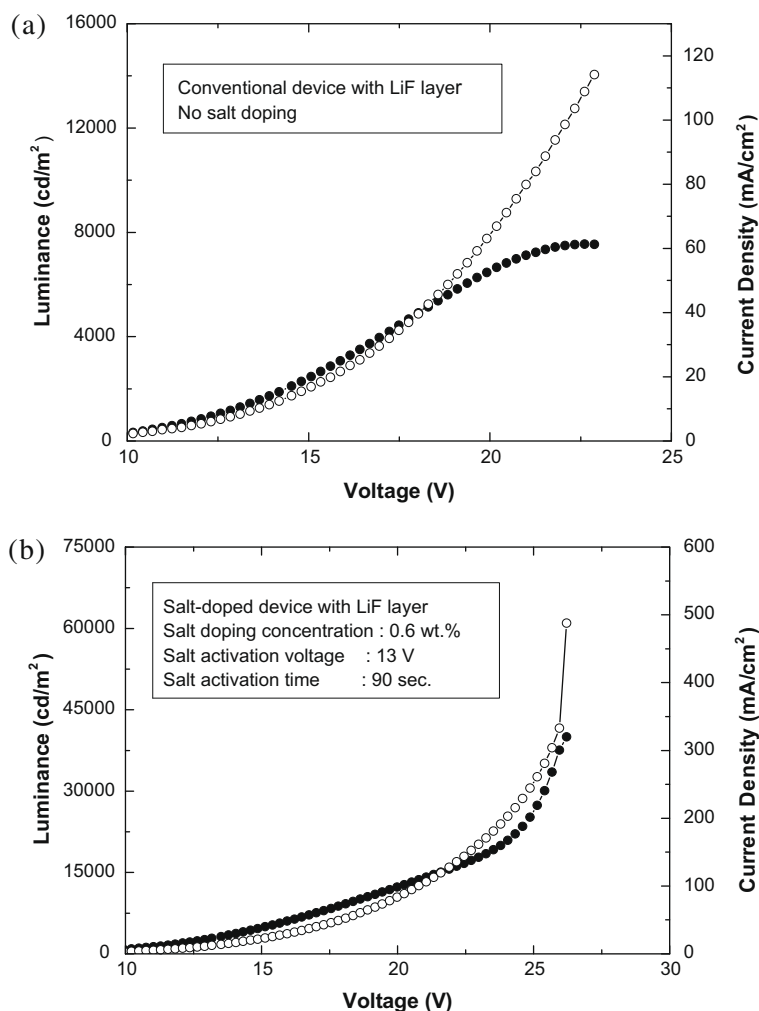
For comparison, we showed the similar L–V and I–V curves for the un-doped and salt-doped devices with an electron-injecting LiF layer in Fig. 3. In the figure, we have arbitrarily scaled the L–V and I–V curves so as for the curves to fit as close as possible each other. As can be seen


Fig. 3. The current density–voltage (open symbol) and luminance–voltage (solid symbols) curves for the (a) un-doped device with LiF layer and (b) salt-doped devices with LiF layer after the activation for 90 s. The scales of luminance and current density were adjusted so as to have the curves fit as close as possible.

in the figure, the *L–V* and *I–V* curves were found to be quite different unlike the curves for the previous salt-doped devices without LiF layer. The addition of LiF layer facilitates the injection of electrons at the cathode via the reduction of energy barrier independently with the hole injection. In the case of conventional un-doped devices with LiF layer, the current density keeps increasing while the increase in brightness tends to slow down at high applied voltages. This tendency is significantly reduced when the conventional devices with LiF layer are simply doped with the organic salt as shown in Fig. 3b. We think that the organic salt doping greatly improves the carrier balance in the devices such as the case of frozen-junction LECs. But still the carrier balance cannot be achieved if the LiF layer is used in the devices.

In order to investigate the relations between the *L–V* and *I–V* curves further, we show the luminance–current density (*L–I*) curves for the devices (without LiF layer) after the salt activation for different times in Fig. 4. When the salt activation is incomplete (salt activation time less than 90 s), the concave *L–I* curves are observed in low current density region which means that the current flows through the devices much more compared with the light emission in the region. After the salt activation is complete (salt activation time longer than 90 s), the *L–I* curves become almost linear showing that the electrons and holes are balanced for the emission throughout the whole region of current density. In the whole region, the luminous efficiency was found close to 15 cd/A. We show an enlarged graph of the lower left box of Fig. 4a in Fig. 4b. The maximum luminous efficiency was found close to 20 cd/A and always higher than 13 cd/A with the luminance level from 0 to 10,000 cd/m².

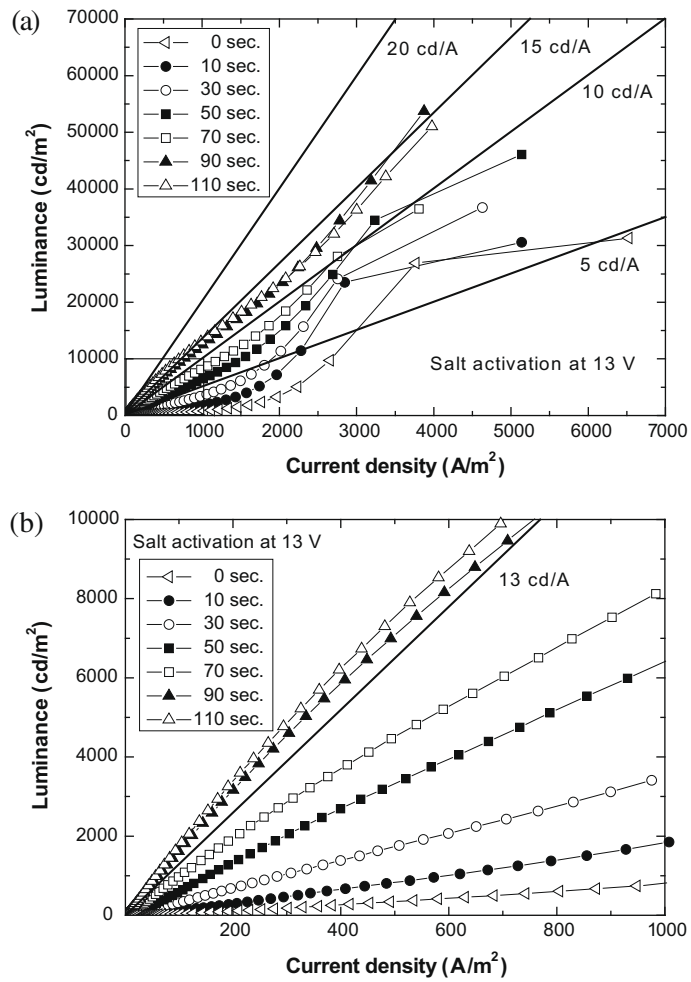
The maximum luminance of the conventional un-doped devices with the LiF layer was found 14,000 cd/m² as shown in Fig. 5, while that of salt-doped devices (with the LiF layer) after the activation leached higher than 40,000 cd/m². The maximum luminance of the salt-doped


Fig. 4. (a) The luminance–current density curves for the salt-doped devices without LiF layer after the activation for various time durations. (b) The enlarged graph of the box at bottom-left corner of (a).
Fig. 5. The comparison between the luminance–current density curves for the salt-doped and un-doped devices.

device without the LiF layer was found even higher with a linear *L–I* characteristic. An important thing to note from the figure is that the salt doping makes the devices possible to handle much higher current density. We think that it is due to the enhanced balance of electrons and holes provided by the salt doping. Up to the luminance of 55,000 cd/m^2, the luminous efficiency was found steadily over 10 cd/A, even showing the higher efficiency with the higher current density. It should be mentioned here that the organic salt-doped devices showed high luminous efficiency even up to high current density, which means that the salt doping did not help only for the carrier injection but also for the carrier mobility. As can be seen in Fig. 5, the luminance tends to saturate above the current density of 1000 A/m^2 for the conventional devices with LiF layer. Even though the PBD acting as an electron transporting material in our PVK-based electro-phosphorescent LEDs, main host material in the PLEDs with ITO/PEDOT:PSS/ PVK + TPD + PBD + Ir(ppy)$_3$ + Bu$_4$NBF$_4$/Al structure is PVK. The hole mobility is known to be generally much greater than the electron mobility in PVK-based LEDs, because PVK is one of the famous hole transporting materials [20]. As increasing driving voltage, the energy barriers for hole and electron injection might be decreased resulting increase of hole and electron population in the emitting layer. Therefore, the injected holes will accumulate at the interface between the emitting layer and Al cathode because of the difference of charge carrier mobility. Presumably, the saturation in luminance might be due to the exciton quenching which may be caused by the hole accumulation at cathode interface [21,22]. From the experimental results shown in Fig. 5, however, the doping of organic salt in the devices seems to prevent the saturation in luminance regardless of the existence of LiF injection layer. Therefore, the doping of organic salt seems to increase the carrier mobility, more importantly the electron mobility in the emissive layer in that the high luminous efficiency is sustained even up to high current density of 4000 A/m^2. Since the electrical conductivity is directly proportional to the carrier mobility at a fixed doping concentration, the sustainment of high luminous efficiency at high current density evidences the increased carrier mobility upon the doping of organic salt.

4. Conclusions

We have showed that the doping of organic salt into a polymer emissive layer and the appropriate activation could greatly enhance the balance of electrons and holes in the devices. By enhancing the carrier balance, the salt-doped devices have exhibited much higher luminance compared with un-doped counterparts. The salt-doped devices showed the maximum luminance of 55,000 cd/ m^2 after the salt activation. Due to the enhanced carrier balance, the luminous efficiency of about 15 cd/A was maintained throughout the whole luminance range up to the maximum luminance.

the performance of TEOLEDs encapsulated with each of these polyurea/Al_2O_3 pairs were tested to find optimal thin-film encapsulation design in regard to efficiency and lifetime of TEOLEDs.

In this study, we fabricated TEOLEDs by using Ag(100 nm)/ITO(10 nm) as a reflective anode, LiF(1 nm)/Mg:Ag(10:1 mass ratio, 18 nm) as a semitransparent cathode [11], and tris(8-hydroxyquinolinato)aluminum (Alq_3) doped with 2-wt% 2,3,6,7-tetrahydro-1H, 5H, 11H-10-(2-benzothiazolyl)quinolizino-[9,9a,1gh] Coumarin (C-545T) as an emitting layer (EML). N,N′-Bis(1-naphthyl)-N,N′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) and Alq_3 were used as a hole transport layer (HTL) and an electron transport layer (ETL), respectively. Thickness of HTL, EML, and ETL were selected to optimize microcavity effect, so that the structure of TEOLEDs was Ag(100 nm)/ITO(10 nm)/NPB(190 nm)/Alq_3(33 nm) + C-545T(2 wt%)/Alq_3(30 nm)/LiF(1 nm)/Mg:Ag(18 nm)/NPB(60 nm). The 60-nm NPB capping layer was added for refractive-index matching to maximize light extraction [12]. Prior to deposit organic layers, reflective anode Ag/ITO was treated with 60-watt oxygen plasma for 90 s. All the organic layers and the Mg:Ag semitransparent cathode were deposited via thermal evaporation in vacuum better than 1.33×10^{-4} Pa.

We tested 6 different encapsulation schemes for identical TEOLEDs. The first TEOLED, Device A, was encapsulated
Fig. 1. Cross-sectional SEM image of 5 pairs of Al_2O_3/polyurea layers on top of a 0.8-μm-thick polyurea layer. Polyurea and Al_2O_3 layers were deposited by alternating sputtering and VPD processes, respectively.

with glass under nitrogen atmosphere while placing getter on one side not to block the light path. The other 5 TEOLEDs were encapsulated with alternating layers of Al_2O_3 and polyurea, and labeled according to the number of Al_2O_3/polyurea layer pairs: Device B-1, B-2, B-3, B-4, and B-5. Inorganic Al_2O_3 layers were deposited by RF magnetron sputtering under the condition of 42-sccm argon flow, 0.29-Pa working pressure, and 300-W RF power. Organic polyurea layers were deposited at room-temperature from isocyanate monomer and diamine precursor via vapor deposition polymerization (VDP) at the working pressure of 0.49 Pa, and the deposition rate was 1 nm/s. For thin-film encapsulation, we first transferred a TEOLED to the VDP chamber to deposit 0.8-μm thick polyurea that was necessary to minimize damage to TEOLED during Al_2O_3 sputtering. Next, the TEOLED was transferred back and forth between the sputtering and VDP chambers to deposit 50-nm Al_2O_3 and 20-nm polyurea layers in sequence. The structure of encapsulation layer for Device B-1 was polyurea(0.8 μm)/Al_2O_3(50 nm)/polyurea(20 nm), and those for other devices were similar except the number of Al_2O_3(50 nm)/polyurea(20 nm) pairs on top of the 0.8-μm thick polyurea layer. The active area of all the TEOLEDs were 2×2 mm^2. Keithley238 and PR650 were used as a source-measurement unit and a luminance meter, respectively, in measuring $I–V–L$(current-voltage-luminance) characteristics.

Fig. 1 shows a cross-sectional scanning electron microscopy (SEM) image of 5 pairs of Al_2O_3(50 nm)/polyurea(20 nm) layers on top of the 0.8-μm thick polyurea layer, which is equivalent to the thin-film encapsulation for Device B-5. Polyurea and Al_2O_3 layers appear darker and less dark in the SEM image, respectively. This SEM picture confirms the formation of a good quality stack of Al_2O_3 and polyurea layers by alternating sputtering and VPD processes.

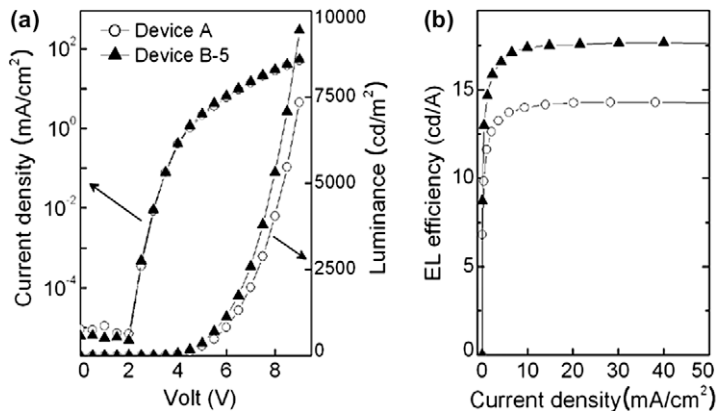
In Fig. 2a, we compare operation characteristics of Device B-5 (thin-film-encapsulated TEOLED) and Device A (glass-encapsulated TEOLED). It is interesting to note that current density variation with respect to driving voltage is almost identical between Device A and Device B-5. This observation indicates that our thin-film encapsulation pro-


Fig. 2. Comparison of the operating characteristics of Device B-5 (thin-film-encapsulated TEOLED) with those of Device A (glass-encapsulated TEOLED): (a) current density and luminance versus applied voltage, and (b) luminance yield (EL efficiency) versus current density.

cess did not induce any damage to the TEOLEDs. However, there is a noticeable increase in luminance of Device B-5 compared to that of Device A at identical bias voltages. We attribute the luminance increase of Device B-5 to the optical effects of the thin-film stack. The luminance increase results in improvement of electroluminance (EL) efficiency as shown in Fig. 2b. At the current density of 10 mA/cm², the EL efficiency of Device B-5 is 17.4 cd/A that corresponds to 23.4% improvement from 14.1 cd/A of Device A.

Table 1 shows the position and width of EL peaks, from which CIE color coordinates are deduced, and the EL efficiency of the aforementioned six TEOLEDs at the current density of 10 mA/cm². It is obvious that there is a periodic dependence of TEOLED performance on the number of Al_2O_3/polyurea pairs for the thin-film encapsulation devices. In particular, when even number of Al_2O_3/polyurea pairs was used, the EL efficiency was improved only 11% (Device B-2) and 15% (Device B-4) compared to that of Device A with glass encapsulation. However, there were respectively 30%, 25%, and 23% improvement in the EL efficiency when one (Device B-1), three (Device B-3), and five (Device B-5) pairs of Al_2O_3/polyurea layers were used for encapsulation. It is apparent that the optics of multi-layer stacks resulted in the observed periodic variation of the EL efficiency, and the position and width of EL peaks.

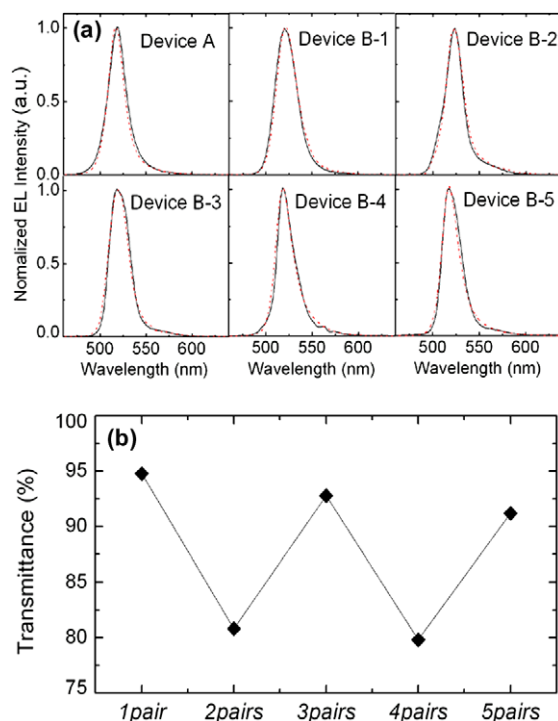
We simulated the experimentally observed EL peaks through the combination of the photoluminance (PL) spectrum of the Coumarin-doped Alq_3, which we used to represent the original emission from the EML, with the rigorous modeling of multi-layer optical effects that stem from the structure of each device. It was surprising to find that slight thickness adjustment of two NPB layers and a thick polyurea layer was sufficient to simulate the EL spectra of all five thin-film-encapsulated TEOLEDs. The thickness values of these layers, which we used to produce the simulated EL spectra in Fig. 3a, are listed in Table 1. To manifest the origin of the periodic variation of the EL efficiency, we compared the simulated transmittance of the five encapsulating thin films at the wavelengths corresponding to EL peaks. As shown in Fig. 3b, the transmittance varies periodically with respect to the increase of number of Al_2O_3-polyurea pairs, and higher transmittance is available from odd number of Al_2O_3-polyurea pairs. It is worth emphasizing that the EL efficiency of each of the five thin-film-encapsulated TEOLEDs is better than that of Device A. In the case of glass-encapsulated TEOLEDs, wave-guide-mode loss is inevitable because the light emitted from the EML has to enter an encapsulating glass, having


Fig. 3. (a) Comparison of EL spectra (dash lines) simulated based on the structural parameters in Table 1 with measured EL spectra (solid lines): (b) systematic variation of simulated transmittance of the five encapsulating thin films at the wavelengths corresponding to EL peaks.

refractive-index of 1.53, through the air gap. However, similar refractive-indexes of Al_2O_3 and polyurea, 1.66 for Al_2O_3 and 1.52 for polyurea, makes thin-film-encapsulated devices free from wave-guide loss.

Fig. 4 shows the decrease of luminance, starting from the initial value of 1000 cd/m², with respect to operation time for Device A, and Device B-1, B-3, and B-5. We find that the half-decay lifetime of Device B-1 was only 592 hours, whereas that of Device A was 2985 h. It seems that 1-μm thick polyurea and one pair of Al_2O_3/polyurea layers were not sufficient enough to block permeation of water vapor and oxygen. However, as we increased the number of Al_2O_3/polyurea pairs to three (Device B-3) and five (Device B-3), the half-decay lifetime improved to 1618 and 2570 h, respectively. It is worth emphasizing that the half-decay lifetime of Device B-5 (2570 h) is about 86% of that of Device A (2985 h). The variation of lifetime indicates that protection against the permeation of water va-

Table 1

Basic unit for thin-film encapsulation is Al_2O_3(50 nm) and polyurea(20 nm).
Fig. 4. Comparison of half-decay lifetime of the TEOLEDs encapsulated with 1, 3, and 5 pairs of Al_2O_3 and polyurea layers (Device B-1, B-3, and B-5, respectively) to that of the glass-encapsulated TEOLED (Device A). Initial luminance L_0 was 1000 cd/m^2. Inset shows a photograph of the device with 5 pairs of Al_2O_3 and polyurea layers (Device B-5) after the lifetime test.
Fig. 5. The result of WVTR measurement at 37.8 °C and 100% RH for a set of Al_2O_3(50 nm)/polyurea(20 nm) layers on a PET film. Each data point represents the average of three-sample measurements. The WVTR of one, two, three, four, and 5 pairs of Al_2O_3(50 nm)/polyurea(20 nm) layers on a PET film were measured as 5, 0.23, 0.04, 0.008, and 0.0005 g/m^2 day, respectively, whereas the WVTR of a bare PET film was 8.2 g/m^2 day.

por and ambient oxygen improves in accordance with the increase of the number of Al_2O_3/polyurea pairs. Nevertheless, the EL peak positions of Device B-1, B-3, and B-5 are identical, and the widths of EL peaks of these TEOLEDs are similar, so that their CIE$_{x,y}$ color coordinates are only slightly different, because thin-film encapsulation is designed in such a way to minimize the change in color coordinates from those of the original glass-encapsulated TEOLED, Device A.

Inset in Fig. 4 is a photograph of the device with 5 pairs of Al_2O_3 and polyurea layers (Device B-5) after the lifetime test, which shows that the degradation of the Al_2O_3/polyurea-encapsulated OLEDs occurred typically from the edge due to the permeation of water vapor and ambient oxygen through the polyurea layers. Fig. 5 shows the result of independent measurement of water vapor transition rate (WVTR) for a set of Al_2O_3(50 nm)/polyurea(20 nm) layers on PET films. This WVTR measurement was carried out at 37.8 °C and 100% RH by using the AQUTRAN Model-1 (MO-CON Co. Ltd.) with the detection range from 5×10^{-4} to 60 g/m^2 day. The average of three-sample measurements for each number of Al_2O_3(50 nm)/polyurea(20 nm) pairs showed that the WVTR of one, two, three, four, and 5 pairs

of Al_2O_3(50 nm)/polyurea(20 nm) layers on a PET film are 5, 0.23, 0.04, 0.008, and 0.0005 g/m^2 day, respectively. It should be noted that the WVTR of the four pairs of Al_2O_3/polyurea layers on a PET film is about three orders of magnitude smaller than that of a bare PET film, which is 8.2 g/m^2 day, and that the WVTR of the 5 pairs of Al_2O_3/polyurea layers on a PET film is close to the detection limit of the apparatus we used.

In summary we developed a room-temperature process for thin-film encapsulation of TEOLEDs via alternating stacking of organic polyurea and inorganic Al_2O_3 layers. Initial deposition of a 0.8-μm-thick polyurea layer on top of TEOLEDs turned out to be effective to prevent TEOLEDs from experiencing noticeable damage during sputtering processes. We were able to prove that 5 pairs of Al_2O_3/polyurea layers were sufficient for significant improvement of half-decay lifetime of the TEOLED, to the 86% of the lifetime of the glass-encapsulated TEOLED. Moreover, we achieved 23% improvement in EL efficiency without noticeable change in color coordinates because the thickness of the Al_2O_3/polyurea pairs, the thick polyurea buffer layer, the transparent Mg:Ag layer, and the two NPB layers were selected to maximize light extraction without color distortion. Independent measurement of WVTR for a set of Al_2O_3/polyurea layers on PET films showed that the barrier property against water vapor can be so good that the WVTR can be as low as 5×10^{-4} g/m^2 day with 5 pairs of Al_2O_3/polyurea layers, which indicates that the hybrid thin-film encapsulation based on Al_2O_3/polyurea layers has the application potential in developing flexible top-emitting OLEDs.

or hole-transport material [8]. Thus the circuit is complete and the system regenerative.

To date the most efficient dye sensitizers have been based on heteroleptic ruthenium complexes such as the 'gold standard' [cis-di(thiocyanato)-bis(4,4'-dicarboxylate-2,2'-bipyridyl)]ruthenium(II) **1** (N3) [9]. The development of the ruthenium dyes has focused on the following key properties: improving light absorption both in terms of wavelength range and molar extinction coefficient – the lowest energy transition is believed to exhibit 'metal-to-ligand charge transfer' (MLCT) character which leads to intramolecular spatial charge separation in the excited state; strong adsorption and binding to the support photoanode; and rapid (*fs*) and efficient injection of the excited electron into the TiO₂. This combination of properties yields peak internal quantum efficiencies of near 100%.

The power conversion efficiency (η) of a DSSC is strongly related to the light harvesting efficiency (LHE) of the dye sensitizers. The LHE has been estimated using Eq. (1) [10]:

$$LHE(\lambda) = 1 - 10^{-\varepsilon(\lambda)\cdot\Gamma} \tag{1}$$

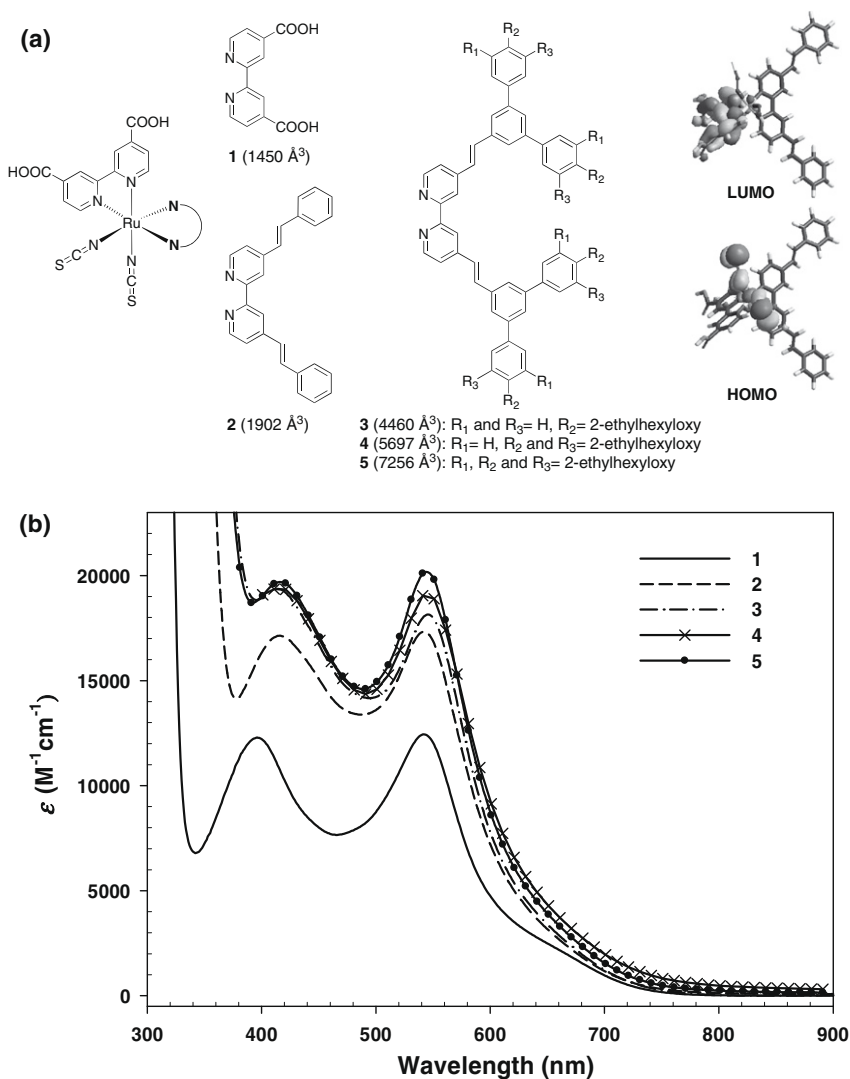
where, ε is molar extinction coefficient at wavelength λ and Γ is the adsorption capacity onto the TiO₂ photoanode (the dye uptake). From Eq. (1) it is clear that the molar extinction coefficient must be maximized over the solar wavelength range. This imperative has motivated numerous studies to fine tune the absorption properties of the ruthenium complexes by introducing conjugated moieties to one of the bipyridyl ligands of the basic structure of **1** [11–14]. This approach has given rise to ruthenium complexes with enhanced ε and absorptions at longer wavelengths compared to **1**. However, the enhanced spectral properties of such ruthenium complexes have not always led to the expected improvements in overall device effi-


Fig. 1. (a) The chemical structures of the materials and graphical representation of the frontier orbitals of **2** calculated by the ZINDO-1 parameter method (HyperChem 7.0). ciency (η) [15–17] with some apparently contradictory results in dye comparison studies [11,15].

In this manuscript we use ruthenium complex-cored dendrimers where Γ (the adsorption capacity or dye uptake) from Eq. (1) can be tuned to understand why improvements in device performance have not always followed increased light absorption and to explain the aforementioned conflicting device performance. In most reports on DSSCs the role of adsorption has been largely ignored, or if commented on not studied in any detail [12]. The dendrimers are similar to N3 (Fig. 1: **1**) but with the carboxylic acid moieties on one bipyridyl ligand replaced with first generation biphenyl dendrons connected to the ligand via vinyl units (Fig. 1: **3**, **4**, and **5**) [18]. The dendronised complexes have the same chromophores and only differ in the number of surface groups. The use of the same chromophore means that the absorption properties will be essentially the same enabling the direct investigation of the effect of molecular volume through Eq. (1). We also compare the properties of the non-dendronised complex **2** (Fig. 1), which has the same extended conjugated bipyridyl ligand but without the branched dendrons and surface groups for comparison.

2. Results and discussion

The first step in understanding the role of adsorption in device performance was the determination of the molecular volumes of the dendrimers. The propensity of N3 to aggregate in solution [18] and the polar carboxylic acid groups meant that gradient diffusion NMR and gel permeation chromatography were not useful, and hence the molecular volumes of the materials in this study were determined by semi-empirical quantum chemical calculations (see Section 4). The molecular volumes are shown in Fig. 1a along with a model showing the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) states of **2**. An interesting observation from these calculations is that for all the materials the

HOMO resides mainly on the ruthenium and isothiocyanate moieties and the LUMO on the 4,4′-dicarboxy-2,2′-bipyridyl unit meaning that the lowest energy transitions, and hence optoelectronic properties of all the studied materials should be similar.

Most studies on ruthenium sensitizers focus on the improvement of the long wavelength absorption. Fig. 1b shows a comparison of the absorption spectra of our materials and N3 **1** at a concentration of 5×10^{-5} mol L^{-1} in *N,N*-dimethylformamide. The λ_{max} and ε of the longer wavelength band for **2** [λ_{max}: 543 nm, (ε [M^{-1} cm^{-1} = 17,300)] are slightly red-shifted and increased, respectively relative to **1** [λ_{max}: 541 nm, (ε [M^{-1} cm^{-1} = 12,400)]. Introducing the (2-ethylhexyloxy) surface group containing phenyl moieties to form the first generation dendronised ligands of **3**, **4**, and **5** also causes a slight shift of the λ_{max} and an increase in the molar absorption coefficients [λ_{max}: 546 nm, (ε [M^{-1} cm^{-1} = 18,100)]; [λ_{max}: 547 nm, (ε [M^{-1} cm^{-1} = 19,200)]; and [λ_{max}: 548 nm, (ε [M^{-1} cm^{-1} = 20,200)], respectively]. However, it is important to note that in addition to the absorption increase in the longer wavelength band, the molar extinction coefficients of the new compounds are higher over all wavelengths indicating that they should be better light harvesters than **1**. Based only on the absorption characteristics of the materials the efficiency of the DSSCs made with the new dyes should be expected to increase in the order **1 < 2 < 3 < 4 < 5**.

However, as stated earlier the performance of a DSSC is not only based on the absorption of the harvesting (macro) molecule but also on the total amount of dye present. The dye uptake was determined by immersing the TiO$_2$ photoanodes (0.88 cm^2 surface area) into a cuvette of dye solution (1×10^{-4} mol L^{-1}), and the change in the absorbance of the dye solution at λ_{max} of the longest wavelength band was measured *in situ* as a function of time (see Section 4). The dye uptake amount (Γ) was then determined by comparison with standard solutions of known dye concentration. Fig. 2 shows the dye uptake profiles as a function of time for the materials of Fig. 1. In all cases the
Fig. 2. The adsorption data for the Ru complexes onto TiO$_2$ films measured over a period of 24 h (solid line represents the numerical regression fit).

rate of dye adsorption is initially rapid and eventually reaches a plateau. The plateau represents the equilibrium value associated with maximum dye uptake. These profiles are typical for organic adsorbates into nano-porous inorganic matrices [19,20]. The chemisorption of all the materials onto the surface of the TiO_2 was confirmed by infrared spectroscopy, which showed absorptions corresponding to bidentate- or bridging-mode bonding of two carboxylate units [1610 cm^{-1}: v_{as}(–CO$_2$–) and 1380 cm^{-1}: v_s(–CO$_2$–)] [18] in a similar manner to that reported for other ruthenium complexes [21,22] independent of the molecular volume. The fact that all the materials bind in the same way to the TiO_2 and their long wavelength optical transitions are similar means that the electronic communication between the dyes and the TiO_2 will be essentially the same. Hence differences observed in performance can be directly related to the effect of molecular volume and how much dye is adsorbed. It can clearly seen in Fig. 2 that the molecular volume affects dye uptake with the smallest dye 1 (98.1×10^{15}/cm^2) having the greatest amount of dye-adsorbed, and then decreasing in the order 2 (73.7×10^{15}/cm^2) > 3 (63.6×10^{15}/cm^2) > 4 (45.8×10^{15}/cm^2) > 5 (33.0×10^{15}/cm^2). The exact mechanism(s) by which molecular volume affects dye uptake are reported in detail elsewhere [18,23]. In summary, the kinetic studies of the adsorption show that at equilibrium the amount of dye uptake is controlled by the dye occupancy area (steric hindrance). Furthermore, chemisorption (rather than bulk
Fig. 3. Plot of the integrated absorption coefficient (grey circle) and light harvesting efficiency (black diamond) from 390 nm to 900 nm versus the molecular volume of the Ru complexes.
Fig. 4. J–V curves for devices constructed from compounds 1–5. Note the results shown are representative of multiple devices for each dye and do not represent the highest efficiencies obtained.

diffusion) is the rate-limiting step in the uptake process and kinetic hindrance also controls the initial rate. Hence, for a photoanode substrate of specific binding site density and mesoscopic porosity, the dye uptake is directly related to molecular volume.

To summarize thus far, the light absorption data shows that the new dyes absorb more strongly than **1**. In contrast, **1** is adsorbed to a greater extent than the new ruthenium complexes. To see how these two parameters affect the

overall LHE of the ruthenium complex based materials we calculated the LHE by two different methods. In the first case we only took into account the light absorption and integrated ε (from Fig. 1b) from 390 to 900 nm, thus avoiding the contribution of the TiO$_2$ nanoparticle absorption [E_g = ca 3.2 eV (390 nm) for anatase] [24]. Fig. 3 shows that the integrated ε values for **2**, **3**, **4** and **5** are higher than that of **1**. However, when the adsorption is taken into account in the calculation of the LHE, the order reverses apart

Table 1

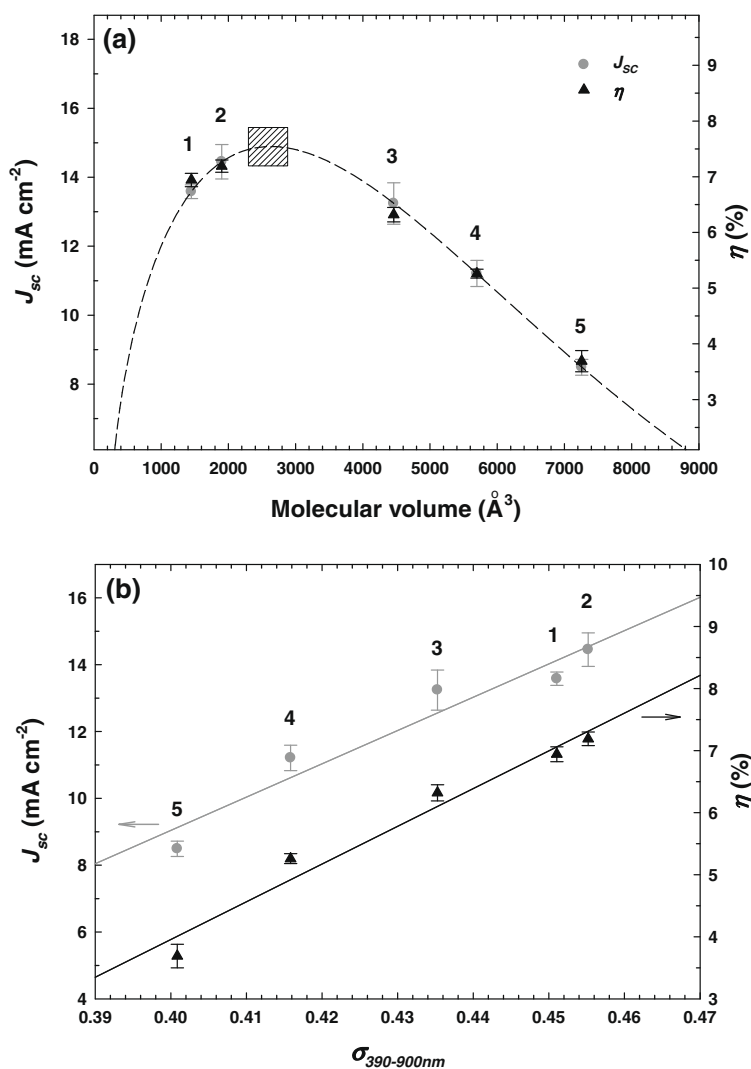

Fig. 5. (a, b) Plot of short-circuit photocurrent density (grey circle) and power conversion efficiency (black triangle) versus the molecular volume of the Ru complexes (a) and the σ index calculated from modified light harvesting efficiency equation (b) under AM 1.5G illumination (100 mW cm^{-2}).

from **2**, which has a higher overall light harvesting efficiency than **1**. These results show strongly that molecular volume will play a first order role in the light harvesting efficiency.

In order to understand the effect of molecular volume and test whether the calculated LHE correlates with device efficiency, batches of devices were constructed from the dyes (see Section 4). It is important to note that in each case, dye uptake was optimized according to the kinetics and solvent systems used to obtain the data in Fig. 2. It is also important to note that short-circuit current densities (J_{sc}) and conversion efficiencies (η) were measured on multiple devices to obviate cell-to-cell fabrication differences and that measurements were validated at two external laboratories for cross-calibration purposes (results in agreement to within 5% of the measured values). Current–voltage curves for typical devices containing each material are shown in Fig. 4 and the average measured diode parameters for each dye batch (J_{sc}, V_{oc}, Fill Factor (*FF*) and η) along with statistics under standard AM1.5G conditions are summarized in the Table 1.

Fig. 5a illustrates how J_{sc} and η vary with molecular volume. The striking correlation between the molecular volume and device performance is immediately clear. Although **4** and **5** have higher ε, we do not see enhancement of η due to their high molecular volumes and reduced uptake per unit TiO$_2$ area. **2** Appears close to the optimum in this trade-off, but the form of the dependence suggests that there is (as yet) unexplored opportunity to maximize device efficiency in these ruthenium complexes. Scaling our best **1** results with the highest so far obtained (~11%) would suggest that this molecular volume tuning approach could yield overall conversion efficiencies of >13% with ruthenium dyes (square box in Fig. 5a).

Finally, we have determined the relationship between the LHE and the device performance. In the first analysis we determined the LHE from Eq. (1), which takes into account the molar extinction coefficient and the adsorption. However, to more accurately determine the LHE it is necessary to include a weighting due to the response of the dye to the AM1.5 spectrum. When the AM1.5 spectrum is taken into account it is possible to determine a normalized light harvesting efficiency ($\sigma_{390-900\ nm}$) according to Eq. (2):

$$\sigma_{390-900\ nm} = \frac{\int_{390\ nm}^{900\ nm} \Phi_p(\lambda)(1 - 10^{-\varepsilon(\lambda)\cdot\Gamma})d\lambda}{\int_{390\ nm}^{900\ nm} \Phi_p(\lambda)d(\lambda)} \quad (2)$$

where $\Phi_p(\lambda)$ is the AM1.5 hemispherical irradiance incident on a 37° tilted plane measured in Wm^{-2} nm^{-1} as enunciated by (for example) ISO 9854-1 [25], and Eq. (2) represents a weighted ordinate normalization for the solar spectrum, and ε and Γ are as determined previously. Fig. 5b shows this normalized light harvesting efficiency ($\sigma_{390-900\ nm}$) plotted against the measured J_{sc} and η from the devices based on each dye. In both cases there is a systematic linear relationship confirming that, all else being equal, both ε and Γ are first order parameters in device efficiency. Furthermore, this correlation suggests that the simple solution measurements of absorption and adsorption can be used to predict the light harvesting efficiency

of potential new ruthenium dye systems without recourse to device construction.

3. Conclusion

In summary, we have demonstrated that dendronized light harvesting ruthenium complexes can be used for DSSCs. We have used this dendritic architectural approach to tune the dye molecular volume while leaving the optoelectronic characteristics the same, allowing a systematic investigation of the effect of the molecular volume on the light harvesting efficiency for the first time. We have demonstrated that molecular volume and molar extinction coefficient are both first order parameters in achieving high conversion efficiencies. Enhanced solar absorption does not necessarily lead to enhanced light harvesting efficiency because of the associated increase in molecular volume. Our analysis provides a strategy for molecular engineering new ruthenium complex based dyes whereby tuning the molecular volume in conjunction with the extinction coefficient could ultimately yield higher efficiency dye systems. Dendronisation also has the potential to improve other device properties including: reducing dye desorption, leading to longer device lifetimes; tuning solubility and compatability with electrolyte systems (particularly in all-solid-state structures); and controlling parasitic reaction rates.

4. Experimental

4.1. Materials

The compounds **2**, **3**, **4**, and **5** were prepared according to the previous reference [18]. All organic solvents used for UV/vis absorption and dye adsorption measurements were of spectroscopic quality from Aldrich, and *N,N*-dimethylformamide (DMF) was distilled before use. TiO$_2$ electrodes were purchased from Dyesol Pty. Ltd. (Queanbeyan, NSW Australia) and consisted of a 11–12 μm thick film of 20 nm anatase particles randomly interspersed with 400 nm scattering centers (10% by weight) with a specific surface area of approximately 70–80 m^2/g deposited onto 15 Ω^2 fluorine doped tin-oxide (FTO) coated glass. The platinum catalyst electrodes were purchased from Dyesol and consisted of 12 × 9 mm^2 area of platinum screen printed onto a glass substrate coated 15 Ω^2 FTO. The molecular volumes (represented by the overlapping van der Waals atomic spheres model) of the ruthenium complexes were calculated by the quantitative structure–activity relationship (QSAR) property [26,27] module in the HyperChem 7.0 package after geometry optimization using a ZINDO-1 parameter [28,29]. This methodology has been used extensively to yield realistic molecular volumes at a relatively low computational cost [26,27].

4.2. Dye adsorption measurements

The optimized solvent compositions for adsorption of **1** [*t*-butanol:acetonitrile (1:1)], **2** [DMF:acetonitrile (1:1)], **3** [DMF:acetonitrile (9:1)], **4** [DMF:acetonitrile (9:1)] and **5**

[DMF:acetonitrile (1:1)] were used in the study. The absorption spectra of the initial dye solution (1×10^{-4} mol L^{-1}) were measured by a Cary 5000 UV–VIS–NIR spectrophotometer. The prepared TiO$_2$ substrates (ca. 0.88 cm^2 of active area) which were baked at 450 °C for 30 min and kept at 80 °C before immersion into the dye solution in a UV cuvette (1 cm × 1 cm). The absorbance changes were monitored hourly for 9 h and then at 24 h. The chemisorption of all Ru complexes onto TiO$_2$ films were characterized by ATR-FT-IR spectrometer (Spectrum 100, Perkin Elmer).

4.3. Solar cell fabrication and characterization

Prior to dye sensitization, the TiO$_2$ films (active area: ca. 0.20 cm^2 measured by using the ImageJ software package) were treated with a solution of titanium tetrachloride solution and heated to ~450 °C for 30 min before being allowed to cool to ~80 °C. The TiO$_2$ films were immersed in the dye solution (3×10^{-4} mol L^{-1}) at room temperature for 24 h to adsorb dye onto the TiO$_2$ surfaces. Excess dye was removed by rinsing with DMF and acetonitrile. Platinum (Pt) counter electrodes on FTO glass was also preheated to ~450 °C for 10 min and a single hole (ca. 0.5 mm diameter) was drilled in the Pt electrode to allow for electrolyte filling. The dye-adsorbed TiO$_2$ electrode and Pt counter electrodes were assembled into a sealed sandwich-type cell by heating a hot-melt ionomer film (Surlyn 1702, 25 µm thickness, Solaronix) as a spacer between the electrodes. An electrolyte solution (electrolyte of 0.6 M 1-n-butyl-3-methylimidiazole iodide, 0.03 M iodide, 0.1 M guanidinium thiocyanate, and 0.5 M tert-butylpyridine in 15/85 (v/v) mixture of valeronitrile and acetonitrile) was injected by a vacuum backfilling method. Finally, the hole was sealed by using Bynel (Dyesol) and a glass cover slide (0.1 mm thickness).

Device efficiencies were measured with a Thermo Oriel 150 W Xenon arc lamp which was designed to give ~100 mW/cm^2 using AM1.5D and AM0 filters. Prior to each measurement, the solar simulator illumination intensity was measured using a Hamamatsu reference silicon photodiode (S1133) with white light filter (spectral mismatch <5% with respect to an N3 DSSC response). The exact white light illumination intensity was used in each case for the power conversion calculations. The J–V characteristics were measured using a Kiethley Source Meter Unit (SMU) and an appropriate photomask to illuminate only the cell area. The J–V scan and acquisition were driven by purpose-written LabView software. The cell data for each dye were averaged using at least 5 devices for consistency and the statistics calculated on that basis. Incident photon to electron conversion efficiencies (IPCE) were also measured for representative devices from each batch using the same Thermo Oriel lamp and a Princeton Instruments Acton SpectraPro 2300i monochromator equipped with the PI SpectraHub data acquisition system and a Newport 818-UV silicon photodiode. The reference diode and multiple devices were also cross-calibrated (IPCE and J–V) with two separate laboratories (CSIRO Melbourne and Monash University, Melbourne, Australia) and the results found to be in agreement to within 5%.

On the other hand, high-performance true-blue phosphorescent dopants are also under intensive development [8–12]. Some reported Ir complexes have been proven highly efficient; however, the emission spectra are still not the desired true-blue color [8–10]. Previously, we reported that a parent heteroleptic Ir^{III} complex (**Ir1** [Ir(dfppy)(fppz)$_2$], Fig. 1) possessing one cyclometalated 4,6-difluorophenyl-2-pyridyl chelate (dfppy) and two 3-(trifluoromethyl)-5-pyridyl pyrazolate ligands (fppz) can produce true-blue phosphorescence with CIE$_y$ of ~0.2 [12]. Yet, the EL quantum efficiency achieved is till below 10% photon/electron. In this work, by placing tertiary butyl or methyl substituents at different locations of chelates, we are able to synthesize three additional derivatives **Ir2** [Ir(dfppy)(fbppz)$_2$], **Ir3** [Ir(dfmppy)(fbppz)$_2$], and **Ir4** [Ir(dfbppy)(fbppz)$_2$] (Fig. 1), aiming at further raising the EL efficiencies of true-blue phosphorescent OLEDs based on such materials. Subsequent results show that the EL efficiency of true-blue OLEDs based on these new emitters can raise up to 13.7% photon/electron, 20.4 cd/A and showing true-blue color chromaticity with CIE$_{x,y}$ coordinates (0.157, 0.189).

2. Experimental

2.1. Material synthesis and characterization

The preparation of the iridium complexes were best executed by heating of a 1:1 mixture of 4,6-difluorophenyl pyridine (dfppy), 4-methyl-2-(2,4-difluorophenyl)pyridine (dfmppy) or 4-tert-butyl-2-(2,4-difluorophenyl)pyridine (dfbppy) and IrCl$_3$·3H$_2$O in methoxyethanol (140 °C, 4 h), followed by addition of 2.1 equiv. of 3-trifluoromethyl-5-(2-pyridyl) pyrazole (fppz) or 3-(trifluoromethyl)-5-(4-tert-butylpyridyl) pyrazolate (fpbpz) in presence of Na$_2$CO$_3$ (140 °C, 12 h). The products are then separated by column chromatography on silica gel eluting with a mixture of ethyl acetate and hexane (1:1) or with pure CH$_2$Cl$_2$. The synthetic logic relies on the prior generation of an intermediate with formula [(dfppy)IrCl$_2$]$_x$ or [(dfmppy)IrCl$_2$]$_x$ or [(dfbppy)IrCl$_2$]$_x$ [13], which would react with the two equiv of fppz or fpbpz anions in the subsequent reaction. **Ir1** [Ir(dfppy)(fppz)$_2$], **Ir2** [Ir(dfppy)(fbppz)$_2$], **Ir3** [Ir(dfmppy)(fbppz)$_2$], and **Ir4** [Ir(dfbppy)(fbppz)$_2$] were obtained from these one-pot reactions in moderate yields. Spectroscopic examinations were also performed to confirm their structural identity and sample purity.

2.2. OLED fabrication and characterization

All as-synthesized compounds were subject to temperature-gradient sublimation under high vacuum before use. OLEDs were fabricated on the ITO-coated glass substrates with multiple organic layers sandwiched between the transparent bottom indium–tin-oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of <10^{-6} torr. The deposition rate of

organic layers was kept at ∼0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 2×2 mm^2, as defined by the shadow mask for cathode deposition.

Current–voltage–luminance (I–V–L) characterization of the devices was measured using a source-measurement unit (SMU) and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. UV/Vis spectra were measured using a Shimadzu UV-1650PC spectrophotometer.

3. Results and discussions

3.1. Emission properties of Ir complexes

Photoluminescence (PL) of Ir complexes was measured using a Charge-Coupled Device (CCD) spectrograph and the 325 nm line of the He–Cd laser as the excitation source. For determining PL quantum yields, the samples (either solutions or thin films) were mounted in a calibrated integrating sphere coupled with the CCD spectrograph. By comparing the spectral intensities of the excitation laser and the PL emission, quantum yields (PLQY) were determined [14]. All four Ir(III) complexes show similar PL spectral profiles and quantum yields of nearly 50–80% (either in solutions or as dopants in wide-gap host films), as summarized in Fig. 2 and Table 1.

3.2. Testing of device structures

For achieving true-blue OLEDs with these large-triplet-energy phosphorescent Ir complexes (i.e. $E_T \geqslant 2.7$ eV), host materials with wide-triplet-gap are essential to prevent reverse energy transfer from guest molecule back to the host matrix [15]. Furthermore, the device structures must be carefully designed to achieve more balanced carrier injection/transport and appropriate confinement of carriers and excitons. We therefore used the parent complex Ir1 to test the suitability of host materials and device configurations (Figs. 3 and 4).

[a] Data obtained in degassed CH$_2$Cl$_2$ solution at RT with the concentration of 10^{-5} M.
[b] Obtained from 8 wt.%-doped thin films using CzSi as the host material.

Devices A was first constructed employing CzSi as the host material (Fig. 3). Complex Ir1 exhibits similar PLQY in both dilute solutions and as doped thin film of the wide-gap host CzSi, which had been reported to possess a large triplet energy of 3.02 eV [16]. Therefore, CzSi is appropriate for Ir1 in terms of confinement of triplet excitons on dopants. The device structure was: ITO/α-NPD (30 nm)/TCTA (30 nm)/CzSi doped with 15 wt.% of Ir1 (25 nm)/TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm), where 4,4′-bis[N-(1-naphthyl)-N-phenyl-amino] biphenyl (α-NPD) and 4,4′,4″-tris(carbazol-9-yl)-triphenylamine (TCTA) were used as the hole-transport layers (HTLs) [17], 3-(4-biphenylyl)-4-phenyl-5-(tert-butylphenyl)-1,2,4-triazole (TAZ) as the electron-transport layer (ETL) [18], LiF as the electron-injection layer [19], and aluminum as the cathode. The structural drawing of materials and device architecture used for our investigation are shown in Figs. 3 and 4, respectively.

The recorded EL characteristics of device A are depicted in Fig. 5 and Table 2. This device showed EL predominantly from Ir1, but with only a modest external quantum efficiency of about 3.3% photon/electron, which was substantially lower than its PLQY recorded in solution. In addition, EL spectra of the device showed a notable emission in near-UV region, which implied carrier recombination in the charge-transport layers (TCTA and/or TAZ, both are know to exhibit near-UV emission at ∼400 nm) [20].

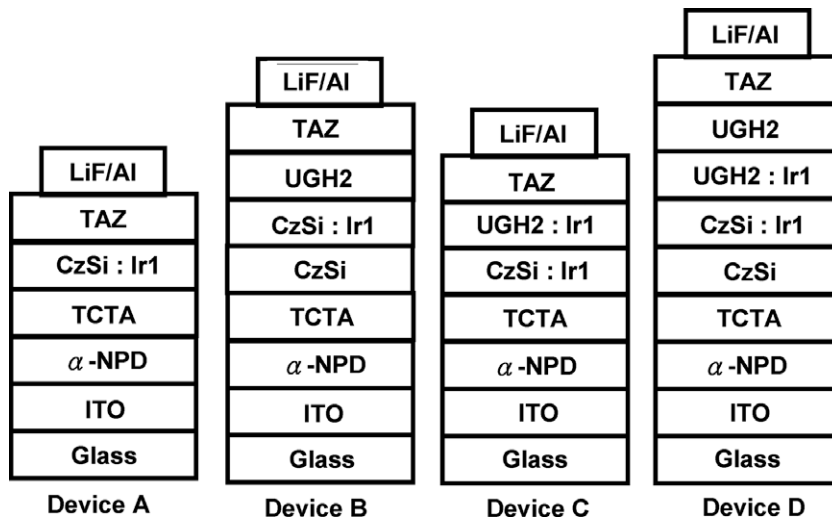
To achieve better confinement of triplet excitons and/or carriers in the emitting layer, two additional device architectures B and C were constructed and tested (Fig. 4). In device B, a thin layer of non-doped CzSi (3 nm) and UGH2 [p-bis(triphenylsilyl)benzene, 3 nm] were inserted between the emission and hole-transport layers and between the emission and electron-transport layers, respectively [21,22]. The hole-transporting CzSi possesses high triplet energy [16] and, thus, is capable to block the high-energy triplet excitions (on the dopant) from migrating to TCTA (with a lower triplet energy than the dopant) [17]. On the other hand, the electron-transporting UGH2 with high triplet energy (3.18 eV) [23,24] is expected to retard the high-energy triplet excitions (on the dopant) from migrating to TAZ (with a lower triplet energy than the dopant) [18]. In device C, double emission layers [25–27] (25-nm hole-transporting CzSi and 3-nm electron-transporting UGH2 doped with 15 wt.% Ir1) were used to achieve better balance between hole and electron injection/transport and thus to move the exciton formation zone away from the interfaces between the carrier-transport layers, taking
Fig. 3. Structural drawings of functional materials used in OLEDs.


Fig. 4. Schematic device structures employed in this study.

advantage of the inherent physical nature of both CzSi and UGH2.

Again, EL characteristics of device B and C are shown in Fig. 5 and Table 2. In comparison to those of device A, peak quantum efficiencies of devices B and C (4.7% and 5.0%) are substantially enhanced, indicating the effectiveness of the added electron and hole buffer layers. We thus decided to combine the fabrication concept of devices B and C, giving the device D, which had the device structure of: ITO/α-NPD (30 nm)/TCTA (30 nm)/CzSi
Fig. 5. (a) EL spectra, (b) current–voltage characteristics, (c) luminance versus voltage, (d) external quantum efficiency versus luminance for devices A, B, C, and D.

(3 nm)/CzSi doped with 15 wt.% of **Ir1** (25 nm)/UGH2 doped with 15 wt.% of **Ir1** (3 nm)/UGH2 (2 nm)/TAZ (50 nm)/LiF (0.5 nm)/Al (150 nm). By simultaneously

adopting the double emission layers and the high-triplet-energy buffer layers on two opposite sides of the emitting layers for better confinement of triplet excitons and carriers, device D further raised the peak quantum efficiency up to 7.2% (11.7 cd/A, 6.4 lm/W) (Fig. 5 and Table 2).

3.3. Optimization of dopant concentrations

After establishing the effective device structure for the phosphorescent emitter (**Ir1**), we then varied the dopant concentration in the emission layers to further optimize device performances. Upon fixing the architecture of device D, the concentration of **Ir1** was next varied from 6 wt.% to 20 wt.%. The EL characteristics of devices for these devices are shown in Fig. 6 and Table 3. The highest EL quantum efficiency was obtained around a dopant concentration of ~6 wt.% (similarly for the other three Ir complexes, as will be seen later in Table 4). At this concentration, the device gave peak efficiencies of up to 8.6%, (13.1 cd/A, and 8.2 lm/W), which is possibly attributed to the reduced concentration quenching and triplet–triplet annihilation.

3.4. Comparing EL characteristics of various Ir complexes

It seems to us that the optimized EL efficiencies of **Ir1** are somewhat equivalent to the PLQY of the dopant, suggesting that other modified blue-emitting phosphors, such as **Ir2**–**Ir4**, are equally applicable in fabrication of OLEDs employing similar device structure and adequate dopant concentration. In Table 4, EL characteristics of type-D devices incorporating all four iridium-based blue emitters (**Ir1**, **Ir2**, **Ir3**, and **Ir4**), with varied dopant concentrations from 6 wt.%, 8 wt.%, to 10 wt.%, are summarized. All Ir complexes show the highest EL efficiency around the dopant concentration of 6 wt.%. To verify that it is indeed an optimized concentration, in particular, we also examined **Ir4** devices with an even more extended concentration range of 2–10 wt.% (Table 4). Lower EL efficiencies were observed at concentrations lower than 6 wt.%, perhaps due to the incomplete energy transfer from hosts to guests.

Fig. 7 compares EL characteristics of type-D devices using these Ir(III) complexes at the optimized dopant concentration of 6 wt.%. All devices exhibited turn-on voltages of slightly smaller than 4 V. The peak efficiencies were (8.6%, 13.1 cd/A, 8.2 lm/W) for **Ir1**, (11.0%, 18 cd/A, 12.8 lm/W) for **Ir2**, (13.0%, 20 cd/A, 14.1 lm/W) for **Ir3**, and (13.7%, 20.4 cd/A, 14.0 lm/W) for **Ir4**, respectively. Except for the more significant deviation in the EL efficiency of **Ir2** (maybe associated with the detailed energy levels of each compound), these peak EL quantum efficiencies are somewhat close to the ideal values one would expect from PLQY's of these Ir complexes (in doped thin films, Table 1), assuming similar internal quantum efficiencies in both PL/ EL and assuming a ~20% optical out-coupling efficiency. Such results suggest the effectiveness of the present device architecture for true-blue phosphors. The devices retained rather high efficiencies at the practical brightness of 100 cd/m^2. Among all these Ir complexes, **Ir3** and **Ir4** gave highest EL efficiencies. In particular, **Ir4** gave the highest

Table 2

are considered to arise from (i) the improved dispersion between the host and dopant upon incorporating either methyl or *tert*-butyl groups on the dopant phosphors and (ii) the reduced back energy transfer from dopant to host due to their increased spatial separation. This observation is consistent with a recent report that bulky *tert*-butyl group on pyridyl ring of green-emitting analogues of [Ir(p-py)$_3$] reduces the need for development of hosts with a high triplet level for electrophosphorescent devices [28]. Again, the related iridium phosphors with *tert*-butyl substituted benzothiazolate and benzoimidazolate chromophores were also used for fabrication of red-emitting polymer LEDs [29]. Apparently, the steric influences would reduce aggregation and phase separation in polymer LEDs, which seems to dominate how to give high efficiencies under lower current density.

Moreover, these devices all showed the anticipated blue phosphorescence deriving from the Ir(III) dopants, for which the respective EL spectra and CIE coordinates are shown in Fig. 8a and b. It is notable that all these blue-emitting devices exhibited color chromaticity with the CIE$_y$ value being smaller or around 0.2. In particular, the **Ir4** device had the most blue-shifted emission with CIE$_{x,y}$ coordinates of (0.157, 0.189), which is much superior than those obtained from the blue phosphorescent complexes such as bis(4′,6′-difluorophenylpyridinato)iridium(III) picolinate (FIrpic) and bis(4′,6′-difluorophenylpyridinato)iridium(III) tetra(1-pyrazolyl)borate (FIr6), their CIE$_{x,y}$ coordinates are also marked in Fig. 8b as reference [8–10]. Thus these new iridium dopants **Ir1**–**Ir4** are promising for blue phosphorescent OLEDs with high EL efficiencies and adequate color chromaticity, both are extremely important for display and lighting applications.

peak efficiencies of (13.7%, 20.4 cd/A, 14.0 lm/W) and the high brightness of up to 14,460 cd/m^2 at 18 V. The superior performances of both **Ir3** and **Ir4** over those of **Ir1** and **Ir2**

4. Conclusions

A series of new device architectures were evaluated for construction of true-blue phosphorescent OLEDs. It involves a double emission layers (one hole-transport, one electron-transport) and double buffer (confinement) layers for enhancing the performance characteristics. In addition, we also added methyl and bulky *tert*-butyl substituents to the parent true-blue emitting iridium phosphor **Ir1**, and

obtained an improved performance characteristic for OLEDs fabricated under identical conditions. Thus, combination of these new phosphors and the double emission and buffer layers architectures afforded the true-blue electrophosphorescence with high efficiencies up to (13.7% photon/electron, 20.4 cd/A) and with $CIE_{x,y}$ color coordinates of (0.157, 0.189). Consequently, high-efficiency OLEDs in the blue/deep-blue region were successfully prepared. We thus believe that our device integration, plus the new design of Ir(III) phosphors presented in this study should convince the readers of its perspective en route to the true-blue phosphorescent OLEDs.

tionally its T_1 energy is 2.56 eV (corresponding to 483 nm, which is estimated from the T_1 emission [3]). It does not have sufficient high triplet state energy for blue phosphorescent dopants such as iridium bis(4,6-difluorophenypyridinato) picolate (FIrpic) with 2.66 eV T_1 energy and iridium bis (4,6-difluorophenylpyridinato-N, $C^{2\prime}$) [5-(2-pyridyl)tetrazolate] (FIrN4) with 2.71 eV T_1 energy [4].

Recently three fluorescent materials were investigated to check their suitability as host for blue OLEDs. They are 1,3-bis(9-carbazolyl)benzene (mCP), 3,5-bis(9-carbazolyl)tetraphenylsilane (SimCP), and bis(3,5-di(9H-carbazol-9-yl) phenyl)diphenylsilane (SimCP2). The molecular structures are shown in Fig. 1. Two 3,5-di(9H-carbazol-9-yl) phenyl groups are attached to Si in SimCP2, which is different from SimCP with only one 3,5-di(9H-carbazol-9-yl) phenyl group.

Of the three materials, we found that SimCP2 host gives external quantum efficiency η_{ext} of 17.7% and power efficiency of 24.2 lm/W at 100 cd/m^2 for FIrpic blue emitter from OLED device with structure of ITO/PEDOT:PSS(35 nm)/14 wt% FIrpic:host(35 nm)/TPBi(28 nm)/LiF/Al [5]. This power efficiency is much higher than 10.4 and 5.9 lm/W in the cases of SimCP and mCP hosts, respectively [5]. Here TPBi means 1,3,5-tris(N-phenyl-benzimidazol-2-yl)benzene, which is used as electron transport layer.

Several papers have reported the EL efficiency of FIrpic doped in CBP, mCP, and SimCP hosts. For example, 8.9 lm/W (η_{ext} = 7.5%) and 7.7 lm/W (η_{ext} = 6.1%) were obtained from devices of ITO/CuPc/α-NPD/6%FIrpic:host/BAlq/LiF/Al with mCP and CBP hosts, respectively [6], 9.3 lm/W (η_{ext} = 12.3%) and 12.9 lm/W (η_{ext} = 14.4%) from devices of ITO/α-NPD/7%FIrpic:host/TPBi/LiF/Al with mCP and SimCP hosts [7], and 13.3 lm/W (η_{ext} = 10.4%) from device of ITO/TNATA/α-NPD/7%FIrpic:mCP/13%FIrpic:mCP/Bphen/LiF/Al [8]. To our knowledge, there have been no previous reports of EL efficiency higher than 24.2 lm/W and 17.7% which were obtained using FIrpic doped in SimCP2 host. Very high external quantum efficiency of 43.3% was recently reported using FIrpic doped in mCP [9]. However, its device structure is quite different from previous ones, e.g., tandem white OLED structure which has two EL units connected with a charge generation layer and two emitting layers. Green–red emitting (fbi)$_2$Ir(acac) (0.75 wt%) is codoped with FIrpic (6.5 wt%) in mCP host

to obtain white emission from the emitting layer. Therefore we cannot compare this case with the case of blue emission from FIrpic doped in SimCP2.

The present paper attempts to clarify the reason why the SimCP2 is a novel host material for blue emitter. We report not only thermal and electrical properties but also spectroscopic property of SimCP2, because the optical property of SimCP2 is unknown. Comparison with mCP and SimCP is also presented.

2. Experimental method

SimCP2 was synthesized as follows. Bis(4-(3,5-dibromophenyl) diphenylsilane) (4.17 g and 6.4 mmol) [10]) and carbazole (5.34 g and 30.7 mmol) were dissolved in dry xylenes (40 mL) containing potassium carbonate (12.72 g and 92.0 mmol) and palladium acetate (0.057 g and 0.25 mmol). After the injection of tri-tert-butylphosphine (0.20 mL and 0.8 mmol), the resulting mixture was stirred for 16 h at refluxing temperature under the protection of nitrogen atmosphere. After cooling to ambient temperature, the reaction was quenched with excess water (100 mL). The mixture was extracted with dichloromethane. The organic phase was washed with water and dried by magnesium sulfate. After the removal of magnesium sulfate, the mixture was evaporated to dryness and the residual was subjected for flash column chromatography (silica gel, dichloromethane/hexanes, 2/8). The product was isolated as a white powder and became a faint yellow glassy solid after sublimation.

The glass transition temperature was measured with a differential scanning calorimetry (Perkin–Elmer DSC-6) method. The highest occupied molecular orbital (HOMO) energy was measured with a Riken Keiki AC-2 photoelectron emission spectrometer. The carrier mobility was measured with the time of flight (TOF) method that has been described before [11].

For optical study, thin films of neat SimCP2 were prepared by thermal vacuum deposition. The deposition was performed using a high-vacuum thermal evaporator (ULVAC) at a chamber pressure of 10^{-6} Torr. Film thickness of neat SimCP2 was determined by quartz thickness monitor (ULVAC CRTM-6000) and it was 30 nm. Thin films of polystyrene (PS) doped with 3, 5, 10, 15, and 20 wt% Sim-
Fig. 1. Molecular structures of mCP, SimCP, and SimCP2.

CP2 were prepared by spin-coating a dichloromethane solution onto quartz substrates at ambient temperature.

Optical absorption spectra were measured with a Shimadzu UV-3100PC spectrophotometer. The photoluminescence (PL) and photoluminescence excitation (PLE) spectra were measured at various temperatures between 10 and 300 K with a Spex Fluorolog-3 fluorophotometer. The excitation source was a 450 W Xe-lamp. Filters were used to avoid the half and second harmonics of the excitation light.

3. Experimental results and discussion

3.1. Glass morphology, HOMO energy, and carrier mobility

Fig. 2 shows the DSC thermogram of neat SimCP2 film. The glass transition temperature (T_g) was estimated to be 148 °C. It is higher than T_g of mCP and SimCP, which are 55 and 101 °C, respectively [11]. The heat exchange energy related to this phase transition increases on going from mCP to SimCP to SimCP2, i.e., from 0.9 to 1.1 to 1.9 kJ/mol. Although it was not detected for SimCP2 by DSC, the heat exchange energy at the melting temperature also increases on going from mCP to SimCP, i.e., from 33.9 to 82.6 kJ/mol, which are all significantly larger than the heat exchange for the glass phase transition. We have put the sample (SimCP2) under the microscope and heated the sample up to 180 °C. We saw no phase transition (solid to liquid) happened to the sample. From these results, it is concluded that the endothermic signal around 148 °C is due to glass transition and not due to phase transition of melting.

Fig. 3 shows the photoelectron spectra of the neat SimCP2 film. The HOMO energy is estimated as 6.12 eV, which are close to the 6.15 and 6.10 eV HOMO energies of mCP and SimCP, respectively [4]. The photoelectron spectra were also measured at room temperature after the neat film was heated at 70 °C, 120 °C, and 150 °C (Fig. 3), but no change was observed among them.

The neat film, which was kept in open air at room temperature after annealing at 150 °C, shows morphological stability, i.e., neither aggregation nor crystallization was
Fig. 3. The HOMO energy of SimCP2 obtained from the photoelectron emission spectroscopy for neat non-annealed SimCP2 film and neat SimCP2 films annealed at 70 °C, 120 °C and 150 °C.

observed after 60 days when we look the film by eyes. In cases of neat mCP and SimCP films, quick morphology degradation was found after annealing at 70 °C [11]. This indicates that the SimCP2 film is morphologically more stable and more robust to water and oxygen molecules than mCP and SimCP. This is consistent with Fig. 3 which shows that no change occurs in the HOMO energy value between the SimCP2 films unheated and heated at 150 °C. From this result we confirm that high glass transition point is necessary to obtain morphologically stable and uniform amorphous thin films.

Fig. 4 shows example of the TOF curve for electron and hole carriers of neat SimCP2 film with thickness of 220 nm, respectively. The carrier mobility μ is estimated using equation $\mu E = L/t_T$, where E is electric field, L is film thickness, and t_T is transit time which is determined from the log–log plotted curve as shown in inset of Fig. 4. Carrier mobility of electron and hole is plotted against electric field in Fig. 5, and compared with those of mCP and SimCP. Like the cases of various organic semiconductors [12,13], the electron and hole mobility of SimCP2, mCP and SimCP follows the linear relationship with applied electric field (Poole–Frenkel model) when the mobility is log plotted against square root of electric field. The hole and electron mobility in SimCP2 is found to be 4.8×10^{-4} and 2.7×10^{-4} cm^2 V^{-1} s^{-1}, respectively, at electric field of 9×10^4 V cm^{-1}. This indicates that SimCP2 has a balanced bipolarity although the hole mobility is a little higher than the electron mobility. The mobility is higher for SimCP2 than for mCP and much higher than for SimCP. High charge carrier mobility of the material is one of the factors that can reduce the driving voltage of OLED and hence increase the power efficiency (lm/W) of the device.

Based on the Poole–Frenkel model, the mobility at zero-field (called zero-field mobility) is obtained by extraction. Table 1 summarizes the zero-field electron and hole mobility for SimCP2, mCP, and SimCP. For comparison, the mobility is also shown for neat films of CBP [14,15] and N, N′-bis(1-naphtyl)-N, N′-diphenyl-1,1′-biphenyl-4,4′-diamine (α-NPD) [16] in Table 1. The zero-field mobility of SimCP2 is lower than those of CBP, while it is higher than those of NPB and Alq$_3$.

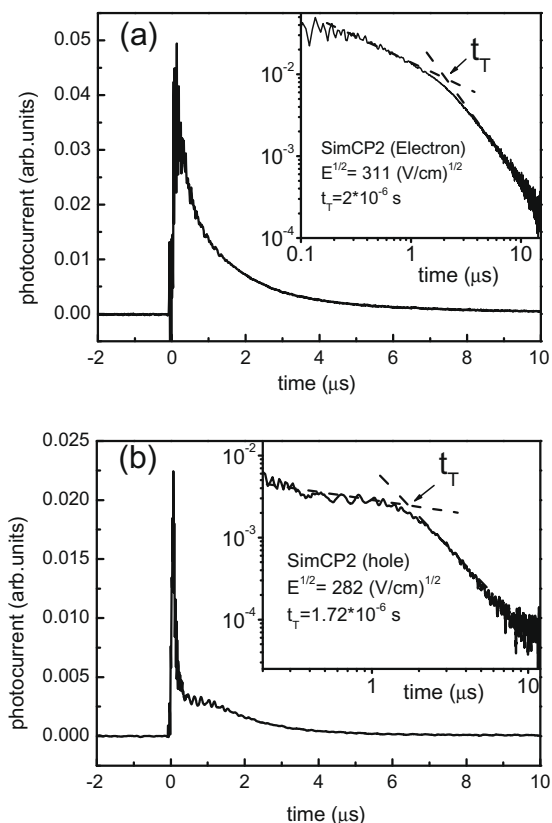

Fig. 4. Example of transient time of flight curves for electrons (a) and holes (b) of SimCP2 measured at electric fields 311 and 282 V/cm, respectively. Inset shows the log–log plotted curve.
Fig. 5. Plot of electron and hole mobilities of SimCP2 against the electric field, compared with those of mCP and SimCP.

3.2. Spectroscopic properties

Fig. 6 shows absorption and emission spectra of SimCP2 diluted in dichloromethane (CH_2Cl_2) solution and absorption spectrum of neat SimCP2 film at room temperature. Similar absorption spectrum was also obtained from SimCP2 diluted in chloroform ($CHCl_3$) solution. Absorption peaks due to SimCP2 molecule are observed at 339, 325,

Table 1
Zero-field mobilities, μ_{oh} and μ_{oe} for holes and electrons, respectively, in neat SimCP2, mCP, SimCP, CBP, and α-NPD films.

	μ_{oh} ($cm^2\,V^{-1}\,s^{-1}$)	μ_{oe} ($cm^2\,V^{-1}\,s^{-1}$)
SimCP2	2.4×10^{-4}	1.3×10^{-4}
mCP	1.2×10^{-4}	3.4×10^{-5}
SimCP	5.8×10^{-5}	5.0×10^{-5}
CBP	3.8×10^{-4} [14,15]	4.4×10^{-4} [14,15]
α-NPD	1.8×10^{-4} [16]	1.0×10^{-5} [16]
Fig. 6. Absorption and PL spectra of SimCP2 in CH_2Cl_2 and absorption spectrum of neat SimCP2 film. Absorption spectrum is cut at $\lambda < 240$ nm for the case of solution because of strong absorption by the solvent.

311, 292, 285, and about 255 nm for the solution. On the other hand, absorption peaks are observed at 342, 328, 313, 296, 290, 240, 227, and 207 nm in the neat film. Two absorption spectral line shapes are quite similar to each other. The emission spectrum consists of three vibronic peaks at 349, 363 and 378 nm where their intensities decrease with decreasing photon energy. This emission is attributed to the S_1 emission, i.e., emission due to electronic transition from the lowest singlet state S_1 to the ground state $^1S_0$.

Fig. 7 shows the absorption spectra of SimCP2 in PS films doped with 5 and 15 wt% SimCP2 and in neat SimCP2 film. The three spectra are quite similar to each other. This
Fig. 7. Absorption spectra of SimCP2 which are measured using PS films with 5 and 15 wt% SimCP2 and using neat SimCP2 film at 296 K.

indicates that no aggregation is formed with increasing concentration of the dopant. We observe the absorption edge (i.e., onset) at about 348 nm (3.56 eV). The lowest unoccupied molecular orbital (LUMO) energy is approximated by the difference of the HOMO energy and the absorption edge of the UV absorption spectra [17–19]. Therefore, from the HOMO energy of 6.12 eV, the LUMO energy of SimCP2 is determined to be 2.56 eV.

Fig. 8 shows the PL and PLE spectra for PS films doped with 3, 15, and 20 wt% SimCP2 at 10 K. The PLE spectra for 370 nm S_1 emission (curves 4 and 5) consist of peaks at 338.1, 324.1, 311.0, and 293.0 nm, which are quite similar to the absorption spectra of Figs. 6 and 7. The PLE bands at 338.2, 325.1, and 311 nm are attributable to the S_1 state.

Intense emission peaks are observed at 343.8, 360.1, and 378 nm for the 3 wt% film, and weak PL bands are observed at 412.2, 433, and 441.8 nm. Like the case of mCP and SimCP [4,11], the latter bands are attributed to the T_1 emission. Although the T_1 emission is enhanced with decreasing temperature, it is too weak to observe clearly for the 20 wt% doped film even at 10 K. It is noted that the T_1 emission intensity decreases with increasing concentration and not observed in neat film (see Fig. 9).

Comparison of the PL spectra among SimCP2, mCP, and SimCP is presented in Fig. 10, where the spectra are normalized at the most intense peak height of the zero-phonon band of the S_1 emission. The spectrum of SimCP2 is quite similar to those of mCP and SimCP. Taking into account that SimCP and SimCP2 consist of one and two mCP molecules, respectively, this indicates that the S_1 and T_1 electronic states of mCP, SimCP, and SimCP2 are determined predominantly by mCP molecule. Difference, however, is found among the three materials, e.g., the vibronic structure in the S_1 emission. The intensity ratio of the one-phonon vibronic band to the most intense zero-phonon band is 0.53, 0.76, and 0.90 for SimCP2, mCP, and SimCP, respectively. The Huang–Rhys parameter (or called Huang–Rhys factor) S is approximately estimated from this intensity ratio [20,21], i.e., $S = 0.53$ for SimCP2.

Fig. 9. Intensity ratio of the 412 nm T_1 emission to the 344 nm S_1 emission at 12 K plotted against concentration of SimCP2 doped in polystyrene.
Fig. 10. PL spectra of mCP, SimCP and SimCP2 at 12 K, which were obtained from the PS films doped with 3 wt% mCP, SimCP and SimCP2, respectively.

The Huang–Rhys factor becomes large with increasing the distance between the equilibrium position $Q(S_1)_0$ of the S_1 electronic excited state and the equilibrium position $Q(S_0)_0$ of the S_0 ground state. The distance becomes large when the electron–phonon coupling in the excited state becomes largely different from the coupling in the ground state [21]. Therefore Fig. 10 suggests that the electron–phonon coupling difference between the S_1 and S_0 states is smaller in SimCP2 than in mCP and SimCP.

Another difference of the PL spectra among SimCP2, mCP, and SimCP is the intensity ratio of the T_1 emission to the S_1 emission. The ratio is approximately estimated from the ratio of intense zero-phonon band intensity of the T_1 emission to that of the S_1 emission, which is 0.08, 0.12, and 0.35 for SimCP2, mCP, and SimCP, respectively. The ratio reflects strength of spin–orbit coupling. Therefore Fig. 10 indicates that the spin–orbit coupling is weaker for SimCP2 than for mCP and SimCP. The weak spin–orbit coupling reduces the rate of intersystem crossing (ISC) from the S_1 state to the triplet states. In the case of FIrpic doped in hosts with high gap energy such as SimCP2, mCP, and

Fig. 8. PL spectra of SimCP2 which are measured using PS films with 3, 15, and 20 wt% SimCP2 excited at 305 nm at 10 K, and PLE spectra of SimCP2 for 370 nm emission which are measured using PS films with 3 and 20 wt% SimCP2 at 10 K.

SimCP, the Förster energy transfer (ET) occurs from the excited singlet state of the host to the singlet state of FIrpic dopant. If the ISC rate is low, we expect high energy transfer to the dopant from competition between two relaxation processes of ISC and ET. Therefore it is suggested that Sim-CP2 host with lower ISC rate gives higher energy transfer rate to the dopant than mCP and SimCP hosts, resulting in higher external quantum efficiency and higher power efficiency for SimCP2 than for mCP and SimCP. This is consistent with the results obtained from FIrpic-based OLED devices that are mentioned in Section 1.

4. Summary

SimCP2. presents the most intense zero-phonon S_1 emission band at 344 nm and the T_1 emission band at 412 nm, which gives 3.01 eV as the T_1 energy. The HOMO and LUMO energies are determined to be 6.12 and 2.56 eV, respectively. High gap energy is also observed for mCP and SimCP. SimCP2, however, is morphologically more stable than mCP and SimCP because of T_g of 148 °C which is much higher than mCP and SimCP, and additionally SimCP2 has higher mobility for both electron and hole (4.8×10^{-4} and 2.7×10^{-4} cm^2 V^{-1} s^{-1}, respectively, at electric field of 9×10^4 V cm^{-1}) than mCP and SimCP. The zero-field mobility is also higher for SimCP2 than for mCP and SimCP. The intersystem crossing rate is smaller for SimCP2 than for mCP and SimCP, leading to higher rate of energy transfer to FIrpic dopant from SimCP2 host than from mCP and SimCP hosts. From these thermal, electrical, and optical properties, we understand that SimCP2 is superior to mCP and SimCP as the host material for blue phosphorescence emitter in OLEDs. The PL and absorption spectra of SimCP2 are not so different from those of mCP and SimCP because they are determined predominantly by the common mCP moiety. However, the glass transition point and morphological stability are quite different. Unlike the case of SimCP, two mCP moieties locate around Si symmetrically in SimCP2. It is suggested that such a molecular structure gives rise to very stable morphology for SimCP2 because molecule with asymmetric structure such as SimCP leads to form aggregation at lower temperature.

2. Experimental

The following configuration was used for device fabrication: indium tin oxide (ITO, 150 nm)/N,N′-diphenyl-N, N′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/N, N′-di(1-naphthyl)-N,N′-diphenylbenzidine (NPB, 20 nm)/4,4′,4″-tris(N-carbazolyl) triphenylamine(TCTA)/TCTA:PH1:iridium(III) tris(2-phenylpyridine)(Ir(ppy)$_3$):iridium(III) bis(2-phenylquinoline) acetylacetonate(Ir(pq)$_2$acac)(x nm)/TCTA:PH1 (5 nm)/2-methyl-9,10-di(2-naphthyl) anthracene (MADN):DAF (30-x nm, 7%)/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, 5 nm)/tris(8-hydroxyquinoline) aluminum (Alq$_3$, 20 nm)/LiF (1 nm)/Al (200 nm). The doping concentrations of Ir(ppy)$_3$ and Ir(pq)$_2$acac were 10% and 0.7%, respectively. The relative composition of TCTA:PH1 in the red/green layer was fixed at 3:1 and the thickness of the red and green emitting layer was 5 and 10 nm, respectively. An interlayer which separates the fluorescent blue emitting layer from the red/green emitting layer was inserted between the two emitting layers and the TCTA:PH1 interlayer compositions were 9:1 and 3:1. The PH1 was supplied from Merck Co. and it had a spirobifluorene backbone structure with good electron transport properties. The highest occupied molecular orbital of the PH1 was 5.9 eV, while the lowest unoccupied molecular orbital was 2.8 eV. A blue device with MADN as the host in the blue fluorescent emitting layer was also fabricated to evaluate the performance of the DAF dopant. The device structure for the evaluation of the DAF dopant in the blue device was ITO (150 nm)/DNTPD (60 nm)/NPB (30 nm)/MADN:DAF (30 nm, x%)/Alq$_3$ (20 nm)/LiF (1 nm)/Al (200 nm). The doping concentrations of the DAF dopant were 3%, 5% and 7%. Fig. 1 shows a schematic diagram of the device structures of the white device and chemical structure of the dopant materials used in this work. The energy levels of the materials were measured by cyclic voltammetry.

The current density–voltage–luminance characteristics and electroluminescence (EL) spectra of the WOLEDs were measured in the normal direction without any outcoupling enhancements using a Keithley 2400 source measurement unit and a CS 1000 spectroradiometer. Lambertian distribution of the light emission was assumed for the measurement of the luminance.

3. Results and discussion

The DAF dopant used in this study had a diphenylaminofluorene emitting core unit combined with a styryl group, and high efficiency could be realized through an extended conjugation structure. In addition, a deep blue color could be obtained due to the wide bandgap of the fluorene group in the backbone structure and the t-butyl blocking group. The device performances of the DAF blue dopant were optimized by controlling the doping concentration of the DAF. Fig. 2 shows the quantum efficiency–luminance curves of the DAF-doped blue fluorescent device. The quantum efficiency of the blue fluorescent device was optimized at a doping concentration of 7%, and a high quantum efficiency of 7.1% at 1000 cd/m^2 was obtained. The quantum efficiency of the DAF device was superior to other blue fluorescent devices reported earlier [10,11], and the use of DAF in WOLEDs can increase their quantum efficiency.

The EL spectra of the blue fluorescent devices with the DAF dopant are shown in Fig. 3. The DAF-doped blue device showed a maximum peak at 459 nm with vibration peaks at high wavelength. Pure deep blue emission was observed from the DAF-doped device and the color coordinate of the blue device was (0.15, 0.18).

The doping concentration of DAF in the WOLEDs was fixed at 7% and a mixed host emitting structure codoped with red and green phosphorescent emitting materials was used. The mixed host emitting structure is advantageous because the charge balance can be controlled easily

by just changing the host composition and charge injection from the charge transport layer [12]. In this study, a mixed host of TCTA and PH1 was used as the host material in the red/green emitting layer. The PH1 host was reported in previous work and has good electron transport properties [12]. The TCTA to PH1 ratio in the red/green emitting layer was optimized to TCTA:PH1 (3:1) as the quantum efficiency of the red/green doped TCTA:PH1 mixed host devices was maximized in the TCTA:PH1 (3:1) device. The doping concentrations of $Ir(ppy)_3$ and $Ir(pq)_2acac$ were 10% and 0.7%, respectively, in order to balance the intensity of red and green emission. The total thickness of the emitting layer was 30 nm and the thickness of the red and green emitting layers were 5 nm and 10 nm, respectively. A mixed layer of TCTA and PH1 was used to control the emission spectra of the WOLEDs, and the interlayer structure was managed to match the color index of the WOLEDs.

Fig. 4 shows the current density–voltage and luminance–voltage curves of the WOLEDs with different interlayer and emitting layer structures. The current density was not affected greatly by the interlayer structure and a similar current density was obtained in the WOLEDs fabricated in this study. The current density is determined mainly by charge injection from the charge transport layers to the emitting layer and the thickness of the organic layers. All devices had the same interface structure between the emitting layer and charge transport layers, and the thickness of the total emitting layer was the same in all devices, resulting in a similar current density. The lumi-
Fig. 4. Current density–voltage–luminance curves of the white organic light-emitting diodes with different interlayer and emitting layer structures.

nance of the WOLEDs followed the same trend as the current density.

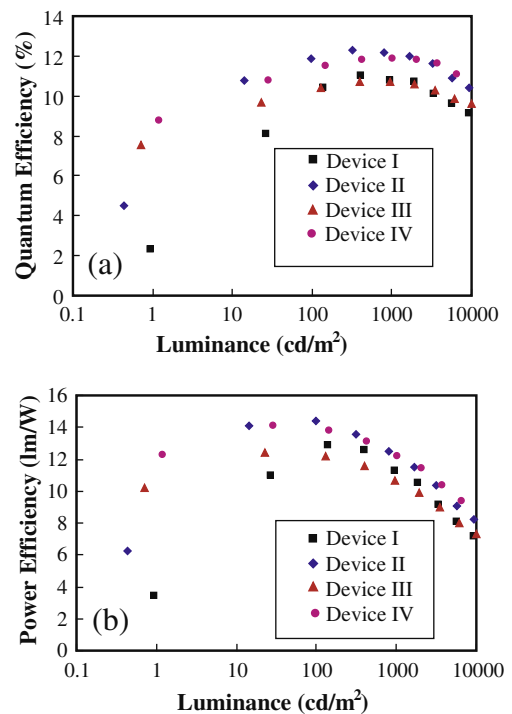
Fig. 5 presents the quantum efficiency–luminance and power efficiency–luminance curves of the WOLEDs. The quantum efficiency was dependent on the interlayer structure, and devices I and III with the TCTA:PH1 (9:1) interlayer showed a lower efficiency than devices II and IV with the TCTA:PH1 (3:1) interlayer. The effect of the emitting layer thickness on the quantum efficiency was not significant. The high quantum efficiency of devices II and IV can be explained by the high quantum efficiency of the


Fig. 5. Quantum efficiency–luminance (a) and power efficiency–luminance (b) curves of the white organic light-emitting diodes with different interlayer and emitting layer structures.

red/green phosphorescent emitting layer. The DAF-doped blue device showed a quantum efficiency of 7.1%, while the red/green device had a quantum efficiency of 13.1%. Therefore, more red/green emission rather than blue emission might improve the quantum efficiency of WOLEDs. The TCTA:PH1 (9:1) interlayer has a strong hole transporting character and shifts the emission zone of the emitting layer from red/green to the blue emitting layer, as shown in Fig. 6. Therefore, high quantum efficiency was obtained in devices II and IV. The quantum efficiency of the devices II and IV were 12.3% and 11.9% respectively.

The power efficiency of the WOLEDs is also shown in Fig. 5. The power efficiency of the device II and IV was higher that of the device I and III due to the high quantum efficiency of the device II and IV. The power efficiency at 1000 cd/m^2 was 12.2 lm/W, which is higher than that of other pure color WOLEDs for display applications [7–9]. Although any p-doped or n-doped charge transport layer was not applied in this work, a fairly high power efficiency was achieved and the power efficiency can be improved over 20 lm/W if high mobility charge transport layer or p/n-doped charge transport layer is used.

The normalized EL spectra of the WOLEDs (Fig. 6) clearly show red, green and blue peaks. The interlayer and thickness of each emitting layer was found to affect the EL spectra of the WOLEDs. The blue emission was intensified in the WOLED with a TCTA:PH1 (9:1) interlayer and a thick blue emitting layer. More holes were injected from the red/green layer to the blue layer using the TCTA:PH1 (9:1) interlayer instead of TCTA:PH1 (3:1) due to the hole transport properties of TCTA, resulting in strong blue emission. The strong blue emission of the device with a thick blue emitting layer was attributed to the high probability of exciton formation in the thick emitting layer. The color coordinates of device I with the TCTA:PH1 (9:1) interlayer and the 25 nm thick blue emitting layer was (0.34, 0.36), which is suitable for display applications. There was a red shift in the color coordinates of the other devices and device IV showed color coordinates of (0.38, 0.38).

The change in the EL spectra of device IV was monitored according to the luminance to determine the color stability of the WOLEDs. Fig. 7 shows the EL spectra of device IV from 150 to 6500 cd/m^2. There was little change in the
Fig. 6. Electroluminescence spectra of the white organic light-emitting diodes with different interlayer and emitting layer structures.
Fig. 7. Electroluminescence spectra of the device IV according to luminance.

spectra according to luminance from 150 to 6500 cd/m^2, even though the blue emission was slightly higher at high luminance. The good color stability of device II originated from the balanced emission zone shift due to the mixed interlayer and mixed host structure in the emitting layer.

4. Conclusions

High efficiency pure color WOLEDs were fabricated for display applications using a high efficiency DAF blue fluorescent dopant. A high quantum efficiency of 12.3% was obtained from the WOLED with the DAF dopant. The WOLED showed pure white color coordinates between (0.34, 0.36) and (0.38, 0.38), which were stable up to a luminance of 6500 cd/m^2.

phthalocyanine CuPc, although they proceed quite high hole mobility values [15,16]. The aim of this study is to compare the obtained results with those reported previously for the interfaces formed between Au and ITO substrates and thin films of other MePcs as well as different organic molecules.

2. Experimental

The experiments were carried out in an ultra high vacuum system, described previously [17]. ITO films on glass substrates with a sheet resistance of $\sim 10 \, \Omega/cm^2$ were ultrasonically cleaned ex situ with ethanol followed by thorough rinsing in deionised water. After this chemical cleaning, in situ Ar ion sputtering (argon pressure of 5×10^{-6} mbar, accelerating voltage of 1 KeV and an incidence angle of 45°) was used in order to remove carbon contamination from the ITO surface. ITO surface was characterized by XPS and UPS. Commercial NiPc and CoPc powders (Alfa Aesar) were thermally evaporated in the preparation chamber, from a home-made deposition source kept at 425 °C and 385 °C, respectively and thin films with total thickness of ~ 10.0 nm were deposited on ITO surface at a vacuum about 5×10^{-8} mbar and room temperature. Each deposition step was followed by XPS (non-monochromatic AlKα source at 1486.6 eV) and UPS (HeI at 21.22 eV) measurements. The spectrometer was calibrated by the Au4f$_{7/2}$ core level peak (84.10 ± 0.05 eV) for clean Au foil. The XPS resolution measured by the full width at half maximum (FWHM) of the Au4f$_{7/2}$ was 1.7 eV for a constant pass energy of 97.0 eV. All XP spectra were fitted with mixed Gaussian and Lorentzian functions after the subtraction of a Shirley-type background. The thickness of the organic film was estimated from the intensity ratio of the substrate XPS In3d$_{5/2}$ and the overlayer C1s peak, assuming a layered-like growth mode for the initial deposition steps. During the UPS measurements, a negative bias of 12.28 V was applied to the sample to separate secondary electrons originating from sample and spectrometer and to estimate the absolute work function value from the Ultra-Violet Photoemission spectra. The overall analyser resolution is determined from the width of the Au Fermi edge (0.16 eV). Therefore, work function and HOMO cut-off positions determined from the high binding energy cut-offs and HOMO onsets of UP spectra were corrected for the analyser broadening by adding 0.08 eV.

3. Results and discussion

Carbon and oxygen species, in the form of OH groups, were the only contaminants detected at the surface of ITO after the ex situ chemical cleaning. The XPS and UPS results showed that both ITO surfaces are identical after the in situ cleaning procedure. After argon ion sputtering the carbon peak was eliminated, while a small amount of hydroxides remained at the surface. For perfectly stoichiometric ITO surface the value of $[O]/(1.5[In] + 2[Sn])$, where $[X]$ is the concentration of species X as determined from the XPS measurement, would equal to one [18]. In the present study, this ratio for the sputtered ITO was

found to be ~ 0.6 and this deviation from unity expresses a deficiency of oxygen atoms at the surface. Furthermore, the total cation content ($[Sn]/[In]$) was decreased from 0.13 to 0.06 after the sputtering procedure. Sn cations are responsible for the conductivity of ITO.

According to the UPS results the work function of the sputtered-clean ITO surface was determined equal to be 4.2 ± 0.1 eV, in good agreement to reported values for similar treated surfaces [19]. The valence band maximum (VBM) was found to be at 1.0 ± 0.1 eV in good agreement with references [20] and considering an energy gap equal to 3.6 eV according to literature [21,22], the position of the Fermi level is closer to the valence band.

Upon the deposition of the organic materials on ITO, the XPS ITO core level peaks (In3d, Sn3d, O1s) attenuate as new XPS peaks (C1s, N1s, Ni2p and Co2p) related to the organic materials (NiPc and CoPc) appear at the X-ray photoelectron wide scan spectrum of the surface (not shown) and their intensity increases as the organic film becomes thicker. In both interfaces, the characteristic peaks of the substrate remain stable in shape and binding energy position until they completely disappear from the spectra after the deposition of a thick organic layer. The core levels (C1s, N1s, Ni2p$_{3/2}$, Co2p$_{3/2}$) of the organic molecules (NiPc and CoPc) are shifted towards lower binding energies as the organic film grows thicker. Fig. 1 shows the change in the binding energy of the XPS C1s peak in both cases (NiPc/ITO and CoPc/ITO), as a function of the organic film coverage. For comparison, the corresponding change of the C1s peak during the formation of the NiPc/Au interface, studied previously, is also traced [23]. According to Fig. 1, the C1s peak in the NiPc/ITO interface exhibits a slight (~ 0.1 eV) shift towards lower binding energies for NiPc coverage up to less than 1.0 nm. Similar behaviour is observed at the CoPc/ITO interface, where the C1s peak exhibits a larger downward shift of ~ 0.5 eV. For thicker organic films the C1s peak remains stable in both interfaces, which indicates the absence of band bending at the organic energy levels. All the XPS MePc related peaks (N1s, Ni2p$_{3/2}$, Co2p$_{3/2}$) exhibit similar behaviour to the C1s peak.
Fig. 1. Energetic shifts of the XPS C1s peak during the formation of the NiPc/Au, NiPc/ITO and CoPc/ITO interfaces.

For the NiPc/ITO interface, the XPS C1s peak for a 5.0 nm thick organic film is located at 284.95 ± 0.05 eV of binding energy and can be resolved into three components according to the different chemical bonds of C atoms in the MePcs molecule. The main peak centered at 284.80 eV is due to the benzene-C atoms. A lower intensity peak at 286.20 eV of binding energy is attributed to the pyrrole-C atoms, while a small contribution from the benzene-C shake up feature which has been suggested to appear at similar binding energy cannot be excluded, although it cannot be resolved experimentally [24,25]. Finally, a shake up feature of the pyrrole-C atoms is found at a binding energy of about 2 eV higher from the main contribution of C–N bonds to the overall C1s peak. Similar results were obtained by the analysis of the XPS C1s peak for a thick (∼5.0 nm) CoPc film.

The XPS N1s peak of the organic film has lower intensity than that of C1s peak because of the atomic ratio N/C (=8/32) in the MePc's molecule. The N1s peak of the NiPc overlayer consists of a broad peak at 399.30 ± 0.05 eV and a weaker feature at higher binding energies. The main peak can be ascribed to the two chemically nonequivalent nitrogen atoms of the organic molecule, separated by about 0.30 eV, but not resolved experimentally, while the weaker peak is attributed to the satellites of the main peak [26]. The $Ni2p_{3/2}$ peak is a unique peak due to C–N–Ni bonds and appears at 855.90 ± 0.05 eV of binding energy [27]. In the case of CoPc/ITO interface the $Co2p_{3/2}$ peak appears at 780.80 ± 0.05 eV of binding energy and is attributed to the bonding between the Cobalt atom and the four central nitrogen atoms in the Pc's molecule [27].

Any covalent chemical interaction between ITO and MePcs is expected to result in the appearance of additional peaks at different binding energies than those observed at the XPS spectra of the bulk materials (ITO, NiPc and CoPc). In the absence of new features in the measured core line spectra and a broadening of the XPS peaks at thinner films compared to the thicker organic layers, we conclude that there is no significant chemical reaction between the oxide substrate and the organic semiconductors.

The observed XPS core level shifts towards lower binding energies occurred at small coverage could be explained by increasing efficiency of intra-layer screening, going from individually adsorbed molecules to a complete layer as the chemical reaction was excluded. The screening of the photohole generated in the organic film at lower coverage occurs mostly by the neighbour organic molecules and less by the weakly metallic substrate, thereby enhancing the screening and thus reducing the binding energy. However, the dielectric constant of the organic molecules is similar to that of ITO indicating that no final state effects are expected [28]. Consequently, the XPS shifts at the MePc/ITO interfaces can be explained only in the context of a possible formation of a dipole layer across the interface at the very first steps of deposition. Comparing the behaviour of the core levels at the above studied interfaces with that observed at the NiPc/Au interface [23], an opposite dependence of the binding energies as a function of the coverage is found, as presented in Fig. 2. The NiPc/Au interface was found to be non-reactive and the initial binding energy shift is attributed exclusively to the decreasing effect of metal screening by the substrate. The photohole which is generated in the organic molecule is screened more effectively near a metal surface at submonolayer coverage, where the screening induced by the other organic molecules is still quite weak, than away from the metal. The further small shift observed at thicker organic films, is attributed to band bending at the organic energy levels. A possible gradual structural rearrangement of the NiPc molecules deposited on Au at thicker coverage, can be ruled out according to recent studies, where core level shifts point towards lower binding energies, which is not the case in the present study [29]. Similar variations of the energetic position of the core levels are also present at the CuPc/ITO and CuPc/Au interfaces for organic film thickness up to 1.5 nm [10,11]. In the case of Au substrate, the final state screening effects significantly affect the binding energy of the core levels which are shifted at ∼0.5 eV towards higher binding energies, while at the CuPc/ITO interface an opposite binding energy shift of ∼0.4 eV is observed and it is attributed to charge transfer from the organic molecules to ITO. This is also confirmed by the broadening of the C1s peak at submonolayer coverage compared to thick layer [10,11,28], which cannot be resolved experimentally in the present study.

By the UPS data, presented in Fig. 2 we can draw additional useful information in order to explain the observed XPS shifts. Fig. 2a and b present the changes of the UP spectra of the NiPc/ITO and CoPc/ITO interfaces respectively, after every deposition step up to ∼10.0 nm of organic film thickness. The full spectra are shown in the centre part of each figure. The bottom spectrum represents the clean ITO substrate where the upper part of the filled valence band including the broad structures at 5.0 eV and 10.4 eV mainly consist of O2p derived levels [30,31]. After the deposition of ∼0.3 nm (∼1 ML) of organic material on the sputtered-clean ITO surface, new features appear at the valence band spectra and upon incremental deposition of the molecular film those of O2p gradually attenuate. The valence band structure of NiPc and CoPc is fully developed at ∼2.0 nm of coverage and exhibits four distinct features at binding energies 1.50 eV, 3.80 eV, 6.60 eV and 8.85 eV in the case of the NiPc overlayer and five main features at 1.25 eV, 2.10 eV 3.55 eV, 6.15 eV and 8.60 eV of binding energy in the case of CoPc, in agreement with theoretical calculations [32]. No other features in the energy range of the UP spectra are observed, which would point to a chemical reaction between ITO and the organic molecules, confirming also the XPS results.

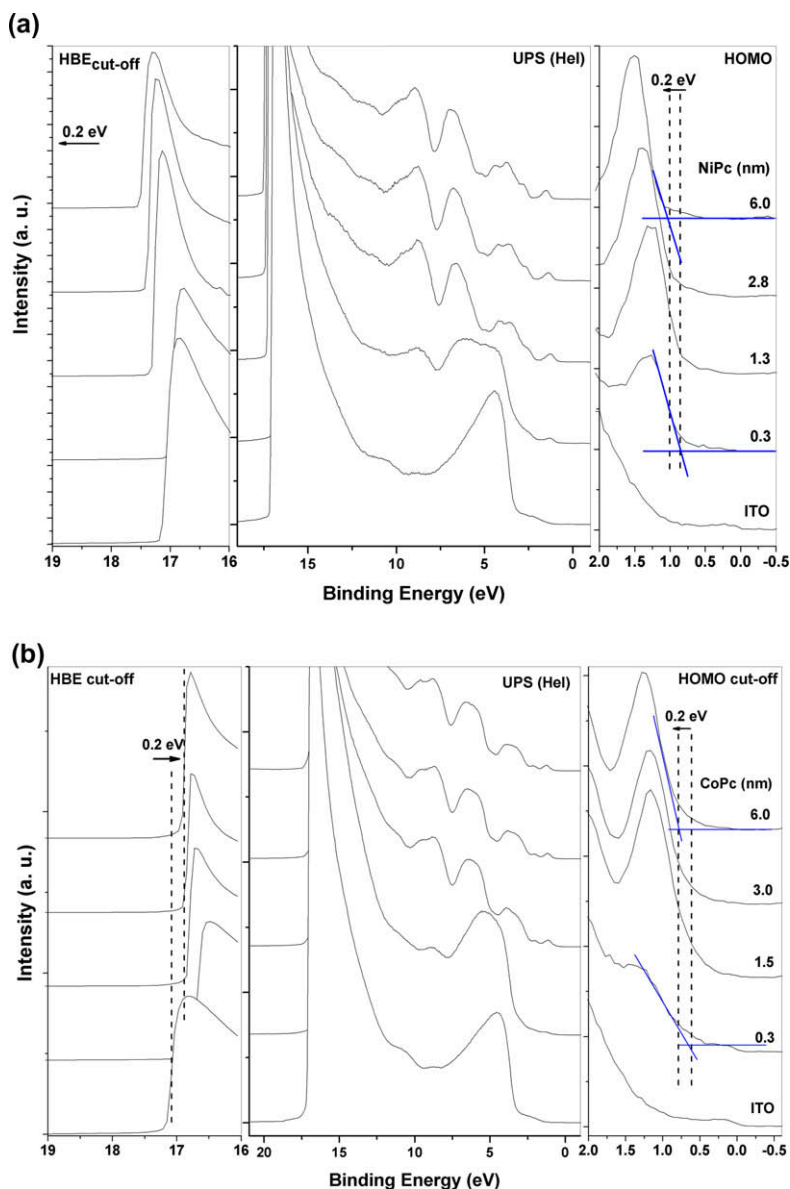
The HOMO (highest occupied molecular orbital) feature of the MePcs is firstly observed at about monolayer coverage as shown in the right part of Fig. 2a and b. As the coverage increases, beyond 1 ML, the HOMO peak is shifted towards higher binding energies for about 0.2 eV in both interfaces, while it appears to be slightly broader with a decreasing organic film thickness. The HOMO$_{cut-off}$ position for the thick NiPc and CoPc layers was found to be at 1.00 eV and 0.80 eV of binding energy, respectively. The thickness dependence of the HOMO peak can be explained by increasing efficiency of intra-layer screening as the coverage increases, since the possibility of an interaction


Fig. 2. HeI UP spectra of the (a) NiPc/ITO and (b) CoPc/ITO interfaces. The full spectra are shown in the center part. On the right part, the development of the HOMO peak and on the left, the high binding energy cut-off regions are shown magnified for clarity.

through charge transfer was excluded by the XPS results [33].

Fig. 2a and b displays the evolution of the UPS during the formation of both interfaces (NiPc and CoPc on ITO). In the case of ITO surface, the work function can be measured by subtracting the total width of the UP spectra from the HeI (21.22 eV) radiation. The width of the spectra is determined by the position of the high binding energy cut-off (HBE), shown at the left part of Fig. 2a and b, in respect to the Fermi level of the analyser. According to these figures, during the deposition of the first few atomic organic monolayers, the HBE$_{cut-off}$ at the NiPc/ITO interface is shifted to higher binding energies corresponding to the lowering of the vacuum level (E_{vac}^F) at the sample surface, while in the case of CoPc/ITO the observed shift

is towards lower binding energies, yielding an increase of the E_{vac}^F. The changes of the vacuum level after every deposition step are shown in Fig. 3. In the same graph, the energetic shift of C1s peak during the formation of the NiPc/ITO interface is also traced for comparison. According to Fig. 3, at the early stages of deposition and up to the completion of one organic monolayer the E_{vac}^F in both interfaces (NiPc/ITO and CoPc/ITO) shows a tendency towards higher values, while for thicker films it changes until it reaches a plateau. At the NiPc/ITO interface there is a total decrease of the E_{vac}^F of 0.2 eV, while in the case of CoPc/ITO interface, the total absolute value for the E_{vac}^F increase is 0.2 eV.

According to Fig. 3, the fact that both the core level shifts and the main change of the HBE cut-off occur up to same organic
Fig. 3. Variation of the high binding energy cut-off region for the NiPc/ITO and CoPc/ITO interfaces as the organic layer increases. In the same graph the energetic shifts of the XPS C1s peak during the formation of the NiPc/ITO interface are also displayed.

coverage, suggests that these shifts should be considered in the context of the formation of a dipole layer across the interface. In addition, we note that the shift in HOMO energy level match the shift in vacuum cut-off energies, which shows that the spectral energy shifts are purely a result of different interfacial dipoles [34].

Several research groups have studied the formation of organic/metals and organic/semiconductor interfaces by surface science techniques and have reached to similar conclusions about the physical phenomena that occur at the interfaces. The Fermi level alignment at organic/metal interfaces can be explained through the formation of an interface dipole (eD) and a possible band bending at the organic energy levels. The formed dipole can be attributed to several reasons such as: (i) charge transfer due to the different values for the work function (Φ), the electron affinity (E_A) and the ionization potential (I) of the organic material, (ii) to the formation of gap states due to chemical interaction yielding the change of the Fermi level position in the gap of the organic semiconductor and, (iii) the modification of the substrate surface dipole due to the presence of the organic molecules [35,36]. Smaller values for the interface dipole are expected at the organic/semiconductor and organic/organic interfaces, where the charge transfer mechanism will be less pronounced or absent, since there are no free electrons or effective density of states, nor surface dipole due to the tailing of the electron cloud towards the vacuum as in the case of metal surfaces [37,38].

In the case of organic/metal interfaces, the surface dipole of a metal is modified by the presence of the conjugated organic molecules. The repulsion between the molecule electrons and the metal surface electrons compresses the electron tail resulting in the decrease of the metal work function. This process leads also to an increase in the distance between the Fermi level and the organic HOMO position which is the barrier for the injection of holes [23,36]. That is the reason why at the organic/metal interfaces we expect higher interface dipoles as well as barriers for hole injection compared to the organic/ITO interfaces.

In the present study, in the absence of chemical interaction between MePcs and ITO as well as the formation of

additional gap states, the observed vacuum level shift should be attributed to the formation of an interfacial dipole layer possibly due to the reduction of the substrate surface dipole. At the NiPc/ITO interface, the total E_{vac}^F change (-0.2 ± 0.1 eV) leads to a dipole of -0.2 eV, while in the case of the CoPc/ITO interface the formatted dipole is $+0.2$ eV due to a total 0.2 ± 0.1 eV increase of E_{vac}^F. The formation of the eD could be explained as a result of a net charge exchange between the MePcs and ITO. In particular, at the NiPc/ITO interface the observed outward pointing dipole (" + " away from the surface) indicates a net charge transfer *from* the NiPc molecules *to* the ITO, while in the case of the CoPc/ITO interface, the downward pointing electric dipole points at a charge transfer *from* ITO surface *to* the organic layer. The dipoles found at the MePc/ITO interfaces (0.2 eV) are considerable smaller than these measured at the NiPc/Au interface (1.0 eV) and this is due to the different chemical character of the substrates, as ITO has significantly less density of states close to the Fermi level compared to a metal like Au and also lower work function value (the work function for the clean polycrystalline Au foil was found to be 5.20 eV). Respectively, at the CuPc/Au interface the interface dipole was found to be (1.2 eV) significantly higher than that in the case of ITO substrate (0.3 eV) due to the pillow effect which affect the metal surface dipole.

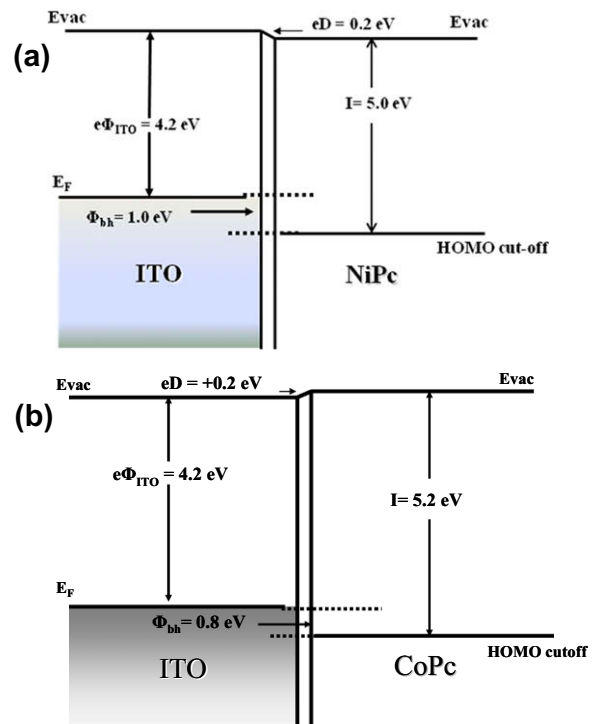
The direction of the dipole formed at the interface is related to the electronic properties of the organic semiconductor. The ionization potential for the NiPc layer was found equal to 5.0 ± 0.1 eV and 5.2 ± 0.1 eV for the


Fig. 4. Schematic energy level diagram deduced from the photoemission measurements for the (a) NiPc/ITO and (b) CoPc/ITO interfaces, considering Fermi level alignment.

CoPc, respectively. The different value of the ionization potential for the two above MePcs, points at different electronic properties between the two organic materials and results in the formation of dipoles with different direction in both studied interfaces.

The hole injection barrier (Φ_{bh}) was also determined at the organic semiconductor/ITO interfaces. In the case of NiPc/ITO interface it is found equal to 1.0 ± 0.1 eV, while at the CoPc/ITO interface 0.8 ± 0.1 eV.

Finally, Fig. 4 summarizes the energy level line-up at the interfaces that NiPc and CoPc form with the ITO-coated glass substrate, as derived by the photoemission results. The determined values for the interface dipole, ionization potential and barrier for hole injection have been added in the diagrams for better comparison between Cobalt and Nickel phthalocyanines. The Φ_{bh} at the NiPc/ITO interface is found 0.2 eV higher than in the case of CoPc. Comparing NiPc/ITO and CuPc/ITO interfaces the Φ_{bh} is found similar ($\sim$1.0 eV). Furthermore, if we consider the interfaces that ITO forms with several other organic molecules (Ooct-OPV5, Alq$_3$, TPD et al.) the Φ_{bh} is found to be significantly lower at the MePc/ITO interfaces, indicating that metal phthalocyanines, can improve the hole injection process when applied as active layer in electronic devices.

4. Summary

The combination of the photoemission results for the study of the interfaces between two metal phthalocyanines and ITO showed that a chemical interaction, as well as a modification of the surface dipole of ITO by the presence of the organic molecules, is excluded. Formation of a dipole layer across the interfaces occurs and the formed dipoles point to different directions as a result of the higher ionization potential determined for the CoPc overlayer compared to the NiPc. The barrier for the injection of holes was found to be lower at the CoPc/ITO interface revealing the beneficial applications of this material compared to other metal phthalocyanines.

insulator interface can be altered by its surface modification for performance improvement of OTFTs [10–12].

Pentacene is a promising organic semiconducting material for OTFTs due to its high mobility and good semiconducting properties. A thermal evaporation-deposited pentacene film on SiO$_2$ surface consists of a substrate-induced "thin film" phase and a "triclinic bulk" phase that can be detected only when its thickness is large enough. The triclinic structure of the pentacene single crystal composes two molecules in a unit cell with lattice parameters of $a = 0.628$ nm, $b = 0.771$ nm, $c = 1.444$ nm, $\alpha = 76.75°$, $\beta = 88.01°$, and $\gamma = 84.52°$ [13], and the pentacene molecules are packed into a layered structure to form a herringbone pattern. Thickness-driven phase transformation from orthorhombic to "triclinic bulk" phase is believed to take place in the thin films [14,15]. However, the modified-layer-driven microstructure transformation of a pentacene polymorphic film at a fixed thickness has not yet been reported. Further, pentacene films on various modified gate insulator surfaces could reveal their polycrystalline structure and morphologies as well. Since the structural change of an organic semiconductor layer in the channel is critical to the OTFTs performance, there is a great need to investigate the growth dynamics and microstructure transformation of a pentacene film caused by modified-layers on the dielectric surface for fundamental insights, leading to further improvement of OTFT performance.

In this work, we fabricated a series of pentacene OTFTs with various interface modified-layers on thermally grown SiO$_2$ gate insulator by using phenyltrimethoxysilane C$_6$H$_5$Si (OCH$_3$)$_3$ (PhTMS) for performance improvement, while investigating the structural phase transformations induced by various modified-layer such as octadecyltrichlorosilane (OTS) and PhTMS on SiO$_2$ gate insulator. For the first time, we experimentally studied effects of the modified-layer on the molecular vibrational modes and structure change of the organic semiconductor. These microstructure transformations might imply the carrier transport improvement in pentacene OTFT devices.

2. Experimental

Top-contact (TC) pentacene OTFTs were fabricated with heavily doped silicon substrates by thermally growing 310 nm SiO$_2$ (SiO$_2$, dielectric constant $k = 3.35$) dielectric layer as the gate electrodes (Fig. 1a). The SiO$_2$/Si substrates were diced followed sequentially by cleaning in sulfuric acid/hydrogen peroxide (7:5 v/v) at room temperature for 45 min, rinsing thoroughly with de-ionized (DI) water, ultra-sonicating for 30 min in acetone and DI water, rinsing and drying under nitrogen. The cleaned substrates were immediately coated with PhTMS or OTS modified-layer via spin coating at a rate of 3000 rps for 30 s. The coating solutions containing 2.3‰ PhTMS and 2.3‰ OTS in toluene (v/v) were used, respectively for spin-coated modifications [16]. The molecular structures of PhTMS and OTS and chemical process between modified-layer and surface of SiO$_2$/Si substrate are shown in Fig. 1b–d, respectively. A 60 nm-pentacene thin film was subsequently deposited under a vacuum of $\sim$10^{-6} Pa at a deposition rate of 0.03 nm/s and room temperature for the substrate. Finally, Au source and drain electrodes (60 nm thickness) were deposited by thermal evaporation through a shadow mask. All devices were fabricated to have an identical channel width and length ratio of $W/L = 570$ μm/57 μm. All electrical characterizations were carried out under ambient conditions using Agilent Semiconductor Analyzer (E5270B) + Cascade probe station.

3. Results and discussions

The output characteristics of the fabricated devices in Fig. 2 show saturation behaviors at high V_{DS} for all devices. Interestingly, the saturation currents are increased remarkably with modified-layers, especially with PhTMS. As shown in Fig. 2c, the output characteristics of the PhTMS-treated OTFT device t display a pronounced curvature at low V_{DS}, indicating the existence of contact resistance (R_C), possibly due to the energy barrier for

carrier injection [17,18]. Fig. 3 illustrates the transfer characteristics of the OTFTs with V_{GS} swept from 10 to −30 V at constant V_{DS} of −20 V. The field-effect mobilities of the OTFTs were calculated in the saturation regime, as shown in Fig. 3b, using the relationship given by [19]

$$\mu_{\text{EF}} = \frac{2L}{WC_i}\left(\frac{\partial\sqrt{I_{DS}}}{\partial V_{GS}}\right)^2 \tag{1}$$

where I_{DS} and C_i are the drain current and the capacitance per unit area of the gate layer, respectively; while W and L

Three-dimensional AFM images of different gate insulators: (a) bare SiO₂/Si substrate, (b) OTS/SiO₂/Si insulator, (c) PhTMS/SiO₂/Si insulator: (d–f) are AFM images of pentacene film deposited on corresponding substrate and their grain size distributions. Pentacene film has an average thickness of 60 nm. The scale bar represents 4 μm × 4 μm.

are device channel width (570 μm) and length (57 μm), respectively.

From Fig. 3a and b electrical parameters of OTFTs including on/off ratio, threshold voltage and sub-threshold swing were extracted and summarized in Table 1. Fig. 3a shows the measured drain current at an applied positive gate voltage from +5 to +10 V. An n-type behavior of pentacene OTFTs is expected, but am-bipolar behavior is not observed because of the large electron-injection barrier from the gold electrode to the pentacene layer. For am-bipolar characteristics of a pentacene device, n-channel operation is only observed in a vacuum [20–22]. Therefore, the measured drain current at a positive gate voltage might come from leaks through gate insulators when the gate and drain current are considered together in Fig. 3a.

After PhTMS treatment, the carrier mobility is 0.32 cm^2/Vs at V_{DS} = −20 V, which is about eleven and three times higher than that without any treatment and with OTS treatment, respectively. This clearly indicates that the dielectric modification could significantly improve the carrier mobility. The sub-threshold slope is also improved to 0.42 V/decade for PhTMS-treated OFETs. Such a mobility improvement is very likely contributed from the matched surface energy and chemical functionality at the pentacene/insulator interface [23]. Static water contact angles were measured to determine the surface energy. The results show that the bare SiO$_2$ typically has a contact angle between 20° and 25°, while OTS- and PhTMS-treated SiO$_2$ have contact angles between 75° and 80° and between 55° and 60°, respectively, indicating that the surface energy of the PhTMS-treated SiO$_2$ is lower than that of bare SiO$_2$ (59.27 mJ/m^2), but higher than that of OTS-treated SiO$_2$ (28.12 mJ/m^2), and is very close to that of pentacene films (43 mJ/m^2) [24,21]. Thus during preparation, covalent bonds can form through reactions between surface [–OH] groups on the SiO$_2$/Si surface and [–Cl, –OCH$_3$] groups of OTS and PhTMS. Fig. 4 shows the bonding structure between the molecule and the substrate surface, in which the molecular length is calculated through chemical bond length. After formation of a pre-stretched configuration with the substrate, it is possible to modify the interface by tuning the surface terminal group (–C$_{18}$H$_{37}$, –C$_6$H$_5$) of the modified-layer. The matched surface energy and surface terminal group could improve the crystallization of pentacene thin films, thereby, enhancing the device performance [25].

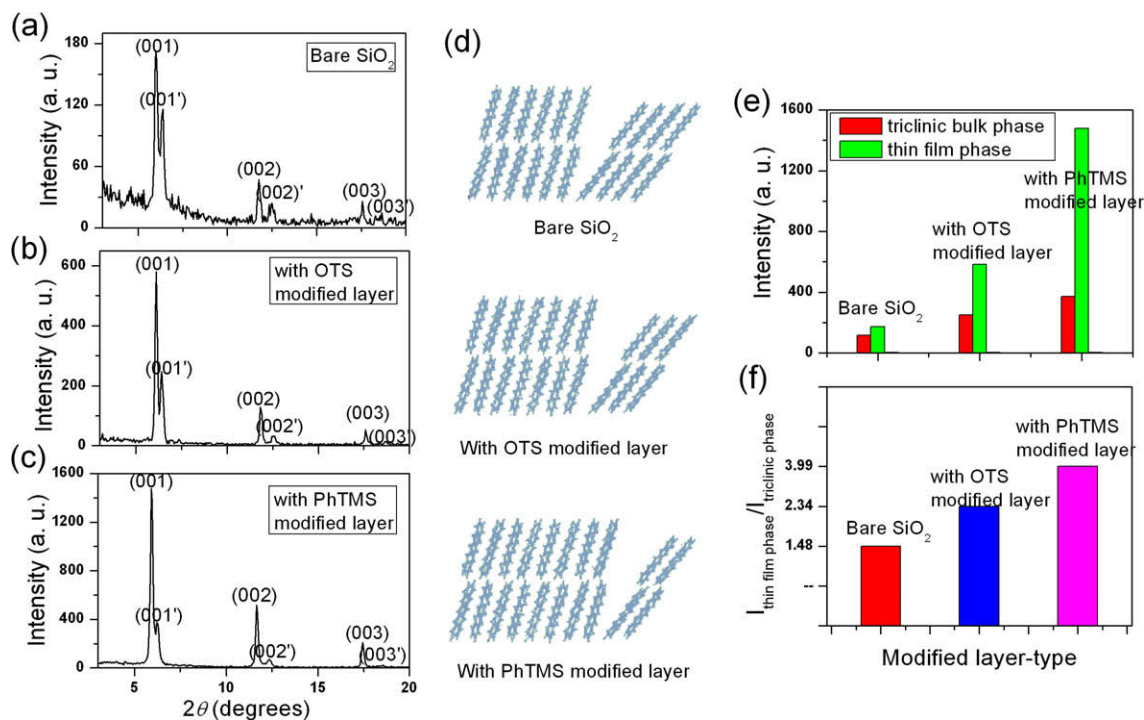
Roughness of the gate insulator surface is reported to affect the carrier mobility greatly [21]. AFM was used to investigate the effect of the dielectric surface roughness on the morphology of the grown pentacene film and the device performance. The measured three-dimensional AFM images of SiO$_2$ gate dielectric surface with different modified-layers shown in Fig. 5a-c illustrate identical smooth surfaces with the root-mean-square (RMS) roughness (R_q) in the range of 0.3–0.6 nm, which is very comparable to the thermal SiO$_2$ surface ($R_q \approx 0.4$ nm). Hence, the possibility of effects of the surface roughness of gate insulators on the morphology of the pentacene thin film and OTFT performance can be excluded for the performance improvement.


Fig. 6. XRD patterns of pentacene on treated-SiO$_2$/Si substrates with various modified-layers, (a) bare SiO$_2$/Si; (b) with OTS; (c) with PhTMS; (d) corresponding growth model of petancene thin films; (e) diffraction peak intensities of "thin film" and "triclinic bulk" phase and (f) the ratio of diffraction peak intensities between $I_{thin\ film}$ and $I_{triclinic\ bulk}$ of pentacene films on corresponding substrates.

However, the AFM morphologies of the pentacene thin films deposited onto these physically identical gate insulator surface (Fig. 5d–f) exhibit distinct features. On PhTMS/SiO$_2$/Si gate insulator, pentacene grains have a dendritic structure with significantly larger grains than others while having a broad size distribution range from 100 nm to 1.3 μm and each grain displays a layered structure (a series of terraces are shown in Fig. 5f). However, a dramatic morphological change with an observed large number of small grains with the size distribution from 100 nm to 600 nm appears in the pentacene film on OTS/SiO$_2$ gate insulator, as shown in Fig. 5e. Normally, the OTFT performances, particularly the carrier mobility, can be considerably improved when the grain size of the semiconductor increases, while significantly decreased with small grain size because of more grain boundaries as trap sites of charge in polycrystalline and small-molecule organic semiconductor [26,27]. This may explain why the mobility is greatly enhanced particularly by PhTMS modified-SiO$_2$/Si

gate insulator (Fig. 5f). For more deep scientific insight, the effect of the dielectric layer modification possibly indicates that the surface modified molecules enhance the favorable crystal packing and the texture with all grains oriented into the [0 0 1] direction, approximately perpendicular to the substrate for a high degree of intermolecular π-orbital overlap in the plane of the film, thus boosting the carrier mobility [28].

4. Growth model and structure phase transformation of pentacene films

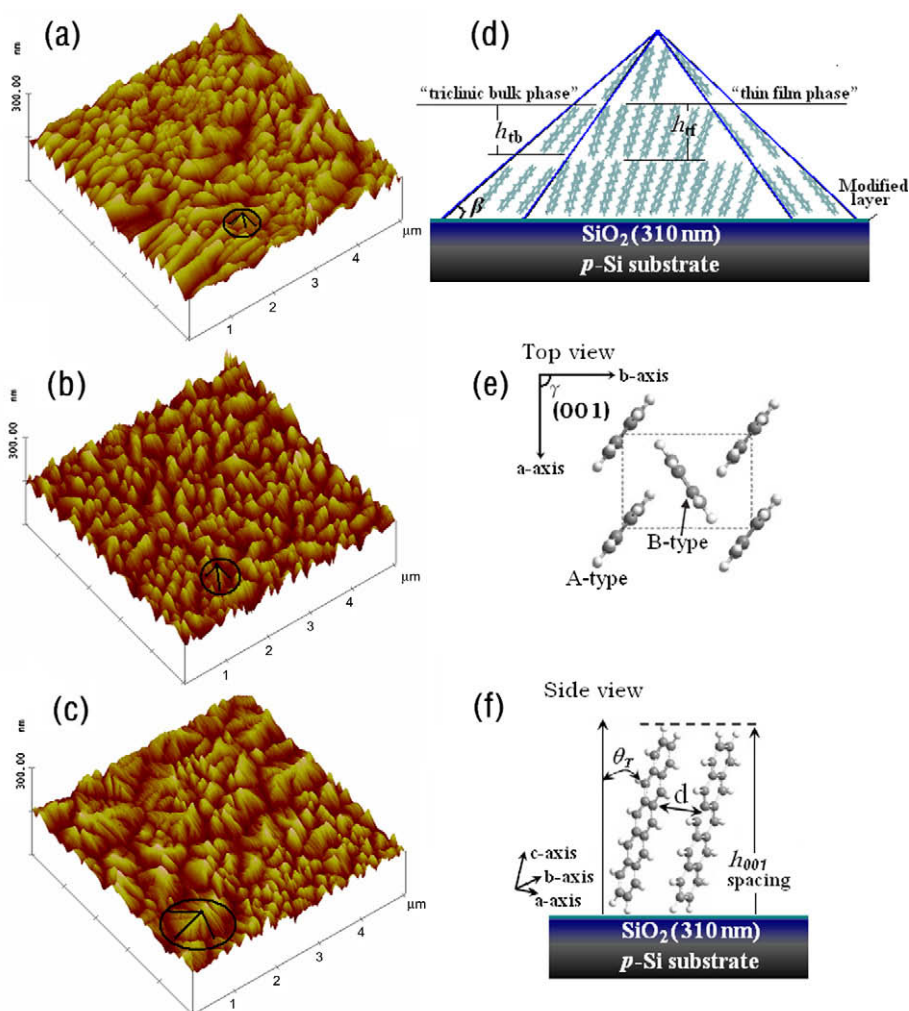
To form the solid phase (for example "thin film" or "triclinic bulk" phase) in pentacene films [29–32], pentacene molecules are arranged in a herringbone pattern with the molecule's center at (0, 0, 0) and (1/2, 1/2, 0) (see Figs. 5 and 7e [15]). The intermolecular bonding in pentacene is a result of the dipole–dipole interactions and weak van der Waals interactions. Consequently, it can be reasonably


Fig. 7. Three-dimensional AFM images of pentacene film deposited on different gate insulators: (a) bare SiO$_2$/Si, (b) OTS/SiO$_2$/Si, (c) PhTMS/SiO$_2$/Si insulator (d) the growth model of pentacene on various substrates, (e) Normal top view of the a–b planes of thin-films pentacene and (f) the side view. On SiO$_2$ substrate, grains are oriented with the a–b plane parallel to the substrate.

assumed that d varies with various modified-layers between pentacene and gate insulators. The d value could be derived from the in-plane lattice parameters (a, b, γ) and the tilt angle (θ_T) of pentacene moleculeusing [33]

$$d^2 = \frac{1}{4}(\cos\theta_T)^2[(a\sin\gamma)^2 + (b - a\cos\gamma)^2] \quad (2)$$

The in-plane lattice parameters of pentacene in its "thin film" phase $(h_{001} = 15.4\,\text{Å})$ were reported as $a = 5.77\,\text{Å}$, $b = 7.49\,\text{Å}$, and $\gamma = 91.2°$. Based on the h_{001}-spacing and the length of the pentacene molecule (ca. 16.2 Å), the θ_T could be derived (see also Fig. 7) [34].

The pentacene molecules grown on the SiO_2 surface are packed into a layer structure with a herringbone pattern as shown in Fig. 5d, which is further confirmed by XRD measurements (Fig. 6a) that the films consist of a dominant phase with a first-order diffraction peak of 5.91° corresponding to an h_{001}-spacing of 15.4 Å, attributed to the "thin film" phase, and also a secondary phase with a second-order diffraction peak of 6.32° corresponding to an $h_{001'}$-spacing of 14.5 Å, ascribed to the "triclinic bulk" phase. The intensity of XRD spectrum for bare SiO_2 seems low (<200 counts). It is possibly due to larger mismatch of surface energy between pentacene and SiO_2 gate insulator [32].

As shown in Fig. 7f, after OTS and PhTMS modified-layer treatment, the tilt angle (θ_T) of pentacene molecule from c-axis toward a-axis in lattice unit cell is decreased, resulting in the gradual transition from the "triclinic bulk" to the "thin film" phase (see Fig. 6b–d). The diffraction peak intensities of the "thin film" and "triclinic bulk" phase and their ratio for different substrates are shown in Fig. 6e and f. It is known that the "thin film" phase of pentacene is high mobility phase. Therefore, the performance improvements of OTFTs with the various modified-layer treated-SiO_2 insulators are mainly due to the modified-layer-driven microstructure transformation of pentacene polymorphic films and the separation distance between adjacent pentacene molecules is reduced. It is necessary to maximize the value of l (l, reflecting the strength of intermolecular electronic interactions between adjacent molecular) while the reorganization energy (E_l) has to be low and to ensure efficient carrier transport in pentacene films [35], which already was proved by Sancho-Garcia and Olivier et al. [36,37].

Based on the experimental results and analysis above, a growth model of pentacene on various substrates is proposed as shown in Fig. 7d. At the early stage of growth, the pentacene tends to assembly vertically on the substrate to form the orthorhombic phase [37]. With formation of the grains, the grain boundaries are gradually produced along with the grain steep hillsides. Then, the pentacene grows on the inclined plane, leading to a increased θ_T as shown in Fig. 7f. The "thin film" and "triclinic bulk" phase of pentacene films could form at a higher thickness level [38,8], and the unit cell of the crystal contains two pentacene molecules (see Fig. 7e).

5. Conclusions

In a brief, PhTMS was used to modify SiO_2 insulator and significantly enhanced the pentacene based OTFTs. The experimental results show a decreased tilt angle (θ_T) of pentacene molecules from c-axis toward a-axis after the modification of SiO_2 insulator, indicating that polymorphs transformation from the "triclinic bulk" phase to the "thin film" phase and orthorhombic phase occurs. The results provide strong evidence that the performance improvement of OTFT after PhTMS modification is related to the microstructure transformation of the semiconductor. It suggests that the modified-layer may alter the molecular geometry and further induce structural phase transitions in the pentacene films for the performance improvement.

Inverse photoemission spectroscopy (IPES) is one of the frequently used techniques to determine directly the electron affinity in solids [3]. This gives electron transport level, namely, the LUMO (lowest unoccupied molecular orbital level) level occupied by one electron and the HOMO is filled. Exciton level, namely, LUMO level occupied by an electron which is bound to the hole in the HOMO level is the optical transition energy determined by absorption/emission spectroscopy. However concern has been raised on the large exciton binding energies in organic solids which makes the transport level and exciton level to be different [4]. It is of interest to compute all the energy levels for organic solids by a method of calculation uniformly applied to a wide variety of molecules and compare with experimental values. In a recent report electron affinity of isolated molecule was computed theoretically and compared with the value in solid state with an assumption that 'solid state effect' is same for all molecules [4]. This assumption may not hold well for a wide range of molecules that are used in organic electronics. For example, polarization energy of organic molecules in solid state can vary from 0.9 eV to 3.0 eV [5,6]. Thus, a realistic modeling of solid state effect in theoretical calculations is required. The calculation must take into consideration distribution of charge in the molecule and 'solvation' of the molecule in solid by molecules of its own type. In this context, polarizable continuum model (PCM) is shown to be successful in recent studies [7–9].

In a recent paper [9], we reported calculation of ionization potential (HOMO level) in solid state using (density functional theory) DFT and PCM. In continuation of the previous work, a method is now described to determine the electron affinity of organic molecules in solid state using DFT and PCM. We show that the computationally determined EA for 13 organic molecular solids agree well with the experimental values, validating the proposed method. In addition to the determination of EA, we also discuss calculation of the optical band gap, transport gap (E_t) and exciton binding (E_b) energies of the molecules. An important feature of our method is that no experimental data for the molecule, other than the molecular structure, is required to determine the EA value in solid state.

2. Methods of computation

Thirteen organic molecules, for which experimental values of electron affinity of solid films are known, were chosen for this study. Density functional theory (DFT) was used in all the calculations using Gaussian03 [10]. The DFT method used here is based on the hybrid B3LYP functional [11]. The geometries of all the molecules were optimized at 6-31G (d) basis functions. Molecular cavity for polarizable continuum model (PCM) was built by following the new definition using united atom model [12], i.e., by putting a sphere around each atom except hydrogen. Hydrogen atoms are enclosed in the sphere of the atom to which they are bonded.

The molecule in solid was considered as solvated by molecules of its own type. The solvent in the PCM calculation is defined by the dielectric constant, the number of solvent molecules in unit volume and radius of the molecule. Following methods were used to obtain these values. The dielectric constant, ε was obtained by Clausius–Mossotti equation

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4\pi}{3} \frac{\rho}{M} N_A \alpha,$$

where ρ, M, N_A and α are the density of material, molecular mass, Avogadro number and the electronic polarizability, respectively. $\rho N_A / M$ is reciprocal of the molecular volume. Molecular volume was obtained at 6-31G (d) level (tight option was taken in all the calculation for better accuracy). Isotropic polarizability (at zero frequency) of molecules was calculated for the optimized geometry of the molecules at 6-31G (d) level. Radius of the molecule is defined as the radius of a sphere which has equivalent volume of the concerned molecule.

Single point energy of the molecule was calculated at 6-311++G(d,p) level with PCM, The single negative state with the same molecular geometry of the molecule was also calculated using same basis set and PCM. The difference in energies gave the vertical electron affinity in the solid state. Single point calculation of the molecule is also done without PCM, which gives the gas phase electron affinity. Ionization potentials in the solid state were also determined using the method reported earlier [9]. Singlet optical transition energy was calculated using time-dependent density functional theory (TD-DFT) at 6-311++G(d,p) level and PCM. Singlet optical transition energy for isolated molecule was also determined using TD-DFT at the same basis set level.

3. Results and discussion

Fig. 1 shows the molecular structures for 13 organic molecules, which are commonly used in organic electronics for different purposes. In organic solids, molecules are solvated by the molecules of its own type. The solvent is modeled as an isotropic, continuous dielectric that surrounds a solute cavity. This simple model is appropriate for amorphous and glassy solid films. Though experimental values of dielectric constant and density for some molecules in solid state are known, we used consistently the calculated values for dielectric constant and molecular volume, so that calculation can be done for any new molecule without reference to the experimental value.

Table 1 shows the calculated values of dielectric constant, number of molecules in 1000 Å^3, radius of the molecule, EA in gas phase and solid state. Experimental values of EA reported for these molecules in solid state are also given. Fig. 2 shows a plot between calculated and experimental value of electron affinity in solid state. The plot shows an excellent linear correlation. The slope of the fitted line is 1.05 ± 05, the intercept value is 0.05 ± 0.13 and the correlation coefficient $r^2 = 0.988$. This correlation

Fig. 3. Plot of calculated transport gap with experimental values (UPS and IPES) for 13 organic molecules in solid state (see Table 2).

shows that it is possible to determine the electron affinity of organic molecules in solid state within ±0.35 eV, which is the typical error associated with the experimental values.

For the sake of comparison, EA values were calculated for isolated molecules in gas phase, which are also shown in Table 1. It is gratifying to note that the calculated values of EA in gas phase for some of the molecules match well (see Table 1) with the calculated values of adiabatic EA using DFT, reported earlier [13]. These values are also close to the experimental values in gas phase compared therein [13,14]. The large difference between EA value of molecules in isolated condition and solid state shows that the 'solvation' effect on the value of EA is quite substantial.

Ionization potential for the 13 molecules in solid state were determined by a similar method, reported earlier [9]. The difference in EA and IP is the transport gap (E_t) in organic solid (Table 2), which is the energy difference between free electron and free hole levels in organic solid. Fig. 3 shows a linear correlation with near unity slope between experimentally obtained transport gap and computationally determined transport gap. This result shows that calculated IP values are independently in good agreement with experimental values. Transport gap in molecular solids is an important parameter as it gives the minimum

energy required for the formation of a free electron and hole pair.

Time dependent DFT (TD-DFT), together with PCM was shown to be a successful method to compute optical transitions in aqueous and non-aqueous solutions [15]. Thus, lowest energy singlet optical transitions for the 13 organic molecules in solid state were calculated using TD-DFT and PCM as the 'solvation' model. Table 2 shows the lowest optical transition energy (E_{opt}) in solid state as well as the value in gas phase for isolated molecule. The difference in energy between optical transition of isolated molecule and 'solvated' molecule is small (0–0.15 eV). In solids, the optical transition is associated with electronic transition. For the rest of the paper, the lowest energy optical transition is referred to as the optical band gap or exciton level in solids. For all the molecules, calculated optical band gap (E_{opt}) in solid state is less than the calculated transport gap (E_t) and the difference is the exciton binding energy. It may be noted that the exciton binding energy mainly depends on the dielectric constant of the material, molecular size and charge distribution on the molecule. Because of the molecular nature of organic solids and low dielectric constant the binding energy is high for the 13 molecules (0.5–1.7 eV).

Pentacene (planar molecule) and Alq$_3$ (non-planar molecule) are studied extensively for which physical and opti-

cal data are reported. A comparison of calculated and experimental values are as follows. Calculated vs experimental, Pentacene. Dielectric constant: 4.82 vs. 4 [24]; number of molecules per 1000 $Å^3$: 3.02 vs. 2.87 [25], (based on density 1.33 g/cm^3); IP: 5.03 vs. 4.85 eV [5]; EA: 2.63 vs. 2.75 eV [19]; E_{opt}: 1.85 vs. 1.9 eV [26]. Alq_3: dielectric constant: 2.69 and 3.0 ± 0.3 [27]; number of molecules per 1000 $Å^3$: 1.78 vs. 1.68 [28], (based on density 1.282 g/cm^3); IP: 5.82 vs. 5.80 eV [23]; EA: 1.66 vs. 1.96 eV [17]; E_{opt}: 2.83 vs. 2.7 ± 0.1 eV [29]. These molecules are known to be polymorphic crystalline materials. Considering that the experimental values are for crystalline solid and the calculated values are appropriate for amorphous/glassy solid the agreement is reasonable within ±15% for the energy level parameters.

The above results and discussions establish that energy level parameters of organic molecular solids which are important for organic electronics can be calculated with reasonable accuracy using molecular structure as the only input in the calculation. However, precise calculation of energy levels, especially for anion radicals, will require special attention to specific wavefunction associated with the odd electron [30,31].

4. Conclusions

A method is described for theoretical calculation of realistic electron affinity, ionization potential, transport gap, optical band gap (exciton energy) and exciton binding energy of organic molecules in solid state using the DFT, TD-DFT method and polarizable continuum model. This method gives a good estimate of all the energy levels in organic solids. The method requires the molecular structure as the only input and therefore a very useful method to design molecules for organic electronics.

but has been found to improve by two to three orders (300–600 S/cm) by adding high boiling point polar compounds or solvents (diethylene glycol, ethylene glycol, dimethylsulfoxide, sorbitol, mannitol, glycerol) into the solution mixture. The exact reason for the improvement is still unclear, but has been suggested to be linked to changes in the PEDOT morphology and chain interaction [16].

There have been many demonstrations of utilizing PEDOT:PSS as a replacement to ITO as the transparent anode electrode in the conventional device architecture, however, these electrodes show a much lower conversion efficiency compared to ITO due to the lower conductivity of the PEDOT:PSS [17–19]. Recently, it was demonstrated by improving the PEDOT:PSS conductivity through processing with a high boiling point solvent, these organic polymer electrodes could reach efficiencies as high as 3% [3]. The top cathode electrode in these devices is still deposited by high vacuum which makes the processing less ideal for low-cost solar cells. To avoid using high vacuum to deposit the top electrode, an inverted architecture can be used which uses a high work function metal anode (Ag, Au) to collect holes and an metal oxide (TiO_2, ZnO) as an electron selective layer at the ITO interface to collect electrons. Previously, we have demonstrated that this type of unencapsulated inverted architecture solar cell using an evaporated Ag electrode stored 40 days in ambient retains over 80% of its conversion efficiency [20]. Furthermore, we demonstrated the possibility to utilize non-vacuum solution processible Ag nanoparticles as the top electrode in inverted solar cells by spraycoating leading to efficiencies as high as 3% [21]. It has already recently been demonstrated that PEDOT:PSS can also be used as the replacement anode electrode (energy level of −5.1 eV) in inverted solar cells by spraycoating the polymer. However, due to the thick films formed from spraycoating, the electrodes are non-transparent and require high vacuum to remove excess moisture to improve the performance [22]. There have been currently no studies on utilizing PEDOT:PSS as a replacement cathode electrode to replace ITO as the transparent charge collecting contact in inverted solar cells.

This letter reports on the replacement of the ITO transparent conducting oxide electrode with a solution processible PEDOT:PSS electrode as the electron collecting cathode in inverted solar cells. The thickness of the PEDOT:PSS electrode was varied showing that the thickness can affect both the transparency and sheet resistance of the electrode

and therefore the final performance of the solar cell. These electrodes were also applied to flexible polymer substrates showing similar performance to glass substrates. These inverted flexible substrate PEDOT:PSS electrode devices show ∼20% lower in conversion efficiency compared to ITO based flexible substrate inverted devices. Cyclic bending tests were performed on these flexible substrates showing slight performance degradation from the PEDOT:PSS based electrodes while the ITO based electrodes show significant degradation after 300 bend cycles. PEDOT:PSS was also used to replace the anode Ag electrode in ITO based inverted solar cells demonstrating a semi-transparent solar cell. The semi-transparency of these cells allows for new potential power generating applications such as solar windows or other applications that require semi-transparency. Additionally, both the top anode and bottom cathode electrodes were replaced with PEDOT:PSS demonstrating a completely solution processed semi-transparent inverted solar cell.

The inverted device architectures that were used in this study are shown in Fig. 1. To fabricate the ITO electrode based inverted solar cells, ITO-coated glass substrates (15 Ω/□) and ITO-coated plastic substrates (60 Ω/□) (Bayview Optics) were cleaned with detergent, de-ionized water, acetone, and isopropyl alcohol. A thin layer of ZnO nanoparticles (ZnO-NPs) (∼50 nm), synthesized using the method described by Beek et al. [23], was spin-coated onto ITO-coated glass. A monolayer of C_{60}-SAM was then deposited as previously reported to improve the contact properties between the metal oxide and the active layer. [24,25]. Afterward, a chlorobenzene solution of poly(3-hexylthiophene) (P3HT) (Rieke Metals) and [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM) (American Dye Source) (60 mg/ml) with a weight ratio of (1:0.6) was spin-coated on the ZnO modified layer to achieve a thickness of (∼210 nm) and annealed at 160 °C for 10 min in an Ar filled glovebox. After annealing, PEDOT:PSS (CLEVIOS^{TM} P VP Al 4083) was spin-coated onto the active layer to achieve a thickness of ∼50 nm and annealed for 10 min at 120 °C. The silver electrode was vacuum deposited (100 nm) at a pressure of 1×10^{-6} torr to complete the device. For PEDOT:PSS electrode based inverted solar cells, glass and plastic substrates were cleaned with detergent, de-ionized water, acetone, and isopropyl alcohol. The substrates were treated by O_2 plasma for 2 min to improve wettability of the PEDOT:PSS solution. A solution of PEDOT:PSS (CLEVIOS^{TM} PH500) with the addition of 5% DMSO was sonicated
Fig. 1. Device architectures of the inverted solar cells using various cathode and anode electrodes.
Fig. 2. Transparency vs. wavelength of varying thicknesses of PEDOT:PSS – 5% DMSO electrodes on glass as compared to transparency of ITO on glass as referenced against air. Legend also indicates corresponding sheet resistances obtained as measured by 4-point probe.
Fig. 3. Illuminated *J–V* characteristics of functioning inverted devices fabricated on ITO substrates with an ~80 nm PEDOT:PSS CLEVIOS™ P VP Al 4083 or CLEVIOS™ PH500 with 5% DMSO inserted between the ITO and ZnO-NPs as compared to inverted devices with only ITO and ZnO-NPs.

for 5 min prior to use. For the first layer (~40 nm), the PEDOT:PSS solution was spin-coated onto the O$_2$ plasma treated substrates at 7 krpm for 30 s and annealed at 120 °C for a 2 min. Subsequent PEDOT:PSS layers were spin-coated at 2 krpm for 20 s and annealed at 120 °C for a 2 min to achieve the desired thickness (~130 nm, ~175 nm, ~220 nm). The final PEDOT:PSS layers were annealed for 10 min at 120 °C prior to depositing the rest of the layers as described in the ITO-based devices to complete the device. To deposit the top PEDOT:PSS anode electrodes for the semi-transparent devices, a patterned PDMS stamp was pressed onto the substrates of the top buffer PEDOT:PSS (CLEVIOS™ P VP Al 4083) and heated at 120 °C for 30 s. Afterwhich, the sample was removed from the hotplate and the PDMS stamp was peeled off removing only the PEDOT:PSS from the active layer in contact with the stamp leaving behind a patterned PEDOT:PSS layer. Solutions of the PEDOT:PSS and DMSO were spin-coated at 3–5 krpm which coats only the area with the patterned PEDOT:PSS. Multiple PEDOT:PSS layers were built up by annealing the layers at 120 °C for 2 min prior to spincoating the next layer. The unencapsulated solar cells were tested under ambient conditions using a Keithley 2400 SMU and an Oriel Xenon lamp (450 W) with an AM1.5 filter. A mask was used to define the device illumination area of 0.0314 cm^2 to minimize photocurrent generation from the edge of the electrodes [26,27]. The light intensity was calibrated to 100 mW/cm^2 using a calibrated silicon solar cell with a KG5 filter which has been previously standardized at the National Renewable Energy Laboratory.

To evaluate the possibility for using PEDOT:PSS as a transparent electrode to replace ITO, both the transparency and sheet resistance of different thicknesses of PEDOT:PSS processed with DMSO were measured. Fig. 2 shows the transparency as measured by UV–Vis spectroscopy of various thicknesses of PEDOT:PSS on glass substrates referenced against air which were compared to ITO-coated glass substrates. A PEDOT:PSS layer that is ~130 nm thick has comparable transparency to the ITO-coated glass substrate. However, the sheet resistance of the PEDOT:PSS layer as measured by four point probe is ~25 times higher than that of ITO (15 Ω/□). Thicker PEDOT:PSS layers show a reduction in sheet resistance to as low as 160 Ω/□ with a
Fig. 4. (a) AFM image of ~130 nm PEDOT:PSS – 5% DMSO layer coated onto glass. (b) AFM image of ZnO-NPs spin-coated on top of the PEDOT:PSS – 5% DMSO electrode.

~220 nm thick film, but also show a decrease in transparency due to the absorbance from the PEDOT:PSS film.

Replacement of ITO electrode with PEDOT:PSS as the anode has already been demonstrated in conventional architecture devices, but there has not been any study utilizing it as a cathode to collect electrons. To assess the feasibility of using PEDOT:PSS as a cathode, inverted solar cells were fabricated by spincoating a thick ~80 nm PEDOT:PSS layer from CLEVIOS™ P VP Al 4083 or CLEVIOS™ PH500 with 5% DMSO onto ITO-coated glass substrates prior to spincoating the ZnO-NPs electron selective layer followed by the rest of the device layers as described in the experimental section. Interestingly, the inverted solar cells with the PEDOT:PSS inserted between the ITO and ZnO-NPs layers behaved similarly to devices without the PEDOT:PSS layer as can be seen by Fig. 3. It has already been shown in literature that the interface contact between the heavily p-doped PEDOT:PSS and the unintentionally heavily n-doped ZnO in solar cells can be ohmic leading to minimal energy losses and minimal degradation of the voltage in the cell [28]. From this result and finding, "ITO-free" inverted solar cells using PEDOT:PSS as the cathode and ZnO-NPs as the electron selective layer were investigated. An atomic force microscopy image of a ~130 nm PEDOT:PSS film on glass in Fig. 4a shows a relatively smooth topography having a surface roughness of 1.7 nm RMS. Fig. 4b shows a much rougher surface topography (4.1 nm RMS) and different morphology after spincoating the ZnO-NPs on top of the PEDOT:PSS layer signifying that the ZnO-NPs layer is coated on top.

The illuminated J–V characteristics of the inverted solar cell devices fabricated with different electrode PEDOT:PSS thicknesses as compared to ITO-based devices are shown in Fig. 5a and Table 1 summarizes these device performance parameters. Devices fabricated using a ~40 nm thick PEDOT:PSS as the electrode had a short circuit current (J_{sc}), fill factor (FF), and power conversion efficiency (PCE) of 9.59 mA/cm^2, 39.4%, and 2.32% respectively. Increasing the PEDOT:PSS electrode thickness to ~130 nm lead to an improvement in the overall PCE reaching ~3.08%, however a lowering of the J_{sc} to 9.41 mA/cm^2 while an increase in FF to 53.3% is observed. Electrodes using a ~175 nm PEDOT:PSS film show further decrease in J_{sc} to 8.57 mA/cm^2 while further increasing of FF to 57.2% leading to efficiencies of 2.99%. Increasing the PEDOT:PSS electrode thickness to ~220 nm again shows further lowering of J_{sc} (8.15 mA/cm^2) and improved FF (60.0%) which gives a PCE of 2.98%. This trend of lower photocurrent and increasing fill factor as a function of increasing PEDOT:PSS electrode thickness can be correlated to the lower transparency and reduced sheet resistance with increasing layer thickness. The transparency and sheet resistance of the electrodes are important to consider as they can affect both the photocurrent and fill factor device parameters. The lower transparency leads to a reduction of the potential photons that are able to be absorbed by the active layer therefore leads to lower photocurrent densities. The reduction in sheet resistance minimizes the resistance losses in the solar cells and improves fill factor. With higher sheet resistance, the energy

Table 1

Average device performance of inverted ZnO-NP/C$_{60}$-SAM/P3HT:PCBM bulk-heterojunction solar cells fabricated using glass/PEDOT:PSS, plastic/PEDOT:PSS, glass/ITO and plastic/ITO as the cathode electrode and vacuum deposited Ag as the anode electrode. Average device performance of semi-transparent inverted solar cells using PEDOT:PSS as the anode electrode on glass/ITO and glass/PEDOT:PSS cathode electrodes. Average was obtained from multiple device tests.

Electrode (cathode)	Electrode (anode)	Voc (V)	Jsc (mA/cm^2)	FF (%)	PCE (%)
ITO/glass	Ag	0.62	10.25	66.6	4.20
PEDOT:PSS (∼40 nm)/glass	Ag	0.61	9.59	39.4	2.32
PEDOT:PSS (∼130 nm)/glass	Ag	0.61	9.41	53.3	3.08
PEDOT:PSS (∼175 nm)/glass	Ag	0.61	8.57	57.2	2.99
PEDOT:PSS (∼220 nm)/glass	Ag	0.61	8.15	60.0	2.98
ITO/plastic	Ag	0.61	9.86	61.2	3.73
PEDOT:PSS (∼175 nm)/plastic	Ag	0.62	8.42	57.7	2.99
ITO/glass	PEDOT:PSS	0.61	7.86	52.0	2.51
PEDOT:PSS (∼130 nm)/glass	PEDOT:PSS	0.31	5.49	27.7	0.47

lost from the lateral charge collection through the PEDOT:PSS electrode become much more apparent. This can be observed in PEDOT:PSS devices with ∼40 nm and ∼220 nm films showing an improved fill factor from 39.4% to 60.0% when the sheet resistance was decreased from 2800 Ω/□ to 160 Ω/□. Due to the competing effects of the photocurrent and fill factor, the PCE efficiency of the devices saturates to ∼3% as the thickness of the PEDOT:PSS electrode is increased. Solar cells fabricated from ITO-coated glass substrates had an average PCE of ∼4.20%, J$_{sc}$ = 10.25 mA/cm^2, FF = 66.6% and V$_{oc}$ = 0.62 V which are over 1% higher than the PEDOT:PSS based electrodes. This is due to the higher transparency (∼10% higher) and lower sheet resistance (∼10 times less) as compared to the ∼220 nm thick PEDOT:PSS electrode.

To demonstrate that this PEDOT:PSS electrode can be applied onto flexible substrates, solar cells using a ∼175 nm PEDOT:PSS electrode were fabricated onto plastic substrates. The devices fabricated from the PEDOT:PSS electrode show similar performance (PCE ∼3%) to that of solar cells fabricated onto glass substrates as shown in Fig. 5b. These cells are still however ∼20% lower in efficiency compared to ITO based plastic substrates which have an average PCE of ∼3.7%. Another important consideration for the practicality of flexible electronics which is often ignored is the mechanical stability. The mechanical stability of these flexible solar cell devices was evaluated by subjecting them to a cyclic bending (bend radius ∼7.4 mm) test. Fig. 6a shows the illuminated J–V characteristics of a flexible ITO based electrode device subjected to multiple bending cycles. As the number of bend cycles is increased, a decrease in J$_{sc}$ and fill factor can be observed and eventually even a lowering of V$_{oc}$. This was compared to devices fabricated from the PEDOT:PSS electrodes which show negligible degradation in J$_{sc}$ and V$_{oc}$, but some slight
Fig. 6. (a) Plot of illuminated *J–V* characteristics of inverted devices fabricated from flexible ITO electrode substrates under multiple bending cycles. (b) Plot of illuminated *J–V* characteristics of inverted devices fabricated from flexible PEDOT:PSS – 5% DMSO electrode substrates under multiple bending cycles. (c) Comparison of the normalized power conversion efficiency of devices fabricated from flexible ITO and flexible PEDOT:PSS electrodes as a function of bending cycles.

degradation in fill factor after multiple bend cycles (Fig. 6b). The normalized device efficiency of these electrodes were compared as a function of bending cycles showing a retention of ~92% in the PEDOT:PSS electrodes while only ~50% in the ITO electrodes after 300 bend cycles (Fig. 6c). The improved mechanical stability from the PEDOT:PSS electrodes as compared to ITO electrodes is an important step to the eventual realization of flexible electronic devices.

Recently, there has been a successful demonstration of spraycoating PEDOT:PSS as an anode electrode in inverted solar cells achieving efficiencies of ~2%, however, this electrode is thick and non-transparent [22]. We have developed a technique to selectively remove the PEDOT:PSS buffer layer in our inverted solar cell by using a patterned PDMS stamp (Fig. 7). By heating the substrates at an elevated temperature (~120 °C for 30 s) with the PDMS stamp, the stamp can be removed to selectively lift-off regions of PEDOT:PSS leaving behind the hydrophobic polymer/PCBM active layer. By spincoating solutions of the highly conductive PEDOT:PSS which only wets the PEDOT:PSS buffer layer, a patterned top semi-transparent an-

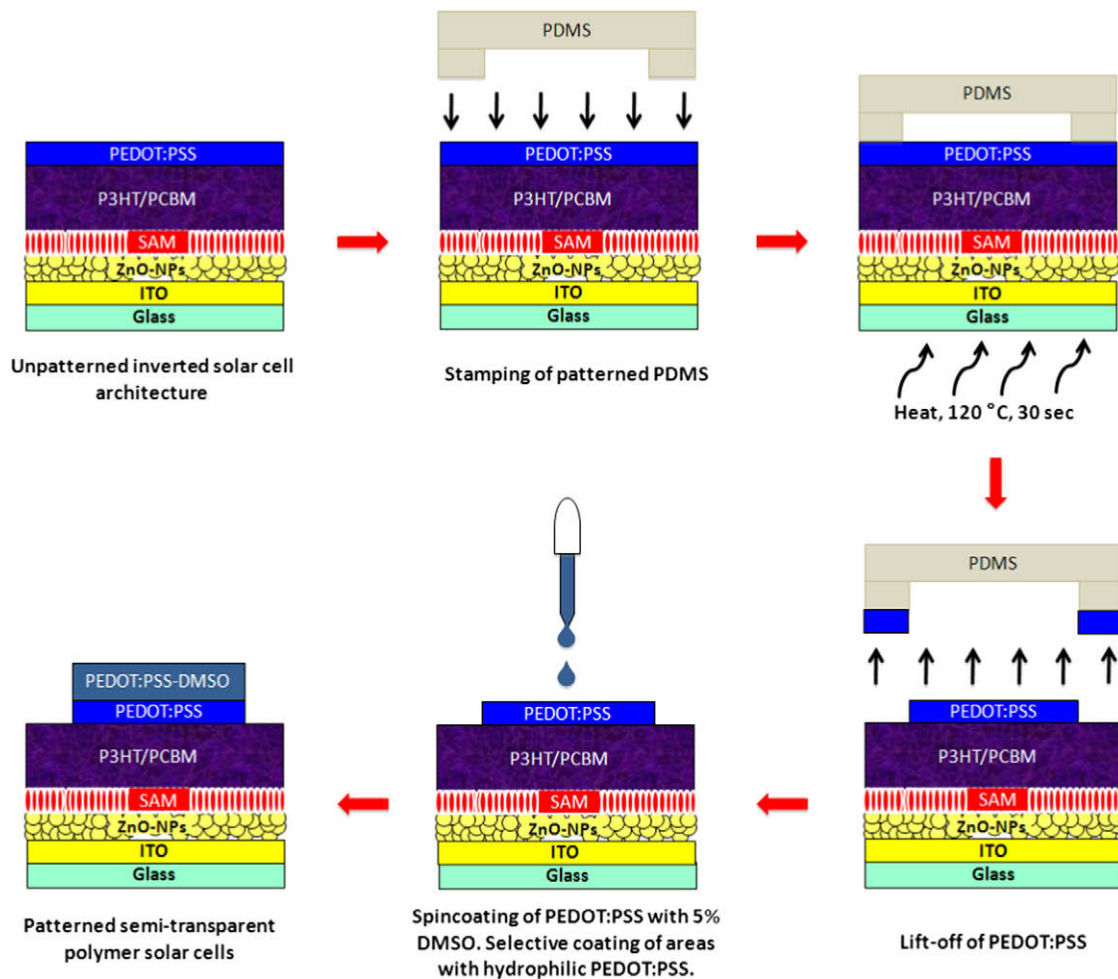
ode electrode can be formed. From this, semi-transparent inverted devices using ITO-coated glass substrates as the cathode and PEDOT:PSS as the top anode were fabricated. Fig. 5c shows the log J–V characteristics of these semi-transparent solar cells. These solar cells had an average PCE of 2.51%, a V_{oc} = 0.61 V, J_{sc} = 7.86 mA/cm^2, and FF = 52.0%. The lower performance especially in photocurrent is most likely due to the non-reflective electrode which unlike Ag does not reflect any unabsorbed light back into the active layer for further absorbance. In addition, the higher sheet resistance of the electrodes (ITO 15 Ω/□, PEDOT:PSS ~370 Ω/□) can also contribute to losses in device performance. Furthermore, an all solution processed semi-transparent inverted solar cell is demonstrated by replacing the bottom ITO electrode with a PEDOT:PSS electrode. These PEDOT:PSS top anode and PEDOT:PSS bottom cathode solar cells show a PCE of 0.47%, V_{oc} = 0.31 V, J_{sc} = 5.49 mA/cm^2 and FF = 27.7%. The relatively low efficiency is attributed to the much higher sheet resistance of the two electrode contacts (>400 Ω/□) which leads a significant deterioration in all the solar cell performance parameters due to the high resistance from the lateral


Fig. 7. Schematic of patterning PEDOT:PSS by PDMS removal of PEDOT:PSS. Selective removal of the hydrophilic PEDOT:PSS leaves behind the hydrophobic P3HT:PCBM film where spincoating of the conducting PEDOT:PSS–DMSO wets only the region with the PEDOT:PSS pattern leading to semi-transparent solar cells.

charge transport through the PEDOT:PSS electrodes. In addition, the significant drop in V_{oc} is likely attributed to the reduced built-in field of the device due to the symmetric PEDOT:PSS electrodes used for both contacts. Because of the high sheet resistance, the active device area is limited to a small area in order to minimize the lateral current losses through the electrodes. The sheet resistance of two electrode contacts can potentially be improved by using metalized grids. Using very dense metalized grids should limit the lateral current flow losses and lead to lower sheet resistances. This approach will become important when considering the scaling of the size of the solar cell device to larger active areas.

In conclusion, the replacement of ITO with PEDOT:PSS as the cathode electrode in inverted solar cells has been demonstrated. As the thickness of the PEDOT:PSS electrode was systematically increased, both the transparency and sheet resistance decreased which affected the photocurrent and fill factor of the solar cells. As the transparency of the electrode decreased, the available photons to be absorbed by the active layer were reduced leading to a lower photocurrent density. However, this lowering of photocurrent was offset by an increase in fill factor due to the lower sheet resistance which led to saturation in PCE of ~3% as the electrode thickness was increased. These PEDOT:PSS electrodes were applied onto flexible plastic substrates showing similar device efficiencies to devices fabricated on glass. The flexible PEDOT:PSS electrodes has better mechanical stability than the flexible ITO based electrodes showing a conversion efficiency retention of ~92% as compared to ~50% under 300 cyclic bends, respectively. Semitransparent inverted solar cells using ITO as the cathode and PEDOT:PSS as the top anode showed PCE of 2.51%. A completely solution processed semi-transparent inverted solar cell was demonstrated by replacing the ITO cathode with a PEDOT:PSS cathode and a PEDOT:PSS top anode showing efficiencies of 0.47%. The semi-transparency of these devices can potentially lead to window based solar applications or other application where semi-transparency is required. More importantly, the replacement of ITO as a transparent electrode with a cheaper transparent electrode will be needed to realizing low-cost flexible polymer solar cells.

long excited triplet lifetime of 1.29 µs. Therefore it could be conjecture that the interaction between CuPc and Ir(piq)$_2$acac phosphors would occur by codoping the two phosphors into the same host in EL device. In terms of above arguments it is speculated that the interaction should be an energy transfer from the red emitting Ir-comlex to CuPc phosphor. In this letter, we fabricate CuPc and Ir(piq)$_2$acac codoped device with CBP as host to enhance the NIR emission of CuPc. By optimize the device structure the NIR emission intensity of CuPc was enhanced by factors of about fifteen compared with the reference device without the Ir-complex codopant.

All the chemicals were commercially available. Organic films and Al cathode were deposited on indium tin oxide (ITO) glass substrate with a sheet resistance of 25 Ω/□ by thermal evaporation in a vacuum chamber with a base pressure $<3.0 \times 10^{-4}$ Pa. Various OLEDs with an active area of 2×3 mm^2 were fabricated and encapsulated under drying N$_2$ atmosphere for device analysis. The NIR EL signals were focused into a monochromator and detected with a liquid-nitrogen-cooled Ge detector, using standard lock-in techniques, and the NIR photoluminescence (PL) signals were detected by spectrophotometer with a InGaAs photodiode with a boxcar averager. The transient decays of Ir(piq)$_2$acac were measured by a spectrophotometer with a Spex 1403 photomultiplier with a boxcar averager, under excitation by Nd:YAG laser at a wavelength of 355 nm with 10 ns pulse width. The absorption spectrum of neat CuPc film were recorded at a UV–Vis–NIR scanning spectrophotometer UV3101 (SHIMADZU), and The PL spectrum of Ir(piq)$_2$acac film determined by Hitachi F-4500 spectrophotometer equipped with a continuous 150 W Xe-arc lamp. The electrode work functions, the data of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) levels of m-MTDATA, TPD, CBP, Ir(piq)$_2$acac, and TPBI were cited from literatures [14,15].

Firstly, we investigated the PL of CuPc film and Ir(piq)$_2$acac:CuPc blend film. Under an illumination of 355 nm Nd:YAG laser with energy density 30 mW/cm^2, no emission was observed from a 40 nm CuPc film. But in the 40 nm blend film Ir(piq)$_2$acac:CuPc, we observed the
1120 nm emission of CuPc. By modify the weight ratio of the two components, the Ir(piq)$_2$acac:CuPc blend film with 1:1 weight ratio emits the most intensive NIR emission from CuPc, and the intensity can be compared with that of Yb^{3+} in (dibenzoylmethanato)$_3$-(bathophenanthroline)-ytterbium which under an illumination of 532 nm Nd:YAG laser with energy density 50 mW/cm^2.

Based on the results of PL, we fabricated OLED devices with structures of ITO/m-MTDATA (20 nm)/TPD (20 nm)/ CBP: CuPc:Ir(piq)$_2$acac (x, y wt%, 30 nm)/TPBI (40 nm)/ LiF(1 nm)/Al (150 nm), here, x and y express the concentrations of Ir(piq)$_2$acac and CuPc. m-MTDATA, TPD and TPBI denote 4,4′,4″-tris[3-methyl-pheny(phenyl)-amino] triphenylamine, N,N′-diphenyl-N,N′-bis(3-methylphenyl)-1,1′-biphenyl-4,4′diamine, and 2,2′,2″-(1,3,5-benzenetriyl) tris-[1-phenyl-1H-benzimidazole], respectively.

Fig. 1 shows CuPc EL intensity as a function of concentration of Ir(piq)$_2$acac dopant, and the optimal concentrations of Ir(piq)$_2$acac and CuPc locates 10 and 12 wt%, respectively. The device with the optimal concentration called optimal device, and the 12 wt% CuPc monodoped device will be called reference device. Because we adopted m-MTDATA as hole injection layer, LiF as cathode buffer layer, and TPD, a low efficient PL and EL material, as hole transport layer, the NIR emission intensity of the reference device was enhanced by about two times comparing with the reported CuPc device [12] under the same measurement condition.

Fig. 2 shows the EL spectra at the NIR spectral zone for the optimal and reference devices, respectively. It can be seen that the CuPc EL intensity was enhanced by about 15 times compared with reference device. Furthermore, in optimal device, the red emission of Ir(piq)$_2$acac was too weak to be detected, although the maximal current efficiency and luminance of the Ir(piq)$_2$acac monodoped device can offer 10.17 cd/A and 11 000 cd/m^2, respectively. Inset denotes the chemical structures of CuPc and Ir(piq)$_2$acac. In order to understand the enhanced mechanism

Fig. 1. CuPc EL intensity in 1.1 µm as a function of concentration of Ir(piq)$_2$acac dopant.
Fig. 2. The NIR EL spectra of CuPc in the optimized device (red) and reference device (black). (The absolute emission intensity is not referred to in this work purely because of the difficulty for our testing system.). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

of the NIR emission of CuPc, we determined the absorption spectrum of CuPc film and emission spectrum of Ir(piq)₂acac film. It is found that there is a markedly overlapping between the two spectral bands, as indicated in Fig. 3, which implies that the energy transfer from the Ir-complex to CuPc in device would occur. Besides we also measured the photoluminescence transient decays in the 50 nm thick CBP: Ir(piq)₂acac (10 wt%), and CBP: Ir(piq)₂acac: CuPc (10, 12 wt%) mixing film, respectively. It is found that the excited triplet lifetime of Ir(piq)₂acac in the CBP: Ir(piq)₂acac mixing film is 1.29 μs, while in the codoped films it was shortened to 0.82 μs. Basing on the above-mentioned spectral overlapping and the shortened excited triplet lifetime of Ir(piq)₂acac phosphor, we can deduce that the improvement in NIR EL intensity is mainly attributed to the primarily energy transfer to CuPc from the red emitting Ir-complex.

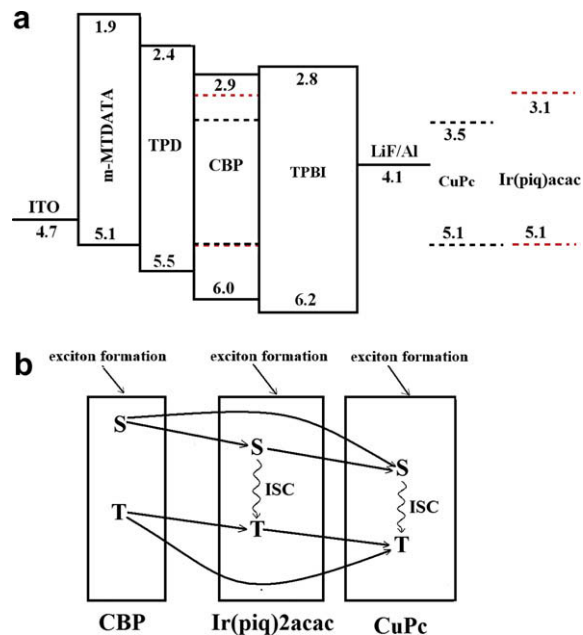
To further prove the energy transfer from the red Ir-complex to CuPc in the codoped devices, we also fabricated other two series of OLED devices. Series A: ITO/m-MTDATA (20 nm)/TPD (20 nm)/CBP: CuPc (x wt% 30 nm)/CBP: Ir(piq)₂acac (y wt% 30 nm)/TPBI (40 nm)/LiF(1 nm)/Al (150 nm); Series B: ITO/m-MTDATA (20 nm)/TPD (20 nm)/ CBP: Ir(piq)₂acac (y wt% 30 nm)/CBP: CuPc (x wt% 30 nm)/ TPBI (40 nm)/LiF(1 nm)/Al (150 nm). We have taken any values of x and y in the two series devices, but the NIR emission enhancement was not as much as the optimal device. The reasons could be understood as follow. In CuPc and Ir(piq)₂acac codoped device the intermolecular contact between two dopants are more close and behaves more favorite for Dexter energy transfer. For the other two series devices, the two dopants distribute in two layers separately, so the probable energy transfer process is only the Förster mechanism, which leads to lower efficiency process comparing with the codoping system. Therefore we conclude that the two phosphors codoped device provides more favorite surroundings for the sensitization of CuPc emission by the red Ir-complex than other device system.


Fig. 4. The schematic energy diagram of the codoped drvice (a) and the energy transfer processes in the codoped system (b). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

In term of the codoped device structure, here we show the schematic energy diagram, as in Fig. 4. Under the energy diagram, the improvement of NIR emission of CuPc was also understood as follows. Under excitation of the electrical field, the excitons are firstly formed on CBP molecules with the singlet-to-triplet ratio of 1/3. On the other hand, triplet excitons can be formed directly on the phosphor centers by trapping both the injected holes and electrons. The singlet energy of CBP can be directly transferred to that of both Ir(piq)₂acac and CuPc via Förster process, while the triplet of CBP can be directly transferred to the triplet states of Ir(piq)₂acac and CuPc by Dexter process. The singlet energy of the two phosphors may rapid converted to their triplet states by intersystem crossing (ISC) due to strong spin orbit coupling. Due to the efficient ISC of Ir(piq)₂acac, energy transfer from the singlet of Ir(piq)₂acac to CuPc is less and hence can be ignored. Because the triplet energy level of Ir(piq)₂acac is about 0.6 eV lower than that of CBP, which restricts the back energy transfer from Ir(piq)₂acac to CBP, thus, there are two probable pathways to relaxation of Ir(piq)₂acac triplet, i.e., one is radiating to its ground states and another is transferring to CuPc triplet. Weak emission of Ir(piq)₂acac in the two phosphors codoped EL device indicates that the fraction of the radiation of Ir(piq)₂acac should be small. The shorter excited lifetime of CuPc (<50 ns) [16] comparing with Ir(piq)₂acac (1.29 μs) is another essential conditions for the energy transfer from Ir(piq)₂acac to CuPc. Thus, nearly all the exciton energies could be transferred to the CuPc triplet, as a result the NIR emission of CuPc increased.

Curry and Gillin have reported the NIR EL emission from erbium (III) tris(8-hydroxyquinolate) (ErQ) based de-

Fig. 3. The absorption spectrum of neat CuPc film and PL spectrum of Ir(piq)₂acac. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

vice with structure of Si/NPB (40 nm)/ErQ (50 nm)/Al (200 nm), and a internal quantum efficiency of ~0.01% was obtained [17]. We have fabricated the similar EL device using ITO rather than Si as the anode substrate. By comparing the heights of EL emission peaks which origin from Er^{3+} in ErQ device and CuPc in our sensitized device under the same determining condition, the internal quantum efficiency of the sensitized emission of CuPc was estimated roughly. Basing on the estimation, our sensitized CuPc device with the red Ir-phosphor offers an internal quantum efficiency of about 0.1%, which is little higher than that of CuPc reported by Rosenow et al. [18].

In summary, the NIR emission of CuPc was enhanced by $Ir(piq)_2acac$ in codoped device system. The improvement was attributed to the intermolecular energy transfer from $Ir(piq)_2acac$ to CuPc in the same host (CBP). The observation of the enhanced NIR emission of the CuPc would inspire us to design and develop other new type of sensitized phosphorescent OLEDs by intermolecular energy transfer processes. The concept can also be used for the application in efficient organic photovoltaic cells with new triplet materials.

are commonly used in PhLEDs. Since the electron mobility of PVK is poor, most PVK-based PhLEDs have an electron transporting component added to the emitting layer. One substance commonly used for this purpose is 1,3-bis[5-(4-tert-butylphenyl)-1,3,4-oxadiazole-2-yl]benzene (OXD-7), which has a lowest unoccupied molecular orbital (LUMO) at −2.7 eV and a highest occupied molecular orbital (HOMO) lower than −6.5 eV [11].

In a recent investigation aimed at developing high efficiency OLEDs, we have found that solution-processed, red emissive PhOLEDs can be fabricated by adding (Et-Cvz-PhQ)₂Ir(pic) or (EO-Cvz-PhQ)₂Ir(pic) as phosphorescent dopants to a host polymer matrix comprised of PVK blended with the hole transport material N,N′-diphenyl-N,N′-(bis(3-methylphenyl)-[1,1-biphenyl]-4,4′-diamine (TPD) and the electron transport material OXD-7. TPD was employed as a co-dopant in the emitting layer for two reasons. First, the utilization of PEDOT:PSS leaves a ca. 0.6 eV barrier for hole injection to PVK. Thus, it is expected that addition of a sufficiently large concentration of TPD would cause a reduction in the barrier for hole injection. Second, TPD, when used in high loadings and doped into PVK, has been shown to function as a hole transporting layer [12]. As a result, addition of TPD should allow holes to penetrate more deeply into the emitting layer.

In this investigation, the red emissive Ir complexes, (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic), were synthesized by using procedures developed in our previous work [13]. The 2-(2-methoxyethoxy)ethyl unit instead of an ethyl unit are introduced into the carbazole moiety in these substances in order to enhance their solubilities. PVK, OXD-7 and TPD were purchased from Sigma–Aldrich and Lum. Tec. Co. The devices fabricated in the current study had the configuration ITO/PEDOT:PSS/PVK:OXD-7:TPD:Ir complex/cathode. The molecular structures of (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) along with the PhOLED configuration and the HOMO and LUMO energy levels of the materials are shown in Fig. 1.

The cathode consisted of Ba/Al with a 20 nm thick layer of OXD-7 between the emitting and electron injection layers. The anode, consisting of ITO/glass substrates pre-coated with PEDOT:PSS (H.C.Stack, 4083), was used as a buffer layer. Prior to spin coating with PEDOT:PSS, the ITO was pre-cleaned and UV-ozone treated for 15 min. Then, a 40 nm thick layer of PEDOT:PSS was spin coated onto the ITO and baked at 150 °C for 20 min. Individual solutions of PVK, OXD-7, TPD and (Et-Cvz-PhQ)₂Ir(pic) or (EO-Cvz-PhQ)₂Ir(pic) in chlorobenzene were mixed to give various weight percentages. The solutions, filtered by using a 0.45 μm PTFE (hydrophobic) syringe filter, were spin coated onto the PEDOT:PSS layer in order to obtain emitting layer thicknesses of 70–80 nm. In all cases, the concentrations of the dopants, (Et-Cvz-PhQ)₂Ir(pic) or (EO-Cvz-PhQ)₂Ir(pic), were 6 wt.%.

The emitting layer was then annealed at 80 °C for 30 min. A typical cathode, consisting of OXD-7/Ba/Al (20 nm OXD-7, 3 nm Ba, and 100 nm Al), was deposited with effective area of 4 mm² at a pressure of 5×10^{-6} Torr. The cathode thickness was measured by using a α-Step IQ surface profiler (KLA Tencor, San Jose, CA). In order to evaluate the performances of the PhOLEDs, current density–voltage–luminance (J–V–L) values were determined by using a current/voltage source meter (Keithley 236) and an optical power meter (CS-1000). All measurements were carried out at room temperature under an ambient atmosphere without encapsulation.

The HOMO and LUMO energies (−5.15 and −2.63 eV, respectively) of (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) were determined by using cyclic votammetry. The similarities of the molecular structures of the Ir complexes give rise to similar electro-optical properties. Energy band diagrams show that the, respective HOMO and LUMO energy levels of these complexes lie above and below those of PVK. Thus, it is possible that the Ir complexes will trap both electrons and holes in the PhOLED configuration. The LUMO energy level of OXD-7 is well aligned with that

Fig. 2. Normalized absorption spectra of (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) and photoluminescence spectrum of PVK doped with OXD-7 in film state. Inset: doping concentration dependence of EL spectra.

of the Ir complexes in the emitting layer, an important factor that should facilitate carrier injection into the both the transport molecules and the complexes.

The absorption spectra of Ir complexes and emission spectrum of PVK doped with OXD-7 in film state are shown in Fig. 2. As can be seen by viewing these spectra, good overlap exists between the emission band of the host and the metal-to-ligand charge transfer (MLCT) absorption

bands of the Ir complexes, an outcome which ensures efficient Förster energy transfer between hosts and guests and/or direct charge trapping of the Ir complexes.

In order to investigate the effect of TPD on performance, PhOLEDs were fabricated with variable concentrations (0%, 4%, 8%, 12% and 16%) of TPD. As shown in the inset of Fig. 2, the EL spectra of PhOLEDs, using (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic), display peaks corresponding to the dopant emission maximum of 608 nm, an excellent color purity at a CIE coordinate of (0.62, 0.38), and the absence of emissions from PVK, TPD and OXD-7.

Current density–voltage–luminance (J–V–L) characteristics of (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) at several different concentrations of TPD in PVK:OXD-7 are shown in Fig. 3. The maximum brightness of the (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) based PhOLEDs, in the absence of TPD in emitting layer, were 1779 and 1414 cd/m², respectively. However, the addition of increasing concentrations of TPD led to dramatic increases in the performances of PhOLEDs. Maximum brightnesses of the PhOLEDs using (Et-Cvz-PhQ)₂Ir(pic) and (EO-Cvz-PhQ)₂Ir(pic) (8768 and 6285 cd/m², respectively) were obtained when the concentration of TPD was 16 wt.%. The J–V characteristics of the PhOLEDs clearly demonstrate that current density is directly dependent on the TPD concentration. The results indicate that the enhancement of the current density is related to improved hole injection caused by

the presence of TPD in the emitting layer, a phenomenon that can be explained in terms of the *L–V* characteristics of the PhOLEDs as shown in Fig. 3.

The results of current density–luminescence efficiency measurements of the PhOLEDs (Fig. 4, Table 1) show that PhOLEDs based, on (Et-Cvz-PhQ)$_2$Ir(pic) and EO-Cvz-PhQ)$_2$Ir(pic), that do not contain TPD have respective external quantum, luminance and power efficiencies of 6.21%, 9.15 cd/A and 1.93 lm/W, and 4.96%, 7.40 cd/A and 1.16 lm/W, respectively. When the concentration of TPD in the PhOLEDs consisting of (Et-Cvz-PhQ)$_2$Ir(pic) was 16 wt.%, the turn-on voltage was significantly reduced from 7 to 5 V and the external quantum, power and luminance efficiencies were increased to 10.56%, 6.42 lm/W and 17.5 cd/A, respectively. The performances of the PhOLED using the (EO-Cvz-PhQ)$_2$Ir(pic) emitter have similar TPD concentration dependences as those of the device based (Et-Cvz-PhQ)$_2$Ir(pic). Specifically, the injection barrier for the hole is reduced from 0.6 to 0.3 eV with increasing TPD concentration and it reaches an effectively optimized value at 16 wt.% concentration of TPD. As a result, the driving voltage was reduced and this led to an improved PhOLED performance.

The respective triplet energy levels (T_1) of the (Et-Cvz-PhQ)$_2$Ir(pic) and (EO-Cvz-PhQ)$_2$Ir(pic) emitters were estimated to be 2.18 eV and 2.11 eV by using low temperature (77 °K) phosphorescence spectroscopy. Energy transfer from the triplet state of the Ir complexes to the triplet states of the charge-transport materials does not take place because the triplet energies of charge-transporting materials [TPD ($T_1 \sim 2.34$ eV), OXD-7 ($T_1 \sim 2.7$)] [14] and host material [PVK ($T_1 \sim 2.5$ eV)] are higher than those of the Ir complexes. This finding indicates that a triplet energy confinement on the Ir complexes emitter is sufficient to cause high quantum efficiencies of the devices.

In this investigation we explored the performance characteristics of red emissive PhOLEDs, based on (Et-Cvz-PhQ)$_2$Ir(pic) and (EO-Cvz-PhQ)$_2$Ir(pic) and having a configuration of ITO/PEDOT:PSS/PVK:OXD-7:TPD:Ir complex/cathode. The effects of TPD concentration in the PhOLEDs were determined. By increasing the TPD concentration up to 16 wt.%, the performance of PhOLEDs was markedly increased. Importantly, the PhOLED consisting of (Et-Cvz-PhQ)$_2$Ir(pic) and containing an optimum TPD concentration exhibited maximum external quantum, power and luminance efficiency values of 10.56%, 6.42 lm/W and 17.5 cd/A.

Although encapsulation of the device can protect it from water and oxygen of the environment and many of the processes cited above have been identified and controlled, few studies have explored degradation of Alq$_3$ films by exposure to light and the related photo degradation products, responsible for quenching of luminescence. Priestley and collaborators [13] studied photo degradation of thermally evaporated Alq$_3$. Photo oxidation was carried out under illumination with full spectrum by a 150 Watt xenon lamp while blowing air or oxygen through the cell. Transient photoluminescence and photoconductive response were measured and the sample which was photo oxidated in oxygen showed more pronounced degradation effects in comparison with that in air, which allowed them to concluded that water vapor, always present in air, does not contribute substantially to the photo oxidation. The same work reported that photo oxidation could introduce chemical modifications in Alq$_3$ through incorporation of O_2 molecules in its chemical structure, whose products resulted in quenching of photoluminescence. Thangaraju et al. [14] studied the decrease of photoluminescence of Alq$_3$ films upon the effects of air and white light for various time periods. They concluded that photoluminescence intensity decreases with increasing light exposure time. Infrared (IR) absorption measurements were performed in order to determine the structural changes on Alq$_3$. The spectrum shows a band at 1697 cm^{-1} that corresponds to vibrational band of carbonyl group, which would act as a luminescence quencher. Similar results were also reported by Kumar and collaborators [15]. Nevertheless, neither of these studies concentrated efforts in attempt to elucidate the chemical structures of the degradation products.

In this work we investigate the stability of Alq$_3$ thin films under light and air exposure, with consequent photoluminescence decrease. With this aim, thermally deposited Alq$_3$ thin films were exposed to UV radiation and analyzed through Fourier transform infrared spectroscopy (FTIR) and optical absorption in UV–Vis region. Several possible degradation products are proposed and density functional theory (DFT) calculations of vibrational frequencies and reaction Gibbs free energies are performed. Based on comparisons between experimental and theoretical data, we identify the most likely degradation products of Alq$_3$.

2. Experimental details

Alq$_3$ thin films (100 nm thick) were thermally deposited in high vacuum environment onto glass, quartz and silicon substrates. The substrates were initially cleaned by ultrasonication using a detergent solution, followed by toluene degreasing, and then cleaned again by ultrasonication with pure isopropyl alcohol. The base pressure for deposition was 6.67×10^{-4} Pa and during the evaporation the pressure was roughly 9.33×10^{-4} Pa. The deposition rate was about 0.1 nm/s. The layer thickness was controlled in situ through a quartz crystal monitor and confirmed by perfilometer measurements. The films were exposed for 11 h to UV radiation, using a He–Xe lamp ($\lambda = 307$ nm). The incident power density was roughly 0.42 mW/cm^2 for all irradiated samples. The irradiated and non-irradiated films were analyzed through Fourier transform infrared spectroscopy (FTIR) and optical absorption in UV–Vis region. All the measurements were carried out in ambient atmosphere.

3. Computational details

The modified mer-Alq$_3$ structures were first submitted to a conformational search using semiempirical methods available on the HyperChem Software [16]. The most stable structures were selected and submitted to *ab initio* density functional theory (DFT) optimization calculations and vibrational frequency calculations, carried out using Gaussian 03 package [17]. Frequency calculations were done to confirm the stability of the structure and to generate the IR spectra. The calculations were performed with TPSS (Tao, Perdew, Staroverov, and Scuseria) meta-GGA functional [18] of Kohn–Sham DFT, in combination with 6–31G(d,p) basis set [17]. TPSS is a nonempirical meta-GGA, which was submitted to several tests on molecules, solids, and solid surfaces, all showing its good performance for a diverse range of properties and systems [19].

Due to the neglect of mechanical anharmonicity, approximations in the treatment of electron correlation and basis set effects, theoretical vibrational frequencies typically overestimate experimental ones. It is a common practice to rescale the theoretical frequencies in order to match experiments, so we use a scaling factor of 0.992, chosen to match experimental and our theoretical spectra for Alq$_3$.

4. Results and discussion

4.1. Selection of degradation products and reactions

Earlier experimental and theoretical works have shown that meridional (mer) isomer of Alq$_3$ is the predominant form, over facial (fac) form, both in solution and in sublimed films [20–24]. Therefore, structural modifications suggested here are all derived from mer-Alq$_3$, shown in Fig. 1.

Alq$_3$ is a trischelate organic complex with a distorted octahedral symmetry. Consequently, the three quinolate ligands are not equivalent, and receive labels a, b, and c (Fig. 1), according to their different Al–O and Al-N bond lengths, as obtained from X-ray structure analysis [20]. According to Thangaraju et al. [14], only one of the three 8-hydroxyquinoline (HQ) units in the Alq$_3$ molecule suffers chemical structural modifications during light exposure, resulting, as evidenced by infrared absorption spectra, in the introduction of a carbonyl group in the chelate. The same work gives a possible explanation for the chemical modification based on redox behavior associated with Al–O bond. Then, in the present work, our first proposal for degradation products of Alq$_3$ consists in the rupture of one of the Al–O bonds and consequently rupture of the benzene ring of one HQ unit (Fig. 2a). More precisely, the c-quinolate ligand is chosen to be modified since our theoretical calculations (and also previous work [25]) shows that it has the largest Al–O bond length.
Fig. 1. The geometry of mer-Alq$_3$ with labels a–c indicating the three different quinolate ligands. Pink, red, blue, dark grey and light grey balls represent Al, O, N, C and H atoms, respectively. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

Therefore, our first suggestions of degradation products are complex molecules with broken Al–O bond and modifications on c-quinolate oxygen by including carbonyl units in the form of aldehyde, carboxyl acid or ketone groups. All these choices produce chelates that show IR spectra which are not in good agreement with experiments. As a representative example of this class, we present in more detail the results for aldehyde substitution. (Fig. 2, product P1).

Another class of modifications in the Alq$_3$ molecule involves keeping the Al–O bond intact and breaking the phenoxide ring (Fig. 2, P2, P3, P4 and P5). These changes can result from oxidation, while the previous modifications are result from reduction. Oxidations are more plausible to occur here since measurements are carried out in the air. It is well known that UV light, as used in the present study, produce O$_3$ from air O$_2$ [26], therefore it is important to consider that degradation occurs in the presence of both O$_2$ and O$_3$ and then, oxygenations and ozonolysis reactions are considered, as shown in Table 1.

Following this analysis, we generated four structures, the products P2, P3, P4 and P5 (Fig. 2). All these products have one extra oxygen atom at one end of the broken ring, forming a carboxylate group bounded to Al, but they differ

Table 1
Ozonolysis and oxygenation degradation reactions and respective Gibbs free energy differences for products P2–P5.

Ozonolysis	
Alq$_3$ + O$_3$ → P2	−569 kJ/mol
Alq$_3$ + 2/3 O$_3$ → P3	−338 kJ/mol
Alq$_3$ + 5/3 O$_3$ → P4 + H$_2$C$_2$O$_2$	−921 kJ/mol
Alq$_3$ + 7/3 O$_3$ → P4 + H$_2$C$_2$O$_4$	−1445 kJ/mol
Alq$_3$ + 4/3 O$_3$ → P5 + H$_2$C$_2$O$_2$	−687 kJ/mol
Alq$_3$ + 2 O$_3$ → P5 + H$_2$C$_2$O$_4$	−1211 kJ/mol
Oxygenations	
Alq$_3$ + 3/2 O$_2$ → P2	−408 kJ/mol
Alq$_3$ + O$_2$ → P3	−231 kJ/mol
Alq$_3$ + 5/2 O$_2$ → P4 + H$_2$C$_2$O$_2$	−653 kJ/mol
Alq$_3$ + 7/2 O$_2$ → P4 + H$_2$C$_2$O$_4$	−1070 kJ/mol
Alq$_3$ + 2 O$_2$ → P5 + H$_2$C$_2$O$_2$	−473 kJ/mol
Alq$_3$ + 3 O$_2$ → P5 + H$_2$C$_2$O$_4$	−890 kJ/mol
Fig. 2. Schematic representation of possible mechanisms for Alq$_3$ degradation: (i) Rupture of Al–O bond and consequent rupture of the ring, which leads to degradation product P1; (ii) rupture only of the ring, preserving the Al–O bond and leading to products P2–P5.

in the chemical groups at the other extremity of the ring: products P2 and P4 have carboxyl acids, and products P3 and P5 have aldehyde groups. However, in products P4 and P5 two extra C atoms are removed the phenoxide side. As shown in Table 1, for chemical reactions involving P4

and P5, removal of extra C atoms was balanced by extra products: ethanedioic acid (or oxalic acid, $H_2C_2O_4$) and ethanedial (or glyoxal, $C_2H_2O_2$). These reactions are based on oxidation of quinoline and ozonolysis mechanism, which can produce carboxylic acid, aldehyde, and ketone
Fig. 3. Optimized structures of degradation products, P1, P2, P3, P4 and P5.
Fig. 4. Infrared spectra obtained for Alq$_3$. The top panel shows experimental results obtained for irradiated (red) and non-irradiated (black) Alq$_3$. The lower panel shows the theoretical IR spectrum for pristine Alq$_3$. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

through breaking of double bonds of one of the quinolines, consistent with the spatial localization of frontier molecular orbitals. [27–29]. We only consider modifications in one of the quinoline since, according to theoretical results, the HOMO and LUMO of Alq$_3$ are localized at only one of quinolate ligands [25]. Fig. 3 shows the optimized structures of degradation products, P1–P5.

Table 1 shows the Gibbs free energy differences for all reactions. As we see, all reactions are favorable. The most favorable reaction is the ozonolysis responsible for the for-

mation of P4 and ethanedioic acid, followed by P5 and ethanedioic acid.

4.2. IR theoretical versus experimental spectra

We now compare experimental IR spectra with theoretical ones. We start by testing our methodology with pristine Alq$_3$, shown in Fig. 4. The agreement is very good, except for small discrepancies in the regions from 1340 cm^{-1} to 1250 cm^{-1} and from 840 cm^{-1} to 770 cm^{-1}.
Fig. 5. Experimental infrared spectrum of irradiated Alq$_3$ and theoretical spectra of products P1–P5, as well as reaction subproducts. From upper to lower panels, spectra are shown in the following order: irradiated Alq$_3$ film (experimental), P1, P2, P3, P4 (black) plus glyoxal (red) and P5 (black) plus oxalic acid (red). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 6. Experimental (red) and theoretical (black) IR spectra for degraded Alq$_3$. The theoretical spectrum is a composition between 95% pristine Alq$_3$ and 5% of products P4 and ethanedial. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

These discrepancies could be attributed to anharmonic effects for modes involving hydrogen atoms and to the fact that calculations are performed for isolated molecules, whereas experiments are done in thin films. In fact, recent works show that calculated vibrational frequencies for aromatic rings including solvent effects show up to 21 cm^{-1} difference between frequencies obtained in vacuum and considering the environment [30,31]. Fig. 4 also shows the IR spectrum for the irradiated sample, for comparison with the pristine case. The essential difference between them is a band around 1697 cm^{-1}, which corresponds to a vibrational band of the carboxyl group.

In Fig. 5, we plot again the spectrum of the irradiated sample (upper panel), in order to compare it with the theoretical spectra for the P1–P5 products. For all the plots, the height of the most intense peak was normalized to 1. The products P2 and P4, which have only carboxyl acid and not aldehyde, show two extra peaks around 1766 cm^{-1} and 1694 cm^{-1} (for P2) and 1768 cm^{-1} and 1716 cm^{-1} (for P4). On the other hand, products P3 and P5, which have aldehyde groups in the structure, show only one peak at 1704 cm^{-1} and 1714 cm^{-1}, respectively. All these peaks are related to C=O vibrations and they occur in the same spectral region as the experimental peak at 1697 cm^{-1}. Based on the fact that it is not possible to see a double-peak structure from experiments, we could be inclined to favor products P3 and P5. However, the experimental feature at 1697 cm^{-1} is somewhat broad and we cannot definitely rule out that it is composed of two unresolved peaks. Fig. 5 also shows the calculated IR spectra of possible degradation subproducts ethanedial (glyoxal) and etanedioic acid (oxalic acid).

On the other hand, product P1, obtained from breaking the Al–O bond (a reduction reaction, unlikely to occur in a environment rich in O$_2$ and O$_3$) does not show peaks in region of interest, besides showing a peak at 1548 cm^{-1}, which does not appear in experimental spectrum. These results indicate that, contrary to previous suggestions, P1 and related compounds are unlikely degradation products of Alq$_3$.

It is important to notice that the intensity ratio of the carbonyl peak with respect to other peaks in all the products P2–P5 is much larger theoretically than experimentally. This simply results from the fact that degradation is not complete, i.e., only a small fraction of the molecules suffer degradation reactions. Therefore, a closer agreement between theoretical and experimental IR spectra can be achieved if one properly combines the theoretical spectra of degraded and non-degraded Alq$_3$ so as to match the experimental peak heights. Of course, this procedure should be regarded as semi-quantitative at most, since the exact composition of degradation products is unknown (products P2–P5 can be present at the same time in the degraded samples). However, just as an illustration, we show the result of such fitting procedure in Fig. 6, for the particular case of product P4 with ethanedial. In this case, the ratio between the degraded and non-degraded spectral components is approximately 5%, which gives a rough estimate of the fraction of degraded molecules in the sample.

5. Conclusions

In conclusion, the products of photo degradation of Alq$_3$ films under UV radiation were investigated through the comparison of experimental results and theoretical calculations. The experimental IR spectrum obtained from irradiated Alq$_3$ thin films exhibits a peak assigned to a vibrational band of carbonyl group at 1697 cm^{-1}, exactly as obtained by Thangaraju et al. [14]. Different degradation products were proposed and the feasibility of them was analyzed by Gibbs free energy calculations and by comparing theoretical and experimental IR spectra.

Among the five suggested degradation products, P1, a product involving the breaking of Al–O bond and resultant from reduction process was considered the only unlikely option, since its theoretical IR spectrum showed poor agreement with experiments. This is not unexpected, since the experiments were performed in highly oxidizing environment. Nevertheless, it is important to point out that P1-like products were previously suggested in literature. The other suggested products, P2–P5, involve keeping the Al–O bond and breaking the phenoxide ring. To the best of our knowledge, such degradation products have not been previously considered in literature. Theoretical IR spectra for these products are all in good agreement with experimental results and Gibbs free energy calculations show that all suggested reactions leading to them are thermodynamically

favorable. The association between theory and experimental IR indicates that the degradation of Alq3 forms carboxylate groups bound to Al.

diffusion through or even around the top electrode into the photo-active layer, which slows down degradation processes appreciably thus making it a tedious task to understand the mechanisms of the interaction of oxygen with the active layer. The use of gas permeable electrodes together with the exclusion of water from the ambient atmosphere provides a direct and efficient tool to study oxygen induced degradation on the timescale of minutes which allows the observation of the concomitant existence of reversible and irreversible oxygen effects.

2. Experimental

To manufacture the semi-transparent cell, an inverted architecture was chosen, which allows the placement of the hole extraction layer on top of the cell. After cleaning the glass/ITO substrate (15 $\Omega/\square$) by sonication in acetone and isopropanol, a proprietary electron extraction layer was applied, followed by the P3HT:PCBM (ratio 1:0.8) active layer, and a highly conductive PEDOT:PSS formulation (50 S/cm), which acts as the hole extraction layer and as the electrode. For the electron extraction layer (EEL), several different organic and inorganic materials were employed. All layers are applied out of solution by doctor blading. The devices were completed with thermal evaporation of 500 nm of Ag, either as a metal grid (fingers with a distance of 2 mm and a width of 0.l5 mm), or as a solid electrode in the case of reference devices (Fig. 1). The processing of the cells is described in more detail elsewhere [14]. The PEDOT:PSS layer has a conductivity of around 100–200 $\Omega/\square$ and an optical absorption loss of ca. 20%. Before evaporation, all cells were annealed in nitrogen at 140 °C for 5 min.

For characterization, the cells were illuminated with the AM1.5 g spectrum of a Steuernagel Solartest 1200 solar simulator at 100 mW/cm^2. All reported results are corrected by the determined mismatch factor of 0.75. JV-characteristics (current density vs. voltage) were recorded using a Keithley 2400 SMU together with a Keithley 7001 Multiplexer system and custom software. To avoid errors in cell area, associated with the use of the highly conductive PEDOT:PSS, all measurements were performed with a shadow mask, with an area of 72 mm^2, placed directly on top of the cells [15]. During the measurements the cells were placed in a custom holder that allows illumination of the cells from both sides under controlled atmospheres. The holder was sealed on all sides, such that it could be selectively flooded with either dry nitrogen (99.9% N_2, H_2O < 1 ppm) or synthetic air (80% N_2, 20% O_2, H_2O < 1 ppm) during the measurements.

3. Results

Results of the initial JV-characterization in dry nitrogen are shown in Fig. 2 and the performance parameters are summarized in Table 1. The semi-transparent cells perform at the same level as the cells with the solid metal electrode, indicating that in these cells almost all light is collected in the first pass through the semiconductor. When illuminated from the grid electrode side there is a ca. 25% drop in the short circuit current (J_{sc}), which agrees well with the measured 20% absorption loss due to the PEDOT:PSS layer in conjunction with a 7% shadowing loss due to the antenna structure. Cells with solid electrodes and grid electrodes show the same fill factors and have the same injection currents, indicating that the grid spacing of 2 mm is sufficiently small, in agreement with what is expected from literature [16,17].

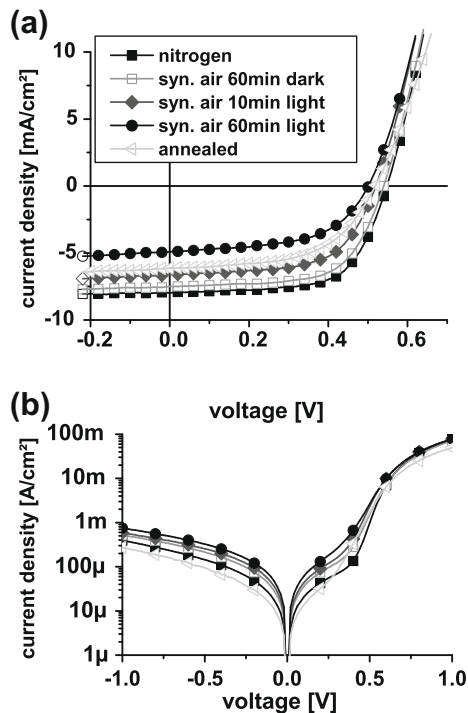
To investigate the influence of oxygen, two sets of samples, each consisting of four cells with semi-transparent electrodes, were prepared. One set of samples was kept under dry nitrogen, while the second set was exposed to syn-
Fig. 1. Cell stack; solid metal electrode (diffusion dense) and grid metal electrode (diffusion open). For the experiments shown in Figs. 2 and 3, an organic HBL was used.


Fig. 2. (a) Light *JV*-characteristics of a PEDOT:PSS cell with a grid metal electrode (mesh width 2 mm) at different illumination times under dry nitrogen and synthetic air and after annealing at 140 °C for 5 min inside the GB. Devices were illuminated from the ITO side. (b) Dark *jV* curve under nitrogen and synthetic air.

thetic air. For the first 60 min all cells were stored in the dark, and only exposed to light during the *JV*-measurement (for less than 1 min per measurement) after 30 and 60 min.

Table 1
Comparison of the initial performance of solar cells with solid and grid metal electrode illuminated from the ITO side.

	J_{sc} [mA/cm²]	V_{oc} [V]	FF [%]	Efficiency [%]
Solid metal electrode	8.19	0.54	64	2.83
Grid metal electrode	7.97	0.54	66	2.84

Following the 60 min of storage in the dark, the cells were continuously exposed to light for 120 min, and *JV*-sweeps were performed after 5, 10, 30, 60 and 120 min.

The evolution of the performance parameters is shown in Fig. 3 for a cell comprising an organic EEL. The results for cells with inorganic EELs are qualitatively the same. In the dark, in both in nitrogen and synthetic air, the performance changes only little. When AM1.5 illumination is turned on, in the nitrogen atmosphere only small changes in performance are observed. However, when the cells are exposed to oxygen and light at the same time, a dramatic effect on cell performance is observed. The largest change is observed in J_{sc}, which decreases by more than 50% during 120 min of exposure. At the same time the fill factor (FF) drops by ca. 20%, and the open circuit Voltage (V_{oc}) by ca. 15%, resulting in a total loss of efficiency by more than 60% within 2 h of exposure. A small increase of the dark leakage current in reverse bias indicates doping of the photo-active layer upon exposure to oxygen and light. The degrading effect caused by light and oxygen is also responsible for the small J_{sc} drop observed after the exposure to oxygen in the dark, where the samples had to be illuminated during characterization, effectively adding up to a total of ca. 3 min of light exposure during the 60 min of dark exposure.

Fig. 3. Relative changes of the performance parameters as a function of time in the dark (first 60 min) and under illumination (from 60 to 180 min) for two sets of solar cells, stored under dry nitrogen (black) and dry synthetic air (grey), respectively. (a) Short circuit current (J_{sc}), (b) open circuit voltage (V_{oc}), (c) fill factor (FF), (d) efficiency. All *JV*-measurements were performed under AM1.5 illumination.

Fig. 4. Surface resistance of a PEDOT:PSS layer exposed to different atmospheres under AM 1.5 illumination as a function of time.

To investigate the reversibility of the degradation processes caused by exposure to light and oxygen, the degraded devices were heated on a hot plate at 140 °C for 5 min under nitrogen atmosphere. The heat treatment restores about 30% of the loss of performance, with most of the recovery observed for J_{sc} (Fig. 3).

In order to examine the loss of conductivity of PEDOT:PSS as a possible source for the drop of performance, we performed resistivity measurements using the transmission line method [18] on PEDOT:PSS layers which were exposed to a variety of conditions (Fig. 4). Obviously, the small changes in resistivity under oxygen and illumination obtained in these experiments cannot account for the dramatic decrease in J_{sc} which we observe in our cells.

Other possible sources for the observed degradation are oxygen induced effects on P3HT or PCBM. The stability of P3HT has been studied extensively in Organic Field Effect Transistors (OFETs). A number of studies found an increase in the off-current of OFETs which is the result of p-doping due to the formation of a charge transfer complex (CTC) between P3HT and oxygen [19–23]. CTC formation is significantly accelerated by the exposure to light [19]. Several publications note that the effects of oxygen are either partially or fully reversible through vacuum storage or by annealing the polymer near the glass transition temperature, with the degree of reversibility depending on the conditions during exposure to oxygen.

The effect of oxygen on films and single crystals of C_{60} has also been studied by several groups. C_{60} shows a decrease of both dark [24–29] and photoconductivity [30] by up to five orders of magnitude, upon exposure to oxygen which acts as a compensating dopant in the n-type semiconductor C_{60}. These doping effects can be reversed by heating the samples in vacuum [28]. Exposure of C_{60} to light in the presence of oxygen leads to the formation of deep localized traps [25,31] due to irreversible chemical reactions [32–34].

4. Conclusion

In this paper we demonstrate the use of inverted semi-transparent cells with gas permeable top electrodes as a tool to investigate environmental degradation of organic solar cells. The simultaneous exposure of these cells to oxygen and light results in a strong reduction of J_{sc}, accompanied by only small reductions in V_{oc} and FF, which hints to the deterioration of charge separation in the photo-active layer [13,35] rather than to problems with charge extraction at the interfaces. The latter are usually characterized by an increase in the serial resistance and/or the appearance of a kink in the fourth quadrant, which strongly reduces the FF. This interpretation is further confirmed by the fact that no change in the conductivity of the PEDOT:PSS layer is found. Moreover, the degradation behavior of the cells shows strong similarities to that observed in OFETs, e.g., the partial recovery of cell performance by heat treatment under nitrogen. While our measurements are not able to resolve all the details of the degradation process, they indicate that both, the reversible and the irreversible component of the observed degradation take place in the photo-active layer. At this point in time it is not possible to resolve the question whether the degradation is due to chemical changes of the P3HT, PCBM or both species. Further work is also needed to investigate the doping of the active layer.

Semi-transparent cells with gas permeable top electrodes are a useful tool for investigating degradation mechanisms in organic solar cells, allowing the observation of reversible and irreversible oxygen effects on short time scales. This method is thus a significant step forward in quantifying and analyzing the degradation of polymer solar cells.

When donor and acceptor molecules are combined to prepare donor-σ-acceptor molecules through the σ-bond, they are promising candidates for the construction of molecular rectifiers [12,13] or organic solar cells [14–16], either as active layers or as models for the investigation of the origin of the photoinduced energy and electron transfer.

As an electron acceptor, PDI is a well-known n-type semiconducting molecule and a photostable dye suitable for applications in organic solar cells [17,18]. Thus, PDIs have been recently linked to small molecules [[60] fullerene, pyrenes, phthalocyanines, porphyrins, or tetra-thiafulvalene], thiophene-based oligomers, and conjugated polymers, as the donor counterpart aiming toward the induction of PET [19–22].

Charge transfer complexation is often observed in the ground states of solids through strong intermolecular interactions, which are sometimes unavoidable. There are several reports explaining how two electronically opposite moieties can be isolated to form a self-organized individual/homogeneous domain with a mesoscopic scale. Bauer et al. recently reported the energy transfer and PET processes of donor-σ-acceptor molecules in terms of absorption and photophysical properties [23]. Tetra-phenylbenzidine and PDI were selected to be an electron donor and an electron acceptor, respectively. A long alkyl-ene spacer was employed to make two semiconducting moieties separate to show their independent electronic and photophysical properties, claiming to be a good model for the study of energy- and electron-transfer processes in dual function semiconductors.

More recently, an oligo(p-phenylenevinylene)-fullerene dyad was employed for efficient photovoltaic cells. They were fabricated with a configuration of ITO/poly(3,4-ethylenedioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS)/dyad/poly-(dimethyl siloxane-b-methyl methacrylate)/Al. The PCE reached 1.28% which is the highest reported value for dyad-based photovoltaic cell [24].

X-shaped, organic soluble semiconducting molecules were reported by authors of the present study [25]. 1,2,4,5-Tetrakis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl)-benzene (HPBT) contains bithiophene units in four periphe-ral arms. The molecule is highly soluble in organic solvents and is pseudo-planar and easily stacked, inducing a high de-gree of crystallization. The carrier mobility of organic thin film transistors fabricated with HPBT was measured to be $3.0–5.0 \times 10^{-3}$ cm^2/V s. The employment of HPBT-based donors in combination with PDIs can be quite useful, as HPBT with relatively high quantum yield undergoes aroma-tization upon oxidation, providing thermodynamically sta-ble radical ionic species. Thus, we decided to synthesize HPBT-n(PDI) (n = 1, 2, and 4), in which a PDI electron accepting unit has been covalently attached to an HPBT through flexible alkylene spacer(s), providing a high degree of freedom to both semiconducting moieties. It was antici-pated that the incorporation of HPBT as a donor and PDI as an acceptor moiety would result in self-organized thermal crystallization by virtue of a high degree of independent aggregation.

2. Experiment

2.1. Synthesis

Compounds **1**, **4**, **7**, **8**, **13**, **21**, and **22** were synthesized by following the literature method [25–29].

Compound 2: A mixture of 6-amino-1-pentanol (16.0 g, 0.16 mol) and zinc acetate (0.07 g, 0.38 mmol) in *N,N*-dimethylacetamide (DMAc) (250 mL) was heated to 110 °C under a nitrogen atmosphere. Compound **1** (26.0 g, 0.041 mol) was added and the reaction mixture was stirred at 110 °C for 3 h. Then, the reaction continued at 160 °C for 15 h under a nitrogen atmosphere. The excess solvent was distilled off. The crude product was purified by silica-gel column chromatography using chloroform. The product was precipitated into methanol. The material was filtered and dried in a vacuum oven. Yield: 20.0 g (68%). ^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm) 8.63–8.52 (m, 8H), 5.24–5.14 (m, 1H), 4.22 (t, 2H), 3.70 (t, 2H), 2.30–2.23 (m, 2H), 1.97–1.77 (m, 4H), 1.74–1.65 (m, 2H), 1.32–1.21 (m, 26H), 0.834 (t, 6H). Anal. calcd for C$_{46}$H$_{54}$N$_2$O$_5$: C 77.28; H 7.61; N 3.92, found: C 76.71.0; H 6.97; N 3.20. MS (*m/z*): [M$^+$+H] calcd for C$_{46}$H$_{54}$N$_2$O$_5$ 714.4; found 715.6.

Compound 3: Compound **2** (15.0 g, 20.0 mmol), 4-dimethylaminopyridine (DMAP) (1.28 g, 10.4 mmol), and triethylamine (TEA) (3.18 g, 31.4 mmol) were dissolved in 250 mL of dichloromethane. And succinic anhydride (4.72 g, 47.2 mmol) was added and the reaction mixture was allowed to stir for 24 h under argon at room tempera-ture. The reaction mixture was extracted by chloroform and water. The crude product was purified by silica-gel col-umn chromatography (eluent; ethyl acetate:chloroform, 1:6, v/v). The solid product was precipitated into methanol. The product was filtered and dried in a vacuum oven. Yield: 15.0 g (88%). ^{1}H NMR (400 MHz, CDCl$_3$) δ (ppm) 8.56–8.43 (m, 8H), 5.19–5.15 (m, 1H), 4.20–4.13 (m, 4H), 2.72–2.65 (m, 4H), 2.28–2.20 (m, 2H), 1.91–1.85 (m, 2H), 1.81–1.70 (m, 4H), 1.57–1.51 (m, 2H), 1.40–1.10 (m, 24H), 0.80 (t, 6H). Anal. calcd for C$_{50}$H$_{58}$N$_2$O$_8$: C 73.68; H 7.17; N 3.44, found: C 74.0; H 6.87; N 3.20. MS (*m/z*): [M$^+$+H] calcd for C$_{50}$H$_{58}$N$_2$O$_8$ 814.4; found 814.8.

Compound 5: Compound **4** (14.0 g, 42.5 mmol) and potassium acetate (8.34 g, 85.0 mmol) were dissolved in 300 mL of DMF. The reaction mixture was allowed to stir for 24 h under argon at 60 °C. The mixture was extracted by chloroform and water. The crude product was purified by silica-gel column chromatography (eluent; ethyl ace-tate:hexane = 1:10, v/v) to yield 6-(2,2′-bithiophen-5-yl)-hexyl acetate, **5**. Yield: 9.0 g (83%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 7.13 (d, *J* = 4.0 Hz, 1H), 7.08 (d, *J* = 4.4 Hz, 1H), 6.97–6.70 (m, 2H), 6.65 (d, *J* = 3.52 Hz, 1H), 4.03 (t, 2H), 2.76 (t, 2H), 2.02 (s, 3H), 1.70–1.57 (m, 4H), 1.37 (t, 4H). Anal. calcd for C$_{16}$H$_{20}$O$_2$S$_2$: C 62.30; H 6.54; S 20.79, found: C 62.46; H 6.54; S 20.63. MS (*m/z*): [M$^+$+H] calcd for C$_{16}$H$_{20}$O$_2$S$_2$ 308.1; found 308.4.

Compound 6: DMF (14.6 g, 0.2 mmol) and 1,2-dichloro-ethane (300 mL) was stirred at 0 °C. POCl$_3$ (6.33 g, 41.3 mol) was slowly added to the mixture for 30 min. Compound **5** (8.50 g, 27.5 mmol) in 1,2-dichloroethane (20 mL) was added dropwise over 20 min. The mixture

was stirred for 12 h at 60 °C. After completing the reaction, it was poured into 300 mL of ice water, and neutralized with NaHCO$_3$ aqueous solution. The aqueous solution was extracted with chloroform. The organics were then dried over Na$_2$SO$_4$, filtered, and the solvent was removed *in vacuo*. The resulting product was purified by silica-gel column chromatography (eluent; dichloromethane:hexane = 12:1, v/v) to yield 6-(5′-formyl-2,2′-bithiophen-5-yl)hexyl acetate, **6**. Yield: 8.20 g (89%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 9.83 (s, 1H), 7.65 (d, J = 4.28 Hz, 1H), 7.18–7.16 (m, 2H), 6.74 (d, J = 3.52 Hz, 1H), 4.06 (t, 2H), 2.82 (t, 2H), 2.04 (s, 3H), 1.74–1.60 (m, 4H), 1.42 (t, 4H). Anal. calcd for C$_{17}$H$_{20}$O$_3$S$_2$: C 60.68; H 5.99; S 19.06, found: C 60.65; H 5.90; S 19.17. MS (*m/z*): [M$^+$+H] calcd for C$_{16}$H$_{20}$O$_2$S$_2$ 336.1; found 337.3.

Compound 9: Octaethyl benzene-1,2,4,5-tetrayltetrakis(methylene)tetraphosphonate, **8** (2.71 g, 3.99 mmol), compound **6** (1.1 g, 3.23 mmol), and compound **7** (2.7 g, 9.70 mmol) were dissolved in 250 mL of dried THF. And potassium *tert*-butoxide (0.94 g, 8.40 mmol) in THF was slowly added and the reaction mixture was allowed to stir for 7 h under argon. It was poured into ethanol and HCl was added to obtain solid precipitate. The resulting product was purified by silica-gel column chromatography (eluent: toluene) to yield 6-(5′-((E)-4-((E)-2-(5′-heptyl-2,2′-bithiophen-5-yl)vinyl)-2,5-bis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl) styryl)-2,2′-bithiophen-5-yl)-hexyl acetate, **9**. Yield: 0.90 g (18%). ^{1}H NMR (300 MHz, CDCl$_3$): δ (ppm) 7.64 (s, 2H), 7.13 (s, 8H), 7.03–6.98 (m, 12H), 6.69 (d, J = 3.57 Hz, 4H), 4.06 (t, 2H), 2.79 (t, 8H), 2.05 (s, 3H), 1.71–1.63 (m, 10H), 1.42–1.28 (m, 22H), 0.89 (t, 9H). Anal. calcd for C$_{72}$H$_{80}$O$_2$S$_8$: C 70.08; H 6.53; S 20.79, found: C 69.12; H 5.96; S 20.30. MS (*m/z*): [M$^+$+H] calcd for C$_{72}$H$_{80}$O$_2$S$_8$ 1232.4; found 1232.3.

Compound 10: Compound **9** (0.80 g, 0.648 mmol) was dissolved in 250 mL of dried THF. LiOH (0.12 g, 2.85 mmol) in H$_2$O was added to mixture and allowed to stir for 24 h under argon. The mixture was neutralized with HCl aqueous solution. The aqueous solution was extracted with chloroform. The organics were then dried over Na$_2$SO$_4$, filtered, and the solvent was removed *in vacuo*. The resulting product was purified by silica-gel column chromatography (eluent: chloroform) to yield 6-(5′-((E)-4-((E)-2-(5′-heptyl-2,2′-bithiophen-5-yl)vinyl)-2,5-bis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl)-styryl)-2,2′-bithiophen-5-yl)hexan-1-ol, **10**. Yield: 0.6 g (85%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 7.63 (s, 2H), 7.13 (d, 8H), 7.02–6.98 (m, 12H), 6.68 (d, J = 4.76 Hz, 4H), 3.68–3.62 (m, 2H), 2.83–2.77 (m, 8H), 1.73–1.63 (m, 10H), 1.44–1.28 (m, 22H), 0.89 (t, 9H). MS (*m/z*): [M$^+$+H] calcd for C$_{70}$H$_{78}$OS$_8$ 1190.4; found 1191.0.

Compound 12: Compound **8** (1.44 g, 2.12 mmol) and compound **6** (3.0 g, 8.91 mmol) were dissolved in 250 mL of dried THF. And potassium *tert*-butoxide (3.0 g, 27.0 mmol) in THF was slowly added and the reaction mixture was allowed to stir for 7 h under argon. When the spot of compound **11** disappeared in the TLC, the mixture was poured into excess amount of H$_2$O. The filtrate was concentrated and organics were then dried over Na$_2$SO$_4$, filtered, and the solvent was removed *in vacuo*. The resulting product was purified by silica-gel column chromatography

(eluent: chloroform) to yield 6,6′,6″,6‴-(5′,5″,5‴,5‴′-(1E,1′E,1″E,1‴E)-2,2′,2″,2‴-(benzene-1,2,4,5-tetrayl)tetrakis-(ethene-2,1-diyl)tetrakis(2,2′-bithiophene-5′,5-diyl))-tetra hexan-1-ol. Yield: 0.7 g (28%). ^{1}H NMR (300 MHz, CDCl$_3$): δ (ppm) 7.89 (s, 2H), 7.49 (d, J = 15.0 Hz, 4H), 7.24–7.15 (m, 16H), 6.81 (d, J = 3.6 Hz, 4H), 4.37 (t, 4H), 2.79 (t, 8H), 2.51 (s, 8H), 1.63–1.33 (m, 32H). Anal. calcd for C$_{70}$H$_{78}$O$_4$S$_8$: C 67.81; H 6.34; S 20.69, found: C 67.14; H 6.51; S 19.81.

Compound 14: Compound **7** (4.62 g, 16.6 mmol) and compound **13** (4.0 g, 8.32 mmol) were dissolved in 250 mL of freshly dried THF. Potassium *tert*-butoxide (1.86 g, 16.64 mmol) in THF was slowly added and the reaction mixture was allowed to stir for 24 h under argon. It was poured ethanol to quench potassium *tert*-butoxide. The resulting crude product was purified by silica-gel column chromatography (eluent: chloroform) to yield 5′,5″-(1E,1′E)-2,2′-(2,5-dibromo-1,4-phenylene)bis(ethene-2,1-diyl)bis(5-hexyl-2,2′-bithiophene). Yield: 4.5 g (70%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 7.81 (s, 2H), 7.17 (d, J = 15.6 Hz, 2H), 7.11 (d, J = 15.6 Hz, 2H), 7.04–7.02 (m, 6H), 6.71 (d, J = 3.6 Hz, 2H), 2.80 (t, 4H), 1.71–1.66 (m, 4H), 1.39–1.30 (m, 12H), 0.90 (t, 6H). MS (*m/z*): [M$^+$+H] calcd for C$_{38}$H$_{40}$Br$_2$S$_4$ 782.0, found 782.3. Anal. calcd for C$_{38}$H$_{40}$Br$_2$S$_4$: C 58.16; H 5.14; S 16.34, found: C 58.85; H 5.01; S 17.16.

Compound 15: Methyltriphenylphosphonium iodide (6.0 g, 14.8 mmol) and potassium-*tert*-butoxide (1.66 g, 14.8 mmol) were mixed in 200 mL THF. The mixture was turned to be a yellow suspension. The reaction was allowed to stir for 10 min at room temperature and 50 mL, THF solution of compound **6** (5.0 g, 14.8 mmol) was slowly added into the mother mixture. After completion of the reaction, it was poured ethanol and hexane. The filtrate was concentrated and hexane was added to make precipitation of triphenylphosphate. The organics were then dried over Na$_2$SO$_4$, filtered, and the solvent was removed *in vacuo*. The resulting product was purified by silica-gel column chromatography (eluent: chloroform) to yield 6-(5′-vinyl-2,2′-bithiophen-5-yl)hexyl acetate. Yield: 1.5 g (31%). ^{1}H NMR (300 MHz, CDCl$_3$): δ (ppm) 6.97–6.93 (m, 2H), 6.84 (d, J = 3.9 Hz, 1H), 6.79–6.69 (m, 1H), 6.67 (d, J = 3.6 Hz,1H), 5.53 (d, J = 16.5 Hz, 1H), 5.13 (d, J = 10.8 Hz, 1H), 4.05 (t, 2H), 2.78 (t, 2H), 2.04 (s, 3H), 1.73–1.62 (m, 4H), 1.45–1.37 (m, 4H). MS (*m/z*): [M$^+$+H] calcd for C$_{18}$H$_{22}$O$_2$S$_2$ 334.1; found 334.1. Anal. calcd for C$_{18}$H$_{22}$O$_2$S$_2$: C 64.63; H 6.63; S 19.17, found: C 64.75; H 6.64; S 19.31.

Compound 16: Compound **14** (0.44 g, 1.8 mmol), compound **15** (1.3 g, 4.0 mmol), and tri-*o*-tolylphosphine (0.22 g, 0.72 mmol) were dissolved in 200 mL of DMF. Then, tributylamine (0.67 g, 3.6 mmol) was added into the mixture. After 10 min stirring, Pd(OAc)$_2$ (0.040 g, 0.18 mmol) was added and the mixture was stirred at 95 °C overnight. Then, water (150 mL) was added to the reaction mixture. The resultant precipitate was filtered and washed with methanol twice. The precipitate was purified by silica-gel column chromatography (eluent; chloroform:hexane = 2:1, v/v). Yield: 0.57 g (24%). ^{1}H NMR (300 MHz, CDCl$_3$): δ (ppm) 7.60 (s, 2H), 7.12–6.97 (m, 20H), 6.67 (d, J = 3.0 Hz, 4H), 4.06 (t, 4H), 2.79 (t, 8H),

2.05 (s, 6H), 1.70–1.62 (m, 12H), 1.42–1.31 (m, 20H), 0.90 (t, 6H). MS (m/z): [M$^+$+H] calcd for $C_{74}H_{82}O_4S_8$ 1290.4; found 1291.7. Anal. calcd for $C_{74}H_{82}O_4S_8$: C 68.79; H 6.40; S 19.86, found: C 67.94; H 6.35; S 20.14.

Compound 17: Compound **16** (1.50 g, 1.14 mmol) were dissolved in 200 mL of THF. LiOH (1.0 g, 23.8 mmol) in H_2O was added to mixture and allowed to stir for 24 h under argon at 75 °C. It was poured into excess amount of H_2O. The filtrate was concentrated and organics were then dried over $NaSO_4$, filtered, and the solvent was removed *in vacuo*. The resulting product was purified by silica-gel column chromatography (eluent; 1,2-dichloroethane:THF = 10:1, v/v). Yield: 1.2 g (86%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 7.65 (s, 2H), 7.15 (s, 8H), 7.03–6.99 (m, 12H), 6.69 (d, J = 3.2 Hz, 4H), 3.68–3.62 (m, 4H), 2.83–2.77 (m, 8H), 1.73–1.63 (m, 10H), 1.43–1.20 (m, 22H), 0.89 (t, 6H). MS (m/z): [M$^+$+H] calcd for $C_{70}H_{78}O_2S_8$ 1206.3; found 1206.4. Anal. calcd for $C_{70}H_{78}O_2S_8$: C 69.60; H 6.51; S 21.24, found: C 68.76; H 6.19; S 23.63.

HPBT-1(PDI), 18: Compound **10** (0.59 g, 0.49 mmol), compound **3** (0.64 g, 0.79 mmol), dicyclohexylcarbodiimide (DCC) (0.17 g, 0.837 mmol), and 4-(dimethylamino)-pyridium-4-toluene sulfonate (DPTS) (0.22 g, 0.74 mmol) were dissolved in 150 mL of 1,2-dichloromethane at room temperature under argon. The reaction mixture was allowed to stir for 24 h. After completion of the reaction, the solution was concentrated to the crude solid. Using chloroform, dissolution and filtration were repeated for removing white dicyclohexyl urea. The resulting mixture was poured into methanol to make the precipitate and the crude product was filtered. The resulting product was purified by silica-gel column chromatography (eluent; chloroform:ethyl acetate = 50:1, v/v) and soxhlet extraction (methanol, 24 h). Yield: 0.82 g (83%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 8.61–8.50 (m, 8H), 7.48 (d, J = 5.6 Hz, 2H), 7.03–6.93 (m, 18H), 6.91 (d, J = 4.0 Hz, 2H), 6.69–6.66 (m, 4H), 5.18–5.10 (m, 1H), 4.12–4.08 (m, 6H), 2.80 (t, 8H), 2.62 (s, 4H), 2.23–2.14 (m, 2H), 1.91–1.82 (m, 4H), 1.70–1.67 (m, 12H), 1.52–1.19 (m, 48H), 0.90 (t, 9H), 0.81 (t, 6H). Anal. calcd for $C_{120}H_{137}O_8S_8$: C 72.47; H 6.79; N 1.41; S 12.90, found: C 72.73; H 6.65; N 1.20; S 12.13.

HPBT-2(PDI), 19: Compound **17** (0.7 g, 0.57 mmol), compound **3** (1.63 g, 2.0 mmol), DCC (0.47 g, 2.29 mmol), and DPTS (0.62 g, 2.11 mmol) were dissolved in 150 mL of 1,2-dichloromethane at room temperature under argon. The reaction mixture was allowed to stir for 36 h. After completion of the reaction, the solution was concentrated to the crude solid. Using chloroform, dissolution and filtration were repeated for removing white dicyclohexyl urea. The resulting mixture was poured into methanol to make the precipitate and the crude product was filtered. The resulting product was purified by silica-gel column chromatography (eluent: chloroform:THF = 20:1, v/v) and soxhlet extraction (methanol, 24 h). Yield: 1.1 g (68%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 8.56–8.45 (m, 16H), 7.37 (s, 2H), 6.99 (m, 20H), 6.68 (d, J = 3.6 Hz, 4H), 5.18–5.12 (m, 2H), 4.12–4.08 (m, 12H), 2.82–2.77 (m, 8H), 2.62 (s, 8H), 2.23–2.17 (m, 4H), 1.89–1.84 (m, 8H), 1.72–1.63 (m, 14H), 1.52–1.19 (m, 74H), 0.90 (t, 6H), 0.81 (t, 12H). Anal. calcd for $C_{170}H_{190}N_4O_{16}S_8$: C 72.87; H 6.84; N 2.00; S 9.16, found: C 72.75; H 6.64; N 1.66; S 9.72.

HPBT-4(PDI), 20: Compound **12** (0.5 g, 0.4 mmol), compound **3** (1.47 g, 1.8 mmol), DCC (0.39 g, 1.89 mmol), and DPTS (0.498 g, 1.69 mmol) were dissolved in 150 mL of 1,2-dichloromethane at room temperature under argon. The reaction mixture was allowed to stir for 36 h at 60 °C. After completion of the reaction, the solution was concentrated to the crude solid. Using chloroform, dissolution and filtration were repeated for removing white dicyclohexyl urea. The resulting mixture was poured into methanol to make the precipitate and the crude product was filtered. The resulting product was purified by silica-gel column chromatography (eluent: chloroform:THF = 10:1, v/v) and soxhlet extraction (methanol, 24 h). Yield: 0.5 g (28%). ^{1}H NMR (400 MHz, CDCl$_3$): δ (ppm) 8.56–8.33 (m, 32H), 7.13 (s, 2H), 6.97 (d, J = 3.6 Hz, 4H), 6.93 (d, J = 3.6 Hz, 4H), 6.84 (d, J = 3.6 Hz, 4H), 6.78 (d, J = 15.6 Hz, 6H), 6.68–6.64 (m, 6H), 5.16–5.12 (m, 4H), 4.13–4.07 (m, 24H), 2.83–2.79 (m, 8H), 2.62 (s, 16H), 2.23–2.18 (m, 8H), 1.90–1.85 (m, 16H), 1.75–1.66 (m, 28H), 1.51–1.42 (m, 22H), 1.36–0.20 (m, 96H), 0.81 (t, 24H). Anal. calcd for $C_{270}H_{302}N_4O_{32}S_8$: C 73.24; H 6.87; N 2.53; S 5.79, found: C 72.22; H 6.24; N 2.08; S 4.88.

2.2. Instrumental analysis

^{1}H NMR spectra were recorded on a Varian Mercury NMR 400 Hz spectrometer using deuterated chloroform purchased from Cambridge Isotope Laboratories, Inc. Elemental analyses were performed by the Center for Organic Reactions (Sogang University, Seoul, Korea) using an EA1112 (Thermo Electron Corp.) elemental analyzer. Mass analysis was performed on a JMS-AX505WA (JEOL) mass spectrometer. Thermal properties were studied under a nitrogen atmosphere on a Mettler DSC 821^e instrument. Thermal gravimetric analysis (TGA) was conducted on a Mettler TGA50 (temperature rate 10 °C/min under N$_2$). The redox properties of HPBT-n(PDI) were examined using cyclic voltammetry (Model: EA161 eDAQ). Thin films were coated on a platinum plate using chloroform as a solvent. The electrolyte solution employed was 0.10 M tetrabutyl-ammonium hexafluorophosphate (Bu$_4$NPF$_6$) in freshly dried methylene chloride (MC). The Ag/AgCl and Pt wire (0.5 mm in diameter) electrodes were utilized as reference and counter electrodes, respectively. The scan rate was at 50 mV/s. The X-ray diffraction (XRD) experiment (2θ = 1°–40°) was performed at varying temperatures using the synchrotron radiation (1.542 Å) of the 3C2 beam line at the Pohang Synchrotron Laboratory, Pohang, Korea. The film samples were fabricated by drop-casting on a silicon wafer, followed by drying at 80 °C under vacuum. Absorption spectra of samples in a film were obtained using a UV–vis spectrometer (HP 8453, photodiode array type) in the wavelength range of 190–1100 nm. PL spectra were recorded with a Hitachi's F-7000 FL Spectrophotometer.

2.3. OPV device fabrication

ITO (indium tin oxide) glass (resistance of 19.5 Ω/cm) was cleaned by a conventional cleaning method. This cleaned ITO-coated glass was treated with O$_2$ plasma with a microwave-generated plasma reactor (Plasmatic Systems

Inc., PLASMATIC-PREENII, 24 GHz) for 15 min, and a 30 nm thick PEDOT:PSS layer (Baytron P, 1 S cm^{-1}) was deposited by spin-coating. HPBT-n(PDI) (thickness = 150 nm) was dissolved in anhydrous monochlorobenzene (conc. 2 wt.%), then 0.8 nm thick LiF was vacuum deposited on top of the active layer and the 150 nm thick aluminum was evaporated. The thickness of the photoactive film was measured with a surface profiler (TENCOR®, P-10 α-step). Current–voltage characteristics were measured with a Keithley 2400 source-measure unit. A 300 W Xe lamp was used as a light source to produce an intensity of 100 mW cm^{-2} (AM 1.5). The intensity of the incoming light power was measured with a calibrated broadband optical power meter (Spectra Physics model 404).

3. Results and discussion

3.1. Materials synthesis and properties

First a multi-step synthesis was performed for new donor-σ-acceptor molecules, such as **18**, **19**, and **20** (see Scheme 1 and 2). Scheme 1 illustrates the synthesis of PDI derivative, **3** and thiophene-based carbaldehyde, **6**. The synthesis of **3** was conducted using a modified literature method [17b,19a,22a].

Succinic anhydride was reacted in the presence of dimethyl aminopyridine/triethylamine to attach the carboxylic acid group to the hydroxyl group in the PDI precursor molecule, **2**. In order to synthesize 6-(5′-formyl-2,2′-bithiophen-5-yl)hexyl acetate, **6**, compound **4** was reacted with potassium acetate in DMF to yield compound **5**. Then, using Vilsmeier–Haak reaction condition, formylation was performed in a good yield (89%).

In order to prepare the X-shaped thiophene-based molecule, **10**, **6** and **7** were employed for the Horner–Emmons coupling reaction [25]. After mixing two carbaldehydes with 1:3 ratio, Horner–Emmons coupling reaction into octaethyl benzene-1,2,4,5-tetrayltetrakis(methylene)tetraphosphonate, **8** produces 6-(5′-((E)-4-((E)-2-(5′-heptyl-2,2′-bithiophen-5-yl)vinyl)-2,5-bis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl)styryl)-2,2′-bithiophen-5-yl)-hexyl acetate, **9**. After deprotecting an acetate group in **9** to generate hydroxyl group in the presence of lithium hydroxide, **10** was prepared successfully. Following the same coupling method for **10**, the compound **12** bearing four hydroxyl groups at the outer periphery was also pre-

pared by using **6–8** and *in situ* deprotection reaction of acetate groups in compound **11** was conducted in the presence of excess amount of potassium *tert*-butoxide (see Scheme 2).

When preparing the compound **17**, we synthesized 5′,5″-(1E,1′E)-2,2′-(2,5-dibromo-1,4-phenylene)bis(ethene-2,1-diyl)bis(5-hexyl-2,2′-bithiophene), **14** by reacting **7** with tetraethyl (2,5-dibromo-1,4-phenylene)bis(methylene)diphosphonate, **13**. Using 6-(5′-formyl-2,2′-bithiophen-5-yl)hexyl acetate, Wittig reaction was performed to produce 6-(5′-vinyl-2,2′-bithiophen-5-yl)hexyl acetate using methyltriphenylphosphonium iodide and potassium-*tert*-butoxide in THF.

Then, Pd-catalyzed Heck coupling reaction with tri-*o*-tolylphosphine ligand was performed to yield compound 6,6′-(5′,5″-(1E,1′E)-2,2′-(2,5-bis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl)-1,4-phenylene)bis(ethene-2,1-diyl)bis(2,2′-bithiophene-5′,5-diyl))bis(hexane-6,1-diyl) diacetate, **16**. Deprotection reaction of acetate groups yields **17** bearing two hydroxyl groups (see Scheme 3).

Then, individual donor molecule such as **10**, **12**, or **17**, bearing hydroxyl group(s) and **3** bearing a carboxylic acid group were combined through dicyclohexylcarbodiimide (DCC) catalyzed esterification in the presence of 4-(dimethylamino)-pyridium-4-toluene sulfonate (DPTS). Finally, three new donor-σ-acceptor molecules: HPBT-1(PDI), **18**, HPBT-2(PDI), **19**, and HPBT-4(PDI), **20**, were successfully synthesized for the study (see Scheme 4).

We also prepared 1,2,4,5-tetrakis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl)benzene (HPBT) having four hexyl substituted bithiophene peripheral groups, which will be denoted as **21** in this work [25]. In addition, a symmetric PDI molecule, **22** was also synthesized by following the literature method for using it as a n-type semiconducting molecule [26]. The identity and purity of the synthesized materials were confirmed by ^{1}H NMR, mass spectrometry, and elemental analysis. They were found to have good self-film forming properties and were well-soluble in various organic solvents such as chloroform, xylene, methylene chloride (MC), monochlorobenzene, and tetrahydrofuran (THF).

The thermal properties of the donor-σ-acceptor molecules were characterized by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). DSC measurements were carried out at a heating (cooling) scan rate of 10 (−10) °C/min under N$_2$ with the highest temperature below the decomposition temperature. In DSC
Scheme 1. Reagents and conditions; (i) 5-aminopentan-1-ol, DMAc, Zn(OAc)$_2$, 160 °C, 15 h, (ii) succinic anhydride, TEA, DMAP, 1,2-dichloroethane, r.t., 24 h, (iii) KOAc, DMF, 60 °C, 24 h, (iv) POCl$_3$, DMF, 1,2-dichloroethane, 60 °C, 12 h.

thermograms, **18** and **19** exhibited a distinct crystalline-isotropic transition at 140 °C and 117 °C, respectively. The crystallization temperatures of **18** and **19** were also observed at 111 °C and 87 °C, during the cooling cycle. In contrast, **20** did not show a crystalline melting temperature, but it did show a glass transition temperature at 75 °C only, indicating its amorphous nature (see Table 1). TGA measurements at a heating rate of 10 °C/min under nitrogen revealed good thermal stability of the donor-σ-acceptor molecules. These molecules exhibit the onset decomposition temperatures at around 389–391 °C. The density of PDI unit did not affect the decomposition behavior.

3.2. Absorption and photoluminescence spectroscopy

The absorption spectra of HPBT-n(PDI)s were recorded both in solution (conc. 5×10^{-6} M in CHCl$_3$) and in film

states. The solution of **22** exhibited a typical singlet transition in the range of 410–550 nm with a well-resolved vibronic structure, attributed to the vibration of the perylene structural unit.

Meanwhile, the donor, **21** showed absorption bands in the range of 300–510 nm. The spectra of HPBT-n(PDI)s illustrated that coupled compounds demonstrate $\pi-\pi^*$ energy transitions in individual **21** and **22**. The absorption spectrum of **18** showed characteristic bands arising from the presence of the PDI groups, with maxima at 527, 486, and 422 nm in the solution state, the latter overlapping with the lowest energy band from HPBT (λ_{max} = 419 nm). In the spectra of **19** and **20**, three characteristic bands at 456, 489, and 527 nm were commonly observed and their absorbance was shown to be linearly proportional to the number of PDI units in the molecule (see Fig. 1A).

Fig. 1B shows the absorption spectra of the thin films of **18**, **19**, and **20**. Compared to the solution spectra, a drastic

spectral change in the film state was observed; possibly attributable to a high degree of intermolecular interaction [24,29,25,30]. The HPBT moieties can interact strongly to induce broadening of the spectrum. In addition, PDI molecules can also exhibit intermolecular interaction to induce spectral broadening and a bathochromic shift. A linear additive spectral feature was maintained, similar to the solution spectra of HPBT-n(PDI). It should be noted that the absorption spectra of HPBT-n(PDI) exhibit superposition of the characteristics peaks of pure HPBT and pure PDI without indications of additional spectral features in either the solution or in the solid state. This observation indicates that there is no significant interaction between the electroactive units in the ground state.

The HOMO and LUMO energy values must fulfill the energetic conditions required for the energy transfer as well as for the electron transfer. The energy is transferred from the excited donor to the acceptor, which can be interpreted as photoluminescence (PL) quenching of the donor and a simultaneous emission from the acceptor.

In Fig. 2A, absorption spectra of **21** and **22** and corresponding PL spectra were overlaid. From the figure, it is readily observed that the emission spectrum of HPBT and the absorption spectrum of PDI are favorably overlapped, which enables efficient Förster energy transfer. In a solution state, an efficient energy transfer process could occur to exhibit the unique emission of PDI only. Only the three solution samples of HPBT-n(PDI) showed fluorescent emission behavior ($\lambda_{excitation}$ = 418 nm) resulting from PDI moi-
Fig. 2. (A) Absorption and photoluminescence spectra of **21** and **22** in solution (conc; 5×10^{-6} M) states. Solid line: absorption spectrum, Dotted line: PL spectrum. (B) PL spectra of HPBT-n(PDI)s both in solution and film states. (c) **18**, (d) **19**, (e) **20**. *Inset: solution PL spectra of blend samples of **21** and **22**. (f) **21**:**22** = 1:1, (g) **21**:**22** = 1:2, (h) **21**:**22** = 1:4 (mole ratio).

ety, indicating highly efficient energy transfer from HPBT. In the inset of Fig. 2B, the PL spectra of blend samples with **21** and **22** were displayed with the blend ratio. Three ratios were selected as the same mole ratios in HPBT-*n*(PDI)s. The emission spectrum of **21** is clearly overlapped with that of **22**. The PL intensity at 550 nm emitted from **21** was enhanced with the mole fraction of **21** in the mixture. Shortly, covalent bonding between the donor and acceptor increases the energy transfer efficiency even in the solution states.

All film samples were selectively excited at 400 nm; **3** had minimal absorbance at this wavelength. No emission behaviors were observed in three film samples (see Fig. 2B, dotted lines). The PL quenching behaviors can be explained as follows; the aggregation-induced self-quenching of the excited states of HPBT and PDI units can occur. In the other respect, it might be due to the intermolecular electron transfer from the photoexcited HPBT to PDI moieties. The photoinduced charge transfer in other conjugated molecular composites by PL quenching can be found in the literatures [31]. Besides a rapid electron transfer process, some diffusion-limited processes were also suggested [32].

3.3. Electrochemical analysis

To probe the electrochemical properties of HPBT-*n*(PDI) films, cyclic voltammetry was carried out in a three-electrode cell setup. All potentials reported were referenced to an Fc/Fc$^+$ standard. The results are tabulated in Table 1. Voltammograms of HPBT-*n*(PDI) in the film state showed that the lowest oxidative waves of **18**, **19**, and **20** were at +0.85, +0.84, and +0.85 V, respectively, which indicates no significant effect by the density of the electron acceptor. The oxidation potentials of the three molecules were almost identical to that of **21** ($E_{\text{onset}}^{\text{ox}} = +0.85$ V). As shown in Table 1: **18**, **19**, and **20** have HOMO levels of −5.25, −5.24, and −5.25 eV, respectively, which indicates no significant effect by the density of the electron acceptor. The oxidation potentials and HOMO levels of the three molecules were almost identical to that of **21**. In addition, **18**, **19**, and **20** have LUMO energy levels of −3.71, −3.71, and −3.72 eV, respectively. The LUMO level is almost consistent with that ($E_{\text{LUMO}} = 3.72$ eV) of the individual PDI molecule, **22**.

Although two opposite electroactive moieties were bound together, HOMO and LUMO levels were not significantly changed, which implies that the two moieties were isolated well enough so as not to be able to interact with each other, even in the solid state; this is also reflected in the fact that the UV–vis absorption spectrum shows no charge transfer band.

It should be noticed that HOMO levels of **21** and all donor-σ-acceptor molecules are almost similar to that of poly(3-hexylthiophene). ($E_{\text{HOMO}} \sim 5.20$–5.21 eV) Considering the LUMO level ($E_{\text{LUMO}} \sim 3.77$–3.82 eV) of PDI unit, the combined molecules may exhibit reasonably high open circuit voltage (V_{oc}) in the photovoltaic devices as this energy is closely related to the energy difference between the HOMO of an electron donor and the LUMO of an electron-accepting molecules. As can be seen from the energy

levels, there is an adequate energy offset for electron transfer from HPBT to the PDI unit.

Shortly, resulting from absorption spectral analysis and electrochemical analysis, the electron donor and accepting molecules do not interact intra- and intermolecularly significantly. Therefore, we can employ their isolated electronic properties for optoelectronic applications. In particular, regarding the photovoltaic devices, we can utilize their structural uniqueness, displaying the covalent binding of electron donor and electron acceptor. One of the important issues is whether their intrinsically opposite semiconducting domain can be separated in a nano-scale regime for generating the continuous electron and hole channels in one matrix.

3.4. Materials structures

In order to study the crystallinity and variation of crystalline conformation of HPBT-*n*(PDI), X-ray diffraction (XRD) experiments were performed at varying temperatures using the synchrotron radiation (1.542 Å) of the 3C2 beam line. The film samples ($t \sim 50$–60 nm) were fabricated by spin-coating on silicon wafer, followed by drying at 80 °C under vacuum (solvent: chloroform, concentration of the solution: 10 mg/mL). The measurements were obtained in a scanning interval of 2θ between 1° and 40°. As previously reported [21], HPBT molecules are well associated and stacked by the interaction between terminal hexyl groups, which are already known to induce long-range ordering. In the literature, well-defined XRD patterns also demonstrate facile crystallization of planar PDI molecules [30–33].

First, the diffraction scans of the film of **18** were displayed in a small angle region under a heating and cooling cycle. In the as-coated sample, two major diffraction peaks were observed, which are attributed, to some degree, to lamella ordering. When the temperature of the sample was increased to 80 °C, a very high intensity and narrow diffraction peak appeared at $2\theta = 3.13°$ ($d = 28.24$ Å). Although a weak diffraction peak was observed at around 5.57° ($d = 15.80$ Å), the main peak at 3.13° is clearly assigned to the edge-to-edge transverse packing of the peripheral arms in HPBT moieties, which is fairly consistent with the calculated distance ($d = 29.0$ Å).

Upon subsequent heating to 150 °C, the peak at 3.13° disappears and the peak at 5.57° grows, accompanying the weak and broad reflection peaks at 14.7° ($d = 6.02$ Å). At this high temperature, it is noted that PDI molecules begin to be ordered by independent crystallization. During the cooling cycle, the crystallinity in the PDI molecular domains is maintained or a little enhanced and it is possible to regenerate the relatively small crystalline domain with the HPBT moieties.

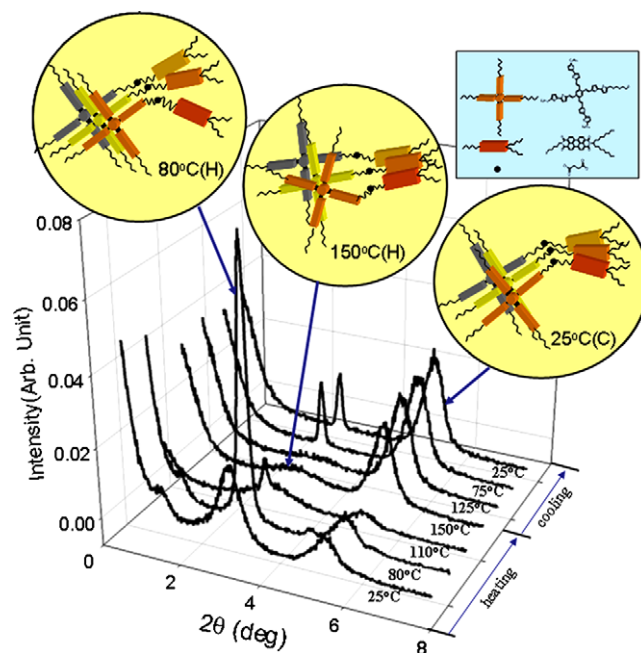
As a result, the HPBT moieties are self-associated to be highly crystallized at around 80–90 °C. The X-ray diffraction (XRD) result in the small angle region and the schematic diagram of the expected localized molecular conformation are depicted in Fig. 3. However, we cannot exclude the possibility for HPBT-1(PDI) to exhibit intercalation between the donor and acceptor moieties.


Fig. 3. XRD analysis of HPBT-1(PDI), **18** with the temperature. *Possible molecular geometry of the HPBT and PDI unit in the solid state. (H): heating cycle, (C) cooling cycle.
Fig. 4. XRD analysis of HPBT-2(PDI), **19** with the temperature. *Possible molecular geometry of the HPBT and PDI unit in the solid state. (H) Heating cycle, (C) cooling cycle.

Meanwhile, the XRD results of **19** showed different X-ray diffractograms with the temperature (see Fig. 4). The diffraction scans of the film of **19** also displayed in a small angle region under a heating and cooling cycle. At 25 and 80 °C, we could observe two small diffraction peaks at 3.33 (d = 26.54 Å) and 5.56° (d = 15.7 Å) from the ordering

of HPBT and PDI units to a small extent. At 105 °C, the lower angle diffraction peak shifted to 3.28° whose *d*-spacing is 26.95 Å, which indicates that the HPBT moieties placed in an energetically favorable ordered structure. At 130 °C, the diffraction intensity arising from HPBT ordering significantly reduced. When cooling cycle, very strong diffraction peak at 2.96° (*d* = 29.86 Å) appeared again with smaller full width at half maximum and maintained until cooling to 25 °C.

Compared to the diffraction behaviors of **18**, the HPBT moieties exhibited relatively more uniform ordering. At this temperature range during cooling, it is noted that HPBT central moieties induce high degree of lamella ordering accompanied with PDI ordering. The HPBT moieties are highly self-associated to be crystallized until cooling from melting temperature to 25 °C. The compound **20** showed less crystalline property and amorphous nature compared to that of **18** and **19**, which is due to the steric effect of HPBT moiety.

3.5. Photovoltaic properties

Finally, the potential of the newly synthesized donor-σ-acceptor molecules as photoactive materials in a PV cell is explored. In a macroscopic respect, the solid state of HPBT-*n*(PDI) can form either an intermolecular charge transfer complex or heterogeneous domains. It is more likely to be a bulk heterojunction in which **21** and **22** are connected through covalent bonding. The electronically opposite two moieties were aggregated in individual domains that can form a uniform interpenetrating network.

The device configurations are as follows: **Device A**: ITO/PEDOT:PSS/**21:22** (1:1, mole ratio)/LiF/Al, **Device B**: ITO/PEDOT:PSS/**18**/LiF/Al, **Device C**: ITO/PEDOT:PSS/**19**/LiF/Al, **Device D**: ITO/PEDOT:PSS/**20**/LiF/Al. Fig. 5 illustrates the device configurations and the current density–voltage characteristics of the most effective as-fabricated devices in the dark and under air mass (AM) 1.5 simulated solar illumination. The PV device performances are tabulated in Table 2. The PCE of the **21:22** (1:1 mol ratio) blend device was calculated to be 0.04% (V_{oc} = 0.55 V, J_{sc} = 0.28 mA cm^{-2}, fill factor = 0.28), which is significantly poor. Highly improved device performance was observed when using **18** as the photoactive layer than with the device using the blend sample.

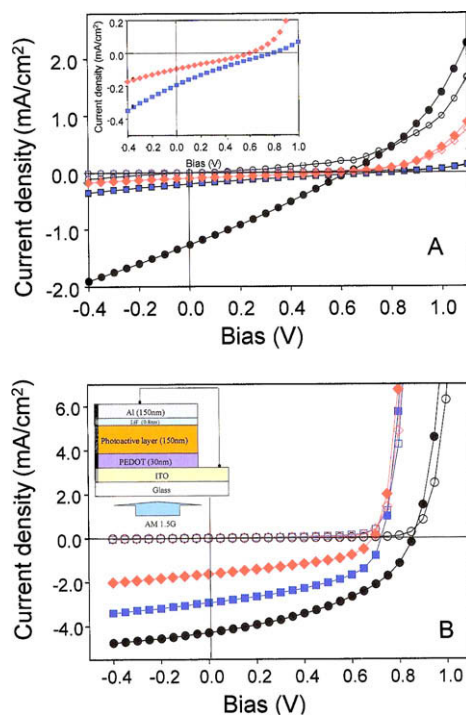
In **Device B**, the sample was annealed at 80 °C for 20 min. The PV cell gave a relatively large PCE of 0.22% with a V_{oc} ranging from 0.62 to 0.63 V. It should be noted that the sample annealed at 120 °C only exhibited 0.038% of the PCE. As a result of the XRD study, the association of HPBT moieties were disrupted at 120 °C to randomize the p-channels for hole transport. Crystallization of HPBT moieties at 80 °C is significant to the enhancement of PV properties. The annealed **Device C** exhibited a relatively low J_{sc} value and 0.034% of the PCE. Since larger amount of PDI moiety in the photoactive layer exists, interpenetrating network cannot be formed uniformly; p-channel HPBT domain was surrounded by n-channel moieties and hole transporting channel might be disrupted. Therefore, it exhibits poor hole transport through the HPBT moieties to induce charge build-up, which results in poor PCE. As


Fig. 5. Current density–voltage characteristics of PV devices under AM 1.5 simulated solar illumination of 100 mW cm^{-2}. *Filled symbol: photocurrent density, open symbol: dark current density. (A) (circle) **18**, (square) **19**, (diamond) **20**. *Inset: expanded curves of **19** and **20**-based PV devices. Table 2
Summary of device performance for HPBT-*n*(PDI) and its blend with PCBM based photovoltaic (PV) cells.

|	V_{oc} (V)	J_{sc} (mA cm^{-2})	FF	PCE (%)
Device A	0.549	−0.277	0.277	0.040
Device B	0.629	−1.267	0.273	0.217
Device c	0.798	−0.195	0.218	0.034
Device D	0.607	−0.097	0.283	0.017
Device E	0.855	−4.300	0.435	1.600
Device F	0.722	−2.935	0.490	1.039
Device G	0.690	−1.636	0.455	0.513

can be expected, the amorphous **20**-based **Device D** exhibited a much lower PCE value of approximately 0.017%.

Subsequently, efforts were made to improve the PV properties by adding PCBM into the donor-σ-acceptor molecules. Three more devices were also fabricated for characterization under an identical device configuration: **Device E:** ITO/PEDOT:PSS/**18**:PCBM/LiF/Al, **Device F**: ITO/PEDOT:PSS/**19**:PCBM/LiF/Al, **Device G**: ITO/PEDOT:PSS/**20**:PCBM/LiF/Al. When PCBM was added into the molecules (1:4 mol ratio), the film samples showed significant increment of the absorption in the visible range. Resulting from the addition of extra PCBM molecules, the device performances were significantly enhanced, as was expected. Keeping in mind the previous tendencies of the PCEs in the three devices, **B**, **C**, and **D**, **Device E** exhibited the best efficiency (η = 1.60%); the value is higher than seven times

that of **Device B**. The other two devices also showed significant enhancement of PCE compared to the devices containing no PCBM. **Device**s **F** and **G** exhibited almost 15–16-fold J_{sc} values, providing 30 times higher PCE, respectively, when compared to **Devices C** and **D** containing no PCBM (see Table 2). Enhancement of PCE arises from the increase of the short circuit current (J_{sc}) which is mainly attributed to increase of absorption in the visible range.

4. Conclusion

New donor-σ-acceptor molecules bearing the cruciform p-type HPBT molecule and PDI derivatives have been demonstrated. HPBT-1(PDI), **18** and HPBT-2(PDI), **19** are typical molecules displaying mesoscopic self-organization by virtue of crystallization of HPBT moieties. PV devices were fabricated, either with PCBM or without PCBM. Additional PCBM enhance the absorption in the visible light region. Thus the power conversion efficiency and fill factor were significantly enhanced. The results in this work demonstrate the high potential of donor-σ-acceptor molecules as photovoltaic materials. Instead of HPBT moiety, a low-bandgap donor molecule is introduced in D-σ-A structures and characterization of their ability is now in progress.

SAM dielectrics is comparable to or smaller than the current density through the gate dielectrics of modern silicon field-effect transistors that use high-temperature-grown inorganic gate oxides with a thickness of 2–3 nm [25,26].

In order to better understand the properties of the thin oxide/SAM double-layer dielectrics it is necessary to distinguish between the influence of the thin oxide and the influence of the molecular monolayer on the performance of the double-layer dielectric. In this work we compare the electrical characteristics of thin aluminum oxide/SAM double-layer dielectrics prepared using two different oxidation procedures and five different aliphatic phosphonic acids (Fig. 1c) on aluminum electrodes. To separate the effects of the oxide and the SAM on the insulating properties, we have performed current-voltage measurements on metal/oxide/SAM/metal capacitors and cyclic voltammetry measurements on ITO/SAM devices.

2. Experimental

The aluminum oxide (AlO$_x$) layers have a thickness of about 3.6 nm and the SAMs range in thickness from 0.4 to 2.4 nm. For each combination of oxidation procedure and SAM thickness, capacitor devices (Al/AlO$_x$/SAM/Au) and bottom-gate, top-contact pentacene organic TFTs (in which the AlO$_x$/SAM stack serves as the gate dielectric) were fabricated and characterized.

The aluminum electrodes were prepared by thermal evaporation of 30 nm thick aluminum through a stencil mask onto glass substrates. To create a thin AlO$_x$ layer, the surface of the freshly evaporated aluminum was plasma-activated using one of two methods. Method A is an oxygen-plasma treatment performed in a turbo-pumped parallel-plate reactive ion etcher (process pressure: 0.1 mbar, plasma frequency: 13.56 MHz, plasma power: 200 W, duration: 30 s) that produces an AlO$_x$ layer with a thickness of about 3.6 nm and a permittivity of nine [2]. Method B is a mild-air plasma (2 mbar, 40 kHz, 200 W, 120 s) which creates an AlO$_x$ film with approximately the same thickness and surface roughness (rms roughness = 1.5 nm, measured by atomic force microscopy) as method A, but with smaller density and hence smaller permittivity (ε = 5). After the plasma treatment, the substrates

were immersed in a 2-propanol solution containing 5 mM of one of five different alkyl phosphonic acids (dicyl-PA [C$_2$-PA], hexyl-PA [C$_6$-PA], decyl-PA [C$_{10}$-PA], tetradecyl-PA [C$_{14}$-PA], octadecxl-PA [C$_{18}$-PA]) to allow a monolayer with a thickness approximately proportional to the length of the molecule (assuming similar molecular tilt angles) to self-assemble on the hydroxyl-terminated surface of the plasma-oxidized aluminum. The solution was kept at room temperature, and substrates remained in solution for about 24 h. Substrates were then rinsed with 2-propanol, dried, and briefly baked at a temperature of 60 °C on a hotplate. Static contact angles of 105–110° were obtained for all films, except for the substrates with C$_2$-PA on which a slight corrosion of the aluminum patterns was observed and a smaller static contact angle of 80° was measured. The capacitors were completed by evaporating 30 nm thick gold through a stencil mask on top of the SAMs, resulting in capacitors with areas of 30 × 30 μm^2, 50 × 50 μm^2 and 100 × 100 μm^2 (Fig. 1a and b). Organic TFTs were completed by evaporating 30 nm thick pentacene on top of the SAM-coated aluminum gate stack through a stencil mask, followed by evaporating 30 nm thick gold through another stencil mask to create the source/drain contacts (Fig. 1d and e). The pentacene TFTs have a channel length (L) of 30 μm and a channel width (W) of 450 μm.

For cyclic voltammetry measurements, the SAMs were prepared on ITO-coated glass substrates from solution with the same process described above for the Al/AlO$_x$/SAM/Au capacitors, but without an AlO$_x$ layer and without a metal top contact. Static contact angles after SAM formation on ITO were similar to those for SAMs on aluminum oxide (105–115°). The ITO/SAM devices have an electrode area of 288 mm^2, which is much larger than the area of the Al/AlO$_x$/SAM/Au capacitors. The cyclic voltammetry measurements were carried out in a 0.9% NaCl(aq) solution using K$_3$[Fe(CN)$_6$] as a redox-active indicator.

3. Results and discussion

3.1. Capacitor devices

To investigate the dielectric properties of the double-layer insulator stacks we have measured the capacitance

of each Al/AlO$_x$/SAM/Au device at frequencies from 10 kHz to 1 MHz and the current density through each stack as a function of applied voltage up to dielectric breakdown. Each measurement was repeated on at least four capacitors. The results are independent of the capacitor cell area. The measured capacitances are summarized in Table 1 and compared with the capacitances calculated using the equation $C_{total} = 1/(1/C_{SAM} + 1/C_{AlO_x})$ assuming a permittivity of 2.5 for the SAM [27], a permittivity of nine for the oxygen-plasma-grown AlO$_x$, a permittivity of five for the mild-air-plasma-grown AlO$_x$, a thickness of 3.6 nm for the AlO$_x$, and a thickness between 0.41 and 2.44 nm for the SAM, depending on alkyl chain length. The measured capacitances are between 0.38 µF/cm^2 for mild-air-plasma-grown AlO$_x$/C$_{18}$-PA SAM and 1.75 µF/cm^2 for oxygen-plasma-grown AlO$_x$/C$_2$-PA SAM, and they are in good agreement with the calculated values.

Fig. 2 shows the measured current density as a function of applied voltage. For the series of capacitors with oxygen-plasma-grown AlO$_x$ (ε = 9; see Fig. 2a), the breakdown voltage is essentially the same (4.4 V) for devices without SAM and devices with short SAM (C$_6$-PA, C$_2$-PA). When the SAM chain length is increased to C$_{10}$ and beyond, a monotonic increase in breakdown voltage is observed, up to 5 V for C$_{18}$-PA. With the exception of the devices with C$_2$-PA (which appears to corrode the aluminum) the current density at low voltages ($\sim$1–2 V) is similar for all devices with SAM regardless of chain length and slightly smaller than for devices without SAM (4×10^{-7} A/cm^2 at 1 V; 4×10^{-6} A/cm^2 at 2 V). When the voltage is increased beyond 2 V, the increase in current density with increasing voltage is greater for the devices with shorter SAM chain length than for those with longer SAM chain length. At large voltage ($\sim$4 V), the current density through the devices with C$_{18}$-PA SAM is two orders of magnitude smaller than through the devices without SAM, confirming the important role of the SAM in limiting the current density.

The devices based on mild-air-plasma-grown AlO$_x$ (ε = 5) show slightly different results (see Fig. 2b). Most significantly, the devices without SAM have a smaller breakdown voltage and a larger current density than the oxygen-plasma-grown AlO$_x$ without SAM (breakdown voltage is 4 V instead of 4.4 V; current density at 2 V is 1×10^{-1} A/cm^2 instead of 2×10^{-5} A/cm^2). We attribute

these findings to the lower quality of the mild-air-plasma-grown AlO$_x$ compared with the oxygen-plasma-grown AlO$_x$ (lower density, larger number of leakage paths). Consequently, the devices with mild-air-plasma-grown AlO$_x$ and SAM also show larger current density than the oxygen-plasma-grown AlO$_x$/SAM devices. In the devices with C$_{10}$-PA, C$_{14}$-PA and C$_{18}$-PA SAM the current density at 2 V is larger by about one order of magnitude ($\sim$3 $\times$ 10^{-5} A/cm^2 instead of 4 $\times$ 10^{-6} A/cm^2), while the devices with C$_6$-PA SAM show a more pronounced dependence on the oxide quality and hence a current density that is more than two orders of magnitude larger (8 $\times$ 10^{-4} A/cm^2 instead of 4 $\times$ 10^{-6} A/cm^2 at 2 V) than for the devices with oxygen-plasma-grown AlO$_x$. This indicates that at least for the longer alkyl chains the lower quality of the mild-air-plasma-grown AlO$_x$ is compensated by the SAMs. When the voltage is increased beyond 2 V, the increase in current density with increasing voltage is essentially the same for the devices with C$_{10}$-PA, C$_{14}$-PA and C$_{18}$-PA SAM, while the breakdown voltage shows the same trend with SAM chain length as in the series with oxygen-plasma-grown AlO$_x$, indicating that the electrical properties at large electrical fields are dominated by the SAMs, rather than the oxide. Due to the smaller permittivity of the mild-air-plasma-grown AlO$_x$, the capacitance measured in these devices is smaller, but follows the trend related to the contribution of the SAM chain length (see Table 1).

3.2. Cyclic voltammetry

To study the chain-length-dependent insulating properties of the phosphonic acid SAMs without the contribution of the insulating metal oxide (AlO$_x$) we have also prepared monolayers of C$_6$-PA, C$_{10}$-PA and C$_{18}$-PA SAMs on conducting indium tin oxide (ITO) electrodes and performed cyclic voltammetry (CV) measurements. Note that in contrast to the Al/AlO$_x$/SAM/Au capacitors discussed in the previous section, the ITO/SAM devices for the cyclic voltammetry analysis have no AlO$_x$ layer and no Au contact. Therefore, any pinholes present in the SAM would be permeable for the electrolyte and thus result in a substantial leakage current that would be expected to be independent of the alkyl chain length. On the other hand, if the pinhole density is negligible, the currents through the SAM will be due to

(d) CV-current of the oxidation and reduction peaks vs. alkyl chain length of the SAM.

quantum-mechanical tunneling, with a monotonic dependence on the molecular chain length.

The experimental results are summarized in Fig. 2c and d. In all measurements, the redox behavior is reversible, without noticeable damage to the organic monolayers. The results show that the indicator response decreases monotonically with increasing molecular chain length. The CV measurements thus confirm the conclusions from the Al/AlO$_x$/SAM/Au capacitor measurements, namely that the insulating properties of the SAMs are indeed a strong, monotonic function of the molecular chain length.

3.3. Organic transistors

In a field-effect transistor, the voltage-dependent current through the gate dielectric leads to an undesired gate current during device operation. Thus, for transistors the quality of the dielectric is best described by the gate current (I_G) and by the ratio between the drain current and the gate current (I_D/I_G) as a function of gate-source voltage (V_{GS}).

The gate currents as a function of gate-source voltage of pentacene TFTs based on oxygen-plasma-grown AlO$_x$ (ε = 9) with four different SAMs (C$_6$-PA, C$_{10}$-PA, C$_{14}$-PA and C$_{18}$-PA) are shown in Fig. 3a. The drain currents as a

function of gate-source voltage of the same TFTs are shown in Fig. 3b. In general, these devices exhibit small gate currents and large I_D/I_G ratios, as observed previously for C$_{18}$-PA SAMs on oxygen-plasma-grown AlO$_x$ [2]. However, a monotonic increase in gate current is observed as the SAM chain length is reduced from C$_{18}$-PA to C$_{14}$-PA, C$_{10}$-PA and C$_6$-PA (1.5×10^{-10} A, 3.7×10^{-10} A, 6.1×10^{-10} A and 3.2×10^{-9} A at $V_{GS} = -2.5$ V). In devices with C$_2$-PA SAM the gate current exceeds the drain current, making these devices unsuitable for practical applications. For each TFT the charge carrier mobility was calculated in the saturation regime using the standard formalism for field-effect transistors: $\mu = 2$ L/($W \cdot C_{diel}$) $\cdot$ ($\delta I_D/\delta V_{GS}$)^2, where C_{diel} is the measured dielectric capacitance, I_D is the drain current, and V_{GS} is the gate-source voltage. Mobilities of 0.18 cm^2/Vs for C$_{18}$-PA, 0.28 cm^2/Vs for C$_{14}$-PA and 0.15 cm^2/Vs for C$_{10}$-PA were calculated for the TFTs with oxygen-plasma-grown AlO$_x$. Devices based on C$_6$-PA exhibit a notably smaller mobility of 0.05 cm^2/Vs. In addition to the mobility and the ratio between drain current and gate current (I_D/I_G), Table 1 also lists the ratio between the maximum and the minimum drain current (on/off ratio) of each TFT.

The TFTs with mild-air-plasma-grown AlO$_x$/SAM gate dielectrics (permittivity of AlO$_x$ = 5) show a larger gate leakage compared to the TFTs with oxygen-plasma-grown

AlO$_x$ (see Fig. 4). To prevent the gate currents from exceeding 10 nA these TFTs were measured only up to a maximum gate-source voltage of -2 V. In addition to the generally larger gate currents, the increase in gate current with reduced SAM chain length from C$_{18}$-PA to C$_{14}$-PA and C$_{10}$-PA is more pronounced (7.3×10^{-10} A, 3.4×10^{-9} A and 1.5×10^{-8} A at $V_{GS} = -2.0$ V). As a consequence, the I$_D$/I$_G$ ratio is smaller by about one to two orders of magnitude than in TFTs with oxygen-plasma-grown AlO$_x$ (see Table 1). As a result of this trend, the C$_{14}$-PA SAM is a lower limit in terms of the minimum chain length for the mild-plasma-grown oxide. In TFTs with C$_2$-PA SAM (aluminum corrosion) and C$_6$-PA SAM the gate current exceeds the drain current, in line with the trend observed for the current density in the capacitors. Using the measured capacitance values, charge carrier mobilities of 0.17 cm^2/Vs for C$_{18}$-PA, 0.13 cm^2/Vs for C$_{14}$-PA and 0.03 cm^2/Vs for C$_{10}$-PA have been calculated.

For both series of TFTs (oxygen-plasma-grown AlO$_x$, mild-air-plasma-grown AlO$_x$) the mobility decreases as the alkyl chain length of the SAM is reduced from C$_{14}$-PA

to C$_{10}$-PA and to C$_6$-PA. This indicates that the ordering in the SAM is systematically reduced as the alkyl chain length and hence the strength of the cohesive interactions between the phosphonic acid molecules is reduced [28], since less ordering in the SAM is likely to also induce less ordering in the pentacene layer and thus lower mobility.

Hill et al. have recently reported pentacene TFTs with a 100 nm thick SiO$_2$ gate dielectric obtained by thermal oxidation of the silicon substrate and functionalized with alkyl phosphonic acid SAMs with alkyl chain length ranging from C$_6$-PA to C$_{18}$-PA [29]. Due to the excellent insulation provided by the thick SiO$_2$ layer, the gate current in these TFTs is insignificant. The largest mobility was obtained with a C$_8$-PA SAM (1.2 cm^2/Vs). As the chain length was increased from C$_8$-PA to C$_{18}$-PA, the mobility decreased monotonically to 0.2 cm^2/Vs. For TFTs with a C$_6$-PA SAM a mobility of 0.5 cm^2/Vs was reported. It appears that the trend of the mobility as a function of alkyl chain length observed by Hill et al. is quite different from the one we have observed in our TFTs. However, the results are not easily compared, since the mechanisms that con-

trol adsorption, binding, and monolayer formation of alkyl phosphonic acids on aluminum oxide and on silicon dioxide are fundamentally different [30], and so the microscopic structure of the monolayers is expected to be quite different as well.

4. Conclusion

We have demonstrated that varying the molecular chain length (n) of aliphatic C_n-phosphonic acids influences the electrical characteristics of SAMs based on these molecules. In capacitors that utilize AlO_x/SAM stacks as double-layer dielectrics the breakdown voltage correlates with the chain length of the self-assembling molecules, while the current density at low fields and the increase in current density with increasing voltage are determined by the quality of the thin AlO_x layer underneath the SAM. The important role of the chain length of the organic self-assembling molecules in determining the insulating properties of the monolayers has been confirmed using cyclic voltammetry measurements on large-area ITO/SAM devices. Similar trends were found for the gate current in pentacene TFTs that utilize an AlO_x/SAM stack as the gate dielectric. Reliable low-voltage transistor operation with mobility greater than 0.1 cm^2/Vs has been observed for gate dielectrics with C_{18}-PA and C_{14}-PA SAM on AlO_x of different quality. When using a high-quality oxygen-plasma-grown AlO_x, the SAM approach can be extended to SAMs as short as C_{10}-PA. This suggests that low-cost processes for the activation of the metal gate electrodes are suitable and that alkyl chains shorter than C_{18} provide adequate insulating properties for large-area devices.

to the first ML, but rather extends into the second ML, at least.

2. Experimental

PTCDA films were grown by means of organic molecular beam epitaxy (OMBE) on substrates kept in ultrahigh vacuum (UHV) at room-temperature. The quality of the substrates and of the deposited films was monitored by Auger electron spectroscopy (AES), low-energy electron diffraction (LEED), and scanning tunneling microscopy (STM). The good quantitative agreement of the PTCDA film structures observed by us on Au(1 1 1) and Au(1 0 0) with the published ones [7–10] decisively enhances the comparability between different measurements. Briefly summarized, our epitaxial PTCDA films exhibit flat-lying molecules forming two closed MLs before island growth sets in (Stranski–Krastanov growth, cf. Refs. [7,9]). Film thicknesses were estimated using a quartz crystal microbalance and calibrated more precisely with STM.

Beside the well-accessible molecular frontier orbitals (highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO)) measured, e.g., with photoelectron spectroscopies [1–4], it has been challenging to determine the optical absorption behavior of ultra-thin films on metal surfaces because standard setups in transmission geometry are inappropriate. However, the application of DRS [11,12] followed by a numerical algorithm with the purpose to extract the dielectric function of the molecular adsorbate [13] allows for a detailed optical characterization of such systems. In general, the relation between electronic and optical behavior tends to be intricate since the electronic transport gap $E_{transport}$ differs from the optical gap $E_{optical}$ by the exciton binding energy $E_{exciton}$ which can be as large as 1 eV [14]. In addition, (de-)localization, diffusion, and dielectric screening of molecular excitons are naturally to be distinguished from those of free charge carriers. No attempt will therefore be made to directly establish energy diagrams, but some relevant *indirect* conclusions will be drawn from the optical measurements performed here aiming for an explanation of the observed behavior. Note that a thorough theoretical analysis of large aromatic molecules adsorbed on metal surfaces is still rather demanding. While density functional theory (DFT) can achieve consistency with the experimental determination of the workfunction modification and the HOMO/LUMO alignment with respect to the substrate Fermi energy [15], a reliable prediction of the optical absorption behavior of such systems is currently not feasi-

ble. Calculations of stacked PTCDA, i.e., 2 ML or more on a metal surface are not available at present.

Optical spectra were recorded during deposition, i.e., without interruption of the film growth, using a home-built DRS setup described previously [12,16]. The experimental accuracy is estimated to be ±0.02 eV for spectral positions (±0.04 eV for spectral differences). It is outlined in Ref. [12], that the application of the DRS technique can routinely achieve submonolayer resolution, with very good signal-to-noise ratios even down to a surface coverage of 0.1 ML of aromatic molecules. The DRS compares the reflectance of a bare substrate $R(E, 0)$ with the reflectance $R(E, d)$ of the same substrate covered with an adsorbate of thickness d as follows:

$$\text{DRS}(E, d) := \frac{R(E, d) - R(E, 0)}{R(E, 0)}. \tag{1}$$

We extract the complex dielectric function $\hat{\varepsilon}(E, d) = \varepsilon'(E, d) - i\varepsilon''(E, d)$ from the DRS with the help of a *model-free* numerical algorithm fulfilling Kramers–Kronig consistency [13]. The imaginary part ε'' is discussed here as a measure for the absorbance behavior of the adsorbate in dependency of the film thickness, thereby closely monitoring the interface formation. The DRS intensity is in first approximation proportional to the film thickness (cf. Ref. [11]) as manifested in Fig. 2. In contrast to the DRS, the complex dielectric function being a material property bears an *indirect* thickness-dependence only, since the observed spectral developments are caused by molecule–molecule or molecule–substrate interactions and *not* merely by the amount of material.

In the following, we will discuss the thickness-dependent ε'' spectra of our PTCDA films on gold substrates. As the optical behavior of PTCDA on Au(1 0 0) resembles that on Au(1 1 1) to a large extent, the latter surface will be in focus here. The identification of the spectral features of the PTCDA films will then be substantiated by comparison with soluble perylene derivatives which are optically very
Fig. 2. Differential reflectance spectra (DRS, cf. Eq. (1)) of PTCDA films on Au(1 1 1). The DRS intensity is in first approximation proportional to the film thickness (cf. Ref. [11]) as manifested in this spectral series. ε'' values were extracted from these spectra up to $d \approx 1$ ML (cf. Fig. 6, lower part). Thin gray lines represent intermediate film thicknesses.

similar to PTCDA. Finally, we will propose an explanation for the assumed charge transfer effects in the context of interface dipole (Δ) formation.

3. Results and discussion

The DRS as a function of PTCDA film thickness on Au(1 1 1) is shown in Fig. 2. Motivated by the abruptly emerging sharp features in the DR spectra we expand the two components (metal/n MLs PTCDA) to a hypothetical three-phase system (metal/1st ML PTCDA/($n - 1$)MLs PTCDA) by setting a new baseline after completion of the 1st ML of PTCDA, such that

$$\mathrm{DRS}^*(E, d^*) := \frac{R(E, d^*) - R(E, d_0)}{R(E, d_0)}, \qquad (2)$$

where $d^* = d - d_0$ means the reduced nominal film thickness, and $R(E, d_0)$ is the reflectance of the metal covered with $d_0 := 1$ ML of PTCDA. We would like to emphasize that we do not introduce any sort of model here, as Eq. (2) is in fact an approximation based on the observation that the optical response of the first ML appears to be separated from further layers grown on top, as demonstrated in the following. It is already visible in Fig. 2 that the DRS signal of up to $d \approx 1$ ML is broad and essentially featureless. Distinct peaks suddenly appear upon growing the 2nd ML of PTCDA, as also evidenced in the DRS* (cf. Fig. 3).

A closeup view of the DRS* of $d^* = 1$ ML of PTCDA on Au(1 1 1) as plotted in Fig. 3 is given in Fig. 4 on an inverted scale for convenience. Additionally, the substrate's coefficients A and B for gold, as introduced in Ref. [12], are depicted. They are derived from the substrate bulk dielectric function $\hat{\varepsilon} = \varepsilon' - i\varepsilon''$ [17]. It was shown in Ref. [12] that the DRS can be approximated by DRS $\approx -(8\pi d/\lambda) \times A \times \varepsilon''_{\mathrm{film}}$ provided that the condition $|A| \gg |B|$ is fulfilled. This so-called McIntyre approximation [11] is also valid for DRS* and d^* with similar accuracy. It can be seen in Fig. 4 that $|A| \gg |B|$ holds indeed for gold at low photon energies $E \lesssim 2.3$ eV. Then, two completely *independent*

Fig. 4. Unfiltered reduced differential reflectance spectrum of $d^* = 1$ ML of PTCDA on Au(1 1 1) from Fig. 3, plotted here on an inverted scale (i.e., $-\mathrm{DRS}^*$) for convenience. In addition, the substrate's coefficients A and B for gold are plotted on a separate scale. Note that $|A| \gg |B|$ for $E \lesssim 2.3$ eV, see text for details.
Fig. 5. Imaginary part $\varepsilon''_{\mathrm{film}}$ of the dielectric function of $d^* = 1$ ML of PTCDA on Au(1 1 1) derived from the measured DRS* shown in Fig. 4 by two *independent* methods: McIntyre approximation $\varepsilon''_{\mathrm{film}} \approx \mathrm{DRS}^* \times \lambda/(-8\pi d^* \times A)$ (no noise filtering) and Kramers–Kronig transformation (smoothed during application of the numerical algorithm).

analysis methods can be used to extract the imaginary part $\varepsilon''_{\mathrm{film}}$ of the adsorbate dielectric function: (i) the McIntyre approximation given above and in Ref. [12], and (ii) the model-free numerical algorithm based on the Kramers–Kronig transformation. It is evident in Fig. 5 that both methods yield comparable results, and especially the position and the shape of the peaks are indeed very similar. Admittedly, the overall height of these two spectra is not identical, which is particularly apparent for high photon energies, where the condition $|A| \gg |B|$ is invalid for gold, and hence the McIntyre approximation can not be applied. Still, it is very clear from Fig. 5 that a peak at 2.05 eV (see below) is observed for both analysis techniques, and no artificial features are introduced by the numerical method chosen for the evaluation of our data.

Fig. 3. Reduced differential reflectance spectra (DRS*, cf. Eq. (2)) of PTCDA films on Au(1 1 1). ε'' values were extracted from the highlighted spectra for $d^* > 0$ ML (cf. Fig. 6, upper part). Thin gray lines represent intermediate film thicknesses.

Fig. 6. Imaginary part ε'' of the dielectric function of PTCDA films on Au(111). The ε'' spectra for $d \lesssim 1$ ML were extracted from the original DRS depicted in Fig. 2, while those for $d \gtrsim 1$ ML (i.e., $d^* > 0$ ML) are based on the DRS* depicted in Fig. 3 (see text). For clarity, only selected spectra are presented. Arrows indicate the development with increasing film thickness. The independently determined ε'' spectrum of a comparatively thick polycrystalline (pc) PTCDA film on glass is shown in comparison (adapted from Ref. [18]).

The ε'' spectra extracted from the original DRS and from the reduced DRS, i.e., DRS*, are depicted in Fig. 6. The broad character of the 1st ML of PTCDA in the DRS directly translates to broad ε'' spectra centered at 2.26 eV. As a matter of fact, the submonolayer spectra ($d < 1$ ML) exhibit virtually no deviation from the $d \approx 1$ ML spectrum and therefore only a selection is shown in Fig. 6. Because of the large intermolecular distance between nearest neighbors the in-plane dimerization should be negligible, as recently demonstrated for insulating substrates [19,20]. However, the spectrum of the 1st ML of PTCDA on Au(111) does *not* exhibit the monomeric shape known on inert (i.e., non-metallic) surfaces, most evidently on mica and KCl [19,20]. This behavior must be due to a comparatively strong coupling of molecular orbitals to electronic states extending perpendicularly from the metal surface. Consequently, significant broadening of the adsorbate levels, as described, e.g., by the Anderson–Newns model [21,22], is observed which may be additionally accompanied by charge transfer. This effect is also called metal–organic "hybridization" in the literature [15,23] and has been observed for the molecular energy levels by means of photoelectron spectroscopy and electron energy loss spectroscopy measurements [6,24]. The impact of this phenomenon on the optical transitions of molecular adsorbates on metal surfaces as reported here has been described previously in Ref. [25].

For PTCDA thicknesses higher than $d > 1$ ML (i.e., $d^* > 0$ ML), several peaks emerge, as depicted in the upper

part of Fig. 6 and also in Fig. 5, and show almost no variation until completion of the 2nd ML (i.e., $d^* = 1ML$; intermediate film thicknesses omitted for clarity). Clearly, this spectrum of $d^* = 1$ ML can be divided into two different parts which will now be discussed separately.

In the range $E \gtrsim 2.2$ eV the spectral shape can be assigned to neutral monomers since the main feature at 2.32 eV with its vibronic progression of $\Delta E \approx 0.17$ eV corresponds to the spectra recorded in solution and on insulating surfaces [19,20]. This means in turn that there can only be marginal coupling between the 2nd and the 1st ML of PTCDA providing further legitimation for the above three-phase approach. This is somehow surprising as one would intuitively expect physical dimerization between face-to-face stacked aromatic molecules. However, for $E \gtrsim 2.2$ eV the 2nd ML of PTCDA remarkably behaves optically like an ensemble of monomers, or, in other words, like the 1st ML on an *insulating* substrate. Taking into account our results for quaterrylene heteroepitaxially grown on an atomically thin hexa-*peri*-hexabenzocoronene ML [25] we conclude that the energy levels of the 1st PTCDA ML on Au must also differ considerably from the levels of decoupled PTCDA in the subsequent layers, thereby inhibiting noticeable coupling.

It is intriguing to note that in the range $E \lesssim 2.2$eV a new peak at 2.05 eV (or 2.03 eV, respectively, for an identical PTCDA thickness on Au(100)) has emerged which does not belong to the absorbance of neutral PTCDA monomers. Considering the ε'' spectra of comparatively thick PTCDA films on glass [18] it is obvious that this feature can also not be explained by aggregation effects. Hence, it must be of different nature, and we attribute this peak to PTCDA radical cations (PTCDA·⁺). For a univocal identification of this feature it would be advisable to compare our ε'' values to absorbance spectra of charged PTCDA in solution. However, to our knowledge such data are not available which is probably due to PTCDA's rather poor solubility. Still, several publications contain optical absorption spectra of soluble neutral and charged PTCDA derivatives, namely DBPI and PBI (cf. Fig. 1) with a high degree of optical equivalence of the according perylene-derived chromophores [26,27]. Although ionized with dissimilar methods, the energy difference ΔE of the cationic main peaks with respect to the associated neutral molecules amounts to 0.29 eV and 0.28 eV, respectively (cf. Fig. 7). Here, we compare relative peak positions rather than absolute values due to the presence of different solvent shifts and dielectric backgrounds in the respective experiments. The positions of the new PTCDA peaks observed here shifted by 0.27 eV and 0.29 eV compared to the main monomeric features on Au(111) and Au(100), respectively, nicely agree with the above values. In contrast, the spectral signatures of the anionic PTCDA derivatives exhibit a multitude of pronounced features shifted by more than 0.5 eV toward lower energies compared to the absorption peaks of the corresponding neutral species [26,27]. Hence, we can exclude the presence of anionic PTCDA in the 2nd ML on Au(111) and Au(100).

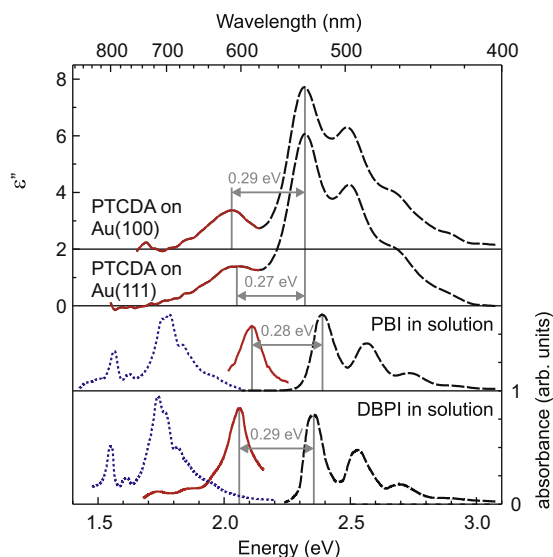
The two parts of the $d^* = 1$ ML spectrum can thus be assigned to the cationic and neutral PTCDA absorption, respectively. For an estimation of their proportionate


Fig. 7. ε'' spectra for $d^* = 1$ ML of PTCDA on Au(1 1 1) and Au(1 0 0) compared to absorbance spectra of dissolved DBPI and PBI, in the neutral (dashed lines), anionic (dotted lines), and cationic (solid lines) states, not to scale (adapted from Refs. [26,27], reproduced by permission of the owner societies). The dissimilar dielectric environments cause energetic shifts of the complete spectra, yet the differences between cationic peaks and main transitions of the neutral species are almost identical. For clarity, the spectra are shifted on the vertical scale.

contributions we determine the *relative* oscillator strengths of both parts ($OS_{charged} + OS_{neutral} = OS_{total}$) via

$$OS = \int_{\text{absorption band}} \varepsilon''(E)E \, dE \qquad (3)$$

(cf. Ref. [28]) by fitting the $\varepsilon''(E) \times E$ curves with several Gaussian functions (not shown here). Assuming similar *molecular* oscillator strengths (i.e., per molecule), the fraction of charged molecules with respect to the total number of molecules can be expressed as $OS_{charged}/OS_{total}$ and amounts to about 20%, in a first order approximation.[4] This value remains almost constant in between $0 \text{ ML} \leqslant d^* \leqslant 1$ ML.

For further increasing film thickness a characteristic development of the ε'' spectra sets in (Fig. 6 upper part, $d^* > 1$ ML). The monomeric features begin to disappear, and the spectral shape broadens forming a new shoulder at ≈ 2.2 eV. The peak at 2.05 eV (or 2.03 eV, respectively) assigned to cationic PTCDA vanishes suggesting that the 3rd ML and further layers bear no or just very few charges, and, accordingly, this feature diminishes with rising film thickness as the fraction of neutral PTCDA steadily increases. The development is accompanied by distinct intersections of all spectra in three isosbestic points at $\approx$ 2.12 eV, 2.25 eV, and 2.40 eV. Here, we would like to place emphasis on an independently measured ε'' spectrum of a

rather thick polycrystalline (*pc*) PTCDA film on a glass substrate [18] which also coincides very nicely with these intersections. Further, the fast convergence of our ε'' spectra toward the *pc* bulk behavior is remarkable as it indicates that the adsorbate dielectric function becomes substrate-independent at quite low film thicknesses. Isosbestic points are an expression of aggregation to higher quasi-one-dimensional PTCDA stacks, i.e., the physical monomer → oligomer transition [19,29]. The persistence of the monomeric feature at 2.32 eV for several nominal MLs confirms the Stranski-Krastanov growth with clusters forming on top of a closed 2 ML thick film.

All of the above key statements about the optical spectra and their film-thickness-dependent development made primarily for PTCDA on Au(1 1 1) are equally valid on Au(1 0 0) as substrate, except for some very slight deviations within the experimental accuracy on the energy scale (cf. Fig. 7). Consequently, we can rule out that our observations would be a mere effect of film structure which exhibits a number of different phases and orientations due to the distinct substrate symmetries and surface reconstructions [8]. The dissimilarities between PTCDA films on Au(1 1 1) and Au(1 0 0) actually play only a minor role in the respective optical response. Hence, we will not explicitly discuss the results obtained for PTCDA on Au(1 0 0) in detail.

Although classified as a weakly interacting system [6,15], the suggested charging of PTCDA on Au can only arise from the proximity of the metal surface. However, the explanation of the charge transfer is not trivial as it should have the most intense impact on the layer of contact. It seems unlikely that only the 2nd PTCDA ML would directly transfer charge to Au. The very broad optical absorption of the 1st PTCDA ML on Au (cf. Fig. 6, $d \approx 1$ ML) does actually not permit an unambiguous identification of possible charged features but does also not contradict charging effects in the first place. However, as stated in a recent ultraviolet photoelectron spectroscopy (UPS) study "no clear signature of molecule–metal reaction-induced peaks within the energy gap region of PTCDA was observed in the spectra of PTCDA/Au(1 1 1), even at sub-monolayer coverage" [6]. Thus, it seems contradictory to optically detect a (partly) positively charged 2nd ML. To resolve this apparent discrepancy we would like to focus on the interface dipole (Δ) formation upon molecular adsorption. In fact, the vacuum level is decreased by 0.2 eV for 1 Å and further by roughly the same value up to 48 Å of PTCDA [6]. This means in particular that Δ between the 1st and 2nd MLs does *not* vanish on Au(1 1 1). Although such an interface dipole may have several causes [1], it will be more often than not an expression of charge transfer whose direction is correlated to the sign of Δ: for a decrease of the vacuum level upon deposition of a molecular layer one would expect an accumulation of positive charges on the adsorbate's side of the interface [2–4]. This complies with our observation of molecular cations at the interface between 1st and 2nd MLs of PTCDA on Au(1 1 1) and Au(1 0 0).

4. Conclusions

In summary, the optical spectra of thin PTCDA films on Au presented here suggest that there is a clear difference in

---

[4] Judging from absorbance data of dissolved DBPI [26] one may conclude that the fraction of the *molecular* oscillator strengths of the cation with respect to the neutral species can be as low as ≈ 0.6, which would consequently mean an even higher percentage of charged molecules in the $d^* = 1$ ML spectrum reported here.

the electronic properties between the layer of contact and further layers grown on top. The behavior of the 2nd PTCDA ML is somewhat unexpected though: surprisingly, physical dimerization does not occur between the face-to-face stacked 1st and 2nd PTCDA MLs on Au(111) and Au(100). The interaction between the contact layer and the Au surface is efficient enough to shift the molecular energy levels considerably and to cause consequently a decoupling effect of further layers. Yet, the most important observation is the occurrence of charged PTCDA in these solid state optical spectra. From the optical data we deduce the formation of a (partly) positively charged 2nd ML of PTCDA films on Au(111) and Au(100). Assuming a similar molecular oscillator strength for neutral PTCDA and the cation we estimate the fraction of charged PTCDA to be $\approx$ 20%. We conclude that the interface dipole formation between 1st and 2nd MLs of PTCDA on Au as reported before [6] is responsible for the charging observed here. The simple correlation of the sign of the interface dipole to the direction of charge transfer as proposed in this contribution might not reflect the full picture, but it can give at least an appropriate tendency. Further experimental and theoretical work will be necessary to yield a comprehensive explanation of charge transfer effects in the proximity of metals.

ratio. A 30 nm-thick electron-transporting layer of Alq_3 (Sigma–Aldrich, 99.995%) was sublimated at 6.66×10^{-4} Pa pressure. Finally, a 200 nm aluminum cathode was deposited by thermal evaporation in the same vacuum to complete the device. Fig. 1 shows the energy band diagram of the overall structure.

The PVK/Alq_3 bi-layer yields a greenish, 50 nm-wide electroluminescence spectrum. To widen the spectrum and achieve white light emission, red-emitting quantum dots were incorporated in PVK. CdSe/ZnS core–shell quantum dots (Evident Technologies Ltd.) of 5.8 nm in diameter were dispersed in the PVK:toluene solution. The weight ratio (R) of CdSe/ZnS to PVK was set at 0.9:10. To add spectral components to the blue side of the electroluminescence spectrum, it is necessary to use quantum dots with a smaller diameter. However, we found that such particles only emit weakly and tend to be unstable because of their large surface/volume ratio. A different approach is to use phosphorescent molecules. To this end, we dissolved blue-light-emitting molecules Ir(III)DP into PVK to enhance the spectrum in the 450–500 nm region. The weight ratios of CdSe/ZnS to Ir(III)DP and to PVK are 0.9:10 and 8.3:10, respectively.

3. Results and discussion

Fig. 2 shows the normalized electroluminescence spectra of the device with and without the addition of quantum dots or Ir(III)DP. The luminescence of the reference structure (without quantum dots or molecules) peaks at 526 nm and takes a greenish appearance, whereas quantum dots produce a luminescence spectrum centered at 620 nm with a 30 nm FWHM. The color pictures in Fig. 3 show color coordinates that gradually approach that of pure white light (0.33, 0.33).

For devices without Ir(III)DP, the external quantum yield is 0.45% (at a bias of 14 V) without QDs and 0.40% (at a bias of 14 V) when QDs are included into the device at weight ratio R = 9%. Here, we stress that our main goal was not to optimize the device but rather to understand how the QDs affect the operating mechanisms of OLEDs. For this task the measurement of quantum yield is especially valuable.
Fig. 2. Electroluminescence spectrum of (a) the reference PVK/Alq_3 device, (b) with red-emitting quantum dots and (c) with Ir(III)DP plus red-emitting quantum dots. Device (c), the only one with blue-emitting molecules, shows a blue shift and produces white light of better quality.

The arrangement offers a high degree of flexibility. The characteristic of the device's electroluminescence spectrum can be controlled by choosing various ratios of Ir(III)DP and quantum dot to PVK, and by using different quantum dot sizes. However, because the three types of light emitters interact in a non-trivial way, the relative emission efficiency is not a simple function of concentration or voltage. To fully exploit and tailor the device to a specific application, it is important to understand the luminescence mechanisms involved. For example, quantum dots can luminesce *via* Förster energy transfer of excitons [6–9] and/or injection of electron–hole pairs [10–13]. Having a large absorption cross section, these particles can also, in theory, be excited by absorbing photons generated inside the device with energies above the CdSe band gap (<700 nm). The rest of this paper focuses on exploring these mechanisms.

Fig. 4 shows the surface morphology of various PVK films with and without quantum dots. The microscope pictures show that the surface of pure PVK is homogeneous on a small scale. On the other hand, PVK with quantum dots (R = 3%, image b), shows small aggregates dispersed on the surface. At higher concentration, R = 9%, the surface morphology suggests aggregates, on the same scale as reported by Son et al. in Ref. [15]. In their work on PVK films with quantum dots, TEM images reveal PVK clusters enveloped with quantum dots. Aggregation, it seems, takes the form of a blend of the two materials, making the film effectively uniform on a scale above 300 nm. The fact that quantum dots would be thus embedded into the film (and not just concentrated at the surface) is an important element in explaining the operation of the OLED.

We now proceed with an analysis of the emission profiles of devices with and without quantum dots. It is significant that the EL spectrum of the reference OLED (Fig. 2a) shows no evidence of light emission by the PVK. Since excitons are mainly formed at PVK/Alq_3 interface, and since holes easily migrate from PVK to Alq_3 (the potential barrier

is only 0.1 eV versus the 1 eV barrier for electrons going from Alq_3 into PVK), electron–hole recombination occurs principally in the Alq_3 layer, in accordance with previous works [16,17]. Fig. 5 shows the electroluminescence spectrum of the PVK/Alq_3 device with quantum dots. At low voltages, near the threshold voltage of 12 V, the spectrum is dominated by Alq_3 emission, but as the voltage increases, the contribution from quantum dots exceeds that of Alq_3.

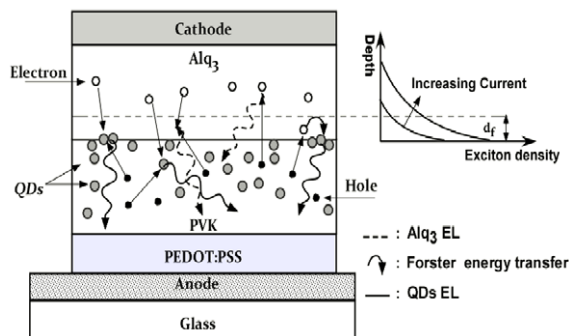
The overlap between the QD absorption profile and the photoluminescence spectrum of Alq_3 [9] suggests the possibility of exciton transfer from Alq_3 to QDs *via* the Förster mechanism [18]. Coe et al. [7] demonstrated that, for a trilayer hybrid QDs/organic LED, the Förster energy transfer of excitons from organic materials to the QDs dominates the EL process rather than charge injection into QDs. As Fig. 6 illustrates, at low voltages the majority of excitons recombining in Alq_3 do so very close to the interface with
Fig. 5. Emission spectra profiles of ITO/PEDOT: PSS/PVK: QD/Alq_3/Al devices with quantum dots. The relative contribution of QDs and Alq_3 varies with voltage, as shown in inset.


Fig. 6. Exciton generation and luminescence processes in a quantum dot-doped OLED.

PVK. This favours excitonic pumping of QDs, which are located in the PVK. Increasing voltage causes excitons to recombine further into Alq$_3$ and farther away from QDs, which does not favour the Förster mechanism. (Exciton energy transfer to quantum dots occurs within the Förster radius d_f). In our devices, however, quantum dots consistently emit more efficiently at higher voltages, in spite of the fact that electroluminescence from Alq$_3$ saturates (see Fig. 5). Furthermore, QDs emit steadily even when emission from Alq$_3$ declines with time. This trend is clearly shown in Fig. 7, whereby the red emission of QDs exhibits remarkable stability for over 15 s. These data suggests that Förster energy transfer is not the dominant excitation process of QDs in our OLEDs. Instead, charge injection appears to be an important additional mechanism of electroluminescence in QDs.

Fig. 8 shows how doping PVK with QDs does not change the shape of the I–V curve. In both concentrations shown, the curves are best fitted by a space-charge-limited conduction model (SCLC) with an exponential distribution of traps [20]. The current density J is well described by the equation [19]
Fig. 8. Current–voltage curves of ITO/PEDOT: PSS/PVK: (CdSe/ZnS)/Alq$_3$/Al devices with CdSe/ZnS mass loadings of 0% and 9%.

$$J = q^{(1-m)} \varepsilon^m \mu_{ef} \frac{N_{ef}}{N_{tr}^m} \left(\frac{m}{m+1}\right)^m \left(\frac{2m+1}{m+1}\right)^{m+1} \frac{V^{m+1}}{d^{2m+1}}$$

where q is the electron charge, m is a characteristic energy distribution parameter of traps, ε is the electrical permittivity, μ_{ef} is the effective mobility, N_{ef} is the density of states in the transport band, N_{tr} is the total concentration of traps, V is the applied voltage and d is the sample thickness. However, doping does induce a decrease of current density and an increase of m from 7 to 12. According to SCLC theoretical framework, this variation in m indicates that traps are deeper in the doped structure. As it should be and shown in Fig. 1, the electron affinity level of the QDs is well below the PVK LUMO level. This suggests that electrons could easily be trapped by QDs. Then, doping PVK with QDs results in, (1) an increase in traps concentration and thus a decrease in current density and (2) an increase in m because QDs act as deep traps. In contrast, the PVK HOMO level is well above the QDs ionization energy level. The holes injected in the PVK/QDs layer then diffuse through the PVK molecules. Because holes can tunnel through the Zn shell into the valence band of the CdSe quantum dots (attracted by the trapped electron), the QDs can thus emit light *via* electron–hole pair recombination. Therefore, the charge injection into QDs appears to be an important mechanism of excitation in quantum dots which adds to the Förster energy transfer.

On the other hand, the mechanism of photoemission from Ir(III)DP also appears to be from current excitation. Indeed, photoexcitation would require absorption of light at wavelengths below 450 nm, whereas very little light is emitted by Alq$_3$ bellow 500 nm.

4. Conclusions

In conclusion, we have demonstrated an hybrid organic device for generation of electroluminescence with adjustable properties. By using different excitation mechanisms for light emission, quantum dots add flexibility to OLED composition and can be used towards the manipulation
Fig. 7. The temporal evolution of the electroluminescence ITO/PEDOT: PSS/PVK: (CdSe/ZnS)/Alq$_3$/Al device a constant voltage of 30 V applied.

of their spectral emission profile in order to produce, among others, white light of high quality.

the electrode metal surface with strong electron acceptor or donor molecules prior to deposition of the active organic semiconductor [12,13]. For instance, the hole injection barrier (HIB; energy difference between the highest occupied molecular level and the metal Fermi-level) from Au into vacuum sublimed molecular layers can be reduced by up to 1.2 eV with a monolayer of the acceptor 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) [12]. The underlying mechanism has been clearly identified as a bidirectional charge transfer between the metal (e.g., Cu) and F4-TCNQ [14,15]. This introduces dipoles at the metal surface with their negative ends oriented away from the surface, which increases the metal work function (Φ). The energy levels of any organic material deposited on top of this modified electrode are then re-aligned relative to this modified surface potential [12].

However, to date this powerful adjustment of the HIB at metal/organic interfaces was only shown to be operative under very restrictive conditions, i.e., ultrahigh vacuum (UHV), on atomically clean metal surfaces, and in situ vacuum sublimed acceptor layers and organic semiconductors. These conditions are quite different from those that prevail during low-cost device fabrication, e.g., by spin-coating or printing techniques in inert gas or even ambient atmosphere, where the presence of (residual) oxygen, water and hydrocarbons result in ubiquitous impurities/contamination of interfaces.

Our present work explores the possibility of transferring the concept of optimizing the HIB at metal/organic interfaces with strong electron acceptors from UHV to solution-based methods in ambience conditions that are realistic for actual device fabrication. Using X-ray photoelectron spectroscopy (XPS) and photoelectron emission yield (PEY) spectroscopy we show that Cu electrode surfaces can be appropriately modified with the acceptors tetracyanoquinodimethane (TCNQ) and F4-TCNQ (for acceptors' chemical structure see Fig. 1) by simple solution casting, leading to high Φ values – even stable in air on timescales of ca. one hour. Such modified Cu electrodes are proven to result in significantly improved performance in flexible polymer OFETs built on poly(ethyleneterephthalate)-foil, as revealed by higher I_{on} and lower V_{T} values.

2. Experimental

All experiments are based on Cu covered and pre-patterned poly(ethyleneterephthalate)-foil (Cu/Pet-foil) (from Fraunhofer IZM, München, Germany), that was also used as substrate for OFET fabrication. The modification process of the Cu surface with acceptor molecules comprised two key preparation steps.
  (1) Etching off the native oxide layer at the Cu surface by washing in 2 M hydrochloric acid (HCl) and subsequent rinsing in deionized water and ethanol. After this treatment in ambient atmosphere samples were brought into an inert gas glove-box for further processing.
  (2) F4-TCNQ (Fluka) and TCNQ (Fluka) were applied to Cu electrodes by drop casting from chlorobenzene solution (1 mg/ml). Subsequently samples were
Fig. 1. Chemical structure of (a) TCNQ, (b) F4-TCNQ, and (c) poly (3-hexylthiophene)-dithienyltetrafluorobenzene (P3HT-TFT).

washed in copious amounts of chlorobenzene to remove excess non-chemisorbed (on Cu) acceptor molecules.

Before any treatment (pristine) and after each preparation step, the chemical composition of Cu electrodes was studied using X-ray photoelectron spectroscopy (XPS), and the surface work function was determined by photoelectron emission yield (PEY) spectroscopy.

XPS spectra were collected with a hemispherical Multitechnique Electron Spectrometer (Kratos Analytical), with monochromatized Kα line radiation of an aluminum anode for excitation, and an analyzer pass energy of 20 eV. The base pressure in the analysis chamber was 2×10^{-10} mbar. Fitting of XPS spectra was performed with the program WINSPEC (developed at the University of Namur, Belgium).

Sample Φ was determined from PEY spectra recorded at ambient conditions with an AC-2 Photoelectron-Spectrometer (Riken Keiki Co., Ltd.). The apparatus detects photoemitted electrons per second (CPS) as a function of photon energy using a UV light source for excitation and a gas-flow Geiger counter. For the relation between CPS and photon energy Bouwman and Sachtler adopted an approximated equation [16]

$$CPS = \frac{M(h\nu - \varphi)^2}{2k^2} \tag{1}$$

Here M is an emission constant, $h\nu$ the photon energy, Φ the work function, and k the Boltzmann constant. In this method the value of Φ is determined by a linear extrapolation of CPS$^{1/2}$ to zero yield [17]. PEY spectra were fitted using the software provided by the spectrometer supplier.

OFETs were fabricated in a top-gate and bottom-contact configuration, comprising the pre-structured Cu/PET-foil as substrate and source/drain electrodes. The pre-structuring process was done at the Fraunhofer IZM (München, Germany) using photolithography, with channel length

L = 40 μm and channel width *W* = 40 mm. For OFET preparation with acceptor modified electrodes, the entire prestructured Cu/PET-foil was treated as described above for Cu electrodes. As active polymer layer (channel) we used the statistical co-polymer poly(3-hexylthiophene)-dithienyltetrafluorobenzene (P3HT-TFT), which comprises poly(3-hexylthiophene) (P3HT) segments with additional 5 mol% of 1,4-dithienyl-2,3,5,6-tetrafluorobenzene (TFT) in the main-chain (for chemical structure see Fig. 1) with a molecular weight of M_W = 22,300 g/mol. This polymer was chosen as semiconducting material because it is more stable against doping by oxygen compared to standard P3HT [18], resulting in better device stability and longer lifetime. P3HT-TFT was spin cast from chlorobenzene solution (10 mg/ml) in inert atmosphere, resulting in a film thickness of 30 nm. The organic gate dielectric layer P121 (Merck KGaA) was spin cast in inert conditions with a thickness of 1 μm. After each spin-coating process samples were annealed at 120 °C for 30 min. The silver gate electrode was evaporated subsequently using a shadow mask. The OFET electrical characteristics were measured directly after fabrication in ambient conditions in the dark, using two Source-Measure Units 236 combined with a Trigger-Control Unit 2361 and Metrics Software (Keithley Instruments).

3. Results and discussion

First, we present the chemical and work function analysis of acceptor-treated Cu electrodes in comparison to pristine Cu, in order to establish that the acceptors are indeed chemisorbed and lead to the desired increase of Φ. Fig. 2 shows XPS wide-range survey spectra of the Cu electrodes (on the Cu/PET-foil) as received ("untreated", Fig. 2a), after etching with HCl to remove the native surface oxide layer ("etched", Fig. 2b), and after TCNQ and F4-TCNQ solution treatment (Fig. 2c and d). Apparently, the Cu surface is heavily oxidized in its as-received state and contaminated with carbon species (surface stoichiometry 35% Cu, 25% C, 40% O). After HCl etching the surface carbon content remains essentially unchanged, and the amount of oxygen decreases to 16%; but it does not vanish completely due to finite time in ambient air (*i.e.*, re-oxidation occurs) during transport into inert gas glove-box or XPS chamber. This is further exemplified by more detailed XPS spectra of the O1s region (Fig. 3). The O1s peaks can be adequately fitted by two peaks, where the peak at lower binding energy (BE) of *ca.* 530.5 eV represents oxygen atoms in the surface copper oxide (*i.e.*, Cu_2O and CuO) that forms (immediately) after exposure to oxygen. The peak at higher BE (centered at *ca.* 532 eV) is due to a range of electron deficient oxygen species, *e.g.*, surface hydroxyl groups (–OH) and oxygen bound to carbon in various configurations ("C–O"; due to a superposition of many different species a more detailed assignment is impracticable). The etching process does not change the intensity ratio of these two peaks dramatically (compare Fig. 3a and b).

The intensity ratio of the two peaks in the O1s spectrum after treatment of etched Cu electrodes with TCNQ-solution (Fig. 3c) is similar to that of just etched Cu;
Fig. 2. XPS survey spectra of the Cu electrode of a Cu/PET-foil (a) untreated, (b) etched with HCl, (c) etched and treated with TCNQ solution, (d) etched and treated with F4-TCNQ solution. [The strong emission feature near 567 eV binding energy is due to Cu LMM Auger processes (kinetic energy of *ca.* 915 eV)].
Fig. 3. XPS O1s spectra of the Cu electrode of a Cu/PET-foil (a) untreated, (b) etched with HCl, (c) etched and treated with TCNQ solution, (d) etched and treated with F4-TCNQ solution. The intensity of spectrum (a) was multiplied by 0.3.

noteworthy, the overall oxygen content of the TCNQ-treated surface is even slightly higher than that of etched Cu. This is most likely due to the *ca.* two times longer transport time through air of acceptor-treated samples. Furthermore, this observation indicates that TCNQ does not cover the Cu surface completely or that TCNQ cannot inhibit Cu oxidation efficiently. In contrast, F4-TCNQ solution treatment of Cu leads to a small overall decrease of the surface oxygen content, and the intensity ratio of metal oxide (low BE) and contamination (high BE) species is almost reversed compared to etched Cu (Fig. 3d). This suggests that the Cu surface coverage with F4-TCNQ is higher than achieved with TCNQ, and that this acceptor layer efficiently slows down surface metal oxidation.

Detailed XPS scans of the N1s region directly evidence the stable adsorption of both molecular acceptors on Cu (Fig. 4); note that excess acceptors were removed by washing with the solvent (*c.f.* Section 2). While no nitrogen is present on pristine and etched Cu surfaces (Fig. 4a and b), clear N1s signals are measured after TCNQ and F4-TCNQ solution treatment (Fig. 4c and d). The main contributions of the two N1s spectra (low BE component in each spectrum) are assigned to chemisorbed acceptor molecules that form charge transfer complexes with the Cu surface (TCNQ* and F4-TCNQ*) [12], and the high BE component in each spectrum is assigned to shake-up satellites. High photoemission intensity of such satellite peaks can occur for strongly chemisorbed molecules [19]. We cannot formally rule out the presence of residual neutral acceptor species; however, this is very unlikely due to solvent wash-

ing. In addition, we find a clear F1s XPS signal for F4-TCNQ-treated Cu surfaces (inset in Fig. 4d), as expected. A consistent quantification of the fraction of nominal full acceptor monolayer coverage is not possible by XPS, but the N1s and F1s intensities show that coverage in the (sub-)monolayer regime is reached (higher coverage yet with F4-TCNQ than with TCNQ), which also represents the theoretical limit. Repeated acceptor solution treatment of Cu electrodes did not result in higher coverage.

After having established that both acceptors can be stably chemisorbed on the Cu electrode, we turn towards the surface work function. PEY spectra taken at ambient conditions of the differently treated Cu surfaces are shown in Fig. 5. Φ of untreated Cu is 4.8 eV, and decreases to 4.5 eV after HCl etching. This is due to the reduction of polar surface groups and the removal of the surface oxide layer, as observed by XPS (see Figs. 2 and 3). Note that despite the higher work function of the Cu surface with the native oxide its use as electrode is inadvisable as the oxide layer will act as spacer for charge tunneling into an active organic layer, which his detrimental for achieving high current density. Φ increases to 4.9 eV for the TCNQ solution treated electrode and to 5.1 eV for F4-TCNQ-treated Cu (Fig. 5c and d). Such an increase in Φ is expected due to the net electron transfer from the metal to the molecules [14]. The fact that the increase in Φ due to TCNQ is smaller than that for F4-TCNQ can be rationalized by the lower

Fig. 4. XPS N1s spectra of the Cu electrode of a Cu/PET-foil (a) untreated, (b) etched with HCl, (c) etched and treated with TCNQ solution, (d) etched and treated with F4-TCNQ solution. The inset in (d) is the corresponding F1s spectrum.
Fig. 5. PEY spectra (measured in air) of the Cu electrode of a Cu/PET-foil (a) untreated, (b) etched with HCl, (c) etched and treated with TCNQ solution, (d) etched and treated with F4-TCNQ solution. The extracted work function (Φ) values are indicated.

electron affinity of TCNQ, and the lower overall surface coverage (see XPS results). However, the achieved effect for F4-TCNQ solution treatment is smaller than that of an evaporated F4-TCNQ monolayer on a Cu(1 1 1) single crystal in UHV, for which a maximum Φ of 5.6 eV was reported [14]. This is not surprising, as the present experimental conditions deviate significantly from UHV. The Cu surface after HCl etching is still contaminated with various hydrocarbon species and contains some oxide. This already reduces the surface area available for intimate acceptor-metal interaction (*i.e.*, charge transfer), *i.e.*, the surface dipole density that is responsible for increasing Φ. Moreover, details of the F4-TCNQ/Cu charge transfer may be different from the UHV case due to the contaminants and oxide (*e.g.*, amount of charge transferred, molecular conformation). Nonetheless, these results demonstrate that the general method of increasing metal surface Φ by adsorption of strong electron acceptor molecules is transferable from UHV to device fabrication relevant conditions, even using solution processing.

Finally, we show that the electrode Φ increase can reduce R_c in a device, using OFETs as example. The influence of solution-based acceptor electrode modification in OFETs with P3HT-TFT as semiconductor was investigated in comparison to conventional OFETs with only HCl etched Cu electrodes. The output characteristics of such OFETs (Fig. 6) exhibit typical p-type performance with well defined saturation behavior. I_{on} in the saturation regime at -60 V gate-source voltage (V_{gs}) increases from 6.1×10^{-6} A for OFETs without acceptor modified Cu electrodes to 9.9×10^{-6} A for TCNQ modification, and to 1.2×10^{-5} A for F4-TCNQ modification. This is consistent with the increase of the electrode Φ shown above. In the simple model of the Schottky–Mott limit, the hole injection

barrier (HIB) at electrode/organic interfaces can be estimated as the difference between the electrode Φ and the organic material ionization energy [20]. For the present electrodes and the ionization energy of P3HT-TFT of *ca.* 5.1 eV [18] this leads to the following HIB values: 0.6 eV for etched Cu, 0.2 eV for TCNQ-treated Cu, and the HIB would even become zero for F4-TCNQ-treated Cu. A decrease of the HIB consequently leads to higher I_{on}, as holes can be accumulated more effectively in the channel.

Transfer characteristics were taken at -60 V source-drain voltage (V_{ds}) varying V_{gs} from +20 V to -60 V (Fig. 7a). Since the source-drain current (I_{ds}) in the saturation part of the transfer characteristic can be described with

$$I_{ds,sat} = \frac{W}{2L} C \mu_{sat} (V_{gs} - V_T)^2 \qquad (2)$$

where W is the channel width and L the channel length, the saturation mobility (μ_{sat}) and the threshold voltage (V_T) can be calculated from the slope and the intercept of a line drawn through the linear part of an $I_{ds}^{1/2}$ *vs.* V_{gs} plot (Fig. 7b). The values obtained in this way (together with other characteristic sample and device parameters) are summarized in Table 1. It can be seen that V_T decreases from -20 V to -10 V for TCNQ electrode modification and to -7 V for F4-TCNQ modification. In addition, a shift in the off-state towards positive V_{gs} of more than 20 V due to the acceptor modification of the Cu electrodes is observed (Fig. 7a). Both observations indicate that even for $V_{gs} = 0$ V (*i.e.*, no charge carrier accumulation) positive charges are available in the channel, resulting in a finite current between source and drain electrodes; *i.e.*, after electrode modification the gate has to be biased positively to turn it off. This is a consequence of the vanishing barrier for hole injection after
Fig. 6. Output characteristics of P3HT-TFT p-type OFETs with (a) unmodified, (b) TCNQ, and (c) F4-TCNQ modified Cu electrodes. Device channel length $L = 40$ μm, channel width $W = 40$ mm and gate capacitance $C_i = 1$, 5 nF cm^{-2}.
Fig. 7. Transfer characteristics (a) show well-defined on and off states. Square-root plots (b) show good linear behavior in the saturation regime and a decrease of the threshold voltage (V_{Th}) for OFETs with acceptor modified Cu electrodes.

Table 1
Surface work function values and key OFET performance parameters with and without acceptor solution treated Cu electrodes.

Treatment of the Cu electrode surface	HCl etched	Etched and TCNQ	Etched and F4-TCNQ
Work function Φ [eV]	4.5	4.9	5.1
Mobility μ_{sat} [cm²/Vs]	4.9×10^{-3}	5.2×10^{-3}	5.6×10^{-3}
Threshold voltage V_T [V]	-20	-10	-7
On-current I_{on} [A]	6.1×10^{-6}	9.9×10^{-6}	1.2×10^{-5}
$(I_{on}/I_{off})_{max}$	2.6×10^{3}	4.0×10^{3}	$>1.3 \times 10^{3}$

acceptor-treatment of the electrodes, as holes can diffuse into the channel region without having to overcome (significant) energy barriers. In addition, it may be possible that some residual (not strongly Cu-bound) acceptor molecules penetrate into the organic semiconductor layer during spin-coating of the polymer, which can results in p-type doping of P3HT-TFT. We cannot formally rule out the presence of F4-TCNQ molecules on the PET substrate even after washing with copious amounts of the solvent used for spin-coating the polymer (which is also a good solvent for the acceptor). However, even if this were the case it is unlikely that these contributed to doping because they should be stationary in/on PET as they were not even removed by the solvent. This is supported by our observation that transistor performance did not depend on the number of washing cycles.

It is worth pointing out that μ_{sat} was constant at *ca.* 5×10^{-3} cm²/Vs regardless of the Cu electrode modification. This is a strong indication that the solution-based TCNQ and F4-TCNQ deposition on the Cu electrode does

not influence the morphology/structure of the spin coated active polymer, as the carrier mobility depends critically on these parameters.

4. Conclusions

We demonstrated the feasibility of using solution-based processing to increase the work function of metal electrodes with strong electron acceptor molecules. The work function in air for Cu electrodes was increased from 4.5 eV (pristine) to 4.9 eV (with TCNQ) and 5.1 eV (F4-TCNQ). Furthermore, it was shown that this method can be used to reduce the contact resistance at electrode/organic semiconductor interfaces. The on-current of flexible polymer OFETs was increased from 6.4×10^{-6} A (pristine Cu) to more than 1.2×10^{-5} A (with F4-TCNQ), and the threshold voltage was reduced from -20 V to -7 V. The simplicity of our solution-based process to achieve favorable electrode/organic interface energetics can readily be adapted for other electrode materials and printing

techniques to realize a wide range of different organic electronic devices, such as light emitting diodes or photovoltaic cells, without the need for impractical and rigorous UHV conditions.

spatial resolution, which to date is limited only by tool-making capabilities. Apart from its unrivalled high-resolution, NIL has several more advantages over competing patterning methods such as self-aligned ink-jet printing [7] or high-resolution ink-jet printing [8]. It allows a higher aspect ratio, a larger number of compatible materials, a shorter process times which is inherent to parallel structuring techniques and an easier implementation into a standard r2r facility [9,10].

Hot Embossing is the oldest NIL technique and has already proven to be applicable in defining sub-micrometer channel lengths of OTFTs based on rigid silicon substrates [11,26] as well as of entirely patterned OTFTs based on thin organic gate dielectrics and on polyester film substrates [13]. However, in the latter case Hot Embossing can be detrimental to the fabrication process of large circuits since it often requires a temperature surpassing the glass transition temperature of the duroplastic films, thereby generating dimensional instabilities and complicated registration. Furthermore, Hot Embossing always produces a residual layer of the thermoplastic resist which has to be removed by anisotropic etching. This etching process is particularly undesirable because it is costly, difficult to control and might be harmful for an organic layer underneath.

In an alternative approach – UV-Nanoimprint Lithography (UV-NIL) – the thermoelastic imprint resist is replaced by a UV-curable polymer, bringing about several advantages in comparison to Hot Embossing. With UV-NIL, pressure, process time and thermal stress for the substrate can be significantly reduced during imprinting. Due to the major advances in nanometre patterning along with low-cost and high throughput [14], substantial work has been put into the development of suitable UV-curable polymer materials [15–17]. Today, a large number of UV-NIL resists are commercially available such as Amonil-MMS4 by AMO GmbH or mr-UVCur06 by micro resist technology GmbH. So far, none of them enables both residue-free imprinting and a lift-off process by a sufficiently gentle solvent.

Here we report on a novel nanoimprint process for the fabrication of entirely patterned submicron OTFTs in a bottom-gate configuration. This process requires no extra temperature budget, imprints residue-free thereby rendering etching obsolete, is time saving due to short curing times, eco-friendly due to a water-based lift-off and fully r2r compatible. This method is based on UV-NIL combined with a novel imprint resist whose outstanding chemical and physical properties are responsible for the excellent results in structure transfer to both rigid and flexible substrates. It is shown that the UV-NIL technique works perfectly even when ultra-thin organic and hybrid films are used as gate dielectrics. Employing this method, functional submicron pentacene-based OTFTs are fabricated, which show good saturation of the drain currents, low switch-on voltage ($\sim$3 V) and a sufficient on–off ratio (10^3) of the drain current.

2. Materials and methods

We have fabricated submicron coplanar OTFTs with pentacene as the active layer and a bilayer of about 100 nm of a benzocyclobutene derivative (BCB) and 30 nm of poly(vinyl cinnamate) (PVCi) as the gate dielectric. All devices have a channel width to length ratio (W/L) of 50. The aluminum gate electrodes are fabricated on a pre-cleaned glass substrate by a combination of a photolithographic process, e-beam evaporation of a 45 nm thick metal layer and a lift-off procedure using acetone as the solvent. The BCB layer is applied onto the aluminum gate electrodes by spin coating 0.33 wt.% of XU 71918 (Dow Chemicals) dissolved in 1,3,5-trimethylbenzene (Aldrich). The layer is crosslinked at 290 °C for 60 s on a hotplate. The PVCi layer (Aldrich) is fabricated by spin coating a solution of 0.2 wt.% of PVCi in chloroform at 2000 rpm. It is prebaked for 5 min at 80 °C to remove the solvent and UV-crosslinked for 60 min at 254 nm with a Benda NU-72 KM UV-lamp in inert atmosphere.

The thickness and optical constants of the dielectric layers are determined by ellipsometry based on a variable angle spectroscopic ellipsometer (VASE, J.A. Woolam Inc). The layer thickness is determined by fitting the ellipsometry data employing a simple Cauchy-model for the refractive index to be 29–31 nm for PVCi and 97 nm for BCB [18].

The silicon imprint stamp is patterned by electron beam lithography. The resist structures are permanently transferred to the silicon stamp by reactive ion etching (SF6-Ar) resulting in a final depth of about 1 μm. After stripping, an anti-sticking layer (perfluorchloroctyl–tricholorosilane) is applied to the stamp.

The UV-NIL-resist ACMO is fabricated by a mixture of GENOCURE*LTM and ACMO (acryloyl morpholine, both by Rahn AG) and chloroform at a mass ratio of 1:20:400, yielding a low-viscous material. Spin coating at 2000 rpm results in a homogeneous layer with a thickness of 600 nm. Curing is performed through UV exposure at 365 nm for a maximum time of 2 min. The UV-NIL structuring of the gold source–drain electrodes is done in an EVG 620 mask-aligner. A 30 nm thick gold layer is deposited by either e-beam or thermal evaporation. The lift-off is performed by dissolving the UV-resist with deionized water.

The 40 nm thick pentacene layer is thermally evaporated onto the sample in high-vacuum conditions at a rate of 0.2 nm/min for the first 5 nm and 0.8 nm/min for the remaining 35 nm.

Prior to the focused ion beam/scanning electron microscopy (FIB/SEM) investigations the specimens are covered with a 20 nm carbon layer to minimize charging of the sample. In the focused ion beam instrument Pt layers are grown by electron beam induced deposition (EBID) followed by ion beam assisted deposition (IBAD). These Pt layers protect the surface against incoming Ga ions during the cutting out and milling of the lamellas. The lamellas are transferred to a transmission electron microscopy (TEM) grid and thinned down to several tens of nanometre.

The TEM investigations are performed using a Philips CM20 (S)TEM (twin lens) with a thermionic LaB$_6$ cathode operated at 200 kV equipped with a Gatan Imaging Filter (GIF 200). For energy dispersive X-ray spectroscopy an HPGe detector (Noran/Thermo Fisher Scientific) employing Noran System Six software is used. Electron energy loss spectroscopy (EELS) and energy filtered TEM (EFTEM) are performed using a Gatan Imaging Filter (GIF) with a

1024 × 1024 CCD (YAG scintillator) attached to the microscope. Elemental maps were calculated using the three-window-technique.

3. Results and discussion

3.1. Imprint resist

The key component of our UV-NIL process for the patterning of submicron-spaced source and drain electrodes is an imprint resist called UV-NIL-ACMO, which is based on an acryloyl morpholine monomer (ACMO). It is curable by UV-initiated radical polymerization, is soluble in water, and shows a low viscosity. The actually applied special formulation of UV-NIL-ACMO is composed of ACMO mixed with a photoinitiator blend (GENOCURE) and highly diluted in chloroform, resulting in a low viscosity.

Acryloyl morpholine (for the chemical formula see Fig. 1a) is perfectly matches our NIL processes requirements for a variety of reasons: It provides removability by a lift-off process due to the lack of functional groups that could crosslink during polymerization, thereby preventing its solubility. Furthermore, the lift-off process can be accomplished with water as a cheap and eco-friendly solvent because of similarities in the polarity of the functional side group (morpholine) and the solvent water.

3.2. Residue-free UV-Nanoimprint Lithography

The principle of the UV-NIL process is illustrated in Fig. 2a. The first step (A) is to align the silicon stamp, which contains the elevated source–drain electrode pattern, with respect to the gate electrode. This is done in a mask-aligner. The aligned stamp is pressed into the low-viscous resist at low pressure, displacing the resist underneath the source–drain structures (B). A novelty here is the etch-free

process enabled by residue-free displacement of the UV-NIL-ACMO resist due to the high difference in polarity of resist and stamp. Curing is performed by UV exposure for up to 2 min, depending on the initiator concentration, during which the source–drain pattern is permanently transferred into the resist. After removing the stamp (C) the source–drain material – in the present case gold – is evaporated onto the device (D). The subsequent lift-off is performed by dissolving the resist with deionized water; the evaporated gold layer on top of the resist is removed while the imprinted areas are preserved (E). An optical microscope image of the source–drain structures after the lift-off step is shown in Fig. 2b illustrating the complete transfer of the stamp's source–drain pattern into the gold layer. The lift-off works perfectly for the complete electrode pattern and even for the large contact pads. Finally the active semiconductor material, here pentacene, is evaporated thus finalizing the transistor structure (F). In Fig. 2c an AFM phase signal of the pentacene layer on top of the contacts and the channel is displayed. The difference in morphology is distinctive: small (⩽200 nm) grains are formed on the gold layer, whereas terraced crystalline grains with a maximum size of about one micron are observed on the gate dielectric in the channel. Such a pentacene grain size is reasonable for an rms-roughness of the BCB/PVCi layer of approximately 0.4 nm [19–21].

The residue-free imprint is facilitated by the use of the aforementioned water-soluble low viscosity UV-NIL-ACMO resist in combination with an adjustment of the stamp's surface energy to maximize the contact angle. In order to minimize the polarity of the silicon stamp it was rinsed with perfluorchloroctyl-tricholorosilane.

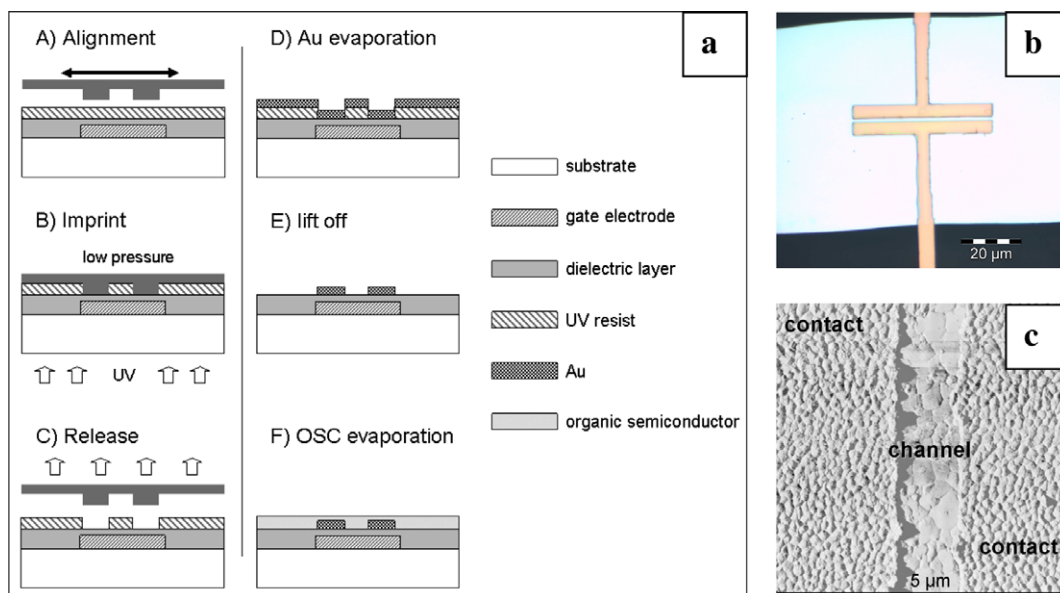
Contact angle measurements of the UV-NIL-ACMO resist and water on the modified silicon stamp reveal that the contact angle of the imprint resist on the modified stamp is very high (82°, see Fig. 1b) and approaches that
Fig. 1. (a) Chemical formula of acryloyl morpholine. Comparison of the contact angle of (b) the UV-imprint resist and of (c) water on the anti-sticking layer (perfluorchloroctyl-tricholorosilane) modified silicon stamp.


Fig. 2. (a) Scheme of the residue-free UV-NIL process: A silicon stamp containing the source–drain structures is aligned with respect to the gate electrodes of a resist-coated substrate (A). The stamp is pressed into the resist, thereby completely displacing the resist below the source–drain structures (B). Subsequently the resist is cured by UV exposure. After the stamp removal (C) the source–drain material is evaporated onto the substrate (D). The imprint resist is dissolved with water which leaves the metal source–drain electrodes well preserved (E). Finally the sample is covered by an organic active layer, pentacene. (b) Optical microscope image of the gold source–drain pattern of a submicron OTFT with $L = 950$ nm after lift-off. (c) AFM phase image (5×5 μm) of the pentacene layer formed on top of the contacts and in the submicron channel. The gate dielectric is BCB/PVCi.

of water on the modified silicon stamp (100°, see Fig. 1c). In addition to the low resist viscosity we suggest that a large difference in the polarity of the modified silicon stamp (non-polar) and the resist (polar) is an important factor for the absence of a residual layer.

In order to characterize the individual layers of the transistor devices the specimens were investigated by transmission electron microscopy (TEM). Cross section lamellas of the samples were prepared using a focused ion beam instrument (FIB, compare Fig. 3a inset) [22]. Fig. 3 shows a sample after the imprint step. SEM images of the lamella and its cutout are shown in Fig. 3a and the inset, respectively. The organic layers are clearly observed

as dark areas in-between the glass substrate and the platinum layers used for sample protection during FIB-cutting. The image gives an overview of the appearance of the imprinted troughs for the electrodes and the resist in the center as a placeholder for the channel. A more detailed view is presented in Fig. 3b, it is a TEM bright field image showing one edge of the resist in the channel. The glass substrate, the aluminum electrode and the organic layers can clearly be distinguished. The three involved polymer layers BCB, PVCi and UV-NIL-ACMO appear as a single layer. However, since their elemental composition is distinctly different, the layers can be identified by analytical methods such as electron energy loss spectroscopy.
Fig. 3. A sample after the imprint step. (a) A cross section lamella of the sample, where the imprinted organic layer appears dark in-between the glass and protective Pt layers. The lift out of the FIB prepared lamella is seen in the inset. (b) A TEM bright field image of the edge of the channel. (c) Superposition of EELS elemental maps (N = green; Si = blue; C = red; Al = white) enables a clear distinction of the three involved polymers. The white arrow points towards a bump in the imprinted area which is identified as PVCi. A UV-resist residual can be excluded. IBAD = ion beam assisted deposition, EBID = electron beam induced deposition. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

BCB can be identified by its silicon content and UV-NIL-ACMO by its nitrogen content. A superposition of elemental maps of different elements is shown in Fig. 3c, where the nitrogen map is green (representing UV-NIL-ACMO), the silicon map is blue (representing BCB and glass), the carbon map is red and the aluminum map is white (representing the gate electrode). Now the three polymer layers can clearly be distinguished by a color code. In this way it is shown that the UV-NIL-ACMO resist is fully displaced; no residue is observed in the imprinted areas. Even bumps in the surface, indicated by the white arrow in Fig. 3c, can be identified as PVCi, thus corroborating the residue-free imprint. Despite the perfect displacement of the resist it is worth noting that both the BCB and particularly the PVCi layer seem to be compressed due to the imprint step. The influence of the compression on the electrical performance of the dielectric layers will be topic of further investigations. Furthermore, it is observed that the appearance of the resist is wedge-shaped. This is a direct consequence of the stamp's rounded edges stemming from an isotropic etch step during the stamp fabrication. With NIL all structures of the stamp (including artifacts and defects) are strictly and precisely transferred to the resist/sample.

Since no residuals of UV-NIL-ACMO are left at imprinted areas the specimen can be covered with the source–drain electrode material without prior etching. This is particularly favorable since the dielectric layers are fairly thin and thus can easily be damaged by the etching process. The final transistor structure is shown in Fig. 4, where a scheme (Fig. 4a) and a cross section TEM image (Fig. 4b) are presented. As shown, the gold electrode is perfectly preserved in the imprinted region (right part of the image) whereas it is gone in the channel where the UV-NIL-ACMO was dissolved (left part of the image).

3.3. Electrical characterization of submicron OTFTs fabricated by residue-free UV-NIL

The introduced residue-free UV-NIL route obviously leads to well-defined transistor structures. Devices with channel lengths down to 700 nm were fabricated. Consequently, appropriate device characteristics are expected.

The results of the $I(V)$-characterization of submicron transistors based on the 130 nm thick BCB/PVCi bilayer as the gate dielectric are shown in Fig. 5. Important parameters such as the specific gate capacitance C_i and the dielectric breakdown voltage E_{br} that are intrinsic to the gate dielectric are also specified in the table. The motivation for the usage of an additional ultra-thin PVCi layer forming the direct interface to pentacene is to adjust the surface energy and roughness in such a way that the semiconductor growth is optimized.

In the output characteristics (second column in Fig. 5) no difference is observed between devices with submicron channel lengths varying from 950 to 700 nm and constant W/L ratio, which is an indication for a constant charge carrier mobility μ. All curves show saturation of the drain current. This is due to the fact that the gate dielectric layer thickness is smaller by more than a factor 5 than the channel length, thus preventing an unbalanced increase of the lateral electric field with respect to the vertical one. As was shown previously [11–13], an adequate downscaling of channel length and dielectric layer thickness leads to short channel effects such as channel length modulation resulting in a loss of current saturation. Moreover, at small drain voltages the drain current increases perfectly linear meaning that the transport is not limited by the contact resistance. Hysteresis effects between forward and reverse drain voltage sweeps are negligible.

From the semi-logarithmic representation of the transfer characteristics $I_D(V_G)$ in saturation (first column in Fig. 5) the subthreshold swing S and the switch-on voltage V_{so} were determined. The latter is taken as the gate voltage at which the drain current is one order of magnitude higher than the off-current I_{off}. The transfer characteristics of submicron devices for different channel lengths collapse into one curve as is expected for transistors having identical geometry (W/L ratio) and mobility. All submicron OTFTs are normally-on as is reflected by the small positive V_{so} (see Fig. 5). A shift of the onset of transistor operation to the positive voltage regime was reported to be induced by negative charges in the BCB dielectric probably caused by water [23,24].

The charge carrier mobility of the UV-NIL fabricated submicron OTFTs is in the range of 10^{-3} cm²/Vs which is
Fig. 4. (a) A scheme of a completed transistor structure and (b) a corresponding TEM bright field image of a cross section lamella. The gold electrode is well preserved at the imprinted areas and lifted off elsewhere.

Transfer characteristics $I_D(V_G)$ **Output characteristics $I_D(V_D)$**

$C_i = 28.5$ nF/cm^2

S = 2.2V/dec $V_{so} = 2.8$V

$E_{br} = 1.5$ MV/cm

$\mu \sim 10^{-3}$ cm^2/Vs $I_{off} = 2 \cdot 10^{-11}$ A
Fig. 5. Electrical performance of UV-NIL fabricated pentacene OTFTs based on a double layer of BCB/PVCi as the gate dielectric. In the first and the second columns the saturated transfer and output characteristics of the submicron transistors are shown. Critical parameters revealing the properties of the gate dielectric are also listed, such as the specific gate capacitance C_i and the breakdown voltage E_{br}. From the transfer characteristics important transistor parameters are extracted: the subthreshold swing S, the switch-on voltage V_{so}, the off-current I_{off} and the charge carrier mobility in saturation μ.

rather low compared to hot embossed submicron OTFTs with SiO$_2$ as the gate dielectric [12]. One parameter that influences the mobility and is directly related to the channel resistance is the pentacene grain size. As deduced from the AFM phase image in Fig. 2c the maximum pentacene grain size is well below 1.5 μm, which we found to be the average threshold for grain boundary limited transport [25]. If the grain size is smaller than one micron the transport is dominated by grain boundary effects. This leads to a decreased mobility in the range of 10^{-3} cm^2/Vs as is indeed observed in the BCB/PVCi submicron transistors. Moreover, the large amount of interface trap states that is reflected by a large subthreshold swing [26] – compared to hot embossed devices [12,13], – clearly has a negative effect on the mobility because it obstructs the charge transport by scattering carriers at the pentacene-dielectric interface. With an additional UV-ozone treatment, as described in Ref. [12], the pentacene grain size could be strongly increased both in the channel and on the contacts thus resulting in charge carrier mobilities up to 0.3 cm^2/Vs for SiO$_2$-based submicron OTFTs.

4. Conclusion

In summary, we have fabricated fully functional OTFTs with submicron channel lengths using an improved UV-NIL process. The nanoimprinted OTFTs are comprised of pentacene as active semiconductor and a thin bilayer gate dielectric composed of BCB and PVCi. With our novel UV-NIL process, devices with channel lengths down to 700 nm were fabricated, showing good drain current saturation and low switch-on voltages. This process is based on a UV-NIL resist formulation containing acryloyl morpholine, which perfectly matches the requirements of fast and precise nanoimprinting of organic electronic components. Since no heating step is involved in the process,

thermal stress can be disregarded and, more importantly, thermally unstable materials can be used as substrates and gate dielectrics. Furthermore, UV-NIL-ACMO is cured by UV-initiated radical polymerization which reduces the fabrication time considerably, thus enabling a high throughput. Remarkable is the absence of any residual layer of UV-NIL-ACMO after the imprint step, which makes etching obsolete. This is particularly convenient, since O$_2$-etching of organic dielectrics is known to increase the gate leakage and the number of OH-groups acting as traps at the interface. Furthermore, reactive ion etching is difficult to implement in a standard printing line. Finally, UV-NIL-ACMO allows a lift-off with deionized water, which is a substantial advantage due to its ubiquitous availability, its potential for immediate recycling and its environmental sustainability, resulting in a decrease of the production costs and an increase of process safety. Optimization is still needed with respect to the semiconductor/dielectric interface which shows an increased number of traps leading to reduced effective charge carrier mobilities after the UV-imprint step. Here, a special treatment prior to the application of the semiconductor could be beneficial and furthermore increase the pentacene grain size. In conclusion, UV-NIL has a huge potential as a high-resolution patterning process for large-area fabrication of flexible organic electronics.

2. Experimental

The fabrication of sol–gel processed ZnO nanoparticle films with planar and nano-ridge structures were made from spin coating the same precursor solution but annealing under different conditions. The precursor solution, consisting of 0.75 M zinc acetate dihydrate and 0.75 M monoethanolamine in 2-methoxyethanol [18], was first spun-coated onto indium tin oxide (ITO) substrates at 2000 rpm for 40 s. For the ZnO planar film, the substrate was immediately placed onto a hot plate that was preheated at 275 °C and annealed for 5 min. In order to form

the ZnO nano-ridge film, the spin-coated substrate was first placed onto a hot plate that was initially at room temperature while it was still not completely dry. The temperature was then raised at a ramping rate of 50 °C/min to 275 °C and the substrates were subsequently removed from the hot plate when the final temperature was reached. We noticed an increase in sheet resistance of the ITO films when the substrates were heated at higher temperatures, so the annealing temperature the ZnO films was limited at 275 °C. Quartz substrates were used when measuring the transmittance of the ZnO films.

The resulting ZnO films were rinsed in de-ionized water, acetone, and isopropyl alcohol and then dried to remove residual organic material from the surface. All processes thus far were done in ambient air. The substrates were then transferred into a nitrogen-filled glovebox for polymer coating. Poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C_{61} butyric acid methyl ester (PCBM) blend films were spun-coated onto the substrates from a 1:1 wt-ratio solution in 1,2-dichlorobenzene (20 mg of P3HT/ ml of solvent) at 600 rpm using the slow-growth method [1], followed by annealing on a hot plate at 110 °C for 10 min. To complete the solar cell devices, a 10 nm layer of V_2O_5 (serving as a buffer layer for hole collection [8]), following by 70 nm of Al was deposited by thermal evaporation through shadow masks. The device area, as defined by the overlap between the ITO and Al electrodes, was 0.09 cm². The solar cells were measured under simulated illumination at AM 1.5 G, 100 mW/cm² with a Keithley 2400 source meter controlled by a computer program.

3. Results and discussion

The atomic force microscope (AFM) images of the nano-ridge and planar films are shown in Fig. 2a and b, respectively. Nano-ridges of ZnO nanoparticles with thickness ranging from 50 nm to 120 nm were formed and the valley to valley distance of the nano-ridges was about 500 nm. The ZnO nano-ridge structure was formed by the reorganization of gel particles during the slow drying process [19,20]. The ZnO planar film was relatively smooth with an r.m.s. roughness of about 2.6 nm. The r.m.s. roughness of the nano-ridge film was about 4.0 nm at the top of the ridge. As the morphologies are very different between the two structures, it is difficult to make a direct comparison in the r.m.s. roughness between them. Fig. 2c and d shows the close-up AFM images of the nano-ridge and planar films, respectively.

The transmittance spectra of the ZnO films and absorbance of the ZnO films coated with P3HT:PCBM are shown in Fig. 3. The ZnO nano-ridge film had a slightly lower transmittance over a broad range of wavelengths as compared to the ZnO planar film. This was due to the increase in light scattering by the nano-ridges and was consistent with the white foggy appearance of the film [21]. The polymer films with both types of ZnO morphology showed very similar absorption.

The current–voltage (J–V) characteristics of the solar cell devices with ZnO nano-ridge and planar films under simulated sunlight were shown in Fig. 4a. The device perfor-

mance is summarized in Table 1. The ZnO nano-ridge device showed a remarkable improvement over the device with the planar film. The average power conversion efficiency of 20 devices fabricated with nano-ridge films was 3.87%, while devices with planar films showed an efficiency of only 3.06%. The best device performance obtained from the nano-ridge device was 4.00%. The major improvement in device performance arises from the higher fill factor (FF) of the ZnO nano-ridge device, while the open circuit voltage (Voc) and short-circuit current density (Jsc) remained almost unchanged. This is reflected in the series and shunt resistance as well. The shunt resistance showed a difference of about an order of magnitude while the series resistance was almost the same. Thus, it is unlikely that the improvement in the device performance is due to the change in carrier concentration or work function. We attributed this enhancement to lower leakage current due to the improvement in hole blocking capability and electron collection efficiency of the nano-ridge structured film.

The dark J–V curve (Fig. 4b) shows a lower leakage and higher forward bias current for the ZnO nano-ridge device, indicating better charge selectivity over the ZnO planar film. This is due to the difference in the packing density of the films. As the ZnO nano-ridge film is formed by a slower heating process, there is sufficient time for the gel film to structurally relax before crystallizing, resulting in a denser film [18] than that of ZnO planar film [22]. A denser film with fewer defects would be more effective in blocking the transport of holes, leading to lower leakage current, i.e. a larger shunt resistance and higher FF.

To clarify whether the nano-ridge structure of the ZnO played a role in improving charge extraction, bilayer devices without PCBM were also fabricated. The Jsc for the ZnO nano-ridge bilayer device was close to two times higher than that of the device with the ZnO planar film, indicating a much larger interfacial area for charge separation. Similar to the results of ZnO nanorods [22,23], we believe that our ZnO played a comparable role, albeit a smaller one, to that of the ZnO nanorods-based solar cells. The larger surface area of electrode contact and undulate network structure minimized the distance charge carriers need to travel in the active polymer to reach the electrodes.

4. Conclusion

We reported a ZnO nano-ridge structured film that can be formed by a simple ramp annealing process. The nano-ridge structure has comparable excellent electron collection properties as that of ZnO nanorods and yet can be made with similar simple fabrication processes as the ZnO planar film. The effect of the viscosity of the solution and the solvent evaporation rate on the nano-structured pattern is to be further studied. Both inverted bulk heterojunction polymer solar cells and ZnO:P3HT hybrid solar cells showed remarkable improvements in efficiency when the ZnO nano-ridge structure was used. We attributed the improvement in FF to higher electron selectivity and more efficient charge collection, leading to a 4.00% inverted polymer solar cell.

localized conducting filaments through the middle layer due to the electroformation, which could lead to NDR due to uneven local temperatures in the filaments [15,16]. Localized hot spots have been reported to support the filament concept [17]. Within this hypothesis, the homogeneous and controlled creation of filaments would be essential for reproducibility and scalability. Electrode surface engineering and patterning [18–20] and dispersion of semiconducting fullerenes within insulating polymer [21] have been incorporated to control localized electric fields to trigger and control filament growth. Importantly, there exists a wealth of other explanations based on tunnelling of charges in an amorphous medium also incorporating impurities and space charges [4,22,23]. Altogether, more detailed understanding is needed for reproducible device design.

Here we pursue the hypothesis that an essential point could be to "trigger" and to control the filament formation during the electroformation. This might be accomplished by creating sufficiently dense sites of enhanced local electric fields by e.g. topography engineering of the electrode surfaces (see e.g. [20]) or by dispersions within the polymer layer, e.g. by nanoparticles [7] or fullerenes [10,21]. However, the distribution of the dispersion is difficult to master due to aggregations. This encourages to search new routes for homogeneous dispersions. One route could be based on block copolymers where, unlike the usually incorporated self-assembled state [24], the disordered state is selected, where the different polymers are located in average separated by the radia of gyration.

Here we aim to suppress the aggregation by using a triblock copolymer polystyrene–*block*-poly(9,9-di-*n*-hexyl-2,7-fluorene)–*block*-polystyrene (PS–*b*-PDHF–*b*-PS) (Fig. 1), having a short semiconducting middle block between insulating end blocks. In comparison, a purely insulating polymer, polystyrene (PS), was used as a reference. Fig. 2 illustrates the probed concept. In addition, we studied the scalability limits for devices by altering the device area and the effect of the interface by modifying the oxide layer on the bottom electrode. Finally, the bistability of the devices was tested with consecutive programming cycles.

2. Experimental

Aluminium bottom electrodes (thickness 40 nm) were thermally evaporated (1 Å/s) in a nitrogen glove box through a shadow mask on well-cleaned glass substrates. The bottom electrodes were exposed to air in order to let a few nanometres thick native aluminium oxide layer grow on the electrodes. Alternatively, a controlled oxide layer was produced on the electrodes by keeping them for 1 h in an oxygen plasma etcher, which is a known method to produce an oxide layer on aluminium [26,27]. This treatment increased the oxide layer thickness to 5–10 nm, as determined with capacitive measurements. Then a polymeric layer was spin-coated on the electrodes, again in a nitrogen glove box. Several spinning speeds were used to find the optimal film thickness, which was found to exist near 85 nm. The film thickness values were measured with an Optical Profiler (Veeco). All the results presented in this paper are measured from 85 nm thick films. Thicker films (>100 nm) showed inconsistent negative differential resistance (NDR). The triblock copolymer polystyrene–*block*-poly(9,9-di-*n*-hexyl-2,7-fluorene)–*block*-polystyrene (molecular weights: PS: 17,100 – PDHF: 2900 – PS: 17,100 g/mol, polydispersity 1.63) was provided by Polymer Source Inc. As a reference, an insulating homopolymer polystyrene (250,000 g/mol) was used (Agros Organics). We used *p*-xylene as a solvent for both polymers (Fluka, >99%). The polymeric films were dried in a vacuum oven for 48 h at 150 °C in order to remove the solvent residues. Subsequently, the top aluminium electrodes (40 nm) were evaporated on the dried films at a rate of 1 Å/s.

The SAXS measurements were performed with a rotating anode Bruker Microstar microfocus X-ray source with Montel Optics. PS–*b*-PDHF–*b*-PS showed only a broad correlation peak at the length scale of 6 nm (data not shown). Bright-field TEM was performed on a FEI Tecnai 12 transmission electron microscope operating at an accelerating voltage of 120 kV and did not show self-assembled structures (data not shown). These results support that the polymer is in the disordered state.

I–V measurements were performed with a Keithley 4200 Semiconductor Characterization System. If the device shows negative differential resistance (NDR) after the first, a so called forming sweep, it may be used as a memory element utilizing unipolar switching [16]. We used a voltage sweep from 0 to 15 V and back to 0 V with voltage steps of 0.25 V and a delay of 0.1 s between successive steps. The top electrode was always used as the positive electrode. The devices with only the native oxide on the

Fig. 1. The molecular formula of polystyrene–*block*-poly(9,9-di-*n*-hexyl-2,7-fluorene)–*block*-polystyrene (PS–*b*-PDHF–*b*-PS). The approximative radia of gyration are given for the used block lengths, indicating the sizes of the dispersed PDHF chains [25] as separated by the insulating PS chains. Note that the length of the PDHF is small, leading to a disordered phase.

Fig. 2. Suggested schemes for the effect of dispersions. (a) Dispersion of fullerenes or nanoparticles in inert matrix. Local enhanced electric field in the dielectric constituents is also illustrated, which might control filament formation. (b) Semiconducting polymer chains (PDFH) forming the middle block of a block copolymer with insulating end blocks (PS). In the disordered state, the PDHF chains of average sizes $R_g^{PDHF} \approx 2$ nm are separated by the PS chains (radius of gyration $R_g^{PS} \approx 4$ nm). (c) Purely insulating polymer film, where the formation of the filaments is suggested to be controlled solely by the electrode surface structures and device inhomogeneities.

bottom electrode did not show a clear threshold voltage value during the first sweep and the current values were high already in the beginning of the first scan. However, the first sweep was usually noisy, i.e. NDR was achieved only after the forming sweep. The plasma treated electrodes had a threshold voltage value near 5 V, after which the high current level was achieved. After the *I–V* measurements, the same devices were used for programming tests. The devices were written to a low conductivity state (OFF state) by applying a 100 ms voltage pulse of 9 V, and to a high conductivity state (ON state) with a 100 ms voltage pulse of 4 V. The current levels were read with 1 V after each writing step. Also all the electronic measurements were performed in a nitrogen glove box to eliminate environmental effects.

3. Results and discussion

3.1. I–V measurements

At first we investigated devices with PS–*b*-PDHF–*b*-PS or PS layers between the electrodes with only a native oxide layer. The electrode overlap area was systematically varied from 4.7 to 0.38 mm². Fig. 3 shows the *I–V* curves for 85 nm thick polymer films in all cases, averaged from 3 to 4 devices. The presented results are collected from one polymer film containing devices of each overlap area, ensuring that the manufacturing process is exactly the same for each device. The averaged values are presented to clarify the differences. The first forming sweeps are not included in the figures. In both cases, NDR was observed, where curiously the current levels are slightly higher for PS. The figures show that the chemical nature of the polymer does not have a significant influence on the NDR effect. Also a simple insulating polymer like polystyrene shows strong NDR behaviour, enabling the mem-

ory effect, thus agreeing previous observations [4,6] and supporting the hypothesis of filamentary conduction. Interestingly, the figures also show that the shape of the *I–V* curve smoothens when the device area increases, i.e. the smallest area produces a noisy curve. This suggests that the probability of having enough working filaments is higher when the area is large. Note also that the current values rise when the area increases, i.e. approximate scalability at large device areas is achieved. This suggests that instead of just one filament, several working filaments contribute to the device operation, which might be compared to previous results which present infrared camera pictures of devices showing only few hot spots, corresponding to a conducting filament or possibly groups thereof in the ON state [17]. Scalability enables us to tune the current levels with size, even though the minimum size is limited by the regularity of the *I–V* curves. Thus the electrode overlap area cannot be miniaturized much below millimeter-scale for such simple devices. One can conclude, that the hypothesis of incorporating homogenous dispersion of semiconducting polymer chains due to disordered structure of block copolymers to trigger filament growth does not receive experimental support, which suggests to emphasize electrode surface engineering.

Next we studied the effect of an additional aluminium oxide layer on the bottom electrodes. Fig. 4 shows the *I–V* curves of the 4.7 mm² devices having an 85 nm thick PS–*b*-PDHF–*b*-PS layer sandwiched between the aluminium electrodes and an oxide layer on the bottom electrode, which was either a native oxide layer or produced with an oxygen plasma treatment. The forming sweeps are again not included in the figure and the graph shows individual, consecutive sweeps of two different devices (no averaging was done). Surprisingly, the additional oxide layer seems to clearly reduce the probability of having a clear current maximum in the NDR curve, in contrast to the previous results [18]. This suggests that either the peaks of the bottom

a

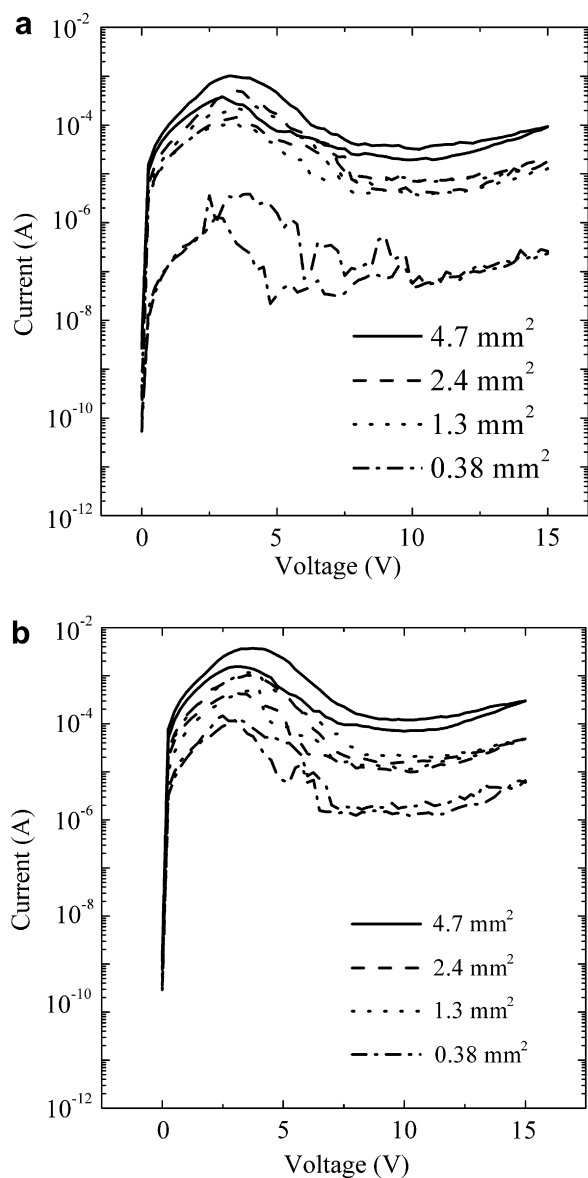
b


Fig. 3. NDR and the effect of device area on the *I–V* characteristics for: (a) a PS–*b*-PDHF–*b*-PS and (b) a PS layer sandwiched between aluminium electrodes.

electrode are flattened, or the morphology of the oxide layer changes during the plasma treatment. Either way, the filaments do not have enough starting points to grow after the plasma treatment.

The surface roughness of the both oxide layers was studied with AFM on a small scale and with an optical profiler on a larger scale. The numerical surface roughness values, measured with either method, did not differ significantly when plasma-treated and native oxide layers were compared. In addition, the optical profiler studies did not reveal any existence of random higher oxide peaks, which might act as starting points for the filaments. However, the resolution of the optical profiler might not be enough to detect such peaks. It is thus not quite clear whether it is

Fig. 4. The effect of oxygen plasma treatment of the bottom electrode on the negative differential resistance of PS–*b*-PDHF–*b*-PS (85 nm) memory device.

the possible smoothing of the oxide or morphological changes that degrade NDR in the plasma-treated devices. Nonetheless, it is evident that just the presence of the oxide layer does not guarantee reliable operation, as shown also by Steyrleuthner et al. [20], but the processing method of the oxide has an effect also.

3.2. Programming

We tested all the described devices by applying a 4 V pulse to switch the devices to the ON state and a 9 V pulse to switch them to the OFF state, keeping the reading voltage at 1 V. Fig. 5 shows the best results for the programming cycle of the devices incorporating PS–*b*-PDHF–*b*-PS for the area of 4.7 mm^2 using the native oxide and ~85 nm film thickness. Fig. 5 illustrates that in principle the present devices could allow memory device operation.
Fig. 5. Programming results showing consistent switching and ON–OFF current ratios greater than three orders of magnitude for PS–*b*-PDHF–*b*-PS (85 nm), utilizing the largest device area (4.7 mm^2) and only native oxide on the bottom electrode.

But notably, the reproducibility still remains poor, even though NDR was easy to produce for a sufficiently high device area (>4 mm^2) and a thin polymer film (<100 nm). These results further suggest that reliable operation requires control over the surface topography to create starting points to the filaments, at least in order to keep the device area below mm scale. Since both the aluminium oxide layer and a certain amount of starting points for the growth of the filaments appear to be prerequisite for reproducible operation, the best suggestion for printable devices could be patterning of the bottom electrode or the substrate underneath. This might be possible by using surface-patterned electrodes – metallic or polymeric – and roll-to-roll atomic layer deposition [28] to provide the aluminium oxide layer on the bottom electrode.

4. Conclusions

We tested whether well dispersed semiconducting polymer chains with radius of gyration of ca. 2 nm as separated by insulating polymer chains with radius of gyration of ca. 4 nm, i.e. a disordered triblock copolymer polystyrene–*block*-poly(9,9-di-*n*-hexyl-2,7-fluorene)–*block*-polystyrene, would allow control of filament formation upon electroforming, in comparison to purely insulating PS. The present work did not show major differences in the electronic properties of thin film memory devices in these two cases. Programming of the polymeric devices to distinct ON and OFF states was possible, but not reliably reproducible. The current passing through the device was area dependent, which implies that multiple filaments contribute to the memory effect, but scalability was suppressed for small areas. The larger device area (4.7 mm^2) also improved the stability of the NDR curve, indicating that multiple defects on the bottom electrode are needed in order to guide the growth of the filaments. Also the processing method of the aluminium oxide layer on the bottom electrode had a significant effect on the NDR. In comparison to a native oxide layer, devices with oxygen plasma treated bottom electrodes showed inferior *I–V* characteristics, most probably due to the differences in the oxide layer morphology or smoothness. Thus the critical step in possible forthcoming work would be to study if the filament-forming process can be nucleated by a surface topography treatment.

cells can dramatically influence the air stability of the devices. Specifically, annealing the polymer photoactive layer after top electrode deposition results in air stable polymer solar cells; the average device efficiency is maintained at 90% of the highest value even after exposure to air for 10 days. On the other hand, annealing the photoactive layer prior to top electrode deposition results in devices with stability that is far inferior compared to devices whose photoactive layer was annealed after top electrode deposition. We attribute this discrepancy in the stability of devices to differences in the metal grain structure of the top electrode, which in turn is a direct manifestation of the underlying morphology of the photoactive layer.

2. Experimental

Inverted bulk-heterojunction polymer solar cells were fabricated on pre-patterned indium tin oxide (ITO) on glass (15 Ω/sq.; Colorado Concept Coatings). Prior to the deposition of the polymer photoactive layer, we deposited a 30 nm thick layer of titania via hydrolysis of titanium isopropoxide (Ti[OCH(CH$_3$)$_2$]$_4$, Aldrich, 99.999%) as the electron transport layer [10,11]. Specifically, titanium isopropoxide was dissolved in isopropyl alcohol to make a 1 wt.% solution and the solution stirred for at least 30 min. The solution was then spin coated on pre-patterned ITO/glass substrates at 4500 rpm for 30 s. Hydrolysis occurred at room temperature for 1 h before the substrates were annealed at 170 °C for 10 min. The polymer photoactive layer (180 nm) consisted of poly(3-hexylthiophene), P3HT (Merck Chemicals Ltd.), and a fullerene derivative of [6,6]-phenyl-C$_{61}$-butyric acid methyl ester, or PCBM (American Dye Source, Inc.), which were first codissolved at equimass ratio in chlorobenzene to yield a 2.4 wt.% solution prior to spin coating on titania-coated substrates. Thermal annealing of the polymer photoactive layer took place at 140 °C for 30 min either before or after top electrode deposition. The top electrode consisted of 80 nm of silver deposited via thermal evaporation through a stencil mask resulting in devices with an active area of 0.127 cm^2. The schematic of our device architecture is

shown in the inset of Fig. 1a. We have previously demonstrated inverted polymer solar cells with gold top electrodes [10,11]. Given that silver is more reflective than gold [12] and it readily oxidizes in air to form silver oxide with a work function that facilitates hole collection [13], we opted to use silver as our top electrodes in this study. All the devices examined in this study were fabricated and tested in air without any external packaging or encapsulation. The devices were stored in air and tested periodically for extended periods to gauge the air stability. Current density–voltage (J–V) characteristics of the devices were measured with a Keithley 2400 source measurement unit under AM 1.5G 100 mW/cm^2 illumination. Atomic force microscope (AFM) images of the polymer photoactive layer and of the silver top electrode were acquired on a Veeco multimode AFM with a nanoscope IIIa controller in tapping mode.

3. Results and discussion

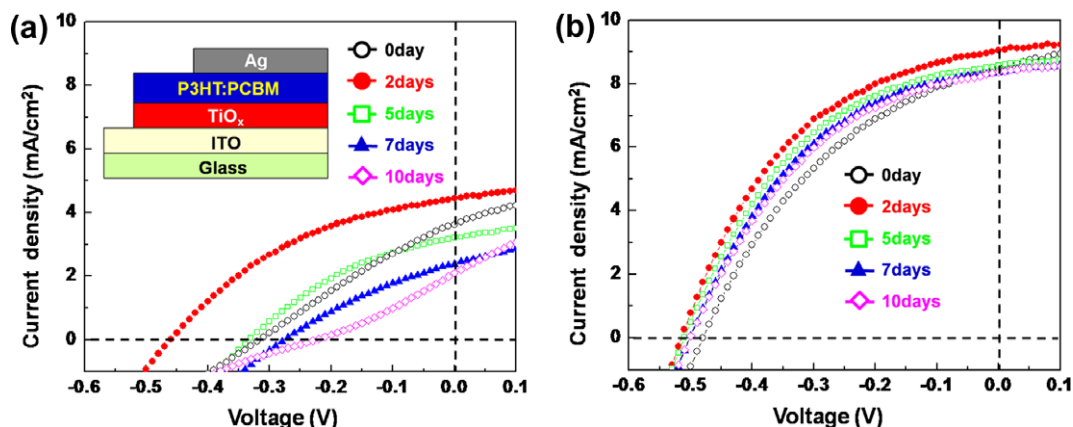
Fig. 1 contains the J–V characteristics of representative polymer solar cells acquired under illumination with exposure to air. Specifically, the J–V characteristics in Fig. 1a were acquired on a polymer solar cell in which its photoactive layer was annealed before silver electrode deposition whereas the J–V characteristics in Fig. 1b were acquired on an analogous polymer solar cell in which thermal annealing took place after silver electrode deposition. The individual J–V curves shown in Fig. 1 were acquired after the polymer solar cells had been illuminated for ten minutes where upon the transient photovoltaic characteristics associated with the filling of shallow electron traps in titania have saturated [11]. As fabricated, the polymer solar cell in which its photoactive layer was annealed before silver electrode deposition exhibits a short-circuit current density, J$_{sc}$, of 3.6 mA/cm^2 and an open-circuit voltage, V$_{oc}$, of 0.32 V. We extracted a fill factor (FF) of 0.29 for the same device, amounting to a device efficiency, η, of 0.32%. The average device characteristics, along with relevant standard deviations of five devices tested are recorded in Table 1. On exposure to air for two days, both the J$_{sc}$


Fig. 1. J–V characteristics under illumination (100 mW/cm^2) of inverted polymer solar cells as function of exposure time in air for devices in which the photoactive layer was annealed (a) before and (b) after top electrode deposition. The inset shows a scheme of our inverted polymer solar cell architecture with silver top electrode; no external packaging or encapsulation was used. All devices were fabricated and tested in air.

Table 1

Photovoltaic characteristics of polymer solar cells as function of exposure time in air for devices in which the photoactive layer was annealed before and after top electrode deposition.

	J_{sc} (mA/cm^2)	V_{oc} (V)	Fill factor	Efficiency (%)
Annealed before Ag deposition				
0 day	3.63 ± 0.36	0.32 ± 0.02	0.29 ± 0.01	0.32 ± 0.08
2 days	4.44 ± 0.67	0.46 ± 0.03	0.39 ± 0.03	0.81 ± 0.11
5 days	3.22 ± 0.19	0.33 ± 0.02	0.30 ± 0.02	0.38 ± 0.05
7 days	2.38 ± 0.11	0.28 ± 0.02	0.31 ± 0.02	0.20 ± 0.02
10 days	2.09 ± 0.10	0.22 ± 0.02	0.18 ± 0. 01	0.09 ± 0.01
Annealed after Ag deposition				
0 day	8.50 ± 0.61	0.48 ± 0.02	0.37 ± 0.02	1.88 ± 0.11
2 days	9.06 ± 0.78	0.51 ± 0.01	0.37 ± 0.01	2.09 ± 0.18
5 days	8.71 ± 0.37	0.51 ± 0.01	0.37 ± 0.02	1.96 ± 0.09
7 days	8.66 ± 0.61	0.51 ± 0.01	0.37 ± 0.01	1.85 ± 0.15
10 days	8.58 ± 0.20	0.51 ± 0.02	0.37 ± 0. 01	1.80 ± 0.10

(4.4 mA/cm^2) and the V_{oc} (0.46 V) of the same device improve dramatically, resulting in a concomitant increase in the FF (0.39) and η (0.81%). That the device improves with storage was previously observed with inverted polymer solar cells with gold top electrode; this improvement in the photovoltaic characteristics is attributed to oxygen doping of P3HT [11,14]. On extended storage in air, however, the photovoltaic characteristics of the device deteriorate significantly. After ten days in air, the J_{sc} and the V_{oc} drop to 2.1 mA/cm^2 and 0.22 V, respectively, resulting in

an FF of 0.18 and an η of 0.09%. The air stability of inverted polymer solar cells in which the photoactive layer was thermally annealed prior to silver electrode deposition appears to be not significantly better than analogous solar cells made in the conventional architecture. On the other hand, the scenario is different when we examined inverted polymer solar cells that were thermally annealed after silver electrode deposition; relevant J–V characteristics of a representative device are shown in Fig. 1b for comparison. As fabricated, this inverted polymer solar cell exhibits a J_{sc} of 8.5 mA/cm^2, and a V_{oc} of 0.48 V, resulting in an FF of 0.37 and an η of 1.9%. The difference in the photovoltaic characteristics of the as-fabricated devices is attributed to the strong temperature dependence of silver oxidation [18]. Because oxygen diffuses significantly faster at 140 °C compared to at room temperature, the silver top electrode oxidizes at a faster rate in the device that is annealed after silver deposition. And since that the rate at which the work function of silver is altered is tied to the rate of silver oxidation, this difference is manifested as discrepancies in the photovoltaic characteristics of the two devices acquired on the 0th day.

Storage in air for two days results in oxygen doping of P3HT; the device characteristics improve as a consequence. Specifically, the J_{sc} and V_{oc} increase to 9.1 mA/cm^2 and 0.51 V, respectively, resulting in an increase in the overall efficiency (2.1%). In sharp contrast to the device character-

Fig. 2. AFM (a) height and (b) 3D renditions of as-cast P3HT:PCBM on titania and (c) height and (d) 3D renditions of P3HT:PCBM thermally annealed at 140 °C for 30 min.

istics shown in Fig. 1a, the photovoltaic characteristics of the inverted polymer solar cell that was thermally annealed after silver electrode deposition do not vary significantly on extended exposure to air. After ten days in air, the J_{sc} and V_{oc} of the same device remain at 8.6 mA/cm^2 and 0.51 V, respectively. As such, η (1.8%) remains at 90% of its peak value over the duration of this study.

While it is generally accepted that the details of processing conditions can dramatically alter device characteristics [15–19], it is initially surprising to learn that the annealing sequence of the polymer photoactive layer can influence the stability of inverted solar cells. To examine how the annealing sequence of the polymer photoactive layer is affecting the air stability of devices, we carried out AFM studies to characterize the morphology of as-cast and thermally annealed P3HT:PCBM films on titania. Fig. 2 contains the AFM height images of (a) as-cast and (c) thermally annealed P3HT:PCBM films. The corresponding three-dimensional renditions of the height images are shown in Figs. 2b and d, respectively. The as-cast P3HT:PCBM film is smooth; we extracted a root-mean-square (rms) roughness of 0.55 ± 0.18 nm from this 2 × 2 micrometer image. The film roughens significantly with thermal annealing; we extracted an rms roughness of 1.39 ± 0.31 nm from Fig. 2b. This roughening of P3HT:PCBM films was previously observed and was attributed to the phase separation and crystallization of P3HT and PCBM on heating [20,21]. Given that the morphology of the polymer photoactive layer is different during the deposition of the top electrode, it necessarily influences
Fig. 3. AFM (a) height and (b) phase contrast images of the silver top electrode on as-cast P3HT:PCBM; (c) height and (d) phase contrast images of the silver top electrode on thermally annealed P3HT:PCBM; and (e) height and (f) phase contrast images of the silver top electrode on as-cast P3HT:PCBM after the bilayers have been thermally annealed at 140 °C for 30 min.

the grain structure of the subsequently deposited metal. We thus conducted AFM studies to characterize the grain structure of silver that is deposited on as-cast and thermally annealed P3HT:PCBM films on titania. Figs. 3a and b contain the height and phase contrast images of 80 nm of silver that is deposited on as-cast P3HT:PCBM on titania whereas Figs. 3c and d contain the height and phase contrast images of silver that is deposited on thermally annealed P3HT:PCBM on titania. We observe drastic differences when comparing these two sets of images. Specifically, the grain size of silver that is deposited on as-cast P3HT:PCBM is large, of order several hundred nanometers, compared to silver that is deposited on thermally annealed P3HT:PCBM (of order tens of nanometers grain size). The larger grains also appear to be more interconnected in the silver film that is deposited on as-cast P3HT:PCBM. The difference in grain size and grain structure must stem from differences in the morphology of the underlying polymer photoactive layer. The as-cast P3HT:PCBM film is smooth and featureless; silver that is subsequently deposited on this polymer forms interconnected grains that are hundreds of nanometers in size. In contrast, the thermally annealed P3HT:PCBM film is significantly rougher; we observe tall spikes and deep valleys in the scan window shown in Fig. 2d. Such surface heterogeneities can in turn serve as additional nucleation sites during silver deposition [22]. It follows that silver that is deposited on such film forms smaller, less interconnected grains. As a final comparison, we conducted AFM on silver that is deposited on as-cast P3HT:PCBM after the bilayers have been thermally annealed at 140 °C for 30 min; the height and phase contrast images corresponding to this silver surface is shown in Figs. 3e and f. We observe that these images exhibit silver grain size and structure that are comparable to those in Figs. 3a and b, a strong indication that the morphology of the electrode is defined during silver deposition; thermal annealing after the deposition of silver does not further influence its morphology.

Our microscopy study implicates a strong correlation between the grain size of the silver electrode and the air stability of our inverted polymer solar cells. Devices are significantly more stable in air when the silver grains are interconnected and the average grain size large. The silver electrode with a larger grain size has a lower density of grain boundary through which moisture can diffuse. Given that extended exposures to moisture can damage the polymer photoactive layer [4,6], we speculate it is the suppression of moisture diffusion through the silver electrode that has significantly extended the air stability of our inverted polymer solar cells. When the polymer photoactive layer is thermally annealed prior to electrode deposition, the roughness of the photoactive layer provides additional nucleation opportunities for silver, resulting in films with small grains and high grain boundary densities. Such films allow significant moisture diffusion through grain boundaries, leading to decreasing device characteristics with time.

Fig. 4 compares the stability of our inverted polymer solar cells; the average efficiency of inverted polymer solar cells in which the photoactive layer was annealed before (open circles) and after (filled circles) silver electrode deposition is plotted as a function of exposure to air. For

Fig. 4. Normalized average device efficiency as function of exposure time in air for devices in which the photoactive layer was annealed before (open symbols) and after (solid symbols) top electrode deposition. The error bars represent standard deviations calculated from the testing of five devices.

ease of comparison, the device efficiencies for both types of devices were normalized against the highest values. Devices in which the polymer photoactive layer was annealed before silver deposition experience a sharp increase in efficiency during initial exposure to air due to the oxygen doping of P3HT [14]. The efficiency decreases dramatically beyond the second day because moisture that diffuses through the grain boundaries in the silver electrode can react with the photoactive layer. In contrast, the average efficiency of devices that were thermally annealed after silver deposition is maintained at 90% of its highest value.

4. Conclusion

Our study demonstrates that the details of processing not only affect device performance; they can dramatically influence device stability. In this particular case, the sequence with which the photoactive layer is annealed alters the grain structure of the top electrode, which in turn influences the level of moisture penetration into the photoactive layer. The elucidation of such processing-structure–function relationships should lead to the engineering of more robust, next-generation devices.

in an Ohno potential, Kobrak and Bittner indicated that the electroluminescence quantum yield may be as high as 59%, substantially greater than the 25% predicted by simple spin statistics [7].

Since the spin of an exciton is closely related to the spin orientations of polarons which the exciton derives from, it is expected that the manipulation of polaron spin orientation may open a way to tune the relative population of singlet/triplet excitons and consequently enhance the electroluminescence efficiency. The spin orientation of a polaron is mainly determined by (i) the magnetism of the electrode from which spin polarized electrons (or holes) are provided and (ii) spin-conserving transport in the polymer spacer. On one hand, since spin injection into π-conjugated polymers has been recently achieved [8,9], it is possible to employ ferromagnetic materials instead of conventional electrodes in a PLED to achieve spin controlled charge injection [10]. On the other hand, electron spin diffusion length is expected long in conjugated polymers due to the weak spin–orbital coupling and hyperfine interaction [11], which provides possible long-range spin-conserving transport and spin-conserving recombination [12]. Therefore, the spin-PLED structure with ferromagnetic electrodes can be used to control the spin orientation of polarons, improve the yield of singlet excitons, and consequently enhance the electroluminescent efficiency.

Since the basic process of photoemission in PLEDs is the formation of excitons, the dynamic intrachain collision process of oppositely charged polarons has been studied under different strength of an external electric field [13]. Especially, the intrachain spin-dependent formation of excitons in PLEDs and factors affecting the formation in PLEDs have been studied from the energy point of view [7,14]. However, much less is known about the yields of excitons in a spin PLEDs. In this paper, we will consider the formation of singlet and triplet excitons from two spin polarons in a conjugated polymer chain, where the angle between the spin orientations of the polarons is focused. By simulating the collision of the polarons using a dynamic evolution method and analyzing the product after collision, we try to find the yields of singlet and triplet excitons. The model and method are described in the following section. Results and discussion are shown in Section 3. Finally a conclusion is given in the last section.

2. Model and formula

Our simulations begin with two oppositely charged polarons which already form at a polymer chain, as shown in Fig. 1. Under an external electric field, two polarons will

Fig. 1. The scheme of two oppositely charged polarons with spin angle θ.

move towards each other along the chain and then a collision will take place.

We describe the system by an extended Su–Schrieffer–Heeger (SSH) + Hubbard model, and the external electric field is also involved

$$H = H_{SSH} + H_{Hub} + H_{ext}, \tag{1}$$

where the extended SSH model is [15,16]

$$H_{SSH} = -\sum_{n,s}[t_0 - \alpha(u_{n+1} - u_n) - (-1)^n t_e]\left(C_{n+1,s}^\dagger C_{n,s} + h.c.\right)$$
$$+ \frac{K}{2}\sum_n (u_{n+1} - u_n)^2 + \frac{M}{2}\sum_n \dot{u}_n^2. \tag{2}$$

Here t_0 denotes the zero-displacement hopping integral between the nth and $(n+1)$th atoms, α the electron–lattice coupling constant, u_n the displacement of the nth site from its equidistant position and t_e the Brazovskii–Kirova symmetry breaking term for a non-degenerate polymer [16]. $C_{n,s}^\dagger (C_{n,s})$ denotes electron creation (annihilation) operator at site n with spin s. K is the elastic constant and M the mass of a CH group.

The Hubbard model [17]

$$H_{Hub} = U\sum_n C_{n,\uparrow}^\dagger C_{n,\uparrow} C_{n,\downarrow}^\dagger C_{n,\downarrow} \tag{3}$$

is used to describe the electron–electron (e–e) interactions and is treated in a simple mean-field approximation. U is the on-site repulsion between electrons with spin-up and spin-down.

An external electric field is applied to drive the charged polarons,

$$H_{ext} = -\sum_{n,s}|e|E(na + u_n)\left(C_{n,s}^\dagger C_{n,s} - 0.5\right), \tag{4}$$

where E is the applied electric field. e and a are the electronic charge unit and the lattice constant, respectively.

The wavefunction of an electronic state consists of both spin-up and spin-down components:

$$|\Psi_\mu(t)\rangle = \sum_n \begin{pmatrix} \psi_{\mu,\uparrow}(n,t) \\ \psi_{\mu,\downarrow}(n,t) \end{pmatrix}|n\rangle. \tag{5}$$

The spin orientation of the electronic state is given in probability by $\cos\theta_\mu = \sum_n|\psi_{\mu,\uparrow}(n,t)|^2 - \sum_n|\psi_{\mu,\downarrow}(n,t)|^2$. $\theta_\mu = 0°$ and $\theta_\mu = 180°$ denote that the electron is in a spin-up and spin-down state, respectively.

The simulation starts from the state that the hole and the electron have been injected to the polymer. A positive and negative polarons have formed at the left and right sides, respectively. In the calculations, we assume that the spin orientation of the left positive polaron is along $+\vec{z}$ direction, which is denoted as spin-up. And the spin orientation of the right negative polaron is described by spin angle θ, which is the magnetization angle of the electrodes. Since the two polarons are separated far enough, they are independent of each other. The initial lattice configuration of the system without e–e interactions is a combination of two isolated polaron lattice configurations without e–e interactions, while the initial lattice configuration of the system with e–e interactions is a combination of two isolated polaron lattice configurations with e–e interactions

of the same strength. The initial wavefunctions are given by linear combinations of the wavefunctions obtained from the initial lattice configuration. The aim of linear combinations is to make sure that the two polarons are isolated. The spin orientation of a polaron is same with that of its unpaired electronic state. Therefore for the left positive and right negative polarons, the spin angles of their unpaired electronic states are set by linear combinations to be $\theta_{positive} = 0$ and $\theta_{negative} = \theta$, respectively, to ensure the spin orientation of the corresponding polaron.

It should be mentioned that the spin orientation of the polaron is supposed to be determined by the wavefunction. Therefore, in the present calculations the dynamic evolution of spin polaron is given by the evolutions of its electronic states, the spin-up and spin-down parts of which are established respectively. The evolution of the electronic state is obtained by solving the time-dependent Schrödinger equation,

$$ih\dot{\psi}_{\mu,s}(n,t) = [U\rho_{n,n}^{-s}(t) - |e|E(na + u_n)]\psi_{\mu,s}(n,t)$$
$$- [t_0 - \alpha(u_{n+1} - u_n) - (-1)^n t_e]\psi_{\mu,s}(n+1,t)$$
$$- [t_0 - \alpha(u_n - u_{n-1}) - (-1)^n t_e]\psi_{\mu,s}(n-1,t). \tag{6}$$

Due to the strong electron–lattice coupling in polymer, the lattice $\{u_n\}$ will distort with the evolution of electronic state, which is determined classically by Newton equation

$$M\ddot{u}_n(t) = K[u_{n+1}(t) + u_{n-1}(t) - 2u_n(t)] + 2\alpha[\rho_{n,n+1}^c(t)$$
$$- \rho_{n-1,n}^c(t)] - |e|E(t)\left[\rho_{n,n}^c(t) - 1\right]. \tag{7}$$

The charge density matrix $\rho_{n,n'}^c$ is given by

$$\rho_{n,n'}^c(t) = \rho_{n,n'}^\uparrow(t) + \rho_{n,n'}^\downarrow(t), \tag{8}$$
$$\rho_{n,n'}^s(t) = \sum_\mu \psi_{\mu,s}^*(n,t) f_\mu \psi_{\mu,s}(n',t). \tag{9}$$

f_μ denotes the time-independent distribution function of electronic state $|\Psi_\mu(t)\rangle$ determined by the initial occupations. The coupled differential Eqs. (6) and (7) can be solved numerically with a Runge-Kutta method of order eight with step-size control [18], which has been proved to be an effective approach to study the electronic state evolution [19,20].

The state $|\Psi(t)\rangle$ of the whole electronic system at time t is obtained through a Slater determinant of the occupied single-electron evolutional wavefunction $|\Psi_\mu(t)\rangle$. If we consider a collision of a pair of polarons, the product after collision usually is a mixed state, which may contain excitons and polarons. To recognize the final state, we introduce the instantaneous eigenstate $|\Phi^K(t)\rangle$ of a system, where K denotes the state index or one kind of product after collision in the present case. $|\Phi^K(t)\rangle$ is constructed by the instantaneous single-electron eigen wavefunctions

$$|\Phi_v(t)\rangle = \sum_n \begin{pmatrix} \phi_{v,\uparrow}(n,t) \\ \phi_{v,\downarrow}(n,t) \end{pmatrix}|n\rangle \tag{10}$$

with the occupation presenting a certain product. The component $\phi_{v,s}$ is determined by the instantaneous eigenvalue equation

$$\varepsilon_v(t)\phi_{v,s}(n,t) = [U\rho_{n,n}^{-s}(t) - |e|E(na + u_n)]\phi_{v,s}(n,t)$$
$$- [t_0 - \alpha(u_{n+1} - u_n) - (-1)^n t_e]\phi_{v,s}(n+1,t)$$
$$- [t_0 - \alpha(u_n - u_{n-1}) - (-1)^n t_e]\phi_{v,s}(n-1,t), \tag{11}$$

where $\varepsilon_v(t)$ is the instantaneous eigen energy level.

Yield $I_K(t)$ of state $|\Phi^K(t)\rangle$ in final state $|\Psi(t)\rangle$ is given by

$$I_K(t) = |\langle\Phi^K(t)|\Psi(t)\rangle|^2 \tag{12}$$

The parameters for the polymer are those referring to *cis*-polyacetylene [21], $t_0 = 2.5$ eV, $\alpha = 4.1$ eV/Å, $t_e = 0.05$ eV, $K = 21$ eV/Å^2, $a = 1.22$ Å, $M = 1349.14$ eV fs^2/Å^2. The electric field applied to the polymer is set to be $E_0 = 5 \times 10^{-4}$ V/Å.

3. Results and discussion

It has been known that the collision of two oppositely charged polarons may form exciton states. There are two types of interactions that may lead to the formation of a bound excitons in organic polymer. One is the direct Coulomb attractions between two oppositely charged polarons. The other is the electron–lattice interactions. A positive and a negative polarons are confined in the same lattice defect to form a self-trapping state, which is unique in organic molecules. Let us firstly consider the situation that the e–e interactions are neglected, in which case the formation of exciton is due to the interactions between electrons and lattice. From Eqs. (6) and (7), we know that, in this approximation, spin will be a good quantum number. Therefore, evolutions of the charge distribution and the lattice configuration are independent of the spin angle θ. Evolutions of net charge $\rho_n(t) \equiv \rho_{n,n}^c(t) - 1$ and order parameter $y_n(t) = (-1)^n[2u_n(t) - u_{n+1}(t) - u_{n-1}(t)]/4$ are depicted in Fig. 2, respectively. Before collision, the two polarons move towards each other along the chain and keep their shapes unchanged. After collision, from the charge distribution, it seems that there are two separate wave-packets. However, the net charge quantity included in each wave-packet becomes less, which means that the polarons may exchange some charges after collision. From the lattice configuration, there are some lattice oscillations left after collision. Such oscillations are some new phonon modes created in the collision process [22,13], which is not concerned in the present work. Except for these lattice oscillations, the lattice distortions induced by the residual charges keep moving under the driving field. Since the charge quantity included in the two wave-packets is same but the opposite sign, the total charge of the system is conserved during the collision. Therefore, we can just treat of the charge quantity included only one wave-packet when the charge property is talked about. It should be mentioned that in the present work there are no spin-flip interactions involved, so that the total spin of system is also conserved during the collision.

It has been known that the products of collision contain singlet and triplet excitons as well as positive and negative polarons. The spin of an exciton is related to the spin orientations of the two polarons or spin angle θ between them. We use Eq. (12) with different electronic occupation to give
Fig. 2. Evolution of (a) net charge distributions $\rho_n(t)$ and (b) staggered bound parameter $y_n(t)$. In (a), the blue and cyan areas represent the positive net charge, and the red and yellow ones denote negative charge distributions. In (b), the red and yellow areas indicate the center of localized wave-packets. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the yield of each kind of products. The yield of singlet excitons is obtained from a singlet exciton occupation on the instantaneous eigen level $\varepsilon_v(t)$; similar approaches are applied to the triplet excitons and polaron pairs. The results are shown in Fig. 3. With the present parameters, the total yield of excitons is only about 33.50%, which indicates that it is not a complete annihilation. Since the e–e interactions are not included, the total yield of excitons is independent of the spin angle $\cos\theta$. For a collision with parallel spins ($\theta = 0°$) of polarons, no singlet exciton is produced, and consequently all the excitons are triplet. By increasing the spin angle θ, some singlet excitons are produced and at the same time the yield of triplet excitons is decreased. For a collision of spin antiparallel polarons ($\theta = 180°$), the yield of singlet excitons reaches the maximum. In such case the yields of singlet and triplet excitons are the same, and each is about 16.75%. It is found that the yields of singlet and triplet are directly proportional to $\cos\theta$ (insets in Fig. 3). Therefore the yield of singlet excitons can be controlled by the spin manipulation of injected polarons and consequently electroluminescent efficiency can be improved.

However, when the e–e interactions are involved, the total yield of excitons will change with spin angle θ. Taking
$U = 0.3$ eV as an example, a maximum yield of about 38.09% is obtained in the case of spin-parallel polaron collision ($\theta = 0°$). With the increasing of the angle, it is found that the yield will decrease and reach the minimum, about 22.72%, around $\theta = 100°$. By further increasing the angle θ, the yield increases again and reaches about 33.50% for a spin-antiparallel collision (Fig. 4a). Therefore, the e–e interactions will adjust the yield of excitons with different spin angles of the polarons.

Then let us analyze the yield of singlet excitons included in each collision. For a spin-parallel collision, there is no singlet excitons created and the yield of singlet excitons is zero, which is independent of the e–e interactions. For a spin-antiparallel collision, the yield of singlet and the triplet excitons are equal, which is independent of the e–e interactions either. For the other cases, as showed in Fig. 4b, it is found that the yield of singlet excitons is depressed by e–e interactions. For example, for a collision of polarons with angle $\theta = 100°$, the yield of singlet excitons decreases from 9.83% at $U = 0$ eV to 6.14% at $U = 0.3$ eV. As a mean-filed treatment is applied in the present work, we only investigate the situation of weak e–e interactions and it is found that the stronger e–e interactions are, the more significant depression is induced on the singlet exciton formation.

In the presence of e–e interactions, the spin angular dependence of the yield of excitons can be reflected by the order of energy levels. At the beginning, two polarons are far from each other. Considering the spin freedom of electrons, each polaron has four isolated levels in the energy gap. For the positive polaron with up spin, apparently only spin-up one of two lower isolated energy levels is occupied. Consequently, the spin-up and spin-down charge distributions of the whole system are different. The on-site repulsion between spin-up and spin-down electrons represented by the Hubbard e–e interactions breaks the spin degeneracy of energy levels. Therefore, the empty spin-down one of the two lower isolated energy levels is a little higher than the spin-up one. For the two empty higher isolated energy levels, the spin-down one is also a little higher than the spin-up one. However, for the negative polaron with arbitrary θ, the order of the two higher isolated energy levels is determined by their occupation probabilities.

Fig. 3. The yield of singlet excitons, triplet excitons, and total excitons as a function of the angle θ (or $\cos(\theta)$ in inset) in the absence of e–e interactions.

Fig. 4. The yield of (a) total excitons and (b) singlet excitons as a function of the angle θ without or with e–e interactions.

The occupation probability on the spin-up (spin-down) one of higher isolated energy levels is $\cos^2(\theta/2)[\sin^2(\theta/2)]$. Due to the on-site repulsion between spin-up and spin-down electrons, the energy level with more charge occupation probability is lower than the other one. Therefore, the order of the energy levels is indirectly determined by the spin orientation of the negative polaron. In addition, the order of two occupied lower isolated energy levels is identical to the order of higher isolated energy levels. Since there is no spin-flip interaction in the present model, the spin during charge transfer is conserved. Then the charge transfer probability during the collision is determined by the order of energy levels. Therefore, the charge transfer probability during the collision is also indirectly determined by the spin orientations of the polarons or the spin angle between the polarons. Moreover, the order of the energy levels after collision is determined by the charge transfer probability during the collision. Therefore, the amount of the residual charges localized in each generated wave-packet is affected by the e–e interactions (Fig. 5). For example, the amount of residual charges is 0.546e when the e–e interactions are neglected. But when the e–e interactions are included, it is found that the amount is a non-monotonous function of the spin angle θ. For a spin-parallel collision, the amount of residual charges will be 0.467e at $U = 0.3$ eV. By increasing the spin angle θ, the amount of

residual charges is increased. The maximum of the residual charges is 0.702e, which appears at about $\theta = 100°$. However, for a spin-antiparallel collision the amount is identical to the case without e–e interactions. As an exciton is neutral, less residual charges correspond to a higher yield of excitons. As a result, the dependence of singlet excitons formation rate on spin angle is also strongly affected by e–e interactions.

4. Conclusion

In this paper, we studied the dependence of exciton formation rate on the spin orientation of polarons by simulating the collision process of two polarons. It was found that neglecting e–e interactions, the yield of total excitons is independent of θ, while the yield of singlet and triplet exciton presents a linear variation with $\cos\theta$, where θ is the angle between the spin orientations of polarons. However, the on-site e–e interactions will break the spin degeneracy of energy levels. Although, the yield of singlet excitons from spin-parallel or spin-antiparallel polaron is not influenced by the e–e interactions, the presence of e–e interactions shows a depression on the yield of singlet exciton in the other cases. In the manufacture of spin PLEDs to improve the luminescent efficiency, the e–e interactions should be unfavorable factors.

Fig. 5. Dependence of the residual charges on the spin angle between two polarons after collision.

printing, combines robustness, speed and proven roll-to-roll compatibility with a good accuracy [3]. Another advantage compared to gravure-off set and flexographic printing is the absence of a rubber transfer plate, which lacks sufficient resilience against the organic solvents typically used for LEP inks (e.g. toluene, anisole, xylene, etc.) to allow for a robust and stable printing process. Furthermore, gravure printing does not suffer from plate or screen wear, typically observed for off-set lithography and screen printing. Roll-to-roll inkjet printing is generally believed to be insufficiently fast and robust, despite advantages relating to non-contact fluid transfer and digital free-form flexibility.

To avoid time consuming trial-and-error experimentation, it is desirable to model the printing process in order to be able to predict optimal process conditions for printed layer formation. Since gravure printing is a complex process involving many non-linearly interrelated parameters, statistical modeling, despite its 'black-box' nature, is often preferred over physical modeling. Artificial neural networks (ANN) have proven to be useful predictive statistical models for a wide range of applications [4]. ANNs are capable of modeling any linear or non-linear relationship between sets of input and output parameters. ANNs applied in manufacturing technology are often based on a supervised learning protocol during which the network is repetitively exposed to input data with a known (e.g. measured) response. During this process a cost function is minimized by adapting the network's coefficients. Once properly trained, the network is capable of calculating the correct response to new values and combinations of the input parameters, not previously included in the training data set. In the field of the graphic arts, artificial neural networks have shown to be viable tools in process control and development. Well-known examples are color processing and proofing [5], inkjet printing [6], and off-set lithography [7]. Also in fields related to graphical printing, such as solder paste printing for printed circuit boards, the use of neural networks for process optimization has been reported [8]. Ding et al. [9] recently reported on the use of a fuzzy neural network to establish the link between process parameters and gravure printed dot features.

The gravure printing process has to some extent also been modeled physically. One should discriminate here between forward gravure printing [10–12] (image transfer, as is the case for this work), whereby the web and the gravure roll move in the same direction, and reverse gravure [13], which is essentially a coating technique, as gravure roll and web move in opposite directions. The forward gravure printing models, though elegant, generally oversimplify the real life situation as they only describe single cell withdrawal events in two dimensions. These models could, for instance, be used to predict the ratio of transferred to contained ink as a function of the separation velocity between gravure roll and substrate. However, their limited geometrical scope renders them unsuitable for the actual prediction of printed layer thickness and homogeneity in large area applications. The overall process is yet too complex to be modeled reliably in a physical manner using state of the art computing facilities.

In this paper, we show for the first time the application of ANN modeling in printed organic electronics. The network models the characteristics of forward, direct rotogravure printed layers of LEP on a non-porous, conductive poly-(ethylenedioxythiophene)/poly(styrene sulfonate)-covered poly(ethylene terephthalate) substrate (PET-PEDOT/PSS). The network is set-up and trained to predict the relation between three input parameters: (i) gravure cell engraving depth, (ii) printing speed, and (iii) LEP concentration, and three output parameters: (i) mean printed layer thickness, (ii) relative root mean square (RMS) roughness, and (iii) printed layer anisotropy. We clarify the selection of these parameters and show how fairly accurate predictions can be made once the network has been properly trained. We give a quantitative definition of printed layer anisotropy, since we believe that root mean square deviation by itself insufficiently describes printed layer homogeneity, especially for printed OLED lighting applications. Finally, we show how the trained network can be used to map the input parameter space for each output parameter in order to find optimum values and to gain qualitative insight in the behavior of the ink during the printing process.

2. Materials and methods

The LEP gravure printing inks were based on an in-house developed light-emitting polymer. This LEP had a weight-averaged molecular weight of 628 kDa and a polydispersity index of 2.1. The sample solutions were prepared by dissolving the LEP in a 30/70 (w/w) mixture of toluene and anisole under nitrogen (Table 2 lists the used LEP concentrations). In order to increase the optical absorptivity of the printed layers in the visible wavelength range we added Oil Blue N as a low molecular weight dye to the formulations. What's more, the addition of the dye fully quenched the polymer's fluorescence, thus ruling out possible disturbing optical factors stemming from the polymer's intrinsic emissive properties. The amount of dye (by weight) was kept twice as low as the polymer quantity. Owing to its low molecular weight and concentration, the dye was assumed to not influence the rheological properties of the inks.

Prints were made using an IGT Testing Systems F1 lab-scale printability tester running in direct forward gravure mode. Commercial Orgacon EL-350 PEDOT/PSS-coated PET foil (Agfa-Gevaert) with a total thickness of 125 μm was used as substrate. The PEDOT/PSS layer has been applied by slot coating, which gives very homogenous layers with low amplitude undulations (typically a few %) extending over several tens of centimeters. The Orgacon foil was mounted onto the backing roller of the gravure printer and cleaned by gentle wiping with a non-scratching cloth containing 2-propanol. For making a print, typically about 0.5 mL LEP/dye ink was applied onto the gravure roll in the nip between the doctor blade and the roller, after which the ink was printed in one pass at a given speed setting and a constant gravure roll-to-substrate force setting of 250 N. The gravure roll used in this study contained patterned areas of square pyramidal cells, stylus engraved (120° stylus angle) under a screen angle of 53° at a density of 70 lines/cm. The total engraved pattern contained ten patches,

each having a surface area of about 6 cm². Each patch corresponds to a different cell engraving depth in the range 11–48 μm, roughly corresponding to an ink containment volume of 0.2–12 mL/m². The printed layers were left to dry under ambient conditions in a matter of seconds.

The printed LEP/dye layers were characterized using a microdensitometer (Joyce-Loebl MDM-6), fitted with a Philips halogen lamp, type 7012 (12 V, 50 W). The microdensitometer measured and recorded the integrated optical density of a sample layer as a function of X, Y-coordinate, on a scale with a cut-off value of 4096. The printed layers were scanned at a lateral resolution of 20 μm using a wavelength range of 300 < λ < 800 nm. The total measured optical density of the printed layers (i.e., the summed values for the LEP, the dye, and the PET-PEDOT/PSS substrate), was typically in the range 1800–2100, considerably below the cut-off threshold. The crude optical density data was corrected for the optical density of the 125 μm thick PET-PEDOT/PSS substrate, as recorded at the site of each printed patch. Correction occurred by subtraction of the substrate's optical density from the total measured value. The thus corrected optical density of the printed LEP/dye layers was in the range 50–200. The scanning software was adapted as to scan exclusively within the printed patches corresponding to the various cell engraving depth levels. The edges of the prints were not included in the scans to avoid artifacts related to incomplete engraving, often observed at the edges of engraved patterns on gravure rolls. When printing an OLED, one would make sure that such edge artifacts would fall outside the active (emissive) area of the device. The scanning data was filtered, normalized, and processed using MATLAB R2008a.

In order to convert the measured optical density values into actual printed layer thickness information, we recorded the optical density of reference LEP/dye layers of known thickness, spin-coated from toluene solution on glass slides. This solution contained 10 mg/mL of LEP and 5 mg/mL Oil Blue N, giving the same LEP-to-dye ratio as used for the gravure printing inks involved in the neural network study. The measured values were corrected by subtracting the optical density of the glass substrate. The absolute thickness of the reference samples was determined using a Veeco DekTac M6 stylus profilometer.

Neural network analyses were performed using a home-built algorithm in C++. The ANN used in this study (Fig. 1) was a double layer Perceptron (MLP) neural net, using feed forward of input data and back propagation of error information [4]. The output of the hidden (V) and output units (Y) was calculated using logistic sigmoidal and linear transfer functions (Eqs. (1) and (2), respectively).

$$f(x) = \frac{a-b}{1+\exp(-sx)} + a \tag{1}$$
$$f(x) = sx. \tag{2}$$

Here, x and f(x), respectively, represent the neuron's input and output; a and b are the lower and upper asymptotic values of the logistic sigmoid, and s is the steepness. During training the synaptic weights ($w_{i,j}$ and $z_{j,k}$) and bias values (b) were optimized in an iterative procedure, minimizing the cost function expressed by Eq. (3).
Fig. 1. Neural network architecture used in this study; input, hidden, and output units are denoted X, V, and Y, respectively; synaptic weights are denoted $w_{i,j}$ and $z_{j,k}$ for the first and second layer, respectively; the bias units are denoted b.

$$E = \sum_i (t_i - y_i)^2. \tag{3}$$

Here, t_i and y_i represent the target (measured) response and calculated output corresponding to a certain set of input parameters (input vector). Usually, a neural net is not allowed to reach maximum convergence to avoid over-fitting, as an over-fitted network will be better at memorizing its training data set than predicting output to new input data. To avoid over-fitting a separate testing data set was used to check the network's predictive capability during training. Prior to training all input data was normalized in a bipolar fashion: $-1 \leqslant n \leqslant 1$. This allowed faster training and ensured the error information terms calculated for the output parameters to be of comparable magnitude. Relating to this, we chose the asymptotic values of the sigmoid activation function of the hidden units (Eq. (1)) to be a = −1.2 and b = 1.2, slightly extending beyond the largest and smallest target values [4]. For presentation the calculated data was denormalized. The steepness of both activation functions (s in Eqs. (1) and (2)) was set to 0.5.

3. Results and discussion

We start with defining the ANN's input and output parameters. The input parameters are settings relating to the printing process (printing parameters), whereas the output parameters are quantifiable characteristics of the printed LEP/dye layers. The printing parameters may be categorized as gravure roll-, process-, ink-, or substrate-related. Table 1 lists the most important parameters in this categorized fashion. Naturally, these parameters do not all influence the printed layer characteristics equally strongly. We selected (i) cell engraving depth (d), (ii) printing speed (v), and (iii) LEP concentration (c) as a limited, but highly relevant set of input parameters for the neural network model. These input parameters represent three of the four categories defined above. Their selection is partly based on prior experience with LEP printing. We also note that several of the parameters defined in Table 1 can be expressed as functions of the selected parameters. For example, rheological parameters such as zero shear viscosity and fluid elasticity, are strongly related to the solute

Table 1

Summary of the gravure printing parameter space.

Gravure roll	Process	Ink	Substrate
Cell engraving depth	Pressure/force	Viscosity	Material
Cell shape	Printing speed	Elasticity	Surface energy
Screen angle		Surface tension	Roughness
Stylus angle		Volatility	Pre-treatment
Surface energy		Solvent composition	Cleaning method
Radius		Polymer concentration	
		Molecular weight	

concentration. Other parameters, such as surface tension and evaporation rate, are not included in the model, as we used the same solvent system throughout the study. In this context, we assumed the polymer (and dye) concentration not to have an appreciable effect on the surface tension and evaporation, especially in the early stages of drying during which solute transport is most likely to occur. Naturally, if one would want the neural network to also predict the solvent characteristics, a more extended model is necessary. By using the same gravure roll which is cleaned the same way prior to printing, we did not vary the parameters in the gravure roll category, except for cell engraving depth. We found a gravure roll force exceeding 150 N to be of little influence on the thickness and appearance (homogeneity) of the prints. Forces below this value did not allow full (web wide) transfer of the ink. From the substrate category no parameters were selected. The reason for this is the limited number of available possibilities to vary the nature of the rather delicate PEDOT/PSS layer. We settled down on the mild cleaning method described in the Experimental Section as a suitable non-destructive pre-treatment that still allows proper wetting of the LEP ink.

Three output parameters were defined (see Fig. 1): (i) mean printed layer thickness, (ii) roughness, and (iii) 'stripiness' or anisotropy. In order to obtain reasonable estimates of the mean printed layer thickness, optical density scans produced by the microdensitometer were converted into actual thickness matrices using the calibration curve depicted in Fig. 2. This line was constructed by recording the optical density of spin-coated LEP/Oil Blue N layers (same ratio as for the gravure printing inks) on glass substrates (the inset illustratively showing the absorption spectrum of the LEP/Oil Blue N blend). The layers were coated at different spinning velocities, giving a range of thicknesses. The absolute thickness of these reference layers was determined using profilometry. These values were then plotted as a function of the measured optical density. As the graph shows, the data suggest a linear relationship between thickness and optical density, at least within the window of the measurement. Despite this (partial) linearity, the curve does not seem to obey the Beer–Lambert law, as the suggested straight line does not pass through the origin of the graph. In stead, it would abscise the horizontal axis at an optical density of about 45. However, physically, the origin itself should lie on the curve, as a zero optical density is recorded when no material is present at all. Unfortunately, it proved difficult to obtain homogeneous layers with a thickness in the range 0–75 nm. We

Fig. 2. Layer thickness as a function of integrated optical density for spin-coated reference layers of the 2:1 LEP/Oil Blue N mixture on glass slides. The line is a fit to the measured values, including the origin as an extra data point. The curve has been extrapolated into the upper range of the optical density values measured by the microdensitometer on the gravure printed layers. For illustration: the inset depicts the absorption spectrum of the LEP/dye mixture in the range $300 < \lambda < 800$ nm.

therefore included the origin as one extra data point and, as an approximation, fitted a calibration curve using a continuous, fully differentiable mathematical function capable of passing through the origin as well as describing the linear behavior observed for higher optical densities, as suggested by the measurement. The mean printed layer thickness was obtained simply by calculating the average value of the thickness matrix. The (relative root-mean-square) roughness of the printed layers was defined as the standard deviation from the mean taken as a fraction (or percentage) from the mean value. Below we will mostly use the term 'roughness' to denote the relative RMS roughness.

The third output parameter, the printed layer anisotropy, requires a little more clarification. In general, printed layer irregularities may occur during three stages of the gravure printing process: (i) ink transfer (e.g. due to fluid film or ligament instabilities), (ii) leveling on the substrate (e.g. due to incomplete merging or leveling of deposited fluid dots from separate engraved cells), and (iii) drying (surface tension-driven flow of solute during solvent evaporation). The latter cause was assumed to be strongly suppressed by the relatively high viscosity of the LEP inks (around 30 mPas at $t = 0$, as determined by separate measurements), as well as the rapid viscosity increase due to

the high volatility of the solvent mixture. This assumption was supported by the fact that the printed LEP layers did not show signs of the well-known 'coffee stain effect' [14] or other drying patterns that can be attributed to surface tension-induced solute transport [15]. For this, we suggest that the irregularities encountered in the gravure printed LEP layers predominantly originated from instabilities during fluid transfer or incomplete merging and leveling, or a combination of both. The appearance of the print depends on which of the two causes prevails. Fig. 3 depicts photographs of four exemplary gravure printed layers fabricated with the same LEP ink, printed at different cell engraving depths. Although this ink was based on a different LEP (a poly(*p*-phenylenevinylene) derivative) than the one used in the neural network study, the printed layer appearance as a function of gravure roll engraving depth is qualitatively similar. At a low engraving depth (22–30 μm) the amount of ink transferred to the substrate is

simply too low to give integral printed layers (see Fig. 3, top left and top right). The print corresponding to a 22 μm cell depth does not show merging of the fluid dots at all. The dots only start merging once more fluid is applied, and give an integral layer at an engraving depth of 34 μm (Fig. 3, bottom left). At larger cell depths (e.g. 38 μm) too much ink is applied, which leads to the formation of ridges of polymer running parallel to the printing direction (Fig. 3, bottom right). Notably, regions adjacent to the ridges show considerable ink depletion. The formation of these ridges may be explained by a collapse of multiple fluid ligaments pulled from adjacent cells. The irregularity of these layers is anisotropic, as the ridges appear exclusively parallel to the printing direction.

It immediately becomes clear that although the roughness as defined above gives a good indication of general layer homogeneity, it does not provide any information about the appearance or anisotropy of the irregularities encountered in the printed layers. This is illustrated by Fig. 4. This figure shows optical density scans of LEP layers printed using different sets of input parameters (left: $d = 46$ μm, $v = 0.5$ m/s, $c = 22$ mg/mL; right: $d = 42$ μm, $v = 1.5$ m/s, $c = 22$ mg/mL). Similar roughness values were obtained (6.2% and 6.5%, respectively), despite the large difference in appearance of the prints. Fig. 4 (right) shows isotropically distributed irregularities, whereas print Fig. 4 (left) has a much more stripy appearance due to ridge formation parallel to the printing direction. For OLED production it is desirable to be able to predict printed LEP layer roughness in general terms, as well as in terms of anisotropy or directionality. This is explained as follows. Scattering renders intensity variations in the emitted light due to highly frequent, isotropically distributed layer thickness variations to be much less obvious than variations stemming from a relatively small number of ridges in an essentially smooth layer (see Fig. 5). Furthermore, as mentioned, a deficiency of printed material is encountered adjacent to the ridges, giving the risk of shorts.

The question now raises how to quantify the anisotropy. In tribology, the kurtosis (Ku) of a distribution is often used to discriminate between a layer with an isotropic (Gaussian) distribution of many irregularities (low Ku) and one that is essentially flat, except for a few

Fig. 3. Light emitting polymer gravure printed ($v = 0.9$ m/s, $c = 10$ mg/mL) onto PET-ITO foil at different cell engraving depths (stylus angle 120°, screen angle 53°, 70 lines/cm): 22 μm (top left: separate dots of ink corresponding to engraved cells), 30 μm (top right: dots start to merge), 34 μm (bottom left: merging leads to an integral layer), 38 μm (bottom right: ridges and trenches appear parallel to the printing direction). The grainy appearance of the prints is caused by the fact that they have been photographed against a white paper background.

Fig. 4. Color-height images of gravure printed LEP layers corresponding to different input parameter sets: left, $d = 46$ μm, $v = 0.5$ m/s, $c = 22$ mg/mL; right, $d = 42$ μm, $v = 1.5$ m/s, $c = 22$ mg/mL. The prints have roughness and anisotropy values of 11.9% and 42.9, and 12.7% and 3.8, respectively.

Fig. 5. Gravure printed flexible OLED devices (33 × 15 mm): left, printed LEP layer containing ridges of polymer in the printing direction; right, printed LEP layer containing highly frequent, isotropically distributed irregularities, apart from two dust particle-induced spots.

large deviations (high *Ku*). The kurtosis is defined by Eq. (4).

$$Ku = \frac{1}{mn\sigma^4} \sum_{i=1}^{m} \sum_{j=1}^{n} Z(i,j)^4. \tag{4}$$

Here, the layer is represented by an $m \times n$ matrix of local height values $Z(i,j)$, and σ is the standard deviation of the height distribution. Unfortunately, due to the nature of the scanning data and the high noise-sensitivity relating to the 4th power *Z*- and σ-dependency, *Ku* did not discriminate properly between gravure printed layers with high and low anisotropy: the prints represented by Fig. 4 have a kurtosis of 3.5 and 3.9, respectively. For this reason, we wrote an algorithm dedicated to recognize and quantify the anisotropy. This algorithm, which is essentially represented by Eq. (5), performs separate row- and column-wise summations of the elements of binary representations of the scanning data matrices. Amplification factors were implemented which magnitudes increase with the longitudinal extent of the ridges (represented by "ones") and trenches (represented by "zeros"). Hypothetically, if comparable numbers of ridges would run both parallel and perpendicular to the printing direction, the anisotropy (*A*) will be low:

$$A = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n} \chi_{i,j}^{row} u_{i,j}^{b}}{\sum_{j=1}^{n}\sum_{i=1}^{m} \chi_{i,j}^{column} u_{i,j}^{b}}. \tag{5}$$

Here, $\chi_{i,j}^{row}$ and $\chi_{i,j}^{column}$ are the amplification factors for the row and column summations, respectively, and $u_{i,j}^{b}$ are the binarized optical density values (0 or 1). The amplification factor was increased stepwise as long as the value of a matrix element did not differ from that of the previous neighboring element in the same row or column. In case the next neighboring element did have a different value the amplification factor was reset to one, effectively indicating the end of a ridge or trench. The necessary binary representations of the scans were obtained using Eq. (6).
$$U_b(i,j) = H(Z(i,j) - \bar{Z}). \tag{6}$$

Here, *H* is the Heaviside step function and $\bar{Z}$ the mean height (or optical density). Eq. (5) proved much less discriminative when applied to non-binarized data, resulting

Table 2
Levels of the input parameters used to build up the total data set.

Level	Cell depth (μm)	Printing speed (m/s)	Concentration (mg/mL)
1	30	0.5	22
2	34	0.8	27
3	38	1.0	30
4	42	1.2	–
5	44	1.5	–
6	46	–	–

Fig. 6. Binarized versions of the prints presented by Fig. 4; white represents thickness values exceeding the mean, whereas black represents areas with a thickness lower than the mean.

in a loss of information on anisotropy. Fig. 6 represents binarized versions of the scans depicted in Fig. 4. We note that the print corresponding to Fig. 4 (right) and Fig. 6 (right) shows an anisotropy in a different sense in that the layer thickness is generally higher on top of the print

than at the bottom. This effect, which is observed for a minority of the prints, is explained by partial incomplete filling of the engraved cells during inking of the gravure roll. This hardly avoidable issue relates to the operational limitations of the gravure printer in combination with
Fig. 7. Measured (closed/solid) and predicted (open/dashed) values for mean printed layer thickness (left), relative RMS roughness (left), and feature anisotropy (right) for the validation data set (prints corresponding to d = 44 μm).
Fig. 8. Calculated mean layer thickness plotted in color grades as a function of cell depth (d) (in μm) and printing speed (v) (in m/s) at c = 22.0, 25.0, 27.5, and 30.0 mg/mL (top left to bottom right).

the manual operation, and will be absent in an industrial gravure printing environment owing to automated inking. These fluctuations are not accounted for by the neural network and will to some extent impart uncertainty in the prediction accuracy. On the other hand, we note that the algorithm expressed by Eq. (5) is relatively insensitive to this kind of printed layer anisotropy.

Using Eqs. (5) and (6), the anisotropy of the prints represented by Fig. 4 was determined to be 42.9 and 3.8, respectively, clearly discriminating between the two prints. Unfortunately, the quality of the scanning data was not sufficient to include quantitative information about the height of the ridges as well.

To build up an input–output data set for training and validation of the neural net, we performed prints and scans varying the input parameters at preset levels (Table 2). Three LEP concentration levels were chosen in a realistic range (22, 27, and 30 mg/mL), corresponding to a suitable dry LEP layer thickness, without the viscosity becoming too high or too low for proper printing. Five levels of printing speed were selected, effectively covering the whole speed range setting of the gravure printer (0.5, 0.8, 1.0, 1.2, and 1.5 m/s). As for cell engraving depth, six levels were used in the range 30–46 μm (i.e. 30, 34, 38, 42, 44, and 46 μm). By experience we know that LEP layers printed with gravure cell depths in this range typically give working OLEDs. Prints produced at lower cell depth values do not give integral layers due to incomplete merging of the depos-ited ink dots. Cell depth values exceeding the indicated range usually give highly irregular, rather messy prints having areas containing hardly any material and areas in which material is accumulated into very thick patches. Both extremes usually lead to short circuited devices.

As the total cell depth range expressed by Table 2 has been patch-wise engraved onto the same gravure roll, we were able to acquire all cell depth information within one single print (per level of LEP concentration and speed setting). Practically, the whole study required only 15 prints (three concentration levels × 5 speed levels) and 4 scans, as the set-up allowed us to scan four printed strips of substrate in one session. Thus we collected a total data set of $3 \times 5 \times 6 = 90$ three-element input-target vector pairs. Of this total data set all vector pairs corresponding to a 44 μm cell depth (15 in total) were kept aside for validation of the trained network. Of the remaining 75 vector pairs ten were randomly selected to form the testing set. The 65 vector pairs left formed the actual training data set. During training, the network was iteratively exposed to the 65 training vectors, during which the synaptic weight and bias values were optimized to reduce the cost function (Eq. (3)). At set times during training the predictive power of the network was assessed by calculating the total squared error of the predicted output to the testing data set. Once this value did not further decrease, training was aborted and the optimized weight and bias values were saved.
Fig. 9. Calculated relative RMS roughness plotted in color grades as a function of cell depth (d) (in μm) and printing speed (v) (in m/s) at c = 22.0, 25.0, 27.5, and 30.0 mg/mL (top left to bottom right).

As for the hidden layer it is well known that a large number of units may lead to fast convergence of the net, which is an advantage if computational time is a limiting factor. However, many hidden units and fast convergence impart the risk of over-fitting. The optimal number of hidden units was determined to be around 12 by trial-and-error. We varied the actual contents of the training and testing sets to check whether the selection of testing vectors had a significant effect on the prediction error of the testing set. We found that this was not the case as long as the testing set was randomly chosen.

After training to optimal convergence, the validation vector set, corresponding to the 44 µm cell engraving depth, was fed into the neural net. Fig. 7 shows that the net is indeed capable of predicting the output to this new input set with a very reasonable accuracy. The prediction error is generally around 10%, 20%, and 25% for mean layer thickness, roughness, and anisotropy, respectively. Especially for roughness and anisotropy, though, some values were predicted with an error that falls outside the range indicated by this 'typical' prediction error. The number of these outliers, as well as their deviation from the error distribution, somewhat depends on the distribution of the training data over the training and testing data sets. General trends in the printed layer characteristics as a function of the input parameters are very well distinguished by the neural net. Issues such as mechanical play of parts of the

printer's engine, and experimental errors induced by fluctuations in manual operation may lead to experimental deviations that are not easily captured by any (statistical) model. We further note that all output parameters are less accurately calculated when any one of the input parameters is left out during training. One could, for instance, imagine that the mean layer thickness is predominantly determined by concentration and cell depth, the printing speed being of little or no influence. However, leaving out printing speed as an input parameter led to significantly larger prediction errors. In general, the mean printed layer thickness may seem somewhat higher than ideal for the fabrication of OLEDs, but we note that these layers contain ~30 vol.% dye (assuming a density of 1 g/cm^3 for both LEP and dye). Omitting the dye would indeed give LEP layers with a thickness in the desired range.

As mentioned above, the optimized synaptic weight and bias values were stored after training. This allowed us to systematically calculate the output of the trained net as a function of the full space determined by the three input parameters. Figs. 8–10 represent color-height plots of the mean layer thickness, roughness and anisotropy as a function of cell engraving depth and printing speed, calculated at four different polymer concentration levels. Fig. 8 clearly shows a general increasing trend of the mean layer thickness with concentration. This is to be expected, but the effect is not linear: no large changes are observed
Fig. 10. Calculated anisotropy plotted in color grades as a function of cell depth (d) (in µm) and printing speed (v) (in m/s) at c = 22.0, 25.0, 27.5, and 30.0 mg/mL (top left to bottom right).

for a polymer concentration in the range $c = 22.0$ – 27.0 mg/mL, whereas a pronounced increase of the mean thickness is predicted for higher concentrations. This may be indicative of a non-linear increase in fluid elasticity due to an increasing polymer entanglement density with concentration. Separate viscosity measurements showed the overlap concentration of this LEP to be around 25 mg/mL in toluene/anisole 30/70 (w/w), which falls within the tested concentration range (see Table 2). In contrast, no strong dependency of the mean layer thickness on printing speed is observed. Expectedly, a general increase of layer thickness with cell engraving depth is predicted. The non-linearity of this increase, however, becomes more pronounced at high LEP concentrations. This is indicative of an increasingly non-Newtonian behavior with polymer concentration.

As for the roughness (Fig. 9), at low polymer concentrations ($22.0 < c < 24.5$ mg/mL) an optimum (minimum) is predicted for intermediate speed and cell engraving depth settings (0.9–1.2 m/s and 36–40 μm, respectively). This optimum seems to shift towards higher engraving depths for higher LEP concentrations ($c > 26.0$ mg/mL). Besides this optimum, the roughness shows a trend-wise decrease with increasing cell engraving depth for the entire LEP concentration range. Interestingly, this relation changes from non-linear at low concentrations to more linear at high concentrations. This is indicative of a difficulty in the leveling of the printed dots at low cell engraving depths, despite the fact that integral layers are obtained. Expectedly, this effect becomes more pronounced if the viscosity increases due to a rise in LEP concentration. It is further noted that for any LEP concentration the roughness is highest when a low cell depth is used in combination with a high printing speed. This is especially the case for low LEP concentrations. Together with the low mean layer thickness obtained under these conditions, this is explained by a very low fluid transfer volume.

A high anisotropy at any concentration is obtained by combining a high cell engraving depth with a low printing speed (Fig. 10), the effect being most pronounced at high concentrations (∼30.0 mg/mL). Gradually going down in polymer concentration, it decreases to a minimum around $c = 26.0$ mg/mL, but increases again at lower concentrations. A minimum in anisotropy is obtained for intermediate concentrations ($23.5 < c < 25.5$ mg/mL) in combination with intermediate to low printing speed and cell engraving depth settings (0.5–1.1 m/s and 30–42 μm, respectively). Clearly, for the whole concentration range a much stronger speed-dependence is observed for the anisotropy than for the mean layer thickness and the roughness. This indicates that the directionality of the irregularities in a print is strongly related to the rheology of the ink.

4. Conclusions

We have shown that artificial neural network modeling may be used as a viable tool to predict gravure printed light-emitting polymer layer characteristics for flexible OLED lighting applications. The gravure printed LEP layers were analyzed using microdensitometry, after which the scanning data was converted into (local) layer thickness information and used to train a multi-layer neural network using error back propagation. Polymer concentration, printing speed and cell engraving depth were used as input parameters. Mean layer thickness, roughness, and feature anisotropy were defined as output parameters of the neural net. Despite the limited number of input parameters a reasonable to fair prediction accuracy was obtained once new input data was fed into the trained network. The prediction error for the three output parameters was of the order anisotropy > roughness > mean layer thickness. Calculating the magnitude of the output parameters as a function of the total space determined by the input parameters can be used as a way to find optimal printing conditions. The plots also express the highly non-linear dependency of the output on the input parameters.

[8,9]. TEM images have shown improved phase separation by increasing the domain sizes of P3HT and PCBM [3,4,10]. Most XRD results have shown that P3HT crystals in P3HT:PCBM films have the (1 0 0) preferred orientation, and the average crystalline size of the (1 0 0) axis increases with thermal annealing [11–14]. Preferred orientation and enlarged crystalline size of P3HT crystals were attributed to the improved performance of the solar cells upon thermal annealing. In contrast, it was recently reported that the higher crystallinity of a P3HT:PCBM film was a disadvantageous in organic photovoltaic devices because it induced more phase separation and thermally unstable morphology [15].

Despite these results, more morphological information is needed to clearly explain the device performance, mainly because most of the structural studies have been performed on P3HT:PCBM thin films without Al electrodes. The device performance improves when the blended polymer films are annealed after the deposition of an Al electrode on top of the polymer films [7]. Therefore, the structural change should be studied in the presence of an Al electrode on the blended films to determine the relationship between film structure and device performance. In addition, most of the available morphological data are limited to lateral microscopic phase separation images; information on the microstructure in the vertical direction is very limited [8–14]. The vertical connection of the separated phases is as important as the lateral phase separation, because the former is related to the collection of the charges generated at the interface between the P3HT and PCBM phases.

This paper analyzes the effects of Al electrodes on the nanostructure of P3HT:PCBM solar cell blends during thermal annealing with synchrotron X-rays, and the relationship to solar cell performance is discussed. The results clearly demonstrate that the improved solar cell performance resulting from thermal annealing in the presence of an upper Al layer is related the crystalline properties of P3HT such as the crystal size, the volume fraction and the angular spread of crystals in the film. Among these, the improved performance is strongly affected by the angular spread of the crystals, which helps to form interpenetrated networks. In addition, the polymer film surface structure is significantly different when the Al layer is present. A thin layer between the Al electrode and the blended film is formed by Al diffusion into the organic layer during thermal annealing, assisting in the formation of interpenetrated networks.

2. Experimental

P3HT was obtained from RIEKE metals (Mw = 55–60 kg/mol, 93% RR), and PEDOT:PSS was obtained from Baytron P. P3HT and PCBM were blended at a ratio of 1:0.65 by weight using a chlorobenzene (18 mg of P3HT:PCBM with 1000 ml chlorobenzene) solvent. A 40 nm PEDOT:PSS film was spin-coated on a glass substrate and baked for 1 min at 140 °C on a hot plate. Blended P3HT:PCBM films were spin-coated to a thickness of 70 nm. The samples were thermally annealed on a hot plate in a glove box for 30 min at different temperatures.

Al electrode layers were thermally evaporated onto P3HT:PCBM/PEDOT:PSS/Glass samples. The Al thickness was 40 nm. After Al was deposited, we annealed the samples in a glove box for 30 min at different temperatures.

Grazing-incidence wide angle X-ray scattering (GI-WAXS) and X-ray reflectivity measurements were performed with a 5A beam line from Pohang Light Source (PLS) of Korea. This is a high flux beam line with an inserted multipole wiggler. X-rays coming from the wiggler are focused in the vertical direction using a collimating mirror and monochromated using a double crystal monochromator. The beam is equipped with a kappa type 6-circle diffractometer and a 2D image plate detector. The X-ray incident angle was defined with the 6-circle diffractometer, and a 2D image plate detector was used to obtain 2D diffraction patterns.

The X-ray penetration depth is dependent on the X-ray wavelength and the refractive index of the material. In the X-ray region, the refractive index of a material is defined by $n = 1 - \delta - i\beta$ [16]. The constant δ is the dielectric constant of a material, and β is defined by $\lambda\mu/4\pi$, where μ is the linear absorption coefficient. With 1.069 Å X-rays, the critical angle of the P3HT:PCBM film was 0.113°, and δ and β were 1.95×10^{-6} and 2.15×10^{-9}, respectively. The X-ray reflectivity curves of the films with Al layers were analyzed using Parratt's formula for Fresnel reflection in a multilayer system. We assumed that P3HT:PCBM was infinite compared with the Al layer, and the interface between Al and P3HT:PCBM was gradually varied.

3. Results and discussion

Two sets of solar cells based on P3HT:PCBM (1:0.65 by weight) blends were annealed at 150 °C before and after deposition of an Al electrode. Fig. 1 shows the current–voltage curves of the devices, and the device characteristics are summarized in Table 1. The power conversion efficiency (PCE) of the devices annealed prior to the deposition of an Al layer is about 1.6%. In contrast, the PCE of the

Fig. 1. Current density–voltage (J–V) characteristics of solar cells based on P3HT:PCBM blends with not annealed (solid line), annealed at 150 °C in the absence of an Al layer (blue filled triangles), and annealed at 150 °C in the presence of an Al layer (red open circles) processes. The J–V characteristics were obtained under AM1.5-simulated sunlight. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1

Short circuit currents (J_{sc}), open circuit voltages (V_{oc}), fill factors (FF), and power conversion efficiencies (PCE) of solar cells based on P3HT:PCBM blends (1:0.65 by weight) with different annealing processes.

	Not annealed	150 °C without Al	150 °C with Al
J_{sc} (mA/cm²)	2.6	6.7	7.4
V_{oc} (V)	0.54	0.49	0.65
FF	0.33	0.52	0.64
PCE (%)	0.5	1.6	3.0

devices annealed after Al deposition increases to 3.0% at 150 °C. This performance is similar to that in previously reported results [17,18].

Grazing-incidence X-ray scattering provided information about the film nanostructure, including the crystalline size, the number of crystals, and the crystal orientation distribution. Fig. 2a and b show the 2D X-ray diffraction images of the spin-coated (not annealed) films and the films that were thermally annealed at 150 °C in the absence of an Al layer measured at the incident angle of 0.13°, respectively. Fig. 2c and d are 2D images of not annealed and the annealed at 150 °C in the presence of an Al layer measured at the incident angle of 0.16°, respectively. These diffraction images can be analyzed based on the known crystal structure of P3HT (orthorhombic with $a = 16.8$ Å, $b = 3.83$ Å and $c = 7.8$ Å with the main polymer chain parallel to the c axis and the alkyl side chain inducing a lamellar reflection along the a-axis) [19,20]. The structural information is summarized in Table 2 and Fig. 3.

The P3HT crystals grow by thermal annealing as expected and the size of the P3HT crystals is not significantly influenced by the presence of an Al layer as summarized in Table 2 and Fig. 3a. For example, annealing at 150 °C causes

the average crystal size of the edge-on crystals to increase from 15 nm to 20–25 nm in the [1 0 0] direction for both the cases. The increase in crystal size from 15 to 20 nm via thermal annealing at 150 °C is in agreement with previously reported TEM results analyzed by frequency-filtered Fourier transformation [4].

However, the presence of an Al layer during thermal annealing has a marked influence on the total amount of vertically aligned edge-on P3HT crystals. As shown in Fig. 3b, the integrated intensity of the edge-on P3HT (1 0 0) peak along the circular direction maintains almost constant or reduced a little with annealing temperature in the presence of an Al layer, whereas the integrated intensity increases to 2.5 times if the films are annealed above 120 °C in the absence of an Al layer. This fact indicates that the Al layer on the blended films disrupts improvement of the total crystallinity of P3HT.

One more significant difference is the angular spread of the P3HT crystal orientation represented by the FWHM of the edge-on P3HT (1 0 0) peak in the circular direction. The FWHM of the edge-on P3HT (1 0 0) peak increases almost linearly with annealing temperature in the presence of an Al layer, whereas it is kept constant in the absence of an Al layer. Since the intensity variation of the P3HT (1 0 0) peak in the circular direction is related to the angular spread of the P3HT crystals in a film, the presence of an Al layer during the thermal annealing reduces the preferred orientation of the P3HT crystals.

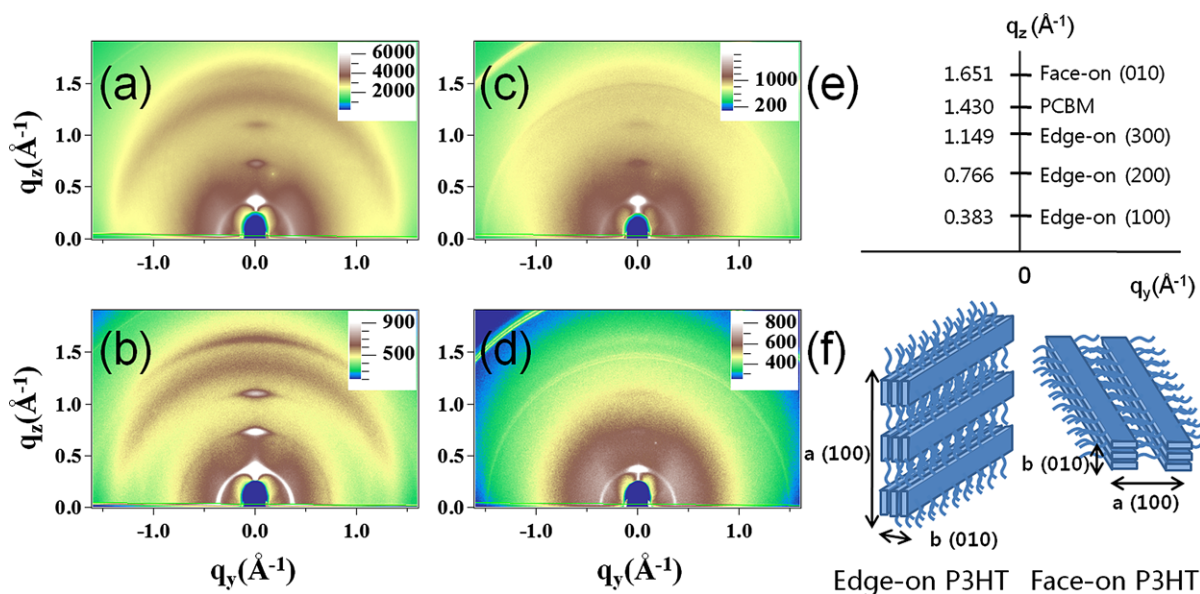
Reduction of the preferred orientation of P3HT crystals in the presence of an Al electrode is more clearly manifested in Fig. 4a, where the angular volume fractions of the P3HT crystals are plotted against the angle for a pristine film and the annealed films at 150 °C in the presence and absence of an Al electrode. The angular volume fractions were obtained from the intensity distribution in the


Fig. 2. 2D GIWAXS images of (a) not annealed and (b) annealed at 150 °C in the absence of an Al layer. (c) and (d) are images of not annealed and annealed at 150 °C in the presence of an Al layer, respectively. Indexing of the 2D images is in (e). (f) is schematic diagram of the edge-on and face-on P3HT crystals.

Table 2
Summary of the nanostructure of pristine (not annealed) P3HT:PCBM films and 150 °C annealed films with and without an Al layer on the surface. (ND: not detected).

	Not annealed	150°C without Al	150°C with Al
Edge-on (1 0 0) size	14 nm	20 nm	21 nm
Edge-on (0 1 0) size	2 nm	6 nm	ND
Face-on (1 0 0) size	8 nm	18 nm	23 nm
Face-on (010) size	3 nm	8 nm	ND
FWHM of (1 0 0) – preferred orientation	11.2°	10.9°	17.1°
Integrated intensity of (1 0 0)	1	2.5	0.86

P3HT (1 0 0) hallo in the 2D diffraction images by counting all the crystals having the same angular orientation from the surface normal but different orientations in the in-plain direction (x–y plane) under the assumption that the films are homogeneous in the in-plane direction. Angular volume fraction of the P3HT crystals is defined as the volume fraction of the P3HT crystals whose [1 0 0] direction is located between θ and $\theta + \delta\theta$ from surface normal of the films. Since the 2D diffraction image is the cross sectional view of the Ewald sphere of a film, the spherical integration must be performed as shown in Fig. 4b to include all

the crystals having angular orientation of θ from the surface normal. The integration was performed numerically using the following equation. We sectioned the (1 0 0) diffraction hallo of the P3HT crystals every 2° from the surface normal (q_z, $\theta = 0°$) toward the in-plain direction (q_y, $\theta = 90°$) for the numerical integration.

$$f_n(\theta_n) = \frac{\int_{\theta_n}^{\theta_n + \Delta\theta} q^2 I(\theta) \sin(\theta) d\theta}{\int_0^{\pi/2} q^2 I(\theta) \sin(\theta) d\theta}$$

$$\approx \frac{I[(n+1)\Delta\theta)] \sin[(n+1)\Delta\theta]}{\sum_{n=0}^{N-1} I(n\Delta\theta) \sin(n\Delta\theta)\Delta\theta},$$

where $\Delta\theta = \pi/2N$.

Fig. 4a clearly shows the different orientational distributions of the P3HT crystals by thermal annealing in the absence and presence of an Al layer. If all crystals are randomly distributed, the angular fraction must follow the dotted line in the figure. P3HT crystals are preferentially aligned along (1 0 0) direction even in the pristine film. The preferred orientation becomes more prevalent by the thermal annealing in the absence of an Al layer, so that the main tilting angle moves to 2° with narrower angular spread than the pristine film. In contrast, the presence of an Al electrode on the film induces more random

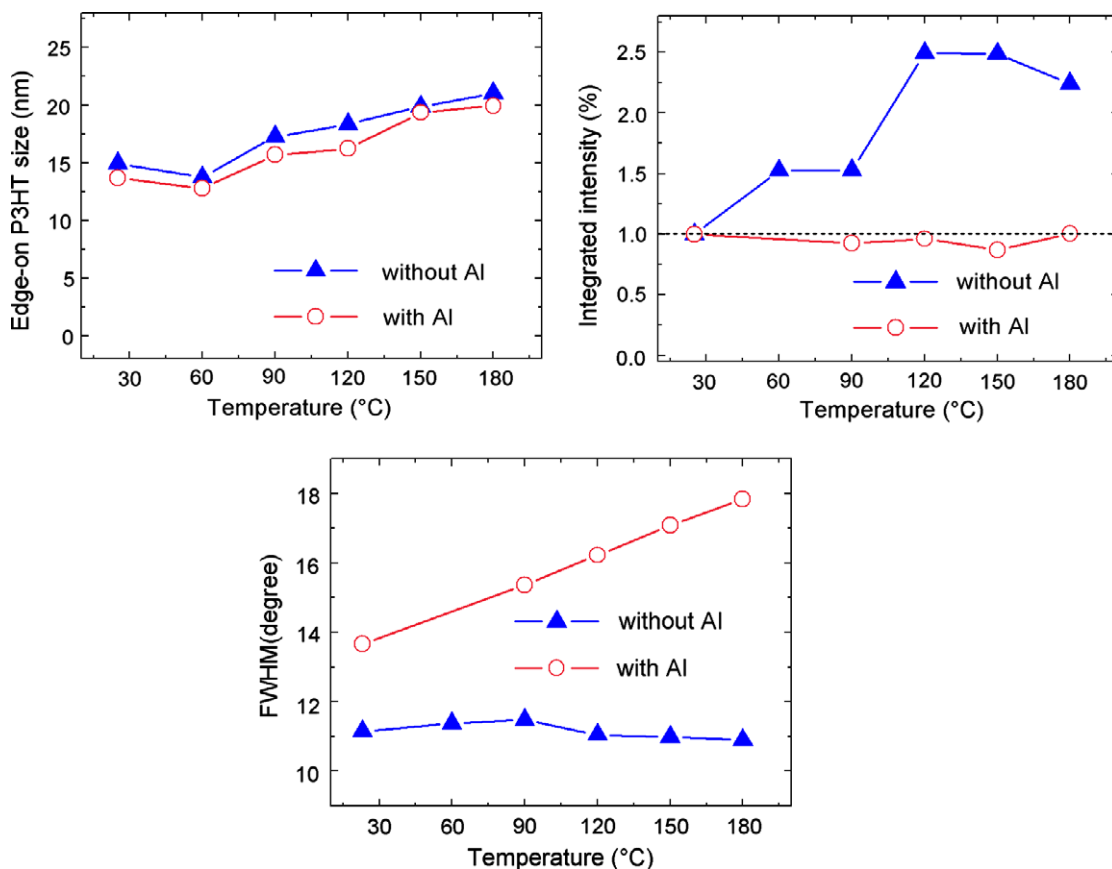

Fig. 3. Structural evolution of P3HT crystals in P3HT:PCBM films during annealing in the absence (filled triangle) and presence (open circle) of an Al layer; (a) the average P3HT (1 0 0) crystal size, (b) the ratio of integrated intensity of the P3HT (1 0 0) peak in the annealed film to that of the pristine film, (c) the FWHM of the P3HT (1 0 0) peak in the circular direction of the 2D diffraction images.
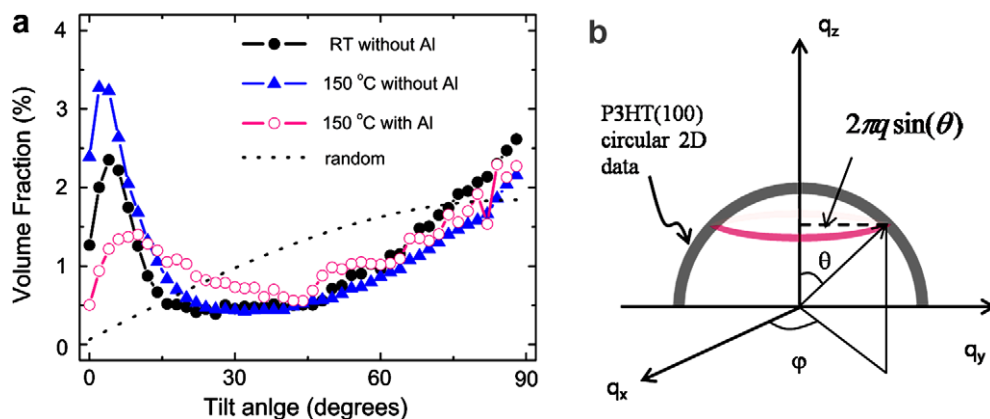

Fig. 4. (a) Angular volume fractions of the P3HT crystals in the pristine (black closed circle) and thermally annealed films at 150 °C in the absence (blue closed triangle) and presence (red open circle) of an Al layer. The dotted line is the curve of equally distributed crystals such as powder samples. We did not calculate the volume fraction over 86° due to surface enhancement effect. (b) Integration geometry of P3HT (1 0 0) 2D circular peak data in the spherical coordinate. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

distribution in the crystal orientation by the thermal annealing at 150 °C, resulting in almost equal angular volume fraction against the tilting angle.

Interestingly enough, very thin amorphous like face-on P3HT layers were found in the surface region of the films in the absence of Al layer. The structural information in the surface region of the films in the absence of an Al layer were obtained by using a lower incident angle (0.1°) than the critical angle (0.113°) of the P3HT:PCBM film. The X-ray penetration depth at the incident angle of 0.1° is ~26 nm for the 1.069 Å X-rays by the calculation using Parratt's equation. The face-on crystals near the surface region (~26 nm from the surface) grow only in the lateral direction as shown in Fig. 5. The average crystal size in the [1 0 0] direction is about 23 nm after annealing at 150 °C. In contrast, the average crystal size in the [0 1 0] direction remains 0.7 nm and does not change with thermal annealing up to 180 °C. The crystals are almost plane-like, composed of a molecular bi-layer in the vertical direction.
Fig. 5. The evolution of face-on crystals in the surface region (squares) and the bulk region (circles) in [0 1 0] direction (filled) and [1 0 0] direction (open) during thermal annealing in the absence of Al layer.

The growth of the plane-like face-on P3HT layer in the annealed film in the absence of Al layer will result in a smooth surface and it was confirmed by AFM measurements. The surface roughness of the pristine film is 0.8 nm, but it decreases to 0.5 nm after thermal annealing at 150 °C. The presence of the thin face-on P3HT layer at the surface region seem to act as a barrier for electron transport from the P3HT:PCBM matrix to the cathode if the blend films are annealed in the absence of Al.

This plane-like face-on P3HT layer was not detected if annealed in the presence of an Al electrode as evidenced by the lack of (0 1 0) peak in Fig. 2d. To check the chances of screening of the peak by the Al layer, we analyzed the X-ray penetration depth and intensity ratios. X-ray path length in the 40 nm thick Al layer is about 28 μm at 0.16° incident angle, and the X-ray penetration depth of Al layer is about 200 μm in the wavelength of 1.069 Å which was used in this experiment. This X-ray penetration depth is long enough to detect (0 1 0) peak in the presence of Al layer if the layer exist. Moreover intensity ratio of (0 1 0) peak to (2 0 0) peak in the annealed films in the absence of an Al layer (Fig. 2b) is 0.68. This value is much higher than the intensity ratio of the background to (2 0 0) peak in the annealed films in the presence of an Al layer (Fig. 2d) which is 0.31. Therefore we can safely say that the plane-like face-on P3HT layer is not formed if the film is annealed in the presence of an Al layer.

The nanostructural differences in the P3HT:PCBM films thermally annealed in the presence of an Al layer result from the interface between the Al and P3HT:PCBM layers. We performed X-ray reflectivity measurements for the as-cast and 150 °C annealed films with Al layers and could get mass density profiles by analysis [21]. The mass density profile showed that a thin interlayer is formed at the interface between the Al and P3HT:PCBM layers, even before thermal annealing. The thickness of the intermediate layer increases gradually up to ~17 nm with increasing annealing temperature due to inter-diffusion of Al atoms into the organic layer. This Al diffusion might restrict the lateral growth of the face-on P3HT crystals near the surface and

reduce the total crystallinity and the preferred orientation of the P3HT crystals in the blended film.

To understand the relationship between the structure and the device performance, we analyzed J–V characteristics of pre annealed and post annealed devices at 150 °C for 30 min. The pre annealed device shows the power conversion efficiency (PCE) of 1.6%, the short circuit current (J_{sc}) of 6.69 mA/cm^2, the open circuit voltage (V_{oc}) of 0.49 V, and the fill factor (FF) of 0.52, while the post annealed device shows PCE of 3.0%, J_{sc} of 7.4 mA/cm^2, the V_{oc} of 0.65, FF of 0.64, respectively. The series resistance (R_s) of the pre annealed device was 4.48 Ω cm^2, while it was 1.76 Ω cm^2 in the post annealed device. The increase of the short circuit current and the fill factor in the post annealed device seems to be related to the improved interpenetrating networks and the formation of better p–n junctions by the donor/acceptor molecules between the cathode and anode in the annealed film in the presence of an Al layer due to more random distribution than the annealed film in the absence of an Al layer. The decrease of the series resistance in the post annealed films must be related to the interface properties between Al electrode layer and P3HT:PCBM layer. It was published that Al–PCBM complex could be formed at the interface between the Al layer and the active layer by post annealing [2]. The diffusion of Al atoms into the active layer may be related to the formation of Al–PCBM complex, and the lateral growth of face-on P3HT near surface region seems to restrict the formation of Al–PCBM complex in the pre annealed device. As a result, the series resistance is lower in the post annealed device than the pre annealed device.

4. Conclusion

In summary, our results demonstrate that the crystal size itself is not the main factor improving device performance in P3HT:PCBM bulk heterojunction solar cells. Another important factor is the orientational distribution of the P3HT crystals. The presence of an Al layer on top of the P3HT:PCBM layer reduces the preferential orientation and total crystallinity of the P3HT crystals during thermal annealing, aiding in the formation of interpenetrating networks. Al inter-diffusion may play a role in disrupting the alignment of P3HT crystals. In addition, face-on P3HT crystals in the surface region affect device performance. These very thin P3HT layer grow laterally during thermal treatment in the absence of an Al electrode and act as a barrier for electron transport from the P3HT:PCBM matrix to the cathode. The lateral growth of the face-on P3HT crystals

near the surface region might be restricted by Al inter-diffusion. An interlayer is formed at the interface between organic layer and the Al electrode through inter-diffusion Al into the organic layer if annealed in the presence of an Al electrode. As a result of all the combined effects, devices annealed in the presence of an Al layer perform better than devices annealed without an Al layer.

the simplest and most manufacturable device configurations will require optimized semiconductor performance in "bottom-contact" TFT geometries, in which the semiconductor is deposited on the D–S contacts [6]. In either configuration, the device is turned on only when a voltage is applied between the S–G electrodes giving rise to accumulated charges in the semiconductor channel. Key TFT parameters include the field-effect mobility (μ) and the current on/off ratio (I_{on}/I_{off}), which quantify the average charge carrier drift velocity per unit electric field and D–S current gain when the device is turned on, respectively. Applications require the field-effect mobility and on/off ratio to be as high as possible.

In this paper we report the optical, electrochemical, and structural characteristics of benzodithiophene-based compounds **1**–**5** (Fig. 1) as well as their thin-film optical, morphological, and TFT semiconductor properties. Compounds **1** and **2** are tetrathia-[7]-helicenes ([7]-TH), that are chiral molecules with an helical shape, whereas compounds **3**–**5** are olefins substituted at the positions 1 and 2 of the double bond with benzodithiophene units. This helical shape could provide unique charge transport properties as observed for DNA and oligophenylureas [6c]. The geometry of the double bond is *Z* in alkene **3**, whereas alkenes **4** and **5** were obtained as pure *E* isomers. During the present study, a paper appeared in the literature reporting on the semiconducting properties of compound **4**, together with some morphological characterizations [7]. Some compounds of this family have interesting optical and electronic properties and both theoretical and experimental work have shown that they are potential candidates for nonlinear optic applications [8–10]. In particular, some of us are involved in the design and establishment of appropriate synthetic methodologies to achieve various substituted tetrathia-[7]-helicenes as well as their olefinic precursors, such as alkenes **4** and **5**, from which helicenes can be easily obtained through an oxidative photochemical cyclization. Tetrathia-[7]-helicenes are thermally and configurationally very stable chiral compounds [11] and can

be easily functionalized in the positions 2 and 13 of the two terminal thiophene rings, as well as in the central arene ring of the helical system (*i.e.* positions 7 and 8). This allows the introduction of different functional groups in a regioselective manner and therefore enables the tuning of their steric and electronic properties. Contrary to helicenes **1** and **2**, alkenes **4** and **5** are not chiral due to the complete planarity of the π-conjugated system. The two electron-withdrawing perfluorinated chains mostly employed to induce n-channel transport have been introduced in compound **5** in order to compare its properties with those of compound **4** [12]. The syntheses of compounds **1**–**4** have been reported previously [13] and here we describe only synthetic optimization of new compound **5**. In addition, the full chemical and physical characterization of compounds **1**–**5** (Fig. 1), morphological analysis of the corresponding films and the TFT performance are described.

2. Experimental

2.1. Reagents and methods

Reagents obtained from commercial sources were used without further purification. Before being used, the THF was dried by distillation over sodium wires/benzophenone, and the butyl lithium solutions in hexane were titrated. Unless otherwise stated, all of the reactions were performed under an inert atmosphere, after the glassware had been flame-dried. In order to monitor the progress of the reactions, thin layer chromatography (TLC) was performed using Merck silica gel 60 F254 pre-coated plates. Flash chromatography was performed using Merck silica gel 60, 230–400 mesh. Melting points were determined by means of a Büchi B 540 apparatus and are uncorrected. The IR spectra were recorded on a Perkin–Elmer FT-IR 1725X and only noteworthy absorption bands are listed. Solution emission and absorption spectra were obtained with a Cary 1 Ultraviolet/Visible Spectrometer and a PTI QM2 Fluores-

Fig. 1. Structures of the compounds **1**–**5** employed in this study.

cence Instrument. The mass spectra were recorded on LCQ Advantage Thermo equipped with ion trap and APCI source in 50–2000 m/z range. High-resolution mass spectra were recorded on a Vg Analytical 7070 EQ. ^{1}H NMR (300 and 200 MHz) and ^{13}C NMR (75 MHz) spectra were recorded on Bruker AC 300, Bruker AC 200 and Bruker AMX 300.

2.2. Synthesis

2.2.1. 2-Tridecafluorohexyl-benzo-[1,2b;4,3b′]-dithiophene (compound 7) [12]

A suspension of Cu (1.473 g, 23.16 mmol, 5.23 equiv.) in dry DMSO (14.7 mL) was heated at 125 °C for 15 min under nitrogen atmosphere. Tridecafluorohexyliodide (2.41 mL, 11.07 mmol, 2.5 equiv.) was added dropwise into the suspension while keeping the temperature below 135 °C. The suspension was heated at 125 °C for 45 min and then a solution of 2-iodo-benzodithiophene 6 (1.4 g, 4.43 mmol, 1 equiv.) in 9.1 mL of DMSO was added dropwise at 115 °C. The mixture was stirred at 115 °C for 6 h. The reaction was quenched with 45 mL of cold water and extracted with ether (1 × 100 mL, 2 × 20 mL). The combined organic phases were then washed with water. The organic phase was separated and dried over Na$_2$SO$_4$, and the solvent was evaporated under reduced pressure affording 2.40 g of crude reaction mixture as a solid. The mixture was purified by means of gravimetric column chromatography, eluent light petroleum, to give the expected compound 7 in 78% yield (1.76 g) together with the disubstituted derivative 8 in 8% yield (295 mg).

Compound 7: HRMS calcd. for C$_{16}$H$_5$F$_{13}$S$_2$: 507.96251, found 507.9631; mp (hexane): 64–65 °C; ^{1}H NMR (300 MHz, CDCl$_3$,) = 7.65 (d, J = 5.4 Hz, 1H), 7.74 (d, J = 5.4 Hz, 2H), 7.81 (d, J = 8.7 Hz, 2H), 7.94 (d, J = 8.7 Hz, 2H), 8.05 (s, 1H) ppm. ^{13}C NMR (75 MHz, CDCl$_3$) = 105.0, 108.1, 111.6, 115.5, 119.6 (m, C$_q$F); 118.6, 121.7, 122.0, 125.8, 128.2 (CHar); 129.9 (t, ^2J = 28.1 Hz, C$_q$CF), 133.6, 135.6, 137.6, 138.6 (Cq) ppm; ^{19}F NMR (282.23 MHz, CDCl$_3$) = −81.2 (s, 3F), −102.0 (s, 2F), −121.8 (s, 4F), −123.1 (s, 2F), −126.5 (s, 2F); MS (EI): m/z (%) = 508 (M$^+$,50), 489 ([M−F]$^+$, 15), 239 ([M−(C$_5$F$_{11}$)]$^+$), 100).

Compound 8: HRMS calcd. for C$_{22}$H$_4$F$_{26}$S$_2$: 825.93393, found 825.9325; mp (hexane): 57–58 °C; ^{1}H NMR (300 MHz, CDCl$_3$,) = 7.95 (s, 2H), 8.1s (s, 2H) ppm. ^{13}C NMR (75 MHz, CDCl$_3$) = 107.2, 111.3, 115.0, 118.5 (m, C$_q$F); 120.8, 124.9 (CHar); 131.1 (t, ^2J = 28.5 Hz, C$_q$CF), 133.8, 138.9 (Cq) ppm; ^{19}F NMR (282.23 MHz, CDCl$_3$) = −81.2 (s, 3F), −102.1 (s, 2F), −121.7 (s, 4F), −123.1 (s, 2F), −126.4 (s, 2F); MS (EI): m/z (%) = 826 (M$^+$,50), 807 ([M−F]$^+$, 20), 776 ([M−(CF$_2$)]$^+$), 15), 757 ([M−(CF$_3$)]$^+$), 5), 557 ([M−(C$_5$F$_{11}$)]$^+$), 100), 507 ([M−(C$_6$F$_{13}$)]$^+$), 15).

2.2.2. 7-Tridecafluoroexyl-benzo-[1,2b;4,3b′]-dithiophene-2-carboxaldehyde (compound 9)

A n-BuLi solution in hexane (1.47 M, 1.56 mL, 2.29 mmol; 1.15 equiv.) was added dropwise under stirring and nitrogen atmosphere to a solution of 8 (1.01 g, 1.99 mmol) in dry THF (12 mL) at −78 °C. The solution was stirred for 30 min at −78 °C and then treated with dry DMF (0.31 mL, 3.97 mmol, 2 equiv.).The progress of the reaction was monitored by TLC (light petroleum–AcOEt

9.5:0.5; $R_{f\ 8}$ = 0.75; $R_{f\ 9}$ = 0.38). After 30 min at −78 °C, the solution was quenched with a saturated aqueous solution of NH$_4$Cl (10 mL). The mixture was taken up with CH$_2$Cl$_2$ (40 mL) and the aqueous phase extracted twice with 5 mL of CH$_2$Cl$_2$. The organic phase was washed with water and dried over Na$_2$SO$_4$; the solvent was removed under reduced pressure affording 1.07 g of compound 9 as pale yellow solid in quantitative yield. HRMS calcd. for C$_{17}$H$_5$F$_{13}$OS$_2$: 535.95743; found: 535.95874; mp 161–163 °C. ^{1}H NMR (300 MHz, CDCl$_3$) = 7.95 (d, J = 9.0 Hz, 1H), 7.99 (d, J = 9.0 Hz, 1H), 8.11 (s, 1H), 8.41 (s, 1H), 10.17 (s, 1H, CHO) ppm. ^{13}C NMR (75 MHz, CDCl$_3$) = 108.1, 111.5, 115.5, 119.5 (m, C$_q$F); 122.1, 122.7, 125.4, 131.2 (CHarom), 131.8 (t, ^2J = 28.6 Hz, C$_q$CF), 134.7, 134.9, 139.2, 141.5, 144.6, (C$_q$), 184.5 (CHO) ppm; ^{19}F NMR (282.23 MHz, CDCl$_3$) = −81.1 (s, 3F), −102.2 (s, 2F), −121.7 (s, 4F), −123.1 (s, 2F), −126.5 (s, 2F); IR (Nujol): 1669 cm^{-1} (C=O); MS (EI): m/z (%) = 536 (M$^+$,65), 267 ([M−(C$_5$F$_{11}$)]$^+$, 100), 238 ([M−(CHO+C$_5$F$_{11}$)]$^+$, 10).

2.2.3. 1,2-Bis-(7-tridecafluorohexyl-benzo-[1,2b;4,3b′]-dithiofen-2-yl)-ethene (compound 5)

To a stirred solution of 9 (342 mg, 0.638 mmol, 1 equiv.) in 6.8 mL of dry THF at −5 °C, pure TiCl$_4$ (0.083 mL, 0.765 mmol, 1.2 equiv.) was added dropwise. After 30 min, at −5 °C, 104 mg of powdered Zn (1.59 mmol, 2.5 equiv.) was added and the suspension was stirred for 15 min. The mixture was refluxed for 1.5 h. After removing the solvent at reduced pressure, 10 mL of HCl 37%/water (1/1 v/v) was added at RT and the suspension stirred for 1 h, then filtered and the solid washed with cold MeOH affording pure 5 in 85% yield as a yellow solid (280 mg).

Compound 5: HRMS calcd. for C$_{34}$H$_{10}$F$_{26}$S$_4$: 1039.92501, found 1039.92660; mp: 223–225 °C; ^{1}H NMR (300 MHz, THF-D8) = 7.44 (s, 2H, CH=), 7.93 (d, J = 8.7 Hz, 2H), 7.97 (d, J = 8.7 Hz, 2H), 8.00 (s, 2H), 8.34 (s, 2H); ^{13}C NMR (75 MHz, THF-D8) = 108.3, 112.3, 116.3, 120.0 (m, C$_q$F); 120.0, 122.3, 123.1, 125.2, 127.3 (CHar), 129.7 (t, ^2J = 28.2 Hz, C$_q$CF), 134.2, 137.0, 137.9, 139.6, 144.5, (Cq) ppm; ^{19}F NMR (282.23 MHz, THF-D8) = −80.7 (s, 3F), −101.0 (s, 2F), −120.9 (s, 4F), −122.3 (s, 2F), −127.7 (s, 2F); MS (EI): m/z (%) = 1040 (M$^+$,100), 1021 ([M−F]$^+$, 10), 771 ([M−(C$_5$F$_{11}$)]$^+$, 15), 552 ([M−(C$_9$F$_{20}$)]$^+$, 5), 520 ([M−(C$_{10}$F$_{21}$)]$^+$, 10), 502 ([M−(C$_{10}$F$_{22}$)]$^+$, 5), 251 ([(M−(C$_{10}$F$_{22}$))/2]$^+$, 50); UV/Vis (CH$_2$Cl$_2$): λ_{max} = 419, 395, 374, 355 nm.

2.3. Electrochemistry

Cyclic voltammetry was performed in an electrolyte solution of 0.1 M tetrabutylammonium hexafluorophosphate (Bu$_4$N$^+$PF$_6^-$) in THF with scan rates between 70 and 100 mV/s. A ferrocene/ferrocenium redox couple was used as an internal standard and potentials obtained in reference to a silver electrode were converted to the saturated calomel electrode (SCE) scale.

2.4. Device fabrication

Prime grade p-doped silicon wafers (100) having 300 nm thermally grown oxide (Montco Semiconductors)

were cleaned by sonication in ethanol (200 proof) for 3 min and by oxygen plasma treatment for 5 min. Hexamethyldisilazane (**HMDS**) was deposited by placing the cleaned SiO$_2$ substrates into a N$_2$-refilled chamber saturated with **HMDS** vapor for 72 h. Organic compounds were vacuum-deposited (3×10^{-6} Torr) at a growth rate of 0.2–0.3 Å s^{-1} at various substrate temperatures (T_Ds), 25, 55, and 90 °C. Grown films were ~500 Å thick (as determined by a calibrated in situ quartz crystal monitor). For TFT device fabrication, top-contact electrodes (700 Å) were deposited by evaporating gold (pressure <1 $\times 10^{-6}$ Torr); channel dimensions were 100 µm (L) by 5000 µm (W).

2.5. Thin film characterization

Thin films were analyzed by wide-angle X-ray diffraction (XRD), using standard θ–2θ techniques, with monochromated Cu Kα radiation. Atomic force microscopy (AFM) images are collected using a NT-MDT Solver Scanning Probe Microscope in the tapping mode using Si cantilever with the samples kept in air. UV–visible absorption and photoluminescence (PL) spectra for films of compound **5** were obtained with a Cary 1 Ultraviolet/Visible Spectrometer and a PTI QM2 Fluorescence Instrument. Except compound **5**, for all the thin films of other compounds, UV–visible absorption spectra were recorded with a JASCO V-550 spectrophotometer and PL spectra were collected in transmission by a Hamamatsu multichannel optical analyzer exciting the samples **1**, **2**, **3** with the 355 nm line of a 10 Hz, 25 pulse duration, Q-switched Quantel Nd:YAG laser and sample **4** with a Nichia laser diode module with emission at 405 nm. The Nd:YAG laser beam energy per pulse was 1.3 µJ and the laser diode beam power was 40 mW. A GG420 cut-off filter is used for truncating the 405 nm excitation without modulating the PL emission. All the PL measurements were carried out in high vacuum.

2.6. Single crystal X-ray diffraction of compound *3*

The intensity data of compound **3** were collected at 173 K on a ENRAF NONIUS CAD 4 single crystal diffractometer using a graphite monochromated Cu Kα radiation. Crystallographic and experimental details of the structure are summarized in Table S1. The structure was solved by Fourier methods and refined by full-matrix least-squares procedures, first with isotropic thermal parameters and then with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms (M. Sheldrick, *SHELXL-97*, Program for Crystal Structure Refinement, University of Göttingen, Germany, 1997). The hydrogen atoms were introduced into the geometrically calculated positions and refined riding on the corresponding parent atoms.

2.7. Electrical measurements

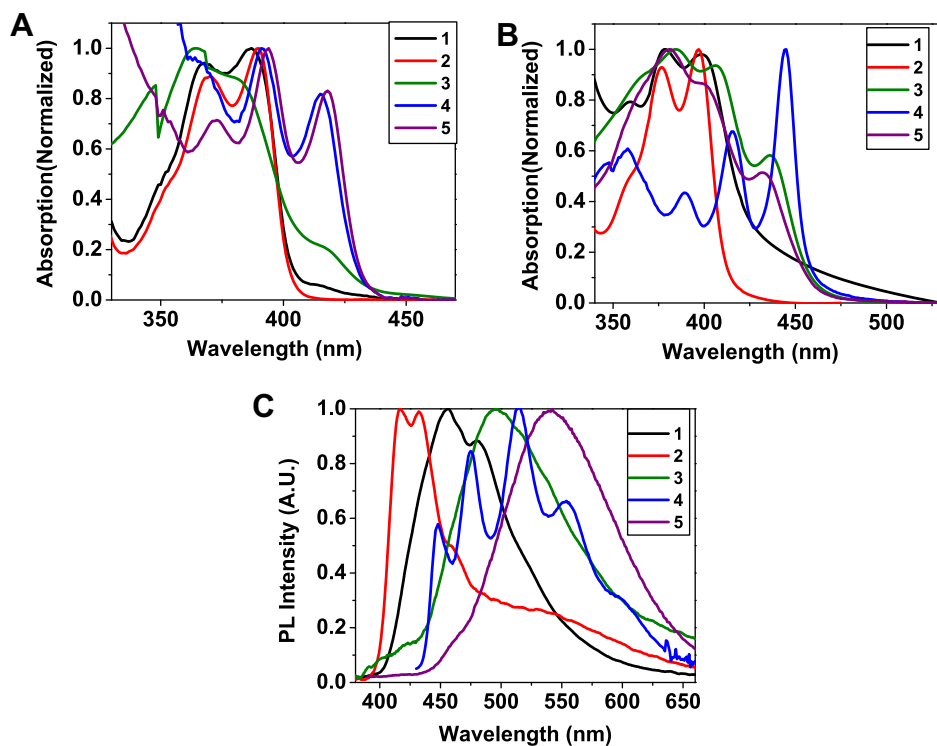
Electrical measurements were carried out under vacuum (<1 $\times 10^{-5}$ Torr) using a Keithly 6430 subfemtometer and a Keithly 2400 source meter, operated by a local Labview program and GPIB communication. Triaxial and/or coaxial shielding was incorporated into Signatone probe stations to minimize the noise level.

3. Results and discussion

3.1. Synthesis of compound *5*

The synthesis of polyfluorinated alkene **5** was accomplished as reported in Scheme 1. Considering that compound **5** is a symmetrically substituted alkene, an appropriate methodology is a McMurry reductive coupling of the aldehyde **9**. In fact, during our research to find suitable methodologies for the preparation of symmetrically substituted 1,2-bis(benzodithienyl)ethenes [13b,d], we verified that this method is simple, versatile, and efficient enabling the achievement of **5** from **9** in one-step. The synthesis of aldehyde **9** starts from 2-iodobenzodithiophene **6** where the perfluorohexyl chain was attached through a Cu-mediated coupling with tridecafluoro-1-iodohexane, in DMSO at 125 °C [12]. In this way, compound **7** was obtained in 78% yield as white solid, together with a small amount (8%) of the disubstituted derivative **8**. Aldehyde **9** was then obtained from **7** by deprotonating the free α-position of the thiophene ring (position 7) and the resulting anion was reacted with DMF as formylating reagent. In this way, **9** was isolated in quantitative yield as a light yellow solid. The last step of the synthesis consists of the McMurry reductive coupling of aldehyde **9** using TiCl$_4$/Zn reductive reagent. Pure *E* isomer **5** was obtained in 85% yield as yellow solid.

3.2. Optical properties

Optical absorption and emission maxima of compounds **1**–**5** were performed in solution (Fig. 2A) and as thin films on glass substrates (Fig. 2B, vide infra thin-film deposition condition). In CH$_2$Cl$_2$, compounds **1** and **2** exhibit very similar absorption spectra with two absorption maxima located at 368 and 387 nm for **1** and 370 and 390 nm for **2**. Note that there is a small (~3 nm) bathochromic shift going from **1** to **2** in agreement with the electron-donating nature of the propyl substituents. Thin-film absorption spectra of **1** and **2** are also very similar and exhibit two absorption maxima at 378 and 398 nm for **1** and 377 and 397 nm for **2**. A small bathochromic shift (< 10 nm) is observed going from solution to the thin film, evidence of J-aggregate formation [14]. Compound **3** in solution exhibits three major absorptions located at 364 and 380 nm, very close to those of compounds **1** and **2**, and the third peak falls at far longer wavelength (416 nm). The thin-film optical spectrum of compound **3** also exhibits three absorption maxima at 384, 406, and 436 nm, which are red-shifted by ~20 nm compared to those in solution. This result may be accounted by formation of J-aggregates or conjugated core planarization. Alkenes **4** and **5** also show similar absorption spectra in solution with absorption maxima located at 370, 391, and 415 nm for **4** and 373, 394, and 418 nm for **5**. The strong absorption maxima at ~415 nm, which is not present in compounds **1**–**3** spectra is a clear signature of the *E* isomers.[15] Thin films of compound **4** and


Scheme 1. Synthetic route to compound **5**.

Fig. 2. UV–visible absorption spectra of compounds **1–5** in CH_2Cl_2 solution (A), as thin films on glass substrates (B), and photoluminescence emission spectra as thin films on glass substrates (C).

5 exhibit absorption maxima at 357, 386, 415, and 445 nm for **4** and 382, 399, and 432 nm for **5** with strong absorption at >410 nm.

Thin film photoluminescence emission spectra of all compounds are shown in Fig. 2C. Thin films of compounds **1** and **2** exhibit two emission peaks located at 456 and 478 nm for **1** and 417 and 432 nm for **2**. Compound **3** shows one emission maximum at 498 nm. Compounds **4** and **5** have multiple peaks at 448, 475, 515, and 555 nm for **4** and at 468 and 542 nm for **5**. Compound **4** exhibits very small Stokes shifts of ~3 nm between the absorption and emission maxima compared to those of compounds **1**–**3**; this suggests a greater core rigidity of thin film phase affording TFT active device (vide infra) [16]. Band gaps for the present compounds are estimated from the low-energy band edges of the thin-film optical spectra, taking 10% of the maximum as the band edge (Table 1). The optical band gaps of compounds **1**–**5** are estimated to be 2.9, 3.0, 2.7, 2.7, and 2.7 eV, respectively.

3.3. Electrochemical properties

Oxidation and reduction potentials for the present compounds were measured by cyclic voltammetry (CV). Cyclic voltammograms of the compounds **1**–**5** in solution are shown in Fig. 3, and electrochemical data are summarized in Table 2. Compounds **1**–**3** exhibit onset oxidation potentials of ~1.5, ~1.3, and ~1.0 V, respectively (vs. SCE) without obvious reduction peaks. On the other hand, compounds **4** and **5** exhibit one reduction located at –1.7 and –1.5 V, respectively, but no oxidations.

Table 2
Electrochemical (in THF) and energetic properties of compounds **1**–**5**.

Compound	E_{ox}^{onset} (V)[a]	E_{red}^{onset} (V)[b]	E_{HOMO} (eV)[c]	E_g (eV)[c]	E_{LUMO} (eV)[c]
1	1.5	–	–5.9	2.9	–3.0
2	1.3	–	–5.7	3.0	–2.7
3	1.0	–	–5.4	2.7	–2.7
4	–	–1.7	–5.4	2.7	–2.7
5	–	–1.5	–5.6	2.7	–2.9

[a] Onset voltage for oxidation vs. SCE.
[b] Onset voltage for reduction vs. SCE.
[c] $E_{LUMO} = E_{HOMO} + E_g$.

From these oxidation and reduction potentials, HOMO and LUMO energies were estimated knowing that the SCE energy level is –4.4 eV below the vacuum level ($E_{HOMO} = -E_{ox}^{onset} - 4.4, E_{LUMO} = -E_{red}^{onset} - 4.4$) (Table 2) and the band gaps obtained by optical absorption data [17]. Using these relations, the HOMO values are estimated to lie at –5.9, –5.7, and –5.4 eV for **1**, **2**, and **3**, respectively. Similarly, the LUMO values are calculated as –2.7 and 2.9 eV for **4** and **5**.

3.4. Single crystal X-ray diffraction of compound **3**

An ortep view of compound **3** structure is shown in Fig. 4A with caption of the most important bond distances and torsion angles. In the crystal structure of compound **3**, the two benzodithiophene units lie on almost perpendicular planes with dihedral angle between the mean planes of

Table 1
Solution (in CH₂Cl₂) and film optical absorption maxima, film emission maxima (λ, nm), and energy gaps (E_g, eV) of compounds **1**–**5**.

Compound	λ_{sol}^{ab} (nm)	λ_{film}^{ab} (nm)	λ_{film}^{em} (nm)	E_g (eV)[a] Sol	Film
1	368, 387	359, 378, 398	456, 478	3.1	2.9
2	370, 390	377, 397	417, 432	3.1	3.0
3	364, 380, 416	384, 406, 436	498	2.9	2.7
4	370, 391, 415	357, 386, 415, 445	448, 475, 515, 555	2.9	2.7
5	373, 394, 418	382, 399, 432	468, 542	2.9	2.7

[a] Optical band gap estimated from the low-energy band edge in the film optical spectrum. Concentrations are 10^{-4}–10^{-6} M.
Fig. 3. Cyclic voltammograms of compounds **1**–**5** in 0.1 M Bu₄N⁺PF₆⁻) solution in THF at a scan rate of 100 mV/s. In all experiments, ferrocene is used as the internal standard (first peak in the CV scan). Inset: enlarged CV plot for compound **5** indicating reduction peak.

87.72(2)°. This is the consequence of the Z-isomer configuration. The phenyl ring is almost coplanar (dihedral angle of 3.42(1)°) and conjugated with one of benzodithiophenes in such a way as the (C15)C16=C17(C18,C23) double bond system.

The packing of the molecules along the b-axis is shown in Fig. 4B. The distances between adjacent mean planes of the conjugated systems, defined by the phenyl ring, the double bond system, and the benzodithiophene unit, are 3.719(1) and 3.192(1) Å, while those between adjacent mean planes of the other benzodithiophene unit are 3.338(1) and 3.348(1) Å. Thus, in principle, the interplanar distances could allow efficient intermolecular charge transfer. However, as shown in the Fig. 4B, the co-facial motif does not extend to the entire system with conjugations only between one thiophene and the phenyl ring and between two thiophene rings of co-facial conjugated systems (distances between the centroids of those rings being 4.017(2) and 3.632(2) Å, respectively), and between two thiophene rings and two phenyl rings of the benzodithiophene groups lying perpendicular to the conjugated system (distances between the centroids of those rings of 3.612(2) and 4.038(1) Å, respectively).

This weak interaction and small overlap between molecules fully explain the poor TFT activity of compounds 3 (vide infra). Note that the crystal structure of compound 3 confirms an NMR study reported elsewhere on an analogous alkene [13c], where the configuration in Fig. 5 is the most stable for cis-alkene precursors of tetratia-[7]-helicenes in solution and in solid state.

The crystal structures of compounds 1 and 2 have been already reported elsewhere [18,19]. It has been seen that only weak interactions of 3.77 and 4.038(2) Å, respectively are present between phenyl rings of adjacent molecules, indicating poor direct π-electrons overlap between adjacent rings and justifying the low TFT activity of such compounds, especially of compound 2.
Fig. 5. Preferred conformation of compound **3** as more stable form based on single crystal XRD.

3.5. Thin-film transistor performance

Top-contact OTFTs [100 μm channel lengths (L) and 5.0 mm channel widths (W)] were fabricated by vapor-depositing **1**–**5** films on 300 nm SiO_2 (**Bare**) and **HMDS**-treated SiO_2 (**HMDS**) substrates maintained at various substrate temperatures (25, 55, and 90 °C), followed by Au deposition through a shadow mask to define the source and drain electrodes. OTFT measurements were performed under vacuum and the device performance (mobility, on/off ratio, and threshold voltage) data are summarized in Table 3. Mobilities (μ) were calculated in the saturation regime using the relationship: $\mu_{sat} = (2I_{sd}L)/[WC_{ox}(V_{sg} - V_{th})^2]$, where I_{sd} is the source-drain saturation current; C_{ox} is the areal capacitance value, V_{sg} is the gate voltage, and V_{th} is the threshold voltage. The latter can be estimated as the x intercept of the linear section of the plot of V_{sg} vs. $(I_{sd})^{1/2}$. The mobility numbers are the average of at least four chips.

Fig. 4. (A) Ortep view of compound **3**. Ellipsoids are drawn at 30% probability level. Bond distances (Å) and torsion angles (°):C2–C3 1.430(3), C3–C4 1.422(3), C4–C5 1.425(3), C6–C7 1.433(3), C7–C8 1.416(3), C8–C9 1.434(3), C12–C13 1.379(3), C16–C17 1.352(3), C20–C21 1.374(3); S2–C15–C16–C17 14.33(1), C15–C16–C17–C18–0.90(1), C15–C16–C17–C23 178.03(1), S3–C18–C17–C23–85.08(1). (B) Molecular packing of compound **3**. View along b-axis.

Table 3
Mobilities 3, current on/off ratios ($I_{on}:I_{off}$), and threshold voltages (V_T, V) for vapor-deposited films of compounds **1–5** deposited at various substrate temperatures (T_D, °C).

Compound	T_D	Substrate	μ	$I_{on}:I_{off}$	V_T
1	25	Bare	1.7×10^{-7}	10^2	−66
2			–		
3	25	Bare		–	
	90		4.8×10^{-7}	10^1	−20
	25	HMDS	1.1×10^{-5}	10^3	−44
	90		1.2×10^{-7}	10^3	−48
4	25	Bare	9×10^{-4}	10^6	−49
	55		7×10^{-3}	10^6	−66
	90		3×10^{-4}	10^6	−46
	25	HMDS	2×10^{-2}	10^7	−56
	55		2×10^{-2}	10^6	−44
	90		4×10^{-4}	10^6	−62
5			–		

With the exception of compound **4**, all the other compounds-based devices show no (**2** and **5**) or very poor (**1** and **3**) TFT activities with mobilities of 10^{-5}–10^{-7} cm²/Vs and on/off ratios of 10^1–10^3. For compound **4**, mobilities strongly depend on both dielectric surface treatment and deposition temperature (T_D). Representative OTFT transfer and output characteristics of compound **4**-based devices are shown in Fig. 6. Overall, the devices based on compound **4** perform better on **HMDS** (with mobilities of 4×10^{-4}–2×10^{-2} cm²/Vs) than on **Bare** (with mobilities of 3×10^{-4}–7×10^{-3} cm²/Vs) substrates. All devices based on compound **4** exhibit very high current on/off ratio of 10^6–10^7. Considering the correlation between T_D and the device performance, 55 °C seems to be the optimum temperature affording the highest mobilities on both substrates. Deposition temperature-dependent device performance can be ascribed to the differences in film crystallinity and morphology (vide infra).

3.6. Film morphology and microstructure

To investigate semiconductor film microstructure, wide-angle X-ray diffraction (WAXRD) was performed on the films of compounds **1**, **3**, and **4**. The XRD spectra of **1** and **3** films exhibit no reflections in the 2–30° 2θ range,

indicating amorphous films. This result is fully in agreement with the poor device performance. Fig. 7 shows the θ–2θ scans for **4** films deposited at T_D = 55 and 85 °C on **HMDS** substrates, demonstrating that these vapor-deposited films are highly crystalline. The progression of Bragg reflections corresponds to a d-spacing of 18.6 Å (2θ = 5.25°), affording an edge-on substrate molecular orientation with almost perpendicular molecular orientation to the substrate. Since the TFT performance of the device of **4** is quite sensitive to the substrate temperature, the XRD patterns were also examined at various T_Ds. Films deposited at T_D = 55 °C show much stronger intensity compared to those at T_D = 90 °C, indicating higher film crystallinity in agreement with the improved device performance.

The AFM images of **1–5** films show a variety of morphological features such as tubular, grains, or smooth surface morphologies (Figs. 8 and S2). Representative AFM images of **1** and **4** films are shown in Fig. 8. Films of **1** deposited on both **Bare** and **HMDS** substrates at 25 °C exhibit tubular, nanowire-like structure. These morphological features can be understood from the analysis of the crystal packing of the racemate of compound **1**. The structure presents an alternate stacking of the two molecular enantiomers (P and M) along the c-axis so that the two central benzene rings almost overlap in upturned positions.[18] Thus, each nanowire is likely formed by chains of alternating helicene enantiomers.
Fig. 7. Wide-angle XRD spectra of compound **4** on **HMDS**-treated SiO₂ substrate at the indicated substrate temperatures.
Fig. 6. OTFT performance (A: transfer B: output) characteristics of compound **4** on **HMDS** (films deposited at 55 °C). The gate voltage was swept at a constant V_{DS} = −100 V.

Fig. 8. AFM images of (A) compound **1** on **Bare** (left) and on **HMDS** (right) deposited at 25 °C, (B) compound **4** on **Bare** deposited at 25 (left), 55 (middle), and 90 °C (right). The scale bar is 1 μm.

Films of **1** grown at 90 °C afford a lot of grains possibly due to dewetting from high substrate temperature. Films of **2**, **3** and **5** exhibit smooth, amorphous morphologies indicating no or poor TFT activity.

The AFM images of films of compound **4** show somewhat different morphologies compared to those of the other compounds. From Fig. 8B, it is clear that the film growth depends significantly on the substrate temperature.

Films grown on **Bare** at low temperature (25 and 55 °C) form well-connected and faceted grains (>1 μm), affording moderate field-effect mobilities. Different substrate does not affect film morphology significantly exhibiting similar morphology on **HMDS** (not shown). However at high substrate temperature, huge gaps between large grains can be seen from AFM images, possibly compromising charge transport resulting in relatively low TFT performance compared to low substrate temperature.

4. Conclusions

We have synthesized and characterized two helicenes (**1**, and **2**) and three alkene (**3–5**) derivatives as semiconductors for OTFT. Compounds **1**, **2**, **3** and **5** afford poor (with the mobilities of 10^{-5}–10^{-7} cm^2/Vs) or no TFT activity, probably because of the poor film crystallinity or morphology. Compound **1** exhibits nanowire-like morphology for the films grown at 25 °C, observed for the first time for vapor-deposited helicene molecule with helical shape. Compound **4** is a p-channel material with hole mobilities approaching 0.02 cm^2/Vs and current on/off ratio of 10^6–10^7. The carrier mobilities were found to depend on the substrate deposition temperature and surface treatments, which was correlated to the corresponding film morphologies and crystallinities.

of conducting material. Remarkably, the π-conjugated polymer-based photorefractive composite is reported as one part excessively [11]. It is well known that π-conjugated polymers, due to their delocalized π-electron distribution, have much larger carrier mobility than those of general photorefractive polymers. Thus, π-conjugated polymer-based photorefractive composites are expected to exhibit faster response, owing to their high mobility. In our previous paper, we reported a novel 3,3′-dicarbazole-based non-π-conjugated polymer (DiCz) in the main-chain, and showed adequate photorefractive properties for optical applications under moderate experimental conditions (Fig. 1) [12].

Here, we have focused our attention on preparation of a new type of NLO chromophore-doped π-conjugated polymer composite consisting of copoly[6,6′-bis(9-(2-ethylhexyl)carbazole-3-yl)/thieno-(2,5-b)thiophenylidene-vinylene] (EHCzThThZ) and 2-[3-[(E)-2(piperidine)-1-ethenyl]-5,5-dimethyl]-2-cyclohexenyliden]malononitrile (P-IP-DC), and their optical properties [13]. It is possible that this may overcome aggregation of NLO chromophore by attaching a bulky alkyl branch group at the 9-position of the carbazole in a working device. With this mind, in this work, we extended our study to investigate the photoconductive and photorefractive properties of π-conjugated polymer EHCzThThZ in photorefractive composite, also in comparison to non-conjugated polymer DiCz that was investigated in Ref. [12]. It is hoped that EHCzThThZ-based photorefractive composite may endow the composite with fast photorefractive response time. We will relate the results obtained in our laboratory concerning the quantitative comparison of optical properties in EHCzThThZ composite and that obtained for a similar composite composed of DiCz composite. In order to clearly confirm the influence of different photoconducting structures, the π-conjugated composite was compared to a DiCz composite system with the similar weight ratio of the photorefractive ingredients, with the same NLO chromophore and photosensitizer in the photoconducting matrix. Chemical structures of these materials are provided in Fig. 1.

2. Experimental section

2.1. Materials and device fabrication

In this work, a low-T_g photorefractive composite was prepared by doping the optically anisotropic chromophore, P-IP-DC, into the photoconducting polymer matrix, EHCzThThZ sensitized by C_{60} EHCzThTh and P-IP-DC were synthesized using previously described methods [13,7,14]. C_{60} was obtained from Aldrich Chem. Co. Inc. and was used after purification by sublimation under vacuum. The composition of polymeric composite was EHThThZ:P-IP-DC:butyl benzyl phthalate (BBP):C_{60} = 61:30:8:1 by wt.%. For sample preparation, the mixture (total 100 mg) was dissolved in 400 mg of 1,1,2,2-tetrachloroethane, and the solution was filtered through a 0.2 μm membrane. The composite was cast on a patterned indium tin oxide (ITO) glass substrate, dried slowly for 12 h at ambient temperature, and then was vacuum dried at 30 °C for 24 h to completely remove the residual solvent. The composite was then softened on a hot plate at 100 °C and next sandwiched between ITO glasses with Teflon film spacer of 50 μm to yield a film with a uniform thickness. The thickness of the active layer was near 50 μm.

2.2. Electro-optic measurements

The electro-optic property of the polymeric composite was determined by transmission ellipsometric method

Fig. 1. There are two kinds of composites in this study.

(I = 10 mW/cm^2). The sample tilted by 45° was placed between the polarizer and the analyzer with the polarization set to + 45° and −45°, respectively. The Δn of composite was determined from the variation of the transmitted intensity (T) through crossed polarizers upon the application of electric field, as described by the following equation [14]:

$$T = \sin^2 \left(\frac{2\pi}{\lambda} \cdot l \cdot \Delta n \right), \tag{1}$$

where λ is the wavelength and l is a distance of light path.

2.3. Photoconductivity measurements

The photoconductivity measurements were performed on about 50 μm thick samples sandwiched between ITO electrodes at I = 13 mW/cm^2 using a simple DC photocurrent method [15]. The current flowing through the composite was measured using the Keithley 6485 during illumination with an operating wavelength of 632.8 nm. The dark current and photoconductivity were calculated using the following equation:

$$\sigma = I \cdot \frac{d}{VA}, \tag{2}$$

where I is current, d is the sample thickness, V is the applied voltage, and A is the laser beam area. The dark conductivity (σ_{dark}), the conductivity in the presence of light (σ_{light}), and the photoconductivity ($\sigma_{photo} = \sigma_{light} - \sigma_{dark}$) were obtained.

2.4. Degenerated four-wave mixing (DFWM) measurements

Two coherent laser beams with λ = 632.8 nm were irradiated on the sample in the tilted geometry at an incident angle of θ = 30° and 60° with respect to the sample's normal axis. The intensity of s-polarized writing beams was 60 mW/cm^2. The recorded photorefractive grating was read by a p-polarized counter-propagating beam. An attenuated reading beam with a very weak intensity of 0.1 mW/cm^2 was used. The internal diffraction efficiency (η_{int}) of the photorefractive material was determined using the following equation:

$$\eta_{int} = \frac{I_{R,diffracted}}{(I_{R,diffracted} + I_{R,transmitted})}, \tag{3}$$

where $I_{R,diffracted}$ and $I_{R,transmitted}$ are the diffracted and transmitted intensities of the reading beam, respectively. The photorefractive grating buildup time was also analyzed. The photorefractive grating buildup rate is very important for real applications such as a real-imaging and real-data processing. The buildup time of the photorefractive composites was evaluated from the buildup of the beam intensity of the DFWM measurement. The time constants, τ_1 and τ_2, were calculated by fitting the evolution of the growth of the diffraction signal, $\eta(t)$. Quantitative information about the grating growth can be obtained by an empirical biexponential function of the following Eq. (4) fitted to the data of diffraction efficiency [16]:

$$\eta(t) = A_1 \left\{ 1 - \exp\left(-\frac{t}{\tau_1} \right) \right\} + A_2 \left\{ 1 - \exp\left(-\frac{t}{\tau_2} \right) \right\}, \tag{4}$$

where A_1 and A_2 are fitting parameters, and τ_1 and τ_2 are the fast and slow time constants, respectively.

3. Results and discussion

The T_g value of the current composite from the DSC data was $T_g \sim 28$ °C, which assure the facile orientation of P-IP-DC at temperatures around T_g The mixture of the composite was sandwiched between two indium tin oxide glass plates to from a 50 μm thick film along with a Teflon spacer. All experiments were performed near the T_g of photorefractive composite under an operating wavelength of 632.8 nm.

As given in Fig. 2, the birefringence (Δn) of the photorefractive composite is increased quadratically with an external electric field. This data from the transmission ellipsometer experiments can be used to predict both the steady-state holographic contrast of the photorefractive composite and to quantify the sample. At an applied potential of 50 V/μm, $\Delta n = 2.62 \times 10^{-3}$, which are sufficiently large values for the preparation of efficient photorefractive materials. The value of Δn of composite was determined from the variation of the transmitted intensity (T, Fig. 2 inset) through the crossed polarizers upon the application of the electric field, as described by the following Eq. (1). That is attributed the high birefringence due to a large dipole moment induced, as well as to the high polarizability anisotropy of the P-IP-DC chromophore [17].

The photoconductivity is governed by the photogeneration quantum efficiency and the charge mobility via an applied electric field and a light intensity. The photoconductivity increases with increasing electric field. The observed nonlinear dependence on the electric field strength is thought to be due the fact that both the quantum efficiency and the charge mobility depend strongly on the electric field strength. Photoconductivity measurements (λ = 633 nm) were carried out on the device, and showed photoconductivity of σ_{photo} = 1.19 pS/cm for EHCzThThZ composite, using a light intensity of 13 mW/cm^2 and an applied electric field of 60 V/μm (Fig. 3). Unfortunately, the EHCzThThZ composite also exhibited high dark conductivity at relatively higher electric field. The dark conductivity was calculated to be 0.39 pS/cm under an electric field of 60 V/μm. Comparing the photoconductivity of the EHCzThThZ composite (σ_{photo} = 0.86 pS/cm under potential of 50 V/μm) with that of the DiCz composite (σ_{photo} = 1.24 pS/cm under a potential of 50 V/μm) shows that the former is lower due to the higher dark conductivity (σ_{dark} = 0.39 pS/cm under potential of 50 V/μm) of EHCzThThZ composite. We observed that, when an electric field is applied to the sample, σ_{dark} decrease with an increase in the electric field occurs. This σ_{dark} in high fields may be attributed to the orientation of the NLO chromophore's under the electric field [18]. This value is found to be greater than that of the DiCz-based one, presumably due to π-conjugated backbone of EHCzThThZ. The EHCzThThZ polymer is probably effective for π-stacking of polymer rigid backbone through hydrophobic interaction between branched-chain alkyl groups. This result in higher dark conductivity than DiCz composite, suggesting that photogenerated holes should be diminished in
Fig. 2. Electric field induced birefringence of polymeric photorefractive composites versus various applied electric fields. The inset shows the transmittance for the EHCzThThZ composite on voltage applied to the device. The lines are guides for the eye.
Fig. 3. The conductivity as a function of external electric field strength. The lines are guides for the eye.

EHCzThThZ composite, therefore, shows lower photoconductive properties. The photoconductivity was extracted as photosensitivity.

In polymeric photorefractive materials, the magnitude of space-charge field, $|E_{SC}|$ takes the form [19]

$$|E_{SC}| = \frac{mE_q\sqrt{E_0^2 + E_d^2}}{\sqrt{E_0^2 + (E_d + E_q)^2}} \times \frac{1}{1 + \frac{\sigma_{dark}}{\sigma_{photo}}}, \tag{5}$$

where $m = \sqrt{I_1 I_2}/(I_1 + I_2)$ is the modulation depth, where I_1 and I_2 is the write beams, $E_q = eN_{eff}/(\varepsilon_0\varepsilon_r K_G)$ is the trap-density-limited space-charge field, where N_{eff} is the effective trap density, ε_r is the dielectric constant relative to the permittivity of free space ε_0, K_G is the grating wave vector, and e is the fundamental unit charge, $E_d = k_B T K_G/e$ is the diffusion field, where k_B is Boltzmann's constant and T is the absolute temperature. The second part of the numerator of Eq. (5) corresponds to the conductivity con-

tribution, and this part is related to photorefractive response. As depicted in Fig. 4, this undesirable operation resulted in a maximum in the $1/(1 + \sigma_{dark}/\sigma_{photo})$ for the EHCzThThZ composite device at $E = 60$ V/μm, with a subsequent increase in this figure-of-merit (FOM) above these voltages. The FOM may be defined as $Q = n^3 r_e/\varepsilon_r$, where n is the optical index of refraction, r_e is the effective electro-optic coefficient [20]. This ratio means that the photocharge is mobile while the other is stationary, or at least one type of charge is more mobile than the other. The implications of this functioning with regard to the overall photorefractive properties will be discussed as the relevant data are presented. The photosensitivity S_{photo} (photoconductivity per unit light intensity) of EHCzThThZ composite at excitation wavelength of 632.8 nm is presented in Fig. 4 and was calculated according to the following equation:

$$S_{photo} = \frac{J_{photo}}{EI}, \tag{6}$$

where J_{photo} is the photocurrent density, E is the applied electric field, σ_{photo} is the photoconductivity. The photosensitivity is proportional to the carrier photogeneration rate, mobility, and life-time [21]. The photosensitivity was calculated as $S_{photo} = 8.6 \times 10^{-11}$ cm/ΩW under potential of 60 V/μm (Fig. 4). This value is of the higher order of magnitude as the one reported in the efficient photorefractive composites for high-speed applications base on poly(N-vinylcarbazole) [22].

The DFWM experiment is a good choice for probing weak gratings and studying the dynamics of the photorefractive effect. The diffraction efficiency of the photorefractive material was determined using a DFWM experiment. In the DFWM experiment, the diffraction efficiency (η) was determined by the ratio of the intensity of the diffracted signal to that of the incident reading beam. The

steady-state diffraction efficiency in the presence of the orientational enhancement effect is determined by the applied electric field and the space-charge field amplitude. Fig. 5 shows the electric field dependence of the diffraction efficiency. The diffraction efficiency increased with the applied electric field and the diffraction efficiency of the current composite was 37.2% at 50 V/μm at 30 °C. The diffraction efficiency is rather low. This result may be explained by a previously reported study [23]. The reason for the low diffraction efficiency EHCzThThZ composite may be a low space-charge field due to a low trap density. Also, this result may be connected with highest occupied molecular orbital (HOMO) of photorefractive materials. In our photorefractive material, the HOMO level of EHCzThThZ (-5.24 eV) is lower than that of P-IP-DC (-5.32 eV), i.e., the P-IP-DC chromophore do not contribute to carrier trapping [12,24]. Therefore, the lower HOMO level of EHCzThThZ, compared with DiCz (-5.38 eV), may lead to slightly lower photoconductivity and space-charge field, which is consistent with our experiment results.

The response of the holographic grating formation was studied by measuring the time constants of the grating formation in the DFWM experiment. In Fig. 6, the dynamics of the diffraction grating formation process for different applied voltages is presented. Analysis of the changes in the curves' shape in function of the applied voltage allows us to affirm that there is a strong correlation between the characters of the evolution of diffracted signal and electric field. The buildup time of the photorefractive composite was evaluated from the buildup of the beam intensity of the DFWM measurement. The grating formation speed increased as the applied electric field strength increased. Fig. 7 shows the τ_1 and τ_2 of the current composite, which measured at different electric fields between 20 and 50 V/μm. The photorefractive speed strongly depends on

**Fig. 4.** Electric field dependence of photosensitivity and $1/(1 + \sigma_{photo}/\sigma_{dark})$ for EHCzThThZ composite. The lines are guides for the eye.

the photogeneration efficiency, drift mobility, NLO chromophore's mobility and other parameters.

An elevated external electric field causes faster grating formation in EHCzThThZ composite, as was expected, since the charge mobility as well as the photocharge generation efficiency increase with electric field. As displayed in Fig. 7, the moderate response time of the EHCzThThZ composite (0.16 s at 50 V/μm) having the higher τ_1 than that of DiCz composite (1.18 s at 50 V/μm) [12]. It may be considered

by the fast rate constants that the rigidity of the matrix affect the dynamics of photorefractive grating formation with the charge carrier generation and its mobility, and the hole trap density. The fast response time of EHCzThThZ composite is caused by the possibility of delocalizing charges along on polymer chain without hopping compared to the DiCz composite [25]. Since the photorefractive effect is based on the photoinduced buildup of a space-charge field in an electro-optic material, the photogenera-

tion of charge carriers and their subsequent migration by diffusion or drift in an electric field play a key role in determining the magnitude and speed of the photorefractive response. Table 1 provides a summary of the EHCzThThZ composite measured using optical properties.

4. Conclusions

In summary, we have prepared a novel π-conjugated polymer-based photorefractive composite with low T_g. We emphasize the importance of taking into account the birefringence, photoconductivity, diffraction efficiency, and the speed of grating formation of π-conjugated polymer-based photorefractive composites in order to measure their optical properties. This composite has faster photorefractive grating formation speed due to π-conjugated main-chain, as compared with the non-conjugated polymer-based photorefractive composite. The EHCzThThZ composite showed a diffraction efficiency of 37.2% in moderate electric field of 50 V/μm, with a response time of the diffraction efficiency of 0.16 s in an applied field of 50 V/μm. Therefore, we believe that the photorefractive composite containing π-conjugated polymer shows promise as a highly efficient photorefractive material, and takes our research one step closer to the goal of finding a polymeric material that can find application in various optical devices.

efficiencies as well as reduced roll-off [15–17]. However, there are few electron transport-type wide band-gap hosts, which resulted in limitation for introducing a mixed host structure into blue PHOLEDs. Recently, several good host materials with high electron mobility as well as triplet energy were reported, and we have taken advantage of the characteristics of these hosts to develop mixed host blue [7,18].

In this work, various mixed host structures for blue PHOLEDs were developed to study the relationship between the device performances and the combination/composition of host materials. A hole transport-type host material, 4,4′,4″-tris(N-carbazolyl)triphenylamine (TcTa), was combined with an electron transport-type host material, 2-(diphenylphosphoryl)spirofluorene (SPPO1) [18] or an bipolar transport-type host material, (26DCzPPy) [7]. We found that a mixed host structure was effective to control the charge carrier injection and exciton distribution in emissive layer (EML), thus obtained highly improved and stable efficiency in blue PHOLEDs.

2. Experimental

A series of blue PHOLEDs in this study were fabricated using the configuration: indium tin oxide (ITO) (70 nm)/1,1-bis[(di-4-tolylamino)phenyl]cyclohexane (TAPC) (50 nm)/emissive layer (30 nm)/1,3,5-tri(m-pyrid-3-yl-phenyl)benzene (Tm3PyPB) (20 nm)/Tm3PyPB:Cs (30 nm)/LiF (1 nm)/Al (120 nm). Six different mixed host devices were prepared to investigate the effect of host material properties on device characteristics of mixed host devices. Two standard devices with single 26DCzPPy or SPPO1 host material were also fabricated as references for comparison. Bipolar transport-type 26DCzPPy (Device A) or electron transport-type SPPO1 (Device B) composition in the mixed host device were 50%, 70%, and 90%, respectively. A blue light-emitting iridium(III)bis(4,6-difluorophenyl)-pyridinato-N,C2′)picolinate (FIrpic) was doped in the mixed host emissive layer and the doping concentration of FIrpic was fixed at 10%.

To achieve efficient blue PHOLEDs, effective confinements of both charge carriers and triplet excitons are necessary [7,11,13]. Therefore, TAPC and Tm3PyPB with wider triplet energy level (T_1 = 2.9 and 2.78 eV, respectively, which are higher than that of FIrpic (T_1 = 2.62 eV)) and low-lying the highest occupied molecular orbital (HOMO) and high-lying the lowest unoccupied molecular orbital (LUMO) energy levels, respectively, were used as a hole-transporting layer (HTL) and as an electron transporting layer (ETL), respectively. In addition, n-doped ETL (4 mol % Cesium doped TmPyPB) was introduced for effective electron injection and charge carrier balance within emissive layer because the electron mobility of Tm3PyPB ($\sim$7.0 × 10^{-4} cm^2/Vs at 2.5 × 10^5 V/cm) [19,20] is one to two orders of magnitude lower than the hole mobility of TAPC ($\sim$1.0 × 10^{-2} cm^2/Vs at $\sim$$10^5$ V/cm) [13]. The energy level diagrams and chemical structures of materials used in this study were shown in Fig. 1.

ITO was cleaned by the standard oxygen plasma treatment. The OLED grade materials were purchased and used without further purification. All organic layers were depos-

Fig. 1. Energy level diagrams and chemicals structures for the materials tested in this study.

ited in a high vacuum chamber below 5 × 10^{-7} torr and thin films of LiF and Al were deposited as a cathode electrode. The OLEDs were transferred directly from vacuum into an inert environment glove-box, where they were encapsulated using a UV-curable epoxy, and a glass cap with a moisture getter. The electro-luminescence spectrum was measured using a Minolta CS-1000. The current–voltage (I–V) and luminescence–voltage (L–V) characteristics were measured with a current/voltage source/measure unit (Keithley 238) and a Minolta CS-100. Photoluminescence (PL) spectra were recorded using Spex Fluorolog-3 spectrofluorometers.

3. Results and discussion

The current density–voltage–luminance (I–V–L) curves of the TcTa:26DCzPPy mixed host devices (Device A) are shown in Fig. 2a according to the relative content of two host materials. The current density of Device A was gradually increased with increasing TcTa content in the mixed host devices. Since FIrpic is a well-known electron transport-type triplet emitter and their relatively low-lying LUMO level compared with those of 26DCzPPy and SPPO1, the electrons injection and transport behavior in case of both Device A and B would be similar [19]. Therefore, the increased the current density with the addition of TcTa to 26DCzPPy is mainly originated from facilitated hole injection and transport from TAPC to 26DCzPPy through TcTa content. The hole injection from TAPC to 26DCzPPy was slightly restricted due to the HOMO level difference of 0.55 eV between TAPC and 26DCzPPY. However, in case of TcTa:26DCzPPy mixed host Device A, the hole injection from TAPC to EML was enhanced by TcTa addition which has higher-lying HOMO level (5.7 eV) than that of 26DCzPPy (6.05 eV). In addition, the hole mobility of TcTa is higher than that of 26DCzPPy. Therefore, increased
Fig. 2. Current density versus voltage (*I–V*) and voltage versus luminance (*V–L*) characteristics of (a) Device A (TcTa:26DCzPPy) and (b) Device B (TcTa:SPPO1).

Fig. 3. Normalized electro-luminescence (EL) spectra and CIE coordinates of (a) Device A (TcTa:26DCzPPy), (b) Device B (TcTa:SPPO1).
**Fig. 4.** Normalized photoluminescence (PL) spectra of the mixed host samples.

current density in TcTa:26DCzPPy mixed host Device A could be obtained. The luminance at the same voltage was also increased as similar as the current density behavior.

In the case of the combination of TcTa and an electron transport-type SPPO1 host (Device B), the current density as well as luminance behavior was more dramatic than those in the case of Device A as shown in Fig. 2b. This is attributed to the huge hole injection barrier (1.0 eV) from TAPC to SPPO1 and the inferior hole mobility of SPPO1 compared to 26DCzPPy [18]. Moreover, the driving voltages of Device B consequently reduced with increasing TcTa content in the mixed host devices and were 6.1, 5.2, 4.5, and 4.2 V at a luminance of 1000 cd/m^2, respectively. By gathering up above results, we found that charge carrier density and injection properties in the EML were correlated with the combination/composition of the host materials, and could be controlled by device engineering.

Fig. 3 shows the electro-luminescence spectra and the Commission Internationale de L'Eclairage (CIE) coordinates of the Device A and B at a current density of 10 mA/m^2. All Device A exhibited a similar maximum luminescence wavelength, near 474 nm, which is originated from the triplet emission of FIrpic emitter. However, as the TcTa content increased in the Device B, emission at 474 nm was decreased while the shoulder peak around 500 nm was increased.

These different electro-luminescence spectra could be presumed to be vibronic coupling between different host materials [21,22] and/or optical effect through the recombination zone shift [18]. Firstly, we conducted photoluminescence study to examine vibronic coupling between two host materials in the mixed host devices. Nine different mixed host samples (30 nm-thick films on quartz plate) with 10% doped FIrpic were prepared. Additionally, three reference samples with TcTa, 26DCzPPy, and SPPO1 single host were also studied for compression. As shown in Fig. 4, we could not find any differences between the mixed host samples and reference samples. Therefore, we excluded the vibronic coupling effect as an origin of spectral change in our mixed host blue PHOLEDs. Secondly, the optical effect caused by the recombination zone change was also considered [18]. As shown in Fig. 5, we could ob-

serve the electro-luminescence changes in blue PHOLEDs with FIrpic doped single TcTa, 26DCzPPy, or SPPO1 host layers. The hole and electron recombination zone in the Device B with SPPO1 single host is positioned in the SPPO1:FIrpic EML close to the HTL side due to preferred charge (electron) carrier mobility of SPPO1 material. However, the recombination zone of the Device B with TcTa:SPPO1 mixed host structure would be shifted from the HTL/EML side to the center of the EML as increasing TcTa content in the EML. In other words, balanced exciton recombination in the EML could be achieved by using a mixed host structure, in which enhancement of light-emitting efficiency was expected.

The external quantum efficiency (EQE) of the blue PHOLEDs with mixed host structure were plotted against luminance or current density in Fig. 6. Both Device A and B with mixed host structure showed highly improved performance than 26DCzPPy or SPPO1 single host devices. The maximum efficiency was obtained in the 1:9 mixed host in case of Device A (TcTa:26DCzPPy, EQE of 20.4%), while Device B (TcTa:SPPO1, EQE of 21.8%) showed the best performances in the 3:7 mixed host. Enhanced EQE in the mixed host devices is mainly due to charge carrier injection/transport balance as well as recombination region distribution within EML by the optimization of mixed host properties. [23] Moreover, these behavior were more dramatic in TcTa:SPPO1 mixed host devices because SPPO1 materials is an electron transport-type material while 26DCzPPy is a bipolar material. Additionally, the power efficiency of the mixed host devices also highly improved due to the reduced driving voltage as well as the enhanced quantum efficiency. The peak power efficiencies of Device B were improved from 28 (TcTa:SPPO1 = 0:10) to 53 lm/W (TcTa:SPPO1 = 3:7) by using mixed host structure (see Fig. 7).

It has been known that the narrow recombination zone was inferior for the efficiency roll-off due to its high exciton density which induces the triplet exciton quenching process [12,14,19]. Therefore, as shown in Fig. 6, the device performances of the single host devices at high current density region were greatly decreased. Especially, this detrimental efficiency roll-off was distinguished in the SPPO1

Fig. 5. Normalized electro-luminescence (EL) spectra of single host devices.

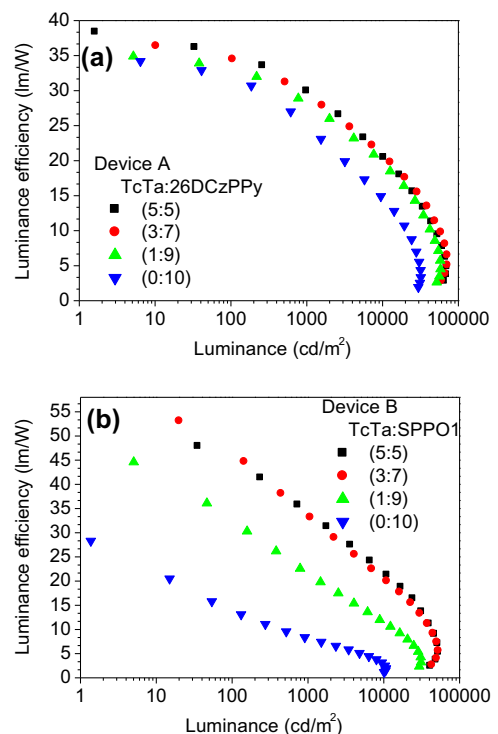
Fig. 6. External quantum efficiency versus luminance characteristics of (a) Device A (TcTa:26DCzPPy) and (b) Device B (TcTa:SPPO1) (Inset: EQE versus current density characteristics).


Fig. 7. Luminance efficiency versus luminance characteristics of (a) Device A (TcTa:26DCzPPy) and (b) Device B (TcTa:SPPO1).

single host device because SPPO1 is electron transport-type material which resulted in a shallow recombination zone. However, the distributed recombination zone through balanced charge carrier injection/transport in the mixed host devices showed remarkably stable efficiency roll-off. The external quantum efficiencies of the Device A (TcTa:26DCzPPy = 1:9) and Device B (TcTa:SPPO1 = 5:5) showed over 18% at a luminance of 10,000 cd/m^2 and decreased to half at a current density of J_0 = 258 and 230 mA/cm^2, respectively. Both values are better than any other efficiency roll-off values for blue electro-phosphorescent devices [19], indicating a highly reduced roll-off in efficiency.

4. Conclusion

In summary, light-emitting performances of blue PHOL-EDs could be enhanced by host layer engineering. Mixed host structure devices of TcTa:26DCzPPy or TcTa:SPPO1 showed effective distribution of recombination zone as well as balanced charge carrier injection, which resulted in highly improved efficiency roll-off at high current density.

Fig. 1. Molecular structure of **DTP-FLU**.

2,6-bis[2-(9,9-dihexyl-9H-fluorene)]-*N*-(4-hexylphenyl)-dithieno[3,2-*b*:2′,3′-*d*]pyrrole (**DTP-FLU**) oligomer (Fig. 1) were discussed.

2. Experimental section

DTP-FLU oligomer was synthesized by Suzuki coupling of 2,6-dibromo-*N*-(4-hexylphenyl)-dithieno[3,2-*b*:2′,3′-*d*]pyrrole and 9,9-dihexyl-9H-fluorene-2-boronic acid. Scheme 1 represents the synthetic route leading to the target compound (**DTP-FLU**). The detailed synthesis, characterization, photophysical and electrochemical properties of a series of DTP derivatives are reported separately [15].

Absorption spectra were recorded using Shimadzu 1601 PC spectrophotometer and fluorescence was measured using Shimadzu RF 5301 spectrofluorophotometer. The samples for the spectroscopic studies were prepared by spin coating chloroform solution of **DTP-FLU** on a quartz substrate. The quantum yield in chloroform was measured using quinine sulfate (0.1 M H_2SO_4) as a reference. The solid state photoluminescence quantum yield was determined using an integrating sphere (Lab Sphere Com) with He–Cd laser (325 nm; 11 mW) as an excitation source [16].

For time-of-flight photoconductivity measurement, the oligomer film samples were prepared by drop casting the chloroform solution of **DTP-FLU** (concentration: 37 mg/ml) onto an indium tin oxide (ITO) patterned glass slide in a solvent saturated environment. A 100 nm thick alumi-num electrode was evaporated onto the **DTP-FLU** film using an Edwards thermal evaporator. The thickness of the oligomer film was measured using a surface profiler (KLA-Tencor P10 surface profiler) and it was found to be 4.4 μm. The TOF measurement system was composed of a pulsed nitrogen (N_2) laser (Oriel 79074), a pulse generator (SRS-DG535), a DC voltage source (Kenwood PWR18-2), and a digital oscilloscope (Agilant-Infiniium, 1 GHz, 4 Gsa/s). The N_2 laser with pulse width <4 ns, and pulse repetition rate 1 Hz, was illuminated on the ITO side of the device. The photocurrent under the influence of applied electric field was monitored across a variable resistor using an oscilloscope. It was ensured that the time constant of the setup is less than the transit time (RC < t_{tr}). The details of the TOF setup have been described elsewhere [17]. The active area of the device was 4 mm². The sample was mounted in a temperature controlled continuous flow cryostat under vacuum of ~10^{-5} mbar. The charge mobilities were calculated using the relation $\mu = d^2/Vt_T$, where d is the thickness of the film, V is the applied voltage and t_T is the transit time. The transit time was obtained from the inflection points in a double logarithmic plot of photocurrent *versus* time.

3. Results and discussion

The solid state absorption and emission spectra of **DTP-FLU** is shown in Fig. 2. The absorption spectrum shows a broad band with a maximum around 426 nm with two shoulder peaks at 214 and 271 nm. The fluorescence spectrum in film state is characterized with emission maxima at 505 nm with full width at half maximum (FWHM) of 49 nm. The Stokes shift was found to be 79 nm. The quality of the emission spectra was assessed based on the Commission International de L'Eclairage (CIE) chromaticity coordinates (see inset of Fig. 2). The color coordinate was found to be in the green region (0.2422, 0.5019). The band gap was calculated from the onset of the absorption spectra and it was found to be 2.5 eV.

DTP-FLU has a strong solution state photoluminescence with a quantum efficiency of 75%. The solid state quantum yield was measured using an integrating sphere and it was
**Scheme 1.** Synthesis of **DTP-FLU**.

Fig. 2. Solid state absorption and emission spectra of **DTP-FLU**. Inset: CIE coordinates in film sample.

found to be 22%. The surface morphology of the **DTP-FLU** film was studied using atomic force microscopy (AFM). The experiment was performed at room temperature using a commercial AFM Nanoscope IV (Dimension 3100, Digital Instruments) in the tapping mode. The film was prepared by spin coating the **DTP-FLU** oligomer solution in chloroform on a cleaned ITO substrate. Fig. 3 shows the AFM image of the film and from the 3D view (Fig. 3D) it is noted that the film is uniform with grain size in the nanoregime.

The time-of-flight (TOF) photocurrent transients were measured to determine the carrier drift mobility by monitoring the time taken by the carriers generated at one end of the sample to reach the other end under the influence of constant electric field. The device architecture used for the TOF measurement was ITO/**DTP-FLU** (4.4 μm)/Al. Fig. 4 shows a linear plot of TOF transients for holes in **DTP-FLU** at various applied voltages at 298 K and the corresponding double logarithmic plot is shown in the inset. It
Fig. 3. (A) AFM height image of the spin coated film (10 μm × 10 μm) of **DTP-FLU** on ITO coated glass substrate. (B) magnified image of A (2 μm × 2 μm). (C) height profile of AFM image B and (D) the 3D view of the AFM image showing the surface morphology of the film.

is clear from the figure that the initial decay in the photocurrent follows a constant current plateau. This appearance of constant current plateau is due to the non-dispersive nature of the hole transport. The subsequent decay in the current is due to the holes reaching the other electrode at which they are discharged.

The transit time t_T, for the arrival of carriers were readily obtained from the inflection point in the double logarithmic plot of photocurrent *versus* time. The carrier mobility μ, was extracted using the relation $\mu = d^2/Vt_T$. In order to get an in-depth knowledge of the transport property of **DTP-FLU,** a detailed investigation was carried out at
a temperature range of 218–308 K. It is observed that at low temperature, the transport become dispersive in nature. The linear plot of TOF hole transients obtained at various temperatures are shown in Fig. 5.

At 298 K, the hole mobility was found to be 7.7×10^{-6} cm^2/Vs at an applied electric field of 2.9×10^5 V/cm. It is noteworthy that the field-dependences of the hole mobilities are in good agreement with the Pool–Frenkel relationship $(\mu = \mu_{(E=0)} \exp(\gamma E^{1/2}))$, where $\mu_{(E=0)}$ is the zero-field mobility and γ is the slope of the field dependence of charge mobility, at all temperatures studied [17–20]. The Pool–Frenkel plots of hole mobility in **DTP-FLU** at various temperatures are shown in Fig. 6. The hole mobility was found to be increasing with increase in temperature. At 238 K, the hole mobility was found to be 1.2×10^{-6} cm^2/Vs at an applied field of 2.7×10^5 V/cm, but at 278 K the mobility was increased to 4.1×10^{-6} cm^2/Vs and at 308 K, it was found to be 8.4×10^{-6} cm^2/Vs with the same applied electric field. The zero-field mobility $(\mu_{(E=0)})$ and γ were extracted from this Pool–Frenkel plot and the zero-field mobility was plotted against temperature (Fig. 7A). It is clear from the plot that the zero-field mobility increases with increase in temperature and the slope (γ) decreases with increase in temperature. This illustrates the typical hopping mechanism of charge transport in **DTP-FLU**. Generally, in conjugated molecular solids, the transport of charges occurs *via* hopping between the localized sites on individual molecules. It is known that the disorder in energies of localized sites arises from variations in conjugation length, conformation of the molecule or intermolecular interactions. This leads to a distribution

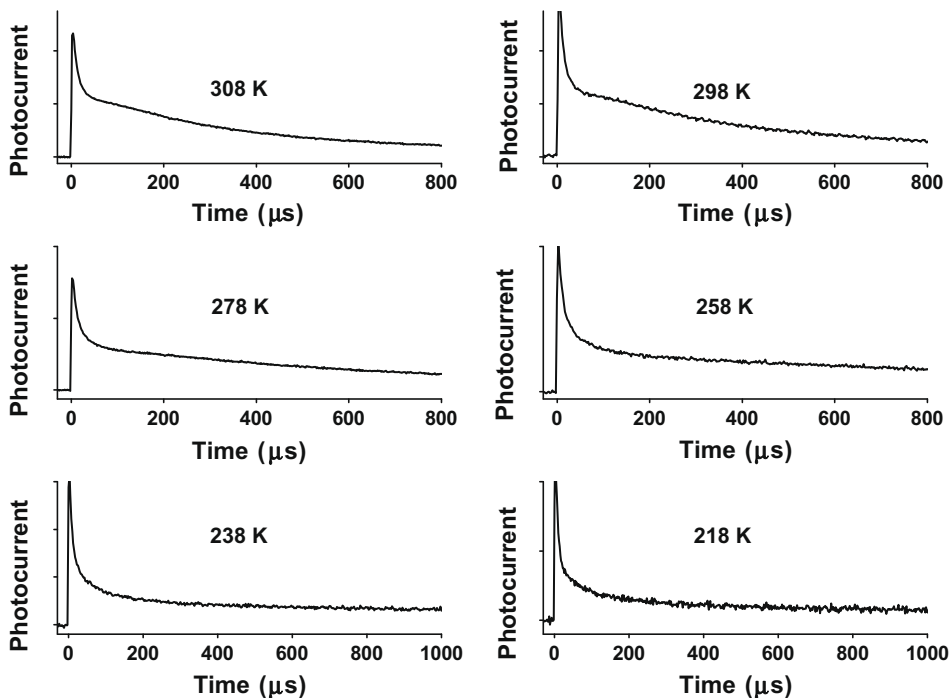

Fig. 4. Linear plot of time-of-flight hole current transients for different applied voltage in **DTP-FLU** film at 298 K. The inset shows the corresponding double-logarithmic plot.

Fig. 5. Linear plot of TOF photocurrent transients at various temperatures in **DTP-FLU** (Field: 2.7×10^5 V/cm).
Fig. 6. Poole–Frenkel plots of hole mobility in **DTP-FLU** at various temperatures.

of site energies and such distributions give rise to a significant dispersion in the charge hopping times.

The mechanism of charge transport and the relation between the Gaussian energy distribution and characteristics of time-of-flight transients in disordered organic materials was interpreted by various models [21]. Gaussian disorder model (GDM), proposed by Bässler et.al. is one of the empirical expression which has been widely used to characterize the field and temperature dependence of charge transport in amorphous organic solids [21–23]. In GDM, it is assumed that the charge transport occurs through a hopping mechanism with Gaussian distribution of energetic disorder of localized hopping sites and intermolecular positional disorder. Energetic disorder (σ) and positional disorder parameter (Σ) are the two crucial parameters which influence the carrier mobility [21]. The energetic disorder corresponds to the width of the Gaussian density of states and it arises from the distribution of conjugation length. The positional disorder parameter arises from the fluctuations of intermolecular distances or mutual orientation of neighboring molecules. This GDM model also accounts for the crossover from non-dispersive to dispersive transport at low temperatures [24–26]. In Gaussian model, the dependence of hole mobility on electric field and temperature can be expressed by Eq. (1) [24].

$$\mu_{GDM} = \mu_\infty \exp\left[-\left(\frac{2\sigma}{3kT}\right)^2\right] \times \exp\left[C\left\{\left(\frac{\sigma}{kT}\right)^2 - \Sigma^2\right\}E^{1/2}\right] \tag{1}$$

where μ_∞ is the high temperature limit of the mobility, σ is the energetic disorder bandwidth, Σ is the parameter of positional disorder and C is the empirical constant. The empirical constant indicates the hopping distances that a charge carrier has to overcome to be transferred from one site to another. The energetic disorder parameter and high temperature limit of mobility was extracted from the plot of logarithmic zero-field mobility *versus* $1/T^2$ (Fig. 7A) and it was found to be $\mu_\infty = 6.1 \times 10^{-4}$ cm²/Vs and $\sigma = 100$ meV. Also the positional disorder parameter and the empirical constant C were extracted by plotting

Fig. 7. (A) Temperature dependence of mobilities at zero-field in **DTP-FLU.** (B) The slope of the field dependence of the logarithmic mobility *versus* $(\sigma/kT)^2$ the solid line is a linear fit according to Eq. (1). (C) The slope of the field dependence of the logarithmic mobility *versus* $(\sigma/kT)^{3/2}$, the solid line is a linear fit according to Eq. (2).

the slope of the field dependence (γ) against $(\sigma/kT)^2$ (see Fig. 7B) and the values of Σ and C were obtained from the linear fit and was found to be 2.4 and 4.6×10^{-4} (cm/V)$^{1/2}$, respectively.

It is reported that long range correlations due to charge–dipole interaction exists in disordered organic materials [27]. But in GDM model, the correlation between the sites is not accounted. This lead to the development of another model called Correlated disorder model (CDM) which accounts for the charge–dipole interactions [28]. According to CDM, the non-dispersive mobility in correlated media can be represented by Eq. (2).

$$\mu_{CDM} = \mu_\infty \exp\left[-\left(\frac{3\sigma}{5kT}\right)^2\right]$$
$$\times \exp\left[0.78\left\{\left(\frac{\sigma}{kT}\right)^{3/2} - 2\right\}\sqrt{\frac{eaE}{\sigma}}\right] \tag{2}$$

Carrier hopping among the sites is arranged on a cubic lattice with a cell spacing a. Also the high temperature limit of mobility may have additional temperature dependence due to other less correlated sources of energy disorder or polaron effects. The major difference between GDM and CDM is the predicted temperature dependence of γ. Fig. 7C shows the variation of γ with $(\sigma/kT)^{3/2}$ and the linear fit is according to CDM (Eq. (2)). The average cell spacing (a) was obtained from this linear plot and it was found to be 1.4 nm. The energetic disorder parameter according to CDM model was also calculated from the plot of logarithmic zero-field mobility *versus* temperature (Fig. 7A) and was found to be 111 meV. The localization length for the charges was calculated by using Eq. (3) with the derived values of energetic disorder parameter, μ_∞ and average cell spacing.

$$\mu_\infty = \frac{ea^2 \upsilon_{ph}}{\sigma} \exp\left(\frac{-2a}{L}\right) \tag{3}$$

where υ_{ph} is the phonon frequency for hopping ($\sim 10^{12}$ s^{-1}). The localization length was estimated to be 5 Å. The results obtained from both the models (GDM and CDM) are summarized in Table 1.

The charge transport parameters obtained from the GDM/CDM analysis are similar to the established conjugated materials such as poly (*p*-phenylenevinylene) (PPV), polyfluorene (PFO) etc [29,30]. It is interesting to note that the intersite hopping constant and energetic disorder obtained in the case of **DTP-FLU** is found to be similar to that in PFO (intersite hopping constant = 2.4×10^{-4} (cm/V)$^{1/2}$ and σ_{GDM} = 90 meV) [31], and in (2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylenevinylene)/C60 (MEH-PPV/C$_{60}$) composite [32]. Also it is noteworthy that that the average site spacing (a = 1.4 nm) and the localization length (L = 5 Å) in **DTP-FLU** is similar to the fully conjugated materials [33]. Therefore it can be concluded that

DTP based materials have similar transport properties as that of other conjugated materials such as PFO or PPV which have potential uses in device applications. Therefore the charge transport parameters of DTP based molecules can be controlled and optimized to enable us to fine tune and fabricate the optoelectronic devices.

4. Conclusion

The charge transport properties of **DTP-FLU** were studied by using time-of-flight photoconductivity method. The film morphology and photophysical properties of this oligomer was also investigated in detail. The compound is found to be hole transporting. The hole mobililites were measured over a range of temperatures from 218 to 308 K and the mobilities were in the order of 10^{-6} cm^2/Vs at all temperatures. The field and temperature dependence was analyzed by Gaussian disorder model (GDM) and Correlated disorder model (CDM) and charge transport parameters were extracted. The energetic disorder parameter and positional disorder parameter estimated using Gaussian disorder model was found to be 100 meV and 2.4, respectively. Most interestingly the transport parameters of this material are similar to the other conjugated materials such as PFO and PPV. The results indicate that dithienopyrrole-based compounds will be a promising new material for various optoelectronic applications.

metathesis reaction [24–32]. Such copolymers attracted significant attention due to the strong self-assembly induced by $\pi-\pi$ interactions and exhibited quite different ordered morphologies in comparison with the reported rod–coil block copolymers [9–21].

Polythiophene is one of the most widely explored polymers in the optoelectronic devices, especially in transistor and photovoltaic applications [33,34], because of the excellent charge-transporting mobility and highly regioregular structure. Several all-conjugated thiophene-based polymers have been reported recently [28–32]. MuCullough first reported the synthesis of poly(3-hexylthiopehene)(P3HT)-block-poly(3-dodecylthiophene) by the sequential addition of different monomers [28]. Soon after, Yokozawa and coworkers prepared an amphiphilic P3HT-block-poly(3-methoxyethoxyethoxylmethylthiophene) by the similar approach [29]. Recently, Hashimoto and his coworkers discovered that the poly[3-(2-ethylhexyl)thiophene] (P3EHT) segment in P3HT-b-P3EHT could promote the self-organized P3HT domains in the film state and showed a higher crystalline absorption intensity than a P3HT homopolymer [30]. The nanowire morphology of crystalline-crystalline conjugated diblock copolymer of P3HT-block-poly(3-octylthiophene) was developed with the aim of a photovoltaic cell application recently [32]. One of us also prepared alternative well-controlled block copolythiophenes, P3HT-block-poly(3-phenoxymethylthiophene) (P3HT-b-P3PT, Chart 1), with a nanofiber-like morphology [31]. Although the all-conjugated copolymers were successfully synthesized, the studies on the morphology and optoelectronic device characteristics are still quite limited. The nano-scaled morphologies of P3HT-b-P3PT could play an important role in the charge transport and optoelectronic properties.

In this study, the morphology and device characteristics of P3HT-b-P3PT are reported, including field-effect transistor (FET) and photovoltaic cell (PV). The polymer surface structures were explored through different solvent mixtures of chloroform ($CHCl_3$) and dichlorobenzene (DCB). The optical absorption, FET, and PV characteristics were correlated with their surface structures. This present

study provided a new insight into the morphology and device characteristics of all conjugated block copolymers.

2. Experimental part

2.1. Materials

The monomer of 2,5-dibromo-3-phenoxymethylthiophene and the block copolythiophene of P3HT-b-P3PT, were prepared according to our previous report [31]. Ultra-anhydrous solvents and common organic solvents were purchased from Tedia, Merck, and J.T. Baker. Octadecyltrichlorosilane (ODTS) used as self-assembled monolayer (SAM) on the gate dielectric surface was purchased from Aldrich. P3HT (M_n: 17,730, regioregularity: 98.5%) and [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) were obtained from Rieke-Metal and Nano-C, respectively. All reagents were used as received.

2.2. Polymer structure of P3HT-b-P3PT

The molecular weights of different blocks in P3HT-b-P3PT were well-controlled through the feed ratio of the monomers and the initiator, according to our previous report [31]. The number average molecular weight (M_n) of the studied P3HT-b-P3PT estimated from GPC was around 30,100, with polydispersity index of 1.17. The degree of polymerization of P3HT and P3PT segments estimated from the ^{1}H NMR spectrum, appended in Fig. S1, were 150 and 27, respectively. The regioregularity of P3HT-b-P3PT was found to be 98% (P3HT block) and 69% (P3PT block), respectively, estimated from the ^{1}H NMR spectrum by comparing the signal intensities of the methylene protons next to the thiophene ring.

3. Characterization

UV–Vis absorption spectra of the spin-coated polymer films on quartz substrates were recorded on a Hitachi U-4100 spectrophotometer. For these thin film spectra, polymer solutions (ca. 10 mg/ml) were filtered through syringe filters with PTFE membrane (0.45 μm pore size), then spin-coated at a speed rate of 450 rpm for 60 s onto the quartz substrate, and annealed for 10 min under nitrogen. Cyclic voltammetry (CV) was conducted with the use of a three-electrode cell in which ITO (polymer film area about 0.5×0.7 cm^2) was used as a working electrode. A platinum wire was used as an auxiliary electrode. All cell potentials were taken with the use of a homemade Ag/AgCl, KCl (sat.) reference electrode. The energy level of HOMO was determined from the onset oxidation (E_{onset}^{ox}) based on the reference energy level of ferrocene (4.8 V below the vacuum level) according to the following relation : HOMO = $-e(E_{onset}^{ox} - E_{ferrocene}^{1/2} + 4.8)$ (eV). The LUMO level was calculated from the HOMO and the value of optical band gap according to the relation: LUMO = HOMO + E_g^{opt} (eV) [35,36]. The thickness of the prepared polymer films was measured with an Alpha-step 500 surface profiler (TEN-COR). Atomic force micrographs (AFM) of polymer films on a device surface were obtained with a Nanoscope 3D

n = 150, m = 27
Chart 1. Polymer structure of the studied diblock copolythiophene, P3HT-b-P3PT.

Controller AFM (Digital Instruments, Santa Barbara, CA) operated in a tapping mode at room temperature. Commercial silicon cantilevers (Nanosensors, Germany) with typical force constants (5–37 Nm^{-1}) was used and the images were taken continuously with the scan rate of 0.8 Hz.

3.1. Fabrication and characterization of polymer field-effect transistor

A polymer field-effect transistor was fabricated through the bottom-contact and bottom-gate geometry. A thermally grown 200 nm thickness of SiO$_2$ was used as the gate dielectric with a capacitance of 17 nF/cm^2. The source/drain regions were defined by a 130 nm thickness of Au through a shadow mask, and the channel length (L) and width (W) were 25 and 500 μm, respectively. Before gilding the devices, the clean substrates were immersed in anhydrous ODTS toluene solution and left to form a self-assembled monolayer for 6 h at room temperature under nitrogen. In the following, the ODTS-treated substrate was taken out from the solution, rinsed with toluene for several times, and baked at 100 °C for 30 min under ambient air. The ODTS-modified substrate was kept in a dry box before use. A polymer solution (5 mg/ml) in CHCl$_3$, DCB, or mix-solvents was first filtered through 0.45 μm syringe filters, spin-coated at a speed rate of 1000 rpm for 60 s onto the ODTS-modified substrate, and then annealed at 150 °C for 1 h under nitrogen. Output and transfer characteristics of the transistor devices were performed using a Keithley 4200 semiconductor parametric analyzer. All the electronic measurements were conducted at ambient atmosphere.

3.2. Fabrication and characterization of polymer photovoltaic cells

The bulk-heterojunction photovoltaic cell was fabricated through the following preparation procedures: The glass–indium tin oxide (ITO) substrate (obtained from Sanyo, Japan (8 Ω/□)) was first patterned by lithograph, then cleaned with detergent, and ultrasonicated in acetone and isopropyl alcohol, and subsequently dried on a hot plate at 120 °C for 5 min, and finally treated with oxygen plasma for 5 min. Poly(3,4-ethylenedioxy-thiophene):poly(styrene-sulfonate) (PEDOT:PSS, Baytron P VP AI4083) was passed through a 0.45 μm filter and then spin-coated at 3000 rpm on ITO in air and dried at 150 °C for 30 min inside the glove box. The thickness of the prepared PEDOT:PSS film was around 30 nm. The polymer/PCBM blend was prepared by dissolving them together in CHCl$_3$, DCB, or mix-solvents followed by spin-coating on the top of the PEDOT:PSS layer. The device was then annealed at 150 °C or 240 °C for 10 min in glove box. Subsequently, the device was coated with a 30 nm thickness of Ca and a 100 nm thickness of Al by thermal evaporation under high vacuum (<10^{-6} torr), respectively. The active area of the device is 4 mm^2.

The current–voltage (J–V) measurement of the polymer photovoltaic cell was conducted by a computer-controlled Keithley 2400 source measurement unit (SMU) with a Peccell solar simulator under the illumination of AM 1.5 G, 100 mW/cm^2. The illumination intensity was calibrated by a standard Si photodiode detector with KG-5 filter.

4. Result and discussion

4.1. Optical and electrochemical properties

Fig. 1(a, left) shows the UV–Vis absorption spectra of P3HT-b-P3PT and P3HT films cast from either CHCl$_3$ or DCB and annealed at 150 °C for 10 min under nitrogen. The absorption maximum (λ_{max}) of P3HT-b-P3PT prepared from DCB is around 554 nm with a shoulder peak around 604 nm while that from CHCl$_3$ is around 516 nm without a clear shoulder peak. The much higher λ_{max} of P3HT-b-P3PT processed from DCB than that from CHCl$_3$ suggests that the stronger π–π interchain interaction in the former. In comparison, the λ_{max} of pristine P3HT prepared from DCB is around 558 nm with a shoulder peak around 605 nm. The shoulder peak around 605 nm is generally assigned to the crystalline structure, resulting from strong intermolecular interaction [30–32]. The weight fraction of P3HT to P3PT in P3HT-b-P3PT is around 83%. Thus, the slightly higher intensity of the shoulder peak in the pristine P3HT of Fig. 1(a, left) than that of P3HT-b-P3PT is as expected since P3PT is an amorphous segment from our previous study [31]. In contrast, an opposite behavior was observed after annealing at 240 °C, which is above the melting point of P3HT as shown in Fig. 1(a, right). P3HT-b-P3PT could still maintain a more intense peak around 605 nm than pristine P3HT exhibiting a significant reduction of the crystalline peak It supports that the introduction of P3PT segments probably enhances the stability of the self-organized crystalline structure of P3HT segments.

The AFM images of the prepared polymer films on quartz could further provide a detailed characterization on the polymer surface structure. The amorphous-rich polymer domain structure of the film cast from CHCl$_3$ shown in Fig. 1b provides another evidence for the unclear shoulder peak of P3HT-b-P3PT in the optical absorption in Fig. 1(a, left). The volatile CHCl$_3$ solvent is rapidly evaporated during spin-coating and thus limits the crystalline structure formation of P3HT-b-P3PT. However, the P3HT-b-P3PT film cast from DCB followed by annealing at 150 °C shows elongated fiber-like structure (Fig. 1b), which is almost identical to the fiber structure of pristine P3HT as shown in Figure S2. It suggests the importance of the less volatile cast solvent for the formation of crystalline domains in conjugated polymer. The polymer domain structure changes from the fiber-like to the worm-like after annealing at the elevated temperature of 240 °C, which is correlated with the slightly weaken intensity of the shoulder peak around 605 nm in UV–Vis absorption compared to that annealed at 150 °C (Fig. 1(a, right)).

Fig. 2 shows the cyclic voltammagram (CV) of the P3HT-b-P3PT film in acetonitrile at a potential scanning rate of 0.1 V s^{-1}. The onset oxidation (E_{onset}^{ox}) and the estimated HOMO energy level are 0.55 V and −4.91 eV, respectively. The calculated optical band gap (E_g^{opt}) of P3HT-b-P3PT from the absorption spectrum (DCB) is about 1.91 eV. Hence, the
Fig. 1. (a) UV–Vis absorption spectra of P3HT on quartz processed from DCB and P3HT-*b*-P3PT (Diblock) film on quartz processed from CHCl₃, CHCl₃/DCB (ratio = 1:1), or DCB. The insert is the variation of UV–Vis absorption spectra of P3HT-*b*-P3PT film processed from DCB (annealed at 150 and 250 °C) and the P3HT film (annealed at 250 °C). (b) Their corresponding AFM phase images (scale: 1.5 μm × 1.5 μm) on quartz.

LUMO energy level estimated from the difference between the E_g^{opt} and HOMO energy level is −3.00 eV. The E_g^{opt}, HOMO, and LUMO of P3HT-*b*-P3PT are almost identical to those of regioregular P3HT (1.9, −5.1, and −3.2 eV, respectively) reported in the literature [37], but unlike some random polythiophene derivatives reported in the literatures [33].
Fig. 2. Cyclic voltammogram of P3HT-*b*-P3PT thin film on ITO glass at a scanning rate of 0.1 V s⁻¹ in 0.1 M TBAPF₆ solution.

4.2. Thin film transistor characteristics

The charge-transporting mobility of P3HT-*b*-P3PT was explored by the bottom-contact and bottom-gate field-effect transistor devices. Figs. 3 and 4 show the transfer and output characteristic curves of the P3HT-*b*-P3PT films on the ODTS-modified SiO₂ processed from different solvents of CHCl₃, CHCl₃/DCB (1:1 ratio), and DCB. As shown in the figures, P3HT-*b*-P3PT exhibits typical *p*-channel output characteristics (source–drain current (I_d) versus drain voltage (V_d) at different gate voltages (V_g)) when operated in the accumulation mode. In the saturation region ($V_d > V_g − V_t$), I_d can be described by Eq. (1) [38]:

$$I_d = \frac{WC_o\mu_h}{2L}(V_g - V_t)^2 \tag{1}$$

where μ_h is the field-effect hole mobility, W is the channel width, L is the channel length, C_o is the capacitance per unit area of the gate dielectric layer (SiO₂, 200 nm, C_o = 17 nF/cm²), and V_t is the threshold voltage, respectively. The saturation region field-effect mobility of the studied copolymer was thus calculated from the transfer characteristics of the FETs involving plotting $(I_d)^{1/2}$ versus V_g. The estimated hole mobilities of P3HT-*b*-P3PT from different solvents are listed as below: ∼6.0 × 10⁻³ (CHCl₃), ∼8.0 × 10⁻³ (CHCl₃/DCB = 1/1), and 2.0 × 10⁻² (DCB). The I_{on}/I_{off} ratios of the studied TFT devices are around
Fig. 3. Transfer characteristics of P3HT-*b*-P3PT device, in different processed solvents, with an ODTS-modified surface and anneal at 150 °C, where V_{ds} = −100 V.

$2.1–5.5 \times 10^4$ and V_t of −3.0 to −6.0 V, as summarized in Table 1. It suggests that the hole mobility increases by increasing the DCB content in the processing solvent. As discussed in the optical absorption spectra, the P3HT-*b*-P3PT processed from a CHCl$_3$ solution is largely amorphous while that from a DCB solution is mostly crystalline. It probably explains the above trend on the hole mobility with the processing solvent.

The surface structure of the P3HT-*b*-P3PT processed from different solvents may provide another insight to the above hole mobility. Fig. 5 shows the AFM images of P3HT-*b*-P3PT film on the ODTS-modified silicon surface processed from different solvents of CHCl$_3$, CHCl$_3$/DCB (1:1 ratio), and DCB. As shown in the figure, a continuous roundish phase is observed in the polymer film processed from the CHCl$_3$ or CHCl$_3$/DCB solution, but a web-like silk phase is exhibited in that processed from the DCB solution. Interestingly, the domain size of the roundish phase in polymer film decreases from 80 nm (CHCl$_3$) to 40 nm (CHCl$_3$/DCB). The various surface structures are probably resulted from the different volatility of CHCl$_3$ and DCB and the miscibility between the processed solvents and

polymer blocks. Apparently, the less volatile DCB could provide enough time to rearrange the polymer chains, forming the web-like structure. Such ordered structure is similar to the pristine P3HT nanostructure with the characteristics of planar π-stacked chains, an elongated domain, and less grain boundary as compared to the roundish structure [39], which enhances to stabilize the *p*-channel and allow higher hole mobility. The obtained hole mobility of P3HT-*b*-P3PT is similar to that of the commercial P3HT (around $\sim 2.0 \times 10^{-2}$ cm^2 V^{-1} S^{-1} with an on/off ratio of $\sim 2.00 \times 10^4$ and V_{th} of −5 to 5 V under the same preparation condition and device structure) and comparable to the values reported in the literature [40–42], despite the existence of 17 wt.% of the amorphous P3PT. The above results indicate that the all conjugated block copolythiophene, P3HT-*b*-P3PT, could have a tunable hole mobility through the processing solvent.

4.3. Photovoltaic cell characteristics

The BHJ solar cells based on the studied copolymer P3HT-*b*-P3PT were fabricated with a sandwich structure of ITO/PEDOT:PSS (30 nm)/polymer:PCBM/Ca (30 nm)/Al (100 nm). The *J*–*V* characteristics and the related parameter of polymer solar cells prepared from the blends of polymer:PCBM (1:0.5–1:2, *w/w*) are shown in Fig. 6 and summarized in Table 1. The P3HT-*b*-P3PT:PCBM film in the device was also processed from three different solvent systems of CHCl$_3$, CHCl$_3$/DCB (1:1 ratio), and DCB in order to investigate the relationship between morphology and solar cell performance [43].

As listed in Table 1, in the case of polymer:PCBM (1:1, *w/w*), the photovoltaic properties of the devices fabricated from CHCl$_3$ and CHCl$_3$/DCB (1:1 ratio) reveal the smaller short-circuit current (J_{sc}) and fill factor (*FF*) than the DCB fabricated devices. The power conversion efficiencies (PCE) of the photovoltaic cells are 1.88%, 2.13%, and 2.60%, for the cast solvents of CHCl$_3$, CHCl$_3$/DCB (1:1 ratio), and DCB, respectively. The poorer performance of the former two is significantly influenced by the surface structure besides the hole mobility trend discussed above. As seen from the Fig. 7a, the domain of the polymer:PCBM (1:1) blend film onto the device processed from CHCl$_3$ or
**Fig. 4.** Output characteristics of P3HT-*b*-P3PT device processed from (a) CHCl$_3$/DCB = 1:1 and (b) DCB.

[b] All devices are annealed at 150 °C for 10 min.
[c] The average value of power conversion efficiency is calculated from 4 pixels in the device.
[d] The ratio in bracket is the weight ratio of polymer to PCBM.
Fig. 5. Height (top) and phase (bottom) AFM images of the P3HT-*b*-P3PT films, in different processing solvents of (a) CHCl₃, (b) CHCl₃/DCB = 1:1, and (c) DCB, on ODTS-modified SiO₂ surface (The image sizes are 1.5 μm × 1.5 μm and the RMS is root mean square roughness.).

CHCl₃/DCB solution is composed of island-like structures and shows large phase separation, which causes the drop in J_{sc} and *FF*. In a sharp contrast, the DCB fabricated devices retain the orderly elongated fiber-like structure induced by P3HT-*b*-P3PT, except for the case of blend ratio, polymer:PCBM (1:2), as shown in Fig. 7b. The discrepancy in surface morphology is undoubtedly resulted from the processing solvents. DCB could provide sufficient time for the polymer to form ordered structures, then filled with PCBM, and therefore form a better microphase-separation. Besides, the P3PT segment is supposed to preferably dissolve PCBM due to the better miscibility than the crystalline P3HT segment when PCBM packs the fiber-like domain. Different ratios of PCBM/P3HT-*b*-P3PT from 0.5 to 2.0 were

investigated to address the effect on the polymer structure and PCE. Fig. 7b presents the phase images of these blend films, whose RMS are all around 1 nm. All blend films, PCBM/P3HT-*b*-P3PT, with the ratio under 1.0 preserve the order structure observed in pristine P3HT-*b*-P3PT. Among them, the polymer/PCBM (1:0.7, w/w) shows the best PCE of 2.80% higher than 2.60% of polymer/PCBM (1:1, w/w). The 17% amorphous P3PT probably affects the polymer surface structure and thus the optimal blend ratio is 1:0.7, which corresponds to the weight ratio of P3HT in the block to PCBM (1:0.84). As the PCBM ratio increase to 1:2, the dark region corresponding to PCBM-rich domains become larger and more aggregated than the other blend ratios, suggesting that the order domain formed by
Fig. 6. J–V characteristics of polymer solar cells with the structure of ITO/P3HT-b-P3PT:PCBM/Al under the illumination of AM 1.5G, 100 mW/cm^2. The ratio in bracket is the weight ratio of polymer to PCBM.

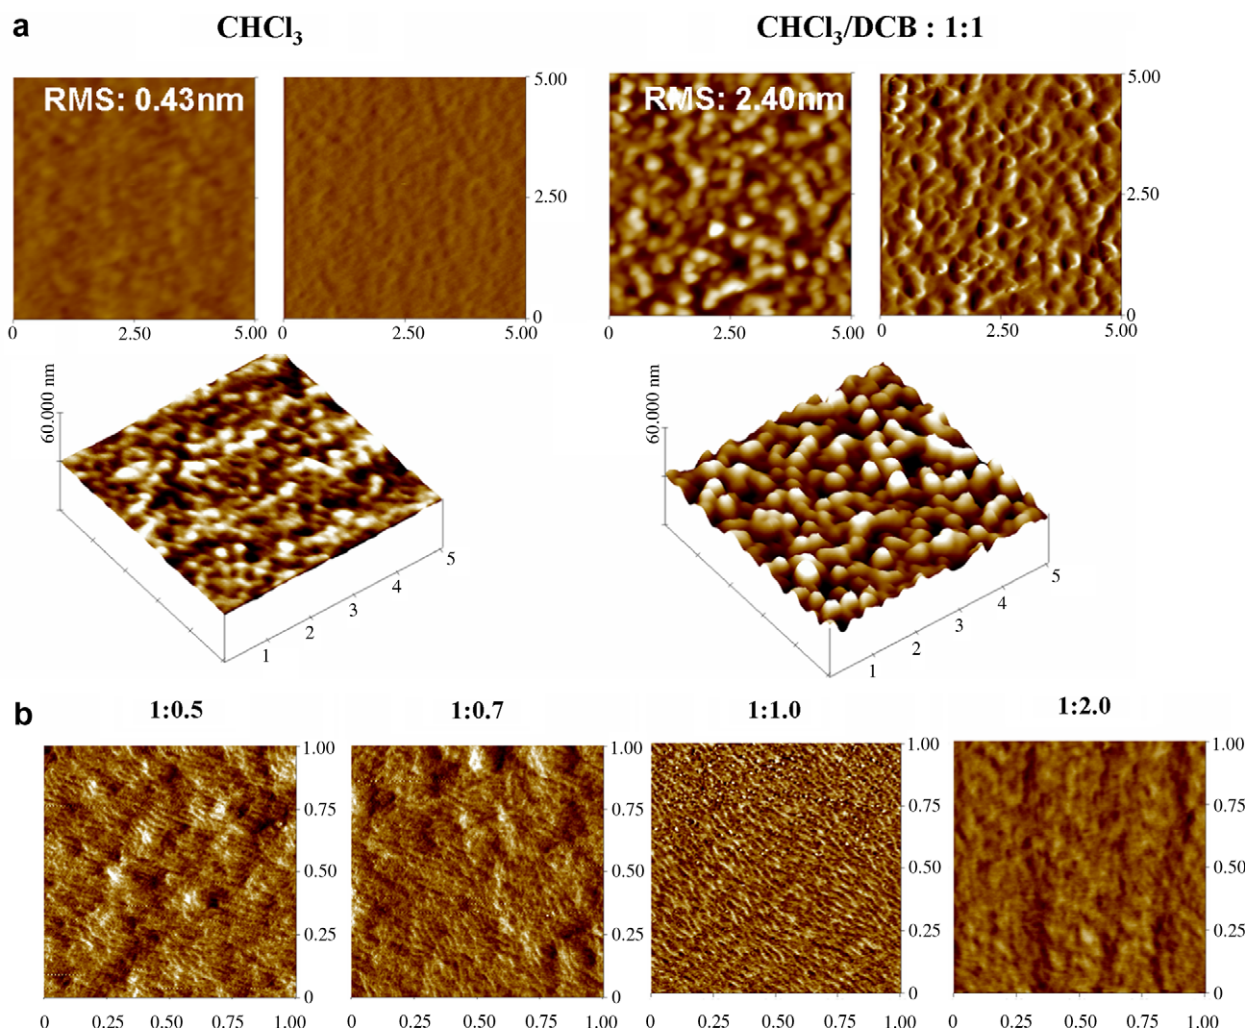
P3HT-b-P3PT was destroyed at the high blend ratio of PCBM. The J_{sc} dramatically decreases to 3.10 mA/cm^2 at such high PCBM blend ratio. Although the polymer/PCBM (1:0.5, w/w) shows an order domain, the PV performance is inferior to those from the blend ratios of 1:0.7 and 1:1. It could be ascribed to the unbalanced carrier transport and thus efficient electron separation is not obtained. Unfortunately, the highest PCE (2.80%) based the studied P3HT-b-P3PT/PCBM blend system is still lower than that (3.04%) of the commercial P3HT/PCBM (1:0.7, w/w) device under the same preparation conditions (J_{sc}: 8.60 mA/cm^2, V_{oc}: 0.61 V, and FF: 0.58). It is probably due to the lower absorption coefficient of the present blend system than that of P3HT/PCBM, as shown in Fig. 8. However, the present study did address the manipulation of photophysical properties, charge-transporting mobility and photovoltaic characteristics on such all-conjugated diblock copolymers.


Fig. 7. (a) Height (left), phase (right), and its 3D images (bottom) of the P3HT-b-P3PT/PCBM (1:1) blend film cast from CHCl$_3$ and CHCl$_3$/DCB = 1:1. The image sizes are all 5 μm × 5 μm and the Z range is 30 nm and 60°; (b) phase images of the P3HT-b-P3PT/ PCBM (1:0.5–1:2.0) blend film cast from DCB. The image sizes are all 1 μm × 1 μm and the Z range is 10°.

5. Conclusion

We have shown the manipulation on the surface structure and optoelectronic device applications of all-conjugated diblock copolythiophene, P3HT-*b*-P3PT, through different cast solvent mixtures. The optical absorption spectra showed the much enhanced intensity on the crystalline absorption peak from the DCB solution but not in the case of CHCl$_3$. The AFM images suggested that highly volatile CHCl$_3$ led to the amorphous-rich structure, while less volatile DCB resulted in the largely orderly fiber-like structure of the P3HT-*b*-P3PT. The FET hole mobility increased from $\sim 6.0 \times 10^{-3}$, $\sim 8.0 \times 10^{-3}$ to 2.0×10^{-2} cm^2 V^{-1} s^{-1} as the DCB content in the solvent mixture was raised. Such difference on the polymer structure and hole mobility also resulted in the variation on the power conversion efficiency (PCE) of the photovoltaic cells. The PCE of P3HT-*b*-P3PT /PCBM (1:1, w/w) based photovoltaic cells was 2.60% processed from the DCB solution was higher than 1.88% using CHCl$_3$. The PCE of polymer/PCBM was further improved to 2.80% at the 1:0.7 blend ratio of polymer to PCBM. The present study suggested that the photophysical properties, charge-transporting mobility and photovoltaic characteristics of all-conjugated diblock copolymers could be efficiently tuned by solvent polarity, block segment characteristic, and blend composition.

promote efficient exciton dissociation at donor/acceptor interfaces yet with bicontinuous networks to facilitate charge collection. The most efficient polymer blend solar cells utilise blends of a conjugated polymer with a methanofullerene derivate (6,6)-phenyl-C_{61}-butyric acid (PCBM) [7,8]. The ability of P3HT to form highly ordered, nanocrystal domains in blends with PCBM is cited as one of the reasons for the high efficient of the P3HT/fullerene system [9,10]. The structure and charge transport properties of polymer/fullerene blends have been well-studied [11–13], demonstrating efficient ambipolar charge transport [14] and the ability to form bicontinuous phases [10]. However, there are fewer reports in the literature of combined structure–transport studies of blends of two conjugated polymers [15–17]. Such investigations are of interest not only from an academic point of view, since polymer/polymer blends represent a distinct materials class to polymer/fullerene blends, but also from a technological point of view with all-polymer solar cells having the potential to contribute to development of organic photovoltaic technology. In particular, compared to polymer/fullerene blends, the use of two conjugated polymers in a polymer blend solar cell offers greater flexibility in materials design. This flexibility allows for tuning of the electronic properties of the materials (affecting the optical band gap and open circuit voltage amongst others [18]) and tailoring of the physical properties of the blend such as interfaces and phase separation [19].

Recently, we have demonstrated efficient photovoltaic operation from a blend of poly(3-hexylthiophene) (P3HT) with the polyfluorene co-polymer poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthien-5-yl)-2,1,3-benzothiadiazole]-2′,2″-diyl) (F8TBT) [20] (see Fig. 1 for chemical structures and energy level diagram). Power conversion efficiencies of nearly 2% were demonstrated for this blend, one of the highest for all-polymer solar cells [4]. The successful utilisation of the semicrystalline high-mobility P3HT in efficient all-polymer solar cells also represents an important development [20]. Understanding of the structure of P3HT in blends with F8TBT and its influence on hole transport is therefore important in furthering the

development of all-polymer solar cells. To this end, here we report a joint time-of-flight charge transport and X-ray diffraction study of P3HT/F8TBT blends.

2. Materials and methods

2.1. Materials, sample preparation and device fabrication

Regioregular P3HT was supplied by Merck with a molecular weight (M_w) of 52 kg mol^{-1}, polydispersity of 2.0 and a regioregularity of 95.6%. Regiorandom P3HT was supplied by Rieke Metals with a molecular weight of 90 kg mol^{-1} and polydispersity of 2.4. F8TBT and was supplied by Cambridge Display Technology Ltd. with molecular weight of 54 kg mol^{-1} and polydispersity of 2.4. The glass transition temperature of F8TBT is ~360–370 K [21]. Films for both time-of-flight and X-ray diffraction studies were prepared at the same time from the same solutions, by dissolving in anhydrous chloroform at 80 mg mL^{-1} and spin-coating in a nitrogen glovebox. Rotation speed was varied to obtain approximately the same film thickness. In particular, regioregular P3HT films were spin-coated at 1000 rpm to give a film thickness of 1.6 ± 0.2 μm, regiorandom P3HT films were spin-coated at 1000 rpm to give a film thickness of 1.8 ± 0.2 μm and F8TBT films were spin-coated at 2000 rpm to give a film thickness of 1.4 ± 0.1 μm. Blend films of regioregular P3HT and F8TBT were prepared by mixing equal volumes of 80 mg mL^{-1} P3HT and F8TBT solutions (1:1 weight ratio) and spin-coating at 1500 rpm to give a film thickness of 1.4 ± 0.1 μm. All film thicknesses were measured with a Dektak 6 M surface profilometer. To avoid unnecessary and repetitive clarification, any reference to P3HT will henceforth refer to regioregular P3HT unless specified. Films were annealed either in the glovebox on a hotplate for 10 min at temperatures of 373, 413 or 453 K with quenching to room temperature; or *in situ* in the X-ray diffractometer (see below). Films for X-ray diffraction study were spin-coated onto cleaned silicon substrates with a 100 nm thermally grown oxide. TOF devices were fabricated with an ITO/TiO$_2$/P3HT:F8TBT/Au architecture. TiO$_2$ (anatase) acts as a hole-blocking layer and was deposited by spray pyrolysis as follows. ITO-coated glass substrates were heated to 743 K and sprayed with the organic precursor di-iso-propoxy-titanium bis(acetylacetonate) (75 wt% in isopropanol, Aldrich) from ethanol (1:10 volume ratio). After 45 min drying on the hot plate, a thickness of 50 nm of TiO$_2$ was achieved. Au (20 nm) was deposited through vacuum evaporation in a chamber inside the glovebox at a pressure of 10^{-6} mbar. Devices were encapsulated in the glovebox before removal and testing.

2.2. Time-of-flight details

Time-of-flight (TOF) measurements were performed using a Nd:YVO4 Q-switched laser (AOT model YVO-25QSPX) with 500 ps pulse duration and wavelength of 532 nm near the absorption maximum of all polymers used [22]. Voltage was supplied by a battery array (9–72 V) with current recorded using a high speed current amplifier (Femto DHPCA-100) and an oscilloscope (Agilent

5.37 eV

DSO6052A). Pulse energies of less than 10 nJ/pulse were used, with the beam defocused to cover the active area of the device (4.5 mm^2). To avoid possible space-charge or recombination effects, the laser intensity was limited such that the collected charge was less than 10% of the capacitor charge. Transit times were estimated from the intersection of asymptotes fitted to the pre- and post-knee regions on a log–log plot of current vs. time as is standard for analysis of dispersive current transients [23]. Due to the high extinction coefficient of both polymers, the majority of light is absorbed within the first 100 nm of the film [24]. Mobility was calculated as $\mu = d/(Et_{tr})$ where d is the thickness of the film, E is the electric field strength and t_{tr} the transit time.

### 2.3. X-ray diffraction details

X-ray diffraction (XRD) experiments have been performed on a Bruker D8 Discover diffractometer using radiation from a copper sealed tube. On the primary side polycapillary optics with a divergence of 0.3° and a 0.6 mm slit were used. On the secondary side conventional slit optics in combination with a graphite monochromator were mounted in front of a scintillation counter. A domed heating stage supplied by Anton Paar Ltd. [25] was used as a protective sample stage as well as for *in situ* annealing of samples *in vacuo*. Annealing in the diffractometer was performed with a ramp of 30 K/min to the anneal temperature where the temperature was held for 10 min followed by a slow cooling back to room temperature. One sample of the blend material was annealed between 373 and 453 K in subsequent steps of 20 K for 10 min at each temperature. In a final step the blend sample was annealed at 453 K for 1 hr. As a reference, one pure P3HT film was annealed at 413 K and 453 K in subsequent steps as above. All XRD measurements were performed at room temperature and in vacuum using a graphite dome to minimize degradation due to X-ray and UV radiation. Careful alignment of the sample has been performed in the primary beam to exclude misalignment errors in the experimental results.

The interplanar distances (d-values) were determined using Bragg's formula taking the 2θ-position of the experimentally observed diffraction peaks. In case of P3HT two different methods were applied (i) using the single 2θ-position of the 100 reflection and (ii) using all three diffraction peaks and correcting them towards misalignment errors. No significant difference could be observed between these two methods. Therefore, the interplanar distances of the different samples were obtained by using only the 100 diffraction peaks in order to apply the same procedure also to the blend samples where the higher order peaks were weaker. Crystal size determination was performed by using the integral peak width of the individual 100 diffraction peaks by using the Scherrer equation.

3. Results

3.1. Time-of-flight measurements

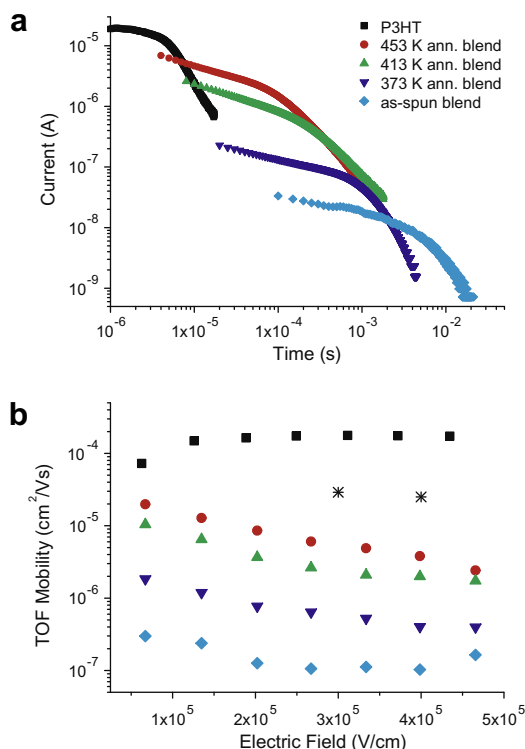
Fig. 2a presents representative time-of-flight transients of P3HT/F8TBT blends annealed at different temperatures


Fig. 2. (a) Time-of-flight (TOF) hole transients in P3HT/F8TBT blends and unblended P3HT. Squares represent the unblended P3HT hole transient, while diamonds represent the as-spun blend film, inverted triangles the 373 K annealed blend, triangles the 413 K annealed blend and circles the 453 K annealed blend. (b) Electric field dependence of the TOF mobility for as-spun and annealed P3HT/F8TBT blends and unblended P3HT using the same symbol key as for part (a) Also included are TOF mobilities measured for regiorandom P3HT (asterisks).

compared with that of an unblended P3HT film (unannealed). The transients in Fig. 2a were measured at an electric field strength of 2.7×10^5 V cm^{-1} for blends and 2.4×10^5 V cm^{-1} for the P3HT film. Fig. 2a shows a systematic decrease in the transit time with increasing annealing temperature for the blend films. In particular, the transit time improves from ~5 ms (diamonds) to 100 μs (circles) when the as-spun film is annealed at 453 K. The transit for the highest annealing temperature still lags that of the unblended P3HT, ~5 μs (squares). Fig. 2b plots the calculated TOF mobility of blended and unblended films as a function of electric field strength. The change in transit time of 5 ms–100 μs corresponds to an increase in TOF mobility of nearly two orders of magnitude from ~8×10^{-8} to 6×10^{-6} cm^2 V^{-1} s^{-1}. The TOF mobility of the 453 K annealed blend is still over an order of magnitude less than that of the unblended P3HT film that has a TOF mobility of ~2×10^{-4} cm^2 V^{-1} s^{-1}, similar to values measured previously [23]. Examining the electric-field dependence of mobility, Fig. 2b, the blends in general exhibit a pronounced negative field dependence, compared to a relatively flat electric-field dependence of the hole mobility of unblended P3HT. The observation of a strong negative electric-field dependence in the blends compared to the unblended material may be attributed to the higher

degree of spatial disorder in the blend [26]. For comparison, we also present the TOF mobilities measured on films of regiorandom P3HT (asterisks in Fig. 2b). Despite having an amorphous film structure, the regiorandom P3HT film has a time-of-flight mobility only an order of magnitude lower than that of the regioregular film, and significantly higher than that of the 453 K annealed P3HT:F8TBT blend. This demonstrates that the lower TOF mobilities of the blend compared to the pure P3HT are related to the film microstructure and not simply the result of P3HT disorder.

We have also investigated the influence of annealing on the unblended regioregular P3HT films, Fig. 3, taken at an electric field strength of 2.4×10^{-5} cm^2 V^{-1} s^{-1}. A systematic decrease in transit time is also seen with increasing annealing temperature, however the change in the TOF mobility is more modest, increasing from 1.7×10^{-4} cm^2 V^{-1} s^{-1} for the unannealed film to $\sim 3.0 \times 10^{-4}$ cm^2 V^{-1} s^{-1} for the 453 K annealed film. Our observation of a large change in the P3HT hole mobility in the blend with annealing, but only a modest change in mobility in the pure P3HT film with annealing, is similar to previous observations for P3HT blended with the methanofullerene PCBM [9].

3.2. X-ray diffraction results

Specular X-ray diffraction experiments on the as-spun P3HT film show well pronounced 100, 200 and 300 diffraction peaks of the crystalline state without observation of an amorphous scattering contribution (Fig. 4). Annealing of the P3HT film at 413 and at 453 K induces an enhancement of the diffraction peaks in intensity together with peak narrowing. Additionally an increase in the interplanar distances is observed, consistent with previous observations [27,28]. We obtain a shift in the d-value from 1.662 nm for the as-prepared sample to 1.667 nm for the same sample after annealing at 453 K (circles in Fig. 5). We note that there is a large variation in the reported d-values of P3HT in the literature [29], but our observations are consistent with reports on similar molecular weight materials measured by Yang et al. [30] and Kline et al. [28]. The F8TBT diffraction pattern shows an amorphous

Fig. 4. Specular X-ray diffraction curves of 453 K annealed and as-spun P3HT/F8TBT films (top two curves), and P3HT films (next two curves) and of an as-spun F8TBT film (bottom curve). The curves have been shifted for clarity.

halo at around $2\theta = 21°$ which does not change after annealing. For the blend, in the as-spun state only the 100 P3HT reflection is observed together with the amorphous diffraction feature characteristic of F8TBT with a possible contribution from disordered P3HT.

Annealing of the blend leads to a more pronounced 100 diffraction peak and the emergence of second and third order peaks. In general we find a larger d-spacing for P3HT in blends compared to that measured for pure films. Furthermore, with annealing we see a general trend of decreasing d-spacing with annealing, opposite to the trend observed for pure P3HT films. Specifically, for blend samples that were annealed separately in a nitrogen atmosphere at different temperatures, the P3HT d-spacing is observed to decrease from 1.677 nm for the as-spun film to 1.668 nm for the 453 K annealed film (triangles in Fig. 5). For the case of *in situ* annealing of the same sample in the X-ray diffractometer, the d-spacing was observed to remain rather constant up to 453 K (squares in Fig. 5), but extended annealing at 453 K (for one hour) resulted in a drastic decrease of the d-value to 1.673 nm, as indicated by an arrow in Fig. 5. The differences in the trends for the two blend

Fig. 3. Change in the dynamics of TOF hole transients of unblended P3HT with annealing.

Fig. 5. The upper panel shows changes in the interplanar distances of the 100 plane with annealing for blends and unblended P3HT. The lower panel shows the effect of annealing on the integral breadth of the 100 reflection as a function of annealing temperature. The right hand axis in the lower panel displays the corresponding crystallite size calculated using the Scherrer equation.

sample sets likely arise from the different annealing procedures, with the *in situ* annealed samples gradually cooled to room temperature rather than quenched. It is interesting to note that in all cases, with annealing there appears to be a convergence of the *d*-spacing to a value of ~1.668 nm.

For all samples, with annealing there is a significant narrowing of the 100 peak width consistent with an increase in P3HT crystallite size (lower panel in Fig. 5). As calculated using the Scherrer equation, the mean P3HT crystallite size in the unblended film increases from 3.7 nm in the as-spun state to 6.2 nm in the sample annealed at 453 K. The crystallite size in the blend increases from 3.3 nm in the as-spun film, to 3.8 nm with annealing at 373 K, to 5.0 nm with annealing at 413 K (average of two samples) and to 6.0 nm with annealing at 453 K, close to the value for 453 K annealed P3HT. The increase of the crystal size is slightly larger in case of the blends, which can be seen from the steeper negative slope of the integral breadth above 373 K (Fig. 5).

4. Discussion

The experimental results reveal that the 1:1 blends of P3HT and F8TBT show a phase separation in two components with a crystalline part and an amorphous part. Within the X-ray diffraction pattern of the as-prepared sample the presence of a crystalline component is deduced from the presence of the diffraction peak at a *d*-value of 1.677 nm, while the amorphous part is clearly evident from the amorphous halo at around $2\theta = 21°$. Since the *d*-value of the crystalline part is close to the P3HT value, it can be attributed to P3HT crystallites. However, this crystalline part cannot be formed only from pure P3HT, since the experimentally observed *d*-values as well as the relative intensities between the reflections are noticeably different. These two experimental observations reveal that the P3HT crystals in the blend are distorted. Since spin-coating is a non-equilibrium process, the packing of P3HT in the blend may be affected by solvent molecules or F8TBT molecules enclosed as impurities in the P3HT crystals. A recent report has also observed an increase in the *d*-spacing of the polythiophene poly(2,5-bis(3-tetradecyl-thiophen-2-yl)thieno[3,2-b]thiophene) (pBTTT) when blended with PCBM attributed to the intercalation of PCBM between the side-chains of pBTTT [31]. In contrast, blends of PCBM with P3HT show no change in the *d*-spacing of P3HT [8,32] as the side-chains in P3HT are too dense to allow intercalation of the bulky PCBM [31].

Annealing of the polymer blends leads to a gradual approach of the *d*-values of the crystalline part of the blend to that of pure P3HT. Since remaining solvent molecules within spin-coated films are evaporated at annealing temperatures well below 373 K [33], it can be inferred that the P3HT crystallites are distorted by the presence of F8TBT polymer chains. This distortion could be either a direct incorporation of F8TBT polymer chains into P3HT crystals or the intermixing of the side-chains from both types of polymers. With increasing annealing temperature the two *d*-values of blend and pure P3HT come closer which

reveals that the influence of F8TBT on P3HT packing decreases. The increasing crystallite size from 3.3 nm in the as-prepared state to 6.2 nm in the sample annealed at 453 K is a clear marker that a major re-arrangement happens during the annealing process. Such a re-arrangement would allow a reduction in the influence of F8TBT impurities on the packing of crystalline P3HT, evolving to a packing comparable to pure P3HT. We conclude that the final state of the blend consists of separated regions of amorphous F8TBT and crystalline P3HT containing only a negligible amount of F8TBT molecules as impurities.

We now turn to explain the trends in the TOF data in terms of the observed microstructure. Curiously, both unblended P3HT and P3HT/F8TBT blend films were found to have similar crystallite sizes as a function of annealing temperature. Thus the large discrepancy in general between the TOF mobilities of blended and unblended P3HT cannot be explained by differences in the size of P3HT crystallites alone. Similarly, the vast improvement in the mobility of P3HT/F8TBT films (nearly two orders of magnitude) cannot be explained in terms of variations in P3HT crystallite size in annealed blends, as only a modest change in mobility is observed in unblended P3HT for a similar change in crystallite size. As discussed in Section 3.1 where we noted the moderate TOF mobility of regiorandom P3HT films, differences in the overall degree of crystallinity of P3HT also cannot explain the orders of magnitude improvement in hole mobility in the blend with annealing. We therefore seek to explain the observed trends in terms of P3HT packing distortions and film morphology as follows.

Firstly from the X-ray diffraction measurements there is strong evidence for the presence of F8TBT chains in P3HT crystallites in as-spun and mildly annealed P3HT/F8TBT films. These F8TBT chains that are incorporated inside P3HT crystallites represent defects that may act as scattering or trapping sites for holes, impeding charge transport [34]. (We note however, that since F8TBT has a deeper HOMO, 5.37 eV, compared to P3HT, 4.9 eV, F8TBT is unlikely to act as a hole trap in itself.) Secondly, the physical structure of the blend will adversely affect hole transport particularly if P3HT crystallites are isolated due to an enclosing F8TBT phase. The observation of a strong negative electric-field dependence in the blends absent in pristine P3HT supports this assertion, with a negative electric-field dependence attributed to spatial disorder [26]. While we are unable to directly determine the crystallite content from the XRD measurements, recent photophysical studies estimate the crystallite content of unblended P3HT at 40–50% [35]. Thus in a blend with another polymer the crystallite content will be further diluted, with crystallite percolation pathways more likely in annealed films with larger crystallites than in unannealed films with smaller crystallites. Similar percolation thresholds have been observed for electron transport in blends of conjugated polymers with fullerene derivatives [14]. Given the amorphous nature of F8TBT and the propensity of P3HT to form isolated fibrils [13], it is indeed likely that the bulk morphology of the film will favour isolated P3HT domains surrounded by a continuous F8TBT phase, particularly at low anneal temperatures. Furthermore, the measured

P3HT crystallite size does not necessarily represent the P3HT aggregate size, and films annealed at higher temperatures (and/or for longer times) will therefore have the opportunity for P3HT crystallites to move and aggregate. Fig. 6 schematically presents the proposed structures of as-spun and annealed P3HT and P3HT/F8TBT films. For the case of unblended P3HT, annealing serves to increase the crystallite size, improving charge transport through a reduction in the number of inter-domain hops. However, in both unannealed and annealed P3HT films there is relatively good interconnectivity between domains with only a modest increase in mobility. For the case of uannealed P3HT/F8TBT, it is proposed that the distorted P3HT crystallites are surrounded by a continuous F8TBT phase that inhibits inter-domain hops. Hole transport relies either on inefficient inter-domain hopping possibly mediated by disordered P3HT chains that may exist as a minority component in the F8TBT phase. In contrast, in annealed P3HT/F8TBT films the crystallites have a chance to aggregate as they grow establishing interconnected percolation pathways. It is this change from isolated to interconnected domains that then accounts for the order of magnitude increase in hole mobility in the blend with annealing.

These measurements also have implications for understand photovoltaic device performance. It is found that an annealing temperature of 413 K is required for an optimum photovoltaic performance [22]. The results here show that at this annealing temperature the film is still in an intermediate state of phase separation and purity of P3HT crystallites. Furthermore, the charge transport mobility of the P3HT phase still lags that of 453 K annealed

films that demonstrate inferior device performance [36]. Therefore it appears that it is not bulk charge transport that is primarily determining the efficiency of P3HT/F8TBT blends in solar cell devices, but rather the intermediate state of phase separation that exists in 413 K annealed films balances the two processes of charge generation (exciton diffusion and dissociation and donor/acceptor interfaces [36,37]) and charge separation (separation of bound electron–hole pairs from the donor/acceptor interface [38]). Also of interest, particularly for photovoltaic operation, is the influence of film microstructure and morphology on electron transport. However, the transport of electrons in P3HT/F8TBT blends is adversely affected by trapping effects making the observation of clean TOF transients difficult [39] and beyond the scope of this study. Curiously the intercalation of F8TBT chains in P3HT crystallites may represent a microstructural origin for electron trapping in these blends and further research is planned to investigate this.

5. Conclusions

We have measured the charge transport properties and microstructure of P3HT/F8TBT blends. The X-ray diffraction results reveal that P3HT/F8TBT blends show a phase separation of the two components with a crystalline part attributed to P3HT and an amorphous part attributed to F8TBT. In as-spun and mildly annealed blends, the measured d-values and relative intensities between the P3HT reflections are noticeably different to unblended P3HT indicating an incorporation of F8TBT in P3HT crystallites that distorts the crystal structure. At higher anneal temperatures the blend d-values approach that of unblended P3HT suggesting a well separated blend with almost pure P3HT crystallites. We explain the increase in hole mobility in the blend with annealing in terms of an increase in the P3HT crystallite purity and the aggregation of P3HT crystals to form percolation pathways.

grown by chemical vapor deposition (CVD) found a SWCNT/pentacene contact resistance as low as 30 kΩ cm ($V_G = -50$ V) [18]. However, the CVD method is expensive and laborious, so solution-phase preparation of CNT films is more desirable for applications. Solution-processed CNTs have also been found to make good contact to poly(3,3'''-didodecylquarterthiophene) [19], but it is not clear that this result could be expanded to pentacene, where contact resistance in bottom-contacted devices is more problematic. Here, we demonstrate transparent films of commercially-available SWCNTs produced by airbrushing from aqueous solution as electrodes for pentacene and poly-3-hexylthiophene (P3HT) thin-film transistors (TFTs). Airbrushing CNT thin films is an additive process that allows quick, large area patterning over any substrate and is compatible with ink-jet printing. CNT films deposited by spraying have been found to be rougher but exhibit similar sheet resistance for a given transparency as most other methods [14]. The channel-length-dependent output characteristics of the SWCNT-contacted TFTs on SiO_2/Si substrates are used to extract the mobility μ (0.093 cm^2/Vs for pentacene, 0.014 cm^2/Vs for P3HT) and contact resistivity. In the case of pentacene, we demonstrate that solution-processed SWCNT bottom-contact electrodes make moderately low-resistance (as low as 30 kΩ cm) contacts, which extends previous results for pentacene contacted by CVD-grown SWCNTs [20] to this much more easily processed material. For P3HT, we verify low contact resistance (<50 kΩ cm) bottom-contact to solution-processed SWCNTs, similar to previous results for poly(3,3'''-didodecylquarterthiophene) [19]. We also demonstrate the use of solution-processed films of SWCNTs as source, drain, and gate electrodes to fabricate flexible, transparent SWCNT-contacted pentacene TFTs on plastic polyethylene terepthalate (PET) substrates.

2. Materials and methods

SWCNT films were prepared as follows. A dispersion of 1 mg/mL SWCNTs ("P3", carbon solutions) in 1% by wt. sodium dodecyl sulfate (SDS) and water was exfoliated by sonication for 90 min followed by differential centrifugation at 12,000 rpm for one hour to remove carbonaceous impurities [4]. The top 2/3 of the supernatant was extracted and used as the airbrush feedstock. The source/drain (S/D) electrodes of the test devices were made by using an airbrush (Aztek A470 airbrush kit) to deposit a 30–40 nm thick film onto a 500 nm-SiO_2/n^{++}–Si platform at a temperature of 165 °C. The deposited films are then soaked in water for one hour to remove surfactant, and dried with a N_2 gun. The SWCNT film was patterned using photolithography and O_2 reactive ion etching. In order to determine the organic–SWCNT contact resistance, a set of devices of varying gate length L from 3 to 1262 μm was fabricated; the channel width W is 1.6–2.0 mm. The optical transparency of the carbon nanotube thin-film T was obtained from the ratio of the measured transparency of CNT-coated PET, prepared by airbrushing directly onto PET, to that of the PET substrate prior to nanotube coating.

Pentacene films were deposited onto the prepared electrodes in vacuum (<2 × 10^{-7} torr) by evaporation through

a shadow mask to form the active area of the TFT. P3HT transistors were fabricated on the prepared electrodes by first vapor coating the SiO_2 substrate with hexamethyldisilazane and then spin casting P3HT at 1250–2000 rpm from trichlorobenzene heated to 100 °C at a concentration of 10 mg/mL followed by a vacuum bake at 100 °C for one hour [21]. The doped Si substrate acts as a back-gate electrode. All electrical characterization was done in a N_2 atmosphere in the dark to prevent unintentional doping during the measurements.

3. Results and discussion

3.1. Carbon nanotube thin films as transparent electrodes

Fig. 1 shows the optical transparency T of the airbrushed CNT films as a function of film sheet resistance. The airbrushed films have a sheet resistance as low as 1 kΩ/sq. for T = 80%, and 5 kΩ/sq. for T = 90%, compared with 0.0278 kΩ/sq. @ 80%T for ITO coated glass [22]. The method of dispersing SWCNTs and subsequently spraying them to form a thin-film has been reported by several groups [12–14]. The T vs. sheet resistance behavior is in agreement with a model proposed by Hu et al. [23] which predicts.

$$\%T = \frac{100}{\left(1 + \frac{2\pi}{cR_\square} \frac{\sigma_{ac}}{\sigma_{dc}}\right)^2} \qquad (1)$$

where $R_\square$ is the sheet resistance, σ_{ac} is the optical conductivity, σ_{dc} is the dc conductivity, and c is the speed of light; a fit to Eq. (1) is shown in Fig. 1. The only free parameter used is the ratio of σ_{ac} to σ_{dc}; we find that a ratio of 0.74 +/− 0.03 gives the best fit to the data. This value is slightly smaller than the value of 1 obtained by Hu et al. [23].

3.2. Pentacene and P3HT transistors with carbon nanotube electrodes

Scanning electron microscopy was performed on the pentacene/SWCNT TFTs after electrical measurement of

Fig. 1. The percent transparency at a wavelength of 550 nm vs. sheet resistance of airbrushed carbon nanotube films and fit using Eq. (1).

the transistors. Parts of one of the pentacene/SWCNT TFT are shown in Fig. 2a and Fig. 2b (a closeup) illustrating the morphology of the pentacene layer on both the bare SiO$_2$ as well as the CNT film. The pentacene on the bare SiO$_2$ forms $\sim$250 nm grains separated by relatively thin grain boundaries whereas the pentacene on the CNT film forms a discontinuous film of rod-like grains. The crystal structure of these grains is unknown at this time and is the subject of further investigation.

Fig. 3a and b show output characteristics for example pentacene/SWCNT and P3HT/SWCNT TFTs, respectively. The resistance R of each device was found as a function of L and gate voltage V_G from the slope of drain current vs. drain voltage $I(V_D)$ for -1 V $< V_D < 1$ V. A threshold voltage V_T was extracted from the conductance vs. V_G plot for each channel length; this allowed us to compare measurements performed at the same effective gate voltage $V_G^* = V_G - V_T$, correcting for any possible length-dependent threshold shift [24].

Fig. 4a and b show R vs. L at various values of V_G^* for the pentacene/SWCNT and P3HT/SWCNT TFTs respectively. R vs. L obeys a linear relationship $R(L, V_G^*) = \alpha(V_G^*)L + R_c(V_G^*)$. The intrinsic field-effect mobility may be found from α [25]:

$$\mu_{FE}(V_G^*) = \frac{1}{WC_{ox}} \frac{\partial(\alpha^{-1})}{\partial V_G^*}. \qquad (2)$$

The contact resistivity is defined to be $\rho_c = R_c W$, where W is the channel width. For pentacene/SWNCT devices, ρ_c is finite and gate voltage dependent, saturating at <30 kΩ cm for $V_G^* < -40$ V. Values for the contact resistance using Au bottom-contacts vary from 20 to 110 kΩ cm depending on the gate voltage applied, the work function and conductivity of the injecting electrode, the temperature of the substrate during deposition and the thickness of the pentacene layer [26,27]. Au top contacts exhibit contact resistances an order of magnitude smaller [27]. In our devices, the intrinsic mobility is 0.093 cm^2/Vs. On/off current ratios ($V_D = -60$ V, -60 V $\leqslant V_G \leqslant 60$ V) were >10^6. For P3HT/SWCNT devices, ρ_c is less than 50 kΩ cm at all gate voltages in the ON state, higher than control devices fabricated with Au bottom-

contacts whose ρ_c is 1–10 kΩ cm [25,28]. Intrinsic field-effect mobility was as high as 0.014 cm^2/Vs. On/Off current ratios >10^5 ($V_D = -60$ V, -60 V $\leqslant V_G \leqslant 50$ V) were obtained for P3HT/SWCNT devices.

The bottom-contact resistance obtained with Au deposited on a relatively thin Cr or Ti wetting layer as is typically used to make bottom-contacts is higher than that for Au top contacts, and shows non-linear $I(V_D)$ characteristics, attributed to the presence of an injection barrier [29] or disruption of the pentacene morphology at the interface of the bottom-contacts [30]. Thus our observation that bottom-contact SWCNT electrodes offer slightly lower contact resistance to pentacene might either be due to narrowing of the injection barrier due to the high electric field at the SWCNT ends [31], or by allowing better ordering of the pentacene on SiO$_2$ at the electrode interface. Given the close packing of SWCNTs in our thick (30–40 nm) SWCNT film, and the thick (500 nm) gate dielectric, we consider electric-field enhancement unlikely. We propose that SWCNT electrodes allow more favorable growth of pentacene on the neighboring SiO$_2$ substrate, or that the morphology of pentacene on the SWCNTs themselves does not give rise to a significant injection barrier. In the case of P3HT, SWCNT contacts show a contact resistance similar to that obtained with Au [25,32,33].

3.3. Demonstration of transparent organic thin-film transistors

Finally, we show that solution-processed SWCNT electrodes can be used to fabricate an all-carbon transparent, flexible TFT in which SWCNT films are used as the source, drain, and gate electrodes, and pentacene as the semiconductor. Cao et al. demonstrated a SWCNT-contacted pentacene thin-film transistor (TFT) on a plastic substrate using SWCNTs grown by chemical vapor deposition (CVD) and patterned by photolithography [33]. Here, SWCNT gate electrodes were airbrushed through a shadow mask onto PET (Dupont Teijin™ Melinex 454/700; thickness 170 $\sim$ μm). The SWCNT gate had a sheet resistance of 3.1 kΩ/sq and a transparency of >91% that was interpolated from the sheet resistance vs. transparency fit using Eq. (1).

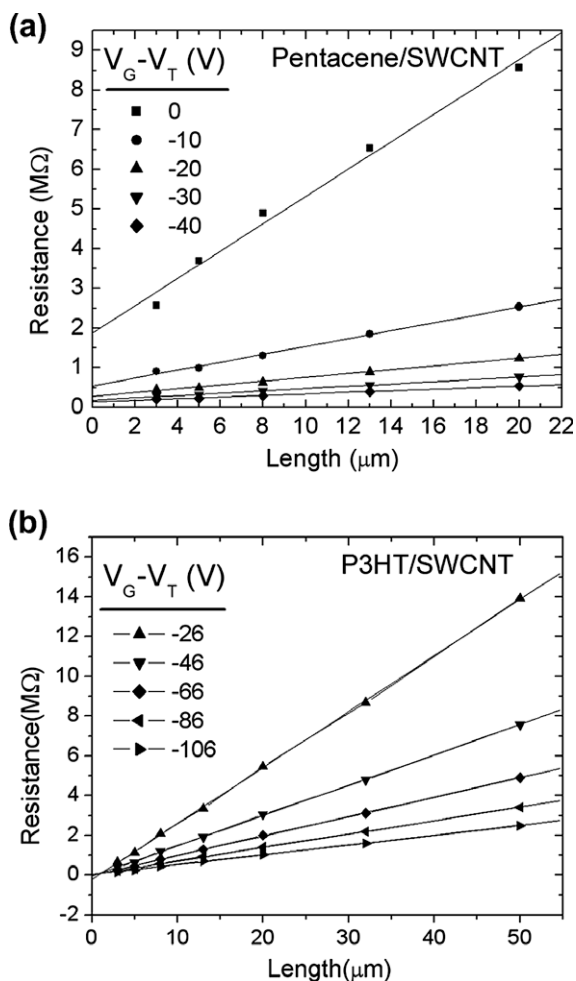

Fig. 4. (a) Resistance vs. channel length for effective gate voltages $V_G - V_T = 0$–60 V in 10 V steps for carbon nanotube film-contacted pentacene transistors and (b) carbon nanotubes film-contacted P3HT transistors with. $V_G - V_T = -26$ to -106 in 20 V steps.

To facilitate probing the CNT layer, a 100 nm Au layer was deposited onto the four sides of the CNT gate electrode. The dielectric layer was applied in two steps. In the first step, a 1 μm thick layer of PMMA was spun cast onto a transfer substrate and printed onto the device substrate at 500 psi and $T = 170 \, °C$ for three minutes [34]. In the second step, SWCNT source and drain electrodes (sheet resistance of 1 kΩ/sq and $T > 78\%$) were patterned on a SiO_2/Si transfer substrate following the scheme outlined above, coated with 50 nm of alumina (electron beam evaporation at 2×10^{-6} torr) followed by a 1 μm thick spin coated layer of PMMA and then printed onto the device substrate. The alumina layer served to minimize the leakage current from the source and drain electrodes to the gate. The capacitance of the resulting gate dielectric is estimated to be 1.33 nF/cm². Finally, 30 nm thick pentacene was evaporated through a shadow mask as described earlier to complete the devices. Devices had a channel width of 97–98 μm and channel length from 37 to 47 μm.

Fig. 5a shows a micrograph of the completed device. The single cross-shaped CNT film acts as a common gate for all four transistors. Silver paint was applied to the ends of two of the gate contacts to facilitate repeated probing of the CNT film. Fig. 5b shows the output characteristics of the device. The field-effect mobility obtained for these devices (uncorrected for contact resistance) was as high as 0.06 cm²/Vs with an average of 0.04 cm²/Vs, assuming a dielectric constant for PMMA of 3.6. As fabricated, the devices exhibited $V_T > 60$ V, so the on/off current ratio could not be accurately determined. After aging the devices for several months in an inert environment (<0.1 ppm moisture content) the threshold voltages shifted to between −10 and −20 V indicating diffusion of dopants out of the device over time. The on/off current ratios for the aged devices ranged from 10^3 to 10^4 ($V_D = -60$ V, -60 V $\leqslant V_G \leqslant$ 60 V), and the saturation mobility values decreased by 10–15%. The low on/off current ratios compared to devices on SiO_2 are likely due to the more than four times lower gate capacitance as well as possibly charge trapping at

Fig. 5. (a) Optical micrograph of four transparent, flexible carbon nanotube film-contacted pentacene thin-film transistors (TFTs) on polyethylene terepthalate) (PET) substrate. (b) Output characteristics for one of the TFTs pictured in (a).

the pentacene/Al_2O_3 interface which prevent the off state from being reached.

4. Conclusion

In conclusion, we have used airbrushed SWCNT films with sheet resistance below 1 kΩ/sq at $T = 80\%$ as electrodes to make bottom-contact pentacene transistors with contact resistance as low as 26 kΩ cm, lower than typically achievable with Au/Cr bottom-electrodes, and comparable to results achievable with CVD-grown CNTs. If we assume that the organic/CNT contact resistance is inversely proportional to mobility [25] even lower contact resistance should be possible with organic films optimized for higher mobility. The low contact resistance between the pentacene and CNT film is surprising given the significant differences in morphology observed for pentacene deposited on SiO_2 vs. CNTs (see Fig. 2). Solution-processed SWCNT films also make bottom-contact electrodes to P3HT with contact resistance comparable to that of Au. We have also demonstrated that solution-processed electrodes can be patterned onto a flexible plastic substrate both directly (gate electrode with transparency >91%) and via transfer printing (source–drain electrode), as components of a Pn TFT (with >78% transparency) using a relatively transparent PMMA/Al_2O_3 dielectric and PET substrate with a transparency of 80–90%.

mercial product that has been widely used as a hole injecting and transporting material [8–10] due to its electronic, optical and film forming properties [11–13]. Significantly, optical quality PEDOT:PSS thin films can be readily deposited on various substrates by solution processing techniques, such as spin-coating, inkjet printing, and roll-to-roll printing. [8–16].

Substantial efforts have been dedicated to develop PEDOT:PSS films with high electrical conductivity. One of the primary motivations has been that low conductivity leads to lower PLEDs performance since the average electric filed across the device is decreased and Joule heating can lead to a decrease in operational lifetime [15,16]. However, high-conductivity is necessary when PEDOT:PSS films are used as the anode itself [15,17,18]. Atop ITO, PEDOT:PSS functions as a buffer layer to remedy electrical shorts and stabilize the work function. Under these conditions it is the out-of-plane resistance that contributes more significantly to the device resistance.

In this communication, we demonstrate that low conductivity PEDOT:PSS in combination with a novel high-conductivity, glycerol-modified PEDOT:PSS layer can be used to fabricate phosphorescent PLEDs with high luminous efficiency (LE), power efficiency (PE) and external quantum efficiency (EQE). This manuscript is organized as follows. The difference in PLEDs performance as function of different commercially available PEDOT:PSS formulations are provided first as a baseline measure. Subsequently, we show that the addition of glycerol as an additive during the spin-coating step leads to large increases in PEDOT:PSS conductivity. Finally, we integrate two different PEDOT:PSS layers with different electrical properties to fabricate PLEDs that displays remarkably improved LE, PE and EQE. These discoveries are anticipated to enable further improvement of the present efficiency of PLEDs and may minimize the efficiency gap relative to vacuum-deposited small molecular devices.

2. Experimental details

A host–guest system, consisting of poly(vinylcarbazole) (PVK) blended with 2-(4-biphenylyl)-5-(4-tert-butyl-phenyl)-1,3,4-oxadiazole (PBD) and green emitting iridium complex, Iridium tris(2-(4-tolyl)pyridinato-$N,C^{2'}$) (Ir(mppy)$_3$), is used as emitting layer. PVK and PBD were purchased from Aldrich and used as received. Ir(mppy)$_3$ was purchased from America Dyes Sources. The three types of PEDOT:PSS was purchased from H.C. Starck, Inc.

The fabrication of PLEDs followed well-established processes and can be referenced elsewhere [16]. For the preparation of glycerol-modified PEDOT:PSS layer, solution blending consisting of glycerol (1.0 wt%) dispersed in the commercially obtained PEDOT$_{8000}$ solution was dropped cast at a speed of 2000 rpm on the top of the prepared PEDOT$_{8000}$. All dispersion were filtered with 0.45 μm PVDF filter before spin-coating. It is important to disperse glycerol by using a high frequency mixer. The obtained PEDOT films were then dried on a hotplate at 160 °C for 10 min. The current density–luminance–voltage (J–L–V) characteristic was measured using a Keithley 236 source-measurement

unit and a calibrated silicon photodiode. The luminance was calibrated by a spectrophotometer (Photo Research, Model: SpectraScan PR-705). The external quantum efficiency of device was collected by measuring the total light output in all directions in an integrating sphere (IS-080, Labsphere).

The conductivity of PEDOD:PSS film at room temperature was measured by the two-point probe or four-point probe method or I–V curve sweeps in dry glove box filled with N$_2$ gas using a Keithley 2410 source meter. AFM images were obtained with a Nanoscope IIIa instrument (Digital Instruments), in the tapping mode. A crystal silicon tip, with a resonant frequency of 300–350 kHz and a spring constant of 20–100 N m^{-1} was used. The scanner was a 10 μm piezo scanner and the scan rate was 1–2 Hz. Off-line image processing and analysis (grain size, roughness) were performed using DI off-line software (Veeco Corp).

3. Results and discussion

Three different commercial PEDOT:PSS versions were used to fabricate phosphorescent PLEDs. The three PEDOT:PSS versions are (together with their abbreviations in this manuscript): BAYTRON P (PEDOT$_P$), BAYTRON P AI 4083 (PEDOT$_{4083}$), and BAYTRON P CH 8000 (PEDOT$_{8000}$); their typical electrical conductivity are $\sim$1 S cm^{-1}, $\sim$10^{-3} S cm^{-1} and $\sim$10^{-5} S cm^{-1}, respectively [19]. The emitting layer (EML) used throughout the studies contains 70 wt% of poly(vinylcarbazole) (PVK), 29 wt% of 2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (PBD) and 1 wt% of Iridium tris(2-(4-tolyl)pyridinato-$N,C^{2'}$) (Ir(mppy)$_3$). Fig. 1a presents the resulting current density–luminance–bias (J–L–V) characteristics. One observes that J is dependent on the conductivity of the PEDOT:PSS layer. The current density of the PEDOT$_{8000}$ device is controlled by the high resistance of the buffer layer, as a result the peak luminance of 14369 cd m^{-2} is obtained at a current density of 52 mA cm^{-2} (see Table 1 for a summary of relevant device characterization), much lower than that of the PEDOT$_P$ or PEDOT$_{4083}$ device. However, we note that this device exhibits better control over the leakage current in the small voltage region (0–3 V). For example, as shown in Fig. 1a, the leakage current before turn-on is $\sim$10^{-5} mA cm^{-2}, at least 2–3 orders of magnitude lower than those of PEDOT$_P$ and PEDOT$_{4083}$ devices.

The luminous efficiency–current density (LE–PE–J) characteristics of the PLEDs described above are shown in Fig. 1b. Foremost, one can observe a peak LE of 86 cd A^{-1} for the PEDOT$_{8000}$ device at 0.15 mA cm^{-2} (6.0 V), which corresponds to an EQE of 26%. The peak PE (52 lm W^{-1}) was obtained at 0.030 mA cm^{-2} (5.1 V). At a high forward view luminance of 1000 cd m^{-2}, the efficiency slightly decreased to 77 cd A^{-1} (corresponding to an EQE of 23%) and PE still retained as high as 30 lm W^{-1}. These performance parameters are superior relative to those observed with PEDOT$_P$ or PEDOT$_{4083}$ (see Table 1) and are consistent with the fact that the peak LE and EQE occur in the small current density region [20]. We also note that the efficiencies are competitive with, and even exceed, those of vacuum-deposited OLEDs reported to date [2–5]. In contrast, a peak

LE of 47 cd A^{-1} (EQE = 14%) at 4.4 mA cm^{-2} (8.1 V) and a peak PE of 21 lm W^{-1} was observed at 6.9 V for PEDOT$_{4083}$ device, while a peak LE of 32 cd A^{-1} (EQE = 9.6%) at 11 mA cm^{-2} (8.4 V) and a peak PE of 13 lm W^{-1} at 7.5 V for the PEDOT$_P$ device. At a high forward view luminance of 1000 cd m^{-2}, LE and PE for the PEDOT$_{4083}$ and PEDOT$_{8000}$ device are 44.7 cd A^{-1}, 19 m W^{-1} and 28 cd A^{-1}, 12 lm W^{-1}, respectively. It is very important to note, the peak LE, EQE of the PEDOT$_{8000}$ device are 1.8 times (=86 cd A^{-1}/47 cd A^{-1}) of that of route PEDOT$_{4083}$ device while the peak PE of the PEDOT$_{8000}$ device is 2.5 times (=52 lm W^{-1}/21 lm W^{-1}) of that of PEDOT$_{4083}$ device. Obviously, the above more significant enhancement in PE for PEDOT$_{8000}$ device is due to the combination of improved LE (Fig. 1b) and reduced power consumption (Fig. 1c).

In order to get insight of the influence of the anode buffer layer on the transport and injection of hole, and the electrical characteristics of the device, it is necessary to compare the sole current of hole. Fig. 2a presents J–V characteristics of hole-only devices with the following configuration: ITO/PEDOT:PSS/Emitting layer/Au. It is important to note that the hole carrier density of the device with PEDOT$_{8000}$ is 4–5 orders lower in magnitude than that of the PEDOT$_P$ device and 1–2 orders lower than that of the PEDOT$_{4083}$ throughout most of the applied voltage region, indicating effective attenuation of hole flux and an excellent control over electrical leakage. Given the thickness of each PEDOT layer (PEDOT$_P$, PEDOT$_{4083}$, and PEDOT$_{8000}$) was 50 nm, 40 nm and 80 nm, respectively, and the nominal resistivity of these three types of PEDOT, the nominal out-of-plane resistance are 2.9×10^{-5} Ω, 1.2×10^{-2} Ω–1.2×10^{-1}Ω, and 4.7–14 Ω, respectively (the cross section area the device is 0.17 cm^2 for our device). The calculation suggests that for all types of PEDOT films, their out-of-plane resistances are actually too small when compared to the intrinsic resistance of the active layer (usually in order of MΩ–GΩ as derived form I–V curve and can be treat as insulator), also smaller than the sheet resistance of ITO anode (~20 Ω), thus can be neglected. Note that the nominal out-of-plane resistances (which is too small to count) is inconsistent with Fig. 1a because the significant difference in the J–V characteristics at high voltage region. When the device is operated at high bias region, where huge amount of charge carriers are injected from the electrodes,

(b) Double logarithmic plot of the data in (a) to show that the J–V characteristics are consistent with Ohmic law (slope = 1.1 with R = 0.999) at small bias region and SCLC (slope = 2.1 with R = 0.991) at higher bias region. Circles are for devices with PEDOT$_P$, squares for PEDOT$_{4083}$, and diamonds for PEDOT$_{8000}$.

as a result of the injection, the density of free charge carriers increase accordingly, the conductivity of the active

Table 2
Summary of resistivity measurement of several of PEDOT films and their nominal value.

PEDOT buffer layer	PEDOT:PSS ratio	Measured normal resistivity (Ω cm)	Measured lateral resistivity (Ω cm)	Nominal resistivity (Ω cm)	Normal to lateral ratio
PEDOT$_P$	1:2.5	$(1.3 \pm 0.07) \times 10^5$	0.66 ± 0.22	1.0	2.0×10^5
PEDOT$_{4083}$	1:6	$(2.9 \pm 0.09) \times 10^5$	$(1.9 \pm 0.06) \times 10^3$	500–5000	1.6×10^2
PEDOT$_{8000}$	1:20	$(4.3 \pm 0.49) \times 10^6$	$(1.9 \pm 0.33) \times 10^5$	$(1.0–3.0) \times 10^5$	22
P$_{8000}$/P$_{8000}$ + 1 wt% glycerol (1:1)	–	$(1.6 \pm 0.54) \times 10^6$	$(4.9 \pm 0.77) \times 10^4$	–	33
P$_{8000}$/P$_{8000}$ + 1 wt% glycerol (1:4)	–	$(1.1 \pm 0.23) \times 10^5$	$(6.2 \pm 0.85) \times 10^3$	–	1.7×10^2

layer is significantly enhanced by several orders of magnitudes (retain as high as kΩ to hundreds of Ω, but still much higher than that of PEDOT layer). In order to further clarify the different J–V characteristics at high voltage region, direct measurement on the three types of PEDOT sandwiched between ITO and Au metal contact was performed, revealing that the actual resistance of the buffer layer are $(3.7 \pm 0.2)\,\Omega$, $(6.9 \pm 0.2)\,\Omega$, and $(202 \pm 23)\,\Omega$ for the three types of PEDOT layer in the device, and the calculated resistivity was summarized in Table 2. High resistance of the PEDOT 8000 ($\sim(202 \pm 23)\,\Omega$, much higher than the nominal value of 4.7 Ω) is coherent with the J–V characteristics at high voltage region shown in Fig. 1a. On the other hand, our simulation shows that for PH 500 and PEDOT 4083 device, an addition resistance of 200–400 Ω (corresponding to the resistance of PEDOT 8000 layer) could shift the J–V characteristics of the device towards higher voltage region, similar to that of PEDOT 8000 (not shown), but had no any influence on the small bias region due to their MΩ–GΩ of resistance, indicating that the conductivity of PEDOT layer itself only plays minor role on electrical leakage. The effective attenuation of hole flux and an excellent control over electrical leakage in the PEDOT$_{8000}$ devices can be attributed to a significantly reduced absolute injection efficiency [21] will occurred, which is defined as the ratio of the actual current to the ideal trap-free, space charge limited current (SCLC), is responsible for the good control over electrical leakage, hole flux attenuation and the subsequent enhanced device performance as a result of more balanced charge injection and transport [22]. This is also supported by photovoltaic measurements [6], which show identical built-in potentials (±0.05 V); thus the reduced absolute injection efficiency is realized via reduced injection height can be ruled out.

Furthermore, as the J–V characteristics of ITO/PEDOT$_P$/EML/Au device in Fig. 2a is replotted in double logarithmic form (Fig. 2b), one can see that the J–V characteristics fit Ohm's law at small bias and the SCLC model at higher bias region, which is given by Mott–Gurney equation $J = \frac{9}{8}\mu\varepsilon\frac{V^2}{d^3}$. [23]. Thus, direct electrical leakage bypassing the EML from irregularities of the ITO surface can be neglected: most of the hole flux is injected from the anode into the EML. One can further conclude that electrical leakage and hole flux attenuation are not realized by conductivity changes, but by the contact resistance between isolated PEDOT segments, which in turn significantly influences hole mobility and hole density since the conductivity is gi-

ven by $\sigma = pq\mu$ [24]. These conditions result in a reduction of the absolute injection efficiency.

Despite the improved LE, EQE and PE obtained using PEDOT$_{8000}$, the peak J and peak luminance are limited by the large out-of-plane resistance. In light of these challenges, we relied on recent reports that show the conductivity of PEDOT:PSS can be increased by two to three orders of magnitude if the aqueous dispersion is mixed with a small amount of additives [14–16,25–35]. Our approach consists of first spin-coating a thin layer (80 nm) of PEDOT$_{8000}$ atop ITO under normal experimental conditions. Subsequently, a second layer of PEDOT$_{8000}$ was spun coated after dilution in either 1:1 or 1:4 volume ratios with a water solution containing 1% glycerol. Partial removal of the PEDOT:PSS underlayer takes place, and the thicknesses of the resulting PEDOT:PSS films decreases from 80 nm to 50 nm (1:1), or to 23 nm (1:4). The normal resistivity of the resulting anode buffer layer film determined using I–V curve sweeps is $(1.6 \pm 0.54) \times 10^6\,\Omega$ cm, $(1.1 \pm 0.23) \times 10^5\,\Omega$ cm (Table 2), in other word, the electrical conductivity of the resulting films were increased by a factor of 1.6 and 39 as compared to the film of PEDOT 8000 (Table 2).

Fig. 3a–c shows the J–L–V, LE–PE–J and PE–V characteristics of PLEDs with PEDOT$_{8000}$ and PEDOT$_{8000}$/PEDOT$_{8000}$ + 1 wt% glycerol in either 1:1 or 1:4 ratios. Comparison of the data shows that peak luminance were enhanced by 79% to 2.6×10^4 cd m^{-2} and 113% to 3.1×10^4 cd m^{-2}, respectively, with the new buffer combination. More importantly, high luminous efficiency (72–76 cd A^{-1}), high power efficiency (39–47 lm W^{-1}) and high luminance ($\sim2.5 \times 10^4$–3.0×10^4 cd m^{-2}) were realized. Even at ca. 10 mA cm^{-2} one observes an efficiency of 60 cd A^{-1}. At a high forward view luminance of 1000 cd m^{-2}, LE and PE for the 1:1 and 1:4 devices are 71 cd A^{-1}, 26 m W^{-1} and 67 cd A^{-1}, 30 lm W^{-1}, respectively. In addition, as shown in Fig. 1b and Fig. 3b, as a result of controlling the leakage current at small biases, the LE–PE–J characteristics of the PEDOT$_{8000}$ device and the glycerol-modified PEDOT$_{8000}$ device display a gradual roll-off from its peak efficiency, which is typically observed at small current region (~0.010–1.0 mA cm^{-2}) (Fig. 3b). In contrast, due poor control over electrical leakage current, the LE–PE–J characteristics of the PEDOT$_P$ and PEDOT$_{4083}$ devices adopt a much sharper profile with a much steeper decline in efficiency (Fig. 1b), with the best efficiencies appearing between 1 mA cm^{-2} and 10 mA cm^{-2}. Also, as a result of more balanced charge carriers in the devices and reduced
**Fig. 3.** Influence of additive on the PLEDs performance. (a) Current density–voltage (*J–V*) characteristics (filled) and luminance–voltage (*L–V*) characteristics (open); (b) luminous efficiency–current density (LE–*J*) characteristics (filled) and power efficiency–current density (PE–*J*) characteristics (open) for the devices; (c) power efficiency–current density (PE–*J*) characteristics. Diamonds are for PEDOT$_{8000}$, upwards triangles for PEDOT$_{8000}$/PEDOT$_{8000}$ + 1 wt% glycerol (=1:1) and downwards triangles for PEDOT$_{8000}$/PEDOT$_{8000}$ + 1 wt% glycerol (=1:4).

power consumption, the PE-V characteristics of the PEDOT$_{8000}$ device and the glycerol-modified PEDOT$_{8000}$ device display a gradual roll-off from its peak efficiency after turn-on (4–5 V, Fig. 3c), while the peak PE for the PEDOT$_P$ and PEDOT$_{4083}$ devices appeared at 7–8 V, though PE is in inverse proportion to bias.

Moreover, as summarized in Table 1, the efficiencies of the PEDOT$_{8000}$ device and the glycerol-modified PEDOT$_{8000}$
Fig. 4. The phase image of the PEDOT films with an area of 1um × 1um as obtained by tapping mode AFM. All films were obtained via spin-coating on ITO substrates and were dried at 160 °C. Panels (a)–(e) correspond to PEDOT$_P$, PEDOT$_{4083}$, PEDOT$_{8000}$, PEDOT$_{8000}$/PEDOT$_{8000}$:1 wt% glycerol (1:1) and PEDOT$_{8000}$/PEDOT$_{8000}$:1 wt% glycerol (1:4), respectively. Panels (h)–(j) correspond to the respective off-line image processing and analysis (grain size), performed by DI off-line software (Veeco Corp).

PLEDs at a series of typical current densities (ca. 0.1, 1.0, 10.0 mA cm^{-2}) are also superior to those of PEDOT$_{4083}$ and PEDOT$_P$. These data highlight the importance of controlling the leakage current, and demonstrate a novel and very simple approach to bridge the performance gap between PLEDs and OLEDs. It is also worth pointing out that if PEDOT$_{8000}$:1 wt% glycerol (1:1) is directly spin-coated at top of ITO, the device performance is limited by its high resistance, similar to the neat PEDOT$_{8000}$ devices (Table 1).

Atomic force microscopy (AFM) was used to characterize surface morphologies of different PEDOT:PSS films. The phase images of the AFM studies obtained by tapping mode are shown in Fig. 4. Consistent with the different PEDOT:PSS ratios and mean particle/grain size in the three types of materials, for the PEDOT$_P$ film (Fig. 4a) and PEDOT$_{4083}$ (Fig. 4b) films, considerable surface roughness and grain-like features are visible, while a more homogenous film is observed for PEDOT$_{8000}$ (Fig. 4c). Phase separation of PEDOT grains and PSS matrix is observed with glycerol treatment. For example, for PEDOT$_{8000}$/PEDOT$_{8000}$:1 wt% glycerol (1:1) (Fig. 4d) and PEDOT$_{8000}$/PEDOT$_{8000}$:1 wt% glycerol (1:4) (Fig. 4e), one observes the emergence of larger grains within a three-dimensional network. These grains can be more clearly seen in Fig. 4f–j in which off-line image processing and analysis (grain size) was applied to the same scans. The observation that incorporation of glycerol leads to increase in granularity is consistent with previously reports [16,32–34]. The changes have been interpreted to be due to a decrease of the overall PSS-to-PEDOT ratio, due to an excess of PSS is washed away upon rinsing with glycerol, as revealed by X-ray and ultraviolet photoelectron spectroscopy [14,28,34,36]. In other word, as a result of excess PSS being washed away and morphology change induced by glycerol and the grains merged [14,32], a three-dimensional network of highly conducting PEDOT/PSS is formed [28,32,34], thus responsible for the enhancement of conductivity.

It is worthy pointing out that the conductivity of PEDOT:PSS film is very anisotropic [35,37–39] due to its unique morphology. Currently, the most common accepted description of film morphology of PEDOT:PSS is that PEDOT-rich grains (islands) are surrounded by lamellas formed by excess PSS [14,28,30,32,37,39]. Thus, the material has a metallic character in the plane of the film, while it behaves more like a dielectric in the direction perpendicular to the plane. Our direct measurement on these films confirm that lateral and normal conductivities may be different by 2–5 orders of magnitude (Table 2), and are consistent with previously reported measurement by a source meter in in-plane/out-of-plane configuration [37] and by conductive atomic force microscopy [39].

The concept can be applied to other emitting layers. PLEDs were fabricated containing a typical poly(*p*-phenylenevinylene) (PPV) derivative, green emitting poly [2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-*p*-phenylenevinylene] (P-PPV) [6], and the five types of PEDOT:PSS layers. The device performance observed vary greatly. It was found that PEDOT$_{8000}$ and glycerol-modified PEDOT$_{8000}$ devices have a peak LE of more than 25 cd A^{-1} while 18 cd A^{-1} for the PEDOT$_{4083}$ device and 3.5 cd A^{-1} for the PEDOT$_P$ device, respectively. In contrast, with poly(9,9-di-*n*-octylfluo-rene-*alt*-benzothiadiazole) (F8BT) as the EML, which is a typical n-type EL polymer, [40] the reverse is observed. The PEDOT$_{4083}$ device is more efficient than PEDOT$_{8000}$ based device, fully consistent with the influence of charge carrier matchup on the efficiency via hole flux attenuation/expansion. Again, our results indicate that for most of PLEDs, in which p-type of organic semiconductor (where mobility of hole is much higher than that of electron) is used as active layer, replacement with PEDOT$_{8000}$ and glycerol-modified PEDOT$_{8000}$ can lead to significant enhancement in efficiencies, as compared to that of devices with routine PEDOT:PSS.

4. Conclusions

In summary, we report a new approach for the preparation of anode buffer layer for efficient PLEDs by using glycerol to modify relative low conductivity PEDOT$_{8000}$. This new type of anode buffer layer allows for a 50–60% increase in device performance in terms of luminous efficiency, and external quantum efficiency, while 90–130% in power efficiency, as compared to devices fabricated using route PEDOT:PSS with moderate conductivity, without significant loss of peak luminance. Green emitting phosphorescent PLEDs with this modified anode buffer exhibit very high efficiencies, representing a significant step forward to matching and exceeding the efficiencies reported to date with vacuum-deposited small molecular devices. We found that this enhancement stems from good control over leakage and hole flux attenuation in p-type devices, leading to more balanced charge injection and transport. Furthermore, modification with glycerol can significantly enhance the conductivity of typically low conducting types of PEDOT:PSS by a magnitude of 1–2 orders as a result of the film morphology and structure change. This modified PEDOT:PSS retains excellent properties of good control over electrical leakage, while at the same time it does not cause appreciable potential drop due to its low serial out-of-plane resistance. We anticipate that these findings can provide a simple experimental procedure for improvement of PLEDs.

Quantum–mechanical calculations based on density-functional theory (DFT) have been successful in understanding the interfacial properties of self-assembled monolayers (SAMs) chemically adsorbed on metal surfaces [15–18]; however, fewer DFT studies have been reported on weakly interacting interfacial systems, where the molecules forming the monolayer are physically adsorbed on the metal surface [19–22]. Previous DFT calculations [20,21] optimized the pentacene adsorption geometry on the Au(0 0 1) surface while assuming a flat-lying geometry of the pentacene molecules with their molecular planes parallel to the surface.

Here, we report on a DFT study of the interface made of a pentacene monolayer adsorbed on the Au(1 1 1) surface. The equilibrium structure and adsorption energy of the pentacene monolayer, the work-function change of the Au(1 1 1) surface upon pentacene adsorption, and the energy level alignment at the interface are calculated and compared with recent experimental data [3,5,7,10,12–14]. In addition, the band structures of the pentacene–Au interface are analyzed in detail to extract the electronic couplings between the HOMO level of pentacene and the gold surface and between adjacent pentacene molecules within the monolayer.

2. Methodology

We use a repeated-slab approach and model the Au(1 1 1) surface with a $c(\sqrt{3} \times 6)$ surface unit cell with lateral unit cell parameters $a = 5.11$ Å and $b = 17.71$ Å along the $\langle 11\bar{2} \rangle$ and $\langle 1\bar{1}0 \rangle$ directions. The surface unit cell parameters are derived from the optimized bulk gold lattice parameter without taking into account the Au(1 1 1) surface reconstruction [23–28], as discussed in Ref. [15]. In the direction perpendicular to the c-axis ($\langle 1 1 1 \rangle$ direction) of the unit cell, a slab consisting of five layers of gold atoms is used to model the surface, with each layer containing 12 gold atoms (resulting in 60 gold atoms per unit cell). The gold atoms within the top two layers of the slab are fully relaxed while the bottom three layers are frozen (see the lateral view in Fig. 1a). The c lattice parameter of the unit cell is taken to be 45.28 Å; since the thickness of the relaxed gold slab is about 10 Å, this leaves a vacuum gap of about 35 Å between each repeated gold slab along the c-direction (which effectively prevents any interactions from slab to slab).

To model the monolayer coverage, each surface unit cell of the gold is made to accommodate one pentacene molecule. Interestingly, the experimental observed surface lattice parameters of the pentacene monolayer on the gold surface ($a = 5.76$ Å, $b = 15.3$ Å, $\gamma = 79.1°$ [10] or $a = 5.7$ Å, $b = 15.5$ Å, $\gamma = 84°$ [12]) are different from those of the clean gold surface unit cell. However, it would be very difficult to model two sets of non-commensurate lattice parameters in a DFT calculation under periodic boundary conditions; to take into account the lattice parameters for both the gold surface and the pentacene monolayer at the same time, a much larger super cell would need to be adopted, which would be computationally unpractical. Therefore, in the present study
Fig. 1. Side view (a) and top view (b) of the relaxed structure of the pentacene–Au interface. In (a), the adsorption height z (defined as the distance between the lowest hydrogen atom of the pentacene molecule and the average height of the gold atoms in the top layer of the slab, projected along the lattice c-direction) is equal to 3.13 Å; the tilt angle between the pentacene molecular plane and the gold surface θ, is equal to 37.7°. The surface unit cell is indicated by the red contour in (b). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

where the a lattice parameter is taken to be 5.11 Å, neighboring pentacene molecules are constrained to lay at a distance *ca.* 0.6–0.65 Å shorter than the one experimentally observed; this is expected to slightly affect the optimization of the pentacene adsorption geometry due to the increased steric hindrance, as we will discuss below.

As a starting geometry, the pentacene molecules were positioned 2.48 Å (measured as the distance between the lowest hydrogen atom of the pentacene molecule and the average height of the gold atoms in the top layer of the slab, projected along the lattice c-direction) above the clean Au(1 1 1) surface, with their molecular long axis parallel to the surface along one of the diagonals in the surface unit cell (see the top view in Fig. 1b), and the molecular plane perpendicular to the Au(1 1 1) substrate. The vacuum gap between the top atom of the pentacene molecule and the next gold slab is then larger than 28 Å. All atoms in the pentacene molecule and in the top two layers of gold surface slab

were relaxed using a damped molecular dynamics scheme until the remaining forces were lesser than 0.03 eV/Å.

The DFT calculations were performed with plane-wave basis sets with an energy cutoff of 22 Ryd to expand the Kohn–Sham orbitals of the valence electrons; the projector augmented-wave (PAW) method [29,30] was used to describe the core electrons and valence-core interactions. The generalized gradient approximation (GGA) exchange–correlation functional of Wang and Perdew [31] was chosen since it was found earlier to perform better than other traditional functionals for weakly bonded systems [32]. All calculations were carried out using the VASP code [33]. In all slab calculations (including the Au(1 1 1) surface, the pentacene–Au interface, and the isolated pentacene monolayer where the molecules are maintained in their optimized adsorption geometry), a $8 \times 3 \times 1$ Monkhorst–Pack k-point grid [34] was used for both geometry optimizations and total energy calculations. A Methfessel–Paxton occupation scheme [35] with a broadening of 0.2 eV was employed in all calculations.

To compute the total energy of an isolated pentacene molecule, a periodically repeated box of $16 \times 27 \times 17$ Å^3 was used with the pentacene molecule sitting at the center of the box. For this large supercell, only the Γ-point was used in the geometry optimization and total energy calculation.

To compensate for the dipole resulting from the consideration of asymmetric slabs, a dipole sheet is introduced in the middle of the vacuum gap [36]. This procedure allows one to properly extract the electrostatic potentials on both sides away from the asymmetric slabs.

For the pentacene–Au interface, as well as for the isolated pentacene monolayer, the electronic coupling for the highest occupied molecular orbital (HOMO) or lowest un-occupied molecular orbital (LUMO) between neighboring pentacene molecules within the monolayer, was estimated from the band dispersion corresponding to each orbital. The electronic coupling between the pentacene monolayer and the Au(1 1 1) surface was extracted from the band-structure calculations by solving the following eigen-function equation based on the tight-binding model:

$$\begin{pmatrix} \varepsilon_1 & V_{12} \\ V_{12} & \varepsilon_2 \end{pmatrix} \Psi = E\Psi \tag{1}$$

where V_{12} is the electronic coupling and ε_1 and ε_2 denote the energies of the unperturbed states of the pentacene monolayer and Au(1 1 1) surface; E is the eigen-value of the corresponding eigen-state Ψ, which comprises the contributions of both the monolayer and the Au(1 1 1) surface. Based on the eigen-value E and eigen-state Ψ extracted from the band-structure calculations, the electronic coupling V_{12} is obtained by solving Eq. (1). Since the main goal of our band-structure calculations was to extract the electronic couplings between neighboring pentacene molecules within a monolayer and between the pentacene monolayer and the gold surface, the spin polarization and spin–orbit interactions for the gold atoms were not taken into account in these calculations.

3. Results and discussion

3.1. Gold surface

The structure of the Au(1 1 1) surface was optimized first. After full relaxation of the top two layers of gold atoms in the slab, the work-function of the surface slab (Φ_{Au}) was calculated as the energy difference between the Fermi energy (E_F) of the surface and the electrostatic potential energy (V_{vac}) of an electron in the vacuum region at the distance where the potential energy has reached its asymptotic value. For the $c(\sqrt{3} \times 6)$ surface unit cell used in our calculation, the work-function is calculated to be 5.25 eV; this value agrees very well with the reported results of 5.2–5.35 eV from both experimental [37–39] and computational studies [15,40].

3.2. Pentacene adsorption geometry

Starting from the separately optimized geometries of the clean gold surface and the isolated pentacene molecule, the pentacene–Au interface system was relaxed from the starting geometry described above, in the following sequence: at first, only the pentacene monolayer was relaxed while the gold slab remained frozen; then both the pentacene monolayer and the top two layers of the gold slab were relaxed simultaneously.

After geometry optimization, the pentacene molecules are found to tilt towards the gold surface with a tilt angle $\theta = 37.7°$ due to a rotation along the molecular long axis, which remains parallel to the surface (see Fig. 1a). The molecular long axis also slightly rotates towards the b-direction of the lattice with respect to its original direction along the unit cell diagonal and forms an angle of about 81° with the a-direction; this value agrees very well with the γ angle (79.1° or 84°) reported from STM experiments [10,12]. The optimized tilt angle of pentacene ($\theta = 37.7°$) is larger than the one measured in NEXAFS experiments ($\theta = 13°$) [14]. This difference can be attributed to the shorter distance between neighboring pentacene molecules along the molecular short axis that we were forced to consider in our computations, as discussed in Section 2. In spite of the numerical difference in tilt angle θ, it is clear that the pentacene molecules tend to lean towards the gold surface in the course of the geometry optimization of the interface, rather than keep the initial perpendicular orientation of the molecular plane, even though the steric hindrance can prevent reaching a more flat configuration.

The perpendicular distance between the lowest hydrogen atom of the adsorbed pentacene molecule and the gold surface (as defined in Section 2) is found to be 3.13 Å, about 0.4 Å lower than the adsorption height (3.52 Å) previously calculated for the Au(0 0 1) surface [21]. To further characterize the sensitivity of the interface to the adsorption height, the total energy of the pentacene–Au system was calculated by shifting the pentacene molecule along the c-direction around the optimized position, while keeping the optimized structures of both pentacene molecules and gold substrate. The total energy vs. the shift Z is given
Fig. 2. Total energy of the pentacene–Au interface as a function of a shift of the pentacene molecules along the c-direction (the geometries of the pentacene molecules and gold slab are kept rigid); Z = 0 corresponds to the fully optimized situation (we note that the extreme flatness of the potential energy surface between in the range $Z \sim 0.0$–0.4 Å does not allow for a very accurate determination of the optimal Z distance).

in Fig. 2. The main result is that the potential energy surface remains very flat for distance Z between −0.2 and +0.5 Å from the optimized distance. Thus, small fluctuations in pentacene–Au distance can be expected (such small fluctuations do not change the work-function of the modified Au(1 1 1) surface to any appreciable extent, see Section 3.5 below).

3.3. STM image

Based on the optimized structure of the pentacene–Au interface, the constant-current STM image was simulated using a tip voltage of −0.6 V and compared with the experimental image reported in Ref. [12], see Fig. 3. The overall appearance of the simulated STM image is in very good agreement with experiment. In the simulated STM image, the angle formed between the molecular long axis and the a-vector (parallel to the dark zig-zag stripe) is about 81°, which agrees very well with the angle γ (84°) measured

in the STM experiment and shown in Fig. 3a [12] (note that the molecular long axis is taken as lattice vector b in Ref. [12], which corresponds to a notation different from ours).

3.4. Adsorption energy

The adsorption energy E_{ads} per pentacene molecule is calculated as:

$$E_{ads} = E_{PEN–Au} - E_{Mol} - E_{Au} \qquad (2)$$

where $E_{PEN–Au}$ is the energy of the pentacene–Au system, E_{Mol} is the energy of an isolated pentacene molecule and E_{Au} is the energy of the clean Au(1 1 1) slab. The adsorption energy is calculated to be −0.16 eV, which is ca. 0.1 eV smaller than the adsorption energy (−0.28 eV) calculated previously by Lee et al. [20] for a pentacene molecule adsorbed on the Au(0 0 1) surface, using the GGA functional of Perdew–Burke–Ernzerhof [41]. It was also found by these authors that the local density approximation (LDA) tends to overestimate the adsorption energy (−3.2 eV for pentacene on Au(0 0 1) surface), while a GGA functional tends to underestimate it. The adsorption energy measured by temperature-programmed desorption (TPD) experiments is on the order of −1.1 eV [10] for a pentacene monolayer on the Au(1 1 1) surface. The large discrepancy between the computational results and experiment is due to the lack of consideration of dispersion interactions in the exchange–correlation functional used in the present DFT approach. This is definitely an issue that warrants further improvement.

3.5. Work-function modification

The work-function of the gold surface modified by the pentacene monolayer was calculated in the same way as for the clean gold surface; the result is given in the upper panel of Fig. 4. Upon adsorption of the monolayer, the work-function of the modified gold surface ($\Phi_{PEN–Au}$) becomes 4.29 eV; this corresponds to a work-function decrease of 0.96 eV with respect to the clean Au(1 1 1) surface ($\Phi_{Au} = 5.25$ eV). This calculated work-function
Fig. 3. Comparison between: (a) the experimental constant-current STM image at a bias voltage V_s = −0.6 eV from Ref. [12] over an area of 5.6 nm × 5.6 nm; and (b) the calculated constant-current STM image from E_F to (E_F −0.6) eV over an area of 7.8 nm × 8.2 nm.
Fig. 4. Electrostatic potentials for the clean Au(1 1 1) surface and the pentacene–Au interface (upper panel); charge density difference upon monolayer adsorption and interface dipole (ID) obtained by solving the Poisson equation (lower panel). The Fermi level is set at zero. The locations of the gold slab and pentacene molecule are illustrated at the bottom.

modification ($\Delta\Phi = -0.96$ eV) is in excellent agreement with the value recently reported based on angle-resolved UPS (ARUPS) experiments, there the work-function change of the clean gold surface upon adsorption of a pentacene monolayer was measured to be -0.95 eV [7].

In the course of our previous theoretical work on self-assembled monolayers chemically bonded on the metal surface [15–18], the work-function change $\Delta\Phi$ of the metal was decomposed into two largely independent contributions coming from the bond dipole around the metal–molecule bond and the electrostatic potential energy step (ΔU_{vac}) across the monolayer itself. Here, as expected from the non-polar character of the molecule and near-flatness of the monolayer over the surface, the contribution to the work-function change due to the potential energy step across the isolated pentacene monolayer is very small (0.04 eV). The potential energy change due to the charge redistribution within the pentacene–Au interface region (that we define here as the interface dipole, ID, since no chemical

bond is formed between the pentacene and the gold surface) can be derived by solving the Poisson equation:

$$\frac{d^2V(z)}{dz^2} = -\frac{1}{\varepsilon_0}\Delta\rho(z) \tag{3a}$$

$$\Delta\rho(z) = \rho_{PEN-Au}(z) - \rho_{Au}(z) - \rho_{PEN}(z) \tag{3b}$$

where $V(z)$ represents the electrostatic potential energy, ε_0 the vacuum permittivity, and $\Delta\rho(z)$ the averaged surface-charge-density difference over the ab plane; the three terms on the r.h.s. of Eq. (3b) denote the plane-averaged surface charge densities for the pentacene–Au interface system, the clean Au(1 1 1) surface, and the isolated pentacene monolayer (evaluated with the same geometric structure as in the pentacene–Au system), respectively. The central panel of Fig. 4 shows the charge difference $\Delta\rho$ and induced electrostatic potential energy V as a function of the distance z taken from the bottom of the slab. The charge difference $\Delta\rho$ changes from slightly negative to positive upon crossing of the gold surface (near $z \sim 10$ Å) and reaches a maximum at $z \sim 11$ Å; it then becomes negative in the space between gold and pentacene ($z \sim 12$ Å), and reaches a minimum at the lower edge of the monolayer. This evolution neatly illustrates the push-back of the gold electron density towards the surface due to pentacene adsorption, i.e., the so-called pillow effect referred to by experimentalists [7]. Correspondingly, the potential energy $V(z)$ (see the lower panel of Fig. 4) is flat inside the gold slab, then drops abruptly by 1.0 eV in the region from $z \sim 10$–14 Å, and finally flattens again in the region high above the adsorbed monolayer. This potential energy change of -1.0 eV is by far the dominant contribution to the total work-function change of -0.96 eV, with the potential energy step (ΔU_{vac}) due to the pentacene monolayer providing only a very small contribution ($+0.04$ eV). Thus, the total work-function modification ($\Delta\Phi$) can be well expressed as the sum of the vacuum potential energy step (ΔU_{vac}) and the interface dipole (ID):

$$\Delta\Phi = \Delta U_{vac} + ID = 0.04 - 1.00 = -0.96 \text{ eV} \tag{4}$$

This result is consistent with the conclusions obtained from our analysis of chemically bonded SAM-metal systems [15–18,42].

Since fluctuations of the pentacene–Au distance can be expected, we also calculated the total work-function modification $\Delta\Phi$ of the pentacene–Au interface for two adsorption distances larger by 0.2 and 0.5 Å than the optimized pentacene–Au distance. The corresponding work-function modifications were calculated to be -0.95 and -0.89 eV, respectively, that is 0.01 and 0.07 eV smaller than for the optimized distance. Such small variations in work-function modifications are within the usual experimental resolution of UPS measurements and do not affect our main results neither qualitatively nor quantitatively.

3.6. Energy level alignments

The energies of the levels corresponding predominantly to pentacene molecular orbitals (MOs) in the interface system can be resolved by projecting the total density of
Fig. 5. (a) Density of states projected onto the pentacene molecule, PDOS (note that the horizontal axis runs from right to left); (b) band-structure of the pentacene–Au system along the ΓX (a-axis) and ΓY (b-axis) directions. The Fermi energy is set at zero. For the sake of clarity, the bands comprising mainly the contributions from the d-orbitals of the gold atoms in the bulk-like states are removed from the plot.

states (DOS) into the molecular region. Fig. 5a shows the DOS projected to all carbon atoms in the pentacene monolayer for the pentacene–Au system. Below the Fermi energy (E_F), the projected density of states (PDOS) shows a broad HOMO band spanning about 0.6 eV, with a tail extending over E_F. The LUMO band is centered at 0.9 eV above the Fermi energy, and is about 0.2 eV narrower than the HOMO band. The charge density distributions corresponding to the contributions from both the HOMO level of the pentacene molecule and the gold surface in the pentacene–Au interface system are shown in Fig. 6 and compared to the HOMO and LUMO levels of isolated pentacene in Fig. 7.

The ARUPS spectra of a pentacene monolayer on gold have recently been reported (see Fig. 1d in Ref. [7]). The calculated occupied PDOS width of 0.6 eV agrees well with the width of the pentacene HOMO band in Ref. [7]. However, there is a significant discrepancy in the energy level alignment between theory and experiment. In the ARUPS spectra, the onset of the pentacene HOMO band is found *ca.* 0.7 eV below the Fermi level of the gold surface. This discrepancy between the theoretical and experimental results is related to the lack of many-body correlation effects in the Kohn–Sham single-particle approximation used in the current DFT method; as a consequence, the excited-state energies and surface polarization response are not adequately treated and the energetic positions of molecular frontier orbitals with respect to the Fermi energy of the metal contact cannot be described accurately [43,44]. A further study based on the GW approximation [45] is currently in progress.

3.7. Pentacene–pentacene in-plane coupling vs. pentacene–gold coupling

To estimate the electronic coupling of the HOMO and LUMO levels between neighboring pentacene molecules within the monolayer, as well as the coupling between the monolayer and the gold surface, we calculated the band structures of the pentacene–Au system along the ΓY (b-direction of the unit cell) and ΓX directions (a-direction of the unit cell) in reciprocal space (see Fig. 5b). Along the b-direction, since the intermolecular interactions between rows of pentacene molecules are very weak due to the large intermolecular distances (see Fig. 1), the two bands corresponding to the HOMO and LUMO levels of the pentacene monolayer (or highest valence (HV) band and lowest conduction (LC) band) are flat along ΓY. Along the ΓX direction, the HV band shows a dispersion of *ca.* 0.43 eV (starting at *ca.* 0.4 eV below E_F from Γ and ending at *ca.* 0.03 eV above E_F at X). In a tight-binding context, this leads to an in-plane electronic coupling of *ca.* 0.11 eV for the HOMO level of the monolayer along the a-direction. The LC band dispersion along the same direction is about 0.27 eV, which corresponds to an in-plane electronic coupling of *ca.* 0.07 eV for the LUMO level. In addition to the smaller intramolecular electron-vibration coupling calculated for holes than electrons in the pentacene molecule [46], this result points to better transport properties for holes than for electrons along the pentacene layer.

The electronic coupling between the adsorbed monolayer and the gold surface is estimated by comparing the band structures for the gold surface in the pentacene–Au
(a)

(b)
Fig. 6. Charge density for the pentacene–Au system corresponding to the bands near the Fermi energy at the *X* point in Fig. 5b: (a) illustrates the charge density for the bottom band among the three, and (b) for the top band.

(a)

(b)

Fig. 8. Band-structure along the ΓX (*a*-axis) and ΓY (*b*-axis) directions for the pentacene–gold model system where the pentacene molecule are shifted 10 Å above their optimized adsorption positions. The Fermi energy is set at zero. For the sake of clarity, the bands comprising mainly the contributions from the *d*-orbitals of the gold atoms in the bulk-like states are removed from the plot.

system and for a model system in which the monolayer is shifted 10 Å away from its optimized adsorption height on the gold surface (see Fig. 8). The band structures for the gold surface in both systems appear very similar, except near the Fermi energy around the *X* point (see Figs. 5b and 8). In the separated model system (Fig. 8), the single band above the HV band actually comprises two quasi-degenerate bands which keep their quasi-degeneracy all along the ΓX direction. These two bands are found to be the bonding states of *s*- and *d*-orbitals of the surface gold atoms. Interestingly, for the interacting system (Fig. 5b), we observe three bands at *X* near the Fermi energy. The bottom one is made of a larger contribution from the HV band of the pentacene monolayer and a smaller contribution from the *s*- and *d*-orbitals of the surface gold atoms (Fig. 6a shows the charge distribution corresponding to this band). The other two bands can be traced to the quasi-degenerate bands near the Γ point, which become split near the Fermi level and reach a maximum splitting (0.023 eV) at the *X* point; the upper of these two bands comes from a hybridization of the *s*- and *d*-orbitals of the surface gold atoms and the HV band of the pentacene monolayer (charge distribution shown in Fig. 6b), while the other one is essentially due to contributions from the surface gold atoms. This result shows that the electronic coupling between the adsorbed pentacene molecules and the gold surface is large enough to break the quasi-degeneracy of the two bands originating in the gold surface.

Applying the tight-binding approximation to the model Hamiltonian (Eq. (1)) for the top and bottom bands which comprise contributions from both the pentacene

monolayer and the gold surface, we estimate that the maximum electronic coupling between the HOMO of the pentacene molecules and the gold surface is about 0.02 eV; thus, this value is about one fifth the corresponding pentacene–pentacene electronic coupling along the *a*-direction, 0.11 eV. In our earlier work on the interface between pentacene and graphene [47], we found that: (i) the electronic coupling between pentacene and graphene is *ca.* 0.04 eV, i.e., nearly twice as large as the pentacene–gold electronic coupling; and (ii) the pentacene–pentacene in-plane coupling is ∼0.01 eV, i.e., one order of magnitude smaller than on the gold surface; on graphene, the pentacene molecular plane is parallel to the graphene sheet and the shortest distance between neighboring pentacene molecules (measured as molecular center-to-center distance along the molecular short axis) is large, about 6.3 Å. It would be interesting to evaluate how these differences in electronic coupling impact the rates of electron transfer across the interface when pentacene is deposited on gold vs. graphene/graphite.

4. Conclusions

DFT calculations have been carried out to study the interface formed by a pentacene monolayer adsorbed on the gold (1 1 1) surface. The optimized geometry agrees very well with STM images. The work-function modification of the gold surface upon pentacene adsorption is calculated to be −0.96 eV and is fully consistent with the results of UPS measurements. We have found that the charge distribution over the clean gold surface is altered due to pentacene adsorption and leads to a significant potential energy change at the pentacene–gold interface. Our results neatly illustrate the concept of surface-electron push-back based on UPS experiments [7].

The energy level alignment at the pentacene–gold interface has been resolved from band-structure calculations and the corresponding DOS. Although the calculations are able to reproduce the overall broadening of the pentacene HOMO level upon adsorption, the differences between our calculated values and the experimentally observed pentacene binding energy and level alignments are most likely related to the lack of many-body correlation effects in the Kohn–Sham approximation. A further study based on the GW approximation [45] is in progress to clarify this issue.

The estimated electronic interaction between the gold surface states and the pentacene HOMO level is much smaller than the one between neighboring pentacene molecules within the monolayer. We are therefore interested in the near future in determining the rates of charge transfer across the gold–pentacene interface, such as the one that can be found in pentacene-based field-effect transistors.

fast-switching and low-power OFETs. Since the number of tested ILs are still very limited for OFETs, further exploration is desired in quest for the best gating ILs among varieties of the existing materials.

It was reported that the components of pure ILs are not completely dissociated into ions and that considerable part of the ions form multiple-ion pairs; 30–40% of the ions form dimer and trimer which do not contribute to the ionic conduction [14–16]. As the result, it can be expected that total number of carriers accumulated at the surface of the semiconductors are reduced. To enhance the degree of dissociation of ILs, it is known that addition of highly electronegative inorganic salts is very effective; for example, in the case of lithium salts which has the strongest electrostatic interactions, only with the mole fraction of 0.15, half of multiple-ion pairs are dissociated into ions and the number of ions responsible for the ionic conduction is considerably enhanced [17–19].

To further improve the performance of the IL-gated OFETs, we introduce the binary ILs with the inclusion of lithium and potassium salts. It turned out that capacitance of the binary ILs drastically increased, especially at high-frequency. The faster ionic diffusion in response to the voltage application results mainly from the enhancement of the degree of dissociation of the ILs. Rubrene single-crystals EDL-FETs are fabricated with the binary ILs and their performance is compared with that with pure ILs. The devices show mobility as high as 2.9 cm^2/Vs with the binary ILs, indicating that good solid/liquid interfaces are possibly attained even with the inorganic salts. The results demonstrate that the binary ILs provide an effective way to achieve fast-switching, low-power, and high-mobility OFETs.

2. Experimental

The basal IL which we use in this experiment is 1-ethyl-3-methylimidazolium bis(fluorosulfonyl)imide ([emim]-[FSI]); the structures of the constituent molecules are shown in Fig. 1a. Since it has been demonstrated that the highest mobility 9.5 cm^2/Vs is achieved for the OFETs with [emim][FSI] devices [13], which is only a fraction of the values given for the air-gap transistors, the material is suited to examine the effect of the binary ILs. The binary ILs including lithium ([Li]) or potassium ([K]) salts are prepared by mixing 0.32 mol/kg of [Li][FSI] or [K][FSI] powders with [emim][FSI] to make [Li][emim][FSI] and [K][emim][FSI], respectively. The mole fraction of [Li]-[FSI]/[Li][emim][FSI] and [K][FSI]/[K][emim][FSI] are 0.09. It has been reported in several ILs that the degree of dissociation is enhanced with increasing the amount of lithium or potassium salts as long as mole fraction of lithium- or potassium-based ionic liquids are lower than 0.15.

We have formed a well structure of polydimethylsiloxan (PDMS) elastomer for the substrate on which a rubrene single-crystal is electrostatically attached as previously reported [12,13]. The electrodes for the gate, source, and drain are all prepared with Cr/Au films. Typical dimensions of the channel length L, channel width w, and the gap layer are 40 μm, 150–200 μm, and 25 μm, respectively. The ILs are poured underneath the rubrene single-crystal by the
Fig. 1. (a) Chemical structures of [emim][FSI], (b) capacitance of the ionic liquids as a function of frequency measured by the ac impedance technique with pure [emim][FSI] (green), [K][emim][FSI] (blue) and [Li][emim][FSI] (red). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

capillary force, so that the EDLs in the ILs can induce high-density carriers at the surface of the crystal with the application of gate voltage. We use the four-terminal method to measure transfer characteristics of the device. All the measurements are done in air at room temperature with an Agilent Technology B1500A semiconductor parameter analyzer. Before we introduce the ILs, the rubrene single-crystals are characterized by measuring transistor performance with the application of gate voltage to the air-gap layer. The values of obtained mobility μ are in the range of 10–37 cm^2/Vs with the average values around 20 cm^2/Vs [13], which is comparable to the best value ever reported for the rubrene single-crystal transistors [20,21].

EDL capacitance C_{EDL} of the ILs is measured using a test device consisting of the same PDMS substrates, where the top surface is structured with Cr/Au evaporated on the PDMS substrate. Solartron 1260 and 1296 impedance analyzers are used to obtain the frequency profiles over the range from 0.1 Hz to 10 MHz with the application of AC voltage amplitude of 5 mV. We emphasize that more than 10 devices are measured for each IL to confirm the reproducibility within the deviation of 10%.

3. Results and discussion

As shown in Fig. 1b, the values of the capacitance increase with decreasing frequency for all the ionic liquids. With adding lithium and potassium ions, absolute values of the capacitance in the binary ILs are enhanced particularly in the high-frequency regime and the frequency

dependence is weakened in common. It is to be emphasized that the EDL capacitance of the binary ILs does not significantly diminish with increasing frequency and remains more than 3.5 $\mu F/cm^2$ for [Li][emim][FSI] and 1.5 $\mu F/cm^2$ for [K][emim][FSI] even at 0.1 MHz: the values are only less than one order of magnitude lower than that at 0.1 Hz for the both compounds, demonstrating fast ionic diffusion in response to the voltage application. This is because that the degree of dissociation of ILs are enhanced and the number of the ions which contribute to the ion conduction is enhanced especially at high-frequency. Since the quick formation of the EDLs enables rapid accumulation of high-density carriers at the IL/semiconductor interfaces for IL-gated OFETs, the high ionic response directly relates to the fast-switching operation of OFETs in response to the gate voltage application.

The variation in the lower-frequency capacitance among the three ionic liquids is also to be addressed because the observation of the highest capacitance in [Li][emim][FSI] is reproducible for all the three measured samples, though the property gives less impact on the performance of the high-speed switching transistors. Since [Li][emim][FSI] shows larger capacitance than [K][emim][FSI], the difference possibly comes from effects of the impurities on the EDL thickness. If lithium and potassium ions by themselves are attracted to the electrodes so that they take considerable part in the EDLs with the application of the gate voltage, it can be expected that thinner EDLs are formed to enhance the capacitance in the binary ILs due to their smaller ionic radius than the main components in the ILs. As a counter effect, the stronger electrostatic interactions of the lithium and potassium ions may attract large crowds of anions, which could lead to thicker Helmholtz layers; however this effect appears to be minor in the present experiments because the observed faster ionic motion in the binary liquids is not in line with the assumption that the lithium and potassium ions moves together with anions. In addition, including influences of differences in semiconductor surfaces and inevitable inclusion of water molecules, it is to be further investigated to elucidate microscopic mechanisms of the formation of EDLs in the vicinity of the solid/binary IL interfaces.

Fig. 2 shows output characteristics of the rubrene-crystal FETs with the two binary ILs. With increasing drain voltage V_D, drain current I_D show the linear regimes and fairly good saturation behavior with the application of less than -0.2 V for both V_G and V_D. Simultaneously measured gate leakage current I_G through the electrolytes is negligibly small as compared to the drain current I_D, that is less than 0.1 nA as long as $|V_G|$ is less than 0.5 V. Rather large saturation current of the order of μA are obtained at very low gate and drain biases, demonstrating the low-voltage, high-current operation due to the high-density carrier accumulation at the IL/rubrene liquid-to-solid interfaces.

Fig. 3a and b shows typical transfer characteristics of the device with [Li][emim][FSI] and [K][emim][FSI], respectively. A sweeping rate of 0.1 V/s results in negligible hysteresis for all the ILs and is translated to the frequency of 10 Hz to change 10 mV, which is the amplitude of the capacitance measurement shown in Fig. 1. Typical turn-on voltage of the devices are 0.40 V and 0.25 V for [Li][e-

Fig. 2. Output characteristics of the devices with [Li][emim][FSI] (a) and [K][emim][FSI] (b) with different gate voltages (V_G = 0.20, 0.15, 0.10, 0.05, 0.00, -0.05, -0.10, -0.15, -0.20 V, respectively).

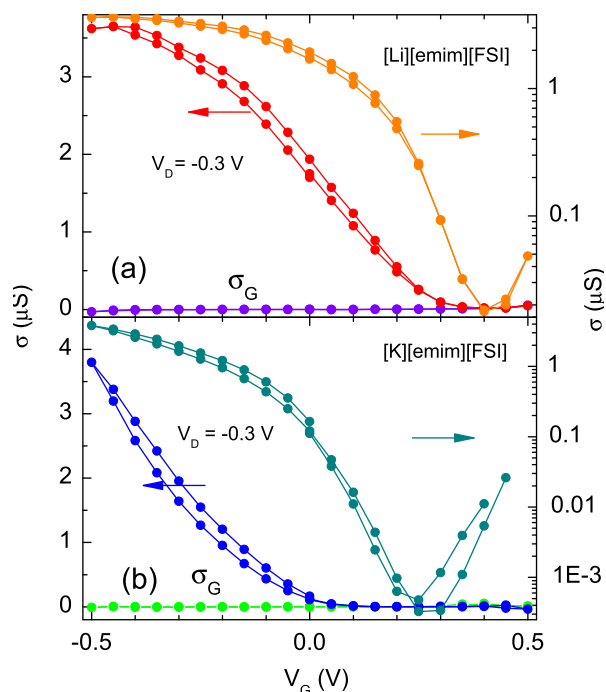

Fig. 3. Transfer characteristics of the EDL OFETs with [Li][emim][FSI] (a) and [K][emim][FSI] (b). Conductivity of gate leakage σ_G is also plotted.

mim][FSI] and [K][emim][FSI], respectively. We note that the turn-on voltage reproducibly shifts to positive values with the inclusion of the impurity ions among several

transistors prepared. Since lithium and a potassium salts have hydrophilic property, the shift of the turn-on voltage can be also due to inevitable inclusion of water from atmosphere or impurities in the ILs. We speculate that the impurities in the ILs and inclusion of water from atmosphere are both involved in the observation, providing additional dipoles and/or hole-trapping levels at the ILs/organic single-crystal boundaries.

The hole mobility μ is estimated from the transfer characteristics by employing the standard formula in the Ohmic regime. Assuming the values of C_{EDL} at 10 Hz, the average mobility values are 1.5 cm^2/Vs for [Li][emim][FSI] and 2.9 cm^2/Vs for [K][emim][FSI]. These values are relatively high in the standard of ever reported EDL-gated FETs, partially due to the use of the rubrene single-crystals with high intrinsic mobility. Because of the achieved reproducibility, we can argue that the present results qualitatively follow the tendency of higher μ with the gating ILs with smaller capacitance. Similar tendency of the decreasing μ with increasing capacitance is reported for OFETs with *solid* dielectrics [22,23] and ILs [13]. At this low-frequency, the variation of μ as function of C_{EDL} appears to be in the same trend as that for previously measured pure ILs in the [emim] families, for which the mobility systematically decreases with capacitance approximately to the power of -1.5. Since the increase in the carrier density at a certain gate voltage is compensated by more significant decrease in mobility, the overall transconductance, which is proportional to the product of mobility and capacitance, is reduced with the binary ILs. The observation still suggests that the surface of the rubrene single-crystal is not seriously damaged by using the binary ILs as was the case for the pure ILs.

In contrast to the diminished transconductance in the low-frequency region, the benefit of the binary ILs appear to be at higher frequencies than 100 Hz; capacitance is almost 10 times higher at 10 kHz for the Li-doped ILs than that for the pure ILs though μ differs only by the factor of 6 with each other. Therefore, the devices with the binary ILs are potentially attractive for high-frequency switching, despite that the present sample dimensions are not suitable for high-frequency response because of their relatively long channel length L. If the devices with 5-μm channel length can be developed with improved fabrication processes for example, the theoretical cut-off frequency $f = \mu V_D / L^2$ can reach 1 MHz for the device with Li-doped ILs, as long as injection at the metal/semiconductor contacts do not cause significant delay during the on–off switching. Since the ionic motion is proportional to the inverse ionic conductance and the thickness of the ionic liquid layer in addition, development of the devices with shorter channel length and shallower well structures is under way to realize the faster-switching EDL-OFETs with the combination of high-mobility rubrene single-crystals and the Li-doped ILs.

4. Conclusion

We have introduced binary ILs electrolytes for the future development of high-speed OFETs with very low operating gate voltages. As the result of comparative experiments with high-mobility rubrene single-crystal devices incorporating with and without inclusion of small amount of inorganic ions, it is shown that the EDLs are formed much more rapidly in the binary ILs and that the high-mobility rubrene surface is well preserved at the interface to the binary ILs. The above two results suggest that binary-IL gated devices can be promising candidates for fast-switching OFETs with extremely low operating gate voltage.

formulate high boiling point solvents in the active layer [15–20]. Phase separation and crystallization of the active layer were observed in OSCs with a high boiling solvent in the active layer. Peet et al. reported that the efficiency of OSCs was doubled by incorporating an alkanedithiol as the high boiling solvent [16]. The alkanedithiol dissolves the PCBM phase selectively without affecting the hole transport type polymer, resulting in phase segregation. Extensive percolating pathway formation was proposed as the main factor for the improved efficiency. Nitrobenzene [19] and 1-chloronaphthalene [20] have also been used for this purpose. Surface modification of the electrode was also successful in controlling the nanomorphology of the active layer [21–23]. Vertical segregation of the active layer was reported in the P3HT:PCBM blend depending on the surface properties of the substrate, even though the detailed device performance was not reported [21]. Other than these, Au was also successful as a modifier for the OSCs [24].

This paper reports an approach to control the nanomorphology of the P3HT:PCBM active layer. A hydrophobic fluorinated polymer, polyvinylidenefluoride (PVDF), was inserted at the interface between poly-3,4-ethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS) and P3HT:PCBM active layers. The effect of the PVDF interlayer on the morphology, crystallinity and charge transport properties of the OSCs was examined. The efficiency of the OSCs was improved by the extensive phase separation and crystallization of the active layer during thermal annealing by the hydrophobic PVDF interlayer.

2. Experimental

A basic OSC device configuration of indium tin oxide (ITO, 150 nm)/PEDOT:PSS(70 nm)/PVDF (4 nm)/P3HT:PCBM(1:0.7, 120 nm)/LiF(1 nm)/Al(200 nm) was used to fabricate OSCs. The PVDF was inserted at the interface between PEDOT:PSS and P3HT:PCBM. The PVDF polymer was spin-coated from a 0.05 wt.% dimethylformamide solution at a spin speed of 2000 rpm followed by baking at 160 °C for 30 min to remove the residual solvent. The P3HT:PCBM was coated from a 4 wt.% dichlorobenzene solution and the film was baked at 150 °C for 30 min. Hole-only devices of ITO/PEDOT:PSS (70 nm)/PVDF/P3HT:PCBM (120 nm)/Au (200 nm) and ITO/PEDOT:PSS (70 nm)/PVDF/PPV(80 nm)/ Au (200 nm) were fabricated to monitor hole injection from the active layer to the PEDOT:PSS layer. The PPV was a super yellow® from Merck with a HOMO level of 5.2 eV. The active area of the pixel of the OSCs was 4 mm^2.

The solar cell performances of the OSCs were characterized using a Keithley 2400 source measurement unit and an Abet solar cell simulator under AM1.5 condition (100 mW/cm^2). The surface morphology of the PEDOT:PSS, PVDF and P3HT:PCBM blended films was analyzed by non-contact mode atomic force microscopy (AFM, XE100, PSIA Co.). The ultraviolet–visible (UV–Vis) absorption spectra were recorded using a UV–Vis spectrophotometer (Shimadzu, UV-2501PC) and the phases were examined by grazing-incidence X-ray diffraction. The cross-section of the fabricated device was analyzed by transmission electron microscopy (TEM, model JEM-2100F, Jeol Co.) after sampling using a focused ion beam method.

3. Results and discussion

PVDF is a well-known ferroelectric polymer with a high dielectric constant owing to the strong electron withdrawing fluorine group on the main chain [25]. It is also known as a hydrophobic polymer with a contact angle of up to 90°. The strong hydrophobic characteristics of PVDF can affect the nanomorphology of the P3HT:PCBM blend. Therefore, it was used as an interlayer between the PEDOT:PSS and P3HT:PCBM blends. PVDF can be spin-coated from a ketone or non-aromatic solvent, and can form an orthogonal film with P3HT:PCBM spin-coated from an aromatic solvent. There was no intermixing between the PVDF and P3HT:PCBM layers during spin coating of the blend. Therefore, PVDF can be applied effectively as an interlayer in the OSCs by a simple spin coating method. Although other surface modification methods, such as a self-assembled monolayer coating on the PEDOT:PSS, have been reported [21], it was difficult to modify the PEDOT:PSS surface without damaging the PEDOT:PSS layer. Compared to those methods, PVDF modification of the PEDOT:PSS is advantageous in that surface modification can be carried out by a simple spin coating of the PVDF.

PVDF was spin-coated from a 0.05 wt.% dimethylformamide solution, and its morphology after spin coating on PEDOT:PSS was examined. Fig. 1 shows AFM images of the PEDOT:PSS and PVDF coated PEDOT:PSS layers. The average surface roughness of the PDVF coated PEDOT:PSS surface was 0.89 nm, while that of the PEDOT:PSS was 0.57 nm. Although the surface roughness of the PVDF coated PEDOT:PSS was slightly higher than that of the PEDOT:PSS, the PVDF layer had a surface roughness < 1 nm. The slight increase in surface roughness of the PVDF coated PEDOT:PSS surface might be due to the minute crystallite formation in the PVDF thin film, as shown in the AFM image [25]. A small needle-like surface texture was observed in the PVDF-modified PEDOT:PSS. PVDF can form crystalline domains during film formation, which leads to an irregularity in a spin-coated film. However, crystalline domain formation is rather limited in thin films compared to that in the bulk, resulting in low surface roughness < 1 nm in PVDF coated PEDOT:PSS. PVDF thin film formation on the PEDOT:PSS also changed the surface properties from hydrophilic to hydrophobic. The contact angle of PEDOT:PSS and PVDF was 22° and 89°, respectively.

The thickness of the PVDF interlayer was measured from the transmission electron microscopy (TEM) images of the fabricated film. Fig. 2 shows a cross-section image of the PEDOT:PSS/PVDF/P3HT:PCBM. A focused ion beam method was used as a sampling method to examine the cross-section of the sample. The TEM image shows that the PEDOT:PSS and P3HT:PCBM layers were separated by a PVDF interlayer. The thickness of the PEDOT:PSS and P3HT:PCBM layers was 70 and 120 nm, respectively. The thickness of the PVDF layer, which was measured from the magnified cross-section image, was approximately 4 nm. The PVDF layer formed an almost continuous film at the interface between the PEDOT:PSS and P3HT:PCBM blend, which confirms the formation of a PVDF layer on PEDOT:PSS.
**Fig. 1.** Atomic force microscopic pictures of the PEDOT:PSS and PVDF coated PEDOT:PSS.

Fig. 2. Transmission electron microscopic pictures of the cross-section.

OSCs with a PVDF interlayer was fabricated to examine the effect of the PVDF layer on the device performance of P3HT:PCBM OSCs. A device architecture of ITO/PEDOT:PSS(70 nm)/PVDF/P3HT:PCBM(120 nm, 1:0.7)/LiF(1 nm)/Al(100 nm) was used, and an OSC without PVDF was also fabricated. In each device structure, two samples were fabricated with and without thermal annealing at 150 °C for 30 min. Fig. 3 presents the current density–voltage curves of the four OSCs. In the case of the OSCs without thermal annealing, the Jsc and fill factor of the P3HT:PCBM OSC with the PVDF interlayer were slightly lower. The reduced fill factor resulted in a low efficiency in PVDF-modified devices. This suggests that without thermal annealing, the PVDF interlayer is not effective in achieving high efficiency in the P3HT:PCBM device. The Jsc of the P3HT:PCBM OSCs after thermal annealing was enhanced by more than 15%, and the efficiency of the OSCs was improved by more than 10% using the PVDF interlayer. The Jsc and efficiency was increased from 6.5 to 7.5 mA/cm^2 and from 2.4% to 2.7%, respectively. In general, the Jsc of the OSCs depends on the energy barrier for charge transport from the P3HT:PCBM active layer to the electrodes and the morphology of the active layer including the phase morphology and crystallinity [9,10]. Therefore, the increased Jsc of the PVDF OSCs after thermal annealing and
Fig. 3. Current density–voltage curves of the PEDOT/P3HT:PCBM and PEDOT/PVDF/P3HT:PCBM solar cells under illumination. Two devices were annealed at 150 °C (black and blue lines) and the other two devices were dried at room temperature (red and pink lines). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the reduced Jsc without thermal annealing might be closely related to charge transport through the interface between the PEDOT:PSS and P3HT:PCBM active layers or charge transport inside the active layer. The PVDF interlayer might alter the interfacial energy barrier between the PEDOT:PSS and P3HT:PCBM layers, affecting the Jsc of

the OSCs. In addition, the morphological change induced by PVDF might have a significant effect on the Jsc of the OSCs. The origins of the improved Jsc and the efficiency of the PVDF-modified OSCs after thermal annealing were examined. Compared to the Jsc, the open circuit voltage (Voc) of the OSC was not greatly affected by the PVDF interlayer. The Voc of the OSCs was almost constant despite PVDF modification. The Voc is determined typically by the HOMO level of the P3HT donor and the lowest unoccupied molecular orbital (LUMO) level of the PCBM electron acceptor in addition to the interfacial contact properties between the organic materials and electrodes. The same P3HT:PCBM active layer was used in the OSCs with and without the PVDF interlayer, which means that the Voc of the OSCs may not be affected by the active layer. However, the Voc from the interface between the organic layers and electrodes can be affected by the PVDF interlayer. The Voc is not affected by the energy level of the electrodes assuming that ohmic contact behavior dominates charge injection from the electrodes to the organic layer [26]. In the case of the P3HT:PCBM devices used in this study, there was no difference in the interface between the electrodes and organic layers, leading to a similar Voc in the two devices. The fill factor was not changed by the PVDF interlayer.

Although the Jsc and efficiency of the P3HT:PCBM OSCs were enhanced by the PVDF interlayer after thermal annealing, the mechanism for improving the device performances is unclear. Therefore, the origin of the improved device performances in the PVDF OSCs was examined using the device performances of the hole-only devices, light absorption and morphological analysis of the active layer. The hole-only devices of the OSCs with and without the PVDF interlayer were fabricated to confirm the origin of the high Jsc of the OSC with a PVDF interlayer. A device with a configuration of ITO/PEDOT:PSS/PVDF/P3HT:PCBM/Au was prepared, and the hole current density from the Au electrode to the ITO electrode was measured. The holes are transported from the P3HT:PCBM active layer to the PEDOT:PSS layer through the PVDF layer. Therefore, a comparison of the hole current density from the Au electrode to the ITO electrode can shows the effect of the PVDF inter-

layer on the hole transport behavior in the OSCs. Fig. 4 shows the current density–voltage curves of the hole-only devices with and without the PVDF interlayer. The P3HT:PCBM active layer was thermally annealed at 150 °C for 30 min after spin coating. The hole current density from the Au to ITO was higher in the hole only device with the PVDF interlayer. This suggests that hole transport from the P3HT:PCBM active layer to the ITO electrode is more efficient in the OSC with the PVDF interlayer than in the OSC without the PVDF interlayer. This shows that the high Jsc in the PVDF OSCs is due to enhanced charge transport from the active layer to the ITO electrode. The hole current density is affected by the interface between the organic layers and the bulk charge transport properties of the active layer. However, it is unclear if the high hole current density of the OSC with the PVDF interlayer is due to an interface effect, such as band bending or a bulk effect, such as enhanced crystallinity. The hole current density reflects both the interface effect and bulk effect of the active layer because hole-only devices of the OSC were prepared under the same experimental condition as the OSC.

In order to separate the effect of the interface and bulk properties of the P3HT:PCBM active layer, hole-only devices, which were not thermally annealed at 150 °C, were fabricated because thermal treatment of the active layer induces phase separation and crystallization of the active layer. Moreover, the morphological change would be affected by the PVDF interlayer. Therefore, a comparison of the hole-only devices with the same morphology would be better for examining the interface effect by the PVDF interlayer. The P3HT:PCBM active layer, which was not thermally annealed at elevated temperatures showed an almost amorphous morphology with very little crystalline phase. In addition, the degree of phase separation of the P3HT and PCBM was similar, as shown in Fig. 7. Therefore, the bulk effect of the P3HT:PCBM active layer can be eliminated in the hole only device data of the pristine P3HT:PCBM layer without thermal annealing. A comparison of the hole current density in the P3HT:PCBM hole only device without thermal treatment shows only the interface effect of the PVDF interlayer. In addition, two hole-only devices with a polyphenylenevinylene (PPV) based amorphous active layer were also prepared to confirm the interface effect by the PVDF interlayer. The PPV polymer shows a fully amorphous morphology with a similar HOMO level as P3HT. Therefore, the interface effect of the PVDF in the OSCs can be examined indirectly. Fig. 5 shows the hole only device data of the pristine P3HT:PCBM devices without thermal treatment and the PPV devices. The hole current density of the pristine P3HT:PCBM and PPV devices decreased when a PVDF interlayer was inserted at the interface between the PEDOT:PSS and P3HT:PCBM layers or PPV. This suggests that the PVDF interlayer hinders hole transport from the organic layer to the PEDOT:PSS layer. Photoelectron spectroscopy showed that the HOMO level of the PEDOT:PSS was shifted from 5.3 to 5.4 eV by the PVDF interlayer, which has an adverse effect on hole transport from the active layer to the PEDOT:PSS. Hole transport may be facilitated in the PVDF free hole only device due to the large driving force for hole

Fig. 4. Current density–voltage curves of the hole-only devices with a device configuration of ITO/PEDOT/P3HT:PCBM/Au and ITO/PEDOT/PVDF/ P3HT:PCBM/Au. Positive vias was applied to the Au electrode and the P3HT:PCBM was annealed at 150 °C.
Fig. 5. Current density–voltage curves of the hole-only devices with a device configuration of ITO/PEDOT/P3HT:PCBM/Au and ITO/PEDOT/PVDF/P3HT:PCBM/Au. Positive vias was applied to the Au electrode and P3HT:PCBM was dried at room temperature. Hole-only devices of ITO/PEDOT/PPV/Au and ITO/EPDOT/PVDF/PPV/Au were also fabricated.

injection. There was a 0.2 eV energy barrier for hole injection from the P3HT with a HOMO level of 5.1 eV to the PEDOT:PSS with a HOMO level of 5.3 eV. However, the energy barrier for hole injection was increased from 0.2 to 0.3 eV by PVDF interlayer modification. Therefore, hole transport was reduced in the hole-only devices with the PVDF interlayer. This also explains why the bulk effect of the P3HT:PCBM, such as improved light absorption, extensive phase separation and accompanying high crystallinity by the PVDF interlayer, are responsible for the high hole current density in the PVDF-modified hole-only devices after thermal annealing. This means that the high Jsc of the OSCs with the PVDF interlayer is not due to the interface effect but to the bulk effect dominated by the morphology of the active layer.

UV–Vis absorption of the P3HT:PCBM film on PEDOT:PSS and PEDOT:PSS/PVDF after annealing was measured to examine the change in P3HT:PCBM bulk properties by the PVDF interlayer. Fig. 6 shows the UV–Vis absorption spectra of P3HT:PCBM. The absorption of PEDOT:PSS and PEDOT:PSS/PVF was too weak to be observed in the UV–Vis absorption spectra and PVDF absorption was negligible. The UV–Vis absorption of the P3HT:PCBM was not changed by the PVDF interlayer after
Fig. 6. Ultraviolet–visible absorption spectra of the PEDOT/P3HT:PCBM and PEDOT/PVDF/P3HT:PCBM films after annealing at 150 °C.

coating on the PEDOT:PSS and PEDOT:PSS/PVDF layers and thermal treatment. The PVDF did not affect the UV–Vis absorption of the P3HT:PCBM. The constant UV–Vis absorption spectra in the PEDOT:PSS/PVDF/P3HT:PCBM film after annealing suggests that the bulk absorption properties of the P3HT:PCBM active layer were not affected by the PVDF interlayer during the annealing process. This suggests that the high current density in PVDF-based OSCs is not due to increased charge generation in the active layer because strong light absorption leads to more exciton generation and charge density in the active layer.

As light absorption in the P3HT:PCBM film was not enhanced by the PVDF interlayer, the morphological change in the P3HT:PCBM layer on PVDF may be responsible for the increase in the Jsc of PVDF-based OSCs. Therefore, the morphology of the P3HT:PCBM film was monitored. Fig. 7 shows AFM images of the pristine and annealed P3HT:PCBM film on PEDOT:PSS and PEDOT:PSS/PVDF. The PVDF had little effect on the morphology of P3HT: PCBM, and similar AFM images were obtained in the pristine P3HT:PCBM film irrespective of the presence of a PVDF interlayer. Microscopic phase separation of the P3HT and PCBM was observed, and the domain size of each domain was small. Phase separation of the P3HT and PCBM was altered significantly by the thermal treatment, and the extent of phase separation was increased considerably after the thermal treatment. The domain size of the P3HT and PCBM was increased after the thermal treatment. In particular, the domain size of the annealed P3HT:PCBM film on PEDOT:PSS/PVDF was large due to the extensive phase separation of P3HT and PCBM. Charge transport in the blended P3HT:PCBM was enhanced by phase separation due to channel formation for the charge transport [16]. Charge hopping between the P3HT or PCBM domains was difficult due to the long distance for charge hopping, and should be minimized in order to improved charge transport in the P3HT:PCBM blend. Charge hopping between domains dominates charge transport in the P3HT:PCBM blend with a small domain size, while charge hopping between molecules dominates charge transport in the blend with a large domain size. In addition, there was excessive crystalline domain formation in the P3HT:PCBM with a large domain size. Therefore, a high current density can be obtained in the P3HT:PCBM blend with a large domain size, which explains the high Jsc of the PVDF OSCs. Extensive phase separation of the P3HT:PCBM after annealing on PEDOT:PSS/PVDF improved the Jsc of the PVDF OSCs.

The main reason for the extensive phase separation of the P3HT:PCBM on PEDOT:PSS/PVDF was the hydrophobic nature of the PVDF with a water drop contact angle of 89°. The strong hydrophobicity of PVDF induces phase separation of the P3HT and PCBM. This agrees with a report showing that the vertical phase separation of the P3HT and PCBM was induced using a self-assembled monolayer [21]. The hydrophobic self-assembled monolayer segregated the P3HT and PCBM, resulting in phase separation. Similarly, PVDF assisted in promoting the phase separation of P3HT and PCBM due to the low surface energy during the thermal annealing process. Phase separation by PVDF could not be induced in a pristine P3HT:PCBM film without thermal annealing. Therefore, phase separation during the

Fig. 8. Schematic diagram of the crystalline phase formation during thermal annealing process. Extensive crystallization of the P3HT and PCBM in the PVDF-modified OSCs is described after annealing.

thermal annealing process is the key factor for the increased Jsc in the PVDF-based OSCs. Fig. 8 shows a schematic diagram of the phase separation procedure. The P3HT:PCBM blend showed a similar morphology after spin coating on PEDOT:PSS and PVDF-modified PEDOT:PSS without a thermal treatment. The phase separation was induced during thermal treatment of the spin-coated P3HT:PCBM film, and the degree of phase separation was high on the PVDF-modified surface due to the surface energy-induced crystallization of the P3HT:PCBM.
Fig. 9. X-ray diffraction pattern of the PEDOT/P3HT:PCBM and PEDOT/PVDF/P3HT:PCBM film thermally annealed at 150 °C.

Phase separation is closely related to the crystallization of the P3HT:PCBM. Therefore, the XRD patterns of the pristine and annealed P3HT:PCBM on PEDOT:PSS and PEDOT:PSS/PVDF were investigated. Fig. 9 presents the grazing-incidence XRD patterns of the P3HT:PCBM film. The intensity of the diffraction peak at 5.2° 2θ, which was assigned to the (1 0 0) plane of P3HT, was higher in the P3HT:PCBM film annealed on PEDOT:PSS/PVDF, while it was weak in the P3HT:PCBM film annealed on PEDOT:PSS. The high intensity of the 5.2° 2θ peak suggests that the crystallinity of the P3HT in the annealed P3HT:PCBM was increased by thermal annealing on PEDOT:PSS/PVDF. This also indicates that PVDF facilitates the phase separation of P3HT and PCBM, and film crystallization is induced during phase separation. The high crystallinity of the P3HT:PCBM film also plays a role in charge transport in the active layer, contributing to the high Jsc of the PVDF OSCs. Therefore, the high Jsc in the PVDF OSCs is due mainly to the phase separation and crystallization of P3HT:PCBM induced by the hydrophobic PVDF interlayer. The high Jsc improved the efficiency of the PVDF OSCs.

4. Conclusions

A PVDF interlayer was introduced at the interface between the PEDOT:PSS and P3HT:PCBM layers to improve the short circuit current and power conversion efficiency of the OSCs by inducing phase separation and crystallization of the P3HT:PCBM blend. The hydrophobicity of the PVDF thin film was responsible for the extensive phase separation and high crystallinity. The phase segregation of the P3HT:PCBM active layer was induced mainly during the thermal annealing process of the film. Therefore, the PVDF interlayer can be used as an interlayer to improve the device performance of OSCs.

transport in the PVK:Au NPs hybrid memory device is dominated by the PVK matrix (i.e., by means of the hopping of holes among the carbazole groups of PVK polymer chains). The role of Au NPs is to store the electrons donated from PVK to keep the high-conductivity state stable. Hence, in the present work, I–V characteristics of the Al/PVK:Au NPs/Al device are examined by fitting the J–E curves to various conduction models. It is revealed that the carrier conduction is governed by the energy-band offsets at the metal–semiconductor (Al–PVK or Au–PVK) junctions. The resistive switching of the Al/PVK:Au NPs/Al device can be explained by the variation of depletion width at the Al–PVK or Au–PVK Schottky barrier junctions, owing to the change of PVK Fermi level position upon applying bias. In addition, memory retention test demonstrates that the device remains the excellent performance at 154 °C in ambient atmosphere.

2. Experimental procedures

The memory device had a structure shown in the inset of Fig. 1a. The polymer active layer, consisting of PVK and Au NPs, is sandwiched between Al electrodes. PVK (M_w = 1100000, T_g = 220 °C) was purchased from Sigma–Aldrich, Inc. Au NPs with a diameter of approximately 4 nm were synthesized by Brust's two-phase reaction method [14] and capped with saturated alkanethiols of 1-dodecanethiol (DT). PVK and Au NPs were mixed and dissolved in 1,2-dichlorobenzenic solution with the weight ratio of Au NPs:PVK = 0.083:1. The solution was spun on the Al/glass substrate followed by a heat treatment at ~60 °C for 5 min to form the active layer. The film thickness was about 120 nm as measured with scanning electron microscope. Finally, the top aluminum electrode was deposited on the polymer active layer by electron-beam evaporation through a shadow mask. The electrode area is 0.04 mm². The spin-coating process and electrical measurements (with Agilent 4156C semiconductor parameter analyzer) were conducted in ambient condition.

3. Results and discussion

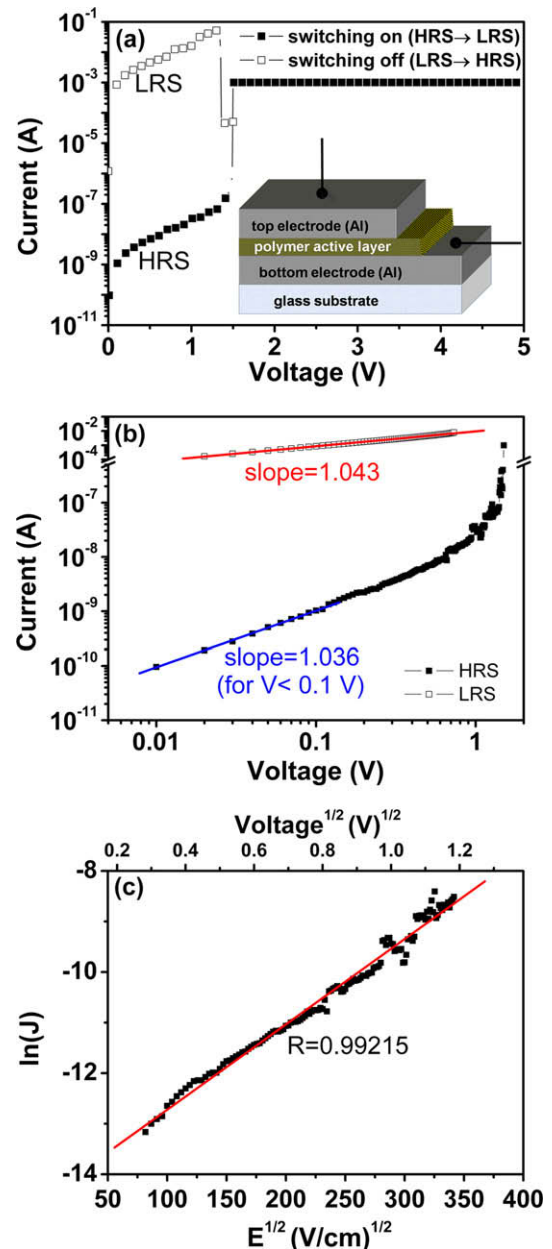
Fig. 1a and b shows the I–V characteristics of the PVK:Au NPs hybrid memory devices in semi-log and log–log scales, respectively. The as-fabricated device shows a high-resistance state (HRS) until the threshold voltage where the device is switched to a low-resistance state (LRS) with a current compliance of 1 mA. Once the transition is achieved, the device remains at the LRS even after the applied voltage is removed, indicative of the non-volatile switching property. The conductance of LRS is different from that of HRS by a factor of 10^5 at room temperature. When the current compliance is released, the device can be switched back to the HRS by the application of a positive voltage below 2 V (see Fig. 1a). For further analysis, the I–V curve is replotted in a log–log scale in Fig. 1b. It can be seen that the I–V characteristic in the LRS follows a linear Ohmic conduction (the slope is close to 1). The conduction behavior in the HRS is governed by Ohmic law at a low voltage region (<0.1 V) with a slope ~1. How-


Fig. 1. I–V characteristics of the Al/PVK:Au NPs/Al device in (a) semi-log scale and (b) log–log scale at 25 °C. The inset in (a) represents the schematic structure of the memory device. (c) J–E curve (for V > 0.1 V) of the Al/PVK:Au NPs/Al device at the high voltage region in the HRS fitted with the Schottky emission model.

ever, the current is not a simple straight line in the voltage region of greater than 0.1 V. This region is fitted with the Schottky emission model [15] as follows:
$$J = A^* T^2 \exp\left[\frac{-q\left(\phi_B - \beta\sqrt{E}\right)}{kT}\right], \tag{1}$$

where J is the current density, A^* is the effective Richardson constant, T is the absolute temperature, q is the elec-

tronic charge, ϕ_B is the barrier height, β is the Schottky coefficient, E is the electric field, and k is the Boltzmann constant. A plot of $\ln(J)$ vs. $E^{1/2}$ indeed exhibits a linear relation, as shown in Fig. 1c, indicating that the conduction behavior in the HRS is governed by Schottky emission at the voltage greater than 0.1 V. The unipolar switching behavior and mechanism are significantly different from the space-charge-limited-conduction (SCLC) effects observed for other PVK-based memory devices so far [10,11].

To acquire further insight into the resistive switching phenomenon, the dependence of the electrical conduction property on temperature was investigated. Fig. 2a shows log I–log V curves of the Al/PVK:Au NPs/Al memory device measured at temperatures ranging from 25 to 154 °C. The retention performance in LRS has also been examined under biased at voltage 1 V for temperatures ranging from 25 to 154 °C. The result indicates that the current remains constant as time passed for the devices tested at all individual temperatures; therefore, only the stress test in LRS for the device measured at 154 °C is presented to demonstrate the outperformed thermal stability, as shown in Fig. 2b. The memory device remains to be programmable at 154 °C, which is superior to other polymer [3,10] and even inorganic memory devices [16].

The Schottky emission mechanism is further confirmed by replotting the I–V curves obtained at various tempera-

tures in form of $\ln(J/T^2)$ vs. $V^{1/2}$. In the $\ln(J/T^2)$ vs. $V^{1/2}$ plot, the voltage range where the linear relationship holds is defined as "Schottky voltage region". After that, $\ln(J/T^2)$ is plotted with respect to $1/T$ for different voltages within the Schottky voltage region, and various activation energies ($E_{act.} = q(\phi_B - \beta d^{-1/2} V^{1/2})$, where d: film thickness) can be extracted from the curves associated with different voltages. In the $\ln(J/T^2)$ vs. $1/T$ plot, one can also find that only in the temperature range 25–75 °C, the linear relationship holds well. Therefore, the Schottky emission model may not fully explain the conduction behavior of the Al/PVK:Au NPs/Al memory device when operating at high temperatures ($T \geqslant 100$ °C). The reason for it is yet to be explored.

The $E_{act.}$ is then plotted as a function of $V^{1/2}$, as shown in Fig. 3, to extrapolate the Schottky barrier height, ϕ_B. It is found that $\phi_B = 0.71$ and 1.89 eV for the voltage regions of 0.1 V $\leqslant$ V $\leqslant$ 0.6 V and V $\geqslant$ 1 V, respectively. These two ϕ_B, 0.71 and 1.89 eV, correspond nicely to the energy difference between work function of Au NPs (5.1 eV) [17] and HOMO (highest occupied molecular orbital) of PVK (5.8 eV) [18], and to the energy difference between the work function of Al electrode (3.9 eV) [19] and HOMO of PVK, respectively. The schematic energy-level diagrams for Al, Au and PVK prior to contact are shown in Fig. 4, where the Fermi levels of Al and Au, as well as the LUMO and HOMO levels of PVK are at 3.9, 5.1, 2.2 [18] and 5.8 eV, respectively. (All the energy levels are relative to the vacuum level.) After contact, Fermi level is a constant through the system at thermal equilibrium. The energy-band diagrams for the Al–PVK and Au–PVK junctions thus will depend on the position of PVK Fermi level ($E_{F, PVK}$), and band bending will occur in the PVK (i.e., the semiconductor) layer. The degree of band bending in PVK shall govern the carrier transport across the Al–PVK and Au–PVK junctions, which will subsequently affect the current conduction in the resistive switching memory devices, as discussed in the following.

The position of $E_{F, PVK}$ is dependent on the hole carrier concentration in PVK. The higher hole concentration, the closer $E_{F, PVK}$ approaches to $HOMO_{PVK}$. In the pristine state, the hole concentration in PVK is relatively low. Assuming that $E_{F, PVK} - HOMO_{PVK} = 1.0$ eV at the beginning of bias

application. In this case, $E_{F, Au}$ is slightly lower than $E_{F, PVK}$, while $E_{F, Al}$ is higher than $E_{F, PVK}$. Accordingly, Au forms an Ohmic contact to PVK while Al forms a Schottky contact to PVK [20], and the schematic energy-band diagrams for Al–PVK and Au–PVK junctions is drawn in Fig. 5a. Because of the high Schottky barrier (∼1.9 eV), it is less likely for hole

carriers to be conducted through the Al–PVK junction. However, there will be some Au NPs inevitably contacting with the Al electrodes during the device fabrication. The Au–PVK Ohmic contact provides a channel for hole conduction from the Al electrode to the HOMO of PVK, via the Au NPs, at the low voltage region. Therefore, the Ohmic conduction is observed in the HRS at the low voltage region (<0.1 V).

Upon the application of external voltage, PVK carbazole groups will donate their electrons to Au NPs to increase the hole concentration and conductivity of the polymer, leading to the down-shift of $E_{F, PVK}$ (approaching to $HOMO_{PVK}$). Subsequently, the work function of PVK would be larger than that of Au, which results in the Schottky conduction at both Au–PVK junction (barrier height ∼0.7 eV) and Al–PVK junction (barrier height ∼1.9 eV), as illustrated in Fig. 5b (where $E_{F, PVK} - HOMO_{PVK}$ is assumed to be 0.5 eV). Therefore, a Schottky barrier height of ∼0.7 eV is extracted from the $E_{act.}$ vs. $V^{1/2}$ plot (Fig. 3) within the voltage region of 0.1∼0.6 V. When the applied bias approaches 1 V, the probability for holes to surmount the energy barrier at the Al–PVK junction is enhanced. Accordingly, the Schottky barrier height extracted from the $E_{act.}$ plot (Fig. 3) corresponds adequately to the energy offset between $E_{F, Al}$ and $HOMO_{PVK}$ (∼1.9 eV).

Switching of the device from the HRS to LRS can also be explained via the energy-band diagrams. As the PVK carbazole groups continuously donate electrons to Au

Fig. 5. The schematic energy-level diagrams for PVK–Au and PVK–Al junctions. Assuming that PVK possesses: (a) a rather low carrier concentration, where $E_{F, PVK} - HOMO_{PVK} = 1.0$ eV; (b) a medium low carrier concentration, where, $E_{F, PVK} - HOMO_{PVK} = 0.5$ eV.

NPs upon applying bias, the amount of hole carriers increases. High carrier concentration will further lower $E_{F, PVK}$ and narrow the width of depletion region at the Al–PVK Schottky barrier junction, which eventually leads to the tunneling of holes at the Al–PVK junction, as illustrated in Fig. 6a (where $E_{F, PVK} - HOMO_{PVK}$ is assumed to be 0.3 eV). As a result, a sharp increase of current is observed, which corresponds to the switching from HRS to LRS. The tunneling of carriers at the metal–semiconductor junction due to the thinning of depletion width of Schottky barrier may be analogous to the steep change of current of a PN diode under a large reverse bias (Zener effect). Therefore, the current increases (from HRS to LRS) abruptly.

According to the energy-level diagram, when an electron is conducted across the Au–PVK junction, it needs to overcome the energy difference (barrier) between $E_{F, Au}$ and $LUMO_{PVK}$, as schematically shown in Fig. 6b. Because of the large value of $LUMO_{PVK} - E_{F, Au}$, the trapped electrons will be stably trapped in Au NPs. Therefore, after the memory device is switched to the LRS, a subsequent voltage scan reveals that the current instantly reaches the level of compliance current (I–V curve not shown). Regarding to switching from the LRS to HRS, the current compliance needs to be released or lifted, such that the external voltage is effectively applying on the device and the hole concentration in PVK will increase with the increasing applied voltage (via the electron donation from PVK to Au NPs). Increase of hole concentration leads to thinning of the depletion region at the Au–PVK Schottky

barrier junction. Consequently, the holes will have a large probability to tunnel through the thin depletion region and neutralize the trapped electrons in Au NPs. As a result, the carrier concentration in PVK is significantly reduced and the $E_{F, PVK}$ moves upwards, resembling the situation of Fig. 5a or b. Consequently, the device is switched back to HRS.

The work done by Song et al. [12] also utilized PVK:Au NPs hybrid as the active layer for non-volatile memory devices but the top and bottom electrodes are Al and TaN, respectively. Both Song et al.'s and our works agree that the role of Au NPs is to accept electrons donated from PVK. However, they observed bipolar switching behavior and the resistive switching is attributed to the change of the electronic states due to the formation of the electric-field-induced charge transfer complex between the PVK and Au NPs. Additionally, the conduction mechanism (J–E curve fitting) was not investigated in their work. We employed Al as both top and bottom electrodes to simplify the device structure and observed unipolar switching character. The current conduction is mainly governed by Schottky emission, and the hole concentration in PVK increases *via* donating electrons to Au NPs upon applying electrical field. As a result, the resistive switching is correlated with the width of depletion region in Al–PVK or Au–PVK Schottky barrier junction. Because Schottky emission phenomenon is highly dependent on the electrode materials, the dissimilar observations and conclusions between Song et al.'s and our works may be attributed to the different electrode schemes of the memory devices. Definitely, the

Fig. 6. The schematic energy-level diagrams for PVK–Au and PVK–Al junctions. Assuming that PVK possesses: (a) a high carrier concentration, where $E_{F, PVK} - HOMO_{PVK} = 0.3$ eV; (b) a very high carrier concentration, where $E_{F, PVK} - HOMO_{PVK} = 0.1$ eV.

exact explanation for the dissimilarity is yet to be further explored.

4. Conclusion

The Al/PVK:Au NPs/Al memory device is investigated for non-volatile memory applications with the conductance difference ratio between the HRS and LRS by a factor of 10^5. Furthermore, the Au nanoparticle/PVK hybrid memory device can be programmed and exhibits excellent thermal stability at 154 °C in ambient atmosphere. It is elucidated that the carrier conduction in the HRS is mainly governed by the Schottky emission model and the barrier height is associated with the energy-band offsets at the Al–PVK or Au–PVK junction. However, the position of PVK Fermi level, characterized by the hole carrier concentration, also changes upon applying bias due to donation of electrons from PVK to Au NPs. As a result, depletion width at the Al–PVK or Au–PVK Schottky barrier junction varies with the applied bias, leading to the tunneling of carriers and subsequently inducing the resistive switching in the Au nanoparticle/PVK hybrid memory device.

Pentacene-based OTFTs incorporating a PMMA gate insulator usually possess a large operating voltage (∼−20 V), related to the thickness of the PMMA layer [7,8]. It is normally difficult to produce a pinhole-free film that is <150 nm in thickness because of the large free volume of the polymer. One encouraging result is that of Noh et al. who have reported devices operating at gate voltages <8 V with a 30 nm thick cross-linked PMMA layer [9,10]. The particular chemical cross-linking methodology that was used, exploiting the cross-linking agent 1,6-bis(trichlorosilyl)hexane (C6-Si), is a rather demanding procedure as it requires processing in a very high purity inert atmosphere. In this work, we focus on a physical method to cross-link PMMA.

During ion-beam irradiation of polymers, both cross-linking and scission occur simultaneously, but the relative effectiveness of the two processes depends upon polymer structure and also on the linear energy transfer (LET, eV nm^{-1}) from the radiation source [11,12]. For example, in the case of PMMA at low LET, most radicals do not cross-link because of wide physical separation between them and chain scission predominates. Cross-linking is however possible at high LET [12] because the radical density is then higher and the separation between them is reduced. In this work, the irradiation was undertaken using a 1.515 MeV ^{4}He$^+$ ion beam to achieve a high LET and effective cross-linking.

2. Experiment

Top source and drain contact OTFTs were fabricated. Glass slides were used as substrates after cleaning sequentially in an ultrasonic bath with acetone, isopropanol and deionized water. An aluminium gate, thickness 40 nm, was defined by thermal evaporation through a shadow mask. To form the gate dielectric, a 2.44 wt% anisole (MicroChem) solution of PMMA (Mw = 93,000, Sigma–Aldrich) was spin-coated at 3000 rpm spinning speed for
Fig. 1. Atomic force microscope images of (a) 57 nm thick PMMA film spin-coated onto a glass slide, (b) 33 nm thick cross-linked PMMA film by ion-beam irradiation, (c) 33 nm thick cross-linked PMMA film after development in acetone, and (d) 40 nm thick pentacene film thermally evaporated on top of the cross-linked PMMA.

50 s on Al and baked for 30 min at 120 °C; this resulted in a 57 nm thick layer with 0.65 nm rms roughness.

A 1.515 MeV ^{4}He$^+$ ion beam was delivered to the sample surface at 7° grazing incidence using a National Electrostatics Corporation 5SDH Pelletron accelerator. The total charge of the beam was 6 μC per irradiated spot and the incident beam had a diameter of 2.4 mm. The irradiated area therefore was elliptical with axes of 2.4 and 19.7 mm and a total area of 37.1 mm^2. The beam fluence was $1.0 \pm 0.1 \times 10^{14}$ ions cm^{-2}, and had an LET figure of about 220 keV μm^{-1} (assuming a polymer density of 1.20 g cm^{-3}). The energy loss and range of MeV ions in solids are well-documented and may be calculated using the
Fig. 2. Current density versus applied electric field for PMMA films (80 and 430 nm in thickness) and a cross-linked PMMA film (33 nm) sandwiched between aluminium and gold electrodes.

SRIM software made available by Ziegler et al. [13]. The total range of the ion beam used would be approximately 8.6 μm in PMMA, and in our experiments the energy loss of the beam traversing 57 nm PMMA at 7° is approximately 0.1 MeV. The variation in stopping power (energy loss/distance traversed) of the ion beam over this range is <4%. Therefore, we can be confident that the level of radiation-induced cross-linking is similar throughout the film.

Pentacene (Sigma–Aldrich) was thermally deposited onto the irradiated PMMA layer at room temperature to a thickness of 40 nm using a shadow mask. The deposition rate was 0.02 nm s^{-1} at chamber pressure of approximately 3×10^{-7} mbar. Finally, a further shadow mask was used to define the source and drain contacts, formed by the thermal evaporation of 40 nm of gold.

The thickness and morphologies of the various layers were studied using a Digital Instruments Nanoscope atomic force microscope. The transistor characteristics were measured under ambient conditions using an HP 4140B Picoammeter/DC Voltage source. The current versus voltage characteristics were measured using a Keithley 485 picoammeter and 2400 source meter. The capacitance versus voltage behavior was monitored with an HP4192A impedance analyser.

3. Results and discussion

Fig. 1 shows atomic force microscope images of the surface of a 57 nm spin-coated PMMA film (Fig. 1a), the same film (now 33 nm in thickness) following ion-beam irradiation (Fig. 1b), the irradiated PMMA film after development in acetone (Fig. 1c) and the surface of a 40 nm pentacene

Fig. 3. Capacitance versus voltage characteristics, measured at 1 MHz and 1 kHz and a voltage scan rate of 0.05 V s^{-1} for aluminium/cross-linked PMMA (33 nm)/pentacene (40 nm)/gold structure. Inset: capacitance versus frequency characteristics for 33 nm thick cross-linked PMMA layer sandwiched between the aluminium and gold electrodes.

film, which was subsequently evaporated onto the irradiated PMMA (Fig. 1d). Following irradiation, the thickness of the PMMA has been reduced by about one half and the film is no longer soluble in solvents such as acetone or iso-propyl alcohol: methyl iso-butyl ketone in a 3:1 ratio (used as a developer for PMMA). This suggests that the PMMA has become cross-linked. The ion-beam irradiation has also resulted in an increase in the rms surface roughness – from 0.65 to 1.34 nm. However, subsequent evaporation of pentacene onto cross-linked PMMA reveals a high quality film with a relatively large grain size (Fig. 1d). The cross-linked PMMA film is referred to as cPMMA in the forthcoming sections.

A parallel plate capacitor structure (Al/insulator/Au) was fabricated to investigate the dielectric properties of the cPMMA. The area of the capacitor was nominally 1.8×10^{-3} cm^2 (exact area values were measured and used in the calculations of current density and permittivity). Fig. 2 contrasts the current density J versus the electric field F behavior for spin-coated PMMA (80 and 430 nm

films) and for cPMMA (33 nm). The leakage current density of the cPMMA was <10^{-8} A cm^{-2} for fields up to 0.35 MV cm^{-1} and this remained below 10^{-6} A cm^{-2} for fields up to 2 MV cm^{-1}. Similar data were measured for the uncross-linked PMMA. In a previous paper [7], we have discussed the origin of the electrical characteristics of spin-coated of PMMA films. The conclusion was that high electrical field processes, resulting from the Poole–Frenkel effect or from Schottky emission, may dominate the electrical behavior in thin films. In the case of Schottky emission, the conductivity will be limited by the electrodes, perhaps accounting for the similar conductivity values of our cross-linked and uncross-linked films. Further work is needed to clarify this point. However, for the purposes of this study, the measured leakage current densities are sufficiently small to enable a 33 nm cPMMA film to be used as the gate dielectric in an OTFT.

The capacitance, C, versus voltage, V, characteristics, measured at 1 MHz and at 1 kHz and a voltage scan rate of 0.05 V s^{-1}, for an aluminium/cPMMA/pentacene/gold
Fig. 4. (a) Output and (b) transfer characteristics of a pentacene-based OTFT using cross-linked PMMA as the gate dielectric. Forward and reverse voltage scans are shown for both sets of data. Device channel length = 50 μm; channel width = 500 μm.

metal-insulator-semiconductor (MIS) structure are depicted in Fig. 3; the inset shows the measured capacitance per unit area as a function of frequency for a 33 nm thick cPMMA layer sandwiched between aluminium and gold electrodes. Using the latter curve, the dielectric constant of the cPMMA layer was calculated to be 3.90 ± 0.10 at 1 kHz and 2.89 ± 0.10 at 1 MHz. These values are almost the same as those reported for PMMA [7]. The accumulation capacitance for the MIS structure was found to scale with the cPMMA thickness and the calculated dielectric constant was the same, within experimental errors, with the value calculated from the inset of Fig. 3. The C–V curves shown in Fig. 3 reveal only a very small degree of hysteresis on reversing the voltage scan direction. This is very similar to that observed with pentacene/PMMA OTFTs and is consistent with a relatively 'clean' (in an electronic sense) interface between the pentacene and the cross-linked polymer [7].

The output and transfer characteristics for an OTFT with a 33 nm cPMMA gate insulator, formed by spin-coating and ion-beam irradiation, are shown in Fig. 4 (device channel length = 50 μm, and width = 500 μm). The output characteristics of the device plotted in Fig. 4a reveal the drain current, I_{DS}, as a function of source-drain voltage, V_{DS}, for different values of gate voltage, V_{GS}. The device shows excellent characteristics in the linear and saturation regions. Moreover, the thin-film transistor operates at relatively low voltages, <10 V. The transfer characteristics of the device Fig. 4b, are measured at $V_{DS} = -8$ V. Plots are given in the form of both $\log(I_{DS})$ versus V_{GS} and $(I_{DS})^{1/2}$ versus V_{GS}. The on/off current ratio, threshold voltage, V_T, and sub-threshold slope for the device were 1.1×10^6, -0.9 V, and 219 mV decade^{-1}. Such characteristics compare very favorably with other recent published data for pentacene/PMMA OTFTs, the insulator thicknesses of which are greater than reported in this work [7,8,14–16].

The field-effect mobility, μ, was estimated in the saturation region of the transistor, using

$$I_{DS(\text{sat})} = \frac{WC_i}{2L}\mu(V_{GS} - V_T)^2 \tag{1}$$

where $I_{DS(\text{sat})}$ is the saturated drain-source current, W and L are the channel width and length, respectively, C_i is the dielectric capacitance per unit area. The value of μ may therefore be evaluated from a plot of $(I_{DS(sat)})^{1/2}$ versus V_{GS}. Using the data from Fig. 4b provided a mobility of 1.1 cm^2 V^{-1} s^{-1} (using a permittivity value of 3.9 for the cPMMA). This will be a mean value, as the field-effect mobility will vary along the channel of the OTFT. The mobility figure obtained in this work is higher than that previously obtained with thicker PMMA films [7]. Other workers on organic transistors have reported mobilities that depend on the gate voltage, even when V_G exceeds V_T [17–20]. One explanation for this phenomenon can be based on the theory described by Necliudov and coworkers [17]. According to this model, in pentacene-based OTFTs operating above threshold, most of the charge induced by the gate-source voltage is trapped and only a fraction of

the carriers participate in the current conduction. The number of accumulated carriers at the pentacene surface will depend on the gate voltage, an increase in which will result in an increase in the surface carriers. Such a process may explain the higher field-effect mobilities found with decreased thickness of gate insulator for our pentacene/PMMA OTFTs.

4. Conclusions

We have been able to cross-link PMMA by ion-beam radiation and to use the resulting thin film as the gate dielectric in pentacene-based field-effect transistors. We have achieved a high-performance device, possessing a field-effect mobility of over 1 cm^2 V^{-1} s^{-1}, a threshold voltage of around -1 V, an on/off current ratio over 10^6, and a sub-threshold slope of about 220 mV decade^{-1}. The cross-linking methodology using an ion beam may not seem to fit with the low-cost rationale for organic electronics noted earlier. However, the experiments reported here are feasibility studies and indicate that physical cross-linking of the PMMA gate dielectric can be used effectively to produce thin-film transistors with high carrier mobility and operating at low voltages. Other solutions, e.g. based on reactive ion etching, may prove to be more appropriate for manufacture.

ultrafast (~100 fs) hot exciton dissociation [14]. Subsequently, Virgili et al. studied the ultrafast intrachain photoexcitation in isolated polymer chains [11]. They presented the first experimental evidence of intrachain generation and recombination of free charges, and attributed the charge generation to the dissociation of some higher excited states.

Both Hendry [6] and Virgili [11] speculated that the initial excitation products are excitons and some higher excited states. However, the yields of excitons and the higher excited states have not been investigated theoretically as they are a function of the photoexciting pulse. "By-hand" exciting one electron from a low occupied molecular orbital to high empty one, An et al. considered the single-electron transition in a polymer [13]. They found that transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) results in an exciton, while transition from Below-HOMO to Above-LUMO will lead to the formation of a high-energy exciton (as called in Ref. [13] a mixed stated consisting of an exciton and a polaron pair). Due to the higher energy than that of an exciton, the high-energy exciton is found to be responsible for the generation of free charges [8]. In their theoretical treatment, the excited electrons have been supposed to lie in higher energy orbitals, while the photoexciting process was neglected. So they could not give a relation between the excited states and the photoexciting pulse. In this paper, we employ an AC field to simulate a photoexcitation, through which the spontaneous electron transitions are realized. The excitation products are recognized by projecting the evolution state onto the instantaneous eigenstates of some well known excited states. The paper is organized as follows. The model and method are presented in Section 2. The results and discussions are shown in Section 3. Finally in Section 4, a summary is given.

2. Model and method

Here we consider the photoexcitations in a PPV molecule, which has exhibits attractive optoelectronic properties. As early as the 1990s, Choi and Rice proposed a Su–Schrieffer–Heeger (SSH) -like Hamiltonian to describe the geometry and electronic structure of PPV [15], where all the carbon atoms in the benzene rings are included. In 2007, according to the SSH-like Hamiltonian we proposed a relatively simple model for a PPV molecule [8]. That is, by a renormalization treatment for the benzene rings, a PPV molecule can be regarded as a one-dimensional chain and each PPV monomer contains six carbon atoms along the chain direction. In this work, we will continue to use the latter model, since we have found that the change between the two models has a minor effect on the photoexcited results through a comparison.

For a PPV molecule, the Hamiltonian consists of three parts

$$H = H_e + H_{latt} + H_E. \tag{1}$$

Here

$$H_e = -\sum_n t_{n,n+1}(C_{n+1}^+ C_n + C_n^+ C_{n+1}) \tag{2}$$

shows the electron hopping between the nearest-neighboring sites of the system with the spin index omitted for clarity. The transfer integral $t_{n,n+1}$ between site n and $n + 1$ is written as

$$t_{n,n+1} = t_0 - \alpha(u_{n+1} - u_n) - t_1 \cos n\pi$$
$$+ t_2 \cos\left(\frac{n+1}{3}\pi\right) \cdot \delta\left(\frac{n+1}{3}, \text{int}\right), \tag{3}$$

where $\delta\left(\frac{n+1}{3}, \text{int}\right) = 1$, if $\frac{n+1}{3} = \text{int}$; and $\delta\left(\frac{n+1}{3}, \text{int}\right) = 0$, if $\frac{n+1}{3} \neq \text{int}$. "int" means an integer. t_0 represents the nearest-neighbor transfer integral for a uniform bond structure, α the electron-lattice interaction constant and u_n the displacement of a unit at site n. t_1 and t_2 are the symmetry-breaking parameters introduced to reflect the lattice feature of a PPV monomer. C_n^+ (C_n) is the creation (annihilation) operator of an electron at site n.

$$H_{latt} = \frac{1}{2}K\sum_n (u_{n+1} - u_n)^2 + \frac{1}{2}M\sum_n \dot{u}_n^2 \tag{4}$$

describes the classical treatment of the elastic potential and kinetic energy of the sites. K denotes the elastic constant and M the mass of a site.

$$H_E = \sum_n eE(t)(na + u_n)(C_n^+ C_n - 1) \tag{5}$$

shows the photoexciting effect through a time-dependent AC field $E(t)$, where e is the electronic charge and a lattice constant. To numerically simulate a femtosecond electric pump pulse [6,11], we choose $E(t)$ as a Gaussian form with width T centered at t_c,

$$E(t) = E_0 \exp\{-[(t - t_c)/T]^2\} \cos(\omega t), \tag{6}$$

by which Streitwolf et al. have successfully investigated the formation of solitons [16]. E_0 and ω separately shows the photoexciting intensity and frequency.

The evolution of an electronic state $|\Phi_v(t)\rangle$ depends on the time-dependent Schrödinger equation

$$i\hbar\frac{\partial}{\partial t}|\Phi_v(t)\rangle = \left(H_e + \sum_n eE(t)(na + u_n)C_n^+ C_n\right)|\Phi_v(t)\rangle. \tag{7}$$

Displacement u_n is not fixed in present case due to the strong electron-lattice interactions. With the evolution of the electronic states, u_n is developed upon the Newtonian equation of motion

$$M\ddot{u}_n = -K(2u_n - u_{n+1} - u_{n-1}) + 2\alpha(\rho_{n,n+1}(t)$$
$$- \rho_{n-1,n}(t)) + eE(t)(\rho_{n,n}(t) - 1) - \lambda M\dot{u}_n. \tag{8}$$

$\rho_{n,n'}(t)$ is the electronic density matrix defined as

$$\rho_{n,n'}(t) = \sum_v \Phi_{v,n}^*(t)f_v\Phi_{v,n'}(t), \tag{9}$$

where $\Phi_{v,n}(t) = \langle n|\Phi_v(t)\rangle$. f_v denotes the occupation of state $|\Phi_v(t)\rangle$ and is determined by the initial electron occupation (0, 1 or 2). In Eq. (8), a damping term is introduced to describe the energy dissipation into the surrounding medium by a tuning parameter λ [17].

To recognize the final states after photoexcitation, we introduce instantaneous eigenstate $|\phi_\mu(t)\rangle$, which is obtained by the instantaneous Eigen equation

$$\left[H_e + \sum_n eE(t)(na + u_n)C_n^+ C_n\right]|\phi_\mu(t)\rangle$$
$$= \varepsilon_\mu(t)|\phi_\mu(t)\rangle, \tag{10}$$

with the Hamiltonian determined by the instantaneous site position u_n. $\varepsilon_\mu(t)$ is the Eigen energy of instantaneous state $|\phi_\mu(t)\rangle$.

In present investigation, we set $|\Phi_v(t=0)\rangle = |\phi_v(t=0)\rangle$ at beginning. When a photoexcitation is applied, the state $|\Phi_v\rangle$ will experience an evolution determined by the coupled differential Eqs. (7) and (8), which are solved by the Runge–Kutta method of order eight with step-size control [18,19].

The actual state of the whole electronic system at any time is obtained through a Slater determinant of the occupied single-electron evolutional wavefunction $|\Phi_v(t)\rangle$. It is different from the simple adiabatic approximation, where the state of the system is given by instantaneous eigenstate $|\phi_\mu(t)\rangle$. Therefore, the present approach is a nonadiabatic one.

3. Results and discussion

In the simulations, we start from a ground state, which is determined by minimizing the total energy of a PPV molecule. The parameters are set as $\alpha = 10.29$ eV/Å, $t_0 = 2.66$ eV, $a = 1.22$ Å, K = 99 eV/Å^2, and M = 1349.14 eV fs^2/Å^2 referring to Refs. [20,21]. By adjusting the magnitudes of t_1 and t_2, we get an energy gap of $E_g = 2.8$eV between HOMO and LUMO, in agreement with other works on pristine PPV [20,21]. If there is no any external perturbation, the molecule will keep its ground state unchanged. In this equilibrium state, we have $|\Phi_v(t)\rangle = |\phi_v(t)\rangle = |\phi_v(t=0)\rangle$ with Eigen energy ε_v. Fig. 1 shows the schematic diagram of the molecular orbitals for a PPV molecule in a ground state, where we denote ε_μ ($\mu = 1, 2 \cdots$) to be the μth occupied orbital counted from HOMO, and ε_μ^* ($\mu = 1, 2 \cdots$) to be the μth unoccupied one counted from LUMO.

When the molecule is photoexcited, electrons will gain energy and $|\Phi_v(t)\rangle$ evolves with time, which means that electrons may transit among the instantaneous eigenstates $|\phi_\mu(t)\rangle$. The "by-hand" simulations treat the transitions by moving electrons from the occupied orbitals to the unoccupied ones. Here let us excite the molecule with a femtosecond electric pump pulse with the form of Eq. (6), in which E_0 and T is fixed to be 1.0 MV/cm and 25 fs, respectively. The final state after the photoexcitation is analyzed by calculating $F_\mu(t) = \sum_v f_v|\langle\phi_\mu(t)|\Phi_v(t)\rangle|^2$, which gives the electron occupation on instantaneous eigenstate $|\phi_\mu(t)\rangle$ at time t. The variations of $F_\mu(t)$ reflect electron transitions among the instantaneous eigenstates. A result with photoexciting energy $\hbar\omega = 2.7$ eV is shown in Fig. 2. At beginning, the molecule is in its ground state with electron occupation $F_\mu(t) = f_\mu$. A photoexcitation is applied to the molecule at $t_c = 40$ fs. It is found that electrons on the occupied orbitals gain energy to transit to the unoccupied

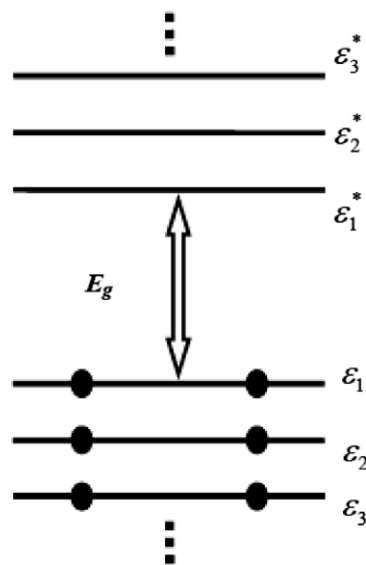

Fig. 1. Schematic diagram of the molecular orbitals for a PPV molecule in a ground state, where the filled circles indicate electrons with the spin omitted.

Fig. 2. Variations of occupation $F_\mu(t)$ on the six instantaneous eigenstates near the gap during the evolution with photoexciting energy $\hbar\omega = 2.7$ eV.

ones with different probabilities. Especially, apparent transitions take place between ε_1 and ε_1^*. About 30 fs later, the transitions stop.
Transition probability of electron or distribution of $F_\mu(t)$ is found to be dependent upon the photoexciting energy. Fig. 3 shows the dependence of the transferred electrons $\Gamma = \sum F_\mu(\mu = \varepsilon_1^*, \varepsilon_2^*, \cdots)$ on the photoexciting energy $\hbar\omega$. It is found that there exists a critical value of $\hbar\omega_c = 2.6$ eV, below which electrons in the occupied orbitals can not transit to the unoccupied ones. The reason is that there is a big energy gap between HOMO and LUMO. In fact, this critical value corresponds to experimentally obtained optical energy gap [22–24]. When the photoexciting energy is larger than the critical value, electrons begin to transit. As the orbitals are discrete, the transition probabil-

Fig. 3. Dependence of the transferred electrons Γ on the photoexciting energy $\hbar\omega$.

Fig. 4. Probabilities of the PPV molecule in a ground state (dash-dotted line), an exciton (solid line), a biexciton (dashed line), and a high-energy exciton (dotted line) during the evolution with $\hbar\omega = 2.7$ eV (a) and $\hbar\omega = 3.0$ eV (b), respectively.

ity is strong only at some photoexciting energies. As shown in Fig. 3, we find that there separately appears a transition peak at $\hbar\omega = 2.7$ eV, $\hbar\omega = 3.0$ eV, and $\hbar\omega = 3.4$ eV, et al. As we know, in a photoexcitation the most probable dipole-allowed transitions are those from ε_μ to ε_μ^* (i.e., $\varepsilon_\mu \rightarrow \varepsilon_\mu^*$). By a further check for these transition peaks, we can clearly see that the first peak corresponds to the transition $\varepsilon_1 \rightarrow \varepsilon_1^*$ (see Fig. 2), the second one $\varepsilon_2 \rightarrow \varepsilon_2^*$, and the third one $\varepsilon_3 \rightarrow \varepsilon_3^*$, etc. For the peak value, we find that it decreases remarkably with the photoexciting energy. It shows that, in a photoexcitation process, a higher-energy transition is not easy to be obtained.

It has been known that transition $\varepsilon_1 \rightarrow \varepsilon_1^*$ with one electron will result in the formation of an exciton, while that with two electrons will produce a biexciton. But the photoexcitation can not give the ideal transitions. As shown in Fig. 3, the transferred electrons for transition $\varepsilon_1 \rightarrow \varepsilon_1^*$ are about $0.3e$ in present parameters. Now let us recognize the final state corresponding to the transition $\varepsilon_1 \rightarrow \varepsilon_1^*$, which has the highest transition probability. To do so, we calculate the projection $i_{S_k}(t) = |\langle \phi_{S_k}|\Phi(t)\rangle|^2$ of the evolution state onto the instantaneous ground state [denoted as $S_0(F_{\varepsilon_1^*} = 0, F_{\varepsilon_2^*} = 0)$], exciton [denoted as $S_1(F_{\varepsilon_1^*} = 1, F_{\varepsilon_2^*} = 0)$], and biexciton [denoted as $S_2(F_{\varepsilon_1^*} = 2, F_{\varepsilon_2^*} = 0)$], which gives the yield i_{S_k} of one kind state S_k. The results are shown in Fig. 4a. After the photoexcitation, it is found that the molecule may still in its ground state with a probability of 72%, or lie in an exciton with a probability of 26%, or lie in a biexciton with a probability of 2%. As we know, biexcitons have some characteristics different from those that excitons or other excited states have, such as the abnormal polarization [25]. Here the calculated yield of a biexciton is much smaller than that of an exciton, which may be related to the weak photoexciting intensity ($E_0 = 1.0$ MV/cm in present model). For the second transition peak corresponding to $\varepsilon_2 \rightarrow \varepsilon_2^*$, we find that the probability in ground state is 82%. But the probability in an exciton or biexciton is nearly negligible, which means that the photoexcitation at this photoexciting energy ($\hbar\omega = 3.0$ eV) can not get excitons or biexcitons. To recog-

nize the excitation product, we have to introduce another excited state. As An et al. indicated in Ref. [13], transition $\varepsilon_2 \rightarrow \varepsilon_2^*$ will result in the formation of a high-energy exciton [denoted as $S_3(F_{\varepsilon_1^*} = 0, F_{\varepsilon_2^*} = 1)$]. By projecting the evolution state onto the instantaneous state S_3, we get a yield of 18%, as shown in Fig. 4b. Hence the photoexcitation at $\hbar\omega = 3.0$ eV produces a higher excited state or high-energy exciton. Due to the higher photoexciting energy (0.3 eV in present parameters), a high-energy exciton is found to be more easily dissociated into free charges contributing to photocurrent than an exciton [8].

For other higher energy photoexcitations, we obtain that a transition $\varepsilon_{odd} \rightarrow \varepsilon_{odd}^*$ finally leads to the formation of excitons, while $\varepsilon_{even} \rightarrow \varepsilon_{even}^*$ high-energy excitons. The results agree with the speculations by Hendry [6] and Virgili [11], as stated in Section 1. In addition, from Fig. 3 we can obtain a relation between the photogenerations of the two excitation products and the photoexciting energies, which is helpful for optoelectronic applications of organic semiconductors. As we know, in photovoltaic devices, such as photovoltaic cells or electrophotographic devices, one would like free charges to be efficiently produced. Since free charges result from the dissociation of high-energy excitons, we should control the photoexciting energy to improve the yield of high-energy excitons. While in light-emitting devices, one would like to suppress the formation of free charges and enhance the yield of excitons.

In actual applications, the photoexciting intensity also plays an important role for the photoexciting process. It has been experimentally observed that, at high photoexciting intensities, biexcitons will be photogenerated [26]. It means that, at a higher photoexciting intensity, biexcitons should have a higher yield. This question will be specially discussed in a future work. In addition, a superlinear dependence of the charge photogeneration (CPG) yield on the photoexciting intensity has also been reported [11]. Here we investigate the effect of the photoexciting intensity on the generation of high-energy excitons. Fig. 5 shows the dependence of the yield of high-energy excitons (corresponding to the second transition peak) on the photoexcit-
Fig. 5. Dependence of the yield of high-energy excitons on the photoexciting intensity E_0.

ing intensity E_0. An apparent superlinear increase of the yield of high-energy excitons with the photoexciting intensity is obtained when the photoexciting intensity is not strong ($E_0 < 1.5\,\text{MV/cm}$). The result is consistent with the experimental observations, if we consider that the dissociation of high-energy excitons is independent upon the photoexciting intensity. When the photoexciting intensity is strong ($E_0 \geqslant 1.5\,\text{MV/cm}$), the yield of high-energy excitons is found to gradually reach a constant ($\sim 40\%$ in present parameters).

Finally, it should be stressed that, despite the model is parameterized for PPV, some molecular effects on the photoexciting process are not taken into account. An innegligible effect is the thermally-induced or solvent-induced rotations of the benzene rings out of the energetically favored planar conformation. For example, Ginder and Epstein demonstrated the importance of the ring-torsion angle in polyaniline [27]; Brédas et al. also discussed the influence of ring-torsion dimerization on the band gap of aromatic conjugated polymers [28]. Both of the two works indicate that the rotations of benzene rings can cause many interesting optoelectronic properties. In addition, an external photoexcitation or thermal perturbation must cause the quantum fluctuations of the lattices as discussed by Shuai et al. [29]. So, further investigations should be done in the future that include the molecular effects, such as the rotations of benzene rings and the quantum fluctuations of the lattices, on the excitation products and the corresponding yields in PPV.

4. Summary

In summary, by numerically applying a femtosecond electric pump pulse we investigated the photoexciting process in a PPV molecule, which will be vital to understand the light-emitting efficiency and the photoconductance of organic semiconductors. We found that the initial excitation products are excitons, biexcitons, and high-energy excitons. The yields were calculated and it was found that the photogenerations of them are determined by the photoexciting energy. A relation between their photogenerations and the photoexciting energy was obtained, which is helpful for optoelectronic applications of organic semiconductors. In addition, effect of the photoexciting intensity on the photogeneration of high-energy excitons was discussed. We found a superlinear increase of the yield of high-energy excitons with the photoexciting intensity, which is consistent with the experimental observations.

trodes to the emitting materials is so similar that does not always allow sufficiently selective injection (and therefore emission) depending on the external bias. Quantum-dot-based LEDs is an alternative method to tune the outcoming light by controlling the size and shape of the quantum-dot [7]. However, the blue component is rather difficult to obtain due to the diminute dimensions of the quantum-dots required. The synergic combination of organic and inorganic semiconducting materials is a recently reported approach to obtain color tunable devices [8,9]. As we will demonstrate, the very different charge injection properties of these two dissimilar materials can also provide a fine voltage controlled color tunability. White emission in polymeric devices has also been previously reported [3,4,10], however they are either no voltage controlled, imply ternary blends or use no solution processable materials.

Therefore, we merge together two of the most promising technologies in the last decade – organic electronics and nanotechnology – to report blue to red voltage tunable emitting devices that can also be white for certain voltages. As previously mentioned, one needs the three RGB components in a white device. We obtain green and blue from the same polymer with the approach of deliberately oxidizing commercially available PFO from American Dye Source. The green band of PFO has been studied in detail by Sims et al. mainly by means of photoluminescence [9,10]. We report experimental procedures to fabricate blue and/or green emitting diodes depending on the controlled oxidation degree of PFO. In order to achieve white light, the red component arises from the addition of also commercially available CdSe/ZnS quantum dots with a diameter of 5.8 nm. The charge injection properties into PFO and QDs are that different that allows our devices to balance the Red, Green and Blue components if both, the blend composition (PFO and QD) and the PFO oxidation degree are exactly adjusted. Moreover, when this balance is broken, the same device can emit towards either blue or red depending on the externally applied voltage.

2. Experimental

2.1. Solution preparation

Fifteen milligram of PFO (American Dye Source) were dissolved in 1 mL of chlorobenzene using different procedures, in order to achieve either pure blue emission or a combination of blue and green.

– Solution preparation for non-oxidized PFO (pure blue emission):The semiconductor solution was heated at 80 °C during intervals of 10 s; enough to dissolve the polymer but preventing temperature activated oxidation. The semiconductor and the substrates were at room temperature during spin-coating process.
– Solution preparation for deliberately oxidized PFO (blue/green emission):The solution to obtain blue–green emission was stirred at 88 °C during 1 h 30′. The semiconductor was spin coated directly from the hot solution. Furthermore, after spin coating the semiconductor, the substrates were annealed at 88 °C for 5 min.

In order to prepare the PFO:QD blends, commercial dispersions of quantum dots in toluene from Evident were used (CdSe/ZnS, 5.8 nm diameter 5 mg mL^{-1}). Different ratios of the QD dispersion were used as the percentage in volume of the initial PFO solution. Blends were stirred at 50 °C for 1 h.

2.2. Device fabrication and instruments

Four inch circular glass wafers completely covered with ITO from VISIONTEK were in-house structured by means of photolithography to produce 15×15 mm square substrates with a 7 mm wide centered ITO stripe. The ITO substrates were cleaned in acetone and isopropanol 5 min ultrasonic baths. Commercially available Baytron PEDOT:PSS AI4083 from HC Starck was spin coated on the ITO. PEDOT films were heated at 100 °C for 5 min to evaporate any residual water in the film. The either PFO or PFO:QD were spin-coated under different conditions depending on the solution used. Finally, metallic cathodes of 10 nm calcium and 200 nm silver were thermally evaporated under high vacuum (<4 × 10^{-6} mbar) through a shadow mask, giving four diodes of 9 mm^2 on each substrate.

Samples were measured inside a nitrogen glove box with a Minolta CS100-A spectroradiometer applying voltages controlled by a Keithley VMU 2420.

3. Results and discussion

Fig. 1 shows the emission of two diodes fabricated with PFO under different conditions (see Section 2), fresh or non-oxidized, and trying to promote polymer oxidation. The emission of sample 1 (triangles) is the typical PFO blue emission habitually reported [11,12]. For sample 2 (squares) the green band grows as a function of the polymer oxidation until it becomes clearly dominant. The mechanisms to explain the green band have been previ-

Fig. 1. Electroluminescence spectra measured at 8 V for different ITO/PEDOT:PSS/PFO/Ca/Ag diodes. The original PFO solution was prepared differently (see experimental details); while for triangles a minimum degree of oxidation was aimed, for squares oxidation steps were intentionally introduced.
ously reported [13,14]. It is commonly accepted that oxidation leads to a fluorenone formation (ketone (C=O)) group at the C-9 position following dealkylation. It is additionally believed that further manipulation of fluorenone-containing chains is necessary to activate the green emission. In essence, there seems to be a requirement that fluorenone groups are able to aggregate before the green emission can appear. Temperature and/or solvent assisted chain mobilization (swelling) is then envisaged to facilitate aggregation. Therefore, by modifying and controlling the solution and film preparation conditions one can achieve different color emission. Fig. 2 shows the IVL characteristics of the same two diodes. The chemical oxidation of the PFO responsible for the green emission introduces competing non-radiative processes that negatively affect the emitting properties of the device in terms of luminance. However, one can benefit from this fact to obtain outcoming color tuning by adjusting the blue and green components at wish when either the efficiency and/or efficacy of devices is not the limiting factor.

In order to also obtain the red component from the same emitting film, different amounts of a 5 mg/ml commercial dispersion of CdSe/ZnS quantum dots with diameter of 5.8 nm were added to the original PFO solution (15 mg/ml in chlorobenzene). The emission spectra of different PFO:QD combinations can be seen in Fig. 3. The triangles containing curve (70:30 in vol) denotes a nearly perfect white emission (CIE X: 0.34–0.35/Y: 0.35–0.36) while the squares containing curve (only PFO partially oxidized) and the circles containing curve (30:70) show a larger blue and red component, respectively. It has to be pointed out that devices made with PFO solutions minimally either over or under oxidized did not show white emission.

Once we have obtained the desired white emission, it is additionally possible to further tune the color by adjusting the applied voltages. Fig. 4 shows the electroluminescence spectra of a diode fabricated with a 70:30 blend at different voltages. Three different regimes can be seen in the same device depending on the applied bias. The original white emission can be modified according to the charge injection properties of each material. While small voltages exclu-

Fig. 3. Emission spectra at 12 V for PFO and different PFO:QD combinations. Samples were prepared as described in the Section 2. White emission (CIE X: 0.34–0.35/Y: 0.35–0.36) was achieved by precisely controlling both the oxidation degree of PFO and tuning the PFO and QD amounts in the solution.
Fig. 4. Electroluminescence spectra for a 70:30 PFO:CdSe blend at different applied voltages. The same initially white emitting device can be tuned towards either blue or red depending on the applied bias. Increasing the voltage favors red emission from the QD while decreasing values promotes red/green emission from the partially oxidized PFO. Inset: chromatic coordinates for the emission obtained at different voltages. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 2. IVL characteristics for ITO/PEDOT:PSS/PFO/Ca/Ag diodes made from different original PFO solutions as explained for Fig. 1. Triangles denote non-oxidized PFO, and squares denote deliberately oxidized PFO. Current values can be read in the left Y-axis (open symbols) and luminance values can be read in the right Y-axis (filled symbols).

sively allow charge injection to PFO – and therefore blue–green emission –, larger voltages induce the QD red emission.

It is noticeable – from Figs. 3 and 4 – how the green band of PFO is also affected by both the presence of QD and the applied voltage. Both effects therefore favor the formation and subsequent aggregation of fluorenone group containing polymer chains, which supporting the interpretation of Ferenczi et al. [14], triggers the green emission. Unfortunately, the chemical oxidation of PFO is not reversible, and once the green band has arisen is not removable. Fig. 5 shows the IVL characteristics of the PFO:QD diode before and after obtaining white emission. The applied
Fig. 5. IVL characteristics for ITO/PEDOT:PSS/PFO:QD(70:30)/Ca/Ag diodes before (triangles) and after (squares) obtaining white emission, i.e. before raising the voltage over 10 V. Current values can be read in the left *Y*-axis (open symbols) and luminance values can be read in the right *Y*-axis (filled symbols).

voltage, i.e. the current flowing through the polymer, is also believed to play a crucial role in the oxidation of the polymer. Therefore, increasing the applied voltage to obtain the red component also contributes to further oxidize the PFO. This favors the green emission also detrimenting the blue component, and makes the process non-reversible. Once we have observed white emission it is not possible to achieve blue again, but certain degree of voltage tunability between green and red is still feasible.

Voltage tunable emission has been previously reported in both polymer:QD [8] and polymer:polymer [5,6] devices. There are usually two different processes to explain color tunability from the same device. One relies on dipole–dipole interaction (Förster transfer) in which an excited state is transferred from the host to the guest if certain conditions are fulfilled. Basically, the absorption of the guest has to overlap the emission of the host. If additionally, different polymer chains are within a minimum distance (Förster radius), the whole emitted energy by the host is re-absorbed by the guest [15,16]. Therefore phase-segregation even in the nanoscale has to be avoided.

On the other hand, materials with different miscibility properties, that consequently tend to phase-segregate (like conjugated polymers and quantum dots), can also be made to simultaneously emit if they are excited at once [6]. Controlling for example the charge injection properties in both phases, it is an additional possibility to achieve voltage tunable emission. Polymers and QD tend to segregate and therefore we observe simultaneous emission from both of the components that can either be polymer (blue–green) or QD (red) biased depending on the external applied voltage.

4. Conclusion

In summary, we have shown the possibility to combine organic conjugated polymers with inorganic semiconducting nanoparticles in order to fabricate white emitting diodes. Their emission can be finely tuned towards either red or blue by modifying the external applied bias. This can be achieved with a precise control of the oxidation degree of the polymer and the adequate percentage of both components – polymer and QD – in the solution. Oxidation and phase separation are controlled via specifically developed solution preparation techniques. Devices can then be processed from these solutions via a simple wet coating process. We chose spin-coating for its simplicity at lab scale, but there are no restrictions for other processes more suitable for mass production (doctor blading, inkjet printing) to result in the same desired phase segregation between polymers and quantum dots in the film. This segregation allows for the important selective charge injection to a particular material phase depending on the voltage. With this approach it is possible to cover the whole color gamut with only a single device.

(LT-632) with side chains have been used in order to get uniform thin films. In addition to the molecular modification, many efforts have been made to fabricate multilayer structure by solution process, such as synthesis of cross-linked materials [3], water/methanol soluble materials [7], lamination method [8], liquid buffer layer [9], and blade coating method [10]. All-solution-processed OLEDs in multilayer device structure, hole transport layer (HTL)/emissive layer (EML)/electron transport layer (ETL), have been fabricated by blade coating without applying any cross-linked materials. In such devices the LiF/Al is used as the cathode, without any low work function metals like Ca, Ba, or Mg. The performance of the device by all-solution process is close to that by evaporation but the cost would be reduced dramatically due to the cheap solution process.

All-solution-processed multilayer blue light OLED with high device efficiency has been compared with its counterpart by vacuum deposition. Three devices with device structure of ITO/PEDOT:PSS/HTL/EML/ETL/LiF/Al were made to compare the different fabrication processes, including the device by all evaporation process (device A), the device with solution-processed HTL and evaporated EML/ETL (device B), and the device by all-solution process (device C). Four devices by all-solution process with different annealing temperatures of ETL layer, 20 °C (device C-1), 50 °C (device C-2), 70 °C (device C-3), and 90 °C (device C-4) for 10 min were made to optimize the device performance. Furthermore a device without ETL by solution process was made as comparison (device D). ITO is indium tin oxide and PED-

OT:PSS is poly-(3,4-ethylenedioxythiophene):poly-(styrenesulfonate) (CLEVIOS™ P VP CH 8000, purchased from HC Starck). PEDOT:PSS was spin coated to form a 40 nm thin film on pre-cleaned the ITO substrate and then was baked at 100 °C for 40 min. N,N′-Bis(naphthalen-1-yl)- N,N′-bis (phenyl)- 9,9-dimethyl-fluorene (DMFL-NPB, from Luminescence Technology Corporation), acting as HTL, was dissolved in chlorobenzene to form a 20 nm film by blade and spin coating. LT-492 and LT-632 provided by Luminescence Technology Corporation, act as blue host and blue dopant individually. The 2 wt% LT-632 in the host LT-492 were dissolved in chlorobenzene and blade coated to form a 50 nm film on top of DMFL-NPB. Blade and spin coating is the process to use first blade coating to form the wet film and then spin coating until dried film is formed. Blade coating is the process only to use the blade coating without any spin coating. The DMFL-NPB and LT-492:LT-632 layers were baked at 120 °C for 10 min and 125 °C for 5 min in vacuum (10^{-3} torr). The 2,2′,2″-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi, from Luminescence Technology Corporation), acting as the ETL and hole blocking layer, was dissolved in methanol to form a 20 nm film by blade and spin coating. The film thickness by blade coating can be controlled by the solution concen-

the devices were coated with LiF(1 nm)/Al(100 nm) cathode and packaged in a glove box. Ionization potential is measured by cyclic voltammetry and electron affinity is calculated by Ionization potential plus band gap determined by the ultraviolet absorption spectrum. The electroluminescence (EL) spectra and current–luminance–voltage (I–L–V) characteristics are measured by a Photo Research PR650 spectrophotometer integrated with Keithley 2400 multimeter.

Fig. 2 shows the device performances of device A (all evaporation), device B (only HTL by solution process), device C-2 (all-solution process), and device D (all-solution process, without TPBi). While operating at 10 mA/cm^2, the device efficiency is 6.3 cd/A of device A, 5.6 cd/A of device B, 4.8 cd/A of device C-2, and 0.01 cd/A of device D. The maximum luminance is 7054 cd/m^2 of device A, 11,460 cd/m^2 of device B, 3677 cd/m^2 of device C-2, and 26 cd/m^2 of device D. The maximum luminance of the devices is defined as the luminance that can be achieved of the device. The luminance will decay after this maximum luminance even the bias increases. There are some damages occurred of the devices after the maximum luminance. The device performance of device D without TPBi as ETL is obviously poor, indicating TPBi layer is required to offer efficient electron injection. As can be seen in I–V–L relation, the current and luminance of all-solution-processed device C-2 at low bias before 9 V are about the same as those of device B and are higher than those of all-evaporated device A. At higher bias larger than 10 V, the current and luminance of device C become saturated and lower than those of device A and device B. Moreover the electroluminescent (EL) spectra of the devices with solution-processed EML (device C-2 and device D) show red-shift compared with the devices with evaporated EML (device A and device B). This may be attributed to the slight dissolution between the HTL and EML during blade coating, which might cause exciplex formation in such mixing area. The dissolution has been verified to be less than 10 nm by measuring the total film thickness. In order to study the detail of the different processes, the microscopic morphologies of each layer of device A and device C-2 have been checked by AFM. The results are shown in Fig. 3. The roughness of the evaporated layers is 1.04 nm for DMFL-NPB, 0.87 nm for LT-492 LT-632, and 1.01 nm for TPBi. The roughness of the solution-processed layers is 0.42 nm for DMFL-NPB, 0.46 nm for LT-492:LT-632, and 1.39 nm for TPBi. The morphologies of each layer by evaporation are about the same. The uniformity of the solution-processed DMFL-NPB and LT-492:LT-632 are better than the evaporated ones but a few spots still can be seen in the solution-processed DMFL-NPB. There are even more spots shown in the solution-processed TPBi layer due to the fact that there is no side chains in the TPBi molecules. We speculate that crystallization occurs in the solution-processed DMFL-NPB and TPBi and such crystallization could be regarded as one kind of impurity, which would quench the excitons. That is the reason why the efficiency decreases in device B and even more in device C-2. On the

[b] S: solution process.

other hand, the crystallization in DMFL-NPB may cause higher mobility in device B and device C-2, therefore the current density is higher than that of device A at lower bias range (below 9 V). While the bias increasing, the emission zone will move to the interface between EML and TPBi due to the carrier blocking effect and the excitons would be quenched by the large crystallization of TPBi. Therefore the luminance of device C-2 becomes lower at higher bias range (after 10 V). In order to optimize the all-solution-processed OLED, devices with different annealing temperatures of TPBi layer have been made, which are device device C-1 (20 °C), C-2 (50 °C), device C-3 (70 °C), and device C-4 (90 °C). The results are shown in Fig. 4. The efficiencies while operating at 10 mA/cm^2 are 2.9 cd/A for device C-1, 4.8 cd/A for device C-2, 2.1 cd/A for device C-3, and 1.7 cd/A for device C-4. The maximum luminance are 2125 cd/m^2 for device C-1, 3677 cd/m^2 for device C-2, 856 cd/m^2 for device C-3, and 315 cd/m^2 for device C-4. The device performance of device C-1 is lower than that of device C-2, indicating that the crystallization of device C-2, as can be seen in Fig. 3f, may increase the carrier mobility and help the electron transporting. In device C-3 and device C-4 large crystallization occurs and obvious spots can be seen by naked eyes, therefore the device performances are poor due to the exciton quenching effect. the crystallization of organic film is detrimental to the device and should be avoided. The case of TPBi films annealed at 70 °C and 90 °C indeed shows the crystal formation at the scale of μm or larger in organic films which can be observed by naked eyes. The performance of the devices with TPBi at 70 °C or 90 °C shows poor efficiency. On the other hand the TPBi film at 50 °C has very small spots (much less than μm). We speculate that the films at 50 °C just start packing and cause higher carrier mobility than that annealed at 20 °C but less harmful than that with real crystals. Furthermore, according to the AFM image the morphology and roughness of HTL/EML (annealed at 125 °C, 5 min) seems to be about the same as those of HTL (annealed at 120 °C, 10 min). However the morphology and roughness changed after adding the ETL (annealed at 20 °C, 50 °C, 70 °C, or 90 °C for 10 min). Because the annealing temperature of ETL is less than that of HTL or HTL/EML, we think the roughness and morphology change should be resulted from the crystallinity change of TPBi layer, not from other layers (HTL, EML). We suggest that vapor-quality devices from solution process can be obtained with all the small molecules including hole/electron transport and emissive materials modified with side chains to get a uniform thin film without crystallization. All the device performances are summarized in Table 1.

In conclusion we have demonstrated all-solution-processed multilayer blue OLEDs by blade coating without any cross-linked materials. This kind of device combines the advantages of small molecular organic materials and large area manufacture process with low cost. Blue organic host and guest have been used with side chains to get a uniform thin film by solution process. The performance of the solution-processed device with multilayer structure can be very close to the evaporated one, and the cost of the solution-processed can be reduced dramatically.

gives mobility values which are anisotropic and might be far away from those in a real device because factors like disorder and experimental conditions (like nature of charge generation, electric field range and charge concentration [10]) may significantly influence mobility values.

Conventionally charge carrier mobility in organic materials has often been measured by TOF in which the transit time (t_{tr}) of a sheet of charge carriers, flash photo-generated in a thin, initial region of the sample, is measured in a transient experiment. But π-conjugated polymers are slightly different in the sense that poor sample quality and low mobilities often make the TOF measurements difficult. TOF needs thick samples (in µm range) with optical density in excess of 10. However, the thickness of polymer solar cells is a couple of hundreds of nanometer. Therefore, the mobility values obtained from TOF experiments are not the measured values for an actual device of interest. Furthermore, the necessary conditions for the applicability of TOF techniques is that the dielectric relaxation time $\tau_\sigma = \varepsilon\varepsilon_0/\sigma$ (ε is the dielectric permittivity, σ is the conductivity) is larger than the charge carrier transit time, $t_{tr} = d^2/\mu V$ (here d is the inter-electrode distance, μ is the mobility of charge carriers, V is the magnitude of voltage), otherwise the drifting charges will relax before they reach the opposite electrode [11]. Moreover, the equilibrium charges will be sufficient to significantly redistribute the electric field inside the sample leading to anomalous electric field dependence of mobility [12]. Hence, the mobility results from TOF do not reflect the actual situation of a real solar cell device due to thick film. Hence, it can be seen that each of these mobility measurement techniques lacks the universality of application or desired accuracy.

Another method available for mobility measurements is the Charge Extraction by Linearly Increasing Voltage (CELIV) technique. The theory behind CELIV has been presented elsewhere [13]. CELIV has the advantage of being experimentally very simple and measured values are not influenced by contact barriers of sandwich sample. The CELIV method also demonstrates advantage against the popular TOF method because for CELIV it is not necessary to fulfill the TOF condition. Hence, the mobility values are for the actual OPV nanometer thick optimized films not micron thick as required in TOF. Although all methods suffer from some problems but values obtained from CELIV are inherently closer to the actual value in the device; also because CELIV is based on the charge carrier extraction current, which causes the electric field redistribution in the device.

Theoretically both electron and hole mobility measurements are possible using CELIV but it has proved to be very difficult in the past. The only restriction imposed by the experimental setup is that at least one contact of the sample should be blocking. Nonetheless, measurements have not been very straightforward as only one extraction peak is seen in CELIV. The main difficulty has been to resolve the electron and hole mobility peaks. Up until now only one of the values has reportedly been possible to extract for OPV blends [14]. The only reported data on bipolar mobility values by CELIV is by Andersson et al. [15] where they see two distinct peaks at critical acceptor loading greater than 75%.

But 75% is very high loading for the acceptor and does not represent the conditions for optimized solar cells. To identify the type of carrier they correlate their data to FET (where the polarity of charge carriers can be chosen at will), but still not all materials show obvious electron currents in FETs. Hence, a universal method is needed which can be applied to optimized films to get individual electron or hole mobility values. In this work, all measurements were performed on optimized bulk heterojunction (BHJ) active layers with a systematic variation of the donor:acceptor weight ratio over a wide range to emphasize the universality of the method and to demonstrate that this can indeed be used to study mobility in any kind of system. Appropriate blocking electrodes to block one type of carriers in the film were used in this case. This suppresses the CELIV transient corresponding to the carrier that has been blocked resulting in one broad peak converting to a sharper peak corresponding to the carrier that has not been blocked. This is, in effect, something similar to deconvolution.

However, it is an inherent problem of mobility measurement that it is very sensitive to the interface chemistry of the dielectric used [16]. Recently Quiles et al. [17] provided evidence that vertical segregation and hence transport in a polymer film depends on several processing parameters; one of them being the type of substrate used. A blocking electrode near the anode (effectively a material other than PEDOT–PSS) might change the film morphology perpendicular to the electrode. The transport characteristics and hence mobility values of the test device might then be different from those of the real devices. Hence, instead of using the blocking electrode on the anode side, it was introduced on the cathode side above the polymer layer. In this manner, the morphology of the polymer active layer was not disturbed and hence the mobility values obtained should be more reflective of the actual values.

2. Materials and methods

In this letter, optimized solar cells based on various poly-alkylthiophene: [6,6]-phenyl-C_{61}-butyric acid methyl esters (PCBM) were fabricated. Samples of regio-regular (RR)-poly (3-butylthiophene) (RR-P3BT), RR-poly (3-octylthiophene) (RR-P3OT) and RR-poly (3-dodecylthiophene) (RR-P3DT) were investigated by the CELIV method. The materials were purchased from Reike-metals and were used without further purification. The alkylthiophenes and PCBM were separately dissolved in 1,2-dichlorobenzene, then blended together with 1:x wt/wt ratio to form a 2.0 wt.% solution. The PCBM loading concentration was systematically varied with respect to the alkylthiophene polymer and hence $x = 0.5, 1.0, 2.0$ was used. This solution was spin coated at 700 rpm for 40 s, and the wet film was dried in a covered glass Petri dish as by Li et al. [18]. The dried film was then annealed at 120 °C for 10 min in the glove box. The active film thickness was 230–250 nm measured by a Dektak 3030 profilometer. The cathode was 10 nm Ca covered by 100 nm Al. The device structure was ITO/PEDOT–PSS/BHJ/Ca/Al. The power conversion efficiency (PCE) for the different systems is shown in Table 1.

Table 1
Power conversion efficiency (PCE) and fill factor (FF) for BHJs of different alkylthiophene:PCBM BHJ. The leftmost column indicates ratio of alkylthiophene:PCBM. The upper values in columns 2, 3 and 4 indicate PCE while the lower values indicate FF. Device structure was ITO/PEDOT/BHJ/Ca/Al.

	P3BT	P3OT	P3DT
2:1	1.89%	2.1%	0.09%
	65.16	53.7	43.6
1:1	1.64%	0.52%	0.18%
	46.0	32.11	48.9
1:2	0.94%	0.6%	0.03%
	43.55	47.3	23.3

Successful extraction of hole mobilities is demonstrated by blocking the electrons for various poly-alkylthiophene:PCBM BHJ at varying amounts of PCBM loading percentage. This is achieved by using appropriate blocking electrode to suppress the peak for one carriers (block this carrier) thus in effect separating the electron and hole mobility peaks. The authors propose this as a generalized method which can be applied to any of the polymeric systems. N,N′-bis(3-methylphenyl)-N,N′-diphenyl-[1,1′-biphenyl]-4,4′-diamine (TPD) (a well-known electron blocking material in small molecule solar cells as shown in Fig. 1c, with highest occupied molecular orbital (HOMO) and lowest occupied molecular orbital (LUMO) levels of 5.4 eV and 2.2 eV [19] respectively), was the material of choice to be thermally deposited between the polymer BHJ and the Ca/Al electrode. The device structure was ITO/PEDOT–PSS/BHJ/TPD/Ca/Al as shown in Fig. 1b. The TPD layer thickness was 7–8 nm and was deposited at a base pressure of 1×10^{-6} torr. Vacuum was broken after deposition of TPD and the film was exposed to air for less than a minute while it was loaded into another chamber for deposition of Ca/Al electrode. BHJ's as detailed in Table 1 were used in this structure. I–V curves on introduction of

additional TPD layer show a reduction in efficiency due to blocking of electrons by the TPD layer.

The experimental setup for the CELIV is shown in Fig. 1d and was the same as in Ref. [20]. A variable pulse generator Wavetek Datron 195 and a memory oscilloscope Tektronix TDS 430A were used to recode the extraction currents. In this technique charges that cause conductivity in the dark are extracted by a triangular voltage pulse [13]. The extraction field pulls charges towards the electrodes which gives rise to a current transient. The initial of the pulse current is equal to the capacitive displacement current given by:

$$j(0) = \frac{A\varepsilon\varepsilon_0}{d}$$

(where A is the ramp rate of voltage, d the film thickness, ε is relative dielectric permittivity and ε_0 is the dielectric permittivity with respect to free space). By selecting the appropriate voltage rise speed ($A = V/t$) the current goes over the maximum, and from the peak extraction time t_{max} (marked by arrows in the corresponding figures) the mobility can be calculated as:

$$\mu = \frac{2d^2}{3At_{max}^2 \left[1 + 0.36\frac{\Delta j}{j(0)}\right]} \quad \text{if } \Delta j < j(0)$$

Current maxima is calculated from the zero intersect to the peak position and this excludes ohmic effects.

3. Results and discussion

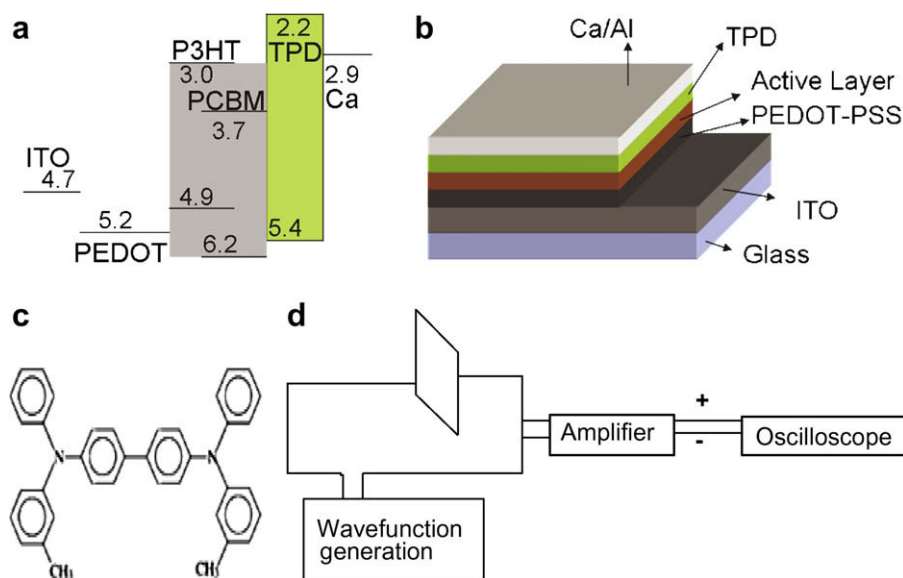
Fig. 2a shows the CELIV transient for the structure ITO/PEDOT–PSS/P3BT:PCBM/Ca/Al. It is quite apparent that the transient peak is quite broad with poorly defined maxima for certain PCBM loading concentrations (1:1 and 2:1). It has been argued that the mobility obtained from peaks for CELIV transients corresponds to the majority carriers


Fig. 1. (a) Energy diagram and (b) device structure for ITO/PEDOT/alkylthiophene:PCBM/TPD/Ca/Al, (c) chemical structure of TPD, and (d) schematic of CELIV setup used for the experiments.
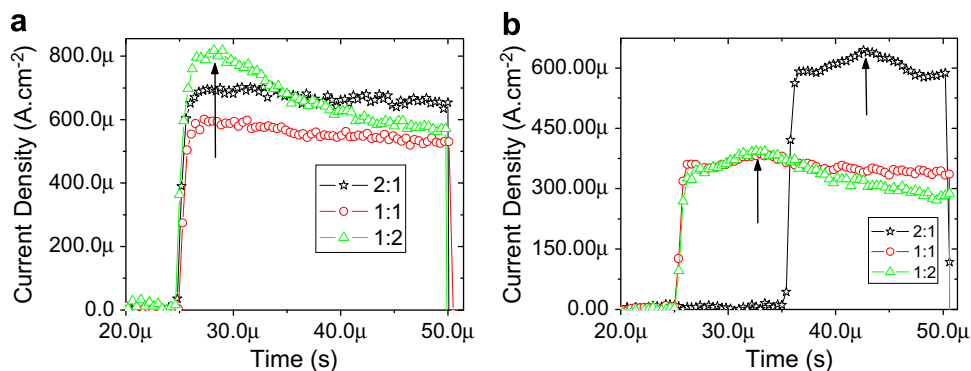

Fig. 2. CELIV curves for P3BT:PCBM BHJ. The device structure is (a) ITO/PEDOT:PSS/P3BT:PCBM/Ca/Al and (b) ITO/PEDOT:PSS/P3BT:PCBM/TPD/Ca/Al using a blocking electrode (TPD) at the cathode. The label in each of the subfigures indicates the ratio by weight percent (black star = 2:1, red circle = 1:1 and green triangle = 1:2) of P3BT:PCBM in the active layer. Approximate peak positions are indicated by arrows. In Fig. 2a only the mobility for ratio 1:2 (△) can be pointed by the arrow. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

[13,21] and the integrated area under the peak gives the carrier number. However, it is difficult to extract exact mobility values from broad peaks due to uncertainty associated with t_{max} in broad peaks (such as in Fig. 2a). These imply probably a superposition of peaks for both the carriers resulting in a particularly broad peak. Hence, if the electrons are blocked the peak corresponding to electrons should be very small (if any). Based on this underlying principle, CELIV transient for P3BT:PCBM system with the blocking TPD layer (structure ITO/PEDOT–PSS/P3BT:PCBM/TPD/Ca/Al) is shown in Fig. 2b (voltage ramp *A* for 2:1, 1:1 and 1:2 blends being 330, 195 and 195 kV/s). For the P3BT:PCBM ratio of 2:1 a higher ramp voltage has been applied to get a better hole peak. This will not influence the extracted mobility values. These peaks were ascribed to hole mobility as explained earlier. The calculated mobility values for the different loading concentrations of PCBM are shown in Table 2. It is to be noted that these peaks are much more prominent and sharper than those compared to those in Fig. 2a. This will be discussed in more detail later.

To test the method for more systems, similar thiophene–backbone based polymers (as P3BT) but with longer side chains (P3OT and P3DT) were used. The TPD layer was used in a similar architecture as shown in Fig. 1b to demonstrate extraction of hole mobility. The CELIV transients for these polymers with the structure ITO/PEDOT–PSS/alkylthiophene:PCBM/TPD/Ca/Al has been shown in Fig. 3 (for 2:1, 1:1 and 1:2 blends, the ramp *A* was 204, 270 and 230 kV/s for P3OT and 270, 195 and 230 kV/s for P3DT). A summary of the calculated values of hole mobili-

ties has been given in Table 2. It is to be noted that for 1:1 ratio of thiophene:PCBM, P3BT with the shortest four carbon alkyl side chain shows higher mobility among all three polymers under study in agreement with some previous reports [22] (measured using FET). These results agree with the correlation between mobility and the length of the alkyl side chain. Assuming the same degree of regioregularity as well as polymerization degree for all three P3ATs, the hole mobility should increase as the length of the side chains decreases due to their contribution to the degree of intermolecular order and chain packaging density. However, this trend is not observed for 2:1 or 1:2 blends. There are also contrary reports of a non-monotonous decrease in mobility with side chain length for pure alkylthiophene polymers [23] (measured by FET). From the experimental results, it is concluded that mobility is a complex function of interlayer distance, crystallinity, crystallite size etc.; all of which will be influenced by external factors such as PCBM loading concentrations. Hence, it is all more important to study mobility values for actual solar cell devices. Therefore, results reported earlier using FET or TOF might not reflect the actual mobility values in real devices. These hole mobility values are, not surprisingly, lower than those reported by FET: approximately 10^{-3} cm² V^{-1} s^{-1} for P3OT [24] and 2×10^{-3} cm² V^{-1} s^{-1} for P3DT [25]. Previous literature [26] shows that there is at least an order of magnitude difference between FET and CELIV mobility, with FET mobilities being the higher, for this class of system.

For P3BT, there seems to be an increase in hole mobility on increasing the PCBM concentration. Although on increasing the PCBM percentage, the order of mobility change is very small. This increase is less prominent in P3DT and almost absent in P3OT. Increase in hole mobility of polymers with increase in PCBM percentage has also been observed for other polymers also and has been reported earlier [27,28]. According to Pacios et al. [29], the change in film morphology upon adding PCBM molecules results in an enhanced intermolecular interaction and therefore an improved charge transfer between adjacent molecules. Though under optimized annealing conditions,

Table 2
Hole mobilities (unit: cm² V^{-1} s^{-1}) extracted from CELIV peak maxima of Fig. 2 for various alkylthiophene:PCBM (given in row 1) loading conditions.

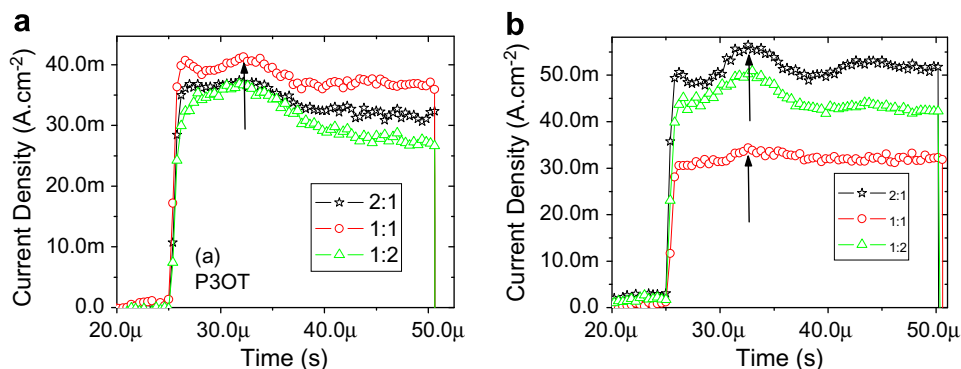
	P3BT	P3OT	P3DT
2:1	1.89 E−6	3.26 E−5	1.70 E−5
1:1	4.11 E−5	2.90 E−5	1.84 E−5
1:2	6.13 E−5	3.25 E−5	7.01 E−5


Fig. 3. CELIV curves for (a) P3OT:PCBM and (b) P3DT:PCBM BHJ using a blocking electrode (TPD) at the cathode. The device structure is ITO/PEDOT:PSS/ P3BT:PCBM/TPD/Ca/Al. The label in each of the subfigures indicates the ratio by weight percent (black star = 2:1, red circle = 1:1 and green triangle = 1:2) of alkylthiophene:PCBM in the active layer. Approximate peak positions are indicated by arrows. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

PCBM crystallizes out of the matrix of the BHJ [30,31], leaving the polymer chains behind which will try to reorganize and obtain an optimized morphology. Hence, for optimized devices, even on increasing PCBM loading concentration, the hole mobility should not vary by a huge factor.

For the CELIV transients shown, the peak corresponding to electrons should either be absent or highly suppressed. But on comparing the prominent hole peaks, it can be seen that some peaks are considerably sharper (distinguishable extraction time t_{max}), while others are still broad. It is suspected that in systems corresponding to sharp peaks (e.g. 2:1 ratio in P3BT:PCBM system), the hole and electron mobility is balanced, i.e. the peak for hole and electron mobility (even if a small one) overlap. According to Melzer et al. [32] and Li et al. [19], for high fill factors (and hence PCE) for BHJ solar cells, the charge carrier mobility should be balanced. In this case, all systems with sharp peaks indeed have considerably high fill factors (and consequently PCE) as reported in Table 1. In fact, CELIV signals for the highest fill factor for a particular donor:acceptor system have the most well defined extraction time t_{max} for that set. Based on above arguments a mobility balance is expected for the sharp peak of 2:1 ratio for P3BT:PCBM. It has also been reported that electron mobilities increase with acceptor (PCBM) loading concentrations [33]. If this is true then the peak for electron mobility should occur at lower time scales (left shifted) on increasing PCBM loading concentration. Indeed, for this case, the curves corresponding to higher PCBM concentrations are broader than those at lower PCBM concentrations. The authors believe that the electron mobility is indeed higher at higher PCBM concentrations and hence the electron mobility peak (appearing at lower time scales) is demerged from the hole peak, broadening the overall peak.

4. Conclusion

Summarizing, it has been shown in this letter that it is possible to obtain resolved hole mobility peaks through CELIV for the alkylthiophene:PCBM system by choosing the appropriate blocking electrode and the observations

agree with the existing theories. This method does not affect the organization in the polymer BHJ layer and hence it is expected that the mobility values obtained by this method will be closer to the real values. Universality of the method was demonstrated by using polymers from alkylthiophene system with varying side chain length and hole mobility for the optimized BHJ films were extracted. Since mobility is not the only factor affecting PCE, so based on these measurements no concrete conclusions for the varying performance between different alkylthiophene systems could be reached. But, it was shown, as suggested earlier, that a balance of hole and electron mobility is necessary for high fill factors. It is well known that further insight into the performance limiting properties of the solar cells can be gained by correlating the transport measurements with solar cell data. It is in this light that this method will help understand this correlation and the balance between electron and hole mobility, which is crucial to solar cells.

layer surface, and poor contact with the top electrode [11,12]. In this letter, we report the growth of dense arrays of vertically aligned, polycrystalline copper phthalocyanine (CuPc) molecular nanorods with diameter down to 20 nm using the high vacuum oblique angle deposition (OAD) process [13–15]. By infiltrating the CuPc nanorod arrays with the acceptor of [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) using spin-coating, we demonstrate interdigitated, bulk heterojunction organic PV devices with a maximum power conversion efficiency of $\eta_p = (1.8 \pm 0.1)\%$ under 1 sun AM1.5 solar illumination, a twofold improvement over that of optimized bilayer, planar heterojunction CuPc/PCBM device.

The nanorod arrays are grown on glass substrates pre-coated with a layer of indium-tin-oxide (ITO, sheet resistance $\sim 20 \, \Omega/\square$) in a high vacuum chamber (base pressure $\sim 1 \times 10^{-7}$ Torr). Different from normal high vacuum deposition processes in which the ballistic molecular or atomic beam typically arrives at the substrate surface from near-normal directions, in an OAD process (also known as glancing angle deposition), [13–15] the molecular/atomic beam arrives at the surface with a large angle from the substrate normal, nearly 90°. Due to the self shadowing effect by the deposited molecules and the limited adatom diffusion on the substrate surface, nanorod arrays with various morphologies can be obtained by controlling the incident angle of the molecule flux as well as the surface diffusivity of the molecules [14]. In our experiments, the molecular beam incident angle from the substrate normal was $\alpha \approx 80°$ during the nanorod growth. The substrate was either stationary or rotated at a speed of $\sim$5 rpm.

PV devices were fabricated by spin-coating PCBM solution (in chlorobenzene) onto the CuPc nanorod films at 1000 rpm for 45 s in a nitrogen glove box integrated with the vacuum system. The CuPc/PCBM composite films were then annealed at 80 °C for 15 min to remove residual solvent and further enhance PCBM infiltration. We have not observed any significant changes in the optical, morphological or electronic properties of the CuPc films upon such quick exposure to the chlorobenzene solvent. An 8 nm thick bathocuproine (BCP) exciton-blocking layer [16] was then deposited on top of the organic active region in high vacuum, followed by a 100 nm thick aluminum cathode to complete the device and form device areas of 4 mm². An Agilent 4155C semiconductor parameter analyzer was used to measure the current–density–voltage (J–V) characteristics of PV devices in the dark and under simulated AM 1.5 solar illumination from an Oriel solar simulator equipped with a Xe-arc lamp. The light intensity was measured using a calibrated single-crystalline silicon reference cell with a KG1 filter, and the spectral mismatch factor was corrected according to the ASTM Standard E973 [17]. X-ray diffraction (XRD) patterns of the organic films were obtained using a Philips X'pert MRD diffractometer in the θ–2θ geometry with a Cu K_α radiation source. The film morphology was investigated using a JOEL 6335F field-emission gun scanning electron microscope (SEM).

Fig.1a and b show the topographic SEM images of CuPc nanorod arrays grown with a stationary or rotational substrate, respectively, whereas Fig. 1c and d are the corresponding cross-sectional images. With a stationary
Fig. 1. Topographic ((a) and (b)) and cross-sectional ((c) and (d)) scanning electron microscope (SEM) images of CuPc nanorods grown on a stationary ((a) and (c)) or rotational ((b) and (d)) substrate. The scale bar is 100 nm in all four images.

substrate [Fig. 1a and c], slanted nanorods with 20–40 nm in diameter were grown on the ITO surface, tilting towards the direction of the incoming molecule flux during deposition [14]. On the other hand, the CuPc nanorods grown with rotational substrates have larger diameters, typically 40 to 70 nm, and are mostly in the up-right orientation. Moreover, large gaps (>50 nm) between the nanorods can be occasionally observed. However, upon closer observation we have found that the larger nanorods are in fact made up of a bundle of several smaller nanorods. This is consistent with the proposed morphology evolution model of OAD growth on rotational substrate [14].
Fig. 2. X-ray diffraction pattern of a CuPc nanorod film with 300 nm long nanorods and a 100 nm thick flat CuPc film.

The XRD pattern of a CuPc nanorod film grown with a rotational substrate is shown in Fig. 2 along with that for a CuPc flat film deposited in the normal fashion (i.e. molecules arriving at the surface roughly from the normal direction). The XRD patterns are very similar, showing diffraction peaks at $2\theta = 6.9°$, which suggest the existence of polycrystalline α-CuPc phase in the nanorods as well as in the flat film [18,19]. The polycrystalline structure of the CuPc nanorods is important to ensure high mobility for hole transport through the donor material, leading to high collection efficiency for photogenerated holes in the PV devices.

With the obtained CuPc nanorod arrays, an interdigitated bulk heterojunction was achieved by spin-coating a chlorobenzene solution of PCBM onto the nanorod arrays. Fig. 3 shows two cross-sectional SEM images of CuPc nanorods/PCBM composite films with different PCBM loading. No obvious voids or pin-holes are observed in either film, indicating good infiltration of PCBM into the spacing between CuPc nanorods. With a high PCBM loading (30 mg/mL in chlorobenzene), the spacing between CuPc nanorods is completely filled, resulting in a relatively smooth top surface [see Fig. 3b]. However, when a much lower PCBM loading (15 mg/mL) was used, the amount of

PCBM molecules deposited was insufficient to completely fill the spacing between the CuPc nanorods, leading to a corrugated and rough surface as shown in Fig. 3a. This suggests that the CuPc nanorods still stand vertically on the substrate and the spin-coating process does not damage the contact of the nanorods with the underlying ITO electrode, which is important for hole collection in PV devices.

To fabricate PV devices, planar (i.e. flat) and/or CuPc nanorod films with 40–60 nm long nanorods were deposited. A PCBM solution with a concentration of 22 mg/mL was spin-coated on top of the CuPc films at 1000 rpm, which leads to an average PCBM layer thickness of approximately 50 nm. Fig. 4 shows the J–V characteristics under 1 sun AM 1.5G illumination for PV devices based on CuPc nanorods grown with a stationary or rotational substrate (labeled as "NR-S", and "NR-R", respectively). The structure of the NR-R device is shown in the inset. Also shown for comparison are the characteristics of a bilayer, planar heterojunction CuPc/PCBM device (labeled as "Planar") with a 30 nm thick flat CuPc film and a PCBM layer deposited under the same condition as the nanorod-based devices. The layer thicknesses in this bilayer device are very close to optimized [20].

As shown in Fig. 4, the short-circuit current density is $J_{SC} = (4.4 \pm 0.2)$ mA/cm^2 for both NR-S and NR-R devices, higher than the planar heterojunction device, which is only (3.4 ± 0.2) mA/cm^2. The open-circuit voltage is the same for all three devices, at $V_{OC} = 0.57$ V, close to the previously reported value for the same D–A material system [20]. The fill factor (FF) of the NR-S device is, however, much lower than that for the NR-R device, 0.40 vs. 0.55, which could be attributed to the differences in the nanorod array morphology. The tilted nanorods obtained with a stationary substrate may present more challenges for the complete infiltration with PCBM molecules than the mostly up-right nanorods grown with a rotational substrate. Nevertheless,
Fig. 3. Cross-sectional scanning electron microscope (SEM) images of CuPc nanorod/PCBM composite films with PCBM concentration of (a) 15 and (b) 30 mg/mL in the chlorobenzene solution. The scale bars are 100 nm.
Fig. 4. Current–density–voltage (J–V) characteristics of four CuPc/PCBM photovoltaic cells under 1 sun AM 1.5G illumination: a bilayer cell (labeled as "Planar") with a 30 nm thick flat CuPc film, two devices with CuPc nanorods grown on ITO with a stationary ("NR-S") or rotational ("NR-R") substrate, and a device with a 20 nm thick flat CuPc film followed by a nanorod film ("Planar-NR"). The inset schematically illustrates the device structure of the NR-R device.
Fig. 5. (a) Current–density–voltage (J–V) characteristics in the dark for the Planar, NR-R, Planar-NR devices; (b) external quantum efficiency (EQE) as function of wavelength λ for Planar and Planar-NR devices.

the power conversion efficiency is $\eta_p = (0.95 \pm 0.05)\%$ for the NR-S device and $(1.4 \pm 0.1)\%$ for the NR-R device, both higher than $\eta_p = (0.85 \pm 0.05)\%$ for the bilayer device.

To further improve the efficiency of the nanorod-based devices, a 20 nm thick planar CuPc layer was inserted between the nanorods (approximate length ~40 nm) and the ITO. The planar layer can further improve the hole transport across the film and also provide additional absorption of the incident photons, similar to that in a planar-mixed heterojunction device [9,21]. As shown in Fig. 4, J_{SC} of this device (labeled as "Planar-NR") was improved to (5.6 ± 0.3) mA/cm^2 and a high FF of 0.53 was achieved. The Planar-NR device also shows a slightly higher V_{OC} of 0.60 V, leading to a power conversion efficiency of $\eta_p = (1.8 \pm 0.1)\%$, approximately doubling that of the optimized bilayer CuPc/PCBM device.

Fig. 5a shows the dark J–V characteristics for the Planar, NR-R, and Planar-NR devices. The NR-R device shows significantly higher leakage currents than the other two devices. The shunt resistance of the NR-R device as estimated from the dark J–V characteristics around $V = 0$ V is approximately $5 \times 10^4 \, \Omega \, cm^2$, compared to approximately $1 \times 10^7 \, \Omega \, cm^2$ for the Planar device and $3 \times 10^6 \, \Omega \, cm^2$ for the Planar-NR device. The difference in

the shunt resistance can be explained by considering the direct contact of the PCBM acceptor phase with the ITO anode in the NR-R device, which provides a direct leakage path between the two electrodes. Such leakage path does not exist when a flat CuPc layer has been deposited on the ITO anode, a case for both the Planar and Planar-NR devices. These results in turn also suggest that we have achieved excellent infiltration of PCBM molecules deep into the gaps of the CuPc nanorods.

A comparison of the external quantum efficiency (EQE) for the Planar and Planar-NR devices as a function of the incident light wavelength λ is shown in Fig. 5b. In both the CuPc (550 nm < λ < 800 nm) and PCBM (λ < 550 nm) absorption regions, the Planar-NR device possesses a 60–70% higher EQE than the Planar device. This efficiency increase is attributed to the increased interface area between the donor and acceptor species as enabled by the nanorod-based architecture. Note that integrating the EQE spectra shown in Fig. 5b with the standard AM1.5G solar spectrum [17] yields a 1 sun short-circuit current density of $J_{SC} = 5.3$ mA/cm^2 for the Planar-NR device and 3.2 mA/cm^2 for the Planar device, both within the experimental errors of the actual measured J_{SC}.

In conclusion, we have demonstrated that vertically aligned polycrystalline CuPc nanorods with diameters as small as 20 nm can be grown using the oblique angle deposition method. An interdigitated bulk heterojunction structure was subsequently realized by infiltrating the CuPc nanorod array with solution processed PCBM molecules. Growth of ~40 nm long CuPc nanorods on a thin planar CuPc film results in organic PV cells with power conversion efficiency approximately doubling that of an optimized bilayer CuPc/PCBM device. With further optimization of the nanorod growth and device fabrication processes, the structure described here could prove to be an effective architecture for very efficient organic PV cells.

A potential approach is to use Cs_2CO_3 as the electron-injection and hole-blocking layer in TiO_2 or ZnO-based devices [6,9,10]. Another approach is to improve the morphology and charge injection ability using the self-assembly monolayer (SAM) technique. SAM can adjust the work function (WF) of a substrate by producing a permanent dipole moment at interface [11,12]. As SAM links the substrate with an interfacial dipole directed towards the substrate, it would create an electric field which increases the WF of the substrate. Using this concept, numerous studies reported that the WF of the transparent substrate ITO or mirror substrate Ag is increased by linking a SAM with the high electronegativity terminal group to enhance the performance of PLEDs [11–15]. However, few reports have investigated that the WF of a cathode for I-LEDs is lowered by SAM technique.

In this study, two silane-based SAMs with different terminal groups were used to modify the TiO_2 surface. The presence of an amine group at the outer surface of *N*-[3-(trimethoxysily)propyl]ethylenediamine (PEDA-TMS)-modified substrate induces a strong dipole due to its low electronegativity, which lowers the WF of the cathode. The performance of I-PLED is enhanced by this compound. The device performance of 3-chloropropyltrimethoxysilane (CP-TMS) modified I-PLED is different from that of a device modified by PEDA-TMS because the chlorine atom owns the electron-withdrawing ability. The functions of the two SAMs on the TiO_2 surface are confirmed by ultraviolet photoelectron spectroscopy (UPS) measurement and electron-dominated devices. A storage test was performed on the PEDA-TMS-based device to measure the stability of both electrodes in air. The inverted device without sealing maintained a luminescence of about $120 \, cd/m^2$ after 48 h (the initial luminous was about $124 \, cd/m^2$).

2. Experimental

To fabricate the devices, ITO-coated glass substrates (received from RITEK Corp., 15 $\Omega/\square$) were cleaned in an ultrasonic bath with detergent, deionized water, acetone, and isopropyl alcohol and then dried under a N_2 stream. The substrates were treated using a UV/O_3 photoreactor to eliminate surface contaminants. Titanium isopropoxide $(Ti(OC_3H_7)_4$, Aldrich, 99.999%) diluted in *n*-butyl alcohol was spin-coated onto the ITO/glass substrate at 5000 rpm for 60 s. The spin-coating process was conducted in a N_2-filled glove box. $(Ti(OC_3H_7)_4)$ then underwent hydrolysis and was converted to TiO_x in air for at least 1 h. The TiO_x film underwent thermal annealing at 450 °C for 30 min to transform it into TiO_2. The glass/ITO/TiO_2 substrate was immediately surface modified by immersing it in 1 wt.% PEDA-TMS (Aldrich, 97%) or CP-TMS (Aldrich, 97%) toluene solution for 2 min in an ultrasonic bath. After the reaction, the substrate was rinsed with toluene and then dried in a N_2 steam. The glass/ITO/TiO_2 substrates with and without SAM were then transferred into a N_2-filled glove box. High-yellow phenyl-substituted poly(*para*-phenylenevinylene) copolymer (HY-PPV)(EL emission centered at 560 nm) was spin-coated onto the substrates and used as the light-emissive layer. A MoO_3 interfacial layer with a

thickness of 6 nm was thermally evaporated over the polymer, followed by the evaporation of Au(20 nm)/Ag(80 nm) at a pressure of 10^{-6} torr. A conventional PLED was also fabricated for comparison. ITO/PEDOT:PSS (Baytron-P AI 4083) and Ca/Al were used as the cathode and anode part, respectively, for this PLED.

The UPS experiments were carried out in VG CLAM4, whose illumination was a non-monochromatic He(I) UV source (21.2 eV). The total energy resolution of the measurement was 0.38 eV. The entire process was performed in a multi-chamber ultrahigh vacuum (UHV) system, which included the UPS analysis chamber base $(P_{base} \sim 8 \times 10^{-10}$ torr) and the preparation chamber $(P_{base} \sim 9 \times 10^{-10}$ torr). The work function (Φ) of the films is defined as $\Phi = hv - \Delta E$, where hv is the photo energy (21.2 eV) and ΔE is determined from the distance of the binding energy between the secondary electron emission cutoff edge (E_{cut}) and the Fermi level. The current density–voltage–luminance $(J–V–L)$ measurements were performed using a Keithley 2400 source measure unit and a Keithley 2000 digital multimeter with a silicon photodiode, calibrated using a Minolta LS-100 luminous meter. All measurements, expect for the storage test, were performed in a N_2-filled glove box.

3. Results and discussion

The mechanism of silanization is shown in Fig. 1. The molecules are hydrolyzed when they come close to the TiO_2 surface, which is covered with an H_2O film. Chains are then bonded to the substrate via hydrogen bonds. Water is then removed to link the silane molecule to the surface of TiO_2. The SAM substrates were analyzed using X-ray photoelectron spectroscopy (XPS) (not shown here). The feature peak of Si_{2p} is found at 103 eV [16]. The Si_{2p} peak appears on the substrates, demonstrating that the silane molecule was bound to the TiO_2 surface.

UPS is a valuable tool for investigating the electronic properties of a semiconductor. Fig. 2 shows the UPS spectra of ITO/TiO_2 and ITO/TiO_2/SAM substrates. The work function (WF) of a sample can be determined from UPS spectra using the difference between the photo energy and the width spectrum, the latter being given by the energetic separation of the high binding energy (secondary electron) cutoff and the Fermi level. In other words, the position of the cutoff corresponds to the position of the vacuum level relative to the Fermi level. The inset of Fig. 2 shows the emission cutoffs for these substrates. For the ITO/TiO_2 substrate, E_{cut} is located at 17.08 eV. The WF of TiO_2 was calculated to be 4.12 eV. Because TiO_2 is N-type semiconductors, its WF is close to the molecular energy level of the conduction band. From our previous study, the band gap of TiO_2 is 3.20 eV [17]. Therefore, the valance band of TiO_2 was calculated to be 7.32 eV. For the PEDA-TMS-modified substrate, E_{cut} increased by about 0.32 eV to give a WF of 3.80 eV. This result is attributable to the presence of the amine group. The high electron-donating ability of the amine group polarizes electrons, which results in an interfacial dipole that is directed away from the ITO/TiO_2 surface. The interfacial dipole decreases the vacuum level outside the TiO_2
Fig. 1. Scheme for the formation of self-assembled monolayers on ITO/TiO₂ substrates.

Fig. 2. UPS spectra of ITO/TiO₂ substrate with and without self-assembled monolayers.

layer since the Fermi level of the system is not changed. A lower vacuum level implies a lower injection barrier for electrons in the PEDA-TMS-modified device. For the CP-TMS-modified substrate, E_{cut} is 0.37 eV lower than that for the untreated TiO2 surface, giving a WF of 4.49 eV. Because the chlorine atom has an electron-withdrawing ability, the polarization of electrons has the opposite effect of that for the PEDA-TMS-modified substrate. Therefore, there is a 0.69 eV gap between the PEDA-TMS and CP-TMS-modified substrates.

The effect of SAMs on electron-injection was studied using Ca/Al as a cathode. Due to the low work function of

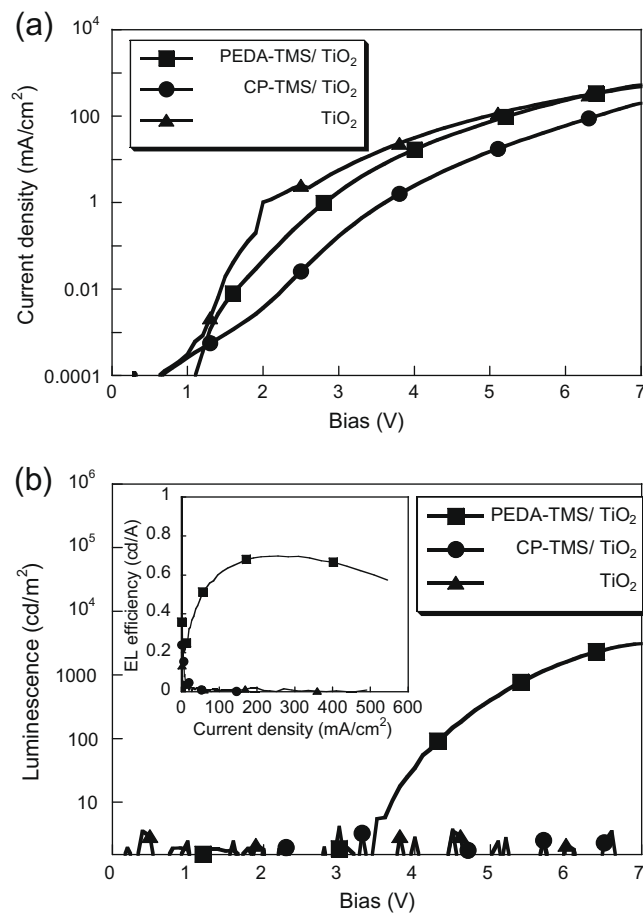
Ca, the hole injection is inhibited and the devices should be electron-dominated. The J–V curves of ITO/TiO₂/HY-PPV/Ca/Al and ITO/TiO₂/SAM/HY-PPV/Ca/Al are shown in Fig. 3. Because there is a high electron-injection barrier of 1.42 eV due to the energy mismatch of the LUMO of HY-PPV (2.70 eV) and the WF of ITO/TiO₂ cathode (4.12 eV), the current density for this device is very low even at a high driving voltage (0.38 mA/cm² at 7 V). The threshold voltage of the PEDA-TMS-modified device is greatly reduced compared to that of the base one. From UPS results, the effective dipole created by PEDA-TMS lowers the WF of the ITO/TiO₂ cathode by 0.32 eV, thereby eliminating the
Fig. 3. Current density–voltage curves of electron-dominated devices with and without self-assembled monolayers.


Fig. 4. (a) Current density–voltage and (b) luminescence–voltage curves of the devices with and without self-assembled monolayers. Inset: EL efficiency vs. current density.

electron-injection barrier and enhancing electron-injection into HY-PPV. In addition, the electron current is even more suppressed by the ITO/TiO$_2$ cathode modified with CP-TMS. As demonstrated above, the effective dipole created

by this SAM increases the WF of ITO/TiO$_2$ to 4.49 eV. This modification results in an electron-injection barrier of 1.79 eV between HY-PPV and ITO/TiO$_2$. Therefore, the electron current is almost completely suppressed.

Fig. 4a plots the J–V curves of the devices with and without SAM layers. The figure shows that the driving voltage for the devices with the SAM layers is higher than that for the device without SAM layers. The majority carriers in these devices are holes because the injection barrier for holes is much lower than that for electrons. Majority carriers determine J–V characteristics. Inserting SAM layers between HY-PPV and TiO$_2$ induces a higher resistance for holes, and thus produces a higher driving voltage. This indicates that SAM layers have hole-blocking capability. The L–V curves and EL efficiency vs. J are shown in Fig. 4b. The light turn-on voltage for the PEDA-TMS-modified device is 3.1 V. The light intensity was 3148 cd/m^2 at 7 V. The EL efficiency for this device was 0.7 cd/A at 200 mA/cm^2. However, no luminescence was observed for the other devices. From the results of UPS and electron-dominated devices, the enhanced EL efficiency for the PEDA-TMS-modified device is mainly attributed to the decrease in the WF of the cathode, which lowers the

injection barrier for electrons to enhance the probability of hole-electron recombination. In addition, injected electrons for the other devices are too few to emit light.

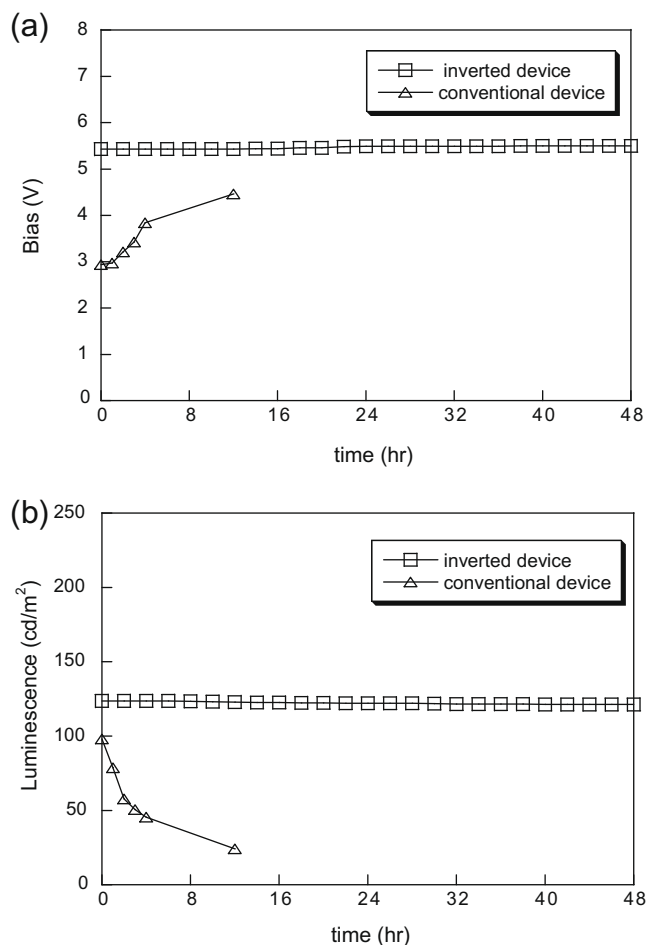
Fig. 5 shows the decays of device parameters, including light output and operating bias from the storage test without sealing. At a constant current of 0.5 mA/cm^2, the inverted device has an initial brightness of about 124 cd/m^2 and an initial driving voltage of 5.4 V. After 48 h of exposure to air, the light output decayed by less than 1% and the driving voltage slightly increased. For the conventional device, the light decayed by more than 75% after 12 h of exposure. The improved stability for the inverted device is attributed to two factors. (1) The conventional device consists of both Ca and acidic PEDOT:PSS layer. It is well known that Ca is easily oxidized by air. The acidic PEDOT:PSS has been proven to cause corrosion of ITO in air [18]. Both of them have a negative influence on the device stability. In the inverted device, ITO/TiO$_2$/PEDA-TMS and MoO$_3$/Au were chosen for the cathode and anode, respectively. They are not oxidized and reacted with ITO because both electrode materials are stable in air. (2) Several groups reported that the photoluminescence (PL) in PPV-type polymers rapidly weakens when irradiated in air


Fig. 5. Device parameters as a function of storage time for an inverted device and a conventional device: (a) bias vs. storage time and (b) luminescence vs. storage time.

[19–21]. The kinetic of the degradation depends on light, oxygen and the structure of the polymer [22,23]. TiO_2 has a scavenging effect due to its photocatalytic activity and intrinsic oxygen deficiency [24–26]. This can prevent the intrusion of O_2 or H_2O into the active layer, thereby improving the lifetime of unpackaged devices exposed to air. In addition, TiO_2 has strong absorption in the ultraviolet region [17], so it may protect the active layer from radiation damage.

4. Conclusions

A SAM technique was proposed for modifying the ITO/TiO_2 substrate for application in PPV-based I-PLEDs. The WF can be effectively decreased by linking the PEDA-TMS layer to the TiO_2 surface. The decrease is attributable to the presence of the amine group at the outer surface of TiO_2, which results in an interfacial dipole that is directed away from the ITO/TiO_2 surface. The PEDA-TMS modified substrate can be utilized as an effective cathode to improve the electron-injection ability and EL efficiency of I-PLED. For the CP-TMS-modified substrate, a contrary result is obtained due to the presence of a chlorine atom. In addition, the emission characteristics of the PEDA-TMS modified device were almost unchanged after exposure to air for 48 h.

ever, while n-channel ZnO TFTs have been widely reported (for example, [1,2]), there are no reports of stable, high-mobility, p-channel devices. In contrast, p-channel organic TFTs typically have higher mobility and better stability than n-channel organic devices. While the stability and field-effect mobility of most organic TFTs are poor compared to ZnO TFTs, organic TFTs can be fabricated using very simple solution processing, which may provide a path to an inexpensive and simple to implement CMOS process.

There have been several previous reports of hybrid inorganic–organic CMOS processes. Katz et al. demonstrated CMOS inverters using amorphous silicon and α-hexathienylene TFTs fabricated on separate substrates, with field-effect mobility of <1 cm²/V s and <0.03 cm²/V s, respectively [3]. Bonse et al. demonstrated ring oscillator circuits with a minimum propagation delay of 5 µs using a-Si:H and pentacene devices fabricated on a single substrate [4]. Low-voltage ZnO–pentacene CMOS circuits were demonstrated where both the ZnO and pentacene TFT mobilities were ~1 cm²/V s, and a ZnO–pentacene inverter was shown to respond up to a 10 Hz input frequency with rise and fall times of 4 and 13 ms, respectively [5]. 5-stage hybrid CMOS ring oscillator circuits fabricated using indium gallium zinc oxide and pentacene TFTs operated with a minimum propagation delay of 1 ms/stage at 10 V [6]. All of the previous reports used vacuum-based processes to deposit the gate dielectric layer as well as both semiconducting layers. In addition, different metallization steps and pattering steps were required for the organic and inorganic semiconductor TFTs. These vacuum-based processes and additional mask steps result in a more complicated, expensive process. In addition to the complex processing, the dynamic performance of ZnO-based hybrid CMOS circuits thus far has been limited to >1 ms/stage. In this report we demonstrate a simple 4-mask CMOS process with bifunctional Ti/Au contacts and ZnO/organic hybrid circuits operating at <150 ns/stage at a supply voltage of 35 V.

We previously demonstrated a low-temperature (200 °C), atmospheric pressure, spatial atomic layer deposition process that allows rapid deposition (10–20 nm/min) of high-quality, uniform, and stable Al_2O_3 and ZnO thin films [7]. We have also demonstrated that these films can be used to fabricate high-mobility TFTs (>15 cm²/V s) and fast ring oscillators (<31 ns/stage for 4 µm channel length) [8]. The fast circuits, good subthreshold slopes, and device stability are consistent with low interface state densities at the Al_2O_3/ZnO interface in these TFTs [7,8]. We have also previously reported that the organic semiconductor difluoro 5,11-bis(triethylsilylethynyl) anthradithiophene (diF TES-ADT) yields a different and more ordered microstructure on and near pentafluorobenzene-thiol-treated gold electrodes than on untreated oxide surfaces, resulting in high-mobility (~0.1–1 cm²/V s) and a self-patterning character for diF TES-ADT TFTs and circuits [9,10]. The nature of this crystallization phenomenon and its impact on the electrical properties of the material and interfaces is related to contact treatments and molecular design and has been described in detail in several previous reports [9–12]. Using this self-patterning microstructure we demonstrated simple all-organic circuits operating at

3.3 µs/stage with no direct patterning of the organic layer [11]. We report here an integrated approach that combines these two technologies in a simple way to form high-speed, low-temperature CMOS circuits.

2. Experimental

The hybrid inorganic/organic CMOS circuits were fabricated on 2.5″ × 2.5″ borosilicate glass substrates, with an ion beam sputtered and photolithographically patterned chromium layer used for both the organic and inorganic TFT gates. Spatial ALD was used to deposit 150 nm of Al_2O_3 and 100 nm ZnO at 200 °C and atmospheric pressure. Photolithography and wet etching were used to pattern the ZnO and Al_2O_3 layers. Next, using a double-layer photoresist (Novalak/PMMA) mask, we first Ar ion beam-etched our ZnO contact surface and then deposited ion beam-sputtered Ti/Au (10/100 nm) and patterned electrodes by lift-off. The ion beam etching of the contact area improves the contact resistance to the ZnO [13]. Ti/Au was used because the Ti bottom layer makes a good contact to the n-channel ZnO and the Au top layer makes a good contact to the p-channel diF TES-ADT, minimizing the processing and mask steps required for device fabrication. The Ti/Au electrodes were then treated with the self-assembled monolayer pentafluorobenzene thiol (PFBT), and the Al_2O_3 dielectric was treated with hexamethyldisilazane (HMDS). The diF TES-ADT organic semiconductor was then spin-cast from a 2.5 wt.% solution in chlorobenzene with a chlorobenzene solvent vapor ambient maintained above the sample during spin-casting to promote uniform, large grain growth on and near the near the PFBT-treated contacts [14]. The solvent spinning combined with the contact-related microstructure previously mentioned is a straightforward way to achieve a highly controlled organic crystallization. The samples received a 30 min bake at 90 °C to remove residual solvent and were then tested. All devices and circuits were measured in air. A schematic cross-section and optical micrograph of a CMOS inverter and enlarged images showing the organic thin-film differential microstructure on gold and oxide are shown in Fig. 1. The differential microstructure between the treated gold electrodes and the untreated oxide areas provides enough device isolation for simple circuit operation without direct patterning of the organic semiconductor. The entire process required no vacuum processing to deposit the semiconducting and dielectric layers and only four masks and lithography steps.

3. Results

Discrete n-channel ZnO and and p-channel diF TES-ADT transistors were tested. The 150-nm-thick Al_2O_3 layer had a dielectric constant of eight. The n-channel ZnO transistors had mobility of 12–15 cm²/V s and threshold voltage of ~0–1 V. The p-channel diF TES-ADT transistors had mobility of ~0.1–0.2 cm²/V s and threshold voltage of ~8–12 V. In both transistors the off current was limited to ~1 µA due to residual leakage through the unpatterned organic layer and not through the ZnO layer which is fully

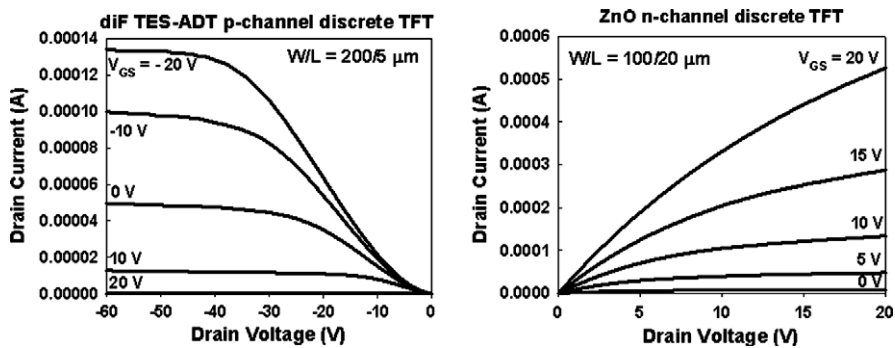

Fig. 2. Drain current as a function of drain voltage for several gate voltages for discrete p-channel (left) and n-channel (right) devices. The p-channel device has a field-effect mobility of $\sim$0.1 cm^2/V s and the n-channel device has a field-effect mobility of $\sim$12 cm^2/V s.
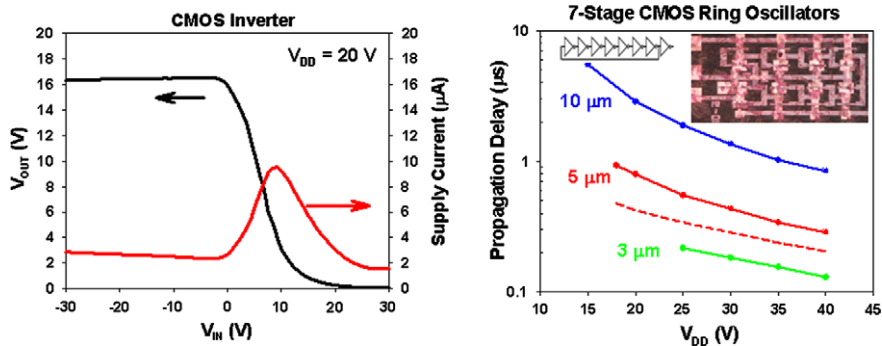

Fig. 3. Output voltage and supply current for a unit CMOS inverter with a beta ratio of 10 (left). Experimentally measured propagation delay as a function of channel length for 7-stage CMOS ring oscillators with AIMSpice simulated propagation delay in the dotted line (right).

depleted even at 100 nm thickness. The off current of these devices would be improved by patterning the organic layer, but the circuits operate well without patterning. In addition, because the p-channel organic material covers the ZnO layer in the n-channel device, these devices are ambipolar. However, because the mobility for the ZnO is $\sim100\times$ higher than the diF TES-ADT and the ZnO layer is relatively thick (100 nm), resulting in reduced gate capacitance, the p-channel channel formation in the organic layer on top of the n-channel ZnO devices has minimal impact and results mainly in a small shift in the n-channel threshold voltage (<3 V). This impact would also be removed by using a patterned organic layer. Plots of the drain current as a function of drain voltage for several gate voltages are shown in Fig. 2 for both the n-channel and p-channel devices.

Fig. 3 (left) shows the characteristics of a hybrid inorganic ZnO – organic diF TES-ADT CMOS inverter. The static off current and power consumption of the circuits were limited by the unpatterned diF TES-ADT organic layer, and the supply current peak is partially due to the depletion mode organic TFT with threshold voltage of 8–12 V. In addition, the inverter was designed with a $[W/L_{p\text{-channel}}]/[W/L_{n\text{-channel}}]$ ratio of 10, but the mobility was actually $\sim100\times$ larger in the n-channel device. Patterning the organic material and optimizing the circuit design would allow for substantially improved gain and power consumption. However, despite these non-idealities, the robustness of CMOS digital circuits allows acceptable operation for a range of integrated circuit applications. As an example, we fabricated simple 7-stage ring oscillators. Fig. 3 (right) shows the propagation delay as a function of supply voltage for three different TFT channel lengths. For the organic TFTs, the mobility has significant channel length dependence. This is due to the treated contact-related microstructure self-patterning which results in diF TES-ADT grains which extend completely across short channel length devices, but not longer channels, and thus in a mobility that increases with decreasing channel length. As a result the decrease in propagation delay as a function of channel length is more substantial than would be expected for a constant mobility versus channel length devices. AIMSpice [15] was used to fit I–V curves for discrete 5 μm channel length diF-TES-ADT and ZnO TFTs and to simulate ring oscillator operation. The result is shown in Fig. 3 (right, dotted line) and shows a reasonable match to the experimental results. Because AIMSpice does not have time constants for charge states this reasonable match is evidence that slow-interface states do not dominate the electrical performance of these devices. Seven-stage ring oscillators fabricated with a beta ratio of 10, 3-μm channel lengths, and 1-μm gate/source and gate/drain overlaps oscillated at a frequency >500 kHz, corresponding to a propagation delay of <150 ns/stage at a supply voltage of 35 V.

4. Conclusion

We have fabricated hybrid inorganic ZnO n-channel and organic diF TES-ADT p-channel CMOS circuits by depositing both the dielectric and semiconductor layers at atmospheric pressure and low-temperature (<200 °C). The CMOS circuit fabrication process is simplified to only four masks by using bifunctional Ti/Au contacts for both the ZnO and diF TES-ADT TFTs. In addition, the functionalized organic semiconductor provided a contact-related microstructure which allowed simple circuits to operate without directly patterning the organic semiconductor layer. Thin-films transistors were formed and the n-channel ZnO had field-effect mobility of 12–15 cm²/V s and the p-channel diF TES-ADT had field-effect mobility of 0.1–0.2 cm²/V s. Using these devices seven-stage CMOS ring oscillators were fabricated and operate at >500 kHz corresponding to a propagation delay <150 ns/stage at a supply bias of 35 V, the fastest hybrid organic/inorganic circuits reported to date.

The junction between the electrode and the organic semiconductor has a significant influence on the performance of an organic device [19]. A buffer layer is usually sandwiched at the metal–organic semiconductor interface to improve the charge-injection capability and overall device performance [20–22]. Although the output current in vertical-type transistors is dramatically enhanced when a thin buffer layer of LiF is incorporated between the emitter electrode and the organic emitter [13,23], the OFF current usually remains high – sometimes even higher than that of the device lacking a LiF layer. This behavior might be attributable to the diffusion of metal into the active layer or unfavorable chemical reactions between the organic layer and the metal electrode when operating the devices under high electric fields. Moreover, because the leakage current of a vertical transistor depends mainly on its film thickness, the presence of a thin LiF layer cannot help to reduce the leakage current. Hence, the choice of the buffer layer is a crucial factor toward improving the overall device performance.

Employing the diverse electronic properties of transition metal oxides could provide a unique opportunity to lower the energy barrier between metal and organic for the charge-injection. When a metal oxide film is sandwiched between the metal and organic semiconductor, the fundamental principle governing charge-injection at the junction is controlled by the doping concentration of the film. Therefore, a thicker film can be incorporated to prevent the diffusion of metal into the active layer and unfavorable chemical reactions between the active layer and metal electrode, while maintaining the charge-injection capability. In this Letter, we describe how the performance of organic base-modulation triodes (OBMTs) is improved after inserting a metal oxide film between the emitter electrode and the organic emitter. The OBMTs featuring molybdic oxide (MoO_3)/Al bilayer emitter electrodes exhibited increased output current; as a result, the current ON/OFF ratio reached as high as 10^3, thereby allowing inverters to be prepared exhibiting higher gains.

2. Experimental

The structure of the OBMTs is revealed in the inset to Fig. 1. Prior to deposition, the glass substrates were cleaned using detergent, acetone, and isopropyl alcohol and then treated in a UV–ozone cleaner for 15 min. A 30-nm-thick Au layer was deposited on the glass substrate to serve as a collector electrode. A 50-nm-thick layer of copper phthalocyanine (CuPc, Luminescence Technology) was thermal deposited on the Au layer to smoother the surface morphology and then a 270-nm-thick layer of pentacene (ca. 98% purity, Luminescence Technology), which served as the collector of the p-channel triode, was thermal evaporated. A 30-nm-thick Al strip was thermally evaporated onto the pentacene layer to function as the base electrode. A thin Al film (10 nm) was then deposited and a lithium fluoride (LiF) layer of 0.4 nm was thermally evaporated to function as a hole injection enhancement layer. A 20-nm-thick layer of N,N'-bis(naphthalen-1-yl)-N,N'-bisphenylbenzidine (NPB) was thermally evaporated to enhance the

carrier energy. Pentacene was then thermally evaporated to form the 100-nm-thick emitter layer. Finally, for comparison, three types of emitter electrodes were used: 30-nm-thick Au, 30-nm-thick Ag, and 50-nm-thick MoO_3/30-nm-thick Al. The patterns of each layer were defined using different metallic shadow masks. The active area of the device, defined by the crossover between the emitter and collector electrodes, was 0.0042 cm^2. The work functions of Al, Au, and Ag and the energy level of MoO_3 are presented schematically in Fig. 2a [20]. All organic materials were used without further purification and were deposited through thermal evaporation at a base pressure of ca. 2×10^{-6} torr. The current–voltage (I–V) characteristics of the devices in a glove-box ambient (H_2O and O_2 contents: <1 ppm) were measured using a Keithley 4200 semiconductor parameter analyzer. X-ray photoelectron spectroscopy (XPS) was performed using a PHI 5000 VersaProbe system (ULVAC-PHI Chigasaki, Japan) and a microfocused (100 μm, 25 W) Al X-ray beam with a photoelectron take-off angle of 45°.

3. Results and discussion

Fig. 1a displays the collector-to-emitter current (I_{CE}) versus the collector-to-emitter voltage (V_{CE}) characteristics of the OBMT employing MoO_3/Al as the emitter electrode, with base–emitter voltages (V_{BE}) ranging from 0 to −5 V at a step of 0.5 V. The value of I_{CE} reached up to −16.1 μA when V_{CE} and V_{BE} were both −5 V. The current ON/OFF ratio, defined as I_{CE} (V_{BE} = −5 V)/I_{CE} (V_{BE} = 0 V) at V_{CE} = −5 V, was ca. 3.08×10^3. For comparison, we also tested Au and Ag as emitter electrodes. We found that the emitter electrode of the emitter–base (EB) diode had a significant influence on the electronic properties of the OBMTs. Table 1 summarizes the device parameters of the OBMTs employing Au, Ag, and MoO_3/Al as emitter electrodes. The device featuring MoO_3/Al as the emitter electrode had the highest ON current, while maintaining an OFF current similar to those of the other systems. Although a small energy barrier exits between Au and pentacene, metals deposited onto the pentacene surface penetrate the surface, thereby doping the upper layer of pentacene to form a metallic overlayer. Due to charge transfer across the metal/organic semiconductor interface, redistribution of electron cloud, and interfacial chemical reaction, an interface dipole forms immediately, increasing the barrier height between the metal and pentacene [24,25]. The modified MoO_3 layer interface provided protection against metal diffusion into the organic layer and unfavorable chemical reactions between the organic and metal electrodes; it decreased the intensity of the interface dipole and enhanced the degree of charge-injection. Besides, we also observed the output current of the device was modulated by the base current. Fig. 1b and c displays the I_{CE} versus V_{CE} under common-base mode and common-emitter mode. As the following two equations [16]:

$$\alpha = \frac{I_{CE} - I_{CE}(I_E = 0A)}{I_E} \tag{1}$$

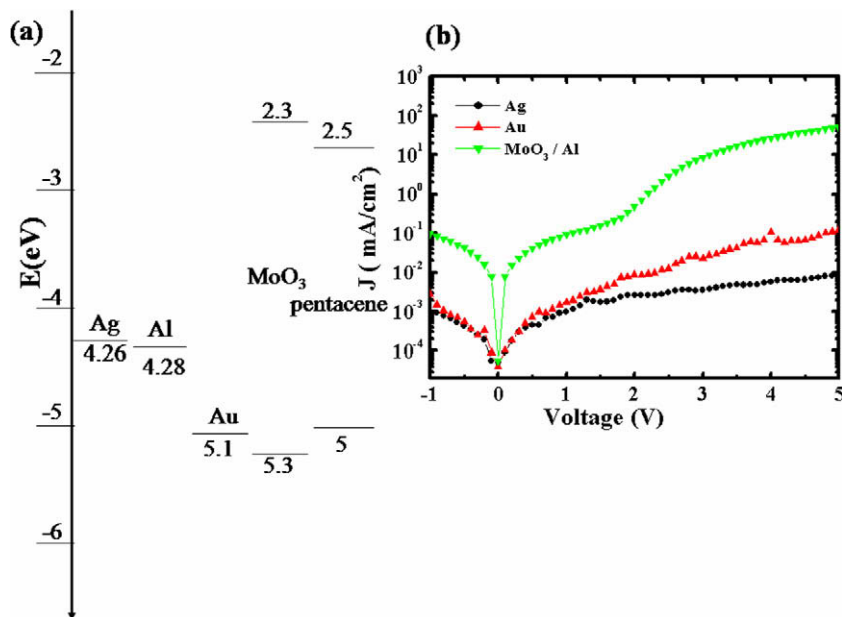
$$\beta = \frac{I_{CE} - I_{CE}(I_B = 0A)}{I_B} \tag{2}$$
Fig. 1. (a) Collector-to-emitter current (I_{CE}) plotted as a function of the collector-to-emitter voltage (V_{CE}) for base voltages ranging from 0 to −5 V at a step of −0.5 V. (b) I_{CE} as a function of V_{CE} for emitter current ranging from 0 to 400 μA under the common-base mode. (c) I_{CE} as a function of V_{CE} for base current ranging from 0 to 400 μA under the common-emitter mode. Inset: schematic representation of the device structure with emitter electrode MoO₃/Al.


Fig. 2. (a) Current density (J) versus voltage (V) characteristics of EB diodes featuring Au, Ag, and MoO₃/Al as emitter electrodes. (b) Energy level diagrams of the organic materials and the metals.

The I_E and I_B are the input emitter current and the base current under common-base and common-emitter mode, respectively. Under Eqs. (1) and (2), the transport factor (α) of 0.1 and current gain (β) of 0.1 were measured. To determine the reason why the barrier between the electrode and organic layer influenced the performance of

Table 1
Device performance of OBMTs featuring Au, Ag, and MoO$_3$/Al as emitter electrodes; V_{CE} and V_B were both -5 V.

Emitter electrode	Output current (A)	OFF current (A)	Current ON/OFF ratio
Au	3.51×10^{-6}	4.42×10^{-9}	7.94×10^2
Ag	1.29×10^{-8}	5.43×10^{-9}	2.37
MoO$_3$/Al	1.61×10^{-5}	5.23×10^{-9}	3.08×10^3

the OBMTs, we measured the current density (J) versus voltage (V) characteristics of EB diodes featuring Au, Ag, and MoO$_3$/Al as emitter electrodes. Fig. 2b reveals that the EB diode incorporating the MoO$_3$ layer provided improved hole injection and an obvious turn-on effect at ca. 1.4 V in Fig. 1 when V_{BE} was -5 V. For the same CB diode structure, the output current of the OBMT is determined by the currents of the forward-bias EB diode and the reverse-bias CB diode [18]. Therefore, the output current of the OBMTs was enhanced when using MoO$_3$/Al as the emitter electrode.

Because we deposited the MoO$_3$ layer through thermal evaporation, inevitably it decomposed into various Mo species. We recorded XPS spectra to identify the chemical species present in the "MoO$_3$" layer (Fig. 3). In Fig. 3b, we observe two measured binding energies (228.5 and 231.5 eV), suggesting that the layer included two or more Mo species. Contamination from the boat introduced into the film during thermal evaporation resulted in the shifting of the two peaks [26] from their expected values for MoO$_3$ and MoO$_2$ [27]. The intensities of the signals for MoO$_2$ and MoO$_3$ were similar, suggesting that MoO$_2$ was heavily doped into the MoO$_3$ film. Therefore, the MoO$_3$ film behaved as a degenerate semiconductor, to align the work function of the metal and the Fermi-level of the MoO$_3$ layer, with the depletion region at the MoO$_3$–Al interface being so narrow that the carriers had a high probability of tunneling through the barrier when a suitable bias voltage was applied to the EB diode. To further demonstrate this phenomenon, we fabricated emitter electrodes featuring different thicknesses of the MoO$_3$ interfacial layer; Fig. 4 presents the J–V characteristics of the resulting EB
Fig. 4. Current density (J) versus voltage (V) characteristics of EB diodes having the structure Al (30 nm)/thin Al (10 nm)/LiF (0.4 nm)/NPB (20 nm)/pentacene (100 nm)/MoO$_3$ (0–70 nm)/Al (30 nm).

diodes. The devices employing MoO$_3$/Al bilayers had larger current densities than that featuring the bare Al layer; the maximum value occurred at a MoO$_3$ thickness of 50 nm. Because a thicker MoO$_3$ interfacial layer would result in a longer carrier transport pathway, the probability of carrier capture would increase rapidly and the number of carriers received by the electrode would decrease. Therefore, OBMTs employing a suitable MoO$_3$ thickness would provide superior hole–injection contact and enhance the output current of the EB diode.

One of the advantages of the OBMTs requiring voltage driving is that they can be used to construct organic inverters. Fig. 5a and b displays the measured transfer characteristics of organic inverters composed of the OBMT connected with various resistances and corresponding gains, respectively. The resistance ranged from 2 to 10 MΩ at a step of 2 MΩ; a supply voltage of -5 V was applied. The inset displays the structure of a vertical OBMT with a load resistor. The corresponding gain of the inverter changed with respect to the resistance, with a maximum calculated gain of 6 arising when the OBMT was connected with a resistance of 10 MΩ. This resistor is, however, not an ideal switch; it resulted in the value of V_{out} of the inver-

Fig. 5. Measured transfer characteristics and corresponding gain of inverters measured at a value of V_{DD} of -5 V with resistances ranging from 2 to 10 MΩ at a step of 2 MΩ. Inset: sketch of the inverter structure and OBMT employing MoO_3/Al as emitter electrode.

ter varying upon increasing $|V_{in}|$. To overcome this drawback, the n-type OBMT should replace the resistor to form a complementary inverter; such a study is currently under investigation.

4. Conclusion

In conclusion, we have fabricated OBMTs featuring three types of emitter electrodes (Au, Ag, and MoO_3/Al). The output currents of these OBMTs were strongly related to the nature of the interface between the emitter electrode and the organic semiconductor layer. XPS analysis revealed that the MoO_3 films formed through thermal evaporation had degenerate semiconductor characteristics, resulting in a tunnel current component at the EB diode. Therefore, the devices featuring MoO_3/Al as the emitter electrode exhibited a current ON/OFF ratio of 10^3. Connecting different resistances to the OBMT allowed us to prepare inverters.

PEDOT:PSS showed lower resistivity, however, careful control of the doping level was required because excess doping caused phase separation and defects in PEDOT:PSS. On the other hand, Yoon and Berger [9] inserted an additional buffer layer between ITO and PEDOT:PSS to modify the contact condition. Facilitating hole collection by adjusting interface energy step resulted in an improved PCE in PSCs but an extra evaporation step in a vacuum is not a recommended method in the cost point of view.

In this study, we used external light irradiation: ultraviolet (UV) light to control not only the bulk resistance but also the contact condition of the PEDOT:PSS. This is a simple and cost-effective method compared to those attempted thus far. With a UV-irradiated PEDOT:PSS buffer layer, the PSCs showed an improved short-circuit current (J_{sc}) and fill factor (FF) so overall performance was enhanced.

To fabricate the PSCs, an indium tin oxide glass was cleaned and then exposed to oxygen plasma for 10 min before use. A buffer layer of PEDOT:PSS (Baytron P) was then spin-coated to a thickness of ~40 nm. After annealing the PEDOT:PSS films at 200 °C for 5 min, they were irradiated for 20, 40, and 60 min by a UV light source (output power density of 544 μW/cm^2) with its emission centered at 365 nm. An active layer composed of P3HT (Rieke Met. Inc.) and PCBM (Nano-C) (1:0.6 in weight ratio) were spin-coated from chlorobenzene with 220 nm ± 5 nm thin films. The prepared organic film was then thermal-annealed at 110 °C for 10 min. Finally, LiF (0.6 nm) and Al (100 nm) electrodes were deposited under a pressure of 5×10^{-7} torr. The defined active area was 9 mm^2 and all procedures were performed in a N$_2$ gas-filled glove box. The current-density-voltage (J–V) curves were measured by a Keithley 2000 source-measure unit. The photocurrent was obtained under illumination from a Thermal Oriel solar simulator (AM 1.5G). The illumination intensity used was calibrated by a standard Si photodiode detector (Fraunhofer ISE, certificate no. C-ISE269).

Fig. 1 shows the current-voltage (J–V) characteristics of the devices under illumination of AM1.5G, at an overall
Fig. 1. Current–voltage characteristics of PVs with different UV irradiation times on PEDOT:PSS films: pristine PEDOT:PSS (■); with 20 min UV irradiation (□); with 40 min irradiation (▲); with 60 min UV irradiation (▽).

intensity of 100 mW/cm^2 with different UV irradiation times on PEDOT:PSS films. To ensure the reproducibility, we fabricated five individual cells for each case, and photovoltaic parameters with mean deviation are summarized in Table 1. After UV irradiation, the reduced series resistance of the devices resulted in increased J_{sc} and FF values. Device without UV irradiation shows J_{sc} and FF, values of (9.10 ± 0.16)% and (54 ± 1.2)%, respectively, whereas with 40 min UV irradiation J_{sc} and FF reach to (9.89 ± 0.28)% and (57 ± 1.5)%, so calculated PCE increased from (3.05 ± 0.04)% to (3.46 ± 0.04)%. With further UV irradiation, the PCE is increased from (3.46 ± 0.04)% to (3.50 ± 0.03)%, however, the change is small respect to the irradiation time so it can be considered that the effect of UV irradiation becomes saturated after 40 min. In general, the origin of the series resistance of a photovoltaic cell can be either due to the limited charge transfer within the layers (bulk resistance) and/or charge transport between the layers (contact resistance) [10]. In the present case, all devices were fabricated in the same manner while changing only UV irradiation time, therefore it can be assumed that the reduction of series resistance comes from the bulk and/or contact resistance change of PEDOT:PSS by UV irradiation. To evaluate the effect of UV irradiation on bulk resistance of PEDOT:PSS, Raman spectroscopy and four-probe method (CMT SR2000 by A.I.T) were applied.

Fig. 2 shows the Raman spectra of PEDOT:PSS films with and without UV irradiation. The clearest difference between pristine and UV-irradiated PEDOT:PSS was the shoulder signal at 1445 cm^{-1}. The UV-irradiated PEDOT:PSS exhibited a weaker band in this region, and this indicates that the resonant structure of the PEDOT chains changes from a benzoid to a quinoid structure [11,12,16]. The benzoid structure favors coil conformation while the quinoid structure favors linear or expanded coil conformation. In the coil conformation, the C$_\alpha$–C$_\alpha$ bond between the two thiophene rings is similar to a σ bond and has a low density of conjugated π-electrons. Thus, the conjugated π-electrons are not completely delocalized so PEDOT films have a low level of charge-carrier mobility. In contrast, in the linear or coil-expanded conformation, thiophene rings in the PEDOT chains can be oriented in nearly the same plane. Therefore, the conjugated π-electrons are delocalized through the entire chain, giving the PEDOT films high charge-carrier mobility [11,12]. Hence, the conformational change of the PEDOT films from benzoid to quinoid results in a decrease of the bulk resistance of the PEDOT:PSS. The resistivity of the PEDOT:PSS films evaluated by the four-probe-method is summarized in Table 1.

Nextly, in order to examine the effect of the UV irradiation on PEDOT:PSS on the contact resistance of the devices, the impedance spectroscopy of the devices were measured in a dark condition [13]. Fig. 3 shows the impedance spectra of the devices at 0 V in a frequency range of 10^{-1} Hz–10 MHz. The diameter of semi-circle on the Z' axis represents the contact resistance. The resistance of the device without UV irradiation is approximately 0.52 MΩ, but it is decreased to 0.33, 0.27, and 0.21 MΩ after 20, 40, and 60 min UV irradiation, respectively. This result indicates that UV irradiation reduces the interface resistance

Table 1

Performance of ITO/PEDOT:PSS/P3HT:PCBM/LiF/Al photovoltaic devices with different UV irradiation times under an illumination of AM1.5 (100 mW/cm^2). The values of photovoltaic parameters are averaged over five individual cells.

Anode	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)	Resistance of PEDOT: PSS film[a] (MΩ cm)
Pristine PEDOT:PSS	0.608 ± 0.003	9.10 ± 0.16	54 ± 1.2	3.05 ± 0.04	0.72
With UV 20 min on PEDOT:PSS	0.614 ± 0.007	9.20 ± 0.11	57 ± 1.0	3.29 ± 0.08	0.58
With UV 40 min on PEDOT:PSS	0.612 ± 0.006	9.89 ± 0.28	56 ± 1.5	3.46 ± 0.04	0.42
With UV 60 min on PEDOT:PSS	0.616 ± 0.004	9.83 ± 0.17	57 ± 1.4	3.50 ± 0.03	0.39

between the PEDOT:PSS buffer layer and the P3HT:PCBM active layer, leading to a lower device series resistance. Theoretically, hole mobility is a few orders higher than electron mobility in organic material systems such as P3HT/PCBM [14], hence, holes are accumulate in the devices and the photocurrent is governed by space-charge limited conditions [15]. However, in this case, the bulk

and contact resistance of PEDOT:PSS as reduced by UV irradiation promotes hole extractions so that the accumulation of holes can be decreased. This results in improved J_{sc} and FF values, as shown in Table 1 and Fig. 1. Here, the surface morphology should be noted because the roughened surface of the PEDOT:PSS also can cause an increase in the value of J_{sc} [16]. From AFM tapping mode images (5 × 5 μm^2) (Fig. 4), the root mean square (rms) roughness value of pristine PEDOT:PSS was 1.563 nm, and 1.326 nm with 60 min UV irradiation. There was no significant change in the surface morphology in the PEDOT:PSS layer after UV irradiation.
Fig. 5. Work function change of PEDOT:PSS layer according to the UV irradiation time. The inset is a diagram of the proposed energy level indicating work function change of the PEDOT:PSS before and after UV irradiation.

Besides these effects, UV irradiation of PEDOT:PSS film has one additional effect: an increase in work function [17]. This change in the work function can be critical to the performance of polymer PVs because it can change the hole extraction barrier between active layer and PEDOT:PSS buffer layer. Accordingly, the change in the work function by UV irradiation was examined through a Kevin probe method. This revealed that the work function change was about 0.25 eV by 1 h UV irradiation (Fig. 5). Thus, after a UV treatment, the PEDOT:PSS films can have an extraction barrier 0.05 eV (Fig. 5, inset). There are two mechanisms for charge carrier injection/extraction at the interface, thermionic emission [18] and electron tunneling [19]. Since photovoltaic cells are operated at high temperature (around 300 K) and showed temperature-dependent current–voltage behavior [20], it can be concluded that thermionic emission dominates charge carrier extraction at the interface. For thermionic emission model,

$$J = A^* T^2 \exp(-\Phi_b/kT)$$

where A^* is Richardson constant, T is temperature (K), k is Boltzmann constant, Φ_b is Schottky barrier height. From this equation, about 5% charge carrier can be trapped at the interface by 0.05 eV energy barrier. So if the PEDOT:PSS film with lower work function is used to eliminate the energy barrier, higher PCE can be obtained by UV irradiation.

In conclusions, this study demonstrated that the efficiency of polymer solar cells can be improved by simple UV treatment on PEDOT:PSS buffer layer. From Raman spectroscopy, four-probe point and impedance spectroscopy measurements, it was found that UV-irradiated PEDOT:PSS films show reduction in both the bulk and contact resistance without changes of the surface morphology. This results in improved J_{sc}, FF and overall photovoltaic efficiency. From the analysis of change in work function of modified buffer layer (~0.25 eV), we found that higher photovoltaic performance can be obtained by adjusting buffer layer work function.

ORGANIC ELECTRONICS
materials • physics • chemistry • applications

Aims and scope

Organic Electronics is a primary journal whose interdisciplinary focus is organic materials, devices and phenomena, with application to devices such as organic light emitting diodes, thin film transistors, photovoltaic cells, etc.

Papers suitable for publication in this journal cover such topics as photoconductive and electronic properties of organic materials, thin film growth and characterization, charge and exciton transport, organic electronic and optoelectronic devices, etc.

Organic Electronics provides the only forum for both applied and fundamental contributions spanning the many different disciplines addressing the wide range of electronic properties and applications of organic materials. A Letters section is included for rapid publication of short articles announcing significant and highly original results.
