mained around 8.2 ± 02 mA cm^{-2} and V_{OC} increased to 0.59 ± 0.01 V. The decrease in FF observed for 0.1 mg ml^{-1} of PDMS-b-PMMA might be attributed to the thick active layer (116 nm), compared with the film without PDMS-b-PMMA (73 nm), as shown in Fig. 2. Since the optimum thickness for this device parameter is around 73 nm, the thicker active layer could cause the recombination of charges in the bulk-heterojunction films and therefore deterioration of FF. When more than 0.1 mg ml^{-1} of PDMS-b-PMMA was added to the solution, I_{SC} and FF first increased and peaked around 0.3 mg ml^{-1} and then gradually decreased, while V_{OC} continuously increased up to ca. 0.62 V. As the result, the optimum parameters were achieved with 0.3 mg ml^{-1} of PDMS-b-PMMA for which average values of PCE, V_{OC}, I_{SC} and FF of $3.56 \pm 0.04\%$, 0.61 ± 0.00 V, 8.68 ± 0.10 mA cm^{-1} and $67.4 \pm 0.7\%$, respectively, were observed. The highest PCE of 3.86% was achieved with 0.4 mg ml^{-1} PDMS-b-PMMA and V_{OC} of 0.60 V, I_{SC} of 9.61 mA cm^{-2} and FF of 67.0% in a different trial (Fig. 4). Since the active layer thickness did not change at this concentration of PDMS-b-PMMA (Fig. 2), this enhancement of the device performance can be attributed to the improved interfacial charge transport between the organic layer and the metal electrode.

For comparison, a commonly used buffer layer, LiF, was vacuum deposited on the P3HT:PCBM layer and used for the photovoltaic devices. The highest PCE of 3.19% was achieved in the device with 0.5 nm of LiF with V_{OC} of 0.58 V, I_{SC} of 8.69 mA cm^{-2} and FF of 63.4%. The improvement of the performance was more significant with PDMS-b-PMMA than with LiF. Along with the easy preparation in the single solution process, the PDMS-b-PMMA layer has a great advantage compared to the other buffer layers deposited by dry processes.

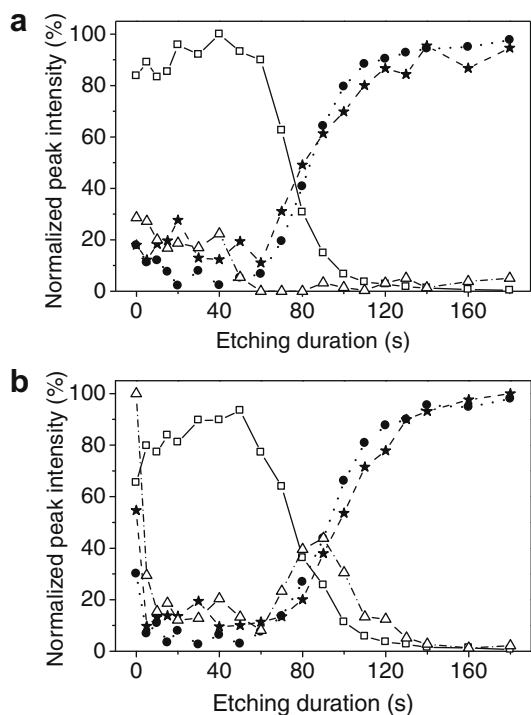
The detailed mechanisms occurring in the buffer layers are still unclear and several mechanisms have been proposed such as dipole-layer formation, protecting the organic layer surface from evaporated metals, or interfacial passivation preventing charge recombination [2,13–15]. In the current case, PDMS-b-PMMA itself does not have strong molecular dipole unlike the fluoroalkyl-attached fullerene compound, therefore the origin of the improvement is not likely the energy matching at the interface.
Fig. 4. The I–V curves of the OPVs under 100 mW cm^{-2} AM1.5 irradiation, showing the highest PCE with 0.4 mg ml^{-1} PDMS-b-PMMA (solid line) and without PDMS-b-PMMA (dashed line).


Fig. 5. XPS depth profiles of Al (squares), C (circles), S (stars) and Si (triangles) for the (a) P3HT:PCBM/Al and (b) P3HT:PCBM/PDMS-*b*-PMMA/Al layers.

To investigate the possibility of the protecting effect by PDMS-*b*-PMMA from the evaporated metal, the XPS depth profile was performed on the P3HT:PCBM films coated with vacuum deposited Al with and without 1.0 mg ml^{-1} of PDMS-*b*-PMMA added in the solutions (Fig. 5). The intensities are normalized to the maximum signal intensity of each atom. In both samples, as the etching proceed from the surface, Al peak start to decrease and C and S peaks start to increase at the interface. After 120 s etching, Al peaks were completely disappeared and intensities of C and S peaks became constant. Si peak is detected between the Al and the organic layers (i.e. appearance of C and S) when PDMS-*b*-PMMA was used (Fig. 5b). This showed that PDMS-*b*-PMMA formed a buffer layer at the interface between Al electrode and the organic layer as expected. The comparison of the detection limit of Al between the films indicated that the depth of Al penetration into the films was almost the same in each sample (approximately 10 nm). These results suggested that there was no detectable protecting effect of the PDMS-*b*-PMMA layer from the penetration of Al into the organic films. Another possible role of the PDMS-*b*-PMMA layer is provision of an interfacial passivation effect similar to the case of silicon solar cells with an ultra thin layer of SiO$_2$ passivation layers [18–20]. PDMS-*b*-PMMA is an electronically inert material and could reduce the number of charge recombination sites at the interface between the aluminum cathode and organic active layers, resulting in improvement of the device performance. Because of the insulation property of PDMS-*b*-PMMA, adding an excessive amount (0.6–1.0 mg ml^{-1}) of PDMS-*b*-PMMA results in excessively thick

passivation layers (more than 3 nm) being formed that hinder electron transport from the organic layer to the aluminum electrode and therefore degrades I_{SC} and FF.

Finally, it is worth to note that silicone compounds similar to PDMS-*b*-PMMA are often used as lubricants in many apparatuses and therefore may easily contaminate the materials. In fact, we observed similar Si accumulation on the surface by XPS *even without adding PDMS-b-PMMA* when we used a plastic disposable syringe with a rubber gasket for the sample preparation. Considering the fact that even a small amount of PDMS-*b*-PMMA may affect the device performance, one should take extra care in avoiding the contaminations in order to observe consistent device results.

In conclusion, we have demonstrated that PDMS-*b*-PMMA mixed into the active layer solution spontaneously formed a buffer layer in OPV devices. Addition of the proper amount of PDMS-*b*-PMMA improves the OPV performance, while the performance was decreased when an excessive amount was added. The highest PCE of 3.86% was achieved for the OPV device with 0.4 mg ml^{-1} of PDMS-*b*-PMMA as a self-organized layer. The approach reported herein will provide a facile and versatile way to control the interface between semiconducting materials and metal electrodes in various organic electronic devices.

ARTICLE INFO

ABSTRACT

The lowest unoccupied molecular orbital (LUMO) energies of a variety of molecular organic semiconductors have been evaluated using inverse photoelectron spectroscopy (IPES) data and are compared with data determined from the optical energy gaps, electrochemical reduction potentials, and density functional theory (DFT) calculations. A linear fit to the electrochemical reduction potential (relative to an internal ferrocene reference) vs. the LUMO energy determined by IPES gives a slope and intercept of -1.19 ± 0.08 eV/V and -4.78 ± 0.17 eV, respectively, and 0.92 ± 0.04 and -0.44 ± 0.11 eV, respectively, based on the DFT calculated LUMO energies. From these fits, we estimate the LUMO and exciton binding energies of a wide range of organic semiconductors.

1. Introduction

As the field of organic electronics continues to mature, designing high performance devices requires that the frontier energies of molecular semiconductors be accurately determined. For example, the energy of the highest occupied molecular orbital (HOMO) of molecular thin films can be determined with reasonable accuracy (with an error of typically ±0.2 eV) [1] using ultraviolet photoelectron spectroscopy (UPS). Furthermore, the lowest unoccupied molecular orbital (LUMO) can also be determined from inverse photoelectron spectroscopy (IPES), which allows for a direct measurement of the electron affinity [2,3]. The transport gap (E_t) of these materials is then taken as the difference between the HOMO and the LUMO energy levels. In practice, the LUMO energy is often inaccurately defined as the HOMO energy plus the optical energy gap (E_{opt}), referred to here as the "optical LUMO", where E_{opt} corresponds to the energy of the long wavelength edge of

the exciton absorption band. While E_{opt} can be measured to within ±0.05 eV, the value of E_t can exceed this by as much 0.5–1.0 eV due to the exciton binding energy [4]. Additionally, lower energy transitions into intermediate states can lead to an underestimation of both E_{opt} and E_t, and consequently, the LUMO energy. This incomplete picture has led to confusion about charge carrier injection, the role of heterojunction interfaces in determining energy transfer, and charge transport in organic materials. Unfortunately, the consistent use of UPS and IPES can be both time consuming and complex, with differences in measurement conditions resulting in variations in measured energies for the same material [1]. In practice, therefore, indirect methods have been employed to estimate the HOMO and LUMO energies of organic solids, leading to further confusion in the interpretation and comparisons of these various results.

Rather than use data from optical and UPS measurements to locate the LUMO energy, a common alternative is to use results from electrochemical measurements. In principle, the LUMO energy can be determined from the electrochemical reduction potential (E_{red}), a process analo-

gous to charge injection in organic films. However, E_{red} must be adjusted to account for the differing dielectric media in which the measurements are performed. Nevertheless, E_{red} measured for organic compounds have been shown to depend linearly on their electron affinities in the gas phase [5,6]. The use of E_{red} to determine LUMO energies was originally applied to conjugated oligomers, and has recently been extended to include small molecular weight materials [7,8]. One drawback to this approach is the need to establish an electrochemical reference potential to vacuum. The ferrocenium/ferrocene (Fc$^+$/Fc) couple with a potential of 4.80 eV relative to vacuum, is commonly used for this purpose [9]. Alternatively, aluminum tris-8,hydroxyquinolate (Alq$_3$) has recently been shown to be a useful electrochemical reference with a potential of −2.30 V with respect to Fc$^+$/Fc [10]. The LUMO energy of Alq$_3$ is found to be 2.25 ± 0.25 eV measured by IPES [11]. Implicit in all of these methods is a linear dependence between E_{red} and IPES measured values with a slope equal to unity. However, we recently reported a relationship between the HOMO energy (measured by UPS) and the oxidation potential (E_{ox}) of molecular organic semiconductors [12] that had a linear dependence with a slope of 1.4. The slope was found to be determined, in part, by image forces between the electronic orbital distribution and the metal electrode immersed in a dielectric solution.
Fig. 1. Molecular structures for the compounds listed in Table 1.

Here, we present the interrelationships between the LUMO energies of a variety of molecular organic semiconductors measured by several techniques. These correlations allow us to evaluate the accuracies and advantages of the various methods, and to extract a relationship between the exciton binding energy and the energy gap.

The electron affinities for 24 compounds shown in Fig. 1 are presented in Table 1. Included in the table are LUMO and HOMO energies obtained from IPES and UPS, the optical energy gap, the optical LUMO (UPS plus E_{opt}), the electrochemical reduction potential, and the LUMO energies obtained from electron density functional theory (DFT) calculations. The LUMO energies obtained by IPES span a range of approximately 5 eV, and include both organic compounds and inorganic complexes. The criteria used to select compounds for Table 1 is that both IPES and reversible reduction energies were available. The errors are ±0.2 eV for UPS, and ±0.35 eV for IPES data. The values do not account for ambiguities in some reports of IPES data taken from the peak maxima, as opposed to others that report the peak onset of the spectra. The use of the peak onset data can lower the IPES values by several 100 meV, an issue that is addressed in detail by Krause et al. [13]. The optical energy gap is estimated from the low energy edge of the absorption band of the lowest energy exciton manifold, preferably where the normalized absorption and fluorescence spectra intersect. This value has an error of ±0.05 eV. To determine the optical LUMO values, data were taken from UPS measurements which give a direct measure of the HOMO energy. Reduction potentials are either taken from literature values, or measured using cyclic voltammetry vs. a Fc^+/Fc reference. A correction was applied to literature values recorded in acetonitrile (0.40 V) or dimethylformamide (0.45 V) vs. a standard calomel electrode (SCE) for comparison purposes [14].

A plot of the transport gap, determined from the difference between the LUMO and HOMO energies measured by photoelectron spectroscopic methods (IPES and UPS, respectively), and the optical gap for the materials in Table 1 is shown in Fig. 2. A linear fit to the data gives a slope and intercept of 1.39 ± 0.15 and −0.46 ± 0.38 eV, respectively, with a correlation coefficient of $r^2 = 0.80822$. The slope indicates that, as the energy gap increases, the exciton binding energy (E_{BE}) increases as well, with a minimum of approximately $E_{BE} = 0.25$ eV for $E_t = 2$ eV, to $E_{BE} = 1.5$ eV at $E_t = 6$ eV (i.e. $E_{BE} - 0.3(E_t - 1 \text{ eV})$). These values fall within the range of independent measurements of the binding energy, determined either from peak-to-peak [4] or peak onset [13] UPS–IPES data, and also correspond to behavior commonly observed in inorganic semiconductors. In that case, the material polarizability (and hence permittivity, ε) decreases with increasing band gap. Then, since $E_{BE} \sim 1/\varepsilon$, we expect to see a linear increase in binding energy with band gap, as observed here for organic semiconductors. We caution, however, that the charge density and distribution, which depend on molecular size, influence the binding

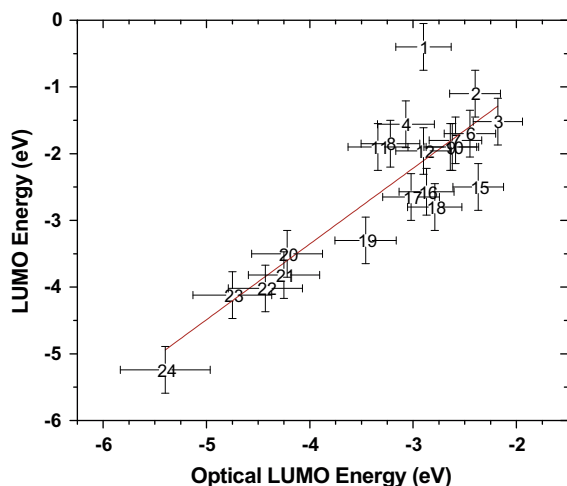
[h] A value of 4.6 eV is given in Ref. [23].

energy and must also be considered in a full analysis of the energy gap.

A plot of the optical LUMO (equal to $|E_{opt} + HOMO|$) vs. LUMO energies measured via IPES is shown in Fig. 3. A linear fit to the data gives a slope and intercept of 1.14 ± 0.16 and 1.19 ± 0.52 eV, respectively, with a correlation coefficient of $r^2 = 0.72019$. The slope is consistent with an increase in the exciton binding energy with increasing electron affinity. For linear acenes, this increase has also been attributed to larger electron-hole Coulombic interactions in smaller π-systems [15]. The relatively poor correlation coefficient is a consequence of two distinct regions apparent in the plot. A linear correlation exists for compounds with optical LUMO energies greater than 4.0 eV,


whereas the data show considerable scatter for compounds with higher energies. Some of the variability can be ascribed to ambiguities in assigning the energy of the HOMO–LUMO gap from optical data. For example, we note that compounds such as benzene, BCP, and Ir(ff-ppy)$_3$ (compounds 1, 4, and 11) have weak optical transitions at energies lower than their strong ($>1000\ M^{-1}\ cm^{-1}$) absorption bands. For these compounds, E_{opt} does not represent a transition to an orbital involved in electron capture, and hence, E_{opt} may underestimate the actual transport gap. This is in contrast to the other materials studied here.

A plot of LUMO energies determined from IPES data vs. the reduction energy, E_{red}, is given in Fig. 4. A linear fit to the data presented gives a slope and intercept of -1.19 ± 0.08 eV/V and 4.78 ± 0.17 eV, respectively, with a correlation coefficient of $r^2 = 0.92140$. The value of the intercept is in agreement with that commonly assumed for the Fc$^+$/Fc reference energy relative to vacuum (4.80 eV). The slope implies that compounds with large transport energy gaps are slightly destabilized as neat solids relative to the fluid dielectric medium used to perform the electrochemical measurements. The correlation coefficient is markedly higher than that from Fig. 3, and indicates that reduction potentials are more strongly correlated with the actual LUMO energies, particularly for compounds with large transport gaps.

The dependence of IPES measured LUMOs on LUMO energies obtained from DFT calculations is shown in Fig. 5. A linear fit to the data gives a slope and intercept of 0.92 ± 0.04 and 0.44 ± 0.11 eV, respectively, with a correlation coefficient of $r^2 = 0.95067$. This result is a consequence of the correlations shown by DFT calculations with gas phase electron affinities [16,17]. Since the LUMO energies from DFT calculations are equivalent to values in the gas phase, the near unity value for the slope in Fig. 5 implies that there is relatively constant polarization energy for these materials in the solid state [18]. The quality of the fit indicates that DFT calculations can provide a

reliable estimate for LUMO energies of organic solids where the needed experimental data are not available.

In summary, the correlations of IPES data with other methods currently used to estimate the LUMO energies of organic solids demonstrate several strengths and weaknesses among the various approaches. While the optical LUMO data can give a reasonable estimate for the LUMO energy for many compounds in the solid state in cases where the exciton binding energy is known, care must be taken to ensure that the lowest energy value of E_{opt} represents the appropriate HOMO–LUMO transition. Uncritical use of this method for some materials can give LUMO energies that can significantly differ from the true LUMO energy. The strong correlation between E_{red} and IPES shows that solution electrochemistry provides a satisfactory means to estimate the LUMO energy in the solid state. For compounds where it is difficult to obtain E_{red} values, use of the LUMO energy derived from DFT calculations also gives an accurate estimate of the transport level.

2. Experimental

The absorption spectra of NPD, BCP, CBP and F_4-TCNQ were recorded in dichloromethane solvent using a Hewlett–Packard 4853 diode array spectrometer. Cyclic voltammetry and differential pulse voltammetry were performed using an EG&G potentiostat/galvanostat model 28. Anhydrous DMF (Aldrich) was used as the solvent under a nitrogen atmosphere, and 0.1 M tetra(*n*-butyl)ammonium hexafluorophosphate was used as the supporting electrolyte. A Pt wire acted as the counter electrode, Ag wire was used as the pseudo-reference electrode, and the working electrode was glassy carbon. The working electrode was 0.2 cm in diameter by 1.5 cm long. The redox potentials are based on values measured from differential pulse voltammetry and are reported relative to an internal ferrocenium/ferrocene reference. Electrochemical reversibility was determined using cyclic voltammetry. The solutions contained only micro-molar concentrations of the sample solutes to prevent shifts in oxidation potential

due to concentration effects, and the voltage between the working and counter electrodes was swept at a scan rate of 100 mV/s. DFT calculations were performed structures that were geometry optimized at a B3LYP level using either 6–31 G* (hydrocarbons) or LACVP** (organometallics) basis sets using the Titan software package (Wavefunction, Inc.).

ARTICLE INFO

ABSTRACT

The alpha-quaterthiophene is widely considered an interesting material for the realization of organic electronics and opto-electronics. Compared to other oligothiophenes, the performances of transistors based on this compound are limited by its kind of growth on the typical materials used for device realization. Here we show that via seeded supersonic beams we can lead to a nice improvement of both morphological and electrical properties of the film grown, through a better control of the initial state of the precursor in the vapor phase. Using the high kinetic energy achievable in the supersonic beams, we increase the dimensions of the grains and the coalescence of different islands, limiting the grain boundary formation. As consequence, the performance of the realized field effect transistors is enhanced of one order of magnitude.

Small molecules are widely considered an interesting and viable way to understand the intrinsic properties and the processes involved in charge and energy transport in semiconductor conjugated polymers [1]. These are key issues in the fabrication of improved, reliable, and efficient devices both for electronics and electro-optics [2]. In particular, oligothiophenes are an appealing class of compounds for their high stability to oxidation processes [3] and for their high degree of flexibility in "molecular engineering". On the other hand major difficulties arise from the solid state packing of this class of molecules, where lack of control on structure, morphology and grain boundaries formation reduces the efficiency of the charge transport [4] limiting the performances of the organic devices [5].

The processes that control the thin films formation depend on the delicate balances between molecule–molecule and molecule–surface interactions [6], which regulate the kind of growth (Frank van der Merwe, Volmer-Weber, Stransky-Krastanov) [7]. Nevertheless for the feeble nature of the forces involved in the formation of molecular solids and for the large number of polymorphs and orientations possible in the organics [8,9], it is hard to have a good control on growth. The objective of our work is to improve

the performances of devices, field effect transistor (FET) in particular, improving the control on the molecular assembling.

Starting from these problematic and knowing the different works that have shown the importance of the state (in terms of translational, rovibrational and momentum) of the molecules in the processes involving their collision and the energy transfer with the surface [10], we have proposed a new approach to grow organic thin films, based on seeded supersonic beams [11]. Supersonic beams give, indeed, the possibility to control the energetic state in terms of kinetic energy (E_k), momentum and internal degree of freedom of the impinging particles, by setting the initial working conditions such as the source nozzle dimensions, the temperature and pressure of the reservoir, etc. Seeding the vapors of the organic semiconductors in a lighter carrier gas (He in our experiments) that defines the conditions of the free jet expansion, makes it possible to control the final state of the seeded molecules [12]. During the supersonic expansion, the internal degrees of freedom of the molecules undergo a strong cooling process while the kinetic energy can be increased, from the few hundreds of meV of an effusive source, up to several eV by varying the degree of seeding [11]. For this reason supersonic molecular beam deposition (SuMBD) allows to overcome some of the difficulties inherent to the available techniques for the growth of films of organic molecules.

Here we show the results achieved in the growth of quaterthiophene ($\alpha - 4T$) on SiO_x/Si for the realization of organic field effect transistors by SuMBD. The $\alpha - 4T$ molecules on this kind of surface typically present a 3D growth that strongly limits the performances in devices [13]. We will see that varying the E_k of the impinging molecules, it is possible to modify the growth of the $\alpha - 4T$, improving its morphology. To verify the importance of E_k, we selected two different regimes of growth: the first one where the seeded $\alpha - 4T$ molecules have an average E_k of 3.0 eV and the second one where their E_k is in the order of 7.5 eV. We have characterized the obtained films by atomic force microscopy to optimize the growth processes and to understand the effect of the kinetic energy of the impinging molecules in the thin film growth. We then used these films to build FETs in top contact configuration. Thus we are able to correlate the films morphology to the devices performances showing that a fine control on the state of the molecules can improve the characteristic of our transistors.

The experimental apparatus and the method used to realize the seeded supersonic beams of $\alpha - 4T$ are described elsewhere [11]. It essentially consists of: two stages/chambers differentially pumped high vacuum apparatus, a hyperthermal source placed in the first chamber, an ultra high vacuum deposition chamber and a time of flight mass spectrometer (ToF-MS) used to verify the purity of the materials, to determine the energetic properties of the seeded molecules, and to determine the molecular flux. The ionization of the molecules/atoms in the beam is obtained with the 4th harmonic of a Nd::YAG laser (266 nm/4.66 eV). The $\alpha - 4T$ was grown on highly doped silicon (n^{++}) wafers covered with 50 nm thermally grown silicon oxide, cleaned in hot (325 K) isopropylic alcohol,

treated with ozone for 30 min, and then outgassed at 455 K for 12 h in ultra high vacuum. All the depositions were performed at room temperature (298 K) with a flux of about 0.2 nm/min. XRD spectra was collected in Bragg-Brentano geometry with a Panalitycal X'Pert Pro diffractometer. We used a Cu anode with wavelength of 1.5406 Å. The step size was 0.05° (2Θ) and the average time was 60 s/step. Topographic characterization of the films has been performed by AFM microscopy in air, using a Smena SFC050 scanning head by NT-MDT. Depending on the sample, measurements have been carried out in semi-contact mode AFM (using NSG11 silicon cantilevers by NT-MDT) or in contact mode (using CSG10 Au-coated silicon cantilever by NT-MDT).
Fig. 1. AFM topographic images of a film grown on SiO_x/Si with impinging molecules having 3.0 eV of E_k. (a) Image 10 × 10 μm² acquired in semi-contact mode; (b) detail of a grain (2 × 2 μm²) acquired in contact mode.

Fig. 1 shows the typical morphology of our films grown on SiO_x/Si using 3.0 eV of E_k. In particular, Fig. 1a reports a large area ($10 \times 10 \ \mu m^2$) where it is possible to recognize the kind of growth of the films. Two aspects are clear: the 3D (Volmer-Weber) growth and the crystallinity of the films. The first one is recognizable from the aspect of the grains that are developed in height presenting sharp walls. This is more evident when the thin films growth is stopped with a nominal thickness lower than the mono-layer (ML). In this case, the islands produced from the nucleation of the $\alpha - 4T$ molecules, typically present a height of about 5 nm (about 3 MLs) leaving uncovered most of the underneath surface. When increasing the coverage, we observe both a growing of the islands surface and height. The coalescence of the islands starts when the nominal thickness of the films is of about 50 nm. In these conditions the average islands height is about 100 nm, indicating that ~50% of the surface is uncovered by the molecules. When the growth is carried out further, the islands begin to join together up to the point of forming a "polycrystalline" film, whose thickness is already several layers (Fig. 1a). This growth results to be different respect to the case of pentacene growth by SuMBD in which, in similar conditions, we observe the starting formation of islands of one molecule in height and their coalescence without the formation of the second layer [14]. For pentacene films about 50 nm thick, we find 1–2 μm^2 terraced grains that completely cover the surface [15].

The shape of the grains gives us the information relative to the crystallinity of films grown with this E_k. In fact, the islands present a polygonal form typical of ordered structure (crystal), with an average size of the grain of 2–3 μm^2 and no preferential direction of growth. In this situation the main problem in the FET realization is related to the poor interconnection between the different islands and the consequent need to increase the thickness of the film. This limits the device's performances. If we compare this kind of morphology with the morphology reported in literature growing the $\alpha - 4T$ molecules on the same surface in similar conditions [13,16], we see that in our case the grains seem to be more regular and with a larger size. This effect is probably related to the increased energy of the impinging molecules (3.0 eV in respect to about 150 meV of a thermal evaporation) that, in our case, allows their better rearrangement.

The growth is completely different in the case of impinging molecules having E_k = 7.5 eV. Fig. 2 shows the typical morphology obtained in this case. The islands present really different shapes and dimensions. On the large area (Fig. 2a) we observe that typically the films are formed by elongated terraced islands with dimensions in some cases larger than 10 μm. At the same time, the ratio between the covered surface and the islands' height increases, thus realizing more homogenous films with less grain boundaries. The high E_k achievable in this case is able to partially overcome the low affinity between the $\alpha - 4T$ and the surface, leading to formation of these structures. Also in this case, starting the characterization from the sub-monolayer growth, we observe the difficulty of the $\alpha - 4T$ molecules to cover completely the SiO_x/Si surface. Going into detail (Fig. 2b) we observe that the grains present the terraced structure typical
Fig. 2. AFM topographic images of a film grown with impinging molecules having E_k = 7.5 eV. (a) Image $10 \times 10 \ \mu m^2$; (b) zoom on a few grains (region indicated by the black square, $3 \times 3 \ \mu m^2$). Both images have been acquired in contact mode AFM.

of a layered morphology with steps of one molecule in height. With respect to the steps visible on the top of the islands in the low E_k films the lateral size of these terraces present a large surface. This indicates a better rearrangement of the molecules giving rise to a more ordered structure. A similar situation was found for pentacene growth at different E_k of the impinging molecules, where the effect of higher E_k is an increase of the lateral size of the terraces [15]. This kind of growth indicates that, by increasing the kinetic energy of the impinging molecules, we are able to modify the preferred growth of the $\alpha - 4T$ molecules, thus having the possibility to realize films with a prevalent layer plus island growth. This gives the possibility to decrease the number of grain boundaries that, for devices realization, is

an important point in order to improve their performances. To confirm that the films grown at higher kinetic energy are more ordered with a larger grain size, we made a structural characterization by X-ray diffraction. Fig. 3 shows the XRD spectra of two samples grown at low (black) and high (grey, orange online) energy, respectively, 3.0 and 7.5 eV. The films have the same nominal thickness determined by a quartz microbalance. Both spectra show the same peak positions: 5.8°, 11.6°, 17.5°, 23.4°, 35.3°, 41.5° and 47.7°. All of them confirm, in both cases, the structure of the low temperature phase of $\alpha - 4T$ [17]. The right panel of Fig. 3a shows a detail of the 008 reflection, rescaled to show the difference between the two spectra. Comparing the peaks line shapes we note that the full width at half maximum for the films grown at high E_k is narrower (0.208°) with respect to that grown at low E_k (0.233°). This confirms the indication that the typical crystal size of the high energy grown films is larger with respect to that of the films grown at low E_k and is in agreement with the observation of AFM micrographs, reflecting an improved order of the film.

We have realized a series of top contact field effect transistors to confirm that the growth by SuMBD permits to obtain films with better optical [18], morphological and electrical characteristics, due to the control achievable on the energetic state of the precursor. The devices (length $L = 30\ \mu m$; width $W = 200\ \mu m$) have been realized on the thickest films previously characterized by AFM, by depositing the 30 nm gold contacts (source and drain) through a shadow mask. The electrical characterization was performed in a probe station equipped with an Agilent 4156 C source meter. Making devices on films previously charac-

terized by AFM could limit their performances, but our objective is the correlation of the electrical performances with the growth conditions and the morphological-structural properties.

Fig. 4 shows the typical transfer characteristics in saturation (Fig. 4a) and in the linear (Fig. 4b) regimes of our $\alpha - 4T$ FETs in the case of films grown at low E_k (grey line, orange online) and in the case of films grown at high E_k (black line, blue online). From these curves, we can evaluate the electrical properties that characterize our devices [19].

In particular, in the linear regime, the drain current I_D can be written as:

$$I_D = \frac{WC_j\mu_{FE}}{L}\left(V_G - V_T - \frac{V_D}{2}\right)V_D \qquad (1)$$

where L is the channel length and W the channel width, C_j is the capacitance for unit area of the dielectric, V_T is the threshold voltage, and μ_{FE} is the field effect mobility. We can therefore calculate the mobility in the linear regime from the slope of the curve obtained by plotting I_D versus V_G for sufficient low V_D. The threshold voltage in this case is determined as the intercept ($I_D = 0$) for the slope of I_D. In the saturation regime, the drain current saturates and can be modeled by the following equation:

$$I_D = \frac{WC_j\mu_{FE}}{2L}(V_G - V_T)^2 \qquad (2)$$

In the saturation regime, μ_{FE} can be calculated from the slope of the plot of $\sqrt{|I_D|}$ versus V_G, and, in the same way, V_T can be calculated as the intercept ($I_D = 0$) of the slope
Fig. 3. XRD spectra of two samples grown at 3.0 eV (top left) and 7.5 eV (bottom left, orange online), respectively. At right a zoom on the 008 reflection, comparing in detail the width of the peak in both spectra. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 4. Transfer curves of a low E_k grown sample (nominal thickness about 100 nm) (grey, orange online) and a high E_k grown sample (nominal thickness about 100 nm) (black, blue online). The curves are compared both in (a) saturate (VD = −41 V) and (b) linear regime (VD = −1 V). The inset shows the transconductance of the same devices in both regimes. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

of $\sqrt{|I_D|}$ versus V_G. From the semilogarithmic plot of I_D versus V_G we extracted the I_{on} over I_{off} ratio and the subthreshold slope. The typical values obtained for our devices, grown at the different E_k, are reported in Table 1.

Fig. 4 and Table 1 give us the information about the strong impact of the growth conditions on the perfor-

Table 1
Main working parameters of the devices fabricated. The first two columns show the low E_k sample values, while the last two columns refer to the high E_k sample.

	E_k = 3.0 eV		E_k = 7.5 eV	
	V_D = −1 V	V_D = −41 V	V_D = −1 V	V_D = −41 V
V_T[V]	−15.9	−22.5	−11.2	−16.0
I_{ON}/I_{OFF}	1.1×10^3	1.6×10^4	8×10^4	1.8×10^5
S_T slope[V dec^{-1}]	2.0	2.5	0.98	1.66
μ[cm^2 V^{-1} s^{-1}]	0.75×10^{-3}	1.7×10^{-3}	3.8×10^{-3}	1.22×10^{-2}

mances of the devices. Indeed FETs grown at low E_k have characteristics in terms of mobility, threshold voltage, I_{on}/I_{off} ratio and subthreshold slope comparable with the majority of $\alpha - 4T$ transistors reported in literature [20]. This is a first good result considering the absence of optimization in our realization processes. However, if we compare these results with those obtained for the growth at 7.5 eV of E_k, we see the great advantage given by the growth method that we have developed. The extracted mobility for these devices (about $1.2 \cdot 10^{-2}$ V cm^{-1} s^{-1}) is about one order of magnitude larger with respect to the first one and the performances of these transistors are better or comparable to the best ones reported in literature [21–23].

We have investigated the correlation of the observed enhanced mobility with the structure/morphology of the films and in particular the average grain size of the crystallites composing the film grown. In Fig. 5 we plotted the field effect mobility measured for samples as a function of the mean grain size calculated from their AFM images. It appears evident that there is a linear dependence, showing that the improved transport properties of the films grown at high energy come from increasing grain size and hence from the consequent decrease of grain boundaries, as previously reported [24,25].

As a conclusion, we have shown that the growth dynamics of organic thin films starting from the vapor phase are governed by a delicate equilibrium between the molecule/molecule and the molecule/surface interactions and for this reason are also strongly dependent on the energetic state of the precursors. It can be obtained, and above all determined, by using the free jet expansion and the supersonic beam technique, thus improving the organic material growth. The key factor is the high kinetic energy achievable with this technique (up to 15 eV for the $\alpha - 4T$ seeded in H$_2$) by the impinging molecules. When colliding with the surface, the kinetic energy of the seeded molecules is rearranged among the different degrees of freedom and partially converted into energy E_k
Fig. 5. Graph reporting the field effect mobility of some devices as a function of the grain size of the film they were fabricated on. It is quite clear the linear dependency.

parallel to the surface via a complex mechanism involving inelastic molecule–molecule and molecule–surface energy transfer processes [10]. It is reasonable to assume, by extending consolidated growth models [5,26], that molecules with higher E_k diffuse over longer distances before aggregating or being captured by preformed molecular islands. The total amount of energy exchange at the surface is quite relevant to modify locally the physical–chemical processes occurring but definitely too small to produce any change of the sample temperature, in the order of 10 pW for cm^2. The final effect, as we have shown for the $\alpha - 4T$, is an increase in grain size while increasing the kinetic energy and an enhancement of the order inside the grain. The better morphology in terms of order and limiting of grain boundaries gives also the possibility to grow devices with better performances. The electrical characteristics of our FETs obtained at 3.0 eV are comparable to the ones of transistors realized with the same materials but with different techniques. However, in the case of transistors obtained on films grown at 7.5 eV the performances are similar to the state of the art but without using any optimization processes. The SuMBD is a very promising technique to fabricate devices with better performance and stability and opens interesting perspectives in the realization of FET sensors based on oligothiophene derivatives.

All-polymer thin film transistors on patterned elastomeric substrates

Hyewon Kang, Tae-il Kim, Keon-kook Han, Hong H. Lee *

School of Chemical and Biological Engineering, Seoul National University, Seoul 151-744, Republic of Korea

ABSTRACT

A patterned soft elastomeric substrate is utilized for fabricating an all-polymer thin film transistor (TFT). With a polymer solution for the source/drain electrodes, it is difficult to form a well defined narrow channel. The problem is resolved with the aid of a micromolding technique and the patterned substrate. When the all polymer TFT is subjected to bending, the polymer gate dielectric is the layer that experiences the most stress. This stress problem, which can lead to device failure, can be relieved to an extent by introducing a small fraction of ethyl cellulose to the polymer dielectric. The effects of the ethyl cellulose content on the device performance are not significant.

Organic thin film transistors (TFTs) based on conjugated polymers [1,2] have received much attention for a number of reasons. Low cost fabrication of the device afforded by solution processability [3] is one major reason. Flexible devices and its application to flexible displays is another.

The substrates typically used for flexible devices and displays are polymers [4–7], metal foils [8], and thin glasses [9]. However, polymeric substrates such as polyethylene terephthalate (PET) are favored because they have less mechanical, thermal, or electrical problems that are associated with metal foils and thin glasses. All-polymer flexible transistors have been fabricated with poly(3-hexylthiophene) (P3HT) semiconductor and PET substrate [5–7]. Not often used as a polymeric substrate is an elasto-

mer such as poly(dimethylsiloxane) (PDMS). A flat PDMS substrate was used for an organic transistor with rubrene monocrystalline semiconductor and metal electrodes [10]. The PDMS slab was also used to laminate a fabricated circuit on PET for better flexibility [11]. An elastomer has many advantages over a plastic substrate, such as crack and scratch protection, and easy recovery from any deformation. In all-solution processing that is typically employed in fabricating all-polymer transistor, the most demanding patterning task is to form a well defined narrow channel, in particular with a polymer solution that is used for forming the source/drain electrodes such as poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) or polyaniline (PANI). Various techniques have been utilized to define the transistor channel with these polymer solutions. These include photolithography [12], ink-jet printing [13], stamping [14], and dewetting

[15]. Photolithography requires many processing steps and the solvent used in resist development is detrimental to organics. It is not surprising, therefore, that the performance of the device fabricated on PET with photolithography is not good [6,7]. Ink-jet printing and stamping usually do not lead to good resolution mainly due to smearing problem. To overcome the problem, a polyimide film was patterned as a blocking layer on a glass substrate with photolithography [13]. Dewetting [15] on a prepatterned silicon dioxide partition on a silicon substrate, which is in turn treated with a self-assembled monolayer (SAM), was also used to define the channel. It is desirable in defining the channel with the polymer solution on a flexible substrate to avoid photolithography, which can be accomplished with the use of a prepatterned PDMS substrate. In addition to the advantages offered by PDMS as a substrate, it is rather straightforward to produce a well defined narrow channel by a molding technique with PDMS, which is an excellent molding material.

Often unrecognized in flexible transistor is that the gate dielectric layer is most susceptible to mechanical failure such as cracking when the device is subjected to stress as in bending. The flexibility of a layer is inversely proportional to t^3 where t is the layer thickness. The dielectric layer is generally much thicker than the other layers. Moreover, in our system, the dielectric layer covers the whole device area. In contrast, all the other layers are present as stripes or islands. Therefore, the flexibility of the dielectric layer is essentially equivalent to that of the device.

In this letter, we present a technique for forming a well defined narrow channel with an electrode-forming polymer solution and an elastomeric substrate for flexible, all-polymer TFT. We also present a method for making the device more stress-tolerant by introducing a ductile material to the dielectric layer. The device performance does not change much with increasing content of the added material.

The polymer TFT (PTFT) considered in this work is a top gate transistor. Illustrated schematically in Fig. 1a are the processing steps in fabricating the device. The patterned PDMS (Dow corning, Sylgard 184) substrate was prepared from a master mold that had been made by conventional photolithographic method with a channel length of 65 μm and a width of 3 mm. As shown in the figure, the two hollow channels are to be filled with PEDOT:PSS to form the source and drain, thereby defining the transistor channel. After a oxygen plasma treatment to make the PDMS surface hydrophilic, the technique of micromolding in capillaries (MIMIC) [16] was used to fill the channels by placing droplets of PEDOT:PSS at the inlets of the channels. A flat PET film was placed on the prepatterned PDMS substrate to induce capillarity. After drying for 30 min at 60 °C, the top plate was removed, which showed no residue of PEDOT:PSS. The semiconductor layer of P3HT was shaped by drop casting a 0.3 wt% regioregular P3HT (Aldrich Co., M_w = 87,000) solution in toluene onto the source-drain pattern [20]. For the gate dielectric, poly(methylmethacrylate) (PMMA) (Aldrich Co., M_w = 350,000) was used instead of poly(hexaethyl methacrylate) (PHEMA), which is known to be a better dielectric

[17] than PMMA with P3HT, because of the solvent compatibility problem discussed later. Onto the spin-coated and dried dielectric layer, PEDOT:PSS was dropped for the gate electrode. It was then dried for 30 min at 60 °C. All the processing steps were carried out in open air.

Shown in Fig. 1b is an optical microscopy image of the channel formed by the MIMIC technique with prepatterned PDMS substrate. The source and drain electrodes of PEDOT:PSS (dark shade) are seen to be clearly separated from each other by the protruding PDMS wall (light shade). Although the channel length in this study is 65 μm (top image of Fig. 1b), it can be made smaller with the technique. The smallest feature size that can be patterned with PDMS mold is about 0.5 μm when the aspect ratio is larger than unity [18]. The bottom images of Fig. 1b show various channel lengths patterned by MIMIC technique with PEDOT. While the smallest channel size is 35 μm, fabrication of smaller channel should be possible with this technique.

The transistor with PDMS substrate invariably failed to function unless the substrate was handled very carefully. The PDMS substrate is very flexible and readily deforms. This deformation causes the device failure, the deformation leading to fracture of the layers constituting the transistor. The fracture should occur in the dielectric layer for two reasons. The first is that all the other layers are present in stripes or islands whereas the dielectric layer blankets the whole device area. These stripes and islands can withstand strains far in excess of the fracture strain [19–21] whereas a blanket layer is subject to the usual fracture strain. The other reason is that the dielectric layer is usually the thickest layer in the stacked layer configuration of thin film transistor. The flexibility of a layer is inversely proportional to Et^3 where E is Young's modulus and t is the layer thickness [22]. Since the Young's moduli for all the polymers in the TFT are similar in magnitude, the dielectric layer is least flexible and stiffest.

To relieve this fracture problem, we chose to add a ductile polymer to PMMA and use that blend as the dielectric layer. Although a rubber [23] or ductile polymer [24] mixed with PMMA and a solution treatment [25] of PMMA were also used to increase the ductility, these involved either material synthesis [23,24] or an elaborate solution treatment [25]. Therefore, a ductile polymer of ethyl cellulose (Aldrich Co.) was used. According to the manufacturer, ethyl cellulose dissolves in a solvent mixture of 80% toluene and 20% ethanol. PMMA does dissolve in this solvent mixture whereas PHEMA does not, which is the reason why PMMA was chosen in place of PHEMA. When the ratio of ethyl cellulose to PMMA exceeds 3/7, a phase separation takes place. Therefore, the ratios of 3/7, 2/8, and 1/9 were tested for enhancing the ductility of the dielectric layer. In all experiments, PMMA and ethyl cellulose were dissolved in the mixed solvent to 10% by weight.

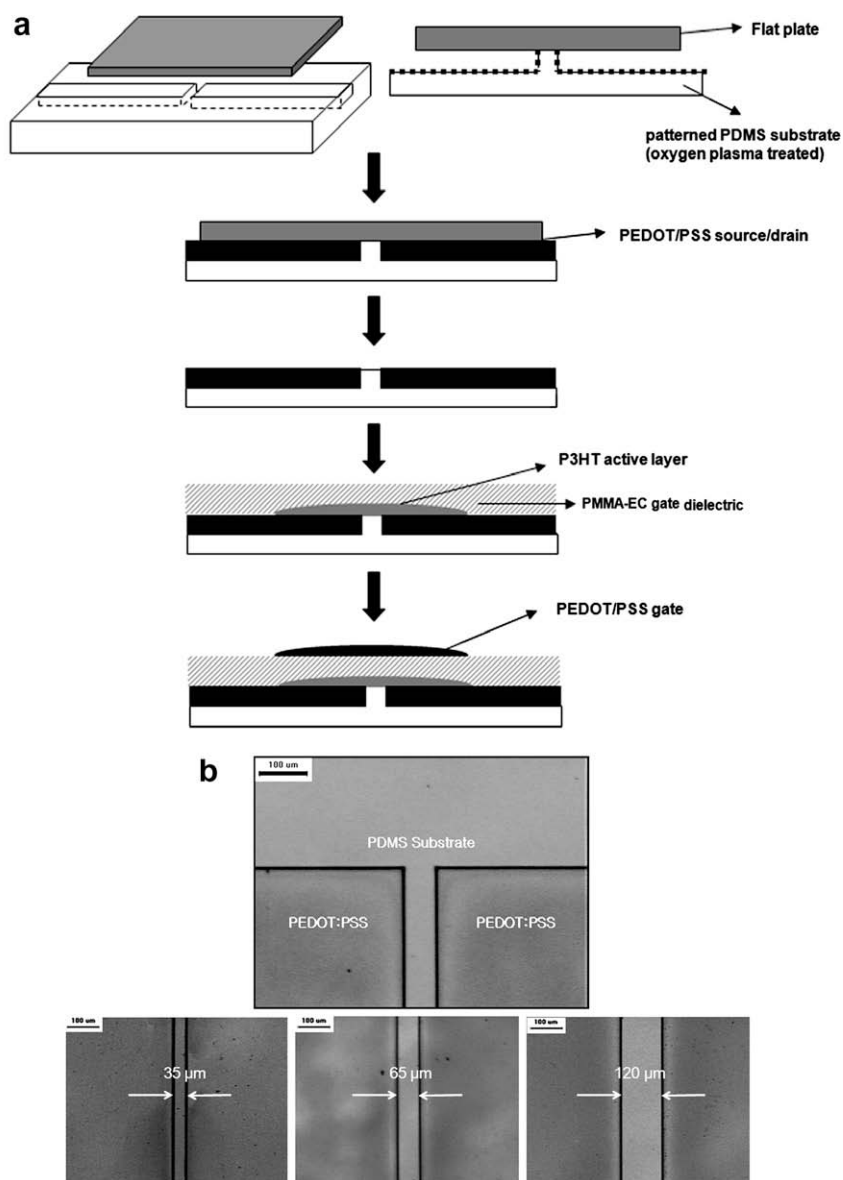
The mechanical and electrical characteristics of the transistor as affected by the addition of ethyl cellulose are summarized in Table 1. The critical bending radius in the last column of the table is the radius of curvature above which the off current increases dramatically. It is noted in this regard that the thickness of PDMS sheet and that of dielectric layer are approximately 3 mm and 1 μm, respectively. The electrical characteristics of the devices that


Fig. 1. (a) Schematic illustration of fabrication procedure of soft, all-polymer TFT. (b) Optical microscope image of the source-drain pattern prepared by MIMIC. Darker areas are PEDOT:PSS source-drain electrodes and lighter area including the center line separating the electrodes is PDMS substrate.

Table 1
Electrical characteristics and critical bending radii of soft, all-polymer TFTs. The TFTs were prepared with different mixing ratios of PMMA and ethyl cellulose (EC). The capacitance was measured at 10^5 Hz and -20 V.

Dielectric	Capacitance (nF/cm^2)	Mobility (cm^2/Vs)	Threshold voltage (V)	On/off ratio	Critical bending radius (cm)
PMMA 10%	7.5	Not meaningful			Device failure
PMMA 9% + EC 1%	3.4	2.3×10^{-3}	-17	1.5×10^2	1.0
PMMA 8% + EC 2%	2.6	2.8×10^{-3}	-15	3.6×10^2	0.9
PMMA 7% + EC 3%	2.2	2.5×10^{-3}	-13	2.8×10^2	0.8

were fabricated with pure PMMA dielectric were not meaningful because of abnormally high off current, which were on order of 10–10^2 nA and therefore the on–off ratios were less than 10 in some cases. Toluene that is a solvent of PMMA can also dissolve P3HT. Therefore there would

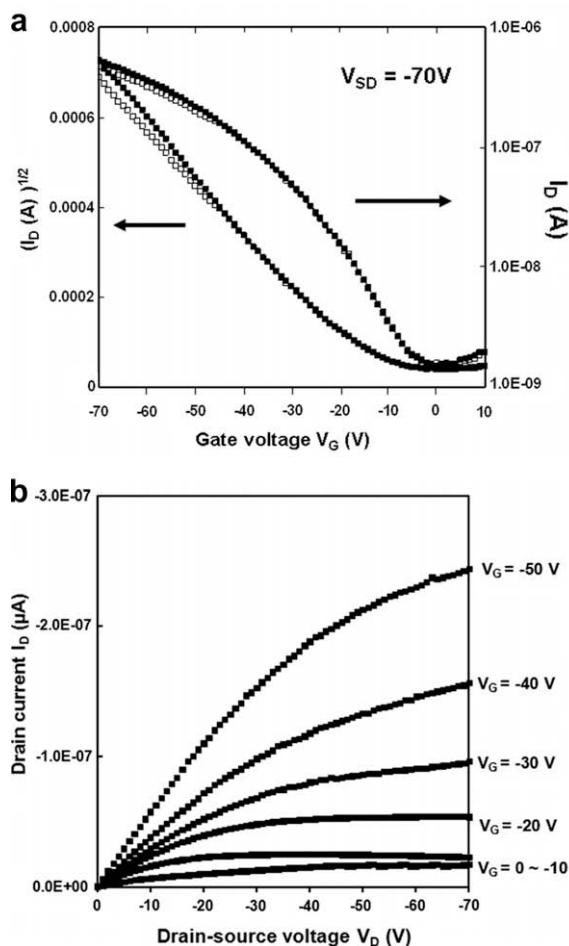
be a damage problem during spin-coating of the dielectric layer. However, the mixed solvent of toluene and ethanol becomes very viscous when PMMA and EC are dissolved in the solvent and thus the dissolution becomes much less of a problem. A value for the critical bending radius is not


Fig. 2. Electrical characteristics of soft, all-polymer TFT. Gate dielectric is PMMA and ethyl cellulose content is 20%. Channel width is 3 mm and channel length is 65 μm. Thickness of dielectric layer is about 1 μm. Gate leakages before and after bending were 1.48 and 1.57 nA. (a) Electrical transfer characteristics of the device before (dark rectangles) and after (open rectangles) the bending. Drain voltage is −70 V. (b) Electrical output characteristics of the device at various gate voltages.

table was obtained in the saturation regime [26] from the transfer characteristics of the device at the source-drain voltage of −70 V. It is noted in this regard that the device performance with EC addition is better than that reported in the literature for all-polymer transistors [5–7].

The device characteristics before and after device bending are of interest, which are shown in Fig. 2. The transfer characteristics show that there is not much difference between the device before (dark rectangles) and that after (open rectangles) the bending. The EC content in the dielectric layer was 20%. The output characteristics of the device are shown in Fig. 2b. When the performance of device was compared with that reported on all polymer transistors on flexible substrates [5–7] the on–off current ratio is about the average but the mobility is better.

In summary, a soft, all-polymer TFTs have been fabricated on a patterned elastomeric substrate of PDMS. Because of the soft and shape-changing nature of the substrate, the TFT easily fails to function unless the substrate is handled carefully. It has been found that the failure is caused by the fracture of the gate dielectric layer. By introducing a small amount of ductile polymer to the polymer dielectric, the device can be made flexible without causing the device failure. When a polymer solution is used as the electrode material, it is difficult to form a well defined narrow channel. With the micromolding technique of MIMIC [16] and the prepatterned substrate, the channel can be defined as small as possible without any smearing problems that are associated with a liquid source. The results presented here should be useful for low cost, flexible electronics.

listed for the device with no ethyl cellulose in the first row of the table because the handling involved in trying to bend the PDMS invariably led to device failure and the device characteristics were not meaningful due to high off current. The addition of ethyl cellulose (EC) allowed for the determination of the critical bending radius. The maximum solubility of EC in the mixed solvent of toluene and ethanol is 5% by weight. The content of EC was varied from 1% to 3% because the electrical characteristics were the best for EC content of 2%. The capacitance of pure PMMA layer was 7.5 nF/cm^2 but when the EC content was 1%, it decreased to 3.4 nF/cm^2. The capacitance decreased with increasing EC content. As given in the table, the critical bending radius is 1 cm for 10% EC, decreasing down to 0.8 cm for 30% EC. In general, the capacitance decreases with increasing EC content. As apparent from the table, the device performance is not significantly affected by the addition up to EC content of 30%. The mobility in the

Calculation of ionization potential of amorphous organic thin-films using solvation model and DFT

Pabitra K. Nayak, N. Periasamy *

Department of Chemical Sciences, Tata Institute of Fundamental Research, Homi Bhabha Road, Colaba, Mumbai 400005, India

ABSTRACT

Density functional theory and polarizable continuum model are used to calculate ionization potential of thin-films of 12 organic molecules. Computed values are compared with experimental values obtained from ultraviolet photoemission spectroscopy. The excellent correlation shows that it is possible to determine the ionization potential of organic molecules in solid-state within ±0.15 eV of the experimental value. This method is useful for chemists in designing molecules for organic electronics.

1. Introduction

Organic electronics has attracted much attention in recent research activity in molecules and materials. Organics based light emitting devices (OLEDs), solar cells (OSC), and field effect transistors (FET) are important devices under development in electronic industry. In organic semiconductor devices, thin solid films of organic molecules are used as active or passive functional layers. Information about the charge (electron or hole) carrier levels in organic thin-films, and relative energy levels with respect to electrodes are needed in understanding and fabricating the devices. For example, in OLEDs multiple layers of organic thin-films are used [1]. Carrier injection and transport occurs in HOMO or LUMO levels of organic material. The difference in the energy levels at the interface of the layers

determines the flow of carrier and formation of excitons (excited state of molecule). A method to calculate these energy levels of organic solids will be highly useful for a synthetic chemist in designing the structure of organic molecules for organic electronics.

Energy levels and properties of isolated organic molecules can be calculated theoretically. Energy levels and properties in solid thin-film are usually different from those of isolated molecule, due to interaction among the molecules in the solid-state. A method is required to modify the energy levels calculated theoretically for isolated molecules to obtain a value appropriate for solid films.

Ultraviolet photoemission spectroscopy (UPS) is one of the frequently used techniques to determine the vertical ionization potentials in solids [2]. This gives the HOMO level of solid films. The ionization potentials of organic solids determined by UPS were compared with experimental and computational values for isolated molecules [3–6]. Not

E-mail address: peri@tifr.res.in (N. Periasamy).

surprisingly, there is a big offset between the values for molecules in gas phase and solid-state. There have been attempts to bridge this offset by appropriate theoretical models [7,8]. For example, Lee and Han used the crystal structure data and molecular cluster model in the DFT calculation, which is successful for a sufficiently a large cluster of CuPc ($n = 6$).

In this letter, a method is described to determine the ionization potential of large organic molecules in solid-state using DFT method and polarizable continuum model. The polarizable continuum model [9,10] has been very successful in calculating realistic values of energy properties of molecules in liquid-like condensed phase. We show that the computationally determined ionization potentials for twelve organic molecular solids agree well with the experimental values, validating the proposed method. A novel feature of our method is that no experimental data for the molecule, other than the molecular structure, is used.

2. Methods of computation

Twelve organic molecules, for which experimental values of ionization potential of solid films are known, were chosen for this study. Density functional theory (DFT) was used in all the calculations using Gaussian 03 [11]. The DFT method used here is based on the hybrid B3LYP functional [12]. The geometries of all the molecules were optimized at 6-31G (d) basis functions. Molecular cavity for polarizable continuum model (PCM), was built using united atom topological model [13], i.e. by putting a sphere around each atom except hydrogen. Hydrogen atoms are enclosed in the sphere of the atom to which they are bonded.

The molecule in solid was considered as solvated by the molecules of its own type. The solvent in the PCM calculation is defined by the dielectric constant, the number of solvent molecules in unit volume and radius of the molecule. Following methods were used to obtain these values. The dielectric constant, ε was obtained by Clausius–Mossotti equation

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4\pi}{3} \frac{\rho}{M} N_A \alpha$$

where ρ, M, N_A and α are the density of material, molecular mass, Avogadro number and the electronic polarizability, respectively. $\rho N_A / M$ is reciprocal of the molecular volume. Molecular volume was obtained at 6-31G (d) level (tight option was taken in all the calculation for better accuracy). Isotropic polarizability (at zero frequency) of molecules was calculated for the optimized geometry of molecules at 6-31G (d) level. Radius of the molecule is defined as radius of a sphere which has equivalent volume of the concerned molecule.
Fig. 1. Geometry optimized structure of molecules used in this study. 1: *N,N*′-bis(3-methylphenyl)-*N,N*′-diphenyl-[1,1′-biphenyl]-4,4′-diamine(TPD); 2: *N,N*′-bis-(1-naphthy)-*N,N*′- diphenyl-[1,1′-biphenyl]-4,4′-diamine (NPD); 3: *N,N*′-bis(3,6-dimethyl carbazolyl)-3,5-benzene (mCP); 4: 4,4′-*N,N*′-bis(3,6-dimetylcarbazolyl)biphenyl (mCBP); 5: Tris(8-hydroxyquinolate)aluminium(III) (Alq₃); 6: 4,4′-*N,N*′-bis-carbazolyl-biphenyl (CBP); 7: *N,N*′-dicarbazolyl-3,5-benzene (CP); 8: 4,7-diphenyl-1,10-phenanthroline (BCP); 9: 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (Bphen); 10: *N-N*′-diphenyl-1,4,5,8-napthyl-tetracarboxyl-diimide (DPNTCI); 11: 7,7,8,8-tetracyano-p-quinodimethane (TCNQ); 12: 2,3,5,6-tetrafluoro-7,7,8,8-tetracyano-p-quinodimethane (F4TCNQ).

Single point energy calculation of the molecule was calculated at 6-311++G(d,p) level with PCM, The single positive state with the same molecular geometry of the molecule is also calculated using same basis set and PCM. The difference in energies gave the vertical ionization potential in the solid-state. Single point calculation of the molecule is also done without PCM, which gives the gas phase ionization potential.

3. Results and discussion

Fig. 1 shows the geometry optimized structures of 12 organic molecules, which are commonly used in organic electronics for different purposes. This series of molecules were chosen in such a way that they cover a wide range of ionization potential. Some molecules like TPD and NPD are used as hole transporting material in OLED, molecules like Alq$_3$, BCP are used as hole blocking material, molecule like TCNQ and F4TCNQ are used as p-doping material.

In organic powder/thin-film samples, the organic molecule can be considered as 'solvated' by the molecules of its own type. Hence, it is more realistic that calculation of the ionization potential of the molecule in thin-film takes into account 'solvation' due to the presence of other molecules.

But it is not possible to include an assembly of molecules in DFT calculation. Instead, a continuum solvent model can be considered to represent the surrounding molecules. Here, the solvent is modeled as an isotropic, continuous dielectric that surrounds a spherical or non-spherical 'solute' cavity. In this way, polarizable continuum model (PCM) [10] provides an efficient way to include the 'solvent' effect for the calculation of ionization potential.

Organic molecular solids are generally polycrystalline or amorphous. In amorphous solids, molecules are oriented randomly. Though there is a degree of anisotropy in polarizability at the molecular level, it has little effect in determining the bulk dielectric property of the amorphous organic solid [14]. The isotropic polarizability, used in the calculation of dielectric constant, is the algebraically averaged value of α_{xx}, α_{yy} and α_{zz}. Dielectric constants (ε) obtained from the calculation, for the organic solids, are listed in Table 1. It may be noted that the calculated values for TPD and Alq$_3$ agree well with the experimental values: 4.2 ± 0.2 [15] and 3.0 ± 0.3 [5], respectively. Table 1 also shows other values (number of molecules in 1000 Å^3 and radius of the molecule) used as inputs for the PCM calculation. All the values were calculated as described earlier. Though experimental values for some molecules are known, the calculated values were used, so that calculation

Fig. 2. The correlation of calculated ionization potential using PCM with experimental ionization potential of 12 molecules in solid-state.

can be done for any new molecule without reference to the experimental value.

Vertical ionization potential (IP) is the energy difference between the neutral molecule and positively charged molecule while keeping the molecular geometry of the two states remains same. Therefore, in order to get the vertical ionization potential in the calculation, identical molecular geometries were used for both neutral and charged state. Table 1 shows the calculated values of IP. Experimental values reported for these molecules are also shown.

Fig. 2 shows a plot between calculated and experimental value of ionization potential. The plot shows an excellent linear correlation. The slope of the fitted line is 1.004 with the intercept value of 0. This correlation shows that it is possible to determine the ionization potential of organic molecules in solid-state within error bar (±0.15 eV) of the experimental value. Table 1 also shows values of IP for isolated molecule in gas phase. The large difference between IP values of isolated molecule and solid-state shows that the solvation effect on the value of IP is very substantial.

The method described here is more appropriate for amorphous films because molecular orientational details are ignored as if the molecules in the solid film are in a liquid-like environment. Irrespective of this limitation, it is highly useful for a synthetic chemist to estimate IP values of solid films of organic molecules before actual synthesis.

4. Conclusions

A method is described for theoretical calculation of realistic ionization potential of organic molecules in solid-state using the DFT method and polarizable continuum model. In this method, no experimental data is required other than the molecular structure. This method will be useful to design molecules for organic electronics with a good estimation of the ionization potentials in the solid-state.

ARTICLE INFO

ABSTRACT

In this article, we have demonstrated solar cell performance of the inkjet-printed PEDOT:PSS layer and the roles of additives in device efficiency. The newly proposed PEDOT:PSS inks with additives of glycerol and surfactant show the improved surface morphology and high conductivity resulting in the enhanced photovoltaic performance. Using the optimized ink formulation of PEDOT:PSS, we have demonstrated a 3.16% efficient solar cell with an inkjet printing.

1. Introduction

During the past decade, there has been an intensive search for cost-effective photovoltaics [1–3]. As an alternative to inorganic solar cells, polymer solar cells could provide a significant cost reduction since their low temperature processing may allow for the printing of large area solar cells on flexible substrates at low fabrication cost [4]. Progress in the field of polymer solar cells is rapid [5,6]. The performance of polymer solar cells has been improved by using new materials [7], new structures [8] and new techniques in devices. Recently, several printing techniques have been used to fabricate various polymer based organic devices. Among them, inkjet printing is a commonly used technique for the controlled deposition of solutions of functional materials in specific locations on a substrate. It facilitates easy and fast deposition of polymer films over a large area. Moreover, it may be suitable for the large scale production of various electronic devices. In addition, inkjet printing is very promising because the polymer devices can be fabricated easily, due to their compatibility with various substrates and already complete patterning. Inkjet printing has been extensively used in the fields of polymer light emitting diodes (LEDs), and thin film transistors (TFT) [9–12]. Inkjet printing technology has also been used for fabricating polymer:fullerene bulk heterojunction solar cells, but not many results have been reported. Aernouts et al. developed polymer solar cells with an active layer of P3HT:PCBM using inkjet printing [13]. Steirer group recently reported inkjet-printed thin film electrodes for polymer.

Poly(3,4-ethylenedioxythiophene) doped with poly(4-styrenesulfonate) (PEDOT:PSS) has attracted much attention and has been widely used as an antistatic coating

material, as electrodes for capacitors or photodiodes, and as a hole transport layer in organic LEDs during the last decade [14–17]. PEDOT:PSS is optically transparent and easily processed using simple coating methods such as spin-coating [18–20]. Many researchers reported on the conductivity modification of PEDOT:PSS by adding several additives such as polyols, metals and different solvents [21–23]. The increase in conductivity of the PEDOT:PSS improves characteristics such as electromagnetic radiation shielding and electrical transport. In spite of such a potential use of PEDOT:PSS, few studies dealing with a PEDOT:PSS printing technique have been reported. Steirer et al. only reported inkjet-printed thin film electrodes of PEDOT:PSS for polymer solar cells [24].

In this paper, we report on the performance of bulk heterojunction polymer solar cells with an inkjet-printed PEDOT:PSS layer. The morphological and electrical studies and device performance of the inkjet-printed PEDOT:PSS layer in polymer solar cells are discussed in this article.

2. Experimental

PEDOT:PSS was purchased from Bayer (Baytron P AI 4083) and used alone, as well as mixed with additives of glycerol and ethylene glycol butyl ether (EGBE) to make inks for printing. (Details are given in Table 1.) The polymer solar cell device was fabricated with a configuration of indium tin oxide (ITO)/PEDOT:PSS/P3HT:PCBM/LiF-Al. Patterned ITO glass was cleaned with chloroform, acetone and isopropyl alcohol using an ultrasonication method, and then treated with an O_2-plasma. After solvent cleaning, the PEDOT:PSS thin films were coated by using inkjet printing (UJ2100, Unijet, Korea) and dried for 20 min at 140 °C. An active layer of P3HT:PCBM (mixed solution of 1:0.7 wt.%) was cast on top of the PEDOT:PSS film by spin-coating and dried for 1 h at 50 °C in a nitrogen atmosphere. To complete the device, LiF was evaporated on the active layer to about 0.7 nm thicknesses, and then Al evaporated to about 150 nm thicknesses under vacuum (10^{-6} torr). This device was encapsulated to measure the solar cell performance. The current versus voltage (I–V) characteristics of the solar cell devices in the dark and under white light illumination were measured with an AM 1.5G solar simulator (300 W, Newport, USA) and 100 mW/cm^2 conditions, adjusted with a standard PV reference cell (2 × 2 cm, a monocrystalline silicon solar cell, calibrated at NREL, Colorado, USA) with a Keithley 2400 source-measure unit. In order to avoid the underestimation of the area of the devices due to cross conduction of

a highly conducting PEDOT:PSS used in this study, we used a black mask fitted to the active area (3 × 3 mm) of the device [25,26]. The surface topography and morphology of the inkjet-printed PEDOT:PSS thin films were analyzed using polarization microscopy (JEOL-2010), surface profiler (SNU Precision SIS3747) and atomic force microscopy (AFM, VECCO, 613R1). All the characterizations were performed at room temperature.

3. Results and discussion

Polarization microscopy images of the inkjet-printed PEDOT:PSS films were completed to examine film morphology and thickness uniformity at the millimeter length scale (Fig. 1). As shown in Fig. 1a, the surface of the inkjet-printed films appeared non-uniform for PEDOT:PSS ink without any additives (ink 1 in Table 1). It appears to be composed of discontinuous clusters which do not stick to ITO substrates. The PEDOT:PSS accumulates in the center of the substrate due to spreading and wetting on the substrate and the drying behavior of the inkjet-printed films. The surface anchoring forces want to align the PEDOT:PSS parallel to the bottom surface and perpendicular to the top surface of the film. The elastic forces work against the resulting vertical distortions of the director field. Inkjet-printed PEDOT:PSS film with 6 wt.% glycerol (ink 2) gives better uniformity than film from ink 1 as shown in Fig. 1b. The colors shown in the images are due to the Newton colors of thin films which depend on the thickness of the film. Fig. 1c shows an image of PEDOT:PSS film with glycerol 6 wt.% and 0.2 wt.% EGBE added (ink 3). This ink had the best uniform film thickness and density. This
Fig. 2. Surface profile images of inkjet-printed PEDOT:PSS films (a) without additives (pure PEDOT:PSS): ink 1, with (b) glycerol (6 wt.%): ink 2, (c) glycerol (6 wt.%), and EGBE (0.2 wt.%): ink 3, (d) glycerol (6 wt.%) and EGBE (0.4 wt.%): ink 4.

may be due to the EGBE surfactant in the dispersion which minimizes the interfacial tension between the PEDOT:PSS and glycerol, allowing the pitch size (distance between individual droplets from the inkjet head) to be smaller than the droplet diameter. When the EGBE ratio is increased to 0.4 wt.%, the formation of the film seems to be disturbed, and film uniformity decreases as shown in Fig. 1d.

Fig. 2 shows the surface profile images of inkjet-printed PEDOT:PSS films without and with additives. A significant distinction in the film surface profile was observed in inkjet-printed PEDOT:PSS films. The surface profile image of the inkjet-printed PEDOT:PSS film without any additives (ink 1 in Table 1) shows significantly rough surface in 500 μm length scale. The surface roughness was dramatically improved in the inkjet-printed PEDOT:PSS film with adding 6 wt.% glycerol (ink 2). With adding of additional EGBE surfactant of 0.2–0.4 wt.% (ink 3 and 4), the surface roughness were slightly changed and smoother surface
Fig. 3. AFM images of inkjet-printed PEDOT:PSS films (a) without additives (pure PEDOT:PSS): ink 1, with (b) glycerol (6 wt.%): ink 2, (c) glycerol (6 wt.%), and EGBE (0.2 wt.%): ink 3, (d) glycerol (6 wt.%) and EGBE (0.4 wt.%): ink 4.

profiles were obtained. The surface morphology was further studied with AFM. Fig. 3 represents the AFM images of the inkjet-printed PEDOT:PSS films without and with additives in different amounts. Similarly with a surface profile result, the inkjet-printed PEDOT:PSS film from ink 1 without any additives shows relatively rough surface morphology with an rms roughness of 6.67 nm. The AFM images of the inkjet-printed PEDOT:PSS films from ink 2 and ink 3 with additives provide significantly reduced roughness profiles with similar rms roughness values of 1.64 and 1.63 nm. The rms roughness of inkjet-printed PEDOT:PSS film from ink 4 was slightly reduced up to 1.36 nm. A non-uniform surface roughness and profile, especially in the PEDOT:PSS film without additives (ink 1), may affect the interfaces between PEDOT:PSS and the photoactive layer, and therefore the performance of the inkjet-printed solar cell devices [9].

Fig. 4 shows the conductivity results of the PEDOT:PSS films with and without additives. The conductivity was enhanced in the inkjet-printed PEDOT:PSS film by the addition of 6 wt.% glycerol (ink 2) and with further addition of 0.2 wt.% EGBE (ink 3). The conductivity of PEDOT:PSS increased from 7.82×10^{-1} to 1.52×10^{2} S/cm for PEDOT:PSS by adding 6 wt.% glycerol and to 1.64×10^{2} S/cm by adding 0.2 wt.% EGBE. However, the conductivity decreases to 1.28×10^{0} S/cm when EGBE is increased to 0.4 wt.%. The addition of glycerol to the aqueous PEDOT:PSS dispersion is known to enhance the conductivity of the thin films by several orders of magnitude, depending on its concentration [27]. The conductivity of the PEDOT:PSS is strongly dependent on the film morphology and its chemical structure. F. Zhang et al. recently reported that PEDOT:PSS with glycerol shows higher performance in solar cells than pure PEDOT:PSS film due to the swelling and aggregation of colloidal PEDOT-rich particles that ultimately facilitate conduction in the film [36]. Several reports show that the dramatic effect of glycerol as a
processing additive is due to the reorganization and stabilization of the PEDOT and PSS chains during subsequent thermal annealing of the films by a plasticizing effect [28–35]. In our study, the addition of glycerol and surfactant EGBE may also affect the morphology and physical structures of inkjet-printed PEDOT:PSS film. Here, we propose a hypothesis to explain the basic principles of molecular interactions between the surfactant, glycerol and the PEDOT:PSS film. Normally PEDOT:PSS film originates from a core-shell type framework, as shown in Fig. 2d, where PSS molecules are located around the PEDOT units through ionic interaction. Similarly, upon addition of glycerol, the polar functionality (–OH) in the glycerol molecule might directly interact with cationic species of PEDOT. Probably stronger ionic interactions between the glycerol and PEDOT are responsible for the highly conductive network formation in glycerol added PEDOT:PSS, when compared to PSS and PEDOT in pure PEDOT:PSS film. A mild repulsive force may be exerted between the PSS and glycerol units. The level of conductive network formation is further extended by an incorporation of 0.2 wt.% EGBE surfactant, which has both a polar alcoholic (–OH) group and a nonpolar alkyl group (butyl) at the other end. However, with a higher weight percentage of EGBE surfactant, the conductive network formation is significantly suppressed by the formation of hydrophobic areas. The alkyl group in the EGBE surfactant aggregates along with PSS units to form hydrophobic domains that will decrease the surface poten-

tial of the PEDOT:PSS film in order to reduce conductivity. The work is still underway to find an exact mechanism.

To study the effect of additives on solar cell device performance, polymer bulk heterojunction solar cells (device 1–4) from different PEDOT:PSS inks (inks 1–4 as shown in Table 1) have been fabricated in the configuration of ITO/PEDOT:PSS inks/P3HT:PCBM/LiF-Al by inkjet printing. Current-density versus voltage (*J*–*V*) characterization has been performed in the dark and under simulated illumination as shown in Fig. 5. The resulting characteristics are shown in Table 2. Without any additives (device 1), the device performance was very poor showing low power conversion efficiency (EFF), circuit current density (Jsc) and fill factor (FF). This is due to the roughness surface profile as indicated in surface morphology results and low conductivity of PEDOT:PSS layer. The Jsc, FF and EFF of the device 2 from inkjet-printed PEDOT:PSS with glycerol were more than that of the pure PEDOT:PSS (device 1). Especially, Jsc was dramatically enhanced in device 2. This enhancement in the Jsc as well as device efficiency may be due to the improvement of the surface morphology and the improved charge collection by increased conductivity of the PEDOT:PSS with glycerol compared with pure PEDOT:PSS [37,38]. This may also be explained by the swelling and aggregation of colloidal PEDOT-rich particles which form a highly conductive network in the films [36,39]. The device performance (device 3) further improved with the addition of 0.2 wt.% EGBE surfactant from

2.92% to 3.16% in efficiency. Jsc and FF values were also enhanced in device 3. The conductivity of PEDOT:PSS film in this device is almost the same as glycerol added to PEDOT:PSS (device 2), but the surface roughness is optimal compared to other films. When the amount of EGBE in the PEDOT:PSS film is increased from 0.2 to 0.4 wt.%, it decreases the conductivity of the film, therefore efficiency and Jsc decrease in device 4.

In order to investigate the reproducibility of solar cell devices with inkjet-printed PEDOT:PSS layers, we have prepared several solar cell devices from inkjet-printed PEDOT:PSS inks in the different batches and their solar cell properties were measured. Fig. 6 shows the photovoltaic characteristics of three solar cell devices. All devices show good reproducibilities in Voc, Jsc, FF and efficiency. The best solar cell performance was obtained in device 3.

4. Conclusion

We have demonstrated solar cell performance of the inkjet-printed PEDOT:PSS layer and the roles of additives in device performance. We have used glycerol and EGBE surfactant as additives for improve the surface morphology and conductivity of PEDOT:PSS inks. The newly proposed ink formulation of PEDOT:PSS increases the photovoltaic performance such as Jsc, FF and efficiency of inkjet-printed PEDOT:PSS resulting in a reliable print head with optimum wetting, spreading and drying. Using the newly developed

ink formulation of PEDOT:PSS (ink 3) with glycerol and optimized EGBE surfactant, we have demonstrated a 3.16% efficient and reliable solar cell with an inkjet-printed PEDOT:PSS layer (device 3). This high photovoltaic performance indicates the potential of inkjet printing for the mass production of organic photovoltaics.

ABSTRACT

The on/off ratio of a vertical-type metal-base organic transistor was significantly improved by subjecting it to heat treatment in air. The heat treatment of the collector layer and the base electrode reduced the off current that is mainly due to leakage current between the base and the collector, resulting in a considerable decrease in the off current. As a result, a high on/off ratio greater than 10^5 was achieved, in addition to the low-voltage and high current operation of the vertical-type organic transistor.

1. Introduction

Organic transistors have been extensively studied and are expected to be used for producing flexible displays and low-cost radio frequency identification systems [1–4]. Most studies conducted on organic transistors have focused on organic field-effect transistors (OFETs) having "lateral" structures. In these structures, the channel carriers flow along the plane of the organic semiconductor film. Further, the channel length in these structures, which is determined by the fine patterning technique commonly employed, can be reduced to less than several microns only by expensive techniques such as lithography.

Recently, several researchers have proposed different types of organic transistors that have a "vertical" structure. In such structures, channel carriers flow across the thin film in a direction perpendicular to the substrate. Therefore, the channel length in this case corresponds to the thickness of the film and can be easily reduced to less than one micron. In order to achieve enhanced transistor performance, for example, high current modulation, low-voltage operation, and high frequency response, it is important to have a short channel length. Thus far, several types of vertical transistors have been proposed; for example, organic static induction transistors with a striped central electrode [5–7], vertical organic triodes [8–10], vertical transistors made of organic–inorganic hybrid materials [11–13], and polymer space-charge-limited transistors [14,15].

We have recently proposed a metal-base organic transistor (MBOT), which is a promising vertical-type organic transistor [16,17]. This transistor has a simple structure

in the form of organic/metal/organic layers. The middle electrode of the MBOT can be fabricated by techniques other than the fine patterning technique; further, the MBOT has a high current modulation of over 100 mA/cm^2 and low-voltage operation of the order of several volts.

Generally, vertical-type transistors have a low on/off ratio because their short channel length tends to increase the leakage current. The on/off ratio of the proposed MBOT was also reported to be low (around 100). However, we have already reported a slight improvement in the on/off ratio by exposing the device to air [18]; this improvement was accompanied by a decrease in the on current. In this study, we propose an efficient method for decreasing the leakage (off) current; this method involves subjecting only the collector semiconductor layer and the base electrode to heat treatment in air. By this method, the off current is reduced significantly without a decrease in the on current, resulting in a very high on/off ratio.

2. Experimental

In this study, the transistor device with a simple layered structure (Fig. 1) was fabricated by vacuum evaporation. The first organic layer (collector layer) of N,N'-dimethyl-3,4,9,10-perylene tetracarboxylic diimide (Me-PTC) (Dainichiseika Color and Chemicals Manufacturing Co., Ltd.) with a thickness of 500 nm and an aluminum layer (base electrode) with a thickness of 20 nm were deposited successively on a clean indium tin oxide (ITO) glass substrate that was subjected to ultrasonic cleaning in acetone, methanol and deionized water. At this stage, the two layers were subjected to heat treatment at 150 °C in air. Next, the remaining layers, i.e., the second organic layer of C$_{60}$ (100 nm) and the emitter electrode layer of Ag (30 nm) were deposited. The chamber was flushed with dry nitrogen gas, but the substrate was exposed to air after each deposition. The size of the active area on which the three electrodes were deposited one over the other was 4 mm^2. The current modulation of this transistor was measured
using a common emitter circuit (Fig. 1) with two source-measure units (Keithley Instruments Inc., model 236) under vacuum (10^{-1} Pa) at room temperature. The collector voltage (V_C) was applied between the collector and emitter electrodes, and the base voltage (V_B) was applied between the emitter and base electrodes; in both these cases, the emitter was negatively biased. The current amplification factor (h_{FE}) is defined as the ratio of the change in the collector current (I_C) to that in base current (I_B) induced by applying the input voltage (V_B). The HOMO level of the organic semiconductor was measured by photoelectron yield spectroscopy (Sumitomo Heavy Industries, PYS-201), and the HOMO–LUMO gap was estimated from the absorption spectrum.

3. Results and discussion

The output current (I_C) was increased by the application of base voltage (V_B), and h_{FE} exceeded unity; therefore, the device functions effectively as an MBOT. Fig. 2 shows the effect of the time for which the layers were subjected to heat treatment on the on and off currents at $V_C = 5$ V, where the on and off currents are the I_C at $V_B = 3$ and $V_B = 0$ V, respectively. For the heat treatment time equal to zero (no heat treatment), a large off current was observed, and the on/off ratio remained around 100. The off current decreased significantly as the heat treatment time increased and subsequently, it decreased by approximately three orders of magnitude within several hours of heat treatment. In contrast, the on current decreased by only a slight amount. As a result, the on/off ratio increased with increasing heat treatment time and attained a maximum value of 3×10^5. Such a high on/off ratio of a vertical-type organic transistor is desirable and comparable to that of lateral-type OFETs.

Fig. 3 shows the current modulation characteristics of the device subjected to heat treatment for 2 h ($V_C = 3$, 5 and 7 V). Those of the device without heat treatment are also shown ($V_C = 5$ V). Fig. 3a shows the I_C–V_B curves at various values of V_C. From the figure, it is clearly observed that the output collector current (I_C) was modulated by the input base voltage (V_B) by five orders of magnitude. It should be noted that a large current density of over 100 mA/cm^2 was obtained at a low operation voltage, that is, when $V_C = 5$ V and $V_B = 2$ V. The current amplification factors (h_{FE}) for these modulations are shown in Fig. 3b. The value of h_{FE} reached around 140 at $V_C = 7$ V and $V_B = 2.5$ V, which indicates that small input base current is amplified to large output collector current. This low-voltage operation of the transistor is attributed to its vertical structure with a very short channel length. The fact that the I_C–V_B curves are coincident for various values of V_B suggests that the output current reaches a saturation point as V_C increases. Such a saturation of the output current, similar to that observed in OFETs, is also a desirable but uncommon feature of vertical-type organic transistors. Furthermore, the decrease of leakage current by the heat treatment resulted in high reproducibility and stability in the fabrication of MBOTs.

The decrease in the off current by heat treatment in air can be explained by the suppression of electron injection from the base electrode. The operation mechanism of the

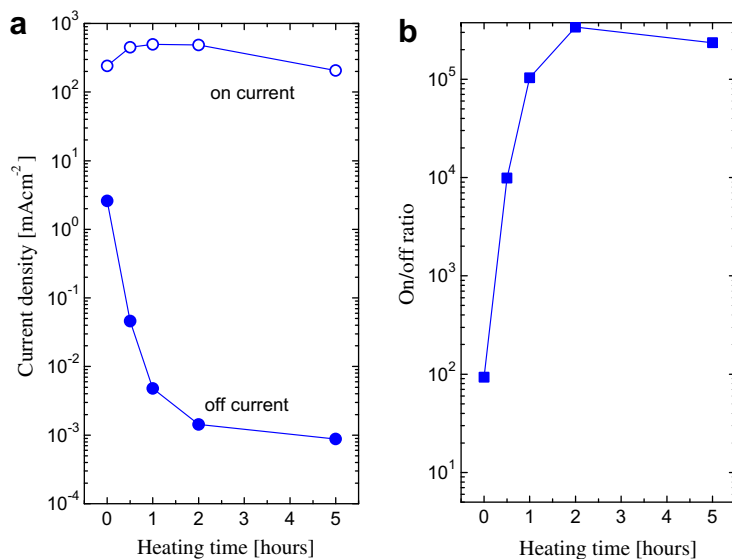
Fig. 1. Structure of metal-base organic transistors and the system for measurement of transistor performance. Both collector voltage (V_C) and base voltage (V_B) were applied with the emitter electrode negatively biased.


Fig. 2. Dependence of (a) on and off currents and (b) on/off ratio on the heat treatment time at $V_C = 5$ V and $V_B = 3$ V.

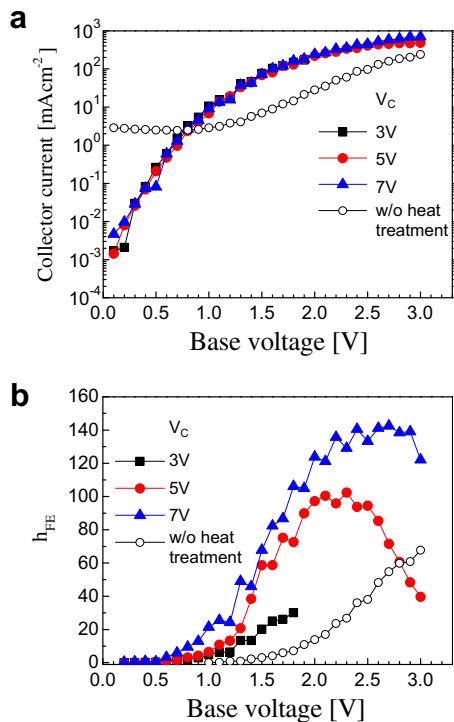
MBOT is explained with the help of a schematic energy diagram shown in Fig. 4a. The real energy level of each layer is illustrated in Fig. 4b. To explain its operation, we propose the following mechanism of electron transmission through the base electrode [16,17]. The electrons injected from the emitter on applying V_B are transmitted across the thin base electrode with a high probability and are collected on the ITO electrode through the Me-PTC layer. This mechanism induces high current modulation of I_C for a small increase in I_B, namely, current amplification. In the off state, there is no potential difference between the emitter and base because $V_B = 0$. Therefore, the major component of the off current is regarded as the leakage current from the base to the collector. Furthermore, this component is attributed to the flow of electrons from the base electrode because


Fig. 3. Modulation characteristics of the MBOT subjected to optimized heat treatment (150 °C for 2 h) and without heat treatment; (a) I_C–V_B curves and (b) h_{FE}–V_B curves.
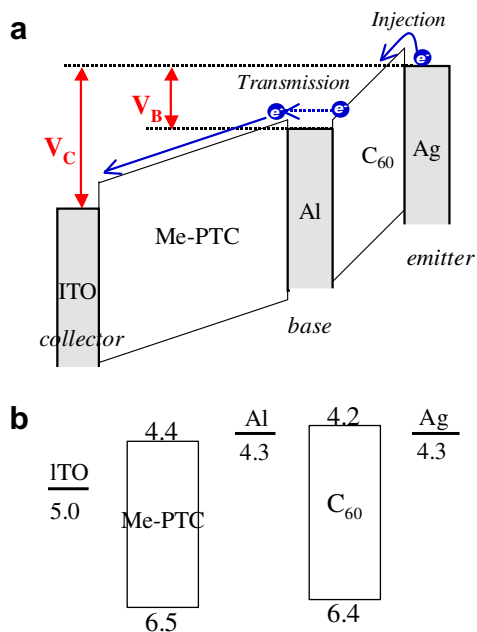

Fig. 4. (a) Energy diagram of MBOT during its operation. The emitted electrons pass through the base electrode with high probability. The off current (I_C at $V_B = 0$) corresponds to the current of the electrons injected from the base electrode to the Me-PTC layer. (b) HOMO and LUMO levels of the organic semiconductors, and work function of each electrode.

Me-PTC is a well-known n-type semiconductor [19–21]. Thus, it is concluded that heat treatment of the device in air suppresses the current due to electron injection at the Me-PTC/Al interface, causing a decrease in the off current. In fact, two-terminal $I–V$ curves between the base and collector indicated clear decrease of current after the heat treatment.

The current saturation that occurs with increasing V_C, as shown in Fig. 3b, can also be explained by the above mentioned mechanism. In the proposed mechanism, the number of electrons injected from the emitter depends only on V_B, and the collector voltage V_C facilitates the collection of these carrier electrons by the collector electrode. Therefore, I_C is expected to saturate when the upper limit of the current due to the injected electrons is reached. In the present study, the ideal current modulation observed is also believed to be attributed to the decrease in the additional leakage current. This behavior also suggests that V_C has no effect on the electron injection at the emitter interface; that is, the electric flux lines between the emitter and collector are completely separated by the base electrode.

To further investigate the effect of heat treatment, we performed some additional experiments. We tried heat treating only the Me-PTC layer before depositing the base electrode on it. However, this technique did not decrease the off current, which indicates that the heat treatment did not alter the bulk transport properties of Me-PTC. In addition, no significant change was observed in HOMO and LUMO levels of the Me-PTC film. Therefore, change in the morphology or energy levels of the film was excluded as a possible cause of the decrease in the off current, and this decrease was concluded to be attributed to the Me-PTC/Al interface. Such a heat treatment including aluminum associates us with some oxidation process. However, the in-plane resistance of the base electrode was maintained at several hundred ohms and did not increase by heat treatment, which suggests that even after the heat treatment, the base electrode functions effectively. From all these results, we speculated that the heat treatment forms some oxidation layer mainly at the Me-PTC/Al interface, and this layer efficiently blocks electron injection into Me-PTC. It was an interesting observation that this layer did not block the electrons emitted from the emitter. However, the exact mechanism of electron transmission through the base electrode is still unclear and requires further investigation.

4. Conclusion

In conclusion, we successfully decreased the leakage (off) current by subjecting the collector layer and base electrode to heat treatment in air and therefore realized a vertical-type MBOT with a very high on/off ratio while maintaining high current and low-voltage operation. The fact that this method also improves stability and reproducibility of the fabrication of MBOTs has encouraged us to further elucidate the operation mechanism systematically.

ARTICLE INFO

ABSTRACT

We report on a novel method for patterned deposition of conductive polymers, which is derived from and fully compatible with fast in-line printing methods. The method is aimed at improving resolution, homogeneity and edge sharpness of printed conductive structures for applications in the field of printed electronics. The surface energy of a foil substrate, which has been increased by means of corona treatment, was reduced in selected areas through contact with materials that have suitable surface properties and can be patterned at micrometer scale (i.e. printing plates). A conductive fluid was sprayed onto the chemically heterogeneous surface. The fluid accumulated at areas with higher surface energy. After the drying process, the conductive polymer structures were used as source/drain contacts for the preparation of OFETs.

1. Introduction

In recent years, considerable progress has been made in the relatively new field of printed electronics. Conductive, semiconductive and insulating functional polymers were successfully formulated as inks and applied in a patterned way by means of mass printing methods, like offset, flexographic and gravure printing. On the basis of these technologies, all-printed, fully polymeric electronic devices (transistors, inverters, ring oscillators) were realised in a continuous process at a process speed of approx. 1 m/s, [1,2]. The printed conductive structures, however, have a limited resolution and the layer morphology is not optimal especially with offset printing [3]. In order to enhance the performance of polymer electronic devices, research currently focuses on new technological approaches that improve layer homogeneity and reduce structure sizes. A

major challenge is to guarantee the compatibility of new technological approaches with the continuity of conventional printing and the utilised materials. Moreover, material availability and processability are important issues [4].

Various approaches and methods for the preparation of patterns on surfaces which are pre-structured in terms of surface tension (so-called wetting structuring) have been described. The increasing demand for miniaturisation of structure sizes led to the development of complex technologies, like microcontact printing (μCP) [5–7]. One aspect of μCP, the transfer of PDMS oligomers during contact between PDMS stamp and substrate, is discussed from various perspectives in the literature [8–11]. In [11] a method for applying low-molecular siloxane oligomers with PDMS stamps to a substrate is presented. This method was used for the preparation of a TFT (thin film transistor). Another interesting method is plasma mask technology for surface structuring of polymers [12]. However, reasonable integration of the above mentioned methods into a conventional printing process seems impossible, because contact times of several minutes [11] or complex cleaning

Fig. 1. Wetting structuring – process scheme.

procedures [13] are necessary. The method described in [14] uses ink jet printing for applying droplets of an aqueous dispersion of PEDOT/PSS to a SiO_2/n^+–Si substrate. Electron beam lithography, vacuum deposition and lift-off processes were used to apply hydrophobic self-assembled monolayers (SAMs) of fluorodecyltrichlorosilane (FDTS) to the raised areas of the SiO_2 substrate surface. When PEDOT/PSS droplets hit the hydrophobic areas, the liquid dewetted into two parts, which were employed as source/drain electrodes in field-effect transistors. The width of the raised SiO_2 structures to which FDTS was applied determined the channel length. Channel lengths down to 500 nm have been realised.

2. Experimental

In conventional printing processes, surface activation by corona is usually employed to improve wetting behaviour of foil substrates. Corona treatment results in areas with different surface energies. In the simplest case, these differences result from the fact that only parts of the substrate are corona-treated while others remain untreated. This can be done by either turning the corona on and off or by partial treatment of the web with segmented corona electrodes. The usual area treatment, however, fails in continuous processes where the surface energy has to be modified at micrometer scale in running direction and perpendicular to it.

The process presented here is based on contact between a surface-modified foil substrate with the surface of a non-inked printing plate processed with a reduced light detacking (UVC) time of 5 min, as for instance used in flexographic printing (Flint Group nyloflex® FAH). The partial reduction of the surface energy by contact requires the structuring of the printing plate in printing and non-printing areas. In flexographic printing the printing elements are raised. Contact with the foil substrate and, thus, reduction of the surface energy only takes place at raised areas. After contact between printing plate surface and corona-treated foil, which shall be termed "wetting structuring", the surface of the foil has areas of different wetting behaviour. The surface energy of the polymer formulation is adapted by adding a mixture of surfactants (about 0.03% by weight) in order to match the foil areas having a high surface energy. The conductivity of the dried layer is improved by adding glycerol (15% by weight).

When these formulations are applied to the substrate it is mainly the high surface energy areas that are wetted.

Table 1
Functional layers – OFET.

Functional layer	Material	Layer thickness [μm]	Application process
Substrate	PET foil	50	
Source/drain	PEDOT:PSS	0.1	Spraying
Semiconductor	F8T2	0.05	Spin coating
Dielectric	Cytop/Luxprint 8153	10	Spin coating
Gate	PEDOT:PSS	1	Dispensing

The amount of liquid that is applied per unit area is a crucial factor for the preparation of homogenous polymer structures with defined outlines. Only exact dosing guarantees that a pinhole-free, sufficiently thick layer is applied and non-image areas are not wetted. Preparatory experiments showed that spraying via nozzle is a suitable method for the precise application of a functional polymer liquid. A two fluid nozzle with a nozzle diameter of 0.4 mm producing a spray with a Sauter mean diameter of approx. 8 μm was chosen. The PET foil Melinex 401 with a thickness of 50 μm was used as substrate. The surface energy of the foil was increased from 47 to approx. 60 mN/m by means of corona pre-treatment (system by Arcotec GmbH) on a laboratory printing press. The layout of the flexographic printing plate consisted of source/drain structures for transistors and connecting lines, which allow for more complex functions (e.g. inverters). The channel
Fig. 2. Surface energy of corona-treated PET foil (contact angle measurement: sessile drop; calculation method: Owens–Wendt).

lengths on the printing plate were 10 μm. The formulation of the conducting function polymer PEDOT:PSS in aqueous dispersion (Baytron P, now Clevios P, by H.C. Starck GmbH, Germany) was sprayed onto the wetting-structured foil surface in order to prepare source/drain structures for field-effect transistors. The process is explained in Fig. 1. The other layers of the top-gate transistors were applied by means of spin coating or dispensing. Table 1 provides
Fig. 4. OFET output characteristics (V_{GS} = 0 to −60 V).

an overview of the utilised materials, layer thicknesses and application methods.

3. Results and discussion

Corona treatment increases the surface energy of PET foil from 47 to approx. 60 mN/m. Fig. 2 shows the characteristics of the surface energy depending on the corona energy. The corona energy is defined as the energy that is applied to the substrate in order to modify its surface energy. It is determined by the generator power, the speed of the foil web and the width of the electrodes, i.e. the width of the corona discharge. Under the given conditions – web speed 0.5 m/s and width of the corona discharge 35 mm – the surface energy of the foil reaches a state of saturation at a corona dose of >10 kWs/m^2. Contact with the flexographic printing plate results in a reduction of the surface energy of the foil (dispersive contribution) at the contact points. The difference in surface energy between contact and non-contact areas is 12 mN/m. The surface energy of the aqueous PEDOT:PSS dispersion is adjusted to guarantee wetting of the non-contact areas, i.e. areas with a higher surface energy, on the foil (cf. Fig. 3b). The PEDOT:PSS formulation is sprayed onto the foil immediately after wetting structuring. Drying is realized in a hot air stream adjusting a PET surface temperature of 130 °C for 20 s. The SEM micrograph in Fig. 3c shows a profile scan of one finger of a source/drain structure with a channel length of 10 μm and a cross section height of the finger of approx. 100 nm. The surface roughness (Ra) is low, approx. 10 nm. Typical output characteristics of an OFET which is based on these source/drain structures with a channel length of 10 μm and a channel width of 2.5 mm is shown in Fig. 4. Mobility is 4×10^{-4} cm^2/Vs and on/off ratio 275.

4. Conclusions

A new approach for the preparation of conducting polymer structures by means of a continuous process was presented. Very thin, homogenous layers with low roughness were produced. The minimum channel length of 10 μm is determined by the limited resolution of the used printing plate. There is a difference in channel length between Fig. 3b (∼15 μm) and Fig. 3c (∼10 μm) due to the limited depth of field of the light microscope used for Fig. 3b.

Fig. 3. (a) Flexographic printing form with source/drain layout: finger width F = 150 μm; channel length L = 10 μm, (b) PEDOT:PSS structures after spraying and drying, (c) SEM micrograph + profile scan of one line shown in (b).

Challenges are the durability of the printing plate surface, as there is a decrease in homogeneity of the surface energy reduction regarding the contact area when using the same plate for several times, and the spraying parameters, which have to be adjusted in order to achieve very small structure sizes and channel lengths. Other substrates, pre-treatment methods, like atmospheric pressure plasma (plasma spot), application methods for conducting polymers, like dipping or blading, and the combination with other functional materials in OFETs will be tested in order to further improve the technology.

ARTICLE INFO

ABSTRACT

In this study, we prepared all-solution-processed inverted polymer solar cells (PSCs) incorporating two solution-processed electrodes – surface-nickelized polyimide films (NiPI films) as cathodes and high-conductivity poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonate) (PEDOT:PSS) films as anodes – and an active layer with a bulk heterojunction morphology of poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl-C_{61}-buytyric acid methyl ester (PCBM). The granular Ni thin films, which exhibited good adhesion and high-conductivity (ca. 2778 S cm^{-1}) on the polyimide (PI) substrates and possessed a work function different from that of pure Ni metal (WF, 5.4 eV). Using ultraviolet photoelectron spectroscopy, we determined that the WF of the NiPI films was ca. 3.9 eV. Prior to the coating of the photoactive layer, the surface of the NiPI films were treated with titanium(diisopropoxide)bis(2,4-pentanedionate) (TIPD) solution to facilitate the deposition of high-quality active layer and further as a hole blocking layer. The solution processed anodes (solvent-modified PEDOT:PSS films) were further coated and subjected to mild oxygen plasma treatment on the active layer. Short exposure (5 s) to the plasma improved the quality of the surface of the active layer for PEDOT:PSS deposition. These inverted PSCs on flexible granular NiPI films provided a power conversion efficiency of 2.4% when illuminated under AM 1.5 conditions (100 mW cm^{-2}). The phenomenon of light absorption enhancement in those inverted PSCs was observed as indicated in reflective UV–vis, haze factor and external quantum efficiency (EQE) responses. The resulting fill factor (FF) of 0.43 is still significantly lower than the FF of 0.64 for standard devices. When compared to the planar structure, the improvement of absorbance of light and good haze factors was obtained for granular structure which suggests NiPI as a better back contact electrode through enhancing the light trapping and scattering in inverted PSCs.

1. Introduction

Polymer solar cells (PSCs) have recently received considerable attention because of their low cost, light weight, high flexibility, and solution-processability. The power conversion efficiency (PCE) of PSCs has been improved to 5% under AM 1.5G conditions [1–4] when using a bulk heterojunction (BHJ) structure comprising a blended film of poly(3-hexylthiophene) (P3HT) as the donor and [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) as the acceptor. In addition to their improved device efficiency [1–5] and lifetime [6,7], PSCs possessing inverted structures have also been investigated to further reduce production costs and to facilitate high-throughput production [8–22]. Among inverted PSCs, two major structures are studied most frequently. One employs modified layers located between the active layer and the electrodes to change the energy level of the whole device, i.e., the roles of the indium tin oxide (ITO) material (as the cathode) and the metal

electrode (as anode) are different from those of standard PSCs systems [ITO (anode)/PEDOT:PSS/active layer/metal (cathode)] (Fig. 1A). For this inverted system, in which the roles of the electrodes are exchanged, the use of solution processing methods results in enhanced efficiency from the collocation of appropriate energy levels for the electron- and hole-collection layers [8–14]; in addition, a roll-to-roll suited module would be achieved when introducing an inject-printed metal as the anode (Fig. 1B). The second type of inverted PSC possessing a layer sequence has great promise for use as a cost-efficient roll-to-roll suited module, i.e., starting with the metallic electron contact on a plastic substrate [16–23]. The active layer is coated on the metal layer, followed by the PEDOT:PSS layer, which forms the transparent hole contact. In this inverted system, the roles of the anode and cathode are similar to those in standard cells, but the processing method employed to build the PSCs is different (Fig. 1C). Moreover, the preparation of this second type of inverted PSC would presumably provide higher efficiency and lower device fabrication costs when using ITO-free materials. Another advantage when using this inverted PSC system [22,23] with high topographical variations of metals is that it would lead to an imposed topography on the photovoltaic device; it could also be used to couple light into the film, increasing the optical length in the device. Based on these previous studies, we suspected that combining the technologies for all-solution processing with the high topographical variations of the metal and the high-conductivity of PEDOT:PSS would allow us to obtain ITO-free inverted PSCs for high-throughput production on flexible substrates.

Recently, polyimide (PI) films have become generally used components for flexible electronic devices because they exhibit high glass transition temperatures, low surface roughnesses, low coefficients of thermal expansion (CTE), and high chemical resistance under typical fabrication conditions. Surface-metalized PIs have been developed widely using various metals, including Ag, Cu, and Ni [24–27]. In a previous study [26], we developed an all-solution method for fabricating thin granular Ni films on PI (NiPI) with high adhesion and conductivity (ca. 2778 S cm^{-1}). These NiPI films are readily fabricated through alkaline hydrolysis to open the imide rings of the pristine PI film, followed by ion exchange with Ni ions and their subsequent reduction on the PI (Fig. 2A–E).

In this paper, we report the fabrication of all-solution-processed inverted PSCs featuring NiPI as the cathode material (back contact electrode) on flexible substrates; these devices have the following configuration: PI/Ni (cathode)/titanium(diisopropoxide)bis(2,4-pentanedionate (TIPD)/P3HT:PCBM/PEDOT:PSS (anode). From the many reports describing the insertion of a buffer layer between the cathode and the active layer to improve device performances [4,28–30], we chose the solution-processable TIPD as the buffer layer in this study because Tan et al. [30] demonstrated that the TIPD interface dramatically reduces the degree of interface resistance between the cathode and the active layer. Furthermore, because the energy level of the lowest unoccupied molecular orbital (LUMO) of TIPD is ca. 3.9 eV, we suspected that it would be easy to transport electrons to the NiPI film [work function (WF) = 3.9 eV]. In addition, we developed a low-temperature fabrication process (<150 °C) to obtain high-conductivity PEDOT:PSS films in these inverted ITO-free PSCs. We readily obtained these high-conductivity PEDOT:PSS films (ca. 283 S cm^{-1}) through spin-coating of a solvent (methoxyethanol, ME) onto pre-coated PEDOT:PSS films [31]; this method appears to be more suitable for plastic substrates because it does not require a very high-temperature (>150 °C) to remove any polyalcohol [32–37] and, thereby, decreases the likelihood of destroying the active layer. Based on the previous report, [31] the sheet resistance of PEDOT:PSS electrode (a distance effect for PED-

OT:PSS based ITO-free PSC devices) increased as the area of the device increasing, and hence decreased the device performance. The low conductivity of the PEDOT:PSS electrode is actually limited for larger area cells. Therefore, we further deposited a Au grid (thickness at 100 nm) onto the PEDOT:PSS films to efficiently collect holes and efficiently increase the sheet conductivity of the transparent electrode.

2. Experimental

2.1. Nickelized polyimide films (cathodes and substrates)

The process for the direct all-wet-chemical treatment of Ni-coated conductive films was performed according to the procedure outlined in Fig. 2A–F. The PI films were synthesized from pyromellitic dianhydride (PMDA; from TCI) and 4,4′-diaminodiphenylether (ODA, 98%; from Aldrich); the experimental details for fabricating the PI and nickelized PI films are available elsewhere [26]. Briefly, the PI films

were first immersed in 5 M aqueous KOH at 25 °C for 7 min and then rinsed with deionized water. Next, the K⁺ counterions associated with the opened imide rings on the surface of the PI films were exchanged with Ni²⁺ ions through immersion in 50 mM aqueous nickel sulfate at 25 °C for 5 min, followed by rinsing with deionized water. The surface Ni²⁺ ions were then reduced in aqueous NaBH₄ (0.2 g/100 ml deionized water) at 25 °C for 5 min to form Ni nanoparticles on the PI surface (Ni-NPs/PI films), which were then rinsed with deionized water. The Ni NP-seeded PI films were immersed in an electroless nickel bath (EN solution) at 50 °C for 8 min to form thin Ni layers on the PI films (NiPI). The EN solution was prepared from a 4:1 (v/v) mixture of a Ni stock solution [nickel sulfate (40 g l⁻¹), sodium citrate (20 g l⁻¹), and lactic acid (10 g l⁻¹) in deionized water) and a DMAB solution (1 g l⁻¹ in deionized water). A cartoon representation and a photograph of the patterned NiPI are presented in Fig. 2F and G, respectively. The NiPI films have long-term air stability in the atmosphere. Prior to the deposition of

the photoactive layer, the NiPI films were cleaned with organic solvents.

2.2. Active-layer materials

Because of the large differences in the values of the contact angles and surface energies of Ni and PI surfaces (Table 1), the solution-processable titanium chelate TIPD (from Aldrich) was pre-coated as the cathode buffer layer on the patterned NiPI film surfaces to facilitate the fabrication of high-quality active layers. Next, a blend [1:0.8 (w/w), 17 mg ml^{-1} in dichlorobenzene (DCB)] of P3HT (Rieke Met. Inc.) and PCBM was stirred overnight in DCB, filtered through a 0.2 μm poly(tetrafluoroethylene)(PTFE) filter, and then spin-coated (500 rpm, 60 s) on top of the NiPI films.

2.3. High-conductivity PEDOT:PSS films (anodes)

The high-conductivity PEDOT:PSS anodes were prepared using a two-step method [31]. In the first step, a 95:5 (w/w) mixture of PEDOT:PSS solution (HC V4; from H. C. Starck) and dimethyl sulfoxide (DMSO; from Aldrich) was filtered through a 0.45 μm filter prior and then deposited (spin-coating at 4000 rpm in the air) onto the active layers with a mild oxygen plasma exposure for 5 s (plasma cleaner PDC-32G, Harrick Scientific, Ossining, NY) at a thickness ca. 50 nm. In the second step, the surface-modifying solvent, ME, was spin-coated onto the pristine PEDOT:PSS films at 3000 rpm, which were then dried at 100 °C for 5 min inside a glove box. The device was completed by coating a 100 nm-thick layer of Au as a metal grid and a mask to improve hole-collection and define the active area, respectively. The cell was then encapsulated using UV-curing glue (Nagase, Japan). The active area of each photovoltaic (PV) cell was 0.036 cm^2. Fig. 4A displays the architecture of the inverted ITO-free polymer/fullerene solar cells.

2.4. Instrumentation

The NiPI films were transferred within 3 min of their formation into the sample-loading chamber of an ultraviolet photoelectron spectroscopy (UPS) system. UPS (VG ESCA-Lab 250, HeI hν = 21.2 eV) spectra were recorded at a sample bias of −5.0 V to observe the secondary electron cutoff, from which the work function could be derived from the width of the Fermi edge of a Au substrate. XPS spectra were recorded using a VG Scientific Microlab 350 spectrometer operated in the constant analyzer energy mode with a pass energy of 50 eV and Mg · Kα (1253.6 eV) radiation as the excitation source (with normal emission detected). The sheet resistances of the PEDOT:PSS films were measured using a four-point probe; the average of the measured values is reported. The transmittance spectra were recorded using an HP8453 UV–vis spectrometer. Contact angles and surface energies were measured and calculated using the geometric mean approximation (GMA) and a FTA-200 dynamic contact analyzer operated with H$_2$O and CH$_2$I$_2$ as the two standard liquids. The crystalline phase of samples was characterized using a BEDE D1 grazing incidence X-ray diffractometer (GIXRD) and Cu · Kα radiation. The incident angle of the X-ray beam was fixed at 0.5°. The surface morphologies and phase changes of the PEDOT:PSS films were analyzed using a VEECO DICP-II atomic force microscope (AFM) operated in the tapping mode (Si tips on Si cantilevers having a spring constant of 2 N m^{-1} and a set point of ca. 0.8–0.9) in the air. A JEOL JSM-6500F scanning electron microscope (SEM) was employed to investigate the thicknesses of the PEDOT:PSS films. Samples for transmission electron microscopy (TEM) analysis were prepared through microtoming with a Leica Ultracut Uct apparatus into 90 nm-thick slices that were placed onto a 200-mesh carbon-coated Cu TEM grid (Agar Sci., Inc.). TEM images were recorded using a JEOL-2010 transmission electron microscope and an internal charge-coupled device (CCD) camera. Current–voltage (I–V) curves of the PSC devices were measured using a computer-controlled Keithley 2400 source measurement unit (SMU) equipped with a Peccell solar simulator under AM 1.5 illumination (100 mW cm^{-2}). The spectral irradiance data of the light source was similar to the AM 1.5G solar spectrum (spectral mismatch <5% in the range 350–800 nm). The illumination intensity was calibrated using a standard Si photodiode detector equipped with a KG-5 filter. All of these measurements were performed under an ambient atmosphere at room temperature. All of these inverted PSCs are identified by "PTXNiPI-X", the first number denoting to the incorporating different concentrations of TIPD (wt%), the follow number denoting to the thermal annealing time (min). The absorption spectra were recorded using a Hitachi U-4100 UV–vis spectrometer with the integrating sphere. The planar and granular substrates were characterized by optical spectrometry (MFS-530 commercialized by Hong-Ming Technology): the total and scattered reflectivity have been measured and the haze factors ($H_R(\lambda)$) have been calculated for each of the substrates according to the equation, $H_R(\lambda)$ = Rscat(λ)/Rtot(λ), and these optical measurements have been performed in air.

3. Results and discussion

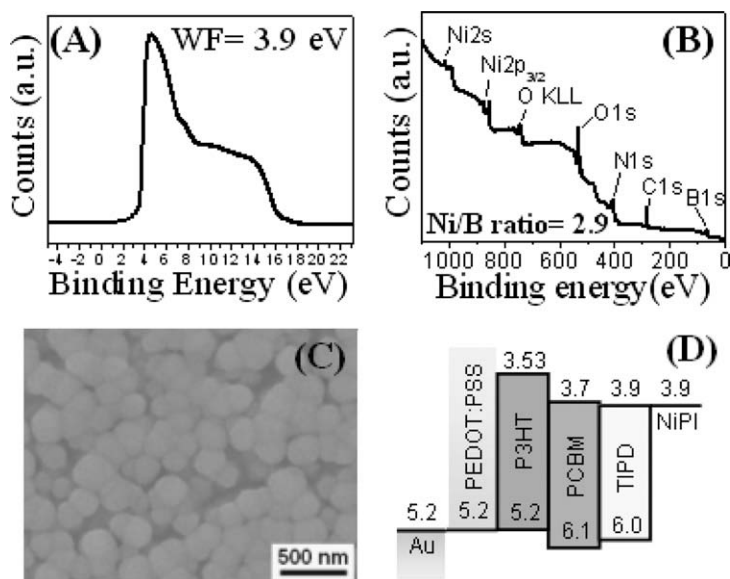
To examine the feasibility of using NiPI as the cathode (back contact electrode), we used UPS to determine that


Fig. 3. (A) Photoelectron spectrum of NiPI film. (B) XPS spectrum of NiPI surface. (C) SEM image of NiPI surface. (D) Schematic representation of the energy levels of an ITO-free inverted PSC on PI.

the WF of the surface-nickelized PI (NiPI) was 3.9 eV, i.e., it differs from that of pure Ni (Fig. 3A) [38]. Because this value is lower than that of the Al cathode (ca. 4.2 eV), it appeared suitable for application as the back contact electrode in inverted PSCs. To understand why there was a difference in the WFs of NiPI and pure Ni, we performed an XPS survey and then obtained the Ni/B ratio of NiPI (ca. 2.9) by using the Shirley method to estimate the peak areas of the atom contents on the NiPI surface in Fig. 3B. According to previous reports [26,27] and the results of this XPS analysis, in addition to a small amount of oxygen (representing native oxides or B_2O_3) formed on the NiPI surface, we suspect that the Ni–B component, which arose from the use of dimethylamine borane (DMAB) as the reductant in the Ni electroless deposition process, was responsible for the WF of the NiPI film to differ from that of pure Ni. The SEM image in Fig. 3C reveals that the granular NiPI consisted of fine particles (ca. 200–300 nm) with a continuous and interconnected network. Fig. 3D provides a schematic energy level diagram. The WF of NiPI allows efficient electron transfer from the LUMO of PCBM. Based on the previously report [30], the TIPD layer could improve the electron collection and reduce the interface resistance between the active layer and the metal cathode. From the view of energy level, the WF of TIPD matches the transport levels of the respective charge carriers for efficient charge transferring, however, other effects like oxide layers, dipole layers or the interface morphology of the photoactive layer might affect the charge injection. Table 1 summarizes the contact angle (CA) and surface energy (SE) data. On the surface of patterned NiPI, the difference in the H_2O contact angles of PI (CA = 75.5°) and Ni (CA = 104.9°) was dramatic. We attempted to improve the device performance through solvent annealing (slow drying) with DCB, a solvent with a high-boiling-point, to enhance the degree of microcrystalline lamellar stacking in the solid state packing of the ac-

tive layer [39]. We found, however, that the slow drying process had a negative effect on the quality of the P3HT:PCBM film when using the patterned NiPI as the substrate. After spin-coating the P3HT:PCBM solution onto the patterned NiPI film, droplets of P3HT:PCBM tended to aggregate on the Ni surface through slow growth and the thickness of the active layer became non-uniform. To overcome this problem, we pre-coated the TIPD onto the NiPI surface. The TIPD-modified, patterned NiPI film, which we refer to as TNiPI, had a contact angle of 87.0°; therefore, droplets of the P3HT:PCBM solution covered the TNiPI surface more completely, resulting in uniform P3HT:PCBM films that we name PTNiPI.

Because of the large variation in the values of CA of P3HT:PCBM and PEDOT:PSS (Table 1), the deposition of PEDOT:PSS on the highly hydrophobic P3HT:PCBM surface requires a preliminary treatment process to ensure wettability and adhesion. Chaudhary et al. [40] demonstrated that short exposure (5 s) to Ar plasma can effectively tailor the wettability of P3HT:PCBM layers for subsequent deposition of single-wall carbon nanotubes (SWNT) from an aqueous solution. In our present study, oxygen plasma treatment was more convenient than Ar plasma treatment; therefore, we subjected our PTNiPI film to a short (5 s exposure) oxygen plasma treatment to facilitate the deposition of PEDOT:PSS on the active layer. The oxygen plasma-treated PTNiPI film exhibited values of CA and SE of ca. 55.8° and 47.4 mJ m^{-2}, respectively, similar to those of the PEDOT:PSS film. To determine the influence of the 5 s oxygen plasma treatment on the surface of the active layer, we analyzed the performance of standard PSC structures (glass/ITO/PEDOT:PSS/P3HT:PCBM/Ca/Al) formed with and without plasma treatment. The variation in the PCE was less than ca. 0.1%, arising mostly from a slight loss in the current density; the values of V_{oc} and the fill factor (FF) were unaffected, as revealed by the I–V characteristics

(Table 3). The treatment of oxygen plasma might predominately destroy the P3HT phase, but not the PCBM phase. As the consequence, the electron injection interface might still be working for standard cell. However, this may significant effect the anode interface. To investigate if and how the effect through oxygen plasma treatment, we employed XPS measurements to quantitative determine the thiophene defects through oxygen plasma treatment (Fig. 4A). The S(2p) core level spectra showed that there were 96% thiophene (at 164 eV) preserved and only 4% thiophene defects (at 168.5 eV) were observed through 5 s oxygen plasma treatment on the active layer surface. In the inverted geometry, this would lead to a destruction of the anode interface; however the effect is not significant as a result of XPS spectra.

To apply PSCs in an economical roll-to-roll-suited module, the major requirement to reduce the cost of produc-

tion is substitution of a cheap material in place of the ITO electrode. In a previous report, Zimmermann et al. [18] constructed an ITO-free PSC module that comprised PSCs on metal-coated plastic substrates with an inverted layer sequence. Based on their module concept, we examined the solution processing of NiPI, our surface-nickelized PI film, as the cathode/substrate and the high-conductivity PEDOT:PSS as the anode for the all-solution processing of PSCs (Fig. 4B). Fig. 4B–D presents the structure, optical and TEM images of the inverted PSC cell on NiPI. Although the TIPD layer was too thin to identify, the cross-sectional TEM image of the device clearly indicates the presence of individual layers without interlayer mixing (Fig. 4D). The PSCs had the following device structure: PI/Ni (385 nm ± 77 nm)/TIPD/P3HT:PCBM (100 nm)/PEDOT:PSS (45 nm).

The conductivity of NiPI and ITO were 2778 and 7143 S cm^{-1}, respectively (Table 2). The resistive loss of NiPI could be ignored for small cell device. Nonetheless, NiPI layer is actually limited for larger area cells similar to the ITO based devices. To form a transparent conducting anode, we employed the low-temperature processing of high-conductivity PEDOT:PSS. When processing with a polyalcohol, the conductivity of PEDOT:PSS films can be enhanced for their application in PSCs. Although adding a polyalcohol would obviously decrease the sheet resistance of the PEDOT:PSS films, higher processing temperatures (>140 °C) and longer thermal treatment times are necessary to remove the high-boiling-point (>200 °C) additive [32–37], which may damage the P3HT/PCBM blends in our inverted structure. Herein, we selected DMSO and ME as solvents to investigate their ability to enhance the conductivity of PEDOT:PSS at low processing temperatures. The pristine PEDOT:PSS film (H; HC V4 from H. C. Starck) had the lowest conductivity (5 S cm^{-1}). When we added 5 wt% DMSO into this pristine PEDOT:PSS aqueous solution, the conductivity of the HD film was enhanced to 170 S cm^{-1}. Furthermore, consistent with our results from a previous study [31], surface solvent-treatment of HD films with ME (HDM) led to a dramatic increase in the conductivity of the PEDOT:PSS to 283 S cm^{-1} and a corresponding processing temperature lower than that required for the polyalcohol system.

If transparent electrodes are to be used in PV devices, they must have high transparency in the visible region. Thicker PEDOT:PSS films will lead to transmittance and vertical conductivity problems. We observed that the transmittances of the thin PEDOT:PSS films (<100 nm) of H, HD, and HDM on glass (each ca. 96%) were better than that of ITO (ca. 89.6%; Table 2). From a comparison of the electrical conductivities of ITO (same as the anode of a standard cell), and NiPI, we observed that the highest conductivity of PEDOT:PSS (HDM) was enhanced to 283 S cm^{-1} with a order less than ITO and NiPI. We suspect that combining a suitable metal grid (such as a metal grating or random metal nanowire mesh) with HDM film may be compatible with the future development of flexible PSCs [41,42].

Because TIPD was present as an ultrathin layer on NiPI (Fig. 4D), it was necessary for us to determine the thickness of P3HT:PCBM on the highly topographically variant NiPI to obtain the optimized parameters for these inverted PSCs, because the effect of a thinner active layer (higher speed of coating of the P3HT:PCBM solution) on the imposed topography of the anode would increase the risk of creating short circuits (i.e., lower the efficiency of the device) [22]. If the P3HT:PCBM solution was spin-coated on TNiPI for 700 rpm, the thinner active layer film on the imposed topography of anode would increase the risk of creating short circuits to lower the efficiency of the device. As the result of the device performance and the TEM cross-sectional image, the minimum active layer film thickness was suggested to be ca. 200 nm. Thus, under the optimal conditions for spin-coating of the P3HT:PCBM solution onto TNiPI (500 rpm), we investigated the concentrations with respect to the thickness of the TIPD layer of the whole devices. Prior to the coating of the photoactive layer, the TIPD layers were treated at the temperature of 80 °C and 160 °C for 5–30 min to investigate the temperature effect of the TIPD film without a superimposed effect of the active layer. Similar cell performances were obtained as the temperature and annealing condition change. First, to understand the thermal stability of the TIPD-coated devices, we examined the device performances after employing various thermal annealing times. Table 3 summarizes the device performance under AM 1.5 illumination at an intensity of 100 mW cm^{-2}. The device formed using an interfacial layer of 3.75 wt% TIPD (PT3NiPI-5) and a short thermal annealing time (5 min; 140 °C), exhibited poor performance: V_{oc} = 0.54 V; J_{sc} = 9.0 mA cm^{-2}, FF = 0.29; PCE = 1.4%. After increasing the thermal annealing time at 140 °C to 15 min, the values of V_{oc}, J_{sc}, and FF all increased, thereby improving the value of PCE to 2.4%. When TIPD was incorporated at 1.88 wt% (PT1NiPI-15), we obtained similar results, i.e., improved performance after longer periods of thermal treatment; after thermal annealing for 15 min, the values of V_{oc}, J_{sc}, FF, and PCE were 0.59 V, 9.2 mA cm^{-2}, 0.37, and 2.0%, respectively. Consistent with previous results, this TIPD-coated NiPI was stable to thermal annealing at 140 °C for several minutes. We suspect that this TIPD-coated NiPI would be more suitable than the corresponding ITO/PET system [43,44] for long-time high-temperature annealing.

To compare the performance of devices incorporating different concentrations of TIPD (0.94, 1.88, 3.75, 7.5, and 15 wt%), we performed AFM measurements to determine the underlying mechanism of TIPD incorporation on NiPI. We observed interesting morphologies with high topographical variations for the pristine NiPI and TIPD-coated NiPI surfaces (Fig. 5). After coating with TIPD at 0.94, 3.75, and 15 wt%, the root-mean-square roughness (Rms) changed from 33.8 nm for pristine NiPI to 24.6, 24.3, and 25.3 nm, respectively. Thus, coating with different TIPD concentrations did not have a significant effect on the value of the Rms. Furthermore, in the phase image of NiPI, the topographical variations of granular Ni films were expressed as a darker edge effect (Fig. 5b). After coating TIPD onto NiPI, we expected the phase changes to be more obvious at the darker edges of the granular NiPI. The previous study have been reported [17] that charge collection could

be enhanced by using a thin layer of Ti/TiO$_x$ on top of the Al electrode; in the absence of this Ti compound coating, the oxide formed on Al blocked charge transport. For our TIPD systems, even a small amount of oxygen (representing native oxides or B$_2$O$_3$) formed on the NiPI surface (Fig. 3B), we suspected that a higher concentration of the coating TIPD solution (3.75 wt%) would be more effective at enabling charge collection in the inverted cells than would a coating of 0.94 wt%. From an analysis of the PSCs' performances, we found that higher concentrations of TIPD led to improved PCE, presumably because a more uniform TIPD layer on NiPI enhanced electron transport to the anode (Fig. 5c–f). Increasing the concentration of TIPD from 3.75 to 15 wt% decreased the current density, which led to poorer performance. Based on the similar values of V_{oc} of the PT3NiPI-15, PT7NiPI-15, and PT15NiPI-15 devices (Table 3 and Fig. 6), it appears that exceeding the critical con-

centration of TIPD (3.75 wt%) led to a lower variation of the angles in the phase images (cf. Fig. 5g and h), which would block the degree of electron transport to NiPI and, thereby, decrease the current density.

Roman et al. [23] have reported that the light-trapping effects from active layers on the periodic Al metal nano-structures, and those structures could further enhance PSCs performance. Comparing the dimension of the granu-

lar NiPI with the Al grating structure, the NiPI films were believed to have the same effect in PSCs. To complement the observed degree of light confinement in whole devices, herein, we performed reflective UV–vis, reflection haze factor (H_R) [45] and external quantum efficiency (EQE) measurements of overall inverted PSCs process of the plane AlPI and the granular NIPI films. Fig. 7A and B showed the SEM image of planar AlPI and granular NiPI films, respectively. In the reflective UV–vis spectra of absorbance, Fig. 7C represents that the granular NiPI films were well-adapted to improve the light-trapping in 200 nm thick P3HT:PCBM cells. Based on the previous reports, [46,47] the refractive indices of PEDOT:PSS and P3HT:PCBM were 1.1–1.6 and 1.6–2.2, respectively, in the range 400–800 nm. The higher H_R was obtained from rougher NiPI structure through reflective haze factor measurements (Fig. 8A). The total internal reflection could occur where light travels from a P3HT:PCBM film with a higher refractive index to the PEDOT:PSS film with a lower refractive index. The absorption, haze factor and EQE analysis, Figs. 7C–E, C–f and 8A show that there were more light absorptions in granular NiPI of devices (PT3NiPI device) than the planar structures of electrode (PT3AlPI device) in the range of wavelengths 400–650 nm. The beam of light scattering on the granular NiPI shows better light confinements than planar AlPI of devices. Therefore, a light trapping effect were presumed by the NiPI layer in the range 400–800 nm, hence the EQE of P3HT devices show enhance-

ment in the range 400–620 nm (Fig. 8A). Although different materials of cathodes may cause to the different device performance, in this study, the comparison of haze factors and EQE results, give some information of optical path length enhancement in the active layer. The Rms of coated photoactive was ca. 5.6 nm and its surface roughness was smoother than NiPI substrate (Rms $\sim$ 33.8 nm). The cross-sectional TEM image showed the thickness of the photoactive layer was ca. 200 nm and the granular NiPI film can actually be well covered by the photoactive layer. The thin film architecture of device suggests that the variation in the film thickness would not be a problem for charge carrier extraction. As shown in Fig. 8B and C, the cartoon illustration summarized the representations of light-reflection and light-scattering properties in PSCs, and the schematic representations can be presumed that, in the active layer, rougher NiPI would induce better of light trapping than planar AlPI.

4. Conclusions

We have developed a procedure for the all-solution processing of inverted PSCs on PI substrates. In this approach, the solution processing led to the chemical formation of granular Ni thin films with high-conductivity (ca. 2777.8 S cm^{-1}) and a suitable WF for use as back contact cathodes in PSCs. We used a TIPD solution to modify the surface energy of the patterned NiPI film prior to further P3HT:PCBM coating. An analysis of the values of PCE revealed that a suitable concentration of the TIPD coating led to improved PV performance. After performing a mild

oxygen plasma treatment for 5 s on the P3HT:PCBM surface, the active layer was appropriately modified for further coating with PEDOT:PSS. Moreover, we further investigated the low-temperature fabrication of high-conductivity PEDOT:PSS films by employing DMSO and ME as additives; using this approach, we obtained a high-conductivity (ca. 283.1 S cm^{-1}) HDM film after thermal treatment at just 100 °C for 5 min. The ITO-free inverted PSCs incorporating HDM films as anodes and TNiPI as the modified layer/cathodes exhibited high performance, with the PCE reaching 2.4% under AM 1.5 illumination (100 mW cm^{-2}). Although the deposition of Au grids (thickness at 100 nm) was helpful for decreasing the distance effect of PEDOT:PSS layer (hole-collection), the FF of of 0.43 is still significantly lower than the FF of 0.64 for standard devices. It was believed that higher conductivity of NiPI films and PEDOT:PSS films still need for further improving the device performance. As the results of the absorption, haze factor and EQE responses, the granular NiPI was presumed to be a better electrode/substrate through enhancing the light scattering and trapping in inverted PSCs.

ARTICLE INFO

ABSTRACT

We report on studies of poly-(2,5-dihexyloxy-*p*-phenylenevinylene) (PDHeOPV), a symmetric side-chain polymer, as a potential new donor material for polymer:fullerene blend solar cells. We study the surface morphology of blend films of PDHeOPV with PCBM, the transport properties of the blend films, and the performance of photovoltaic devices made from such blend films, all as a function of PCBM content. In each case, results are compared with those obtained using the asymmetric side chain polymer, poly[2-methoxy-5-(3,7-dimethyloctyloxy)-1,4-phenylenevinylene] (MDMO-PPV), in order to investigate the influence of polymer side chain symmetry on solar cell performance. AFM images show that large PCBM aggregates appear at lower PCBM content (50 wt.% PCBM) for PDHeOPV:PCBM than for MDMO-PPV:PCBM (67 wt.% PCBM) blend films. Time-of-Flight (ToF) mobility measurements show that charge mobilities depend more weakly on PCBM content in PDHeOPV:PCBM than in MDMO:PPV:PCBM, with the result that at high PCBM content the mobilities in PDHeOPV:PCBM are significantly lower than in MDMO:PPV:PCBM blend films, despite the higher mobilities in pristine PDHeOPV compared to pristine MDMO-PPV. Photovoltaic devices show significantly lower power conversion efficiency (∼0.93%) for PDHeOPV:PCBM (80 wt.% PCBM) blend films than for MDMO-PPV:PCBM (2.2% at 80 wt.% PCBM) blends. This is attributed to the relatively poor transport properties of the PDHeOPV:PCBM blend, which limit the optimum thickness of the photoactive layer in PDHeOPV:PCBM blend devices. The behaviour is tentatively attributed to a higher tendency for the symmetric side-chain polymer chains to aggregate, resulting in poorer interaction with the fullerene and poorer network formation for charge transport.

1. Introduction

The performance of bulk heterojunction solar cells based on the blend of a conjugated polymer and a fullerene derivative is critically dependent on the nano- and micro-scale morphology of the thin solution-processed semiconductor blend layer [1–6]. In several systems it has been observed that optimum device performance is achieved for blend films that feature a certain degree of phase separation (∼10 nm length scale). This positive effect of phase segregation is attributed to improved charge transport or light harvesting as a result of increased crystallinity of components [7] and to a reduction in bimolecular [8] or geminate [9] charge recombination with less intimate phase mixing. Large scale (>100 nm) phase segregation, on the other hand, leads to poor device performance due to the limited interfacial area available for charge

separation [10]. Control of the microstructure of the active layer is therefore critical for the optimisation of photovoltaic device performance.

One means by which the blend morphology can be controlled is through the self-organising nature of the molecular components used, for instance, the degree of crystallinity of the polymer or fullerene [7] or the interaction energy between the components [11]. In the case of conjugated polymers, polymer chain packing is known to be influenced by the length and nature of the polymer side chains. In particular, symmetric side chains in poly-*p*-phenylenevinylene (PPV) polymers are known to lead to more rigid chain conformations and a higher degree of chain aggregation than asymmetric chains [12,13]. A recent study by Blom and co-workers [14,15] has shown that hole transport in blend films of a symmetrically substituted PPV polymer with PCBM is insensitive to composition, in contrast to blend films of the widely studied asymmetrically substituted polymer poly[2-methoxy-5-(3′,7′-dimethyloctyloxy)-1-4-phenylene vinylene] (MDMO-PPV) with PCBM, suggesting that side chain symmetry can affect blend film morphology. In this paper, we investigate the influence of the polymer donor side chain symmetry on the morphology of PPV polymer:PCBM blend films, on charge transport in the blend films and on the behaviour of the corresponding bulk heterojunction photovoltaic devices. We select two alternative dialkoxy-*p*-phenylenevinylene polymers as the donor material, the symmetrically substituted polymer 2,5-dihexyloxy-*p*-phenylenevinylene (PDHeOPV) and the asymmetrically substituted polymer MDMO-PPV. We show that the symmetrically substituted polymer leads to larger scale phase separation and poorer device performance, and that the differences in device performance are correlated both to the different degree of phase segregation and to a very different dependence of the electron and hole transport properties of the blend films on PCBM content. The results demonstrate the critical influence of polymer phase behaviour on bulk heterojunction performance.

2. Experimental

The PDHeOPV polymer (number average molecular weight ~25 kDa (approximately 82 repeat units)) was prepared as detailed in Ref. [16]. For atomic force microscopy (AFM, Burleigh Instruments) and photoluminescence (PL, FluoroMax-3, Jobin-Yvon) measurements, blend films of thickness ~50 nm were spin coated from chlorobenzene solution onto indium tin oxide (ITO) coated glass substrates coated with a ~70 nm layer of polystyrene sulphonate doped poly(ethylenedioxythiophene) (PEDOT:PSS). This sample structure was used in order to simulate conditions in the solar cell as closely as possible, since it is known that substrate influences phase segregation. Devices for time-of-flight (ToF) mobility measurements were made by spin coating films of pristine PDHeOPV and blend films of PDHeOPV:PCBM blends containing 0, 20, 33, 50, 67 and 75 wt.% PCBM from chlorobenzene solutions onto indium tin oxide (ITO) coated glass substrates. Pristine films of PDHeOPV (92 mg/ml) and blend

films of PDHeOPV:PCBM containing 20 (18 mg/ml), 33 (30 mg/ml), 50 (45 mg/ml), 67 (60 mg/ml) and 75 (67 mg/ml) wt.% PCBM were spin-coated on to ITO at spin speeds of 2000, 1800, 1500, 1500 and 1000 rpm, respectively. The ToF devices were then completed by thermal evaporation of a shadow masked, aluminum top contact (~100 nm), at a typical pressure of 10^{-6} mbar. Film thicknesses were measured with a Sloan Dektak™ surface profilometer. Hole mobility values were obtained by analysis of ToF photocurrent transients as described in Ref. [17]. Bulk heterojunction solar cells with the sandwich structure ITO/PEDOT:PSS (70–75 nm)/X/Al were fabricated where X was a blend layer of either PDHeOPV or MDMO-PPV with a varying weight fraction of PCBM. All devices were illuminated through the semitransparent ITO electrode with AM1.5G light from a filtered Xe lamp at an intensity of 100 mW/cm^2.

3. Results and discussions

The electric field dependence of hole mobility of PDHeOPV and MDMO-PPV at room temperature is shown in Fig. 1. The data for both samples follow the Poole-Frenkel form, generally found in a wide range of disordered materials [18]. The hole mobility of symmetrically substituted PDHeOPV (~10^{-5} cm^2/Vs) at low fields is about an order of magnitude higher than the hole mobility of the asymmetrically substituted MDMO-PPV (~10^{-6} cm^2/Vs). This is also true of the hole mobility of other symmetrically substituted dialkoxy-poly-*p*-phenylene vinylenes, even those with longer side chains [16]. The higher low field mobility for the symmetrically than for the asymmetrically substituted PPVs thus implies that the nature of chain packing is important in determining the hole-transporting characteristics of these materials. This is reflected in the ToF photocurrent transients shown in the inset to Fig. 1. The photocurrent transients of PDHeOPV films exhibit relatively non-dispersive behaviour (characterised by the pronounced knee in the transient when plotted on double logarithmic axes) in comparison to MDMO-PPV at similar fields. Weak dependence of hole mobility on electric field, such as that seen for PDHeOPV in Fig. 1, is often correlated with low energetic disorder and non-dispersive charge transport [19].

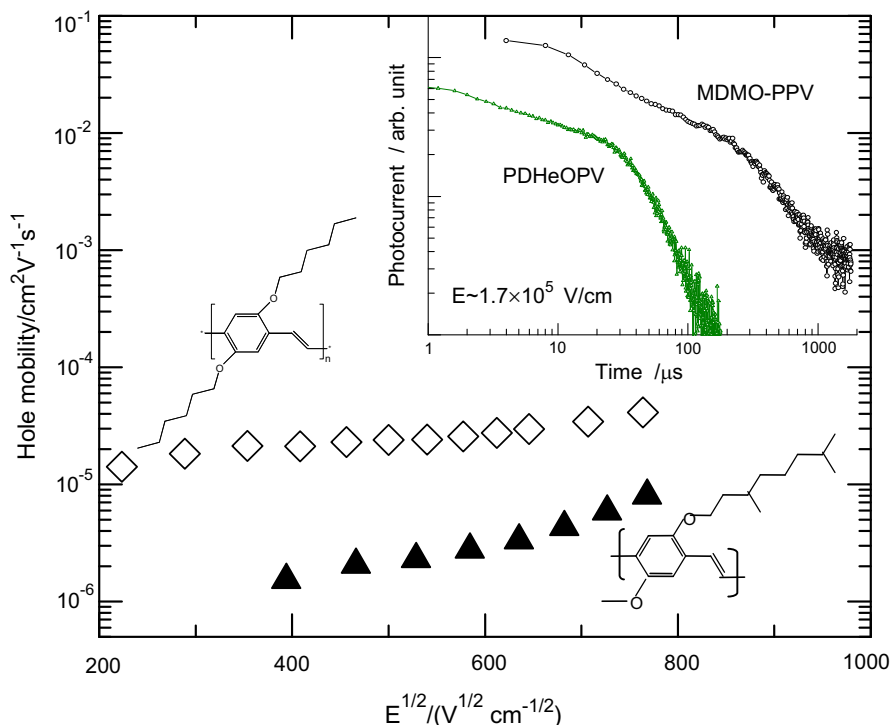
Fig. 2 shows the zero-field electron and hole mobilities in PDHeOPV:PCBM blend films as a function of PCBM content, obtained by extrapolation of Poole-Frenkel fits to the field dependent mobility data. The zero-field ToF mobility of holes and electrons in MDMO-PPV:PCBM blend films [20] are also presented as a function of PCBM content in the same plot for comparison. Whilst both electron and hole mobility increase continuously with increasing PCBM content from 16 to 67 wt.% PCBM in the case of MDMO-PPV:PCBM blend films, leading to a net increase of two to four orders of magnitude, the zero-field electron and hole mobilities of PDHeOPV:PCBM blends are relatively insensitive to PCBM content. The mild increase in electron mobility with PCBM content in PDHeOPV:PCBM blends can be attributed to improved electron percolation with PCBM network formation. A similar weak dependence of hole mobility on PCBM content was observed previously for an-


Fig. 1. The electric field dependent ToF hole mobility at room temperature in pristine PDHeOPV (open diamonds) and MDMO-PPV (filled triangles) films of thicknesses 1.2 and 1.6 μm, respectively. The inset shows the structure of the respective polymers and the ToF photocurrent transients for PDHeOPV, MDMO-PPV samples plotted on double logarithmic axes at similar electric field ∼1.7 × 10^5 V/cm.

other symmetrically substituted dialkoxy PPV polymer [14]. Although the strong dependence of charge transport on PCBM content observed for MDMO-PPV:PCBM blend films has not been unambiguously explained, the influence
Fig. 2. Zero-field electron (circles) and hole mobilities (squares) in (a) PDHeOPV:PCBM and (b) MDMO-PPV: PCBM blends as a function of PCBM concentration. Open symbols represent PDHeOPV:PCBM and filled symbols MDMO-PPV:PCBM blends.

of PCBM on polymer chain packing is thought to be relevant [6,20].

The very different composition dependence of charge carrier mobilities in PDHeOPV:PCBM blends compared to MDMO-PPV:PCBM may result from different polymer chain conformations. Symmetric side chain polymers are expected to assume more rigid conformations [12] and therefore the PDHeOPV chain morphology may be less strongly affected by the presence of PCBM than MDMO-PPV with its asymmetric side chains and tendency to form ring-like structures [13]. This difference may be enhanced by the fact that the side chains in MDMO-PPV are branched while those in PDHeOPV are linear. The observation of phase segregation at 50 wt.% PCBM in PDHeOPV:PCBM blends while none is seen in MDMO-PPV:PCBM until ∼67 wt.% [3,21] is consistent with the hypothesis that the more rigid, symmetrically substituted PDHeOPV polymer chains have a stronger tendency to aggregate than the asymmetrically substituted MDMO-PPV chains, and consequently are less strongly affected by the presence of PCBM.

Fig. 3 shows the photoluminescence spectra (480 nm excitation) for PDHeOPV:PCBM blend films as a function of PCBM content. The PL of PDHeOPV is increasingly quenched with the addition of PCBM up to a content of 70–80 wt.% PCBM, consistent with photoinduced charge transfer in these composite films. The PL spectra of the PDHeOPV:PCBM blend films exhibit well resolved vibronic structure and resemble the spectra of pristine PDHeOPV [16], at all PCBM contents. In contrast, it has been shown
Fig. 3. PL spectra from PDHeOPV:PCBM blend films as a function of PCBM weight percentage for excitation at 480 nm. The inset shows the AFM phase images of the PDHeOPV:PCBM blend films of 80, 75, 67 and 50 wt.% PCBM.

that the PL spectra of MDMO-PPV:PCBM blend films become structureless with increasing PCBM content, completely losing the red shoulder seen in the PL spectrum of pristine MDMO-PPV at PCBM contents greater than 30 wt.% [3]. This again suggests that the morphology of the blend film made from the symmetrically substituted polymer will be quite different from that of the blend made from the asymmetrically substituted polymer.

As a further probe of morphology, the PDHeOPV:PCBM blend films were studied with atomic force microscopy (AFM) as a function of PCBM content. Fig. 3 (inset) shows the height images obtained by AFM for composite PDHeOPV:PCBM films ($\sim$50 nm) for four different compositions. Whilst the surface roughness of pristine films of both PDHeOPV and PCBM films is low (root-mean-square roughness, $z_{RMS} < 1$ nm), the PDHeOPV:PCBM blend films are rough ($z_{RMS} \geqslant 10$ nm) and exhibit separate domains of diameter >100 nm, with both surface roughness and domain size increasing with PCBM content. These roughness values and domain sizes are much larger than those observed for MDMO-PPV:PCBM blend films at similar PCBM content ($z_{RMS} < 1$ nm, domain size 60–80 nm at 80 wt.% PCBM [3,10] compared to $z_{RMS} \sim 12$ nm, domain size 500 nm for PDHeOPV:PCBM). Larger domains may lead to a lower efficiency of exciton dissociation, depending on the purity of the domains observed. The height fluctuations of the PDHeOPV:PCBM blend films thus account for a significant fraction of the total thickness of the thin films used to make devices, as discussed below.

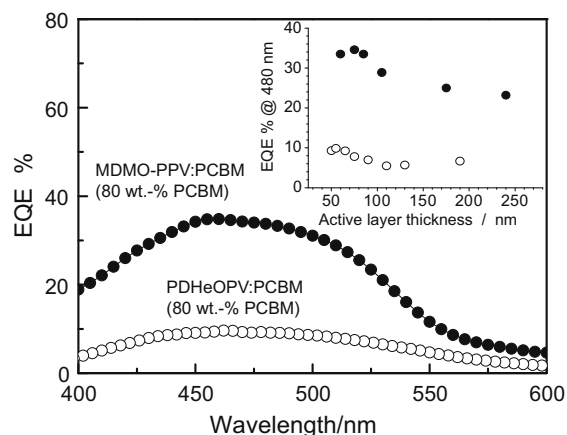
Photovoltaic devices were made from PDHeOPV:PCBM blends containing 50, 67, 75 and 80 wt.% PCBM. The high-est EQE was obtained at 80 wt.% PCBM. To optimise device structure, device performance was then studied as a function of blend film thickness for the composition (80 wt.% PCBM). Film thickness was varied from 50 to 240 nm by changing either solution concentration or the rate of spin coating. For all devices, blend films were spin coated on to PEDOT:PSS layers (70–75 nm thick) and finished with Al top contacts. A similar series of MDMO-PPV:PCBM de-


Fig. 4. External quantum efficiency (EQE) spectra for PDHeOPV:PCBM (80 wt.% PCBM) and MDMO-PPV:PCBM (80 wt.% PCBM) blend devices with photoactive layer film thicknesses of 55 nm and 75 nm, respectively. The inset shows the EQE of both blends with various photoactive layer thicknesses at an excitation wavelength of 480 nm.

vices was made for comparison and the resulting EQE spectra are depicted in Fig. 4. The data clearly show that the EQE of the devices based on PDHeOPV:PCBM is substantially lower than that of MDMO-PPV:PCBM based devices, across the thicknesses range. The EQE shows a maximum 35% for the MDMO-PPV:PCBM device with a 75 nm thick active layer while for the PDHeOPV:PCBM devices, the lowest thickness studied (50–55 nm) produced the highest EQE (∼10%). Good quality devices with thinner active layers could not be made, probably due to defects such as pinholes in the active layer.

The value of the optimum active layer thickness in a bulk heterojunction solar cell is determined by the competition between light absorption and charge carrier mobility. Given that the optical absorption of the two polymers is similar, the lower optimum thickness for PDHeOPV:PCBM than for MDMO-PPV:PCBM is consistent with the lower electron and hole mobilities of the former blend.

Fig. 5 shows a plot of the photovoltaic parameters, the short circuit current density, J_{sc}, open circuit voltage, V_{oc}, power conversion efficiency η and fill factor FF for the series of PDHeOPV:PCBM (80 wt.% PCBM) devices with different active layer thickness in comparison with those for a series of MDMO-PPV:PCBM (80 wt.% PCBM) devices.

The dependence of J_{sc} on active layer thickness for PDHeOPV:PCBM and MDMO-PPV:PCBM blend devices resembles that of the EQE with an optimum at 55 nm for PDHeOPV:PCBM and at 75 nm for MDMO-PPV:PCBM, after which J_{sc} tends to decrease with increasing thickness as a result of the competition between transport and recombination, as discussed above. In the case of MDMO-PPV:PCBM blend devices J_{sc} shows a broad local minimum around ∼100 nm which can be attributed to optical interference and is expected theoretically [22]. Similar structure is also visible in the case of PDHeOPV:PCBM blend films.

Open-circuit voltages were comparable for the two blend types (∼0.7–0.8 V) and relatively insensitive to film thickness, as previously observed [23,24]. However, a fall-off in both V_{oc} and fill factor with reducing thickness for the thinnest PDHeOPV:PCBM blend devices suggests shunt losses possibly due to non-uniformities in film thickness.

The highest power conversion efficiencies are found for the device thicknesses that led to the highest J_{sc}, i.e. 55 nm ($\eta = 0.93\%$) in the case of PDHeOPV:PCBM blend devices and 75 nm ($\eta = 2.2\%$) in the case of MDMO-PPV:PCBM blend devices, in good agreement with previous results for solar cells based on same materials [10]. The inferior performance of PDHeOPV:PCBM devices compared to MDMO-PPV:PBM is likely to result from the lower photon to electron conversion efficiency, resulting both from the lower mobility (enhancing recombination) and the relatively large domain size (possibly reducing exciton dissociation efficiency) relative to MDMO-PPV:PCBM. In addition, the relatively high surface roughness (∼10 nm) is likely to limit the performance of thinner devices through charge leakage along shunt paths between the electrodes.

4. Conclusions

Polymer:PCBM blend films and devices were made using dialkoxyPPV polymers with symmetric (PDHeOPV) and asymmetric (MDMO-PPV) side chains and their transport and photovoltaic properties were studied. The effects of PCBM content and active layer thickness on PDHeOPV:PCBM blend photovoltaic device parameters were also examined. We have optimised the active layer thickness for PDHeOPV:PCBM and MDMO-PPV:PCBM blend solar cells and found efficiency maxima of 0.93% at 55 nm for PDHeOPV:PCBM and 2.2% at 75 nm for MDMO-PPV:PCBM devices. The maximum EQE for PDHeOPV:PCBM blend devices was found to be about 10% in the range of
Fig. 5. Photovoltaic parameters V_{OC}, J_{SC}. FF and η as a function of active layer thickness for ITO/PEDOT:PSS/PDHeOPV:PCBM (80 wt.% PCBM)/Al (filled squares) and ITO/PEDOT:PSS/MDMO-PPV:PCBM (80 wt.% PCBM)/Al (filled circles) devices.

420–520 nm compared to about 34% for MDMO-PPV:PCBM blend devices.

AFM images show that the surface morphology is different for PDHeOPV:PCBM and for MDMO-PPV:PCBM blend films and that the morphology is affected differently by blend composition in the two cases. For example, phase segregation is observed at 50 wt.% PCBM in PDHeOPV: PCBM blends while none is seen in MDMO-PPV:PCBM until ~67 wt.%. The poorer device performance for PDHeOPV: PCBM than for MDMO-PPV:PCBM can be attributed to the more phase-segregated morphology and poorer transport properties, which in turn limit the thickness of the PDHeOPV:PCBM active layer that can be used for efficient device performance. Furthermore, the strong positive effect of PCBM addition on the hole transport properties observed in MDMO-PPV:PCBM blends was not observed in the case PDHeOPV:PCBM; the mechanism requires further investigation but the different morphology of the blend films is likely to be a factor. Thus it appears that the choice of the symmetric or asymmetric side chains has a clear influence on the blend morphology and transport properties within the blend, and should be taken into consideration in the design of new conjugated polymer materials for photovoltaic applications.

ARTICLE INFO

ABSTRACT

Co atoms will permeate into the soft organic material to form a magnetic permeated sublayer (MPS) during the fabrication of an organic spin device, such as Co/OSC/LSMO. We considered the OSC as a two-sublayer structure of MPS and pristine OSC, and then established a dynamic spin-diffusion equation to study the effect of MPS on the spin current polarization and the magnetoresistance of the device. It was found that the MPS will change the spin transport due to its different spin-flip time and mobility from that in the pristine OSC. The splitting of spin-flip times will be favorable to the spin polarization transport. Mobility of spin polarons in the MPS will be reduced due to the scattering of the Co atoms, which will weaken the spin polarization. For a given device, effect of the thickness of the MPS on the spin polarization is discussed. Finally, we calculated the magnetoresistance of a Co/OSC/LSMO device. A theoretical result which is consistent with the experimental data was obtained.

z1. Introduction

Organic semiconductors (OSCs) are a class of functional materials that have attracted considerable attention during the last decades. They have revolutionized important technological applications including large-area electrics, owing to their processing and performance advantages compared with conventional semiconductors for low-cost or large-area device applications [1–3]. Recently, another application of OSCs as spin transport materials has been found. Their soft lattice structure and capability of reconstructing the structure provide an opportunity to form a good interface with ferromagnetic metal (FM) or half-metal contacts, reducing the probability of spin scattering at the interface. In addition, the spin-orbit coupling and hyperfine interaction are very weak in the OSCs, so that the electron spin-diffusion length of an OSC is expected to be much longer than that of a usual inorganic material [4]. A new field called organic spintronics is emerging out and attracting the attention of both physical scientists and chemical scientists [5–7,15]. In 2002, Dediu's group firstly reported spin injection into a thin film of conjugated organic material sexithienyl (T_6) on a nanostructured planar hybrid junction $La_{0.7}Sr_{0.3}MnO_3/T_6/La_{0.7}Sr_{0.3}MnO_3$ (LSMO) at room temperature [5]. The spin-diffusion length in T_6 they observed is about 200 nm at room temperature. Xiong et al. have also observed spin injection and transport in a $La_{0.7}Sr_{0.3}MnO_3/Alq_3/Co$ organic spin valve. The measured magnetoresistance can be as high as 40% at low temperature [6]. Majumdar et al. have observed as much as 80% magnetoresistance (MR) at 5 K and 1.5% MR at room

temperature in the structure of $La_{0.67}Sr_{0.33}MnO_3$/poly 3-hexylthiophene/Co organic spin valve [7]. On the theoretical side, Yu et al. studied the influence of weak magnetic field for spin transport process in magnet/polymer/magnet structures [8]. Xie et al. suggested a model for $Re_{1-x}Sr_xMnO_3$/polymer structure and studied the spin density distribution of the system from the Su–Schrieffer–Heeger-like Hamiltonian [9]. They indicated that the carriers in OSCs contain spin polarons and spinless bipolarons. We used the spin-dependent diffusion model [8,10–12] of the electrochemical potential and studied the spin polarized injection and transport in the structure of FM/OSC hetero junction and FM/OSC/FM trilayers [13,14]. By supposing that polarons and bipolarons coexist in OSCs with a given proportion r, we found that spin polarons are the dominant carriers of the spin polarized current. Further considering the polaron–bipolaron transition, we found that spinless bipolarons will affect the spin polarization of the OSC device [16], which is different from the case in a normal inorganic semiconductor.

Otherwise, the permeation of metal atoms into OSC in a metal/organic semiconductor interface had been exposed experimentally [17–20]. And it might be a prevalent phenomenon due to the thermal evaporation technique, which made it easy that the metal atoms diffuse from an electrode into the soft OSC layer. Recently, people predicated the existence of MPS in the Co/OSC interface in a spin valve [6,21,27,30], but the effect of MPS on the spin injection and transport was not explicit. The investigation of Co doped Alq_3 [22] has indicated that it will result in superparamagnetic behavior, but the investigation on a magnetic doped inorganic semiconductor (for example, Co doped ZnO [23]) implied that magnetic impurities can result in the ferromagnetism if the concentration of magnetic impurity is high enough. Thus the influence of the magnetic impurities of MPS on the spin injection and transport may be crucial.

Among all the experimental investigation, Xiong et al. revealed the interfacial characteristics between the ferromagnetic electrode (Co) and the organic layer [6]. They predicated that a magnetic permeated region exists in the organic layer, which has a width of up to 100 nm. It was suggested that transport channel is composed of two sublayers: one with a thickness of up to 100 nm immediately attached to the Co electrode that contains Co inclusions; and the other of pristine deposited Alq_3 attached to the LSMO electrode. Xiong et al. assumed that the injected carriers through the Co/OSC interface reached the pristine sublayer without any losing of spins. In other words, they neglected the decay of spin in the MPS. In fact, the magnetic atoms in the MPS may influence the spin transport in two main aspects: mobility and spin-flip time of a spin carriers or polarons. In this paper, basing on the drift-diffusion model, we calculate the current polarization and magnetoresistance of a Co/Alq_3 device. We will focus on the influence of magnetic permeation on the spin transport in an OSC layer. Section 2 will provide a description of the model and the derivation of relevant formulae, numerical results will be presented and discussed in Section 3, and the conclusions will be drawn in Section 4.

2. Model and method

We consider an organic device Co/Co + Alq_3/Alq_3/LSMO referring to the experimental fabrications [6] as shown in Fig. 1, where Co + Alq_3 means the MPS. Spin polarized carriers are injected from the Co electrode into the Co + Alq_3 layer ($0 < x \leqslant x_0$). They transport under a driving field from the MPS (Co + Alq_3 layer) to the pristine Alq_3 layer and then finally into the right LSMO electrode. Here we will investigate the transport of carriers in the OSC (Co + Alq_3/Alq_3). We suppose that Co electrode and the Co + Alq_3 layer have the same magnetic orientation with different magnetization intensities. When spin polarized electrons are injected into the organic layer, they will evolve into spin polarons as described elsewhere. Here we neglect the possible formation of bipolarons from a pair polarons, although it has been predicated that spinless bipolarons may affect the current polarization to some extent [16]. As a polaron has particle-like characteristic, whose transport may be described by the classical diffusion equation. Firstly, the mobility of polarons will be different in the MPS from that in the pristine OSC due to the additional scattering from the magnetic impurity atoms [26].

$$\mu(x) = \frac{1}{a + bN_m(x)}, \tag{1}$$

where $N_m(x)$ means the magnetic impurity density, a and b the parameters related to temperature and the fabrication conditions. It indicates that the mobility of polarons in MPS is position dependent because of the nonuniform permeation of the impurity atoms. Secondly, in the MPS the spin-flip time $\tau_{\uparrow\downarrow}$ (from spin-up to spin-down) will be different from $\tau_{\downarrow\uparrow}$ (from spin-down to spin-up) due to the effect of the magnetization of the impurity atoms, which should also be dependent on the impurity density,

$$\tau_{\uparrow\downarrow(\downarrow\uparrow)}(x) = \tau_0 \pm cN_m(x), \tag{2}$$

where τ_0 means a spin-flip time of a polaron in the pristine OSC, c (>0) is a constant parameter. It indicates spin-up polarons take a longer time to reverse its spin than spin-down ones.

Now let us consider the transport behavior of the spin polarons in the device. Based on the drift-diffusion model [24,25], the evolution of the densities of polarons $n_{\uparrow(\downarrow)}$ are written as,

$$\frac{\partial n_{\uparrow(\downarrow)}}{\partial t} = \frac{1}{e} div \vec{j}_{\uparrow(\downarrow)} \pm \left(\frac{n_\downarrow}{\tau_{\downarrow\uparrow}} - \frac{n_\uparrow}{\tau_{\uparrow\downarrow}} \right), \tag{3}$$
Fig. 1. A schematic diagram of the "Co/MPS/OSC/LSMO" structure.

where $-e$ is the electron charge. $\vec{j}_{\uparrow(\downarrow)}$ is the current density of spin-up (down) polarons, which can be described by:

$$\vec{j}_{\uparrow(\downarrow)} = \sigma_{\uparrow(\downarrow)}\vec{E} + eD\nabla n_{\uparrow(\downarrow)}, \tag{4}$$

where $\sigma_{\uparrow(\downarrow)} = en_{\uparrow(\downarrow)}\mu$ is the conductivity of polarons with up (down) spin. $\vec{E}$ is the applied external electric field. D and μ are the diffusion coefficient and mobility of polarons which obey Einstein relation $D/\mu = k_BT/e$, where k_B is Boltzmann constant and T the temperature. We neglect the spin dependence of the diffusion coefficients and mobilities of polarons in present investigation.

Substituting Eq. (4) into Eq. (3), we finally obtain the evolution equations for spin polarons along the x-direction,

$$\frac{\partial n_{\uparrow(\downarrow)}}{\partial t} = D\frac{\partial^2 n_{\uparrow(\downarrow)}}{\partial x^2} + \left(\mu E + \frac{\partial D}{\partial x}\right)\frac{\partial n_{\uparrow(\downarrow)}}{\partial x}$$
$$+ \left(\frac{\partial \mu}{\partial x}E + \mu\frac{\partial E}{\partial x}\right)n_{\uparrow(\downarrow)} \pm \left(\frac{n_{\downarrow}}{\tau_{\downarrow\uparrow}} - \frac{n_{\uparrow}}{\tau_{\uparrow\downarrow}}\right). \tag{5}$$

3. Results and discussion

The investigation of spin transport through the MPS and the pristine OSC sublayer is performed based on Eq. (5). We set the initial and boundary conditions as $n_{\uparrow}(x = 0^+, t = 0) = 3.5 \times 10^{16}$ cm^{-3} and $n_{\downarrow}(x = 0^+, t = 0) = 1.5 \times 10^{16}$ cm^{-3}. This assumption may be rational for Co contact (the spin polarization in cobalt is about 0.4) if we neglect the spin-flip at the interface due to the so-called self adjusting capability of organic materials [6,9]. We choose parameters in the pristine OSC as follow: $\mu_0 = 1.0 \times 10^{-7}$ cm^2/Vs and $\tau_0 = 2.7 \times 10^{-3}$ s [27]. All the other parameter values are listed in the caption of the corresponding figures. To simple the calculation, we suppose the density of impurity in the MPS is uniform with $N_m(x) = N_m(x \leqslant L_{MPS})$, where L_{MPS} is the thickness of the MPS, which gives a constant mobility and spin-flip time as $\mu(x) = \mu_1$ and $\tau_{\uparrow\downarrow(\downarrow\uparrow)} = \tau_0 \pm \Delta\tau$ in the MPS, where $\Delta\tau \geqslant 0$. We take a numerical calculation by a driving electric field $E = 3.0 \times 10^4$ v/cm, which is supposed to be uniform along the MPS and OSC layer. It should be pointed out that the current density along the whole system should obey conservation law. For the total drift current density $j = e(n_{\uparrow} + n_{\downarrow})\mu E$, a constant assumption of the deriving field means that product $\mu(n_{\uparrow} + n_{\downarrow})$ is constant along the whole system. However, either mobility μ or the total charge distribution $(n_{\uparrow} + n_{\downarrow})$ may be changeable in space.

When a deriving field is switched on, spin polarized charge will be injected into the organic layers from the ferromagnetic electrode. After a long-time evolution from Eq. (5), we obtain that the system will reach a steady state and in this case the spin distribution is time-independent, i.e., $\partial n_{\uparrow(\downarrow)}/\partial t|_{t\to\infty} = 0$. However, the spin polarization is position dependent, which may be reflected by the density of polarons defined as,

$$P(x) = (n_{\uparrow} - n_{\downarrow})/(n_{\uparrow} + n_{\downarrow}). \tag{6}$$

If the MPS was not considered, it was obtained that the spin polarization decays exponentially in the OSC as described elsewhere [16,25]. As there is a MPS in a real organic spin device, which is reflected in present model,

the spin polarization will be different from that in a pristine OSC due to the effect of two factors: the spin-flip time and the mobility of polarons in the MPS.

Firstly, let us consider the effect of spin-flip time on the spin polarization. As the magnetization of the MPS comes from the permeated Co clusters or atoms, we suppose that the magnetization of the MPS is less than that of the Co electrode, which asks $\Delta\tau \leqslant P_0\tau_0$, where $P_0 = 0.4$ is the spin polarization of Co at Fermi level [29]. The distribution of spin polarization with different spin-flip time in the MPS is shown in Fig. 2, in which $\tau_0 = 2.7 \times 10^{-3}$ s and $\Delta\tau = 0.0$, $0.1\tau_0$, $0.3\tau_0$, and $0.38\tau_0$, respectively. It is found that the spin polarization decays slowly in the MPS, but in the pristine OSC it decays rapidly with an exponential form. We also note that the spin polarization in the MPS is related to the spin-flipping time. A large splitting of $\tau_{ss'}$ or $\Delta\tau$ will result in a high spin polarization, where s and s' denote the different spin orientation. It can be understood as follow: If $\Delta\tau = 0$, the probability of a spin from up to down is equal to that from down to up. As the amount of spin-flipping from s to s' is proportional to $n_s/\tau_{ss'}$, the system will finally reach a spin degenerate state with $n_{\uparrow} = n_{\downarrow}$ or $P(+\infty) = 0$. If $\Delta\tau \neq 0$, however, the situation will be different. The flipping probability of a spin from up to down is always smaller than that from down to up. Therefore, the system will exist in a spin non-degenerate state with $n_{\uparrow} > n_{\downarrow}$. In present parameters, $\Delta\tau = 0.4\tau_0$ means that the MPS has the same characteristic as the Co electrode and it keeps a maximum spin polarization unchanged. If $\Delta\tau < 0.4\tau_0$, the injected polarons in the MPS will experience a spin evolution and finally reach a dynamic equilibrium with $P(+\infty) \neq 0$.

Then we consider the effect of the mobility of polarons on the spin polarization, which is shown in Fig. 3. As the mobility is smaller in the MPS than that in the OSC due to the additional scattering of Co on polarons, we give the results of $\mu_1 = \mu_0$, $0.8\mu_0$, and $0.4\mu_0$, respectively in Fig. 3. It is found that the effect of mobility is related to the spin-flip time. In the case of a large splitting of the spin-flip time, for example $\Delta\tau = 0.35\tau_0$ as shown in
Fig. 2. Distribution of spin polarization with different spin-flip time $\Delta\tau = r_1\tau_0$ in the MPS. The dotted, dash-dotted, dashed, and solid lines indicate r_1 = 0.0, 0.1, 0.3, and 0.38, respectively. The other parameters are $\mu = \mu_0 = 1.0 \times 10^{-7}$ cm^2/Vs, $\tau_0 = 2.7 \times 10^{-3}$ s, $\mu_1 = 0.8\mu_0$, and $L_{MPS} = 90$ nm.
Fig. 3. Distribution of spin polarization with different polaron mobility in the MPS. (a) $\Delta\tau = 0.35\tau_0$, (b) $\Delta\tau = 0.1\tau_0$. The solid, dashed, and dash-dotted lines are for $\mu_1 = \mu_0$, $0.8\mu_0$, and $0.4\mu_0$, respectively. The other parameters are same as those in Fig. 2.

Fig. 4. Distribution of spin polarization with the thickness (L_{MPS}) of MPS. The solid, dashed, dotted, and dash-dotted lines indicate L_{MPS} = 90, 50, 5, and 0 nm, respectively. The parameters are $\mu_1 = 0.8\mu_0$, $\Delta\tau = 0.2\tau_0$, and L = 160 nm, the other parameters are same as those in Fig. 2.

Fig. 3a, the effect of mobility on spin polarization is not apparent. But in the case of a small splitting of the spin-flip time, for example $\Delta\tau = 0.1\tau_0$ as shown in Fig. 3b, the spin polarization will have an apparent decrease with the mobility. As the thickness of the MPS is limited, a small mobility means that a polaron will experience a long time to move through the MPS, which means that the polaron has a long time to reverse its spin in this layer. Therefore, the spin polarization will become small in the MPS. It also predicates that a small mobility in the MPS is not favorable for the transport of spin.

It has been reported that the thickness of the MPS may distribute from a few nanometers to nearly one hundred nanometers upon the concrete preparation of a device [6,21,30]. Except for the spin-flip time and the mobility of a polaron, the thickness of the MPS will also affect the current spin polarization of the device. Here we consider a device with a preparation thickness of the OSC layer (MPS + pristine layer) $L = L_{MPS} + L_{p-OSC}$. A deep permeation means a large L_{MPS} and so a small L_{p-OSC}. Dependence of the spin polarization on the thickness of the MPS with a large splitting of spin-flip time is shown in Fig. 4, in which L = 160 nm and L_{MPS} = 0, 5, 50, and 90 nm, respectively. L_{MPS} = 0 means that there is not any permeation of Co atoms. In this case, it is found that the spin polarization decays exponentially as $\exp(-x/\lambda)$, where λ is the spin-diffusion length [25]. For a shallow permeation, for example L_{MPS} = 5 nm, the spin polarization keeps nearly the same as that with no permeation. It is also found that, for a shallow permeation, the polarized polarons could not conserve its spin orientation when it reaches the right side of the OSC layer as the polarization $P(L)$ is nearly zero. But in the case of a deep permeation, for example L_{MPS} = 90 nm, a much change will take place for the spin polarization. It has a slow decay both in the MPS and the pristine OSC. Most importantly, the polarons will keep a large spin
polarization $P(L)$ = 0.05, which means that a spin polarized current will appear in a Co/OSC/LSMO device if there is a deep permeation of Co.

Finally we calculate the magnetoresistance of a spin valve Co/OSC/LSMO. Let $P_1 = P(L)$ be the spin polarization of polarons at the OSC side near the OSC/LSMO interface, and P_2 the spin polarization of LSMO at Fermi level. Magnetoresistance $\Delta R/R$ is given by the Julliere formula [6,28]

$$\frac{\Delta R}{R} = \frac{R_{AP} - R_p}{R_{AP}} = \frac{2P_1 P_2}{1 + P_1 P_2} = \frac{2P_1}{1 + P_1}, \qquad (7)$$

where we suppose that the detecting contact LSMO is 100% polarized, i.e., $P_2 = 1$. The results with different thickness of OSC layer are shown in Fig. 5. The dotted line is the result that there is no any Co permeation ($L_{MPS} = 0$). The solid line is the result that there is a MPS with a thickness of $L_{MPS} = 90$ nm. Apparently, the theoretical calculation is quite consistent to the experimentally data [6] if a deep permeation layer is considered. It is found that the permeation of Co is seriously important to the magnetoresistance
Fig. 5. The GMR value of Co/MPS/OSC/LSMO device with the different thickness of the OSC layer. The circles is for the experimental data [6], the dotted and solid lines for L_{MPS} = 0 and 90 nm, respectively. The parameters are $\mu_1 = 0.8\mu_0$ and $\Delta\tau = 0.35\tau_0$. The other parameters are same as those in Fig. 2.

of a spin device. The existence of a Co permeation layer especially a deep permeation one will be favorable to a large magnetoresistance of a device.

4. Summary

In summary, we investigated the effect of a magnetic permeated sublayer on the spin transport in a Co/OSC/LSMO device. We established a dynamic spin-diffusion equation and calculated the spin polarization and the magnetoresistance. It was found that, due to the permeation of magnetic atoms or the appearance of the MPS, the spin transport in the MPS will be adjusted with both the spin-flip time and the mobility of polarons. The spin-flip time from spin-up to down and that from spin-down to up will split due to the magnetization of MPS, which will result in a slow decay of spin polarization. As the mobility of polarons is reduced due to the additional scattering of the permeated Co atoms, the spin polarization will be weakened. For a given device, we discussed the effect of different permeation thickness on the spin polarization. Finally, we calculated the magnetoresistance of a Co/OSC/LSMO device. A theoretical result which is consistent with the experimental data was obtained. It was found that the permeation of Co is seriously important for the current polarization of the device. A deep permeation will be favorable to a large magnetoresistance of the device.

ARTICLE INFO

ABSTRACT

Organic field-effect transistors (OFETs) with regioregular poly(3-hexylthiophene) (P3HT) have been designed and fabricated aiming at the lowest possible working point (i.e. the adjusted values of gate voltage and drain–source voltage) for the use as sensor in electrolytes. Using thermally grown silicondioxide with a thickness of 45 nm it has been possible to dramatically lower the gate potential. Even around one volt the channel current and its modulation are still large enough for detection with simple operational amplifiers.

The experimental results indicate a strong dependence of the transistor performance on the solvent used for spin coating the organic film. A theoretical analysis based on an analytical model allowed us to relate the different behavior of the transistor to their mobility, which is in turn dependent on the density of traps. In the context of this paper the leakage currents – as a non-zero gate current – have been analyzed. The observed gate leakage currents of the electrode structures themselves as well as of the complete transistors can be well described by Fowler's and Nordheim's field enhanced tunneling.

1. Introduction

Molecular electronics have been standing in the spotlight of semiconducting materials research for several decades now. Oligo- and polymers seem to offer a way out of the energy dissipating and cost intensive fabrication technologies needed for silicon-based electronics. On the other side, the high sensitivity of the organic molecules to physical and chemical influences seems to open a unique application niche in the sensing field [1–5]. One crucial obstacle in the use of organic transistors is the low mobility of charge carriers in these films and consequently the huge ratio between driving voltage and modulated current which leads to a high vulnerability to noise effects.

If one considers medical and biosensing applications, the currently common voltage levels are not fulfilling the safety requirements in those fields. In many cases – for example when device areas are in contact with ionic solutions – unwanted electrochemical reactions of the molecules could no longer be prevented. The measured signals would therefore be affected by large errors, which would hinder the proper operation of the devices. In the case of cell signal studies, high voltages can disturb ion concentration gradients and induce action potentials. For defining the proper working point of a field-effect transistor, i.e. the adjusted values of gate voltage and drain–source voltage, a suitable range of the current–voltage curves is required. This is typically chosen by applying a constant drain–source voltage and a constant gate voltage at high values of the transistor transconductance (constant voltage mode). Environmental influences acting as gating potential result in corresponding changes of the drain current. Changes in the drain–source current (as sensor output

signal) can eventually be converted into voltages and amplified.

One solution to the above mentioned problems involves the enhancement of the current density in the field-effect transistor channel. In recent years great progress has been achieved in the chemical design of competitive active materials [6]. As the identified limiting factor for the carrier mobility has been identified in the hopping process between molecules in the disordered organic films, ordering has proven a successful way [7,8].

A second strategy focused on tailoring the electric field between the gate electrode and the semiconducting layer which is responsible for carrier accumulation. The nature of the insulating material has therefore become an important issue. Assuring high fields at low voltages is achieved in traditional semiconductor technology via the use of *high-k* dielectrics [9–13]. One central drawback is the fact that the expensive *high-k* layer preparation outweighs the simple and cheap deposition methods of organic semiconductors. As the growth processes of these insulators are carried out often at high temperatures [14] or in wet surrounding [11], it is at the moment not clear if they will be a reasonable way to reduce the operating voltage of organic transistor devices. The biocompatibility of *high-k* materials is also an important question. For example barium, widely used in BZT [9] layers, is known to act as an ion channel inhibitor [15]. Lead ions in the alternative compound PZT are also well-known to be poisonous [16]. Toxic side-effects of self-assembling monolayers for gate dielectrics have not been investigated to a satisfying extend. A second problem of the latter mentioned molecules for any use in biochemical applications is their solubility in typical organic fluids [11], which hinders their biochemical application.

In using classical established insulating materials such as SiO_2, higher electric fields have been achieved by thinning the oxide layer separating the gating electrode and the channel. A dramatic increase of leakage currents is the expected consequence [17,18]. Unfortunately, a clear analysis of the gate currents in organic thin-film transistors (OTFTs) is still missing.

It is worth mentioning that stability problems related to the use of a silicon dioxide insulating layer in sensors can lead to a slow and widely monotonic shift of the threshold voltages [19–21]. The amount of drifting is not only dependent on the material [22], but also very intensely on the deposition process [23,20]. Meanwhile those effects can be side-stepped very elegantly by taking into account the drift with theoretical models [21,24,25] that have even been applied to real-time compensation systems [26]. In this context also a separation of the sensor as a disposable and the read-out as well as compensation circuitry appears reasonable. Mechanical damage in long-term use, e.g. flaking or crumbling, can be prevented quite effectively by covering the dielectric surface with very thin Si_3N_4-layers grown by CVD.

We designed and fabricated organic field-effect transistors based on thin silicondioxide dielectric layers showing the possibility to lower the driving voltages to ranges suitable for in vitro biosensing applications and evaluate the leakage currents in the complete devices. Parallel to the experimental investigation, we have carried out a theoretical analysis of the transport phenomena in our OTFTs. Such study allows us to extract valuable information about the operation of the device.

2. Structure fabrication

The field-effect transistor devices have been fabricated on two-inch boron-doped silicon wafers (with a doping level around 10^{18} cm^{-3}, conductivity $\approx$10,000 S/m, obtained from Si-Mat, Landsberg). A bottom-gate bottom-contact structure was used in this work (see the inset of Fig. 2). The use of silicon substrates is justified by considering that silicon CMOS electronics can be used for processing the biosensors' signal.

Initially the wafers have been treated with a full two-step RCA cleaning procedure. On the $\langle 100 \rangle$-surface a 45 nm thick silicondioxide layer was grown in a dry oxidation process at 1000 °C. The back side of the wafers was etched using hydrofluoric acid (HF). Afterwards the source/drain electrode structures were patterned by lift-off on the silicondioxide dielectric layer in an optical lithography step. A 4 nm titanium sticking layer was followed by a gold coating with a height of about 46 nm deposited by RF-sputtering. The resulting pattern of each transistor was an interdigitated electrode structure (10 mm^2), half of that area building the source/drain contacts (see Fig. 1). The silicondioxide surface has explicitly not been treated by silanisation or similar methods, but was left hydrophilic. The values for the channel length *L* were chosen between 10 μm and 100 μm.

The active organic semiconductor (regioregular poly(3-hexylthiophene), P3HT, Sigma–Aldrich) was used as received and spun out of toluene and chloroform (both with
Fig. 1. Layout of the used gold structure for the source/drain electrodes.

a concentration higher than 99.5%), respectively, with a mass relation of 1 to 100.

The films (1000 rpm for 20 s) were deposited onto the wafers under nitrogen atmosphere and no other thermal treatment was applied. An Agilent 4156B parameter analyzer was used to probe the devices. All measurements took place at room temperature in normal atmosphere.

3. Experiments

In the following the input characteristics (drain current vs. gate voltage for varying drain–source voltages) as well as the output characteristics (drain current vs. drain–source voltage for varying gate voltages) of various transistors will be analyzed. In addition to such standard measurements, the leakage current across the oxide layer will also be investigated, as it constitutes an important limiting factor for biosensing applications.

3.1. Transistor performance

The field-effect mobility for positive charge carriers of the processed transistors differed between toluene and chloroform solutions, as is well known in the literature [27]. The devices spun with P3HT from the halogenic solvent reached mobility values around 10^{-3} cm^2/Vs, whereas the toluene samples stayed behind with approximately 2×10^{-4} cm^2/Vs. These values were extremely constant throughout all samples. Such mobility values have been extracted from the transfer characteristics of the P3HT transistors in the standard way [28].

As the surface of the silicon dioxide was not treated separately, nearly all transistors showed a positive threshold voltage of about +5 V. The described devices displayed a clearly conducting channel already at a zero gate voltage.

Thus, one is allowed to choose a low working point for measurements of current modulations.

The latter is an optimal method for lowering the operating voltage of transistor-based sensor devices.

Fig. 2 shows the output characteristic of an exemplary organic field-effect transistor with P3HT as the semiconductor layer spun out of toluene and the used structure as an inlay. The channel length was 20 μm with a ratio of $W/L = 13350$. Consistent with previous findings [29], the drain current and the on/off ratio (calculated from the highest on-current and the lowest off-current from the transfer curve) become higher when the channel length is reduced. For the produced devices the current could be controlled over a bandwidth of nearly four decades with a voltage range within 10 volts. The logarithmic transfer curves shown in Fig. 3 stems from a P3HT transistor spun out of toluene with a channel length of 50 μm and a ratio of $W/L = 2100$. Compared with the device characteristics shown in Fig. 2 the lower drain current values and on/off ratio are in agreement with the difference in the geometrical dimensions.

3.2. Analysis of leakage currents

The most important fact preventing the use of thin dielectric layers in organic field-effect transistors are leakage currents through the insulator [30]. Nevertheless, a thorough study of the underlying mechanisms is rarely performed. A suiting model could open the way for estimating the exact influence of the insulator's thickness on the leakage behavior, thus helping to design low-voltage transistors and sensors. The dominating effect for leakage currents of the present samples is expected to be a field assisted tunneling through the oxide between source/drain and gate contacts.
Fig. 2. Output characteristics of an OFET with P3HT spun out of toluene with a channel length of 20 μm and $W/L = 13350$ on 45 nm silicondioxide, the structure of the transistor samples is presented schematically in the inset.
Fig. 3. Transfer behavior of an P3HT transistor with $L = 50$ m and $W/L = 2100$ spun out of toluene.

The leakage current between the bottom gate and the source/drain contacts has been measured with and without the presence of the polymer. The results are displayed in Fig. 5. To show the relatively low current of devices without the polymer layer, the y axis is shown with a log scale. For this measurement, the silicondioxide surface has also explicitly not been treated by silanisation or by other methods to avoid undefined surface properties. The source and drain contacts have been shorted and biased against the bottom gate electrode. After spin-coating the P3HT layer, the edge of all 2″ wafers has been cleaned with acetone to ensure that no direct ohmic paths to the back gate exist along the P3HT film. Apart from this the semi-conductor layer fully covers the substrate. Fig. 6 displays the gate current of the gold source/drain structure fully covered with P3HT, together with the fitting curve (see next section).

In the very detailed work by Jia et al. [31], leakage currents have been reduced by lithographically patterning the P3HT so it is only present in the channel area. In their re-
Fig. 4. Fitted subthreshold characteristics of two P3HT devices. Symbols denote experimental data while lines represent model calculations. The upper (lower) curves belong to a device fabricated with chloroform (toluene) solvent.
Fig. 5. Leakage currents between the source/drain electrodes and the back gate of the structure itself without an active layer and of the complete transistor.
Fig. 6. Leakage current through the thermally grown silicon oxide with a thickness of 45 nm and the fitted formula (1) with the 0.95 side bands around for the error values as solid lines in blue color. In this case the surface of the 2″ wafer was fully covered with P3HT.

sults however the leakage currents already of the unpatterned P3HT structures strongly influenced the shape of the I–V characteristic, although the thermally grown silicondioxide dielectric layer was 100 nm thick. In our case the distortion on the output characteristics for low drain–source voltages was much lower, although the dielectric layer is among the thinnest used with such a large device area. This may be partly an effect caused by

the cleaning treatments they applied prior to the P3HT solution coating, which we explicitly avoided here.

4. Theoretical analysis

The theoretical analysis focuses on the influence of trap states on the current–voltage characteristics as well as on

the leakage current through the gate at almost zero drain–source bias.

4.1. Analysis of trap states

Our analysis is based both on finite element drift-diffusion simulations (Dessis, Synopsis) and analytic transistor models that account for the influence of trap states on the current–voltage characteristics of the OTFTs. By fitting the sub-threshold characteristics, the approximate energy and density of trap levels can be determined. Details of the models can be found elsewhere [32]. In the following we will compare our model against the experimental characteristics of our set of organic transistors and extract relevant trap parameters. As traps reflect the quality of fabrication process and materials, such parameters are valuable information in performance benchmarking and device optimization.

Chloroform and toluene related films do not only show differences in obvious properties such as color shading. We observed that the fabrication process with chloroform solvent yields higher mobility over a wide variety of tested devices. This behavior has already been reported in [6] and was related to the influence of the solvent on the formation of semi-crystalline regions in the semiconductor [7,27,33]. As an example Yang et al. determined via X-ray diffraction analysis that P3HT films from chloroform solution have a higher tendency to form ordered fibrillar networks without sharp boundaries. In the following, we investigate wether the general mobility trend is related to the presence of trap states. The transfer characteristics of two randomly chosen representative chloroform and toluene P3HT OTFTs are therefore fitted using our model. The resulting curves are shown in Fig. 4. We are able to precisely reproduce the experimental data using the parameters given in Table 1.

In our derivation, the traps are assumed to populate the semiconductor–insulator interface with a density N_{At}. Their energy E_{At} is located somewhere between the Fermi level E_F and the valence band energy E_v. Generally, the obtained trap densities and energies are within the expected range [34,35]. Our results indicate that the device with inferior mobility (toluene) also exhibits a substantially higher trap density. The traps are additionally located closer to the valence band which increases their effectiveness. This agrees with the notion that less ordered films possess more structural defects which act as trapping centers and reduce the effective mobility [34].

Table 1
Results for exemplary subthreshold analysis.

Solvent	Chloroform	Toluene
W/L	2100	510
$\mu(\text{cm}^2/(\text{Vs}))$	7.2×10^{-4}	3.5×10^{-4}
V_0 (V)	4.6	-4
E_{At} (eV)	0.22	0.12
N_{At} (cm^{-2})	7.7×10^{11}	3.9×10^{12}

Table 2
Results for leakage analysis.

Scenario	A (A/V^2)	B (V)
Without active layer	$(1.87 \pm 0.10) \times 10^{-13}$	(3.44 ± 0.62)
Fully covered surface	$(3.92 \pm 0.10) \times 10^{-10}$	(3.13 ± 0.13)

4.2. Theoretical analysis of leakage currents

In an ideal case, leakage currents should be dominated by tunneling effects. When neglecting thermal effects and barrier lowering mechanisms of the contacting material, the Fowler–Nordheim-tunneling can be simply described by the following approximation [36,37]:

$$I = AU^2 \cdot \exp\left(-\frac{B}{|U|}\right) \tag{1}$$

where I is the current, U the potential difference across the insulating layer and A, B are constants left as fitting parameters (the physical meaning of those constants is described in [36]). All the experimental curves have been evaluated using such model. The results are reported in Table 2.

The scenario *without active layer* represents the leakage current through the oxide, while the *fully covered surface* describes the case in which the organic layer was spun onto the whole wafer removing only the outermost areas (at wafer edges) to prevent paths to the bottom gate as mentioned before. Whereas the second parameter B varies only within a small interval between the two cases, A shows a variation of more than two orders of magnitude. The A parameter in Eq. (1) is proportional to the contact cross section area. Since the gate contact extends over the whole wafer, the presence of P3HT effectively increases the overall contact area by a factor 400.

In addition, we believe that the P3HT layer leads to an enhanced tunneling probability, related to a higher electric field under the P3HT than under the gold contact, and to the presence of the LUMO orbital providing a resonant channel for the tunneling process that in turn induces the presence of electrons in the P3HT. A confirmation of this condition can be seen in the data shown in Fig. 7, depicting the standard I–V characteristics of an OTFT (upper panel) together with an enlargement of the low drain-to-source bias region. In such region a positive current is observed at high negative gate bias (evidenced by the circle in the lower panel of Fig. 7), which is a direct signature of the presence of electrons at the interface to the oxide. Tunneling of holes from the side of the semiconductor into the gate contact is excluded, since the energy barrier seen by the holes lays approximately 3 eV above that for the electrons. The present model can only take into account those effects roughly as an increased effective contact area, thus in the coefficient A. Further experimental and theoretical work for better understanding those processes is in progress.

5. Conclusion

In this paper, we demonstrated the possibility to reduce the driving voltages of OTFTs with a bottom contact config-
Fig. 7. Graph of the output curves from a 20 μm transistor with the same geometry as in Fig. 2. The full area of the 2″ wafer was covered with P3HT. The displayed intersection region of the single curves around $V_{ds} = 0$ V shows already the worst observed distortion of the output characteristics during the study. Nevertheless it is still confined to a very sharp area.

uration by reducing the thickness of the dielectric layer. The values reached for the transistor working point are now compatible with in vitro biosensing applications in order to avoid unwanted electrochemical reactions as well as action potentials of attached cells.

A preliminary test on biocompatibility was performed by the authors with L929 cells from culture. The untreated poly(3-hexylthiophene) showed a positive result after 48 h. All negative reference samples behaved as they were supposed to. Further results will be published later.

First test measurements in electrolytes have shown that the performance of the transistors did not deteriorate. We are currently studying the influence of different solutions on the performance of the devices.

The leakage currents of these devices have been analyzed by means of a field assisted tunneling model based

on the Fowler–Nordheim-formula. The increased leakage currents in the presence of the polymer has been explained in terms of an increased number of electronic states available at one side of the oxide layer with respect to the case in which only the metal contacts are there. The influence of tunneling through thinner oxide layers can be clearly seen. The data extracted from the subthreshold analysis indicate not only that the choice of solvent, which is used during spin coating, influences the observed mobility. Good mobility also coincides with a reduced density of traps.

A comparison with classical biosensors shows that the driving voltages and the modulated current values are within the specification of the required purposes.

ABSTRACT

Degradation process of organic light-emitting diodes (OLEDs) is examined directly by X-ray photoelectron spectroscopy with *in situ* high-energy C_{60}^+ and low-energy Ar^+ co-sputtering. It is proven that this analytical technique clearly indicates the elemental depth profile of as-prepared OLED device (Al/LiF/2,2′,2″-(1,3,5-benzinetriyl)-tris(1-phenyl-1-*H*-benzimidazole) (TPBi)/4,4′-bis(carbazol-9-yl)biphenyl:bis(3,5-difluoro-2-(2-pyridyl)-phenyl-(2-carboxypyridyl) iridium (III) (CBP:FIrpic)/poly(ethylenedioxythiophene): poly(styrene sulfonic acid) (PEDOT:PSS)/ITO). Devices operated for different durations are subjected to this profiling technique for studying the change of elemental distribution. In addition to some of the accepted degradation mechanisms, it is observed that small TPBi molecules migrate towards the ITO anode under a direct driving voltage while retaining its original structure. It is also observed that oxygen diffused into the device through the Al cathode and along the Al–organic interface. Molecules with high stereo-hindrance may have less degradation due to the electron migration.

1. Introduction

Over the past two decades, organic light-emitting diodes (OLEDs) have drawn considerable attention as a potential technology for flat panel displays [1–3]. One of the basic requirements in any emissive device is providing adequate stability to ensure a sufficiently long lifetime. In the development of long lifetime devices, a variety of degradation models have been proposed [4].

In general, the degradation of OLEDs can be ascribed to three independent mechanisms: (i) dark-spot degradation,

(ii) catastrophic failure, and (iii) intrinsic degradation [4]. Dark-spot degradation is caused by environmentally induced electrode degradation and can be suppressed by proper encapsulation. Catastrophic failure is the result of the development of electrical shorts across the device and can be alleviated by proper substrate cleaning and adequate control over the fabrication process. On the other hand, although significant works on understanding the intrinsic reason have been reported, a fully consistent mechanism is still lacking and limits the progress of OLED development.

Currently, it is accepted to divide intrinsic degradation into five mechanisms: (i) morphological instability, (ii) unstable cationic aluminum tris(8-hydroxyquinoline) (Alq_3), (iii) indium migration, (iv) mobile ionic impurities, and (v) immobile positive charge accumulation [4]. Exper-

---

imentally, these mechanisms have been proposed by studying the lifetimes of different devices [4–6]. Therefore, this observation has been indirect. Recently, degradation has been directly studied using a peel-off technique [7] and cross-sectional scanning electron microscopy [8]. However, the depth-resolution and the information regarding chemical composition measured in these means is not sensitive enough to yield a complete picture of the true degradation mechanism.

X-ray photoelectron spectroscopy (XPS) is one of the most common techniques for studying the surface of materials due to its high surface sensitivity and the wealth of elemental and molecule information. When combined with *in situ* ion sputtering, the depth distribution of materials close to the surface can be profiled with nanometer resolution as well. Monoatomic argon sputtering is the most accepted technique for both removing surface contaminants and acquiring information on the depth distribution of a species within a sample. However, this erosion technique is known to cause severe damage to organic samples and cannot be used to analyze organic materials [9].

Recently, buckminsterfullerene (C_{60}) ions have been used to sputter materials away in order to study surface composition. Molecular dynamics (MD) calculations suggest that C_{60}^+ ions are more efficient than monoatomic ions in removing material [10] and leaving behind a relatively thin damaged layer [11]. Experimental result also confirmed a reduction in surface damage when using C_{60}^+ sputtering compared with Ar^+ sputtering [12]. The application of C_{60}^+ profiling for thick organic films is further extended by applying a secondary low-energy Ar^+ ion beam concurrently [13]. Although it is found that this analysis technique causes comparable damage to inorganic specimens [14], it provides a direct method for analyzing the distribution of materials in organic electronics with high depth-resolution and is adopted in this work in the attempt to study the degradation processes of OLED.

2. Experimental

2.1. Fabrication of OLED devices

Details on the fabrication and properties of the OLED devices can be found elsewhere [15]. In short, a hole-transporting layer (HTL) consisting of poly(ethylenedioxythiophene): poly(styrene sulfonic acid) (PEDOT:PSS, 35 nm), Baytron® P VP AI 4083, PEDOT:PSS ~1:4.5) was spin-coated on a 125 nm-thick indium tin oxide (ITO) glass. A light emissive layer (EL, 40 nm) comprising a 4,4′-bis(carbazol-9-yl)biphenyl (CBP) molecular host doped with 14 wt% bis(3,5-difluoro-2-(2-pyridyl)-phenyl-(2-carboxypyridyl) iridium (III) (FIrpic) was spin-coated on the HTL. On the EL, an electron-transporting layer (ETL, 32 nm) consisting of 2,2′,2″-(1,3,5-benzinetriyl)-tris(1-phenyl-1-*H*-benzimidazole) (TPBi) was then thermal-evaporated. Finally, an additional electron injection layer (EIL, 0.7 nm) of LiF and the Al cathode (150 nm) were evaporated on the ETL. The luminescence area is 2 mm × mm and each chip contains 4 devices separated by 2 mm.

2.2. XPS measurements

The experiments were performed with a PHI 5000 VersaProbe (Chigasaki, Japan) XPS system. Micro-focused (25 W, 100 µm) Al Kα X-ray was used and the take-off angle of the photoelectron was 45°. Throughout data acquisition, the X-ray and acceptance lens of the analyzer was rastering over an area of 500 µm × 500 µm and centered at the center of luminescence area of the device. A dual-beam charge neutralizer (7 V Ar^+ and 30 V flooding electron beam) was used for charge compensation. The Ar^+ sputter source was operated at 0.2 kV, 300 nA with an incident angle of 45°. The C_{60}^+ ion source was operated at 10 kV, 10 nA with an incident angle of 70°. Both ion beams were rastered over an area of 2 × 2 mm at the same time. The beam currents were measured with the target current on an Au foil and were stable for at least two weeks of continuous operation. Between each profile, reference devices on the same chip were profiled to ensure the steady sputtering condition and to eliminate chip-to-chip variation. This experimental design also allows the direct comparison between degraded device and as-prepared referencing device.

3. Results and discussion

Fig. 1a shows the elemental depth profile of the as-prepared (reference) OLED device using *in situ* C_{60}^+ and Ar^+ sputtering concurrently in the XPS. At the top-most surface, oxidized Al (as in Al_2O_3) is observed, as Al is known to be easily oxidized in the air. At the bottom of the Al layer, O is also observed. The O 1s binding energy in this region (180–220 min) is 532.4 eV (Fig. 1b), which is close to the oxygen in the top-most Al_2O_3 layer. In addition, two Al 2p peaks are observed at 72.7 and 75.4 eV (Fig. 1c) that indicate Al^0 and Al^{3+}, respectively. In comparison, oxygen is not observed on identical organic layers that do not have the Al cathode so that the oxygen source cannot be attributed to the adsorption [13]. It can be therefore concluded that oxygen diffuses through the interface of the Al cathode and the organic layers; hence both sides of the Al cathode are oxidized. Right below the oxidized layer of the Al metal, traces of Li and F at ~1:1 ratio are observed.

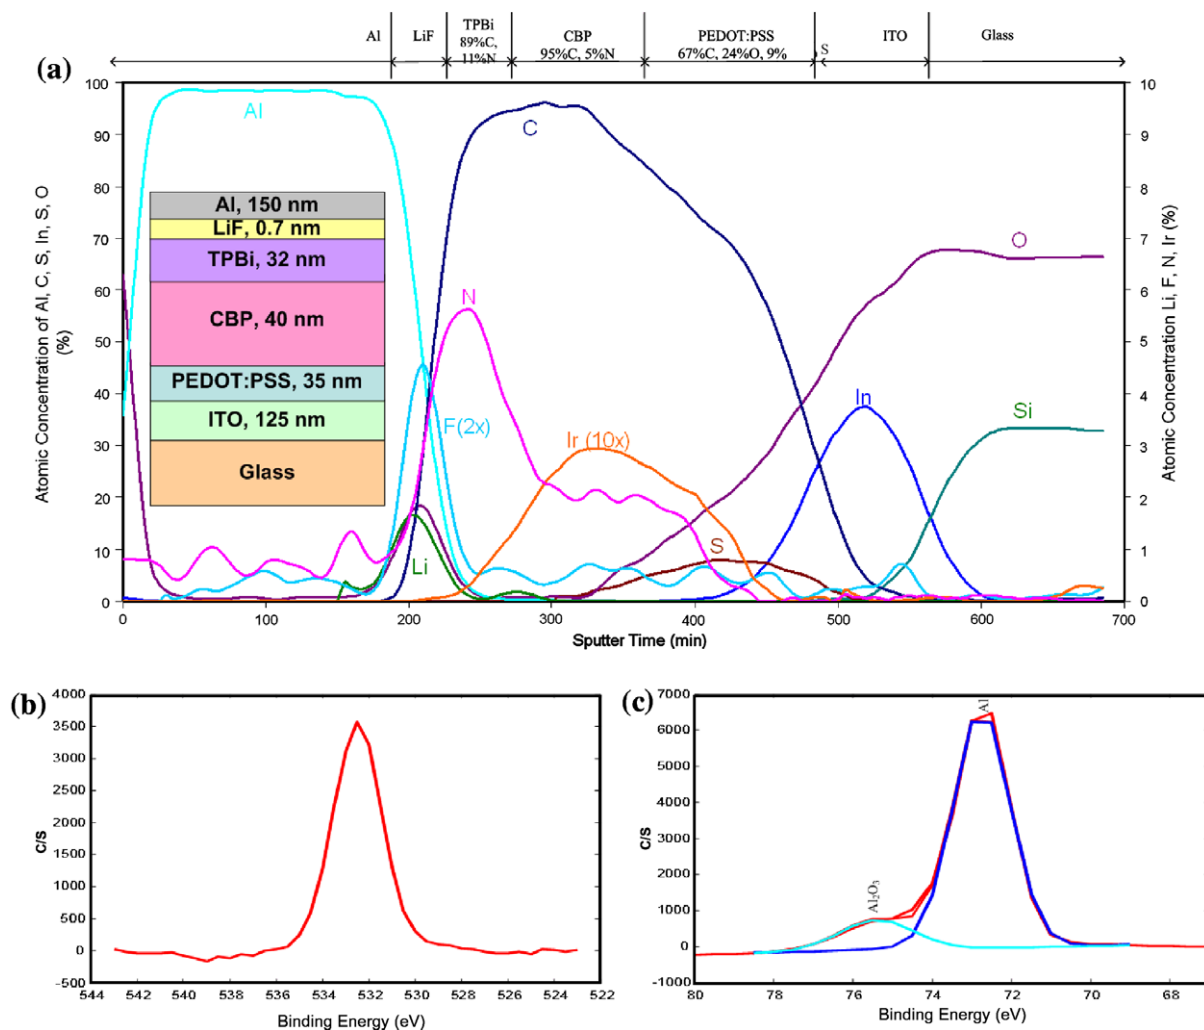
Below the inorganic layers, TPBi and CBP layers that have different C to N ratios are observed. Although the C concentration is slightly higher than the value expected due to carbon implantation from the C_{60}^+ beam, the difference between TPBi and CBP is still observable. Trace amount of Ir is also observed at the CBP layer, indicating that the FIrpic dye is mainly confined in the CBP layer; hence the host-guest EL structure is evident. Following with the EL, S is observed, indicating the HTL layer, which consists of PEDOT:PSS. At the interface of EL and HTL, the Ir signal extends slightly deeper into the HTL than N. This result suggests that some FIrpic-dye from the EL infiltrates into the HTL. Finally, below the HTL, ITO and glass substrate are observed. It is noteworthy that although the total thickness of the organic layer is thinner than that of inorganic layer, the time required to remove the organic layer is longer. The apparent slower sputtering rate of organic


Fig. 1. (a) XPS elemental depth profiles of as-prepared (reference) OLED device. (b) O 1s spectrum extracted from 180 to 200 min. (c) Al 2p spectrum extracted from 180 to 200 min.

layer maybe be attributed to ion-induced cross-linking of organic molecule [16].

The depth profile correctly reflects the multilayer structure of the referencing OLED device. Therefore, it can be concluded that such a profiling technique is suitable for profiling the OLED device. To study the degradation of the OLED device, as-deposited devices are operated at a constant 5 V forward bias for 15 min, 1, 3, 6, and 12 h and are subject to depth profiling. Fig. 2a shows the depth profile of the device after operating for 12 h in an ambient environment.

It is clear that a significant portion of the Al cathode is oxidized showing increased oxygen concentration throughout the Al layer. Therefore, the organic layer appears later in the sputtering because the sputtering rate of Al_2O_3 is lower than that of Al. In addition, Al diffused into the organic layer. Based on the binding energy of the Al 2p peak, both Al^0 and Al^{3+} are observed (350–500 min, Fig. 2b). Such results suggest that electron migration of Al may have occurred. In addition, the LiF signal indicates

that Li^+ migrated into the Al cathode and F^- diffused slightly into both Al and the organic layer.

In the organic layers, all the profiles are more diffused than that of the reference device; thus, it is evident that the interface is broadened by the electrical current. By examining the elemental profile more closely, it is obvious that the change in the C to N ratio is less clear in the ETL/EL interface than that in the reference device (Fig. 2c). The increase of N ratio in the EL region indicates that the N-rich ETL (TPBi, 11% N) diffuses into the EL (CBP, 5% N). Nevertheless, the N 1s doublet at 398 and 400 eV due to the non-planar TPBi structure [9] is still observed (350–500 min, Fig. 2d). Note that the peak at 400 eV is stronger than that at 398 eV due to the overlap with the N in CBP. Therefore, it can be concluded that the TPBi is not decomposed and the whole molecule migrates into the EL under the electric current.

Similarly, the change in atomic ratio is also observed in the N to S ratio in the EL/HTL interface and the S to In ratio in the HTL/ITO interface. In addition, trace amounts of C
Fig. 2. (a) XPS elemental depth profiles of OLED device aged at 5 V forward bias for 12 h. (b) Ir 7f and Al 2p spectra of aged device extracted between 350 and 500 min. (c) N distribution before (solid line) and after operation for 12 h (broken line). (d) N 1s spectrum of aged device extracted between 350 and 500 min.

and N are observed deep in the ITO layer (600–700 min) where no S is observed in the same region. These results indicate that the TPBi and/or CBP migrate into the ITO anode through the PEDOT:PSS layer while the polymeric HTL does not migrate into the ITO. As the small-molecular organics migrate into the ITO layer and possibly In diffused into the organic layer, the thickness of the In-containing layer increases; thus the time required to remove the ITO layer becomes longer.

In order to obtain information on the progress of degradation, similar profiles are acquired after the device is operated for 15 min, 1, 3, and 6 h (Fig. 3). After 15 min of operation, most of the profiles remain unchanged. However, the change in the N to C ratio reflects that the interface between TPBi and CBP is less sharp than that in the reference device. As time progresses, the N intensity at the Al-TPBi interface decreases while the N intensity in CBP increases. It is clear that the migration of TPBi into CBP starts immediately after applying voltage.

It is reported that, although the efficiency is lower, a device using Al complexes as hole-blocking-layers yields longer device lifetime than that by employing TPBi [17]. This difference in lifetime can be explained by molecule migration. Al complexes are ball-shaped molecules that have higher stereo-hindrance than that of planar TPBi. Therefore, under a similar driving force, it is easier for TPBi to migrate through the pores of amorphous organic materials. It is also reported that using inorganic silicate nanodots in the HTL, the lifetime increases [18]. Since the silicate is crystalline, the dense structure acts as a blockade to small molecules, thus molecular migration is suppressed and the lifetime increased.

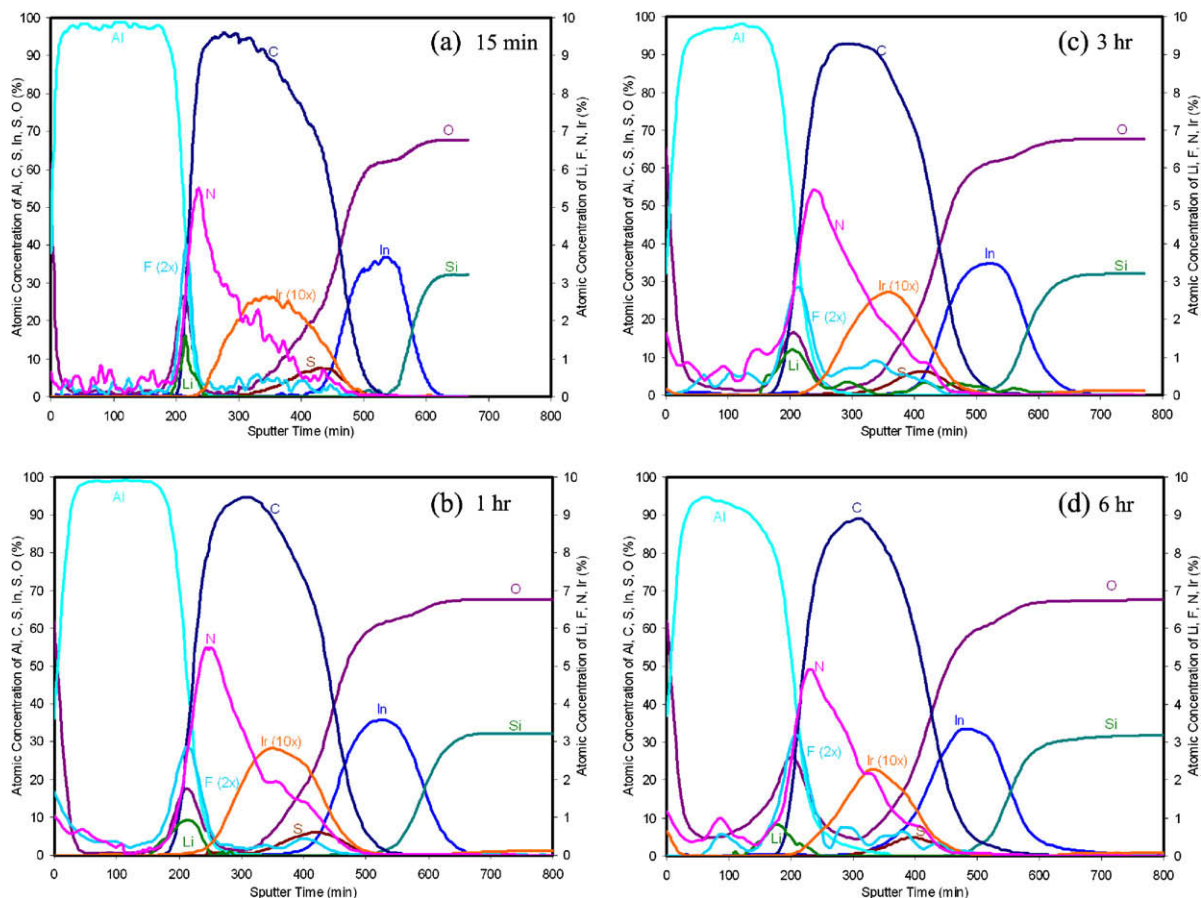
After 1 h operation, the thickness of the surface Al_2O_3 layer increases significantly, indicating that oxidation of the Al cathode occurs. Nevertheless, besides oxidation of the Al cathode and continuous migration of TPBi into CBP, there is no other change in the device at this stage of aging. At 3 h, a considerable amount of oxygen diffuses


Fig. 3. XPS elemental depth profiles of OLED devices aged at 5 V forward bias for different times.

into the Al cathode from the surface and diffusion of Li into the cathode is observed. A trace amount of Al atoms is also observed in the organic layer, indicating the occurrence of electron-migration of the Al atoms.

At 6 h, a significant amount of oxygen is observed at the interface of the cathode and the organic layer. The oxygen concentration is higher at the Al-organic interface than on the outer surface at this point. This result suggests that oxygen diffuses into the organic layer through the interface. Even though diffusion through the interface is observed later than that through the Al cathode, the diffusion rate through the interface is actually higher; the oxygen has to diffuse through a distance of 500 μm to reach the analyzing region while only 150 nm is required through the Al layer. This result confirms the hypothesis that device degradation is caused by oxygen diffusion along the interface [19]. In addition, at this stage, the migration of Li into Al and organic materials into ITO is clear.

4. Conclusion

Using *in situ* co-sputtering of high-energy C_{60}^+ and low-energy Ar^+ in XPS, OLED devices (Al/LiF/TPBi/CBP:FIrpic/ PEDOT:PSS/ITO) operated for different times are profiled to study the degradation process. As soon as the device is

under voltage bias, the TPBi molecules in the ETL start to migrate toward the ITO anode. Eventually, small organic molecules migrate all the way down to the ITO layer. Nevertheless, the molecular structure of TPBi appears unchanged during this migration. As the device is not encapsulated, oxygen diffuses into the device through the Al cathode and along the Al/TPBi interface, and the diffusion rate is faster through the interface than that through the Al layers. Meanwhile, while F appears to be stationary, Li diffuses into the Al cathode and Al diffuses into organic layers.

ABSTRACT

Herein we discuss the topographical and nanomorphological aspects of spray deposited organic photovoltaics. We show that the solvent properties have a massive impact on the topography, but less on the nanomorphology formation of composites based on the electron donor poly(3-hexylthiophene) (P3HT) and the electron acceptor [6,6]-phenyl C61 butyric acid methyl ester (PCBM). An adapted solvent mixture consisting of ortho-dichlorobenzene (oDCB) and 1,3,5-trimethylbenzene (mesitylene) allows us to demonstrate spray coated organic photovoltaic devices with 3.1% power conversion efficiency (PCE). Moreover, we show that spray coating is a feasible technology to deposit all solution processable layers of organic solar cells, including the hole transporting layer poly(3,4-ethylene dioxythiophene) doped with polystyrene sulphonic acid (PEDOT:PSS) as well and demonstrate fully spray coated devices with 2.7% PCE.

Organic photovoltaics (OPVs) are of increasing interest as new materials for future light-activated energy sources. OPVs have the virtue of being lightweight and flexible and could open up many new applications due to their easy processing offering the potential for low fabrication cost [1]. A variety of approaches have been used to deposit or-

ganic semiconductors based on the nature of those materials. The commonly applied technique is the solution-processed deposition, such as spin coating, doctor blading [2] or printing, which are evaluated as one of the future key technologies opening up completely new applications and markets for photovoltaics [1]. Printing technologies such as screen printing [3], gravure, offset, micro-contact and inkjet printing [4] are attractive candidates to utilize a low-cost OPV roll to roll production.

At present, bulk heterojunction (BHJ) structures based on blends of polymer donor and a highly soluble fullerene

derivative as acceptor have been the material system with the highest reported power conversion efficiencies (PCE) [5] and the demonstration of solar cells with 5% PCE under calibrated AM 1.5 conditions have been regarded as an important milestone to prove the technology's potential [6]. Among other technologies, spray coating [7] was recently reported as an elegant coating technique for the fabrication of BHJ devices. Recently, Vak et al. showed that spray coating the active layer from chlorobenzene solutions gives highly efficient devices [8]. Furthermore, Green et al. presented spray deposited poly(3-hexylthiophene) (P3HT): [6,6]-phenyl C61 butyric acid methyl ester (PCBM) films from a variety of common organic solvents with different boiling points [9].

In this communication, we investigate spray coating as a production technique for depositing the active layer in organic BHJ solar cells. We specifically investigate the film formation, surface topography and the morphology of spray coated mono- and bilayers based on pristine solvents compared to mono- and bilayers based on multiple solvent systems. Furthermore, we studied the impact of the ink formulation and specifically the solvent properties such as vapor pressure, boiling point, viscosity and surface tension on the topography, nanomorphology

Fig. 1. Device architecture of a solar cell ITO/PEDOT:PSS/P3HT:PCBM blend/Ca/Ag under study.

and device performance of spray coated photoactive P3HT:PCBM films. In detail, we show that a mixture of high and low boiling solvent, in our case 68% ortho-dichlorobenzene (oDCB) and 32% 1,3,5-trimethylbenzene (mesitylene) allows to produce spray coated organic solar cells with AM 1.5 calibrated PCE of over 3.1%. Interestingly, the large surface roughness of the films does not seem to impact the device performance. Moreover, we show that spray coating is a feasible technology to deposit all solution processable layers of organic solar cells, including poly(3,4-ethylene dioxythiophene) doped with polystyrene sulphonic acid (PEDOT:PSS) as well and demonstrate fully spray coated cells with a PCE of 2.7%. The device performance of spray coated films is demonstrated based on the common device configuration glass/ITO/doctor bladed or spray coated PEDOT:PSS/spray coated active layer/Ca/Ag, depicted in Fig. 1.

In the spray coating technique, organic thin films are generated stepwise. Single droplets are deposited by the transfer gas pressure with a high velocity onto the substrate. Spray coated films are formed via droplets, drying immediately when hitting the surface of the substrate. This is very different to most conventional printing technologies such as inkjet printing [4], where the film formation is based on the spreading of droplets and combining with adjacent droplets, forming a liquid bulk that dries during vaporization of the organic solvents. To achieve rapid drying, the semiconductor ink must fulfill certain requirements, which are primarily defined by the solvent properties, such as boiling point, vapor pressure, viscosity and surface tension, as presented in Table 1. In this study, the ink is processed at ambient conditions and is not heated during the spray deposition. To be compatible with the nozzle of the airbrush, the viscosity needs to be rather low at room temperature. High viscous inks require higher temperatures to decrease the viscosity and adapt the fluid properties on the airbrush setup. If the nozzle-to-substrate distance is constant, inks with too low drying rates the liquid droplets are immediately pushed sidewards by the pressure gas of the airbrush, resulting in non-uniform wetting. On the other hand, organic solvents with too high evaporation rates, at a certain nozzle-to-substrate distance the spray deposited droplets may be dry prior to reaching the substrate surface and a film deposition is inhibited. According to this, we studied two ink formulations differing in the drying behaviour. The first ink formulation is based on pristine chlorobenzene (**IF1**) and features a low boiling point and high vapor pressure resulting in rapid drying. The low surface tension for the blended semiconductor solutions guarantees decent wettability, which is also indicated by the small contact angle, represented in

Table 1
Solvent properties.

Solvent	Vapor pressure at 20 °C (mm Hg)	Boiling point (°C)	Surface tension (dynes cm^{-1})	Viscosity at 25 °C (mPa)
Chlorobenzene	11.70	132	33.0	0.76
ortho-Dichlorobenzene	1.20	180	37.0	1.32
Mesitylene	1.86	165	28.8	1.04

Table 2
Measured values of ink properties with appropriate random errors, thickness of spray coated active layer and rms roughness.

Ink formulation	Surface tension (dynes cm^{-1})	Contact angle on PEDOT:PSS (°)	Kinematic viscosity (m^2 s^{-1})	Active layer thickness mono/bi (nm)	RMS roughness mono/bi (nm)
P3HT:PCBM in chlorobenzene (**IF1**)	29.5 ± 0.1	9.7 ± 0.2	1.8 ± 0.02	250/400	67.9/46.0
P3HT:PCBM in oDCB/ mesitylene (**IF2**)	28.0 ± 0.3	7.7 ± 0.2	2.4 ± 0.2	250/400	24.1/51.7

Fig. 2. AFM images representing the surface topographies of the devices under study. (a) Chlorobenzene (**IF1**), spray coated monolayer. (b) Chlorobenzene (**IF1**), spray coated bilayer. (c) Chlorobenzene (**IF1**), doctor bladed reference, rms 3.3 nm. (d) oDCB/mesitylene (**IF2**), spray coated monolayer. (e) oDCB/mesitylene (**IF2**), spray coated bilayer. (f) oDCB/mesitylene (**IF2**), doctor bladed reference, rms 4.1 nm.

Table 2. The second ink formulation is based on 68% oDCB and 32% mesitylene organic solvents (**IF2**) showing higher

boiling points and lower vapor pressures for a slow drying. The surface tension of the blend solution and the low

contact angle again guarantee good wettability. More details on the development of ink formulation **IF2** can be found elsewhere [4].

The atomic force microscope (AFM) images of the mono- and bilayer spray coated P3HT:PCBM films on doctor bladed PEDOT:PSS substrates are presented in Fig. 2. Due to the high surface roughness and to better reveal the film topography, the height scale is chosen to be 200 nm for all spray deposited layers. For both ink formulations, the spray coated films demonstrate a significantly larger grain size and higher roughness compared to doctor bladed layers. Single dried droplets are identified and indicate a stepwise film formation. Considering **IF1** spray deposited active layers (Fig. 2a and b), the monolayer (Fig. 2a) exhibits an rms roughness of 67.9 nm, whereas the rms roughness of the bilayer sprayed film (Fig. 2b) could be reduced to 46.0 nm due to smaller droplet sizes while depositing the film in two steps (bilayer). In this study, the thickness of mono- and bilayers for both ink formulations was adjusted to 250 and 400 nm, respectively. The overall film thickness can be varied by the spraying time interval, the droplet size and the flow rate. To obtain a 400 nm thickness for bilayer sprayed films, the flow volume per time was slightly reduced compared to monolayers, resulting in smaller droplets. Otherwise, by using the same spraying parameter as for monolayers, the film thickness would be doubled. With this spray coating setup it was not possible to obtain equal film thicknesses of 250 nm for both, mono- and bilayers without altering the spraying parameters nozzle distance and ink flow rate as well as solution concentrations significantly. This modification would lead to entirely different processing conditions for mono- and bilayers, which prevent a fair comparison between **IF1** and **IF2**. Therefore, we set the film thickness to 250 nm for monolayers and 400 nm for bilayers. We achieved the same film thickness for **IF1** and **IF2**, measured by both AFM, as well as optical absorption measurement (Fig. S3). The lower surface roughness for **IF1** bilayers is explained by the smaller droplets. Spraying the second layer, the droplets fill the gaps produced by the first sprayed layer and thus, the overall surface roughness is reduced. The doctor bladed reference film is shown in Fig. 2c and provides a completely different topography with very smooth layer and little grain sizes resulting in an rms roughness of only 3.3 nm.

The spray deposited monolayer based on **IF2** (Fig. 2d) demonstrates a considerably lower rms roughness of 24.1 nm compared to the monolayer from **IF1**. Using identical nozzle-to-substrate distances for both ink formulations but decreased ink flow rates for **IF2** over **IF1**, the dried droplets based on **IF2** show a smaller diameter and a more circular shape. The lower rms roughness can be related to the improved wetting behaviour of **IF2** due to the low surface tension of the component mesitylene which results in an overall decreased surface tension of the P3HT:PCBM-**IF2** and a lower contact angle on doctor bladed PEDOT:PSS. Regarding the **IF2** spray deposited bilayer (Fig. 2e) with its rms roughness of 51.7 nm, the surface topography indicates significant differences in the film formation compared to **IF1** bilayers (Fig. 2b). While the AFM image of the **IF1** bilayer clearly exhibits individu-

ally dried droplets from two sequential steps, the film formation of the **IF2** bilayer (Fig. 2e) is dominated by the film forming dynamics, where the second layer partially redissolves the first layer. This difference in the surface topography between the **IF1** bilayer and **IF2** bilayer is attributed to the differences in boiling points and, more important, to distinct vapor pressures by almost a factor 10. According to the higher vapor pressure and thus, faster drying condition, the spray deposition of a second **IF1** layer will not influence/reorder and redissolve the first **IF1** layer as much as the second **IF2** layer, since all deposited droplets are dried at their impact. This is also consistent with Fig. 2b showing clear dried droplets and a sequential film formation of the **IF1** bilayer. While spraying a second **IF2** layer on top of a first layer, leads to a reordering and mixing between the two layers due to a lower drying rate of **IF2** and therefore, the droplets contain higher solvent residual at their impact. This reorganization does affect the film quality and the morphology which is in good accordance with the AFM image in Fig. 2e showing a more blended structure of the two successive deposited layers. If the droplets are not dry at all or too wet at their impact, spray coating as a deposition method is not capable, since the droplets would not adhere to the substrate, but rather pushed sidewards due to the transfer gas pressure. The doctor bladed reference film based on **IF2** is demonstrated in Fig. 2f with observably smaller grain sizes and rms roughness is calculated to be 4.1 nm. The AFM analysis of the spray coated films indicates significant distinctions in the surface topography compared to doctor bladed films. In the next paragraph, we will discuss whether differences in film topography can be related to differences in nanomorphology and device performance.

The nanomorphology of mono- or bilayer spray coated films was investigated by analyzing the device performance of organic solar cells. The cells were fabricated in an identical manner using either **IF1** or **IF2** as organic solvents for the spray deposition of the P3HT:PCBM active layer on doctor bladed PEDOT:PSS (see Section 1). A statistical analysis of the solar cell device parameters under AM 1.5 illumination can be found in the supplementary information (Fig. S1). The **IF2** monolayer (Fig. 2d) is formed by depositing smaller droplets yielding a more uniform film with decreased rms roughness (Table 2) and a lower pinhole density. Correspondingly, the shunt is reduced while the fill factor (*FF*) and open circuit voltage (*Voc*) increase, as also indicated by the representative current–voltage (*J–V*) behaviour under illumination shown in Fig. 3b. A better molecular distribution of PCBM within the P3HT domains and the improved intermixing of the first and second spray deposited layer for the **IF2** bilayer are indicated by a reduced reverse bias dependence of the photocurrent and results in significant better charge transport properties (Fig. 3).

For a detailed investigation of the morphology, the current–voltage behaviour of representative solar cell devices is analyzed [10].

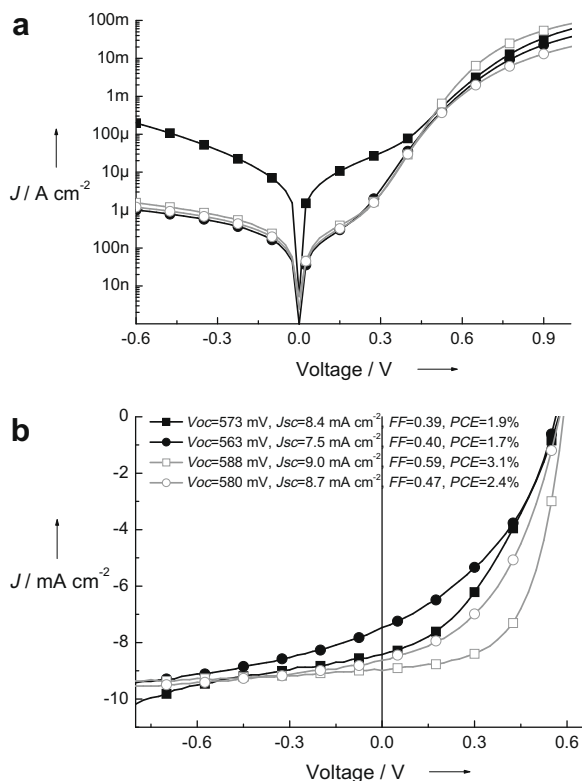
$$J = J_0 \left(e^{\frac{-q(V-JR_S)}{nkT}} - 1 \right) + \frac{V - JR_S}{R_P} + J_{light} \tag{1}$$


Fig. 3. Current density–voltage (J–V) characteristics of the devices under study: chlorobenzene (**IF1**) monolayer (black squares), chlorobenzene (**IF1**) bilayer (black dots), oDCB/mesitylene (**IF2**) monolayer (grey open squares) and oDCB/mesitylene (**IF2**) bilayer (grey open dots). (a) Representative dark J–V characteristics in a semi-logarithmic representation in the voltage range revealing the opening of the diode. (b) J–V curves under AM 1.5 illumination with 100 mW cm^{-2}.

The above equation represents the J–V characteristics of a solar cell according to a standard replacement circuit as demonstrated elsewhere [10], where J reveals the measured current density throughout the device, J_0 shows the reverse current of the diode (saturation current), V the applied voltage, R_S and R_P the serial and parallel resistances, J_{light} the photogenerated current of the device, e evidences the natural exponential function and q the elementary charge [10]. The diode ideality factor n represents the opening of the diode, which is the recombination at the interfaces between the donor and acceptor material. Therefore n correlates with the number of distributed interfaces within the blend [11] and reflects the morphology of the blend. The dark J–V curves (Fig. 3a) between 0 and the built in potential V_{BI} are characteristic for the diode behaviour of the solar cells, as defined by the ideality factor n and saturation current J_0. Variations in the absolute values of n are related to different morphologies, where $n = 1$ is representative for a bilayer system and $n = 2$ represents an intimate mixing of the donor with the acceptor throughout the bulk. Values larger than 2 indicate more complex carrier recombination mechanisms. From the dark J–V characteristics between 0.3 and 0.6 V (Fig. 3a) all fabricated devices reveal, within the accuracy of the

analysis method, similar values for n in the range of 1.6–1.9 which are typical values for polythiophene:PCBM blend devices. The dark J–V curve of **IF1** spray coated monolayer (Fig. 3a, black squares) solar cell exhibits a huge limitation in the shunt and can therefore not be simulated with this model. The **IF1** spray deposited bilayer (Fig. 3a, black dots) and the doctor bladed equivalent (not shown) indicate similar values within the certainty of the fit of $n = 1.8 \pm 0.1$ and 1.9 ± 0.05, respectively. Comparing the dark J–V characteristics of **IF2** based spray deposited devices (Fig. 3a, grey curves) with their doctor bladed equivalent (Fig. S2a), the differences are also within the certainty of the fit, namely $n = 1.8 \pm 0.1$ for the mono- and bilayer and $n = 1.6 \pm 0.05$ for the doctor bladed (dark J–V curve of doctor bladed device, see Supplementary information, Fig. S2a). For both solvents we can not measure a significant difference in the ideality factor between a spray coated and doctor bladed devices. Typically such an observation is explained by a rather comparable distribution of the donor and acceptor interface throughout the bulk of the heterojunction. Even though the similar ideality factors are not a direct proof for identical nanomorphologies, our experience on several material systems showed good correlation between ideality factor and morphology [10,11]. In contrast, there is a significant variation in the charge carrier extraction between the various spray coated solar cells (Fig. 3b) and doctor bladed devices (Fig. S2b). That variation is correlated to differences in the mobility-lifetime product as clearly seen by the simulations. The low $\mu\tau$-product goes hand-in-hand with the lower fill factors for spray coated devices as discussed in more detail below. The AFM images show clear distinctions in the topography (Fig. 2). Furthermore, the dark J–V characteristics distinguish significantly in the series resistance R_S (Fig. 3a). Independent of the ink formulation, the monolayers demonstrate a lower R_S than the spray coated bilayers due to the lower film thickness for the monolayers. In addition, the dark J–V characteristics exhibit low leakage currents for the **IF1** bilayer (Fig. 3a, black dots), the **IF2** monolayer (Fig. 3a, grey open squares) and **IF2** bilayer (Fig. 3a, grey open dots), whereas the dark J–V curve of the monolayer based on **IF1** (Fig. 3a, black squares) reveals an atypical shape, low currents in forward direction and high leakage current in reverse bias indicating decreased bottom contact selectivity. The diagram in Fig. 3b summarizes the J–V characteristics under AM 1.5 illumination with 100 mW cm^{-2}. A clear difference in the device performance is visible comparing **IF1** with **IF2** devices. The **IF1** monolayer device (Fig. 3b, black squares) exhibits a Voc of 573 mV, a short circuit current density (Jsc) of 8.4 mA cm^{-2}, a FF of 0.39 resulting in 1.9% PCE. The bilayer device based on **IF1** (Fig. 3b, black dots) shows the lowest solar cell parameters with $Voc = 563$ mV, $Jsc = 7.5$ mA cm^{-2}, FF of 0.40 and a PCE of 1.7%. The strong limitation in FF for **IF1** devices is attributed to a reduced extraction of the charge carriers. In contrast, the **IF2** spray deposited devices perform significantly better, with a Voc of 588 mV, Jsc of 9.0 mA cm^{-2}, a high FF of 0.59 for the monolayer (Fig. 3b, grey squares). This corresponds to a power conversion efficiency of 3.1%. The bilayer based on **IF2** (Fig. 3b, grey dots) features similar performance,

Voc = 580 mV, Jsc = 8.7 mA cm^{-2}, but shows the main limitation in FF with 0.47 corresponding to a PCE of 2.4%. Comparing the shape of the J–V characteristics under illumination, there is an obvious distinction in the curve progression. Clearly, bilayer devices have lower FF due to the larger R_S. Moreover, a difference due to the mobility-lifetime ($\mu\tau$) product can be seen. The photogenerated carriers are field driven [10], therefore a product of internal field and $\mu\tau$ smaller than the film thickness will lead to a loss in photocurrent. At larger external negative bias the field for the carriers is large enough to be completely extracted, which can be seen for all illuminated J–V curves showing the same photocurrent at bias around -0.6 V. The monolayer of **IF2** (Fig. 3b, grey squares) shows a nearly constant photocurrent for voltages < 0.2 V. The thicker bilayer devices of **IF2** (Fig. 3b, grey dots) are affected by a $\mu\tau$ limitation, and it needs reverse bias of -0.3 V to extract all photogenerated carriers. The monolayer of **IF1** (Fig. 3b, black squares) shows also a lower photocurrent at 0 V than at -0.3 V, while the bilayer (Fig. 3b, black dots) shows a complete extraction only at -0.6 V. Monolayer devices with a thickness of 250 nm are much weaker field dependent than thicker bilayer devices. In good agreement with earlier reports [5], the more slowly dried **IF2** films have a larger $\mu\tau$-product, sufficient to extract all carriers under J_{SC} conditions.

Fig. 4a represents the J–V behaviour of a fully spray coated device, comprising a 60 nm spray deposited PEDOT:PSS layer on top of ITO and a subsequent spray deposited P3HT:PCBM based on **IF2** (monolayer with 250 nm P3HT:PCBM film thickness; these parameters resulted in the most efficient spray coated active layer device). The fully spray deposited solar cell exhibits a decent device performance (Fig. 4a), Voc of 560 mV, Jsc of 9.1 mA cm^{-2} and a FF of 0.52. This corresponds to a power conversion efficiency of 2.7% for a fully spray coated device. Comparing the **IF2** monolayer reference solar cell device (grey open squares in Fig. 3) with the "fully sprayed" device comprising a spray deposited PEDOT:PSS and a spray coated P3HT:PCBM (J–V behaviour is shown in Fig. 4a), a clear difference of the device performance is visible, which can be attributed to the spray deposited PEDOT:PSS. The fully sprayed solar cell (see Fig. 4a) indicates a 5% lower Voc (560 mV) compared to the **IF2** monolayer device with doctor bladed PEDOT:PSS, grey squares in Fig. 3b (588 mV), whereas the Jsc is in the same range (9.0 mA/cm^2 for **IF2** monolayer and 9.1 mA/cm^2 for fully sprayed solar cell). Comparing the FF of both devices, there is a clear distinction between the **IF2** monolayer reference and the fully sprayed solar cell device, namely 0.59 and 0.52, respectively. This lower FF for the fully sprayed solar cell is attributed to the spray deposited PEDOT:PSS due to higher surface roughness (rms = 20.7 nm) and higher leakage current, while same low R_S. Fig. 4b shows the AFM image of the PEDOT:PSS film with rms roughness of 20.7 nm and Fig. 4c reveals a reference doctor bladed PEDOT:PSS film with rms roughness of 3.7 nm. A significantly larger droplet size is observed for PEDOT:PSS spray coated films compared to spray deposited P3HT:PCBM layers. This larger droplet size is attributed to the higher surface tension of the water based PEDOT:PSS solution compared to the
Fig. 4. Fully spray deposited solar cell with spray coated PEDOT:PSS and spray coated P3HT:PCBM. (a) J–V characteristics under AM 1.5 illumination with 100 mW cm^{-2}. The inset shows the dark J–V curve in a semilogarithmic plot; (b) surface topography of a spray deposited PEDOT:PSS film and (c) surface topography of a reference doctor bladed PEDOT:PSS film.

P3HT:PCBM solution where smaller drop sizes can be created.

In this study, an alternative method is presented to deposit P3HT:PCBM blend and PEDOT:PSS to produce high efficiency devices. We discussed the topographical and

the nanomorphological aspects between a spray deposited mono- and bilayer based on a pristine solvent compared to a multiple solvent system. The AFM images in Fig. 2 indicate significant topographical differences between spray deposited and doctor bladed films. A J–V analysis (Fig. 3a) revealed similar ideality factors of mono- and bilayer spray coated films over doctor bladed ones indicating similar interface between the donor and acceptor in the BHJ, but differences in the charge carrier extraction between spray coated solar cells among themselves (Fig. 3b) and doctor bladed devices. The solvent properties such as boiling point, vapor pressure, viscosity and surface tension have a massive impact on the topography as shown by the AFM analysis. An optimized spray coating formulation is found with **IF2**, which allows to spray deposit films with outstanding high carrier transport properties, directly comparable to high qualitatively doctor bladed films. This resulted in an enhanced device performance with 3.1% PCE for spray coated polymer:fullerene based solar cells. Interestingly to note that the nearly 10 times higher surface roughness of **IF2** spray coated compared to doctor bladed films does not negatively influence the device performance. Moreover, we show that spray coating is a feasible technology to deposit among others also the PEDOT:PSS film without affecting the device parameters adversely. The high photovoltaic performance of 2.7% PCE for fully sprayed cells proves the outstanding potential of spray coating as a novel manufacturing method for organic electronics.

1. Experimental section

The devices were built on transparent indium tin oxide (ITO) coated glass substrates, purchased from TFD. The glass was cleaned for 10 min in acetone and another 10 min in isopropyl alcohol using an ultrasonic bath and finally with an ozone treatment lasting 10 min. A thin 60 nm layer of poly(3,4-ethylene dioxythiophene) doped with polystyrene sulphonic acid (PEDOT:PSS) was deposited by doctor blading on top of the ITO bottom electrode. For our devices the Baytron PH, comprising a PEDOT:PSS ratio of 1:2.5 by weight, purchased from H.C. Starck was used. After the PEDOT:PSS doctor blading step, the samples were stored in inert atmosphere for at least 2 h. For spray deposited PEDOT:PSS layers, the Baytron PH dispersion was diluted with deionized water in a ratio of 1:3. The thickness of the spray deposited PEDOT:PSS film was measured to be 60 nm. In comparison to doctor bladed PEDOT:PSS, the spray deposited PEDOT:PSS on ITO was used as prepared for the spray deposition of the P3HT:PCBM. The photoactive layer consists of 1.5 w% P3HT blended with fullerene PCBM in a 1:0.8 weight ratio and dissolved in pristine chlorobenzene or ortho-dichlorobenzene/mesitylene solvent mixture. The deposition of the active layer by spray coating was performed with an airbrush system in ambient surroundings with 3 bar pressure. For the fabrication of bilayers, no additional drying procedure among mono- and bilayer deposition was applied, despite the delay of 2 min needed by the setup between the two successive spray deposited films. On top of the active layer, an additional Ca–Ag top electrode was deposited by physical vapor deposition to complete the bulk heterojunction solar cell. Prior to evaporation of the top electrode, all devices were subjected to a thermal treatment at 140 °C for 10 min. For efficiency evaluation the device area was defined by the overlap between the underlying ITO and the top electrode. Solar cells with an active area of typically 20 mm^2 were studied. The current density–voltage (J–V) characteristics were assessed with a source measurement unit SMU 2400 from Keithley under nitrogen atmosphere. For illumination a Steuernagel Solarsimulator was used providing an AM 1.5G spectra at 0.1 W cm^{-2}. AFM images of the thermally annealed spray coated films were recorded on glass substrates coated with a 60 nm PEDOT:PSS layer with a NanoSurf easyScan 2 operating under ambient conditions in contact mode. Measurements were performed using a pointprobe-plus silicon-SPM cantilever. Surface tensions and contact angles were measured with a Krüss easy drop tool. The kinematic viscosity of the two blend formulations was determined at room temperature with a micro Ubbelohde capillary viscosimeter from Schott.

ARTICLE INFO

ABSTRACT

A series benzoimidazole-based dendritric complexes of iridium dendrimers containing Fréchet-type dendrons with peripheral fluorenyl surface groups have been synthesized. These iridium dendrimers are green-emitting with high phosphorescence quantum yield, and can be spin-coated as films of good quality. From cyclic voltammograms (CV), high onset potentials at 1.42–1.58 V due to the peripheral fluorene group were observed. Device from a second generation dendrimer **17** with structure of ITO/PEDOT:PSS/CBP: 20 wt% **17**/TPBI/LiF/Al (PEDOT:PSS = poly(ethylene dioxythiophene): polystyrenesulfonate and CBP = bis(N-carbazolyl)biphenyl) has the best performance: maximum external quantum efficiency of 13.58% and maximum current efficiency of 45.7 cd/A. Space-charge-limited current (SCLC) flow technique was used to measure the mobility of charge carriers in the blend films of the compounds in CBP. Blend films of higher generation dendrimers have lower hole mobility, albeit with higher device efficiencies.

1. Introduction

Since Tang and coworkers reported electroluminescent devices based on tris(8-hydroxyquinoline) aluminum (Alq_3) in 1987, organic light-emitting diodes (OLEDs) have attracted great attention [1]. In recent years, there are increasing numbers of solution-processed OLED devices fabricated from fluorescent polymers or dendrimers [2]. However, the devices exhibit only low efficiencies in most cases. A lot of efforts have been directed to phosphorescent materials in order to improve device efficiencies [3]. Because both singlet and triplet excitons can be harvested, theoretical 100% internal quantum efficiency is possible

to be achieved in electrophosphorescent devices [4]. However, intermolecular interaction frequently leads to quenching of excited states and reduces the performance of OLEDs, fabricated via either vacuum deposition or solution-processing.

An ideal approach to suppress intermolecular interaction and retain high emission quantum yields is to use bulky and/or rigid peripheries to encapsulate the emitting core, i.e., dendritic approach [5,6]. Indeed, dendritic LEDs (DLEDs) using electrophosphorescent iridium dendrimers as emitters were reported to exhibit high luminous efficiency even without any host. For example, a maximum external quantum efficiency (EQE) of 13% and a maximum luminous efficiency of 34.7 cd A^{-1} were reported for green light-emitting iridium dendrimers with benzoimidazole-based ligands containing carbazolyl dendrons [7]. Similarly, a high EQE value of 13.6% (30 lm/W, 47 cd/A, 110 cd/m^2) was also achieved on a host-free DLED based on a dendrimer with a

fac-tris(2-phenylpyridyl)iridium(III) core [8]. Possibly due to the presence of void space and the insulating linkages inside a dendrimer, the carrier mobility generally decreases as the dendrimer generation increases [9]. Consequently, the dendrimers are commonly doped in host materials, such as bis(*N*-carbazolyl)biphenyl (CBP) [10], in order to improve the device efficiency. Red- [11], green- [7,12], and blue-emitting [13] DLEDs have been fabricated to demonstrate very promising efficiencies. It is worthy to note that besides encapsulation, dendrons surrounding the phosphorescent core also allow one to tether with suitable surface groups for enhancing the solubility of the dendrimer to facilitate spin-coating of the film [14], or tether with carrier-transport units for improving charge transporting [11,15].

Previously we synthesized a series of phosphorescent cyclometalated iridium complexes containing benzoimidazole-based ligands [16]. High performance DLEDs based on the complexes were fabricated via vacuum deposition. In a recent report we extended our study to Fréchet-type dendritic benzoimidazole ligands [17], and electroluminescent (EL) devices with good efficiencies can be achieved by solution-processing. In an attempt to further enlarge the size of Fréchet-type dendron, we tethered periphery with a fluorene moiety which was beneficial to raising the solubility and reducing the intermolecular interactions [12b]. Furthermore, fluorene moiety is also possible to assist in carrier hopping [18]. In this paper, we report the first- and second-generation cyclometalated iridium dendrimer, in which Fréchet-type benzyl ether-based dendrons were tethered with peripheral alkylated fluorenyl groups. DLEDs fabricated from these dendrimers by spin-coating technique will also be discussed.

2. Experimental

2.1. Characterization

The ^{1}H NMR spectra were recorded on a Bruker AMX400 spectrometer. FAB-mass spectra were collected on a JMS-700 double focusing mass spectrometer (JEOL, Tokyo, Japan) with a resolution of 3000 for low resolution and 8000 for high resolution (5% valley definition). For FAB-mass spectra, the source accelerating voltage was operated at 10 kV with a Xe gun, using 3-nitrobenzyl alcohol as the matrix. MALDI-mass spectra were collected on a Voyager DE-PRO (Applied Biosystem, Houston, USA) equipped with a nitrogen laser (337 nm) and operated in the delayed extraction reflector mode. Elemental analyses were performed on a Perkin–Elmer 2400 CHN analyzer. Cyclic voltammetry experiments were performed with a BHI-621B electrochemical analyzer. All measurements were carried out at room temperature with a conventional three-electrode configuration consisting of a platinum working electrode, an auxiliary electrode, and a nonaqueous Ag/AgNO$_3$ reference electrode. The $E_{1/2}$ values were determined as $1/2(E_p^a + E_p^c)$, where E_p^a and E_p^c are the anodic and cathodic peak potentials, respectively. The solvent used was CH$_2$Cl$_2$ and the supporting electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate. Electronic absorption spectra were obtained on a Cary 50 Probe UV–visible spectrometer.

Emission spectra were recorded in deoxygenated solutions at 298 K by a JASCO FP-6500 fluorescence spectrometer. The emission spectra were collected on samples with o.d. ~0.1 at the excitation wavelength. UV–visible spectra were checked before and after irradiation to monitor any possible sample degradation. Emission maxima were reproducible within 2 nm. Luminescence quantum yields (Φ_{em}) were calculated relative to **Ir(ppy)$_3$** (Φ_{em} = 0.40 in toluene) [19]. Luminescence quantum yields were taken as the average of three separate determinations and were reproducible within 10%. Luminescence lifetimes were determined on an Edinburgh FL920 time-correlated pulsed single-photon-counting instrument. Samples were degassed via freeze–thaw–pump cycle at least three times prior to measurements. Samples were excited at 337 nm from a nitrogen pulsed flashlamp with 1 ns FWHM pulse duration transmitted through a Czerny-Turner design monochromator. Emission was detected at 90° via a second Czerny-Turner design monochromator onto a thermoelectrically cooled red-sensitive photomultipler tube. The resulting photon counts were stored on a microprocessor-based multichannel analyzer. The instrument response function was profiled using a scatter solution and subsequently deconvoluted from the emission data to yield an undisturbed decay. Nonlinear least square fittings of the decay curves were performed with the Levenburg–Marquardt algorithm and implemented by the Edinburgh Instruments F900 software. The reported values represent the average of at least three readings.

2.2. Light-emitting devices fabrication

A layer of 70 nm thick poly(ethylenedioxythiophene):poly(styrene-sulfonic acid) (PEDOT:PSS) (Baytron PVP CH 8000) films was spin-coated on pre-cleaned ITO-coated glass substrates as the hole injection layer and then baked at 100 °C in air for 1 h. Next, the film of CBP containing iridium dendrimer or the neat iridium film (thickness at ~45 nm for **16** and **18**, ~70 nm for **17** and **19**, respectively) as the emitter was spin-coated using dichloroethane as the solvent (concentration: 10 mg mL^{-1} for the host and × wt% Ir dendrimer as the guest) at a spin rate of 2800 rpm (revolution per min.). Then, a electron-transporting and hole blocking 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBI) film of 40 nm thick was vacuum deposited in a vacuum chamber less than 2.5×10^{-5} torr. Finally, the device was completed by thermal deposition of a LiF/Al (1 nm/120 nm) cathode.

2.3. Hole-only devices fabrication

The hole-only devices in this study consists of a 20 wt% of **16** (or **17**–**19**) in CBP blend thin film sandwiched between transparent indium tin oxide (ITO) anode and metal cathode. Before device fabrication, the ITO glasses (1.5 × 1.5 cm^2) were ultrasonically cleaned in detergent, de-ionized water, acetone and isopropyl alcohol before the deposition. After routine solvent cleaning, the substrates were treated with UV ozone for 15 min. Then a modified ITO surface was obtained by spin-coating a layer of poly(ethylene dioxythiophene): polystyrenesulfonate

(PEDOT:PSS) (∼30 nm). After baking at 130 °C for 1 h, the substrates were then transferred into a nitrogen-filled glove box. The active layer was spin coated (spin rate = 2800 rpm; spin time = 45 s) on top of PEDOT:PSS and then dried in covered glass Petri dishes. The film thickness of the active layer was measured to be 55, 50, 50 and 50 nm, for **16**, **17**, **18** and **19**, respectively. Subsequently, a 20 and 100 nm thick of MoO_3 and aluminum was thermally evaporated under vacuum at a pressure below 6×10^{-6} torr thorough a shadow mask. The active area of the device was 0.12 cm^2.

3. Materials

Chemicals and solvents were reagent grades and purchased from Aldrich, Acros, TCI, and Lancaster Chemical Co. Solvents were dried by standard procedures. All reactions and manipulations were carried out under N_2 with the use of standard inert atmosphere and Schlenk techniques. Solvents were dried by standard procedures. All column chromatography was performed by using silica gel (230–400 mesh, Macherey-Nagel GmbH & Co.) as the stationary phase in a column which is 25–35 cm in length and 2.5 cm in diameter.

3.1. 9,9-Dihexyl-9H-fluorene-2-carbaldehyde (1)

2-Bromo-9,9-dihexyl-9H-fluorene (20.2 g, 48.9 mmol) was dissolved in 100 mL of dry THF and the solution was cooled to −78 °C. n-Butyl lithium in hexane (1.6 M, 30.5 mL, 48.9 mmol) was added dropwise over a period of 30 min. The mixture was allowed to warm to −20 °C in the next 1 h, and 3.8 mL of dry DMF was added. The mixture was stirred at room temperature for 12 h. The reaction was quenched with water and the solution was extracted with diethyl ether. The combined organic extracts were washed with brine solution, dried over MgSO$_4$, and evaporated to dryness. The residue was purified by column chromatography using a mixture of CH$_2$Cl$_2$ and hexanes (1:1) as the eluent to afford a white solid (13.4 g, 75%). ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 10.04 (s, 1H, CHO), 7.85 (s, 1H), 7.83–7.80 (m, 2H), 7.76–7.74 (m, 1H), 7.37–7.33 (m, 3H), 2.00–1.97 (m, 4H, CH$_2$), 1.07–0.97 (m, 12H, CH$_2$), 0.75 (t, J = 7.2 Hz, 6H, CH$_3$), 0.56–0.53 (m, 4 H, CH$_2$).

3.2. 4-(9,9-Dihexyl-9H-fluoren-2-yl)benzaldehyde (2)

4-Bromobenzaldehyde (9.25 g, 50 mmol), 9,9-dihexyl-9H-fluoren-2-yl-boronic acid (22.5 g, 1.2 equiv.), Na$_2$CO$_3$ (12.0 g, 2 equiv.), and Pd(OAc)$_2$ (112 mg, 0.01 equiv.) were dissolved in a mixture of 30 mL of acetone and 35 mL of water. The mixture was stirred at room temperature for 16 h. The reaction was then quenched by pouring the solution into water and the desired compound was extracted with diethyl ether. The collected organic extracts were collected, dried over MgSO$_4$. Filtration and removal of the solvent provided a white solid. It was purified by column chromatography using a mixture of dichloromethane and hexanes (1:1) as the eluent to give a yellow oil in 73% yield (16.0 g). ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 10.06 (s, 1H, CHO), 7.97 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.82 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.78 (d, J = 8.0 Hz, 1H, fluorene), 7.75–7.73 (m, 1H, fluorene), 7.62–7.60 (m, 2H, fluorene), 7.38–7.30 (m, 3H, fluorene), 2.04–1.99 (m, 4H, CH$_2$), 1.12–1.04 (m, 12H, CH$_2$), 0.75 (t, J = 7.2 Hz, 6H, CH$_3$), 0.68–0.66 (m, 4H, CH$_2$).

3.3. (9,9-Dihexyl-9H-fluoren-2-yl)methanol (3)

Compound **1** was dissolved in 40 mL of THF and 40 mL of methanol. Sodium borohydride (2 equiv.) was added slowly to the above solutions in portions, and the solution was allowed to stir for 24 h. The reaction was quenched by pouring the solution into water and the desired compound was extracted with diethyl ether. The organic extracts were collected and dried over anhydrous MgSO$_4$. Filtration and removal of the solvent provided a white solid. It was purified by column chromatography using a mixture of dichloromethane and hexanes (1:1) as the eluent to afford a white powder in 75% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.67–7.64 (m, 2H), 7.32–7.25 (m, 5H), 4.75 (s, 2H, OCH$_2$), 1.96–1.91 (m, 4H, CH$_2$), 1.11–1.00 (m, 12H, CH$_2$), 0.75 (t, J = 7.2 Hz, 6H, CH$_3$), 0.61–0.55 (m, 4H, CH$_2$).

3.4. 4-(9,9-Dihexyl-9H-fluoren-2-yl)phenyl)methanol (4)

Compound **4** was synthesized by the same procedure as illustrated for compound **3** except that compound **1** was used instead of compound **2**. The compound was isolated as a white solid in 75% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.77–7.73 (m, 2H, fluorene), 7.69 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.59–7.57 (m, 2H), 7.48 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.39–7.31 (m, 3H, fluorene), 4.74 (d, J = 2.0 Hz, 2H, OCH$_2$) 1.99–1.96 (m, 4H, CH$_2$), 1.09–1.01 (m, 12H, CH$_2$), 0.73 (t, J = 7.2 Hz, 6H, CH$_3$), 0.66–0.64 (m, 4H, CH$_2$).

3.5. 2-(Bromomethyl)-9,9-dihexyl-9H-fluorene (5)

A mixture of compound **3** (1.82 g, 5.0 mmol) and triphenylphosphine (1.1 equiv.) was dissolved in THF (15 mL) and cooled to 15 °C. N-bromosuccinimide (1.1 equiv.) was added all at once. The reaction was stirred for additional 10 min and immediately quenched by cold water. The solids formed were extracted into dichloromethane. The organic extracts were collected, washed with brine, and dried over anhydrous MgSO$_4$. After filtration and removal of the solvent, the crude product was further purified by column chromatography on a silica gel column using a mixture of CH$_2$Cl$_2$ and hexanes (1:5 by volume) as the eluent to afford the pure compound as a white solid in 85% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.67–7.61 (m, 2H, fluorene), 7.36–7.30 (m, 5H, fluorene), 4.59 (s, 2H, CH$_2$Br), 1.98–1.90 (m, 4H, CH$_2$), 1.12–1.05 (m, 12H, CH$_2$), 0.75 (t, J = 7.2 Hz, 6H, CH$_3$), 0.59–0.50 (m, 4H, CH$_2$).

3.6. 2-(4-(Bromomethyl)phenyl)-9,9-dihexyl-9H- fluorene (6)

Compound **6** was synthesized by the same procedure as illustrated for compound **5** except that compound **3** was used instead of compound **4**. The product was isolated as

a white solid in 76% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.73 (d, J = 8.0 Hz, 1H, fluorene), 7.70 (d, J = 7.2 Hz, 1H, fluorene), 7.62 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.54 (dd, J = 8.0 Hz and 1.6 Hz, 1H, fluorene), 7.51 (d, J = 1.2 Hz, 1H, fluorene), 7.47 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.34–7.28 (m, 3H, fluorene), 4.55 (s, 2H, CH$_2$Br), 1.99–1.96 (m, 4H, CH$_2$), 1.09–1.01 (m, 12H, CH$_2$), 0.73 (t, J = 7.2 Hz, 6H, CH$_3$), 0.66–0.64 (m, 4H, CH$_2$).

3.7. (3,5-Bis((9,9-dihexyl-9H-fluoren-2-yl)methoxy)phenyl)-methanol (7)

A mixture of 3,5-dihydroxybenzyl alcohol (2.80 g, 20 mmol), potassium carbonate (6.67 g, 40 mmol), compound 5 (2.1 equiv.), and 18-crown-6-ether (0.52 g, 0.2 mmol) in acetone (30 mL) was heated to reflux for 48 h. After being cooled, water was added and the solution was extracted with dicholormethane. The organic extracts were collected, washed with brine, and dried over anhydrous MgSO$_4$. After filtration and removal of the solvent, the crude product was further purified by column chromatography using a mixture of CH$_2$Cl$_2$ and hexanes (1:1 by volume) as the eluent. The product was isolated as a white solid in 70% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.67 (d, J = 8.0 Hz, 4H, fluorene), 7.37–7.28 (m, 10H, fluorene), 6.64 (d, J = 2.0 Hz, 2H, C$_6$H$_3$), 6.62 (t, J = 2.0 Hz, 1H, C$_6$H$_3$), 5.10 (s, 4H, OCH$_2$), 4.62 (s, 2H, OCH$_2$), 1.95–1.91 (m, 8H, CH$_2$), 1.12–0.97 (m, 24H, CH$_2$), 0.74 (t, J = 7.2 Hz, 12H, CH$_3$), 0.64–0.56 (m, 8H, CH$_2$).

3.8. (3,5-Bis(4-(9,9-dihexyl-9H-fluoren-2-yl)benzyloxy)-phenyl)methanol (8)

Compound 8 was synthesized by the same procedure as illustrated for compound 7 except that 5 was used instead of 6. The product was isolated as a white solid in 70% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.74–7.68 (m, 4H, fluorene), 7.67 (d, J = 8.4 Hz, 4H, C$_6$H$_4$), 7.56–7.49 (m, 4H, fluorene), 7.47 (d, J = 8.4 Hz, 4H, C$_6$H$_4$), 7.33–7.25 (m, 6H, fluorene), 6.67 (d, J = 2.0 Hz, 2H, C$_6$H$_3$), 6.60 (t, J = 2.0 Hz, 1H, C$_6$H$_3$), 5.07 (s, 4H, OCH$_2$), 4.61 (s, 2H, OCH$_2$), 1.95–1.91 (m, 8H, CH$_2$), 1.12–0.97 (m, 24H, CH$_2$), 0.74 (t, J = 7.2 Hz, 12H, CH$_3$), 0.64–0.56 (m, 8H, CH$_2$).

3.9. Compound 9

Compound 9 was synthesized by the same procedure as illustrated for compound 5 except that compound 3 was used instead of compound 7. The product was isolated as a white solid in 70% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.68 (d, J = 8.4 Hz, 4H, fluorene), 7.41–7.25 (m, 10H, fluorene), 6.66 (d, J = 2.0 Hz, 2H, C$_6$H$_3$), 6.62 (t, J = 2.0 Hz, 1H, C$_6$H$_3$), 5.09 (s, 4H, OCH$_2$), 4.39 (s, 2H, OCH$_2$), 1.95–1.91 (m, 8H, CH$_2$), 1.09–1.00 (m, 24H, CH$_2$), 0.74 (t, J = 7.2 Hz, 12H, CH$_3$), 0.56–0.53 (m, 8H, CH$_2$).

3.10. Compound 10

Compound 10 was synthesized by the same procedure as illustrated for compound 5 except that compound 3 was used instead of compound 8. The product was isolated

as a white solid in 72% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.74–7.69 (m, 4H, fluorene), 7.67 (d, J = 8.4 Hz, 4H, C$_6$H$_4$), 7.56–7.54 (m, 4H, fluorene), 7.51 (d, J = 8.4 Hz, 4H, C$_6$H$_4$), 7.34–7.26 (m, 6H, fluorene), 6.67 (d, J = 2.0 Hz, 2H, C$_6$H$_3$), 6.61 (t, J = 2.0 Hz, 1H, C$_6$H$_3$), 5.09 (s, 4H, OCH$_2$), 4.43 (s, 2H, OCH$_2$), 1.99–1.95 (m, 8H, CH$_2$), 1.11–1.03 (m, 24H, CH$_2$), 0.73 (t, J = 7.2 Hz, 12H, CH$_3$), 0.67–0.63 (m, 8H, CH$_2$).

3.11. 4-(1-Phenyl-1H-benzo[d]imidazol-2-yl)phenol (11)

N-Phenyl-*o*-phenylenediamine (9.21 g, 50 mmol), and 4-hydroxybenzaldehyde (6.10 g, 50 mmol) were dissolved in 40 mL of 2-methoxyethanol. The mixture was heated to reflux for 48 h. After cooling, the deposited solids were filtered, washed with dichloromethane, and dried under vacuum to give the desired product (5.1 g, 35%). ^{1}H NMR (DMSO-d_6, 400 MHz, ppm): δ 7.71 (d, J = 7.6 Hz, 1H), 7.57–7.51 (m, 3H), 7.36 (d, J = 7.6 Hz, 2H), 7.32 (d, J = 8.4 Hz, 2H), 7.26 (t, J = 7.2 Hz, 1H), 7.20 (t, 7.2 Hz, 1H), 7.11 (d, J = 8.0 Hz, 1H), 6.68 (d, 8.4 Hz, 2H). FABMS: m/z 287.2 (M+H)$^+$. Anal. Calcd for C$_{19}$H$_{14}$N$_2$O: C, 79.70; H, 4.93; N, 9.78. Found: C, 79.29; H, 5.04; N, 9.58.

Ligands 12, 13, 14, and 15 were synthesized by similar procedures, as described below for compound 12. Compound 11 (0.73 g, 2.5 mmol), K$_2$CO$_3$ (0.35 g, 2.5 mmol), and compound 5 (1.06 g, 2.5 mmol) were dissolved in 30 mL of DMF. The mixture was heated at 100 °C for 24 h. After cooling, the reaction was quenched with water and the mixture was extracted with dicholormethane. The organic extracts were collected, washed with brine, and dried over anhydrous MgSO$_4$. After filtration and removal of the solvent, the crude product was further purified by column chromatography using a mixture of CH$_2$Cl$_2$ and hexanes (3:1 by volume) as the eluent to provide 12 as a white solid in 73% yield. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.84 (d, J = 8.0 Hz, 1H), 7.67 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 7.55–7.43 (m, 5H), 7.35–7.27 (m, 8H), 7.20 (d, J = 8.0 Hz, 2H), 6.92 (d, J = 8.4 Hz, 2H, C$_6$H$_4$), 5.10 (s, 2H, OCH$_2$), 1.94–1.90 (m, 4H, CH$_2$), 1.10–1.00 (m, 12H, CH$_2$), 0.74 (t, J = 7.2 Hz, 6H, CH$_3$), 0.60–0.58 (m, 4H, CH$_2$). FABMS: m/z 633.3 (M+H)$^+$. Anal. Calcd for C$_{45}$H$_{48}$N$_2$O: C, 85.40; H, 7.64; N, 4.43. Found: C, 85.24; H, 7.79; N, 4.35.

13: White solid. Yield = 75%. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 8.14 (d, J = 8.0 Hz, 1H), 7.68–7.60 (m, 8H), 7.54–7.46 (m, 3H), 7.38–7.18 (m, 13H), 6.89 (d, J = 8.4 Hz, 2H), 6.67 (d, J = 2.0 Hz, 2H, C$_6$H$_3$), 6.62 (t, J = 2.0 Hz, 1H, C$_6$H$_3$), 5.09 (s, 4H, OCH$_2$), 4.99 (s, 2H, OCH$_2$), 1.94–1.86 (m, 8H, CH$_2$), 1.09–0.99 (m, 24H, CH$_2$), 0.73 (t, J = 7.2 Hz, 12H, CH$_3$), 0.65–0.54 (m, 8H, CH$_2$). FABMS: m/z 1101.9 (M+H)$^+$. Anal. Calcd for C$_{78}$H$_{88}$N$_2$O$_3$: C, 85.05; H, 8.05; N, 2.54. Found: C, 85.15; H, 8.22; N, 2.60.

14: White solid. Yield = 56%. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm): δ 7.84 (d, J = 8.0 Hz, 1H), 7.72 (d, J = 8.0 Hz, 1H), 7.69 (d, J = 7.2 Hz, 1H), 7.65 (d, J = 8.0 Hz, 2H), 7.55–7.45 (m, 9H), 7.31–7.28 (m, 6H), 7.22–7.18 (m, 2H), 6.91 (d, J = 8.8 Hz, 2H), 5.09 (s, 2H, OCH$_2$), 1.99–1.96 (m, 4H, CH$_2$), 1.09–1.01 (m, 12H, CH$_2$), 0.73 (t, J = 6.8 Hz, 6H, CH$_3$), 0.66–0.64 (m, 4H, CH$_2$). [a] Measured in CH₂Cl₂ at 298 K at a concentration of 10⁻⁵ M. ε is the absorption coefficient.
[b] Recorded in toluene solutions at 298 K. Excitation wavelength was 410 nm for all compounds. Quantum yield was measured in toluene relative to *fac*-Ir(ppy)₃ (Φ_p = 0.40).
[c] Neat-film data measured at 298 K. PL quantum efficiencies in films were measured in an integrating sphere.
[d] Measured in toluene solutions at 298 K.
[e] $\tau_r = \tau/\Phi_p$.
[f] Oxidation potential reported is adjusted to the potential of ferrocene ($E_{1/2}$ = 270 mV vs. Ag/AgNO₃) which was used as an internal reference. Conditions of cyclic voltammetric measurements: platinum working electrode; Ag/AgNO₃ reference electrode. Scan rate: 100 mV/s. Electrolyte: tetrabutylam-monium hexafluorophosphate.
[g] E_g: bandgap. E_g was obtained from the absorption spectra.
[h] HOMO level were calculated from CV potentials using ferrocene as a standard [HOMO = 4.8 + (E_{ox} − E_{Fc})].
[i] LUMO derived via equation, E_g = HOMO − LUMO.
[j] Ref. [7].

ether to give μ-chloro-bridged Ir(III) dimer. One equiv. of μ-chloro-bridged Ir(III) dimer was mixed with 2.5 equiv. of K_2CO_3, 2.0 equiv. of **12**, and glycerol (5.0 mL) in a flask. The mixture was heated at 190 °C for 24 h. After cooling, the reaction was quenched with water and the mixture was extracted with dicholormethane. The combined extracts were then washed with brine, dried over $MgSO_4$, filtered, and dried under vacuum. The crude product was isolated by column chromatography using a mixture of CH_2Cl_2 and n-hexane (1:1 by volume) as the eluent.

4. Results and discussion

4.1. Syntheses

Bouveault's synthesis [20] and palladium-catalyzed Suzuki reaction [21] were used to prepare two aldehydes, 9,9-dihexyl-9H-fluorene-2-carbaldehyde (**1**), and 4-(9,9-

dihexyl-9H-fluoren-2-yl)benzaldehyde (**2**) (Scheme 1). Reduction of **1** and **2** with $NaBH_4$ gave the benzyl alcohol **3** and **4** in ~80% yield, which was then treated with N-bromosuccinimide and triphenylphosphine to form the benzyl bromides, **5** and **6** [4]. Reaction of compound **5** (or **6**) with 3,5-dihydroxybenzyl alcohol provides compound **7** (or **8**) containing two fluorene branches. Similar to the synthesis

of **5** from **3**, compounds **7** and **8** can be converted to **9** and **10**, respectively. Compound **11**, prepared from *N*-phenyl-*o*-phenylenediamine and 4-hydroxybenzaldehyde, was then allowed to react with **5**, **6**, **9**, and **10**, respectively, using

Williamson ether synthesis to form dendritic benzoimidazole ligands **12**–**15** in 30–90% yields. The preparation of tris-cyclometalated iridium complexes **16–19** involved a two-step synthesis (see Scheme 2): (1) reaction of IrCl$_3 \cdot$ 3H$_2$O with dendritic ligands **12**–**15** to from a chloro-bridged dimer intermediate; (2) reaction of the dimer with additional 12–**15** in glycerol at 190 °C. Only the facial (*fac*) isomer was isolated for **16**–**19**, as evidenced from the NMR spectra.

4.2. Optical properties

The photophysical data of compounds **12–19** are summarized in Table 1. The absorption spectra and photoluminescence (PL) spectra of compounds **12–15** and **16–19** are shown in Figs. 1 and 2, respectively. Absorption bands at ~310 nm ($\varepsilon \sim 10^4$–10^5 M^{-1} cm^{-1}) are π–π^* transition characteristic of the benzoimidazolyl moiety, and those at ~275 nm ($\varepsilon \sim 10^4$–10^5 M^{-1} cm^{-1}) can be attributed to π–π^* the transition of the peripheral fluorene. Besides the π–π^* transition bands of the ligands, the dendritic iridium complexes **16–19** also exhibit weak absorption bands in the range of ~350–450 nm due to metal-to-ligand charge transfer transitions, ^{1}MLCT and ^{3}MLCT.

The dendritic ligands **12–15** emit in the violet-purple region ($\lambda_{em} \sim 355$ nm) in CH_2Cl_2. Because of non-conjugated nature between the iridium center and the dendron, all dendritic iridium complexes emit green light both in toluene solution and neat film state ($\lambda_{em} = 510$–529 nm), similar to their non-dendronized congener, **(G0)$_3$Ir** [7]. The solution PL quantum yields (0.55–0.74 in toluene) of **16–19** compared favorably with that (0.45 in toluene) of the non-dendronized congener, **(G0)$_3$Ir** [7], indicating that the encapsulation indeed more effectively suppresses triplet–triplet annihilation of the emitting core. The phosphorescent lifetimes (1.02–1.46 µs) of these complexes fall into the range of prototype non-dendronized tris-cyclometalated iridium complexes [19]. Apparently, the incorporation of flexible alkyl group or ether linkage does not lead to facile non-radiative decay pathways. The encapsulation efficiency increases as the surface group becomes bulkier (i.e., Φ_{PL} (**18**) > Φ_{PL} (**16**) and Φ_{PL} (**19**) > Φ_{PL} (**17**)), or the generation of the dendron increases (i.e., Φ_{PL} (**17**) > Φ_{PL} (**16**) and Φ_{PL} (**19**) > Φ_{PL} (**18**)). Similar to the quantum yields of the solutions, the trend retains in the film state. The studies of concentration quenching on **16–19** and non-encapsulated complex **(G0)$_3$Ir** further witness the merit of encapsulation from the dendron, that is, the solution quantum yield of **(G0)$_3$Ir** decreases more rapidly than **16–19** as the concentration increases from 10^{-6} M to 5×10^{-4} M (see Fig 3). Compared to the solution state in Table 1, there is a significant drop of PL quantum yields in the solid film state ($\Phi_{PL} = 0.15$–0.33). This is consistent with concentration quenching observed in the toluene solution (*vide supra*). Similar behavior was also reported in other phosphorescent dendrimers [5]. No emission from the peripheral fluorene was noticed, indicating that energy transfer from the peripheral fluorene to the iridium center may occur, or there exists inner filter effect. We found that excitation at the ^{1}MLCT band (~ 410 nm) of **17** in the film state led to phosphorescent emission of higher intensity by 2.0–2.5 times compared to excitation at the peripheral fluorene (250–300 nm). Therefore, the energy transfer from the dendron to the iridium center is not likely to be the main cause of the increased quantum yields in the larger dendrimers. This is in contrast to FIrpic (iridium(III) bis[[(4,6-difluoro-phenyl)pyridinato-$N,C^{2'}$]-3-hydroxypicolinate) derivatives with N,N'-dicarbazolyl-3,5-benzene-based dendrons [22], which were described to have efficient singlet–singlet and triplet–triplet energy transfer from the dendron to the iridium center.

4.3. Film morphology

Good thin film quality is prerequisite for good performance of OLEDs. Therefore, AFM was used to examine the morphology of the spin-casting films for these complexes. All compounds can be fabricated as good-quality films by spin-coating technique. Fig. 4 shows the AFM images of the spin-coating films (45–70 nm thick), obtained from iridium complexes **16–19**, on plasma treated indium tin oxide (ITO) substrates. The root mean square (RMS) surface roughness of neat film in **16–19** was found to be 0.489, 1.055, 1.287, and 0.667 nm, respectively. The blend films of CBP with 20 wt% of **16–19** had slightly larger RMS surface roughness at 1.175, 0.741, 2.264, and 3.121 nm, respectively.

4.4. Electrochemical studies

The electrochemical properties of the ligands (**12**–**15**) and the complexes (**16**–**19**) were studied by cyclic voltammetric (CV) method, and the electrochemical data are summarized in Table 1. All ligands show an irreversible oxidation wave with an onset potential at 1.42–1.58 V vs. Ag/AgNO₃, which is characteristic of the peripheral fluorene group. Besides the irreversible oxidation wave of the ligands, a quasi-reversible one-electron oxidation wave attributed to the oxidation of the iridium(III) was detected in the range of ~0.39–0.41 mV vs. Ag/AgNO₃. The negligible influence of the dendrons on the oxidation potential of the iridium center is likely due to non-conjugated nature of the spacer between the dendron and the iridium center. No reduction waves up to -2.0 V were detected in these iridium dendrimers. The HOMO (highest occupied molecular orbital) energy levels of compounds **12**–**19** were calculated from cyclic voltammogram in comparison with ferrocene (4.8 eV) [23]. The thus obtained HOMO levels, (~6.0 eV for **12**–**15** and ~4.95 eV for **16**–**19**) in combination with the optical bandgaps which were derived from the optical edges of absorption spectra, were used to calculate the LUMO (lowest unoccupied molecular orbital) energy levels [24]. Both HOMO and LUMO data are collected in Table 1.

4.5. Electroluminescent properties

Electroluminescent (EL) devices of bilayered configuration, ITO/PEDOT:PSS/neat **16**–**19** or *x* wt% of dopant **16**–**19** in CBP (45–70 nm)/TPBI (40 nm)/LiF (1 nm)/Al (120 nm), were fabricated via spin-coating technology (see Fig. 5). Spin-coating technology was used for device fabrication except for the vacuum deposition of TPBI (the electron-transporting and hole-blocking layer). The LED devices without the use of TPBI will not be discussed because the efficiency dropped at least two orders in both cases. The energy band structures of the devices are shown in Fig. 6, and the performance data are presented in Table 2. The EL spectra are shown in Fig. 7. All devices emitted green light and the EL spectra were superimposed with the PL spectra. The absence of emission from CBP suggests that either energy transfer from CBP to the complexes is complete or the trapping of electrons and holes by the complexes is efficient.

Although neat films of good quality can be obtained by spin-coating technique (*vide supra*), the devices using the neat films of the complexes have efficiencies far from ideal: the maximum external quantum efficiencies are lower than 7.1%. The following four factors are probably responsible for the low device efficiencies: (1) T–T annihi-

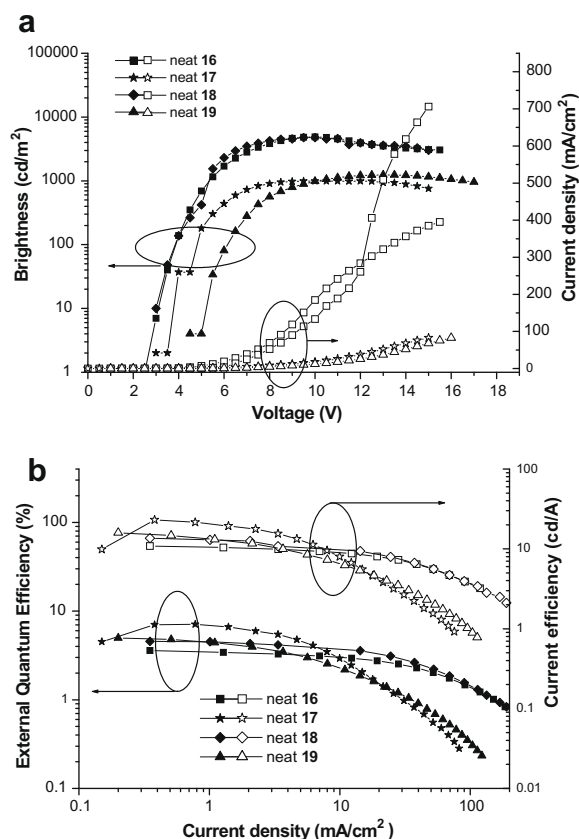
Fig. 7. EL spectra at a driving voltage of 12 V of DLEDs containing (a) **16**–**19** doped with CBP, (b) **16**–**19** neat film.


Fig. 8. The electro-optical characteristic of DLEDs containing neat **16**–**19** (a) brightness and current density as a function of voltage, and (b) current efficiency and EQE as a function of current density.

lation due to the high concentration of the guest; (2) the large energy gap between PEDOT:PSS and the HOMO level of peripheral fluorenyl group which hampers the hole injection into the emitting layer; (3) inefficient carrier mobility of the dendrons; (4) quenching of phosphorescence via energy transfer from the iridium center to the dendron due to small gap ($\sim$1000 cm^{-1}) between the triplet energies of the two. Foe example, **15** E_T (77 K, toluene) = 2.55 eV; **10**, E_T (77 K, toluene) = 2.53 eV; **16**, E_T (77 K, toluene) = 2.34 eV. The current–voltage–brightness (I–V–L) characteristic and the EQEs and current efficiency vs. current density for the devices based on neat films of **16**–**19** are shown in Fig. 8. DLEDs based on **17** and **19** exhibit much lower current density and brightness. Our observations are consistent with previous report illustrating that the carrier mobility decreases as the dendrimer generation increases [9]. The I–V–L characteristic and the EQEs and current efficiency vs. current density of DLEDs containing CBP doped with complexes **16**–**19** are shown in Fig. 9. Among them, the best efficiencies were found to be $\eta_{\text{ext,max}}$ = 9.8%, 13.6%, 8.3%, and 9.0%, and $\eta_{\text{c,max}}$ = 33.8, 45.8, 27.9, and 31.1 cd/A for the devices with 4.65, 2.77, 4.20, and 2.45 mol% of **16**, **17**, **18**, and **19**, respectively. The significant drop of device efficiencies at dopant concentrations above 40% for all the complexes is likely due to T–T annihilation. The best device performance was

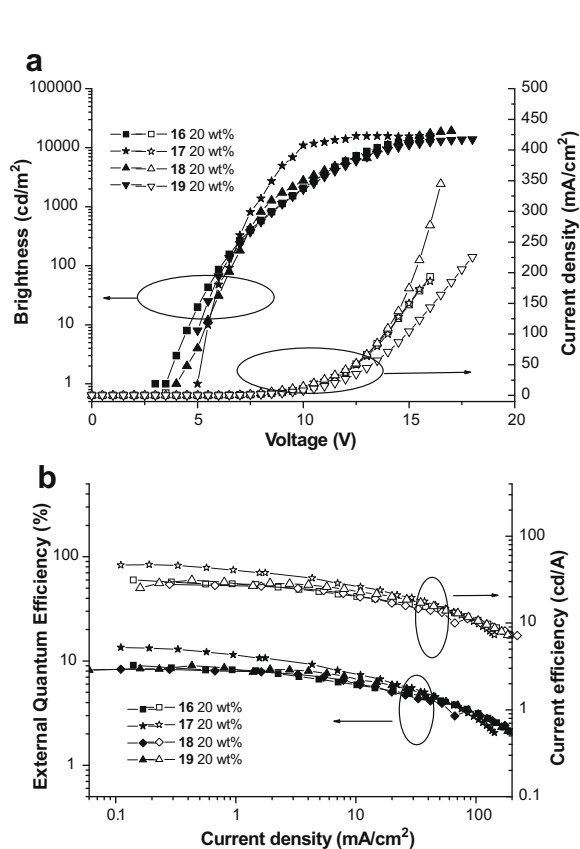
achieved at a lower dopant concentrations (mol%) for the devices based on the second-generation dendrimers (**17** and **19**) compared to the devices based on the first-generation dendrimers (**16** and **18**), which may be attributed to the inefficient carrier conductivity of the fluorene-containing dendrons. Inefficient carrier conductivity of the dendron is evident from the I–V plots (Fig. 10) of **16** (first generation dendrimer) and **19** (second generation dendrimer) at different doping concentrations: the current decreases as the doping concentration increases at the same driving voltage. Though the current density of **18**-based device was higher than that of **19**-based device, **16**- and **17**-based devices were found to have comparable current density, where the conductivity might be affected by the film morphology. Nevertheless, the efficiency of the device increases as the generation of the dendrimer increases, i.e., **17** > **16** and **19** > **18**. Arylamine-based dendrimers with stilbene dendrons were also reported to have better device efficiency and inferior carrier mobility as the generation increases [9]. It was suggested that the increased spacing of hopping sites in the bulkier dendrimers inhibited transport of majority charge carriers and resulted in a reduction of the mobility. The influence of the dendron on the device efficiency may also be accounted by the same token in our


Fig. 9. The electro-optical characteristic of DLEDs containing x wt% **16**–**19** in CBP: (a) brightness and current density as a function of voltage; (b) current efficiency and EQE as a function of current density.

case. It is interesting to note that neat film devices also behave similarly (see Fig. 11).

4.6. Hole mobility properties

Space-charge-limited current (SCLC) flow technique was used to measure the mobility of charge carriers in the films [25]. In spite of the ambipolar carrier-transporting characteristic of CBP [26], no discernible currents were detected for the blend film of CBP with the compounds synthesized in electron-only devices, indicating that the electron mobility was negligible in the film. This is consistent with the poor performance of DLEDs without the presence of TPBI (*vide supra*). In comparison, from the hole-only devices the hole mobilities can be determined precisely by fitting the dark current vs. voltage (J–V) curves for single carrier devices to SCLC model [27–28]. The dark current is given by $J = 9\varepsilon_0\varepsilon_r\mu V^2/8L^3$ [29], where $\varepsilon_0\varepsilon_r$ is the permittivity of the dendrimer, μ is the carrier mobility, and L is the device thickness. From the capacitance–voltage measurements we have obtained a relative dielectric constant ε_r of 0.65, 1.81, 1.30, 1.98 for the blend film of 20 wt% of **16**, **17**, **18**, and **19** in CBP, respectively. Therefore, the hole mobilities were calculated to be 1.85×10^{-7}, 9.80×10^{-8}, 4.76×10^{-8}, and 2.43×10^{-8} cm^2/Vs for the blend films of **16**, **17**, **18** and **19**, respectively. These observations are consistent with the lower current density measured for DLEDs based on larger dendrimers, i.e., device of **17** < device **16** and device **19** < device **18** (*vide supra*). The lower hole mobility of the larger dendrimers (**17** and **19**) is likely due to increased spacing of hopping sites [9]. The better efficiencies of the devices for the larger dendrimers may be stemmed from the increased waiting time of charge carriers which will increase the probability of recombination, similar to that reported for triarylamine-cored distyrylbenzene-based dendrimers [9]. The device based on the neat film has a lower efficiency than that based on the CBP blend film, which may also be attributed to the non-conductivity of the former, and the very narrow exciton recombination region near the interface between the neat film and TPBI. Compared with the iridium complexes encapsulated with benzyl ether dendrons we reported earlier [17], the hole mobilities of the dendrimers in this study appear to be ~one order lower. The hole mobilities of the previous dendrimers were measured to be 2.7×10^{-6}, and 9.2×10^{-7} cm^2/V s for the 20 wt% CBP blend films of **(G1)$_3$Ir** (first generation dendrimer) and **(G2)$_3$Ir** (second generation dendrimer), respectively. Possibly the larger fluorene moiety increases spacing of hopping sites and results in a reduction of the mobility (*vide supra*). The somewhat lower device efficiencies in this study may be due to the less balanced hole and electron mobilities (the electron mobility of TPBI is ~10^{-5} cm^2/(V s) [30]).

5. Conclusions

In conclusion, we have synthesized a series of benzoimidazole-based dendritic complexes of iridium dendrimers containing Fréchet-type dendrons with peripheral fluoenyl surface groups. These iridium dendrimers emit green light with high PL quantum yields, and can be spin-cast as films of good quality. The electroluminescent devices fabricated by the spin-coating technique have high-performance of electro-optical properties. One of the devices with the structure of ITO/PEDOT:PSS/CBP: **17** (20 wt%)/TPBI/LiF/Al has a maximum EQE of 13.58% and a maximum current efficiency of 45.7 cd/A. The high HOMO level of the peripheral fluoenyl surface group leads to a larger turn on voltage. EL devices based on the dendrimers of higher generation have a lower current density because of the slower carrier mobility of the higher generation dendrimer. However, EL devices from dendrimers of higher generation exhibit higher EQEs and current efficiencies.

ARTICLE INFO

ABSTRACT

A number of semiconducting organic molecules capable of wet processing exhibit high carrier mobility and current modulation. In this work, we synthesized photopatternable π-conjugated star-shaped molecules and characterized their physical properties. The solubility of the synthesized molecules is very good for solution processing. The synthesized organic semiconducting multi-branched molecules are capable of photopatterning by virtue of photopolymerization of the reactive pentadienyl end groups. The transistor devices using these molecules provided a field-effect mobility of $1.3(\pm0.2) \times 10^{-3}$–$3.7(\pm0.5) \times 10^{-3} \, cm^2 \, V^{-1} \, s^{-1}$ as well as a high current on/off ratio ($I_{on/off} > 10^3$) and a low threshold voltage. In the case of the photoreactive star-shaped conjugated molecule HP2P, it was found that field-effect mobility was maintained even after the photocrosslinking process. This result can be used in the design of photopatternable semiconductor molecules for thin-film transistor electronic applications.

1. Introduction

There has been growing interest in π-conjugated systems over the last several years due to their unique semiconducting and electro-optical properties and because of their potential applications in different electronic devices, such as organic field-effect transistor devices (OFETs) [1,2] and organic photovoltaic devices (OPVs) [3,4]. Among the various types of soluble organic semiconducting materials, star-shaped crystalline molecules have been attractive for synthesis because of their strong potential advantages. Compared with the linear organic conjugated

oligomers and polymers currently used in OFETs, these molecules have a number of advantages including the ability to demonstrate multifunctionality in one molecule [5,6]. The synthesis of π-conjugated star-shaped molecules raises the possibility of creating thiophene derivatives that are fully tethered to the aromatic core. Furthermore, the solubility problem in conjugated linear oligothiophene is resolved under dendritic architecture [7,8]. Recently, the authors demonstrated some star-shaped molecules showing good solubilities, film-forming properties, and reasonably high field-effect carrier mobilities [9].

The development of OFETs has generated a great deal of interest in solution-processible organic semiconductors, which can combine high charge transport mobility, stability, and patternability [10]. However, the carrier mobility of the linear thiophene-based liquid crystalline molecule

---

was observed to decrease after the photocrosslinking reaction due to the disruption of the preferred anisotropic molecular packing. [10]. In this work, the authors report the design of a new class of hole transporting semiconductor materials incorporating photoreactive end groups, which can undergo a photopolymerization without a photoinitiator. In this instance, the core of the molecule is designed to have conjugative connecting properties, which will be discussed later. The photopolymerizable 1,4-pentadien-3-yl group at the periphery was used because of its ability to undergo photopolymerization. [11,12]. Ultraviolet (UV) radiation ($\lambda = 254$–270 nm) at room temperature is effective in inducing photopolymerization, forming cross-links between the reactive units, which results in the formation of insoluble 2-D or 3-D polymer networks.

2. Experiment

2.1. Material

All commercially available starting reagents or reactants were purchased from Aldrich or Acros Organics Co. and used without further purification unless otherwise stated. All solvents used in this study were freshly dried under the standard distillation method.

Compounds 4 [13], 9 [14], and 11 [9] were prepared according to the procedures in the literature. Compounds 1 [15,16], 2 [16,17] were also synthesized using similar methods that have been reported in the literature. Compound 7 was prepared using the reaction between penta-1,4-dien-3-ol and succinic anhydride in the presence of 4-dimethylaminopyridine and triethylamine in a quantitative yield.

2.2. Synthesis

2.2.1. 5′-((Tert-butyldimethylsilyloxy)methyl)-2,2′-bithiophene-5-carbaldehyde, 3

A solution of compound 2 (31.0 g, 100 mmol) in tetrahydrofuran (THF, 200 mL) was cooled to −78 °C in an acetone/dry ice bath. N-Butyllithium (105 mmol, 42 mL, 2.5 M in hexane) was added through a syringe over 10 min. The temperature of the reaction mixture was slowly raised to −30 °C and was maintained for 1 h. Next, N,N-dimethylformamide (DMF, 9.0 mL, 120 mmol) was added through a syringe over 5 min. The mixture was allowed to stir at room temperature for 2 h and then was quenched with an aqueous ammonium acetate solution. The organic layer was separated and the aqueous phase was extracted with ether. The combined organic layer was condensed and the residue was purified with silica-gel column chromatography using chloroform/hexane (1/15 v/v) and then crystallized in methanol to afford 24.7 g of solid: yield 73%.

^{1}H NMR (400 MHz, CDCl$_3$): δ(ppm) 9.85 (s, 1H), 7.65 (d, $J = 4.0$ Hz, 1H), 7.21 (d, $J = 4.0$ Hz, 1H), 7.20 (d, $J = 4.0$ Hz, 1H), 6.86 (d, $J = 4.0$ Hz, 1H), 4.86 (s, 2H), 0.94 (s, 9H), 0.13(s, 6H).

Anal. Calcd for C$_{16}$H$_{22}$O$_2$S$_2$Si: C, 56.76; H, 6.55; found: C, 56.96; H, 6.52.

2.2.2. 1,2,4,5-Tetrakis((E)-2-(5′-((tert-butyldimethylsilyloxy)methyl)-2,2′-bithiophen-5-yl)vinyl)benzene, 5

A solution of potassium tert-butoxide (2.6 g, 23 mmol) in 50 mL of THF was added to a mixture of octaethyl benzene-1,2,4,5-tetrayltetrakis(methylene) tetraphosphonate (3.4 g, 5.0 mmol), 5′-((tert-butyldimethylsilyloxy)methyl)-2,2′-bithiophene-5-carbaldehyde 3 (7.8 g, 23 mmol), and 50 mL of THF over 10 min under magnetic stirring. The mixture was allowed to stir at room temperature overnight. Then, ethanol (200 mL) was added to the reaction mixture. The resultant precipitate was filtered and washed with methanol and then purified with silica-gel column chromatography using chloroform/hexane (1/2 v/v). After that, it was crystallized in THF/methanol to afford 4.4 g of red–yellow solid: yield 62%.

^{1}H NMR (400 MHz, CDCl$_3$): δ(ppm) 7.65 (s, 2H), 7.18 (d, $J = 16.0$ Hz, 4H), 7.13 (d, $J = 16.0$ Hz, 4H), 7.07 (d, $J = 4.0$ Hz, 4H), 7.05 (d, $J = 4.0$ Hz, 4H), 7.01 (d, $J = 4.0$ Hz, 4H), 6.82 (d, $J = 4.0$ Hz, 4H), 4.86 (s, 8H), 0.95 (s, 36H), 0.13(s, 24H).

Anal. Calcd for C$_{74}$H$_{94}$O$_4$S$_8$Si$_4$: C, 62.75; H, 6.69, found: C, 62.61; H, 6.70.

2.2.3. (5′,5′′,5′′′,5′′′′-(1E,1′E,1′′E,1′′′E)-2,2′,2′′,2′′′-(Benzene-1,2,4,5-tetrayl)tetrakis (ethene-2,1-diyl)tetrakis(2,2′-bithiophene-5′,5-diyl))tetramethanol, 6

Compound 5 (2.83 g, 2.0 mmol) was dissolved in 50 mL of THF. Dilute hydrochloric acid (6.0 mL, 0.75 N) was added and the mixture was stirred at room temperature for 3 h. Triethylamine (6.0 mmol) was added to neutralize the acid; then, 100 mL of water was added slowly to precipitate out the product. The product was collected by filtration, washed, and dried in vacuo to give a quantitative yield.

Anal. Calcd for C$_{50}$H$_{38}$O$_4$S$_8$: C, 62.60; H, 3.99, found: C, 63.01; H, 4.14.

2.2.4. 1′′,1′,1-(5′,5′′,5′′′-(1E,1′E,1′′E)-2,2′,2′′-(5-((E)-2-(5′-((4-((Z)-Hexa-1,4-dien-3-yloxy)-4-oxobutanoyloxy)methyl)-2,2′-bithiophen-5-yl)vinyl)benzene-1,2,4-triyl)tris(ethene-2,1-diyl)tris(2,2′-bithiophene-5′,5-diyl))tris(methylene) 4-tri-(penta-1,4-dien-3-yl) tributanedioate, 8 (HB4P)

To a solution of 6 (0.96 g, 1.0 mmol) and 7 (0.92 g, 5.0 mmol) in 50 mL of dichloromethane (DCM)/THF (1:3), 4-(dimethyl-amino)pyridinium p-toluenesulfonate (DPTS) (1.32 g, 4.5 mmol) was added; the mixture was allowed to stir at room temperature under nitrogen atmosphere for 15 min. N,N′-Dicyclohexylcarbodiimide (DCC, 0.93 g, 4.5 mmol) was then added and the mixture was allowed to stir at 40 °C for 5 days. The reaction mixture was filtered and the filtrate was concentrated under a reduced pressure. The crude product was then purified by silica-gel column chromatography (eluent; ethyl acetate/CHCl$_3$ = 1:10 v/v) to afford 1.03 g of a red solid: yield 63%.

2.3. Instrumental analysis

^{1}H NMR spectra were recorded on a Varian Mercury NMR 400 MHz spectrometer using deuterated chloroform (Cambridge Isotope Laboratories, Inc.). Elemental analyses were performed using an EA1112 elemental analyzer (Thermo Electron Corp.). Thermal properties were studied under a nitrogen atmosphere on a Mettler DSC 821^e instrument and a TGA50 (Heating rate of 5 °C/min under N$_2$). Fourier transform infrared (FT-IR) spectra were recorded using a Perkin–Elmer 783 infrared spectrophotometer (*sample on KBr window). The redox properties of the star-shaped molecules were examined using cyclic voltammetry (Model: EA161 eDAQ). Thin films were coated on a platinum plate using chloroform as a solvent. The electrolyte solution employed was 0.10 M tetrabutylammonium hexafluorophosphate (Bu$_4$NPF$_6$) in a freshly dried MC. The Ag/AgCl and Pt wire (0.5 mm in diameter) electrodes were used as the reference and counter electrode, respectively. The scan rate was 50 mV/s.

The X-ray diffraction (XRD) experiment was performed at varying temperatures using the synchrotron radiation (1.542 Å) of the 3C2 beam line at the Pohang Synchrotron Laboratory, Pohang, Korea. The film samples were fabricated by drop-casting on a silicon wafer, followed by drying at 70 °C under vacuum (solvent: chloroform, solution concentration: 10 mg/mL). The measurements were obtained in a scanning interval of 2θ between 1° and 40°.

Atomic force microscopy (AFM, Digital Instruments Multimode equipped with a nanoscope IIIa controller) operating in tapping mode with a silicon cantilever was used to characterize the surface morphologies of the samples. The film samples were fabricated by spin-coating (1500 rpm) on silicon wafer followed by drying at 60 °C

under vacuum (solvent: chloroform, solution concentration: 10 mg/mL).

Absorption spectra of the samples in a film and solution state (chloroform, concentration 1×10^{-5} mol/L) were obtained using a UV–vis spectrometer (HP 8453, photodiode array type) in the wavelength range of 190–1100 nm. To study absorption behavior, the films of the two molecules were fabricated on quartz substrates: The solution (1 wt%) of each molecule in chloroform (**HB4P**) and monochlorobenzene (**HB2P**) was spin-coated onto the quartz glass. The films were dried overnight under vacuum.

2.4. OFET fabrication

Bottom-contact OFET devices were fabricated using the gold source and drain electrodes, which were thermally evaporated using the conventional method. P-doped polycrystalline silicon was used as a gate electrode; its 300-nm bare and surface-modified SiO$_2$ layer was used as a gate dielectric insulator. The deposition of a self-assembled monolayer (SAM) with octyltrichlorosilane (OTS) on the

SiO$_2$ gate dielectric was performed according to the method in the literature [18].

The gold was deposited onto the untreated and OTS-treated SiO$_2$ surface via thermal evaporation. The current–voltage (*I–V*) characteristics of the OTFTs were measured under vacuum below 10^{-2} Torr using a Keithley 237 SMU. A wire bonder (Kunche & Sona 4524) was used for electrical contact from the Au electrodes to a chip carrier for the OTFTs. Field-effect mobility in cross-linked organic semiconducting films was measured by exposure to the films under UV light ($\lambda = 254$ nm, $I = 40.64$ mW/cm^2) for 5 min at room temperature.

3. Results and discussion

3.1. Synthesis

The authors report the easy, high-yield synthesis of new photopolymerizable p-type thiophene-based star-shaped semiconducting molecules. In Scheme 1, **5** was prepared by the Horner–Emmons coupling of [1,2,4,5-tetra-(dieth-
Scheme 1. Synthetic route of **8** (**HB4P**).

oxy-phosphorylmethyl)-benzyl]-phosphonic acid diethyl ester and 5′-((tert-butyldimethylsilyloxy)methyl)-2,2′-bithiophene-5-carbaldehyde. After deprotecting TBDMS, the esterification of **6** and 4-oxo-4-(penta-1,4-dien-3-yloxy)butanoic acid **7** produces **HB4P** in a good yield (63%). **HB4P** came to have four pentadienyl reactive groups in each arm.

However, in Scheme 2, the Horner–Emmons coupling of tetraethyl (2,5-dibromo-1,4-phenylene)bis(methylene)diphosphonate and 5′-((tert-butyldimethylsilyloxy)methyl)-2,2′-bithiophene-5-carbaldehyde produces **10**. The Heck coupling reaction was then used to attach 5-hexyl-5′-vinyl-2,2′-bithiophene for the synthesis of **12**. The same method was employed for preparing **HB2P**.

The identity and purity of the synthetic materials were confirmed by ^{1}H NMR, ^{13}C NMR, and elemental analysis. They were found to have good self-film-forming properties and to be well-soluble in various organic solvents such as chloroform, dichloromethane, ethyl acetate, chlorobenzene, and tetrahydrofuran.

Furthermore, computer calculations using the AM1 theoretical model incorporated into the Spartan program ('06) were performed to determine the minimum energy conformations for **HB4P** and **HB2P** [19]. Such calculations have been found reliable for the determination of geometrical shapes in cruciform molecules. The optimized geometrical structures of the two molecules are illustrated in Fig. 1. The shapes of the molecules are expected to be quite similar. **HB4P** is likely to have randomly oriented photoreactive peripheral moieties. It is interesting to note why they have a low degree of crystallization during cooling, which will be discussed in Section 3.6. In particular, **HB2P** has two hexyl peripheral groups with a zig-zag extended confor-

mation, which can be interdigitated due to molecular interaction.

3.2. Thermal analysis

When employing the photopolymerizable star-shaped molecules for OFET applications, their thermal stabilities and dynamic behaviors are emphasized for device fabrication. The thermal properties of the molecules were characterized by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). DSC measurement was performed at a heating (cooling) scan rate of 5 °C/min under nitrogen with the highest temperature limited to below the decomposition temperature (Fig. 2). **HB4P** and **HB2P** displayed distinct melting temperatures at 76 °C and 142 °C, respectively. **HB4P** and **HB2P** exhibited distinct isotropic-to-crystalline transitions at 58 °C and 116 °C during cooling cycles, respectively. On comparison of the crystalline and melting points of **HB4P**, **HB2P**, and 1,2,4,5-tetrakis((E)-2-(5′-hexyl-2,2′-bithiophen-5-yl)vinyl) benzene [9], the authors determined that the hexyl peripheral groups play a key role in increasing the crystallinity due to the presence of 2-D lamella ordering.

3.3. Confirmation of photocrosslink

3.3.1. FT-IR spectroscopy

An FT-IR investigation was carried out to confirm that photopolymerization had occurred between the diene units. Fig. 3 shows FT-IR spectra of the HB4P and **HB2P** film before and after UV exposure (λ = 254 nm, I = 40.64 mW/cm^2). The characteristic absorption bands at 932, 993, 1150, 1640, and 1737 cm^{-1}, which can be unambiguously

Fig. 2. Thermal properties of **HB4P** and **HB2P** molecules.

assigned to the diene photoreactive groups, are labeled in Fig. 3. Clear evidence for polymerization was demonstrated by the disappearance of the stretching band of the C=C bond at 1641 cm^{-1}. The difference spectrum shows a differential line shape at $\sim$1737 cm^{-1}, corresponding to a spectral shift of the C=O transition of the diene groups as a result of cross-linking. This shift occurs because the transition is inductively coupled to the double bond, which breaks during polymerization. The decrease in intensity of the =CH wag transitions at 993 and 932 cm^{-1} further verified cross-linking.

3.3.2. Solubility test

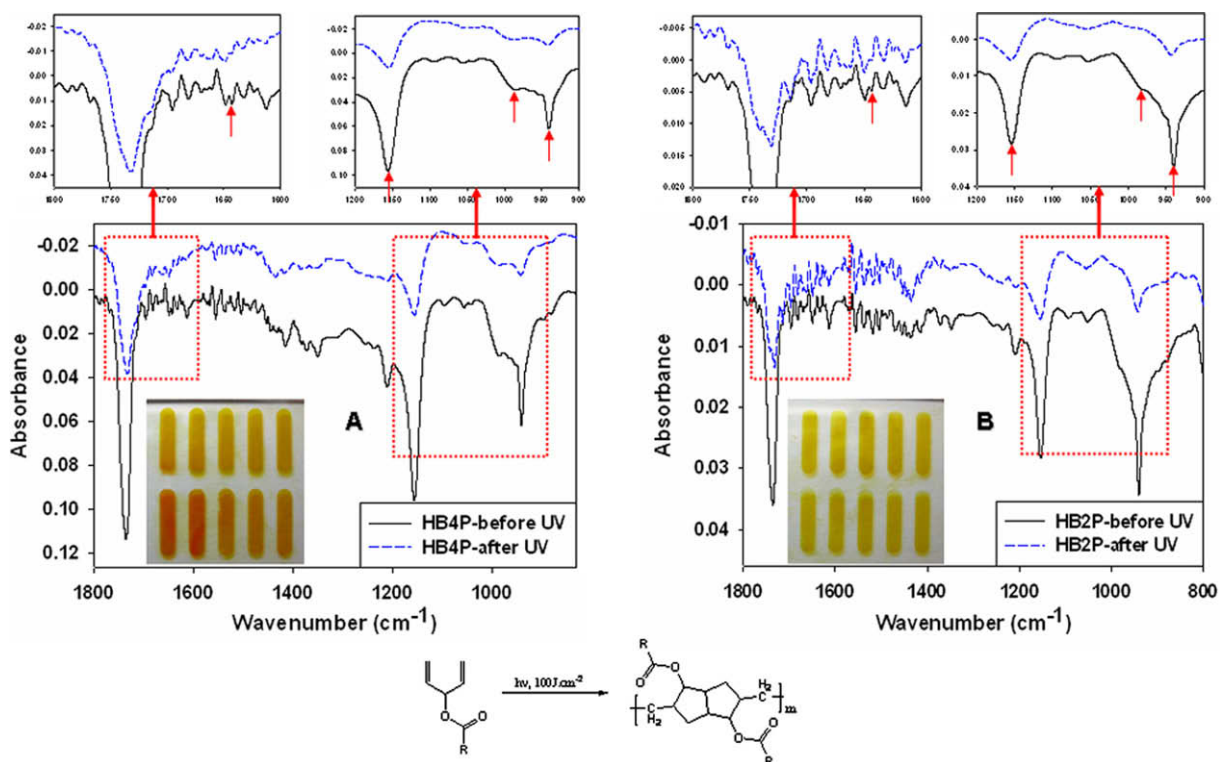
Approximate 100-nm-thick films of **HB4P** and **HB2P** were spin-coated on the quartz glass and annealed at proper temperatures. The films were exposed to UV light (λ = 254 nm, I = 40.64 mW/cm^2) for 10 min. No photoiniti-


Fig. 3. FT-IR spectra before and after UV expose of molecules. (A) **HB4P** and (B) **HB2P**.
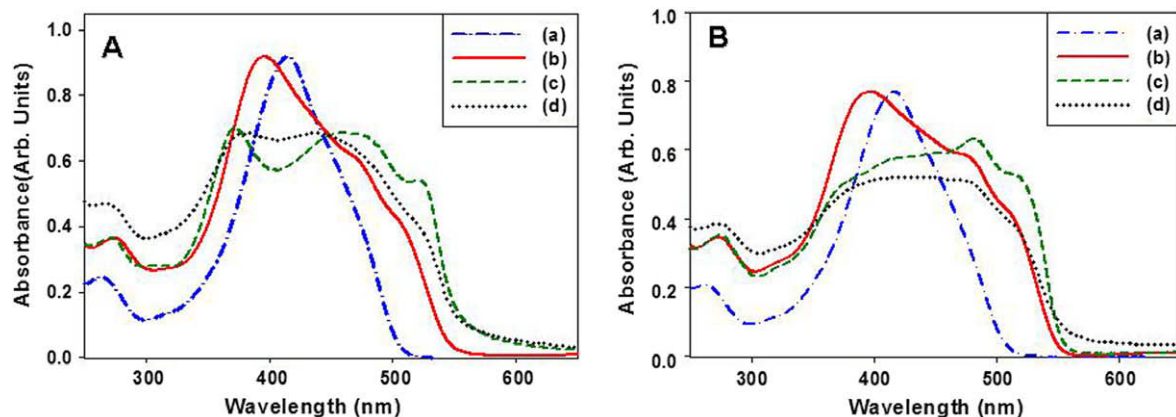

Fig. 4. UV–vis absorption spectra of **HB4P** (A) and **HB2P** (B). (a) Solution, (b) pristine film, (c) annealed film, (d) annealed and UV exposure.

ator was used. The exposed films were immersed into chloroform for 60 s. The partially polymerized regions of the film were washed away. The thickness decreased about ~10% after washing, indicating that only a small amount of the material is removed. This confirms conclusively that insoluble networks were formed in the film of our two molecules predominantly. Furthermore, the patterning processes were carried out using a photo mask. The photo-patterned images of UV-crosslinked films after washing unexposed parts were also showed as an inset in Fig. 3.

3.4. Optical properties

The absorption spectra of the samples in chloroform and thin films were obtained (Fig. 4). Similar absorption maxima of **HB4P** and **HB2P** in solution state are located at 415 and 416 nm, respectively. A drastic spectral change is observed in the film states of these molecules, which is attributed to a high degree of intermolecular interaction. For instance, in the film state after annealing, the absorption spectrum is significantly red-shifted with vibronic transitions; this shift may be due to the formation of an ordered structure with an intermolecular π-stacking. The difference between the HOMO–LUMO gaps in solution and film states provides useful information for understanding intermolecular interactions. The difference in the HOMO–LUMO gaps results from the difference in the intramolecular conjugation through the core. The larger difference (0.20 and 0.22 eV) in **HB2P** and **HB4P** imply a higher de-

gree of intermolecular interaction in the film states (Table 1).

3.5. Electrochemical analysis

Electrochemical characterization of these molecules revealed that their oxidation is reversible, which is a necessary condition for a stable FET active material. The values of the ionization potential match well with the work function of a gold electrode. Cyclic voltammograms (CV) were recorded on a film sample and the potentials were obtained relative to an internal ferrocene reference (Fc/Fc$^+$). These CV scans in the range of −2.0–+2.0 V (vs Ag/AgCl) show quasi-reversible oxidation peaks. Unfortunately, the reduction behaviors were irreversible; therefore, accurate estimation of HOMO and LUMO energies was not possible. To determine the LUMO levels, the oxidation potential in CV was combined with the optical energy band gap (E_g^{opt}) resulting from the absorption edge in the absorption spectrum. HOMO and LUMO levels of the two molecules in solution state and film state before and after UV exposure are shown in Table 1. These levels indicate that the molecules behave as a p-type semiconductor.

3.6. X-ray diffraction analysis

To study the crystallinity and preferred orientations of the star-shaped molecules, XRD was performed at varying temperatures. The star-shaped molecular layers in **HB2P**

Table 1

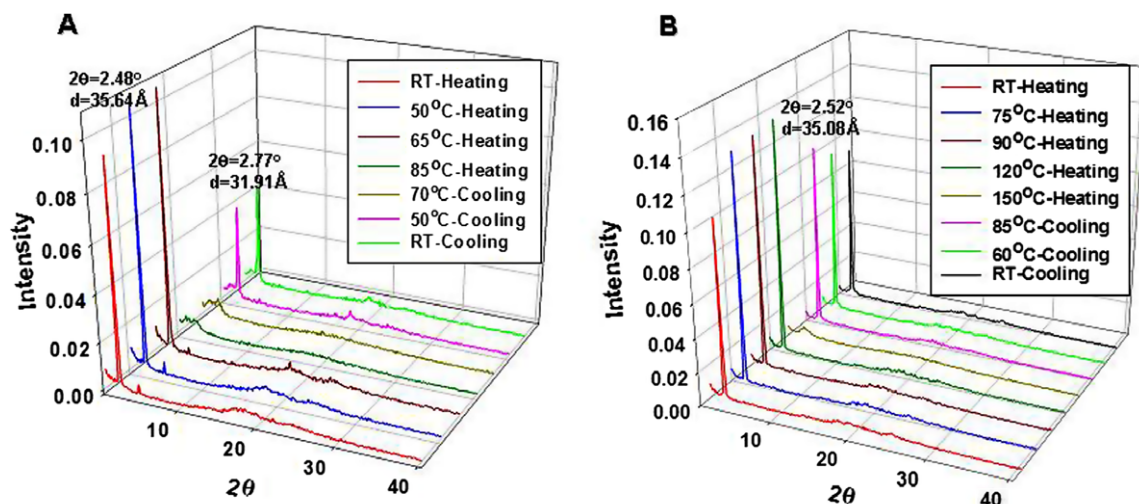

Fig. 5. Temperature dependence of X-ray diffraction patterns of molecules. (A) **HB4P** and (B) **HB2P**.

must be associated with the layered stacking properties brought about by the terminal alkyl groups, which are already known to induce long-range lamella ordering. The X-ray diffraction scans of **HB4P** and **HB2P** films annealed at different temperatures reveal the temperature at which the highest crystalline order is achieved (Fig. 5). In the film samples, the preferred orientation is clearly indicated by the high reflection intensity of the peaks at about 35 Å ((100) reflection) and the ambiguous presence of peaks in the 3–5 Å ((010) reflection) region, as seen in the X-ray diffractograms. The former spacing corresponds to the edge-to-edge transverse packing of the peripheral arms and the latter to a π–π stacked distance with a π-electron cloud overlap. This result implies that most of the crystallites in these molecules are preferentially oriented along the (100)-axis in the plane. **HB4P** showed a smaller degree of lamella ordering during cooling, while **HB2P** exhibited comparable diffraction peaks during cooling. It implies that the hexyl peripheral groups enhance the intermolecular ordering to improve the crystallinity in **HB2P**.

In the case of **HB4P**, the layer distance before annealing is approximately 35.64 Å (2.48°). However, after annealing, the distance is reduced to 31.91 Å (2.77°). A possible explanation could be related to the fact that during cooling, some molecules are forced to adopt a slightly closer packing arrangement. In contrast, in the case of **HB2P**, the layer distances before and after annealing remain constant. This phenomenon could be explained by the role of hexyl group of **HB2P**. Usually long alkyl peripheral groups can interact between themselves by van der Waals interaction, which induce highly packed crystalline structure even at room temperature.

Aside from using the vacuum evaporation technique, it is difficult to achieve high crystallinity for the films of organic molecules. However, in the solution-processed films in this study, significantly high crystalline properties and the preferential orientation of the ordered molecular domains were found in the samples.

Fig. 6 showed X-ray diffraction patterns of **HB4P** and **HB2P** before and after UV exposure. **HB4P** showed a large
Fig. 6. X-ray diffraction patterns of molecules. (A) **HB4P** and (B) **HB2P**. (a) Before and (b) after UV exposure.

decrease of lamella ordering after UV exposure. The layer distance before UV exposure is approximately 35.64 Å (2.48°). However, after exposure, the distance was reduced to 31.12 Å (2.77°). The d-spacing decrements after polymerization occur as a result of conformation changes such as changes in the tilt angle and the extent of their interdigitation, resulted in closer packing arrangement. The full width at half maximum (FWHM) also increased from 0.15 Å before UV exposure to 0.42 Å after UV exposure. In addition, the degree of crystallization was also decreased after UV exposure. This phenomenon might be due to disruption of the molecular ordering significantly.

In the case of **HB2P**, with a higher packed crystalline structure, the layer distance only slightly reduced from 35.08 Å (2.52°) before UV exposure to 32.74 Å (2.70°) after UV exposure. FWHM also increased from 0.15 Å before UV exposure to 0.31 Å after UV exposure. The degree of crystallinity determined by integration of diffraction peak, maintained constantly even after UV exposure. In comparison with **HB4P**, **HB2P** showed a smaller decrease of lamella ordering after UV crosslinking. It implies that the hexyl peripheral groups enhance the intermolecular interaction of the star-shaped conjugated structure, which can relatively prevent disruption of molecular ordering during the crosslinking.

3.7. Optical and atomic force microscopic study of molecules

By using a hot-stage optical microscope (Mettler Co.), the crystalline shape of the molecules was observed at different temperatures under crossed polarizers from room temperature to their melting points. Fig. 6 shows the crystalline structures of **HB4P** and **HB2P** after inducing crystallization. Under the same magnification (×200), the crystallites of **HB2P** are significantly bigger than those of **HB4P**.

Further study of film morphology was obtained by AFM (Fig. 7). The solutions of the molecules **HB4P** and **HB2P** were spin-coated on a silicon wafer and annealed at their crystalline points (58 °C and 116 °C, respectively). The images of the molecules are quite similar; however, the crystals of **HB2P** are significantly bigger than those of **HB4P** due to the presence of intermolecular ordering.

In **HB2P**, the crystallite size was observed to be larger than that of **HB4P**, which is consistent with the optical microscope results. The optical spectroscopy and AFM micrographs results could provide indirect evidence of the strong intermolecular interaction and preferred molecular orientation of these molecules in the crystalline film, particularly for **HB2P**. In addition to the long-range molecular structural organization confirmed by the X-ray study, the AFM micrographs display well-resolved surface structures on the dielectric layer.

3.8. Properties of OFET made from star-shaped molecules

Bottom-contact OFET devices were fabricated using gold source and drain electrodes which were thermally evaporated using the conventional method. A 400-nm-thick film of the semiconductor was deposited by dropcasting a 2 wt% solution of **HB4P** in chloroform or **HB2P** in monochlorobenzene. To achieve optimal performance, the OFET devices made of **HB4P** and **HB2P** were further annealed at 65 °C and 115 °C, respectively, for 30 min. The output characteristics showed very good saturation behaviors and clear saturation currents that were quadratic to the gate bias (Figs. 8 and 9). The saturated field-effect mobilities, μ_{FET}, can be calculated from the amplification characteristics by using the classical equations describing field-effect transistors [20]. The mobility values obtained by measuring different devices are listed in Table 2 (Fig. 10).

The transistor devices of **HB4P** and **HB2P** after annealing provided a field-effect mobility of $1.3(\pm0.2) \times 10^{-3}$–$3.7(\pm0.5) \times 10^{-3}$ cm^2 V^{-1} s^{-1} as well as a high current on/off ratio and a low threshold voltage ($V_{th} < -15$ V). Compared to **HB4P**, **HB2P** showed higher mobility. This molecule exhibited a carrier mobility of $3.7(\pm0.5) \times 10^{-3}$ cm^2 V^{-1} s^{-1} for a 10-μm channel length device, with the current on/off ratio higher than 10^3 and a threshold voltage of -16 V. The best mobility obtained was $6.0(\pm0.2) \times 10^{-3}$ cm^2 V^{-1} s^{-1}; however, it is not reproducible. When using the bare SiO$_2$ gate insulator, the mobilities were much lower than those with the OTS-treated SiO$_2$ (Table 2).

HB2P	116	142	416	518(557)	5.4(±0.5) × 10^{-4}	>10^3	3.7(±0.5) × 10^{-3}	>10^3	3.6(±0.5) × 10^{-3}	>10^3
Fig. 10. Output (left) and transfer (right) characteristics of the OFET made by the drop-casting of **HB2P** from monochlorobenzene solution, annealed at 115 °C for 30 min.

As mentioned above, **HB2P** showed a more compact structure on the surface with bigger crystallites. It is thought that the highly packed crystalline molecules on the dielectric layer help the carrier transport by producing good connection behavior. As observed in X-ray analysis, it is assumed that the hexyl peripheral groups and lamella ordering induce higher intermolecular interaction and preferred molecular orientation, leading to increased carrier mobility.

In previous reports about photopolymerizable linear organic semiconductors, the reduction in charge transport was observed. Field-effect mobility in cross-linked films was reduced approximately 10-fold [10]. This phenomenon was explained by suggesting a reduced degree of molecular ordering induced by cross-linking. During the formation of polymer main chains, some molecules are forced to adopt a slightly closer packing arrangement randomly, whereas others are "pulled away" to accommodate these structural changes. As a result, there is a broader distribution of molecular axis angles with respect to the director, and consequently, a lower degree of π-orbital overlap between the adjacent aromatic cores.

However, in the case of the star-shaped conjugated molecule **HB2P**, the field-effect mobility in cross-linked films was well maintained. As discussed in Section 3.6, a possible explanation could be related to the strong intermolecular interaction of the star-shaped conjugated structure, which could arrest the molecular axis under push–pull force during the cross-linking and is accompanied by a high degree of lamella ordering in two directions. Thus, a star-shaped molecular structure seems to be a suitable design for photopatternable semiconductor molecules in practical electronic applications.

4. Conclusion

This work provides the first demonstration of working field-effect transistor devices fabricated from novel, solution-processable, photopolymerizable, star-shaped conjugated molecules. These compounds have a good solubility and application to soluble processing. The patterning process was carried out by photopolymerization of the reactive dienyl end groups, creating an insoluble network. Dendritic molecules bearing pentadiene groups can be photopolymerized without a photoinitiator, which can behave as a charge trap. The maximum field-effect mobility of annealed **HB2P** was found to be approximately $3.7(\pm 0.5) \times 10^{-3}$ cm^2 V^{-1} s^{-1} with a current on/off ratio

higher than 10^3. It was also found that **HB2P** exhibited great persistency of field-effect mobility even after photopolymerization, which suggests that the patternable process is feasible for the fabrication of OTFT array device structures. This result can be applied to the design of photoreactive semiconductor molecules for practical electronic applications. Although the measurement and the device fabrication were not fully optimized in this study, the field-effect mobility showed promise for future studies. Further studies to improve the charge mobility (μ) and current on/off ratio are now in progress.

ARTICLE INFO

ABSTRACT

A novel ligand 9-(4-(4-chlorophenyl)phthalazin-1-yl)-9H-carbazole (HCPC) was designed and prepared, and the corresponding tris-cyclometalated iridium(III) complex Ir(CPC)$_3$ was readily synthesized by the reaction of the ligand with IrCl$_3 \cdot$ 3H$_2$O at 80 °C for 20 h. A highly efficient organic light-emitting device using this complex as a dopant was obtained. The device fabricated by solution process showed a maximum luminance of 2948 cd/m^2 at a current density of 115.6 mA/cm^2 and a maximum external quantum efficiency of 20.2% at 0.18 mA/cm^2.

1. Introduction

Organic light-emitting diodes (OLEDs) have attracted great attention in the past decades because of their potential advantages in full-color displays [1]. As phosphorescent dopants in the emitting layers, heavy metal complexes, such as iridium(III), platinum(II), osmium(II), and ruthenium(II) complexes, can harvest both singlet and triplet excitons for emission and hence lead to efficient OLEDs with the internal quantum efficiency potentially as high as 100% [2–5]. By reason of the theoretical limit from simple classical optics, the external quantum efficiency is confined to ∼20% [6]. An external quantum efficiency of 19.2%

ph/el at a current density of 0.55 mA/cm^2 was achieved by using tris(2-phenylpyridine) iridium(III) (Ir(ppy)$_3$) as a dopant [7]. Kang et al. reported the efficient OLEDs based on Ir(2-(1-cyclohexenyl)pyridine)$_3$ with a maximum external quantum efficiency of 18.7% [8]. Most of reported highly efficient OLEDs were achieved by vacuum deposition technique, and yet solution process owning low cost and convenience advantages is expected to be important to OLEDs for large-area displays [9]. A solution processed OLEDs with an external quantum efficiency of 13.3% at 6.3 mA/cm^2 has been prepared by adopting a neutral osmium(II) complex other than iridium complexes [10].

Recently, we have reported the red device using tris-(1-(2,6-dimethylphenoxy)-4-(4-chlorophenyl)phthalazine) iridium(III) as a dopant by solution process with internal quantum efficiency of nearly 100% [11]. Mi et al. reported

efficient and thermally stable OLEDs using tris(1,4-bis(phenyl) phthalazine) iridium(III) [12]. Based on these works, it is found that the ligands which have the structure of an sp^2-hybrid N-atom adjacent to the chelating N-atom, such as phenylpyridazine and phenylphthalazine derivatives [13], are beneficial for iridium(III) complexes due to the shorter bonding length and the stronger bonding strength between the chelating N-atom and Ir-atom, compared with these analogues which have a C-atom instead of the non-chelating N-atom. It is well known that carbazole-based compounds have been widely used as the host materials for OLEDs due to their high triplet energy and good hole-transporting ability. In addition, there are many reports about the integrations of carbazole modules and iridium(III) complexes which possess the dual functions of light emission and hole transportation [14–20].

In this article, we introduce carbazole unit into a phenylphthalazine derivative to get a novel ligand 9-(4-(4-chlorophenyl)phthalazin-1-yl)-9H-carbazole (HCPC). The ligand can bond to the Ir-atom more strongly, which leads to efficient mixing of the singlet and triplet excited states [12], and the incorporation of carbazole unit is beneficial to improve the charge balance in the electroluminescent (EL) process and enhance thermal stability [21–25]. The corresponding tris-cyclometalated iridium complex Ir(CPC)$_3$ is synthesized by the reaction of the ligand with IrCl$_3$ · 3H$_2$O at 80 °C for 20 h, directly. The thermal, photophysical and electrochemical properties of the complex are studied, and the performance of OLEDs fabricated by solution process is investigated.

2. Experimental

2.1. General information

The solvents were purified by routine procedures and distilled under an atmosphere of dry nitrogen before use. All reagents, unless otherwise specified, were purchased from Aldrich and were used as received. The original compound 1-chloro-4-(4-chlorophenyl)phthalazine was prepared according to the procedure previously reported [26]. ^{1}H NMR spectra were recorded on a Varian Inova500NB spectrometer using CDCl$_3$ as solvent. Elemental analyses of carbon, hydrogen, and nitrogen were performed on a Vario EL microanalyzer. Thermal gravimetric analysis (TGA) was performed under a flow of nitrogen at a heating rate of 10 °C/min with a Perkin–Elmer Pyris Diamond TG/DTA thermal analyzer. Differential scanning calorimetry (DSC) was performed on a Netzsch DSC-200PC instrument at a heating rate of 10 °C/min. Photoluminescence (PL) spectra were measured with a Shimadzu RF-5301PC fluorescence spectrophotometer. Luminescence lifetime was determined on an Edinburgh FL920 time-correlated pulsed single-photon-counting instrument. UV–vis absorption spectra were recorded on a Shimadzu UV-2501 PC spectrophotometer. PL quantum yield was measured at room temperature in an argon prepurged tetrahydrofuran (THF) solution and compared with quinine sulfate in 1.0 N H$_2$SO$_4$ (Φ_{PL} = 0.546) as a standard [27]. Electron ionization (EI) mass spectrum were recorded on a Shimadzu GC–MS-QP2010 PLUS mass spectrometer, and electron

spray ionization (ESI) mass spectra on a Thermo LCQ DECA XP mass spectrometer. Cyclic voltammetry (CV) was performed with a Solartron SI 1287 voltammetric analyzer. It was conducted at room temperature in a typical three-electrode cell with a working electrode (Pt disk), a reference electrode (saturated calomel electrode), and a counter electrode (Pt wire) under a nitrogen atmosphere at a sweeping rate of 100 mV/s in a solution of 0.1 M tetra-n-butylammounium hexafluorophosphate (Bu$_4$NPF$_6$) in anhydrous CH$_2$Cl$_2$. Each oxidation potential was calibrated with that of ferrocene.

2.2. Synthesis of 9-(4-(4-chlorophenyl)phthalazin-1-yl)-9H-carbazole (HCPC)

A 60.5% suspension of sodium hydride (1.0 g, 25 mmol) in paraffin oil was added slowly to a solution of carbazole (4.18 g, 25 mmol) in anhydrous dimethylformamide (70 mL) under nitrogen as a protective gas. After stirred for 1 h at room temperature, this mixture was added dropwise to a solution of 1-chloro-4-(4-chlorophenyl)phthalazine (6.88 g, 25 mmol) in anhydrous dimethylformamide (70 mL) with an ice bath. Then the mixture was stirred at room temperature for 12 h. After reaction, the resulting mixture was poured into water and extracted with chloroform. The extracts were combined, washed with brine, dried over anhydrous magnesium sulfate, and filtered. Then the solvent was evaporated. The product thus obtained was purified by silica gel column chromatography using chloroform as the eluent to give a yellow solid. Yield: 78%. mp: 191–193 °C. ^{1}H NMR (CDCl$_3$): δ 8.22–8.18 (t, 3H), 7.96–7.92 (t, 1H), 7.88–7.84 (d, J = 8.6 Hz, 2H), 7.82–7.78 (t, 1H), 7.76–7.72 (d, 1H), 7.65–7.61 (d, J = 8.6 Hz, 2H), 7.4–7.33 (m, 4H), 7.29–7.26 (d, 2H). EI-MS (m/z): 404 (100%), 405 (68%), 406 (43%), 407 (23%).

2.3. Synthesis of Ir(9-(4-(4-chlorophenyl)phthalazin-1-yl)-9H-carbazole)$_3$ [Ir(CPC)$_3$]

9-(4-(4-Chlorophenyl)phthalazin-1-yl)-9H-carbazole (0.408 g, 1.00 mmol) was dissolved in 2-ethoxyethanol (12 mL) in a 25 mL round-bottom flask. Iridium trichloride hydrate (0.1 g, 0.284 mmol) and water (4 ml) were then added to the flask. The mixture was stirred under nitrogen at 80 °C for 20 h and then cooled to room temperature. The precipitate formed in the mixture was collected and washed with methanol, ether and dried. The product thus obtained was purified by silica gel column chromatography using dichloromethane as the eluent to give a red solid. Yield: 34%. ^{1}H NMR (CDCl$_3$): δ 8.98–8.95 (d, J = 8.7 Hz, 1H), 8.30–8.27 (d, J = 8.7 Hz, 1H), 7.90–7.86 (t, 1H), 7.82–7.78 (d, J = 7.5 Hz, 1H), 7.70–7.67 (d, J = 7.7 Hz, 1H), 7.53–7.48 (t, 1H), 7.23–7.20 (d, J = 8.5 Hz, 1H), 7.20–7.19 (d, J = 2.3 Hz, 1H), 7.13–7.09 (dd, J = 8.5, 2.3 Hz, 1H), 6.92–6.88 (t, 1H), 6.65–6.60 (t, 1H), 6.55–6.52 (d, J = 8.2 Hz, 1H), 6.47–6.43 (t, 1H), 6.00–5.92 (m, 2H). ESI-MS (m/z): [M$^+$+H] Calcd. for C$_{78}$H$_{46}$N$_9$Cl$_3$Ir 1404.26 (29%), 1405.23 (30%), 1406.25 (97%), 1407.25 (82%), 1408.21 (100%), 1409.21 (74%), 1410.20 (44%),1411.23 (22%). Found 1404.25 (33%), 1405.25 (30%), 1406.25 (100%), 1407.25 (82%), 1408.24(99%), 1409.25 (68%), 1410.25 (46%),

2.4. OLED fabrication and measurements

The indium tin oxide (ITO) glass substrate was washed in turn with a substrate-cleaning detergent, deionized water, acetone, and ethanol for 15 min, under ultrasonic condition, and finally treated with ozone for about 20 min. Poly(3,4-ethylenedioxythiophene) doped with poly (styrene sulfonic acid) (PEDOT) (Baytron P4083, Bayer AG) in water was spin-coated at a rate of 3000 rpm on the ITO substrate and dried by baking in air at 120 °C for 10 h. Then the solution of poly(vinylcarbazole) (PVK, M_w = 81,800) (68 wt%) blended with 2-tert-butylphenyl-5-biphenyl-1,3,4-oxadiazole (PBD) (30 wt%) and Ir(CPC)$_3$ (2 wt%) in chloroform was spin-coated at a rate of 1300 rpm on top of the PEDOT layer. The assembly was transferred into a deposition chamber with a base pressure of 3×10^{-6} Torr, a film of 1,3,5-tris(N-phenylbenzimidazol-2-yl)-benzene (TPBI) was evaporated onto the polymer layer. Finally, the Ba and Al layers were evaporated. Current density–voltage–luminance data were collected using a Keithley 236 source measurement unit and a calibrated silicon photodiode. External quantum efficiency was obtained by measuring the total light output in all directions in an integrating sphere (IS080, Labsphere). Luminance and luminous efficiency were measured by a silicon photodiode and calibrated using a PR-705 photometer (Photo Research).

3. Results and discussion

3.1. Synthesis and characterization

The synthetic procedures of the ligand and the complex are shown in Scheme 1. The cyclometalating ligand HCPC was prepared from 1-chloro-4-(4-chlorophenyl)phthalazine reacted with carbazole by an alkali of NaH in a polar solvent. Cl-atom on phthalazine has been replaced by carbazole unit, but Cl-atom on benzene ring did not take part in reaction due to low activity.

The complex Ir(CPC)$_3$ was synthesized by a simple procedure. HCPC reacted with IrCl$_3$ · 3H$_2$O directly formed the tris-cyclometalated iridium complex Ir(CPC)$_3$ at 80 °C for 20 h. Generally, the synthesis of tris-cyclometalated iridium(III) complexes is in need of Ir(III) organic complexes, such as (C^N)$_2$Ir(O^O), (C^N)$_2$Ir(μ-Cl)$_2$Ir(C^N)$_2$ or Ir(O^O)$_3$ (C^N = cyclometalating ligand, O^O = β-diketonate anion),

reacted with excessive free cyclometalating ligand precursors at high temperature [28]. We believe this special reaction is relative to the strong bonding strength and the small steric hindrance between the ligand and the centric Ir-atom. Research on the mechanism of this reaction is currently underway. The complex was also characterized by ^{1}H NMR spectroscopy. The spectra indicate the facial isomer is formed, because three ligands surrounding the iridium atom are magnetically equivalent [29].

3.2. Thermal, absorption, photophysical and electrochemical properties

The thermal properties of the complex were characterized with TGA and DSC under a nitrogen stream. The TGA data reveal that the 5% weight-reduction temperature of Ir(CPC)$_3$ is 444 °C. In comparison, the analogous complex Ir(MPCPPZ)$_3$ which contains 2,6-dimethylphenoxy group instead of carbazole commences decomposition at 388 °C [11]. So, the introduction of carbazole unit can observably improve the thermal stability of the complex. The DSC curve shows no crystallization and melting peaks, and it is revealed that the complex is amorphous. The absorption and photoluminescence spectra of Ir(CPC)$_3$ in dichloromethane at room temperature are shown in Fig. 1. The absorption spectra show broad bands from 270 to 600 nm, and the most intense bands between 270 and 330 nm are attributed to the spin allowed π–π^* transitions from the cyclometalating ligand. The absorption bands around 350–470 nm can be assigned to the spin-allowed metal-ligand charge transfer band (^{1}MLCT). The absorption features at the lowest energy (λ > 470 nm) are attributed to the formally spin-forbidden ^{3}MLCT transition. Upon irradiation with 400 nm light, the complex gives a strong photoluminescence in dichloromethane at 615 nm. The PL quantum yield of Ir(CPC)$_3$ in THF at room temperature is 0.46. The emission decay curve of Ir(CPC)$_3$ in solid state is shown in Fig. 2. The lifetime of Ir(CPC)$_3$ shows double exponentials as 0.182 and 0.837 μs, respectively. Because long lifetime will give rise to the emission saturation and elevate the triplet–triplet annihilation, the suitable lifetime of Ir(III) complex ($\sim$0.1–3 μs) is beneficial to improve the efficiency of OLEDs [30].

The electrochemical properties of Ir(CPC)$_3$ were examined by cyclic voltammetry. The complex showed reversible oxidation processes during the anodic scan in dichloromethane solution, but no clear reduction peak was observed. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital

Fig. 2. Emission decay curve of Ir(CPC)$_3$ in solid state.

Fig. 3. General structure for the device and molecular structures of the relevant compounds.
Fig. 4. Electroluminescence spectra of the device.

Fig. 5. Current density–voltage–luminance curves of the device.

(LUMO) energy levels of Ir(CPC)$_3$ are −5.35 eV and −3.15 eV, estimated by using the oxidation potential and UV–vis absorption spectrum edge. Because its HOMO level is above that of the hosts (−5.8 eV for PVK, −6.2 eV for PBD) and its LUMO level is below that of the hosts (−2.2 eV for PVK, −2.6 eV for PBD), the complex can function as trap for both electrons and holes [31].

3.3. Electroluminescent properties

For studying EL properties of the complex, the OLEDs using Ir(CPC)$_3$ as a dopant was fabricated by solution process with the following structure: ITO/PEDOT(45 nm)/ 2 wt% Ir(CPC)$_3$+ 68 wt% PVK+ 30 wt% PBD (80 nm)/ TPBI(30 nm)/Ba(4 nm)/Al(100 nm). PEDOT was used as a hole-injecting material. PVK and PBD were selected as the host material and the electron transport material, respectively. TPBI acted as both a hole-blocker and an electron-transporter. Fig. 3 shows the general structure of the device and the molecular structures of the compounds used in the device.

The device has a maximum emission at 620 nm (Fig. 4), and the fine vibronic structure of the EL spectra leads us to conclude that EL emission originates from a mixed

^{3}MLCT/$^3\pi$–π^* state [30]. The Commission Internationale de L'Eclairage (CIE) coordinate is (0.65, 0.33) at a driving voltage of 12 V. No emission from the PVK–PBD blend is detected, which implies that the energy transfer from the blend to Ir(CPC)$_3$ is efficient under electrical excitation.

As shown in Fig. 5, the device gives a maximum luminance of 2948 cd/m^2 at a current density of
Fig. 6. External quantum efficiency vs. current density curve of the device.

115.6 mA/cm². A maximum external quantum efficiency of 20.2% corresponding to a luminous efficiency of 11.3 cd/A is obtained at a current density of 0.18 mA/cm². To the best of our knowledge, it is one of the highest reported efficiencies for red-emission OLEDs. Such an outstanding performance can be explained by the high PL quantum yield of Ir(CPC)$_3$ (Φ_{PL} = 0.46), which is higher than those of other known high-performance iridium(III) complexes, such as Ir(ppy)$_3$ (Φ_{PL} = 0.40) and Ir(piq)$_3$ (piq = 1-phenylisoquinolinato) (Φ_{PL} = 0.26) [7,30]. The rigid ligand can significantly reduce the non-radiative transition. Moreover, the hole-transporting carbazole unit in the complex can improve the charge-balance properties in the EL process [21–23]. Compared to other OLEDs fabricated by vacuum deposition, this solution processed device has more advantages for large-area displays, such as low cost, simple preparation.

However, the efficiency roll-off, mostly due to triplet–triplet annihilation of phosphor-bound excitons, is severe at high current density as shown in Fig. 6. An external quantum efficiency of 10.9% is obtained at a current density of 10.6 mA/cm². When the current density increases to 92.7 mA/cm², the external quantum efficiency is 5.7% with a decrease of 47.7%. We believe this poor result arises from unstable thin-film morphology probably induced by the planar structure of the cyclometalating ligand, which tends to cause aggregation of molecules at high current density and then leads to excited-state intermolecular interactions.

4. Conclusions

In summary, we synthesized a new tris-cyclometalated iridium(III) complex by the reaction of 9-(4-(4-chloro-phenyl)phthalazin-1-yl)-9H-carbazole with IrCl$_3$ · 3H$_2$O at 80 °C for 20 h. The device using the complex at 2 wt% doping concentration exhibited excellent performance. A maximum external quantum efficiency of 20.2% corresponding to a luminous efficiency of 11.3 cd/A at a current density of 0.18 mA/cm² and a maximum luminance of 2948 cd/m² at 115.6 mA/cm² were obtained. The optimization to the device for suppressing efficiency roll-off at high current density is in progress.

ABSTRACT

We have demonstrated the electroluminescent (EL) properties of 2-mercaptobenzothiazolate complexes of rare earth metals [Ln(mbt)$_3$, Ln = Y, Sm, Eu, Gd, Tb, Dy, Tm] using simple non-doped two-layer organic light emitting diode with the configuration of indium tin oxide/N,N'-bis(3-methylphenyl)-N,N'-diphenylbenzidine/Ln(mbt)$_3$/Yb. It was found that 2-mercaptobenzothiazolate complexes have highly efficient intra-energy transfer from the singlet to the triplet state of the ligand, and then to the excited state of the central lanthanide ions. Thus Y(mbt)$_3$ and Gd(mbt)$_3$ exhibit the broad ligand-centered emission with maximum near 600 nm and Dy(mbt)$_3$, Tb(mbt)$_3$ and Tm(mbt)$_3$ complexes exhibit pure sharp emission bands from the intra f–f transitions of lanthanide ions Tb^{3+}: $^5D_4 \rightarrow {}^7F_6$ (492 nm), $^5D_4 \rightarrow {}^7F_5$ (547 nm), $^5D_4 \rightarrow {}^7F_4$ (589 nm), $^5D_4 \rightarrow {}^7F_3$ (624 nm); Dy^{3+}: $^4F_{9/2} \rightarrow {}^6H_{13/2}$ (575 nm) and Tm^{3+}: $^3H_4$–$^3H_6$ (795 нм).

1. Introduction

The rare earth metals are unique elements which fascinating luminescent properties lead to an outstanding role in light conversion technologies [1]. In the past decade, the main attention was focused on the application of lanthanide complexes as electroluminescent materials for organic light emitting diodes (OLED) [2,3]. One of the most important problems in this field is a selection of suitable ligands which would provide high efficiency of emission of the metal ions. Up to now the basic research are focused on the lanthanide β-diketonate complexes and its analogues which are limited in terms of practical applications by their poor photo and electro stability [4,5]. Recently, we have proposed the homoleptic 2-mercaptobenzothiazo-

late complexes of rare earth metals Ln(mbt)$_3$ (Ln = Y, La, Sm, Eu, Gd, Tb, Er, Tm) as a new class of luminescent materials [6]. The 2-mercaptobenzothiazolate ligands in these complexes are bonded to the metal atom in η^2-fasion via nitrogen and terminal sulfur atoms forming the chelating structure. These complexes exhibit at 77 K ligand-centered bands of fluorescence (at 395 nm) and phosphorescence (at 550 nm) and weak emission of lanthanide ions (Eu or Tb). Due to the phosphorescence – an emission from the lowest excited electronic triplet state to the electronic singlet ground state – these complexes can be formalized as the triplet emitters. It is well known that the triplet emitters based on metal–organic complexes have attracted significant attention [7]. Nowadays many research groups have focused on the development of efficient light emitting phosphorescent materials based on iridium, platinum, osmium, and ruthenium complexes [7–12]. However, the little attention in this area has been given to the rare earth complexes,

---

meanwhile the rare earth complexes are characterized by highly efficient intra-energy conversion from the ligand singlet to the triplet, and then to the excited state of the central metal ion in the case of lanthanide [1]. The lanthanide ions may be luminescent, either fluorescent (Pr^{3+}, Nd^{3+}, Ho^{3+}, Er^{3+}, Yb^{3+}) or phosphorescent (Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Tm^{3+}) or have no f–f transition (La^{3+} and Lu^{3+}) [13]. So the rare earth complexes may offer to give phosphorescent materials with emission properties in OLED technology.

In this work, we describe the electroluminescent properties of 2-mercaptobenzothiazolate complexes of rare earth metals and their utility in simple two-layer non-doped OLED devices. The prepared devices consisted of exclusively vacuum deposited layers using ITO glass as the anode, N,N'-bis(3-methylphenyl)-N,N'-diphenylbenzidine (TPD) as the hole-transporting layer, $Ln(mbt)_3$ as the electron-transport/emission layers and Yb as the cathode.

2. Experimental section

2.1. General

All manipulations were carried under vacuum using standard Schlenk techniques. The lanthanide complexes $Ln[N(SiMe_3)_2]_3$ [14], $[(Me_3Si)_2N]_3Tb(\mu\text{-Cl})Li(THF)_3$ [15] and $Ln(mbt)_3$ (Ln = Y, Gd, Sm, Eu, Tb, Er, Tm) [6] were synthesized according to the published procedure. Commercial 2-mercaptobenzothiazole (Aldrich) was used without additional purification. IR spectra were obtained on a Perkin Elmer 577 spectrometer and recorded from 4000 to $450 \, cm^{-1}$ as a Nujol mull on KBr plates.

2.2. Synthesis

2.2.1. Tris(benzothiazole-2-thialato-N,S)-dysprosium [Dy(mbt)₃]

The compound was prepared similarly to other $Ln(mbt)_3$ complexes [6]. To a solution of $Dy[N(SiMe_3)_2]_3$ (283 mg, 0.44 mmol) in THF (5 ml) was added a solution of 2-mercaptobenzothiazole (221 mg, 1.32 mmol) in THF (10 ml). The reaction mixture was stirred for 45 min at room temperature and the solvent was evaporated under vacuum. The solid residue was washed with toluene and the beige powder of $Dy(mbt)_3$ was dried under vacuum. Yield: 280 mg, 95%. $C_{21}DyH_{12}N_3S_6$ (661.25): calcd. C 38.14, H 1.83, Dy 24.58; found: C 38.11, H 1.87, Dy 24.52. IR (Nujol, cm^{-1}): 3050 (w), 1597 (w), 1446 (br), 1321 (m), 1247 (m), 1078 (s), 1035 (s), 1013 (s), 753 (s), 727 (w), 708 (br), 670 (m), 606 (w).

2.2.2. Tris(benzothiazole-2-thialato-N,S)-bis(tetrahydrofuran)-terbium tetrahydrofuran solvate [Tb(mbt)₃(THF)₂](THF)

To a solution of $Tb[N(SiMe_3)_2]_3$ (156 mg, 0.24 mmol) in THF (20 ml) was added a solution of 2-mercaptobenzothiazole (121 mg, 0.72 mmol) in THF (20 ml). The reaction mixture was stirred for 15 min at 12 C and then was placed in a freezer for 2 days. The beige crystals suitable for X-ray analysis of $[Tb(mbt)_3(THF)_2](THF)$ was separated by filtration, washed with toluene, and dried under vacuum. Yield: 78 mg, 37%. $C_{33}H_{36}N_3O_3S_6Tb$ (873.99): calcd. C 45.35, H 4.15, Tb 18.18; found: C 45.31, H 4.19, Tb 18.13. IR (Nujol, cm^{-1}): 3054 (w), 1597 (w), 1445 (br), 1321 (m), 1248 (m),

2.2.3. Tris(1,2-dimethoxyethane-O,O′)-lithium-tetra(benzo-thiazole-2-thialato-N,S)-terbium [Tb(mbt)₄Li(DME)₃]

Solution of 2-mercaptobenzothiazole (121 mg, 0.72 mmol) in 5 ml DME was added to a solution of [(Me₃Si)₂N]₃Tb(μ-Cl)Li(THF)₃ (215 mg, 0.24 mmol) in 5 ml DME. The reaction mixture was stirred for 45 min at room temperature and then was placed in a freezer for 2 days. The formed beige crystals were separated by decantation, washed with toluene and dried in vacuum to give 140 mg (53%) of Tb(mbt)₄Li(DME)₃. C₄₀H₄₆LiN₄O₆S₈Tb (1101.23): calcd. C 43.63, H 4.21, Tb 14.43; found: C 43.61, H 4.19, Tb 14.46. IR (Nujol, cm⁻¹): 3054 (w), 1597 (w), 1445 (br), 1321 (m), 1248 (m), 1080 (s), 1027 (s), 1012 (s), 998 (m), 751 (s), 727 (m), 706 (br), 670 (m), 606 (w).

2.3. X-ray crystallography study

The X-ray diffraction data were collected on a SMART APEX diffractometer (graphite-monochromated, MoKα-radiation, φ–ω-scan technique, $\lambda = 0.71073$ Å). The intensity data were integrated by SAINT program [16]. SADABS [17] was used to perform area-detector scaling and absorption corrections. The structures were solved by direct methods and were refined on F^2 using all reflections with SHELXTL package [18]. All non-hydrogen atoms were refined anisotropically. H-atoms in [Tb(mbt)₃(THF)₂](THF) were found from Fourier synthesis and refined isotropically except for the H-atoms of THF molecules in the Er-complex, which were placed in calculated positions and refined in the "riding-model". Details of crystallographic, collection and refinement data for [Tb(mbt)₃-

emission layer were fabricated (Fig. 1). A commercial ITO on glass substrate with 100 Ω/sq. was used as anode material (Merck Balzers) and commercial Yb metal (Sigma–Aldrich) as cathode material. The constituent organic (20 nm) and metal (150 nm) layers were deposited using thermal vacuum evaporation (at a base pressure of approximately 10⁻⁶ mbar) of commercial grade TPD and Yb metal, freshly synthesized Ln(mbt)₃ (Ln = Y, Gd, Sm, Eu, Dy, Tb, Er, Tm). The active area of the devices was a circle with ∅ 8 mm. The EL spectra and current–voltage luminescence characteristics were measured with an Ocean Optics USB-2000 fluorimeter and a computer controlled TEC-23 power supply under ambient conditions.

3. Results and discussion

3.1. Synthesis and structure

The 2-mercaptobenzothiazolate lanthanide complexes Ln(mbt)₃ (Ln = Y, Sm, Eu, Gd, Tb, Dy, Tm) for investigation of their electroluminescent properties were synthesized from the corresponding Ln[N(SiMe₃)₂]₃ and 2-mercapto-benzothiazole, using a previously developed method [6].

For preparation of the terbium complex in crystalline form suitable for X-ray investigation the modified method was used: diluted THF solution of Tb[N(SiMe₃)₂]₃ was added slowly to a diluted solution of 2-mercaptobenzothi-azole at reduced temperature. Another type of terbium 2-mercaptobenzothiazolate has been obtained using the ate-complex [(Me₃Si)₂N]₃Tb(μ-Cl)Li(THF)₃ as the starting reagent. Predictably the treatment of it with 2-mercapto-benzothiazole in DME resulted in a formation of Tb(mbt)₄Li(DME)₃ which was isolated from a reaction clear solution in 53% yield as colorless crystals soluble in THF and DME.
(THF)₂](THF) and Tb(mbt)₄Li(DME)₃ are shown in the Table 1.

2.4. Device fabrication

OLED devices were prepared in a vacuum system with different evaporation chambers for different types of organic and metal layers (cluster-tool) [19]. The simple non-doped two-layer devices ITO/TPD/Ln(mbt)₃/Yb, consisting of triphenyldiamine derivative (TPD) as a hole transport layer, and 2-mercaptobenzothiazolate complex of rare earth metal Ln(mbt)₃ as an electron transport and

Molecular structures of the complexes are shown in Figs. 2 and 3, selected structural parameters are listed in Table 2.

X-ray single crystal structure analysis has revealed that the [Tb(mbt)$_3$(THF)$_2$](THF) is isostructural to the previously reported [Eu(mbt)$_3$(THF)$_2$](THF) and [Er(mbt)$_3$-(THF)$_2$](THF) [6]. The molecules of [Tb(mbt)$_3$(THF)$_2$](THF) have distorted dodecahedral arrangement with the bidentate coordination mode of mbt ligands. The difference between Tb(1)–S(N) and Eu(1)–S(N) or Er(1)–S(N) distances are close to the difference in their ionic radii of the metals whereas the geometric parameters of mbt ligands in the complexes are practically the same. Four-membered metallocycle TbSCN is planar. The mercaptobenzothiazolate Tb(mbt)$_4$Li(DME)$_3$ is ate-complex, containing [Tb(mbt)$_4$]$^-$ anion and Li(DME)$_3^+$ counterion. In a crystal there are two independent types of the molecules, which negligibly differ to each other by geometry of the anionic fragments. One of the types is presented in Fig. 3. Four bidentate mbt ligands form a distorted Tb-centered dodecahedron. Its structure and geometric parameters is similar to that of [Nd(mbt)$_4$] in the complex [K(15-crown-5)$_2$][Nd(mbt)$_4$] [20] and virtually coincide with those of respective fragment in [Tb(mbt)$_3$(THF)$_2$](THF). It should be noted that solvent plays the important role in formation, structure and properties of the complexes. To

gain more insight into the problem we calculated the shielding of central metal atom by ligand solid angle approach (*G*-parameter) [21]. The *G* -parameter in [Tb(mbt)$_3$(THF)$_2$](THF) (88.6(2)%) noticeably exceeds the analogous value in Tb(mbt)$_4$ anion (83.7(2)%). In the molecule of [Tb(mbt)$_3$(THF)$_2$](THF) only two THF ligands coordinate the Tb cation whereas the third THF molecule remains free in crystalline space. Each intersphere THF ligand shields 12–13% space at the Tb atom and consequently there is no room in coordination sphere for the third THF molecule. At the same time, the hypothetical Tb(mbt)$_3$ complex (free of coordinated THF) would have too low value of *G*-parameter, 62.8(2)%. Thus the coordination of two THF molecules stabilizes [Tb(mbt)$_3$-(THF)$_2$](THF) complex and influences on his structure. The different situation is observed in Tb(mbt)$_4$Li(DME)$_3$. The value of *G*-parameter of DME molecules in rare earth complexes is 29.9(6)%. The additionally coordination of DME should increase the shielding of central metal up to 113% that is impossible. Thus, despite the fact that DME is a strongly coordinated solvent, there is insufficient room about the Tb atom to accommodate the DME molecule. In other words, non-bonding ligand–ligand interactions in coordination sphere of Tb prevent the intersphere solvatation of the lanthanide atom.

3.2. EL properties

To follow up on the discovery of electroluminescent properties of these complexes we fabricated the simple non-doped two-layer OLEDs with the structures of ITO/TPD/Ln(mbt)$_3$/Yb. It should be noted that all these devices do not reveal the emission according the fluorescence component at 395 nm. Predictably as Y^{3+} have 4f^0 electronic configuration the device based on Y(mbt)$_3$ exhibits the broad peak centered at 600 nm (Fig. 4), which is contributed to phosphorescent emission at 550 nm. As it is shown in Fig. 4, the gadolinium complex, due to the stability of the half-filled 4f^7 shell configuration in Gd^{3+} ion, demonstrates the broad emission band centered at 640 nm. Note that the device based on the complex with heavy and strong paramagnetic gadolinium ion exhibit the higher luminance than the device based on the complex with diamagnetic yttrium ion. In contrast, Dy(mbt)$_3$, Tb(mbt)$_3$ and Tm(mbt)$_3$
Fig. 4. EL spectra of the devices with different emitting layers ITO/TPD/Gd(mbt)$_3$/Yb (1), and ITO/TPD/Y(mbt)$_3$/Yb (2) obtained at 12 V.

Fig. 6. Current density as a function of operating voltage for OLED devices ITO/TPD/Tb(mbt)$_3$/Yb (1), ITO/TPD/Eu(mbt)$_3$/Yb (2), and ITO/TPD/Sm(mbt)$_3$/Yb (3).
Fig. 7. EL spectra of the devices with different emitting layers ITO/TPD/Tb(mbt)$_3$/Yb (1), ITO/TPD/[Tb(mbt)$_3$(THF)$_2$](THF)/Yb (2), and ITO/TPD/Tb(mbt)$_4$Li(DME)$_3$/Yb (3) obtained at 12 V.
Fig. 8. Luminance as a function of operating voltage for OLED devices ITO/TPD/Tb(mbt)$_3$/Yb.

complexes exhibit only sharp emission bands from the intra f–f transitions of lanthanide ions Tb^{3+}: $^5D_4 \rightarrow {}^7F_6$ (492 nm), $^5D_4 \rightarrow {}^7F_5$ (547 nm), $^5D_4 \rightarrow {}^7F_4$ (589 nm), $^5D_4 \rightarrow {}^7F_3$ (624 nm); Dy^{3+}: $^4F_{9/2} \rightarrow {}^6H_{13/2}$ (575 nm) and Tm^{3+}: $^3H_4$–$^3H_6$ (795 нм). (Figs. 5 and 7) Unfortunately, EL devices based on Sm(mbt)$_3$ or Eu(mbt)$_3$ turned out the luminescence though their current–voltage (I–V) characteristics are quite similar to that of Tb(mbt)$_3$ (Fig. 6).

Compared to the previous results [6] of the photoluminescence of these complexes the EL spectra have a red shift which can be attributed to the solvent influence (for PL) or to the congregated molecular state (for EL). It is well known that as a model system, the undoped OLEDs directly based on the molecular properties of emitting material in which both the singlet and triplet states are populated by excitation. The fact that an emission from the singlet state is not observed in EL spectra is resulted from the efficient intersystem crossing from the singlet to the triplet excited state for all of these complexes. For lack of emission from the triplet to the ground state in the case of Tb, Dy, Tm, Sm and Eu complexes suggests subsequent efficient crossing from the triplet to the emissive and non-emissive intra

f levels of these lanthanide ions. Furthermore, the pure metal-centered emission of Tb, Dy and Tm also confirms this statement.

Comparing the luminescent characteristics of the EL devices based on Tb(mbt)$_3$, [Tb(mbt)$_3$(THF)$_2$](THF) and [Tb(mbt)$_4$][Li(DME)$_3$] we have found that emission intensity of the first complex is significantly higher than that of two latter compounds (Fig. 7). One of plausible explanation of it is decreased thermal stability of THF and Li containing compounds, which partially decompose at sublimation during the OLED device fabrication. Moreover OLED device ITO/TPD/Tb(mbt)$_3$/Yb displays significant improvements in EL performance compared with the devices based on another Ln(mbt)$_3$ complexes. Fig. 8 presents the luminance–voltage (L–V) characteristic of this device, Fig. 9 shows the current efficiency (in cd/A), and Fig. 10 shows the power efficiency (in lm/W) vs. the current density. It is found that even for the device which is not yet optimized, the green emission appears when the bias is above 7.7 V, and at 12 V the current efficiency of 0.16 cd/A is achieved. Note that the efficiency decreases slowly with an increase of the current
Fig. 9. Current efficiency vs. current density for OLED devices ITO/TPD/Tb(mbt)$_3$/Yb.
Fig. 10. Power efficiency vs. current density for OLED devices ITO/TPD/Tb(mbt)$_3$/Yb.

density, suggesting that the device based on Tb(mbt)$_3$ demonstrates the rather high stability in a current than lanthanide β-diketonate complexes. This gives the ground to consider 2-mercaptobenzothiazolate lanthanide complexes as a promising material for design of efficient OLED.

4. Conclusions

In summary, we report for the first time the EL properties of 2-mercaptobenzothiazolate complexes of rare earth metals with the non-doped simple OLEDs of configuration ITO/TPD/Ln(mbt)$_3$/Yb. Depending on the nature of the rare earth metal in the complexes, emission wavelengths span from the broad visible spectrum considering the ligand-centered phosphorescence to the sharp emission bands from the intra f–f transitions of lanthanide ions. This suggests that 2-mercaptobenzothiazolate complexes have highly efficient intra-energy transfer from the singlet to the triplet state of the ligand, and then to the excited state of the central lanthanide ions, to give phosphorescent materials with emission properties which may be tuned specifically for optimum performance in OLED technology.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC nos. 710983 and 710984 for [Tb(mbt)$_3$(THF)$_2$](THF) and Tb(mbt)$_4$Li(DME)$_3$. This material can be obtained upon request to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (www.ccdc.cam.ac.uk; email: deposit@ccdc.cam.ac.uk).

Donor acceptor type neutral state green polymer bearing pyrrole as the donor unit

Selin Celebi, Abidin Balan, Bugra Epik, Derya Baran, Levent Toppare *

Department of Chemistry, Middle East Technical University, 06531 Ankara, Turkey

ABSTRACT

A new neutral state green polymer, poly (2,3-bis(4-tert-butylphenyl)-5,8-di(1H-pyrrol-2-yl) quinoxaline) (PTBPPQ) was synthesized and its potential use as an electrochromic material was investigated. Spectroelectrochemistry studies showed that polymer reveals two distinct absorption bands as expected for a donor–acceptor type polymer, at 408 and 745 nm. In addition, polymer has excellent switching properties with satisfactory optical contrasts and very short switching times. Outstanding optical contrast in the NIR region and stability make this polymer a great candidate for many applications. It should be noted that PTBPPQ is one of the few examples of neutral state green polymeric materials with superior switching properties. Hence, PTBPPQ can be used as a green polymeric material for display technologies.

1. Introduction

Conjugated polymers have attracted a great attention after their discovery [1], since these materials can be used as active layers in polymer light emitting diodes [2], sensors [3], batteries [4], artificial noses and muscles [5], transistors [6] and electrochromic devices [7]. Electrochromism is defined as the reversible and visible change in the transmittance and/or reflectance of a material caused by an applied voltage [8,9]. First studies in the field of electrochromism were on inorganic materials such as tungsten oxide (WO_3) and iridium dioxide (IrO_2) [10]. Inorganic materials lack color tuning and require use of relatively high voltages to operate devices. Organic compounds such as conducting polymers became great candidates for electrochromic devices. As regards to the advantages of conducting polymers; high optical contrasts [11], short switching time [12,13], processability [14], fine tuning of the band gap via structure modification [15], and more importantly low applied voltages [16] are worth to mention.

Due to the extended delocalization of π electrons along the polymer backbone, an optical absorption band in the visible region of the electromagnetic spectrum occurs. The insertion of an anion or a cation occurs when the redox processes generate charge carriers on the conjugated backbone [17]. One of the method of increasing stability of the doping process is to incorporate donor–acceptor (D–A) units into the polymer backbone. Moreover, D–A method is also used for reducing the band gap energy [18–20]. While electron donor group raises the HOMO energy and lowers the oxidation potential, electron acceptor group

lowers the energy of conduction band (LUMO) hence; reduction occurs easily [21–23].

Several pyrrole derivatives were employed in the field of electrochromism, such as; the use of modified pyrrole [16], in situ synthesis of pyrrole [24–27], and use of pyrrole in donor acceptor type polymers. Up to date there are few studies where pyrrole has been used as the donor/acceptor unit [28]. In our previous studies, quinoxaline derivatives [29–31] were efficiently used as the acceptor unit. Ethylenedioxythiophene (EDOT) and thiophene derivatives were used as the donor units for those studies. Pyrrole was rarely used as the donor unit with a quinoxaline acceptor unit in D–A type polymers [32,33].

There are a number of electrochromic polymers reflecting red and blue color in their neutral states [34,35] whereas few studies have been reported related to polymers reflecting green color [36–38]. In order to have red or blue color in reduced state, the materials have to absorb at only one dominant wavelength. On the contrary, for a green color, there should exist at least two simultaneous absorption bands in the red and blue regions of the visible spectrum where these bands should be controlled with the same applied potential.

Here we report the synthesis of a newly designed donor–acceptor type polymer. The unique polymer bears pyrrole as the donor unit. The polymer, namely 2,3-bis(4-tert-butylphenyl)-5,8-di(1H-pyrrol-2-yl)quinoxaline, revealed higher optical contrast in near IR region and faster switching time compare to 2,3-bis(4-tert-butylphenyl)-5,8-(2,3-dihydrothieno[3,4-b][1,4]dioxin-7yl)quinoxaline (TBPEQ) [30] and (2,3-bis(4-tert-butylphenyl)-5,8-bis(4-hexylthiophen-2-yl)quinoxaline) (HTQ) [31].

2. Experimental

2.1. Materials

All chemicals were purchased from Aldrich except anhydrous tetrahydrofuran (THF) which was purchased from Acros. 4,7-Dibromobenzo[1,2,5]thiadiazole [39], 3,6-dibromo-1,2-phenylenediamine [40], benzoin [41], benzyl [41], 1,2-bis(4-tert-butylphenyl)-2-hydroxyethanone [42], 1,2-bis(4-tert-butylphenyl)ethane-1,2-dione [42], 5,8-dibromo-2,3-diphenylquinoxaline [43], tert-butyl pyrrole-1-carboxylate [44], N-(tert-butoxycarbonyl)-2-(trimethylstannyl)pyrrole [44] were synthesized according to previously described methods. Electropolymerization was performed with a Voltalab 50 potentiostat in a three-electrode cell consisting of platinum wire or Indium Tin Oxide (ITO) coated glass as the working electrodes, platinum wire as the counter electrode, and an Ag wire as the pseudo reference electrode. Electrodeposition was performed from a 0.1 M solution of tetrabutylammonium perchlorate (TBAPC) at a scan rate of 100 mV/s for 15 cycles. UV–Vis–NIR spectra were recorded on a Varian Cary 5000 spectrophotometer at a scan rate of 2000 nm/min. ^{1}H and ^{13}C NMR spectra were recorded in CDCl$_3$ on Bruker Spectrospin Avance DPX-400 Spectrometer. Colorimetry measurements were performed via Minolta CS-100 Spectrophotometer.

2.2. Monomer synthesis

2.2.1. 5,8-Bis[N-(tert-butoxycarbonyl)-2-pyrrolyl]2,3-bis(4-tert-butylphenyl) quinoxaline

5,8-Dibromo-2,3-bis(4-tert-butylphenyl) quinoxaline (550 mg, 1.0 mmol), and N-(tert-butoxycarbonyl)-2-(tributylstannyl)pyrrole (2.29 g, 5.0 mmol) were dissolved in anhydrous THF (150 ml) and purged with argon for 30 min. Then, dichlorobis(triphenyl phosphine)-palladium(II) (75 mg, 0.068 mmol) was added at room temperature under argon atmosphere. The mixture was refluxed for 3 days. Solvent was evaporated under vacuum and the crude product was purified by column chromatography on neutral alumina (eluent DCM:hexane, 2:1 v/v) to obtain 456 mg (63%) of 5,8-bis[N-(tert-butoxycarbonyl)-2-pyrrolyl]2,3-bis(4-tert-butylphenyl) quinoxaline. ^{1}H NMR (CDCl$_3$, δ): 0.9 (s, 18 H), 1.22 (s, 18 H), 6.26 (t, 2H, J = 6.4 Hz), 6.32 (d, 2H, J = 7.0 Hz), 7.22 (d, 4 H, J = 8.8 Hz) 7.43 (d, 4 H, J = 8.4 Hz), 7.48 (q, 2 H, J = 3 Hz), 7.66 (s, 2 H). ^{13}C NMR (CDCl$_3$, δ): 152.0, 151.2, 149.8, 139.0, 136.1, 133.3, 131.5, 129.7, 128.0, 125.1, 123.0, 115.0, 110.4, 83.0, 34.7, 31.2, 27.2.

2.2.2. 5,8-Bis [2-pyrrolyl] 2,3-bis(4-tert-butylphenyl) quinoxaline (TBPPQ)

5,8-Bis [N-(tert-butoxycarbonyl)-2-pyrrolyl] 2,3-bis(4-tert-butylphenyl) quinoxaline (350 mg, 0.48 mmol) was dissolved in 60 ml methanol. About 120 mg Na, (5.2 mmol) was added and the reaction mixture was heated under reflux for 24 h. The solvent was evaporated and the residue was treated with water and extracted with dichloromethane. The organic extracts were dried over MgSO$_4$, the solvent was evaporated and the residue chromatographed on a column with silica gel using hexane:DCM (2:1 v/v) as eluent. In the second fraction 180 mg (72%) of product TBPPQ isolated. ^{1}H NMR (CDCl$_3$, δ): 1.31 (s, 18 H), 6.27 (m,2H), 6.82(m, 2H), 6.90 (m, 2H), 7.35 (d, 4 H, J = 8.4 Hz), 7.41 (d, 4 H, J = 8.8 Hz), 8.00 (s, 2 H), 11.93 (s, 2 H). ^{13}C NMR (CDCl$_3$, δ): 152.7, 151.4, 138.0, 136.4, 131.4, 129.7, 126.3, 125.8, 125.7, 119.7, 109.5, 107.7, 35.1, 31.6. MS: m/e 525 (M$^+$). IR (drift) v: 1084, 1112, 1392, 1473, 1608, 2962, 3350 cm^{-1}

3. Results and discussion

3.1. Monomer synthesis

The reagent 2,1,3-benzothiadiazole was brominated in the presence of a HBr/Br$_2$ mixture (95%) and reduced with an excess amount of NaBH$_4$ to give 3,6-dibromo-1,2-phenylenediamine as pale yellow solid. The purified compound was condensed with 1,2-bis(4-tert-butylphenyl)ethane-1,2-dione in ethanol to afford 5,8-dibromoquinoxaline. In oder to achieve N-(tertbutoxycarbonyl)-2-(tributylstannyl)pyrrole (2), pyrrole was N-protected by using di-tert-butyl dicarbonate (Boc)$_2$O and reacted with tri-n-butylstannyl chloride after lithiation at the 2 position. Deprotection of pyrrole substituents in (3) after coupling reaction between (1) and (2) resulted in donor acceptor type monomer TBPPQ (Scheme 1).
Scheme 1. Synthetic route of monomer.

3.2. Electropolymerization

The potentiodynamic electropolymerization of monomer on ITO was performed in a 0.1 M TBAPC and 1×10^{-2} M TBPPQ solution applying potentials between 0.0 V and +1.0 V at a scan rate of 100 mV/s via multiple scan voltammetry. Due to the poor solubility of the monomer in acetonitrile (ACN), a mixture of ACN and dichloromethane (DCM) (95/5, v/v) was chosen as the solvent. The representative electrochemical growth revealing electroactivity of monomer TBPPQ and formation of corresponding insoluble polymer are given in Fig. 1. Polymerization was repeated on a Pt (1 cm × 1 cm) elec-

trode to obtain a 20 μ thick free standing film for conductivity measurement (10^{-2} S/cm). The monomer oxidation potential was observed at 0.54 V (0.27 V vs Fc/Fc$^+$), which is quite lower than the oxidation potentials of either of pyrrole, TBPEQ and HTQ. This observation can be attributed to a more effective D–A match. After the first cycle, an oxidation peak at 0.23 V and its reverse cathodic peak at 0.13 V appeared. These values are also quite lower than those for polypyrrole and PHTQ and comparable with PTBPEQ. A direct relation between current response and scan rate was observed for polymer film which proved that the film was well adhered on the electrode surface and electroactive (Fig. 2). The TBPPQ was coated on Pt wire potentiodynamically over 40 cycles from a 0.01 M monomer and 0.1 M TBAPC DCM/ACN (5/95, v/v) solution.

Fig. 1. Repeated potential scan electropolymerization of TBPPQ (10^{-2} M) at 100 mV/s in 0.1 M TBAPC in DCM/ACN (5/95, v/v) on ITO electrode vs Ag wire after 40 cycles.
Fig. 2. Scan rate dependence of PTBPPQ film on Pt vs Ag wire in 0.1 M TBAPC/ACN (a) 100, (b) 150, (c) 200, (d) 250, (e) 300 mV/s.
Fig. 3. Switching ability of PTBPPQ on ITO coated glass slide vs Ag wire in 0.1 M TPAPC/PC with a 200 mV/s scan rate at −0.5 V and +1.0 V.

Anodic and cathodic peak currents revealed a linear relationship as a function of scan rate for polymer film, indicating that electrochemical processes are not diffusion limited and reversible even at high scan rates [45,17].

The long-term switching stability is a severe requirement for electrochromic polymers due to their potential uses in numerous commercial applications, especially smart windows [46]. To investigate this characteristic, PTBPPQ film was deposited on ITO electrode with repeated scanning in TBAPC/DCM/ACN. The polymer film was washed with ACN to remove unreacted monomer, later cycled for 4000 times with a scan rate of 200 mV/s in 0.1 M TBAPC/propylenecarbonate (PC). The overall charge involved in the electrochemical process was calculated. Once the polymer electrochemical equilibration has been reached after 400 cycles, PTBPPQ showed 13% decrease upon cycling for 4000 times (Fig. 3).

3.3. Spectroelectrochemistry

Spectroelectrochemical studies were performed in order to monitor in situ optical changes upon doping. Spectral changes were recorded by UV–Vis–NIR spectrophotometer in a monomer free, 0.1 M TBAPC/ACN solution while varying the applied potential between −0.5 V and +1.1 V. Generally, donor acceptor type polymers show two distinct absorption maxima due to high energy and low energy π–π^* transitions [47]. As a donor acceptor polymer, PTBPPQ showed these absorption maxima due to the transitions from pyrrole based valence band to its antibonding counterpart as well as to the substituent localization narrow conduction band [48]. In order to achieve green color these absorption bands should be observed in the visible region at around 400 nm and 700 nm. PTBPPQ showed π–π^* transitions centered at 408 nm and 745 nm. As doping proceeds, formation of charge carriers leads to new absorption bands at 1100 nm and 1480 nm while absorptions for the neutral state are decreasing. This change represents the formation of polaron and bipolaron bands respectively [49]. The band gap of the polymer is 1.25 eV which was calculated from the onset of the second π–π^* transition. This value is in good agreement with values reported for the polymers having the same acceptor unit, with EDOT and 3-hexylthiophene as the donor units (PTBPEQ: 1.18 eV and PHTQ: 1.75 eV) [30,31]. Spectroelectrochemical studies for the polymer film showed that the color of the film changed from saturated green (Y:464, x:0.301, y:0.401) to brownish green (Y:492, x:0.309, y:0.358) during oxidation (Fig. 4). Coloration efficiency is the ratio between the injected/ejected change per unit area of the electrode and the change in the optical density at a dominant wavelength. Coloration efficiency of the PTBPPQ was found to be 85 cm² C⁻¹ at 100% full switch at 408 nm.
Fig. 4. Spectroelectrochemistry of PTBPPQ film on ITO-coated glass slide in a monomer free, 0.1 M TBAPC/ACN electrolyte–solvent couple at applied potentials (V) vs Ag wire: (a) −0.5, (b) −0.4, (c) −0.3, (d) −0.2, (e) −0.1, (f) 0.0, (g) 0.1, (h) 0.15, (i) 0.2, (j) 0.25, (k) 0.3, (l) 0.35, (m) 0.4, (n) 0.45, (o) 0.5, (p) 0.6, (q) 0.7, (r) 0.8, (s) 0.9, (t) 1.0, and (u) 1.1.
Fig. 5. Electrochromic switching, percent transmittance change monitored at 1480 nm for PTBPPQ in 0.1 M TBAPC/ACN.

3.4. Kinetic studies

In order to determine switching time and percent transmittance change ($\Delta T\%$) of the polymer between neutral and oxidized states, it was polymerized on ITO coated glass slides. The polymer film was stepped between −0.5 V and 1.1 V with a switching interval of 5 s in 0.1 M TBAPC/ACN while recording percent transmittance as a function of time (Fig. 5). PTBPPQ film showed 21% optical contrast at 408 nm and a 12% optical contrast at 745 nm. In the NIR region it showed a remarkable contrast of 65% which confirmed that it can be used for near-IR applications. A square-wave potential step method was used to calculate switching time. The polymer achieved 95% of its optical contrast in 0.6 s at 408 nm. At 745 nm, which corresponds to the second π–π^* transition, switching time recorded as 0.3 s. In the near-IR region (1480 nm), polymer film showed a remarkably fast switching time of less than 0.2 s [50–52]. Kinetic studies for polymer film showed that PTBPPQ has not only a comparable optical contrast, but also faster switching times compare to its competitors, PTBPEQ [30] and PHTQ [31].

4. Conclusion

A novel pyrrole substituted quinoxaline monomer was synthesized via Stille coupling reaction. Monomer was electrochemically polymerized to investigate its potential use as a neutral state green electrochromic material. The polymer revealed high optical contrast in NIR region with excellent switching properties, and stability. PTBPPQ was shown to be one of the few examples of neutral state green polymeric materials in literature. Stability and very fast switching times make this neutral state green polymer a robust candidate for the completion of RGB color space. Considering these advanced properties, many quinoxaline derivatives can be utilized in the polymer backbone for synthesis of new superior polymers to be used in electrochromic devices.

The energy level alignment and chemical reaction at the interface between the hole injection and transport layers in an organic light-emitting diode (OLED) structure has been studied using in-situ X-ray and ultraviolet photoelectron spectroscopy. The hole injection barrier measured by the positions of the highest occupied molecular orbital (HOMO) for N,N'-bis(1-naphthyl)-N,N'-diphenyl-1,1'-biphenyl-4,4'-diamine (NPB)/indium tin oxide (ITO) was estimated 1.32 eV, while that with a thin WO₃ layer inserted between the NPB and ITO was significantly lowered to 0.46 eV. This barrier height reduction is followed by a large work function change which is likely due to the formation of new interface dipole. Upon annealing the WO₃ interlayer at 350 °C, the reduction of hole injection barrier height largely disappears. This is attributed to a chemical modification occurring in the WO₃ such as oxygen vacancy formation.

1. Introduction

OLEDs (organic light-emitting diodes) are display devices composed of multiple organic layers that create light by electron-hole recombination. The improvement of OLED performance has been achieved by controlling the charge carrier injection and transport passing through each layer. The inorganic/organic interfacial contact in OLEDs is important to charge injection and transport characteristics since the choice of interlayer structure has a large influence on the electron/hole injection efficiency. For instance, by adopting ultrathin metal oxides such as SiO_2, WO_3, MoO_3, and V_2O_5 layers between the anode and the hole transport layer (HTL), the OLED performance could be largely enhanced [1–5].

Among them, tungsten trioxide (WO₃) is lately drawing strong attention as a promising hole injection layer (HIL) since it has a very high work function (~6.2 eV) and is highly transparent in visible region [6]. The bulk structure of WO₃ has various phases at different temperatures. It is monoclinic at temperatures from 17 °C to 330 °C, orthorhombic from 330 °C to 740 °C, and tetragonal above 740 °C [7]. J. Meyer et al. reported that an OLED using the WO₃ layer exhibited a largely reduced operation voltage and its power efficiency was improved by about twice compared to the OLED without the WO₃ layer [6]. In addition, Li et al. reported that after thermal annealing WO₃ buffer layer at 450 °C, the structure of WO₃ was changed from amorphous to crystalline phase and consequently WO₃ further enhanced the device performance at the WO₃ thickness of 1.0 nm [8]. Also many other reports have shown that the WO₃ interlayer adopted as an HIL improved the device efficiency [9,10]. However, the mechanism for

this improvement is not clearly understood yet at the film interface level. Therefore the elucidation of the interfacial electronic structures between anode and organic semiconductor is necessary for understanding and further improving the device performance.

In this paper, we will show ultraviolet photoelectron spectroscopy (UPS) studies of the N,N′-bis-(1-naphyl)-N,N′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB)/indium tin oxide (ITO) interface, and the structure of a thin WO_3 layer inserted between the NPB and ITO anode. We have studied the change in the electronic structures and the energy level alignment at each interface. Also, to investigate the structural and chemical changes of WO_3 upon the annealing, X-ray photoelectron spectroscopy (XPS) is applied.

2. Experimental

The part of OLED structures used here were NPB/WO_3 on ITO substrate, in which the NPB, WO_3, and ITO covered glass substrate were used as HTL, HIL, and anode, respectively. ITO coated glass had been cleaned by chemicals and undergone a UV ozone treatment before insertion into a chamber. After each deposition of a target film, the sample was transferred to an analysis chamber without exposing to air. WO_3 layers were prepared below 2.0×10^{-7} Torr by thermal evaporation of WO_3 powder (99.99% purity) in a crucible wound with W filament for heating. NPB film was also deposited similar way. The film thickness was controlled by a quartz crystal microbalance. The typical deposition rate was 0.1 Å/s. To investigate the influence of the WO_3 structural change on the interface, the WO_3 film was annealed in ultra high vacuum (UHV) at 350 °C for 15 min ($P = 2.0 \times 10^{-8}$ Torr) and subsequently cooled down to room temperature. The heating temperature was measured by a thermocouple connected to the sample.

The experiments were performed in an UHV system consisting of a sample preparation chamber and analysis chamber. The UPS spectra were recorded on VG ESCALAB 220i system with a hemispherical electron energy analyzer using a HeI (21.2 eV) gas discharge lamp. And the samples were biased to −10 and −5 V for the measurement of secondary cutoff region and near Fermi level (E_F, binding energy = 0), respectively. For XPS measurement, a Mg K_α (1253.6 eV) radiation was used as the excitation source. The XPS and UPS spectra were collected under normal emission.

A fitting procedure was performed on the W 4f spectra using an XPS curve fitting program. Each W 4f emission peak was fit with a doublet of Voigt functions with a constant branching ratio (0.75) and a spin-orbit splitting (2.12 eV) between $4f_{7/2}$ and $4f_{5/2}$.

3. Results and discussion

Fig. 1 shows the UPS spectra of secondary cutoff for work function measurement, valence band region, and the zooming in near E_F region, respectively as a function of NPB thickness on ITO film. Upon the adsorption of NPB, the film work function gradually decreases to 4.08 eV at the NPB thickness of 2 nm in Fig. 1a. The total work function change measures 0.74 eV possibly due to the formation of interface dipole between NPB and ITO [11,12]. The NPB/ITO interface spectra in Fig. 1b clearly show a series of characteristic peaks for the valence band structure of NPB at 9.1, 7.0, and 4.0 eV as the NPB thickness increases. Those peak positions are in good agreement with the previous results for the molecular orbitals of the NPB film [13–15]. In particular, the highest occupied molecular orbital (HOMO) is mainly localized on the N-nonbonding orbitals. As shown in the near E_F region of
Fig. 1. UPS spectra as a function of NPB thickness on ITO substrates. (a) Secondary cutoff region, (b) valence band region and (c) near E_F region (arrow in graph: hole injection barrier height).

Fig. 1c, the HOMO level of NPB moves slightly to the high binding energy side as the layer thickens. This movement of the HOMO peak is not due to the charging of the NPB films, since a time-dependent measurement of UPS spectra does not show any change with irradiation time. Rather than that, the initial shift of the HOMO position is related to molecular orientation change and interface dipole formation at submonolayer regime. This means there is no serious misleading in determination of peak positions upto this film thickness. The hole injection barrier height, estimated by the difference between the onset of HOMO energy and the Fermi level (E_F), is 1.32 eV at the 2 nm thickness. This value is readily in the range of previously reported results [1,5].

In the UPS spectra of WO_3/ITO interface in Fig. 2b, the increase of the WO_3 layer thickness clearly shows new emission features at 4.5 and 6.4 eV. These peaks are attributed to O 2p-derived band (4.5 eV) and O 2p-W 5d hybridized states (6.4 eV), respectively [16]. Another weak feature near E_F in Fig. 2c is attributed to W 5d band, which is originated from imperfect stoichiometry of WO_3 [16,17]. For WO_3 layer thicker than 1.5 nm, the valence band region does not show any peak changes or new emission features. Since thicker WO_3 films showed worse electrical performance [8], we concluded that the saturated behaviour in terms of UPS spectra at the WO_3 thickness of 1.5 nm is a good choice for the platform for the following NPB deposition. Moreover, the work function of the WO_3 film already reaches a high value of 6.26 eV at the thickness of 1.5 nm. When NPB is deposited on the WO_3/ITO layer, the secondary cutoff moves toward high binding energy by about 1.50 eV (Fig. 2a). The valence band spectra show different binding energies for NPB at 8.4, 6.3, and 3.3 eV in Fig. 2b.

The overall energy shift by 0.7 eV toward the low binding energy side is observed in comparison with NPB/ITO case in Fig. 1b. In case of MoO_3, Lee et al. observed a gap state at 0.15 eV for 0.1 and 0.3 nm of NPB on MoO_3 in HOMO region [5]. But there is no such new emission peak in NPB/WO_3/ITO film in Fig. 2c. The most remarkable change is the hole injection barrier height of NPB, which is largely decreased to 0.46 eV by the insertion of WO_3 layer (Fig. 2c). The origin of this result will be discussed in Fig. 6. In addition we could observe the barrier height of 0.24 eV at the WO_3/ITO interface.

As mentioned before, the WO_3 has various bulk phases at different temperatures and its structure transformation influences the electrical properties of an OLED film [8]. To investigate any change of interfacial electronic structure of WO_3 due to high temperature treatment, UHV annealing was performed at 350 °C for 15 min after 1.5 nm of WO_3 deposition on ITO. As shown in the Fig. 3a, the total shift of the secondary cutoff position of NPB on the annealed WO_3 is 0.59 eV. Fig. 3b shows that the valence band spectra of WO_3 and NPB/WO_3 become broadened and overall peaks are largely attenuated by the annealing of WO_3 film. On the other hand, the very small peak close to the E_F on WO_3 gains intensity upon annealing. Since this peak is attributed to W 5d state [16,17], its intensity increase means the partial reduction of W atoms. This change is consistent with W 4f core level spectra, as discussed below. In addition, the hole injection barrier for the annealed WO_3 is decreased to 0.06 eV in Fig. 3c. However, the energy difference between the HOMO of NPB (2 nm) and the E_F is increased to 1.50 eV. In addition, other high binding peaks are shifted back to 9.5, 7.4, and 4.4 eV in comparison with those in Fig. 2b.
Fig. 2. UPS spectra of NPB/WO_3/ITO interface. (a) Secondary cutoff region, (b) valence band region and (c) near E_F region (arrows in graph: whole injection barrier heights).
Fig. 3. UPS spectra for WO_3 films on ITO before and after annealing, and 2 nm of NPB on the annealed WO_3. (a) Secondary cutoff region, (b) valence band region and (c) near E_F region (arrows in graph: hole injection barrier heights).

To look into the reason for the above changes induced by the WO_3 interlayer, we carried out XPS experiments. Fig. 4 shows the XPS core level spectra of W 4f for different multilayer films. As prepared by thermal deposition in Fig. 4a, the W 4f spectrum presents a sharp doublet peak at 36.09 eV ($4f_{7/2}$) and a broad $5p_{3/2}$ core level peak approximately at 42 eV. These peak positions have been assigned to the WO_3 compound in W^{6+} chemical state [16–20]. When NPB film is deposited on the WO_3 layer, the W 4f peak shape and position do not change at all,
but its intensity is slightly attenuated as shown in Fig. 4b. After annealing the WO_3 film under UHV, the W 4f peak becomes broad with a clear shoulder on the low binding energy side in Fig. 4c. In similar way, the $5p_{3/2}$ peak area can be regarded negligible in fitting the spectra hereafter. The W 4f peak is fitted by three different components at the $4f_{7/2}$ binding energies of 35.98 (W1), 34.66 (W2), and 36.93 eV (W3). This spectral change and peak decomposition upon the annealing are consistent with the previous study where the WO_3 film is annealed in UHV at high temperatures or exposed to synchrotron beam radiation [16,17]. The peak position for the W1 component remains at the same position for the W^{6+} of the WO_3 as before annealing. On the other hand, the new species W2 indicates reduced W atoms in WO_{3-x}. This is also confirmed by the decrease of O 1s intensity after annealing (not shown here). The third component W3 has been attributed to the inhomogeneities in barrier height on the surface [17,21]. The defect formation on the surface or at the WO_3/ITO interface leads to the charge localization, so the barrier height inhomogeneities increase because the photoelectrons become difficult to be emitted from the surface. A common defect in WO_3 film is oxygen vacancy, which induces negative charge accumulation in order to compensate the electronegative oxygen ion vacancy. Such charge makes up a donor-like level below conduction band minimum, which forms a E_F at a different position. This is why the W3 is located at the higher binding energy than that for W^{6+}.

Upon the deposition of NPB molecules even on the annealed WO_3, the W 4f does not show any change in Fig. 4d. This and the above result in Fig. 4b mean that there are no chemical reactions between NPB and WO_3 layers whether the WO_3 film is annealed or not. These results present that the existence of oxygen vacancies and conse-

Fig. 4. XPS core level spectra of W 4f peak and their peak fittings for (a) WO_3/ITO, (b) NPB/WO_3/ITO, (c) annealed WO_3/ITO, and (d) NPB/annealed WO_3/ITO interfaces.
Fig. 5. XPS core level spectra of N 1s for (a) NPB/ITO, (b) NPB/WO₃/ITO, (c) NPB/annealed WO₃/ITO interfaces.

quent formation of WO_{3-x} component are not related with chemical reaction between NPB and annealed WO_3.

Specifically, due to the annealing-induced reduction WO_{3-x} species have relatively low electronegativity compared with WO_3 state, thus, the charge density is expected to increase at the NPB. Therefore the reduction of tungsten significantly causes the charge redistribution of the interface dipole between NPB and annealed WO_3 layer.

To further investigate how the annealed WO_3 layer affects the electronic structure of NPB, we performed XPS measurement of N 1s core level. The N 1s core level peaks for three different films with NPB layer are shown in Fig. 5. The N 1s peak for NPB film on ITO surface is located at 399.89 eV in Fig. 5a. But its position on the WO_3/ITO in Fig. 5b is shifted to 399.09 eV without any change in peak shape. When the NPB is deposited on annealed WO_3 in

Fig. 5c, the N 1s peak moves back to 400.14 eV by the shift of 1.05 eV (Fig. 5b and c). This binding energy shift is almost same as the valence band energy shift of about 1.1 eV as already shown in Fig. 3b. These remarkable changes demonstrate the rearrangement of electronic charge between NPB and annealed WO_3 due to the formation of new chemical states such as WO_{3-x}.

From the above experimental results, the interfacial energy level diagrams are summarized in Fig. 6. The average value for the work functions of ITO surfaces used here is 4.82 eV. In the energy level alignment diagram at the NPB/ITO interface, the barrier height for the hole injection, corresponding to the energy difference between the HOMO of NPB and the E_F of the ITO, is 1.32 eV in Fig. 6a. However, the NPB/WO₃/ITO interface shows a different vacuum level (E_{vac}) and a small hole injection barrier because the WO_3 interlayer has a large work function (6.0–6.5 eV) in Fig. 6b. When NPB is deposited on the WO₃/ITO, the WO_3 is suggested to draw charge from the NPB because the NPB is relatively strong electron donor. Therefore there forms an additional dipole layer between NPB and WO_3 as well as WO₃/ITO interface. Due to the large E_{vac} shift, the HOMO level of NPB also moves near to the E_F level. Therefore the hole injection barrier is remarkably reduced to 0.46 eV by the insertion of WO_3 layer between NPB and ITO. This demonstration was supported by binding energy shifts of valence band and N 1s core level, respectively, in Figs. 2 and 5. In case of NPB/WO₃/ITO interface, the total up shift of HOMO level in Fig. 6a and b is 0.86 eV which is comparable to the N 1s binding energy shift from NPB/ITO to NPB/WO₃/ITO interfaces in Fig. 5. From this energy level alignment we can conclude that the thin WO_3 layer plays a strong role in reducing the total barrier height for hole injection. Therefore this is the main reason for the reduction of the operation voltage and high power efficiency in the organic electroluminescence by WO_3 interlayer [6].
Fig. 6. Schematics of energy level alignment diagrams at the interfaces (a) NPB/ITO, (b) NPB/WO₃/ITO, and (c) NPB/WO₃ (after annealing)/ITO interfaces from UPS.

In case of annealed WO_3 film, the net barrier height for hole injection is increased to 1.50 eV in Fig. 6c. As mentioned before, this result was due to the redistribution of electron charge at the interface between annealed WO_3 and NPB. The annealing of WO_3 layer produces various chemical states due to the oxygen vacancy formation. This nonstoichiometric WO_{3-x} formation upon annealing is supported by the increased intensity of W 5d band in Fig. 3c, and the appearance of W2 and W3 species in Fig. 4c. On consequence, the work function of the WO_3 surface is reduced and the E_{vac} level of NPB is shifted back toward the E_F level. By the modification of energy level at the interface, the HOMO energy level of NPB is pulled down. Therefore annealed WO_3 would not improve the hole injection at the interfaces under the present scheme. The previous report argued that a high temperature annealing (450 °C) in air brings out a better performance in OLED characteristics [8]. The reason was explained by a positive structural change, which was in favor of electrical conduction. However, its actual enhancement in $L–I–V$ curves was marginal probably due to a small change in work function (0.27 eV). Thus, the device performance will be determined by the various factors such as interface energy level alignment shown here and electrical conductivity of films.

An exact interpretation of structural change of ultrathin (1.5 nm) WO_3 film upon annealing is far from practical. However, from previous literatures where thick films (>100 nm) undergo marginal change in structure up to 400 °C annealing [17–19,22], one can assume that the structural change is not severe, as a relatively low-temperature annealing at 350 °C has been performed here. If a strong structural change took place upon the 350 °C annealing, the intensities of substrate In 3d and/or W 4f core levels would change significantly. But such changes were not observed in this experiment. Instead, relatively low-temperature annealing at 350 °C in UHV brings out stoichiometric change of the WO_3 film and possibly micro-crystallization.

4. Conclusion

We have shown by photoelectron spectroscopy that with a thin WO_3 layer inserted between the NPB and ITO films, the hole injection barrier height was significantly lowered from 1.32 eV to 0.46 eV. This phenomenon is followed by a large work function change which is likely due to the formation of new interface dipole layer. This result explains well the reduction of the operation voltage and enhancement in power efficiency observed in OLEDs with WO_3 interlayer. Upon UHV annealing of the WO_3

interlayer at 350 °C, the hole injection barrier was largely increased back to 1.50 eV. When the WO_3 layer is annealed, an oxygen vacancy is formed and various chemical states of tungsten oxide are generated. Therefore, the stoichiometry and defects inside the tungsten oxide film largely influence the energy level alignment at the NPB/WO_3 interface.

ABSTRACT

We report on a new p-type organic semiconductor single crystal, 5,10,15-trimethyl-10,15-dihydro-5*H*-diindolo[3,2-*a*:3',2'-*c*]carbazole (*N*-trimethyltriindole). This molecule crystallizes forming a highly ordered columnar structure in which stacked molecules are situated at two alternating distances (3.53 Å and 3.68 Å) along the column as determined by single crystal X-ray diffraction analysis. These short intermolecular distances between adjacent units, make this system an ideal candidate for charge-transport processes along the stacks.

Relevant parameters for transport (i.e. internal reorganization energies, transfer integral) have been estimated by DFT calculations at a 6-311G(d,p)/B3LYP level of theory. As a double check for the transfer integral, the electronic band structure of a one-dimensional stack of molecules has been computed. The electronic properties of this material have been studied both theoretically and experimentally. Its HOMO value is found to coincide with Au work function (Φ_{Au} = 5.1 eV), thus low barriers are expected for hole injection from gold electrodes. The hole mobility of this material has been predicted theoretically considering a hopping-type mechanism for the charge-transport and determined experimentally at the space charge limited current (SCLC) regime of the current–voltage measurements. Both theoretical and experimental values are in good agreement. The high hole mobility (μ_{min} = 0.4 cm^2 V^{-1} s^{-1}) of this material points towards its useful application in the organic electronics arena. *N*-Trimethyltriindole single crystals constitute an essential model to study transport properties of triindole-based materials and to design new derivatives with improved electronic performance.

1. Introduction

The field of organic electronics has experienced in a few years a rapid development moving from a basic research level to the construction of molecule-based devices that are already commercially viable [1]. These devices have in common that their performance depend on how efficiently the charge carriers are injected and transported in the different organic active layers. Therefore, important advances achieved in this field have been connected to the enhancement of the charge carrier mobility of the organic molecules. However the incorporation of organic molecules in the electronic devices shows still serious stability and processability limitations. At this stage one of the main needs is to find new stable organic semiconducting materials.

In the quest for new molecular conducting systems, two-dimensional polycyclic aromatics (with extended π-conjugated systems) are among the best candidates. This type of molecules tend to form highly ordered structures due to self-assembly facilitated by strong π–π-interactions, paving the way for increased charge mobility in

the bulk of the material as the result of a favorable inter-molecular π-orbital overlap. In close relation with the supramolecular order, the highest charge carrier mobility is usually obtained in organic single crystals [2]. Furthermore, organic single crystals offer an excellent opportunity to investigate structure-properties relationships and to elucidate charge-transport mechanism in organic materials [3]. In response to this need a large effort is being made to find new classes of crystalline charge carrier transport organic materials, even if the realization of devices based in single crystal implies important technological challenges [4].

In this context we became interested on the electron-rich 10,15-dihydro-5H-diindolo[3,2-a:3',2'-c]carbazole (triindole, **1**). This molecule can be formally considered as an extended π-system in which three carbazole units share an aromatic ring (Scheme 1). The particular relation of this polycyclic aromatic system to the well known hole transporter carbazole [5], together with its π-extended structure render triindoles attractive candidates for organic electronics. Curiously, in contrast with its all carbon analogue truxene [6,7] this platform has been very scarcely studied in the context of molecular electronics [8]. We have found that triindole-based discotic liquid crystals exhibit high charge mobility values ($\mu \sim 0.03$ cm^2 V^{-1} s^{-1}) in the mesophases since they combine its inherent donor character with the supramolecular organization typical of disc-like mesogens [9]. Additionally, we have recently reported that it is possible to optimize the electronic as well as the self assembly properties of this platform through functionalization of its peripheral positions [10].

In this paper we describe the synthesis, crystal structure, and the electronic properties of N-trimethyltriindole (**2**) (Scheme 1) a molecule that crystallizes forming a highly ordered columnar structure, with short intermolecular distances between adjacent units within the stacks yielding a high hole mobility system. The electronic properties of this material have been studied both theoretically and experimentally. Quantum mechanical calculations have been performed to investigate the electronic structure and to determine relevant parameters for charge-transport such as internal reorganization energies and hole transfer integral. The hole mobility of this material has been predicted theoretically considering a hopping-type mechanism for the charge-transport and determined experimentally at the space charge limited current (SCLC) regime of the current–voltage measurements. Both theoretical and experimental values are in good agreement.
2. Results and discussion

2.1. Synthesis and molecular properties

The synthesis of N-methyltriindole (**2**) was straightforward by deprotonation of triindole (**1**) with n-BuLi and trapping of the trianion with MeI. The thermal stability of **2** has been determined by thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC), this material is thermally stable up to 400 °C (see Supplementary Material, Fig. S1). In order to estimate the value of the HOMO level, the electron-donating nature and redox stability of **2**, cyclic voltammetry has been performed. Compound **2** shows two reversible oxidation waves at 761 mV and 1370 mV vs. Ag/Ag$^+$ in the accessible potential window of the solvent (CH$_2$Cl$_2$) reflecting its oxidation to a stable cation radical and subsequent generation of further oxidized species. From the first oxidation process an HOMO energy value of −5.11 eV can be estimated for **2**. This value matches very well with the work function of gold (Φ_{Au} = 5.1 eV) and therefore low barriers are expected for hole injection (see Supplementary Material, Fig. S2).

The electronic properties of **2** have also been studied by UV–vis absorption (Fig. 1). The absorption spectrum of a 10^{-5} M solution of **2** in CHCl$_3$ shows the maximum absorption at 3.89 eV (319 nm) and the lowest transition at 3.35 eV (370 nm). From this lowest transition a HOMO–LUMO energy gap 3.35 eV can be estimated [11].

In order to determine the effect of chemical oxidizing agents on the molecular electronic levels of this molecule (doping), the oxidation of **2** with trifluoroacetic acid (TFA) has been monitored by UV–vis spectroscopy. TFA has been extensively used as a one-electron oxidant to generate radical cations [12], eventhough there is controversy about how the oxidation actually occurs [13]. Thus, addition of 10 equivalents of (TFA) to a 10^{-5} M CHCl$_3$ solution of **2**, increases the intensity of the 3.06 eV band (Fig. 1) while the intensity of the bands corresponding to the neutral species decreases. This absorption band is related to oxidized molecules, whose gap between HOMO and LUMO energy levels has therefore varied by about 0.3 eV. For concentrations of oxidant above 20 equivalents two new bands can be distinguished around 3.17 and 1.72 eV corresponding to further oxidized species.

2.2. Crystal structure

Long needle-like hexagonal colorless crystals of **2** suitable for single crystal X-ray analysis were obtained from

Scheme 1.
Fig. 1. Evolution of the UV–vis absorption of **2** in CHCl$_3$ as a function of TFA content. The spectrum in dashed line corresponds to a 5×10^{-4} M of TFA in chloroform and is the origin of the steep optical density (O.D.) increase above 4 eV as the TFA content increases. The upper inset shows the second derivatives of the neutral solution and two oxidized stages.

slow evaporation of an CH$_2$Cl$_2$:acetone (3:1) solution. X-ray analysis indicates that the triindole core is slightly twisted, with the three peripheral rings bending ($\sim$8°) out of the plane of the central aromatic ring (Fig. 2). The

methyl groups are slightly out of the molecular plane in an all-*syn* conformation [δ (C5-C4-N1-C9): -18.5°].

Compound **2** crystallizes in *R-3* space group, forming stacks along the crystallographic *c*-axis (Fig. 3). Each stack
Fig. 2. ORTEP representation of **2**.
Fig. 3. View of the unit cell along the *c*-axis of **2**.

is surrounded by six neighbouring stacks that interact only through weak Van der Waals forces.

Within the stacks the molecules are oriented face-to-face in an alternate arrangement, one molecule rotated 60° with respect to the next molecular unit, being the central aromatic rings perfectly superimposable. Such a perfect cofacial arrangement between aromatics is rarely observed since repulsive interactions involving approaching π-electron clouds are generally minimized through parallel displacement resulting normally in an offset stack [14]. The triindole units are situated at two different distances that alternate along the column reflecting the steric hindrance by the methyl groups. The centroid–centroid distance of the central aromatic rings of two adjacent molecules are 3.53 Å (d_S) and 3.68 Å (d_L) respectively (Fig. 4).

The short intermolecular distances between adjacent units observed experimentally by X-ray analysis, as well as the easy reversible oxidation of *N*-trimethyltriindole make this system an ideal candidate for charge-transport studies along the stacks.
2.3. Electronic structure calculations

Quantum mechanical methods have been used to analyze the electronic structure, the equilibrium geometry and the electronic density distribution of neutral and oxidized (+1) molecules in order to determine important parameters for charge-transport (internal reorganization energies and hole transfer integral) and estimate the hole mobility of this compound.

The electronic structure of a single *N*-trimethyltriindole molecule **2** both in its neutral (M) and charged state (M$^+$) have been optimized by density functional calculations (DFT) at a 6-311G(d,p)/B3LYP level of theory. The obtained optimized molecular structure of **2** compares well with the experimental structure derived form the X-ray data, the largest difference between theory and experiment being found in the dihedral angles that measure the deviation of the methyl groups from the molecular plane [δ (C5-C4-N1-C9): −18.5° (exp.), −25.3° (calc.)]. This is probably due to the lack of intermolecular steric effects (packing effects) in the geometry optimization of the isolated molecule [15].

The energies of the HOMO and LUMO levels have been derived from the DFT calculations of the neutral molecule M. The HOMO level is found at −5.01 eV, in good agreement with the value obtained from cyclic voltammetry (−5.11 eV). In contrast the predicted HOMO–LUMO gap (4.25 eV) results larger than the value obtained experimentally by UV–vis spectroscopy (3.35 eV).

The Mulliken analysis of the electronic charge distribution of **2** is displayed in Fig. 5a. The largest negative net charge (−0.55 *e*) is found at the N positions, while the largest positive net charge (0.22 *e*) is found at the three C atoms of the central benzene ring that are bonded to the N atoms. Carbon atoms with partial positive and negative charge alternate in the central aromatic ring, resulting in a charge distribution that is probably responsible for the perfect columnar arrangement observed in the solid state. Thus a close inspection of the crystal packing shows that the experimental configuration of the closest neighbouring

The size of the circles is proportional to the calculated spin density.

molecules (Fig. 4), results in the approach of atoms with partial charges of opposite sign.

We have performed a Mulliken population analysis of the spin density of the oxidized molecule M^+ (Fig. 5b). The largest spin density is located on one of the nitrogen positions and on the C atom of the central aromatic ring in para to the former nitrogen (approximately $0.26\,e$). However extensive delocalization of the unpaired electron density on all the atomic centers can be observed explaining the stability of the cation radical as revealed from the easy reversible oxidation of N-trimethyltriindole.

The geometry optimization of N-trimethyltriindole in its cationic state, M^+, shows a molecular distortion due to the Jahn–Teller coupling between the electronic and vibrational degrees of freedom. This coupling originates from the fact that the HOMO of N-trimethyltriindole is a twofold degenerated electronic state that belongs to the irreducible representation E of the C_3 point group. The analysis of the Jahn–Teller distortion shows that specific C–C and C–N bonds in M^+ become larger or smaller than in the neutral state, M. Interestingly, enlargement of bonds in M^+ correlate with the presence of in-phase bonding amplitudes in the HOMO of the neutral molecule M, while shortening of bonds in M^+ are related to the presence of nodal planes in the HOMO of M. This behaviour is illustrated in Fig. 6, where we compare one of the E components of the HOMO for the neutral molecule M (Fig. 6a), with the Jahn–Teller distortion of M^+ (Fig. 6b) by presenting, for those bond distances with largest variation, the difference between the equilibrium values found in M^+ and M.

2.4. Hole mobility calculations

At room temperature, the hole mobility of organic semiconducting materials is often described by a hopping process [16], where the transport mechanism between neighbouring molecules can be formulated as a hole transfer by the equation

$$M + M^+ \rightarrow M^+ + M \qquad (1)$$

where M and M^+ play the role of electron donor and electron acceptor molecules, respectively.

The hole-transfer rate, k_t, can be approximated by the Marcus electron-transfer theory [17] with the equation

$$k_t = \frac{4\pi^2}{h}\frac{1}{\sqrt{4\pi K_B T}}t^2 \exp\left(-\frac{\lambda}{4K_B T}\right) \qquad (2)$$

where h and K_B are Planck's and Boltzmann's constants, T is the temperature, t is the electronic transfer integral between the donor and acceptor molecules, and λ is the reorganization energy for hole transfer between both molecules. Therefore the transport process, is determined by two important molecular parameters: the internal reorganization energy (λ) which needs to be small for an efficient charge-transport and the intermolecular hole transfer integral (t) which describes the strength of the electronic coupling between adjacent molecules [16].

The reorganization energy for hole transfer, λ, is the sum of two contributions, $\lambda_1 + \lambda_2$, that are defined as

$$\lambda_1 = E_0(M^+) - E_0(M) \qquad (3)$$
$$\lambda_2 = E_1(M) - E_1(M^+) \qquad (4)$$

where $E_0(M^+)$ and $E_0(M)$ represent the energies of the neutral molecule at the cation geometry and at the optimal ground-state geometry respectively. $E_1(M)$ and $E_1(M^+)$ represent the energy of the charged state at the neutral geometry and optimal cation geometry, respectively.

Using the DFT optimized molecular configurations for M and M^+ we found the values $\lambda_1 = 123$ meV and $\lambda_2 = 113$ meV, giving an estimate for the λ value for hole transport in this molecule of 236 meV.

The hopping integral for intermolecular hole transfer, t, can be estimated from the energy splitting between the electronic level HOMO, e_H, and the HOMO-1, e_{H-1}, taken from the closed-shell configuration of the neutral state of a dimer M_2 by the relation

$$t = \frac{e_H - e_{H-1}}{2} \qquad (5)$$

The value of the transfer integral t depends strongly on the molecular configuration of the dimer. As shown in Fig. 4, in the crystal of N-trimethyltriindole two alternating M_{2S} and M_{2L} dimer configurations can be observed. The electronic structure of both N-trimethyltriindole dimers
Fig. 6. (a) Isosurface representation for the HOMO wavefunction of **2** in its neutral state M. Only one component of the two-fold degenerate *E* molecular orbital is shown. The interval between contour lines is 25×10^{-8} Å$^{-3/2}$. (b) Changes in the bond distances in pm (0.01 Å) found for the optimized structure of *N*-trimethyltriindole in its cationic state, M$^+$, with respect to the neutral state M. Only distances modified by more than 1 pm are shown. The Jahn–Teller coupling is responsible for this structural change.

has been studied by DFT in order to obtain the value of the transfer integral for both configurations. However in a crystal the charge mobility will be most likely controlled by the smaller value of the transfer integral, corresponding to the M$_{2L}$ configuration.

Fig. 7 shows the value of *t* as derived from the optimized M$_{2L}$ configuration (solid line) *vs* the separation between the molecular units, as well as the results obtained by using the experimental M$_{2L}$ dimer configuration found in the crystal structure (dashed line). Both sets of results show very similar behaviour. However the optimized structure provides values for the transfer integral, *t*, slightly smaller than the derived from the experimental dimer configuration. This is probably related to the larger deviation from planarity found in the optimized structure
when compared with the experimental one, due to the lack of packing effects.

The transfer integral, *t*, depends on the geometrical parameters and plays an important role in our theoretical predictions. Therefore, we double checked the value of *t* performing a band structure calculation for a stack of molecules forming a quasi-1D crystal (Fig. 4). From these calculations the transfer integral has been obtained as half of the bandwidth. Fig. 7 (dotted line) displays *t* vs. the distance d_L. Taking into account the approximations involved in the model, the agreement with our previous calculations based on localized basis and a different prescription for exchange and correlation is remarkable.

The calculated values of *t* and λ allows us to derive the transfer rate of holes, k_t, as a function of temperature from the Marcus expression in Eq. (2). For the purpose of estimating the hole-transfer rate we have taken the value of *t* corresponding to the optimized dimer geometry at the experimental intermolecular distance of 3.68 Å (t = 34 meV).

By considering the expression for the diffusion coefficient associated to a one-dimensional jumping process.

$$D = K_B d_L^2 \tag{6}$$

the hole mobility, μ, can then be obtained from the following expression

$$\mu = eD/kT \tag{7}$$

where *e* is the electron charge. At 300 K we obtain a transfer rate, k_t, of 4×10^{12} s^{-1} and a corresponding hole mobility of 0.21 cm^2 V^{-1} s^{-1}.

2.5. Electrical measurements

The electrical conductivity of *N*-trimethyltriindole crystals was measured along the crystallographic *c*-axis, which coincides with the longest direction of the needle-like single crystals, in a two contact configuration by gluing a sin-

Fig. 7. Comparison of the evolution of the hole transfer integral, as a function of the distance, calculated for the optimized structure of the triindol dimer M$_L$ (solid line), the experimental structure of the dimer M$_L$ (dashed line) and a one-dimensional stack of triindole units (dotted line).

gle crystal with silver paint to two gold electrodes (distance between electrodes 2 mm). A value of $\sigma = 2 \times 10^{-7}\ Ohm^{-1}\ cm^{-1}$ at 298 K has been obtained (Fig. 8a).

Upon exposure to different oxidizing vapours, HNO_3 or trifluoroacetic acid (TFA), the conductivity increases several orders of magnitude depending on the oxidation time (Fig. 8b). External oxidation would remove electrons from the HOMO level of N-trimethyltriindole increasing the hole density (doping) explaining the observed variations of the conductivity. Non-linearity in the I–V curves was detected for heavily oxidized crystals. The observed complex I–V behaviour, which could not be analysed straightforwardly with the usual conduction mechanisms, is probably related to deficiencies of the contacts regarding their stability and the control of the oxidation effects on the interfaces. However an ohmic behaviour of the resistance is evidenced for as grown crystals, as well as for lightly oxidized crystals, for applied voltages up to 800 V.

Both as grown and oxidized crystals, show a temperature activated conductivity (90–500 K) indicating the predominance of a polaron hopping mechanism in this system as invoked in the previously shown theoretical calculations

Because of the relatively high conductivity of the crystals, in order to measure the mobility, we needed to obtain the high electric field regime and therefore to shrink the distance between the electrodes. Also, to reduce possible problems arising from silver paint contacts and from deficient crystal–gold interfaces, several single crystals where grown directly on a glass substrate with previously deposited Cr/Au electrodes (distance between electrodes 200 μm). This configuration allowed us to measure the high field I–V characteristics and to observe the space charge limited current (SCLC) regime. The results for as grown crystals are shown in Fig. 9. Trace (a) is the measured current which shows the ohmic behaviour at low voltages (dashed line). This observation indicates that non-linearities due to Schottky barriers at the interfaces are negligible as a result of the good alignment of the work function of the gold electrode with the HOMO level of the
Fig. 9. (a) I–V curve of the as grown crystals. The dashed line corresponds to the ohmic part. (b) Non linear part of the current. The upper inset shows the V^2 dependence of the current.

N-trimethyltriindole. By subtracting this ohmic contribution from the measured current we obtain trace (b). The I–V^2 plot (inset) evidences the typical behaviour of the space charge limited current (SCLC) regime where the Mott–Gurney equation [18] applies:

$$J = \frac{9\varepsilon_0 \varepsilon \mu V^2}{8L^3} \tag{8}$$

J is the measured current density, ε_0 is the vacuum permittivity, ε is the relative dielectric constant of the material (we have used the commonly estimated value for organic materials of 3), μ is the charge mobility, L is the distance between the contact electrodes and V is the applied voltage. In this configuration several crystals are connecting the gold electrodes. Therefore, in order to calculate the current density J, the section for conduction has been estimated from the resistance in the linear regime and the resistivity previously determined for an isolated crystal.
Fig. 8. (a) I–V measurements at room temperature of as grown crystals and (b) of crystals lightly oxidized upon exposure to HNO_3 and TFA vapours for 10 min.

Although our measurements are performed on pure single crystals, it is likely that shallow traps play a role, therefore the Mott–Gurney law is only expected to provide a lower limit for the mobility (μ_{min}). The linear fit on the I–V^2 curve, gives a value of μ_{min} = 0.4 cm^2 V^{-1} s^{-1}, in reasonable agreement with the value predicted by our calculations using the Marcus electron-transfer theory (μ = 0.21 cm^2 V^{-1} s^{-1}).

3. Conclusion

In summary, the positive synergy between molecular structure (electron-rich, extended π-system) and bulk arrangement (close packing, efficient intermolecular π-orbital overlap) results in the construction of a novel high hole mobility crystalline material.

The title molecule crystallizes forming a highly ordered columnar structure, with short intermolecular distances between adjacent units, favouring the charge-transport along the stacks and resulting in the high measured mobility (0.4 cm^2 V^{-1} s^{-1}). The structure and electronic states, as well as the relevant parameters governing the charge-transport, as internal reorganization energies, transfer integral and hole mobility, have been calculated. This theoretical analysis agrees well with our experiments and supports the interpretation of our results.

This single crystalline material fulfils many conditions for a good organic hole transport in the construction of devices namely: (i) its HOMO value almost coincides with the Au work function, (ii) its mobility is high, (iii) the conductivity can be increased by several orders of magnitude by doping, and (iv) its energy gap lies above the visible range which is necessary for combining it with optical active materials in order not to absorb the visible excitation or emission energies.

The interesting electrical properties obtained for this material along with the synthetic versatility of this platform make heptacyclic triindoles promising candidates in the search for new tunable organic semiconductors. N-Trimethyltriindole single crystals constitute an indispensable model to study transport properties of this new type of compounds and in the design of new triindole derivatives with optimal semiconductor properties.

4. Experimental section

4.1. Synthesis and characterization of 5,10,15-trimethyl-10,15-dihydro-5H-diindolo[3,2-a:3',2'-c]carbazole (2) [19]

To a stirred solution of **1** (170 mg, 0.5 mmol) in THF (3 mL) at -80 °C was added n-BuLi (2.0 M pentane, 110 μL, 1.78 mmol). The reaction was stirred for 1 h (−78 °C → −10 °C). Then, methyl iodide (153 μL, 2.46 mmol) was added and the mixture was stirred for 1 h. The mixture was diluted with CH$_2$Cl$_2$ and washed with water and with saturated aqueous NaCl solution, dried (Na$_2$SO$_4$) and evaporated. The residue was triturated with acetone to give **2** as a white solid (149 mg, 77 %): mp > 230 °C; ^{1}H NMR (300 MHz, CDCl$_3$) δ 8.44 (d, J = 8.1 Hz, 3 H), 7.57 (d, J = 7.5 Hz, 3 H), 7.45 (t, J = 7.4 Hz,

3 H), 7.34 (t, J = 8.0 Hz, 3 H), 4.43 (s, 9 H); ^{13}C NMR (CDCl$_3$, 50 MHz) δ 141.93, 139.06, 122.89, 122.79, 121.74, 119.62, 109.66, 102.55, 35.92; FAB-MS m/z (%) 387 (M$^+$, 49), 307 (36), 154 (100). HR MS (FAB) calcd. for. C$_{27}$H$_{21}$N$_3$ 387.1735, found 387.1737.

4.2. Cyclic voltammetry measurements and determination of the HOMO energy value

Cyclic voltammetric (CV) experiments were performed on an Epsilon Electrochemical Analyzer in a three electrode cell (Pt working electrode) at room temperature, under nitrogen atmosphere. Electrochemical measurements were performed in a millimolar CH$_2$Cl$_2$ solution of **2** containing 0.1 M of recrystallized supporting electrolyte tetra-n-butylammonium hexafluorophosphate (TBAPF$_6$). Potentials were measured against Ag/AgCl as reference electrode. A large area coiled Pt wire was used as a counter electrode. The measurement was calibrated using a ferrocene/ferrocenium redox system as an internal standard by adding a equimolar amount of ferrocene and then measuring the complete voltamogram.

The HOMO energy value for **2** was calculated from the first oxidation potential value with respect to ferrocene, based on the value of −4.8 eV for Fc with respect to zero vacuum level. This value is obtained from the calculated value of −4.6 eV for the standard electrode potential ($E°$) using a normal hydrogen electrode (NHE) [20] on the zero vacuum level and the value of 0.2 V for Fc vs. NHE [21].

4.3. UV–vis spectrometry

UV–vis spectrometry analyses were performed in a Varian-Cary 4000 spectrophotometer.

4.4. X-ray structure determinations

Colorless crystals of **2** showing well defined faces were mounted on a Bruker Smart CCD diffractometer equipped with a normal focus, 2.4 kW sealed-tube X-ray source (MoKα radiation, λ = 0.71067 Å) operating at 50 kV and 20 mA. Data were collected over a hemisphere of the reciprocal space by a combination of three exposure sets. Each exposure of 10 s covered 0.3° in ω over the range 2° < θ < 28°. The first 100 frames were recollected at the end of the data collection to monitor crystal decay. The intensities were corrected for Lorentz and polarization effects. The structures were solved by the Multan and Fourier methods.

Crystal dimensions: 0.30 × 0.20 × 0.20 mm^3, unit cell dimensions **a** = 21.4897(11), **c** = 7.2102(5) Å, γ = 120(0)°, **V** = 2883.6(3) Å^3, **Z** = 6, hexagonal, R-3 space group, ρ calcd. 1.339 Mg/m^3. **2** was refined anisotropically R1(F) = 0.0912 for observed data (I > 2σ(I)), R1(F) = 0.1185 for all data; GOF(F2) = 1.11.

Most of the calculations were carried out with SMART [22] software for data collection and reduction, and SHEL-XTL [23] for structure solution and refinements of **2**. CCDC 670066 contains the supplementary crystallographic data for **2**. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the

4.5. Theoretical methods and computational details

The electronic structure of a single *N*-trimethyltriindole molecule, both for its neutral (M) and charged (M$^+$) states, as well as the electronic structure of *N*-trimethyltriindole dimers (M$_2$) have been studied using the Gaussian program package [24]. The ground state geometries have been optimized by density functional theory (DFT) with the B3LYP functional to approximate the exchange and correlation energy [25] and the standard 6-311G(d,p) basis set [26]. Optimization of the neutral molecule M has been performed by applying constraints compatible with the C_3 point group symmetry, while for the cationic state, M$^+$, no symmetry constraints were imposed. For dimer configurations, we have optimized the ground state geometry by constraining the point symmetry of the dimer to the S_6 group, which is the symmetry observed in the *N*-trimethyltriindole crystal.

To compute the electronic band structure of a one-dimensional stacking of *N*-trimethyltriindole monomers density functional theory [27] was used within the generalized-gradient approximation [28] with a plane-waves basis set and norm-conserving pseudopotentials. Band structure calculations for the quasi-1D crystal have been performed using the CASTEP code [29]. Periodic boundary conditions are used to fill the space by repeating a basic unit cell. A kinetic energy cutoff of 30 Ry has been used to define the number of plane-waves in the basis, and the Brillouin zone has been sampled with four points equally spaced along the Γ–X direction [30]. Norm-conserving pseudopotentials have been chosen because their good performance to describe molecules and materials made with N, C and H atoms.

A rhombohedral unit cell is constructed including 102 atoms representing two molecules separated by d_s and oriented face-to-face as previously described. On the plane of the dimer the unit cell is defined by fixed length vectors ($a = b = 25$ A, 60°), while in the perpendicular direction we optimize the distance between unit cells ($c = d_S + d_L$, 90°). All atoms, and the c distance, are allowed to relax until forces and stresses are below 0.2 eV/A and 0.3 GPa respectively. The symmetry group P-3 (C3 l-1) has been imposed throughout the optimization. The resulting geometry is comparable to the experimental one, predicting a slightly shorter inner distance between molecules ($d_S = 3.51$ A, 0.5% off from the experimental value) and a larger value on the outer side ($d_L = 3.86$ A, 5% off). In this cell, lateral interactions between long threads for molecules are negligible.

4.6. Electrical measurements

DC electrical conductivity was measured along the crystallographic *c*-axis which coincides with the long edge of the needle-like single crystals using a Keithley 2410 1100 V sourcemeter for current measurements and power supply. The typical cross section of the crystals is 0.1×0.1 mm^2 and their length is up to 10 mm.

To perform resistance measurements in wide temperature ranges, it was necessary to maintain only one end of the crystal glued to the sample holder of the cryostat. The other end was only attached to the Pt wire. First attempts to measure the resistance gluing both ends to the sample holder result in the breaking of the crystal due to the different expansion coefficients of both materials.

ARTICLE INFO

ABSTRACT

A novel tripodal compound, tris[2-(7-diethylamino-coumarin-3-carboxamide)ethyl]amine (tren-C), and a model compound, N-butyl-7-(diethylamino)-coumarin-3-carboxamide, were synthesized and characterized by elemental analysis, infrared and ^{1}H NMR spectra. The structure of the model compound was characterized by single crystal X-ray crystallography. The electroluminescence devices of ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: tren-C or model compound (wt%, 30 nm)/Bu-PBD (30 nm)/LiF (1 nm)/Al (100 nm) were fabricated and characterized. The EL spectra of the devices comprising vacuum vapour-deposited films using tren-C as a dopant are similar to the PL spectrum of tren-C in chloroform solutions. At the concentration of 0.5 wt% tren-C, a blue-emitting OLED with an emission peak at 464 nm, a maximum external quantum efficiency (EQE) of 1.39% and a maximum luminous efficiency of 2 cd/A at the current density of 20 mA/cm^2, and a maximum luminance of 1450 cd/m^2 at 12 V are achieved.

1. Introduction

Coumarins are an important class of naturally occurring and synthetic compounds, which have been extensively investigated for electronic and photonic applications [1–6], such as fluorescence probe, charge-transfer agents, solar energy collectors, and nonlinear optical properties due to their high emission yield, excellent photo-stability, extended spectral range, good solubility and their relative ease of synthesis. As emitting materials, their fluorescent wavelength and the fluorescence quantum yield strongly depend on the nature, the position of the substituent and also on the rigidity of the molecule [7–10]. Moreover, for each derivative the fluorescence wavelength, the fluores-

cence quantum yield and other photophysical properties exhibit strong solvent effect. Since Tang et al. [11] first used 3-(2-benzothiazolyl)-7-diehylaminocoumarin (coumarin 6) as an electroluminescent (EL) material successfully, coumarin dyes have attracted much interest owing to their potential application in organic light-emitting diodes (OLEDs). However, coumarin dyes are easily suffered from self-quenching in solid state due to interaction and aggregation with its neighboring compounds. As a result, they were always used as guest that doped in host materials with optimized transport and luminescent properties in organic electroluminescence field [11–15]. This guest–host doped emitter system can not only obtain rather high-efficiency, but also enhance the device operational stability by transferring the electrogenerated exciton to the highly emissive and stable dopant site thus minimizing its possibility for nonradiative decay [16]. Prior work on guest–host doped

emitter systems, most of them were involved with the green fluorescent dopants such as coumarin 6, coumarin 545 and coumarin 545T. Apart from the commercial coumarin dyes directly using as highly fluorescent dopants, many efforts have been devoted to explore new EL materials [17–23]. To add steric spacers to minimize dye–dye interaction at high dopant concentration, Chen and coworkers rigidized the alkylamino donor moiety via cyclization to the julolidine ring to develop new coumarin 545 analogues (C-545P, C-545 TB) and fabricated efficient green OLEDs [17,21]. Swanson and coworkers [18] incorporated diphenylamine replacing diethylamine in 7-position of coumarin ring to obtained coumarin 6 and coumarin 7 analogues (C-6S and C-7S), which efficiency and stability are superior to their commercial dialkylamino analogues. Suzuki and coworkers [22] reported a new coumarin red dopant and bright red OLEDs (max. luminance, 5600 cd/m^2), though the efficiency of the device was not shown. Fujiwara et al. [20] prepared a series of symmetrical biscoumarin blue dyes, in which the same coumarin chromophorics were combined through aromatic ring bridges, to overcome the stability of the blue dyes at the vacuum deposition in the EL device production process, and they investigated the EL devices using these blue dyes as a dopant. Zhang et al. [23] reported the photoluminescent and electroluminescent properties of a new amide-type coumarin derivative, this compound in solution state and in PVK matrix exhibited blue emission, and the doped double-layer device displayed brighter pure blue emission with the low turn-on voltage at 6.3 V and high external quantum efficiency of 0.8%. Compared with green coumarin dyes, there were few OLEDs using red and blue coumarin dyes as guest–host doped emitter.

Recently, we have synthesized a new tripodal compound in which three fluorophores, 7-diethylamino-coumarin moiety, were incorporated into tris(2-aminoethyl)amine (tren) to form tris[2-(7-diethylamino-coumarin-3-carboxamide)ethyl]amine (tren-C) (Scheme 1). The strategies for designing the tripodal compounds with coumarin fluoro-

phores are: To attach three coumarin fluorophores onto the terminal amido groups of tren is expected to separate the coumarin fluorophores each other, keeping the optical properties of the molecule identical to the pristine coumarin fluorophore. Another reason is to increase the spatial extent of the molecule and reduce the interactions such as aggregation and dye self-quenching between the numerous terminal groups. To verify the conception, in the present paper *N*-butyl-7-(diethylamino)-coumarin-3-carboxamide as the model compound was synthesized and the performance of the electroluminescent devices doped with the compound and tren-C was compared.

2. Experimental details

2.1. Materials and methods

4-(*N,N'*-diethylamino) salicylaldehyde from Zhejiang Huadee Dyestuff Chemical Co., Ltd. (China) was recrystallized from ethanol. Tris(2-aminoetheyl)amine (tren) was purchased from Fluka. Thionyl chloride was freshly distilled prior to use. Butylamine was bought from Shanghai No. 3 Chemical Reagent Factory (Chain). 4,4'-bis(9-carbazolyl) biphenyl (CBP), 2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (Bu-PBD), 4,4',4''-tris-*N*-naphthyl-*N*-phenylamino-triphenylamine (2-TNATA) and *N,N'*-bis-(naphthyl)-*N,N'*-diphenyl-1,1'-biphenyl-4,4'-diamine (NPB) were purchased from Electro-Light Technology Corp., Beijing. The other solvents were analytical grade reagents.

IR spectra (400–4000 cm^{-1}) were measured on a Shimadzu IRPrestige-21 FT-IR spectrophotometer. ^{1}H NMR spectra were obtained on Unity Varian-500 MHz. UV–vis absorption and photoluminescent spectra were recorded on a Shimadzu UV-2550 spectrometer and on a Perkin–Elmer LS-55 spectrometer, respectively. The cyclic voltammogram was performed on a Model CHI660 Electrochemical Analyzer (CH instruments, Austin, TX). The electroluminescent spectra were measured on a Hitachi MPF-4 spectrometer.
Scheme 1. Synthetic route for tren-C.

2.3. Synthesis and characterization of tris[2-(7-diethylamino-coumarin-3-carboxamide)ethyl]-amine (tren-C)

The synthetic route was shown in Scheme 1. The intermediates, ethyl 7-(diethylamino)-coumarin-3-carboxylate and 7-(diethylamino)-coumarin-3-carboxylic acid, were obtained as previously described [24].

7-(Diethylamino)-coumarin-3-carboxylic acid (6 g, 0.023 mol) was dissolved in 50 ml of dichloromethane, and then thionyl chloride (10 ml) was droped stepwise under ice bath. The mixture was refluxed for 10 h. The resulting solution was evaporated to dryness under reduced pressure and the residue was dispersed in dry toluene (20 ml). After elimination of the solvent under reduced pressure, and the process was repeated twice. The residue was dried under vacuum.

7-(Diethylamino)-coumarin-3-carbonyl chloride (1.4 g, 5 mmol) was dissolved in anhydrous pyridine (10 ml) and added with stirring to a solution of tris(2-amino-ethyl)amine (0.2 g, 1.36 mmol) in anhydrous pyridine (10 ml). After 5 h at room temperature, the resulting mixture was poured into 100 ml water and extracted with chloroform (3 × 50 ml). The organic phase was washed with water (2 × 50 ml) and dried over anhydrous MgSO$_4$. After filtering, the filtrate was evaporated to dryness under reduced pressure. The crude was purified by chromatography on silica gel using chloroform/methanol (1:24, v/v) as the eluent to give a white powder (0.52 g, 42.7%). mp. 116–118 °C. IR: 3348 (N–H), 2970, 2930, 2870, 2816 (C–H, aliphatic), 1701 (C=O, lactone), 1635 (C=O, amide), 1620, 1585, 1512 cm^{-1}; ^{1}H NMR (CDCl$_3$, TMS): 8.97 (s, 3H, 4-H), 8.62 (s, 3H, NH), 7.38 (d, 3H, 5-H), 6.60 (d, 3H, 6-H), 6.42 (s, 3H, 8-H), 3.58 (d, 6H, CONH–CH$_2$), 3.44–3.39 (m, 12H, 7-N–CH$_2$), 2.88 (t, 6H, N–CH$_2$), 1.23 (t, 18H, CH$_3$).

2.4. Synthesis and characterization of N-butyl-7-(diethylamino)-coumarin-3-carboxamide

The model compound, *N*-butyl-7-(diethylamino)-coumarin-3-carboxamide, was obtained from 7-(diethylamino)-coumarin-3-carbonyl chloride and butylamine following a procedure similar to that described for tren-C. The crude was purified by chromatography on silica gel using ethyl acetate/petroleum(1:5, v/v). Yield: 60.5% m.p. 107–109 °C. IR (KBr pellet, cm^{-1}): 3336 (N–H), 3043 (aryl–CH), 2969, 2929, 2866 (alkyl–CH), 1697 (C=O, lactone), 1644 (C=O, amide), 1617, 1582, 1525, 1509, 1377, 1133. ^{1}H NMR (CDCl$_3$, δ, ppm): 8.77 (s, 1H, NH), 8.71 (s, 1H, 4-H), 7.42 (d, 1H, 5-H), 6.65 (d, 1H, 6-H), 6.51 (s, 1H, 8-H), 3.48–3.41 (m, 2H, CONH–CH$_2$), 3.48–3.41 (m, 4H, 7-N–CH$_2$), 1.60 (m, 2H, CH$_2$), 1.42 (m, 2H, CH$_2$), 1.24 (m, 6H, CH$_3$), 0.95 (t, 3H, CH$_3$). Anal. Calc. for C$_{18}$H$_{24}$N$_2$O$_3$ (%): C, 68.33; H, 7.65; N, 8.85. Found: C, 68.40; H, 7.61; N, 8.79.

2.5. Crystallography

Suitable single crystal of the model compound was obtained from methanol solution. The diffraction data were collected with a Bruker Smart Apex CCD area detector using a graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at 20 °C. The structure was solved by using the program SHELXL and Fourier difference techniques, and refined by full-matrix least-squares method on F^2. All hydrogen atoms were added theoretically.

2.6. OLEDs fabrication

The multilayer OLEDs were fabricated by vacuum-deposition method. ITO-coated glass with a sheet resistance $R_\square \sim 20\ \Omega/\square$ was cut into 3 cm × 3 cm plates and etched
Fig. 1. The molecular structures of materials and the structure of EL device.

in dilute hydrochloric acid for 20 min. Then the ITO substrates were routinely cleaned by ultrasonic treatment in solvents and then cleaned by exposure to an UV-ozone ambient. All organic layers were sequentially deposited without breaking vacuum (2×10^{-4} Pa). Thermal deposition rates for organic materials, LiF and Al were $\sim$2, $\sim$1 and 10 Å/s, respectively. The active area of the devices was 12 mm^2. The EL spectra and Commission Internationale de 1'Eclairage (CIE) coordinates were measured on a Hitachi MPF-4 fluorescence spectrometer. The characterization of brightness–current–voltage (*B–I–V*) were measured with a 3645 DC power supply combined with a 1980A spot photometer and were recorded simultaneously. All measurements were done in the air at room temperature without any encapsulation.

The molecular structures of the materials and the structure of devices used in this work are shown in Fig. 1. Tren-C: CBP and Model compound: CBP were employed as the emitters, 2-TNATA, NPB, and PBD were used as hole injection, hole transport and electron transport materials, respectively. LiF was used as the electron-injection layer.

3. Results and discussion

3.1. Synthesis

Preparation of the compound tren-C was performed in four steps from 4-(diethylamino)-2-hydroxybenzaldehyde by means of Knoevenagel condensation with diethyl malonate as the key step (Scheme 1). The hydrolysis of ethyl 7-(diethylamino)-coumarin-3-carboxylate was easily realized by alkaline hydrolysis followed by acidification to afford 7-(diethylamino)-coumarin-3-carboxylic acid. Subsequent treatment with thionyl chloride led to the intermediate 7-(diethylamino)-coumarin-3-carbonyl chloride that then reacted with tris(2-aminoethyl)amine (tren) to afford the final compound tren-C in 42.7% yield. 7-(diethylamino)-coumarin-3-carbonyl chloride reacted with butylamine to give the model compound, *N*-butyl-7-(diethylamino)-coumarin-3-carboxamide in 60.5% yield.

When 7-diethylamino-coumarin-3-carboxamide was incorporated into the tris(2-aminoethyl)amine (tren), a tripodal compound was obtained which shows a three-dimensional space. Three coumarin fluorophores were attached to an apical N atom through the isolating chains

and formed a cage cavity. The molecular design concept of this work was to realize the absence of significant interactions between the three coumarin fluorophore groups in the tripod tren-C and compel them to emit simultaneously. Moreover, it will reduce the interactions such as crystallization and aggregation of the molecules due to the three-dimensional space to prevent the dye self-quenching. In addition, the tripod tren-C has a flexible structure characteristic, therefore the host molecule can enter into the cage cavity of the guest tren-C when forming emitting layer. It can avoid the occurrence of phase segregation.

3.2. X-ray crystal structure of the model compound

The crystal structure and packing diagram of the model compound are given in Figs. 2 and 3, respectively. Crystal data: $C_{18}H_{24}N_2O_3$, $M = 316.39$, monoclinic, crystal dimensions $0.37 \times 0.22 \times 0.07$ mm, space group C2/c, $a = 22.603$ (6) Å, $b = 9.002$ (4) Å, $c = 18.276$ (5) Å, $\beta = 109.532$ (7), $\lambda = 0.71073$ Å, $T = 187(2)$ K, $U = 3505$ (2) Å^3, $Z = 8$, $Dc = 1.199$ g cm^{-3}, $\mu = 0.082$ mm^{-1}. Reflections (8691) measured, 3083 unique ($R_{int} = 0.0392$), 211 refined parameters, transmission factors 0.9942 and 0.9705. The final discrepancy factors were $R_1 = 0.1037$, $wR_2 = 0.2715$, good-
Fig. 3. Three-dimensional packing diagram of the model compound, H atoms are omitted for clarity.
Fig. 2. Crystal structure of the model compound.

ness-of-fit $S = 1.054$ on F^2, largest difference peak and hole 0.392 and -0.271 eÅ^{-3}. CCDC reference number 716852.

There is an intermolecular π–π stacking between the model compound molecules in crystal lattice as shown in Fig. 3. The interplanar distance is approximately 3.468 Å, it is the rather short π–π interaction and possibly plays a role in the radiationless quenching of the fluorescent emission.

3.3. UV–vis absorption and photoluminescence spectra

Fig. 4 shows UV–vis absorption and photoluminescent spectra of tren-C in the solution of dichloromethane and solid state. It is clear that tren-C exhibits two observable peaks at ca. 257 and 415 nm in the absorption spectrum. The absorption bands of tren-C were blue-shifted obviously compared to that of its precursor, 7-diethylamino-coumarin-3-carboxylic acid (DCCA), which exhibits two peaks in the absorption spectrum at 261 and 432 nm [24], but a similarity in absorption spectral shape between tren-C and DCCA is observed. The similarity can be attributed to the commonality of the center core (i.e., 7-diethyl-amino-coumarin-3-carbonyl). From the molecular structures of tren-C and DCCA, it can be seen that they have the same electron-donor groups (diethylamino group) at 7-position and different electron-acceptor groups (imide for tren-C and carboxyl for DCCA) at the 3-position. Clearly, the efficiency of electron-acceptance of the latter is slightly higher. Furthermore, contrasted with the absorption spectrum of 7-diethylamino-coumarin which exhibits two peaks at 256 and 376 nm [25], the longer wavelength band of tren-C is red-shifted to 415 nm due to the fluorophores bearing an electron-acceptance group in 3-position, but the absorption spectral shapes of them are markedly alike in dichloromethane solution, which displayed a rather weak band at shorter wavelength followed by a intense band at longer wavelength. From above comparison, it was clearly indicated that three fluorophores in tren-C are independent units and no interactions each other.

In addition, the absorption band at 415 nm corresponds to the lowest unoccupied molecular orbital level of tren-C, and it has a significant influence on the characteristic emission spectra, so the PL spectra of tren-C was selected

at 415 nm as the excitation wavelength. The maximum optical absorption edge of tren-C is at ca. 450 nm, the optical bandgap energy (E_g) is calculated to be 2.78 eV.

Tren-C has different PL spectra in the solid state and in the solution of dichloromethane (1×10^{-5} mol/l) (Fig. 4). Tren-C exhibits bright green emission with the peak at 519 nm in the solid state, whereas the photoluminescence of tren-C in dichloromethane has blue emission with the peak at 464 nm, and it was found that the PL spectrum in the solid state is much broader than that in dichloromethane solution and the full width at halfmaximum (fwhm) are 65 nm for the former and 40 nm for the latter, respectively. The results are suggested that the compound in the solid state has more intermolecular interaction than that in solution situation, and thus may lead to change of the emission band.

Fig. 5 shows the photoluminescent behaviors of tren-C doped in poly(methyl methacrylate) (PMMA). Mixed systems of tren-C with PMMA were prepared by dissolving the compound with a certain weight ratios into acetone. The samples for spectroscopy were fabricated by spin-coating the acetone solutions onto clean quartz substrates. It was illustrated that the emission spectral features of the compound in the tren-C/PMMA systems change with the weight ratios of the compound and PMMA. It is noticed that the emission located at 463 nm increases gradually with increasing the weight ratio and reaches a maximum at about concentration of 0.5 wt% the compound. When the concentration was higher than 0.5 wt%, the fluorescence emission was decreasing, and the emission band was broadening and bathochromically shifted. Noteworthily, when the concentration exceeded 2 wt%, an additional emission band appeared at around 520 nm, which corresponds to the emission in the solid state. Moreover, as the concentration exceeded 10 wt%, we can find that the emission band at 463 nm disappeared and the emission band at 520 nm reserved. The results show that the fluorescence intensity is intensively quenched by concentration of the compound, so it was found that a self-quenching was occurred. On the other hand, the shape of emission spectra is intensively affected by the intermolecular interaction, thus may lead to

Fig. 5. The PL spectra of the thin film of tren in the tren-C/PMMA system ($C_{PMMA} = 10$ mg/ml, $\lambda_{ex} = 416$ nm).
Fig. 6. Normalized UV–vis absorption spectrum and PL spectra of the model compound.

change of the emission band with increasing the weight ratios.

Fig. 6 shows the UV–vis absorption spectrum and PL spectra of the model compound in the solution of dichloromethane (1×10^{-5} mol/l^{-1}) and in thin film. It is clear that the model compound exhibits two observable bands at about 257 and 415 nm, which is similar to that of tren-C. The PL spectra of the compound in thin film with the emission peak at 451 nm is identical with that in the solution of dichloromethane, but the former is much broader than the latter.

3.4. Electrochemical properties and OLED performance

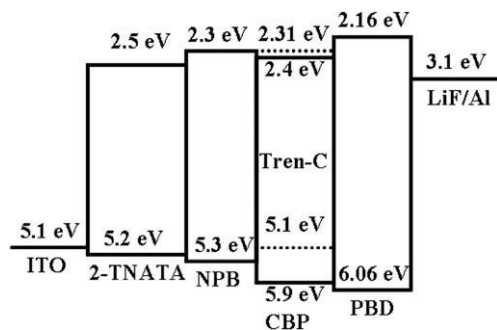
The electrical property of tren-C was first investigated using the cyclic voltammetry (CV), from which the highest occupied molecular orbital (HOMO) level of tren-C was determined. The HOMO level is related to the hole injection/transporting property of tren-C. Tren-C was dissolved in dichloromethane with tetra-n-butylammonium tetrafluoroborate (0.1 mol/l) as the electrolyte. A platinum working electrode and a saturated Ag/AgCl reference electrode were used. Ferrocene was used for potential calibration. Fig. 7 shows the cyclic voltammogram of tren-C and ferrocene reference material. The oxidation onset at
Fig. 7. Cyclic voltammograms of the ferrocene (dotted line) and tren-C (solid line) (scan rate: 10 mV/s, solvent: dichloromethane).


Fig. 8. The energy-level diagram of the blue-emitting device.

0.70 V was clearly observed in the CV curve of tren-C. In the CV cure of ferrocene, the oxidation peak and the reductive peak were observed at 0.55 and 0.25 V, respectively, then the $E_{1/2}$ (Fc/Fc$^+$) is 0.40 V. From the oxidation onset of tren-C, the HOMO of tren-C is determined to be -5.10 eV regarding the energy level of ferrocene/ferrocenium as -4.80 eV [26]. Then the LUMO of tren-C is calculated to be -2.32 eV.

The device with the configuration of ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: tren-C (x wt%, 30 nm)/PBD

Fig. 10. The luminance versus voltage and current density versus voltage (inset) curves of the devices with different dopant concentrations.

Table 1
EL performances of the tren-C doped devices.

Entry (wt%)	Maximum efficiency (cd/A)	Efficiency at 20 mA/cm^2	Maximum external quantum efficiency (EQE)	CIE$_{x,y}$
0.25	3.32 @ 0.20 mA/cm^2	1.89	2.81%	(0.132, 0.124)
0.5	3.85 @ 0.10 mA/cm^2	1.89	2.85%	(0.134, 0.161)
1.0	2.71 @ 0.63 mA/cm^2	1.99	1.56%	(0.149, 0.225)
2.0	2.65 @ 0.23 mA/cm^2	1.75	1.25%	(0.193, 0.295)

(30 nm)/LiF (1 nm)/Al (100 nm) and the corresponding HOMO-LUMO energy levels are depicted in Fig. 8. From the energy diagram, the strong hole traping can be expected due to the lower HOMO level of tren-C than that of CBP. On the other hand, little variation in LUMO level between tren-C and CBP allows electron easier to inject into tren-C. Moreover, it is clear that NPB and PBD can act as substantial electron-blocking and hole-blocking layers, respectively. As a result, effective electron-hole pairs confinement in the emission layer can be expected.

Fig. 9 shows the EL spectra of the device with tren-C doped at concentrations of 0.25, 0.5, 1 and 2 wt%. All devices exhibit blue emissions with the maximum peaks at ca. 464 nm. The EL spectra are identical to the PL spetrum of tren-C in dichloromethane solution. Such results indicate that these emissions take place from the tren-C molecules. As shown in Fig. 9, it can be seen that the EL spectral width broadens gradually with tren-C dopant concentrations in CBP host increase, this suggests that there is slight interaction between tren-C molecules as increase of the dopant concentration.

Fig. 10 shows the luminance–current density–voltage characteristics of the devices for various concentrations of tren-C molecules. It can be seen that the increasing doped concentrations suppressing the luminance and current density of the devices, indicating that strong charge trapping occurred in present device structures. Table 1 summarized the performances of the devices with various tren-C doping concentrations in CBP host. The 0.5 wt% tren-C doped device has maximum efficiency of 2 cd/A at 20 mA/cm^2, which has a blue color with a CIE$_{x,y}$ of (0.134, 0.161). From the results, it is indicated that there is an optimal doping concentration of tren-C.

It is obvious that the optimal tren-C concentration in the CBP host is 0.5 wt%, and the 0.5 wt% tren-C doped device showed maximum luminance was 1450 cd/m^2 at 12 V. Fig. 11 shows the relationship between current efficiency and the current density in the devices with various tren-C doping concentrations. It is shown that all doped devices have higher efficiencies at low current densities, and then the efficiencies fall off fleetly at higher current densities. The above finding indicates that the electron hole recombination may not be effective under high current density, revealing that the present host, CBP, might not be an optimal host material. The present device performance could be further improved by substituting other host candidates.
Fig. 12. EL spectra of the device with ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: Model compound (1.5 wt%, 30 nm)/PBD (30 nm)/LiF (1 nm)/Al (100 nm) at different applied voltages.

Fig. 11. Current efficiency–current density characteristics of the doped devices with various dopant concentration.
Fig. 13. The luminance versus voltage and current density versus voltage (inset) curves of the devices doped the model compound with different concentrations.
Fig. 14. Current efficiency–current density characteristics of the devices doped the model compound with different concentrations.

To compare the performance of the devices doped with tren-C, the devices with the model compound doped at concentrations of 0.5 and 1.5 wt% were fabricated. Fig. 12 shows the EL spectra of the device with concentration of 1.5 wt% the model compound at different driving voltages. The EL spectrum is almost identical to the PL spectrum of the model compound thin film, a bright blue emission at 451 nm was observed. The representative current–luminance–voltage characteristics of the device doped the model compound with different concentrations are depicted in Fig. 13. The devices show a turn-on voltage about 10 V. At the doped concentration of 1.5 wt%, the luminance reaches as high as 270 cd/m^2 at 17 V. The 1.5 wt% model compound doped device has a maximum efficiency of 0.8 cd/A at 20 mA/cm^2, which has a blue color with a CIE$_{x,y}$ of (0.141, 0.084) (Fig. 14).

From above results, we can find that the performance of the tren-C doped devices is be superior to that of the model compound doped devices.

In conclusion, we designed and prepared a new tripodal compound, tris[2-(7-diethylamino-coumarin-3-carboxamide)ethyl]amine (tren-C), which exhibits different colors emission in a solid states and solutions. The doped devices fabricated from tren-C doped in CBP show the blue emissions with the maximum peaks at ca. 464 nm and have the EL spectra identical to the PL spectrum of tren-C in dichloromethane. The ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: tren-C (0.5 wt%, 30 nm)/PBD (30 nm)/LiF (1 nm)/Al (100 nm) device displayed the pure brighter blue emission, a maximum external quantum efficiency (EQE) of 1.39%, a maximum luminous efficiency of 2 cd/A at the current density of 20 mA/cm^2, and maximum luminance of 1450 cd/m^2.

High temperature carrier mobility as an intrinsic transport parameter of an organic semiconductor

K.K. Tsung, S.K. So *

Department of Physics and Centre for Advanced Luminescence Materials, Hong Kong Baptist University, Kowloon Tong, Hong Kong, China

ARTICLE INFO

ABSTRACT

The high temperature limit of hole mobility (μ_∞) in *N,N'*-diphenyl-*N,N'*-bis(1-naphthyl)(1,1'-biphenyl)-4,4'diamine (NPB) has been studied by time-of-flight technique. The effect of dopants on μ_∞ was also investigated. It was found that the μ_∞ is independent of the nature of dopants. The common μ_∞ can be applied to estimate the full temperature dependence of zero-field mobility (μ_0), if μ_0 at one temperature is known. We demonstrate this concept by predicting the room temperature μ_0 of NPB-doped with copper phthalocyanine (CuPc). The mobility prediction of CuPc-doped-NPB was then verified by the classic work of Hoesterey and Letson [D.C. Hoesterey, G.M. Letson, J. Phys. Chem. Solids 24 (1963) 1609].

1. Introduction

Charge carrier transport behaviors in organic semiconductors have been intensively studied by both industry and academia for many years [1,2]. The interests in studying organic materials are driven by their applications in optoelectronic devices including e.g. organic light emitting diodes, thin film transistors and photovoltaic cells [3–5]. To date, carrier mobility measurement has emerged to be a key technique for the characterization of organic material [6]. In addition, the measurement of mobility provides a means of examining carrier transport inside organic semiconductors. Generally, measuring the room temperature carrier mobility (μ_{RT}) is the first step to characterize transport behaviors of an organic material. However, μ_{RT} can be easily affected by dopants (intrinsic or extrinsic) and defects inside the material. Therefore, μ_{RT} is clearly not the

best parameter to describe the intrinsic transport properties of the organic materials.

Below, we demonstrate that the high temperature limit of carrier mobility (μ_∞) is a better parameter for quantifying the charge transport properties of an organic material because it is less sensitive to the presence of dopants and defects. Previous reports suggested that μ_∞ can be utilized to estimate transport parameters such as the average inter-site distance (a), the localization length (L) with the relation [7,8]:

$$\mu_\infty = \frac{ea^2 v_0}{\sigma} \exp(-2a/L) \tag{1}$$

In Eq. (1), e is the electron charge, v_0 is the attempt-to-escape frequency. But the value of v_0, which is ranged between 10^{-12} and $10^{-14}\,s^{-1}$, is a big uncertainty. The practical use of μ_∞ is still not very evident.

In this study, we measure μ_∞ of *N,N'*-diphenyl-*N,N'*-bis(1-naphthyl)(1,1'-biphenyl)-4,4'diamine (NPB) by time-of-flight (TOF) technique. NPB is widely used in

OLEDs as a hole transporter. It possesses trap-free hole-transporting property, excellent film forming ability, and chemically stability [9]. Hence, the research on the intrinsic hole-transporting properties of NPB is of clear importance. The effect of dopants on μ_∞ of NPB will be examined. Furthermore, knowledge of μ_∞ allows us to estimate the full temperature dependence of zero-field mobility (μ_0), if μ_0 at one temperature is known. We demonstrate this concept by doping NPB with copper phthalocyanine (CuPc).

2. Experimental

All TOF samples had a structure of indium-tin-oxide (ITO)/undoped-NPB or doped-NPB(7–10 μm)/CuPc(100 nm)/Al(15 nm). Table 1, second column, shows the chemical structures of the host (NPB) and the dopants. All doped samples are represented with the notation NPB:X, where X is the name of the dopant. The full names of all dopants are spelt out in Table 1. Doping was achieved by thermal co-evaporation of the two materials (i.e. NPB and dopant) on

Table 1

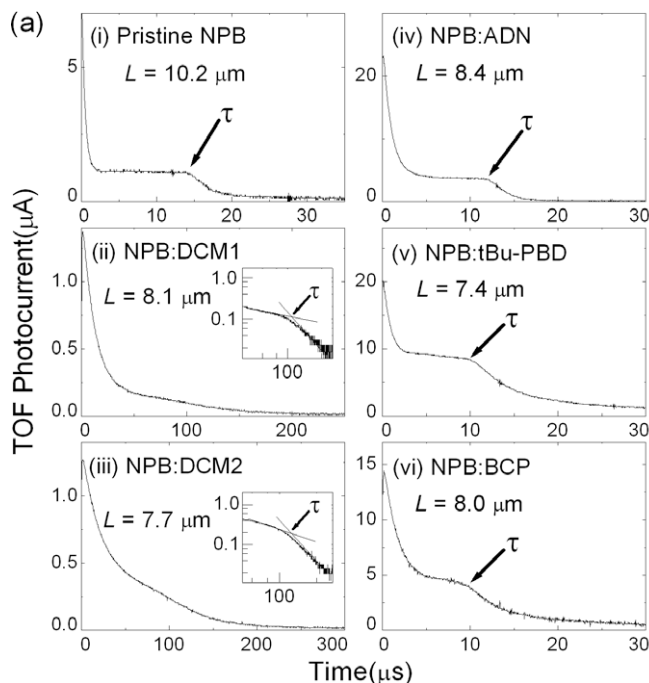
[a] ADN: 9, 10-di(2-naphthyl) anthracene.
[b] tBu-PBD: 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole.
[c] BCP: 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline.
[d] DCM1: 4-(dicyanomethylene)-2-methyl-6-(p-dimethylaminostyryle)-4H-pyran.
[e] DCM2: 4-dicyanomethylene-2-methyl-6-[2-(2,3,6,7-tetra-hydro-1H,5H-benzo[ij] quinolizin-8-yl)vinyl]-4H-pyran.
[f] CuPc: copper phthalocyanine.


Fig. 1a. Typical time-of-flight transients for (i) Pristine NPB, (ii) NPB:DCM1 (iii) NPB:DCM2 (iv) NPB:ADN and (v) NPB:tBu-PBD (vi) NPB:BCP under an applied field of 0.14 MV/cm at room temperature. In (ii) and (iii), the insets show the log–log plots. The film thicknesses L are also shown.

ITO under a pressure of about 10^{-6} Torr. The coating rate for NPB and the dopants were fixed at 9.85 and 0.15 Å/s, respectively. So, the doping concentration was fixed at 1.5% by volume. Three of the dopants, ADN, tBu-PBD, and BCP were chosen to act as hole scatterers in NPB because they possess low-lying highest occupied molecular orbitals (HOMO) relative to the HOMO of NPB (Table 1, third column) [10–13]. The other three dopants, DCM1, DCM2, and CuPc were chosen as hole traps in NPB because they have high-lying HOMO relative to NPB [14,15]. During hole mobility measurement, the sample was reverse-biased. A nitrogen pulsed laser (λ = 337.1 nm) was irradiated on the semi-transparent Al/organic interface to generate electron-hole pairs. Since CuPc has strong absorption at 337.1 nm, over 90% of the incident photons were absorbed by the CuPc layer [16]. A dc power supply was used to provide the bias voltage for hole detection. Free holes are drifted towards the negatively biased anode.

3. Results and discussion

Fig. 1a shows the representative TOF hole transients for pristine NPB and doped-NPB at room temperature and an applied electric field strength (F) of 0.14 MV/cm. The hole transit time (τ) can be determined at the instant at which the plateau drops abruptly in the TOF signal. Pristine NPB exhibits non-dispersive hole transport with a very well-defined plateau region. Similarly, when NPB is doped with scatterers (i.e. ADN, tBu-PBD, and BCP), the plateau region is still evident for the extraction of τ. When NPB is doped with traps (i.e. DCM1/2), the plateau region in the TOF signal is less evident. However, τ can be defined from the
Fig. 1b. Hole mobilities of NPB and doped-NPB at room temperature. Solid lines are the best linear fits to the data.

inserted log–log plots of Fig. 1a(ii) and (iii). For CuPc-doped-NPB, the TOF signals were very dispersive. τ Cannot be determined at room temperature. This observation will be discussed later. Once the transit time is determined, the hole mobilities can be evaluated by $\mu_h = L^2/(V \cdot \tau)$ where L is the thickness of the sample and V is the applied voltage [6]. Fig. 1b shows the hole mobilities for doped and pristine NPB at room temperature. A plot of $\mu(F,T)$ vs $\sqrt{F}$ generally yields a straight line. Extrapolation of this line to $F = 0$ results in μ_0. Table 1, fifth column summarizes all μ_0 at room temperature. Subsequently, the experiment was re-
Fig. 2. The zero-field mobilities μ_0 vs $(1000/T)^2$ for NPB (■) and doped-NPB. For a doped sample, the data are labeled with the name of the dopant. Solid lines are best linear fits to the data sets. μ_∞ can be extracted from the y-intercept of these plots. For NPB:CuPc, only one data point labeled with the filled star symbol (★) can be determined from TOF signals at 389 K. The open star symbol (☆) is the extrapolated μ_0 of NPB:CuPc at room temperature (290 K).

peated at different temperatures to investigate the dependence of μ_0 on T. Fig. 2 shows the temperature dependences of μ_0 for pristine and doped-NPB. The temperature dependent mobility data were then analyzed by the Gaussian disorder model (GDM) [17]. The essence of the GDM can be embodied in the following equation for the carrier mobility:

$$\mu(F,T) = \mu_\infty \exp\left[-\left(\frac{2\sigma}{3kT}\right)^2\right] \exp\left\{ C\left[\left(\frac{\sigma}{kT}\right)^2 - \Sigma^2\right]F^{\frac{1}{2}}\right\} \tag{2}$$

In Eq. (2), μ_∞ is the high temperature limit of carrier mobility, σ is the energetic disorder, Σ is the positional disorder, T is the absolute temperature, k is the Boltzmann constant, F is the applied electric field, and C is a fitting constant. Generally, $\ln(\mu_0) \sim -\frac{1}{T^2}$ as predicted by Eq. (2). For a particular sample, μ_∞ and σ can be extracted from the y-intercept and the slope of this plot, respectively (Table 1, sixth and seventh columns). For pristine NPB, the extracted μ_∞ and σ were about 1.7×10^{-2} cm^2/Vs and 75 meV, respectively. From Fig. 1b, we see that charge scatterers (i.e. ADN, tBu-PBD, BCP) have little effects on hole mobilities or μ_0 in NPB. As a result, the temperature dependent μ_0 for undoped-NPB and NPB-doped with charge scatterers have almost overlapping data. In contrast, charge traps (i.e. DCM1, DCM2, CuPc) severely hinder hole mobilities in NPB. The reduction of μ_0 is more than one order down for NPB:DCM1 or NPB:DCM2 compared to the pristine case at room temperature (Table 1, fifth column). Irrespective of the nature of the dopant, we note that all samples appear to have a common y-intercept, i.e. μ_∞, from Fig. 2 (Table 1, sixth column). The mean value of

$\mu_\infty = 1.5 \pm 0.3 \times 10^{-2}$ cm^2/Vs remain almost the same as the pristine case. This suggests that μ_∞ is independent of the nature of dopants. At $T \to \infty$, it is expected that charge carriers gain sufficient thermal energy to overcome all energetic barriers which are formed by the dopant molecules. Hence, the μ_∞ should not be affected by the presence of dopant molecules.

Below, we employ this common μ_∞ to estimate the full temperature dependence of μ_0 for NPB:CuPc. When CuPc was doped into NPB, the mobile holes are severely trapped by CuPc molecule. This explains why the TOF transient for NPB:CuPc was very dispersive as shown in Fig. 3a. Subsequently, the temperature of the sample was increased. Non-dispersive signals with well-defined plateau regions were observed at $T = 389$ K. An example is shown in Fig. 3b. Fig. 3 shows μ_h ($T = 389$ K) of NPB:CuPc at different electric fields. μ_0 ($T = 389$ K) can be extracted from the y-intercept of this plot. This data point is shown with a "star" symbol (★) in Fig. 2. The full temperature dependence of μ_0, however, still cannot be obtained experimentally. To obtain a full temperature dependence of μ_0, we fit a straight line to μ_∞ and μ_0 ($T = 389$ K) as shown in the dashed line in Fig. 2. With this fitted line, we can extrapolate the value of μ_0 at room temperature to be 4.2×10^{-7} cm^2/Vs (open "star" symbol, ☆ in Fig. 2). The energetic disorder, σ can also be evaluated from the slope of the fitting line $\left(= -\frac{4\sigma^2}{9(1000)^2k^2}\right)$, and the value is about 121 meV. These extrapolations concur with the expectations that μ_h should be strongly reduced when deep traps (trap depth ~300 meV for CuPc-doped into NPB) are introduced into NPB. The overlap between the HOMO of CuPc molecules and the upper part of the density of state of NPB would broaden the hopping transport manifold and lead to an increase in the energetic disorder [18]. The overall hole transport properties of NPB are summarized in Table 1.
Fig. 3. Hole mobilities of NPB:CuPc at 389 K. Typical TOF transients of (a) NPB:CuPc at room temperature (RT), (b) NPB:CuPc at 389 K under an applied field of 0.2 MV/cm.

The mobility extrapolation of NPB:CuPc can be cross-examined by the classic work of Hoesterey and Letson (H&L) which was originally developed for organic crystals [19]. The formalism is based on discrete trap energy and devoid of the effects of disorder. They proposed that in the presence of traps, the mobility is given by:

$$\mu_{\text{trap}}(c) = \mu_{\text{trap-free}} f^{-1} = \mu_{\text{trap-free}} \left[1 + c \exp\left(\frac{E_t}{kT}\right) \right]^{-1} \qquad (3)$$

where f is a trapping factor reflecting the transit time spent by a carrier in traps, $\mu_{\text{trap-free}}$ is the trap-free mobility, c is the doping concentration, k is the Boltzmann constant, and E_t is the trap depth, i.e. the energy level difference between host and trap [18]. The validity of Eq. (3) has been demonstrated in small organic molecules [20,21]. Besides affecting the mobility, the presence of traps also affect the energetic disorder. From the well-known GDM and Eq. (3), the effective energetic disorder parameter (σ_{eff}), which is the width of the cumulative density of states (DOS) in the presence of traps, can be described by [22]:

$$\left(\frac{\sigma_{\text{eff}}}{\sigma}\right)^2 = 1 + \left(\frac{3kT}{2\sigma}\right)^2 \left[\ln(c) + \frac{E_t}{kT}\right] \qquad \text{for } c\left[\exp\left(\frac{E_t}{kT}\right)\right] \geqslant 1 \qquad (4)$$

where σ is the intrinsic energetic disorder (i.e. the width of the intrinsic DOS in the absence of traps). Below, we employ Eqs. (3) and (4) to cross-examine the transport parameters extrapolated from Fig. 2 for NPB:CuPc.

For NPB:CuPc, substituting the known values of $c \sim 0.015$, $E_t \sim (5.5\text{–}5.2)\text{eV} = 0.3$ eV, $\mu_{\text{trap-free}}$ (μ_0 of NPB) $\sim 3 \times 10^{-4}$ cm^2/Vs, and σ (NPB) ~ 75 meV into Eqs. (3) and (4). It yields a μ_{trap} of 1.2×10^{-7} cm^2/Vs (μ_0 of NPB:CuPc) and a σ_{eff} (NPB:CuPc) of 129 meV at room temperature. The computed results from the work of H&L only deviate with our mobility extrapolation (4.2×10^{-7} cm^2/Vs) within half an order and agree to our energetic disorder extrapolation (121 meV). Exact agreement is not expected between the computed results [by Eqs. (3) and (4)] and our extrapolated results in Fig. 2 as there is an uncertainty in E_t of at least ~ 0.1 eV due to uncertainties in the HOMO values of NPB and CuPc. However, this agreement shows that μ_∞ can be used to estimate the full temperature dependence of μ_0.

4. Conclusion

In conclusion, when dopants were introduced into NPB, the measured mobilities were reduced compared to the intrinsic values, especially for the cases of trapping. However, the values of the μ_∞ remain nearly the same as the pristine case. This indicates that μ_∞ is indeed an intrinsic property of organic semiconductor, irrespective of the nature of dopants. The application of the common μ_∞ for mobility extrapolation was demonstrated from the case of NPB:CuPc. The results generally agree to the classic work of Hoesterey and Letson.

ARTICLE INFO

ABSTRACT

Two novel *p*-phenylenediamine-substituted fluorenes have been designed and synthesized. Their applications as hole injection materials in organic electroluminescent devices were investigated. These materials show a high glass transition temperature and a good hole-transporting ability. It has been demonstrated that the 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) doped *p*-phenylene-diamine-substituted fluorenes, in which F4-TCNQ acts as *p*-type dopant, are highly conducting with a good hole-transporting property. The organic light emitting devices (OLEDs) utilizing these F4-TCNQ-doped materials as a hole injection layer were fabricated and investigated. The pure Alq_3-based OLED device shows a current efficiency of 5.2 cd/A at the current density of 20 mA/cm^2 and the operation lifetime is 1500 h with driving voltage increasing only about 0.7 mV/h. The device performance and stability of this hole injection material meet the benchmarks for the commercial requirements for OLED materials.

1. Introduction

Organic semiconductors have been intensively studied as active materials in various electronic and optoelectronic devices because of the low cost, ability to tune the functional/material properties by means of chemical structural modifications, ease of fabrication, and feasibility for flexible devices [1]. In addition, the high absorptivity in the visible range of organic semiconductors offers the possibility to prepare a thin-film for photovoltaic cells (OPV) and photodetectors [2]. Hence, in the past decade, these materials have been intensively studied as alternative active materials in various electronic and optoelectronic devices. Recently, enormous progresses have been made in tailoring properties of organic semiconductors through chemical structure modification [3]. Organic semiconductors are generally in the form of undoped amorphous state when used as carrier transporters in thin-film optoelectronic devices. However, the inherent low charge mobility of organic semiconductors resulting from the hopping transport in disordered organic thin-films often gives rise to a high operating voltage. For example, the hole mobility in amorphous organic thin-films is in the range of 10^{-3}–10^{-5} cm^2 v^{-1} s^{-1}, which is about 1000 times lower than that of the amorphous Si thin-film. To improve the

conductivity of organic semiconductors, doping concepts have been adopted from their inorganic counterparts. Similar to the conventional doping in inorganic semiconductors, the basic concept of doping in organic semiconductor is to add a strong electron-donor or electron-acceptor which either transfer an electron to the lowest unoccupied molecular orbital (LUMO) of a host molecule to produce a free electron (*n*-type doping) or remove an electron from the highest occupied molecular orbital (HOMO) of a host molecule to generate a free hole (*p*-type doping) [4]. In this concept, by matching the LUMO/HOMO of the dopant to the HOMO/LUMO of the organic semiconductor, the Fermi level of the organic semiconductor can be successfully shifted towards the transport states, and hence, the organic devices will be beneficial from reducing ohmic losses, lowering carrier injection barriers and increasing the built-in potential of Schottky- or *p*–*n*-junctions [5]. The organic optoelectronic device with a hole transporting layer (HTL) doped with *p*-type dopant such as 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ), and an electron transporting layer (ETL) doped with *n*-type dopant such as alkali metal atoms are widely reported, and the device structure is known as *p*–*i*–*n* [6]. Currently, *p*–*i*–*n* organic light emitting devices (OLED) [7] and *p*–*i*–*n* OPV [8] are two of the hot topics in the organic optoelectronic devices due to the improved ohmic contact and electrical conductivity in the devices. For instance, a very low-operation-voltage multilayered OLED with high efficiency has been achieved by combining a thick F4-TCNQ doped 4,4′,4″-*tris*(N,N-diphenylamino)-triphenylamine (TDATA) as a HTL with a thin undoped buffer layer [9]. This OLED exhibits a turn-on voltage of 2.5 V at a luminance of 1 cd/m² and an operating voltage of 3.4 V at a luminance of 100 cd/m² for pure *tris*-(8-hydroxyquinoline) aluminum (Alq₃) device without dopant emitter. Most recently, a *p*–*i*–*n* white OLED reached a high efficiency of 23.3 lm/W [10]; and a *p*–*i*–*n* red phosphorescent OLED obtained an external quantum efficiency of 12.4% with extremely high lifetime of about 1×10^7 h [11]. Among the *p*-doped hole transporting systems, F4-TCNQ is the-state-of-art dopant, and most of the host materials for *p*-doping are based on the wide bandgap amorphous hole transporting materials with triphenylamine unit, such as 4,4′,4″-*tris*-N-naphthyl-N-phenylamino-triphenylamine (TNATA), N,N,N′, N′-tetrakis-(4-methoxyphenyl)benzidine (MeO-TPD) [7a], 4,4′,4″-*tris*(3-methylphenyl-phenyl-amino)triphenylamine (m-MTDATA) [7b]. Low bandgap metal phthalocyanines can also be efficiently doped with F4-TCNQ. However, phthalocyanines are not well suited for OLEDs due to their small energy gap between HOMO and LUMO levels of phthalocyanines, which leads to re-absorption and electron injection from the emitting layer to the HTL [12]. Other type of materials that can be doped with F4-TCNQ are very rarely reported. In the practical point of view, device stability is an important issue that governs the key factor to realize the success of commercialization. In order to achieve the practically targeted stability, organic semiconductors with high thermal stability are necessary to be developed. Fluorene derivatives have been received considerable attention as potential candidates for the active materials in OLED due to their good chemical stability and high luminescence over the past decade [13]. By attaching appropriate functional substituent, fluorene derivatives can act as a HTL [14], or an ETL [15], or a deep-blue emitting material (EM) [16] in OLEDs. To the best of our knowledge, there is no report on the applications of fluorene derivatives as a *p*-doping host in OLEDs. In this contribution, we have designed and synthesized two new *p*-phenylenediamine-substituted fluorenes for the hole injection application. It is anticipated that these materials show a high glass transition temperature (T_g) and a good hole transport ability because of the highly thermally stable nature of fluorene and phenylenediamine moieties as well as the good hole transporting property of phenylenediamine functional group. We have demonstrated that controlled *p*-type doping system using F4-TCNQ as a dopant can be extended to materials with a fluorene core which was found to be efficient and stable in application of OLED devices. It has been shown that high conductivities can be achieved through doping with F4-TCNQ in these two derivatives. On the other hand, for good device performance, the ionization potential of the host also plays an important role. The lower the ionization potential of the host, the better is the performance. The best Alq₃-based OLED device using such a host material doped with F4-TCNQ as a hole injection layer (HIL) shows an efficiency of 5.2 cd/A and operation lifetime of 1500 h at 20 mA/cm², with the driving voltage increasing about 0.7 mV/h. This material with the best performance can be used to replace the currently employed triphenylamine based HIL materials.

2. Results and discussion

2.1. Synthesis and characterization

Scheme 1 shows the synthetic route utilized to prepare *p*-phenylenediamine-substituted fluorenes, **4a** and **4b**. 2,7-dibromofluorene derivatives **1a** and **1b** were prepared according to the literature procedures [16a]. Double amination of 2,7-dibromofluorene derivatives **1a** and **1b** with two equivalent of diphenylamine in the presence of Pd(OAc)₂:2P(o-tolyl)₃ as a catalyst afforded the corresponding diamination product **2a** and **2b** in 72% and 68% yield, respectively. Bromination of diphenylamino end-capped fluorene derivatives **2a** and **2b** with NBS in chloroform yielded tetrabromo-substituted intermediates **3a** and **3b** in excellent yields. Palladium catalyzed amination of **3a** and **3b** with diphenylamine afforded the desired *p*-phenylenediamine-substituted fluorene derivatives in good yields. All the newly synthesized hole injection materials were fully characterized with ¹H NMR, ¹³C NMR, MALD-TOF HRMS, and elemental analysis and found to be in good agreement with their structures. The detail procedures are shown in experimental section. These fluorene derivatives were purified by the flash column chromatography and degassed under vacuum before used for deposition. Table 1 summarizes the physical properties measured by the corresponding techniques. As determined by differential scanning calorimeter and thermal gravimetric ana-

[f] Determined by thermal gravimetric analyzer with a heating rate of 10 °C min⁻¹ under N₂.

lyzer with a heating rate of 10 °C min⁻¹ under N₂, both fluorene derivatives possess a high glass transition temperature (T_g), > 125 °C and thermal decomposition temperature (T_{dec}), >520 °C, respectively. Such high T_g values are superior to most of the commonly used hole transporting materials (i.e. T_g of 4,4′,4″-*tris*(*N*-(2-naphthyl)-*N*-(phenylamino)triphenylamine (2T-NATA) = 110 °C) [17]. It is well-known that the higher the T_g of a material, the better is the morphological stability of an organic thin-film. Hence, high morphological stability is anticipated using these materials as a hole transporting material in an OLED application.

Cyclic voltammetry (CV) was carried out in a three-electrode cell set-up with 0.1 M of Bu₄NPF₆ as a supporting electrolyte in CH₂Cl₂ to examine the electrochemical properties of these molecules. All the potentials reported are referenced to Fc/Fc⁺ standard and the results are tabulated in Table 1. These fluorene derivatives exhibit a low first reversible one-electron anodic redox wave corresponding to phenylenediamine oxidation with $E_{1/2}^{oxd1}$ at 0.39–0.48 V and followed by a reversible one-electron and two-electron anodic redox waves with $E_{1/2}^{oxd2}$ at 0.52–0.58 V and $E_{1/2}^{oxd3}$ at 0.86–0.89 V, respectively. Such a facile first electrochemical oxidation of phenylenediamine moiety suggests a very low first ionization potential of the materials which was confirmed by the estimated HOMO level around −5.1 eV as determined by ultraviolet photoemission spectroscopy. The low HOMO level make them feasible to be removed an electron to generate a free hole upon doped with a strong electron-acceptor. On the other hand, these fluorene derivatives also exhibit an irreversible cathodic wave with $E_{1/2}^{red1}$ at −1.00 to −1.27 eV, which corresponds to the formation of the radical anion on the fluorene/fluorone core.

2.2. Charge-transfer complex of 4 and F4-TCNQ

Due to the strong electron-donating nature of **4** and the strong electron-accepting property of F4-TCNQ, **4** and F4-TCNQ can interact to form a charge-transfer (CT) complex via partial electron transfer upon mixing with which free carriers would be generated as depicted in Fig. 1. There are two possible reaction routes for one-electron transfer between electron-donor **4** and electron-acceptor F4-TCNQ, as shown in Fig. 1. Assuming that there is only one route dominates the one-electron transfer process, the reaction between **4** (represented as D) and F4-TCNQ (represented as A) can be written as [18]:

$$D + A \overset{K}{\rightleftharpoons} D^+ + A^- \quad E_{1A} - E_{1D} \tag{1}$$

where, E_{1A} and E_{1D} are the first reduction potential of the electron-acceptor and the first oxidation potential of the electron-donor, respectively. Thus the equilibrium constant (K) for electron transfer can be given:

$$\log K = \log\left[\frac{[D^+][A^-]}{[D][A]}\right] = \frac{E_{1A} - E_{1D}}{0.059} \tag{2}$$

Using E_{1D} of 0.39 and 0.48 V for **4a** and **4b** from Table 1, respectively and E_{1A} of 0.568 V for F4-TCNQ [19], the reaction constants of $K_{4a\text{-}F4\text{-}TCNQ}$ and $K_{4b\text{-}F4\text{-}TCNQ}$ obtained were $10^{3.02}$ and $10^{1.49}$, respectively. With such large positive values, the corresponding reactions for one-electron transfer between **4** and F4-TCNQ are likely to occur. The occurrence of such electron transfer reactions are also reflected in the UV–Vis absorption spectra as shown in Fig. 2. Upon addition of F4-TCNQ, new bands/peaks at longer wavelengths appear in the solution mixture as compared to the spectra of their pure solutions. In the **4a** and **4b** absorption spectra, there are no absorption above 700 nm, while the mixture of F4-TCNQ with **4a** and **4b** show additional strong absorption peaks around 760 and 870 nm, which are attributed to the absorption of anion radical of F4-TCNQ [20]. Concomitantly, the absorption intensity of F4-TCNQ decreases dramatically
Fig. 1. Possible reaction mechanism for electron-donor **4** and electron-acceptor F4-TCNQ.
Fig. 2. (a) UV–Vis absorption of 4a (10^{-5} M), F4-TCNQ (10^{-5} M) and 4a (10^{-5} M) + F4-TCNQ (10^{-5} M) in DCM and (b) UV–Vis absorption of 4b (10^{-5} M) and 4b (10^{-5} M) + F4-TCNQ (10^{-5} M) in DCM.

in the solution mixture. This illustrates that the charge transfer (CT) complex is formed between 4a (and 4b) and F4-TCNQ which also implies that these materials doped with F4-TCNQ would form a good p-type system. In addition, the charge transfer band of F4-TCNQ doped 4a system was about 10 times higher than that of F4-TCNQ doped 4b system, suggesting a more efficient charge transfer between F4-TCNQ and 4a than F4-TCNQ and 4b. This may explain the better hole conduction in the 4a doped with F4-TCNQ thin-film shown in the next section.

2.3. p-Type doping properties in thin-films

From a chemical point of view, in amorphous thin-films, the p-type doping of a hole transporting molecules D by electron-acceptor molecules A is determined by a mass action law (In this case, D concentration is much higher than A concentration):

$$D + \hat{D}A \rightleftharpoons D + [\hat{D}^+A^-] \rightleftharpoons D^+ + \hat{D}A^- \qquad (3)$$
Here, D is a random matrix molecule and $\hat{D}$ is the matrix molecule adjacent to the electron-acceptor, which is sup-

posed to give the electron to the acceptor in the initial charge transfer step, this is exactly the reaction shown in Fig. 1 and Eq. (1). Thus, the intermediate state $[\hat{D}^+A^-]$ is a local charge transfer state, where the charges may be bound by different interactions and form a kind of complex. The final state is assumed to be unbound, i.e. the matrix molecule that carries the positive charge is so far away from the ionized acceptor that it does not feel the Coulomb interaction. In such a situation, the positive charge can move by hopping and the density of D^+ can be associated with the hole density p. If a very strong electron-acceptor is used and the initial charge transfer (first step of reaction (3)) is complete, the hole density will be governed by the second step of reaction (3). The problem of the generation of free carriers is not only about the Coulomb attraction between two molecules with opposite charge. It is about the difference in the total energy between the following two states: (a) a matrix with a certain density of charged acceptors with holes bound to the acceptors and (b) the same matrix with mobile holes. Here, all kind of structural relaxation and quantum chemical reorganization processes have to be considered [21]. In our case, it could be thought or assumed that the F4-TCNQ acceptors could react with the host molecules in a great extent or even completely because of the energetically favorable reaction and the small electron-acceptor concentration. Therefore, the free hole density in the doping system shall be only controlled by the dissociation of the intermediate state $[\hat{D}^+A^-]$. In other words, besides the high tendency for electron transfer from electron-donor to electron-acceptor, another important factor that influences the conductivity of the doped system is the status of the intermediate $[\hat{D}^+A^-]$: the easier the dissociation, the higher conductivity is the doped system.

In order to study the hole transporting properties of 4a and 4b without or with doping, we fabricated hole-only devices with the structure of ITO/4a and 4b with 0% or 1.5% F4-TCNQ (60 nm)/NPB (10 nm)/Al (where NPB = N,N′-bis-(1-naphthyl)-N,N′-dipheny-1,1′-biphenyl-4,4′-diamine). N,N′-bis-(1-naphthyl)-N,N′-dipheny-1,1′-biphenyl-4,4′-diamine). For comparison, the 2T-NATA hole-only devices with and without F4-TCNQ were fabricated simultaneously. The I–V measurements were carried out on these devices and the results are shown in Fig. 3. It is clearly indicated that the F4-TCNQ doped films of 4a, 4b and 2T-NATA exhibit significantly higher current as compared to their undoped counterparts, demonstrating high conductivity in the doped films. In the F4-TCNQ doped systems, 4a-based film shows a greater improvement in conductivity with about 2–3 orders of magnitude increase in hole current with respect to the undoped film. It is important to note that the current densities of F4-TCNQ doped 4a, 4b, and 2T-NATA hole-only devices at 3 V are 135, 6.6 and 51.8 mA/cm^2, respectively. These findings are consistent with the HOMO data determined which indicate that the HOMO level of 4a is lower than that of 4b and 2T-NATA, as shown in Table 1. In addition, the absorption spectra in the doping system indicate that the degree of charge transfer in 4a/F4-TCNQ system is higher than that of 4b/F4-TCNQ system due to the lower HOMO of 4a. Therefore, F4-TCNQ doped 4a film showed higher hole conductivity than those of F4-TCNQ doped 4b and 2T-NATA
Fig. 3. I–V characteristics of (a) **4a**, (b) **4b,** and (c) 2T-NATA hole-only devices with and without F4-TCNQ.

films. As a result, **4a** is anticipated to be a better candidate for the *p*-type doping host material than 2T-NATA.

2.4. Application in OLED devices

Encapsulated OLED devices with a sheet desiccant inside a glass cover were fabricated using F4-TCNQ doped

4a and **4b** as a HIL. The device structure is ITO/**4a** or **4b**:1.5% F4-TCNQ (150 nm)/NPB (10 nm)/Alq$_3$ (60 nm)/LiF (1 nm)/Al. The performance of the devices was tested and the *I–V–B* characteristics are shown in Table 2 and Fig. 4. The operation lifetimes were measured at a constant current of 20 mA/cm^2. The lifetime was recorded after a 10-h burn-in. For comparison, the OLED using 2T-NATA doped with F4-TCNQ as a HIL was also fabricated and tested under the same conditions. The results are summarized in Table 2.

Due to the doping of HIL, a high luminance is achieved at low voltage which results in a high power efficiency even though a comparatively thick HTL (160 nm in thickness) is used. For the **4a**-based device, the turn-on voltage, defined as the bias at a brightness of 1 cd/m^2, is only 2.7 V. At 20 mA/cm^2, the device driving voltage is 6.0 V and current efficiency is 5.2 cd/A as compared to the commonly used 2T-NATA doped with F4-TCNQ as a HIL, the driving voltage is 6.7 V with a current efficiency of 4.5 cd/A at the same current density. These results indicate that **4a** is a superior material for the HIL in OLED. For **4b**-based device, it shows a slightly higher driving voltage which agrees with its relatively inferior hole transporting properties in F4-TCNQ doped thin-film and a shorter lifetime. Fig. 5 shows the stability curve of **4a**-based device to its half brightness. As shown in the figure that such an OLED device has an operation lifetime of 1500 h at 20 mA/cm^2, and the driving voltage increasing is about 0.7 mV/h. This result demonstrates that our material **4a** is a very useful and stable *p*-type dopant host for the use of OLEDs and has a great potential for practical applications.

3. Experimental

3.1. Synthesis

2a. A mixture of 2,7-dibromo-9,9-bis(*n*-butyl)fluorene, **1a** (4.36 g, 10.0 mmol), diphenylamine (3.72 g, 22.0 mmol), palladium(II) acetate (0.11 g, 0.5 mmol), tri-(*o*-tolyl)phosphine (0.30 g, 1.0 mmol) and sodium *tert*-butoxide (2.88 g, 30.0 mmol) in dry toluene (50 mL) was stirred under a nitrogen atmosphere at 110 °C for 24 h. After cooling to room temperature, the reaction mixture was poured into a saturated aqueous solution of ammonium chloride and extracted with dichloromethane (3 × 60 mL). The combined organic extract was washed with water and dried over anhydrous Na$_2$SO$_4$. Evaporation of volatiles gave a brown solid, which was separated by silica gel column chromatography using petroleum ether/dichloromethane as a gradient eluent affording **2a** in 72% yield (4.4 g) as a white solid. ^{1}H NMR (400 MHz, CDCl$_3$, δ) 7.47 (d, *J* = 8.0 Hz, 2H), 7.22–7.25 (m, 8H), 7.07–7.13 (m, 10H), 6.97–7.01 (m, 6H), 1.73–1.77 (m, 4H), 1.02–1.10 (m, 4H), 0.72 (t, *J* = 7.6 Hz, 6H), 0.64–0.67 (m, 4H). ^{13}C NMR (100 MHz, CDCl$_3$, δ) 152.0, 148.0, 146.4, 136.2, 129.1, 123.7, 123.6, 122.3, 119.7, 119.4, 54.9, 39.7, 26.1, 22.9, 13.9. MS (MAL-DI-TOF) *m/z* 612.8 (M$^+$).

2b. The synthetic procedure for **2a** was followed using 2,7-dibromofluorenone, **1b** (3.38 g, 10.0 mmol), Ph$_2$NH (3.72 g, 22.0 mmol), *t*-BuONa (2.88 g, 30.0 mmol), Pd(OAc)$_2$

(0.11 g, 0.5 mmol), P(o-tolyl)$_3$, (0.30 g, 1.0 mmol) and dry toluene (50 mL). The product was purified by silica gel column chromatography using petroleum ether/dichloromethane as a gradient eluent affording 3.48 g (68%) of **2b** as a dark red solid. ^{1}H NMR (400 MHz, CDCl$_3$, δ) 7.24 (d, J = 2.0 Hz, 2H), 7.14–7.19 (m, 10H), 6.94–7.04 (m, 14H). ^{13}C NMR (100 MHz, CDCl$_3$, δ) 193.3, 148.1, 147.0, 137.9, 135.7, 129.4, 128.5, 124.5, 123.4, 120.3, 119.3. HRMS (MALDI-TOF) Calc. for C$_{37}$H$_{26}$N$_2$O: 514.2040. Found: 514.2041.

3a. A mixture of **2a** (4.28 g, 7.0 mmol) and NBS (5.0 g, 28.0 mmol) in 50 mL of CHCl$_3$ were stirred at room temperature for 4 h. Evaporation of solvent under vacuum re-

sulted in a yellow solid that was adsorbed on silica gel and purified by flash column chromatography using dichloromethane/petroleum ether mixture as eluent affording **3a** in 97% yield (6.30 g) as a white solid. ^{1}H NMR (400 MHz, CDCl$_3$, δ) 7.49 (d, J = 8.0 Hz, 2H), 7.34 (d, J = 8.8 Hz, 8H), 7.02 (d, J = 2.0 Hz, 2H), 6.97 (m, 10H), 1.75–1.79 (m, 4H), 1.02–1.10 (m, 4H), 0.72 (t, J = 7.2 Hz, 6H), 0.61–0.69 (m, 4H). ^{13}C NMR (100 MHz, CDCl$_3$, δ) 152.3, 146.6, 145.6, 136.6, 132.2, 125.1, 123.6, 120.1, 119.3, 115.2, 55.0, 39.6, 26.1, 22.9, 14.0. MS (MALDI-TOF) m/z 928.1 (M$^+$).

3b. The above procedure for **3a** was followed using **2b** (3.4 g, 6.6 mmol) and NBS (4.71 g, 26.5 mmol). The crude product was purified by silica gel flash column chromatography using dichloromethane/petroleum ether mixture as eluent affording **3b** in 92% yield (5.04 g) as a dark purple solid. ^{1}H NMR (400 MHz, CDCl$_3$, δ) 7.37 (d, J = 8.8 Hz, 8H), 7.28–7.30 (m, 4H), 7.11 (dd, J = 2.0, 8.0 Hz, 4H), 6.94 (d, J = 8.8 Hz, 8H). ^{13}C NMR (100 MHz, CDCl$_3$, δ) 192.7, 147.4, 145.6, 138.6, 135.8, 132.6, 129.0, 125.8, 120.8, 119.6, 116.4. MS (MALDI-TOF) m/z 829.9 (M$^+$).

4a. A dried 250 mL two-necked flask containing the solution of **3a** (4.64 g, 5.0 mmol), Ph$_2$NH (4.06 g, 24.0 mmol), t-BuONa (2.88 g, 30.0 mmol), Pd(dba)$_2$ (116 mg, 0.2 mmol), tri-tert-butylphosphine (40 mg, 0.2 mmol) and 70 mL of dry toluene was heated at 90 °C overnight with good stirring under N$_2$. After cooling to room temperature, the purple-blue mixture was poured into a saturated aqueous solution of ammonium chloride and extracted twice with toluene. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate and evaporated under vacuum. The residue was rapidly eluted through silica gel column using toluene/hexane (4:1) to give crude product, which was further purified by crystallization from EtOAc/EtOH affording 5.44 g (85% yield) of **4a** as a light-yellow solid. ^{1}H NMR (400 MHz, C$_6$D$_6$, δ) 7.35–7.38 (m, 4H), 7.21 (dd, J = 1.6, 8.0 Hz, 2H), 7.12–7.16 (m, 24H), 7.00–7.08 (m, 24H), 6.83 (t, J = 7.6 Hz, 8H), 1.70–1.73 (m, 4H), 0.94–1.07 (m, 4H), 0.84–0.91 (m, 4H), 0.63 (t, J = 7.6 Hz, 6H) ^{13}C NMR (100 MHz, C$_6$D$_6$, δ) 152.5, 148.4, 147.1, 143.7, 143.0, 136.5, 129.5, 125.9, 125.0, 124.2, 123.7, 122.7, 120.4, 119.4, 55.2, 40.0, 26.5, 23.2, 14.1. HRMS (MALDI-TOF) calc. for C$_{93}$H$_{80}$N$_6$: 1281.6471. Found: 1281.6514, Anal. Calc. for C$_{93}$H$_{80}$N$_6$: C 87.15, H 6.29, N 6.56. Found: C 87.30, H 6.19, N 6.40.

4b. The general amination procedure was followed using **3b** (2.1 g, 2.53 mmol), Ph$_2$NH (2.06 g, 12.2 mmol),

Pd(dba)$_2$ (58.7 mg, 0.1 mmol), P(t-Bu)$_3$ (20.2 mg, 0.1 mmol), t-BuONa (1.46 g, 15.2 mmol) and toluene. The crude product was purified by silica gel flash column chromatography (toluene/hexane) and then by crystallization from THF/CH$_3$OH affording 2.03 g (68% yield) of **4b** as a red solid. ^{1}H NMR (400 MHz, C$_6$D$_6$, δ) 7.68 (d, J = 2.0 Hz, 2H), 7.09–7.13 (m, 18H), 7.02–7.06 (m, 16H), 6.93–6.98 (m, 16H), 6.89 (d, J = 8.0 Hz, 2H), 6.83 (t, J = 7.2 Hz, 8H). ^{13}C NMR (100 MHz, C$_6$D$_6$, δ) 192.7, 148.6, 148.2, 144.0, 142.2, 137.9, 136.4, 129.6, 127.6, 125.9, 125.5, 124.5, 123.0, 120.6, 118.6. HRMS (MALDI-TOF) calc. for C$_{85}$H$_{62}$N$_6$O: 1182.4980; Found: 1182.4988. Anal. Calc. for C$_{85}$H$_{62}$N$_6$O: C 86.27, H 5.28, N 7.10; found: C 86.14, H 5.17, N 7.02.

3.2. Device fabrication

OLED and hole-only devices were fabricated using a vacuum thermal evaporation chamber with a base pressure of 1×10^{-6} Torr. All the materials were deposited in one pump-down. Two shadow masks were used to define the deposition areas for organic and metal cathode, respectively. The I–V characteristics of hole-only devices were measured with a computer-controlled DC power supply at room temperature in open air. OLED devices were encapsulated with sheet desiccant under dry N$_2$ atmosphere before measurements. The luminance of OLEDs was measured with PR650 spectrophotometer and a KETHLEY 236 source meter. The lifetime of OLED device was recorded by a homemade lifetime measurement system at constant current mode. The ionization potential (or HOMO) of a thin-film was measured by ultraviolet photoemission spectroscopy using Surface Analyzer model AC-2.

4. Conclusions

In summary, we have designed and synthesized two new p-phenylenediamine-substituted fluorenes, **4a** and **4b** which possess a high glass transition temperature and a good hole transport ability. The p-type doping properties of these materials were studied using F4-TCNQ as a p-type dopant in hole-only device. Furthermore, the mechanism in the doping system was discussed and some insights were highlighted. The OLED device with a HIL utilizing **4a/4b** doped with F4-TCNQ were fabricated and characterized. The pure Alq$_3$-based device using **4a** doped with F4-TCNQ as a HIL shows an operation lifetime of 1500 h at 20 mA/cm^2, and the driving voltage increasing about 0.7 mV/h. These results suggest that **4a** is a useful and stable hole injection material for OLEDs which shows a great potential for practical applications.

enhancing processability and increasing the quantum efficiency. The bulky functional alkyl groups are expected to reduce aggregation of the perylene derivatives as is the case in conjugated polymers [12]. The successful synthesis of the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene molecule reported here is a practical implementation of the aforementioned theories resulting in a product with improved solubility and reduced aggregation.

The two-photon-absorption (TPA) properties of derivatives of perylene have been scarcely investigated [13–16] and yet are extremely useful for potential applications in two-photon-pumped frequency up conversion lasers [14], TPA optical limiters [17], three-dimensional optical storage, three-dimensional photo polymerisation, photodynamic therapy, micro fabrication and microlithography [18–23]. The synthesis of new nonlinear optical (NLO) materials is fundamental in the development of optoelectronic technologies [24]. The open-aperture Z-scan is a convenient and quick experimental method for analysis of nonlinear optical properties of materials [25] and has been successfully applied in this paper.

Herein is presented the synthesis, characterisation and optical limiting properties of the novel 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene. The parent molecule was chosen as 3,4,9,10-perylene-tetracarboxylic-dianhydride (PTCDA) an archetypal molecule whose basic properties have been studied for more than a decade [26]. In addition, in this paper, we demonstrate the useful nonlinear optical property of this dye.

2. Experimental

2.1. Synthesis

A 95% yield of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene was produced by refluxing 1 g of PTCDA in a 5:1 1-iodododecane $(CH_3(CH_2)_{11}I)$ and 1-dodecanol $(CH_3(CH_2)_{11}OH)$ mix over 5 g of potassium carbonate (K_2CO_3) at 110 °C for 7 days (see Scheme 1). The product was dissolved in chloroform and the K_2CO_3 filtered out. The chloroform was extracted, followed by a filtration yielding a golden yellow product which was dried in a vacuum oven at 60 °C. The compound was characterised by ^{1}HNMR, ^{13}CNMR, FTIR, mass spectroscopy and chemical analysis to confirm the product. The sharp ^{1}HNMR peaks obtained are indicative of very high material purity.

^{1}H NMR (400 MHz, $CDCl_3$): δ 0.89 (t, 12H, CH_3), 1.44(m, 72H, 9(CH_2)), 1.50 (m, 8H, O–C–CH_2), 4.33(t, 8H, O–C–CH_2), 8.05(d, 4H, CH), 8.30(d, 4H, CH). ^{13}C NMR (100 MHz, CDCl3) 14.2, 22.7, 26.0, 28.6, 29.3, 29.5, 29.6, 29.7, 31.9, 66.6, 121.4, 128.9, 1129.1, 130.4, 133.1, 168.5. FTIR (NaCl): υ = 2954.0, 2919.4, 2850.3, 1731.9, 1719.6, 1584.5, 1471.9,

1292.2, 1279.5, 1173.5, 747.2 cm^{-1}. MS 1100. *Anal.* Calc. for $C_{72}H_{108}O_8$: C 78.50%, H 9.88%, (M, 1100) Found: 77.54.0%, 9.81%, (M$^+$, 1100)].

2.2. Characterisation

The ^{1}HNMR spectra were recorded on a Bruker Avance III 400 spectrometer with a proton resonance of 400.23 MHz. ^{13}CNMR were recorded on a Bruker Avance III 400 spectrometer with a C resonance of 100.65 MHz, tip angle of 30°, an acquisition time of 0.5 s and a relaxation delay of 1 s. Tetramethoxysilane (TMS) was used as the internal reference with deuterated chloroform ($CDCl_3$) as the NMR solvent. A Micromass LCT Orthogonal Acceleration TOF Electrospray mass spectrometer was used to determine the molecular weight of the compound. The FTIR spectra were taken on a Nicolet NEXUS FTIR spectrometer in the transmission mode. UV–Vis absorption was recorded on a CARY 6000i UV–Vis–NIR spectrophotometer. The fluorescence was carried out on a PerkinElmer LS55 Luminescence Spectrometer. Thermal responses were studied using PerkinElmer Thermo gravimetric Analyser Pyris TGA and PerkinElmer Pyris Diamond DSC. Structural studies were carried out on a Nanoscope 111a AFM machine, a Hitachi S-4300 Field Emission microscope operating in high vacuum mode for HRSEM images and a Jeol 2100 Transmission Electron Microscope.

2.3. Nonlinear optical measurement

The Z-scan technique is a well-known method applicable to study the nonlinear optical properties of materials, including nonlinear absorption, scattering or refraction [25]. A standard open-aperture Z-scan system [24,27] was used to measure the nonlinear extinction (NLE) coefficients, as well as the optical limiting properties of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene at 1 g cm^{-3} chloroform solution concentration. The experiment was performed using 6 ns pulses from a Q-switched Nd:YAG laser. The laser, operating at its second harmonic, 532 nm, with a pulse repetition rate of 10 Hz, was spatially filtered to remove higher-order modes, and tightly focused with a 9 cm focal length lens. In order to enhance NLO response, all samples were tested in 1 cm quartz cells [27,28].

3. Experimental results and discussion

3.1. Solubility

The Hildebrand solubility parameter is chosen as a measure of solubility since its solvent spectrum includes the
Scheme 1. Chemical reaction for the synthesis of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene from PTCDA.

complete solvent range and most solubility scales can be easily related to it. The Hildebrand solubility parameter, δ, of a material is given by the square root of the cohesive energy density as in Eq. (1) [29,30].

$$\delta = \sqrt{\left(\frac{\Delta E}{V}\right)} \qquad (1)$$

The cohesive energy density is the energy ΔE needed to remove a molecule from its nearest neighbours per unit volume V of the moved molecule. The enthalpy of mixing of a solution, ΔH_{mix}, can then be calculated from Eq. (2),

$$\Delta H_{mix} = V_{mix}(\delta_1 - \delta_2)\Phi_1\Phi_2 \qquad (2)$$

where V_{mix} is the total volume of is mixing, δ_1 is the Hildebrand solubility parameter of the solvent, δ_2 is the Hildebrand solubility parameter of the solute, Φ_1 and Φ_2 are the respective solvent and solute volume fractions [30]. A good solution is formed at zero enthalpy of mixing and this occurs when the solute and solvent Hildebrand solubility parameters are the same, hence the chemistry adage "Like dissolves like".

At room temperature, the parent molecule in the synthesis PTCDA, was found to be best soluble in NMP, $\delta = 23.1\,(MPa)^{1/2}$ and weak or partially soluble in both pyridine $\delta = 21.7\,(MPa)^{1/2}$ and DMSO $\delta = 26.4\,(MPa)^{1/2}$ [31]. These results suggest a Hildebrand solubility parameter for PTCDA as $(23 \pm 2)\,(MPa)^{1/2}$. PTCDA is therefore best soluble in polar aprotic solvents. Previous studies have shown that PTCDA is insoluble or poorly soluble in organic solvents [32]. The solvents which minimize the enthalpy of mixing for PTCDA are generally harsh and toxic therefore not preferred for use in device fabrication due to the inherently low solubility, the production of PTCDA based devices is mostly by thermal evaporation with extremely high expenses. The synthesis of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene from PTCDA adds 12-C chain alkyl groups to the peri-positions of the perylene core making it easily soluble at room temperature in most common organic solvents like chloroform $\delta = 18.7\,(MPa)^{1/2}$, dichloromethane $\delta = 20.2\,(MPa)^{1/2}$, tetrahydrafuran $\delta = 18.5\,(MPa)^{1/2}$ and toluene $\delta = 18.3\,(MPa)^{1/2}$ [31]. This improvement in solubility makes device fabrication in solution possible by such methods as spin coating, dipping and/or casting which are less expensive relative to thermo sublimation. The soluble product can also be easily blended with polymers in such cases as the production of optoelectronic devices where bulky heterojunctions are made from intimate mixtures of donors and acceptors, as is the case in organic photovoltaic cells, so reducing the chance of exciton recombination. The improvement in solubility can be attributed to the introduction of the alkoxycarbonyl groups which reduce the interaction between the perylene rings.

3.2. Linear optical properties

Dilute solutions of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene have an intense yellowish-green colour and show a bright emission when exposed to ordinary light. Fig. 1 shows the normalized absorption and fluorescence spectra of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene in chloroform. The spectra are strongly structured
Fig. 1. Normalized absorption and fluorescence spectra of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene in chloroform.

with peak wavelengths for absorption and fluorescence at 472 and 489 nm, respectively, resulting in a narrow Stokes's shift of 17 nm. A second absorption peak occurs at 444 nm with a shoulder occurring at 417 nm. This structure is similar to the perylene ring progression of π–π^* S_0–S_1 or S_1–S_0 transitions [7]. The fluorescence spectrum is a close mirror image of the absorption spectra but with different relative intensities. Previous studies on similar materials of the form 3,4,9,10-tetra-(n-alkoxycarbonyl)-perylene where $2 \leqslant n \leqslant 10$ showed similar spectra confirming that the perylene core has a greater influence on the absorption and emission rather than the alkyl chain length [7,33,34]. In fact, this observation is consistent independent of the position of substitution in all perylene derivatives, be it peri-, bay- or at the N-atom in perylene imides [3,33]. The absorption and emission peaks remain the same independent of solvent, as is the case for relative peak intensities, but the actual intensities decrease in the order dichloromethane, chloroform, toluene and tetrahydrafuran. The peak integrals for absorption increased linearly with wavelength and were proportional to the concentration. The energy difference between peaks is 0.16 eV, about the same (0.15 eV) as that of the benzene ring stretch oscillation of perylene [35]. This suggests that the dilute series absorbances are controlled by monomeric absorption. No shift in the peak wavelengths was observed for concentration dependent UV–Vis in the individual solvents. The photoluminescence excitation spectra resembled the absorption spectra in solution.

Fig. 2 shows the normalized absorption and fluorescence of a spin cast film of the compound from a chloroform solution. Both spectra are very broad, unstructured and bathochromically shifted compared to the spectra of the monomeric solution. This red shift and broadening are due to fluorescence emanating from excimers owing to the different energetic environments [36]. For absorption, the trend is attributed to additional interactions between individual molecules and their surroundings, much stronger in the solid phase than in monomeric solution. Evidence of aggregation in thin films of perylene derivatives usually occurs in the form of an additional absorption
Fig. 2. Normalized absorption and fluorescence spectra of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene spin cast onto glass from a chloroform solution.

Fig. 3. Van Tauc plot of absorbance squared vs. photon energy for determination of the band gap energy of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene by extrapolation to zero absorbance.

Fig. 4. Concentration dependent photoluminescence, PL, and photoluminescence excitation, PLE, results of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene in chloroform, showing the response to cuvette path length.

peak around 570 nm [37]. The absence of this absorption peak in the case of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene is possibly due to lack of dimmers or higher aggregates as a result of steric hindrance by the bulky alkyl chains. For the emission spectra, there is no corresponding band in the absorption spectra thus the mirror symmetry exhibited in solution is lost. The formation of excimers in thin films is highly likely as the distance between adjacent molecules is much shorter than in solution.

The optical band gap was determined by applying the Tauc relation [38,39], given in Eq. (3), to the optical absorption edge of the thin film of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene,

$$Ah\nu = (h\nu - E_g)^n \tag{3}$$

where A is the absorbance, E_g is the band gap corresponding to a specific absorption in the thin film, $h\nu$ is the photon energy and n has the values 1/2, 2, 3/2, and 3, respectively for allowed direct, allowed indirect, and forbidden indirect transitions materials. An extrapolation of absorbance to zero on the straight line section of the plot of absorbance squared versus photon energy (Fig. 3.), was used to determine the optical band gap as 3.81 eV. The exciton energy, E_{ex}, 2.63 eV, determined from $E_{ex}(\text{eV}) = 1240/\lambda_{max}$, gives 1.2 eV as the exciton binding energy for the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene. This suggests Frenkel type excitons and consequently a small dielectric constant for the material conclusive also from the dielectric constants of the solvents in which it readily dissolves. This result is consistent with previous findings on the exciton binding energies of small molecule or oligomeric organic semiconductors [40].

The results of a concentration dependence fluorescence study are shown in Fig. 4 on a logarithmic scale. An initial study using a 10 mm × 10 mm cuvette revealed a deviation from linearity at high concentrations. This would normally be attributed to some complex processes like aggregation or some equivalent effect. Rickard et al. have shown that the deviation is due to the inner filter effect and re-absorption [41]. The inner filter effect is attributed
to the instrument, where light absorbed by the cuvette's edge will fluoresce but the detector is not able to detect the fluorescence. Re-absorption occurs where the fluorescence emission and absorption spectra overlap as shown in the region just below 500 nm in Fig. 1. The use of a smaller path length cuvette reduces the two effects and more so re-absorption. A second study using a 2 mm × 2 mm micro-cuvette showed linearity over the whole range of concentrations and so suggesting absence of or reduced aggregation or equivalent effects.

3.3. Thermal responses

Fig. 5 shows the TGA and its first derivative (DTGA) curves for 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene performed in an air environment at a scan rate of 10 °C/min. The 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene is thermally stable up to 300 °C in air which is very good for normal everyday operations. The onset of the weight loss begins around 300 °C and is completed at 557 °C with
Fig. 5. The thermal response TGA and its derivative DTGA of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene at 10 °C/min in air.

100% weight loss. This trend is similar to that of perylene, the aromatic core for 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene. The first and second endothermic peaks at 300 and 450 °C, respectively can therefore be attributed to the destruction of the perylene core, the third endothermic peak at 521 °C corresponds to of any remaining organics. In some perylene imides, the alkyl group on the diimide nitrogen is lost between 416 and 513 °C [3,42].

The melting point for 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene was determined using DSC to be at 80 °C (Fig. 6). This is much lower than that of the parent molecules PTCDA which is above 200 °C. Introduction of alkyl chains to the aromatic perylene core lowers the melting temperature independent of the position to which the chain is added [3,7]. The low melting point implies that boiling water can be used to achieve melting. The liquid crystalline phase is absent in the DSC trace, normally present in similar 3,4,9,10-tetra-(n-alkoxycarbonyl)-perylenes for $2 \leqslant n \leqslant 9$. Previous studies [7] have shown that these 3,4,9,10-tetra-(n-alkoxycarbonyl) perylenes form liquid crystals for $n = 2$ to $n = 9$ with the $n = 10$ showing no liquid crystalline phase just like the $n = 12$ being reported here.
This gives partial support for the reduced aggregation behavior. The molecular volume is much smaller for shorter C-chains than for longer ones, thus the higher molecular volume due to long chains is unfavorable for stacking.

3.4. Morphology

Dilution series of 3,4,9,10-tetra-(12-alkoxycarbonyl) perylene in chloroform were spin cast and drop cast onto glass, ITO and Si(1 1 1) substrates for structural studies using scanning electron microscopy (SEM) and contact mode atomic force microscopy (AFM). As shown in Fig. 7, the AFM micrographs of spin cast solutions on respective substrates indicate clusters less than 7 nm in height. Compared to drop cast samples, the clusters in the spin cast films are less coalescent whereas extended coalescence is observed in drop cast films. This trend was also confirmed by SEM (Fig. 8).

In drop cast films, the coalescence increases with concentration as does the height of the clusters. Two possibilities are pertinent to the formation of clusters, they are either formed dynamically during film formation or they already exist in solution. Further studies are currently underway to investigate this trend. Transmission electron microscopy (TEM) studies have revealed nanoparticles less than 100 nm in diameter as source of the clusters (Fig. 9).

3.5. Optical limiting

The NLE coefficient, β_{eff}, for the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene solution in chloroform was measured by the open aperture Z-scan method at 532 nm. The incident laser pulsed energy used in the Z-scan measurement was altered from 0.10 to 0.32 mJ. The corresponding on-focus beam intensity varied from 0.68 to 1.91 GW cm^{-2}. All Z-scans performed in this experiment

Table 1
Summary of typical NLO results for 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene.

Conc. [mg/mL]	Transmission [%]	α_0 [cm^{-1}]	β_{eff} [cm W^{-1}]	Im$\{\chi^{(3)}\}$ [esu]
1	95.6	0.045	$(3.0 \pm 0.6)e^{-10}$	$(11 \pm 2)e^{-14}$

showed a reduction in the transmission about the focus of the lens, indicating the optical limiting property.

As evident in the Z-scan signature shown in Fig. 10, the depth of reduction changes along with the variation of the on-focus intensity. The β_{eff} were deduced from the Z-scan data by curve fitting theory based on an intensity dependent extinction coefficient [25]. The linear and NLO results for the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene solution are summarized in Table 1.

The nonlinear transmission has an apparent discontinuity, corresponding to the limiting threshold. The transmission keeps roughly constant when the energy fluence is below the threshold. When the incident fluence exceeds the threshold, the transmission reduces significantly. The optical limiting trace of the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene solutions is analogous to that of SWNT dispersions, resulting from the thermally-induced nonlinear scattering [27,28]. Therefore, it is believable that the optical limiting for the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene solutions is largely due to the nonlinear scattering, as is implied by both the evident limiting threshold and the strong scattering signal observed at 532 nm whose response is shown in Fig. 11.

Referring to the nonlinear scattering mechanism of SWNT dispersions [27,28,43,44], the scattering centres in the perylene solutions may arise from the formation of the solvent bubbles and/or the vapor bubbles, resulting from the sublimation of the nanoparticles by the aggregation of the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene molecules (see Fig. 9). Nevertheless, we cannot rule out the contribution of TPA to the optical limiting response, but the contribution should be very restricted since (1) the wavelength of the incident beam 532 nm is far away from the TPA resonant wavelength of the perylene solutions [15,17] and (2) the nanosecond incident pulses are inferior for the TPA-induced optical limiting [45,46]. In addition, the excited state absorption, such as reverse saturable absorption or saturable absorption could have influence on the nonlinear responses of the perylene solutions. However, such nonlinear absorption effects can be suppressed when nonlinear scattering becomes significant since the increased scattering cross section results in the reduced absorption cross section [47,48]. Although, the optical limiting efficiency of the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene solutions is lower to the present laser source, it is expected that the perylene solutions would
Fig. 11. Evidence of limiting threshold from optical limiting trace and the scattering response of 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene.

be effective to attenuate the laser beam with shorter pico-second or femtosecond pulses and suitable wavelength in the near infrared [9,45].

3.6. Chemical Stability

The reproducibility of all results from fresh samples to samples aged up to 24 months in all experiments described in this paper are evidence of the chemical stability of the 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene.

4. Conclusions

The 3,4,9,10-tetra-(12-alkoxycarbonyl)-perylene dye offers both chemical and thermal stability, strongly absorbs and fluoresces in the blue section of the UV–Vis range with the added benefits that it can be processed in solution and its bulky alkyl chains hamper aggregation. In addition, the molecule is optically limiting with a high absorption cross section. The solubilisation exhibited by the molecule is due to the alkyl chains and makes the molecule desirable for polymer blending or film casting thus reducing the cost of device fabrication. These results have opened a window for ongoing investigations regarding a wide variety of possible optoelectronic applications.

phosphorescent materials have to be adopted in the WOL-EDs to improve the efficiency and to realize pure white emission.

In this work, a deep blue phosphorescent emitting material, tris((3,5-difluoro-4-cyanophenyl)pyridine) iridium (FCNIr), was used as a blue emitter in WOLEDs. A pure white emission with a color coordinate of (0.29, 0.31) and a high current efficiency of 28 cd/A was demonstrated by using the deep blue phosphorescent dopant and red/green phosphorescent materials.

2. Experimental

A device configuration of indium tin oxide(ITO, 150 nm)/poly-3,4-ethylenedioxythiophene:polystyrene-sulfonate(PEDOT:PSS, 60 nm)/N,N′-di(1-naphthyl)-N,N′-diphenylbenzidine(NPB, 30 nm)/N,N′-dicarbazolyl-3,5-benzene(mCP, 10 nm)/mCP :FCNIr(x nm, 15% doping)/4,4′,4″-tris(N-carbazolyl)triphenylamine(TCTA):1,3,5-tris-(N-phenylbenzimidazole-2-yl)benzene(TAZ):iridium(III) tris(2-phenylpyridine)(Ir(ppy)$_3$):iridium(III) bis(2-phenyl-quinoline) acetylacetonate(Ir(pq)$_2$acac)(30-x nm)/4,7-di-phenyl-1,10-phenanthroline(Bphen, 20 nm)/LiF(1 nm)/Al(200 nm) was used to fabricate all phosphorescent pure white color WOLEDs. The doping concentration of Ir(ppy)$_3$ and Ir(pq)$_2$acac was 10% and 0.7%. The relative ratios of TCTA and TAZ in red:green emitting layers were 75:25 and the thickness of the blue emitting layer (x) was varied as 10, 15, 20 nm. Three devices were named as device I, device II and device III respectively. In addition, device IV with TCTA between the NPB and mCP hole transport layer was also fabricated. Chemical structures and device structures of WOLEDs fabricated in this work are shown in Fig. 1. TCTA, TAZ, mCP, Bpehn and NPB were supplied from Dongyang Creditech Co. after purification by sublimation and FCNIr was synthesized according to the procedure reported in our previous

work [12]. Ir(ppy)$_3$ and Ir(pq)$_2$acac were products of Gracel Display Co. and they were sublimed twice. Electroluminescence (EL) characteristics and EL spectra of WOLEDs were measured with Keithley 2400 source measurement unit and CS 1000 spectroradiometer. Voltage sweep method was used to measure current density–voltage–luminance characteristics of the WOLEDs. Data were collected at an interval of 0.5 V. The EL spectra and luminance were obtained after calibration of the spectroradiometer and EL spectra were normalized to compare relative intensity of the red, green and blue emissions.

3. Results and discussion

A pure white device for display application should have red, green and blue peaks and a WOLED with red, green and blue three colors was fabricated. A deep blue emitting material is strongly required to achieve pure white color in WOLEDs. However, there have been few materials available to get pure blue emission [11]. One of the deep blue materials which can be used in WOLEDs is FCNIr [11,12]. The material can emit deep blue color because of wide bandgap of FCNIr. The strong electron withdrawing F and CN substituents in the phenyl unit of the FCNIr lowers the highest occupied molecular orbital (HOMO) of the material, leading to a wide triplet bandgap of 2.8 eV for deep blue emission. A quantum efficiency of 9% with a color coordinate of (0.15, 0.16) was obtained [11]. Therefore, it is suitable as a deep blue emitter in the WOLEDs to get pure white emission. A stack structure of blue/red:green was used to realize three color peaks in the WOLEDs. A mixed host of TCTA:TAZ was used as a host in the red:-green emitting layer and common Ir(ppy)$_3$ and Ir(pq)$_2$acac were used as dopant materials. The red/green layer was stacked on the mCP blue emitting layer to balance holes and electrons in the light-emitting layer.

Fig. 2. Current density–voltage–luminance curves of red:green and blue single layer devices. (a) Current density–voltage, (b) luminance–voltage and (c) quantum efficiency–luminance.

Fig. 2 shows current density–voltage–luminance curves of the blue and red/green devices. The blue device had an optimized device configuration of ITO/N,N′-diphenyl-N,N′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine(DNTPD, 60 nm)/NPB(20 nm)/mCP(10 nm)/mCP:FCNIr(30 nm)/Bphen(20 nm)/LiF(1 nm)/Al(100 nm)

and the red/green device had a device structure of ITO/PEDOT:PSS(60 nm)/NPB(20 nm)/TCTA(10 nm)/TCTA:TAZ:Ir(ppy)₃:Ir(pq)₂acac(30 nm)/Bphen(20 nm)/LiF(1 nm)/Al(100 nm). High current density and luminance were observed in the red:green device, while the blue device showed lower current density and luminance than the blue device. The low current density of the blue device is due to poor electron injection from electron transport layer to the mCP emitting layer as can be seen in the energy level diagram of the in Fig. 3. In addition, the use of DNTPD with relatively low conductivity compared with PEDOT:PSS is also responsible for the low current density. In the case of red:green device with a mixed host structure, hole and electron injection are favored as reported in our early work [13]. The deep blue device showed a quantum efficiency of 9% [11], while the red/green device showed a quantum efficiency of 13% in the optimized device structure.

Fig. 4 shows current density–voltage–luminance curves of the three peak WOLEDs. The thickness of the whole emitting layer was fixed at 30 nm and the thickness of the blue emitting layer was controlled from 10 to 20 nm. The current density of the WOLEDs was greatly dependent on the thickness of the blue and red:green emitting layers. The device III with 10 nm thick blue emitting layer showed the highest current density, while the device I with 20 nm thick blue emitting layer showed the lowest current density. As the thickness of the blue emitting layer increased, the current density was decreased. The low current density in the device with thick blue emitting layer is due to low electron mobility of the mCP layer. Electron transport in the FCNIr doped mCP layer is limited because of electron trapping by the FCNIr dopant. There is a LUMO level difference of 0.4 eV between the mCP and the FCNIr (Fig. 3), resulting in significant electron trapping by the FCNIr as reported previously [11]. In addition, the low mobility of the mCP host is also responsible for the low current density in the WOLED with thick blue emitting layer [14]. Compared with the FCNIr doped mCP layer, the red:green doped TCTA:TAZ layer is advantageous in terms of hole and electron transport. Relative composition of the TCTA and TAZ in the mixed host was 75:25 and the mixed host can form a percolation path for holes and electrons [15]. As the hole transport through TCTA and electron transport through TAZ are efficient at the host composition, high current density was obtained in the device III. In addition, device IV with TCTA interlayer exhibited higher current density than device II without TCTA interlayer due to
Fig. 3. Energy level diagram of the materials used in this work.

Fig. 5. Quantum efficiency and current efficiency of WOLEDs with different blue emitting layer thicknesses. Device I (20 nm), device II (15 nm), device III (10 nm) and device IV (15 nm). (a) Quantum efficiency–luminance, (b) current efficiency–luminance and (c) power efficiency–luminance.

facilitated hole injection. The HOMO level gap between the NPB and mCP is 0.6 eV and the insertion of the TCTA can reduce the energy barrier, enhancing the hole density in the emitting layer.

The luminance of the WOLEDs also followed the same tendency as the current density. As the luminance of OLEDs depends on the current density and the recombination efficiency in the device [16], the device with the thick red:green emitting layer showed higher luminance than other devices. The highest luminance was obtained in the device IV due to high current density and high recombination efficiency which will be shown in Fig. 5. The driving voltage at 1000 cd/m² was 5.3 V in the device IV.

The quantum efficiency and the current efficiency of the WOLEDs were plotted against luminance in Fig. 5. The device III showed high quantum efficiency, while the device II and the device I showed rather low quantum efficiency values. The high quantum efficiency in the device III can be explained by the relative contribution of the blue emission to the red/green emission. As can be seen in the electroluminescence spectra of the WOLEDs in Fig. 6, the red/green intensity was increased in the device with thick red/green emitting layer. The quantum efficiency of the blue single layer device was 9% and the quantum efficiency

Fig. 6. Electroluminescence spectra of WOLEDs with different blue emitting layer thicknesses. Device I (20 nm), device II (15 nm), device III (10 nm) and device IV (15 nm).

of red/green single layer device was 14%. Therefore, the increase of the red/green intensity resulted in the improvement of the quantum efficiency. Current efficiency of the WOLEDs was also high in the WOLED with thick red/green
Fig. 7. Electroluminescence spectra of the device IV WOLED with TCTA interlayer according to the luminance.

emitting layer. The current efficiency of the device III was 25 cd/A with a color coordinate of (0.35, 0.34) and the current efficiency of the device II was 21 cd/A with a color coordinate of (0.30, 0.30). The combination of the high efficiency deep blue device and red/green mixed host device improved the current efficiency of the pure white WOLEDs. The efficiency of the WOLEDs was further enhanced by using the TCTA inserted hole transport layer and a high current efficiency of 28 cd/A with a color coordinate of (0.29, 0.31) was obtained in the device IV. The TCTA layer improved the hole injection and the charge balance was enhanced, leading to better efficiency. The efficiency value is better than any other current efficiency value reported in the pure white WOLEDs. The power efficiency was also improved by the TCTA layer and a high power efficiency 18.1 lm/W was obtained in the white device IV.

Fig. 6 shows the electroluminescence (EL) spectra of three WOLEDs fabricated in this work. Sharp emission peaks from the red, green and blue phosphorescent emitters are observed from the WOLEDs even though relative intensity of the peaks depended on the device structure. The blue emission was strong in the device I with 20 nm thick blue layer and red/green emission was strong in the device III with 10 nm thick blue layer. The thickness of the emitting layer affected the relative intensity of blue and red/green emission.

The EL spectra of the WOLEDs were monitored according to the luminance and the EL spectra are shown in Fig. 7. The spectrum change of the device IV with TCTA interlayer was plotted representatively. The luminance of the device IV was changed from 100 to 5000 cd/m^2. There was little change of emission spectrum within the luminance range investigated and the color coordinate of (0.29, 0.31) was changed into (0.30, 0.33) at high luminance. The shift of the color coordinate was less than 0.02 from 100 to 5000 cd/m^2. Similar results were obtained in other devices. The good color stability of the WOLEDs may be due to hole blocking properties of TAZ and electron blocking properties of mCP. The charge blocking properties of the host materials may limit the charge leakage and exciton diffusion at high luminance.

4. Conclusions

In summary, a high efficiency pure white WOLED was developed by using a deep blue phosphorescent emitting material. A high efficiency of 28 cd/A and a pure white color coordinate of (0.29, 0.31) were obtained from the all phosphorescent pure white WOLED. The combination of mCP and TCTA:TAZ mixed host was effective to improve the efficiency of the WOLEDs.

[12,13], FIr6-based PHOLEDs show deeper blue emissions than FIrpic-based devices, and therefore are more advantageous for lighting and display applications. However, the higher triplet energy (T_1) of FIr6 than that of FIrpic (2.72 eV vs. 2.62 eV) [11] makes it even more challenging to efficiently generate and confine excitons on the phosphor molecules. Also note that the deeper blue emission of FIr6-based devices leads to an approximately 20% lower photopic sensitivity by the human eyes compared to that of FIrpic devices.

Recently we have shown that external quantum efficiencies (η_{EQE}) up to 18% can be achieved in FIr6-based PHOLEDs by using the hole transport material of 1,1-bis-(di-4-tolylaminophenyl)cyclohexane (TAPC, T_1 = 2.87 eV) [14]. Furthermore, we employed a dual-emissive-layer (D-EML) structure using p-bis(triphenylsilyly)benzene (UGH2) and N,N'-dicarbazolyl-3,5-benzene (mCP) as the host materials for FIr6 in the two adjacent emissive layers to maximize the exciton formation on FIr6 molecules, and applied the p-i-n device structure with highly conductive charge injection/transport layers to lower the device operating voltage. As a result, a high power efficiency of η_P = 25 lm/W at a luminance of L = 100 cd/m^2 was demonstrated, which was only slightly reduced to η_P = 20 lm/W at L = 1000 cd/m^2 [15].

Here, we compare performance of FIr6-based D-EML PHOLEDs with three different electron transport materials, bathocuproine (BCP), 4,7-diphenyl-1,10-phenanthroline (BPhen), and tris[3-(3-pyridyl)mesityl]borane (3TPYMB) [16–19], and study the effect of doping alkaline metals (Li and Cs) [20] into these charge transport materials. We show that η_{EQE} = 20% and maximum η_P = 36 lm/W can be achieved in devices with 3TPYMB as the electron transport material and 3TPYMB:Cs as the electron injection layer. The high efficiencies are attributed to the high triplet energy of 3TPYMB, T_1 = 2.95 eV [19], compared to 2.5 eV for BCP and BPhen [16,17], as well as the increased conductivities due to alkaline doping.

2. Experimental

Glass substrates precoated with an indium tin oxide (ITO) anode (sheet resistance ~20 Ω/□) were degreased in detergent and de-ionized water, and cleaned with ultrasonic baths of acetone and isopropanol consecutively for 15 min each. The substrates were then exposed to an ultraviolet-ozone ambient for 15 min immediately before being loaded into a high-vacuum thermal evaporation system (background pressure ~3 × 10^{-7} Torr), where all the organic and metal layers were deposited successively without breaking the vacuum.

The schematic energy level diagram of the D-EML p-i-n deep-blue PHOLEDs [15] and the molecular structures of FIr6 and the three electron transport materials are shown in Fig. 1 (energy levels are taken from the literature) [11,13,21,22]. The D-EML structure composed of 4 wt% FIr6 doped mCP (7 nm thick) and 25 wt% FIr6 doped UGH2 (15 nm thick) layers was used to maximize the exciton generation within the broadened charge recombination zone [15]. TAPC serves as the hole transporting/

electron blocking layer (HTL), whereas an undoped layer of BCP, BPhen, or 3TPYMB was used as the electron transporting/hole blocking layer (ETL). The thicknesses of both HTL and ETL were x nm with x varying from 5 to 20. A (40-x) nm thick N, N'-diphenyl-N,N'-bis(3-methylphenyl)-[1,1'-biphenyl]-4,4'-diamine (MeO-TPD) layer doped with 2 mol% tetrafluoro-tetracyanoquinodimethane (F$_4$-TCNQ) was used as the p-type hole injection layer (HIL) [21], whereas Li or Cs was doped into the ETL material to serve as the n-type electron injection layer (EIL), whose thickness was also (40-x) nm. As a comparison, "conventional", i.e. non-p-i-n type, devices were also fabricated, which did not contain the p- and n-doped charge injection layers. The thicknesses of HTL and ETL in the conventional devices were both 40 nm.

For the alkaline doping of the electron transport materials, lithium metal was used as the Li source, whereas cesium carbonate (Cs$_2$CO$_3$), which decomposes during thermal evaporation to generate cesium atoms (2Cs$_2$CO$_3$ → 4Cs + O$_2$↑ + 2CO$_2$↑) [23], was used as the Cs source. The cathode consisting of a 0.5 nm thick layer of LiF followed by a 50 nm thick Al was deposited through an in situ shadow mask, forming active device area of 4 mm^2. 3TPYMB, mCP, UGH2, and FIr6 were purchased from Luminescence Technology Corp., and used as obtained without further purification.

Luminance (L)–current density (J)–voltage (V) measurements were carried out in ambient using an Agilent 4155C semiconductor parameter analyzer and a calibrated Newport silicon detector. The luminance was calibrated using a Konica Minolta LS-100 luminance meter assuming Lambertian emission pattern. Electroluminescence (EL) spectra were taken using an Ocean Optics HR4000 high-resolution spectrometer. The luminous, power, and external quantum efficiencies (η_L, η_P, and η_{EQE}, respectively) were derived based on the recommended methods [24]. The conductivities of nominally undoped or alkaline doped electron transport materials were obtained from the ohmic regions of the J–V characteristics of 100 nm thick films sandwiched between two Al electrodes.

3. Results and discussions

3.1. Conventional devices with different ETLs

Fig. 2 shows the comparison of η_{EQE} of three conventional devices with different ETLs. The layer thicknesses and ETL materials for these devices are summarized in Table 1. A maximum η_{EQE} = 14% is achieved at a current density of J < 10^{-2} mA/cm^2 in device A with BCP as the ETL, compared to the maximum of η_{EQE} = 16% in device B with a BPhen ETL, which is obtained at J ≈ 0.1 mA/cm^2. In device C which uses 3TPYMB as the ETL, η_{EQE} is substantially higher than in the other two devices, and reaches a maximum of 20%. This is the highest η_{EQE} ever reported for deep-blue PHOLEDs without any particular light extraction enhancement mechanism. As the light extraction efficiency in these planar-type OLEDs is generally believed to be 20% [2,25] (although there have been recent evidences that it could be slightly higher [10]), this suggests that the internal
Fig. 1. Schematic energy level diagram of the dual-emissive-layer (D-EML) *p-i-n* phosphorescent organic light-emitting devices (PHOLEDs) and molecular structures of the deep-blue phosphor (FIr6) and the three different electron transporting materials used (BCP, BPhen, and 3TPYMB).

quantum efficiency (η_{IQE}) could be very close to 100% in device C.

Among the most important properties for an ETL in a PHOLED are the electron mobility (μ_e), the energy levels of the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO, respectively), and the triplet energy. The electron mobility affects the charge balance in the device, hence the location of the charge recombination zone. The HOMO and LUMO energies affect the hole blocking and electron injection properties, respectively, at the ETL/EML interface, whereas the triplet energy of the ETL significantly impacts the exciton confinement within the EML. As BCP and BPhen have similar HOMO/LUMO (6.5/3.0 eV) [18] and T_1 (2.5 eV) [16,17], the higher η_{EQE} of device B compared to that of device A should be attributed to the more balanced charge injection due to the

higher μ_e of BPhen than that of BCP ($\sim 10^{-4}$ cm^2/V s vs. $\sim 10^{-6}$ cm^2/V s) [18,26] (the hole mobility of the TAPC HTL is $\sim 10^{-2}$ cm^2/V s) [27]. However, charge balance cannot be used to explain the higher η_{EQE} in device C compared with device B, as the electron mobility of 3TPYMB ($\mu_e \sim 10^{-5}$ cm^2/V s) [19] is approximately one order of magnitude lower than that of BPhen. The different efficiencies of these two devices should therefore be attributed to the much higher T_1 = 2.95 eV of 3TPYMB [19] enabling better confinement of triplet exciton in the EML, although the 0.3 eV lower HOMO of 3TPYMB (6.8 eV) [19] than that of BCP/BPhen (6.5 eV) also results in more effective hole blocking at the EML/ETL interface. The electroluminescence (EL) spectra of these three devices as shown in the inset of Fig. 2 (measured at 1 mA/cm^2) are very similar. The minor differences in the relative intensities of the multiple vibronic peaks are possibly due to the different optical properties of the three ETLs as well as the slightly different position of the recombination zone. The peak luminous efficiency (η_L) of device C reached 36 cd/A, com-
Fig. 2. External quantum efficiencies (η_{EQE}) of conventional deep-blue PHOLEDs with different electron transporting materials: BCP (device A), BPhen (device B), and 3TPYMB (device C). (Inset) Electroluminescent (EL) spectra of these three devices.

Table 1
List of thicknesses and materials of charge injection and transport layers of dual-emissive-layer (D-EML) OLEDs. The general device structure is ITO/ HIL/HTL/D-EML/ETL/EIL/LiF/Al, where HIL = hole injection layer, HTL = hole transport layer, ETL = electron transport layer, and EIL = electron injection layer. The D-EML consists of mCP:4 wt%FIr6 (7 nm) and UGH2:25 wt%FIr6 (15 nm) for all devices.

pared to 26 and 30 cd/A for the BCP and BPhen based devices, respectively, even though device C showed the highest deep-blue color purity with CIE coordinates of (0.15, 0.25) (also see Table 2 for various device characteristics of devices B and C).

3.2. p-i-n devices with BPhen ETL/EIL

We have shown previously [15] that the operating voltages of the deep-blue D-EML PHOLEDs can be significantly reduced by employing the p-i-n device structure [20] that incorporates highly conductive p- and n- doped charge injection layers to reduce the total resistance of the organic layers and enhance charge injection from the electrodes. In that work [15], we used BPhen doped with Li as the n-type EIL and a thin, nominally undoped BPhen layer was sandwiched between the doped BPhen layer and the EMLs as the ETL. Here we further studied the effect of different ETLs and different alkaline (Li or Cs) doping in the EIL on performance of the p-i-n deep-blue PHOLEDs. For devices with BPhen:Li as the EIL, as shown in Fig. 3a, when the layer thickness of the undoped BPhen ETL as well as the TAPC HTL is reduced from 20 nm (device D) to 10 nm (device E), the current at a given voltage ($V > 4$ V) is improved by approximately an order of magnitude. However, as shown in Fig. 3b, η_L is drastically reduced from 35 cd/A (device D) to 11 cd/A (device E). When Cs is used instead of Li as the dopant in BPhen, with a 10 nm thick undoped BPhen layer, the PHOLED (device F) has slightly higher current injection than device E as

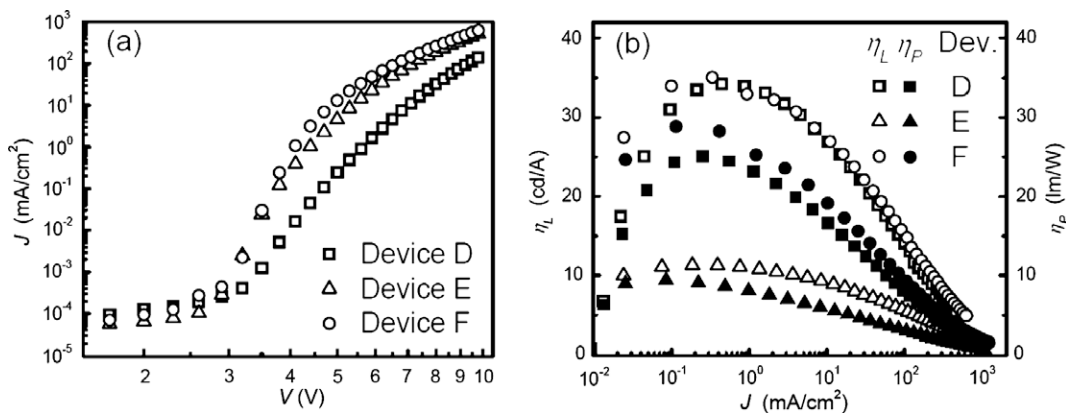
shown in Fig. 3a. This could be attributed to the difference in the electrical conductivity of the doped EILs. As summarized in Table 3, the conductivity of BPhen:Cs (with a weight ratio of 15:1, corresponding to a molar ratio of 1:0.2) is measured to be $\sigma = (6 \pm 2) \times 10^{-6}$ S/cm, approximately doubling that of BPhen:Li (with the same weight ratio), although both are approximately four orders of magnitude higher than that of undoped BPhen. More importantly, however, device F has essentially the same η_L as device D as shown in Fig. 3b, although a further reduction of the undoped BPhen layer thickness to 5 nm also leads to a substantial reduction in η_L (data not shown here). The efficiency drop for very thin ETLs can be attributed to the diffusion of the alkaline dopants from the EIL to the EBL/EML interface or even into the EML where they act as luminescence quenching centers for excitons in the EML. The results here also suggest that Cs has a lower diffusivity than Li, consistent with the apparent difference in their atomic sizes [20]. While device F has almost identical η_L as device D, the thinner undoped HTL/ETL in device F (10 nm vs. 20 nm) leads to a reduction of device operating voltage, therefore an increase in η_P by approximately 15%, from a maximum of 25 lm/W [15] to 29 lm/W (also see the comparison of device parameters summarized in Table 2). The EL spectra of Li and Cs doped p-i-n PHOLEDs are slightly different, and the CIE coordinates are shifted from (0.16, 0.28) for device D to (0.18, 0.30) for device F, possibly due to the different optical properties of BPhen:Li and BPhen:Cs and/or shift of recombination zone toward HTL with a higher conductivity of BPhen:Cs [28].


Fig. 3. Device characteristics of three p-i-n devices (D, E, and F) using BPhen as the electron transporting/injection material: (a) Current density (J)–voltage (V) characteristics, and (b) luminous (η_L, open symbols) and power (η_P, filled symbols) efficiencies. BPhen:Li is used as the electron injection layer in devices D and E, whereas BPhen:Cs is used for device F. The undoped BPhen layer thickness is 20 nm for device D, and 10 nm for devices E and F.

Table 3
Conductivities of pure and alkaline doped BPhen and 3TPYMB films.

ETL	Dopant	Weight ratio of ETL:dopant	Molar ratio of ETL:dopant	Conductivity (S/cm)
BPhen	None	–	–	$(4 \pm 1) \times 10^{-10}$
	Li	15:1	1:1	$(3 \pm 1) \times 10^{-6}$
	Cs	15:1	1:0.2	$(6 \pm 2) \times 10^{-6}$
3TPYMB	None	–	–	$(2 \pm 1) \times 10^{-13}$
	Li	15:1	1:1.8	$(2 \pm 1) \times 10^{-6}$
	Cs	15:1	1:0.3	$(4 \pm 2) \times 10^{-6}$

3.3. p-i-n devices with 3TPYMB ETL/EIL

We also measured the electrical conductivities of un-doped and alkaline doped 3TPYMB films. As listed in Table 3, while the conductivity of pure 3TPYMB, $\sigma = 2 \times 10^{-13}$ S/cm, is much lower than that of pure BPhen ($\sigma = 4 \times 10^{-10}$ S/cm), the conductivities of Li or Cs doped 3TPYMB (with the same weight ratio of ETL:dopant = 15:1) are very similar to those of doped BPhen films, on the order of 10^{-6} S/cm. Although we have not carried out a complete study of the doping concentration dependence, it appears that Cs doped 3TPYMB films can also achieve approximately twice higher conductivities than the Li-doped films.

To understand the effect of alkaline doped 3TPYMB EILs on device efficiencies, we fabricated two p-i-n devices with Li (device H) or Cs (device I) doped 3TPYMB EIL as well as a p-i-i device with a 40 nm thick undoped 3TPYMB ETL but no EIL (device G). Similar to BPhen based devices, a 20 nm thick undoped 3TPYMB ETL is used for Li-doped EIL (device H), which is reduced to 10 nm in device I with Cs doping. It is apparent from Fig. 4a that device I has the best charge injection due to the high conductivity of 3TPYMB:Cs and the very thin undoped ETL layer. The external quantum efficiencies of these three devices, how-ever, are nearly identical with maximum $\eta_{EQE} = 20\%$, as shown in Fig. 4b. This suggests that the apparent difference in charge balance for these three devices does not affect exciton generation/recombination appreciably. This, in

fact, is consistent with the superior exciton confinement/charge blocking provided by the TAPC and 3TPYMB charge transport layers. The large HOMO level offset ($\Delta E \sim 0.7$ eV) between FIr6 and 3TPYMB provides sufficient confinement of holes in the EML so that those holes injected into the EML will ultimately recombine with electrons injected from the ETL. In addition, the high triplet energy of 3TPYMB ensures negligible loss of excitons created in the EML regardless whether the position of the recombination zone, which is determined by charge balance, is close to the EML/ETL interface or not. The power efficiencies of these three 3TPYMB-based devices, however, do show appreciable differences due to the differences in device operating voltages. The peak η_P for device G, H, and I are 29, 32, and 36 lm/W, respectively. Device I especially has a very low turn-on voltage of 3.0 V, and needs a bias of 3.8 and 4.3 V to achieve a luminance of 100 and 1000 cd/m^2, respectively. The CIE coordinates of these three devices remain at approximately (0.16, 0.28).

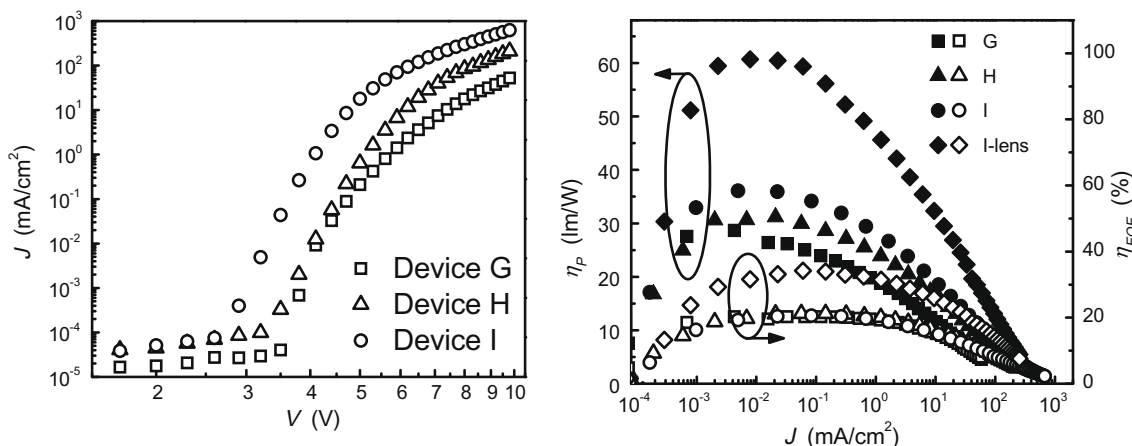
Note that typically for a planar-type OLED, only about 20% of the overall emission can escape the device in the for-ward viewing directions, while the rest is trapped in the glass substrate and in the ITO and organic layers as wave-guiding modes [2,25]. While there have been active re-search in enhancing the light extraction efficiencies in OLEDs [4,29], here we simply attached a near-hemispheri-cal lens (BK-7 plano-convex lens, diameter 25.4 mm and height 9.5 mm) to the glass substrate of device I using


Fig. 4. Device characteristics of three devices (G, H, and I) using 3TPYMB as the electron transporting/injection material: (a) Current density (J)–voltage (V) characteristics and (b) power (η_P, filled symbols) and external quantum (η_{EQE}, open symbols) efficiencies versus luminance (L). Device G is a p-i-i type device with a 40 nm thick undoped 3TPYMB ETL, whereas the other two are p-i-n devices with Li (device H) or Cs (device I) doped 3TPYMB EIL. See Table 1 for detailed device structures. The total power and external quantum efficiencies of device I with a near-hemispherical lens attached to the light-emitting surface were also shown (labeled as "I-lens").

refractive index matching gel ($n = 1.517$). As shown in Fig. 4b, attaching the macrolens to device I (labeled as I-lens) leads a maximum $\eta_{EQE} = (34 \pm 2)\%$, or approximately 70% enhanced compared to the device without the macrolens, which is in general agreement with previous reports [30]. The power efficiency of device I with the lens attached reaches a maximum of $\eta_P = (61 \pm 4)$ lm/W at $L \approx 10$ cd/m^2, slightly reducing to (57 ± 3) lm/W at $L = 100$ cd/m^2 and (44 ± 2) lm/W at $L = 1000$ cd/m^2. With more complicated optical designs to achieving 2.3 times enhancement in light extraction [29], power efficiencies up to 80 lm/W could be achieved in the FIr6-based deep-blue PHOLEDs.

4. Conclusions

We have shown that the efficiencies of FIr6-based deep-blue PHOLEDs significantly depend on the properties of the electron transport and injection materials. A maximum $\eta_{EQE} = 20\%$ was achieved using an ETL of 3TPYMB, substantially higher than those of similar devices with BCP or BPhen as the ETL, respectively. This is attributed to the nearly perfect charge and exciton confinement provided by the 3TPYMB as the ETL and the counterpart HTL of TAPC. We also showed that alkaline doping (Li and Cs) in the 3TPYMB ETL can effectively increase its conductivity by several orders of magnitude, similar to the effect in the more widely studied BPhen ETL. Incorporation of such doped layers in *p-i-n* devices led to significantly improved charge injection and lower device drive voltage. As a result, peak power efficiency of 36 lm/W and a turn-on voltage of only 3.0 V were achieved for these deep-blue PHOLEDs with CIE coordinates of (0.16, 0.28). The efficiencies were further improved to the maxima of $\eta_{EQE} = 34\%$ and $\eta_P = 61$ lm/W by attaching a near-hemispherical lens to the light-emitting surface of the glass substrate, and η_P has the potential to be further improved to up to 80 lm/W by using more complicated optical designs to enhance the light extraction.

present to prevent the excess water from ALD process to penetrate into PVP which (ii) being highly hygroscopic can be loaded with significant amount of water which can then be released into P3HT.

To solve this problem, here we propose an enhanced sealing architecture by adding a stopping layer against water penetration under the PVP/Al$_2$O$_3$ stack. The additional layer has to satisfy the following requirements: it has to be compact and non polar, in order to avoid water diffusion, and it has to be integrated in the existing process, without destroying the previously deposited layer (P3HT) and without being destroyed by the deposition of the subsequent layers.

To address these constraints we adopt a PVP-based cross-linkable layer. Such material has been previously used as gate insulator for all-organic field effect transistors by Facchetti and coworkers [15]. They showed that cross-linked PVP is insoluble in common organic solvents and it has better insulating properties than normal PVP, suggesting that the cross-linked polymer is more compact and pin-hole free.

2. Experimental details

Devices are based on a bottom contact structure using highly p-doped Si as common gate electrode and 130 nm of thermally grown SiO$_2$ as gate insulator. Platinum source and drain contacts have been realized by means of a standard photolithographic process on the oxide surface (Microfab, Bremen). Devices with channel lengths ranging from 3 to 18 μm have been used (channel width 15 mm). The oxide surface has been carefully cleaned with chloroform and acetone and then plasma polished for 10 min. Immediately after the cleaning process, the SiO$_2$ surface has been functionalized by exposure to dimethyl-dichlorosilane vapors, in order to maximize the mobility and reduce the hysteresis [16]. Solution of Regio-Regular poly-(3-hexylthiophene) (MW = 33 kDa) in toluene (5 mg ml^{-1}) was filtered through a 0.45 μm pore size PTFE membrane and finally spin coated at 4000 rpm on the substrate, achieving a thickness of about 30 nm. Samples were then cured at 110 °C for 20 min in high vacuum (p = 10^{-5} mbar) in order to remove any trace of solvents.

According to the process reported in [15] the cross-linked layer was obtained as follows: a solution of PVP (MW = 11 kD) in anhydrous tetrahydrofuran (THF) (4 mg ml^{-1}) was mixed with 1,6-bis(trichlorosilyl)-hexane (9 μl ml^{-1} in anhydrous THF) in a 1:1 by volume solution. The blend was then spun (5000 rpm) on the P3HT film. Even though THF is not a very good solvent for P3HT, in order to minimize its interaction with the P3HT film, we put in rotation the spin coater *before* dropping the THF-based solution. When P3HT films were compact and smooth, they withstood this step without experiencing any sizeable dissolution.

A thermal curing treatment was finally performed (110–120 °C, 20 min in high vacuum). At this stage the cross-linking agent reacts with OH groups on the PVP so that PVP chains are σ-bonded to a siloxane network [15].

Glassware for solutions containing the cross-linking agent have been derivatized by exposure to dimethyl-dichlorosilane vapors prior to use, since 1,6-bis(trichlorosilyl)-hexane is quite moisture sensitive.

As OH groups are consumed during the cross-linking process, the final layer is apolar, and therefore can act as water stopping layer, and is insoluble and therefore can easily sustain the subsequent deposition of PVP from ethyl acetate (MW = 20 KDa, solution 1 mg/ml spun at 6000 rpm). Solvents, dimethyl-dichlorosilane, PVP, 1,6-bis(trichlorosilyl)-hexane (Aldrich) were used as received without further purification.

Finally, the capping structure was completed by the deposition of Al$_2$O$_3$ by ALD according to the experimental details reported in our previous paper [14].

To summarize, the capping layer is now composed of three thin films: (i) cross-linked PVP, which is deposited directly on the P3HT and acts as water stopping layer; (ii) PVP which provides the —OH groups to act as TMA stopping layer; (iii) atomic layer deposited Al$_2$O$_3$ which is the actual capping layer (Fig. 1).
Fig. 1. Cross section of the device capped with the three-layer structure.
Fig. 2. Trend of the mobility and I_{ON}/I_{OFF} ratio during the process (channel length 18 μm). The first three points are measured in vacuum, the last point in ambient atmosphere. The effect of the process on the mobility is marginal and the final value is close to the value measured in the uncapped devices (as deposited). On the contrary, the I_{ON}/I_{OFF} ratio drops after the deposition of the cross-linked PVP before improving after the ALD growth and it finally stabilizes around 10^4. Note that the I_{ON}/I_{OFF} ratio has been calculated as the ratio between the current driven at V_G = −30 V and the current at V_G = 0 V.

3. Results and discussion

We monitored the electrical characteristics of the devices step by step throughout the whole capping process, in order to evaluate the impact of each single stage on the performance of the devices. *In high vacuum* the uncapped devices showed mobilities between 0.5×10^{-2} and 0.8×10^{-2} cm^2/Vs with on/off ratio close to 10^6. After the deposition and the cross-linking of PVP, the I_{ON}/I_{OFF} ratio drops between 10^2 and 10^3 while the mobility is less affected (Fig. 2). The reduction of the I_{ON}/I_{OFF} ratio is probably due to residual unreacted —OH groups on PVP chains. The subsequent deposition of PVP does not modify the mobility or the on/off ratio.

Finally the sample is capped by Al_2O_3. From now on, all electrical measurements are performed in *ambient air*. While the mobility decreases slightly, the on/off ratio reaches values around 10^4, with an improvement of more than one order of magnitude with respect to the previous stage (Fig. 2). It is likely that during the ALD growth, some TMA molecules reach the cross-linked PVP layer, reacting and consuming the residual —OH groups responsible for the P3HT doping.

We realized, capped and tested a total of 33 devices on different substrates in the same ALD run. We found that for all the tested devices the mobility was marginally affected by the capping process. Regarding the I_{ON}/I_{OFF} ratio, a certain dispersion was observed, ranging from less than 10^2 to 10^4, with a majority of devices (55%) in the range 10^2–10^3. From now on, we focus on the best performing samples with on/off ratio greater than 10^3, which represent about the 30% of the devices tested.

Fig. 3 compares transfer characteristics (right) and external characteristics (left) measured in air in samples capped with PVP + Al_2O_3 and capped with cross-linked-PVP + PVP + Al_2O_3. In order to better compare the *off* current in the two structures, transfer characteristics are shown in a logarithmic scale. It is clear that the *off* current is reduced by about two orders of magnitude in the "three-layers" structure, if compared to the PVP + Al_2O_3 structure. This demonstrates that the cross-linked layer is really effective as barrier against water diffusion.
Fig. 3. Comparison between the performances obtained from the different capping structures (measurements performed in air, channel length 3 μm). The sample with the cross-linked PVP layer shows an improvement of the on/off ratio of about two orders of magnitude and a better saturation of the drain current with respect to the sample capped with PVP/Al_2O_3.
Fig. 4. Left, trend of the mobility and I_{ON}/I_{OFF} ratio as a function of time for the three-layer capped device (channel length 18 μm). Right, evolution of transfer characteristics curves of the same device.

By comparing the external characteristics we realize that the saturation of the drain current is improved in the sample with the cross-linked PVP with respect to the sample capped with PVP/Al_2O_3. This is due to the reduced doping which improves the channel pinch-off at the drain side.

Finally, we tested the performances of the capped devices over some months, in order to prove the robustness and the long term stability of the capping layer. Graph in Fig. 4 (left) shows the trend of the mobility and I_{ON}/I_{OFF} ratio measured in *ambient* atmosphere as a function of time. After almost two months from the deposition the I_{ON}/I_{OFF} ratio is still very high in the range of 10^4, comparable to the value measured just after the ALD growth. In the following 60 days the on/off ratio diminishes but maintains a value larger than 10^3. The mobility does not change significantly over the whole period that we monitored, remaining between 0.6×10^{-2} and 0.8×10^{-2} cm^2/Vs.

Fig. 4 (right) shows the evolution of transfer characteristics measured on the same device ($L = 18$ μm) in ambient atmosphere. The curves measured in the device just after the ALD growth (0 days) and after 50 days are practically coincident, while after 120 days a marginal increase of the *off* current can be noticed.

4. Conclusions

To conclude, we have developed a three-layers structure for the effective encapsulation of P3HT based TFT. The structure is comprised of an ALD deposited Al_2O_3 layer, and of two spin-cast films acting as stopping layers for Al_2O_3 precursors: PVP against TMA and cross-linked PVP against water. With respect to our previous two-layer structure [14], this latter layer provides a dramatic improvement of the I_{ON}/I_{OFF} ratio, which reaches values between 10^3 and 10^4 in ambient atmosphere. Encapsulated devices have shown ambient stability in excess of a few months.

Fig. 1. The design of controlled solution process system.

pentacene [7], rubrene [8], and pentacene [9–11]. Headrick et al. with a four-channel transistor configuration and hollow-pen deposition method, measured the hole mobility of polycrystalline TIPS pentacene films along the hollow-pen writing direction and its vertical direction [7]. On the other hand, by using transient photoconductivity technique, Ostroverkhova et al. studied TIPS pentacene single crystals, and estimated the mobility anisotropy of a–b plane to be 3.5 ± 0.6 [12].

In this work, besides suggesting a maximum anisotropic ratio of 10 in solution-processed TIPS pentacene thin films, which was supported by Headrick's work [7], our results demonstrated a unique example of systematic study on charge-transport anisotropy in single-crystal textured TIPS pentacene films by using direct mobility measurement. Furthermore, information about the molecular alignments in crystalline TIPS pentacene thin films was collected from electron and polarized light microscopy, which revealed frequent twinning across the $(1\bar{2}0)$ planes that are the lateral facets for single crystalline domains in the TIPS pentacene films. The [2 1 0] direction is close to one of the two π–π stacking directions in TIPS pentacene unit cell, and was identified as an excellent pathway for hole transport in solution-processed TIPS pentacene thin films.

Most importantly, we exhibited the potential of controlled solution deposition in fabricating single-crystal textured TIPS pentacene films with adjustable morphologies, which may be transferable to the studies of other solution-processible organic molecular semiconductors. The controlled solution deposition system (Fig. 1) allowed us to study in detail the effect of grain size [4], thermal cracking [13], and crystal orientation (this work) on the charge transport of TIPS pentacene thin films.

2. Experimental

2.1. Materials

6,13 bis(triisopropylsilylethynyl) pentacene (TIPS pentacene) was in the form of dark-blue needle-shaped crystals, prepared through a one-step reaction from 6,13 pentacenequinone [5].

2.2. X-ray diffraction

X-ray diffraction of TIPS pentacene films on the silicon wafer was performed with a Rigaku Miniflex and a Brukers D8. Both one-dimension (2θ vs. intensity) and two-dimension diffraction results (diffraction pattern) were obtained and compared with simulated data from Cerius,[2] which is a molecular modeling platform commercially available from Accelrys.

2.3. Polarized light microscopy

A Nikon OptiPhot2-POL polarized optical microscope, equipped with Spot RT Color 2.2.1 CCD camera (Diagnostic Instruments, Inc.), was used for taking polarized optical micrographs of solution-processed TIPS pentacene thin films.

2.4. TEM

TEM and selected area electron diffraction (SAED) experiments were conducted on a Philips CM12, working at 120 kV. Electron diffraction pattern were obtained with spot size 6 or 7, and compared with simulations from Cerius[2] (intensity factor 10, and accelerating voltage 120 kV).

2.5. Transistor fabrication and characterization

TIPS pentacene thin films were fabricated in the controlled solution-process chamber (Fig. 1). The silicon wafers used in this study were heavily arsenide-doped and the insulator layer was thermally grown silicon dioxide of 200 nm thickness. About 100 nm-thick gold electrodes (source and drain) were thermally evaporated through a laser-machined shadow mask. Transistor characteristics were measured with a Keithley 4200 or HP 4145 semiconductor parameter analyzer and an Alessi-3200 probe station. Transistor characterization was conducted at room temperature in dark. Both transfer (I_d–V_g) and output (I_d–V_d) characteristics were tested five times for each transistor. The I_d–V_d curves were obtained upon sweeping gate voltage V_g from -40 to 0 V, and then varying the source–drain voltage from -40 to 0 V. The I_d–V_g curves were collected with the gate voltage increase from -60 to 20 V at a constant V_d of -40 V. Saturation mobility was then extracted from the slope of the transfer curve V_g–$(I_d)^{1/2}$, according to the equation $I_d = \mu W C_i (V_g - V_T)^2 / 2L$, where W and L are channel width and length respectively, C_i the specific capacitance in the insulator layer, V_T the threshold voltage, and μ the saturation mobility. W and L were about 300 and 25 μm.

3. Results and discussion

In the controlled solution deposition system, [4] temperature control of the deposition chamber was achieved with a hot stage and surface thermometer. Nitrogen gas was released from a compressed gas cylinder through a flow meter (Key Instruments), which monitored and regulated the nitrogen gas flow (0–0.5 l/min). The nitrogen gas

flowed in and out of the system through syringe needles, to provide an oxygen-free environment, and to vary the solvent evaporation rate in a systematic manner. Droplets of TIPS pentacene solutions (0.1–1 wt% in bromobenzene or toluene) were placed on a pre-cleaned [13] Si substrate (2000 Å thermally oxidized SiO_2) inside the deposition chamber, and allowed to dry in minutes or hours depending on the nitrogen flushing rate and deposition temperature.

The acene planes in TIPS pentacene are known to take an "edge-on" orientation in thin films on glass and amorphous carbon substrates [5,14,15]. X-ray diffraction of TIPS pentacene films on glass yielded a sharp (001) peak at 1.683 nm [5]. Here we studied the molecular orientation of TIPS pentacene films fabricated with the controlled deposition chamber on an oxidized Si wafer. In both 1-D and 2-D out-of-plane X-ray diffraction, strong reflections of lattice spacing (001), (002), and (003) were visible (Fig. 2). These results and further in-plane X-ray diffractions suggested that, in the thin films fabricated with the controlled solution deposition chamber, the TIPS pentacene molecules arranged with the same "edge-on" orientation on SiO_2 substrates. In other words, the TIPS pentacene films on oxidized Si wafers fabricated with the controlled solution process had [001] projection as the top view, identical to the case with amorphous carbon substrates in TEM and electron diffraction experiments [14,15]. TEM experiments revealed that in these solution-processed films, the long axis of the needle-shaped TIPS pentacene grains was parallel to [210], and the short axis was close to [$1\bar{2}0$] [14,15].

At relatively low nitrogen flushing rates (0–0.04 l/min) and proper temperatures (from room temperature to 90 °C), TIPS pentacene thin films with well ordered textures could be fabricated over relatively large areas (up to several square millimeters) (Fig. 3a), using the controlled solution deposition system [4]. If the deposition temperature was close enough (∼90 °C) to the previously reported solid-to-solid structural phase transition temperature (124 °C), [14] numerous crystallographic facets along (120) would uniformly appear in single crystalline TIPS pentacene domains (Fig. 3b). Similar (120) facets were frequently observed under bright-field TEM in TIPS pentacene

thin films briefly annealed above the phase transition temperature (124 °C) (Fig. 3c and d). More importantly, these (120) facets provided unambiguous evidences of frequent twinning between the large grains (with typical grain widths W_G of microns to hundred microns) of the solution-processed TIPS pentacene films (Fig. 3b–d). Fig. 3e is a simplified crystal modeling top view of these solution-processed TIPS pentacene films, showing the different characteristic crystallographic planes and axes.

It is necessary to point out that deposition conditions for generating (120) facets (i.e. 90–130 °C) only served the purpose to understand the molecular orientations in TIPS pentacene thin films. Deposition temperatures for the active layer of actual devices were significantly lower (10–50 °C), in order to avoid the effect of thermal faceting or cracking, which has been shown to reduce the effective mobility by up to several times [13].

A top-contact thin film transistor configuration was used throughout this study (Fig. 4a). TIPS pentacene films were solution-cast from 0.1 to 1 wt% bromobenzene or toluene solution with the controlled solution process system [4] at relatively low temperatures (10–50 °C) and very low (0–0.04 l/min) nitrogen flushing rates. Generally five transfer and output characteristics measurements were performed on each transistor, which had standard deviations of 5–20% of the average mobility.

Fig. 4b shows an optical image of an actual device layout in top view. On top of the Si wafer, the crystalline TIPS pentacene films had a central nucleus (Fig. 4b); the needle-shaped grains stretched out in different directions and meet the later-deposited gold source–drain channel array at various θ angles (Fig. 4c). Here the angle between [210] (the long axis of TIPS pentacene grains) and the channel direction was defined as θ (Fig. 4c). The fabricated TIPS pentacene films in Fig. 4 had thicknesses of ∼150 nm according to atomic force microscopy experiments. Representative transfer (Fig. 4d) and output (Fig. 4e) characteristics of these TIPS pentacene thin film transistors are shown as a function of the θ angle, demonstrating a strong orientation-dependence of effective mobility. Noticeably, non-linear I_{ds}–V_{ds} responses at low V_{ds} region were mainly observed in devices with low θ angle (e.g. $\theta = 20°$ in Fig. 4e). This may be explained by the facts that channel

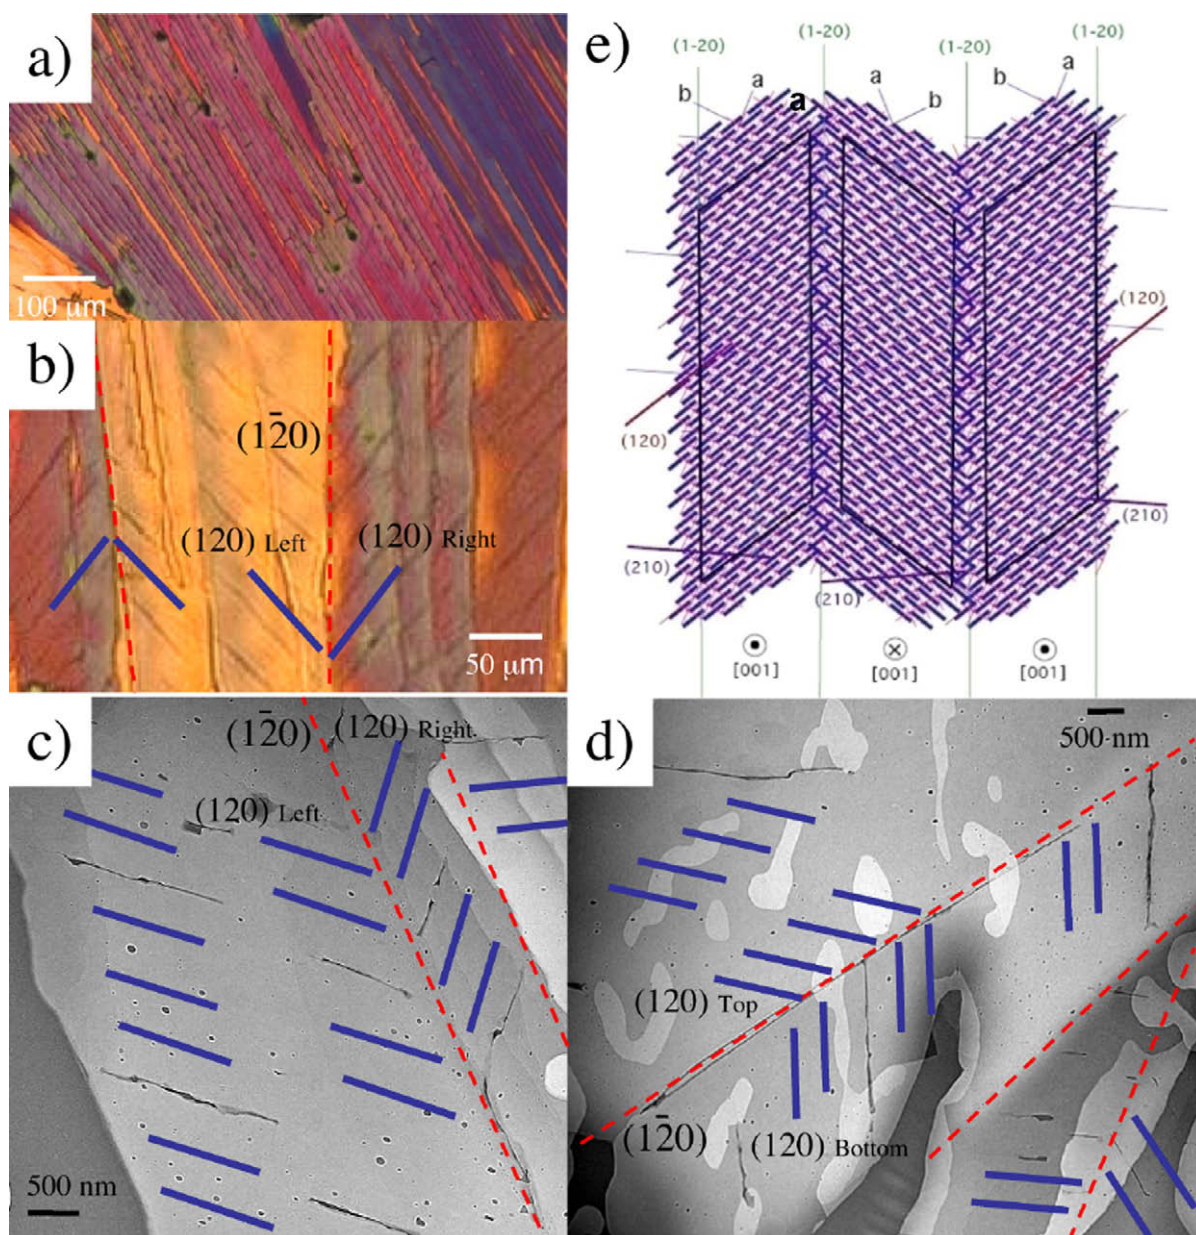

Fig. 3. (a) At very low nitrogen flushing rates (0–0.04 l/min) and proper temperatures (room temperature to 90 °C), TIPS pentacene thin films with well ordered texture could be fabricated over a relatively large area (up to several millimeter by several millimeter) by using the controlled solution deposition system [4]. (b) If the deposition temperature was close enough (~90 °C) to the previously reported solid-to-solid structural phase transition temperature (124 °C), [14] numerous crystallographic facets along (120) could be uniformly seen in a single crystalline TIPS pentacene domain. (c, d) Similar (120) facets were frequently observed under bright-field TEM in TIPS pentacene thin films briefly annealed above the solid-to-solid structural phase transition temperature (124 °C). These (120) facets provided unambiguous evidences of frequent twinning along [210] in large grain (grain width W_G of microns to hundred microns) solution-processed TIPS pentacene films. (e) A simplified crystal modeling top view of the solution-processed TIPS pentacene films shows different crystallographic planes and axes.

resistance is made up of contact and channel resistance; contact resistance is relatively constant for devices in this work as they have similar grain width, while channel resistance is orientation-dependent and will sharply decrease as the θ angle decreases. In addition, we found that threshold voltage and on/off ratio did not change dramatically as a function of crystal orientation. In Fig. 4d, as the θ angle increased, the threshold voltages increased by only a cou-

ple of volts (from 0.2 to about –2 V), and the on/off ratios decreased slightly (from 10^6 to $10^{5.5}$).

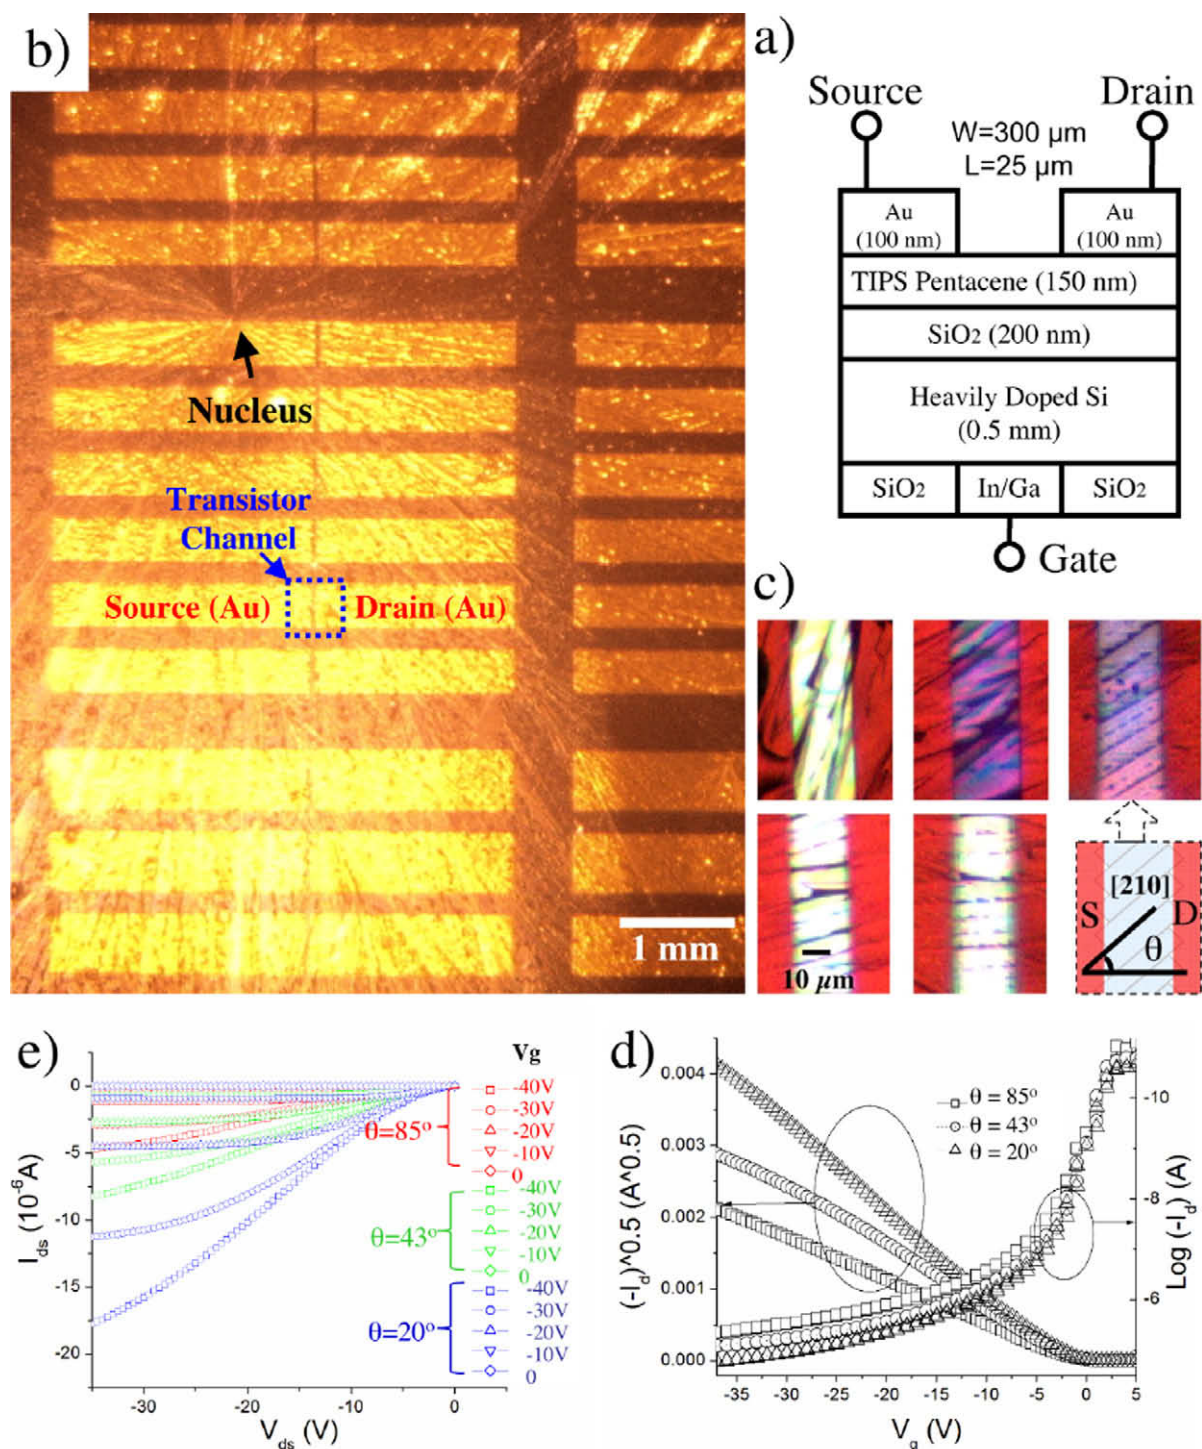
Several sets of these θ angle dependent mobilities were obtained, which showed similar anisotropic trends to the 10-transistor data set presented in Fig. 5a, on the top right quadrant (0–90°) of a 360° pole figure. The other three quadrants of the pole figure (90–360°) were symmetrically plotted with the experimental fit of the data in the first


Fig. 4. (a) A not-to-scale schematic of the top-contact thin film transistor configuration used in this study. (b) An optical image of an actual device layout in top view. On top of the Si/SiO$_2$ wafer, TIPS pentacene films had a central nucleus. (c) Needle-shaped grains stretched out to different directions and the later-deposited gold source–drain channel array met the grains at various θ angles. quadrant, due to the film symmetry. As the θ angle increased, the effective hole mobility decreased by up to ten-fold (from 0.04 to 0.004 cm^2/V s in Fig. 5a).

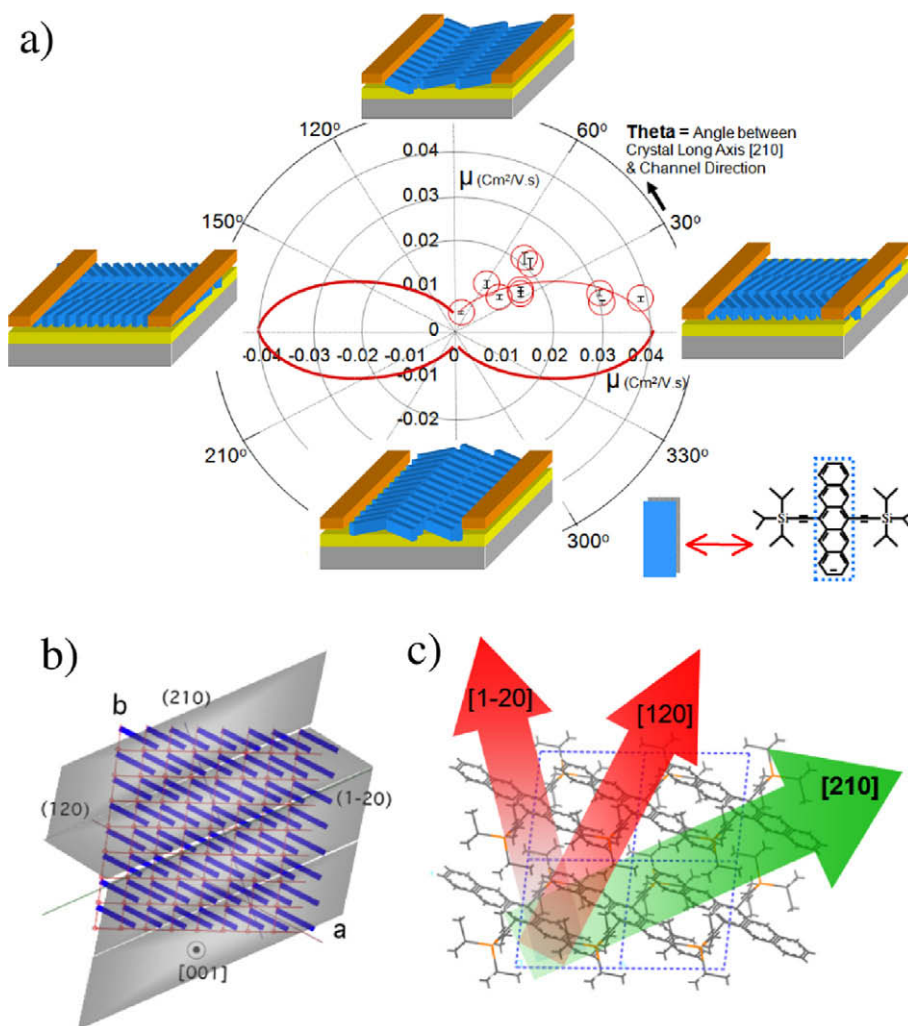
It has been argued theoretically that TIPS pentacene crystals should be essentially two-dimensional in their band structures due to the π–π stacking along both the


Fig. 5. (a) The experimental results of the θ angle dependent charge carrier mobility were presented on the top right quarter (0–90°) of the 360° pole figure. The other three quarters of the pole figure (90–360°) were symmetrically plotted with the experimental fit of the data in the first quarter, based on the film symmetry. TIPS pentacene molecules were over-magnified and simplified as plates (underneath source/drain electrodes) in the device cartoons to show the relative positions of twin boundaries and regular grain boundaries. (b, c) Because of a combination of good π–π stacking and low boundary density, [2 1 0] is the best charge carrier pathway in large grain solution-processed TIPS pentacene thin films. The needle-grain-textured TIPS pentacene films with frequent twinning across [2 1 0] (b) were plotted against the relative positions of important crystallographic planes and axes (b and c).

"a" and "b" directions (Fig. 5b and c) [16,17]. However, the frequent twinning across the (1$\bar{2}$0) lateral facets and grain boundaries (Fig. 3b–e) in a typical solution-processed TIPS pentacene thin film significantly limited the charge transport along the [1$\bar{2}$0] direction, which was the short axis of the needle-shaped TIPS pentacene grains and close to the [0 1 0] axis (Figs. 3 and 5). In contrast, the [2 1 0] direction (the long axis of the needle-shaped TIPS pentacene grains) is close to the [1 0 0] axis. Because of a combination of good π–π stacking and low boundary density, the [2 1 0] direction was found to be the best charge carrier pathway in these solution-processed TIPS pentacene thin films (Fig. 5b and c).

Occasionally single grain TIPS pentacene crystals (with grain widths W_G > 25 μm, or the channel length) occupied the whole channel (300 μm by 25 μm), with [2 1 0] axis perpendicular to the channel direction. This was actually very similar to the case with θ close to 90° in Fig. 4c, but without grain boundaries in channel. These "single-crystal" transistors with $\theta \sim 90°$ were found to have large mobilities, nearly equivalent to those with θ = 0–10°. This agreed well with the two-dimensional π–π stacking crystal structure of TIPS pentacene (Fig. 5c), and confirmed that the strong anisotropic (10:1) charge-transport behavior of solution-processed TIPS pentacene films is essentially due to their grain geometry and boundary distribution.

Most importantly, the controlled solution deposition system (Fig. 1) was shown to yield relatively uniform, adjustable morphologies of single-crystal textured TIPS pentacene films. With the controllable nitrogen flow and chamber temperature, fine tuning of the resultant film morphology becomes possible, which can potentially lead

to both enhanced performance reproducibility and better understanding of the structure–property relationships in small-molecule solution-processible organic semiconductors.

From the micrograph in Fig. 3, some crystallographic discontinuities or additional defects beyond the regular and twin boundaries were visible, possibly representing internal fractures and cleavage planes, or perhaps merged boundary facets generated during crystal growth. Therefore, the crystal orientation-dependent mobility illustrated in Fig. 5 may actually represent combined influences of these extra structural complexities as well as the more obviously conceived crystal structure anisotropy and grain boundaries. Precise determination of the actual impact of these extra structural complexities on charge-transport is beyond the scope of this paper and has been partially addressed elsewhere [13]. In addition, micrographs in Figs. 3 and 4 occasionally demonstrated tiny circular particles on top of, or inside the crystallographically well defined grains. Some of these particles were previously reported as a second layer (or islands) of TIPS pentacene crystals on top of the bottom films [7]. However, we cannot rule out the possibilities of impurity inclusions and heterogeneous nucleation, which may be resulted from the slow crystallization process. Since the TIPS pentacene transistors with systematically varied crystal orientations are likely to suffer from this effect equally, we do not expect the overgrown TIPS pentacene crystals or slight film irregularities to significantly interfere with the trend of anisotropic charge transport illustrated in Fig. 5.

It needs to be pointed out that some of the structural analysis in this work, such as crystallographic planes and directions of grain boundaries and cracks, were presented previously in the context of TIPS pentacene films with similar crystal orientation angles ($\theta \sim 30°$) but systematically varied grain widths (1.5–33 μm) [4]. However, according to our knowledge, the correlation of charge-transport mobility and TIPS pentacene grain boundaries have not been reported as a function of crystal orientation in films with uniform grain widths, and this is the key focus of the current work (with grain width W_G of ~10 μm). In addition, although the controlled solution deposition method was already used previously [4] to generate TIPS pentacene films with systematically varied grain sizes, this paper is aimed to reveal the optimal deposition conditions for fabricating films with large grains but different crystal orientations ($\theta = 0$–90°). For example, the gas flushing rates used in Ref. [4] were varied between 0 and 0.5 l/min, while the films studied in this work were fabricated with a very slow nitrogen flow speed (<0.04 l/min). Through the temperature control in this work, the TIPS pentacene twin boundaries were conveniently identified in large grain TIPS pentacene crystalline films with optical microscopy and associated with charge-transport anisotropy, which was not achieved in Ref. [4].

Compared to the mobility anisotropy measurements in Ref. [7], the key advantages of this work are three-fold. (1) The measurements in Ref. [7] were performed on films deposited with a hollow-pen, which generated grain sizes with large variations, while the films tested in this work were fabricated with a controlled solution casting method that yielded a consistent grain width of about 10 μm. Grain sizes of TIPS pentacene grains have a large effect on charge-transport, [4] and the effect of grain size should be removed in order to precisely determine the charge-transport anisotropy. (2) The channel length and width in this work (25 and 300 μm) were significantly smaller than those in Ref. [7] (75 and 1000 μm). The reduced channel area significantly minimized the effect of crystal orientation variation within the same transistor channel. In other words, the estimation of crystal orientation angle in this work was much more accurate. (3) With the controlled solution deposition, it is now possible to generate the data set in Fig. 5 with as many as 10 different crystal orientation angles, while the four-channel electrode array in Ref. [7] only provided mobility comparison between two orientations (hollow-pen writing pathway and its vertical direction).

We notice that the mobilities achieved in this work were considerably smaller than those reported previously [18]. The measured hole mobilities of TIPS pentacene crystals are strongly dependent on the impurity level, substrate treatment, deposition methods, and other factors. The focus of this work is on the crystal orientation-dependent charge transport, instead of achieving the highest mobility possible. Some of the requirements for generating TIPS pentacene grains with uniform grain widths but different orientations may be even contradictory to the ones for achieving the highest mobility. For example, no surface treatment was performed on the silicon dioxide substrate in this study. A very slow crystallization is beneficial for crystal orientation study, but may lead to higher impurity levels. In this work, no efforts were made to maximize the measured mobility values, which could be the reason for the relatively low mobilities observed.

4. Conclusions

In summary, a controlled solution process system with variable deposition temperatures and nitrogen gas flow rates was used to fabricate active layers of TIPS pentacene thin film transistors with relatively large grains ($W_G \sim 10$ μm) and different crystal orientations. Acene planes of TIPS pentacene crystals took an "edge-on" orientation on the oxidized Si wafer substrates, and one of the π–π stacking directions was close to [2 1 0] – the long axis of the needle-shaped TIPS pentacene grains. Frequent twinning across the $(1\bar{2}0)$ planes was evidenced by both optical and transmission electron microscopy. A maximum charge-transport anisotropic ratio of 10 was measured upon systematically changing the θ angle (i.e. the angle between [2 1 0] and the source–drain direction). Our results also demonstrate the possibilities of controlled solution deposition in fabricating single-crystal textured TIPS pentacene films with uniform and adjustable morphologies, which may be applicable to the studies of other solution-processible organic molecular semiconductors.

0084304 and DMR-6518079). TEM studies and electrical characterizations were conducted in the Electron Microbeam Analysis Laboratory and Solid State Electronics Laboratory at the University of Michigan at Ann Arbor.

(red–green–blue, RGB) has remained elusive. The problem was that the green polymeric electrochromics should have at least two absorption bands (blue and red) in their neutral state and these bands should also deplete simultaneously during oxidation [24] and it has been difficult to control both absorption bands by the application of a voltage pulse. Fortunately, a real advance on polymeric electrochromics came in the year 2004 by the work of Wudl and Sonmez et al. which brought all the problem to a close by designing hybrid materials in which electron rich (donor) and electron poor (acceptor) units were combined [24,25]. Nevertheless, the examples of neutral state green polymeric materials have still been very rare [26–30] and the newer ones are welcome.

During the course of a programme aimed at the synthesis and applications of novel photo- and electro-active materials [31–33], we have recently reported that the donor–acceptor systems which were based on thiophene and/or EDOT units as donor parts and 2,1,3-benzoselenadiazole as acceptor part, respectively, provided neutral state green polymeric electrochromic material [34]. In this paper, we wish to report the synthesis and properties of a novel and highly stable neutral state green polymeric electrochromic material which is based on 5,8-bis(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)-2,3-di(1H-pyrrol-2-yl)quinoxaline, 1 [35–37] (Chart 1). Although the synthesis of 1 was previously reported by Anzenbacher et al., to our best knowledge, no attention has been paid to the electrochromic properties of its polymer P1. P1 has an ambipolar character (n- and p-doping process) and it exhibits a green color in the neutral state and a highly transmissive blue color in the oxidized state, which is a quite important feature for RGB applications. Furthermore, the optical, electronic and electrochromic properties of P1 were discussed in comparison with the precedent analogues P4–P6 [27,28].

2. Results and discussion

2.1. Electropolymerization

In order to elaborate the redox behavior of 1, cyclic voltammetry studies were carried out in 0.1 M tetrabutylammonium hexafluorophosphate (TBAH)/dichloromethane (DCM) solution. As depicted in Fig. 1, 1 showed an irreversible peak ($E_{m,a}^{ox}$ = 0.85 V vs Ag/AgCl) during anodic scan. On the other hand, during the cathodic scan, a reversible reduction peak with a half peak potential ($E_{1/2}^{red}$) of −1.39 V (vs Ag/AgCl) was observed for stable radical anion formation.

For 1, new reversible redox couples and concomitant increase in the current intensities were observed during
Fig. 1. Cyclic voltammogram of 1.0×10^{-3} M 1 in 0.1 M TBAH/DCM at 100 mV/s.
Fig. 2. Electropolymerization of 1.0×10^{-3} M 1 in 0.1 M TBAH/DCM at 100 mV/s by potential scanning to give P1.

the repetitive anodic potential scan in 0.1 M TBAH/DCM solution when it was clipped at 0.95 V (Fig. 2). This clearly indicated the formation of an electroactive polymer film on the electrode surface. After electrodeposition, we were delighted to note that the as-prepared polymer was green in the neutral state.

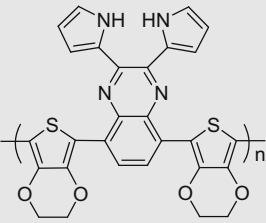
However, at this stage it was tempting to think that the polymerization of 1 might proceed in two different ways, since two different heterocyclic rings (EDOT and pyrrole) which generally exhibited distinct oxidation potentials were available for oxidative polymerization. In order to reveal that the polymerization preceded exclusively through the EDOT units, two similar systems were taken into account: 2 [35–37] where the oxidative polymerization through pyrrole rings was precluded by the presence of chlorine atoms, and 3 [35–37], where the oxidative polymerization, if possible yet, is only feasible through pyrrole rings, since EDOT units were eliminated from the structure.

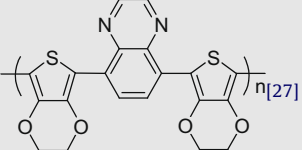
It was reported that 2 could give the corresponding conducting material electrochemically through EDOT units [35–37]. On the other hand, it was noted that 3 did not polymerize alone to yield a polymer film [35–37]. Undoubt-
Scheme 1. Electrochemical polymerization of 1 to give P1.
Fig. 3. Cyclic voltammograms of n- and p-doped P1 film in 0.1 M TBAH/ACN at a scan rate of (a) 50, (b) 75, (c) 100, (d) 125, (e) 150, (f) 175, (g) 200, (h) 225 and (i) 250 mV/s.

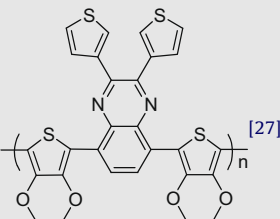
edly, these results suggested that the electrochemical polymerization of **1** proceeded through EDOT units to give **P1** (Scheme 1).

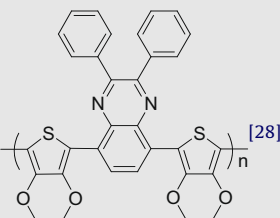
The redox behavior of the polymer film was investigated in monomer-free electrolyte solution containing 0.1 M TBAH/DCM. **P1** has an ambipolar (n- and p-doping

process) character and it exhibited single and well-defined reversible redox couples during p-doping at $E_{1/2}^{ox} = 0.10$ V (Fig. 3). The peak currents were linearly proportional to the scan rates which indicated a non-diffusional redox process and well-adhered electroactive polymer film (Fig. 4). The n- and p-doping processes take place much easier for **P1** when compared to **P4** (Table 1).

On the other hand, **P1** also exhibited a true n-doping behavior which mainly took place in the acceptor (quinoxaline) parts of the polymer chain (Fig. 3). The polymer film has a stable and well-defined reversible n-doping process with a half peak potential ($E_{p,1/2}^{red}$) of -1.34 V and the peak currents were intensified linearly as a function of scan rate indicating that redox couple was non-diffusion-controlled.








It is noteworthy to mention that n- and p-doping processes with the same material make it an excellent candidate for battery, supercapacitor and light-emitting diode applications [8]. Of special interest, the characteristic feature of electrochemical capacitors is the shape of cyclic voltammogram which should ideally be a rectangle with wide potential window. In order to probe the utility of **P1** film as a capacitor, it was cycled as a function of scan rate. As illustrated in Fig. 5, the flat current response was observed even after high scan rates, indicating a fast charge (doping)/discharge (dedoping) process. It was also noted that the polymer film exhibited perfect stability under multiple cycle between 0.0 and 1.0 V at a scan rate of 200 mV/s since no appreciable changes in the shape of the voltamogram was observed after a thousand of scans (Fig. 6). The stability upon switching or cycling is also crucially important feature for such materials to be amenable for practical and commercial applications. The stability of polymer film was recorded between neutral and oxidized states by potential scanning at a scan rate of 200 mV/s. After thousand of cycles, no appreciable change was observed in the redox response of **P1** which unambiguously showed that it is highly robust and/or stable (Fig. 6). These intriguing features pave the way of utilizing **P1** in

supercapacitors as either cathode or anode electrode material with broad potential window.

2.2. Electrochemistry

The electro-optical properties of the polymer film were investigated using the changes in electronic absorption spectra under a voltage pulse. Before p-doping process, the polymer film was initially neutralized at −0.5 V. It is noteworthy that **P1** is unique since it has shown three well-defined absorption maxima at 334 nm (3.60 eV), 427 nm (2.90 eV) and 746 nm (1.66 eV) in the neutral state (Fig. 7), and all the other analogues, **P4**–**P6** have shown only two absorption bands (see Table 1). The deep valleys (at 353 and 507 nm) among the three absorption bands of P1 control the hue and brightness of the green color [24]. Estimated differences in transmittance of the bands (at 334, 427 and 746 nm) with respect to these deep valleys

were found to be 2.7%, 14.2%, 25% for 353 nm and 16.2%, 27.8%, 38.6% for 507 nm. These values are quite enough to get the green color with various hue.

Although three sets of band gap (E_g) values can be calculated from the onset of the low energy end of three π–π^* transition bands (at 334, 427 and 746 nm) for green **P1** as 3.58, 2.54 and 1.25 eV, respectively, it is evident that E_g is 1.25 eV which was also supported by either cyclic (1.20 eV) or differential pulse voltammetry (1.17 eV) (Fig. 8a–c). It is also reasonable to assume that the E_g of **P1** from the optical study is 1.25 eV which is quite lower than that of **P4** and in well-agreement with the all other analogues (Table 1).

Upon oxidation, the polymer film exhibited a color change from green to transparent sky blue. It is of worth noting that the color change from green to sky blue is a quite significant trait in electrochromic devices and/or displays along with the green color of the neutral state.
Fig. 5. (a) Capacitance effect of P1 film by cyclic voltammetry at a scan rates of (a) 50, (b) 75, (c) 100, (d) 125, (e) 150, (f) 175, (g) 200, (h) 225 and (i) 250 mV/s. (b) Relationship of anodic (●) and cathodic (○) current peaks as a function of scan rate for P1 film in 0.1 M TBAH/ACN.
Fig. 6. Stability of P1 film by cyclic voltammetry at a scan rates of 200 mV/s in 0.1 M TBAH/ACN between 0.0 and 1.0 V.
Fig. 7. Electronic absorption spectra of P1 (11 mC/cm^2) on ITO in 0.1 M TBAH/ACN at various applied potentials between −0.5 and 1.0 V.

At low doping levels, the intensities of the three π–π^* transition bands of **P1** decreased simultaneously and a new absorption band around 1080 nm started to intensify due to the polaron formation in Fig. 7. Upon further oxidation, the absorption band at 334 nm reached the minimum intensity and the bands at 427 and 746 nm diminished completely. The percentage transmittance changes ($\Delta\%T$) between the neutral (at −0.5 V) and oxidized states (at 1.0 V) were found to be 7.3% for 334 nm, 36.4% for 427 nm, 19.2% for 746 nm and 49.9% for 1080 nm.

The promising true n-doping behavior of **P1** film was also confirmed by the changes in the electronic absorption spectra during reduction (Fig. 9). When the polymer film was reduced, its color changed from green to gray-purple

(Fig. 10) and the three π–π^* transition bands began to decrease simultaneously and new absorption bands started to intensify at 345, 496, 541 and 984 nm with a concomitant appearance of four isosbestic points (377, 457, 618 and 922 nm). This indicated that only two phases did coexist during the process (n-doping).

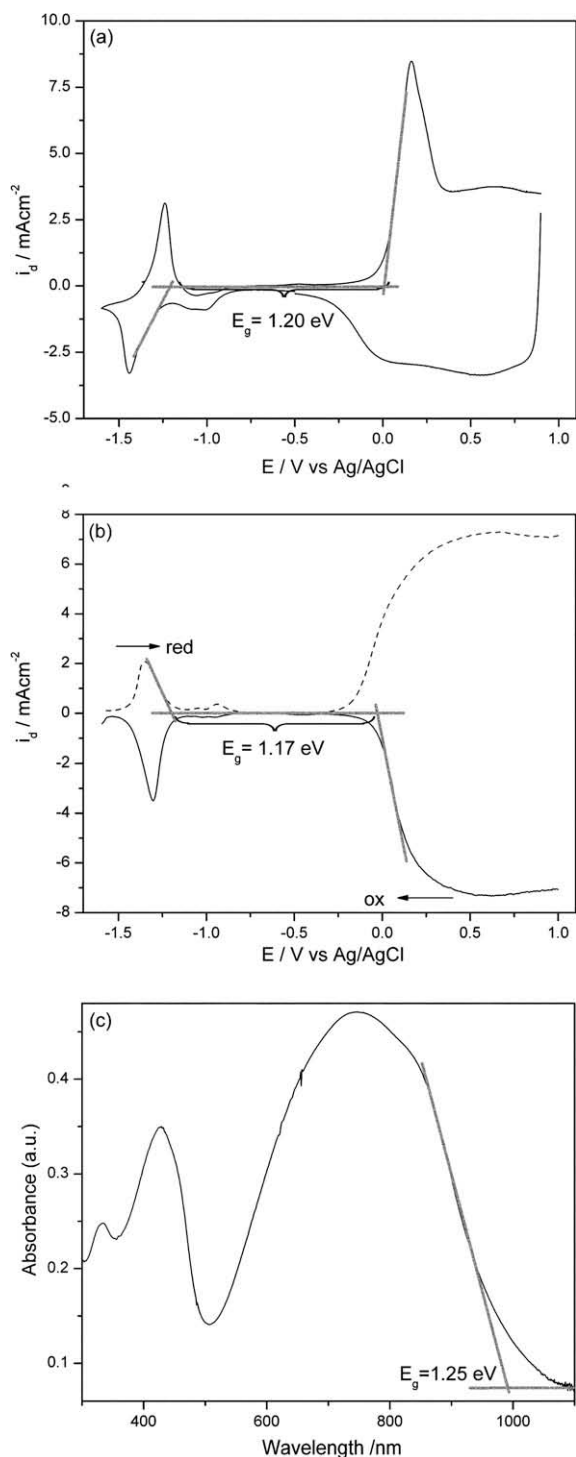
P1 film was found to be one of the most promising polymers bearing three absorption bands and durable n- and p-doping processes. Furthermore, the robustness and the stability of the system suggest that **P1** is an excellent candidate for electrochromic devices and optical displays. The transmittance changes (optical contrast) was measured as a function of switching time of 10, 5, 2 and 1 s via square–wave potential methods between −0.5 and 1.0 V. As shown in Fig. 11, the variation changes in the optical contrast at 334, 427 and 746 nm are 1.7%, 3.8% and 0.1%, respectively, as the switching time is increased from 10 to 1 s. This


Fig. 8. (a) Cyclic voltammetry, (b) differential pulse voltammetry, and (c) electronic absorption spectrum of P1 at −0.5 V (at neutral state) in 0.1 M TBAH/ACN.

Fig. 9. Electronic absorption spectra of P1 (11 mC/cm^2) on ITO in 0.1 M TBAH/ACN at various applied potentials between −1.00 and −1.90 V.

result clearly indicates that **P1** gave response in a very short time with no appreciable change in the optical contrast values, when it was switched for p-doping process.

3. Conclusion

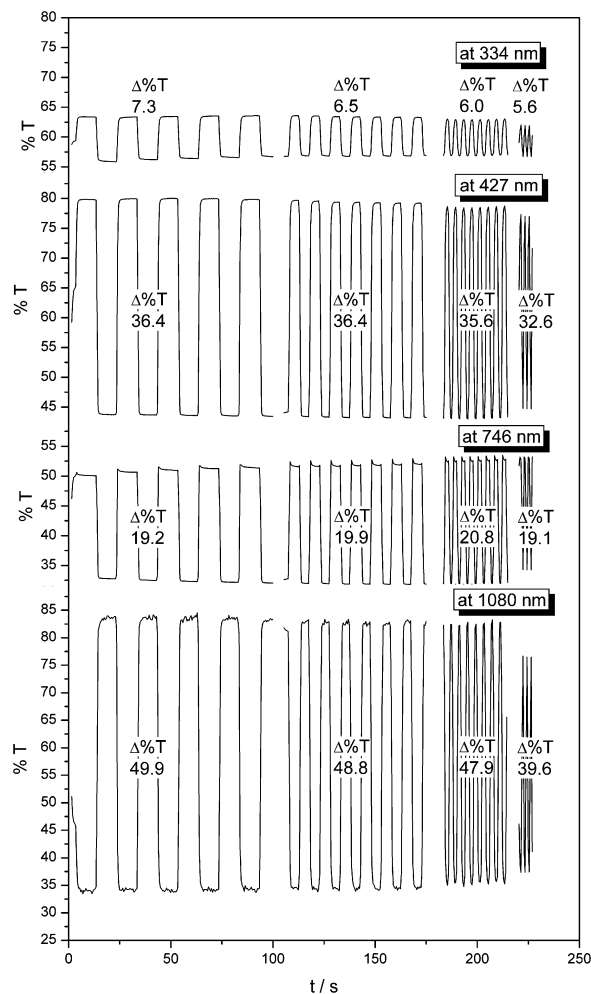
In summary, a new and highly stable neutral state green polymeric electrochromic based on quinoxaline (acceptor) and EDOT (donor) units, **P1**, was synthesized electrochemically and the intriguing features were described. **P1** is green in the neutral state and it exhibits three well-defined absorption bands. Furthermore, **P1** has a narrow band gap (1.17 eV). The n- and p-doping processes suggest that **P1** is one of the promising neutral state green polymers and it can be used in supercapacitors as either cathode or anode electrode material. Apart from the stability and the robustness of the polymer film, **P1** shows multi-electrochromic behavior; gray-purple in the reduced form and highly transmissive blue color in the oxidized state. Further work along these lines is currently underway in our laboratories and the results will be reported in due time.


Fig. 11. Chronoabsorptometry experiments for P1 on ITO in 0.1 M TBAH/ACN while the polymer was switched between −0.5 and 1.0 V with a switching time order of 10, 5, 2 and 1 s.

4. Experimental

4.1. General

All chemicals were purchased from Aldrich Chemical. 0.1 M tetrabutylammonium hexafluorophosphate (TBAH) dissolved in freshly distilled dichloromethane (DCM) and acetonitrile (ACN) was used as electrolyte solution. A platinum disk (0.02 cm^2) and a platinum wire were used as working and counter electrodes, respectively, as well as Ag/AgCl in 3 M NaCl(aq) solution as a reference. Repetitive cycling or constant potential electrolysis was used to obtain the polymer films. Electro-optical properties were investigated by using an indium–tin oxide (ITO, Delta Tech. 8–12 Ω, 0.7 cm × 5 cm) electrode as well as a platinum wire as counter electrode and a Ag wire as a pseudo-reference electrode (calibrated externally using 5 mM solution of ferrocene/ferrocenium couple). In order to equilibrate the redox behavior of the polymer film and to obtain repeated results, the coated polymer films were switched between their neutral

and oxidized states several times before electroanalytical and optical studies. Electroanalytical measurements were performed using a Gamry PCI4/300 potentiostat–galvanostat. The electro-optical spectra were monitored on a Hewlett–Packard8453A diode array spectrometer. Photographs of the polymer films were taken by using a Canon (PowerShot A75) digital camera. 5,8-bis(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)-2,3-di(1H-pyrrol-2-yl)quinoxaline (**1**) was synthesized according to the literature [35–37].

panels, and various cheap mass products, notably electronic paper and radio-frequency identification (RFID) tags [9–12]. The most mature memory cell structure for use in digital integrated circuit (IC) applications consists of a single field-effect-transistor (FET) that includes a binary information storage element and acts as a memory-cell addressing switch. The data sensing mode of single-FET memory structures renders them robust against read current distortions to the storage mechanism; an important advantage over their two-terminal contenders (i.e. cross-point resistive memories where parasitic leakage currents in a passive array can affect the reading process) [13,14]. In memory transistors, the storage element is incorporated in between the channel and the gate electrode. It can be placed in two readily discernible physical states that modulate the channel conductivity enabling data to be read electrically by sensing the current level of the transistor. Various storage elements based on: (1) charge injection and trapping in inorganic dielectrics [15], organic dielectrics [16] or nanoparticles [17], (2) ferroelectric polarization of dielectrics [18] as well as (3) proton motion and trapping in dielectrics [19] have been investigated as alternatives to the conventional polysilicon floating-gate of the transistor based Flash memories. In the case of high-density Si-based ICs, an aggressive reduction of the physical thickness of the gate dielectric storage element is required for scaling the size of the FET memory cell beyond 20 nm. On the other hand, single-FET memory structures with large feature sizes and thick storage elements compatible with organic electronic processing may be further exploited in emerging large-area low-performance logic circuit applications on flexible substrates.

In this direction, we recently proposed a simple approach for producing proton storage elements that can be reliably incorporated into the gate dielectric of inorganic and/or organic transistors [20]. Basically, a proton memory device utilizes the motion of protons within the gate dielectric of a Metal–Insulator–Semiconductor (MIS) transistor, and presents the benefit to be programmed at much lower voltages than charge-trapping memory devices, thus offering a better alternative for low-power consumption [21,22]. Our approach is based on solution-processed polymeric materials and enables the manipulation of the storage element properties simply via formulation or/and chemical synthesis. Realization of non-volatile memory devices is achieved using a stacked structure consisted of a proton-conducting polymeric layer (PCL) based on a tungsten heteropolyacid and poly(methyl methacrylate) (PMMA), and a proton-trapping polymeric layer (PTL) based on PMMA containing amine proton trapping sites, as depicted in Fig. 1 in the case of a MIS-type capacitor. Application of a positive voltage to the gate electrode with the substrate connected to ground ("Write" operation) allows for the dissociation of neutral (n) sites of the PCL into anions (−) and protons (+), motion and trapping of protons in the PTL. This induces a negative flat-band voltage shift of the capacitor C–V characteristics (Fig. 1). A subsequent negative voltage moves back the trapped protons leading to the reformation of neutral sites within the PCL ("Erase" operation).

The concept of using a PCL/PTL stack for the realization of non-volatile proton memory devices is quite simple and
Fig. 1. Schematic illustrating the structure and the operation principle of a non-volatile bistable MIS memory device with a molecular-based proton storage element consisting of a proton-conducting polymeric layer (PCL) and a proton-trapping polymeric layer (PTL) bi-layer stacked structure.

many materials are possible candidates. The materials' selection is primarily guided by requirements of memory performance and process integration compatibility that strongly depend on the physicochemical properties of the candidate materials. In the present paper, we provide a more detailed analysis of the relationship between the material properties and electrical performance of the PCL/PTL stack reported in our previous communication [20]. Particular emphasis is placed on the thermal processing conditions and their optimization to avoid undesirable phenomena like reactions within the PCL and inter-mixing of the PCL and PTL. Moreover, based on a combination of UV spectroscopy studies and transient current experiments, a comprehensive picture about the protons involved in the memory effect and their motion through the PCL is presented. Finally, the write characteristics and scalability prospects of molecular proton memory devices are examined in terms of the physical properties of generic PCL/PTL bi-layer stacked structures.

2. Experimental

The PCL consists of a PMMA film containing molecules of 12-tungstophosphoric acid ($H_3PW_{12}O_{40}$; here referred as HPW), whereas the PTL is a PMMA film with embedded 2-aminoanthracene (AA) molecules. Details on materials' preparation are reported in [20]. UV–vis spectra were acquired on a Perkin–Elmer Lambda 40 spectrophotometer. Fourier transform infrared spectroscopy (FTIR) transmittance spectra were collected on a Bruker, Tensor 27 spectrometer using 128 scans at $4 \, cm^{-1}$ resolution. The thicknesses of the polymeric layers were measured using an Ambios Technology XP-2 profilometer.

The devices examined consist of MIS structures with a PCL fabricated by spin coating of a HPW/PMMA solution onto an n-type silicon substrate pre-coated with a 3.5 nm-thick SiO_2 layer. The thickness of the PCL is about 270 nm. The gate electrode ($9 \times 10^{-4} \, cm^2$ area) is made of aluminum deposited by e-beam evaporation and defined by conventional optical lithography and metal etching. Further details on device structure and fabrication can be found in [20]. Proton motion in the HPW/PMMA layer was investigated by monitoring the time evolution of the gate current for various gate voltages. All measurements were carried out using a HP4140B pA meter/DC voltage source under ambient conditions in a light-free probe station.

3. Results and discussion

3.1. Material characterization

The thermal processing conditions of the HPW/PMMA film (PCL) may have a significant negative impact on the material chemical stability and subsequently on the proton motion, if the strong Brønsted acid used (HPW), participates in undesirable acid catalysed or redox [23] reactions with the polymer matrix promoted by temperature. In order to investigate possible reactions of the HPW molecules with the PMMA matrix, especially under thermal treatment, the HPW/PMMA films were monitored by means of FTIR spectroscopy. As depicted in Fig. 2, where the effect of thermal treatment temperature on the HPW/PMMA films at a fixed time (5 min) is presented, no significant changes in HPW and PMMA peak widths and positions were observed for $T \leqslant 120\,^\circ C$ indicating that up to that temperature no reaction between HPW and PMMA takes place inside the film (at least not to the extent that could be detectable with the FTIR spectrometer). In contrast, for $T \geqslant 130\,^\circ C$ substantial changes can be detected in the PMMA-related-FTIR peaks. These data point out possible formation of glutaric anhydride through the acid-catalyzed hydrolysis of PMMA by HPW in presence of water (derived from the atmosphere) and the subsequent dehydration of the poly(methacrylic acid) formed [24,25]. The changes in FTIR peaks that support the hypothesis of the anhydride formation are the following: (a) decrease of the broad O—H absorption peak at $\sim 3500\,cm^{-1}$; (b) decrease of the carbonyl peak at $1732\,cm^{-1}$ characteristic of PMMA, and simultaneous appearance of twin carbonyl peaks at 1802 and $1761\,cm^{-1}$ characteristics of the anhydride; (c) appearance of the C—O—C peak at $1020\,cm^{-1}$. On the other hand, the FTIR peaks of the $[PW_{12}O_{40}]^{3-}$ anion attributed to (a) the asymmetric stretching of the P—O_a bond ($1081\,cm^{-1}$), (b) the asymmetric stretching of the W—O_d bond ($981\,cm^{-1}$), (c) the asymmetric stretching of the W—O_b—W bridge ($898\,cm^{-1}$) and (d) the asymmetric stretching of the W—O_c—W bridge ($820\,cm^{-1}$) where O_{a-d} are different oxygen atoms of the HPW structure [26–30],
are not affected by this reaction, indicating therefore, that only the protons of the HPW molecules participate in the aforementioned reaction with PMMA whereas the anions of the HPW molecules remain unaffected.

Continuing in this direction, the effect of the thermal treatment duration on the HPW/PMMA film composition was also studied by FTIR spectroscopy at 120 °C. As shown in Fig. 3, for up to 60 min duration of the thermal treatment no significant change in the FTIR peaks was detected. Two small shoulders appear first at 1021 and $1802\,cm^{-1}$, which can be barely observed for the 60 min thermal treatment, indicating that such a reaction would evolve for higher annealing times as it is indeed observed in Fig. 3. As a result, it was concluded that the thermal treatment at 120 °C of the HPW/PMMA film should not be extended for longer than 60 min, in order to avoid undesirable PMMA reactions and thus alteration of the device performance.

On the other hand, the possible undesirable intermixing of the two layers (PCL and PTL) had to be addressed, since the same solvent is used for both layers. It is well known that the thermally treated PMMA films dissolve very slowly in organic solvents, due to the reduction of the film free volume during the treatment and the better packing of the polymer chains. For that reason, PMMA is used as a positive resist, where the unexposed film areas dissolve much more slowly than the exposed regions in selected solvents [31]. In order to investigate whether undesirable intermixing occurs under the conditions of our experiments, we monitored possible changes in intensity of the characteristic HPW peak at 266 nm induced by the coating of a PMMA layer on top of the HPW/PMMA layer (Fig. 4). In this study the lower layer (HPW/PMMA) was first treated thermally at 120 °C for a duration ranging from 10 to 60 min (taking into account the results of the previous FTIR analysis). As shown in Fig. 4, after a thermal treatment at 120 °C for 60 min of the HPW/PMMA layer the subsequent coating of the PMMA layer on top of it causes only a minor ($\sim$5%) decrease in HPW concentration. Such a decrease could be attributed to the dissolution of the HPW molecules located near the surface of the HPW/PMMA layer. In contrast, for

Fig. 2. FTIR spectra showing the effect of the thermal treatment temperature on the HPW/PMMA film. The duration of all thermal treatments was 5 min. Solution: HPW/PMMA 5/5% (w/w).
Fig. 3. FTIR spectra showing the effect of the duration of the 120 °C thermal treatment on the HPW/PMMA film. Solution: HPW/PMMA 5/5% (w/w).
Fig. 4. UV spectra showing the change of the characteristic HPW peak at 266 nm of the HPW/PMMA layer induced by the coating of a PMMA layer on top of it. The lower layer (HPW/PMMA) was treated thermally at 120 °C for two different durations: 10 and 60 min. The upper layer (PMMA) was treated thermally at 120 °C for 5 min in both cases. Solutions: PMMA 5% (w/w) and HPW/PMMA 5/5% (w/w).

thermal treatments of the HPW/PMMA layer at 120 °C for 10 and 30 min 33% and 29% decrease in HPW concentration was observed respectively (data for the 10 min case are presented in Fig. 4), indicating solvent penetration to the bottom layer and intermixing of the two layers. Consequently, the thermal treatment selected for the HPW/PMMA film was 120 °C for 60 min as it fulfilled both requirements to prevent reactions between HPW and PMMA and to avoid intermixing in the bi-layer structures. The above thermal treatment was also applied to the other films (AA/PMMA and PMMA) used in this study in order to have comparable PMMA packing in all the films.

The concentration of the HPW molecules within the HPW/PMMA layer annealed at 120 °C for 60 min was determined by applying the Lambert–Beer law ($A = \varepsilon\, c\, l$) to the characteristic HPW peak at 266 nm. In a typical experiment using the absorbance of this 266 nm peak ($A_{266} = 0.5303$), a film thickness, l, of 346 nm (measured by profilometry), and the molar absorptivity of HPW at 266 nm obtained from literature ($\varepsilon_{266} = 4.85 \times 10^4$ $M^{-1}\,cm^{-1}$; [32–34]), the HPW concentration in the film is found to be equal to 0.316 mol l^{-1} (1.903×10^{20} molecules cm^{-3}). Given that the size of the HPW molecules is approximately 1 nm, the above HPW concentration value corresponds to an average distance between the molecules of ca. 1 nm, for a close packing arrangement of HPW molecules within the PMMA matrix. The mass density of the HPW-embedded matrix, ρ, can be expressed as: $\rho = (n_{HPW} M_{HPW}/N_A)\,[(c_m + 1)/c_m]$. Here, n_{HPW} is the concentration of the HPW molecules within the HPW/PMMA layer, N_A is the Avogadro number, $M_{HPW} = 2880.17$ g/mol the molecular weight of HPW and $c_m = m_{HPW}/m_{matrix}$ the relative mass concentration of HPW molecules and matrix material. Thus, for the PCL layer under investigation (i.e., an HPW-embedded PMMA matrix with equal weights of HPW and PMMA, $c_m = 1$), the extracted HPW concentration of $n_{HPW} = 1.903 \times 10^{20}$ molecules cm^{-3} is found to correspond to an HPW/PMMA mass density ρ of about 1.82 g cm^{-3} (to be compared with the given mass density of PMMA matrix $\rho_{PMMA} = 1.19$ g cm^{-3} at 25 °C [35]). Finally, regarding the protons inside the film, in the general case of an HPW-embedded PMMA matrix, the number of dissociated protons per HPW molecule, which are expected to attach to the PMMA basic sites, i.e. the ester oxygens

[36], is expected to range between zero (case of no dissociation) and three (case of complete dissociation). In our case, the dissociation of HPW in low basicity solvents or matrices (as PMMA) is expected to be one proton per HPW molecule [37].

3.2. Electrical characterization

Fig. 5 shows typical transient gate current vs time (I–t) characteristics of the MIS device. For clarity, the applied gate voltage (V_G) during current measurements is also indicated. A constant V_G (ranging from 1 to 5 V) was applied (bias on) for 10 min to the gate electrode and then abruptly switched off (bias off). The time dependence of the induced polarization ($t \leqslant 600$ s) and depolarization ($t > 600$ s) currents is plotted in Fig. 5a and b, respectively (note that the recorded polarization and depolarization currents have opposite directions).

For the 1 V V_G regime (Fig. 5a), the current decays with time and vanishes after about 250 s, while for higher V_G values it reaches a quasi steady state that expresses a non-ohmic leakage current I_L of 0.4, 1.8, 4 and 7 pA for the 2, 3, 4, and 5 V regimes, respectively (see inset of Fig. 5a). Based on our previous capacitance–voltage investigations [20], we attribute the observed polarization current decays to the mobile protons of the HPW/PMMA layer, which migrate and accumulate toward the lower edge of this layer under application of positive V_G. The counter anions stay in a region close to the upper edge of HPW/PMMA layer forming a symmetric charge distribution around the center of the HPW/PMMA layer. In principle, for ion-blocking electrodes, one expects the contribution from ionic current after a potential step to vanish after sufficiently long times (i.e., when the total number of ions that contributes to the current, for a given polarization, is close to the electrodes). The low leakage current levels, I_L, detected for $V_G \geqslant 2$ V (Fig. 5a) seems most likely to be due to electrons that flow from the Si substrate to the Al gate electrode. Such an electron flow would involve tunnelling through the thin oxide barrier and hopping between localized states in the HPW/PMMA layer and therefore, could result in non-linear I_L–V_G characteristics in agreement with our observations (inset of Fig. 5a). It is pointed out that I_L must be considered in any estimation
Fig. 5. Polarization (a) and depolarization (b) transient currents after the displayed bias steps. The inset (a) shows the displayed leakage current I_L as a function of the applied bias, and the inset (b) plots the depolarization currents in logarithmic time scale.

of the migrated protonic charge, Q, by direct integration of the polarization current. In our case (Fig. 5a), the leakage current is subtracted from the total measured current before integration [38]: $Q = \int_0^{t_{steady}} [I(t) - I_L] dt$. Q calculations allow extraction of the number density of proton carriers, n_p, that contribute to the current ($n_p = Q/qV$, with q the absolute electronic charge and V the volume of the HPW/PMMA layer).

Further information on the transport behaviour of protons can be gained by examining the depolarization current curves presented in Fig. 5b. After the gate voltage is cut off at $t = 600$ s, the protons that were accumulated close to the lower edge of HPW/PMMA layer will move back toward the counter anions restoring thus, the equilibrium state of the unbiased device. Plotting the depolarization current in a logarithmic time scale (inset in Fig. 5b), an almost polarized-independent characteristic time for the return to equilibrium (ca. 300 s) is found, for $V_G \geqslant 2$ V. Such behaviour can be exploited for long-refresh volatile memory applications [20]. During depolarization, it is believed that the migration of protons is governed by the proton concentration gradient in the HPW/PMMA layer initially established during the polarization regime. Regardless of the exact nature of proton transfer mechanism, the total amount of proton's charge that accumulates close to the lower edge of the HPW/PMMA layer should also contribute to the depolarization current, in the absence of any permanent trapping of the migrated proton. In this case, an equal magnitude of the integrated current for each polarization/depolarization experiment should take place (i.e., area of $I(t) - I_L$ curves in Fig. 5a = area of the corresponding $I(t)$ curves in Fig. 5b), in agreement with our integrated current vs V_G results depicted in Fig. 6. The resulting proton density, n_p, normalized to the maximum estimated value, n_p^{max}, is shown in the inset of Fig. 6. n_p^{max} is the value expected if each HPW molecule gives one mobile proton (i.e., n_p^{max} = HPW concentration within PMMA, ca. 1.9×10^{20} cm^{-3}, see Section 3.1). As depicted, the number of migrated protons in the sample gradually increases with V_G and exhibits a trend to saturation ($n_p \sim 3.8 \times 10^{17}$ protons/cm^3 for $V_G = 5$ V). The latter result indicates that only 2 protons per 1000 HPW molecules contribute to
Fig. 6. Migrated protonic charge, Q, calculated by direct integration of the polarization (bias on; after the subtraction of the leakage current) and the depolarization currents (bias off). The inset shows the extracted ratio of the number proton density n_p and the maximum proton density n_p^{max} vs applied gate voltage V_G.

the current under full polarization conditions (saturation regime) and thereby, reveals that the main part of the dissociated protons is mainly immobile.

The polarization $I–t$ curves can also be used to obtain information about proton conductivity (σ_{dc}) and mobility (μ) and therefore, to estimate the number of protons (n_p) that contribute to the current according to: $\sigma_{dc} = n_p q \mu$. In the case of $V_G = 1$ V where no leakage current flows across the sample, the extracted σ_{dc} and μ values are 5.0×10^{-13} S cm^{-1} and 2.8×10^{-10} cm^2 V^{-1} s^{-1}, respectively [20]. We find that about 1.1×10^{16} cm^{-3} protons/cm^3 contribute to the current under 1 V polarization. This n_p value is comparable to that previously extracted by the integrated current method at $V_G = 1$ V ($n_p \sim 7.4 \times 10^{16}$ protons/cm^3, see inset of Fig. 6).

3.3. Write characteristics and scalability prospects of molecular proton memories

This section treats the performance of a generic molecular proton memory. In particular, it examines the write

characteristics of the device depicted in Fig. 1 from a material perspective of its bi-layer storage element (i.e. PCL/PTL). The memory window, the write time and the write voltage of this type of memory device are successively discussed in terms of PCL/PTL material features such as the proton mobility and the mobile proton concentration in the PCL as well as the PCL and PTL thicknesses.

3.3.1. Memory window

By neglecting the finite size of protons and counter ions, we can express the symmetric effective proton and anion charges per unit area that develop under complete polarization close to the lower and upper edges of the PCL as: $Q_{proton} = |Q_{anion}| = n_p q d$, with d being the thickness of the PCL. Hence, in the case of the MIS device, the maximum magnitude of the induced negative flat band voltage shift, $\Delta V_{FB}(-)$, due to the accumulation of protons at the lower edge of the PCL can be expressed as:

$$\Delta V_{FB} = -\frac{n_p q d^2}{\varepsilon_i} \tag{1}$$

where ε_i is the dielectric constant of the PCL. In Fig. 7, the resulting $|\Delta V_{FB}(-)|$ is plotted as a function of the thickness of the PCL with the mobile proton number density, n_p, as a parameter and an assumed effective relative dielectric constant of 3.9 [20]. By increasing the mobile proton density the thickness of the PCL must decrease in order to maintain a constant memory window. For n_p values of 0.1, 0.5, 1 and 5×10^{17} cm^{-3}, the estimated thickness of the PCL for a constant memory window of about 3.5 V is close to 270, 120, 85 and 40 nm, respectively.

3.3.2. Write time

By assuming in the case of an initial uniform charge distribution that the protons have moved a distance $d/2$ on average before reaching a PCL layer edge, the magnitude of the write time can be estimated according to [20]:

$$\tau = \frac{d}{2E\mu} \tag{2}$$

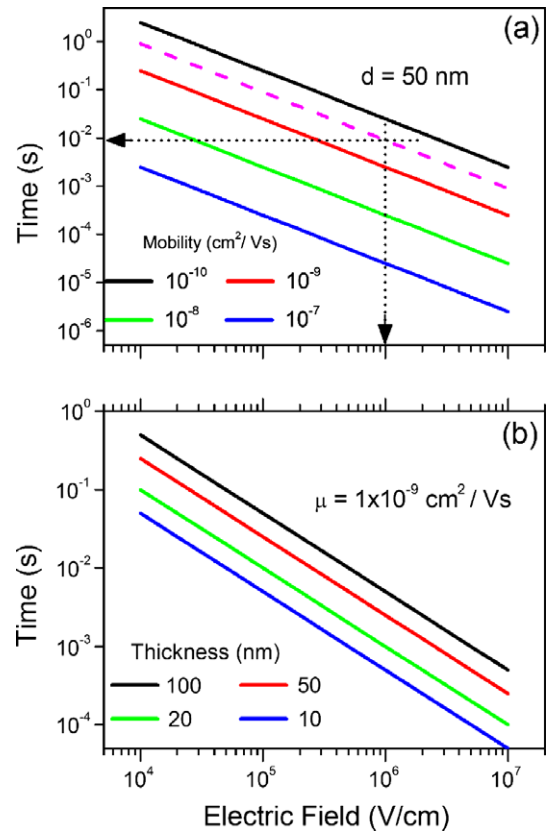
where E is the "write" electric field. Fig. 8a depicts write time estimations as a function of the applied electric field
Fig. 7. Flat band voltage estimations for complete polarization as a function of the HPW/PMMA thickness for different densities of mobile protons.


Fig. 8. Write time estimations for complete polarization as a function of the applied write electric field for: (a) different proton mobilities and constant thickness of the PCL; (b) different PCL thicknesses and constant proton mobility.

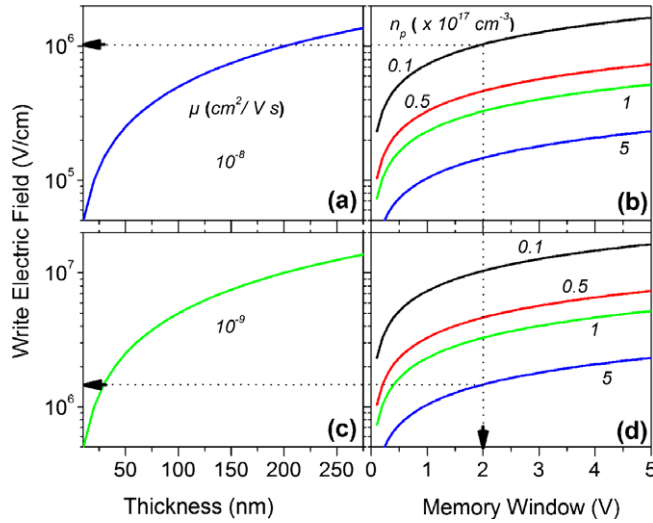
for different mobility values and constant thickness of the PCL. In the case of 50 nm PCL thickness, the experimentally extracted μ value of 2.8×10^{-10} cm^2 V^{-1} s^{-1} for the HPW/PMMA layer (dashed curve) affords write times of around 10 ms at a write electric field as low as 1 MV/cm. Shorter write times are attainable by decreasing further the thickness of the PCL layer (Fig. 8b); in such a case, attention should be drawn to maintain a detectable memory window, as the latter is proportional to the thickness of the PCL for a given effective protonic charge per unit area, Q_{proton}. For the case of 1 ms write time, Fig. 9 connects the write electric field and the resulting memory window with the physical properties of the PCL (i.e., the proton mobility, μ, the proton number density, n_p, and the layer thickness, d). A PCL with material features: $\mu = 10^{-8}$ cm^2 V^{-1} s^{-1}, $n_p = 10^{16}$ cm^{-3} and a thickness of about 200 nm can induce a memory window of 2 V under application of a write electric field of $\sim$1 MV/cm for 1 ms, Fig. 9a and b. By decreasing the proton mobility (case of Fig. 9c and d), the thickness (d) and the proton number density (n_p) must decrease and increase, respectively (d to $\sim$30 nm and n_p to $\sim$5 × 10^{17} cm^{-3}), in order to maintain the write characteristics of the device (i.e., a write time of 1 ms, a write electric field in the 1 MV/cm regime, and a memory window of 2 V).


Fig. 9. Write electric field vs memory window estimations for complete polarization under 1 ms write time, for different physical properties of the PCL (i.e., proton mobility, proton density and thickness).
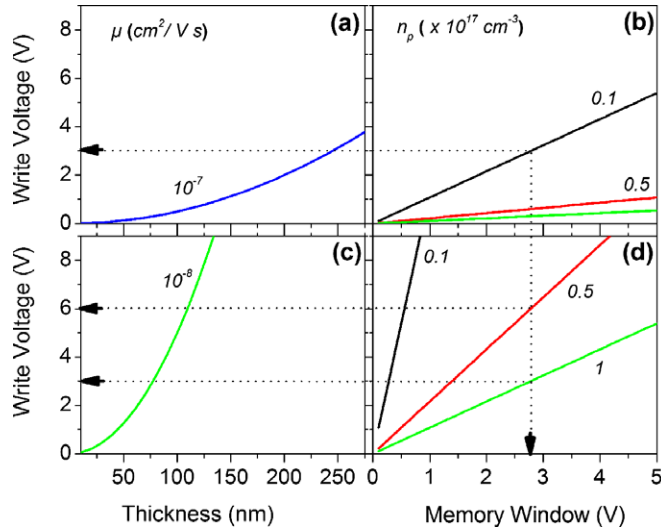

Fig. 10. Write voltage vs memory window estimations in the limit $d_{PTL} \ll d_{PCL}$, for complete polarization under 1 ms write time, for different physical properties of the PCL.

3.3.3. Write voltage

Ignoring the work function difference between the semiconductor substrate and the metal gate electrode, the write voltage, V_w, can be expressed as: $V_w = E\, d_{total}$, where d_{total} represents the total physical thickness of the PCL/PTL stack (i.e., $d_{total} = d_{PTL} + d_{PCL}$). In the limit $d_{PTL} \ll d_{PCL}$ (e.g., in the case of a PTL made by a small number of monolayer containing basic sites), V_w can be approximated under complete polarization (i.e., full write) through a combination of the previous relations of the memory window (ΔV_{FB}) and write time (τ), i.e. Eqs. (1) and (2), such as:

$$V_w = \frac{\varepsilon_i \Delta V_{FB}}{2 n_p q \mu \tau} = \frac{d^2}{2\mu\tau} \qquad (3)$$

In Fig. 10, in an analogous way to Fig. 9, the overall write characteristics of the device (i.e., the write voltage and the resulting memory window) for 1 ms pulsed time are plotted as a function of the physical properties of the PCL. A PCL with $\mu = 10^{-7}$ cm^2 V^{-1} s^{-1}, $n_p = 10^{16}$ cm^{-3} and $d_{PCL} \sim 245$ nm leads to a memory window of about 2.8 V under an applied write voltage of 3 V for 1 ms (Fig. 10a and b). As depicted in Fig. 10c and d, for lower proton mobility (10^{-8} cm^2 V^{-1} s^{-1}) the layer thickness has to decrease to $\sim$75 nm, while the proton density must increase to 10^{17} cm^{-3}, in order to maintain the write characteristics of the memory device (i.e. $V_w/\tau = 3$ V/1 ms, $\Delta V_{FB} = 2.8$ V). Note that, an intermediate decrease (increase) of the thickness (proton density) of the PCL to 110 nm (5×10^{16} cm^{-3})

requires a twofold increase of the write voltage, i.e. from 3 to 6 V, to conserve a memory window of 2.8 V for a write time of 1 ms.

It should be here emphasized that the write voltage scalability of a proton memory device with equal PCL and PTL thicknesses can be approximated under complete polarization (i.e., full write), and for proton trapping in a region close to PTL/PCL interface, through the relation:

$$V_w = \frac{\varepsilon_i \Delta V_{FB}}{n_p q \mu \tau} = \frac{d^2}{4\mu\tau} \tag{4}$$

In such a case the thickness d corresponds to the total PCL and PTL thicknesses. For example, a PCL with $\mu = 10^{-7}$ cm^2 V^{-1} s^{-1}, $n_p = 2 \times 10^{16}$ cm^{-3} and $d_{PCL} = 175$ nm on the top of a PTL of equal thickness (175 nm) leads to a memory window of about 2.8 V under an applied write voltage of 3 V for 1 ms. From the above discussion it is clear that a proton memory device using a PCL with appropriate proton mobility (μ) and density (n_p) does not require an aggressive scaling in PCL and PTL thicknesses for low-voltage operation.

4. Conclusions

Physicochemical and transient current experiments have been conducted on stacked bilayer structures consisted of a proton conducting layer (PCL) and a proton trapping layer (PTL) for the development of molecular proton memory. FTIR investigation of the effect of the thermal processing parameters (temperature and duration) on the HPW/PMMA layer (PCL) resulted in the successful prevention of two undesirable phenomena: (a) the reaction between HPW and PMMA matrix inside the PCL, and (b) the intermixing of the PCL and PTL layers. By means of UV spectroscopy, the concentration of the HPW molecules within the HPW/PMMA layer is estimated to approximately 1.9×10^{20} HPW molecules cm^{-3}. Transient current measurements on MIS devices allowed the determination of the concentration of mobile protons within the HPW/PMMA layer as well as an estimation of the proton mobility. The extracted proton density of ~3.8×10^{17} protons/cm^3 under full polarization conditions corresponds to only 2 mobile protons per ~1000 HPW molecules, indicating that the main part of the dissociated protons which are attached to polymer basic sites is mainly immobile. Finally, the analysis of a generic molecular proton memory revealed that several material features of the PCL/PTL bilayer stacked structure should affect the write characteristics of this type of memory device. Our calculations point out the dependence of the device memory window, write time and write voltage on the proton mobility, the mobile proton concentration and the PCL and PTL thicknesses.

to passivate inorganic surface traps as well as mediate forward charge transfer to reduce back recombination at the interface leading to much improved fill factors and photocurrent densities [8]. These improvements have lead to efficiencies as high as 4.9% while maintaining good ambient device stability. This is important because the encapsulation process can be potentially performed under ambient conditions which will lead to reduced fabrication costs. However, the devices in our previous studies have been based on vacuum deposited Ag as anode which is not as ideal in terms of simplicity for large area, roll-to-roll processing.

In this letter, we investigate the possibility of utilizing a spraycoating process for the deposition of Ag-NPs as the anode electrode in inverted solar cells. These spraycoated Ag electrodes show good performance and similar ambient device stability when compared to the ones fabricated using the conventional vacuum deposition process. Devices were also fabricated onto flexible ITO substrates to demonstrate the feasibility of making flexible solar cells closer to the ideal large area, roll-to-roll processing.

To fabricate the inverted solar cells, ITO-coated glass substrates ($15\ \Omega/\square$) and ITO-coated plastic substrates ($60\ \Omega/\square$) (Bayview Optics) were cleaned with detergent, de-ionized water, acetone, and isopropyl alcohol. A thin layer of ZnO nanoparticles ($\sim$50 nm), synthesized using the method described by Beek et al. [9], was spin-coated onto ITO-coated glass. The C_{60}-SAM was then deposited as previously reported [7]. Afterward, a chrolobenzene (CB) solution of poly(3-hexylthiophene) (P3HT) (Rieke Metals) and [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM) (American Dye Source) (60 mg/ml) with a weight ratio of (1:0.6) was spin-coated onto the ZnO modified layer to achieve a thickness of ($\sim$210 nm) and annealed at 160 °C for 10 min in an argon glovebox. After annealing, PEDOT:PSS was spin-coated multiple times and annealed for 10 min at 120 °C in air between subsequent spincoating steps onto the active layer to achieve a thickness of $\sim$150 nm. The silver electrode was vacuum deposited (100 nm) at a pressure of 1×10^{-6} torr or spraycoated on top of PEDOT:PSS to complete the device. For the spraycoating, a solution of Ag-NPs (NanoMas: contents of 25% Ag-NPs, 25–60% dodecane, 0–50% cyclohexane, 0–20% terpineol) was diluted in 1:40 (v:v) in hexane. An airbrush spraycoater is used to spray the dilute solution onto a masked device (7 mm) at a distance of 6 cm with a spray pressure of 15 psi using N_2 as the gas. This is repeated until the desired number of coats is achieved. Spraycoating the Ag-NPs leads to extremely rough films which make measuring the exact thickness difficult, but the film thickness as measured by a profilometer is in the range of $\sim$1–2 μm. The devices coated with the Ag-NPs electrode were then annealed at 120 °C for 5 min in air as suggested by NanoMas to promote the nanoparticle interconnectivity. The unencapsulated solar cells were tested under ambient conditions using a Keithley 2400 SMU and an Oriel Xenon lamp (450 W) with an AM1.5 filter. A mask was used to define the device illumination area to minimize photocurrent generation from the edge of the electrodes [10,11]. The light intensity was calibrated to 100 mW/cm^2 using a calibrated silicon solar cell with a KG5 filter which has been

previously standardized at the National Renewable Energy Laboratory.

The spraycoating technique has been previously demonstrated by others for the deposition of the active layers

[12,13] as well as PEDOT:PSS-based electrodes [14] in polymer solar cells. The spraycoating process has many variables that can be controlled including the solution viscosity, spray pressure, the spray distance from sample, spray time and number of spray coats which can affect the formation of the final coating of the film. In this study, most of these variables are held constant except for the number of coating layers. The number of coats (from 20 to 100) of the Ag-NPs was systematically studied to explore the effect on device performance.

The illuminated $J–V$ characteristics of the devices fabricated by different number of coating layers of Ag-NPs are compared to vacuum deposition of Ag in Fig 1a and b. With a coating of 20, the diode characteristics are poor, but are improved as the number of coatings increase. Table 1 summarizes the average device performance of these spraycoated electrodes to the ones prepared by vacuum

deposition. Devices with a coating of 20 show a low short circuit current (J_{sc}), fill factor (FF), and power conversion efficiency (PCE) of 7.71 mA/cm^2, 44.5%, and 2.10%, respectively. The photocurrent increases with increasing coating layers but saturates to ~8.3 mA/cm^2 at 100 coats. However, the FF dramatically improves from 44.5% with a coating of 20–54.2% with a coating of 40 and further improves to 59.6% with a coating of 100. This leads to an average PCE of ~3.00% by spraying 100 coats of the Ag-NPs. The device series resistance of the different number of coats was estimated at 1.5 V showing a resistance of 26.1 Ω cm^2 with 20 coats. Increasing the number of coats show lowering of the device series resistance eventually saturating around ~7 Ω cm^2 with 100 coats. This resistance is still higher than the evaporated Ag which had a resistance of ~5 Ω cm^2. Overall, the vacuum deposited Ag devices had higher performances in J_{sc}, FF, and PCE of 9.34 mA/cm^2,

Table 1

Average device performance of inverted ZnO NP/C$_{60}$-SAM/P3HT:PCBM bulk heterojunction solar cells fabricated on glass/ITO and plastic/ITO substrates by either vacuum deposition of Ag or spraycoating of Ag-NPs as the anode electrode. Average was obtained from multiple device tests. Sheet resistance of vacuum deposited Ag and different spraycoated Ag-NPs electrodes.

Electrode deposition	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)	R_s (Ω cm^2)	Ag sheet resistance (Ω/□)
Vacuum	0.61	9.34	62.2	3.55	5.0	0.51

Fig. 3. UV–Vis transmission spectrum of spraycoated Ag-NPs electrodes from 20 to 100 coats compared to a 100 nm Ag evaporated electrode on glass substrates.

62.2% and 3.55%, respectively. Fig 2a shows two devices, one of which is fabricated using the spraycoating technique (100 coats) and the other is by vacuum deposition (100 nm). The spraycoated electrode with 100 coats shows similar device series resistance and fill factor compared to the evaporated electrode, however a 0.55% lower PCE mainly from the lower J_{sc} in the spraycoated electrode devices is unaccounted for.

To understand the reason for this difference in efficiency the spraycoated and evaporated electrodes were characterized by measuring the sheet resistance using the four-point probe technique, transmission by UV–Vis spectroscopy and surface morphology by scanning electron microscopy (SEM). Table 1 shows the sheet resistance of the Ag electrodes as measured by four-point probe. A sheet resistance was not able to be measured on the electrode with 20 coats which is attributed to the poor nanoparticle interconnectivity in forming a film as can be seen in the SEM image in Fig 2b. As a note, even the devices fabricated using 20 coats had poor stability and performance degraded rapidly after multiple I–V scans. Increasing to 40 coats a sheet resistance of 7.55 Ω/□ was obtained and the performance of devices after multiple I–V scans was stable. Further increasing the coating to 100 lead to a sheet resistance of 0.71 Ω/□ which is comparable to the evaporated electrode (0.51 Ω/□). This reduced sheet resistance is the main reason for the improvement in device fill factor in the spraycoated electrode devices. The minimized sheet resistance improves the device series resistance in both the 100 coats and evaporated Ag film which leads to similar fill factors. However, this does not explain the reason for the difference in photocurrent density between the 100 spray coat and Ag evaporated electrode. The transmission spectrum measured by UV–Vis of the spraycoated and evaporated electrodes are shown in Fig 3. At the P3HT absorbance peak (~550 nm), the spraycoated electrode with 20 coats has a transparency of ~45%. Increasing the number of coats to 80 and 100 reduces the transmission to ~12% and ~9%, respectively which is still much higher than the transparency of evaporated Ag film (~1%). Fig 2c

and d shows the SEM images of the Ag-NPs film by spray-coating 20 coats, 100 coats and the Ag evaporated film. The 100 coat film shows a much denser aggregation and interconnection of the Ag-NPs compared to the 20 coat film which explains the reduced sheet resistance. However, even the 100 coat film show many voids which is the reason for the higher transparency and higher sheet resistance compared to the Ag evaporated film which does not have these voids. One potential reason for the difference in photocurrent is the higher transmission in the 100 coat films compared to the Ag evaporated films which reduces the potential for light to be reflected back into the active layer from the electrode to increase absorption.

The spraycoating procedure was used to fabricate solar cells on flexible plastic ITO substrates which were compared to evaporated Ag electrodes. The illuminated J–V characteristics are shown in Fig 1c. Devices with the spray-coated electrode on the plastic substrate show a lower J_{sc}, FF and PCE of 6.90 mA/cm^2, 34.0% and 1.40%, respectively compared to the evaporated electrode which had a J_{sc}, FF and PCE of 8.31 mA/cm^2, 34.3% and 1.73%, respectively. The lower performance especially in fill factor compared to the ITO/glass substrates is due to the lower transparency of the flexible ITO substrate as well as the higher sheet resistance [15]. The unencapsulated devices stored in ambient for 21 days also show that the device with Ag-NPs electrodes have similar stability as previously reported with the Ag evaporated electrodes [6].

In conclusion, the performance of inverted solar cells using spraycoated Ag-NPs has been systematically studied showing that the number of coating layers can affect its final device performance. With higher number of coating layers, a better nanoparticle interconnectivity and morphology is achieved which reduces the sheet resistance and transparency of the Ag electrode leading to improved fill factor and device performances of ~3.00%. This efficiency is lower than the evaporated Ag film which is attributed to the higher transmission of light due to a rougher and less dense Ag-NPs film which leads to a reduction of photocurrent. Furthermore, spraycoating of the Ag electrode onto flexible ITO substrates devices shows a performance of ~1.40%. The ability to use a non-vacuum technique to deposit the electrode in polymer solar cells is important for large area, flexible, roll-to-roll production of low-cost solar cells.

Great efforts have been made to address this problem by optimizing thin-film morphology to improve the charge transport and suppress recombination [12–15]. Moreover, the bulk heterojunction structure based on organic small-molecule dyes could be formed through donor–acceptor (D–A) co-deposition [16–19]. However, the carrier recombination rate in such type of mixed layer remains at a very high level [20].

In this paper, a multistepped (MS) structure of a device made from a CuPc:C_{60} heterojunction materials system is introduced. Through simultaneous dynamic alteration of the relative deposition rates of the two kinds of materials, the C_{60} content in the device ascends from the anode to the cathode, while that of CuPc descends from the anode to the cathode, which seems similar to the graded junction solar cell design for inorganic solar cells [22–24]. However, in organic solar cells, only Sullivan et al. [17], Drees et al. [13], and Koeppe et al. [5] have made similar structures by other methods. Sullivan et al. produced a five-layered device based on the CuPc/C_{60} materials system where the CuPc:C_{60} composition varies from purely donor to purely acceptor via three mixed layers of increasing acceptor concentration, which are 25%, 50%, and 75% [17]. Drees et al. propelled the interdiffusion of an initial MEH-PPV/C_{60} bilayer by simple heat treatment to obtain a bulk heterojunction with a concentration gradient of donor and acceptor [13]. Koeppe et al. used a pyrollidinofullerene compound with chelating pyridyl groups (PyF) that can interact with the Zn atom in the Zn-phthalocyanine (ZnPc) molecule in the bilayer solar cell, which may also induce a similar molecular architecture [5]. These devices all exhibit good photovoltaic performance, but its causes were discussed from the aspect of mixed film morphology only. Based on this concept, we envisioned MS device as a different approach to obtain a high photovoltaic performance. Thus, the effect of different sizes of concentration gradients of donor and acceptor on the solar cell performance is further discussed. Also, the optimization mechanism based on the theory of excitonic solar cells [6] is investigated to better understand the potential advantages of both bilayer heterojunction cell and homogeneously mixed cell in this structure.

Several devices with three different structures were designed for comparison (Fig. 1 inset). These are as follows:

- A: ITO/CuPc (30 nm)/C_{60} (30 nm)/TPBI (6 nm)/Al (80 nm);
- B: ITO/CuPc:C_{60} (MS, 60 nm)/TPBI (6 nm)/Al (80 nm); and
- C: ITO/CuPc:C_{60} (1:1,60 nm)/TPBI (6 nm)/Al (80 nm).

Among them, A is the bilayer heterojunction device (standard device), B is the MS device, and C is the 1:1 homogeneously mixed device. The CuPc:C_{60} (1:1) homogeneously mixed device is chosen owing to the fact that the total CuPc content is the same as that of C_{60} in the MS layers, and could thus be used to compare with these MS devices as the extreme case without the gradient. The 2,2,2-(1,3,5-benzenetriyl)tris-[1-phenyl-1H-benzimidazole] (TPBI) layer in each device acts as an exciton blocking layer.

Glass/indium tin oxide (ITO) substrate with a sheet resistance of 20 Ω/sq was cleaned in an ultrasonic bath using detergent water, de-ionized water, acetone, and ethanol in
Fig. 1. Absorption spectra of CuPc/C_{60} bilayer, MS100 layer, and 1:1 homogeneously mixed layer deposited on quartz substrates. Inset: schematic of the PV devices investigated. A is the bilayer heterojunction device (standard device); B is the MS device; and C is the 1:1 homogeneously mixed device.

turn for 15 min. Afterwards, it was treated in an ultraviolet-ozone chamber (UVO) then coated with layers of 30 nm CuPc, 30 nm C_{60}, and 6 nm TPBI through thermal evaporation in a high-vacuum chamber especially designed for organic materials. In circumstances where the vacuum conditions are not broken, the substrate was moved into the vacuum chamber particularly for metals to be coated with an 80 nm Al layer. This eventually becomes the standard device. The MS layers could be produced through dynamic alteration of the relative deposition rates of the two kinds of materials evaporated simultaneously. The thicknesses of the MS films were all controlled at 60 nm and there were a total of 10 steps in the MS system. Take MS100 for example, in which the CuPc concentration was gradually decreased from 100% in the first step to 0 in the last step. The preparation process is detailed as follows. First, the initial deposition rates of CuPc and C_{60} were respectively controlled at 0.5 Å/s and 0 Å/s. In the former 30 nm, every time the deposition layer thickness increased by 6 nm, the deposition rate of C_{60} increased by 0.1 Å/s, whereas that of CuPc maintained the initial value. When the rates of these two reached 1:1 (both 0.5 Å/s), the layer thickness was just 30 nm. In the latter 30 nm, the deposition rate of C_{60} was kept at 0.5 Å/s, whereas that of CuPc was gradually decreased from 0.5 Å/s to 0 Å/s by the same alteration speed maintained by C_{60} before. Other MS layers were all similarly prepared following these steps in addition to the different relative deposition rates in order to make different concentrations. We believed that the rate changes between steps were so

small that the concentration gradients in the MS system approached that of a diffusive method. The active area of the cell was 2×2 mm = 0.04 cm^2, and the J–V curve of the cell was measured on a computer-controlled Keithley 2000 current meter. The solar simulator YSS-50A (Yamashita DESO) was at a light intensity of 100 mW/cm^2 (AM1.5G). The measuring processes used in this study were performed under vacuum conditions at room temperature.

Three kinds of MS devices were fabricated similar to the structure of the cell B shown in the inset of Fig. 1. Fig. 2a shows the detailed stepped distributions of CuPc and C_{60} in their photoactive layers. Since all their CuPc concentration decreased from 100% in the first step to 0 in the last step and the major difference lies in the position of the step when the CuPc concentration reached 50%, they are exhibited as MS100 a/b/c, respectively. As shown in Fig. 2a, the distributions of concentration gradients in the bulk of the MS100 b/c layers are asymmetrical while that of the MS100 a is symmetrical around the center of the layer. Their characteristics are summarized in Table 1. We observe that all their V_{oc} displays the same value. However, the short-circuit current (J_{sc}) and fill factor (FF) of the MS100 a device are both the highest among the three. It is suggested that the centrosymmetrical distributions of concentration gradients in the MS100 a film might help the balance of hole and electron transport on both sides. Later, we will lay emphasis on an MS system of this kind.

Fig. 1 shows the absorption spectrogram of the photoactive layers of the standard device, the MS100 device, and
Fig. 2. Stepped distributions of CuPc and C_{60} concentration in (a) three kinds of MS layers with different symmetries of concentration gradients of donor–acceptor; (b) a series of MS layers with the same symmetries but different sizes of concentration gradients and 1:1 homogeneously mixed film. The shadow denotes the apparent effective CS interfacial area in the film. When two substances blend, the apparent interfacial area depends on the surface area of the substance of less content. In this paper, we use the material content to stand for its approximate surface area. Of all these MS layers, the former half contains less C_{60} and the latter half contains less CuPc, thus the apparent effective CS interfacial area is as shown in the shadow.

Table 1

Photocurrent–voltage characteristics of organic thin-film PV devices investigated under 100 mW/cm^2 AM1.5G illumination. Each cell has the common parts, that is, ITO as the anode contact and TPBI (6 nm)/Al (80 nm) as the cathode.

	Device	V_{oc} (V)	J_{sc} (mA/cm^2)	FF	η_P (%)
A	CuPc/C$_{60}$	0.50	3.95	0.60	1.19
B	MS100[a]	0.52	9.17	0.45	2.15
	MS86	0.49	9.26	0.42	1.94
	MS73	0.46	10.25	0.40	1.88
	MS67	0.45	9.90	0.40	1.78
C	CuPc:C$_{60}$ (1:1)	0.40	8.78	0.41	1.44
D	MS100[b]	0.52	7.82	0.37	1.51
	MS100[c]	0.52	8.05	0.44	1.84

[b] MS100 b.
[c] MS100 c.

the 1:1 homogeneously mixed device. The pure CuPc film has two peaks centered at wavelengths of 620 and 695 nm; the longer wavelength peak is dominant in the gas phase or dilute solution, and the shorter wavelength feature results from molecular aggregation [21]. We observe that the absorbance of the MS100 layer within the absorption wave band of aggregation CuPc is slightly lower than that of the CuPc/C$_{60}$ bilayer even though their photoactive materials content are the same. This suggests that the MS100 structure could also inhibit molecular aggregation as a homogeneously mixed structure does, which may lead to reduced carrier transport in the film [19]. However, compared with the standard device (3.95 mA/cm^2), the J_{sc} of both the MS100 device and the 1:1 homogeneously mixed device has increased tremendously (Table 1). We suggest that the structural advantages of the MS device

over the standard device lie in the D–A interpenetrating networks morphology and increased charge-separation (CS) interface area, which seems similar to the mixed device. Actually, as evident in Fig. 2b, the apparent effective CS interfacial area in the MS100 layer seems smaller than that of 1:1 homogeneously mixed film. However, the J_{sc} of the MS100 device reaches 9.17 mA/cm^2, which is even higher than the aforementioned device (8.78 mA/cm^2). Thus, aside from the increased CS interfacial area, there must be other plausible reasons behind the increase in J_{sc} of the MS100 device. Moreover, we observe a minimal increase in the V_{oc} of the MS100 device and a decrease in the V_{oc} of CuPc:C$_{60}$ (1:1) homogeneously mixed device as compared with the standard device. It seems that the MS100 structure takes the advantages of both a bilayer heterojunction cell (limited by exciton dissociation) and a homogeneously mixed cell (limited by carrier transport).

To understand the effect of concentration gradients of donor and acceptor on the device performance, we prepared a series of four MS devices similar to the MS100 device with different sizes of concentration gradients, where CuPc concentration gradually decreased from 100%, 86%, 73%, and 67% in the first step to 0, 14%, 27%, and 33% in the last step, respectively, as indicated in Fig. 2b (MS100/86/73/67, respectively). Thus, according to the sizes of concentration gradients: MS100 > MS86 > MS73 > MS67 > 1:1 mixed layer. Fig. 3 shows the current density–voltage (J–V) characteristics as a function of the sizes of concentration gradients. Interestingly, V_{oc} increases as the gradient increases, despite the fact that the electrodes and photoactive materials of these devices are the same. Although there are no direct experimental data that could explain such result, the features of exciton solar cells proposed
Fig. 3. J–V curves of the devices with the photoactive layers in Fig. 2b under 100 mW/cm^2 AM1.5G illumination. Inset: V_{oc} vs. J_{sc} as a function of the sizes of concentration gradients.

by Gregg [6] are adopted. Generally speaking, the V_{oc} of a solar cell is a function of both the built-in electrical potential energy differences ($\emptyset_{bi}$) and the photoinduced chemical potential energy differences ($\nabla\mu_{hv}$) across the cell [6]. According to the expression for the chemical potential energy gradient $\nabla\mu_{hv} = kT/n(x)\nabla n(x)$, where $n(x)$ is the concentration of charge carriers, and k and T are Boltzmann's constant and absolute temperature, respectively, the MS device may introduce an extra $\nabla\mu_{hv}$ because the concentration gradient of donor and acceptor may form a decreasing gradient of "excitons queue" from the center of the photoactive layer to each side. Moreover, the higher concentration gradient of charge carriers (proportional to $\nabla\mu_{hv}$) may produce a higher value of $\nabla\mu_{hv}$, which could enhance the V_{oc} as well. Therefore, the increase in V_{oc} can be attributed to the increase in $\nabla\mu_{hv}$.

Introducing a concentration gradient will also contribute to the improved photogenerated charge carrier transport and a higher gradient may result in a higher J_{sc} [22–24] because $\emptyset_{bi}$ and $\nabla\mu_{hv}$ are equivalent forces that drive the current flow of all electronic devices [6]. On the other hand, as shown in Fig. 2b, when the concentration gradient is higher, the apparent effective CS interfacial area seems smaller, which may lead to fewer photogenerated charges and hence a lower J_{sc}. Based on these two factors, the J_{sc} displays a different trend from V_{oc} as shown in Fig. 3. At the extreme case with zero gradient, as the CuPc:C$_{60}$ (1:1) homogeneously mixed device, the V_{oc} and the J_{sc} are both the lowest. As the gradient is increased, probably owing to the more favorable effect of improved photogenerated charge carrier transport, the J_{sc} increases at MS67, and then peaks at MS73. A further increase of the gradient leads to a fall in current, probably due to the smaller CS interfacial area and fewer photogenerated charges. However, the FF follows a similar trend to the V_{oc}. This may result from the reduced resistances across the devices, consistent with improved charge transport due to the increased gradients. Consequently, the MS100 device exhibits the best performance, with η_p = 2.15% at 1 sun.

According to the expression for the $\nabla\mu_{hv}$, when the temperature, pressure, and the concentration of charge carriers are identified, the chemical potential has the only determined value [6]. In the present devices, although the MS100 structure induced a larger $\nabla\mu_{hv}$, the V_{oc} is still a severe limitation probably due to a smaller $\emptyset_{bi}$ at the CuPc/C$_{60}$ interface. We note that the highest occupied molecular orbital (HOMO) level of H$_2$Pc (5.24 eV) [25] is slightly larger than that of CuPc (5.05 eV) [26]. If CuPc was replaced with H$_2$Pc, which may exhibit a similar $\nabla\mu_{hv}$ due to the similar concentration gradient of charge carriers in the device but a larger $\emptyset_{bi}$ due to the larger HOMO, the V_{oc} is expected to enhance in addition to J_{sc}. Indeed, by using H$_2$Pc, we observe an increase in the V_{oc} from 0.52 to 0.54 V as well as the enhancement of J_{sc} (9.98 mA/cm^2). Compared with the standard H$_2$Pc/C$_{60}$ bilayer device, both J_{sc} and V_{oc} have been improved simultaneously and the resulting η_p reaches 2.42%. Our results give further space for changing the $\nabla\mu_{hv}$ or $\emptyset_{bi}$ to improve the efficiency of the MS100 structure.

In sum, we have produced an MS device by dynamic alteration of the relative deposition rates of CuPc and C$_{60}$.

Its V_{oc} still maintains a high value even though its J_{sc} is more than twice that of the conventional bilayer device. The multidirectional experiments conducted in this study indicate that the improved photovoltaic performance is possibly due to a high $\nabla\mu_{hv}$ produced by the concentration gradient of donor and acceptor in addition to a large CS interface in the photoactive layer. Finally, the η_p has been increased from 1.19% of the simple CuPc/C$_{60}$ bilayer device to 2.15% of the MS100 device with the largest gradient. By replacing CuPc with H$_2$Pc, which can produce a larger $\emptyset_{bi}$ when interacted with C$_{60}$, both J_{sc} and V_{oc} have been improved simultaneously and the η_p reaches 2.42%. These results highlight the potential of a co-deposition technique and well-defined structures, wherein through the careful design of co-deposition methods, solar cells improvement based on small molecules could be further achieved.

surrounding the channel width effect has been carried out in field effect transistors based on metal oxide silicon [10], poly-crystalline silicon [11], or hydrogenated amorphous silicon [12] and thus the channel width effects on the OTFT's performance are not well known at the present time.

This work focuses on the three issues as follows: (1) thin film study of 6,13-bis(triisopropyl-silylethynyl)-pentacene (TIPS-pentacene) with semiconducting polymer binder (poly-triarylamine, PTAA) in order to impose a function as forming a good interfacial contact between the organic semiconductor (OSC) and the source/drain electrodes; (2) employing two kinds of metals, one with a low work function (Ag) and the other with a high work function (Au), in order to compare the function of metallurgy for low cost devices; and (3) a structural study of the channel dimension in order to optimize the device parameters effectively and to obtain good performance of the device characteristics.

2. Experimental

Fig. 1c shows a schematic diagram of the OTFT structure where an insulator layer of silicon dioxide (SiO_2) is thermally grown on top of a heavy doped p-type Si wafer to act as the gate contact. A highly doped p-type Si wafer was used both as a substrate and as a gate electrode for the bottom-contact structure. Initially, the gate insulator, for most of the devices, was thermally grown to a thickness of 100 nm. Sequentially, a 200 nm-thick source-drain Au and Ag contacts were fabricated on top of the insulator by a thermal evaporation method (DOV Co., Ltd) to give the channel widths in the range of 500–2500 μm, and the channel length of 100 μm using a shadow mask. Particularly, the source-drain interdigitatd finger (SDIF) type electrode were employed in our device configuration since this SDIF pattern permits the use of printing and other techniques for fabricating display backplanes that are not capable of attaining the fine resolution limits of standard silicon processing using photolithography. Next, the TIPS-pentacene mixed with PTAA were deposited by a drop casting from a 2 wt% solution of TIPS-pentacene in monochlorobenzene. Fig. 1a and b exhibit the molecular structures of TIPS-pentacene and PTAA, respectively. In our sample, PTAA was employed as a dopant and TIPS-pentacene was used as a host material. Also, in order to improve device performance, polymer binder, PTAA was employed to fabricate OTFT device with organic soluble TIPS-pentacene for decreasing the injection barrier from the metal electrode to the OSC and used as a hole conductor between the OSC and source-drain contacts for reducing the surface dipoles [13]. Here, TIPS-pentacene was synthesized following the procedure reported by our previous study [14]. PTAA was synthesized by following the literature method and a modified method [15–18]. All reactions were performed under an argon atmosphere unless otherwise stated. Finally, after coating the OSC, the device was annealed using a hotplate at 110 °C for 1 min.

The optical absorption spectra of the host-guest (TIPS-pentacene-PTAA) system film was obtained uisng UV spectrometry (Ultraviolet–visible, UV–vis, HP 8453, PDA, type λ = 190–1100 nm). The surface morphology of the OSC lay-
Fig. 1. The molecular structure of (a) TIPS-pentacene, (b) PTAA and (c) the schematic geometry of the OTFT on heavy doped silicon wafer with SDIF bottom contacts varying the *W/L* ratio from 25 down to 5 (channel length: 100 μm).

ers was observed using an AFM (XE-100 system). The transistor characteristics were measured using a Keithley SCS/4200 in a dark box.

3. Result and discussion

Fig. 2a shows the optical absorption spectra of the host-guest (TIPS-pentacene-PTAA) system film. Each spin-coated thin film (1 wt% solution) was formed by using the monochlorobenzene solvent. OSC films with 1:1 or 10:1 weight ratio mixture of TIPS-pentacene and PTAA were measured individually before and after the annealing process, as shown in Fig. 2a. The spectrum of TIPS-penta-

cene shows the crystalline properties, confirmed by the baseline floating phenomenon. When preparing the thin film without polymer binder, the quality of the surface of OSC was not well defined. Whereas, after mixing PTAA with a proper concentration, we could obtain much better film forming property. Therefore, the OSC was prepared with TIPS-pentacene and PTAA for improving film forming properties in a large area using the host-guest system, which produces a better film condition than the OSC without the polymer binder. Additionally, as it can be observed from the spectrum of Fig. 2a, the crystalline properties of the OSC film with 1:1 (TIPS-pentacene:PTAA) is not relatively lower than that with 1:10 (TIPS-pentacene:PTAA).
Fig. 2. (a) UV–vis spectra of thin films of spin-coated TIPS-pentacene (black), PTAA (red), OSC (TIPS-pentacene: PTAA = 1:1) film before annealing (blue), OSC (TIPS-pentacene: PTAA = 1:1) film after annealing (dark cyan), OSC (TIPS-pentacene: PTAA = 10:1) film before annealing (magenta), and OSC (TIPS-pentacene: PTAA = 10:1) film after annealing (dark yellow), individually. AFM images of OSC films for 1:1 (b) and 10:1 (c) weight ratio mixture of TIPS-pentacene and PTAA, respectively, after annealing. Scan size: 5 μm × 5 μm. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 2b and c shows AFM (atomic force microscope) images of the OSC films for 1:1 and 10:1 weight ratio mixtures of TIPS-pentacene and PTAA after annealing, respectively. Bright areas in the images indicate higher values of the film thickness. Fig. 2b is a topographic image of the OSC film with 1:1 (TIPS-pentacene: PTAA) that shows discontinuous ∼1 μm-TIPS-pentacene clusters, while Fig. 2c is the OSC film with 10:1 (TIPS-pentacene: PTAA) that shows continuous OSC film with regularly formed 20–30 nm-TIPS-pentacene clusters. It was clearly seen that the surface film showed straight line without any preferential orientation (dotted arrow in inset of Fig. 2c). Although good film has been obtained using the polymer binder, as shown in Fig. 2a, the TIPS-pentacene cluster can be a cause of poor carrier field effect mobility due to interference with the flowing carriers in the active channel. Therefore, the OSC (i.e., 10:1 weight ratio mixture of the TIPS-pentacene

and PTAA) film, formed by drop casting a 2 wt% solution in monochlorobenzene, was prepared. As smaller concentration of polymer binder is used, the preferential orientation of TIPS-pentacene molecules is sustained on the surface of the blend film.

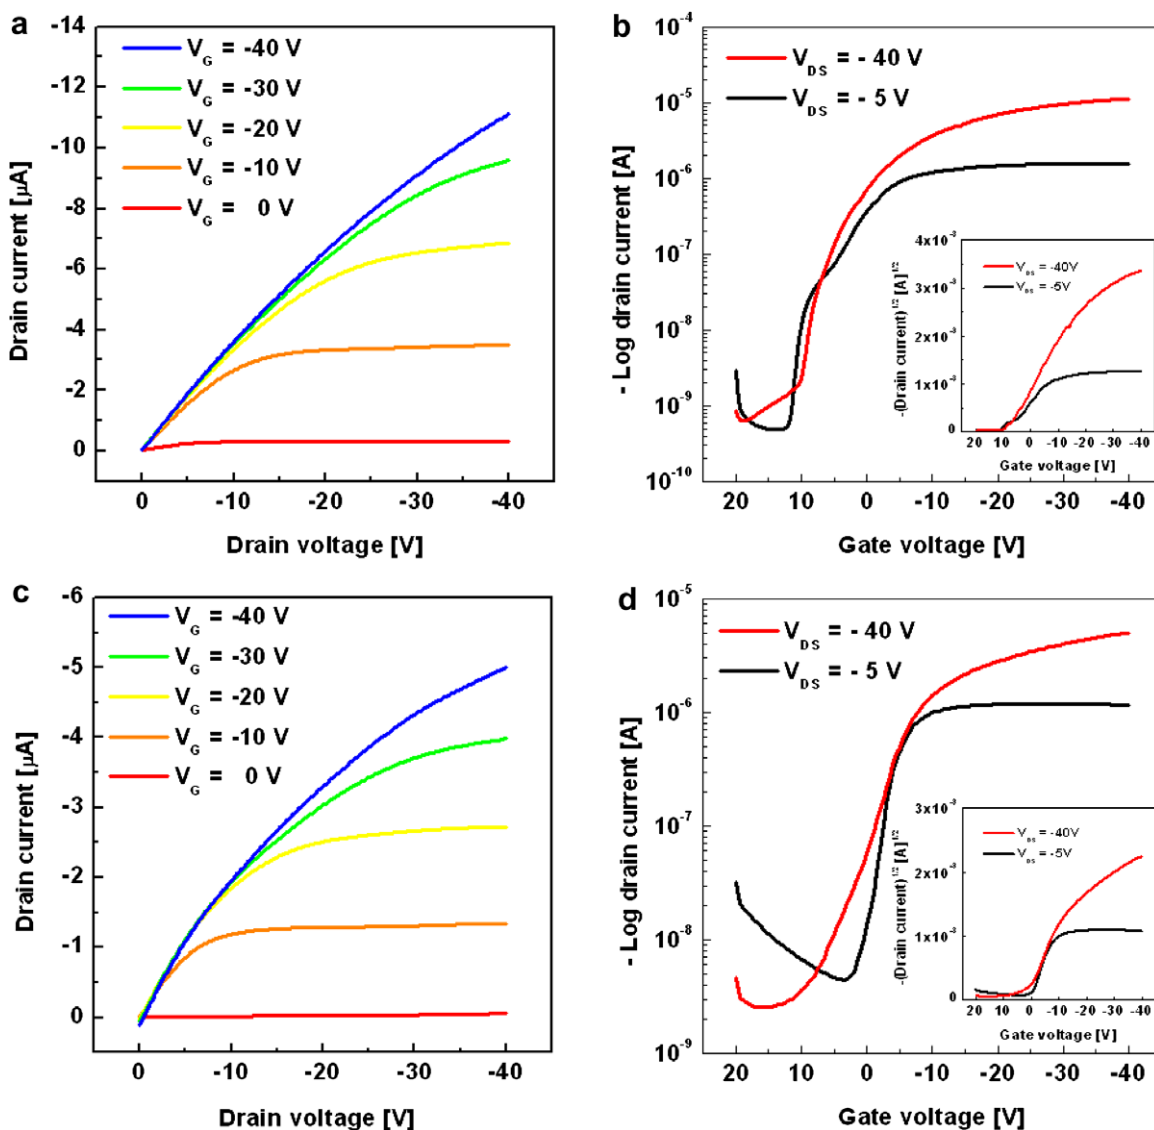
Fig. 3a and c shows the output characteristics of OTFTs with $L = 100$ μm and $W = 2500$ μm. The gate voltage (V_G) was increased in a stepwise manner from 0 V to −40 V for OTFTs with different electrodes of Au and Ag, respectively. Obviously, the output confirms typical characteristics of p-type OTFTs working in an accumulation mode. Fig. 3a and c shows that the drain-source current (I_{DS}) also saturates at an increasingly higher drain-source voltage (V_{DS}) with increasing V_G. However, the data in Fig. 3a and c shows that the linear and saturation regimes for each curve cannot be clearly distinguished, especially at high values of the gate bias, V_G, and when there is a lack of sat-


Fig. 3. Output characteristics I_{DS} vs. V_{DS} for OTFTs with different electrodes of Au (a) and Ag (c). Transfer characteristics $-\log(I_{DS})$ vs. V_G and $-\sqrt{I_{DS}}$ vs. V_G (inset) measured for an OTFT ($W/L = 2500$ μm/100 μm) with Au contact (b) and Ag contact (d), respectively.

uration in I_{DS}. We believe this phenomenon, similar to the 'punch-through effect' [19] for the metal-oxide-semiconductor field effect transistor (MOSFET), which is caused by space charge limiting current [20], is preventing saturation.

Fig. 3b and d shows graphs of $-log(I_{DS})$ against V_G with their insets, $-\sqrt{I_{DS}}$ vs. V_G, for Au and Ag contacts, respectively. For each device, the carrier field effect mobility and the threshold voltage (V_T) were extracted in the linear ($V_{DS} = -5$ V) and saturation ($V_{DS} = -40$ V) regimes at a V_G of -40 V, where the results are shown in Fig. 4. Additionally, OTFTs with a channel length of 100 μm and a channel width range from 500 to 2500 μm were fabricated for different electrodes. However, all devices, regardless of their channel widths, exhibited a current on/off ratio between 10^4 and 10^5 for Au contacts, and between 10^3 and 10^4 for Ag contacts.

The data in Fig. 4 represent average values of device parameters such as field effect mobility and V_T when using Au and Ag electrodes. Here, we measured at least four devices to average the parameters for these plots.

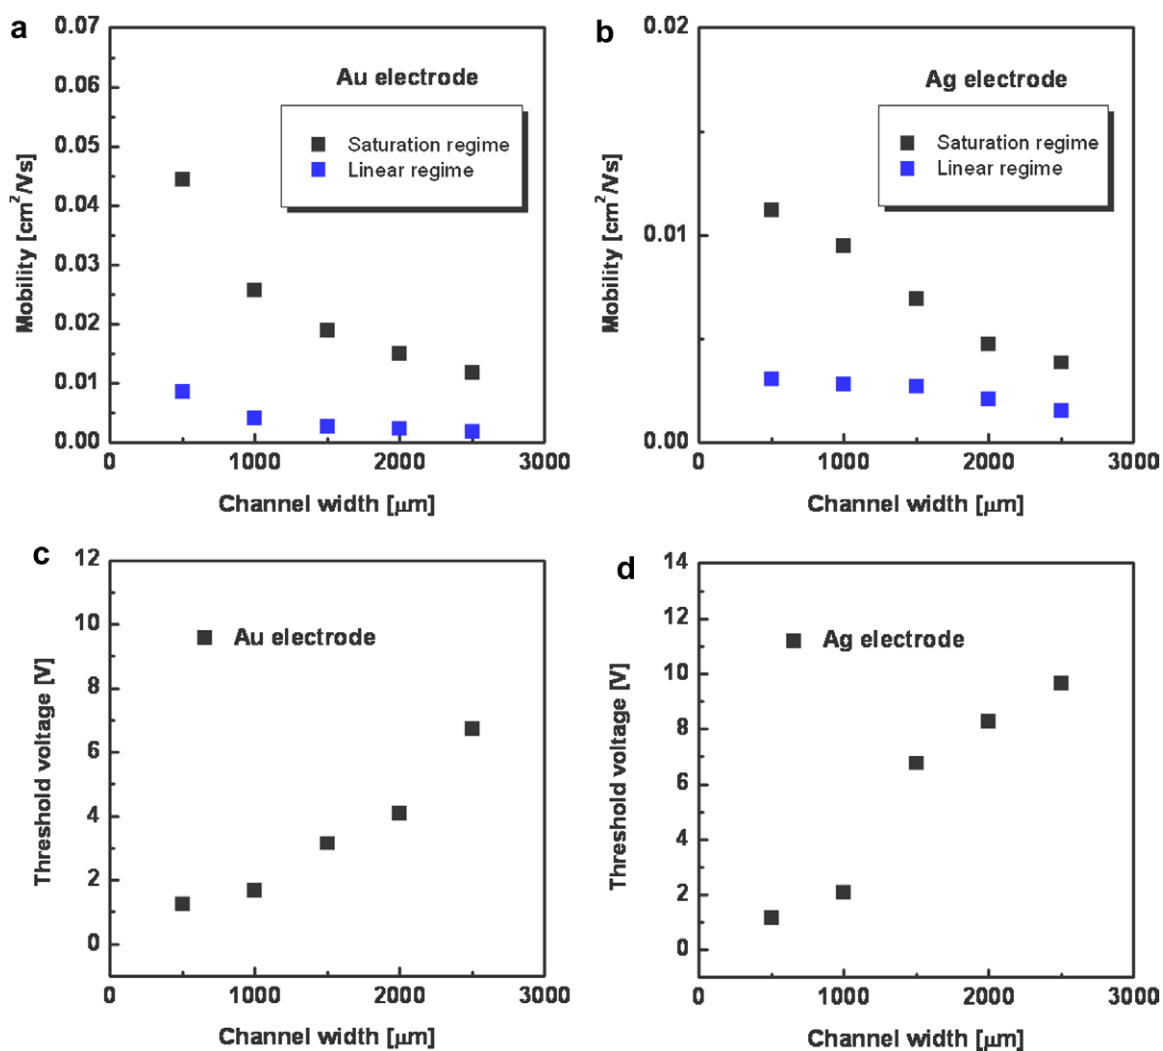
In order to explore the effects of different source-drain electrodes on the performance of OTFTs, two kinds of electrodes having different work-functions were employed. Fig. 4 shows the transistor parameters of devices with Au and Ag electrode materials as source-drain contacts. It also shows the variation of carrier mobility and V_T as functions of the channel width W for devices with constant channel length $L = 100$ μm. The decreasing behaviors of carrier mobilities in both saturation and linear regimes with increase in channel width are observed from Fig. 4a and b, where the saturation mobility depended much more on the channel width than the linear mobility. Moreover, with increasing the channel width from 500 μm to 2500 μm, V_T is increased, as shown in Fig. 4c and d. These results, variation of carrier mobility and V_T as function of channel width, are in good agreement with previously reported work using inorganic TFT [11,12].


Fig. 4. Carrier field effect mobilities of Au contact (a) and Ag contact (b), and threshold voltage of Au contact (c) and Ag contact (d), extracted from the transfer characteristics. The channel widths range from 500 to 2500 μm; the channel length is 100 μm in all cases. The carrier mobilities were extracted at a V_G of -5 V and -40 V, respectively.

The field effect mobility increases with decreasing channel width, while V_T increases with increasing channel width in the saturation ($V_{DS} = -40$ V) and linear ($V_{DS} = -5$ V) regimes. Here, the I_{DS} of the devices increases with increasing channel width [10] since the transistor channel width to length ratio, which means larger I_{DS}, is proportional to the larger channel width. Although I_{DS} increases with increasing channel width [21], saturation and linear mobility reduce with increasing channel width since V_T increases. This, in turn, results not only in a significant increase in V_T but also in its pronounced channel width dependency.

4. Conclusion

In summary, in order to enhance device performance, TIPS-pentacene was employed as a host materials and a small amount of PTAA was used as a guest material. The host–guest system gave improved and uniform film formation in a large area, and helped the TIPS-pentacene to form a stronger binding between the source/drain electrodes onto the dielectric layer. Additionally, the devices were fabricated using different electrodes such as Au and Ag. Maximum saturation mobilities of 5.44×10^{-2} and 1.33×10^{-2} cm^2/Vs for OTFTs were obtained using Au and Ag contacts, respectively. From these results, it can be predicted that Ag-based devices would be expected to provide dramatic reductions in cost and to significantly improve the device performance upon full optimization. Finally, experimental observations showed that the field effect mobility depends on V_T. Although the field effect mobility values should increase as I_{DS} is proportionally increased, by increasing channel width, decrease in mobility were observed since V_T also increased.

poorer electrical/thermal stability [14] compared to metals. Metal nanoparticle (NP) based inks are more often used to demonstrate solution-based, highly conductive pathways and contacts, generally obtained by sintering via annealing at relatively low temperatures [15,16], or else by laser [17] or microwave [18] treatment. These conductive metals have for example been used in the production of thin-film transistors (TFTs), where they serve as source and drain electrodes [19]. Their deposition on top of organic semiconductors, however, is challenging because organic materials are damaged either by the temperatures required for sintering the NPs or by the solvent dissolving the underlying layer. Most of the research has thus focused on the production of bottom-contact devices, where ink-jet printing has been used to pattern lines on the substrates, either glass, silicon or plastic foils. In this way, the constraints on the process are not severe, since the sintering temperature and solvent choice are only limited by the substrate.

The deposition of metal NPs on top of organic semiconductors requires, then, to overcome these two limitations. Recently, Sekitani et al. produced top contact TFTs with a silver solution deposited directly onto the surface of organic semiconductor films using a subfemtoliter ink-jet printer [20]. Noguchi et al. showed that it is important to deposit small volumes of a silver ink on top of the organic material in order to limit the degradation of the transistor performance caused by a large amount of solvent [21]. Their work shows that reducing the volume of each droplet makes it possible to manufacture TFTs with characteristics comparable to those with vacuum evaporated top contacts. Nevertheless, this deposition method is not easily applicable to organic solar cells, where the need for a fast deposition technique able to cover large area contacts is contradictory to the precise deposition of well aligned, micron-scale droplets. An attempt to produce solar cells with an inkjet printed silver top contact can be found in the work by Eom et al., albeit for devices with a limited performance [22]. In this work, we spray coat a Ag NP film followed by sintering at low temperatures to achieve a solution processed and patterned metal contact deposited directly on top of the organic device, yielding solar cells with efficiencies very close to those with evaporated top contacts [23].

Spray coating is a well established technique in graphic arts, industrial coatings, and painting. In spray coating systems, the ink is atomized at the nozzle by pressure or ultrasounds and then directed toward the substrate by a gas flow. A random distribution of tiny droplets then land on the surface producing either a full wet layer, in the case of large flow rates, or depositions characterized by sparse arrangements of dots that dry independently, in the case of reduced flow rates [11]. The key advantage of the technique is the ability to cover relatively large areas by the superposition of femtoliter-size droplets, characterized by a fast drying time on the order of μs [24,25]. As a consequence, the impact of the solvent on the underlying layer is reduced as compared to other solution based deposition techniques, considering that subsequent droplets are deposited on top of dried droplets rather than directly on the underlying layer.

In this study, we deposited a silver nanoparticle ink (25 wt% silver ($\varnothing$ = 5 nm) in cyclohexane, NanoMas Technologies, Inc.) using a commercially available airbrush (Badger 200 NH) powered by N_2 gas to spray a 0.5 cm wide pattern of droplets characterized by volume on the order of femtoliters, as deduced from a statistical analysis performed on sparse depositions. Standard settings included gas pressure of 20 psi and an airbrush-substrate distance of approximately 10 cm. We achieved a uniform coverage of the complete sample by moving the airbrush across the substrate (1.25 cm × 1.25 cm) and patterned the deposition by simple shadow masking.

In order to define the optimal temperature and time conditions to obtain highly conductive contacts, we first investigated the behavior of the material on glass substrates. With the airbrush, we sprayed a 200–400 nm thick film on pre-cleaned samples (acetone and isopropanol, 10 min each in ultrasonic bath) between two indium-tin oxide (ITO) stripes, the latter to provide an easy contact for probes. We first probed and connected the structure to a parameter analyzer (Agilent 4156C) and only then put the samples in contact with a pre-heated hot plate at a fixed temperature. The resistance of the silver pads was then recorded versus time for a period of 10 min. We corrected the curve to the final resistivity (ρ) of each sample, calculated via $\rho = R_\square \cdot d$, where $R_\square$ is the sheet resistance, evaluated at room temperature with a four probe station (FPP 5000 Veeco Instruments Inc.), and d is the average thickness of the deposition (Dektak V 200-Si profilometer). This was done to eliminate the geometry and temperature dependence of the resistance measurements. The results are plotted in Fig. 1 for a range of temperatures between 100 °C and 180 °C along with the resistivity of 100 nm ITO and 100 nm evaporated Ag.

The resistivity of the films dropped rapidly to 10^2 μΩ cm, by several orders of magnitude, after a critical annealing time, which depends on the annealing temperature. An annealing time of the order of a few seconds is sufficient for annealing temperatures above 150 °C. The resistivity of the layer typically saturates at values around 40–100 μΩ cm. Interestingly, these values are close to those obtained with the evaporated Ag layer (24 μΩ cm): the higher final resistivity of the sprayed depositions could be explained by their roughness, with peak-to-valley
Fig. 1. Resistivity (ρ) of Ag nanoparticles during sintering recorded versus time, *t*. Measured values of ρ for ITO and vacuum evaporated Ag are reported as reference.

values in the order of a few tens of nanometers, and the presence of voids inside the layer. The calculation of resistivity was performed on the average thickness for these samples, while the minimum thickness greatly impacts the electrical performance of the layer.

The curves in Fig. 1 show a two step profile, revealing a two phase characteristic of the sintering process [19]. In order to understand this, we should recall that the NP solution is composed of Ag NPs capped by a functional group that prevents their aggregation and allows them to be dispersed in the solvent. After the deposition, the solvent evaporates leaving an agglomerate of NPs still capped by the functional group, which insulate them from each other. The resistivity of the layer at this stage is extremely large (10^6–10^8 μΩ cm). The first step of the thermal treatment thus removes the thin capping layer and allows for direct contact between NPs, creating conductive percolating paths: curves show a sudden change in the resistivity at this point when the layers also become reflective. However, the conduction is still restrained by the limited contact between the NPs. The second step is then the effective sintering process, where the Ag NPs coalesce together into larger aggregates, resulting in a highly conductive film [19,26]. The process is activated at temperatures as low as 100 °C indicating a high surface energy of the NPs owing to their small size [27]. From this analysis we can deduce that the two fundamental characteristics of an ink suitable for a top contact are the presence of functional groups that evaporate or decompose at low temperatures (<150 °C) and an average size of the NPs limited to values in the nanometer range (<10 nm). From scanning electron microscopy (SEM, Fig. 2) imaging of the top surface, performed on the samples treated at 100 °C, 140 °C and 180 °C, it is clear that the increase of the sintering temperature is concomitant with an increase of agglomerate size.

Fig. 3 plots the annealing time for the layer to reach a threshold resistivity of ρ_t = 1 mΩ cm as well as the final resistivity ρ after the 10 min sintering treatment, both versus the applied temperature. The temperature dependence of the time to reach the threshold ρ_t follows a simple Arrhenius relation, as expected from a thermally-induced process. The data points can be fitted with an exponential law, represented by the equation:

$$t = t_i + t_0 \cdot e^{-E_a/kT_s} \tag{1}$$

where k is Boltzmanns constant and T_s is the sintering temperature. The initial delay t_i = 3.0 s, calculated from

$$\frac{\partial^2 T}{\partial x^2} = \frac{\rho c}{k} \frac{\partial T}{\partial t} \tag{2}$$
Fig. 3. Time, t, to reach a threshold resistivity, ρ_t, of 1 mΩ cm and ρ of the samples at 10 min sintering versus the applied temperature. The red curve shows the exponential fit using Eq. (1). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

has been introduced to consider the time needed to heat the top surface of the glass substrate (thickness = 0.7 mm) to 95% of the final temperature. The activation energy E_a required by the NPs can be calculated from Eq. (1) as 0.211 eV. The time needed to reach the threshold ρ_t is almost halved for every 10 °C increment of the applied temperature, resulting in a drop from 254 s at 100 °C to less than 6 s at 180 °C. The final ρ after the 10 min treatment shows that temperatures as low as 100 °C are sufficient to achieve conductive contacts. Nevertheless, the resistivity of the films treated with temperatures below 120 °C is higher than that of ITO and thus not favorable as a top contact. The resistivity plot shows a minimum at 150 °C: at higher temperatures the NPs sinter into domains that become large enough that voids are introduced between neighboring domains (cf. Fig. 2c), thus limiting the conductivity.

At 150 °C the film resistance reaches saturation after 120 s, an interval that is shorter than the typical annealing conditions for organic solar cells based on poly(3-hexyl thiophene) (P3HT) and (6,6)-phenyl C61-butyric acid methyl ester (PCBM) mixture. Post annealing treatments are often performed at temperatures in the range of 130–150 °C for time intervals in the range of 5–10 min. Since our standard post-production annealing conditions for P3HT:PCBM organic solar cells consist of 300 s at 150 °C, our process already satisfies the requirement for the sintering of the top contact, without the need to introduce further thermal treatments.

Silver is characterized by a work function of −4.3 eV that shifts towards −5.0 eV for silver oxide [28]. This shift

Fig. 2. Scanning electron micrographs of Ag nanoparticle layers annealed at (a) 100 °C, (b) 140 °C and (c) 180 °C show that the increase of the sintering temperature is concomitant with an increase of agglomerate size. The white scale bars represent 100 nm.

should be taken into account when employing NPs, since their large surface-to-volume ratio renders them extremely sensitive to oxidation. The work function makes Ag more suitable as a hole collecting rather than as an electron collecting contact. The ideal structure in order to use Ag as a top contact is therefore a reverse structure, as demonstrated by White et al. [28]. Among the different reverse structures suggested [28–31], the one comprising a thin zinc oxide (ZnO) NP film between ITO and the active layer as a cathode is attractive because it can be processed from solution [28,32]. On top of the active layer, a thin film of PEDOT:PSS is usually spin coated [29,30,33,32], producing at the same time a hole-selective interlayer, a protection for the active layer and a smooth surface for a silver top contact. Since the HOMO level of PEDOT:PSS is positioned at −5.1 eV from the vacuum level, it is clear that an oxidization of silver during the deposition is not detrimental to the functioning of the contact, but rather improves the ohmic contact between the two materials.

Devices have been produced according to the steps previously introduced in an all-solution process on top of patterned ITO-glass samples (Merck Display Technologies, ITO thickness 100 nm, sheet resistance <20 $\Omega/\square$).

Samples were first cleaned by detergent, de-ionized water, acetone and isopropyl alcohol in an ultrasonic bath. A dispersion of ZnO NPs in acetone was spin coated in air on the samples to produce a 55 nm thick layer. After a 10 min annealing step on a hot plate at 150 °C, samples were brought in a nitrogen glovebox for the deposition of the active layer. A solution of P3HT (Rieke Metals) and PCBM (Solenne) dissolved in ortho-dichlorobenzene (oDCB) in a 1:1 ratio with a concentration of 30 mg/ml was prepared and stirred for 24 h at 50 °C. Spin coating was performed at 1000 rpm for 60 s (resulting thickness: 250 nm) and then samples were allowed to dry under a petri-dish, according to the "slow drying" method [34,35]. The hydrophobic surface of the P3HT:PCBM layer was rendered hydrophilic with a short oxygen-plasma treatment (6 s; oxygen pressure: 0.26 Torr; power: 100 W). The PEDOT:PSS (H.C. Starck, Baytron P VPAI4083) layer was spin coated in air at 3000 rpm for 60 s, to produce a 46 nm thick layer. Samples were then transferred again in a N₂ glovebox, where a thermal treatment to

remove the excess water was performed at 120 °C for 10 min. Samples were then fixed on a sample holder and covered with a shadow mask. With the previously mentioned settings the top contact was sprayed, resulting in 8 devices per sample with an active area of 3 mm². Samples were then finalized with the sintering step (150 °C for 5 min).

Fig. 4 shows the layer structure and the thicknesses of each layer, together with two cross sections of the device performed with SEM and transmission electron microscopy (TEM), the latter on a sample prepared by focused ion beam (FIB) lift-out technique. A CVD glass layer and a sputtered Au layer are deposited on the area of interest in order to protect the specimen during the FIB wedge milling. The TEM analyses are performed with a FEI Tecnai (F30) FEG transmission microscope operating at 200 kV. From the SEM scan we can observe once more that the top Ag NP contact is not a fully sintered bulk Ag film, but is characterized by a merging of NPs into domains which allow a much higher conductivity compared to non treated NPs. Similar conclusions can be made for the ZnO layer in that it is also an agglomerate of NPs rather than a uniform, continuous layer. Concerning the solvent damage, the TEM scan shows that the spray deposition of cyclohexane does not dissolve the PEDOT:PSS layer and that the interface between PEDOT:PSS and the active material is clearly preserved. The TEM scan reveals the presence of voids between the PEDOT:PSS layer and the Ag NPs, indicated by arrows, reducing the electrical contact between the two layers. Moreover, single particles or clusters are found in the PEDOT:PSS layer, highlighted by the circle, confirming the role of PEDOT:PSS as buffer layer that prevents the diffusion of Ag to the active layer, where it would act as quenching center for charge carriers as well as excitons.

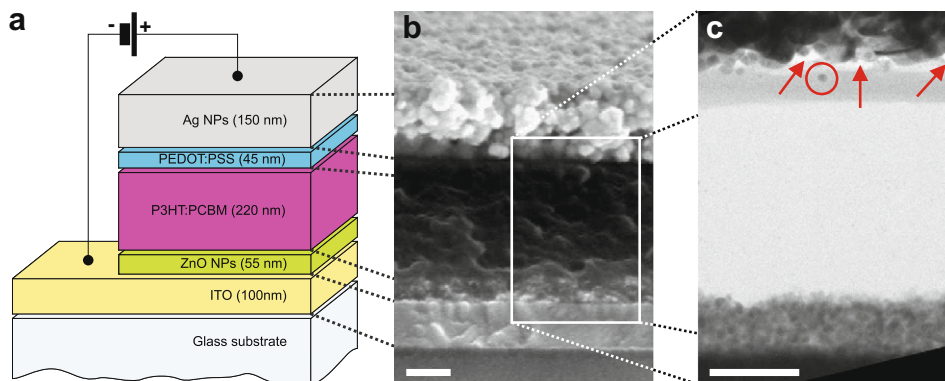
The photovoltaic characteristics were measured in a N₂ atmosphere using an Agilent 4156C parameter analyzer and under 100 mW/cm² AM1.5 simulated illumination using a LOT-Oriel Group Europe solar simulator with a 1000 W Xenon arc lamp fitted with AM 1.5D filters. Calibration was performed by a KG3 band pass filter and a calibrated Si photodetector. The current density vs. voltage (J–V) curves of the produced solar cells are


Fig. 4. (a) Structure, (b) SEM and (c) FIB/TEM cross sections of the inverted polymer solar cell with a spray coated Ag top contact. The white scale bars represent 100 nm. The arrows indicate voids between PEDOT:PSS and the Ag NPs, while the circle highlights a NP embedded within the PEDOT:PSS layer.
Fig. 5. The current density-voltage characteristics of solar cells produced with either an evaporated (red) or spray-coated (black) Ag top contact in the dark (dashed curves) or under 100 mW/cm^2 AM1.5 simulated illumination (solid curves). The inset graph shows a semi-log plot of the same devices in dark. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

reported in Fig. 5. The red curve represents an evaporated Ag top contact reference device, while the black line is the sample with the solution processed Ag top contact. The reference device shows performances in line with the values reported in literature [28,32]. The solution processed Ag top contact cell is characterized by a slightly higher series resistance as indicated by lower current values at biases >0.7 V.

The higher series resistance affects the fill factor (*FF*), reduced from 53% (evaporated) to 48% (solution processed). This could be due to the voids at the interface between the Ag layer and PEDOT:PSS observed with FIB/TEM (*cf.* Fig. 4c), which may increase the contact resistance between the two layers. A high short circuit current (J_{SC}) is extracted from the contacts (9 mA/cm^2 for the evaporated and 8.3 mA/cm^2 for the solution processed), and the open circuit voltage (V_{OC}) reaches values as high as 620 mV. The attained final power conversion efficiency (*PCE*) of the cell with solution processed Ag is 2.5%, close to that of the reference cell with evaporated Ag (2.9%), showing that this solution processed top contact is well suited for the production of organic solar cells.

In conclusion, a Ag NP based ink was sprayed on a thin PEDOT:PSS layer deposited on top of the active layer of a P3HT:PCBM film in a reverse structure, in which a sintered layer of solution-processed ZnO acts as cathode and a solution-processed bi-layer of PEDOT:PSS and sintered Ag NPs acts as anode. The whole process was performed at room pressure from solutions and with temperatures below 150 °C and, apart from the ITO patterning, did not require any lithographic step. The devices showed efficiency similar to control devices produced with the same structure and an evaporated Ag top contact. Spray coating, the deposition technique used in this work, offers the ability to cover relatively large areas by the superposition of femtoliter-size droplets, reducing the impact of the solvent on the underlying layer as compared to other solution based deposition techniques. Moreover, this technique is easily scalable to large areas by proper choice of the atomizing pattern or by coupling several nozzles in arrays, making it possible to scale this method to a high-through-

put roll-to-roll deposition, virtually without limits in the achievable area.

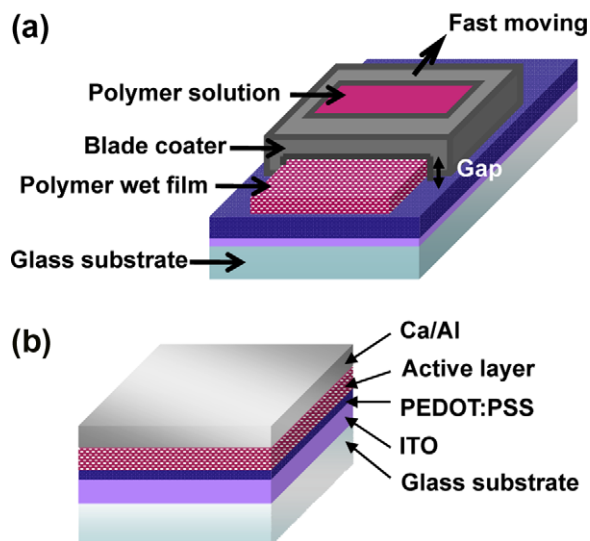

Fig. 1. (a) Schematic working principle of blade coating. The polymer wet film is formed by moving the blade coater. The thickness of polymer wet film is defined by the gap of the blade coater. (b) The schematic device structure of the bulk hetero-junction cells.

structured by printing in organic solar cells, blade coating for large area fabrication has been proved to be the better way [6]. The film thickness by blade coating can be reduced to nanometer scale by carefully controlling the fabrication parameters such as the solution concentration, the blade gap, and the blade coating speed. Recently we verified the feasibility of blade coating for high-efficiency polymer light-emitting diodes [8]. Unlike spin coating, the area can be easily scaled up and the material usage is almost 100% in blade coating. In this work, blade coating is applied to poly(3-hexylthiophene) (P3HT) and (6,6)-phenyl-C61-butyric acid methyl ester (PCBM) blend in the toluene solution which has a lower boiling point (110 °C) and is less toxic. High efficiency is achieved from toluene solution without the slow solvent evaporation process.

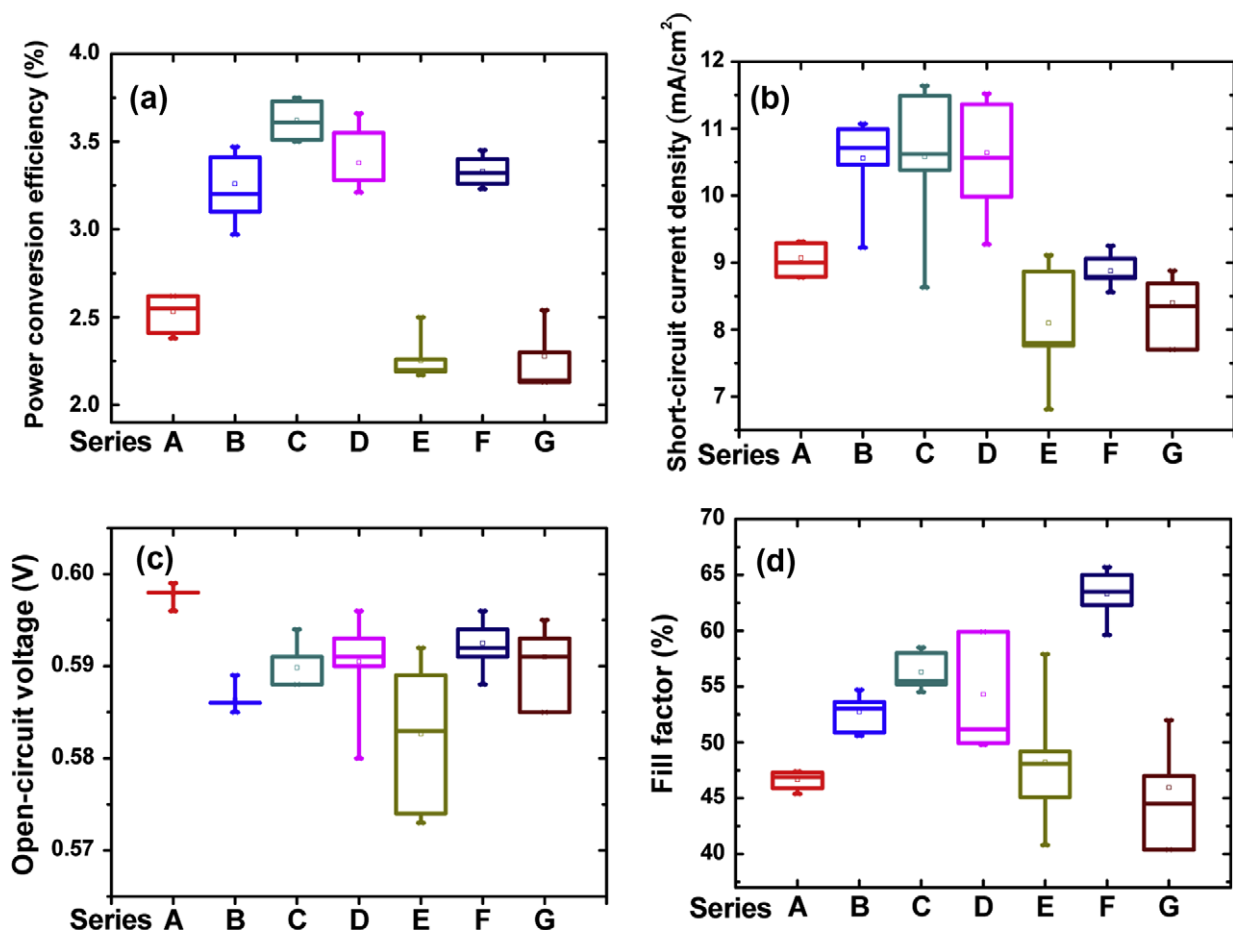
Fig. 1a shows the schematic working principle of blade coating. The thickness of the wet polymer film is defined by the gap. The polymer dry film thickness is tuned by the polymer concentration in solution and the gap of the blade coater. The polymer wet film is deposited by dragging the blade coater at a certain speed about 15 cm/s. We first focus on solar cells with P3HT:PCBM blend dissolved in toluene. Device performances are compared for


Fig. 2. Statistical results of the seven series of devices: (a) the power conversion efficiency, (b) the short-circuit current, (c) the open-circuit voltage and (d) the fill factor. The horizontal lines in the box denote the 25th, 50th, and 75th percentile values. The error bars denote the 5th and 95 percentile values. The open square inside the box denotes the mean value.

different coating methods including spin coating, blade coating, blade coating on a hot plate, as well as blade and spin coating. For the blade and spin coating the polymer wet film is deposited by blade coating which is followed by spinning until the dry film is formed. In all cases the weight ratio of P3HT and PCBM is 1:1. The device structure is ITO/PEDOT:PSS/P3HT:PCBM/Ca/Al shown in Fig. 1b. ITO is indium tin oxide and PEDOT:PSS is poly-(3,4-ethylenedioxythiophene):poly-(styrenesulfonate) (Baytron PVP AI 4083). A 40 nm PEDOT:PSS layer is spin coated on a patterned ITO substrate and baked at 200 °C in nitrogen for 15 min.

Seven series of devices with six devices in each are made to study the different coating processes with different solvents statistically. Among them, five series are made with toluene solution to compare the coating processes, including spin coating (series A), blade coating (series B), blade coating on a hot plate at 60 °C (series C), as well as blade and spin coating (series D). In addition, the devices with the PEDOT:PSS layer by blade coating at 100 °C and P3HT:PCBM by blade and spin coating from toluene solution is made to study the feasibility of bladed PEDOT:PSS layer (series G). The other two series made from two conventional high boiling point solvents, chlorobenzene (series E) and dichlorobenzene (series F), are compared with those from toluene by blade and spin coating. After coating all the P3HT:PCBM layers are annealed at 140 °C for 20 min in nitrogen. The Ca(35 nm)/Al(100 nm) cathode is deposited by thermal evaporation. The active area of the device is 0.04 cm^2. All the devices are packaged in the glove box and measured in the ambient environment. The power conversion efficiency is measured by the solar simulator (PEC-L11, Peccell Technologies) under AM1.5G irradiation. The incident photon-to-electron conversion efficiency (IPCE) is measured by the spectral response measurement system (SR300, Optosolar GMBH). The morphology of P3HT:PCBM is monitored by atomic force microscope (AFM, Dimension 3100, Digital Instruments).

Fig. 2 shows the statistical results of the seven series of devices. Among the series based on toluene solution (series A, B, C, D, and G), the series of devices by blade coating have the higher efficiencies except the series with bladed the PEDOT:PSS layer. Because the open-circuit voltages V_{oc} are about the same, the high performances of series B, C, and D result from the high short-circuit currents J_{sc} and fill factor. Among the series by blade and spin coating (series D, E, and F), the series of devices from toluene solution and dichlorobenzene have the higher performances. While the J_{sc} of series E and series F are about the same, the high performance of series F results from the relatively high fill factor. For further discussion, the best devices in each series are chosen to show the advanced device properties.

Fig. 3a shows the current–voltage (J–V) curves of five devices in toluene solution made by different active layer coating processes. The short-circuit currents J_{sc} made by blade coating (device B, C, and D) are larger than that of the device made by conventional spin coating (device A). Using blade coating the J_{sc} increases from 9.3 mA/cm^2 with spin coating to 11.5 mA/cm^2. The fill factor rises from 47% to 55% and the open-circuit voltage V_{oc} remains the same. The efficiency, which is proportional to J_{sc}, V_{oc}, and fill fac-

tor as a whole, is improved from 2.6% (device A) by spin coating to 3.8% (device C) by blade coating on a hot plate.

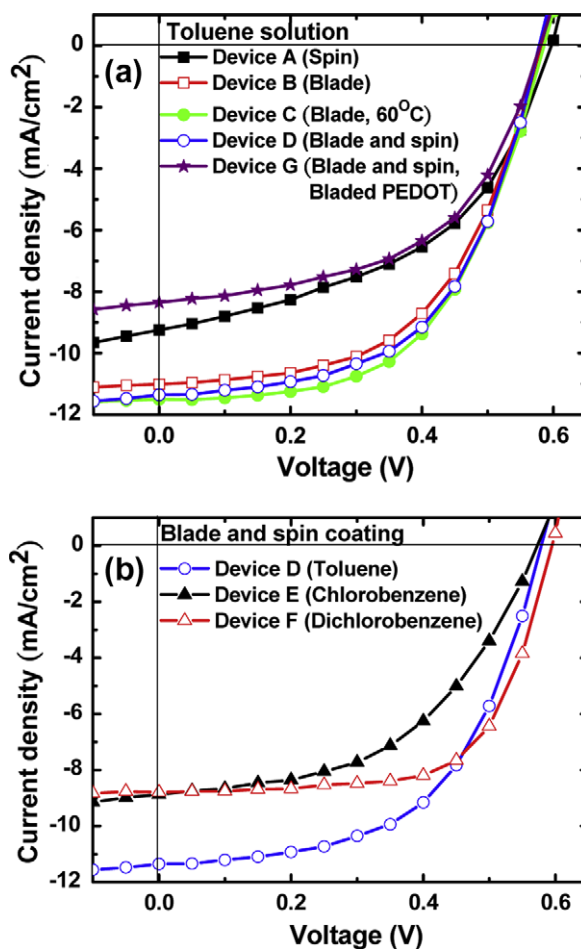
It is believed that in order to get a high efficiency in bulk hetero-junction polymer solar cell the microscopic morphology of the active layer needs to be well controlled to achieve an ordered structure by certain annealing processes such as slow solvent evaporation [1] and postproduction heat treatment [2,9]. Such annealing promotes molecular self-organization and makes the polymer chains more ordered in its domains. In spin coating for low boiling point solvents such as toluene (110 °C), high volatility leads to the fast drying of the active layer and may limit the self-assembly as well as the power conversion efficiency. However, the polymer films made by blade coating could be more ordered than those by spin coating due to the fact that the polymer chains are relatively free to move in the absence of centrifugal force. Therefore even without the slow drying process the donors and acceptors quickly


Fig. 3. Current–voltage (J–V) relations of the devices in this work. (a) Devices made by spin coating (device A, solid square), blade coating (device B, empty square), blade coating at 60 °C (device C, solid circle), and blade and spin coating (device D, empty circle) in toluene solution, blade and spin coating with bladed PEDOT:PSS (device G, solid star). (b) Devices made by blade and spin coating in toluene solution (device D, empty circle), chlorobenzene solution (device E, solid triangle), and dichlorobenzene solution (device F, empty triangle).

Table 1
Performance of bulk hetero-junction solar cells in this work.

Label	J_{sc} (mA/cm^2)	V_{oc} (V)	Fill factor (%)	PCE (%)	Thickness (nm)
A. (Toluene) spin	9.25	0.59	47	2.6	223
B. (Toluene) blade	11.07	0.59	53	3.5	412
C. (Toluene) blade at 60 °C	11.49	0.59	55	3.8	304
D. (Toluene) blade and spin	11.36	0.58	55	3.7	245
E. (Chlorobenzene) blade and spin	8.87	0.57	49	2.5	345
F. (Dichlorobenzene) blade and spin	8.79	0.60	66	3.5	242
G. (Toluene) blade and spin with bladed PEDOT:PSS (120 nm)	8.35	0.59	52	2.5	245

self-assemble into the desired ordered and interpenetrating morphology during the blade coating process. We speculate that the quick assembly occurs at the beginning of the blade coating because the device made by blade and spin coating (device D) shows high efficiency as well. Interestingly, device B, C, and D have different film thickness but similar performances. High efficiency is maintained for device B with 412 nm thickness probably because pure

blade coating with neither heating nor spinning give the highest freedom to chain motions and the most ordered morphology. In short, the blade coating method allows an ordered polymer morphology in a fast drying solution like toluene. In addition, the result of the device with the bladed PEDOT:PSS and blade and spin coated P3HT:PCBM layer is also shown in Fig. 3a. The efficiency of device G is 2.5% with J_{sc} of 8.35 mA/cm^2, V_{oc} of 0.59 V, and fill factor
Fig. 4. AFM images of the devices in this work. P3HT:PCBM thin film made by: (a) spin coating, (b) blade coating, (c) blade coating at 60 °C, (d) blade and spin coating and (e) blade and spin coating in chlorobenzene solution, (f) blade and spin coating in dichlorobenzene solution. The P3HT:PCBM films in (a)–(d) are made in toluene solution.

of 52%. The relative low performance of device G results from the thick PEDOT:PSS film (120 nm), which causes high series resistance. It is difficult for us to reduce the PEDOT:PSS film thickness now because we use the PEDOT:PSS solution from H. C. Stark without any further dilution. The concentration needs to be lowered without sacrificing the conductivity to get the normal film thickness (40 nm). More experiments need to be done to optimize the PEDOT:PSS layers by blade coating. Nevertheless, such device shows the feasibility of all blade coated devices with very low cost and high throughput in mass production.

Now we turn to different solvent systems. Two devices are made by conventional high boiling points solvents chlorobenzene (device E) and dichlorobenzene (device F). Fig. 3b shows the results of the devices by the fast-drying blade and spin process with different solvents. There is no slow solvent evaporation in the fabrication process. The power conversion efficiencies are 2.5% in the device from chlorobenzene solution (device E) and 3.5% in that

from dichlorobenzene solution (device F). The J_{sc} are both about 8.8 mA/cm^2, which is significantly smaller than J_{sc} of 11.4 mA/cm^2 in device D from toluene. Interestingly high boiling point solvents give higher J_{sc} for spin coating but smaller J_{sc} for blade coating. There are probably more P3HT/PCBM interfaces in toluene solution than those in chlorobenzene and dichlorobenzene solutions, resulting in more efficient exciton dissociation. It is remarkable that the fill factor of dichlorobenzene solution is 66%, much higher than 55% for toluene and 49% for chlorobenzene. Dichlorobenzene has the highest boiling point among the three solvents. The highest fill factor in dichlorobenzene solution may result from the highest carrier mobility due to the enhanced self-assembly of P3HT taking place during the relatively slow drying in spinning. The device performances are summarized in Table 1.

The AFM images of the devices are shown in Fig. 4. The root-mean-square roughness are 2.3 nm for device A, 15.1 nm for device B, 4.9 nm for device C, 2.8 nm for device D, 1.9 nm for device E, and 5.8 nm for device F. The different root-mean-square values are attributed to the different fabrication processes with different solvents. Neat P3HT layers by any process would be very rough (15 ± 3 nm) due to the fact that the polymer chains have the trend to form crystallization, and the neat PCBM could not even form thick films by blade coating. We think that the devices with high efficiency (device B, C, D, and F) have stronger self-organization than those with low efficiency(device A and E). Higher surface roughness corresponds to higher degree of self-organization. [10,11] However, there is no clear evidence for the correlation between self-organization and device efficiency. Nevertheless, we speculate that device B by blade coating shows clear self-organization, implying ordered structures within each components. Therefore, the carrier mobility is high and the power conversion efficiency is high as well even with a thick film of 412 nm. The clear self-organizations in device C and device F also could be seen due to their relative high roughness. Interestingly, the roughness of device D by blade and spin coating is just slightly higher than that of device A only by spin coating, but the efficiency of device D is still much higher. This may be due to the ordered structure occurred at the beginning of blade coating, combined with thicker film thickness by blade coating. As for the low efficiency devices such as device A and device E, the films are relatively smooth. The images show that the self-organization could be achieved within the short drying time by blade coating.

Fig. 5a shows the absorption spectra of the P3HT and PCBM blend films deposited by different methods and solutions. The IPCE for all devices are shown in Fig. 5b. Despite of the different morphologies there is no significant variations among the absorption spectra. So the differences in the device performances must come from the exciton dissociation and carrier transport processes. The IPCE values appear similar in all the devices except that of device G and show slightly difference at about 600 nm. However, the J_{sc} values show much difference among the devices. In principle the measured J_{sc} should be proportional to the product of the IPCE and the illuminating spectrum, integrated over all wavelengths. We may attribute the incon-
Fig. 5. (a) The absorption spectra of the devices and (b) the incident photon to current efficiency (IPCE) in this work. The inset shows the IPCE from 400 nm to 600 nm for clarity. Devices made by spin coating (device A, solid square), blade coating (device B, empty square), blade coating at 60 °C (device C, solid circle), and blade and spin coating (device D, empty circle) in toluene solution. Devices made by blade and spin coating in chlorobenzene solution (device E, solid triangle), and in dichlorobenzene solution (device F, empty triangle), as well as blade and spin coating with bladed PEDOT:PSS (device G, solid star).

sistency between IPCE and J_{sc} values to the different spectral-mismatch factors of the different light sources.[6]

In conclusion we develop the blade coating method to fabricate bulk hetero-junction polymer solar cells with decent power conversion efficiency of 3.8%. The active layer is deposited in toluene solution, which is less toxic than the conventional chlorobenzene and dichlorobenzene solution optimized for spin coating. In sharp contrast to spin coating there is almost no material waste in blade coating. Moreover, this method can be easily scaled up to large sizes as meters and can be applied in a future roll-to-roll fashion for high volume production.

microscopy images were taken in a Jeol JSM-6460 LV scanning microscope. The sample was metalized with gold–palladium alloy in a Denon Desk II metallizer. The infrared spectra were measured in a FT-IR Perkin–Elmer Spectrum BX model equipped with a DTGS detector.

2.1. Synthesis

The synthesis of monomers (Fig. 1) was carried out by Ullmann coupling according to literature procedures [9].

2.1.1. N,N,N′,N′-tetra-p-tolyl-4,4′-diaminodiphenylmethane [1]

In a hermetically sealed glass bottle, 5 ml of dry and degassed toluene were mixed with 4-iodotoluene (5.25 g, 24 mmoles), 4,4′-diaminodiphenylmethane (1.2 g, 6 mmoles), CuI (0.080 g, 0.4 mmol), 1,10-phenanthroline (0.081 g, 0.4 mmol) and potassium *tert*-butoxide (4 g, 36 mmoles). The mixture was sealed, and then heated at 120 °C in a sand bath for 50 h in an argon atmosphere with vigorous stirring. After finishing the reaction, 10 ml of toluene was added, the whole mixture was filtered and the solid was washed with three aliquots of 10 ml of toluene. All the liquid fractions were combined and the solution was dried in a rotary evaporator. The solid was purified twice by chromatography in a silica gel column (1.5 × 20 cm, Merck 60, 0.040–0.06 mm grain) with hexane/cyclohexane (2:1) as solvent. The elution was monitored by TLC in silica plates (Merck 60) with the same solvent mixture, using standards of the initial reagents. The product was collected after the elution of the 4-iodotoluene and, by evaporation, yielded a white powder. Yield: 20%. Pf: 184–187 °C. m/z (%) = 558 [M+] (100). Calculated theoretical mass: 558 g/mol.

2.1.2. N,N,N′,N′-tetraphenyl-4,4′-diaminodiphenylmethane [2]

In a hermetically sealed glass bottle, 5 ml of dry and degassed toluene were mixed with iodobenzene (5 g, 24 mmoles), 4,4′-diaminodiphenylmethane (1.2 g, 6 mmoles), CuI (0.080 g, 0.4 mmol), 1,10-phenanthroline (0.081 g, 0.4 mmol), potassium *tert*-butoxide (4 g, 36 mmoles). The mixture was sealed, and then heated at 120 °C in a sand

bath for 50 h in an argon atmosphere with vigorous stirring. After finishing the reaction, 10 ml of toluene was added, the whole mixture was filtered and the solid was washed with three aliquots of 10 ml of toluene. All the liquid fractions were combined and the solution was dried in a rotary evaporator. The solid was purified twice by chromatography in a column of silica gel (1.5 × 20 cm, Merck 60, 0.040–0.06 mm grain). Elution solvent was a gradient starting with a mixture of hexane/cyclohexane (1:1) and finishing with hexane/cyclohexane/toluene (1:1:0.25). The elution was monitored by TLC in silica plates (Merck 60) with the final elution mixture, using standards of the initial reagents (Rf of the product was 0.75) and, by evaporation, yields a white powder. Yield: 23%. m/z (%) = 502.10 [M+] (100). Calculated theoretical mass: 502 g/mol.

2.1.3. N,N′-diphenyl-N,N′-ditolyl-4,4′-diaminodiphenyl-methane [3]

In a hermetically sealed glass bottle, 5 ml of dry and degassed toluene were mixed with N-pheny-N-tolylamine (2 g, 10 mmoles), 4,4′-diiododiphenylmethane (2 g, 4.7 mmoles), CuI (0.03 g, 0.15 mmol), 1.10-phenantroline (0.03 g, 0.15 mmol), potassium *tert*-butoxide (4 g, 36 mmoles). The mixture was sealed, and then heated at 120 °C in a sand bath for 50 h in an argon atmosphere with vigorous stirring. After finishing the reaction, 10 ml of toluene was added, the whole mixture was filtered and the solid was washed with three aliquots of 10 ml of toluene. All the liquid fractions were combined and the solution was dried in a rotary evaporator. The solid was purified twice by chromatography in a column of silica gel (1.5 × 20 cm, Merck 60, 0.040–0.06 mm grain) with hexane/cyclohexane (2:1) as solvent. The elution was monitored by TLC in silica plates (Merck 60) with the same solvent mixture, using standards of the initial reagents (Rf of the product was 0.50) and, by evaporation, yields a white powder. Yield: 23%. m/z (%) = 530 [M+] (100). Calculated theoretical mass: 530 g/mol.

2.2. Electrochemical characterization

Electrolysis and cyclic voltammetries were performed in a conventional three-electrode electrochemical cell. A mixture of MeCN/Toluene 1:4 was used as electrolysis solvent and $TBAPF_6$ 0.1 M as supporting electrolyte [10]. The working electrode was either indium-doped tin oxide covered glasses (ITO glasses, VisionTeK Systems, Ltd., UK) or a 0.5 mm diameter platinum disc (99.99% purity). A plate of pure gold was used as counterelectrode, and a standardized (ferrocene/ferrocenium+ couple in acetonitrile [11]) double junction electrode of Ag/Ag+ in acetonitrile was used as reference. The platinum electrode was polished with 1% alumina powder (1 μm) in water over a piece of cloth, cleaned in an ultrasonic bath with absolute ethanol and dried in air. All redox potentials are referred to NHE.

2.3. Electropolymerization of [2]

The electropolymerization of [2] was performed potentiostatically on ITO covered glasses of a 10^{-2} M solution in
Fig. 1. Chemical formula of species involved in this study.

electrolysis solvent. A constant potential of 1500 mV was applied for 10 min and then reduced to 0 mV until the current dropped to less than 1% of the initial value. The electrode was washed with the solvent mixture in order to eliminate the rest of [**2**] and then with ethanol to remove the remaining supporting electrolyte. The film was characterized by FT-IR and SEM, and showed no TBAPF$_6$ crystals.

2.4. Spectroelectrochemistry

An ITO covered glass with a film about 0.5 μm thick was placed in a 1 cm path-lenght quartz cell filled with electrolysis solution without [**2**]. The spectrum was obtained at the selected potential after the final current dropped to less than 1% of the initial value and the absorbance remained stable.

2.5. Characterization by infrared spectroscopy

Samples were prepared on ITO covered glasses of 1×3 cm. The film was deposited on a subarea of 1×2 cm. Three films were prepared for 0.5, 1 and 1.5 h of electrolysis. The adhered polymers were reduced at 0 mV until the current dropped to less than 1% of the initial value. After this treatment, the electrode was placed in the electrolysis solution free of [**2**] and it was cycled for 1 h between 0 and 1500 mV at 50 mV/s in order to make sure that there was no monomer occluded in the films. The samples were removed from the cell at the reduced state (uncolored), then washed with ethanol to eliminate the rest of TBAPF$_6$, and dried in air. These film-covered glasses were scraped with a spatula and mixed with BrK in a mortar to prepare transparent tablets for FT-IR analysis.

3. Results

The cyclic voltammetry of [**1**] showed a remarkable similarity to the voltammogram of tri-p-tolylamine (TTA). Only one quasireversible wave was observed at $E^{1/2}$ = 1150 mV (1130 mV in TTA) with ΔE = 90 mV. The UV–vis spectrum of oxidized [**1**] was very similar to that reported for TTA, although it stayed stable only for a few minutes (Fig. S1, see Supplementary material). Absorption bands in the NIR were not observed for the transient specie. On the contrary, a complex process was observed in the first voltammogram of a solution of [**2**], which was very similar to triphenylamine (TPA), with an oxidation wave at 1370 mV and reduction waves around 1020 and 1130 mV [12] (Fig. 2a). The different height and shape of the current peaks suggests that a coupled chemical process, in which the oxidized specie participates, follows the redox reaction. In the successive cycles, two new reversible waves were observed at $E^{1/2}$ = 1030 mV and 1150 mV, with the characteristic shape of an adsorbed species redox process [13]. In order to verify this assignment, the Pt electrode was rinsed with clean solvent and immersed in new electrolysis solution without [**2**]. The voltammogram of this sample showed the disappearance of the wave at 1370 mV and the permanence of the recently formed peaks (Fig. 2b). SEM pictures of ITO electrodes show that the deposited film completely
Fig. 2. (a) Cyclic voltammetry of [**2**] (0.01 M) in electrolysis solution. Scan rate: 25 mv/s. (b) Cyclic voltammetry of electrodeposited film on ITO glass in electrolysis solution (free of [**2**]).

covers the electrode with a homogenous texture (Fig. S2, see Supplementary material).

The infrared spectrum of the electropolymerized film material (p-[**2**] from now on) showed substantial differences with its molecular precursor [**2**]. The last one presented bands at 690 and 750 cm^{-1}, associated with the five adjacent CH out-of-plane bending in the terminal phenyl rings. These two bands are remarkably diminished in the film spectrum, in which a new band appears at 815 cm^{-1}. This band, which is characteristic of the para-substitution in benzene, is not present in the spectrum of [**2**] (Fig. S3, see Supplementary material).

Fig. 3 shows the evolution of the film UV–vis spectrum with potential, as it oxidizes from 0 to 1500 mV. Three successive bands are observed at 360, 485, and 760 nm. As it can be seen in the inset image (absorption at these three wavelengths), the band at 360 nm corresponds to the
Fig. 3. Spectroelectrochemistry of p-[**2**] deposited on ITO glass. Potentials varied from 0 to 1500 mV. Inset shows absorbance as a function of voltage for 350, 490 and 750 nm. Data was extracted from the spectroelectrochemical experiment.

reduced form of the film, the one at 485 nm to the singly oxidized form, and the one at 760 nm to the fully oxidized film.

In order to estimate the molar absorptivity of singly oxidized TPB fragments in the film, a potential step experiment from 1030 to 0 mV was carried out. In that potential range, the signal at 485 nm was sufficiently high to be distinguished from the base noise (although it was as low as to diminish the errors of Lambert–Beer's law deviations), whereas the band at 760 nm (two electron oxidation) was not observed. The film's absorbance was plotted against the charge accumulated from the start of the potential step to a given time t_i. A strongly non-linear relationship (sigmoid) was obtained, thus we concluded that it is not possible to obtain a reliable measurement of the molar absorptivity.

Fig. S4, see Supplementary material shows the spectrum of the oxidized p-[2] film (at 1030 mV) between 400 and 2000 nm (solvent mixture NIR cutoff). We observed an intense band at 1470 nm (besides the one at 485 nm), which we assigned to the intervalence charge transfer corresponding to the TPB fragments in p-[2].

In order to evaluate the electrochromic response, a series of potential pulses were applied to the film. We observed that when increasing the potential from 0 to 1500 mV the time to reach 95% of absorbance at 760 nm was 100 s. When repeating the experience with potential steps from 0 to 1000 mV and measuring the absorbance at 490 nm this time was 130 s. Notice that these times are slower than in polymer films with greater delocalization [14]. After 1 h of applying pulses to the film, the absorbance steps at 490 and 760 nm dropped less than 5% when changing from neutral to fully oxidized species (Fig. 4).

4. Discussion

Although it is not possible to assign the structure of the electrogenerated p-[2] exactly, a qualitative analysis of the experimental results can be used to make some useful inferences.
Fig. 4. (a) Absorbance at 490 nm when rising from 0 to 1000 mV, and (b) Absorbance at 750 nm from 0 to 1500 mV.

Previous studies on polymerization of arylamines have demonstrated that, when these molecules are oxidized, they form dimeric [12,15] or polymeric [10] species through the para-position (whenever it is not substituted). In the case of the aniline oxidation, for instance, position 4 of one molecule is bound to the nitrogen of another one, generating a conductive polymer that adheres to the electrode [16,17]. It has been observed on studies made on the triphenylamine oxidation [12] that two radicals TPA$^+$ rapidly react to yield tetraphenylbenzidine (TPB). Its formation can be verified in the cyclic voltammogram of TPA either by means of the appearance of new redox peaks corresponding to the generated species, or by spectroelectrochemistry where the electronic transitions corresponding to TPB are also seen. The polymerization of arylamines that are interconnected by bridges containing double and triple bonds [18] and by electron donor-acceptor structures [19] has also been studied. They all follow the same polymerization pattern through para-positions and form films that remain adhered at the electrodes.

In our case, it is reasonable to assume that linear polymerization is a necessary previous step at the early stages of the film growth. At the beginning of the process, a pair of phenyl rings from two independent molecules of [2] probably reacts to start a dimer, eventually forming a benzidine chain separated by methylene groups. It has been reported that linear polymers of arylamines (comparable to our case) are soluble in intermediate polarity solvents like chloroform and toluene [20]. In our case, the presence of soluble and colored substances was observed during electrolysis in the neighborhood of the electrode. The same happened with the electropolymerization of [3] which was only able to form linear arrangements and did not form any film at the electrode (Fig. S5, see Supplementary material). We then infer that the insoluble species that form the film cannot be only linear, but may come from the interweaving of previously formed linear chains, after polymerization of the remaining free phenyl as a cross linker between them.

It is observed from the IR spectrum of the film that the bands at 750 and 690 cm^{-1} originally present in [2] diminish their intensity in p-[2]. The vibration band at 815 cm^{-1} suggests that the polymer presents rings with substitutions in para-. This fact has already been described in the case of electropolymerization of TPA [10]. Then, in the case of [2], polymerization might lead to the structure shown in Fig. 5.

Note that neither the bands at 750 and 690 cm^{-1} disappear completely, nor the band at 815 cm^{-1} reaches its maximum height as compared to the IR spectrum of [1] (a full para-substituted model compound). The vibration pattern in the IR spectrum is independent of the oxidation time used in the film growing and also of the time of voltammetry cycling after the film was already formed (in the absence of [2]). This indicates that the substitution pattern in p-[2] is the same at any film stage and, once it is deposited, its reoxidation would not increase the substitution in para- of the remaining (and free) phenyls. Consequently, the polymer precipitation freezes the reactivity of the unreacted phenyl groups, virtually preventing the film from obtaining further interweaving.
Fig. 5. Proposed reaction for electropolymerization of [2].

Molecules that present two electronically connected redox sites show intervalence charge transfer phenomena when they are in certain oxidation states. According to the degree of electronic interaction between these sites, intervalence compounds have been classified by Robin and Day in three classes [21–24]. In Class I compounds, both redox centers have different chemical surroundings and the valence is located in one of them at any time scale. In Class II, both redox centers present small structural differences although the valence is still located in one of them at the vibrational time scale (10^{-12} s). In Class III, the valence is delocalized as much in the time scale of the vibrations as in the spatial distribution of electron density. In Classes II and III, the greater electronic interaction shows up by the appearance of an electronic transition called intervalence charge transfer, and by a disturbance in the redox potentials compared to the isolate fragments (i.e. without electronic interaction). Although the original classification applies to inorganic extended solid compounds, organic radicals with two electroactive sites can also be classified using this criterion [25–28].

In the case of [1], the cyclic voltammetry and the UV–vis spectrum show a remarkable similarity to TTA [29], suggesting that the arylamine fragments that compose [1] would behave independently. This is consistent with the absence of intervalence band in the NIR. So, we can infer that [1] is a Class I intervalence compound. The uncoupling phenomena observed between redox centers can be associated with the fragment that connects arylamines. The presence of a tetrahedral methylene carbon allows adjacent phenyl rings (pertaining to different triarylamines) to take a space conformation so that the planes containing them are 90° rotated to each other. This conformation diminishes repulsion energy between phenyls due to hydrogen neighboring, and induces a symmetry that prevents the π-orbital interaction [30]. This fact derives in each redox site being not sensitive to the other, and therefore, polymerization from triarylamine to benzidine in one side of the molecule would not electronically disturb the capacity of the other site to react in the same way and efficiency.

It has been previously reported [18] that branching in arylamine polymers is a less likely event than the formation of linear chains. Cationic radicals lying in the backbone of the polymer are more delocalized that the terminal ones, thus diminishing the charge at the reactive position. As a consequence, polymerization via terminal arylamines should be preferable (and faster) because the terminal cation is more reactive. This argument also suggests that the linear chains of [2] formed during the early stages of polymerization correspond to Fig. 6a and not to Fig. 6b because the first one is the faster process, as it does not involve any of the arylamines that already participate in benzidines (a much less reactive cation).

High amounts of disconnected benzidines would also be responsible for the slow electrochromic response in comparison with other published arylamine polymers. The absence of delocalization may produce electronic hopping, being the preferred charge transport mechanism between isolated benzidines in the film and there would be no conduction through electronic bands.

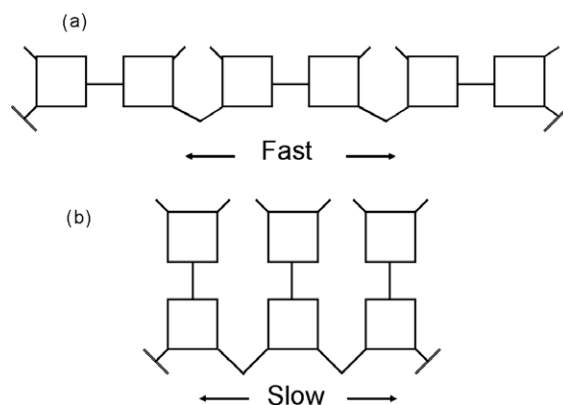
The relationship between electronic coupling and the twist degree between adjacent arylamine fragments in substituted TPB analogs has been previously reported [30]. The presence of methyl groups in positions 2 and 6 twists the rotation planes of adjacent rings, interrupting the π-conjugation along the molecule. This phenomenon is translated both in a substantial change in the UV–vis spectra (including the intervalence band) and in the separation of successive redox potentials (ΔE), another indication of coupling. The UV–vis spectra of TPB fragments in p-[2] in their mixed valence state (Fig. S4, see Supplementary material) showed remarkable similarity with specie 4 of Ref. [30] in which the whole molecule is coplanar and highly coupled. Although the small ΔE makes p-[2] comparable to the less coupled TPB examples (species 5a and 5b in Ref. [30], the most twisted ones), we think that this indication of coupling is not reliable because the matrices that contain the electroactive species are different (solid film versus solution). Thus, we think that the TPB fragments that are comprised in the film of p-[2] are planar and that


Fig. 6. (a) More efficient polymerization mechanism proposed, (b) slower possibility.

the arylamine coupling is the same as that observed in specie 4 of Ref. [30].

5. Conclusions

In the present work, an electrochromic film formed by cross linked phenylbenzidines was synthesized by electrochemical methods. This synthesis is much simpler than a multi-step polymerization approach. The film remained stable during the oxidation/reduction cycling. Its high insolubility in several solvents (hexane, cyclohexane, toluene, dichloromethane, acetonitrile, methanol, ethanol and water) makes it useful in layered devices production because it allows using spin coating mixtures without any risk of dissolution. The suggested polymerization pattern would allow the introduction of diverse substituents (donors, acceptors, ionophores) through covalent unions with unsubstituted phenyls, which would allow its use in fields like optoelectronics, manufacture of electrochromic devices and sensors, etc. We are also working on the chemical modification of the methylene spacer in order to explore the effect of different bridges in adhesive and electronic properties.

operation temperature [14], film crystallinity and electrode structure [15] on electric fatigue were systematically studied and fatigue recovery was observed in fatigued films after a long-time rest [16]. However, ferroelectric polymers are semi-crystalline with coexistence of amorphous and crystalline phases and thus have more complicated morphology than inorganic ferroelectrics. All these experimental results mentioned above originated from macroscopic measurements and were the complicated average of fatigue in thousands of ferroelectric domains. To reveal the mechanism of polarization fatigue, it is necessary to characterize fatigue from microscopic viewpoint. In this paper, we tried to understand polarization fatigue from SPM-based experimental observations.

2. Experimental

Copolymer films were spin-coated on electrode-deposited glass slides from a 5.0% by weight solution of 78/22 P(VDF-TrFE) in butanone. The films had a thickness of ~800 nm and were annealed at 142 °C for 6 h to increase their crystallinity. Both top Au and bottom Al electrodes were vacuum deposited. The top electrodes had a round shape with a thickness of 15 nm and a diameter of 1.0 mm.

The simultaneous measurements of microscopic surface vibrations and macroscopic polarization–voltage (*P–V*) hysteresis loops were performed by an integration of a home-made sawyer–Tower circuit and a scanning probe microscope (SPM, Ultraobjective, SIS, Germany), as shown in Fig. 1. An AC driving signal and a DC driving signal were superposed by an additional circuit SUM and were applied onto ferroelectric films. The switching current through sampling resistance *R* was recorded by an oscilloscope OSC, the integration of which resulted in macroscopic *P–V* loops. Thus we could get the value of remanent polarization (Pr) at different fatigue stages, which would be used to characterize macroscopic electric fatigue. Voltage-excited local vibrations were detected by SPM's probe, which was located at a fixed position on a sample surface. SPM

worked in a tapping mode and the probe was made of silicon with resonance frequency of 75.6 kHz. When the amplitude of the applied voltage was lower than that of the coercive voltage (for the films used in our experiments, this value was about 40 V), the detected local vibrations were linearly dependent on the driving voltage. However, when the amplitude of driving voltage had exceeded that of the coercive voltage, though local vibrations could still be observed, these vibrations were no longer linearly dependent on the driving voltage. In a driving cycle, dual vibration peaks had been induced and these nonlinear vibrations were caused by ferroelectric switching [17]. Local butterfly loops could be obtained by plotting these nonlinear vibrations as a function of driving voltage. With this integration system, we observed the evolution of local vibrations and macroscopic *P–V* loops during fatigue process. Polymer films were fatigued by applying an alternating triangular voltage with amplitude of 100 V, high enough to cause ferroelectric switching, and frequency of 500 Hz. The fatigue process was interrupted at precalculated intervals to conduct measurements of macroscopic *P–V* loops and local vibrations.

3. Results

Typical SPM morphology of a well-grown P(VDF-TrFE) films is shown in Fig. 2. Film surface was covered with lamellar crystallites with dimensions of ~500 nm length and ~120 nm width. In this paper local vibrations at two certain locations were characterized by SPM: one was just on the crystallites, as indicated by solid squares in Fig. 2, the other was at the boundaries between crystallites, as indicated by solid circles.

Firstly, we reported the dependence of local piezoelectricity on electric fatigue. A bipolar triangular driving voltage with amplitude of 70 V_{pp} (lower than the coercive voltage) and frequency of 5.0 Hz was applied to the sample after a given switching cycle and the voltage-excited vibration was detected by SPM. The typical result is shown in Fig. 2. Local vibration (Fig. 2b) of virgin sample displayed a linear dependence on driving voltage with a peak-to-peak vibration displacement of ~2.36 nm. With the increased fatigue cycles, vibration amplitude gradually decreased. After 2.30×10^5 cycles (curve c), the peak-to-peak displacement decreased to ~1.66 nm, but local vibration still showed a linear dependence on driving voltage. However, after 1.28×10^6 cycles (curve d), vibration amplitude induced by driving voltage was so small that it was hard to be distinguished from noise.

Macroscopic fatigue rate was determined by the decrease of Pr. Microscopic fatigue rate was characterized according to the attenuation of local piezoelectric coefficient d_{33}, which was defined as:

$$d_{33} = A_{pp}/V_{pp} \tag{1}$$

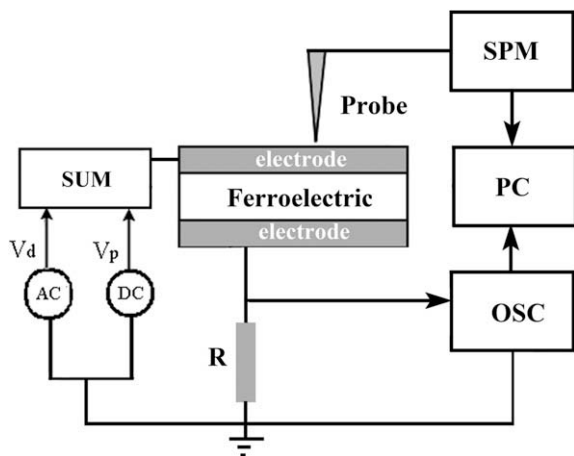
where A_{pp} was the peak-to-peak vibration amplitude in nanometer, excited by a voltage with peak-to-peak amplitude V_{pp}. According to both definitions we could study electric fatigue at different characteristic locations (crystallites and boundaries in this paper).


Fig. 1. Schematic diagram for the simultaneous measurements of local vibrations and macroscopic *P–V* loops.
Fig. 2. SPM morphology of a well-grown P(VDF-TrFE) film, which was obtained on film surface without top electrode. Several spots are marked to indicate the possible sampling locations to be used for microscopic observations: crystallites are indicated by solid squares and boundaries between crystallites are indicated by solid circles.
Fig. 3. Local vibrations detected by the SPM's probe at the boundaries between crystallites. Curve (a) indicates the driving voltage with amplitude of 70 V_{pp} and frequency of 5.0 Hz. Curve (b) indicates the voltage-driven local vibrations before fatigue and curves (c) and (d) indicate recorded local vibrations after (c) 2.30×10^5 and (d) 1.28×10^6 fatigue cycles.

In Fig. 4 a typical experimental result of local electric fatigue on crystallites is shown. For comparison, macroscopic fatigue rate was also plotted. It was very clear that the attenuation of local vibration amplitude was much slower than the decrease of macroscopic Pr. Two kinds of local fatigue processes were observed on crystallites. From Fig. 4a, it can be seen that with the increase of fatigue cycles, local vibration amplitude measured on crystallites also gradually decreased, though the local fatigue rate was slower than the macroscopic fatigue rate obtained from the decrease of Pr. For example, after 1.86×10^7 fatigue cycles, macroscopic Pr decreased to 52.6% of its original values, while local vibration amplitude only decreased to 86.4% of its original value. Interestingly, in Fig. 4b, we observed a nearly unchanged local vibration, though macroscopic Pr had decreased to 70% of its original value after 4×10^7 cycles in our experimental observation. Both phenomena were observed just on crystallites.

In Fig. 5 a typical fatigue characteristic observed at the boundaries between crystallites is shown. Again, for comparison, macroscopic fatigue rate defined by the decrease of Pr with fatigue cycles was plotted. Different from the slow decrease of local vibration amplitude observed on crystallites, local vibration amplitude measured at boundaries greatly decreased with fatigue cycles and the local fatigue rate was much faster than macroscopic rate from the decrease of Pr (Fig. 5a, compare the black curve with the blue one). For example, after 3.8×10^5 fatigue cycles, macroscopic Pr only attenuated to 86.3% of its original value, while local vibration amplitude had decreased to 48.4% of its original value. We observed this fast attenuation of local vibration amplitude at all boundaries between crystallites. However, at some boundaries, with the further increase of fatigue cycles, we observed a surprising increase of local vibrations, though the macroscopic Pr continuously decreased, as indicated by the red curve shown in Fig. 5a. At this boundary, the local vibration amplitude firstly decreased to 34.6% of its original value after 6.8×10^5 fatigue cycles, then, with the continuous increase of fatigue cycles, local vibration amplitude began to increase and rapidly

reached double of its original value after 9.4×10^6 cycles and finally remained at this value until the end of our experimental observation. In fact, after local vibration amplitude began to increase abnormally, the voltage-excited local vibration was no more linearly dependent on the applied voltage but showed a rounded shape, as shown in Fig. 5b. A simple quadratic relationship could be used to well fit such a local vibration with respect to the applied voltage.

If an alternating voltage with amplitude larger than that of coercive voltage of ferroelectric films was applied to the sample, ferroelectric switching would occur when the voltage reached the value of coercive voltage. Ferroelectric switching would result in the occurrence of dual-peak vibrations and then local butterfly loops. A typical dual peak vibration is shown in Fig. 6a. Local butterfly loops could be obtained by plotting local vibration as a function of driving voltage, as shown in Fig. 6b. By this means the evolution of local butterfly loops at different fatigue levels could also be used as a characteristic to evaluate fatigue process.

Macroscopic P–V loops and microscopic butterfly loops were simultaneously recorded during fatigue process. Both kinds of loops were measured by a poling voltage with amplitude of 80 V and frequency of 1.0 Hz. In this experiment, at each sampling point, three measurements were conducted: macroscopic P–V loop, measured by Sawyer–Tower circuit, and local butterfly loop on a given crystallite and local butterfly loop at a given boundary, measured by SPM. The evolution of both kinds of loops with increased fatigue cycles is shown in Fig. 7.

Before fatigue, the film showed a P–V loop with a rectangle shape (Fig. 7a1), which implied high crystallinity from macroscopic viewpoint. The local butterfly loop on the crystallite (Fig. 7b1) exhibited a relatively sharp ferroelectric switching. However, the local loop obtained at the boundary showed a rounded shape with a wide distribution of ferroelectric switching from 30 to 70 V.

With the increase of fatigue cycles, macroscopic loops gradually became rounded and the remanent polarization
Fig. 4. Polarization fatigue characterized by the attenuation of macroscopic Pr of the whole film (black curves) and local d_{33} just on crystallites (red curves). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 5. (a) Dependence of polarization fatigue on fatigue cycles and (b) voltage-excited local vibration after 1.19×10^7 fatigue cycles. Local vibration was measured at the boundaries between crystallites. In Fig. 5a, electric fatigue is characterized by the attenuation of macroscopic Pr (blue curve) and local d_{33} (black and red curves). In Fig. 5b, the lower curve shows the applied triangular voltage with amplitude of 70 V_{pp} and frequency of 5.0 Hz and the upper curve shows the local vibrations. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 6. (a) Local dual-peak vibrations and (b) the local butterfly loop. In Fig. 6a, the black curve indicates a whole cycle of the applied voltage with amplitude of 156.0 V_{pp} and frequency of 2.4 Hz and the blue curve indicates the voltage-excited local vibration. The film had been fatigued by 2.20×10^5 cycles.

Pr decreased from the original value of 0.091 C/m² (a1) to 0.074 C/m² (a2) and 0.057 C/m² (a3), corresponding to fatigue cycles of 2.00×10^5 (a2) and 1.60×10^7 (a3). Local butterfly loops also revealed some interesting changes. For the loops obtained on crystallites, with increased fatigue cycles, ferroelectric switching became smoother and smoother, the change in film thickness decreased from 5.86 nm (b1), 5.3 nm (b2) to 3.3 nm (b3). For loops observed at boundaries, the change in film thickness decreased with increased cycles from 5.3 nm (c1) to 4.4 nm (c2), as was the same as that observed on crystallites; however, at some boundaries we also observed an abnormal increase of film thickness with further fatigue cycles (9.5 nm in Fig. 3c) and local butterfly loop displayed a slim shape (that is to say, for a given voltage, the change in film thickness due to ferroelectric switching was almost similar as that due to piezoelectricity) at such a situation. We should emphasize again that this slim loop was only observed at

few boundaries. Such a slim loop was very similar to that observed from electron-irradiated P(VDF-TrFE) films [18]. Different from relaxor ferroelectric behavior in electron-irradiated P(VDF-TrFE) films, in our experiments, the slim loops were only observed in microscopic measurements and macroscopic P–V loops still showed large hysteresis.

4. Discussions

Compared to inorganic ferroelectrics, ferroelectric polymers have more complicated morphology with coexistence of crystalline phase and amorphous phase. Macroscopic fatigue characterization in ferroelectric polymers was only a complicated average of fatigue characteristic from microscopic structures, such as crystallites, amorphous phase and boundaries between crystallites. To understand fatigue mechanism, it is necessary to distinguish different contributions from different microscopic structures. The changes
Fig. 7. The evolution of (a) macroscopic P–V loops measured by Sawyer–Tower circuit and local butterfly loops obtained (b) on the crystallite and (c) at the boundary between crystallites with increased fatigue cycles. Loops a1, b1 and c1 were measured before the sample was fatigued. Loops a2, b2 and c2 were measured after 2.00×10^5 fatigue cycles and loops a3, b3 and c3 were measured after 1.60×10^7 cycles.

of local piezo- and ferro-electricity with increased fatigue cycles are measured in our experiments. Here we will make some discussions on our microscopic fatigue characterization.

4.1. About our characterization technique of microscopic fatigue

AFM is well known for its excellent lateral resolution down to an atomic scale. The lamellar crystallites of P(VDF-TrFE) are known to be about several tens of nanometers thick [19], and considerably larger in the other two directions (by electron microscopy it has been found that the crystallites can have lateral size up to 3 mm [20]), and these crystallites are known to be oriented with their large dimensions perpendicular to the surface [21]. So the local vibrations, detected by SPM, are not averaged properties of several adjacent structures in the directions parallel to sample plane, but vibrations on a single crystallite or just at one boundary. However, films used in this paper are about 800 nm thick, so it should be a complicated combination of crystallites, boundaries and even amorphous phase in the direction normal to the film plane, that is to say, the observed local vibrations are most likely the

integrated results of all these local structures (crystallites, boundaries and amorphous phase) along film-thickness direction. However, in our microscopic measurements, we do observe the shape difference of local butterfly loops on crystallites and at boundaries (Fig. 7). It should not be an occasional observation because we have detected similar results on several films. We still cannot understand why we observe such a difference, though it seems to imply that local vibrations are more sensitive to the structure near the surface. Further work should be done to give a reasonable explanation. Also to distinguish the different contributions of crystallites, boundaries and amorphous phase to electric fatigue, it is necessary to prepare ultrathin ferroelectric polymer films to make sure that only one structure exists along the direction normal to film plane. Langmuir–Blodgett technique should be preferable to get such a high-quality ultrathin film. In this paper we only put forward a possible method to characterize local electric fatigue.

4.2. About the origination of electric fatigue

Many macroscopic experiments have been conducted on ferroelectric fatigue in polymers [9–16]. All these experimental observations seem to imply the charge effect on

fatigue. In fact, trapped charge is a crucial factor in fatigue origination of inorganic ferroelectrics [8]. With increased switching cycles, more and more charges are injected into ferroelectrics through electrodes and trapped at the boundaries between crystallites and captured by the defects in crystallites and especially in amorphous phase. These trapped charges in ferroelectrics inhibit the reversal of electric diploes and thus induce polarization fatigue. So fatigue in polymers should depend on voltage profile, electrode structure, film morphology (crystallinity and defects) and so on. Our previous work reported the effect of film crystallinity on ferroelectric fatigue and found the well-grown P(VDF-TrFE) films show a much better fatigue endurance than films with low crystallinity [22], as was due to the amorphous phase in low-crystallinity films that had more defects and could trap more charges.

In this paper, local fatigue observed on crystallites shows a slower rate than macroscopic fatigue rate from the whole film, while local vibration amplitude at boundaries show a much faster attenuation, though at some boundaries we observe an abnormal increase of vibration amplitude at deep fatigue state. This can be well understood according to fatigue mechanism mentioned above. In the study of ferroelectricity in polymers, Eisenmenger, et al. [23] proposed an opinion that space charges would prefer to be trapped at boundaries between crystallites. Furthermore, from the lamella model the boundaries between crystallites should consist of most of amorphous phase with much lower crystallinity [24]. So more charges can be accumulated at boundaries, as results in the worse fatigue endurance. However, we have to emphasize again that here we have only considered the structures on surface or near the surface and not the complicated combination along film-thickness direction. We believe that space charges are captured preferentially by defects and boundaries on surface or subsurface and then by these structures in the film.

4.3. About the slim butterfly loops

In the measurements of local butterfly loops, especially at some boundaries, we observed slim loops (Fig. 7 curves b3, c3) in deeply fatigued films, though macroscopic P–V loops still show large hysteresis. Zhang, et al. [18] attributed the slim hysteresis loops in electron-irradiated P(VDF-TrFE) films to the formation of relaxor ferroelectric: electron irradiation broke up polarization domain in normal ferroelectric copolymer into nanopolar regions. In our fatigue researches, for the whole ferroelectric films, it is hard to transfer normal ferroelectric polymer into relaxor ferroelectric only by millions of ferroelectric switching which can only inject a finite number of charges into ferroelectric. However, a much large local charge density can be expected at some local areas, especially at some boundaries which have lower crystallinity and more defects. So it is very possible that such local areas can possess part of relaxor ferroelectric behaviors and show slim loops. But in our present work we still have not observed such a relaxor-like behavior on any of crystallites, as may be due to the limited fatigue cycles and much high crystallinity.

4.4. About the abnormal increase of vibration amplitude

In this paper we characterize both microscopic fatigue processes according to the attenuation of local vibration amplitude and macroscopic fatigue according to the decrease of P_r. It is usually believed that voltage-excited surface vibration in ferroelectric polymers originates from the dimensional effect, which is linearly dependent on driving voltage, and the electrostriction, which is proportional to the square of the applied voltage. For normal ferroelectric polymers, vibrations induced by electrostriction effect can be negligible. Macroscopic measurements have already approved that piezoelectric coefficient has a linear dependence on spontaneous polarization in ferroelectric polymers [25,26]. So the voltage-excited local vibration amplitude can be regarded as a measurement of local polarization at the certain location and the attenuation of local vibrations can be used to compare with macroscopic decrease of Pr.

In deeply fatigued films, we observe an abnormal increase of vibration amplitude at some of boundaries between crystallites, which is no more linearly dependent on the driving voltage and can be fitted according to a simple quadratic relationship with respect to the voltage (V). However, it must be emphasized that such large local vibrations are not only dependent on V^2, but also determined by the polarity of this voltage. The voltage-excited vibrations have the same frequency as driving voltage. This is very different from the effect of electrostriction, which is defined only by V^2 and the vibration frequency due to electrostriction should double the frequency of driving voltage. It is regarded that the abnormal increase of vibration amplitude in fatigued films should be the combined action of dimensional effect, electrostriction and the interaction between the applied electric field and trapped charges. In this paper, we still cannot evaluate to what extent these three parts contribute to our experimental observations.

5. Conclusion

In this paper we characterized electric fatigue in ferroelectric polymers from the macroscopic decrease of remanent polarization and the microscopic attenuation of vibration amplitude measured on crystallites and at boundaries between crystallites. Experimental results indicated that local crystallites had much better fatigue endurance than the boundaries had. At few boundaries we observed an abnormal increase of local vibration amplitude at deep fatigue state, which was assumed to be due to the combined action of dimensional effect, electrostriction and the interaction between the applied electric field and trapped charges.

(on-grid) energy production lies somewhere in the future. There have been relatively few reports on large scale fabrication of polymer solar cells that explore the full potential of R2R processing [11–14] and common to all of them is that they employ indium-tin-oxide (ITO) as the transparent electrode. In one example a rigid cost-analysis based on the materials and effort consumed was made showing the actual cost [14]. This study underlined that polymer solar cells can conceivably be made at low cost but that this is not automatically granted and that this will only come at an effort. In addition any large scale commercial future for polymer solar cells is unlikely to be shared with ITO. In the latter case ITO accounted for ~30% of the overall module cost [14]. The commercially available substrates with ITO (rigid and flexible) are exclusively obtained via a vacuum coating step where the ITO is applied. A valiant cause is thus not only to alleviate the need for ITO but also the need for vacuum coating steps in the process as these add unnecessarily to the cost. It is not a simple matter to avoid the use of ITO as the process technology for polymer solar cells has evolved and matured to its current level with ITO and it is nearly implicit that the device illumination is through (the transparent) substrate that has ITO as the transparent conductor. One line of research simply replace the ITO with high conductivity PEDOT:PSS [15] or with a metallic grid or a thin metal with an overlayer of PEDOT:PSS [16–18] and otherwise employ a normal device geometry. Other methods either employ an inverted geometry or illumination through the back electrode [19]. Neither of the reported attempts however avoids the use of a vacuum coating step nor do they present full R2R compatibility with all solution processing. An additional desire is the possibility to process the devices entirely in the ambient atmosphere. While large scale processing can be envisaged in an inert and clean room environments the aim is to find the simplest process conditions to minimise the cost.

In this report a fully R2R compatible process to complete polymer solar cell modules is presented with processing of all five layers from solution on virtually any flexible substrate. The device geometry is inverted and there is no requirement for transparency of the substrate. The process is compatible with most polymer bulk heterojunction mixtures and is exemplified here using P3HT-PCBM as the active material.

2. Experimental

2.1. Materials

Poly(3-hexylthiophene) was prepared according to the McCullough route [20] and the purified material had a regioregularity >97% and M_n = 18,700, M_w = 36,600, M_p = 33,900, PD = 1.9. [60]PCBM was purchased from Solenne BV with a purity of 99%. Silver nanoparticles with an average diameter of 100 ± 15 nm as determined by light scattering were used for slot-die coating the non-transparent back electrode as the first layer. Zinc oxide nanoparticles (ZnO np) were prepared and stabilized with methoxyethoxyacetic acid (MEA) as described earlier [21]. The thermocleavable solvent WS-1 was obtained as described in the

literature [22,23]. PEDOT:PSS was purchased as a screen printing paste from Agfa (Orgacon EL-P 5010, www.agfa.com). The silver electrode was purchased from Dupont as a screen printing paste (Dupont PV410, www.dupont.com). The PEN substrate was obtained from Dupont and had a thickness of 130 micron and a roll width of 305 mm. The material was used as received. Cold lamination with a mechanical protection layer was carried out after completion of the device on top of the silver back electrodes, using a 25 μm thick Fasson overlaminating polyester material from Avery Dennison.

2.2. Ink formulations

2.2.1. Silver back electrode ink

Silver nanoparticles (100 ± 15 nm) were dispersed in a 1:1 mixture of triethyleneglycolmonomethylether and ortho-xylene. The final concentration of silver nanoparticles was 25% (w/v) and used directly for printing after formulation.

2.2.2. ZnO nanoparticle ink

A stock solution containing ZnO nanoparticles (5 g) in chlorobenzene stabilized with MEA (20% w/w) was mixed with WS-1 (20 mL) and evaporated at 70 °C for 30 min. The slightly turbid WS-1 solution of MEA stabilized ZnO nanoparticles was diluted with ortho-xylene (80 mL) and mixed well before filtering through a 0.45 micron Teflon filter. The final clear colourless solution was 50 mg mL^{-1} in ZnO and was used directly for coating. The solution is stable for several weeks with the exclusion of moisture from the atmosphere.

2.2.3. The P3HT-PCBM ink

P3HT (2.2 g) was dissolved in 1,2-dichlorobenzene (50 mL) at 90 °C with stirring for 3 h. PCBM (2.0 g) was added and the mixture was stirred for an additional 1 h at 90 °C. The mixture was then cooled and CHCl$_3$ (50 mL) was added. The final solution was 22 mg mL^{-1} in P3HT and 20 mg mL^{-1} in PCBM. The solution was allowed to stand at room temperature for 2 h before use. This repository time allows for aggregation that was found to be beneficial during coating. The ink was stable for several days at room temperature.

2.2.4. The PEDOT:PSS and silver grid front electrode

A commercially available screen printing formulation (Agfa EL-P 5010) was diluted with isopropanol 10:5 (w/w) and stirred for 1 h using a large magnetic stirring bar. The best viscosity for the coating was found to be around 200 mPa s. The final viscosity was reached by adding a small amount of isopropanol. The final mixture was typically 10:6 (w/w). The solution was stable for several days at room temperature. The silver ink for screen printing the silver grid front electrode was used as received.

2.3. R2R processing

The R2R coating was carried out on a BC30 basecoater from Solarcoating Machinery GmbH (Germany). All coating

was performed with tension control on the web using the coating roller to drive the web at fixed speed. The system comprised: unwinder, corona treater (Arcotec), double roller edge guiding system (BST), double sided web cleaning unit (TekNek), tension roller, coating roller, ink jet printer for labelling (Domino), drier (1 m length), cooling roller, tension roller, speed monitoring roller and rewinder. The temperature and relative humidity during all the coating experiments described here were respectively, $20 \pm 1\,^{\circ}\text{C}$ and $35 \pm 5\%\text{rh}$.

2.3.1. Slot-die coating of the silver back electrode

The silver ink was slot-die coated at a web roll speed of $0.9\ \text{m min}^{-1}$ and was dried in the hot air oven at $130\,^{\circ}\text{C}$. The web was cleaned using adhesive rollers on both the front and backside of the web (TekNek). In order for the final silver to adhere better to the PEN surface a corona treatment was employed (1070 W) in conjunction with antistatic removal. This gave a highly reflective smooth and non-transparent silver back electrode (Fig. 1).

The electrode stuck well to the PEN and had a typical sheet resistance of $0.01\ \Omega\ \text{square}^{-1}$. The pattern for the device structure has been presented earlier [11,13].

2.3.2. Slot-die coating of ZnO

The ZnO ink (Section 2.2.2) was slot-die coated with a web speed of $0.7\ \text{m min}^{-1}$ and drying at $130\,^{\circ}\text{C}$. The ZnO film was slightly opaque and insoluble in common organic solvents after the drying step. The position of the ZnO layer was off-set 1 mm with respect to the silver line allowing for later contact to be made to the silver bottom electrode that was prepared in Section 2.3.1. The serial connection between the individual cells of the module is shown in Fig. 2. The wet thickness of the layer was 16 μm and the

dry thickness of the layer was 140 nm. The coating of the ZnO is shown in Fig. 3.

2.3.3. Slot-die coating of P3HT-PCBM

The P3HT-PCBM ink (Section 2.2.3) was slot-die coated at a web speed of $0.4\ \text{m min}^{-1}$. The drying temperature was $130\,^{\circ}\text{C}$. The wet thickness of the layer was 17 μm and the dry thickness of the layer was 600 nm. The coating of P3HT-PCBM is shown in Fig. 3.

2.3.4. Slot-die coating of PEDOT:PSS

The PEDOT:PSS solution was slot-die coated at a web speed of $0.2\ \text{m min}^{-1}$. It was necessary to wet the surface of the P3HT-PCBM layer with isopropanol immediately prior to coating 4 cm before the coating meniscus. Otherwise the PEDOT:PSS solution does not wet the surface of the P3HT-PCBM film. Drying at $130\,^{\circ}\text{C}$ yielded a dark blue semitransparent PEDOT:PSS film. The optical transmission of the PEDOT:PSS was >10% in the range of wavelengths from 350 to 750 nm and >15% in the range of wavelengths from 375 to 650 nm with a maximum of 20% at 450 nm. The sheet resistivity of the PEDOT:PSS layer was typically 75–78 $\Omega\ \text{square}^{-1}$ and the devices were functional at this point. To achieve a good extraction of carriers it was found necessary to apply a silver grid front electrode.

2.3.5. Sheet-fed screen printing of the silver front electrode grid

The silver front electrode grid was printed through a 120 mesh screen with the grid pattern. The printing speed was $525\ \text{mm s}^{-1}$ and the sheets with the wet print were loaded into a rack. The time between printing and drying was kept as short as possible and was typically less than
Fig. 1. Slot-die coating of the silver back electrode onto PEN. The wet print that has an opaque green colour is seen behind the slot-die coating head (top right). The dried and highly reflective silver back electrode is shown on the rewinding side (top right). The menisci during coating of the eight stripe module is also shown. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Fig. 2. Schematic cross section of the device showing the order of the layers and their juxtaposition. With each coating cycle the position of the layer was shifted 1 mm to the left (on the figure). The device comprising 1 stripe is shown.

10 min for the first print. Batches of 40 sheets were processed each time. The rack was then loaded into a hot air oven preset at 140 °C. Upon introduction the temperature in the oven drops due to the heat capacity of the rack and the rack was left in the oven for 10 min during which time a temperature of 140 °C was reached after about 5 min. The devices were then removed from the oven and were cooled in air.

2.4. Device testing

The devices were either characterised as prepared or cold laminated with a 25 μm PET film using an acrylic adhesive. Electrical contacts were made with alligator clips and electrical measurements of the IV-characteristics were carried out with a Keithley 2400 source-measure unit. Solar simulation was carried out using a KHS575 solarkonstant from Steuernagel Lichttechnik GmbH (Germany). The luminous intensity at the sample position was calibrated using a precision radiometer from Eppley laboratories and monitored continuously during measurements using a CM4 high temperature pyranometer from (Kipp&Zonen). The emission spectrum of the solar simulator was monitored using an optical spectrum analyzer from Avantes. The solar simulator was for the duration of the experiments Class AAA. The conditions for the devices were 1000 W m^{-2}, AM1.5G, 72 ± 2 °C and a relative humidity of 35 ± 2%rh.

3. Results and discussion

3.1. The need for new processing methods

One of the great promises of polymer and organic photovoltaics is the possibility for preparing the solar cell

using commonly available materials at temperatures around room temperature under ambient conditions. Most scientific reports have concentrated on preparation of devices under inert conditions in a glovebox on small glass substrates using spin coating as the film forming technique. In addition evaporated metal electrodes are used almost exclusively. There are few reports that employ processing in air and avoid the use of vacuum deposited metal electrodes [8,11,13,14,21]. From a technological point of view the vacuum deposition of a metal electrode in large volume using R2R methods is feasible and not viewed as a hindrance. It is however very attractive if the same coating equipment can be employed for processing all layers in the solar cells and particularly attractive if vacuum coating steps can be avoided. In addition a device geometry that does not necessitate the need for a transparent substrate is also viewed as an advantage as it will allow for the polymer solar cells to be processed onto virtually any substrate surface (provided that the substrate can withstand the solvents and process conditions). The current state-of-the-art has evolved around transparent bottom electrodes and rigid glass substrates and it is thus a significant challenge to find a new device geometry that outperforms (or even approaches) the current state of the art. It is however clear that a significant research effort has to be directed towards finding methods that deviates from the current state-of-the-art while solving some of the pertinent problems. Even if this implies a sacrifice in performance it should be viewed as a valiant cause.

3.2. All solution, all air R2R processing of OPV

It is possible to process devices entirely from solution on ITO substrates using an inverted device geometry whereby the transparent front ITO electrode becomes
Fig. 3. The menisci during slot-die coating of ZnO (A). The ZnO stripes are shifted 1 mm to the right with respect to the underlying silver pattern (top). The wet layer during coating of P3HT-PCBM (B) and PEDOT:PSS (C) are shown just after the slot-die coating head. Sheet-fed screen printing of the silver front electrode grid before (D) and after the printing (E).

the electron accepting electrode (the cathode) and the metallic back electrode becomes the hole accepting electrode (the anode). This has some advantages in terms of device stability as the metals used for the back electrode can be less reactive towards water and oxygen in the atmosphere. This approach has been followed in a series of papers where ZnO nanoparticles [24–27] are processed onto the ITO. The ZnO nanoparticles are excellent for transporting electrons and block hole transport while being highly transparent. The use of ITO in combination with ZnO gives a highly transparent electrode that allows for illumination of the active layer and such a device does not require the back electrode to be transparent [11]. It is however possible to have semi-transparency of the device since PEDOT:PSS can be used as the back electrode on its own or in conjunction with a conducting

printed metal grid structure. This was shown earlier to be possible with all solution, all air R2R processed modules that gave quite a good device performance. The typical performance was well in excess of 1% for large area devices (120 cm^2) and up to 2.3% for devices with small areas (4.8 cm^2) using P3HT:PCBM as the active layer [13]. The account however employed the use of ITO and had to make use of a thick PEDOT:PSS layer to avoid that the solvents in the silver metal paste electrode destroyed the active layer. Back illumination was possible but at the expense of performance that was about 5 times lower than front face illumination [13]. There have so far been no convincing reports of an all-solution processable transparent anode/cathode couple. In order to reach the objectives of not using ITO or vacuum coating the semi-transparent back electrode structure presented earlier

[13] could be used in conjunction with a non transparent electrode thus sacrificing performance while gaining in processing ease.

3.3. Choice of substrate, materials, device structure and performance

Polyethyleneternaphthalate (PEN) was chosen as the device substrate. While the material presents excellent transparency it is not strictly needed in this experiment since the bottom electrode is non-transparent.

The bottom electrode was chosen as a solution processable silver electrode. Highly reflective electrodes can be prepared in this manner by slot-die coating the silver nanoparticle solution from a mixture of triethyleneglycol-monomethylether and ortho-xylene as shown in Fig. 1. This electrode had excellent conductivity and sheet resistivities as low as 0.01 Ω square^{-1} were typically observed. By use of corona treatment the silver stuck quite firmly to the surface of the PEN and was insoluble allowing for subsequent solution processing of the next layers in the stack. It was found crucial to prewash the silver layer using isopropanol immediately before slot-die coating of the ZnO layer. In the first experiments this step was not performed and it gave rise to poor operating voltage for the devices (Fig. 4). The isopropanol pre-washing enables good wetting of the subsequent ZnO ink solution and possibly also removes some impurities on the surface of the silver electrode. After slot-die coating the ZnO layer and drying, the layer was insoluble and slot-die coating of P3HT:PCBM proceeded in the same manner as reported earlier [13]. The PEDOT:PSS layer was slot-die coated using prewashing with isopropanol and gave functional devices after drying. The sheet resistivity of the PEDOT:PSS is however too high for efficient extraction of the current from the large area devices. Each stripe has a nominal active area of 15 cm^2. The silver grid front electrode was printed using screen printing of silver grid lines with a width of 0.2 mm and a spacing of 1 mm. This gave an open aperture of 80%. The transmission of the PEDOT:PSS electrode was 15–20% in the range of wavelengths where P3HT:PCBM absorbs

Fig. 5. IV-curves for the 1, 2, 3 and 8 stripe modules with careful prewashing using isopropanol and fast drying of the silver grid electrode (1000 W m^{-2}, AM1.5G).
Fig. 6. Maturation of the IV-curve for an 8 stripe device during light soaking. Initially the device presents a poor fill factor with an inflection point reminiscent of a transport barrier (1000 W m^{-2}, AM1.5G).

meaning that the effective transmission of light to the active layer was 12–16%. After completion of the devices they were screened for function and the functional modules were cold laminated using a 25 micron PET layer with an acrylic resin. The device performance was in the 0.2–0.3% range for the active layer for the best devices after light soaking (Fig. 5) using and incident light intensity of 1000 W m^{-2} (AM1.5G). It is noteworthy that these devices consistently gave a relatively poor performance when freshly prepared and after light soaking without UV-filtering they gradually improved as shown in Fig. 6.

3.4. Comparison with the state-of-the-art

All of the objectives that served as motivation for this work were successfully met. The process described here allows for full R2R processing of complete polymer solar cell

Fig. 4. IV-curves and maximum power output for the 1, 2, 3 and 8 stripe modules without careful pre-washing using isopropanol and fast drying of the silver grid electrode (1000 W m^{-2}, AM1.5G).

modules on both transparent and non-transparent sub-strates. The process only employs solution coating of five stacked layers and does not involve vacuum steps nor is ITO used in the device. The material used as the active layer is the well known P3HT:PCBM system that has been documented to give around 3.5% power conversion effi-ciency under idealized conditions when taking an average of many devices [28]. The performance obtained here for significantly larger devices is about ten times lower. To make a fair comparison and seek for possible means to im-prove the device performance it is reasonable to compare with the performance obtained for a similarly prepared de-vice with the same inverted device geometry. When pre-paring the same device by replacing the bottom silver electrode with ITO a performance of up to 1.78% PCE (1000 W m^{-2}, AM1.5G) for an 8-stripe module [13] as com-pared to 0.27% PCE obtained for the 8-stripe device re-ported here. However, the earlier report [13] employed illumination through ITO and the higher performance is as-cribed to more efficient light access to the active layer. A direct comparison is also possible since the earlier report employed the same grid electrode as back electrode. In this report the grid electrode is employed as front electrode. A comparison of the earlier result employing illumination through the printed grid electrode which allow for direct comparison with the results obtained here show that a similar performance has been reached in this experiment and that the device within reasonable error presents the expected performance. The earlier report had a slightly higher V_{oc} and a better fill factor. The low performance ob-tained here is thus most rationally ascribed to a poor front electrode that transmits the light poorly due to both sha-dow loss of the grid and poor transmission of the PED-OT:PSS electrode. The shadow loss from the grid electrode amounts to 20% and while it can be anticipated that it can be improved to maybe only 10% this will not lead to the most significant improvement. It is possible to prepare PEDOT:PSS with a much better transmission at the expense of a higher sheet resistivity and an optimum must in that case be found between the highly conducting metal grid structure and the poorer conducting PEDOT:PSS layer. In the case here the choice of a thick poorly transmit-ting PEDOT:PSS electrode was however necessary for de-vice function. Thinner PEDOT:PSS electrodes were found to lead to short circuited devices. The reason for this has been found to be the solvents in the metal paste employed for printing the silver grid electrode. When the wet print of the silver grid is applied the solvents readily diffuse through the PEDOT:PSS layer and into the active layer leading to short circuit of the devices. By application of a thicker PEDOT:PSS and fast drying it was possible to pre-pare functional devices. There is thus little room for improving the process presented here and new material combinations must be found allowing for a more transpar-ent composite grid electrode that can still be processed from solution without destroying the underlying layers.

3.5. Future directions

One possible solution to the electrode transparency problem in the process described here that comprise a non-transparent bottom electrode is to employ materials for the active layer that is not soluble after processing. In this process the bottom electrode and the ZnO layer were insoluble after processing while the P3HT:PCBM layer was not. Some materials exist that do allow for solubility switching after processing. The most successful class so far has been the thermocleavable materials [29–36] that have enabled the preparation of very stable devices while performance have been somewhat poor. This has improved recently where a PCE of up to 1.5% has been reported for devices prepared on rigid glass using native polythiophene [34]. In addition multilayer processing has been demon-strated for tandem cells prepared with thermocleavable materials without the use of orthogonal solvents [35]. One limitation of the thermocleavable materials is that they need to be heated to a temperature of around 200 °C in order to achieve insolubility. This is not possible for common polymer materials such as PET or even PEN as employed here. PEN endure higher processing tempera-tures than PET and that was also one of the reasons for employing PEN in this study. While PET melts at tempera-tures much above 140 °C PEN does withstand tempera-tures as high as 200 °C briefly but it was found that the material shrinks significantly in a direction perpendicular to the web making the registration of the printed pattern with subsequent processing of layers impossible. It should be noted that the use of PET substrates in conjunction with thermocleavable materials have been demonstrated with processing temperatures as low as 140 °C [14] with a sac-rifice in processing time. In the latter case thermocleavage for 4 h was found to be necessary to achieve insolubility. Such a long processing time is clearly impractical in a roll-to-roll process. There are methods to lower the tem-perature of thermocleavage such as acid catalysis in con-junction with THP ether sidegroups [37] and there are also precursor routes to conjugated polymers [38–40]. There would thus seem to be a significant challenge in either obtaining a low cost substrate that readily allows for processing of thermocleavable materials without shrinkage or the development of a solution processable transparent high conductivity cathode that does not em-ploy ITO.

4. Conclusions

In this work a process is presented that offer full roll-to-roll processing of polymer solar cells on flexible substrates entirely from solution. A device comprising five layers was prepared employing slot-die coating for the first four lay-ers and screen printing for the last layer. The process does not involve the use of ITO and no vacuum steps are in-volved. In addition the illumination of the device is through the top electrode enabling the use of non-trans-parent substrates. While the process efficiently met all the objectives set out and solves many of the problems cur-rently encountered in the attempts to upscale and transfer the polymer solar cell technology to industry, there is a sacrifice in performance due to poor light transmission of the PEDOT:PSS-silver grid composite electrode. This poor transmission was due to a requirement for a thick PED-

OT:PSS layer that served the purpose of enabling printing of a silver grid electrode involving solvents that damage the active layer which consisted of P3HT:PCBM. A comparison with the state-of-the-art in an identical geometry with a transparent bottom electrode showed that the device was working properly and the decreased performance was due to the poor optical transmission of the composite PEDOT:PSS-silver grid electrode. Possible means to improve the process through usage of thermocleavable materials that allow for processing using a larger variety of solvents were identified while these have a requirement for a low cost thermally stable substrate.

memory device, comprising a conjugated polymer coating a CNT transistor irradiated with UV light at 365 nm, provided an ON/OFF ratio of ca. 4 at a value of V_{GS} of 4 V, but with a retention time of over 16 h [5].

It appears that commercially viable TFT memory devices exhibiting high ON/OFF current ratios and long retention times (particularly when the gate voltage is turned off) are difficult to prepare. Approaches toward improving device performances while simplifying their fabrication processes are, therefore, necessary for the development and application of future commercial memory devices.

Bulk heterojunctions [10], in which n-type (e.g., fullerene) and p-type (e.g., conjugated polymer) materials are intimately mixed on the nanometer scale to form interpenetrated networks, have been adopted recently to achieve efficient photoinduced charge generation and separation [11,12]. On the other hand, semiconductor nanocrystal quantum dots (QDs) have also been used in such organic optoelectronic devices as solar cells [13] and light-emitting diodes (LEDs) [14]. Recently, the first bulk heterojunction photoresponsive OTFT memory device incorporating P3HT and CdSe QDs by our group was reported to have an ON/OFF ratio of ca. 10^2; because the CdSe QDs served as trap centers, the memory effect of the device was maintained for 1 h-even without a gating voltage [15].

Type-I core/shell structured QDs, in which the conduction and valence bands of the shell material are higher and lower, respectively, than the corresponding values of the core material, feature a quantum well structure that can confine both holes and electrons in the core [16]. Hence, the quantum well structure of such QDs enhances their electroluminescence (EL) in LED applications [17].

In this paper, we report bulk heterojunction polymer TFT memory devices exhibiting long retention times and high ON/OFF ratios that we fabricated using quantum well-structured QDs comprising CdSe cores and ZnSe shells (CdSe@ZnSe). To the best of our knowledge, this system is the first to employ a quantum well structure to enhance the memory effect of polymer TFTs.

2. Experiment

2.1. Materials

Regioregular poly(3-hexylthiophene) was obtained from Rieke Metals and used as received. Cadmium acetate dihydrate [Cd(OAc)$_2$ · 2H$_2$O] was obtained from Fisher Chemicals. Selenium (Se, 99.999%) and hexadecylamine (HDA, tech. 90%) were obtained from Aldrich. Trioctylphosphine oxide (TOPO, 98%), n-octylphosphonic acid (OPA, 98%), and trioctylphosphine (TOP, tech. 90%) were purchased from Alfa Aesar. Zinc stearate was obtained from J.T. Baker. The solvents heptane, toluene, methyl alcohol, and chloroform (HPLC-grade) were obtained from commercial sources.

TOPO-capped CdSe and CdSe@ZnSe QDs were synthesized using a modification of a procedure reported previously [18,19]: A mixture of Cd(OAc)$_2$ · 2H$_2$O (105 mg), HDA (1.39 g), OPA (225 mg), and TOPO (1.95 g) was heated in a 25-ml three-neck flask at 270 °C under an argon flow to obtain a colorless, clear solution. At this temperature,

the Se solution (100 mg in 2.4 ml TOP) was injected rapidly. The growth temperature was maintained at 270 °C for 100 s and then the reaction mixture was cooled to room temperature. The CdSe QDs were collected as powders after their precipitation with MeOH. A colloidal solution of the CdSe QDs (ca. 20 mg) in heptane (4 ml) was heated in a 25-ml three-neck flask under an argon flow. After addition of TOPO (2.5 mg) and HDA (1.5 mg), the mixture was heated at ca. 190 °C to completely remove the heptane. Zinc stearate (316 mg) was dissolved in toluene (2.5 ml) at ca. 60 °C. After cooling to room temperature, the resulting 0.2 M solution was mixed with TOP (2.5 ml) and Se (39.48 mg). This mixture was injected via syringe pump (0.085 ml/min) into the reaction flask containing the CdSe QDs at ca. 190 °C. After the addition was complete, the crystals were annealed at 190 °C for an additional 1 h. The CdSe@ZnSe QDs were collected as powders after their precipitation with MeOH.

2.2. Device fabrication and measurement

A solution of P3HT in CHCl$_3$ was blended with a solution of the QDs in CHCl$_3$; the P3HT/QD composite weight ratio was 1:0.1. The P3HT and P3HT/QD TFT devices were fabricated in a bottom-gate configuration. An n+ silicon wafer (<0.005 Ω cm) was used as the substrate and gate; 900-Å thermal SiO$_2$ (capacitance: 38.4 nF/cm^2) was the gate insulator; a photolithographically patterned Au/Cr layer (thickness: 600/50 Å) functioned as the source and drain electrodes (W = 1000 μm; L = 10 μm). Octadecyltrichlorosilane (OTS) was deposited by immersing the substrate in 1 mM heptane solution for 10 min; the substrates were rinsed with heptane and isopropanol, followed by drying with N$_2$. The P3HT and P3HT/QD films (thickness: ca. 60 nm) were deposited through spin-coating and then they were annealed at 150 °C for 5 min inside a glove box under N$_2$ atmosphere. The samples were then transferred to a cryogenic probe station (VFTTP4, Lakeshore). The performance of each device was measured under vacuum (<1 × 10^{-5} torr) in the dark using a Hewlett–Packard 4156C semiconductor parameter analyzer. The devices were illuminated under vacuum using a tungsten halogen lamp (2.75 mW/cm^2).

2.3. Characterization

TEM images were obtained using an FEI Tecnai Spirit TWIN apparatus operated at 120 keV. For TEM analysis, the devices were placed into 1% HF solution; after the active layers had floated to the solution surface, they were transferred to the TEM grid. A Hitachi U-4100 spectrophotometer was used to obtain optical absorption spectroscopy in the UV–vis range; a Hitachi F-4500 FL spectrophotometer was employed to obtain photoluminescence spectra.

3. Results and discussion

To discern the effect that the ligands on the QDs had on the performance of the memory devices, we investigated
Fig. 1. (a) Absorption and photoluminescence spectra of the CdSe and CdSe@ZnSe QDs. (b) Energy level diagram for the CdSe and ZnSe bulk materials, P3HT, and the electrode materials.

trioctylphosphine oxide (TOPO) as the ligand because TOPO-capped CdSe QDs feature large barriers that prevent electron tunneling into P3HT and better dispersion than pyridine-capped CdSe QDs in P3HT (see Fig. S1, Supplementary material).

Fig. 1a presents the UV–vis and photoluminescence (PL) spectra of CdSe and CdSe@ZnSe QDs that we prepared from the same concentrations in toluene. The first excitonic absorption peak of the CdSe QDs appeared at ca. 540 nm, suggesting an average particle size of ca. 2.85 nm [20], which is consistent with the dimensions obtained from transmission electron microscopy (TEM) image analyses. The presence of the ZnSe shell caused a red shift in the absorption spectrum and enhanced the PL intensity.

Fig. 1b displays a schematic energy level diagram of the CdSe and ZnSe bulk materials, P3HT, and Au electrodes [21,22]. Because the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO) of P3HT lie above the conduction band (CB) and valance band (VB) edges of the CdSe and ZnSe materials, respectively, the P3HT–ZnSe interface forms an offset band heterojunction; in contrast, the CdSe core and ZnSe shell form a type-I heterojunction. When illuminated, excitons were generated in the QDs and P3HT, charge separation occurred at the P3HT–QDs interface, and then electrons and holes were transferred into the QDs and P3HT, respectively [23]. The work function of Au (5.1 eV) matched the HOMO of P3HT (4.9 eV); therefore, an Ohmic contact formed for hole injection, resulting in hole-only transport in the P3HT/QD TFTs.

Fig. 2a displays the transfer curves (drain-to-source voltage, $V_{DS} = -20$ V) of the P3HT-only and P3HT/QD (including CdSe and CdSe@ZnSe) bulk heterojunction TFTs in the dark and under white light (2.75 mW/cm^2). All of the devices exhibited the characteristic behavior of p-channel field-effect transistors. The hole mobility μ_h was obtained using the following equation [24]:

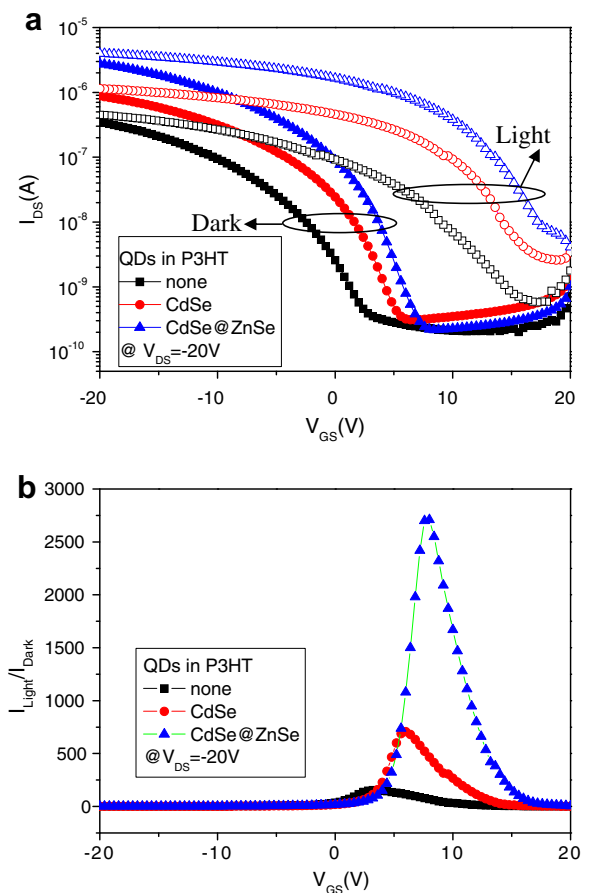
$$I_{DS} = \frac{W}{2L} \mu_h C (V_{GS} - V_{th})^2 \tag{1}$$


Fig. 2. (a) Transfer characteristics ($V_{DS} = -20$ V) of TFTs incorporating P3HT-only, P3HT/CdSe, and P3HT/CdSe@ZnSe blend films and operated in the dark and under white light (2.75 mW/cm^2). (b) Relative I_{light}/I_{dark} ratios of the transfer characteristics of the drain current in the dark and under white light.

where V_{th} is the threshold voltage, W is the channel width, L is the channel length, C is the gate oxide capacitance per

unit area, and V_{GS} is the gate voltage. In the saturation regime, the hole mobilities of the P3HT-only, P3HT/CdSe QD, and P3HT/CdSe@ZnSe QD devices were 4×10^{-4}, 8×10^{-4}, and 3×10^{-3} cm^2 V^{-1} s^{-1}, respectively. Since the HOMO of the P3HT is much higher than the VB of CdSe QDs, this energy difference constitutes a larger energy barrier that prevents holes transferring from P3HT to CdSe QDs [25]. Thus, incorporation of the CdSe and CdSe@ZnSe QDs into the P3HT enhanced the hole mobility of the devices slightly, owing to the fact that it is possible that the QDs reduced the density of traps in the polymer [the concentration of the QDs in the P3HT film was 10% (w/w)]. The hole mobility of each of these three composites was lower than that reported recently for pure P3HT (ca. 10^{-2} to 10^{-3} cm^2 V^{-1} s^{-1}) [26]. Note, however, that several factors, such as the molecular weight of the P3HT, its methods of preparation and purification, the channel dimensions, and the substrate treatment conditions, can influence the characteristics of a TFT device. The values of V_{th} of the P3HT-only, P3HT/CdSe QD, and P3HT/CdSe@ZnSe QD devices were 0.8, 3.4, and 3.8 V, respectively; i.e., those of the blended devices shifted to more-positive values, indicating the existence of a permanent electric field at the interface. The increase in the drain current of the polymer/QD blends under illumination resulted from accumulation of the majority carriers (holes) inside the active layer; these holes tended to drift toward the drain electrode, whereas the electrons will stay in the QDs or the insulator layer. It is well-known that the properties of the interface between the insulator and the semiconductor can critically influence the device performance. When the OTFT is illuminated, the electrons are attracted to the interface with the gate dielectric by a positive gate voltage; they are then trapped either in the dielectric layer or at the interface. Acceptor-like traps, when the traps are filled by electrons, leads to a positive threshold voltage. After turning the light off, electron detrapping under a negative gate bias indicates a returning to the initial state.

Fig. 2b present plots of the ratio I_{light}/I_{dark} versus V_{GS}. We obtained the ratio I_{light}/I_{dark} from the transfer curves of the drain current for samples either in the dark or irradiated under white light (2.75 mW/cm^2). The I_{light}/I_{dark} ratio depends on the gate bias for a given drain bias; it decreases as the gate bias is applied above or below the switch-on voltage. In the depletion regime, the maximum I_{light}/I_{dark} ratios for the P3HT-only, P3HT/CdSe, and P3HT/CdSe@ZnSe devices were 1.6×10^2, 7.1×10^2, and 2.7×10^3, respectively; i.e., the photosensitivity of the P3HT/CdSe@ZnSe device was higher than that of the P3HT-only and P3HT/CdSe devices. Because the switch-on voltages, which were defined by the maximum I_{light}/I_{dark} ratios, for the P3HT/CdSe and P3HT/CdSe@ZnSe devices were 5.6 and 8 V, respectively (Fig. 2b), we chose to operate these two devices at a value of V_{GS} of 5 V for our subsequent time-response studies.

Fig. 3a displays the evolution of the normalized drain current for the P3HT/CdSe and P3HT/CdSe@ZnSe devices at values of V_{DS} and V_{GS} of −20 and 5 V, respectively, after they were subject to a light of 2.75 mW/cm^2 with a duration of 100 s. At the onset of illumination, the drain currents of both the P3HT/CdSe and P3HT/CdSe@ZnSe
Fig. 3. Time responses of the normalized drain currents of the P3HT/CdSe and P3HT/CdSe@ZnSe devices (V_{DS} = −20 V) illuminated by a light of 2.75 mW/cm^2 with a duration of 100 s at values of V_{GS} of (a) 5 and (c) 0 V. (b) Schematic representation of the relaxation processes within the bulk heterojunction P3HT/CdSe@ZnSe active layers in TFT devices. Red: slow decay process; blue: fast decay process. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

devices increased dramatically, and then dropped off to form plateaus when light is turned off. After the light had been turned off for 400 s, the drain current of the P3HT/CdSe@ZnSe device had decreased by 14%, compared with a corresponding loss of 60% for the P3HT/CdSe device. We suspect that the mechanism underlying this behaviors

involved two relaxation processes: (i) rapid decay corresponding to the recombination of closely spaced charge carriers and (ii) slow decay resulting from the recombination of well-separated carriers [27] (Fig. 3b). The slow decay might be manifested by the fact that, in a heterojunction device, the spatially separated holes and electrons will move differently-the holes drifting toward the channel and then reaching the drain electrode, the electrons mostly confined in the QDs and at the P3HT-SiO$_2$ interface. After the light was turned off, the devices existed in a non-equilibrium state; some of the photogenerated holes presumably recombined with some residual electrons that were not confined in QDs, causing a reduction in the drain current, eventually reaching a metastable state. Because the coverage of the CdSe QDs surfaces by TOPO was only ca. 55% [21], the ZnSe shell layer between the CdSe core and the P3HT polymer in the P3HT/CdSe@ZnSe devices resulted in an additional tunneling barrier that prevented the electrons from tunneling back to P3HT, leading to a smaller decrease in the drain current and a larger retention time relative to those of the CdSe QDs devices, as indicated by the slope of the drain currents at 600 s.

Because low power consumption is an important feature for non-volatile memory applications, it is preferable to operate optoelectronic memory devices in the absence of a gate voltage. Fig. 3c displays the evolution of the normalized drain currents at values of V_{DS} and V_{GS} of −20 and 0 V, respectively, for the devices subjected to a light of 2.75 mW/cm^2 with a duration of 100 s. After turning off the light, the P3HT/CdSe@ZnSe and P3HT/CdSe devices exhibited losses of 8 and 35%, respectively, of their ON state currents, with ON/OFF ratios of 36 and 1.5, respectively. Therefore, we conclude that Type-I heterojunction core/shell QDs are more suitable than homogenous QDs for memory applications both with and without applied gate voltages.

Fig. 4 presents TEM images of the CdSe and CdSe@ZnSe QDs dispersed in the P3HT matrix at a P3HT-to-QD weight ratio of 1:0.1. The bright appearance of the P3HT regions relative to dark QD regions in the contrast image was probably due to the large difference in their respective electron densities. The CdSe QDs were distributed rather homogenously in the P3HT matrix; we suspect that the lower homogeneity of the P3HT/CdSe@ZnSe film was due to a loss of TOPO coverage during the growth of the shell. The TEM images in the insets to Fig. 4 reveal that the CdSe and CdSe@ZnSe QDs had average sizes of ca. 2.9 and 4.3 nm, respectively. The ZnSe shell thickness was ca. 0.7 nm, i.e., slightly larger than the critical penetration length of electrons (ca. 0.5 nm) [21].

To determine the optimal operating conditions, we fabricated 10 devices from three independently prepared P3HT/CdSe@ZnSe films; the optimal ON/OFF ratio was greater than 1000 at a value of V_{GS} of 10 V. Fig. 5 reveals that the P3HT/CdSe@ZnSe devices exhibited a high ON/OFF ratio of 2700 at a value of V_{GS} of 10 V-without any noticeable decay after the light had been turned off for 8000 s. This result indicates that incorporating core/shell QDs into a conjugated polymer significantly extends the lifetime of the memory states of the resulting polymer TFTs. Moreover, the inset to Fig. 5 also displays the
Fig. 4. TEM images of (a) the CdSe QDs and (b) the CdSe@ZnSe QDs dispersed in the P3HT matrix Insets: TEM images of the CdSe and CdSe@ZnSe QDs (scale bar: 20 nm).
Fig. 5. Time response of the value of I_{DS} of the P3HT/CdSe@ZnSe device at V_{GS} = 10 V and V_{DS} = −20 V illuminated by a light of 2.75 mW/cm^2 with a duration of 100 s. Inset: Time response of the P3HT/CdSe@ZnSe device after a negative gate voltage pulse (V_{GS} = −10 V) was applied at 7000 s to erase the memory.

dynamic responses of the optical programming and electrical erasing of the P3HT/CdSe@ZnSe device. The ON state current could be erased effectively when using a single

pulse of the gate voltage (-10 V) for a short duration (1 s). When this negative pulse gate bias was applied, the Fermi level of CdSe and ZnSe modulated up towards the conduction band, thereby reducing the barrier height. As a result of the decrease in the barrier hight, electron jump back into the P3HT and recombine with hole. Thus, we suspect that the trapped electrons were induced by the electric field to move out of the QDs and recombine with the holes to reform the OFF state. Based on this protocol of operation, it was possible for us to program the P3HT/CdSe@ZnSe device optically and then erase it electrically.

4. Summary

In summary, we have examined the optoelectronic properties and memory effects of polymer TFTs incorporating P3HT/CdSe and P3HT/CdSe@ZnSe QDs as an active layer. After illumination, the presence of the quantum well-structured core/shell CdSe@ZnSe quantum dots in the P3HT film substantially enhanced the ON/OFF ratio to 2700, maintaining this value for 8000 s without noticeable decay. This fabrication approach opens up the possibility of improving the memory performance of polymeric materials prepared at low cost using simple processes.

to interface contact barrier [6,7] and irregular deposition or poor morphology of the semiconductor film around the already patterned source and drain contacts [8–10].

In an OTFT device, either one or both of the above described effects can be operational. Therefore, it is not only important to identify the dominant effect but also to understand the actual device operation mechanism for enhancing the device performance. The methods for investigating these mechanisms are based on experimental techniques such as potentiometry studies [10–14] and innovative device structures [15]. Potentiometry studies on an operating device are able to reveal the voltage drops around the source and drain electrodes that are cumulative of voltage drop due to the metal-semiconductor contact barrier and disordered region in the vicinity of the metal electrodes [10–14]. Alternative device structure like a combination of top and bottom contact configuration, as proposed by Yoshida et al. [15], is also an important experimental tool to describe the device operation mechanism.

Due to the complexity involved in the transistor operation, it is often difficult to identify the actual physical mechanisms that have significant impact on the device characteristics, solely by a simple analysis of the experimental data based on analytical models. These analytical models can predict the overall device behavior, but are often unable to identify the underlying microscopic behavior. In this respect, two-dimensional physics-based numerical simulation has proven to be of great help not only in understanding the detailed microscopic processes in the interior of the device, but also in enhancing the possibility of the investigations of those physical quantities that would otherwise be difficult to obtain [16–18]. Such examinations lead to the analysis of the cause of the non-ideal performance of the device behavior and its optimization towards obtaining the best electrical characteristics, for e.g. contact resistance [19–21]. Towards these goals, in this article, we build on the previous efforts by combining detailed device simulation with experiments to systematically identify the reasons for the large differ-

ence in device performance of top and bottom contact device structures. It is also our goal to obtain a calibrated standard and established simulation tool which can then be used to design devices further.

2. Experimental and device simulation procedure

2.1. Experimental procedure

A highly doped (1 0 0) n++ silicon wafer with 200 nm thick thermally grown oxide acts as a gate electrode for both top and bottom contact devices. A measurement of impedance of n++ Si/SiO_2/aluminum structure yields capacitance of the oxide gate dielectric $C_i = 1.65 \times 10^{-8}$ F cm^{-2}.

For bottom contact devices, the source and drain electrodes (Ti (5 nm)/Au (40 nm)) are defined through photolithography and lift off methods, while for top contact devices, gold electrodes are deposited through a shadow mask. The channel length (L) for both top and bottom contact devices is 30 μm and their widths (W) are 1 and 3.6 mm, respectively. Pentacene films with thicknesses of 50 nm are deposited by thermal evaporation at the rate of 0.03–0.04 nm/s at substrate temperature of 65 °C. The transistor characteristics were measured using a Keithley 4200 semiconductor characterization system.

2.2. Corrections to the measured data

In order to obtain a comparative nature of the device characteristics of the top and bottom contact device structures, we first made preliminary corrections on the measured transistor characteristics, which are based on the gate leakage and metal-semiconductor contact resistance. The method of correction for the gate leakage currents and metal-semiconductor contact resistance is described in the Sections 2.2.1 and 2.2.2, respectively. These corrections to the measured device data for both the top contact and bottom contact devices are shown in Fig. 1.
Fig. 1. Output curves for (a) top contact device and (b) bottom contact device. The 'symbol' represents the as-measured data and the 'line' represents the data corrected for gate leakage and contact resistance. The pentacene thickness is 50 nm and L = 30 μm.

2.2.1. Correction for the gate leakage currents

In the output curves, it was observed that for all the gate voltages, at $V_D = 0$, the drain current is not zero. The offset in drain current is attributed to the gate leakage currents, which are often substantial in OTFTs because OTFTs require a large gate field in order to induce enough charge to attain a reasonable conductance.

Zeitzoff et al. [22] and Shih et al. [23] demonstrated through physically based simulations, a correction to the device characteristics in the presence of gate leakage in MOSFETs having a thin or high dielectric constant insulator layer. They show that by following a common practice of accounting for the gate leakage current as having equal proportion from source and drain, the error can be reduced to 3–10% at high values of V_G. Therefore, at time of measuring transistor characteristics, we simultaneously measured gate and added half of the gate leakage current to the drain current at each gate voltage. In spite of the correction, we reason that we may still have 3–10% error in the corrected drain currents, especially at high gate voltages and low drain voltages. After correction, it was found that there is no drain offset and the drain current at zero drain voltage is zero. Additionally, there is an increase in the drain current by approximately 3% after correcting for the gate leakage currents.

2.2.2. Correction for the metal-semiconductor contact resistance

In order to correct the device characteristics for the metal-semiconductor contact resistance, we consider an equivalent circuit model for a transistor with additional source and drain contact resistances (R_s and R_D), respectively, as described in Refs. [3] and [24]. Due to the presence of contact resistances, the applied voltages (gate voltage V_G and drain voltage V_D) will not represent the actual drop in the channel, but are modulated due to the voltage drop across the contact resistances [3,24]. In such a case, assuming $R_s = R_D$, the drain current (I_D) corrected for the contact resistance are according to Refs. [3,24].

The total parasitic resistance, R_P, is sum of R_s and R_D. To estimate the R_P, the method of transmission line (TLM)

[3,25] is used Eq. (1), where R_{ON} ($=V_D/I_D$) at different V_G is estimated for several channel lengths. The intercept of the straight line fit of $R_{ON}W$ vs. L curve at $L = 0$ gives the value of R_P [3,25].

$$R_{ON} = \frac{V_D}{I_D} = \frac{L}{\mu W C_i (V_G - V_T)} + R_P$$

$$\text{or} \quad R_{ON}W = \frac{L}{\mu C_i (V_G - V_T)} + R_P W \tag{1}$$

where μ and V_T are mobility and threshold voltage, respectively. This data is represented in Fig. 2 for the top and bottom contact devices. Once, the total parasitic resistance is determined (half at both source and drain), it can be used to correct the drain currents to their equivalent values in a device with no metal-semiconductor contact resistance [3,24]. These curves are then used for further analysis, and also for comparison with simulations, in which the contacts are considered ohmic.

The contact resistance corrected field effect mobility and the threshold voltage for the OTFT can also be extracted by plotting the inverse of the slope of Eq. (1) at different gate voltages. The slope of the resultant plot thus determines the contact corrected mobility, while the x-axis intercept obtains the corrected threshold voltage.

2.2.3. Device simulation procedure

A two-dimensional device simulator ATLAS (Silvaco) is used for numerical simulations. The simulator predicts the electrical characteristics associated with a specified physical structure and bias conditions by solving systems of Poisson's equation and continuity equation which are a set of coupled, partial differential equations given for holes by Eqs. (2) and (3) below:

$$\varepsilon \nabla^2 \psi = -pq \tag{2}$$

$$\frac{\partial p}{\partial t} = \frac{1}{q} \nabla \cdot J_p + G_p - R_p \tag{3}$$

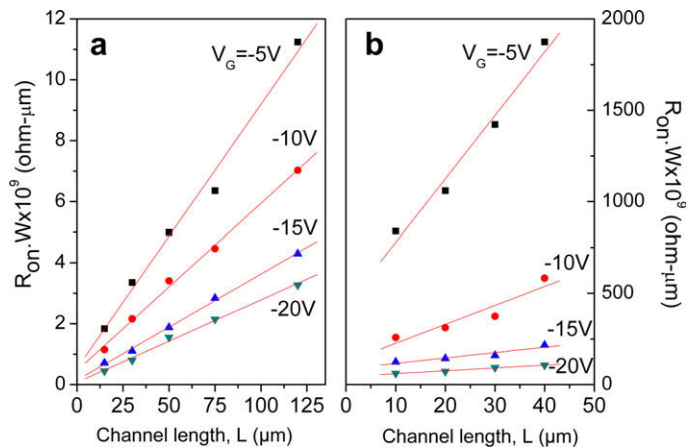
where ε is the dielectric constant, ψ is the potential, p is the local hole density, q is the fundamental electronic charge, G_p is the charge generation rate, R_p is the charge recombina-


Fig. 2. Plot of $R_{ON}W$ as a function of channel length for (a) top contact device and (b) bottom contact devices. The gate voltage is varied from −5 to −25 V in −5 V steps.

tion rate, and J_p is the current density which is given considering its drift and diffusion components by Eq. (4):

$$J_p = qp\mu_p F + qD_p\nabla p \tag{4}$$

where μ_p is the mobility of holes, F is the local electric field, and D_p is the hole diffusion coefficient. This simulator was primarily developed for silicon devices and, therefore, its applicability to organic materials is limited. However, the simulator can still predict the qualitative device characteristics correctly, as demonstrated by available literature [18,26–29] on simulation of organic devices.

The bandgap of pentacene is taken as an average of values reported in literature, 2.2 eV [30–35], electron affinity (E_A) as 2.8 eV [31–35], density of both conduction and valance band states as 2×10^{21} cm^{-3} [31–35] and dielectric constant as four [31–35]. The acceptor doping concentration is estimated according to procedure defined in Ref. [36] and taken as 3×10^{16} cm^{-3}; furthermore, even if the doping density is varied by two orders of magnitude, the transistor characteristics show only a minor change. The work function of the source, drain and gate metal is assumed to be 5.0 eV.

The simulation of the experimental output and transfer curves after correcting for gate leakage and contact resistance of the top contact devices was performed with the input parameters as described above. However, we observed a mismatch between the experimental and simulated curves. In the output curves, the experimental drain currents were lower than the simulated values at all the gate voltages, whereas in the transfer curves, experimental drain currents were lower than the simulated currents above the threshold voltage and higher in the sub-threshold region. Thus, additional simulation parameters related to traps were included to calibrate the simulation.

The mismatch between the experimental and simulated curves could at first be attributed to the difference in the measured threshold voltages and those extracted from the simulated curves. The threshold voltage for the simulated curves was 0.8 V, whereas the experimentally obtained value is -3.2 V. This, difference in threshold voltage can be removed by including a positive interface charge of approximately $q \times 3 \times 10^{11}$ C-cm^{-2} (q is charge of an electron) at insulator/pentacene interface. The match above the threshold region is nearly perfect with the above mentioned fixed charge, but in the sub-threshold region of the transfer curves, the experimental drain currents are still higher than that simulated. This discrepancy is subsequently resolved by including interface acceptor traps of the concentration 2×10^{12} cm^{-2} eV^{-1} at an energy level of 0.52 eV from the valence band edge.

With these set of calibration data, the simulator predicts the electrical behavior of a top contact device. With this as the basis of simulations, the paper then discusses additional features that need to be incorporated to calibrate a bottom contact device.

3. Results and discussion

We begin by comparing device characteristics in the top and bottom contact configurations, fabricated and measured according to method described in Section 2.2. In both cases, the gate is at the bottom and the two configurations differ in the order the semiconductor and the source/drain contacts are placed on the gate/insulator substrate. For comparison, the dotted curves in Fig. 1 depict the as measured output characteristics of (a) top and (b) bottom contact device at various gate voltages (V_G); the channel length (L) is 30 μm and pentacene thickness is 50 nm in these devices. Clearly, the drain currents per unit width in top contact devices are higher, for example at $V_G = -20$ V, by two orders of magnitudes as compared to bottom contact devices. This difference is further characterized by extraction of field effect mobility from detailed output and transfer curves.

From the as measured curves, the extracted field effect mobility for top and bottom contact devices are 0.125 cm^2/Vs and 1.74×10^{-3} cm^2/Vs, respectively, in the saturation region. Similarly, in the linear region, we determined the hole mobility for top and bottom contact devices as 0.085 cm^2/Vs and 1.44×10^{-3} cm^2/Vs, respectively. From these measurements, whether based on linear or saturation region, the field effect mobility measured in the top contact configuration is significantly greater than that in bottom contact device. In addition, the mobilities extracted from the saturation region in either configurations, top or bottom, is slightly greater than that in the linear region.

First we examine the cause of difference in mobilities extracted from linear and saturation region, and then focus on the reasons for differences in the top and bottom contact devices. These differences could first be ascribed to the gate leakage and, especially, contact resistance, which are important in the linear region. Therefore, both these corrections to the measured data are made according to the method described in Section 2.2, after which the mobilities are again extracted. The metal-semiconductor contact resistance (R_p) value at a gate voltage is extracted from the $R_{ON}W$ vs. L plot, (as described in Section 2.2), and is shown in Fig. 2a and b for the top and the bottom contact devices, respectively.

The corrected output characteristics, at a gate voltage for both device configurations are also included in Fig. 1, as solid lines. Following this correction, the mobility of holes from the linear region, and corresponding threshold voltage of the device is also estimated according to the method defined in Section 2.2. This correction yields an effective mobility of 0.14 cm^2/Vs and 3.2×10^{-3} cm^2/Vs for the top and bottom contact devices, respectively, and the corresponding V_T are -3.2 V and -8.5 V. Hence, after correction, the hole mobilities are similar from both saturation and linear region, but still the mobility in bottom contact configuration is poor in comparison to that in top contact configuration.

Since the corrected mobility value of the bottom contact devices does not increase significantly, it suggests that the contact resistance is not the only reason for the deterioration of the mobility in bottom contact configuration. We therefore investigate the difference in mobilities in the two geometries by simulating the impact of possible structural differences on transistor characteristics.

3.1. Simulation of top and bottom contact devices under normal conditions

A top contact device differs from a bottom contact device in that in the former, source/drain current passes through the thickness of the semiconductor (although very thin in comparison to the channel length) and that the bulk conduction could be slightly higher. In order to identify the possible variations in the device characteristics due to the device configuration in top and bottom contact devices, we simulated the device characteristics in both the structures with identical pentacene thickness and material parameters, according to details in Section 2.2. Corresponding to the case of channel length as 30 μm, pentacene thickness as 50 nm and hole mobility in pentacene as 0.14 cm^2/Vs (the same as that extracted for the top contact device), the output characteristics of the top and bottom contact devices are simulated. As expected, the output curves of top and bottom contact devices overlay on each other, implying that neither the current flow through the thickness of pentacene nor bulk current can justify lower effective field effect mobility in bottom contact configuration.

Effectively, the simulation clarifies that the device structure by itself is not a major factor for the lower mobility of the bottom contact devices. The other factors which may be responsible for the observed differences could depend upon the differences in the manner that two devices are fabricated.

3.2. Effect of unfilled region at the edges near the source and drain contacts

In the bottom contact devices, source and drain contacts are deposited first and then the pentacene layer is deposited. In this case, it is possible that a shadow cast by metal during evaporation of pentacene could lead to unfilled corners at the source/drain contacts, which in turn could result in lower effective device mobility. We modelled this possibility in our simulations by introducing a vacuum layer of 50 nm × 45 nm at the edge near the source and drain contacts, as illustrated in Fig. 3a for a bottom contact configuration. The mobility of the pentacene is taken as 0.14 cm^2/Vs, which is equal to the corrected mobility value of the top contact devices. This attempt is made in order to find out whether the introduction of the vacuum layer in bottom contact devices would lead to a lower effective device mobility in the simulated transistor characteristics than the top contact devices.

Fig. 3b illustrates that the simulated drain currents in the bottom contact device with the unfilled region and without the unfilled region at the source and drain contact edges are only slightly different. It is clear that the drain currents simulated on the assumption of unfilled region at the contact edges cannot match with the experimental curves, which are also depicted in Fig. 3b (dotted line).

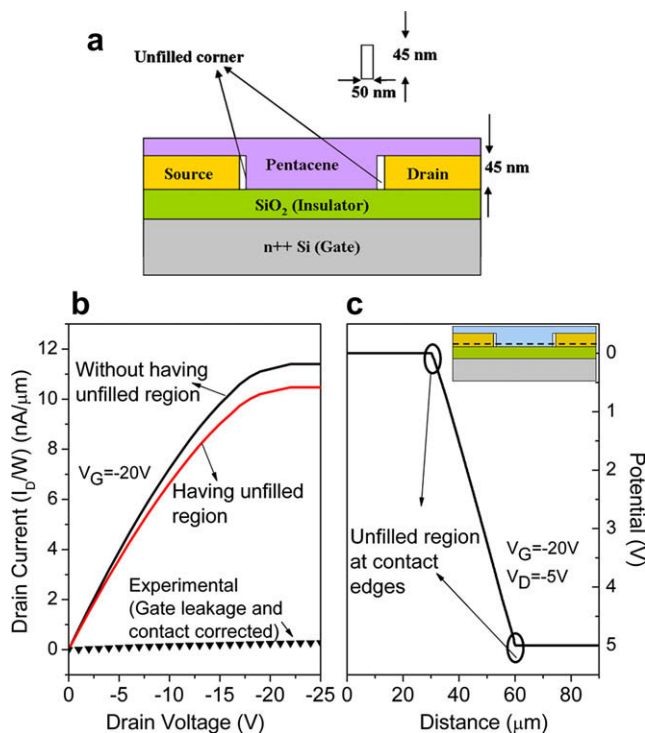
In order to gain insight into device operation of this device, we study the current flowlines in the pentacene


Fig. 3. (a) Schematic diagram of the bottom contact device showing unfilled region of 50 nm × 45 nm near the source and drain contact edges. The thickness of the source and drain contacts is 45 nm, (b) comparison of the output curves of bottom contact devices with and without having the unfilled region at the source and drain contact edges at $V_G = -20$ V and (c) potential profiles above source and drain contacts for different mobilities of the low-mobility-region at $V_G = -20$ V, $V_D = -5$ V. Source, drain and channel lie between 0–30 μm, 60–90 μm and 30–60 μm, respectively. (The pentacene thickness is 50 nm and $L = 30$ μm. The mobility of the rest of the pentacene is taken as 0.14 cm^2/Vs.)

film for the device without the unfilled region (Fig. 4a) and with (Fig. 4b) the unfilled region near the contact edges at the gate voltage of −20 V and drain voltage of −5 V. As expected, for a device with no unfilled region adjacent to source and drain (Fig. 4a), the current between source and drain is confined in few tens of nanometers above the dielectric. The remaining portion of the source and drain contacts are inconsequential in current injection. However, when an unfilled region of size 45 nm × 50 nm (as in Fig. 3a) is introduced in the same device, no longer can current be injected from the sides of the metal contact. In this case, as shown in Fig. 4b, on the introduction of the unfilled region at contact edges, the current starts injecting/extracting from the top surface of the source/drain contacts. An expanded view in Fig. 4c illustrates that the current injected from the top surface of the source contact traverses through the pentacene film adjacent to the unfilled region, reaches the insulator interface and then is extracted from the top surface of the drain electrode (see Fig. 4d). In their study of surface potential profile in the bottom contact devices, Li et al. [20] also studied a similar case where they modelled the region adjacent to the contacts as low-mobility-region and observed that injection/extraction process involves top surface of the contacts.

The injection/extraction process causes a small potential drop across the unfilled region, which is depicted through a potential profile across the channel region, taken 1 nm above the dielectric interface (represented through a dashed horizontal line in the inset of Fig. 3c). Across this horizontal line, source lies between 0–30 μm and the drain lies between 60–90 μm, and the pentacene film lies between 30–60 μm. Due to the involvement of top surface of the contacts, there is a small decrease in the drain current for the device having the unfilled region, unlike the case without having the unfilled region, where the injection/extraction takes place only from a very thin region of the contacts adjacent to the insulator (Fig. 4a).

Based on the above results, it is clear that the unfilled region at the source and drain contact edge cannot explain the large difference in the behavior of top and bottom contact devices. Therefore, as another possibility, we study the effect of pentacene morphology around the source and drain contacts to further examine the cause for inferior performance of bottom contact devices.

3.3. Effect of pentacene morphology at the contact edge and on source/drain contacts

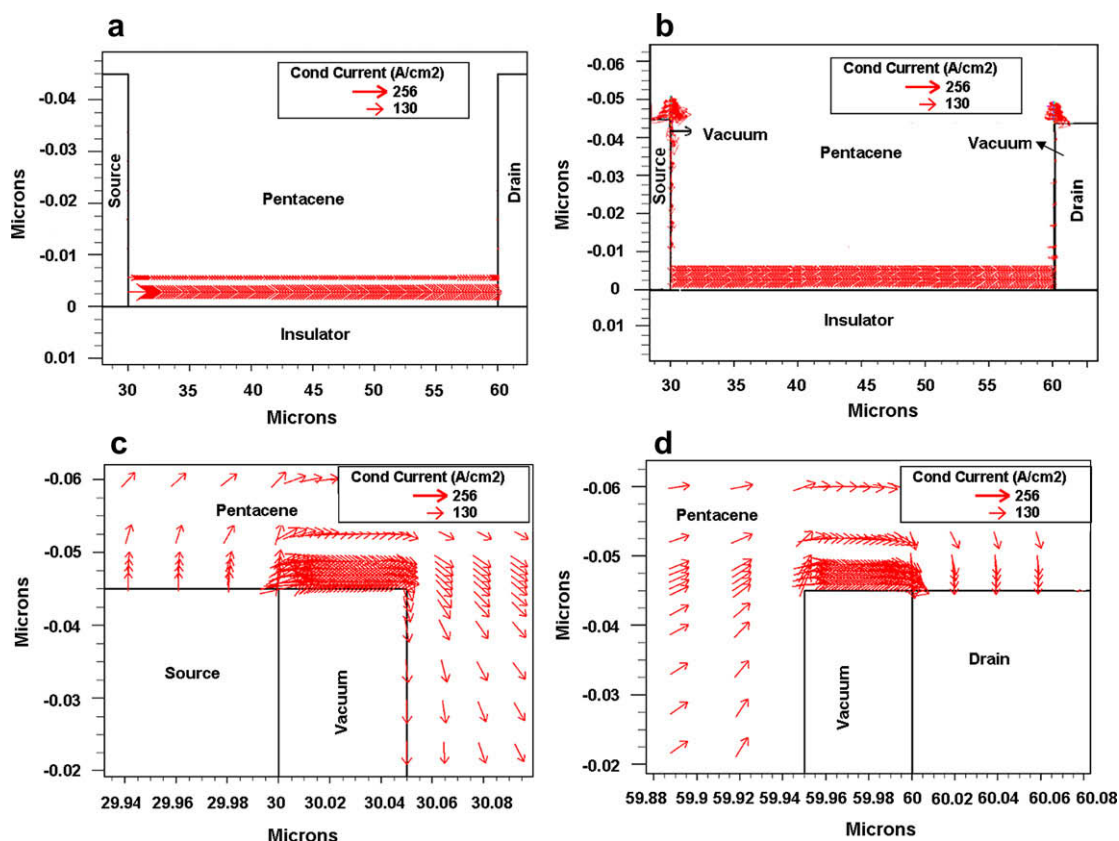
In the top contact devices, the pentacene film is deposited on the dielectric layer, whereas, in the bottom contact device, since contacts are made first, a part of pentacene film deposits on the contact metal. Therefore,


Fig. 4. Schematic diagram for the current flow path in pentacene film in a bottom contact device (a) without an unfilled corner adjacent to the source and drain contacts and (b) with an unfilled corner adjacent to the source and drain contacts. Expanded view of the current flow path in pentacene film with an unfilled region (modelled as vacuum layer) adjacent to (c) the source contact and (d) the drain contact.
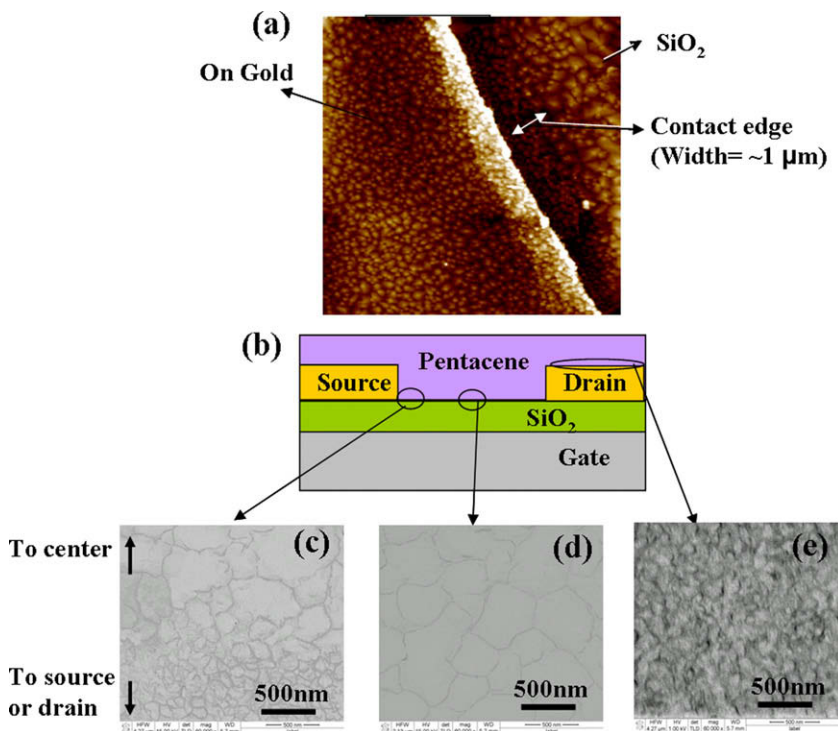

Fig. 5. (a) Atomic force micrograph of pentacene on gold and SiO₂ (Image size = 6 μm × 6 μm), (b) schematic of the bottom contact device showing different region of pentacene morphology. Scanning electron micrograph of pentacene on gold contact (c) near gold contact edge on SiO₂, (d) far away from gold contact edge on SiO₂ and (e) on gold contacts.

the morphology of pentacene film in the vicinity of metal in the bottom contact devices could be different.

Fig. 5 contains the image of pentacene film deposited in a bottom contact geometry, and the different regions are pictorially represented in Fig. 5b. Based on atomic force microscopy (AFM) (Fig. 5a) and scanning electron microscopy (SEM) (Fig. 5c–e) images, change in the morphology of pentacene film (50 nm thick) on gold and SiO₂ can be clearly seen. Fig. 5a, which is an AFM image near the step caused by gold contacts, clearly shows two distinct regions. The grain size adjacent to the gold contact is comparatively smaller than the grain size in the channel region away from the contact. This is further illustrated by SEM images of pentacene film in the channel region near metal contact (Fig. 5c; notice the orientation of the image), in the middle of the channel (Fig. 5d), and on gold contacts (Fig. 5e). The micrographs depict a marked change in the morphology of pentacene film grown in the three regions. The large grain structure far away from the source/drain contact edges changes into a small grain structure as one move closer to the edge of the channel, near the gold electrodes. On SiO₂, the average grain size is 0.57 μm and on the source and drain contacts, the grain size is 0.15 μm. As represented in Fig. 5a, the effect of the gold contact in reducing the grain size permeates upto a distance of 1.0 μm.

The reason for the different morphology is attributed to the difference in surface energies of metal and dielectric layers [8,9,37]. When pentacene is deposited on a metal surface, the back bone of the pentacene molecule is at-

tracted to the metal leading to a lying down configuration of pentacene molecules. While on SiO₂, low surface energy causes the pentcene molecules to stand vertically. Near the source/drain contact edges, pentacene molecules tend to have both lying down and standing mode leading to poor packing and poor molecular ordering [8,9,37].

In order to understand the consequences of morphological differences in device characteristics, we modelled this small grain size region by assigning it a lower mobility value as compared to rest of the pentacene. Fig. 6a is a schematic diagram illustrating this low-mobility-region near the source and drain contact edges and above the contacts in a bottom contact device. The width of this low-mobility-region on the insulator is 1 μm, as determined from Fig. 5a. Fig. 6b depicts the output curves (at $V_G = -20$ V) as a function of the various low values of mobility in this region. The bulk mobility value of the remaining pentacene is taken as 0.14 cm²/Vs, as before. It is clear from Fig. 6b that the drain current decreases in proportion to the reduction in mobility of the low-mobility-region. The combined effect of bulk mobility as 0.14 cm²/Vs and this low-mobility-region on the effective device mobility value extracted from output characteristics is illustrated in Fig. 6c. From Fig. 6c, it is observed that the extracted device mobility in the saturation region forms almost a linear relationship with the mobility value of the low-mobility-region.

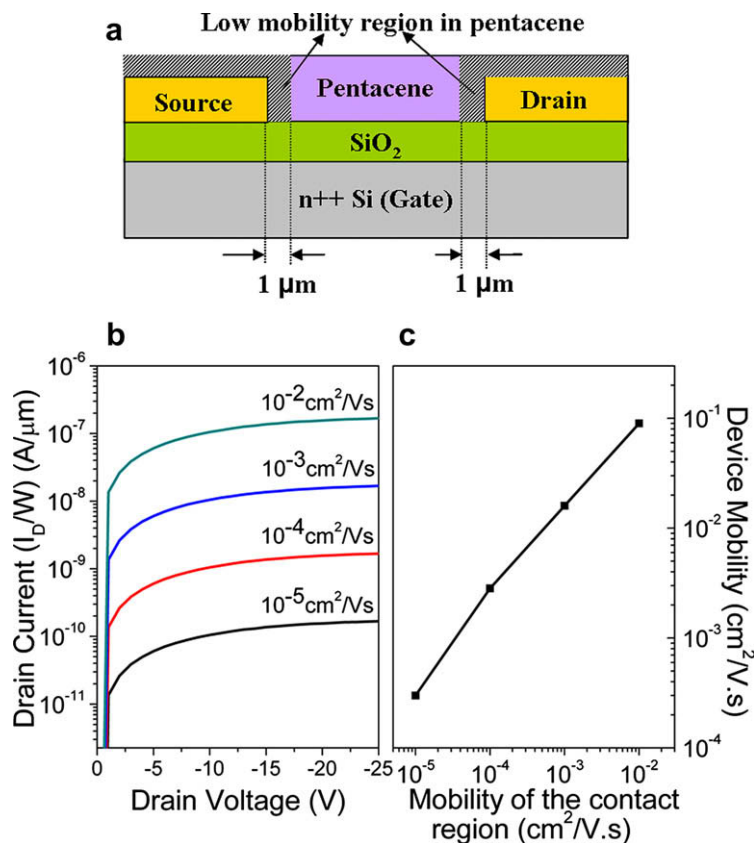
The reason for such a behavior could again be understood by examining the charge injection/extraction process. In Fig. 4b, introducing an unfilled region forced the current injection from the top of the contact (and similarly


Fig. 6. (a) Schematic of the 1 μm wide low-mobility-region near the source and drain contact edges and above the contacts in bottom contact devices, (b) output curves plotted for different mobility values of the low-mobility-region adjacent to and above the source and drain contacts and (c) extracted mobility of the device for different mobility values of the low-mobility-region adjacent to and above the source and drain contacts. (The pentacene thickness is 50 nm and $L = 30$ μm. The mobility of the rest of the pentacene is taken as 0.14 cm²/Vs).
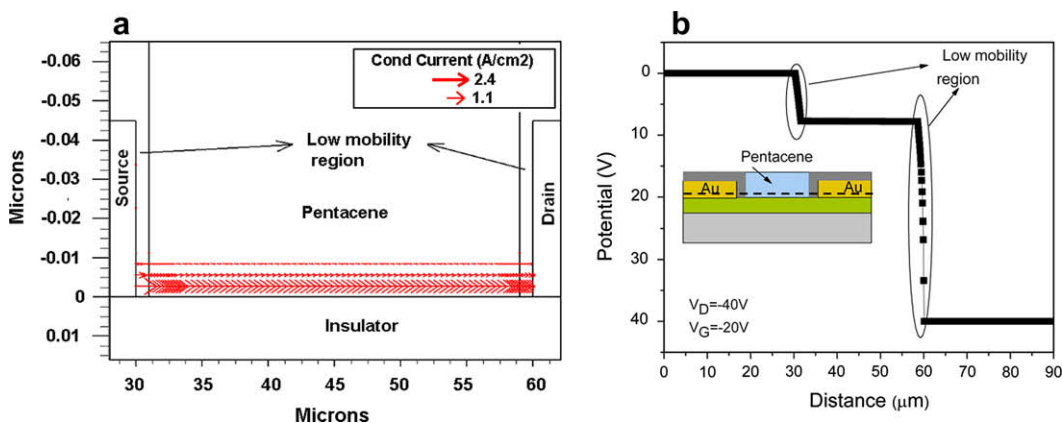

Fig. 7. (a) Schematic diagram for the path of the current flow in pentacene film (line with the arrow) in a bottom contact device having a low-mobility-region adjacent to and above the source and drain contacts and (b) surface potential profile 1 nm above the dielectric surface (source, drain and channel lie between 0–30 μm, 60–90 μm and 30–60 μm, respectively). The mobility of low-mobility-region is 1×10^{-4} cm²/Vs at $V_G = -40$ V and $V_D = -20$ V. (The pentacene thickness is 50 nm and $L = 30$ μm. The mobility of the rest of the pentacene is taken as 0.14 cm²/Vs.)

for the current collection at the drain). However, on introducing a low-mobility-region all around the metal contact forces the current injection and extraction again to the lower region of metal contacts (within 5 nm region from the insulator), as illustrated in Fig. 7a, forcing the current to pass through the low-mobility-region. Due to this, a large potential drop is expected to take place in the low-mobility-region at the contact edges.

Fig. 7b shows the potential profile between the source and drain contacts at 1 nm above the dielectric interface (along a horizontal dashed line in the inset of Fig. 7b), for the mobility value of the low-mobility-region as 1×10^{-4} cm^2/Vs. Clearly, almost all the applied potential is accommodated in the low-mobility-region at the contact edge, forcing its effect on the overall device characteristics. As a result, the apparent field effect mobility value is much lower compared to the bulk mobility value of 0.14 cm^2/Vs. The apparent mobility values are in fact very close to the mobility value of the contact edge, which shows that this region becomes dominant in determining the overall device characteristics. Also, the voltage drop near the drain is much higher than that at the source, which is reflective of the depletion region near the drain in the saturation region. The reports on surface potential studies in the bottom contact devices through Kelvin probe force microscopy or electrostatic force microscopy revealed a large potential drop near the source and drain contacts, attributed to poor morphology of pentacene near the metal contact edges [10–14]. These simulations further confirm this phenomenon, emphasizing the importance of the morphology of the pentacene films near the contact edges and on the source and drain contacts. Improvement of the morphology of pentacene at the contact edges by the surface treatments or by using polymer electrodes could significantly increase the device mobility values [9,37,38]. In short, based on these simulations, we determine that the possible cause of differences observed in bottom and top contact devices could be due to differences in pentacene morphology leading to low-mobility-regions near the contacts.

3.4. Low-mobility-region in the top contact devices

In a top contact device, since the pentacene is deposited first, its morphology in the channel region is not expected
Fig. 8. Schematic diagram for the path of the current flow in pentacene film (line with the arrow) in a top contact device having a low-mobility-region under the source and drain contacts.
Fig. 9. Comparison of the experimental (gate leakage and contact corrected) and the simulated (a) output and (b) transfer curves. The mobility of the low-mobility-region is 1.5×10^{-4} cm^2/Vs and bulk mobility of pentacene is 0.14 cm^2/Vs. Pentacene thickness is 50 nm and L = 30 μm.

to be different from the contact region. However, due to metal diffusion into the pentacene may reorganize the morphology of pentacene under the contact which in turn causes the mobility of pentacene below the electrodes to be lower than the bulk mobility [39,40]. Therefore, to make a comparison with the bottom contact devices, we also evaluated the effect of the low-mobility-region under the source and drain contacts in the top contact devices. As an extreme case, a low-mobility-region, with mobility value of 1×10^{-3} cm^2/Vs, is located across the full thickness of pentacene. Still, we do not observe any significant change in the device behavior between with or without low-mobility-layer cases. The reason for this can be understood from Fig. 8 illustrating the current flow path in a top contact device. In this case the charge is injected from the side/corner of the contacts, bypassing the low-mobility-region (Fig. 8). Thus top contact devices would be less susceptible to morphological variations caused by the presence of metal.

3.5. Comparison with the experimental device behavior

On the basis of the above discussion, we determine that the cause of the low mobility of the bottom contact devices in comparison to top contact devices is due to the poor morphology/domain structure of pentacene at contact edges and on gold source and drain contacts. While the bulk mobility of holes in pentacene may be 0.14 cm^2/Vs, we determine that introducing a low-mobility-region of mobility value 1.5×10^{-4} cm^2/Vs in the bottom contact devices yields a good comparison with the measured data, as shown in Fig. 9a (output curves) and Fig. 9b (transfer curves).

4. Conclusions

The difference in the drain currents and mobility values of the top and bottom contact devices is not inherent to the device configuration, but is a result of the manner in which bottom contact devices are fabricated. The pentacene film near the source/drain contact edges and on the contacts exhibits poor morphology as compared to the film far away from the contacts. This region is modelled as a low-mobility-region with a mobility value of 1.5×10^{-4} cm^2/Vs as compared to the mobility value of 0.14 cm^2/Vs for the rest of pentacene film. The low-mobility-region incurs most of the potential drop due to which the extracted mobility from the bottom contact devices becomes significantly lower than the top contact devices. A reasonable matching of the experimental curves with the simulated curves is obtained on substituting the above described mobility values in the bottom contact devices.

Also, first calibration of simulator was achieved for a top contact device (details in Section 2). Finally, by including special considerations of low-mobility-regions in a bottom contact device, the simulation tool is further calibrated for use in design of devices.

junctions consisting of PEDOT:PSS and InZnO have been rarely reported so far. In this research, we investigated the *I–V* characteristics of ITO/PEDOT:PSS/InZnO devices for two sets of samples. The first set is composed of PEDOT:PSS as-prepared, while the second set is composed of PEDOT:PSS irradiated by UV light source. Following that, the electronic, structure, and morphological changes of the PEDOT:PSS films were analyzed using ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM). The effect of storage on the electrical properties of the fabricated devices is also reported.

2. Experiment

The substrates used for the fabrication of the devices were 2×2 cm^2 glass plates coated with 100 nm layer of indium tin oxide (ITO). The substrates were cleaned following standard procedure. Next, a 300 nm thick PEDOT:PSS layer was then deposited by multiple spin-coating. After each spin-coating, the PEDOT:PSS layer was baked at 130 °C for 10 min in air. PEDOT:PSS (Baytron P AI 4083) was purchased from Starck. In our experiment, two sets of four samples each were prepared in the same way. In the first set, PEDOT:PSS films on glass substrates were irradiated for 10 min by UV light source (output power density of 4 W/cm^2) with emission centered at 355 nm (referred to as: UV-exposed devices). The second set of samples is composed of PEDOT:PSS on glass substrates without UV irradiation (referred to as: un-exposed devices). The InZnO thin films (80 nm) fabricated by rf magnetron sputtering at room temperature were deposited on top of PEDOT:PSS through a shadow mask. The active area of the devices is about 16 mm^2. The final structure of the device is shown in Fig. 1. The current–voltage characteristics of the fabricated devices were measured by an Agilent 4156C semiconductor parameter analyzer in laboratory atmosphere at room temperature and under dark condition. After the first measurements, the samples were stored in normal laboratory environment in a Vacuum Desiccator. All the measurements were repeated on the stored samples after 30 days. We used a monochromatic Al Kα source (1486.6 eV) for XPS analysis. The binding energy was calibrated with the core-level spectrum of Au 4f. UPS spectra were obtained, using HeI radiation (40.8 eV) from a He-resonance lamp. Surface morphology was investigated by AFM (Model SPI-3800, SII).
3. Results and discussion

The *I–V* characteristics of UV-exposed and un-exposed devices are shown in Fig. 2. Each curve represents the average value of four samples. The *I–V* characteristics of un-exposed devices are shown in Fig. 2a and that of UV-exposed devices are shown in Fig. 2b. Also shown in the figures are the *I–V* characteristics measured after 30 days on the same samples. It can be seen from Fig. 2a that the *I–V* characteristics of the un-exposed devices show asymmetrical nonlinear behavior. The current does not show any linear dependence with voltage even in the low voltage region (see inset). In the case of UV-exposed devices, a linear region is seen at low voltages (see inset) indicating an ohmic conduction mechanism. This implies that the work function of PEDOT:PSS (4.8–5.3 eV [14]) is close to that of InZnO electrode (5.2 eV [15]).

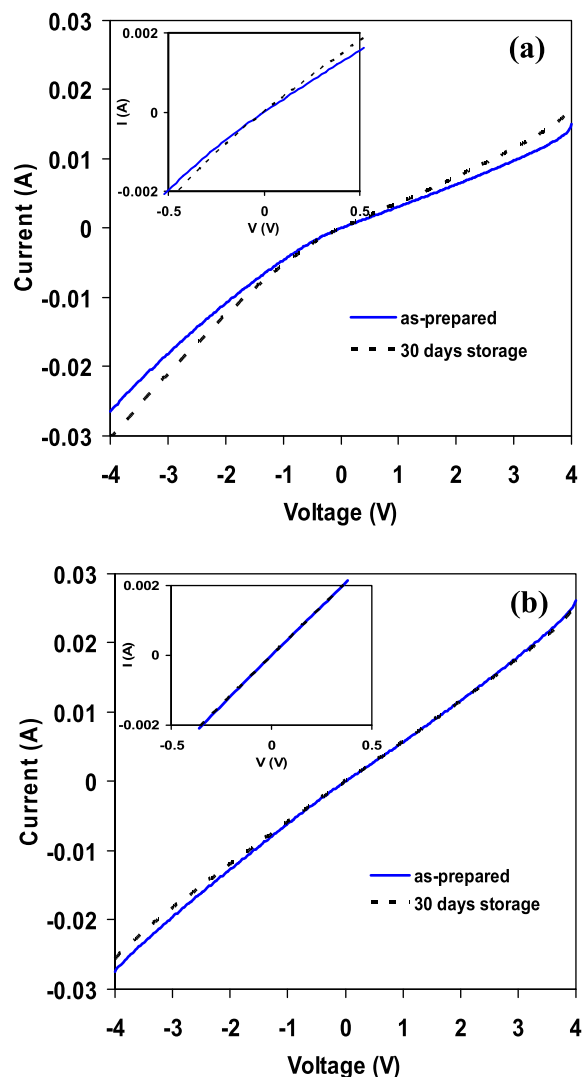
Fig. 1. Schematic representation of the device structure.


Fig. 2. Current–voltage characteristics for as-prepared and stored samples: (a) un-exposed devices and (b) UV-exposed devices.

The *I–V* characteristics measured after one month of storage show no significant degradation of the devices, which demonstrates the excellent stability of these organic/metal junctions. The excellent stability is most likely due to the storage in the Vacuum Desiccator, which prevents interaction of the environment and because of PEDOT:PSS is an air-stable material [16]. We see a slight deviation between the measured data before and after storage, this deviation is more pronounced in the case of un-exposed devices as it appears in Fig. 2a. However, it is difficult to draw firm conclusions regarding the observed results, because we were able to find some samples (before averaging) with excellent reproducibility (not shown here). An additional factor that can affect the durability of organic/metal contact is the degradation of the metal electrodes. This degradation appears mainly after the first measurement [17] or after performing several consecutive sweeps in the forward and backward direction [18]. Fig. 3 shows the *I–V* measurements of UV-exposed devices taken from 20 consecutive forward and backward sweeps. Identical *I–V* responses are obtained, the data points fall on top of each other, showing that there is no sign of deterioration after consecutive sweeps. We performed the sweeps between ±2 V in order to verify the stability of the electrodes and prevent the degradation of our devices for further studies.

Fig. 4 shows the *I–V* characteristics of the samples with and without UV treatment superimposed on the same axes. The un-exposed film was more electrically resistive than the exposed one. In the case of UV-exposed devices, the *I–V* characteristics exhibit better response than that obtained with un-exposed devices. In the forward bias, the magnitude of the current at any voltage was higher and the devices show a linear *I–V* behavior. The plot is linear over a potential range of approximately 8 V. It is well known that local joule heating reduces the contact resistance between conducting polymer and metal electrodes.

Fig. 4. Comparison of *I–V* characteristics of UV-exposed and un-exposed devices.

Since Joule heating occurs at the interface region during electrical measurement, both the physical and chemical properties of the interface region could be altered. Our devices based on PEDOT:PSS/InZnO contact did not show any thermal degradation due to current injection during operation. After several sweeps (Fig. 3) and within the applied voltage range, current performance without noticeable degradation is notable. We found no evidence for significant Joule heating in our devices, which indicates good thermal contact between the thin polymer film and metal electrode. We suggest that the linear *I–V* curve obtained with UV-exposed devices is mainly due to the changes in the work function of PEDOT:PSS layer induced by UV irradiation.

We employed XPS and UPS to determine the origin of the conductivity enhancement. The changes in work function of PEDOT:PSS films with and without UV treatment are obtained from UPS (Table 1). The work function of as-prepared film was 4.89 eV and that of UV-treated film was 5.07 eV. The XPS spectra for S2p and O1s with curve fitting results obtained on samples with and without UV treatment are shown in Figs. 5 and 6, respectively. For S2p, four peaks were clearly resolved. Curve fitting analysis shows that the lower binding energy peaks at 164.3 and 165.7 eV correspond to the sulfur atom of PEDOT. The two decomposed peaks at 169.5 and 168.5 eV are due to neutral and ionic sulfur in the PSS dopant [19,20]. The S2p doublet, which could not be resolved in these mea-

surements, was fitted by a single peak. For O1s, two peaks were resolved. A shoulder at 533.3 eV with high binding energy corresponding to the oxygen atoms of the PEDOT chain, and a strong peak at 531.7 eV with lower binding energy arising from the SO_3H and SO_3Na units of the PSS chains [21]. The chemical composition of PEDOT:PSS surface was calculated based on the core level peak areas and their relative sensitivity factors. The results are shown in Table 1. As is evident from the spectra of S2p and O1s and the films composition analysis (Table 1), the UV treatment does not induce any significant changes in the core level features of PEDOT:PSS films. However, we found that the binding energies of all core levels have been shifted to lower binding energies. The binding energy of sulfur, oxygen and carbon (not shown here) shifted by 0.9, 0.4 and 0.7 eV, respectively. This suggests that the change in work function is not primarily due to chemical changes in the films. Instead, we suggest that the reason for this change is to be found in morphological changes induced by the UV irradiation. In order to see the differences of morphologies of our samples, we investigated the AFM images of

as-prepared and UV-treated films. From the AFM images of both samples, we could not find significant difference on surface morphology except slight reduction in degree of surface roughness (Table 2). Reduced root mean square (RMS) surface roughness and the increase of electrical conductivity of the film by UV treatment support the conformational change of PEDOT:PSS films observed by Lee et al. [4]. Such changes in surface structure most probably change the surface dipole structure and thereby influence the measured binding energies [22]. The trend in device performance could be explained by the observed changes in the work function of the PEDOT:PSS layer.

In order to examine if InZnO electrode played a role in the improved stability of our devices, a set of ITO/PEDOT:PSS/Al samples were fabricated in the same conditions and tested. The *I–V* curves of ITO/PEDOT:PSS/Al are shown in Fig. 7. When ITO and Al are used as anode and cathode, respectively, the *I–V* characteristics change, becoming asymmetric with a rectification value around 20 at 1.5 V. The difference in the work function values (in vacuum) of the Al electrode (∼4.3 eV [23]) and PEDOT:PSS introduces

Table 2
RMS roughness, average roughness, and mean height of as-prepared and UV-treated samples measured by AFM.

Sample	RMS (nm)	Average roughness (nm)	Mean height (nm)
As-prepared	2.46	1.97	20.04
UV-treated	2.15	1.80	14.20

Fig. 8. AFM images of Al and InZnO electrodes: (a) before application of voltage and (b) after application of voltage.

a built-in potential that can be seen in the I–V characteristics of ITO/PEDOT:PSS/Al, where at low forward bias the intrinsic field is opposing the charge injection until around 0.75 V. After the first sweep, the current gradually decreased, indicating that the Al electrode was immediately deteriorated. The overall current values have decreased by almost 300% causing a reduction in the rectification ratio. AFM was used to investigate the electrodes before and after voltage application. A smooth and defect-free surface was observed for the un-operated Al-electrode (Fig. 8a). After bias application, some blisters were seen on the Al contact over the active area of the device (Fig. 8b). It is well known that poly(4-styrenesulfonate) (PSS) of PEDOT:PSS has strong acidic characteristics and can be corrosive to the electrode. Thus, the Al electrode damage under voltage might be due to the highly acidic property of the PSS. The InZnO electrode does not show any blisters even after applying high voltage and repeated measurements (Fig. 8b). For the operated InZnO electrode surface, a smooth and crack-free layer is observed. The InZnO films before and after voltage application show a RMS roughness of 4.95 and 1.43 nm, respectively. The improvement of surface morphology of operated InZnO electrode may be due to the chemical interaction between PEDOT:PSS and InZnO under voltage, or the trapped moisture during measurement gets electrolyzed as the bias is applied and the gases are released causing the change in the surface morphology of InZnO film.

4. Summary

The effects of UV irradiation on the work function of PEDOT:PSS films have been investigated in this study. Based on the UPS, XPS, and AFM measurements, it was found that UV irradiation leads to an increase in the work function and the enhancement of electrical conductivity of PEDOT:PSS films, resulting from the morphological change in the polymer chain of PEDOT:PSS. The UV-exposed devices show an ohmic contact over a large potential range. We also studied the effect of storage on the electrical properties of ITO/PEDOT:PSS/InZnO devices. No significant changes of electrical characteristics have been found after storing the devices for a period of 30 days. AFM investigations show no blistering of InZnO contacts in devices on application of voltage. InZnO contacts may provide a good solution to develop reliable and low resistance ohmic contacts.

tional buffer layer or poly (ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS) being considered to have several latent issues such as chemical reaction with ITO anodes [9,10] efforts to replace PEDOT:PSS with metal-oxide semiconductors are currently receiving an increased attention. In the area of organic light-emitting diodes (OLED), which already perceived the beneficial role of these metal-oxide semiconductors as buffer layers or as part of multilayer electrodes, tungsten oxides (WO_3) have also been recognized as important buffer layers with a good hole-injecting property [11–13]. In spite of its significance in OLEDs, its application as an anodic buffer layer in organic solar cells was relatively limited. Chan et al. [14] used WO_3 as an anodic buffer on ITO in vacuum-deposited copper phthalocyanine (CuPc)/C_{60} solar cells, and Janssen et al. [15] used it as a part of intermediate electrode in their hybrid tandem cells consisting of BHJ bottom cells and CuPc/C_{60} top cells in which WO_3 functioned also as a buffer for CuPc/C_{60} cells. Recently Tao et al. [16], have employed WO_3 as a buffer layer in solution-processed P3HT:PCBM BHJ cells, but their devices were in so-called inverted geometry where WO_3 layer is grown on top of P3HT:PCBM films. It is noted that the fact that a buffer layer works in vacuum-deposited cells or in inverted-geometry BHJ cells does not necessarily mean it will work also in bulk-heterojunction (BHJ) cells of conventional geometry in which active layers are deposited on top of the buffer by solution processing, (i) because the fabrication compatibility is not always guaranteed and, moreover, (ii) because its presence can influence the properties of BHJ active layers such as molecular ordering and phase separation, all of which carry important implications for operation of BHJ cells. In this work, we explore thermally-evaporated WO_3 layer as an anodic buffer in the popular P3HT:PCBM-60 BHJ cells in their conventional non-inverted geometry with a special attention paid to the film properties of thermally-evaporated WO_3 layers in context of their effect on the properties of BHJ active layers as well as device performance.

2. Experimental

Thin films of WO_3 (Alfa Aesar) were thermally evaporated in high vacuum (2×10^{-6} Torr) onto ITO films on glass substrates or onto 30 nm-thick PEDOT:PSS layers (Baytron P AI 4083, H.C. Starck, Inc.) spun on those ITO films.

After deposition of WO_3 layers, samples were transferred to a nitrogen-filled glove box, where the BHJ layers were spin-coated at 700 rpm for 60 s from a solution of P3HT:PCBM-60 (17 mg/mL, 1:0.9 by volume) in dichlorobenzene [1]. Devices without buffer layers or those with a buffer layer consisting only of 30 nm-thick PEDOT:PSS layers were also fabricated for comparison experiments. Annealing was done at 110 °C for 10 min on a hot plate. Then the samples were re-loaded into the chamber for deposition of Ca electrodes that are capped with Al. Schematic diagram for overall device structure is presented in Fig. 1. The active area A of the fabricated devices was in the range of 0.05–0.10 cm^2. Photovoltaic measurement was done using the illumination from 150 W solar simula-
Fig. 1. [Color online] Schematic device structure of organic solar cells under study.

tor (ABET technologies) with AM1.5G filters. Irradiance was measured each time using a Si photodiode the response of which was cross-checked with the calibrated reference cell. Throughout the fabrication and photovoltaic measurement, samples were not exposed to ambient air to avoid any potential contamination or degradation.

3. Results and discussion

3.1. Film properties of WO_3

3.1.1. Film morphologies and surface properties of WO_3 films

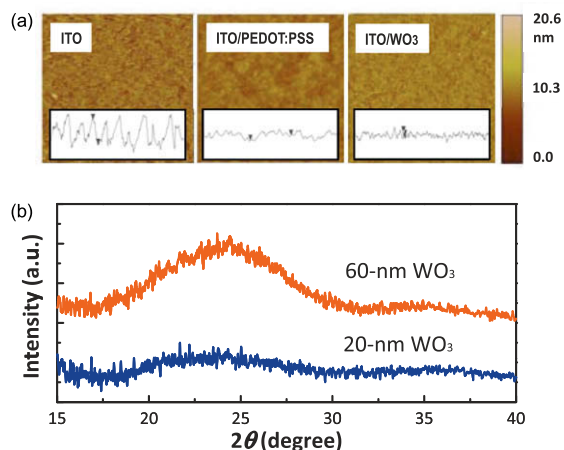
In order for buffer layers for ITO to work effectively, it is often desired to form a smooth and uniform layer when being deposited onto ITO surface. According to the atomic force microscopy (AFM) images shown in Fig. 2a, deposition of thin WO_3 layer (10 nm) on ITO was shown to yield a highly smooth surface with the RMS roughness as small as 0.88 nm. This RMS roughness is comparable to that of PEDOT:PSS (=0.81 nm) spun on ITO and much smaller than that of bare ITO surface (=2.8 nm). Such smoothening effect of WO_3 is expected to reduce the chance of direct shorts and local high fields and thus to help prevent leakage current and formation of defects that can possibly be induced by those [17]. Fig. 2b presents the X-ray diffraction (XRD) pattern of both 20 nm- and 60 nm-thick WO_3 films grown on SiO_2. No crystalline peaks are observed except for a


Fig. 2. [Color online] (a) AFM images of the surface and cross sectional profile of ITO, PEDOT:PSS on ITO, and WO_3 on ITO. (Tapping mode, 3×3 um^2 scan size). (b) X-ray diffraction patterns of 20 nm and 60 nm-thick WO_3 thin films evaporated on SiO_2/Si wafer.

broad feature near 23°, and thus WO$_3$ films under study can be regarded amorphous. From the perspectives of large-area fabrication of organic devices or similar systems involving (semi)conductive oxide materials, being amorphous is regarded important, provided that it can yield a device performance that is sufficient for each target application, because it can reduce the chance of spatial non-uniformity which can often occur in polycrystalline materials with limited grain sizes [18].

In addition to the film morphologies, the surface energy of the film onto which photoactive layers will be deposited is often of interest because it is known that it can play a subtle but important role in growth of ordered films as well as in wetting properties. Results for contact angle measurement of a bare ITO substrate or those having WO$_3$ or PEDOT:PSS layers are presented in Fig. 3a, and it can be easily seen that WO$_3$ surface is more hydrophobic than the bare ITO or PEDOT:PSS-coated surfaces. Surface energy for each case was calculated using Young–Dupre equation [19] with the contact angles measured for deionized (DI)-water and diiodomethane liquid, and it is estimated to be 64.0, 72.4, and 47.6 mJ/m^2, respectively, for bare ITO (plasma-treated), PEDOT:PSS on ITO, and WO$_3$(10 nm) on ITO. Note that there were several reports suggesting that hydrophobic surfaces or those treated by self-assembled monolayer (SAM) promote an ordered growth of P3HT films [20–22], although it appears there are several other factors that can affect the growth of P3HT [23,24]. It was also reported, although the physical origin was not clearly identified, that performance in inverted-geometry OPV cells with Cs$_2$CO$_3$ buffer layers (for bottom cathodes) correlates inversely with the surface energy of the buffer layers [6]. As shown in Fig. 3b, we were also able to observe that P3HT films grown on WO$_3$ layers exhibit the slightly higher ordering than those grown on ITO or PEDOT:PSS. The tendency of P3HT to organize with a higher degree of ordering is expected to improve the mobility of P3HT films. In an effort to study the effect of buffer layer on the carrier mobility of P3HT films, we have

measured the current density (J)–voltage (V) characteristics of hole-only devices in a geometry of ITO/PEDOT:PSS/P3HT (70 ± 6 nm)/Au and ITO/WO$_3$ (15 nm)/P3HT (70 ± 6 nm)/Au (see the inset of Fig. 3b). One can easily see from the log–log plots of J–V characteristics (at $V > \sim 1$) that both types of devices (four devices each) follow the typical V^2-dependence of space-charge-limited current (SCLC) given by [25]:

$$J = \frac{9}{8}\varepsilon_0\varepsilon_r\mu\frac{V^2}{d^3} \qquad (1)$$

in which ε_0 is the permittivity of vacuum, ε_r the relative dielectric constant, μ the mobility, and d the active layer thickness. In addition, one can note in the plot that WO$_3$-based devices exhibited a better device-to-device reproducibility than PEDOT:PSS-based devices. Using Eq. (1) and the Y-cut of the apparent linear fit for log–log plot in each case, the hole mobility values of the P3HT films on PEDOT:PSS and WO$_3$ are extracted to be $(1.0 ± 0.3) \times 10^{-4}$ cm^2/V s and $(2.4 ± 0.6) \times 10^{-4}$ cm^2/V s, respectively, with ε_r of 3.0 [26]. Such improvement in carrier mobility is known to be beneficial for OPV device performance by reducing bias-dependent recombination as it effectively increases the mean free path of photogenerated-carriers [27] or by decreasing the possibility of space-charge build-up [28].

3.1.2. Electronic properties of WO$_3$ films

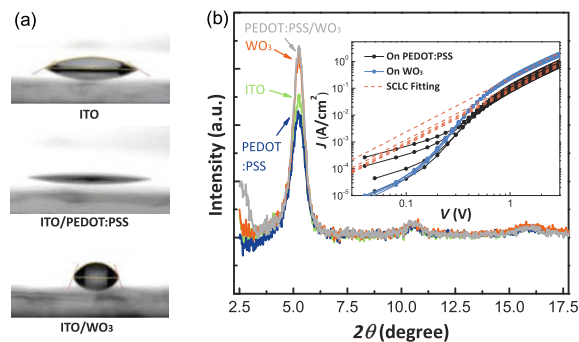
Current density (J)–voltage (V) characteristics of a device in a structure of ITO/WO$_3$ (70 ± 10 nm)/Al is presented in Fig. 4a. It is observed that J–V exhibits a linear relation-


Fig. 3. [Color online] (a) Contact angle measurement of ITO, WO$_3$ on ITO, and PEDOT:PSS on ITO surfaces for DI-water. (b) X-ray diffraction patterns of P3HT films grown on various buffer layers under study. Inset: Current density (V)–voltage (V) characteristics of hole-only devices in a geometry of ITO/X/P3HT (70 ± 6 nm)/Au with X being WO$_3$ (15 nm; blue) or PEDOT:PSS (black). Fitting curves using the equation for space-charge limited current [SCLC; Eq. (1)] are shown as red dashed lines for each case. Fig. 4. [Color online] (a) Electrical characteristics of ITO/ WO$_3$ (70 nm)/Al device. (b) Electrical characteristics of ITO/x/P3HT/Ca/Al [x = WO$_3$ (black) or PEDOT:PSS/WO$_3$ (red)] under illumination (solid) and in dark (dashed). Inset in (a): Optical transmission spectrum of 10 nm-thick WO$_3$ films. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

ship throughout the voltage range applied. Such linear relationship is consistent with the fact that some transition metal oxides such as V_2O_5, MoO_3, and WO_3 are p-doped semiconductors as prepared when they are grown by thermal evaporation, due to the presence of impurities and different oxidation states, etc. [29]. From its slope, the conductivity of WO_3 films used in this study is estimated to be $(6 \pm 1) \times 10^{-6}$ S/cm, which is comparable to that of doped p-type organic semiconductors used in pin-type OLEDs [30]. This level of conductivity will be large enough to ensure the series resistance owing to insertion of a WO_3 layer to be negligible unless it is too thick.

Another important parameter would be the effective work function of the anode system, because V_{OC} tends to correlate with the work function of an anode for a given cathode in BHJ type cells [6] although it can be influenced by a combination of several other factors. Moreover, the energy level of the anode system should provide cells with efficient pathways for carrier collection with no, or if any, negligible energy barrier. According to the previous reports, the work function of WO_3, or Φ_{WO3} can range from 4.7 to 6.4 eV depending on film preparation conditions [13,16,31,32]. To estimate Φ_{WO3} of the layer used in the present study, we have investigated the light and dark characteristics of devices based on single active layers in a geometry of ITO/X/P3HT/Ca/Al with X being WO_3 (10 nm) or PEDOT:PSS as shown in Fig. 4b. In such single-layer structure Malliaras et al. showed that the built-in voltage V_{bi}, or $|\Phi_{anode} - \Phi_{cathode}|/e$ correlates with the compensation voltage V_0 at which the current density values under dark and illuminated conditions become equal [33]. From Fig. 4b, V_0 is found to be 1.26 V for a WO_3-based device and 1.22 V for a PEDOT:PSS-based device, respectively. Since these devices have the same kind of active layers and cathode structures, the observed small difference in V_0 indicates that Φ_{WO3} can be approximated to the work function of PEDOT:PSS or Φ_{PEDOT}, which is known to be about 5.1–5.2 eV [4]. Using the optical energy gap of WO_3 films measured by UV/vis transmission spectrum (see the inset of Fig. 4a), the approximate energy diagram ignoring band bending at interfaces is summarized as shown in the inset of Fig. 5.
Fig. 6. [Color online] Current density–voltage (J–V) characteristics under illumination of simulated AM1.5G (100 mW/cm^2) for (a) fabricated P3HT:PCBM organic solar cells without buffer layers (green, dash dot) or with buffer layers of PEDOT:PSS (orange, dash), 5 nm-thick WO_3 (red, short dash), 15 nm-thick (blue, dot) WO_3, or 30 nm-thick WO_3 (black, solid) films. The inset shows the semi-logarithmic plot for J–V characteristics of the cell with 30 nm-thick WO_3 films for both dark (solid) and illumination (short dash) cases. The device with 30 nm-thick WO_3 films was fabricated in a separate batch. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.2. Photovoltaic properties of organic solar cells with WO_3 buffer layers

The current density (J)–voltage (V) characteristics of OPV cells measured under the simulated AM 1.5G illumination (100 mW/cm^2) are presented in Fig. 6 for solar cells made in a structure of ITO/buffer layer (=x)/P3HT:PCBM-60/Ca/Al in which x is WO_3 (5 nm, 15 nm, or 30 nm), PEDOT:PSS (30 nm), or nothing. The best device with x of 5 nm-thick WO_3 exhibited the PCE of 3.1% [3.0%] and FF of 0.69 [0.69], while the best device fabricated in the same batch without buffer or with x of PEDOT:PSS exhibited the PCE and FF of 1.9% and 0.56 and 2.5% and 0.60, respectively. The best device with x of 30 nm-thick WO_3, which was fabricated in a separate batch, exhibited the PCE and FF of 3.1% and 0.70, respectively. The fact that the cell performance does not show a significant dependence on the thickness of WO_3 layers may be beneficial in optimizing the optical/electrical structure of OPV cells. For example, one can vary the thickness of WO_3 layers (at least up to a few tens of nanometers) without a significant compromise in cell electrical properties until the optical absorption by active layers is maximized with the help of multilayer thin-film optics [34] as in the work by Kim et al. [35] in which TiO$_x$ buffer layers function also as an optical spacer for such purpose.

The effect of WO_3 on PV performance is presented in a statistical sense in Fig. 7 showing the box graph for photovoltaic parameters obtained in total of 90 devices fabricated in five independent batches. One can note that WO_3-based devices exhibit improvement in FF, V_{OC}, and efficiency over ITO-based cells, and in FF and efficiency over PEDOT:PSS-based cells, with a significantly better batch-to-batch consistency. Recalling the correlation of

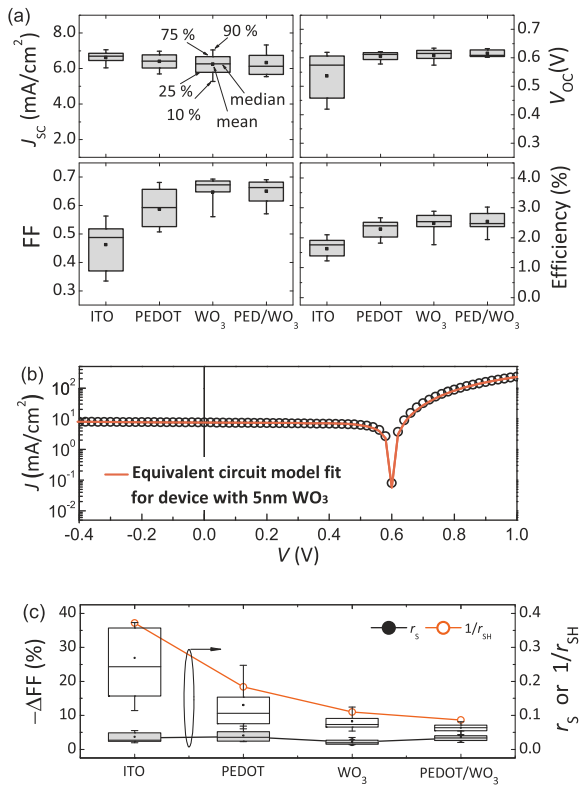
Fig. 5. (a) Schematic energy diagram of the OPV cells under study. Band bending and a formation of interface dipoles, etc. could be possible but are ignored in this diagram. Values are given in unit of electron volt with respect to the vacuum level.


Fig. 7. [Color online] (a) Statistical box graph for J_{SC}, V_{OC}, FF, and efficiency for total of 90 devices (13 of ITO, 27 of PEDOT:PSS, 32 of WO_3, and 18 of PEDOT/WO_3-based cells) over five independent batches. Thickness of WO_3 ranges between 5 and 30 nm. (b) Current density–voltage (J–V) characteristics (black, open circle) and its fitting curve (red, solid) under equivalent circuit model in which $n = 1.85$, $J_0 = 27$ nA/cm², $R_{sh} A = 1000\ \Omega$ cm², and $R_s A = 1.0\ \Omega$ cm². (c) The average values of the normalized series resistance r_s and a reciprocal of shunt resistance r_{sh}, and the statistical box graph for the relative decrease in fill factors in% ($\equiv -\Delta$FF) due to each of r_s (shaded) and r_{sh} (clear). The points for r_s are behind the box graph because $-\Delta$FF due to r_s follows approximately $\sim r_s$ itself. To estimate the decrease in FF due to r_{sh}, the diode ideality factor n of 2.0 was assumed. Lines in graph (c) are guide to eyes and bear no physical meaning. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

V_{OC} value in a BHJ cell with the work function of its anode [6], the V_{OC} values observed in WO_3-based devices that are larger than those of ITO based devices can be attributed to the work function of WO_3 layers that is larger than that of ITO ($\sim$4.7 eV) [4], as described in Section 3.1. On the other hand, short-circuit current density J_{SC} showed a relatively wide device-to-device and batch-to-batch variation, possi-

bly due to the local variation in the active layer thickness resulting from the low-speed spin-coating process.

Note that common enhancement in WO_3-based devices over buffer-free or PEDOT:PSS-based devices is the consistently high FF values. Most of the FF values that are being reported for the P3HT:PCBM cells employing PEDOT:PSS buffer layer are typically in the range of 0.5–0.6 except for a few notable cases [2]. For comparison's sake, FF values in MoO_3- or V_2O_5-based cells were reported to be about 0.59–0.62 and were virtually same as that of PEDOT:PSS-based cells [8], and those in devices using NiO_x buffer layer were as high as 0.69 [4]. As can be seen in Table 1, MoO_3, V_2O_5, NiO_x, and WO_3 all have LUMO levels that can provide a significant energy barrier for electrons in PCBM so that chances of electron recombination can be suppressed near anodes. However, it is noted that the surface roughness values of MoO_3 and V_2O_5 is much larger than those of NiO_x and WO_3 layers. Since the local high electric fields due to the roughness of buffer or electrode layers are likely to increase a chance of bias-dependent carrier recombination [27], one may consider that the large FF values found in WO_3- and NiO_x-based devices come partly from their smooth surface morphologies.

The fill factor of solar cells can be influenced (i) by the voltage drop due to the non-zero series resistance R_s that results from contact resistance and limited bulk transport properties; and (ii) by the current leakage resulting from either the presence of electrical shunt paths or voltage-dependent carrier recombination both of which can be conveniently modeled as a finite shunt resistance R_{sh} [36]. The effect of these parasitic resistances on FF can be quantified using normalized series and shunt resistances, r_s and r_{sh}, which are defined by $R_s A|J_{sc}|/V_{oc}$ and $R_{sh} A|J_{sc}|/V_{oc}$, respectively [36]. Fig. 7b shows that the J–V characteristics of the P3HT:PCBM cells under study can be reasonably modeled by the simple equivalent circuit model (ECM) shown in Ref. [36] which consists of (i) a diode characterized by the reverse saturation current density J_0 and the diode ideality factor n, (ii) a dc current source, and (iii) R_{sh} and R_s. The closed and open circles in Fig. 7c present the mean values of r_s and $1/r_{sh}$ extracted for each type of the cells under study (illuminated case) under the ECM, respectively, and the box graphs with [without] shades present the statistics for the relative decrease in FF due to R_s [R_{sh}] which was analyzed using the formula given in Refs. [36–38].

One can note that it is the relatively large shunt resistance of WO_3-based cells that resulted in most of the improvement in FF. On the other hand, R_s and its effect on FF do not show much variation both for the type of buffer layers and for different batches and samples.

Table 1
Comparison of metal oxide buffer layers used on ITO electrodes in OPVs.

	MoO_3	V_2O_5	NiO_x	WO_3

[a] Measured for $\sim$10 nm-thick films.

Under illumination, low R_{sh} is related to a recombination of photogenerated-carriers unless it is limited by the current leakage through local shorts [27]. Irwin et al. pointed out that the energy offset between the LUMO levels of NiO_x layer and PCBM-60 layers can prevent unwanted electron captures at anodes in their NiO_x-based cells [4]. The LUMO of WO_3 being approximately 1.6 eV as described in Section 3.1, it is also expected to provide a sufficient energy barrier at LUMO levels, as in the NiO_x case, for electrons that are present in PCBM-60 molecules near the anode, considering that the LUMO of PCBM-60 is around 4.0 eV [4]. Another factor that can influence carrier recombination is the carrier mobility μ of each active layer because the mean free path, or the characteristic distance over which a carrier can travel before it recombines at a given voltage, is proportional to the carrier mobility [27]. Therefore, the relatively high hole mobility (and thus long mean free path) observed in P3HT films grown on WO_3 layers may also be linked to the improvement in FF in WO_3-based cells, as discussed in Section 3.1. Low recombination of photo-generated carriers will be important also in ensuring the large open-circuit voltage, because too small r_{sh} or non-linear voltage-dependence of recombination can decrease V_{OC} as well as fill factor [27,36,37].

4. Conclusions

In summary, we demonstrated that a thin layer of WO_3 can enhance the photovoltaic performance of P3HT:PCBM-60 solar cells when it is inserted between the anode and active layers. It was shown that WO_3 layers thermally evaporated on ITO form uniform amorphous films with the RMS roughness of 0.88 nm and a relatively low surface energy and that P3HT films grown on WO_3 films have a higher degree of ordering and larger hole mobility than those grown on PEDOT:PSS films. It was shown that WO_3 layers thermally evaporated on ITO form uniform amorphous films with the RMS roughness of 0.88 nm and with a relatively low surface energy. Analysis using electrical characteristic of ITO/WO_3 (70 nm) /Al indicates that WO_3 layers under study can be regarded as doped semiconductors so that Ohmic injection from a conductor to WO_3 is easily realized. Near-ideal, high shunt-resistance OPV characteristics was consistently observed in cells with WO_3 layers, leading to fill factor values often as high as 0.67–0.70 and V_{OC} values that are comparable to PEDOT:PSS-based cells and are larger than ITO-based cells. Such improvement is considered to originate partly from the HOMO level of WO_3 that matches relatively well with that of P3HT and thus allows for efficient hole collection from P3HT as in the case of PEDOT:PSS and at the same time from its LUMO level that provides a sufficient energy barrier for photogenerated electrons in PCBM-60 and thus prevents them from being recombined near the anode. The smoothness of WO_3 layers and the improved hole mobility of P3HT films grown on WO_3 are also expected to benefit OPV cells by reducing the chance of bias-dependent carrier recombination. Considering that WO_3 films presented in this work are amorphous, the work shown here can potentially lead to scalable OPV technologies. In addition, as WO_3 films can be prepared by a simple thermal evaporation, the results shown here may get easily extended to a tandem-cell structure employing WO_3 layer as a part of intermediate electrodes [15] for high efficiency OPV cells [11].

[38] To estimate the effect of r_{sh} on FF, the diode ideality factor n of 2.0 was assumed. In fact, the error associated with this assumption falls within ∼±10% when n varies between 1.5 and 2.5.

In this paper, we report on small-molecule-based, efficient WOLEDs with a high CRI, that can be fabricated by combining a solution process and a vacuum deposition process. We employed a double-emitting layer (DEL) structure in a phosphorescent WOLED device, whereby one emitting layer is fabricated in a solution process (emitting layer I) and the other emitting layer is fabricated by vacuum deposition (emitting layer II). Emitting layer I consists of three materials: a hole-transporting host, blue phosphorescent guest, and green phosphorescent guest. Emitting layer II, on the other hand, consists of a hole-blocking host and red phosphorescent guest. Emitting layer II acts to block holes and emit red light in the DEL device to obtain a white emission. We found that using this combined process is an easy way to obtain efficient WOLEDs with high CRIs, since double emitting layers distribute the emission region within the device. Furthermore, we measured the transient phosphorescence behavior, which is important information to discuss the energy transfer mechanism in WOLED, by using very short electrical pulses.

2. Experimental

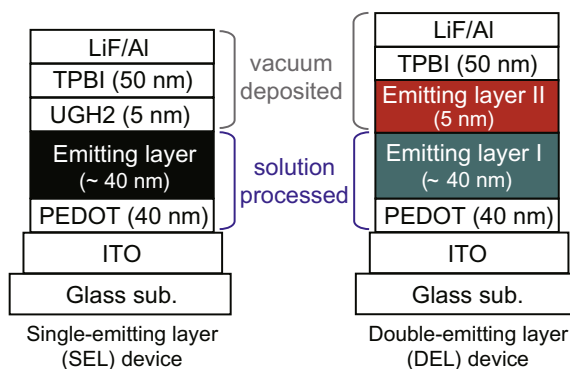
The selection of host material for the emitting layer is one of the most critical issues in the solution process for small-molecule-based WOLEDs. In this study, we used 2,2-bis(4-carbazolyl-9-ylphenyl)adamantane (Ad-Cz) as the host material, which has solubility to organic solvents, high T_g ($\sim 160\,^\circ$C), carrier-transport ability, and high T_1 [17]. There are two types of phosphorescent WOLEDs with high CRI; one includes three phosphorescent guests and the other includes blue fluorescent guest and two phosphorescent guests [5,8,9,18,19]. We selected the former type not only to obtain high efficiency but also to discuss the energy transfer mechanism of triplet exciton in WOLED. Three phosphorescent guests we relied on are the previously reported iridium(III)bis(4′,6′-difluoro-phenylpyridinato)tetrakis(1-pyrazolyl)borate [FIr6], fac tris(2-phenylpyridine) iridium (III) [Ir(ppy)$_3$] and tris[1-phenylisoquinolinato-C2,N] iridium (III) [Ir(piq)$_3$]. Two WOLED devices were developed, one having a single emitting layer (SEL) and the other having a DEL. The OLEDs were produced on a glass substrate coated with a 200-nm-thick indium-tin-oxide (ITO) layer having a sheet resistance of 10 Ω/square. Prior to fabrication of the organic layers, the substrate was cleaned with ultra-purified water and organic solvents, and treated with a UV-ozone ambient. The OLEDs were fabricated as follows. Poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonic acid) (PEDOT/PSS; Baytron P CH8000) as a hole injection layer was spin-coated from a water solution onto the ITO substrate and dried in air at 180 °C for 1 h. The first emitting layer of the SEL and DEL devices, which consisted of Ad-Cz and Ir complexes, was spun onto the PEDOT/PSS layer from a 0.5 wt.% tetrahydrofuran solution. The emitting layer of the SEL device has four different materials (Ad-Cz (79.4 wt.%), FIr6 (20 wt.%), Ir(ppy)$_3$ (0.2 wt.%), and Ir(piq)$_3$ (0.4 wt.%)). The film thickness of emitting layer is about 40 nm. Moreover, a 5-nm-thick p-bis(triphenylsilyly)benzene (UGH2) layer is formed by vacuum deposition to act


Fig. 1. Device structure of SEL and DEL devices.

as a electron-transporting and hole-blocking layer, since Ad-Cz is a hole-transporting host [17]. The film thickness of the UGH2 layer is very thin, which is adjusted to obtain high power efficiency (η_p). With the increase of the thickness of UGH2 layer, the lower η_p is obtained due to the low carrier mobility of UGH2 [20]. On the other hand, emitting layer I of the DEL device has three different materials (Ad-Cz (79.8 wt.%), FIr6 (20 wt.%), Ir(ppy)$_3$ (0.2 wt.%)). The film thickness of emitting layer I is about 40 nm. The 5-nm-thick emitting layer II is formed by co-depositing 0.8 wt.%–Ir(piq)$_3$ with UGH2. The reason why the guest concentrations of Ir(piq)$_3$ in both devices are different will be described in the next section. After formation of the hole-blocking layer of SEL device or emitting layer II of the DEL device, a 50-nm-thick 1,3,5-tris(N-phenylbenzimidazol-2-yl)benzene (TPBI) was deposited as the electron-transporting layer. Finally, a 0.5-nm-thick LiF layer and 100-nm-thick Al layer were deposited as the cathode. Device configurations used in this experiment are shown in Fig. 1. The devices were encapsulated using a UV-epoxy resin and a glass cover within a nitrogen atmosphere, after cathode formation. The electroluminescent (EL) spectra and luminance were measured with a spectroradiometer (Minolta CS-1000). A digital source meter (Keithley 2400) and a desktop computer were used to operate the devices. We assumed that the emissions from the OLED device were isotropic, such that the luminance was Lambertian, and calculated the external quantum efficiency from the luminance, current density, and EL spectra.

3. Results and discussion

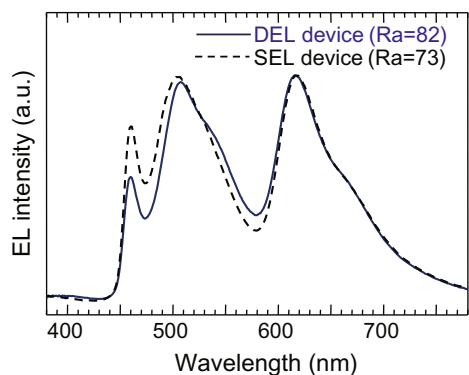
Fig. 2 shows the electroluminescence spectra of the SEL and DEL devices at a current density of 10 mA/cm². The CIE coordinates and CRI values for the emissions from the SEL device are respectively (0.42, 0.42) and 69 at 0.1 mA/cm² and (0.36, 0.40) and 73 at 10 mA/cm², whereas they are (0.38, 0.47) and 82 at 0.1 mA/cm², and (0.38, 0.43) and 82 at 10 mA/cm² for the DEL device. We also fabricated the another SEL device, where the guest concentrations in emitting layer are similar to that of DEL device (Ad-Cz (79.0 wt.%), FIr6 (20 wt.%), Ir(ppy)$_3$ (0.2 wt.%), and Ir(piq)$_3$ (0.8 wt.%)). However, the white emission was not obtained, e.g., the CIE coordinates of the device was (0.55, 0.38) at


Fig. 2. EL spectra for two different WOLED devices at current density of 10 mA/cm². One device (SEL) had a single emitting layer and the other had two emitting layers (DEL). The CRI values of these devices are also shown.

10 mA/cm². Although, the guest concentration of Ir(piq)$_3$ varies slightly, we decided that it is suitable to compare the performance of white light-emitting SEL device with that of DEL device as proposed in experimental section. The external quantum efficiencies (η_{ext}) of the two WOLED devices are plotted as a function of current density in Fig. 3. η_{ext} of the SEL device was about 6%, whereas it was 11.7% for the DEL device. The maximum η_p of the DEL device was 16 lm/W, which is relatively high compared with the previously reported value for solution-processed WOLEDs [9]. This improvement can be explained by the distribution of the emission region within the two emitting layers. In both devices, a high density of Ad-Cz excitons are formed at the Ad-Cz/UGH2 interface, and phosphorescence occurs through host–guest energy transfer [17]. The emitting region of the SEL device becomes narrow, resulting in a lower η_{ext} due to the unconfinement of triplet energy in the light-emitting region. The T_1 energy of TPBI is 2.58 eV, which is smaller than that of FIr6 [21]. Thus, it is expected that the triplet excitons diffuse to the TPBI layer through the thin UGH2 layer [18,22]. In contrast, the emitting region of
the DEL device is distributed as a result of doping Ir(piq)$_3$ in the UGH2 layer, and this enables the confinement of triplet energy in the light-emitting region compared to SEL device.

To understand the distribution mechanism of the emitting region, we examined the transient decay of electroluminescence by applying an electrical pulse with a pulse width of 100 ns to the DEL device [23]. It is usually difficult to operate the OLEDs by the duration of 100 ns input voltage [24]. However, we prepared the specialized pulse generator which can apply the voltage of about 30 V with a pulse width of 100 ns. By synchronizing the pulse generator with the streak camera (C4334, Hamamatsu) in cycle of 500 μs, the few microsecond range transient phenomena can be observed. For comparison, transient decays in three other single doped OLEDs, each doped with one of the three phosphorescent guests (FIr6, Ir(ppy)$_3$ and Ir(piq)$_3$) was also examined. Fig. 4a shows the transient decays of the OLEDs and (b) summarizes the electroluminescence lifetimes (τ) of each phosphorescent guest in the single doped OLEDs. The triplet lifetimes of each guest were estimated from the fitting lines, as illustrated in the figure. The measured τ values of FIr6, Ir(ppy)$_3$, and Ir(piq)$_3$ were 2.0 μs, 1.4 μs, and 1.0 μs, respectively. There are small differences in τ between the previously reported photoluminescent values and the current electroluminescent ones [25,26]. However, the correlation is quite similar; that is, τ of FIr6 is the longest, and τ of Ir(piq)$_3$ is the shortest. A detailed discussion about the difference in τ value between estimated from photoluminescence and estimated from electroluminescence will be described elsewhere.

Here, we discuss the emission mechanism in the DEL device, on the basis of the estimated τ of each phosphorescent guest. Fig. 4c shows the transient decay for each phosphorescent guest. The triplet lifetimes of FIr6, Ir(ppy)$_3$ and Ir(piq)$_3$ were taken from their emission peaks centered at λ = 460, 520, and 620 nm, respectively. The lifetimes of FIr6 and Ir(ppy)$_3$ decrease to 1.1 μs, which is similar to τ of Ir(piq)$_3$ in the single doped OLEDs. These results suggest that the FIr6 and Ir(ppy)$_3$ emissions are primarily quenched by energy transfer to Ir(piq)$_3$, as illustrated in Fig. 4d [5]. Therefore, the distribution mechanism of the emitting region is dominated by energy transfer between phosphorescent guests, as illustrated by the arrows in Fig. 4d, and not dominated by the direct charge trapping by Ir(piq)$_3$ in the UGH2 layer [17]. The emission mechanism in the DEL device can be summarized as follows. First, carrier recombination occurs at the Ad-Cz/UGH2 interface, and singlet and triplet excited states of Ad-Cz are generated. Next, energy transfer from the singlet exciton of the Ad-Cz to FIr6 occurs via Förster energy transfer [27], and energy transfer from the triplet exciton of the Ad-Cz to FIr6 occurs via Förster and/or Dexter energy transfer, since the guest concentration of FIr6 is significantly higher than those of other guests in the DEL device. Therefore, the transfer processes originate from the excitation of FIr6. Accordingly, energy is transferred from FIr6 to both Ir(p-py)$_3$ and Ir(piq)$_3$, and in addition, energy might be transferred from Ir(ppy)$_3$ to Ir(piq)$_3$. The energy transfer between phosphorescent guests in the DEL device leads to the emitting region becoming distributed and a decrease

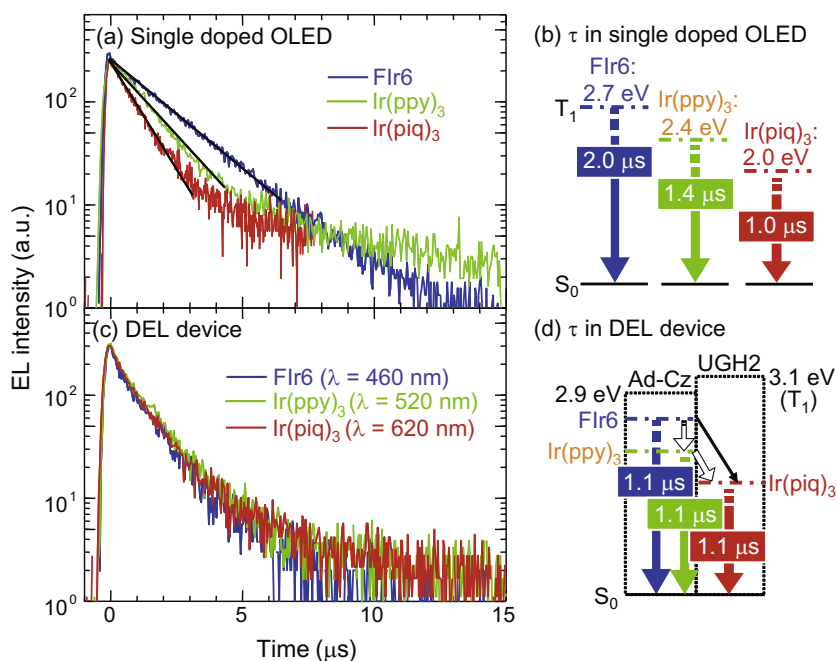
Fig. 3. External quantum efficiency and power efficiency vs. current density for the two WOLED devices.


Fig. 4. Transient electroluminescent decay for FIr6, Ir(ppy)$_3$, and Ir(piq)$_3$ in single doped OLED devices (a) and DEL device (c). The transient decays of each phosphorescent guest are distinguished by their colors. The estimated phosphorescence lifetimes of emitters in the single doped OLED devices and DEL device are summarized in (b) and (d), respectively. The energy transfer pathways between FIr6, Ir(ppy)$_3$, and Ir(piq)$_3$ in the DEL device is also shown in (d).

Table 1
Selected WOLED architectures with their corresponding performance characteristics. All the WOLEDs are based on phosphorescent dye and have a high CRI.

Architecture	Fabrication process	η_{ext} [%]	η_P [lm/W]	CIE	CRI	Refs.
DEL device	Solution + deposition	12	16.2	(0.38, 0.43)	82	This work
Triple-doped emissive layer (polymer based)	Solution	14.4	9.5	(0.34, 0.47)	77	[9]
Triple-doped emissive layer	Deposition	12	26	(0.43, 0.45)	82	[5]
Three kinds of single-doped emissive layer	Deposition	16.6	32	(0.38, 0.39)	80	[8]

in the possible diffusion path of the triplet excitons of FIr6 to TPBI layer.

Table 1 compares the performances of our structure and previously reported phosphorescent WOLEDs with high CRIs. The fabrication methods are also compared. The fabrication process of vacuum-deposited WOLEDs tends to be complicated, since at least three phosphorescent guests in WOLED are essential to obtain high CRI. On the other hand, the fabrication process of our solution processed and vacuum-deposited WOLED is much easier. The guest concentration of three kinds of molecules (one host and two guests) in one emitting layer can be easily controlled by solution process. Moreover, the fabrication process of the other emitting layer is one time co-evaporation, which is similar to that of conventional POLEDs. The η_P of our devices is lower than that of the vacuum-deposited WOLEDs. However, it is significantly higher than that of the polymer-based device fabricated by solution process. Thus, small-molecule-based WOLEDs likely have more potential than polymer-based ones. The problem we have to consider here is that it might be difficult to fabricate high-efficient, SEL WOLEDs with a solution process due to the lack of suitable host materials. Most host materials suitable for

solution-processed WOLEDs are unipolar, which makes the emitting region narrow. The DEL structure, however, distributes the emitting region, and it enables efficient, high CRI WOLEDs to be easily fabricated.

4. Summary

We succeeded in demonstrating a highly efficient, high CRI WOLED with a double-emitting layer, wherein one emitting layer is fabricated in a solution process and the other is fabricated by vacuum deposition. The device had a maximum power efficiency of 16 lm W^{-1} and CIE coordinates that varied from (0.38, 0.47) at 0.1 mA/cm^2 to (0.38, 0.43) at 10 mA/cm^2, with CRI = 82. By distributing the emitting region with the double-emitting layer, the confinement of triplet energy in the light-emitting region was achieved. The distribution mechanism of the emitting region was investigated by measuring the electroluminescent transient decays of the phosphorescent guests in the WOLED. The results clearly demonstrate that the distribution mechanism is energy transfer between phosphorescent guests.

for LEDs based on a green phosphorescent dendrimer [15]. However, the influence of the film morphology on the photophysical and electronic properties is still unexplored and a better understanding of how these properties are affected by the processing conditions is now required for further improvements in the device performance.

In this paper, we investigate the effects of thermal annealing on the photophysical properties of a conjugated dendrimer film. The structure of the first generation dendrimer is shown in the inset of Fig. 1. It consists of a bisfluorene core with two *n*-hexyl groups attached to the 9-position of each of the fluorenyl moieties, and first generation phenylene dendrons with 2-ethylhexyloxy surface groups attached to the 7-position of the fluorenyl groups. Previous studies have shown that this fluorescent dendrimer exhibits good hole mobility of $\sim 10^{-4}$ cm^2/Vs at a field of 0.55 MV/cm [23,24] and makes fluorescent blue LEDs with an external quantum efficiency of 1.2% [25]. Recently, this dendrimer has been successfully incorporated into one and two-photon pumped lasers [22,26]. The photophysical properties of poly(fluorene)s are strongly influenced by film morphology [8] and hence it was of interest to determine whether blue emissive fluorescent dendrimers behave in a similar way. Our results show that thermal annealing affects the absorption and photoluminescence (PL) spectra of the dendrimer film but does not significantly modify the PL efficiency and lifetime, singlet–singlet exciton annihilation, or ASE threshold. Spectroscopic ellipsometry measurements indicate that the film becomes birefringent on annealing, the bisfluorene chromophores preferentially adopting an orientation in the plane of the film. This study demonstrates that thermal annealing strongly modifies the molecular rearrangement within the dendrimer film but has only a mild effect on the photophysical properties. Thus annealing provides an efficient way to finely tune the emission colour of the dendrimer film without a strong decrease in PLQY and ASE threshold.
Fig. 1. Absorption and steady state PL spectra of a neat film of the bisfluorene-cored dendrimer before (solid line) and after (dotted line) thermal annealing. PL spectra are normalized according to the measured PLQY values. The PL spectrum of the dendrimer in THF is also shown (dashed line). The chemical structure of the dendrimer is shown in the inset (R = 2-ethylhexyl).

2. Experimental

Neat bisfluorene-cored dendrimer films were deposited onto precleaned quartz substrates by spin-coating from chloroform at concentrations in the range 10–20 mg/mL. The films were annealed at 100 °C for 1 h with the sample under a vacuum (8×10^{-5} mbar) to prevent any oxidation effects. Absorption spectra were measured using a Varian model 300 absorption spectrophotometer. PL measurements were performed in 180 nm thick films. Time integrated PL spectra were recorded by a Jobin Yvon Fluoromax 2 fluorimeter. Film PLQYs were determined with an integrating sphere under flowing nitrogen atmosphere [27]. The samples were excited at 325 nm by a helium–cadmium laser with a power of nearly 0.2 mW. Time resolved PL measurements were carried out by using 100 fs light pulses at 330 nm for excitation with a repetition rate of 5 kHz and a synchroscan Hamamatsu streak camera for detection. The excitation spot size corresponding to the full-width at half maximum was determined by using a beam profiler to be 200 µm. These measurements were carried out at room temperature and the samples were placed in a vacuum chamber with a pressure lower than 8×10^{-5} mbar. In order to characterize the spectral line narrowing by ASE, films were photoexcited with the same 100 fs excitation pulses. The energy of the pulses was adjusted using a set of neutral density filters. The excitation light was shaped into a stripe of length approximately 1 mm and width 30 µm and focused near the edge of the film. The spatial uniformity of the pump intensity was checked with a beam profiler. The light emitted from the waveguide edge was then detected with an optical fiber connected to an Ocean Optics CCD spectrometer.

Variable-angle spectroscopic ellipsometry (VASE) measurements were carried out to measure the refractive index and the extinction coefficient of the films. The ellipsometric Ψ and Δ data were acquired in the reflection mode using a J.A. Woollam, Inc. M-2000DI system, and analyzed by means of the WVASE32® data analysis software. The incidence angle was typically varied from 45° to 75° across a wavelength range from 190 to 1700 nm. The wide range of angles used allowed the path length of the probe beam inside the sample to be changed. In addition, some angles were chosen in order to ensure that, at several wavelengths, Δ was close to 90°, as it increases sensitivity in the data analysis [28]. Parameter correlation was further reduced by analyzing simultaneously VASE data from several samples with significantly different film thicknesses [29] within the range 50–180 nm, and by fitting normal incidence intensity transmittance spectra in addition to the Ψ and Δ data [30].

An air-film-substrate model was assumed, with the interface between the film and the substrate being abrupt and no film surface roughness. The dielectric function of the films was described using a Kramers–Kronig consistent parametric functional model, with the absorption bands in the imaginary part of the dielectric function being modelled using a sum of Gaussian oscillator functions. The optical constants of the substrates were determined independently by performing VASE measurements on bare substrates. For both as-deposited and annealed films, isotropic and uniaxial

models were constructed. In the case of the pristine samples, both types of models produced nearly identical dispersion relations, with the uniaxial model providing only a modest improvement to the fit quality. In contrast, it was found that, following annealing, only a uniaxial model, with the optical axis perpendicular to the plane of the films, could yield a close fit to the experimental data.

3. Results and discussion

The film absorption and the steady state PL spectra of the bisfluorene-cored dendrimer before and after annealing are shown in Fig. 1. Peaks at 267 nm and 350 nm are observed in the absorption spectrum of the film before annealing, arising from, to a first approximation, the biphenyl moieties within the dendrons and the bis(phenylfluorene) chromophoric unit. That is, although the core is defined as the bis(fluorene) unit the first two phenyl groups of the dendrons are attached in such a manner that they are part of the delocalised π-electron pathway of the main chromophoric unit. The *meta* linkages around the branching phenyl of the dendrons limits the electron delocalisation, and hence the phenyl units that have the surface groups attached are not part of the main chromophoric unit. The annealing unusually induced a blue-shift of the PL spectrum by 15 nm. We also observed that the annealed film shows a blue shift as compared to solution, which suggests a twisting of the bisfluorene core out of planarity with the benzene ring of the dendron or an increase of the dihedral angle between fluorene units. The decrease in PL intensity of the (0,0) transition relative to the (0,1) transition in the annealed film arises simply from the fact that the short wavelengths of the emission spectra overlap more strongly with the absorption spectrum. It is important to note that annealing the dendrimer film does not give rise to the "greenish" emission that is often observed in polyfluorenes on annealing [31]. The PLQY of the bisfluorene dendrimer film before and after annealing was measured to be 92 ± 5% [32] and 83 ± 4%, respectively. The film PLQY before thermal treatment is close to that measured in solution which indicates that concentration quenching of the PL does not occur in the solid state. It should be noted that annealing the samples for a further 12 h did not cause more changes in the photophysical properties of the film, which indicates that a thermal treatment of 1 h is sufficient to induce these morphological effects.

Fig. 2 shows the excitation density dependence of the PL kinetics in the film before and after annealing. The PL kinetics at low excitation densities are described satisfactorily by a single exponential decay yielding a PL lifetime constant τ_{ph} of 730 and 660 ps in films before and after the annealing respectively. The radiative and non-radiative decay rates, denoted k_R and k_{NR}, were then calculated by combining the following equations: PLQY = $k_R \tau_{ph}$ and $1/\tau_{ph} = k_R + k_{NR}$. We found, in both samples, $k_R = 1.3 \times 10^9 \text{ s}^{-1}$. There is an increase in k_{NR}, from $1.1 \pm 0.6 \times 10^8 \text{ s}^{-1}$ for the pristine film to $2.6 \pm 0.6 \times 10^8 \text{ s}^{-1}$ for the annealed film, but the key point is that the PLQY remains very high in both cases.

At excitation densities higher than $5 \times 10^{17} \text{ cm}^{-3}$, the decays become faster and strongly deviate from a single
Fig. 2. Emission decay curves measured in the window 395–495 nm under various laser excitation densities of the films before and after thermal annealing. Solid lines are the fits obtained with a single exponential: $I(t) = I_0 \exp(-t/\tau_{ph})$ for the curve obtained at the lowest excitation density and with Eq. (1) for the other decays.

exponential. This behaviour is due to singlet–singlet exciton annihilation [33,34]. In the case of a time independent annihilation rate γ, the density of singlet excitons $N(t)$ which is directly proportional to the PL intensity can be described as:

$$N(t) = \frac{N_0 \exp(-kt)}{1 + \frac{\gamma}{k} N_0 [1 - \exp(-kt)]} \qquad (1)$$

where N_0 is the exciton density just after the laser pulse excitation and $k = 1/\tau_{ph}$ is the decay rate of excitations in the absence of annihilation. Fig. 2 shows the best fits obtained with γ values of $4.5 \pm 0.9 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$ and $5.5 \pm 1.5 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$ in the films before and after annealing, respectively. The fact that the PL decays at different excitation intensities can be fitted with time independent γ values indicates that the annihilation process is diffusion controlled and that exciton diffusion is three-dimensional. The two γ values are within experimental error and show that no substantial change in exciton diffusivity occurs upon thermal annealing. It is interesting to note that the γ value for the dendrimer film is two orders of magnitude smaller than that reported in poly(9,9-dioctylfluorene) [35], which demonstrates that addition of the dendrons strongly reduces the exciton diffusivity. Energy transfer of singlet excitons in fluorescent materials occurs by Förster type dipole–dipole interactions. This mechanism depends on the average centre-to-centre spacing distance between adjacent emitters R and its rate is proportional to R^{-6} [36]. The dendrons attached to the bisfluorene-cored dendrimer emitter cause an increase in the intermolecular spacing between the emitting moieties

which modifies the diffusion constant of the singlet excitons. In contrast, the charge carrier mobility of the dendrimer and poly(9,9-dioctylfluorene) are similar [24]. A possible explanation is that charge transport through films is controlled by traps, whereas the exciton diffusion takes place over much shorter distances and is not affected by these traps. The fact that the charge mobility of the bis-fluorene-cored dendrimer and poly(9,9-dioctylfluorene) are similar but the annihilation constant in the dendrimer is lower suggests that dendrimers may be attractive for high brightness blue LEDs. The lower exciton annihilation is particularly interesting in applications such as lasers and optical amplifiers [37–39].

The annihilation constant is related to the diffusion constant D in the three-dimensional case by the relation: $\gamma = 4\pi R_a D$, where R_a is the annihilation radius. We assume that R_a is the same as an average distance between chromophores, which was estimated to be 17.4 Å for the bisfluorene-cored dendrimer from its molecular weight using a uniform film density of 1.1 g/cm^3 measured by neutron reflectivity (data not shown) and assuming the molecules to be hard spheres. The diffusion constant was calculated to be $D = 2 \times 10^{-4}$ cm^2 s^{-1} leading to a 3D diffusion length, defined as $L_d = (3D\tau_{ph})^{1/2}$, equal to 6 nm.

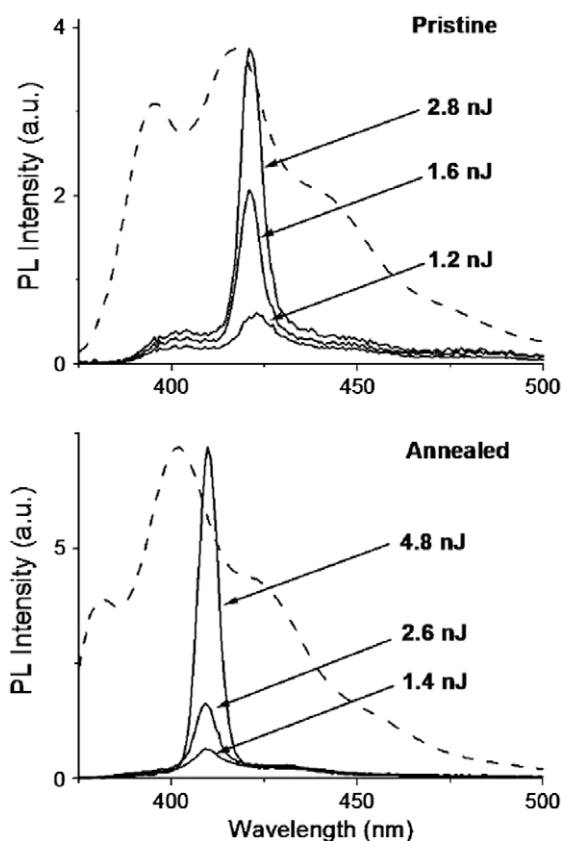
Fig. 3 shows the emission spectra collected at various pump excitation energies in the neat bisfluorene-cored dendrimer film before and after annealing. When the pump pulse energy was lower than 1.2 nJ, a broad PL spectrum characteristic of spontaneous emission and similar to that shown in Fig. 1 was detected with the emission from the annealed film blue-shifted relative to the unannealed. The shape of the spectrum was found not to be dependent on the pump excitation density for low pump energies. As the pump pulse energy was increased above 1.2 nJ, a substantial reduction in the full-width at half maximum (FWHM) of the spectra for both films was observed. Increasing the pump level above this threshold results in a gradual spectral narrowing of the emission band from a FWHM of 53 nm to a FWHM of 6 nm centered at 421 nm for the pristine film. The spectral line narrowing observed here is due to ASE [40–44]. Spontaneously emitted photons were waveguided in the structure and amplified by stimulated emission due to the population inversion. ASE is generally observed where the net gain, (after taking account of absorption and the scattering losses) is highest. The ASE peak is slightly red-shifted with respect to the fluorescence maximum because re-absorption losses decrease towards longer wavelengths. The ASE peak in the annealed film is 11 nm blue-shifted relative to that measured in pristine films, which is consistent with the shift observed in the steady state PL spectrum. However, no significant difference in the ASE threshold and linewidths was observed. Waveguide modelling shows cut off thicknesses for the TE$_0$ and TM$_0$ modes of 70 nm and 100 nm which indicate that both modes are waveguided in the 180 nm thick films. Because the film thickness is much higher than the cutoff thicknesses, we can exclude the changes in refractive indexes upon annealing as a possible reason for the blue-shift of the ASE spectrum [44]. These measurements can be used to compare directly the threshold densities for ASE and singlet–singlet exciton annihilation, which are


Fig. 3. Photoluminescence ASE spectra collected from the edge of a 30 μm × 1 mm stripe in the bisfluorene-cored dendrimer films before and after annealing and at different light pump energies. The dotted lines correspond to the PL steady state spectra.

5×10^{17} cm^{-3} and 1.5×10^{18} cm^{-3}, respectively. The threshold for ASE is generally higher than the laser threshold due to the absence of feedback, and hence the fact that the threshold for ASE is lower than for singlet–singlet exciton annihilation means lasing without exciton annihilation should be obtained using a bisfluorene dendrimer as a gain medium. These results confirm the fact that light-emitting fluorescent dendrimers are promising materials for optical amplifiers and lasers.

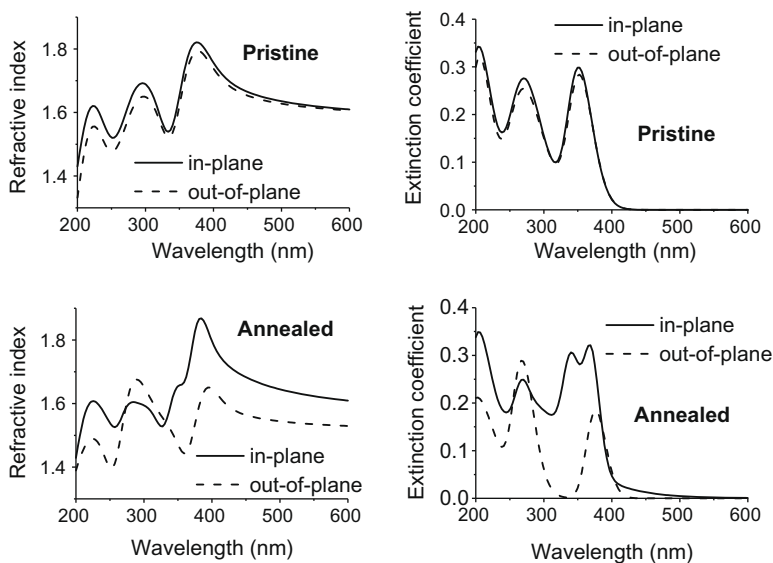
To gain further insights into the effects of the thermal annealing, the optical constants of the films were measured before and after annealing using VASE. Fig. 4 shows the dispersion curves of the refractive index and extinction coefficient for light polarised with its electric field in the plane of the film and for light polarised perpendicular to the film (out-of-plane). The pristine film before annealing was found to be very close to isotropic, which implies no significant orientation of the molecules. In contrast, we observed in the annealed film a measurable optical uniaxial anisotropy in addition to a redistribution of the oscillator strengths in the absorption spectra. In the absorption region of the bisfluorene core between 330 and 400 nm the ordinary (in-plane) refractive index n_o and extinction coefficient k_o are higher than the extraordinary (out-of-plane) index n_e and coefficient k_e. Thus, in this region, the peak values of n_o and n_e vary, respectively, from 1.82 and 1.79


Fig. 4. Refractive index and extinction coefficient of the pristine and annealed films for light polarised with its electric field in the plane of the film and for light polarisation perpendicular to the film (out-of-plane).

before annealing to 1.87 and 1.65, following annealing. As the transition dipole moment for the lowest energy electronic transition in polyfluorenes is polarised along the long molecular axis [45], this optical anisotropy indicates that the bisfluorene chromophores are preferentially oriented in the plane of the film (that is, parallel to the substrate surface). Quantitative information about molecular orientation can be obtained from the measurement of the ratio k_e/k_o and the angular distribution $d_{\pi\theta}$, defined as [46]:

$$d_{\pi\theta} = \frac{1}{1 + \frac{k_e}{2k_o}} \qquad (2)$$

where θ refers to the polar angle in between the molecular axis and the normal to the film. For a uniform molecular distribution, $d_{\pi\theta} = 2/3$ is expected, whilst a value close to 1 should be obtained in the case of a strongly uniaxial film. In the case of the pristine samples, we find k_e/k_o at the peak wavelength of the bisfluorene core transition to be 0.95, giving $d_{\pi\theta} = 0.68$, therefore close to 2/3, as expected for a nearly isotropic film. Following annealing, the dispersion relation of k_o shows two maxima in this spectral region. Thus, in this case, we have calculated k_e/k_o at both peak wavelengths, and then averaged the results, giving $k_e/k_o = 0.25$. This gives $d_{\pi\theta} = 0.89$, which is much closer to 1, indicating substantial alignment. If all the molecules pointed in the same direction this would imply they were at an angle of 71° to the normal to the film. Whilst of course there will be a distribution of orientations, Ref. [46] suggests this procedure as a way of visualising molecular orientation.

An increase in the optical anisotropy upon annealing has been previously reported in films of conjugated polymers [47,48]. In contrast, k_e is larger than k_o in the absorption region of the biphenyl dendrons between 270 and 300 nm, which suggests a preferential alignment of the dendrons perpendicular to the substrate.

During the thermal annealing, bisfluorene dendrimers tend to rearrange themselves to minimize the energy of the film. Ellipsometry data show that the bisfluorene cores re-orient upon annealing to lie preferentially in the plane parallel to the substrate. However, the rigid dendrons and surface groups have less ability to move or relax due to steric hindrance. Reorientation of the bisfluorene core upon annealing is likely to increase the dihedral angle between the branching phenyl and the fluorenyl groups of the core, therefore, excitations in the annealed films would be more localised on the bisfluorene core, which would explain the blue-shift of the PL and ASE spectra. Finally, we note that the PLQY, lifetime and ASE threshold are not modified after annealing, which indicate that the formation of close contacts between bisfluorene cores remains inhibited and that even first generation dendrons are extremely effective in preventing core–core interactions.

4. Conclusion

Annealed films of a bisfluorene-cored dendrimer show a 15 and 11 nm blue-shift of the PL and ASE peaks respectively relative to pristine films. Variable-angle spectroscopic ellipsometry measurements show that the refractive index and extinction coefficient become anisotropic after annealing with larger optical constants observed for light polarisation in the plane of the film than the corresponding out-of-plane values in the absorption region of the bisfluorene core. This anisotropy indicates that in annealed films the bisfluorene cores are preferentially oriented parallel to the substrate. This molecular rearrangement however did not change the fluorescence efficiency, singlet–singlet exciton annihilation rate, and threshold for ASE, which are important properties for organic LEDS and lasers. In addition, our results give a means of fine-tuning the colour of dendrimer lasers and LEDs

without any significant losses in their efficiencies. Possible control of the ordinary and extraordinary refractive indexes in annealed conjugated dendrimer films might also be an interesting opportunity for fabricating photonic structures such as microcavity LEDs. It is worth noting that this work provides the first evidence of the effect of film morphology on the optoelectronic properties of fluorescent dendrimers. Importantly, the size of these morphological effects is much lower than those typically observed in conjugated polymers such as poly[2-(2′-ethylhexyloxy)-5-methoxy-1,4-phenylenevinylene)] or polyfluorenes, suggesting that dendrimers might have the advantage of much lower sensitivity to processing.

Ovchinnikov et al. and Cao et al. have separately synthesized an organic ferromagnet called *poly*-BIPO, which can be obtained by replacing the H atom of polyacetylene alternately with a heterocycle containing an unpaired electron which we call a side radical, as schematically shown in the central part of Fig. 1. The main zigzag chain consists of carbon atoms with π itinerant electrons. There exists antiferromagnetic coupling between the spin of π-electron along the main chain and the residual spin of the side radical. From an extended SSH + Heisenberg (SSH=Su-Schrieffer-Heeger) model, one obtains that the system will have the lowest energy when the spins of side radical forms a ferromagnetic order [11–13]. Recently, several designs of organic ferromagnetic device have been proposed theoretically and some interesting phenomena such as spin filtering and spin-current rectification are predicted [14–16].

At present, most investigations on an organic polymer ferromagnet are limited to ground state properties of the system. In reality, external stimulations including photoexcitation, magnetic field or temperature etc may drive the magnetic molecule deviate from ground state. Several experiments have revealed the underlying function of spin excited states in electron transport through a magnetic molecule. For example, Petukhov et al. gave an evidence of spin excited states existing in a molecular magnet based on electron paramagnetic resonance (EPR) measurements [17]; Heersche et al. observed a complete current suppression and negative differential conductance in a single Mn_{12} molecular magnetic device, which is believed to have a relation with the spin excited states of the molecule [6]. For organic ferromagnet *poly*-BIPO, the spin excited state means that the ferromagnetic order of radical spins is destroyed owning to the spin flipping, which induces the magnetic molecule to a high-energy state. As the radical spins are correlated with the π-electrons in the main chain, it is expected that the spin excited state will affect the π-electron transport along the main chain. In this paper, we construct a metal/organic ferromagnet/metal (M/OF/M) device and then investigate the spin-polarized transport when the organic ferromagnetic molecule is in different spin excited states. The paper is organized as follows: The model and formula are described in Section 2. In Section 3, we give the numerical calculation and the results are analyzed. Finally, in Section 4, a summary is given.

2. Model and method

As shown in Fig. 1, an organic ferromagnetic device M/OF/M is modeled as a quasi-one-dimensional chain. The central organic ferromagnetic molecule is connected with two noninteracting semi-infinite one-dimensional metallic chains. The complete Hamiltonian is written as,

$$H = H_{OF} + H_l + H_r + H_{coup} + H_E \tag{1}$$

The first term is the Hamiltonian of organic ferromagnetic molecule [12,13],

$$
\begin{aligned}
H_{OF} = &-\sum_{n,s}[t_0 - \alpha(u_{n+1} - u_n)](c_{n,s}^+ c_{n+1,s} + c_{n+1,s}^+ c_{n,s}) \\
&+ \frac{K}{2}\sum_n (u_{n+1} - u_n)^2 + J_f \sum_n \delta_{n,o} \bar{S}_{nR} \cdot \bar{S}_n \\
&+ U\sum_n c_{n,\uparrow}^+ c_{n,\uparrow} c_{n,\downarrow}^+ c_{n,\downarrow} + V\sum_{n,s,s'} c_{n,s}^+ c_{n,s} c_{n+1,s'}^+ c_{n+1,s'}
\end{aligned}
\tag{2}
$$

where t_0 is the hopping integral of π-electrons along the main chain with a uniform lattice. α stands for the electron-lattice coupling parameter and u_n the lattice displacement at site n. K is the elastic constant of the lattice atoms, and $c_{n,s}^+(c_{n,s})$ denotes the creation (annihilation) operator of an electron at site n with spin s. The third term in Eq. (2) describes the correlation between spin $\vec{S}_n$ of π-electron and residual spin $\vec{S}_{nR}$ of radical R. It is assumed that the side radicals are connected with the odd sites of the main chain, which is denoted by $\delta_{n,o}$. Coupling constant J_f is assumed to be positive (antiferromagnetic coupling). We use mean-field approximation to treat the radical spin $\vec{S}_{nR}$ as $\langle S_{nR}^z \rangle$, where $\langle \cdots \rangle = \langle G| \cdots |G \rangle$ is the average with respect to the ground state $|G\rangle$. Then the third term can be written as $\frac{J_f}{2}\sum_n \delta_{n,o} \langle S_{nR}^z \rangle \cos\theta_{nR}(c_{n,\uparrow}^+ c_{n,\uparrow} - c_{n,\downarrow}^+ c_{n,\downarrow})$ and θ_{nR} the radical spin orientation at site n (angle with -z axis). The last two terms describe the e–e (electron–electron) interactions between π-electrons under the extended Hubbard model. As spin coulomb drag effect may exist between spin-up and spin-down electrons and affect the spin-polarized current during transport [18,19], it is very necessary to take the consideration of the interactions among electrons. So far, may theoretical techniques can deal with e–e interactions, for example, mean-field approximation, perturbation, full coulomb interactions [20,21] and density matrix renormalization group (DMRG) calculation etc [22–24]. As the first step of our investigation, in this paper, we will just adopt the simple mean-field approximation to deal with the Hubbard term. Its validity will be discussed in the later summary.

$H_{l(r)}$ is the Hamiltonian of the left (right) electrode, which is a semi-infinite metal chain,

$$H_{l(r)} = \sum_{m,s} \varepsilon_{l(r)} a_{m,s}^+ a_{m,s} + \sum_{m,s} t_{l(r)}(a_{m,s}^+ a_{m+1,s} + h.c.) \tag{3}$$
Fig. 1. Simplified structure of a metal/*poly*-BIPO/metal nanojunction. The arrows indicate the spin orientation of radical spins.

where $\varepsilon_{l(r)}$ is on-site energy of a metal atom comparing to that of a carbon atom and $t_{l(r)}$ the transfer integral of adjacent sites. $a_{m,s}^+(a_{m,s})$ is the creation (annihilation) operator of an electron in electrodes.

The coupling between the electrodes and the molecule is assumed to take place only at the nearest connecting atoms at the interfaces,

$$H_{coup} = \sum_s t_{lM}(a_{0,s}^+ c_{1,s} + h.c.) + \sum_s t_{rM}(c_{N,s}^+ a_{N+1,s} + h.c.) \quad (4)$$

$t_{l(r)M}$ is the interfacial coupling, which is simplified by neglecting the spin-dependent scattering at the interfaces. N is the total number of the sites in the organic ferromagnetic interlayer.

The last term is the contribution of driving field E arising from the bias voltage V between the two electrodes,

$$H_E = -\sum_{n,s} |e|E\left[\left(n - \frac{N+1}{2}\right)a + u_n\right]c_{n,s}^+ c_{n,s}$$
$$+ \sum_n |e|E\left[\left(n - \frac{N+1}{2}\right)a + u_n\right] \quad (5)$$

with e being the electronic charge and a the lattice constant. The first term is the electric potential energy of electrons of all sites and the second term is the electric potential energy of lattice ions. It is assumed that the field is uniform along the whole molecule chain and $E = V/[(N-1)a]$. This linear treatment is suitable for the case that the bias applied on the molecule is not too large.

For the M/OF/M device, the current measured at the right electrode is contributed by both the spin-conserving scattering and spin-flip scattering. As the spin-orbit coupling and hyperfine interaction in an organic material are usually very weak, they will result in a large spin relaxation length [1,25]. In this work, we neglect the spin-flip scattering during the transport. Then the spin-dependent current can be calculated with Landauer-Büttiker formula,

$$I_s(V) = \frac{e}{h} \int_{-\infty}^{+\infty} T_{ss}(E,V)[f(E-\mu_l) - f(E-\mu_r)]dE \quad (6)$$

where $f(E-\mu_{l(r)}) = 1/\{1+\exp[(E-\mu_{l(r)})/k_BT]\}$ is the Fermi function and $\mu_{l(r)} = E_F \pm eV/2$ is the chemical potential of the left (right) electrode with Fermi energy E_F.

The spin-conserving transmission coefficient T_{ss} (E,V) can be obtained from Lattice Green Function through Fish-Lee relation [26] $T_{ss}(E,V) = Tr[\Gamma_l G_{ss} (E,V) \Gamma_r G_{ss}^+(E,V)]$, where $G_{ss}(E, V) = \frac{1}{E-H_{OF}^s-H_{elec}^s-\sum_l-\sum_r}$ with $\Sigma_l(\Sigma_r)$ being the self-energy operators due to the coupling with left (right) electrode. H_{OF}^s and H_{elec}^s correspond to the electron Hamiltonian with spin s in Eqs. (2) and (5). $\Gamma_{r(l)}$ denotes the broadening matrix which is related to self energy with $\Gamma_{r(l)} = i[\sum_{r(l)} - \sum_{r(l)}^+]$.

The calculation is performed as follows: we firstly solve the electronic eigenequation of an isolated poly-BIPO molecule. By minimizing the total energy, the lattice and the electronic structures of an isolated poly-BIPO molecule can be obtained self-consistently. Then we use Green's function formula to calculate the transmission probability of spin s, and the spin-dependent current is obtained from Eq. (6).

In order to investigate the spin-polarized transport properties of the M/OF/M sandwiched device, we define the spin polarization (SP) of the current as,

$$P = \frac{I_\uparrow - I_\downarrow}{I_\uparrow + I_\downarrow} \quad (7)$$

In the calculation, the parameters are chosen as follows [12,15]: For the organic ferromagnet, $t_0 = 2.5$ eV, $\alpha = 4.1$ eV/Å, $K = 21.0$ eV/Å^2, $J = J_f/t_0 = 0.8$. As the mean-field approximation is only valid in the case of weak $e-e$ interactions, we choose $U = 1.0$ eV and $V = U/3$. In ground state, the radical spin is supposed to be $\langle S_{nR}^z \rangle = -\frac{1}{2}$, $\theta_{nR} = 0$. For the electrodes, $\varepsilon_{l(r)}$, $t_l = t_r = 2.5$ eV, $E_F = 1.55$ eV. The interfacial coupling is taken as $t_{lM} = t_{rM} = 1.0$ eV.

3. Results and discussion

We firstly consider the ground state and spin excited state of an isolated poly-BIPO chain. In ground state, the radical spins form a ferromagnetic order. There exists an antiferromagnetic SDW of π-electrons in the main chain [11]. The SDW is depicted in Fig. 2, where the SDW order parameter is defined as $s_n = (-1)^{n+1}(n_{n\uparrow} - n_{n\downarrow}) \cdot n_{ns} = \sum_\mu' |Z_{\mu,n,s}|^2$ is the electronic charge density of spin s at site n and $Z_{\mu,n,s}$ the eigenvector obtained by solving Schrödinger equation of Hamiltonian H_{OF}^s. A spin excited state means that there is one or several radical spins flipped. For example, if a radical spin at site n_0 is excited from $\theta_{n_0R} = 0$ to $\theta_{n_0R} = \pi$, we obtain a single-spin excited state. In this case, the SDW of the molecule will be destroyed and a localized spin defect around site n_0 appears in the main chain. As shown in Fig. 2, the defect has a width of about $5 \sim 7a$, which depends on the electron-lattice coupling constant. In the meantime, the appearance of an excited state will result in the change of the electronic states and the energy levels from that of the ground state. It is found that LUMO (lowest unoccupied molecular orbital) of spin-up electrons will departure from the Fermi level and the case is opposite for spin-down ones. Both spin-up and spin-down electronic states near the Fermi level tend to be weakly localized. It is expected that these variations due to spin
Fig. 2. SDW in the ground state and a single-spin excited state.

excitations will seriously affect the conductance and current polarization of such a spin device.

If two or more radical spins are excited, it is found that they will attract each other to form a coupled spin excitation, which will be lower in energy than separated ones. With the increasing of the number of excited radical spins, the system will lay in a high spin excited state in energy. We define the excited energy as,

$$\Delta E(m) = E(m) - E_0 \qquad (8)$$

Here $E(m)$ denotes the total energy of system when there are m radical spins being excited, and E_0 the ground state. Fig. 3 shows the dependence of $\Delta E(m)$ on the number of the excited radical spins. It is found that spin excitation energy increases with the number of excited spins. We note that when $m > m_0 = 8$, the excitation energy keeps nearly unchanged. The reason is that the ferromagnetic molecule is degenerate with $\langle S_{nR}^z \rangle = \pm 1/2$. When $m > m_0$, the excited zone of the system forms a stable domain and excitation energy only exists in the domain walls.

In the following, we investigate the electron transport properties of a *poly*-BIPO device in different spin excited states. Firstly, we consider the effect of spin excitations on total current through the device. The result is shown in Fig. 4. We see that, at a fixed bias voltage $V = 0.5$ V, the total current decreases apparently with the number of excited spins. This current suppression effect on the transport of high spin state has been found in single molecular magnets experimentally [6]. It is predicated that such an organic ferromagnetic device can realize a controllable charge transport. In present parameters, a current suppression ratio $\gamma = -(I_{ex} - I_g)/I_g = 34\%$ is obtained for only one single-spin excitation. Especially, if the molecule lay in a high-energy excited state, it is found that the current may disappear, which means that the device may have a function of a conductance switch.

It has been found that the ferromagnetic molecule has spin-filter function in ground state. Now we consider the spin-polarized transport property through the device when the molecule is excited. A spin excitation may appear either at the interface of M/OF/M or in the interior of the molecule, which has a little difference of about 0.025 eV

Fig. 4. Dependence of total current on the number of excited radical spins at $V = 0.5$ V.

in energy for a single-spin excitation. Here, we only consider the case of low spin excited states, i.e. there is a single-spin excitation or a double-spin excitation. The results are shown in Fig. 5 for the dependence of SP on the external bias. It is found that the SP has a little decrease whether the spin excitation is at the interface or in the interior. There is no much difference for the case of a double-spin and a single-spin excitation.

To understand the effect of spin excitations on SP, we fix bias $V = 0.5$ V and calculate the dependence of SP on the number of exited radical spins. The result is shown in Fig. 6. It is found that, if the number of excited spins is less ($m \leqslant 3$ in present case), the decreasing of SP is m not apparent. In this case, the device can serve as a spin function with a high spin polarization. However, if the number of the excited spins is close to half of the total radical spins, it is found that the SP will decrease to near zero, which means that the spin-up electrons and the spin-down

Fig. 3. Dependence of spin excitation energy ΔE on the number of excited radical spins.

Fig. 6. Current spin polarization as a function of the number of excited radical spins at $V = 0.5$ V.

electrons have the same probability to tunnel through the molecule. Of course, such a spin excitation needs a high energy as indicated in Fig. 3. Therefore, an M/OF/M device is stable to serve a spin filter.

To give the explanation of total current suppression in Fig. 4 and SP modulation effect in Fig. 6, we depict the spin-dependent transmission coefficient at a fixed bias $V = 0.5$ V with the number of excited radical spins from $m = 0$ to $m = 5$. The results are shown in Fig. 7. When there is no spin excitation in the system, it is found that only the transmission peak of spin-up LUMO lies in the conducting region [−0.25 V, +0.25 V]. In this case, the current is contributed mainly by spin-up electrons and so the SP through the device is nearly 100%. With the exciting of the radical spins, the peak corresponding to the spin-up LUMO is moving away from conducting region gradually. As no (or not apparent) any other transmission enter the conducting region all the time, so the conductance decreases. At a high
spin excited state, for example $m = 5$, the transmission becomes nearly zero in the conducting region, so there is no current in this case. From Fig. 7 we also note that the transmission strengths become weaker and weaker with the number of excited radical spins. It is because the electronic states near the Fermi level tend to be weakly localized with the appearance of excited spin defect.

As stated above, spin excitations can affect the conductance and the current polarization of an M/OF/M device. However, the investigation also shows that a low-energy excitation could not destroy the SP and the device can serve a SP function. To give a further understanding, we consider the effect of temperature on the SP as thermal fluctuation may make the radical spins to deviate from the ferromagnetic ground state. It is supposed that the angle $\theta_{nR} \in [0, \theta_0]$ of radical spin $\vec{S}_{nR}$ is randomly valued and obeys a uniform distribution. Here θ_0 means the strength of thermal perturbation, which is related to temperature through a simple Boltzman relation $\Delta\varepsilon \approx k_B T / 2$, where $\Delta\varepsilon$ denotes the energy difference per site freedom between states at a distribution $\{\theta_{nR}\}$ and the ground state of the system. We firstly calculate the order parameter $\langle s_n \rangle$ of the molecule. It is found that the order parameter will decrease with temperature. In present work, the order parameter will decrease to nearly zero when temperature is higher than the critical value $T = T_c \approx 360$ K, which is close to the experimental value [7]. It means that the magnetism of the molecule will vanish beyond the critical point. Then we investigate the behavior of SP in different temperature. The results are shown in Fig. 8, where the inset gives the dependence of SP on temperature at a fixed bias $V = 0.5$ V. From it we see that, although there is a decreasing of the SP with the temperature, the current through the device is still apparently spin polarized if temperature is not too high. In present parameters, the current can keep a high spin polarization when temperature is less than 280 K. However, when temperature approaches the critical point, the SP drops rapidly and becomes very small when temperature is beyond the critical point.

4. Summary

In summary, spin excited states in organic ferromagnet *poly*-BIPO are investigated to study the spin transport in an organic metal/*poly*-BIPO/metal device under a finite temperature. The picture of spin excited state is elucidated by calculating the SDW along the molecular chain and the spin excited energy. A localized defect of SDW appears when a spin excited state forms. The spin excited energy increases with the number of excited spins and keeps nearly unchanged when the number of excited spins is over a certain value. Then the spin-dependent transport through a metal/*poly*-BIPO/metal device is investigated. It is found that a suppression of the total current may take place when the magnetic molecule is in a spin excited state, which predicts a conductance switch function of the device. It is also found that a low spin excited state has little effect on SP and the device may still function as a spin filter. The intrinsic mechanism is explained by calculating the spin-dependent transmission in different spin excited states. The temperature effect on the spin-polarized transport is studied. The current can keep a high spin polarization when temperature is not too high. The result indicates that the device may serve as a stable spin filter. Finally, it should be mentioned about the validity of the $e–e$ interactions adopted in present work. Usually Hubbard model is considered to be the simplest one to treat $e–e$ interactions, although it is only valid in a narrow-band system. In organic semiconductors, Hubbard model is widely adopted, and the strength of Hubbard U is considered to be widely distributed from 1.0 to 11.0 eV [27]. A strong $e–e$ interaction will seriously affect the electronic structure of the system and so the spin current polarization. For example, a spin-polarized ground state may be obtained in the case of large U. As the first step to understand the spin current polarization in an organic device, in present work, we only considered the case of a weak Hubbard interaction. The effect of $e–e$ interactions was mainly reflected in the structure of the electronic energy levels of the system, which will affect the transmission probability of spin-up and spin-down electrons to some extent. In the further work, we will try to consider the effect of $e–e$ interactions on the ferromagnetic ground state and the spin drag effect with a more effective technique beyond the mean-field approximation.

processing, including ink-jet printing, screen printing [23], soft lithography [24,25], laser-assisted patterning [26,27], contact printing [28], and self-organization processes [29–33]. Among these methods, self-organization has great potential for use in the fabrication of high-throughput, low-cost electronics without degrading their OTFT performances. For example, Bao et al. [29] reported a microcontact printing (μCP) method for transferring low-molecular-weight siloxane oligomers from PDMS stamps to pattern organic poly(3-hexylthiophene) (P3HT) and poly(vinyl phenol) (PVP) materials via selective wetting/dewetting to fabricate regions with and without oligomers [29]; nevertheless, the interface of the channel region was only the bare surface, lacking a modification layer. Many authors have determined that modification layers present between the dielectric and organic active material are necessary to improve the interfacial adhesion and the film's crystallinity, thereby providing more-stable devices exhibiting higher carrier mobilities [10]. During the preparation of this manuscript, two research groups published self-organization processes featuring the treatment of two modification layers on silicon oxide surfaces [32,33]. Minari et al. [32] reported a surface presenting phenyl-terminated SAMs as channel regions and hexamethyldisilazane (HMDS) units covering the rest of the surface. Small organic molecules that had been drop-cast from toluene solutions were selectively crystallized on the phenyl-presenting SAM regions. Kim et al. [33] coated a hydrophobic fluoropolymer film onto silicon dioxide and then modified the channel regions with HMDS. A soluble pentacene derivative was then self-deposited from a xylene solution onto the channel areas. Although these two initial studies [32,33] appear to have several advantages over simple mono-modification treatment [29–31] the authors studied the patterning of semiconductors in nonpolar solvents only; they did not explore the use of other materials (e.g., conducting polymers, organic gate dielectrics) or other polar and nonpolar solvents. In addition, the origins of the self-organization processes were considered to occur mostly through differences in the water contact angles of the substrates inducing the hydrophilic/hydrophobic properties; there remains much room to provide a more appropriate explanation of these phenomena.

In this study, we developed a new system for the self-patterning of two types of SAMs on silicon dioxide surfaces, with HMDS forming channel regions and octyltrichlorosilane (OTS) covering the remaining areas. We prepared these patterns readily using traditional photolithography processes. In addition to investigating several organic and inorganic semiconductors, we also processed the conducting polymers from aqueous solutions and employed organic gate dielectric materials. We explain the self-patterning phenomena in terms of surface energy differences – rather than the previously reported simple hydrophilic/hydrophobic water contact angle theory.

2. Experimental section

Materials: PVP (M_w = 20,000), PMF (M_w = 511), OTS, HMDS, chlorobenzene, toluene, propylene glycol mono-methyl ether acetate (PGMEA), CH_2Cl_2, hexane, and acetone were purchased from Sigma–Aldrich and used without further purification. Regioregular P3HT was purchased from Aldrich and purified through Soxhlet extractions with hexane and CH_2Cl_2 to remove low-molecular-weight chains. 13,6-N-sulfinylacetamidopentacene (NSFAAP) and zinc acetate were also obtained commercially from Aldrich and used directly. Poly(9,9-dioctylfluorene-alt-bithiophene) (F8T2) was purchased from American Dye Source. The PEDOT:PSS water solution (AI4083) was purchased from Bayer.

Device fabrication: We prepared the substrate using the self-patterning process presented in Fig. 1. We employed a silicon wafer presenting thermally grown SiO_2 (d = 100 nm) as the substrate. The source and drain (S/D) Pt/Ti (50 nm/2 nm) electrodes having channel widths and lengths of 1000 and 10 μm, respectively, were prepared using a photolithography/Pt–Ti deposition/lift-off (acetone) process. The entire device surface was treated with HMDS vapor and then cured at 150 °C for 0.5 h, and then the channel regions of the device were covered with photoresist using conventional photolithography processing. The remaining region not covered with the photoresist was treated through O_2 plasma bombardment and then treated with OTS vapor then cured at 100 °C for 0.5 h. Finally, the photoresist was removed to provide a substrate presenting HMDS in the channel regions and OTS over the remaining areas.

Electrical Measurements: All TFT devices arrays in this study, each containing 20 devices were fabricated. To ensure accuracy of data that were collected, we measured at least 10 devices for each array and no significant (<10%) variations were observed from device to device. All I–V measurements of our OTFT devices were recorded at room temperature under ambient conditions using an Agilent 4156C semiconductor parameter analyzer. The thicknesses of the corresponding films were determined through cross-sectional scanning electron microscopy (SEM). The surface energies of the various SAM surfaces were determined through contact angle measurements using a FACE contact-angle meter (Kyowa Kaimenkagaku Co.) and distilled water and CH_2I_2 as probe liquids.

3. Results and discussion

We employed various solutions of organic and inorganic materials to examine the scope of this self-patterning method; Fig. 2 presents their chemical structures. After depositing a drop of the semiconductor solution [P3HT (5 mg) in dichlorobenzene (1 mL)] onto the HMDS/OTS-presenting S/D electrode-patterned substrate and then decanting the substrate to remove the large droplet, we found that some small droplets remained adhered to the HMDS regions. After the solvent had dried, the resulting films were isolated with finely featured shapes on the HMDS region. Thus, using this approach, we fabricated a bottom gate, bottom contact configuration of the patterned P3HT-OTFT. Fig. 3a displays an optical micrograph of the with uniformly patterned P3HT-OTFT device array. A magnified image of the P3HT-OTFT single device (Fig. 3b)
Fig. 1. Schematic procedure used for the self-patterning of OTFTs.
Fig. 2. Chemical structures of the materials used to prepare the patterned organic and inorganic films.

reveals rectangular features (250 μm × 300 μm). In addition, when we used the HMDS/OTS-presenting substrate lacking any S/D electrodes, we formed films of the organic conductor poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulfonic acid) (PEDOT:PSS) from an aqueous solution (Fig. 3c) and of poly(vinyl phenol) (PVP), a commonly used dielectric layer, from a propylene glycol methyl ether acetate (PGMEA) solution (Fig. 3d); these polymers were also well defined in the desired regions, with their films were exhibiting uniformly striped rectangular featured having areas of 100 μm × 1000 μm. Thus, a series of materials could be self-patterned using HMDS/

OTS substrates through solution processing with a wide range of solvents.

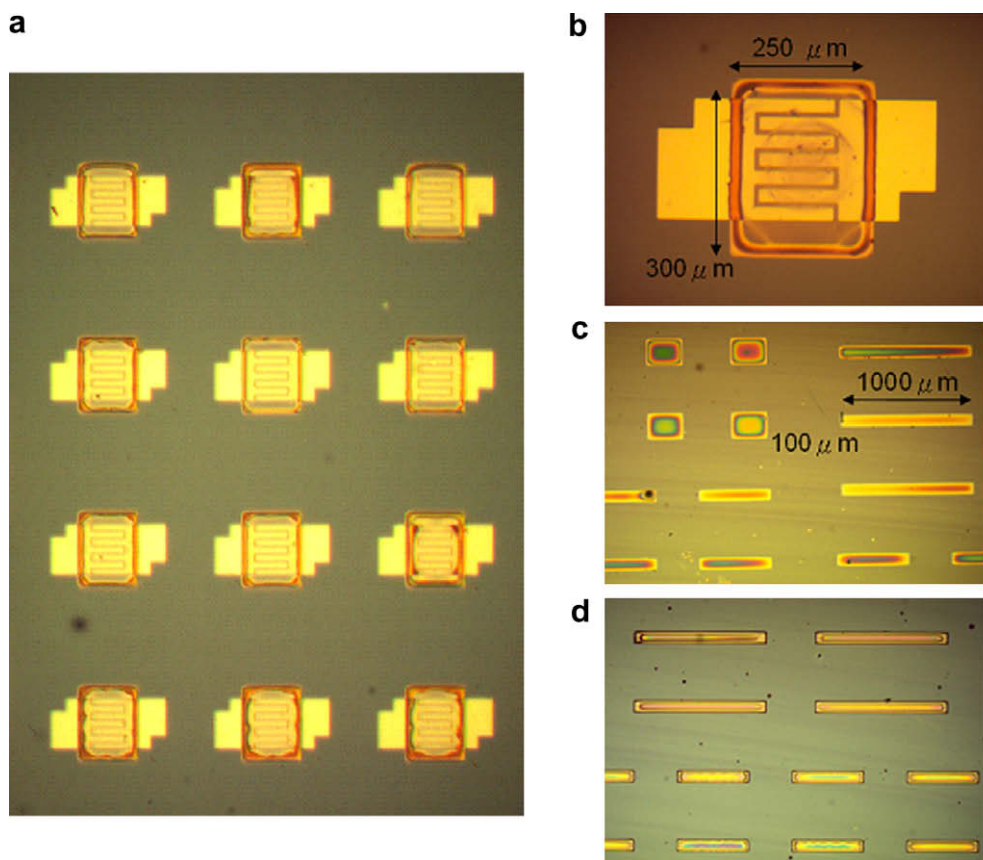
We used an energy dispersive spectrometer (EDS) to analyze the surfaces of the patterned P3HT-OTFT devices to determine whether any residues or contaminants existed outside the active region after performing the solution deposition process. Before taking SEM photographs, we deposited a thin Pt film to make the substrate conductive. So the Pt signals were observed at both regions. Fig. 4 presents EDS spectra recorded over an active P3HT region and over a P3HT-free region. P3HT has the chemical formula $C_{10}H_{14}S$; we found S and C atom signal distributions


Fig. 3. Optical micrographs of silicon substrates presenting (a) a P3HT-OTFT array, (b) a single P3HT-OTFT device, (c) a PEDOT:PSS array, and (d) a PVP self-patterned array.
Fig. 4. SEM images and EDS spectra of a P3HT-OTFT device prepared using the self-patterning method.

in the EDS profile of active region, as well as O, Si, and Pt atom signals representing the SiO$_2$ substrate and the S/D Pt electrodes. In contrast, the EDS profile recorded away from the HMDS region, i.e., the region presenting OTS, reveals signals only for O, Si, and Pt atoms, suggesting that no or non-sufficient P3HT residues or other organic contaminants were present in this area.

In addition to rr-P3HT, we also employed two other organic semiconductors – poly(9,9-dioctylfluorene-*alt*-bithiophene (F8T2; 20 mg in 1 mL of CHCl$_3$), 13,6-*N*-sulfinylacetamidopentacene (NSFAAP; 15 mg in 1 mL of CHCl$_3$) – and one inorganic semiconductor (ZnO precursor solution; zinc acetate-to-ethanolamine molar ratio, 1:1; mixture concentration, 0.375 M in 2-methoxyethanol) to prepare OTFTs using the HMDS/OTS substrates. Again, we found that all of the resulting films exhibited isolated, fine feature shapes located in the HMDS regions, thereby providing bottom gate, bottom contact configurations for their patterned OTFTs. Moreover, we prepared corresponding controlled non-patterned P3HT-OTFT devices to compare their off currents with those of the patterned devices. Fig. 5 presents the electronic characteristics of the OTFT devices; we determined the transfer characteristics of P3HT, F8T2, and pentacene devices by operating the devices at a value of V_{ds} of −40 V and values of V_G ranging from +40 to −40 V and of ZnO device by operating at a value of V_{ds} of 20 V and values of V_G ranging from −10 to 60 V. We define the carrier mobility (μ) and the threshold voltage V_{th} using Eq. (1):
Fig. 5. (a) Transfer curves and (b and c) output curves of P3HT devices prepared on non-patterned and self-patterned semiconductor films. (d–f) Transfer curves of the (d) F8T2, (e) pentacene precursor, and (f) ZnO TFT devices.

$$\sqrt{I_{D,SAT}} = \sqrt{\frac{W\mu C_{ox}}{2L}}(V_G - V_{th}) \tag{1}$$

where $I_{D,sat}$ is the saturated drain current, C_{ox} is the gate capacitance per unit area, W and L are the conducting channel width and length, respectively, and V_G is the applied gate voltage. We extracted the mobilities from the slopes of the linear plots of the square root of the drain current versus the gate voltage. The transfer curve of the non-patterned P3HT-OTFT device (Fig. 5a) exhibited an off current of 10^{-9} A. The on/off ratio, the mobility, and the threshold voltage were 8.9×10^4, 3.2×10^{-2} $cm^2 V^{-1} s^{-1}$, and 8 V, respectively. For the patterned P3HT-OTFT device (also presented in Fig. 5a), the on/off ratio improved dramatically from 8.9×10^4 to 3.8×10^7, with the off current decreasing from 10^{-9} to 10^{-12} A. We suspect that the off current was suppressed effectively as a result of self-patterning. The mobility of the patterned P3HT device decreased only slightly (to 2.6×10^{-2} $cm^2 V^{-1} s^{-1}$) relative to that of the non-patterned device ($3.2 \times 10^{-2} cm^2 V^{-1} s^{-1}$). The differences of mobilities caused by patterning of P3HT layer was also found by Jia et al. [17] Fig. 5b and c present the I_D–V_D output characteristics of the non-patterned and self-patterned P3HT-OTFTs, respectively; the insets provide the drain current (I_D) offset, defined as the value of I_D at various gate biases, when the drain voltage was zero [18]. Ideally, the value of the I_D offset would be zero when V_D is zero. For the non-patterned device (Fig. 5b inset), the value of the I_D offset increased when higher gate voltages were applied; the I_D–V_D output curve in the linear region was clearly distorted. On the other hand, the I_D–V_D output curve of the patterned device exhibited an ideal I_D offset (Fig. 5c inset), thanks to the patterning effect of the semiconductors. Note that

NSFAAP is transformed into pentacene through thermally degradation, and that ZnO films are formed from zinc acetate during high temperature annealing. Fig. 5d–f display the transfer curves of the F8T2, pentacene, and ZnO TFTs, respectively. The on/off ratio, mobility, and threshold voltage of the F8T2 device were 2×10^5, 2.1×10^{-5} $cm^2 V^{-1} s^{-1}$, and −5 V, respectively; for the pentacene-containing device, these values were 7×10^6, 3.5×10^{-2} $cm^2 V^{-1} s^{-1}$, and 7 V, respectively; for the ZnO-based device, they were 3×10^3, 0.31 $cm^2 V^{-1} s^{-1}$, and 5 V, respectively. Thus, all of these OTFT devices exhibited moderate to good electrical characteristics after performing self-patterning, suggesting that this method has great potential for application to the preparation of large-area, low-cost organic electronic devices.

To determine the origins of the self-patterning effect, we determined the surface energies of the SAM-treated dielectrics by measuring their contact angles for distilled water and CH_2I_2 as probe liquids and employing the geometric mean Eq. (2) [34]:

$$(1 + \cos\theta)\gamma_{pl} = 2(\gamma_s^d \gamma_{pl}^d)^{1/2} + 2(\gamma_s^p \gamma_{pl}^p)^{1/2} \tag{2}$$

where γ_s and γ_{pl} are the surface energies of the sample and probe liquid, respectively, and the superscripts d and p represent the dispersion and polar components of the surface energy, respectively. Table 1 summarizes the contact angles and surface energies of our various SAM-modified surfaces. The surface energies of the active regions (HMDS on SiO_2: 37.4 mJ m^{-2}; HMDS on Pt: 40.7 mJ m^{-2}) of the P3HT-OTFT devices were higher than those of the non-active regions (OTS on SiO_2: 24.5 mJ m^{-2}; OTS on Pt: 31.9 mJ m^{-2}). Because the surface energy is related to the absorbance of the surface, a surface having a high surface energy more readily absorbs the contacting liquid. Fig. 6

Table 1
Contact angles and surface energies of various SAM-modified surfaces.

Surface treatment	Contact angle		Surface energy (dispersion component) γ_s^d (mJ m^{-2})	Surface energy (polar component) γ_s^p (mJ m^{-2})	Surface energy (substrate) γ_s (mJ m^{-2})
	Water(°)	CH$_2$I$_2$(°)			
Bare SiO$_2$	61.5	53.9	32.1	14.6	46.7
Bare SiO$_2$ + HMDS	74.8	59.4	28.9	8.5	37.4
Bare SiO$_2$ + O$_2$ plasma	25.2	43.1	38.0	32.0	70.0
Bare SiO$_2$ + O$_2$ plasma + OTS	98.2	69.6	23.1	1.5	24.5
Bare Pt	86.9	40.8	37.2	1.6	40.8
Bare Pt + HMDS	85.2	41.9	38.6	2.1	40.7
Bare Pt + O$_2$ plasma	87.6	35.8	41.7	1.2	42.8
Bare Pt + O$_2$ plasma + OTS	95.0	56.0	30.9	1.0	31.9

presents the surface energies of the HMDS/OTS-treated surfaces with S/D Pt electrodes (stripe pattern; W = 500 μm, L = 10 μm) as well as their relative locations. We observe that the contacting liquids more readily adhere to the HMDS surface with its higher surface energy than to the OTS surface with its lower surface energy. When we placed a drop of P3HT in dichlorobenzene onto the device substrate's surface, the droplet selectively wetted/adhered to the HMDS regions and dewetted the OTS regions. After decanting the substrate, the remaining P3HT solution was located (adhered) only on the areas of higher surface energy. As the solvent was evaporated, the P3HT film formed in the desired areas with confined features. The use of contacting liquids of other organic and inorganic semiconductors in either CHCl$_3$ or methoxyethanol, of PEDOT:PSS in aqueous solutions, and of PVP in PGMEA solution was also compatible with this method.

We note that both the HMDS- and OTS-SiO$_2$ surfaces possessed large water contact angles, i.e., the surfaces are

hydrophobic; therefore, aqueous solutions should not adhere to them at all. Indeed, several researchers have reported self-organization processes in which HMDS-SiO$_2$ [32] and OTS-SiO$_2$ [30,31] act as dewetting regions. In our case, however, the two HMDS- and OTS-SiO$_2$ surfaces provided a unique patterning platform for successful solution processing using a wide range of solvents. Therefore, the simple hydrophilic/hydrophobic interactions cannot explain our wetting phenomena. We believe that the surface energy interactions – considering the differences in surface energy of the two SAMs – is more suitable for explaining this self-patterning phenomenon.

4. Conclusions

In summary, we have developed a solution-processable self-patterning method using a two-phase SAM-modified silicon dioxide surface for the deposition of a variety of

organic and inorganic materials from both organic and aqueous solutions. The resulting films were self-patterned in the desired regions with well-defined feature shapes. From analyses of substrates presenting S/D electrodes, all of our self-patterned TFT devices exhibited moderate to good electronic characteristics. This method has great potential for application to the fabrication of large-area, low-cost, fully-solution-processed electronics when combined with mature photolithographic technology for mass production. Surface energy interaction explains this self-patterning phenomenon more suitably than does a simple hydrophilic/hydrophobic interaction.

Television System Committee (NTSC) blue color standard (0.14, 0.08).

It is extremely difficult to produce highly efficient blue light emitters with long device life-times because, with a wide band gap, their electronic levels are likely to be mismatched with the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of the other OLED layers such as the hole transporting layer (HTL) and the electron transporting layer (ETL). These differences between the electronic levels result in a mismatched carrier balance of electrons and holes, and a low EL efficiency and short life-time.

Many types of blue light emitting derivatives of diarylanthracene [16], di(styryl)arylene [17], fluorene [18], pyrene [19], and fluoranthene [20] have been intensively investigated, and attempts have been made to improve their EL properties. The commercial product 4,4-bis(2,2-diphenylvinyl)-1,1-biphenyl (DPVBi) [17] has a low glass transition temperature (T_g) of 64 °C [17b], undergoes re-crystallization after long operation, and has a shorter device life-time than green and red light emitters. Another well known blue compound, 2-methyl-9,10-di(2′-naphthyl)anthracene (MADN) [21], has a high T_g, a longer life-time and better $CIE_{x,y}$ coordinates than DPVBi; however, MADN has low luminance efficiency, which reduces its utility in full color displays. Thus, much research is being directed at developing a new high efficiency blue light emitter.

Cheng and coworkers reported pyrene derivatives with color coordinates of (0.15, 0.11) and a maximum external quantum efficiency (EQE) of 5.2% [22], and Jenekhe and coworkers described oligoquinoline derivatives with a very high EQE (6.56%) and color coordinates of (0.15, 0.16) [23].

Highly efficient synthetic blue light emitters with an anthracene core and *m*-terphenyl or triphenylbenzene side groups have recently been reported [24,25]. The synthesized compounds are 10-bis(3′,5′-diphenylphenyl)anthracene (MAM), 9-(3′,5′-diphenylphenyl)-10-(3‴,5‴-diphenylbiphenyl-4″-yl) anthracene (MAT), and 9,10-bis(3″,5″-diphenylbiphenyl-4′-yl)anthracene (TAT) (Scheme 1).

An aromatic ring in the meta rather than the para position was selected because the former has a shorter conjugation length; this is advantageous because it reduces the *y*-CIE coordinate value of the emitter [26]. In addition, the introduction of a bulky and non-planar side group prevents π–π* stacking interactions, which leads to the

formation of more reliable amorphous films [22,27]. This is expected to have a positive effect on the life-time of operating OLED devices. Furthermore, the absolute PL quantum efficiency of the *m*-terphenyl group is 0.29 [28], which is higher than that of the more commonly used naphthalene group (0.21) [29], so an increase in EL efficiency is expected. Interestingly, as the photoluminescence efficiency of the side groups has increased, the performance of the synthesized blue light emitters has also improved substantially. In particular, TAT had a higher PL fluorescence quantum efficiency (QE) than MADN, and had a T_g more than 30 °C that of MADN. Its color coordinates (0.156, 0.088) meet the NTSC blue standard, and it exhibits an excellent EQE value (7.18%) about twice that of MADN; these are the best reported results for non-doping deep-blue fluorescence OLED emitter [25]. Thus, large variations in device efficiency have been found for compounds with the same core but different side groups, confirming the importance of the latter.

In this study, a phenyl group (Ph) in three synthetic blue light emitters reported in a previous study was changed to an amine group (Am) to produce three new emitting compounds. Thus, three types of organic compound with asymmetric structure were synthesized by substituting an *m*-terphenyl group with a diphenylamine group, and a triphenylbenzene group with a triphenylamine group. This gave rise to the synthetic compounds 10-(3,5-diphenylphenyl)-N,N-diphenylanthracen-9-amine (MADa), 4-(10-(3,5-diphenylphenyl)anthracen-9-yl)-N,N-diphenylaniline (MATa), and 4-(10-(3′,5′-diphenylbiphenyl-4-yl)anthracen-9-yl)-N,N-diphenylaniline (TATa), where M, A, T, Da and Ta denote *m*-terphenyl, anthracene, triphenylbenzene, diphenylamine, and triphenylamine, respectively (Scheme 1). It was hypothesized that addition of an amine unit [12] commonly contained by other highly efficient blue dopants could increase the luminance efficiency of the three synthesized compounds. In addition, the bulky side group could prevent interactions between molecules, and potentially enhance the formation of more reliable amorphous films. The syntheses was also undertaken to address one of the biggest issues with blue light emitters, namely that of increasing device life-time.

The thermal, electrochemical and spectroscopic properties of the synthesized materials were characterized using differential scanning calorimetry (DSC), thermogravimetric
Scheme 1. Chemical structures of the synthesized materials.

analysis (TGA), cyclic voltammetry (CV), atomic force microscopy (AFM), and UV–visible and photoluminescence (PL) spectroscopy. Multi-layered EL devices were fabricated using the materials as non-doped emitting layers.

2. Experimental

2.1. General Information

[1]H nuclear magnetic resonance (NMR) spectra were recorded on Bruker Avance 300 and Avance 500 spectrometers. Fourier transform infrared spectroscopy (FT-IR) spectra were recorded on a Thermo Electron Nicolet IR-200 spectrometer. Fast atom bombardment (FAB[+]) and positive electron impact (EI[+]) spectra were recorded on a JEOL, JMS-AX505WA, HP5890 series II mass spectrometer. The optical absorption spectra were obtained with a HP 8453 UV–VIS–NIR spectrometer. Crystals of MATa and TATa were obtained from THF/hexane at room temperature, sealed in glass capillaries under nitrogen, and mounted in a diffractometer. The ground state geometries were fully optimized using density functional theory (DFT) [32] with the B3LYP hybrid functional at the basis set level of 6-31G[*]. All calculations were performed using Gaussian 03 software [32c] on a PowerLeader workstation. Atomic force microscopy (AFM) imaging was performed in air using a PicoScan system (Molecular Imaging) equipped with a 5×5 µm scanner. Magnetic-ac(Mac) mode (a non-contact mode) was used for all the AFM images. The melting temperatures (T_m), glass transition temperatures (T_g), and degradation temperatures (T_d) of the compounds were measured by differential scanning calorimetry (DSC) under a nitrogen atmosphere using a DSC2910 differential calorimeter (TA Instruments), and thermogravimetric analysis (TGA) was performed using a SDP-TGA2960 (TA Instruments). The redox potentials of the compounds were determined by cyclic voltammetry (CV) using an EG&G 362 electrochemical workstation with a scanning rate of 50–200 mV/s. The synthesized materials were dissolved in N,N-dimethylformamide (DMF) with 0.1 M tetrabutyl-ammonium tetrafluoroborate as the electrolyte. We used a platinum working electrode and a saturated Ag/AgNO$_3$ reference electrode. Ferrocene was used for potential calibration and for reversibility criteria. A Perkin Elmer luminescence spectrometer LS50 (Xenon flash tube) was used for photo- and electro-luminescence spectroscopy, and to determine the fluorescence quantum yields (φ_F) [30]:

$$\Phi_{F(A)} = \Phi_{F(ref)} \times \frac{PL_A}{UV_A} \times \frac{UV_{ref}}{PL_{ref}} \times \left(\frac{\eta_A}{\eta_{ref}}\right)^2 \qquad (1)$$

where $\varphi_{F(ref)} = 1.00$ (relative PL quantum efficiency (φ_F) of MADN in ethanol solution); $\varphi_{F(A)}$ is relative φ_F in ethanol solution of synthesized materials; PL$_A$ and PL$_{ref}$ are the integrated emission intensities of the sample and the standard, respectively; UV$_A$ and UV$_{ref}$ are the absorbances of the sample and the standard at the excitation wavelength, respectively; and η_A and η_{ref} are the refractive indexes of the corresponding solutions (pure solvents were assumed).

The diffraction experiments were carried out on a Rigaku R-AXIS RAPID diffractometer equipped with a Mo-Kα

and Control Software using the RAPID AUTO at 293 (±2) °C. Empirical absorption corrections were applied automatically. The structures were solved with direct methods and refined with a full-matrix least-squares technique using the SHELXS v. 5.1 programs [33]. The space groups were determined from the systematic absences and their correctness was confined by successful solution and refinement of structures. Anisotropic thermal parameters were refined for all the non-hydrogen atoms. The hydrogen atoms were added in idealized position and refined with isotropic displacement.

For the EL devices, all organic layers were deposited under 10^{-6} torr at a deposition rate of 1 Å/s, to give an emitting area of 4 mm^2. The LiF and aluminum layers were subsequently deposited under the same vacuum conditions. The current–voltage (I–V) characteristics of the fabricated EL devices were obtained using a Keithley 2400 electrometer. The light intensities were determined using a Minolta CS-1000A. OLED device was encapsulated for life-time with glass-lid under the nitrogen.

2.2. Single crystal X-ray diffraction data

(MATa): Empirical formula: C50 H35N, formula weight: 649, temperature: 293(2) K, wavelength: 0.71073 Å, crystal system, space group: monoclinic, $P2(1)/c$, unit cell dimensions: $a = 10.468(2)$ Å, $b = 19.184(4)$ Å, $c = 17.903(4)$ Å, $\alpha = 90°$, $\beta = 100.70(3)°$, $\gamma = 90°$, volume: 3532.7(12) Å^3, Z, calculated density: 104, 1.321 Mg/m^3, absorption coefficient: 0.093 mm^{-1}, $F(0\,0\,0)$: 1456, crystal size: $0.109 \times 0.138 \times 0.276$ mm, θ range for data collection: 3.14–27.47°, limiting indices: $-13 < h < 13$, $-24 < k < 20$, $-23 < l < 23$, reflections collected/unique: 5934/5934 [R(int) = 0.0000], completeness to $\theta = 27.48$: 99.0%, refinement method: full-matrix least-squares on F^2, data/restraints/parameters:8019/0/460, goodness-of-fit on F^2: 0.825, final R indices [$I > 2\sigma(I)$]: $R1 = 0.0695$, $wR2 = 0.1994$, R indices (all data): $R1 = 0.1882$, $wR2 = 0.2943$.

(TATa): Empirical formula: C56 H39N, formula weight: 725, temperature: 293(2) K, wavelength: 0.71073 Å, crystal system, space group: triclinic, $P\bar{1}$, unit cell dimensions: $a = 9.900(2)$ Å, $b = 14.436(3)$ Å, $c = 17.901(4)$ Å, $\alpha = 103.22(3)°$, $\beta = 104.72(3)°$, $\gamma = 107.03(3)°$, volume: 2235.1(8) Å^3, Z, calculated density: 66, 1.349 Mg/m^3, absorption coefficient: 0.097 mm^{-1}, $F(0\,0\,0)$: 940, crystal size: $0.108 \times 0.189 \times 0.394$ mm, θ range for data collection: 3.11–27.48°, limiting indices: $-12 < h < 12$, $-18 < k < 18$, $-22 < l < 23$, reflections collected/unique:22145/10099 [R(int) = 0.0913], completeness to $\theta = 27.48$: 98.5%, refinement method: full-matrix least-squares on F^2, data/restraints/parameters:10099/0/559, goodness-of-fit on F^2 : 0.917, Final R indices [$I > 2\sigma(I)$]: $R1 = 0.1072$, $wR2 = 0.2756$, R indices (all data): $R1 = 0.2556$, $wR2 = 0.3674$.

2.3. Synthesis

2.3.1. Synthesis of compound 1

Bromobenzene (30 mL, 0.28 mol) was added in 300 mL of dry THF solution and stirred at -78 °C, then 1.6 M n-BuLi

(260 mL) was added. Next, isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (87 mL, 0.42 mol) was added to the reaction mixture after 30 min. After the reaction had finished, the reaction mixture was extracted with diethyl ether and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The mixture was evaporated. The residue was purified by column chromatography with CHCl$_3$:*n*-hexane (1:1) eluent to afford colorless solution (compound **1**) (50 g , 87%). ^{1}H NMR (500CDCl$_3$, δ): 7.81 (d, 2H), 7.41 (t, 1H), 7.33 (t, 2H), 1.30 (s, 12H), EI$^+$-Mass: 204.

2.3.2. Synthesis of compound **2**

Compound **1** (32 g, 155 mmol), 1,3,5-tribromobenzene (20 g, 62 mmol), and Pd(PPh$_3$)$_4$ (3.57 g, 3.1 mmol) were added to 300 mL of dry THF solution, then 2 M K$_2$CO$_3$ solution (50 mL) was added to reaction mixture. The mixture was heated to 65 °C for 5 h under nitrogen. After the reaction finished, the reaction mixture was extracted with diethyl ether and water. The organic layer was dried by anhydrous MgSO$_4$ and filtered. The solution was evaporated. The product was isolated by silicagel column chromatography using CHCl$_3$:*n*-hexane (1:19) eluent to afford white solid (compound **2**) (12 g, 62.4 %) ^{1}H NMR (300CDCl$_3$, δ): 7.70 (s, 3H), 7.60 (d, 4H), 7.46(t, 4H), 7.36 (t, 2H), EI$^+$-Mass: 310.

2.3.3. Synthesis of compound **3**

Compound **2** (12 g, 38.7 mmol) was added in 300 mL of dry THF solution and stirred at −78 °C, then 1.6 M *n*-BuLi (36 mL) was added. Next, isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (12 mL, 58 mmol) was added to the reaction mixture after 30 min. After the reaction had finished, the reaction mixture was extracted with diethyl ether and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The mixture was evaporated. The precipitate was filtered and washed with an excess of methanol. The yellowish powder was purified by using column chromatography with CHCl$_3$:*n*-hexane (1:1) eluent to afford white solid (compound **3**) (13 g , 94%). ^{1}H NMR (500CDCl$_3$, δ): 8.03 (s, 2H), 7.90 (s, 1H), 7.69 (d, 4H), 7.44(t, 4H), 7.35 (t, 2H), 1.37 (s, 12H) EI$^+$-Mass: 356.

2.3.4. Synthesis of compound **4**

Compound **3** (3 g, 8.4 mmol), 9-bromoanthracene (2.37 g, 9.25 mmol), Pd(OAc)$_2$ (0.190 g, 0.85 mmol), and (cyclohexyl)$_3$P (0.22 g, 0.85 mmol) were added toluene (150 mL) solution, then tetraethylammonium hydroxide (20 wt%) 10 mL was added to the reaction mixture. The mixture was heated to 110 °C for 2 h under nitrogen. After the reaction had finished, the reaction mixture was extracted with chloroform and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The solution was evaporated. The residue was re-dissolved in CHCl$_3$ and added to methanol. The precipitate was filtered and washed with methanol. The yellowish powder was purified by using column chromatography with CHCl$_3$:*n*-hexane (1:5) eluent to afford a beige solid (compound **4**) (3.1 g, 90.9 %). ^{1}H NMR (500CDCl$_3$, δ): 8.53 (s, 1H), 8.06 (d, 2H), 8.01 (t, 1H), 7.83 (d, 2H), 7.74 (m, 4H), 7.68 (d, 2H), 7.46(m, 6H), 7.36 (m, 4H), Fab$^+$-Mass: 406.

2.3.5. Synthesis of compound **5**

Compound **4** (2 g, 4.92 mmol) and NBS (0.98 g, 5.5 mmol) were added to 150 mL of CHCl$_3$ solution. The mixture was heated to 60 °C for 30 min under nitrogen. After the reaction had finished, solution was evaporated. The residue was re-dissolved in acetone and added to methanol. The precipitate was filtered and washed with methanol to get compound **5** of yellowish color. (2.3 g, 96.4 %). ^{1}H NMR (500CDCl$_3$, δ): 8.64 (d, 2H), 8.02 (t, 1H), 7.82 (d, 2H), 7.74 (m, 4H), 7.62 (d, 2H), 7.60 (m, 2H), 7.44 (m, 8H), Fab$^+$-Mass: 486.

2.3.6. Synthesis of MAMa

Compound **5** (1 g, 2.06 mmol), diphenylamine (0.51 g, 3.0 mmol), t-BuONa (0.58 g, 6.18 mmol), and Pd$_2$(dba)$_3$ (0.05 g, 0.6 mmol) were added to dried toluene solvent (150 mL), then (t-Bu)$_3$P was added into the reaction mixture. The mixture was heated to 110 °C for 1 h under nitrogen. After the reaction mixture cooled, it was then acidified with 1 N HCl solution, and extracted with CHCl$_3$. The organic layer was dried by anhydrous MgSO$_4$ and filtered. The solution was evaporated. The residue was dissolved in CHCl$_3$ and added to acetone. The precipitate was filtered and washed with acetone. The dark yellow residue was purified by column chromatography with CHCl$_3$:*n*-hexane (1:1) eluent to afford yellowish-green solid (MAMa) (0.9 g, 76.5%). ^{1}H NMR (500CDCl$_3$, δ): 8.21 (d, 2H), 8.03(s, 1H), 7.88 (d, 2H), 7.75 (q, 6H), 7.47 (t, 4H), 7.36 (m, 6H), 7.17 (m, 8H), 6.89 (t, 2H), ^{13}C NMR(500CDCl$_3$, δ):147.96, 142.04, 140.94, 139.91, 136.61, 137.48, 131.63, 130.62, 129.41, 129.28, 129.11, 127.87, 127.55, 126.73, 125.77, 125.36, 124.64, 121.41, 120.46, Fab$^+$-Mass: 574, FI-IR (KBr, cm^{-1}): 3061 (s, C–H stretch), 3032 (s), 1589 (m, C = C aromatic), 1496 (m), 1275 (m, C–N stretch), 751 (s, meta-sub aromatic), 694 (m, 1,3,5-sub aromatic).

2.3.7. Synthesis of compound **6**

4-Bromo-N,N-diphenylaniline (8 g, 24.7 mmol) was added in 300 mL of dry THF solution and stirred at −78 °C, then 1.6 M *n*-BuLi (31 mL) was added. Next, isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (10.3 mL, 50 mmol) was added to the reaction mixture after 30 min. After the reaction had finished, the reaction mixture was extracted with diethyl ether and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The mixture was evaporated. The residue was purified by column chromatography with EA:*n*-hexane (1:1) eluent to afford colorless solution (compound **6**) (5.0 g , 54.6%). ^{1}H NMR (500CDCl$_3$, δ): 7.87 (d, 2H), 7.22 (m, 4H), 7.10 (m, 6H), 6.97 (t, 2H), 1.32 (s, 12H), EI$^+$-Mass: 372.

2.3.8. Synthesis of MATa

Compound **5** (1.5 g, 3.1 mmol), compound **6** (1.26 g, 3.4 mmol), Pd(OAc)$_2$ (0.145 g, 0.65 mmol), and (cyclohexyl)$_3$P (0.16 g, 0.65 mmol) were added toluene (200 mL) solution, then tetraethylammonium hydroxide (20 wt%) 10 mL was added to the reaction mixture. The mixture was heated to 110 °C for 5 h under nitrogen. After the reaction had finished, the reaction mixture was extracted with chloroform and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The solution

was evaporated. The residue was re-dissolved in CHCl$_3$ and added to acetone. The precipitate was filtered and washed with acetone. The yellowish powder was purified by using column chromatography with CHCl$_3$:n-hexane (1:3) eluent to afford a greenish-yellow solid (MATa) (1.2 g, 59.6 %). ^{1}H NMR (500CDCl$_3$, δ): 8.02 (s, 1H), 7.87 (m, 4H), 7.74 (t, 6H), 7.46 (t, 4H), 7.34 (m, 18H), 7.08 (t, 2H), ^{13}C NMR(500CDCl$_3$, δ): 148.02, 147.40, 142.02, 141.04, 140.36, 137.43, 136.85, 132.81, 132.34, 130.34, 130.20, 129.61, 129.31, 129.10, 127.81, 127.54, 127.34, 127.24, 125.45, 125.26, 124.92, 123.32, Fab$^+$-Mass: 649, FI-IR (KBr, cm^{-1}): 3059 (s, C–H stretch), 3031 (s), 1589 (m, C = C aromatic), 1497 (m), 1275 (m, C–N stretch), 761 (s, meta-sub aromatic), 670 (m, 1,3,5-sub aromatic).

2.3.9. Synthesis of compound 7

Compound **3** (8 g, 22.5 mmol), 1,4-dibromobenzene (50 g, 212 mmol), andPd(PPh$_3$)$_4$ (1.3 g, 1.125 mmol) were added to THF (400 mL) solution, then 2 M K$_2$CO$_3$ solution (50 mL), which was dissolved in H$_2$O, was added to the reaction mixture. The mixture was heated to 65 °C for 4 h under nitrogen. After the reaction finished, the reaction mixture was extracted with diethyl ether and water. The organic layer was dried by anhydrous MgSO$_4$ and filtered. The solution was evaporated. The product was isolated by silicagel column chromatography using CHCl$_3$:n-hexane (1:10) eluent to afford white solid (compound **7**) (5 g, 57.7%). ^{1}H NMR (500CDCl$_3$, δ): 7.79 (s, 1H), 7.73 (s, 2H), 7.68 (d, 4H), 7.60 (d, 2H), 7.56 (d, 2H), 7.48 (t, 4H), 7.39 (t, 2H), Fab$^+$-Mass: 385.

2.3.10. Synthesis of compound 8

Compound **7** (3 g, 7.8 mmol), anthracen-9-ylboronic acid (1.55 g, 7.0 mmol), Pd(OAc)$_2$ (0.175 g, 0.78 mmol), and (cyclohexyl)$_3$P (0.20 g, 0.78 mmol) were added toluene (150 mL) solution, then tetraethylammonium hydroxide (20 wt%) 10 mL was added to the reaction mixture. The mixture was heated to 110 °C for 2 h under nitrogen. After the reaction had finished, the reaction mixture was extracted with chloroform and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The solution was evaporated. The residue was re-dissolved in CHCl$_3$ and added to methanol. The precipitate was filtered and washed with methanol. The yellowish powder was purified by using column chromatography with CHCl$_3$:n-hexane (1:5) eluent to afford a beige solid (compound **8**) (2.8 g, 82.8 %). ^{1}H NMR (500CDCl$_3$, δ): 8.52 (s, 1H), 8.07 (d, 2H), 7.96 (s, 2H), 7.93 (d, 2H), 7.86 (s, 1H), 7.77 (t, 6H), 7.55 (d, 2H), 7.50 (m, 6H), 7.39 (m, 4H), Fab$^+$-Mass: 483.

2.3.11. Synthesis of compound 9

Compound **8** (2 g, 4.14 mmol), NBS (0.89 g, 5 mmol) were added to 150 mL of CHCl$_3$ solution. The mixture was heated to 60 °C for 30 min under nitrogen. After the reaction had finished, solution was evaporated. The residue was re-dissolved in acetone and added to methanol. The precipitate was filtered and washed with methanol to get compound **9** of yellowish color. (2.3 g, 98.8 %). ^{1}H NMR (500CDCl$_3$, δ): 8.64 (d, 2H), 7.95 (s, 2H), 7.93 (d, 2H), 7.86 (s, 1H), 7.76 (t, 6H), 7.61 (t, 2H), 7.52 (m, 6H), 7.42 (m, 4H), Fab$^+$-Mass: 562.

2.3.12. Synthesis of TATa

Compound **9** (1.74 g, 3.1 mmol), compound **6** (1.26 g, 3.4 mmol), Pd(OAc)$_2$ (0.145 g, 0.65 mmol), and (cyclohexyl)$_3$P (0.16 g, 0.65 mmol) were added toluene (200 mL) solution, then tetraethylammonium hydroxide (20 wt%) 10 mL was added to the reaction mixture. The mixture was heated to 110 °C for 5 h under nitrogen. After the reaction had finished, the reaction mixture was extracted with chloroform and water. The organic layer was dried with anhydrous MgSO$_4$ and filtered. The solution was evaporated. The residue was re-dissolved in CHCl$_3$ and added to acetone. The precipitate was filtered and washed with acetone. The yellowish powder was purified by using column chromatography with CHCl$_3$:n-hexane (1:3) eluent to afford a greenish-yellow solid (TATa) (1.2 g, 59.6 %). ^{1}H NMR (500CDCl$_3$, δ): 7.98 (s, 2H), 7.95 (d, 2H), 7.87 (d, 3H), 7.78 (t, 6H), 7.60 (d, 2H), 7.51 (t, 4H), 7.74(m, 6H), 7.34(m, 6H), 7.30(m, 6H), 7.08(t, 2H), ^{13}C NMR(500CDCl$_3$, δ): 148.03, 147.39, 142.70, 142.26, 141.38, 140.43, 138.67, 137.37, 136.72, 132.82, 132.34, 132.12, 130.34, 130.12, 129.62, 129.12, 127.83, 127.62, 127.56, 127.35, 127.20, 125.53, 125.45, 125.35, 125.23, 124.92, 123.32, Fab$^+$-Mass: 726, FI-IR (KBr, cm^{-1}): 3058 (s, C–H stretch), 3032 (s), 1592 (m, C≡C aromatic), 1391 (m), 1275 (m, C–N stretch), 764 (s, meta-sub aromatic), 671 (m, 1,3,5-sub aromatic).

3. Results and discussion

3.1. Synthesis and optical properties

Scheme 1 shows the chemical structures of the synthesized compounds, which were purified by using silica column chromatography and re-crystallization to produce very pure powders that were characterized by NMR, FT-IR and FAB mass spectrometry analysis (overall yields: 50–60%).

The synthetic routes to the three compounds are shown in Scheme 2. Boration and metal aryl–aryl coupling reactions were used in all syntheses. As the bulky side groups 5-bromo-[1,13,1]terphenyl (compound **2**) and 5-(p-bromophenyl)-[1,13,1]terphenyl (compound **7**) are substituted with halogens, it was easy to couple them with anthracene by using the metal-catalyzed aryl–aryl coupling reaction. Thus, the side groups can be incorporated in other core molecular structures. Asymmetrical compounds have the disadvantage of being generally difficult to separate from the many compounds created at the time of synthesis. However, the asymmetric compounds in this study were synthesized with relative ease and high yield using a combination of compounds **2** and **7**; this should be of considerable value to asymmetric compounds research involving functional organic materials.

The UV and PL spectra of the synthesized compounds in CHCl$_3$ solution and in thin films are shown in Table 1. In solution, MATa and TATa had a UV$_{max}$ of 398 nm and a blue PL$_{max}$ of about 475 nm. However, MADa had a UV$_{max}$ of 428 nm and a PL$_{max}$ of 509 nm, indicating a red shift of about 35 nm relative to MATa and TATa. The PL spectra of the compounds in thin films, fabricated by vacuum

[d] Ref. [21].

deposition, showed that MATa and TATa had a PL_{max} in the blue region at 463 nm, and MADa had a PL_{max} at 498 nm, the latter again representing a red shift of about 35 nm. All three synthesized compounds showed a PL wavelength that was red shifted 10 nm in solution compared to the film. Since there is a $\pi-\pi^*$ interaction between molecules in a film, this state typically shows red shifts relative to molecules in solution. The amine unit in the synthesized compounds created a dipole within the molecule and with the solvent, which in solution may have resulted in the red shift in the PL spectrum. In a previous study, PL spectra of MAM, MAT and TAT without the amine unit showed normal red shifts in the film relative to in solution [25].

To accurately interpret the EL efficiency of the compounds, their relative PL quantum efficiencies (QEs(φ_F)) in solution were measured [30] using the method described in the Section 2. The QE of the reference material (MADN) was set at 1.00, and the relative QE of the synthesized compounds was measured. All the compounds showed high PL QE values: MADa (0.92), MATa (0.76), and TATa (1.02). A more accurate QE comparison was possible for MATa and TATa because they had identical spectra and PL_{max}. TATa (side group, triphenylbenzene) had a higher QE than MATa (side group, m-terphenyl) because the QE of triphenylbenzene is higher than that of m-terphenyl; this result emphasizes the importance of the side group [25].

3.2. Electrochemical properties and electronic energy levels

The HOMO values of the synthesized compounds were determined using cyclic voltammetry (CV). Based on these analyses, all three compounds were found to have an electrochemical stability greater than 50 cycles. The energy band gaps and HOMO and LUMO levels of MADa, MATa, and TATa were estimated by CV and analysis of the absorption edge using a plot of (hv) vs. $(ahv)^2$, where a, h, and v are absorbance, Plank's constant, and the frequency of light. The results of these analyses are summarized in Table 1. The band gaps of MADa, MATa, and TATa were 2.62, 2.87, and 2.87 eV, respectively, and the HOMO values for MADa, MATa, and TATa were 5.44, 5.35, and 5.37 eV, respectively.

These HOMO values were different from the HOMO values of other anthracene derivatives, 5.5–5.6 eV, that do not include an amine unit, such as MADN [21,25,31]. In particular, MATa and TATa had HOMO values about 0.2 eV higher than that for MAT and TAT, and MADa had a HOMO value 0.1 eV higher than that of MAM [25]. Molecular calculation was performed to interpret these results.

The HOMO and LUMO electron densities of MADa, MATa, TATa, and TAT were determined by DFT/B3LYP/6-31G* calculations using Gaussian 03 software [32] (Fig. 1).

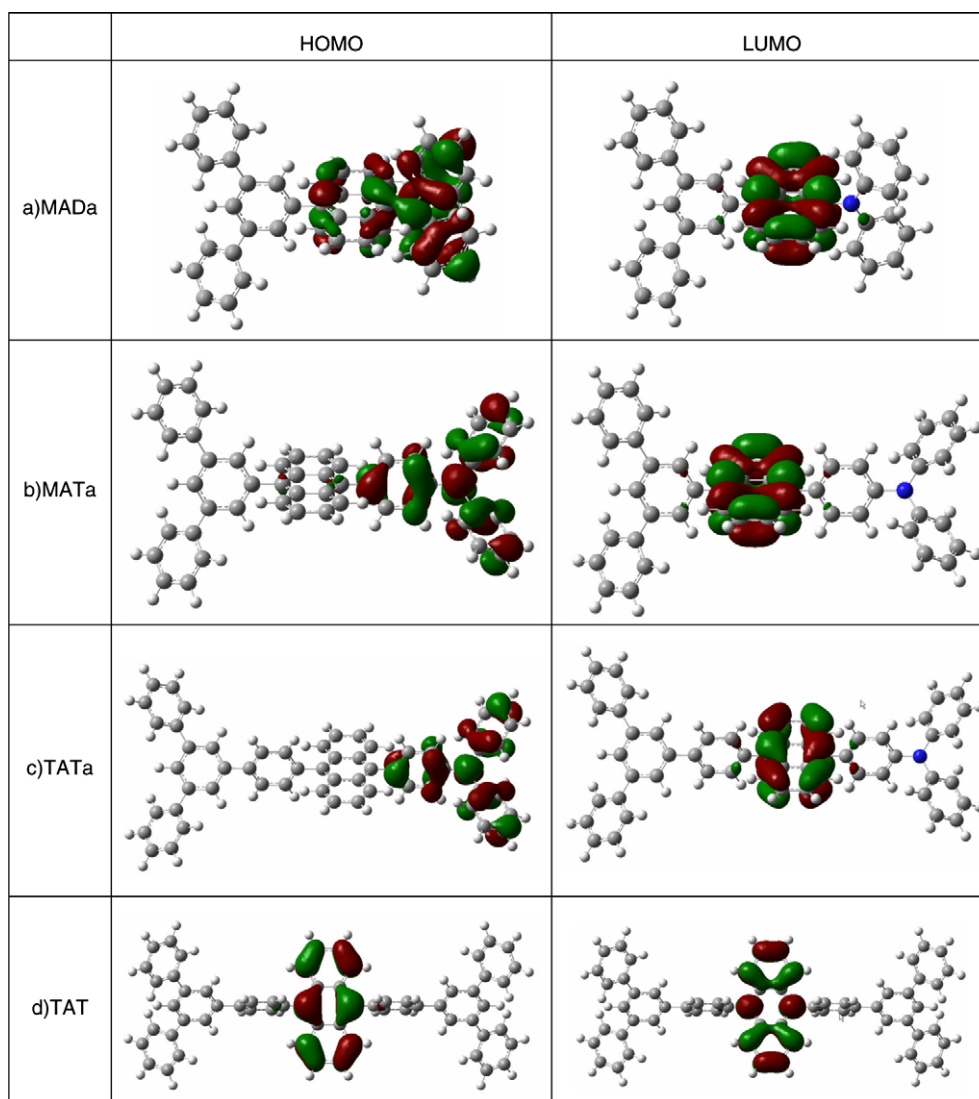
Fig. 1 shows the molecular structures of MADa, MATa, TATa and TAT in the ground state, and the HOMO and LUMO electron density distributions. Fig. 2 shows the single crystal structure of MATa and TATa. Unfortunately, THF molecule was found together for the TATa single crystal because it was incorporated into the TATa crystal. The calculated structures of MATa and TATa were found to be very similar to the actual single crystal structure, indicating that molecular calculation is very accurate.


Fig. 1. HOMO and LUMO electronic density distributions of (a) MADa, (b) MAMa, (c) TATa, and (d) TAT calculated at the DFT/B3LYP/6-31G* for optimization and Time Dependent DFT (TDDFT) using Gaussian 03.
Fig. 2. The crystal structures of (a) MATa and (b) TATa.

The HOMO electron distributions of the four compounds were substantially different (Fig. 1). The HOMO electrons of MATa and TATa were in the triphenylamine unit, while those of TAT were in the anthracene moiety. This indicates that the triphenylamine unit is more easily oxidized as it has more electrons.

Moreover, from the structure obtained by molecular calculation, the phenyl unit incorporated at the 9th and 10th positions of anthracene has a torsion angle of about 90, which allows the anthracene unit and the side group to form independent conjugation systems. Consequently, the HOMO shapes of MATa, TATa, and TAT are different.

The HOMO electron distribution of MADa was present in both the anthracene and diphenyl amine groups. The torsion angle (C–C–N–C) between anthracene and the diphenylamine groups was about 138. Thus, conjugation in MADa between the anthracene and diphenylamine units was possible. The LUMO electron density of all four compounds was found to occur in the electron deficient anthracene unit. Calculation of each HOMO value for the anthracene and triphenylamine compound, triphenylamine, had a HOMO value approximately 0.3 eV higher than anthracene [34]. Thus, MATa and TATa (which have HOMO electrons in the triphenylamine unit, where electrons are comparatively more abundant than in anthracene) had relatively higher HOMO energy levels (5.35 and 5.37 eV, respectively) than TAT (5.54 eV) [25]. For MADa, where the HOMO electron is distributed at both the anthracene and amine groups, the HOMO value was intermediate (5.44 eV).

3.3. Thermal properties

We carried out and DSC analyses to determine the thermal properties of the synthesized molecules (see Table 1).

A high T_g value indicates that the morphology of the material will not easily be changed by the high temperatures generated during the operation of OLED devices, and is closely correlated with long OLED device life-times [27,35]. MADa, MATa and TATa all had T_g values above 120 °C TATa had a T_g value above 139 °C, which is twice that of DPVBi (64 °C) and much higher than that of MADN (120 °C). The degradation temperature (T_d) of MADa, MATa, and TATa, measured at the 5% weight loss point, was 374, 427, and 479 °C respectively. TATa had the highest T_d (479C), indicating it has the greatest heat stability.

To investigate the morphological stabilities of TATa and MADN, we prepared thin films (50 nm) of these materials by vapor deposition on glass substrates, and determined their surface morphologies before and after annealing at 100 °C for 6 h under a nitrogen atmosphere by using AFM.

Fig. 3 shows the surface immediately after vacuum deposition (Fig. 3a), after storage for 6 h at room temperature under air (Fig. 3b), and after storage for 6 h at 100 °C under nitrogen (Fig. 3c).

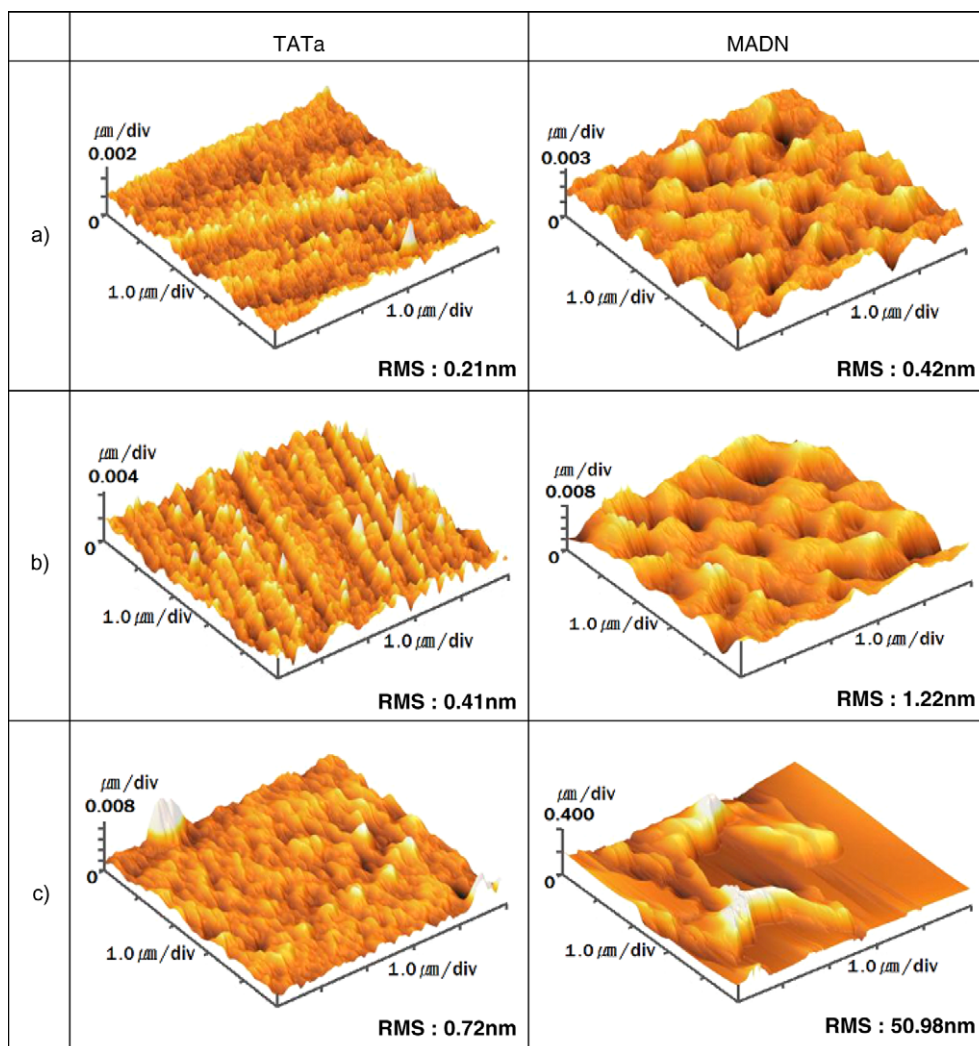
Immediately after deposition, the RMS roughnesses of TATa and MADN were 0.21 nm and 0.42 nm, respectively, indicating that the film surface characteristics of TATa are superior to those of MADN, probably due to the amine unit allowing dipole formation within the molecules. Organic molecules in OLED devices are very sensitive to oxygen and moisture, and this directly affects the device lifetime. The stability of the deposited films to moisture and oxygen was assessed by exposing the film to air for 6 h, at which time the RMS had increased relative to the RMS immediately after deposition (Fig. 3b). The RMS values for MADN (1.22 nm) and TATa (0.41 nm) represented an increase of three and two times, respectively, relative to the RMS immediately following deposition. The RMS for TATa (0.41 nm) was similar to that of MADN immediately


Fig. 3. AFM images of TATa and MADN: (a) immediately following deposition, (b) following storage at room temperature under air for 6 h, and (c) following storage at 100 °C under nitrogen for 6 h.

after vapor deposition, indicating that it has excellent surface characteristics. The organic film in an OLED device can be degraded by heat resulting from device operation, and this is directly related to the life-time of the device. The MADN film had an RMS value of 50.98 nm after 6 h at 100 °C under nitrogen (Fig. 3c), which was more than 40 times that immediately after vapor deposition. For TATa, almost no damage to the film was evident (RMS = 0.72 nm). Consequently, devices using TATa as the emitting layer would be expected to have a longer life-time than those using MADN.

3.4. Electroluminescence properties

We fabricated EL devices using the synthesized compounds in the following configuration: ITO/4,4′,4″-tris(N-(2-naphthyl)-N-phenyl-amino)-triphenylamine (2-TNATA) (60 nm)/N,N′-bis(naphthalen-1-yl)-N,N′-bis(phenyl)benzidine (NPB) (15 nm)/synthesized emitting materials
Fig. 4. Current density–voltage characteristics of ITO/2-TNATA (60 nm)/ NPB (15 nm)/MADa (■) or MATa (●) or TATa (▲) or MADN(▼) (30 nm)/ Alq₃ (30 nm)/LiF (1 nm)/Al (200 nm) devices.

(30 nm)/8-hydroxyquinoline aluminum (Alq$_3$) (30 nm)/LiF (1 nm)/Al (200 nm). We compared the EL properties of these devices with those of a standard device: ITO/2-TNAT-A (60 nm)/NPB (15 nm)/MADN (30 nm)/Alq$_3$ (30 nm)/LiF (1 nm)/Al (200 nm).

Fig. 4 shows the I–V characteristics of the four devices. Devices with MADa, MATa, or TATa as the emitting layer had better I–V characteristics than the device with MADN as the emitting layer. This is likely to be due to highly efficient carrier injection compared to the MADN device, due to the effect of the narrower band gap.

The EL performances of the devices with a current density of 10 mA/cm^2 are summarized in Table 2. Although the device that used MADa as the emitting layer was highly efficient (10.3 cd/A), it had a bluish-green color coordinate of (0.199, 0.152). The device with MATa as the emitting layer had a performance of 4.67 cd/A and an EQE of 4.69%, while the device with TATa had a performance of 6.07 cd/A and an EQE of 6.19%. The CIE values for the MATa and TATa devices were (0.151, 0.177) and (0.149, 0.177), respectively. Thus the efficiency of the TATa device was higher than that of the MATa device, this is identical to the PL QE result. In comparison to MAM, MAT, and TAT only composed of phenyl group in side part [25], MADa, MATa, and TATa that include amine group in molecules showed increase in cd/A and lm/W and reduction of EQE.

Table 2
EL performances of multi-layered devices with the structure ITO/2-TNATA (60 nm)/NPB (15 nm)/emitting layer (30 nm)/Alq$_3$ (30 nm)/LiF (1 nm)/Al (200 nm) at 10 mA/cm^2.

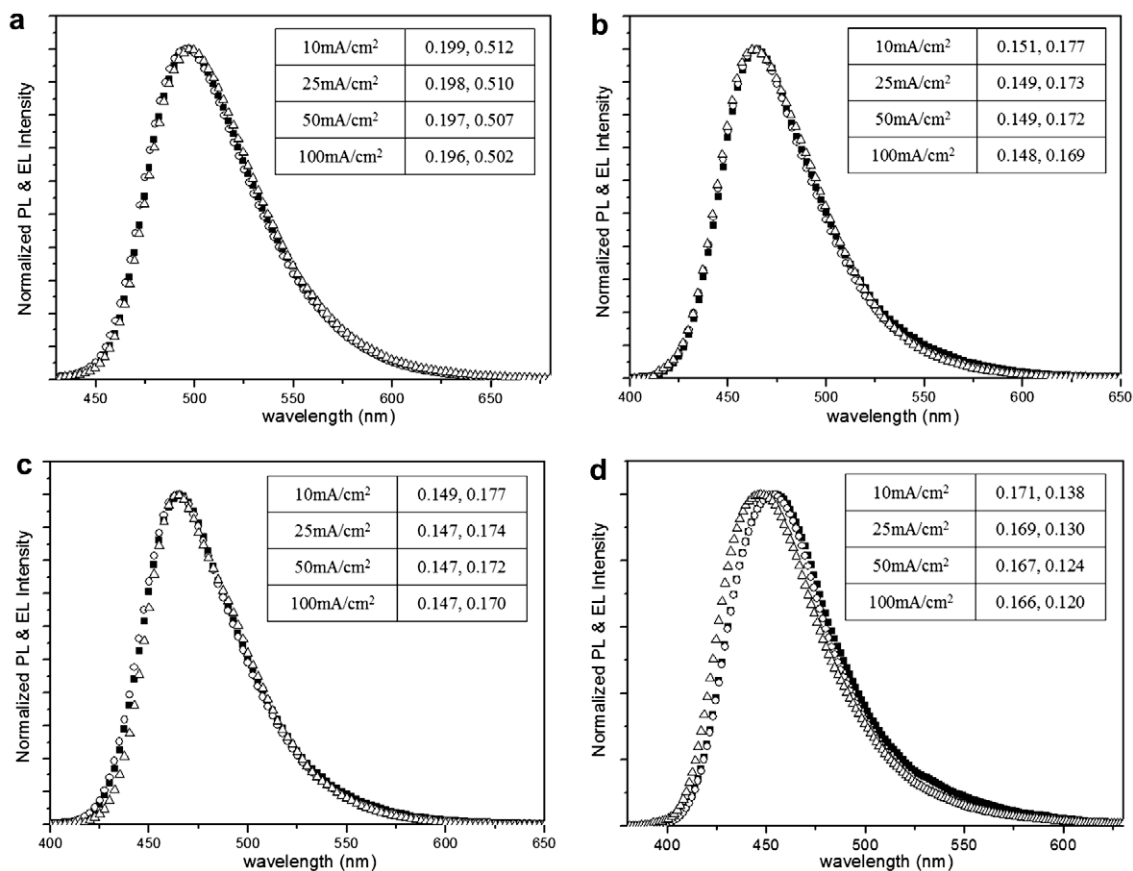
Blue EMLs	EL$_{max}$ (nm)	FWHM (nm)	Voltage (V)	Brightness (cd/m^2)	CIE (x, y)	Luminance efficiency (cd/A)	Power efficiency (lm/W)	External quantum efficiency (%)
MADa	497	63	6.27	1030	0.199, 0.512	10.3 (±0.40)	5.68 (±0.10)	4.18 (±0.20)
MATa	464	57	6.27	467	0.151, 0.177	4.67 (±0.30)	2.59 (±0.05)	4.69 (±0.10)
TATa	465	56	6.26	607	0.149, 0.177	6.07 (±0.30)	3.37 (±0.05)	6.19 (±0.20)
MADN	454	62	6.71	286	0.171, 0.138	2.86 (±0.20)	1.48 (±0.05)	3.18 (±0.20)


Fig. 5. Normalized PL (△) and EL 10 mA/cm^2: (■) 100 mA/cm^2: (○) spectra of MAMa (a), MATa (b), TATa (c), and MADN (d). Inset: CIE$_{x,y}$ values of EL devices according to current densities.

Increase in cd/A and lm/W resulted from reduction in the energy-barrier between inside layers of device due to the formation of relatively narrow band-gap by the intermolecular dipole caused by amine group. As a result, easier movement of hole and electron brings lower operating voltage and higher cd/A and lm/W. However, since sensing effect of photon differs according to the wavelength during EQE measurement, narrow band-gap is thought to have caused bathochromic shift of EL spectrum and reduction in EQE. Although the CIE value of the TATa device was slightly different from that of the MADN device, its luminance efficiency and power efficiency were more than two times that of the latter device (2.86 cd/A, 1.48 lm/W). The TATa device also had an excellent FWHM value (56 nm) despite its asymmetric structure. This value was lower than for MADN (62 nm) because the bulky side group effectively prevented π–π^* stacking interactions between molecules.

The EL spectra for current densities of 10 mA/cm^2 and 100 mA/cm^2, as well as the PL spectra, are shown in Fig. 5.

Agreement between the EL and PL spectra indicates that the emitting zone of the device was inside the emitting layer, and not at the interface between the layers. In addition, the EL spectra as a function of current density of MAMa, MATa, and TATa were identical, but that of MADN was slightly different.

Based on the CIE$_{x,y}$ values at 100 mA/cm^2 and 10 mA/cm^2, the TATa device was especially the same unlike the MADN device, indicating stable CIE characteristics with variable current density.(Fig. 5 inset) Among synthesized compounds, life-time of TATa which showed the best EL efficiency in this series was measured under initial luminance of 500 cd/m^2 as shown in Fig. 6. Its life-time was more than twice that of MADN, which can be explained by the more stable morphology of TATa.

Fig. 7 shows the EL spectra of devices using MADa, TATa, or TAT [25] as the emitting layer. Although the layer included the same core moieties, the EL maxima changed according to the side group. This finding suggests that changing the side group mainly affected the HOMO elec-

Fig. 7. Normalized EL spectra of ITO/2-TNATA (60 nm)/NPB (15 nm)/ MADa (■) or TATa (●) or TAT (▲) (30 nm)/Alq$_3$ (30 nm)/LiF (1 nm)/Al (200 nm) devices at 10 mA/cm^2.

tron density distribution and the HOMO level, as well as the band gap in this series.

4. Conclusions

New OLED blue emitters (MADa, MATa, and TATa) were synthesized with bulky side groups asymmetrically substituted at the anthracene core.

The frontier orbital of HOMO and the band gap could be changed by varying the side groups, and thus the PL and EL spectra were easily changed even though the core remained the same.

TATa synthesized by asymmetric coupling of the bulky side groups triphenylbenzene and triphenylamine to anthracene had a high T_g (139 °C) and better surface morphology than MADN in a thin film. As a result, the OLED devices constructed using TATa as the blue emitting layer had a luminance efficiency of 6.07 cd/A and power efficiency of 3.37 lm/W (more than twice the levels obtained for the MADN device), as well as a high EQE (6.19%). Moreover, the TATa device had a life-time more than twice that of the MADN device.

Fig. 6. Life-time comparison of ITO/2-TNATA (60 nm)/NPB (15 nm)/TATa (■) or MADN (●) (30 nm)/Alq$_3$ (30 nm)/LiF (1 nm)/Al (200 nm) devices (L_0 = 500 cd/m^2, under nitrogen).

(EML) improved the device efficiency [20]. Poly(9,9′-dioc-tylfluorene-*co*-N-(4-butylphenyl)diphenylamine) (TFB) was used as the interlayer, where it was spin-coated onto the PEDOT:PSS layer and then thermally treated above the glass transition temperature (T_g), followed by spin-rinsing with an organic solvent to obtain insoluble TFB interlayer. The interlayer can bring about significant improvement of efficiency [20–27], lifetime [23–25], and lowering turn-on voltage [20,21,24–27].

It is, however, often observed that the insertion of the hole-transporting interlayer causes severe reduction of current density. Chin et al. reported that the current reduction could been understood in terms of the thicker inter-layer, since the introduction of a thin (∼10 nm) interlayer increased in current of the device [24]. Harding et al. stud-ied of various combinations of interlayer-polymers and light-emitting polymers (LEPs). They found that the inter-layers alter the hole injection property in PLEDs in spite of their highest occupied molecular orbital (HOMO) levels very similar to the LEPs [26]. Whereas, we attribute the current reduction to thermal treatment above T_g. According to the study of Lee et al. a thermal treatment at elevated temperature reduced the hole mobility of inter-layer-polymers and thus reduced the hole current in the EML, which resulted in lower device efficiency [23]. It is expected that hole transport layers (HTL) formed without the thermal treatment above T_g bring about improvement in the performance of PLEDs.

We have reported that a polymer thin film preparation technique, evaporative spray deposition using ultradilute solution (ESDUS) has enabled preparing an organic thin film from highly diluted solutions at a concentration of 1 ppm, and fabricating PLEDs [28], organic photovoltaics [29], and organic field-effect transistors [30]. In addition, this method has been exhibited that a successive polymer layer can be deposited without damaging the proceeding polymer layer using a same organic solvent for each layer deposition [31,32]. Therefore, it is enable to construct poly-mer bilayer structure with a bottom layer prepared in var-ious conditions.

In this report, we have successfully achieved a signifi-cant improvement in the performance of bilayer PLEDs prepared by ESDUS using HTL annealed below T_g as com-pared with that of PLEDs having the interlayer that was formed by the thermal treatment above T_g.

2. Experimental

2.1. Materials

We used two typical conjugated polymers for PLEDs, poly(9,9′-dioctylfluorene-*co*-N-(4-butylphenyl)diphenyl-amine) (TFB; M_w = 267,000) and poly(9,9′-dioctylfluorene-*alt*-benzothiadiazole) (F8BT; M_w = 69,000) supplied from Sumitomo Chemical Co., Ltd., without further purification. The chemical structures of these polymers are shown in Fig. 1a. The energy band gap of each polymer was estimated from the absorption spectra edge at the thin polymer films using UV–VIS–NIR spectrophotometer (UV-3150, Shimadzu). The ionization potential of each
Fig. 1. (a) Chemical structures of TFB and F8BT. (b) The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) levels of TFB and F8BT.

material was determined by photoemission spectroscopy (AC-2, Rikenkeiki). The energy level diagram, which is de-rived from the ionization potentials and the optical band gaps of the polymers, is shown in Fig. 1b. The HOMO levels of the TFB and the F8BT are 5.4 eV and 5.9 eV, and the low-est unoccupied molecular orbital (LUMO) levels are 2.5 eV and 3.5 eV, respectively.

2.2. Device fabrication

A thin film of PEDOT:PSS (P VP AI 4083, H. C. Starck) (40 nm) was spin-coated as an anode buffer layer on trans-parent electrode, indium tin oxide (ITO), followed by dry-ing at 120 °C for 5 min on a hot plate in atmosphere. Prior to PEDOT:PSS deposition, the ITO-coated glass sub-strates were cleaned in an ultrasonic bath with detergent, deionized water, acetone, and ethanol, and were treated with UV-ozone. For single-layer devices, 100 nm thick F8BT layer was formed as an EML on top of the PEDOT:PSS layer by a spin-coating from mixed-xylene solution (device *A*) or by ESDUS from tetrahydrofuran (THF) solution (de-vice *B*). For interlayer devices (device *C* and *G*), TFB was spin-coated from mixed-xylene solution onto the PED-OT:PSS layer and then annealed at 180 °C (>T_g of TFB) for 1 h in a N_2 glove box. To prevent mixing of the interlayer with the EML, the soluble part of TFB was removed by a spin-rinsing with mixed-xylene. In this manner, 20 nm-thick interlayer was obtained. F8BT was then spin-coated as the EML onto the interlayer with 85 nm. For ESDUS bi-layer devices (device *D*, *E*, *F* and *H*), TFB was spin-coated as a HTL (40 nm) onto the PEDOT:PSS layer and then an-nealed at 130 °C for device *D* and *H*, 180 °C for device *E* and 230 °C for device *F* for 20 min in the glove box. F8BT was then deposited as the EML (65 nm) directly onto the TFB layer using ESDUS from THF solution. All F8BT layers

were annealed at 80 °C for 20 min in the glove box. Finally, cathodes were deposited at pressures less than 10^{-4} Pa; a cathode buffer layer of LiF (1.0 nm) for device *A* to *F* or Ca (10 nm) for device *G* and *H* was thermally deposited in a vacuum evaporator, followed by an Al (100 nm) electrode through a shadow mask to obtain active areas of 2×2 mm^2. Devices with Ca/Al electrode were encapsulated in the glove box before measurements. The fabrication conditions of device *A–H* were listed in Table 1.

For hole only devices, 170 nm-thick TFB was spincoated onto the PEDOT:PSS and then annealed at 80 °C, 130 °C, 180 °C and 230 °C for 20 min in the glove box. Au cathode was thermally deposited to ensure no injection of electrons into the LUMO of the TFB.

2.3. Measurements and characterization

The current–voltage–luminance (*L–J–V*) characteristics were measured using a source–measure unit (Keithley 238) and using a luminance meter (BM-5A, Topcon). The electroluminescence (EL) spectra were measured using a multi-channel analyzer (PMA-11, Hamamatsu Photonics). The external quantum efficiency (EQE) and the power efficiency (PE) were calculated from the *L*, *J*, *V* and EL spectrum of each device. The thickness and the surface roughness of the polymer films were determined using an atomic force microscopy (AFM) (Nanopics 100, SII). A differential scanning calorimeter (DSC) (Q100, TA Instruments) was used to determine the T_g of the TFB sample studied in this research at a rate of 10 °C min^{-1}. The T_g was determined by the second heating scans.

3. Results and discussion

3.1. The comparison of single-layer devices prepared by spin-coating or ESDUS

On comparison of device performance of the single layered spin-coating device (device *A*) and ESDUS device (device *B*), the *L–J–V* characteristics were almost comparable as shown in Fig. 2. Leakage current in device *B* was higher at the low voltage region below turn-on. Root mean square
Fig. 2. The luminance–current density-voltage characteristics for single-layer devices composed of F8BT layer prepared by spin-coating (device *A*; circles) and by ESDUS (device *B*; up-pointing triangles). Solid lines and dashed lines represent the current density–voltage characteristics and the luminance–voltage characteristics, respectively.

roughness (R_{rms}) of the F8BT film prepared by ESDUS, which was examined using an AFM, was higher ($R_{rms} = 8.2$ nm, in the scale of 20 μm × 20 μm) than that of one prepared by spin-coating ($R_{rms} = 0.5$ nm, in the scale of 20 μm × 20 μm). The heterogeneity represented by the roughness would cause the leak-current at low-voltage regions though the light emission of two devices is homogeneous.

3.2. Improvement in the PLEDs performance using HTL without thermal treatment above T_g

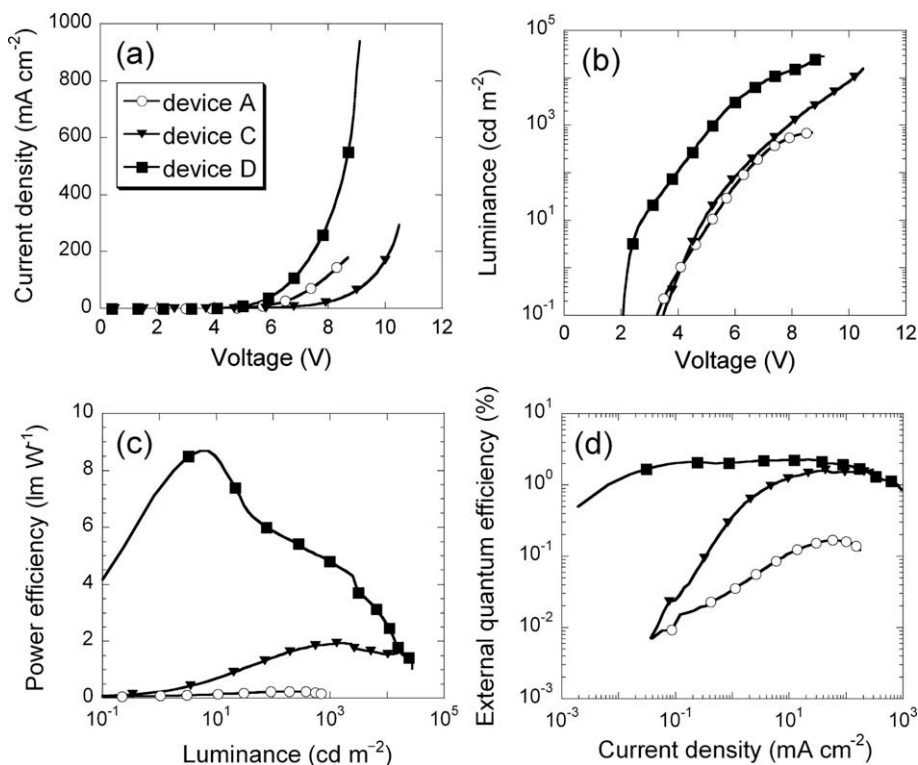
Fig. 3a and b shows the *L–J–V* characteristics for device *A*, *C* and *D*. The current in interlayer devices (device *C*) was much lower than that of single-layer devices (device *A*), but the turn-on voltage for luminance (>1 mcd m^{-2}) of device *C* is almost identical to that of device *A*. Yang et al. reported that the residual thickness of the interlayer was dependent on the molecular weight of the interlayer-polymer and the characteristics of the underlying PEDOT:PSS [22]. They proposed that the formation of the insoluble polymer layer is due to the binding of individual chains at the surface of PEDOT:PSS. The molecular weight of the


Fig. 3. (a) The current density–voltage characteristics, (b) the luminance–voltage characteristics, (c) the power efficiency–current density characteristics and (d) the external quantum efficiency–current density characteristics for the single-layer device prepared by spin-coating (device *A*; opened circles), the interlayer device (device *C*; closed down-pointing triangles) and the ESDUS bilayer device (device *D*; closed squares).

TFB used in this research is so high that the thickness of the interlayer would be relatively thicker. The resulting current density of interlayer devices was lower than that of single-layer devices. On the other hand, the current density of ESDUS bilayer devices (device *D*) having thicker TFB layer (40 nm) than device *C* was significantly higher than that of device *A* and *C*. In addition, the turn-on voltage was 1.2 V lower and the luminance of device *D* is markedly enhanced, so that the PEs of device *D* were improved significantly through the whole luminance region as shown in Fig. 3c. In particular, the maximum PE of device *D* showed 8.7 lm W^{-1} and surpassed other devices (PE$_{MAX}$ of device *A* = 0.24 lm W^{-1}, PE$_{MAX}$ of device *C* = 1.9 lm W^{-1}). These higher current and lower turn-on voltage of device *D* would be caused by improvement in hole injection and transport in the device due to the insertion of TFB layer as HTL, which has a high hole mobility [33,34] and a low ionization potential (5.4 eV) creating the stepped electronic profile [21,27] between PEDOT:PSS (5.2 eV) and F8BT (5.9 eV). Fig. 3d shows the EQE-J characteristics for the PLEDs. The maximum EQE of device *D* was improved drastically (2.3%) as compared with that of device *A* (0.17%) and *C* (1.6%). The enhancement of the EQEs of device *D* at low-current region is especially notable, therefore, the EQEs of device *D* tended to be a constant (about 2%) through the wide current region. While, those of device *A* and *C* showed a gradual increase as current density was getting higher.

The gradual increase in EQEs of device *A* can be explained mainly by a carrier imbalance at low voltage region due to the injection barrier difference at the anode and the cathode, and a shift of the carrier recombination site. Generally conjugated polymers exhibit different mobilities for holes and electrons, and the electric field dependence of each mobility is also quite different. In single-layer PLEDs, the carrier recombination site should be located close to an electrode where the less mobile carrier is injected. The emission would be quenched by a non-radiative energy transfer near an electrode surface, causing low EQE. As the electric field is getting higher, the mobility difference between electrons and holes often becomes smaller due to different electric field dependence [35–37]. The recombination site would extend away from the electrode, reducing non-radiative energy transfer [38,39]. In the case of device *A*, the recombination process should occur at a PEDOT:PSS/F8BT interface since F8BT is a good electron transport material [40].

The steep rise in the EQEs of device *D* at the low-current region and the following plateau indicate the charge injection and transport to be balanced at lower electric field, and the balance to be maintained through the wide range. These tendencies can be understood as has been discussed in bilayer organic LEDs [4,41–44], i.e., the blocking of carriers at the organic/organic interface prevents the majority carriers from reaching the opposite electrode without forming excitons, and accumulation of them causes a
Fig. 4. The electroluminescence spectra for the single-layer device prepared by spin-coating (device *A*; solid line), the interlayer device (device *C*; dashed line) and the ESDUS bilayer device (device *D*; dotted line) driving at 100 mA cm^{-2}.

redistribution of the electric field within the device, which promotes injection of the minority carriers, and the recombination zone is away from the electrode.

As shown by the EL spectra of device *A*, *C* and *D* driving at 100 mA cm^{-2} in Fig. 4, we could see the F8BT emission (peaking at 544 nm) from these devices. Similarly the shoulder at 575 nm of device *C* and *D* became stronger and weaker relatively to the main peak, respectively. We attribute shift in EL spectrum of device *C* to the formation of an exciplex at TFB/F8BT heterojunctions [45,46]. However, the weaker shoulder of the EL spectrum for device *D* cannot be explained only by the formation of the exciplex. The difference among spectra of device *A*, device *C* and device *D* should be ascribed to interference effects between the emission directly out of the active layer and the reflection at the metal electrode since the location of the emission zone has changed due to the position of the TFB/F8BT interface [47–49]. In device *C*, the recombination zone might be located away from the PEDOT:PSS due to the insertion of interlayer, preventing the exciton quenching by PEDOT:PSS, and it also contributes to the improvement in the EQEs of device *C* [20].

However, the gradual increase of the EQEs of device *C* suggests that the carrier balance was not as good as device *D* in spite of the interlayer insertion. Another interlayer device composed of TFB (interlayer)/F8BT (ESDUS) showed much lower current and gradual increase in EQEs as device *C*. Therefore, the difference between device *C* and *D* would be caused by the annealing temperature for TFB layer.

3.3. The influence of the annealing temperature for HTL on PLEDs characteristics

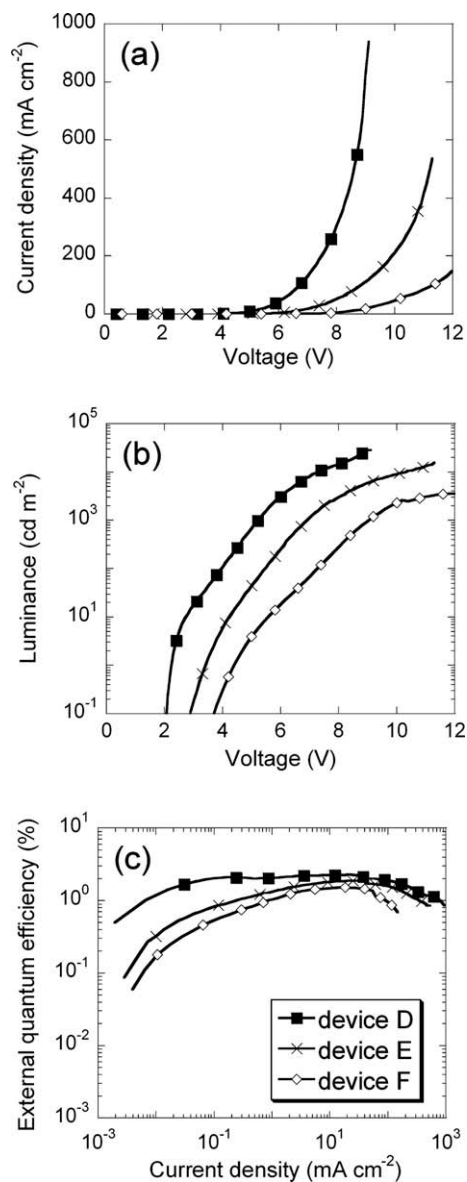
We studied the effect of the higher annealing temperature for TFB layer on the performance of bilayer PLEDs. Fig. 5 shows the *L–J–V* and the EQE-*J* characteristics of ESDUS bilayer devices with TFB layer annealed at various temperatures (device *D*, *E* and *F*). The current density and luminance were reduced as the thermal treatment temperature of TFB layer increased from 130 °C to 230 °C regardless of having the same thickness and structure as shown


Fig. 5. (a) The current density–voltage characteristics, (b) the luminance–voltage characteristics, (c) the external quantum efficiency–current density characteristics for ESDUS bilayer devices with TFB layer annealed at 130 °C (device *D*; closed squares), 180 °C (device *E*; crosses) and 230 °C (device *F*; opened diamonds).

in Fig. 5a and b. The maximum EQE of device *E* and *F* were 1.9% and 1.5%, respectively, and lower than that of device *D* (2.3%). The EQEs of device *E* and *F* in the low-current region significantly reduced and showed a gradual increase with current density as shown in Fig. 5c. We consider that the inferior performance of the bilayer PLEDs with TFB annealed at higher temperature would be caused a decrease in hole current since the insertion of TFB as HTL brought about the improvement in carrier balance of electron-rich F8BT devices.

To investigate the change of hole current as a function of the annealing temperature of TFB layer, we fabricated hole
Fig. 6. The current density–voltage characteristics for hole only devices; ITO/PEDOT:PSS/TFB (170 nm)/Au, whose TFB layer were annealed at 80 °C (circles), 130 °C (squares), 180 °C (diamonds) and 230 °C (triangles). The inset shows differential scanning calorimetry curve of TFB used in this research.

only devices of ITO/PEDOT:PSS/TFB (170 nm)/Au structure. Fig. 6 shows the *J–V* characteristics of the hole only devices with TFB layer annealed at various temperatures. The plots of the devices annealed at 80 °C and 130 °C were almost identical, although, the hole current decreased as the thermal treatment temperature increased from 130 °C to 230 °C. Furthermore, it is remarkable that the turn-on voltages for hole injection became large when annealing temperature exceeded in 180 °C. According to a DSC measurement, the T_g of TFB used in this study is determined 156.0 °C as shown in the inset of Fig. 6. We consider that the thermal treatment above T_g of TFB would induce the degradation of hole injection property. Therefore, interlayers should be damaged the intrinsic nature of the interlayer-polymers as a good hole transporting material, since they are annealed above the T_g and rinsed with a organic solvent, and the insoluble residue of them remains as interlayers. The preparation process of interlayers, which needs the thermal treatment above T_g, would also affect the current reduction of PLEDs with interlayers apart from the thickness of interlayers and the interlayer-LEP combination. We suppose that the interlayer in this study would not greatly improve in hole injection and transport of device C.

But it remains open now what problems arise by thermal treatment above T_g. No changes in surface morphology, absorption and ionization potential were observed in TFB films annealed at 80 °C, 130 °C, 180 °C and 230 °C. As shown by other reports, absorption and photoluminescence, vibrational transitions, redox energy levels and the surface potential of interlayers is almost identical to those of "bulk" polymer layers [20,22]. It is required that the investigation into the interface of PEDOT:PSS/TFB.

We fabricated another ESDUS bilayer device having thinner TFB layer (20 nm) without the thermal treatment above T_g. The L–J–V characteristics were found to be almost identical to those of device D. It is well known for conventional small-molecule-base OLEDs, the device characteristics are not sensitive to thickness of a hole transporting layer because most of applied electric field is concentrated on an electron transporting layer [50,51]. The device characteristics independent of the TFB thickness in the

ESDUS devices suggests that the interlayer thickness should not be a major issue for the inferior performance in the interlayer devices but the thermal degradation of TFB would be the most important.

3.4. The electron-rich devices having a cathode with lower work function on the bilayer PLEDs

We fabricated more electron-rich devices by applying the Ca/Al cathode to interlayer devices (device *G*) and ESDUS bilayer devices (device *H*). Fig. 7a and b shows the L–J–V characteristics of device *G* and *H*. On comparison between ESDUS bilayer devices (device *D* and *H*), the current and luminance of the Ca/Al cathode devices (device *H*) showed the rapid rise at much lower voltage than those of the LiF/Al cathode devices (device *D*), so that the PEs of device *H* were much higher throughout the luminance region, and exhibited 12 lm W^{-1} in the maximum as shown in Fig. 7c. On the other hand, in the interlayer devices, the PEs of the more electron-rich devices (device *G*) showed inferior PE$_{MAX}$ of 1.3 lm W^{-1} where device *C* showed 1.9 lm W^{-1}, though the current and luminance of device *G* showed rise as compared with device *C*.

Fig. 7d shows the EQE-J characteristics of device *G* and *H*. The EQEs of device *H* with the ESDUS bilayer structure showed the flat tendency at the wide range of the current density and the maximum EQE of device *H* was 2.3%, which was same value to that of device *D*. The EL spectrum of device *H* was identical to the F8BT emission without the TFB emission, being almost identical to that of device *D*. The EQE is the ratio of the number of photons coming out of a device to the number of charge carriers injected into it, and EQE is given by EQE = $\gamma\eta_r\varphi_f\eta_{ext}$ using the charge-balance factor γ, the efficiency of production for singlet excitons η_r, the quantum efficiency of fluorescence φ_f, and the extraction efficiency of light from the device η_{ext} [52]. Almost same value of EQEs of device *D* and *H* suggests that the ESDUS bilayer devices would attain the γ value close to 1.0 assuming that the value of η_r, φ_f and η_{ext} is constant. Therefore, these observations indicate that electrons are effectively blocked at the TFB/F8BT interface and the carrier balance is maintained despite using more electron-rich cathode in the ESDUS bilayer devices. On the other hand, the EQEs of device *G* decreased as compared with device *C* and the maximum EQE reduced to 0.91%, which results in the severe decrease in PEs of device *G*. The reduction of EQEs of the more electron-rich devices suggests that the interlayer is not working as an efficient electron blocking layer, which was reported by Harding et al. [26], despite the large difference of LUMO level between TFB and F8BT (1.0 eV). Probably due to the thin thickness of the interlayer and/or the degree of intermixing at TFB/F8BT interface, the interlayer composed of TFB exhibits the inefficient electron blocking.

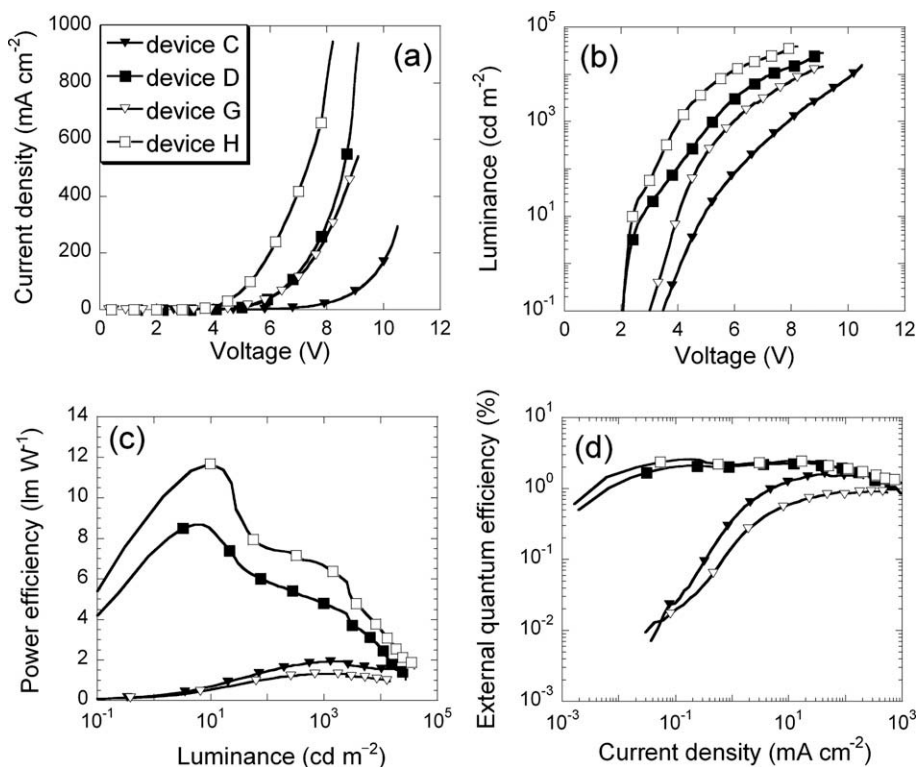
Interlayers are easy to be formed and certainly useful for improvement in EQE of PLEDs to keep the carrier recombination zone away from the PEDOT:PSS and to enhance the hole injection compared with single-layer devices, although, they cannot act as strong carrier blocking layers. The further development would be brought for PLEDs by forming more effective polymer heterojunction.


Fig. 7. (a) The current density–voltage characteristics, (b) the luminance–voltage characteristics, (c) the power efficiency–current density characteristics and (d) the external quantum efficiency–current density characteristics for the interlayer device with LiF/Al cathode (device C; closed down-pointing triangles), the ESDUS bilayer device with LiF/Al cathode (device D; closed squares), the interlayer device with Ca/Al cathode (device G; opened down-pointing triangles) and the ESDUS bilayer device with Ca/Al cathode (device H; opened squares).

4. Conclusions

We have successfully achieved a significant improvement in the performance of bilayer PLEDs by introducing TFB as HTL without thermal treatment above T_g through the stack of EML using ESDUS. Comparison with characteristics of devices having the TFB annealed at various temperatures indicates that the thermal treatment above T_g induces the degradation of hole injection, and that thermal treatment temperature for HTL can varies the carrier balance of bilayer PLEDs. The higher current and lower turn-on voltage, and therefore the higher power efficiency can be achieved in the ESDUS bilayer PLEDs which do not require a severe annealing for HTL formation. On the other hand, interlayers which are often used for PLEDs are formed through the thermal treatment above T_g. Some studies have been reported that the thickness of interlayers and the interlayer-LEP compatibility were discussed for inferior device performance in their PLEDs. The thermal degradation would be the major factor for inferior performance in the interlayer devices.

The EQEs of the ESDUS bilayer devices showed the constant value through the wide current region even in the more electron-rich condition, whereas, those of the interlayer devices showed lower and a gradual increasing tendency. These observations suggest that electrons are effectively blocked at the TFB/F8BT interface in ESDUS

bilayer devices but the electron block of the interlayer is not as effective.

It is required the degradation of polymers by thermal treatment above T_g is taken into consideration in case of constructing bilayer PLEDs. The multilayer structure has been proved to be quite effective for improvement of device performance in small molecule-based OLEDs. The further improvement in PLEDs would be also brought by more effective processes which do not require any procedure inducing degradation of the materials. Cross-linkable polymers could be one of promising candidates in order to insolubilize the bottom layer without thermal treatment. ESDUS method would be another.

would degrade significantly during operation, thus limit their practical applications. In order to overcome this problem and obtain efficient WPLEDs with high color quality and long-term stability, an alternative approach is to use efficient deep-blue polymer as both host material and blue emitter to fabricate multiple dopants all-polymer WPLEDs. So far, polyfluorenes (PFs) and its derivatives are the most frequently used deep-blue polymer for WPLEDs although their luminous efficiency is typically between 1 and 2 cd A^{-1}, making the efficiency of WPLEDs based on these polymers rarely exceed 10 cd A^{-1} [15]. Therefore, it is expected that the efficiency of all-polymer WPLEDs can be significantly enhanced if more efficient blue emitter be used in these devices.

In this paper, we report realization of efficient WPLEDs with good color quality based on blending of fluorescent polymers with RGB emission covering the entire visible spectrum. The polymers used here include, a newly synthesized efficient deep-blue emitting polyfluorene derivative named poly[(9,9-bis(4-(2-ethylhexyloxy)phenyl)-+fluorene)-co-(3,7-dibenziothiene-S,S-dioxide10)] (PPF-3,7SO10) [19], a green light-emitting poly[2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-p-phenylenevinylene] (P-PPV) and an orange–red light-emitting 2-methoxy-5-(2′-ethylhexyloxy)-1, 4-phenylenevinylene (MEH–PPV), respectively. Optimized device shows a peak luminous efficiency of 14.0 cd A^{-1} and a peak power efficiency of 7.6 lm W^{-1}, with a CIE of (0.33, 0.35) at a current density of 10 mA cm^{-2}.

2. Experimental details

The device structure in this study is indium tin oxide (ITO)/PEDOT:PSS/PPF-3,7SO10 (100 wt%):P-PPV (x wt%): MEH–PPV (y wt%)/Ba/Al, where PEDOT:PSS is poly(ethylendioxythiophene):poly(styrene sulfonic acid), purchased from H. C. Starck, Inc., while the polymers PPF-3,7SO10, P-PPV and MEH–PPV were synthesized in our laboratory and the chemical structures of these materials show in Fig. 1. The devices were fabricated following a well-established procedure. First, a 40 nm film of PEDOT:PSS (Baytron P4083) was spin coated on a precleaned ITO substrate and baked to dry in a vacuum oven at 80 °C for 12 h. The poly-

mer blend consisting of PPF-3,7SO10, P-PPV and MEH–PPV were spin coated from toluene solution, resulting in an emissive layer of 80 nm (as determined by a profiler, Tencor Alfa-Step 500). Finally, 4 nm barium and 120 nm aluminum layer were evaporated with a shadow mask at a base pressure of 3×10^{-4} Pa. The thickness of the evaporated cathodes was monitored by a quartz crystal thickness/ratio monitor (Model:STM-100/MF, Sycon). The overlapping area between the cathode and anode defined a pixel size of 19 mm^2. Except for the deposition of the PEDOT:PSS layers, all of the fabrication processes were carried out inside a controlled atmosphere of nitrogen drybox (Vacuum Atmosphere Co.) containing less than 10 ppm oxygen and moisture. Current density (j)–voltage (V)–luminance (L) data was collected using a Keithley 236 source meter and a calibrated silicon photodiode. The EL spectra and CIE coordinate was recorded using PR-705 SpectraScan spectrophotometer (Photo Research), while the color rendering index (CRI) was calculated following the CIE publication released in 1974 [19]. After the devices were annealed atop of a hotplate at high temperature (120–200 °C) for 2–12 h, spectral stability of EL upon thermal annealing were performed in atmosphere by a PR-705 SpectraScan spectrophotometer soon after cooling down to room temperature. The stability of the white emitting PLEDs was studied in atmosphere by applying a constant current stress with an initial luminance of 1500 cd m^2. Before annealing in atmosphere and stress test, the PLEDs were encapsulated with a UV-cured epoxy resin.

3. Results and discussion

For the monochromatic devices based on MEH–PPV (red), P-PPV (green), and PPF-3,7SO10 (blue), peak LE of 2.5 cd A^{-1}, 22.2 cd A^{-1} and 5.1 cd A^{-1} were recorded, which corresponded to external quantum efficiencies (EQE) of 2.5%, 9.0% and 6.1%, respectively. The 1931 CIE coordinate of the RGB devices were (0.61, 0.39), (0.46, 0.52), and (0.16, 0.16), respectively. While keeping in mind the CIE coordinates of the primary RGB color system adopted by National Television System Committee (NTSC) for color TV are (0.67, 0.33) (R), (0.21, 0.71) (G) and (0.14,

Fig. 1. The chemical structures of PPF-3,7SO10, P-PPV and MEH–PPV device.
Fig. 2. EL spectra of PPF-3,7SO10, P-PPV and MEH–PPV device.

0.08) (B), it can be clearly seen that the blue emitter match the NTSC best. Also, as shown in Fig. 2, the emission of the monochromatic devices based on the RGB emitters covers the entire visible light spectrum. It is expected that white emission can be realized if emission of each color is carefully balanced.

To obtain white emission with good color quality, a series of devices with various doping concentrations and ratios were fabricated and evaluated, and their device performance was summarized in Table 1. Depending on the doping concentration, devices were referred to as device A1–device D1, with structure like ITO/PEDOT:PSS/ PPF-3,7SO10 (100 wt%):P-PPV (x wt%) and MEH–PPV (y wt%)/Ba/Al, in which x vary within 0.5–1.0, y within 0.2–0.5. As seen from the normalized EL spectra of devices (Fig. 3a), three intense peaks around 450 nm 482 nm and 573 nm were clearly observed, which can be assigned to the emission from PPF-3,7SO10 and MEH–PPV, respectively. Since there is considerable overlap between the EL peak of P-PPV (550 nm) and the shoulder of PPF3, 7SO10 (Fig. 2), the former is merged and could not be seen very clearly in Fig. 3a. Device B1 (with a blend ratio of 100:0.8:0.5 between the RGB emitters) exhibit the most balanced RGB emission, with a CIE coordinate of (0.341, 0.348), very close to the equi-energy white point (0.333, 0.333). Consistent with our previous study on the blue emitter [20], there is a considerable enhancement in LE and EQE for the white emission PLEDs when a thin layer of PVK was inserted at the anode side to facilitate hole injection and transport. The devices with PVK as anode buffer layer were denoted as device A2–D2 and their performances were also included in Table 1 for comparison. Similar to its analog device B1, device B2 had a CIE coordinate of (0.331, 0.353) also very close to the equal-energy point as device B1.

It is interesting to consider the origin of the efficient white emission from this system. Two independent excitation mechanisms may occur: energy transfer from the fluorescent host to the guest materials and charge trapping at the emitter sites [5,21]. As can be seen in Fig. 4a, there is significant overlap between the PL spectrum of PPF-3,7SO10 and the absorption of P-PPV and MEH–PPV (large overlap between the PL spectrum of P-PPV and absorption of MEH–PPV is also observed, not shown here), implying effective energy transfer from PPF-3,7SO10 to P-PPV and MEH–PPV, or from P-PPV to MEH–PPV could readily take place. However, upon blending with other emitting species, charge trapping at the low band gap emitting sites may also occur. Comparison of PL spectra (Fig. 3b) from the emitting layers with the EL spectra (Fig. 3a) of the devices reveals that the EL spectra have a much higher contribution from the narrow band gap red/green emitters, indicating that charge trapping is the dominant process [5,10]. As shown in Fig. 4b, the HOMO energy levels for PPF-3,7SO10, P-PPV and MEH–PPV are −5.6 eV, −5.3 eV and −4.9 eV, respectively, while the lowest unoccupied molecular orbital (LUMO) are −2.8 eV, −2.9 eV and −2.9 eV, respectively. That is, the HOMO level of the low band gap emitters is above (closer to vacuum level) that of the host, while at the same time, the LUMO level of the guest is below (deeper from vacuum level) that the host. Therefore, when charge carriers are injected from electrodes, simultaneous excitation of the green and red emitting polymers via direct charge trapping could occurs as this is energetically favored [22].

Fig. 5 shows the typical current density–luminance– voltage (J–L–V) characteristics and luminous efficiency– power efficiency–current density (LE–PE–J) characteristics of device B1 and device B2. For device B1, a maximal luminous efficiency of 8.7 cd A^{-1} was observed at a current density of 5.5 mA cm^{-2} (5.4 V) with a luminance of 484 cd m^{-2}, while a maximal power efficiency 5.6 lm W^{-1} was reached at 1.2 mA cm^{-2} (4.5 V). It is important to note that the turn-on voltage (defined as the voltage at which a luminance of 1 cd m^{-2} is reached) of device is as low as 3.0 V, which is very helpful to reduce power consumption and obtain high power efficiency. With increasing current density, the device retains high efficiency. For example, at a current density of 120 mA cm^{-2}, the LE is 7.0 cd A^{-1}, only 20 % roll-off from its peak, corresponding to a luminance of 8480 cd m^{-2}. As shown in Fig. 5, for device B2, a maximal LE of 14.0 cd A^{-1} and a maximal EQE of 6.9%

Fig. 5. The current density–luminance–voltage (J–L–V) (a) and luminous efficiency–power efficiency–current density (LE–PE–J) (b) characteristics of device B1 and B2.
Fig. 6. The EL spectra of the device B2 at different current density (a), annealed at different temperatures and hours (b) and under continuous operation at an initial luminance of 1500 cd m^{-2} (c).

can be obtained at a current density of 1.0 mA cm^{-2} (the maximal power efficiency 7.6 lm W^{-1} was reached at 0.18 mA cm^{-2}). It exhibited a turn-on voltage of 5.7 V and a maximum brightness of 20546 cd m^{-2} at 454 mA cm^{-2}. At a luminance of practical applications for solid-state lighting (SSL) application, for example, 1000 cd m^{-2}, good forward viewing LE and PE values are maintained: 12.5 cd A^{-1}, 3.7 lm W^{-1} at 8.9 mA cm^{-2} and 9.6 V for device B2. As shown in Table 1, most of the white emission devices had appropriate color temperature (as measured as correlated color temperature (CCT) within 2500–6500 K and relative higher color rendering index (CRI) suitable for solid-state lighting. At a current density of 10 mA cm^{-2}, the CRI were 72 and 79 for device B1 and device B2, respectively, representing a good color quality for white lighting source.

Spectral stability upon change of current density, thermal annealing and stress was also studied. When the current density varied from 2.5 mA cm^{-2} to 210 mA cm^{-2}, as shown in Fig. 6a, the emission color of a typical device B2 did not change much, which is important for illumination. And the CIE coordinates of the white light emission showed a slight change from (0.31, 0.35) to (0.34, 0.36), still close to the white equivalent-energy point of (0.33, 0.33). Fig. 6b showed the EL spectra of device B2 annealed at 80, 120, 160 and 200 °C for 2 h, and 120 °C for 12 h,

respectively. It is important to note that the emission color remained nearly unchanged even high temperature was applied, in consistent with what was found in our previous report on the blue emitter [19]. Moreover, the evolution of spectral stability under continuous stress was also carried out with an initial luminance of 1500 cd m^{-2} for device B2. As revealed in Fig. 6c, there is no obvious change with variation of the operating time up to 60 min. Thus, the device B2 represented a good spectral stability upon operational stress, indicating good device stability can be obtained in this white system. It is important to note that, much longer lifetime can be expected if the initial luminance be set as a typical luminance of 100 cd m^{-2} and a more reliable encapsulation technology was used.

4. Conclusions

In summary, we report white polymer light-emitting devices with both high efficiency and good color quality, stability based on a newly synthesized efficient blue emitting polymer which dually functions as host material and blue emitter, with appropriate blending ratio with two typical electroluminescent polymers, green emitting P-PPV and orange–red emitter MEH–PPV. Optimized device shows a peak LE of 14.0 cd A^{-1} (corresponding to an EQE of 6.9%) with a CIE of (0.33, 0.35) at a current density of

10 mA cm^{-2}. Furthermore, our devices are characterized by very good color quality, both in term of color rending index (~79) and color temperature 2800–6600 K), suitable for solid-state lighting applications. Upon change of current density, continuous operation and annealing at high temperature, the EL spectra shows negligible change, indicating good device stability can be obtained in this system.

the electrical conductance of the semi-conductor channel and thus distinguishes two logic states, the ON or OFF states of the channel current for memory function [3,5]. Because spontaneous polarization directly controls channel conductance, neither the ferroelectric cell capacitance nor the requirement of a high polarization are determining factors in the device operation potentially beneficial for high density as well as low-power consumption. Furthermore, utilization of organic and polymeric semi-conducting channels turned out beneficial in FeFET for low cost, flexible memory, including vacuum deposited pentacene [6–8], poly(3-hexylthiopene) (P3HT) [9] and poly[2-methoxy, 5-(2'-ethyl-hexyloxy)-p-phenylene-vinylene] (MEH-PPV) [3].

For the successful non-volatile ferroelectric memory, high ON/OFF ratio at zero gate voltage should be guaranteed for distinct data recognition. In principle both ON and OFF source–drain current strongly depend upon the charge density of semi-conducting layer in contact with gate insulator at each polarization state. An imperfect ferroelectric gate insulator with many structural defects often results in the leakage current between gate and drain electrode usually larger than that between source and drain one at OFF state, which leads to high OFF current and low ON/OFF ratio in the device. In fact, a thin film of semi-crystalline PVDF and PVDF-TrFE contains many defects arising from crystalline grain–grain mismatch and trapped residual solvent in the film. One way to overcome the problem is obviously to introduce a ferroelectric gate insulator thick enough to minimize the leakage current. The method is; however, not effective because it dramatically increases operating gate voltage required for polarization switching of PVDF-TrFE with relatively large coercive electric field of approximately 50 MV/m. The selection of a proper solvent that can give rise to very dense thin PVDF-TrFE film was another way to reduce the gate leakage. Viscous cyclohexanone has been successfully employed for low operation voltage FeFET with PVDF-TrFE gate insulator [9].

Insertion of an additional interlayer between PVDF-TrFE and gate electrode has been proposed for controlling the leakage [10]. In particular a polymeric interlayer would be beneficial because it forms easily on a substrate based on spin coating and provides a good interface with PVDF-TrFE. We have recently employed 200 nm thick poly(4-vinylphenol) (PVP) and poly(melamine-co-formaldehyde) film known as a good dielectric layer for OTFTs into a FeFET with single crystal 6,13-bis(tri-isopropylsilylethynyl) pentacene (TIPS-PEN) semi-conducting layer [11]. The sufficiently low OFF current was obtained of approximately 10^{-11} A which guaranteed high ON/OFF ratio with very reliable data retention property. More detailed study was also performed to understand the role of PVP interlayer in both metal-ferroelectric-insulator-semiconductor (MFIS) and FeFET architectures [12]. We found that PVP in the MFIS effectively prevented the shifting of the C–V hysteresis curve toward the negative bias voltage. The recent work by Lim et al. has also shown that a PVP layer was successfully incorporated in a FeFET with ZnO semi-conducting layer [13]. In spite of the studies with PVP for improving the performance of FeFETs with PVDF-TrFE, only few work has been devoted to systematic approaches to address fundamental issues including interfacial energy with a ferroelectric layer, surface roughness, dielectric properties and film thickness of an interlayer for minimizing both gate leakage current and operating voltage.

There are in general several factors to be considered when one designs a polymeric interlayer incorporated with PVDF-TrFE. First of all, a firm interface should be obtained between a polymer interlayer and PVDF-TrFE. Good miscibility of poly(methylmethacrylate) (PMMA) with PVDF-TrFE insures the solid and firm interface with surface energy matched with each other [14]. Secondly, a polymeric interlayer should be chemically and thermally resistive to remain stable upon the spin coating and subsequent thermal annealing of a thin PVDF-TrFE layer. A cross-linkable polymer would be one of the candidates for satisfying the requirement. Finally an interlayer with high dielectric constant needs in principle to be used for low operating voltage. We do not; however, have many design rules in this aspect because most of polymer interlayers fall into less than 10 in their dielectric constants.

In this contribution, we employ a new type of polymeric interlayer to systematically investigate the effect of interlayer thickness on FeFETs with ferroelectric PVDF-TrFE. Upon consideration of the aforementioned requirements, we chose an interlayer of a poly(styrene-random-methylmethacrylate) copolymer (P(S-r-MMA)) containing benzocyclobutene (BCB) as a cross-linking agent. The cross-linkable P(S-r-MMA) which has been used for surface modification of self assembled block copolymers [15] is easily spin coated on a substrate with well controlled film thickness ranging from even a few to tens of nanometers. In addition, simple cross-linking of a film by thermal baking provides excellent chemical resistance against various organic solvents. Our study shows that gate-drain leakage current is effectively shielded with a P(S-r-MMA) layer of the thickness greater than approximately 25 nm in a bottom gate FeFET containing ca. 350 nm thick PVDF-TrFE layer.

2. Experimental

2.1. Materials

A P(S-r-MMA) used as an insulating layer in the study was anionically polymerized with a lithium initiator. The random copolymer contains 45% of PS moiety with reactive 4-vinylbenzocyclobutene (~3 mole%). Molecular weight (M_n) and polydispersity index (PDI) were characterized by typical size-exclusion chromatography (SEC) of 30,000 g/mol and 1.3, respectively. A poly(vinylidene fluoride-co-trifluoroethylene) (PVDF-TrFE) with 27.5 wt% TrFE was kindly supplied by MSI Sensor PA, USA. The melting (T_m) and Curie (T_c) temperature of the polymer are 150 and 80 °C, respectively. Pentacene (purity = 99%) was purchased from Aldrich Chem. Co.

2.2. Interlayer preparation

Thin P(S-r-MMA) films were spin coated from the solutions in toluene onto either Boron dope Si substrate or Al

electrode with various concentrations. The films were controlled in thickness ranging from 5 to 30 nm. The cross-linked networks were formed when the films were subsequently heated at 250 °C for 15 min under a nitrogen atmosphere. In this study, the films with six different thicknesses were prepared, denoted to P(S-*r*-MMA)1 to 6 in Table 1. The thickness measured by an ellipsometry (Gaertner Scientific Co., USA) is listed in Table 1.

2.3. Capacitor and Fe-FET fabrication

Thin PVDF-TrFE films with the thickness of approximately 250 and 350 nm were formed on the P(S-*r*-MMA) interlayers by spin coating (spin rate of 2000 rpm for 1 min) from a 3 to 5 wt% solution in methylethylketone (MEK) for capacitors and FeFET devices, respectively. The films were subsequently annealed at 135 °C for 2 h for enhancing the degree of crystallinity. Metal/PVDF-TrFE/P(S-*r*-MMA)/metal capacitors were made with a highly Boron doped Si substrate as the bottom electrode. Aluminum top electrodes were thermally evaporated on polymer films using a shadow mask with holes of 200 μm in diameter under a pressure of 7.5×10^{-7} torr and rate of 1 Å/s. Metal/P(S-*r*-MMA)/metal capacitors were also prepared for characterization of the thin interlayer films. Capacitance–voltage measurements were performed using HP4284A at 1 MHz. Ferroelectric properties were obtained using a virtual ground circuit (Radiant Technologies Precision LC unit).

Fabrication of a FeFET memory with pentacene active channel starts with the formation of a bilayered PVDF-TrFE/P(S-*r*-MMA) gate dielectric consecutively spin coated on a heavily Boron doped Si gate electrode. Pentacene channel and source/drain Au films were sequentially patterned on the gate insulators through shadow mask on the substrate at room temperature by thermal evaporation in a vacuum chamber at a base pressure of 9.0×10^{-7} torr. The deposition rates were fixed at 0.3 Å/s for the pentacene, and at 1 Å/s for Au electrodes. The pentacene and the Au films were 60 and 100 nm thick, respectively. The pentacene channel length and width were 50 μm and 200 μm, respectively. The schematic of a pentacene FeFET device with bilayered PVDF-TrFE/P(S-*r*-MMA) gate insulator is shown with the detailed chemical structures of the components in Fig. 1. The electrical properties of the devices were recorded using semiconductor systems (E5270B, HP4284A, Agilent Technologies). All measurements were done in metallic shielded box at room temperature in air.

Fig. 1. Schematic of a bottom gate FeFET with pentacene active layer and bilayered PVDF-TrFE/P(S-*r*-MMA) gate dielectric.

2.4. Measurement and characterization

Tapping Mode Atomic Force Microscope(TM-AFM, Nanoscope IV.Digital Instrument) was used to examine the surface morphologies of P(S-*r*-MMA) and PVDF-TrFE films. Both initial and final morphologies of pentacene on PVDF-TrFE were also characterized by AFM and Field Emission Scanning Electron Microscope (FESEM) (Jeol 2000). The crystalline structure of PVDF-TrFE was characterized by 2 dimensional (2D) Grazing-Incidence X-ray Diffraction (GIXD). The GIXD was performed on the 4C2 beam line at the Pohang Accelerator Laboratory in Korea (incidence angle: 0.09°–0.15°). Monochromatized X-rays ($\lambda = 0.1608$ nm) under vacuum and the full range of available incidence angles are used. The scattered beam intensity was recorded with an SCX: 4300-165/2 CCD detector (Princeton Instruments). 2D GIXD patterns we obtained in the range $0 < q_z < 2.33$ Å^{-1}, $0 < q_{xy} < 2.33$ Å^{-1} ($q = 4\pi \sin\theta/\lambda$ with z perpendicular and xy parallel to the substrate).

3. Results and discussion

First of all, we characterized thin film properties of P(S-*r*-MMA) interlayers with different film thickness. All films are very smooth and their root mean square (RMS) roughness values range from 0.43 to 0.59 nm with the standard deviation of 0.07 nm, regardless of the film thickness as shown in Table 1. The capacitance values measured from metal/P(S-*r*-MMA)/metal capacitors are also listed in Table 1. In addition, the relative dielectric constants of the interlayers were calculated, based on the contact area and film thickness in Table 1. One can easily notice that the capacitance values are almost inversely proportional to the film thickness within experimental uncertainty, giving rise to

Table 1
Characteristics of thin P(S-*r*-MMA) interlayer films.

Samples	Thickness (nm)	RMS (nm)	Capacitance (pF)	Dielectric constant
P(S-*r*-MMA)1	5.23	0.598	111.73	2.10
P(S-*r*-MMA)2	11.28	0.569	56.48	2.29
P(S-*r*-MMA)3	15.09	0.432	43.42	2.44
P(S-*r*-MMA)4	19.68	0.442	33.18	2.35
P(S-*r*-MMA)5	25.06	0.555	27.85	2.51
P(S-*r*-MMA)6	29.15	0.446	21.94	2.36

dielectric constants all similar for the films. The dielectric constant values of P(S-r-MMA) samples are between 2.1 and 2.5 and their average value is 2.34 with the standard deviation 0.139. Compared with the dielectric constants of PS, PMMA and BCB of approximately 2.5 [16], 2.6 [17] and 2.7 [18] at 1 MHz, respectively, the values we obtained from the random copolymers are slightly lower. Our interlayers turn out to be well controlled in thickness with fairly constant surface and dielectric properties.

The microdomain and crystalline molecular structures of a thin PVDF-TrFE film were visualized on a P(S-r-MMA)2 with FE-SEM and GIXD in Fig. 2a and b, respectively. The PVDF-TrFE film annealed at 135 °C for 2 h clearly exhibits the characteristic needle-like crystalline domains randomly organized with the length and width of approximately 200 and 40 nm, respectively, as shown in Fig. 2a. The crystalline structure of the film by 2D GIXD in Fig. 2b shows an intensified reflection on the meridian arising from the preferred (1 1 0) crystals aligned along the film surface normal with the polymer chains lying on the surface, consistent with our previous results obtained on Al or Si substrates [19,20]. The ordered (1 1 0) reflection
on the meridian is again desirable for polarization switching upon electric field, allowing the effective rotation of b-axis, polarization axis around chain backbone. PVDF-TrFE films on the other interlayers also exhibit the similar micro and molecular structures. The data indicate that ferroelectric PVDF-TrFE microdomains are also well developed with the proper crystalline orientation to polarization switching on our P(S-r-MMA) interlayers.

The ferroelectric polarization behavior of a 250 nm thick PVDF-TrFE film was characterized using typical polarization-applied voltage (P–V) hysteresis loop on P(S-r-MMA) interlayer with different film thickness as shown in Fig. 3a. A capacitor of the PVDF-TrFE film spin coated and subsequently annealed at 135 °C for 2 h on highly Boron doped Si electrode without an interlayer shows a typical square-like and symmetrical hysteresis loop, resulting in a remanent polarization, P_r of approximately 7 μC/cm² and a coercive Voltage, V_c of 11.9 V, when sweep voltage is applied above ±30 V as shown in Fig. 3a (black squares). Incorporation of an interlayer requires higher sweep voltage for the saturation of PVDF-TrFE polarization, giving rise to the increase of the apparent coercive voltage with the thickness of an interlayer as displayed in Fig. 3a. The P_r values of the capacitors with the hysteresis loops fully saturated remain almost same as approximately 7 μC/cm² irrespective of interlayer thickness.

A capacitor with bilayered PVDF-TrFE/P(S-r-MMA) with the architecture of metal-insulator-ferroelectric-metal(-MIFM) is treated as two independent and individual capacitors connected in series similar to the previous works by others [13,21,22]. In particular a PVDF-TrFE film we prepared is in pristine unpoled state just like a dielectric one at the beginning. In this condition, the voltage applied should be shared with our interlayer according to the series model, giving rise to the increase of the apparent coercive voltage as observed in our experiment. It should be noted that the effective coercive voltage applied only to the PVDF-TrFE film is supposed to be same regardless of the interlayers. Each capacitor takes the part of the voltage applied proportional to film thickness and inversely proportional to dielectric constant. In our cases, at least ±30 V should be exerted on a 250 nm thick PVDF-TrFE layer for full polarization saturation. The total voltage applied in a bilayered capacitor should therefore, increase linearly with the thickness of interlayer. In addition, the relatively low 2.5 dielectric constant of P(S-r-MMA), compared to that of PVDF-TrFE (~10), makes the sweep voltage higher than ±90 V even with 30 nm thick interlayer. In fact, a plot of the apparent V_c as a function of the interlayer thickness clearly displays a linear relation as shown in Fig. 3b. The ferroelectric properties of the capacitors including coercive voltage and remnant polarization are also summarized in Table 2. In our experiments; however, the effective coercive voltage also slightly increases with the interlayer thickness. The reason may be due to the leakage current in the interlayer. We speculate that at the voltage close to the breakdown one of an interlayer, there must be some leakage current which again influences the polarization of PVDF-TrFE. In addition, the polarization behavior of a PVDF-TrFE layer different on an interlayer from on metal surface without the interlayer may result

Fig. 2. (a) A FESEM image (b) a 2D GIWAXD pattern of ca. About 250 nm thick PVDF-TrFE film spin coated and subsequently annealed at 135 °C for 2 h on 10 nm thick P(S-r-MMA) layer. The characteristic needle-like crystalline microdomains are well developed on the interlayer with the length and width of approximately 200 and 40 nm, respectively. The preferentially aligned (1 1 0) reflection is apparent on the meridian in (b).

Fig. 3. (a) Polarization vs. applied voltage (P–V) hysteresis loops of metal/ 250 nm thick PVDF-TrFE/P(S-r-MMA)/metal capacitors with different P(S-r-MMA) interlayers. The inset shows a schematic of a capacitor. (b) Plots of remanent polarization (P_r) (left hand side) and coercive voltage (V_c) (right hand side) as a function of the P(S-r-MMA) interlayer thickness in the capacitors.

in the increase of the effective V_c due to the complicated PVDF-TrFE/interlayer interfacial properties containing surface charges, defects and residual solvent molecules and so on.

A pentacene FeFET with single layered PVDF-TrFE film clearly exhibits the hysteresis of source–drain current (I_{DS}) as a function of gate voltage due to the ferroelectric PVDF-TrFE gate dielectric layer as shown in Fig. 4a. The sharp increase of I_{DS} with negative bias gate voltage was attributed to excess holes accumulated in the pentacene layer in particular at the vicinity of the interface between pentacene and PVDF-TrFE layer. When gate voltage became back to zero, I_{DS} still remains at the value saturated with the gate voltage of −40 V due to the non-volatility of H–F dipoles in PVDF-TrFE film. The subsequent applica-

tion of positive gate voltage on the device gradually switches the H–F dipoles with H atoms pointing to pentacene layer, giving rise to the rapid decrease of I_{DS}. The nonvolatility of polarization again makes the current remaining same even after the removal of the positive voltage as shown in Fig. 4a.

The ON and OFF current were obtained of approximately 1.28×10^{-7} and 5.83×10^{-9} A, respectively, leading to the ON/OFF bistability ratio of approximately 20 as shown in both Fig. 4a and Table 2. The lower ON current in our device than a typical bottom gate pentacene OTFT with SiO_2 gate dielectric ($\sim 10^{-5}$ A) arose from the roughened crystalline surface of PVDF-TrFE layer directly in contact with pentacene, consistent with our recent results observed in a FeFET with single crystal TIPS-PEN as an active layer [11]. On the other hand, the OFF current in our device is much higher than that observed in a pentacene OTFT we prepared in our laboratory ($\sim 10^{-11}$ A). In addition, the single crystal TIPS-PEN FeFET displayed the OFF current of approximately 10^{-11} when 200 nm thick PVP interlayer was employed. The high OFF current did not arise from the pentacene channel between source and drain electrode but from the leakage current between gate and drain electrode.

The gate current simultaneously measured with the source–drain current hysteresis arises from both H–F dipole switching which corresponds to peaks and leakage during accumulation and depletion cycle as shown in the inset of Fig. 4a. The leakage becomes significant with gate voltage and becomes as large as approximately 5×10^{-8} A. This value is smaller than ON source–drain current observed ($\sim 1.28 \times 10^{-7}$ A), which implies that ON current is mainly attributed to the channel current arising from holes accumulated in the pentacene layer. The OFF current is, on the other hand, apparently dominated by the large gate leakage, as observed in Fig. 4a.

In order to gain the insight of the high OFF current in the pentacene FeTET, we investigated the cross-section of a 200 nm thick PVDF-TrFE film spin coated and subsequently annealed at 135 °C by FE-SEM in Fig. 4b. As noticed, there exist many pin holes which arise from the crystalline defects as well as residual solvent in the film. The origin of the defective microstructure is currently under investigation. It is; however, apparent that the defective film structure gave rise to the high OFF current of the FeFET mainly originated from the leakage current between gate and drain electrode.

The incorporation of P(S-r-MMA) interlayer between gate electrode and PVDF-TrFE film significantly influences

Table 2
Device performances of FeFETs and MFIM Capacitors with P(S-r-MMA) interlayers.

Samples	P_r (μC/cm^2)	V_c (V)	I_{on} (A)	I_{off} (A)	I_{on}/I_{off}	Mobility (cm^2/V s)
w/o P(S-r-MMA)	6.67	11.9	1.28E-07	5.83E-09	$10^{1.34}$	0.0065
P(S-r-MMA)1	6.68	16.6	8.07E-08	1.20E-09	$10^{2.28}$	0.0065
P(S-r-MMA)2	6.79	21.6	1.42E-07	1.18E-09	$10^{2.46}$	0.0065
P(S-r-MMA)3	6.82	27.1	1.28E-07	5.05E-10	$10^{2.6}$	0.0066
P(S-r-MMA)4	7.72	30.4	1.06E-07	1.90E-10	$10^{2.98}$	0.0061
P(S-r-MMA)5	7.29	36.1	1.25E-07	5.34E-11	$10^{3.58}$	0.0064
P(S-r-MMA)6	6.86	45.6	9.20E-08	7.09E-11	$10^{3.16}$	0.0066
Fig. 4. (a) Transfer characteristic curve (I_{DS}–V_G) of a pentacene FeFET with ca. 350 nm thick PVDF-TrFE gate insulator at V_D = −5 V. The inset displays I_G–V_G curve simultaneously obtained with the transfer curve. (b) A FESEM image of a thin PVDF-TrFE film with the thickness of approximately 200 nm annealed at 135 °C for 2 h on Si substrate.

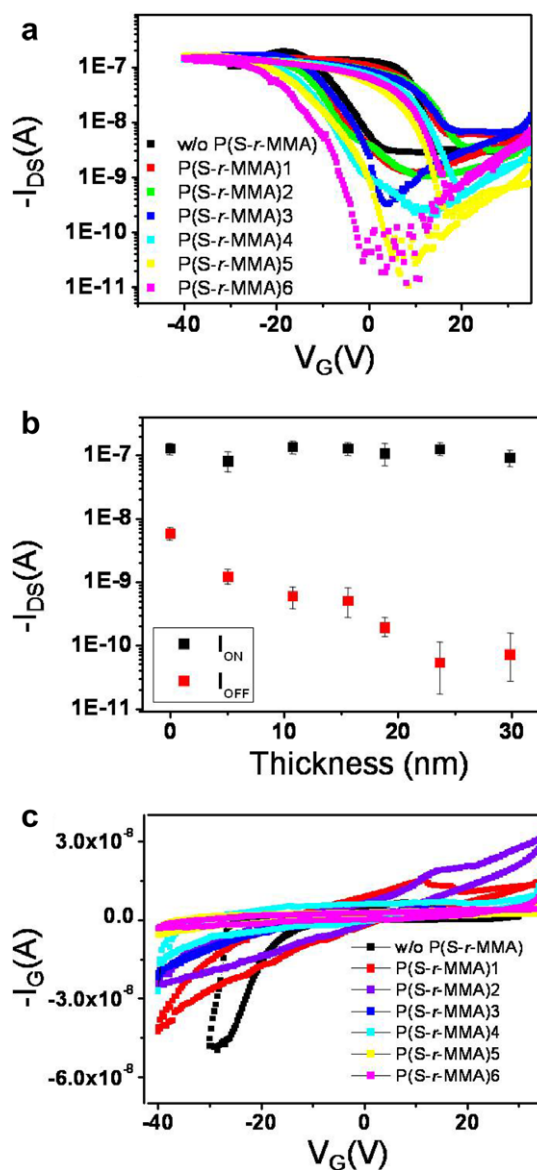
OFF current in pentacene FeFETs, depending upon inter-layer thickness as shown in Fig. 5a. To avoid the experimental error due to uneven pentacene evaporation, all devices with the different interlayers were fabricated in a same batch and the ON and OFF current of a FeFET memory were averaged with 4 sets of samples. It should be noted that the I_{DS} hysteresis curves in Fig. 5a are the representative ones with the different interlayers. The gate voltage is generally swept from 40 to −40 V in double mode with which gate voltage is swept twice from positive to negative value to confirm the bistability of the drain current. One can easily notice that OFF current becomes significantly lowered with the interlayer with a certain thickness while ON current remains all similar at approximately 1×10^{-7} A, which indicates that the interlayer indeed shields the gate leakage current present in bare PVDF-TrFE layer. A plot of ON and OFF current as a function of the interlayer thickness in Fig. 5b clearly displays that OFF current gradually decreases with interlayer thickness and reaches at approximately 10^{-11} A when the interlayer becomes thicker than 25 nm. The OFF currents we chose for comparison as a function of the interlayer thickness was the values at V_g equal to 0, the condition for non-volatility of the data. The reduction of OFF source–drain current with the interlayers apparently results in the improvement of data bistability characterized with the ratio of ON to OFF current. For instance the ON/OFF current ratio of approximately 20 in a FeFET without an interlayer was signifi-


Fig. 5. (a) Transfer characteristic curves (I_{DS}–V_G) at V_D = −5 V of pentacene FeFETs with six different P(S-r-MMA) interlayers. The transfer curve of the FeFET without P(S-r-MMA) layer (Fig. 4a) is also plotted for comparison. (b) Plots of ON and OFF current as a function of the P(S-r-MMA) interlayer thickness. While ON current remains all similar, OFF current gradually decreases with the interlayer film thickness up to approximately 25 nm. (c) I_G–V_G curves of the FeFETs simultaneously obtained with the transfer curves show that gate leakage current becomes significantly reduced with the thickness of the interlayer.

cantly enhanced to the value greater than 1000 with 25 nm thick interlayer. Detailed ON and OFF current information with different P(S-r-MMA) interlayers is also shown in Table 2.

The reduction of OFF source–drain current with the interlayers is also confirmed with the gate currents simultaneously obtained with the hysteresis curves in Fig. 5c. As expected, the gate current remarkably decreases with the thickness of P(S-r-MMA) interlayers. In particular the gate
Fig. 6. (a) A FESEM image of pentacene layer deposited on PVDF-TrFE film with 1 nm nominal thickness exhibits non-spherical pentacene domains grown on randomly ordered needle-like crystal domains of the PVDF-TrFE layer. (b) An AFM image of ca. 60 nm thick pentacene layer grown on a PVDF-TrFE film shows both pentacene grains with approximately 200 nm in size and unusually protuberant ones.

leakage of a FeFET with P(S-*r*-MMA)6 becomes negligible with the gate voltage sweep of ±40 V and does not contribute to the OFF source–drain current any more. The OFF current observed now mainly arises from the pentacene channel current in depletion mode in our experimental set up.

It is noteworthy that the coercive voltages observed in MFM capacitors are not the same as the turn-on gate voltages in the transistors. For instance, the apparent V_c of a capacitor with 250 nm thick PVDF-TrFE/P(S-r-MMA)6 is approximately 45 V while the turn-on voltage of 350 nm thick PVDF-TrFE/P(S-r-MMA)6 is 40 V. A transistor with PVDF-TrFE has shown very complicated device behavior such as flat band shift depending on the majority carrier type of organic semiconductors [5]. Furthermore, the insertion of an interlayer renders it more difficult to fully understand the device performance. The difference of coercive voltage between MFIM and transistor structure is one of those unsolved issues. Although it is obvious that turn-on voltage of a ferroelectric transistor is directly proportional to coercive field of the ferroelectric layer, the voltage does not coincide with the coercive voltage of a capacitor in particular when an interlayer is inserted.

The field effect mobility of a FeFET was calculated from the slope of I_{DS} vs. gate voltage (V_G) in Fig. 5a, using an equation suitable for linear regime of drain current-voltage due to the application of a low source–drain voltage (V_{DS}) of −5 V in our device. The equation is given by $I_{DS} = (W/2L)C_i\mu[2(V_G − V_T)V_{DS} − V^2_{DS}]$, where W and L are the width and length of channel and C_i, μ, and V_T correspond to the capacitance per unit area of either PVDF-TrFE or P(S-r-MMA)/PVDF-TrFE gate insulator, the field effect mobility and threshold voltage, respectively [23]. The hole mobility values with the different interlayers are all similar of approximately 0.006 cm^2/V s which is much smaller than a typical value of a bottom gate, top contact pentacene OTFT with oxide gate dielectric (0.5–1 cm^2/V s). The similar field effect mobilities irrespective of the interlayers imply that the variation of OFF current observed with the interlayers was not ascribed to the pentacene active layer. The lower field effect mobility in our FeFET device may arise from the rough surface of a semi-crystalline PVDF-TrFE film with the needle-like microdomains shown in Fig. 2a as reported by Stadlober et al. [24]. The rough surface of a PVDF-TrFE film was confirmed by RMS roughness

of approximately 2.3 nm, measured and averaged from several AFM images.

In order to examine the effect of the rough PVDF-TrFE surface on pentacene layer formation, we monitored the early stage deposition of pentacene layer on a PVDF-TrFE film annealed at 135 °C for 2 h. A pentacene layer with 1 nm nominal thickness deposited on the PVDF-TrFE film clearly exhibits non-circular shape pentacene domains sporadically distributed with approximately 200 nm in size as shown in Fig. 6a. These anisotropic pentacene domains at early stage of deposition are all observed with P(S-r-MMA) interlayers beneath PVDF-TrFE. All 60 nm thick pentacene films used for the FeFET devices with the interlayers show a unique surface morphology in which approximately 200 nm pentacene grains are closely packed with characteristic protruding peaks as evidenced in Fig. 6b. Both small grains and the unusual peaks developed from the initial anisotropic domains may result in the relatively low hole mobility of the devices. More detailed understanding of the crystalline pentacene structure is under investigation.

4. Conclusion

Our results demonstrated that new P(S-r-MMA) films were successfully utilized as interlayers between ferroelectric PVDF-TrFE layer and gate electrode for bottom gate penetacene FeFET memory devices. Both chemically and thermally resistive interlayers were beneficial not only for forming thin and uniform PVDF-TrFE films with the characteristic ferroelectric domain well developed but also more importantly for reducing gate leakage current in the devices, leading to both low OFF source–drain current and high ON/OFF current ratio. In particular such a low OFF current of approximately $10^{−11}$ A was obtained with the P(S-r-MMA) interlayers thicker than 25 nm, giving rise to the ON/OFF current ratio greater than 10^3 which was improved two orders of magnitude larger than that without an interlayer at operating sweep voltage of ±40 V.

in the application of computer desktop visualization in which bright saturated colors are widely used, adding a white sub-pixel may not be as efficient as in the video application. Moreover, if the size of each sub-pixel is kept the same, adding additional sub-pixel will reduce the display's resolution. On the contrary, if the display's resolution is kept the same, the sub-pixel's size has to be reduced to accommodate the additional sub-pixel. In this work, we present a novel method to characterize the display performance over the whole color space, and we introduce a color usage frequency to simulate real world images. By adjusting the color usage frequency, the advantage of the white sub-pixel can be clearly deduced.

2. Color matching

Since there are three different types of the retinal receptors in human eyes that provide the photopic vision, in principle, any arbitrary color can be reproduced by three primary colors [17]. In a RGB display, any color within the triangle enclosed by the red, green, and blue primary colors can be reproduced (Fig. 1), and the color matching is unique. The following equations give the amount of each primary needed to produce a color at a certain luminance:

$$m_1 = \frac{\left(\frac{1}{y_2}-\frac{1}{y_3}\right)\frac{x}{y} - \left(\frac{1}{y}-\frac{1}{y_3}\right)\frac{x_2}{y_2} - \left(\frac{1}{y_2}-\frac{1}{y}\right)\frac{x_3}{y_3}}{\left(\frac{1}{y_2}-\frac{1}{y_3}\right)\frac{x_1}{y_1} + \left(\frac{1}{y_3}-\frac{1}{y_1}\right)\frac{x_2}{y_2} + \left(\frac{1}{y_1}-\frac{1}{y_2}\right)\frac{x_3}{y_3}} m$$

$$m_2 = \frac{\left(\frac{1}{y_3}-\frac{1}{y_1}\right)\frac{x}{y} - \left(\frac{1}{y}-\frac{1}{y_1}\right)\frac{x_3}{y_3} - \left(\frac{1}{y_3}-\frac{1}{y}\right)\frac{x_1}{y_1}}{\left(\frac{1}{y_2}-\frac{1}{y_3}\right)\frac{x_1}{y_1} + \left(\frac{1}{y_3}-\frac{1}{y_1}\right)\frac{x_2}{y_2} + \left(\frac{1}{y_1}-\frac{1}{y_2}\right)\frac{x_3}{y_3}} m \quad (1)$$

$$m_3 = \frac{\left(\frac{1}{y_1}-\frac{1}{y_2}\right)\frac{x}{y} - \left(\frac{1}{y}-\frac{1}{y_2}\right)\frac{x_1}{y_1} - \left(\frac{1}{y_1}-\frac{1}{y}\right)\frac{x_2}{y_2}}{\left(\frac{1}{y_2}-\frac{1}{y_3}\right)\frac{x_1}{y_1} + \left(\frac{1}{y_3}-\frac{1}{y_1}\right)\frac{x_2}{y_2} + \left(\frac{1}{y_1}-\frac{1}{y_2}\right)\frac{x_3}{y_3}} m$$

where m and (x, y) is the amount and chromaticity coordinates of the color to be produced, m_1, m_2, m_3 and (x_1, y_1), (x_2, y_2), (x_3, y_3) are the required amounts and chromaticity coordinates of the three primaries, respectively.

With the additional freedom induced by the fourth primary, the color matching becomes not unique. For example, for a color located inside the triangle enclosed by the
green, blue, and white, it could be produced either by red, green, and blue without white, or by green, blue, and white without red. Furthermore, if all the four primaries are used, the solution becomes infinite. To simplify the calculation and take full advantage of the white emitter, we divide the large triangle formed by the primary R, G, and B into three small triangles formed by the primary W with other primaries as illustrated in Fig. 1. Any color will be reproduced by the vertexes of the small triangle where the color is located inside. By this simple color matching scheme, the white emitter is utilized at the maximum rate.

3. Uniform luminance color space

To characterize the display performance, the traditional method is to calculate the efficiency of the display at 200 cd/m^2 white. However, in a four primary color display with white emitter, characterizing the display at the white point will not be sufficient. For example, if the color coordinates of the white emitter is right at the D_{65} white position, the display's efficiency will be equal to that of the white emitter, regardless of the efficiencies of the other three primary colors. To characterize the display in a way close to that under actual operation, we present uniform luminance color space, in which all the color points in the color space have a luminance of 200 cd/m^2, and we characterize the display's performance all over the whole color space, not limited only to the white point. The process of characterization is listed in Scheme 1. For every reproducible color point, we calculate the amount of each primary required for the full color pixel to emit 200 cd/m^2 light at that color point. After all the values are obtained, the average luminance of each primary in the uniform luminance color space is given by the following equations:

$$\bar{m}_{R,G,B,W} = \frac{\sum_i m^i_{R,G,B,W}}{\sum_i} \quad (2)$$

where i is the index of the reproducible colors, and m is the luminance of each primary.

4. PLED devices

To simulate the display's performance, we fabricated polymer OLEDs (PLEDs) emitting R, G, B and W lights whose device structures are listed in Table 1. Their current density (J)–bias (V)–luminance (L) characteristics are shown in Fig. 2, and the external quantum efficiency (EQE)-J characteristics are shown in the inset. Detailed descriptions of device making have been reported elsewhere [13,14,18,19]. The CIE chromaticity coordinates of the R, G, B and W primaries for high definition television (HDTV) are also included in Table 1 for comparison [17,20]. Since the chromaticity coordinates of the PLEDs are very close to those of HDTV ones, in the following sections, our calculations will be carried out based on the real electroluminescent (EL) characteristics of the devices and the CIE coordinates of HDTV primary colors.

5. Display structures

To find out the performance of the display based on the fabricated devices, we assume a full color pixel consisting of 3 or 4 sub-pixels in the planar configuration in which the sub-pixels are laid side by side. As mentioned early, adding a fourth sub-pixel will alter the display's structure. If the size of each sub-pixel is kept the same, the display resolution will lose 25% by adding the fourth sub-pixel. If we keep the display resolution intact, the sub-pixel size has to be reduced by 25% as shown in Fig. 3. In the following calculations comparing the performances between the RGB display and the RGBW display, we will assume the

display resolution is the same for both displays. As a result, if the size of the full color pixel is set to 100 µm × 100 µm, and each sub-pixel has the same size, the sub-pixel size is 33.3 µm × 100 µm for the RGB panel, and 25 µm × 100 µm for the RGBW panel. To simplify the calculation, the aperture ratio is set to 100%. The actual luminance of each sub-pixel is first obtained in the uniform luminance color space following the process described in Section 3. Then, the luminous efficiency, the pixel power, and the power efficiency of the full color pixel are calculated based on the performance of the primary color devices shown in Fig. 2.

6. Results

The actual luminance of each sub-pixel in the uniform luminance color space is listed in Table 2 as well as the characteristics of the full color pixel in both the RGB panel and the RGBW panel. As shown, the RGBW display with the luminous efficiency of 8.05 cd/A and the power efficiency

Table 2
The characteristics of the full color pixel in both the RGB display and the RGBW display in the uniform luminance color space.

Method	Performance	R	G	B	W	Full pixel
RGB	Areal luminance (cd/m^2)	72	110	18	–	200
	Actual luminance (cd/m^2)	217	329	54	–	600
	Luminous efficiency (cd/A)	8.45	8.25	2.56	–	6.91
	Pixel power (μW)	0.56	0.56	0.48	–	1.60
	Power efficiency (lm/W)	4.05	6.16	1.18	–	3.93
RGBW	Areal luminance (cd/m^2)	57	58	13	72	200
	Actual luminance (cd/m^2)	228	232	52	288	800
	Luminous efficiency (cd/A)	8.43	7.69	2.57	13.1	8.05
	Pixel power (μW)	0.44	0.31	0.34	0.36	1.45
	Power efficiency (lm/W)	4.02	5.90	1.19	6.34	4.33

of 4.33 lm/W, is more efficient than the RGB one with the luminous efficiency of 6.91 cd/A and the power efficiency of 3.93 lm/W. In addition, it takes less pixel power in the RGBW display (1.45 μW) to produce 200 cd/m^2 light than that in the RGB displays (1.60 μW). The efficiency improvement and the power consumption reduction are due to the high performance of the white emitter, since the emission of the W sub-pixel accounts for 36% of the full color pixel's luminance in the uniform luminance color space. At the required luminance of 288 cd/m^2, the luminous efficiency and the power efficiency of the white emitter are as high as 13.1 cd/A and 6.34 lm/W, respectively. However, if the efficiency of the white emitter is low, the RGBW display may not possess any advantage in terms of power efficiency in comparison with the RGB display. We recalculated the RGBW display's efficiency by varying the white emitter's efficiency while fixing the efficiencies of the red, green, and blue emitters. The result shows that only when the white emitter's efficiency is larger than 4.46 lm/W, the RGBW display becomes more power efficient than the RGB display (Fig. 4a).

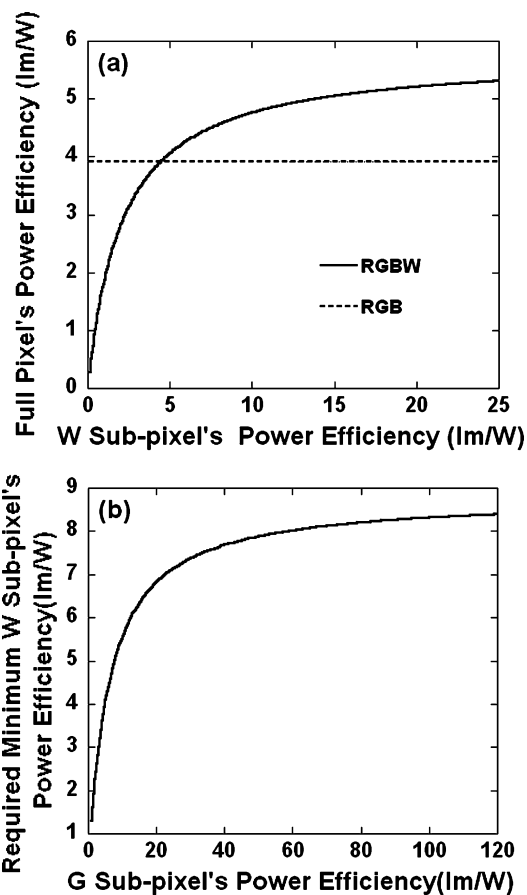
In the RGB display, the most used primary color is green, since the human eyes are most sensitive to the green color. Apparently, increasing the green emitter's efficiency will improve the display's efficiency. Recently, the power efficiency of the green OLED has reached 102 lm/W at 100 cd/m^2 [21]. At such high green emitter's efficiency, without a high efficient white emitter, the RGBW display will not be as power efficient as the RGB display. To find out the minimum efficiency of the W sub-pixel required for the RGBW display to be as efficient as the RGB display, we fixed the efficiencies of the red and the blue emitters, and varied the green emitter's efficiency to carry out the simulation. The result is plotted in Fig. 4b. The curve illustrates that the white emitter's efficiency has to keep up with the green emitter's efficiency to ensure the RGBW display's power efficiency. For the currently highest green emitter with the power efficiency of 102 lm/W, the white emitter's efficiency has to reach 8.32 lm/W. It is worth noting that when the green emitter's efficiency increases from 1 to 25 lm/W, the white emitter's efficiency has to go from 1.3 to 7.1 lm/W to catch up. However, at the high efficiency region, when the green emitter's efficiency increases from 25 to 120 lm/W, the white emitter's efficiency only goes from 7.1 to 8.4 lm/W. It reveals that, in order for the RGB display to be as efficient as the RGBW display, the power efficiency requirement for the green emitter is much higher than the requirement for the white


Fig. 4. (a) The dependence of the full color pixel's power efficiency in the RGBW display on the white emitter's power efficiency with fixed R, G, and B sub-pixels' efficiencies. (b) The minimum efficiency of the W sub-pixel required for the RGBW display to be as efficient as the RGB display at various green sub-pixel's efficiency.

emitter in the RGBW display in order for the RGBW display to be as efficient as the RGB display. The said feature allows for utilizing low efficient green emitter in RGBW display while achieving high display efficiency.

7. Color usage frequency

The OLED team in Eastman Kodak Company has sampled more than 13,000 digital images to find out that the

most prevalent colors in nature are unsaturated colors around the white point [3]. Lacking their resources, we introduce a color usage frequency f taking the form of a Gaussian distribution into the uniform luminance color space to simulate the nature colors:

$$f_i = \exp\left[-\frac{(x_i - x_W)^2 + (y_i - y_W)^2}{0.043/\alpha}\right] \quad (3)$$

where f_i is the color usage frequency, (x_W, y_W) is the CIE coordinates of HDTV white located at (0.313, 0.329), and α is the normalization non-negative factor defined by the boundary conditions. We use the blue primary usage frequency to set the boundary conditions as follows:

$$\begin{aligned} f_W &= 1 \\ f_B &= 10^{-\alpha} f_W \end{aligned} \quad (4)$$

Fig. 5a illustrates the color usage frequency with $\alpha = 1$, i.e. $f_B = 10\%$, while Fig. 5b shows the color usage frequency with $\alpha = 10$. As the value of α increases, the color usage frequency approaches the probability of color usage in nature images [3]. When α takes the value of zero, all the reproducible colors have the same probability of usage, which simulates the color usages in the application of computer desktop visualization in which bright saturated colors are widely used. After the color usage frequency is introduced, the average luminance of each primary in the uniform luminance color space is modified into the following equation:

$$\bar{m}_{R,G,B,W} = \frac{\sum_i f_i \times m_{R,G,B,W}^i}{\sum_i f_i} \quad (5)$$

The characterizations of a full color pixel in both the RGB and the RGBW displays were carried out in the uniform luminance color space coupled with the color usage frequency. The average luminance of each primary was calculated with different α value and shown in Fig. 6a. In the RGBW display, the contribution of white emitter grows from 43% to 67% of the total luminance as α increases from 1 to 10, while the contribution of the other three primaries steadily decreases, especially R and B primaries. With α increasing, the usage frequency of the saturated colors becomes lower. As a result, the average luminance contributions of R, G, and B primaries decrease from 23.5%, 28.2%, and 5.3%, to 8.9%, 21.7%, and 2.7% of the total luminance, respectively, when α grows from 1 to 10. In the RGB display, G primary makes the most contributions to the total luminance. As α increases, the average luminance of G primary also increase while the luminance of the other two primaries drop, which means the RGB display mostly depends on the G primary in displaying natural images.

The dependence of a full color pixel's power efficiency on the color usage frequency in both the RGB and the RGBW displays is shown in Fig. 6b. As revealed in Fig. 6a, when α is large, the luminance of the RGBW display depends mostly on W sub-pixel. Therefore, the efficiency of the white emitter plays a critical role in the full color pixel's efficiency. Shown in Fig. 6b, the full color pixel's power efficiency in the RGBW display rises rapidly with the increase of α. It reaches 6.4 lm/W at $\alpha = 10$ from 4.8 lm/W at $\alpha = 1$. In the simulation, the white emitter has a high effi-
Fig. 5. The color usage frequency with (a) $\alpha = 1$ and (b) $\alpha = 10$.

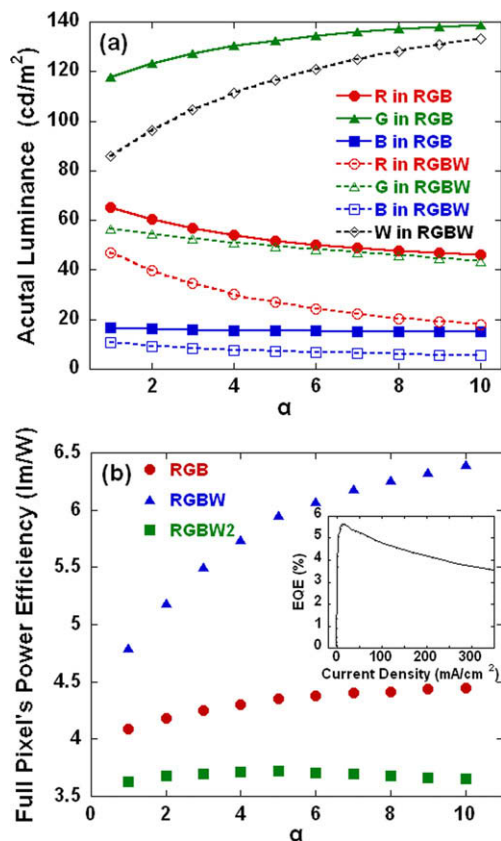
ciency illustrated in Fig. 2. For comparison, another white emitter with the configuration of ITO/PEDOT:PSS/PVK/PFO-poss/Ir(Bu-ppy)$_3$:(Piq)$_2$Ir(acaF)/Ba/Al was fabricated and utilized as W primary in the RGBW display denoted as RGBW2. Detailed descriptions of device fabrication could be found in Ref. [7]. The *EQE-J* characteristics of the device are shown in the inset of Fig. 6b. The power efficiency of a full color pixel in the RGBW2 display dependent on α was as well calculated and plotted in Fig. 6b. For RGBW2 display, although the full color pixel's power efficiency increases from 3.63 to 3.72 lm/W as α increases from 1 to 5, it begins to drop thereafter, and falls to 3.65 lm/W when α reaches 10. The power efficiency's drop at large α value is attributed to the low white emitter's efficiency. Since the full color pixel's efficiency in the RGBW display is mostly determined by the white emitter's EL performance at large α value, the more contribution of the W sub-pixel, the more power consumption of the full color pixel if the white emitter has a low efficiency, which leads to the reduction of the power efficiency. For the RGB display, the full pixel's power efficiency is not seriously


Fig. 6. (a) The average luminance of each primary in the RGBW display and the RGB display with different α. (b) The power efficiencies of a full color pixel in the RGB and the RGBW displays with different α. Inset of (b): *EQE-J* characteristics of the white PLED in RGBW2.

affected by the color usage frequency. It only changes from 4.09 to 4.45 lm/W as α goes from 1 to 10. The difference of the full pixel's power efficiency between the RGBW and the RGB displays becomes larger as α increases. Thus, by utilizing highly efficient white emitters, the RGBW display will be much more energy efficient than the RGB display for video applications. As the simulation revealed, in the RGBW display, video applications transfer the huge luminance requirements from R, G, and B primaries to W primary. Therefore, if the white emitter has a long lifetime, the RGBW display will have a long lifetime limited only by the white emitter.

8. Summary

In summary, the performances of the flat panel displays utilizing PLEDs with both RGB sub-pixels and RGBW sub-pixels layouts were analyzed theoretically and experimentally. A simple color matching scheme was applied to maximize the usage of the white sub-pixel. Uniform luminance color space was introduced to better characterize

the display performance than the traditional single white point characterization. In the uniform luminance color space, the RGBW sub-pixel display will be more energy efficient than the RGB display, when the power efficiency of the white emitter reaches a threshold determined by the green emitter's efficiency. To simulate the real natural images, the color usage frequency with Gaussian distribution was adopted in the calculation. As the color usage frequency distribution gets closer to that in the real images, the full color pixel's power efficiency of the RGBW display is more dependent on the EL performance of the white emitter. In order for the RGBW display to be more energy efficient than the RGB display with the same red, green, and blue emitters, a highly efficient white emitter is necessary.

convenient chromaticity-tuning they afford. However, the use of multiple dopants in either a single layer or multi-layer stack is complicated by the different energy transfer efficiencies involving the host and different dopants in the system, which can lead to significant imbalance in the white emission and current/brightness-dependent color changes [1]. These problems can be substantially mitigated by use of a single dopant which emits over a broad spectral range as is the case with materials which exhibit both monomer and excimer emission. Excimers usually lack a bound ground state and therefore color mixing from another dopant can be feasible to optimize white light emission without complications from inter-dopant energy transfer [1,4]. Further, the use of broad-band emitters simplifies chromaticity tuning, and reduces the number of device layers, processing steps and cost.

White/near-white electrophosphorescence due to combined monomer and excimer emission from "FPt" complexes [e.g., (2-(4′,6′-difluorophenyl)pyridinato-N,C$^{2'}$)(2,4-pentanedionato)platinum(II)] has been first reported by Thompson, Forrest and co-workers [4]. The peak power efficiency obtained for devices featuring singly-doped FPt2:CBP films was 2.5 lm/W; improvement to 4.4 lm/W and balanced white was obtained by doubly-doping CBP with both the FPt1 complex and a blue iridium phosphor (FIrpic), attaining a maximum CRI of 78. More recently, Williams, Cocchi, Kalinowski and co-workers have reported the synthesis [10] and electrophosphorescent properties [11] of cyclometalated platinum (II) complexes (PtL^{2}Cl), featuring N^C^N-coordinated terdentate ligands based on 1,3-dipyridylbenzene. Optimized WOLEDs fabricated from this material in an intricate device architecture produced a CRI of 90 and external quantum efficiency of 6.5% [11]. The emission was assigned to monomer emission of the PtL^{2}Cl molecule, triplet excimer emission of the PtL^{2}Cl: PtL^{2}Cl dimer, as well as a PtL^{2}Cl: *m*-MTDATA exciplex (hetero-molecular dimer) emission, where *m*-MTDATA = 4,4′,4″-tris(*N*-(3-methylphenyl)-*N*-phenylamino)triphenylamine. Further variation and optimization of device structure from the same dopant has allowed these researchers to obtain an external quantum of 15.5% and color coordinates close to that of an incandescent lamp (0.43, 0.43) [12]. Other notable research on electrophosphorescence from Pt(II) complexes has been reported by Chang et al. utilizing pyridyl azolate-based chelates, attaining maximum external quantum and power efficiencies of 5.9% and 6.4 lm/W, respectively, for the best dopant and attaining color tunability by varying the dopant concentration [13]. The luminescence in this work [13] has been assigned to metal–metal-to-ligand charge transfer in excimers and oligomers. In general, these literature precedents of Pt(II) complexes have shown rather strong sensitivity of device performance to the device structure (necessitating addition of exciton- and charge-blocking layers [11–15]) and color tuning by controlling the excimer/monomer ratio. However, the operational stability suggested by the roll-off of device efficiency and color metrics at higher brightness, voltage, and current density is generally inferior in devices based on such Pt(II) square planar complexes [4,11–15] compared to those known for Ir(III) cyclometalated octahedral complexes [1].

Here, we report an investigation of photoluminescence (PL) and electroluminescence (EL) of singly-doped thin films and OLEDs based on a new electrophosphorescent dopant, Pt(ptp)$_2$ = bis[3,5-bis(2-pyridyl)-1,2,4-triazola-to]platinum(II). We investigate the effect of Pt(ptp)$_2$ concentration in the common OLED host 4,4′-bis(car-bazol-9-yl)triphenylamine (CBP) on the PL properties of the thin films as well as the EL properties of OLEDs utilizing a basic device architecture. The overall results of this work suggest an excellent potential for OLEDs based on Pt(ptp)$_2$ to overcome the aforementioned inferior operational stability of devices based on other Pt(II) complexes while retaining the facile color-tuning advantage.

2. Experimental

2.1. Materials synthesis and characterization

Pt(ptp)$_2$, a new metal-organic phosphorescent material, was synthesized by refluxing two equivalents of 3,5-bis(2-pyridyl)-1,2,4-triazole with one equivalent of *cis*-bis(ben-zonitrile)dichloroplatinum(II) in pyridine/acetone under a nitrogen ambient for three days. The insoluble product was washed with acetonitrile and diethyl ether and dried overnight under vacuum. The material was subsequently purified by sublimation. The complex exhibits poor solubility in common organic solvents, which precluded standard spectroscopic and chromatographic characterization methods. However, single crystals were successfully grown from a dichloromethane/methanol mixed solvent to form poorly-diffracting long orange needles. X-ray diffraction identified the formula as Pt(ptp)$_2$ based on X-ray intensity data measured on a Bruker SMART APEX CCD area detector system equipped with an Oxford Cryosystems 700 Series Cryostream cooler, a graphite monochromator, and a Mo Kα fine-focus sealed tube (λ = 0.71073 Å). The data frames were integrated with the Bruker SAINT-PLUS software package. The data were corrected for absorption effects using the multi-scan technique (SADABS). The structure was solved and refined using the Bruker SHELXTL software package. Room temperature photoluminescence (PL) and photoluminescence excitation (PLE) of neat and various doped films of Pt(ptp)$_2$ were measured using a calibrated PTI QuantaMaster Model QM-4 scanning spectrofluorome-ter. The excitation and emission spectra were corrected for the wavelength-dependent lamp intensity and detector response, respectively. All films were deposited by thermal evaporation/co-evaporation using a computer-controlled Trovato system. The doped thin films in the PL and EL experiments have different doping levels as only a general correlation for the variation of the excimer/monomer emission trends vs. the doping concentration was sought.

2.2. Device fabrication and characterization

Organic light emitting diodes with the structure: glass/ITO/NPB (40 nm)/*x*% Pt(ptp)$_2$:CBP (25 nm)/TPBI (30 nm)/Mg:Ag, 1:10, (200 nm) were fabricated by sequential thermal evaporation. Prior to device fabrication the glass/ITO substrates were cleaned by sonication in acetone then methanol for 15 min, and afterward subjected to an oxy-

gen plasma treatment for ITO surface conditioning. A Photo Research PR650 camera integrated with a Keithley 2420 source-measure unit via LabView was used for quantitative electro-optical characterization. The software is also commercially available from Photo Research Inc., and reports all of the pertinent data: radiometric, photometric, CIE, CRI and color temperature. Both the PR650 and the Keithley 2420 are factory calibrated. All measurements were performed at room temperature and only the forward outcoupled light was measured.

3. Results and discussion

Fig. 1 represents the molecular structure of $Pt(ptp)_2$ obtained by X-ray crystallography. Although the X-ray diffraction data show significant disorder in the non-coordinated pyridine ring of each ptp ligand, the PtN_4 coordination geometry is determined accurately showing a bidentate $\mu_2–N,N'–$ coordination mode from the nitrogen atom of the other pyridine ring and the nitrogen atom in the 1–position of the triazolate moiety to the platinum(II) center. The Pt(II) pyridyltriazolate square-planar units
Fig. 1. Molecular structure (top) and packing diagram (bottom) of $Pt(ptp)_2$ as determined by single crystal X-ray diffraction.

stack into infinite chains with relatively strong Pt(II)···Pt(II) intermolecular interactions extended in columnar one-dimensional chains. These intermolecular forces belong to the general category of closed-shell "metallophilic interactions" known for multiple classes of molecular materials, including d^8 and d^{10} complexes, which have been ascribed to correlation effects that are strengthened by relativistic effects [16]. Detailed structural refinement and improvement thereof using solid-state density-functional quantum mechanical computations are in progress and, upon completion, will be reported. Overall, the X-ray structure confirms that $Pt(ptp)_2$ is a non-organometallic/non-cyclometalated square-planar complex with no C–Pt bonds, and that it exhibits intermolecular interactions that warrant formation of fully-overlapped excimer units. The desired advantages of the design include the symmetry of the coordination sphere, which facilitates formation of fully-overlapped excimers, and the extended π system (six aromatic rings total), which renders the molecule an excellent antenna with visible absorptions. The homoleptic nature of the $Pt(N^\wedge N)_2$ coordination sphere in $Pt(ptp)_2$ is distinctly different from the heterolyptic $Pt(C^\wedge N)(O^\wedge O)$ or $Pt(N^\wedge C^\wedge N)Cl$ coordination spheres in the aforementioned most efficient Pt(II) complexes used in the OLED literature thus far. None of these literature precedents has exhibited the symmetric overlap of adjacent square planar complexes in dimeric units or stacked chains as that seen in the structure of $Pt(ptp)_2$.

Room temperature photoluminescence (PL) and photoluminescence excitation (PLE) of neat $Pt(ptp)_2$ films as well CBP films doped with different percentages of $Pt(ptp)_2$ (i.e., films in their device formats) are presented in Fig. 2. The PLE maxima for all doped films correspond
Fig. 2. Thin film photoluminescence excitation (thinner curve) and photoluminescence (thicker curve) spectra of neat CBP, $Pt(ptp)_2$ and different volume percentages $Pt(ptp)_2$ in CBP.

to the 340 nm excitation of CBP, thus indicating a common excitation pathway involving energy transfer from the host to the dopant; direct excitation is seen only as weak shoulders in the PLE for only the two highest-doped films. These weak PLE features are similar to those in the neat film (Fig. 2). The absence of CBP emission in the spectra of the doped films suggests that the energy transfer is complete in all cases; note that the PLE of neat $Pt(ptp)_2$ overlaps with the entire emission profile of CBP. These PL and PLE data of $x\%$ $Pt(ptp)_2$:CBP thin

films suggest that the excitation mechanism in OLEDs employing this material system as the emissive layer will be dictated by the host instead of the dopant; i.e., primarily host excitons will form upon electrical excitation and direct excitation/recombination on the dopant will be negligible up to ~25% doping levels (above which direct excitation starts to contribute but only as a minor route). Neat films exhibit no or hardly detectable electroluminescence in the device structure used in this work. With increasing doping levels in the in $x\%$ $Pt(ptp)_2$:CBP

Fig. 4. Current–voltage curves for devices with different dopant concentration.

thin films, the spectral character of the PL red-shifts, and progressively changes from monomer- to excimer-dominated emission. This result is consistent with an increase in the number of pairs of Pt(ptp)$_2$ molecules with the separation required for excimer formation as the dopant concentration increases. The neat film exhibits PL maximum that is further red-shifted from the excimer band in doped films, which we assign to formation of extended excimers in the neat material but localized excimers in the doped films. A careful inspection of the PL data in Fig. 2 suggests a red shift in the excimer band at high concentration levels. While it is difficult to ascertain the crystal structure of aggregates in doped films, it is known from the published literature for molecular
Fig. 5. Luminance–voltage curves for devices with different dopant concentration.
Fig. 6. Peak luminous efficiency (solid squares) and power efficiency (open squares) as a function of Pt(ptp)$_2$ doping percent.

excimers (best-established for pyrene) that a greater overlap between the two planar monomer units results in a red shift in the excimer emission band [17], suggesting increased overlap of the planar monomer units that constitute the excimeric luminophore upon increasing the doping concentration.

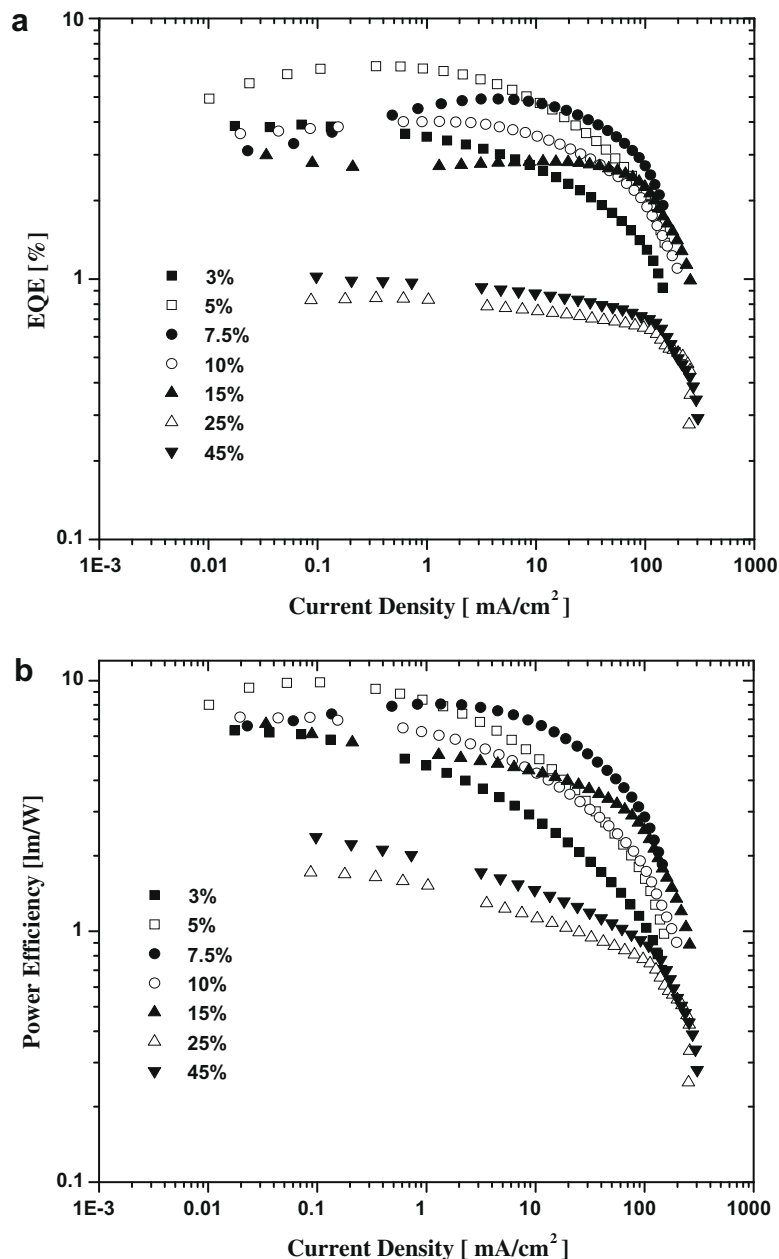
Similar to the photoluminescence, a shift from monomer- to excimer-dominated emission with increasing dopant concentration is observed in the electroluminescence, as the normalized spectra in Fig. 3 show. The CBP emission in the spectrum of the sample doped at 3% suggests that this doping level is insufficient for optimal energy transfer from the host to the dopant. We interpret the NPB shoulder in the electroluminescence of the samples doped at 25% and 45% to mean that the carrier mobility associated with the dopant is strongly influencing the carrier transport properties of the emissive layer, and thus the extent of the recombination zone. As Fig. 4 shows, a decrease in the electrical threshold voltage and an increase in the current at a given voltage generally accompanies the dopant concentration increase. The luminance as a function of voltage dependence is shown in Fig. 5. In the 5–15 doping percent range, the average brightness was ~7200 cd/m^2 at 9 V. We expect that the incorporation of hole injecting and/


Fig. 7. External quantum efficiency (a) and power efficiency (b) as a function of current density.

or electron-blocking layers into the device structure might lower the turn-on voltages seen. A doping concentration of 5% produced peak luminous and power efficiencies of 15 cd/A and 9.8 lm/W, respectively. Interestingly, the power efficiency at high luminance was higher for the 7.5% device, decreasing from a peak value of 8.07 lm/W only to 7.29 lm/W at 1000 cd/m^2; the EQE likewise de-creased from 4.91% only to 4.89%. The dependence of the luminous and power efficiencies on doping concentration for the full series of devices studied in this work is pre-sented in Fig. 6. As Figs. 7 and 8 show, the reduction in power efficiency and external quantum efficiency parame-ters under high current, brightness, and voltage conditions is relatively moderate compared to the sharp reduction in
Fig. 8. External quantum efficiency and power efficiency as a function of luminance for devices doped at 5% and 7.5%.

efficiency that characterizes typical electrophosphorescent devices.

Fig. 9 is representative of the CIE and CRI dependence on drive voltage. For this dopant concentration (7.5%) the color rendering index is 36 at 6 V and 35 at 10 V. The electroluminescence spectral features are essentially voltage-independent and, as Fig. 9 depicts, the ratio of monomer to excimer emission is essentially constant for the voltage range used in this study; i.e., we see little or no evidence of preferential saturation of monomer compared to excimer excited states with increased device current, or vice versa. In general all of the devices in this work exhibited better color stability than that reported for other square planar Pt(II) complexes [4,11–15]. The CRI increased with doping concentration and the maximum value obtained was 56. To the naked eye the emission appeared to be white with a green hue. Table 1 is a summary of the pertinent electro-optical performance metrics for OLEDs based on Pt(ptp)$_2$ in this work, showing both peak values as well as values at 1000 cd/m^2. This luminance level is deemed an appropriate reference level for OLEDs by the US Department of Energy [18], although device performance data at this high luminance level is rarely seen in the published literature for electrophosphorescent OLEDs. The overall data in Table 1 and Fig. 8 show that OLEDs based on Pt(ptp)$_2$ in this work exhibit remarkably insignificant roll-off in performance metrics at this high luminance, albeit to a different extent in devices with different doping levels. We expect this general device stability to improve upon further optimization of the device architecture.

4. Conclusion

In summary, we have demonstrated near-white electrophosphorescence with moderately high external power efficiencies (10 lm/W) in a basic OLED architecture with a singly-doped emissive layer based on a new homoleptic Pt(II) complex. The shift of emission wavelength with dopant concentration affords some degree of chromaticity tuning. It is expected that device structures which include hole injection and/or electron blocking layers will result in improved external efficiencies, as such approaches increased the efficiency of singly-doped devices based on other Pt(II) complexes by nearly an order of magnitude [14,15] vs. an earlier generation of devices that employed a similar device structure to the one used herein [4]. Similarly, inclusion of a deep-blue fluorescent emitter and/or engineering device structures with different emission regions of Pt(ptp)$_2$ monomer and excimer emission are expected to yield a more balanced white EL than what has been attained in this work.

between the energy levels of CBP and the red triplet dopants usually results in direct charge trapping within the emitting layer (EML). Therefore, red phosphorescent devices based on CBP often require high operation voltages and provide unsatisfactory PEs. To break free from these constraints, several attempts have been made recently to use host materials possessing narrower band gaps [28–30] or bipolar characteristics [31–33] to improve the charge injection and electroluminescence (EL) performance of red phosphorescent OLEDs. Nevertheless, the PEs of the red electrophosphorescence remain far below those reported for blue- or green-emitting devices [3,20–27].

In this paper, we report the fabrication of efficient red phosphorescent OLEDs incorporating the bipolar host 2,7-bis(diphenylphosphoryl)-9-[4-(N,N-diphenylamino) phenyl]-9-phenylfluorene (POAPF) doped with the efficient red-emitting phosphor $Os(fptz)_2(PPh_2Me)_2$ (fptz = 3-trifluoromethyl-5-pyridyl-1,2,4-triazole); Fig. 1 presents their chemical structures. This charge–neutral osmium complex has been used previously as a phosphor in red-emitting devices displaying high EQEs [22,34]. The relatively low oxidation potential of $Os(fptz)_2(PPh_2Me)_2$, however, results in severe charge trapping in devices using CBP as the host, resulting in high driving voltages and unsatisfactory PEs. POAPF, which contains an electron-rich triphenylamine group and an electron-deficient bis(diphenylphosphoryl)fluorene unit [35–37], has recently been developed as a host material exhibiting bipolar characteristics [38] that not only provide suitable frontier orbital energies for facile hole- and electron-injection but also improve the balance of charge flux in the emission layer. Moreover, the triplet energy (E_T) of POAPF is estimated to be 2.72 eV – a value that is sufficiently high for POAPF to act as a host material for red, green, and even blue phosphorescent emitters. Indeed, blue phosphorescent OLEDs based on POAPF doped with FIrpic can exhibit high values of EQE and PE [38]. We expected that POAPF could also be utilized as a host for the red-emitting $Os(fptz)_2(PPh_2Me)_2$, thereby improving charge injection and enhancing charge balance to result in highly efficient red phosphorescent devices.

2. Experimental

The bipolar host molecule POAPF [38] and the red phosphorescent emitter $Os(fptz)_2(PPh_2Me)_2$ [22] were prepared using previously reported procedures. The hole-transport material 4,4′-bis(3-methylphenylphenylamino)biphenyl (TPD), the conventional host material CBP, and the electron-transport material 4,7-diphenyl-1,10-phenanthroline (BPhen) were all purchased from LumTec Corp. and used without further purification.
The oxidation and reduction potentials were measured, respectively, in anhydrous CH_2Cl_2 and anhydrous DMF, containing 0.1 M $TBAPF_6$ as the supporting electrolyte, at a scan rate of 50 mV/s against a Ag/Ag^+ (0.01 M $AgNO_3$) reference electrode, with ferrocene as the internal standard. The onset potentials were determined from the intersection of two tangents drawn at the rising current and background current of the cyclic voltammogram.

The EL devices were fabricated through vacuum deposition (10^{-6} torr) of the materials onto ITO glass (sheet resistance: 25 Ω/square). All of the organic layers were deposited at a rate of 1.0 Å/s. The cathode was completed through thermal deposition of LiF (15 Å; deposition rate: 0.1 Å/s) and then capping with Al metal (100 nm) through thermal evaporation (deposition rate: 4.0 Å/s). The current–voltage–luminance relationships of the devices were measured using a Keithley 2400 source meter and a Newport 1835C optical meter equipped with an 818ST silicon photodiode. The EL spectrum was obtained using a Hitachi F4500 spectrofluorimeter.

3. Results and discussion

Fig. 2 presents the current density–voltage (I–V) characteristics of the hole-only devices having the configuration indium tin oxide (ITO)/TPD (30 nm)/host material (30 nm)/TPD (30 nm)/Al (100 nm) and the electron-only devices having the configuration ITO/BPhen (30 nm)/host material (30 nm)/BPhen (30 nm)/LiF (15 Å)/Al (100 nm). Here, "host material" refers to either the bipolar host POAPF or the conventional host CBP. Because of the high LUMO energy level (−2.20 eV) of TPD in the hole-only devices and the low HOMO energy level (−6.40 eV) of BPhen in the electron-only devices, injections of electrons and holes were prohibited in the hole- and electron-only devices, respectively; accordingly, the measured I–V characteristics were dominated by holes and electrons, respectively. Fig. 2 reveals that the POAPF-based devices exhibited lower turn-on voltages and higher current densities than did the CBP-based devices under the same bias.

Fig. 4. I–V characteristics of devices incorporating (a) POAPF and (b) CBP as hosts at various doping concentrations.

The reduced driving voltages in the POAPF-based devices may be due to the decrease in barrier heights for hole- and electron-injection from the charge transport layers (CTLs) to POAPF.

To further understand the improved injection of holes and electrons in the POAPF-based devices, we employed cyclic voltammetry (CV) to estimate the HOMO and LUMO energy levels of POAPF and CBP (Fig. 3a), using a three-electrode cell with ferrocene as the internal standard. Because of its triphenylamine donor unit, POAPF exhibits a lower onset of its oxidation potential (0.44 V) relative to that of CBP (0.74 V). On the other hand, the onset of the reduction potential of POAPF (−2.32 V), originating from its bis(diphenylphosphoryl)fluorene unit, is significantly less negative than that of CBP (−2.72 V). On the basis of these onset values for oxidation and reduction, we estimated the HOMO and LUMO energy levels of POAPF (−5.24 and −2.48 eV, respectively) and CBP (−5.54 and −2.08 eV, respectively) relative to ferrocene (4.80 eV below the vacuum) as a reference [39]. According to the energy level diagram in Fig. 3b, the hole-injection barrier from TPD and the electron-injection barrier from BPhen to the POAPF layer were both considerably lower than those to the CBP layer. As a result, the presence of POAPF facilitates hole- and electron-injection, as observed in the hole- and electron-only measurements (vide supra).

Using POAPF as the host material, we fabricated red OLEDs in the configuration ITO/TPD (30 nm)/R-EML (30 nm)/BPhen (30 nm)/LiF (15 Å)/Al (100 nm), where

TPD and BPhen were employed as hole- and electron-transporting layers, respectively, and R-EML refers to the POAPF layer doped with various concentrations of Os(fptz)₂(PPh₂Me)₂. For comparison, we also fabricated reference devices incorporating CBP as the host. Fig. 4 depicts the I–V characteristics of these red-emitting OLEDs. As expected, the POAPF-based devices exhibited significantly higher current densities than did the CBP-based devices under the same bias. The I–V characteristics of the POAPF-based devices underwent no apparent changes when we increased the doping concentration of Os(fptz)₂(PPh₂Me)₂ from 0 to 10 wt%. This phenomenon can be explained by considering the energy level diagram of the devices (Fig. 3b). Because the HOMO energy level of Os(fptz)₂(PPh₂Me)₂ is merely 0.34 eV higher than that of POAPF, it behaves as a less-effective trapping sites for holes; meanwhile, because the LUMO energy level of Os(fptz)₂(PPh₂Me)₂ is 0.28 eV above that of POAPF, electrons injected from the BPhen layer into the POAPF layer are mostly transported through the POAPF layer without being trapped in the osmium phosphor. Thus, varying the concentration of Os(fptz)₂(PPh₂Me)₂ in the EML should not significantly alter the degree of charge injection in POAPF-based devices. On the other hand, the current density of the CBP-based devices exhibited a strong dependence on the doping concentration. Because the HOMO energy level of Os(fptz)₂(PPh₂Me)₂ is 0.64 eV higher than that of CBP, holes can potentially be trapped at

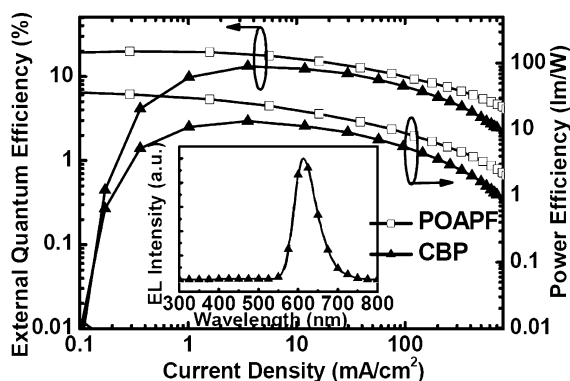

Fig. 5. EQE and PE of 7 wt% $Os(fptz)_2(PPh_2Me)_2$-doped POAPF- and CBP-based devices plotted with respect to the current density. Inset: EL spectra (applied voltage: 5 V) of the POAPF- and CBP-based devices.

$Os(fptz)_2(PPh_2Me)_2$ at low doping concentrations. When the concentration of the osmium phosphor was increased, we attribute the resulting increased hole-injection efficiency to direct charge injection from the hole-transporting layer (HTL) into $Os(fptz)_2(PPh_2Me)_2$. Accordingly, employing POAPF as the host for $Os(fptz)_2(PPh_2Me)_2$ significantly reduced the degree of charge trapping within the EML.

The optimal performances of both the POAPF- and CBP-based devices occurred at a doping concentration of 7 wt%. Table 1 lists the key characteristics of these red electrophosphorescent devices. The POAPF-based red-emitting device had a relatively low turn-on voltage of 2.3 V (corresponding to 1 cd/m^2) and, at a practical brightness of 1000 cd/m^2, its driving voltage was merely 3.7 V. These

values are much lower than those of the CBP-based device (3.5 and 5.1 V, respectively). We ascribe the reduced driving voltage of the POAPF-based device to facile hole/electron-injections and less-effective charge trapping within this bipolar host. Fig. 5 presents the EQE and PE profiles plotted with respect to the current density. The POAPF-based device exhibited a maximum EQE of 19.9% (at a luminance of 96 cd/m^2) – 1.5 times greater than that of its CBP-based counterpart (13.2%). These values reveal that the presence of the bipolar host material resulted in balanced charge fluxes within the EML and, therefore, a high EQE. Notably, the PE of the POAPF-based device (34.5 lm/W) was 2.5 times higher than that of its CBP-based counterpart (13.4 lm/W). We attribute this large enhancement in device performance to the substantially lower driving voltage and improved charge balance within the POAPF-based device. In addition to its highly efficient device performance, the POAPF-based OLED displayed a less-problematic efficiency roll-off at higher luminance. The efficiencies remained fairly high (18.6% and 26.1 lm/W) at a practical luminance of 1000 cd/m^2. Our POAPF-based red-emitting device possesses superior EL performance, particularly in terms of its PE (Table 2), relative to those of previously reported red electrophosphorescent OLEDs [29,31,32,34]. Both the POAPF- and CBP-based devices emitted saturated red light (each main peak at 616 nm) and Commission Internationale de L'Eclairage (CIE) coordinates of (0.64, 0.36) at 5 V (inset to Fig. 5).

To further utilize the superior host properties of POAPF, we fabricated white light-emitting devices – featuring red emission from $Os(fptz)_2(PPh_2Me)_2$ and complementary blue/green emission from FIrpic – having the configuration ITO/TPD (30 nm)/R-EML (x nm)/B-EML (30−x nm)/BPhen (30 nm)/LiF (15 Å)/Al (100 nm). Here, we used POAPF as the bipolar host material for both the red EML [R-EML; doped with 7 wt% $Os(fptz)_2(PPh_2Me)_2$] and the blue EML (B-EML; doped with 7 wt% FIrpic); the total thickness of these dual emission layers was fixed at 30 nm in each device. To realize white light emission from such composite emission systems, we adjusted the thickness ratio at various compositions to achieve appropriate fractions of excitons for both triplet emitters. Fig. 6 reveals an increase in the blue emission intensity relative to red emission upon decreasing the thickness of the R-EML. We obtained white emission when the thicknesses of the R-EML and B-EML were 1 and 29 nm, respectively. This white-emitting device also exhibited a low turn-on voltage (2.2 V) and an applicable luminance of 1000 cd/m^2 at merely 3.0 V (Fig. 7a); its maximum EQE reached 18.4% at a luminance of 90 cd/m^2. As a result of the low driving voltage, the PE reached as high as 43.9 lm/W (Fig. 7b). Even when the luminance

was 1000 cd/m², the EL efficiencies remained high (14.9% and 29.5 lm/W). The EL efficiency of this white electrophosphorescence is among the highest values ever reported for white light-emitting diodes [12,40,41]. The EL spectra of this device revealed a virtually stable white color emission (inset to Fig. 7b). The CIE coordinates shifted slightly from (0.40, 0.34) at a luminance of 1057 cd/m² to (0.38, 0.34) at 15,170 cd/m²; nevertheless, the color coordinates remained in the white light region.

4. Conclusion

We have realized highly efficient red electrophosphorescence in OLEDs incorporating the bipolar host POAPF doped with the red-emitting osmium phosphor $Os(fptz)_2(PPh_2Me)_2$. The bipolar characteristics of POAPF resulted in the red-emitting devices exhibiting very low driving voltages and achieving EL efficiencies as high as 19.9% and 34.5 lm/W – the highest performance of any red phosphorescent OLED reported to date – with a saturated red emission located at CIE coordinates of (0.64, 0.36). In addition, we used POAPF to fabricate a white light-emitting device possessing a dual EML configuration; it also exhibited satisfying efficiencies (18.4% and 43.9 lm/W). The white emission remained stable, with the CIE coordinates shifting slightly from (0.40, 0.34) at a luminance of 1057 cd/m² to (0.38, 0.34) at 15,170 cd/m². The performance of these phosphorescent devices makes them very attractive materials for potential commercial applications.

hand, the pyridine group is classically well-known to have electron affinity rather than hole and coordination ability with metal cation.

2. Results and discussion

2.1. Synthesis and thermal properties

Pyrene derivatives were readily synthesized by the Pd(0)-catalyzed Suzuki-Miyaura cross-coupling reaction of two equivalent of pyrene-1-boronic acid pinacol ester with 3,5-dibromopyridine for **PY1** and with 2,6-dibromopyridine for **PY2** (Scheme 1). The compounds were purified by train sublimation, and were characterized by ^{1}H- and ^{13}C-NMR, mass spectrometry, and elemental analysis. The details of synthesis and characterization are available in the supporting information. These pyrene oligomers are thermally stable. Thermogravimetric analysis (TGA) of the compounds showed that they had high thermal stability with 5% weight loss occurring at temperatures greater than 400 °C. Glass transition temperatures were 107 °C for **PY1** and 99 °C for **PY2**, determined by differential scanning calorimetry (DSC) measurement (Table 1).

2.2. Photophysical properties

UV–vis absorption and photoluminescence (PL) spectra of the pyrene oligomers in the solid state were measured for the vacuum deposited films on quartz (Fig. 1). PL spec-

Fig. 1. UV spectra of **PY1** and **PY2**.

tra showed 70–95 nm of large red shift compared with those of the chloroform solutions due to their excimer formation, which is typical for the emission from pyrene derivatives in the solid state. Absolute PL quantum efficiency of the film (F_{film}) was determined by using an integrating sphere system under argon atmosphere. A high F_{film} of 75% was found for **PY1**, which is one of the highest among the electroluminescent small molecules ever reported. The other compound also exhibited relatively high F_{film} of 66% for **PY2**. The F_{film} of **Alq₃** determined in the same condition was 22%, which is consistent with the value previously reported [8]. The reason of high F_{film} might be related with less quenching through vibrational mode due to their rigid structure and small structural difference between ground state and excited state, or less self absorption due to small overlap between the absorption and the emission spectrum of the neat film.

2.3. Electrochemical and electron-transporting properties

Ionization potential (I_p), estimated by photoelectron spectrometer surface analyzer [9,10], was 5.99 eV for **PY1** and 5.94 eV for **PY2**, and electron affinity (E_a), estimated by the difference of optical band gap, was 2.90 eV for **PY1** and 2.94 eV for **PY2**. The two pyrene derivatives showed no difference in their electronic energy state derived from their molecular structure. Charge mobilities of

the pyrenes were measured by time of flight (TOF) method. **PY1** and **PY2** showed partially nondispersive photocurrent (Figs. S1 and S2). The electron mobility were estimated to be 9.4×10^{-5} cm^2 V^{-1} s^{-1} for **PY1**, 1.7×10^{-4} cm^2 V^{-1} s^{-1} for **PY2** at 6.4×10^4 V/cm, which are higher than that of **Alq$_3$**, 1.7×10^{-6} cm^2 V^{-1} s^{-1}, determined in the same experimental condition (Fig. 2). For comparison, electron mobilities of smaller π-conjugated analogues, 3,5-difluorenylpyridine (**FL1**), and 2,6-difluorenylpyridine (**FL2**) shown in Fig. 3, were measured. **FL1** showed dispersive photocurrent (Fig. S3) and much lower electron mobility of
10^{-8} cm^2 V^{-1} s^{-1} and that of **FL2** was not measurable. These results demonstrated that much faster electron mobility of the pyrenylpyridines than that of **Alq$_3$** is due to their π-conjugated pyrene moieties and the π–π stacking.

2.4. OLED performance

The two pyrenes, **PY1** and **PY2**, showed no large difference in ionization potential, electron affinity, and electron mobility, and generally, those three parameters are regarded as important parameters for OLED. However, they showed a considerable difference in OLED performance as an electron-transporting material. OLEDs with the configuration of ITO/NPD (40 nm)/**Alq$_3$** (30 nm)/ETL (**Alq$_3$**, **PY1**, **PY2**, **FL1**, or **FL2**) (30 nm)/LiF (0.5 nm)/Al (100 nm) were fabricated to examine the electron-transporting materials (Fig. 4 and Table 2). Driving voltages at 100 cd/m^2 for **PY1** was 2.6 V lower than that for **PY2**, and even 1.8 V lower than that for **Alq$_3$**. Power efficiency, η_p (lm/W), for **PY1** was higher than that for **Alq$_3$**. Power efficiency η_p (lm/W) is more practically important in terms of energy consumption rather than current efficiency η_c (cd/A) or η_e external quantum efficiency (%). Higher performance observed for **PY1** compared with **PY2** cannot be explained in terms of their electronic properties such as ionization potential, electron affinity, and electron mobility because those are similar in the two compounds. We therefore assume that the barrier height for the electron injection from Al cathode through LiF to **PY1** must be lower than that to **PY2**.

The mechanisms of the improvement of electron injection by the thin LiF interlayer have been discussed [11]. Li ion in LiF is expected to be reduced to Li metal by the thermally activated Al during vacuum deposition process, and interact with electron-transporting materials as an electron donor [12]. In such cases, steric hindrance of the organic materials should affect the reaction, and the bulky pyrene group substituted on 2,6-position of the pyridine ring may prevent coordination to Li. In contrast, the nitrogen atom of the pyridine ring of **PY2** is available for the coordination to Li. Such steric effect was also observed

Fig. 2. Electron mobility measured by time of flight (TOF) method.

[a] Power efficiency.
[b] Current efficiency.
[c] External quantum efficiency.

for **FL1** and **FL2**. **FL1**, having substituents at 3 and 5 positions, also showed lower driving voltage than **FL2**, in which the positions of the substituents at the pyridine ring are at 2 and 6 positions. Efficiencies of the device with **FL1** were as high as those with **Alq$_3$** and better than those of **PY2**, although the electron mobility of **FL1** is much smaller than that of **PY2** and **Alq$_3$**. These results suggest that the electron injection from cathode is an important process determining driving voltage. In particular, specific affinity of the electron-transporting materials with cathode metal or metal halide is dominant to determine the barrier height for the electron injection. To take a close look at the injection process, electron only devices with the configuration of ITO/BCP (10 nm)/ETL (**Alq$_3$**, **PY1**, or **PY2**) (100 nm)/LiF (0.5 nm)/Al (100 nm) were fabricated, where BCP was used as hole blocking layer (Fig. 5). **PY2** showed much smaller current density than that of **Alq$_3$** and **PY1**. These results also support that the barrier height for the electron injection from Al to **PY2** is high, compared with **Alq$_3$** and **PY1**. However, in contrast to the current density–voltage characteristics of the OLED device (Fig. 4), **Alq$_3$** showed higher current density than that of **PY1** in the electron only device. Probably, in the OLED device with **PY1**, better hole injection from NPD to **PY1** was achieved, and the holes

were consumed in recombination with electron, which contributed to the increase of whole current density. In terms of the ionization potentials, **PY1** and **Alq$_3$** have almost same barrier height for the hole injection from NPD, which are 0.44 and 0.38 eV, respectively. The better hole injection from NPD to **PY1** than that to **Alq$_3$** could be considered to be resulted from a better molecular contact between the pyrene group of **PY1** and the naphthalene group of NPD.

In the design of ETL materials, their *chemical affinity* with cathode metal or metal halide is more important than their *electron affinity*, and their electron mobility is not necessary to be very high compared with **Alq$_3$**.

3. Experimental

3.1. Measurement

Minolta CS-200, respectively. External quantum efficiencies were calculated assuming Lambertian emission pattern and considering all spectral features in the visible.

3.2. Materials

Pyrene-1-boronic acid was purchased from TCI-Japn. 3,5-Dibromopyridine was purchased from Aldrich. 2,6-Dibromopyridine was purchased from Acros. 2-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dimethylfluorene was synthesized according to the literature.

3.3. PY1

A mixture of pyrene-1-boronic acid (2.17 g, 8.82 mmol), 3,5-dibromopyridine (0.95 g, 4.0 mmol), tetrakis(triphenylphosphine)palladium(0) (0.46 g, 0.40 mmol), potassium carbonate (3.32 g, 24.0 mmol), water (12 ml), ethanol (40 ml), and toluene (80 ml) was degassed and placed under nitrogen, and then heated at 80 °C for 12 h. The mixture was allowed to cool to room temperature and then chloroform was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed and the residue was purified by column chromatography over silica using a chloroform as eluent to give a pale yellow solid (1.54 g, 3.21 mmol, 80%). The product was purified again by train sublimation. ^{1}H-NMR (400 MHz, CDCl$_3$, TMS, ppm) 9.04 (2H, d, J = 2.1 Hz), 8.32–8.20 (9H, m), 8.14–8.10 (8H, m), 8.05 (2H, t, J = 7.7 Hz). ^{13}C-NMR (100 MHz, CDCl$_3$, TMS, ppm) 149.77, 139.46, 136.61, 133.31, 131.44, 131.31, 130.89, 128.82, 128.32, 128.01, 127.77, 127.35, 126.27, 125.57, 125.24, 125.04, 124.89, 124.80, 124.40. EI–MS (m/z) calcd. 479.57; found 480. Elemental analysis calcd. for C$_{37}$H$_{21}$N: C, 92.67; H, 4.41; N, 2.92; found: C, 92.58; H, 4.26; N, 2.96.

3.4. PY2

A mixture of pyrene-1-boronic acid (2.17 g, 8.82 mmol), 2,6-dibromopyridine (0.95 g, 4.0 mmol), tetrakis(triphenylphosphine)palladium(0) (0.46 g, 0.40 mmol), potassium carbonate (3.32 g, 24.0 mmol), water (12 ml), ethanol (40 ml), and toluene (80 ml) was degassed and placed under nitrogen, and then heated at 80 °C for 12 h. The mixture was allowed to cool to room temperature and then chloroform was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed and the residue was purified by column chromatography over silica using a chloroform: n-hexane mixture (1:1) as eluent to give a pale yellow solid (1.05 g, 2.19 mmol, 55%). The product was purified again by train sublimation. ^{1}H-NMR (400 MHz, CDCl$_3$, TMS, ppm) 8.62 (2H, d, J = 9.5 Hz), 8.37 (2H, d, J = 7.6 Hz), 8.30 (2H, d, J = 7.7 Hz), 8.23–8.08 (11H, m), 8.03 (2H, t, J = 7.5 Hz), 7.85 (2H, d, J = 7.7 Hz). ^{13}C-NMR (100 MHz, CDCl$_3$, TMS, ppm) 159.52, 136.57, 135.98, 131.46, 131.43, 130.94, 128.75, 127.99, 127.92, 127.87, 127.46, 126.02, 125.35, 125.12, 125.07, 125.04, 124.90, 124.89, 124.02. EI–MS (m/z) calcd. 479.57; found 479. Elemental analysis calcd. for C$_{37}$H$_{21}$N: C, 92.67; H, 4.41; N, 2.92; found: C, 92.61; H, 4.33; N, 2.93.

3.5. FL1

A mixture of 2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dimethylfluorene (2.8 g, 8.8 mmol), 3,5-dibromopyridine (0.95 g, 4.0 mmol), tetrakis(triphenylphosphine)palladium(0) (0.46 g, 0.40 mmol), potassium carbonate (3.32 g, 24.0 mmol), water (12 ml), ethanol (40 ml), and toluene (80 ml) was degassed and placed under nitrogen, and then heated at 80 °C for 12 h. The mixture was allowed to cool to room temperature and then chloroform was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed and the residue was purified by column chromatography over silica using a chloroform as eluent to give a white solid (1.76 g, 3.80 mmol, 95%). The product was purified again by train sublimation. T_g 88 °C. $T_{d5\%}$ 360 °C. I_p 6.4 eV. E_g 3.59 eV. ^{1}H-NMR (400 MHz, CDCl$_3$, TMS, ppm) 8.89 (2H, d, J = 2.3 Hz), 8.15 (1H, t, J = 2.1 Hz), 7.86 (2H, d, J = 8.2 Hz), 7.80–7.77 (2H, m), 7.71 (2H, d, J = 1.4 Hz), 7.65 (2H, dd, J = 7.7, 1.8 Hz), 7.49–7.47 (2H, m), 7.40–7.34 (4H, m), 1.57 (12H, s). EI–MS (m/z) calcd. 463.61; found 464. Elemental analysis calcd. for C$_{35}$H$_{29}$N: C, 90.67; H, 6.30; N, 3.02; found: C, 90.97; H, 6.36; N, 3.07.

3.6. FL2

A mixture of 2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dimethylfluorene (2.8 g, 8.8 mmol), 3,5-dibromopyridine (0.95 g, 4.0 mmol), tetrakis(triphenylphosphine)palladium(0) (0.46 g, 0.40 mmol), potassium carbonate (3.32 g, 24.0 mmol), water (12 ml), ethanol (40 ml), and toluene (80 ml) was degassed and placed under nitrogen, and then heated at 80 °C for 12 h. The mixture was allowed to cool to room temperature and then chloroform was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed and the residue was purified by column chromatography over silica using a toluene:n-hexane mixture (2:3) as eluent to give a white solid (1.48 g, 3.19 mmol, 80%). The product was purified again by train sublimation. T_g 84 °C. $T_{d5\%}$ 340 °C. I_p 6.3 eV. E_g 3.33 eV. ^{1}H-NMR (400 MHz, CDCl$_3$, TMS, ppm) 8.25 (2H, d, J = 1.3 Hz), 8.16 (2H, dd, J = 8.1, 1.8 Hz), 7.87–7.75 (7H, m), 7.49–7.47 (2H, m), 7.40–7.33 (4H, m), 1.59 (12H, s). EI–MS (m/z) calcd. 463.61; found 464. Elemental analysis calcd. for C$_{35}$H$_{29}$N: C, 90.67; H, 6.30; N, 3.02; found: C, 90.74; H, 6.36; N, 3.02.

P3HT is still under development, and it is uncertain whether the specialized film-forming techniques for achieving high mobility in P3HT OTFTs will be compatible with the to-be-determined manufacturing process. Therefore, it is important that more options for controlling the P3HT morphology to obtain high field-effect mobility are available, so that the commercial applications of the P3HT OTFTs can be facilitated.

In this study, we explore the plausibility of manipulating the morphology of P3HT films with a post-casting solvent–vapor exposure treatment (vapor annealing) to achieve high field-effect mobility in P3HT OTFTs. Vapor annealing has been shown to enhance the crystallization and thus improves the carrier mobility of P3HT molecules in bulk-heterojunction solar cells, but its effects on P3HT-based OTFTs have not been reported [12]. We analyze the film morphology and the OTFT characteristics resulting from exposing P3HT films to unsaturated and saturated solvent vapor conditions, based on which we determine the vapor annealing conditions that achieve optimal OTFT characteristics. We also characterize the lifetime of the OTFT devices, a property important to practical use, as a function of the vapor annealing condition, and we then demonstrate encapsulation methods capable of sufficiently extending the lifetime.

2. Materials and methods

P3HT (regioregular ratio 98.5%, molecular weight 87 k) was purchased from Sigma–Aldrich Co. and used as received. The substrates were p-type heavily-doped silicon wafers with a 200 nm thermal oxide capping layer that was used as the gate dielectric. The OTFTs used in this study were bottom-gate, bottom-contact devices, and the fabrication process is as follows. First, the SiO_2 gate dielectric was treated with octadecyltrichlorosilane (OTS) to form a self-assembled monolayer (SAM) [9]. Second, a 100 nm gold layer was thermally evaporated through a shadow mask onto the substrates to form the source and drain electrodes, whose channel length/width (L/W) was 100 μm/1500 μm. Third, a P3HT layer was spin-coated from a 1 wt% dichlorobenzene (DCB) solution at 800 rpm to complete the devices. Conditions of the various solvent–vapor annealing treatments applied to the P3HT film are as follows. For the control, the P3HT film was spun to dry for 60 s, followed by a 30 min bake at 130 °C. The unsaturated solvent–vapor annealing treatment consisted of the following steps: (1) spin-cast a P3HT film with a 30 s spin, when it was partially dry, (2) transfer the film to a partially sealed volume maintained at 25 °C, which was controlled so that the film was dried after 10 min, (3) bake the film at 130 °C for 30 min. The saturated solvent–vapor annealing treatment was similar except that the partially dried P3HT films were placed in a fully sealed volume filled with saturated DCB vapor, where it was stored for 60 min before being retrieved. All steps of the fabrication process were performed in a nitrogen-filled glove box. The *I–V* characteristics of the devices were measured in air using a Keithley 4200-SCS Semiconductor Characterization System. The mobility values reported were effective mobility that neglected the effects of con-

tact resistance. The morphology of the P3HT films was observed using a Nanoscope 3D Controller Atomic Force Microscope (AFM) (Digital Instruments) operated at the tapping mode and a X-ray diffraction graph was observed using Rigaku TTRAXIII X-ray diffractometer (XRD).

3. Results and discussion

The saturated and unsaturated solvent–vapor annealing treatments improved the field-effect mobility of the P3HT OTFTs in two distinct manners, as shown in Fig. 1 and Table 1. With unsaturated annealing (which results in slow drying), the mobility increased by ∼9 folds, from 0.0013 to up to 0.012 cm²/V s. With saturated annealing, however, a drastic increase in the mobility occurred, raising the mobility to 0.11 cm²/V s. With unsaturated vapor annealing, the increase in the mobility was found to result from enhanced crystallization of the P3HT molecules, as can be seen in the AFM micrographs in Fig. 2 and in the XRD patterns in Fig. 3. The AFM micrographs show that fiber-like features, which are characteristic of crystalline P3HT [7,8], were indistinct in the unannealed samples but were significantly more defined and larger in size upon unsaturated vapor annealing. Similarly, the XRD pattern of the unsaturated-vapor-annealed samples shows an increase in the intensity of the peak corresponding to the (1 0 0) lattice plane of the P3HT crystal unit cell. The observed effects of solvent–vapor annealing in this stage were similar to what have been reported for P3HT-containing bulk-heterojunction photovoltaic cells and P3HT thin films, i.e., enhanced crystallization and increased hole mobility [8,12]. It should be noted that the rather high and positive threshold voltages of the devices are due to the p-doping effects of H_2O/O_2 from air as well as the low capacitance of the thick SiO_2/OTS gate insulator, and are characteristic of P3HT OTFTs with similar insulator materials. [4,5,9,13]

With saturated solvent–vapor annealing treatment, a change in the appearance of the P3HT films accompanied the drastic increase in the mobility. Upon saturated annealing (prior to the final bake), the films started to reflow as they fully absorbed the solvent vapor, and because of the greater affinity of P3HT to itself and to the gold con-

Table 1
Electrical characteristic of P3HT OTFTs made with different vapor annealing conditions.

	Mobility (cm^2/V s)	On/off ratio	Threshold voltage (V)
No vapor annealing	0.0013	1.5×10^4	22
Unsaturated solvent annealing	0.012	6.7×10^4	28
Saturated vapor annealing	0.11	1.9×10^6	18
Fig. 2. AFM topography images of P3HT films: (a) without solvent vapor annealing, (b) annealed in unsaturated solvent vapor, and (c) annealed with saturated solvent vapor (reflowed); inset: a scan showing the thickness of the reflowed film, where the scan was made over a scraped line through the film. (d) AFM topography image of the SiO_2–OTS surface.

tacts than to the SiO_2–OTS surface of the FET channel area, the P3HT films reflowed out of the FET channels into a few isolated drops on the large gold contact pads in the non-device area, leaving the FET channels free of visible P3HT film. A schematic drawing illustrating this process is given in Fig. 4. Despite showing no visible P3HT film, the FET channels did retain a thin layer of P3HT that was ∼2 nm in thickness as determined by AFM (see Fig. 2c inset), which corresponded to 2–3 monolayers; moreover, the FET characteristics of the reflowed devices (Fig. 5) showed that the thin P3HT layer was functional as the semiconductor layer. The normal FET function of the thin P3HT layer was consistent with the knowledge that charge transport in OTFTs proceeds mostly via the 1–2 monolayers of the organic semiconductor adjacent to the gate dielectric. The mechanism that resulted in the high mobility of the re-flowed P3HT may be that the reflow motion caused the P3HT chains to extend horizontally along the surface, so that charges were better able to transport along the chains (intramolecular charge transport) rather than across the chains (intermolecular charge transport) (see Fig. 4). This mechanism may be similar to that of the dip coating technique reported by Cho et al. and Wang et al. [4,5], where the dipping motion applied to coat P3HT films helped to extend the P3HT chains along the surface, producing 2–3-monolayer P3HT thin films with similarly high FET mobility. Consistent with the fibril/grain-like crystal morphology observed for the dip-coated P3HT films, the surface of the reflowed films also appeared to consist of small fibrils and grains, as can be seen by comparing the AFM images of the reflowed P3HT layer and the SiO_2–OTS surface (on which the P3HT layer was coated) in
Fig. 3. X-ray diffraction patterns of P3HT films before (solid line) and after (dotted line) unsaturated vapor annealing.

Fig. 2c and d). In terms of uniformity of the OTFTs produced by the reflow process, the uniformity in the mobility was slight better than that of the pristine devices on

$1.5 \times 2.0\ cm^2$ square substrates with 10 devices: The standard deviation was 10% of the average mobility for the reflowed device, as opposed to 14% for the non-reflowed devices. This good uniformity, despite the randomness of the reflow process, was attributed to the large affinity differential between P3HT–gold and P3HT–SiO$_2$/OTS, which ensured that the bulk of the P3HT film retreated to the large gold contact pads, where it could be easily removed. It should be noted that the mobility values observed for the reflowed devices may have been underestimated due to the high contact resistance [13,14]; however, the deviation should have been small, as devices with a different gate length/width ratio showed identical mobility values (see Supplementary Materials).

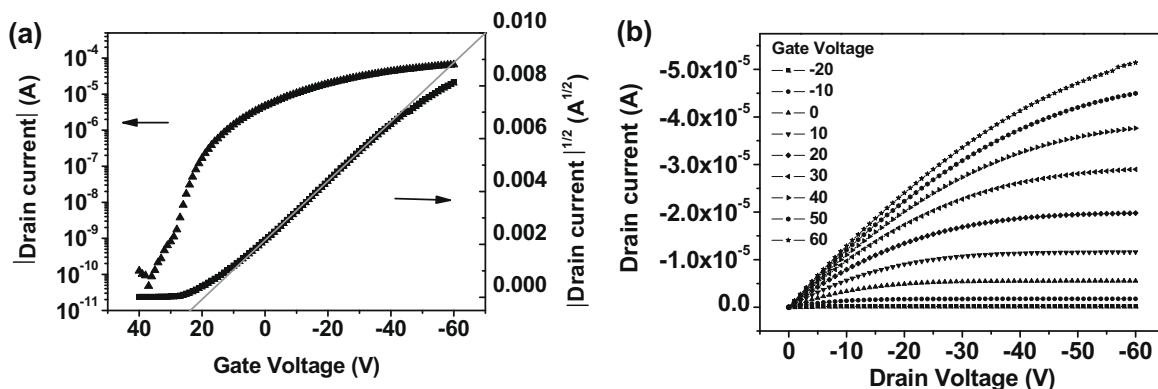
Some interesting phenomena arose when the reflowed and non-reflowed (unsaturated-vapor-annealed) OTFTs were observed after various times of being stored in air: In terms of the mobility, the reflowed devices degraded much more rapidly than that of non-reflowed devices, while the opposite was observed in terms of the off current, as shown in Fig. 6. P3HT OTFTs are susceptible to degradations induced by O$_2$ and H$_2$O via two main mechanisms: photo-oxidation and p-type doping, the former of which disrupts the conjugation of P3HT to impede charge
Fig. 4. Schematic drawing of the reflow process during saturated vapor annealing: Top row: top views; bottom row: side views.


Fig. 5. (a) Transfer and (b) output characteristics of the P3HT OTFTs annealed in saturated solvent vapor (reflowed). The transfer characteristics were measured at a source-drain bias of 60 V.

transport and the latter of which introduces charge carriers that contribute to high off current [15–17]. The different stability in air of the two types of P3HT OTFTs can be
Fig. 7. FTIR spectra of unsaturated-vapor-annealed P3HT layer (a) before and (b) after being stored in air for 24 h under sunlight.

accounted for by considering the effects of their drastically different thickness on the two degradation mechanisms described above. In photo-oxidation, the reflowed P3HT film's ultra thinness (~2 nm) allowed the whole of itself to be quickly photo-oxidized, thereby showing rapid decline in the mobility; the non-reflowed P3HT film, on the other hand, was of regular thickness (25 nm) and therefore required more time for photo-oxidation to propagate through the film. Evidence of photo-oxidation was observed in the FTIR spectra of the non-reflowed film (Fig. 7), where a carbonyl stretching peak at $1650 \, cm^{-1}$ appeared after air exposure; the reflowed film was too thin to have measurable IR signal. As to doping by O_2 and H_2O, the reflowed film had far smaller capacity to absorb the dopants than the non-reflowed film, and therefore its doping-induced off current was of a much smaller magnitude.

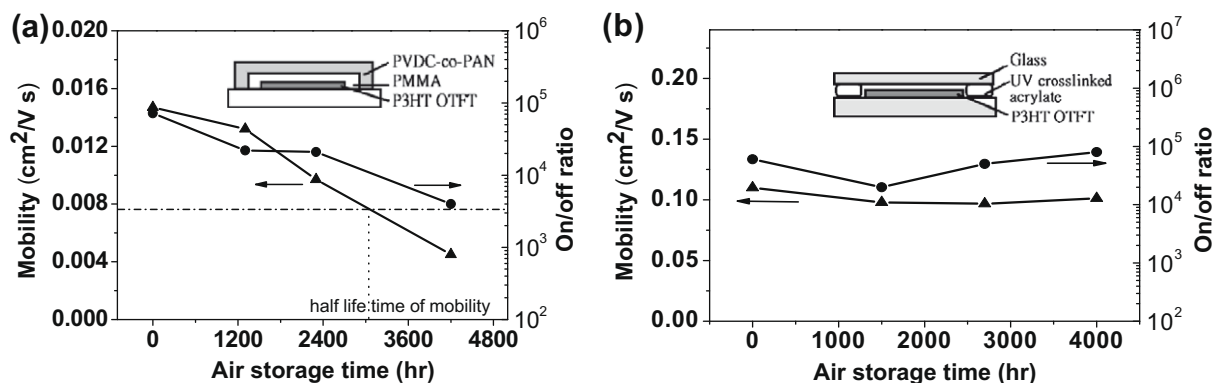
The air-induced degradation of the reflowed P3HT OTFTs was greatly reduced by encapsulating them with either an adhesive-sealed glass plate or with a bilayer polymer film composed of a poly(methyl methacrylate) (PMMA) and a poly(vinylidene chloride-co-acrylonitrile) (PVDC-co-PAN) layer, as can be seen by comparing Fig. 6 with Fig. 8, which shows that the mobility and on/off ratio of the encapsulated devices degrade slowly (with PMMA/


Fig. 8. Mobility and on/off ratio of reflowed P3HT OTFTs as a function of storage time in air: (a) encapsulated with PMMA/PVDC-co-PAN, (b) encapsulated with adhesive-sealed glass lid.

PVDC-co-PAN) or remain stable (with glass/adhesive) with time. The lifetime of the reflowed P3HT OTFTs, which is the time required to reduce the mobility by one-half of the pristine mobility, increased from 3 h without encapsulation to ~3000 h with PMMA/PVDC-co-PAN encapsulation; moreover, the devices encapsulated with adhesive-sealed glass showed only slight degradation upon 4000 h of storage in air. However, the PMMA/PVDC-co-PAN encapsulation caused pronounced upon-encapsulation decline in the mobility to the reflowed devices, from 0.11 down to 0.014 cm^2/V s. This degradation was attributed to the direct contact of the P3HT layer with the PMMA film, which may interfere with charge transport in P3HT through intermixing or stress, and because the reflowed P3HT layer contained only 2–3 monolayers, the effects of the PMMA film were magnified. The encapsulation-induced degradation of the reflowed devices was avoided by the glass encapsulation, where the P3HT layer was not contacted by the encapsulation materials. The above results indicate that, although the reflowed P3HT films offer high mobility, their encapsulation or passivation requires special attention to prevent encapsulation- or passivation-induced degradations.

4. Conclusion

Room-temperature solvent–vapor annealing of spin-coated P3HT films improved the field-effect mobility of the resultant OTFT devices in two distinct manners. With unsaturated solvent vapor annealing, the mobility increased moderately, from 0.0013 to 0.012 cm^2/V s, because the solvent vapor enhanced crystallization of P3HT. With saturated solvent vapor annealing, the P3HT films liquefied and reflowed, leaving an ultra-thin film of 2–3 monolayers in the device area, where the P3HT chains were extended by the reflowing motion so that the mobility was greatly increased, to 0.11 cm^2/V s. Upon exposure to air, the reflowed P3HT films showed more quickly declined mobility yet more slowly increased off current due to their ultra-thin thickness, as the small thickness allowed rapid and thorough photo-oxidization but low air-doping uptake. The reflowed P3HT OTFTs' lifetime were extended to more then 3000 h when they were encapsulated with either a bilayer polymer film or with an adhesive-sealed glass plate; and upon-encapsulation degradation was avoided by keeping the encapsulant from direct contact with the P3HT films, which were susceptible to intermixing with

or stress exerted by a directly contacting encapsulant due to their small thickness.

only observed at low temperatures and high current levels in a conventional Alq$_3$-based device. This leads us to suggest that temperature and driving current would play important roles in the magnetic field effects (MFEs) on EL as mentioned above.

In this letter, we presented detailed studies on the influence of temperature and driving current upon the magnetic-field modulated EL to further investigate the MFEs in Alq$_3$-based OLEDs with the structure of ITO/copper phthalocyanine (CuPc)/N,N′-di(naphthalene-1-yl)-N,N′-diphenyl-benzidine (NPB)/Alq$_3$/lithium fluoride (LiF)/Al. We found that the EL intensity increases at low fields and reaches its maximum at about 35 mT. With further increasing the field, the EL intensity either saturates or decreases, depending on the temperature and driving current. The low-field-increase, which exists in all the temperature and driving current measurement range, was mainly attributed to the magnetic-field dependent singlet-to-triplet conversion of electron-hole pairs. The high-field-decrease, evidently observed at low temperatures and high current levels, was demonstrated to be in fair agreement with the magnetic-field mediated TTA process.

2. Experimental

The OLEDs with the structure of ITO (100 nm)/CuPc (15 nm)/NPB (60 nm)/Alq$_3$ (80 nm) LiF (1 nm)/Al (100 nm) were fabricated, where CuPc is buffer layer, NPB is the hole transport layer, and Alq$_3$ is the electron transport/emission layer, respectively. LiF was used to improve the electron injection into Alq$_3$. All the organic materials were used as received without additional purification and deposited by thermal evaporation under high vacuum ($\sim10^{-6}$ Pa). The evaporation rate and thickness of the deposited layers were detected by a calibrated quartz crystal monitor. Hundred nanometer Al cathode was thermally evaporated on the LiF film through a shadow mask (active areas: 2×3 mm^2). After preparation, the samples were mounted on the cold finger of the close-cycle cryostat (Janis CCS-350s) with variable temperature that was located between the pole pieces of an electromagnet (Lakeshore EM647). The magnetic field with the maximum strength of 0.5 T was applied parallel to the device surface and measured by Hall probe GaussMeter (Lakeshore 421) which was placed close to the sample. The devices were driven by a Keithley 2400 SourceMeter and the EL intensity was measured by using a silicon photodetector and a Keithley 2000 apparatus. The photodetector was tested to make sure there was no field dependence on its output.

3. Results and discussion

Fig. 1a shows the magnetic field effects on EL and voltage for the device driven with constant current of 400 µA at 15 K. It is seen that a sharp increase in EL at low magnetic fields followed by a significant decrease at high fields larger than about 35 mT. While the behavior of voltage shows a saturation at high fields after its sharp decrease at low fields. Similar MFEs in EL at constant voltage (the
Fig. 1. (a) The magnetic field effects on EL and voltage for the device driven by 400 µA at 15 K, (b) the magnetic field effects on EL and current for the device driven by constant voltage (27.35 V) at 15 K.

voltage bias of 27.35 V gives an injection current of $\sim$400 µA) at 15 K is shown in Fig. 1b. The low-field increase in EL (low field effect, LFE) and high-field decrease in EL (high field effect, HFE) is the common feature of the studied devices at low temperatures. The MFEs on current at constant voltage bias is also shown in Fig. 1b. The current increases rapidly at low fields but then tends to saturate at high fields. The two distinct behaviors of EL at low fields and high fields suggest that the LFE and HFE should be caused by different mechanisms. This is also indicated by the different field dependences between the EL and current at high fields mentioned above.

According to the qualitative formula EL $\propto \eta I$ [8], where η is the quantum efficiency of EL and I is the current, one can deduce a simple relationship as: ΔEL/EL = $\Delta\eta/\eta$ + $\Delta I/I$. It means that the variation of the EL reflects the combination of the field induced variations of both current and quantum efficiency [18]. For simplicity, in this work we focused on the constant-current driving experiment, i.e. $\Delta I = 0$, to exclude the extra effects caused by the field-enhanced current on EL. Fig. 2 shows the evolution of MFEs on EL over a temperature range from 15 to 150 K. The relative change of EL is described by ΔEL/EL= [EL(B) − EL(0)]/EL(0), where EL(B) and EL(0) are the EL in the presence and absence of a magnetic field B. As shown in Fig. 2, for the current level at both 50 and 400 µA the LFE exists at all the temperature range and the lower the temperature is, the weaker LFE is observed. However, the HFE shows more remarkable temperature dependence. As the temperature is increased, the HFE becomes weaker and finally disappears at 150 K at current level of 50 µA. The MFEs with different driving currents at 15 and 150 K are demonstrated
Fig. 2. Relative change of EL as a function of applied magnetic field at different temperatures between 15 and 150 K, (a) the driving current is 50 μA, (b) the driving current is 400 μA.

in Fig. 3a and 3b, respectively. All the curves show both LFE and HFE at 15 K. It's discernible that large driving current results to weak LFE and strong HFE. Furthermore, at 150 K the HFE becomes weaker compared to that at 15 K and completely vanishes at driving currents less than 200 μA while the LFE still survives. The different temperature and driving current dependences between the LFE and

HFE confirm the conclusion drawn from Fig. 1 that LFE and HFE are controlled by different mechanisms.

In our case the LFEs displayed in Figs. 1–3 are somewhat similar to those observed by Kalinowski et al. [8]. In their work sharp increases in EL and also in current were observed within a small field range and these effects were attributed to the magnetic-field affected hyperfine mixing of electron-hole pairs. According to Kalinowski's pioneer interpretation, singlet intermolecular electron-hole pairs can evolve into triplet pairs via the hyperfine interaction. The spin conversion between the singlet and triplet states would be efficient between the degenerate states [19]. In the absence of a magnetic field, the singlet and triplet pairs nearly degenerate because of the negligible exchange interaction due to the large distances between the holes and electrons. So the spin conversion from the singlet to triplet pair states is efficient. When an external magnetic field greater than the hyperfine coupling strength is applied, the Zeeman splitting of triplet states removes the degeneracy between T_+, T_- and S states, leading to a decrease in singlet-to-triplet conversion and an increase in singlet electron-hole pairs. On one hand, some of the net singlet pairs would evolve into singlet excitons and then enhance the EL intensity due to their radiative decay [8]. On the other hand, the current would also be enhanced when the other net pairs dissociate into free carriers [15]. These positive MFEs on EL and current are expected to saturate at high fields when the energy splitting between T_0 and $T_\pm$ states becomes much greater than the hyperfine coupling energy. This is consistent with our observed behaviors of EL at current level of 50 μA at 120 and 150 K as shown in Fig. 2a. However, at low temperature of 15 K, the EL intensity decreases significantly at high fields larger than about 35 mT as shown in Fig. 3a. This high-field decrease of EL is not expected by Kalinowski's model, and it might originate from other reason.

Triplet-charge annihilation (TQA) has also been proposed to explain the MFEs [5]. This mechanism was well illustrated by Ern and Merrifield [6]. The TQA process may increase with decreasing temperature and rising driving current due to an increase in triplet excitons and carrier density in the device. However, in our experiment the TQA process could be neglected because of the following reasons: TQA process increases the free-to-trapped charge concentration ratio and leads to the enlargement of the current; a magnetic field-induced monotonous decrease in TQA rate constant would result in a decrease in the current [6] which is at variance with our experiment results. Fig. 1b clearly shows that the current increases with increasing magnetic field strength. It is also reported that the interaction of the triplet exciton with a deep-trapped carrier would produce phosphorescence in Alq_3 at low temperature [20], while this phosphorescence was found to be not dependent on magnetic field [10]. Moreover, the TQA process should be minimized for balanced charge injection [2,4]. Considering the hole mobility in NPB is higher than the electron mobility in Alq_3, we insert 15 nm CuPc between ITO and NPB as buffer layer to reduce the holes injection from anode and balance it with the electrons injection from cathode [21]. So we believe that the TQA process is unimportant in the MFEs in our devices.

Another possible mechanism of MFEs on EL is based on TTA process which has been widely reported in molecular crystals [16,17], polymer-based OLEDs [22] and also Alq_3-based OLEDs [3,23]. According to Merrifield' theory [24], TTA process can be modulated by a magnetic field and produce a small rise of EL at low fields and a subsequent fall at high fields. These results are similar to our observed phenomena at 15 K in which the EL contains a low-field increase and a high-field decrease (as shown in Fig. 3a). However, we fail to observe consistent behavior of EL when the temperature and driving current are varied. With elevating the temperature and lowering the driving current the HFE becomes weaker and the LFE gets larger. Interestingly, as the temperature is increased to 150 K and the driving current is decreased to 50 μA, the HFE disappears completely while the LFE still survives and even gets larger as shown in Fig. 2a. This suggests that the low-field increase in EL, that is, LFE in our devices can not be well explained by magnetic-field mediated TTA process.

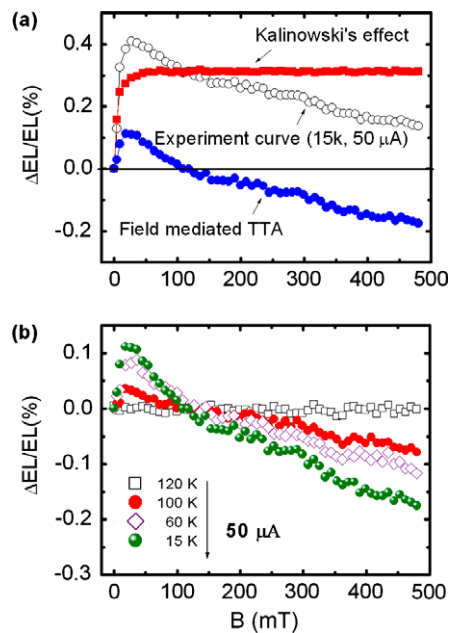
Since no single mechanism can explain all the observed MFEs on EL, a composite model is proposed here, containing both the magnetic-field dependent singlet-to-triplet conversion (Kalinowski's effect) and magnetic-field mediated TTA process. In principle, the Kalinowski's effect leads to a saturation of EL at high fields while the field mediated TTA process induces a significant decrease. Thus the decrease of EL at high fields confirms that the field mediated TTA process is dominant in the HFEs in our devices. Both the Kalinowski's effect and field mediated TTA process can cause an increase in EL at low fields but the former effect is believed to be most important. This is supported by the fact that LFE survives and even gets larger while the HFE disappears (suggesting that TTA process is suspended) at higher temperature and lower driving current, as shown in Fig. 3b. Moreover, the ΔEL/EL curves at low current level of 50 μA and high temperature of 120 and 150 K all sharply increase at low fields and then tend to saturate at high fields as shown in Fig. 2a, suggesting that the ΔEL/EL caused by Kalinowski's effect approximately have the same magnetic-field dependence under these conditions. So the ΔEL/EL curves should show a sharp low-field-increase and a high-field-saturation at low temperature if the TTA process does not occur. The ΔEL/EL trace measured at 150 K with 50 μA driving current is selected to characterize how the LFE would change with increasing field. Because the delayed EL caused by TTA process was observed to fall below its zero-field level at about 125 mT in OLEDs with amorphous Alq_3 films [10], we therefore regard the ΔEL/EL value at 125 mT of the experiment curve as the saturated magnitude of Kalinowski's effect in our Alq_3-based devices. By subtracting the MFE's component due to Kalinowski's effect from the measured ΔEL/EL data, the contribution from the field mediated TTA process is obtained (as shown in Fig. 4a). The component due to field mediated TTA process reaches its maximum at B_0 = 17 mT which corresponds to energy of about 1.7 μeV ($E_B = g\mu_B B_0$), which is very close to the zero-field splitting parameter in Alq_3 measured to be 1.4 μeV by Cölle et al. [3]. The great similarities between our results with those field modulated delayed EL due to TTA observed in anthracene crystal [17]


Fig. 4. (a) Composite model for the MFEs on EL. The Kalinowski's effect component (solid squares) dominates the low-field increase, while the filed mediated TTA process part (solid circles) causes the high-field decrease; (b) effects of the pure field mediated TTA process at 50 μA at temperature range from 15 to 120 K.

and Alq_3-based OLEDs [10] strongly support our TTA interpretation for high-field decrease of ΔEL/EL.

Interestingly, Davis and Bussman observed anthracene crystal-like MFEs in some special OLEDs and suggested that magnetic-field modulated TTA process would be operative in the MFEs [2]. But in later publication [25], enhancements of EL exceeding 14% at low magnetic field (∼80 mT) were found at low drive levels (the drive levels so low that TTA process is unimportant). Thus, they excluded TTA mechanism for MFEs and attributed the low fields increase to a field-induced preference for charge-pair (electron-hole pair) state to form singlet exciton. Their results also confirm the conclusion that the field dependent singlet-to-triplet conversion, that is, Kalinowski's effect is dominant in the LFE. Fig. 4b shows the evolution of ΔEL/EL caused by field mediated TTA process at 50 μA over a temperature range from 15 to 120 K. The anthracene crystal-like MFEs become more remarkable as temperature is decreased, suggesting that stronger TTA process exhibits at low temperature. This is consistent with the experiment results observed by Cölle et al [3] that the intensity of the delayed luminescence caused by TTA shows an increase with the decreasing temperature.

It's generally believed that in OLEDs triplet excitons have much longer lifetime than singlet excitons and therefore are able to diffuse larger distance. The dissociation of the triplet excitons at the interface between Alq_3 and cathode can enhance the charge injection. Such an effect is called excitonic injection [8]. A magnetic field reduction in TTA rate constant reduces the number of quenched triplets, their flux towards the cathode increases the current

tending to saturation as shown in Fig. 1b. Although the triplet excitons can be increase by applying a magnetic field to decrease the interaction rate constant of TQA process, it is not a dominant process in our device because TQA has been minimized by balanced charge injection as previously discussed.

Further investigation of the temperature and driving current dependences of the HFE and LFE was demonstrated in Fig. 5. The value of the HFE is defined as HFE = [EL(450 mT) − EL(35 mT)]/EL(35 mT), while the magnitude of LFE is defined as LFE = [EL(35 mT) − EL(0 mT)]/EL(0 mT). As shown in Fig. 5a, the magnitude of the HFE becomes smaller with the increasing temperature and completely disappears at 150 K. Another feature of the HFE is that higher current level leads to larger HFE at a certain temperature. The magnitude of the LFE decreases by a factor of ∼1.7 at 15 K when increasing the current from 20 to 400 µA (as shown in Fig. 5b). Similar driving current dependence of the LFE can also be seen at other temperatures. As mentioned above, the magnetic-field mediated TTA process is responsible for the HFE in our devices. The probability of TTA process is expected to be proportional to the square of the triplets density considering its bimolecular process [3]. And the density of triplets is proportional to the current. Therefore, it is reasonable to conclude that TTA process should be much stronger at larger driving current, leading to a more significant decrease in EL at high fields. With further decreasing the temperature, the lifetime of the triplets increases due to a reduced phonon-assisted decay [3], thus increasing the triplet density and also the total annihilation rate γ_{tot}, as proposed by Merrifield [24]. This is why one can observe large HFE at low temperature and

large current levels. The driving current dependence of the LFE as shown in Fig. 5b is in agreement with Kalinowski's equation [8] $\Delta EL/EL = [\kappa_{ST}(0) - \kappa_{ST}(B)]/[\kappa_{-1} + \kappa_C + \kappa_{ST}(B)]$, where κ_{-1} is the dissociation rate of singlet electron-hole pair, κ_C is the condensation rate from singlet pairs to singlet excitons, $\kappa_{ST}(B)$ and $\kappa_{ST}(0)$ are the intersystem crossing rate between singlet and triplet states with and without external magnetic field B, respectively. According to the assignment of Kalinowski et al. [8], κ_C, $\kappa_{ST}(B)$, and $\kappa_{ST}(0)$ are assumed to be constant while κ_{-1} is varying with applied voltage. At a low applied voltage, κ_{-1} is small thus almost no contribution to $\Delta EL/EL$. However, at a high applied voltage the κ_{-1} increases and contributes markedly to the denominator of the equation, leading to a decreasing in $\Delta EL/EL$. Given the fact that large applied voltage corresponds to high current level in the OLEDs, it is reasonable that the decrease in $\Delta EL/EL$, that is, the lower LFE would occur at larger driving current.

4. Conclusions

In summary, we have presented detailed studies on the MFEs on EL in Alq_3-based OLEDs driving by different current levels and over a broad range of temperature (15–150 K). We found that at low temperature the MFEs consist of a sharp increase in EL at low fields and a significant decrease at high fields. The HFE becomes weaker and even disappears at higher temperatures and lower driving currents while LFE always survives, suggesting that the LFE and HFE would be caused by different mechanisms. We propose a composite model to explain the observed MFEs and attribute the HFE mostly to the magnetic-field mediated TTA process while the LFE mainly to the magnetic-field dependent singlet-to-triplet electron-hole pairs conversion.

have shown high field-effect mobilities in thin-film states. For example, pentacene-based transistors show a hole mobility on the order of ca. 1.0 cm^2/Vs that corresponds to a performance close to that of hydrogenated amorphous silicon-based transistors. Nevertheless, in comparison to a variety of p-type devices, there have only been a few n-type OTFTs reported to date [12–18]. This dearth in study is ascribed to the fact that most n-type organic compounds are sensitive to environmental contaminants such as moisture and oxygen that can penetrate into the active channel region. Therefore, the transistor characteristics of most n-type OTFTs have been obtained either under inert atmosphere or under vacuum. Since power-efficient logic elements use complementary circuits that require both p- and n-type transistors, it is desirable to improve performance of the n-type devices to match that of the p-type devices in fabricating all organic-based electronics. Among the n-type materials such as C$_n$ (n = 60, 70), metallophthalocyanines and perylene derivatives, a series of perylene compounds have attracted particular attention given their good transport and high electron affinities. Recently, Tatemichi et al. reported the characteristics of transistors based upon N,N′-ditridecylperylene-3,4,9,10-tetracarboxylic diimide (P13) which is an extended π-conjugated molecule with a strong electron affinity (3.4 eV) [12]. The P13 transistors whose active layers were thermally annealed at 140 °C displayed a high electron mobility of 2.1 cm^2/Vs under vacuum. Typical electron mobilities of other perylene derivatives-based transistors have been reported ranging between 2.5×10^{-3} and 1.7×10^{-2} cm^2/Vs [14,17,18].

In this article, we report our first application of the NCBD method to prepare P13-based, n-type OTFTs with a top-contact structure (Fig. 1). A systematic analysis was carried out to examine the influence of surface modification and thermal post-treatment on device characteristics and operational stability. The structure-device performance relationship is also discussed. In addition, we present the comparative characteristics of transport mechanisms responsible for the conduction of electron carriers as a function of temperature from 300 down to 10 K for various devices. To the best of our knowledge, no mechanistic study of the transport phenomena of the P13-based OTFTs has been reported thus far.

2. Experiment

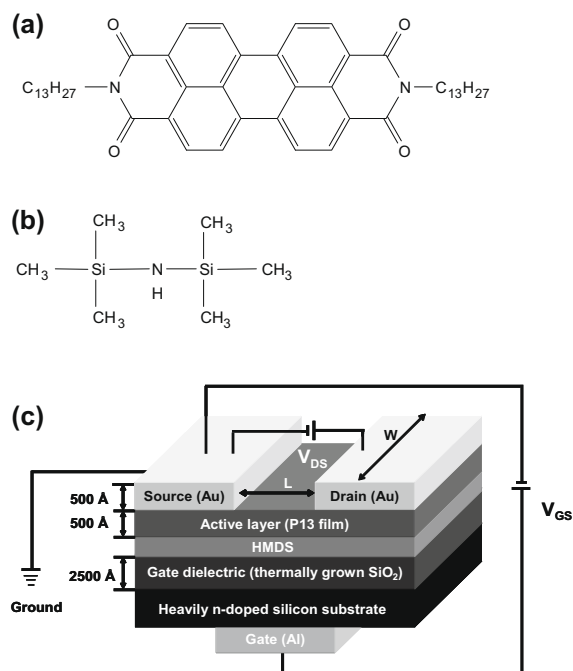
Fig. 1 shows the molecular structures of the P13 and HMDS, and a schematic diagram of a transistor along with the bias condition. The substrates consisted of a highly doped, n-type Si wafer coated with an aluminum layer as the gate electrode and thermally grown 2500 Å-thick SiO$_2$ layers as the gate dielectric. A rigorous procedure for cleaning the substrates was adopted. The substrates were first cleaned by a series of sequential ultrasonic treatments in acetone, hot trichloroethylene, acetone, HNO$_3$, methanol, and deionized water, and then blown dry with dry N$_2$ [19]. The substrates were finally exposed to UV (254 nm) for 15 min [20]. Such a cleaning procedure turned out to be very efficient in significantly increasing device performance. For surface modification, the cleaned


Fig. 1. Molecular structures of (a) P13 and (b) HMDS and (c) a schematic diagram of a transistor under bias conditions.

substrates were immersed in HMDS for 10 h at room temperature.

The P13 active layers were prepared by a homemade NCBD system [1]. The apparatus consisted of an evaporation crucible, a drift region, and the substrate. The as-received P13 sample was placed inside the enclosed cylindrical crucible cell (with a 1.0-mm diameter, a 1.0 mm-long nozzle) and sublimated by resistive heating between 550 and 580 K. At a working pressure of approximately 4.5×10^{-6} Torr, the P13 vapor underwent adiabatic supersonic expansion into the high-vacuum drift region. Highly directional, weakly bound P13 neutral cluster beams were formed at the throat of the nozzle and directly deposited onto the substrates with an average thickness of ca. 500 Å, at a rate of 0.5–0.8 Å/s. For thermal post-treatments, the active layers were heated to 100 °C in a vacuum oven for 1 h and then slowly cooled down to room temperature. Thickness, contact angle, surface morphology, and structural properties of the P13 active layers were characterized using an alpha-step surface profile monitor, a contact-angle goniometer, atomic force microscopy (AFM), and X-ray diffractometry (XRD).

To produce the transistors with a channel width (W) of 500 μm and a channel length (L) of 200 μm in a top-contact configuration, electron-beam evaporation using a rectangular-shaped shadow mask was utilized to produce a 500 Å-thick Au source and drain electrodes. The optimized thickness and deposition rate of Au were 500 Å and 6–8 Å/s, respectively. The current–voltage (I–V) characteristics of the transistors and their temperature-dependence were measured by an optical probe station connected to a HP4140B pA meter-dc voltage source unit and a 10 K-closed cycle refrigerator, over the temperature range of 10–300 K

and at a base pressure of 1×10^{-2} Torr. Various parameters were derived from the fits of the I–V characteristics.

3. Results and discussion

Characterization of the surface morphology for various NCBD-based P13 films prepared at room temperature was performed using an AFM apparatus in the non-contact mode. The 2-dimensional AFM micrographs at a nominal thickness of 500 Å are shown in Fig. 2. These P13 films exhibited complete substrate coverage with grain crystallites with the thermal post-treatment increasing grain crystallite size in both hexamethyldisilazane (HMDS)-untreated and -pretreated films. The four root-mean-square roughness (R_{rms}) average-values for the P13 films deposited on the untreated, thermally post-pretreated, HMDS-pretreated, and HMDS-pretreated/thermally post-treated SiO$_2$ substrates were measured 71 ± 8, 20 ± 4, 41 ± 2, and 23 ± 2 Å, respectively. The low surface R_{rms} observed in this study clearly exhibited that the weakly bound P13 cluster beams undergo efficient fragmentation into energetic individual molecules, leading to uniform, highly packed thin films. The entire HMDS-pretreated films showed lower roughness and high packing densities, suggesting that the amphiphilic HMDS molecules provided favorable deposition conditions at the early stages of grain growth. In addition, in the case of thermally post-treated films, substantial improvement in the surface roughness due to thermal annealing has been observed. The annealing process appears to favor formation of larger grain crystallites. The effect of thermal post-treatment is more clearly displayed in the XRD measurements below.

Fig. 2 also shows the whole XRD diffractograms for four different kinds of 500 Å-thick P13 thin films. According to the previous crystallographic investigations, P13 crystals are known to have a triclinic structure. All thin films in Fig. 2 show a highly ordered structure. The strong and sharp first- and second-order peaks, as well as distinctive higher-order multiple peaks, can be fitted to a series of (0 0 1) reflection lines with multiple d spacing. In the case of as-deposited, untreated thin films, the four reflection peaks located at 2θ = 3.3°, 6.7°, 10.0°, and 13.3° were assigned to (0 0 1), (0 0 2), (0 0 3), and (0 0 4). Based on the crystallographic parameters of P13, the corresponding d-spacings were determined to be 26.4, 13.2, 8.8, and 6.6 Å, respectively, which were in good agreement with the XRD measurements conducted by Tatemichi et al. [12]. For the thermally and/or surfactant-treated films in Fig. 2, a higher signal-to-noise in the XRD patterns was observed together with larger (0 0 3) and (0 0 4) reflection peaks, suggesting that the treatments significantly enhanced long-range crystallinity. It should be noted in the diffractograms that the thermal annealing effect was more pronounced in comparison to the surfactant-pretreatment effect. The high-temperature annealing seems to clearly promote the formation of larger grains with better crystallinity through a favorable self-assembling process. The XRD results are also consistent with the aforementioned AFM measurements, in which the larger grain crystallites showed more distinct, sharper reflection peaks.

The organic P13 active layers behaved as n-type semiconductors. OTFT performance was examined in the accumulation mode: as the gate electrode is positively biased with respect to the grounded source electrode, an accumulation of electrons near the SiO$_2$ dielectric−P13 interface is induced. Typical plots of drain-source current (I_{DS}) as a function of the drain-source voltage (V_{DS}) for various gate-source voltages (V_{GS}) are displayed in Fig. 3. Overall OTFT characteristics were adequately described by the standard field-effect transistor equations working in the accumulation mode. At a fixed V_{GS}, I_{DS} increases linearly with V_{DS} in the low V_{DS} regime while I_{DS} tends to be saturated in the large V_{DS} regime due to the pinch off in the accumulation layer. In the saturation regime, I_{DS} is given by Eq. (1):

$$I_{DS} = \frac{W C_i \mu}{2L}(V_{GS} - V_T)^2 \tag{1}$$

where W is the channel width of 500 μm, L is the channel length of 200 μm, μ_{eff} is the field-effect mobility, and V_T is the threshold voltage. The value C_i is the capacitance per unit area, which is 13.8 nF/cm^2 for the thermally-grown, 2500 Å-thick, SiO$_2$ gate dielectric. From the analysis of the observed I–V characteristics, several device parameters can be derived and are listed in Table 1. The maximum mobilities (μ_{eff}) are listed with the average mobilities (μ_{eff}^{avg}) with the standard deviation (σ). Here, it should be noted that before characterizing the performance of the devices kept in air and N$_2$, the operational stability was first checked under ambient conditions as a function of time. Since the P13-based devices were sensitive to moisture and oxygen, device parameters such as mobilities deteriorated with time as shown in Fig. 4a. To minimize these environmental effects, the whole parameters in Table 1 were derived as fast as possible within a duration of 2 h just after device production, as marked with the brackets in Fig. 4a.

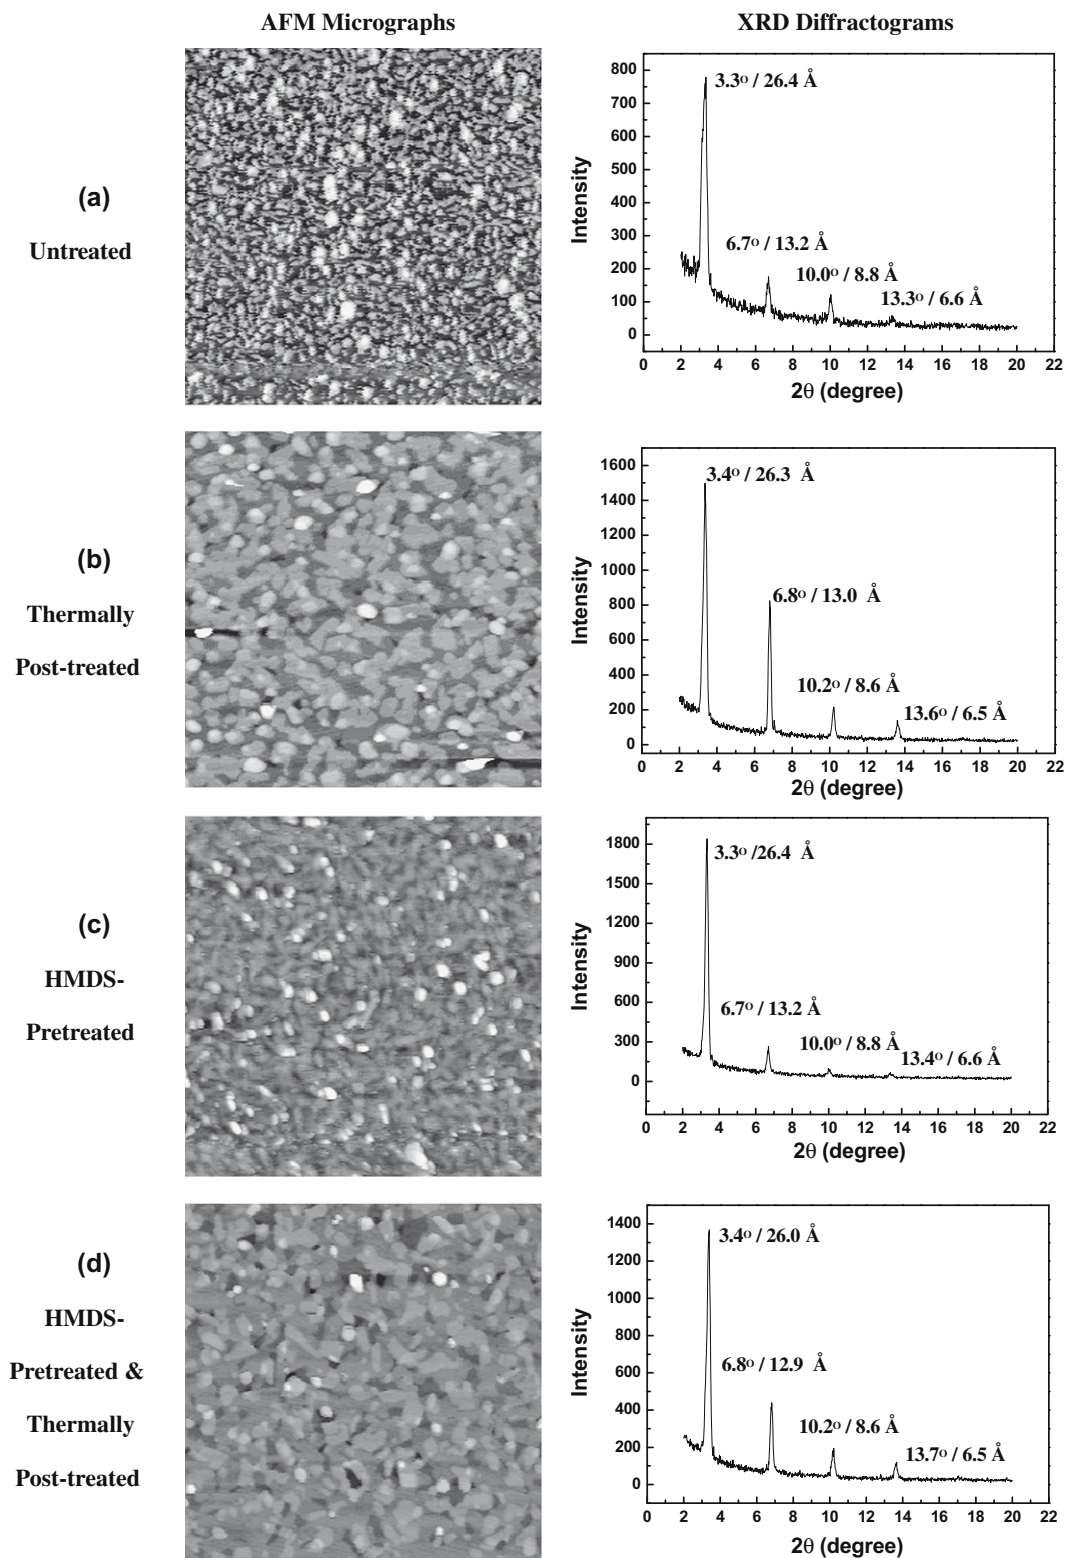
Several characteristic features can be found in Table 1. Firstly, compared to the typical mobilities reported in the range between 1.7×10^{-2} and 2.5×10^{-3} cm^2/Vs [14,17, 18], all NCBD-based OTFTs showed higher room-temperature mobilities: 0.16, 0.58, 0.34, and 0.32 cm^2/Vs for the untreated, thermally post-treated, HMDS-pretreated, and HMDS-pretreated/thermally post-treated thin-film transistors, respectively. A μ_{eff} of 0.34 cm^2/Vs for the HMDS-pretreated transistors was found to be comparable to the value of μ_{eff} = 0.29 cm^2/Vs, measured by Hosoi and Furukawa [14]. Here, it should be noted that unlike the mobilities derived from the devices not working at all when exposed to the atmosphere [12], the whole field-effect mobilities for all NCBD-based OTFTs in this study were measured under ambient conditions. In Table 1, the surface passivation and thermal post-treatment clearly improved device performance, including mobilities, current on/off ratio (I_{on}/I_{off}), threshold voltage (V_T), and especially subthreshold slope (SS). In particular, the drastic reduction of the subthreshold slope, generally governed by material properties, indicated that the treatment significantly improved the quality of the NCBD-based P13 active layers. It can be concluded that after thermal post-treatment and/or surfactant pre-treatment, favorable formation of


Fig. 2. Comparison of 2-dimensional AFM micrographs and XRD diffractograms for the four 500 Å-thick P13 thin films prepared on: (a) untreated; (b) thermally post-treated; (c) HMDS-pretreated; and (d) HMDS-pretreated/thermally post-treated SiO_2 substrates, using the NCBD method. The micrographs were taken over an area of 5×5 µm^2 and the diffractograms were obtained using Cu Kα radiation in a symmetric reflection, coupled θ–2θ scanning mode.
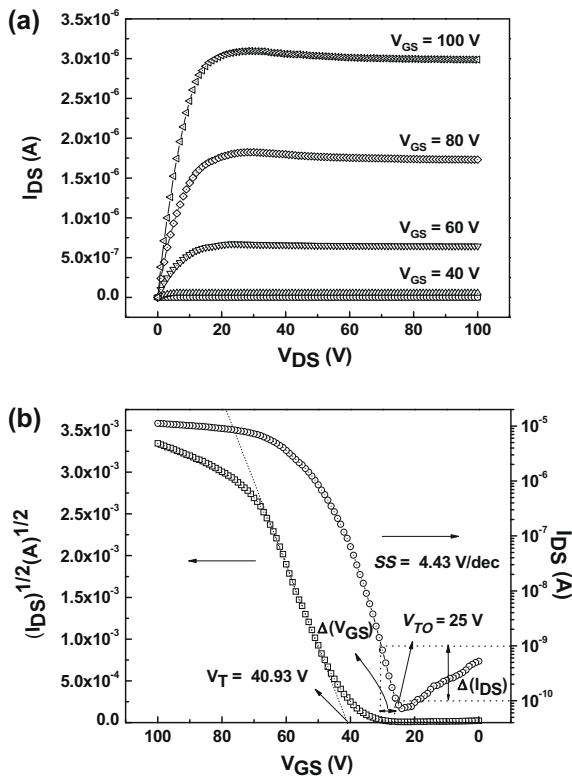

Fig. 3. (a) Current–voltage characteristics at various gate voltages for the thermally post-treated transistors. (b) Variation of $I_{DS}^{1/2}$ (left axis) and $\log(I_{DS})$ (right axis) vs. V_{GS} at a constant $V_{DS} = 100$ V.

Fig. 4. (a) Stability of P13-based devices as a function of time (hours). Inset shows a long-term stability as a function of time (days). The brackets represent the period of measured time, during which whole device parameters were derived to minimize environmental effects. (b) Comparison of temperature-dependence of the electron mobilities for the untreated, thermally post-treated, HMDS-pretreated, and HMDS-pretreated/thermally post-treated OTFTs.

the P13 active layers with higher structural organization and better film connectivity induced more efficient charge-carrier transport via face-to-face intermolecular interactions between the π–π stacks. The observed performance is also consistent with the results revealed in the AFM and XRD micrographs.

Secondly, total trap density (N_{trap}) strongly correlated with device performance. The N_{trap} value can be obtained by the relationship (2):

$$N_{\text{trap}} = \frac{C_i |V_T - V_{TO}|}{e} \qquad (2)$$

where V_{TO} is the turn-on voltage and e the elementary charge [21]. The four trap densities for the untreated, thermally post-treated, HMDS-pretreated, and HMDS-pre-

treated/thermally post-treated devices were estimated to be 2.70×10^{12}, 1.37×10^{12}, 1.86×10^{12}, and 1.57×10^{12} / cm^2, respectively. The traps can be identified as structural disorders and/or defects. The observed lower trap densities of the whole treated thin films can be ascribed to the characteristic growth of well-connected, polycrystalline thin films produced by the NCBD method, which were directly reflected in the efficient carrier conduction with high mobilities especially in the thermally post-treated P13-based transistors.

Table 1
Device parameters deduced from the OTFT characteristics.

Surface pretreatment	μ_{eff} (cm^2/Vs)	$\mu_{\text{eff}}^{\text{avg}} \pm \sigma$ (cm^2/Vs)[*]	$I_{\text{on}}/I_{\text{off}}$	V_T (V)	V_{TO} (V)	SS (V/decade)	N_{trap} (10^{12}/cm^2)	E_a (meV)
Untreated	0.16	0.11 ± 0.03	10^4	46.32	15	10.18	2.70	28.4
Thermally post-treated	0.58	0.42 ± 0.10	10^5	40.93	25	4.43	1.37	17.1
HMDS-pretreated	0.34	0.28 ± 0.04	10^5	37.50	16	4.29	1.86	21.2
HMDS-pretreated/thermally post-treated	0.32	0.28 ± 0.04	10^5	36.25	18	4.00	1.57	21.8

[*] The mobility data (μ_{eff}) in the text represents the best values. Considering the distributions of the OTFT characteristics, the μ_{eff} values lie within $\mu_{\text{eff}}^{\text{avg}} \pm 2\sigma$ (standard deviation).

Thirdly, the temperature-dependence behavior of μ_{eff} in the P13 films was measured for the first time to characterize the transport mechanism responsible for the conduction of mobile electron carriers. Fig. 4b shows that the typical logarithmic plots of μ_{eff} for the untreated P13 films in the temperature range of 10–300 K. Two different mechanisms were found to exist to account for observed regions I and II. The temperature-independent region I, below 40 K, was ascribed to the quantum tunneling mechanism. Conversely, the conduction mechanism for region II (40 K < T < 300 K) corresponded to a thermally activated transport, where the electron carriers should overcome the shallow traps present in the P13 active layer through thermal excitation. The behavior in region II is well described by the Arrhenius relationship: $\mu_{eff} \propto \exp(-E_a/kT)$, where E_a and k are the activation energy and Boltzmann constant, respectively. From the slope analysis of the logarithmic plots, the four activation energies were estimated to be 28.4, 17.1, 21.2, and 21.8 meV for the untreated, thermally post-treated, HMDS-pretreated, and HMDS-pretreated/thermally post-treated devices, respectively. Direct comparison cannot be made due to the absence of a mechanistic study of the transport phenomena for the P13-based OTFTs. Instead, Chesterfield et al. reported the activation energies ranging between 39 and 85 meV for N-alkyl perylene diimide-based OTFTs [15]. The significantly lower E_a and N_{trap} values observed in this study strongly suggest that the high quality of the P13 films ultimately lead to a more efficient carrier transport in the well-connected grains, as well as the excellent mobilities in the NCBD-based OTFTs.

4. Summary

Our first application of the NCBD method to prepare P13-based, n-type OTFTs with a top-contact structure is presented. The effects of surface passivation and thermal post-treatment on surface morphology, crystallinity, and device performance were systematically investigated, with the operational stability as a function of time. A high room-temperature field-effect mobility of 0.58 cm^2/Vs for the thermally post-treated devices was obtained under ambient conditions. A comparative study of transport mechanisms in-between 10–300 K indicated that surface modification and thermal post-treatment decreased the total trap density and activation energy for carrier transport by reducing structural disorder. The fabrication of several P13-based devices, including unipolar and ambipolar light-emitting OTFTs through the NCBD method, is underway. We hope these investigations to provide further insights into the organic-based optoelectronic devices at the molecular level.

moieties are formed either from the defects already presented in the polymer (when monoalkylated fluorenes are present as impurities and incorporated into the polymer during polymerization) or later by thermal-oxidative, photo-, or electro-oxidative degradation processes of PFs [28,29]. Therefore, any method which aims to decrease the defects or enhance the anti-oxidation capability of the polyfluorene should help to suppress the green emission and to improve the stability of the blue emission [30]. Much efforts had been done through the functionalization at C-9 position of fluorene. Holmes and co-workers [31] synthesized defect-free 9,9-dioctyl-9H-fluorene via an alkylative cyclization route, which exhibited minimal green emission owing to fluorenone formation. Huang and co-workers [32] introduced spiro-fluorene into polyfluorene backbone resulting in narrower emission with a smaller tail at longer wavelength. Müllen et al. [33] introduced triphenylamine-substituted fluorene at C-9 position and developed fully arylated poly(ladder-type-pentaphenylene), which suppressed the long wavelength emission. Alkoxyphenyl substitution fluorene at C-9 position is an effective way to suppress the long wavelength emission. Lee and Hwang [34] prepared a homo-poly (9,9-bis(4′-n-octyloxyphenyl) fluorene-2,7-di-yl) (PBOPF), showing a stable blue emission with the CIE coordinates of (0.136, 0.162). It is believed that the oxidation probability of fluorene can be decreased by reducing the electron density on the reactive site through proper substitution [35]. Li et al. [36] developed novel fluorene- and phenylene-based blue light-emitting polymers with sulphonate side group. The improved spectral stability was attributed to the electron-deficient sulphonate group substituted on the phenylene backbone. Dibenzothiophene (FS) unit has excellent hole-injection/transportation character and the dibenzothiophene–fluorene copolymer is a potential blue emitter [37,38]. Unlike dibenzothiophene, dibenzothiophene-S,S-dioxide (FSO) possesses strong electron-withdraw ability and can significantly improve the electron affinity [39,40]. Perepichka et al. [41] introduced (3,7-diyl)dibenzothiophene-S,S-dioxide unit into the oligo-fluorenes, in which there were no green emission observed in the PL spectra after thermal annealing. Further studies on solvatochromic effect for fluorene-dibenzothiophene-S,S-dioxide oligomers in polar solvents [42] and the singlet excited-state dynamics in poly((9,9-dioctylfluorene)-co-(dibenzothiophene-S,S-dioxide)) copolymers were investigated by steady-state and time-resolved fluorescence spectroscopies. The studies revealed that the excited state of F–S co-oligomers/polymers have both excitonic (denoted as local exciton, LE) and charge transfer (CT) character depending on the local environment [43]. Our group also reported the copolymer based on dibenzothiophene-S,S-dioxide with alkoxyphenyl-substituted fluorene. Devices fabricated from these copolymers showed high efficiency and spectral stability. The excellent performances were owed to the combined results from both alkoxypheyl substitution at C-9 position of fluorene unit which suppressed the side chain degradation and electron-deficient dibenzothiophene-S,S-dioxide unit [44]. Very recently, King et al. show their results of incorporating FSO at a relatively high content up to 30% into

polyfluorene which lead to broad emission due to the dual LE/CT fluorescence character [45]. In order to achieve stable and efficient blue light emission while simultaneously avoid the probable emission broadened by the CT interaction of FSO unit in high content (up to 20–30 mol%), we herein incorporated a small amount of dibenzothiophene-S,S-dioxide isomers (1–10 mol%) into the backbone of poly(9,9-dioctylfluorene). The influence of FSO unit on the photo- and electroluminescent properties of the copolymers were further investigated.

2. Experimental section

2.1. Materials

Reagents were distilled from appropriate drying agents prior to use. Commercially available reagents were used without further purification. 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (1) 2,7-dibromo-9,9-dihexyl-fluorene (2), 2,8-dibenzothiophene-$S,$ S-dioxide (3) and 3,7-dibenzothiophene-S,S-dioxide (4) were prepared according to literatures. [39–41,44].

2.1.1. General procedures of Suzuki polycondensation taking PF-3,7FSO10 as an example

To a mixture of monomer **1** (321 mg, 0.50 mmol), monomer **2** (219 mg, 0.40 mmol), monomer **4** (37.4 mg, 0.1 mmol), Pd(acetate)$_2$ (2.5 mg) and tricyclohexylphosphine (5.7 mg) were dissolved in a mixture of toluene (5 ml) and THF (2 ml) under an argon atmosphere. The mixture was heated to 70 °C and stirred, then (Et)$_4$NOH (2 ml) and deionized water (1 ml) were added into the mixture. The solution was kept in the region of 90–100 °C with vigorous stirring under argon for 48 h. At the end of polymerization, polymers were sequentially end-capped with monomer **1** and bromobenzene to remove bromine and boronic ester end groups in order to avoid a possible quenching effect or excimer formation by boronic and bromine end groups in LEDs. The whole mixture was then poured into methanol. The crude polymer was filtrated through silica gel chromatography with toluene as eluent to remove catalyst residue. The toluene solution of polymer was concentrated and reprecipitated into methanol for three times. The pure copolymer was obtained after drying under vacuum at 50 °C overnight. Yield: 222 mg, 60%. ^{1}H NMR (300 MHz, CDCl$_3$, δ): 8.12 (s, Ar-H), 7.88 (br, 2H), 7.68 (br, 4H), 2.14 (br, 4H), 1.16–1.01 (m, 24H), 0.78 (br, 6H). Element Anal. Found: C 87.66%, H 9.51%, S 0.73%.

PF-3,7FSO1: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (268.5 mg, 0.49 mmol), and monomer **4** (3.7 mg, 0.01 mmol). Yield: 224 mg, 58%. ^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 7.85 (br, 2H), 7.80 (br s, 2H), 7.70 (br, 2H), 2.10 (m, 4H), 1.21–0.97 (m, 24H), 0.82 (br, 6H). Anal. calcd. for PF-3,7FSO1, found: C 88.06%, H 10.17%, S 0.25%.

PF-2,8FSO1: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (268.5 mg, 0.49 mmol), and monomer **3** (3.7 mg, 0.01 mmol). Yield: 228 mg, 60%. ^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 7.85 (br, 2H), 7.78 (br s, 2H), 7.72 (br, 2H), 2.08 (m, 4H), 1.21–0.95 (m, 24H), 0.86 (br, 6H). Anal. calcd. for PF-2,8FSO1, found: C 88.61%, H 9.74%, S 0.27%.

PF-3,7FSO3: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (257.6 mg, 0.47 mmol), and monomer **4** (11.2 mg, 0.03 mmol). Yield: 202 mg, 53%. ^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 7.84 (br, 2H), 7.72 (br s, 2H), 7.68 (br, 2H), 2.06 (m, 4H), 1.24–0.97 (m, 24H), 0.83 (br, 6H). Anal. calcd. for PF-3,7FSO3, found: C 87.17%, H 9.65%, S 0.47%.

PF-2,8FSO3: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (257.6 mg, 0.47 mmol), and monomer **3** (11.2 mg, 0.03 mmol). Yield: 213 mg, 56%. ^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 7.86 (br, 2H), 7.71 (br, 2H), 7.29 (s, 2H), 2.13 (br, 4H), 1.16 (br, 24H), 0.86–0.74 (m, 6H). Anal. calcd. for PF-2,8FSO3, found: C 89.16%, H 10.26%, S 0.29%.

PF-3,7FSO5: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (246.6 mg, 0.45 mmol), and monomer **4** (18.7 mg, 0.05 mmol). Yield: 242 mg, 64%. ^{1}H NMR (300 MHz, CDCl$_3$, δ): 7.87 (br, 2H), 7.73 (br, 4H), 2.09 (s, 4H), 1.18–1.02 (br, 24H), 0.88–0.76 (m, 6H). Element Anal. Found: C 88.89%, H, 9.79%, S, 0.47%.

PF-2,8FSO5: Monomer **1** (321 mg, 0.5 mmol), monomer **2** (246.6 mg, 0.45 mmol), and monomer **3** (18.7 mg, 0.05 mmol). Yield: 196 mg, 52%. ^{1}H NMR (300 MHz, CDCl$_3$, δ): 7.86 (br, 2H), 7.59 (br, 4H), 2.13 (s, 4H), 1.16–0.99 (br, 24H), 0.84–0.79 (m, 6H). Element Anal. Found: C 89.37%, H 10.22%, S 0.37%.

PF-2,8FSO10: Monomer **1** (321.0 mg, 0.5 mmol), monomer **2** (219.2 mg, 0.40 mmol), and monomer **3** (37.4 mg, 0.10 mmol). Yield: 196 mg, 53%. ^{1}H NMR (300 MHz, CDCl$_3$,

δ): 8.17 (s, Ar-H), 7.84 (br, 2H), 7.52 (br, 4H), 7.34 (s, Ar-H), 2.11 (s, 4H), 1.13–0.83 (br, 30H). Element Anal. Found: C 88.48%, H 9.97%, S 0.88%.

2.2. Measurements

^{1}H NMR spectra were recorded on a Bruker DRX 300 spectrometer operating, respectively, at 300 MHz, in deuterated chloroform solution with tetramethylsilane as a reference. The molecular weights of the polymers were determined by a Waters GPC 2410 with tetrahydrofuran (THF) as eluent and a calibration curve with standard polystyrene as a reference. Cyclic voltammetry (CV) data were measured on a CHI660B electrochemical workstation using Bu$_4$NPF$_6$ (0.1 M) in acetonitrile as electrolyte at a scan rate of 50 mV/s at room temperature under the protection of argon. A platinum electrode coated with a thin polymer film was used as the working electrode. A Pt wire was used as the counter electrode, and a calomel electrode was used as the reference electrode. Elemental analyses were performed on a Vario EL elemental analysis instrument (Elementar Co.). Thermogravimetric analyses (TGA) were performed on a Netzsch TG 209 at a heating rate of 20 °C/min. Differential scan calorimetry (DSC) measurements were perform on a Netzsch DSC 204 under N$_2$ flow at heating and cooling rates of 20 °C/min. UV–Vis absorption spectra were recorded on a HP 8453 spectrophotometer.
Scheme 1. Synthetic route of the copolymers.

Table 1
Structural characteristics and thermal properties of the copolymers.

Polymer	FSO content [mol%] in		M_n ($\times 10^3$)	PDI	T_g (°C)	T_d (°C)
	Feed ratio	Polymer				
PF-2,8FSO1	1	–	57	1.7	72	405
PF-2,8FSO3	3	3.2	31	1.6	88	406
PF-2,8FSO5	5	4.4	17	1.7	81	405
PF-2,8FSO10	10	9.2	15	2.2	103	400
PF-3,7FSO1	1	–	17	2.3	74	396
PF-3,7FSO3	3	3.0	17	1.5	89	400
PF-3,7FSO5	5	5.5	11	1.7	110	407
PF-3,7FSO10	10	8.5	17	1.9	–	397

The PL quantum yields were measured using an Integrating Sphere IS080 (LabSphere) to collect the emitted light in all directions under the excitation of 325 nm HeCd laser (Melles Griot).The luminance (*L*)-current density (*J*)-luminance efficiency (*LE*) characteristics were collected by using a Keithley 236 source measurement unit and a calibrated silicon photodiode. The luminance was calibrated by a PR-705 SpectraScan spectrophotometer (Photo Research), with simultaneous acquisition of the EL spectra and CIE coordinates, driven by Keithley model 2400 voltage–current source. The device fabrication process was described previously by the literatures [45–47]. After the samples and devices were annealed atop of a hotplate at high temperature (80–120 °C) for 1–4 h, spectral stability of PL and EL upon thermal annealing were performed in atmosphere by a PR-705 SpectraScan spectrophotometer soon after cooling down to room temperature. The stability of the blue emitting PLEDs was studied in atmosphere by applying a constant current stress with an initial luminance of 150 cd/m². Before annealing in atmosphere and stress test, the PLEDs were encapsulated with a UV-cured epoxy resin.

2.3. Theoretical section

Density functional theory (DFT) calculation was carried out using the Gaussian 03 series of programs. The ground state optimization were performed by DFT at B3LYP/6-31g* level [48–50]. The sketch map of HOMO and LUMO orbital were generated by GaussView software.

3. Results and discussion

3.1. Synthesis and characterization

The synthesis route is shown in Scheme 1. Monomers 1, 2, 3 or 4 were polymerized via Suzuki polycondensation. The monomer feed molar ratios of F/2,8FSO as well as F/3,7FSO are 99:1, 97:3, 95:5, 90:10 and the corresponding polymers were referred to PF-2,8FSO1, PF-2,8FSO3, PF-2,8FSO5, PF-2,8FSO10 and PF-3,7FSO1, PF-3,7FSO3, PF-3,7FSO5, PF-3,7FSO10, respectively. The calculated values of FSO unit in copolymers were resulted from elemental analysis and listed in Table 1. The copolymers are soluble in common organic solvents, such as THF,

Fig. 1. UV–Vis absorption (a) and photoluminescence spectra (b) of the copolymers.
Fig. 2. PL spectra of PF-2,8FSO5 (a) and PF-3,7FSO1 (b) under thermal annealing in air at varied temperatures.

chloroform, and toluene at room temperature. The num-ber-average molecular weights (M_n) of these polymers, using THF as an eluent and polystyrene standards for cali-bration are between 10,000 and 50,000 g/mol with a poly-dispersity index (PDI) in the range of 1.5–2.3. The thermal properties of the polymers were determined by differential

scanning calorimetry (DSC) and thermal gravimetric anal-ysis (TGA) measurements. The decomposition tempera-tures (T_d, corresponding to 5 wt% loss) are over 395 °C. The glass transition temperatures (T_g) of PF–FSO copoly-mers, ranging from 72 to 110 °C, are higher than PFO homopolymer (70 °C). The relatively high T_g of these

copolymers are important and desirable for many opto-electronic applications.

3.2. Photo-physical and electrochemical characteristics

The absorption spectra of PF-3,7FSO and PF-2,8FSO copolymers in film are displayed in Fig. 1a. The absorption spectra of PF-3,7FSO copolymers slightly red-shift while that of PF-2,8FSO copolymers blue-shift with increasing the FSO content (deducing from absorption edge). The PL spectra of both PF-3,7FSO and PF-2,8FSO copolymers are red-shifted with increasing the content of FSO (Fig. 1b). The absorption and emission spectra shift in different solvents, suggesting an ICT character of PF–FSO copolymers. (See supporting information)

The PL spectral stability of the copolymers PF–FSO was studied by annealing the films in air at 80, 120 and 200 °C for 4 h and then measuring the fluorescent spectra after cooling down to room temperature. Fig. 2 shows the PL spectra of the polymers PF-2,8FSO5 and PF-3,7FSO1 before and after annealing. It can be seen that the PL spectra of the copolymers remain nearly identical after annealing, indicating a highly stable spectra upon thermal annealing.

The electrochemical behaviors copolymers are examined by cyclic voltammetry (CV). The onset of oxidation potentials (E_{ox}) of copolymers are recorded with respect to the saturated calomel electrodes (SCE) as the reference electrode [51]. The highest occupied molecular orbit (HOMO) and the lowest unoccupied molecular orbit (LUMO) energy levels of the copolymers are calculated according to the empirical formula $E_{HOMO} = -e(E_{ox} + 4.40)$ eV and $E_{LUMO} = -e(E_{red} + 4.40)$ eV, respectively. The estimated HOMO and LUMO energy levels lies in the range of −5.80 to −5.90 eV and −2.77 to −2.95 eV, respectively. The detailed CV data of copolymers were summarized in Table 2.

3.3. Theoretical computation

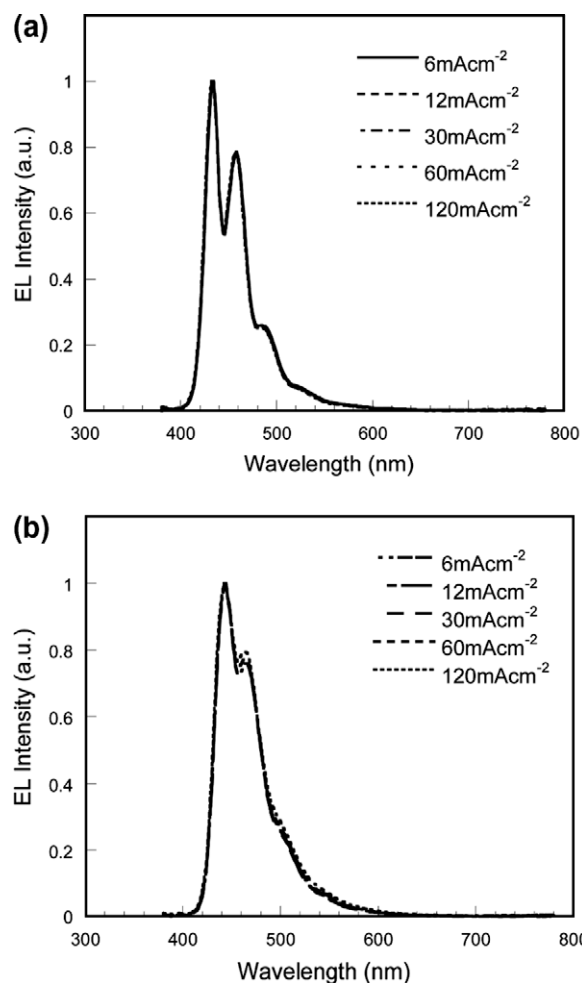
To understand the frontier molecular orbitals and spectral properties of the copolymers, density functional theory (DFT) were carried out to calculate the following pentamers: fluorene (FFFFF), fluorene/2,8-FSO (2,8-FFSFF) and
Fig. 4. EL spectra of the copolymers.


Fig. 5. EL spectra of PF-2,8FSO1 (a) and PF-3,7FSO5 (b) under different applied current densities.

fluorene/3,7-FSO (3,7-FFSFF) as shown in Scheme 2. Through computation, the energy band of dibenzothiophene-*S,S*-dioxide (4.85 eV) is lower than that of fluorene (5.04 eV). The HOMO–LUMO energy gaps for three pentamers decrease in the order: FFFFF (3.59 eV) > 2,8-FFSFF (3.57 eV) > 3,7-FFSFF (3.36 eV). The HOMO and LUMO orbitals of fluorene pentamers are plotted in Fig. 3. The LUMO orbital characters of the pentamers with and without FSO unit show significant differences. The HOMOs of pentamers are delocalized all over the backbone while the LUMOs of the 2,8-FFSFF and 3,7-FFSFF pentamers are strongly confined to the FSO unit. The emission transition from LUMO to HOMO in fluorene pentamer FFFFF is mainly from the fluorene to fluorene units, while the LUMO → HOMO transitions of 3,7-FFSFF and 2,8-FFSFF basically arise from FSO unit, and thus reduce the possibility of the distribution of fluorene in excitation.

3.4. Electroluminescent properties

The devices with the configuration of ITO/PEDOT:PSS(40 nm)   /polymer(80 nm)/Ba(4 nm)/Al(120 nm) were fabricated. Fig. 4 shows the EL spectra of the copolymers. The EL spectra of PF-3,7FSO10 peaked around 450 nm is 12 nm red-shifted compared with PF-2,8FSO10. The similar trend can be observed in other PF-3,7FSO and PF-2,8FSO polymers with same amounts of FSO units. In order to testify the spectral stability, the experiments concerning on the dependence of EL spectra on current densities and annealing temperatures were carried out. The EL spectra of PF-2,8FSO1 and PF-3,7FSO5 copolymers remain nearly identical with variation of current densities from 6 to 120 mAcm^{-2} (Fig. 5) or after annealing at 80 and 120 °C for 1 h (Fig. 6), respectively. No long wavelength emission as usually observed in fluorene-based polymers appears. In addition, the evolution of spectral stability under continuous stress has been carried out for the device with an initial luminance of 150 cd m^{-2}. It is revealed by the online spectrophotometer, after 45 h continuous stress despite the luminance reduced by 50%, no obvious change was observed in the EL spectra of the device based on PF-3,7FSO5 (Fig. 7). Therefore, it is safe to conclude that the EL spectra of the PLEDs based on the copolymer are highly stable with a lifetime of at least 45 h. It is important to note that, longer lifetime can be expected if the initial luminance was set as a typical luminance of 100 cd m^{-2} and a more reliable encapsulation technology was used.

Table 3 shows the device performances of PF-2,8FSO and PF-3,7FSO co polymers. All of the devices exhibit high efficiencies, especially, the device based on PF-3,7FSO5 exhibits the best overall performances, in terms of low turn on voltage of 4.4 V, a maximal luminous efficiency(LE) of 4.6 cd A^{-1} (corresponding to an EQE of 3.8%) with the CIE coordinate of (0.15, 0.12). The devices based on PF-2,8FSO copolymers show even bluer emission with the CIE coordinates of (0.16, 0.07-0.08). For the device based on PF-2,8FSO1, a moderate turn on voltage of 5.4 V, and maximum LE of 3.7 cd A^{-1} (EQE = 3.6%) with the CIE coordinate of (0.16, 0.07) are realized. The typical CIE coordinates of the devices for PF-2,8FSO and PF-3,7FSO copolymers are in the range of (0.16, 0.07-0.08) and

0.08). The turn-on voltages of the devices decline with increasing the content of FSO unit in the polymers, indicating that the FSO unit may improve the carrier injection and transportation. Compared with the homo-polyfluorene PFO, there are reductions of 0.14 and 0.17 eV in LUMO levels of PF-2,8FSO10 and PF-3,7FSO10, respectively, which lowers the injection barrier of electron, and therefore improves the device performances. Moreover, the devices are able to maintain considerably high efficiencies at high current density (100mAcm^{-2}), mostly of which drop less than 40% of the maximum quantum efficiencies. (As shown in Table 2) Fig. 8 shows the luminance-current density-luminous efficiency (L–J–LE) characteristics of PF-2,8FSO1 and PF-3,7FSO10 copolymers. The device efficiencies of PF-2,8FSO1 and PF-3,7FSO10 remain as high as 2.0 and 0.8 cd A^{-1} at an even higher current density of 500 mA cm^{-2} with the luminance over 6800 and 3000 cd m^{-2}, respectively. The luminous efficiencies decline slightly with increasing the current density, also indicating that the materials and devices have a good stability.

4. Conclusion

Fluorene-co-dibenzothiophene-S,S-dioxide copolymers with spectral stability and high efficiency were prepared.

The electron-withdraw FSO unit enhances the intramolecular charge transfer in polyfluorene backbone, which benefits the spectral stability by decreasing the possibility of the formation of exciton on fluorene units. Moreover, the FSO unit lowers the LUMO energy level, balances the injection and transportation both electron and hole in the polymers, and therefore improves the device efficiencies.

grain boundaries in thin films and lead to higher device performance. They are beneficial to the studies of the intrinsic transport property and the integration of organic single crystals to micro- and nanoelectronic devices. The micro- and nanometer-sized single crystals are grown by either vapor or solution processes. The solution process is easier to carry out and potentially offers a cost-effective method for fabricating large-area electronic components from organic materials. Therefore, there is a growing need to explore organic single crystals with micro- and nano-structures for the solution-processable materials. The solubility and the high performance of thiophene-based hybrid materials make them good candidates for the studies of solution-processed single-crystal transistors.

So far, the intrinsic charge-transport properties of thiophene-based hybrid materials have seldom been studied. In this paper, we study the optical and the single-crystal FET properties of three new thiophene-based hybrid materials: 5-(9-butyl-3-carbazolyl)terthiophene (**BCTT**), 2,5-bis(9-butyl-3-carbazolyl)thiophene (**BBCT**) and 2-(9-butyl-3-carbazolyl)-5-(2-dibenzothienyl)thiophene (**BCDT**). Compared with **BCTT**, the molecular rigidity in **BBCT** and **BCDT** is enhanced by introducing fused-rings in the one side of thiophene, which is intended to maximize the interchain interaction by reducing the freedom of rotation in the oligomer. This variation causes significant differences in interchain aggregation, morphology and electronic properties. Beyond our expectation, **BCTT** shows the highest carrier mobility in both thin-film and single-crystal FET devices. The enhanced rigidity in the molecules of **BBCT** and **BCDT** is not in favor of the carrier transport.

2. Experimental

2.1. Chemicals and instruments

All chemicals were purchased from Aldrich and Acros and used as received without further purification. 9-Butyl-3-bromocarbazole, 9-butyl-3-carbazolylboronic acid and 2-bromodibenzothiophene were prepared according to the published procedures [26,27]. Solvents were purified and dried according to the standard procedures.

^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance 400 spectrometer. Elemental analyses were performed using a German Vario EL III elemental analyzer. Absorption measurements were carried out on a TU-1800 spectrophotometer. Photoluminescence (PL) measurements were recorded on a Hitachi F-4500 fluorescence spectrophotometer with a 150 W Xe lamp. Thermogravimetric analyses (TGA) were measured on a SDT Q600 V8.0 calorimeter, under nitrogen atmosphere with a heating rate of 10–600 °C/min. The atomic force microscopy (AFM) images were obtained by using a Digital Instruments (DI) Dimension 3100 operating in tapping mode. Scanning electron microscope (SEM) measurements were performed on a Hitachi S-4800 field emission scanning electron microscope. The X-ray diffraction (XRD) investigations were carried out on a Bruker D8 advanced diffractometer equipped with Cu Kα radiation (λ = 1.5406 Å). The data were collected using a Ni-filtered Cu-target tube

at room temperature in the 2θ range from 2° to 40°. Single-crystal X-ray diffraction measurements were conducted on a Bruker Smart APEX2 CCD area-detector diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71069 Å). Processing of the intensity data were carried out using the Bruker SMART routine, and the structure was solved by direct methods and refined by a full-matrix least-squares technique on F^2 using SHELXL-97 programs [28]. CCDC reference number 691,496. For crystallographic data in CIF or other electronic format, see http://www.ccdc.cam.ac.uk.

Organic thin-film transistors were fabricated in the top contact configuration. Organic semiconductors were deposited at a rate of 0.1 Å s^{-1} under a pressure of about 5.0×10^{-4} Pa. Gold electrodes were deposited using shadow masks with width-to-length ratio (W/L) of ca. 60/1.

The single-crystal transistors were fabricated as follows: A minimum volume of chlorobenzene solution of sample (1 mg/mL) was injected on the octyltrichlorosilane (OTS)-pretreated SiO$_2$/Si substrate in a closed chamber. After the slow evaporation of the solvent, the microribbons were obtained. Then Au electrodes were thermally evaporated by laying a copper grid on the microstructures as the mask. OFET characteristics were obtained at room temperature in air on Keithley 4200 SCS.

2.2. Synthesis

5-tributylstannylterthiophene. n-BuLi (2.5 M in hexane, 1.6 mL, 4.0 mmol) was added dropwise into a solution of terthiophene (1.10 g, 4.44 mmol) in THF (20 mL) at -78 °C under nitrogen. After stirring at -78 °C for 1 h, tributyltin chloride (1.1 mL, 4.05 mmol) was added dropwise. The reaction mixture was slowly warmed up to room temperature and stirred for another 1 h. Then the mixture was partitioned between Et$_2$O (100 mL) and brine (150 mL) and the organic layer was dried over anhydrous Na$_2$SO$_4$. The solvent was removed under reduced pressure to give a blue viscous liquid. The product was used instantly for the next step without further characterization or purification.

5-(9-butyl-3-carbazolyl)terthiophene (**BCTT**). 5-Tributylstannylterthiophene was dissolved in dry toluene (25 mL). 9-Butyl-3-bromocarbazole (1.2 g, 3.97 mmol) and Pd(PPh$_3$)$_4$ (20 mg) were added under nitrogen. Then the mixture was refluxed for 24 h. After cooling to room temperature, the mixture was poured into H$_2$O (40 mL) and extracted with HCCl$_3$. The organic phase was combined and dried over MgSO$_4$. Evaporation of the solvent, the product was chromatographed on silica gel (petroleum ether/THF = 14:1) to afford the yellow solid (1.33 g, 2.84 mmol, 71.5% yield). ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 0.96 (t, J = 7.3 Hz, 3H), 1.41 (m, 2H), 1.88 (m, 2H), 4.32 (t, J = 7.1 Hz, 2H), 7.04 (dd, J = 3.6, 5.1 Hz, 1H), 7.11–7.12 (m, 2H), 7.18–7.20 (m, 2H), 7.22–7.28 (m, 3H), 7.40 (d, J = 5.1 Hz, 1H), 7.41(d, J = 4.7 Hz, 1H), 7.47–7.51 (m, 1H), 7.72 (dd, J = 1.7, 8.5 Hz, 1H), 8.14 (d, J = 7.7 Hz, 1H), 8.31 (d, J = 1.5 Hz, 1H). ^{13}C NMR (CDCl$_3$, 100.62 MHz) δ: 13.86, 20.55, 31.17, 43.00, 108.94, 109.05, 117.62, 119.13, 120.53, 122.63, 122.77, 123.34, 123.60, 123.77, 123.93, 124.37, 124.40, 124.65, 125.21, 126.03, 127.87, 135.09, 135.79, 136.68, 137.29, 140.16, 140.98, 144.96. Anal. Calcd

for $C_{28}H_{23}NS_3$: C, 71.60; H, 4.94; N, 2.98; S, 20.48. Found: C, 72.05; H, 5.01; N, 2.86; S, 20.63.

2,5-bis(9-butyl-3-carbazolyl)thiophene (**BBCT**). To a mixture of 2,5-dibromothiophene (0.32 mL, 2.78 mmol), 9-butyl-3-carbazolylboronic acid (1.8 g, 6.8 mmol), sodium carbonate (6.0 g, 56.6 mmol) and palladium Pd(PPh$_3$)$_4$ (20 mg) were added a degassed mixture of THF and water (3:1 in volume,75 mL). The mixture was stirred at 80 °C for 30 h. After the mixture was cooled to room temperature, the organic layer was separated, dried over sodium sulfate and evaporated to dryness. The crude product was chromatographed on silica gel (petroleum ether) to afford the pale yellow solid (0.46 g, 0.875 mmol, 31.5% yield). ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 0.97 (t, J = 7.3 Hz, 6H), 1.42 (m, 4H), 1.87 (m, 4H), 4.33 (b, 4H), 7.24–7.28(m, 2H), 7.34 (b, 2H), 7.42 (d, J = 7.9 Hz, 4H), 7.49 (t, J = 7.2 Hz, 2H), 7.78 (b, 2H), 8.16 (d, J = 7.7 Hz, 2H), 8.37 (b, 2H). ^{13}C NMR (CDCl$_3$, 100.62 MHz) δ: 13.87, 20.57, 31.17, 43.00, 108.88, 108.98, 117.48, 119.01, 120.54, 122.87, 123.32, 123.93, 125.90, 139.97, 140.97, 143.88. Anal. Calcd for $C_{36}H_{34}N_2S$: C, 82.09; H, 6.51; N, 5.32; S, 6.09. Found: C, 82.61; H, 7.05; N, 5.305; S, 6.52.

2-Thienyldibenzothiophene. From 2-bromothiophene (2.86 g, 17.55 mmol) and Mg turnings (0.64 g, 26.7 mmol) in Et$_2$O (30 mL), the corresponding Grignard reagent was prepared and coupled with 2-bromodibenzothiophene (3.35 g, 12.74 mmol) and Ni(dppp)Cl$_2$ (0.36 g, 0.67 mmol) in THF (30 mL). The reaction mixture was refluxed for 6 h. After cooling to room temperature, the solution was poured into water and extracted several times with Et$_2$O. The organic phase was combined and dried over MgSO$_4$. Evaporation of the solvent, the product was chromatographed on silica gel (petroleum ether) to afford the solid (1.7 g, 6.4 mmol 50.3% yield). ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 7.14 (dd, J = 3.6, 5.1 Hz, 1H), 7.33 (dd, J = 1.1, 5.1 Hz, 1H), 7.42 (dd, J = 1.1, 3.6 Hz, 1H), 7.47–7.50 (m, 2H), 7.72 (dd, J = 1.8, 8.3 Hz, 1H), 7.84–7.87 (m, 2H), 8.21–8.23 (m,

1H), 8.36 (d, J = 1.8 Hz, 1H). ^{13}C NMR (CDCl$_3$, 100.62 MHz) δ: 118.28, 121.25, 122.45, 122.64, 122.76, 124.02, 124.31, 124.55, 126.53, 127.67, 130.62, 134.84, 135.64, 138.08, 139.48, 143.97. Anal. Calcd for $C_{16}H_{10}S_2$: C, 72.14; H, 3.78; S, 24.07. Found: C, 72.54; H, 3.59; S, 24.19.

2-(9-butyl-3-carbazolyl)-5-(2-dibenzothienyl)thiophene (**BCDT**). **BCDT** was prepared according to the same procedure as that for **BCTT** from 2-thienyldibenzothiophene (0.26 g, 0.98 mmol) and 9-butyl-3-bromocarbazole (0.3 g, 0.99 mmol). The product was chromatographed on silica gel (petroleum ether) to afford the pale yellow solid (0.25 g, 0.51 mmol, 52.4% yield). ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 0.97 (t, J = 7.3 Hz, 3H), 1.43 (m, 2H), 1.89 (m, 2H), 4.33 (t, J = 7.1 Hz, 2H), 7.25–7.27(m, 1H), 7.37(d, J = 3.6 Hz, 1H), 7.42–7.44 (m, 3H), 7.48–7.51 (m, 3H), 7.77–7.80 (m, 2H), 7.86–7.88 (m, 2H), 8.16 (d, J = 7.7 Hz, 1H), 8.24–8.26 (m, 1H), 8.38 (d, J = 1.5 Hz, 1H), 8.42 (d, J = 1.4 Hz, 1H). ^{13}C NMR (CDCl$_3$, 100.62 MHz) δ: 13.40, 20.08, 30.68, 42.52, 108.45, 108.56, 117.14, 117.79, 118.61, 120.05, 121.26, 122.33, 122.45, 122.47, 122.62, 122.86, 123.47, 123.65, 124.01, 124.12, 125.05, 125.52, 126.49, 130.85, 134.91, 135.69, 137.79, 139.52, 139.63, 140.50, 141.79, 144.72. Anal. Calcd for $C_{32}H_{25}NS_2$: C, 78.81; H, 5.17; N, 2.87; S, 13.15. Found: C, 78.52; H, 4.87; N, 2.76; S, 13.10.

3. Result and discussion

3.1. Synthesis and characterization

Scheme 1 illustrates the synthesis routes for the hybrid materials **BCTT**, **BBCT** and **BCDT**. **BBCT** was prepared by the Suzuki coupling. Both **BCTT** and **BCDT** were obtained by the Stille coupling. In comparison with **BCTT**, the ended bisthienyl is replaced by a carbazolyl in **BBCT** and a dibenzothienyl in **BCDT**. These hybrid materials are readily

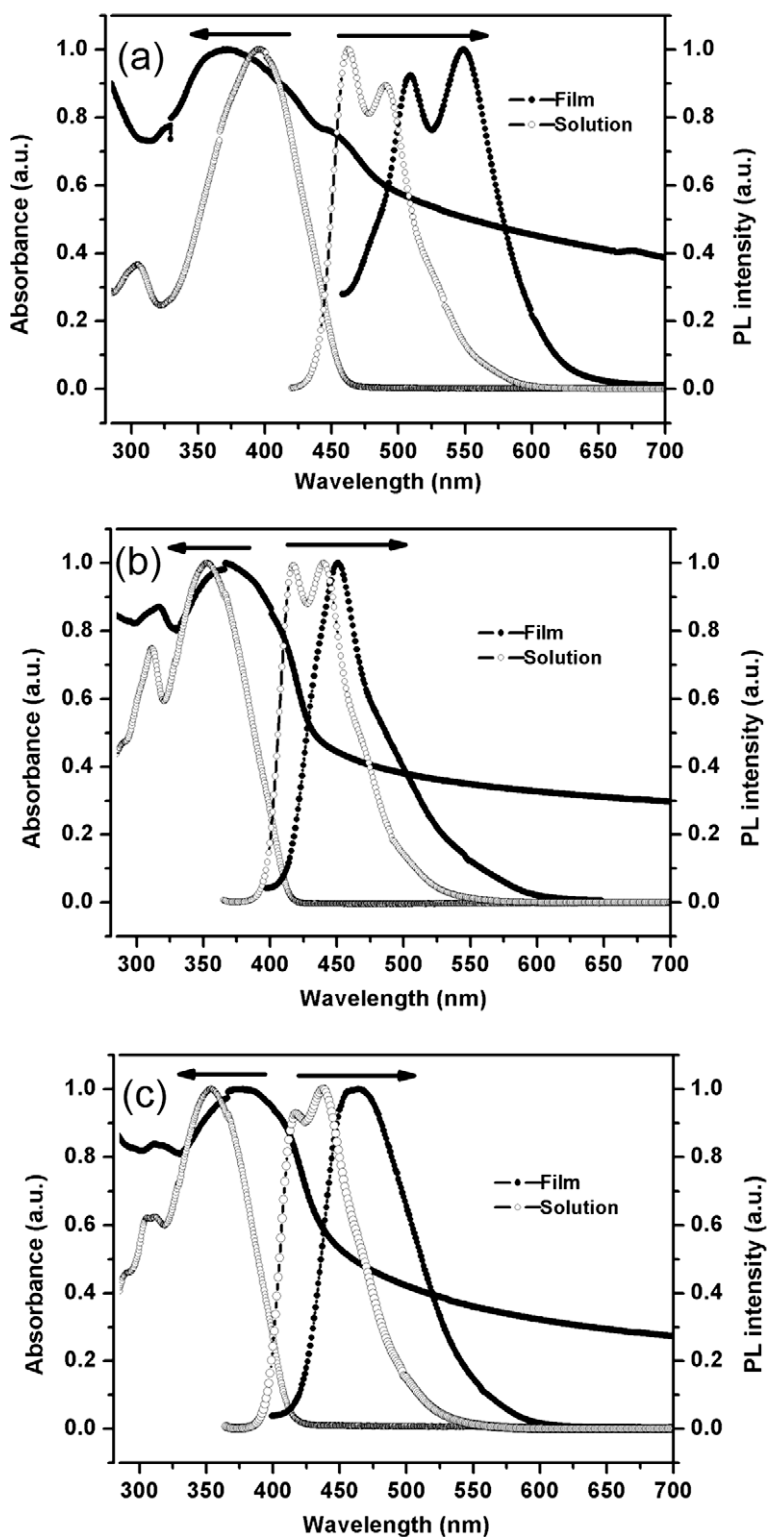

Fig. 1. Normalized optical absorption (UV/vis) and emission (PL) spectra in toluene solution and as thin-film of **BCTT** (a), **BBCT** (b) and **BCDT** (c). The PL spectra were obtained by exciting at 400 nm for **BCTT**, 353 nm for **BBCT** and **BCDT**.

soluble in common solvents such as THF, dichloromethane and chloroform, allowing them to be easily purified by column chromatography. The intermediate precursors and

the final products were characterized by elemental analysis, ^{1}H and ^{13}C NMR spectra. The results are consistent with the predicted chemical structures. All three compounds are

stable under 300 °C as revealed by thermogravimetric analysis (TGA) measurements.

3.2. Photophysical properties

Optical absorption and fluorescence emission spectra of compounds **BCTT**, **BBCT** and **BCDT** were measured both in toluene solution (concentration 1×10^{-5} mol L^{-1}) and as thin films (see Fig. 1). The absorption maxima of **BCTT**, **BBCT** and **BCDT** in solution state are located at 396, 353 and 353 nm, respectively. **BCTT** exhibits the highest λ_{max} due to its long effective intramolecular conjugation length. Comparison of the absorption spectra between the solution and the corresponding films reveals two drastically different behaviors. The film absorption spectrum of **BCTT** displays blue shift as compared with that in solution suggesting H aggregation. In the type of H aggregation, two interacting molecules have their long axes parallel to each other. The coupling between the transition dipoles leads to Davydov splitting of the excited level into two exciton bands, in which the low-energy transitions are forbidden. The major absorption band in the solid state corresponds to the allowed high-energy transitions of interacting molecules [10,29]. In contrast, the film spectra of **BBCT** and **BCDT** show bathochromic shift, indicating J aggregation with adjacent molecules presenting head-to-tail alignment. For this type of aggregation, the low-energy transition is allowed, which leads to a red shift of the absorption spectrum. The aggregation mode of **BBCT** and **BCDT** was further proved by powder XRD. The interlayer spacing of **BBCT** and **BCDT** is about 16 Å from the diffraction peak at the low angle. Based on the similarity of three compounds in molecule structure and the crystal structure of **BCTT**, the molecular length of **BBCT** and **BCDT** is estimated to be 21 Å. Thus, the tilt angle between the dipole direction and the line of molecule centers is about 49.6°, which is lower than 54.7°. According to the molecular exciton coupling model of Kasha et al. [30], the molecules form J-like aggregates in the solid state of **BBCT** and **BCDT**. This result is in accordance with bathochromic shift in the absorption spectra. Therefore, the change of substitution at the one end of thiophene leads to totally different aggregation modes in the solid state. The HOMO–LUMO gaps obtained from the end-absorption are 2.7 eV for **BCTT**, 3.0 eV for **BBCT** and **BCDT**, respectively. All films showed red shift of the emission maxima compared with those of the diluted solutions. The fine structure appearing in the fluorescence spectra is possibly due to vibronic coupling that is typical for oligothiophenes [31].

3.3. Crystal structure

The single crystal of **BCTT** was obtained by slow evaporation from chloromethane solution. Unfortunately, we were unable to obtain millimeter-sized single crystals of **BBCT** and **BCDT** despite numerous attempts. The crystal data and intensity collection parameters of **BCTT** are summarized in Table 1. Fig. 2 shows the molecular structure and packing diagram of **BCTT**. Compound **BCTT** crystallizes in the $P2_1/n$ space group and has four inequivalent molecules per unit cell. The molecules adopt a typical herring-

bone packing motif and the two long axes of interacting molecules are aligned with each other, which leads to the blue shift of the major band in the absorption spectrum of the film in comparison with the solution. The torsion angle between the carbazole ring and the adjacent thiophene ring is 20.6°, which is larger than that of the two external thiophene rings (13.6°). There exist $C–H \cdots \pi$ and $C \cdots S$ interactions between the carbazole portion and the outer thiophene ring of two closely packed molecules. These results indicate that the molecules of **BCTT** in the crystal

have high packing property with a large overlap of intermolecular π-orbitals, which is beneficial to carrier transport.

3.4. Investigations on the morphology

Fig. 3 illustrates the SEM images of **BCTT**, **BBCT** and **BCDT** directly precipitated on the SiO$_2$/Si substrate from 1 mg/mL chlorobenzene solution. The **BCTT** molecules easily assembled into 1D microribbons, which indicate that the growth of **BCTT** from solution is mainly governed by the intermolecular interactions between the π-conjugated molecules. Compared with **BCTT**, the microstructures of **BBCT** and **BCDT** show high flexibility. The precipitations of **BBCT** and **BCDT** from solution formed flexible microribbons. They can even bend themselves into cycles. The difference in the flexibility is closely related to the variation in the intermolecular aggregation. The weak intermolecular interaction in the J aggregation of **BBCT** and **BCDT** may result into the highly flexible microstructures.

The OFET performance is considered to have a close relationship with the film morphology. Fig. 4 shows the AFM images of the vacuum-deposited film. The film of **BCTT** reveals highly crystalline microstructure with plate-like grains in good connectivity. However, the images of **BBCT** and **BCDT** show amorphous characteristics. The morphology difference of these films would have great influence on the OFET performance.

The orientation of the vacuum-deposited films was also investigated by XRD. Fig. 5 shows the XRD patterns of **BCTT**, **BBCT** and **BCDT**, deposited on SiO$_2$/Si at 50 °C. In the case of **BCTT**, the sharp and strong peaks, assignable to multiple (0 0 l) reflections, indicate a high degree of lamellar ordering and crystallinity. The d-spacing obtained from the first reflection ($2\theta = 4.04°$) is 21.9 Å, which is nearly one-half the distance of the unit cell c-axis from the single-crystal structure. This result suggests that the molecules of **BCTT** potentially adopt an edge-on orientation on the substrate, which is an ideal molecular arrangement for carrier transport. On the other hand, the films of **BBCT** and **BCDT** show no discernible reflection peak, suggesting a disorder orientation on the Si/SiO$_2$ substrate.

3.5. OFET properties

Organic thin-film transistors of **BCTT**, **BBCT** and **BCDT** were fabricated using top-contact geometry. Among the three materials, both **BBCT** and **BCDT** display no transistor activities. Only **BCTT** shows moderate hole transport properties and the results are shown in Table 2. The differences in OFET performance of these hybrid materials are mainly due to the great differences in film morphology as shown by the XRD patterns and AFM micrographs. The carrier mobility strongly depends on the strength of the electronic coupling between the HOMO levels of adjacent molecules for the hole transport. The stronger intermolecular interac-

tion in organic crystalline films is more helpful for carrier transport [9].

The 1D microtransistors of **BCTT**, **BBCT** and **BCDT** were also fabricated and studied. A minimum volume of chlorobenzene solution of sample was injected on the OTS-pretreated SiO$_2$/Si substrate in a closed chamber. After the

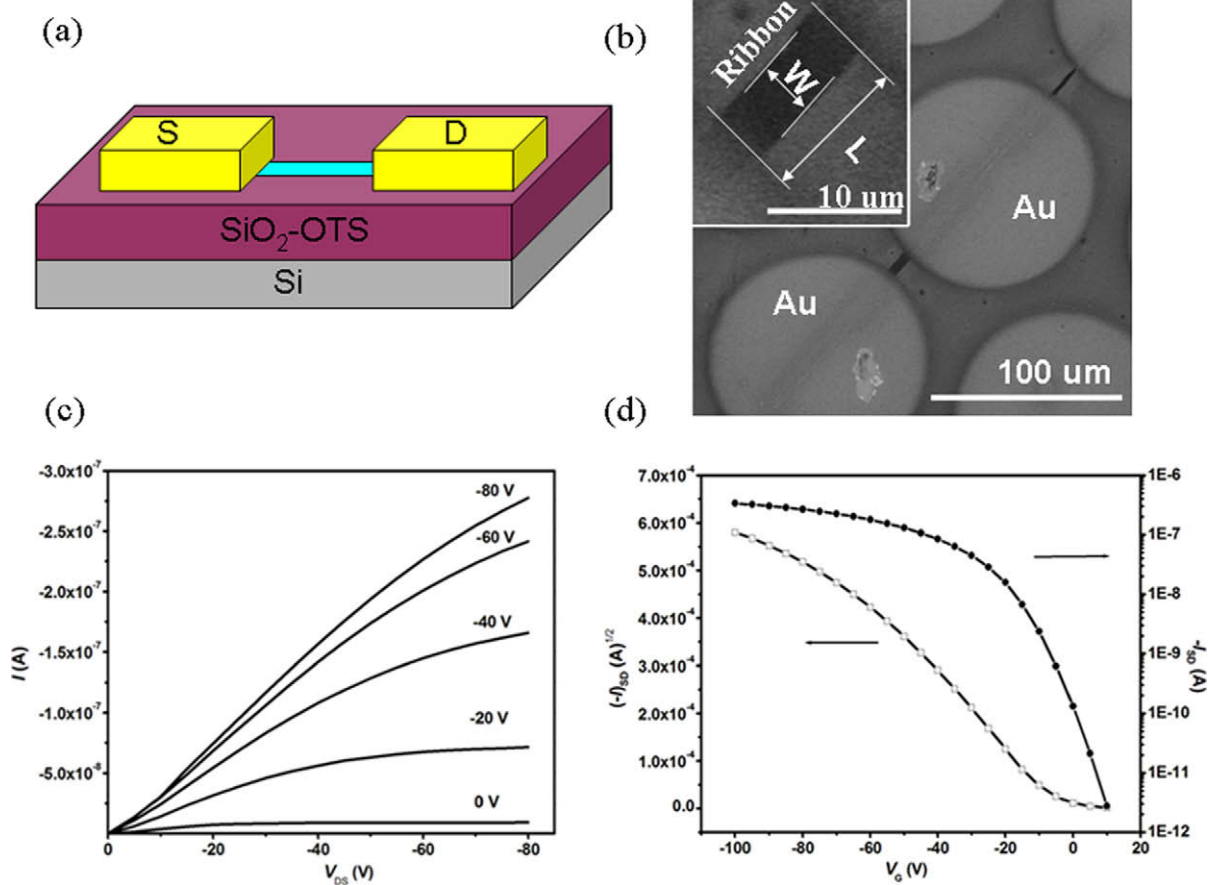
slow evaporation of the solvent, the 1D microribbons were obtained by the self-assembly of molecules along the π–π stacking direction. The powder XRD peaks and the polarized optical microscopic images (POM) showed clearly that all these 1D microstructures were ordered crystal [32,33]. Then Au electrodes were thermally evaporated by laying a copper grid on the microribbons as the mask [25]. Fig. 6A shows the schematic of a typical structure of an FET based on a single microribbon. Fig. 6B is a representa-


Fig. 6. (a) Schematic diagram of a microtransistor based on an individual microribbon. (b) SEM image of an individual **BCTT** microribbon and electrodes formed by copper grid mask. tive SEM image of a top-contact device constructed from a single microribbon of **BCTT**. The channel length and width of the FET device are estimated according to the length of the **BCTT** single-crystal ribbon between the Au electrodes and the width of the ribbon, respectively. As shown in Table 2, the carrier mobilities of the single-crystal **BCTT** microtansistors are much higher than those of the thin-film transistors because of the elimination of disorder and grain boundaries, which always exist in the thin films. Fig. 6C and D show the transfer and output characteristics of the single-crystal FET. The average field-effect mobility is 0.059 cm^2 V^{-1} s^{-1} with an on/off current ratio of 10^4–10^5. The highest mobility was found to be 0.094 cm^2 V^{-1} s^{-1} with a very low threshold voltage of 1.1 V. The carrier mobility of **BCTT** is much higher than those of **BBCT** and **BCDT**. The main reason for this improvement is probably the stronger interchain interaction in the **BCTT** crystal with H aggregation than those in the **BBCT** and **BCDT** crystals with J aggregation. Furthermore, the devices made from single-crystal **BCTT** show good environmental stability. The carrier mobility and on/off ratio were still on the same order of magnitude as those of the freshly prepared devices after the microtransistors were exposed to ambient environment for 45 days. The good device stability is possibly due to the stability of crystals under ambient conditions and the good contact at the interface between the semiconductor and the dielectric.

4. Conclusion

Three new hybrid materials based on fused-ring and thiophene were synthesized and characterized. The slight change of substituent at the one end of thiophene leads to the dramatic differences in morphology, optical and electronic properties. Molecules of **BCTT** adopt H aggregation. Whereas, both **BBCT** and **BCDT** exhibit the formation of J aggregation. The microstructures of **BBCT** and **BCDT** display high flexibility. The microtransistors of these materials were easily fabricated by direct solution process. The carrier-transport properties of **BCTT** are much higher than those of **BBCT** and **BCDT**, probably due to the stronger interchain interaction in the solid. These results would be beneficial to understanding the structure-property relationships and related studies on the intrinsic transport properties of hybrid materials.

Liq molecules in excited state would recombine with ground Liq molecules to form excimers in LEL, and also with hole transporting molecules to form exciplexes at interface between LEL and hole-transporting layer (HTL), which would induce red-shifted of electroluminescence (EL) spectra, blue-green light emitting, lowered current efficiency, and shortened lifetime of OLED [11,12].

To solve above problems, a novel Liq-derived blue-light OEM, bis[(8-hydroxyquinolin)lithium·8-hydroxyquinolin] sodium ([Liq·q$^-$]$_2$·2Na$^+$), was synthesized and characterized as the blue-light OEM with better properties than Liq.

2. Experimental section

2.1. Synthesis

All chemicals and reagents were used and received from commercial sources without further purification. All reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. Liq was synthesized according to the literature route [13]. 8-Hydroxyquioline acetone solution (0.5 mol L^{-1}, 50 ml) and lithium hydroxide (LiOH) water solution (1 mol L^{-1}, 12.5 ml) were poured into a two-necked flask under nitrogen. The mixture was heated (t = 50 °C) and stirred for nearly 1 h. Then, sodium hydroxide (NaOH) water solution (1 mol L^{-1}, 12.5 ml) was dropped into the flask, the mixture was kept on stirring for about 6 h. After reaction, the reaction mixture was filtered, and solid residue was gained. The solid residue was washed with acetone several times and further purified by acetone recrystallization. The final residue was dried in oven and purified by vacuum sublimation. Finally, [Liq·q$^-$]$_2$·2Na$^+$ was gained as light gray-green powder in 84% yield. ^{1}H NMR (300 MHz, DMSO, δ): 6.52, 6.61, 7.20, 7.29, 8.07, 8.44. IR (KBr): v = 1570, 1497, 1466, 1385, 1321, 1105, 824, 521, 445 cm^{-1}. Anal. calcd for C$_{36}$H$_{24}$O$_4$N$_4$Li$_2$Na$_2$: C 67.92, N 8.81, H 3.77; found: C 66.82, N 8.68, H 3.79.

2.2. Properties characterization

Fluorescence spectra were recorded on LS-50B fluorescence spectrometer, and test solutions were [Liq·q$^-$]$_2$·2Na$^+$ methanol solution (10^{-5} mol L^{-1}) and Liq methanol solution (10^{-5} mol L^{-1}). Fluorescence quantum yield was calculated according to method introduced in literature [14–16], standard sample was tris(8-hydroxyquinoline)aluminum chloroform solution (10^{-5} mol L^{-1}, Φ_{fs} = 0.116). The voltammetric curve was recorded on Autolab/PG STAT302 electrochemical system at room temperature in a solution of tetrabutylammonium perchlorate (n-Bu$_4$NClO$_4$, 0.1 mol L^{-1}) in dimethyl formamide (DMF) at a scan rate of 50 mV s^{-1}, the voltage increased from 0 to 1.5 V. Two platinum chips and a calomel electrode were used as working electrode, counter electrode and reference electrode, respectively, and test solutions were [Liq·q$^-$]$_2$·2Na$^+$ methanol solution and Liq methanol solution. Fluorescence lifetime was recorded on Edinburgh Analytical Instruments F900 single-electron counting fluorescence lifetime testing instrument. Thermogravimetric (TG) and differential ther-

mal analysis (DTA) were recorded on NETZSCH STA409C thermal analyzer, protection gas and purge gas were argon at gas flow-rate between 10 and 30 ml min^{-1}, respectively, and heating rate was 10 °C min^{-1}. The atomic force microscope (AFM) image of [Liq·q$^-$]$_2$·2Na$^+$ film was recorded on SPA-300HV AFM. The X-ray photoelectron spectra (XPS) of [Liq·q$^-$]$_2$·2Na$^+$ film was recorded on ESCALAB250 X-ray electron spectrometer.

Table 1
Test data of fluorescence lifetime.

	A	B_1	τ_1 (ns)	B_2	τ_2 (ns)	τ (ns)
$[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$	0.6730	2.117×10^3	13.00	3.009×10^3	26.97	23.43
Liq	0.4960	2.266×10^3	20.66	2.710×10^3	8.486	16.64

2.3. OLED fabrication and measurements

Prepatterned indium tin oxide (ITO) substrates with an area of 4 mm × 5 mm were cleaned with deionized water, anhydrous alcohol, and anhydrous acetone in turn, and dried by nitrogen gas flow. In OLEDs, copper phthalocyanine (CuPc), N,N′-Di-[(1-naphthalenyl)-N,N′-diphenyl]-(1,1′-biphenyl)-4,4′-diamine (NPB) and aluminum (Al) were used as hole-injection layer, HTL and cathode, respectively. OLEDs were fabricated by vacuum deposition of 5 nm of CuPc, 30 nm of NPB film, 30 nm of $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ or Liq and 30 nm of Al on ITO in turn. The luminance–current density–voltage–current efficiency (L–J–U–η_C) characteristic of OLED was recorded on a Keithley 2400 source meter equipped with ST-900PM optical meter and integrating sphere. Electroluminescence spectra were recorded on SPR-920D fluorescence spectrometer.

3. Results and discussion

According to reported literature, it is suggested that the molecular structure of $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ is nearly identical with that of $[(\text{Clq})(\text{ClqH})\text{Na}]_2$ [17]. The Li$^+$ can also conjunct with 8-hydroxyquinoline and form a similar structure of $[(\text{Clq})(\text{ClqH})\text{Na}]_2$, owing to its bigger electronegativity ($\chi = 1.0$) than that of Na$^+$ ($\chi = 0.9$) and smaller ionic radius ($r = 0.68$ Å) than that of Na$^+$ ($r = 0.95$ Å). In addition, it had been reported that the actual molecular specie of Liq is $[\text{Liq}_2]^-[\text{Li}]^+$ [8]. During synthesis of $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$, Li$^+$ conjuncts with 8-hydroxyquinoline to form $[(\text{Liq})\text{Hq}]_2$ initially since the molecular ratio of LiOH to 8-hydroxyquinoline is 1:2. Then, $[(\text{Liq})\text{Hq}]_2$ reacts with NaOH under heating and stirring, the H$^+$ ions of $[(\text{Liq})\text{Hq}]_2$ are neutralized by OH$^-$ ions, the Na$^+$ ions adhere around $[\text{Liq}\cdot q^-]_2$ owing to existence of big steric hindrance in the center of $[\text{Liq}\cdot q^-]_2$, and $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ formed eventually. Hence, the molecular structure of $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ is present in Fig. 1.

As shown in Fig. 1, it can be seen that $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ is of stereo structure, which is distinguished from planar

structure of Liq. Therefore, $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ molecules possess large steric hindrance and long intermolecular distance between adjacent molecules.

3.1. Photophysical property

The fluorescence spectra of $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ are shown in Fig. 2. In excitation spectrum, the peak at 413 nm (Fig. 2a) attributes to transition absorption between the Highest Occupied Molecular Orbit (HOMO) located in phenol ring and the Lowest Unoccupied Molecular Orbit (LUMO) located in pyridine ring of 8-hydroxyquinoline, and so does the peak at 373 nm for Liq (Fig. 2b) [10]. It is indicated that

Table 2
Test data of electrochemical property.

	E_0^{ox} (V)	E_{HOMO} (eV)[a]	E_{LUMO} (eV)[c]	E_g (eV)[b]
$[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$	0.92	−5.66	−2.81	2.85
Liq	0.84	−5.58	−2.60	2.98

[a] The HOMO level was calculated according to the equation: E_{HOMO} (eV) = -4.74 eV $- e\,E_0^{ox}$.

[b] The band gap (E_g) was evaluated by the energy value of crossover point of linear excitation band energy and energy axis in $(h\nu a)^2$ vs $h\nu$ curve.

[c] The LUMO level was calculated according to the equation: E_{Lumo} (eV) = $E_{\text{HOMO}} + E_g$.

Fig. 3. The electrochemical property. (a) The oxidation curves: $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ (—■—), Liq (—□—); the differential oxidation curves (inset): $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ (—■—), Liq (—□—); (b) The $(h\nu a)^2$ vs $h\nu$ curves: $[\text{Liq}\cdot q^-]_2\cdot 2\text{Na}^+$ (—■—), Liq (—□—). The $(h\nu a)^2$ vs $h\nu$ curve is determined by fluorescence excitation spectra with relationship: $h\nu a = B\,(h - E_g)^n$, where a is intensity, h is Planck's constant, ν is light wave frequency, E_g is band gap, n is usually 0.5 and B is a coefficient relevant to material.
Fig. 4. The TG/DTA/DTG curves of [Liq·q⁻]₂·2Na⁺.

[Liq·q⁻]₂·2Na⁺ present a 40 nm red-shift relative to Liq in long wavelength range.

It is interesting that Liq also shows an absorption peak at 265 nm which attributes to $\pi \rightarrow \pi^*$ transition absorption located in benzene ring [8], while this peak nearly disappears for [Liq·q⁻]₂·2Na⁺. In Jablonski energy level diagram of Liq, the peaks between 265 and 373 nm attribute to $S_0 \rightarrow S_2$ and $S_0 \rightarrow S_1$ transition, respectively [18]. Similar to the case for inorganic semiconductor, Na⁺ ions in [Liq·q⁻]₂·2Na⁺ are reasonably regarded as *n*-dopant that can generate a donor level (E_D). When [Liq·q⁻]₂·2Na⁺ is excited, the excited electrons from S_0 level are nearly all bounded by E_D level at first and transfer to S_1 level immediately, with few transfer from S_0 level to S_2 level [19]. Therefore, the peak at 265 nm attributing to $S_0 \rightarrow S_2$ transition is very weak in excitation spectrum of [Liq·q⁻]₂·2Na⁺. It is suggested that Na⁺ ions in [Liq·q⁻]₂·2Na⁺ ensures that most of excitation energy is consumed in HOMO → LUMO transition to increase fluorescence quantum yield (Φ_f) eventually. Meanwhile, the maximum emission peak at

518 nm in fluorescence emission spectrum of [Liq·q⁻]₂·2Na⁺ which is similar to Liq, indicates that introduction of Na⁺ ions into Liq molecules had little influence on fluorescence emission.

The Φ_f value of [Liq·q⁻]₂·2Na⁺ and Liq were calculated as 0.25 and 0.14, respectively, by the method introduced in literature [14–16]. Owing to stereo structure, [Liq·q⁻]₂·2Na⁺ molecules in solution exhibit small molecular degree of freedom, low probability of molecular collision and thus low energy loss for radiationless transition. Moreover, Na⁺ ions in [Liq·q⁻]₂·2Na⁺ can also increase Φ_f. Therefore, Φ_f of [Liq·q⁻]₂·2Na⁺ is higher than that of Liq.

The fluorescence decay curves of [Liq·q⁻]₂·2Na⁺ and Liq were recorded consulting Time-Correlated Single-Photo Counting (TCSPC) testing method and were fitted by Eq. (1). The fluorescence lifetime (τ) was given by Eq. (2) [20].

$$N_c(t_k) = A + B_1 \exp(-t_k/\tau_1) + B_2 \exp(-t_k/\tau_2) \tag{1}$$

$$\tau = \frac{B_1 \tau_1^2 + B_2 \tau_2^2}{B_1 \tau_1 + B_2 \tau_2} \tag{2}$$

Table 1 lists the corresponding test data. For planar structure and small intermolecular distance, excimers, which are mainly fluorescence quenching centers, are
Fig. 5. The AFM image of [Liq·q⁻]₂·2Na⁺ film.
Fig. 6. The XPS spectrum of [Liq·q⁻]₂·2Na⁺ film.

generated when Liq is excited. However, stereo structure and big intermolecular distance of $[Liq·q^-]_2·2Na^+$ hinder generation of excimers and prolong τ eventually [21]. Hence, it can be seen that τ of $[Liq·q^-]_2·2Na^+$ (23.4 ns) is longer than that of Liq (16.64 ns).

3.2. Electrochemical property

The electrochemical property of $[Liq·q^-]_2·2Na^+$ was studied according to method introduced in literature, the test results were summarized in Table 2 and Fig. 3 [22–24]. Compared with Liq, $[Liq·q^-]_2·2Na^+$ shows smaller band gap (2.85 eV) than that of Liq (2.98 eV), which results in red-shift in fluorescence excitation spectrum, in good agreement with the conclusion gained from fluorescence spectra analysis. Wherein, the LUMO level of $[Liq·q^-]_2·2Na^+$ (−2.81 eV) is 0.21 eV lower than that of Liq (−2.60 eV) and the HOMO level of $[Liq·q^-]_2·2Na^+$ (−5.66 eV) is only 0.08 eV lower than that of Liq (−5.58 eV), indicating that the electron cloud density around pyridine ring of $[Liq·q^-]_2·2Na^+$ is much lower than that of Liq, but the electron cloud density around phenol ring of $[Liq·q^-]_2·2Na^+$ is a little smaller than that of Liq [25]. Therefore, it is presumed that Na^+ ions in $[Liq·q^-]_2·2Na^+$ molecules locate in the area between adjacent molecules and near pyridine ring.

3.3. Thermal property and film property

Thermal property of $[Liq·q^-]_2·2Na^+$ was investigated by TG and DTA (Fig. 4). $[Liq·q^-]_2·2Na^+$ presents a melting temperature (T_m) of 364 °C in DTA curve and an onset sublimation temperature (T_s) of 403 °C in TG curve. At the temperature lower than T_s, $[Liq·q^-]_2·2Na^+$ is stable and has no weight loss process, which ensures the probability that $[Liq·q^-]_2·2Na^+$ forms amorphous film by vacuum deposition.

Additionally, the much higher molecular weight of $[Liq·q^-]_2·2Na^+$ than Liq, may also play a role in raising its glass transition temperatures (T_g) [26]. It is presumed that the thermal stability of $[Liq·q^-]_2·2Na^+$ film is much better than that of Liq film, which would reduce film crystallization by Joule heat and prolong device lifetime when $[Liq·q^-]_2·2Na^+$ is used as LEL in OLED.

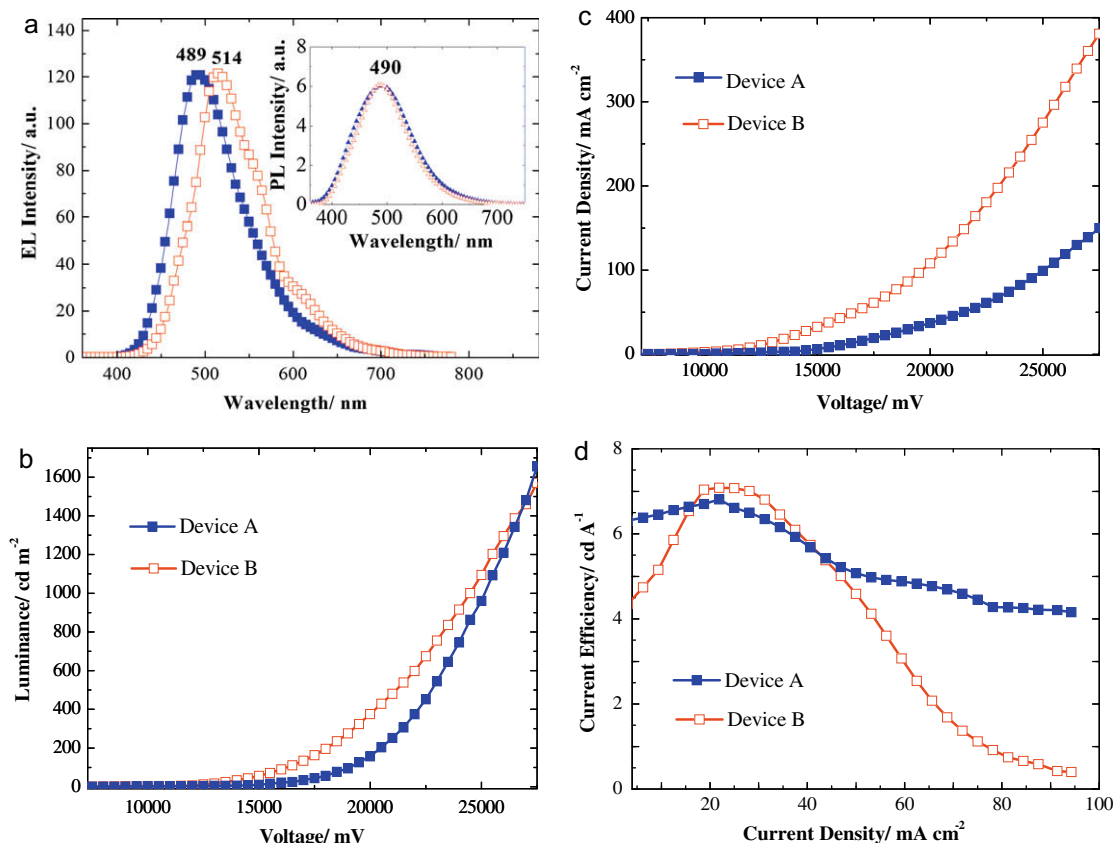
By observation of AFM image, the film formability of $[Liq·q^-]_2·2Na^+$ was characterized. $[Liq·q^-]_2·2Na^+$ film is very compact and homogeneous (Fig. 5). Because of the connection between adjacent molecules by Na^+ ions, $[Liq·q^-]_2·2Na^+$ molecules overlap each other adhesively and deposit onto substrate uniformly during film formation by vacuum deposition. Consequently, $[Liq·q^-]_2·2Na^+$ possesses excellent film formability.


Fig. 7. The electroluminescence property. (a) The EL spectra of Device A (−■−) and Device B (−□−); the PL spectra (inset) of $[Liq·q^-]_2·2Na^+$ film (−▲−) and Liq film (−△−); (b) luminance (L) versus voltage (U) curves: Device A (−■−), Device B (−□−); (c) current density (J) versus voltage (U) curves: Device A (−■−), Device B (−□−); (d) current efficiency (η_C) versus current density (J) curves: Device A (−■−), Device B (−□−).

In order to identify the presence of Na^+ ions in $[Liq \cdot q^-]_2 \cdot 2Na^+$ film, the XPS of $[Liq \cdot q^-]_2 \cdot 2Na^+$ film was measured, as presented in Fig. 6. The peak at 1071.06 eV is attributed to Na_{1s} binding energy, suggesting the existence of Na^+ ions in $[Liq \cdot q^-]_2 \cdot 2Na^+$ film.

3.4. Electroluminescence property

To illustrate electroluminescence property of $[Liq \cdot q^-]_2 \cdot 2Na^+$, two OLEDs with $[Liq \cdot q^-]_2 \cdot 2Na^+$ and Liq as LEL separately were fabricated. The device structures were: ITO/CuPc (5 nm)/NPB (30 nm)/$[Liq \cdot q^-]_2 \cdot 2Na^+$ (30 nm)/Al (30 nm) (Device A) and ITO/CuPc (5 nm)/NPB (30 nm)/Liq (30 nm)/Al (30 nm) (Device B).

Owing to large steric hindrance and long intermolecular distance, it is difficult to generate excimers and exciplexes with $[Liq \cdot q^-]_2 \cdot 2Na^+$ as LEL in OLED. The maximum emission wavelength (λ_{max}) in EL spectrum of Device A (Fig. 7a) is 489 nm, which exhibits a 25 nm blue-shift relative to Device B ($\lambda_{max} = 514$ nm). It is indicated that $[Liq \cdot q^-]_2 \cdot 2Na^+$ can emit bluer light than Liq when used as LEL in OLED [8,9]. Meanwhile, it can also be seen in Fig. 7a that the EL spectrum of Device B exhibits a 24 nm red-shift relative to photoluminescence (PL) spectrum of Liq film, which is due to the presence of excimers and exciplexes in Device B. However, the EL spectrum of Device A is nearly identical with PL spectrum of $[Liq \cdot q^-]_2 \cdot 2Na^+$ film, verifying the fact that it is difficult to generate excimers and exciplexes when $[Liq \cdot q^-]_2 \cdot 2Na^+$ is used as LEL in OLED.

It has been identified by XPS that $[Liq \cdot q^-]_2 \cdot 2Na^+$ film contains Na^+ ions. In Device A, Na^+ ions act as electron traps. Electrons injected from cathode are captured by Na^+ ions at first, and recombine with holes injected from HTL to realize blue-light emission after neutralization of Na^+ ions [27]. Hence, it can be seen in Fig. 7b that the turn-on voltage (U_{th}) of Device A (8.5 V) is about 1 V higher than that of Device B (7.5 V) and the luminance of Device A is a little lower than that of Device B. In OLED, excimers and exciplexes also act as fluorescence quenching centers. With increasing voltage, more excimers and exciplexes are generated in Device B, and correspondingly the luminance increment of OLED Device B is reduced. The luminance of Device A (1654 cd m^{-2}) becomes higher than that of Device B (1570 cd m^{-2}) when voltage increases to 27 V.

Compared with Liq, $[Liq \cdot q^-]_2 \cdot 2Na^+$ exhibits lower electron mobility owing to its large steric hindrance and long intermolecular distance. Hence, the current density (J) of Device A is much smaller than that of Device B (Fig. 7c). The lower electron mobility of $[Liq \cdot q^-]_2 \cdot 2Na^+$ would benefit effective recombination of electrons and holes in LEL, and result in high inter quantum efficiency and current efficiency (η_C) of OLED [28,29]. Moreover, it is more difficult in generating of excimers and exciplexes in Device A than in Device B with increasing J. As a result of the above two reasons, η_C stability of Device A is better than Device B, that is to say, the drop in η_C of Device A is much slower than that of Device B with increasing J. As presented in Fig. 7d, with increasing J, the η_C of Device A drops from 6.80 cd A^{-1} to above 4 cd A^{-1}, however, that of Device B drops remarkably from 7.08 cd A^{-1} to below 1 cd A^{-1}.

4. Conclusions

In summary, $[Liq \cdot q^-]_2 \cdot 2Na^+$ was synthesized by a simple route and its properties were characterized. Different from planar structure of Liq, stereo structure of $[Liq \cdot q^-]_2 \cdot 2Na^+$ results in higher Φ_f and longer lifetime. Taking Liq as reference, the presence of Na^+ ions between adjacent $[Liq \cdot q^-]_2 \cdot 2Na^+$ molecules induces 40 nm red-shift in fluorescence excitation spectrum, 0.21 and 0.08 eV lowering of LUMO and HOMO, respectively. $[Liq \cdot q^-]_2 \cdot 2Na^+$ exhibits excellent thermal stability and film formability. When $[Liq \cdot q^-]_2 \cdot 2Na^+$ is used as LEL in OLED, its λ_{max} in EL spectrum is 489 nm and exhibits a 25 nm blue-shift relative to Liq, its luminance is higher than Liq above voltage of 27 V, and its η_C stability is better than that of Liq. In one word, $[Liq \cdot q^-]_2 \cdot 2Na^+$ is a novel blue-light OEM with excellent properties. In addition, $[Liq \cdot q^-]_2 \cdot 2Na^+$ also exhibits excellent electron injection property since $[Liq \cdot q^-]_2 \cdot 2Na^+$ molecules contain Na^+ ions. It is prospected that $[Liq \cdot q^-]_2 \cdot 2Na^+$ can be used as EIL in OLED to improve device performance as Liq does. This work will be published in future report.

(as shown in Scheme 1). Electroluminescent devices using the two luminescent materials as the emitting layer were fabricated and the devices performances were reported.

2. Results and discussion

As shown in Scheme 2, three types of reactions, including Vilsmeier reaction, Wittig reaction, and Suzuki coupling reaction, were performed to the synthesis of luminescent materials based on indolo[3,2-*b*]carbazole. Firstly, aldehyde group was readily introduced to 6-position of indolo[3,2-*b*]carbazole through Vilsmeier reaction performed on compound **1**. And the structure of the obtained aldehyde, compound **2**, was further confirmed by X-ray single crystal analysis. Secondly, compound **3** was facilely synthesized with very high yield through Wittig reaction in dry dichloromethane solutions at room temperature under ambient atmosphere. Finally, two new luminescent compounds, TPAP–ICZ and DBFP–ICZ, were obtained through Suzuki coupling reaction of compound **3** with the corresponding boronic acid. All the intermediate precursors and the final products were fully characterized by ¹H NMR, ¹³C NMR, MS, and elemental analysis, and the results were well consistent with the predicted structures. The thermal properties of TPAP–ICZ and DBFP–ICZ were investigated by thermogravimetric analysis (TGA). TGA results shown the decomposition temperatures (T_d, which is corresponding

to a 5% weight loss) all above 400 °C, indicating the compounds have good thermal stabilities. However, no obvious glass transition phenomena were observed for both the two compounds according to the DSC results.

The optical properties of TPAP–ICZ and DBFP–ICZ were measured in toluene solutions (1×10^{-5} M) and in the thin films deposited on quartz substrates. All the results are listed in Table 1. TPAP–ICZ and DBFP–ICZ exhibited maximum absorptions at 342 and 340 nm, respectively, in toluene solutions, which were very similar to the to the absorption maximum of 5,11-dioctylindolo[3,2-*b*]carbazole [17]. According to the literature [19], the UV absorption maximum of conjugated molecule is closely associated with its conjugation length. The very similar absorption maximum of TPAP–ICZ and DBFP–ICZ may indicate that the introduction of functional groups on 6-position of indolo[3,2-*b*]carbazole almost have no effect on the conjugation length of the whole molecule even though the functional groups were linked on 6-position of indolo[3,2-*b*]carbazole through double bond. Therefore, the absorption characteristics of TPAP–ICZ and DBFP–ICZ should be mainly accounted to the indolo[3,2-*b*]carbazole core. The absorption maximum of TPAP–ICZ and DBFP–ICZ is assigned to the second electronic excitation, while the weak absorption around ∼420 nm is correspond to the S_0–S_1 electronic transition [20]. The optical bandgaps (E_g) of TPAP–ICZ and DBFP–ICZ were 2.62 and 2.63 eV,

Table 1
Optical properties, energy band gaps and thermal stability of TPAP–ICZ and DBFP–ICZ.

DBFP–ICZ	340	330	499	503	2.63	0.94	−5.10	−2.47	408

[a] In dilute toluene solution (1×10^{-5} M).
[b] E_g^{opt} values were determined from UV–vis absorption spectra in solution with toluene.
[c] The HOMO levels of the compounds were determined by using the onset positions of the oxidation.
[d] Decomposition temperature observed from TGA correspond to a 5% weight loss at 10 °C min⁻¹ under nitrogen.
Fig. 1. Photoluminescent and UV–vis absorption spectra of TPAP–ICZ and DBFP–ICZ both in solutions and in thin films.

respectively, which were estimated from the long-wavelength absorption edge. The photoluminescent (PL) spectra of TPAP–ICZ and DBFP–ICZ are shown in Fig. 1. The two compounds were highly fluorescent both in solution and in the solid state. The fluorescent quantum yields of TPAP–ICZ and DBFP–ICZ were 0.40 and 0.45, respectively, in solution with 9,10-diphenylanthracene ($\phi_F = 1.0$) as the reference. According to the PL spectra, they all exhibit narrow emission peaks located at 499 nm in toluene solution. Maybe we can presumed that the emission and absorption wavelengths are controlled mostly by the indolo[3,2-b]carbazole unit according to their very similar optical properties. Moreover, the two compounds exhibited similar λ_{max} of emission both in solution and in the thin films, which indicated that there were minimal intermolecular interactions in the ground state in the films [21]. Furthermore, the two compounds showed narrow FWHM (full width at half maximum) in the thin films (which are 55 nm for TPAP–

ICZ and 57 nm for DBFP–ICZ, respectively.), thus had good color purity.

The electrochemical properties of TPAP–ICZ and DBFP–ICZ were studied by cyclic voltammetry (CV) in dichloromethane solutions with Ag/AgCl as reference electrode. All the two compounds are electrochemically reversible (as shown in Figs. S1 and S2). We also measured measured the CV properties of 5,11-dioctylindolo[3,2-b]carbazole (Fig. S3). According to the CV of 5,11-dioctylindolo[3,2-b]carbazole, the first and third pair of reversible peaks of TPAP–ICZ and the first and second pair of reversible peaks of DBFP–ICZ should be accounted to 5,11-dioctylindolo[3,2-b]carbazole, the second pair of reversible peak of TPAP-ICZ should be assigned to the triphenylamine group. The onset oxidation potentials (E_{ox}^{onset}) of TPAP–ICZ and DBFP–ICZ were both 0.70 V. Accordingly, the highest occupied molecular orbital (HOMO) energy levels of TPAP–ICZ and DBFP–ICZ were estimated to be both 5.10 V (HOMO = E_{ox}^{onset} + 4.4 eV). The lowest unoccupied molecular orbital (LUMO) energy levels of TPAP–ICZ and DBFP–ICZ were estimated to be −2.48 and -2.47 eV, respectively, which were calculated from the HOMO energy level and energy bandgap (E_g) determined from the threshold of the optical absorption (LUMO = HOMO + E_g eV).

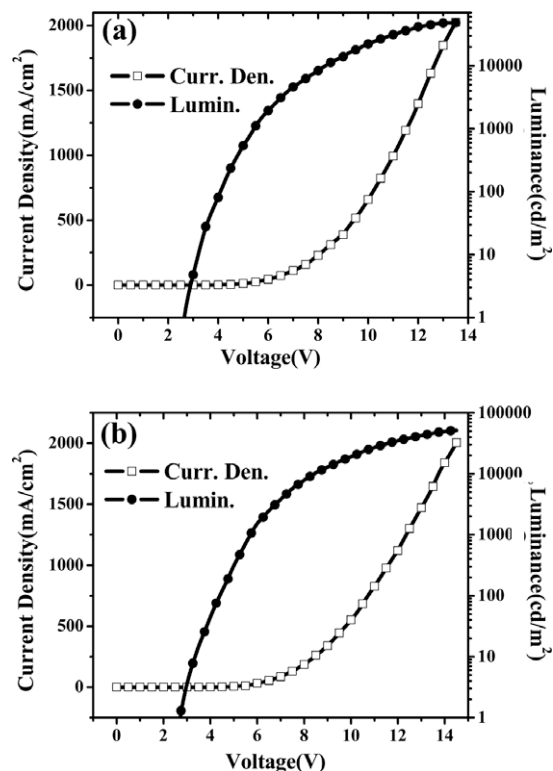
To evaluate the utility of the two indolo[3,2-b]carbazole derivatives as the emitting layer (EML) in the EL devices, we fabricated EL devices with the configuration of indium tin oxide (ITO)/4,4′-bis[N-(1-naphthyl)-N-phenylamino]-biphenyl (NPB) (30 nm)/EML (40 nm)/1,3,5-tris(N-phenylbenzimidazol-2-yl)benzene (TPBI) (40 nm)/LiF (1 nm)/Al (80 nm). NPB (HOMO = −5.70 eV, LUMO = −2.60 eV) [22] was used as the hole-transporting layer (HTL); the indolo[3,2-b]carbazole derivatives were used as the emitting layer (EML); TPBI (HOMO = −6.20 eV, LUMO = −2.70 eV) [23] was used as the electron-transporting layer, and LiF
Fig. 2. The band diagram of the ITO/NPB/TPAP–ICZ or DBFP–ICZ/TPBI/LiF/Al EL devices.
Fig. 3. The EL spectra of (a) TPAP–ICZ and (b) DBFP–ICZ.


Fig. 4. The current density–voltage–luminescence (J–V–L) characteristics of the EL devices: (a) TPAP–ICZ; (b) DBFP–ICZ.

was the electron-injection layer. The hypothetical band diagrams of the EL devices were depicted in Fig. 2. According to the band diagrams, there were hole transport barriers about 0.60 eV both at the NPB/TPAP–ICZ and NPB/DBFP–ICZ interfaces. In contrast, the barrier at the TPAP–ICZ/TPBI and DBFP–ICZ/TPBI interfaces for the electron transport were −0.22 and −0.23 eV, respectively. Therefore, for both TPAP–ICZ and DBFP–ICZ, the electrons could be more easily injected to the emitting layer than the holes. This is beneficial to the improvement of the balance of charge carrier injection and transport, and thus the hole-electron recombination becomes more efficient in emitting layer.

The EL spectra from the device are illustrated in Fig. 3. No changes are observed in the EL spectra upon being operated at various driving voltages. Notably, all the EL devices show similar peaks with that in PL spectra of the thin films. The EL maximum emission was 502 nm with narrow FWHM of 67 nm for TPAP–ICZ, while 503 nm and 70 nm for DBFP–ICZ, respectively. This indicates that both PL and EL originate from the same radiative-decay process of the single excitons [24–26].

The current density–voltage–luminescence (J–V–L) characteristics of the EL devices are illustrated in Fig. 4. The EL devices exhibited excellent EL performances and all the results are summarized in Table 2. The EL devices exhibit very low turn-on voltages (brightness = 1 cd m^{-2}) with 2.90 V for TPAP–ICZ and 2.65 V for DBFP–ICZ, respectively. The maximum luminance efficiency and maximum brightness of the EL device using TPAP–ICZ as the emitter

Table 2
Summary of EL devices performances.

Compounds	TPAP–ICZ	DBFP–ICZ
Turn-on voltage (V)[a]	2.9	2.65
Maximal brightness (cd m^{-2})	65739[b]	68729[c]
Maximal luminance efficiency (lm W^{-1})	6.74	7.92
Maximal current efficiency (cd A^{-1})	6.90	7.06
Maximal external quantum efficiency (%)	2.39	2.79
EL λ_{max} (nm)[d]	502	503
CIE[d] (x, y)	(0.224, 0.562)	(0.214, 0.568)

[a] Recorded at 1 cd m^{-2}.
[b] Recorded at 13.5 V.
[c] Recorded at 13 V.
[d] Recorded at 8.

are 6.90 cd A^{-1} and 65739 cd m^{-2} (at 13.5 V), respectively, with the external quantum efficiency of 2.39% and the Commission Internationale de L'Eclairage (CIE) color coordinates located at (0.224, 0.562), while those of the EL device using DBFP–ICZ as the emitter were 7.06 cd A^{-1} and 68729 cd m^{-2} (at 13 V), respectively, with the external quantum efficiency of 2.79% and the CIE color coordinates of (0.214, 0.568). Given that the entire device fabrication and characterization were carried out in air without encapsulation, the unoptimized EL efficiency values reported here were remarkably high. Further improvements would

likely be obtained through the optimization of the device architectures and layer thickness. Therefore, we concluded that indolo[3,2-b]carbazole is a very promising block for highly efficient electroluminescent materials.

3. Conclusions

In summary, new efficient luminescent materials have been designed and synthesized through peripheral substitutions at 6-position of indolo[3,2-b]carbazole. They are highly luminescent both in solutions and in films. Electroluminescent devices with indolo[3,2-b]carbazole luminescent materials as the emitting layer were fabricated and exhibited excellent EL performance with low turn-on voltage, high brightness, and high efficiency. Our results demonstrated that indolo[3,2-b]carbazole is a very promising building block for the design of new efficient electroluminescent materials.

4. Experimental

4.1. Materials and characterization

5,11-di-n-octylindolo[3,2-b]carbazole (**1**) [17], 4-(Diphenylamino)phenylboronic acid [27], and 9,9′-di-n-butylfluorenyl-2-boronic acid [28] were synthesized according to the literature. The ^{1}H NMR and ^{13}C NMR spectra were obtained on a Bruker AV400 spectrometer. Elemental analyses were performed with a PE2400 elemental analyzer. UV–vis spectra were measured on a TU-1800SPC spectrophotometer. The fluorescence spectra measurements were performed with a Hitachi 4500 FL spectrophotometer. Thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC) measurements were carried out under a nitrogen atmosphere at a heating rate of 10 °C min^{-1} with a Perkin–Elmer Diamond thermogravimetric analyzer and a Perkin–Elmer Diamond DSC thermal analysis system, respectively. Electrochemical experiment were performed by using an EG&G model 283 electrochemical system. A platinum-disk working electrode, a platinum-wire auxiliary electrode, and an Ag/AgCl reference electrode were used in a three electrode configuration. The concentration of the samples in dichloromethane was 1.0 mM and Bu$_4$NClO$_4$ (0.1 M in dichloromethane) was used as supporting electrolyte with 50 mV/s scan speed.

4.2. Synthesis of 5,11-di-n-octyl-6-formyl-indolo[3,2-b]carbazole (**2**)

POCl$_3$ (0.22 mL, 2.4 mmol) was slowly dropped into a dry 100 mL flask, which contained DMF (0.19 mL, 2.4 mmol) and has been cooled with ice water bath in advance. The mixture was stirring while POCl$_3$ was dropping. A whole white solid bulk appeared in the flask soon end of dropping. 5,11-Di-n-octylindolo[3,2-b]carbazole (**1**) (962 mg, 2.0 mmol) dissolved in 30 mL 1, 2-dichloroethane was added to the flask, then ice water bath was removed. After the white solid bulk disappeared under room temperature, the reaction mixture was stirred and refluxed for about 24 h. The 1, 2-dichloromethane was evaporated out after completion of

the reaction. The remains were poured into 100 mL ice water. Sodium carbonate aqueous solution was added to modify the pH under vigorously stirring. After the pH at 8, continuously stirring was kept for about 1 h. The suspension was extracted with dichloromethane and washed with water and brine. The organic extracts were dried over anhydrous sodium sulfate. After removing the solvents under reduced pressure, the residue was purified by flash chromatography with light petroleum/dichloromethane (4:1) as eluent, and gave compound **2** (Yield: 477 mg, 40.8%) as orange solid. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm) δ: 0.83-0.86 (m, 6H), 1.23–1.46 (m, 20H), 1.79–1.83 (m, 2H), 1.90–1.95 (m, 2H), 4.42–4.46 (t, J = 7.29 Hz, 2H), 4.55–4.59 (t, J = 7.80 Hz, 2H), 7.28–7.32 (m, 2H), 7.45–7.56 (m, 4H), 8.19 (d, J = 7.66 Hz, 1H), 8.27 (s, 1H), 8.61 (d, J = 8.14 Hz, 1H), 11.35 (s, 1H). ^{13}C NMR (CDCl$_3$, 100.61 MHz, ppm) δ: 13.65, 22.11, 26.32, 26.88, 28.20, 28.44, 28.70, 28.83, 28.92, 31.27, 31.32, 42.68, 46.79, 104.82, 108.27, 109.33, 115.54, 118.34, 119.04, 119.35, 121.25, 121.83, 122.20, 124.41, 124.90, 126.13, 135.19, 135.48, 141.65, 142.92, 189.81. Anal. Calcd for C$_{35}$H$_{44}$N$_2$O: C, 82.63; H, 8.72; N, 5.51. Found: C, 82.61; H, 8.69; N, 5.50. Crystal structure of compound **2**: C$_{35}$H$_{44}$N$_2$O, M = 508.72, monoclinic, space group $P2_1/c$, a = 15.566(5) Å, b = 5.434(5) Å, c = 18.950(5) Å, β = 102.089(5)°, V = 1567.4(16) Å^3, Z = 2, T = 293(2) K, D_c = 1.078 g/cm^3. Unique 3592 reflections were measured by Bruker APEX2 CCD area-detector diffractometer using graphite monochromated Mo–Kα radiations (λ = 0.71069 Å, 2θ < 55°). The structure was solved by a direct method and refined by full-matrix least-squares calculations against F^2 with absorption corrections (SAD–ABS) using a program package SHELXL-97 (Sheldrick, 1997). Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in geometrically idealized positions and constrained to ride on their parent atoms with C–H distance in the range 0.93–0.97 Å. The final $R_1(F)$ = 0.0779 and $wR(F^2)$ = 0.2117, for 1156 ($I > 2\sigma(I)$) and independent 3592 reflections, respectively. Parameters were 182 and S = 0.919. Max shift/esd = 0.000. CCDC Reference Number 626638.

4.3. Synthesis of 5,11-di-n-octyl-6-(4-bromo-phenylethylenyl)indolo[3,2-b]carbazole (**3**)

Compound **2** (1.275 g, 2.5 mmol) and 4-bromobenzyl(triphenyl)phosphonium bromide (1.926 g, 3.75 mmol) was added to a dry 250 mL flask, and then added 100 mL dried dichloromethane. The mixture was stirred at room temperature and t-BuOK (2.526 g, 22.55 mmol) was slowly added to the mixture. The reaction mixture was stirred at room temperature for about 24 h. Then the suspension was extracted with dichloromethane and washed with water and brine. The organic extracts were dried over anhydrous sodium sulfate. After removing the solvents, The crude product was chromatographed on silica gel using petroleum/dichloromethane (4:1) as eluent, and gave compound **3** (Yield: 1.431 g, 86.3%) as yellow solid. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm) δ: 0.84–0.88 (m, 6H), 1.14–1.31 (m, 16H), 1.38–1.39 (m, 2H), 1.45–1.47 (m, 2H), 1.73–1.76 (m, 2H), 1.93–1.97 (m, 2H), 4.38–4.41 (t,

$J = 7.32$ Hz, $J = 7.23$ Hz, 2H), 4.45–4.39 (t, $J = 8.02$ Hz, $J = 7.88$ Hz, 2H), 6.93–6.97 (m, 1H), 7.04–7.08 (m, 1H), 7.21–7.25 (m, 1H), 7.37–7.47 (m, 4H), 7.49–7.61 (m, 4H), 7.97–8.02 (m, 2H), 8.18–8.25 (dd, $J = 7.65$ Hz, $J = 7.94$ Hz, 2H). ^{13}C NMR (CDCl$_3$, 100.61 MHz, ppm) δ: 14.06, 22.61, 27.07, 27.42, 28.76, 29.22, 29.25, 29.46, 31.74, 31.84, 43.19, 45.08, 97.88, 108.21, 108.77, 115.76, 117.84, 118.30, 119.97, 120.98, 121.94, 122.86, 123.21, 123.79, 125.26, 125.39, 125.88, 127.95, 132.14, 133.30, 134.85, 135.96, 136.01, 141.80, 142.65. MALDI–TOF, m/z: cal: 660.31, found: 660.2. Anal. Calcd for C$_{42}$H$_{49}$BrN$_2$: C, 76.23; H, 7.46; N, 4.23. Found: C, 76.60; H, 7.56; N, 4.12.

4.4. Synthesis of 5,11-di-n-octyl-6-[4-(triphenylamino)-phenylethylenyl]indolo[3,2-b]-carbazole (TPAP–ICZ)

Compound **3** (500 mg, 0.76 mmol), 4-(Diphenylamino)-phenylboronic acid (289 mg, 1 mmol), tetrakis(triphenyl-phosphine)palladium (0.116 g, 0.1 mmol), 20 mL THF and 10 mL (2 M) sodium carbonate aqueous solution under nitrogen, were added to a three-necked flask equipped with a magnetic stirrer, a reflux condenser, and a nitrogen input tube. The reaction mixture was refluxed in an oil bath under nitrogen. A yellow product was obtained after heating and stirring for about 24 h. The mixture was cooled to room temperature, extracted with 100 mL dichloro-methane, washed with water and dried over anhydrous so-dium sulfate. After removing the solvent under reduced pressure, the crude product was chromatographed on silica gel using petroleum/dichloromethane (4:1) as eluent, and gave TPAP-ICZ (Yield: 588 mg, 93.6%) as a yellow solid. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm) δ: 0.78–0.81 (m, 3H), 0.84–0.88 (m, 3H), 1.12–1.35 (m, 16H), 1.37–1.45 (m, 2H), 1.47–1.51 (m, 2H), 1.75–1.77 (m, 2H), 1.93–1.96 (m, 2H), 4.37–4.41 (t, $J = 7.11$ Hz, $J = 7.12$ Hz, 2H), 4.49–4.53 (t, $J = 7.70$ Hz, $J = 7.76$ Hz, 2H), 7.01–7.08 (m, 4H), 7.14–7.18 (m, 7H), 7.26–7.30 (m, 4H), 7.37–7.47 (m, 4H), 7.54–7.56 (m, 2H), 7.66–7.71 (m, 4H), 7.96–8.03 (m, 2H), 8.19 (d, $J = 7.65$ Hz, 1H), 8.34 (d, $J = 7.93$ Hz, 1H). ^{13}C NMR (CDCl$_3$, 100.61 MHz, ppm) δ: 14.05, 14.07, 22.61, 22.63, 27.09, 27.44, 28.77, 29.23, 29.28, 29.32, 29.48, 29.49, 31.75, 31.86, 43.18, 45.10, 97.67, 108.11, 108.76, 116.33, 117.84, 118.21, 119.95, 121.10, 122.92, 123.03, 123.07, 123.35, 123.72, 123.83, 124.21, 124.52, 125.19, 125.80, 126.95, 127.05, 127.59, 129.31, 133.40, 134.44, 135.58, 135.65, 136.05, 140.28, 141.80, 142.65, 147.37, 147.66. MALDI–TOF, m/z: cal: 825.5, found: 825.5. Anal. Calcd for C$_{60}$H$_{63}$N$_3$: C, 87.23; H, 7.69; N, 5.09. Found: C, 87.62; H, 7.75; N, 5.01.

4.5. Synthesis of 5,11-di-n-octyl-6-[4-(9,9′-di-n-butylfluorenyl)phenylethylenyl]-indolo[3,2-b]carbazole (DBFP–ICZ)

DBFP–ICZ was obtained by a similar procedure as for TPAP–ICZ. Yield: 567 mg, 86.8%. ^{1}H NMR (CDCl$_3$, 400 MHz, ppm) δ: 0.63–0.72 (m, 8H), 0.79–0.82 (m, 3H), 0.85–0.88 (m, 3H), 1.06–1.16 (m, 5H), 1.19–1.34 (m, 16H), 1.36–1.44 (m, 2H), 1.46–1.50 (m, 2H), 1.53 (s, 1H), 1.76–1.80 (m, 2H), 1.92–2.00 (m, 2H), 2.04–2.06 (m, 4H), 4.41–4.54 (m, 4H), 7.06–7.10 (m, 2H), 7.30–7.50 (m, 8H),

7.64–7.67 (m, 2H), 7.74–7.81 (m, 6H), 7.98–8.09 (m, 2H), 8.21 (d, $J = 7.70$ Hz, 1H), 8.36 (d, $J = 7.95$ Hz, 1H). ^{13}C NMR (CDCl$_3$, 100.61 MHz, ppm) δ: 13.82, 13.85, 14.06, 14.08, 22.59, 22.61, 22.63, 33.10, 26.02, 27.11, 27.45, 28.81, 29.24, 29.50, 31.73, 31.86, 40.29, 43.17, 45.06, 55.12, 108.16, 108.80, 117.87, 118.27, 119.77, 120.01, 121.22, 122.91, 123.05, 123.36, 124.40, 125.19, 125.81, 126.83, 126.98, 127.11, 127.63, 135.69, 135.91, 139.42, 140.66, 140.75, 141.31, 151.00, 151.47. MALDI–TOF, m/z: cal: 858.59, found: 858.6. Anal. Calcd for C$_{63}$H$_{74}$N$_2$: C, 88.06; H, 8.68; N, 3.26. Found: C, 88.44; H, 8.77; N, 3.17.

4.6. Device fabrication and characterization

Triple-layer devices were fabricated with a configura-tion of indium tin oxide (ITO)/NPB (30 nm)/EML (40 nm)/TPBI (40 nm)/LiF (1 nm)/Al (80 nm). The ITO glass was cleaned in ultrasonic baths of detergent, deionized water and acetone in sequence, and followed oxygen plasma cleaning. The organic films and metal electrode were sequentially deposited on the substrate by thermal evapo-ration under a vacuum of 10^{-6} Torr. The deposition rates were 2–3 Å/s for the organic materials and 5–7 Å/s for the cathode metals. The emitting area of the device was 4 mm^2. The thickness of films was measured by a Dektak surface profilometer. The EL spectra and current–voltage–luminance (J–L–V) characteristics were measured with a Spectrascan PR650 photometer and a computer-controlled DC power supply. All the measurements of the devices were carried out under ambient conditions.

It is advantageous, or may even be essential, to certain applications to employ materials with large band gap as transport or host materials. For instance, N,N′-bis(1-naphtyl)-N,N′-diphenyl-1,1′-biphenyl-4,4′-diamine (α-NPD), 4,4′-Bis(N-carbazolyl)-1,1′-biphenyl (CBP) and other aromatic diamine or carbazole derivatives are commonly used as hole transport materials and/or as ambipolar wide band gap hosts for phosphorescent dopants in organic light emitting diodes (OLEDs) [13]. P-type doping of these materials with F_4-TCNQ has been demonstrated, but is not as efficient as in the phthalocyanines. For α-NPD, the HOMO energy is 280 meV lower than the LUMO energy of F_4-TCNQ, resulting in a 40% lower doping efficiency when compared to F_4-TCNQ doping of ZnPc [8]. Only little effect on the electrical conductivity is expected when doping CBP and other carbazole-derivatives with ionization energies (IE) significantly larger ($\sim$1 eV) than the electron affinity (EA) of F_4-TCNQ, as was demonstrated for 4,4′,4″-tris(N-carbazolyl)-triphenylamine (TCTA) [14].

Transition metal oxides have been the subject of recent studies on charge transport and injection in organic electronic devices, and have been found to have a significant impact on their performance. Tokito et al. used thin sputtered metal oxide as anode interlayer for OLEDs and observed a significant decrease in driving voltage [15]. Their results were subsequently confirmed and attributed to a reduction in charge injection barrier [16–21]. Other applications of these high-work function materials have included electrodes for organic thin-film transistors [22] and charge injection layers for admittance spectroscopy [23]. Thin layers of MoO_3 or WO_3 have also been used as interconnecting units in tandem OLEDs [24,25] and organic photovoltaic (OPV) cells [26], demonstrating the high relevance of transition metal oxides for organic device applications. However, despite numerous papers related to the application of transition metal oxides in organic electronic devices, the underlying physical mechanisms pertaining to their electronic structure remain somewhat undefined.

We present in this paper a comprehensive study of p-type doping of α-NPD and CBP via co-evaporation with MoO_3. Doping of these materials is confirmed by charge carrier transport measurements and ultraviolet and inverse photoelectron spectroscopy (UPS/IPES) on MoO_3 and MoO_3-doped α-NPD and CBP thin films deposited on various substrates. The latter two techniques provide a conclusive explanation for the observed doping.

2. Experimental

Doping was performed by co-evaporation of organic molecules and MoO_3. MoO_3 (99.99% purity) and α-NPD were purchased from Sigma–Aldrich. Sublimed-grade CBP was obtained from Universal Display Cooperation. For thermal evaporation of MoO_3, we used a shielded high temperature evaporation source (CreaTec HTC) to minimize radiative heating of the sample. The organic materials were evaporated from resistively heated quartz crucibles. Deposition rates were measured by a quartz crystal microbalance (QCM) and controlled by the applied temperature. The deposition rate for the organic materials was $\sim$0.1 nm/

s and for MoO_3 set according to the targeted doping concentration. Characteristic film thicknesses were 50 nm for the I–V measurements and 10 nm for UPS and IPES experiments.

Device preparation for the I–V measurements and Kelvin Probe (KP) characterization was carried out at the TU Braunschweig in a multi-chamber vacuum system, with separate chambers for organic molecular beam deposition (OMBD, $p < 10^{-8}$ Torr) and metal electrode deposition ($p < 10^{-6}$ Torr). In-vacuo KP measurements were accomplished using a KP 6500 from McAllister Technical Services. I–V characteristics were recorded by a computer-controlled Keithley 2400 source-measure unit.

UPS and IPES spectra were taken at Princeton University using an ultra-high vacuum UPS/XPS/IPES analysis system ($p < 5 \times 10^{-10}$ Torr), which was connected to a growth chamber ($p < 5 \times 10^{-9}$ Torr) for the thermal evaporation of $MoO3$ and the organic materials.

We used the He I ($h\nu = 21.22$ eV) and He II ($h\nu = 40.81$ eV) lines of a He discharge lamp to measure the occupied electronic states. The experimental resolution for UPS was 0.15 eV, determined from the width of a Au Fermi step. The intensity of the He lamp photon line and the sample exposure time were kept to a minimum in order to reduce photo-induced damage. Unoccupied states were measured via IPES with a resolution of 0.5 eV [42]. The Fermi level reference for UPS and IPES measurements was determined for both techniques on a Au surface. The vacuum level was obtained from the secondary-electron cutoff as seen in the low kinetic-energy regime of the He I UPS spectra. EA and IP were approximated by the intersection of a linear extrapolation of the LUMO and HOMO edges, respectively, and the background signal.

3. Results and discussion

Single-carrier ("hole-only") devices were fabricated, consisting of an intrinsic or doped molecular film of CBP or α-NPD sandwiched between a hole-injecting electrode, i.e. indium tin oxide (ITO) covered with a 5 nm thin MoO_3 layer, and aluminum, i.e. a blocking contact. Another
Fig. 1. I–V characteristics of hole-only CBP devices as a function of Mo_3O_9 concentration. Doping concentration from bottom to top: 0/0.5/0.8/1.4/2.6/13.6/22.1 (mol%).

5 nm thin MoO_3 layer is introduced between Al and the organic semiconductor. Fig. 1 displays the current density vs. electric field (J–E) characteristics of CBP devices as a function of doping concentration (0–22.1 mol%). The device structure is given in the inset. Positive bias was applied to the bottom ITO contact, from which holes are injected into the device. Electron injection from the cathode can be neglected, due to the large electron injection barrier, which is even increased by inserting a MoO_3 interlayer. Thus, charge transport in this device is limited to holes. The current density for a given voltage increases with doping concentration, up to five orders of magnitude at the highest doping concentration investigated here. A comparable increase in current density is observed for doped α-NPD devices (not shown here).

As it has been reported before that the formation of a conducting path through transport via the dopant does not occur [14], the observed increase in current density can have two different origins: (1) a reduction in barrier height for hole injection, as already observed for MoO_3-doped α-NPD intermediate injection layers designed to facilitate hole injection into intrinsic α-NPD thin films [16], (2) a doping-induced increase in bulk conductivity. It was previously reported [3] that both effects must be taken into account when discussing transport characteristics of doped organic thin films. As the devices presented in Fig. 1 already include thin MoO_3-interlayers to facilitate charge injection [18,20,21], most of the observed increase in current density can be attributed to higher bulk conductivity in the doped samples.

The doping mechanism is investigated by comparing the electronic structure of MoO_3, α-NPD and CBP via UPS and IPES. The filled (valence) and empty state spectra of a 30 nm thick MoO_3 film on Au are shown at the bottom of Fig. 2a. Both spectra are referenced to the vacuum level. The density of filled states (valence band) of MoO_3 was recorded with the He II line because of a significant parasitic background due to the He I* line (23.09 eV) in the He I spectrum. The shape and position of the valence band, which are dominated by O 2sp electrons, are in agreement with published results [27–29]. In oxygen-deficient MoO_{3-x}, photoemission from Mo 4d orbitals would appear within the gap. The absence of gap-states suggests that the MoO_3 film is fully oxidized. In addition, the binding energy of the Mo $3d_{5/2}$ core level (232.1 eV) determined via X-ray photoemission spectroscopy (XPS, data not shown here) is found to be in good agreement with that of the Mo^{6+} species characteristic of stoichiometric MoO_3 [29,30]. The top of the valence band of the MoO_3 film, determined by linear extrapolation of the leading edge of the valence spectrum, is at 9.68 ± .1 eV below vacuum level.

In the context of p-doping, the energy of the unoccupied states of the acceptor dopant, are of major interest. The IPES data from the MoO_3 film, plotted at the bottom of Fig. 2a, show the conduction band (CB) edge at 6.7 eV below vacuum level (the relevance to the doping process of measurements on a MoO_3 film is discussed below). Combined with the UPS results, these IPES data define a band gap of 2.98 eV, in very good agreement with the band gap determined by optical measurements [31]. The position of the Fermi level appears to be pinned slightly below the CB edge, giving a work function Φ of 6.86 eV. The electronic structure reported here (IE = 9.68 eV and EA = 6.7 eV) is significantly different from that commonly cited in the literature (IE = 5.3 eV and EA = 2.3 eV) [20,22]. While these latter numbers do not result from direct experimental evidence, our results are confirmed by two independent, direct measurements, techniques (UPS and KP), which yield very similar work functions for MoO_3. Furthermore, different preparation and analytical conditions can severely affect the experimental result, as any contamination on a high-work function surface is likely to decrease the work function.

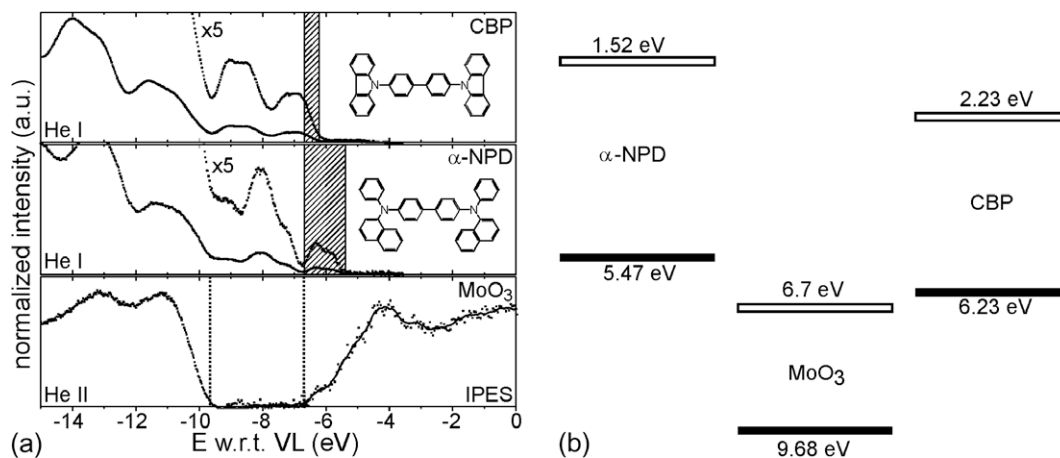
The UPS spectra of intrinsic CBP and α-NPD thin films are also included in Fig. 2a. The low binding energy edges of the HOMO features give ionization energies (IE) of 5.47 eV and 6.23 eV for α-NPD and CBP, respectively. The dashed area within the plots indicates the overlap between the unoccupied states of MoO_3 and the occupied states of α-NPD or CBP. The corresponding energy level diagrams


Fig. 2. (a) UPS and IPES spectra of a MoO_3 film (bottom), and UPS spectra of CBP (top) and α-NPD (middle) films, referenced to vacuum level, (b) Energy level alignment derived from UPS and IPES measurements, unfilled bars represent the empty states, filled bars represent the occupied states.

(Fig. 2b and [32]) indicate that electron transfer from the HOMO of CBP or α-NPD to the unoccupied states of MoO_3 is energetically favorable, with likely p-doping of these organic materials. The amount of MoO_3 incorporated into the organic thin film, the nature of the incorporated oxide species, and their impact on the electronic structure of the film, must be investigated. The analysis of MoO_3 sublimation from a Knudsen cell via mass spectroscopy has shown a predominance of polymeric species, i.e. $(MoO_3)_n$, $n > 2$, with a major fraction of the vapor consisting of Mo_3O_9 clusters [33]. In this work, we therefore assume that mainly Mo_3O_9 clusters are embedded into the organic matrix, an assumption that is largely validated below, and we refer to doping concentrations as the molar concentration of Mo_3O_9 clusters. In that context, one should consider that the electronic structure of Mo_3O_9 clusters may differ from that of the MoO_3 thin film discussed in Fig. 2, thus putting in question the energy diagram of Fig. 2b. However, theoretical calculations on transition metal oxide clusters based on density functional theory (DFT) have been published by several groups and have been used to predict the geometry and electronic structure of these clusters [34–36]. In particular, bulk-like properties have been predicted for W_4O_{12} and larger clusters, with a band gap of 3.5 eV [36]. These results were confirmed by UPS experiments on single $Mo_3O_9^-$ anions and ionized tungsten oxide clusters in a mass spectroscopy setup. In the neutral cluster, O 2p derived states make up the HOMO, while the LUMO is derived from Mo 4d orbitals. Furthermore, for the $Mo_3O_9^-$ anion, a gap of 3.2 eV was measured between the singly occupied Mo 4d derived states and the doubly occupied O 2p derived states [35]. Although the neutral cluster undergoes a change in geometry upon ionization, [34] a change which may also cause a difference in energy gap, the reported gap of 3.2 eV for the anion cluster should give a fairly good estimate of the band gap of the neutral Mo_3O_9 cluster. Hence, the energy gap of Mo_3O_9 clusters (~3.2 eV) is only slightly larger than the gap we measure on MoO_3 thin films (~3.0 eV). Therefore we suggest that the energy level alignment given in Fig. 2b gives a reasonable approximation of the electronic structure of the system, and justifies the electron transfer from the organic molecules to the Mo_3O_9 clusters.

The UPS spectra of 10 nm CBP films with various Mo_3O_9 doping concentrations are shown in Fig. 3a. The center plot represents the full valence spectrum recorded under He I excitation. Zoom-in plots of the secondary-electron cutoff and HOMO region are displayed on the left and right side, respectively. Vertical dotted lines mark the onset of photoemission, one of the valence features and the HOMO edge as a function of doping concentrations. A rigid shift of all these features towards lower binding energy occurs as the doping concentration increases, indicating a corresponding shift of the Fermi level within the gap towards the HOMO edge. Similar UPS measurements (not shown here) were conducted on MoO_3-doped α-NPD thin films, and produced very similar results. A summary of these UPS experiments on p-doped CBP and α-NPD thin films is given in Fig. 3b, where the position of the Fermi level with respect to the HOMO edge is plotted against the doping concentration. Two different regimes can be identified.
Fig. 3. (a) UPS spectra of MoO_3-doped CBP thin films for various Mo_3O_9 doping concentrations, (b) Energy difference between Fermi level and HOMO edge vs. Mo_3O_9 doping concentration in CBP (left) and α-NPD (right) films on ITO substrate, (c) Fermi level position in the gap of the organic semiconductor for an intrinsic/low doped film (left) and in the Fermi level pinning regime (right).

For low doping concentrations (<2 mol%), the Fermi level rapidly shifts towards the HOMO edge. This regime corresponds to a very large (relative) increase in carrier concentration, as the organic film changes from nearly intrinsic to fairly highly doped. In the second regime, further increase

of the doping concentration (>2 mol%) results in a comparably small Fermi level shift, as the Fermi level approaches regions of large density of states and is finally pinned at about 0.5 and 0.4 eV above the CBP and α-NPD HOMO edge, respectively. Similar results were previously obtained for the p-doping for α-NPD with F_4-TCNQ [8]. In that system, the difference between E_F pinning position and HOMO edge was explained by (i) the doping barrier for the α-NPD:F_4-TCNQ pair and (ii) the structural reorganization of ionized α-NPD molecules, which causes energetic relaxation of the molecular state above the HOMO. In the two present cases, the doping barrier should not be an issue, the EA of MoO_3 being larger than the IE of the two organic materials. A likely explanation for the observed Fermi level pinning involves therefore structural and energetic disorder of thermally evaporated molecular thin films, as depicted in Fig. 3c. Charge carriers in amorphous organic solids are relatively strongly localized to single molecules and polarization significantly affects the electronic structure of these solids [37]. Structural disorder will cause energetic disorder due to differences in the polarization energy for individual molecules. Energetic disorder in organic solids is often considered by assuming a Gaussian distribution of HOMO states, as indicated in Fig. 3c. In contrast, the HOMO edge is approximated by a linear extrapolation of the experimental data (Fig. 3c: dotted line). Depending on the distribution of the density of states close to the gap, there may be a significant density of tail states above the so-called HOMO edge. For low doping concentrations (here: < 2 mol%), the Fermi level rapidly shifts towards the HOMO edge. As the Fermi level approaches the HOMO edge (>2 mol%), a small shift is sufficient to induce a large change in the population of the tail states.

The difference in the magnitude of Fermi level shift between CBP and α-NPD (Fig. 3b) can be traced to the initial
Fig. 4. Energy level diagrams of interfaces between various substrates and intrinsic or MoO_3-doped α-NPD thin films, as derived from UPS and KP.

position of the Fermi level in the gap of the material (Fig. 4), which in turns depends on the energy level alignment, i.e. the interface HOMO and LUMO positions, for the specific substrate. In the cases presented here, the Fermi level position in the gap is mainly determined by the work function of the underlying substrate and the IE and EA of the organic semiconductor, as only a small dipole is observed at the interface. Upon doping, the position of the Fermi level is pinned less than 0.5 eV above the HOMO edge of the organic film, and nearly independent of the substrate work function. Since the Fermi level is deeper in the gap of undoped CBP (larger IE), the shift upon doping is expected to be larger, as indeed observed.

The effect of doping on the electronic structure and the conductivity of the molecular films can, in part, be derived from the I–V measurements presented in Fig. 1. The "hole-only" devices consisted of a single layer of either intrinsic or MoO_3-doped CBP, sandwiched between two inorganic electrodes. Using thin interlayers of neat MoO_3 greatly reduces the hole injection barrier at the ITO electrode, and increases the electron injection barrier at the Al electrode, insuring unipolar transport [21]. Although injection on the ITO/MoO_3 side may still limit the device characteristics to a certain extent, we assume ohmic charge injection. The slope of the current density vs. electric field (log–log plot) is nearly equal to unity in the low-field regime, indicating ohmic conduction. A linear fit of the ohmic regime can then be used to evaluate the conductivity. The essence of these I–V measurements is displayed in Fig. 5a, which shows the conductivity plotted against Mo_3O_9 concentration, along with the change in surface work function Φ measured by UPS and KP. As noted before, the Fermi level rapidly shifts towards the HOMO for low dopant concentrations (<2 mol%), inducing a rapid increase in work function. Higher doping levels lead to Fermi level pinning, which is reflected in a slower increase in Φ. A very similar relation is found for the electrical conductivity σ. For low doping concentrations, σ drastically increases upon doping. High doping concentrations still lead to an increase in conductivity but the slope of this increase is significantly reduced. The transition between the two regimes is around 2 mol%, in excellent agreement with the transition towards Fermi level pinning observed in UPS and KP measurements.

To understand this point, we model the DOS with a Gaussian distribution

$$g_{HOMO}(E) = \frac{N_{HOMO}}{w\sqrt{2\pi}} e^{-\left(\frac{E}{2w}\right)^2}, \tag{1}$$

where N_{HOMO} is the density of HOMO states and w is the Gaussian standard deviation. The energy E is referenced to the HOMO peak position, which was measured at 6.8 eV below the vacuum level. N_{HOMO} can be estimated at 3.8×10^{21} cm^{-3} by assuming a film density of 1.5 g/cm^3 and taking two HOMO states per molecule into account. The conductivity can be expressed as a function of Fermi energy following

$$\sigma(E_F) = e\mu_h n_h(E_F) \tag{2}$$

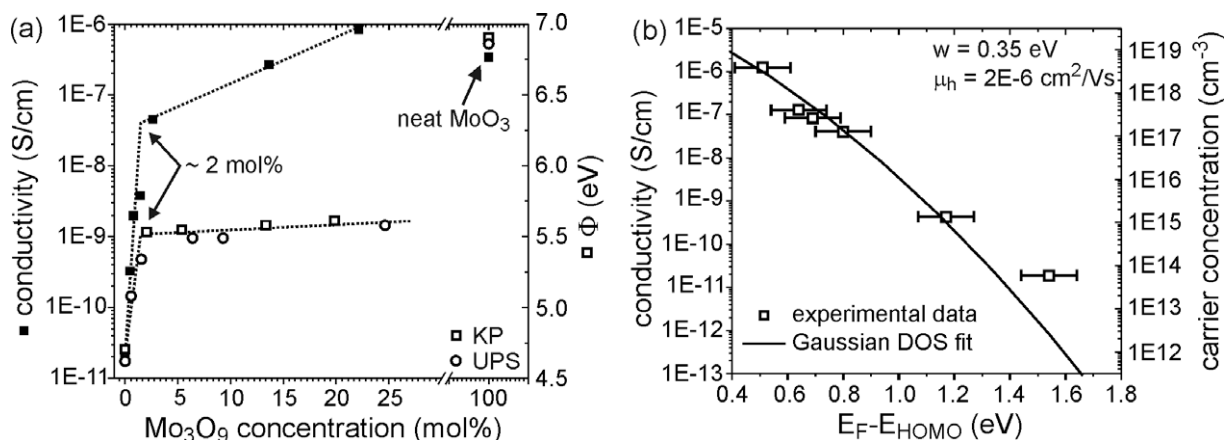
with e as the elementary charge, μ_h the hole mobility and n_h the hole carrier density. Applying expression (1) and Fermi statistics, Eq. (2) can be written as


Fig. 5. (a) Evolution of conductivity and WF vs. MoO$_3$ doping concentration in CBP thin films, (b) Conductivity vs. Fermi level position for the same samples.

$$\sigma(E_\mathrm{F}) = e\mu_\mathrm{h}\frac{N_\mathrm{HOMO}}{w\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{e^{-\left(\frac{E}{2w}\right)^2}}{1+e^{\frac{E-E_F}{k_\mathrm{B}T}}}dE \qquad (3)$$

We assume here a constant hole mobility μ_h to simplify the expression. Knowing that the carrier mobility in organic semiconductors may well depend, among other parameters, on the carrier concentration, [38] we expect a certain error within our calculations. The significance and impact of this error will be discussed later. In Fig. 5b we compare the experimental results for the conductivity to a calculation corresponding to Eq. (3). The experimental data was extracted from Figs. 3b and 5a by correlating the measured Fermi level position for a given doping concentration with the interpolated conductivity (see dotted line in Fig. 5a) at the same doping concentration. A close match between Eq. (3) and experiment can be established using the Gaussian standard deviation and the carrier mobility as fitting parameters. Only the intrinsic sample conductivity is much higher than predicted, which will be discussed later. The fit shown in Fig. 5b corresponds to $w = 0.35$ eV and $\mu_\mathrm{h} = 2 \times 10^{-6}$ cm^2/Vs. The standard deviation w is slightly larger than the corresponding value for similar calculations on n-doped pentacene (0.3 eV) [6]. Considering the lower degree of disorder in polycrystalline pentacene, both values appear very reasonable.

The discrepancy between the above CBP hole mobility and the higher mobilities determined by time-of-flight (TOF) measurements [39,40] or admittance spectroscopy (AS) [23] merits further discussion. The TOF and AS numbers were obtained for intrinsic CBP films, except for the work of Matsusue et al. [39] which included a study of electron transport in Ir-phosphor doped CBP. For these measurements, a doping concentration of a less than one percent leads to a dramatic mobility decrease to less than 10^{-6} cm^2/Vs. Although the interaction between matrix and dopant is clearly different for phosphor-doping (neutral dopant) than for electrochemical doping (ionized dopant), the effect of doping on charge transport should in both cases be modeled by a dopant-induced change in the DOS. Theory predicts that in disordered electronic systems, the interaction between dopant and matrix mole-

cules leads to additional broadening of tail states [41]. Furthermore, Coulomb-trapping of excess carriers at ionized dopant sites affects the carrier mobility. Depending on the initial width of the density of states distribution, a decrease in mobility of several orders of magnitude was calculated for high doping levels. Compared to the reference, our model calculations overestimate the initial width of the DOS by a factor of three or less, since broadening of the DOS due to p-doping is not been considered for reasons of simplicity. Still the mobility obtained from a model involving a Gaussian DOS is well within range of what can be expected when Coulomb trapping is considered.

Our calculations yield a carrier concentration which is equivalent to a dopant activation of about 0.5% or even less. Estimating the carrier concentration from the width of the depletion layer at the electrode interface (data not shown here) confirms a dopant activation of ∼0.4%. Yet, a much larger dopant activation could be expected from the energy level alignment depicted in Fig. 2b. This discrepancy may just be a result from the strong interaction, which is implied by the energy levels. The exchange of charge between the acceptor and the matrix molecules presumably leads to a strongly bound charge-transfer (CT) state, and only a small fraction of the exchanged charges participates in the current transport. As previously reported, the increase in near-infrared absorption in WO$_3$-doped TCTA may be an indicator for such a CT state [14].

There are two reasons for the calculated fit not to agree with the data obtained for the undoped CBP sample. As already mentioned, the carrier mobility should be a function of doping concentration, and is expected to be about three orders of magnitude higher for the undoped sample. Given the fact that a constant mobility is used in our calculation, the fit is likely to underestimate the real conductivity of intrinsic thin films. Furthermore, we showed that the position of the Fermi level in undoped thin films is not an intrinsic property of the film itself, but is strongly affected by the underlying substrate. Consequently, the position of the data point for the intrinsic sample becomes arbitrary with respect to the energy scale.

4. Conclusions

In conclusion, p-doping of organic large band gap materials using MoO_3 has been demonstrated and further investigated by photoemission spectroscopy. Very high EA (6.7 eV) and work function (6.86 eV) were measured on MoO_3 thin films. These values are assumed to give a good approximation of the electronic structure of Mo_3O_9 clusters, leading to a prediction of energetically favorable electron transfer from the HOMO of many hole transport materials to the deep-lying acceptor state of embedded Mo_3O_9 clusters. At low doping concentration (<2 mol%) in CBP and α-NPD, a rapid shift of the Fermi level towards the HOMO states and a steep increase in conductivity are observed. Further increase of the doping concentration leads to Fermi level pinning several 100 meV above the HOMO edge. The experimental results were modeled using a Gaussian distribution of the DOS, which yields a reasonable explanation for the observed phenomena. Due to a similar electronic structure, our results may possibly be valid for other transition metal oxides (e.g. WO_3), either being used as thin interlayer to enhance charge injection or as p-dopants for large IE host materials. Further, the observation of an extremely high-work function of MoO_3 may have a severe impact on other applications in related fields, for instance hybrid organic–inorganic photovoltaics.

performance in EL devices with related terbium complexes. DPPOC is synthesized by modification of the chemically active C3 and C6 positions on carbazole. Phenyl substitution at the 9-position of carbazole also has little effect on the photophysical characteristics of its derivatives [17,18]. We chose diphenylphosphine oxide moieties as building blocks to synthesize TPPO derivatives for both their coordinating abilities and carrier transport properties. Thermal stability was improved by 4-tert-butylphenyl substitution at the 9-position on carbazole. The complex Tb(PMIP)$_3$DPPOC was also synthesized and characterized. The high molecular weight of the complex precludes direct thermal evaporation so the terbium complex film was formed by co-deposition of complex **B** and DPPOC in vacuum for the OLED application. This technique was similar to previously reported work [19]. Stable pure green electroluminescence with high efficiency based on the multilayer emission structure of terbium complexes is thus demonstrated.

2. Experimental

2.1. General information

AlQ was synthesized according to literature procedures [20] and sublimed twice prior to use. NPB and BCP were purchased from Aldrich and used after a single sublimation. Tb(PMIP)$_3$(H$_2$O)$_2$ and Tb(PMIP)$_3$(TPPO)$_2$ were synthesized as in our previous report [13]. Chromatographic separation was carried out on silica gel (200–300 mesh). The ^{1}H NMR spectra were recorded on a Varian 400 MHz instrument using Me$_4$Si as an internal reference. Mass spectra were recorded on a ZAB-HS and BIFLEX III. Elemental analyses were performed on a VARIO EL analyzer. Thermogravimetric and differential thermal analyses were carried out on Q600SDT and Q100DSC instruments at an elevation temperature rate of 10 °C/min under 100 ml min^{-1} nitrogen. The IR spectra were recorded with a Magna-IR 750. PL spectra and phosphorescence decay lifetimes were recorded with an Edinburgh Analytical Instruments FLS920 spectrometer after removing oxygen in the solution by a vacuum technique (3 or 4 freeze–pump–thaw cycles). Absorption spectra were measured on a Shimadzu UV-3100 UV–visible spectrometer. Cyclic voltammetry was performed with a computer controlled EG&G potentiostat/galvanostat model 283. All measurements were carried out at room temperature with a conventional three electrode configuration consisting of a one compartment electrolysis cell with a platinum button, a platinum wire, a Ag/AgCl working electrode, counter electrode and reference electrode. Cyclic voltammograms were obtained at a scan rate of 50 mV s^{-1} in HPLC-grade dichloromethane. The concentration of the complexes was 1.0 mM and each solution contained 0.1 M tetrabutylammonium hexafluorophosphate (TBAP) as an electrolyte. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels were calculated by reference to the ferrocene/ferrocenium energy level of −4.8 eV. Fluorescence microscopy images were taken on an OLYMPUS BX51.

2.2. OLED fabrication and measurement

EL devices were fabricated by sequentially depositing organic layers using thermal evaporation in one run under high vacuum (<8 × 10^{-5} Pa) onto a cleaned indium tin oxide (ITO) glass substrate with a sheet resistance of 7 Ω/sq. The active device area was 3 × 3 mm. The cathode was made of a 200 nm thick layer of Mg$_{0.9}$Ag$_{0.1}$ alloy with an 80 nm thick Ag cap. The thickness of the deposited layer and the evaporation speed of the individual materials were monitored in a vacuum with quartz crystal monitors. Deposition rates were maintained at 0.05–0.2 nm s^{-1} for organic materials and 0.2–0.3 nm s^{-1} for the Mg$_{0.9}$Ag$_{0.1}$ alloy. All electrical testing and optical measurements were performed under ambient conditions. The EL spectra were measured with a Spectra Scan PR650. The current–voltage (I–V) and luminance–voltage (L–V) characteristics were measured with a computer controlled Keithley 2400 Sourcemeter unit with a calibrated silicon diode.

2.3. Materials

The synthetic route leading to DPPOC is presented in Scheme 1.

9-(4-tert-butylphenyl)carbazole (1): A suspension of carbazole (1.67 g, 10 mmol), 1-bromo-4-tert-butylbenzene (2.13 g, 10 mmol), copper (2.56 g, 40 mmol), K$_2$CO$_3$ (11.04 g, 80 mmol) and 18-crown-6 (0.53 g, 2 mmol) in 1,2-dichlorobenzene (100 ml) was stirred at 190 °C in an oil bath for 36 h under nitrogen. The solvent was evaporated and the solid residue was extracted with benzene. The combined organic extracts were evaporated and the crude product was purified via column chromatography on silica gel using a mixture of dichloromethane/petroleum ether (1/2) as eluent. The compound was further purified by recrystallization from a mixture of benzene–ether to give a white powder (2.09 g, yield 70%). ^{1}H NMR (400 MHz, CDCl$_3$, δ): 8.14 (d, J = 4 Hz, 2H), 7.60 (d, J = 4 Hz, 2H), 7.48 (d, J = 4 Hz, 2H), 7.37–7.43 (m, 4H), 7.27 (d, J = 8 Hz, 2H), 1.43 (s, 9H). EIMS (m/z (%)): 299 (100) [M$^+$].

9-(4-tert-butylphenyl)-3,6-dibromocarbazole (2): Compound **2** was synthesized according to the literature procedure [21] in a yield of 82%. EIMS (m/z (%)): 457 (100) [M$^+$]. ^{1}H NMR (400 MHz, CDCl$_3$, δ): 8.18 (d, J = 2 Hz, 2H), 7.61 (d, J = 4 Hz, 2H), 7.47–7.50 (m, 2H), 7.41 (d, J = 6 Hz, 2H), 7.26 (d, J = 4 Hz, 2H), 1.42 (s, 9H).

9-(4-tert-butylphenyl)-3,6-bis(diphenylphosphino)-carbazole (3): Compound **2** (2.0 g, 4.37 mmol) was dissolved in tetrahydrofuran (THF, 150 ml) under a nitrogen atmosphere. The reaction vessel was immersed in a dry ice/acetone bath until the temperature was about −78 °C. To this solution 8.17 ml (13.1 mmol) of 1.6 M n-BuLi solution in hexane was added dropwise and stirred for 1 h. Chlorodiphenylphosphine (2.39 ml, 13.1 mmol) was then added to the solution and stirred for 3 h in a dry ice/acetone bath. The mixture was allowed to gradually warm to room temperature overnight and then quenched with water. The desired product was extracted with dichloromethane and purified by column chromatography on silica gel with dichloromethane/petroleum ether = 1/4 as eluent produc-
Scheme 1. Synthetic route of DPPOC and chemical structures of the terbium complexes.

ing a white solid product (1.46 g, yield 51%). EIMS (*m/z* (%)): 667 (100) [*M*⁺]. ¹H NMR (400 MHz, CDCl₃, δ): 8.06 (d, 2 Hz, 2H), 7.57 (d, *J* = 6 Hz, 2H), 7.44 (d, *J* = 4 Hz, 2H), 7.37–7.40 (m, 4H), 7.33 (d, 20H), 1.40 (s, 9H).

9-(4-tert-butylphenyl)-3,6-bis(diphenylphosphineoxide)-carbazole (DPPOC): Compound **3** (1.33 g, 2 mmol) was dissolved in dichloromethane (50 ml) and excess 30% H₂O₂/H₂O (10 ml) was added with stirring to the ice bath for 1 h. The mixture was extracted with dichloromethane and dried with MgSO₄. The solution was concentrated by rotary evaporation and the crude product was purified by high vacuum thermal gradient sublimation to get the final product as a white solid (1.26 g, yield 90%). EIMS (*m/z* (%)): 699 (100) [*M*⁺]. ¹H NMR (400 MHz, CDCl₃, δ): 8.43 (d, 6 Hz, 2H), 7.66–7.74 (m, 10H), 7.61 (d, 4 Hz, 2H), 7.52–7.54 (m, 4H), 7.42–7.48 (m, 12H), 1.41 (s, 9H). IR ([cm⁻¹], KBr): 3042 (s, *ν*(C–H)); 1622, 1592 (benzene ring); 1436 δ(p-C₆H₅); 1198 *ν*(P=O); 1365, 1394, 1465 (t, δ(C–H)).

Tb(PMIP)₃DPPOC: To a 1.0 mmol solution of Tb(PMIP)₃(H₂O)₂ in 20 ml ethanol was added (dropwise) 1.0 mmol DPPOC in 50 ml ethanol while stirring and the mixture was heated to reflux for 4 h. The product was purified by recrystallization from ethanol with a yield of 80%. Anal. calcd for C₉₀H₉₀N₇O₉P₂Tb: C 66.54, H 5.33, N 6.17; Found: C 66.44, H 5.41, N 6.04. MALDI-TOF MS (*m/z*): 1344 (Tb(PMIP)₂(DPPOC)⁺, 100%), 1289 (45%). IR ([cm⁻¹], KBr):

cm⁻¹: 3057 (s, *ν*(C–H)); 1614, 1593 (benzene ring); 1439 δ(p-C₆H₅); 1172 *ν*(P=O).

3. Results and discussion

3.1. Absorption, fluorescence and phosphorescence

Fig. 1 shows the room temperature absorption (CH₂Cl₂, 10⁻⁵ M), fluorescence (CH₂Cl₂, 10⁻⁵ M) and phosphorescence (ethanol, 10⁻⁵ M) of TPPO, DPPOC and related terbium complexes. The distinct absorption of DPPOC at shorter wavelengths of 254 and 278 nm with ε around 5 × 10⁴ dm³ mol⁻¹ cm⁻¹ may be assigned to the localized benzene π → π* transition and the broad absorption bands at 325–350 nm are attributed to the carbazole-based lowest π → π* transitions which resemble the absorption of the carbazole monomer [18]. Complex **A** with absorption peaks at around 253 and 277 nm has similar UV–visible characteristics to DPPOC but a much higher ε of about 1.2 × 10⁵ dm³ mol⁻¹ cm⁻¹. This indicates that the absorption is due to both the anionic ligand PMIP and the neutral ligand DPPOC.

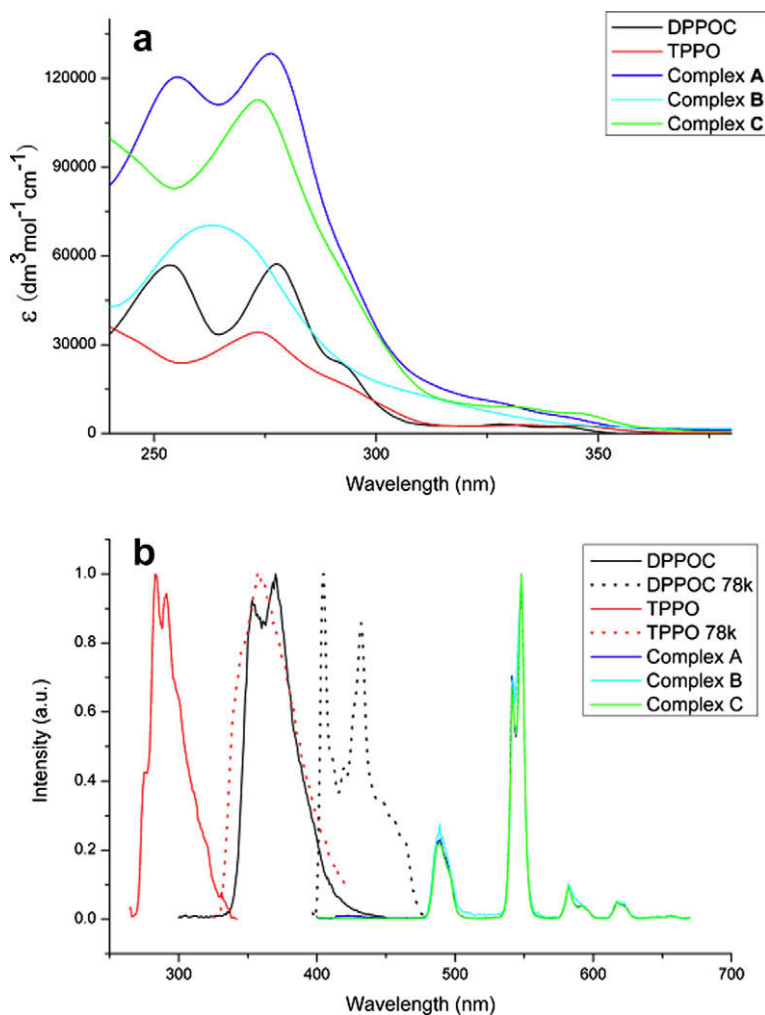
The PL spectra of the complexes showed strong terbium ion emission at λ = 488 nm (⁵D₄ → ⁷F₆), 548 nm (⁵D₄ → ⁷F₅), 582 nm (⁵D₄ → ⁷F₄) and 617 nm (⁵D₄ → ⁷F₃). The fluorescence spectrum of DPPOC with peaks at 353


Fig. 1. Absorption spectra of TPPO, DPPOC and related complexes (10^{-5} M in CH_2Cl_2) at room temperature (a), fluorescence (solid line, 10^{-5} M in CH_2Cl_2) and phosphorescence spectra (dotted line, 10^{-5} M in ethanol) of neutral ligands and related terbium complexes (b).

and 370 nm as well as its gadolinium complex's phosphorescence spectrum (at 78 K) with a peak at 405 nm (see Fig. 1) are similar to those of the unsubstituted carbazole monomer. These peaks may be attributed to the lowest π–π^* transitions of the central carbazole chromophore in DPPOC [17]. The phosphorescence spectrum reveals the lowest triplet energy level of DPPOC which is estimated to be 24,691 cm^{-1} (3.04 eV). The 4300 cm^{-1} energy difference allows energy transfer between DPPOC and the $^5D_4$ level (20,400 cm^{-1}) of Tb(III). The lowest triplet energy level of TPPO is at 27,933 cm^{-1} (3.46 eV). The overall luminescent quantum yields of the three terbium complexes are 10.4%, 14.6% and 16.7% for Tb(PMIP)$_3$(H$_2$O)$_2$, Tb(PMIP)$_3$(TPPO)$_2$ and Tb(PMIP)$_3$DPPOC, respectively (see Table 1). DPPOC thus performs better than TPPO as a neutral ligand because of its better suited triplet energy level [22].

The deposited DPPOC film exhibits a different emission spectrum compared with its CH_2Cl_2 solution and a new broad peak at 424 nm is observed (Fig. 2). There is little

overlap between the absorption spectrum of the Tb(PMIP)$_3$ film made by vacuum deposition of complex **B** [13] and the emission spectrum of the DPPOC film. When a vacuum co-deposited film of complex **B** and DPPOC (molar ratio = 1:1) was made, the fluorescence of DPPOC film at 424 nm is quenched as the emission is mainly observed from the $^5D_4 \rightarrow {}^7F_j$ (j = 3–6) transitions of the terbium ion. The data thus confirms that the energy absorbed by DPPOC is transferred to a terbium ion and thus sensitizes it efficiently upon coordination. The emission is very weak with a peak at 420 nm which is due to unchelated DPPOC in the co-deposited film as reported previously [19].

3.2. IR spectra

To confirm chelation the IR spectra of the co-deposited Tb(PMIP)$_3$ and DPPOC film and the deposited DPPOC film (both 800 nm thick) were measured and compared to solid powder samples of Tb(PMIP)$_3$DPPOC and DPPOC which were synthesized as described in the experimental section.

Table 1

Fig. 2. Absorption (dotted line) spectrum of the Tb(PMIP)$_3$ film and PL spectra (solid lines) of the vacuum deposited DPPOC film and the co-deposited Tb(PMIP)$_3$ and DPPOC film.

The characteristic P=O stretching vibration of DPPOC powder is found at 1198 cm^{-1}. There are two P=O stretching vibration bands of Tb(PMIP)$_3$DPPOC powder at 1195 cm^{-1} (similar to free DPPOC) and at 1172 cm^{-1} which is 25 cm^{-1} red shifted and shows that chelation between P=O and the terbium ion occurred. This data is similar to that for TPPO and related terbium complexes as previously reported [23]. The two different v(P=O) absorption bands indicate that both the P=O donors in DPPOC did not chelate simultaneously. The absorption bands of v(P=O) in the deposited DPPOC film was found at 1194 cm^{-1} and is similar to the DPPOC powder. In the co-deposited Tb(PMIP)$_3$ and DPPOC film two peaks at 1168 and 1195 cm^{-1} were observed which agrees with the Tb(PMIP)$_3$DPPOC powder data. The chelation of DPPOC and complex **B** thus occurs when they are co-deposited on the substrate and the emitting material produced after co-deposition may be a mixture of polymeric materials that are linked by DPPOC bridges. This vacuum co-deposition technique is favorable for EL device fabrication.

3.3. Cyclic voltammetric studies

Cyclic voltammetry (CV) was conducted to investigate electrochemical properties of the compounds. The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the materials were estimated by CV and UV–visible. Only oxidation potentials of the terbium complexes were measured as CH$_2$Cl$_2$ can not be used to determine reduction potentials from −2.7 to −3.5 V [24]. The three complexes have the same first oxidation potential and the same lowest energy absorption edge as shown in their UV–visible absorption spectra (Fig. 1). This indicates that they have similar HOMO and LUMO energy levels of 5.4 and 1.9 eV, respectively.

3.4. Thermal properties and morphological stabilities

Thermal properties were determined by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The melting point (T_m) of DPPOC is about 301 °C and

the thermal decomposition temperature (T_d) is 440 °C with a T_g of 137 °C, which shows that DPPOC exhibits better thermal stability than TPPO (T_m 156 °C, T_d 228 °C and no T_g observed). The complex Tb(PMIP)$_3$DPPOC also shows higher thermal stability (T_d 440 °C) than Tb(PMIP)$_3$(TPPO)$_2$ (T_d 350 °C) and Tb(PMIP)$_3$(H$_2$O)$_2$ (T_d 253 °C). The morphological stability of the material was confirmed by fluorescence micrographs and these are shown in Fig. 3. The co-deposited Tb(PMIP)$_3$DPPOC film (image A) was stable and showed no apparent crystallization or aggregation at 120 h after fabrication. The Tb(PMIP)$_3$(TPPO)$_2$ film (image B) showed obvious dewetting after 24 h, and serious crystallization (bright spots in B3 and B4) after 48 h. These morphological changes of the amorphous films are caused by poor thermal stability of the unchelated TPPO. In accordance with our molecular design we substituted DPPOC for TPPO which produced a morphologically stable amorphous film and would thus significantly improve OLED's stability.

3.5. Electroluminescence properties

By introducing NPB and AlQ as hole and electron transporting materials respectively and BCP as a hole blocking material devices A1–A4 were fabricated. The structures were ITO/NPB (30 nm)/co-deposited Tb(PMIP)$_3$DPPOC (A1: 20 nm, A2: 30 nm, A3: 40 nm, A4: 60 nm)/BCP (10 nm)/AlQ (30 nm)/Mg$_{0.9}$Ag$_{0.1}$. Different thicknesses of co-deposited Tb(PMIP)$_3$DPPOC were used as the emitting layer (Fig. 4). All of the devices showed the characteristic green emission from Tb^{3+} at low voltage. At practical brightness an emission from NPB was observed and device A1 only showed a small amount of emission from the terbium complex (Fig. 5). This indicates that DPPOC has fairly good electron transport properties and that the small energy gap between the LUMO of the terbium complex and of NPB allows electron transport into the NPB layer. By increasing the thickness of the complex layer from 20 to
Fig. 4. The EL device structure and chemical structures of the materials employed.

60 nm the emissive area changed from NPB layer to the terbium complex layer at high voltage. The power efficiencies increased from 2.6 lm W^{-1} (6.0 V) for device A1 to 5.2 lm W^{-1} (7.0 V) for device A4 (Fig. 6). Because DPPOC has both electron and hole transporting groups, the carriers mainly recombined in the co-deposited Tb(PMIP)$_3$DPPOC layer when its thickness was increased. The higher PL quantum yield of the lanthanide complexes led to higher EL efficiencies. The greater thickness of the EML (emission layer), however, resulted in lower current density which limited the luminance of the devices. Device A2 had the highest luminance of 1331 cd m^{-2} at 19 V. A small improvement in efficiency at high voltage was observed but the current density and the luminance decreased significantly when the EML thickness was increased beyond 30 nm.

Devices B1–B3 with configurations of ITO/NPB (10 nm)/Tb(PMIP)$_3$ (B1: 10 nm; B2: 15 nm, B3: 20 nm)/co-deposited Tb(PMIP)$_3$DPPOC (30 nm)/BCP (10 nm)/AlQ (20 nm)/
Fig. 3. Fluorescence microscopy images of vacuum co-deposited complex **A** (Tb(PMIP)$_3$DPPOC) and complex **C** (Tb(PMIP)$_3$(TPPO)$_2$) films on glass at different times after fabrication at room temperature.
Fig. 5. Intensity normalized EL spectra of devices A1–A4 at 100 cd m^{-2} (inset: intensity normalized EL spectra at highest brightness).
Fig. 6. Power efficiency (solid symbols) and luminance (open symbols) versus voltage of devices A1–A4.

Mg$_{0.9}$Ag$_{0.1}$ were fabricated to confine carriers in the emitting layer for better EL performance. Co-deposited Tb(PMIP)$_3$DPPOC layer was kept at 30 nm and Tb(PMIP)$_3$ complemented as hole-transporting material. With a Tb(PMIP)$_3$ layer thickness increased from 10 to 20 nm the carriers were confined within the layers of the complexes and thus more excitons contributed to the lanthanide luminescence process. Compared to device A4, from which the emission of NPB was observed at practical luminance (Fig. 5), device B3 showed pure emission that originated from the terbium complex even at the highest applied voltage (Fig. 7). The maximum brightness improved from 1020 cd m^{-2} (16 V) for A4 to 2256 cd m^{-2} (16 V) for B3 and the power efficiency from 5.2 lm W^{-1} (7 V) to 16.1 lm W^{-1} (5 V), respectively. This also confirmed that

the carrier recombination zone was confined well within the complex layers so the maximum brightness and highest efficiency were both achieved in device B3. At a practical brightness of 119 cd m^{-2} (11 V) the efficiency remained above 4.5 lm W^{-1}, 15.7 cd A^{-1} (Fig. 8). The EML with a multilayer structure for the lanthanide ions is quite different from that of other phosphor materials such as iridium complexes. Multilayer structures with EMLs usually emit hybrid light which are used in white emitting OLEDs [25]. For lanthanide complexes extremely pure light is achievable because their emission is due to electronic transitions of the central ions and this emission is different to the MLCT emission of iridium complexes. Lanthanide complexes are advantageous as their sharp emission bands are maintained while ligands are modified to improve PL
Fig. 7. EL spectra of device B3 at different applied voltages.
Fig. 8. Power efficiency (open squares), current efficiency (solid circles) and voltage characteristics of device B3 (inset: luminance, current density and voltage characteristics of device B3).

efficiencies. Based on this multilayer EMLs devices, recombination zone was limited and pure emission from lanthanide ions was achieved with a high efficiency.

4. Conclusions

We have synthesized new diphenylphosphine oxide substituted carbazole derivative (DPPOC) that retains suitable triplet energy level while exhibiting enhanced morphological stability with a high glass transition temperature. By the vacuum co-deposition technique a terbium complex (Tb(PMIP)$_3$DPPOC) film was formed and OLED devices were fabricated. Electroluminescent performance revealed that the multilayered emission structure helped to capture all the injected charges to form excitons in a confined zone. Highly pure Tb^{3+} ion emission was achieved even at the highest applied voltage and high efficiency was obtained. The modification for suitable ligands and multilayered EML structures may improve lanthanide EL properties for future use in devices.

devices with different gate metals were studied by the repetitive gate voltage sweep of OTFTs, and capacitance–voltage (C–V) and trap loss-voltage ($G_p/\omega-V$) measurements of metal–insulator–semiconductor (MIS) devices. It showed that the hysteresis in OTFTs was associated with electron injection from gate electrode to insulator. The application of gate metal with high work function increased the injection barrier between gate and insulator. As a result, low hysteresis OTFTs were obtained.

2. Experimental

2.1. Materials

The Corning 7059 alkali-free glass substrates were purchased from Chengdu Guangming Optoelectronic Co. (China). The glass substrates were cleaned in two sequential steps with chromic acid lotion and deionized water in ultrasonic bath. BCBO derivatives (Fig. 1a) were synthesized according to Ref. [18]. BCBO derivatives were dissolved in tetrahydrofuran, and the solution was filtered three times through a 0.22 μm glass syringe filter. The vanadyl-phthalocyanine (VOPc) was purchased from Aldrich Company (USA). The para-sexiphenyl (p-6P) sample was synthesized according to a described method [19]. Both of the samples were purified twice by thermal gradient sublimation prior to deposition.

2.2. Fabrication of vanadyl-phthalocyanine (VOPc) TFTs and MIS diodes

Fig. 1b shows the schematic structure of VOPc thin-film transistors. Before the deposition of the metals, 140 nm BCBO films were spin-coated onto glass substrates to smooth the rough glass surfaces. Thermal-evaporated Al and Au films about 100 nm and magnetron-sputtered Cr film about 200 nm were deposited on the glass substrates respectively, and were used as gate electrodes. The room-meat-square (rms) roughness of Al, Cr and Au are 1.3 nm, 1.2 nm and 1.3 nm measured by atomic force microscopy (AFM). The 200 nm Ta_2O_5 films were deposited by magnetron-sputter on the gate electrodes. The rms roughness of Ta_2O_5 on Al, Cr and Au is 2.7 nm, 2.5 nm and 2.6 nm, respectively. These surfaces are too rough for the growth of organic semiconductors [20]. One percent benzocyclobutenone (BCBO) thin layer was spin-coated onto the Ta_2O_5 film to obtain preferable interface. Then, the BCBO film about 140 nm was cross-linked by ultraviolet exposure and formed double-layer insulator. As shown in Fig. 2, the double-layer insulator exhibits very smooth surfaces with rms roughness about 6 Å. The reduction of rms roughness for double-layer insulator is caused by the viscous BCBO solution which fills up the valley regions of the rough metal/Ta_2O_5 substrate [21]. The rms of Al and Al/Ta_2O_5 are also given in Fig. 2. Three nanometers p-6P and a 30 nm VOPc were successively deposited on the double-layer insulator by vacuum thermal deposition at a substrate temperature of 180 C under the pressure of 10^{-4} Pa. We selected VOPc as the active layer because it is a kind of organic semiconductor with good physics and chemistry stability [22,23]. During the analysis of hysteresis, the influence from active layer can be excluded. VOPc showed weak epitaxy growth (WEG) behavior on the ordered p-6P layer [22]. The growth mode of VOPc film is changed to be layer-by-layer growth behavior rather than the island

growth. The weak epitaxy growth (WEG) of VOPc molecules on the p-6P layer lead to their high in-plane orientation. In addition, the VOPc films are consisted of lamellar crystals, which are intimately connected with each other. Therefore, the traps at grain boundaries and interface are quite less. Finally, 40 nm Au source/drain electrodes were thermally evaporated onto the VOPc films by a shadow mask. The defined channel width (W) and length (L) were 1000 and 150 μm, respectively. The current–voltage measurements were carried out by two Keithley 236 source measurement units at room temperature. Circular dots of metal films with 2 mm diameter were also deposited onto VOPc films by the shadow mask to fabricate the MIS de-

vices. The Electrical characterization of the MIS devices was performed with an Agilent E4980A *LCR* meter at room temperature in a dark electromagnetic shielding box.

3. Results and discussion

Fig. 3 shows the transfer characteristics of VOPc TFTs with different metals Al, Cr and Au as gate electrodes at the drain voltage V_{DS} of -20 V. All of the involved data are listed in Table 1. The leakage current of all TFTs is at the 10^{-9} A level. This low leakage current is owing to the excellent insulation of Ta_2O_5/BCBO double-layer. Therefore, the analysis below is not affected by the leakage current. Devices with low work function metals Al and Cr as

[c] The threshold voltage shift of hysteresis of *I–V*.

gate electrodes exhibited large hysteresis when the gate bias swept from 10 V to −50 V and back from −50 V to 10 V. The average threshold voltage shift was 2.6 V for Al as gate electrode and 2.5 V for Cr as gate electrode, respectively. But the devices using high work function metal Au as gate electrode showed a lower hysteresis under the completely same range of voltage scans. Fig. 3c shows the representative current–voltage (I–V) curves of OTFTs with Au as gate electrode. The average threshold voltage shift of several devices was 0.7 V. So, the lower hysteresis OTFTs have been realized by using Au as gate electrode instead of Al or Cr as gate electrodes.

There are several arguments as to the origin of the hysteresis of OTFTs: (1) charge injection, movement, and storage in the dielectrics [11,24–28], (2) channel/dielectric interface trap [23,29–31], (3) slow polarization of gate dielectric [24,32,33]. Slow polarization and channel/dielectric interface trap are not the dominant mechanism of the hysteresis in this case, because these devices have the same insulator materials and channel/dielectric interface. Therefore, electron injection is likely to be the dominant mechanism of hysteresis.

Repetitive gate voltage sweep of VOPc TFTs was used to analyze the reason for the variation of hysteresis, as shown in Fig. 4. Fig. 4a and b shows the transfer characteristics of the devices using Al and Cr as gate electrodes. Threshold voltage moved to more positive side until the gate voltage sweep was repeated up to five times, from −7.9 V to −4.0 V for Al as gate electrode and from −9.2 V to −6.2 V for Cr as gate electrode. It is presumed that electrons have been injected to the insulator from Cr and Al gate electrodes under the applied electric fields during the repeated voltage

sweep [25]. However, for the transistor in which Au was used as gate electrode, the fifth transfer curve almost coincided with the first transfer curve (Fig. 4c). The negligible threshold voltage shift demonstrates that electron injection decreases in a great extent compared with devices using Al and Cr as gate electrode. Robertson and coworkers have calculated the electron schottky barrier height of various metals including Al and Au on Ta_2O_5, which are 0.9 eV for Al and 1.34 eV for Au on Ta_2O_5 [34]. The work function of Cr (about 4.5 eV) is slightly higher than the work function of Al (about 4.3 eV), and is lower than the work function of Au (about 5.1 eV). From the results of I–V and the work function value of the three metals, the barrier height of Cr on Ta_2O_5 should be slightly higher than the value of Al on Ta_2O_5 and is lower than the value of Au on Ta_2O_5. In other words, the electron barrier heights of Al and Cr on Ta_2O_5 are lower than the electron barrier height of Au on Ta_2O_5. Therefore, Al and Cr give electrons to Ta_2O_5 insulator more easily compared with Au. In this case, it exhibited more threshold voltage shift using Al and Cr as gate electrodes. Based on the comprehensive analysis of the hysteresis characteristics, the electron injection from gate electrode to insulator may be the reason of hysteresis in these devices.

Capacitance–voltage (C–V) measurement is another effective approach to analyze the hysteresis characteristics of devices. In order to verify the place where hysteresis took place, another kind of MIS devices consisting of Cr/BCBO/6P/VOPc/Au were fabricated. Fig. 5a–d show the C–V curves of MIS diodes, in which the gate bias sweep is from 20 V to −20 V and back from −20 V to 20 V. As shown in Fig. 5a and b, the hysteresis is negligible for Cr/BCBO/6P/
Fig. 5. Capacitance–voltage characteristics of VOPc MIS devices with different metals as gate electrodes and different insulators: (a) Cr–BCBO, and (b) Cr–Ta_2O_5/BCBO, and (c) Al–Ta_2O_5/BCBO, and (d) Au–Ta_2O_5/BCBO. The gate voltage swept in both directions.

VOPc structure while it is obvious in Cr/Ta$_2$O$_5$/BCBO/6P/VOPc structure. This indicates that the hysteresis comes from the Ta$_2$O$_5$ layer rather than the interface between BCBO and active layer. So, the use of BCBO as second-layer insulator eliminated the effect of the interface charges and interface traps of Ta$_2$O$_5$ on hysteresis [15–17]. As shown in Fig. 5b–d, the hysteresis decreases with increasing work function of gate electrodes, which is consistent with the I–V characteristic of OTFTs. For the closed loop of C–V curves, the integral corresponds to the stored charge after a sweep cycle. For the Cr and Al as gate electrodes, the integral of closed loop of C–V curves are not equal to zero. Obviously, from Fig. 4b and c we can see the charge is negative. According to the reasoning above, this negative charge is owing to the electron injection from Cr and Al electrodes to Ta$_2$O$_5$.

Fig. 6 shows the C–V curves of MIS diodes using Ta$_2$O$_5$/BCBO double-layer insulator with Al, Cr and Au as gate electrodes, the gate bias is repeatedly swept from 20 V to −20 V. The C–V curves moved to more positive voltage when Al or Cr was used as gate electrode, which also indicated that electrons had been injected to Ta$_2$O$_5$ insulator [35]. However, the C–V curve almost didn't move for devices with Au as gate electrode. It indicates electrons injected to Ta$_2$O$_5$ insulator were decreased. Fig. 7 shows the G_p/ω–V curves of MIS diodes with different metals as gate electrodes at the constant frequency of 50 Hz. At neg-
Fig. 7. The trap loss G_p/ω of VOPc MIS diodes with Al, Cr and Au as gate electrode versus gate voltage at the constant frequency of 50 Hz.

ative voltage, extra energy loss peaks were observed when Cr or Al was used as gate electrodes compared with Au as gate electrode. Combined with experiment of repetitive gate bias sweep of C–V for devices with different metals as gate electrodes, we can conclude the generation of energy loss peaks originated from the electron injection from gate metal to Ta$_2$O$_5$ [35]. When Au was used as gate electrode, the electron barrier between gate electrode and Ta$_2$O$_5$ was enhanced. The higher electron barrier reduced the amount of electron injection from Au to Ta$_2$O$_5$. Therefore, there were no peaks in G_p/ω–V curves at negative voltage region. These experiments about MIS structure also proved that the hysteresis originated from the electron injection from gate metal to Ta$_2$O$_5$. Therefore, choosing high work function metal as gate electrode is an effective method to fabricate low hysteresis devices.

4. Conclusion

In conclusion, we have demonstrated the influence of work function of gate electrode on the hysteresis characteristics of VOPc devices with Ta$_2$O$_5$/BCBO as double-layer gate insulator. Hysteresis was caused mainly by electrons injection from gate electrodes to Ta$_2$O$_5$ insulator when low work function metals, such as Cr and Al, were used as gate electrodes. Using high work function Au as gate electrode could enhance the barrier and weaken the electron injection between gate electrode and Ta$_2$O$_5$ insulator. Thus low hysteresis organic thin-film transistors were obtained. It is a simple and effective way to decrease hysteresis.

thyl-containing molecule which was used as light emitting material in OLED with a turn-on voltage of 2.2 V, a maximum luminance of 8315 cd m^{-2}, and a maximum luminescence efficiency of 1.95 cd A^{-1}.

One of the significant properties of the electroluminescence (EL) devices is the durability. The degradation mechanisms in the OLEDs are not yet fully understood, but several studies indicate that one reason of the degradation is the morphological changes of the organic layers [20,21], such as dimerization and crystallization which seem to be caused by joule heating during device operation [22]. The organic materials tend to dimerize or crystallize when they are allowed to stand at ambient temperature or heated above their glass-transition temperature (T_g) [23]. Thus organic materials with high T_g is propitious to realize high stability OLEDs [23–27]. In addition, it was found that the lower the energy barrier of hole injection at the interface of the ITO/hole-transporting layer (HTL), the lower joule heat produced at the interface [6,28]. For this reason, the energy barrier between the ITO/HTL interface should be as small as possible in order to implement high stable OLEDs, which means the HTM should have a proper the highest unoccupied molecular orbital (HOMO) energy level for hole injection [6]. Therefore, the ideal HTM should have excellent solubility, good film forming property from solution, high thermal stability, proper HOMO energy level for efficient hole injection and high mobility.

Along this respect, in this paper, we reported two solution-processable and thermal-stable hole-transporting triphenylamine-based dendrimers whose structures are shown in Scheme 1 [29]. As compared to those of reported cases, the dendrimers showed high thermal stability with high T_g of 115 °C for Tr-TPA3 and 140 °C for Tr-TPA9 and the Tr-TPA9-based device exhibited the turn-on voltage of 2.5 V, the maximum luminance of about 11,058 cd m^{-2} and the maximum current efficiency of 4.01 cd A^{-1}. The dendrimers also exhibited excellent solubility, good film forming property, and proper HOMO energy level for hole injection.

2. Experimental

2.1. Materials and measurements

The synthesis of two truxene-centered dendric triphenylamine derivatives Tr-TPA3 and Tr-TPA9 have been described in our previously work [29]. Poly-(3,4-ethylene-dioxy-thiophene):poly-(styrenesulphonic acid) PEDOT:PSS was purchased from Bayer AG. Alq$_3$ and NPB were synthesized in our laboratory and purified by train sublimation.

Differential scanning calorimetry (DSC) measurements and thermogravimetric analysis (TGA) were performed on a NETZSCH (DSC-204) and a Perkine Elmer Pyris 1 analyzer under N$_2$ atmosphere, respectively. Photoluminescence (PL) and absorption spectra were recorded by a Shimadzu RF-5301PC fluorescence spectrophotometer and a Shimadzu UV-3100 spectrophotometer, respectively. Electrochemical measurements of these derivatives were performed with a Bioanalytical Systems BAS 100 B/W electrochemical workstation.

2.2. OLED fabrication and measurement

A double-layer devices with a configuration of ITO/dendrimers (70 nm)/Alq$_3$ (60 nm)/LiF (0.6 nm)/Al were fabricated, in which dendrimers were used as HTL and Alq3 was used as the electron-transporting layer (ETL) and emitting layer. The indium-tin oxide ITO-coated (20Ω/□) glass substrates were cleaned by ultrasonic treatment in detergent solutions, rinsed with acetone, boiled in isopropyl alcohol, rinsed with methanol, and then with de-ionized water. The dendrimers was spin-coated on the pre-cleaned ITO glass at the speed of 2000 cycles/min for 30 s from the 10 mg/ml chloroform solution. The thickness of
Scheme 1. Chemical structures of the dendrimers.

the dendrimer layer was ∼70 nm, measured by the Ambios Technology XP-2. A 60 nm-thick Alq₃ was deposited onto the hole-transporting layer (HTL) at a rate of 0.1–0.3 nm/s as the ETL and emitting layer through a mask at a pressure of 3×10^{-4} Pa. The devices were completed by evaporating a 0.6 nm LiF layer protected by 100 nm of Al at a base pressure of 5×10^{-4} Pa. A device with similar configuration but using NPB evaporation film as HTL was also prepared under the identical conditions. The hole-only devices with a general structure of ITO/PEDOT:PSS/dendrimers (70 nm)/Au (60 nm) were fabricated in the same way for hole mobility measurement by space-charge-limited current (SCLC) method. The EL spectra and current–voltage–luminescence characteristics were measured with a Spectrascan PR 650 photometer and a computer-controlled direct-current (DC) power supply. All the measurements were performed under ambient atmosphere at room temperature.

3. Results and discussion

3.1. Thermal properties

The thermal stabilities of dendrimers were examined by DSC and TGA analysis. From the DSC thermograms of dendrimers measured at a scanning rate of 10 °C/min in nitrogen, the dendrimers exhibited glass-transition at 115 °C for Tr-TPA3 and 140 °C for Tr-TPA9, respectively. The T_g of the dendrimers enhanced with the increase of the generation because the multibranched molecules with higher generation tend to hinder translational, rotational, and vibrational motions of the molecule. The T_g of dendrimers is higher by 19 °C for Tr-TPA3 and 44 °C for Tr-TPA9, respectively, than that of the widely used HTM NPB (96 °C), suggesting better morphological stability of the dendrimers. In addition, the dendrimers shows excellent decomposition temperature by TGA measurement (T_d, which corresponded to a 5% weight loss) at 409 °C for Tr-TPA3 and 426 °C for Tr-TPA9, respectively. To investigate the dendrimers morphology, we prepared thin films of the dendrimers through spin-coating from chloroform solution onto ITO substrates and imaged them using atomic force microscopy (AFM, Supplementary Fig. S3). The surface topographies clearly revealed that the spin-coated films exhibited fairly smooth morphologies with a root-mean-square (RMS) surface roughness of 0.58 nm for Tr-TPA3 and 1.06 nm for Tr-TPA9. The films had smooth surfaces with no obvious crystallized aggregation or cracks which demonstrate that Tr-TPA3 and Tr-TPA9 are capable of forming amorphous films through solution processing.

3.2. Photophysical properties

The absorption of dendrimers in dilute chloroform solutions and solid films are presented in Fig. 1. For the UV–vis absorption spectra in chloroform solution, Tr-TPA3 displays two absorption peaks at 311 and 392 nm, respectively. The first absorption peak in the short wavelength region at 311 nm was attributed to the triphenylamine moiety. The second absorption peak at 392 nm was ascribed to the TPA-vinylene modified truxene unit [30,31].
Fig. 1. Normalized absorption spectra of Tr-TPA3 and Tr-TPA9 in dilute chloroform solution (1×10^{-6} M) and solid films.

A red-shift in the absorption maximum of Tr-TPA3 was observed in comparison with the triphenylbenzene core dendrimer (TPB-TPA3, λ_{max} = 384 nm) [30] and truxene linked with vinylene (TM3, λ_{max} = 311 nm) [31], which was indicative of enhanced effective conjugation length. While Tr-TPA9 displays two absorption peaks at 310 and 413 nm, which exhibit similar behavior to Tr-TPA3. These results also demonstrate that the effective conjugation length improves with the increasing generation of the dendrimers. The absorption behaviors of Tr-TPA3 and Tr-TPA9 in the solid films are quite similar to those in solution. The absorption maxima of Tr-TPA3 and Tr-TPA9 in the films are red-shifted 4 and 1 nm, which demonstrates that the higher of the generation, the smaller the red-shift in the absorption. The absorption of the dendrimers indicates that there is no aggregation in the dendrimers because of the large size of the molecules with six butyl substituents in truxene and lots of noncoplanar triphenylamines dendrons. There is no significant ordering of the dendrimers either from aggregation or crystallization, and hence the dendrimers films are in good amorphous states [32], which are very important for the application of materials in optical and electronic devices such as OLEDs.

Fig. 2 illustrates the PL spectra of dendrimers in dilute chloroform solutions and solid films. For the emission spectra in dilute chloroform solutions, Tr-TPA3 and Tr-TPA9 display similar behaviors. The emission peaks of Tr-TPA3 and Tr-TPA9 locate at 445 and 476 nm, respectively. The red-shifted of 31 nm of the emission peak of Tr-TPA9 from that of Tr-TPA3 shows that there is obvious $\pi–\pi^*$ delocalization and the significant increase of the effective conjugation length with the increase of the generation of dendrimers [33]. The two peaks in PL of Tr-TPA3 film can be ascribed to the S1–S0 0–0 transition at about 440 nm (about 22,750 cm^{-1}) and the vibronic satellites with an appr. 1200 cm^{-1} vibration, respectively. In solution the vibronic splitting is less obvious because the individual components are broadened. Tr-TPA9 displays similar behaviors to Tr-TPA3. Actually, the principal character of the PL spectra is the same for film and solution.

3.3. Electrochemical properties

The electrochemical behaviors of Tr-TPA3 and Tr-TPA9 were examined by cyclic voltammetry measurement. As shown in Fig. 3, two reversible oxidation potentials for Tr-TPA3 and Tr-TPA9 were observed. The first oxidation potentials of Tr-TPA3 and Tr-TPA9 are 0.57 and 0.53 V, and the second oxidation potentials are 0.94 and 0.71 V, suggesting a successive formation of the cation radical and then dication species [10]. All of the oxidations should be attributed

to the removal of electrons from the triphenylamine groups. The lower oxidation potential of Tr-TPA9 is likely to be related to the extended π-conjugation length [10].

On the basis of the roughly evaluated onset oxidation potentials (E_{Red}^{onset}), the HOMO energy levels of Tr-TPA3 and Tr-TPA9 are estimated as −5.12 and −4.95 eV, respectively (HOMO = $-e(E_{ox}^{onset}+ 4.66)$) [34–36]. The LUMO energy levels of Tr-TPA3 and Tr-TPA9 are −2.28 and −2.26 eV, respectively, calculated from the HOMO energy level and energy bandgap (E_g) determined from the UV–vis absorption threshold (LUMO = HOMO − E_g). The electrochemical properties as well as the energy level parameters of the dendrimers are listed in Table 1. From Table 1 it can be seen that the electron donating ability of the dendrimers increased with the increase of the number of triphenylamine units and resulted in the enhancement of the HOMO energy level. Fig. 4 shows the energy levels of the dendrimers and that of NPB and Alq$_3$. It can be seen that the HOMO energy level of Tr-TPA3 and Tr-TPA9 are higher than that of NPB [37], which means that the energy barrier at the interface of ITO and dendrimers is smaller than that of ITO and NPB resulting in the better hole injection from ITO to dendrimers than to NPB and lower joule heat produced at the interface during device operation.

3.4. EL properties

To investigate the hole-transport ability of triphenylamine-based dendrimers, double-layer OLEDs with the

Fig. 5. The current density–luminance–voltage curves of the ITO/Tr-TPA3 or Tr-TPA9/Alq$_3$/LiF/Al device and the ITO/NPB/Alq$_3$/LiF/Al standard device.

Fig. 6. The current efficiency–current density characteristic of the ITO/Tr-TPA3 or Tr-TPA9/Alq$_3$/LiF/Al device and the ITO/NPB/Alq$_3$/LiF/Al standard device.

configuration of ITO/dendrimers (70 nm)/Alq$_3$ (60 nm)/LiF/Al were fabricated, where dendrimers as HTL and Alq$_3$ as emitting layer and ETL. As comparison, a standard device with the similar structure but using NPB as the HTL was also prepared. The devices based on dendrimers showed green emission from Alq$_3$ with a peak at 528 nm, suggesting that the charge recombination is localized in the Alq$_3$ layer and dendrimers act primarily as HTM without causing exciplex formation at the interface with Alq$_3$. The density–voltage (J–V) and luminance–voltage (L–V) characteristics of the devices are shown in Fig. 5. The Tr-TPA3-based device turns on at a voltage of 3 V, and the brightness of the device is 4265 cd m^{-2} at 10 V. The Tr-TPA9-based device turns on at a voltage of 2.5 V, and the brightness of the device reach 11,058 cd m^{-2} at 10 V. It is clear that the brightness of the Tr-TPA9-based device is comparable with the NPB standard device. The low turn-on voltage of the Tr-TPA3 and Tr-TPA9 devices is attribute to the lower hole injection barrier from ITO to dendrimers than that from ITO to NPB.

Fig. 6 shows the current efficiency–current density characteristics of the dendrimers devices. The Tr-TPA9-based device gives a maximum current efficiency of 4.01 cd A^{-1}, which is substantively higher than that (3.24 cd A^{-1}) of the Tr-TPA3-based device. The current efficiency for the Tr-TPA3-based device decreases more rapidly with increasing current density above 25 mA cm^{-2}. While the current efficiency for the Tr-TPA9-based device remains almost constant with current density up to 150 mA cm^{-2} and shows only a small decline even when the current density increases to 620 mA cm^{-2}. The EL properties of the devices are summarized in Table 2. Significantly, even at the present stage when the device has not
yet to be optimized, the EL performances of the Tr-TPA9-based device are already comparable to those of the NPB/Alq$_3$ device, which suggests that Tr-TPA9 is at least as good as NPB when used as a HTM in EL devices, apart from its high T_g, good solubility and film forming property from solution.

We also evaluate the hole mobilities of the dendrimers by analyzing space-charge-limited current (SCLC) from the hole-only device with the configuration of ITO/PEDOT:PSS/dendrimers/Au [38–41], where L varied between 50 and 100 nm. The hole mobilities of the dendrimers were calculated according to the following equations [42]:

$$J_{SCLC} = \frac{9}{8}\varepsilon_0\varepsilon_r\mu_0\frac{(V_{appl} - V_{bi})^2}{L^3}\exp\left[0.891\gamma\sqrt{\frac{V_{appl} - V_{bi}}{L}}\right]$$

$$\ln\left[\frac{JL^3}{(V_{appl} - V_{bi})^2}\right] = \ln\frac{9}{8}\varepsilon_0\varepsilon_r + \ln\mu_0 + 0.891\gamma\sqrt{\frac{V_{appl} - V_{bi}}{L}}$$

The results are plotted as $\ln(JL^3/V^2)$ versus $(V/L)^{0.5}$, as shown in Fig. 7. The hole mobilities of Tr-TPA3 and Tr-TPA9, calculated from the intercepts of the corresponding lines, are about 10^{-5} cm^2/Vs and 10^{-4} cm^2/Vs, respectively. The hole mobilities of dendrimers are comparable to those of well-known triphenylamine derivatives [11]. The spatial geometry of the dendrimers could be beneficial for intra- and intermolecular hole transportation and the excellent hole mobility observed in Tr-TPA9 than Tr-TPA3 is likely to be related to the extended π-conjugation length which may enhance the capability of the effective interchromophore interaction between the neighboring molecules [38,43].

Table 2
Summary of device performances.

HTL	EL (nm)	V_{on} (V)	L_{max} (cd m^{-2})	Maximum current efficiency (cd A^{-1})	Maximum power efficiency (lm W^{-1})
NPB	528	3.5	10,220	3.45	1.78
Tr-TPA$_3$	528	3	4265	3.24	2.91
Tr-TPA$_9$	528	2.5	11,058	4.01	3.60

4. Conclusions

To summarize, two novel solution-processable dendrimers, Tr-TPA3 and Tr-TPA9, were used as HTM in OLEDs. The photophysical properties of dendrimers demonstrate that the films of dendrimers are in good amorphous states. The dendrimers possess excellent solubility and good film forming property. The T_g of dendrimers is higher than that NPB, suggesting better thermal stability of the dendrimers. The Tr-TPA9-based double-layer device exhibited similar EL brightness, slightly higher maximum current efficiency and lower turn-on voltage comparing with the NPB-based device. Therefore, the triphenylamine-based dendrimers with truxene as cores can be good candidates for HTM in OLEDs.

time scale. In order to determine the rate-limiting process, transient or ac response of a rectifier may be studied. Rectifiers in the radio-frequency range are also required for applications as radio-frequency identification tags (RFID).

Operation of organic rectifiers under ac voltage has recently been reported [13–16]. In this article, we present results from an assembly between a donor and an acceptor molecule (donor/acceptor assembly) under ac voltage. Here, we have varied frequency of ac voltage and studied the characteristics of the rectifier. From the frequency-response of rectification, we comment on the process that limits molecular rectification.

2. Experimental

The donor/acceptor system for the present study consists of a phthalocyanine derivative and a xanthene molecule as a donor and an acceptor, respectively. Fig. 1 shows the energy diagram and structural formulae of the components of the diode. Molecular orbitals of such assemblies favor electron flow in the A to D direction. Briefly, the donor/acceptor (D/A) assemblies were formed by electrostatic adsorption of tetrasodium salt of copper phthalocyanine (CuPc), an inert polycation, and (sodium salt of) fluorescein in sequence. As the polycation, we have used poly(allylamine hydrochloride) (PAH, M_W = 70,000). Due to anionic nature of CuPc derivative and fluorescein in water solution, the CuPc/PAH/fluorescein assemblies could be formed via LbL method. Adsorption of the molecules has been confirmed from the electronic absorption spectra of the LbL films on quartz substrates. In practice, a highly doped single crystalline Si wafer (1 1 1) with a resistivity of 3 mΩ.cm was first dipped in a CuPc bath. After a through rinse in three water baths to wash-off extra molecules that were not bound electrostatically, the substrate was dipped in a PAH bath followed by the same rinsing procedure. To complete a D/A assembly, a layer of fluorescein was deposited by dipping the slide in a fluorescein bath followed by the same rinsing protocol. The mechanism of LbL adsorption process, that is, surface charge reversal during every layer adsorption, assured that only one monolayer was deposited during each dipping event. All the dipping baths were water-based with a dye or polycation concentration of 10 mM. The deionized water for the solution and washing baths, obtained from Milli-Q Academic, had a resistivity of 18.2 MΩ.cm.

The D/A assemblies were annealed in vacuum at 120 °C for 1 h. Electrical characteristics of the assemblies were recorded with mercury as the other electrode. The assemblies were placed in a bell-jar under vacuum (10^{-3} Torr) with the film facing downwards. Mercury blob in a metal syringe was pushed from outside the chamber to touch the film. Current–voltage (I–V) characteristics were recorded by applying a bias to the mercury electrode with respect to the doped Si substrate. As control experiments to rule out any role of interfaces, monolayers of the components, namely CuPc and fluorescein, were characterized. In addition, and more importantly, a reverse junction, that is, a junction based on monolayers of fluorescein and CuPc in sequence, was formed and characterized under the same experimental conditions. Characteristics from Si/CuPc/fluorescein/Hg and Si/fluorescein/CuPc/Hg were compared to eliminate any effect of the interfaces. For both the assemblies and their components, I–V characteristics were recorded at different points on the films to check the reproducibility of the results. While absolute value of current depended on the size of mercury blobs, rectification ratio calculated from different measurements remained unaltered.

For dc measurements, a Yokogawa model 7651 programmable source provided the voltage. A Keithley model 486 picoammeter measured the dc current. Real time response of current under ac voltage and the voltage itself were recorded with a Hewlett–Packard model 5600B double-channel digital oscilloscope. A Hewlett–Packard model 3245A universal source provided sinusoidal voltages. Frequency of the ac voltage was varied between 50 Hz and 1 MHz (2 points per decade). To record time response of current through the junctions, voltage drop against a known resistor was recorded with the oscilloscope.

3. Results and discussion

I–V characteristics under dc voltage of a D/A junction with CuPc and fluorescein monolayer in sequence are shown in Fig. 2a. Characteristics from a reverse junction (A/D) are also shown in the same figure. In both the cases, doped-Si and Hg were the electrodes. Both the characteristics show rectifying behavior; direction of rectification in one case is opposite to that in the other. Opposing nature of rectification in D/A and A/D junctions first of all rules out any effect of interfaces in the observed characteristics. The results show that electron flow was always favorable from A to D moiety and hence clearly bring out rectifying nature of a D/A assembly. Further control experiments with the components of the junctions, that is, a CuPc monolayer and a fluorescein monolayer separately, returned mostly symmetric I–V characteristics. The results are presented in Figs. 2b and 2c, respectively. The little variation from the symmetric nature that may be present in the characteristics can be due to different work functions of the electrodes.
Fig. 1. Energy diagram and structural formulae of the components of a CuPc/fluorescein diode.
Fig. 2. Current–voltage characteristics of (a) D/A and A/D assemblies with the same set of electrodes (doped-Si and Hg). Characteristics from the components are shown in (b) and (c). Legends specify the monolayer that has been characterized.

We studied the rectifying assemblies under ac voltage. Frequency of sinusoidal voltage was varied between 50 Hz and 1 MHz. Typical examples for D/A assemblies under 100 Hz and 100 kHz are shown in Fig. 3a and b, respectively. Current response, along with the ac voltage, is shown in each of the figures. The assemblies act mostly as half-wave rectifiers. Current in the forward bias segment of ac voltage is much higher than that in the reverse bias segment. It should be noted here that considering the biasing arrangement, application of a negative voltage to Hg contact of Si/D/A/Hg structure meant a forward-biased D/A rectifier. We also have characterized the A/D assemblies under ac bias of different frequencies. Again, results from A/D assemblies under two typical frequencies (100 Hz and 100 kHz) are shown in Fig. 4a and b, respectively. The A/D assemblies also behaved as half-wave rectifiers. Here, current under positive-segment of sinusoidal ac voltage (forward-bias) is much higher than that in the negative-voltage segment (reverse-bias). The results hence show that the donor/acceptor assemblies based on a junction between a monolayer of donor molecules and a monolayer of acceptor molecules act as a rectifier under ac voltage or a half-wave rectifier. The components of the assemblies, namely a monolayer of CuPc or a monolayer of fluorescein expectedly did not behave as a rectifier under ac voltage (figure not shown).

It is important to know the phase-lag between the ac voltage and current. When current response is compared with the sinusoidal voltage, there is little or no phase lag in the low frequency region. At higher frequencies, the current lagged the voltage. The phase-lag rose to 40° at the highest frequency of measurement (Fig. 5). Capacitive component of the D/A assembly, which can be represented as a parallel combination of a resistor and a capacitor (C_P–R_P), may also give rise to a phase lag. Such a phase-lag between the real and imaginary components of complex impedance as a function of ac test-frequency saturated within 1 kHz. The phase-lag of current with respect to sinusoidal voltage, on the other hand, increased monotonically with the frequency of the voltage (Fig. 5). This shows that one of the steps/processes of electron flow through the donor/acceptor composite is slower than the time-scale of a half-wave of the sinusoidal voltage. It may be recalled that in the forward bias the three steps of electron movement from an electrode to the other are (1) addition of an electron from an electrode to the LUMO of acceptor moiety, (2) withdrawal of an electron from the HOMO of donor moiety to the other electrode, and (3) electron transfer from the anionic-acceptor to the cationic donor moiety of D/A complexes. The Fig. 6 shows that band-diagram of a donor/acceptor assembly under forward bias with the following steps:

Step 1: $M_1/D - \sigma - A/M_2 \rightarrow M_1/D - \sigma - A^-/M_2^+$

Step 2: $M_1/D - \sigma - A^-/M_2^+ \rightarrow M_1^-/D^+ - \sigma - A^-/M_2^+$

Step 3: $M_1^-/D^+ - \sigma - A^-/M_2^+ \rightarrow M_1^-/D - \sigma - A/M_2^+$
Fig. 3. Current and sinusoidal voltage as a function of time for D/A assemblies at two different frequencies as mentioned in the legends.

Fig. 4. Current and sinusoidal voltage as a function of time for A/D assemblies at two different frequencies as mentioned in the legends.

In the reverse-bias, neither addition of an electron to the donor moiety nor withdrawal of an electron from the acceptor is favorable; current in the reverse-bias is hence small. Since the former two steps may occur simultaneously, it could be interesting to know if the latter process (step 3) or the former ones (steps 1 and 2) limits the rectifier at high frequencies.

In order to find the rate-limiting process, we have plotted amplitude of forward and reverse current as a function of frequency (Fig. 7). Frequency response of rectification ratio has also been plotted in the same figure. The ratio in the D/A assembly is as such low since the ultrathin film could not withstand much bias voltage due to possibility of a breakdown under a high electric-field. The plot shows that the rectification ratio starts to decrease at higher frequencies. The decrease in the ratio is in fact due to increase in current under reverse-bias section of the voltage; the current in the forward bias remained invariant with the increase in frequency in the range of our measurement. Increase in the reverse-bias current with frequency implies that there must have been a residual effect at high-frequencies. That is, in a Si/CuPc/fluorescein/Hg rectifier at high-frequencies and under forward-bias (mercury electrode being negative), electron transfer from all the anionic-acceptors to the cationic-donors may not have become complete; upon reversal of bias at this stage, elec-

trons may have back-flowed from fluorescein-anion to Hg electrode (oxidation of reduced fluorescein). Similarly, electrons from the Si-electrode may have neutralized the

Fig. 6. Band diagram of a donor/acceptor assembly with doped-Si and Hg electrodes under forward bias showing the three steps (as mentioned in boxes).
Fig. 7. Current under forward- and reverse-bias at 2.0 V and −2.0 V, respectively, of a D/A assembly as a function of frequency of sinusoidal voltage. Rectification ratio of the assembly at 2.0 V is shown in the lower panel of the figure. Lines are to guide the eye.

CuPc cations. These electron-movements would seem like a current flow in the external circuit. This extra current due to residual carriers along with current due to injection of carriers (electron-injection to the donor and hole-injection to the acceptor moieties) yield an increase in current in the reverse-bias at higher frequencies. The step (3) of molecular rectification, namely the charge-transfer between A^- and D^+, meant oxidation of reduced fluorescein; this process, which involves conformational-change of fluorescein molecules, might be a slow one leading to residual or left-over A^- and D^+ species for the next half-cycle. These species have yielded a higher reverse-bias current in high-frequencies.

4. Conclusions

In conclusion, we have shown that a donor/acceptor assembly between a molecular layer of donor molecules and another molecular layer of acceptor molecules, when sandwiched between two electrodes, acts as a half-wave rectifier under ac voltage. In a reverse junction, that is, in an acceptor/donor assembly with the same set of electrodes, the direction of rectification also reversed ruling out any effect of interfaces in the observed rectification. At higher frequencies, the current lagged the applied sinusoidal voltage. From the frequency dependence of rectification, we have commented on the time response of the three steps that are responsible for a molecular rectification. We show that the charge-transfer between an anionic-acceptor and a cationic-donor may be a slow process since a change in its conformation is involved during oxidation of the reduced-acceptors. The results show that high-frequency half-wave (molecular) rectifiers can be fabricated and characterized from an assembly of a donor and an acceptor molecule.

Fig. 1. Typical current–voltage (I–V) curves for organic bistable device with the structure ITO/Al (5 nm)/Alq$_3$ (120 nm)/Al$_2$O$_3$ (5 nm)/Al (100 nm).

The switching from OFF to ON state could be realized in milliseconds by applying a voltage between V_{th} and V_{max}, while the switching from ON to OFF state could be achieved in microseconds by applying a voltage close to V_{min}, as is described in our recent work [23]. In previous reports, most research efforts focused on the voltage V within the switching range, $V_{th} < V < V_{min}$, while less attention was paid to the electrical properties beyond this range, i.e., in the voltage regions of $V < V_{th}$ and $V > V_{min}$. Recently, we have found that when biased at voltages below the threshold voltage V_{th}, i.e., $V < V_{th}$, the OBDs can automatically switch from OFF state to ON state after a certain period of time. Such "switch time" scales from a few seconds to about 10^4 s, depending on the biased voltage [23]. However, there have been no report so far to investigate the electrical properties of OBDs in the voltage range of $V > V_{min}$ to show the effect of such higher voltage on OBDs.

In the present work, we systematically investigate the effect of higher voltage $V > V_{min}$ on OBDs. It is found that when the scan termination voltage V_T exceeds V_{min}, the bistable effect of OBDs gets worse and worse with the increasing V_T in the following scan. When the voltage reaches a very high value of about $2V_{min}$, the device completely loses its bistability. However, it is found that the lost bistability can be recovered by applying a voltage pulse close to V_{min} for milliseconds or longer. The possible underlying mechanism of the OBDs studied is suggested based on the existence of micro-conducting channels in the organic layer.

2. Experimental

We fabricated OBDs with structure of indium tin oxide (ITO)/Al (5 nm)/tris (8-hydroxyquinoline) aluminum (Alq$_3$) (120 nm)/Al$_2$O$_3$ (5 nm)/Al (120 nm). The 5 nm Al layer on the ITO electrode acts as the anode to form symmetrical OBDs. Alq$_3$ used in the present study is one of the most important organic electron-transporting materials in organic light-emitting diodes. Experiments showed that insertion of 5 nm Al$_2$O$_3$ between the organic layer and Al electrode improved the electrical stability of the devices, which means the device can endure more bistability loss

and recovery cycles before being damaged. The devices were fabricated on pre-cleaned glass substrates coated with transparent conducting ITO of sheet resistance about 17 Ω/square. The substrate was heated to 150 °C in air after solvent cleaning and then loaded into a high vacuum chamber ($\sim 5 \times 10^{-6}$ Pa). A 5 nm-thick aluminum (Al) layer was first deposited onto the ITO substrate with a deposition rate of 0.3 Å/s, followed by deposition of Alq$_3$ layer of about 120 nm with deposition rate of 1.0 Å/s, which is the optimized thickness to make the device show good NDR effect, ON/OFF ratio (the conductance comparison) and electrical stability. Then a 5 nm-thick Al layer was deposited on the Alq$_3$ layer without breaking the vacuum. Subsequently, the sample was transferred into another chamber to get the thin Al layer oxidized. Finally the sample was sent back into the vacuum chamber and a top Al electrode of 120 nm was deposited with a deposition rate of 1 Å/s. The area of the organic bistable device was 9 mm^2, defined by 3 mm-wide ITO stripes over-crossed by 3 mm-wide top Al stripes. The current–voltage (I–V) characteristics of the devices were measured by Keithley 236. The scan step was 0.2 V and each step lasted for about 500 ms. All the measurements of bistability and switching characteristics of the devices were carried out at room temperature in a glove box (O$_2$ < 1 ppm, H$_2$O < 1 ppm). The micrograph of the devices was observed with an optical microscope.

3. Results and discussion

Fig. 1 shows the typical I–V characteristics of a bistable device with the structure of ITO/Al (5 nm)/Alq$_3$ (120 nm)/ Al$_2$O$_3$ (5 nm)/Al (120 nm). The device was initially set to the ON state and then the applied voltage was scanned, first from 0 to 6 V, next from 0 to 8 V and so on, finally from 0 to 14 V, i.e., the termination voltage V_T increased stepwise. As shown in Fig. 1, NDR effect exists in the region between V_{max} (the voltage corresponding to the local current maximum) and V_{min} (the voltage corresponding to the local current minimum). Intermediate states, i.e., those between the ON and OFF resistance values, are obtained in the region $V < V_{th}$ (V_{th} is the threshold voltage, at which the current increases abruptly). The larger the V_T ($V_{max} < V_T < V_{min}$) is, the lower the conductance of the device in the region of $V < V_{th}$ in the next scan will be. With the increase of termination voltage V_T, the current peak value and the corresponding voltage V_{max} show little change. The typical I–V characteristics are essentially the same as those reported before by us [23] and other groups [3,4,21,22]. However, how the I–V characteristics and bistable effect of the OBDs will change when V_T exceeds V_{min} has not been addressed.

Fig. 2 shows the I–V characteristics of another device with the same structure but different V_T exceeding V_{min}. For this device, when the device shows complete bistability, V_{th}, V_{max} and V_{min} are 2, 5 and 14 V, respectively. In order to investigate the effect of high voltage exceeding V_{min} on the OBDs, the device was first set to the OFF state and then the applied voltage was scanned, first from 0 to 14 V, next from 0 to 16 V and so on, finally from 0 to 28 V. Here the curve of solid squares shows the result of
Fig. 2. *I–V* characteristics of device ITO/Al (5 nm)/Alq$_3$ (120 nm)/Al$_2$O$_3$ (5 nm)/Al (120 nm) with V_T exceeding V_{min}. The device was first set to the OFF state and then the applied voltage was scanned, first from 0 to 14 V, next from 0 to 16 V and so on, finally from 0 to 28 V.

scan from 0–14 V, with a current maximum of 4.5 mA at $V_{max} \sim 5$ V. During the subsequent scanning from 0 to 16 V, shown by the hollow circle curve, the peak current deduced to 2.4 mA, while the corresponding voltage V_{max} increased to 5.5 V. With the V_T increasing from $V_{min} \sim 14$ V to $2V_{min} \sim 28$ V, the peak current decreased from 4.5 to 0.31 mA, while V_{max} increased from 4.5 to 14.5 V and the ON/OFF ratio of bistable effect got worse. In the last scan of 0–28 V, shown by the hollow left-triangle curve, the current increased with voltage monotonously, i.e., the NDR effect almost disappeared. Meanwhile, when the device was tested by applying voltage pulse with an amplitude exceeding V_{min} instead of a voltage scan $0 \sim V_T$, similar results were obtained, i.e., the device showed the same *I–V* characteristics. That means the termination voltage V_T of the scanning process determined the *I–V* characteristics of the device in the next scan.

In order to test whether the device could switch from OFF state to ON state after experiencing a high voltage of 28 V, a write voltage of 5 V was applied to the device for about 20 min. Under the write voltage of 5 V, the current was very small, of the order of 10^{-4} mA, and showed little change with time. The device did not switch from the OFF state to the ON state in 20 min. This means the device lost bistability completely. Therefore, for such kind of OBDs, after applying high voltage (about $2V_{min}$), the device can not realize the function of writing and hence loses bistability completely.

Further investigation shows that the bistability destroyed by high voltage can be recovered by certain method, rather than lost forever. In our experiment, it is demonstrated that for the device which has lost bistability by high voltage (28 V), a voltage pulse of $V_{min} \sim 14$ V applied for milliseconds or longer can recover its bistability, i.e., the device can then be switched from OFF state to ON state by applying voltage pulse in the region of $V_{th} < V < V_{max}$ (2–5 V). Therefore, it is concluded that the bistability-lost devices can recover their bistability upon the application of a voltage pulse of V_{min}. Indeed, in our experiments, it is shown that the first scan from 0–14 V on a bistability-lost device does not show NDR effect and bistability, while the next scan of 0–14 V shows NDR effect

and bistability again, shown in Fig. 3. If the scan changes from V ($V \geqslant V_{min}$) to 0 V, for instance, from 28 to 0 V, even in the first scan, NDR effect reappears, showing the bistability recovered. This is because in such a scan process, the device experienced a voltage pulse of 14 V, resulting in immediate recovery of the bistability. Meanwhile, a series of voltage pulses with amplitude of V_{min} and shorter duration applied on the device can also recover the device bistability, although gradually. The sum of pulse durations approximately equals to the longer voltage pulse of similar amplitude with the same effect of bistability recovery. That means the effect of applied voltage pulse is accumulative over time.

In addition, applied voltage in the region of V_{max} (the maximum voltage for the device showing complete bistability, shown in Fig. 1, which does not change with the increasing termination voltage)$\sim V_{min}$ can partly recover the bistability. Fig. 4 shows the *I–V* characteristics of another bistability-lost device which had experienced a certain voltage between V_{max} (5 V) $< V < V_{min}$ (12 V). First voltage of $2V_{min}$ (24 V) was applied on the device to destroy its bistability, then different voltage 7, 8, 10, or 12 V was applied for about 5 s on the device, and voltage was then scanned over 0–12 V. The solid square curve shows 0–12 V scan of the device after applying a constant voltage of 7 V on the device. The device did not show any NDR effect or any electrical transition (an abrupt current increase) in the region of 2–5 V either. However, constant voltage 8 V can partly recover the lost bistability – the *I–V* curve shows weak NDR effect, as shown by the hollow circle curve in Fig. 4, with very low ON/OFF ratio (the conductance comparison). Similarly, constant voltage 10 V made the NDR effect much more obvious and better recovery of the bistability. Meanwhile, constant voltage as high as 12 V applied on the device resulted in complete recovery of the bistability, shown by the most obvious NDR effect with the highest current peak value.

We have previously suggested a phenomenological mechanism involving localized conducting micro-channels to account for the bistability [23]. These micro-channels are, in principle, similar to those existing in inorganic metal–insulator–metal structures [13], formed by incorporation of metallic nanoparticles into the organic layer during deposition of the top electrode [3,4]. The ON and
Fig. 3. *I–V* characteristics of a bistability-lost device by applying a voltage of 28 V. Two 0–14 V scans were sequentially applied.
Fig. 4. *I–V* characteristics of a bistability-lost device after being applied a constant voltage *V* between V_{max} and V_{min}. The device was initially set to lose its bistability by an applied voltage of 24 V, then different voltages 7, 8, 10, or 12 V were applied for about 5 s each, and then 0–12 V was scanned.

OFF states of the device are respectively related to open and close of the channels, and V_{th} mentioned above is the threshold voltage needed for the channels to be opened.

The existence of the conducting micro-channels is confirmed by the fact that the protection by the oxygen-free glove box is necessary for the measurements of the bistability and switching characterization. It is found that the appearance and the amplitude of the NDR are dependent on the oxygen content. Once a device is removed from vacuum to ambient condition, the current in the NDR region and bistability region may drop by 3–4 orders of magnitude and the device may not show any behavior of the bistability at all. Block of the conducting micro-channels due to oxidation is likely the reason for that.

Further evidence for the existence of the conducting micro-channels is from the examination of the localized pathways in Alq_3 thin films deposited on ITO substrate by means of conducting atomic force microscopy (CAFM). During measurements of the current distribution in the Alq_3 thin film, some localized current peaks exist in some locations of the sample while other locations have very low current. When measuring the *I–V* characteristics (scanning from −10 to 10 V) at the places where current peaks exist, NDR effect was observed, as shown in Fig. 5.
Fig. 5. *I–V* curves measured by CAFM at the location where current peaks exist in the current distribution map of Alq_3 thin films. The scan is from −10 to 10 V.

No NDR effect was observed at other locations. In this case, asperities on the bottom ITO electrode rather than nanoparticle from the top electrode should be the origin of the localized conducting micro-channels.

Given the existence of the localized conducting micro-channels, the switching ON/OFF behavior of the devices can be properly explained. Overloading the micro-channels by applying a voltage higher than V_{min} may partly disable them for conduction. The higher the voltage $V > V_{min}$ is applied, the more the channels are disabled. The disabled micro-channels will not contribute to the switch-on effect in the next scan, leading to the appearance of a lowered value of peak current. When the voltage reaches $2V_{min}$, almost all the micro-channels are disabled, corresponding to the bistability-lost effect. On the other hand, with voltage pulse of amplitude close to V_{min}, the switching characteristics of the micro-channels can be recovered, thus recalling the bistability. By examining the surface morphology of the device with an optical microscope, it is found that after the electrical stress of 28 V applied on the ITO/Al/Alq_3/Al_2O_3/Al device local damages and bubbles appeared. In addition, it is found that after many cycles of losing and recovery of bistability by repeatedly applying high voltage and V_{min}, the device's bistability could not be recovered any more even with voltage pulse of V_{min} applied. The *I–V* characteristics show normal P–N heterojunction characteristics. The micro-channels might be disabled or destroyed completely and could not recover any more.

Moreover, typical organic light-emitting diodes (OLEDs) with structure of ITO/NPB (50 nm)/Alq_3 (70 nm)/LiF (1 nm)/Al were fabricated. The devices also showed typical bistability in the voltage range of 0–4 V. In the ON state, the current in the voltage range of 0–4 V was comparable with the current in the range of 6–10 V, but the devices showed no electroluminescence in the voltage region of 0–4 V while good electroluminescence was detected in the voltage region of 6–10 V. This means the high current in the region of 0–4 V in the ON state does not contribute to electroluminescence. It might flow through some localized conducting micro-channels rather than through the entire organic thin film homogeneously. In contrast, the current in the region of 6–10 V mostly consists of current flowing through the entire organic thin film homogeneously rather than through local micro-channels, and hence results in electroluminescence.

4. Conclusions

In conclusion, the effect of high voltage stress exceeding V_{min} on OBDs has been investigated. It is found that bistability can be completely destroyed under voltage of about $2V_{min}$ and can be recovered by applying voltage pulse of amplitude close to V_{min} for milliseconds or longer. The existence of localized conducting micro-channels in the devices might be the origin of bistability.

vice. Based on these advantages, SS was studied as a gate electrode as well as a substrate in this research. Both 304 SS and 430 SS were used and the effect of the surface roughness was studied using chemical mechanical polishing (CMP) process. Aluminum oxide (Al_2O_3) insulating layer was deposited using ALD process and was used as a gate insulator. Metal/insulator/metal (MIM, Au/Al_2O_3/304 SS, 430 SS and N++Si) structures were fabricated and characteristics such as dielectric constant and leakage current of Al_2O_3 layer were measured. Pentacene TFTs with 304 SS, 430 SS and N++Si (heavily doped *n* type silicon) as a substrate were fabricated and performance of them were compared. Additionally, pentacene TFT with polished 304 SS was characterized in a bent state to check the bending on the device performance.

2. Experimental

304 SS and 430 SS substrate were supplied by POSCO and were polished with CMP process (KEMET P25FRS-A3) with alumina slurry of 0.05 μm diameter for 10, 20, 30 and 40 min, respectively. Then, they were washed with distilled water and acetone. N++Si substrate (Silicon Material Inc.) was cleaned in piranha solution (H_2SO_4: H_2O_2 = 7:4 vol%) for 1 h at 100 °C and washed with distilled water. Al_2O_3 films of various thicknesses (50, 100, 200 and 500 nm) were deposited in a hot-wall ALD reactor on 304 SS, 430 SS and N++ Si substrate. Trimethyl aluminum and distilled water were employed as a precursor and a oxidizing reaction gas. The line from the precursor bottle to the reactor was maintained at 60 °C and the pressure and temperature of the reactor were fixed at 1 Torr and 150 °C, respectively. N_2 (99.999%) gas was employed as a carrier and purge gas. Flow rate of N_2 gas for purging and for carrying vaporized water was fixed at 100 sccm and 10 sccm, respectively. The ALD cycle of Al_2O_3 film was precursor injection (1 s)–purge (5 s)–water vapor injection (1 s)–purge (10 s).

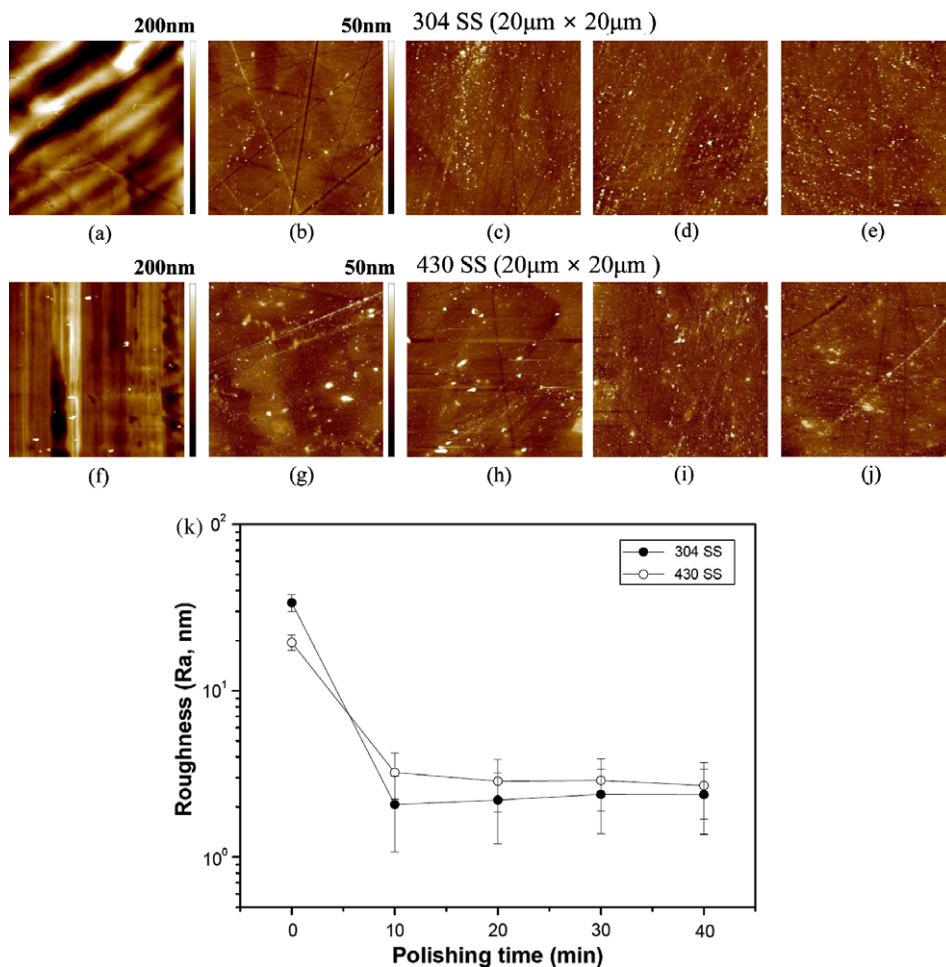
Pentacene (purchased from Aldrich Chemical Co.) films of 50 nm were deposited at R.T. with a deposition rate of 0.2–0.3 Å/sec in an organic molecular beam deposition (OMBD) system at a pressure of 2×10^{-6} Torr. Au elec-


Fig. 1. Surface morphologies of 304 SS and 430 SS polished with an alumina slurry of 0.05 μm diameter for various durations: (a) without polishing, (b) 10 min, (c) 20 min, (d) 30 min, (e) 40 min polishing for 304 SS, (f) without polishing, (g) 10 min, (h) 20 min, (i) 30 min, (j) 40 min polishing for 430 SS and (k) roughness of SS versus the polishing time.

trodes (50 nm) for MIM structure and pentacene TFT were formed through a shadow mask using a thermal evaporator. The channel length and width were 150 and 1500 μm, respectively.

The morphology and surface roughness of SS and pentacene were investigated with atomic force microscope (AFM). The crystallinity of pentacene on SS was examined by X-ray diffraction (XRD) with 3C2 beam line at the Pohang Accelerator Laboratory. The dielectric constant (C_i) at 1 MHz and leakage current of Al_2O_3 film were measured using HP 5270A. The current–voltage ($I–V$) characteristics of pentacene TFTs were obtained using HP 4284A.

3. Results and discussion

Fig. 1a–j show AFM images of 304 SS and 430 SS which were polished using CMP process for various times (10, 20, 30 and 40 min) and Fig. 1k shows the change of surface roughness as a function of the polishing time. Prior to the CMP process, surface roughness of 304 SS was about 33.8 nm and that of 430 SS was about 19.5 nm. Both were smoothed down to the level of ~2.5 nm after a CMP process of above 10 min.

Fig. 2a shows the MIM structure and Fig. 2b–d show the leakage current when the voltage of 0–40 V was applied to the top electrode on Al_2O_3 of different thickness (50, 100, 200 and 500 nm) on N++Si substrate, 304 SS and 430 SS. Al_2O_3 films thicker than 200 nm on each substrate showed a leakage current level as low as 10^{-11} A. But the breakdown voltage was observed in the MIM structure with 100 nm Al_2O_3 on 304 SS at ~5 V and on 430 SS at ~30 V. Al_2O_3 film of 50 nm on N++Si substrate maintained insulating properties up to 20 V. The N++Si substrate has a low roughness of 0.2 nm so that Al_2O_3 films on N++Si substrate shows better insulating characteristic than that on bare 304 SS or 430 SS at the same thickness. The insulating properties of Al_2O_3 film on SS can be improved with reducing surface roughness using CMP process and actually, breakdown voltage was not observed in MIM structures with Al_2O_3 film of 100 nm on polished 304 SS and 430 SS. On the other hand, C_i values of Al_2O_3 films (100 nm) on each substrate show almost the same value of ~65 nF/cm^2 regardless of the substrate type.

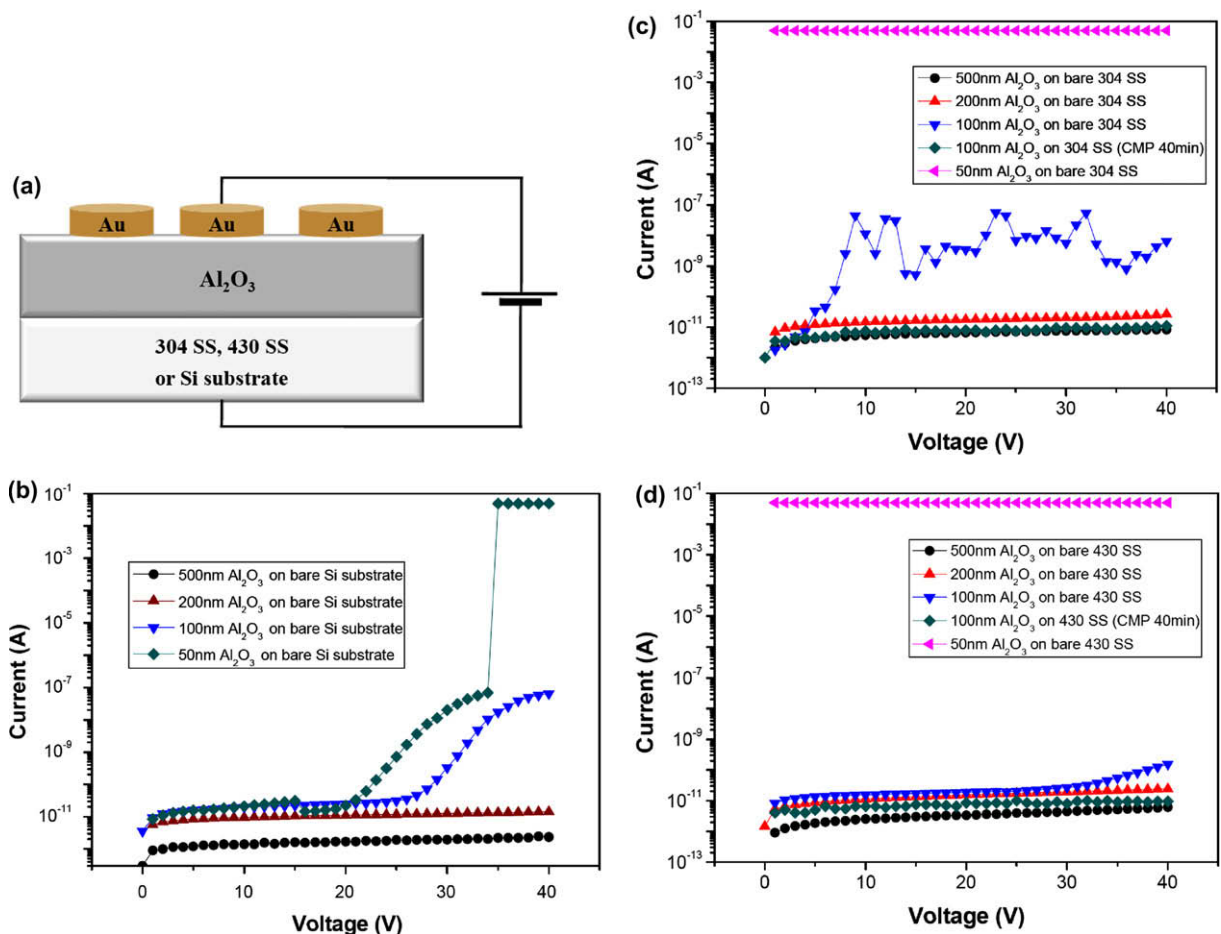
Fig. 3a shows the structure of the top-contact pentacene TFT which was characterized to compare the performance of the pentacene TFTs on each substrate. Transfer charac-


Fig. 2. (a) Metal–insulator–metal (MIM) structure of Au/Al$_2$O$_3$/304 SS, 430 SS and Si substrate and current–voltage characteristics of Au/Al$_2$O$_3$/, (b) Si substrate, (c) 304 SS and (d) 430 SS.
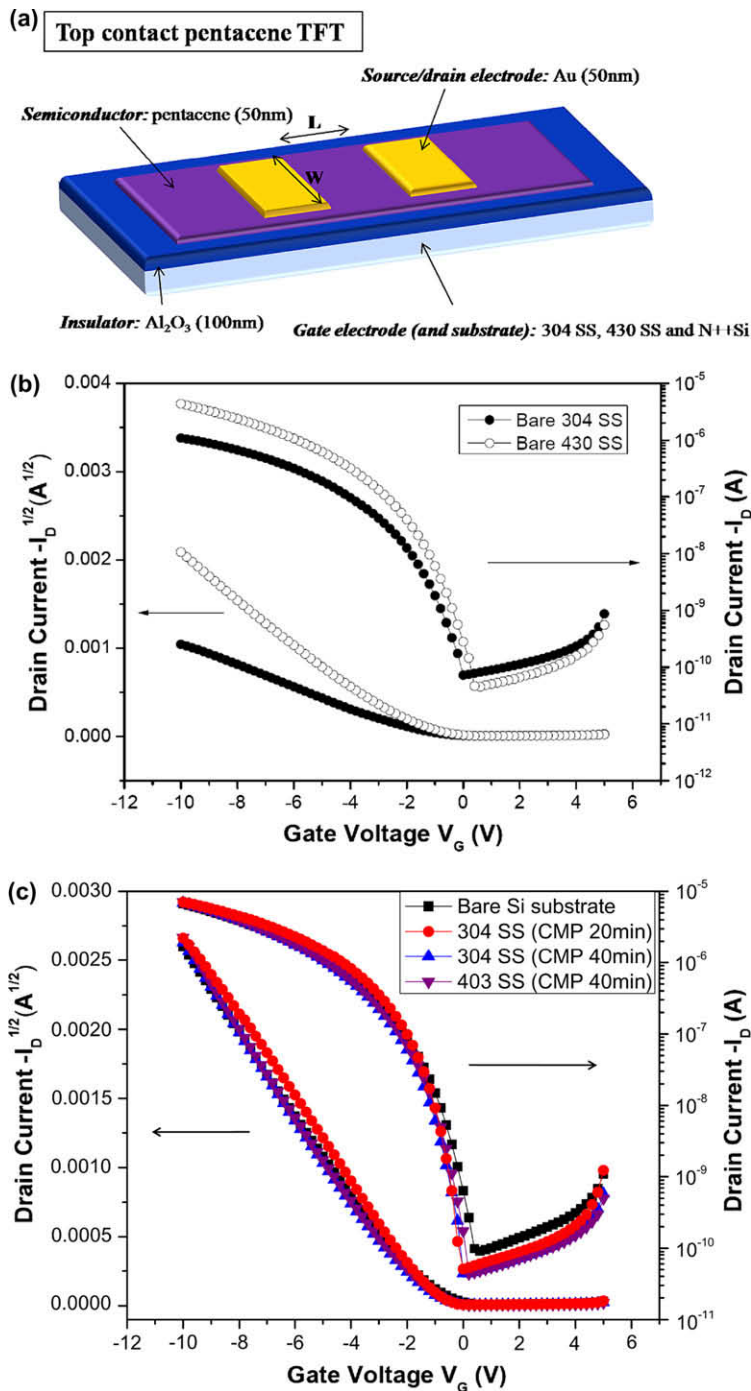

Fig. 3. (a) Schematic structure of the top-contact pentacene thin-film transistor, (b) comparative transfer characteristics of the pentacene TFT on bare 304 SS and bare 403 SS and (c) comparative transfer characteristics of pentacene TFT on Si, bare 304 SS, 20 min polished 304 SS, 40 min polished 304 SS and 40 min polished 430 SS: $\log_{10}|I_D|$ versus V_G and $|I_D|^{1/2}$ versus V_G at −10 V.

teristics of the pentacene TFTs with bare 304 SS and 430 SS are shown in Fig. 3b and transfer characteristics of the pentacene TFTs with N++Si and polished SS are compared in Fig. 3c. All pentacene TFTs fabricated with SS showed p-type transistor-characteristics, even though their device performance was different. Most pentacene TFTs on bare 430 SS showed higher saturation currents at each V_G than those pentacene TFTs on 304 SS, as shown in Fig. 3b, but current levels were lower than the pentacene TFTs on N++Si substrate. The saturation currents and transfer char-

Table 1
Summary of the pentacene OTFT characteristics fabricated on the various substrates.

Substrate	Field-effect Mobility (cm²/Vs)	On/off Current ratio	Threshold Voltage (V_{th})	Substrate	Field-effect Mobility (cm²/Vs)	On/off Current ratio	Threshold Voltage (V_{th})
N++Si	0.17–0.34	$\sim10^5$	~-1.5	OTS treated Al$_2$O$_3$/N++Si	0.63–0.90	$\sim10^6$	~-1
Bare 304 SS	0.005–0.17	10^3–10^4	−0.5 to −1.5	OTS treated Al$_2$O$_3$/430 SS	0.45–0.85	$\sim10^6$	~-1
Bare 430 SS	0.11–0.36	$\sim10^5$	−1.0 to −2.0	OTS treated Al$_2$O$_3$/304 SS	0.40–0.70	$\sim10^6$	~-1
304 SS (CMP 10 min)	0.23–0.40	$\sim10^5$	~-1.5	–			
304 SS (CMP 20 min)	0.23–0.41	$\sim10^5$	~-1.5	–			
304 SS (CMP 40 min)	0.24–0.38	$\sim10^5$	~-1.5	–			
430 SS (CMP 40 min)	0.27–0.42	$\sim10^5$	~-1.5	–			

acteristics of pentacene TFTs on SS were improved with CMP process close to the pentacene TFT on N++Si substrate as shown in Fig. 3c. The field-effect mobility in the saturated regime ($V_D = -10$ V) was calculated using the formula given below:

$$I_{DS} = \frac{WC_i}{2L}(V_G - V_T)^2\mu \tag{1}$$

where I_{DS} is the drain current at specific gate voltage (V_G), W is the channel width, L is the channel length, V_T is the threshold voltage, μ is the carrier field-effect mobility and C_i is the capacitance per unit area of the gate insulator (C_i of 100 nm thick Al$_2$O$_3$ was measured to be 65nF/cm²). The field-effect mobility (μ), on/off ratio and threshold voltage (V_G) of pentacene TFTs on various substrates are summarized in Table 1. μ and on/off ratio of pentacene TFTs on bare 304 SS are in a wide range of 0.005–0.17 cm²/Vs and on/off ratio of 10^3–10^4 depending on the location of the substrate. μ and on/off ratio of pentacene TFTs on bare 430 SS are in a range of 0.11–0.36 cm²/Vs and on/off ratio of $\sim10^5$. Bare 304 SS has a roughness of 33.8 nm and that of 430 SS was about 19.5 nm and so the variation of the OTFT characteristics was significant for 304 SS but less significant for 430 SS.

Pentacene TFTs on 304 SS and 430 SS polished using CMP process showed a high mobility of 0.25–0.40 cm²/Vs and on/off ratios of $\sim10^5$ which is slightly better than pentacene TFTs on Al$_2$O$_3$/N++Si substrate (μ: 0.17–0.34 cm²/Vs, on/off ratio: $\sim10^5$). The local variation was not significant for polished substrate.

Fig. 4a and b show the morphology of the pentacene film grown on Al$_2$O$_3$ (100 nm) deposited on bare 304 SS and 430 SS and Fig. 4c and d show the morphology of the pentacene film grown on Al$_2$O$_3$ (100 nm) deposited on polished 304 SS and 430 SS. Even though the roughness of the bare SS are much higher than the polished SS, grain shape and grain size of the pentacene film on bare SS are nearly the same as on polished SS. Crystallinity of the pentacene film on Al$_2$O$_3$ (100 nm) deposited on bare SS and polished SS is shown in Fig. 4e and the peaks show that the crystallinity is almost the same for all the pentacene films. XRD patterns contain the series of (0 0 k), indicating the thin film phase of material and (0 0 k′), indicating the crystalline bulk phase of the material [11,12]. Both the thin film and the bulk phase mean highly ordered and crystallized states. Thin film phases of (0 0 k) were mainly observed at both pentacene films grown on Al$_2$O$_3$(100 nm) deposited on bare SS and polished SS, and there is no significant change in intensity of (0 0 k) between pentacene films
Fig. 4. AFM images of pentacene (50 nm) grown on Al$_2$O$_3$ (100 nm). (a) Bare 304 SS, (b) bare 430 SS, (c) 40 min polished 304 SS and (d) 40 min polished 430 SS and XRD spectrum of pentacene (50 nm) grown on Al$_2$O$_3$ (100 nm)/bare SS and polished SS.

grown on Al$_2$O$_3$ (100 nm) deposited on bare SS and polished SS. Based on above results, it was confirmed that properties including crystallinity and morphology of pentacene film grown on Al$_2$O$_3$ (100 nm) deposited on bare SS are almost similar to that grown on Al$_2$O$_3$ (100 nm)
Fig. 5. (a) Comparative transfer characteristics: $\log_{10}|I_D|$ versus V_G and $|I_D|^{1/2}$ versus V_G at -10 V, (b) output characteristics: drain current (I_D) versus drain voltage(V_D) of pentacene TFT with and without OTS treatment on Al_2O_3 (100 nm)/40 min polished 430 SS and (c) field-effect mobility versus polishing time of SS.
Fig. 6. (a) Optical image of fabricated pentacene TFT in bent state, (b) half-round glass tubes with different diameters (D = (i) 70, (ii) 45 and (iii) 24 mm) and (c) comparative transfer characteristics of pentacene TFT with OTS treated Al_2O_3(100 nm)/40 min polished 304 SS in bent state: $\log_{10}|I_D|$ versus V_G and $|I_D|^{1/2}$ versus V_G at -10 V.

deposited on polished SS. Good pentacene TFTs on bare SS show mobility of $\sim$0.3 cm^2/Vs and on/off ratio of $\sim$10^5, which is nearly at the same level of pentacene TFTs on polished SS.

OTS monolayer has been widely employed as a buffer layer to improve the crystallinity of organic semiconductor grown on it [12–14]. OTS treatment was performed on Al_2O_3 layer to improve the performance of the pentacene TFTs. In Fig. 5a and b, transfer and output characteristics of pentacene TFT with OTS treated Al_2O_3/430 SS are compared to the pentacene TFTs with bare Al_2O_3/430 SS. With OTS treatment, the saturation currents at the same V_G were increased and the hysteresis between forward and backward transfer curve was removed. As shown in Table 1, the μ and on/off ratio of pentacene TFTs on SS were improved with OTS treatment up to 0.40–0.85 cm^2/Vs and $\sim$10^6, respectively. These values are comparable to the performance of the pentacene TFTs with OTS treated Al_2O_3/N++Si substrate (0.63–0.90 cm^2/Vs and $\sim$10^6). The mobility of pentacene TFTs on various substrates are shown all together in Fig. 5c, and this graph confirms that high performance pentacene TFT can be fabricated with polished SS as with N++Si substrate.

Not like N++Si substrate, SS is bendable and I–V characteristics of the pentacene TFT with OTS treated Al_2O_3/304 SS were measured in bent state as well as in flat state. Pentacene TFTs were bent over a half-round glass tube with bending diameter (D) of 24, 45 or 70 mm during the

I–V measurement. The pentacene TFT in bent state is shown in Fig. 6a and half-round glass tubes with different diameters were shown in Fig. 6b. μ and V_{th} of pentacene TFTs without bending strain is 0.50 cm^2/Vs and -0.49 V. μ is decreased by 14% when OTFT was placed on the curved surface with D = 70 mm, by 16% with D = 45 mm and by 24% with D = 24 mm, and V_{th} is slightly shifted to the positive direction. Nevertheless, the device performed well showing the standard transistor characteristics including the linear regime and the saturation regime and on/off ratio was also maintained at $\sim$10^6 steadily in bent state, as shown in Fig. 6c. It was already pointed out that tensile strain in the FET device induced an increase in the intergrain boundaries and the interdomain structural mismatch leading to the decrease in the mobility of OTFT devices [7]. Also it was pointed out that tensile strain caused a larger spacing between molecules resulting in a decrease in the mobility [8].

4. Conclusion

In summary, we fabricated pentacene OTFT with aluminum oxide as a gate dielectric on a rough SS substrate and on a polished SS using CMP process. MIM structures and pentacene TFTs on a rough and polished SS were fabricated and characterized. Pentacene TFTs on a rough SS showed a wide range of device characteristics depending on the location at the substrate surface and mostly poorer perfor-

mance was obtained compared to the device on a flat N++Si substrate. With polishing using CMP process, performance of the pentacene TFTs on SS was improved up to the same level of pentacene TFT on the N++Si substrate. Leakage current through Al_2O_3 layer on SS was also reduced with polishing. Additionally, mobility and on/off ratio of pentacene TFT on SS was increased with OTS treatment. Characteristics of the pentacene TFTs on SS in bent state were also measured and it was confirmed that the mobility was reduced with the tensile strain.

of the emitting layers by the stamp transfer printing method and an efficiency improvement by the double layer emitting structure was demonstrated.

2. Experimental

A device structure of indium tin oxide (ITO, 150 nm)/ polyethylene-3,4-dioxythiophene:polystyrenesulfonate (PEDOT:PSS, 60 nm)/poly(9,9′-dioctylfluorene-co-bis-N,N′- (4-ethoxycarbonylphenyl)-bis-N,N′-phenyl-benzidine (PFO- co-NEPB, 30 nm)/4,4′,4″-tris(N-carbazolyl)triphenylamine (TCTA):tris(2-phenylpyridine)iridium (Ir(ppy)$_3$) (20 nm, 5% doping)/3-(biphenyl-4-yl)-4-phenyl-5-(4-tert-butyl- phenyl)-1,2,4-triazole (TAZ):Ir(ppy)$_3$ (20 nm, 5% doping)/ 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, 5 nm)/tris(8-hydroxyquinoline)aluminium (Alq$_3$, 20 nm)/ LiF (1 nm)/Al (200 nm) was used to prepare the double emitting layer device. Single emitting layer devices with TCTA:Ir(ppy)$_3$ or TAZ:Ir(ppy)$_3$ were also fabricated to compare the device performances of the double emitting layer PHOLED. Fig. 1 shows the device structures of the soluble PHOLEDs used in this work. The TCTA:Ir(ppy)$_3$ and the TAZ:Ir(ppy)$_3$ layers were coated from a 1.0 wt% toluene solution. The wt% was a concentration of the host material. The coated emitting layer was baked at 110 °C for 30 min to remove residual solvent. The stamp transfer printing of the TAZ:Ir(ppy)$_3$ layer using polymethylsiloxane (PDMS) stamp was carried out according to the procedure reported earlier [12]. Detailed process for the stamp transfer printing is described in Fig. 2. Current density–voltage–luminance characteristics of the devices were obtained by Keithley 2400 source measurement unit and a CS 1000 spectroradiometer.

3. Results and discussion

A double layer emitting structure was reported in a vacuum deposited PHOLEDs and the quantum efficiency was significantly improved compared with common single layer PHOLEDs [9–11]. However, the double layer emitting structure could not be realized in soluble PHOLEDs because of intermixing of the two emitting layers during spin-coating. The problem can be avoided by using a dry patterning method which utilizes a transfer process for the film for-

mation [12,13]. In this work, a stamp transfer printing process was used to fabricate the double emitting layer green PHOLEDs and device performances were investigated. The transfer process was reproducible and the yield of the device was over 90%.

Fig. 3 shows the current density–voltage–luminance curves of the single and double layer green PHOLEDs. The current density was high in the PHOLED with the double layer emitting structures, while it was low in the PHOLEDs with single layer emitting structure. The current density was greatly enhanced in the green PHOLED with the double layer emitting structure. The increased current density in the double emitting layer device can be explained by the efficient hole and electron injection from the charge transport layers. Hole injection from the PFO-co-NEPB to the TCTA:Ir(ppy)$_3$ emitting layer and the electron injection from the BCP to the TAZ:Ir(ppy)$_3$ layer are efficient because there is little energy barrier for the charge injection as can be seen in the energy level diagram (Fig. 4). Compared with the double emitting layer device, the hole injection is limited in the TAZ:Ir(ppy)$_3$ device and the electron injection is hindered in the TCTA:Ir(ppy)$_3$ device, resulting in low current density. The luminance–voltage curves were similar to the current density–voltage curves even though the luminance of the TAZ:Ir(ppy)$_3$ device was low. The low luminance of the TAZ:Ir(ppy)$_3$ device is due to electron leakage from the emitting layer to the hole transport layer as seen in the EL spectra of the device (Fig. 6).

The quantum efficiency and power efficiency of the green PHOLEDs are shown in Fig. 5. The efficiency of the double emitting layer device was much higher than that of the single layer device. The high efficiency of the double emitting layer device is due to charge confinement and charge balance in the emitting layer. Both holes and electrons are effectively injected from the hole and electron transport layers and charge balance is improved in the double emitting layer structure. In the case of the TCTA:Ir(ppy)$_3$ device, the charge balance is degraded because of poor electron injection. Poor hole injection in the TAZ:Ir(ppy)$_3$ device disrupts the charge balance, decreasing the quantum efficiency of the TAZ:Ir(ppy)$_3$ device. Therefore, the stacking of the two emitting layers by the stamp transfer printing method was effective to enhance the quantum efficiency of the soluble green PHOLEDs. The quantum efficiency of the green PHOLEDs was quadrupled by the stacking of the

Fig. 2. Stamp transfer printing process for the fabrication of the stacked emitting layers.
Fig. 3. Current density–voltage–luminance curves of the TCTA:Ir(ppy)$_3$, TAZ:Ir(ppy)$_3$, and TCTA:Ir(ppy)$_3$/TAZ:Ir(ppy)$_3$ devices.
Fig. 4. Energy level diagram of the materials used in this work.

two emitting layers. In addition, the power efficiency was also greatly improved due to the high quantum efficiency and high current density.

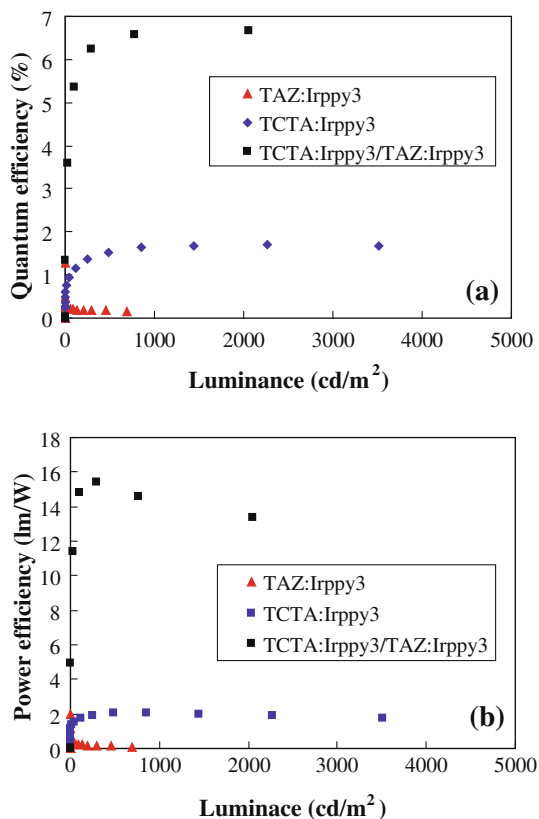
The EL spectra of the soluble green PHOLEDs fabricated in this work are shown in Fig. 6. The EL spectra were measured at 1000 cd/m^2. The double emitting layer device showed a typical EL emission of Ir(ppy)$_3$ based green PHOLEDs. Peak maximum of the EL spectra was observed at 515 nm and no peak except for the Ir(ppy)$_3$ was detected in the device. The TCTA:Ir(ppy)$_3$ device exhibited a similar EL spectrum. However, the EL spectrum of the TAZ:Ir(ppy)$_3$ device was different from those of the TAZ:Ir(ppy)$_3$ and double emitting layer devices. In addition to the Ir(ppy)$_3$ emission, a broad peak was observed in the blue emission region. The broad blue emission peak is originated from


Fig. 5. Quantum efficiency–luminance (a) and power efficiency–luminance (b) curves of the TCTA:Ir(ppy)₃, TAZ:Ir(ppy)₃, and TCTA:Ir(ppy)₃/TAZ:Ir(ppy)₃ devices.

the emission of the PFO-co-NEPB hole transport material. There is an energy barrier of 0.9 eV between the PFO-co-NEPB and TAZ, limiting the hole injection from the PFO-co-NEPB to TAZ emitting layer and hole accumulation at the interface between the PFO-co-NEPB and TAZ. In addition to the hole accumulation, TAZ has a strong electron transport character and electrons can be transported to the interface between the PFO-co-NEPB and TAZ emitting layer. The hole accumulation and high electron density near PFO-co-NEPB induces electron leakage from the TAZ layer to the PFO-co-NEPB layer in spite of 0.4 eV energy barrier, leading to hole-electron recombination at the interface between PFO-co-NEPB and TAZ. Hole blocking properties of the TAZ due to the highest occupied molecular orbital of 6.3 eV contribute to the charge accumulation and PFO-co-NEPB emission. The PFO-co-NEPB emission is responsible for the low current efficiency of the TAZ:Ir(ppy)₃ device.

4. Conclusions

In summary, high efficiency soluble green PHOLEDs could be developed by using the double layer emitting structure fabricated by the stamp transfer printing method. Two emitting layers could be effectively stacked by the stamp transfer printing process and the current efficiency of the green PHOLEDs could be improved by more than four times.

Table 1
Physical and electrical characteristics of the hybrid dielectrics.

Dielectric type	Thickness (nm)	Dielectric constant	Surface roughness (nm)	Capacitance (nF/cm²)	Dielectric strength (MV/cm)
15 mol% Zr(OPr^i)$_4$ hybrid dielectrics (YHD15)	140	5.3	0.242	33	2.3
30 mol% Zr(OPr^i)$_4$ hybrid dielectrics (YHD30)	105	6.3	0.263	53	2.1

materials were potential candidates for gate dielectrics in OTFTs [11]. Choi and Bae also studied methacryloxypropyl trimethoxysilane and diphenylsilanediol based hybrid materials for application as gate dielectrics [12]. In our previous work, we selected 3-methacryloxypropyltrimethoxysilane and Zr alkoxide as precursors to design a dielectric with a high dielectric constant and low leakage current. The resulting photopatternable hybrid dielectric exhibited excellent surface morphology, a high dielectric constant (5.5), and reasonable dielectric strength (1.5–2.0 MV/cm) [10]. In this letter, we focus on an in-depth investigation of the microstructural features of hybrid dielectrics as a function of Zr alkoxide content in an attempt to understand its influence on TFT performance.

2. Experimental

The organic–inorganic hybrid gate dielectric solution was synthesized by sol–gel reactions between 3-methacryloxypropyltrimethoxysilane (MEMO, Sigma–Aldrich), zirconium isopropoxide (Zr(OPr^i)$_4$, 70% in 1-propanol, Sigma–Aldrich), and methacrylic acid (MAA, 97%, Sigma–Aldrich). In the first step, MEMO solution was mixed with 0.2 M HCl as a catalyst, followed by vigorous stirring for 30 min. A mixture of Zr(OPr^i)$_4$, MAA, and 1-propanol was also prepared at a 1:1:1 molar ratio. The Zr(OPr^i)$_4$ to MEMO solution ratio was varied to control the dielectric constant of the resulting gate dielectric. Two different molar ratios of MEMO:Zr(OPr^i)$_4$ = 8.5:1.5 (denoted YHD15) and 7:3 (denoted YHD30) were selected. When Zr(OPr^i)$_4$ was mixed with MEMO, the alkoxy groups present in both precursors were partially hydrolyzed. DI-water was then added to facilitate the hydrolysis and condensation reac-

tions. After further stirring for 24 h in air, the synthesized sol–gel solution was diluted with 1-propanol to control viscosity.

Hybrid dielectric films were obtained by spin coating the precursor solution at 4000 rpm for 30 s on an n-type heavily doped silicon wafer substrate. After spin coating, the films were immediately prebaked at 110 °C on a hot plate in air for 30 min to evaporate the solvent and improve adhesion to the substrate. A final thermal treatment was carried out at 170 °C for 3 h. For comparison with the hybrid dielectric, a PVP dielectric was also prepared from poly(4-vinylphenol) and poly(melamine-co-formaldehyde) as a cross-linking agent, in propylene glycol monomethyl ether acetate (PGMEA). These materials were mixed in the weight ratio 10:5:85. The PVP dielectric films were obtained by spin coating the precursor solution at 4000 rpm for 30 s on an n-type heavily doped silicon wafer substrate and cross-linking at 175 °C for 30 min in air.

Fig. 2. HRTEM images of: (a) 15 mol% Zr(OPr^i)$_4$ and (b) 30 mol% Zr(OPr^i) hybrid dielectrics. The inset shows the diffraction pattern of a selected area. Arrows indicate the selected particulate crystalline ZrO$_2$ phase among many nanocrystals.

Fig. 1. XRD patterns of 15 mol% Zr(OPr^i)$_4$ and 30 mol% Zr(OPr^i) hybrid dielectrics.

To study the electrical performance of gate dielectrics, capacitance–voltage (*C–V*) at 1 MHz and leakage current–voltage (*I–V*) characteristics were measured using an Agilent 4284A precision LCR meter and an Agilent 5263A source-measure unit, respectively. Solution-processed OTFTs based on either the hybrid sol–gel dielectric or PVP were also fabricated. To fabricate co-planar transistors, Au/Cr electrodes were deposited through a shadow mask on either the hybrid dielectric or PVP film. The channel electrodes had the dimension of the width ~3 mm and the length ~50 μm. Bis(triisopropylsilylethynyl) pentacenes (TIPS–PEN) were then drop-cast as an organic semiconductor between the source and drain electrodes, and the samples were annealed at 100 °C in a vacuum oven for 20 min. The transistor on–off ratio, mobility, and threshold voltage were measured in air.

The microstructure and chemical composition of the hybrid films were observed by X-ray diffraction (XRD, X'Pert-PRO MRD, Phillips), high-resolution transmission electron microscopy (HRTEM, JEM-4010, JEOL), and X-ray photoelectron spectroscopy (XPS, Escalab 220-XL). XPS spectra were recorded in the constant energy mode at 50 eV. The C 1s lines were taken as internal references with a binding energy (BE) of 285 eV. The crystal structures and film morphologies of TIPS–PENs deposited on different dielectrics were compared by optical mode of confocal laser scanning microscopy (LEXT OLS3000, Olympus) and XRD analysis.

3. Results and discussion

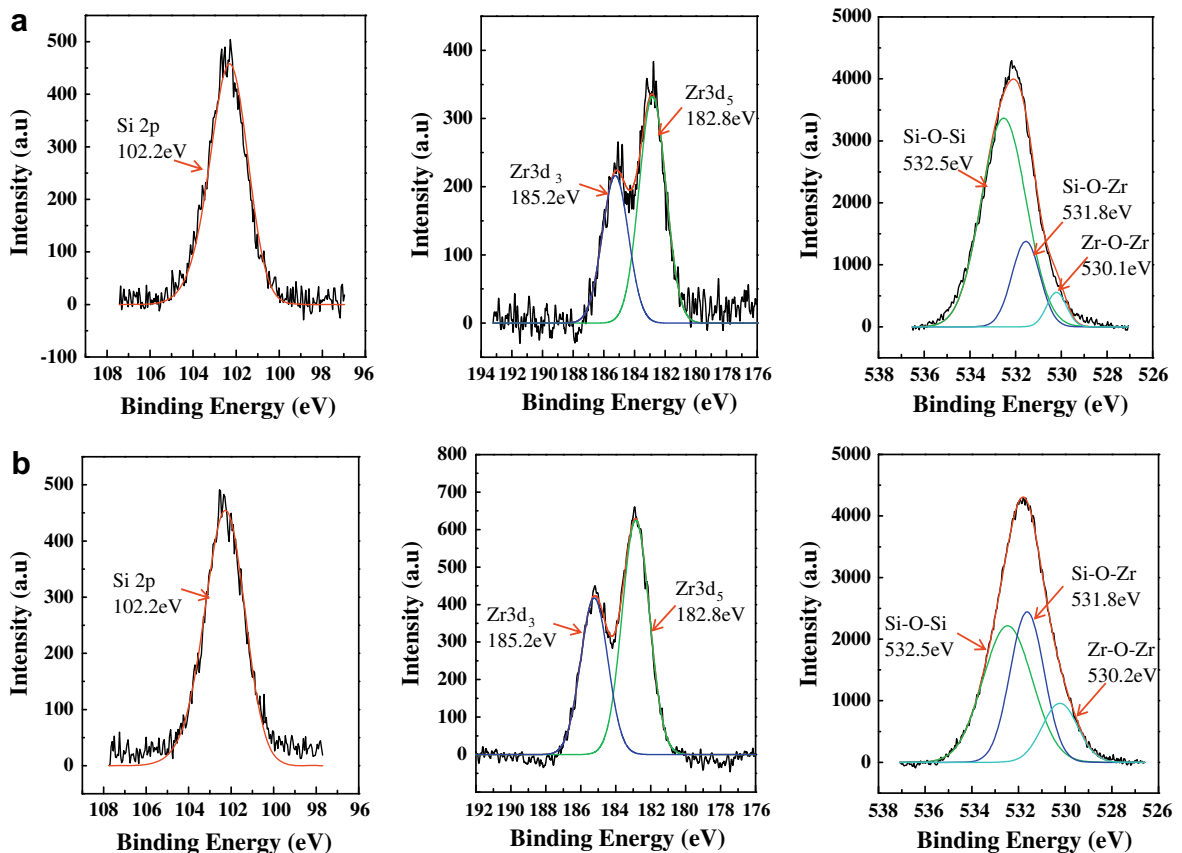
An organic–inorganic hybrid precursor solution was synthesized using a mixture of MEMO and $Zr(OPr^i)_4$. MEMO is a silicon-based alkoxide with a three alkoxy groups and one methacryl group, which can be cross-linked by either photo- or thermal-energy. $Zr(OPr^i)_4$ is a typical zirconium-based alkoxide with four alkoxy groups. We synthesized hybrid solution containing either 15 or 30 mol% $Zr(OPr^i)_4$ to control the dielectric properties. The two different compositions showed slightly different characteristics. The dielectric film properties are summarized in Table 1. The surface roughness in a 2×2 μm scan area was similar and the average RMS values for YHD15 and YHD30 were 0.242 and 0.263 nm, respectively. The YHD30 dielectric film was slightly thinner than the YHD15 film even though the two films were coated under identical processing conditions. The leakage current of the two films was also nearly identical. The dielectric strength, defined as the electric field at a current density of 10^{-6} A/cm^2, changed slightly from 2.1 to 2.3 MV/cm with increasing zirconium alkoxide. By contrast, the dielectric constant,


Fig. 3. XPS spectra of hybrid dielectrics showing Si 2p, Zr 3d, and O 1s spectra: (a) 15 mol% $Zr(OPr^i)_4$ and (b) 30 mol% $Zr(OPr^i)_4$.

which is influenced by the Zr concentration, increased from 5.3 at 15 mol% $Zr(OPr^i)_4$ to 6.3 at 30 mol% $Zr(OPr^i)_4$.

XRD patterns of both hybrid dielectric films are shown in Fig 1. Sharp diffraction patterns observed at $2\theta = 53.8°$ and $55.6°$ originate from the Si wafer substrate. There are no other diffraction peaks that can correspond to ZrO_2 or relevant crystalline phases, indicating that the hybrid material is amorphous regardless of the Zr precursor content. Further microstructural investigation of the hybrid dielectrics was performed by HRTEM. As shown in Fig. 2a, ~5 nm crystallites are distributed in the amorphous-like matrix in the YHD15 dielectric film. More crystallites of similar sizes are observed in the YHD30 dielectric film. Because the ZrO_2 nuclei are surrounded by a rigidly grafted siloxane backbone, their growth is limited to a few nanometer-sized clusters regardless of the difference in Zr precursor concentration. Selected area diffraction (SAD) patterns obtained from both samples show the presence of crystalline ZrO_2 as shown in Fig 2a (inset). Monoclinic ZrO_2 is thermodynamically stable, but ortho-

rhombic ZrO_2 exists in a metastable phase due to the surface energy effect. No other diffraction patterns except for ZrO_2 appear. HRTEM analysis confirmed that the hybrid dielectrics comprised ZrO_2 crystallites embedded in an amorphous organosiloxane matrix; these crystals were too small to detect using X-ray analysis [13]. Fig. 2b shows the presence of an increased number of nanocrystallites in the YHD30 dielectric film.

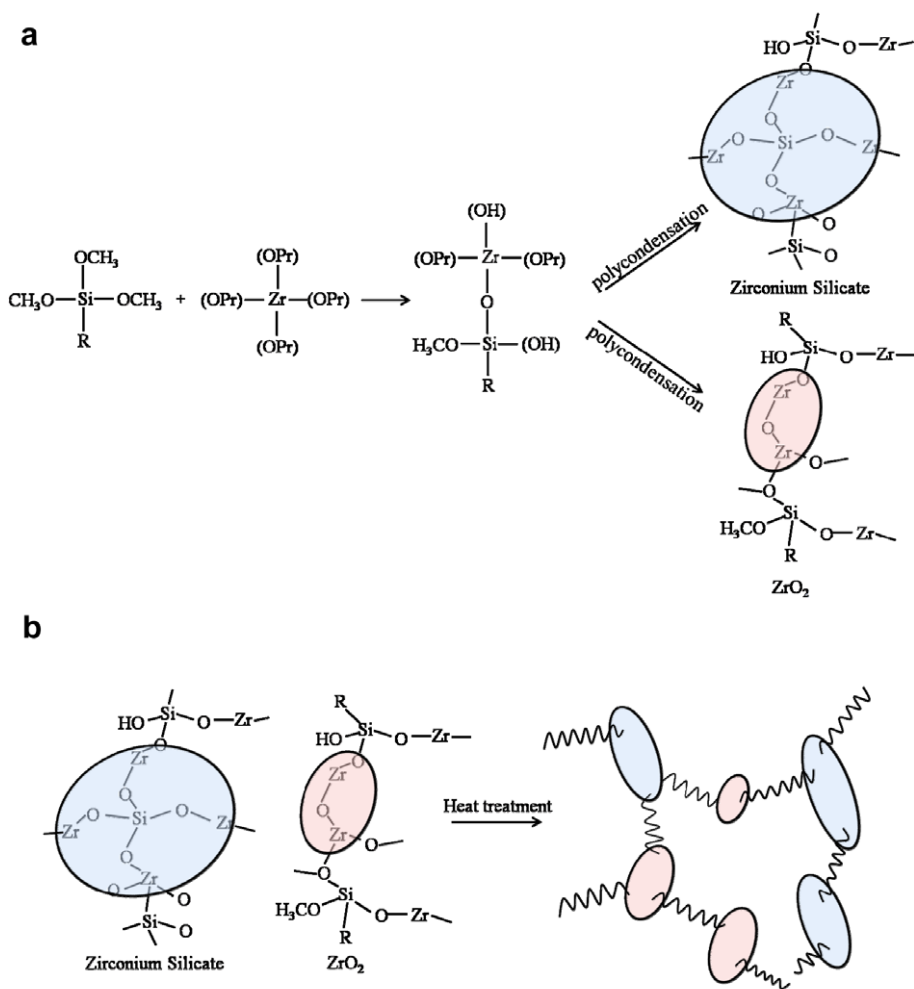
The chemical composition and bonding nature of the constituents were studied by XPS. Wide scan spectra of both YHD15 and YHD30 films contain Zr 3d, O 1s, C 1s and Si 2p peaks. Nearly identical Si spectra were detected for both films as shown in Fig. 3. The Si peak could be fitted to Si 2p with a 102.2 eV BE, which was shifted by 1.2 eV compared to the Si 2p BE for SiO_2. A similar Si 2p BE shift was observed by Guittet et al. in which the zirconium silicate (zircon, $ZrSiO_4$) Si 2p BE is smaller than SiO_2 by a factor of 1.35 eV [14]. This chemical shift depends on the number of second nearest neighboring Zr atoms, indicative of the presence of zirconium silicate in our hybrid films [15,16].


Fig. 4. Schematics showing the formation mechanism of the nanoparticle-dispersed hybrid dielectrics via sol–gel reaction: (a) hydrolysis and condensation reactions between MEMO and $Zr(OPr^i)_4$ precursors, leading to ZrO_2 and $ZrSiO_4$ particles and (b) the overall microstructure after crosslinking. The spring represents the organosiloxane matrix.

The Zr 3d spectrum consists of doublet peaks in which Zr 3d3 and Zr 3d5 spin-orbital splitting are characterized by 185.2 and 182.8 eV BEs, respectively. The Zr 3d BEs were slightly shifted toward a higher value compared to ZrO_2. These data are consistent with a previous report in which Zr 3d BEs of $ZrSiO_4$ were 0.5 eV larger than ZrO_2 [14,16,17]. An increased Zr 3d BEs also indicates the formation of zirconium silicate. The Si 2p and Zr 3d BE shifts can be explained by the principle of electronegativity equalization. Electrons are more withdrawn from Zr in zirconium silicate than ZrO_2, because the Si and O electronegativities are larger than Zr [17]. In addition, the Zr doublet intensity increases about two-fold as the Zr precursor concentration increases from 15 to 30 mol%, indicating increased ZrO_2 and zirconium silicate concentrations (Fig. 3). The O 1s spectrum can be resolved into three peaks as shown in Fig. 3. The peak at a 532.5 eV BE is assigned to oxygen in the Si–O–Si species, whereas the 530.1 eV is peak considered oxygen in the Zr–O–Zr species. An additional peak at a 531.8 eV BE located between the Si–O–Si and Zr–O–Zr oxygen peaks can be attributed to O in a Zr–O–Si bonding configuration, considering that the peak is shifted 1.6 eV toward a higher energy from ZrO_2 [16,17].

The oxygen atoms are commonly involved in three major phases in the hybrid dielectric: organosiloxane, ZrO_2, and $ZrSiO_4$. Thus, quantitative analysis of the O 1s three peaks can provide the relative composition of each phase. The relative concentration of Si–O–Si, Si–O–Zr, and Zr–O–Zr species in the YHD15 film was 75.2%, 18.3%, and 6.5%, respectively, and 59.4%, 26.6% and 14% in YHD30. This result clearly supports the idea that increased zirconium silicate and ZrO_2 form with increased $Zr(OPr^i)$. The ZrO_2 content in YHD15 is approximately two times that in YHD30.

XPS analysis confirmed that the hybrid dielectrics are composed of organosiloxane, ZrO_2, and $ZrSiO_4$. It is believed that amorphous $ZrSiO_4$ and ZrO_2 crystallites are present in the amorphous organosiloxane matrix. These small particulates are uniformly distributed, so that there is no difference in the film surface roughness, as described in Table 1, even though the number of particles differs. In contrast, the dielectric constant (ε) increases with increasing Zr precursor concentration. Both $ZrSiO_4$ ($\varepsilon = 12.6$) and ZrO_2 ($\varepsilon = 25$) have high dielectric constants and are considered promising alternatives to conventional SiO_2 gate dielectrics [17,18]. Therefore, increased $ZrSiO_4$ and ZrO_2 phases would increase the dielectric constant of an organosiloxane matrix. A hybrid dielectric composed of three phases can be estimated using the following generalized rule of mixture [19]:

$$\varepsilon_{eff} = f_1\varepsilon_1 + f_2\varepsilon_2 + f_3\varepsilon_3 + \cdots = \sum_i f_i\varepsilon_i,$$

where ε_{eff} is the dielectric constant of a composite material, f_i is the volume fraction and ε_i is the dielectric constant of constituent phase i. Using the volume fraction for each phase obtained from the O 1s spectra analysis, the calculated dielectric constants are 5.04 for YHD15 and 6.38 for YHD15, which agree relatively well with the experimentally measured values in Table 1.

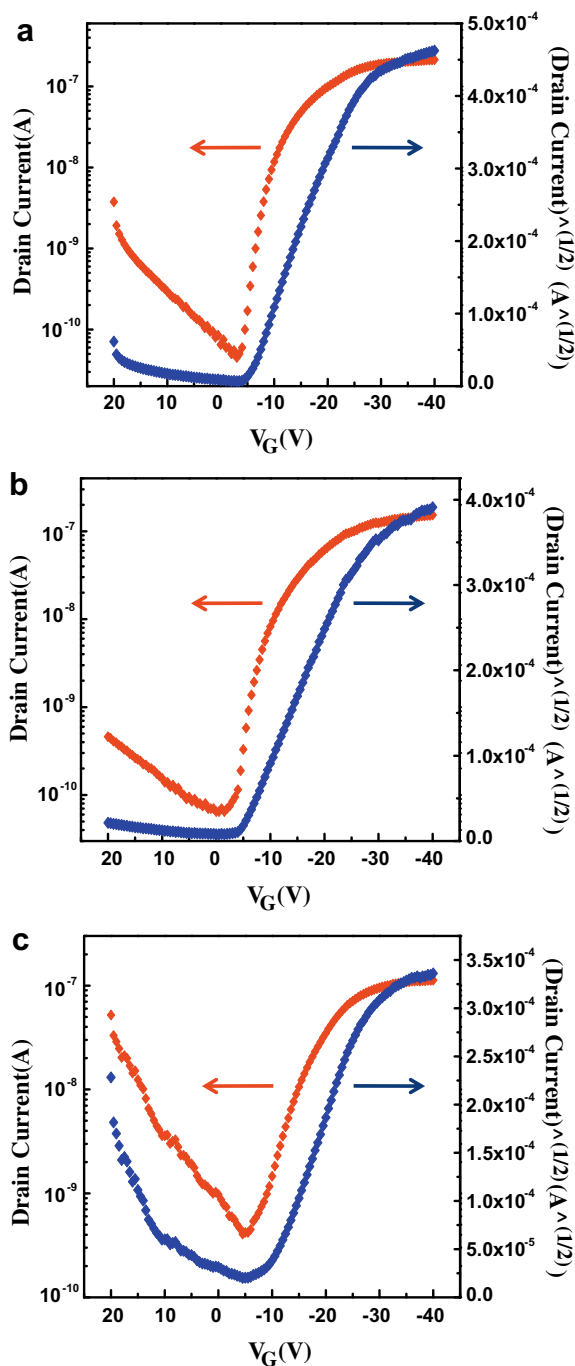
The formation mechanism for sol–gel derived ZrO_2/$ZrSiO_4$ particle-dispersed hybrid material is schematically depicted in Fig. 4. First, MEMO is partially hydrolyzed in a pre-mixing step. The resulting silanol group (Si–OH) is relatively stable under acidic conditions and not subject to self-condensation. When mixed with Zr isopropoxide,


Fig. 5. Transfer characteristics of organic thin-film transistors fabricated using: (a) 15 mol% $Zr(OPr^i)_4$, (b) 30 mol% $Zr(OPr^i)$ hybrid dielectrics and (c) PVP. Drain voltage was set to -20 V.

the Si–OH group joins with a Zr precursor via hydrolysis-condensation, producing –Si–O–Zr– networks as an intermediate product. Further re-hydrolysis and polycondensation of –Si–O–Zr– upon introducing additional water results in $ZrSiO_4$ formation within the organosiloxane matrix. It is believed that not all Zr precursors undergo polycondensation with MEMO. In our synthetic conditions, variable reactivity toward hydrolysis and condensation of the two precursors prevent a continuous silica–zirconia network from forming. Methacrylic acid coordinated with Zr alkoxide sterically hinders immediate re-hydrolysis and polycondensation with MEMO. Rather, slow polycondensation occurs between the remaining Zr precursor at a later stage, leading to ZrO_2 particles nucleated within the organosiloxane matrix. As a result, ZrO_2 particles and zirconium silicate coexist in the amorphous matrix as confirmed by XPS analysis.

Fig. 5 shows the electrical characteristics of TIPS–PEN TFTs based on the YHD15 and YHD30 dielectrics. The devices works in the accumulation mode with a well-defined linear regime at $V_D < V_G$ followed by a saturation regime at $V_D > V_G$ for a given gate voltage V_G. Furthermore, the amplification mode of I_D is observed when V_G increases. A negative I_D under a negative V_D and V_G indicates the transport of holes in these devices, therefore, the organic layer behaves as a p-type semiconductor. The threshold voltage V_T and field-effect mobility μ in the saturation region were determined by plotting the square root of the drain current versus gate voltage and fitting the data to the following equation [20]:

$$I_D = \frac{WC}{2L}\mu(V_G - V_T)^2$$

where C is the capacitance of the dielectric, W is the channel width, and L is the channel length. The OTFT based on the YHD15 hybrid dielectric has an off-current of 4.5×10^{-11} A, an on/off-current ratio of 4.5×10^3, a carrier mobility of 1.3×10^{-2} cm^2 V^{-1} s^{-1}, and a threshold voltage of -5 V. The OTFT based on the YHD30 hybrid dielectric has an off-current of 6.5×10^{-11} A, an on/off-current ratio of 2×10^3, a carrier mobility of 1.1×10^{-2} cm^2 V^{-1} s^{-1}, and a threshold voltage of -1 V. The characteristic electric parameters of these devices are summarized in Table 2.

All electrical parameters except for V_T are similar for both devices. It was clear that using hybrid dielectrics with a high dielectric constant significantly reduces the threshold voltage from -5 to -1 V. We fabricated OTFT based on

Table 2
Electrical performance parameters, off-current (I_{OFF}), on-current (I_{ON}), threshold voltage (V_T), and field-effect carrier mobility (μ_{FET}) of OTFTs fabricated using hybrid dielectrics.

Dielectric type	I_{ON} (A)	I_{OFF} (A)	V_T (V)	μ_{FET} (cm^2 V^{-1} s^{-1})
15 mol% Zr(OPr^i)$_4$ hybrid dielectrics	2.1×10^{-7}	4.5×10^{-11}	-5	1.3×10^{-2}
30 mol% Zr(OPr^i)$_4$ hybrid dielectrics	1.5×10^{-7}	6.5×10^{-11}	-1	1.1×10^{-2}
PVP dielectrics	1.1×10^{-7}	4.2×10^{-10}	-6	1.2×10^{-2}
Fig. 6. (a) X-ray diffraction patterns and (b) film morphologies of TIPS–PENs deposited onto YHD15, YHD30, and PVP dielectric layer. The inserted scale is 30 μm.

PVP dielectric, a widely investigated organic material, for comparison. The PVP-based transistor has an off-current of 4.2×10^{-10} A, an on/off-current ratio of 2.6×10^2, a carrier mobility of 1.2×10^{-2} cm^2 V^{-1} s^{-1}, and a threshold voltage of -6 V. Higher off-current in TFT with PVP dielectric layer is attributed to the hydroxyl group in the PVP dielectric, which acts as trap-sites for charge carriers and in turn contributes to a high leakage current through a dielectric layer. In TIPS–PEN TFTs, other electric parameters, such as on-current, mobility, and threshold voltage, are directly related to the structures of TIPS–PEN [21]. We investigated the crystal structures and film morphologies of TIPS–PENs deposited onto the dielectric layers. As shown in Fig. 6, All TIPS–PENs are well-crystallized and exhibit long lamellar structures regardless of the dielectric material types. This is in agreement with the fact that all TFTs show similar field-effect mobility values and on-currents. However, it is noted that V_T of each TFT is quite different, depending on the dielectric layer.

The threshold voltage depends on various factors such as the capacitance of the gate dielectric, the flat-band voltage caused by the work function difference between the gate electrode and the semiconductor, and the density of trap states residing in semiconductor channel [22]. It can be assumed that the flat-band voltage and the amount of trap states in the semiconductor are identical for all transistors tested here, as these parameters are related to the intrinsic properties of the electrode and the semiconductor, irrelevant to the dielectrics. Therefore, it can be suggested that the capacitance difference primarily influences the threshold voltage shift. Additionally, V_T of TFT with PVP dielectric is also affected by water molecules absorbed from air. The interaction between hydroxyl groups in PVP dielectric and water molecules leads to dissociation of hydroxyl groups and the generation of mobile ions [23]. The corresponding mobile ions are drifted by an applied gate voltage, which induces more charge carriers at semiconductor/dielectric interface and in turn shifts a threshold voltage toward a zero bias. In contrast, the hydroxyl group in YHD dielectrics is nearly eliminated by a proper thermal treatment. Thus, it is considered that the threshold voltage of TFT based on YHD is not influenced by water molecules in air. We observed that when TFT is fabricated using YHD dielectric whose capacitance is similar to that of a 200 nm-thick thermally-grown SiO$_2$, V_T of TFT based on YHD is almost identical to that of TFT based on a 200 nm-thick thermally-grown SiO$_2$ [10]. A thermally-grown SiO$_2$ is well-known for a stable dielectric under air atmosphere.

Taken the consideration of the interaction effect of the dielectric with water that can shift the threshold voltage toward a zero voltage, V_T of TFT based on PVP dielectric is still -6 V, whereas TFT based on YHD30 dielectric exhibit -1 V. This observation supports that the influence of higher capacitance is predominant over a water-induced V_T shift and enables the TFT based on YHD dielectric with smaller threshold voltage (the capacitance of PVP, YHD15, and YHD30 is 10, 33, and 53 nF/cm^2, respectively). Both the presence of fewer hydroxyl groups and the incorporation of high-k ZrO$_2$ phase make YHD-based dielectrics

better to PVP-based dielectrics, in terms of lower off-current, higher on/off current ratio, and threshold voltage closer to a zero bias.

4. Conclusions

We performed microstructural and chemical investigations on sol–gel derived organic–inorganic hybrid dielectrics. HRTEM revealed that ZrO$_2$ crystallites of approximately 5 nm are uniformly distributed in the amorphous organosiloxane matrix, although these could not be detected by X-ray. XPS analysis confirmed that another phase, ZrSiO$_4$, coexists as an amorphous phase in the matrix. The relative ZrO$_2$, ZrSiO$_4$, and organosiloxane compositions can be estimated by deconvoluting the O 1s spectrum. The effective dielectric constant of the hybrid dielectric was calculated using a general rule of mixture. The calculated values match the experimentally-measured dielectric constants, indicating that the hybrid dielectric is composed of three phases. OTFTs based on hybrid dielectrics exhibited better electrical performance to those based on PVP. Using a dielectric with a higher dielectric constant and fewer hydroxyl groups allowed us to fabricate a transistor with a lower off-current, higher on/off current ratio, and lower threshold voltage.

with low Φ_m metal are needed to understand clearly how the interaction between the metal and the organic layer affects the energy-level alignment at organic/metal interfaces. In this paper, we present the systematic study of the VL shifts at Cu-phthalocyanine (CuPc)/metal interfaces over a wide range of Φ_m (=2.5–5.3 eV) using the Kelvin probe (KP) method. We observed the transition of the energy-level alignment from Φ_m dependence to Φ_m independence by decreasing Φ_m. Our results show that the injection barrier cannot be shorter than a threshold value. This transition can be explained by considering that the ID layer on the metal surface plays two major roles in the energy-level alignment: the formation of the ID and the passivation of the metal surface. Considering the roles of the ID layer, we propose a model of the energy-level alignment at organic/electrode interfaces that includes clean and passivated metal substrates.

2. Experimental

CuPc with a quoted purity of 99% and sublimation grade was purchased from Sigma–Aldrich. We used Au, Ag, Mg, Ca, and Sm films deposited by vacuum evaporation on silicon wafers as metal substrates. The CuPc films were vacuum deposited onto these substrates in ultra-high vacuum (UHV) ($\sim 1 \times 10^{-6}$ Pa). The thickness and the rate of deposition ($\sim$0.1 nm/min) of the CuPc film were monitored with a quartz crystal microbalance. The deposition was performed in a stepwise manner with the KP measurements at each step. The KP measurements were also performed in UHV ($\sim 8 \times 10^{-8}$ Pa) using an apparatus described elsewhere [12].

3. Results and discussion

Fig. 1 shows the VL energy of the CuPc film (ε_{vac}^F) relative to the substrate Fermi level (E_F) deposited on metal substrates as a function of the film thickness (d) using the KP method. The large shifts of ε_{vac}^F observed at the interface ($d < 5$ nm) of all the substrates were indicated by the charge redistribution at the interface. The ε_{vac}^F sharply shifted right at the interfaces when the thickness was less than 1 nm. In the thicker region than 1 nm, the ε_{vac}^F were almost independent of the thickness on Au and Ag substrates. The little VL shifts observed on these substrates within 1–2 nm may be induced by the changing of the molecular orientation [13,14]. It should be noted that such VL shifts are not caused by the final-state screening because the KP measurement does not use the photoionization process [12]. These shifts were caused by the ID formation [1]. The ε_{vac}^F(ID) was defined as

$$\varepsilon_{vac}^F(\mathrm{ID}) = \Phi_m + \varDelta_{\mathrm{ID}} \tag{1}$$

where the $\varDelta_{\mathrm{ID}}$ is the VL shift caused by the ID layer. On the other hand, gentle downward shifts on the Mg substrate and sharp upward shifts on Ca and Sm substrates were observed when the thickness increased up to 5 nm. It should be stressed that such energy-level shifts at the interface were responsible for the energy-level alignment at the thick film region because little VL shifts occurred in the thicker region than 5 nm on all the substrates.

Fig. 2 shows the ε_{vac}^F(bulk), which was defined as the ε_{vac}^F of the thick films ($d = 14$ nm for Ca and $d = 20$ nm for others) against Φ_m of the various metal substrates based on the results in Fig. 1. Open circles identify results in this work. Closed circles represent the results taken from Refs. [14–16]. The ε_{vac}^F(bulk) depended on Φ_m at the higher Φ_m above Mg with $S = 0.5 \pm 0.1$ ($S = d\varepsilon_{vac}^F(\mathrm{bulk})/d\Phi_m$). On the other hand, the ε_{vac}^F(bulk) no longer depended on Φ_m at the lower Φ_m below Mg with $S = 0.0 \pm 0.1$. The Mg substrate is supposed to remain around the critical value of Φ_m. In this paper, we refer to the regions with $S = 0$ and

Fig. 1. Variation in the ε_{vac}^F on Au, Ag, Mg, Ca, and Sm substrates as a function of the CuPc thickness d. The ε_{vac}^F sharply shifts right at the interfaces when the thickness is less than 1 nm. In the thicker region than 1 nm, the ε_{vac}^F were almost independent of the thickness on Au and Ag substrates. The little VL shifts observed on these substrates within 1–2 nm may be induced by the changing of the molecular orientation [13,14]. These shifts are caused by the ID formation; the $\varDelta_{\mathrm{ID}}$ for the CuPc film on Au substrate is shown.

Fig. 2. The ε_{vac}^F(bulk) are plotted as a function of Φ_m; the ε_{vac}^F(bulk) stands for the ε_{vac}^F at 20 nm (Au, Ag, Mg, and Sm) and 14 nm (Ca). Open circles identify results in this work. Closed circles represent the results taken from Refs. [14–16]. The dotted lines show the results of fitting analysis by the least squares method with linear function S. The estimated S parameters are given in the figure.
Fig. 3. The schematics of the energy-level diagrams in: (a) the noninteger S regime and (b) the E_F pinning regime. The Δ_{ID} is caused by the ID formation. The $\varepsilon_{vac}^F(ID)$ can be regarded as the work function of the passivated metal substrates. In (a) the noninteger S regime, little VL shift occurred in the thicker region than the ID layer. Therefore the energy-level alignment is mainly determined by the Δ_{ID}, and the $\varepsilon_{vac}^F(bulk)$ satisfies Eq. (2). In (b) the E_F pinning regime, the spontaneous CT from the metal to the CuPc film (CT layer) should occur via tunneling through the ID layer until Eq. (4) is satisfied. The δ is the maxima barrier height for the occurrence of the spontaneous CT.

S = 0.5 as the "E_F pinning regime" and the "noninteger S regime," respectively. The energy-level alignment models for organic/metal interfaces such as the IDIS model, electronegativity model, and MIGS model cannot explain the separated S regimes and the VL shift in the case of the CuPc/Ca interface.

The energy-level alignment at CuPc/metal interfaces is discussed with the simple model depicted in Fig. 3. Fig. 3a and b represents the energy-level alignments at the CuPc/Au interface as an example of the noninteger S regime and the CuPc/Ca interface as an example of the E_F pinning regime, respectively. When the CuPc molecule adsorbs on a metal surface, the ID layer is formed at the interface. It is still difficult to predict the estimation of the Δ_{ID} quantitatively, because the ID layer should be formed from multiple origins, as shown in Ref. [1]. In this discussion, we consider the ID layer as a role of passivating the metal surface. Such passivation of the metal surface by the ID layer prevents the molecular orbital of the CuPc layer from overlapping the metal wave functions. It means that the ID layer/metals are the passivated metal substrates, and the $\varepsilon_{vac}^F(ID)$ is the work function of the passivated substrates. Consequently, the energy-level alignment at the thicker film region than the ID layer/metal interfaces can be described as the system at organic/passivated substrate interfaces [8–11].

In the noninteger S regime with high Φ_m, little VL shift occurred in the thicker region than the ID layer as shown in Fig. 1. Therefore the energy-level alignment is mainly determined by the Δ_{ID}, and the $\varepsilon_{vac}^F(bulk)$ satisfies the equation:

$$\varepsilon_{vac}^F(bulk) \sim \varepsilon_{vac}^F(ID) = \Phi_m + \Delta_{ID} \tag{2}$$

On the other hand, in the E_F pinning regime, the lowest unoccupied molecular orbital (LUMO) level of the CuPc layer on the passivated metal substrate stayed below the substrate E_F; for instance, in the case of the CuPc/Ca interface, the LUMO level of the CuPc (d > 1 nm) layer should be

located below the E_F by 0.66 eV because $\varepsilon_{vac}^F(ID)$ and the electron affinity (E_A) of CuPc are 2.5 and 3.16 eV [17], respectively; and the spontaneous charge transfer (CT) from the metal to the CuPc (d > 1 nm) layer occurred via tunneling through the ID layer to establish the thermodynamic equilibrium. The spontaneous CT will take place if the following condition is found:

$$\varepsilon_{vac}^F(ID) < E_A + \delta \tag{3}$$

where the δ is the relaxation energy which is the maxima barrier height for the occurrence of the spontaneous CT. It means that the spontaneous CT will occur until the LUMO level of the CuPc layer is located above the E_F by the δ. From the results of the inverse photoemission spectroscopy at CuPc/Mg, Ca, and Sm interfaces (not presented here), the δ was estimated to be about 0.4 eV [18]. According to the ICT model, it is supposed to be existed the ICT states just below the LUMO level of molecules. Although the origin of the ICT states in small molecules such as the CuPc molecule is still unclear, energy differences between LUMO levels of molecules (or polymers) and ICT states are good agreement with the δ at CuPc/metals interfaces [8,9]. The complicated behaviors of the VL shifts at low Φ_m substrates such as Mg, Ca, and Sm, as observed in Fig. 1, must be caused by the charge redistribution with the spontaneous CT from the passivated metal substrates into CuPc layers, and this induced the VL shifts (Δ_{CT}) from a 1 nm to 5 nm thickness, i.e., Δ_{CT} = 0.9 eV and 0.5 eV for Ca and Sm, respectively. The spontaneous CT no longer occurs and the VL shift is not observed if the following condition is satisfied:

$$\varepsilon_{vac}^F(ID) + \Delta_{CT} = E_A + \delta \tag{4}$$

here, the "$\varepsilon_{vac}^F(ID) + \Delta_{CT}$" corresponded to the $\varepsilon_{vac}^F(bulk)$, and we can rewrite Eq. (4) as a simpler equation:

$$\varepsilon_{vac}^F(bulk) = E_A + \delta \tag{5}$$

The ε_{vac}^{F}(bulk) is mainly determined by the E_A of organic molecule. We suppose that little VL shifts in the thicker region than 5 nm at CuPc/Mg, Ca, and Sm interfaces are observed, and the spontaneous CT no longer occurs because Eq. (5) is satisfied.

4. Conclusion

In conclusion, we investigated the energy-level alignment at CuPc/metal interfaces. It was found that there are separated S regimes with the noninteger S regime and the E_F pinning regime. The organic layer on a metal surface plays two important roles in the energy-level alignment: the ID formation and the passivation of the metal surface. In the noninteger S regime, the energy-level alignment is mainly determined by the Δ_{ID} because little VL shifts occurred in the thicker region than the ID layer. This shows that the organic layer on the ID layer is little influenced by the passivated metal substrate. On the other hand, in the E_F pinning regime, the energy-level alignment is determined not only by the Δ_{ID} but also by the spontaneous CT between the organic film and the passivated metal substrate. In this regime, while the Δ_{ID} scattered in various metal substrates, the same energy-level alignments were realized for the thick film region. In the case of 3,4,9,10-perylene tetracarboxylic dianhydride (PTCDA)/metal interfaces, a similar trend has been reported [19]. Although the obvious differences in interface states depending on the metals were observed, the same energy-level alignments for the thick film region were also realized. The model we suggested can also explain the energy-level alignments at PTCDA/metal interfaces and other reported results [20,21].

Finally, this model, which deals with the energy-level alignment between the thicker region than the ID layer and the passivated metal substrate, provides a new perspective on the energy-level alignment at organic/electrode interfaces that include clean and passivated metal substrates.

We find $W = 0.5 \ \mu m$, which translates into $\beta = 10^{-2}$, in good agreement with recent theoretical predictions [1].

Before turning to the results obtained on OFETs, we need to discuss the methodology that enabled us to directly compare experimental surface potentials to theoretical model predictions.

SKPM offers the unique possibility to look inside operational electronic devices on truly nanoscopic length scales [9]. A drawback of SKPM is that the obtained potential traces do not reflect the real surface potential $V(x)$ but rather a convolution of $V(x)$ with a usually unknown instrument response function [10–14]. The physical reason for this is that not only the tip apex contributes to the signal but the entire metalized tip, consisting of apex, cone and lever, interacts with the sample due to the relatively long range of the electrostatic force [15]. As a result, the obtained surface potentials are distorted in both shape and magnitude; the error in the latter may exceed 40%, even at nominally zero lift height [15]. To surmount these intrinsic SKPM limitations, two fundamentally different approaches are possible, i.e. prediction and reconstruction.

Prediction methods aim to convolute a 'real' surface potential, which e.g. follows from theoretical considerations, with a theoretically or experimentally known tip response. So far, all reported prediction methods are based on a theoretical tip response [10,11,15] Reconstruction methods aim to deconvolute the experimental surface potential with a theoretically or experimentally known response function in order to extract the real surface potential [12,13].

For our present purposes, we developed a flexible and convenient method for both predicting and reconstructing SKPM surface potentials. In contrast to previous works, the entire instrument response is contained in an *experimentally* determined transfer function. Hence, there is no need to explicitly evaluate the electrostatic interactions using either (approximate) analytical expressions [10–12,16] or brute force numerics [15]. The method is equally valid for SKPM based on electrostatic force detection, as employed here, as for SKPM based on force gradient detection [16].

The hypothesis underlying the (re)construction of SKPM measurements is that the measured surface potential y is a convolution of the real surface potential x with a transfer function h, i.e. $y = h \otimes x$. For brevity and to stress the general nature of the methodology, in the following discussion signals are denoted as x and y, rather than as V's. In general, h will depend on the measurement system, in this case the tip geometry, its orientation with respect to the sample and the vertical distance from the sample. Since all electrostatic forces are implicitly contained in the transfer function h there is no need to quantify any electrostatic forces. From the convolution theorem we then have [17]

$$F(y) = F(h)F(x) \tag{2}$$

where $F()$ indicates the Fourier transform. The transfer function h is experimentally determined from a reference measurement. This is most conveniently done on a step edge, for which case the mathematical link between x_{step}, y_{step} and h is simply

$$F(h) = F(y'_{step}) \tag{3}$$

where the prime denotes the spatial derivative. Eq. (3) follows by applying (2) to the step edge, $F(y_{step}) = F(h)F(x_{step})$. Using the property $F(y') = i\omega F(y)$ and taking the spatial derivative of both x_{step} and y_{step}, one obtains $F(y'_{step}) = F(h)F(x'_{step})$. This reduces to (3) by using $x'_{step} = \delta$ with δ the Dirac delta function and $F(\delta) = 1$. Once the transfer function h of a particular configuration is determined, any experimental surface potential can be inverted to obtain the 'real' surface potential x using $x = F^{-1}(F(y)/F(h))$ and similarly for prediction from a known x. Here, F^{-1} denotes the inverse Fourier transform. Numerical implementation of these equations is relatively straightforward [18].

In order to be applicable to thin film OFETs, the transfer function h should formally be determined on a step buried under a dielectric layer. However, electrostatic finite element calculations (not shown) indicate that the effect of a $\sim$100 nm thick polymer layer with $\varepsilon_r \approx 3$ on the surface potential is negligible as compared to the experimental uncertainty.

In order to experimentally determine the step edge response, we made a step edge of a few monolayers of Ti on Au, see top inset of Fig. 1. These reference samples were manufactured using standard UV photolithography. Starting from chemically cleaned silicon wafers with 200 nm of thermal SiO_2 on top, 5 nm of Ti as adhesion layer and 25 nm of Au were subsequently deposited by electron beam evaporation under high vacuum conditions. A classical lift-off procedure was employed to pattern a second Ti layer on top of the Au. The SKPM-AFM was a Veeco/Dimension 3100/extended Nanoscope IIIa working in lift mode under ambient conditions. We used Pt-coated Si tips (Olympus OMCL-AC240TM-B2, $f_0 \approx 70$ kHz, $k \approx 2$ N/m, $R_{apex} < 25$ nm).

The main panel of Fig. 1 shows typical SKPM measurements on the Ti:Au step edge for different lift heights z_{lift}. The relatively small difference in work functions observed between Ti and Au is due to the ambient conditions during the experiments, but the actual step height does not affect the procedure. The right inset is the transfer function h for increasing lift height. The increasing width with increasing lift height reflects the obvious loss in spatial resolution. Moreover, the asymmetric shape of h is due to the asymmetric measurement configuration in which the cantilever is oriented perpendicular to the step edge. An orientation parallel to the edge yields a symmetric h [15]. In principle, additional broadening of h also results from fabrication imperfections, like the step edge not being perfectly straight and infinitely steep, while uncertainty in h may also arise due to inter-tip variations. We estimate the total resulting effect to be around 50 nm, which is small compared to the broadening by the non-local electrostatic coupling which we are interested in, and aim to correct for.

We now return to the problem of measuring the actual recombination profile in an ambipolar OFET. The methodology described above was applied to surface potentials measured by SKPM on ambipolar OFETs that have been extensively described before [8,19]. In short, these devices consist of a thin nickel dithiolene (NiDT) layer on a Si/SiO_2
Fig. 1. Main panel: SKPM step edge response with the tip orthogonal to the channel for different lift heights, lines are the measured surface potential over the step edge at (bottom to top) z_{lift} = 0, 25, 50, 100, 150, 200, 500, 1000 nm. Top inset: layout of Ti (dark gray) step edge on Au (yellow) sample deposited on SiO$_2$ (light gray), scanned by an SKPM probe (black). Right inset: transfer function h for different z_{lift} (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.).

Fig. 2. Comparison of surface potential prediction methods applied to an ambipolar OFET. Symbols: experiment taken for V_{sd} = 9 V and $V_g - V_{th}$ = 5.3 V at z_{lift} = 100 nm; lines: transfer function method (black), 3D numerical (red) and theoretical potential used as input (blue). Inset: schematic layout of the ambipolar OFET. When $0 < V_g - V_{th} < V_{sd}$ with V_g, V_{th} and V_{sd} the gate, threshold and source–drain voltage, respectively, electron and hole accumulation layers form on the left and right of a recombination zone, respectively. The source is grounded (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.).

(200 nm) substrate with Ti/Au bottom contacts in a circular transistor configuration with a channel width and length of 2500 and 10 µm, respectively, see inset to Fig. 2. By choosing proper bias conditions electron and hole accumulation regions, separated by a recombination zone, are simultaneously present. Electron and hole mobilities that are used in the numerical drift–diffusion calculations discussed below are obtained from transport characteristics and equal 1×10^{-11} and 2×10^{-12} m^2/Vs for holes and electrons, respectively.

In Fig. 2 two different prediction methods are applied to a representative surface potential as measured by SKPM on the NiDT ambipolar transistor. The required input signal, x in (2), is calculated from the variable range hopping model discussed in Ref. [19] using $V_g - V_{th}$ = 5.3 V and V_{sd} = 9 V and is shown as blue line. It is important to point out that this model assumes $W = 0$, i.e. $\beta = \infty$. From that, the black line is calculated using (2) with a transfer function h obtained from (3) as discussed above. Clearly, the predicted curve follows the experimental one closely. For comparison we also used a computationally much more demanding 3D finite element model to predict the SKPM response of x [15]. The result is shown as red line, and is in close agreement with the much easier obtained result of (2). From this we conclude that the transfer function method provides a convenient way to transform a known surface potential into an actual SKPM response. However, a close inspection of both curves in the recombination zone reveals a maximum field that is significantly higher than observed experimentally. Below, this will be related to the nonzero value of W.

In Fig. 3, the experimental response and its reconstructed surface potential are compared to the theoretical surface potential for again $V_g - V_{th}$ = 5.3 V and V_{sd} = 9 V. Both the magnitude reduction of the experimental curve and most of its asymmetric distortion due to the asymmet-

ric tip-channel orientation are removed by the transfer function procedure outlined above. However, the infinite field at the point where n- and p-type accumulation regions meet, as implicitly assumed in the model of Ref [19], is not observed. At this point, it is tempting to take the width of the derivative profile of the reconstructed surface potential, shown as thin black line in the insets of Fig. 3, as a measure of the actual recombination zone width W. However, despite the fact that the analytical model underlying (1) correctly predicts the recombination profile,
Fig. 3. Reconstruction of the surface potential of an ambipolar OFET. Symbols: experiment taken for V_{sd} = 9 V and $V_g - V_{th}$ = 5.3 V at z_{lift} = 100 nm; lines: transfer function method (black) and theoretical potential as calculated according to Ref. [19] (blue). Upper inset: normalized first derivative of the curves in the main panel. Lower inset: zoom-in on reconstructed first derivative profile (black) and calculated profile for a recombination zone width of 0.5 µm (red) (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.).

it makes no predictions of the corresponding potential profile, and the widths of the two profiles are usually not equal [8]. Since an analytical calculation of the potential profile in an ambipolar transistor is only possible under assumption of a zero recombination zone width [19], we performed a numerical drift-diffusion analysis as outlined in Ref. [8]. The (spatial derivative of the) resulting potential profile is compared to the reconstructed experimental profile in the lower inset of Fig. 3. We find optimal agreement between the two derivative profiles when parameters that give rise to a recombination zone width of 0.5 μm are used. With $d = 200$ nm and estimating $\delta = 3$ nm, it follows from (1) that $\beta \approx 10^{-2}$, which is also used in the numerical calculations. This implies that the bimolecular recombination rate is two orders of magnitude below the value predicted by the Langevin expression. This finding is in good agreement with the results from Monte Carlo simulations by Groves and Greenham [1] who find values for β between 10^{-1} and 10^{-2} for similar parameters as in the present experiment.

Summarizing, we presented a practical method for prediction and reconstruction of surface potentials measured by SKPM. The method is based on (de)convolution with a transfer function containing the whole electrostatic tip-sample coupling. The transfer function is experimentally calibrated on an 'ideal' step edge. Using this method we determined a recombination zone width of 0.5 μm for a NiDT ambipolar OFET, indicating a bimolecular recombination rate that is two orders of magnitude below the Langevin value.

[18] Numerical noise and spurious peaks in FFT signals could greatly be reduced by making all discrete signals $X_N = (x_1, \ldots, x_N)$ periodic by extending them to $X_{2N} = (x_1, \ldots, x_N, \ldots, x_1)$. To avoid extrapolation to low frequencies in Fourier space, the size of the reference scan was at least the size of the to-be-converted measurement or calculation. In the inversion procedure, a high frequency cutoff was used to avoid division-by-zero errors at frequencies where $F(h)$ is close to zero.

Fig. 1. Chemical structure of SPPO2 and device structures of red PHOLEDs used in this work.

(Alq₃, 20 nm)/LiF(1 nm)/Al(200 nm). The doping concentrations of Ir(pq)₂acac were 10%, 15% and 20%. A mixed host device with TCTA:PH1 host instead of the SPPO2 was also fabricated as a standard device [12]. The SPPO2 host material was synthesized by coupling of diphenylphosphine with spirofluorene unit and detailed synthesis will be reported in other work. Chemical structure of SPPO2 and device structure are shown in Fig. 1. Current density–voltage–luminance and electroluminescence characteristics of the red PHOLEDs were measured with Keithley 2400 source measurement unit and CS 1000 spectroradiometer.

The SPPO2 host material has a glass transition temperature of 119 °C and it forms an amorphous film with a surface roughness less than 1 nm due to a twisted structure of the rigid spirobenzofluorene unit. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the SPPO2 were 6.0 and 2.4 eV, respectively. The HOMO level of SPPO2 is suitable for hole injection and the electron transporting property of the phosphine oxide and the spirobenzofluorene unit is appropriate for balancing holes and electrons in the emitting layer. The electron transport property of the SPPO2 was confirmed by the electron only devices and the SPPO2 electron only device showed higher current density than the common Alq₃ electron only device. In addition, the triplet energy bandgap of the SPPO2 measured from low temperature photoluminescence is 2.4 eV which is suitable for triplet energy transfer from the SPPO2 to red emitting Ir(pq)₂acac with a triplet bandgap of 2.2 eV. Therefore, the SPPO2 can be used as a host material for red PHOLEDs.

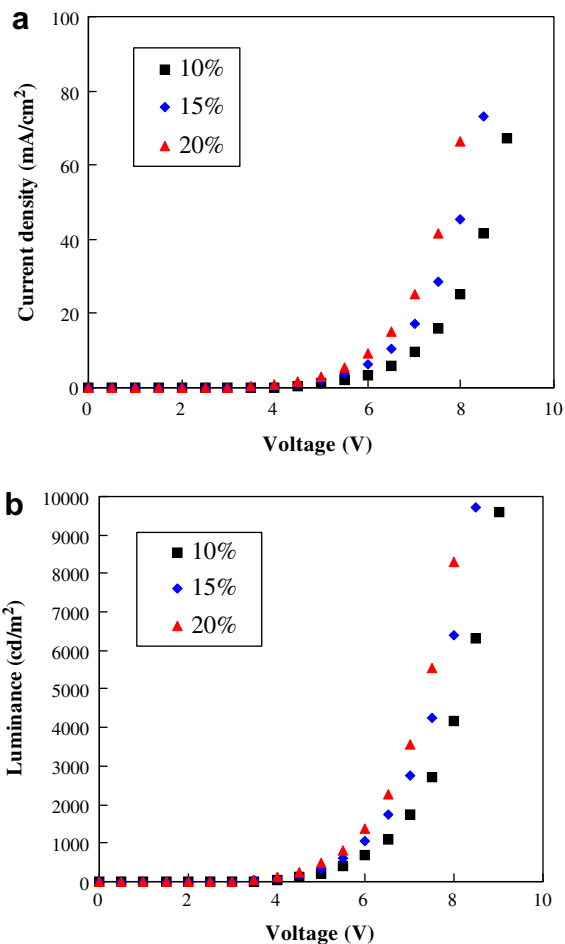
Fig. 2 shows the current density–voltage–luminance curves of the red PHOLEDs with different doping concentration. The current density of the red PHOLEDs was increased according to the increase of doping concentration and the luminance showed a similar tendency. The high current density in the highly doped devices can be explained by the charge trapping effect of the red dopant. The LUMO level of the Ir(pq)₂acac is 3.0 eV compared with 2.4 eV of the SPPO2. Therefore, electrons are trapped by the Ir(pq)₂acac and electron transport in the Ir(pq)₂acac doped emitting layer is retarded due to the electron trapping effect [13]. Energy level diagram of the SPPO2 device is


Fig. 2. Current density–voltage–luminance characteristics of red PHOLEDs with SPPO2 as a host according to doping concentration. (a) Current density–voltage and (b) luminance–voltage.
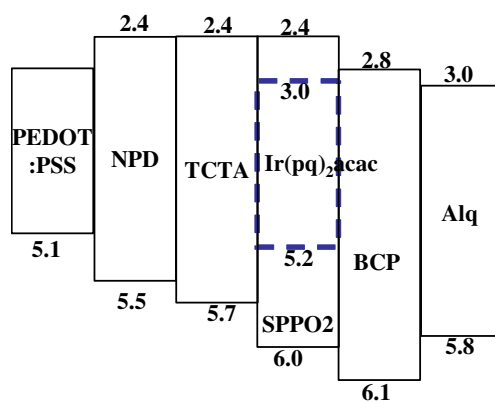

Fig. 3. Energy level diagram of the SPPO2 device.

shown in Fig. 3. At low doping concentration, the long hopping distance between dopant materials limits the electron hopping between the red dopant materials. As the doping concentration is increased, the hopping distance between
Fig. 4. Quantum efficiency of red PHOLEDs with SPPO2 as a host according to doping concentration. The efficiency was compared with that of the TCTA:PH1 host reported in previous work [12].
Fig. 5. Electroluminescence spectra of red PHOLEDs with SPPO2 as a host according to doping concentration.

the red dopants is decreased, resulting in enhanced electron transport. Therefore, high current density was obtained in the highly doped red PHOLEDs.

Quantum efficiency of the red PHOLEDs is shown in Fig. 4. The quantum efficiency was decreased at high doping concentration due to concentration quenching effect and a maximum quantum efficiency was obtained in the red PHOLED with 10% doping concentration. The quantum efficiency of the 10% $Ir(pq)_2$acac doped red PHOLED was 14.3% at 100 cd/m^2 with a current efficiency of 20.4 cd/A. The high efficiency of the SPPO2 red devices can be explained by the charge balance in the emitting layer. Even though SPPO2 has an electron transport character, efficient hole injection from the TCTA to the SPPO2 balances holes and electrons in the SPPO2 emitting layer. The low quan-

tum efficiency of the highly doped device is due to concentration quenching effect [7].

The quantum efficiency of the SPPO2 device was compared with that of the mixed host device which can balance holes and electrons in the light-emitting layer. TCTA:PH1 mixed host structure which was reported in our previous work was used [13]. Even though an efficiency roll-off was observed in the SPPO2 device, the SPPO2 device showed better quantum efficiency than the mixed host device over all luminance range investigated. This indicates that the SPPO2 host is better than the TCTA:PH1 mixed host in terms of charge balance in the emitting layer.

The EL spectra of SPPO2 red devices are shown in Fig. 5. The SPPO2 devices showed typical EL spectra of $Ir(pq)_2$acac. The peak maximum of the EL spectra was 607 nm and the spectra were red-shifted at high doping concentration. There was little charge leakage out of the emitting layer and only emission from the dopant material was observed. Therefore, it can be concluded that charge confinement and charge balance in the SPPO2 light-emitting layer are responsible for the improved quantum efficiency in the SPPO2 red devices.

In summary, a phosphine oxide derivative with a spirobenzofluorene backbone structure, SPPO2, was effective as a red phosphorescent host. A high quantum efficiency of 14.3% and a current efficiency of 20.4 cd/A were obtained due to a triplet bandgap of 2.4 eV for efficient energy transfer and a charge balance in the light-emitting layer. The SPPO2 also showed a smooth surface morphology with an average surface roughness less than 1 nm and a high glass transition temperature of 119 °C. Therefore, the SPPO2 is promising as a host in red and deep red phosphorescent devices.

electrode of the O-CMOS devices. These wafers were cleaned with acetone, ethanol, and de-ionized water. Then, in order to remove involuntary organic residue, the surface of the 300-nm-thick SiO_2 gate dielectric, which grew by plasma enhanced chemical vapor deposition on the substrate at a temperature of 250 °C previously, was cleaned by use of oxygen (O_2) plasma. A polyimide (PI, Nissan RN-1349) layer of 100 nm was spun onto the SiO_2 layer. The PI layer was soft-baked and hard-baked for 5 min at 80 °C and 60 min at 220 °C, respectively. Although the processing temperature is slight higher than most of plastic substrates, it still has an opportunity to apply on polymer substrate with high glass temperature, e.g. polycarbonate (PC) which T_g is above 250 °C. Nevertheless, further lowering of the processed temperature is still required to meet the requirements of most flexible plastics substrate and in progress. Both the SiO_2 and PI layers were acted as the main gate dielectric with capacitance of ~4.0 nF/cm^2 measured at 10 kHz for the O-CMOS devices. The active layers of p-channel and n-channel are 70-nm-thick pentacene film and N,N'-dioctyl-3,4,9,10-perylene tetracarboxylic diimide (PTCDI–C_8H_{17}) film, respectively, in which the deposition rate are all 0.5 Å/s on the PI layer at sublimation pressure of 1×10^{-5} torr. The pentacene was purchased from Aldrich Chem. Co. and the PTCDI–C_8H_{17} was synthesized by us. Finally, the 80-nm-thick silver film was deposited to form source/drain electrodes upon the surface of the pentacene and PTCDI–C_8H_{17} films through a shadow mask in order to complete the O-CMOS device under vacuum of 4×10^{-6} torr. The channel length (L) of O-CMOS is 100 μm, but the width (W) of p-type and n-type transistors are 500 and 2000 μm, respectively, for matching performances of these two transistors as shown in Fig. 1. For comparison, the O-CMOS without the PI modification layer were fabricated simultaneously with the same processes. The current–voltage (I-V), transfer, and alternating current signals of devices were measured by use of a semiconductor parameter analyzer (Keithley 4200-SCS). To minimize
the influence of H_2O from the ambient air on the electrical properties of devices, the electrical characteristics of O-CMOS were measured in a dry nitrogen-atmosphere glove box under dark conditions.

Fig. 2 shows the p-type electrical characteristics of the pentacene-based transistors with and without the PI as modification layers. The drain current of transistor with PI is higher than that without PI, as shown in Fig. 2a, when the gate voltage (V_{GS}) was fixed at −40 V and source-drain voltage (V_{DS}) was scanned from 0 to −50 V. The current–voltage characteristics ($\sqrt{I_D} - V_{GS}$) of the device with the PI layer reveal that the threshold voltage (V_{tp}) is about −12.90 V when the source-drain voltage (V_{DS}) was fixed at −40 V and gate-source voltage (V_{GS}) varied from 20 to −50 V; however, the V_{tp} of the device without PI layer shifts to −16.79 V, as shown in Fig. 2b. The trap states of pentacene film near the surface of the PI layer were smaller than that near SiO_2 layer due to the non-polar surface of the PI layer which was appropriate for the growth of the pentacene film. The grain size for pentacene grown on PI surface is larger than that grown directly on SiO_2 surface, as shown in Fig. 3a and b. Besides, the pentacene film on PI has good homogeneity associated with superior molecular microstructures and larger intermolecular couplings as compared to that on SiO_2 [17]. Low trap states resulted in low threshold voltage for OTFTs [7]. Therefore, the device with the PI layer has higher field-effect mobility ($\mu = 0.921$ cm^2 V^{-1} s^{-1}) and lower subthreshold slope ($ss = 4.71$ V/decade) than that without PI layer whose μ and ss are 0.221 cm^2 V^{-1} s^{-1} and 10.79 V/decade, respectively. The PI layer has an additional advantage to suppress the leakage current of OTFT so that the on/off ratio increases and gate-leakage-current decreases about one order for the device with the PI layer when compared with the device lacking the PI layer, as shown in Fig. 2c.

Next, the n-type PTCDI–C_8H_{17}-based transistors with and without PI as modification layers were measured by the semiconductor analyzer in order to investigate the electrical properties. From the output curves in Fig. 4a, the drain current of the device with the PI is better than that without PI when the V_{GS} was fixed at 40 V and V_{DS} was varied from 0 to 50 V. The superior V_{tn} of 5.87 V and μ of 0.341 cm^2 V^{-1} s^{-1} were obtained from transfer curve in Fig. 4b for the device with the PI layer; however, the device without the PI layer had negative V_{tn} and poor μ(0.01 cm^2 V^{-1} s^{-1}). The performance enhancements of the device when inserting the PI layer were due to the surface energy match for PI (38 mJ/m^2) and PTCDI–C_8H_{17} (32 mJ/m^2) films obtained from contact angle measurements of H_2O and CH_2I_2. Furthermore, the PTCDI–C_8H_{17} on PI surface displays the larger grain texture than that on SiO_2 surface (surface energy of 60 mJ/m^2). Negative shift V_{tn} for p-transistor and normally-on n-type transistor with the PI modification layer were attributed to richly negative center on the SiO_2 surface. The improved on/off ratio and ss and suppression of leakage current for the n-type transistor with the PI layer when compared to the device without the PI layer are similar to p-type transistors as shown in Fig. 4c. Moreover, both the pentacene and the PTCDI TFTs have fairly large gate leakage currents, about 10 nA, due to the SiO_2 gate-dielectric grown at low temperature.

Fig. 5 shows the voltage transfer characteristics and gains of O-CMOS inverters composed of the above-mentioned p-transistor and n-transistor. The input voltage (V_I) was varied from 0 to 50 V at V_{DD} of 30, 40, and 50 V. The O-CMOS inverters demonstrate the switch from high to low states which correspond to the basic logic bit from "1" to "0". Compared with the O-COMS inverter without the PI modification layer, the device with the PI layer has symmetric voltage transfer curves in which the verti-

cal segment occurs at $V_I = V_{DD}/2$ and is bounded by $V_o(A) = V_{DD}/2 - V_{tp}$, $V_o(B) = V_{DD}/2 - V_{tn}$. The performance of switching an O-CMOS inverter can be generally determined by noise margins at high and low logic levels. The noise margins for high (NM_H) and low (NM_L) are defined as [18]

$$NM_H = V_{OH}(E) - V_{IH}(D) \tag{1}$$
$$NM_L = V_{IL}(C) - V_{OL}(F) \tag{2}$$

where V_{OH}(E) and V_{OL}(F) are maximum and minimum output voltages, respectively; V_{IH}(D) and V_{IL}(C) are input voltages at $\partial V_O/\partial V_I = -1$ as shown in Fig. 5a. The NM_H and NM_L are estimate to be 45% and 47.4% of $V_{DD} = 50$ V, respec-

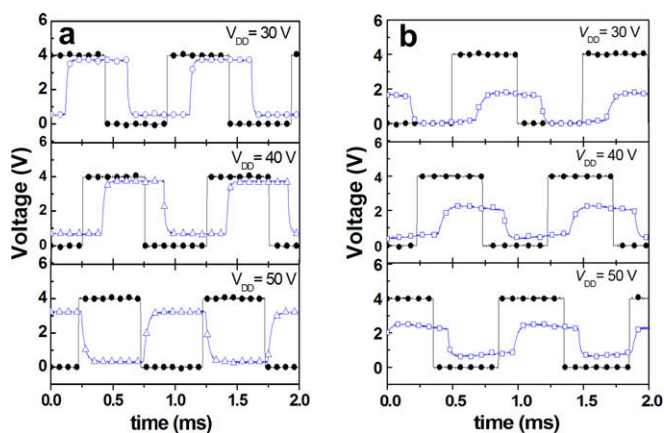
tively. Especially, the noise margin at high level matches that at low level. The voltage of transition region between V_{IH} and V_{IL} is below 10% of the V_{DD} as shown in Fig. 5e. However, the noise margins of organic complementary


Fig. 6. The dynamic characteristics operation of O-CMOS inverters employing (a) the PI, (b) without the PI at 1 kHz and various V_{DD}. The close symbol represents the input signal (V_I) and open symbol represents the output (V_o).

inverters exceed 50% in literature reports, in which the difference of NM_H and NM_L is greater than 10% for some reports [12,19,20]. Therefore, the characteristics of the device with the PI modification layer have the potential for applications in organic inverter circuit designs. Moreover, the small hysteresis phenomenon was observed in the device with the PI layer because of the good matches of drain-currents in both transistors. For obtaining the drain-currents match, the W/L of p- and n-transistors were adjusted to optimize the voltage transfer curve and noise margin of O-CMOS as shown in Fig. 5a and b. The gain of CMOS device was defined as the slope $\partial V_O/\partial V_I$ of the transfer curve. When the O-CMOS was fabricated on a SiO_2 surface, it showed a very low gain as shown in Fig. 5c. The gain was improved by above five times of magnitude when the O-CMOS was fabricated on the PI surface.

The generally studied CMOS demonstrates an important application of MOSFET, namely, its use as a voltage-controlled switch. The characteristics for dynamically operating the O-CMOS inverters are shown in Fig. 6. When the amplitude of alternating input V_I (1 kHz) was fixed at 4 V and V_{DD} varied from 30 to 50 V at step of 10 V, the amplitude of the alternating output V_o for the O-CMOS with the PI layer is almost the same as the input. However, the amplitude of the alternating V_o for the O-CMOS without the PI layer is half of the input because of the mismatch of the drain current and field-effect mobility between n-type and p-type transistors. The propagation delay time (t_p) decreases with the increase of V_{DD} (t_p inversely proportional to μ and V_{DD}) for all O-CMOS inverters, in which the definition of delay time is the same as inorganic CMOS inverter [18]. The propagation delay time of 52 μs was obtained for the O-CMOS inverter at V_{DD} = 50 V among all devices; furthermore, it behaved as an ideal CMOS inverter.

In summary, organic semiconductors pentacene and PTCDI–C_8H_{17} were used to fabricate O-COMS inverters integrated with the PI as surface modification layer on dielectric. The performances of the devices were dramatically improved by introducing PI films. An ideal O-CMOS inverter has been achieved and the n-type organic semiconductors with various alkyl groups are in progress.

donor/acceptor combination using pentacene/PTCDI-C$_8$ thus can harvest light efficiently throughout the visible solar spectrum. PTCDI-C$_8$ thin film also shows high electron mobility (0.6 cm^2 V^{-1}s^{-1}) [18], which ensures balanced field-effect mobilities for n- and p-channels within the device.

In this letter, we report on the photovoltaic properties of an efficient donor/acceptor combined pentacene/PTCDI-C$_8$ heterojunction. Solar cell parameters precisely estimated using the model recently reported by Ishibashi et al. [19] are reported.

The photovoltaic devices were fabricated on patterned indium tin oxide (ITO) coated glass substrates. The sheet resistance of the ITO anode was 10 $\Omega/\square$. All organic materials were purchased from Sigma–Aldrich. Prior to organic layer deposition, ITO substrates were cleaned thoroughly in acetone, isopropyl alcohol and de-ionized water in sequence using an ultrasonic cleaner followed by drying with nitrogen gas. Cleaned ITO anodes were treated with microwave oxygen plasma for 30 s. A 40 nm thick poly(3,4-ethylenedioxythiophene)–poly(styrenesulfonate) (PEDOT:PSS) layer was spin coated on ITO anodes from a 2.8 wt% water solution. Spin coated PEDOT:PSS substrates were annealed at around 110 °C for 1 h to remove the solvent completely. A 50 nm thick pentacene (99.9%) layer was thermally evaporated with a deposition rate of ~0.5 Å/s followed by the deposition of a 40 nm thick PTCDI-C$_8$ (98%) layer. A 10 nm thick electron transporting layer (ETL) of Tris-(8-hydroxyquinolinato) aluminum (AlQ$_3$) was then deposited on the top of the PTCDI-C$_8$ layer to prevent it from being damaged during metal deposition and to enhance the
Fig. 1. electron collection efficiency from the PTCDI-C$_8$ layer to the Al cathode [20]. Finally, an 80 nm thick aluminum top electrode strip was deposited by thermal evaporation through a shadow mask to define a square shaped active area of 4 mm^2. Base pressure during the thermal evaporation was 5×10^{-6} mbar. The thickness of different layers was monitored by quartz crystal monitor and was verified by stylus profilometer (Veeco Dektak3). Atomic force microscopy (AFM) (Veeco Nanoscope-IV) in tapping mode was used to study the surface morphology of different layers of the device. The crystallinity of the pentacene/PTCDI-C$_8$ bilayer was studied using a Philips X-Pert PRO MRD X-ray diffractometer with CuKα radiation ($\lambda = 0.15418$ nm). The absorption spectra of the pentacene/PTCDI-C$_8$ heterojunctions were investigated in the wavelength range 300–1100 nm using a UV–VIS–NIR spectrophotometer (Perkin–Elmer Lambda 45). Current density–voltage (J–V) characteristics of the devices were measured using a Keithley 4200-SCS measurement unit in dark and under AM 1.5 illumination (Newport 67005 solar simulator) with a power density of 100 mW/cm^2. The photocurrent action spectrum was measured under short circuit condition at a chopping frequency of 180 Hz with a lock-in amplifier (Standford research system-SR830 DSP) during illumination with the monochromatic light from a broadband source. All the device characterizations have been carried out under ambient condition.

The performance of the organic photovoltaic devices depends significantly on the morphology of the active layers. Active layers with small and disordered grains may limit the cell performance due to the large number of defect states and recombination losses. Several factors including deposition rate, substrate temperature and the nature of the substrate can influence the film morphology and crystallinity [21,22]. Here pentacene films were deposited at a slow evaporation rate of ∼0.5 Å/s to realize larger crystalline domains [21]. For investigating the morphology of the different layers of the device, taping mode AFM was performed on both pentacene and PTCDI-C$_8$ layers. Fig. 1a shows the morphology of pentacene film deposited on ITO/PEDOT:PSS substrates. The film contains crystalline grains of 800–1100 nm sizes with layered structures. Fig. 1b shows the morphology of PTCDI-C$_8$ layer deposited on ITO/PEDOT:PSS/pentacene substrates, with uniform and densely packed structures. For further analysis, X-ray diffraction (XRD) experiments were performed on pentacene/PTCDI-C$_8$ heterojunctions deposited on ITO/PEDOT:PSS substrates under conventional (θ–2θ) configuration. Fig. 1c shows the corresponding XRD patterns. PTCDI-C$_8$ film shows strong diffraction peak at 4.2° with a d-spacing of 2.10 nm corresponding to the (0 0 1) plane [23] whereas pentacene exhibits a predominant thin film phase with a d-spacing of 1.56 nm at 5.6°, 11.3° and 17.2° corresponding to the (0 0 1), (0 0 2) and (0 0 3) planes, respectively [22,24–26]. Prominent diffraction peaks of pentacene and PTCDI-C$_8$ layers ensure the higher degree of crystallinity of both the p- and n-channels, resulting in low recombination losses and reduced microscopic shorts within the device.

To compare the spectral response of heterojunction device, we have investigated the independent absorption spectra of a 50 nm thick pentacene film, 40 nm thick PTCDI-C$_8$ film and the combined pentacene/PTCDI-C$_8$ heterojunctions in 300–1100 nm wavelength range using a UV–VIS–NIR spectrophotometer. Fig. 2a represents the corresponding absorption spectra of different layers. PTCDI-C$_8$ shows significant absorption in the wavelength range 400–600 nm with peaks at 488, 523 and 567 nm. On the other hand pentacene has strong absorption properties in the range of 500–700 nm with peaks at 583 and 667 nm and visible kinks at 501, 543 and 629 nm. Altogether, the pentacene/PTCDI-C$_8$ heterojunctions show strong absorption throughout the visible solar spectrum. Fig. 2b shows the photocurrent action spectrum of the device. It closely follows the absorption profile of pentacene/PTCDI-C$_8$ heterojunctions with maximum external quantum efficiency (EQE) of ∼60% at 493 nm, which is one of the highest, reported so far for organic photovoltaic devices. External quantum efficiency (EQE) was measured using the relation:

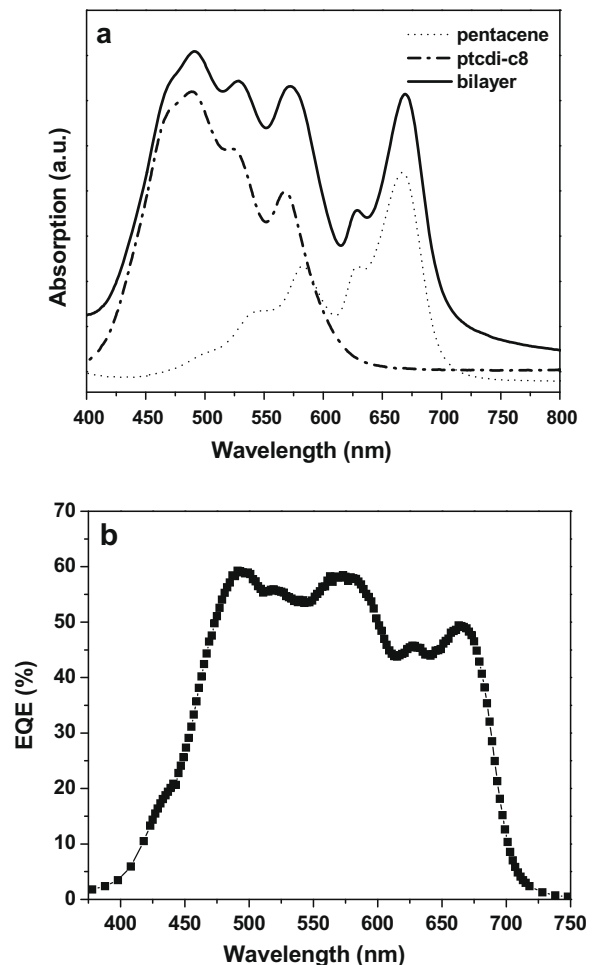
$$EQE(\%) = \left(\frac{100 \times 1240 \times J_{sc}}{\lambda P_0} \right), \tag{1}$$


Fig. 2. (a) Absorption spectrum of a 50 nm thick pentacene film, 40 nm thick PTCDI-C$_8$ film and the pentacene (50 nm)/PTCDI-C$_8$ (40 nm) heterojunctions deposited on glass substrates, (b) photocurrent action spectra of the device; EQE reaches ∼60% at the PTCDI-C$_8$ peak absorption.

where P_0 is the incident light intensity of the source (mW/cm^2), J_{SC} is the short-circuit current density (mA/cm^2), and λ is the wavelength (nm) of incident radiation. It is quite interesting to note that the highest peak of the photocurrent action spectrum corresponds to the maximum absorption peak of the PTCDI-C$_8$ films. This reveals the significant contribution of PTCDI-C$_8$ layer to the device performance in terms of strong light absorption and efficient exciton dissociation at the pentacene/PTCDI-C$_8$ interface.

Fig. 3a shows the J–V characteristics of ITO/PEDOT:PSS/pentacene (50 nm)/PTCDI-C$_8$ (40 nm)/AlQ$_3$ (10 nm)/Al devices under dark and 100 mW/cm^2 AM 1.5 simulated solar irradiation conditions. The device exhibits a short-circuit current density (J_{SC}) of 3.0 mA/cm^2, an open-circuit voltage (V_{OC}) of 0.60 V, and a high fill factor (FF) of 65%. These device parameters lead to power conversion efficiency (η) of 1.2%. Similar results have been found using PTCDI-C$_{13}$, another derivative of PTCDI, as acceptor materials by Pandey et al. [27]. The high fill factor indicates reduced recombination loss and high shunt resistance (R_{SH}) of the device [28].

These may be due to the excellent morphology and high charge carrier mobilities of both the p- and n-channel of the devices. For further clarification, the precise measurement of all solar cell parameters have been made by analysing the J–V curve, shown in Fig. 3a under A.M 1.5 illumination, using the model given by Ishibashi et al. [19]. Shunt resistance (R_{SH}) has been independently derived from the slope of the J–V curve at $J = J_{SC}$ ($V = 0$). Fig. 3b shows the experimental data together with the calculated R_{SH} of the device. Other parameters have been estimated from the y-intercept and the slope of the plot of $(-dV/dI)$ as a function of $\{I_{sc} - I - [V - R_s(I_{sc} - I) - nk_BT/q]/R_{SH}\}^{-1}$, as shown in Fig. 3c, where I_{SC}, R_S, R_{SH}, q, n, k_B and T are the short-circuit current, series resistance, shunt resistance, electron charge, the ideality factor, the Bolzmann constant and the temperature, respectively. The plot of $(-dV/dI)$ exhibits a good linearity in agreement with the model [19]. The device shows a series resistance (R_S) of 18 Ω cm^2, a shunt resistance (R_{SH}) of 2.5 kΩ cm^2 with an ideality factor (n) of 1.6. Low ideality factor
Fig. 3. (a) J–V characteristics of ITO/PEDOT:PSS/pentacene (50 nm)/PTCDI-C$_8$ (40 nm)/AlQ$_3$ (10 nm)/Al devices under dark and 100 mW/cm^2 AM 1.5 simulated solar irradiation conditions, (b) the analysis of the J–V curve under illumination for the calculation of the device shunt resistance (R_{SH}), (c) the plot of $(-dV/dI)$ as a function of $\{I_{sc} - I - [V - R_s(I_{sc} - I) - nk_BT/q]/R_{SH}\}^{-1}$ for the estimation of device series resistance (R_S) and ideality factor (n).

(<2.0) confirms reduced recombination losses within the device. The saturation current (I_0) and photocurrent (I_{Ph}) of the cell have been estimated to be 53.8 pA and 118.3 μA, respectively.

To conclude, we have demonstrated the operation of an efficient solar cell based on pentacene/PTCDI-C_8 discrete heterojunctions. The absorption spectrum and the photocurrent action spectrum of the device confirm that PTCDI-C_8 can be a more suitable choice as an acceptor material than C_{60} for photovoltaic applications. The most promising point with this donor/acceptor combination is that the device exhibits efficient light harvesting throughout the visible region of the solar spectrum. Further improvement of the device performance may be achieved by post- or pre-fabrication annealing treatments and by optimizing the active layers thickness.

of the load capacitance are very strict. Also, the supply voltage needed to drive an organic circuit has to be considered. It has been estimated that a rectifier based on an organic diode would need to deliver a supply voltage of 10 V and a current of 100 μA from an incoming RF signal at 13.56 MHz [9].

In order to exploit the opportunities associated with organic electronics, rectifier diodes based on organic semiconductors should be manufactured with technologies that offer high throughput and reliable processing. So far most of the work has concentrated on evaporated semiconductors and evaporated or sputtered metal electrodes patterned by shadow masking [8,9]. Photolithographic patterning has also been used to define the metal structures [10]. In some studies, spin casting has been used either to deposit the organic semiconductor layer or to deposit an intermediate layer, such as PEDOT:PSS (poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate)), on top of one of the electrodes [7–9]. Spin casting, though it is based on solution processing, cannot be considered a high throughput process. High throughput processes, such as coating and printing technologies, need to be demonstrated to manufacture organic rectifier diodes on a scale that can be of industrial interest.

In this letter we report an organic diode rectifier that delivers excellent DC output at AC input frequencies approaching the RFID HF standard and was made using only mass printing based patterning methods. No shadow mask, ink jet, photolithography or other fine patterning processes were used. The semiconductor layer was sandwiched between copper and silver electrodes and diodes with different semiconductor thicknesses were characterized with respect to their *J–V* and rectifying properties. Contrary to most of the previous studies where the devices have been fabricated either in vacuum or inert atmosphere, the processing and characterization was performed in ambient laboratory conditions. This was enabled by using PTAA (poly(triarylamine)) as the semiconducting layer. PTAA is a well-known amorphous conjugated polymer whose electrical properties have been shown not to degrade in air [12,13].

The diodes were fabricated on metallized polyester (poly(ethylene terephthalate), PET) film, Melinex ST506 from Dupont Teijin Films, using printing processes that are compatible with roll-to-roll fabrication. A 100 nm copper layer was sputtered onto the PET film. The copper was subsequently patterned using a wet etching process in which the etch resist, UV-curable XV1000-2 from Sun Chemical, was printed using rotary screen printing. After etching, the samples were cleaned by rinsing with de-ionized water and 2-propanol. The diodes were fabricated in a dust-free environment (non-certified but close to ISO 14644-1 class 5) at room temperature and RH of 40–50.

The patterned semiconductor layer, poly(triarylamine) PTAA, was single printed with a laboratory-scale automatic gravure printing press, Labratester Automatic from Norbert Schläfli Maschinen, and cured at 115 °C for 5 min. Although the press is sheet-fed, it imitates roll-to-roll printing closely. The anode material, silver ink PM460A from Acheson Industries Ltd., was also deposited with the gravure press and cured at 115 °C for 5 min. Orthogonal

solvents were chosen to avoid interfacial dissolving or mixing of the layers. The resistance of the printed silver lines was measured to be 0.3 Ω/□. Diodes with three different PTAA thicknesses were fabricated. Film thicknesses were measured with a Veeco diCaliber Scanning Probe Microscope in the non-contact mode.

The DC *J–V* characteristics of the diodes were measured using a Keithley 236. The DC output signals were measured for AC supply signals of zero-to-peak amplitude of 10 V. The diode capacitance was measured with HP4192A, and rectification properties with an SRS DS345 30 MHz function generator and Tektronix TDS 3014B oscilloscope. A 47 nF discrete capacitor was used as the load capacitor. The oscilloscope had a 1 MΩ || 16 pF input impedance. The internal load of the oscilloscope was used as the load resistor. The circuit performance was confirmed by testing a few different capacitor and resistor values. All measurements were made in laboratory conditions in dark.

Thicknesses measured by AFM for the PTAA layers were 400 nm, 600 nm and 1100 nm. These values were confirmed by capacitance–frequency measurements. As the frequency is increased, the initially high capacitance decreases. At low frequencies, the interface states follow the alternating current signal while at high frequencies they cannot follow the signal. At this region, the capacitance is constant indicating that the semiconductor is fully depleted and the capacitance is the bulk capacitance of the semiconductor. Using the relative permittivity of the semiconductor ($\varepsilon_r = 3$) and the active area 4 mm^2, the capacitance values of 90, 160 and 220 pF translate into thicknesses of 1200 nm, 700 nm and 500 nm, respectively. Although the capacitance measurements gave systematically slightly higher values for the film thicknesses compared to the AFM measurements, the thickness values are in the same range. The difference can be attributed to a thickness variation between the edge of the PTAA (measured thickness by AFM) and the centre (diode area). Also the relative permittivity value is only an estimate for PTAA semicondutors.

In the Schottky diodes reported here, a printed silver layer acted as the anode and a patterned copper layer as the cathode. The forward current in the diodes depends on the quality of the ohmic contact, and thus the energy barrier between the silver and the highest occupied molecular orbital (HOMO) of the semiconductor. The reverse current depends on the Schottky barrier height between the copper and the highest occupied molecular orbital of the semiconductor. The current in the devices is carried almost exclusively by holes.

In a vertical rectifier diode structure, the semiconductor thickness needs to be thick enough to sustain the voltage applied across the diode but thin enough for charge carriers to move in the semiconducting material at high frequencies. The printing process and the surface properties of the substrate pose restrictions on how thin a layer can be printed. In gravure printing, the resulting film thickness is determined by the printing cylinder cup depth and line density. The rheology of the ink, surface energies of the ink and the substrate, printing pressure and speed also affect the ink transfer from the cup to the substrate. In the diodes reported here, the yield of working devices was im-

proved when the semiconductor layer was double printed with shallow printing cups compared to single printed with deep cups. However, by optimizing the substrate smoothness and ink properties the semiconductor does not need to be double printed.

The log J–V characteristics are depicted in Fig. 1. At 5 V, the samples showed a current density of 2000 μA/cm², 800 μA/cm² and 280 μA/cm² for semiconductor thicknesses of 500 nm, 700 nm and 1200 nm, respectively. In the reverse bias regime, the currents slowly increased for the two diodes with thinner semiconductors, with the current density values at −5 V of 60 nA/cm² and 30 nA/cm². In the thickest diode, the current density at −5 V is 1–3 nA or lower; this is close to the detection limit of the measurement unit. The rectification ratio for all diodes was over 10,000. The diode characteristics showed no significant degradation when the performance was followed for 4 weeks after fabrication. During this period, the diodes were stored and characterized in ambient laboratory conditions.

Rectified output voltages at frequencies up to 10 MHz for diodes with three different PTAA thicknesses are shown in Fig. 2. In these measurements, the input AC zero-to-peak signal was 10 V. The output voltages were constant at approximately 7.4 V, 6.6 V and 5.4 V for PTAA thicknesses of 500 nm, 700 nm and 1200 nm, respectively, for frequencies up to 10,000 Hz and decayed slowly at higher frequencies. At 1 MHz, the output voltage for the thinnest diode was approximately 5.4 V and at 10 MHz approximately 2.7 V. When the AC zero-to-peak signal was increased to 25 V, the thinnest diode gave a DC voltage of 18 V at 1 MHz. This yields a maximum field over the diode of 0.87 MV/cm. At AC voltages larger than 25 V, the diode started to degrade and the output DC voltage decreased. At frequencies over 1 MHz the impedance mismatch of the circuit and the available measurement instruments caused a decrease in the effective input voltage, which lead to a lowering of the rectifier output voltage in Fig. 2; in other words, optimized input circuitry would be expected to yield better rectification performance.

Fig. 2. DC output voltage for 10 V AC input signal as a function of frequency in printed PTAA diodes.

The measured AC response for a printed PTAA diode in a configuration where the diode was connected to a load capacitor (47 nF) and load resistor (1 MΩ) is shown in Fig. 3. The input signal was provided by a function generator. At 1 MHz, the diode was able to rectify an input signal with 10 V zero-to-peak amplitude into a 5.4 V stable DC current. To power an organic circuit, the rectified DC voltage should be as high as possible and the voltage drop across the diode should be as small as possible. Since the organic layer is already relatively thin (500 nm) for a mass printed layer on an inherently non-flat substrate, the challenges in forming thinner films and thus achieving higher frequency rectification are considerable. However, the result achieved here shows the potential of completely printed diodes at MHz frequencies.

To operate as high efficiency DC converters at frequencies required for HF RFID tags, the diode characteristics still need to be improved. This can be done by reducing the diode area, improving the ohmic contact of the diode or

Fig. 1. J–V characteristics of printed diodes with different PTAA thicknesses.
Fig. 3. Rectifying DC output signal at 1 MHz with an input AC signal of 10 V for a diode with PTAA thickness of 500 nm.

modifying the mobility and thickness of the semiconductor [14]. The active diode area, 4 mm^2, is rather large, which resulted in a high capacitance over the diode. Secondly, the contact between silver and PTAA is most probably not completely ohmic, resulting in injection limited rather than space charge limited current. The contact could be improved by choosing an anode with a lower Schottky barrier with the HOMO level of PTAA. Such a gravure printable anode could be for example modified PEDOT–PSS. However, there are concerns related to the stability and high acidity of PEDOT–PSS which can affect the diode performance [15]. The third option to improve the rectification properties of the diode is to improve the mobility of the semiconductor or reduce the printed thickness. Although materials with higher mobilities are being developed, for printable semiconductors it is also of importance that the materials can be formulated to an ink that has the right properties for mass printing. This poses some limitations in terms of suitable solvents and the rheological properties of the ink. Additionally, the printing process will most likely introduce inhomogenities in the organic film thickness. Here, the surface roughness of the underlying patterned metal (and also the polyester substrate) will also have an effect.

With regard to the semiconductor thickness, rectifying properties at high frequency will improve if the thickness is reduced, as shown in equation [8]:

$$f_{max} = \frac{\mu(V_{AC} - V_{DC})}{L^2} \tag{1}$$

where V_{AC} = supply AC voltage amplitude, V_{DC} = output DC voltage, μ = carrier mobility, and L = film thickness, yields the maximum operating frequency (f_{max}) of the diode. The frequency is inversely proportional to the square of the semiconductor thickness. Extrapolating from Fig. 2 that a diode with a semiconductor thickness of 400 nm gives an initial output DC voltage of 8 V, a diode with this thickness would operate at a frequency in the range of 13.56 MHz with an output DC voltage of 4.5 V. This is the frequency needed for RFID applications. Here, it has to be pointed out that when the thickness is reduced also the reverse current of the device will increase, as depicted in Fig. 1. This will worsen the rectification ratio. However, the increase in reverse current may be relatively small when the diode is operated at high frequencies.

In conclusion, a roll-to-roll compatible mass printing process was demonstrated for the fabrication of organic diodes for use in a high frequency rectifier. A PTAA diode, manufactured and measured in air, showed rectification up to 10 MHz with an active layer thickness of 500 nm. By optimizing the device geometry, electrodes, printing parameters and semiconductor properties, the diodes presented here can be improved to rectify at frequencies required for HF RFID applications. The diodes also showed a stable *J–V* performance under ambient room conditions. This study thus shows the possibility of RF-compatible organic rectifier diodes that can be manufactured with roll-to-roll printing processes.

Organic photovoltaic devices utilizing phosphorescent materials have previously been demonstrated, either by employing directly a phosphorescent small molecular or polymer layer [11–14], or by inducing phosphorescence in a fluorescent host via a proximity effect of a heavy-metal-atom containing phosphor dopant [15]. However, because phosphorescent organic semiconductors are typically characterized by low mobilities and absorption that do not overlap well with the solar spectrum [13], their use as active, absorbing layers may be difficult to realize. One notable exception [2] is the acceptor C_{60}, which has a high charge carrier mobility of 5×10^{-2} cm^2/Vs, and $L_D \approx 40$ nm owing to its near unity ISC efficiency [16], albeit with an absorption spectrum still focused in the blue wavelength range.

Here, we demonstrate enhanced photocurrent from a fluorescent material via the process of sensitized phosphorescence. We employ a host:guest system where a fluorescent host material continues to be used for light absorption as well as for charge and exciton transport. The guest serves only to convert initially generated host singlet excitons into triplet excitons, as its low concentration prevents efficient transport and absorption. An advantage of this approach to create triplet excitons on a fluorescent host stems from the fact that due to the lack of an efficient triplet decay pathway, triplet states in fluorescent materials [17,18] generally possess significantly longer lifetimes compared with phosphors containing heavy-metal atoms [19] (e.g. ms compared to μs). To allow for the above processes to occur, the host:guest system needs to obey the following criteria: First, that the lowest excited singlet state of the dopant is lower than that of the host material ($S_{1,dopant} < S_{1,host}$), and there is sufficient overlap between the emission of the host and absorption of the guest to allow for efficient singlet energy transfer (SET). Second, that the triplet energy of the dopant molecule is greater than that of the host ($T_{1,dopant} > T_{1,host}$) for efficient triplet energy transfer (TET) to occur. In addition, care should be taken to allow for efficient charge transport of photogenerated carriers through the host material. Therefore, an additional criterion for a donor material is that the highest occupied molecular orbital (HOMO) of the dopant is greater than that of the host to prevent holes from being trapped on the guest material which would ultimately reduce photocurrent. In the case of an acceptor material, care should be taken that the lowest unoccupied molecular orbital of the dopant is lower than that of the host material to prevent electron trapping.

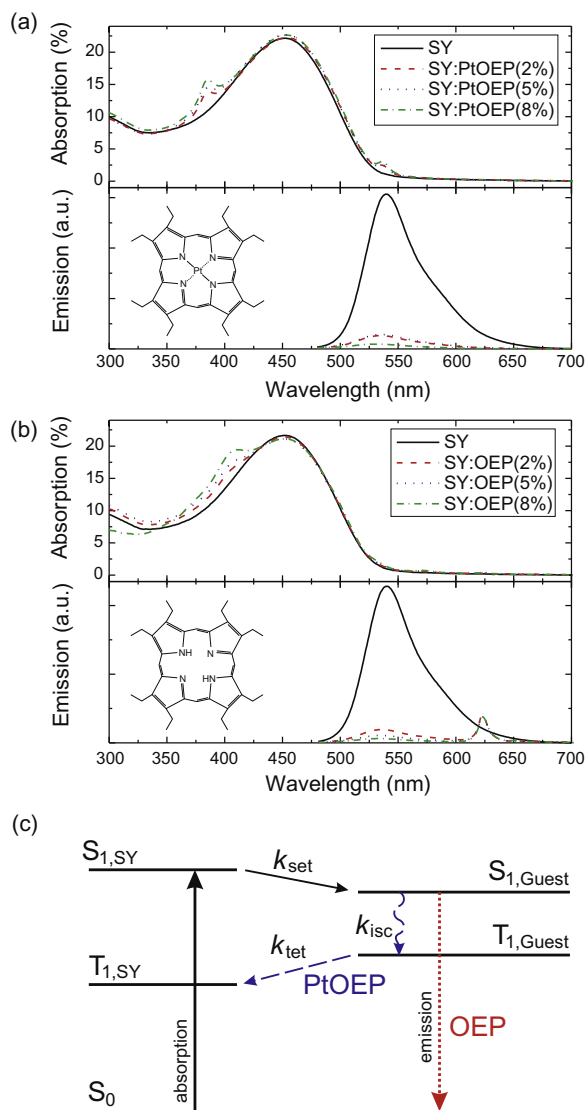
To demonstrate that the process of sensitized phosphorescence can be used to increase the photocurrent of an absorbing layer, we use as an example the phenyl-substituted poly(p-phenylene vinylene) (PPV) donor polymer Super Yellow (SY) doped with the phosphorescent molecule platinum octaethylporphyrin (PtOEP). Furthermore, we investigate the effect of doping with the Pt-free analogue octaethylporphyrin (OEP) to demonstrate the opposite effect: a dopant that allows SET but not TET is expected to actually reduce the photocurrent. Fig. 1a shows the absorption (Shimadzu UV-1601PC) and emission (Shimadzu RF-5301PC) of a pure SY film as well as films doped with PtOEP, whereas Fig. 1b shows SY films


Fig. 1. (a) Absorption (top panel) and photoluminescence (PL) (bottom panel) of 15 nm thick SY and SY:PtOEP thin films with various compositions. The molecular structure of PtOEP is shown as an inset to the bottom panel. (b) Absorption (top panel) and PL (bottom panel) of 15 nm thick SY and SY:OEP thin films with various compositions. The molecular structure of OEP is shown as an inset to the bottom panel. (c) The formation pathways of excitons generated in doped SY. Following absorption in SY to excite a molecule from the ground state (S_0) to the first excited singlet state ($S_{1,SY}$) there is singlet energy transfer to the guest at a rate k_{set}. For the guest PtOEP (blue dashed arrows), intersystem crossing converts singlet excitons to triplet excitons from $S_{1,Guest}$ to $T_{1,Guest}$ at a rate k_{isc}. Finally, the lower triplet energy of SY ($T_{1,SY}$) quenches the PtOEP triplets with a rate k_{tet}. In the case of an OEP guest (red dotted arrow), the lack of an efficient ISC pathway results in singlet emission.

doped with OEP. The absorption shoulders of PtOEP and OEP are present in the doped films, at wavelengths of $\lambda = 385$ and 535 nm for PtOEP and at $\lambda = 410$ nm for OEP, and the intensity of these peaks increases with doping concentration. The SY emission (excitation at $\lambda = 385$ nm), with its peak at $\lambda = 540$ nm, is quenched rapidly as a result of the introduction of either dopant. Significantly, PtOEP

phosphorescence [20] at $\lambda = 650$ nm is not present, whereas OEP fluorescence at $\lambda = 625$ nm is observed. This suggests the excitonic pathways illustrated schematically in Fig. 1c, where for the case of PtOEP there is efficient SET from SY to PtOEP molecules, followed by ISC, and finally TET back to SY owing to the lower triplet energy of SY ($\approx$1.6 eV) compared to that of PtOEP ($\approx$1.9 eV), a phenomenon which has been shown previously for PtOEP in PPV hosts [21]. In the case of OEP, SET onto the OEP dopant occurs, but since OEP is a fluorescent molecule, ISC efficiency is very low and singlet OEP emission is observed.

For the demonstration of sensitized phosphorescence in a solar cell, we use the following device structure: indium–tin–oxide (ITO)/poly(3,4-ethylenedioxythiophene): poly(styrene sulfonate) (PEDOT) (30 nm)/SY (15 nm)/C_{60} (30 nm)/bathocuproine (BCP) (8 nm)/Al (80 nm). Here, ITO/PEDOT serves as the anode, SY as the donor layer, C_{60} as the acceptor layer, BCP as an exciton blocking layer, and Al as the cathode. The reason for employing only a 15 nm thick SY layer is because the use of thicker layers led to a rapidly increasing series resistance for the device, reducing the fill factor (FF) as well as, and even more significantly, the short circuit current density J_{SC}. The ITO coated glass substrates were solvent cleaned followed by UV/O_3 treatment for 10 min. The PEDOT (H.C. Starck, Baytron P VPAI4083) solution was spincast at 3000 rpm for 60 s, followed by baking at 120 °C. The SY was dissolved in toluene at a concentration of 1.7 mg/ml, with doping of PtOEP or OEP by weight, followed by spincasting at 2000 rpm for 60 s. The C_{60}, BCP, and Al layers were then deposited in an ultrahigh vacuum chamber (base pressure < 5×10^{-9} Torr). The device area was measured with an optical microscope, with an average area of 3.3 mm². The current density vs. voltage (J–V) characteristics were measured using an Agilent 4156C parameter analyzer with illumination from a LOT-Oriel 1000 W Xe arc lamp fitted with

AM 1.5D filters. Calibration was performed by a KG3 band pass filter and a calibrated Si detector.

The schematic energy diagram of this device is shown in the inset to Fig. 2, where we also show the J–V characteristics of devices with undoped SY, SY:PtOEP(5%) and SY:OEP(5%) donor layers in the dark and under 100 mW/cm² AM1.5D simulated solar illumination. The undoped SY-based device has $J_{SC} = 3.2$ mA/cm², open circuit voltage $V_{OC} = 0.86$ V, FF = 0.54, and power conversion efficiency $\eta_P = 1.5$%. The doped devices have the same value of V_{OC}, which indicates that the host SY acts as the charge conducting material, a property which is expected for films containing a low concentration of dopant (<10%) and also owing to the shallower HOMO of SY (5.2 eV) with respect to that of either PtOEP (5.3 eV) or OEP (5.5 eV). The PtOEP-doped device has a dark current almost identical to that of the undoped device, and $J_{SC} = 3.5$ mA/cm², FF = 0.52, and $\eta_P = 1.6$% under illumination. In this case, the photocurrent is increased by almost 10%, whereas the FF is slightly decreased, which could indicate that the presence of the PtOEP dopant molecule interrupts charge carrier transport in the SY matrix, making the collection of photogenerated charges more difficult. For the case of 5% OEP doping, $J_{SC} = 2.8$ mA/cm², FF = 0.41, and $\eta_P = 1$%. Here, the OEP dopant increases the series resistance of the cell, as reflected in the lower dark current at $V \geqslant 0.7$ V as compared to the other devices. This has the effect of reducing the FF, but does not significantly impact J_{SC}, as an equally reduced photocurrent can be observed even for negative voltages, where photogenerated carriers are efficiently extracted by the applied field.

To understand better the influence of the dopant and whether sensitized phosphorescence plays a role in the device operation, we show in Fig. 3 the dependence of J_{SC} on dopant concentration for either PtOEP or OEP doping. It should be noted that the roughness and therefore interfacial area of the donor–acceptor heterojunction does not increase with doping concentration, as measurements by
Fig. 2. Current density vs. voltage characteristics in the dark (dotted lines) and under 100 mW/cm² AM1.5D solar illumination (solid lines) with the following device structure: ITO/PEDOT (30 nm)/donor layer (15 nm)/C_{60} (30 nm)/BCP (8 nm)/Al (80 nm). The donor layer is either pure SY (open black triangles), SY:PtOEP(5%) (filled blue squares), or SY:OEP(5%) (open red cirles). Inset: schematic energy diagram of the device structure.
Fig. 3. The normalized short circuit current density vs. dopant concentration for the device structure of Fig. 2 with either PtOEP (filled squares) or OEP (open circles) as the dopant. The data points are representative of the average value of six devices while the error bar indicates the standard deviation. The lines serve as guides to the eye.

atomic force microscopy of doped (8%) and undoped SY films have smooth surface morphologies with root mean square roughnesses of 0.6 nm (data not shown). With an increase in PtOEP concentration, J_{SC} increases by approximately 10%, peaking at a dopant concentration of 5%, beyond which the increase in J_{SC} is reduced. In contrast, the addition of OEP to the SY matrix always results in a decrease of J_{SC}, which appears to saturate at a reduction of approximately 15–18%. This can be understood by considering again the results of Fig. 1, where SY singlets are immediately quenched by the addition of small amounts of the dopant. Once a sufficient doping level has been reached in order to quench a large percentage of the SY excitons, increasing the dopant concentration only suppresses further the transport of charges and/or triplet excitons in the SY layer, resulting in a decreased performance and therefore the presence of an optimal PtOEP concentration. Indeed, the fact that both dopants efficiently quench SY excitons but only PtOEP doping leads to an enhancement of J_{SC} provides significant evidence that excitons are returned to SY in that case, whereas with OEP doping they are lost.

As further evidence of the sensitized phosphorescence mechanism, we consider the external quantum efficiency (η_{EQE}) spectra of doped and undoped devices, as shown in Fig. 4a. To highlight the relative contributions from SY and C$_{60}$, we also show the calculated absorption efficiency (η_A) spectra for SY and C$_{60}$ (using a transfer-matrix based calculation). The SY contribution is centered at $\lambda = 455$ nm, whereas C$_{60}$ is responsible for the shoulder at $\lambda = 435$ nm and the tail extending to $\lambda = 650$ nm. The reduction of η_{EQE} at $\lambda \leqslant 375$ nm is due to reflection and absorption from the glass/ITO substrate, resulting in a "false peak" in the measured η_{EQE} at $\lambda = 375$ nm. The η_{EQE} spectrum of the cell with a pure SY donor layer shows distinct features of both SY and C$_{60}$. From η_A, it is clear that there is a larger contribution to the photocurrent originating from the C$_{60}$ acceptor layer compared to that of SY,

which contributes approximately 15% of the total current, and which is consistent with the fact that OEP doping results in a reduction of J_{SC} by approximately the same amount (cf. Fig. 3). The calculated η_{EQE} spectrum for the undoped device closely fits that of the measured data, and yields an estimate of $L_D = 4 \pm 1$ nm, in excellent agreement to that of other PPV derivatives [22]. For the device with a SY:OEP(5%) donor layer, the contribution from SY is barely visible, functioning instead almost completely on C$_{60}$. Indeed, spectral fitting for this device requires $L_D \approx 1$ nm, indicating that only SY excitons formed at the interface with C$_{60}$ are able to contribute. This is consistent with the fact that OEP quenches most SY excitons and confines them to the OEP dopant (where emission is observed, cf. Fig. 1b), eliminating the opportunity to dissociate at the donor–acceptor interface.

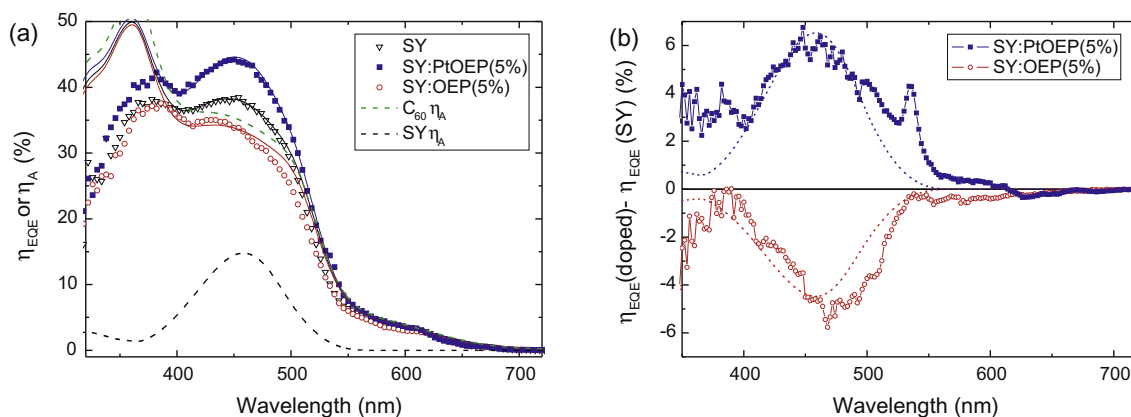
The η_{EQE} spectrum of the SY:PtOEP(5%) shows instead an enhancement of the SY signal, peaking at $\lambda = 450$ nm to $\eta_{EQE} = 45$%. Here, SY contributes approximately 21% of the total current, an increase of about 40% compared to the undoped SY donor layer. In this case, L_D of SY triplet excitons is longer than that of singlet excitons, and therefore a larger percentage of photons absorbed in the SY layer are able to contribute to photocurrent. We are again able to obtain an excellent spectral fit, and this provides an estimate of $L_D = 9 \pm 1$ nm, significantly greater than that of the pure SY film. Indeed, the reported fluorescence lifetime of SY is 400 ps [23], whereas the triplet lifetime has been estimated from delayed fluorescence to be 5.6 ms [17], and therefore an increase in L_D could be expected. If we take the difference between η_{EQE} of doped and undoped devices, we obtain the curves as shown in Fig. 4b. Here the difference between the PtOEP-doped and pure SY devices is a result of increased signal from SY, as well as small contributions from PtOEP at $\lambda = 385$ and 535 nm. These contributions from PtOEP provide further evidence of the triplet transfer process, as direct absorption of PtOEP generates triplet excitons which


Fig. 4. (a) Measured external quantum efficiency (η_{EQE}) spectra for the device structures of Fig. 2 with donor layers of pure SY (open black triangles), SY:PtOEP(5%) (filled blue squares), or SY:OEP(5%) (open red circles). The solid lines show the calculated η_{EQE} spectra, with colors corresponding to that of the data points. The dashed lines show the calculated absorption efficiencies (η_A) of the SY (black) and C$_{60}$ (green) layers within the device structure. (b) The difference in η_{EQE} between devices with doped and pure SY donor layers. The blue line with solid squares shows the device with PtOEP doping, and the red line with open circles shows the device with OEP as a dopant. The dotted lines represent the differences in the fits shown in (a). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

transfer to SY and are transported to the donor–acceptor interface, contributing to photocurrent. By contrast, the difference between the OEP-doped device and pure SY is negative and corresponds to a loss in the SY spectral response. Also in this spectrum, no additional contribution from the OEP dopant is observed, as would be expected for these immobile singlet excitons.

In conclusion, we have experimentally demonstrated an organic solar cell with a donor layer enhanced by the process of sensitized phosphorescence. By converting optically excited singlet excitons to triplet excitons efficiently, L_D was more than doubled, from 4 ± 1 to 9 ± 1 nm, which in turn increased the signal from this layer by 40%. In contrast, a similar dopant which lacks the ability to convert host singlet excitons to triplet excitons was shown to reduce the photocurrent from the host material. The ability to increase L_D, ideally toward distances equal to the absorption length in organic materials will allow simplified bilayer architectures to possess efficiencies approaching that of BHJ devices, or will at least relax the restrictions placed on the phase separation of blends. The design rules and methodology demonstrated here should lead to the development of new materials with suitable mobility and absorption spectra in order to optimize sensitized phosphorescent organic solar cells.

published by several companies and research groups. The most common carrier surface is still plastic film, but paper-based substrates are gaining increasing attention. E-Ink Corp. has demonstrated an electrophoretic display with an ink-on-paper-like appearance and contrast [8]. However, the display was constructed on metal foil, instead of on paper. Linköping University and Acreo AB have presented a fully functional all-polymer electrochromic display on polyethylene-coated fine paper [9]. While RFID tags on paper are already available on the market, the tags are produced by laminating an aluminum foil on paper instead of by printing [10]. The recyclability of such laminated or extrusion coated substrates is poor. The substrate presented in the current work is recyclable, which could be one of the main advantages when developing paper-based printed electronics.

We have developed a multilayer-coated paper-based substrate that is suitable for printed electronics and functionality. The multilayer structure consists of the following layers: precoating, smoothing layer, barrier coating and a top coating (Figs. 1 and 2) [11]. Each of the layers has its specific function that allows a printed device to operate

successfully. The precoated basepaper (90 g/m^2) was first blade-coated with a 7 g/m^2 kaolin layer to decrease the root mean square (RMS) surface roughness from ca. 600 to 300 nm (Fig. 2). On this smoothing layer a barrier layer was coated, consisting of acrylic or styrene acrylic copolymer latex either as 100% latex or blended with mineral pigments (coat weight $0.5–20 \text{ g/m}^2$). The surface was made polar by blending mineral pigments (PCC) with the barrier latex, which makes it possible to coat an aqueous top coat on the barrier layer. The total surface energy of the barrier layer was 33.0 mN/m (apolar component 27.4 mN/m and polar component 5.6 mN/m). If improved barrier properties are aimed for, then high aspect ratio platy pigments are preferred. The top layer is thin and smooth (coat weight $0.7–5 \text{ g/m}^2$, layer thickness $0.8–6 \text{ μm}$ and RMS surface roughness 55–75 nm) consisting of mineral pigments blended with 7–12 pph of styrene-butadiene latex as binder. PCC and Kaolin were studied for use in this layer in order to provide as different absorption properties as possible; PCC giving high and Kaolin low porosity. However, a whole range of other pigments such as fine GCC and Talc or blends of them could also be considered for use in this layer [12,13]. The sorption properties can be adjusted through controlled thickness and porosity enabling optimized printability of given functional materials. The materials in the coating structure were chosen in order to retain the recyclability and sustainability of the substrate.

The RMS surface roughness was measured as an average of three $100 \times 100 \text{ μm}^2$ images for every layer and compared with a 50 μm thick Mylar® A substrate, which is known to be a fairly rough plastic surface on which working organic transistors have been printed [14,15]. After calendering, multilayer-coated paper samples with RMS roughness as low as 55 nm were obtained. Respectively, the roughness of Mylar® A was ca. 30 nm. Roughness levels around 100 nm can in the paper industry be considered relatively smooth [16,17].

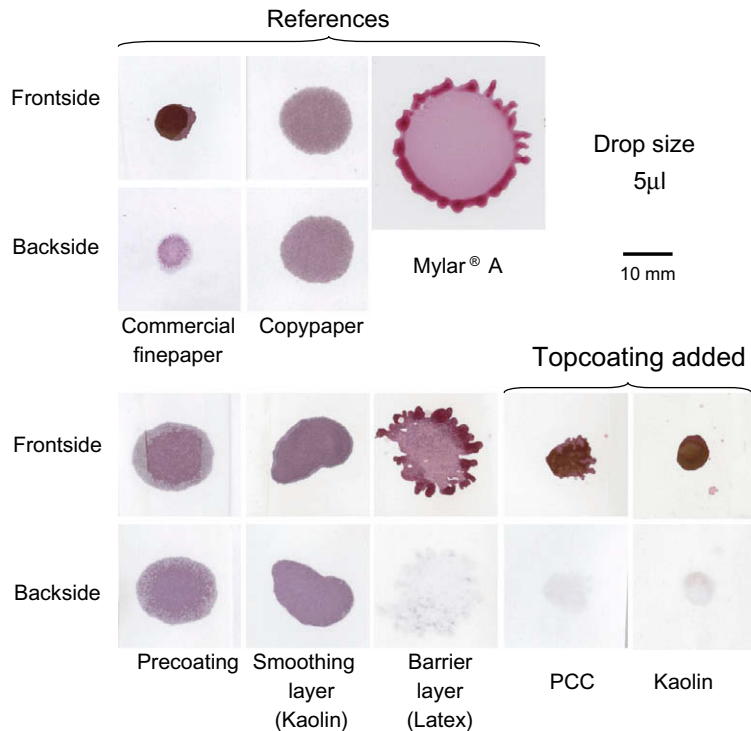
The barrier layer both controls the absorption of the inks and enables the functioning of the printed device. An example of a sorption test for a semiconductor ink,
Fig. 2. Atomic force microscope (AFM) images ($20 \times 20 \text{ μm}^2$) of each layer showing the changes in surface roughness The RMS roughness was measured from $100 \times 100 \text{ μm}^2$ images.


Fig. 3. Drop tests with the organic semiconductor P3HT in DCB. The visible spots on the backside indicate that the active material has penetrated through the paper substrate.

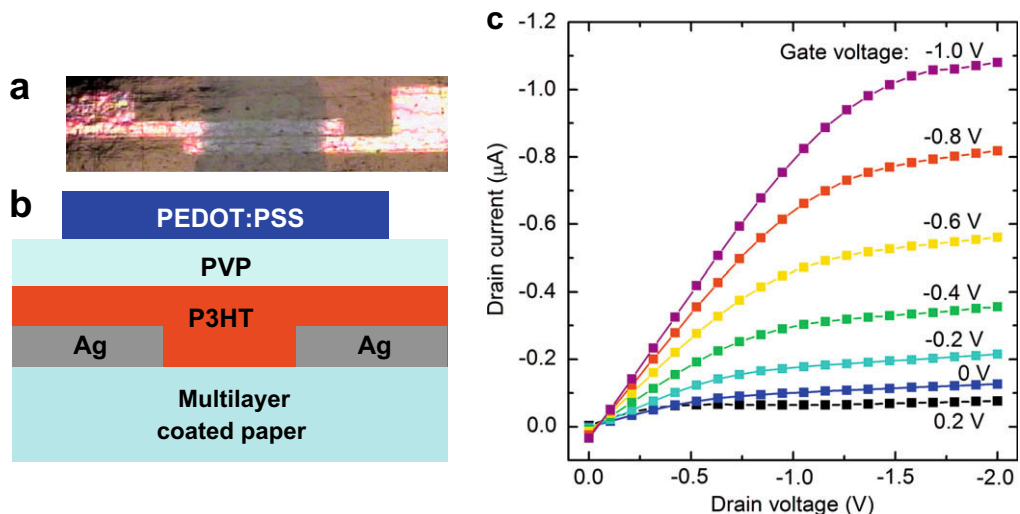
regioregular poly(3-hexylthiophene) P3HT dissolved in ortho-dichlorobenzene (DCB), is shown in Fig. 3. Compared with commercial paper substrates, the multilayer-coated paper shows superior barrier properties. Additionally, the printability (ink spreading) of the P3HT solution was much better controlled than e.g., on Mylar® A. The amount of ink applied was the same for each sample (5 μl), and the scanned areas were 25×25 mm^2 except for the Mylar® A where an area of 35×35 mm^2 was needed because of the excessive droplet spreading. Note also the clearly visible undesired coffee stain effect of P3HT on Mylar® A. The barrier layer withstands solvents such as water, alcohols, ethanediol, DCB, chlorobenzene, xylene, toluene and ethyl acetate.


Fig. 4. Optical (a) and schematic (b) images of the HIFET. Current–voltage characteristics for the transistor on paper measured in room atmosphere at a relative humidity of 19% (c).

If printing with silver-based inks, sintering with sufficient thermal energy is required. During sintering the insulating organic stabilizing agents are decomposed from the surface of the nanoparticles, ensuring high conductivity. If low-cost plastic films, such as Mylar® A are used as substrate, sintering can be carried out in an oven (e.g., 60 min at 120 °C). A more efficient way to sinter is to use infrared radiation (IR) (e.g., 10 s at 180 °C). An advantage of IR is that it rapidly increases the temperature in the sintering layer, and also makes roll-to-roll processing possible. IR could not be used for Mylar® A, because it immediately deformed when exposed to the required amount of IR radiation. In the current study, IR sintering did not have any effect on the barrier properties of the paper substrate.

A hygroscopic insulator field effect transistor (HIFET) [14,15,18] was chosen as the printed device as a proof of concept of the substrate (Fig. 4). The transistor consists of inkjet printed (drop spacing 25 μm) silver (Ag) source and drain electrodes/contacts, P3HT as semiconductor, poly(4-vinylphenol) (PVP) as insulator and poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) as gate electrode. The semiconductor and insulator layers were spin-coated and the gate was drop-cast. The paper substrate consisted of precoating (GCC), smoothing layer (Kaolin), barrier layer (styrene-acrylate) and a 2.1 μm thick top coating (Kaolin blended with styrene-butadiene binder, Tg 8 °C and particle size 140 nm, RMS roughness 74 nm). Fig. 4 demonstrates a working transistor with output curves showing current modulation at low voltages and is similar to the characteristics of a corresponding transistor on a PET substrate [15]. The measurement was done at a rather low relative humidity (19%) and the HIFET has earlier been shown to work at a relative humidity around 20–60% showing faster response at higher humidity levels [19]. Hygroscopic properties of the top coating can be adjusted by use of hydrophilic dispersants, such as commonly used Na-salts of polyacrylic acids [20]. The paper substrate can also be used for printed chemoresistors, such as biosensors or chemical sensors [21]. In principle, the functionalised material itself can be a conductive ink, an organic conductor, semiconductor or insulator, dissolved in a suitable solvent.

In summary, we have demonstrated a recyclable paper-based substrate where good barrier properties have been combined with controlled printability, as well as smoothness necessary for printed functionality. The multilayer-coated papers were produced in laboratory scale using blade, rod and reverse gravure coating in three steps. For large scale manufacturing, curtain coating could be considered as a potential manufacturing method. As long as the base substrate is a standard paper or board, the developed paper substrate is easily recyclable along with other waste paper.

2. Experiment

Bottom contact pentacene TFTs with parylene as the gate dielectric were photo-lithographically fabricated and evaluated. The process steps involved in the fabrication of our pentacene TFTs have been discussed in detail previously [16,17]. The resulting TFTs used for this study showed mobilities of 0.2 ± 0.02 cm^2/V-s with very stable threshold voltages of -2.5 ± 0.2 V and on/off ratio of $5 \times 10^4 \pm 1 \times 10^4$ [17]. Drive current was 0.12 µA/µm at -20 V gate bias. For the CVS studies, we used the metal–insulator–metal (MIM) capacitor structure shown in Fig. 1 to evaluate the time dependent breakdown characteristics of the devices described above. The MIM capacitors were fabricated on Si wafers coated with Si$_3$N$_4$ followed by 50 nm thick chromium films deposited by e-beam evaporation to form the bottom metal electrode. The parylene C used in our work was deposited using a Specialty Coating Systems PDS Model 2010 Labcoater 2. Parylene C was deposited by chemical vapor deposition (CVD) at room temperature by passing parylene through a vaporizing zone (175 °C), a pyrolysis zone (690 °C) and

Fig. 3. Time-to-breakdown vs. applied voltage for a 115 nm thick parylene device for different device areas.

into the chamber where parylene polymerizes on the substrate which is held at room temperature. The base pressure of the system was 5 mTorr and the deposition pressure was 15–22 mTorr. Three different parylene thicknesses were evaluated in this work: 53 nm, 115 nm and 164 nm. Parylene thicknesses were determined by ellipsometery and profilometry. Top metal contacts were formed using a shadow mask process by evaporating 100 nm of Au followed by 250 nm of Cr.

3. Results and discussion

Time dependent dielectric breakdown (TDDB) characteristics [18] of the parylene capacitors were obtained by monitoring the current–time response using an HP

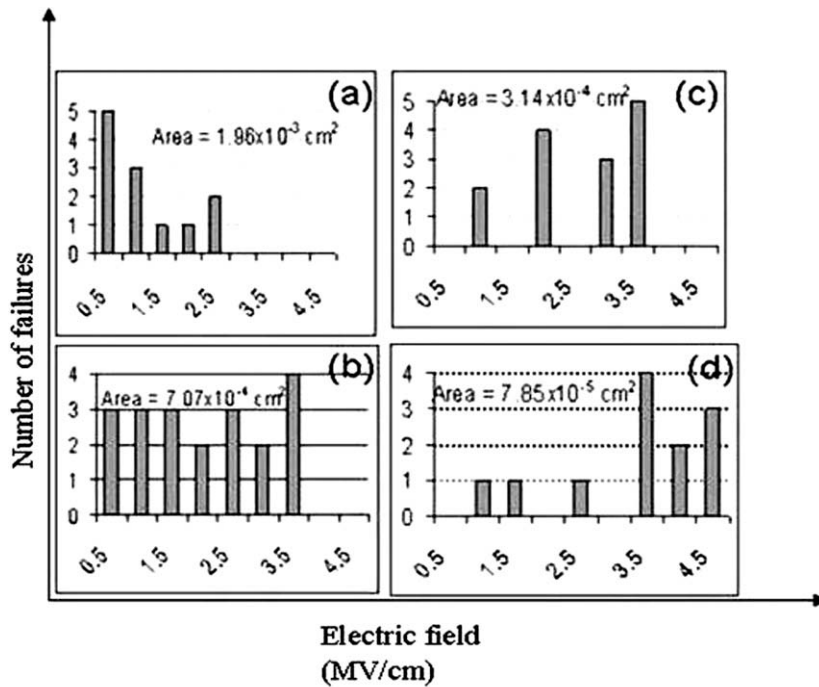
Fig. 1. MIM capacitor schematic cross-section used in the evalauation of TDDB characteristics of parylene.
Fig. 2. Current–time response of parylene capacitor (115 nm) showing three different regimes of operation.
Fig. 4. Time-to-breakdown vs. parylene film thickness obtained at different electric fields.


Fig. 5. (a–d) Distribution of number of failures as a function of applied electric field for capacitor areas 1.96×10^{-3}, 7.07×10^{-4}, 3.14×10^{-4} and 7.85×10^{-5} cm^2, respectively, indicating a shift towards intrinsic breakdown at higher electric fields.

4155A Semiconductor Parameter Analyzer controlled with a Labview data acquisition system. For these measurements, the bottom electrode was negatively biased with respect to the top electrode. A typical current–time response curve of a parylene capacitor is shown in Fig. 2. These data show that the parylene capacitor response for −15 V applied voltage can be divided into three regimes: (a) regime where the current density decreases from an initially high value due to the displacement current from charging the capacitor, (b) a steady state region where current density is almost constant over a period of time, and (c) a breakdown region where the current rapidly increases several orders of magnitude. In this study we define time-to-breakdown (t_b) of the capacitor as the time needed for the current density to increase $10\times$ from the minimum current density value [18].

Fig. 3 shows the mean time-to-breakdown for a 115 nm thick parylene film. Three areas (3.1, 7 and 19×10^{-4} cm^2) and three stress voltages (−15 V, −18 V and −22 V) were used to fully characterize the time-to-breakdown. As expected, for a given area the time-to-breakdown decreases as applied voltage increases, where as for a given applied voltage the time-to-breakdown increases as the area of the capacitor decreases. This indicates that the breakdown mechanism is defect dominated. Fig. 3 also indicates a power law dependence of t_b with applied voltage, given by Eq. (1) [18]

$$t_b \propto V^{-n} \tag{1}$$

where V is the applied voltage and n is a positive integer with a value in the range of 5–9. Similar power law dependence is observed for 53 nm and 164 nm thick parylene films. In Fig. 4 we compare t_b as a function of film thickness at different electric fields and a given device area. For thinner parylene films, t_b is less dependent on applied electric field than for thicker films. In other words, t_b for thinner films is predominantly determined by the number of defects in the dielectric, rather than the applied electric field. t_b shows a power law dependence of capacitor area. Given the fact that t_b shows a power law dependence for both applied voltage and device area we estimated (by extrapolation of curves) the lifetime of pentacene-based TFTs with respect to gate dielectric reliability for a parylene thickness of 115 nm. For this estimate we used a W/L ratio and fixed gate bias of 1000 μm/6 μm and −10 V, respectively. Results show a lifetime of ~945 h operating continuously under these conditions. We note that, besides the impact of gate dielectric in device lifetime, some other factors such as drain-source voltage induced stress and pentacene degradation due to moisture and oxygen could also result in reduced operating lifetime.

Defect density in the parylene thin film (164 nm) was experimentally determined using the time-zero-breakdown technique [19]. In this technique several parylene capacitors with different areas are stressed by varying the applied voltage until dielectric breakdown is observed. The defect density is then calculated by dividing the total number of failures by the total area of the capacitors tested. Using this technique, we evaluated a 164 nm thick parylene film and calculated a defect density of approximately 1.2×10^3 defects/cm^2. Fig. 5a–d shows the distribution of the number of failures at different applied electric fields for different device areas. It is observed that as device area decreases, the number of devices failing at the higher elec-

tric fields increases. As device area decreases there are fewer defects in that area and the capacitor breaks down at higher fields. This indicates a shift from extrinsic breakdown towards intrinsic breakdown [19]. Using the defect density above we estimate the number of defects in the dielectric to be 0.075 for a transistor size of 1000 μm/6 μm.

4. Conclusion

In summary, the time dependent breakdown characteristics of parylene used as a gate dielectric in pentacene-based TFTs was evaluated. The time-to-breakdown is determined to have a power law distribution over the applied voltage and device area and is shown to be driven by the number of defects in the dielectric. Defect density in our parylene thin films was calculated to be 1.2×10^3 defects/cm^2. The impact of parylene reliability on pentacene-based TFT lifetime is estimated based on the power law dependence and is found be 945 h. It is shown that the use of parylene C (as gate dielectric) does not limit the pentacene TFT device lifetime as pentacene degradation due to moisture and oxygen is more likely to have a larger effect on TFT device lifetime than parylene degradation [4].

Fig. 1. (a) The chemical structure of C_{60}TH-Hx and (b) schematic structure of a top-contact OTFT device ink-jet-printed with C_{60}TH-Hx.

dielectric layer, as well as metal electrodes, exhibited mobilities of up to 0.1 cm^2 V^{-1} s^{-1} [11].

Here we report a new C_{60} derivative, which contains an alkylated thiophene unit, for solution-processable OTFTs. More importantly, we have fabricated high-performance n-type OTFT devices by means of the ink-jet-printing method. The fabrication process was carefully optimized in order to achieve a uniform morphology and the desired molecular orientation. The chemical structure of C_{60}-fused *N*-methyl-2-(3-hexylthiophen-2-yl)pyrrolidine (C_{60}TH-Hx) is shown in Fig. 1a. C_{60}TH-Hx was newly synthesized in our laboratory via a Prato reaction between C_{60} and 3-hexylthiophene-2-carboxaldehyde with *N*-methylglycine. The material dissolves well in a variety of organic solvents and is hence suitable for solution-processable OTFT devices.

The redox behavior of C_{60}TH-Hx was studied by means of cyclic voltammetry experiments performed at a scan rate of 50 mV/s in a three-electrode cell using a platinum-plate working electrode, a platinum-wire counter electrode, and an Ag/Ag$^+$ (0.1 mol/L) reference electrode. Tetrabutylammonium tetrafluoroborate (Bu$_4$-NBF$_4$, 0.1 mol/L) in *o*-dichlorobenzene was used as the supporting electrolyte. The potentials are quoted relative to the ferricenium/ferrocene couple. By combining the optical data obtained from UV/vis spectroscopy studies with the electrochemical measurements, the values of the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO) levels were estimated to be 3.8 and 5.3 eV, respectively. Thus, the calculated HOMO–LUMO energy band gap is 1.36 eV. The reported LUMO and HOMO values for C_{60} derivatives including PCBM are in the range of 3.5–3.8 eV and 5.7–6.1 eV, respectively [12,13]. It was noticed that upon introducing a thiophene unit, the HOMO energy level increased whereas the LUMO energy level remained relatively constant due to its highly localized state around C_{60}.

Top-contact transistors shown in Fig. 1b were fabricated on a common gate of heavily doped n-type silicon wafers covered with a 3000 Å-thick silicon dioxide (SiO$_2$) dielectric layer. The substrates were treated with hexamethyldisilazane (HMDS) or octadecyltrichlorosilane (OTS) to produce hydrophobic dielectric surfaces. Amounts of 0.5 and 1.0 wt% of C_{60}TH-Hx were dissolved in chlorobenzene for spin-coating and ink-jet printing, respectively. A film thickness of 30 nm was obtained at a spin rate of 2000 rpm for 60 s. For the ink-jet method, the printer consisted of a single-nozzle drop-on-demand piezoelectric print head and a two-axis motorized positioning system with a CCD camera for visualization of the droplet ejection. Uniform droplet ejection was achieved by applying a 25 μs-long 35 V pulse at a frequency of 600 Hz. At this time, the ejecting solution volume was controlled to 15–20 picoliters from the nozzle, which has a diameter 30 μm. The vertical separation between the nozzle and the substrate was typically 0.5 mm. Bilayer top-contact electrodes consisting of Mg/Al (10 nm/120 nm) were evaporated under high vacuum (10^{-6} mbar) through a shadow mask. The channel length (*L*) and width (*W*) of the transistors were 50 μm and 3 mm, respectively.

All the OTFT devices were encapsulated by a glass can and getters in an inert argon environment inside a glove box system. Electrical measurements were performed at room temperature under Ar atmosphere using an HP4156C semiconductor parameter analyzer. Parameters such as mobility, I_{On}/I_{Off} ratio, and threshold voltage were calculated based on standard semiconductor FET equations in the saturation-current regime [14], see Table 1. All OTFTs showed very well-defined linear and saturation-regime output characteristics. As an example, the current–voltage characteristics of a C_{60}TH-Hx OTFT obtained by ink-jet printing on a Si/SiO$_2$ substrate treated with HMDS are shown in Fig. 2a. Fig. 2b shows the transfer characteristics of ink-jet-printed C_{60}TH-Hx. For comparison, the characteristics of spin-coated C_{60}TH-Hx are also shown. The ink-jet-printed C_{60}TH-Hx devices exhibited an excellent n-channel performance with a highest mobility of 2.8 × 10^{-2} cm^2 V^{-1} s^{-1}, an I_{On}/I_{Off} ratio of about 1 × 10^6, and a threshold voltage of 7 V. In the case of the spin-coated C_{60}TH-Hx devices, a maximum mobility of 1.8 × 10^{-2} cm^2 V^{-1} s^{-1} was achieved on the HMDS-treated substrates.

On the contrary, the PCBM devices showed a maximum mobility of 5.8 × 10^{-3} cm^2 V^{-1} s^{-1}, also on HMDS-treated substrates. These results indicate that the newly synthesized C_{60}TH-Hx material has better properties than PCBM, with high electron mobility, for n-type OTFTs. In addition,

Table 1
Performance of PCBM- and C_{60}TH-Hx-based OTFTs fabricated by means of spin-coating and ink-jet printing after different surface treatments of the Si/SiO$_2$ substrates.

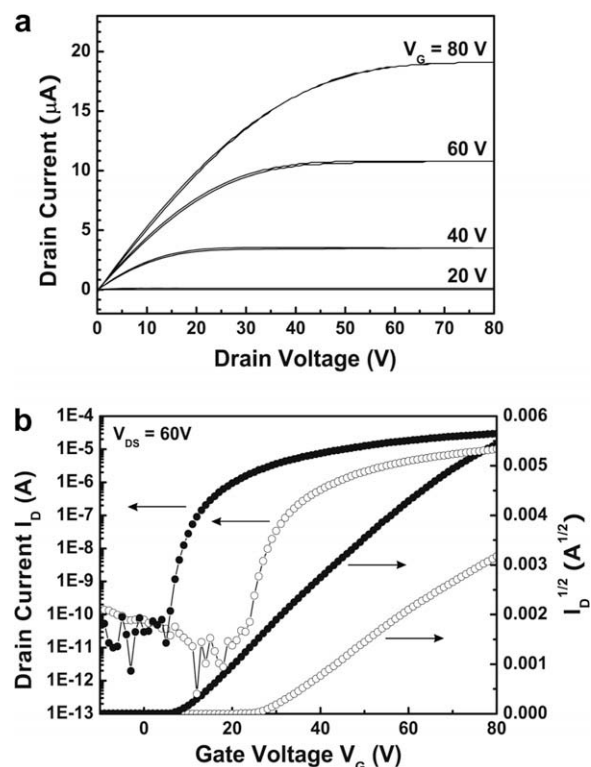
Sample	Processing method	Top electrodes	Surface treatment	Mobility (cm^2 V^{-1} s^{-1})	I_{On}/I_{Off} ratio	Threshold voltage (V)
PCBM	Spin-coating	Mg/Al	HMDS	5.8 × 10^{-3}	≈1 × 10^4	18
			OTS	3.3 × 10^{-3}	≈1 × 10^5	7
C_{60}TH-Hx	Spin-coating	Mg/Al	HMDS	1.8 × 10^{-2}	≈1 × 10^5	14
			OTS	1.4 × 10^{-2}	≈1 × 10^5	29
C_{60}TH-Hx	Ink-jet printing	Mg/Al	HMDS	2.8 × 10^{-2}	≈1 × 10^6	7


Fig. 2. (a) I_D–V_D characteristics of a C_{60}TH-Hx OTFT processed by ink-jet printing. (b) I_D–V_G and $I_D^{1/2}$–V_G plots of ink-jet-printed (closed circles) and spin-coated (open circles) C_{60}TH-Hx.

Fig. 3. $3 \times 3 \, \mu m^2$ AFM images of (a) spin-coated and (b) ink-jet-printed C_{60}TH-Hx films on an HMDS-treated SiO_2/Si substrate. The images were taken in the contact mode.

the performance of OTFT devices was found to depend on the type of top electrode. When a high work-function electrode such as a gold is employed in spin-coated C_{60}TH-Hx devices, the electron mobility decreases to 3.1×10^{-3} cm^2 V^{-1} s^{-1} while the I_{On}/I_{Off} ratio increases to about 1×10^6. Since the energy level of the LUMO of C_{60}TH-Hx is 3.8 eV, the electron-injection current can be limited to high work-function Au ($\approx$5.1 eV) by the contacts. Similar effects have also been reported for other systems based on different materials [15,16]. All the results reported herein are highly reproducible; further optimization of the device performance by using different annealing conditions, as well as an assessment of the long-term stability of the devices, is underway. Interestingly, the performance of ink-jet-printed C_{60}TH-Hx devices is superior to those of spin-coated and PCBM-based devices, with the ink-jet-printed C_{60}TH-Hx devices showing increased mobility and on/off current ratio as well as a reduced threshold voltage. This result indicates that the processing conditions significantly affect the OTFT device performance due to the different evaporation behaviors of the solvents during the drying process, which plays a key role in controlling the film morphology and crystalline structure.

Fig. 3 shows AFM images of spin-coated and ink-jet-printed C_{60}TH-Hx films on HMDS-treated SiO_2/Si substrates. Rough surface and inhomogeneous grain sizes with a diameter of about 200–600 nm are observed in the spin-

coated film. However a smoother surface and less grain boundaries are observed for the ink-jet-printed C_{60}TH-Hx films compared to the spin-coated ones. To obtain a well-ordered crystalline structure and a uniform surface, sufficient time must be available for evaporation of the solvent at the contact line so that nucleation can occur. Cho et al. demonstrated the influence of an evaporation-induced flow within a droplet on the crystalline microstructure of an ink-jet-printed pentacene derivative, namely, 6,13-bis(triisopropylsilylethynyl)pentacene, by varying the composition of the solvent [17]. The choice of an appropriate solvent provided a uniform morphology as well as the desired molecular orientation required to improve the effective field-effect mobility. Therefore, we believe that ink-jet-printed C_{60}TH-Hx devices used with a chlorobenzene solvent can provide more time for the molecules to assemble into large crystalline domains during solvent drying. The resulting highly crystalline C_{60}TH-Hx devices with smooth surfaces exhibit excellent electron mobilities.

In summary, we have demonstrated high-performance n-type OTFTs based on a newly developed material, C_{60}TH-Hx. The devices were fabricated using the ink-jet-

printing method, and a better film quality was obtained in this case as compared to devices fabricated by spin-coating; this has led to improved OTFT performance. The best performance achieved with the ink-jet-printed devices was characterized by an electron mobility of 2.8×10^{-2} cm^2 V^{-1} s^{-1}, an I_{On}/I_{Off} ratio of about 1×10^6, and a threshold voltage of 7 V. These results support the use of C$_{60}$TH-Hx in future organic electronic applications.

equilibrium conditions, and so, in contrast to previous studies, precise thin film growth is possible at a monolayer level [9–14]. As a result, p–n junctions can be formed on a single molecular scale and charge transfer between adjacent molecules can be expected.

Molecular superlattices were fabricated on Si substrates with thermally oxidized surface layers (SiO_2) in a high vacuum ($\sim 10^{-6}$ Pa). The deposition rates were less than 0.03 molecular layers (MLs) per min. Atomic force microscopy (AFM) images (SII SPI-4000, dynamic force mode) and X-ray reflection (XRR) spectra (Bruker AXS, D8 Discover, Cu $K\alpha$; $\lambda = 0.154$ nm) [15,16] were obtained from various films grown at different substrate temperatures with a view to optimizing the growth conditions and examining the morphology, thickness and molecular orientation. By using XRR fitting, the layer densities were estimated to be in the 1.3–1.5 g/cm^3 range, which is comparable to the values reported in previous studies [17,18].

First, we verified the growth of the first PTCDI-C$_8$ monolayer on the SiO$_2$ surface. The molecular structure is shown in Fig. 1a. Fig. 1b shows the XRR spectrum of the PTCDI-C$_8$ monolayer grown at an optimized substrate temperature of 140 °C [8]. The measurement was carried out immediately after the deposition. The thickness was estimated to be 2.7 nm (±0.1 nm) from the fitting curve, indicating that the long axis of the molecule (2.97 nm) was oriented vertically to the surface normal with a small tilting angle [8,17,18]. A schematic illustration is shown in the inset of Fig. 1b. Fig. 1c is an AFM image of PTCDI-C$_8$ (0.6 ML), which clearly shows two-dimensional growth with flat terraces. The surface profile of the AFM images (a typical profile is shown in the inset) revealed that the terraces had an average height of 2.2 nm, which is smaller than that estimated with XRR, and involved a certain fluctuation of about ±0.2 nm. We found that the thickness (height) had a tendency to decrease with time. For example, the reduction in thickness to approximately 1.8 nm (±0.2 nm) was confirmed by XRR and AFM 2 months after the deposition (not shown here). These results imply that the PTCDI-C$_8$ monolayer on the SiO$_2$ is unstable and the molecular orientation inclines gradually.

Next, we examined the surface morphologies, thickness and molecular orientation of quaterrylene/PTCDI-C$_8$ double layers (see Fig. 2a). The AFM images in Fig. 2b–d shows the surface morphologies of the quaterrylene layers deposited on the underlying PTCDI-C$_8$ monolayer. A clear dependence on the substrate temperature was observed. Quaterrylene layers tended to grow in a three-dimensional manner below 150 °C. Meanwhile, the substrate temperature at 160 °C produced 2D layers at the monolayer level. As a result, a well-defined quaterrylene/PTCDI-C$_8$ bilayer was formed. The surface profile shown in the inset proves that the quaterrylene molecules have an upright orientation, i.e., the long axis of the molecule (1.8 nm) is perpendicular to the SiO$_2$ surface normal.

To examine the total thickness of the quaterrylene/PTCDI-C$_8$ bilayer, the XRR spectrum was measured as shown in Fig. 3a. It should be noted that the total thickness estimated with the XRR measurement was only 3.0 nm, which was less than the sum for the two molecules (2.8 + 1.8 nm). We speculate that the reduction in the total thickness can be attributed to the instability of the PTCDI-C$_8$ layer as already mentioned. The orientation of the PTCDI-C$_8$ layer changed during the quaterrylene deposition presumably as a result of heating the substrate. To confirm this presumption, we investigated the effect of temperature on the PTCDI-C$_8$ orientation by thermally treating a PTCDI-C$_8$ single layer on SiO$_2$ at 160 °C for 3 h after the deposition. The XRR spectrum in Fig. 3b reveals that the thickness was reduced to 1.2 nm. This result means that the thermal treatment caused the molecules to lie flat as shown in the inset. Based on these analyses, we concluded that the quaterrylene/PTCDI-C$_8$ bilayer consisted of a vertically orientated quaterrylene layer (1.8 nm) on a prostrate PTCDI-C$_8$ layer (1.2 nm), which yielded a total thickness of 3.0 nm.

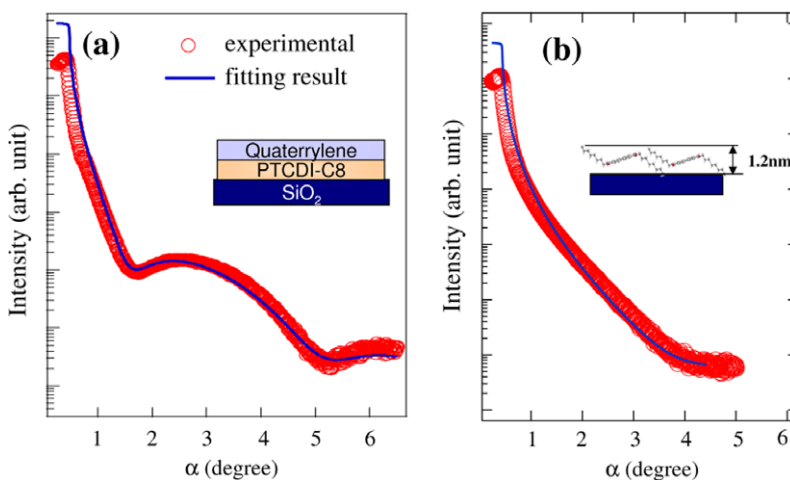
Subsequent layers were deposited and the molecular orientations of each layer were examined. The substrate temperatures were optimized to 160 °C for all the upper layers (2nd–4th layers), in a similar way to that shown in Fig. 2. AFM images were obtained to confirm the surface flatness as shown on the right in Fig. 4a. The XRR spectra
Fig. 1. (a) Chemical structure of PTCDI-C$_8$ molecule. (b) XRR spectrum of PTCDI-C$_8$ monolayer. The experimental result (red circles) and fitted line (blue line) revealed a layer thickness of 2.8 nm. The molecular orientation is shown in the inset. (c) 5 × 5 μm^2 AFM image of 0.6 ML PTCDI-C$_8$. The surface profile shows the PTCDI-C$_8$ layer is 2.2 nm thick, suggesting the layer undergoes a gradual change in orientation. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
Fig. 2. (a) Chemical structure of quaterrylene molecule. (b–d) $5 \times 5 \ \mu m^2$ AFM images of quaterrylene layers grown on the PTCDI-C_8 monolayer at various substrate temperatures. The optimum substrate temperature for growing a 2D layer was 160 ℃.


Fig. 3. (a) XRR spectrum of a PTCDI-C_8/quaterrylene double layer. The experimental result (red circles) and fitted line (blue line) revealed a total thickness of 3.0 nm. (b) XRR spectrum of the PTCDI-C_8 monolayer after thermal treatment, which indicates a change in molecular orientation (see Fig. 1b). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

in Fig. 4b were measured from thus prepared PTCDI-C_8/quaterrylene multiple layers. The fitted pattern revealed the thicknesses of the respective layers as shown in Fig. 4b. The quaterrylene layers (2nd and 4th layers) were very stable with a constant thickness of 1.7 nm, which is almost the same as that of the upright orientation. On

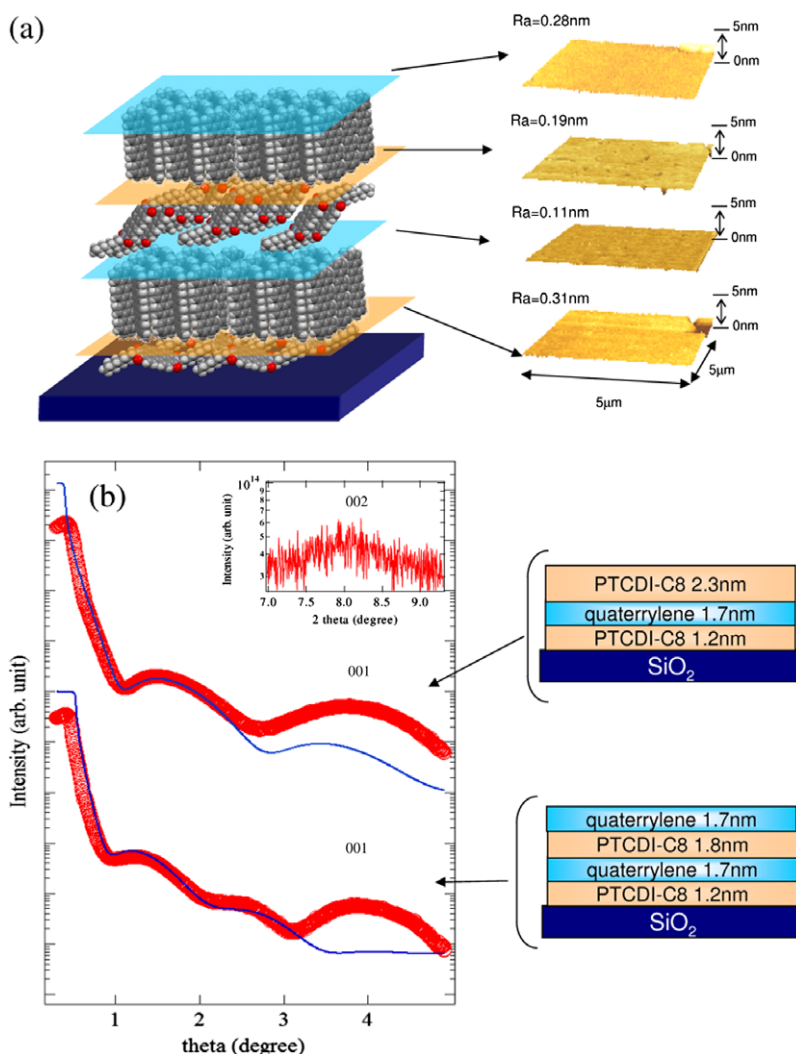
the other hand, the thickness of the PTCDI-C_8 layer (3rd layer) sandwiched between quaterrylenes exhibited a certain variation: 2.3 nm for as-deposited and 1.8 nm after the 4th layer deposition. This variation in thickness resulted from the instability of the PTCDI-C_8 layer and the thermal effect that occurred during the deposition of the other layers


Fig. 4. (a) Illustration of PTCDI-C$_8$/quaterrylene superlattice and AFM images of respective layers. The flat surfaces of each layer confirm well-defined 2D growth. (b) XRR spectra of PTCDI-C$_8$/quaterrylene superlattice. The film constitution and the thicknesses of each layer are shown in the illustration. The disagreement between the experimental results (red circles) and fitted lines (blue lines) around 4 degrees is attributed to the diffraction peak from the (0 0 1) lattice plane. The peak from the (0 0 2) plane observed around 8 degrees is shown in the inset as a reference. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

as discussed for the first PTCDI-C$_8$ layer. In the XRR spectra, we observed a disagreement between the experimental data and the fitted patterns of around 4 degrees. This is accounted for by the fact that the diffraction peak from the (0 0 1) lattice plane of PTCDI-C$_8$ and quaterrylene layers overlapped the reflection patterns. To illustrate this effect, the diffraction peak from the (0 0 2) plane observed around 8 degrees is shown in the inset.

In summary, we produced a molecular superlattice of quaterrylene/PTCDI-C$_8$ using a fine process, where we precisely optimized the deposition conditions for 2D layer growth. The morphologies and molecular orientations in each layer were clarified by AFM and XRR. As a result, the molecular superlattice was found to consist of inclined PTCDI-C$_8$ and upright quaterrylene layers. The molecules in this study function as *n*- and *p*-type semiconductors,

respectively [19,20]. Therefore, this successful layer by layer growth of a molecular superlattice, which has offsets at the HOMO–LUMO energy levels, opens up the possibility of carrier transfer and carrier confinement in a similar manner to that observed with conventional inorganic semiconductors.

$$\sigma = \sigma_0 \exp(-s_c) \tag{3}$$

where σ_0 is a prefactor and s_c is the exponent of the critical percolation conductance $G_c = G_0 e^{-s_c}$ [6]. The onset of percolation is determined by calculating the critical average number of bonds B_c per site:

$$B_c = \frac{N_b(s_c, E_F)}{N_s(s_c, E_F)} \tag{4}$$

where $B_c = 2.8$ for a 3-D amorphous system, N_b and N_s are the density of bonds and the density of sites in a percolation system, respectively. The total density of bonds could be calculated by integrating in energy, over the distance r_{ij}, the product of all available sites (at energy E_i) and all the available target states (at energy E_j) that satisfy the percolation criterion:

$$
\begin{aligned}
N_b &= \int_{\mathbb{R}^5} g(E_i)g(E_j)\theta(s_c - s_{ij})dE_jdE_idx_{ij}dy_{ij}dz_{ij} \\
&= 4\pi \int_{\mathbb{R}^+} r_{ij}^2 \int_{\mathbb{R}^2} g(E_i)g(E_j)\theta(s_c - s_{ij})dE_jdE_idr_{ij}
\end{aligned} \tag{5}
$$

where $r_{ij} = \sqrt{x_{ij}^2 + y_{ij}^2 + z_{ij}^2}$, $g(E)$ is the density of states and θ is the step function that represents the percolation criterion. The density of localized sites N_s can be calculated by excluding all sites that do not satisfy the percolation criterion:

$$N_s = \int_{\mathbb{R}} g(E)\theta(s_c K_B T - |E - E_F|)dE \tag{6}$$

Finally, exploiting the carriers concentration equation, the Fermi level E_F is straightforwardly calculated:

$$p = \int_{-\infty}^{+\infty} g(E)(1 - f(E, E_F))dE \tag{7}$$

where $f(E, E_F)$ is the Fermi–Dirac distribution:

$$f(E, E_F) = \frac{1}{1 + \exp\left(\frac{E - E_F}{K_B T}\right)} \tag{8}$$

Combining Eqs. (4)–(6) along with Eqs. (7) and (8) to calculate the Fermi energy level, the implicit integral Eq. (4) may be numerically solved and the exponent s_c of the critical percolation conductance is calculated:

$$\frac{N_b(s_c, E_F)}{N_s(s_c, E_F)} - 2.8 = 0 \Rightarrow s_c \tag{9}$$

This approach was first used by Vissenberg and Matters [6] to derive an approximate analytical expression of the mobility in an organic thin-film transistor by assuming an exponential DOS:

$$g_E(E) = \frac{N_t}{K_B T_0} \exp\left(\frac{E}{K_B T_0}\right)\theta(-E) \tag{10}$$

where N_t is the total number of states per unit volume and T_0 is the characteristic temperature. Thanks to the mathematical properties of the exponential function, they were able to derive a closed analytical expression of the carriers concentration, of s_c, and of the conductivity as well. The expression of the mobility as a function of the holes concentration p and of the temperature T reads:

$$\mu(p, T) = \frac{\sigma_0}{e}\left(\frac{\left(\frac{T_0}{T}\right)^4 \sin\left(\frac{\pi T}{T_0}\right)}{(2\alpha)^3 B_c}\right)^{\frac{T_0}{T}} p^{\frac{T_0}{T}-1} \tag{11}$$

where e is the electron charge. This is a very good approximation of the real mobility at large concentrations as, for instance, in the channel of organic thin film transistors (OTFTs) [7]. On the other hand, this expression does not correctly account for the mobility at low carriers concentrations, experimentally observed in organic light emitting diodes (OLEDs), that is almost constant. The field and temperature dependencies of the mobility of OLEDs is well described by a 3-D transport model based on hopping in a correlated Gaussian disordered system [8–10]:

$$\mu = \mu_\infty \exp\left\{-\left(\frac{3\sigma_{DOS}}{5K_B T}\right)^2 + 0.078\left[\left(\frac{\sigma_{DOS}}{K_B T}\right)^{\frac{3}{2}} - 2\right]\sqrt{\frac{eaE}{\sigma_{DOS}}}\right\} \tag{12}$$

where μ_∞ is the zero-field mobility when $T \to \infty$, $a \simeq 1/N_t^{1/3}$ is the intersite spacing and σ_{DOS} is the width of the gaussian density of states defined as:

$$g_G(E) = \frac{N_t}{\sqrt{2\pi}\sigma_{DOS}} \exp\left[-\left(\frac{E}{\sqrt{2}\sigma_{DOS}}\right)^2\right] \tag{13}$$

As reported in [11,12], the hole mobility measured on OLEDs shows large differences compared to the hole mobility measured on OTFTs. The large mobility differences, up to three orders of magnitude, measured on the two types of devices originates from the strong dependence of the mobility on the charge carrier concentration and in turn on the density of states. As a matter of fact, based on OLEDs and OTFTs device measurements, Tanase et al. [11] suggested that the mobility increase could be explained by means of a single gaussian DOS.

The parameters of Eqs. (11) and (12) are reported in Table 1. They are calculated by fitting the experimental mobility at high (OTFTs) and low (OLEDs) concentrations, $a = 1.4$ nm is taken from the literature [13]. Since the extracted exponential DOS is well approximated by the gaussian DOS at large carrier concentrations, they concluded that the hole mobility in disordered conjugated polymers could be unified in one single charge transport model.

In this paper, by calculating the exact numerical solution of the VRH Eq. (9) on a generic DOS we show that the gaussian function is a very good approximation of the real DOS at low concentrations only ($<10^{15}$ carrier/cm^3). Furthermore, we show that a single gaussian function is a good approximation of the real DOS only for some spe-

Table 1
Total number of states per unit volume N_t, width of the exponential distribution of localized stats T_0, pre-exponential factor σ_0, overlap parameter α^{-1} and width of the gaussian DOS σ_{DOS} for both P3HT and OC_1C_{10} − PPV [11].

Material	N_t (cm^{-3})	T_0 (K)	σ_0 (S/cm)	α^{-1} (Å)	σ_{DOS} (meV)
P3HT	3×10^{20}	425	1.6×10^4	1.6	98
OC_1C_{10}	3×10^{20}	540	3.1×10^5	1.4	112

cific disordered organic materials, as for instance P3HT (poly(3-hexyl thiophene)), but generally, it is not able to correctly account for the mobility in the whole range of carrier concentration of other materials. It is worth adding that the numerical solution of VRH is in perfect agreement with the analytical expression of Vissenberg and Matters [6]. Finally, exploiting the numerical approach, we were able to calculate the exact numerical DOS that reproduces the mobility in the whole range of carriers concentration for several organic semiconductors as for instance P3HT and OC_1C_{10} (poly(2-methoxy-5-(3′,7′-dimethyloctyloxy)-p-phenylene vinylene)). Basing on the numerical DOS, we were able to investigate the accuracy of several analytical approximations of the DOS and to understand the physical mechanism that influences the mobility behavior. In Fig. 1, the mobility of P3HT and OC_1C_{10} calculated by numerically solving Eq. (9) is shown versus carriers concentration. The numerical solution is compared with experimental results both for the gaussian and for the exponential DOS (parameters are reported in Table 1). The numerical mobility at high carriers concentration calculated with the exponential DOS accurately describes the mobility for both PPV materials (the analytical approximation Eq. (11) is overlapped to the numerical one and it is not shown in the figure). The numerical mobility of P3HT calculated by means of a single gaussian DOS accurately describes the experimental data both at low concentrations (OLEDs regime) and at high concentrations (OTFTs regime). At very high concentrations (>2×10^{19} carriers/cm^3) it is slightly larger than the experimental one.

On the other hand, the mobility of $OC_1C_{10} - PPV$ calculated following the same approach is accurate at low concentrations only and fails at high concentration values. The $OC_1C_{10} - PPV$ mobility abruptly raise when the carriers concentration exceeds 10^{16} cm^{-3} and the kink of the characteristic, corresponding to the transition from the low to high concentration regime, could not be explained by means of a single gaussian function. Furthermore, at high concentrations, the slope of the numerical mobility is close to the experimental one while its absolute value is about one order of magnitude lower. In the VRH framework,
the mobility behavior can be roughly explained by remembering that the mobility is energetically activated; hence, the mean carriers energy in the single gaussian DOS is lower than the real one. To further investigate this issue, we have numerically solved Eq. (9) within an optimization framework in order to calculate the exact numerical DOS that fits the $OC_1C_{10} - PPV$ experimental mobility at room temperature. The optimized numerical DOS is shown in Fig. 2 along with its analytical approximation. The real DOS is very well approximated by:

$$g_N(E) = min\left\{ N_t^{NE} \exp\left(\frac{E}{K_B T_0^{NE}}\right)\theta(-E), \frac{N_t^{NG}}{\sqrt{2\pi}\sigma_{NG}}\right.$$
$$\left. \times \exp\left[-\left(\frac{E}{\sqrt{2}\sigma_{NG}}\right)^2\right]\right\} \tag{14}$$

where $N_t^{NE} = 3 \times 10^{20}$ cm^{-3}, $T_0^{NE} = 540$ K, $N_t^{NG} = 10^{26}$ cm^{-3} and $\sigma_{NG} = 80 \times 10^{-3}$ eV. It is worth noting that the parameters of the exponential DOS at low carrier density are the same of Table 1. Furthermore, the analytical DOS could be easily expressed by combining the functions following the Matissen rule: $1/g_N(E) = 1/g_{Nexp}(E) + 1/g_{Ngauss}(E)$. In Fig. 3, the mobility of $OC_1C_{10} - PPV$ numerically calculated with the analytical DOS of (Eq. (14)) is plotted versus the carrier density at different temperatures. A very good agreement results in the whole set of experimental data at different concentrations and temperatures. Same considerations hold for the mobility of several other disordered organic materials. Therefore, it is reasonable to assert that the mobility of disordered organic materials can be explained by the VRH theory both at low and at high carrier concentrations, while the DOS depending on the material could be approximated by a single gaussian function, an exponential function, or by a combination of them. At high holes concentration the DOS is exponential, at low holes concentration is gaussian and for some materials, as for instance P3HT, a single gaussian function can account for the high concentration regime as well. To further check our approach, in Fig. 4 the mobility calculated by means of the analytical DOS of Eq. 14 is compared with the mobility calculated basing on the experimental DOS reported in

Fig. 3. Experimental (symbols) and calculated (solid lines) $OC_1C_{10} - PPV$ mobility as a function of charge carrier concentration at two different temperatures (○ experimental mobility at $T = 293$ K [11], ◇ experimental mobility at $T = 293$ K [14], ▷ experimental mobility at $T = 275$ K [14]).

[10] and with the experimental one of [11]. One can see a very good agreement at high energy while the apparent remarkable difference at low energy is exactly the same reported by the authors [10] (Fig. 4b). They attribute this discrepancy to the presence of anions that tends to localize the mobile holes. In the light of our analysis, it is clear that the presence of anions that localize the mobile holes strongly influence the DOS at low carrier concentration and this affects the mobility as well. Finally, in order to investigate the dependence of the mobility on the carrier density at low concentrations, in Fig. 5 the charge carrier as a function of the Fermi level of $OC_1C_{10} - PPV$ is shown: the numeric DOS is compared with the exponential one (Table 1). In the concentration range corresponding to OLEDs measurements (10^{14}–10^{16} carriers/cm³), the charge density calculated with the exponential DOS is larger than the numeric one which is roughly gaussian. Since the Fermi level is a measure of the carriers mean energy, the average carriers energy calculated with the numeric DOS turns out to be lar-

ger. In a VRH framework, the mobility based on energy-activated hopping is larger as well. Furthermore, in a gaussian DOS thanks to the quadratic exponential dependence of the density of states on Fermi energy level is larger and almost pinned and the hopping is easier (Eq. (1)). Hence the mobility is larger and large variations of the charge density correspond to small changes of the carriers mean energy and of the mobility as well.

Concluding, the hole mobility of disordered organic semiconductors was calculated by numerically solving the VRH equations. Our calculations show that the hole mobility can be explained by means of the VRH also in the low concentration regime and that the strong dependence on the charge carrier density is strictly correlated to the shape of the DOS. Furthermore, we have numerically calculated the exact DOS of P3HT and $OC_1C_{10} - PPV$ showing that in general a single gaussian function is not sufficient to explain the mobility behavior in the whole range of concentrations (OLED, OTFT); depending on the material, it can be approximated by a single gaussian, an exponential, or by a combination of them.

ilazene (HMDS) [10], octadecyltrichlorosilane (OTS) [11,12], and other silanes [13]. Recent studies have established that among the silanes examined to date, the most hydrophobic molecule, OTS, is the best surface modifier for SiO₂ dielectric layers, in that its use results in more edge-on structures and better electrical characteristics of the over-deposited polymeric semiconductor layer [5,6,14]. Another approach to modifying the dielectric surface to enhance conjugated polymer deposition is the phase separation method. Cho and coworkers have fabricated a hydrophobic semiconductor-top and hydrophilic poly(methylmethacrylate) (PMMA)-bottom structure with high mobility [15]. Such dielectric surface treatment via simple phase separation is of great interest from the viewpoint of OFET commercialization, given the time-consuming nature of the SAM treatment procedure.

Polymeric semiconductors exhibit optimized transistor characteristics when deposited on hydrophobic surfaces, so it is expected to be useful to fabricate a hydrophobic semiconductor-top and a more hydrophobic polymer-bottom structure via phase separation, as arises for a semiconductor on a hydrophobic SAM layer. In the present study, therefore, a hydrophobic PDMS-bottom and F8T2-top structure was fabricated by spin coating a dimethylsiloxane (DMS)/poly(9,9-dioctylfluorene-alt-bithiophene) (F8T2) blend with a curing agent onto a silicon oxide substrate, and then subjecting the resulting layer to thermal treatment. After thermal treatment, the DMS-bottom layer was cured to polydimethylsiloxane (PDMS) and became thinner as a result of the upward motion of the hydrophobic PDMS molecules, as confirmed using XPS, contact angle

measurements, and AFM analysis. An OFET device fabricated from a DMS:F8T2 blend on an untreated SiO_2 dielectric layer was found to exhibit a high FET mobility of 0.01 cm²/Vs, which is similar to that obtained with an OTS-treated SiO_2 dielectric layer.

2. Experimental

F8T2 (M_n = 20,668 g/mol, M_w = 43,137 g/mol) was purchased from Aldrich Chemical Co. Sylgard 184 Silicone Elastomer containing dimethylsiloxane and a curing agent (10:1 [w/w]) was purchased from Dow Corning Co. and used without further purification.

Bottom gate–top contact OFETs were fabricated on a common gate of highly n-doped silicon with a 300 nm thick thermally grown SiO_2 dielectric layer. Films of DMS:F8T2 with various DMS contents (3–30 wt%) were spin coated at 2000 rpm from 0.7 wt% chloroform solution. DMS:F8T2 blend films were cured for 1 h at 120 °C in a convection oven. Gold source and drain electrodes (100 nm) were evaporated on top of the semiconductor. In all measure-

ments, we used a channel length (L) of 150 μm and a channel width (W) of 1500 μm. The electrical characteristics of the FETs were measured in air using Keithley 236 and 2400 source/measure units. AFM (Multimode IIIa, Digital Instruments) operating in tapping mode was used to examine the surface morphologies of the semiconductors. The carrier mobility was calculated in the saturation regime from the slope of a plot of the square root of the drain current versus gate voltage (V_G) by fitting the data to the following equation: $I_{DS} = (WC_i/2L)\mu(V_G - V_{th})^2$, where I_{DS} is the drain current, μ is the carrier mobility, and V_{th} is the threshold voltage. XPS analyses were performed using an ESCA equipped with a Mg Ka X-ray source, 1253.6 eV.

3. Results and discussion

First, we investigated the suitability of a PDMS layer as a dielectric surface modifier. Three polymeric semiconductors known to exhibit high mobilities (>10^{-2} cm²/Vs), specifically F8T2, P3HT, and poly[(1,2-bis-(2′-thienyl)vinyl-5′,5″-diyl)-alt-(9,9-dioctyldecylfluorene-2,7-diyl] (PTVTF) [14], were used as the active layers of thin film transistors

with a bottom gate–top contact geometry. In each case, the SiO$_2$ dielectric surface was modified with HMDS, OTS-8, OTS-18, or PDMS. The SAM treatments were carried out as described elsewhere. For the spin-coated PDMS layer, we used Sylgard 184 Silicone Elastomer containing dimethylsiloxane and a curing agent (10:1 [w/w]) in toluene. The water contact angle of the untreated dielectric was 25 ± 2°, while those of the surface-treated dielectrics were 68 ± 2° (HMDS), 99 ± 2° (OTS), 108 ± 1° (ODTS), and 110 ± 1° (PDMS). The FET mobilities obtained for these transistors are summarized in Fig. 1. We found that regardless of the type of semiconductor, the FET mobility increased as the SiO$_2$ dielectric surface became more hydrophobic. The most hydrophobic modifier examined, PDMS, was found to be a good dielectric surface modifier.

Fig. 2 shows the water contact angles of the various films tested in this study. Based on the huge difference between the contact angles of as-spun DMS (29 ± 2°) and thermally cured PDMS (110 ± 1°), it is expected that when DMS and the curing agent are blended with the polymeric semiconductor (103 ± 1°) and spin coated, the hydrophilic DMS will preferentially bind to the hydrophilic SiO$_2$ substrate to generate a bottom layer. This outcome appears likely because the water contact angles at top surface of homo F8T2 and the as-spun DMS:F8T2 blend are almost the same. Also, at the bottom surface, water contact angle of as-spun DMS and DMS:F8T2 blend are similar. To investigate the distributions of the chemical species in the layers, XPS analysis was performed for both the bottom and top surfaces of the film by carrying out Ar sputtering with an average etching rate of 0.6 nm/min. The bottom surface of the as-spun film was separated from the SiO$_2$ dielectric by immersion in liquid nitrogen, which induces separation due to the difference in thermal expansion coefficient between the organic and inorganic layers. Fig. 3 shows the Si 2p XPS spectra of the top (a) and bottom surfaces (b) of the as-spun film, and the top (c) and bottom (d) surfaces of the thermally cured film. In addition, the O, C and S contents were determined for the as-spun and thermally cured films (Figs. 4 and 5, respectively). In the as-spun film, the silicon and oxygen contents of the top surface are much lower than those of the bottom surface (Fig. 4a and b). On the other hand, the carbon and sulfur contents, which

are mainly due to F8T2, dominate in the top surface (Fig. 4c and d). These findings indicate that the spun film of the DMS:F8T2 blend with curing agent is phase separated, with hydrophilic DMS forming the bottom layer. Comparison of the data in Figs. 4 and 5 reveals another interesting phenomenon associated with thermal curing. Specifically, thermal curing induces a decrease in the oxygen and silicon contents of the bottom surface, indicating that the thickness of the PDMS layer decreases as a result of the thermal curing. At the same time, thermal curing induces dramatic increases in the oxygen and silicon contents of the top surface. These trends indicate that the hydrophobic PDMS molecules move up through the film; PDMS has a very low T_g (-127 °C) and a low T_m (-54 °C). The hypothesis that PDMS molecules move up through the film is supported by the observation that the water contact angle of the cured film of the DMS:F8T2 blend is very similar to that of the PDMS homopolymer. Given that the presence of too much surface modifier in the channel region can hinder charge transport, the thinning of the PDMS layer during thermal curing may improve the transistor performance. Furthermore, because the thermally cured film is covered with PDMS due to the upward motion of PDMS, the cured DMS:F8T2 blends are resistant to solvents such as chloroform, chlorobenzene, and toluene, which is important for solution-processed passivation. This
Fig. 8. Dependence of the FET mobility on the weight ratio of the DMS:F8T2 blend.
Fig. 9. Time dependence of the FET mobility and the on/off ratio for F8T2 on an OTS-18 treated SiO$_2$ dielectric and for a DMS:F8T2 blend on a SiO$_2$ dielectric.

resistance to organic solvents is another advantage of DMS:polymeric semiconductor blends.

The AFM analysis results are shown in Fig. 6. The AFM image of the surface of the as-spun DMS:F8T2 blend shows a homogeneous surface morphology with some nanorod-like crystalline domains, similar to the surface of the F8T2 homopolymer. After thermal curing, the surface has a very rough morphology with an r.m.s. roughness of 4.9 nm (Fig. 6d). In particular, the phase image of the cured film reveals the co-existence of quite different phases. Since there is an increase in the PDMS content of the top surface after thermal curing, the features in this image are thought to result from co-existing crystalline F8T2 and amorphous PDMS phases.

F8T2 FET devices with PDMS-treated dielectric layers were fabricated with a bottom gate–top contact geometry. For the spin-coating of the DMS:F8T2 blend with the curing agent, toluene, chloroform, and chlorobenzene were used as solvents. The performance of the resulting devices was independent of the solvent used. Representative transfer and output curves of the as-spun and thermally cured DMS:F8T2 blend FET devices are shown in Fig. 7. The average FET mobility of the thermally cured devices was found to be 0.013 cm^2/Vs, with an average on/off ratio of 2×10^6. The corresponding values for the as-spun devices, however, were much lower (average mobility 9×10^{-4} cm^2/Vs and on/off ratio 3×10^4). To examine the relationship between the weight ratio of PDMS (DMS + curing agent) and FET performance, devices were fabricated using various weight ratios of PDMS (3, 6, 10, 20 and 30 wt%); the FET mobilities are summarized in Fig. 8. When the weight ratio of PMDS was 3 or 6 wt%, the FETs exhibited optimum performance with mobilities over 10^{-2} cm^2/Vs. For PDMS contents of 10 wt% or more, however, the mobility decreased to less than 10^{-2} cm^2/Vs. This result indicates that the presence of too much PDMS disturbs charge transport in the channel region. In addition, we also tested a P3HT:DMS blend and obtained a similar mobility (above 10^{-2} cm^2/Vs), which shows that the phase separation of DMS:polymer blends can be applied to other polymeric semiconductors.

Finally, to investigate the air-stability of the DMS:F8T2 blend devices, the shelf lifetime of a DMS:F8T2 device was compared with the lifetimes of OFET devices based on F8T2 homopolymer with an OTS-treated SiO$_2$ dielectric layer over a 30-day period (Fig. 9). The thermally cured DMS:F8T2 blend was found to exhibit slightly better air stability, especially in terms of the on/off ratio. Since the top surface is not fully covered by the PDMS layer, it is not clear whether a clear passivation effect has been demonstrated. However, we are currently investigating ways to dramatically enhance the air stability of this blend system by increasing the thickness of the top PDMS layer and by treating the top PDMS layer with oxygen plasma.

4. Conclusions

By spin coating a DMS:F8T2 blend onto a SiO$_2$ substrate and then subjecting the resulting layer to thermal curing, we fabricated a hydrophobic PDMS-bottom and semiconductor F8T2-top structure with a mobility of 1×10^{-2} cm^2/Vs, as confirmed with XPS, AFM, and contact angle measurements. Using this DMS:F8T2 blend, hydrophobic dielectric surface treatment and passivation can be achieved simultaneously by simply coating the blend onto the SiO$_2$ dielectric.

statistical methods to investigate the filament based memory system. The devices were based on a metal/polymer/metal structure, similar to the crosslinkable devices we reported earlier. Polyfluorene (PFO) with dimethyl-benzyl end capping group was chosen as the polymer active layer. Since it contains no known donor and acceptor pairs and only carbon and hydrogen in its chemical formula, the possibility of occurrence of other reported switching mechanisms [4,17–19] is negligible. Batch to batch variation is also lower in the commercially available polymer. We studied the variations between devices with the same processes and the variations between switching cycles within the same device. We proposed a model to explain the results.

2. Experimental

PFO was purchased from American Dye Source and used without further purification. The polymer was dissolved in chlorobenzene (1 wt% of the solvent), and filtered with a 0.45 μm syringe filter. The polymer solution was spin coated onto the glass substrates with pre-patterned indium tin oxide (ITO). Finally, a 50 nm thick aluminum layer was thermally evaporated on top of the polymer film, at a rate of 0.1 nm per second. The device structure is shown in the inset of Fig. 1. The active area of the device was defined by the overlapped region of the top and bottom electrodes, which is about 0.2 mm^2.

The current–voltage (IV) characteristics were measured in a vacuum probe station with an Agilent 4155C semiconductor parameter analyzer. The capacitance was measured using an HP 4284A LCR meter. Cross-section scanning electron microscope (xSEM) images were taken by a FEI Nova 600 Nanolab Dualbeam™ SEM/Focused ion beam (FIB).

3. Results and discussion

A typical IV curve, as shown in Fig. 1, had similar shape as previously studied crosslinkable polymer memory devices [9]. Starting from the low conductivity state (OFF state), when the voltage increased to between 3 and 4 V,
Fig. 1. Basic IV of the polymer memory device. The inset shows the device structure. The ITO bottom electrode is connected as the ground.

the device switched abruptly to a high conductivity state (ON state). A negative differential resistance (NDR) region followed and the current reached a minimum at about 6 V. During the reverse sweep, the device stayed at the ON state even when the voltage dropped below 4 V. The device could also be written to the ON state by a voltage pulse of 4 V, and erased to the OFF state by a pulse between 8 and 10 V. The device was read at 1 V, without disturbing its state.

No noticeable differences in the shape of the IV curves were observed when the switching behavior was tested through a temperature range of −20–85 °C. The conductivities of both ON and OFF devices were also stable for more than 20 h at 85 °C. The capacitances of the device at both states were the same, and depended only on the thickness of the polymer film.

It was noticeable that some of the devices, especially the ones with thicker polymer layers, required an initial forming process [20] before the observation of the memory phenomena. These devices were formed by applying a voltage bias higher than the 4 V writing voltage, ranging from 5 to above 20 V, with a 10 μA current compliance (note: during the erasing process, the current compliance was set at 10 mA). The forming process could also be considered as an abnormal writing process which used a higher voltage since the current compliance would keep the device in the ON state. After the forming process, the device could be switched ON by a writing voltage as low as that of the devices which did not require forming, i.e. 4 V.

3.1. Device to device variation

Since the required forming voltage, or the initial writing voltage, varies from device to device, we first analyzed the distribution of the voltages. We define the switching probability as the percentage of devices which can be successfully written to ON state and erased to OFF state at least one time. The ON state is defined as the state with a current above 100 nA at 1 V, and OFF state is below 10 nA at 1 V. All the writing (forming) pulses were limited with a 10 μA compliance. For every device, the initial writing voltage was 4 V, and if it was not successful, the writing (forming) voltage was increased by 1 V until the device was successfully written.

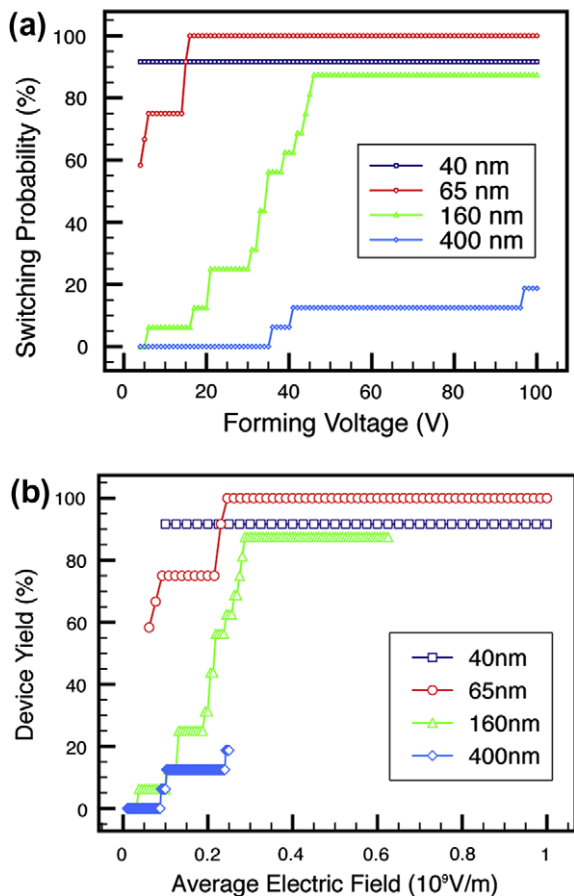
Fig. 2a shows the switching probability as a function of forming voltage for devices with different values of polymer layer thickness. Generally, the switching probability increased with higher forming voltage. The figure also shows that devices with thinner polymer layers were more likely to be switched successfully. Devices with thicker films which did not work at first might work after using a higher forming voltage. However, as shown in Fig. 2b, the probability was not determined by the electric field based on the average thickness of the film. For example, devices with 400 nm thick polymer layers did not have the same switching probability as those with 40 nm thick polymer layers even if 40 V was used. This is consistent with our previous understanding that the switching processes happen at some non-uniform regions within the devices [10].


Fig. 2. Switching probability for devices with different polymer layer thickness, as a function of (a) forming voltage, (b) average electric field calculated from dividing the forming voltage by the average polymer film thickness.

Fig. 3. Cross-section SEM images of the device at different spots. (a) In uniform regions. (b) In non-uniform regions.

Next, we studied the non-uniformities of our device using cross-section scanning electron microscope (xSEM). Cross-section slices of the device were prepared using focused ion beam (FIB). In most regions of the device, the polymer film thickness was uniform at 50 nm, as shown in Fig. 3a. However, at a few spots, we observed a much narrower gap between the electrodes (Fig. 3b). Localized electric field at these spots could be much greater than at other regions. Therefore we believe that these spots are crucial for the switching phenomenon, and their existence determines the device switching probability.

According to this observation, we attribute the switching behavior to the formation and rupture of filamentary conductive paths [10,21–23] at localized spots [8] such as the one shown in Fig. 3b, similarly to the switching mechanism proposed for oxide based resistive memories [12]. During the forming and writing processes, a conductive link can build between the electrodes possibly as a result of the ionization and injection of metallic materials into the film under high electric field [22]. The erasing process at 10 V results in a very high current flowing through the conductive link, causing the rupture of the link [10,22,24,25].

The distribution of electric field near the protrusion from the electrode was studied by solving the Poisson equation using the 3D finite element method. The geometries used in our model were based on the xSEM image. The metallic and polymeric films were simplified as parallel plates. The protrusion from the metal was modeled as a hemisphere with 30 nm radius. Using the capacitance data and geometry of our device, we estimated that the dielectric constant of our polymer film to be around 4.

Fig. 4a shows the distribution of electric field for a 40 nm device under a normal writing voltage of 4 V. The maximum local field strength at the tip of the protrusion can reach 4.86×10^8 V/m, which is more than four times that of the uniform regions. The calculated electric field at localized spots during the writing process is consistent with the data from Cu/P3HT/Al memory system previously reported by Joo et al. [22], which is above 10^8 V/m.

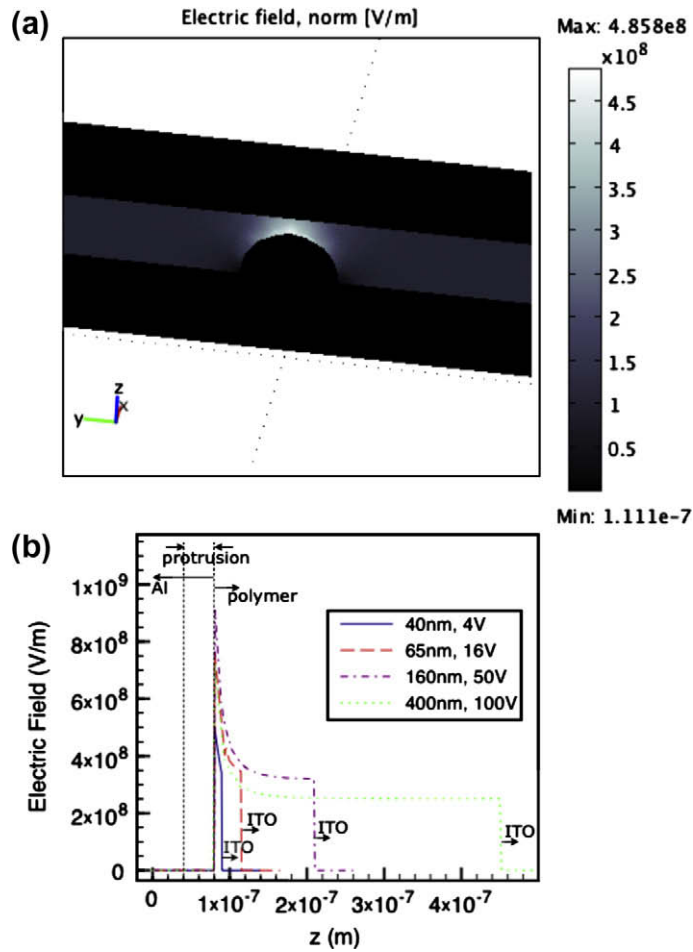
Fig. 4b shows the simulated electric field distribution for devices with different thickness. The voltages used are determined by the minimum voltage required for the maximum switching probability (Fig. 2a), which are 4 V for 40 nm devices, 16 V for 65 nm devices, 50 V for 160 nm devices, and 100 V for 400 nm devices. In all cases the protrusion is assumed to have a radius of 30 nm. The electric field along the vertical line crossing the protrusion tip has been plotted as a function of vertical position z. For 40, 65 and 160 nm devices, the minimum values of the electric field inside the polymer film are about the same, which are above 3.0×10^8 V/m. Correspondingly in Fig. 2, the three types all gave high switching probability (>80%) with necessary writing voltages. For the 400 nm device, even at 100 V, the electric field in the polymer film is comparatively lower (below 2.5×10^8 V/m), and this can be correlated with its low switching probability (<20%).


Fig. 4. Electric field distribution at a localized switching spot in our model. (a) In a 40 nm device. (b) Along the vertical line crossing the protrusion tip.

Therefore we suggest that the switching probability may be related to the localized electric field near the protrusions from the electrode. The role of the high electric field might include: (1) producing a high current and localized heating which dissociate the metal ions from the electrode surface, and (2) driving the metal ions to the other electrode to form a conductive link.

3.2. Cycle to cycle variation

For the same device, the switching capability also varied as write-erase cycles were performed on the device. Typically, after several hundreds of write-erase cycles, the devices could not be written to the ON state with a 4 V pulse. When this happened, using the same forming process as mentioned earlier can turn the device back to the ON state. On the other hand, though at relatively lower probability, there were also cases where the devices became more difficult to be erased. In such situations, using a higher erasing voltage, eg. 12 V, could turn the device to the OFF state.

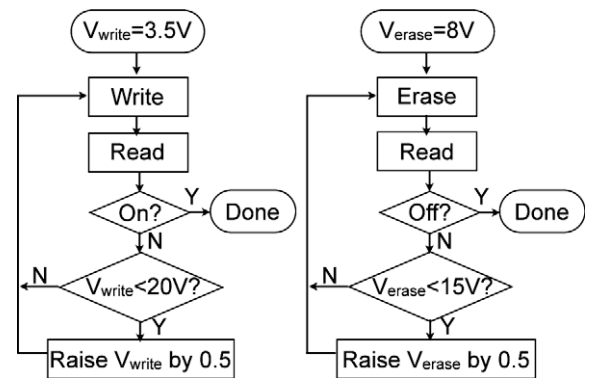
With this in mind, we designed a different cycling test approach which dynamically adjusts both the writing and


Fig. 5. Flow chart for the writing and erasing procedures in the dynamic voltage cycling test.

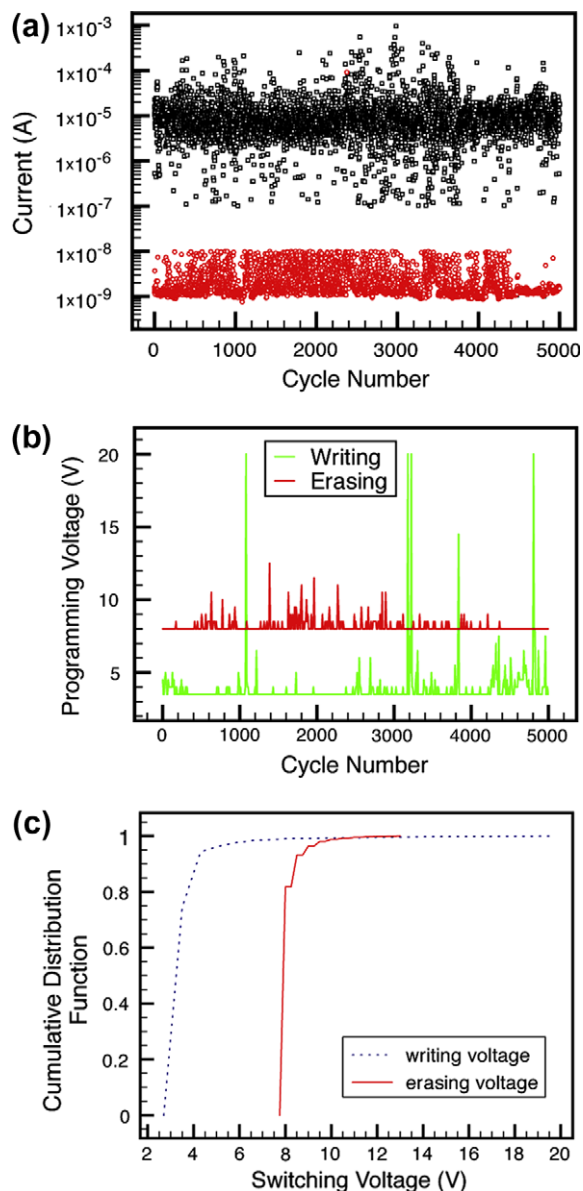
erasing voltages. Instead of using single values for writing and erasing voltages, we set a range for writing and erasing voltages. In each cycle, the writing process began with the minimum writing voltage in the specified range. We determined the status of the device right after the writing pulse

by measuring the current at 1 V. If the writing process failed, it was repeated with a voltage raised by 0.5 V, until the voltage reaches the upper limit of the range. The erasing process was almost the same, except that the voltage range was different from the one used for writing. A current compliance of 10 μA was set during the writing processes. The flow chart for the writing and erasing procedures are shown in Fig. 5.

This cycling test was applied on devices with 100 nm thick polymer film. The writing voltage ranged from 3.5 to 20 V with 10 μA current compliance, while the erasing voltage was set between 8 and 15 V. Fig. 6a shows that


the device worked persistently through 5000 cycles. Fig. 6b reveals the actual voltages used for writing and erasing in each cycle. It was found that the device normally switched at the minimum writing (3.5 V) and erasing (8 V) voltages. However, at certain cycles, higher writing or erasing voltages were needed to ensure a successful switching. These gave rise to the peaks in the recorded voltage values. Fig. 6c shows the distribution of writing and erasing voltages.

We further develop our model in order to explain the dynamic process during repeated switching cycles. After the disconnecting process during erasing, a new gap distance might be established. In normal cases, the new gap should be close enough so that the next writing within 4 V could be successful, as seen in Fig. 6b. However, due to any kind of variations, at certain probability, the gap could be widened and/or the tip could be smoothened, so that in the next cycle, much higher writing voltage would be required, corresponding to the peaks in the writing voltage curve in Fig. 6b. It is also shown in Fig. 6b that there are certain peaks in the erasing voltage curve, which means that at certain cycles, the device could not be erased with 8 V pulse. This could be explained by the variation in the filament thickness formed during each cycle.

4. Conclusion

We have statistically characterized the polyfluorene based memory cells. The switching probability of the devices was linked to the required switching voltage. Based on the variation of required switching voltages among different devices as well as switching cycles, we developed a model which suggests that protrusions from the electrodes are dominating the switching phenomenon, and their varying geometries contribute to the variations in the reproducibility of the memory effect.

The switching sites introduced by the nonuniform geometries have to be better controlled in order to overcome the inconsistency and make the polymer memory devices reproducible and reliable enough for commercialization. In low cost applications where switching speed is less critical and device driving circuit can be more flexibly designed, applying a device programming scheme which dynamically adjusts the switching voltages would be a practical solution. For high end applications, the device structure should be fundamentally improved to minimize the changes of the switching sites. Our future work will include both the memory driving circuit design and device structural optimization to achieve a highly reliable polymer memory system.

Scheme 1. Chemical structures of (a) 5-cyanotetracene (1CT) and (b) 5,11-dicyanotetracene (2CT).

hand, Chao [14] proposed that cyanated pentacence could have small reorganization energies based on theoretical calculations.

Here we first report the synthesis of two novel organic molecules, 5-cyanotetracene (1CT) and 5,11-dicyanotetracene (2CT), as shown in Scheme 1. Our quantum mechanical (QM) calculations predicted that the reorganization energies of 1CT and 2CT are 0.1017 and 0.0881 eV, respectively. Especially, the reorganization energy of 2CT is the smallest among those of all existing organic compounds to the best of our knowledge. We predict that the hole mobilities of 1CT and 2CT are 2.9 and 2.2 cm^2 V^{-1} S^{-1}, respectively, which are comparable to the predicted hole mobility of ruberene, 3.6 cm^2 V^{-1} S^{-1}. Moreover, the synthesized cyanated tetracenes are very stable under air condition.

2. Results and discussion

We performed the quantum mechanics (QM) calculations at hybrid density functional theory (DFT) with UB3LYP/6-311g(d,p) level to calculate reorganization energy [15]. The geometries were fully optimized. For the tetracene framework, our calculations showed that the 5-, 11-terminal substitution positions are superior for reducing reorganization energy. As shown in Table 1, the

calculated reorganization energy of 1CT and 2CT are 0.1017 and 0.0881 eV, respectively. We make the comparisons of reorganization energies for those tetracene and pentacene derivatives. The tetracene derivatives 5,11-dichlorotetracene and rubrene have the calculated reorganization energies of 0.1472 and 0.1521 eV [16], respectively. Moreover, the pentacene derivatives Hexathiapentacene [17] and 6,13-bis(Methylthio)-pentacene [18] have the calculated reorganization energies of 0.1428 and 0.1172 eV [16], respectively. To the best of our knowledge, the 2CT has the lowest reorganization energy among the existing compounds. This result agrees with Marks et al.'s conclusion that the -CN polar functional group results in the decrease of the reorganization energy [9].

The ionization potentials (IP) of 1CT and 2CT are 6.964 and 7.281 eV, respectively. They are close to IP of 5,11-dichlorotetracene, 6.740 eV. Since 5,11-dichlorotetracene functions as p-type semiconductor [13], we expect that 1CT and 2CT would function as p-type semiconductors as well at similar conditions.

Based on the calculation results, we decided that both 1CT and 2CT are valuable p-type organic semiconductors to synthesize. Thus we addressed synthetic routes of these designed compounds as shown in Scheme 2. Since the Friedel–Crafts reaction has been proved to be a useful method for the synthesis of monocyano-derivatives of reactive aromatic hydrocarbons [19], we synthesized 1CT by direct cyanation of tetracene with cyanogen bromide employing aluminium chloride as catalyst. In the case of 2CT, the targeted compound could be obtained in two steps: (1) 5,11-dichlorotetracene (DCT) was synthesized by chlorination of tetracene with solid copper (II) chloride in chlorobenzene at 110 °C for 5 h; then using Pd (II)/ligand as the catalyst system, 2CT was synthesized by cyanation of DCT with potassium hexacyanoferrate(II) in 1-methyl-2-pyrrolidinone solution. Both 1CT and 2CT were isolated by column chromatography and subsequently re-crystallized from chloroform solutions.

Table 1
Calculated self-organization energy (λ), HOMO, LUMO levels and HOMO–LUMO gaps (ΔE)[a].

	λ(eV)	HOMO(eV)	LUMO(eV)	ΔE(eV)
1CT	0.1017	−5.52 (5.19[b])	−2.88 (2.96[b])	2.64 (2.23[b], 2.29[c])
2CT	0.0881	−5.93 (5.42[b])	−3.40 (3.34[b])	2.53 (2.08[b], 2.19[c])
Tetracene	0.1157	−4.87	−2.09	2.78
Pentacene	0.0976	−4.84	−2.64	2.20
Rubrene	0.1521	−4.93	−2.31	2.62

[b] This work, results evaluated from cyclic voltammetry (CV).
[c] This work, results evaluated from UV–vis.
Scheme 2. Synthesis of 1CT and 2CT.

The synthesized 1CT and 2CT were very stable both in solution and crystal form. As shown in Fig. 1, 2CT in chloroform solution remained unchanged under ambient laboratory conditions for several months. As a comparison, the rubrene in chloroform solution lost its color after three days. The oxidized rubrene compound is a mixture with the NMR spectrum provided in Supporting Information (SI). Since the impurities in organic semiconductors dramatically decrease the hole mobility, we expect that our synthesized air-stable 1CT and 2CT promise more friendly device fabrication and packaging environments.

To investigate the electrical properties of 1CT and 2CT, we carried out cyclic voltammetry (CV) (Fig. 2) and UV–vis absorbance measurements (Fig. 3). Based on the oxidation onsets of CV, we estimated that the HOMOs of 1CT and 2CT are 5.19 and 5.42 eV, respectively. The difference between oxidation and reduction onsets of CV gives that band gaps of 1CT and 2CT are roughly 2.23 and 2.08 eV, respectively. The absorption edge of the maximum UV–vis spectrum is corresponding to the HOMO–LUMO energy gap. 1CT chloroform solution has an adsorption edge at 543 nm, which suggests that the band gap is roughly 2.29 eV. Similar analysis suggests the band gap of 2CT in chloroform is 2.19 eV. The band gaps estimated from CV and UV–vis are in good agreement each other. In addition, these values are fairly consistent with the calculated band gaps which were shown in Table 1.

Single crystals grown from chloroform solution were used for the structural analysis (the crystallographic data of 1CT and 2CT were presented in SI). As shown in Fig. 4a and c, the X-ray crystallographic analysis has revealed that the molecular packing of 1CT is packed in a herringbone-type pattern, while 2CT showing face-to-face slipped stacking with an intermolecular distance of 3.403 Å between neighboring molecules along the a-axis. In the 1CT crystal, there are four face-to-edge T type dimers and one face-to-face P type dimmer. In the 2CT crystal, there are two face-to-edge T type dimers and one face-to-face P type dimer.

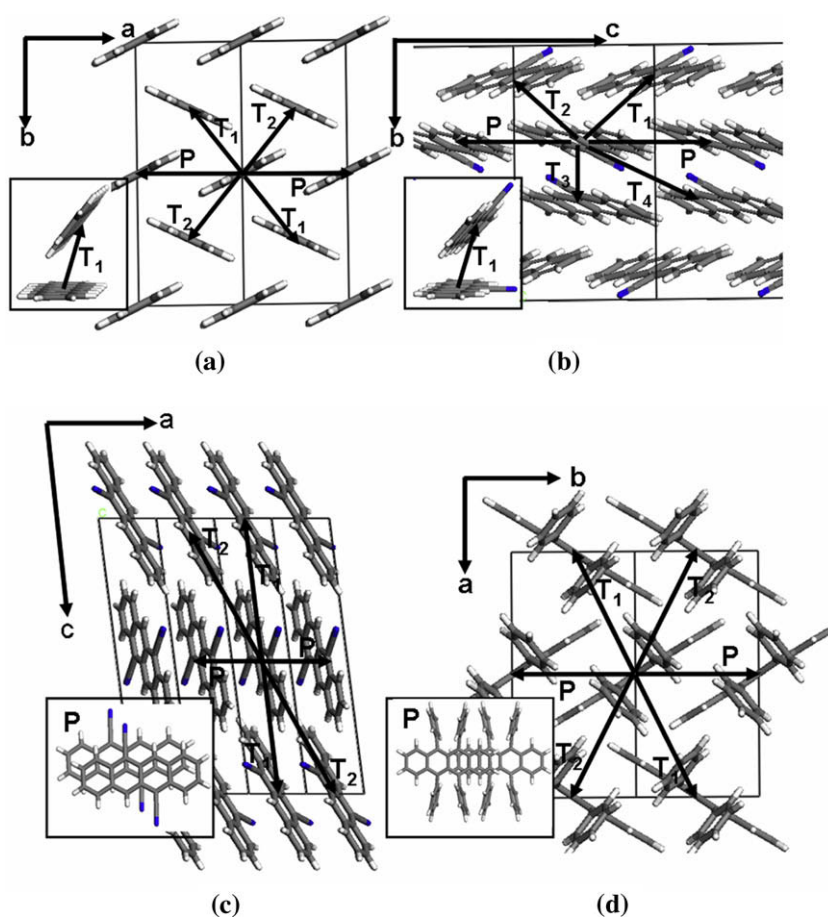
Fig. 1. The comparison of oxygen resistances for 2CT and rubrene in chloroform solution. (from left to right, the first and the third samples are initial 2CT and rubrene solution; the second is 2CT solution after three months and the fourth is rubrene solution after three days, respectively).
Fig. 2. Cyclic voltammogram of (a) 1CT and (b) 2CT.
Fig. 3. UV–vis spectra of (a) 1CT and (b) 2CT.


Fig. 4. Comparison of crystal structures of (a) 1CT (herringbone-type structure), (b) pentacene, (c) 2CT (face-to-face π-stacks) and (d) rubrene.

Based on the crystal structures, we carried out DFT calculations at PW91/TZ2P level to calculate intermolecular couplings between neighbor molecules in crystals. As for comparison, we also calculated the intermolecular couplings in rubrene and pentacene, which are two benchmark organic materials with the highest hole mobilities [8]. In the pentacene crystal, the tilt angles of face-to-edge

dimers T_1 and T_2 dimer are both 51.3° and the separating distances are about 5 Å. In the 1CT crystal, the geometries of T_1 and T_2 dimers with the tilt angles of 47.8° and the separating distance of 5.5 Å are similar to the herringbone face-to-edge dimers in the pentacene crystal. The T_1 and T_2 dimers in the 1CT crystal have the electronic couplings about 0.078 eV close to the couplings of face-to-edge

Table 2
Predicted hole mobility in a–b plane and calculated intermolecular couplings in crystal structures of pentacene, rubrene, 1CT and 2CT.

	Predicted μ(cm^2 V^{-1} s^{-1})	V(eV)	λ(eV)
Pentacene	2.6	$V_{T1} = 0.085$	0.0976
		$V_{T2} = 0.048$	
		$V_P = 0.032$	
Rubrene	3.6	$V_{T1} = 0.019$	0.1521
		$V_{T2} = 0.019$	
		$V_P = 0.089$	
1CT	2.9	$V_{T1} = 0.078$	0.1017
		$V_{T2} = 0.078$	
		$V_{T3} = 0.032$	
		$V_{T4} = 0.012$	
		$V_P = 0.027$	
2CT	2.2	$V_{T1} = 0.006$	0.0881
		$V_{T2} = 0.005$	
		$V_P = 0.084$	

dimers in pentacene (0.085 eV). As shown in Fig. 2c, the pitch and roll angles of P dimers in the 2CT crystal are 27.56° and 17.19°, respectively, which are similar to that of P dimers in the rubrene crystal (30.89° and 0°) [8]. These results suggest that the intermolecular couplings in 2CT may look like that in rubrene. On the other hand, 2CT shows more dense packing than rubrene. The intermolecular distance between neighboring molecules in 2CT is 3.663 Å [8]. The close π-stacking of 2CT should be advantageous for charge transport since both molecular modeling [7,20] and experimental evidence [4,21] suggested that a high mobility is expected for an organic semiconductor with a dense packing structure. The calculated intermolecular coupling of P dimer in 2CT is 0.084 eV, which is comparable to that of P dimer in rubrene, 0.089 eV. We did not discuss the L dimers (out of transport layer plane) since the charge transport in crystals is two dimensional transport while charge transport between layers is less efficient.

Obtaining the crystal structures of cyanated tetracene derivatives, we carried out the calculation of hole mobilities based on the theoretical model we previously developed [7] and the results are shown in Table 2. The calculated hole mobilities of our air-stable cyanated tetracene derivatives in a–b plane are 2.9 cm^2 V^{-1} s^{-1} for 1CT and 2.2 cm^2 V^{-1} s^{-1} for 2CT, respectively. They are close to the calculated hole mobility of rubrene, 3.6 cm^2 V^{-1} s^{-1}. Since our synthesized compounds are air-stable, it makes them attractive to real applications.

3. Conclusion

We synthesized two novel cyanated tetracene derivatives, 1CT and 2CT. The X-ray crystallographic analysis has revealed the molecular packing of 1CT is packed in a herringbone-type pattern, while 2CT showing a face-to-face packing with a relative short intermolecular distance of 3.403 Å between neighboring molecules along the a-axis. Compared with the well-known semiconductor, e.g. rubrene, the synthesized 2CT show more stability which is confirmed by NMR. The reorganization energy of 2CT predicted by UB3LYP/6-311g(d,p) is 0.0881 eV, which is the lowest among known compounds. The calculated hole

mobilities of these air-stable cyanated tetracene derivatives in a–b plane are 2.9 cm^2 V^{-1} s^{-1} for 1CT and 2.2 cm^{2}V^{-1} s^{-1} for 2CT, respectively. These oxygen-resisted organics may offer potential to fabricate the flexible electronics under air conditions. Efforts have been undertaken to determine the semiconducting properties of these new compounds in organic field effect transistors.

4. Experimental section

4.1. Synthesis of 1CT

Tetracene (1.01 g, 4.43 mmol) and anhydrous AlCl$_3$ (1.18 g, 8.87 mmol) were placed in a flask containing CS$_2$ (20 ml) under argon and the mixture was stirred at room temperature for 15 min. Cyanogen bromide (0.94 g, 8.87 mmol) in more CS$_2$ (15 ml) was then slowly added with stirring. The mixture was then stirred and boiled under reflux for 18 h, then cooled, and poured into crushed ice/conc. HCl. The combined CHCl$_3$ extracts were washed with water, dried with MgSO$_4$ and the solvents were removed by rotary evaporation. The solid residue was chromatographed (SiO$_2$, ethyl acetate/hexane) and then recrystallized from CHCl$_3$ to afford product (0.21 g, 18.8%). ^{1}H NMR δ 7.47–7.54 (m, 3H), 7.63–7.67 (m, 1H), 8.01–8.08 (m, 3H), 8.38 (d, 1H, J = 8.8), 8.70 (s, 1H), 8.87 (s, 1H), 8.99 (s, 1H). Elemental anal. Found: C, 89.41; H, 4.79; N, 5.52. Calcd for C$_{19}$H$_{11}$N: C, 90.09; H, 4.38; N, 5.53. HRMS (EI): calcd for C$_{19}$H$_{11}$N [M^{+1}]: 253.0886; found (m/z): 253.0883.

4.2. Synthesis of 2CT

5,11-dichlorotetracene was synthesized according to literature [13]. Potassium hexacyanoferrate(II) (0.736 g, 2 mmol), which is yielded by grinding K$_4$[Fe(CN)$_6$]·3H$_2$O to a fine powder and drying in vacuum at 80 °C overnight, 5,11-dichlorotetracene (1.667 g, 5.61 mmol), Na$_2$CO$_3$ (0.212 g, 2 mmol), Pd(OAc)$_2$ (0.127 g, 0.56 mmol), Tri-tert-butylphosphonium tetrafluoroborate (0.325 g, 1.12 mmol) and 20 ml NMP were mixed in a Schlenk flask under argon. The reaction mixture was then heated to 140 °C slowly and held at that temperature for 14 h. The reaction mixture was then cooled to room temperature, diluted with chloroform and filtered through Celite. The product was isolated by column chromatography (SiO$_2$, ethyl acetate/hexane) after washing the filtrate with water, drying over sodium sulfate and distilling the solvents. (0.406 g, 26%). ^{1}H NMR δ 7.65–7.69 (m, 2H), 7.76–7.80 (m, 2H), 8.20 (d, 2H, J = 8.72), 8.45 (d, 2H, J = 8.64), 9.32 (s, 2H). Elemental anal. Found: C, 86.36; H, 3.75; N, 10.47. Calcd for C$_{20}$H$_{10}$N$_2$: C, 86.31; H, 3.62; N, 10.07. HRMS (EI): calcd for C$_{20}$H$_{10}$N$_2$ [M^{+1}]: 278.0838; found (m/z): 278.0832.

4.3. Computational method

The reorganization energies (λ) in Eq. (1) were calculated directly from the adiabatic potential energy surfaces, shown as Eq. (2) [7]:

$$\lambda = \lambda_0 + \lambda_+ = (E_0^* - E_0 + E_+^* - E_+) \tag{2}$$

where E_0 and E_+ represent the energies of the neutral and cation species in their lowest energy geometries, respectively; E_0^* and E_+^* are the energies of the neutral and cation states with the geometries of the cation and neutral species, respectively. This description holds as long as the potential energy surfaces are harmonic, and the λ_0 and λ_+ terms are close in energy. We used UB3LYP/6-311g(d,p) level calculation implemented in the Jaguar program [15] to calculate the reorganization energy.

Geometries for dimer calculations were obtained from the observed x-ray crystal structure. The intermolecular couplings (V) [22] in Eq. (1) can be calculated directly from the spatial overlap (S_{RP}), charge transfer integral (J_{RP}), and site energies (H_{RR}, H_{PP}). The intermolecular coupling, V, is given by:

$$V = \left| \frac{J_{RP} - S_{RP}(H_{RR} + H_{PP})/2}{1 - S_{RP}^2} \right| \tag{3}$$

We employed the Amsterdam density functional (ADF) [23] program to calculate all couplings. The TZ2P basis set in ADF was used and the local density functional VWN was employed in the conjunction with the PW91 gradient corrections.

After obtained reorganization energy and intermolecular coupling in Eq. (1), we can write the diffusion coefficient of organic semiconductor as [7]:

$$D = \frac{1}{2n} \sum_i r_i^2 W_i P_i \tag{4}$$

where n is the spatial dimensionality; i represents a specific hopping pathway with hopping distance r_i (the intermolecular center-to-center distances of different dimer types). P is the hopping probability which is calculated as by:

$$P_i = \frac{W_i}{\sum_i W_i} \tag{5}$$

The hole mobility μ from charge hopping is then evaluated from the Einstein relation:

$$\mu = \frac{e}{k_B T} D \tag{6}$$

oxide as the anode interlayer for improving the PSC performance has seldom been reported.

The aim of this work is to realize a low-cost and high-efficiency inverted PSC hybridized with ZnO nanorod arrays by introduction of a solution-processed vanadium oxide (V_2O_5) as the anode interlayer. Our investigation shows that the photovoltaic device performance is improved by the introduction of the V_2O_5 interlayer due to the efficient suppression of the leakage currents at the organic/metal interface. Compared to the conventional BHJ structure (indium tin oxide (ITO)/PEDOT:PSS/active layer/Al), the use of the inverted structure overcomes some obstacles such as the facile oxidation of Al [15] and the electrical inhomogeneities of PEDOT:PSS as well as its corrosion to ITO [16]. The inverted PSCs utilize an air-stable high work-function electrode as the back contact to collect holes and metal–oxide nanostructures at the ITO to collect electrons [17–19]. Furthermore, it has been reported that the ZnO nanorods have beneficial effects of collecting and transporting electrons in the inverted PSCs hybridized with the ZnO nanorods [20]. Our works combine these advantages of V_2O_5 interlayer and ZnO nanorods, which thereby suppress the leakage currents and improve the collection and transportation of the charge carriers, resulting in enhancements of PCE, open-circuit voltage (V_{OC}), and fill factor (FF) of the devices. In addition, the V_2O_5 interlayer can serve as an optical spacer to increase light absorption, leading to an increased short-circuit density (J_{SC}). Moreover, the V_2O_5 interlayer and ZnO nanorod arrays both are fabricated from simple solution-based processes, which are well-suited for use in high-throughput roll-to-roll manufacturing.

2. Experimental

The structure and the energy level diagram of the inverted PSCs of ITO/ZnO/P3HT:PCBM/V_2O_5/Ag are schematically presented in Fig. 1. Devices were fabricated on cleaned ITO-coated glass substrates ($\sim$7 Ω/sq.). ZnO seed layer ($\sim$50 nm) was spin-coated from a 0.5-mol solution of zinc acetate dihydrate in 2-methoxyethanol followed by annealing at 200 °C for an hour in air. Hydrothermal

growth of the ZnO nanorod arrays ($\sim$100 nm in length and $\sim$50 nm in diameter) was achieved by suspending the ZnO seed-coated substrates in an aqueous solution of 50-mM zinc nitrate at 90 °C in an oven. Subsequently, a solution containing 20-mg P3HT and 20-mg PCBM in 1-ml o-dichlorobenzene (o-DCB) was spin-coated on top of the ZnO nanorods and dried slowly over the course of 40 min in air, forming the photoactive layer with a thickness of $\sim$300 nm. V_2O_5 powder (Riedel-de Haën, 99%) was homogeneously dispersed and suspended in isopropanol at different concentrations by using ultrasonic agitation. During the process of the ultrasonic agitation, it was observed that the V_2O_5 powder was pulverized to smaller particles. After the ultrasonic agitation, the color of the V_2O_5 colloidal solution is uniformly orange. Then the V_2O_5 colloidal solution was spin-casted in air on top of the photoactive layer. Finally, silver film ($\sim$200 nm) was deposited on top in a vacuum of 2×10^{-6} torr.

Devices were unencapsulated, stored in air, and illuminated at 100 mW/cm^2 from a ThermoOriel 150 W solar simulator with AM 1.5G filters. The solar simulator was calibrated using a reference Si solar cell. All electrical measurements were carried out in air at room temperature. The active area of the device irradiated by the light was defined as 10 mm^2 by using a photomask, so no extra current outside of the defined area was collected. Current density–voltage (J–V) curves were measured with a Keithley 2400 source measurement unit. The surface morphologies of the photoactive layers were measured by atomic force microscopy (AFM). The reflectance spectra of the devices were obtained using a Perkin–Elmer Lambda 35 UV–vis spectrophotometer. The transmission spectrum of the V_2O_5 layer was measured using the same UV–vis spectrophotometer. The crystallinity of V_2O_5 was analyzed at room temperature by X-ray diffraction (XRD) using Cu Kα radiation.

3. Results and discussion

In order to avoid mixing or damaging the photoactive layer during the coating of V_2O_5, the selection of solvent

100	10.75	0.55	60.21	3.56	1.35	620
250	11.16	0.52	51.35	2.98	3.4	431
1000	8.55	0.50	46.78	2	6.3	250

for V_2O_5 is an important issue. That is, the solvent for V_2O_5 must be orthogonal to o-DCB. Several solvents including toluene, chlorobenzene, 2-methoxyethanol, dichlorometh-ane, and isopropanol have been experimented for the V_2O_5. However, only the use of isopropanol as the solvent has negligible influences on the previously deposited photoactive layer due to the polar characteristics of these solvents. In general, the polarity of a solvent is related to its dielectric constant [21]. The relative dielectric constant (ε_r) of isopropanol is $\sim$20, which is much larger than that of the P3HT/PCBM film ($\varepsilon_r \sim 3.5$) [22]. It is believed that the large dielectric constant qualifies isopropanol as an orthogonal solvent in this work.

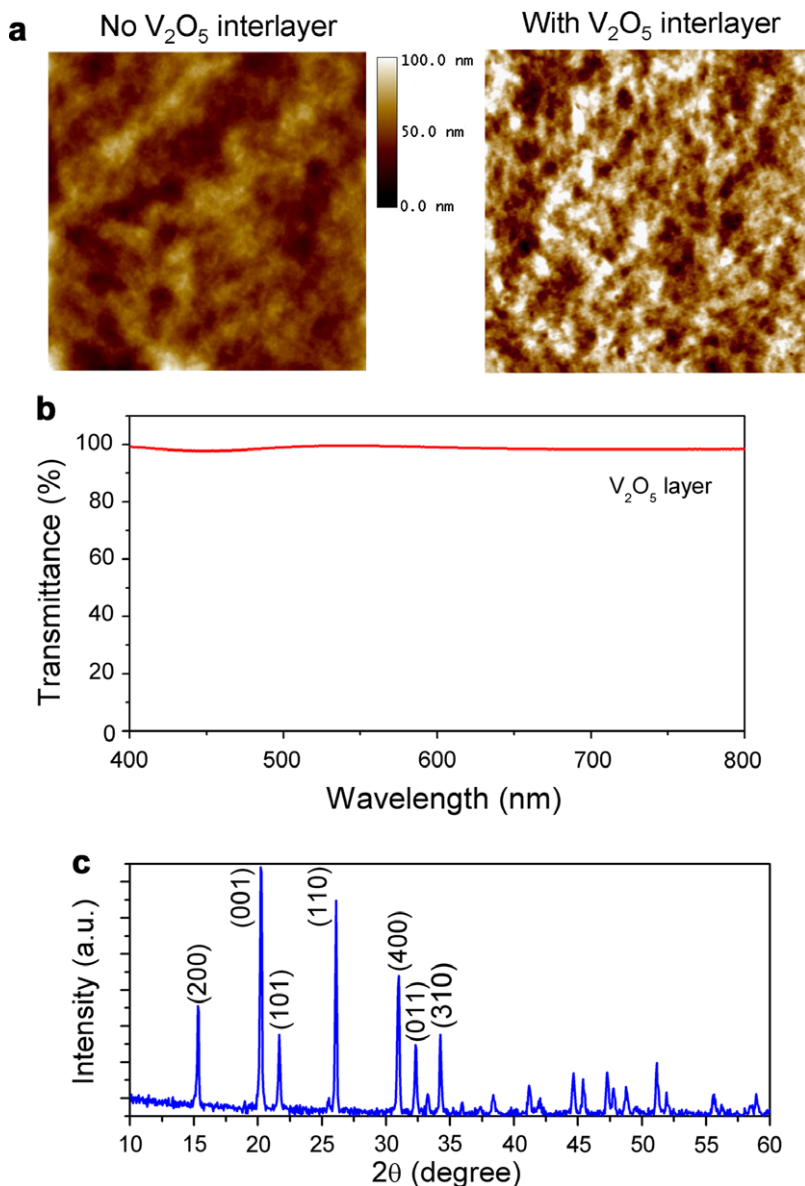
Fig. 2a shows the J–V characteristics of the devices with various concentrations of V_2O_5. The device without the V_2O_5 interlayer exhibits a J_{SC} of 10.21 mA/cm^2, a V_{OC} of 0.5 V, and a FF of 49.36%, resulting in a PCE of 2.52%. The performance is similar to other reports on the same struc-


Fig. 3. (a) AFM images of the photoactive layers covered with and without the optimum V_2O_5 interlayer. AFM image scans are 5 × 5 μm. (b) Transmission spectrum of the V_2O_5 layer (from the 100 μg/ml V_2O_5 colloidal solution) on a glass substrate. (c) XRD spectrum of V_2O_5.

ture without the V_2O_5 interlayer [16,19]. Introducing a 25-µg/ml V_2O_5 interlayer, PCE is slightly improved to 2.67% with J_{SC} of 10.49 mA/cm^2, V_{OC} of 0.51 V, and FF of 49.91%. When the concentration of V_2O_5 further increases to 100 µg/ml, the device has a significant improvement with J_{SC} of 10.75 mA/cm^2, V_{OC} of 0.55 V, and FF of 60.21%. This results in a considerable improvement of PCE up to 3.56%, a 41% improvement. These results show that the V_2O_5 can act as a functional interlayer to enhance the photovoltaic performance.

A series of V_2O_5 concentrations (25, 50, 100, 250, and 1000 µg/ml) is further investigated and summarized in Table 1. The J_{SC}, V_{OC}, and FF increase with the V_2O_5 concentration from 25 to 100 µg/ml. The highest PCE of 3.56% is achieved at the concentration of 100 µg/ml, showing that the optimum V_2O_5 interlayer is obtained. As a low-concentration V_2O_5 interlayer is introduced (50 µg/ml or less), the improvement of device performance is not obvious. It is suspected that the concentration is too low to cover the photoactive layer completely. As a result, the leakage current will not be efficiently reduced. However, as the concentration of V_2O_5 increases to 1000 µg/ml, most V_2O_5 particles cluster together (~2 µm in average), resulting in the increased contact resistance and thus leading to a low photocurrent ($J_{SC} \sim 8.55$ mA/cm^2).

Fig. 3a shows the AFM images of the photoactive layer covered with and without the optimum V_2O_5 interlayer. The V_2O_5 particles can be clearly observed. The root-mean-square roughness (σ_{RMS}) of the photoactive layer with the optimum V_2O_5 interlayer is ~18.4 nm, which is about the 2 times of that without V_2O_5 ($\sigma_{RMS} \sim 10.6$ nm). The AFM images clearly indicate that at the concentration of 100 µg/ml the photoactive layer is almost fully covered with V_2O_5. Fig. 3b shows the transmission spectrum of the V_2O_5 layer deposited from the 100 µg/ml V_2O_5 colloidal solution on a glass substrate. It shows that the V_2O_5 layer is almost transparent in the visible region (transmittance > 97%). Fig. 3c shows the XRD spectrum of V_2O_5. The diffraction peaks appears in the 2θ range from 10° to 35° characterizing the orthorhombic crystalline structure of V_2O_5.

Note that the performance of the device without the V_2O_5 interlayer in our experiments has similar performance to other reports [20,23]. By introducing the optimum V_2O_5 interlayer, the device has significant improvements in FF (from 0.49 to 0.6) and V_{OC} (from 0.5 to 0.55 V). This indicates that V_2O_5 efficiently suppresses the leakage currents at the organic/Ag interface. Considering the device without V_2O_5, both P3HT and PCBM are in direct contact with Ag. It is possible for electrons to transfer from PCBM to Ag, thereby increasing the leakage currents. However, incorporating a V_2O_5 interlayer introduces two additional interfaces, organic/V_2O_5 and V_2O_5/Ag. As shown in Fig. 1b, the conduction band of V_2O_5 (−2.4 eV) (Ref. [8]) is higher than the lowest unoccupied molecular orbital level of PCBM (−3.7 eV), showing that V_2O_5 can block the reverse electron flow from PCBM to Ag. Thereby, V_2O_5 can effectively prevent the leakage current at the organic/Ag interface. In addition, the valence band of V_2O_5 (−4.7 eV) (Ref. [8]) is close to the highest occupied molecular orbital level of P3HT (−5.1 eV), revealing that V_2O_5 will help collecting holes.

Moreover, the series resistance (R_S, defined from the $J–V$ curves near 1.5 V under light illumination) is 1.35 Ω cm^2 and 3.09 Ω cm^2 for the device with and without the optimum V_2O_5 interlayer, respectively. The shunt resistance (R_{SH}, defined from the $J–V$ curves near 0 V under light illumination) is 610 Ω cm^2 and 376 Ω cm^2 for the device with and without the optimum V_2O_5 interlayer, respectively. It is known that the high R_{SH} indicates less leakage current across the cell and contributes to the improved FF and V_{OC} [24]. Another evidence for less leakage current is the rectification ratio (RR, defined as the current ratio at ±1.5 V from the $J–V$ curves measured in the dark). The RR of the device without V_2O_5 is 4.37×10^2, while that of the device with the optimum V_2O_5 interlayer increases to 1.77×10^4. The high RR and elevated R_{SH} both are strong evidences showing that the V_2O_5 interlayer can serve as an electron-blocking layer to effectively prevent the leakage currents, resulting in the dramatic improvement in PCE.

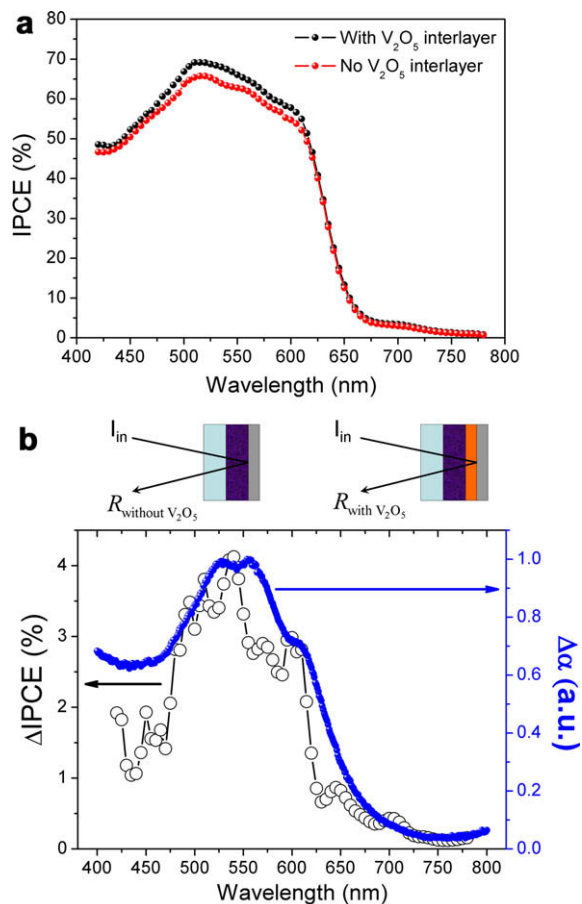
Fig. 4a compares the incident photon-to-current conversion efficiency (IPCE) spectrum of the devices with and without the optimum V_2O_5 interlayer. The IPCE is defined as the number of photogenerated charge carriers


Fig. 4. (a) IPCE spectra for the devices with and without the optimum V_2O_5 interlayer. (b) The change in absorption spectrum [$\Delta\alpha(\lambda)$] and the difference in IPCE spectrum [$\Delta IPCE(\lambda)$] resulting from the insertion of the optimum V_2O_5 interlayer. The inset is a schematic of the optical beam path in the both samples. The variables are defined in the text.

contributing to the current per incident photon. The device with V_2O_5 interlayer shows the typical spectral response of P3HT:PCBM blend with a maximum IPCE of ~69% at 515 nm, while for the device without V_2O_5 interlayer, the peak reaches ~65% only. The IPCE spectra are consistent with the measured J_{SC} in the devices. The insertion of V_2O_5 demonstrates a substantial enhancement of ~6% at 515 nm in the IPCE. This enhancement agrees with the increase in J_{SC} (~5% increase in the device with V_2O_5). It indicates that the V_2O_5 interlayer also contributes to the increase in photocurrent.

To further clarify the role of the V_2O_5 interlayer, we measured the reflectance (R) spectra of the devices with and without the optimum V_2O_5 interlayer. Since the two devices are identical except the addition of the V_2O_5 layer, comparison of the reflectance yields information on the additional absorption, $\Delta\alpha(\lambda)$, in the photoactive layer as a result of the spatial redistribution of the light intensity by the V_2O_5 interlayer (Fig. 4b). The $\Delta\alpha(\lambda)$ is given by [25]

$$\Delta\alpha(\lambda) \approx -\frac{1}{2\sqrt{2}d} \ln\left(\frac{R_{\text{with } V_2O_5}(\lambda)}{R_{\text{without } V_2O_5}(\lambda)}\right)$$

where $R_{\text{with } V_2O_5}(\lambda)$ is the reflection from a device with the V_2O_5 interlayer, $R_{\text{without } V_2O_5}(\lambda)$ is the reflection from an identical device without the V_2O_5 interlayer, and d is the thickness of the photoactive layer (d is ~300 nm in both). The result shows a clear increase in absorption over the spectral region of the interband transitions. Since the spectral features of the P3HT absorption are evident in the $\Delta\alpha$ spectrum, the increased absorption arises from a better match of the spatial distribution of the light intensity to the position of the photoactive layer. Fig. 4b also shows the difference in IPCE spectrum, $\Delta IPCE(\lambda)$, between the devices with and without the optimum V_2O_5 interlayer. This spectrum reveals three peaks at 510, 540, and 600 nm, respectively. It implies that the contribution of the V_2O_5 interlayer in photocurrent is mainly at the three peaks which are vibronic features from the P3HT molecules [26]. Moreover, the feature of the $\Delta IPCE$ spectrum is analogous with $\Delta\alpha$ spectrum, showing that the increased optical absorption is nearly transferred to the photocurrent. Evidently, the V_2O_5 interlayer functions as an optical spacer to increase the optical absorption by spatially redistributed the light intensity and thereby increase the photocurrent.

Although PEDOT:PSS layer can be solution processed, its hygroscopic nature is likely to form insulating patches due to the water adsorption, thus degrading the devices [27]. In contrast, V_2O_5 is relatively insensitive to water and stable in air. The solution-processed V_2O_5 interlayer can serve as a barrier preventing oxygen or water from entering and degrading the photoactive layer. In addition, this approach does not need annealing treatment like PEDOT:PSS nor vacuum equipments, so it is simple, expeditious, and effective. This is very important for commercial realization of low-cost and large-area printed solar cells.

4. Conclusion

In conclusion, we have demonstrated the use of the solution-processed V_2O_5 as the anode interlayer in in-

verted PSCs hybridized with ZnO nanorods. The optimum V_2O_5 interlayer is obtained at the concentration of 100 μg/ml, because the photoactive layer is almost completely covered with V_2O_5 at this condition. The highest PCE of 3.56% is achieved for the device with the optimum V_2O_5 interlayer, which is comparable to that of the devices with a vacuum-deposited V_2O_5 interlayer [28]. Our investigations show that the V_2O_5 interlayer can effectively prevent the leakage currents at the organic/Ag interface leading to improvements in V_{OC}, FF, R_S, and R_{SH}. The optical absorption and IPCE are also improved by the optical spacer effect of the V_2O_5 interlayer, thus leading to the increased photocurrent. Compared to the vacuum-deposited techniques, this approach is simple, expeditious, and effective. It is also advantageous for potential applications to mass production of various large-area printed electronics with a very low cost.

at high temperature so far. Therefore, it is important that the materials used in OLEDs fabrication have high thermal stability as well as ease of sublimation. In particular, molecules of high vapor pressure are needed for mass production, since a large number of samples need to be loaded on a tray at once.

The solution process in OLEDs has recently attracted much attention due to its low cost and eases of device fabrication. Molecules showing good solubility in common organic solvents are suitable for this process. If the molecules have poor solubility, the performance of a solution-processed OLEDs is significantly lowered due to aggregation [13]. Consequently, in order to be suitable molecules for both processes, the molecules need to have high thermal stability, good solubility and an ease of sublimation originated from high vapor-pressure.

Triarylsilyl moieties are known for high chemical stability as well as improved solubility, and thus give improved efficiency compared to alkyl substituents in OLEDs [14]. However, triarylsilyl possess some drawbacks such as lower yield, complexities in synthesis, a delicate purification process and low vapor pressure. On the contrary, trimethylsilyl moieties are introduced easily into the ligand backbone and their derivatives are synthesized in high yields. In addition, trimethylsilyl functional groups confer to molecules such attributes as higher vapor pressure, thermal stability (high T_g), good solubility and steric bulk via higher volume. Such properties of the silyl moiety effectively hinder the aggregation and excimer formation of ppy-based Ir(III) complexes [15]. Therefore, the combination of ppy and bulky trimethylsilyl moieties would be expected to be the best way to achieve an efficient phosphorescent emitter. Herein, we describe the results of our investigation into the preparation, thermal and optical properties and electroluminescent characteristics of a new Ir(ppy)$_3$ derivative containing trimethylsilyl moieties.

2. Experiments

All experiments were performed under dry N$_2$ atmosphere using standard Schlenk technique. All solvents were freshly distilled over appropriate drying reagents prior to use. All starting materials were purchased from either Aldrich or Strem and used without further purification. ^{1}H NMR and mass spectra were recorded on a Bruker DRX 500 MHz spectrometer and JEOL-JMS 700 instrument, respectively. UV/vis and photoluminescent spectra for all samples with concentrations in the range of 10–50 μM were obtained from UV/vis spectrometer Lambda 900 and a Perkin Elmer Luminescence spectrometer LS 50B, respectively. All solutions for photophysical experiments were degassed with more than three repeated freeze-pump-thaw cycles in a vacuum line. Melting points were determined on an Electrothermal 9100 apparatus. Emission lifetimes were measured with the fourth harmonic of a Q-switched Nd-YAG laser using the upper excite state energy transfer with a pulse duration of 6 ns and a repetition rate of 10 Hz. The laser beam had a diameter of 5 mm and an optical power of ∼ 50 mJ. The emission from the film was recorded by a gated intensified diode array detector through a monochromator. The system allows for an integration time (gate width) of detection from 100 ns to 10 ms and a variable delay after excitation. Ultraviolet photoemission spectroscopy (UPS) was conducted according to previous report [16]. Absolute emission quantum yield (η_{PL}) and its dependence for doping concentration were measured by an integrating sphere [17]. Cyclic voltammetry was performed with an Autolab potentiostat by Echochemie under nitrogen atmosphere in a one-compartment electrolysis cell consisting of a platinum wire working electrode, a platinum wire counter electrode, and a quasi Ag/AgCl reference electrode. Cyclic voltammograms were monitored at scan rates of either 100 mV s^{-1} or 50 mV s^{-1} and recorded in distilled dichloromethane. The concentration of the complex was maintained at 0.5 mM or less and each solution contained 0.1 M of tetrabutylammoniumhexafluorophosphate (TBAP) as the electrolyte. The ferrocenium/ferrocene couple was used as the internal standard.

2.1. 1-Bromo-3-(trimethylsilyl)benzene

To a stirring solution of 1,3-dibromobenzene (25 g, 0.11 mol) in diethyl ether (250 mL) was cooled to −78 °C. Addition of n-BuLi (29.4 g, 0.11 mol, 2.5 M in hexane) over 20 min resulted in a pale yellow solution. After stirring for 1 h at this temperature and then quenched with TMSCl (12.7 g, 0.12 mol). The solution was allowed to warm to room temperature overnight. Water (40 mL) was added to the above solution. The organic layer was separated and washed with brine, dried (MgSO$_4$), and concentrated under reduced pressure. The crude material was purified by vacuum distillation. The fraction boiling at 79–80 °C (1.5 mmHg) was collected as a clear oil (20 g, 85%) ^{1}H NMR (CDCl$_3$) δ 7.54 (s, 1H), 7.39 (d, 1H), 7.34 (d, 1H), 7.14 (t, 1H), 0.19 (s, 9H).

2.2. 3-(Trimethylsilyl)phenylboronicacid

To a stirring solution of 1-bromo-3-(trimethylsilyl)benzene (10 g, 43.6 mmol) in diethyl ether (100 mL) was cooled to −78 °C. Addition of n-BuLi (13.3 g, 48 mmol, 2.5 M in hexane) over 20 min resulted in a yellow solution. After stirring for 30 min at this temperature and then quenched with (C$_2$H$_5$O)$_3$B (19.1 g, 130.9 mmol). The solution was allowed to warm to room temperature overnight. The mixture was then cooled to 0 °C and acidified with 1 N HCl. A white precipitate formed. The mixture was stirred for 1 h and then the layers were separated, and the aqueous was extracted with ethylacetate (2 × 100 mL). The organic layers were combined, washed with 1 N HCl, dried (MgSO$_4$), and concentrated under reduced pressure. Further drying under vacuum afforded 5.4 g (64%) of a white solid. The compound was generally used in the following step without further purification: mp 138–140 °C; 1H NMR (CDCl3) δ 8.46 (s, 1H), 8.25 (d, 1H), 7.8 (d, 1H), 7.54 (t, 1H), 0.39 (s, 9H).

2.3. 2-Bromo-5-trimethylsilylpyridine

To a stirring solution of 2,5-dibromopyridine (10 g, 42.2 mmol) in diethyl ether (100 mL) was cooled to

−78 °C. Addition of n-BuLi (11.7 g, 42.2 mmol, 2.5 M in hexane) over 20 min resulted in a dark brown solution. After stirring for 1 h at this temperature and then quenched with TMSCl (5.50 g, 50.6 mmol). The solution was allowed to warm to room temperature overnight. Water (100 mL) was added to the above solution. The organic layer was separated and the aqueous layer was extracted with diethyl ether (2 × 80 mL). The organic layers were combined, dried (MgSO$_4$), and concentrated under reduced pressure. The crude material was purified by vacuum distillation. The fraction boiling at 86–87 °C (1.5 mmHg) was collected as a clear oil (20 g, 85%) ^{1}H NMR (CDCl$_3$) δ 7.54 (s, 1H), 7.39 (d, 1H), 7.34 (d, 1H), 7.14 (t, 1H), 0.19 (s, 9H).

2.4. Ligand dsippy

2-Bromo-5-trimethylsilylpyridine (5.0 g, 21.7 mmol), 3-(trimethylsilyl)phenylboronic acid (5.06 g, 26.1 mmol), and Pd(PPh$_3$)$_4$ (0.75 g, 0.65 mmol), were dissolved in THF (45 mL). A solution of 2 M K$_2$CO$_3$ (15 mL) was added, and the mixture was refluxed with stirring for 18 h in an atmosphere of nitrogen. After being cooled, the mixture was poured into aqueous EDTA and extracted with ether. The organic layer was dried over MgSO$_4$. The solvent was removed under reduced pressure to give a yellow oil. The crude product was purified by chromatography on silica gel (EtOAc/hexane, 1/5, v/v) to obtain a colorless oil (5.92 g, 91%); IR (KBr) 3042, 2950, 1591, 1480, 1437, 1250 cm^{-1}; ^{1}H NMR (CD$_2$Cl$_2$) δ 8.97 (dd, 1H), 8.41 (dd, 1H), 8.16 (m, 1H), 8.01 (dd, 1H), 7.88 (dd, 1H), 7.75 (sex, 1H), 7.60 (sex, 1H), 0.50 (s, 9H), 0.49 (s, 9H). ^{13}C-NMR(CD$_2$Cl$_2$): δ 157.69, 153.99, 141.97, 140.99, 138.70, 134.13, 133.18, 131.94, 128.18, 127.55, 119.93, −1.14, −1.35. Anal. Calcd for C$_{17}$H$_{25}$NSi$_2$ (299.15): C, 68.16; H, 8.41; N, 4.68. Found: C, 68.21; H, 8.39; N, 4.67.

2.5. Complex Ir(dsippy)$_3$

Ligand dsippy (3 g, 10.0 mmol) and Ir(acac)$_3$ (1.22 g, 2.50 mmol) were dissolved in ethylene glycol (50 mL), and the mixture was heated to reflux under nitrogen for 25 h. The reaction mixture was then cooled to room temperature, 1 N HCl was added, and the mixture was filtered to give a crude product, and then flash chromatographed on silica column using dichloromethane to yield 1.1 g (42%). The compound was then further purified by sublimation. IR (KBr) 3040, 2949, 1581, 1476, 1435, 1248 cm^{-1}; ^{1}H-NMR(CD$_2$Cl$_2$): δ 7.98 (d, 3H), 7.86 (s, 3H), 7.80 (d, 3H), 7.52 (s, 3H), 7.04 (d, 3H), 6.94 (d, 3H), 0.29 (s, 27H), 0.12 (s, 27H); ^{13}C-NMR(CD$_2$Cl$_2$): δ 166.70, 161.47, 150.34, 144.01, 141.14, 136.96, 133.23, 129.83, 124.23, 119.73, 118.27, −1.87, −1.93; MS (FAB): m/z = 1087[M$^+$]. Anal. Calcd for C$_{51}$H$_{72}$N$_3$Si$_6$Ir (1087.40): C, 56.31; H, 6.67; N, 3.86. Found: C, 56.35; H, 6.59; N, 3.82.

The glass substrate pre-coated with indium-tin-oxide (ITO) was cleaned by an ultrasonic bath of acetone, followed by 2-propanol. Surface treatment was carried out by exposing ITO to a UV-ozone plasma. OLEDs using CBP as host material is fabricated as follows. The hole-injecting layer, a 10 nm thick film of copper phthalocyanine (CuPc)

was deposited on ITO surface by high vacuum thermal evaporation and a 40 nm thickness 4-4-bis[N-(naphthyl)-N-phenyl-amino]biphenyl (α-NPD) as hole-transporting layer was deposited onto the CuPc. Ir(disppy)$_3$ (disppy = ditrimethylsilyl-substituted ppy) doped host CBP layer were thermally co-evaporated on the α-NPD layer. Ir(disppy)$_3$ doping concentrations was 8% in CBP. A 10 nm thick BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) layer was then deposited as the exciton-blocking and followed by a 40 nm Alq$_3$ (tris-(8-hydroxyquinoline) aluminum(III)) as an electron transporting layer. Finally LiF (1 nm) and Al (100 nm) were deposited on top of the organic layers by thermal evaporation. The fabricated multilayer organic light-emitting devices have the structure of ITO/CuPc (10 nm)/α-NPD (40 nm)/CBP-Ir(disppy)$_3$ (20 nm)/BCP (10 nm)/Alq$_3$ (40 nm)/LiF (1 nm)/Al (100 nm).

3. Results and discussion

The ligand 2-phenylpyridine, containing trimethylsilyl moieties, was synthesized by Suzuki coupling [18], through the reaction of 2-bromo-5-trimethylsilylpyridine with the corresponding 3-trimethylsilyl phenylboronic acid in the presence of K$_2$CO$_3$ and Pd(PPh$_3$)$_4$ catalyst as shown in Scheme 1. This ligand was obtained in good yields (91%).

The titled complex, Ir(disppy)$_3$, was synthesized by slight modification of the previous synthetic methodology reported by Watts and co-workers [19]. Through the reaction of Ir(acac)$_3$ with the trimethylsilyl-substituted ppy ligands under high temperature (>200 °C), the complex was obtained in moderate yields (42%). Both the ligand and the iridium complex were characterized by NMR, mass spectrometry and elemental analyses. In the ^{1}H-NMR spectra, the complex exhibits six well-resolved peaks in the phenyl region due to the ppy rings, indicating that it has a *facial* geometry around the Ir metal center. Ir(disppy)$_3$ is highly soluble in common organic solvent and slightly soluble even in hexane. It may be due to introduced bulky trimethylsilyl groups. This complex is very stable up to approximately 290 °C without degradation under N$_2$ atmosphere. The decomposition temperature, which is defined as 5% weight loss, is 295 °C. The glass transition (T_g) in DSC experiment appears at 184 °C. (Fig. 1).

Moreover, Ir(disppy)$_3$ displayed a consistent and reproducible DSC diagram during two cycles of heating and cooling, proving that this complex is thermally stable up to its melting transition. The T_g value observed for the complex is considerably higher than that of Ir(ppy)$_3$. This suggests that the introduction of silyl moieties in the ppy ring leads to a dramatic increase in thermal stability.

The UV–vis spectra of the complex in solution exhibit strong absorption bands from 250 to 320 nm ($\varepsilon > 10^4$ mol^{-1} dm^3 cm^{-1}), indicating that the electronic transitions are mostly ligand-centered (LC) π–π^* (Fig. 2). As compared to the absorption of Ir(ppy)$_3$, the absorption patterns of Ir(disppy)$_3$ are similar in the 250–550 nm spectral region [20]. Intraligand (IL) π–π^* transitions and metal-to-ligand charge transfer (^{1}MLCT, dπ(Ir)- π(ppy)) transitions are observed in the region of 350–440 nm. In

addition, weaker absorption tails at 450–480 nm, which can be assigned as triplet metal-to-ligand charge transfer

(^{3}MLCT), are also observed. Despite the fact that the Ir(dis-ppy)$_3$ complex shows similar patterns to that of Ir(ppy)$_3$ in

a

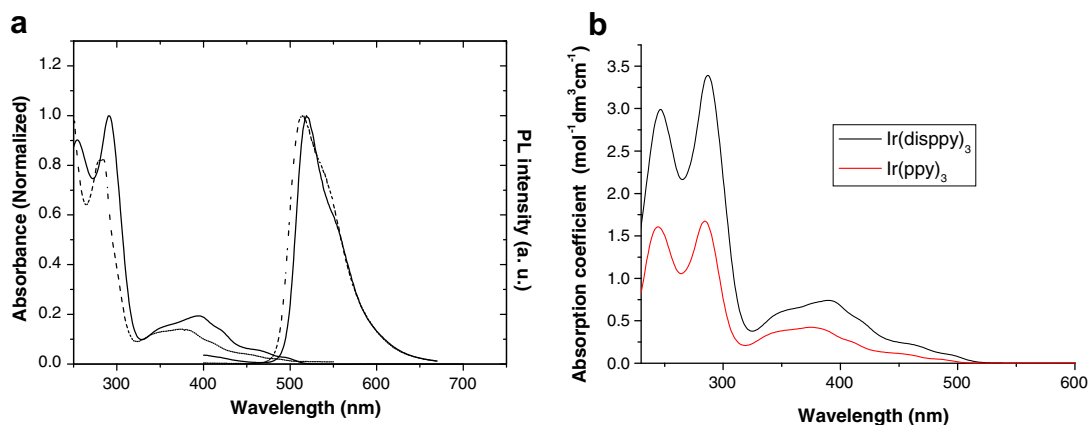
b


Fig. 2. (a) The absorption and emission spectra of Ir(disppy)$_3$. Solid line (diluted solution), dashed line (neat thin film). Wavelength/nm (log ε): 291(5.01), 394(4.32), 419(4.15), 460(3.61). (b) Absorption spectra of Ir(disppy)$_3$ and Ir(ppy)$_3$ at the same concentration. ([M] = 1.0 × 10^{-5}, solvent: 1,2-dichloroethane).

absorption spectrum, it should be noted that a strikingly higher extinction coefficient was observed for Ir(disppy)$_3$ in the charge transfer region (Fig. 2b). The larger molar extinction coefficient observed for ^{1}MLCT and ^{3}MLCT relative to that of Ir(ppy)$_3$ indicates that the substituent silyl groups play a key role in the enhancement of the spin-orbit coupling.

The emission spectra of complex in solution and in film at room temperature are dominated by phosphorescence in the region of 500–600 nm with maximum values of 519 and 513 nm, respectively.

In addition, the emission spectrum of 8%-Ir(disppy)$_3$ doped CBP film is almost the same spectrum of neat film. There are no characteristic emission peaks from CBP, indicating that the emission primarily originates from Ir(disppy)$_3$. Furthermore, no shift of the emission peak was observed, even at a higher doping concentration (30% or 50%). These results apparently support the conclusion that effective energy transfer from the host (CBP) to the dopant the (Ir complex) occurs in the emissive layer.

Interestingly, the emission spectrum of Ir(disppy)$_3$ in the solid state is blue-shifted in comparison to the diluted solution (10^{-5}–10^{-6} M) and the emission spectrum in solution shows a narrow band with a small full-width at half-maximum (solution: 50 nm, thin film: 60 nm). In general, the maximum emission band in the solid state appears at lower energies as compared to that in solution due to the difference in dielectric constant of the environment [21,22]. This observation may indicate that bulky trimethylsilyl groups hamper intermolecular interactions even in the solid state. However, on the one hand, virtually identical shapes of the spectra of Ir(disppy)$_3$ and Ir(ppy)$_3$ were observed, thus indicating that the same excited and/or ground states were involved in the phosphorescent transitions. On the other hand, the part of the trimethylsilyl groups seems to have a negligible effect on the shift of emission maxima, which was demonstrated further by the electrochemical determination of HOMO and LUMO levels.

To investigate electronic effects on the ppy rings caused by trimethylsilyl groups, cyclic voltammetry experiments
Fig. 3. Cyclic voltammograms of Ir(ppy)$_3$ (solid line) and Ir(disppy)$_3$ (dashed line) measured in CH$_2$Cl$_2$:CH$_3$CN [1:1(v/v)] at a scan rate of 100 mV/s.

(Ag/AgCl with a ferrocene/ferrocenium, Fc/Fc$^+$, internal standard) for the complex including Ir(ppy)$_3$ were carried out under the same experimental conditions. Due to the limited range available in dichloromethane and the inability of our instrument to measure reliable reduction potential below −2.0 V, we have obtained only the reliable oxidation potentials.

Ir(disppy)$_3$ shows a single reversible oxidation at 0.67 V (Epa), while the reversible oxidation of Ir(ppy)$_3$ appears at 0.70 V (Epa). Ir(ppy)$_3$ shows a slightly higher reversible oxidation, as shown in Fig. 3. The HOMO level for Ir(disppy)$_3$ was estimated on the basis of an oxidation potential of −4.8 eV (below vacuum level) for Fc/Fc$^+$ [23]. The onset potential of oxidation for Ir(disppy)$_3$ was determined to be 0.60 V (vs Ag/AgCl), corresponding to 0.50 V (vs Fc/Fc$^+$), hence, the HOMO level for Ir(disppy)$_3$ is estimated to be −5.30 eV. This value is slightly higher than that of Ir(ppy)$_3$, showing that the trimethylsilyl substituent introduced to the ppy ring has no significant effect on the HOMO energy level. To obtain HOMO energy more
Fig. 4. PL decay of Ir(ppy)₃ and Ir(disppy)₃ in thin film at room temperature.

accurately, ultraviolet photoemission spectroscopy (UPS) was measured and its result was presented in supporting information. Based on UPS data, HOMO energy of Ir(disppy)₃ appears at −5.2 eV, which is similar to that of electrochemical data.

In order to determine the LUMO of the complex, the optical band gap was used. The optical band gap of the complex was determined by its absorption threshold in thin film. The estimated value is 2.59 eV, thus, the LUMO level of ³MLCT is estimated to be −2.71 eV.

The absolute PL efficiencies (η_{PL}) of 8 wt%-Ir(disppy)₃:CBP and 8 wt%-Ir(ppy)₃:CBP film are 52 ± 2% and 84 ± 2%, respectively. To gain a deeper insight into the factors influencing photoluminescence quantum yields, measured the life time in the excited states for both Ir(disppy)₃ and Ir(ppy)₃ as shown in Fig. 4. The observed lifetime (τ_{obs}) for Ir(disppy)₃ at room temperature is 1.45 μs, which is longer than that of Ir(ppy)₃ (1.0 μs), as shown in Fig. 4. Using the following two equations (Eqs. (1) and (2)), the values for the radiative (kr) and non radiative (knr) decay rates were determined [22].

$$QE(PL) = kr/(kr + knr) \tag{1}$$

$$1/\tau = kr + knr \tag{2}$$

The calculated values of the radiative (kr) and non radiative (knr) decay rates for Ir(disppy)₃ are $3.6 \times 10^5 \text{ s}^{-1}$ and $3.3 \times 10^5 \text{ s}^{-1}$, respectively. While the radiative (kr) and non radiative (knr) decay rates for Ir(ppy)₃ are $8.4 \times 10^5 \text{ s}^{-1}$ and $1.6 \times 10^5 \text{ s}^{-1}$, respectively. This result indicates that the higher quantum yield of Ir(ppy)₃ than that of Ir(disppy)₃ in 8 wt% doping level is most likely due to its faster radiative decay rate [24].

To compare concentration quenching between Ir(ppy)₃ and Ir(disppy)₃ at varied doping concentration, we have conducted PL efficiency (η_{PL}) measurement [25–27]. The η_{PL} of the films was measured using an integrating sphere under nitrogen atmosphere. The Ir(ppy)₃:CBP film showed an η_{PL} of 84% at 8 wt%, 42% at 30 wt% and 24% at 50 wt%, respectively, while the Ir(disppy)₃:CBP film showed 52.0%, 52.4% and 43.97% at each doping levels (wt%) (see Fig. 5). This result further support that the self-quenching in Ir(ppy)₃:CBP film is more effective than observed results in Ir(disppy)₃:CBP film. This increased emission quantum yield as compared to Ir(ppy)₃ in high doping level may be supposed to the lack of thermal vibrations and various intermolecular excited-state interactions caused by the introduction of bulky trimethylsilyl groups into ppy ring. Henceforth, the bulky silyl group on ppy ring seems to play a key role in preventing self-quenching.

To compare the electroluminescence (EL) characteristics of Ir(disppy)₃, we also fabricated EL devices using Ir(ppy)₃. These contained a similar structure under the same experimental conditions. Devices with the Ir phosphor doped into the emissive layer were fabricated. EL device performance was conducted by using Ir(disppy)₃ and Ir(ppy)₃ as dopant, and CBP, (4,4′-N,N′-dicarbazole-biphenyl) as a host in all cases. The device structure used in this work contained a typical multi-layer structure, employing the following components: ITO as the anode, CuPc (10 nm) as the hole injection material, 1,4-bis[(1-naphthylphenyl)-amino]biphenyl (NPD: 40 nm) as the hole transport material, Ir(disppy)₃ and Ir(ppy)₃ (weight 8%) as the dopant material, CBP as the host material (20 nm), 2,9,-dimethyl-4,7,-diphenyl-1,10-phenanthroline (BCP:10 nm) as the hole blocking material, tris(8-hydroxy-quinoline)aluminum

Table 1
Electroluminescent data of Ir(ppy)$_3$ (reference) and Ir(disppy)$_3$ 8 wt%-doped OLEDs.

	EL (λ_{max}) (nm)	Operating voltage (V)[a]	Luminous efficiency (cd/A)[a]	Power efficiency (lm/W)[a]
Ir(ppy)$_3$	516	8.7	32.5	11.7
Ir(disppy)$_3$	524	7.4	39.2	17.3

[a] At 10 mA/cm^2.

(AlQ$_3$: 40 nm) as the electron transport material, LiF as the electron injection layer, (1 nm) and Al (100 nm) as the cathode, as shown in Fig. 6.

Both complexes display strong green emission in the range of 510–530 nm in the EL spectra, which are well matched to those of the PL spectra in dilute solution. More detailed EL characteristics are shown in Table 1. Turn-on voltages (defined as 10 mA/cm^2) of Ir(ppy)$_3$ and Ir(disppy)$_3$ are 8.7 V and 7.1 V, respectively (Fig. 7).

Fig. 8. Luminance efficiency vs current density characteristics of Ir(ppy)$_3$ and Ir(dsippy)$_3$: 8 wt%-doped devices.

The intermolecular interactions (e.g., π–π stacks in molecular crystals) in the solid state and the ability to trap charges in the emissive layer are considered the most important factors in determining the operating voltage.

Effective charge trapping by the dopants increases driving voltages in OLEDs [28]. If the dopant material functions as a hole trap, the HOMO level of dopant could rise above that of the host material. In other words, materials having lower oxidation potential can function effectively in hole trapping in OLEDs. Therefore, the observed lower operating voltages for Ir(disppy)$_3$, relative to Ir(ppy)$_3$, are predominantly caused by the lack of effective hole trapping. These results are consistent with the electrochemical behaviors of Ir(disppy)$_3$ and Ir(ppy)$_3$. As expected, the device fabricated using Ir(disppy)$_3$ exhibited higher brightness and power efficiency, as well as stronger EL intensity than in Ir(ppy)$_3$ (see Figs. 8 and 9). The efficiency of the devices at 10 mA/cm^2 are 32.5 cd/A and 39.2 cd/A, for Ir(ppy)$_3$ and Ir(disppy)$_3$ respectively. Details of electroluminescent data are presented in Table 1.

Fig. 7. Voltage vs current density characteristics of Ir(ppy)$_3$ and Ir(dsippy)$_3$: 8 wt%-doped devices.

4. Conclusions

A novel *fac-tris*{2-(3′-trimethylsilylphenyl)-5-trimethyl-silylpyridinato}iridium, Ir(disppy)$_3$, has been synthesized and its photo-electroluminescent and electrochemical properties have been characterized. This material shows high thermal stability and strong green phosphorescence emission in thin film. This complex demonstrates very high thermal stability, and good solubility in common organic solvent, as well as ease of sublimation due to its high vapor pressure which makes it suitable for mass production. A diminution of turn-on voltage of Ir(disppy)$_3$ was observed when this was used as an emitter in the EL performance test. In addition, a significant improvement of the power efficiency (17.3%), which is nearly 200% higher than that of Ir(ppy)$_3$, was observed under the same conditions.

range, the contact resistance R_C plays a key role on OTFT downscaling and can limit speed performance of logic circuits. Understanding the architecture and process parameters that govern the contact resistance R_C is key to properly afford the miniaturization process of organic electronic circuits.

The contact resistance R_C of an OTFT is affected by the OTFT architecture. Staggered OTFTs are transistors where the metal electrodes and the gate dielectric lay on opposite sides with respect to the OSC thin film. In these architectures the contact resistances R_C can be hundred times lower than in the coplanar case, where the metal electrodes and the gate dielectric lay on the same side with respect to the semiconducting organic layer [16]. Typically, organic thin film transistors with top-gate/bottom-contact configuration fall in the class of staggered OTFTs, while bottom-gate/bottom-contact one fall in the co-planar case. Following the analysis by T. J. Richards and H. Sirringhaus in Ref. [17], the contact resistance of a staggered OTFT is not too much influenced by the height of the energy barrier occurring at the metal/OSC interface [18–20]. Indeed, the contacts have an ohmic behavior in staggered OTFTs and are conversely non-ohmic in coplanar OTFTs [21,22]. In staggered OTFTs the voltage drop due to the contacts is mainly localized between the metal/OSC interface and the accumulation layer [23,24]. Conversely, in a coplanar configuration the main contribution to the voltage drop is localized at the injecting contact area i.e. at the metal/organic-semiconductor interface. Moreover, it has been observed, in p-type OTFTs and especially in the staggered geometry, that the contact resistance R_C has a distinctive decrease as the gate voltage V_G decreases [25–27].

In spite of the role that the contact resistance has in determining the performances of a staggered OTFT, so far, the dependence of the contact resistance on the gate voltage is not well understood. In particular, its link with the material properties of the OSC thin film and the influence of the accumulation layer has not been considered. In this work, we focused on this task: a compact analytical model of the dependence of the contact resistance R_C on the gate voltage V_G has been developed, for the case of staggered OTFTs having a polycrystalline OSC thin film as the active channel.

The paper is organized as follows. In Section 2 previous efforts to model the dependence of the contact resistance on the gate bias in staggered OTFTs are shortly reviewed, and their shortcomings explained. In Section 3, it is introduced the charge trapping occurring at the grain boundaries of a polycrystalline OSC thin film, as a fundamental process influencing the contact resistance. In Sections 4 we report a new model of contact resistance, as a function of the gate bias V_G, based on the two contributions given by: (a) the charge trapping occurring at the grain boundaries and (b) the electric field generated by the accumulation layer. The resulting model is then employed, in Section 4.3, to pave the way for downscaling the device geometry and related technological parameters. Finally, in Section 5 the key results obtained are summarized, together with conclusion remarks.

2. Models of contact resistance in staggered OTFTs

According to the literature, two empirical models consider explicitly the dependence of the contact resistance on the gate bias, in staggered OTFTs.

The first empirical model extends to organic TFTs the model proposed by Luan and Neudeck [28] for amorphous silicon TFTs. According to Luan and Neudeck's model, the contact resistance R_C of a staggered OTFT can be conceived as a minimum effective contact resistance R_{Cint}, determined by the metal/OSC interface, which is in series with a bulk contact resistance R_{Cbulk} ($R_C = R_{Cint} + R_{Cbulk}$, see Fig. 1). The latter contribution R_{Cbulk} is determined by the OSC thin film that injected carries have to cross in order to reach the accumulation layer. R_{Cbulk} can be expressed as an effective sheet resistance which depends on the gate bias V_G and in this model, the width-normalized contact resistance can be written as:

$$R_C \times W = \frac{|I_0|}{\mu C_i (V_G - V_{th})} + R_{Cint} \times W, \tag{1}$$

where $|I_0|$ and $R_{Cint} \times W$ are the coordinates of the common intersection point of the best-fit lines obtained from a Transfer Line Method (TLM) [25,29], μ is an effective electrical mobility of the organic semiconductor, C_i is the gate capacitance per unit area, and V_{th} a threshold voltage of the OTFT.

The second model, recently proposed by Richards and Sirringhaus [17], considers that two contributions can lower the bulk contact resistance R_{Cbulk} with the gate voltage V_G: (1) the increase of the injecting contact area which occurs as the channel resistance scales down, explained by the current crowding model [30], (2) the increase of the carriers density in the OSC thin film accumulation layer induced by the gate voltage V_G.

In panel 1 (a), we have schematically reported the source contact region of a staggered p-OTFT. In the picture, the bulk, interface contact resistances and the distribution of holes in the OSC thin film, considered in reference [17], are evidenced.

In spite of the agreement of these two models with experiments, both of them neglect that charge carriers injected trough the metal electrodes into the accumulation layer can be trapped by trap states localized within the thickness of the OSC thin film.

On the other hand, the effect of trapping on the contact resistance R_C can be modeled empirically by recurring to the Meyer–Neldel rule (MNR) [31], which describes the multiple trapping and release (MTR) process of carriers occurring through trap states that are distributed within the gap of the OSC.

In the MNR trap states have an exponential energy distribution characterized by the average energy E_B (measured with respect to the valence band E_V) and the width E_{MN}, named the Meyer–Neldel energy [32].

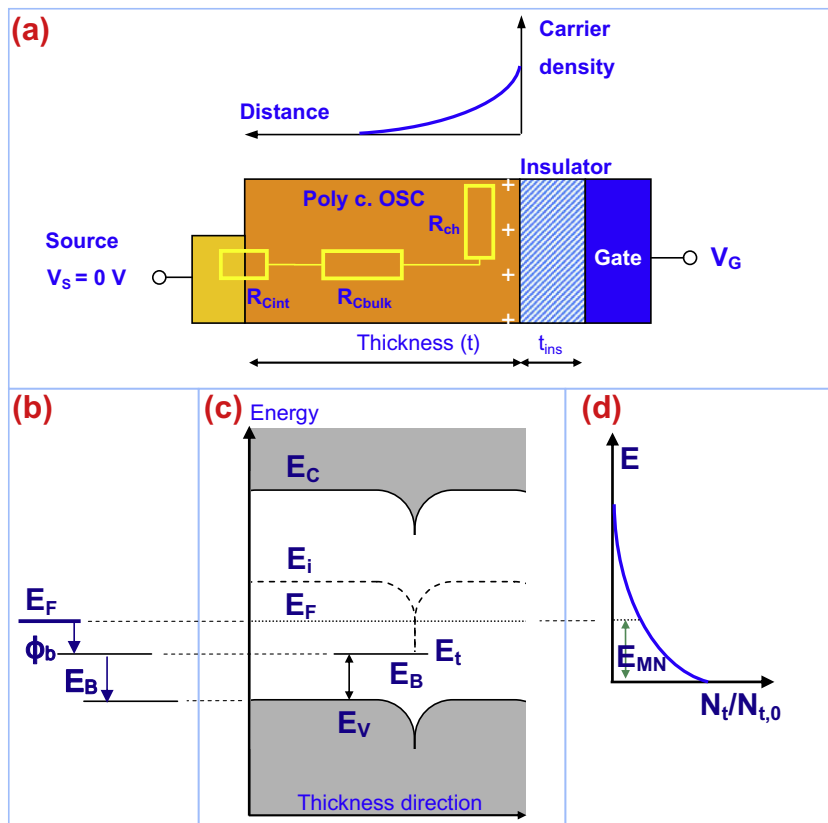
The elements that characterize the MNR model have been sketched in Fig. 1. In particular, panel 1(b), reports the position of the energy trap E_B with respect to the energy injecting barrier ϕ_b of the metal/OSC interface and the Fermi level E_F of the metal. In panel 1(c) we have sketched the band diagram of an OSC thin film as seen in


Fig. 1. Panel (a) reports a sketch of the source contact area in a staggered OTFT. The OTFT is characterized by the thickness t of the polycrystalline organic semiconductor (Poly c. OSC) and the thickness of the insulator t_{ins}. The carrier density as a function of the distance with respect to the active layer has an exponential trend. The contributions to the contact resistance R_C are the interface R_{Cint} and the bulk contact resistance R_{Cbulk}. In the empirical model of Luan and Neudeck [28] both contributions are considered in series $R_C = R_{Cint} + R_{Cbulk}$. Panel (b) shows two distinct energy barriers ϕ_b and E_B contributing to the interface and bulk contact resistance, respectively. Holes injected at the Fermi level E_F thermally activated have to overcome the total energy barrier $\phi_b + E_B$. Panel (c) sketches the band diagram of a polycrystalline OSC thin film. E_v and E_c are the valence and conduction band edge, respectively, E_i is the intrinsic Fermi level, E_F the Fermi level. A trap is located at an energy E_t with respect to E_i, along the thickness t of the OSC thin film. A trapped carrier has to overcome in the average an energy barrier E_B to reach the valence band. According to the grain boundary trapping model, the trapping process is attributed to the presence of traps at the grain boundaries. Panel (d), according to the (Meyer–Neldel rule) MNR model traps are distributed exponentially as a function of the energy E separating the trap from the valence band. E_{MN} marks the width of the distribution; E_B is the average energy of the traps.

the transversal (or charge injection) direction and reported the energy E_B of the trap state. Panel 1(d) depicts the exponential energy distribution of traps characterized by the Meyer–Neldel energy E_{MN}. Incidentally, we may observe as in the case of a self assembled monolayer, the energy gap which localizes the trap states can be larger in the transverse direction with respect to the OSC energy gap in the longitudinal direction because of the π-stacking. In such case, the formation of traps is favored along the transverse direction.

In the MNR model, the contact resistance can be expressed as:

$$R_C \propto \exp\left(\frac{E_B}{kT} - \frac{E_B}{E_{MN}}\right), \qquad (2)$$

where E_B is the average energy of the traps, E_{MN} the Meyer–Neldel energy, k the Boltzmann constant and T the operating temperature.

Although trapping is a fundamental process in a staggered OTFT, the MNR cannot be employed directly to mod-

el the dependence of the contact resistance on the gate bias. This is because we need to specify the nature of the trapping process which determines the energy trap E_B. Although this cannot be done in general, it can be pursued if we consider how the trapping process occurs in a polycrystalline OSC thin film of a staggered OTFT.

3. Trapping processes in polycrystalline semiconductor thin films

In a polycrystalline OTFT, charge trapping processes occur at the grains boundaries (GBs) and can be described by the grain boundary trapping model (GBTM) [33].

Such a model has been previously considered in the literature to model the mobility in polycrystalline organic semiconductor thin film [34]. However, very recently it has been reported that the grains size of polycrystalline OSCs has an influence on the contact resistance [25,26] of staggered OTFTs.

In particular, Jin et al. [25] by recurring to a Levinson's plot [35], correlate the number of traps N_t per unit surface with the average grain size and show that the grain size influences the trend of the contact resistance. In a similar way, Wang et al. [26] argue that traps at the grain boundary can be at the origin of the bulk contact resistance.

Although both works agree on the origin of the contact resistance in staggered OTFT by considering the influence of trapping processes at the grain boundaries, none of them fully develop a grain boundary trapping model for the bulk contact resistance. Indeed, Jin et al. model the contact resistance in the frame of the MNR rule without specifying the origin of the energy trap E_B or its connection with the GB traps.

Because of such evidences it is worth to investigate the connection between the contact resistance and trapping processes occurring at the grain boundaries. In fact, according to the GBTM model an energy barrier E_B determines the hopping of trapped charge carriers between two grains. Indeed, in a polycrystalline OSC thin film grain boundaries contact also metal electrodes. As a consequence charges trapped at the grain boundary can determine a barrier to the carrier injection and hence influence the bulk contact resistance. For this reason we have investigate if an energy barrier E_B determined by the grain boundaries charge trapping can influence the bulk contact resistance as well as its dependence on the gate voltage V_G. On the other hand, thermoionic emission is at the base of the conduction process necessary to overcome the energy barrier at the contact level as well as among grains. Moreover, the grain boundary trapping model shares some common features with the MNR empirical modeling approach. Namely, an exponential energy tail determined by the thermal promoted phenomenon and a trapping process determined by traps of energy E_B which are localized at the GBs. Within the frame of the GBTM the same band diagram depicted in Fig. 1c can be adopted, once the energy trap E_B is attributed to traps at the grain boundaries.

In conclusion, although experimental evidences indicate that the bulk contact resistance in staggered OTFT is connected with trapping processes at the grain boundaries, it lacks today an empirical model which gives an indication of the influence of traps localized at GBs. On the other hand, this model can be formulated if the magnitude of the energy E_B of the trap can be controlled by the gate bias V_G.

4. Results and discussion

In the following, the dependence of the energy barriers contributing to the bulk and interface contact resistance on the gate bias V_G is obtained and merged into a new model of contact resistance, valid for staggered OTFTs. Finally, the model of contact resistance is extended by investigating the effects of device geometrical and technological parameters towards a downscaling approach.

4.1. Bulk contact resistance

Within the framework of the GBTM model the energy barrier at the grain boundary is:

$$E_B = \frac{q^2 N_t^2}{8\varepsilon N_D}, \tag{3}$$

where N_D is the concentration of shallow donors and ε is the dielectric constant of the OSC bulk material. Such a formulation of the energy barrier E_B can take into account the gate bias V_G dependence of the contact resistance. In fact, at low drain voltage V_{SD}, a bias V_G applied to the gate induces a charge density $-N_G$ at the OSC/insulator interface which equals $-N_G = -C_i V_G/q$, where $C_i = \varepsilon_{ins}/t_{ins}$ is the gate capacitance per unit area of the dielectric, with ε_{ins} the dielectric constant of the gate insulator, t_{ins} the thickness of the gate insulator and q the electron unit charge. On the other hand, when a charge density $-N_G$ is induced at the OSC/insulator interface, the energy barrier E_B lowers by ΔE_B because the concentration of donors modifies from N_D to N_D-N_G/t, where t is the thickness of the OSC thin film. As a consequence the contact resistance modifies accordingly into the expression:

$$R_C = R_{C0} \exp\left(\frac{E_B + \Delta E_B}{k\widetilde{T}}\right), \tag{4}$$

where

$$\Delta E_B = E_B \frac{N_G}{N_D t - N_G}, \tag{5}$$

and $(k\widetilde{T})^{-1} = (kT)^{-1} - (E_{MN})^{-1}$ is determined by the contribution of the Meyer–Neldel energy E_{MN}.

By substituting Eq. (5) into Eq. (4), with the hypothesis that $N_D < 0$ the energy barrier resulting from the trapping process at grain boundaries under the control of the gate bias V_G, becomes:

$$\begin{aligned}E_B + \Delta E_B &= E_B \frac{N_D t}{N_D t - N_G} = \frac{q^2 N_t^2}{8\varepsilon} \frac{t}{N_D t - N_G}\\&= \frac{q^2 N_t^2 t}{8\varepsilon} \frac{1}{|N_G| - |N_D|t} = \frac{q^3 N_t^2 t}{8\varepsilon C_i} \frac{1}{|V_G| - \frac{q|N_D|t}{C_i}}.\end{aligned} \tag{6}$$

Hence, the contribution of this kind of trapping process to the specific contact resistance $R_C \times W$ can be expressed by means of the MNR rule exponential law as:

$$(R_C \times W) = (R_C \times W)_0 \exp\left(\frac{q^3 N_t^2 t}{8\varepsilon C_i k\widetilde{T}} \frac{1}{|V_G| - V_{th}}\right), \tag{7}$$

where $V_{th} = q|N_D|t/C_i$ is a threshold bias.

We have tested Eq. (7) with the experimental data reported by Jin et al. in Ref. [25] for the dependence of the contact resistance with the gate bias. In the work of Jin et al. [25], a pentacene 50 nm thin film is deposited on a silicon thermal oxide substrate under two different temperatures of the substrate and completed in an OTFT. According to their experimental results the two different temperatures of deposition of the pentacene allow a control on the trap density N_t per unit area and determine a set of two values which are $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. From their data, for a thermal oxide of 35 nm and a permittivity of the thermal oxide of 3.9, a value of 9.86×10^{-4} F/m^2 for the gate capacitance C_i per unit area can be deduced. In Fig. 2 we have reported in dotted lines the fit of the specific contact resistance data $R_C \times W$ of Jin et al. by employing Eq. (7) with V_{th} and $(R_C \times W)_0$ as best-fit parameters, for the two
Fig. 2. Best-fit of the specific contact resistance $R_C \times W$ data extracted from ref [25] as a function of the absolute value of the gate voltage $|V_G|$. ■ data refer to the case of a trap density $N_t = 5.6 \times 10^{11}$ cm^{-2}, ▲ data refer to a trap density $N_t = 1.2 \times 10^{12}$ cm^{-2}. The thickness t of the OSC is $t = 50$ nm and $\varepsilon = 6$ is the relative dielectric constant of the OSC. The thickness of the gate insulator $t_{ins} = 35$ nm and its relative dielectric constant is $\varepsilon_{ins} = 3.9$, the gate capacitance per unit area is $C_i = 9.86 \times 10^{-4}$ F/m^2. The best-fit in dotted curves (···) has been obtained by employing the grain boundary trapping model (GBTM) expressed by Eq. (7) with $(R_C \times W)_0$ and V_{th} as parameters; the dashed curves (- - -) regard the Poole-Frenkel/Schottky lowering model of Eq. (10) with $(R_C \times W)_0$ and α as parameters; the solid line curves (——) are the combination of the two models (GBTM and Poole-Frenkel/Schottky) as given by Eq. (11), with $(R_C \times W)_0$, V_{th} and α as parameters. According to the best-fit of Eq. (7) the GBTM model provides a threshold voltage of $V_{th} = 8.5$ V and a contribution to the energy barrier $E_B = 11.2$ meV in the $N_t = 5.6 \times 10^{11}$ cm^{-2} case, and $V_{th} = 5.56$ V and a contribution to the energy barrier $E_B = 80$ meV for $N_t = 1.2 \times 10^{12}$ cm^{-2}. According to the best fit of Eq. (11), a threshold voltage of $V_{th} = 7.2$ V and a contribution to the energy barrier $E_B = 13.6$ meV in the $N_t = 5.6 \times 10^{11}$ cm^{-2} case, and $V_{th} = 4.0$ V with a contribution to the energy barrier $E_B = 110.5$ meV for $N_t = 1.2 \times 10^{12}$ cm^{-2}, has been obtained.

case of the density of traps N_t. In the fit a Meyer–Neldel energy $E_{MN} = 64$ meV reported in Ref. [27] and a dielectric constant for pentacene of 6 has been assumed. An evaluation of the energy barrier E_B can be obtained from Eq. (3) by considering the ratio between the quantity $q^3 N_t^2 t/(8 \varepsilon C_i k \tilde{T})$ and the fitted value of the threshold bias V_{th}.

According to the fit we obtained a value of $E_B = 11.2$ meV for $N_t = 5.6 \times 10^{11}$ cm^{-2} and $E_B = 80$ meV for $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. Both values are consistent, being lower than the corresponding activation energies values which have been experimentally measured and reported in Ref. [25].

Although the fit reproduces the trend of the contact resistance with the gate voltage, it shows systematic deviations from the experimental values. Namely, the fitted dotted curves obtained from Eq. (7) are systematically below the experimental data for values of $|V_G|$ below ~15 V, and systematically above the experimental data values for higher values of $|V_G|$.

4.2. Interface contact resistance

The systematic deviations of the GBTM model reported in previous section suggest that this model alone cannot fully describe the decrease of the contact resistance with the gate voltage increase in staggered OTFTs. As a fact, in the hypothesis of a very low density of traps N_t we should expect a negligible energy barrier E_B determining the bulk contact resistance. However, until now we have not examined whether the contact resistance that emerges at the interfaces of the drain and source regions can contribute to the decrease of the contact resistance with the gate bias.

From a heuristic point of view, an evaluation of the interface contact resistance can be achieved from the value of the energy barrier height ϕ_h which emerges at the metal electrode/OSC interface. In fact, if charge carriers are thermally injected into the OSC accumulation layer after overcoming the metal/OSC interface, the contact resistance R_C can be expressed as:

$$R_C = R_{C0} \exp(\phi_h/kT), \tag{8}$$

with R_{C0} having the dimension of a resistance.

On the other hand, within the frame of the canonical theory of metal/semiconductor Schottky barrier, we can express R_{C0} as:

$$R_{C0} = \frac{h^3}{4\pi e^2 m^* kT} \frac{1}{Wt}, \tag{9}$$

where m^* is the carrier effective mass, e the electron charge, h the Planck constant, k the Boltzmann constant, T is the temperature and W the electrode width. In the case of an Au/pentacene interface, with an energy barrier height of $\phi_h = 0.85$ eV [18], an OSC layer thickness of 50 nm and an effective mass equal to the electron mass, a value of 11.3 MΩ cm can be estimated for the width normalized contact resistance $R_C \times W$ at room temperature ($T = 298$ K). Such a value is four orders of magnitude larger than the average value of 50 kΩ cm reported for staggered OTFTs in references [25–27]. If we still consider valid a formulation of the contact resistance based on the occurrence of a Boltzmann factor, a value of 50 kΩ cm for the width-normalized contact resistance can be obtained, with a lower energy barrier height of $\phi_b = 0.6$ eV.

On the other hand, it is well known that, at the OSC/source electrode, holes have to overcome a lower interface energy barrier ϕ_b [23], because of the Schottky mechanism. This effect is determined by an image potential at the source electrode generated by the electric field which emerges in the OSC thin film.

What is the origin of such electric field? In a staggered OTFT, the OSC/electrode interfaces at the source and at the drain are opposite an accumulation layer switched on by the gate voltage V_G. Such accumulation layer generates an electric field whose intensity can be linked to the charge density $-C_i V_G$ of the accumulation layer. An evaluation of the intensity of the electric field according to the equation $E_{field} = C_i |V_G|/\varepsilon$, with data reported in Section 4.1 for pentacene, provides a value of ~10^8 V/m.

On one hand, the electric field generated by the accumulation layer is known to lower the source electrode energy barrier because of the Schottky mechanism while, on the other hand, such value of the electric field is high enough to possibly influence the drain contact region. However, the influence to the drain contact region cannot be

attributed to a Schottky mechanism: indeed, in this region, holes move from the accumulation layer to the drain electrode. Therefore another mechanism must be considered.

It is known that carriers extraction in an insulator can occur based on a Poole-Frenkel mechanism [36]: if high voltage is applied to electrodes on opposite sides of an insulating film, a high electric field is generated, which results in a lowering of the energy barrier of trapped carriers, and corresponds to an abrupt increase of the electric current flowing through the film.

The case of a staggered OTFT differs from the pure insulator case considered by the Poole-Frenkel. In an OTFT, the total drain current is controlled by the bias applied to the drain, for a given V_G, and in the linear regime a low current flows in the OTFT. Nevertheless, a high electric field occurs at the OSC/dielectric interface of the drain, so that locally, in the drain contact region, the electric field generated by the accumulation layer can also determine a lowering of the energy barrier of trapped carriers, in a similar way to a Poole-Frenkel mechanism. Therefore, we have modeled the lowering of the interface energy barrier at the source electrode and drain interface region determined by a Schottky and a Poole-Frenkel mechanism, respectively.

In Fig. 3 we have reported the schematization of a staggered p-type OTFT, where the effects of the electric field generated by the accumulation layer on the source electrode and on the drain electrode, respectively, have been highlighted.

We quantify all the above discussed phenomena in the following way. In a Poole-Frenkel mechanism as well as in a Schottky mechanism the energy barrier is lowered by a quantity which is $(q^3 E_{field}/(4\pi\varepsilon))^{1/2}$. By considering the expression of the electric field determined by the accumulation layer, we have that the lowering of the energy barrier is proportional to $(q^3 C_i |V_G|/(4\pi\varepsilon^2))^{1/2}$. In order to

take into account the Poole-Frenkel effect, occurring at the drain and of the Schottky barrier lowering occurring at the source, we fitted the data from Jin et al. by means of the following equation:

$$
(R_C \times W) = (R_C \times W)_0
$$
$$
\times \exp\left(-\alpha \frac{q^{3/2}(C_i/4\pi)^{1/2}}{\varepsilon k \widetilde{T}} \sqrt{|V_G|}\right), \tag{10}
$$

with α and $(R_C \times W)_0$ as parameters. The dashed lines of the graph of Fig. 2 report the results of such a fit. Also in this case the trend of the dependence of the contact resistance on the gate voltage is reproduced. However slight deviations occur in an opposite fashion with respect to the case of the GBTM model, suggesting that possibly both the phenomena underneath the two models, a trapping process for the bulk contact resistance and a Poole-Frenkel/Schottky mechanism for the interface contact resistance, can act in the lowering of the contact resistance with the gate voltage.

In order to investigate this hypothesis we fitted again the data from Jin et al. by employing the combination of the two energy barriers:

$$
(R_C \times W) = (R_C \times W)_0
$$
$$
\times \exp\left(\frac{q^3 N_t^2 t}{8\varepsilon C_i k\widetilde{T}} \frac{1}{|V_G| - V_{th}}\right.
$$
$$
\left. -\alpha \frac{q^{3/2}(C_i/4\pi)^{1/2}}{\varepsilon k \widetilde{T}} \sqrt{|V_G|}\right). \tag{11}
$$

The solid lines of the graph of Fig. 2 report the fit we obtained from Eq. (11) for the two cases of $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. We may observe a fair agreement of the fitted curves with the experimental data and, based on the computed values of the threshold voltages V_{th}, the following values of the energy barrier of $E_B = 13.6$ meV for $N_t = 5.6 \times 10^{11}$ cm^{-2} and $E_B = 110.5$ meV for $N_t = 1.2 \times 10^{12}$ cm^{-2}, have been obtained. These values are consistent with the experimental values of the activation energies reported in Ref. [25].

As a main conclusion from the fitting we can consider that the trapping process at the grain boundary can raise the energy barrier that holes have to overcome, whereas the energy barrier at the contacts interface is mainly lowered by a Poole-Frenkel/Schottky mechanism determined by the accumulation layer.

In the condition of a very low effect of the trapping process, the Poole-Frenkel/Schottky mechanism has the main influence on the contact resistance. By employing the experimental data reported by Minari et al. [27] we fitted, according to Eq. (10), the specific contact resistance measured as a function of the gate bias and found also a good agreement with their results.

The Poole-Frenkel/Schottky mechanism that lowers the energy barrier in Eq. (10), depends on the gate capacitance C_i by means of the electric field generated by the accumulation layer. Analogously, in developing the GBTM in Section 4.1 we observed as the gate capacitance has also an

Fig. 3. Schematic of the contact regions in a staggered p-type organic thin film transistor. Holes form the accumulation layer as the gate voltage switches on, for negative gate voltages. The accumulation layer generates an electric field that has a different action on the source and on the drain of the OTFT. On the source it generates a Schottky effect that lowers the energy barrier that holes injected at the source electrode have to overcome; at the drain the electric field of the accumulation layer act because of a Poole-Frenkel effect that extracts holes from the accumulation layers towards the drain. The action of the drain bias is to unbalance the accumulation layer surface density and generate a current.

influence on the energy barrier determined by the grain boundary.

The dependence of the contact resistance on the gate voltage and its connection to the gate capacitance suggests that in a staggered configuration in order to decrease the contact resistance it is necessary to increase the overlap area of the gate with the contact electrodes. However, this has as a consequence an increase of the gate overlap capacitance which can affect high speed performances of the OTFT.

4.3. Co-scaling of bulk and interface contact resistance

The contact resistance R_C marks a lower limit to the total resistance of an OTFT. As the channel length L of the OTFT downscales, aiming at improving the speed performances and density of organic electronic integrated circuits, the channel resistance decreases and the contact effects become the predominant term in the total resistance. As a consequence, in order to increase the performances of a staggered OTFT, it is necessary to modify opportunely the contact resistance.

In Section 4.1 and 4.2, we have discussed the influence of trapping processes at the grain boundaries and interface effects on the contact resistance and formulated an equation model (Eq. (11)) where geometrical and physical quantities that can affect the contact resistance have been discussed. Assuming valid our model, we have investigated how the specific contact resistance changes from the two cases we have considered, as we vary the thickness t of the semiconductor OSC and the gate capacitance C_i, by keeping constant all the other parameters.

The results of such an investigation have been plotted in Fig. 4a–c. Fig. 4a reports a 3D plot of the specific contact resistance $R_C \times W$ obtained from Eq. (11) reported as a function of the thickness t and the gate capacitance C_i of the gate dielectric. The upper surface refers to the case of a trap density of $N_t = 1.2 \times 10^{12}$ cm^{-2}, the lower surface refers to the case of $N_t = 5.6 \times 10^{11}$ cm^{-2}. We have supposed that the same threshold voltage V_{th} of 4 V and 7.2 V is valid for different values of t and C_i, for the upper and lower surfaces respectively. Whereas all the calculations refer to a value for the gate voltage of $V_G = -14$ V and at room temperature.

Fig. 4b and c are cross-sections of the 3D plot of Fig. 4a. In Fig. 4b, we investigate the specific contact resistance as a function of the thickness t of the OSC for the two cases $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. In doing such a calculation we have considered that the same threshold bias holds as we vary the thickness ($V_{th} = 7.2$ V for the case of $N_t = 5.6 \times 10^{11}$ cm^{-2}, $V_{th} = 4$ V for the case of $N_t = 1.2 \times 10^{12}$ cm^{-2}) and a gate capacitance of $C_i = 9.86 \times 10^{-4}$ F/m^2. As a general fact, because the trapping process is most likely to occur as the thickness of the OSC increases, the specific contact resistance increases with the OSC thickness. Moreover, the specific contact resistance as a function of the OSC thickness depends on the density of traps N_t and increases with the density of traps N_t.

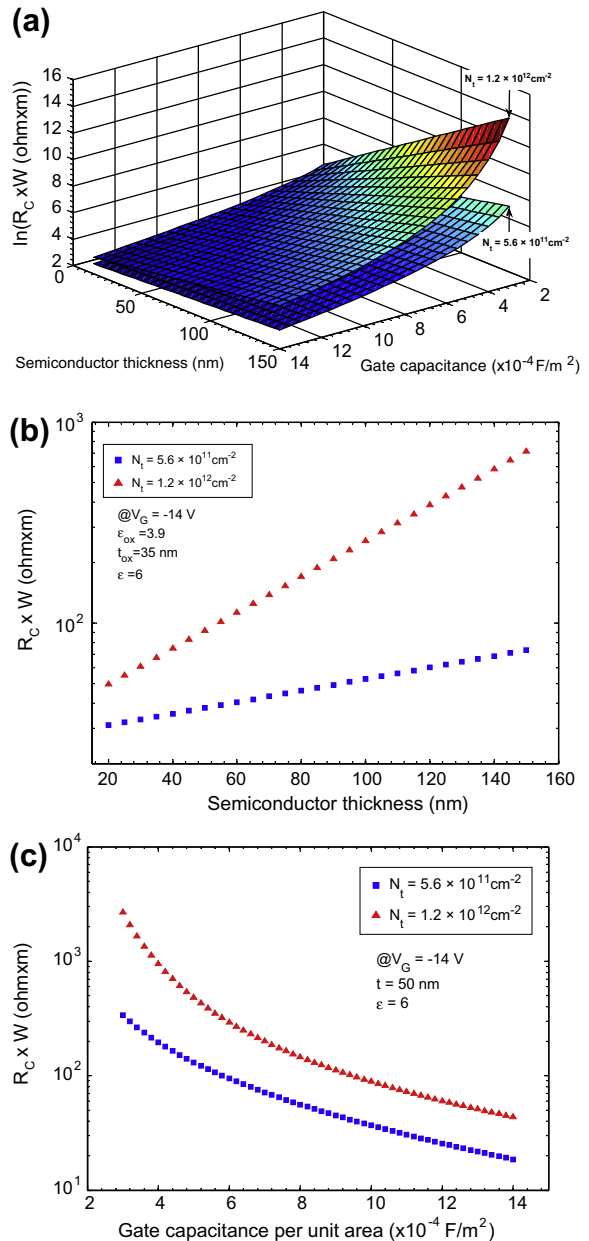
Analogously, we can infer as the specific contact resistance $R_C \times W$ varies because of changes of the gate capac-


Fig. 4. (a) 3D plot of the specific contact resistance $R_C \times W$ (ln plot) interpolated as a function of the semiconductor thickness t and gate capacitance C_i. The upper surface refers to the case of a trap density of $N_t = 1.2 \times 10^{12}$ cm^{-2} with a $V_{th} = 7.2$ V and constant for all cases, the lower surface to $N_t = 5.6 \times 10^{11}$ cm^{-2} and $V_{th} = 4.0$ V. All calculations are considered at room temperature and at a gate bias of -14 V. (b) Cross section of the 3D plot at $C_i = 9.86 \times 10^{-4}$ F/m^2 reporting the increase of the specific contact resistance $R_C \times W$ (in log scale), with the increase of the organic semiconductor thickness in the range of 15–150 nm. The two data set refer to a density of traps of $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. (c) Cross section of 3D plot at the OSC thickness of $t = 50$ nm reporting the decrease of the specific contact resistance $R_C \times W$ (in log scale) with the increase of the gate capacitance per unit area C_i in the range 3×10^{-4} F/m^2 to 1.4×10^{-3} F/m^2. The two data set refer to the density of traps of $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively.

itance per unit area C_i. In Fig. 4c we report the decrease of the specific contact resistance $R_C \times W$ (in log scale) with

the increase of the gate capacitance per unit area C_i in the range 3×10^{-4} to 1.4×10^{-3} F/m^2. We interpolated the values by considering valid the same threshold voltages V_{th} of 7.2 V and 4 V for the cases $N_t = 5.6 \times 10^{11}$ cm^{-2} and $N_t = 1.2 \times 10^{12}$ cm^{-2}, respectively. The gate bias of $V_G = -14$ V and the room temperature has also been assumed, whereas the thickness of the organic semiconductor was 50 nm for this case. As a general trend the specific contact resistance decreases as we increase the gate capacitance per unit area. Moreover the specific contact resistance is lower as the trap density N_t decreases.

5. Conclusion

In conclusion, we have modeled the dependence of the bulk contact resistance R_{Cbulk} on the gate bias V_G, within the frame of the grain boundary trapping model (GBTM) and the MNR rule. By following such an approach, we provided an analytical expression of the dependence of the specific contact resistance $R_C \times W$ on V_G. The GBTM model determines a contribution E_B to the energy barrier that injected holes have to overcome. This contribution caused by the trapping process occurring in the bulk OSC layer interposed between the electrodes and accumulation layer of the OTFT, is indicated as a principal contribution. However, from a best-fit of the experimental data gained from the literature [25], we have observed slight deviations that can be attributed to other mechanisms. In this paper we have shown that the electric field generated by the accumulation layer opposite the source and drain electrode can give also a dependence of the interface contact resistance on the gate bias. In particular, the accumulation layer in a staggered OTFT determines a Schottky lowering of the interface energy barrier ϕ_b at the source electrode. On the other hand, the high value of the electric field determines a Poole-Frenkel mechanism consisting in the extraction of holes from the accumulation layer at the drain contact region.
